where $a \geq 0$ is a constant. In general, the functional Φ can be used to encode our intuition about "what a cluster is". Note that this setup also includes the general case of $\mathcal{F} = \mathcal{H}$, that is the case where we do not want to make any further restrictions on $\mathcal{F}$, for example by setting $\Phi(f_k) \equiv 1$, $a \equiv 0$. As it is the case for Q, we will usually not be able to compute Φ on a finite sample only. Hence we also introduce an empirical counterpart Φ_n which will be used in the finite sample case.

The following theorem will state sufficient conditions for the consistency of nearest neighbor clustering. For simplicity we state the theorem for the case $\mathcal{X} = \mathbb{R}^d$, but the proofs can also be carried over to more general spaces. Also, note that we only state the theorem for the case $d \geq 2$; in case $d = 1$ the theorem holds as well, but the formulas look a bit different.

Theorem 2 (Consistency of nearest neighbor clustering) *Let $\mathcal{X} = \mathbb{R}^d$, $d \geq 2$, $Q : \mathcal{H} \to \mathbb{R}^+$ be a clustering quality function, and $Q_n : \mathcal{H} \to \mathbb{R}^+$ an estimator of this function which can be computed based on the finite sample only. Similarly, let $\Phi : \mathcal{H} \to \mathbb{R}^+$, and $\Phi_n : \mathcal{H} \to \mathbb{R}^+$ an estimator of this function. Let $a > 0$ and $(a_n)_{n \in \mathbb{N}}$ be such that $a_n > a$ and $a_n \to a$. Let $m = m(n) \leq n \in \mathbb{N}$. Finally, denote $d(f,g)$ the 0-1-loss, and let $NN_m(x)$ be the nearest neighbor of x among $X_1, \ldots, X_m$ according to the Euclidean distance. Define the function spaces*

$$\mathcal{F} := \{f : \mathbb{R}^d \to \{1, \ldots, K\} \mid f \text{ continuous a.e. and } \forall k \in \{1, \ldots, K\} \ \Phi(f_k) > a\}$$
$$\mathcal{F}_n := \{f : \mathbb{R}^d \to \{1, \ldots, K\} \mid f(x) = f(NN_m(x)) \text{ and } \forall k \in \{1, \ldots, K\} \ \Phi_n(f_k) > a_n\}$$
$$\widetilde{\mathcal{F}_n} := \bigcup_{X_1, \ldots, X_n \in \mathbb{R}^d} \mathcal{F}_n$$
$$\widehat{\mathcal{F}_n} := \{f : \mathbb{R}^d \to \{1, \ldots, K\} \mid \exists \text{ Voronoi partition of } m \text{ cells: } f \text{ constant on all cells}\}.$$

Assume that the following conditions are satisfied:

1. *$Q_n(f)$ is a consistent estimator of $Q(f)$ which converges sufficiently fast for all $f \in \widetilde{\mathcal{F}_n}$:*
$$\forall \varepsilon > 0, K^m (2n)^{(d+1)m^2} \sup_{f \in \widetilde{\mathcal{F}_n}} \mathbb{P}(|Q_n(f) - Q(f)| > \varepsilon) \to 0,$$
2. *$\Phi_n(f_k)$ is a consistent estimator of $\Phi(f_k)$ which converges sufficiently fast for all $f \in \widehat{\mathcal{F}_n}$:*
$$\forall \varepsilon > 0, K^m (2n)^{(d+1)m^2} \sup_{f \in \widehat{\mathcal{F}_n}} \mathbb{P}(|\Phi_n(f_k) - \Phi(f_k)| > \varepsilon) \to 0,$$
3. *Q is uniformly continuous with respect to the pseudo-distance $d(f,g)$ between $\mathcal{F}$ and $\widetilde{\mathcal{F}_n}$, as defined in Condition (3) of Theorem 1,*
4. *$\Phi_k(f) := \Phi(f_k)$ is uniformly continuous with respect to the pseudo-distance $d(f,g)$ between $\mathcal{F}$ and $\widehat{\mathcal{F}_n}$, as defined in Condition (3) of Theorem 1,*
5. *a_n decreases slowly enough to a:*
$$K^m (2n)^{(d+1)m^2} \sup_{g \in \widehat{\mathcal{F}_n}, k} \mathbb{P}(\Phi_n(g_k) - \Phi(g_k) \geq a_n - a) \to 0,$$

6. $m \to \infty$.

Then nearest neighbor clustering based on m seed points using quality function Q_n is weakly consistent, that is for $f_n \in \operatorname{argmin}_{f \in \mathcal{F}_n} Q_n(f)$ and $f^* \in \operatorname{argmin}_{f \in \mathcal{F}} Q(f)$ we have $Q(f_n) \to Q(f^*)$ in probability.

This theorem is still rather abstract, but pretty powerful. In the following we will demonstrate this by applying it to many concrete clustering objective functions. To define our objective functions, we will from now on adopt the convention $0/0 = 0$.

4. Nearest Neighbor Clustering with Popular Clustering Objective Functions

In this section we want to study the consistency of nearest neighbor clustering when applied to particular objective functions. For simplicity we assume in this section that $\mathcal{X} = \mathbb{R}^d$.

4.1 NNC Using the K-means Objective Function

The K-means objective function is the within-cluster sum of squared distances, called WSS for short. To define it properly, for a given clustering function $f : \mathbb{R}^d \to \{1, \dots, K\}$ we introduce the following quantities:

$$\mathrm{WSS}_n(f) := \frac{1}{n} \sum_{i=1}^{n} \sum_{k=1}^{K} f_k(X_i) \|X_i - c_{k,n}\|^2 \qquad \text{where}$$

$$c_{k,n} := \frac{1}{n_k} \frac{1}{n} \sum_{i=1}^{n} f_k(X_i) X_i \qquad \text{and} \qquad n_k := \frac{1}{n} \sum_{i=1}^{k} f_k(X_i)$$

$$\mathrm{WSS}(f) := \mathbb{E} \sum_{k=1}^{K} f_k(X) \|X - c_k\|^2 \qquad \text{where} \qquad c_k := \frac{\mathbb{E} f_k(X) X}{\mathbb{E} f_k(X)}.$$

Here, WSS_n plays the role of Q_n and WSS the role of Q. Let us point out some important facts. First the empirical quality function is not an unbiased estimator of the true one, that is $\mathbb{E}\mathrm{WSS}_n \neq \mathrm{WSS}$ and $\mathbb{E} c_{k,n} \neq c_k$ (note that in the standard treatment of K-means this can be achieved, but not on arbitrary function classes, see below for some discussion). However, at least we have $\mathbb{E} n_k = \mathbb{E} f_k(X)$ and $\mathbb{E} \frac{1}{n} \sum_{i=1}^{n} f_k(X_i) X_i = \mathbb{E} f_k(X) X$. Moreover, one should remark that if we define $\mathrm{WSS}(\cdot, \mathbb{P}) := \mathrm{WSS}$ then $\mathrm{WSS}_n = \mathrm{WSS}(\cdot, \mathbb{P}_n)$ where $\mathbb{P}_n$ is the empirical distribution.

Secondly, our setup for proving the consistency of nearest neighbor clustering with the WSS objective function is considerably more complicated than proving the consistency of the global minimizer of the K-means algorithm (e.g., Pollard, 1981). The reason is that for the K-means algorithm one can use a very helpful equivalence which does not hold for nearest neighbor clustering. Namely, if one considers the minimizer of WSS_n in the space of *all possible partitions*, then one can see that the clustering constructed by this minimizer always builds a Voronoi partition with K cells; the same holds in the limit case. In particular, given the cluster centers $c_{k,n}$ one can reconstruct the whole clustering by assigning each data point to the closest cluster center. As a consequence, to prove the convergence of K-means algorithms one usually studies the convergence of the empirical cluster centers $c_{k,n}$ to the true centers c_k. However, in our case this whole chain of arguments breaks down. The reason is that the clusters chosen by nearest neighbor clustering *from the set $\mathcal{F}_n$* are not necessarily Voronoi cells, they do not even need to be convex (all clusters are composed by small Voronoi cells, but the union of "small" Voronoi cells is not a "large" Voronoi cell). Also, it is not the case that each data point is assigned to the cluster corresponding to the closest cluster center. It may very well happen that a point x belongs to cluster C_i, but is closer to the center of another cluster C_j than to the center of its own cluster C_i. Consequently, we cannot reconstruct the nearest neighbor clustering from the centers of the clusters. This means that we cannot go over to the convergence of centers, which makes our proof considerably more involved than the one of the standard K-means case.

Due to these technical problems, it will be of advantage to only consider clusters which have a certain minimal size (otherwise, the cluster quality function WSS is not uniformly continuous). To achieve this, we use the functionals

$$\Phi_{\text{WSS}}(f_k) := \mathbb{E} f_k(X), \qquad\qquad \Phi_{\text{WSS}_n}(f_k) := n_k(f).$$

and will only consider clusterings where $\Phi(f_k) \geq a > 0$. In practice, this can be interpreted as a simple means to avoid empty clusters. The constant a can be chosen so small that its only effect is to make sure that each cluster contains at least one data point. The corresponding function spaces are

$$\mathcal{F} := \{f : \mathbb{R}^d \to \{1,\dots,K\} \mid f \text{ continuous a.e. and } \forall k \in \{1,\dots,K\}\ \ \Phi_{\text{WSS}}(f_k) > a\}$$
$$\mathcal{F}_n := \{f : \mathbb{R}^d \to \{1,\dots,K\} \mid f(x) = f(NN_m(x)) \text{ and } \forall k \in \{1,\dots,K\}\ \ \Phi_{\text{WSS}_n}(f_k) > a_n\}$$

Moreover, for technical convenience we restrict our attention to probability measures which have a bounded support inside some large ball, that is which satisfy $\operatorname{supp}\mathbb{P} \subset B(0,A)$ for some constant $A > 0$. It is likely that our results also hold in the general case, but the proof would get even more complicated. With the notation of Theorem 2 we have:

Theorem 3 (Consistency of NNC(WSS)**)** *Assume that $a_n > a, a_n \to a, m \to \infty$ and*

$$\frac{m^2 \log n}{n(a-a_n)^2} \to 0.$$

Then for all probability measures on $\mathbb{R}^d$ with bounded support, nearest neighbor clustering with WSS *is consistent, that is if $n \to \infty$ then* $\text{WSS}(f_n) \to \text{WSS}(f^*)$ *in probability.*

This theorem looks very nice and simple. The conditions on a_n and m are easily satisfied as soon as these quantities do not converge too fast. For example, if we define

$$a_n = a + \frac{1}{\log n} \quad \text{and} \quad m = \log n$$

then

$$\frac{m^2 \log n}{n(a_n-a)^2} = \frac{(\log n)^5}{n} \to 0.$$

Moreover, it is straightforward to see from the proofs that this theorem is still valid if we consider the objective functions WSS_n and WSS with $\|\cdot\|$ instead of $\|\cdot\|^2$. It also holds for any other norm, such as the p-norms $\|\cdot\|_p$. However, it does not necessarily hold for powers of norms (in this sense, the squared Euclidean norm is an exception). The proof shows that the most crucial property is

$$\|X_i - c_{k,n}\| - \|X_i - c_k\| \leq \mathrm{const} \cdot \|c_{k,n} - c_k\|.$$

This is straightforward if the triangle inequality holds, but might not be possible for general powers of norms.

By looking more carefully at our proofs one can state the following rate of convergence:

Theorem 4 (Convergence Rate for $\mathrm{NNC}(\mathrm{WSS})$**)** *Assume that* $\operatorname{supp}\mathbb{P} \subset B(0,A)$ *for some constant* $A > 0$ *and that* $n(a_n - a)^2 \to \infty$*. Let* $\varepsilon \leq 1$ *and* $a^* := \inf_k \mathbb{E} f_k^*(X) - a > 0$*. Then there exists :*

$$\begin{aligned} &N = N((a_n), a^*) \in \mathbb{N}, \\ &C_1 = C_1(a, a^*, \varepsilon, K, A) > 0, && C_2 = C_2(a, a^*, \varepsilon, A, f^*, \mathbb{P}) > 0, \\ &C_3 = C_3(a, d, \varepsilon, K, A) > 0, && C_4 = C_4(a, d, A) > 0 \end{aligned}$$

such that for $n \geq N$ *the following holds true:*

$$\begin{aligned} &\mathbb{P}(|\mathrm{WSS}(f_n) - \mathrm{WSS}(f^*)| \geq \varepsilon) \\ &\leq C_1 e^{-C_2 m} + K^{m+1} (2n)^{(d+1)m^2} \left(C_3 e^{-C_4 \varepsilon^2 n} + 8K e^{-\frac{n(a_n - a)^2}{8}} \right). \end{aligned}$$

At first glance, it seems very tempting to try to use the Borel-Cantelli lemma to transform the weak consistency into strong consistency. However, we do not have an explicit functional form of dependency of C_2 on ε. The main reason is that in Lemma 11 (Appendix) the constant $b(\varepsilon)$ will be defined only implicitly. If one would like to prove strong consistency of nearest neighbor clustering with WSS one would have to get an explicit form of $b(\varepsilon)$ in Lemma 11.

For a general discussion relating the consistency result of $\mathrm{NNC}(\mathrm{WSS})$ in to the consistency results by Pollard (1981) and others see Section 5.

4.2 NNC Using Standard Graph-cut Based Objective Functions

In this section we want to look into the consistency of nearest neighbor clustering for graph based objective functions as they are used in spectral clustering (see von Luxburg, 2007 for details). Let $s : \mathbb{R}^d \times \mathbb{R}^d \to \mathbb{R}^+$ be a similarity function which is upper bounded by a constant C. The two main quantities we need to define graph-cut based objective functions are the cut and the volume. For a given cluster described by the cluster indicator function $f_k : \mathbb{R}^d \to \{0,1\}$, we set

$$\mathrm{cut}(f_k) := \mathrm{cut}(f_k, \mathbb{P}) := \mathbb{E} f_k(X_1)(1 - f_k(X_2)) s(X_1, X_2),$$

$$\mathrm{vol}(f_k) := \mathrm{vol}(f_k, \mathbb{P}) := \mathbb{E} f_k(X_1) s(X_1, X_2).$$

For $f \in \mathcal{H}$ we can then define the normalized cut and the ratio cut by

$$\mathrm{Ncut}(f) := \mathrm{Ncut}(f,\mathbb{P}) := \sum_{k=1}^{K} \frac{\mathrm{cut}(f_k)}{\mathrm{vol}(f_k)},$$
$$\mathrm{RatioCut}(f) := \mathrm{RatioCut}(f,\mathbb{P}) := \sum_{k=1}^{K} \frac{\mathrm{cut}(f_k)}{\mathbb{E} f_k(X)}.$$

The empirical estimators of these objective functions will be $\mathrm{Ncut}(f,\mathbb{P}_n)$ and $\mathrm{RatioCut}(f,\mathbb{P}_n)$, in explicit formulas:

$$\mathrm{cut}_n(f_k) := \frac{1}{n(n-1)} \sum_{i,j=1}^{n} f_k(X_i)(1-f(X_j))s(X_i,X_j),$$

$$\mathrm{vol}_n(f_k) := \frac{1}{n(n-1)} \sum_{i,j=1}^{n} f_k(X_i)s(X_i,X_j), \qquad n_k := \frac{1}{n}\sum_{i=1}^{k} f_k(X_i),$$

$$\mathrm{Ncut}_n(f) := \sum_{k=1}^{K} \frac{\mathrm{cut}_n(f_k)}{\mathrm{vol}_n(f_k)}, \qquad \mathrm{RatioCut}_n(f) := \sum_{k=1}^{K} \frac{\mathrm{cut}_n(f_k)}{n_k}.$$

Again we need to define how we will measure the size of the clusters. We will use

$$\Phi_{\mathrm{cut}}(f_k) := \mathrm{vol}(f_k), \qquad \Phi_{\mathrm{Ncut}}(f_k) := \mathrm{vol}(f_k), \qquad \Phi_{\mathrm{RatioCut}}(f_k) := \mathbb{E} f_k(X).$$

with the corresponding empirical quantities Φ_{cut_n}, Φ_{Ncut_n} and $\Phi_{\mathrm{RatioCut}_n}$. Then, with the notations of Theorem 2, we have:

Theorem 5 (Consistency of NNC(cut), NNC(Ncut) **and** NNC(RatioCut)**)** *Assume that the similarity function s is bounded by a constant $C > 0$, let $a_n > a$, $a_n \to a$, $m \to \infty$ and*

$$\frac{m^2 \log n}{n(a-a_n)^2} \to 0.$$

Then nearest neighbor clustering with cut, Ncut *and* RatioCut *is universally weakly consistent, that is for all probability measures, if $n \to \infty$ we have* $\mathrm{cut}(f_n) \to \mathrm{cut}(f^*)$, $\mathrm{Ncut}(f_n) \to \mathrm{Ncut}(f^*)$ *and* $\mathrm{RatioCut}(f_n) \to \mathrm{RatioCut}(f^*)$ *in probability.*

For these objective functions one can also state a rate of convergence. For sake of shortness we only state it for the normalized cut:

Theorem 6 (Convergence Rate for NNC(Ncut)**)** *Assume that the similarity function s is bounded by $C > 0$ and that $n(a_n - a)^2 \to \infty$. Let $\varepsilon \leq 1$ and $a^* := \inf_k vol(f_k^*) - a > 0$. Then there exist*

$$N = N((a_n),a^*) \in \mathbb{N},$$
$$C_1 = C_1(a,a^*,\varepsilon,K,C) > 0, \qquad C_2 = C_2(a,a^*,\varepsilon,C,K,f^*,\mathbb{P}) > 0,$$
$$C_3 = C_3(a,\varepsilon,K,C) > 0, \qquad C_4 = C_4(a,K,C) > 0.$$

such that for $n \geq N$ the following holds true:

$$\mathbb{P}(|\mathrm{Ncut}(f_n) - \mathrm{Ncut}(f^*)| \geq \varepsilon)$$
$$\leq C_1 e^{-C_2 m} + K^{m+1}(2n)^{(d+1)m^2}\left(C_3 e^{-C_4 \varepsilon^2 n} + 8K e^{-\frac{n(a_n-a)^2}{8}}\right).$$

4.3 NNC Using the Modularity Objective Function

A slightly different objective functions for graph clustering is the “modularity”, which has been put forward by Newman (2006) for detecting communities in networks. In this paper, the modularity is formulated as an objective function to find communities in a finite graph. However, as it is the case for Ncut or RatioCut, the modularity cannot be directly minimized. Instead, a spectral relaxation has been developed to minimize the modularity, see Newman (2006) for details. Of course, the nearest neighbor clustering algorithm can also be used to minimize this objective function directly, without using a relaxation step. Using our own notation we define:

$$\begin{aligned}
&\mathrm{Mod}_n(f) = \\
&\quad \sum_{k=1}^{n} \frac{1}{n(n-1)} \sum_{i \neq j} f_k(X_i) f_k(X_j) \left(\frac{1}{(n-1)^2} \sum_{l, l \neq i} s(X_i, X_l) \sum_{l, l \neq j} s(X_j, X_l) - s(X_i, X_j) \right), \\
&\mathrm{Mod}(f) = \\
&\quad \sum_{k=1}^{n} \int \int f_k(X) f_k(Y) \left(\int s(X,Z) d\mathbb{P}(Z) \int s(Y,Z) d\mathbb{P}(Z) - s(X,Y) \right) d(\mathbb{P} \times \mathbb{P})(X,Y).
\end{aligned}$$

In the proof we will see that as the limit function $\mathrm{Mod}(\cdot)$ is uniformly continuous on $\mathcal{H}$, we do not need to quantify any function Φ or Φ_n to measure the volume of the clusters. The function classes are thus

$$\begin{aligned}
\mathcal{F} &:= \{ f : \mathbb{R}^d \to \{1, \ldots, K\} \mid f \text{ continuous a.e.} \}, \\
\mathcal{F}_n &:= \{ f : \mathbb{R}^d \to \{1, \ldots, K\} \mid f(x) = f(NN_m(x)) \}.
\end{aligned}$$

Theorem 7 (Consistency of $\mathrm{NNC}(\mathrm{Mod})$**)** *Assume that $m \to \infty$ and*

$$\frac{m^2 \log n}{n} \to 0.$$

Then nearest neighbor clustering with Mod *is universally weakly consistent: for all probability measures, if $n \to \infty$ then* $\mathrm{Mod}(f_n) \to \mathrm{Mod}(f^*)$ *in probability.*

4.4 NNC Using Objective Function Based on the Ratio of Within-cluster and Between-cluster Similarity

Often, clustering algorithms try to minimize joint functions of the within-cluster similarity and the between cluster similarity. The most popular choice is the ratio of those two quantities, which is closely related to the criterion used in Fisher linear discriminant analysis. Formally, the between-cluster similarity corresponds to the cut, and the within similarity of cluster k is given by

$$\mathrm{WS} := \mathbb{E} f(X_1) f(X_2) s(X_1, X_2).$$

Thus the ratio of between- and within-cluster similarity is given as

$$\mathrm{BWR}(f) := \sum_{k=1}^{K} \frac{\mathrm{cut}(f_k)}{\mathrm{WS}(f_k)}.$$

Again we use their empirical estimations:

$$\mathrm{WS}_n(f_k) := \frac{1}{n(n-1)} \sum_{i,j=1}^{n} f_k(X_i) f_k(X_j) s(X_i, X_j),$$
$$\mathrm{BWR}_n(f) := \sum_{k=1}^{K} \frac{\mathrm{cut}_n(f_k)}{\mathrm{WS}_n(f_k)}.$$

To measure the size of the cluster we use

$$\Phi_{\mathrm{BWR}}(f_k) := \mathrm{WS}(f_k)$$

and its natural empirical counterpart. This leads to function spaces

$$\mathcal{F} := \{f : \mathbb{R}^d \to \{1, \dots, K\} \mid f \text{ continuous a.e. and } \forall k \in \{1, \dots, K\} \;\; \Phi_{\mathrm{BWR}}(f_k) > a\},$$
$$\mathcal{F}_n := \{f : \mathbb{R}^d \to \{1, \dots, K\} \mid f(x) = f(NN_m(x)) \text{ and } \forall k \in \{1, \dots, K\} \;\; \Phi_{\mathrm{BWR}_n}(f_k) > a_n\}.$$

Theorem 8 (Consistency of NNC(BWR)**)** *Assume that the similarity function s is bounded by a constant $C > 0$, let $a_n > a, a_n \to a, m \to \infty$ and*

$$\frac{m^2 \log n}{n(a - a_n)^2} \to 0.$$

Then nearest neighbor clustering with BWR *is universally weakly consistent, that is for all probability measure if $n \to \infty$ then* $\mathrm{BWR}(f_n) \to \mathrm{BWR}(f^*)$ *in probability.*

5. Relation to Previous Work

In this section we want to discuss our results in the light of the existing literature on consistent clusterings.

5.1 Standard Consistency Results for Center-based Algorithms

For a few clustering algorithms, consistency results are already known. The most well-known among them is the K-means algorithm. For this algorithm it has been first proved by Pollard (1981) that the global minimizer of the K-means objective function on a finite sample converges to the global minimizer on the underlying space.

First of all, we would like to point out that the consistency result by Pollard (1981) can easily be recovered using our theorems. Let us briefly recall the standard K-means setting. The objective function which K-means attempts to optimize is the function WSS, which we already encountered in the last sections. In the standard K-means setting the optimization problem is stated over the space of all measurable functions $\mathcal{H}$:

$$f^* = \operatorname*{argmin}_{f \in \mathcal{H}} \mathrm{WSS}(f).$$

It is not difficult to prove that the solution f^* of this optimization problem always has a particular form. Namely, the solution f^* forms a Voronoi decomposition of the space, where the cluster centers c_k are the centers of the Voronoi cells. Thus, we can rewrite the optimization problem above equivalently as

$$f^* = \operatorname*{argmin}_{f \in \mathcal{G}_K} \mathrm{WSS}(f)$$

where $\mathcal{G}_K$ denotes the set of all clusterings for which the clusters are Voronoi cells. The optimization problem for the finite sample case can be stated analogously:

$$f_n = \operatorname*{argmin}_{f \in \mathcal{G}_K} \mathrm{WSS}_n(f).$$

So in this particular case we can set $\mathcal{F}_n = \mathcal{F} = \mathcal{G}_K$. This means that even though the original optimization problem has been set up to optimize over the huge set $\mathcal{H}$, the optimization only needs to run over the small set $\mathcal{G}_K$. It is well known that the shattering coefficient of $\mathcal{G}_K$ is polynomial in n, namely it is bounded by $K^K n^{(d+1)K^2}$ (cf. Lemma 10). Moreover, the uniform continuity of WSS on $\mathcal{G}_K$ (Condition (3) of Theorem 2) can easily be verified if we assume that the probability distribution has compact support. As a consequence, using similar techniques as in the proofs of Theorem 3 we can prove that the global minimizer of the empirical K-means objective function WSS_n converges to the global minimizer of the true K-means objective function WSS. By this we recover the well-known result by Pollard (1981), under slightly different assumptions. In this sense, our Theorem 1 can be seen as a blueprint for obtaining Pollard-like results for more general objective functions and function spaces.

Are there any more advantages of Theorem 3 in the K-means setting? At first glance, our result in Theorem 3 looks similar to Pollard's result: the global minimizers of both objective functions converge to the true global minimizer. However, in practice there is one important difference. Note that as opposed to many vector quantization problems (cf. Garey et al., 1982), minimizing the K-means objective function is not NP-hard in n: the solution is always a Voronoi partition, there exist polynomially many Voronoi partitions of n points, and they can be enumerated in polynomial time (cf. Inaba et al., 1994). However, the size of the function class $\mathcal{G}_K$ is still so large that it would take too long to simply enumerate all its functions and select the best one. Namely, we will see in Lemma 10 that the number of Voronoi partitions of n points in $\mathbb{R}^d$ using K cells is bounded by $n^{(d+1)K}$, which is huge even for moderate d and K. As a work-around in practice one uses the well-known K-means *algorithm*, which is only able to find a *local* minimum of $\mathrm{WSS}_n(f)$. In contrast, nearest neighbor clustering works with a different function class which is much smaller than $\mathcal{G}_K$: it has only size $n^{\log K}$. On this smaller class we are still able to compute the *global* minimum of $\mathrm{WSS}_n(f)$. Consequently, our result in Theorem 3 is not only a theoretical statement about some abstract quantity as it is the case for Pollard's result, but it applies to the algorithm used in practice. While Pollard's result abstractly states that the global minimum (which cannot be computed efficiently) converges, our result implies that the result of nearest neighbor clustering does converge.

5.2 Consistency of Spectral Clustering

In the previous section we have seen in Theorems 5 and 6 that NNC is consistent for all the standard graph cut objective functions. Now we want to discuss these results in connection with the graph cut literature. It is well known that the discrete optimization problem of minimizing Ncut_n or $\mathrm{RatioCut}_n$ is an NP-hard problem, see Wagner and Wagner (1993). However, approximate solutions of relaxed problems can be obtained by spectral clustering, see von Luxburg (2007) for a tutorial. Consistency results for spectral clustering algorithms have been proved in von Luxburg et al. (2008). These results show that under certain conditions, the solutions computed by spectral clustering on finite samples converge to some kind of "limit solutions" based on the underlying distribution. In the light of the previous discussions, this sounds plausible, as the space of solutions of spectral clustering is rather restricted: we only allow solutions which are eigenfunctions of certain integral operators. Thus, spectral clustering implicitly works with a small function class.

However, it is important to note that the convergence results of spectral clustering do not make any statement about the minimizers of Ncut (a similar discussion also holds for RatioCut). The problem is that on any finite sample, spectral clustering only solves a relaxation of the original problem of minimizing Ncut_n. The Ncut_n-value of this solution can be arbitrarily far away from the minimal Ncut_n-value on this sample (Guattery and Miller, 1998), unless one makes certain assumptions which are not necessarily satisfied in a standard statistical setting (cf. Spielman and Teng, 1996, or Kannan et al., 2004). Thus the convergence statements for the results computed by the spectral clustering algorithm cannot be carried over to consistency results for the minimizers of Ncut. One knows that spectral clustering converges, but one does not have any guarantee about the Ncut-value of the solution. Here our results for nearest neighbor clustering present an improvement, as they directly refer to the minimizer of Ncut. While it is known that spectral clustering converges to "something", for the solutions computed by nearest neighbor clustering we know that they converge to the global minimizer of Ncut (or RatioCut, respectively).

5.3 Consistency of Other Clustering Schemes

To the best of our knowledge, apart from results on center-based algorithms and spectral clustering, there are very few non-parametric clustering algorithms for which statistical consistency has been proved so far. The only other major class of algorithms for which consistency has been investigated is the class of linkage algorithms. While single linkage can be proved to be "fractionally consistent", that is it can at least discover sufficiently distinct high-density regions, both complete and average linkage are not consistent and can be misleading (cf. Hartigan, 1981, 1985). A more general method for hierarchical clustering used in Wong and Lane (1983) is statistically consistent, but essentially first estimates the density and then constructs density level sets based on this estimator.

Concerning parametric clustering algorithms, the standard setting is a model-based approach. One assumes that the underlying probability distribution has a certain parametric form (for example a mixture of Gaussians), and the goal is to estimate the parameters of the distribution from the sample. Estimating parameters in parametric models has been intensively investigated in statistics, in particular in the maximum likelihood framework and the Bayesian framework (for an overview how this can be done for clustering see Fraley and Raftery, 1998, or the book McLachlan and Peel, 2004). Numerous consistency results are known, but typically they require that the true underlying distribution indeed comes from the model class under consideration. For example, in a Bayesian setting one can show that in the large sample limit, the posterior distribution will concentrate around the true mixture parameters. However, if the model assumptions are not satisfied, counter-examples to consistency can be constructed. Moreover, the consistency results mentioned above are theoretic in the sense that the algorithm used in practice does not necessarily achieve them. Standard approaches to estimate mixture parameters are the EM algorithm (in a frequentist of MAP setting), or for example Markov Chain Monte Carlo sampling in a fully Bayesian approach. However, as it is the case for the K-means algorithm, these methods can get stuck in local optima, and no convergence towards the global optimum can be guaranteed. Another way to tackle model-based clustering problems is based on the minimum message length or minimum description length principle. The standard reference for MML approaches to learn mixtures is Figueiredo and Jain (2002), for a general overview on MDL see Grünwald (2007). Consistency results for MML are quite similar to the ones for the Bayesian approach: if the true distribution indeed comes from the mixture class and the number of components is known, then consistency can be achieved. For general results on consistency of MDL see Sections 16 and 17.11 in Grünwald (2007). Often, MML/MDL approaches are interpreted as a particular way to work with small function classes, consisting of functions which can be described in a "compact" way. In this sense, this method can also be seen as a way of achieving "small" function classes.

5.4 Sublinear Time Algorithms Using Subsampling

Some algorithms related to our approach have been published in the theoretical computer science community, such as Indyk (1999), Mishra et al. (2001), or Czumaj and Sohler (2007). The general idea is to use subsampling approaches to approximate clustering solutions, and to prove that these approximations are quite accurate. Given a sample of n points, one draws a subsample of $m \ll n$ points, applies some (approximate) clustering algorithm to the subsample, and then extends this clustering to the remaining points. Using techniques such as concentration inequalities, Chernoff bounds or Hoeffding bounds, one can then prove that the resulting clustering approximates the best clustering on the original point set.

While at first glance, this approach sounds very similar to our nearest neighbor clustering, note that the focus in these papers is quite a different one than ours. The authors do not aim for consistent clustering solutions (that is, solutions which are close to the "true clustering solution" of the underlying space), but they want to find algorithms to approximate the optimal clustering on a given finite sample in sublinear time. The sublinearity is achieved by the fact that already a very small subsample (say, $m = \log n$) is enough to achieve good approximation guarantees. However, our main point that it is important to control the size of the underlying function class, is not revealed in these papers. As the authors mainly deal with K-means type settings, they automatically work with polynomial function classes of center-based clusterings, and the issue of inconsistency does not arise. Moreover, subsampling is just one way of reducing the function class to a smaller size, there can be many others. In this sense, we believe that our "small function class" approach is more general than the subsampling approach.

Finally, one difference between our approach and the subsampling approach is the kind of results of interest. We are mainly concerned with asymptotic results, and on our way achieve approximation guarantees which are good for large sample size n. The focus of the subsampling papers is non-asymptotic, dealing with a small or moderate sample size n, and to prove approximation guarantees in this regime.

5.5 Other Statistical Learning Theory Approaches to Clustering

In the last years there have been several papers which started to look at clustering from a statistical learning theory perspective. A general statistical learning theory approach to clustering, based on a very similar intuition as ours, has already been presented in Buhmann (1998). Here the authors put forward an "empirical risk approximation" approach for unsupervised learning, along the lines of empirical risk minimization for the supervised case. The setting under consideration is that the clustering quality function is an expectation with respect to the true underlying probability distribution, and the empirical quality function is the corresponding empirical expectation. Then, similar to the statistical learning theory for supervised learning, generalization bounds can be derived, for example using VC dimensions. Additionally, the authors discuss regularization approaches and relate them to annealing schemes for center-based clusterings.

A different approach has been investigated in Ben-David (2007). Here the author formalizes the notion of a "cluster description scheme". Intuitively, a clustering problem can be described by a cluster description scheme of size $l \in \mathbb{N}$ if each clustering can be described using l points from the space (and perhaps some additional parameter). For instance, this is the case for center-based clusterings, where the clustering can be described by the centroids only. Ben-David then proves generalization bounds for clustering description schemes which show that the global minimizer of the empirical quality function converges to the global minimizer of the true quality function. The proof techniques used in this paper are very close to the ones used in standard minimum description length results.

Another class of results about K-means algorithms has been proved in Rakhlin and Caponnetto (2007). After computing covering numbers for the underlying classes, the authors study the stability behavior of K-means. This leads to statements about the set of "almost-minimizers" (that is the set of all functions whose quality is ε close to the one of the global optimal solutions). As opposed to our results and all the other results discussed above, the main feature of this approach is that at the end of the day, one is able to make statements about the clustering functions themselves, rather than only about their quality values. In this sense, the approach in Rakhlin and Caponnetto (2007) has more powerful results, but its application is restricted to K-means type algorithms.

All approaches outlined above implicitly or explicitly rely on the same intuition as our approach: the function class needs to be "small" in order to lead to consistent clusterings. However, all previous results have some restrictions we could overcome in our approach. First of all, in the papers discussed above the quality function needs to be an expectation, and the empirical quality function is simply the empirical expectation. Here our results are more general: we neither require the quality functions to be expectations (for example, Ncut cannot be expressed as an expectation, it is a ratio of two expectations) nor do we require unbiasedness of the empirical quality function. Second, the papers discussed above make statements about global optimizers, but do not really deal with the question how such a global optimizer can be computed. The case of standard K-means shows that this is by no means simple, and in practice one has to use heuristics which discover local optima only. In contrast, we suggest a concrete algorithm (NNC) which computes the global optimum over the current function class, and hence our results not only concern abstract global minimizers which are hard to obtain, but refer to exactly the quantities which are computed by the algorithm. Finally, our algorithm has the advantage that it provides a framework for dealing with more general clustering objective functions than just center-based ones. This is not the case in the papers above.

Finally, we would like to mention that a rather general but vague discussion of some of the open issues in statistical approaches to clustering has been led in von Luxburg and Ben-David (2005). Our current paper partly solves some of the open issues raised there.

6. Discussion

Our paper is concerned with clustering algorithms which minimize certain quality functions. Our main point is that as soon as we require statistical consistency we have to work with function classes $\mathcal{F}_n$ which are "small". Our results have a similar taste as the well-known corresponding results for supervised classification. While in the domain of supervised classification practitioners are well aware of the effect of overfitting, it seems like this effect has been completely overlooked in the clustering domain.

We would like to highlight a convenient side-effect of working with small function classes. In clustering, for many objective functions the problem of finding the best partition of the discrete data set is an NP-hard problem (for example, this is the case for all balanced graph-cut objective functions). On the other side, if we restrict the function class $\mathcal{F}_n$ to have polynomial size (in n), then the trivial algorithm of evaluating all functions in $\mathcal{F}_n$ and selecting the best one is inherently polynomial. Moreover, if the small function class is "close" to the large function class, then the solution found in the small function class approximates the best solution in the unrestricted space of all clusterings.

We believe that the approach of using restricted function classes can be very promising, also from a practical point of view. It can be seen as a more controlled way of constructing approximate solutions of NP hard optimization problems than the standard approaches of local optimization or relaxation. While the effects of the latter cannot be controlled in general, we are able to control the effects of optimizing over smaller function classes by carefully selecting $\mathcal{F}_n$. This strategy circumvents the problem that solutions of local optimization or relaxation heuristics can be arbitrarily far away from the optimal solution.

The generic clustering algorithm we studied in this article is nearest neighbor clustering, which produces clusterings that are constant on small local neighborhoods. We have proved that this algorithm is statistically consistent for a large variety of popular clustering objective functions. Thus, as opposed to other clustering algorithms such as the K-means algorithm or spectral clustering, nearest neighbor clustering is guaranteed to converge to a minimizer of the true global optimum on the underlying space. This statement is much stronger than the results already known for K-means or spectral clustering. For K-means it has been proved that the global minimizer of the WSS objective function on the sample converges to a global minimizer on the underlying space (e.g., Pollard, 1981). However, as the standard K-means algorithm only discovers a local optimum on the discrete sample, this result does not apply to the algorithm used in practice. A related effect happens for spectral clustering, which is a relaxation attempting to minimize Ncut or RatioCut. For this class of algorithms, it has been shown that under certain conditions the solution of the relaxed problem on the finite sample converges to some limit clustering. However, this limit clustering is not necessarily the optimizer of the Ncut or RatioCut objective function.

It is interesting to note that the problems about the existing consistency results for K-means and spectral clustering are "reverse" to each other: while for K-means we know that the global minimizer converges, but this result does not apply to the algorithm used in practice, for spectral clustering there exist consistency results for the algorithm used in practice, but these results do not relate to the global minimizer. For both cases, our consistency results represent an improvement: we have constructed an algorithm which provably converges to the true limit minimizer of WSS or Ncut, respectively. The same result also holds for a large number of alternative objective functions used for clustering.

We believe that a big advantage of our approach is that both the algorithm and the statistical analysis is not restricted to center-based algorithms only, as it has been the case for most approaches in the literature (Buhmann, 1998; Ben-David, 2007; Rakhlin and Caponnetto, 2007). Instead, nearest neighbor clustering can be used as a baseline method to construct clusterings for any objective function. In von Luxburg et al. (2008) we have shown how nearest neighbor clustering can be implemented efficiently using branch and bound, and that in terms of quality, its results can compete with algorithms of spectral clustering (for the Ncut objective function) or K-means (for the WSS objective function). We believe that in particular for unusual objective functions for which no state of the art optimizer exists yet, nearest neighbor clustering is a promising baseline to start with. We have seen that for many commonly used objective functions, statistical guarantees for nearest neighbor clustering can be obtained, and we expect the same to be true for many more clustering objective functions.

Finally, it is a fair question how statistical consistency helps in practical applications. Is it any help in solving the big open issues in clustering, such as the question of selecting clustering algorithms for a particular data set, or selecting the number of clusters? In this generality, the answer is no. In our opinion, consistency is a *necessary* requirement which any clustering algorithm should satisfy. If an algorithm is not consistent, even with a high amount of data one cannot rely on a clustering constructed on a finite amount of data—and this is not due to computational problems, but to inherent statistical problems. Such an algorithm cannot be trusted when constructing results on a finite sample; given another sample, it might just come up with a completely different clustering. Or, the more samples one gets, the more "trivial" the solution might become (unnormalized spectral clustering is an example for such an algorithm). In this sense, consistency is just one piece of evidence to discard unreliable clustering algorithms. In our opinion, it is very hard to come up with *sufficient* conditions about "what a good clustering algorithm is". The applications of clustering are just too diverse, and 50 years of clustering literature show that people will not agree on a unique definition of what a good clustering algorithm is. This is the reason why we believe that it is very fruitful to start by studying necessary conditions first. Our current paper is meant as a contribution to this effort.

Appendix A. All Proofs

In this section we concentrate all the proofs.

A.1 The Proof of Theorem 1

The following lemma will be central in our analysis. It allows to take a supremum out of a probability.

Lemma 9 *With the notation in Theorem* 1 *we have:*

$$\mathbb{P}(\sup_{f\in\mathcal{F}_n}|Q_n(f)-Q(f)|\geq\varepsilon)\leq 2s(\widetilde{\mathcal{F}_n},2n)\frac{\sup_{f\in\widetilde{\mathcal{F}_n}}\mathbb{P}(|Q_n(f)-Q(f)|\geq\varepsilon/4)}{\inf_{f\in\widetilde{\mathcal{F}_n}}\mathbb{P}(|Q_n(f)-Q(f)|\leq\varepsilon/2)}.$$

The proof technique is similar to the one in Devroye et al. (1996), Section 12.3. The unusual term in the denominator originates in the symmetrization step. In a more standard setting where we have $\mathbb{E}Q_n = Q$, this term usually "disappears" as it can be lower bounded by $1/2$, for example using

Chebyshev's inequality (e.g., Section 12.3 of Devroye et al., 1996). Unfortunately, this does not work in our more general case, as we do not assume unbiasedness and instead also allow $\mathbb{E}Q_n \neq Q$. However, note that the ratio in Lemma 9 essentially has the form $u_n/(1-u_n)$. Thus, as soon as the term u_n in the numerator becomes non-trivial (i.e., $u_n < 1$ or say, $u_n < 3/4$), then the denominator will only play the role of a small constant (it is lower bounded by 1/4). This means that in the regime where the numerator is non-trivial, the whole bound will essentially behave like the numerator.

Proof First note that we can replace the data-dependent function class $\mathcal{F}_n$ by the class $\widetilde{\mathcal{F}_n}$ which does not depend on the data:

$$\mathbb{P}(\sup_{f\in\mathcal{F}_n}|Q_n(f)-Q(f)| \geq \varepsilon) \leq \mathbb{P}(\sup_{f\in\widetilde{\mathcal{F}_n}}|Q_n(f)-Q(f)| \geq \varepsilon).$$

Now we want to use a symmetrization argument. To this end, let $X_1',\dots,X_n'$ be a ghost sample (that is a sample drawn i.i.d. according to $\mathbb{P}$ which is independent of our first sample $X_1,\dots,X_n$), and denote by Q_n' the empirical quality function based on the ghost sample.

Let $\widehat{f}\in\widetilde{\mathcal{F}_n}$ be such that $|Q_n(\widehat{f})-Q(\widehat{f})|\geq\varepsilon$; if such an $\widehat{f}$ does not exist then just choose $\widehat{f}$ as some other fixed function in $\widetilde{\mathcal{F}_n}$. Note that $\widehat{f}$ is a data-dependent function depending on the sample $X_1,...,X_n$. We have the following inequalities:

$$\begin{aligned}
&\mathbb{P}(\sup_{f\in\widetilde{\mathcal{F}_n}}|Q_n(f)-Q_n'(f)|\geq\varepsilon/2)\\
&\geq \mathbb{P}(|Q_n(\widehat{f})-Q_n'(\widehat{f})|\geq\varepsilon/2)\\
&\geq \mathbb{P}(|Q_n(\widehat{f})-Q(\widehat{f})|\geq\varepsilon, |Q_n'(\widehat{f})-Q(\widehat{f})|\leq\varepsilon/2)\\
&= \mathbb{E}\Big(\mathbb{P}(|Q_n(\widehat{f})-Q(\widehat{f})|\geq\varepsilon, |Q_n'(\widehat{f})-Q(\widehat{f})|\leq\varepsilon/2|X_1,\dots,X_n)\Big)\\
&= \mathbb{E}\Big(\mathbb{P}(|Q_n(\widehat{f})-Q(\widehat{f})|\geq\varepsilon|X_1,\dots,X_n)\mathbb{P}(|Q_n'(\widehat{f})-Q(\widehat{f})|\leq\varepsilon/2|X_1,\dots,X_n)\Big)\\
&= \mathbb{E}\Big(1_{|Q_n(\widehat{f})-Q(\widehat{f})|\geq\varepsilon}\mathbb{P}(|Q_n'(\widehat{f})-Q(\widehat{f})|\leq\varepsilon/2|X_1,\dots,X_n)\Big)\\
&\geq \mathbb{E}\left(1_{|Q_n(\widehat{f})-Q(\widehat{f})|\geq\varepsilon}\inf_{f\in\widetilde{\mathcal{F}_n}}\mathbb{P}(|Q_n'(f)-Q(f)|\leq\varepsilon/2|X_1,\dots,X_n)\right)\\
&= \mathbb{E}(1_{|Q_n(\widehat{f})-Q(\widehat{f})|\geq\varepsilon})\mathbb{E}\left(\inf_{f\in\widetilde{\mathcal{F}_n}}\mathbb{P}(|Q_n'(f)-Q(f)|\leq\varepsilon/2|X_1,\dots,X_n)\right)\\
&= \mathbb{P}(|Q_n(\widehat{f})-Q(\widehat{f})|\geq\varepsilon)\inf_{f\in\widetilde{\mathcal{F}_n}}\mathbb{P}(|Q_n(f)-Q(f)|\leq\varepsilon/2)\\
&= \mathbb{P}(\sup_{f\in\widetilde{\mathcal{F}_n}}|Q_n(f)-Q(f)|\geq\varepsilon)\inf_{f\in\widetilde{\mathcal{F}_n}}\mathbb{P}(|Q_n(f)-Q(f)|\leq\varepsilon/2).
\end{aligned}$$

The last step is true because of the definition of $\widehat{f}$: note that due to the definition of $\widehat{f}$ the event $|Q_n(\widehat{f})-Q(\widehat{f})|\geq\varepsilon$ is true iff there exists some $f\in\widetilde{\mathcal{F}_n}$ such that $|Q_n(f)-Q(f)|\geq\varepsilon$, which is true iff $\sup_{f\in\widetilde{\mathcal{F}_n}}|Q_n(f)-Q(f)|\geq\varepsilon$ (recall that we assumed for ease of notations that all supremum are attained). Rearranging the inequality above leads to

$$\mathbb{P}(\sup_{f\in\widetilde{\mathcal{F}_n}}|Q_n(f)-Q(f)|\geq\varepsilon) \leq \frac{\mathbb{P}(\sup_{f\in\widetilde{\mathcal{F}_n}}|Q_n(f)-Q_n'(f)|\geq\varepsilon/2)}{\inf_{f\in\widetilde{\mathcal{F}_n}}\mathbb{P}(|Q_n(f)-Q(f)|\leq\varepsilon/2)}.$$

Due to the symmetrization we got rid of the quantity $Q(f)$ in the numerator. Furthermore, using the assumption of the theorem that $Q_n(f)$ does not involve any function evaluations $f(x)$ for $x \notin \{X_1, \dots, X_n\}$ we can apply a union bound argument to move the supremum in the numerator out of the probability:

$$\begin{aligned}
&\mathbb{P}(\sup_{f \in \widetilde{\mathcal{F}_n}} |Q_n(f) - Q'_n(f)| \geq \varepsilon/2) \\
&\leq s(\widetilde{\mathcal{F}_n}, 2n) \sup_{f \in \widetilde{\mathcal{F}_n}} \mathbb{P}(|Q_n(f) - Q'_n(f)| \geq \varepsilon/2) \\
&\leq s(\widetilde{\mathcal{F}_n}, 2n) \sup_{f \in \widetilde{\mathcal{F}_n}} \mathbb{P}(|Q_n(f) - Q(f)| + |Q(f) - Q'_n(f)| \geq \varepsilon/2) \\
&\leq 2s(\widetilde{\mathcal{F}_n}, 2n) \sup_{f \in \widetilde{\mathcal{F}_n}} \mathbb{P}(|Q_n(f) - Q(f)| \geq \varepsilon/4).
\end{aligned}$$

This completes the proof of the lemma. ■

Now we are ready to prove our first main theorem.

A.2 Proof of Theorem 1

Additionally to the functions f_n and f^*, we will define

$$\begin{aligned}
f_n^* &\in \operatorname*{argmin}_{f \in \mathcal{F}_n} Q(f), \\
\widetilde{f}^* &\in \operatorname*{argmin}_{f \in \mathcal{F}_n} d(f, f^*).
\end{aligned}$$

To prove the theorem we have to show that under the conditions stated, for any fixed $\varepsilon > 0$ the term $\mathbb{P}(|Q(f_n) - Q(f^*)| \geq \varepsilon)$ converges to 0. We can study each "side" of this convergence independently:

$$\mathbb{P}(|Q(f_n) - Q(f^*)| \geq \varepsilon) = \mathbb{P}(Q(f_n) - Q(f^*) \leq -\varepsilon) + \mathbb{P}(Q(f_n) - Q(f^*) \geq \varepsilon).$$

To treat the "first side" observe that if $f_n \in \mathcal{F}$ then $Q(f_n) - Q(f^*) > 0$ by the definition of f^*. This leads to

$$\mathbb{P}(Q(f_n) - Q(f^*) \leq -\varepsilon) \leq \mathbb{P}(f_n \notin \mathcal{F}).$$

Under Assumption (2) of Theorem 1 this term tends to 0.

The main work of the proof is to take care of the second side. To this end we split $Q(f_n) - Q(f^*)$ in two terms, the estimation error and the approximation error:

$$Q(f_n) - Q(f^*) = Q(f_n) - Q(f_n^*) + Q(f_n^*) - Q(f^*).$$

For a fixed $\varepsilon > 0$ we have

$$\mathbb{P}(Q(f_n) - Q(f^*) \geq \varepsilon) \leq \mathbb{P}(Q(f_n) - Q(f_n^*) \geq \varepsilon/2) + \mathbb{P}(Q(f_n^*) - Q(f^*) \geq \varepsilon/2).$$

In the following sections we will treat both parts separately.

A.2.1 ESTIMATION ERROR

The first step is to see that

$$Q(f_n) - Q(f_n^*) \leq 2 \sup_{f \in \mathcal{F}_n} |Q_n(f) - Q(f)|.$$

Indeed, since $Q_n(f_n) \leq Q_n(f_n^*)$ by the definition of f_n we have

$$\begin{aligned} Q(f_n) - Q(f_n^*) &= Q(f_n) - Q_n(f_n) + Q_n(f_n) - Q_n(f_n^*) + Q_n(f_n^*) - Q(f_n^*) \\ &\leq Q(f_n) - Q_n(f_n) + Q_n(f_n^*) - Q(f_n^*) \\ &\leq 2 \sup_{f \in \mathcal{F}_n} |Q_n(f) - Q(f)|. \end{aligned}$$

Using Lemma 9 we obtain

$$\mathbb{P}(Q(f_n) - Q(f_n^*) \geq \varepsilon/2) \leq 2s(\widetilde{\mathcal{F}_n}, 2n) \frac{\sup_{f \in \widetilde{\mathcal{F}_n}} \mathbb{P}(|Q_n(f) - Q(f)| \geq \varepsilon/16)}{\inf_{f \in \widetilde{\mathcal{F}_n}} \mathbb{P}(|Q_n(f) - Q(f)| \leq \varepsilon/8)}.$$

Now observe that under Assumption (1) the numerator of the expression in the proposition tends to 0 and the denominator tends to 1, so the whole term tends to 0.

A.3 Approximation Error

By definition of f_n^* it is clear that

$$Q(f_n^*) - Q(f^*) \leq Q(\widetilde{f}^*) - Q(f^*).$$

Using Assumption (3) this leads to

$$\begin{aligned} \mathbb{P}(Q(f_n^*) - Q(f^*) \geq \varepsilon/2) &\leq \mathbb{P}(Q(\widetilde{f}^*) - Q(f^*) \geq \varepsilon/2) \\ &\leq \mathbb{P}(d(f, \widetilde{f}^*) \geq \delta(\varepsilon/2)). \end{aligned}$$

The right hand side clearly tends to 0 by Assumption (2).

■

A.4 The Proof of Theorem 2

Before proving Theorem 2, we again need to prove a few technical lemmas. The first one is a simple relation between the shattering coefficients of the nearest neighbor function classes.

Lemma 10 *Let $u \in \mathbb{N}$ and $\widetilde{\mathcal{F}_n}$ and $\widehat{\mathcal{F}_n}$ be the function sets defined in Theorem* 2. *Then*

$$s(\widetilde{\mathcal{F}_n}, u) \leq s(\widehat{\mathcal{F}_n}, u) \leq K^m u^{(d+1)m^2}.$$

Proof The first inequality is obvious as we have $\widetilde{\mathcal{F}_n} \subset \widehat{\mathcal{F}_n}$. For the second inequality observe that

$$s(\widehat{\mathcal{F}_n}, u) \leq K^m s^*(\widehat{\mathcal{F}_n}, u)$$

where $s^*(\widehat{\mathcal{F}_n},u)$ is the maximal number of different ways u points can be partitioned by cells of a Voronoi partition of m points. It is well known (e.g., Section 21.5 of Devroye et al., 1996) that $s^*(\widehat{\mathcal{F}_n},u) \le u^{(d+1)m^2}$ for $d > 1$. Note that for $d = 1$ a similar inequality holds, we do not consider this case any further. ■

The second lemma relates a function evaluated at a point x to the same function, evaluated at the nearest neighbor of x in the training points. This lemma builds on ideas of Fritz (1975).

Lemma 11 *Let $f : \mathcal{X} \to \{1,\dots,K\}$ be continuous almost everywhere and*

$$L_n := \mathbb{P}(f(X) \neq f(NN_m(X))|X_1,\dots,X_n).$$

Then for every $\varepsilon > 0$ there exists a constant $b_f(\varepsilon) > 0$ independent of n such that

$$\mathbb{P}(L_n \ge \varepsilon) \le \frac{2}{\varepsilon} e^{-mb_f(\varepsilon)}.$$

Proof By $B(x,\delta)$ we denote the Euclidean ball of center x and radius δ. The first step of the proof consists in constructing a certain set D (depending on ε) which satisfies the following statement:

For all $\varepsilon > 0$ there exists some $\delta(\varepsilon) > 0$, a measurable set $D \subset \mathbb{R}^d$ and a constant $1 > u > 0$ such that

(a) $\mathbb{P}(D) \ge 1 - \varepsilon/2$

(b) $\forall x \in D : \mathbb{P}(B(x,\delta)) > u$

(c) $\forall x \in D$ the function f is constant on $B(x,\delta)$.

Assume we have such a set D. Then using Properties (c) and (a) we can see that

$$\begin{aligned} L_n &= \mathbb{P}(f(X) \neq f(NN_m(X))|X_1,\dots,X_n) \\ &\le \mathbb{P}(X \notin D|X_1,\dots,X_n) + \mathbb{P}(X \in D, |X - NN_m(X)| > \delta|X_1,\dots,X_n) \\ &\le \tfrac{\varepsilon}{2} + \mathbb{P}(X \in D, |X - NN_m(X)| > \delta|X_1,\dots,X_n). \end{aligned}$$

Using the Markov inequality we can then see that

$$\begin{aligned} \mathbb{P}(L_n > \varepsilon) &\le \mathbb{P}(\mathbb{P}(X \in D, |X - NN_m(X)| > \delta|X_1,\dots,X_n) \ge \tfrac{\varepsilon}{2}) \\ &\le \tfrac{2}{\varepsilon}\mathbb{E}(\mathbb{P}(X \in D, |X - NN_m(X)| > \delta|X_1,\dots,X_n)) \\ &= \tfrac{2}{\varepsilon}\mathbb{P}(X \in D, |X - NN_m(X)| > \delta) \\ &= \tfrac{2}{\varepsilon}\int_D \mathbb{P}(|x - NN_m(x)| > \delta)\, d\mathbb{P}(x). \end{aligned}$$

Due to Property (b) we know that for all $x \in D$,

$$\begin{aligned} \mathbb{P}(|x - NN_m(x)| > \delta) &= \mathbb{P}(\forall i \in \{1,\dots,m\}, x \notin B(X_i,\delta)) \\ &= (1 - \mathbb{P}(B(x,\delta)))^m \\ &\le (1-u)^m. \end{aligned}$$

Setting $b(\varepsilon) := -log(1-u) > 0$ then leads to

$$P(L_n > \varepsilon) \leq \frac{2}{\varepsilon}\mathbb{P}(D)(1-u)^m \leq \frac{2}{\varepsilon}e^{-mb(\delta(\varepsilon))}.$$

Note that this constant $b(\varepsilon)$ will also be used in several of the following lemmas. To finish the proof of the lemma we have to show how the set D can be constructed. By the assumption of the lemma we know that f is continuous a.e., and that f only takes finitely many values $1,...,K$. This implies that the set

$$C = \{x \in \mathbb{R}^d : \exists \delta > 0 : d(x,y) \leq \delta \Rightarrow f(x) = f(y)\}$$

satisfies $\mathbb{P}(C) = 1$. Furthermore, for any $\delta > 0$ we define the set

$$A_\delta = \{x \in C : d(x,y) \leq \delta \Rightarrow f(x) = f(y)\}.$$

We have $\cup_\delta A_\delta = C$, and for $\sigma > \delta$ we have $A_\sigma \subset A_\delta$. This implies that given some $\varepsilon > 0$ there exists some $\delta(\varepsilon) > 0$ such that $\mathbb{P}(A_{\delta(\varepsilon)}) \geq 1 - \varepsilon/4$. By construction, all points in $A_{\delta(\varepsilon)}$ satisfy Property (c).

As the next step, we can see that for every $\delta > 0$ one has $\mathbb{P}(B(x,\delta)) > 0$ almost surely (with respect to x). Indeed, the set $U = \{x : \exists \delta > 0 : \mathbb{P}(B(x,\delta)) = 0\}$ is a union of sets of probability zero. So using the fact that $\mathbb{R}^d$ is separable we see that $\mathbb{P}(U) = 0$. Thus, $\mathbb{P}(\mathbb{P}(B(X,\delta)|X) > 0) = 1$, which implies $\mathbb{P}(\mathbb{P}(B(X,\delta)|X) > \frac{1}{n}) \to 1$. This means that given $\varepsilon > 0$ and $\delta > 0$ there exists a set A and a constant $u > 0$ such that $\mathbb{P}(A) \geq 1 - \varepsilon/4$ and $\forall x \in A, \mathbb{P}(B(x,\delta)) > u$. So all points in A satisfy Property (b).

Now finally define the set $D = A \bigcap A_{\delta(\varepsilon)}$. By construction, this set has probability $P(D) \geq \varepsilon/2$, so it satisfies Property (a). It satisfies Properties (b) and (c) by construction of A and $A_{\delta(\varepsilon)}$, respectively. ■

A.5 Proof of Theorem 2

To prove this theorem we will verify that the conditions (1) - (3) of Theorem 1 are satisfied for the function classes studied in Theorem 2.

Lemma 10 proves that Condition (1) of Theorem 2 implies Condition (1) of Theorem 1. Moreover, it is obvious that Condition (3) of Theorem 2 implies Condition (3) of Theorem 1.

Thus we only have to prove Condition (2) of Theorem 1. We begin by proving that $\mathbb{P}(f_n \notin \mathcal{F}) \to 0$. As $f_n \in \mathcal{F}_n$ by definition we have that $\Phi_n(f_{n,k}) > a_n$ for all $k = 1,\dots,K$. A union bound argument shows that

$$\mathbb{P}(f_n \notin \mathcal{F}) \leq K \sup_k \mathbb{P}(\Phi(f_{n,k}) \leq a).$$

Using the same techniques as in the proof of Lemma 9 we can see that

$$\begin{aligned}\mathbb{P}(\Phi(f_{n,k}) \leq a) &\leq \mathbb{P}(\Phi_n(f_{n,k}) - \Phi(f_{n,k}) \geq a_n - a)\\ &\leq \mathbb{P}(\sup_{g \in \mathcal{F}_n} \Phi_n(g_k) - \Phi(g_k) \geq a_n - a)\\ &\leq 2s(\widehat{\mathcal{F}_n}, 2n)\frac{\sup_{g \in \widehat{\mathcal{F}_n}} \mathbb{P}(\Phi_n(g_k) - \Phi(g_k) \geq (a_n - a)/4)}{\inf_{g \in \widehat{\mathcal{F}_n}} \mathbb{P}(\Phi_n(g_k) - \Phi(g_k) \leq (a_n - a)/2)}.\end{aligned}$$

Moreover, we already proved in Lemma 10 that $s(\widehat{\mathcal{F}_n}, 2n) \leq K^m (2n)^{(d+1)m^2}$. Condition (5) of Theorem 2 then implies that $\mathbb{P}(\Phi(f_{n,k}) \leq a)$ tends to 0.

Now we have to prove that for $f \in \mathcal{F}$ the term $d(f, \mathcal{F}_n) := \min_{g \in \mathcal{F}_n} d(f,g)$ tends to 0 in probability. Let $\widetilde{f}(x) = f(NN_m(x))$. If $\widetilde{f} \in \mathcal{F}_n$ then $d(f, \mathcal{F}_n) \leq d(f, \widetilde{f})$, so the following holds true:

$$\mathbb{P}(d(f, \mathcal{F}_n) \geq \varepsilon) \leq \mathbb{P}(\widetilde{f} \notin \mathcal{F}_n) + \mathbb{P}(d(f, \widetilde{f}) \geq \varepsilon).$$

The second term on the right hand side tends to 0 because of Lemma 11. To deal with the first term on the right hand side, observe that

$$\mathbb{P}(\widetilde{f} \notin \mathcal{F}_n) \leq K \sup_k \mathbb{P}(\Phi_n(\widetilde{f_k}) \leq a_n).$$

Because of Condition (4), for all $\varepsilon > 0, f \in \mathcal{F}$ and $g \in \widehat{\mathcal{F}_n}$ there exists $\delta(\varepsilon) > 0$ such that

$$d(f,g) \leq \delta(\varepsilon) \Rightarrow \Phi(f_k) - \Phi(g_k) \leq \varepsilon.$$

Define $a_n^f := \inf_k \Phi(f_k) - a_n$. Since $f \in \mathcal{F}$ there exists N such that $n \geq N \Rightarrow a_n^f > 0$. For $n \geq N$ we have the following inequalities:

$$\begin{aligned}
&\mathbb{P}(\Phi_n(\widetilde{f_k}) \leq a_n)\\
&= \mathbb{P}(\Phi(f_k) - \Phi_n(\widetilde{f_k}) \geq \Phi(f_k) - a_n)\\
&= \mathbb{P}(\Phi(f_k) - \Phi(\widetilde{f_k}) + \Phi(\widetilde{f_k}) - \Phi_n(\widetilde{f_k}) \geq \Phi(f_k) - a_n)\\
&\leq \mathbb{P}(\Phi(f_k) - \Phi(\widetilde{f_k}) \geq (\Phi(f_k) - a_n)/2) + \mathbb{P}(\Phi(\widetilde{f_k}) - \Phi_n(\widetilde{f_k}) \geq (\Phi(f_k) - a_n)/2)\\
&\leq \mathbb{P}(\Phi(f_k) - \Phi(\widetilde{f_k}) \geq a_n^f/2) + \mathbb{P}(\Phi(\widetilde{f_k}) - \Phi_n(\widetilde{f_k}) \geq a_n^f/2)\\
&\leq \mathbb{P}(d(f, \widetilde{f}) > \delta(a_n^f/2)) + \mathbb{P}(\sup_{g \in \widehat{\mathcal{F}_n}} \Phi(g_k) - \Phi_n(g_k) \geq a_n^f/2)\\
&\leq \frac{2}{\delta(a_n^f/2)} e^{-mb(\delta(a_n^f/2))} + \mathbb{P}(\sup_{g \in \widehat{\mathcal{F}_n}} \Phi(g_k) - \Phi_n(g_k) \geq a_n^f/2).
\end{aligned}$$

If $m \to \infty$ then the first term goes to 0. Indeed, $\delta(a_n^f/2)$ and $b(\delta(a_n^f/2))$ tend to positive constants since $f \in \mathcal{F}$ and thus $a_n^f \to \inf_k \Phi(f_k) - a > 0$. For the second term, the key step is to see that by the techniques used in the proof of Lemma 9 we get

$$\begin{aligned}
&\mathbb{P}(\sup_{g \in \widehat{\mathcal{F}_n}} \Phi(g_k) - \Phi_n(g_k) \geq a_n^f/2)\\
&\leq 2K^m (2n)^{(d+1)m^2} \frac{\sup_{g \in \widehat{\mathcal{F}_n}} \mathbb{P}(\Phi(g_k) - \Phi_n(g_k) \geq a_n^f/8)}{\inf_{g \in \widehat{\mathcal{F}_n}} \mathbb{P}(\Phi(g_k) - \Phi_n(g_k) \leq a_n^f/4)}.
\end{aligned}$$

Under Condition (2) this term tends to 0. ■

A.6 The Proofs of the Consistency Theorems 3, 5, 7 and 8

All these theorems are applications of Theorem 2 to specific objective functions Q_n and Q and to specific functions Φ_n and Φ. For all of them, we individually have to check whether the conditions in Theorem 2 are satisfied. In this section, we do not follow the order of the Theorems in the paper. This is only due to better readability of the proofs.

In most of these proves, we will use the McDiarmid inequality (McDiarmid, 1989), which we recall for the convenience of the reader:

Theorem 12 (McDiarmid inequality) *Let $(X_n)_{n\in\mathbb{N}}$ be a sequence of independent random variables. Let $g : (\mathbb{R}^d)^n \to \mathbb{R}$ be measurable and $c > 0$ a constant such that for all $1 \le i \le n$ we have*

$$\sup_{x_1,\ldots,x_n,x'\in\mathbb{R}^d} g(x_1,\ldots,x_n) - g(x_1,\ldots,x_{i-1},x',x_{i+1},\ldots,x_n) \le c.$$

Then

$$\mathbb{P}(|g(X_1,\ldots,X_n) - \mathbb{E}g(X_1,\ldots,X_n)| \ge \varepsilon) \le 2e^{-\frac{2\varepsilon^2}{nc^2}}.$$

Moreover, several times we will use the fact that $a_n \to a, m \to \infty$ and $\frac{m^2\log n}{n(a-a_n)^2} \to 0$ implies that $n(a-a_n)^2 \to \infty$ and $\frac{m^2\log n}{n} \to 0$.

Before we look at the "combined" objective functions such as Ncut, RatioCut, WSS, we will prove some technical conditions about their "ingredients" cut, vol, $Ef_k(X)$ and WS.

Lemma 13 (Conditions (2), (4), and (5) for cut, vol, $\mathbb{E}f_k(X)$, and WS) *Assume that*

$$\frac{m^2\log n}{n(a-a_n)^2} \to 0$$

then vol, cut, $\mathbb{E}f_k(X)$ *and* WS *satisfy Conditions (2), (4) and (5) of Theorem 2.*

Proof To prove Conditions (2) and (5) we are going to use the McDiarmid inequality. Observe that if one replaces one variable X_i by a new one X_i', then vol_n changes by at most $2C/n$, cut_n changes by at most $2C/n$, $\mathrm{WS}(f_k)$ changes by at most $2C/n$, and $n_k(f)$ changes by at most $1/n$. Using the McDiarmid inequality, this implies that for all $g \in \widehat{\mathcal{F}_n}$ and $\varepsilon > 0$

$$\mathbb{P}(|\mathrm{vol}_n(g_k) - \mathrm{vol}(g_k)| \ge \varepsilon) \le 2e^{-\frac{n\varepsilon^2}{2C^2}},$$

$$\mathbb{P}(|\mathrm{cut}_n(g_k) - \mathrm{cut}(g_k)| \ge \varepsilon) \le 2e^{-\frac{n\varepsilon^2}{2C^2}},$$

$$\mathbb{P}(|\mathrm{WS}_n(g_k) - \mathrm{WS}(g_k)| \ge \varepsilon) \le 2e^{-\frac{n\varepsilon^2}{2C^2}},$$

$$\mathbb{P}(|n_k(g) - \mathbb{E}g_k(X)| \ge \varepsilon) \le 2e^{-2n\varepsilon^2}.$$

So to prove Condition (2) we have to show that

$$\forall\varepsilon > 0, K^m(2n)^{(d+1)m^2}e^{-n\varepsilon} \to 0.$$

This follows clearly from $K^m(2n)^{(d+1)m^2}e^{-n\varepsilon} = e^{-n\left(\frac{m\log K+(d+1)m^2\log(2n)}{-n}+\varepsilon\right)}$ and $\frac{m^2\log n}{n} \to 0$. Moreover, since $n(a-a_n)^2 \to \infty$ Condition (5) is also true.

To prove (4) for each of the objective functions, let $f, g \in \mathcal{H}$ and f_k and g_k be the corresponding cluster indicator functions for cluster k. Then we can see that

$$\begin{aligned}
|\operatorname{vol}(g_k) - \operatorname{vol}(f_k)| &= |\int\int (f_k(X) - g_k(X))s(X,Y)\, dP(X)dP(Y)| \\
&\leq C\int_{\{f_k=g_k\}} 0\, dP(X)dP(Y) + C\int_{\{f_k=g_k\}^c} 1\, dP(X)dP(Y) \\
&= C\mathbb{P}(f_k \neq g_k) \\
&\leq Cd(f,g),
\end{aligned}$$

$$\begin{aligned}
|\operatorname{cut}(g_k) - \operatorname{cut}(f_k)| &= |\int\int f_k(X)(1-f_k(Y))s(X,Y) - g_k(X)(1-g_k(Y))s(X,Y)\, dP(X)dP(Y)\, | \\
&\leq C\int\int_{\{f=g\}^2} 0\, dP(X)dP(Y) + C\int\int_{(\{f=g\}^2)^c} 1\, dP(X)dP(Y) \\
&= C(1-\mathbb{P}(f(X)=g(X))^2) \\
&= C(1-(1-d(f,g))^2) \\
&\leq 2Cd(f,g),
\end{aligned}$$

$$|\mathbb{E}f_k(X) - \mathbb{E}g_k(X)| \leq d(f,g),$$

$$\begin{aligned}
|\operatorname{WS}(f_k) - \operatorname{WS}(g_k)| &= |\int\int (f_k(X)f_k(Y) - g_k(X)g_k(Y))s(X,Y)\, dP(X)dP(Y)\, | \\
&\leq \int_{\{f=g\}^2} 0\, dP(X)dP(Y) + C\int_{(\{f=g\}^2)^c} 1\, dP(X)dP(Y) \\
&= C(1-\mathbb{P}(f=g)^2) \\
&= C(1-(1-d(f,g))^2) \\
&\leq 2Cd(f,g).
\end{aligned}$$

■

Now we are going to check that the "combined" objective functions Ncut, RatioCut, Mod, WSS, BWR satisfy the conditions of Theorem 2. For many of the objective functions, one important step in the proof is to separate the convergence of the whole term into the convergence of the numerator and the denominator.

Lemma 14 (Condition (1) for Ncut) *Assume that*

$$\frac{m^2 \log n}{n} \to 0$$

then Ncut *satisfies Condition (1) of Theorem 2.*

Proof We first want to split the deviations of Ncut into the ones of cut and vol, respectively. To this end we want to show that for any $f \in \widetilde{\mathcal{F}_n}$

$$\{|\operatorname{cut}_n(f_k) - \operatorname{cut}(f_k)| \leq \tfrac{a}{2}\varepsilon\} \bigcap \{|\operatorname{vol}_n(f_k) - \operatorname{vol}(f_k)| \leq \tfrac{a}{2}\varepsilon\}$$

$$\subset \{|\tfrac{\operatorname{cut}_n(f_k)}{\operatorname{vol}_n(f_k)} - \tfrac{\operatorname{cut}(f_k)}{\operatorname{vol}(f_k)}| \leq \varepsilon\}.$$

This can be seen as follows. Assume that $|\operatorname{cut}_n(f_k) - \operatorname{cut}(f_k)| \leq \varepsilon$ and $|\operatorname{vol}_n(f_k) - \operatorname{vol}(f_k)| \leq \varepsilon$. If $\operatorname{vol}(f_k) \neq 0$ then we have (using the facts that $\operatorname{cut}(f_k) \leq \operatorname{vol}(f_k)$ and that $\operatorname{vol}_n(f_k) > a_n > a$ by definition of $\widetilde{\mathcal{F}_n}$):

$$\begin{aligned}
\tfrac{\operatorname{cut}_n(f_k)}{\operatorname{vol}_n(f_k)} - \tfrac{\operatorname{cut}(f_k)}{\operatorname{vol}(f_k)} &= \tfrac{\operatorname{cut}_n(f_k)\operatorname{vol}(f_k) - \operatorname{cut}(f_k)\operatorname{vol}_n(f_k)}{\operatorname{vol}_n(f_k)\operatorname{vol}(f_k)} \\
&\leq \tfrac{(\operatorname{cut}(f_k)+\varepsilon)\operatorname{vol}(f_k) - \operatorname{cut}(f_k)(\operatorname{vol}(f_k)-\varepsilon)}{\operatorname{vol}_n(f_k)\operatorname{vol}(f_k)} \\
&= \tfrac{\varepsilon}{\operatorname{vol}_n(f_k)} \tfrac{\operatorname{cut}(f_k)+\operatorname{vol}(f_k)}{\operatorname{vol}(f_k)} \\
&\leq \tfrac{2\varepsilon}{a}.
\end{aligned}$$

On the other hand, if $\operatorname{vol}(f_k) = 0$ then we have $\operatorname{cut}(f_k) = 0$, which implies $\operatorname{cut}_n(f_k) \leq \varepsilon$ by the assumption above. Thus the following statement holds true:

$$\frac{\operatorname{cut}_n(f)}{\operatorname{vol}_n(f)} - \frac{\operatorname{cut}(f)}{\operatorname{vol}(f)} = \frac{\operatorname{cut}_n(f)}{\operatorname{vol}_n(f)} \leq \frac{\varepsilon}{a} \leq \frac{2\varepsilon}{a}.$$

Using the same technique we have the same bound for $\frac{\operatorname{cut}(f_k)}{\operatorname{vol}(f_k)} - \frac{\operatorname{cut}_n(f_k)}{\operatorname{vol}_n(f_k)}$, which proves our set inclusion.

Now we apply a union bound and the McDiarmid inequality. For the latter, note that if one changes one X_i then $\operatorname{cut}_n(f)$ and $\operatorname{vol}_n(f)$ will change at most by $2C/n$. Together all this leads to

$$\begin{aligned}
&\mathbb{P}(|\operatorname{Ncut}(f) - \operatorname{Ncut}_n(f)| > \varepsilon) \\
&\leq K \sup_k \mathbb{P}(|\frac{\operatorname{cut}_n(f_k)}{\operatorname{vol}_n(f_k)} - \frac{\operatorname{cut}(f_k)}{\operatorname{vol}(f_k)}| > \varepsilon/K) \\
&\leq K \sup_k \Big(\mathbb{P}(|\operatorname{cut}_n(f_k) - \operatorname{cut}(f_k)| > \frac{a}{2K}\varepsilon) + \mathbb{P}(|\operatorname{vol}_n(f_k) - \operatorname{vol}(f_k)| > \frac{a}{2K}\varepsilon)\Big) \\
&\leq 4Ke^{-\frac{na^2\varepsilon^2}{8C^2K^2}}.
\end{aligned}$$

To finish we have to prove that

$$\forall \varepsilon > 0, K^{m+1}(2n)^{(d+1)m^2} e^{-n\varepsilon} \to 0.$$

This follows clearly from $K^{m+1}(2n)^{(d+1)m^2} e^{-n\varepsilon} = e^{-n\left(\frac{(m+1)\log K + (d+1)m^2 \log(2n)}{-n} + \varepsilon\right)}$ and $\frac{m^2 \log n}{n} \to 0$. ■

Lemma 15 (Condition (3) for Ncut**)** Ncut *satisfies Condition (3) of Theorem* 2.

Proof Let $f \in \mathcal{F}, g \in \widetilde{\mathcal{F}_n}$. In the proof of Lemma 13 we have already seen that

$$\begin{aligned} |\,\mathrm{cut}(f_k) - \mathrm{cut}(g_k)| &\leq 2Cd(f,g), \\ |\,\mathrm{vol}(f_k) - \mathrm{vol}(g_k)| &\leq 2Cd(f,g). \end{aligned}$$

If $\mathrm{vol}(g) \neq 0$ then we have (using the fact that we always have $\mathrm{cut}(f) \leq \mathrm{vol}(f)$):

$$\begin{aligned} \tfrac{\mathrm{cut}(f_k)}{\mathrm{vol}(f_k)} - \tfrac{\mathrm{cut}(g_k)}{\mathrm{vol}(g_k)} &= \tfrac{\mathrm{cut}(f_k)\,\mathrm{vol}(g_k) - \mathrm{cut}(g_k)\,\mathrm{vol}(f_k)}{\mathrm{vol}(f_k)\,\mathrm{vol}(g_k)} \\ &\leq \tfrac{(\mathrm{cut}(g_k)+2Cd(f,g))\,\mathrm{vol}(\widetilde{f}) - \mathrm{cut}(g_k)(\mathrm{vol}(g_k)-2Cd(f,g))}{\mathrm{vol}(f_k)\,\mathrm{vol}(g_k)} \\ &= \tfrac{2Cd(f,g)}{\mathrm{vol}(f_k)}\,\tfrac{\mathrm{vol}(g_k)+\mathrm{cut}(g_k)}{\mathrm{vol}(g_k)} \\ &\leq \tfrac{4C}{a} d(f,g)). \end{aligned}$$

On the other hand if $\mathrm{vol}(g_k) = 0$ then we have $|\,\mathrm{cut}(f_k)| \leq |\,\mathrm{vol}(f_k)| \leq 2Cd(f,g)$, in which case the following holds true:

$$\frac{\mathrm{cut}(f_k)}{\mathrm{vol}(f_k)} - \frac{\mathrm{cut}(g_k)}{\mathrm{vol}(\widetilde{f}_k)} = \frac{\mathrm{cut}(f_k)}{\mathrm{vol}(f_k)} \leq \frac{2Cd(f,g)}{a} \leq \frac{4C}{a} d(f,g).$$

So all in all we have

$$\mathrm{Ncut}(f) - \mathrm{Ncut}(g) \leq \frac{4CK}{a} d(f,g).$$

We can use the same technique to bound $\mathrm{Ncut}(g) - \mathrm{Ncut}(f)$. This proves that Ncut is Lipschitz and thus uniformly continuous. ■

Lemma 16 (Condition (1) for RatioCut**)** *Assume that*

$$\frac{m^2 \log n}{n} \to 0$$

then RatioCut *satisfies Condition (1) of Theorem* 2.

Proof Using exactly the same proof as for Lemma 14 (just changing $\mathrm{vol}_n(f_k)$ to n_k and $\mathrm{vol}(f_k)$ to $\mathbb{E} f_k(X)$ and using the fact that $\mathrm{cut}(f_k) \leq C\mathbb{E} f_k(X)$) we get

$$\begin{aligned} &\mathbb{P}(|\,\mathrm{RatioCut}_n(f) - \mathrm{RatioCut}(f)| > \varepsilon) \\ &\leq K \sup_k \left(\mathbb{P}(|\,\mathrm{cut}_n(f_k) - \mathrm{cut}(f_k)| > \frac{a}{(S+1)K}\varepsilon) + \mathbb{P}(|n_k(f) - \mathbb{E} f_k(X)| > \frac{a}{(S+1)K}\varepsilon) \right). \end{aligned}$$

Now a simple McDiarmid argument (using again the fact that changing one X_i changes cut_n by at most $2S/n$) gives

$$\mathbb{P}(|\,\mathrm{RatioCut}_n(f) - \mathrm{RatioCut}(f)| > \varepsilon) \leq 2Ke^{-\frac{na^2\varepsilon}{8C^2K^2}} + 2Ke^{-\frac{na^2\varepsilon^2}{2K^2}}.$$

We conclude the proof with the same argument as in Lemma 14. ■

Lemma 17 (Condition (3) for RatioCut) RatioCut *satisfies Condition (3) of Theorem* 2.

Proof This follows by the same proof as Lemma 14, just changing $\mathrm{vol}_n(f_k)$ to n_k, $\mathrm{vol}(f_k)$ to $\mathbb{E}f_k(X)$ and using the fact that $\mathrm{cut}(f_k) \leq C\mathbb{E}f_k(X)$. ■

Lemma 18 (Condition (1) for BWR) *If* $m^2 \log n/n \to 0$, *then* BWR *satisfies Condition (1) of Theorem* 2.

Proof Let $f \in \widetilde{\mathcal{F}_n}$. Let $\varepsilon \leq a/2$. If $|\mathrm{WS}_n(f_k) - \mathrm{WS}(f_k)| \leq \varepsilon$ and $|\mathrm{cut}_n(f_k) - \mathrm{cut}(f_k)| \leq \varepsilon$ then $\mathrm{WS}(f_k) \geq a/2 > 0$ (because $\mathrm{WS}_n(f_k) > a_n > a$ since $f \in \widetilde{\mathcal{F}_n}$). This implies

$$\begin{aligned}
\frac{\mathrm{cut}_n(f_k)}{\mathrm{WS}_n(f_k)} - \frac{\mathrm{cut}(f_k)}{\mathrm{WS}(f_k)} &= \frac{\mathrm{WS}(f_k)\,\mathrm{cut}_n(f_k) - \mathrm{WS}_n(f_k)\,\mathrm{cut}(f_k)}{\mathrm{WS}_n(f_k)\,\mathrm{WS}(f_k)} \\
&\leq \frac{\mathrm{WS}(f_k)(\mathrm{cut}(f_k)+\varepsilon) - (\mathrm{WS}(f_k)-\varepsilon)\,\mathrm{cut}(f_k)}{\mathrm{WS}_n(f_k)\,\mathrm{WS}(f_k)} \\
&= \frac{\varepsilon}{\mathrm{WS}_n(f_k)} \frac{\mathrm{WS}(f_k)+\mathrm{cut}(f_k)}{\mathrm{WS}(f_k)} \\
&\leq \frac{2C\varepsilon}{a^2}.
\end{aligned}$$

The analogous statement holds for $\frac{\mathrm{cut}(f_k)}{\mathrm{WS}(f_k)} - \frac{\mathrm{cut}_n(f_k)}{\mathrm{WS}_n(f_k)}$. Thus, if $\varepsilon \leq C/a$ then

$$\begin{aligned}
&\{|\mathrm{WS}_n(f_k) - \mathrm{WS}(f_k)| \leq a^2\varepsilon/(2C)\} \cap \{|\mathrm{cut}_n(f_k) - \mathrm{cut}(f_k)| \leq a^2\varepsilon/(2C)\} \\
&\subset \left\{\left|\frac{\mathrm{cut}_n(f_k)}{\mathrm{WS}_n(f_k)} - \frac{\mathrm{cut}(f_k)}{\mathrm{WS}(f_k)}\right| \leq \varepsilon\right\}.
\end{aligned}$$

As a consequence, if $\varepsilon \leq CK/a$ we have

$$\begin{aligned}
&\mathbb{P}(|\mathrm{BWR}_n(f) - \mathrm{BWR}(f)| > \varepsilon) \leq K \sup_k \mathbb{P}\left(\left|\frac{\mathrm{cut}_n(f_k)}{\mathrm{WS}_n(f_k)} - \frac{\mathrm{cut}(f_k)}{\mathrm{WS}(f_k)}\right|| > \varepsilon/K\right) \\
&\quad \leq K \sup_k \left(\mathbb{P}(|\mathrm{WS}_n(f_k) - \mathrm{WS}(f_k)| > a^2\varepsilon/(2CK)) + \mathbb{P}(|\mathrm{cut}_n(f_k) - \mathrm{cut}(f_k)| > a^2\varepsilon/(2CK))\right).
\end{aligned}$$

Using the McDiarmid inequality together with the fact that changing one point changes cut_n and WS_n by at most $C/(2n)$, we get for $\varepsilon \leq CK/a$:

$$\mathbb{P}(|\mathrm{BWR}_n(f) - \mathrm{BWR}(f)| > \varepsilon) \leq 4Ke^{-\frac{na^4\varepsilon^2}{8C^4K^2}}.$$

On the other hand, for $\varepsilon > CK/a$ we have

$$\begin{aligned}
&\mathbb{P}(|\mathrm{BWR}_n(f) - \mathrm{BWR}(f)| > \varepsilon) \\
&\leq \mathbb{P}(|\mathrm{BWR}_n(f) - \mathrm{BWR}(f)| > SK/a) \\
&\leq 4Ke^{-\frac{na^4(SK/a)^2}{8C^4K^2}}.
\end{aligned}$$

So all in all we have proved that

$$\mathbb{P}(|\,\mathrm{BWR}_n(f)-\mathrm{BWR}(f)|>\varepsilon)\leq 2Ke^{-\frac{na^4(\min(\varepsilon,CK/a))^2}{8C^4K^2}}.$$

We conclude the proof with the same argument as in Lemma 14. ■

Lemma 19 (Condition (3) for BWR) BWR *satisfies Condition (3) of Theorem 2.*

Proof Let $\varepsilon>0$, $f\in\mathcal{F}$ and $g\in\widetilde{\mathcal{F}_n}$. We have already proved the two following inequalities (in the proofs of Lemmas 13 and 15):

$$|\,\mathrm{cut}(f_k)-\mathrm{cut}(g_k)|\leq 2Cd(f,g),$$

$$|\,\mathrm{WS}(f_k)-\mathrm{WS}(g_k)|\leq 2Cd(f,g).$$

If $2Cd(f,g)\leq a/2$, then using that $\mathrm{WS}(f_k)>a$ we get $\mathrm{WS}(g_k)\geq a/2>0$. By the same technique as at the beginning of Lemma 18 we get

$$|\,\mathrm{BWR}(f)-\mathrm{BWR}(g)|\leq\frac{2CK}{a^2}2Cd(f,g).$$

Written a bit differently,

$$d(f,g)\leq\frac{a}{4C}\Rightarrow|\,\mathrm{BWR}(f)-\mathrm{BWR}(g)|\leq\frac{4C^2K}{a^2}d(f,g).$$

Now recall that we want to prove that there exists $\delta>0$ such that $d(f,g)\leq\delta\Rightarrow|\,\mathrm{BWR}(f)-\mathrm{BWR}(g)|\leq\varepsilon$.

If $\varepsilon\leq CK/a$ then we have:

$$d(f,g)\leq\frac{a^2}{4C^2K}\varepsilon\leq\frac{a}{4C}\Rightarrow|\,\mathrm{BWR}(f)-\mathrm{BWR}(g)|\leq\frac{4C^2K}{a^2}d(f,g)\leq\varepsilon.$$

On the other hand, if $\varepsilon>CK/a$ then

$$d(f,g)\leq\frac{a}{4C}\Rightarrow|\,\mathrm{BWR}(f)-\mathrm{BWR}(g)|\leq\frac{4C^2K}{a^2}d(f,g)\leq CK/a\leq\varepsilon$$

so we have proved the lemma. ■

Lemma 20 (Condition (1) for WSS) *If* $\frac{m^2\log n}{n}\to 0$ *and that* $\operatorname{supp}\mathbb{P}\subset B(0,A)$, *then* WSS *satisfies Condition (1) of Theorem 2.*

Proof Let $f\in\widetilde{\mathcal{F}_n}$. First note that

$$\begin{aligned}|\,\mathrm{WSS}_n(f)-\mathrm{WSS}(f)|&=\left|\frac{1}{n}\sum_{i=1}^n\sum_{k=1}^K f_k(X_i)\|X_i-c_{k,n}\|^2-\mathbb{E}\sum_{k=1}^K f_k(X)\|X-c_k\|^2\right|\\&\leq\left|\frac{1}{n}\sum_{i=1}^n\sum_{k=1}^K f_k(X_i)\|X_i-c_{k,n}\|^2-\frac{1}{n}\sum_{i=1}^n\sum_{k=1}^K f_k(X_i)\|X_i-c_k\|^2\right|\\&\quad+\left|\frac{1}{n}\sum_{i=1}^n\sum_{k=1}^K f_k(X_i)\|X_i-c_k\|^2-\mathbb{E}\sum_{k=1}^K f_k(X)\|X-c_k\|^2\right|.\end{aligned}$$

Now we will bound the probability for each of the terms on the right hand side. For the second term we can simply apply McDiarmid's inequality. Due to the assumption that $\operatorname{supp}\mathbb{P} \subset B(0,A)$ we know that for any two points $x, y \in \operatorname{supp}\mathbb{P}$ we have $\|x-y\| \leq 2A$. Thus if one changes one variable X_i then the term $\frac{1}{n}\sum_{i=1}^n \sum_{k=1}^K f_k(X_i)\|X_i - c_k\|^2$ will change by at most $A^2/(4n)$. This leads to

$$\mathbb{P}\left(\left| \frac{1}{n}\sum_{i=1}^n \sum_{k=1}^K f_k(X_i)\|X_i - c_k\|^2 - \mathbb{E}\sum_{k=1}^K f_k(X)\|X - c_k\|^2 \right| \geq \varepsilon \right) \leq 2e^{-\frac{2n\varepsilon^2}{A^4}}.$$

Now we have to take care of the first term, which can be written as

$$\frac{1}{n}\sum_{i=1}^n \sum_{k=1}^K f_k(X_i)\left(\|X_i - c_{k,n}\|^2 - \|X_i - c_k\|^2\right).$$

The triangle inequality gives

$$\|X_i - c_{k,n}\|^2 \leq (\|X_i - c_k\| + \|c_{k,n} - c_k\|)^2,$$

and together with the fact that $\operatorname{supp}\mathbb{P} \subset B(0,A)$ this leads to

$$\|X_i - c_{k,n}\|^2 - \|X_i - c_k\|^2 \leq 6A\|c_{k,n} - c_k\|.$$

So at this point we have

$$\left| \frac{1}{n}\sum_{i=1}^n \sum_{k=1}^K f_k(X_i)\|X_i - c_{k,n}\|^2 - \|X_i - c_k\|^2 \right| \leq 6A \sup_k \|c_{k,n} - c_k\|.$$

We will denote the j-th coordinate of a vector X by X^j. Recall that d denotes the dimensionality of our space. Using this notation we have

$$\|c_{k,n} - c_k\|^2 = \sum_{j=1}^d \left(\frac{\mathbb{E}f_k(X)X^j}{\mathbb{E}f_k(X)} - \frac{1}{n_k}\frac{1}{n}\sum_{i=1}^n f_k(X_i)X_i^j \right)^2.$$

Our goal will be to apply the McDiarmid inequality to each coordinate. Before we can do this, we want to show that

$$\{|n_k - \mathbb{E}f_k(X)| \leq \tfrac{a\varepsilon}{A+1}\} \;\cap\; \{|\tfrac{1}{n}\sum_{i=1}^n f_k(X_i)X_i^j - \mathbb{E}f_k(X)X^j| \leq \frac{a\varepsilon}{A+1}\} \;\subset\; \{|c_k^j - c_{k,n}^j| \leq \varepsilon\}.$$

To this end, assume that $|n_k - \mathbb{E}f_k(X)| \leq \varepsilon$ and $|\frac{1}{n}\sum_{i=1}^n f_k(X_i)X_i^j - \mathbb{E}f_k(X)X^j| \leq \varepsilon$.

In case $\mathbb{E}f_k(X) \neq 0$ we have

$$\begin{aligned}
c_k^j - c_{k,n}^j &= \frac{n_k\mathbb{E}f_k(X)X^j - \mathbb{E}f_k(X)\frac{1}{n_k}\frac{1}{n}\sum_{i=1}^n f_k(X_i)X_i^j}{n_k\mathbb{E}f_k(X)} \\
&\leq \frac{(\mathbb{E}f_k(X)+\varepsilon)\mathbb{E}f_k(X)X^j - \mathbb{E}f_k(X)(\mathbb{E}f_k(X)X^j - \varepsilon)}{n_k\mathbb{E}f_k(X)} \\
&= \frac{\varepsilon}{n_k}\frac{\mathbb{E}f_k(X)X^j + \mathbb{E}f_k(X)}{\mathbb{E}f_k(X)} \\
&\leq \frac{(A+1)\varepsilon}{a}
\end{aligned}$$

and similarly for $c^j_{k,n} - c^j_k$.

On the other hand, in case $\mathbb{E} f_k(X) = 0$ we also have $\mathbb{E} f_k(X) X^j = 0$ (as f_k is a non-negative function and $|X|$ is bounded by A). Together with the assumption this means that $\frac{1}{n}\sum_{i=1}^n f_k(X_i) X_i^j \leq \varepsilon$. This implies

$$|c^j_k - c^j_{k,n}| = \frac{1}{n_k}\frac{1}{n}\sum_{i=1}^n f_k(X_i)X_i^j \leq \frac{\varepsilon}{a} \leq \frac{(A+1)\varepsilon}{a}$$

which shows the inclusion stated above. The McDiarmid inequality now yields the two statements

$$\mathbb{P}(|n_k - \mathbb{E} f_k(X)| > \varepsilon) \leq 2e^{-2n\varepsilon^2},$$
$$\mathbb{P}\left(\left|\frac{1}{n}\sum_{i=1}^n f_k(X_i)X_i^j - \mathbb{E} f_k(X)X^j\right| > \varepsilon\right) \leq 2e^{-\frac{2n\varepsilon^2}{A^2}}.$$

Together they show that for the coordinate-wise differences

$$\mathbb{P}(|c^j_k - c^j_{k,n}| > \varepsilon) \leq 2e^{-\frac{2na^2\varepsilon^2}{(A+1)^2}} + 2e^{-\frac{2na^2\varepsilon^2}{A^2(A+1)^2}} \leq 4e^{-\frac{2na^2\varepsilon^2}{\max(1,A^2)(A+1)^2}}.$$

This leads to

$$\begin{aligned}\mathbb{P}(\|c_k - c_{k,n}\| > \varepsilon) &= \mathbb{P}(\sum_{j=1}^d |c^j_k - c^j_{k,n}|^2 > \varepsilon^2) \leq d \sup_j \mathbb{P}(|c^j_k - c^j_{k,n}| > \varepsilon/\sqrt{d}) \\ &\leq 4de^{-\frac{2na^2\varepsilon^2}{d\max(1,A^2)(A+1)^2}}.\end{aligned}$$

Combining all this leads to a bound for the first term of the beginning of the proof:

$$\begin{aligned}&\mathbb{P}\left(\left|\tfrac{1}{n}\textstyle\sum_{i=1}^n \sum_{k=1}^K f_k(X_i)\left(\|X_i - c_{k,n}\|^2 - \|X_i - c_k\|^2\right)\right| \geq \varepsilon\right) \\ &\leq \mathbb{P}\left(\sup_k \|c_{k,n} - c_k\| \geq \varepsilon/(6A)\right) \\ &\leq K \sup_k \mathbb{P}(\|c_{k,n} - c_k\| \geq \varepsilon/(6A)) \\ &\leq 4dKe^{-\frac{na^2\varepsilon^2}{18d\max(1,A^2)A^2(A+1)^2}}.\end{aligned}$$

Now we combine the probabilities for the first and the second term from the beginning of the proof using a union bound to get

$$\mathbb{P}(|\operatorname{WSS}_n(f) - \operatorname{WSS}(f)| > \varepsilon) \leq 4dKe^{-\frac{na^2\varepsilon}{18d\max(1,A^2)A^2(A+1)^2}} + 2e^{-\frac{8n\varepsilon^2}{A^4}}.$$

We conclude the proof with the same argument as in Lemma 14. ■

Lemma 21 (Condition (3) for WSS) *Assume that* $\operatorname{supp}\mathbb{P} \subset B(0,A)$ *then* WSS *satisfies Condition (3) of Theorem 2.*

Proof Let $f \in \mathcal{F}, g \in \widetilde{\mathcal{F}_n}$. We begin with the following inequality, which can be seen by splitting the expectation in the part where $\{f = g\}$ and $\{f \neq g\}$ and using the fact that $\operatorname{supp} \mathbb{P} \subset B(0,A)$:

$$\begin{aligned} |\operatorname{WSS}(f) - \operatorname{WSS}(g)| &= |\mathbb{E}\textstyle\sum_{k=1}^K f_k(X)\|X - c_k(f)\|^2 - g_k(X)\|X - c_k(g)\|^2| \\ &\leq 4A^2 d(f,g) + \textstyle\int_{\{f=g\}} \sum_{k=1}^K f_k(X)\left(\|X - c_k(f)\|^2 - \|X - c_k(g)\|^2\right). \end{aligned}$$

For the second term we have already seen in the proof of the previous lemma that $\|X - c_k(f)\|^2 - \|X - c_k(g)\|^2 \leq 6A\|c_k(f) - c_k(g)\|$. So for the moment we have

$$|\operatorname{WSS}(f) - \operatorname{WSS}(g)| \leq 4A^2 d(f,g) + 6A \sup_k \|c_k(f) - c_k(g)\|.$$

Now we want to bound the expression $\|c_k(f) - c_k(g)\|$. First of all, observe that $|\mathbb{E}f_k(X) - g_k(X)| \leq d(f,g)$ and $\|\mathbb{E}f_k(X)X - g_k(X)X\| \leq Ad(f,g)$.

In case $\mathbb{E}g_k(X) \neq 0$ we have

$$\begin{aligned} \|c_k(f) - c_k(g)\| &= \frac{\|\mathbb{E}g_k(X)\mathbb{E}f_k(X)X - \mathbb{E}f_k(X)\mathbb{E}g_k(X)X\|}{\mathbb{E}f_k(X)\mathbb{E}g_k(X)} \\ &\leq \frac{\|\mathbb{E}g_k(X)\left(\mathbb{E}f_k(X)X - \mathbb{E}g_k(X)X\right)\| + \|\left(\mathbb{E}g_k(X) - \mathbb{E}f_k(X)\right)\mathbb{E}g_k(X)X\|}{\mathbb{E}f_k(X)\mathbb{E}g_k(X)} \\ &\leq \frac{\mathbb{E}g_k(X)\|\mathbb{E}f_k(X)X - g_k(X)X\| + A\mathbb{E}g_k(X)|\mathbb{E}g_k(X) - f_k(X)|}{\mathbb{E}f_k(X)\mathbb{E}g_k(X)} \\ &\leq \frac{2A}{\mathbb{E}f_k(x)} d(f,g) \\ &\leq \frac{2A}{a} d(f,g). \end{aligned}$$

On the other hand, in case $\mathbb{E}g_k(X) = 0$ we also have $\mathbb{E}g_k(X)X = 0$ (as g_k is a non-negative function and $|X|$ is bounded by A). This leads to

$$\|c_k(f) - c_k(g)\| = \|\frac{\mathbb{E}f_k(X)X}{\mathbb{E}f_k(X)} - \frac{\mathbb{E}g_k(X)X}{\mathbb{E}g_k(X)}\| = \|\frac{\mathbb{E}f_k(X)X}{\mathbb{E}f_k(X)}\| \leq \frac{A}{a} d(f,g) \leq \frac{2A}{a} d(f,g).$$

Combining all results leads to

$$|\operatorname{WSS}(f) - \operatorname{WSS}(g)| \leq 4A^2(1 + 3/a)d(f,g)$$

which proves the lemma. ■

Lemma 22 (Condition (1) **for** Mod) *If* $m^2 \log n/n \to 0$, *then* Mod *satisfies Condition* (1) *of Theorem* 2.

Proof Let $f \in \widetilde{f}$. Using McDiarmid inequality one can prove

$$\mathbb{P}(|\sum_{k=1}^K \frac{1}{n(n-1)} \sum_{i \neq j} f_k(X_i) f_k(X_j) s(X_i, X_j) - \sum_{k=1}^K \mathbb{E}f_k(X) f_k(Y) s(X,Y)| \geq \varepsilon) \leq 2e^{-\frac{n\varepsilon^2}{2C^2K^2}}.$$

Now for ease of notation let

$$\begin{aligned}
Q_n(f) &= \frac{1}{n(n-1)^3}\sum_{k=1}^{K}\sum_{i\neq j} f_k(X_i)f_k(X_j)\sum_{l,l\neq i} s(X_i,X_l)\sum_{l,l\neq j} s(X_j,X_l),\\
\widetilde{Q_n}(f) &= \frac{1}{n(n-1)}\sum_{k=1}^{K}\sum_{i\neq j} f_k(X_i)f_k(X_j)\int s(X_i,Z)d\mathbb{P}(Z)\int s(X_j,Z)d\mathbb{P}(Z),\\
Q(f) &= \sum_{k=1}^{K}\int\int f_k(X)f_k(Y)\int s(X,Z)d\mathbb{P}(Z)\int s(Y,Z)d\mathbb{P}(Z)d(\mathbb{P}\times\mathbb{P})(X,Y).
\end{aligned}$$

If we have an exponential bound for $\mathbb{P}(|Q_n(f)-Q(f)|\geq\varepsilon)$ then with the above bound we would have an exponential bound for $\mathbb{P}(|\mathrm{Mod}_n(f)-\mathrm{Mod}(f)|\geq\varepsilon)$. Thus with the same argument than the one at the end of Lemma 14 the current lemma will be proved.
First note that

$$\mathbb{P}(|Q_n(f)-Q(f)|\geq\varepsilon)\leq\mathbb{P}(|Q_n(f)-\widetilde{Q_n}(f)|\geq\varepsilon/2)+\mathbb{P}(|\widetilde{Q_n}(f)-Q(f)|\geq\varepsilon/2).$$

Moreover $\mathbb{E}\widetilde{Q_n}(f)=Q(f)$ and thus with McDiarmid one can prove that

$$\mathbb{P}(|\widetilde{Q_n}(f)-Q(f)|\geq\varepsilon)\leq 2e^{\frac{n\varepsilon^2}{2C^4K^2}}.$$

The next step is to use the fact that for real numbers $a,b,a_n,b_n\in B(0,C)$,

$$|ab-a_nb_n|=|ab-a_nb+a_nb-a_nb_n|\leq C(|a-a_n|+|b-b_n|).$$

This implies the following inequalities:

$$\begin{aligned}
&|Q_n(f)-\widetilde{Q_n}(f)|\\
&\leq\frac{K}{n(n-1)}\sum_{i\neq j}\left|\frac{1}{(n-1)^2}\sum_{l,l\neq i}s(X_i,X_l)\sum_{l,l\neq j}s(X_j,X_l)-\int s(X_i,Z)d\mathbb{P}(Z)\int s(X_j,Z)d\mathbb{P}(Z)\right|\\
&\leq 2CK\sup_i\left|\frac{1}{n-1}\sum_{l,l\neq i}s(X_i,X_l)-\int s(X_i,Z)d\mathbb{P}(Z)\right|.
\end{aligned}$$

Hence the following:

$$\begin{aligned}
\mathbb{P}(|Q_n(f)-\widetilde{Q_n}(f)|\geq\varepsilon)&\leq\mathbb{P}(\sup_i|\frac{1}{n-1}\sum_{l,l\neq i}s(X_i,X_l)-\int s(X_i,Z)d\mathbb{P}(Z)|\geq\varepsilon/(2CK))\\
&\leq n\sup_i\mathbb{P}(|\frac{1}{n-1}\sum_{l,l\neq i}s(X_i,X_l)-\int s(X_i,Z)d\mathbb{P}(Z)|\geq\varepsilon/(2CK)).
\end{aligned}$$

Now to bound the last term we condition on X_i and use the McDiarmid inequality. Then taking the expectation yields the exponential bound:

$$\begin{aligned}
&\mathbb{P}(|\frac{1}{n-1}\sum_{l,l\neq i} s(X_i,X_l) - \int s(X_i,Z)d\mathbb{P}(Z)| \geq \varepsilon/(2CK)) \\
&= \mathbb{E}(\mathbb{P}(|\frac{1}{n-1}\sum_{l,l\neq i} s(X_i,X_l) - \int s(X_i,Z)d\mathbb{P}(Z)| \geq \varepsilon/(2CK)|X_i)) \\
&\leq \mathbb{E}(2e^{-\frac{n\varepsilon^2}{2C^4K^2}}) \\
&= 2e^{-\frac{n\varepsilon^2}{2C^4K^2}}.
\end{aligned}$$

All in all we proved that

$$\mathbb{P}(|\mathrm{Mod}_n(f) - \mathrm{Mod}(f)| \geq \varepsilon) \leq 2e^{-\frac{n\varepsilon^2}{8C^2K^2}} + 2(n+1)e^{-\frac{n\varepsilon^2}{32C^2K^2}}.$$

The n in front of the exponential obviously does not matter for the limit, see end of the proof of Lemma 14. ■

Lemma 23 (Condition (3) **for** Mod**)** Mod *satisfies Condition (*3*) of Theorem* 2.

Proof Let $f \in \mathcal{F}, g \in \widetilde{\mathcal{F}_n}$. Following the proof of Lemma 15 we have:

$$\begin{aligned}
|\mathrm{Mod}(f) - \mathrm{Mod}(g)| &\leq \sum_{k=1}^{K} \int\int_{(\{f=g\}^2)^c} (C + C^2) \\
&= K(C+C^2)(1-(1-d(f,g))^2) \\
&\leq 2K(C+C^2)d(f,g).
\end{aligned}$$

■

A.7 The Proofs of the Convergence Rates in Theorems 4 and 6

The following lemma collects all the bounds given in the previous proofs for WSS. Whenever possible, we used the one-sided McDiarmid inequality.

Lemma 24 *Assume that* $\operatorname{supp}\mathbb{P} \subset B(0,A)$ *for some constant* $A > 0$. *Let* $a_n^* := \inf_k \mathbb{E} f_k^*(X) - a_n$. *Then* $a_n^* \to a^* := \inf_k \mathbb{E} f_k^*(X) - a > 0$. *For all n and* $\varepsilon > 0$ *there exists a constant* $b(a_n^*/2)$ *which tends to a constant* $C' > 0$ *when* $n \to \infty$, *and a constant* $b(\varepsilon/(8A^2(1+3/a)))$ *(see Lemma* 11 *for more details about b) such that the following holds true*

$$\begin{aligned}
&\mathbb{P}(|\mathrm{WSS}(f_n) - \mathrm{WSS}(f^*)| \geq \varepsilon) \\
&\leq 2K^{m+1}(2n)^{(d+1)m^2}\left(\frac{4dKe^{-\frac{na^2\varepsilon}{616d\max(1,A^2)A^2(A+1)^2}} + 2e^{-\frac{n\varepsilon^2}{32A^4}}}{1-4dKe^{-\frac{na^2\varepsilon}{308d\max(1,A^2)A^2(A+1)^2}} - 2e^{-\frac{n\varepsilon^2}{8A^4}}} + \frac{Ke^{-\frac{n(a_n-a)^2}{8}}}{1-e^{-\frac{n(a_n-a)^2}{2}}} + \frac{Ke^{-\frac{na_n^{*2}}{32}}}{1-e^{-\frac{na_n^{*2}}{8}}}\right) \\
&+\frac{4K}{a_n^*}e^{-mb(a_n^*/2)} + (16A^2(1+3/a)/\varepsilon)e^{-mb(\varepsilon/(8A^2(1+3/a)))}.
\end{aligned}$$

A.8 Proof of Theorem 4

First we take care of the last two terms. There exists N' which depends on the rate of convergence of a_n and on a^* such that for $n \geq N'$ we have

$$a_n^* \leq a^*/2.$$

This implies $b(a_n^*/2) \leq b(a^*/4)$ (see Lemma 11 for details). Now let $C_1' := b(\varepsilon/(8A^2(1+3/a)))$ and $C_2' := b(a^*/4)$. Then for $n \geq N'$ we have:

$$\begin{aligned}
&\frac{4K}{a_n^*}e^{-mb(a_n^*/2)} + (16A^2(1+3/a)/\varepsilon)e^{-mb(\varepsilon/(8A^2(1+3/a)))}\\
&\leq 8Ka^*e^{-C_2'm} + (16A^2(1+3/a)/\varepsilon)e^{-C_1'm}\\
&\leq C_1e^{-C_2m}
\end{aligned}$$

with

$$C_1 := \max(8Ka^*; 16A^2(1+3/a)/\varepsilon) \qquad \text{and} \qquad C_2 := \min(C_1'; C_2').$$

C_2 is a positive constant which depends on a, a^*, A, ε and $\mathbb{P}$. C_1 depends on K, a, a^*, ε and A.

Since we assume $n(a_n - a)^2 \to \infty$ there exists N'' which depends on the rate of convergence of a_n and on a^* such that $n \geq N''$ implies:

$$e^{-\frac{n(a_n-a)^2}{8}} \leq 1/2 \qquad \text{and} \qquad e^{-\frac{na_n^*}{32}} \leq e^{-\frac{n(a_n-a)^2}{8}}.$$

This means that for $n \geq N''$:

$$\frac{Ke^{-\frac{n(a_n-a)^2}{8}}}{1-e^{-\frac{n(a_n-a)^2}{2}}} + \frac{Ke^{-\frac{na_n^{*2}}{32}}}{1-e^{-\frac{na_n^{*2}}{8}}} \leq 4Ke^{-\frac{n(a_n-a)^2}{8}}.$$

Finally let $N = \max(N', N'')$ and

$$\begin{aligned}
C_3 &:= \frac{8dK}{1-4dKe^{-\frac{Na^2\varepsilon}{308d\max(1,A^2)A^2(A+1)^2}} - 2e^{-\frac{N\varepsilon^2}{8A^4}}}\\
C_4 &:= \min\left(\frac{a^2}{616d\max(1,A^2)A^2(A+1)^2}; \frac{1}{32A^4}\right).
\end{aligned}$$

Since $\varepsilon \leq 1$ we have with these notations for $n \geq N$:

$$\frac{4dKe^{-\frac{na^2\varepsilon}{616d\max(1,A^2)A^2(A+1)^2}} + 2e^{-\frac{n\varepsilon^2}{32A^4}}}{1-4dKe^{-\frac{na^2\varepsilon}{308d\max(1,A^2)A^2(A+1)^2}} - 2e^{-\frac{n\varepsilon^2}{8A^4}}} \leq (C_3/2)e^{-C_4\varepsilon^2n}.$$

All in all Theorem 4 is proved. ■

The **Proof of Theorem 6** works analogously, we just replace the above lemma by to following one:

Lemma 25 *Assume that the similarity function s is bounded by $C > 0$. Let $a_n^* := \inf_k \operatorname{vol}(f_k^*) - a_n$. Then $a_n^* \to \inf_k \operatorname{vol}(f_k^*) - a > 0$. For all n and $\varepsilon > 0$ there exists a constant $b(a_n^*/(2S))$ which tends to a constant $C' > 0$ when $n \to \infty$, and a constant $b(a\varepsilon/(8SK))$ (see Lemma 11 for more details about b) such that the following holds true*

$$\mathbb{P}(|\operatorname{Ncut}(f_n) - \operatorname{Ncut}(f^*)| \geq \varepsilon)$$

$$\leq 2K^{m+1}(2n)^{(d+1)m^2}\left(\frac{4e^{-\frac{na^2\varepsilon^2}{2048C^2K^2}}}{1-4Ke^{-\frac{na^2\varepsilon^2}{512C^2K^2}}} + \frac{e^{-\frac{n(a_n-a)^2}{32C^2}}}{1-e^{-\frac{n(a_n-a)^2}{8C^2}}} + \frac{e^{-\frac{na_n^{*2}}{128C^2}}}{1-e^{-\frac{na_n^{*2}}{32C^2}}}\right)$$

$$+\frac{4CK}{a_n^*}e^{-mb(a_n^*/(2C))} + \frac{16CK}{a\varepsilon}e^{-mb(a\varepsilon/(8CK))}.$$

Abstract

Various relationships are shown hold between monotonic effects and weak monotonic effects and the monotonicity of certain conditional expectations. Counterexamples are provided to show that the results do not hold under less restrictive conditions. Monotonic effects are furthermore used to relate signed edges on a causal directed acyclic graph to qualitative effect modification. The theory is applied to an example concerning the direct effect of smoking on cardiovascular disease controlling for hypercholesterolemia. Monotonicity assumptions are used to construct a test for whether there is a variable that confounds the relationship between the mediator, hypercholesterolemia, and the outcome, cardiovascular disease.

Keywords: Bayesian networks, conditional expectation, covariance, directed acyclic graphs, effect modification, monotonicity

1. Introduction

Several papers have considered various monotonicity relationships on Bayesian networks or directed acyclic graphs. Wellman (1990) introduced the notion of qualitative causal influence and derived various resulting concerning the propagation of qualitative influences, the preservation of monotonicity under edge reversal, the necessity of first order stochastic dominance for propagating influences and the propagation of sub-additive and super-additive relationships on probabilistic networks. Druzdzel and Henrion (1993) developed a polynomial time algorithm for reasoning in qualitative probabilistic network, based on local sign propagation. More recently, van der Gaag et al. (2004) showed that identifying whether a network exhibits various monotonicity properties is coNP^{PP}- complete. VanderWeele and Robins (2009) introduced the concept of a monotonic effect which is closely related to Wellman's qualitative influence and considered the relationship between monotonicity properties and causal effects, covariance, bias and confounding. In this paper we develop a number of probabilistic properties concerning monotonic effects and weak monotonic effects. Some of these properties give rise to certain inequality constraints that could be used to test for the presence of hidden or unmeasured confounding variables. These inequality constraints which arise from monotonicity relationships provide constraints beyond those already available in the literature (Kang and Tian, 2006). The paper is organized as follows. In Section 2 we describe the notation we will use in this paper and review the definitions concerning directed acyclic graphs. In Section 3 we present a motivating example for the theory that will be developed. In Section 4, we define the concepts of a monotonic effect and a weak monotonic effect in the directed acyclic graph causal framework, the latter essentially being equivalent to Wellman's (1990) qualitative influence. In Section 5, we give a number of results relating weak monotonic effects to the monotonicity in the conditioning argument of certain conditional expectations; we also return to the motivating example and show how the theory developed can be applied to this example. Finally, in Section 6, we give a number of results that relate weak monotonic effects to the existence of qualitative effect modifiers. Section 7 closes with some concluding remarks.

2. Notation and Directed Acyclic Graphs

Following Pearl (1995), a causal directed acyclic graph is a set of nodes $(X_1,...,X_n)$ and directed edges amongst nodes such that the graph has no cycles and such that for each node X_i on the graph the corresponding variable is given by its non-parametric structural equation $X_i = f_i(pa_i, \varepsilon_i)$ where pa_i are the parents of X_i on the graph and the ε_i are mutually independent. We will use Ω to denote the sample space for ε and ω to denote a particular point in the sample space. These non-parametric structural equations can be seen as a generalization of the path analysis and linear structural equation models (Pearl, 1995, 2000) developed by Wright (1921) in the genetics literature and Haavelmo (1943) in the econometrics literature. Directed acyclic graphs can be interpreted as representing causal relationships. The non-parametric structural equations encode counterfactual relationships amongst the variables represented on the graph. The equations themselves represent one-step ahead counterfactuals with other counterfactuals given by recursive substitution. The requirement that the ε_i be mutually independent is essentially a requirement that there is no variable absent from the graph which, if included on the graph, would be a parent of two or more variables (Pearl, 1995, 2000). Further discussion of the causal interpretation of directed acyclic graphs can be found elsewhere (Pearl, 1995, 2000; Spirtes et al., 2000; Dawid, 2002; Robins, 2003).

A path is a sequence of nodes connected by edges regardless of arrowhead direction; a directed path is a path which follows the edges in the direction indicated by the graph's arrows. A node C is said to be a common cause of A and Y if there exists a directed path from C to Y not through A and a directed path from C to A not through Y. We will say that $V_1,...,V_n$ constitutes an ordered list if $i < j$ implies that V_i is not a descendent of V_j. A collider is a particular node on a path such that both the preceding and subsequent nodes on the path have directed edges going into that node, that is, both the edge to and the edge from that node have arrowheads into the node. A path between A and B is said to be blocked given some set of variables Z if either there is a variable in Z on the path that is not a collider or if there is a collider on the path such that neither the collider itself nor any of its descendants are in Z. If all paths between A and B are blocked given Z then A and B are said to be d-separated given Z. It has been shown that if A and B are d-separated given Z then A and B are conditionally independent given Z (Verma and Pearl, 1988; Geiger et al., 1990; Lauritzen et al., 1990). We will use the notation $A \coprod B|Z$ to denote that A is conditionally independent of B given Z; we will use the notation $(A \coprod B|Z)_G$ to denote that A and B are d-separated given Z on graph G. The directed acyclic graph causal framework has proven to be particularly useful in determining whether conditioning on a given set of variables, or none at all, is sufficient to control for confounding. The most important result in this regard is the back-door path criterion (Pearl, 1995). A back-door path from some node A to another node Y is a path which begins with a directed edge into A. Pearl

$$\begin{tikzcd}
& & U \arrow[d, dashed] \arrow[dr] & \\
Q \arrow[r] \arrow[rr, bend right] \arrow[rrr, bend right=50] & A \arrow[r] \arrow[rr, bend left=70, "\oplus"] & R \arrow[r] & Y
\end{tikzcd}$$

Figure 1: Motivating example concerning the estimation of controlled direct effects.

(1995) showed that for intervention variable A and outcome Y, if a set of variables Z is such that no variable in Z is a descendent of A and such that Z blocks all back-door paths from A to Y then conditioning on Z suffices to control for confounding for the estimation of the causal effect of A on Y. The counterfactual value of Y intervening to set $A = a$ we denote by $Y_{A=a}$.

3. Motivating Example

To motivate the theory we develop in this paper consider the following example.

Example 1. Suppose that Figure 1 represents a causal directed acyclic graph. Let A denote smoking; let R hypercholesterolemia; and let Y denote cardiovascular disease. High cholesterol can lead to the narrowing of the arteries resulting in cardiovascular disease; smoking can lead to blood clots through platelet aggregation resulting in cardiovascular disease. Let Q denote some variable that confounds the relationships between smoking and cardiovascular disease and between hypercholesterolemia and cardiovascular disease (e.g., stress). Let U be some unmeasured variable which might confound the relationship between hypercholesterolemia and cardiovascular disease. The researcher is unsure whether the variable U is a cause of R and we therefore represent the edge from U to R as a dashed line. The results of Pearl (2001) imply that it is possible to estimate controlled direct effects of the form $Y_{A=a_1,R=r} - Y_{A=a_0,R=r}$ (i.e., the direct effect of smoking on cardiovascular disease controlling for hypercholesterolemia) on the graph in Figure 1 if that U is not a cause of R. Suppose that although the researcher is unsure about the presence an edge from U to R, it is known that the relationship between A and Y is monotonic in the sense that $P(Y > y|A = a, R = r, Q = q, U = u)$ is non-decreasing in a for all y, r, q and u. In Section 5, we will present theory that will allow us to derive a statistical test for the null hypothesis that there is no unmeasured variable U confounding the relationship between R and Y.

4. On the Definition of a Monotonic Effect

The definition of a monotonic effect is given in terms of a directed acyclic graph's nonparametric structural equations.

Definition 1. *The non-parametric structural equation for some node Y on a causal directed acyclic graph with parent A can be expressed as $Y = f(\widetilde{pa}_Y, A, \varepsilon_Y)$ where $\widetilde{pa}_Y$ are the parents of Y other than A; A is said to have a positive monotonic effect on Y if for all $\widetilde{pa}_Y$ and ε_Y, $f(\widetilde{pa}_Y, A_1, \varepsilon_Y) \geq f(\widetilde{pa}_Y, A_2, \varepsilon_Y)$ whenever $A_1 \geq A_2$. Similarly A is said to have a negative monotonic effect on Y if for all $\widetilde{pa}_Y$ and ε_Y, $f(\widetilde{pa}_Y, A_1, \varepsilon_Y) \leq f(\widetilde{pa}_Y, A_2, \varepsilon_Y)$ whenever $A_1 \geq A_2$.*

As we have defined it above, a causal direct acyclic graph corresponds to a set of non-parametric structural equations and as such the definition of a monotonic effect given above is relative to a particular set of non-parametric structural equations. The presence of a monotonic effect is closely related to the monotonicity of counterfactual variables as is made clear by the following proposition. All proofs of all propositions and lemmas are given in Appendix A.

Proposition 1. *The variable A has a positive monotonic effect on Y if and only if for all ω and all values of $\widetilde{pa}_Y$, $Y_{a_1, \widetilde{pa}_Y}(\omega) \geq Y_{a_0, \widetilde{pa}_Y}(\omega)$ whenever $a_1 \geq a_0$.*

We note that several sets of non-parametric structural equations may yield identical distributions of $X = (X_1, ..., X_n)$ and $\{X_{V=v}\}_{V \subseteq X, v \in supp(V)}$ (Pearl, 2000). In the context of characterizations of causal directed acyclic graphs that make reference to counterfactuals but not to non-parametric structural equations (Robins, 2003), a positive monotonic effect could instead be defined to be present if for all $\widetilde{pa}_Y$ and $a_1 \geq a_0$, $P(Y_{a_1, \widetilde{pa}_Y} \geq Y_{a_0, \widetilde{pa}_Y}) = 1$. If this latter condition holds with respect to one set of non-parametric structural equations it will hold for any set of non-parametric structural equations which yields the same distribution for X and $\{X_{V=v}\}_{V \subseteq X, v \in supp(V)}$. We note that if for $a_1 \geq a_0$ the set $\{\omega : Y_{a_1, \widetilde{pa}_Y}(\omega) < Y_{a_0, \widetilde{pa}_Y}(\omega)\}$ is of measure zero then $Y_{a_1, \widetilde{pa}_Y}$ and $Y_{a_0, \widetilde{pa}_Y}$ could be re-defined on this set so that $Y_{a_1, \widetilde{pa}_Y}(\omega) \geq Y_{a_0, \widetilde{pa}_Y}(\omega)$ for all ω and so that the distributions of X and $\{X_{V=v}\}_{V \subseteq X, v \in supp(V)}$ remain unchanged.

Because for any value ω we observe the outcome only under one particular value of the intervention variable, the presence of a monotonic effect is not identifiable. The results presented in this paper are in fact true under slightly weaker conditions which are identifiable when data on all of the directed acyclic graph's variables are observed. We thus introduce the concept of a weak monotonic effect which is a special case of Wellman's positive qualitative influence (Wellman, 1990). The definition of a weak monotonic effect does not make reference to counterfactuals and thus can be used in characterizations of causal directed acyclic graphs that do not employ the concept of counterfactuals (Spirtes et al., 2000; Dawid, 2002). The stronger notion of a monotonic effect given above is useful in the context of testing for synergistic relationships (VanderWeele and Robins, 2008).

Definition 2. *Suppose that variable A is a parent of some variable Y and let $\widetilde{pa}_Y$ denote the parents of Y other than A. We say that A has a weak positive monotonic effect on Y if the survivor function $S(y|a, \widetilde{pa}_Y) = P(Y > y|A = a, \widetilde{pa}_Y)$ is such that whenever $a_1 \geq a_0$ we have $S(y|a_1, \widetilde{pa}_Y) \geq S(y|a_0, \widetilde{pa}_Y)$ for all y and all $\widetilde{pa}_Y$; the variable A is said to have a weak negative monotonic effect on Y if whenever $a_1 \geq a_0$ we have $S(y|a_1, \widetilde{pa}_Y) \leq S(y|a_0, \widetilde{pa}_Y)$ for all y and all $\widetilde{pa}_Y$.*

Proposition 2. *If A has a positive monotonic effect on Y then A has a weak positive monotonic effect on Y.*

We note that for parent A and child Y, the definition of a weak monotonic effect coincides with Wellman's (1990) definition of positive qualitative influence when the "context" for qualitative influence is chosen to be the parents of Y other than A.

A monotonic effect is a relation between two nodes on a directed acyclic graph and as such it is associated with an edge. The definition of the sign of an edge can be given either in terms of monotonic effects or weak monotonic effects. We can define the sign of an edge as the sign of the monotonic effect or weak monotonic effect to which the edge corresponds; this in turn gives rise to a natural definition for the sign of a path.

Definition 3. *An edge on a causal directed acyclic graph from X to Y is said to be of positive sign if X has a positive monotonic effect on Y. An edge from X to Y is said to be of negative sign if X has a negative monotonic effect on Y. If X has neither a positive monotonic effect nor a negative monotonic effect on Y, then the edge from X to Y is said to be without a sign.*

Definition 4. *The sign of a path on a causal directed acyclic graph is the product of the signs of the edges that constitute that path. If one of the edges on a path is without a sign then the sign of the path is said to be undefined.*

We will call a causal directed acyclic graph with signs on those edges which allow them a signed causal directed acyclic graph. The theorems in this paper are given in terms of signed paths so as to be applicable to both monotonic effects and weak monotonic effects. One further definition will be useful in the development of the theory below.

Definition 5. *Two variables X and Y are said to be positively monotonically associated if all directed paths from X to Y or from Y to X are of positive sign and all common causes C_i of X and Y are such that all directed paths from C_i to X are of the same sign as all directed paths from C_i to Y; the variables X and Y are said to be negatively monotonically associated if all directed paths between X and Y are of negative sign and all common causes C_i of X and Y are such that all directed paths from C_i to X are of the opposite sign as all directed paths from C_i to Y.*

It has been shown elsewhere (VanderWeele and Robins, 2009) that if X and Y are positively monotonically associated then $Cov(X,Y) \geq 0$ and if X and Y are negatively monotonically associated then $Cov(X,Y) \leq 0$. We now develop several results concerning the monotonicity in the conditioning argument of certain conditional expectations.

5. Monotonic Effects and Conditional Expectations

Lemma 1 below can be proved by integration by parts and will be used in the proofs of the subsequent propositions. We will assume throughout the remainder of this paper that the random variables under consideration satisfy regularity conditions that allow for the integration by parts required in the proof of Lemma 1. If conditional cumulative distribution functions are continuously differentiable then the regularity conditions will be satisfied; the regularity conditions will also be satisfied if all variables are discrete. Härdle et al. (1998, p72) also gives relatively weak conditions under which such integration by parts is possible. Alternatively, the existence of the Lebesgue-Stieltjes integrals found in the proof of Lemma 1 suffices to allow integration by parts. Note that Lemma 1 will always be applied either to the function $h(y,a,r) = y$ or to conditional survivor functions which will satisfy the relevant regularity conditions; thus the conditions which are required for integration by parts are only regularity conditions on the distribution of the random variables.

Lemma 1. *If $h(y,a,r)$ is non-decreasing in y and in a and $S(y|a,r) = P(Y > y|A = a, R = r)$ is non-decreasing in a for all y then $E[h(Y,A,R)|A = a, R = r]$ is non-decreasing in a.*

Proposition 3 immediately follows from Lemma 1.

Proposition 3. *Suppose that the A–Y edge, if it exists, is positive. Let X denote some set of non-descendents of Y that includes $\widetilde{pa}_Y$, the parents of Y other than A, then $E[Y|X = x, A = a]$ is non-decreasing in a for all values of x.*

Proposition 4 gives the basic result for the monotonicity of conditional expectations. For the conditional expectation of some variable Y to be monotonic in a conditioning argument A, it requires that the conditioning set includes variables that block all backdoor paths from A to Y. In order to prove Proposition 4 we will make use of the following two lemmas.

Lemma 2. *Suppose that A is a non-descendent of Y and let Q denote the set of ancestors of A or Y which are not descendents of A. Let $R = (R_1, ..., R_m)$ denote an ordered list of some set of nodes on directed paths from A to Y such that for each i the backdoor paths from R_i to Y are blocked by $R_1, ..., R_{i-1}, A$, and Q. Let $V_0 = A$ and $V_n = Y$ and let $V_1, ..., V_{n-1}$ be an ordered list of all the nodes which are not in R but which are on directed paths from A to Y such that at least one of the directed paths from each node to Y is not blocked by R. Let $\overline{V}_k = \{V_1, ..., V_k\}$ then $S(v_k|a, \overline{v}_{k-1}, q, r) = S(v_k|pa_{v_k})$.*

Lemma 3. *If under the conditions of Lemma 2 all directed paths from A to Y are positive except possibly through R then $S(y|a,q,r)$ is non-decreasing in a.*

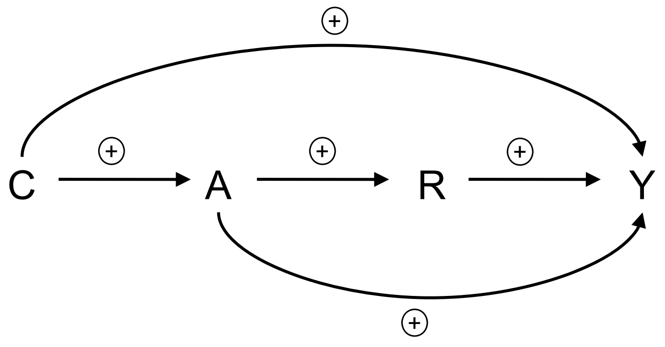
These two lemmas allow us to prove Proposition 4 given below.

Proposition 4. *Suppose that A is a non-descendent of Y and let X denote some set of non-descendents of A that blocks all backdoor paths from A to Y. Let $R = (R_1, ..., R_m)$ denote an ordered list of some set of nodes on directed paths from A to Y such that for each i the backdoor paths from R_i to Y are blocked by $R_1, ..., R_{i-1}, A$ and X. If all directed paths from A to Y are positive except possibly through R then $S(y|a,x,r)$ and $E[y|a,x,r]$ are non-decreasing in a.*

If $R = \varnothing$ the statement of Proposition 4 is considerably simplified and is stated in the following corollary.

Corollary. *Let X denote some set of non-descendents of A that blocks all backdoor paths from A to Y. If all directed paths between A and Y are positive then $S(y|a,x)$ and $E[y|a,x]$ are non-decreasing in a.*

Lemma 3 and Proposition 4 are generalizations of results given by Wellman (1990) and Druzdzel and Henrion (1993). In particular, in Lemma 3 if $R = \varnothing$, then the result follows immediately from repeated application of Theorems 4.2 and 4.3 in Wellman (1990) or more directly from the work of Druzdzel and Henrion (1993, Theorem 4). Lemma 3 generalizes the results of Wellman (1990) and Druzdzel and Henrion (1993) by allowing for conditioning on nodes $R = (R_1, ..., R_m)$ which are on directed paths from A to Y. Proposition 4 further generalizes Lemma 3 by replacing the set Q in



$$\begin{tikzcd} C \arrow[r, "\oplus"] \arrow[rrr, bend left, "\oplus"] & A \arrow[r, "\oplus"] \arrow[rr, bend right, "\oplus"'] & R \arrow[r, "\oplus"] & Y \end{tikzcd}$$

Figure 2: Example illustrating Propositions 4-6.

Lemma 3 which consists of the set of ancestors of A or Y which are not descendents of A with some other set X which consists of some set of non-descendents of A that blocks all backdoor paths from A to Y.

Propositions 5-8 relax the condition that the conditioning set includes variables that block all backdoor paths A to Y and impose certain other conditions; the proofs of each of these propositions make use of Proposition 4.

Proposition 5. *Suppose that A is not a descendent of Y, that A is binary, and that A and Y are positively monotonically associated then $E[Y|A]$ is non-decreasing in A.*

Proposition 6. *Suppose that A is not a descendent of Y, that Y is binary, and that A and Y are positively monotonically associated then $E[A|Y]$ is non-decreasing in Y.*

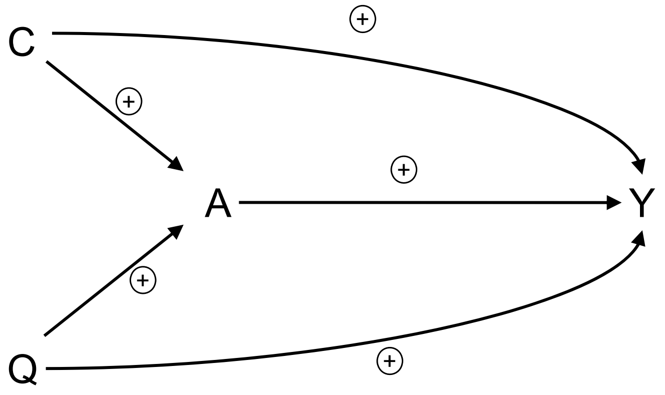
Propositions 5 and 6 require that the conditioning variable be binary. Counterexamples can be constructed to show that if the conditioning variable is not binary then the conditional expectation may not be non-decreasing in the conditioning argument even if A and Y are positively monotonically associated (see Appendix B, counterexamples 1 and 2).

Propositions 5 and 6 can be combined to give the following corollary which makes no reference to the ordering of A and Y.

Corollary. *Suppose that A is binary and that A and Y are positively monotonically associated then $E[Y|A]$ is non-decreasing in A.*

Example 2. Consider the signed directed acyclic graph given in Figure 2. By Proposition 4, we have that $E[Y|A=a,C=c,R=r]$ and $E[Y|A=a,C=c]$ are non-decreasing in a. If A is binary then by Proposition 5, it is also the case that $E[Y|A=a]$ is non-decreasing in a. If Y is binary, then by Proposition 6, $E[A|Y=y]$ is non-decreasing in y. The monotonicity of $E[Y|A=a,C=c,R=r]$ and $E[Y|A=a,C=c]$ also follow directly from the results of Wellman (1990) and Druzdzel and Henrion (1993); the monotonicity of $E[Y|A=a]$ and $E[A|Y=y]$ do not.

Propositions 7 and 8 consider the monotonicity of conditional expectations while conditioning on variables other than the variable in which monotonicity holds but not conditioning on variables that are sufficient to block all backdoor paths between A and Y. Propositions 7 and 8 generalize



$$\begin{tikzcd}
C \arrow[dr, "\oplus"] \arrow[drr, bend left, "\oplus"] & & \\
& A \arrow[r, "\oplus"] & Y \\
Q \arrow[ur, "\oplus"] \arrow[urr, bend right, "\oplus"'] & &
\end{tikzcd}$$

Figure 3: Example illustrating Propositions 7 and 8.

Propositions 5 and 6 respectively.

Proposition 7. *Suppose that A is not a descendent of Y and that A is binary. Let Q be some set of variables that are not descendents of Y nor of A and let C be the common causes of A and Y not in Q. If all directed paths from A to Y are of positive sign and all directed paths from C to A not through Q are of the same sign as all directed paths from C to Y not through $\{Q,A\}$ then $E[Y|A,Q]$ is non-decreasing in A.*

Proposition 8 is similar to Proposition 7 but the conditional expectation $E[A|Y,Q]$ is considered rather than $E[Y|A,Q]$ and Y rather than A is assumed to be binary. The form of the proof differs.

Proposition 8. *Suppose that A is not a descendent of Y and that Y is binary. Let Q be some set of variables that are not descendents of Y nor of A and let C be the common causes of A and Y not in Q. If all directed paths from A to Y are of positive sign and all directed paths from C to A not through Q are of the same sign as all directed paths from C to Y not through $\{Q,A\}$ then $E[A|Y,Q]$ is non-decreasing in Y.*

Propositions 7 and 8 can be combined to give the following corollary which makes no reference to the ordering of A and Y.

Corollary. *Suppose that A is binary. Let Q be some set of variables that are not descendents of Y nor of A and let C be the common causes of A and Y not in Q. If all directed paths from A to Y (or from A to Y) are of positive sign and all directed paths from C to A not through $\{Q,Y\}$ are of the same sign as all directed paths from C to Y not through $\{Q,A\}$ then $E[Y|A,Q]$ is non-decreasing in Y.*

Example 3. Consider the signed directed acyclic graph given in Figure 3. If A is binary, then by Proposition 7, $E[Y|A=a,C=c,Q=q]$, $E[Y|A=a,Q=q]$, $E[Y|A=a,C=c]$ and $E[Y|A=a]$ are all non-decreasing in a. If Y is binary then by Proposition 8, $E[A|Y=y,C=c,Q=q]$, $E[A|Y=y,Q=q]$, $E[A|Y=y,C=c]$ and $E[A|Y=y]$ are all non-decreasing in y. The monotonicity of $E[Y|A=a,C=c,Q=q]$ follows directly from the results of Wellman (1990) and Druzdzel and Henrion (1993); the monotonicity of the other conditional expectations do not.

We now return to Example 1 concerning potential unmeasured confounding in the estimation of controlled direct effects.

Example 1 (Revisited). Consider once again the causal directed acyclic graph given in Figure 1. Suppose that we may assume that A has a weak monotonic effect on Y. Under the null hypothesis that U is not a cause of R (i.e., does not confound the relationship between R and Y) we could conclude by Proposition 4 that $E[Y|A=a,R=r,Q=q]$ is non-decreasing in a for all r and q. Under the alternative hypothesis that U is a cause of R, we could not apply Proposition 4 because of the unblocked backdoor path $R-U-Y$ between R and Y. The monotonicity relationship would thus not necessarily hold. Consequently, if $E[Y|A=a,R=r,Q=q]$ were found not to be monotonic in a then we could reject the null hypothesis that U is not a cause of R. Note that the monotonicity of $E[Y|A=a,R=r,Q=q]$ in a also follows from the results of Wellman (1990) and Druzdzel and Henrion (1993). If, however, there were an edge from U to Q for example, or in more complicated scenarios, the results of Wellman (1990) and Druzdzel and Henrion (1993) would no longer suffice to conclude the monotonicity of $E[Y|A=a,R=r,Q=q]$ in a; one would need to employ Proposition 4.

We now construct a simple statistical test in the case that A,R and Y are all binary (cf. Robins and Greenland, 1992) of the null hypothesis that U is absent from Figure 1. Let n_{ijq} denote the number of individuals in stratum $Q=q$ with $A=i$ and $R=j$ and let let d_{ijq} denote the number of individuals in stratum $Q=q$ with $A=i$ and $R=j$ and $Y=1$. Let p_{ijq} denote the true probability $P(Y=1|A=i,R=j,Q=q)$. From the null hypothesis that U is absent from Figure 1, it follows by Proposition 4 that $p_{1jq}-p_{0jq}\leq 0$ for all j and q. Thus we have $d_{ijq}\sim Bin(n_{ijq},p_{ijq})$ with $\mathbb{E}[\frac{d_{ijq}}{n_{ijq}}]=p_{ijq}$ and $Var(\frac{d_{ijq}}{n_{ijq}})=\frac{p_{ijq}(1-p_{ijq})}{n_{ijq}}$. By the central limit central limit theorem $\frac{(\frac{d_{1jq}}{n_{1jq}}-\frac{d_{0jq}}{n_{0jq}})-(p_{1jq}-p_{0jq})}{\sqrt{\frac{p_{1jq}(1-p_{1jq})}{n_{1jq}}+\frac{p_{0jq}(1-p_{0jq})}{n_{0jq}}}}\dot{\sim}N(0,1)$ and by Slutsky's theorem we have $\frac{(\frac{d_{1jq}}{n_{1jq}}-\frac{d_{0jq}}{n_{0jq}})-(p_{1jq}-p_{0jq})}{\sqrt{\frac{d_{1jq}(n_{1jq}-d_{1jq})}{n_{1jq}^3}+\frac{d_{0jq}(n_{0jq}-d_{0jq})}{n_{0jq}^3}}}\dot{\sim}N(0,1)$. To test the null hypothesis that the edge from U to R is absent from Figure 1 one may thus use the test statistic $\frac{(\frac{d_{1jq}}{n_{1jq}}-\frac{d_{0jq}}{n_{0jq}})}{\sqrt{\frac{d_{1jq}(n_{1jq}-d_{1jq})}{n_{1jq}^3}+\frac{d_{0jq}(n_{0jq}-d_{0jq})}{n_{0jq}^3}}}$ with critical regions of the form: $\{\frac{(\frac{d_{1jq}}{n_{1jq}}-\frac{d_{0jq}}{n_{0jq}})}{\sqrt{\frac{d_{1jq}(n_{1jq}-d_{1jq})}{n_{1jq}^3}+\frac{d_{0jq}(n_{0jq}-d_{0jq})}{n_{0jq}^3}}}>Z_{1-\alpha}\}$ to carry out a one-sided (upper tail) test. The derivation of the power of such a test would require providing explicit structural equations for each of the variables in the model. Similar tests could be constructed for other scenarios. We note that if the test fails to reject the null, one cannot conclude that the arrow from U to R is absent; if the inequality $E[Y|A=a_1,R=r,Q=q]\leq E[Y|A=a_2,R=r,Q=q]$ holds for all $a_1\leq a_2$ this is potentially consistent with both the presence and the absence of an edge from U to R. If, however, the test rejects the null then one can conclude that an edge from U to R must be present, provided the other model assumptions hold. With observational data, the assumption that no unmeasured confounding variable is present can be falsified but it cannot be verified regardless of the approach one takes. It is nevertheless worthwhile testing any empirical implications of the no unmeasured confounding variables assumptions which can be derived, such as those following from Proposition 4.

Tian and Pearl (2002) and Kang and Tian (2007) derived various equality constraints that arise from causal directed acyclic graphs with hidden variables; Kang and Tian (2006) derived various inequality constraints that arise from causal directed acyclic graphs with hidden variables. We note that the inequality constraint $E[Y|A=a_1,R=r,Q=q] \leq E[Y|A=a_2,R=r,Q=q]$ for $a_1 \leq a_2$ does not follow from the results of Tian and Pearl (2002) or Kang and Tian (2006, 2007). The equality and inequality constraints which follow from their work will apply to all causal models consistent with the directed acyclic graph in Figure 1 (without the sign); the inequality constraint $E[Y|A=a_1,R=r,Q=q] \leq E[Y|A=a_2,R=r,Q=q]$ follows only if it can be assumed in Figure 1 that A has a weak positive monotonic effect on Y. More generally, the results in this paper provide a supplementary set of constraints to those of Tian and Pearl (2002) and Kang and Tian (2006, 2007).

6. Effect Modification and Monotonic Effects

If when conditioning on a particular variable, the sign of the effect of another variable on the outcome varies between strata of the conditioning variable, then the conditioning variable is said to be a qualitative effect modifier. The following definition gives the condition for qualitative effect modification more formally.

Definition 6. *A variable Q is said to be an effect modifier for the causal effect of A on Y if Q is not a descendent of A and if there exist two levels of A, a_0 and a_1 say, such that $E[Y_{A=a_1}|Q=q]-E[Y_{A=a_0}|Q=q]$ is not constant in q. Furthermore Q is said to be a qualitative effect modifier if there exist two levels of A, a_0 and a_1, and two levels of Q, q_0 and q_1, such that $sign(E[Y_{A=a_1}|Q=q_1]-E[Y_{A=a_0}|Q=q_1]) \neq sign(E[Y_{A=a_1}|Q=q_0]-E[Y_{A=a_0}|Q=q_0])$.*

Monotonic effects and weak monotonic effects are closely related to the concept of qualitative effect modification. Essentially, the presence of a monotonic effect precludes the possibility of qualitative effect modification. This is stated precisely in Propositions 9 and 10.

Proposition 9. *Suppose that some parent A_1 of Y is such that the A_1-Y edge is of positive sign then there can be no other parent, A_2, of Y which is a qualitative effect modifier for causal effect of A_1 on Y, either unconditionally or within some stratum $C=c$ of the parents of Y other than A_1 and A_2.*

A similar result clearly holds if the A_1-Y edge is of negative sign. We give the contrapositive of Proposition 9 as a corollary.

Corollary. *Suppose that some parent of Y, A_2, is a qualitative effect modifier for causal effect of another parent of Y, A_1, either unconditionally or within some stratum $C=c$ of the parents of Y other than A_1 and A_2 then A_1 can have neither a weak positive monotonic effect nor a weak negative monotonic effect on Y.*

If there are intermediate variables between A and Y then Proposition 9 can be generalized to give Proposition 10.

Proposition 10. *Suppose that all directed paths from A to Y are of positive sign (or are all of negative sign) then there exists no qualitative effect modifier Q on the directed acyclic graph for the causal effect of A on Y.*

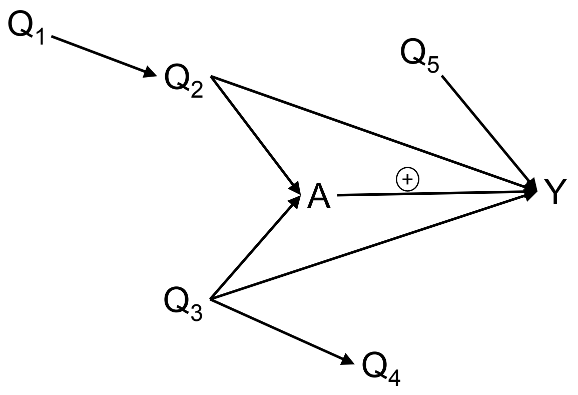


Figure 4: Example illustrating the use of Propositions 9 and 10.

Example 4. Consider the signed directed acyclic graph given in Figure 4 in which the $A-Y$ edge is of positive sign. It can be shown that any of Q_1, Q_2, Q_3, Q_4 or Q_5 can serve as effect modifiers for the causal effect of A on Y (VanderWeele and Robins, 2007). However, by Proposition 9 or 10, since A has a (weak) monotonic effect on Y, none of Q_1, Q_2, Q_3, Q_4 or Q_5 can serve as *qualitative* effect modifiers for the causal effect of A on Y. Conversely, if it is found that one of Q_1, Q_2, Q_3, Q_4 or Q_5 *is* a qualitative effect modifier for the causal effect of A on Y then the $A-Y$ edge cannot be of positive (or negative) sign.

7. Concluding Remarks

In this paper we have related weak monotonic effects to the monotonicity of certain conditional expectations in the conditioning argument and to qualitative effect modification. When the variables on a causal directed acyclic graph exhibit weak monotonic effects the results can be used to construct tests for the presence of unmeasured confounding variables. Future work could examine whether it is possible to weaken the restrictions on R in Proposition 4; another area of future research would include developing an algorithm for what relationships need systematic evaluation in order to test for particular confounding patterns; further research could also be done on the derivation of statistical tests of the type considered at the end of Section 5 for cases in which A, R and Y are not binary and for dealing with issues related to multiple testing problems.

Acknowledgments

We would like to thank the editors and three anonymous referees for helpful comments on this paper.

Appendix A. Proofs

This appendix contains the proofs for all of the results in this paper.

A.1 Proof of Proposition 1

By the definition of a non-parametric structural equation, $Y_{a,\widetilde{pa}_Y}(\omega) = f(\widetilde{pa}_Y, a, \varepsilon_Y(\omega))$ and from this the result follows.

A.2 Proof of Proposition 2

Since A has a positive monotonic effect on Y, for any $a_1 \geq a_0$ we have that $S(y|a_1, \widetilde{pa}_Y) = P(Y > y|a_1, \widetilde{pa}_Y) = P\{f(\widetilde{pa}_Y, a_1, \varepsilon_Y) > y\} \geq P\{f(\widetilde{pa}_Y, a_0, \varepsilon_Y) > y\} = P(Y > y|a_0, \widetilde{pa}_Y) = S(y|a_1, \widetilde{pa}_Y)$.

A.3 Proof of Lemma 1

For $a \geq a'$ we have $E[h(Y,A,R)|A = a, R = r] - E[h(Y,A,R)|A = a', R = r]$ $= \int_{y=-\infty}^{y=\infty} h(y,a,r)dF(y|a,r) - \int_{y=-\infty}^{y=\infty} h(y,a',r)dF(y|a',r) = \int_{y=-\infty}^{y=\infty} h(y,a,r)d\{F(y|a,r) - F(y|a',r)\} + \int_{y=-\infty}^{y=\infty} \{h(y,a,r) - h(y,a',r)\}dF(y|a',r) = [h(y,a,r)\{F(y|a,r) - F(y|a',r)\}]_{y=-\infty}^{y=\infty} - \int_{y=-\infty}^{y=\infty} \{F(y|a,r) - F(y|a',r)\}dh(y,a,r) + \int_{y=-\infty}^{y=\infty} \{h(y,a,r) - h(y,a',r)\}dF(y|a',r)$
$= \int_{y=-\infty}^{y=\infty} \{S(y|a,r) - S(y|a',r)\}dh(y,a,r) + \int_{y=-\infty}^{y=\infty} \{h(y,a,r) - h(y,a',r)\}dF(y|a',r)$. This final expression is non-negative since the integrands of both integrals are non-negative for $a \geq a'$.

A.4 Proof of Proposition 3

We have that $E[Y|X = x, A = a] = E[Y|\widetilde{pa}_Y, A = a]$ and since A has a (weak) positive monotonic effect on Y, we have that $S(y|a, \widetilde{pa}_Y)$ is non-decreasing in a and it follows from Lemma 1 that $E[Y|X = x, A = a] = E[Y|\widetilde{pa}_Y, A = a]$ is non-decreasing in a.

A.5 Proof of Lemma 2

We will say a path from A to B is a frontdoor path from A to B if the path begins with a directed edge with the arrowhead pointing out of A. Let Q^k and R^k be the subsets of Q and R respectively that are ancestors of $\overline{V}_k$. We will show that

$$\begin{aligned} S(v_k|a, v_1, ..., v_{k-1}, q, r) &= S(v_k|a, v_1, ..., v_{k-1}, q, r^k) \\ &= S(v_k|a, v_1, ..., v_{k-1}, q^k, r^k) = S(v_k|pa_{v_k}). \end{aligned}$$

If $R^k = R$, the first equality holds trivially. Suppose that $R^k \neq R$ so that R_m is not an ancestor of V_k. All frontdoor paths from R_m to V_k must include a collider since R_m is not an ancestor of V_k. This collider will not be in $A, V_1, ..., V_{k-1}, Q, R_1, ..., R_{m-1}$ since all these variables are non-descendents of R_m. Thus all frontdoor paths from R_m to V_k will be blocked given $A, V_1, ..., V_{k-1}, Q, R_1, ..., R_{m-1}$. All backdoor paths from R_m to V_k with an edge going into V_k will be blocked given $A, V_1, ..., V_{k-1}, Q, R_1, ..., R_{m-1}$ by pa_{V_k}; note by hypothesis it can be seen that pa_{V_k} will be contained by the variables $A, V_1, ..., V_{k-1}$, Q, R^k since there is a directed path from V_k to Y and Q includes all ancestors of Y not on directed paths from A to Y. All backdoor paths from R_m to V_k with an edge going out from V_k will be blocked given $A, Q, R_1, ..., R_{m-1}$ by hypothesis; otherwise there would be a backdoor path from R_m through V_k to Y not blocked by $A, Q, R_1, ..., R_{m-1}$. But all backdoor paths from R_m to V_k with an edge going out from V_k which are blocked by $A, Q, R_1, ..., R_{m-1}$ will also be blocked by

$A,V_1,...,V_{k-1},Q,R_1,...,R_{m-1}$. This is because such a path concluding with an edge going out from V_k which is blocked by $A,Q,R_1,...,R_{m-1}$ but not blocked by $A,V_1,...,V_{k-1},Q,R_1,...,R_{m-1}$ would require that one of $V_1,...,V_{k-1}$, say V_p, be a collider on the path or a descendent of a collider. If one of $V_1,...,V_{k-1}$ were a collider then the path would in fact be blocked by the parents of the collider since all the parents of $V_1,...,V_{k-1}$ are in $A,V_1,...,V_{k-1},Q,R_1,...,R_{m-1}$. If one of $V_1,...,V_{k-1}$, say V_p, were a descendent of the collider then none of the directed paths from the collider to V_p could contain nodes in $R_1,...,R_{m-1}$ for otherwise the path would not be blocked by $A,Q,R_1,...,R_{m-1}$; for the same reason the collider itself could not be in $R_1,...,R_{m-1}$. But it then follows that the collider must itself be one of $V_1,...,V_{p-1}$ since it is an ancestor of V_p with a directed path to V_p not blocked by R. However, if the collider is one of $V_1,...,V_{p-1}$ then the path would in fact be blocked by the parents of the collider since all the parents of $V_1,...,V_{k-1}$ are in $A,V_1,...,V_{k-1},Q,R_1,...,R_{m-1}$. From this it follows that all backdoor paths from R_m to V_k with an edge going out from V_k are blocked by $A,V_1,...,V_{k-1},Q,R_1,...,R_{m-1}$.

We have thus shown that V_k and R_m are d-separated given $A,V_1,...,V_{k-1},Q,R_1,...,R_{m-1}$ and so

$$S(v_k|a,v_1,...,v_{k-1},q,r) = S(v_k|a,v_1,...,v_{k-1},q,r_1,...,r_{m-1}).$$

Similarly, V_k and R_{m-1} are d-separated given $A,V_1,...,V_{k-1},Q,R_1,...,R_{m-2}$ and so

$$S(v_k|a,v_1,...,v_{k-1},q,r_1,...,r_{m-1}) = S(v_k|a,v_1,...,v_{k-1},q,r_1,...,r_{m-2}).$$

We may carry this argument forward to get

$$S(v_k|a,v_1,...,v_{k-1},q,r) = S(v_k|a,v_1,...,v_{k-1},q,r^k).$$

All backdoor paths from V_k to $Q\backslash Q^k$ will be blocked given $A,V_1,...,V_{k-1},Q^k,R^k$ by pa_{v_k}. Since V_k is not a descendent of $Q\backslash Q^k$ all frontdoor paths from V_k to $Q\backslash Q^k$ will involve at least one collider which is a descendent of V_k. This collider is not in the conditioning set $A,V_1,...,V_{k-1},Q^k,R^k$ since this entire set consists of non-descendents of V_k and so the collider will block the frontdoor path from V_k to $Q\backslash Q^k$.

Thus V_k and $Q\backslash Q^k$ are d-separated given $A,V_1,...,V_{k-1},Q^k,R^k$ and so

$$S(v_k|a,v_1,...,v_{k-1},q,r^k) = S(v_k|a,v_1,...,v_{k-1},q^k,r^k).$$

Furthermore, $A,V_1,...,V_{k-1},Q^k,R^k$ are non-descendents of V_k and include all of the parents of V_k and so

$$S(v_k|a,v_1,...,v_{k-1},q^k,r^k) = S(v_k|pa_{v_k}).$$

We have thus shown as desired that

$$\begin{aligned} S(v_k|a,v_1,...,v_{k-1},q,r) &= S(v_k|a,v_1,...,v_{k-1},q,r^k) \\ &= S(v_k|a,v_1,...,v_{k-1},q^k,r^k) = S(v_k|pa_{v_k}). \end{aligned}$$

A.6 Proof of Lemma 3

Let $V_0 = A$ and $V_n = Y$ and let $V_1,...,V_{n-1}$ be an ordered list of all the nodes which are not in R but which are on directed paths from A to Y such that at least one of the directed paths from each node to Y is not blocked by R. Let $\overline{V}_k = \{V_1,...,V_k\}$. It can be shown by induction that by starting with

$n = k$ and for each k iteratively replacing by their negations the parents of V_k with negative edges into V_k suffices to obtain a graph such that all edges on all directed paths from A to Y not blocked by R have positive sign.

We can express $E[1(V_n > v)|A,Q,R]$ as

$$E[E[...E[E[1(V_n > v)|A,\overline{V}_{n-1},Q,R]|A,\overline{V}_{n-2},Q,R]|...|A,V_1,Q,R]|A,Q,R].$$

Now conditional on $A,\overline{V}_{n-1}\backslash V_i,Q,R$ we have that

$$E[1(V_n > v)|,A,\overline{V}_{n-1},Q,R]$$

is non-decreasing in v_i for $i = 1,...,n-1$ since V_i has either a weak positive monotonic effect or no effect on V_n. Thus conditional on $A,\overline{V}_{n-1}\backslash\{V_i,V_{n-1}\},Q,R$ we have that

$$E[1(V_n > v)|A,\overline{V}_{n-1},Q,R]$$

is a non-decreasing function of v_i and v_{n-1}. Furthermore, by Lemma 2 we have that $S(v_{n-1}|a,v_1,...,v_{n-2},q,r) = S(v_{n-1}|pa_{v_{n-1}})$ and so $S(v_{n-1}|a,v_1,...,v_{n-2},q,r) = S(v_{n-1}|pa_{v_{n-1}})$ is a non-decreasing in v_i for all $a,v_1,...,v_{i-1},v_{i+1},...,v_{n-2},q,r$ since V_i has either a weak positive monotonic effect or no effect on V_{n-1}. Thus by Lemma 1 we have that conditional on $A,\overline{V}_{n-2}\backslash V_i,Q,R$,

$$E[E[1(V_n > v)|A,\overline{V}_{n-1},Q,R]|A,\overline{V}_{n-2},Q,R]$$

is non-decreasing in v_i for $i = 1,...,n-2$. Carrying the argument forward, conditional on A,Q,R, we will have that

$$E[...E[E[1(V_n > v)|A,\overline{V}_{n-1},Q,R]|A,\overline{V}_{n-2},Q,R]|...|A,V_1,Q,R]$$

is a non-decreasing function of v_1 and $v_0 = a$ and since A has either a weak positive monotonic effect or no effect on V_1, $S(v_1|a,q,r) = S(v_1|pa_{v_1})$ will be non-decreasing in a and thus by Lemma 1,

$$\begin{aligned} S(y|a,q,r) &= E[1(V_n > y)|A,Q,R] \\ &= E[E[...E[E[1(V_n > y)|A,\overline{V}_{n-1},Q,R]|A,\overline{V}_{n-2},Q,R]|...|A,V_1,Q,R]|A,Q,R] \end{aligned}$$

will be non-decreasing in a.

A.7 Proof of Proposition 4

Let Q denote the set of ancestors of A or Y which are not descendents of A. Note that if for each i the backdoor paths from R_i to Y are blocked by $R_1,...,R_{i-1},A$ and X then these backdoor paths will also be blocked by $R_1,...,R_{i-1},A$ and Q since for each backdoor path from R_i to X there must be some member of $\{A\}\bigcup Q$ through which the path passes. We may thus apply Lemma 3 to conclude that $E[1(Y > y)|a,Q,r]$. Since Q blocks all backdoor paths from A to Y we have

$$\begin{aligned} S(y|a,x,r) &= E[E[1(Y > y)|a,Q,x,r]|a,x,r] \\ &= E[E[1(Y > y)|a,Q,r]|a,x,r] = E[E[1(Y > y)|a,W,r]|a,x,r] \end{aligned}$$

where W is the subset of Q which are either parents of Y or parents of a node on a directed path from A to Y. Let W' denote the subset of W for which there is a path to Y not blocked by A,X,R

then $E[E[1(Y>y)|a,W,r]|a,x,r] = E[E[1(Y>y)|a,W',r]|a,x,r]$. All backdoor paths from A to W' are blocked given R and X by X since X blocks all backdoor paths from A to Y. Any frontdoor path from A to W' will include a collider since the nodes in W' are not descendents of A. The collider cannot be in X because X includes only non-descendents of A. Suppose the collider were some node R_i; by hypothesis all backdoor paths from R_i to Y are blocked by $R_1,...,R_{i-1},A$ and X; thus the frontdoor path from A to W' would have to be blocked by $A,R_1,...,R_{i-1}$ and X for otherwise there would be a backdoor path from R_i through W' to Y not blocked by $A,R_1,...,R_{i-1}$ and X. From this it follows that every frontdoor path from A to W' must be blocked given R and X either by a collider or by a node in R or X. We have thus shown that all paths from A to W' are blocked given R and X and so W' is conditionally independent of A given R and X and so we have

$$\begin{aligned} E[E[1(Y>y)|a,W',r]|a,x,r] &= E[E[1(Y>y)|a,W',r]|x,r] \\ &= E[E[1(Y>y)|a,Q,r]|x,r]. \end{aligned}$$

We have thus shown that $S(y|a,x,r) = E[E[1(Y>y)|a,Q,r]|x,r]$. Since $E[1(Y>y)|a,Q,r]$ is non-decreasing in a for all q we also have that

$$S(y|a,x,r) = E[E[1(Y>y)|a,Q,r]|x,r]$$

is non-decreasing in a. Finally, since $S(y|a,x,r)$ is non-decreasing in a, it follows from Lemma 1 that $E[y|a,x,r]$ is also non-decreasing in a.

A.8 Proof of Proposition 5

Proposition 5 is in fact a special case of Proposition 7 with $R = \varnothing$ and $Q = \varnothing$. The proof of Proposition 7 is given below.

A.9 Proof of Proposition 6

Proposition 6 is in fact a special case of Proposition 8 with $R = \varnothing$ and $Q = \varnothing$. The proof of Proposition 8 is given below.

A.10 Proof of Proposition 7

By the law of iterated expectations,

$$\begin{aligned} &E[Y|A=a,Q=q] \\ &\quad = \sum_c E[Y|A=a,C=c,Q=q]P(C=c|A=a,Q=q) \end{aligned}$$

We have by Proposition 4 that $E[Y|A,Q,C]$ is non-decreasing in A. Let $(C_1,...,C_n)$ denote an ordered list of the variables in C. Let Q^c be variables in Q which are common causes of C and let $Q^n = Q\backslash Q^c$. Let Q_i^d be the variables in Q^c that are descendents of C_i. Let C_i^d denote the variables in C that are descendents of C_i and let $C_i^n = C\backslash\{C_i,C_i^d\}$. By Proposition 4 we have that $E[Y|A,Q,C]$ is non-decreasing in each component C_i of C by choosing for each i, A in Proposition 4 to be C_i, X in Proposition 4 to be the set $\{Q^n,Q^c\backslash Q_i^d,C_i^n\}$ and R in Proposition 4 to be the set $\{Q_i^d,C_i^d,A\}$. Furthermore,

$$P(C=c|A=a,Q=q) = \frac{P(A=a|C=c,Q=q)P(C=c|Q=q)}{P(A=a|Q=q)}$$

and so

$$P(C=c|A=1,Q=q)=\nu_q(c)P(C=c|A=0,Q=q)$$

where

$$\nu_q(c)=\frac{P(A=0|Q=q)P(A=1|C=c,Q=q)}{P(A=1|Q=q)P(A=0|C=c,Q=q)}$$

which is non-decreasing in each dimension of c since the numerator is non-decreasing in each dimension of c and the denominator is non-increasing in each dimension of c by Proposition 4 by choosing for each i, A in Proposition 4 to be C_i, X in Proposition 4 to be the set $\{Q^n, Q^c \backslash Q_i^c, C_i^n\}$ and R in Proposition 4 to be the set $\{Q_i^c, C_i^d\}$. Thus

$$\begin{aligned}
&E[Y|A=1,Q=q]\\
&=\sum_c E[Y|A=1,C=c,Q=q]P(C=c|A=1,Q=q)\\
&\geq \sum_c E[Y|A=0,C=c,Q=q]P(C=c|A=1,Q=q)\\
&=\sum_c E[Y|A=0,C=c,Q=q]\nu_q(c)P(C=c|A=0,Q=q)\\
&\geq \sum_c E[Y|A=0,C=c,Q=q]P(C=c|A=0,Q=q)\\
&=E[Y|A=0,Q=q].
\end{aligned}$$

The second inequality holds because by an argument similar to that above $E[Y|A=0,Q=q,C=c]$ is non-decreasing in each dimension of c and $P(C=c|A=1,Q=q)=\nu_q(c)P(C=c|A=0,Q=q)$ weights more heavily higher values of each dimension of c than does $P(C=c|A=0,Q=q)$ since $\nu_q(c)$ is non-decreasing in each dimension of c. Thus $E[Y|A=a,Q=q]$ is non-decreasing in a.

A.11 Proof of Proposition 8

By the law of iterated expectations we have that

$$\begin{aligned}
E[A|Y=y,Q=q]&=\sum_c E[A|Y=y,C=c,Q=q]P(C=c|Y=y,Q=q)\\
&=\sum_{c,a} aP(A=a|Y=y,C=c,Q=q)P(C=c|Y=y,Q=q)\\
&=\sum_{c,a} a\frac{P(Y=y,A=a,C=c|Q=q)}{P(Y=y,C=c|Q=q)}P(C=c|Y=y,Q=q)\\
&=\sum_{c,a} a\frac{P(Y=y|A=a,C=c,Q=q)}{P(Y=y|Q=q)}P(A=a,C=c|Q=q)\\
&=E_{C,A}[A\frac{P(Y=y|A,C,Q=q)}{P(Y=y|Q=q)}|Q=q].
\end{aligned}$$

As in the proof of Proposition 7, we have by Proposition 4 we have that conditional on and $Q=q$, $\frac{P(Y=1|A,C,Q=q)}{P(Y=1|Q=q)}$ is a non-decreasing function of A and of each dimension of C. Similarly, $\frac{P(Y=0|A,C,Q=q)}{P(Y=0|Q=q)}$ is a non-increasing function of A and each dimension of C. Over c and a, conditional on and $Q=q$, $\frac{P(Y=y|A=a,C=c,Q=q)}{P(Y=y|Q=q)}$ is a weight function that sums to 1, that is, $E_{C,A}[\frac{P(Y=y|A=a,C=c,Q=q)}{P(Y=y|Q=q)}]=$

$\frac{P(Y=y|Q=q)}{P(Y=y|Q=q)} = 1$. Furthermore, by Proposition 4, $S(a|c,q)$ is non-decreasing in c and we thus have that

$$\begin{aligned} E[A|Y=1,Q=q] &= E_{C,A}[A\frac{P(Y=1|A,C,Q=q)}{P(Y=1|Q=q)}|Q=q] \\ &\geq E_{C,A}[A\frac{P(Y=0|A,C,Q=q)}{P(Y=0|Q=q)}|Q=q] \\ &= E[A|Y=0,Q=q] \end{aligned}$$

and so $E[A|Y,Q]$ is non-decreasing in Y.

A.12 Proof of Proposition 9

Note that by Proposition 3 above if A_1 has a weak positive monotonic effect on Y then $E[Y|A_1 = a_1, A_2 = a_2, C = c]$ must be non-decreasing in a_1 and if A_1 has a weak negative monotonic effect on Y then $E[Y|A_1 = a_1, A_2 = a_2, C = c]$ must be non-increasing in a_1. Since $(Y \coprod A_1|\{A_2,C\})_{G_{\underline{E_1}}}$ where $G_{\underline{E_1}}$ is the original directed acyclic graph G with all edges emanating from A_1 removed, we have $Y_{A_1=a} \coprod A_1|\{A_2,C\}$ (Pearl, 1995). Thus $E[Y_{A_1=a_1}|A_2 = a_2, C = c] = E[Y|A_1 = a_1, A_2 = a_2, C = c]$ and so if A_2 is a qualitative effect modifier for the causal effect of A_1 on Y for stratum $C = c$ then we must two values of A_1, a_1^* and a_1^{**}, and two levels of A_2, a_2' and a_2'', such that $E[Y|A_1 = a_1^{**}, A_2 = a_2'', C = c] - E[Y|A_1 = a_1^*, A_2 = a_2'', C = c] < 0$ and $E[Y|A_1 = a_1^{**}, A_2 = a_2', C = c] - E[Y|A_1 = a_1^*, A_2 = a_2', C = c] > 0$. Either $a_1^{**} > a_1^*$ or $a_1^{**} < a_1^*$. Consider the first case (the second is analogous) then since $E[Y|A_1 = a_1^{**}, A_2 = a_2'', C = c] - E[Y|A_1 = a_1^*, A_2 = a_2'', C = c] < 0$, A_1 does not have a weak positive monotonic effect on Y and since $E[Y|A_1 = a_1^{**}, A_2 = a_2', C = c] - E[Y|A_1 = a_1^*, A_2 = a_2', C = c] > 0$, A_1 does not have a weak negative monotonic effect on Y. Now if A_2 is a qualitative effect modifier for the causal effect of A_1 unconditionally then we must have two values of A_1, a_1^* and a_1^{**}, and two levels of A_2, a_2' and a_2'', such that $E[Y_{A_1=a_1^{**}}|A_2 = a_2''] - E[Y_{A_1=a_1^*}|A_2 = a_2''] < 0$ and $E[Y_{A_1=a_1^{**}}|A_2 = a_2'] - E[Y_{A_1=a_1^*}|A_2 = a_2'] > 0$. Once again either $a_1^{**} > a_1^*$ or $a_1^{**} < a_1^*$. We will consider the first case (the second is analogous). We thus have that $\sum_c E[Y|A_1 = a_1^{**}, A_2 = a_2'', C = c]P(C = c|A_2 = a_2'') = \sum_c E[Y_{A_1=a_1^{**}}|A_2 = a_2'', C = c]P(C = c|A_2 = a_2'') = E[Y_{A_1=a_1^{**}}|A_2 = a_2''] < E[Y_{A_1=a_1^*}|A_2 = a_2''] = \sum_c E[Y_{A_1=a_1^*}|A_2 = a_2'', C = c]P(C = c|A_2 = a_2'') = \sum_c E[Y|A_1 = a_1^*, A_2 = a_2'', C = c]P(C = c|A_2 = a_2'')$ and so A_1 cannot have a weak positive monotonic effect on Y and similarly, $\sum_c E[Y|A_1 = a_1^{**}, A_2 = a_2', C = c]P(C = c|A_2 = a_2') = \sum_c E[Y_{A_1=a_1^{**}}|A_2 = a_2', C = c]P(C = c|A_2 = a_2') = E[Y_{A_1=a_1^{**}}|A_2 = a_2'] > E[Y_{A_1=a_1^*}|A_2 = a_2'] = \sum_c E[Y_{A_1=a_1^*}|A_2 = a_2', C = c]P(C = c|A_2 = a_2') = \sum_c E[Y|A_1 = a_1^*, A_2 = a_2', C = c]P(C = c|A_2 = a_2')$ and so A_1 cannot have a weak negative monotonic effect on Y.

A.13 Proof of Proposition 10

We prove the Theorem for weak positive monotonic effects. The proof for weak negative monotonic effects is similar. Let C denote all non-descendents of A which are either parents of Y or parents of a node on a directed path between A and Y. By the law of iterated expectations we have $E[Y_{A=a_1}|Q = q] - E[Y_{A=a_0}|Q = q] = \sum_c E[Y_{A=a_1}|C = c, Q = q]P(C = c|Q = q) - \sum_c E[Y_{A=a_0}|C = c, Q = q]P(C = c|Q = q)$. We will show that this latter expression is equal to $\sum_c E[Y_{A=a_1}|C = c]P(C = c|Q = q) - \sum_c E[Y_{A=a_0}|C = c]P(C = c|Q = q)$. By Theorem 3 of Pearl (1995) it suffices

$$\begin{tikzcd} C \arrow[r, "\oplus"] \arrow[rr, bend right, "\oplus"'] & A \arrow[r, "\oplus"] & Y \end{tikzcd}$$

Figure 5: Directed acyclic graph illustrating counterexamples to Propositions 5 and 6 when A is not binary.

to show that $(Y\coprod Q|C,A)_{G_{\overline{A}}}$ where $G_{\overline{A}}$ denotes the graph obtained by deleting from the original directed acyclic graph all arrows pointing into A. Any front door path from Y to Q in $G_{\overline{A}}$ will be blocked by a collider. Any backdoor path from Y to Q in $G_{\overline{A}}$ will be blocked by C. We thus have that $E[Y_{A=a_1}|Q=q]-E[Y_{A=a_0}|Q=q]=\sum_c E[Y_{A=a_1}|C=c]P(C=c|Q=q)-\sum_c E[Y_{A=a_0}|C=c]P(C=c|Q=q)$. Since C will block all backdoor paths from A to Y we have by the backdoor path adjustment theorem $\sum_c E[Y|C=c,A=a_1]P(C=c|Q=q)-\sum_c E[Y|C=c,A=a_0]P(C=c|Q=q)=\sum_c\{E[Y|C=c,A=a_1]-E[Y|C=c,A=a_0]\}P(C=c|Q=q)$. If there were a qualitative effect modifier Q for the causal effect of A on Y then there would exist a value q_0 such that $E[Y_{A=a_1}|Q=q_0]-E[Y_{A=a_0}|Q=q_0]<0$. But since all paths between A and Y are of positive sign and since C blocks all backdoor paths from A to Y we have by Proposition 4 that $E[Y|C=c,A=a]$ is non-decreasing in a and so $E[Y_{A=a_1}|Q=q_0]-E[Y_{A=a_0}|Q=q_0]=\sum_c\{E[Y|C=c,A=a_1]-E[Y|C=c,A=a_0]\}P(C=c|Q=q_0)\geq 0$.

Appendix B. Counterexamples

This appendix contains the details of the counterexamples mentioned in the body of the paper.

B.1 Counterexample 1

Consider the directed acyclic graph given in Figure 5. In this example C and Y are binary and A is ternary. Suppose that $C\sim Ber(0.5)$, $\varepsilon_A\sim Ber(0.5)$ and that $P(A=0|\varepsilon_A=0)=1$ and $P(A=C+1|\varepsilon_A=1)=1$. Suppose also that $P(Y=1|A=2)=1$ and that if $P(Y=C|A=0)=1$ and $P(Y=C|A=1)=1$. Clearly then C has a positive monotonic effect on A and on Y and A has a positive monotonic effect on Y and so A and Y are positively monotonically associated. However, we have that $E[Y|A=1]=E[C|A=1]=0*P(C=1|A=1)=0$ but $E[Y|A=0]=E[C|A=0]=1*P(C=1|A=0)+0*P(C=0|A=0)=1/2$.

B.2 Counterexample 2

Consider again the directed acyclic graph given in Figure 5. In this example we will assume that C and A are binary and that Y is ternary. Suppose that $C\sim Ber(0.5)$ and that ε_A takes on the values 0, 1 and 2, each with probability $1/3$. Suppose also that $P(A=0|\varepsilon_A=0)=1$, $P(A=C|\varepsilon_A=1)=1$ and

$P(A=1|\varepsilon_A=2)=1$. Suppose further that $P(Y=0|C=0)=1$ and if $P(Y=A+1|C=1)$. Clearly then C has a positive monotonic effect on A and on Y and A has a positive monotonic effect on Y and so A and Y are positively monotonically associated. However, we have that $E[A|Y=1]=0$ but $E[A|Y=0]=E[A|C=0]=1/3$.

Abstract

In classification, semisupervised learning usually involves a large amount of unlabeled data with only a small number of labeled data. This imposes a great challenge in that it is difficult to achieve good classification performance through labeled data alone. To leverage unlabeled data for enhancing classification, this article introduces a large margin semisupervised learning method within the framework of regularization, based on an efficient margin loss for unlabeled data, which seeks efficient extraction of the information from unlabeled data for estimating the Bayes decision boundary for classification. For implementation, an iterative scheme is derived through conditional expectations. Finally, theoretical and numerical analyses are conducted, in addition to an application to gene function prediction. They suggest that the proposed method enables to recover the performance of its supervised counterpart based on complete data in rates of convergence, when possible.

Keywords: difference convex programming, classification, nonconvex minimization, regularization, support vectors

1. Introduction

Semisupervised learning occurs in classification, where only a small number of labeled data is available with a large amount of unlabeled data, because of the difficulty of labeling. In artificial intelligence, one central issue is how to integrate human's intelligence with machine's processing capacity. This occurs, for instance, in webpage classification and spam email detection, where webpages and emails are automatically collected, yet require labeling manually or classification by experts. The reader may refer to Blum and Mitchell (1998), Amini and Gallinari (2003), and Balcan et al. (2005) for more details. In genomics applications, functions of many genes in sequenced genomes remain unknown, and are predicted using available biological information, see Xiao and Pan (2005). In situations as such, the primary goal is to leverage unlabeled data to enhance predictive performance of classification (Zhu, 2005).

In semisupervised learning, labeled data $\{(x_i, y_i)_{i=1}^{n_l}\}$ are sampled from an unknown distribution $P(x, y)$, together with an independent unlabeled sample $\{x_j\}_{j=n_l+1}^{n}$ from its marginal distribution $q(x)$. Here label $y_i \in \{-1, 1\}$, $x_i = (x_{i1}, \cdots, x_{id})$ is an d-dimensional input, $n_l \ll n_u$ and $n = n_l + n_u$ is the combined size of labeled and unlabeled samples.

Two types of approaches—distributional and margin-based, have been proposed in the literature. The distributional approach includes, among others, co-training (Blum and Mitchell, 1998), the EM method (Nigam et al., 1998), the bootstrap method (Collins and Singer, 1999), Gaussian random fields (Zhu, Ghahramani and Lafferty, 2003), and structure learning models (Ando and Zhang, 2005). The distributional approach relies on an assumption relating the class probability given input $p(x) = P(Y = 1|X = x)$ to $q(x)$ for an improvement to occur. However, the assumption of this sort is often not verifiable or met in practice.

A margin approach uses the concept of regularized separation. It includes Transductive SVM (TSVM; Vapnik, 1998; Chapelle and Zien, 2005; Wang, Shen and Pan, 2007), and a large margin method of Wang and Shen (2007). These methods use the notation of separation to borrow information from unlabeled data to enhance classification, which relies on the clustering assumption (Chapelle and Zien, 2005) that the clustering boundary can precisely approximate the Bayes decision boundary which is the focus of classification.

This article develops a large margin semisupervised learning method, which aims to extract the information from unlabeled data for estimating the Bayes decision boundary. This is achieved by constructing an efficient loss for unlabeled data with regard to reconstruction of the Bayes decision boundary and by incorporating some knowledge from an estimate of p. This permits efficient use of unlabeled data for accurate estimation of the Bayes decision boundary thus enhancing the classification performance based on labeled data alone. The proposed method, using both the grouping (clustering) structure of unlabeled data and the smoothness structure of p, is designed to recover the classification performance based on complete data without missing labels, when possible.

The proposed method has been implemented through an iterative scheme, which can be thought of as an analogy of Fisher's efficient scoring method (Fisher, 1946). That is, given a consistent initial classifier, an iterative improvement can be obtained through the constructed loss function. Numerical analysis indicates that the proposed method performs well against several state-of-the-art semisupervised methods, including TSVM and Wang and Shen (2007), where Wang and Shen (2007) compares favorably against several smooth and clustering based semisupervised methods.

A novel statistical learning theory for ψ-loss is developed to provide an insight into the proposed method. The theory reveals that the ψ-learning classifier's generalization performance based on complete data can be recovered by its semisupervised counterpart based on incomplete data in rates of convergence, when some regularity assumptions are satisfied. The theory also says that the least favorable situation for a semisupervised problem occurs at points near $p(x) = 0$ or 1 because little information can be provided by these points for reconstructing the classification boundary as discussed in Section 2.3. This is in contrast to the fact that the least favorable situation for a supervised problem occurs near $p(x) = 0.5$. In conclusion, this semisupervised method achieves the desired objective of delivering higher generalization performance.

This article also examines one novel application in gene function prediction, which has been a primary focus of biomedical research. In gene function prediction, microarray gene expression profiles can be used to predict gene functions, because genes sharing the same function tend to co-express, see Zhou, Kao and Wong (2002). Unfortunately, biological functions of many discovered genes remain unknown at present. For example, about 1/3 to 1/2 of the genes in the genome of bacterium *E. coli* have unknown functions. Therefore, gene function prediction is an ideal application for semisupervised methods and also employed in this article as a real numerical example.

This article is organized in six sections. Section 2 introduces the proposed method. Section 3 develops an iterative algorithm for implementation. Section 4 presents some numerical examples, together with an application to gene function prediction. Section 5 develops a learning theory. Section 6 contains a discussion, and the appendix is devoted to technical proofs.

2. Methodology

In this section, we present our proposed efficient large margin semisupervised learning method as well its connection to other existing popular methodologies.

2.1 Large Margin Classification

Consider large margin classification with labeled data $(x_i, y_i)_{i=1}^{n_l}$. In linear classification, given a class of candidate decision functions $\mathcal{F}$, a cost function

$$C\sum_{i=1}^{n_l} L(y_i f(x_i)) + J(f) \tag{1}$$

is minimized over $f \in \mathcal{F} = \{f(x) = \tilde{w}_f^T x + w_{f,0} \equiv (1, x^T)w_f\}$ to yield the minimizer $\hat{f}$ leading to classifier sign$(\hat{f})$. Here $J(f)$ is the reciprocal of the geometric margin of various form with the usual L_2 margin $J(f) = \|\tilde{w}_f\|^2/2$ to be discussed in further detail, and $L(\cdot)$ is a margin loss defined by functional margin $z = yf(x)$, and $C > 0$ is a regularization parameter. In nonlinear classification, a kernel $K(\cdot,\cdot)$ is introduced for flexible representations: $f(x) = \sum_{i=1}^{n_l} \alpha_i K(x, x_i) + b$. For this reason, it is referred to as kernel-based learning, where the reproducing kernel Hilbert spaces (RKHS) are useful, see Gu (2000) and Wahba (1990).

Different margin losses correspond to different learning methodologies. Margin losses include, among others, the hinge loss $L(z) = (1-z)_+$ for SVM with its variant $L(z) = (1-z)_+^q$ for $q > 1$; see Lin (2002); the ψ-losses $L(z) = \psi(z)$, with $\psi(z) = 1 - \text{sign}(z)$ if $z \geq 1$ or $z < 0$, and $2(1-z)$ otherwise, see Shen et al. (2003), the logistic loss $V(z) = \log(1 + e^{-z})$, see Zhu and Hastie (2005); the η-hinge loss $L(z) = (\eta - z)_+$ for nu-SVM (Schölkopf et al., 2000) with $\eta > 0$ being optimized; the sigmoid loss $L(z) = 1 - \tanh(cz)$; see Mason, Baxter, Bartlett and Frean (2000). A margin loss $L(z)$ is said to be large margin if $L(z)$ is non-increasing in z, penalizing small margin values. In this article, we fix $L(z) = \psi(z)$.

2.2 Loss Construction for Unlabeled Data

In classification, the optimal Bayes rule is defined by $\bar{f}_{.5} = \text{sign}(f_{.5})$ with $f_{.5}(x) = P(Y = 1|X = x) - 0.5$ being a global minimizer of the generalization error $GE(f) = EI(Y \neq \text{sign}(f(X)))$, which is usually estimated by labeled data through $L(\cdot)$ in (1). In absence of sufficient labeled data, the focus is on how to improve (1) by using additional unlabeled data. For this, we construct a margin loss U to measure the performance of estimating $\bar{f}_{.5}$ for classification through unlabeled data. Specifically, we seek the best loss U from a class of candidate losses of form $T(f)$, which minimizes the L_2-

distance between the target classification loss $L(yf)$ and $T(f)$. The expression of this loss U is given in Lemma 1.

Lemma 1 *(Optimal loss) For any margin loss $L(z)$,*

$$\operatorname*{argmin}_T E(L(Yf(X)) - T(f(X)))^2 = E(L(Yf(X))|X = x) = U(f(x)),$$

where $U(f(x)) = p(x)L(f(x)) + (1 - p(x))L(-f(x))$ and $p(x) = P(Y = 1|X = x)$. Moreover, $\operatorname{argmin}_{f\in\mathcal{F}} EU(f(X)) = \operatorname{argmin}_{f\in\mathcal{F}} EL(Yf(X))$.

Based on Lemma 1, we define $\hat{U}(f)$ to be $\hat{p}(x)L(f(x)) + (1 - \hat{p}(x))L(-f(x))$ by replacing p in $U(f)$ by $\hat{p}$. Clearly, $\hat{U}(f)$ approximates the ideal loss $U(f)$ for reconstructing the Bayes decision function $f_{.5}$ when $\hat{p}$ is a good estimate of p, as suggested by Corollary 5. This is analogous to construction of the efficient scores for Fisher's scoring method: an optimal estimate can be obtained iteratively through an efficient score function, provided that a consistent initial estimate is supplied, see McCullagh and Nelder (1983) for more details. Through (approximately) optimal loss $\hat{U}(f)$, an iterative improvement of estimation accuracy is achieved by starting with a consistent estimate $\hat{p}$ of p, which, for instance, can be obtained through SVM or TSVM. For $\hat{U}(f)$, its optimality is established through its closeness to $U(f)$ in Corollary 5, where our iterative method based on $\hat{U}$ is shown to yield an iterative improvement in terms of the classification accuracy, recovering the generalization error rate of its supervised counterpart based on complete data ultimately.

As a technical remark, we note that the explicit relationship between p and f is usually unavailable in practice. As a result, several large margin classifiers such as SVM and ψ-learning do not directly yield an estimate of p given $\hat{f}$. Therefore p needs to be either assumed or estimated. For instance, the methods of Wahba (1999) and Platt (1999) assume a parametric form of p so that an estimated $\hat{f}$ yields an estimated p, whereas Wang, Shen and Liu (2008) estimates p given $\hat{f}$ nonparametrically.

The preceding discussion leads to our proposed cost function:

$$s(f) = C\left(n_l^{-1}\sum_{i=1}^{n_l} L(y_i f(x_i)) + n_u^{-1}\sum_{j=n_l+1}^{n} \hat{U}(f(x_j))\right) + J(f). \tag{2}$$

Minimization of (2) with respect to $f \in \mathcal{F}$ gives our estimated decision function $\hat{f}$ for classification.

2.3 Connection with Clustering Assumption

We now intuitively explain advantages of $\hat{U}(f)$ over a popular large margin loss $L(|f|) = (1 - |f(x)|)_+$ (Vapnik, 1998; Wang and Shen, 2007), and its connection with the clustering assumption (Chapelle and Zien, 2005) that assumes closeness between the classification and grouping (clustering) boundaries.

First, $\hat{U}(f)$ has an optimality property, as discussed in Section 2.2, which leads to better performance as suggested by Theorem 3. Second, it has a higher discriminative power over its counterpart $L(|f|)$. To see this aspect, note that $L(|f|) = \inf_p U(f)$ by Lemma 1 of Wang and Shen (2007). This says that $L(|f|)$ is a version of $\hat{U}(f)$ in the least favorable situation where unknown p is estimated by $\operatorname{sign}(f)$, completely ignoring the magnitude of p. As displayed in Figure 1, $\hat{U}(f)$ corresponds to an "asymmetric" hat function or the solid line, whereas $L(|f|)$ corresponds to a "symmetric" one or the dashed line. By comparison, $\hat{U}(f)$ enables not only to identify the clustering boundary through the hat function as $L(|f|)$ does but also to discriminate $f(x)$ from $-f(x)$ through an estimated $\hat{p}(x)$. That is, $\hat{U}(f)$ has a smaller value for $f(x) > 0$ than for $-f(x) < 0$ when $\hat{p} > 0.5$, and vice versa, whereas $L(|f|)$ is in-discriminative with regard to the sign of $f(x)$.

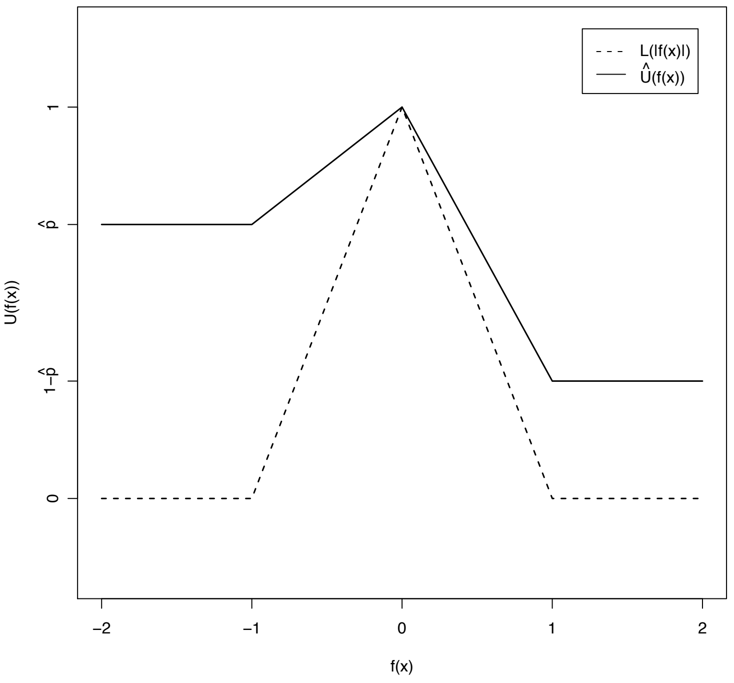

Figure 1: Plots of $L(|f(x)|)$ and $\hat{U}(f(x))$.

To reinforce the second point in the foregoing discussion, we examine one specific example with two possible clustering boundaries as described in Figure 3 of Zhu (2005). There $\hat{U}(f)$ favors one clustering boundary for classification if a consistent $\hat{p}$ is provided, whereas $L(|f|)$ fails to discriminate these two. More details are deferred to Section 4.1, where the simulated example 2 of this nature is studied.

In conclusion, $\hat{U}(f)$ yields a more efficient loss for a semisupervised problem as it uses the clustering information from the unlabeled data as $L(|f|)$ does, in addition to guidance about labeling through $\hat{p}$ to gain a higher discriminative power.

3. Computation

In this section, we implement the proposed semisupervised method through an iterative scheme as well as a nonconvex optimization technique.

3.1 Iterative Scheme

Effectiveness of $\hat{U}$ depends largely on the accuracy of $\hat{p}$ in estimating p. Given an estimate $\hat{p}^{(0)}$, (2) yields an estimate $\hat{f}^{(1)}$, which leads to a new estimate $\hat{p}^{(1)}$ through **Algorithm 0** below. The $\hat{p}^{(1)}$ is expected to be more accurate than $\hat{p}^{(0)}$ for p because additional information from unlabeled data has been used in estimation of $\hat{f}^{(1)}$ through $\hat{p}^{(0)}$ and additional smoothness structure has been used in **Algorithm 0** in estimation of $\hat{p}^{(1)}$ given $\hat{f}^{(1)}$. Specifically, an improvement in the process from $\hat{p}^{(0)}$ to $\hat{f}^{(1)}$ and that from $\hat{f}^{(1)}$ to $\hat{p}^{(1)}$ are assured by Assumptions B and D in Section 5.1, respectively, which are a more general version of the clustering assumption and a smoothness assumption of p. In other words, the marginal information from unlabeled data has been effectively incorporated in each iteration of **Algorithm 1** for improving estimation accuracy of $\hat{f}$ and $\hat{p}$.

Detailed implementation of the preceding scheme as well as the conditional probability estimation are summarized as follows.

Algorithm 0: (Conditional probability estimation; Wang, Shen and Liu, 2008)
Step 1. Specify m and initialize $\pi_t = (t-1)/m$, for $t = 1, \ldots, m+1$.
Step 2. Train weighted margin classifiers $\hat{f}_{\pi_t}$ by solving

$$\min_{f \in \mathcal{F}} Cn^{-1}\left((1-\pi_t)\sum_{y_i=1} L(y_i f(x_i)) + \pi_t \sum_{y_i=-1} L(y_i f(x_i))\right) + J(f),$$

with $1-\pi_t$ associated with positive instances and π_t associated with negative instances.
Step 3. Estimate labels of x by $\text{sign}(\hat{f}_{\pi_t}(x))$.
Step 4. Sort $\text{sign}\{\hat{f}_{\pi_t}(x)\}$, $t = 1, \ldots, m+1$, to compute $\pi^* = \max\{\pi_t : \text{sign}(\hat{f}_{\pi_t}(x)) = 1\}$, $\pi_* = \min\{\pi_t : \text{sign}(\hat{f}_{\pi_t}(x)) = -1\}$. The estimated class probability is $\hat{p}(x) = \frac{1}{2}(\pi^* + \pi_*)$.

Algorithm 1: (Efficient semisupervised learning)
Step 1. (Initialization) Given any initial classifier $\text{sign}(\hat{f}^{(0)})$, compute $\hat{p}^{(0)}$ through **Algorithm 0**. Specify precision tolerance level ε.
Step 2. (Iteration) At iteration $k+1$; $k = 0, 1, \cdots$, minimize $s(f)$ in (2) for $\hat{f}^{(k+1)}$ with $\hat{U} = \hat{U}^{(k)}$ defined by $\hat{p} = \hat{p}^{(k)}$ there. This is achieved through sequential QP for the ψ-loss. Details for sequential QP are deferred to Section 3.2. Compute $\hat{\hat{p}}^{(k+1)}$ through **Algorithm 0**, based on complete data with unknown labels imputed by $\text{sign}(\hat{f}^{(k+1)})$. Define $\hat{p}^{(k+1)} = \max(\hat{p}^{(k)}, \hat{\hat{p}}^{(k+1)})$ when $\hat{f}^{(k+1)} \geq 0$ and $\min(\hat{p}^{(k)}, \hat{\hat{p}}^{(k+1)})$ otherwise.
Step 3. (Stopping rule) Terminate when $|s(\hat{f}^{(k+1)}) - s(\hat{f}^{(k)})| \leq \varepsilon |s(\hat{f}^{(k)})|$. The final solution $\hat{f}_C$ is $\hat{f}^{(K)}$, with K the number of iterations to termination in **Algorithm 1**.

Theorem 2 *(Monotonicity) $s(\hat{f}^{(k)})$ is non-increasing in k. As a consequence,* **Algorithm 1** *converges to a stationary point $s(\hat{f}^{(\infty)})$ in that $s(\hat{f}^{(k)}) \geq s(\hat{f}^{(\infty)})$. Moreover,* **Algorithm 1** *terminates finitely.*

Algorithm 1 differs from the EM algorithm and its variant MM algorithm (Hunter and Lange, 2000) in that little marginal information has been used in these algorithms as argued in Zhang and Oles (2000). **Algorithm 1** also differs from Yarowsky's algorithm (Yarowsky, 1995; Abney, 2004) in that Yarowsky's algorithm solely relies on the strength of the estimated $\hat{p}$, ignoring the potential information from the clustering assumption.

There are several important aspects of **Algorithm 1**. First, loss $L(\cdot)$ in (2) may not be a likelihood regardless of if labeling missingness occurs at random. Secondly, the monotonicity property, as established in Theorem 2, is assured by constructing $\hat{p}^{(k+1)}$ to satisfy $(\hat{p}^{(k+1)} - \hat{p}^{(k)})\hat{f}^{(k+1)} \geq 0$, as opposed to the property of likelihood in the EM algorithm. Most importantly, the smoothness and clustering assumptions have been used in estimating p, and thus semisupervised learning. This is in contrast to the EM, where only likelihood is used in estimating p in a supervised manner.

Finally, we note that in **Step 2** of **Algorithm 1**, given $\hat{p}^{(k)}$, minimization in (2) involves nonconvex minimization when $L(\cdot)$ is ψ-loss. Next we shall discuss how to solve (2) for $\hat{f}^{(k+1)}$ through difference convex (DC) programming for nonconvex minimization.

3.2 Nonconvex Minimization

This section develops a nonconvex minimization method based on DC programming (An and Tao, 1997) for (2) with the ψ-loss, which was previously employed in Liu, Shen and Wong (2005) for supervised ψ-learning. As a technical remark, we note that DC programming has a high chance to locate an ε-global minimizer (An and Tao, 1997), although it can not guarantee globality. In fact, when combined with the method of branch-and-bound, it yields a global minimizer, see Liu et al. (2005). For a computational consideration, we shall use the DC programming algorithm without seeking an exact global minimizer.

Key to DC programming is decomposing the cost function $s(f)$ in (2) with $L(z) = \psi(z)$ into a difference of two convex functions as follows:

$$\begin{aligned} s(f) &= s_1(f) - s_2(f); \qquad (3) \\ s_1(f) &= C\big(n_l^{-1}\sum_{i=1}^{n_l}\psi_1(y_i f(x_i)) + n_u^{-1}\sum_{j=n_l+1}^{n}\hat{U}_{\psi_1}^{(k)}(f(x_j))\big) + J(f); \\ s_2(f) &= C\big(n_l^{-1}\sum_{i=1}^{n_l}\psi_2(y_i f(x_i)) + n_u^{-1}\sum_{j=n_l+1}^{n}\hat{U}_{\psi_2}^{(k)}(f(x_j))\big), \end{aligned}$$

where $\hat{U}_{\psi_t}^{(k)}(f(x_j)) = \hat{p}^{(k)}(x_j)\psi_t(f(x_j)) + (1-\hat{p}^{(k)}(x_j))\psi_t(-f(x_j));\ t = 1,2,\ \psi_1 = 2(1-z)_+$ and $\psi_2 = 2(-z)_+$. Here ψ_1 and ψ_2 are obtained through a convex decomposition of $\psi = \psi_1 - \psi_2$ as displayed in Figure 2.

With these decompositions, we treat (2) with the ψ-loss and $\hat{p} = \hat{p}^{(k)}$ by solving a sequence of quadratic problems described in **Algorithm 2**.

Algorithm 2: (Sequential QP)

Step 1. (Initialization) Set initial $\hat{f}^{(k+1,0)}$ to be the solution of $\min_f s_1(f)$. Specify precision tolerance level ε as in **Algorithm 1**.

Step 2. (Iteration) At iteration $l+1$, compute $\hat{f}^{(k+1,l+1)}$ by solving

$$\min_f \big(s_1(f) - \langle w_f, \nabla s_2(\hat{f}^{(k+1,l)})\rangle\big), \qquad (4)$$

where $\nabla s_2(f^{(k+1,l)})$ is a gradient vector of $s_2(f)$ at $w_{\hat{f}^{(k+1,l)}}$.

Step 3. (Stopping rule) Terminate when $|s(\hat{f}^{(k+1,l+1)}) - s(\hat{f}^{(k+1,l)})| \le \varepsilon |s(\hat{f}^{(k+1,l)})|$.
Then the estimate $\hat{f}^{(k+1)}$ is the best solution among $\hat{f}^{(k+1,l)};\ l = 0,1,\cdots$.

In (4), gradient $\nabla s_2(f^{(k+1,l)})$ is defined as the sum of partial derivatives of s_2 over each observation, with $\nabla\psi_2(z) = 0$ if $z > 0$ and $\nabla\psi_2(z) = -2$ otherwise. By the definition of $\nabla s_2(f^{(k+1,l)})$ and convexity of $s_2(f^{(k+1,l)})$, (4) gives a sequence of non-increasing upper envelops of (3), which can be solved via their dual forms.

The speed of convergence of **Algorithm 2** is super-linear, following the proof of Theorem 3 in Liu et al. (2005). This means that the number of iterations required for **Algorithm 2** to achieve the precision ε is $o(\log(1/\varepsilon))$.

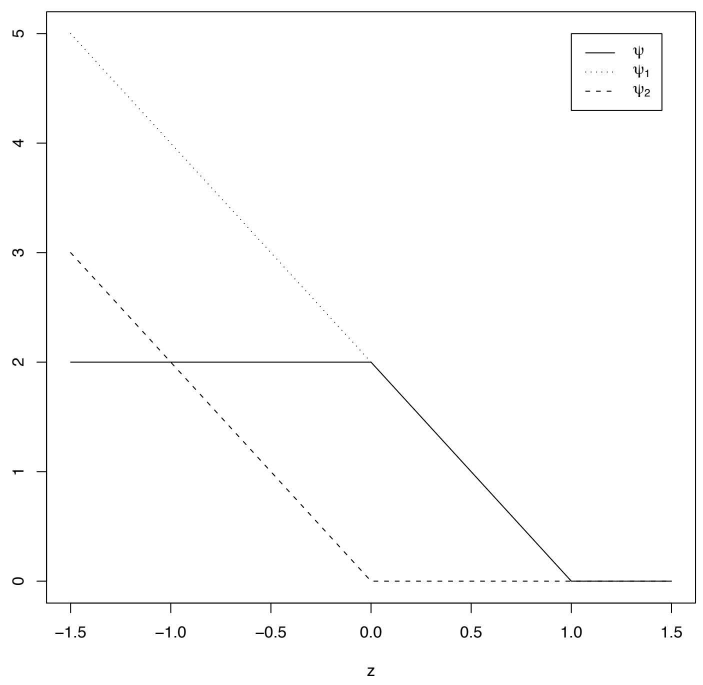

Figure 2: Plot of ψ, ψ_1 and ψ_2 for the DC decomposition of $\psi = \psi_1 - \psi_2$. Solid, dotted and dashed lines represent ψ, ψ_1 and ψ_2, respectively.

4. Numerical Comparison

This section examines effectiveness of the proposed method through numerical examples. A test error, averaged over 100 independent simulation replications, is used to measure a classifier's generalization performance. For simulation comparison, the amount of improvement of our method over $\text{sign}(\hat{f}^{(0)})$ is defined as the percent of improvement in terms of the Bayesian regret

$$\frac{(T(\text{Before}) - \mathit{Bayes}) - (T(\text{After}) - \mathit{Bayes})}{T(\text{Before}) - \mathit{Bayes}}, \tag{5}$$

where $T(\text{Before})$, $T(\text{After})$, and *Bayes* denote the test errors of $\text{sign}(\hat{f}^{(0)})$, the proposed method based on initial classifier $\text{sign}(\hat{f}^{(0)})$, and the Bayes error. The Bayes error is the ideal performance and serves as a benchmark for comparison, which can be computed when the distribution is known. For benchmark examples, the amount of improvement over $\text{sign}(\hat{f}^{(0)})$ is defined as

$$\frac{T(\text{Before}) - T(\text{After})}{T(\text{Before})}, \tag{6}$$

which actually underestimates the amount of improvement in absence of knowledge of the Bayes error.

Numerical analyses are conducted in R2.1.1. In linear learning, $K(x,y) = \langle x,y \rangle$; in Gaussian kernel learning, $K(x,y) = \exp(-\frac{\|x-y\|^2}{\sigma^2})$, where σ is set to be the median distance between positive and negative classes to reduce computational cost for tuning σ^2, see Jaakkola, Diekhans and Haussler (1999).

4.1 Simulations and Benchmarks

Two simulated and five benchmark data sets are examined, based on four state-of-the-art classifiers $\text{sign}(\hat{f}^{(0)})$'s. They are SVM (with labeled data alone), TSVM (TSVM^{DCA}; Wang, Shen and Pan, 2007) , and the methods of Wang and Shen (2007) with the hinge loss (SSVM) and with the ψ-loss (SPSI), where SSVM and SPSI compare favorably against their competitors. Corresponding to these methods, our method, with $m = n^{1/2}$ and $\varepsilon = 10^{-3}$, yields four semisupervised classifiers denoted as ESVM, ETSVM, ESSVM and ESPSI.

4.1.1 SIMULATED EXAMPLES

Examples 1 and 2 are taken from Wang and Shen (2007), where 200 and 800 labeled instances are randomly selected for training and testing. For training, 190 out 200 instances are randomly chosen for removing their labels. Here the Bayes errors are 0.162 and 0.089, respectively.

4.1.2 BENCHMARKS

Six benchmark examples include Wisconsin breast cancer (WBC), Pima Indians diabetes (PIMA), HEART, MUSHROOM, Spam email (SPAM) and Brain computer interface (BCI). The first five datasets are available in the UCI Machine Learning Repository (Blake and Merz, 1998) and the last one can be found in Chapelle et al. (2006). WBC discriminates a benign breast tissue from a malignant one through 9 diagnostic characteristics; PIMA differentiates between positive and negative cases for female diabetic patients of Pima Indian heritage based on 8 biological or diagnostic attributes; HEART concerns diagnosis status of the heart disease based on 13 clinic attributes; MUSHROOM separates an edible mushroom from a poisonous one through 22 biological records; SPAM identifies spam emails using 57 frequency attributes of a text, such as frequencies of particular words and characters; BCI concerns the difference of brain images when imagining left-hand and right-hand movements, based on 117 autoregressive model parameters fitted over human's electroencephalography.

Instances in WBC, PIMA, HEART, and MUSHROOM are randomly divided into two halves with 10 labeled and 190 unlabeled instances for training, and the remaining 400 for testing. Instances in SPAM are randomly divided into halves with 20 labeled and 380 unlabeled instances for training, and the remaining instances for testing. Twelve splits for BCI have already given at http://www.kyb.tuebingen.mpg.de/ssl-book/benchmarks.html, with 10 labeled and 390 unlabeled instances while no instance for testing. An averaged error rate over the unlabeled set is used in BCI example to approximate the test error.

In each example, the smallest test errors of all methods in comparison are computed over 61 grid points $\{10^{-3+k/10};\ k = 0, \cdots, 60\}$ for tuning C in (2) through a grid search. The results are summarized in Tables 1-2.

As suggested in Tables 1-2, ESVM, ETSVM, ESSVM and ESPSI perform no worse than their counterparts in almost all examples, except ESVM in SPAM where the performance is slightly worse but indistinguishable from its counterpart. The amount of improvement, however, varies over examples and different types of classifiers. In linear learning, the improvements of the proposed method are from 1.0% to 51.7% over its counterparts, except in SPAM where ESVM performs slightly worse than SVM; in kernel learning, the improvements range from 0.0% to 23.2% over its counterparts. Overall, large improvement occurs for less accurate initial classifiers when they are sufficiently accurate. However, if the initial classifier is too accurate, the potential for an improve-

Table 2: Gaussian kernel learning. Averaged test errors as well as estimated standard errors (in parenthesis) of ESVM, ETSVM, ESSVM, ESPSI, and their initial counterpartsin the simulated and benchmark examples. Here the amount of improvement is defined in (5) or (6).

ment becomes small or null, such as the cases of SSVM and SPSI with Gaussian kernel in PIMA. If the initial classifier is too poor, then no improvement may occur. This is the case for ESVM with linear kernel in SPAM, where ESVM performs worse than SVM with $n_l = 10$ labeled data alone. This suggests that a better initial estimate should be used together with unlabeled data.

In summary, we recommend SPSI to be an initial classifier for $\hat{f}^{(0)}$ based on its overall performance across all the examples. Moreover, ESPSI nearly recovers the classification performance of its counterpart SVM with complete labeled data in the two simulated examples, WBC and HEART.

4.2 Gene Function Prediction Through Expression Profiles

This section applies the proposed method to predict gene functions through gene data in Hughes et al. (2000), consisting of expression profiles of a total of 6316 genes for yeast S. *cerevisiae* from

1. The error rate is computed on the unlabeled data and averaged over twelve splits.
2. This error rate is approximated by the 10-fold cross validation.

300 microarray experiments. In this case almost half of the genes have unknown functions although gene expression profiles are available for almost the entire yeast genome.

Our specific focus is predicting functional categories defined by the MIPS, a multifunctional classification scheme (Mewes et al., 2002). For simplicity, we examine two functional categories, namely "transcriptional control" and "mitochondrion", with 334 and 346 annotated genes, respectively. The goal is to predict gene functional categories for genes annotated within these two categories by training our semisupervised classifier on expression profiles of genes, where some genes are treated as if their functions are unknown to mimic the semisupervised scenario in complete dataset. At present, detection of novel class is not permitted in our formulation, which remains to be an open research question.

For the purpose of evaluation, we divide the entire dataset into two sets of training and testing. The training set involves a random sample of $n_l = 20$ labeled and $n_u = 380$ unlabeled gene profiles, while the testing set contains 280 remaining profiles.

Table 3: Averaged test errors as well as estimated standard errors (in parenthesis) of ESVM, ETSVM, ESSVM, ESPSI, and their initial counterparts, over 100 pairs of training and testing samples, in gene function prediction. Here I stands for an initial classifier, E stands for our proposed method with the initial method, and the amount of improvement is defined in (6).

As indicated in Table 3, ESVM, ETSVM, ESSVM and ESPSI all improve predictive accuracy of their initial counterparts in linear learning and Gaussian kernel learning. It appears that ESPSI performs best. Most importantly, it demonstrates predictive power of the proposed method for predicting which of the two categories a gene belongs to.

5. Statistical Learning Theory

In the literature, several theories have been developed to understand the problem of semisupervised learning, including Rigollet (2007) and Singh, Nowak and Zhu (2008). Both the theories rely on a different clustering assumption that homogeneous labels are assumed over local clusters. Based on the original clustering assumption, as well as a smoothness assumption on the conditional probability $p(x)$, this section develops a novel statistical learning theory. Specifically, finite-sample and asymptotical upper bounds of the generalization error are derived for ESPSI $\hat{f}_C$ defined by the ψ-loss in **Algorithm 1**. The generalization accuracy is measured by the Bayesian regret $e(\hat{f}_C, \bar{f}_{.5}) = GE(\hat{f}_C) - GE(\bar{f}_{.5}) \geq 0$ with $GE(f)$ defined in Section 2.2.

5.1 Statistical Learning Theory

The error bounds of $e(\hat{f}_C, \bar{f}_{.5})$ are expressed in terms of complexity of the candidate class $\mathcal{F}$, the sample size n, tuning parameter $\lambda = (nC)^{-1}$, the error rate of the initial classifier $\delta_n^{(0)}$, and the maximum number of iteration K in **Algorithm 1**. The results imply that ESPSI, without knowing labels of the unlabeled data, enables to recover the classification accuracy of ψ-learning based on complete data under regularity conditions.

We first introduce some notations. Let $L(z) = \psi(z)$ be the ψ-loss. Define the margin loss $V_\pi(f, Z)$ for unequal cost classification to be $S_\pi(y)L(yf(x))$, with cost $0 < \pi < 1$ for the positive class and $S_\pi(y) = 1 - \pi$ if $y = 1$, and π otherwise. Let $e_{V_\pi}(f, \bar{f}_\pi)E(V_\pi(f,Z) - V_\pi(\bar{f}_\pi, Z)) \geq 0$ for $f \in \mathcal{F}$ with respect to unequal cost π, where $\bar{f}_\pi(x) = \text{sign}(f_\pi(x)) = \arg\min_f EV_\pi(f, Z)$ is the Bayes rule, with $f_\pi(x) = p(x) - \pi$.

Assumption A: (Approximation) For any $\pi \in (0,1)$, there exist some positive sequence $s_n \to 0$ as $n \to \infty$ and $f_\pi^* \in \mathcal{F}$ such that $e_{V_\pi}(f_\pi^*, \bar{f}_\pi) \leq s_n$.

Assumption A is an analog of that of Shen et al. (2003), which ensures that the Bayes rule $\bar{f}_\pi$ can be well approximated by elements in $\mathcal{F}$.

Assumption B. (Conversion) For any $\pi \in (0,1)$, there exist constants $0 < \alpha,\ \beta_\pi < \infty$, $0 \leq \zeta < \infty$, $a_i > 0$; $i = 0,1,2$, such that for any sufficiently small $\delta > 0$,

$$\sup_{\{f \in \mathcal{F}: e_{V_{.5}}(f, \bar{f}_{.5}) \leq \delta\}} e(f, \bar{f}_{.5}) \leq a_0 \delta^\alpha, \tag{7}$$

$$\sup_{\{f \in \mathcal{F}: e_{V_\pi}(f, \bar{f}_\pi) \leq \delta\}} \|\text{sign}(f) - \text{sign}(\bar{f}_\pi)\|_1 \leq a_1 \delta^{\beta_\pi}, \tag{8}$$

$$\sup_{\{f \in \mathcal{F}: e_{V_\pi}(f, \bar{f}_\pi) \leq \delta\}} \text{Var}(V_\pi(f,Z) - V_\pi(\bar{f}_\pi, Z)) \leq a_2 \delta^\zeta. \tag{9}$$

Assumption B describes local smoothness of the Bayesian regret $e(f, \bar{f}_{.5})$ in terms of a first-moment function $\|\text{sign}(f) - \text{sign}(\bar{f}_\pi)\|_1$ and a second-moment function $\text{Var}(V_\pi(f,Z) - V_\pi(\bar{f}_\pi, Z))$ relative to $e_{V_\pi}(f, \bar{f}_\pi)$ with respect to unequal cost π. Here the degrees of smoothness are defined by exponents α, β_π and ζ. Note that (7) and (9) are related to the "no noise assumption" of Tsybakov (2004); and (8) has been used in Wang et al. (2008) for quantifying the error rate of probability estimation, which plays a key role in controlling the error rate of ESPSI. For simplicity, denote $\beta_{.5}$ and $\inf_{\pi \neq 0.5}\{\beta_\pi\}$ as β and γ respectively, where β quantifies the clustering assumption through the degree to which the positive and negative clusters are distinguishable, and γ measures the conversion rate between the classification and probability estimation accuracies.

For Assumption C, we define a complexity measure—the L_2-metric entropy with bracketing, describing the cardinality of $\mathcal{F}$. Given any $\varepsilon > 0$, denote $\{(f_r^l, f_r^u)\}_{r=1}^R$ as an ε-bracketing function set of $\mathcal{F}$ if for any $f \in \mathcal{F}$, there exists an r such that $f_r^l \leq f \leq f_r^u$ and $\|f_r^l - f_r^u\|_2 \leq \varepsilon; r = 1, \cdots, R$. Then the L_2-metric entropy with bracketing $H_B(\varepsilon, \mathcal{F})$ is defined as the logarithm of the cardinality of the smallest ε-bracketing function set of $\mathcal{F}$. See Kolmogorov and Tihomirov (1959) for more details.

Define $\mathcal{F}(k) = \{L(f,z) - L(f_\pi^*, z) : f \in \mathcal{F}, J(f) \leq k\}$ to be a space defined by candidate decision functions, with $J(f) = \frac{1}{2}\|f\|_K^2$. Let $J_\pi^* = \max(J(f_\pi^*), 1)$. In (11), we specify an entropy integral to establish a relationship between the complexity of $\mathcal{F}(k)$ and convergence speed ε_n for the Bayesian regret.

Assumption C. (Complexity) For some constants $a_i > 0; i = 3, \cdots, 5$ and $\varepsilon_n > 0$,

$$\sup_{k \geq 2} \phi(\varepsilon_n, k) \leq a_5 n^{1/2}, \tag{10}$$

where $\phi(\varepsilon, k) = \int_{a_4 M}^{a_3^{1/2} M^{\min(1,\zeta)/2}} H_B^{1/2}(w, \mathcal{F}(k)) dw / M$, and $M = M(\varepsilon, \lambda, k) = \min(\varepsilon^2 + \lambda(k/2 - 1) J_\pi^*, 1)$.
Assumption D. (Smoothness of $p(x)$) There exist some constants $0 \leq \eta \leq 1$, $d \geq 0$ and $a_6 > 0$ such that $\|\Delta^j(p)\|_\infty \leq a_6$ for $j = 0, 1, \cdots, d$, and $|\Delta^d(p(x_1)) - \Delta^d(p(x_2))| \leq a_6 \|x_1 - x_2\|_1^\eta + d/m$ for any $\|x_1 - x_2\|_1 \leq \delta$ with some sufficiently small $\delta > 0$, where Δ^j is the j-th order difference operator and m is defined as in **Algorithm 0**.

Assumption D specifies the degree of smoothness of the conditional density $p(x)$.
Assumption E. (Degree of least favorable situation) There exist some constants $0 \leq \theta \leq \infty$ and $a_7 > 0$ such that $P\big(X : \min(p(X), 1 - p(X)) \leq \delta\big) \leq a_7 \delta^\theta$ for any sufficiently small $\delta > 0$.

Assumption E describes the behavior of $p(x)$ near 0 and 1, corresponding to the least favorable situation, as described in Section 2.3.

Theorem 3 *In addition to Assumptions A-E, let the precision parameter m be* $[\delta_n^{-\beta\gamma}]$ *and* $\delta_n^2 = \min(\max(\varepsilon_n^2, 16 s_n), 1)$. *Then for ESPSI* $\hat{f}_C$*, there exist some positive constants* a_8*-*a_{10} *such that*

$$\begin{aligned} P\Big(e(\hat{f}_C, \bar{f}_{.5}) \geq a_{10} \max(\delta_n^{2\alpha}, (a_{11} \rho_n \delta_n^{(0)})^{2\alpha \max(1, B^K)})\Big) \leq \\ P\Big(e_L(\hat{f}_{.5}^{(0)}, \bar{f}_{.5}) \geq 2 a_{11} \rho_n (\delta_n^{(0)})^2\Big) + 3.5 K \exp(-a_8 n_l (\lambda J_{.5}^*)^{\max(1, 2-\zeta)}) + \\ 3.5 K \exp(-a_9 n (\lambda J_\pi^*)^{\max(1, 2-\zeta)}) + 2 K \rho_n^{-\min(1, \beta)}. \end{aligned}$$

Here $B = \frac{(\theta+1)(d+\eta)\beta\gamma}{2(1+\max(0, 1-\beta)\theta)(d+\eta+1)}$, $a_{11} = \max\left(1, 2^{\frac{3\gamma(d+\eta)}{d+\eta+1}+2} a_1^{\frac{(2\gamma+1)(d+\eta)}{d+\eta+1}}\right)$ *and* $\rho_n > 0$ *is any real number satisfying* $a_{11} \rho_n \delta_n^2 \leq 4 \lambda J_\pi^*$.

Theorem 3 provides a finite-sample probability bound for the Bayesian regret $e(\hat{f}_C, \bar{f}_{.5})$, where the parameter B measures the level of difficulty of a semisupervised problem, with small value of B indicating more difficulty. Note that the value of B is proportional to those of α, β, γ, d, η and θ, as defined in Assumptions A-E. In fact, α, β and γ quantify the local smoothness of the Bayesian regret $e(f, \bar{f}_{.5})$, and d, η and θ describe the smoothness of $p(x)$ as well as its behavior near 0 and 1.

Next, by letting n_l, n_u tending infinity, we obtain the rates of convergence of ESPSI in terms of the error rate $\delta_n^{2\alpha}$ of its supervised counterpart ψ-learning based on complete data, and the initial error rate $\delta_n^{(0)}$, B, and the maximum number K of iteration.

Corollary 4 *Under the assumptions of Theorem 3, as* $n_u, n_l \to \infty$,

$$\begin{aligned} |e(\hat{f}_C, \bar{f}_{.5})| &= O_p\Big(\max(\delta_n^{2\alpha}, (\rho_n \delta_n^{(0)})^{2\alpha \max(1, B^K)})\Big), \\ E|e(\hat{f}_C, \bar{f}_{.5})| &= O\Big(\max(\delta_n^{2\alpha}, (\rho_n \delta_n^{(0)})^{2\alpha \max(1, B^K)})\Big), \end{aligned}$$

provided that the initial classifier converges in that $P\Big(e_L(\hat{f}_{.5}^{(0)}, \bar{f}_{.5}) \geq 2 a_{11} \rho_n (\delta_n^{(0)})^2\Big) \to 0$, *with any slow varying sequence* $\rho_n \to \infty$ *and* $\rho_n \delta_n^{(0)} \to 0$, *and the tuning parameter* λ *is chosen such that* $n(\lambda J_\pi^*)^{\max(1, 2-\zeta)}$ *and* $n_l(\lambda J_{.5}^*)^{\max(1, 2-\zeta)}$ *are bounded away from 0.*

Note that there are two important cases defined by the value of B. When $B > 1$, ESPSI achieves the convergence rate $\delta_n^{2\alpha}$ of its supervised counterpart ψ-learning based on complete data, c.f., Theorem 1 of (Shen and Wang, 2007). When $B \leq 1$, ESPSI performs no worse than its initial classifier because $(\delta_n^{(0)})^{2\alpha\max(1,B^K)}(\delta_n^{(0)})^{2\alpha}$. Therefore, it is critical to compute the value of B. For instance, if the two classes are perfectly separated and located very densely within respective regions, then $B = \infty$ and our method recovers the rate $\delta_n^{2\alpha}$; if the two classes are completely indistinguishable, then $B = 0$ and our method yields the rate $(\delta_n^{(0)})^2$.

For the optimality claimed in Section 2.2, we show that $\hat{U}(f)$ is sufficiently close to $U(f)$ so that optimality of $U(f)$ can be translated into $\hat{U}(f)$. As a result, minimization of $\hat{U}(f)$ over f mimics that of $U(f)$.

Corollary 5 *(Optimality) Under the assumptions of Corollary 4, as $n_u, n_l \to \infty$,*

$$\sup_{f\in\mathcal{F}} \|\hat{U}(f) - U(f)\|_1 \quad = \quad O_p\Big(\max(\delta_n^{\beta\gamma}, (\rho_n\delta_n^{(0)})^{\beta\gamma\max(1,B^K)})\Big),$$

where $\hat{U}(f)$ is estimated $U(f)$ loss with p estimated based on $\hat{f}_C$.

To argue that the approximation error rate of $\hat{U}(f)$ to $U(f)$ is sufficiently small, note that $\hat{f}_C$ obtained from minimizing (2) recovers the classification error rate of its supervised counterpart based on complete data, as suggested by Corollary 4. Otherwise, a poor approximation precision could impede the error rate of ESPSI.

In conclusion, ESPSI, without knowing label values of unlabeled instances, enables to reconstruct the classification and estimation performance of ψ-learning based on complete data in rates of convergence, when possible.

5.2 Theoretical Example

We now apply Corollary 4 to linear and kernel learning examples to derive generalization errors rates for ESPSI in terms of the Bayesian regret. In all cases, ESPSI (nearly) achieves the generalization error rates of ψ-learning for complete data when unlabeled data provides useful information, and yields no worse performance then its initial classifier otherwise.

Consider a learning example in which $X = (X_{\cdot 1}, X_{\cdot 2})$ are independent, following marginal distribution $q(x) = \frac{1}{2}(\kappa_1 + 1)|x|^{\kappa_1}$ for $x \in [-1, 1]$ for $\kappa_1 > 0$. Given $X = 1$, $P(Y = 1|X = x) = p(x) = \frac{2}{5}\,\mathrm{sign}(x_{\cdot 1})|x_{\cdot 1}|^{\kappa_2} + \frac{1}{2}$ with $\kappa_2 > 0$. Note that $f_\pi(x)$ is $x_{\cdot 1} - \mathrm{sign}(\pi - \frac{1}{2})(\frac{5}{4}|2\pi - 1|)^{\frac{1}{\kappa_2}}$, which in turn yields the vertical line as the decision boundary for classification with unequal cost π. The value of κ_i; $i = 1, 2$ describe the behavior of the marginal distribution around the origin, and that of the conditional distribution $p(x)$ in the neighborhood of $1/2$, respectively.

For illustration, Figure 3 displays the marginal and conditional densities from the data distribution with $\kappa_1 = 2$ and $\kappa_2 = 1$. It is evident that the clustering assumption (**Assumption B**) is met since the neighborhood of $f_{.5}(x)$ has low density as showed in the left panel of Figure 3, and the smoothness assumption (**Assumption D**) and the boundedness assumption of $p(x)$ (**Assumption E**) are met as well since $p(x)$ is a hyperplane bounded by $(0.1, 0.9)$ as showed in the right panel of Figure 3. Technical details of verifying assumptions are deferred to Appendix B.

5.2.1 LINEAR LEARNING

Here it is natural to consider linear learning in which candidate decision functions are linear in $\mathcal{F} = \{f(x) = (1, x^T)w : w \in \mathcal{R}^3, x = (x_{\cdot 1}, x_{\cdot 2}) \in \mathcal{R}^2\}$.

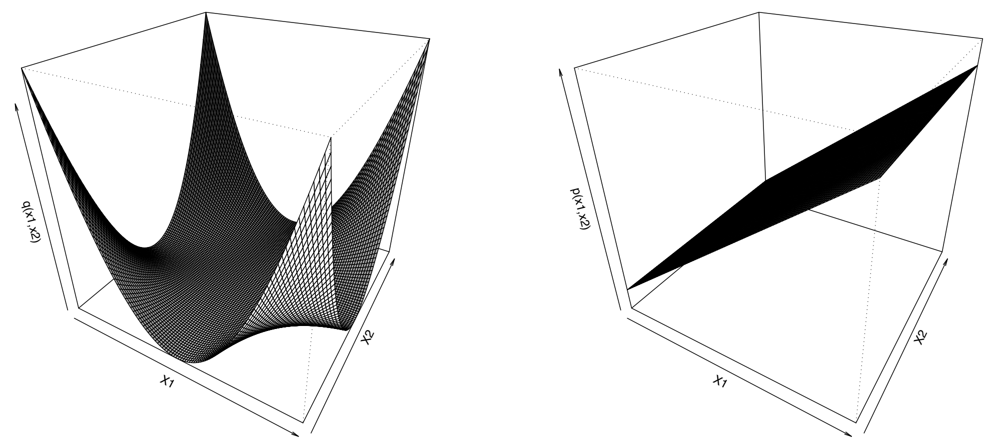

Figure 3: Plots of the marginal and conditional densities from the data distribution with $\kappa_1 = 2$ and $\kappa_2 = 1$.

For ESPSI $\hat{f}_C$, we choose $\delta_n^{(0)} = n_l^{-1}\log n_l$, the convergence rate of supervised linear ψ-learning, $\rho_n \to \infty$ to be an arbitrarily slow sequence and $C = O((\log n)^{-1})$. An application of Corollary 4 yields that $E|e(\hat{f}_C, \bar{f}_{.5})| = O(\max(n^{-1}\log n,\, (n_l^{-1}(\log n_l)^2)^{\max(1,2B^K)}))$, with $B = \frac{(1+\kappa_1)^2}{2\kappa_2(1+\kappa_1+\kappa_2)}$. When $B > 1$, equivalently, $\kappa_1 + 1 > (1+\sqrt{3})\kappa_2$, this rate reduces to $O(n^{-1}\log n)$ when K is sufficiently large. Otherwise, the rate is $O(n_l^{-1}\log n_l)$.

The fast rate $n^{-1}\log n$ is achieved when κ_1 is large but κ_2 is relatively small. Interestingly, large κ_1 value implies that $q(x)$ has a low density around $x = 0$, corresponding to the low density separation assumption in Chapelle and Zien (2005) for a semisupervised problem, whereas large κ_1 value and small κ_2 value indicate that $p(x)$ has a small probability to be close to the decision boundary $p(x) = 1/2$ for a supervised problem.

5.2.2 KERNEL LEARNING

Consider a flexible representation defined by a Gaussian kernel, where $\mathcal{F} = \{x \in \mathcal{R}^2 : f(x)w_{f,0} + \sum_{k=1}^{n} w_{f,k}K(x,x_k) : w_f = (w_{f,1},\cdots,w_{f,n})^T \in \mathcal{R}^n\}$ by the representation theorem of RKHS, see Wahba (1990). Here $K(x,z) = \exp(-\frac{\|x-z\|^2}{2\sigma^2})$ is the Gaussian kernel.

Similarly, we choose $\delta_n^{(0)} = n_l^{-1}(\log n_l)^3$ to be the convergence rate of supervised ψ-learning with Gaussian kernel, $\rho_n \to \infty$ to be an arbitrarily slow sequence and $C = O((\log n)^{-3})$. By Corollary 4, $E|e(\hat{f}_C, \bar{f}_{.5})| = O(\max((n_l^{-1}(\log n_l)^3)^{\max(1,2B^K)},\, n^{-1}(\log n)^3)) = O(n^{-1}(\log n)^3)$ when $\kappa_1 + 1 > 2\kappa_2(1+\kappa_2)$ and K is sufficiently large, and $O(n_l^{-1}(\log n_l)^3)$ otherwise. Again, large κ_1 and small κ_2 lead to the fast rate.

6. Summary

This article introduces a large margin semisupervised learning method through an iterative scheme based on an efficient loss for unlabeled data. In contrast to most methods assuming a relationship between the conditional and the marginal distributions, the proposed method integrates labeled and unlabeled data through using the clustering structure of unlabeled data as well as the smoothness structure of the estimated p. The theoretical and numerical results suggest that the method compares favorably against top competitors, and achieves the desired goal of reconstructing the classification performance of its supervised counterpart on complete labeled data.

With regard to tuning parameter C, further investigation is necessary. One critical issue is how to use unlabeled data to enhance the accuracy of estimating the generalization error so that adaptive tuning is possible.

Appendix A. Technical Proofs

Proof of Lemma 1: Let $U(f(x)) = E(L(Yf(X))|X = x)$. By orthogonality, $E(L(Yf(X)) - T(f(X)))^2 = E(L(Yf(X)) - U(f(X)))^2 + E(U(f(X)) - T(f(X)))^2$, implying that $U(f(x))$ minimizes $E(L(Yf(X)) - T(f(X)))^2$ over any T. Then the proof follows from the fact that $EL(Yf(X)) = E(E(L(Yf(X))|X))$.

Proof of Theorem 2: For clarity, we write $s(\hat{f})$ as $s(\hat{f}, \hat{p})$ in this proof. Then it suffices to show that $s(\hat{f}^{(k)}, \hat{p}^{(k)}) \geq s(\hat{f}^{(k+1)}, \hat{p}^{(k+1)})$. First, $s(\hat{f}^{(k)}, \hat{p}^{(k)}) \geq s(\hat{f}^{(k+1)}, \hat{p}^{(k)})$ since $\hat{f}^{(k+1)}$ minimizes $s(f, \hat{p}^{(k)})$. Then $s(\hat{f}^{(k+1)}, \hat{p}^{(k)}) - s(\hat{f}^{(k+1)}, \hat{p}^{(k+1)}) = \sum_{j=n_l+1}^{n} (\hat{p}^{(k)} - \hat{p}^{(k+1)})(L(\hat{f}^{(k+1)}(x_j)) - L(-\hat{f}^{(k+1)}(x_j)))$, which is nonnegative by the definition of $\hat{p}^{(k+1)}$.

Proof of Theorem 3: The proof involves two steps. In **Step 1**, given $f^{(k)}$, we derive a probability upper bound for $\|\hat{p}^{(k)} - p\|_1$, where $\hat{p}^{(k)}$ is obtained from **Algorithm 0**. In **Step 2**, based on the result of **Step 1**, the difference between the tail probability of $e_\pi(\hat{f}_\pi^{(k+1)}, \bar{f}_\pi)$ and that of $e_\pi(\hat{f}_\pi^{(k)}, \bar{f}_\pi)$ is bounded through a large deviation inequality of Wang and Shen (2007); $k = 0, 1, \cdots$. This in turn results in a faster rate for $e(\hat{f}_{.5}^{(k+1)}, \bar{f}_{.5})$, thus $e(\hat{f}_C, \bar{f}_{.5})$. In this proof, we denote labeled and unlabeled samples by $\{(X_i, Y_i)\}_{i=1}^{n_l}$ and $\{X_j\}_{j=n_l+1}^{n}$ to indicate that they are all random variables.

Step 1: First we bound the probability of the percentage of wrongly labeled unlabeled instances by $\text{sign}(\hat{f}^{(k)})$ by the tail probability of $e_{V.5}(\hat{f}^{(k)}, \bar{f}_{.5})$. For this purpose, define $D_f = \{\text{sign}(\hat{f}^{(k)}(X_j)) \neq \text{sign}(\bar{f}_{.5}(X_j)); n_l + 1 \leq j \leq n\}$ to be the set of unlabeled data that are wrongly labeled by $\text{sign}(\hat{f}^{(k)})$, with $n_f = \#\{D_f\}$ being its cardinality. According to Markov's inequality, the fact that $E(\frac{n_f}{n}) = \frac{n_u}{n} E\|\text{sign}(\hat{f}^{(k+1)}) - \text{sign}(\bar{f}_{.5})\|_1$, and (8), we have

$$\begin{aligned} P\Big(\frac{n_f}{n} \geq a_1(a_{11}\rho_n^2(\delta_n^{(k)})^2)^\beta\Big) &\leq P\Big(\|\text{sign}(\hat{f}^{(k)}) - \text{sign}(\bar{f}_{.5})\|_1 \geq a_1(a_{11}\rho_n(\delta_n^{(k)})^2)^\beta\Big) \\ &\quad + P\Big(\frac{n_f}{n} \geq \rho_n^\beta \|\text{sign}(\hat{f}^{(k+1)}) - \text{sign}(\bar{f}_{.5})\|_1\Big) \\ &\leq P\Big(e_{V.5}(\hat{f}^{(k)}, \bar{f}_{.5}) \geq a_{11}\rho_n(\delta_n^{(k)})^2\Big) + \rho_n^{-\beta}. \end{aligned} \tag{11}$$

Next we bound the tail probability of $\|\hat{p}^{(k)} - p\|_1$ based on "complete" data consisting of unlabeled data assigned by $\mathrm{sign}(\hat{f}^{(k)})$. An application of similar treatment to that in the proof of Theorem 3 of Wang et al. (2008) leads to

$$\begin{aligned} P\Big(\|\hat{p}^{(k)} - p\|_1 \geq & 8^{\gamma} a_1^{2\gamma+1}(a_{11}\rho_n\delta_n^{(k)})^{\beta\gamma}\Big) \leq \\ & P(\exists j : \|\,\mathrm{sign}(\hat{f}^{(k)}_{\pi_j}) - \mathrm{sign}(\bar{f}_{\pi_j})\|_1 \geq 8^{\gamma} a_1^{2\gamma+1}(a_{11}\rho_n\delta_n^{(k)})^{2\beta\gamma}), \end{aligned} \tag{12}$$

with $\pi_j = j/\lceil (a_{11}\rho_n\delta_n^{(k)})^{-\beta\gamma}\rceil$. By (8), it suffices to bound $P(e_{V_\pi}(\hat{f}^{(k)}_{\pi_j}, \bar{f}_{\pi_j}) \geq 8a_1^2(a_{11}\rho_n\delta_n^{(k)})^{2\beta})$ for all π_j in what follows.

We introduce some notations to be used. Let $\tilde{V}_\pi(f,Z) = V_\pi(f,Z) + \lambda J(f)$, and $Z_j = (X_j, Y_j)$ with $Y_j = \mathrm{sign}(\hat{f}^{(k)}(X_j))$; $n_l + 1 \leq j \leq n$. Define a scaled empirical process $E_n(\tilde{V}_\pi(f^*_\pi, Z) - \tilde{V}_\pi(f,Z)) = n^{-1}\Big(\sum_{i\in D_f} + \sum_{i\notin D_f}\Big)\Big(\tilde{V}_\pi(f^*_\pi, Z_i) - \tilde{V}_\pi(f,Z_i) - E(\tilde{V}_\pi(f^*_\pi, Z_i) - \tilde{V}_\pi(f,Z_i))\Big) \equiv E_n(V_\pi(f^*_\pi,Z) - V_\pi(f,Z))$.

By the definition of $\hat{f}^{(k)}_\pi$ and (11),

$$\begin{aligned} P\Big(e_{V_\pi}(\hat{f}^{(k)}_\pi, \bar{f}_\pi) \geq \delta_k^2\Big) \quad &\leq \quad P\Big(\frac{n_f}{n} \geq a_1(a_{11}\rho_n^2(\delta_n^{(k)})^2)^{\beta}\Big) + \\ & \qquad P^*\Big(\sup_{N_k} \frac{1}{n}\sum_{i=1}^{n}(\tilde{V}_\pi(f^*_\pi, Z_i) - \tilde{V}_\pi(f,Z_i)) \geq 0, \frac{n_f}{n} \leq a_1(a_{11}\rho_n^2(\delta_n^{(k)})^2)^{\beta}\Big) \\ &\leq \quad P\Big(e_{V_{.5}}(\hat{f}^{(k)}, \bar{f}_{.5}) \geq a_{11}\rho_n(\delta_n^{(k)})^2\Big) + \rho_n^{-\beta} + I_1, \end{aligned} \tag{13}$$

where $N_k = \{f \in \mathcal{F} : e_{V_\pi}(f, \bar{f}_\pi) \geq \delta_k^2\}$, $\delta_k^2 = 8a_1^2(a_{11}\rho_n\delta_n^{(k)})^{2\beta}$, $I_1 = P^*\Big(\sup_{N_k} E_n(V_\pi(f^*_\pi, Z) - V_\pi(f,Z)) \geq \inf_{N_k}\nabla(f, f^*_\pi), \frac{n_f}{n} \leq a_1(a_{11}\rho_n^2(\delta_n^{(k)})^2)^{\beta}\Big)$, and $\nabla(f, f^*_\pi) = \frac{n_f}{n}E_{i\in D_f}(\tilde{V}_\pi(f,Z_i) - \tilde{V}_\pi(f^*_\pi, Z_i)) + \frac{n-n_f}{n}E_{i\notin D_f}(\tilde{V}_\pi(f,Z_i) - \tilde{V}_\pi(f^*_\pi, Z_i))$.

To bound I_1, we partition N_k into a union of $A_{s,t}$ with

$$\begin{aligned} A_{s,t} &= \{f \in \mathcal{F} : 2^{s-1}\delta_k^2 \leq e_{V_\pi}(f, \bar{f}_\pi) < 2^s\delta_k^2, 2^{t-1}J^*_\pi \leq J(f) < 2^t J^*_\pi\}; \\ A_{s,0} &= \{f \in \mathcal{F} : 2^{s-1}\delta_k^2 \leq e_{V_\pi}(f, \bar{f}_\pi) < 2^s\delta_k^2, J(f) < J^*_\pi\}, \end{aligned}$$

for $s, t = 1, 2, \cdots$. Then it suffices to bound the corresponding probability over each $A_{s,t}$. Toward this end, we need to bound the first and second moments of $\tilde{V}_\pi(f,Z) - \tilde{V}_\pi(f^*_\pi, Z)$ over $f \in A_{s,t}$. Without loss of generality, assume that $4s_n < \delta_k^2 < 1$, $J(f^*_\pi) \geq 1$, and thus $J^*_\pi = \max(J(f^*_\pi), 1) = J(f^*_\pi)$.

For the first moment, note that $\nabla(f, f^*_\pi) \geq e_{V_\pi}(f, f^*_\pi) - \frac{n_f}{n}E|V_\pi(f,Z) - V_\pi(f^*_\pi, Z) + \bar{V}_\pi(f,Z) - \bar{V}_\pi(f^*_\pi, Z)| \geq e_{V_\pi}(f, f^*_\pi) - 4\frac{n_f}{n}$ with $\bar{V}_\pi(f,z) = S_\pi(-y)L(-yf(x))$. Using the assumption that $4\lambda J(f^*_\pi) \leq \delta_k^2$, and Assumptions A and B, we obtain

$$\begin{aligned} \inf_{A_{s,t}} \nabla(f, f^*_\pi) \quad &\geq \quad M(s,t) = (2^{s-1} - 1/2)\delta_k^2 + \lambda(2^{t-1} - 1)J(f^*_\pi), \\ \inf_{A_{s,0}} \nabla(f, f^*_\pi) \quad &\geq \quad (2^{s-1} - 3/4)\delta_k^2 \geq M(s,0) = 2^{s-3}\delta_k^2. \end{aligned}$$

For the second moment, by Assumptions A and B and $|\bar{V}_\pi(f,Z)-\bar{V}_\pi(\bar{f}_\pi,Z)|\le 2$ for any $0<\pi<1$, we have, for any $s,t=1,2,\cdots$ and some constant $a_3>0$,

$$\begin{aligned}
&\sup_{A_{s,t}} \mathrm{Var}(V_\pi(f,Z)-V_\pi(f^*_\pi,Z))\\
\le\ & \sup_{A_{s,t}} \frac{2(n-n_f)}{n}\Big(\mathrm{Var}(V_\pi(f,Z)-V_\pi(\bar{f}_\pi,Z))+\mathrm{Var}(V_\pi(f^*_\pi,Z)-V_\pi(\bar{f}_\pi,Z))\Big)+\\
& \frac{2n_f}{n}\Big(\mathrm{Var}(\bar{V}_\pi(f,Z)-\bar{V}_\pi(\bar{f}_\pi,Z))+\mathrm{Var}(\bar{V}_\pi(f^*_\pi,Z)-\bar{V}_\pi(\bar{f}_\pi,Z))\Big)\\
\le\ & 2a_2M(s,t)^\zeta+8a_1(a_{11}\rho_n^2(\delta_n^{(k)})^2)^\beta+4s_n\le a_3M(s,t)^{\min(1,\zeta)}=v^2(s,t).
\end{aligned}$$

Note that $I_1\le I_2+I_3$ with

$$\begin{aligned}
I_2 &= \sum_{s,t=1}^{\infty} P^*(\sup_{A_{s,t}} E_n(V_\pi(f^*_\pi,Z)-V_\pi(f,Z))\ge M(s,t), n_f/n\le a_1(a_{11}\rho_n^2(\delta_n^{(k)})^2)^\beta);\\
I_3 &= \sum_{s=1}^{\infty} P^*(\sup_{A_{s,0}} E_n(V_\pi(f^*_\pi,Z)-V_\pi(f,Z))\ge M(s,0), n_f/n\le a_1(a_{11}\rho_n^2(\delta_n^{(k)})^2)^\beta).
\end{aligned}$$

Then we bound I_2 and I_3 separately using Lemma 1 of Wang et al. (2007). For I_2, we verify conditions (8)-(10) there. Note that $\int_{aM(s,t)}^{v(s,t)} H_B^{1/2}(w,\mathcal{F}(2^w))dw/M(s,t)$ is non-increasing in s and $M(s,t)$, we have

$$\int_{aM(s,t)}^{v(s,t)} H_B^{1/2}(w,\mathcal{F}(2^t))dw/M(s,t)\le\int_{a_3M(1,t)}^{aM(1,t)^{\min(1,\zeta)/2}} H_B^{1/2}(w,\mathcal{F}(2^t))dw/M(1,t),$$

which is bounded by $\phi(\varepsilon_n^2,2^t)$ with $a=2a_4\varepsilon$ and $\varepsilon_n^2\le\delta_k^2$. Then Assumption C implies (8)-(10) there with $\varepsilon=1/2$, the choices of $M(s,t)$ and $v(s,t)$ and some constants $a_i>0; i=3,4$. It then follows that for some constant $0<\xi<1$,

$$\begin{aligned}
I_2 &\le \sum_{s,t=1}^{\infty} 3\exp\left(-\frac{(1-\xi)n(M(s,t))^2}{2(4(v(s,t))^2+2M(s,t)/3)}\right)\\
&\le \sum_{s,t=1}^{\infty} 3\exp(-a_8n(M(s,t))^{\max(1,2-\zeta)})\\
&\le \sum_{s,t=1}^{\infty} 3\exp(-a_8n(2^{s-1}\delta_k^2+\lambda(2^{t-1}-1)J^*_\pi)^{\max(1,2-\zeta)})\\
&\le 3\exp(-a_8n(\lambda J^*_\pi)^{\max(1,2-\zeta)})/(1-\exp(-a_8n(\lambda J^*_\pi)^{\max(1,2-\zeta)}))^2.
\end{aligned}$$

Similarly $I_3\le 3\exp(-a_8n(\lambda J^*_\pi)^{\max(1,2-\zeta)})/(1-\exp(-a_8n(\lambda J^*_\pi)^{\max(1,2-\zeta)}))^2$. Combining the bounds for I_i; $i=2,3$, we have $I_1\le 3.5\exp(-a_8n(\lambda J^*_\pi)^{\max(1,2-\zeta)})$. Consequently, by (8), (12) and (13)

$$\begin{aligned}
&P\Big(\|\hat{p}^{(k)}-p\|_1\ge 8^\gamma a_1^{2\gamma+1}(a_{11}\rho_n\delta_n^{(k)})^{\beta\gamma}\Big)\le\\
&\quad P\Big(e_{V.5}(\hat{f}^{(k)}_{.5},\bar{f}_{.5})\ge a_{11}\rho_n(\delta_n^{(k)})^2\Big)+\rho_n^{-\beta}+3.5\exp(-a_8n(\lambda J^*_\pi)^{\max(1,2-\zeta)}).
\end{aligned}\tag{14}$$

Step 2: To begin, note that $P\Big(e_{V_{.5}}(\hat{f}^{(k+1)}_{.5},\bar{f}_{.5}) \geq a_{11}\rho_n(\delta_n^{(k+1)})^2\Big) \leq I_4+I_5$ with

$$\begin{aligned} I_4 &= P\Big(e_{V_{.5}}(\hat{f}^{(k+1)}_{.5},\bar{f}_{.5}) \geq a_{11}\rho_n(\delta_n^{(k+1)})^2 \|\hat{p}^{(k)}-p\|_1 < 8^\gamma a_1^{2\gamma+1}(a_{11}\rho_n\delta_n^{(k)})^{\beta\gamma}\Big), \\ I_5 &= P\Big(\|\hat{p}^{(k)}-p\|_1 \geq 8^\gamma a_1^{2\gamma+1}(a_{11}\rho_n\delta_n^{(k)})^{\beta\gamma}\Big), \end{aligned}$$

where $a_{11}\rho_n(\delta_n^{(k+1)})^2 = (a_{12}(a_{11}\rho_n\delta_n^{(k)})^{\frac{(d+\eta)\beta\gamma}{d+\eta+1}})^{\frac{\theta+1}{1+\max(0,1-\beta)\theta}}$ and $a_{12} = 2a_6^{1/(d+\eta+1)}(4a_7)^{-\frac{1}{\theta}}$. By (14), it suffices to bound I_4.

For I_4, we need some notations. Let the ideal cost function be $V_{.5}(f,z)+U_{.5}(f(x))$, the ideal version of (2), where $V_{.5}(f,z)=\frac{1}{2}L(yf(x))$, and $U_{.5}(f(x))=\frac{1}{2}(p(x)L(f(x))+(1-p(x))L(-f(x)))$ is the ideal loss for unlabeled data. Denote by $\hat{U}^{(k)}_{.5}(f(x))=\frac{1}{2}(\hat{p}^{(k)}(x)L(f(x))+(1-\hat{p}^{(k)}(x))L(-f(x)))$ an estimate of $U_{.5}(f(x))$ at **Step** k. So the cost function in (2) can be written as $\tilde{W}(f,z)=W(f,z)+\lambda J(f)$ with $W(f,z)=V_{.5}(f,z)+U_{.5}(f(x))$. For simplicity, we denote a weighted empirical process by $E_n(W(f^*_{.5},z)-W(f,z)) = n_l^{-1}\sum_{i=1}^{n_l}\big(V_{.5}(f^*_{.5},Z_i)-V_{.5}(f,Z_i)\ -E(V_{.5}(f^*_{.5},Z)-V_{.5}(f,Z))\big) + n_u^{-1}\sum_{j=n_l+1}^{n}\big(U_{.5}(f^*_{.5}(X_j))-U_{.5}(f(X_j))-E(U_{.5}(f^*_{.5}(X))-U_{.5}(f(X)))\big)$.

By the definition of $\hat{f}^{(k+1)}_{.5}$, we have

$$\begin{aligned} I_4 \leq P\Big(&\sup_{N'_k} n_l^{-1}\sum_{i=1}^{n_l}(V_{.5}(f^*_{.5},Z_i)-V_{.5}(f,Z_i)) + n_u^{-1}\sum_{j=n_l+1}^{n}(\hat{U}^{(k)}_{.5}(f^*_{.5}(X_j)) - \\ &\hat{U}^{(k)}_{.5}(f(X_j))) + \lambda(J(f^*_{.5})-J(f)) \geq 0,\ \|\hat{p}^{(k)}-p\|_1 < 8^\gamma a_1^{2\gamma+1}(a_{11}\rho_n\delta_n^{(k)})^{\beta\gamma}\Big), \end{aligned}$$

where $N'_k=\{f\in\mathcal{F}: e_{V_{.5}}(f,\bar{f}_{.5}) \geq a_{11}\rho_n(\delta_n^{(k+1)})^2\}$. Then $I_4 \leq I_6+I_7$ with

$$\begin{aligned} I_6 &= P\Big(\sup_{N'_k} n_u^{-1}\sum_{j=n_l+1}^{n} D(f,X_j) \geq \\ &\qquad 8^{\frac{\gamma(d+\eta)}{d+\eta+1}} a_1^{\frac{(2\gamma+1)(d+\eta)}{d+\eta+1}} \rho_n(e_{V_{.5}}(f,f^*_{.5}))^{\frac{\min(1,\beta)\theta}{\theta+1}}(a_{11}\rho_n(\delta_n^{(k+1)})^2)^{\frac{1+\max(0,1-\beta)\theta}{\theta+1}}\Big), \\ I_7 &= P\Big(\sup_{N'_k} E_n(W(f^*_{.5},Z)-W(f,Z)) \geq \inf_{N'_k} E(\tilde{W}(f,Z)-\tilde{W}(f^*_{.5},Z)) \\ &\qquad - 8^{\frac{\gamma(d+\eta)}{d+\eta+1}} a_1^{\frac{(2\gamma+1)(d+\eta)}{d+\eta+1}} \rho_n(e_{V_{.5}}(f,f^*_{.5}))^{\frac{\min(1,\beta)\theta}{\theta+1}}(a_{11}\rho_n(\delta_n^{(k+1)})^2)^{\frac{1+\max(0,1-\beta)\theta}{\theta+1}}\Big), \end{aligned}$$

where $D(f,X_j)=\hat{U}^{(k)}_{.5}(f^*_{.5}(X_j))-\hat{U}^{(k)}_{.5}(f(X_j))-U_{.5}(f^*_{.5}(X_j))+U_{.5}(f(X_j))$.

For I_6, we note that

$$\begin{aligned} E|D(f,X)| &= \frac{1}{2}E|\hat{p}^{(k)}(X)-p(X)|\big|L(f^*_{.5}(X))-L(f(X))-L(-f^*_{.5}(X))+L(-f(X))\big| \\ &\leq \frac{1}{2}\|\hat{p}^{(k)}-p\|_\infty E\big(|L(f^*_{.5}(X))-L(f(X))|+|L(-f^*_{.5}(X))-L(-f(X))|\big). \end{aligned}$$

It thus suffices to bound $\|\hat{p}^{(k)}-p\|_\infty$ and $E\big(|L(f^*_{.5}(X))-L(f(X))|+|L(-f^*_{.5}(X))-L(-f(X))|\big)$ separately.

To bound $\|\hat{p}^{(k)} - p\|_\infty$, note that $EJ(\hat{f}^{(k)}_{\pi_j})$ is bounded for all π_j following the same argument as in Lemma 5 of Wang and Shen (2007). By Sobolev's interpolation theorem (Adams, 1975), $\|\hat{p}^{(k)}\|_\infty \leq 1$ and the fact that $|\hat{p}^{(k,d)}(x_1) - \hat{p}^{(k,d)}(x_2)| \leq \sup_j |\hat{f}^{(k,d)}_{\pi_j}(x_1) - \hat{f}^{(k,d)}_{\pi_j}(x_2)| + d(m^{(k)})^{-1}$ for any x_1 and x_2 based on the construction of $\hat{p}^{(k)}$ with $\hat{f}^{(k,d)}_{\pi_j} = \Delta^d(\hat{f}^{(k)}_{\pi_j})$, there exists a constant a_{13} such that $\|\hat{p}^{(k,d)}\|_\infty \leq a_{13}$ and $|\hat{p}^{(k,d)}(x_1) - \hat{p}^{(k,d)}(x_2)| \leq a_{13}|x_1 - x_2|^\eta + d(m^{(k)})^{-1}$ when $|x_1 - x_2|$ is sufficiently small. Without loss of generality, we assume $a_{13} \leq a_6$. By Assumption D and $m^{(k)} = \lceil (a_{11}\rho_n\delta_n^{(k)})^{-\beta\gamma} \rceil$, we have

$$\begin{aligned}
&\big| |\hat{p}^{(k,d)}(x_1) - p^{(d)}(x_1)| - |\hat{p}^{(k,d)}(x_2) - p^{(d)}(x_2)| \big| \\
\leq\ & |\hat{p}^{(k,d)}(x_1) - \hat{p}^{(k,d)}(x_2)| + |p^{(d)}(x_1) - p^{(d)}(x_2)| \leq 2a_6|x_1 - x_2|^\eta + 2d(a_{11}\rho_n\delta_n^{(k)})^{\frac{\beta\gamma(d+\eta)}{d+\eta+1}}.
\end{aligned}$$

It then follows from Proposition 6 of Shen (1997) that $\|\hat{p}^{(k)} - p\|_\infty \leq 2a_6^{\frac{1}{d+\eta+1}} \|\hat{p}^{(k)} - p\|_1^{\frac{d+\eta}{d+\eta+1}} + 2d(a_{11}\rho_n\delta_n^{(k)})^{\frac{\beta\gamma(d+\eta)}{d+\eta+1}} \leq 2a_6^{\frac{1}{d+\eta+1}} (8^\gamma a_1^{2\gamma+1})^{\frac{d+\eta}{d+\eta+1}} (a_{11}\rho_n\delta_n^{(k)})^{\frac{\beta\gamma(d+\eta)}{d+\eta+1}}$.

To bound $E\big(|L(f^*_{.5}(X)) - L(f(X))| + |L(-f^*_{.5}(X)) - L(-f(X))|\big)$, we note that

$$\begin{aligned}
& E|V_{.5}(f,Z) - V_{.5}(f^*_{.5},Z)| \\
=\ & \frac{1}{2}E\big(p(X)|L(f^*_{.5}) - L(f)| + (1-p(X))|L(-f) - L(-f^*_{.5})|\big) \\
\geq\ & E\frac{\delta}{2}\big(|L(f^*_{.5}) - L(f)| + |L(-f) - L(-f^*_{.5})|\big) I(\min(p(X), 1-p(X)) \geq \delta) \\
\geq\ & \delta\big(E\frac{1}{2}\big(|L(f^*_{.5}) - L(f)| + |L(-f) - L(-f^*_{.5})|\big) - 2a_7\delta^\theta\big)
\end{aligned}$$

by Assumption E. With $\delta = \big(E(|L(f^*_{.5}) - L(f)| + |L(-f) - L(-f^*_{.5})|)/8a_7\big)^{1/\theta}$, it yields that $E\big(|L(f^*_{.5}) - L(f)| + |L(-f) - L(-f^*_{.5})|\big) \leq (4a_7)^{-1/\theta}\big(E|V_{.5}(f,Z) - V_{.5}(f^*_{.5},Z)|\big)^{\theta/\theta+1}$, where

$$\begin{aligned}
& E|V_{.5}(f,Z) - V_{.5}(f^*_{.5},Z)| \leq E|V_{.5}(f,Z) - V_{.5}(\bar{f}_{.5},Z)| + E|V_{.5}(f^*_{.5},Z) - V_{.5}(\bar{f}_{.5},Z)| \\
\leq\ & P(\text{sign}(f) \neq \text{sign}(\bar{f}_{.5})) + E(V_{.5}(f,Z) - V_{.5}(\bar{f}_{.5},Z)) + \\
& \qquad P(\text{sign}(f^*_{.5}) \neq \text{sign}(\bar{f}_{.5})) + E(V_{.5}(f^*_{.5},Z) - V_{.5}(\bar{f}_{.5},Z)) \\
\leq\ & (e_{V_{.5}}(f,f^*_{.5}))^\beta + e_{V_{.5}}(f,f^*_{.5}) + s_n^\beta + s_n \leq 4(e_{V_{.5}}(f,f^*_{.5}))^{\min(1,\beta)}
\end{aligned}$$

by Assumptions A and B. Therefore,

$$E|D(f,X)| \leq 8^{\frac{\beta(d+\eta)}{d+\eta+1}} a_1^{\frac{(2\beta+1)(d+\eta)}{d+\eta+1}} (e_{V_{.5}}(f,f^*_{.5}))^{\frac{\min(1,\beta)\theta}{\theta+1}} (a_{11}\rho_n(\delta_n^{(k+1)})^2)^{\frac{1+\max(0,1-\beta)\theta}{\theta+1}}$$

and $I_6 \leq \rho_n^{-1}$ by Markov's inequality.

To bound I_7, we apply a similar treatment as in bounding I_1 in **Step 1** to yield that $I_7 \leq 3.5\exp(-a_8 n_l(\lambda J^*_{.5})^{\max(1,2-\zeta)})$. Combining the upper bounds of I_6 and I_7, $P(e_{V_{.5}}(\hat{f}^{(k+1)}_{.5}, \bar{f}_{.5}) \geq a_{11}\rho_n(\delta_n^{(k+1)})^2) \leq P(e_{V_{.5}}(\hat{f}^{(k)}_{.5}, \bar{f}_{.5}) \geq a_{11}\rho_n(\delta_n^{(k)})^2) + 3.5\exp(-a_9 n(\lambda J^*_{.5})^{\max(1,2-\zeta)}) + 3.5\exp(-a_8 n_l(\lambda J^*_{.5})^{\max(1,2-\zeta)}) + \rho_n^{-\beta} + \rho_n^{-1}$. Iterating this inequality yields that

$$\begin{aligned}
& P\Big(e_{V_{.5}}(\hat{f}^{(K)}_{.5}, \bar{f}_{.5}) \geq (a_{12}^{\frac{2B(d+\eta+1)}{\beta\gamma(d+\eta)}} (a_{11}\rho_n)^{2B-1})^{\frac{B^{K+1}-1}{B-1}} (\delta_n^{(0)})^{2B^K}\Big) \\
& \leq P\Big(e_{V_{.5}}(\hat{f}^{(0)}_{.5}, \bar{f}_{.5}) \geq a_{11}\rho_n(\delta_n^{(0)})^2\Big) + 3.5K\exp(-a_8 n_l(\lambda J^*_{.5})^{\max(1,2-\zeta)}) + \qquad (15) \\
& \qquad 3.5K\exp(-a_9 n(\lambda J^*_\pi)^{\max(1,2-\zeta)}) + K\rho_n^{-\beta} + K\rho_n^{-1},
\end{aligned}$$

where $B = \frac{(\theta+1)(d+\eta)\beta\gamma}{2(1+\max(0,1-\beta)\theta)(d+\eta+1)}$. Then the desired result follows from Assumption B and the fact that $\delta_k^2 = 8a_1^2(a_{11}\rho_n\delta_n^{(k)})^{2\beta} \geq \max(\varepsilon_n^2, 16s_n) = \delta_n^2$ for any k.

Proof of Corollary 4: It follows from Theorem 3 immediately and the proof is omitted.

Proof of Corollary 5: It follows from (14) and Corollary 4 that $\|\hat{p}_C - p\|_1 = O_p\Big(\max(\delta_n^{\beta\gamma}, (\rho_n\delta_n^{(0)})^{\max(1,1\beta\gamma B^K)})\Big)$, where $\hat{p}_C$ is the estimated probability through $\hat{f}_C$. The desired results follows from the fact that $\|\hat{U}_C(f) - U(f)\|_1 \leq 4\|\hat{p}_C - p\|_1$.

Appendix B. Verification of Assumptions in Section 5.2

We now verify Assumptions A-E for the theoretical examples in Section 5.2.

B.1 Linear Learning

First, note that $(X_{\cdot 1}, Y)$ is independent of $X_{\cdot 2}$, which implies that $ES(f;C) = E(E(S(f;C)|X_{\cdot 2})) \geq ES(\tilde{f}_C^*;C)$ for any $f \in \mathcal{F}$, where $\tilde{f}_C^* = \arg\min_{\tilde{f}\in\mathcal{F}_1} ES(\tilde{f};C)$ with $\mathcal{F}_1 = \{x_{\cdot 1} \in \mathcal{R} : \tilde{f}(x) = (1, x_{\cdot 1})^T w : w \in \mathcal{R}^2\} \subset \mathcal{F}$ and $S(f;C) = C(L(Yf(X)) + U(f(X))) + J(f)$.

Assumption A follows from $e_{V_\pi}(f_\pi^*, \bar{f}_\pi) \leq 2P(|nf_\pi(X)| \leq 1) \leq (\kappa_1 + 1)n^{-1} = s_n$ with $f_\pi^* = nf_\pi$. Easily, (7) in Assumption B holds for $\alpha = 1$. To verify (8), direct calculation yields that there exist some constants $b_1 > 0$ and $b_2 > 0$ such that for any $f \in \mathcal{F}_1$, we have $e_{V_\pi}(f, \bar{f}_\pi) \geq e_\pi(f, \bar{f}_\pi) = b_1\big((\frac{5}{4}(2\pi - 1) + e)^{\kappa_1+\kappa_2+1} - (\frac{5}{4}(2\pi - 1))^{\kappa_1+\kappa_2+1}\big)$ and $E|\text{sign}(f_\pi) - \text{sign}(f)| = b_2\big((\frac{5}{4}(2\pi - 1) + e)^{\kappa_1+1} - (\frac{5}{4}(2\pi - 1))^{\kappa_1+1}\big)$ with $w_f = w_{f_\pi} + (e_0, e_1)^T$ and $e = -\frac{50e_1(\frac{5}{4}(2\pi-1))+10e_0}{4+10e_1} > 0$. This implies (8) with $\beta = \gamma = \frac{1+\kappa_1}{1+\kappa_1+\kappa_2}$. For (9) in Assumption B, by the triangle inequality, $\text{Var}(V_\pi(f,Z) - V_\pi(f_\pi^*,Z)) \leq 2E|V_\pi(f,Z) - V_\pi(\bar{f}_\pi,Z)| \leq 2(\Lambda_1 + \Lambda_2)$, where $\Lambda_1 = E|l_\pi(f,Z) - V_\pi(\bar{f}_\pi,Z)|E|S_\pi(Y)|$ $|\text{sign}(f) - \text{sign}(\bar{f}_\pi)| \leq \big(2^{1+\kappa_2}(\kappa_1+1)^{\kappa_2}\big)^{\frac{1+\kappa_1}{1+\kappa_1+\kappa_2}} e_{V_\pi}(f, \bar{f}_\pi)^{\frac{1+\kappa_1}{1+\kappa_1+\kappa_2}}$, and $\Lambda_2 = E(V_\pi(f,Z) - l_\pi(f,Z)) = E(V_\pi(f,Z) - V_\pi(\bar{f}_\pi,Z)) + E(l_\pi(\bar{f}_\pi, Z) - l_\pi(f,Z)) \leq 2e_{V_\pi}(f, \bar{f}_\pi)$. Therefore (9) is met with $\zeta = \frac{1+\kappa_1}{1+\kappa_1+\kappa_2}$. For Assumption C, we define $\phi_1(\varepsilon, k) = a_3(\log(1/M^{1/2}))^{1/2}/M^{1/2}$ with $M = M(\varepsilon, \lambda, k)$. By Lemma 6 of Wang and Shen (2007), solving (10) yields $\varepsilon_n = (\frac{\log n}{n})^{1/2}$ when $C/J_\pi^* \sim \delta_n^{-2}n^{-1} \sim (\log n)^{-1}$. Assumption D is satisfied with $d = \infty$ and $\eta = 0$, and Assumption E is met with $\theta = \infty$ by noting that $\min(p(x), 1 - p(x)) \geq 1/10$. In this case, $B = \frac{(1+\kappa_1)^2}{2\kappa_2(1+\kappa_1+\kappa_2)}$, and the desired result follows from Corollary 4.

B.2 Kernel Learning

Similar to the linear case, we restrict our attention to $\mathcal{F}_1 = \{x_{\cdot 1} \in \mathcal{R} : f(x_{\cdot 1}) = w_{f,0} + \sum_{k=1}^n w_{f,k}K(x_{\cdot 1}, x_{k1}) : w_f = (w_{f,1}, \cdots, w_{f,n})^T \in \mathcal{R}^n\}$.

Note that $\mathcal{F}_1$ is rich for sufficiently large n in that for function f_π^* as defined in the linear example, there exists a $\tilde{f}_\pi^* \in \mathcal{F}_1$ such that $\|\tilde{f}_\pi^* - f_\pi^*\|_\infty \leq s_n$, and hence $e_{V_\pi}(\tilde{f}_\pi^*, \bar{f}_\pi) \leq 2s_n$. Assumption A is then met. Easily, (7) is satisfied for $\alpha = 1$. To verify (8), note that there exists constant $b_3 > 0$ such that for small $\delta > 0$, $P(|p(x) - 1/2| \geq \delta) = 2P(0 \leq p(x) - 1/2 \leq \delta) = 2P(0 \leq x_{(1)} \leq \frac{5}{2}\delta^{\frac{1}{\kappa_2}}) \leq b_3\delta^{\frac{1+\kappa_1}{\kappa_2}}$. Therefore, $e_{V_{.5}}(f, \bar{f}_{.5}) \geq e_{.5}(f, \bar{f}_{.5}) \geq \delta E|\text{sign}(f) - \text{sign}(\bar{f}_{.5})|I(|p(x)| \geq \delta) \geq 2^{-1}(4b_3)^{-\frac{\kappa_2}{1+\kappa_1}}\|\text{sign}(f) - \text{sign}(\bar{f}_{.5})\|_1^{\frac{1+\kappa_1+\kappa_2}{1+\kappa_1}}$ with $\delta = (\|\text{sign}(f) - \text{sign}(\bar{f}_{.5})\|_1/4b_3)^{\frac{\kappa_2}{1+\kappa_1}}$. This implies $\beta = \frac{1+\kappa_1}{1+\kappa_1+\kappa_2}$ in (8). Similarly, we can verify that there exists a constant $b_4 > 0$ such that

$P(|p(x)-\pi| \geq \delta) = 2P\left(\frac{5}{2}(\pi - \frac{1}{2}) \leq x_{(1)} \leq \frac{5}{2}(\pi - \frac{1}{2} + \delta^{\frac{1}{\kappa_2}})\right) \leq b_4 \delta^{\frac{1}{\kappa_2}}$ when $\pi > \frac{1}{2}$, which implies (8) with $\gamma = \frac{1}{1+\kappa_2}$. For (9), an application of the similar argument leads to $\zeta = \frac{1}{1+\kappa_2}$. For Assumption C, we define $\phi_1(\varepsilon, k) = a_3(\log(1/M^{1/2}))^{3/2}/M^{1/2}$ with $M = M(\varepsilon, \lambda, k)$. By Lemma 7 of Wang and Shen (2007), solving (10) yields $\varepsilon_n = ((\log n)^3 n^{-1})^{1/2}$ when $C/J^*_\pi \sim \delta_n^{-2} n^{-1} \sim (\log n)^{-3}$. Assumption D is satisfied with $d = \infty$ and $\eta = 0$, and Assumption E is met with $\theta = \infty$. Finally, $B = \frac{(1+\kappa_1)}{2\kappa_2(1+\kappa_2)}$, and the desired result follows from Corollary 4.

Abstract

In this paper we introduce NIEME,[1] a machine learning library for large-scale classification, regression and ranking. NIEME relies on the framework of *energy-based models* (LeCun et al., 2006) which unifies several learning algorithms ranging from simple perceptrons to recent models such as the pegasos support vector machine or l1-regularized maximum entropy models. This framework also unifies batch and stochastic learning which are both seen as energy minimization problems. NIEME can hence be used in a wide range of situations, but is particularly interesting for large-scale learning tasks where both the examples and the features are processed incrementally. Being able to deal with new incoming features at any time within the learning process is another original feature of the NIEME toolbox. NIEME is released under the GPL license. It is efficiently implemented in C++, it works on Linux, Mac OS X and Windows and provides interfaces for C++, Java and Python.

Keywords: large-scale machine learning, classification, ranking, regression, energy-based models, machine learning software

1. Introduction

Although many machine learning toolkits have been developed in the past years, it is often the case that they do not scale well to real-world applications. Developing learning algorithms for large-scale applications is a challenging design and implementation problem. In this paper, we introduce NIEME, a C++ library that provides generic tools for large-scale learning. NIEME covers two domains: supervised learning and learning in decision processes. In this paper, we focus on the supervised learning part, made of classification, regression and ranking algorithms. The support of decision processes is still in active development and will be more detailed in further versions of the library.

2. Framework: Energy-based Models

Most learning machines in NIEME rely on the unified framework of energy-based models introduced by LeCun et al. (2006). In this framework, illustrated in Figure 1, a learning machine can be interpreted as a combination of an architecture $\mathcal{A}$ with parameters θ, a per-example loss L , a set of regularizers $\{\Omega_1, \ldots, \Omega_R\}$ and a learner $\mathcal{L}$. Given the architecture, the per-example loss and the

```
(stochastic gradient descent)
for each example:
  gradient = computeGradient(architecture, loss, regularizers, example);
  parameters = parameters - gradient / T;
  T = T + 1;
```

Figure 1: This figure illustrates the framework of energy-based models. Top: the three components that define the learning energy. Bottom: the *learner* component that performs energy minimization.

Model	Architecture	Loss	Regularizers	Learner
Perceptron	linear	perceptron	none	stochastic descent
Logistic regression	linear	log-binomial	none	batch quasi-newton
Pegasos linear SVM	linear	hinge loss	l2	pegasos learner
Multilayer perceptron	linear ∘ transfer ∘ linear	perceptron	none	stochastic descent
L1-maxent classifier	multi-class linear	log-binomial	l1	batch quasi-newton
Pegasos multi-class SVM	multi-class linear	hinge loss	l2	pegasos learner
Least-square regression	linear	squared loss	none	batch quasi-newton
Custom	linear ∘ transfer	absolute loss	l1 + l2	batch rprop
Many others	...	...	...	...

Table 1: This table gives some examples of energy-based models. Each model is defined by its architecture, per-example loss, regularizers and learner. The ∘ symbols denotes architecture composition.

regularizers, we can define a learning loss for a set of examples $S = \{e_1, \dots e_N\}$:

$$\mathcal{L}_S(\theta) = \frac{1}{N}\sum_{i=1}^{N} L(e_i, \mathcal{A}_\theta) + \sum_{i=1}^{R} \Omega_i(\theta).$$

The aim of the learner is then to find parameters θ that minimize the learning loss given the training set S. As illustrated in Table 1, many combinations are possible in the energy-based framework. Some correspond to well-known learning machines, others to more original approaches. We describe the three components that define the learning loss $\mathcal{L}_S(\theta)$ in Section 2.1, describe learners in Section 2.2 and discuss some aspects of features in NIEME in Section 2.3.

2.1 Learning Loss components

The architecture is a parameterized function which computes predictions given input vectors. A simple example is the linear architecture, which computes a single output as a scalar product between the input vector and the parameter vector. NIEME supports elementary architectures (linear, multi-class linear, neural network transfer function) as well as a *composition* operation which allows users to create a new architecture by chaining existing ones. The per-example loss quantifies *how bad* an architecture and its parameters perform on a given learning example. Learning aims at finding parameters which lead to low expected per-example loss. Currently NIEME implements four different loss functions for discriminant learning (perceptron loss, hinge loss, log-binomial loss and exponential loss) and two loss functions for regression (squared and absolute loss). Regularizers are functions which measure the *complexity* of an architecture and its parameters. It has been shown (Vapnik, 1999) that penalizing complex models often leads to better generalization performance. Up to now, NIEME includes the two most commonly used regularizers: the l1-norm and l2-norm of the parameters.

2.2 Learners

The learner is the algorithmic component that performs learning loss minimization. NIEME implements three batch learners: the large-scale limited-memory quasi-Newton method of Lio and Nocedal (1989), the recently proposed method of Andrew and Gao (2007) for minimizing large-scale l1-regularized models and the rprop method of Riedmiller and Braun (1993). If batch learning is not possible for a given problem, NIEME proposes classical online methods such as stochastic gradient descent. Finally, NIEME also offers mini-batch methods including the recent SVM solver of Shalev-Shwartz et al. (2007).

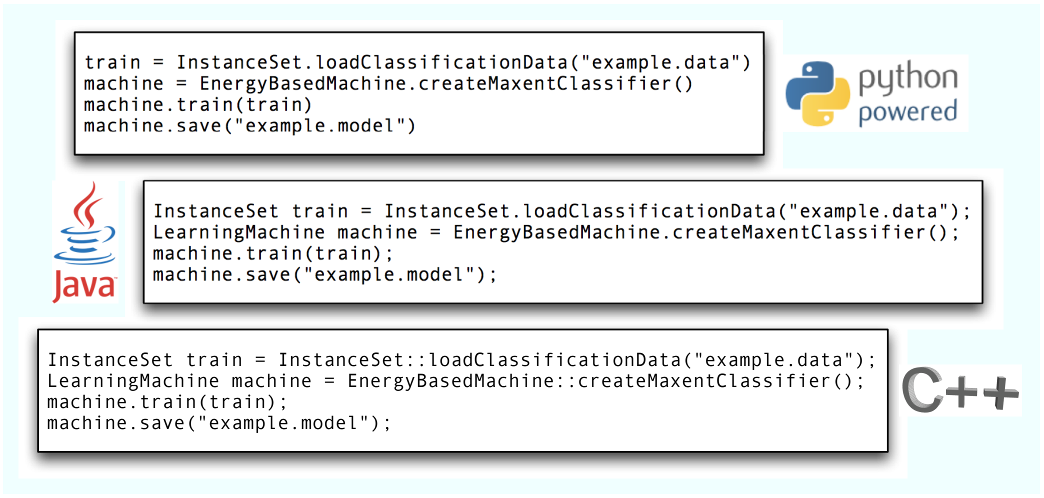
2.3 Feature Space

In large-scale applications, such as text processing, natural language processing, or bioinformatics, examples are often described with sparse feature representations. NIEME has thus been designed for efficient processing of such vectors. Moreover, in online settings, NIEME has the key ability to handle new incoming features at any time within the learning process. Everytime a new feature appears, the parameters of the learning machines are automatically extended to include this new feature. This is particularly interesting when dealing with large data streams for which the feature set cannot be known entirely before learning. Conceptually, all those features exist from the beginning of the learning process although most of them have zero values. Practically, a feature does not affect the learning parameters until it has been seen once.

3. Implementation

The core of NIEME is implemented in portable C++ and compiles currently under Windows (with Visual C++), Mac OS X (with Xcode or Makefiles) and Linux (with Makefiles or KDevelop). The implementation of about 14,000 lines of code is fully object-oriented and makes use of several design-patterns. The code is clear and easy to extend. However, it is not necessary to have a detailed understanding of the implementation in order to use NIEME. Indeed, NIEME includes an easy-to-use interface that can be used from C++, Java or Python, as illustrated in Figure 2. Wrappers for Java and Python are automatically generated thanks to the SWIG tool[2] that makes the glue code. NIEME could even be extended to support languages such as C# or OCaml.

2. SWIG can be found at `http://www.swig.org`.



```
train = InstanceSet.loadClassificationData("example.data")
machine = EnergyBasedMachine.createMaxentClassifier()
machine.train(train)
machine.save("example.model")
```

```
InstanceSet train = InstanceSet.loadClassificationData("example.data");
LearningMachine machine = EnergyBasedMachine.createMaxentClassifier();
machine.train(train);
machine.save("example.model");
```

```
InstanceSet train = InstanceSet::loadClassificationData("example.data");
LearningMachine machine = EnergyBasedMachine::createMaxentClassifier();
machine.train(train);
machine.save("example.model");
```

Figure 2: This figure shows the same program in three languages (Python, Java and C++). The program loads a classification data set, trains a maximum entropy classifier and saves the resulting model in a file called "example.model".

3.1 Tutorials, Documentation, License, Unit Tests

The NIEME website includes a quick-start guide with compilation instructions and tutorials to get started with NIEME in C++, Python or Java. Furthermore, it includes a complete reference documentation of the interface. NIEME is released under the GPL license. All functions of NIEME's interface are unit-tested within the *python unittest* framework.

Abstract

This paper reviews and extends the field of similarity-based classification, presenting new analyses, algorithms, data sets, and a comprehensive set of experimental results for a rich collection of classification problems. Specifically, the generalizability of using similarities as features is analyzed, design goals and methods for weighting nearest-neighbors for similarity-based learning are proposed, and different methods for consistently converting similarities into kernels are compared. Experiments on eight real data sets compare eight approaches and their variants to similarity-based learning.

Keywords: similarity, dissimilarity, similarity-based learning, indefinite kernels

1. Introduction

Similarity-based classifiers estimate the class label of a test sample based on the similarities between the test sample and a set of labeled training samples, and the pairwise similarities between the training samples. Like others, we use the term *similarity-based classification* whether the pairwise relationship is a similarity or dissimilarity. Similarity-based classification does not require direct access to the features of the samples, and thus the sample space can be any set, not necessarily a Euclidean space, as long as the similarity function is well defined for any pair of samples. Let Ω be the sample space and $\mathcal{G}$ be the finite set of class labels. Let $\psi : \Omega \times \Omega \to \mathbb{R}$ be the similarity function. We assume that the pairwise similarities between n training samples are given as an $n \times n$ similarity matrix S whose (i, j)-entry is $\psi(x_i, x_j)$, where $x_i \in \Omega$, $i = 1, \dots, n$, denotes the ith training sample, and $y_i \in \mathcal{G}$, $i = 1, \dots, n$ the corresponding ith class label. The problem is to estimate the class label $\hat{y}$ for a test sample x based on its similarities to the training samples $\psi(x, x_i)$, $i = 1, \dots, n$ and its self-similarity $\psi(x, x)$.

Similarity-based classification is useful for problems in computer vision, bioinformatics, information retrieval, natural language processing, and a broad range of other fields. Similarity functions may be asymmetric and fail to satisfy the other mathematical properties required for metrics or inner products (Santini and Jain, 1999). Some simple example similarity functions are: travel time from one place to another, compressibility of one random process given a code built for another, and the minimum number of steps to convert one sequence into another (edit distance). Computer vision researchers use many similarities, such as the tangent distance (Duda et al., 2001), earth mover's distance (EMD) (Rubner et al., 2000), shape matching distance (Belongie et al., 2002), and pyramid match kernel (Grauman and Darrell, 2007) to measure the similarity or dissimilarity between images in order to do image retrieval and object recognition. In bioinformatics, the Smith-Waterman algorithm (Smith and Waterman, 1981), the FASTA algorithm (Lipman and Pearson, 1985) and the BLAST algorithm (Altschul et al., 1990) are popular methods to compute the similarity between different amino acid sequences for protein classification. The cosine similarity between term frequency-inverse document frequency (tf-idf) vectors is widely used in information retrieval and text mining for document classification.

Notions of similarity appear to play a fundamental role in human learning, and thus psychologists have done extensive research to model human similarity judgement. Tversky's *contrast model* and *ratio model* (Tversky, 1977) represent an important class of similarity functions. In these two models, each sample is represented by a set of features, and the similarity function is an increasing function of set overlap but a decreasing function of set differences. Tversky's set-theoretic similarity models have been successful in explaining human judgement in various similarity assessment tasks, and are consistent with the observations made by psychologists that metrics do not account for cognitive judgement of similarity in complex situations (Tversky, 1977; Tversky and Gati, 1982; Gati and Tversky, 1984). Therefore, similarity-based classification may be useful for imitating or understanding how humans categorize.

The main contributions of this paper are: (1) we distill and analyze concepts and issues specific to similarity-based learning, including the generalizability of using similarities as features, (2) we propose similarity-based nearest-neighbor design goals and methods, and (3) we present a comprehensive set of experimental results for eight similarity-based learning problems and eight different similarity-based classification approaches and their variants. First, we discuss the idea of similarities as inner products in Section 2, then the concept of treating similarities as features in Section 3. The generalizability of using similarities as features and that of using similarities as kernels are compared in Section 4. In Section 5, we propose design goals and solutions for similarity-based weighted nearest-neighbor learning. Generative similarity-based classifiers are discussed in Section 6. Then in Section 7 we describe eight similarity-based classification problems, detail our experimental setup, and discuss the results. The paper concludes with some open questions in Section 8. For the reader's reference, key notation is summarized in Table 1.

2. Similarities as Inner Products

A popular approach to similarity-based classification is to treat the given similarities as inner products in some Hilbert space or to treat dissimilarities as distances in some Euclidean space. This approach can be roughly divided into two categories: one is to explicitly embed the samples in a Euclidean space according to the given (dis)similarities using multidimensional scaling (see Borg and Groenen, 2005, for further reading); the other is to modify the similarities to be kernels and

Ω	sample space	S	$n \times n$ matrix with (i,j)-entry $\psi(x_i,x_j)$
$\mathcal{G}$	set of class labels	s_i	$n \times 1$ vector with jth element $\psi(x_i,x_j)$
n	number of training samples	s	$n \times 1$ vector with jth element $\psi(x,x_j)$
$x_i \in \Omega$	ith training sample	$\mathbf{1}$	column vector of 1's
$x \in \Omega$	test sample	I	identity matrix
$y_i \in \mathcal{G}$	class label of ith training sample	$I_{\{\cdot\}}$	indicator function
$y \in \mathcal{G}^n$	$n \times 1$ vector with ith element y_i	K	kernel matrix or kernel function
$\hat{y} \in \mathcal{G}$	estimated class label for x	k	neighborhood size
$\mathcal{D}$	n training sample pairs $\{(x_i,y_i)\}_{i=1}^n$	L	hinge loss function
$\psi : \Omega \times \Omega \to \mathbb{R}$	similarity function	$\operatorname{diag}(a)$	diagonal matrix with a as the diagonal

Table 1: Key Notation

apply kernel classifiers. We discuss different methods for modifying similarities into kernels in Section 2.1. An important technicality is how to handle test samples, which is addressed in Section 2.2.

2.1 Modify Similarities into Kernels

The power of kernel methods lies in the implicit use of a reproducing kernel Hilbert space (RKHS) induced by a positive semidefinite (PSD) kernel (Schölkopf and Smola, 2002). Although the mathematical meaning of a kernel is the inner product in some Hilbert space, a standard interpretation of a kernel is the pairwise similarity between different samples. Conversely, many researchers have suggested treating similarities as kernels, and applying any classification algorithm that only depends on inner products. Using similarities as kernels eliminates the need to explicitly embed the samples in a Euclidean space.

Here we focus on the support vector machine (SVM), which is a well-known representative of kernel methods, and thus appears to be a natural approach to similarity-based learning. All the SVM algorithms that we discuss in this paper are for binary classification[1] such that $y_i \in \{\pm 1\}$. Let y be the $n \times 1$ vector whose ith element is y_i. The SVM dual problem can be written as

$$\begin{aligned} \underset{\alpha}{\text{maximize}} \quad & \mathbf{1}^T\alpha - \frac{1}{2}\alpha^T \operatorname{diag}(y) K \operatorname{diag}(y)\alpha \\ \text{subject to} \quad & 0 \preceq \alpha \preceq C\mathbf{1}, \quad y^T\alpha = 0, \end{aligned} \tag{1}$$

with variable $\alpha \in \mathbb{R}^n$, where $C > 0$ is the hyperparameter, K is a PSD kernel matrix whose (i,j)-entry is $K(x_i,x_j)$, $\mathbf{1}$ is the column vector with all entries one, and $\preceq$ denotes component-wise inequality for vectors. The corresponding decision function is Schölkopf and Smola (2002)

$$\hat{y} = \operatorname{sgn}\left(\sum_{i=1}^{n} \alpha_i y_i K(x,x_i) + b\right),$$

where

$$b = y_i - \sum_{j=1}^{n} \alpha_j y_j K(x_i,x_j)$$

for any i that satisfies $0 < \alpha_i < C$. The theory of RKHS requires the kernel to satisfy Mercer's condition, and thus the corresponding kernel matrix K must be PSD. However, many similarity

1. We refer the reader to Hsu and Lin (2002) for multiclass SVM.

functions do not satisfy the properties of an inner product, and thus the similarity matrix S can be indefinite. In the following subsections we discuss several methods to modify similarities into kernels; a previous review can be found in Wu et al. (2005). Unless mentioned otherwise, in the following subsections we assume that S is symmetric. If not, we use its symmetric part $\frac{1}{2}\left(S+S^T\right)$ instead. Notice that the symmetrization does not affect the SVM objective function in (1) since $\alpha^T\frac{1}{2}\left(S+S^T\right)\alpha = \frac{1}{2}\alpha^T S\alpha + \frac{1}{2}\alpha^T S^T\alpha = \alpha^T S\alpha$.

2.1.1 INDEFINITE KERNELS

One approach is to simply replace K with S, and ignore the fact that S is indefinite. For example, although the SVM problem given by (1) is no longer convex when S is indefinite, Lin and Lin (2003) show that the sequential minimal optimization (SMO) (Platt, 1998) algorithm will still converge with a simple modification to the original algorithm, but the solution is a stationary point instead of a global minimum. Ong et al. (2004) interpret this as finding the stationary point in a reproducing kernel Kreĭn space (RKKS), while Haasdonk (2005) shows that this is equivalent to minimizing the distance between reduced convex hulls in a pseudo-Euclidean space. A Kreĭn space, denoted by $\mathcal{K}$, is defined to be the direct sum of two disjoint Hilbert spaces, denoted by $\mathcal{H}_+$ and $\mathcal{H}_-$, respectively. So for any $a, b \in \mathcal{K} = \mathcal{H}_+ \oplus \mathcal{H}_-$, there are unique $a_+, b_+ \in \mathcal{H}_+$ and unique $a_-, b_- \in \mathcal{H}_-$ such that $a = a_+ + a_-$ and $b = b_+ + b_-$. The "inner product" on $\mathcal{K}$ is defined as

$$\langle a, b\rangle_{\mathcal{K}} = \langle a_+, b_+\rangle_{\mathcal{H}_+} - \langle a_-, b_-\rangle_{\mathcal{H}_-},$$

which no longer has the property of positive definiteness. Pseudo-Euclidean space is a special case of Kreĭn space where $\mathcal{H}_+$ and $\mathcal{H}_-$ are two Euclidean spaces. Ong et al. (2004) provide a representer theorem for RKKS that poses learning in RKKS as a problem of finding a stationary point of the risk functional, in contrast to minimizing a risk functional in RKHS. Using indefinite kernels in empirical risk minimization (ERM) methods such as SVM can lead to a saddle point solution and thus does not ensure minimizing the risk functional, so this approach does not guarantee learning in the sense of a good function approximation. Also, the nonconvexity of the problem may require intensive computation.

2.1.2 SPECTRUM CLIP

Since S is assumed to be symmetric, it has an eigenvalue decomposition $S = U^T\Lambda U$, where U is an orthogonal matrix and Λ is a diagonal matrix of real eigenvalues, that is, $\Lambda = \operatorname{diag}(\lambda_1, \ldots, \lambda_n)$. Spectrum clip makes S PSD by clipping all the negative eigenvalues to zero. Some researchers assume that the negative eigenvalues of the similarity matrix are caused by noise and view spectrum clip as a denoising step (Wu et al., 2005). Let

$$\Lambda_{\text{clip}} = \operatorname{diag}\left(\max(\lambda_1, 0), \ldots, \max(\lambda_n, 0)\right),$$

and the modified PSD similarity matrix be $S_{\text{clip}} = U^T\Lambda_{\text{clip}}U$. Let u_i denote the ith column vector of U. Using S_{clip} as a kernel matrix for training the SVM is equivalent to implicitly using $x_i = \Lambda_{\text{clip}}^{1/2}u_i$ as the representation of the ith training sample since $\langle x_i, x_j\rangle$ is equal to the (i,j)-entry of S_{clip}. A mathematical justification for spectrum clip is that S_{clip} is the nearest PSD matrix to S in terms of the Frobenius norm (Higham, 1988), that is,

$$S_{\text{clip}} = \arg\min_{K\succeq 0} \|K - S\|_F,$$

where $\succeq$ denotes the generalized inequality with respect to the PSD cone.

Recently, Luss and d'Aspremont (2007) have proposed a robust extension of SVM for indefinite kernels. Instead of only considering the nearest PSD matrix S_{clip}, they consider all the PSD matrices within distance β to S, that is, $\{K \succeq 0 \mid \|K-S\|_F \leq \beta\}$, where $\beta > \min_{K\succeq 0} \|K-S\|_F$, and propose to maximize the worst case of the SVM dual objective among these matrices:

$$\begin{array}{ll} \underset{\alpha}{\text{maximize}} & \underset{K\succeq 0, \|K-S\|_F\leq\beta}{\min} \left(\mathbf{1}^T\alpha - \frac{1}{2}\alpha^T \operatorname{diag}(y) K \operatorname{diag}(y)\alpha\right) \\ \text{subject to} & 0 \preceq \alpha \preceq C\mathbf{1}, \quad y^T\alpha = 0. \end{array}$$

This model is more flexible in the sense that the set of possible K in the hypothesis space lies in a ball with radius β centered around S. Different draws of training samples will change the candidate set of K and could cause overfitting. In practice, they replace the hard constraint $\|K-S\|_F \leq \beta$ with a penalty term and propose the following problem as the robust SVM for S:

$$\begin{array}{ll} \underset{\alpha}{\text{maximize}} & \underset{K\succeq 0}{\min} \left(\mathbf{1}^T\alpha - \frac{1}{2}\alpha^T \operatorname{diag}(y) K \operatorname{diag}(y)\alpha + \rho\|K-S\|_F^2\right) \\ \text{subject to} & 0 \preceq \alpha \preceq C\mathbf{1}, \quad y^T\alpha = 0, \end{array} \tag{2}$$

where $\rho > 0$ is the parameter to control the trade-off. They point out that the inner problem of (2) has a closed-form solution, and the outer problem is convex since its objective is a pointwise minimum of a set of concave quadratic functions of α and thus concave. A fast algorithm to solve (2) is given by Chen and Ye (2008).

2.1.3 SPECTRUM FLIP

In contrast to the interpretation that negative eigenvalues are caused by noise, Laub and Müller (2004) and Laub et al. (2006) show that the negative eigenvalues of some similarity data can code useful information about object features or categories, which agrees with some fundamental psychological studies (Tversky and Gati, 1982; Gati and Tversky, 1982). In order to use the negative eigenvalues, Graepel et al. (1998) propose an SVM in pseudo-Euclidean space, and Pekalska et al. (2001) also consider a generalized nearest mean classifier and Fisher linear discriminant classifier in the same space. Following the notation in Section 2.1.1, they assume that the samples lie in a Kreĭn space $\mathcal{K} = \mathcal{H}_+ \oplus \mathcal{H}_-$ with similarities given by $\psi(a,b) = \langle a_+, b_+\rangle_{\mathcal{H}_+} - \langle a_-, b_-\rangle_{\mathcal{H}_-}$. These proposed classifiers are their standard versions in the Hilbert space $\mathcal{H} = \mathcal{H}_+ \oplus \mathcal{H}_-$ with associated inner product $\langle a,b\rangle_{\mathcal{H}} = \langle a_+, b_+\rangle_{\mathcal{H}_+} + \langle a_-, b_-\rangle_{\mathcal{H}_-}$. This is equivalent to flipping the sign of the negative eigenvalues of the similarity matrix S: let $\Lambda_{\text{flip}} = \operatorname{diag}(|\lambda_1|, \ldots, |\lambda_n|)$, and then the similarity matrix after spectrum flip is $S_{\text{flip}} = U^T\Lambda_{\text{flip}}U$. Wu et al. (2005) note that this is the same as replacing the original eigenvalues of S with its singular values.

2.1.4 SPECTRUM SHIFT

Spectrum shift is another popular approach to modifying a similarity matrix into a kernel matrix: since $S + \lambda I = U^T(\Lambda + \lambda I)U$, any indefinite similarity matrix can be made PSD by shifting its spectrum by the absolute value of its minimum eigenvalue $|\lambda_{\min}(S)|$. Let $\Lambda_{\text{shift}} = \Lambda + |\min(\lambda_{\min}(S), 0)|I$, which is used to form the modified similarity matrix $S_{\text{shift}} = U^T\Lambda_{\text{shift}}U$. Compared with spectrum clip and flip, spectrum shift only enhances all the self-similarities by the amount of $|\lambda_{\min}(S)|$ and does not change the similarity between any two different samples. Roth et al. (2003) propose spectrum shift for clustering nonmetric proximity data and show that S_{shift} preserves the group structure of the original data represented by S. Let $\mathcal{X}$ be the set of samples to cluster, and $\{\mathcal{X}_\ell\}_{\ell=1}^N$ be a partition of $\mathcal{X}$ into N sets. Specifically, they consider minimizing the clustering cost function[2]

$$f\left(\{\mathcal{X}_\ell\}_{\ell=1}^N\right) = -\sum_{\ell=1}^{N} \sum_{\substack{i,j\in\mathcal{X}_\ell \\ i\neq j}} \frac{\psi(x_i,x_j)}{|\mathcal{X}_\ell|}, \tag{3}$$

where $|\mathcal{X}_\ell|$ denotes the cardinality of set $\mathcal{X}_\ell$. It is easy to see that (3) is invariant under spectrum shift.

Recently, Zhang et al. (2006) proposed training an SVM only on the k-nearest neighbors of each test sample, called SVM-KNN. They used spectrum shift to produce a kernel from the similarity data. Their experimental results on image classification demonstrated that SVM-KNN performs comparably to a standard SVM classifier, but with significant reduction in training time.

2.1.5 SPECTRUM SQUARE

The fact that $SS^T \succeq 0$ for any $S \in \mathbb{R}^{n\times n}$ led us to consider using SS^T as a kernel, which is valid even when S is not symmetric. For symmetric S, this is equivalent to squaring its spectrum since $SS^T = U^T\Lambda^2 U$. It is also true that using SS^T is the same as defining a new similarity function $\tilde{\psi}$ for any $a,b \in \Omega$ as

$$\tilde{\psi}(a,b) = \sum_{i=1}^{n} \psi(a,x_i)\psi(x_i,b).$$

We note that for symmetric S, treating SS^T as a kernel matrix K is equivalent to representing each x_i by its similarity feature vector $s_i = \begin{bmatrix}\psi(x_i,x_1) & \dots & \psi(x_i,x_n)\end{bmatrix}^T$ since $K_{ij} = \langle s_i, s_j\rangle$. The concept of treating similarities as features is discussed in more detail in Section 3.

2.2 Consistent Treatment of Training and Test Samples

Consider a test sample x that is the same as a training sample x_i. Then if one uses an ERM classifier trained with modified similarities $\tilde{S}$, but uses the unmodified test similarities, represented by vector $s = \begin{bmatrix}\psi(x,x_1) & \dots & \psi(x,x_n)\end{bmatrix}^T$, the same sample will be treated inconsistently. In general, one would like to modify the training and test similarities in a consistent fashion, that is, to modify the underlying similarity function rather than only modifying the S. In this context, given S and $\tilde{S}$, we term a transformation T on test samples *consistent* if $T(s_i)$ is equal to the ith row of $\tilde{S}$ for $i = 1,\dots,n$.

One solution is to modify the training and test samples all at once. However, when test samples are not known beforehand, this may not be possible. For such cases, Wu et al. (2005) proposed to first modify S and train the classifier using the modified $n\times n$ similarity matrix $\tilde{S}$, and then for each test sample modify its s in an effort to be consistent with the modified similarities used to train the model. Their approach is to re-compute the same modification on the augmented $(n+1)\times(n+1)$ similarity matrix

$$S' = \begin{bmatrix} S & s \\ s^T & \psi(x,x) \end{bmatrix}$$

2. They originally use dissimilarities in their cost function, and we reformulate it into similarities with the assumption that the relationship between dissimilarities and similarities is affine.

to form $\tilde{S}'$, and then let the modified test similarities $\tilde{s}$ be the first n elements of the last column of $\tilde{S}'$. The classifier that was trained on $\tilde{S}$ is then applied on $\tilde{s}$. To implement this approach, Wu et al. (2005) propose a fast algorithm to perform eigenvalue decomposition of S' by using the results of the eigenvalue decomposition of S. However, this approach does not guarantee consistency.

To attain consistency, we note that both the spectrum clip and flip modifications can be represented by linear transformations, that is, $\tilde{S} = PS$, where P is the corresponding transformation matrix, and we propose to apply the same linear transformation P on s such that $\tilde{s} = Ps$. For spectrum flip, the linear transformation is $P_{\text{flip}} = U^T M_{\text{flip}} U$, where

$$M_{\text{flip}} = \operatorname{diag}\left(\operatorname{sgn}(\lambda_1), \ldots, \operatorname{sgn}(\lambda_n)\right).$$

For spectrum clip, the linear transformation is $P_{\text{clip}} = U^T M_{\text{clip}} U$, where

$$M_{\text{clip}} = \operatorname{diag}\left(I_{\{\lambda_1 \geq 0\}}, \ldots, I_{\{\lambda_n \geq 0\}}\right),$$

and $I_{\{\cdot\}}$ is the indicator function. Recall that using $\tilde{S}$ implies embedding the training samples in a Euclidean space. For spectrum clip, this linear transformation is equivalent to embedding the test sample as a feature vector into the same Euclidean space of the embedded training samples:

Proposition 1 *Let S_{clip} be the Gram matrix of the column vectors of $X \in \mathbb{R}^{m \times n}$, where $\operatorname{rank}(X) = m$. For a given s, let $x = \arg\min_{z \in \mathbb{R}^m} \|X^T z - s\|_2$, then $X^T x = P_{\text{clip}} s$.*

The proof is in the appendix.

Proposition 1 states that if the n training samples are embedded in $\mathbb{R}^m$ with S_{clip} as the Gram matrix, and we embed the test sample in $\mathbb{R}^m$ by finding the feature vector whose inner products with the embedded training samples are closest to the given s, then the inner products between the embedded test sample and the embedded training samples are indeed $\tilde{s} = P_{\text{clip}} s$.

On the other hand, there is no linear transformation to ensure consistency for spectrum shift. For our experiments using spectrum shift, we adopt the approach of Wu et al. (2005), which for this case is to let $\tilde{s} = s$, because spectrum shift only affects self-similarities.

3. Similarities as Features

Similarity-based classification problems can be formulated into standard learning problems in Euclidean space by treating the similarities between a sample x and the n training samples as features (Graepel et al., 1998, 1999; Pekalska et al., 2001; Pekalska and Duin, 2002; Liao and Noble, 2003). That is, represent sample x by the similarity feature vector s. As detailed in Section 4, the generalizability analysis yields different results for using similarities as features and using similarities as inner products.

Graepel et al. (1998) consider applying a linear SVM on similarity feature vectors by solving the following problem:

$$\underset{w,b}{\text{minimize}} \quad \frac{1}{2}\|w\|_2^2 + C\sum_{i=1}^{n} L(w^T s_i + b, y_i) \tag{4}$$

with variables $w \in \mathbb{R}^n$, $b \in \mathbb{R}$ and hyperparameter $C > 0$, where $L(\alpha, \beta) \triangleq \max(1 - \alpha\beta, 0)$ is the hinge loss function. Liao and Noble (2003) also propose to apply an SVM on similarity feature vectors; they use a Gaussian radial basis function (RBF) kernel.

In order to make the solution w sparser, which helps ease the computation of the discriminant function $f(s) = w^T s + b$, Graepel et al. (1999) substitute the ℓ_1-norm regularization for the squared ℓ_2-norm regularization in (4), and propose a linear programming (LP) machine:

$$\underset{w,b}{\text{minimize}} \quad \|w\|_1 + C \sum_{i=1}^{n} L(w^T s_i + b, y_i). \tag{5}$$

Balcan et al. (2008a) provide a theoretical analysis for using similarities as features, and show that if a similarity is good in the sense that the expected intraclass similarity is sufficiently large compared to the expected interclass similarity, then given n training samples, there exists a linear separator on the similarities as features that has a specifiable maximum error at a margin that depends on n. Specifically, Theorem 4 in Balcan et al. (2008a) gives a sufficient condition on the similarity function ψ for (4) to achieve good generalization. Their latest results for ℓ_1-margin (inversely proportional to $\|w\|_1$) provide similar theoretical guarantees for (5) (Balcan et al., 2008b, Theorem 11). Wang et al. (2007) show that under slightly less restrictive assumptions on the similarity function there exists with high probability a convex combination of simple classifiers on the similarities as features which has a maximum specifiable error.

Another approach is the potential support vector machine (P-SVM) (Hochreiter and Obermayer, 2006; Knebel et al., 2008), which solves

$$\begin{aligned} \underset{\alpha}{\text{minimize}} \quad & \frac{1}{2}\|y - S\alpha\|_2^2 + \varepsilon\|\alpha\|_1 \\ \text{subject to} \quad & \|\alpha\|_\infty \le C, \end{aligned} \tag{6}$$

where $C > 0$ and $\varepsilon > 0$ are two hyperparameters. We note that by strong duality (6) is equivalent to

$$\underset{\alpha}{\text{minimize}} \quad \frac{1}{2}\|y - S\alpha\|_2^2 + \varepsilon\|\alpha\|_1 + \gamma\|\alpha\|_\infty \tag{7}$$

for some $\gamma > 0$. One can see from (7) that P-SVM is equivalent to the lasso regression (Tibshirani, 1996) with an extra ℓ_∞-norm regularization term. The use of multiple regularization terms in P-SVM is similar to the elastic net (Zou and Hastie, 2005), which uses ℓ_1 and squared ℓ_2 regularization together.

The algorithms above minimize the empirical risk with regularization. In addition, Pekalska et al. consider generative classifiers for similarity feature vectors; they propose a regularized Fisher linear discriminant classifier (Pekalska et al., 2001) and a regularized quadratic discriminant classifier (Pekalska and Duin, 2002).

We note that treating similarities as features may not capture discriminative information if there is a large intraclass variance compared to the interclass variance, even if the classes are well-separated. A simple example is if the two classes are generated by Gaussian distributions with highly-ellipsoidal covariances, and the similarity function is taken to be a negative linear function of the distance.

4. Generalization Bounds of Similarity SVM Classifiers

To investigate the generalizability of SVM classifiers using similarities, we analyze two forms of SVMs: using similarity as a kernel as discussed in Section 2, and a linear SVM using the similarities as features as given by (4). When similarities are used as features, we show that good generalization performance can be achieved by training the SVM on a small subset of m ($< n$) randomly selected training examples, and we compare this to the established analysis for the kernelized SVM.

The SVM learns a discriminant function $f(s) = w^T s + b$ by minimizing the empirical risk

$$\hat{R}_{\mathcal{D}}(f, L) = \frac{1}{n} \sum_{i=1}^{n} L(f(s_i), y_i),$$

where $\mathcal{D}$ denotes the training set, subject to some smoothness constraint $\mathcal{N}$, that is,

$$\underset{f}{\text{minimize}} \quad \hat{R}_{\mathcal{D}}(f, L) + \lambda_n \mathcal{N}(f),$$

where $\lambda_n = \frac{1}{2nC}$. We note that using (arbitrary) similarities as features corresponds to setting $\mathcal{N}(f) = w^T w$, while using (PSD) similarities as a kernel changes the smoothness constraint to $\mathcal{N}(f) = w^T S w$ (Rifkin, 2002, Appendix B), and in fact, this change of regularizer is the only difference between these two similarity-based SVM approaches. In this section, we examine how this small change in regularization affects the generalization ability of the classifiers.

To simplify the following analysis, we do not directly investigate the SVM classifier as presented; instead, as is standard in SVM learning theory, we investigate the following constrained version of the problem:

$$\begin{aligned} &\underset{f}{\text{minimize}} && \hat{R}_{\mathcal{D}}(f, L_t) \\ &\text{subject to} && \mathcal{N}(f) \leq \beta^2, \end{aligned} \tag{8}$$

with truncated hinge loss $L_t \triangleq \min(L, 1) \in [0, 1]$ and $f(s) = w^T s$ stripped of the intercept b.

The following generalization bound for the SVM using (PSD) similarities[3] as a kernel follows directly from the results in Bartlett and Mendelson (2002).

Theorem 1 (Generalization Bound of Similarities as Kernel) *Suppose* (x, y) *and* $\mathcal{D} = \{(x_i, y_i)\}_{i=1}^n$ *are drawn i.i.d. from a distribution on* $\Omega \times \{\pm 1\}$. *Let* ψ *be a positive definite similarity such that* $\psi(a, a) \leq \kappa^2$ *for some* $\kappa > 0$ *and all* $a \in \Omega$. *Let* S *be the* $n \times n$ *matrix with* (i, j)*-entry* $\psi(x_i, x_j)$ *and* s *be the* $n \times 1$ *vector with ith element* $\psi(x, x_i)$. *Define* F_S *to be the set of real-valued functions* $\{f(s) = w^T s \,|\, w^T S w \leq \beta^2\}$ *for a finite* β. *Then with probability at least* $1 - \delta$ *with respect to* $\mathcal{D}$, *every function* f *in* F_S *satisfies*

$$P(yf(s) \leq 0) \leq \hat{R}_{\mathcal{D}}(f, L_t) + 4\beta\kappa\sqrt{\frac{1}{n}} + \sqrt{\frac{\ln(2/\delta)}{2n}}.$$

The proof is in the appendix.

Theorem 1 says that with high probability, as $n \to \infty$, the misclassification rate is tightly bounded by the empirical risk $\hat{R}_{\mathcal{D}}(f, L_t)$, implying that a discriminant function trained by (8) with $\mathcal{N}(f) = w^T S w$ generalizes well to unseen data.

Next, we state a weaker result in Theorem 2 for the SVM using (arbitrary) similarities as features. Let the features be the similarities to m ($< n$) prototypes $\{(\tilde{x}_1, \tilde{y}_1), \ldots, (\tilde{x}_m, \tilde{y}_m)\} \subseteq \mathcal{D}$ randomly chosen from the training set so that $\tilde{s}$ is the $m \times 1$ vector with ith element $\psi(x, \tilde{x}_i)$. Results will be obtained on the remaining $n - m$ training data $\widetilde{\mathcal{D}} = \mathcal{D} \backslash \{(\tilde{x}_1, \tilde{y}_1), \ldots, (\tilde{x}_m, \tilde{y}_m)\}$.

3. If the original similarities are not PSD, then they must be modified to be PSD before this result applies; see Section 2 for a discussion of common PSD modifications.

Theorem 2 (Generalization Bound of Similarities as Features) *Suppose (x,y) and $\mathcal{D} = \{(x_i,y_i)\}_{i=1}^n$ are drawn i.i.d. from a distribution on $\Omega \times \{\pm 1\}$. Let ψ be a similarity such that $\psi(a,b) \leq \kappa^2$ for some $\kappa > 0$ and all $a,b \in \Omega$. Let $\{(\tilde{x}_1,\tilde{y}_1),\ldots,(\tilde{x}_m,\tilde{y}_m)\} \subseteq \mathcal{D}$ be a set of randomly chosen prototypes, and denote $\widetilde{\mathcal{D}} = \mathcal{D}\backslash\{(\tilde{x}_1,\tilde{y}_1),\ldots,(\tilde{x}_m,\tilde{y}_m)\}$. Let $\tilde{s}$ be the $m \times 1$ vector with ith element $\psi(x,\tilde{x}_i)$. Define F_l to be the set of real-valued functions $\left\{f(\tilde{s}) = w^T\tilde{s} \,\middle|\, w^Tw \leq \beta^2\right\}$ for a finite β. Then with probability at least $1-\delta$ with respect to $\widetilde{\mathcal{D}}$, every function f in F_l satisfies*

$$P\left(yf(s) \leq 0\right) \leq \hat{R}_{\widetilde{\mathcal{D}}}(f,L_t) + 4\beta\kappa^2\sqrt{\frac{m}{n}} + \sqrt{\frac{\ln(2/\delta)}{2n}}.$$

The proof is in the appendix.

Theorem 2 only differs significantly from Theorem 1 in the term $\sqrt{m/n}$, which means that if m, the number of prototypes used, grows no faster than $o(n)$, then with high probability, as $n \to \infty$, the misclassification rate is tightly bounded by the empirical risk on the remaining training set $\hat{R}_{\widetilde{\mathcal{D}}}(f,L_t)$. Note that Theorem 2 is unable to claim anything about the generalization when $m = n$, that is, the entire training set is chosen as prototypes. For a further discussion, see the appendix.

5. Similarity-based Weighted Nearest-Neighbors

In this section, we consider design goals and propose solutions for weighted nearest-neighbors for similarity-based classification. Nearest-neighbor learning is the algorithmic parallel of the *exemplar* model of human learning (Goldstone and Kersten, 2003). Weighted nearest-neighbor algorithms are task-flexible because the weights on the neighbors can be used as probabilities as long as they are non-negative and sum to one. For classification, such weights can be summed for each class to form posteriors, which is helpful for use with asymmetric misclassification costs and when the similarity-based classifier is a component of a larger decision-making system. As a lazy learning method, weighted nearest-neighbor classifiers do not require training before the arrival of test samples. This can be advantageous to certain applications where the amount of training data is huge, or there are a large number of classes, or the training data is constantly evolving.

5.1 Design Goals for Similarity-based Weighted k-NN

In this section, for a test sample x, we use x_i to denote its ith nearest neighbor from the training set as defined by the similarity function ψ for $i = 1,\ldots,k$, and y_i to denote the label of x_i. Also, we redefine S as the $k \times k$ matrix of the similarities between the k-nearest neighbors and s the $k \times 1$ vector of the similarities between the test sample x and its k-nearest neighbors. For each test sample, weighted k-NN assigns weight w_i to the ith nearest neighbor for $i = 1,\ldots,k$. Weighted k-NN classifies the test sample x as the class $\hat{y}$ that is assigned the most weight,

$$\hat{y} = \arg\max_{g\in\mathcal{G}} \sum_{i=1}^{k} w_i I_{\{y_i=g\}}. \qquad (9)$$

It is common to additionally require that the weights be nonnegative and normalized such that the weights form a posterior distribution over the set of classes $\mathcal{G}$. Then the estimated probability for class g is $\sum_{i=1}^k w_i I_{\{y_i=g\}}$, which can be used with asymmetric misclassification costs.

An intuitive and standard approach to weighting nearest neighbors is to give larger weight to neighbors that are more similar to the test sample. Formally, we state:

Design Goal 1 (Affinity): w_i should be an increasing function of $\psi(x, x_i)$.

In addition, we propose a second design goal. In practice, some samples in the training set are often very similar, for example, a random sampling of the emails by one person may include many emails from the same thread that contain repeated text due to replies and forwarding. Such similar training samples provide highly-correlated information to the classifier. In fact, many of the nearest neighbors may provide very similar information which can bias the classifier. Moreover, we consider those training samples that are similar to many other training samples less valuable based on the same motivation for tf-idf. To address this problem, one can choose weights to down-weight highly similar samples and ensure that a diverse set of the neighbors has a voice in the classification decision. We formalize this goal as:

Design Goal 2 (Diversity): w_i should be a decreasing function of $\psi(x_i, x_j)$.

Next we propose two approaches to weighting neighbors for similarity-based classification that aim to satisfy these goals.

5.2 Kernel Ridge Interpolation Weights

First, we describe kernel regularized linear interpolation, and we show that it leads to weights that satisfy the design goals. Gupta et al. (2006) proposed weights for k-NN in Euclidean space that satisfy a linear interpolation with maximum entropy (LIME) objective:

$$\begin{aligned} \underset{w}{\text{minimize}} \quad & \left\| \sum_{i=1}^{k} w_i x_i - x \right\|_2^2 - \lambda H(w) \\ \text{subject to} \quad & \sum_{i=1}^{k} w_i = 1,\ w_i \geq 0,\ i = 1, \ldots, k, \end{aligned} \tag{10}$$

with variable $w \in \mathbb{R}^k$, where $H(w) = -\sum_{i=1}^{k} w_i \log w_i$ is the entropy of the weights and $\lambda > 0$ is a regularization parameter. The first term of the convex objective in (10) tries to solve the linear interpolation equations, which balances the weights so that the test point is best approximated by a convex combination of the training samples. Additionally, the entropy maximization pushes the LIME weights toward the uniform weights.

We simplify (10) to a quadratic programming (QP) problem by replacing the negative entropy regularization with a ridge regularizer[4] $w^T w$, and we rewrite (10) in matrix form:

$$\begin{aligned} \underset{w}{\text{minimize}} \quad & \frac{1}{2} w^T X^T X w - x^T X w + \frac{\lambda}{2} w^T w \\ \text{subject to} \quad & w \succeq 0, \quad \mathbf{1}^T w = 1, \end{aligned} \tag{11}$$

where $X = \begin{bmatrix} x_1 & x_2 & \cdots & x_k \end{bmatrix}$. Note that (11) is completely specified in terms of the inner products of the feature vectors: $\langle x_i, x_j \rangle$ and $\langle x, x_i \rangle$, and thus we term the solution to (11) as *kernel ridge*

4. Due to the constraint $\mathbf{1}^T w = 1$, the ridge regularizer actually regularizes the variance of the weights and thus has similar effect as the negative entropy regularizer.

interpolation (KRI) weights. Generalizing from inner products to similarities, we form the KRI similarity-based weights:

$$\begin{aligned} \underset{w}{\text{minimize}} \quad & \frac{1}{2}w^T S w - s^T w + \frac{\lambda}{2} w^T w \\ \text{subject to} \quad & w \succeq 0, \quad \mathbf{1}^T w = 1. \end{aligned} \tag{12}$$

There are three terms in the objective function of (12). Acting alone, the linear term $-s^T w$ would give all the weight to the 1-nearest neighbor. This is prevented by the ridge regularization term $\frac{1}{2}\lambda w^T w$, which regularizes the variance of w and hence pushes the weights toward the uniform weights. These two terms work together to give more weight to the training samples that are more similar to the test sample, and thus help the resulting weights satisfy the first design goal of rewarding neighbors with high affinity to the test sample. The quadratic term in (12) can be expanded as follows,

$$\frac{1}{2}w^T S w = \frac{1}{2}\sum_{i,j} \psi(x_i, x_j) w_i w_j.$$

From the above expansion, one sees that holding all else constant in (12), the bigger $\psi(x_i, x_j)$ and $\psi(x_j, x_i)$ are, the smaller the chosen w_i and w_j will be. Thus the quadratic term tends to down-weight the neighbors that are similar to each other and acts to achieve the second design goal of spreading the weight among a diverse set of neighbors.

A sensitivity analysis further verifies the above observations. Let $g(w; S, s)$ be the objective function of (12), and $w^\star$ denote the optimal solution. To simplify the analysis, we only consider $w^\star$ in the interior of the probability simplex and thus $\nabla g(w^\star; S, s) = 0$. We first perturb s by adding $\delta > 0$ to its ith element, that is, $\tilde{s} = s + \delta e_i$, where e_i denotes the standard basis vector whose ith element is 1 and 0 elsewhere. Then

$$\nabla g(w^\star; S, \tilde{s}) = (S + \lambda I) w^\star - \tilde{s} = -\delta e_i,$$

whose projection on the probability simplex is

$$\nabla g(w^\star; S, \tilde{s}) - \frac{1}{k}\left(\mathbf{1}^T \nabla g(w^\star; S, \tilde{s})\right)\mathbf{1} = \delta\left(\frac{1}{k}\mathbf{1} - e_i\right). \tag{13}$$

The direction of the steepest descent given by the negative of the projected gradient in (13) indicates that the new optimal solution will have an increased w_i, which satisfies the first design goal.

Similarly, if we instead perturb S by adding $\delta > 0$ to its (i, j)-entry ($i \neq j$), that is, $\tilde{S} = S + \delta E_{ij}$, where E_{ij} denotes the matrix with (i, j)-entry 1 and 0 elsewhere, then

$$\nabla g(w^\star; \tilde{S}, s) = (\tilde{S} + \lambda I) w^\star - s = \delta w_j^\star e_i,$$

whose projection on the probability simplex is

$$\nabla g(w^\star; \tilde{S}, s) - \frac{1}{k}\left(\mathbf{1}^T \nabla g(w^\star; \tilde{S}, s)\right)\mathbf{1} = \delta w_j^\star\left(e_i - \frac{1}{k}\mathbf{1}\right). \tag{14}$$

The direction of the steepest descent given by the negative of the projected gradient in (14) indicates that the optimal solution will have a decreased w_i, which satisfies the second design goal.

Experimentally, we found little statistically significant difference between using negative entropy or ridge regularization for the KRI weights. Analytically, entropy regularization leads to an exponential form for the weights that can be used to prove consistency (Friedlander and Gupta, 2006). Computationally, the ridge regularizer is more practical because it results in a QP with box constraints and an equality constraint if the S matrix is PSD or approximated by a PSD matrix, and can thus be solved by the SMO algorithm (Platt, 1998).

5.2.1 KERNEL RIDGE REGRESSION WEIGHTS

A closed-form solution to (12) is possible if one relaxes the problem by removing the constraints $w_i \in [0,1]$ and $\sum_i w_i = 1$ that ensure the weights form a probability mass function. Then for PSD S, the objective $\frac{1}{2}w^T Sw - s^T w + \frac{1}{2}\lambda w^T w$ is solved by

$$w = (S + \lambda I)^{-1}s. \tag{15}$$

The k-NN decision rule (9) using these weights is equivalent to classifying by maximizing the discriminant of a local kernel ridge regression. For each class $g \in \mathcal{G}$, local kernel ridge regression (without intercept) solves

$$\underset{\beta_g}{\text{minimize}} \quad \sum_{i=1}^{k} \left(I_{\{y_i=g\}} - \langle \beta_g, \phi(x_i) \rangle \right)^2 + \lambda \langle \beta_g, \beta_g \rangle, \tag{16}$$

where ϕ denotes the mapping from the sample space Ω to a Hilbert space with inner product $\langle \phi(x_i), \phi(x_j) \rangle = \psi(x_i, x_j)$. Each solution to (16) yields the discriminant $f_g(x) = \langle \beta_g, \phi(x) \rangle = \nu_g^T(S + \lambda I)^{-1}s$ for class g (Cristianini and Shawe-Taylor, 2000), where $\nu_g = \begin{bmatrix} I_{\{y_1=g\}} & \dots & I_{\{y_k=g\}} \end{bmatrix}^T$. Maximizing $f_g(x)$ over $g \in \mathcal{G}$ produces the same estimated class label as (9) using the weights given in (15), thus we refer to these weights as *kernel ridge regression* (KRR) weights.

For a non-PSD S, it is possible that $S + \lambda I$ is singular. In the experiments, we compare handling non-PSD S by clip, flip, shift, or taking the pseudo-inverse (pinv) $(S + \lambda I)^{\dagger}$.

5.2.2 ILLUSTRATIVE EXAMPLES

We illustrate the KRI and KRR[5] weights with three toy examples shown on the next page. For each example, there are $k = 4$ nearest-neighbors, and the KRI and KRR weights are shown for a range of regularization parameter λ.

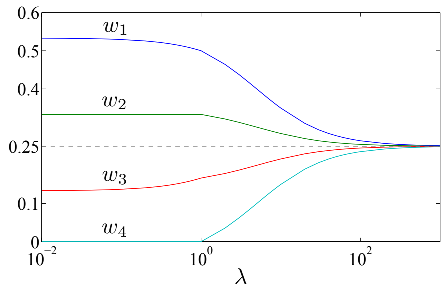
In Example 1, affinity is illustrated. One sees from s that the four distinct training samples are not equally similar to the test sample, and from S that the training samples have zero similarity to each other. Both KRI and KRR give more weight to training samples that are more similar to the test sample, illustrating that the weighting methods achieve the design goal of affinity.

In Example 2, diversity is illustrated. The four training samples all have similarity 3 to the test sample, but x_2 and x_3 are very similar to each other, and are thus weighted down as prescribed the by the design goal of diversity. Because of the symmetry of the similarities, the weights for x_2 and x_3 are exactly the same for both KRI and KRR.

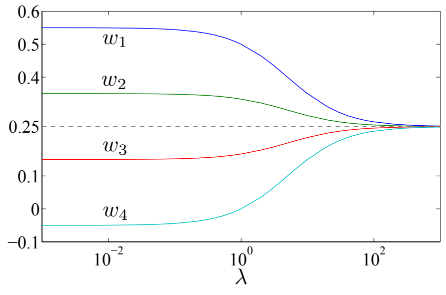
In Example 3, the interaction between the two design goals is illustrated. The S matrix is the same as in Example 2, but s is no longer uniform. In fact, although x_1 is less similar to the test sample than x_3, x_1 receives more weight because it is less similar to other training samples. The

5. For the purpose of comparison, we show the normalized KRR weights $\tilde{w}$ where $\tilde{w} = \left(I - \frac{1}{k}\mathbf{1}\mathbf{1}^T\right)w + \frac{1}{k}\mathbf{1}$. This does not affect the result of classification since each weight is shifted by the same constant.

Example 1: $s^T = \begin{bmatrix} 4 & 3 & 2 & 1 \end{bmatrix}, \quad S = \begin{bmatrix} 5 & 0 & 0 & 0 \\ 0 & 5 & 0 & 0 \\ 0 & 0 & 5 & 0 \\ 0 & 0 & 0 & 5 \end{bmatrix}$

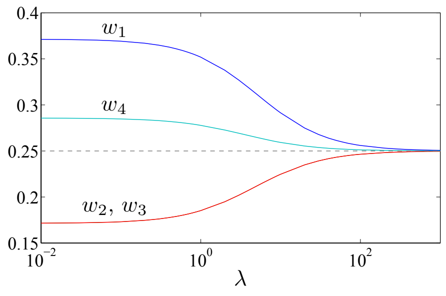


KRI weights

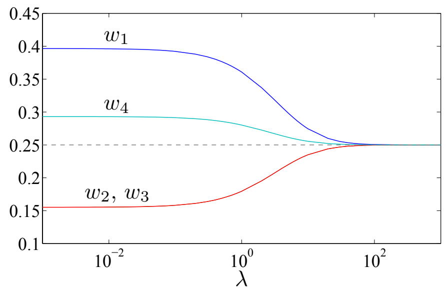


KRR weights

Example 2: $s^T = \begin{bmatrix} 3 & 3 & 3 & 3 \end{bmatrix}, \quad S = \begin{bmatrix} 5 & 1 & 1 & 1 \\ 1 & 5 & 4 & 2 \\ 1 & 4 & 5 & 2 \\ 1 & 2 & 2 & 5 \end{bmatrix}$

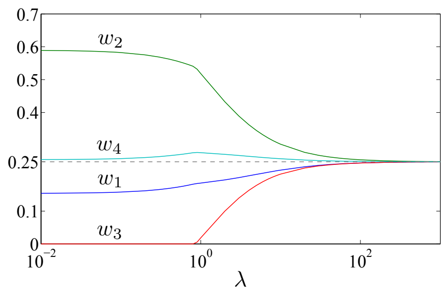


KRI weights

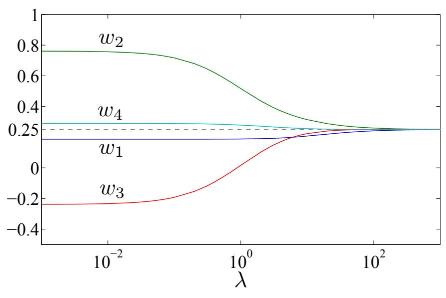


KRR weights

Example 3: $s^T = \begin{bmatrix} 2 & 4 & 3 & 3 \end{bmatrix}, \quad S = \begin{bmatrix} 5 & 1 & 1 & 1 \\ 1 & 5 & 4 & 2 \\ 1 & 4 & 5 & 2 \\ 1 & 2 & 2 & 5 \end{bmatrix}$



KRI weights



KRR weights

affinity goal allots the largest weight to the most similar neighbor x_2, but because x_2 and x_3 are highly similar, the diversity goal forces them to share weight, resulting in x_3 receiving little weight.

One observes from these examples that the KRR weights tend to be smoother than the KRI weights, because the KRI weights are constrained to a probability simplex, while the KRR weights are unconstrained.

6. Generative Classifiers

Generative classifiers provide probabilistic outputs that can be easily fused with other probabilistic information or used to minimize expected misclassification costs. One approach to generative classification given similarities is using the similarities as features to define an n-dimensional feature space, and then fitting standard generative models in that space, as discussed in Section 3. However, this requires fitting generative models with n data points (or less for class-conditional models) in an n-dimensional space. Another generative framework for similarity-based classification termed *similarity discriminant analysis* (SDA) has been proposed that models the class-conditional distributions of similarity statistics (Cazzanti et al., 2008). First we review the basic SDA model, then consider a local variant (Cazzanti and Gupta, 2007) and a mixture model variant that were both designed to reduce bias.

Let X denote a random test sample and x denote a realization of X. Assume that the relevant information about the class label of X is captured by a finite set $\mathcal{T}(X)$ of M descriptive statistics, where the mth descriptive statistic is denoted $\mathcal{T}_m(X)$. In this paper, we take the set of descriptive statistics to be the similarities to class centroids:

$$\mathcal{T}(x) = \{\psi(x,\mu_1), \psi(x,\mu_2), \ldots, \psi(x,\mu_G)\}, \tag{17}$$

where $\mu_g \in \Omega$ is a centroid for the gth class, and G is the number of classes. Although there are many possible definitions of a centroid given similarities, in this paper a class centroid is defined to be the training sample that has maximum sum-similarity to the other training samples of its class. The centroid-based descriptive statistics given by (17) were shown to be overall more effective than other considered descriptive statistics on simulations and a small set of real-data experiments (Cazzanti, 2007).

The classification rule for SDA to minimize the expected misclassification cost is: classify x as the class

$$\hat{y} = \arg\min_{g\in\mathcal{G}} \sum_{h\in\mathcal{G}} C(g,h) P\left(\mathcal{T}(x)\,|\,Y=h\right) P(Y=h), \tag{18}$$

where $C(g,h)$ is the cost of classifying a sample as class g if the truth is class h.

To estimate the class-conditional distributions $\{P(\mathcal{T}(x)\,|\,Y=g)\}_{g=1}^{G}$ the SDA model estimates the expected value of the mth descriptive statistic $\mathcal{T}_m(X)$ with respect to the class conditional distribution $P(\mathcal{T}(x)\,|\,Y=g)$ to be the average of the training sample data for each class g:

$$E_{P(\mathcal{T}(x)\,|\,g)}\left(\mathcal{T}_m(X)\right) = \frac{1}{|\mathcal{X}_g|} \sum_{z\in\mathcal{X}_g} \mathcal{T}_m(z), \tag{19}$$

where $\mathcal{X}_g$ is the set of training samples from class g. Given the $G\times G$ constraints specified by (19), the SDA model estimates each class-conditional distribution as the solution to (19) with maximum entropy, which is the exponential (Jaynes, 1982):

$$\hat{P}(\mathcal{T}(x)\,|\,g) = \prod_{m=1}^{G} \gamma_{gm} e^{\lambda_{gm}\mathcal{T}_m(x)}. \tag{20}$$

Substituting the maximum entropy solution (20) into (18) yields the SDA classification rule: classify x as the class

$$\hat{y} = \arg\min_{g\in\mathcal{G}} \sum_{h\in\mathcal{G}} C(g,h)P(Y=h) \prod_{m=1}^{G} \gamma_{hm} e^{\lambda_{hm}\mathcal{T}_m(x)}.$$

Each pair of parameters $(\lambda_{gm}, \gamma_{gm})$ can be separately calculated from the constraints given in (19) by one-dimensional optimization and normalization.

6.1 Reducing SDA Model Bias

The SDA model may not be flexible enough to capture a complicated decision boundary. To address this model bias issue, one could apply SDA locally to a neighborhood of k nearest neighbors for each test point, or learn a mixture SDA model.

In this paper we experimentally compare to *local SDA* (Cazzanti and Gupta, 2007) with local centroid-similarity descriptive statistics given by (17), in which SDA is applied to the k nearest neighbors of a test point, where the parameter k is trained by cross-validation. If any class in the neighborhood has fewer than three samples, there are not enough data samples to fit distributions of similarities, so every λ is assumed to be zero, and the local SDA model is reduced to a simple local centroid classifier. Given a discrete set of possible similarities, local SDA has been shown to be a consistent classifier in the sense that its error converges to the Bayes error under the usual asymptotic assumption that when the number of training samples $n \to \infty$, the neighborhood size $k \to \infty$ but k grows relatively slowly such that $k/n \to 0$ (Cazzanti and Gupta, 2007).

Cazzanti (2007) explored mixture SDA models analogous to Gaussian mixture models (GMM). He fits SDA mixture models, producing the following decision rule:

$$\hat{y} = \arg\min_{g\in\mathcal{G}} \sum_{h\in\mathcal{G}} C(g,h)P(Y=h) \left(\prod_{m=1}^{G} \sum_{l=1}^{c_m} w_{gml}\gamma_{gml} e^{\lambda_{gml}\psi(x,\mu_{ml})} \right),$$

where $\sum_{l=1}^{c_m} w_{ml} = 1$, and $w_{ml} > 0$. The number of components c_m are determined by cross-validation. The component weights $\{w_{gml}\}$ and the component SDA parameters $\{(\lambda_{gml}, \gamma_{gml})\}$ are estimated by an expectation-maximization (EM) algorithm, analogous to the EM-fitting of a GMM, except that the centroids are calculated only once (rather than iteratively) at the beginning using a k-medoids algorithm (Hastie et al., 2001). Simulations and a small set of experiments showed that this mixture SDA performed similarly to local SDA, but the model training for mixture SDA was much more computationally intensive.

7. Experiments

We compare eight similarity-based classification approaches: a linear and an RBF SVM using similarities as features, the P-SVM (Hochreiter and Obermayer, 2006), a local SVM (SVM-KNN) (Zhang et al., 2006) and a global SVM using the given similarities as a kernel, local SDA, k-NN, and the three weighted k-NN methods discussed in Section 5: the proposed KRR and KRI weights, and affinity weights as a control, defined by $w_i = a\psi(x, x_i)$, $i = 1, \ldots, k$, where a is a normalization constant. Results are shown in Table 3 and 4.

For algorithms that require a PSD S, we make S PSD by clip, flip or shift as discussed in Section 2, and pinv for KRR weights. The results in Table 3 are for clip; the experimental differences between clip, flip and shift, and pinv are shown in Table 4 and discussed in Section 7.4.

7.1 Data Sets

We tested the proposed classifiers on eight real data sets[6] representing a diverse set of similarities ranging from the human judgement of audio signals to sequence alignment of proteins.

The *Amazon-47* data set, created for this paper, consists of 204 books written by 47 authors. Each book listed on `amazon.com` links to the top four books that customers bought after viewing it, along with the percentage of customers who did so. We take the similarity of book A to book B to be the percentage of customers who bought B after viewing A, and the classification problem is to determine the author of the book.

The *Aural Sonar* data set is from a recent paper which investigated the human ability to distinguish different types of sonar signals by ear (Philips et al., 2006). The signals were returns from a broadband active sonar system, with 50 target-of-interest signals and 50 clutter signals. Every pair of signals was assigned a similarity score from 1 to 5 by two randomly chosen human subjects unaware of the true labels, and these scores were added to produce a 100×100 similarity matrix with integer values from 2 to 10.

The *Caltech-101* data set (Fei-Fei et al., 2004) is an object recognition benchmark data set consisting of 8677 images from 101 object categories. Similarities between images were computed using the pyramid match kernel (Grauman and Darrell, 2007) on SIFT features (Lowe, 2004). Here, the similarity is PSD.

The *Face Rec* data set consists of 945 sample faces of 139 people from the NIST Face Recognition Grand Challenge data set.[7] There are 139 classes, one for each person. Similarities for pairs of the original three-dimensional face data were computed as the cosine similarity between integral invariant signatures based on surface curves of the face (Feng et al., 2007). The original paper demonstrated comparable results to the state-of-the-art using these similarities with a 1-NN classifier.

The *Mirex07* data set was obtained from the human-rated, fine-scale audio similarity data used in the MIREX 2007 Audio Music Similarity and Retrieval[8] task. Mirex07 consists of 3090 samples, divided roughly evenly among 10 classes that correspond to different music genres. Humans judged how similar two songs are on a 0–10 scale with 0.1 increments. Each song pair was evaluated by three people, and the three similarity values were averaged. Self-similarity was assumed to be 10, the maximum similarity. The classification task is to correctly label each song with its genre.

The *Patrol* data set was collected by Driskell and McDonald (2008). Members of seven patrol units were asked to name five members of their unit; in some cases the respondents inaccurately named people who were not in their unit, including people who did not belong to any unit. Of the original 385 respondents and named people, only the ones that were named at least once were

6. The data sets along with the randomized partitions are available at `http://idl.ee.washington.edu/SimilarityLearning/`.
7. For more information, see `http://face.nist.gov/frgc/`.
8. For more information, see `http://www.music-ir.org/mirex/2007/index.php/Audio_Music_Similarity_and_Retrieval`.

kept, reducing the data set to 241 samples. The similarity between any two people a and b is $(N(a,b)+N(b,a))/2$, where $N(a,b)$ is the number of times person a names person b. Thus, this similarity ϕ has a range $\{0,0.5,1\}$. The classification problem is to estimate to which of the seven patrol units a person belongs, or to correctly place them in an eighth class that corresponds to "not in any of the units."

The *Protein* data set has sequence-alignment similarities for 213 proteins from 4 classes,[9] where class one through four contains 72, 72, 39, and 30 samples, respectively (Hofmann and Buhmann, 1997). As further discussed in the results, we define an additional similarity termed *RBF-sim* for the Protein data set: $\psi_{\text{RBF}}(x_i,x_j) = e^{-\|s(x_i)-s(x_j)\|_2}$, where $s(x)$ is the 213×1 vector of similarities with mth component $\psi(x,x_m)$.

The *Voting* data set comes from the UCI Repository (Asuncion and Newman, 2007). It is a two-class classification problem with 435 samples, where each sample is a categorical feature vector with 16 components and three possibilities for each component. We compute the value difference metric (Stanfill and Waltz, 1986) from the categorical data, which is a dissimilarity that uses the training class labels to weight different components differently so as to achieve maximum probability of class separation.

Shown in Figure 1 are the similarity matrices of all the data sets. The rows and columns are ordered by class label; on many of the data sets, particularly those with a fewer number of classes, a block-diagonal structure is visible along the class boundaries, indicated by tick marks. Note that a purely block-diagonal similarity matrix would indicate a particularly easy classification problem, as objects have nonzero similarity only to objects of the same class.

7.2 Other Experimental Details

For each data set, we randomly selected 20% of the data for testing and used the remaining 80% for training. We chose the classifier parameters such as C for the SVM, λ for the KRI and KRR weights, and k for local classifiers by 10-fold cross-validation on the training set, and then used them to classify the held out test data. This process was repeated for 20 random partitions of test and training data, and the statistical significance of the classification error was computed by a one-sided Wilcoxon signed-rank test. Multiclass implementations of the SVM classifiers used the "one-vs-one" scheme (Hsu and Lin, 2002).

Nearest neighbors for local methods were determined using symmetrized similarities[10] $\frac{1}{2}(\psi(x,x_i)+\psi(x_i,x))$. Cross-validation choices are listed in Table 2. These choices were based on recommendations and usage in previous literature, and on preliminary experiments we conducted with a larger range of cross-validation parameters on the Voting and Protein data sets.

7.3 Results

The mean and standard deviation (in parentheses) of the error across the 20 randomized test/training partitions are shown in Table 3. The bold results in each column indicate the classifier with lowest average error; also bolded are any classifiers that were not statistically significantly worse than the classifier with lowest average error.

9. The original data set has 226 samples with 9 classes. As is standard practice with this data set, we removed those classes which contain less than 7 samples.
10. Only Amazon-47 and Patrol are natively asymmetric.

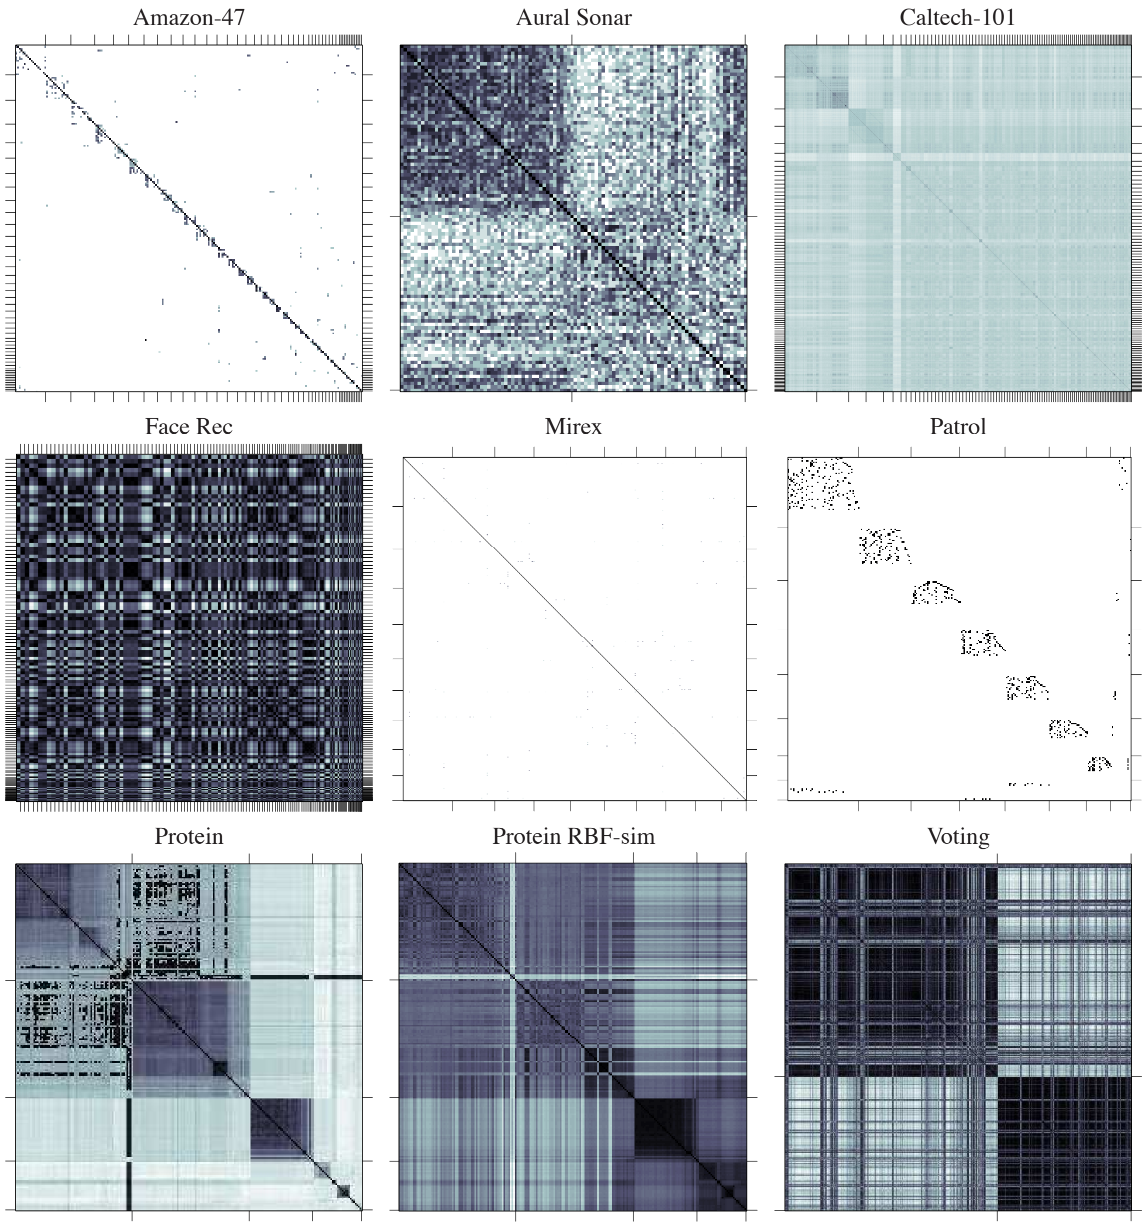


Figure 1: Similarity matrices of each data set with class divisions indicated by tick marks; black corresponds to maximum similarity and white to zero.

The similarity matrices in Figure 1 show that Aural Sonar and Voting exhibit fairly nice block-diagonal structures, indicating that these are somewhat easy classification problems. This is reflected in the relatively low errors across the board and few statistically significant differences in performance. More interesting results can be observed on the more difficult classification problems posed by the other data sets.

All local methods	k:	$1, 2, 3, \ldots, 16, 32, 64, 128$
KRR	λ:	$10^{-3}, 10^{-2}, \ldots, 10$
KRI	λ:	$10^{-6}, 10^{-5}, \ldots, 10$, and 10^{6}

PSVM	C:	$10^{0}, 10^{1}, \ldots, 10^{4}$
SVM-KNN	C:	$10^{-3}, 10^{-2}, \ldots, 10^{5}$
SVM (linear, clip, flip, shift)	C:	$10^{-3}, 10^{-2}, \ldots, 10^{5}$
SVM (RBF)	C:	$10^{-3}, \ldots, 10$
SVM (RBF)	γ:	$10^{-5}, 10^{-4}, \ldots, 10$

Table 2: Cross-validation Parameter Choices

The Amazon-47 data set is very sparse with at most four non-zero similarities per row. With such sparse data, one might expect a 1-NN classifier to perform well; indeed for the uniform k-NN classifier, the cross-validation chose $k = 1$ on all 20 of the randomized partitions. For all of the local classifiers, the k chosen by cross-validation on this data set was never larger than $k = 3$, and out of the 20 randomized partitions, $k = 1$ was chosen the majority of the time for all the local classifiers. In contrast, the global SVM classifiers perform poorly on this sparse data set. The Patrol data set is the next sparsest data set, and the results show a similar pattern. However, the Mirex data set is also relatively sparse, and yet the global classifiers do well, in particular the SVMs that use similarities as features. The Amazon-47 and Patrol data sets do differ from the Mirex data set in that the self-similarities are not always maximal. Whether (and how) this difference causes or correlates the relative differences in performance is an open question.

The Protein data set exhibits large differences in performance, with the statistically significantly best performances achieved by two of the three SVMs that use similarity as features. The reason that similarities on features performs so well while others do so poorly can be seen in the Protein similarity matrix in Figure 1. The first and second classes (roughly the first and second thirds of the matrix) exhibit a strong interclass similarity, and rows belonging to the same class exhibit very similar patterns, thus treating the rows of the similarity matrix as feature vectors provides good discrimination of classes. To investigate this effect, we transformed the entire data set using a radial basis function (RBF) to create a similarity based on the Euclidean distance between rows of the original similarity matrix, yielding the 213×213 Protein RBF similarity matrix. One sees from Table 3 that this transformation increases the performance of classifiers across the board, indicating that this is indeed a better measure of similarity for this data set. Furthermore, after this transformation we see a complete turnaround in performance: for Protein RBF, the SVMs that use similarities as features are among the worst performers (with P-SVM still performing decently), and the basic k-NN does better than the best classifier given the original Protein similarities.

The Caltech-101 data set is the largest data set, and with 8677 samples in 101 classes, an analysis of the structure of this similarity matrix is difficult. Here we see the most dramatic enhancement in performance (25% lower error) by using the KRR and KRI weights rather than k-NN or the affinity

Table 3: % Test misclassified averaged over 20 randomized test/training partitions.

k-NN, suggesting that there are highly correlated samples that bias the classification. In contrast, for the Amazon-47, Aural Sonar, Face Rec, Mirex, and Patrol data sets there is only a small win by using the KRI or KRR weights, or a statistically insignificant small decline in performance (we hypothesize this occurs because of overfitting due to the additional parameter λ). On Protein the KRR error is 1/3 the error of the other weighted methods; this is a consequence of using the pinv rather than other types of spectrum modification, as can be seen from Table 4. The other significant difference between the weighting methods is a roughly 10% improvement in average error on Voting by using the KRR or KRI weights. In conclusion, the use of diverse weights may not matter on some data sets, but can be very helpful on certain data sets.

SVM-KNN was proposed by Zhang et al. (2006) in part as a way to reduce the computations required to train a global SVM using similarities as a kernel, and their results showed that it performed similarly to a global SVM. That is somewhat true here, but some differences emerge. For the Amazon-47 and Patrol data sets the local methods all do well including SVM-KNN, but the global methods do poorly, including the global SVM using similarities as a kernel. On the other hand, the global SVM using similarities as a kernel is statistically significantly better than SVM-KNN on Caltech-101, even though the best performance on that data set is achieved by a local method (KRR). From this sampling of data sets, we conclude that applying the SVM locally or globally can in fact make a difference, but whether it is a positive or negative difference depends on the application.

Among the four global SVMs (including P-SVM), it is hard to draw conclusions about the performance of the one that uses similarities as a kernel versus the three that use similarities as features. In terms of statistical significance, the SVM using similarities as a kernel outperforms the others on Patrol and Caltech-101 whereas it is the worst on Amazon-47 and Protein, and there is no clear division on the remaining data sets. Lastly, the results do not show statistically significant differences between using the linear or RBF version of the SVM with similarities as features except for small differences on Face Rec and Patrol.

7.4 Clip, Flip, or Shift?

Different approaches to modifying similarities to form a kernel were discussed in Section 2.1. We experimentally compared clip, flip, and shift for the KRI weights, SVM-KNN, and SVM, and flip, clip, shift and pinv for the KRR weights on the nine data sets. Table 4 shows the five data sets for which at least one method showed statistically significantly different results depending on the choice of spectrum modification.

For KRR weights, one sees that the pinv solution is never statistically significantly worse than clip, flip, or shift, which are worse than pinv at least once. For KRI weights, the differences are negligible, but based on average error we recommend clip.

Flip takes the absolute value of the eigenvalues, which is similar to the effect of using SS^T (as discussed in Section 2.1.5), which for an SVM is equivalent to using the SVM on similarities-as-features. Thus it is not surprising that for the Protein data set, which we have seen in Table 3 works best with similarities as features, flip makes a large positive difference for SVM-KNN and SVM. One sees different effects of the spectrum modification on the local methods versus the global SVMs because for the local methods the modification is only done locally.

	KRI					KRR

Table 4: Clip, flip, shift, and pinv comparison. Table shows % test misclassified averaged over 20 randomized test/training partitions for the five data sets that exhibit statistically significant differences between these spectrum modifications. If there are statistically significant differences for a given algorithm and a given data set, then the worst score, and scores not statistically better, are shown in italics.

8. Conclusions and Some Open Questions

Similarity-based learning is a practical learning framework for many problems in bioinformatics, computer vision, and those regarding human similarity judgement. Kernel methods can be applied in this framework, but similarity-based learning creates a richer set of challenges because the data may not be natively PSD.

In this paper we explored four different approximations of similarities: clipping, flipping, and shifting the spectrum, and in some cases a pseudoinverse solution. Experimental results show small but sometimes statistically significant differences. Based on the theoretical justification and results, we suggest practitioners clip. Flipping the spectrum does create significantly better performance for the original Protein problem because, as we noted earlier, flipping the spectrum has a similar effect to using the similarities as features, which works favorably for the original Protein problem. However, it should be easy to recognize when flip will be advantageous, modify the similarity as we did for the Protein RBF problem, and possibly achieve even better results. Concerning approximating similarities, we addressed the issue of consistent treatment of training and test samples when approximating the similarities to be PSD. Although our linear solution is consistent, we do not argue it is optimal, and consider this issue still open.

A fundamental question is whether it is more advisable to use the similarities as kernels or features. We showed that the difference for SVMs is in the regularization, and that for similarities-as-kernels generalization bounds can be proven using standard learning theory machinery. However, it is not straightforward to apply standard learning theory machinery to similarities-as-features because the normal Rademacher complexity bounds do not hold with the resulting adaptive non-independent functions. To address this, we considered splitting the training set into prototypes for similarities-as-features and a separate set to evaluate the empirical risk. Even then, we were only able to show generalization bounds if the number of prototypes grows slowly. Complementary results have been shown for similarities-as-features by Balcan et al. (2008a) and Wang et al. (2007), but further analysis would be valuable. Experimentally, it would be interesting to investigate methods using prototypes and performance as the number of training samples increases, ideally with larger data sets than those used in our experiments.

We proposed design goals of affinity and diversity for weighting nearest neighbors, and suggested two methods for constructing weights that satisfy these design goals. Experimental results on eight diverse data sets demonstrated that the proposed weighted k-NN methods can significantly reduce error compared to standard k-NN. In particular, on the largest data set Caltech-101, the proposed KRI and KRR weights provided a roughly 25% improvement over k-NN and affinity-weighted k-NN. The Caltech-101 similarities are PSD, and it may be that the KRI and KRR methods are sensitive to approximations of the matrix S. Preliminary experiments using the unmodified local S and solving KRI or KRR objective functions using a global optimizer showed an increase in performance but at the price of greatly increased computational cost. Compared to the local SVM (SVM-KNN), the proposed KRR weights were statistically significantly worse on the two-class data sets Aural Sonar and Patrol, but statistically significantly better on both of the highly multi-class data sets, Amazon-47 and Caltech-101.

Overall, the results show that local methods are effective for similarity-based learning. It is tempting from the obvious discrepancy between the performance of local and global methods on Amazon and Patrol to argue that local methods will work best for sparse similarities. However, Mirex is also relatively sparse, and the best methods are global. The Amazon and Patrol data sets are different from the other data sets in that they are the only two data sets with non-maximal self-similarities, and this issue may be the root of the discrepancy. For local methods an open question not addressed here is how to efficiently find nearest-neighbors given only similarities. Some research has been done in this area, for example Goyal et al. (2008) developed methods for fast search with logarithmic query times that depend on how "disordered" the similarity is, where they measure a disorder constant D of a set of samples as the D that ensures that if x_i is the kth most similar sample to x, and x_j is the qth most similar sample to x, then x is among the $D(q+k)$ most similar samples to x_j.

Lastly, we note that similarity-based learning can be considered a special case of graph-based learning (see, for example, Zhu, 2005), where the graph is fully-connected. However, most graph-based learning literature addresses the problem of semi-supervised learning, while the similarity-based learning algorithms discussed in this paper are mainly for supervised learning. We have seen no cross-referential literature between these two fields, and it remains an open question which techniques developed for one problem will be useful for the other problem and vice versa.

Appendix A.

Proof of Proposition 1: Recall the eigenvalue decomposition $S_{\text{clip}} = U^T \Lambda_{\text{clip}} U$. After removing the zero eigenvalues in Λ_{clip} and their corresponding eigenvectors in U and U^T, one can express $S_{\text{clip}} = \check{U}^T \check{\Lambda}_{\text{clip}} \check{U}$, where $\check{\Lambda}_{\text{clip}}$ is an $m \times m$ diagonal matrix with m the number of nonzero eigenvalues and $\check{U}$ an $m \times n$ matrix satisfying $\check{U}\check{U}^T = I$. The vector representation of the training samples implicitly used via S_{clip} is $X = \check{\Lambda}_{\text{clip}}^{1/2} \check{U}$. Given test similarity vector s, the least-squares solution to the equation $X^T x = s$ is $x = \left(XX^T\right)^{-1} Xs$. Let $\tilde{s}$ be the vector of the inner products between the embedded test sample x and the embedded training samples X, then

$$\tilde{s} = X^T x = X^T \left(XX^T\right)^{-1} Xs = \check{U}^T \check{U} s = U^T M_{\text{clip}} U s = P_{\text{clip}} s. \qquad \blacksquare$$

The proofs of the generalization bounds of Theorem 1 and Theorem 2 rely on bounding the Rademacher complexity of the function classes F_S and F_I, respectively. We provide the definition of Rademacher complexity here for convenience.

Definition 1 (Rademacher Complexity) *Suppose $\mathcal{X} = \{X_1, X_2, \ldots, X_n\}$ are samples drawn independently from a distribution on Ω, and let F be a class of functions mapping from Ω to $\mathbb{R}$. Then, the Rademacher complexity of F is*

$$\mathcal{R}_{\mathcal{X}}(F) = E_{\sigma,\mathcal{X}} \left(\sup_{f \in F} \left| \frac{2}{n} \sum_{i=1}^{n} \sigma_i f(X_i) \right| \right),$$

where $\sigma = \{\sigma_1, \sigma_2, \ldots, \sigma_n\}$ is a set of independent uniform $\{\pm 1\}$-valued random variables[11] *such that $P(\sigma_i = 1) = P(\sigma_i = -1) = 1/2$ for all i.*

The following lemma establishes that for a class of bounded functions F, the generalization error for any $f \in F$ is bounded above by a function of $\hat{R}_{\mathcal{D}}(f, L)$ and $\mathcal{R}_{\mathcal{D}}(F)$.

Lemma 1 (Bartlett and Mendelson, 2002, Theorem 7) *Suppose (X,Y) and the elements of $\mathcal{D}$ are drawn i.i.d. from a distribution on $\Omega \times \{\pm 1\}$. Let F be a class of bounded real-valued functions defined on Ω such that $\sup_{f \in F} \sup_{x \in \Omega} |f(x)| < \infty$. Suppose $L : \mathbb{R} \to [0,1]$ is Lipschitz with constant C and satisfies $L(a) \geq I_{\{a \leq 0\}}$. Then with probability at least $1 - \delta$ with respect to $\mathcal{D}$, every function in F satisfies*

$$P(Yf(X) \leq 0) \leq \hat{R}_{\mathcal{D}}(f, L) + 2C\mathcal{R}_{\mathcal{D}}(F) + \sqrt{\frac{\ln(2/\delta)}{2n}}.$$

For the proof of Theorem 1, we also require the following bound on the Rademacher complexity of kernel methods.

Lemma 2 (Bartlett and Mendelson, 2002, Lemma 22) *Suppose the elements of $\mathcal{D}$ are drawn i.i.d. from a distribution on $\Omega \times \{\pm 1\}$. Let F_K denote the set of functions $\left\{ f(x) = \sum_i \alpha_i K(x, X_i) \,\middle|\, \sum_{i,j} \alpha_i \alpha_j K(X_i, X_j) \leq \beta^2 \right\}$, then by Jensen's inequality,*

$$\mathcal{R}_{\mathcal{D}}(F_K) \leq 2\beta \sqrt{\frac{E\left(K(X,X)\right)}{n}}.$$

11. Such random variables are called *Rademacher random variables* and their distribution is called the *Rademacher distribution*.

Proof of Theorem 1: Theorem 1 is an application of Lemma 1 and 2 for the function class $F_S = \{f(s) = w^T s \,|\, w^T S w \leq \beta^2\}$. By replacing the kernel function K in Lemma 2 with ψ, and noticing $E(\psi(X,X)) \leq \kappa^2$ since $\psi(a,a) \leq \kappa^2$ for all $a \in \Omega$, we have $\mathcal{R}_{\mathcal{D}}(F_S) \leq 2\beta\kappa\sqrt{1/n}$. It can be verified that the function class F_S is bounded as $|f(s)| \leq \beta\kappa$ for all $f \in F_S$, and thus we can apply Lemma 1. Noting that L_t is Lipschitz with $C = 1$ completes the proof. ■

Proof of Theorem 2: Recall that $\tilde{s} = \begin{bmatrix}\psi(x,\tilde{x}_1) & \dots & \psi(x,\tilde{x}_m)\end{bmatrix}^T$ where $\{(\tilde{x}_1,\tilde{y}_1),\dots,(\tilde{x}_m,\tilde{y}_m)\} \subseteq \mathcal{D}$ is a subset of the training data and $\widetilde{\mathcal{D}} = \mathcal{D}\backslash\{(\tilde{x}_1,\tilde{y}_1),\dots,(\tilde{x}_m,\tilde{y}_m)\}$ is the remaining training set. It is tempting to apply Lemma 2 with the linear kernel, but in this case, this does not satisfy the definition of the function class $F_I = \{f(\tilde{s}) = w^T\tilde{s} \,|\, w^T w \leq \beta^2\}$ defined on these prototypes. The following bound on the Rademacher complexity mirrors that of Bartlett and Mendelson (2002, Lemma 22), but requires an important modification noted below:

$$\begin{aligned}
\mathcal{R}_{\widetilde{\mathcal{D}}}(F_I) &= E_{\widetilde{\mathcal{D}},\sigma}\left(\sup_{f\in F_I}\left|\frac{2}{n}\sum_{i=1}^{n-m}\sigma_i f(\tilde{s}_i)\right|\right) \\
&\leq \frac{2}{n}E_{\widetilde{\mathcal{D}},\sigma}\left(\sup_{\|w\|_2\leq\beta}\left|w^T\left(\sum_{i=1}^{n-m}\sigma_i\tilde{s}_i\right)\right|\right) \\
&\overset{(a)}{\leq} \frac{2}{n}E_{\widetilde{\mathcal{D}},\sigma}\left(\beta\left\|\sum_{i=1}^{n-m}\sigma_i\tilde{s}_i\right\|_2\right) \\
&= \frac{2\beta}{n}E_{\widetilde{\mathcal{D}},\sigma}\left(\sqrt{\sum_{i,j}\sigma_i\sigma_j\tilde{s}_i^T\tilde{s}_j}\right) \\
&\overset{(b)}{\leq} \frac{2\beta}{n}\sqrt{\sum_{i,j}E_{\widetilde{\mathcal{D}},\sigma}\left(\sigma_i\sigma_j\tilde{s}_i^T\tilde{s}_j\right)} \\
&= \frac{2\beta}{n}\sqrt{\sum_{i=1}^{n-m}E_{\widetilde{\mathcal{D}}}\left(\tilde{s}_i^T\tilde{s}_i\right)} \\
&= \frac{2\beta}{n}\sqrt{\sum_{i=1}^{n-m}\sum_{j=1}^{m}E_{\widetilde{\mathcal{D}}}\psi^2(x_i,\tilde{x}_j)} \\
&\leq 2\beta\kappa^2\sqrt{\frac{m}{n}-\frac{m^2}{n^2}} \\
&\leq 2\beta\kappa^2\sqrt{\frac{m}{n}}
\end{aligned}$$

where (a) follows from the Cauchy-Schwarz inequality[12] and (b) follows from Jensen's inequality.

It can be verified that the function class is bounded as $|f(\tilde{s})| \leq \beta\kappa^2\sqrt{m}$ for all $f \in F_I$, and thus we can apply Lemma 1. As before, noting that L_t is Lipschitz with $C = 1$ completes the proof. ■

The proof of Theorem 2 illustrates why using similarities as features has a poorer guarantee on the generalization than using similarities as a kernel. Specifically, the function class corresponding

12. Note that in the proof of Theorem 1 and in Bartlett and Mendelson (2002, Lemma 22) the Cauchy-Schwartz inequality is applied in the RKHS space whereas here it is applied in $\mathbb{R}^m$.

to regularization on $w^T w$ is too large. Of course, this flexibility can be mitigated by using only a set of m prototypes whose size grows as $o(n)$, which can be seen as an additional form of capacity control.

Abstract

We propose a general method called *truncated gradient* to induce sparsity in the weights of online-learning algorithms with convex loss functions. This method has several essential properties:

1. The degree of sparsity is continuous—a parameter controls the rate of sparsification from no sparsification to total sparsification.
2. The approach is theoretically motivated, and an instance of it can be regarded as an online counterpart of the popular L_1-regularization method in the batch setting. We prove that small rates of sparsification result in only small additional regret with respect to typical online-learning guarantees.
3. The approach works well empirically.

We apply the approach to several data sets and find for data sets with large numbers of features, substantial sparsity is discoverable.

Keywords: truncated gradient, stochastic gradient descent, online learning, sparsity, regularization, Lasso

1. Introduction

We are concerned with machine learning over large data sets. As an example, the largest data set we use here has over 10^7 sparse examples and 10^9 features using about 10^{11} bytes. In this setting, many common approaches fail, simply because they cannot load the data set into memory or they are not sufficiently efficient. There are roughly two classes of approaches which can work:

1. Parallelize a batch-learning algorithm over many machines (e.g., Chu et al., 2008).

2. Stream the examples to an online-learning algorithm (e.g., Littlestone, 1988; Littlestone et al., 1995; Cesa-Bianchi et al., 1996; Kivinen and Warmuth, 1997).

*. Partially supported by NSF grant DMS-0706805.

This paper focuses on the second approach.

Typical online-learning algorithms have at least one weight for every feature, which is too much in some applications for a couple reasons:

1. Space constraints. If the state of the online-learning algorithm overflows RAM it can not efficiently run. A similar problem occurs if the state overflows the L2 cache.

2. Test-time constraints on computation. Substantially reducing the number of features can yield substantial improvements in the computational time required to evaluate a new sample.

This paper addresses the problem of inducing sparsity in learned weights while using an online-learning algorithm. There are several ways to do this wrong for our problem. For example:

1. Simply adding L_1-regularization to the gradient of an online weight update doesn't work because gradients don't induce sparsity. The essential difficulty is that a gradient update has the form $a+b$ where a and b are two floats. Very few float pairs add to 0 (or any other default value) so there is little reason to expect a gradient update to accidentally produce sparsity.

2. Simply rounding weights to 0 is problematic because a weight may be small due to being useless or small because it has been updated only once (either at the beginning of training or because the set of features appearing is also sparse). Rounding techniques can also play havoc with standard online-learning guarantees.

3. Black-box wrapper approaches which eliminate features and test the impact of the elimination are not efficient enough. These approaches typically run an algorithm many times which is particularly undesirable with large data sets.

1.1 What Others Do

In the literature, the Lasso algorithm (Tibshirani, 1996) is commonly used to achieve sparsity for linear regression using L_1-regularization. This algorithm does not work automatically in an online fashion. There are two formulations of L_1-regularization. Consider a loss function $L(w,z_i)$ which is convex in w, where $z_i=(x_i,y_i)$ is an input/output pair. One is the *convex constraint formulation*

$$\hat{w} = \arg\min_w \sum_{i=1}^n L(w,z_i) \quad \text{subject to } \|w\|_1 \le s, \tag{1}$$

where s is a tunable parameter. The other is the *soft regularization formulation*, where

$$\hat{w} = \arg\min_w \sum_{i=1}^n L(w,z_i) + g\|w\|_1. \tag{2}$$

With appropriately chosen g, the two formulations are equivalent. The convex constraint formulation has a simple online version using the projection idea of Zinkevich (2003), which requires the projection of weight w into an L_1-ball at every online step. This operation is difficult to implement efficiently for large-scale data with many features even if all examples have sparse features although recent progress was made (Duchi et al., 2008) to reduce the *amortized* time complexity to $O(k\log d)$, where k is the number of nonzero entries in x_i, and d is the total number of features (i.e., the dimension of x_i). In contrast, the soft-regularization method is efficient for a batch setting (Lee et al., 2007) so we pursue it here in an online setting where we develop an algorithm whose complexity is linear in k but independent of d; these algorithms are therefore more efficient in problems where d is prohibitively large.

More recently, Duchi and Singer (2008) propose a framework for empirical risk minimization with regularization called *Forward Looking Subgradients*, or FOLOS in short. The basic idea is to solve a regularized optimization problem after every gradient-descent step. This family of algorithms allow general convex regularization function, and reproduce a special case of the truncated gradient algorithm we will introduce in Section 3.3 (with θ set to ∞) when L_1-regularization is used.

The Forgetron algorithm (Dekel et al., 2006) is an online-learning algorithm that manages memory use. It operates by decaying the weights on previous examples and then rounding these weights to zero when they become small. The Forgetron is stated for kernelized online algorithms, while we are concerned with the simpler linear setting. When applied to a linear kernel, the Forgetron is not computationally or space competitive with approaches operating directly on feature weights.

A different, Bayesian approach to learning sparse linear classifiers is taken by Balakrishnan and Madigan (2008). Specifically, their algorithms approximate the posterior by a Gaussian distribution, and hence need to store second-order covariance statistics which require $O(d^2)$ space and time per online step. In contrast, our approach is much more efficient, requiring only $O(d)$ space and $O(k)$ time at every online step.

After completing the paper, we learned that Carpenter (2008) independently developed an algorithm similar to ours.

1.2 What We Do

We pursue an algorithmic strategy which can be understood as an online version of an efficient L_1 loss optimization approach (Lee et al., 2007). At a high level, our approach works with the soft-regularization formulation (2) and decays the weight to a default value after every online stochastic gradient step. This simple approach enjoys minimal time complexity (which is linear in k and independent of d) as well as strong performance guarantee, as discussed in Sections 3 and 5. For instance, the algorithm never performs much worse than a standard online-learning algorithm, and the additional loss due to sparsification is controlled continuously with a single real-valued parameter. The theory gives a family of algorithms with convex loss functions for inducing sparsity—one per online-learning algorithm. We instantiate this for square loss and show how an efficient implementation can take advantage of sparse examples in Section 4. In addition to the L_1-regularization formulation (2), the family of algorithms we consider also include some non-convex sparsification techniques.

As mentioned in the introduction, we are mainly interested in sparse online methods for large scale problems with sparse features. For such problems, our algorithm should satisfy the following requirements:

- The algorithm should be computationally efficient: the number of operations per online step should be linear in the number of nonzero features, and independent of the total number of features.

- The algorithm should be memory efficient: it needs to maintain a list of active features, and can insert (when the corresponding weight becomes nonzero) and delete (when the corresponding weight becomes zero) features dynamically.

Our solution, referred to as *truncated gradient*, is a simple modification of the standard stochastic gradient rule. It is defined in (6) as an improvement over simpler ideas such as rounding and sub-gradient method with L_1 -regularization. The implementation details, showing our methods satisfy the above requirements, are provided in Section 5.

Theoretical results stating how much sparsity is achieved using this method generally require additional assumptions which may or may not be met in practice. Consequently, we rely on experiments in Section 6 to show our method achieves good sparsity practice. We compare our approach to a few others, including L_1 -regularization on small data, as well as online rounding of coefficients to zero.

2. Online Learning with Stochastic Gradient Descent

In the setting of standard online learning, we are interested in sequential prediction problems where repeatedly from $i = 1, 2, \ldots$:

1. An unlabeled example x_i arrives.
2. We make a prediction based on existing weights $w_i \in R^d$.
3. We observe y_i, let $z_i = (x_i, y_i)$, and incur some known loss $L(w_i, z_i)$ that is convex in parameter w_i.
4. We update weights according to some rule: $w_{i+1} \leftarrow f(w_i)$.

We want to come up with an update rule f, which allows us to bound the sum of losses

$$\sum_{i=1}^{t} L(w_i, z_i)$$

as well as achieving sparsity. For this purpose, we start with the standard stochastic gradient descent (SGD) rule, which is of the form:

$$f(w_i) = w_i - \eta \nabla_1 L(w_i, z_i), \tag{3}$$

where $\nabla_1 L(a, b)$ is a sub-gradient of $L(a, b)$ with respect to the first variable a. The parameter $\eta > 0$ is often referred to as the learning rate. In our analysis, we only consider constant learning rate with fixed $\eta > 0$ for simplicity. In theory, it might be desirable to have a decaying learning rate η_i which becomes smaller when i increases to get the so called *no-regret bound* without knowing T in advance. However, if T is known in advance, one can select a constant η accordingly so the regret vanishes as $T \to \infty$. Since our focus is on sparsity, not how to adapt learning rate, for clarity, we use a constant learning rate in the analysis because it leads to simpler bounds.

The above method has been widely used in online learning (Littlestone et al., 1995; Cesa-Bianchi et al., 1996). Moreover, it is argued to be efficient even for solving batch problems where we repeatedly run the online algorithm over training data multiple times. For example, the idea has been successfully applied to solve large-scale standard SVM formulations (Shalev-Shwartz et al., 2007; Zhang, 2004). In the scenario outlined in the introduction, online-learning methods are more suitable than some traditional batch-learning methods.

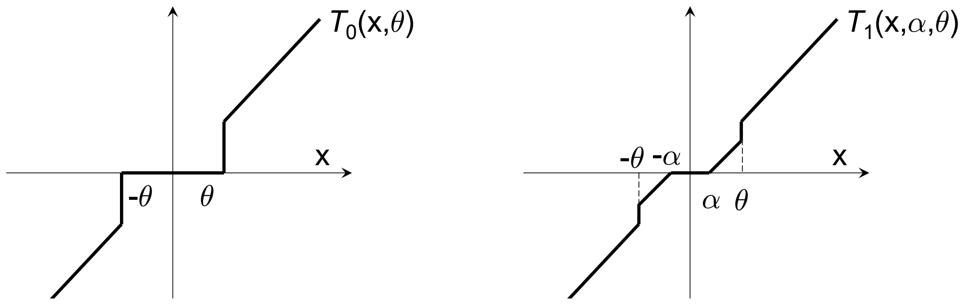

Figure 1: Plots for the truncation functions, T_0 and T_1, which are defined in the text.

However, a main drawback of (3) is that it does not achieve sparsity, which we address in this paper. In the literature, the stochastic-gradient descent rule is often referred to as gradient descent (GD). There are other variants, such as exponentiated gradient descent (EG). Since our focus in this paper is sparsity, not GD versus EG, we shall only consider modifications of (3) for simplicity.

3. Sparse Online Learning

In this section, we examine several methods for achieving sparsity in online learning. The first idea is simple coefficient rounding, which is the most natural method. We will then consider another method which is the online counterpart of L_1-regularization in batch learning. Finally, we combine such two ideas and introduce truncated gradient. As we shall see, all these ideas are closely related.

3.1 Simple Coefficient Rounding

In order to achieve sparsity, the most natural method is to round small coefficients (that are no larger than a threshold $\theta > 0$) to zero after every K online steps. That is, if i/K is not an integer, we use the standard GD rule in (3); if i/K is an integer, we modify the rule as:

$$f(w_i) = T_0(w_i - \eta \nabla_1 L(w_i, z_i), \theta), \tag{4}$$

where for a vector $v = [v_1, \ldots, v_d] \in R^d$, and a scalar $\theta \geq 0$, $T_0(v, \theta) = [T_0(v_1, \theta), \ldots, T_0(v_d, \theta)]$, with T_0 defined by (cf., Figure 1)

$$T_0(v_j, \theta) = \begin{cases} 0 & \text{if } |v_j| \leq \theta \\ v_j & \text{otherwise} \end{cases}.$$

That is, we first apply the standard stochastic gradient descent rule, and then round small coefficients to zero.

In general, we should not take $K = 1$, especially when η is small, since each step modifies w_i by only a small amount. If a coefficient is zero, it remains small after one online update, and the rounding operation pulls it back to zero. Consequently, rounding can be done only after every K steps (with a reasonably large K); in this case, nonzero coefficients have sufficient time to go above the threshold θ. However, if K is too large, then in the training stage, we will need to keep many more nonzero features in the intermediate steps before they are rounded to zero. In the extreme case, we may simply round the coefficients in the end, which does not solve the storage problem in the training phase. The sensitivity in choosing appropriate K is a main drawback of this method; another drawback is the lack of theoretical guarantee for its online performance.

3.2 A Sub-gradient Algorithm for L_1-Regularization

In our experiments, we combine rounding-in-the-end-of-training with a simple online sub-gradient method for L_1-regularization with a regularization parameter $g > 0$:

$$f(w_i) = w_i - \eta \nabla_1 L(w_i, z_i) - \eta g \operatorname{sgn}(w_i), \tag{5}$$

where for a vector $v = [v_1, \ldots, v_d]$, $\operatorname{sgn}(v) = [\operatorname{sgn}(v_1), \ldots, \operatorname{sgn}(v_d)]$, and $\operatorname{sgn}(v_j) = 1$ when $v_j > 0$, $\operatorname{sgn}(v_j) = -1$ when $v_j < 0$, and $\operatorname{sgn}(v_j) = 0$ when $v_j = 0$. In the experiments, the online method (5) plus rounding in the end is used as a simple baseline. This method does not produce sparse weights online. Therefore it does not handle large-scale problems for which we cannot keep all features in memory.

3.3 Truncated Gradient

In order to obtain an online version of the simple rounding rule in (4), we observe that the direct rounding to zero is too aggressive. A less aggressive version is to shrink the coefficient to zero by a smaller amount. We call this idea truncated gradient.

The amount of shrinkage is measured by a *gravity* parameter $g_i > 0$:

$$f(w_i) = T_1(w_i - \eta \nabla_1 L(w_i, z_i), \eta g_i, \theta), \tag{6}$$

where for a vector $v = [v_1, \ldots, v_d] \in R^d$, and a scalar $g \geq 0$, $T_1(v, \alpha, \theta) = [T_1(v_1, \alpha, \theta), \ldots, T_1(v_d, \alpha, \theta)]$, with T_1 defined by (cf., Figure 1)

$$T_1(v_j, \alpha, \theta) = \begin{cases} \max(0, v_j - \alpha) & \text{if } v_j \in [0, \theta] \\ \min(0, v_j + \alpha) & \text{if } v_j \in [-\theta, 0] \\ v_j & \text{otherwise} \end{cases}.$$

Again, the truncation can be performed every K online steps. That is, if i/K is not an integer, we let $g_i = 0$; if i/K is an integer, we let $g_i = Kg$ for a gravity parameter $g > 0$. This particular choice is equivalent to (4) when we set g such that $\eta K g \geq \theta$. This requires a large g when η is small. In practice, one should set a small, fixed g, as implied by our regret bound developed later.

In general, the larger the parameters g and θ are, the more sparsity is incurred. Due to the extra truncation T_1, this method can lead to sparse solutions, which is confirmed in our experiments described later. In those experiments, the degree of sparsity discovered varies with the problem.

A special case, which we will try in the experiment, is to let $g = \theta$ in (6). In this case, we can use only one parameter g to control sparsity. Since $\eta K g \ll \theta$ when ηK is small, the truncation operation is less aggressive than the rounding in (4). At first sight, the procedure appears to be an ad-hoc way to fix (4). However, we can establish a regret bound for this method, showing it is theoretically sound.

Setting $\theta = \infty$ yields another important special case of (6), which becomes

$$f(w_i) = T(w_i - \eta \nabla_1 L(w_i, z_i), g_i \eta), \tag{7}$$

where for a vector $v = [v_1, \dots, v_d] \in R^d$, and a scalar $g \geq 0$, $T(v, \alpha) = [T(v_1, \alpha), \dots, T(v_d, \alpha)]$, with

$$T(v_j, \alpha) = \begin{cases} \max(0, v_j - \alpha) & \text{if } v_j > 0 \\ \min(0, v_j + \alpha) & \text{otherwise} \end{cases}.$$

The method is a modification of the standard sub-gradient descent method with L_1-regularization given in (5). The parameter $g_i \geq 0$ controls the sparsity that can be achieved with the algorithm. Note when $g_i = 0$, the update rule is identical to the standard stochastic gradient descent rule. In general, we may perform a truncation every K steps. That is, if i/K is not an integer, we let $g_i = 0$; if i/K is an integer, we let $g_i = Kg$ for a gravity parameter $g > 0$. The reason for doing so (instead of a constant g) is that we can perform a more aggressive truncation with gravity parameter Kg after each K steps. This may lead to better sparsity. An alternative way to derive a procedure similar to (7) is through an application of convex hull projection idea of Zinkevich (2003) to the L_1-regularized loss, as in (5). However, instead of working with the original feature set, we need to consider a $2d$-dimensional duplicated feature set $[x_i, -x_i]$, with the non-negativity constraint $w^j \geq 0$ for each component of j (w will also have dimension $2d$ in this case). The resulting method is similar to ours, with a similar theoretical guarantee as in Theorem 3.1. The proof presented in this paper is more specialized to truncated gradient, and directly works with x_i instead of augmented data $[x_i, -x_i]$. Moreover, our analysis does not require the loss function to have bounded gradient, and thus can directly handle the least squares loss.

The procedure in (7) can be regarded as an online counterpart of L_1-regularization in the sense that it approximately solves an L_1-regularization problem in the limit of $\eta \to 0$. Truncated gradient for L_1-regularization is different from (5), which is a naïve application of stochastic gradient descent rule with an added L_1-regularization term. As pointed out in the introduction, the latter fails because it rarely leads to sparsity. Our theory shows even with sparsification, the prediction performance is still comparable to standard online-learning algorithms. In the following, we develop a general regret bound for this general method, which also shows how the regret may depend on the sparsification parameter g.

3.4 Regret Analysis

Throughout the paper, we use $\|\cdot\|_1$ for 1-norm, and $\|\cdot\|$ for 2-norm. For reference, we make the following assumption regarding the loss function:

Assumption 3.1 *We assume $L(w, z)$ is convex in w, and there exist non-negative constants A and B such that $\|\nabla_1 L(w, z)\|^2 \leq AL(w, z) + B$ for all $w \in R^d$ and $z \in R^{d+1}$.*

For linear prediction problems, we have a general loss function of the form $L(w, z) = \phi(w^T x, y)$. The following are some common loss functions $\phi(\cdot, \cdot)$ with corresponding choices of parameters A and B (which are not unique), under the assumption $\sup_x \|x\| \leq C$.

- Logistic: $\phi(p, y) = \ln(1 + \exp(-py))$; $A = 0$ and $B = C^2$. This loss is for binary classification problems with $y \in \{\pm 1\}$.
- SVM (hinge loss): $\phi(p, y) = \max(0, 1 - py)$; $A = 0$ and $B = C^2$. This loss is for binary classification problems with $y \in \{\pm 1\}$.
- Least squares (square loss): $\phi(p, y) = (p - y)^2$; $A = 4C^2$ and $B = 0$. This loss is for regression problems.

Our main result is Theorem 3.1 which is parameterized by A and B. The proof is left to the appendix. Specializing it to particular losses yields several corollaries. A corollary applicable to the least square loss is given later in Corollary 4.1.

Theorem 3.1 *(Sparse Online Regret) Consider sparse online update rule (6) with $w_1 = 0$ and $\eta > 0$. If Assumption 3.1 holds, then for all $\bar{w} \in R^d$ we have*

$$\frac{1-0.5A\eta}{T}\sum_{i=1}^{T}\left[L(w_i,z_i)+\frac{g_i}{1-0.5A\eta}\|w_{i+1}\cdot I(w_{i+1}\le\theta)\|_1\right]$$
$$\le\frac{\eta}{2}B+\frac{\|\bar{w}\|^2}{2\eta T}+\frac{1}{T}\sum_{i=1}^{T}[L(\bar{w},z_i)+g_i\|\bar{w}\cdot I(w_{i+1}\le\theta)\|_1],$$

where for vectors $v=[v_1,\ldots,v_d]$ and $v'=[v'_1,\ldots,v'_d]$, we let

$$\|v\cdot I(|v'|\le\theta)\|_1=\sum_{j=1}^{d}|v_j|I(|v'_j|\le\theta),$$

where $I(\cdot)$ is the set indicator function.

We state the theorem with a constant learning rate η. As mentioned earlier, it is possible to obtain a result with variable learning rate where $\eta = \eta_i$ decays as i increases. Although this may lead to a no-regret bound without knowing T in advance, it introduces extra complexity to the presentation of the main idea. Since our focus is on sparsity rather than adapting learning rate, we do not include such a result for clarity. If T is known in advance, then in the above bound, one can simply take $\eta = O(1/\sqrt{T})$ and the L_1-regularized regret is of order $O(1/\sqrt{T})$.

In the above theorem, the right-hand side involves a term $g_i\|\bar{w}\cdot I(w_{i+1}\le\theta)\|_1$ depending on w_{i+1} which is not easily estimated. To remove this dependency, a trivial upper bound of $\theta=\infty$ can be used, leading to L_1 penalty $g_i\|\bar{w}\|_1$. In the general case of $\theta<\infty$, we cannot replace w_{i+1} by $\bar{w}$ because the effective regularization condition (as shown on the left-hand side) is the non-convex penalty $g_i\|w\cdot I(|w|\le\theta)\|_1$. Solving such a non-convex formulation is hard both in the online and batch settings. In general, we only know how to efficiently discover a local minimum which is difficult to characterize. Without a good characterization of the local minimum, it is not possible for us to replace $g_i\|\bar{w}\cdot I(w_{i+1}\le\theta)\|_1$ on the right-hand side by $g_i\|\bar{w}\cdot I(\bar{w}\le\theta)\|_1$ because such a formulation implies we can efficiently solve a non-convex problem with a simple online update rule. Still, when $\theta<\infty$, one naturally expects the right-hand side penalty $g_i\|\bar{w}\cdot I(w_{i+1}\le\theta)\|_1$ is much smaller than the corresponding L_1 penalty $g_i\|\bar{w}\|_1$, especially when w_j has many components close to 0. Therefore the situation with $\theta<\infty$ can potentially yield better performance on some data. This is confirmed in our experiments.

Theorem 3.1 also implies a trade-off between sparsity and regret performance. We may simply consider the case where $g_i = g$ is a constant. When g is small, we have less sparsity but the regret term $g\|\bar{w}\cdot I(w_{i+1}\le\theta)\|_1\le g\|\bar{w}\|_1$ on the right-hand side is also small. When g is large, we are able to achieve more sparsity but the regret $g\|\bar{w}\cdot I(w_{i+1}\le\theta)\|_1$ on the right-hand side also becomes large. Such a trade-off (sparsity versus prediction accuracy) is empirically studied in Section 6. Our observation suggests we can gain significant sparsity with only a small decrease of accuracy (that is, using a small g).

Now consider the case $\theta = \infty$ and $g_i = g$. When $T \to \infty$, if we let $\eta \to 0$ and $\eta T \to \infty$, then Theorem 3.1 implies

$$\frac{1}{T}\sum_{i=1}^{T}[L(w_i, z_i) + g\|w_i\|_1] \leq \inf_{\bar{w}\in R^d}\left[\frac{1}{T}\sum_{i=1}^{T}L(\bar{w}, z_i) + g\|\bar{w}\|_1\right] + o(1).$$

In other words, if we let $L'(w,z) = L(w,z) + g\|w\|_1$ be the L_1-regularized loss, then the L_1-regularized regret is small when $\eta \to 0$ and $T \to \infty$. In particular, if we let $\eta = 1/\sqrt{T}$, then the theorem implies the L_1-regularized regret is

$$\begin{aligned}
&\sum_{i=1}^{T}(L(w_i, z_i) + g\|w_i\|_1) - \sum_{i=1}^{T}(L(\bar{w}, z_i) + g\|\bar{w}\|_1)\\
\leq\ &\frac{\sqrt{T}}{2}(B + \|\bar{w}\|^2)\left(1 + \frac{A}{2\sqrt{T}}\right) + \frac{A}{2\sqrt{T}}\left(\sum_{i=1}^{T}L(\bar{w}, z_i) + g\sum_{i=1}^{T}(\|\bar{w}\|_1 - \|w_{i+1}\|_1)\right) + o(\sqrt{T}),
\end{aligned}$$

which is $O(\sqrt{T})$ for bounded loss function L and weights w_i. These observations imply our procedure can be regarded as the online counterpart of L_1-regularization methods. In the stochastic setting where the examples are drawn iid from some underlying distribution, the sparse online gradient method proposed in this paper solves the L_1-regularization problem.

3.5 Stochastic Setting

SGD-based online-learning methods can be used to solve large-scale batch optimization problems, often quite successfully (Shalev-Shwartz et al., 2007; Zhang, 2004). In this setting, we can go through training examples one-by-one in an online fashion, and repeat multiple times over the training data. In this section, we analyze the performance of such a procedure using Theorem 3.1.

To simplify the analysis, instead of assuming we go through the data one by one, we assume each additional data point is drawn from the training data randomly with equal probability. This corresponds to the standard stochastic optimization setting, in which observed samples are iid from some underlying distributions. The following result is a simple consequence of Theorem 3.1. For simplicity, we only consider the case with $\theta = \infty$ and constant gravity $g_i = g$.

Theorem 3.2 *Consider a set of training data $z_i = (x_i, y_i)$ for $i = 1, \ldots, n$, and let*

$$R(w, g) = \frac{1}{n}\sum_{i=1}^{n}L(w, z_i) + g\|w\|_1$$

be the L_1-regularized loss over training data. Let $\hat{w}_1 = w_1 = 0$, and define recursively for $t = 1, 2, \ldots$

$$w_{t+1} = T(w_t - \eta\nabla_1(w_t, z_{i_t}), g\eta), \qquad \hat{w}_{t+1} = \hat{w}_t + \frac{w_{t+1} - \hat{w}_t}{t+1},$$

where each i_t is drawn from $\{1,\ldots,n\}$ uniformly at random. If Assumption 3.1 holds, then at any time T, the following inequalities are valid for all $\bar{w} \in R^d$:

$$\begin{aligned}
&\mathbf{E}_{i_1,\ldots,i_T}\left[(1-0.5A\eta)R\left(\hat{w}_T, \frac{g}{1-0.5A\eta}\right)\right] \\
\leq &\mathbf{E}_{i_1,\ldots,i_T}\left[\frac{1-0.5A\eta}{T}\sum_{i=1}^{T} R\left(w_i, \frac{g}{1-0.5A\eta}\right)\right] \\
\leq &\frac{\eta}{2}B + \frac{\|\bar{w}\|^2}{2\eta T} + R(\bar{w},g).
\end{aligned}$$

Proof Note the recursion of $\hat{w}_t$ implies

$$\hat{w}_T = \frac{1}{T}\sum_{t=1}^{T} w_t$$

from telescoping the update rule. Because $R(w,g)$ is convex in w, the first inequality follows directly from Jensen's inequality. It remains to prove the second inequality. Theorem 3.1 implies the following:

$$\frac{1-0.5A\eta}{T}\sum_{t=1}^{T}\left[L(w_t,z_{i_t}) + \frac{g}{1-0.5A\eta}\|w_t\|_1\right] \leq g\|\bar{w}\|_1 + \frac{\eta}{2}B + \frac{\|\bar{w}\|^2}{2\eta T} + \frac{1}{T}\sum_{t=1}^{T} L(\bar{w},z_{i_t}). \tag{8}$$

Observe that

$$\mathbf{E}_{i_t}\left[L(w_t,z_{i_t}) + \frac{g}{1-0.5A\eta}\|w_t\|_1\right] = R\left(w_t, \frac{g}{1-0.5A\eta}\right)$$

and

$$g\|\bar{w}\|_1 + \mathbf{E}_{i_1,\ldots,i_T}\left[\frac{1}{T}\sum_{t=1}^{T} L(\bar{w},z_{i_t})\right] = R(\bar{w},g).$$

The second inequality is obtained by taking the expectation with respect to $\mathbf{E}_{i_1,\ldots,i_T}$ in (8). ■

If we let $\eta \to 0$ and $\eta T \to \infty$, the bound in Theorem 3.2 becomes

$$\mathbf{E}\left[R(\hat{w}_T,g)\right] \leq \mathbf{E}\left[\frac{1}{T}\sum_{t=1}^{T} R(w_t,g)\right] \leq \inf_{\bar{w}} R(\bar{w},g) + o(1).$$

That is, on average, $\hat{w}_T$ approximately solves the L_1-regularization problem

$$\inf_{w}\left[\frac{1}{n}\sum_{i=1}^{n} L(w,z_i) + g\|w\|_1\right].$$

If we choose a random stopping time T, then the above inequalities says that on average w_T also solves this L_1-regularization problem approximately. Therefore in our experiment, we use the last solution w_T instead of the aggregated solution $\hat{w}_T$. For practice purposes, this is adequate even though we do not intentionally choose a random stopping time.

Since L_1-regularization is frequently used to achieve sparsity in the batch learning setting, the connection to L_1-regularization can be regarded as an alternative justification for the sparse-online algorithm developed in this paper.

Algorithm 1 Truncated Gradient for Least Squares

```
Inputs:
  • threshold $\theta \geq 0$
  • gravity sequence $g_i \geq 0$
  • learning rate $\eta \in (0,1)$
  • example oracle $O$

initialize weights $w^j \leftarrow 0$ ($j = 1,\ldots,d$)
for trial $i = 1,2,\ldots$
  1. Acquire an unlabeled example $x = [x^1,x^2,\ldots,x^d]$ from oracle $O$
  2. forall weights $w^j$ ($j = 1,\ldots,d$)
      (a) if $w^j > 0$ and $w^j \leq \theta$ then $w^j \leftarrow \max\{w^j - g_i\eta, 0\}$
      (b) elseif $w^j < 0$ and $w^j \geq -\theta$ then $w^j \leftarrow \min\{w^j + g_i\eta, 0\}$
  3. Compute prediction: $\hat{y} = \sum_j w^j x^j$
  4. Acquire the label $y$ from oracle $O$
  5. Update weights for all features $j$: $w^j \leftarrow w^j + 2\eta(y - \hat{y})x^j$
```

4. Truncated Gradient for Least Squares

The method in Section 3 can be directly applied to least squares regression. This leads to Algorithm 1 which implements sparsification for square loss according to Equation (6). In the description, we use superscripted symbol w^j to denote the j-th component of vector w (in order to differentiate from w_i, which we have used to denote the i-th weight vector). For clarity, we also drop the index i from w_i. Although we keep the choice of gravity parameters g_i open in the algorithm description, in practice, we only consider the following choice:

$$g_i = \begin{cases} Kg & \text{if } i/K \text{ is an integer} \\ 0 & \text{otherwise} \end{cases}.$$

This may give a more aggressive truncation (thus sparsity) after every K-th iteration. Since we do not have a theorem formalizing how much more sparsity one can gain from this idea, its effect will only be examined empirically in Section 6.

In many online-learning situations (such as web applications), only a small subset of the features have nonzero values for any example x. It is thus desirable to deal with sparsity only in this small subset rather than in all features, while simultaneously inducing sparsity on all feature weights. Moreover, it is important to store only features with non-zero coefficients (if the number of features is too large to be stored in memory, this approach allows us to use a hash table to track only the nonzero coefficients). We describe how this can be implemented efficiently in the next section.

For reference, we present a specialization of Theorem 3.1 in the following corollary which is directly applicable to Algorithm 1.

Corollary 4.1 *(Sparse Online Square Loss Regret) If there exists $C > 0$ such that for all x, $\|x\| \leq C$, then for all $\bar{w} \in R^d$, we have*

$$\frac{1-2C^2\eta}{T}\sum_{i=1}^{T}\left[(w_i^T x_i - y_i)^2 + \frac{g_i}{1-2C^2\eta}\|w_i \cdot I(|w_i| \leq \theta)\|_1\right]$$
$$\leq \frac{\|\bar{w}\|^2}{2\eta T} + \frac{1}{T}\sum_{i=1}^{T}\left[(\bar{w}^T x_i - y_i)^2 + g_{i+1}\|\bar{w} \cdot I(|w_{i+1}| \leq \theta)\|_1\right],$$

where $w_i = [w^1, \ldots, w^d] \in R^d$ is the weight vector used for prediction at the i-th step of Algorithm 1; (x_i, y_i) is the data point observed at the i-step.

This corollary explicitly states that average square loss incurred by the learner (the left-hand side) is bounded by the average square loss of the best weight vector $\bar{w}$, plus a term related to the size of $\bar{w}$ which decays as $1/T$ and an additive offset controlled by the sparsity threshold θ and the gravity parameter g_i.

5. Efficient Implementation

We altered a standard gradient-descent implementation, VOWPAL WABBIT(Langford et al., 2007), according to algorithm 1. VOWPAL WABBIT optimizes square loss on a linear representation $w^T x$ via gradient descent (3) with a couple caveats:

1. The prediction is normalized by the square root of the number of nonzero entries in a sparse vector, $w^T x / \sqrt{\|x\|_0}$. This alteration is just a constant rescaling on dense vectors which is effectively removable by an appropriate rescaling of the learning rate.

2. The prediction is clipped to the interval $[0,1]$, implying the loss function is not square loss for unclipped predictions outside of this dynamic range. Instead the update is a constant value, equivalent to the gradient of a linear loss function.

The learning rate in VOWPAL WABBIT is controllable, supporting $1/i$ decay as well as a constant learning rate (and rates in-between). The program operates in an entirely online fashion, so the memory footprint is essentially just the weight vector, even when the amount of data is very large.

As mentioned earlier, we would like the algorithm's computational complexity to depend linearly on the number of nonzero features of an example, rather than the total number of features. The approach we took was to store a time-stamp τ_j for each feature j. The time-stamp was initialized to the index of the example where feature j was nonzero for the first time. During online learning, we simply went through all nonzero features j of example i, and could "simulate" the shrinkage of w^j after τ_j in a batch mode. These weights are then updated, and their time stamps are set to i. This lazy-update idea of delaying the shrinkage calculation until needed is the key to efficient implementation of truncated gradient. Specifically, instead of using update rule (6) for weight w^j, we shrunk the weights of all nonzero feature j differently by the following:

$$f(w^j) = T_1\left(w^j + 2\eta(y - \hat{y})x^j, \left\lfloor \frac{i - \tau_j}{K} \right\rfloor K\eta g, \theta\right),$$

and τ_j is updated by

$$\tau_j \leftarrow \tau_j + \left\lfloor \frac{i - \tau_j}{K} \right\rfloor K.$$

This lazy-update trick can be applied to the other two algorithms given in Section 3. In the coefficient rounding algorithm (4), for instance, for each nonzero feature j of example i, we can first perform a regular gradient descent on the square loss, and then do the following: if $|w_j|$ is below the threshold θ and $i \geq \tau_j + K$, we round w_j to 0 and set τ_j to i.

This implementation shows the truncated gradient method satisfies the following requirements needed for solving large scale problems with sparse features.

- The algorithm is computationally efficient: the number of operations per online step is linear in the number of nonzero features, and independent of the total number of features.
- The algorithm is memory efficient: it maintains a list of active features, and a feature can be inserted when observed, and deleted when the corresponding weight becomes zero.

If we directly apply the online projection idea of Zinkevich (2003) to solve (1), then in the update rule (7), one has to pick the smallest $g_i \geq 0$ such that $\|w_{i+1}\|_1 \leq s$. We do not know an efficient method to find this specific g_i using operations independent of the total number of features. A standard implementation relies on sorting all weights, which requires $O(d \log d)$ operations, where d is the total number of (nonzero) features. This complexity is unacceptable for our purpose. However, in an important recent work, Duchi et al. (2008) proposed an efficient online ℓ_1-projection method. The idea is to use a balanced tree to keep track of weights, which allows efficient threshold finding and tree updates in $O(k \ln d)$ operations on average, where k denotes the number of nonzero coefficients in the current training example. Although the algorithm still has weak dependency on d, it is applicable to large-scale practical applications. The theoretical analysis presented in this paper shows we can obtain a meaningful regret bound by picking an arbitrary g_i. This is useful because the resulting method is much simpler to implement and is computationally more efficient per online step. Moreover, our method allows non-convex updates closely related to the simple coefficient rounding idea. Due to the complexity of implementing the balanced tree strategy in Duchi et al. (2008), we shall not compare to it in this paper and leave it as a future direction. However, we believe the sparsity achieved with their approach should be comparable to the sparsity achieved with our method.

6. Empirical Results

We applied VOWPAL WABBIT with the efficiently implemented sparsify option, as described in the previous section, to a selection of data sets, including eleven data sets from the UCI repository (Asuncion and Newman, 2007), the much larger data set rcv1 (Lewis et al., 2004), and a private large-scale data set Big_Ads related to ad interest prediction. While UCI data sets are useful for benchmark purposes, rcv1 and Big_Ads are more interesting since they embody real-world data sets with large numbers of features, many of which are less informative for making predictions than others. The data sets are summarized in Table 1.

The UCI data sets used do not have many features so we expect that a large fraction of these features are useful for making predictions. For comparison purposes as well as to better demonstrate the behavior of our algorithm, we also added 1000 random binary features to those data sets. Each feature has value 1 with probability 0.05 and 0 otherwise.

Data Set	#features	#train data	#test data	task
ad	1411	2455	824	classification
crx	47	526	164	classification
housing	14	381	125	regression

Big_Ads	3×10^9	26×10^6	2.7×10^6	classification

Table 1: Data Set Summary.

6.1 Feature Sparsification of Truncated Gradient

In the first set of experiments, we are interested in how much reduction in the number of features is possible without affecting learning performance significantly; specifically, we require the accuracy be reduced by no more than 1% for classification tasks, and the total square loss be increased by no more than 1% for regression tasks. As common practice, we allowed the algorithm to run on the training data set for multiple passes with decaying learning rate. For each data set, we performed 10-fold cross validation over the training set to identify the best set of parameters, including the learning rate η (ranging from 0.1 to 0.5), the sparsification rate g (ranging from 0 to 0.3), number of passes of the training set (ranging from 5 to 30), and the decay of learning rate across these passes (ranging from 0.5 to 0.9). The optimized parameters were used to train VOWPAL WABBIT on the whole training set. Finally, the learned classifier/regressor was evaluated on the test set. We fixed $K = 1$ and $\theta = \infty$, and will study the effects of K and θ in later subsections.

Figure 2 shows the fraction of reduced features after sparsification is applied to each data set. For UCI data sets, we also include experiments with 1000 random features added to the original feature set. We do not add random features to rcv1 and Big_Ads since the experiment is not as interesting.

For UCI data sets, with randomly added features, VOWPAL WABBIT is able to reduce the number of features by a fraction of more than 90%, except for the ad data set in which only 71% reduction is observed. This less satisfying result might be improved by a more extensive parameter search in cross validation. However, if we can tolerate 1.3% decrease in accuracy (instead of 1% as for other data sets) during cross validation, VOWPAL WABBIT is able to achieve 91.4% reduction, indicating that a large reduction is still possible at the tiny additional cost of 0.3% accuracy loss. With this slightly more aggressive sparsification, the test-set accuracy drops from 95.9% (when only 1% loss in accuracy is allowed in cross validation) to 95.4%, while the accuracy without sparsification is 96.5%.

Even for the original UCI data sets without artificially added features, VOWPAL WABBIT manages to filter out some of the less useful features while maintaining the same level of performance. For example, for the ad data set, a reduction of 83.4% is achieved. Compared to the results above, it seems the most effective feature reductions occur on data sets with a large number of less useful features, exactly where sparsification is needed.

For rcv1, more than 75% of features are removed after the sparsification process, indicating the effectiveness of our algorithm in real-life problems. We were not able to try many parameters in cross validation because of the size of rcv1. It is expected that more reduction is possible when a more thorough parameter search is performed.

The previous results do not exercise the full power of the approach presented here because the standard Lasso (Tibshirani, 1996) is or may be computationally viable in these data sets. We have also applied this approach to a large non-public data set Big_Ads where the goal is predicting which of two ads was clicked on given context information (the content of ads and query information). Here, accepting a 0.009 increase in classification error (from error rate 0.329 to error rate 0.338) allows us to reduce the number of features from about 3×10^9 to about 24×10^6, a factor of 125 decrease in the number of features.

For classification tasks, we also study how our sparsification solution affects AUC (Area Under the ROC Curve), which is a standard metric for classification.[1] Using the same sets of parameters from 10-fold cross validation described above, we find the criterion is not affected significantly by sparsification and in some cases, they are actually slightly improved. The reason may be that our sparsification method removed some of the features that could have confused VOWPAL WABBIT. The ratios of the AUC with and without sparsification for all classification tasks are plotted in Figures 3. Often these ratios are above 98%.

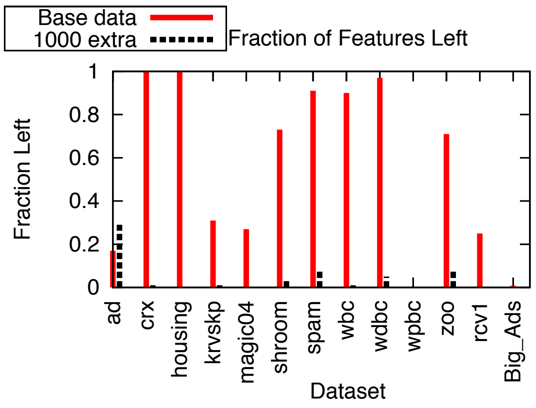
6.2 The Effects of K

As we argued before, using a K value larger than 1 may be desired in truncated gradient and the rounding algorithms. This advantage is empirically demonstrated here. In particular, we try $K = 1$, $K = 10$, and $K = 20$ in both algorithms. As before, cross validation is used to select parameters in the rounding algorithm, including learning rate η, number of passes of data during training, and learning rate decay over training passes.

Figures 4 and 5 give the AUC vs. number-of-feature plots, where each data point is generated by running respective algorithm using a different value of g (for truncated gradient) and θ (for the rounding algorithm). We used $\theta = \infty$ in truncated gradient.

The effect of K is large in the rounding algorithm. For instance, in the ad data set the algorithm using $K = 1$ achieves an AUC of 0.94 with 322 features, while 13 and 7 features are needed using $K = 10$ and $K = 20$, respectively. However, the same benefits of using a larger K is not observed in truncated gradient, although the performances with $K = 10$ or 20 are at least as good as those with $K = 1$ and for the spambase data set further feature reduction is achieved at the same level of performance, reducing the number of features from 76 (when $K = 1$) to 25 (when $K = 10$ or 20) with of an AUC of about 0.89.

1. We use AUC here and in later subsections because it is insensitive to threshold, which is unlike accuracy.



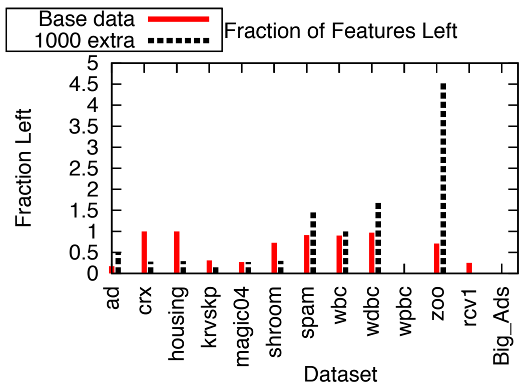


Figure 2: Plots showing the amount of features left after sparsification using truncated gradient for each data set, when the performance is changed by at most 1% due to sparsification. The solid bar: with the original feature set; the dashed bar: with 1000 random features added to each example. Plot on left: fraction left with respect to the total number of features (original with 1000 artificial features for the dashed bar). Plot on right: fraction left with respect to the original features (not counting the 1000 artificial features in the denominator for the dashed bar).

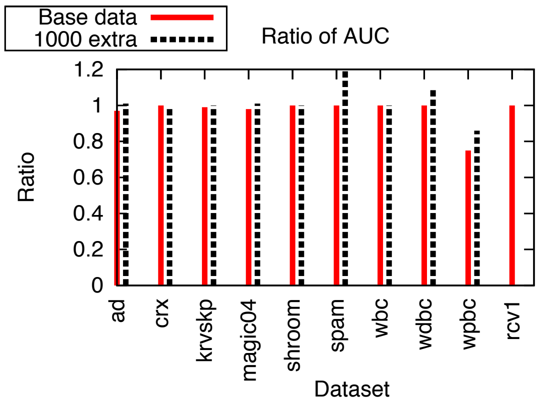

Figure 3: A plot showing the ratio of the AUC when sparsification is used over the AUC when no sparsification is used. The same process as in Figure 2 is used to determine empirically good parameters. The first result is for the original data set, while the second result is for the modified data set where 1000 random features are added to each example.

6.3 The Effects of θ in Truncated Gradient

In this subsection, we empirically study the effect of θ in truncated gradient. The rounding algorithm is also included for comparison due to its similarity to truncated gradient when $\theta = g$. Again, we used cross validation to choose parameters for each θ value tried, and focused on the AUC metric in the eight UCI classification tasks, except the degenerate one of wpbc. We fixed $K = 10$ in both algorithm.

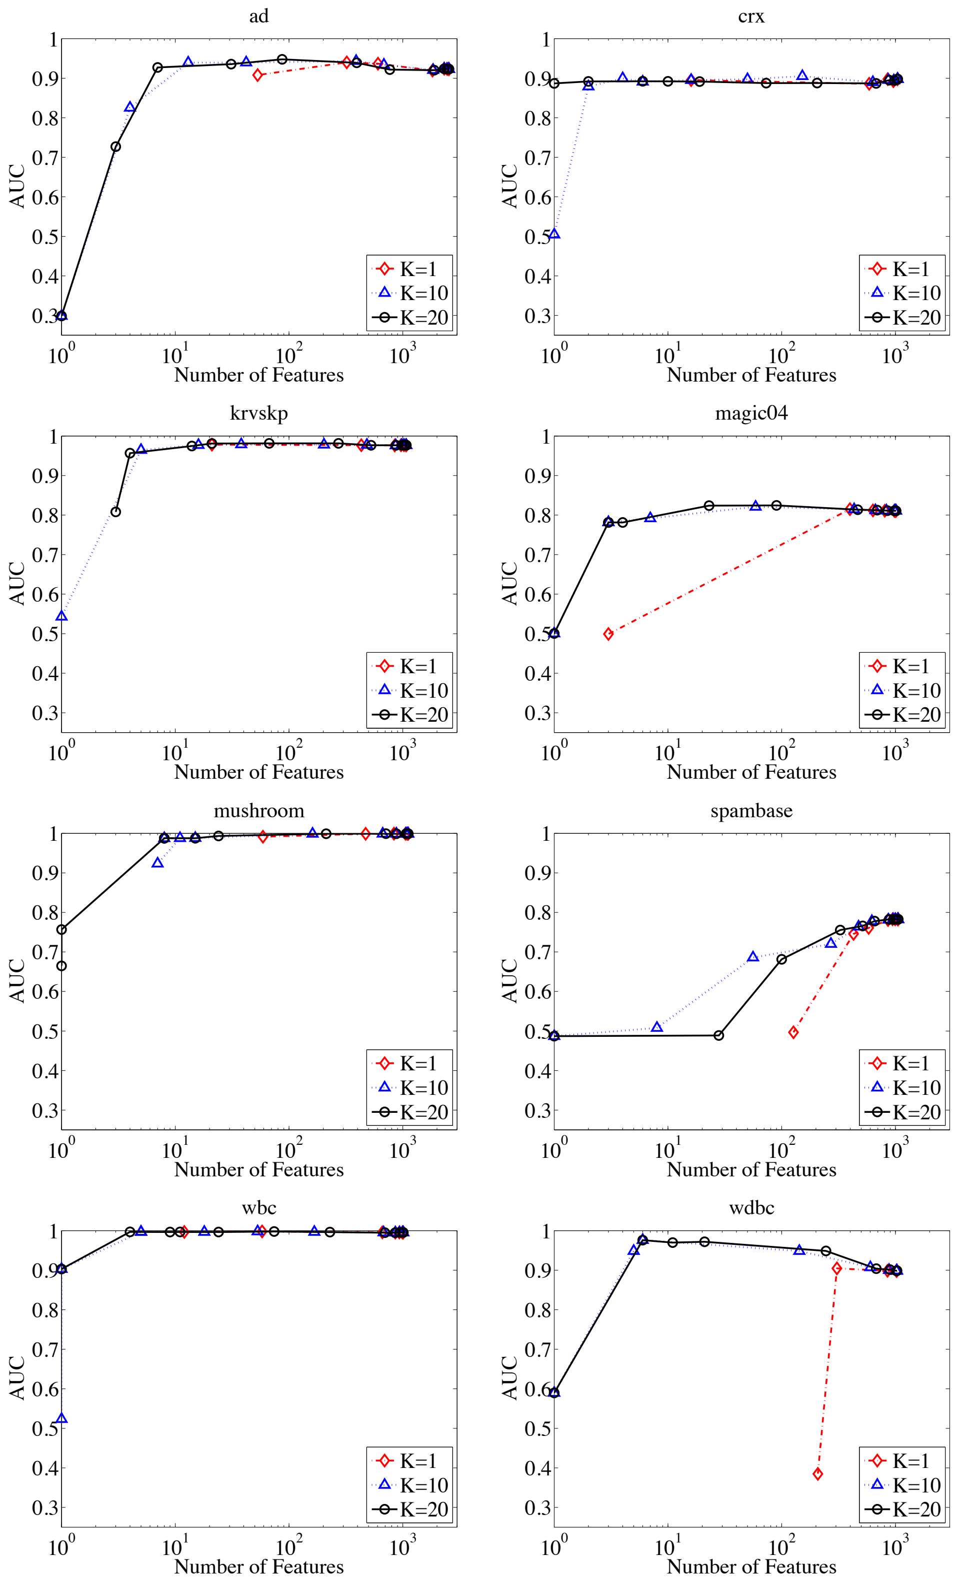

Figure 4: Effect of K on AUC in the rounding algorithm.

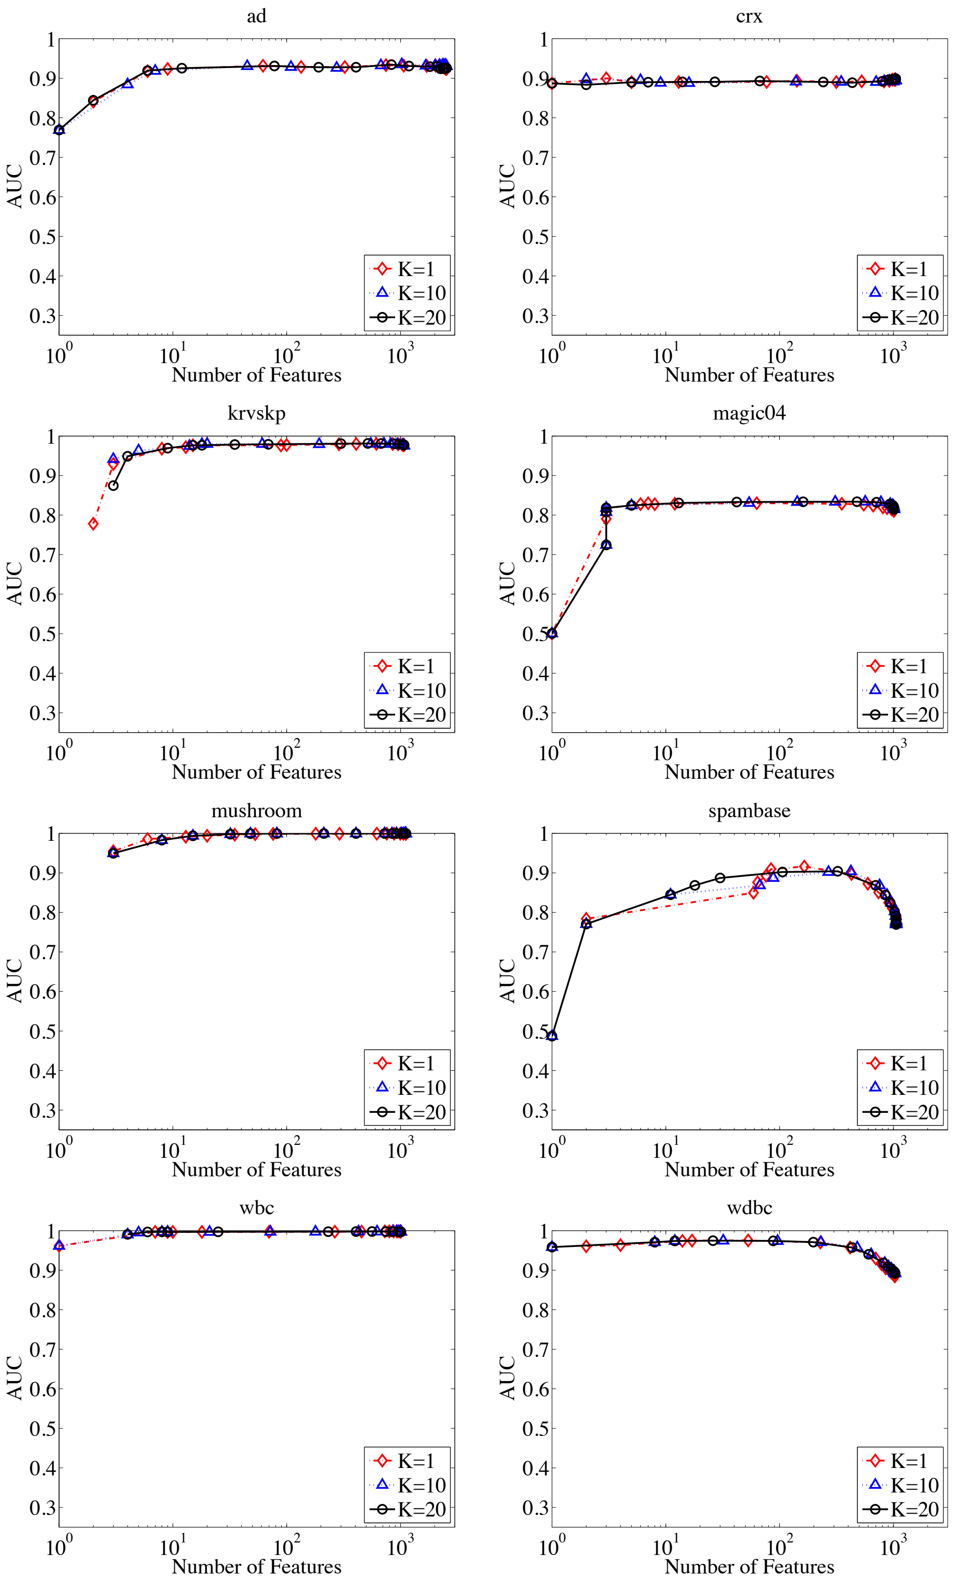

Figure 5: Effect of K on AUC in truncated gradient.

Figure 6 gives the AUC vs. number-of-feature plots, where each data point is generated by running respective algorithms using a different value of g (for truncated gradient) and θ (for the rounding algorithm). A few observations are in place. First, the results verify the observation that the behavior of truncated gradient with $\theta = g$ is similar to the rounding algorithm. Second, these results suggest that, in practice, it may be desirable to use $\theta = \infty$ in truncated gradient because it avoids the local-minimum problem.

6.4 Comparison to Other Algorithms

The next set of experiments compares truncated gradient to other algorithms regarding their abilities to balance feature sparsification and performance. Again, we focus on the AUC metric in UCI classification tasks except wpdc. The algorithms for comparison include:

- The truncated gradient algorithm: We fixed $K = 10$ and $\theta = \infty$, used crossed-validated parameters, and altered the gravity parameter g.
- The rounding algorithm described in Section 3.1: We fixed $K = 10$, used cross-validated parameters, and altered the rounding threshold θ.
- The subgradient algorithm described in Section 3.2: We fixed $K = 10$, used cross-validated parameters, and altered the regularization parameter g.
- The Lasso (Tibshirani, 1996) for batch L_1-regularization: We used a publicly available implementation (Sjöstrand, 2005).

Note that we do not attempt to compare these algorithms on rcv1 and Big_Ads simply because their sizes are too large for the Lasso.

Figure 7 gives the results. Truncated gradient is consistently competitive with the other two online algorithms and significantly outperformed them in some problems. This suggests the effectiveness of truncated gradient.

Second, it is interesting to observe that the qualitative behavior of truncated gradient is often similar to LASSO, especially when very sparse weight vectors are allowed (the left side in the graphs). This is consistent with theorem 3.2 showing the relation between them. However, LASSO usually has worse performance when the allowed number of nonzero weights is set too large (the right side of the graphs). In this case, LASSO seems to overfit, while truncated gradient is more robust to overfitting. The robustness of online learning is often attributed to early stopping, which has been extensively discussed in the literature (e.g., Zhang, 2004).

Finally, it is worth emphasizing that the experiments in this subsection try to shed some light on the relative strengths of these algorithms in terms of feature sparsification. For large data sets such as Big_Ads only truncated gradient, coefficient rounding, and the sub-gradient algorithms are applicable. As we have shown and argued, the rounding algorithm is quite ad hoc and may not work robustly in some problems, and the sub-gradient algorithm does not lead to sparsity in general during training.

7. Conclusion

This paper covers the first sparsification technique for large-scale online learning with strong theoretical guarantees. The algorithm, truncated gradient, is the natural extension of Lasso-style re-

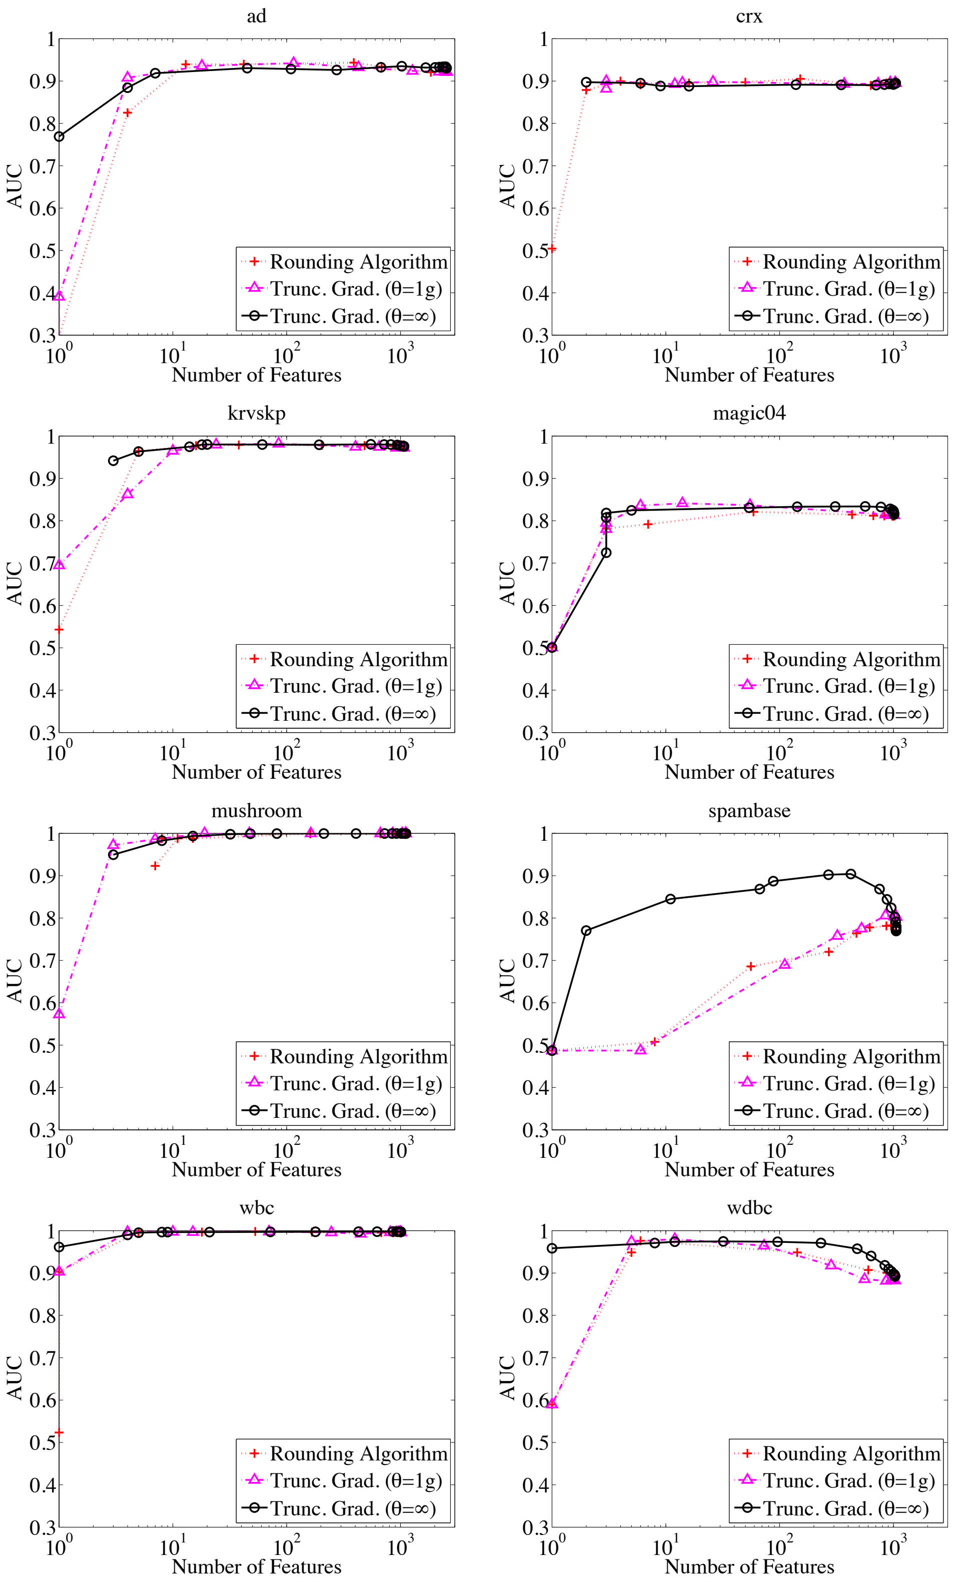

Figure 6: Effect of θ on AUC in truncated gradient.

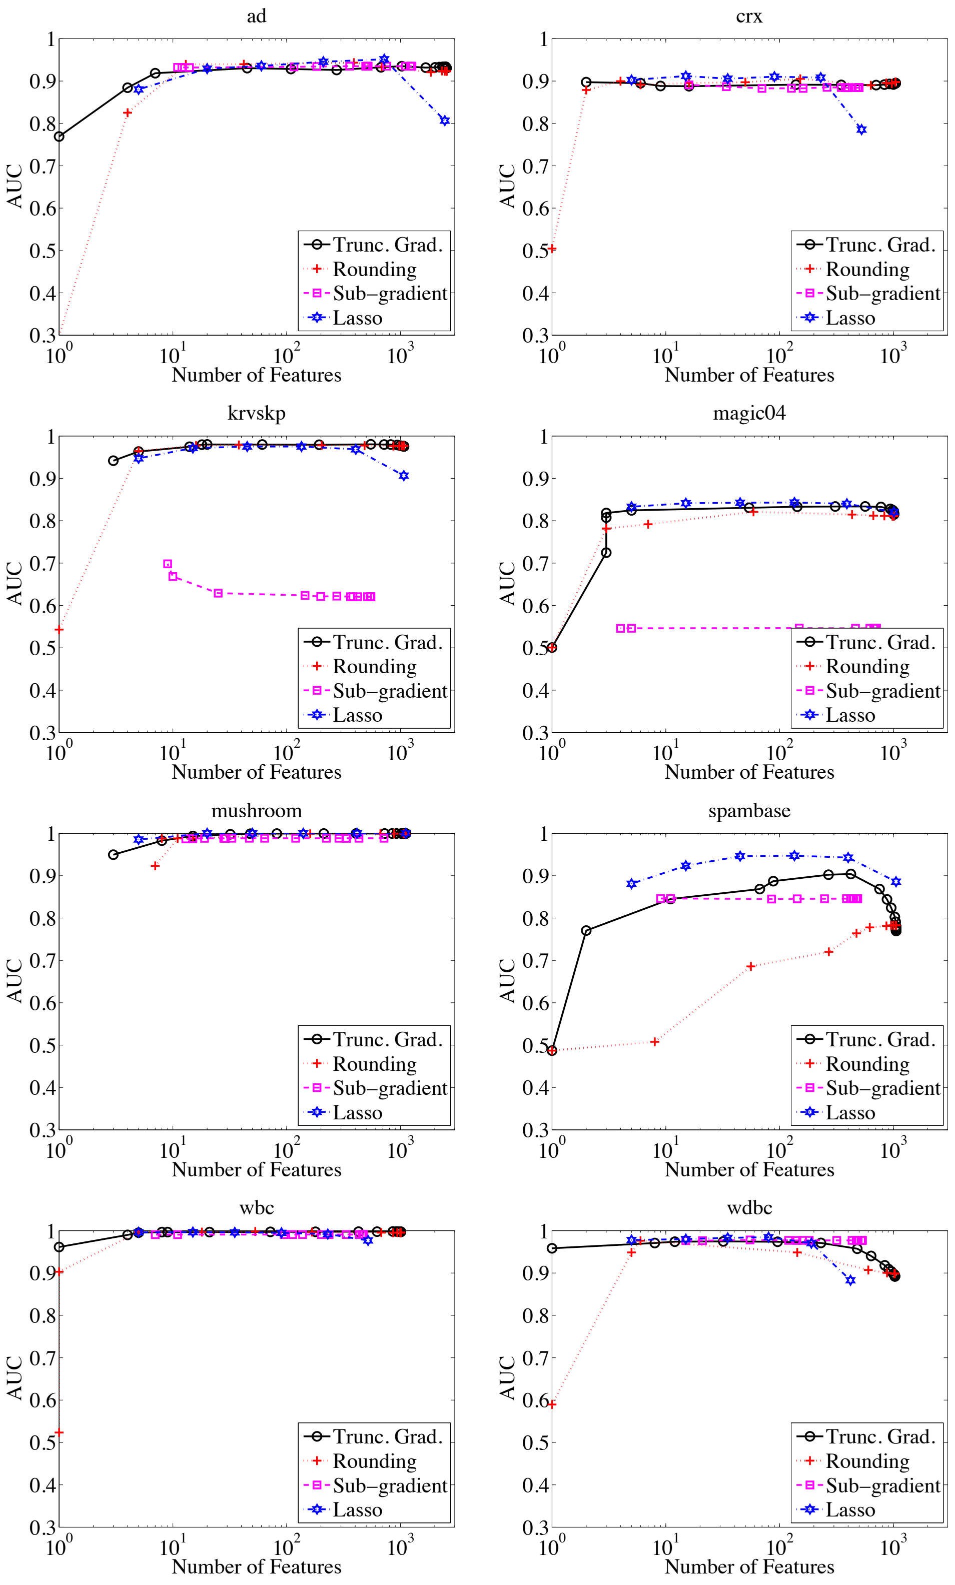

Figure 7: Comparison of four algorithms.

gression to the online-learning setting. Theorem 3.1 proves the technique is sound: it never harms performance much compared to standard stochastic gradient descent in adversarial situations. Furthermore, we show the asymptotic solution of one instance of the algorithm is essentially equivalent to the Lasso regression, thus justifying the algorithm's ability to produce sparse weight vectors when the number of features is intractably large.

The theorem is verified experimentally in a number of problems. In some cases, especially for problems with many irrelevant features, this approach achieves a one or two order of magnitude reduction in the number of features.

Appendix A. Proof of Theorem 3.1

The following lemma is the essential step in our analysis.

Lemma 1 *Suppose update rule (6) is applied to weight vector w on example $z = (x, y)$ with gravity parameter $g_i = g$, and results in a weight vector w'. If Assumption 3.1 holds, then for all $\bar{w} \in R^d$, we have*

$$\begin{aligned}&(1 - 0.5A\eta)L(w,z) + g\|w' \cdot I(|w'| \le \theta)\|_1 \\ \le& L(\bar{w},z) + g\|\bar{w} \cdot I(|w'| \le \theta)\|_1 + \frac{\eta}{2}B + \frac{\|\bar{w} - w\|^2 - \|\bar{w} - w'\|^2}{2\eta}.\end{aligned}$$

Proof Consider any target vector $\bar{w} \in R^d$ and let $\tilde{w} = w - \eta\nabla_1 L(w,z)$. We have $w' = T_1(\tilde{w}, g\eta, \theta)$. Let

$$u(\bar{w}, w') = g\|\bar{w} \cdot I(|w'| \le \theta)\|_1 - g\|w' \cdot I(|w'| \le \theta)\|_1.$$

Then the update equation implies the following:

$$\begin{aligned}&\|\bar{w} - w'\|^2 \\ \le&\|\bar{w} - w'\|^2 + \|w' - \tilde{w}\|^2 \\ =&\|\bar{w} - \tilde{w}\|^2 - 2(\bar{w} - w')^T(w' - \tilde{w}) \\ \le&\|\bar{w} - \tilde{w}\|^2 + 2\eta u(\bar{w}, w') \\ =&\|\bar{w} - w\|^2 + \|w - \tilde{w}\|^2 + 2(\bar{w} - w)^T(w - \tilde{w}) + 2\eta u(\bar{w}, w') \\ =&\|\bar{w} - w\|^2 + \eta^2\|\nabla_1 L(w,z)\|^2 + 2\eta(\bar{w} - w)^T\nabla_1 L(w,z) + 2\eta u(\bar{w}, w') \\ \le&\|\bar{w} - w\|^2 + \eta^2\|\nabla_1 L(w,z)\|^2 + 2\eta(L(\bar{w},z) - L(w,z)) + 2\eta u(\bar{w}, w') \\ \le&\|\bar{w} - w\|^2 + \eta^2(AL(w,z) + B) + 2\eta(L(\bar{w},z) - L(w,z)) + 2\eta u(\bar{w}, w').\end{aligned}$$

Here, the first and second equalities follow from algebra, and the third from the definition of $\tilde{w}$. The first inequality follows because a square is always non-negative. The second inequality follows because $w' = T_1(\tilde{w}, g\eta, \theta)$, which implies $(w' - \tilde{w})^T w' = -g\eta \|w' \cdot I(|\tilde{w}| \leq \theta)\|_1 = -g\eta \|w' \cdot I(|w'| \leq \theta)\|_1$ and $|w'_j - \tilde{w}_j| \leq g\eta I(|w'_j| \leq \theta)$. Therefore,

$$\begin{aligned}
-(\bar{w} - w')^T (w' - \tilde{w}) &= -\bar{w}^T (w' - \tilde{w}) + w'^T (w' - \tilde{w}) \\
&\leq \sum_{j=1}^{d} |\bar{w}_j||w'_j - \tilde{w}_j| + (w' - \tilde{w})^T w' \\
&\leq g\eta \sum_{j=1}^{d} |\bar{w}_j| I(|w'_j| \leq \theta) + (w' - \tilde{w})^T w' = \eta u(\bar{w}, w'),
\end{aligned}$$

where the third inequality follows from the definition of sub-gradient of a convex function, implying

$$(\bar{w} - w)^T \nabla_1 L(w, z) \leq L(\bar{w}, z) - L(w, z)$$

for all w and $\bar{w}$; the fourth inequality follows from Assumption 3.1. Rearranging the above inequality leads to the desired bound. ■

Proof (of Theorem 3.1) Applying Lemma 1 to the update on trial i gives

$$\begin{aligned}
&(1 - 0.5A\eta) L(w_i, z_i) + g_i \|w_{i+1} \cdot I(|w_{i+1}| \leq \theta)\|_1 \\
\leq &L(\bar{w}, z_i) + \frac{\|\bar{w} - w_i\|^2 - \|\bar{w} - w_{i+1}\|^2}{2\eta} + g_i \|\bar{w} \cdot I(|w_{i+1}| \leq \theta)\|_1 + \frac{\eta}{2} B.
\end{aligned}$$

Now summing over $i = 1, 2, \ldots, T$, we obtain

$$\begin{aligned}
& \sum_{i=1}^{T} [(1 - 0.5A\eta) L(w_i, z_i) + g_i \|w_{i+1} \cdot I(|w_{i+1}| \leq \theta)\|_1] \\
\leq \quad & \sum_{i=1}^{T} \left[\frac{\|\bar{w} - w_i\|^2 - \|\bar{w} - w_{i+1}\|^2}{2\eta} + L(\bar{w}, z_i) + g_i \|\bar{w} \cdot I(|w_{i+1}| \leq \theta)\|_1 + \frac{\eta}{2} B \right] \\
= \quad & \frac{\|\bar{w} - w_1\|^2 - \|\bar{w} - w_T\|^2}{2\eta} + \frac{\eta}{2} TB + \sum_{i=1}^{T} [L(\bar{w}, z_i) + g_i \|\bar{w} \cdot I(|w_{i+1}| \leq \theta)\|_1] \\
\leq \quad & \frac{\|\bar{w}\|^2}{2\eta} + \frac{\eta}{2} TB + \sum_{i=1}^{T} [L(\bar{w}, z_i) + g_i \|\bar{w} \cdot I(|w_{i+1}| \leq \theta)\|_1].
\end{aligned}$$

The first equality follows from the telescoping sum and the second inequality follows from the initial condition (all weights are zero) and dropping negative quantities. The theorem follows by dividing with respect to T and rearranging terms. ■

Abstract

We present a general approach for collaborative filtering (CF) using spectral regularization to learn linear operators mapping a set of "users" to a set of possibly desired "objects". In particular, several recent low-rank type matrix-completion methods for CF are shown to be special cases of our proposed framework. Unlike existing regularization-based CF, our approach can be used to incorporate additional information such as attributes of the users/objects—a feature currently lacking in existing regularization-based CF approaches—using popular and well-known *kernel methods*. We provide novel representer theorems that we use to develop new estimation methods. We then provide learning algorithms based on low-rank decompositions and test them on a standard CF data set. The experiments indicate the advantages of generalizing the existing regularization-based CF methods to incorporate related information about users and objects. Finally, we show that certain multi-task learning methods can be also seen as special cases of our proposed approach.

Keywords: collaborative filtering, matrix completion, kernel methods, spectral regularization

1. Introduction

Collaborative filtering (CF) refers to the task of predicting preferences of a given "user" for some "objects" (e.g., books, music, products, people, etc.) based on his/her previously revealed preferences—typically in the form of purchases or ratings—as well as the revealed preferences of other users. In a book recommender system, for example, one might like to suggest new books

∗. Also at Institut Curie, Inserm U900, 75248 Paris, France.

to a new user based on what she and other users have recently purchased or rated. The ultimate goal of CF is to infer the preferences of users in order to offer them new objects.

A number of CF methods have been developed in the past (Breese et al., 1998; Heckerman et al., 2000; Salakhutdinov et al., 2007). Recently there has been interest in CF using regularization-based methods (Srebro and Jaakkola, 2003). This work adds to that literature by developing a novel general approach to regularization-based CF methods.

Recent regularization-based CF methods assume that the only data available are the revealed preferences, where no other information such as background information on the objects or users is given. In this case, one may formulate the problem as that of inferring the contents of a partially observed *preference matrix*: each row represents a user, each column represents an object (e.g., books or movies), and entries in the matrix represent a given user's rating of a given object. When the only information available is a set of observed user/object ratings, the unknown entries in the matrix must be inferred from the known ones—of which there are typically very few relative to the size of the matrix.

To make useful predictions within this setting, regularization-based CF methods make certain assumptions about the *relatedness* of the objects and users. The most common assumption is that the preference function can be decomposed into a small number of factors, resulting in the search for a low-rank matrix which approximates the partially observed matrix of preferences (Srebro and Jaakkola, 2003). The rank constraint can be interpreted as a regularization on the hypothesis space. Since the rank constraint gives rise to a non-convex set of matrices, the associated optimization problem will be a difficult non-convex problem for which only heuristic algorithms exist (Srebro and Jaakkola, 2003). An alternative formulation, proposed by Srebro et al. (2005), suggests penalizing the predicted matrix by its *trace norm*, that is, the sum of its singular values. An added benefit of the trace norm regularization is that, with a sufficiently large regularization parameter, the final solution will be low-rank (Fazel et al., 2001; Bach, 2008).

However, a key limitation of current regularization-based CF methods is that they do not take advantage of additional information, such as known attributes of each user (e.g., gender, age) and object (e.g., book's author, genre), which is often available. Intuitively, such information might be useful to guide the inference of preferences, in particular for users and objects with very few known ratings. For example, at the extreme, users and objects with no prior ratings can not be considered in the standard CF formulation, while their attributes alone could provide some basic preference inference.

The main contribution of this paper is to develop a general framework for the CF setting when user/object attribute information is potentially available and, in particular, to provide several specific algorithms based on new "representer" theorems. More precisely we show that CF, while typically seen as a problem of matrix completion, can be thought of more generally as *linear operator estimation*, where the desired operator maps from a Hilbert space of users to a Hilbert space of objects. Equivalently, this can be viewed as learning a bilinear form between users and objects. We then develop *spectral regularization* based methods to learn such linear operators. When dealing with operators, rather than matrices, one may also work with infinite dimensions, allowing one to consider arbitrary feature space, possibly induced by some kernel function. Among key theoretical contributions of this paper are new representer theorems, allowing us to develop new general methods that learn finitely many parameters even when working in infinite dimensional user/object feature space. These representer theorems generalize the classical representer theorem for minimization of an empirical loss penalized by the norm in a Reproducing Kernel Hilbert Space (RKHS) to more general penalty functions and function classes.

We also show that, with the appropriate choice of kernels for both users and objects, we may consider a number of existing machine learning methods as special cases of our general framework. In particular, we show that several CF methods such as rank-constrained optimization, trace-norm regularization, and those based on Frobenius norm regularization, can all be cast as special cases of spectral regularization on operator spaces. Moreover, particular choices of kernels lead to specific sub-cases such as regular matrix completion and multi-task learning. In the specific application of collaborative filtering with the presence of attributes, we show that our generalization of these sub-cases leads to better predictive performance.

The outline of the paper is as follows. In Section 2, we review the notion of a compact operator on Hilbert Space, and we show how to cast the collaborative filtering problem within this framework. We then introduce spectral regularization and discuss how rank constraint, trace norm regularization, and Frobenius norm regularization are all special cases of spectral regularization. In Section 3, we show how our general framework encompasses many existing methods with proper choice of the loss function, the kernels, and the spectral regularizer. In Section 4, we provide three representer theorems for operator estimation with spectral regularization that allow for efficient learning algorithms. Finally in Section 5 we present a number of algorithms and describe several techniques to improve efficiency. We test these algorithms in Section 6 on synthetic examples and a widely used movie database.

2. Learning Compact Operators with Spectral Regularization

In this section we propose a mathematical formulation for a general CF problem with spectral regularization. We then show in Section 3 how several learning problems can be cast under this general framework.

2.1 A General CF Formulation

We consider a general CF problem in which our goal is to model the preference of a user described by $\mathbf{x}$ for an item described by $\mathbf{y}$. We denote by $\mathbf{x}$ and $\mathbf{y}$ the data objects containing all relevant or available information; this could, for example, include a unique identifier i for the i-th user or object. Of course, the users and objects may additionally be characterized by known attributes, in which case $\mathbf{x}$ or $\mathbf{y}$ might contain some representation of this extra information. Ultimately, we would like to consider such attribute information as encoded in some positive definite kernel between users, or equivalently between objects. This naturally leads us to model the users as elements in a Hilbert space $\mathcal{X}$, and the objects they rate as elements of another Hilbert space $\mathcal{Y}$.

We assume that our observation data is in the form of *ratings* from users to objects, a real-valued score representing the user's preference for the object. Alternatively, similar methods can be applied when the observations are binary, specifying for instance whether or not a user considered or selected an object.

Given a series of N observations $(\mathbf{x}_i, \mathbf{y}_i, t_i)_{i=1,\ldots,N}$ in $\mathcal{X} \times \mathcal{Y} \times \mathbb{R}$, where t_i represents the rating of user $\mathbf{x}_i$ for object $\mathbf{y}_i$, the generalized CF problem is then to infer a function $f : \mathcal{X} \times \mathcal{Y} \to \mathbb{R}$ that can then be used to predict the rating of any user $\mathbf{x} \in \mathcal{X}$ for any object $\mathbf{y} \in \mathcal{Y}$ by $f(\mathbf{x}, \mathbf{y})$. Note that in our notation $\mathbf{x}_i$ and $\mathbf{y}_i$ represent the user and object corresponding to the i-th rating available. If several ratings of a user for different objects are available, as is commonly the case, several $\mathbf{x}_i$'s will be identical in $\mathcal{X}$—a slight abuse of notation. We denote by $\mathcal{X}_N$ and $\mathcal{Y}_N$ the linear spans of $\{\mathbf{x}_i\,, i = 1,\ldots,N\}$ and $\{\mathbf{y}_i\,, i = 1,\ldots,N\}$ in $\mathcal{X}$ and $\mathcal{Y}$, with respective dimensions $m_{\mathcal{X}}$ and $m_{\mathcal{Y}}$.

In the present paper, we uniquely consider learning preference functions $f(\cdot,\cdot)$ that take the form of a linear operator from $\mathcal{X}$ to $\mathcal{Y}$; that is, bilinear forms on $\mathcal{X} \times \mathcal{Y}$,

$$f(\mathbf{x},\mathbf{y}) = \langle \mathbf{x}, F\mathbf{y} \rangle_{\mathcal{X}} \,, \tag{1}$$

for some compact operator F. We now denote by $\mathcal{B}_0(\mathcal{Y},\mathcal{X})$ the set of compact operators from $\mathcal{X}$ to $\mathcal{Y}$. For an introduction to relevant concepts in functional analysis, see Appendix A.

In the general case we consider below, if $\mathcal{X}$ and $\mathcal{Y}$ are not Hilbert spaces, one could also first map (implicitly) users $\mathbf{x}$ and objects $\mathbf{y}$ into possibly infinite dimensional Hilbert feature spaces $\Phi_{\mathcal{X}}(\mathbf{x})$ and $\Psi_{\mathcal{Y}}(\mathbf{y})$ and use kernels. We refer the reader to Appendix A for basic definitions and properties related to compact operators that are useful below. The inference problem can now be stated as follows:

Given a training set of ratings, how may we estimate a "good" compact operator F to predict future ratings?

We estimate the operator F in (1) from the training data using a standard regularization and statistical machine learning approach. In particular, we propose to define the operator as the solution of an optimization problem over $\mathcal{B}_0(\mathcal{Y},\mathcal{X})$ whose objective function balances a data fitting term $R_N(F)$, which is small for operators that can correctly explain the training data, with a regularization term $\Omega(F)$ that controls the complexity of the desired operator. We now describe these two terms in more details.

2.2 Data Fitting Term

Given a *loss function* $\ell(t',t)$ that quantifies how good a prediction $t' \in \mathbb{R}$ is if the true value is $t \in \mathbb{R}$, we consider a fitting term equal to the empirical risk, that is, the mean loss incurred on the training set:

$$R_N(F) = \frac{1}{N}\sum_{i=1}^{N} \ell\left(\langle \mathbf{x}_i, F\mathbf{y}_i \rangle_{\mathcal{X}}, t_i\right) . \tag{2}$$

The particular choice of the loss function should typically depend on the precise problem to be solved and on the nature of the variables t to be predicted. See more details in Section 3. In particular, while the representer theorems presented in Section 4 do not need any convexity with respect to this choice, the algorithms presented in Section 5 do.

2.3 Regularization Term

For the regularization term, we focus on a class of spectral functions defined as follows.

Definition 1 *A function* $\Omega : \mathcal{B}_0(\mathcal{Y},\mathcal{X}) \mapsto \mathbb{R} \cup \{+\infty\}$ *is called a* spectral penalty function *if it can be written as:*

$$\Omega(F) = \sum_{i=1}^{d} s_i\left(\sigma_i(F)\right) , \tag{3}$$

where for any $i \geq 1, s_i : \mathbb{R}^+ \mapsto \mathbb{R}^+ \cup \{+\infty\}$ *is a non-decreasing penalty function satisfying* $s(0) = 0$*, and* $(\sigma_i(F))_{i=1,\ldots,d}$ *are the d singular values of F in decreasing order—d possibly infinite.*

Note that, by the spectral theorem presented in Appendix A, any compact operator can be decomposed into singular vectors, with singular values being a sequence that tends to zero.

Spectral penalty functions include as special cases several functions often encountered in matrix completion problems:

- For a given integer r, consider taking $s_i = 0$ for $i = 1, \ldots, r$, $s_{r+1}(u) = 0$ for $u = 0$, and $s_{r+1}(u) = +\infty$ when $u > 0$. This leads to the function:

$$\Omega(F) = \begin{cases} 0 & \text{if } \operatorname{rank}(F) \leq r, \\ +\infty & \text{otherwise.} \end{cases} \tag{4}$$

  In other words, the set of operators F that satisfy $\Omega(F) < +\infty$ is the set of operators with rank smaller than r.

- Taking $s_i(u) = u$ for all i results in the trace norm penalty (see Appendix A):

$$\Omega(F) = \begin{cases} \|F\|_1 & \text{if } F \in \mathcal{B}_1(\mathcal{Y}, \mathcal{X}), \\ +\infty & \text{otherwise,} \end{cases} \tag{5}$$

  where we note with $\mathcal{B}_1(\mathcal{Y}, \mathcal{X})$ the set of operators with finite trace norm. Such operators are referred to as trace class operators.

- Taking $s_i(u) = u^2$ for all i results in the squared Hilbert-Schmidt norm penalty (also called squared Frobenius norm for matrices, see Appendix A):

$$\Omega(F) = \begin{cases} \|F\|_2^2 & \text{if } F \in \mathcal{B}_2(\mathcal{Y}, \mathcal{X}), \\ +\infty & \text{otherwise,} \end{cases} \tag{6}$$

  where we note with $\mathcal{B}_2(\mathcal{Y}, \mathcal{X})$ the set of operators with finite squared Hilbert-Schmidt norm. Such operators are referred to as Hilbert Schmidt operators.

These particular functions can be combined together in different ways. For example, we may constrain the rank to be smaller than r while penalizing the trace norm of the matrix, which can be obtained by setting $s_i(u) = u$ for $i = 1, \ldots, r$ and $s_{r+1}(u) = +\infty$ if $u > 0$. Alternatively, if we want to penalize the Frobenius norm while constraining the rank, we set $s_i(u) = u^2$ for $i = 1, \ldots, r$ and $s_{r+1}(u) = +\infty$ if $u > 0$. We state these two choices of Ω explicitly since we use these in the experiments (see Section 6) or to design efficient algorithms (see Section 5):

$$\text{Trace+Rank Penalty:} \qquad \Omega(F) = \begin{cases} \|F\|_1 & \text{if } \operatorname{rank}(F) \leq r, \\ +\infty & \text{otherwise.} \end{cases} \tag{7}$$

$$\text{Frobenius+Rank Penalty:} \qquad \Omega(F) = \begin{cases} \|F\|_2^2 & \text{if } \operatorname{rank}(F) \leq r, \\ +\infty & \text{otherwise.} \end{cases}$$

2.4 Operator Inference

With both a fitting term and a regularization term, we can now formally define our inference approach. It consists of finding an operator $\hat{F}$, if there exists one, that solves the following optimization problem:

$$\hat{F} \in \operatorname*{arg\,min}_{F \in \mathcal{B}_0(\mathcal{Y},\mathcal{X})} R_N(F) + \lambda\Omega(F) \,, \tag{8}$$

where $\lambda \in \mathbb{R}_+$ is a parameter that controls the trade-off between fitting and regularization, and where $R_N(F)$ and $\Omega(F)$ are respectively defined in (2) and (3). We note that if the set $\{F \in \mathcal{B}_0(\mathcal{Y},\mathcal{X}) \,, \Omega(F) < +\infty\}$ is not empty, then necessarily the solution $\hat{F}$ of this optimization problem must satisfy $\Omega(\hat{F}) < \infty$.

We show in Sections 4 and 5 how problem (8) can be solved in practice in particular for Hilbert spaces of infinite dimensions. Before exploring such implementation-related issues, in the following section we provide several examples of algorithms that can be derived as particular cases of (8) and highlight their relationships to existing methods.

3. Examples and Related Approaches

The general formulation (8) can result in a variety of practical algorithms potentially useful in different contexts. In particular, three elements can be tailored to one's particular needs: the loss function, the kernels (or equivalently the Hilbert spaces), and the spectral penalty term. We start this section by some generalities about the possible choices for these elements and their consequences, before highlighting some particular combinations of choices relevant for different applications.

1. **The loss function.** The choice of ℓ defines the empirical risk through (2). It is a classical component of many machine learning methods, and should typically depend on the type of data to be predicted (e.g., discrete or continuous) and of the final objective of the algorithm (e.g., classification, regression or ranking). The choice of ℓ also influences the algorithm, as discussed in Section 5. As a deeper discussion about the loss function is only tangential to the current work, we only consider the square loss here, knowing that other convex losses may be considered.

2. **The spectral penalty function.** The choice of $\Omega(F)$ defines the type of constraint we impose on the operator that we seek to learn. In Section 2.3, we gave several examples of such constraints including the rank constraint (4), the trace norm constraint (5), the Hilbert-Schmidt norm constraint (6), or the trace norm constraint over low-rank operators (7). The choice of a particular penalty might be guided by some considerations about the problem to be solved, for example, finding low-rank operators as a way to discover low-dimensional latent structures in the data. On the other hand, from an algorithmic perspective, the choice of the spectral penalty may affect the efficiency or feasibility of our learning algorithm. Certain penalty functions, such as the rank constraint for example, will lead to non-convex problems because the corresponding penalty function (4) is itself not convex. However, the same rank constraint can vastly reduce the number of parameters to be learned. These algorithmic considerations are discussed in more detail in Section 5.

3. **The kernels.** Our choice of kernels defines the inner products (i.e., embeddings) of the users and objects in their respective Hilbert spaces. We may use a variety of possible kernels

depending on the problem to be solved and on the available attributes. Interestingly, the choice of a particular kernel has no influence on the algorithm, as we show later (however, it can easily influence the running time of these algorithms). In the current work, we focus on two basic kernels (Dirac kernels and attribute kernels) and in Section 3.4 we discuss combining these.

- The first kernel we consider is the *Dirac* kernel. When two users (resp. two objects) are compared, the Dirac kernel returns 1 if they are the same user (resp. object), and 0 otherwise. In other words, the Dirac kernel amounts to representing the users (resp. the objects) by orthonormal vectors in $\mathcal{X}$ (resp. in $\mathcal{Y}$). This kernel can be used whether or not attributes are available for users and objects. We denote by $k_D^{\mathcal{X}}$ (resp. $k_D^{\mathcal{Y}}$) the Dirac kernel for the users (resp. objects).
- The second kernel we consider is a kernel between *attributes*, when attributes are available to describe the users and/or objects. We call this an "attribute kernel". This would typically be a kernel between vectors, such as the inner product or a Gaussian RBF kernel, when the descriptions of users and/or objects take the form of vectors of real-valued attributes, or any kernel on structured objects (Shawe-Taylor and Cristianini, 2004). We denote by $k_A^{\mathcal{X}}$ (resp. $k_A^{\mathcal{Y}}$) the attributes kernel for the users (resp. objects).

In the following section we illustrate how specific combinations of loss, spectral penalty and kernels can be relevant for various settings. In particular the choice of kernels leads to new methods for a range of different estimation problems; namely, matrix completion, multi-task learning, and pairwise learning. In Section 3.4 we consider a new representation that allows interpolation between these particular problem formulations.

3.1 Matrix Completion

When the Dirac kernel is used for both users and objects, then we can organize the data $\{\mathbf{x}_i, i = 1, \ldots, n\}$ into $n_{\mathcal{X}}$ groups of identical data points and similarly $\{\mathbf{y}_i, i = 1, \ldots, n\}$ into $n_{\mathcal{Y}}$ groups. Since we use the Dirac kernel, we can represent each of these groups by the elements of the canonical basis $(\mathbf{u}_1, \ldots, \mathbf{u}_{n_{\mathcal{X}}})$ and $(\mathbf{v}_1, \ldots, \mathbf{v}_{n_{\mathcal{Y}}})$ of $\mathbb{R}^{n_{\mathcal{X}}}$ and $\mathbb{R}^{n_{\mathcal{Y}}}$, respectively. A bilinear form using Dirac kernels only depends on the identities of the users and the objects, and we only predict the rating t_i based on the identities of the groups in both spaces. If we assume that each user/object pair is observed at most once, the data can be re-arranged into a $n_{\mathcal{X}} \times n_{\mathcal{Y}}$ incomplete matrix where the learning objective would be to "complete" the missing entries in this matrix (indeed, in this context, it is not possible to generalize to never seen points in $\mathcal{X}$ and $\mathcal{Y}$).

In this case, our bilinear form framework exactly corresponds to completing the matrix, since the bilinear function of $\mathbf{x}$ and $\mathbf{y}$ is exactly equal to $\mathbf{u}_i^\top M \mathbf{v}_j$ where $\mathbf{x} = \mathbf{u}_i$ (i.e., $\mathbf{x}$ is the i-th person) and $\mathbf{y} = \mathbf{v}_j$ (i.e., $\mathbf{y}$ is the j-th object). Thus, the (i, j)-th entry of the matrix M can be assimilated to the value of the bilinear form defined by the matrix M over the pair $(\mathbf{u}_i, \mathbf{v}_j)$. Moreover the spectral regularizer corresponds to the corresponding spectral function of the complete matrix $M \in \mathbb{R}^{n_{\mathcal{X}} \times n_{\mathcal{Y}}}$.

In this context, finding a low-rank approximation of the observed entries in a matrix is an appealing strategy, which corresponds to taking the rank penalty constraint (4) combined with, for example, the square loss error. This however leads to non-convex optimization problems with multiple local minima, for which only local search heuristics are known (Srebro and Jaakkola, 2003). To circumvent this issue, convex spectral penalty functions can be considered. Indeed, in the case of binary preferences, combining the hinge loss function with the trace norm penalty (5) leads to the maximum margin matrix factorization (MMMF) approach proposed by Srebro et al. (2005), which can be rewritten as a semi-definite program. For the sake of efficiency, Rennie and Srebro (2005) proposed to add a constraint on the rank of the matrix, resulting in a non-convex problem that can nevertheless be handled efficiently by classical gradient descent techniques; in our setting, this corresponds to changing the trace norm penalty (5) by the penalty (7).

3.2 Multi-Task Learning

It may be the case that we have attributes only for objects $\mathbf{y}$ (or, similarly, only for users). In that case, for a finite number of users $\{\mathbf{x}_i\,, i = 1, \ldots, N\}$ organized in $n_{\mathcal{X}}$ groups, we aim to estimate a separate function on objects $f_i(\mathbf{y})$ for each of the $n_{\mathcal{X}}$ users i. Considering the estimation of each of these f_i's as a *learning task*, one can possibly learn all f_i's *simultaneously* using a *multi-task learning* approach.

In order to adapt our general framework to this scenario, it is natural to consider the attribute kernel $k_A^{\mathcal{Y}}$ for the objects, whose attributes are available, and the Dirac kernel $k_D^{\mathcal{X}}$ for the users, for which no attributes are used. Again the choice of the loss function depends on the precise task to be solved, and the spectral penalty function can be chosen to enforce some sharing of information between different tasks.

In particular, taking the rank penalty function (4) enforces a decomposition of the tasks (learning each f_i) into a limited number of factors. This results in a method for multi-task learning based on a low-rank representation of the predictor functions f_i. The resulting problem, however, is not convex due to the use of the non-convex rank penalty function. A natural alternative is then to replace the rank constraint by the trace norm penalty function (5), resulting in a convex optimization problem when the loss function is convex. Recently, a similar approach was independently proposed by Amit et al. (2007) in the context of multiclass classification and by Argyriou et al. (2008) for multi-task learning.

Alternatively, another strategy to enforce some constraints among the tasks is to constrain the variance of the different classifiers. Evgeniou et al. (2005) showed that this strategy can be formulated in the framework of support vector machines by considering a *multi-task kernel*, that is, a kernel $k_{multi-task}$ over the product space $\mathcal{X} \times \mathcal{Y}$ defined between any two user/object pairs $(\mathbf{x}, \mathbf{y})$ and $(\mathbf{x}', \mathbf{y}')$ by:

$$k_{multi-task}\left((\mathbf{x},\mathbf{y}),(\mathbf{x}',\mathbf{y}')\right) = \left(k_D^{\mathcal{X}}\left(\mathbf{x},\mathbf{x}'\right) + c\right) k_A^{\mathcal{Y}}\left(\mathbf{y},\mathbf{y}'\right) , \tag{9}$$

where $c > 0$ controls how the variance of the classifiers is constrained compared to the norm of each classifier. As explained in Appendix A, estimating a function over the product space $\mathcal{X} \times \mathcal{Y}$ by penalizing the RKHS norm of the kernel (9) is a particular case of our general framework, where we take the Hilbert-Schmidt norm (6) as spectral penalty function, and where the kernels between users and between objects are respectively $k_D^{\mathcal{X}}\left(\mathbf{x},\mathbf{x}'\right) + c$ and $k_A^{\mathcal{Y}}\left(\mathbf{y},\mathbf{y}'\right)$. When $c = 0$, that is, when we take a Dirac kernel for the users and an attribute kernel for the objects, then penalizing the Hilbert-Schmitt norm amounts to estimating independent models for each user, as explained by Evgeniou et al. (2005). Combining two Dirac kernels for users and objects, respectively, and penalizing the Hilbert-Schmitt norm would not be useful, since the optimal solution would be 0 all points other than training pairs. On the other hand, replacing the Hilbert-Schmidt norm defined by another penalty, such as the trace norm (5), would be an interesting extension when the kernels $k_D^{\mathcal{X}}\left(\mathbf{x},\mathbf{x}'\right) + c$ and $k_A^{\mathcal{Y}}\left(\mathbf{y},\mathbf{y}'\right)$ are used: this would constrain both the variance of the predictor functions f_i and their decomposition into a small number of factors, a potentially nice approach in some multi-task learning applications.

3.3 Pairwise Learning

When attributes are available for both users and objects then it is possible to use the attributes kernels for each. Combining this choice with the Hilbert-Schmidt penalty (6) results in classical machine learning algorithms (e.g., an SVM if the hinge loss is taken as the loss function) applied to the *tensor product* of $\mathcal{X}$ and $\mathcal{Y}$. This strategy is a classical approach to learn a function over pairs of points (see, e.g., Jacob and Vert, 2008). Replacing the Hilbert-Schmidt norm by another spectral penalty function, such as the trace norm, would result in new algorithms for learning low-rank functions over pairs.

3.4 Combining the Attribute and Dirac Kernels

As illustrated in the previous subsections, the setting of the application often determines the combination of kernels to be used for the users and the objects: typically, two Dirac kernels for the standard CF setting without attributes, one Dirac and one attributes kernel for multi-task problems, and two attributes kernels when attributes are available for both users and objects and one wishes to learn over pairs.

There are many situations, however, where the attributes available to describe the users and/or objects are certainly useful for the inference task, but on the other hand do not fully characterize the users and/or objects. For example, if we just know the age and gender of users, we would like to use this information to model their preferences, but would also like to allow for prediction of different preferences for different users even when they share the same age and gender. In our setting, this means that we may want to use the attributes kernel in order to use known attributes from the users and objects during inference, but also the Dirac kernel to incorporate the fact that different users and/or objects remain different even when they share many or all of their attributes.

This naturally leads us to consider the following convex combinations of Dirac and attributes kernels (Abernethy et al., 2006):

$$\begin{cases} k^{\mathcal{X}} = \eta k_{\mathrm{A}}^{\mathcal{X}} + (1-\eta) k_{\mathrm{D}}^{\mathcal{X}}, \\ k^{\mathcal{Y}} = \zeta k_{\mathrm{A}}^{\mathcal{Y}} + (1-\zeta) k_{\mathrm{D}}^{\mathcal{Y}}, \end{cases}$$

where $0 \leq \eta \leq 1$ and $0 \leq \zeta \leq 1$. These kernels interpolate between the Dirac kernels ($\eta = 0$ and $\zeta = 0$) and the attributes kernels ($\eta = 1$ and $\zeta = 1$). Combining this choice of kernels with, for example, the trace norm penalty function (5), allows us to continuously interpolate between different settings corresponding to different "corners" in the (η, ζ) square: standard CF with matrix completion at $(0,0)$, multi-task learning at $(0,1)$ and $(1,0)$, and learning over pairs at $(1,1)$. The extra degree of freedom created when η and ζ are allowed to vary continuously between 0 and 1 provides a principled way to optimally balance the influence of the attributes in the function estimation process.

Note that our representational framework encompasses simpler natural approaches to include attribute information for collaborative filtering: for example, one could consider completing matrices using matrices of the form $UV^\top + U_A R_A^\top + U_A S_A^\top$, where $UV^\top$ is a low-rank matrix to be optimized, U_A and V_A are the given attributes for the first and second domains, and R_A, S_A are parameters to be learned. This formulation corresponds to adding an unconstrained low-rank term $UV^\top$, and the simpler linear predictor from the concatenation of attributes $U_A R_A^\top + U_A S_A^\top$ (Jacob and Vert, 2008). Our approach implicitly adds a fourth cross-product term $U_A T V_A^\top$, where T is estimated from data. This exactly corresponds to imposing that the low rank matrix has a decomposition which includes U_A and V_A as columns. Our combination of Dirac and attribute kernels has the advantage of having specific weights η and ζ that control the trade-off between the constrained and unconstrained low-rank matrices.

4. Representer Theorems

We now present the key theoretical results of this paper and discuss how the general optimization problem (8) can be solved in practice. A first difficulty with this problem is that the optimization space $\{F \in \mathcal{B}_0(\mathcal{Y},\mathcal{X}) : \Omega(F) < \infty\}$ can be of infinite dimension. We note that this can occur even under a rank constraint, because the set $\{F \in \mathcal{B}_0(\mathcal{Y},\mathcal{X}) : \mathrm{rank}(F) \leq R\}$ is not included into any finite-dimensional linear subspace if $\mathcal{X}$ and $\mathcal{Y}$ have infinite dimensions. In this section, we show that the optimization problem (8) can be rephrased as a finite-dimensional problem, and propose practical algorithms to solve it in Section 5. While, as we show in Section 4.1, the reformulation of the problem as a finite-dimensional problem is a simple instance of the representer theorem when the Hilbert-Schmidt norm is used as a penalty function, we prove in Section 4.2 a generalized representer theorem that is valid with any spectral penalty function.

4.1 The Case of the Hilbert-Schmidt Penalty Function

In the particular case where the penalty function $\Omega(F)$ is the Hilbert-Schmidt norm (6), then the set $\{F \in \mathcal{B}_0(\mathcal{Y},\mathcal{X}) : \Omega(F) < \infty\}$ is the set of Hilbert-Schmidt operators. As recalled in Appendix A, this set is a Hilbert space isometric through (1) to the reproducing kernel Hilbert space $\mathcal{H}_\otimes$ of the kernel:

$$k_\otimes\left((\mathbf{x},\mathbf{x}'),(\mathbf{y},\mathbf{y}')\right) = \langle \mathbf{x},\mathbf{x}'\rangle_{\mathcal{X}} \langle \mathbf{y},\mathbf{y}'\rangle_{\mathcal{Y}},$$

and the isometry translates from F to f as:

$$\| f \|_{\mathcal{H}_\otimes}^2 = \| F \|^2 = \Omega(F).$$

As a result, in that case the problem (8) is equivalent to:

$$\min_{f \in \mathcal{H}_\otimes} R_N(f) + \lambda \| f \|_\otimes^2. \tag{10}$$

Therefore the representer theorem for optimization of empirical risks penalized by the RKHS norm (Aronszajn, 1950; Schölkopf et al., 2001) can be applied to show that the solution of (10) necessarily lives in the linear span of the training data. With our notations this translates into the following result:

Theorem 2 *If $\hat{F}$ is a solution of the problem:*

$$\min_{F \in \mathcal{B}_2(\mathcal{Y},\mathcal{X})} R_N(F) + \lambda \sum_{i=1}^{\infty} \sigma_i(F)^2,$$

then it is necessarily in the linear span of $\{\mathbf{x}_i \otimes \mathbf{y}_i : i = 1, \ldots, N\}$, that is, it can be written as:

$$\hat{F} = \sum_{i=1}^{N} \alpha_i \mathbf{x}_i \otimes \mathbf{y}_i, \tag{11}$$

for some $\alpha \in \mathbb{R}^N$.

For the sake of completeness, and to highlight why this result is specific to the Hilbert-Schmidt penalty function (6), we rephrase here, with our notations, the main arguments in the proof of Schölkopf et al. (2001). Any operator F in $\mathcal{B}_2(\mathcal{Y},\mathcal{X})$ can be decomposed as $F = F_S + F_\perp$, where F_S is the projection of F onto the linear span of $\{\mathbf{x}_i \otimes \mathbf{y}_i : i = 1,\ldots,N\}$. $F_\perp$ being orthogonal to each $\mathbf{x}_i \otimes \mathbf{y}_i$ in the training set, one easily gets $R_N(F) = R_N(F_S)$, while $\| F \|^2 = \| F_S \|^2 + \| F_\perp \|^2$ by the Pythagorean theorem. As a result a minimizer F of the objective function must be such that $F_\perp = 0$, that is, must be in the linear span of the training tensor products.

4.2 A Representer Theorem for General Spectral Penalty Functions

Let us now move on to the more general situation (8) where a general spectral function $\Omega(F)$ is used as regularization. Theorem 2 is usually not valid in such a case. Its proof breaks down because it is not true that $\Omega(F) = \Omega(F_S) + \Omega(F_\perp)$ for general Ω, or even that $\Omega(F) \geq \Omega(F_S)$.

The following theorem, whose proof is presented in Appendix B, can be seen as a generalized representer theorem. It shows that a solution of (8), if it exists, can be expanded over a finite basis of dimension $m_\mathcal{X} \times m_\mathcal{Y}$ (where $m_\mathcal{X}$ and $m_\mathcal{Y}$ are the underlying dimensions of the subspaces where the data lie), and that it can be found as the solution of a finite-dimensional optimization problem (with no convexity assumptions on the loss):

Theorem 3 *For any spectral penalty function* $\Omega : \mathcal{B}_0(\mathcal{Y},\mathcal{X}) \mapsto \mathbb{R} \cup \{+\infty\}$, *consider the optimization problem:*

$$\min_{F \in \mathcal{B}_0(\mathcal{Y},\mathcal{X}),} R_N(F) + \lambda \Omega(F) . \tag{12}$$

If the set of solutions is not empty, then there is a solution F in $\mathcal{X}_N \otimes \mathcal{Y}_N$, that is, there exists $\alpha \in \mathbb{R}^{m_\mathcal{X} \times m_\mathcal{Y}}$ such that:

$$F = \sum_{i=1}^{m_\mathcal{X}} \sum_{j=1}^{m_\mathcal{Y}} \alpha_{ij} \mathbf{u}_i \otimes \mathbf{v}_j , \tag{13}$$

where $(\mathbf{u}_1,\ldots,\mathbf{u}_{m_\mathcal{X}})$ and $(\mathbf{v}_1,\ldots,\mathbf{v}_{m_\mathcal{Y}})$ form orthonormal bases of $\mathcal{X}_N$ and $\mathcal{Y}_N$, respectively. Moreover, in that case the coefficients α can be found by solving the following finite-dimensional optimization problem:

$$\min_{\alpha \in \mathbb{R}^{m_\mathcal{X} \times m_\mathcal{Y}}} R_N\left(\operatorname{diag}\left(X \alpha Y^\top\right)\right) + \lambda \Omega(\alpha) , \tag{14}$$

where $\Omega(\alpha)$ refers to the spectral penalty function applied to the matrix α seen as an operator from $\mathbb{R}^{m_\mathcal{Y}}$ to $\mathbb{R}^{m_\mathcal{X}}$, and $X \in \mathbb{R}^{N \times m_\mathcal{X}}$ and $Y \in \mathbb{R}^{N \times m_\mathcal{X}}$ denote any matrices that satisfy $K = XX^\top$ and $G = YY^\top$ for the two $N \times N$ Gram matrices K and G defined by $K_{ij} = \langle \mathbf{x}_i, \mathbf{x}_j \rangle_\mathcal{X}$ and $G_{ij} = \langle \mathbf{y}_i, \mathbf{y}_j \rangle_\mathcal{Y}$, for $0 \leq i,j \leq N$.

This theorem shows that, as soon as a spectral penalty function is used to control the complexity of the compact operators, a solution can be searched in the finite-dimensional space $\mathcal{X}_N \otimes \mathcal{Y}_N$, which in practice boils down to an optimization problem over the set of matrices of size $m_\mathcal{X} \times m_\mathcal{Y}$. The dimension of this space might however be prohibitively large for real-world applications where, for example, tens of thousands of users are confronted to a database of thousands of objects. A convenient way to obtain an important decrease in complexity (at the expense of possibly losing convexity) is by constraining the rank of the operator through an adequate choice of a spectral penalty. Indeed, the set of non-zero singular components of F as an operator is equal to the set of non-zero singular values of α in (13) seen as a matrix. Consequently any constraint on the rank of F as an operator results in a constraint on α as a matrix, from which we deduce:

Corollary 4 *If, in Theorem 3, the spectral penalty function Ω is infinite on operators of rank larger than r (i.e., $\sigma_{r+1}(u) = +\infty$ for $u > 0$), then the matrix $\alpha \in \mathbb{R}^{m_{\mathcal{X}} \times m_{\mathcal{Y}}}$ in (13) has rank at most r.*

As a result, if a rank constraint $\text{rank}(F) \leq r$ is added to the optimization problem then the representer theorem still holds but the dimension of the parameter α becomes $r \times \left(m_{\mathcal{X}} + m_{\mathcal{Y}}\right)$ instead of $m_{\mathcal{X}} \times m_{\mathcal{Y}}$, which is usually beneficial. We note, however, that when a rank constraint is added to the Hilbert-Schmidt norm penalty, then the classical representer Theorem 2 and the expansion of the solution over N vectors (11) are not valid anymore, only Theorem 3 and the expansion (13) can be used. More importantly, this will likely have algorithmic/efficiency consequences.

5. Algorithms

In this section we explain how the optimization problem (14) can be solved in practice. We first consider a general formulation, then we specialize to the situation where many **x**'s and many **y**'s are identical; that is, we are in a matrix completion setting where it may be advantageous to consider other formulations that take into account some group structure explicitly.

5.1 Convex Dual of Spectral Regularization

When the loss is convex, we can derive the convex dual problem, which can be helpful for actually solving the optimization problem. As in the classical representer theorems, this could also provide an alternative proof of the representer theorem in that particular situation.

For all $i = 1, \ldots, N$, we let denote $\psi_i(v_i) = \ell(v_i, t_i)$ the loss corresponding to predicting v_i for the i-th data point. We now assume that each ψ_i is convex (this is usually met in practice). Following Bach et al. (2005), we let $\psi_i^*(\alpha_i)$ denote its Fenchel conjugate defined as $\psi_i^*(\alpha_i) = \max_{v_i \in \mathbb{R}} \alpha_i v_i - \psi_i(v_i)$. Minimizers of the optimization problem defining the conjugate function are often referred to as Fenchel duals to α_i (Boyd and Vandenberghe, 2003). In particular, we have the following classical examples:

- *Least-squares regression*: we have $\psi_i(v_i) = \frac{1}{2}(t_i - v_i)^2$ and $\psi_i^*(\alpha_i) = \frac{1}{2}\alpha_i^2 + \alpha_i t_i$.
- *Logistic regression*: we have $\psi_i(v_i) = \log(1 + \exp(-y_i v_i))$, where $y_i \in \{-1, 1\}$, and $\psi_i^*(\alpha_i) = (1 + \alpha_i t_i)\log(1 + \alpha_i t_i) - \alpha_i t_i \log(-\alpha_i t_i)$ if $\alpha_i t_i \in (-1, 0)$, $+\infty$ otherwise.

We also assume that the spectral regularization is such that for all $i \in \mathbb{N}$, $s_i = s$, where s is a *convex* function such that $s(0) = 0$. In this situation, we have $\Omega(A) = \sum_{i \in \mathbb{N}} s(\sigma_i(A))$. We can also define a Fenchel conjugate for $\Omega(A)$, which is also a spectral function $\Omega^*(B) = \sum_{i \in \mathbb{N}} s^*(\sigma_i(B))$ (Lewis and Sendov, 2002).[1]

Some special cases of interest for $s(\sigma)$ are:

1. Note that results on functions of eigenvalues of symmetric matrices can be extended to functions of singular values of rectangular matrices by using the equivalence between the singular value decomposition of A and the eigenvalue decomposition of $\begin{pmatrix} 0 & A \\ A^\top & 0 \end{pmatrix}$ (Stewart and Sun, 1990).

- $s(\sigma) = |\sigma|$ leads to the trace norm and then $s^*(\tau) = 0$ if $|\tau|$ is less than 1, and $+\infty$ otherwise.
- $s(\sigma) = \frac{1}{2}\sigma^2$ leads to the Frobenius/Hilbert Schmidt norm and then $s^*(\tau) = \frac{1}{2}\tau^2$.
- $s(\sigma) = \varepsilon \log(1 + e^{\sigma/\varepsilon}) + \varepsilon \log(1 + e^{-\sigma/\varepsilon})$ is a smooth approximation of $|\sigma|$, which becomes tighter when ε is closer to zero. We have: $s^*(\tau) = \frac{1}{\varepsilon}(1+\tau)\log(1+\tau) + \frac{1}{\varepsilon}(1-\tau)\log(1-\tau)$. Moreover, $s'(\sigma) = \tau \Leftrightarrow (s^*)'(\tau) = \sigma = \frac{1}{\varepsilon}\log\frac{1+\tau}{1-\tau}$.

Once the representer theorem has been applied, our optimization problem can be rewritten in the *primal* form in (14):

$$\min_{\alpha \in \mathbb{R}^{m_X \times m_Y}} \sum_{i=1}^{N} \psi_i((X\alpha Y^\top)_{ii}) + \lambda\Omega(\alpha). \tag{15}$$

We can now form the Lagrangian, associated with added constraints $v = \operatorname{diag}(X\alpha Y^\top)$ and corresponding Lagrange multiplier $\beta \in \mathbb{R}^N$:

$$\mathcal{L}(v, \alpha, \beta) = \sum_{i=1}^{N} \psi_i(v_i) - \sum_{i=1}^{N} \beta_i (v_i - (X\alpha Y^\top)_{ii}) + \lambda\Omega(\alpha),$$

and minimize with respect to v and W to obtain the *dual* problem, which is to maximize:

$$-\sum_{i=1}^{N} \psi_i^*(\beta_i) - \lambda\Omega^*\left(-\frac{1}{\lambda} X^\top \operatorname{Diag}(\beta) Y\right). \tag{16}$$

Once the optimal dual variable β is found (there are as many of those as there are observations), then we can go back to α (which may or may not be of smaller size), by Fenchel duality, that is, α is among the Fenchel duals of $-\frac{1}{\lambda}X^\top \operatorname{Diag}(\beta)Y$. Thus, when the function s is differentiable and strictly convex (which implies that the Fenchel dual is unique), then we obtain the primal variables α in closed form from the dual variables β. When s is not differentiable, for example, for the trace norm then, following Amit et al. (2007), we can find the primal variables by noting that once β is known, the singular vectors of α are known and we can find the singular values by solving a reduced convex optimization problem.

5.1.1 COMPUTATIONAL COMPLEXITY

Note that for optimization, we have two strategies, following the same two strategies in regular kernel methods: using the primal problem in Eq. (15) of dimension $m_{\mathcal{X}} m_{\mathcal{Y}} \leq n_{\mathcal{X}} n_{\mathcal{Y}}$ (the actual dimension of the underlying data) or using the dual problem in Eq. (16) of dimension N (the number of ratings). The choice between those two formulations is problem dependent.

5.2 Collaborative Filtering

In the presence of (many) identical columns and rows, which is often the case in collaborative filtering situations, the kernel matrices K and L have some columns (and thus rows) which are identical. In such cases, it is computationally more desirable to instead consider the kernel matrices (with their square-root decompositions) $\tilde{K} = \tilde{X}\tilde{X}^\top$ and $\tilde{L} = \tilde{Y}\tilde{Y}^\top$ as the kernel matrices for all distinct elements of $\mathcal{X}$ and $\mathcal{Y}$ (let $n_{\mathcal{X}}$ and $n_{\mathcal{Y}}$ be their sizes). Then each observation $(\mathbf{x}_i, \mathbf{y}_i, t_i)$ corresponds to a pair of indices $(a(i), b(i))$ in $\{1, \ldots, n_{\mathcal{X}}\} \times \{1, \ldots, n_{\mathcal{Y}}\}$, and the primal problem becomes:

$$\min_{\alpha \in \mathbb{R}^{m_{\mathcal{X}} \times m_{\mathcal{Y}}}} \sum_{i=1}^{n} \psi_i(\delta_{a(i)}^\top \tilde{X} \alpha \tilde{Y}^\top \delta_{b(i)}) + \lambda \Omega(\alpha),$$

where δ_u is a vector with only zeroes except at position u. The dual function is

$$-\sum_{i=1}^{N} \psi_i^*(\beta_i) - \lambda \Omega^* \left(-\frac{1}{\lambda} \tilde{X}^\top \sum_{i=1}^{N} \beta_i \delta_{a(i)} \delta_{b(i)}^\top \tilde{Y} \right).$$

Similar to usual kernel machines and the general case presented above, using the primal or the dual formulation for optimization depends on the number of available ratings N compared to the ranks $m_{\mathcal{X}}$ and $m_{\mathcal{Y}}$ of the kernel matrices $\tilde{K}$ and $\tilde{L}$. Indeed, the number of variables in the primal formulation is $m_{\mathcal{X}} m_{\mathcal{Y}}$, while in the dual formulation it is N.

5.3 Low-rank Constrained Problem

We approximate the spectral norm by an infinitely differentiable spectral function. Since we consider in this paper only infinitely differentiable loss functions, our problem is that of minimizing an infinitely differentiable convex function $G(W)$ over rectangular matrices of size $p \times q$ for certain integers p and q. As a result of our spectral regularization, we hope to obtain (approximately) low-rank matrices. In this context, it has proved advantageous to consider low-rank decompositions of the form $W = UV^\top$ where U and V have $m < \min\{p,q\}$ columns (Burer and Monteiro, 2005; Burer and Choi, 2006). Specifically, instead of optimizing a low-rank W directly, we can optimize U and V jointly in training. Burer and Monteiro (2005) have shown that if $m = \min\{p,q\}$ then the non-convex problem of minimizing $G(UV^\top)$ with respect to U and $V^\top$ has no local minima.

We now prove a stronger result in the context of twice differentiable functions, namely that if the global optimum of G has rank $r < \min\{p,q\}$, then the low-rank constrained problem with rank $r+1$ (or any larger rank, for that matter) has no local minimum and its global minimum corresponds to the global minimum of G. The following theorem makes this precise (see Appendix C for proof).

Proposition 5 *Let G be a twice differentiable convex function on matrices of size $p \times q$ with compact level sets. Let $m > 1$ and $(U,V) \in \mathbb{R}^{p \times m} \times \mathbb{R}^{q \times m}$ a local optimum of the function $H : \mathbb{R}^{p \times m} \times \mathbb{R}^{q \times m} \mapsto \mathbb{R}$ defined by $H(U,V) = G(UV^\top)$, that is, U is such that $\nabla H(U,V) = 0$ and the Hessian of H at (U,V) is positive semi-definite. If U or V is rank deficient, then $N = UV^\top$ is a global minimum of G, that is, $\nabla G(N) = 0$.*

The previous proposition shows that if we have a local minimum for the rank-m problem and if the solution is rank deficient, then we have a solution of the global optimization problem. This naturally leads to a sequence of reduced problems of increasing dimension m, smaller than $r+1$, where r is the rank of the global optimum. However, the number of iterations of each of the local minimizations and the final rank m cannot be bounded a priori in general.

Note that using a low-rank representation to solve the trace-norm regularized problem leads to a non-convex minimization problem with no local minima, while simply using the low-rank representation *without* the trace norm penalty and potentially with a Frobenius norm penalty, may lead to local minima. That is, instead of Eq. (14) with the trace norm, we consider the following formulation:

$$\min_{\alpha\in\mathbb{R}^{m_{\mathcal{X}}\times r},\ \beta\in\mathbb{R}^{m_{\mathcal{Y}}\times r}} R_N\left(\mathrm{diag}\left(X\alpha\beta^\top Y^\top\right)\right)+\lambda\sum_{q=1}^{r}\|\alpha(:,k)\|^2\|\beta(:,k)\|^2,$$

where $\alpha(:,k)$ and $\beta(:,k)$ are the k-th columns of α and β. In the simulation section, we compare the two approaches on a synthetic example, and show that the convex formulation solved through a sequence of non-convex formulations leads to better predictive performance.

5.4 Kernel Learning for Spectral Functions

In our collaborative filtering context, there are two potentially useful sources of kernel learning: learning the attribute kernels, or learning the weights η and ζ between Dirac kernels and attribute kernels. In this section, we show how multiple kernel learning (MKL) (Lanckriet et al., 2004; Bach et al., 2004) may be extended to spectral regularization.

We first prove a computationally useful fact about our particular objective function:

Proposition 6 *The dual solution of the optimization problem in Eq. (16) depends only on the matrix $K\otimes G$.*

Proof It suffices to show that for all matrices B, then the positive singular values of $X^\top BY$ only depend on $K\otimes G$. The largest singular value is defined as the maximum of $a^\top X^\top BYb$ over unit norm vectors a and b. By a change of variable, it is equivalent to maximize $\frac{(X^\top\tilde{a})X^\top BY(Y^\top\tilde{b})}{\|X^\top\tilde{a}\|\|Y^\top\tilde{b}\|} = \frac{\mathrm{vec}(\tilde{b}\tilde{a}^\top)(K\otimes G)\mathrm{vec}(B)}{\mathrm{vec}(\tilde{b}\tilde{a}^\top)^\top(K\otimes G)\mathrm{vec}(\tilde{b}\tilde{a}^\top)}$ with respect to $\tilde{a}$ and $\tilde{b}$ (Golub and Loan, 1996). Thus the largest positive singular value is indeed a function of $K\otimes G$. Results for other singular values may be obtained similarly. ■

This shows that the natural kernel matrix to be learned in our context is the Kronecker product $K\otimes G$. We thus follow Lanckriet et al. (2004) and consider M kernel matrices $K_1,\dots,K_M$ for $\mathcal{X}$ and M kernel matrices $G_1,\dots,G_M$ for $\mathcal{Y}$. One possibility could be to follow Lanckriet et al. (2004) and to learn a convex combination of the matrices $K_k\otimes G_k$ by minimizing with respect to the combination weights the optimal value of the problem in Eq. (16). However, unlike the usual Hilbert norm regularization, this does not lead to a convex problem in general. We thus focus on the alternative formulation of the MKL problem (Bach et al., 2004): we consider the sum of the predictor functions associated with each of the individual kernel pairs (K_k,G_k) and penalize by the sum of the norms.

That is, if we let denote $X_1,\dots,X_M$ and $Y_1,\dots,Y_M$ the respective square roots of matrices $K_1,\dots,K_M$ and $G_1,\dots,G_M$, we look for predictor functions which are sums of the M possible atomic predictor functions, and we penalize by the sum of spectral functions, to obtain the following optimization problem:

$$\min_{\forall k,\alpha_k\in\mathbb{R}^{m_x^k\times m_y^k}}\sum_{i=1}^{n}\psi_i\left(\sum_{k=1}^{M}(X_k\alpha_kY_k^\top)_{ii}\right)+\lambda\sum_{k=1}^{M}\Omega(\alpha_k).$$

We form the Lagrangian:

$$\mathcal{L}(v,\alpha_1,\dots,\alpha_M,\beta)=\sum_{i=1}^{n}\psi_i(v_i)-\sum_{i=1}^{N}\beta_i(v_i-\sum_{k=1}^{M}(X_k\alpha_kY_k^\top)_{ii})+\lambda\sum_{k=1}^{M}\Omega(\alpha_k),$$

and minimize w.r.t. v and $\alpha_1, \ldots, \alpha_M$ to obtain the dual problem, which is to maximize

$$-\sum_u \psi_i^*(\beta_i) - \sum_k \lambda \Omega^* \left(-\frac{1}{\lambda} X_k^\top \operatorname{Diag}(\beta) Y_k \right).$$

In the case of the trace norm, we obtain support kernels (Bach et al., 2004), that is, only a sparse combination of matrices ends up being used. Note that in the dual formulation, there is only one β to optimize, and thus it is preferable to use the dual formulation rather than the primal formulation.

6. Experiments

In this Section we present several experimental findings for the algorithms and methods discussed above. Much of the present work was motivated by the problem of collaborative filtering and we therefore focus solely within this domain. As discussed in Section 3, by using operator estimation and spectral regularization as a framework for CF, we may use potentially more information to predict preferences. Our primary goal now is to show that, as one would hope, such capabilities do improve prediction accuracy.

6.1 Data Sets and Metrics

We present several plots created by experimenting on synthetic data. This artificial data set was generated as follows: (1) sample i.i.d. multivariate features for x of dimension 6, (2) generate i.i.d. multivariate features for y of dimension 6 as well, (3) sample z from a random bilinear form in x and y plus some noise, (4) restrict the observed feature space to only 3 features for both x and y. Since part of the data is discarded, the label cannot be perfectly predicted by the known features. On the other hand, since we keep some of them, knowing and using these attributes should work better than not using them. In other words, we expect that setting η and ζ to be values other than 0 or 1 should provide better performance.

We also experimented with the well-known MovieLens 100k data set from the GroupLens Research Group at the University of Minnesota. This data set consists of ratings of 1682 movies by 943 users. Each user provided a rating, in the form of a score from $\{1,2,3,4,5\}$, for a small subset of the movies. Each user rated at least 20 movies, and the total number of ratings available is exactly 100,000, averaging about 105 per user. This data set was rather appropriate as it included attribute information for both the movies and the users. Each movie was labeled with at least one among 19 genres (e.g., action or adventure), while the users' attributes included age, gender, and an occupation among a list of 21 occupations (e.g., administrator or artist). We converted the users' age attribute to a set of binary features identifying one of five age categories.

All test set accuracies are measured as the root mean squared error averaged over 10-fold cross validations. In particular, we focus on the comparisons of intermediate values of η and ζ, compared to the four "corners" of the $\eta/\zeta-$parameter space:

- $\eta = 0, \zeta = 0$: matrix completion
- $\eta = 0, \zeta = 1$ and $\eta = 1, \zeta = 0$: multi-task learning on users or objects
- $\eta = 1, \zeta = 1$: pairwise learning

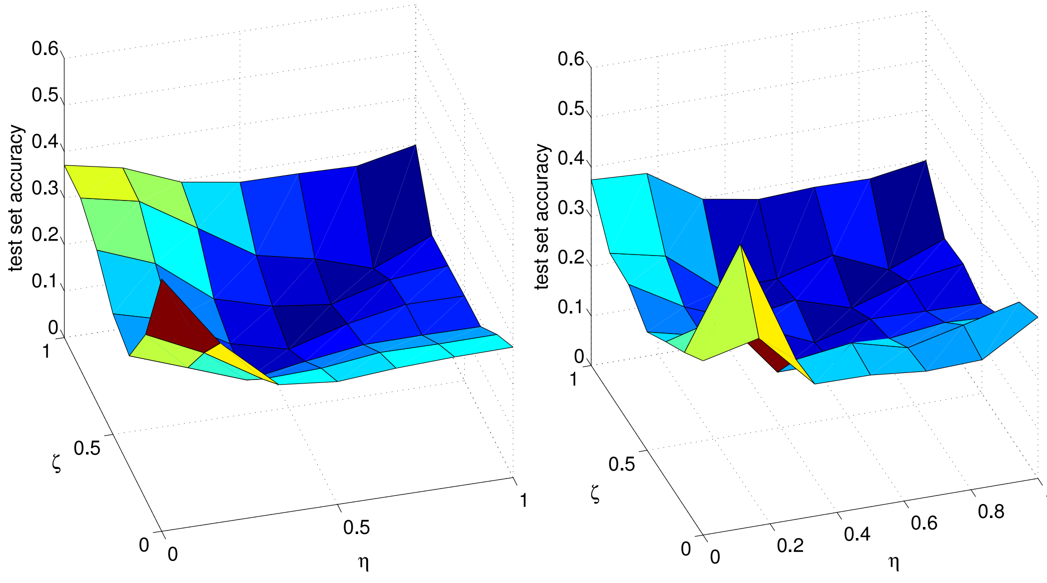

Figure 1: Comparison between two spectral penalties: the trace norm (left) and the Frobenius norm (right), each with an additional fixed rank constraint as described in Section 5.3. Each surface plot displays performance values over a range of η and ζ values, all obtained using the synthetic data set. The minimal value achieved by the trace norm is 0.1222 and the one achieved by the rank constraint is 0.1540.

6.2 Results

We now summarize a number of experimental results for several of the aforementioned algorithms.

6.2.1 TRACENORM VERSUS LOW-RANK

In Figure 1, we present two performance plots over the η/ζ parameter space, both obtained using the synthetic data set. The left plot displays the results when using the trace norm spectral penalty. Here we used the low rank decomposition formulation described in Section 5.3 which (by Proposition 5) has no local minima. The plot on the right uses the same rank-constrained formulation, but with a Frobenius norm penalty instead. The trace norm constrained algorithm performs slightly better. Moreover, best predictive performance is achieved in both cases in the middle of the square and not at any of the four corners.

6.2.2 KERNEL LEARNING

In Figure 2, we show the test set accuracy as a function of the regularization parameter, when we use the kernels corresponding to the four corners as the four basis kernels. We can see that we recover similar performance (error of 0.14 instead of 0.12) than by searching over all η and ζ's. The same algorithm could also be used to learn kernels on the attributes.

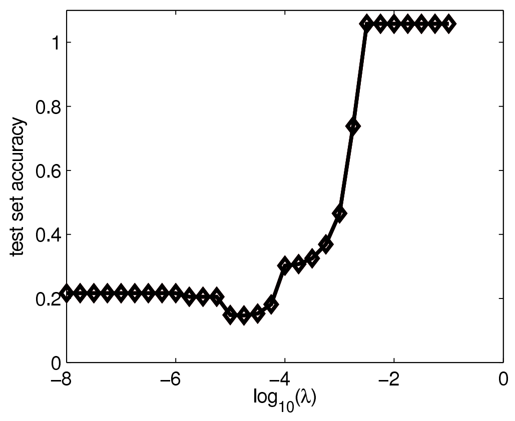

Figure 2: Learning the kernel: test set accuracy vs. regularization parameter. Minimum value is 0.14.

6.2.3 PERFORMANCE ON MOVIELENS DATA

Figure 3 shows the predictive accuracy in RMSE on the MovieLens data set, obtained by 10-fold cross-validation. The heat plot provides some insight on the relative value, for both movies and users, of the given attribute kernels versus the simple identity kernels. The corners have higher values than some of the values inside the square, showing that the best balance between attribute and Dirac kernels is achieved for η, ζ well inside the interior of $[0,1] \times [0,1]$.

7. Conclusions

We have presented a method for solving a generalized matrix completion problem where we have attributes describing the matrix dimensions. The problem is formalized as the problem of inferring a linear compact operator between two general Hilbert spaces, which generalizes the classical finite-dimensional matrix completion problem. We introduced the notion of spectral regularization for operators, which generalizes various spectral penalizations for matrices, and we proved a general representer theorem for this setting. Various approaches, such as standard low rank matrix completion, are special cases of our method. This framework is particularly relevant for CF applications where attributes are available for users and/or objects, and preliminary experiments confirm the benefits of our method.

An interesting direction of future research is to explore further the multi-task learning algorithm we obtained with low-rank constraint, and to study the possibility to derive on-line implementations that may better fit the need for large-scale applications where training data are continuously increasing. On the theoretical side, a better understanding of the effects of norm and rank regularizations and their interaction would be of considerable interest.

Appendix A. Compact Operators on Hilbert Spaces

In this appendix, we recall basic definitions and properties of Hilbert space operators. We refer the interested reader to general books (Brezis, 1980; Berlinet and Thomas-Agnan, 2003) for more details.

Let $\mathcal{X}$ and $\mathcal{Y}$ be two Hilbert spaces, with respective inner products denoted by $\langle \mathbf{x}, \mathbf{x}' \rangle_{\mathcal{X}}$ and $\langle \mathbf{y}, \mathbf{y}' \rangle_{\mathcal{Y}}$ for $\mathbf{x}, \mathbf{x}' \in \mathcal{X}$ and $\mathbf{y}, \mathbf{y}' \in \mathcal{Y}$. We denote by $\mathcal{B}(\mathcal{Y}, \mathcal{X})$ the set of bounded operators from $\mathcal{X}$ to $\mathcal{Y}$, that is, of continuous linear mappings from $\mathcal{Y}$ to $\mathcal{X}$. For any two elements $(\mathbf{x}, \mathbf{y})$ in $\mathcal{X} \times \mathcal{Y}$, we denote by $\mathbf{x} \otimes \mathbf{y}$ their *tensor product*, that is, the linear operator from $\mathcal{Y}$ to $\mathcal{X}$ defined by:

$$\forall \mathbf{h} \in \mathcal{Y}, \quad (\mathbf{x} \otimes \mathbf{y})\, \mathbf{h} = \langle \mathbf{y}, \mathbf{h} \rangle_{\mathcal{Y}} \mathbf{x}.$$

We denote by $\mathcal{B}_0(\mathcal{Y}, \mathcal{X})$ the set of *compact* linear operators from $\mathcal{Y}$ to $\mathcal{X}$, that is, the set of linear operators that map the unit ball of $\mathcal{Y}$ to a relatively compact set of $\mathcal{X}$. Alternatively, they can also be defined as the limit of finite rank operators.

When $\mathcal{X}$ and $\mathcal{Y}$ have finite dimensions, then $\mathcal{B}_0(\mathcal{Y}, \mathcal{X})$ is simply the set of linear mappings from $\mathcal{Y}$ to $\mathcal{X}$, which can be represented by the set of matrices of dimensions $\dim(\mathcal{X}) \times \dim(\mathcal{Y})$. In that case the tensor product $\mathbf{x} \otimes \mathbf{y}$ is represented by the matrix $\mathbf{x}\mathbf{y}^\top$, where $\mathbf{y}^\top$ denotes the transpose of $\mathbf{y}$.

For general Hilbert spaces $\mathcal{X}$ and $\mathcal{Y}$, any compact linear operator $F \in \mathcal{B}_0(\mathcal{Y}, \mathcal{X})$ admits a *spectral decomposition*:

$$F = \sum_{i=1}^{\infty} \sigma_i \mathbf{u}_i \otimes \mathbf{v}_i\,. \tag{17}$$

Here the the *singular values* $(\sigma_i)_{i\in\mathbb{N}}$ form a sequence of non-negative real numbers such that $\lim_{i\to\infty}\sigma_i = 0$, and $(\mathbf{u}_i)_{i\in\mathbb{N}}$ and $(\mathbf{v}_i)_{i\in\mathbb{N}}$ form orthonormal families in $\mathcal{X}$ and $\mathcal{Y}$, respectively. Although the vectors $(\mathbf{u}_i)_{i\in\mathbb{N}}$ and $(\mathbf{v}_i)_{i\in\mathbb{N}}$ in (17) are not uniquely defined for a given operator F, the set of singular values is uniquely defined. By convention we denote by $\sigma_1(F), \sigma_2(F), \ldots$, the successive singular values of F ranked by decreasing order. The *rank* of F is the number $\operatorname{rank}(F) \in \mathbb{N}\cup\{+\infty\}$ of strictly positive singular values.

We now describe three subclasses of compact operators of particular relevance in the rest of this paper.

- The set of operators with finite rank is denoted $\mathcal{B}_F(\mathcal{Y},\mathcal{X})$.
- The operators $F \in \mathcal{B}_0(\mathcal{Y},\mathcal{X})$ that satisfy:
$$\sum_{i=1}^{\infty}\sigma_i(F)^2 < \infty$$
are called *Hilbert-Schmidt* operators. They form a Hilbert space, denoted $\mathcal{B}_2(\mathcal{Y},\mathcal{X})$, with inner product $\langle\cdot,\cdot\rangle_{\mathcal{X}\otimes\mathcal{Y}}$ between basic tensor products given by:
$$\langle \mathbf{x}\otimes\mathbf{y}, \mathbf{x}'\otimes\mathbf{y}'\rangle_{\mathcal{X}\otimes\mathcal{Y}} = \langle \mathbf{x},\mathbf{x}'\rangle_{\mathcal{X}}\langle \mathbf{y},\mathbf{y}'\rangle_{\mathcal{Y}}\,. \tag{18}$$
In particular, the Hilbert-Schmidt norm of an operator in $\mathcal{B}_2(\mathcal{Y},\mathcal{X})$ is given by:
$$\|F\|_2 = \left(\sum_{i=1}^{\infty}\sigma_i(F)^2\right)^{\frac{1}{2}}.$$
Another useful characterization of Hilbert-Schmidt operators is the following. Each linear operator $F:\mathcal{Y}\to\mathcal{X}$ uniquely defines a bilinear function $f_H:\mathcal{X}\times\mathcal{Y}\to\mathbb{R}$ by
$$f(\mathbf{x},\mathbf{y}) = \langle \mathbf{x}, F\mathbf{y}\rangle_{\mathcal{X}}\,.$$
The set of functions f_F associated to the Hilbert-Schmidt operators forms itself a Hilbert space of functions $\mathcal{X}\times\mathcal{Y}\to\mathbb{R}$, which is the reproducing kernel Hilbert space of the product kernel defined for $((\mathbf{x},\mathbf{y}),(\mathbf{x}',\mathbf{y}'))\in(\mathcal{X}\times\mathcal{Y})^2$ by
$$k_{\otimes}\left((\mathbf{x},\mathbf{y}),(\mathbf{x}',\mathbf{y}')\right) = \langle \mathbf{x},\mathbf{x}'\rangle_{\mathcal{X}}\langle \mathbf{y},\mathbf{y}'\rangle_{\mathcal{Y}}\,.$$
- The operators $F \in \mathcal{B}_0(\mathcal{Y},\mathcal{X})$ that satisfy:
$$\sum_{i=1}^{\infty}\sigma_i(F) < \infty$$
are called *trace-class* operators. The set of trace-class operators is denoted $\mathcal{B}_1(\mathcal{Y},\mathcal{X})$. The *trace norm* of an operator $F\in\mathcal{B}_1(\mathcal{Y},\mathcal{X})$ is given by:
$$\|F\|_1 = \sum_{i=1}^{\infty}\sigma_i(F)\,.$$

Obviously the following ordering exists among these various classes of operators:
$$\mathcal{B}_F(\mathcal{Y},\mathcal{X}) \subset \mathcal{B}_1(\mathcal{Y},\mathcal{X}) \subset \mathcal{B}_2(\mathcal{Y},\mathcal{X}) \subset \mathcal{B}_0(\mathcal{Y},\mathcal{X}) \subset \mathcal{B}(\mathcal{Y},\mathcal{X})\,,$$
and all inclusions are equalities if $\mathcal{X}$ and $\mathcal{Y}$ have finite dimensions.

Appendix B. Proof of Theorem 3

We start with a general result about the decrease of singular values for compact operators composed with projection:

Lemma 7 *Let $\mathcal{G}$ and $\mathcal{H}$ be two Hilbert spaces, H a compact linear subspace of $\mathcal{H}$, and Π_H denote the orthogonal projection onto H. Then for any compact operator $F : \mathcal{G} \mapsto \mathcal{H}$ it holds that:*

$$\forall i \geq 1\,, \quad \sigma_i(\Pi_H F) \leq \sigma_i(F)\,.$$

Proof We use the classical characterization of the i-th singular value:

$$\sigma_i(F) = \max_{V \in \mathcal{V}_i(\mathcal{G})} \min_{\mathbf{x} \in V, \|\mathbf{x}\|_{\mathcal{G}}=1} \|F\mathbf{x}\|_{\mathcal{H}}\,,$$

where $\mathcal{V}_i(\mathcal{G})$ denotes the set of all linear subspaces of $\mathcal{G}$ of dimension i. Now, observing that for any $\mathbf{x}$ we have $\|\Pi_H F\mathbf{x}\|_{\mathcal{H}} \leq \|F\mathbf{x}\|_{\mathcal{H}}$ proves the Lemma. ■

Given a training set of patterns $(\mathbf{x}_i, \mathbf{y}_i)_{i=1,\ldots,N} \in \mathcal{X} \times \mathcal{Y}$, remember that we denote by $\mathcal{X}_N$ and $\mathcal{Y}_N$ the linear subspaces of $\mathcal{X}$ and $\mathcal{Y}$ spanned by the training patterns $\{\mathbf{x}_i\,, i = 1, \ldots, N\}$ and $\{\mathbf{y}_i\,, i = 1, \ldots, N\}$, respectively. For any operator $F \in \mathcal{B}_0(\mathcal{Y}, \mathcal{X})$, let us now consider the operator $G = \Pi_{\mathcal{X}_N} F \Pi_{\mathcal{Y}_N}$. By construction, F and G agree on the training patterns, in the sense that for $i = 1, \ldots, N$:

$$\langle \mathbf{x}_i, G\mathbf{y}_i \rangle_{\mathcal{X}} = \left\langle \mathbf{x}_i, \Pi_{\mathcal{X}_N} F \Pi_{\mathcal{Y}_N} \mathbf{y}_i \right\rangle_{\mathcal{X}} = \left\langle \Pi_{\mathcal{X}_N} \mathbf{x}_i, F \Pi_{\mathcal{Y}_N} \mathbf{y}_i \right\rangle_{\mathcal{X}} = \langle \mathbf{x}_i, F\mathbf{y}_i \rangle_{\mathcal{X}}\,.$$

Therefore F and G have the same empirical risk:

$$R_N(F) = R_N(G)\,. \tag{19}$$

Now, by denoting F^* the adjoint operator, we can use Lemma 7 and the fact that the singular values of an operator and its adjoint are the same to obtain, for any $i \geq 1$:

$$\begin{aligned} \sigma_i(G) &= \sigma_i(\Pi_{\mathcal{X}_N} F \Pi_{\mathcal{Y}_N}) \\ &\leq \sigma_i(F \Pi_{\mathcal{Y}_N}) \\ &= \sigma_i(\Pi_{\mathcal{Y}_N} F^*) \\ &\leq \sigma_i(F^*) \\ &= \sigma_i(F). \end{aligned}$$

This implies that the spectral penalty term satisfies $\Omega(G) \leq \Omega(F)$. Combined with (19), this shows that if F is a solution to (12), then $G = \Pi_{\mathcal{X}_N} F \Pi_{\mathcal{Y}_N}$ is also a solution. Observing that $G \in \mathcal{X}_N \otimes \mathcal{Y}_N$ concludes the proof of the first part of Theorem 3, resulting in (13).

We have now reduced the optimization problem in $\mathcal{B}_0(\mathcal{Y}, \mathcal{X})$ to a finite-dimensional optimization over the matrix α of size $m_{\mathcal{X}} \times m_{\mathcal{Y}}$. Let us now rephrase the optimization problem in this finite-dimensional space.

Let us first consider the spectral penalty term $\Omega(F)$. Given the decomposition (13), the non-zero singular values of F as an operator are exactly the non-zero singular values of α as a matrix, as soon as $(\mathbf{u}_1, \ldots, \mathbf{u}_{m_{\mathcal{X}}})$ and $\left(\mathbf{v}_1, \ldots, \mathbf{v}_{m_{\mathcal{Y}}}\right)$ form *orthonormal* bases of $\mathcal{X}_N$ and $\mathcal{Y}_N$, respectively. In order to be able to express the empirical risk $R_N(F)$ we must however consider a decomposition of F over the training patterns, as:

$$F = \sum_{i=1}^{N} \sum_{j=1}^{N} \gamma_{ij} \mathbf{x}_i \otimes \mathbf{y}_j \,. \tag{20}$$

In order to express the singular values from this expression let us introduce the *Gram matrices* K and G of the training patterns, that is, the $N \times N$ matrices defined for $i, j = 1, \ldots, N$ by:

$$K_{ij} = \left\langle \mathbf{x}_i, \mathbf{x}_j \right\rangle_{\mathcal{X}} \,, \quad G_{ij} = \left\langle \mathbf{y}_i, \mathbf{y}_j \right\rangle_{\mathcal{Y}} \,.$$

We note that by definition the ranks of K and G are respectively $m_{\mathcal{X}}$ and $m_{\mathcal{Y}}$. Let us now factorize these two matrices as $K = XX^\top$ and $G = YY^\top$, where $X \in \mathbb{R}^{N \times m_{\mathcal{X}}}$ and $Y \in \mathbb{R}^{N \times m_{\mathcal{Y}}}$ are any square roots, for example, obtained by kernel PCA or incomplete Cholesky decomposition (Fine and Scheinberg, 2001; Bach and Jordan, 2005). The matrices X and Y provide a representation of the pattern in two orthonormal bases which we denote by $(\mathbf{u}_1, \ldots, \mathbf{u}_{m_{\mathcal{X}}})$ and $\left(\mathbf{v}_1, \ldots, \mathbf{v}_{m_{\mathcal{Y}}}\right)$. In particular we have, for any $i, j \in 1, \ldots, N$:

$$\mathbf{x}_i \otimes \mathbf{y}_j = \sum_{l=1}^{m_{\mathcal{X}}} \sum_{m=1}^{m_{\mathcal{Y}}} X_{il} Y_{jm} \mathbf{u}_l \otimes \mathbf{v}_m \,,$$

from which we deduce:

$$F = \sum_{l=1}^{m_{\mathcal{X}}} \sum_{m=1}^{m_{\mathcal{Y}}} \left(\sum_{i=1}^{N} \sum_{j=1}^{N} X_{il} Y_{jm} \gamma_{ij} \right) \mathbf{u}_l \otimes \mathbf{v}_m \,.$$

Comparing this expression to (13) we deduce that:

$$\alpha = X^\top \gamma Y \,.$$

The empirical error $R_N(F)$ is a function of $f(\mathbf{x}_l, \mathbf{y}_l)$ for $l = 1, \ldots, N$. From (20), we see that:

$$f(\mathbf{x}_l, \mathbf{y}_l) = \sum_{i=1}^{N} \sum_{j=1}^{N} \gamma_{ij} K_{il} G_{lj} \,,$$

and therefore the vector of predictions $F_N = (f(\mathbf{x}_l, \mathbf{y}_l))_{l=1,\ldots,N} \in \mathbb{R}^N$ can be rewritten as:

$$F_N = \operatorname{diag}(K\gamma G) = \operatorname{diag}\left(X\alpha Y^\top\right) \,.$$

We can now replace the empirical risk $R_N(F_N)$ by $R_N\left(\operatorname{diag}\left(X\alpha Y^\top\right)\right)$ and the penalty $\Omega(F)$ by $\Omega(\alpha)$ to deduce the optimization problem (14) from (12), which concludes the proof of Theorem 3.

Appendix C. Proof of Proposition 5

Since the function has compact level sets, we may assume that we are restricted to an open bounded subset of $\mathbb{R}^{p \times q}$ where the second and first derivatives are uniformly bounded. We let denote $C > 0$ a common upper bound of all derivatives. The gradient of the function H is equal to $\nabla H = \binom{\nabla G^\top U}{\nabla G \; V}$, while the Hessian of H is the following quadratic form:

$$\nabla^2 H[(dU, dV), (dU, dV)] = 2 \operatorname{tr} dV^\top \nabla G dU + \nabla^2 G[U dV^\top + dU V^\top, U dV^\top + dU V^\top].$$

Without loss of generality, we may assume that the last columns of U and V are equal to zero (this can be done by rotation of U or V). The zero gradient assumption implies that $\nabla G^\top U = 0$ and $\nabla G V = 0$. While if we take dU and dV with the first $m-1$ columns equal to zero, and last columns equal to arbitrary u and v, then the second term in the Hessian is equal to zero. The positivity of the first term implies that for all u and v, $v^\top \nabla G u \geq 0$, that is, the gradient of G at $N = UV^\top$ is equal to zero, and thus we get a stationary point and thus a global minimum of G.

Abstract

We show that all consistent learning methods—that is, that asymptotically achieve the lowest possible expected loss for any distribution on (X,Y)—are necessarily localizable, by which we mean that they do not significantly change their response at a particular point when we show them only the part of the training set that is close to that point. This is true in particular for methods that appear to be defined in a non-local manner, such as support vector machines in classification and least-squares estimators in regression. Aside from showing that consistency implies a specific form of localizability, we also show that consistency is logically equivalent to the combination of two properties: (1) a form of localizability, and (2) that the method's global mean (over the entire X distribution) correctly estimates the true mean. Consistency can therefore be seen as comprised of two aspects, one local and one global.

Keywords: consistency, local learning, regression, classification

1. Introduction

In a supervised learning problem we are given an i.i.d sample $S_n = \{(x_i, y_i)\}_{i=1..n}$ of size n from some distribution P; then a new pair (x,y) is drawn from the same P and our goal is to predict y when shown only x. Our prediction (also called estimate, or guess) of y is written $f(S_n,x)$, some function that depends on the training set and the point at which we estimate (note that it is slightly atypical to have both the training set and point as inputs to f, but this will be very convenient in our setting). We call f a *learning method*; in the context of regression we will also use the term *estimator*, and in the context of classification we will use the term *classifier*. In both of these settings, if f achieves the lowest possible expected loss as $n \to \infty$, for every distribution, then we call f *consistent* (we will formalize all of these definitions later on; for now we just sketch the general ideas). Consistent estimators are of obvious interest due to their capability to learn without knowing in advance anything about the actual distribution.

When we look at the learning methods known to be consistent, we can separate them into two general types. In the first of these we have methods that are defined in a local manner, for example, the k-nearest-neighbor (k-NN) classifier (Stone, 1977; Devroye et al., 1996). The k-NN classifier guesses the class of a point x based on its nearest neighbors in the training set, thus, this classifier behaves in a 'local' way: only close-by points affect the estimate. More generally, by a locally-behaving method we mean one that, given a training set S_n and a point x at which to estimate the value of y, in some way treats the close-by part of the training set as the most important. A second type of consistent learning method is defined in a global manner, for example, support vector machines (see Vapnik, 1998; Steinwart, 2002, for a description and proof of consistency, respectively). It is not clear from the definition of support vector machines whether they behave locally or not: The separating hyperplane is determined based on the entire training set S_n, and furthermore does not depend on the specific point x at which we classify, perhaps leading us to expect that support vector machines do *not* behave locally. Thus, on an intuitive level we might think that some consistent methods behave locally and some do not.

This intuition also appears relevant when we consider regression: The k-NN regression estimator appears to behave locally, while on the other hand support vector regression (see, e.g., Smola and Schoelkopf, 1998), kernel ridge regression (Saunders et al., 1998), etc., seem not to have that property. Another example is that of orthogonal series estimation, that is, of using a weighted sum of fixed harmonic functions (Lugosi and Zeger, 1995); this method appears to not behave locally both because the harmonic functions are non-local and because the coefficients are determined in a way based on all of the data.

Despite the intuition that some consistent methods might not behave locally, we will see that in fact *all* of them necessarily behave in that manner. As mentioned before, we already know that some locally-behaving methods are consistent, since some are in fact defined in a local manner, for example, k-NN. What we will see is that all other consistent methods must *also* behave locally. In classification, this implies that, in particular, (properly regularized) support vector machines and boosting (Freund and Schapire, 1999; Zhang, 2004; Bartlett and Traskin, 2007) must behave locally, despite being defined in a way that appears global. In the area of regression, our results show that neural network estimators, orthogonal series estimators, etc., must behave locally if they are consistent, again, despite their being defined in a way that does not indicate such behavior.

In the rest of this introductory section we will present a summary of our approach and results as well as background regarding related work. While doing so we focus on regression problems since that setting allows for simpler and clearer definitions. For the same reasons we will also focus on regression in the main part of this paper; in a later section we will show how to apply our results to classification.

Our goal in regression is to estimate $f^*(x) = E(y|x)$, that is, the expected value of y conditioned on x, or the regression of y on x. Our hope is that $f(S_n,x)$ is close to $f^*(x)$. We say that f is consistent on a distribution P iff

$$L_n(f) \equiv E\left|f(S_n,x) - f^*(x)\right| \xrightarrow[n\to\infty]{} 0$$

where the expected value is taken over training sets S_n and observations x both distributed according to P (which is suppressed in the notation). If a method is consistent on all P then we call it consistent (this is sometimes called *universal consistency*). Note that there are stronger notions of consistency, such as requiring that the loss converge to 0 with probability 1 (see, e.g., Gyorfi et al., 2002), but we will focus on the loss as just described. Note also that the L_n loss is 'global' in that we average over all x, which makes it all the more interesting to see whether methods that minimize it must end up behaving locally.

The notion of local behavior that we will consider will be called *localizability*, and it entails that the method returns a similar estimate for x when shown S_n in comparison to the estimate it would have returned when shown only the part of S_n that is close to x. In other words, if we define

$$S_n(x,r) = \{(x_i,y_i) \in S_n \,:\, ||x_i - x|| \leq r\}$$

then a localizable method has the property that

$$f(S_n,x) \approx f(S_n(x,r),x)$$

for some small $r > 0$ (the formal definitions of all of these concepts will be given in later sections). More specifically, for any sequence $R_n \searrow 0$ we can see $g(S_n,x) = f\left(S_n\big(x,R_n\big),x\right)$ as a 'localization' of f, since it applies f to the close-by part of the training set for the particular point at which we estimate. In other words, a localizable method is one that behaves similarly to a localization of itself. (Note the convenience of the $f(S_n,x)$ notation here, that is, of seeing f as a function of both S_n and x.)

Why is the concept of localizability of interest? The main motivation for us is that, as we will see later, consistency implies a form of localizability. That is, even an estimator defined in what seems to be a global manner, for example, by minimizing a global loss of the general form

$$\frac{1}{n}\sum_{i=1..n} l\big(f(x_i),y_i\big) + \lambda c(f)$$

where l is, for example, least-squares, and c is (optional) complexity penalization—then even such an estimator must be in some sense localizable, if it is consistent. Thus, our first motivation is to point out that not only locally-defined methods like k-NN behave locally, but also all other consistent methods as well.

Aside from this main motivation for investigating localizability, another reason is that it allows us to answer questions such as, "What might happen if we localize a support vector machine?" That is, we can apply a support vector machine (or some other useful method) to only the close-by part of the training set, perhaps motivated by the fact that training on this smaller set is more computationally efficient, at least if all we need is to generate estimates at a small number of points. If support vector machines are localizable, then we in fact know that such an approach can be consistent; and if they are not localizable, then we may end up with a non-consistent method with poor performance. Thus, localizability can have practical applications.

Note that one can consider other ways to define local behaviour than localizability. In one such approach, we can evaluate the behavior of a method when altering the far-off part of the training set, as opposed to removing it (which is what we do with localizability). Work along those lines (Zakai and Ritov, 2008) arrives at similar conclusions to the ones presented here. Comparing the two approaches, localizability has the advantage of relevance to practical applications, as mentioned in the previous paragraph.

Previous work related to localizability has been done in the context of learning methods that work by minimizing a loss function: We can 'localize' the loss function by re-weighting it so that close-by points are more influential; this has been investigated in the context of Empirical Risk Minimization (ERM; Vapnik, 1998) (Bottou and Vapnik, 1992; Vapnik and Bottou, 1993), as well as in the specific case of linear regression (see, e.g., Cleveland and Loader, 1995, and references therein); this approach has also lead to various applications (Atkeson et al., 1997). In this paper we differ from these approaches in that we work in a more general context: Our approach is applicable to all learning methods, and not just those that are based on minimizing a loss function that can be re-weighted. Another difference is that we consider consistency in the sense of asymptotically arriving at the lowest possible loss achievable by any measurable function, and not in the sense of minimizing the loss within a set of finite VC dimension.

Another related work is that of Bengio et al. (2006), in which it was shown that kernel machines behave locally, in the sense of requiring a large number of examples in order to learn complex functions (because each local area must be learned separately). Our approach differs from this work in the way we define local behavior, and in that we are interested in all (consistent) learning methods, not just kernel machines. However, our conclusion is in agreement with theirs, that even methods that may appear to be global like support vector machines in fact behave locally.

We now sketch our main result, which is that consistency is logically equivalent to the combination of two properties (which will be given later, in Definitions 2 and 5): *Uniform Approximate Localizability* (UAL), which is a form of localizability, and *Weak Consistency in Mean* (WCM), which deals with the mean $Ef(S_n,x)$ estimating the true mean $Ef^*(x)$ reasonably well, where the expected values are taken over S_n and x. It will be easy to see that the UAL and WCM properties are 'independent' in the sense that neither implies the other, and therefore we can see consistency as comprised of two independent aspects, which might be presented as

$$\textbf{Consistency} \quad \Longleftrightarrow \quad \textbf{UAL} \oplus \textbf{WCM}.$$

This can be seen as describing consistency in terms of local (UAL) and global (WCM) aspects (WCM is 'global' in the sense of only comparing scalar values averaged over x).

Note that there are two issues here which might be surprising, the first of which has already been mentioned—that all consistent methods must behave locally. The second important issue is that WCM is sufficient, when combined with UAL, to imply consistency. That is, if our goal is to be consistent,

$$E|f(S_n,x) - f^*(x)| \longrightarrow 0 \tag{1}$$

then it is interesting that all that is needed in addition to behaving locally is a property close to

$$|Ef(S_n,x) - Ef^*(x)| \longrightarrow 0.$$

Note that the latter condition is very weak. For example, it is fulfilled by $g(S_n,x) = \frac{1}{n}\sum_i y_i$, the simple empirical mean of the y values in the sample S_n (ignoring the xs completely), since $\frac{1}{n}\sum_i y_i \longrightarrow Ey = Ef^*(x)$ a.s., where Ey is the mean of y. On the other hand, g does not fulfill the stronger property (1) except on trivial distributions.

Our main result, which has just been described, will also be generalized to settings other than that of methods consistent on the set of all distributions. This will lead to peculiar consequences: Consider, for example, the following two sets of distributions:

$$\mathbb{P}_1 = \left\{P \,:\, y = f^*(x) + \varepsilon \,,\, E\varepsilon = 0 \,,\, \varepsilon \text{ is independent of } x\right\} \quad , \quad \mathbb{P}_2 = \left\{P \,:\, Ey = 0\right\}$$

(note that $\mathbb{P}_1$ is simply regression with additive noise). It turns out that a method consistent on $\mathbb{P}_1$ must behave locally on that set (just as with the set of all distributions), but the same is not true for $\mathbb{P}_2$, where a consistent method does not necessarily behave locally. The reason for this will be explained later.

The rest of this work is as follows. In Section 2 we present the formal setting and other preliminary matters. In Section 3 we present definitions of local properties (and specifically UAL) as well as some results concerning them. In Section 4 we define the global concepts that we need, specifically WCM. In Section 5 we present our main result, the equivalence of consistency to the combination of UAL and WCM. In Section 6 we extend our results to various sets of distributions. In Section 7 we use results from previous sections in order to derive consequences for classification. In Section 8 we summarize our results and discuss some directions for future work. Finally, proofs of our results appear in the Appendices.

2. Preliminaries

We now complete the description of the formal setting in which we work, as well as lay out notation useful later. Most of this section deals with the context of regression; details specific to classification will appear in Section 7.

We consider distributions P on (X,Y) where $X \subset \mathbb{R}^d, Y \subset \mathbb{R}$. We assume that X,Y are bounded, $\sup_{x\in X} ||x||, \sup_{y\in Y} |y| \leq M_1$ for some $M_1 > 0$ which is the same for all distributions. Thus, when we say 'all distributions' we mean all distributions bounded by the same value of M_1. We also assume that our learning methods return bounded responses, $\forall S,x \quad |f(S,x)| \leq M_2$.[1] Let M be a constant fulfilling $M \geq M_1, M_2$. Importantly, note that while these boundedness assumptions are non-trivial in the context of regression, they do not limit us when we consider classification, as we will see in Section 7.

Note that we wrote $f(S,x)$ instead of $f(S_n,x)$ in the previous paragraph. The reason is that n will always denote the size of the original training set, which in turn will always be written as S_n. Since we will also apply f to to other training sets (in particular, subsets of S_n), for clarity of notation we will therefore write S for a general (finite) set of pairs (x_i,y_i) and define learning methods via $f(S,x)$.

Formally speaking, a learning method $f(S,x)$ is defined as a sequence of measurable functions $\{f_k\}_{k\in\mathbb{N}}$, where each f_k is a function on training sets of size k, that is,

$$f_k : (X\times Y)^k \times X \longrightarrow Y.$$

For brevity, we will continue to write f instead of f_k since which f_k is used is determined by the size of the training set that we pass to f, that is, $f(S,x) = f_{|S|}(S,x)$. For example, we will often denote by $\widetilde{S}$ a subset of the original training set S_n. Then in an expression of the form $f(\widetilde{S},x)$ the actual function used is f_m, where $m = |\widetilde{S}|$, and in this example we expect to have $m \leq n$ (where, as mentioned before, n is the size of the original training set S_n).

For any distribution P on (X,Y), we write $f^*(x) = E(y|x)$, as already mentioned, and we denote the marginal distribution on X by μ. We write f^*_P, μ_P instead of f^*, μ to make explicit the dependence on P when necessary. Denote by $\mathrm{supp}_X(P) = \mathrm{supp}(\mu_P)$ the support of μ_P. The measure of sets $B \subseteq X$ will be written in the form $\mu(B)$.

1. Note that this is a minor assumption since for most methods we have $\sup_x |f(S,x)| \leq C\cdot \max_i |y_i|$ for some $C > 0$, and the y_i values are already assumed to be bounded. If this does not hold, then we might in any case want to consider enforcing boundedness based on the sample, that is, to truncate values larger in absolute value than $\max_i |y_i|$, and in doing so perhaps improve performance. Finally, recall that we are concerned with consistent methods, that is, that behave similarly to f^* in the limit, and f^* is bounded.

We denote random variables by, for example, $(x,y) \sim P$ and $S_n \sim P$ where in the latter case we intend a random i.i.d sample of n elements from the distribution P. We will often abbreviate and write $x,y \sim P$ instead of $(x,y) \sim P$; also, we will write $x \sim P$ where we mean $x \sim \mu_P$. To prevent confusion we always use x and y to indicate a pair (x,y) sampled from P.

We will write the mean and variance of random variables v as $E(v) = Ev$ and $\sigma^2(v)$, respectively. More generally, expected values will be denoted by $E_{v \sim V} H(v) = E_v H(v)$ where v is a random variable distributed according to V and $H(v)$ is some function of v; we may write $EH(v)$ when the random variables are clear from the context. The conditional expected value of $H(v)$ given w will be written in the form $E_{v|w}(H(v))$.

We will work mainly with the $\mathcal{L}_1$ loss, which we can now write formally as

$$L_{n,P}(f) \equiv E_{S_n, x \sim P} \left| f(S_n,x) - f^*_P(x) \right|,$$

or, more briefly,

$$L_n(f) \equiv E_{S_n,x} \left| f(S_n,x) - f^*(x) \right|.$$

Note that for purposes of consistency (i.e., $L_n(f) \to 0$) all $\mathcal{L}_p$ losses are equivalent, since

$$\forall 0 < p < q \qquad E|z|^p \le (E|z|^q)^{p/q} \le (2M)^{p(q-p)/q} (E|z|^p)^{p/q}$$

where $z = f(S_n,x) - f^*(x)$. Thus, if one $\mathcal{L}_p$ loss converges to 0, so do all the others. Hence our results apply to all $\mathcal{L}_p$ norms; we work mainly with the $\mathcal{L}_1$ norm for convenience.

For any set $B \subseteq X$, denote by P_B the conditioning of P on B, that is, the conditioning of μ_P on B (and leaving unchanged the behavior of y given x). Denote the ball of radius r around x by $B_{x,r} = \{x' \in \mathbb{R}^d \ : \ ||x - x'|| \le r\}$. Let $P_{x,r} = P_{B_{x,r}}$.

Finally, we mention two useful conventions. Note that we defined consistency on a single distribution, and then consistency in general as the property of being consistent on all distributions. More specifically, for any property **A** that can hold for a method f on particular distributions, we say that f has property **A** on a *set* of distributions $\mathbb{P}$ when f has property **A** on all $P \in \mathbb{P}$. We also say that f has property **A** (without specifying P or $\mathbb{P}$) when it has property **A** on the set of *all* distributions (with bounded support). This convention will be used for consistency as well as for UAL and other properties.

Similarly, when we start by defining a property **A** on the set of all distributions, we then use the convention that f has property **A** on a set $\mathbb{P}$ when we simply replace $\forall P$ with $\forall P \in \mathbb{P}$. This convention will be used with the WCM property.

3. Local Behavior

In this section we consider local properties of learning methods. We will present a series of definitions, leading up to a definition of Uniform Approximate Localizability (UAL).

We start with some introductory definitions. For any two learning methods f, g, we say that they are **mutually consistent** iff

$$D_n(f,g) \equiv E_{S_n,x} \left| f(S_n,x) - g(S_n,x) \right| \underset{n \to \infty}{\longrightarrow} 0.$$

That is, f and g are mutually consistent if they behave asymptotically similarly according to a distance metric D_n. The term ‘mutual consistency’ is used since $D_n(f, f^*) = L_n(f)$ (where we can formally define $f^*(S,x) = f^*(x)$), that is, being mutually consistent with f^* is equivalent to being consistent. Thus, mutual consistency is a natural extension of consistency. Note that D_n obeys the triangle inequality,

$$\forall f,g,h \qquad D_n(f,g) \leq D_n(f,h) + D_n(h,g)$$

which will be convenient later.

We now define some useful notation for the topic of locality. For any training set S and $r \geq 0$, we call

$$S(x,r) = \{(x_i,y_i) \in S \,:\, ||x_i - x|| \leq r\}$$

a **local training set** for x within S, of radius r. For every learning method f and $r \geq 0$, let

$$f|_r(S,x) = f(S(x,r),x).$$

Note that, as mentioned previously, if $f = \{f_k\}_{k\in\mathbb{N}}$ then in the expression $f(S_n(x,r),x)$ (where S_n is, as always, the original training set of size n), we are passing $S_n(x,r),x$ to f_m, where $m = |S_n(x,r)|$, which will in general be smaller than $n = |S_n|$. Thus, formally speaking we might write

$$f|_r(S,x) = f_{|S(x,r)|}(S(x,r),x)$$

but for simplicity we will continue to drop the lower index on f. Note that $f|_r$ can also be formally defined as a series of functions $\{f|_{r,k}\}_{k\in\mathbb{N}}$, but again, for simplicity we avoid this.

In words, $f|_r$ is a learning method that results from forcing f to only work on local training sets of radius r around x, when estimating the value at x. For example, if f is a linear regression estimator then we can see $f|_r$ as performing local linear regression (Cleveland and Loader, 1995).

Continuing in our definitions, for any sequence $\{R_k\}_{k\in\mathbb{N}}, R_k \geq 0, R_k \to 0$, we call $f|_{\{R_k\}}$ a **local version**, or a **localization** of f; by this notation, we mean

$$f|_{\{R_k\}}(S,x) = f\big(S\big(x,R_{|S|}\big),x\big)$$

—that is, which R_k is used from the sequence $\{R_k\}$ depends on the size of the training set passed to $f|_{\{R_k\}}$. In particular, for the original training set S_n we have

$$f|_{\{R_k\}}(S_n,x) = f\big(S_n\big(x,R_n\big),x\big).$$

Note that, as a consequence, local versions are indeed 'local' in the limit since we have $R_n \to 0$.

We can now define one form of local behavior: Call a method f **localizable** on a distribution P iff there exists a local version $f|_{\{R_k\}}$ of f with which f is mutually consistent, that is,

$$D_n\left(f|_{\{R_k\}}, f\right) \underset{n\to\infty}{\longrightarrow} 0.$$

Thus, a localizable method is one that is similar, in the sense of mutual consistency, to a local version of it, which implies that it gives similar results when seeing the entire training set versus only the local part of it; we can localize the method without changing the estimates significantly. Note once more that the requirement $R_n \to 0$ is what makes this definition truly define local behavior.

We will also need a notion of a method that, when localized, is consistent. Call a method f **locally consistent** on a distribution P iff there exists a local version $f|_{\{R_k\}}$ of f which is consistent,

$$L_n\left(f|_{\{R_k\}}\right) = D_n\left(f|_{\{R_k\}}, f^*\right) \underset{n\to\infty}{\longrightarrow} 0.$$

That is, there is a way to localize f so that it becomes consistent.

Are all consistent learning methods localizable and locally consistent? Consider the latter property: It appears as if any consistent method must be locally consistent, since a consistent method can successfully 'learn' given any underlying distribution, and when we localize such a method we are in effect applying that same useful behavior in every local area. Thus, it seems reasonable to expect a localization of a consistent method to be consistent as well, and if this were true then it might have useful practical applications, as mentioned in the introduction. Yet this intuition turns out to be false, and a similar failure occurs for localizability:

Proposition 1 *A learning method exists which is consistent but neither localizable nor locally consistent.*

The proof of Proposition 1 (appearing in Appendix A) is mainly technical, and consists in constructing a method $f = \{f_k\}$ which becomes less smooth as n rises, and asymptotically considerably less smooth than the true f^*. That is, the issue is that we have required merely that the functions f_k be measurable, and it turns out that without additional assumptions they can behave erratically in a manner that renders f not locally consistent. The specific example that we construct in the proof involves functions f_k that behave oddly on an area close to Ex but otherwise perform well. It is then possible to show that the 'problematic area' near Ex can be large enough so that all local versions of the method behave poorly, but small enough so that the original method is consistent.

Now, the counterexample constructed in the proof of Proposition 1 might rightfully be called a 'fringe case'. Yet, it suffices to show that not all consistent methods are localizable, contrary perhaps to intuition. There is therefore the question of what to do. One solution to this matter is to work with a property stronger than consistency, one that includes an additional smoothness requirement. The disadvantage of such an approach is that we cannot immediately derive consequences for the various methods known to be consistent, unless we also prove that they have the stronger property.

Instead, the approach that we will follow is to define more complex notions of local behavior which can be used to arrive at properties equivalent to consistency. Thus, one major goal of this paper is to arrive at suitable definitions for the topic of local behavior, that on the one hand capture the intuition correctly and on the other allow useful results to be proven. The simple definitions given before fail in the second matter; we will now give definitions that remedy that problem.

In order to formulate our improved definitions we first require some preparation. For any $r, q \geq 0$ and distribution P, let

$$\bar{f}|_r^q(S,x) = E_{x' \sim P_{x,q \cdot r}} f(S(x,r),x'). \tag{2}$$

Compared to $f|_r$, $\bar{f}|_r^q$ adds a smoothing operation performed around the x at which we estimate. Note that if $q = 0$ then we interpret the expected value as a delta function and we get $\bar{f}|_r^0 = f|_r$. Note also that we require the actual unknown distribution P in the definition of $\bar{f}|_r^q$, that is, $\bar{f}|_r^q$ cannot be directly implemented in practice—$\bar{f}|_r^q$ is a construction useful mainly for theoretical purposes. However, we can implement an approximate version of $\bar{f}|_r^q(S,x)$ by replacing the true expectation with the empirical one. We will return to this matter later.

We define the following set of sequences:

$$\mathcal{T} = \Big\{ \{T_k\} \ : \ T_k \searrow 0 \ \text{strictly} \Big\}.$$

For any sequence $T = \{T_k\}$, let $\mathbf{T} = \{T_k \ : \ k \in \mathbb{N}\}$, that is, the set containing the elements in the sequence. For any such sequence $T = \{T_k\}$, we then define the set of its infinite subsequences and selection functions on them by

$$\mathcal{R}(T) = \Big\{ R = \{R_k\} \quad : \quad \mathbf{R} \subseteq \mathbf{T} \,,\, R_k \searrow 0 \Big\},$$
$$\mathcal{Q}(T) = \Big\{ Q : \mathbf{T} \to \mathbf{T} \quad : \quad Q(T_k) \searrow 0 \Big\}.$$

For any $T \in \mathcal{T}$ and $\{R_k\} \in \mathcal{R}(T)$, $Q \in \mathcal{Q}(T)$, we call $\bar{f}|_{\{R_k\}}^{\{Q(R_k)\}}$ a **smoothed local version** of f; by this notation, we mean to replace the q, r values in (2) in an appropriate manner, that is,

$$\bar{f}|_{\{R_k\}}^{\{Q(R_k)\}}(S,x) = E_{x' \sim P_{x,Q(R_{|S|}) \cdot R_{|S|}}} f\big(S(x, R_{|S|}), x'\big).$$

Note that on the original training set S_n we get

$$\bar{f}|_{\{R_k\}}^{\{Q(R_k)\}}(S_n,x) = E_{x' \sim P_{x,Q(R_n) \cdot R_n}} f\big(S(x, R_n), x'\big).$$

We now elaborate on these definitions. T is the set of possible values that $Q(R_n), R_n$ can take; these values must approach 0 as our goal is to consider local behavior. $\mathcal{R}(T)$ contains sequences of radii of local training sets; we require that $R_n \searrow 0$, as we are interested in behavior on local training sets with radius descending to 0, that is, that become truly 'local' asymptotically. $\mathcal{Q}(T)$ contains functions that become small when T_k is small; the values $Q(R_n)$ determine radii on which to smooth, via $Q(R_n) \cdot R_n$. Since $Q(R_n) \cdot R_n = o(R_n)$, the smoothing is done on radii much smaller (asymptotically negligibly small) than the radii of the local training sets R_n, and therefore this is a minor operation. In conclusion, a smoothed local version is similar to a local version, but adds an averaging operation on small radii.

We now start with our main definitions. The idea behind them is not overly complex, but their description is necessarily somewhat technical.

Definition 2 *Call a learning method f* ***Uniformly Approximately Localizable (UAL)*** *iff*

$$\begin{aligned}
&\forall P \quad \forall T \in \mathcal{T} \\
&\exists Q \in \mathcal{Q}(T) \\
&\forall Q' \in \mathcal{Q}(T) \,,\, Q' \geq Q \\
&\exists \{R_k\} \in \mathcal{R}(T) \\
&\forall \{R'_k\} \in \mathcal{R}(T) \,,\, \{R'_k\} \geq \{R_k\} \\
&\qquad D_n\left(\bar{f}|_{\{R'_k\}}^{\{Q'(R'_k)\}}, f\right) \underset{n\to\infty}{\longrightarrow} 0.
\end{aligned}$$

(Here the expression $\{R'_k\} \geq \{R_k\}$ simply implies an inequality for the entire series, that is, for all k. $Q' \geq Q$ implies $Q'(T_k) \geq Q(T_k)$ for all k.)

In essence, a UAL learning method is one for whom, for any choice of T, *all* large-enough choices of Q and $\{R_k\}$ are suitable in order to get similar behavior between f and a smoothed local version of f. That is, if we take $\{R_k\}$ and Q slowly enough to 0 then we get local behavior. Note that in any case taking $\{R_k\}$ to 0 very quickly is problematic since we may get empty local training sets, that is, $S_n(x, R_n) = \emptyset$.

Concerning our choice of name for this definition, 'uniformly' appears in the title 'uniformly approximately local' due to the requirement for all large-enough choices of $\{R_k\}, Q$ to be relevant, and 'approximately' appears because we allow smoothed local versions and not just local versions.

Both of these changes from the original definition of localizability are present in order to prevent odd counterexamples. A concrete counterexample was shown in Proposition 1 to make clear the need for smoothing; we do not present one in full for the uniformity requirement in order to save space.

Note that we only consider $\{R_k\}, Q$ taking values in some fixed T, and that while T is arbitrary it does need to be determined in advance. The issue is that if we instead allow all the values $[0,\infty)$ to appear in $\{R_k\}$ and Q then, due to this being an uncountable set, it is not clear to the authors if additional conditions are not required to prove our main results in that case. In any event, a countable set of possible values is of sufficient interest for any practical learning-theoretical purpose, and as already mentioned the actual set of possible values can be chosen in whatever manner is desired.

We also need a definition parallel to that of local consistency, as follows.

Definition 3 *Let **Uniform Approximate Local Consistency (UALC)** be the property defined exactly the same as UAL, except for replacing the last condition with*

$$L_n\left(\bar{f}|_{\{R'_k\}}^{\{Q'(R'_k)\}}\right) = D_n\left(\bar{f}|_{\{R'_k\}}^{\{Q'(R'_k)\}}, f^*\right) \underset{n\to\infty}{\longrightarrow} 0.$$

A UALC method is one whose smoothed local versions are consistent for any large-enough choice of $Q, \{R_k\}$.

We now mention some properties of UAL and UALC, noting first that they are independent, in that each can exist without the other. Consider the following two methods:

$$f_y(S,x) = \frac{1}{|S|}\sum_{i=1..|S|} y_i, \qquad\qquad f_0(S,x) = 0 \tag{3}$$

f_y (called thus because it considers only the y values) is UALC since a local version of it is simply a kernel estimator, using the 'window kernel' $k(x) = 1\{||x|| \le 1\}$, and thus consistent, for any $\{R_k\}$ fulfilling $nR_n^d \to \infty$ (Devroye and Wagner, 1980); $\{R_k\}$ acts as the bandwidth parameter of a kernel estimator. (Note that smoothing has no effect, as the guess does not depend on x.) f_y, however, clearly cannot be UAL (e.g., consider the simple example of x uniform on $[-1,1]$ and $y = \text{sign}(x)$); neither is it consistent. Turning to f_0, this method is clearly UAL but it is neither UALC nor consistent.

Our first main result is that consistency is equivalent to the combination of UAL and UALC:

Theorem 4 *A learning method is consistent iff it is both UAL and UALC.*

In light of the independence of UAL and UALC, mentioned before, we can summarize this as

$$\textbf{Consistency} \quad \Longleftrightarrow \quad \textbf{UAL} \oplus \textbf{UALC}.$$

The proof of $\Leftarrow$ is immediate: Pick any T. We derive some $Q, \tilde{Q}$ from the appropriate $\exists$ clauses of the definitions of UAL and UALC, respectively; let $Q' \in \mathcal{Q}(T)$ fulfill $Q' \ge Q, \tilde{Q}$. Given Q', we can then derive some $\{R_k\}, \{\tilde{R}_k\}$ from the appropriate $\exists$ clauses of UAL and UALC; let $\{R'_k\} \in \mathcal{R}(T)$ fulfill $R'_k \ge R_k, \tilde{R}_k$. It is then clear that

$$D_n\left(\bar{f}|_{\{R'_k\}}^{\{Q'(R'_k)\}}, f^*\right), D_n\left(\bar{f}|_{\{R'_k\}}^{\{Q'(R'_k)\}}, f\right) \longrightarrow 0$$

due to UALC and UAL. By the triangle inequality we get

$$D_n(f,f^*) \le D_n\left(f, \bar{f}|_{\{R'_k\}}^{\{Q'(R'_k)\}}\right) + D_n\left(\bar{f}|_{\{R'_k\}}^{\{Q'(R'_k)\}}, f^*\right) \longrightarrow 0 \tag{4}$$

that is, consistency. Thus, it is fairly immediate from the definitions of UAL and UALC that together they suffice for consistency. What is interesting is that they are equivalent to it. Instead of proving that fact directly, the remainder of the proof of Theorem 4 will be a corollary of the results in Section 5.

4. Global Properties

In this section we define global properties that will be useful in the next section, where we present our main results.

First we need some preliminary definitions. We define the means of f, f^* in the natural way,

$$E_n(f) \equiv E_{n,P}(f) \equiv E_{S_n,x} f(S_n,x),$$

$$E(f^*) \equiv E_P(f^*) \equiv E_x f^*(x) = E_x E(y|x) = Ey$$

the latter expression which is just the global mean of y. We also want to consider the Mean Absolute Deviation (MAD) of f and f^*,

$$\text{MAD}_n(f) \equiv \text{MAD}_{n,P}(f) \equiv E_{S_n,x}\left|f(S_n,x) - E_n(f)\right|,$$

$$\text{MAD}(f^*) \equiv \text{MAD}_P(f^*) \equiv E_x\left|f^*(x) - E(f^*)\right|.$$

We can now define the first version of the global property of interest to us: We say that f is **consistent in mean** iff

$$\forall P \qquad \lim_{n\to\infty} |E_n(f) - E(f^*)| \;=\; \lim_{n\to\infty} |\text{MAD}_n(f) - \text{MAD}(f^*)| \;=\; 0.$$

A consistent in mean learning method is required to correctly estimate $E(f^*)$ and $\text{MAD}(f^*)$; that is, we require that the global behavior of f, averaged over x, be asymptotically equal to that of f^*. Note that we are only interested here in two scalar values which represent global averages of the behavior of f, f^*.

Consistency in mean is obviously a weaker property than requiring that, on average, f behave similarly to f^* on every x separately—that is, consistency—since

$$|E_n(f) - E(f^*)| = |E_{S_n,x} f(S_n,x) - E_x f^*(x)| \le E_{S_n,x}\left|f(S_n,x) - f^*(x)\right|. \tag{5}$$

By consistency the RHS converges to 0, and therefore so does the LHS. Consider now the MAD:

$$\begin{aligned}
\text{MAD}_n(f) &= E_{S_n,x}|f(S_n,x) - E_n(f)| \\
&= E_{S_n,x}|f(S_n,x) - f^*(x) + f^*(x) - E(f^*) + E(f^*) - E_n(f)| \\
&\le E_{S_n,x}|f(S_n,x) - f^*(x)| + E_x|f^*(x) - E(f^*)| + |E(f^*) - E_n(f)| \\
&\le D_n(f,f^*) + \text{MAD}(f^*) + |E(f^*) - E_n(f)|.
\end{aligned}$$

Of the last three expressions, the first converges to 0 by consistency, and the third by (5) (which was implied by consistency). Similarly,

$$\mathrm{MAD}_n(f) \geq \mathrm{MAD}(f^*) - D_n(f,f^*) - |E(f^*) - E_n(f)|$$

showing that $|\mathrm{MAD}_n(f) - \mathrm{MAD}(f^*)| \to 0$. Thus, unsurprisingly, consistency implies consistency in mean.

It turns out that a weaker property than consistency in mean is sufficient for our purposes:

Definition 5 *We say that f is* ***Weakly Consistent in Mean (WCM)*** *iff there exists a function H : $\mathbb{R} \to \mathbb{R}$, $H(0) = 0$, $\lim_{t\to 0} H(t) = 0$, for which*

$$\forall P \qquad \limsup_{n\to\infty} \left|E_n(f) - E(f^*)\right| \,,\, \limsup_{n\to\infty} MAD_n(f) \ \leq \ H\big(MAD(f^*)\big).$$

(Note that the same H is used for all P.) A WCM learning method is required only to do 'reasonably' well in estimating the global properties of the distribution, in a way that depends on the MAD, that is, on the difficulty: We only require that performance be good when the learning task is overall quite easy, in the sense of $f^*(x)$ being almost constant. Note that when $H(\mathrm{MAD}(f^*)) \geq 2M$ we require nothing of f for such f^* (since $|f|, |f^*| \leq M$), and also that for small $\mathrm{MAD}(f^*)$ we may allow the MAD of f to be significantly larger than that of f^* (consider, for example, $H(t) = c \cdot (\sqrt{t} + t)$ for large $c > 0$). Note also that we take the lim sups, that is, we do not even require that the limits exist (except in the trivial case where $\mathrm{MAD}(f^*) = 0$).

To see the justification for the adjective 'weak', note first that consistency in mean immediately implies WCM, using $H(t) = t$. Second, recall the example hinted at in the introduction: $f_y(S,x) = \frac{1}{n}\sum_i y_i$ is clearly not consistent, since it ignores the xs, nor is it consistent in mean, since

$$\mathrm{MAD}_n(f_y) = E_{S_n,x}|f_y(S_n,x) - E_n(f_y)| = E_{y_1,\ldots,y_n}\left|\frac{1}{n}\sum_i y_i - Ey\right| \longrightarrow 0.$$

However, f_y is WCM, since $E_n(f_y) \to E(f^*)$ and, as just mentioned, f_y's MAD converges to 0. (In fact, f_y is WCM with $H \equiv 0$, that is, in the strongest sense. That is, there are even 'weaker' methods that are WCM.)

5. Main Result

In this section we present our main result, the logical equivalence of consistency to the combination of the UAL and WCM properties. This will be arrived at during the course of proving the final step of Theorem 4.

The logical relationships between the concepts of consistency, UAL, UALC and WCM are shown in graph form in Figure 1. Note that we already saw that consistency implies WCM (since consistency implies consistency in mean, which implies WCM), and that UAL combined with UALC implies consistency (shown immediately after the statement of Theorem 4). Instead of proving directly that consistency implies UAL and UALC, we will prove that WCM implies UALC, and hence that consistency implies UALC. Consistency combined with UALC, in turn, implies UAL, since

$$D_n\left(f, \bar{f}|_{\{R_k\}}^{\{Q(R_k)\}}\right) \leq D_n\left(f,f^*\right) + D_n\left(\bar{f}|_{\{R_k\}}^{\{Q(R_k)\}}, f^*\right) \to 0$$

similarly to (4). Thus, in order to complete the picture sketched in Figure 1, it remains to show that

$$\begin{tikzcd} \textbf{Consistency} \arrow[r, shift left] \arrow[drrr] & (\ \textbf{UAL} \arrow[l, shift left] & + & \textbf{UALC}\ ) \\ & & & \textbf{WCM} \arrow[u] \end{tikzcd}$$

Figure 1: Logical relations between consistency, Uniform Approximate Localizability (UAL), Uniform Approximate Local Consistency (UALC) and Weak Consistency in Mean (WCM). That is, consistency is equivalent to the combination of UAL and UALC; consistency implies WCM; and WCM implies UALC.

Lemma 6 *A learning method that is WCM is UALC.*

The proof of Lemma 6 is the most complex of our results; we now sketch it very briefly (the full proof appears in Appendix B). The initial idea is to consider $S_n(x,r)$ as $|S_n(x,r)|$ points derived from $P_{x,r}$. The expected loss of a smoothed local version can then be seen to be approximately equal to a mean of expected losses over $P_{x,r}$ for various x. The expected losses over $P_{x,r}$ can, in turn, be bounded by the MADs of $f^*_{P_{x,r}}$ and f as well as the difference between their means; we bound the latter two using the WCM property. Finally, we construct in a recursive manner Q and $\{R_k\}$ that fulfill the requirements of UALC, using some results from measure theory regarding the asymptotic behavior of $f^*_{P_{x,r}}$.

Based on our results thus far, as summarized in Figure 1, it is obvious that we can also conclude the following:

Corollary 7 *A learning method is consistent iff it is both UAL and WCM.*

This can be stated as

$$\textbf{Consistency} \quad \Longleftrightarrow \quad \textbf{UAL} \oplus \textbf{WCM}$$

since just like UAL and UALC, UAL and WCM are clearly independent in that neither implies the other, in fact, the same two examples seen in (3) apply here: f_y has already been mentioned to be WCM, while clearly it is not UAL, whereas f_0 is UAL but not WCM.

6. Localizable Sets of Distributions

Thus far we have been concerned with consistency in the sense of the set of all (appropriately bounded) distributions; this is a very general case. However, many specific types of learning problems consider more limited sets of distributions. Our goal in this section is to apply our results to such problems. In addition, this section will provide some of the tools used in Section 7 to derive results for classification.

This section relies on the following definition:

Definition 8 *We call a set of distributions $\mathbb{P}$ **localizable** iff*

$$P \in \mathbb{P} \qquad \Longrightarrow \qquad \forall r \geq 0, x \in \text{supp}_X(P) \quad P_{x,r} \in \mathbb{P}.$$

That is, a localizable set of distributions contains all conditionings of its distributions onto small balls. Simple inspection of the proof of Lemma 6 reveals that it holds true on localizable sets of distributions, and not just on the set of all distributions, simply because we apply the WCM property of f only on distributions $P_{x,r}$. Consequently, it is easy to see that our results—specifically, Theorem 4 and Corollary 7—apply to localizable sets in general, and not just to the set of all distributions bounded by some constant $M > 0$ (which is just one type of example of a localizable set). Note that the requirement that a set of distributions be localizable is in a sense the minimal requirement we would expect, since if f is consistent on a distribution P but not on some $P_{x,r}$ then there is no reason to expect f to be UALC. We will say more about this matter in Section 8.

Are all standard learning problems defined (perhaps implicitly) on localizable sets of distributions? The answer is no; for example, if we assume that $Ey = 0$, which implies $E_x f^*(x) = 0$, then this is clearly not necessarily preserved when we consider some $P_{x,r}$. However, the converse is true for many standard setups in statistics and machine learning. Specific examples include the following, to all of which our results apply (assuming the boundedness assumption is upheld):

1. $y = f^*(x) + \varepsilon$, ε is independent of x , $E\varepsilon = 0$

   This is the standard regression model with additive noise (and random design) appearing in statistics. It is clearly a setup that implicitly works on a localizable set since $P_{x,r}$ retains the property that $y = f^*(x) + \varepsilon$.

2. As a subcase of the previous example, we can assume that $f^* \in \mathcal{F}$, where $\mathcal{F}$ is the set of all continuous functions, or alternatively some 'smoothness class', for example, Lipschitz-continuous functions, etc. Note, however, that if the density of the marginal distribution on X is assumed to be bounded then this is no longer a localizable set.

3. $P\big(y = f^*(x)\big) = 1$, $\forall S,x \;\; f(S,x), f^*(x) \in \{-1,+1\}$

   This is a noiseless classification problem, or set-estimation problem with non-overlapping sets, since

   $$P\big(f(S_n,x) \neq y\big) = E_{S_n,(x,y)} 1\{f(S_n,x) \neq y\} = \frac{1}{2} E_{S_n,x} \big|f(S_n,x) - f^*(x)\big| = \frac{1}{2} L_n(f).$$

   That is, the 0-1 loss used in classification is equal to (half) the $\mathcal{L}_1$ loss in this case. Note, however, that we assume $f(S,x) \in \{-1,+1\}$, and smoothed local versions do not have this property; for them the equality between the 0-1 and $\mathcal{L}_1$ losses is not valid. If we are willing to use the $\mathcal{L}_1$ norm for classification, however, then our results apply here.

   In the next section we will see a way to derive results for the 0-1 loss, as well as allow noisy distributions, that is, the standard classification setup. This will require somewhat different definitions than those used for regression.

4. $x = \phi(z)$ for some random variable z, where $\phi : R^d \to R^D$ is smooth and $D > d$.

   We conclude with this final somewhat more complex example in order to show how localizable sets can be present even in settings where we might not expect them. In the setting described here, the original data (z,y) lies on some low-dimensional space, but we observe $(x,y) = (\phi(z),y)$, which lies on a low-dimensional manifold inside a high-dimensional space. This sort of setting is considered in the manifold-learning field in unsupervised learning (see, e.g., Roweis and Saul, 2000; Belkin and Niyogi, 2003); recently such methods have been applied to supervised learning (see, e.g., Kouropteva et al., 2003; Li et al., 2005). Note also the relevance to the kernel trick, in which a kernel implicitly defines such a transformation ϕ.

The assumption of $x = \phi(z)$ (and that ϕ is smooth) is a nontrivial requirement; however, it is easy to see that if we consider the set of all ϕ and z then this set is a localizable set of distributions.

7. Classification

As mentioned in the previous section, noiseless classification in the $\mathcal{L}_1$ norm can be dealt with using the results we have seen thus far, but this is quite limiting. Therefore in this section we consider the standard case of classification, using the natural 0-1 loss, and allowing for the possibility of noise.

In classification (also known as pattern recognition; Devroye et al., 1996) we consider only distributions for whom $Y = \{-1,+1\}$; when we say 'all distributions' in this section we mean only distributions of this sort. Note that such distributions form a localizable set, and thus we might expect our results to apply to them. Note also that $f^*(x) = E(y|x) = 2\eta(x) - 1$ where $\eta(x) = P(y = 1|x)$, the conditional probability. We call a learning method c a **classifier** iff $\forall S,x\ \ c(S,x) \in \{-1,+1\}$. We will use c,d, etc., to denote classifiers, to differentiate them from general learning methods, which we generally denote f,g.

In classification the natural loss is the 0-1,

$$R_{0-1}(c) = P\left(c(S_n,x) \neq y\right) = E_{S_n,(x,y)} 1\{c(S_n,x) \neq y\}$$

and the minimal (Bayesian) loss is

$$R^*_{0-1} = \inf_h E_{x,y} 1\{h(x) \neq y\}$$

where the infimum is taken over all measurable h. Denote the optimal (Bayesian) classification rule by

$$c^*(x) = \operatorname{sign}(f^*(x)) = \operatorname{sign}(2\eta(x) - 1)$$

which clearly minimizes R_{0-1}. We are interested in the relative loss $\Delta R_{0-1}(c) = R_{0-1}(c) - R^*_{0-1}$. This is well-known to be equal to (half the value of)

$$\widetilde{L}_n(c) \equiv E_{S_n,x}|c(S_n,x) - c^*(x)| \cdot |2\eta(x) - 1| = E_{S_n,x}|c(S_n,x) - c^*(x)| \cdot |f^*(x)|.$$

That is, we have the usual $\mathcal{L}_1$ loss but it is weighted according to the distance of $\eta(x)$ from $1/2$. Another difference is that we compare c to $c^* = \operatorname{sign}(f^*)$ and not to f^*. These differences between $\widetilde{L}_n$ and the loss L_n we considered in the main part of this work prevent an immediate application of our results. We will therefore present alternative definitions that will allow us to get around this problem.

First, we define mutual consistency in the context of classification, which we will call **mutual classification-consistency** (or, briefly, **mutual *C*-consistency**), using

$$\widetilde{D}_n(c,d) = E_{S_n,x}|c(S_n,x) - d(S_n,x)| \cdot |2\eta(x) - 1| \longrightarrow 0$$

—that is, we simply add the same weighting as in $\widetilde{L}_n$. This leads to defining **classification-consistency** (or, briefly, ***C*-consistency**) on a distribution P as

$$\widetilde{L}_n(c) = \widetilde{D}_n(c,c^*) = E_{S_n,x}|c(S_n,x) - c^*(x)| \cdot |2\eta(x) - 1| \longrightarrow 0$$

(denoting $c^*(S,x) = c^*(x)$). Note that, in a similar way as in regression, C-consistency is a specific case of mutual C-consistency.

A change needs to be made to smoothed local versions to ensure that they remain classifiers, since $\bar{c}|_r^q$ can return values not in $\{-1,+1\}$. Define, therefore,

$$\widetilde{c}|_r^q(S,x) = \operatorname{sign}\left(\bar{c}|_r^q(S,x)\right) = \operatorname{sign}\left(E_{x' \sim P_{x,qr}} c(S(x,r),x')\right).$$

When we talk of smoothed local versions in the context of classification, we intend $\widetilde{c}|_r^q$.

We can now define a version of UAL for the context of classification, in the following natural way. Let ***C*-UAL** be the same as UAL, but replace D_n with $\widetilde{D}_n$, f with c and $\bar{f}|_r^q$ with $\widetilde{c}|_r^q$.

Instead of proving results 'from scratch' for the definitions given in this section, we can build upon the previous ones, using the following general technique. Let f_{ker} be a consistent Nadaraya-Watson kernel estimator using the window kernel. Define

$$f_{|\cdot|}(S,x) = |f_{\text{ker}}(S,x)|.$$

For any classifier c, define a learning method

$$f_c(S,x) = c(S,x) f_{|\cdot|}(S,x).$$

We can see $f_c(S,x)$ as an estimate of $f^*(x)$, using (in a plug-in manner) $c(S,x)$ to estimate $\operatorname{sign}(f^*(x))$ and $f_{|\cdot|}(S,x)$ to estimate $|f^*(x)|$.

We will now use our results on regression for estimators f_c in order to arrive at conclusions for classifiers c. Note that $|f_c(S,x)| \leq 1$ (since f_{ker} uses the window kernel, it is bounded by the largest $|y_i|$ in the training set, which is 1). Given the additional fact that in classification we have $Y = \{-1,+1\}$, we can conclude that our boundedness assumption on learning methods is of no consequence to our treatment of classification, that is, to get completely general results for classification we need only rely on bounded regression with $M = 1$.

To arrive at results, we will need some minor facts:

Lemma 9 *The following hold true for every P, c, d:*

1. $D_n(f_c, f_d) \to 0 \iff \widetilde{D}_n(c,d) \to 0.$
2. $D_n(f_c, f^*) \to 0 \iff \widetilde{D}_n(c,c^*) \to 0.$
3. *f_c is UALC* $\Rightarrow$ $D_n\left((\bar{f}_c)|_{\{R_k\}}^{\{Q(R_k)\}}, f_{\widetilde{c}|_{\{R_k\}}^{\{Q(R_k)\}}}\right) \to 0$
   for large-enough $Q, \{R_k\}$ in the sense appearing in the definitions UAL,UALC.

The first part of the lemma indicates that the C-mutual consistency of any c, d are linked to the mutual consistency of f_c, f_d; the second does the same for C-consistency and consistency. The third part of the lemma shows that if f_c is UALC then smoothed local versions of f_c are asymptotically equivalent to $f_{c'}$, where c' is a smoothed local version in the sense of classification of c (in other words, we can either smooth f_c or first smooth c and then apply f; the result is similar). A proof of all parts of the lemma appears in Appendix E.

We can now present an example of deriving results for classification from those for regression. Assume that c is C-consistent on some localizable set $\mathbb{P}$. Then f_c is consistent on $\mathbb{P}$ by part 2 of

Lemma 9, hence by Theorem 4 (and what we have seen regarding localizable sets in Section 6) f_c is UAL on $\mathbb{P}$, that is, for every $P \in \mathbb{P}$ we have

$$D_n\left(f_c, (\bar{f_c})|_{\{R_k\}}^{\{Q(R_k)\}}\right) \to 0$$

for large-enough Q, R_k in the sense of the definition of UAL. f_c is also UALC on $\mathbb{P}$, and therefore for large enough Q, R_k we have

$$D_n\left((\bar{f_c})|_{\{R_k\}}^{\{Q(R_k)\}}, f_{\tilde{c}|_{\{R_k\}}^{\{Q(R_k)\}}}\right) \to 0$$

by part 3 of Lemma 9, and therefore we conclude by the triangle inequality that (again, for large enough Q, R_k)

$$D_n\left(f_c, f_{\tilde{c}|_{\{R_k\}}^{\{Q(R_k)\}}}\right) \to 0.$$

Hence, by part 1 of Lemma 9, c and $\tilde{c}|_{\{R_k\}}^{\{Q(R_k)\}}$ are mutually C-consistent for large-enough Q, R_k, that is, c is C-UAL on P. Since this was for every $P \in \mathbb{P}$, we conclude that c is C-UAL on $\mathbb{P}$. Since the entire argument was for an arbitrary localizable set $\mathbb{P}$, we conclude that

Theorem 10 *A C-consistent classifier on a localizable set $\mathbb{P}$ is C-UAL on $\mathbb{P}$.*

In particular, since the set of all distributions (having $Y = \{-1, +1\}$) is localizable, we get

Corollary 11 *A C-consistent classifier is C-UAL.*

In a similar way we can define in the context of classification concepts parallel to UALC and WCM, and prove corresponding results (we do not go into details to avoid repetition).

8. Concluding Remarks

Our analysis of consistency has led to the following result: Consistent learning methods must have two properties, first, that they behave locally (UAL); second, that their mean must not be far from estimating the true mean (WCM). Only a learning method having these two independent properties is consistent, and vice versa; their combination is logically equivalent to consistency.

To further elaborate on this result, note that UAL is clearly a local property, and WCM a global one. Thus, we can see consistency as comprised of two aspects, one local and one global. Note also that the global property, WCM, is a trivial consequence of consistency, and therefore what is worth noting about this result is that consistency implies local behavior. We can then ask, in an informal manner at least, why is this so?

As noted in the introduction, the loss L_n that we considered is a global one, in that we average over x, and hence it does not seem to directly imply local behavior. What does seem to be the crux of the matter is the requirement to perform well on *all* distributions, or more generally on a localizable set; note that the term 'localizable' here is a giveaway. Indeed, if we have a method that is consistent on a *non*-localizable set of distributions, it may not behave locally. As a simple example (but complex enough for the underlying issues to be evident), let us assume we work on distributions having $Ey = 0$ (which was mentioned in Section 6 as being non-localizable). We might consider the following approach on this problem: Let f be some general learning method known to be useful on other data sets; specifically, assume that f is consistent. We can then calibrate its output so that it returns an empirical mean of 0, which makes sense since we know that $Ey = 0$. That is, let

$$g(S,x) = f(S,x) - \frac{1}{|S|} \sum_{i=1..|S|} f(S,x_i)$$

(alternatively, we might calibrate by multiplying by an appropriate scalar, etc.). Then, while g is consistent on the set of distributions with $Ey = 0$ (using the consistency of f on all distributions), g does not behave locally. This can be seen, for example, by considering g on a distribution with x uniform on $[-1,1]$ and $y = \text{sign}(x)$. This distribution fulfills $Ey = 0$, and g is consistent on it, but neither UAL nor UALC, since smoothed local versions of g in fact return values tending towards 0.

Thus, in summary, the fact that the set of all distributions is localizable is what causes consistency to imply local behavior. If we are concerned about that fact (e.g., because we suspect local behavior might lead to the curse of dimensionality; Bengio et al., 2006), then we must do away with consistency on the set of all distributions and instead talk about consistency on a more limited set, one which is not localizable. However, part of the reason why nonparametric methods often outperform parametric ones on real-world data is precisely because they make as few as possible assumptions about the unknown distribution. Consequently, we may find that local behavior is hard to avoid.

We now turn to directions for future work. One such direction is to apply our results towards proving the consistency of learning methods not yet known to be consistent. It appears that in many cases proving the WCM property should not be difficult; hence, what remains is to prove UAL. While not necessarily a simple property to show, it may in some cases be easier than proving consistency directly.

An additional area for possible future work is empirical investigation, as follows. Since a consistent method is necessarily UALC, we can consider using a smoothed local version of the original method, since if chosen appropriately it is also consistent.[2] Now, if for example we have a large training set and only a few points at which to estimate, then by training on the local parts of the original training set we may save time. Of course, there is no guarantee that this will be beneficial on a particular problem, since consistency is an asymptotic property. Future empirical work might therefore examine real-world data sets in detail to see how the performance of local versions of a method compare to the original.

Acknowledgments

We thank the anonymous reviewers of a previous version of this paper for their comments. We also acknowledge support for this project from the Israel Science Foundation as well as partial support from NSF grant DMS-0605236.

2. Note that we might not need smoothing in practice, since the smoothing radius becomes negligibly small, $Q(R_k)R_k = o(R_k)$. That is, local versions might behave similarly enough to smoothed local versions for practical purposes.

Appendix A. Proof of Proposition 1

For any sample S, denote the mean and standard deviation (of the xs) by

$$\hat{E}(S) = \frac{1}{|S|} \sum_{i=1..|S|} x_i \qquad , \qquad \hat{\sigma}(S) = \sqrt{\frac{1}{|S|} \sum_{i=1..|S|} \left(x_i - \hat{E}(S)\right)^2}.$$

Now, start with a consistent method g, which is *translation-invariant* in the sense that

$$\forall S, x, b \qquad g(S,x) = g(S+b, x+b)$$

where $S+b = \{(x_i+b, y_i) \ : \ (x_i, y_i) \in S\}$ (for example, we can take g to be a kernel estimator).

Define, for any $q > 0$,

$$f^q(S,x) = \begin{cases} g(S,x) & x \notin B_{\hat{E}(S),q} \text{ or } x \in \{x_i \ : \ (x_i,y_i) \in S\} \\ 0 & \text{otherwise} \end{cases}$$

and let

$$Q(S) = \frac{\hat{\sigma}(S)}{\log(|S|)}.$$

Finally, let

$$f(S,x) = f^{Q(S)}(S,x).$$

We will first show that f is consistent; then we will show that f is neither locally consistent nor localizable. A brief overview of the proof is as follows: As $n \to \infty$, we get that $Q(S_n) \approx \frac{\text{const}}{\log(n)}$. This means that f is forced to return 0 on an area with vanishing radius, and hence f behaves like g on an area with measure rising to 1, and is consistent. On the other hand, when we consider a local version, we get that $Q(S_n(x,R_n)) \approx O\left(\frac{R_n}{\log(m)}\right)$, where m is the size of $S_n(x,R_n)$. We also get that x, the point at which we are estimating, is at distance $\approx O\left(\frac{R_n}{\sqrt{m}}\right)$ from $\hat{E}(S_n(x,R_n))$, a distance which is asymptotically smaller than Q. Hence x will tend to be in the area on which f is forced to return 0, making f neither locally consistent nor localizable.

We now start with the formal proof, first showing that f is consistent. Since X is bounded, $\hat{\sigma}(S_n)$ is bounded, and hence $Q(S_n) = \frac{\hat{\sigma}(S_n)}{\log(n)} \to 0$. We first assume that there is not a point mass on Ex, which implies $\mu\left(B_{\hat{E}(S_n),Q(S_n)}\right) \to 0$ almost surely, which follows from the fact that, since $\hat{E}(S_n) \to Ex$ a.s. (by the LLN) and $Q(S_n) \to 0$, we must have $\limsup_n B_{\hat{E}(S_n),Q(S_n)} \subseteq \{Ex\}$ with probability 1. We can then use the consistency of g to see that

$$\begin{aligned}
&E_{S_n} E_x |f(S_n,x) - f^*(x)| \\
&\quad \leq E_{S_n} E_x 1\{x \notin B_{\hat{E}(S_n),Q(S_n)} \text{ or } x \in \{x_i \ : \ (x_i,y_i) \in S_n\}\} |g(S_n,x) - f^*(x)| \\
&\qquad + E_{S_n} 2M\mu\left(B_{\hat{E}(S_n),Q(S_n)} \bigcap \{x_i \ : \ (x_i,y_i) \in S_n\}^C\right) \\
&\quad \leq E_{S_n}\left[E_x |g(S_n,x) - f^*(x)| + 2M\mu\left(B_{\hat{E}(S_n),Q(S_n)}\right)\right] \\
&\quad \to 0
\end{aligned}$$

which proves that f is consistent. Consider now the case where there is a point mass on Ex. Recall that $\limsup_n B_{\hat{E}(S_n),Q(S_n)} \subseteq \{Ex\}$ a.s., and note that due to the point mass on Ex, we have $P\big(Ex \in \{x_i \,:\, (x_i,y_i) \in S_n\}\big) \to 1$. Because of these two facts, we get

$$E_{S_n}\mu\left(B_{\hat{E}(S_n),Q(S_n)} \bigcap \{x_i \,:\, (x_i,y_i) \in S_n\}^C\right) \to 0$$

hence once more f is consistent by the consistency of g, by a similar argument as before.

We will now show that f is not locally consistent. For this, it is sufficient to show a single distribution on which $L_n\big(f|_{\{R_k\}}\big)$ does not converge to 0, for any sequence $R_k \to 0$. Take $X = [0,1]$ (higher-dimensional cases can be proved similarly), let μ be uniform on X, and let $y = +1$ with probability $(1 + f^*(x))/2$, and otherwise $y = -1$ (which makes sense if $f^*(x) \in [-1,+1]$). Define

$$f^*(x) = \begin{cases} +1/2 & x \in \left[0, \frac{1}{2}\right] \\ -1/2 & x \in \left(\frac{1}{2}, 1\right] \end{cases}.$$

Fix some $x \in (0,1)$. Note that μ has no point masses, so $P(x \in \{x_i \,:\, (x_i,y_i) \in S_n\}) = 0$, and the relevant condition in the definition of f^q is of no consequence. Now, for large enough n (that is, small enough R_n) we have $x \in [R_n, 1 - R_n]$; we will now focus on that case.

Denote $\widetilde{S} = S_n(x,R_n)$ and $m = m(n,x,R_n) = |\widetilde{S}|$. Notice that m is the sum of i.i.d Bernoulli variables, and that

$$Em = 2nR_n \quad , \quad \sigma^2(m) \le 2nR_n \tag{6}$$

(recall that $Em, \sigma^2(m)$ denote the expected value and variance of the random variable m, respectively). Now, consider the case in which $nR_n \not\to \infty$. Then there is some bounded subsequence, $k_nR_{k_n} \le K$ for all n. Then (using Chebyshev) clearly m is less than $4k_nR_{k_n}$ with non-vanishing probability on this subsequence. Since $R_k \to 0$ then in order for f to be consistent we must, for large enough n, discriminate between the two possibilities $f^*(x) = +1/2, f^*(x) = -1/2$ in a way that does not depend upon x (due to the translation-invariance of f, which stems from the translation-invariance of g). But discriminating between the two cases with arbitrarily small error cannot be done with a bounded sample size, hence the loss cannot go to 0. Thus, we conclude that if $nR_n \not\to \infty$ then f is not locally consistent.

Consider now the other case, of $nR_n \to \infty$. We start by formulating bounds for m, $|x - \hat{E}(\widetilde{S})|$, and $\hat{\sigma}^2(\widetilde{S})$.

- m: Using Bernstein's Inequality and (6), we get

$$P(|m - 2nR_n| \ge t) \le 2\exp\left(-\frac{1}{2}\frac{t^2}{2nR_n + t/3}\right).$$

  Picking $t = t_n = nR_n$, we get

$$P(|m - 2nR_n| \ge nR_n) \le 2\exp\left(-\frac{1}{6}nR_n\right). \tag{7}$$

  Note that this bound converges to 0 since $nR_n \to \infty$.

- $|x-\hat{E}(\widetilde{S})|$: Clearly x is the mean of P_{x,R_n}, and also the mean of the individual observations in $\widetilde{S}$, as they are distributed i.i.d as P_{x,R_n}. Note that for every $x_i \in \widetilde{S}$ (i.e., taken from the distribution P_{x,R_n}) we have $\sigma^2(x_i) = \frac{R_n^2}{3}$. Then, by Hoeffding's Inequality,

$$P\left(\left|x-\hat{E}(\widetilde{S})\right| \geq t\right) \leq E_m\left\{2\exp\left(-\frac{mt^2}{2R_n^2}\right)\right\}.$$

Picking $t = t_n = R_n\sqrt{\frac{\log(nR_n)}{nR_n}}$, we get

$$\begin{aligned}P\left(\left|x-\hat{E}(\widetilde{S})\right| \geq R_n\sqrt{\frac{\log(nR_n)}{nR_n}}\right) &\leq E_m\left\{2\exp\left(-\frac{1}{2}\frac{m}{nR_n}\log(nR_n)\right)\right\} \qquad (8)\\ &\leq 2\exp\left(-\frac{1}{2}\log(nR_n)\right)+4\exp\left(-\frac{1}{6}nR_n\right)\\ &\to 0\end{aligned}$$

using the bound for m above (7).

- A final bound that we will need relates to $\hat{\sigma}^2(\widetilde{S})$. Note that for any sample S and point x,

$$\hat{\sigma}^2(S) = \frac{1}{|S|}\sum_i (x_i-x)^2 - (x-\hat{E}(S))^2$$

Consider the first expression on the RHS. On our (sub)sample $\widetilde{S}$, we have for every $x_i \in \widetilde{S}$ that $E(x_i-x)^2 = \frac{R_n^2}{3}$, and note that $(x_i-x)^2 \leq R_n^2$. Then, by Hoeffding's Inequality,

$$P\left(\left|\frac{1}{m}\sum_{i=1}^{m}(x_i-x)^2 - \frac{R_n^2}{3}\right| \geq t\right) \leq E_m 2\exp\left(-\frac{mt^2}{2R_n^4}\right).$$

Picking $t = t_n = R_n^2\sqrt{\frac{\log(nR_n)}{nR_n}}$, we get

$$\begin{aligned}&P\left(\left|\frac{1}{m}\sum_{i=1}^{m}(x_i-x)^2 - \frac{R_n^2}{3}\right| \geq R_n^2\sqrt{\frac{\log(nR_n)}{nR_n}}\right)\\ &\quad\leq E_m 2\exp\left(-\frac{1}{2}\frac{m}{nR_n}\log(nR_n)\right)\\ &\quad\leq 2\exp\left(-\frac{1}{2}\log(nR_n)\right)+4\exp\left(-\frac{1}{6}nR_n\right)\\ &\quad\to 0\end{aligned}$$

similarly as before. Combined with the bound from before for $|x-\hat{E}(\widetilde{S})|$, we get, for large enough n,

$$\begin{aligned}
&P\left(\hat{\sigma}^2(\widetilde{S}) \leq \frac{1}{12}R_n^2\right) \\
&\quad = P\left(\hat{\sigma}^2(\widetilde{S}) \leq \frac{1}{12}R_n^2\ ,\ \left(x-\hat{E}(\widetilde{S})\right)^2 < R_n^2\frac{\log(nR_n)}{nR_n}\right) \\
&\qquad + P\left(\hat{\sigma}^2(\widetilde{S}) \leq \frac{1}{12}R_n^2\ ,\ \left(x-\hat{E}(\widetilde{S})\right)^2 \geq R_n^2\frac{\log(nR_n)}{nR_n}\right) \\
&\quad \leq P\left(\frac{1}{m}\sum_{i=1}^{m}(x_i-x)^2 \leq \frac{1}{6}R_n^2\right) + P\left(\left|x-\hat{E}(\widetilde{S})\right| \geq R_n\sqrt{\frac{\log(nR_n)}{nR_n}}\right) \\
&\quad \to 0.
\end{aligned}$$

We now have all the bounds we need. Using our results for $m=|\widetilde{S}|$ and $\hat{\sigma}^2(\widetilde{S})$ together, we get

$$\begin{aligned}
&\lim_{n\to\infty} P\left(\left|x-\hat{E}(\widetilde{S})\right| \geq Q(\widetilde{S})\right) \\
&\quad = \lim_{n\to\infty} P\left(\left|x-\hat{E}(\widetilde{S})\right| \geq \frac{\hat{\sigma}(\widetilde{S})}{\log(m)}\right) \\
&\quad = \lim_{n\to\infty} P\left(\left|x-\hat{E}(\widetilde{S})\right| \geq \frac{\hat{\sigma}(\widetilde{S})}{\log(m)}\ ,\ |m-2nR_n| \leq nR_n\ , \hat{\sigma}^2(\widetilde{S}) \geq \frac{1}{12}R_n^2\right) \\
&\quad \leq \lim_{n\to\infty} P\left(\left|x-\hat{E}(\widetilde{S})\right| \geq \frac{R_n}{\sqrt{12}\log(3nR_n)}\right) \\
&\quad \to 0
\end{aligned}$$

where to reach the very last line we used what we know about $|x-\hat{E}(\widetilde{S})|$, as appearing in (8). Thus, for every $x \in \mathrm{supp}_X(P)$ we have $P\left(x \in B_{\hat{E}(\widetilde{S}),Q(\widetilde{S})}\right) \to 1$.

Finally, we can see that

$$\begin{aligned}
E_{S_n}\left|f|_{\{R_k\}}(S_n,x)-f^*(x)\right| &= E_{S_n}\left|f(\widetilde{S},x)-f^*(x)\right| \\
&= E_{S_n}1\{x \in B_{\hat{E}(\widetilde{S}),Q(\widetilde{S})}\}\left|f(\widetilde{S},x)-f^*(x)\right| \\
&\quad + E_{S_n}1\{x \notin B_{\hat{E}(\widetilde{S}),Q(\widetilde{S})}\}\left|f(\widetilde{S},x)-f^*(x)\right| \\
&\geq E_{S_n}1\{x \in B_{\hat{E}(\widetilde{S}),Q(\widetilde{S})}\}\left|f^*(x)\right| \\
&= \frac{1}{2}E_{S_n}1\{x \in B_{\hat{E}(\widetilde{S}),Q(\widetilde{S})}\} \\
&= \frac{1}{2}P\left(x \in B_{\hat{E}(\widetilde{S}),Q(\widetilde{S})}\right) \\
&\to \frac{1}{2}
\end{aligned}$$

where we used that $f^*(x) \in \{-1/2, +1/2\}$. Taking the expected value over x, the dominated convergence theorem gives us

$$\lim_{n\to\infty} L_n\left(f|_{\{R_k\}}\right) \geq \frac{1}{2}.$$

Thus, $f|_{\{R_k\}}$ is not consistent, that is, f is not locally consistent (note that this is even by a relatively large constant factor).

Having shown that f is consistent but not locally consistent, we now show that in addition f cannot be localizable. This is immediate, since if f were localizable, then some sequence $R_k \to 0$ would exist for which $D_n\left(f, f|_{\{R_k\}}\right) \to 0$, and therefore

$$L_n\left(f|_{\{R_k\}}\right) = D_n\left(f|_{\{R_k\}}, f^*\right) \leq D_n\left(f|_{\{R_k\}}, f\right) + D_n(f, f^*) \to 0$$

by the localizability and consistency of f. But this result implies f is locally consistent, contradicting what we saw earlier.

Appendix B. Proof of Lemma 6

Define (as in the proof of Proposition 1) $\widetilde{S} = S_n(x,r)$, $m = m(n,x,r) = |S_n(x,r)|$, the size of the local training set. Note that we can see $\widetilde{S}$ as m points sampled from $P_{x,r}$. Then we get, for any $r, q > 0$,

$$\begin{aligned}
D_n\left(\bar{f}|_r^q, f^*\right) &= E_{S_n,x}\left|E_{x'\sim P_{x,qr}} f(S_n(x,r),x') - f^*(x)\right| \\
&= E_{x,m} E_{\widetilde{S}\sim P_{x,r} \mid m} \left|E_{x'\sim P_{x,qr}} f(\widetilde{S},x') - f^*(x)\right| \\
&\leq E_{x,m} E_{\widetilde{S}\sim P_{x,r} \mid m} E_{x'\sim P_{x,qr}} \left|f(\widetilde{S},x') - f^*(x)\right| \\
&\leq E_{x,m} E_{\widetilde{S}\sim P_{x,r} \mid m\,,\, x'\sim P_{x,qr}} \left|f(\widetilde{S},x') - f^*(x')\right| \\
&\quad + E_{x,x'\sim P_{x,qr}} \left|f^*(x') - f^*(x)\right|.
\end{aligned}$$

We now start to consider the limit behavior of these expressions when we replace $r > 0$ with $\{R_k\} \in \mathcal{R}(T)$ and $q > 0$ with $\{Q(R_k)\}, Q \in \mathcal{Q}(T)$, where $T \in \mathcal{T}$ is arbitrary. First, for any such $\{R_k\}, Q$ we have

$$\lim_{n\to\infty} E_{x,x'\sim P_{x,Q(R_n)R_n}} \left|f^*(x') - f^*(x)\right| = 0$$

by the corollary to the following lemma (and since $R_n, Q(R_n) \to 0$):

Lemma 12 *[Devroye, 1981; Lemma 1.1] For any distribution P and measurable g, if $E_{x\sim P}|g(x)| < \infty$ then*

$$\lim_{r\to 0} E_{x'\sim P_{x,r}} g(x') = g(x)$$

for almost all x.

Corollary 13 *For any distribution P and measurable g, if $E_{x\sim P}|g(x)| < \infty$ then*

$$\lim_{r\to 0} E_{x'\sim P_{x,r}} \left|g(x') - g(x)\right| = 0$$

for almost all x.

Write $\widetilde{S} = S_n(x, R_n)$ (a minor abuse of our notation, as we also write $\widetilde{S} = S_n(x, r)$, but r is always a placeholder for R_n in any case). Then

$$\limsup_{n\to\infty} D_n\left(\bar{f}|_{\{R_k\}}^{\{Q(R_k)\}}, f^*\right) \le \limsup_{n\to\infty} E_{x,m} E_{\widetilde{S}\sim P_{x,R_n}\,|\,m\,,\,x'\sim P_{x,Q(R_n)R_n}} \left|f(\widetilde{S},x') - f^*(x')\right|.$$

To simplify notation for this last expression, define, for any $x \in \operatorname{supp}_X(P), n \in \mathbb{N}, r, q \in T$,

$$C(x,n,r,q) = E_m E_{\widetilde{S}\sim P_{x,r}\,|\,m\,,\,x'\sim P_{x,qr}} \left|f(\widetilde{S},x') - f^*(x')\right|$$

and

$$C(n,r,q) = E_x C(x,n,r,q).$$

It is therefore our goal to show that $C(n,R_n,Q(R_n)) \to 0$ for appropriate $\{R_k\}, Q$. Towards that end, we consider the limit $\limsup_{n\to\infty} C(n,r,q)$, for fixed r,q. We have, for every $x \in \operatorname{supp}_X(P)$,

$$\begin{aligned}
&C(x,n,r,q)\\
&= E_m E_{\widetilde{S}\sim P_{x,r}\,|\,m\,,\,x'\sim P_{x,qr}} \left|f(\widetilde{S},x') - f^*(x')\right|\\
&= \frac{\mu(B_{x,r})}{\mu(B_{x,qr})} E_m E_{\widetilde{S}\sim P_{x,r}\,|\,m\,,\,x'\sim P_{x,r}} \left|f(\widetilde{S},x') - f^*(x')\right| 1\left\{x' \in B_{x,qr}\right\}\\
&\le \frac{\mu(B_{x,r})}{\mu(B_{x,qr})} E_m E_{\widetilde{S},x'\sim P_{x,r}\,|\,m} \left|f(\widetilde{S},x') - f^*(x')\right|\\
&= \frac{\mu(B_{x,r})}{\mu(B_{x,qr})} E_m E_{\widetilde{S},x'\sim P_{x,r}\,|\,m} \left|f(\widetilde{S},x') - E_m(f) + E_m(f) - E(f^*) + E(f^*) - f^*(x')\right|\\
&\le \frac{\mu(B_{x,r})}{\mu(B_{x,qr})} E_m\left[\mathrm{MAD}_{m,P_{x,r}}(f) + |E_{m,P_{x,r}}(f) - E_{P_{x,r}}(f^*)| + \mathrm{MAD}_{P_{x,r}}(f^*)\right]
\end{aligned}$$

where the expected values $E_m(f), E(f^*)$ on the line before last are w.r.t $P_{x,r}$, and the expected values and MADs on the last two lines are all conditional on m.

Now, clearly $m \to \infty$ almost surely (since x is in the support of μ, and $r > 0$ is fixed, so there is a positive probability for an observation to fall within $B_{x,r}$). Hence, by the WCM property of f on $P_{x,r}$ (a *fixed* distribution in the current view),

$$\limsup_{n\to\infty} C(x,n,r,q) \le \frac{\mu(B_{x,r})}{\mu(B_{x,qr})}\left[\mathrm{MAD}_{P_{x,r}}(f^*) + 2H\left(\mathrm{MAD}_{P_{x,r}}(f^*)\right)\right].$$

Using this bound, we can then conclude that

$$\begin{aligned}
\limsup_{n\to\infty} C(n,r,q) &= \limsup_{n\to\infty} E_x C(x,n,r,q)\\
&\le E_x \limsup_{n\to\infty} C(x,n,r,q) \qquad (9)\\
&\le E_x \min\left\{2M\,,\ \frac{\mu(B_{x,r})}{\mu(B_{x,qr})}\left[\mathrm{MAD}_{P_{x,r}}(f^*) + 2H\left(\mathrm{MAD}_{P_{x,r}}(f^*)\right)\right]\right\}
\end{aligned}$$

using the Fatou-Lebesgue theorem for the first inequality, where we rely on the trivial fact that $C(x,n,r,q) \leq 2M$ based on our boundedness assumptions on f, f^*, and using those same boundedness assumptions for the second inequality as well. We define

$$C^*(r,q) = \limsup_{n\to\infty} C(n,r,q),$$
$$\bar{C}^*(r,q) = E_x \min\left\{2M\ ,\ \frac{\mu(B_{x,r})}{\mu(B_{x,qr})}\left[\mathrm{MAD}_{P_{x,r}(f^*)} + 2H\left(\mathrm{MAD}_{P_{x,r}}(f^*)\right)\right]\right\}.$$

Hence, based on (9) we have

$$C^*(r,q) \leq \bar{C}^*(r,q) \tag{10}$$

We will now need the following lemma:

Lemma 14 *[Devroye, 1981; see the proof of Lemma 2.2] For any measure μ, for almost every x,*

$$\lim_{r\to 0} \frac{r^d}{\mu(B_{x,r})} = c_x \quad , \quad |c_x| < \infty.$$

That is, the limit exists and is finite.

We now consider $\bar{C}^*$ for fixed q and varying r. By Lemma 14, we know that for almost every x,

$$\lim_{r\to 0} \frac{\mu(B_{x,r})}{\mu(B_{x,qr})} = \lim_{r\to 0} \frac{c_x r^d}{c_x q^d r^d} = \frac{1}{q^d} \tag{11}$$

and using Lemma 12 we can consider the MAD, as follows. First, by Lemma 12 we have, for almost every x,

$$\lim_{r\to 0} E_{x'\sim P_{x,r}} f^*(x') = f^*(x)$$

so, for almost every x,

$$\begin{aligned}
\lim_{r\to 0} \mathrm{MAD}_{P_{x,r}}(f^*) &= \lim_{r\to 0} E_{x'\sim P_{x,r}} |f^*(x') - E_{x''\sim P_{x,r}} f^*(x'')| \\
&\leq \lim_{r\to 0} E_{x'\sim P_{x,r}} |f^*(x') - f^*(x)| + |f^*(x) - E_{x''\sim P_{x,r}} f^*(x'')| \\
&= \lim_{r\to 0} E_{x'\sim P_{x,r}} |f^*(x') - f^*(x)| \\
&= 0
\end{aligned}$$

using Corollary 13 for the last equality. Combining this with (11), and using the properties of H, we get

$$\lim_{r\to 0} \bar{C}^*(r,q) = \lim_{r\to 0} E_x \min\left\{2M\ ,\ \frac{\mu(B_{x,r})}{\mu(B_{x,qr})}\left[\mathrm{MAD}_{P_{x,r}}(f^*) + 2H\left(\mathrm{MAD}_{P_{x,r}}(f^*)\right)\right]\right\} = 0$$

since we have convergence to 0 for almost every x in the expected value, and can apply the dominated convergence theorem (for which the bound of $2M$ is crucial). Consequently, due to (10) we have

$$\lim_{r\to 0} C^*(r,q) \leq \lim_{r\to 0} \bar{C}^*(r,q) = 0. \tag{12}$$

We now turn to defining $\{R_k\}$ and Q, using what we have seen thus far. Recall that $T = \{T_k\}$ is arbitrary and that $T_k \searrow 0$. Define in a recursive manner, for every $q \in \mathbf{T}$ (where recall that $\mathbf{T}$ is the set containing all the members in the sequence T),

$$\begin{aligned} &K(T_0) = 0, \\ &K(q) = \min\left\{ k \in \mathbb{N} \quad : \quad \begin{array}{c} \forall q' \in \mathbf{T}, q' > q \\ k > K(q') \end{array} \quad \text{and} \quad \begin{array}{c} \forall k' \geq k \, \forall q' \in \mathbf{T}, q' \geq q \\ C^*(T_{k'}, q') \leq q' \end{array} \right\} \end{aligned}$$

(since $T_k \searrow 0$, we start by defining K for the largest value in T, which is T_0, and then proceed to lower ones). Note that the clause regarding C^* is fulfillable by (12) for individual q', and since we consider a finite number of such q', we can take k large enough for them all. Note also that we ensure that $K(T_k)$ strictly increases, for which we rely on the fact that T_k strictly descends.

We now define Q:

$$\begin{aligned} Q(T_0), \ldots, Q(T_{K(T_1)}) &= T_0, \\ Q(T_{K(T_1)+1}), \ldots, Q(T_{K(T_2)}) &= T_1, \\ &\vdots \\ Q(T_{K(T_k)+1}), \ldots, Q(T_{K(T_{k+1})}) &= T_k, \\ &\vdots \end{aligned} \tag{13}$$

Then according to these definitions, for any $Q' \in \mathcal{Q}(T), Q' \geq Q$, and any (large enough) $k' \in \mathbb{N}$,

$$Q'(T_{k'}) \geq Q(T_{k'}) = T_k \quad \text{for some } k \text{ fulfilling} \quad k' > K(T_k)$$

and hence, for all large enough k',

$$C^*(T_{k'}, Q'(T_{k'})) \leq Q'(T_{k'}). \tag{14}$$

We now work towards defining $R = \{R_k\}$, which just as with Q will be done in two stages. First, we define in a recursive manner, for every $r, q \in \mathbf{T}$,

$$\begin{aligned} &N(T_0, T_0) = 0, \\ &N(r, q) = \\ &\min\left\{ \tilde{n} \in \mathbb{N} \quad : \quad \begin{array}{c} \forall r', q' \in \mathbf{T}, r' > r, q' \geq q \\ \tilde{n} > N(r', q') \end{array} \quad \text{and} \quad \begin{array}{c} \forall \tilde{n}' \geq \tilde{n} \, \forall r', q' \in \mathbf{T}, r' \geq r, q' \geq q \\ C(\tilde{n}', r', q') \leq 2C^*(r', q') \end{array} \right\}. \end{aligned}$$

Note that the clause regarding C, C^* is fulfillable by the definition of C^* as the $\limsup$ of C, and hence we can achieve it over a set of finite q, r as well. Note also that we ensure $N(r, q)$ strictly increases when r strictly descends (and q does not rise).

Define, for any $Q' \in \mathcal{Q}(T)$,

$$\begin{aligned} R_0, \ldots, R_{N(T_1, Q'(T_1))} &= T_0, \\ R_{N(T_1, Q'(T_1))+1}, \ldots, R_{N(T_2, Q'(T_2))} &= T_1, \\ &\vdots \\ R_{N(T_k, Q'(T_k))+1}, \ldots, R_{N(T_{k+1}, Q'(T_{k+1}))} &= T_k, \\ &\vdots \end{aligned}$$

Then, for any $R' \in \mathcal{R}(T), R' \geq R$, and if n is large enough,

$$R'_n \geq R_n = T_k \text{ for some } k \text{ fulfilling } \quad n > N(T_k, Q'(T_k)).$$

Note that $Q'(R'_n) \geq Q'(T_k)$. Thus, by the definition of $N(\cdot,\cdot)$,

$$C(n, R'_n, Q'(R'_n)) \leq 2C^*(R'_n, Q'(R'_n)).$$

If we now also assume that $Q' \geq Q$, where Q is as defined in (13), then by (14) we get

$$C(n, R'_n, Q'(R'_n)) \leq 2C^*(R'_n, Q'(R'_n)) \leq 2Q'(R'_n) \underset{n\to\infty}{\longrightarrow} 0$$

completing the proof.

Appendix C. Proof of Lemma 9

1. First, note that

$$\forall P \qquad E_{S_n,x} \left| f_{|\cdot|}(S_n,x) - |f^*(x)| \right| \leq E_{S_n,x} \left| f_{\text{ker}}(S_n,x) - f^*(x) \right| \longrightarrow 0. \tag{15}$$

Now, notice that for any P, c, d,

$$\begin{aligned}
D_n(f_c, f_d) &= E_{S_n,x} \left| c(S_n,x) f_{|\cdot|}(S_n,x) - d(S_n,x) f_{|\cdot|}(S_n,x) \right| \\
&= E_{S_n,x} \left| c(S_n,x) - d(S_n,x) \right| f_{|\cdot|}(S_n,x) \\
&= E_{S_n,x} \left| c(S_n,x) - d(S_n,x) \right| \left| 2\eta(x) - 1 \right| \\
&\quad + E_{S_n,x} \left| c(S_n,x) - d(S_n,x) \right| \left(f_{|\cdot|}(S_n,x) - |2\eta(x) - 1| \right) \\
&= \widetilde{D}_n(c,d) + E_{S_n,x} \left| c(S_n,x) - d(S_n,x) \right| \left(f_{|\cdot|}(S_n,x) - |2\eta(x) - 1| \right).
\end{aligned}$$

The last expression converges to 0 by (15) since

$$E_{S_n,x} \left| c(S_n,x) - d(S_n,x) \right| \left(f_{|\cdot|}(S_n,x) - |2\eta(x)-1| \right) \leq 2E_{S_n,x} \left| f_{|\cdot|}(S_n,x) - |2\eta(x)-1| \right| \to 0$$

which leads directly to the result we wanted.
2. By part 1 we know that $D_n(f_c, f_{c^*}) \to 0 \iff \widetilde{D}_n(c, c^*) \to 0$, so it suffices to prove that $\forall P \quad D_n(f_{c^*}, f^*) \to 0$, which can be shown using (15):

$$D_n(f_{c^*}, f^*) = E_{S_n,x} \left| c^*(x) f_{|\cdot|}(S_n,x) - f^*(x) \right| = E_{S_n,x} \left| f_{|\cdot|}(S_n,x) - |f^*(x)| \right| \to 0.$$

3. We consider $D_n\left((\bar{f}_c)|_r^q, f_{\bar{c}|_r^q} \right)$; later we will replace q, r with $\{Q(R_k)\}, \{R_k\}$. By the definitions,

$$\begin{aligned}
&D_n\left((\bar{f}_c)|_r^q, f_{\bar{c}|_r^q} \right) \\
&= E_{S_n,x} \left| E_{x' \sim P_{x,qr}} c(S_n(x,r),x') f_{|\cdot|}(S_n(x,r),x') - \operatorname{sign}\left(E_{x' \sim P_{x,qr}} c(S_n(x,r),x') \right) f_{|\cdot|}(S_n,x) \right| \\
&\leq E_{S_n,x} \left| E_{x' \sim P_{x,qr}} c(S_n(x,r),x') - \operatorname{sign}\left(E_{x' \sim P_{x,qr}} c(S_n(x,r),x') \right) \right| |f^*(x)| \\
&\quad + E_{S_n,x} \left| \operatorname{sign}\left(E_{x' \sim P_{x,qr}} c(S_n(x,r),x') \right) \left(f_{|\cdot|}(S_n,x) - |f^*(x)| \right) \right| \\
&\quad + E_{S_n,x} \left| E_{x' \sim P_{x,qr}} c(S_n(x,r),x') \left(f_{|\cdot|}(S_n(x,r),x') - |f^*(x)| \right) \right| \qquad (16) \\
&\leq E_{S_n,x} \left| E_{x' \sim P_{x,qr}} c(S_n(x,r),x') - c^*(x) \right| |f^*(x)| \\
&\quad + E_{S_n,x} \left| f_{|\cdot|}(S_n,x) - |f^*(x)| \right| \\
&\quad + E_{S_n,x} E_{x' \sim P_{x,qr}} \left| f_{|\cdot|}(S_n(x,r),x') - |f^*(x)| \right|
\end{aligned}$$

where we used the fact that $|a-\operatorname{sign}(a)| \leq |a-b|$ for any $b \in \{-1,+1\}$. We now consider the final three expressions separately, denoting them (1),(2),(3):

(1) :
$$\begin{aligned}
& E_{S_n,x}\left|E_{x'\sim P_{x,qr}} c(S_n(x,r),x') - c^*(x)\right| |f^*(x)| \\
&= E_{S_n,x}\left|E_{x'\sim P_{x,qr}} c(S_n(x,r),x')|f^*(x)| - f^*(x)\right| \\
&\leq E_{S_n,x}\left|E_{x'\sim P_{x,qr}} c(S_n(x,r),x')\left(|f^*(x)| - f_{|\cdot|}(S_n(x,r),x')\right)\right| \\
&\quad + E_{S_n,x}\left|E_{x'\sim P_{x,qr}} c(S_n(x,r),x') f_{|\cdot|}(S_n(x,r),x') - f^*(x)\right| \\
&\leq E_{S_n,x}E_{x'\sim P_{x,qr}}\left||f^*(x)| - f_{|\cdot|}(S_n(x,r),x')\right| \\
&\quad + E_{S_n,x}\left|E_{x'\sim P_{x,qr}} c(S_n(x,r),x') f_{|\cdot|}(S_n(x,r),x') - f^*(x)\right|.
\end{aligned}$$

Of the last two expressions, the first is equal to the last of the three expressions we arrived at in (16), so we can consider later on double the value of that expression instead of handling it here. Regarding the second, it is simply equal to $D_n\left((\bar{f}_c)|_r^q, f^*\right)$, which we know to converge to 0 for large-enough $Q,\{R_k\}$ since f_c is UALC on P.

(2) : This converges to 0 by (15).

(3) : Since

$$E_{S_n,x}E_{x'\sim P_{x,qr}}\left|f_{|\cdot|}(S_n(x,r),x') - |f^*(x)|\right| \leq E_{S_n,x}E_{x'\sim P_{x,qr}}\left|f_{\text{ker}}(S_n(x,r),x') - f^*(x)\right|$$

we can use the same techniques as in the proof of Lemma 6:

$$\begin{aligned}
& E_{S_n,x}E_{x'\sim P_{x,qr}}\left|f_{\text{ker}}(S_n(x,r),x') - f^*(x)\right| \\
&\leq E_{S_n,x}E_{x'\sim P_{x,qr}}\left|f_{\text{ker}}(S_n(x,r),x') - f^*(x')\right| \\
&\quad + E_x E_{x'\sim P_{x,qr}}\left|f^*(x') - f^*(x)\right| \\
&= E_x \frac{\mu(B_{x,r})}{\mu(B_{x,rq})} E_m E_{\widetilde{S}\sim P_{x,r}\,|\,m}\, E_{x'\sim P_{x,r}}\left|f_{\text{ker}}(\widetilde{S},x') - f^*(x')\right| 1\{x' \in B_{x,rq}\} \\
&\quad + E_x E_{x'\sim P_{x,qr}}\left|f^*(x') - f^*(x)\right| \\
&\leq E_x \frac{\mu(B_{x,r})}{\mu(B_{x,rq})} E_m E_{\widetilde{S},x'\sim P_{x,r}\,|\,m}\left|f_{\text{ker}}(\widetilde{S},x') - f^*(x')\right| \\
&\quad + E_x E_{x'\sim P_{x,qr}}\left|f^*(x') - f^*(x)\right|
\end{aligned}$$

where, as in previous proofs, $m = |S_n(x,r)|$. The expression before last converges to 0 for every $x \in \operatorname{supp}_X(P)$ and fixed $r,q>0$ by the consistency of f_{ker} on $P_{x,r}$ (using the fact that $m \to \infty$ a.s.), and therefore in a similar way as that performed in Lemma 6 we can see that the entire expression (with expected value over x) converges to 0 for slowly-enough descending $Q,\{R_k\}$. The final expression converges to 0 for any $qr \to 0$ by Corollary 13.

Thus, by replacing q,r with large-enough $Q,\{R_k\}$ we can see that the original expression converges to 0, as required.

Abstract

The use of Gaussian processes can be an effective approach to prediction in a supervised learning environment. For large data sets, the standard Gaussian process approach requires solving very large systems of linear equations and approximations are required for the calculations to be practical. We will focus on the subset of regressors approximation technique. We will demonstrate that there can be numerical instabilities in a well known implementation of the technique. We discuss alternate implementations that have better numerical stability properties and can lead to better predictions. Our results will be illustrated by looking at an application involving prediction of galaxy redshift from broadband spectrum data.

Keywords: Gaussian processes, low rank approximations, numerical stability, photometric redshift, subset of regressors method

1. Introduction

The use of Gaussian processes can be an effective approach to prediction in a supervised learning environment. For large data sets, the standard Gaussian process approach requires solving very large systems of linear equations and approximations are required for the calculations to be practical. We will focus on the subset of regressors technique which involves low rank approximations. The goal of the paper is to describe techniques that are fast—requiring $O(nm^2)$ operations where n is the number of data points available for training and m is the rank of a low rank approximation—and have good numerical stability properties in the sense that the growth of computer arithmetic errors is limited.

The paper begins with a review of Gaussian processes and the subset of regressors approach. We then show that implementation of the subset of regressors method using normal equations can be inaccurate due to computer arithmetic errors. A key contribution of the paper is a discussion of alternative implementations of the subset of regressors technique that have improved numerical stability. Another valuable contribution of the paper is a discussion of how pivoting can be incorporated in the subset of regressors approach to further enhance numerical stability. We discuss the algorithm of Lucas (2004, pp. 4-5) for construction of a partial Cholesky factorization with pivoting and emphasize that with this algorithm the flop count, including subset selection, of the subset of regressors calculations is $O(nm^2)$.

In Section 2 we provide background about using Gaussian processes to facilitate prediction. In Section 3 we discuss how low rank approximations lead to the subset of regressors approach. In Section 4 we describe why a commonly used implementation of this technique may suffer from numerical instabilities and in Section 5 we propose two alternative implementations that have better numerical stability properties. In Section 6 we address the subset selection problem and indicate that a solution to this problem can enhance numerical stability. In Section 7 we discuss tools that aid in the choice of rank in the low rank approximation. In Section 8 we illustrate that the numerical stability issues addressed in Section 4 can lead to unacceptably large growth of computer arithmetic errors in an important application involving prediction of galaxy redshift from broadband spectrum data. Our alternative implementations of the subset of regressors method overcome these difficulties. Also in Section 8 we discuss code, available at `http://dashlink.arc.nasa.gov/algorithm/stableGP`, that implements our ideas. Finally, in Section 9 we summarize our results.

2. Gaussian Processes

Supervised learning is the problem of learning input-output mappings using empirical data. We will assume that a training data set is known consisting of a $n \times d$ matrix X of input measurements and a n by 1 vector y of output or target values. The task is to use the training data set to develop a model that can be used to make prediction with new data. We will assume the new data, called the testing data, is contained in an $n^* \times d$ matrix X^* of inputs. The $n^* \times 1$ vector y^* will represent the target values corresponding to X^*. The goal is to predict the value of y^* given X, y, and X^*.

In the Gaussian process approach the prediction of y^* involves selection of a covariance function $k(x,x')$, where x and x' are vectors with d components. It is required that the covariance function be positive semidefinite (Rasmussen and Williams, 2006, p. 80) which implies that the $n \times n$ covariance matrix K with entries $K_{ij} = k(x_i, x_j)$ where x_i and x_j are rows of X is symmetric positive semidefinite (SPS), so that $v^T K v \geq 0$ for any $n \times 1$ real column vector v. The covariance function can be used to construct K and also the n^* by n cross covariance matrix K^* where $K^*_{ij} = k(x^*_i, x_j)$ where x^*_i is the i^{th} row of X^*. The prediction $\widehat{y}^*$ for y^* is given by the Gaussian processes equation (Rasmussen and Williams, 2006, p. 17):

$$\widehat{y}^* = K^*(\lambda^2 I + K)^{-1} y. \tag{1}$$

The parameter λ in this equation represents the noise in the measurements of y and, in practice, it is often selected to improve the quality of the model (Rasmussen and Williams, 2006).

It is often not clear how to choose the covariance function k. There exist many different covariance functions that apply broadly to many cases. Potential covariance function choices include the squared exponential (sometimes called the radial basis function), Matern, rational quadratic, neural network, polynomial or other covariance functions (Rasmussen and Williams, 2006, pp. 79-102). Most of these covariance functions contain free parameters that need to be selected. Such parameters and λ in (1) are called hyperparameters. We will not focus on the choice of a covariance function or alternative methods for selection of hyperparameters in this paper. In the examples discussed in Section 8 we tried out a variety of covariance functions and selected the one that provided the best predictions. Hyperparameters were selected using the Matlab routine minimize (Rasmussen and Williams, 2006, pp. 112-116, 221) which finds a (local) maximum of the marginal likelihood function calculated using the training set data.

We should mention that the choice of the hyperparameter λ can affect the numerical stability of the Gaussian process calculations. Generally larger values of λ lead to reduced computer arithmetic errors but a large value of λ may be a poor theoretical choice—note that $\widehat{y}^* \to 0$ as $\lambda \to \infty$. One needs to select a value of λ that balances such competing errors. The choice of λ in Gaussian processes is closely related to the parameter choice in ridge regression in the statistics literature (Montgomery et al., 2006, pp. 344-355) and in the literature on regularization (Hansen, 1998, pp. 175-208). As mentioned above we select hyperparameters, including λ, using the routine minimize (Rasmussen and Williams, 2006, pp. 112-116, 221). This technique worked well for the practical example presented in Section 8 when used with our algorithms with improved numerical stability.

We should note that Gaussian process approach also leads to an equation for C the covariance matrix for the predictions in (1). If the $n^* \times n^*$ matrix K^{**} has entries $K^*_{ij} = k(x^*_i, x^*_j)$ then (Rasmussen and Williams, 2006, pp. 79-102):

$$C = K^{**} - K^*(\lambda I + K)^{-1} K^{*T}. \tag{2}$$

The superscript T indicates transpose. The pointwise variance of the predictions is diag(C), the diagonal of the $n^* \times n^*$ matrix C.

3. Low Rank Approximation: The Subset of Regressors Method

In (1) the matrix $(\lambda^2 I + K)$ is an n by n matrix that, in general, is dense (that is has few zero entries). Therefore for large n, for example $n \geq 10000$, it is not practical to solve (1) since the memory required to store K is $O(n^2)$ and the number of floating point operations required to solve (1) is $O(n^3)$. Therefore for large n it is useful to develop approximate solutions to (1).

To do this, for some $m < n$, we can partition the matrices K and K^* as follows:

$$K = \begin{pmatrix} K_{11} & K_{12} \\ K_{21} & K_{22} \end{pmatrix} = \begin{pmatrix} K_1 & K_2 \end{pmatrix}, \; K^* = \begin{pmatrix} K^*_1 & K^*_2 \end{pmatrix}. \tag{3}$$

Here K_{11} is $m \times m$, K_{21} is $(n-m) \times m$, $K_{12} = K_{21}^T$ is $m \times (n-m)$, K_{22} is $(n-m) \times (n-m)$, K_1 is $n \times m$, K_2 is $n \times (n-m)$, K^*_1 is $n^* \times m$ and K^*_2 is $n^* \times (n-m)$. Next we approximate K and K^* using

$$K \cong \widehat{K} \equiv K_1 K_{11}^{-1} K_1^T \tag{4}$$

and

$$K^* \cong \widehat{K}^* \equiv K^*_1 K_{11}^{-1} K_1^T$$

and in (1) we replace K with $\widehat{K}$ and K^* with $\widehat{K}^*$. Therefore

$$\widehat{y}^* \cong \widehat{y}^*_N \equiv \widehat{K}^* (\lambda^2 I + \widehat{K})^{-1} y =$$

$$K_1^* K_{11}^{-1} K_1^T (\lambda^2 I + K_1 K_{11}^{-1} K_1^T)^{-1} y =$$
$$K_1^* K_{11}^{-1} (\lambda^2 I + K_1^T K_1 K_{11}^{-1})^{-1} K_1^T y, \text{ so that}$$
$$\widehat{y}_N^* = K_1^* (\lambda^2 K_{11} + K_1^T K_1)^{-1} K_1^T y. \tag{5}$$

Equation (5) is called the subset of regressors method (Rasmussen and Williams, 2006, p. 176) and was proposed, for example, in Wahba (1990, p. 98) and Poggio and Girosi (1990, p. 1489). As we discuss in the next section the subscript N stands for normal equations. We refer to use of (5) as the SR-N approach.

If $m << n$ then (5) is substantially more efficient than (1). For large n the leading order term in the operation count for the calculations in (5) is nm^2 flops or floating point operations (where a floating point operation is either an addition, subtraction, multiplication or division), whereas the calculations in (1) require approximately $2n^3/3$ flops. If $n = 180,000$ and $m = 500$, as in an example discussed later, the solution to (1) requires approximately 4×10^{15} flops which is five order of magnitudes greater than the approximately 4×10^{10} flops required to solve (5). Furthermore, to use (1) one needs to calculate all $n^2 + nn^*$ elements of K and K^* whereas (5) requires that one calculate only the $nm + n^*m$ elements in K_1 and K_1^*. This also improves the efficiency of the calculations and will reduce the memory requirements dramatically.

We should add that if in Equation (2) we use the approximations (4), (3) and

$$K^{**} \cong \widehat{K}^{**} \equiv K_1^* K_{11}^{-1} K_1^{*T}$$

then, in (2) replacing K with $\widehat{K}$, K^* with $\widehat{K}^*$, K^{**} with $\widehat{K}^{**}$ and using algebra similar to that used in deriving (5), it follows that

$$C \cong \widehat{C}_N \equiv \lambda^2 K_1^* (\lambda^2 K_{11} + K_1^T K_1)^{-1} K_1^{*T}. \tag{6}$$

For an alternate derivation of (6) see Rasmussen and Williams (2006, p. 176). Also diag(C) $\cong$ diag($\widehat{C}_N$) so that diag($\widehat{C}_N$) provides approximations for the variance of the predictions.

4. Numerical Instability

The sensitivity of a problem measures the growth of errors in the answer to the problem relative to perturbations in the initial data to the problem, assuming that that there are no errors in the solution other than the errors in the initial data. A particular algorithm implementing a solution to the problem is numerically stable if the error in the answer calculated by the algorithm using finite precision arithmetic is closely related (a modest multiple of) the error predicted by the sensitivity of the problem. An algorithm is unstable if the error in the answer calculated by the algorithm is substantially greater than the error predicted by the sensitivity of the problem.

A straightforward implementation for the subset of regressors approximation using (5) has a potential numerical instability. To see this note that since K is SPS it follows that the $m \times m$ submatrix K_{11} is also. Therefore we can factor the matrix K_{11} with a Cholesky factorization (Golub and Van Loan, 1996, p. 148)

$$K_{11} = V_{11} V_{11}^T \tag{7}$$

where V_{11} is an $m \times m$ lower triangular matrix. Now let

$$A = \begin{pmatrix} K_1 \\ \lambda V_{11}^T \end{pmatrix} \text{ and } b = \begin{pmatrix} y \\ 0 \end{pmatrix}, \tag{8}$$

where 0 is an $m \times 1$ zero vector, A is an $(n+m) \times m$ matrix and b is a $(n+m) \times 1$ vector. Consider the least square problem:

$$\min_x ||Ax - b|| \tag{9}$$

where the norm is the usual Euclidean norm. The normal equations solution (Golub and Van Loan, 1996, p. 237) to this least squares problem is $x = (A^T A)^{-1} A^T b = (\lambda^2 V_{11} V_{11}^T + K_1^T K_1)^{-1} K_1^T y$ and so by (7)

$$x_N = (\lambda^2 K_{11} + K_1^T K_1)^{-1} K_1^T y. \tag{10}$$

Therefore the solution $\widehat{y}_N^*$ presented in (5) can also be written

$$\widehat{y}_N^* = K_1^* x_N. \tag{11}$$

The subscript N indicates the use of the normal equations solution to (8).

The potential difficulty with the above solution is that the intermediate result x_N is the solution to a least squares problem using the normal equation. It is well known that the use of the normal equation can, in some cases, introduce numerical instabilities and can be less accurate than alternative approaches. As discussed in Golub and Van Loan (1996, p. 236-245) the sensitivity of the least squares problem (9) is roughly proportional to $\text{cond}(A) + \rho_{LS} \text{cond}^2(A)$, where $\rho_{LS} = ||b - Ax||$ and $\text{cond}(A) = ||A|| ||(A^T A)^{-1} A^T||$ is the condition number of A. The problem with the normal equations solution to (9) is that the accuracy of the calculated solution is (almost always) proportional to $\text{cond}^2(A)$, the square of the condition number of A, whereas in the case that ρ_{LS} is small the sensitivity of the least squares problem is approximately $\text{cond}(A)$. To quote from Golub and Van Loan (1996, p. 245):

> We may conclude that if ρ_{LS} is small and $\text{cond}(A)$ is large, then the method of normal equations … will usually render a least squares solution that is less accurate than a stable QR approach.

We will discuss use of the stable QR approach and another alternative to the normal equations in the next section.

5. Improving Numerical Stability

The calculation of $\widehat{y}_N^*$ as given by (5) is equivalent to the solution to (9) and (11) using the normal Equations (10). We can reduce the computer arithmetic errors in the calculation of $\widehat{y}_N^*$ if we develop algorithms that avoid the use of the normal equations in the solution to (9) and (11) . We will present two alternative algorithms for solving (9) and (11). We should add that although these algorithms can have better numerical properties than use of (5), all the algorithms presented in this section are mathematically (in exact arithmetic) equivalent to (5).

5.1 The Subset of Regressors Using a QR Factorization

We first describe use of the QR factorization to solve (9). In this approach (Golub and Van Loan, 1996, p.239) one first factors $A = QR$ where Q is an $(n+m) \times m$ matrix with orthonormal columns and R is an $m \times m$ right triangular matrix. Then

$$x_Q = R^{-1} Q^T b = R^{-1} Q^T \begin{pmatrix} y \\ 0 \end{pmatrix} \tag{12}$$

so that

$$\widehat{y}_Q^* = K_1^* x_Q = K_1^* R^{-1} Q^T \begin{pmatrix} y \\ 0 \end{pmatrix}. \tag{13}$$

With the above algorithm $\widehat{y}^*$ can still be solved quickly. Assuming that the elements of K_1 and K_1^* have been calculated, and that $m << n$, then the approximate number of operations for the QR approach is $2nm^2$ flops. Therefore both the QR and normal equations approach require $O(nm^2)$ flops.

We should also note that we can use the QR factorization to reduce computer arithmetic errors in the computation of the approximate covariance matrix in (6). If we let

$$\widehat{C}_{QR} \equiv \lambda^2 (K_1^* R^{-1})(K_1^* R^{-1})^T$$

then mathematically (in exact arithmetic) $\widehat{C}_N$ and $\widehat{C}_{QR}$ are the same. However, for reasons similar to those discussed in Section 4, the computer arithmetic errors in $\widehat{C}_{QR}$ will usually be smaller than those in $\widehat{C}_N$, assuming, for example, that $\widehat{C}_N$ is computed using a Cholesky factorization of $\lambda^2 K_{11} + K_1^T K_1$.

We will refer to the subset of regressors method using the QR factorization as the SR-Q method. We should add that the use of a QR factorization in equations related to Gaussian process calculations is not new. For example Wahba (1990, p. 136) discusses using a QR factorization for cross validation calculations.

5.2 The V Method

If we assume the V_{11} is nonsingular we can define the $n \times m$ matrix V:

$$V = K_1 V_{11}^{-T} \tag{14}$$

where the superscript $-T$ indicates inverse transpose. Note that by (7) it follows that V is lower trapezoidal and that $V = \begin{pmatrix} V_{11} \\ V_{21} \end{pmatrix}$, where $V_{21} = K_{21} V_{11}^{-T}$. Substituting $K_1 = V V_{11}^T$ and (9) into (10) we get

$$x_V = V_{11}^{-T} (\lambda^2 I + V^T V)^{-1} V^T y \tag{15}$$

so that

$$\widehat{y}_V^* = K_1^* x_V = K_1^* V_{11}^{-T} (\lambda^2 I + V^T V)^{-1} V^T y. \tag{16}$$

We should note that this formulation of the subset of regressors method is not new. It is presented, for example, in Seeger et al. (2003) and Wahba (1990, p. 136) presents a formula closely related to (16). We will call the formula (16) for $\widehat{y}^*$ the V method. We should note, as will be seen in Section 6.2, that one can calculate V as part of a partial Cholesky factorization rather than using (14).

We will see in our numerical experiments and the theoretical analysis in Section 6 that the V method is intermediate in terms of growth of computer arithmetic errors between the normal equations and QR approach. Often, but not always, the accuracy of the V method is close to that of the QR approach.

Assuming that the elements of K_1 and K_1^* have been calculated, and that $m << n$, then the approximate number of operations for the V method is $2nm^2$ flops—approximately nm^2 flops to form V and another nm^2 flops to solve for x_V using (15). This is approximately the same as SR-Q and approximately twice the flop count for the SR-N method.

We can also compute the approximate covariance matrix with the V method approach:

$$\widehat{C}_V \equiv \lambda^2 K_1^* V_{11}^{-T} (\lambda^2 I + V^T V)^{-1} V_{11}^{-1} K_1^{*T}.$$

In exact arithmetic $\widehat{C}_N, \widehat{C}_{QR}$ and $\widehat{C}_V$ are identical but the computer arithmetic errors are often smaller in $\widehat{C}_V$ and $\widehat{C}_{QR}$ than $\widehat{C}_N$.

5.3 Examples Illustrating Stability Results

We present two sets of examples that illustrate some of the above remarks.

Example 1 *Let the $n \times n$ matrices K be of the form $K = UDU^T$ where U is a random orthogonal matrix (Stewart, 1980) and D is a diagonal matrix with diagonal entries $s_1 \geq s_2 \geq \ldots s_n \geq 0$. Therefore $s_1, s_2, \ldots, s_n$ are the singular values of K. We will choose a vector $w \in R^n$, where R^n is real n dimensional space, of the form $w = \begin{pmatrix} x \\ 0 \end{pmatrix}$ where $x \in R^m$ is a random vector and 0 indicates a zero vector with $(n-m)$ components. We let the target data be $y = Kw$. We will also assume for simplicity that $\lambda = 0$.*

Due to the structure of w each of x_N (10), x_Q (12), and x_V (15) will calculate x exactly in exact arithmetic. Therefore in finite precision arithmetic $||x - \dot{x}||$, with $\dot{x} = x_N, x_Q$ or x_V will be a measure of the computer arithmetic errors in the calculation.

We carried out an experiment $n = 100$, $m = 50$, $s_i = 10^{-(i-1)/5}$, $i = 1, 2, \ldots, m$, and $s_i = 10^{-10}$, $i = m+1, m+2, \ldots, n$ using a set of one hundred random matrices of this type. For this class of matrices the singular values of K vary between 1 and 10^{-10}, $cond(K) = 10^{10}$ and $cond(K_1) \cong 10^{10}$. The results are:

$\dot{x}$ =	x_N	x_V	x_Q
min $\|\|x-\dot{x}\|\|/\|\|x\|\|$	9.3×10^{-1}	5.1×10^{-7}	2.7×10^{-8}
mean $\|\|x-\dot{x}\|\|/\|\|x\|\|$	9.1×10^{0}	3.6×10^{-6}	1.2×10^{-7}
max $\|\|x-\dot{x}\|\|/\|\|x\|\|$	9.6×10^{1}	9.9×10^{-6}	4.5×10^{-7}

Table 1: Min, mean and max errors, $||x - \dot{x}||/||x||$, for 100 matrices and various methods.

For this set of matrices x_Q and x_V have small errors. However x_N has large errors due to its use of normal equations.

Example 2 *This example will illustrate that, although the V method often greatly improves upon the stability of the SR-N method, this is not always the case. For $0 < s \leq 1$ let $C = \begin{pmatrix} s^2 & 10s \\ 10s & 200 \end{pmatrix}$, let the 4×4 matrix $K = \begin{pmatrix} s^2C & 10sC \\ 10sC & 200C \end{pmatrix}$, let $x = \begin{pmatrix} 1/3 \\ 1/3 \end{pmatrix}$, $w = \begin{pmatrix} x \\ 0 \\ 0 \end{pmatrix}$, $\lambda = 0$ let $y = Kw$.*

Due to the structure of w we again have each of x_N, x_Q and x_V will calculate x exactly in exact arithmetic. However, in finite precision arithmetic the calculated values will not be exact. For this example for small s the errors in both x_N and x_V can be significantly larger than the errors in x_Q. For example if $s = 10^{-4}$ we get the following results:

$\dot{x}$ =	x_N	x_V	x_Q
$\|\|x-\dot{x}\|\|/\|\|x\|\|$	8.8×10^{-1}	2.1×10^{-1}	7.7×10^{-11}

Table 2: Errors $||x-\dot{x}||/||x||$ for a 4×4 matrices and various methods.

In Section 6 and Appendix A we will discuss the reason that the V method performs poorly in this example and show that the numerical instability illustrated in this example can be cured by interchanging the columns and rows of K appropriately. Also we should note that although difficulties like the one illustrated here are possible for the V method, experiments like those in Example 1 suggest that such difficulties are not likely. As we discuss in Section 6, the method performed well when we applied it to real world applications.

6. Pivoting and Subset Selection

In Section 5 we discussed low rank approximations to K which involved the first m columns of K. However one can select any subset of the columns to construct a low rank approximation. The choice of these columns or the "active" set is the subset selection problem. This problem has been addressed by, for example, Smola and Bartlett (2001), Seeger et al. (2003), Csato and Opper (2002) and Fine and Scheinberg (2001). The technique that we will use is the same as that in Fine and Scheinberg (2001). However we will focus on the effect of the resulting choice of the active set on the numerical stability of the resulting algorithm. This is a different motivation than the motivations in the above references.

6.1 The Singular Value Decomposition

To pursue this we will first discuss the singular value decomposition which, in a certain sense, produces an optimal low rank approximation to K. The singular value decomposition (SVD) of the symmetric semidefinite matrix K produces the factorization

$$K = UDU^T = \begin{pmatrix} U_1 & U_2 \end{pmatrix} \begin{pmatrix} D_1 & 0 \\ 0 & D_2 \end{pmatrix} \begin{pmatrix} U_1 & U_2 \end{pmatrix}^T$$

where U is an $n\times n$ orthogonal matrix, D is an $n\times n$ diagonal matrix whose diagonal entries $s_1 \geq s_2 \geq \ldots \geq s_n \geq 0$ are the singular values of K, U_1 is $n\times m, U_2$ is $n\times(n-m), D_1$ is an $n\times n$ diagonal matrix, and D_2 is an $(n-m)\times(n-m)$ diagonal matrix. We then can construct the truncated singular value decomposition (TSVD) low rank approximation to K:

$$\widehat{K}_{SVD} = U_1 D_1 U_1^T. \tag{17}$$

The TSVD approximation $\widehat{K}_{SVD}$ is the best low rank approximation (Golub and Van Loan, 1996, p. 72) to K in the sense that

$$\min_{\text{rank}(\widehat{K})=m} ||K-\widehat{K}|| = ||K-\widehat{K}_{SVD}|| = s_{m+1}. \tag{18}$$

Given an $n\times q$ matrix A with rank $m \leq \min(n,q)$ we will define (Björck, 1996, p. 28) the condition number of A to be $\text{cond}(A) = s_1/s_m$ where s_1 and s_m are singular values of A. This definition generalizes to singular matrices the definition of condition number that we used in Section 4 (where A had m columns). It then follows from (17) that

$$\text{cond}(\widehat{K}_{SVD}) = s_1/s_m \tag{19}$$

where s_1 and s_m are singular values of K (which are the same as the singular values of $\widehat{K}_{SVD}$). Thus the singular value decomposition provides two desirable properties:

- Equation (18) indicates that $\widehat{K}_{SVD}$ will be close to K, if there exists a rank m approximation that is close to K, and
- Equation (19) limits the condition number of $\widehat{K}_{SVD}$ which will limit the growth of computer arithmetic errors in the use of $\widehat{K}_{SVD}$.

However, for large n, it is not practical to calculate the SVD of K since the SVD requires $O(n^3)$ operations and is much more expensive than the algorithms described in Section 5 which require $O(nm^2)$ operations. We would like to construct an approximation that requires only $O(nm^2)$ operations and that produces low rank approximations with properties related to (18) and (19).

6.2 Cholesky Factorization with Pivoting

The algorithms describe in Sections 3 and 5 (which are mathematically but not numerically identical) do not satisfy relations related to (18) and (19) as is apparent from the following example.

Example 3 *For the matrix*

$$K = \begin{pmatrix} 1+\varepsilon & 1-\varepsilon & 0 \\ 1-\varepsilon & 1+\varepsilon & 0 \\ 0 & 0 & 1 \end{pmatrix}$$

if we let $m = 2$ then by (4) and (17) we have

$$\widehat{K} = \begin{pmatrix} 1+\varepsilon & 1-\varepsilon & 0 \\ 1-\varepsilon & 1+\varepsilon & 0 \\ 0 & 0 & 0 \end{pmatrix} \textit{ and } \widehat{K}_{SVD} = \begin{pmatrix} 1 & 1 & 0 \\ 1 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix}$$

so that, for small ε,

$$||K - \widehat{K}_{SVD}|| = 2\varepsilon \;<<\; 1 = ||K - \widehat{K}|| \textit{ and}$$
$$\textit{cond}(\widehat{K}_{SVD}) = 2 \;<<\; 1/\varepsilon = \textit{cond}(\widehat{K}).$$

For this example the low rank approximation $\widehat{K}$ has two problems: (1) it does not provide a good approximation to K even though a good low rank approximation exists and (2) the condition number of $\widehat{K}$ can be arbitrarily large which potentially could lead to a large growth of computer arithmetic errors.

To overcome the difficulties illustrated in this example we can use a Cholesky factorization, with pivoting, to insure that linearly independent columns and rows appear first. The Cholesky factorization with pivoting produces a decompostion

$$P^T K P = LL^T$$

where P is an $n \times n$ permutation matrix and L is an $n \times n$ lower triangular matrix. To produce our low rank approximations to the Gaussian process equations we do not need to factor all of K, rather it is sufficient to calculate a partial factorization that factors only m columns and rows of $P^T KP$. This is a partial Cholesky factorization with pivoting. If the pivoting is done using complete pivoting (that is the pivoting in the Cholesky factorization is equivalent to using complete pivoting in Gaussian elimination) then there are a variety of algorithms that determine the factorization (Higham, 2002, p. 202; Golub and Van Loan, 1996, p. 149; Lucas, 2004, pp. 4-5 and Fine and Scheinberg, 2001, p. 255). Here we will summarize the algorithm presented in Lucas (2004, pp. 4-5) since it is not as widely known as the algorithms in Higham (2002, p. 202) and Golub and Van Loan (1996, p. 149) and is more efficient in our context. The algorithm below is also the same as that in Fine and Scheinberg (2001, p. 255) except for the stopping criteria.

Algorithm 1: Algorithm for the partial Cholesky factorization

```
Data: an $n \times n$ symmetric positive semidefinite matrix $K$
    a stopping tolerance $tol \geq 0$
    the maximum rank, $max\_rank \leq n$, of the low rank approximation
Result: $m$, the rank of the low rank approximation
    an $n \times m$ partial Cholesky factor $V$
    a permutation vector $piv$
    Note: on completion the first $m$ rows and columns of $P^T KP - VV^T$ are
    zero, where $P$ is a permutation matrix with $P_{piv_i,i} = 1$, $i = 1, \ldots, n$
initialize:
    $d_i = K_{ii}$, $i = 1, \ldots, n$
    $K_{\max} = \max_{i=1,\ldots,n}(d_i)$
    $piv_i = i$, $i = 1, \ldots, n$
    $m = max\_rank$
for $j = 1$ to $max\_rank$ do
    $[d_{\max}, j_{\max}] = \max_{i=j,\ldots,n}(d_i)$
    where $j_{\max}$ is an index where the max is achieved
    if $d_{\max} \leq (tol)K_{\max}$ then
        $m = j - 1$ ;
        exit the algorithm ;
    end
    if $j_{\max} \neq j$ then
        switch elements $j$ and $j_{\max}$ of $piv$ and $d$
        for $i = j+1 : n$ let $u_i$ = element $i$ of column $j_{\max}$ of $P^T KP$
        switch rows $j$ and $j_{\max}$ of the current $n \times (j-1)$ matrix $V$
    end
    $V_{jj} = \sqrt{d_{\max}}$
    for $i = j+1$ to $n$ do
        $V_{ij} = (u_i - \sum_{k=1}^{j-1} V_{ik}V_{jk}) / V_{jj}$
        $d_i = d_i - V_{ij}^2$
    end
end
```

There are two choices of the stopping tolerance tol that have been suggested elsewhere. For the choice $tol = 0$ the algorithm will continue as long as the factorization determines that K is positive definite (numerically). This choice of tol is used in LINPACK's routine xCHDC (Dongarra et al., 1979) and also by Matlab's Cholesky factorization chol (which implements a Cholesky factorization without pivoting). The choice $tol = n \times \varepsilon$ where ε is machine precision is suggested in Lucas (2004, p. 5) and in Higham (2002). The best choice of tol will depend on the application.

There are a number of attractive properties of the partial Cholesky factorization.

- The number of floating point operations in the algorithm is approximately $nm^2 - 2m^3/3$ flops. The calculations to determine the pivoting require only $O(nm)$ flops.
- The algorithm accesses only the diagonal entries of K and elements from m columns of K.
- The storage requirement for the algorithm is approximately $n(m+2)$ floating point numbers plus storage for the integer vector piv and any storage needed to calculate entries in K.
- The accuracy and condition number of the low rank approximation to K produced by the algorithm is related to the accuracy and condition number of the low rank approximation produced by the singular value decomposition. In particular

Theorem 1 *Let the $n \times m$ matrix V be the partial Cholesky factor produced by Algorithm 1 and let*

$$\widehat{K}_P = PVV^T P^T. \tag{20}$$

Also let $\widehat{K}_{SVD}$ be the rank m approximation (17) produced by the singular value decomposition. Then

$$||K - \widehat{K}_P|| \leq c_1 \, ||K - \widehat{K}_{SVD}|| \text{ and} \tag{21}$$

$$\text{cond}(\widehat{K}_P) \leq c_2 \, \text{cond}(\widehat{K}_{SVD}) \text{ where} \tag{22}$$

$$c_1 \leq (n-m)4^m \text{ and } c_2 \leq (n-m)4^m. \tag{23}$$

Proof *The theorem follows from results in Gu and Eisenstat (1996) for the QR factorization with pivoting. First we consider a Cholesky factorization, without pivoting, of K so that $K = LL^T$ where L is and $n \times n$ lower triangular matrix. Let $\sigma_i(A)$ represent the i^{th} singular value of a matrix A. Then, making use of the singular value decomposition, it follows easily that $\sigma_i(K) = \sigma_i^2(L)$, $i = 1, \ldots, n$. Consider a QR factorization of L^T with standard column pivoting (Golub and Van Loan, 1996, p. 249-250) so that $QR = L^T P_1$. The permutation matrix P_1 produced by this QR factorization will be identical, in exact arithmetic, to the permutation matrix produced by the Cholesky factorization with pivoting applied to K (Dongarra et al., 1979, p. 9.26). In addition, the Cholesky factorization, with pivoting, of K is $P_1^T K P_1 = R^T R$, assuming the diagonal entries of R are chosen to be nonnegative (Dongarra et al., 1979, p. 9.2). Now we partition the Cholesky factorization:*

$$P_1^T K P_1 = \begin{pmatrix} R_{11}^T & 0 \\ R_{12}^T & R_{22}^T \end{pmatrix} \begin{pmatrix} R_{11} & R_{12} \\ 0 & R_{22} \end{pmatrix}. \tag{24}$$

It follows from Theorem 7.2 in Gu and Eisenstat (1996, p. 865) that

$$\sigma_1(R_{22}) \leq c_3 \, \sigma_{m+1}(L) \text{ and } \frac{1}{\sigma_m(R_{11})} \leq c_4 \frac{1}{\sigma_m(L)} \text{ where } c_3, c_4 \leq \sqrt{n-m} \; 2^m. \tag{25}$$

Now the first m steps of Cholesky factorization, with pivoting, of K will produce identical results to the m steps of the partial Cholesky factorization described in Algorithm 1. Let

$$V = \begin{pmatrix} V_{11} \\ V_{21} \end{pmatrix} \text{ and } R_1 = \begin{pmatrix} R_{11} & R_{12} \end{pmatrix} \text{ so that } R_1^T = \begin{pmatrix} R_{11}^T \\ R_{12}^T \end{pmatrix}. \tag{26}$$

In the (complete) Cholesky factorization with pivoting of K, after the first m steps of the algorithm additional pivoting will be restricted to the last $n-m$ rows and columns of P^TKP. Let P_2 be a $n \times n$ permutation matrix representing the pivoting in the last $n-m$ steps in the algorithm. Then it follows that

$$P_1 = PP_2,\ V_{11} = R_{11}^T \text{ and } R_1^T = P_2^T V.$$

Therefore

$$\widehat{K}_P = PVV^TP = P_1P_2^TVV^TP_2P_1^T = P_1R_1^TR_1P_1^T. \tag{27}$$

By (18), (24), (25), (26) and (27) we can conclude that

$$||K - \widehat{K}_P|| = ||R_{22}^TR_{22}|| = \sigma_1^2(R_{22}) \le c_3^2\, \sigma_{m+1}^2(L) = c_1\, \sigma_{m+1}(K) = c_1\, ||K - \widehat{K}_{SVD}||.$$

Also, by (25), (27) and the interlace theorem (Björck, 1996, p. 15)

$$\sigma_m(\widehat{K}_P) = \sigma_m^2(R_1) \ge \sigma_m^2(R_{11}) \ge \sigma_m^2(L)/c_4^2 = \sigma_m(K)/c_4^2. \tag{28}$$

Next by (27) and the interlace theorem

$$\sigma_1(\widehat{K}_P) = \sigma_1^2(R_1) \le \sigma_1^2(R) = \sigma_1(K). \tag{29}$$

Finally, (19), (28) and (29) imply that

$$cond(\widehat{K}_P) = \sigma_1(\widehat{K}_P)/\sigma_m(\widehat{K}_P) \le c_4^2\, \sigma_1(K)/\sigma_m(K) = c_2\, cond(\widehat{K}_{SVD}).$$

■

The bounds in (23) on c_1 and c_2 grow exponentially in m and in principle can be large for larger values of m. In practice this appears to be very uncommon. For example the constants c_3 and c_4 in (25) are closely related to $||W||$ where $W = R_{11}^{-1}R_{22}$ (Gu and Eisenstat, 1996, p. 865). Numerical experiments indicate the $||W||$ is almost always small in practice (typically less than 10) (Higham, 2002, p. 207 and Higham, 1990). Therefore $c_1 = c_3^2$ and $c_2 = c_4^2$ will not be large in practice. We should add that there are choices of the pivot matrices P in (20) which guarantee bounds on c_1 and c_2 that are polynomials in n and m rather than exponential in m as in (23) (Gu and Miranian, 2004). However algorithms that produce such pivot matrices are more expensive than Algorithm 1 and, in practice, usually do not lead to an improvement in accuracy.

Prior to applying one of the methods—SR-N, SR-V and SR-Q—from Sections 3 and 5 one can carry out a partial Cholesky factorization of K to determine the permutation matrix P, and apply the algorithms of Sections 3 and 5 using the matrices $\widetilde{K} \equiv P^TKP$, $\widetilde{K}^* = K^*P$ and the vector $\widetilde{y} = P^Ty$. If pivoting is used in this manner, we will call the algorithms SR-NP, SR-VP and SR-QP corresponding, respectively, to the algorithms SR-N, SR-V and SR-Q without pivoting.

Since the algorithms SR-N, SR-V and SR-Q are all mathematically (in exact arithmetic) equivalent, then by (4) in all these algorithms the low rank approximation to $\widetilde{K}$ is $\widetilde{K}_1\widetilde{K}_{11}^{-1}\widetilde{K}_1^T$ where $\widetilde{K}_1$ is the first m columns of $\widetilde{K}$ and $\widetilde{K}_{11}$ is the first m rows of $\widetilde{K}_1$. Therefore the low rank approximation to $K = P\widetilde{K}P^T$ would be

$$\widehat{K}_P = P\widetilde{K}_1\widetilde{K}_{11}\widetilde{K}_1^T P^T. \tag{30}$$

We then have

Theorem 2 *In exact arithmetic the matrices $\widehat{K}_P$ in (20) and (30) are the same.*
Proof *Let V be the factor produced by a partial Cholesky factorization, with pivoting, of K. Then, as mentioned in Algorithm 1, the first m columns and rows of $P^T KP - VV^T$ are zero. Since $\widetilde{K} = P^T KP$ it follows that $\widetilde{K}_{11} = V_{11}V_{11}^T$ and $\widetilde{K}_1 = VV_{11}^T$, where V_{11} is the $m \times m$ leading principle submatrix of V. Therefore that $VV^T = \widetilde{K}_1\widetilde{K}_{11}^{-1}\widetilde{K}_1^T$. We conclude $PVV^TP^T = P\widetilde{K}_1\widetilde{K}_{11}^{-1}\widetilde{K}_1^TP^T$.* ■

A key conclusion of Theorems 1 and 2 is that for the algorithms SR-NP, SR-VP and SR-QP which use pivoting, the low rank approximation $\widehat{K}_P$ to K has the desirable properties (21-23) which show that the accuracy and condition number of $\widehat{K}_P$ is comparable to the accuracy and condition number of the low rank approximation produced by the singular value decomposition. Therefore if m is small, difficulties such as those illustrated in Example 3 are not possible since for small m the bound $(n-m)4^m$ for c_1 and c_2 is not large. Furthermore, such difficulties are unlikely for large m since, as mentioned earlier, for large m, the values of c_1 and c_2 are, apparently, not large in practice.

For the algorithm SR-VP one does not need to calculate V using (14) since, as shown in the proof of Theorem 2, V is calculated by the partial Cholesky factorization. Using this fact the floating point operation counts of the six algorithms that we have discussed are:

method	no pivoting	pivoting
SR-N / SR-NP	nm^2	$2nm^2$
SR-V / SR-VP	$2nm^2$	$2nm^2$
SR-Q / SR-QP	$2nm^2$	$3nm^2$

Table 3: Approximate flop counts, for n and m large and $n >> m$, for various algorithms.

We should note that flop counts are only rough measures of actual run times since other factors, such as the time for memory access or the degree to which code uses Matlab primitives, can be significant factors. This is discussed further in Section 8.

Also we should note that all the algorithms listed in Table 3 require memory for $O(mn)$ numbers.

Another advantage of the use of pivoting is that if pivoting is included in the V method then for small examples such as Example 2 the potential numerical instability illustrated in Example 2 cannot occur. We illustrate this in the next example. In Appendix A we describe the reason that the SR-VP method is guaranteed to be numerically stable for small problems and why numerical instability is very unlikely for larger real world problems.

Example 4 *This example illustrates that if one includes pivoting in the V method then the numerical instability illustrated in Example 2 does not occur in the V method. As in Example 2 for* $0 < s \leq 1$

let $C = \begin{pmatrix} s^2 & 10s \\ 10s & 200 \end{pmatrix}$, *let the* 4×4 *matrix* $K = \begin{pmatrix} s^2C & 10sC \\ 10sC & 200C \end{pmatrix}$. *Now let* $x = \begin{pmatrix} 1/3 \\ 1/3 \end{pmatrix}$, $w = \begin{pmatrix} 0 \\ x_2 \\ 0 \\ x_1 \end{pmatrix}$, $\lambda = 0$ *let* $y = Kw$.

Due to the structure of w *(and since, in this example, a partial Cholesky factorization will move column 4 of* K *to the first column of* $\widetilde{K} = P^TKP$*) we again have each of* x_{NP}, x_{QP} *and* x_{VP} *will calculate* x *exactly in exact arithmetic. In finite precision arithmetic the calculated values will not be exact. For this example for small* s *the errors in both* x_{VP} *and* x_{QP} *are very small. For example if* $s = 10^{-4}$ *we get the results in Table 4.*

$\dot{x} \quad =$	x_{NP}	x_{VP}	x_{QP}
$\|\|x-\dot{x}\|\|/\|\|x\|\|$	1.7×10^{-1}	2.6×10^{-11}	9.7×10^{-12}

Table 4: Errors $||x-\dot{x}||/||x||$ for a 4×4 matrices and various methods.

Note that even with pivoting the error in the normal equations approach is large. With the normal equations approach the error in the calculated x *includes a term proportional to cond*$^2(K_1)$. *Even with pivoting cond*$^2(K_1)$ *can be large enough so the accuracy of the normal equations approach is poor.*

7. Rank Selection

In using low rank approximation the choice of rank will affect the accuracy of the approximation. It may be impractical to repeat the computations for a variety of different ranks and it is useful to have techniques to facilitate determination of the accuracy of a variety of low rank approximations.

We first consider the case that the true target values y^* corresponding to the testing data X^* are known. Then if $n^* < n$ the accuracy of the prediction for y^* can be calculated efficiently for all low rank approximations with rank less than a specified value m.

To illustrate this we first consider the QR implementation, (12) and (13), of the subset of regressors method. For the $(n+m)\times m$ matrix A in (8) let $A = QR$ where Q is an $(n+m)\times m$ matrix with orthonormal columns and R is an $m\times m$ upper triangular matrix and let $x = R^{-1}Q^Tb$, as in (12) (where we omit the subscript Q on x to simplify our notation). Then by (13) the predicted values of y^* are

$$\widehat{y}^* = K_1^* x$$

where K_1^* is the $n^*\times m$ matrix defined in (3).

Now for some i, $1\le i\le m$, consider the construction of a prediction for y^* using a rank i low rank approximation. Let $\widetilde{A}$ consist of the first i columns of A. It then follows from (9), (13) and the fact that the last $m-i$ rows of b and $\widetilde{A}$ are zero that the rank i prediction, which we call $\widetilde{y}^*$, for y^* is given by solving

$$\min_{\widetilde{x}} ||\widetilde{A}\,\widetilde{x} - b|| \text{ and letting}$$

$$\widetilde{y}^* = K_1^* \begin{pmatrix} \widetilde{x} \\ 0 \end{pmatrix} \tag{31}$$

where $\widetilde{x} \in R^i$ and the 0 in (31) indicates a vector of $m-i$ zeros. Since $A = QR$ it follows that $\widetilde{A} = Q\begin{pmatrix} \widetilde{R} \\ 0 \end{pmatrix}$ where the 0 here indicates $m-i$ rows of zeros. Therefore if $c =$ (the first i elements of $Q^T b$) it then follows (Golub and Van Loan, 1996, p. 239) that we can construct $\widetilde{x}$ using

$$\widetilde{x} = \widetilde{R}^{-1} c. \tag{32}$$

We can use (32) to construct predictions for y^* for every low rank approximation of rank less than or equal to m. To do this we let C be a $m \times m$ upper triangular matrix whose i^{th} column consists of the first i elements of $Q^T b$ and is zero otherwise. Let $\widetilde{Y}$ be the $n^* \times m$ matrix whose i^{th} columns consists of the prediction for y^* using a rank i approximation. Then, for the reasons described in the last paragraph,

$$\widetilde{Y} = K_1^* R^{-1} C. \tag{33}$$

If y^* is known (33) can be used to calculate, for example, the root mean square error of the prediction for y^* for all low rank approximations of rank less than or equal to m.

After the rank m low rank prediction for y^* is constructed, the above calculations require $O(m^3 + n^* m^2)$ floating point operations. If n^* is less than n, this is less than the $O(nm^2)$ operations required to construct the initial rank m prediction. Although we will not present the details here similar efficiencies are possible when using the normal equations approach or the V method.

If the true value y^* for the test set are not known, one can use the subset of regressors approach to estimate the known y values in the training set (by replacing K_1^* with K_1 in (11), (13) or (16)). Again one can calculate the accuracies in estimating y for every low rank approximation of rank less than a given rank m and this can be done relatively efficiently after the initial rank m low rank approximation is constructed. These accuracies will give some indication of the relative difference in using low rank approximations of different ranks.

Finally, we should note that our algorithms provide a limit on the largest rank that can be used. For example in SR-NP, SR-VP and SR-QP Algorithm 1 is used to determine the subset selection. Algorithm 1 returns a rank m where the factorization is stopped and m can be used as the maximum possible rank. For the SR-V and SR-Q algorithms a Cholesky factorization of K_{11} is required in (7). If Matlab's Cholesky routine chol is used for this factorization there is an option to stop the factorization when it is determined that K_{11} is not positive definite (numerically). The size of the factor that successfully factors a positive definite portion of K_{11} sets a limit on the rank that can be effectively used. Finally, SR-N and SR-NP require solving a system of Equations (5) involving the symmetric semidefinite system $\lambda^2 K_{11} + K_1^T K_1$. A good way to solve this system is to use Matlab's chol, which again has an option that can be used to determine a limit on the rank that can be effectively used. As discussed in the next section if these rank limits are exceeded then the calculated answers are often dominated by computer arithmetic errors and are not accurate.

8. Practical Example

In the Sloan Digital Sky Survey (York et al., 2000) broadband u, g, r, i, z photometric measurements will be made for 100s of million galaxies but only approximately 1 million galaxies will have careful spectroscopic measurements of redshifts. Therefore the estimation of redshift from broadband photometric measurements is important since it can lead to much better constraints on the formation and evolution of large-scale structured element in cosmological models (Way and Srivastava, 2006).

We illustrate our earlier remarks by using a training set of 180045 galaxies, each with five measured u, g, r, i, z broadband measurements. The training set consists of a 180045×5 matrix X of broadband measurements and the 180045×1 vector y with the corresponding redshifts. The testing set will consist of a 20229×5 matrix X^* of broadband measurements and the 20229×1 vector y^* of redshifts. This data is from the SDSS GOOD data set discussed in Way and Srivastava (2006).

To determine a good choice for a covariance function we calculated the root mean square (RMS) error for the prediction $\widehat{y}^*$ for y^* using the Matern (with parameter $\nu = 3/2$ and with parameter $\nu = 5/2$), squared exponential, rational quadratic, quadratic and neural network covariance functions from Rasmussen and Williams (2006, Chap. 4). As mentioned earlier we selected the hyperparameters for each covariance function using the Matlab routine minimize from Rasmussen and Williams (2006, pp. 112-116, 221). The covariance function which produced the smallest RMS error for the prediction of y^* was the neural network covariance function (Rasmussen and Williams, 2006, p. 91). For example, for low rank approximations of rank 500 with bootstrap resampling runs (described below) of size 100 the neural network median RMS error was .0204. The next smallest median RMS error was .0212 for the Matern covariance function with $\nu = 3/2$ and the largest median RMS error was .0248 for the quadratic covariance function. Therefore in the experiments below we will use the neural network covariance function.

To compare, experimentally, the efficiency of our implementations of the subset of regressors method we choose a training set size of 90023 (consistent with the bootstrap resampling runs describe below) and low rank approximations of rank $m = 150$ and $m = 1500$. On a computer with 2.2 GH Core Duo Intel processor we timed the SR-N, SR-V, SR-Q, SR-NP, SR-VP and SR-QP methods. On all the calculations in this section that use Algorithm 1 we set the stopping tolerance tol to 0. We ran each of the methods with the additional calculations required to determine the "history" of the accuracy of all low rank approximations less than the specified rank (either 150 or 1500) and also without these extra calculations. The results are summarized in Figure 1.

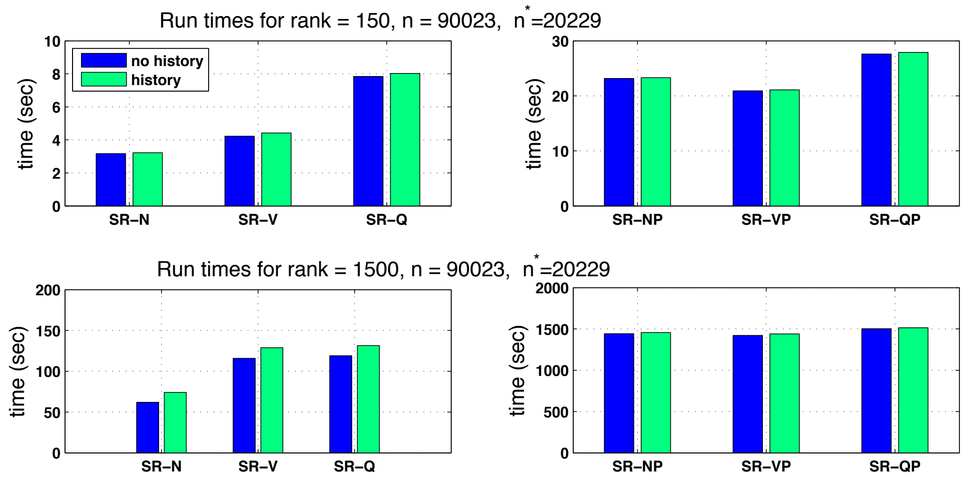

Figure 1: Comparison of run times for implementations of the subset of regressors method.

As can be seen in Figure 1, without pivoting the normal equations approach is the fastest, the QR factorization the slowest and the V method in between. With pivoting all the methods take similar amounts of time (the V method is slightly faster). The reason that all the methods require about the same time when using pivoting is that the code for SR-N, SR-V and SR-Q is written so that the key calculations are done almost entirely with Matlab primitives whereas our implementation of the partial Cholesky factorization contains loops written in Matlab code. The Matlab primitives make use of BLAS-3 (Anderson et al., 1999) routines and will make effective use of cache memory. Therefore, even though the big-O operation counts are similar, the partial Cholesky factorization takes longer to run than SR-N, SR-V or SR-Q and the partial Cholesky factorization dominates the run times in the SR-NP, SR-VP and SR-QP code. We should add that the times for the partial Cholesky factorization would be reduced if a partial Cholesky factorization with pivoting could be implemented using BLAS-3 operations. We are not aware of such an implementation. Finally, we should note that the calculations required to determine the accuracy of all low-order approximations adds only a modest amount to the run times.

To determine the accuracy of the algorithms for different choices of the training set we carried out bootstrap resampling (Efron and Tibshirani, 1993). For each of 100 samples we randomly selected half or 90023 of the 180045 galaxies in the original training set and used this smaller training set to predict the redshift for the 20229 galaxies in the testing set. We considered such resampling with replacement as well as without replacement. For SR-N, SR-V and SR-Q we selected the indices in the active set randomly. Following this we selected the hyperparameters using the minimize routine in Rasmussen and Williams (2006, pp. 112-116, 221). For SR-NP, SR-VP and SR-QP the active set was determined by the partial Cholesky factorization with pivoting. To illustrate the variation in the calculated accuracies, after carrying out a bootstrap resampling run we sorted the 100 RMS errors in increasing order and plotted these errors versus the sample number. The results for low rank approximations of rank 1500, using resampling without replacement, are pictured in Figure 2.

Note that mathematically (in exact arithmetic) SR-N, SR-V and SR-Q will produce identical results; as will SR-NP, SR-VP and SR-QP. Therefore the differences illustrated in Figure 2 between SR-N and SR-V or SR-Q and the differences between SR-NP and SR-VP or SR-QP are due to computer arithmetic and, in particular, the numerical instabilities in using a normal equations approach to solve the least squares problem (9). Also note that although pivoting reduces the numerical instability in using the normal equations approach, still in SR-NP the instability is evident for approximately half of the bootstrap resampling runs. Also we should remark that the $\widehat{y}^*$ predictions calculated using SR-V and SR-Q are essentially identical—they agree to at least seven significant digits in this example—as are the $\widehat{y}^*$ predictions calculated using SR-VP and SR-QP. Finally we should note that for this example the methods that avoid normal equation and use pivoting—SR-VP and SR-QP—are a small amount better than their counterparts, SR-V and SR-Q, that do not use pivoting.

As mentioned earlier, the parameter λ in the Gaussian process computations was selected while optimizing the hyperparameters using the routine minimize from Rasmussen and Williams (2006, pp. 112-116, 221). The values of λ varied over a small range, $.0176 \leq \lambda \leq .0214$, for the 100 samples illustrated in Figure 2. For our stable algorithms these values of λ were good values as can be seen by the accuracy of the results of SR-V, SR-VP, SR-Q and SR-QP pictured in Figures 2, 3 and 4. For SR-N and SR-NP we experimented with a variety of choices of λ but did not reliably achieve accurate predictions for any of our choices.

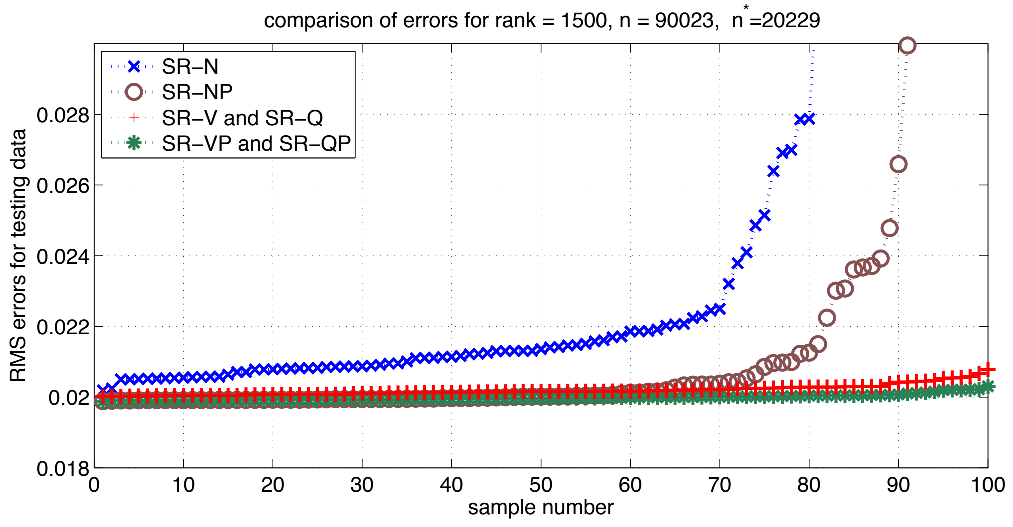

Figure 2: Bootstrap resampling: Comparison of RMS errors for implementations of the subset of regressors method.

We might also add that we tried other types of resampling. We obtained results similar to those illustrated in Figure 2 when using bootstrap resampling with replacement and also when we choose a number of galaxies in the sample size other than 90023.

We can also illustrate the ability to efficiently calculate the accuracy of low rank approximations lower than a specified rank. For the same runs picture in Figure 2 we calculated the mean RMS error of the 100 samples for each rank less than 1500 for each of the six implementations of the subset of regressors method. This is pictured in Figure 3.

As one increases the rank of the low rank approximation the condition number of the matrix A in (9) will tend to increase. This will increase the computer arithmetic errors in the calculated results. The ranks where significant computer arithmetic errors arise are illustrated in Figure 3 by the jumps in the mean errors calculated for the SR-N and SR-NP methods. The ranks where this occurs and the magnitude of the jumps is dependent on the particular data chosen for a bootstrap resampling run and will vary for different bootstrap resampling runs. For the SR-N method the ranks where numerical difficulties were first substantial varied between a rank of 46 to a rank of 839. For the SR-NP method the ranks where numerical difficulties were first substantial varied between ranks of 325 and 1479. For the SR-V, SR-Q, SR-VP and SR-QP methods we did not encounter significant numerical difficulties with these runs and the graphs for these methods smoothly decrease.

The SR-VP and SR-QP method, which use pivoting, are somewhat more accurate than the corresponding methods without pivoting after a rank of approximately 200 but prior to this SR-V and SR-Q are more accurate. Our motivation for subset selection using the Cholesky factorization with pivoting is based on controlling the condition number and improving numerical stability. For smaller ranks it appears that this choice of the active set is good but not optimal. Finally, we should note that Figure 3 indicates for the stable methods the mean RMS errors decrease rapidly for smaller ranks but are only slowly decreasing for larger ranks.

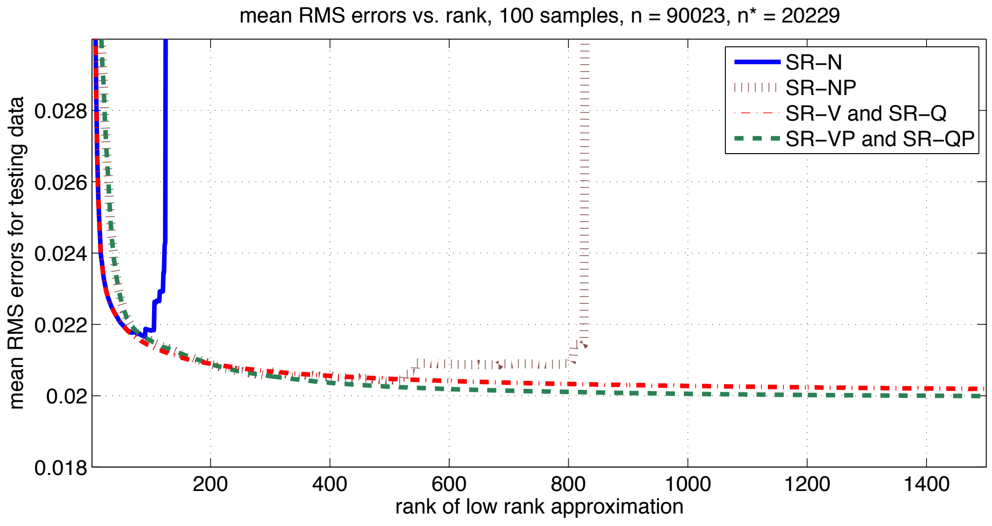

Figure 3: Mean RMS errors versus rank for implementations of the subset of regressors method.

As we mentioned earlier all of our algorithms may limit the rank so that the effective rank can be less than the desired rank. This did not occur on the above runs for SR-V, SR-Q, SR-VP or SR-QP but did occur for SR-N and SR-NP due to our use of the Cholesky factorization to solve the linear system (5). It is possible to solve the linear system in (5) using Gaussian elimination, rather than using a Cholesky factorization, for ranks up to 1500. However the Cholesky factorization in (5) will fail only if the matrix $\lambda^2 K_{11} + K_1^T K_1$ is very ill conditioned. In this case solving the system of equations in (5) by any method will be prone to large computer arithmetic errors. Indeed, for these runs, if we used Gaussian elimination to solve (5) for large ranks the errors became larger than when we limited the rank as we have described earlier. Also when the Cholesky factorization failed in the solution to (5) we tried perturbing K_{11} a small amount following a suggestion in the code provided with Rasmussen and Williams (2006). For our runs this did not improve the calculated results in a significant manner.

In Way and Srivastava (2006) there is a comparison of a variety of methods for predicting red-shift with data from the SLOAN digital sky survey. The methods compared in Way and Srivastava (2006) include linear regression, quadratic regression, artificial neural networks (label ANNz in Figure 4), E-model and Gaussian processes using a quadratic covariance function (labeled GP in Figure 4). In Figure 4 we have compared these methods with our predictions using the SR-VP and SR-QP implementations of the subset of regressors Gaussian processes method with a neural network covariance function. Other than the SR-VP and SR-QP predictions the results in Figure 4 are from Way and Srivastava (2006). As seen in Figure 4, in this example either SR-VP or SR-QP provides overall the best predictions. The E-model approach is also quite good.

We should add that in addition to the data set which was used to generate the results in Figures 1 to 4 we have also carried out experiments using other data sets described in Way and Srivastava (2006) (for example redshift prediction using photometry properties in addition to broadband measurements) and using the SARCOS robot arm inverse dynamics (Rasmussen and Williams, 2006; Vijayakumar et al., 2002). For the other redshift data sets significant computer arithmetic errors in

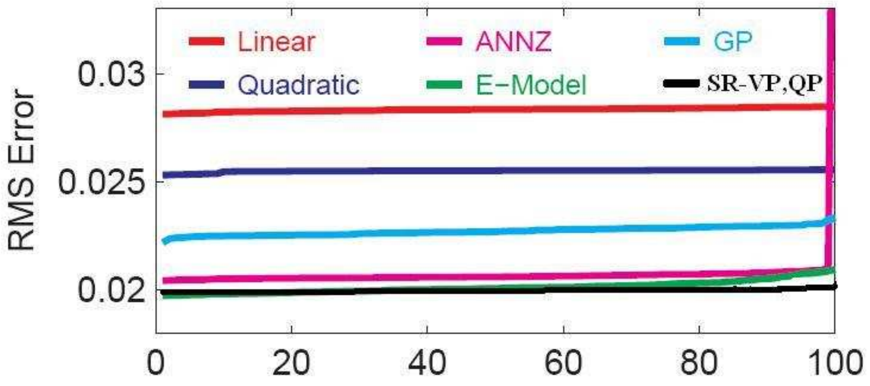

Figure 4: Bootstrap resampling: comparison of RMS errors for six methods of predicting redshift.

the predictions were common for the SR-N and SR-NP algorithms. For some data sets, for example the SARCOS robot arm, computer arithmetic errors were not significant and all the algorithms worked well. Also we might note that although prediction using Gaussian processes was more accurate than alternatives approaches in some cases, in other cases the E-model or artificial neural network approaches provided better accuracy.

Finally, we should note that Matlab code which implements the SR-N, SR-NP, SR-V,SR-VP, SR-Q and SR-QP methods and can produce graphs such as those in Figures 2 and 3 is available at `http://dashlink.arc.nasa.gov/algorithm/stableGP`. Our code makes use of the code from Rasmussen and Williams (2006, p. 221) and the syntax is modeled on that code. We should also note that Foster et al. (2008) and Cayco et al. (2006) discuss additional results related to redshift prediction.

9. Conclusions

An important conclusion of our results is that with the subset of regressors approach to Gaussian process calculations use of normal equations can be unstable and should, in some important practical examples, be avoided. We expect that this principle is also applicable to other approaches to Gaussian process calculations. For example when using approximations based on sparse Gaussian processes with pseudo-inputs (Snelson and Ghahramani, 2006) which is called the FITC approximation in the framework of Quinonero-Candela and Rasmussen (2005) the predicted values are calculated using

$$\widehat{y}^*_{FITC} = K_1^*(\lambda^2 K_{11} + K_1^T(\Lambda+I)^{-1}K_1)^{-1}K_1^T(\Lambda+I)^{-1}y.$$

where

$$\Lambda = diag(K - K_1 K_{11}^{-1} K_1^T)/\lambda^2.$$

Our results suggest that it may be more accurate to carry out these calculations using a QR factorization of $\begin{pmatrix} DK_1 \\ \lambda V_{11}^T \end{pmatrix}$ where $D = (\Lambda+I)^{-1/2}$ rather than, for example, using a Cholesky factorization of $\lambda^2 K_{11} + K_1^T(\Lambda+I)^{-1}K_1$.

To summarize our results, we have presented different implementations of the subset of regressors method for solving, approximately, the Gaussian process equations for prediction. An implementation of the subset of regressors method which uses the normal equations is the fastest approach but also can have poor numerical stability and unacceptable large growth of computer arithmetic errors. An implementation using orthogonal factorization is somewhat slower but in principle has better numerical stability properties. A third approach, which we call the V method, is intermediate between these other two approaches in terms of accuracy and stability. We can use the partial Cholesky factorization to select the active set prior to implementation of any of the above methods. This also will tend to reduce the growth of computer arithmetic errors and can, in some cases, improve the accuracy of the predictions. All of these implementations require $0(nm^2)$ operations where n is the number of data points in the training set and m is the size of the active set or the rank of the low rank approximation used. In this sense all these implementations are efficient and can be much faster than implementation of the full Gaussian process equations. Finally, we have illustrated these result with an important practical application—redshift prediction from broadband spectral measurements. Code implementing our algorithms is available at `http://dashlink.arc.nasa.gov/algorithm/stableGP`.

Finally, we wish to thank the anonymous referees for carefully reading the manuscript and offering excellent suggestions.

Appendix A. Numerical Stability of SR-VP

Here we explain why, even though there is a potential numerical instability in SR-V, as illustrated in Example 2, this difficulty cannot occur with the SR-VP method for small problems and is very unlikely to occur for larger problems from real world applications.

Let P be the $n \times n$ permutation matrix determined by the partial Cholesky factorization with pivoting applied to K, let $\widetilde{K} = P^T K P$ and let $\widetilde{K}_1$ be the first m columns of $\widetilde{K}$. In the SR-VP method we apply Equations (14)-(16) to $\widetilde{K}$ and $\widetilde{K}_1$ rather than K and K_1.

We will begin by considering the special case where $\lambda = 0$ and later consider the more general case. In the case that $\lambda = 0$ the least square problem (9), with K_1 replaced by $\widetilde{K}_1$ since we are incorporating pivoting, is equivalent to

$$\min_x ||\widetilde{K}_1 x - y||.$$

and, by (15), we have

$$x = V_{11}^{-T}(V^T V)^{-1} V^T y. \tag{34}$$

where $\widetilde{K}_1 = V V_{11}^T$. There is a potential concern in using (34) since to construct x the linear system of equations

$$(V^T V)z = V^T y$$

must be solved. Forming $V^T V$ squares the condition number of V which, potentially could lead to the introduction of undesirable computer arithmetic errors. However we will argue that the matrix $B = V^T V$ is diagonally equivalent to a matrix that is guaranteed to be well conditioned for small problems and, in practice, is almost always well conditioned for larger problems. This will limit the growth of computer arithmetic errors. We should add that without pivoting one cannot prove such results, as is illustrated by Example 2.

Now V is formed by a partial Cholesky factorization with pivoting of the symmetric positive semidefinite matrix K. Since pivoting is included in the partial Cholesky factorization of the SPS matrix it follows, for each $i = 1, \ldots, m$, that the i^{th} diagonal entry of $\widetilde{K}_1$ is at least as large in magnitude as any off diagonal entry in row i or column i of $\widetilde{K}_1$ (Trefethen and Bau III, 1997, p. 176) and that the lower trapezoidal matrix V has the property that, for each $i = 1, \ldots, m$, the i^{th} diagonal entry in V is at least as large in magnitude as any entry in column i (Higham, 2002, p. 202). Therefore we can write V as $V = LD$ where D is an $m \times m$ diagonal matrix and L is an $n \times m$ lower trapezoidal matrix with all entries one or less in magnitude and with ones on the diagonal. Indeed this matrix L is identical to the lower trapezoidal matrix produced if Gaussian elimination with complete pivoting is applied to $\widetilde{K}_1$ (Higham, 2002, p. 202). Also since the pivoting has already been applied in forming $\widetilde{K}_1$ Gaussian elimination with complete pivoting will not pivot any entries in $\widetilde{K}_1$ and this implies that Gaussian with partial pivoting will not pivot any entries in $\widetilde{K}_1$ and will produce the same lower trapezoidal factor L. Now it follows from Higham (2002, p. 148) that

$$cond(L) \leq \sqrt{nm}\, 2^{m-1}$$

and therefore for n and m small, as in Example 2, L is well conditioned. More generally, according to Björck (1996, p. 73), if partial pivoting is used in the factorization of $\widetilde{K}_1$ then L is usually well conditioned and, indeed, the discussion in Trefethen and Bau III (1997, p. 169) indicates that, for matrices from applications and for random matrices $\widetilde{K}_1$, the matrix L is almost always well conditioned, in the sense, for example, that cond(L) is far from being exponentially large.

Thus V is a diagonal rescaling of a matrix L that is well conditioned in practice. Now define $U = DV_{11}^T$. It then follows from (34) that

$$x = U^{-1}(L^T L)^{-1} L^T y. \tag{35}$$

Equation (35) is precisely the Peters-Wilkinson method (Peters and Wilkinson, 1970 and Björck, 1996, p. 73) to the least square problem (34). Since L is usually well conditioned then the calculation of $(L^T L)^{-1} L^T y$ can be computed without substantial loss of accuracy and the calculation of x using (35) is more stable than using the normal equation solution to (34) (Björck, 1996, p. 73).

The SR-VP method uses (34) rather that (35). However, since V is a diagonal rescaling of L and U is a diagonal rescaling of V_{11}^T the SR-VP method will also have good numerical stability properties in practice. To demonstrate this we can write $V = LD_1D_2$ where the entries of the diagonal matrix D_1 are between 1 and 2 and where entries in D_2 are exact powers of 2. Since L will be well conditioned in practice then so is $W = LD_1$ (since $\text{cond}(LD_1) \leq \text{cond}(L)\text{cond}(D_1) \leq 2\,\text{cond}(L)$). Now, by (34), we have

$$x = (D_2V_{11})^{-T}(W^T W)^{-1} W^T y. \tag{36}$$

Since W is well conditioned in practice it follows, for the same reasons that (35) has good numerical stability, that (36) will have good numerical stability properties.

To finish the analysis of numerical stability of the SR-VP method in the case that $\lambda = 0$ note that since D_2 has entries that are exact powers of 2, it follows by the discussion in Higham (2002, p. 200) and Forsythe and Moler (1967, 37-39), for any computer using base 2 computer arithmetic, that the x calculated by (36) will be precisely the same, even in floating point arithmetic (as long as there is no overflow or underflow), as the x calculated by (34). Therefore we may conclude that in practice x calculated when using the SR-VP method will have good numerical stability properties and the SR-VP method will usually have smaller computer arithmetic errors than will the SR-N or SR-NP methods.

To consider the case that $\lambda \neq 0$ we note that in this case the condition number of $B = (\lambda^2 I + V^T V)$ will be important in solving

$$(\lambda^2 I + V^T V)z = V^T y.$$

However we have

Theorem 3 *For any* $\lambda \geq 0$, *cond*$(\lambda^2 I + V^T V) \leq$ *cond*$(V^T V)$.

Proof If $V^T V$ has eigenvalues $\alpha_1 \geq \alpha_2 \geq \ldots \geq \alpha_m \geq 0$ then the eigenvalues of $(\lambda^2 I + V^T V)$ are $(\lambda^2 + \alpha_i)$, $i = 1, \ldots, m$. Therefore *cond*$(V^T V) = \alpha_1/\alpha_m$ and *cond*$(\lambda^2 I + V^T V) = (\alpha_1 + \lambda^2)/(\alpha_m + \lambda^2)$. However it follows easily that $\alpha_1/\alpha_m \geq (\alpha_1 + \lambda^2)/(\alpha_m + \lambda^2)$. ■

Since *cond*$(\lambda^2 I + V^T V) \leq$ *cond*$(V^T V)$ we expect that solving $(\lambda^2 I + V^T V)z = V^T y$ with $\lambda \neq 0$ will be more accurate than solving this equation with $\lambda = 0$. Since we have argued that the error growth in solving this equation for $\lambda = 0$ should be limited we expect that this should also be true when $\lambda \neq 0$.

Abstract

We consider the problems of estimating the parameters as well as the structure of binary-valued Markov networks. For maximizing the penalized log-likelihood, we implement an approximate procedure based on the pseudo-likelihood of Besag (1975) and generalize it to a fast exact algorithm. The exact algorithm starts with the pseudo-likelihood solution and then adjusts the pseudo-likelihood criterion so that each additional iterations moves it closer to the exact solution. Our results show that this procedure is faster than the competing exact method proposed by Lee, Ganapathi, and Koller (2006a). However, we also find that the approximate pseudo-likelihood as well as the approaches of Wainwright et al. (2006), when implemented using the coordinate descent procedure of Friedman, Hastie, and Tibshirani (2008b), are much faster than the exact methods, and only slightly less accurate.

Keywords: Markov networks, logistic regression, L_1 penalty, model selection, Binary variables

1. Introduction

In recent years a number of authors have proposed the estimation of sparse undirected graphical models for continuous as well as discrete data through the use of L_1 (lasso) regularization. For continuous data, one assumes that the observations have a multivariate Gaussian distribution with mean μ and covariance matrix Σ. Then an L_1 penalty is applied to $\Theta = \Sigma^{-1}$. That is, the penalized log-likelihood $\ell(\Theta) - \rho||\Theta||_1$ is maximized, where ℓ is the Gaussian log-likelihood, $||\Theta||_1$ is the sum of the absolute values of the elements of Θ and $\rho \geq 0$ is a user-defined tuning parameter. Several papers proposing estimation procedures for this Gaussian model have been published. Meinshausen and Bühlmann (2006) develop a lasso based method for estimating the graph structure and give theoretical consistency results. Yuan and Lin (2007), Banerjee et al. (2008) and Dahl et al. (2008) as well as Friedman, Hastie, and Tibshirani (2008a) propose algorithms for solving this penalized log-likelihood with the procedure in Friedman, Hastie, and Tibshirani (2008a), the *graphical lasso*, being especially fast and efficient.

Here we focus on estimation of networks of discrete, more specifically binary-valued, units with pairwise interactions. These are a special class of Markov networks. The use of L_1 penalties for this

special class as well as more general Markov networks was proposed by Lee, Ganapathi, and Koller (2006a). This problem is more difficult than the continuous Gaussian version because of the need to compute the first and second moments under the model, which are derivatives of the log-partition function. Figure 1 shows an example, and Table 1 shows some sample data from this graph. Given this data and a model for binary graphical data (detailed later), we would like to a) infer a structure something like that of Figure 1, and b) estimate the link parameters itself. For the data in Table 1, Figure 2 shows the path of solutions for varying penalty parameter. Most edges for L_1-norm ≤ 2 are correctly identified as in the graph in Figure 1. However, edge $(1,3)$ is absent in the true model but included in the L_1 penalized model relatively early.

Our main focus in this paper is to develop and implement fast approximate and exact procedures for solving this class of L_1-penalized binary pairwise Markov networks and compare the accuracy and speed of these to other methods proposed by Lee, Ganapathi, and Koller (2006a) and Wainwright et al. (2006). Here, by "exact" procedures we refer to algorithms that find the exact maximizer of the penalized log-likelihood of the model whereas "approximate" procedures only find an approximate solution.

In Section 2 we describe the Ising model as well as the details of the competing methods of Lee, Ganapathi, and Koller (2006a) and Wainwright et al. (2006). Section 3 then introduces the basic pseudo-likelihood model and outlines the computational approach to increase the speed of the algorithm. The pseudo-likelihood is a very interesting and fast approximate method which has

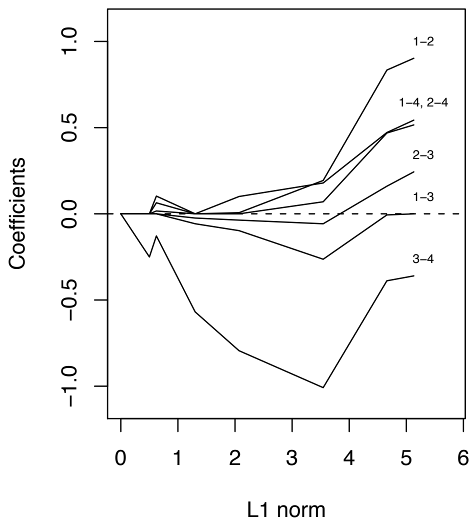

Figure 2: Toy example: profiles of estimated edge parameters as the penalty parameter is varied.

the added advantage that it can be used as a building block to a new algorithm for maximizing the penalized log-likelihood exactly. The adjustments necessary to achieve this are described in Section 4. Finally, Section 5 discusses the results of the simulations with respect to speed and accuracy of the competing algorithms.

2. The Model and Competing Methods

In this section we briefly outline the competing methods for maximizing the penalized log-likelihood. Apart from the method proposed in Lee, Ganapathi, and Koller (2006a), which we already mentioned above, we also discuss a very simple solution that was presented in Wainwright et al. (2006). We first describe the underlying model in more detail. Consider data generated under the Ising model

$$p(\mathbf{x},\Theta) = \exp\left[\sum_{s\in V}\theta_s x_s + \sum_{(s,t)\in E}\theta_{st}x_s x_t - \Psi(\Theta)\right].$$

for a single observation $\mathbf{x} = (x_1,\dots,x_p)^T \in \{0,1\}^p$ and model parameters θ_s and θ_{st} for $s,t \in V = \{1,\dots,p\}$. Here, V denotes the vertices and E the edges of a graph. $\Psi(\Theta)$ is the normalization constant, which is also known as the log-partition function. By setting $\theta_{st} = 0$ for $(s,t) \notin E$, and using the fact that $\mathbf{x}$ is a binary vector we can write the log-likelihood as

$$l(\mathbf{x},\Theta) = \log p(\mathbf{x},\Theta) = \sum_{s\geq t\geq 1}^{p}\theta_{st}x_s x_t - \Psi(\Theta)$$

where Θ is a symmetric $p \times p$ matrix with $\theta_{ss} = \theta_s$ for $s = 1, \dots, p$. Note that for notational convenience, we do not distinguish between θ_{st} and θ_{ts} and therefore we enforce symmetry of Θ although the log-likelihood only uses the lower-triangular matrix of Θ. For the L_1-penalty let $\mathbf{R}$ be a $p \times p$ lower triangular matrix of penalty parameters. The penalized log-likelihood for all N observations is

$$\sum_{s \geq t \geq 1}^{p} (\mathbf{X}^T\mathbf{X})_{st}\theta_{st} - N\Psi(\Theta) - N||\mathbf{R} * \Theta||_1$$

where $*$ denotes component-wise multiplication.

The algorithms that we will discuss in the following sections could be generalized to more general categorical variables or higher order interaction terms than those included in the Ising model. However, as we will see, solving these problems exactly is already computationally demanding in the pairwise binary case so that we chose not to adapt the algorithms to these more general settings.

2.1 The Lee, Ganapathi, and Koller (2006a) Method

The penalized log-likelihood is a concave function, so standard convex programming techniques can be used to maximize it. The main difficulty is that the log-partition function $\Psi(\Theta)$ is the sum over 2^p elements, and therefore it is computationally expensive to calculate Ψ or its derivatives in general. However, for sparse matrices Θ, algorithms such as the junction tree algorithm exist that can calculate Ψ and its derivatives efficiently. Therefore, it is especially important to maintain sparsity of Θ for any optimization method. Lee, Ganapathi, and Koller (2006a) achieve this by optimizing the penalized log-likelihood only over a set F of *active variables* which they gradually enlarge until an optimality criterion is satisfied.

To be more precise, they start out with a set of active variables $F = F_0$ (e.g., the diagonal of Θ if it is unpenalized). Using either conjugate gradients or BFGS, the penalized log-likelihood is maximized over the set of variables F. Then one of the currently inactive variables is selected by the *grafting* procedure (see Perkins et al., 2003) and added to the set F. These steps are repeated until grafting does not add any more features. The algorithm can be used for more general Markov networks, but for ease of implementation they choose to work with binary random variables and we do the same as well.

Their procedure provides an exact solution to the problem when the junction tree algorithm is used to calculate $\Psi(\Theta)$ and its derivatives. In their implementation, however, they used loopy belief propagation, which is faster on denser matrices, but only provides approximate results. In their method as well as ours, any procedure to evaluate $\Psi(\Theta)$ can be "plugged in" without any further changes to the rest of the algorithm; we decided to evaluate the speed and performance of only the exact algorithms. The relative performance of an approximate method using loopy belief propagation would likely be similar. They also provide a proof that under certain assumptions and using the L_1 regularized log-likelihood, it is possible to recover the true expected log-likelihood up to an error ε.

2.2 The Wainwright et al. (2006) Method

Wainwright et al. (2006) propose estimation of the Markov network by applying a separate L_1-penalized logistic regression to each of the p variables on the remaining variables. For every $s \in V$ regress x_s onto $\mathbf{x}_{\setminus s} = (x_1, \dots, x_{s-1}, x_{s+1}, \dots, x_p)^T$. Let the $p \times p$ matrix $\tilde{\Theta}$ denote the estimate of Θ.

Then set $\tilde{\theta}_{ss} = \beta_0$, the intercept of the logistic regression, and $\tilde{\theta}_{st} = \beta_t$, where β_t is the coefficient associated with x_t in the regression.

In the outline above, we assumed that Θ is a symmetric matrix. However, due to the way it was constructed, $\tilde{\Theta}$ is not necessarily symmetric. We investigate two methods for symmetrizing $\tilde{\Theta}$. The first way is to define Θ as

$$\theta_{st} = \theta_{ts} = \begin{cases} \tilde{\theta}_{st} & \text{if } |\tilde{\theta}_{st}| > |\tilde{\theta}_{ts}| \\ \tilde{\theta}_{ts} & \text{if } |\tilde{\theta}_{st}| \leq |\tilde{\theta}_{ts}| \end{cases}$$

which we call “Wainwright-max”. Similarly, “Wainwright-min” is defined by

$$\theta_{st} = \theta_{ts} = \begin{cases} \tilde{\theta}_{st} & \text{if } |\tilde{\theta}_{st}| < |\tilde{\theta}_{ts}| \\ \tilde{\theta}_{ts} & \text{if } |\tilde{\theta}_{st}| \geq |\tilde{\theta}_{ts}| \end{cases}.$$

Wainwright et al. (2006) mainly intended their method to be used in order to estimate the presence or absence of an edge in the underlying graph of the model. They show that under certain assumptions, their method correctly identifies the non-zero edges in a Markov graph, as $N \to \infty$ even for increasing number of parameters p or neighborhood sizes of the graph d, as long as N grows more quickly than $d^3 \log p$ (see Wainwright et al., 2008). Due to the simplicity of the method it is obvious that it could also be used for parameter estimation itself and here we will compare its performance in these cases to the pseudo-likelihood approach proposed below and the exact solution of the penalized log-likelihood. Furthermore, as an important part of this article is the comparison of the speeds of the underlying algorithms, we implement their method, using the fast coordinate descent algorithm for logistic regression with a lasso penalty (see Friedman, Hastie, and Tibshirani, 2008b).

3. Pseudo-likelihood Model

In this section we first introduce an approximate method to infer the structure of the graph that is based on pseudo-likelihoods (Besag, 1975). As we will see in the simulations section, the results are very close to the exact solution of the penalized log-likelihood. In the next section, we use the pseudo-likelihood model to design a very fast algorithm for finding an exact solution for the penalized Ising model.

The main computational problem in the Ising model is the complexity of the partition function. One possibility in this case is to solve an approximate version of the likelihood instead. Approaches of this kind have been proposed in various papers in the statistical literature before, for example the pseudo-likelihood approach of Besag (Besag, 1975) and the treatments of composite likelihoods in Lindsay (1998) and Cox and Reid (2004) among others. Here, we want to apply the approximation proposed in Besag (1975) to our problem. This approach is also related to the method of Wainwright et al. (2006), however instead of performing separate logistic regressions for every column of the parameter matrix Θ, the pseudo-likelihood approach here allows us to estimate all parameters at the same time. This way, the resulting matrix Θ is symmetric and no additional step like the max or min-rule described above is necessary. The log-pseudo-likelihood is then given by

$$\tilde{l}(\Theta|\mathbf{x}) = \sum_{s=1}^{p} \log p(x_s, \Theta|\mathbf{x}_{\setminus s})$$

with

$$\log p(x_s, \Theta|\mathbf{x}_{\setminus s}) = x_i(\theta_{ss} + \sum_{t \neq s} x_t \theta_{st}) - \Psi_s(\mathbf{x}, \Theta).$$

Here, $\Psi_s(\mathbf{x},\Theta)$ is the log-normalization constant when conditioning x_s on the other variables, which is exactly the same as in logistic regression with a logit link-function, that is,

$$\Psi_s(\mathbf{x},\Theta) = \log(1+\exp(\theta_{ss}+\sum_{t\neq s} x_t\theta_{st}))$$

where as above for notational convenience we set $\theta_{st} = \theta_{ts}$ for $t \neq s$. Putting all this together, the pseudo-likelihood for a single observation $\mathbf{x}$ is given by

$$\tilde{l}(\Theta|\mathbf{x}) = \sum_{s=1}^{p}\sum_{t=1}^{p} x_s x_t \theta_{st} - \sum_{s=1}^{p} \Psi_s(\mathbf{x},\Theta).$$

In the usual way, the pseudo-likelihood for all N observations is given by the sum of the pseudo-likelihood of the individual observations

$$\tilde{l}(\Theta|\mathbf{X}) = \sum_{k=1}^{N} \tilde{l}(\Theta|x_k)$$

where $\mathbf{x}_k$ is the kth row of matrix with observations $X \in \mathbb{R}^{N\times p}$.

As this is just a sum of logistic likelihoods, the pseudo-likelihood is a concave function and therefore the L_1-penalized pseudo-likelihood

$$\sum_{k=1}^{N} \tilde{l}(\Theta|\mathbf{x}_k) - N||\mathbf{S}*\Theta||_1$$

is concave as well. Here $\mathbf{S} = 2\mathbf{R} - diag(\mathbf{R})$ and is chosen to be roughly equivalent to the penalty terms in the penalized log-likelihood. The penalty term is doubled on the off-diagonal, as the derivative of the pseudo-likelihood on the off-diagonal is roughly twice as large as the derivative of the log-likelihood (see Equation 1).

3.1 Basic Optimization Algorithm

Due to its simple structure, a wide range of standard convex programming techniques can be used to solve this problem, although the non-differentiability of the L_1 penalty poses a problem. Here, we want to use a local quadratic approximation to the pseudo-likelihood. As the number of variables is $p(p+1)/2$, the Hessian could get very large, we restrict our quadratic approximation to have a diagonal Hessian.

In order to construct the approximation, we need the first and second derivative of $\tilde{l}$ w.r.t θ_{st}. These are

$$\frac{\partial\tilde{l}}{\partial\theta_{st}} = 2(\mathbf{X}^T\mathbf{X})_{st} - (\hat{\mathbf{p}}_s^T\mathbf{X})_t - (\hat{\mathbf{p}}_t^T\mathbf{X})_s \quad s\neq t, \tag{1}$$

$$\frac{\partial\tilde{l}}{\partial\theta_{ss}} = (\mathbf{X}^T\mathbf{X})_{ss} - \sum_{k=1}^{N} \hat{p}_{sk}$$

where $1-\hat{p}_{sk} = 1/(1+\exp(\theta_{ss}+\sum_{s\neq t} X_{kt}\theta_{st}))$. The second derivatives are

$$\frac{\partial^2\tilde{l}}{(\partial\theta_{st})^2} = -(\mathbf{X}^T\text{diag}(\hat{\mathbf{p}}_s)\text{diag}(1-\hat{\mathbf{p}}_s)\mathbf{X})_{tt} - (\mathbf{X}^T\text{diag}(\hat{\mathbf{p}}_t)\text{diag}(1-\hat{\mathbf{p}}_t)\mathbf{X})_{ss} \quad s\neq t,$$

$$\frac{\partial^2\tilde{l}}{(\partial\theta_{ss})^2} = -\sum_{k=1}^{N} \hat{p}_{sk}(1-\hat{p}_{sk}).$$

Algorithm 1: Estimation for L_1 penalized pseudo-likelihood

```
if $\Theta^{(0)}$ not given then
    Set $\Theta^{(0)} = \text{diag}(\text{logit}(\hat{\mathbf{p}}^{(0)}))$ where $\hat{p}_s^{(0)} = \frac{1}{N}\sum_{k=1}^{N} x_{ks}$
end
Set k:=0;
while not converged do
    With current estimate $\Theta^{(k)}$, define local approximation $f_{\Theta^{(k)}}(\Theta)$ to $\tilde{l} - N||\mathbf{S} * \Theta||_1$;
    Find solution $\Theta^*$ of $f_{\Theta^{(k)}}(\Theta)$;
    Perform backtracking line search on the line from $\Theta^{(k)}$ to $\Theta^*$ to find $\Theta^{(k+1)}$;
    Set k:=k+1
end
```

Assume that at the k-th step the parameter estimate is $\Theta^{(k)}$. Then define the local approximation to $\tilde{l}(\Theta|\mathbf{X}) - N||\mathbf{S} * \Theta||_1$ as

$$f_{\Theta^{(k)}}(\Theta) = C + \sum_{s \geq t} \frac{\partial \tilde{l}}{\partial \theta_{st}}(\theta_{st} - \theta_{st}^{(k)}) + \frac{1}{2}\frac{\partial^2 \tilde{l}}{(\partial \theta_{st})^2}(\theta_{st} - \theta_{st}^{(k)})^2 - N||\mathbf{S} * \Theta||_1$$

where C is some constant. As stated above, this is just a quadratic approximation with linear term equal to the gradient of $\tilde{l}$ and a diagonal Hessian with diagonal elements equal to the diagonal of the Hessian of $\tilde{l}$. The main reasons for using this simple structure are that it keeps the computation complexity per iteration low and it is very easy to solve this L_1 penalized local approximation. Let $\tilde{\Theta}$ be the minimizer of the unpenalized $f_{\Theta^{(k)}}(\Theta)$, then

$$\tilde{\theta}_{st} = \theta_{st}^{(k)} - \frac{\frac{\partial \tilde{l}}{\partial \theta_{st}}}{\frac{\partial^2 \tilde{l}}{(\partial \theta_{st})^2}}.$$

As the Hessian is diagonal, the L_1-penalized solution Θ^* of $f_{\Theta^{(k)}}(\Theta)$ can be obtained by soft thresholding as

$$\theta_{st}^* = \text{sign}(\tilde{\theta}_{st})\left(\tilde{\theta}_{st} - s_{st}/\frac{\partial^2 \tilde{l}}{(\partial \theta_{st})^2}\right)_+.$$

Using Θ^*, the next step $\Theta^{(k+1)}$ can now be obtained by, for example, a backtracking line search. The whole algorithm can be seen in Algorithm 1 and a proof of convergence that closely follows Lee, Lee, Abbeel, and Ng (2006b) is given in the appendix.

3.2 Speed Improvements

In practice, there are several things that can be done to speed up the algorithm given above. First of all, as Θ will in general be sparse, all computations to calculate $\hat{\mathbf{p}}$ should exploit this sparse structure. However, the sparseness of Θ can also be used in another way:

3.2.1 USING ACTIVE VARIABLES

As the solutions are usually sparse, calculating the gradient for all variables in every step is wasteful. Most variables are zero and will not change from one iteration to the next. In order to be more

Algorithm 2: Pseudo-likelihood algorithm using active variables

```
if $\Theta^{(0)}$ not given then
    Set $\Theta^{(0)} = \text{diag}(\text{logit}(\hat{\mathbf{p}}^{(0)}))$ where $\hat{p}_s^{(0)} = \frac{1}{N}\sum_{k=1}^N x_{ks}$
end
Set k:=0;
Set $\mathcal{A} = \{(s,t) : s \geq t, \theta_{st} \neq 0\}$ as active variables;
repeat
    while not converged over variables in $\mathcal{A}$ do
        Find $\Theta^{(k+1)}$ using local approximation over variables in $\mathcal{A}$;
        Set k:=k+1;
    end
    Set $\mathcal{A} = \left\{(s,t) : \theta_{st} \neq 0 \text{ or } \left|\frac{\partial \tilde{l}}{\partial \theta_{st}}\right| > s_{st}\right\}$;
until $\mathcal{A}$ did not change ;
```

efficient, it is possible to move variables that are zero only once in a while. Several different kinds of methods have been proposed to exploit this situation, for example grafting (Perkins et al., 2003) and the implementation of the penalized logistic regression in Friedman, Hastie, and Tibshirani (2008b) among others. In our case here, we use an outer and an inner loop. The outer loop decides which variables are active. The inner loop then optimizes over only the active variables until convergence occurs. Active variables are those that are either non-zero, or that have a gradient large enough so that they would become non-zero in the next step. More details are given in Algorithm 2.

When using this method, convergence is still guaranteed. In the outer loop, the criterion chooses variables to be active that are either non-zero already or will be non-zero after one step of the local approximation over all variables. Therefore, if the active set stays the same, no variables would be moved in the next step as all active variables are already optimal and therefore, we have a solution over all variables. However, if the active set changes, the inner loop is guaranteed to improve the penalized pseudo-likelihood and find the optimum for the given set of active variables. As there are only a finite number of different active variables sets, the algorithm has to converge after a finite number of iterations of the outer loop.

3.2.2 SUBSTITUTING THE LINE SEARCH

Calculating the pseudo-likelihood is computationally expensive compared to the cost of the local approximation. Therefore, we save time by not performing a line search after every step. Instead, we fix a step size γ and skip the line search. However, with this method, the algorithm may diverge. In order to detect this, we calculate the penalized pseudo-likelihood every 100 iterations and check that we improved during the last 100 steps. If yes, the step size remains the same. If no, reset the variables to where they were 100 steps ago and divide the step size by 2. If the step size drops below a pre-specified threshold, we revert to the original line-search algorithm. This way, in most cases, we do not have to perform the line-search. However, the algorithm is still guaranteed to converge as it automatically detects convergence problems when the fixed step size is used and reverts to the line-search algorithm, which as stated above is guaranteed to converge.

4. Exact Solution Using Pseudo-likelihood

We now turn to our new method for optimizing the penalized log-likelihood. As the log-likelihood is a concave function, there are several standard methods that can be used for maximizing it, for example, gradient descent, BFGS and Newton's method among others. For each step of these methods, the gradient of the log-likelihood has to be calculated. This requires the evaluation of the partition function and its derivatives, which is computationally much more expensive than any other part of the algorithms. Taking this into considerations, the standard methods mentioned above have the following drawbacks:

Gradient descent: It can take many steps to converge and therefore require many evaluations of the partition function and its derivatives (using the junction tree algorithm). Also, it does not control the number of non-zero variables in intermediate steps well to which the runtime of the junction tree algorithm is very sensitive. Therefore, intermediate steps can take very long.

BFGS: Takes less steps than gradient descent, but similar to gradient descent, intermediate steps can have more non-zero variables than the solution. Thus, same as above, computations of intermediate steps can be slow.

Newton's method: In order to locally fit the quadratic function, the second derivatives of the log-likelihood are needed. Computing these is computationally prohibitive.

Lee, Ganapathi, and Koller (2006a) use the BFGS method only on a set of active variables onto which additional variables are "grafted" until convergence. This mitigates the problem of slow intermediate steps and makes using BFGS feasible. However, this comes at the expense of an increased total number of steps, as only one variable at a time is being grafted. Here, we want to use the pseudo-likelihood in a new algorithm for maximizing the penalized log-likelihood.

The functional form of the pseudo-likelihood is by its definition closely related to the real likelihood and in Section 5 we will see that its solutions are also very similar, indicating that it approximates the real likelihood reasonably well. Furthermore, we can also maximize the pseudo-likelihood very quickly. We want to leverage this by using a quasi-Newton method in which we fit a "tilted" pseudo-likelihood instead of a quadratic function. Specifically, among all functions of the form

$$f_{\Theta^{(k)}} = \frac{1}{2}\tilde{l} + \sum_{s \geq t} a_{st}(\theta_{st} - \theta_{st}^{(k)}) - \gamma \sum_{s \geq t} (\theta_{st} - \theta_{st}^{(k)})^2 - N||\mathbf{R} * \Theta||_1,$$

we fit the one that at $\Theta^{(k)}$ is a first order approximation to the penalized log-likelihood l. Essentially, $f_{\Theta^{(k)}}$ is an L_1-penalized pseudo-likelihood with an added linear term as well as a very simple quadratic term for some $\gamma > 0$. Here, a_{st} will be chosen so that the sub-gradient is equal to the penalized log-likelihood l at $\Theta^{(k)}$. The additional quadratic term with coefficient γ is only being included to ensure the existence of a global maximum. In practice, we can set $\gamma = 0$, unless a convergence problem occurs. In our simulations, $\gamma = 0$ always worked very well.

In particular, for the approximation at $\Theta^{(k)}$, choose a_{st} such that

$$\begin{aligned} f_{\Theta^{(k)}} = \frac{1}{2}\Bigg(& \tilde{l}(\Theta|\mathbf{X}) + \sum_{s>t}(\theta_{st}-\theta_{st}^{(k)})\left((\hat{\mathbf{p}}(\Theta^{(k)})_s^T\mathbf{X})_t + (\hat{\mathbf{p}}(\Theta^{(k)})_t^T\mathbf{X})_s - 2\cdot N\cdot w_{st}(\Theta^{(k)})\right) + \\ & + \sum_s(\theta_{ss}-\theta_{ss}^{(k)})\left(\sum_k \hat{p}_{sk}(\Theta^{(k)}) + (\mathbf{X}^T\mathbf{X})_{ss} - 2\cdot N\cdot w_{ss}(\Theta^{(k)})\right)\Bigg) - \\ & - \sum_{s\geq t}\gamma(\theta_{st}-\theta_{st}^{(k)})^2 - N||\mathbf{R}*\Theta||_1 \end{aligned}$$

where $\mathbf{W}$ is a matrix with elements $w_{st}(\Theta) = \frac{\partial\Psi}{\partial\theta_{st}}(\Theta) = \mathbb{E}_\Theta(x_s x_t)$ is the derivative of the partition function and $\hat{\mathbf{p}}_s$ is as defined in the pseudo-likelihood section.

For the algorithm, we need an initial parameter estimate $\Theta^{(0)}$, which we pick as follows: Let $Z(\theta) = \frac{e^\theta}{1+e^\theta}$ be the logistic function and let Z^{-1} denote its inverse. Then choose

$$\theta_{st}^{(0)} = \begin{cases} 0 & \text{if } s \neq t \\ Z^{-1}\left(\frac{1}{N}\sum_{k=1}^N x_{ks}\right) & \text{if } s = t \end{cases}.$$

In this case we than have $\hat{p}_{sk} = \frac{1}{N}\sum_{k=1}^N x_{ks} \quad \forall k$ and also

$$W_{st} = \begin{cases} \left(\frac{1}{N}\sum_{k=1}^N x_{ks}\right)\left(\frac{1}{N}\sum_{k=1}^N x_{kt}\right) & \text{if } s \neq t \\ \left(\frac{1}{N}\sum_{k=1}^N x_{ks}\right) & \text{if } s = t \end{cases}$$

and together with $\gamma = 0$ we then get that

$$f_{\Theta^{(0)}} = \frac{1}{2}\tilde{l}(\Theta|\mathbf{X}) - N||\mathbf{R}*\Theta||_1$$

and thus just a regular pseudo-likelihood step. The only slight difference is that in this case the penalty term on the diagonal is twice as large as in the pseudo-likelihood case presented above. However, in practice we recommend not to penalize the diagonal at all, so that this difference vanishes. Therefore, this algorithm is a natural extension of the pseudo-likelihood approach that starts out by performing a regular pseudo-likelihood calculation and then proceeds to converge to the solution by a series of adjusted pseudo-likelihood steps.

The algorithm for maximizing the penalized log-likelihood is now very similar to the one presented for maximizing the penalized pseudo-likelihood. Assume our current estimate is $\Theta^{(k)}$. Then approximate the log-likelihood locally by $f_{\Theta^{(k)}}$ and find the maximizer Θ^* of $f_{\Theta^{(k)}}$. This is essentially the pseudo-likelihood and the algorithm presented above can easily be adjusted to accommodate the additional terms. Now, using a line search on the line between $\Theta^{(k)}$ and Θ^*, find the next estimate $\Theta^{(k+1)}$. This algorithm is guaranteed to converge by the same argument as the pseudo-likelihood algorithm. The proof that $f_{\Theta^{(k)}}$ approximates l at $\Theta^{(k)}$ to first order can be found in Appendix B, which is a prerequisite for the convergence proof of the algorithm in Appendix A.

4.1 Speed Improvement

As for the pseudo-likelihood algorithm, we can again save computations by using the active variables technique presented above. Here, the savings in time are especially large due to a special feature of the junction tree algorithm that we use to calculate the derivatives of the partition function.

Algorithm 3: Likelihood algorithm using active variables

```
if $\Theta^{(0)}$ not given then
    Set $\Theta^{(0)} = \mathrm{diag}(\mathrm{logit}^{-1}(\hat{\mathbf{p}}^{(0)}))$ where $\hat{p}_s^{(0)} = \frac{1}{N}\sum_{k=1}^{N} x_{ks}$
end
Set k:=0;
Set $\mathcal{A} = \{(s,t) : s \geq t, \theta_{st} \neq 0\}$ as active variables;
repeat
    while not converged over variables in $\mathcal{A}$ do
        Calculate $\mathbf{W}$ only over variables in $\mathcal{A}$;
        Find $\Theta^{(k+1)}$ using local approximation over variables in $\mathcal{A}$;
        Set k:=k+1;
    end
    Calculate the whole matrix $\mathbf{W}$;
    Set $\mathcal{A} = \left\{(s,t) : \theta_{st} \neq 0 \text{ or } \left|\frac{\partial l}{\partial \theta_{st}}\right| > r_{st}\right\}$;
until $\mathcal{A}$ did not change ;
```

In order to calculate derivatives with respect to non-zero variables, only one pass of the junction tree algorithm is necessary. However, p passes of the junction tree are needed in order to get the full matrix of derivatives $\mathbf{W}$. Therefore, depending on the size of p, using only active variables can be considerable faster. For details, see Algorithm 3.

4.2 Graphical Lasso for the Discrete Case

In the case of Gaussian Markov networks, the graphical lasso algorithm (see Friedman, Hastie, and Tibshirani, 2008a) is an very efficient method and implementation for solving the L_1-penalized log-likelihood. In order to leverage this speed, we extended the methodology to the binary case treated in this article. However, the resultant algorithm was not nearly as fast as expected. In the Gaussian case, the algorithm is very fast as the approach to update the parameter matrix Θ one row at a time allows for a closed form solution and efficient calculations. In the binary case on the other hand, the computational bottleneck is not all of the calculation involved in the update of Θ, but specifically by a large margin the evaluations of the partition function itself. Therefore, any fast algorithm for solving the penalized log-likelihood exactly has to use as few evaluations of the partition function as possible. The graphical lasso approach is thus not suitable for the binary case as it takes a lot of small steps towards the solution.

This observation also explains the improvement in speed of the pseudo-likelihood based exact algorithm over the specific methods proposed in Lee, Lee, Abbeel, and Ng (2006b). Standard convex optimization procedures often rely on either the first or second derivatives of the functions they seek to optimize. Newton-like procedures that use the second derivative often converge in very few steps, however these cannot be used here as it is prohibitively expensive to evaluate the second derivative of the partition function, even in small examples. Approaches like conjugate gradients of BFGS as proposed in Lee, Lee, Abbeel, and Ng (2006b) are somewhat less efficient and take more steps. This is where the advantage of using the pseudo-likelihood as a local approximation comes into play. It usually only takes very few steps to converge and is therefore faster than standard methods.

5. Simulation Results

In order to compare the performance of the estimation methods for sparse graphs described in this article as well as Lee, Ganapathi, and Koller (2006a) and Wainwright et al. (2006), we use simulated data and compare the speed as well as the accuracy of these methods.

5.1 Setup

Before simulating the data it is necessary to generate a sparse symmetric matrix Θ. First, the diagonal is drawn uniformly from the set $\{-0.5, 0, 0.5\}$. Then, using the average number of edges per node, upper-triangular elements of Θ are drawn uniformly at random to be non-zero. These non-zero elements are then set to either -0.5 or 0.5, again each uniformly. In order for Θ to by symmetric, the lower triangular matrix is set equal to the upper triangular matrix. The actual data is generated by Gibbs sampling using Θ as described above.

With respect to the penalty parameters that we use for the different methods, we always leave the diagonal unpenalized and all off-diagonal elements have the same parameter ρ, that is we set

$$r_{st} = \begin{cases} 0 & \text{if } s = t \\ \rho & \text{otherwise} \end{cases}$$

and the penalty term matrix for the pseudo-likelihood $\mathbf{S} = 2\mathbf{R} - \operatorname{diag}(\mathbf{R})$ as defined above. For the Wainwright-methods, the penalty parameter is ρ with no penalty on the intercept. Although the log-likelihood functions that are being penalized are somewhat different, this choice of parameters makes them perform roughly equivalent, as can be seen in Figure 3. The number of edges is plotted against the penalty parameter used and all methods behave very similar. However, in order not to confound some results by these slight differences of the effects of the penalty, all the following plots are with respect to the number of edges in the graph, not the penalty parameter itself.

5.2 Speed Comparison

First, we compare the speed of the four methods for the L_1-penalized model. We used an annealing schedule for Lee, Ganapathi, and Koller (2006a) to improve convergence as suggested in their article. Plots of the speeds of the exact methods can be seen in Figure 4 and the approximate methods are shown in Figure 5. Each plot shows the time the algorithm needed to converge versus the number of edges in the estimated graph. As can be seen, the pseudo-likelihood based exact algorithm described above is considerable faster than the one proposed in Lee, Ganapathi, and Koller (2006a). For the approximate algorithms, we can see that the p logistic regressions in the Wainwright et al. (2006) algorithm take roughly the same amount of time as the pseudo-likelihood algorithm presented above. This is not surprising due to the similarity of the optimization methods and any difference that can be observed in Figure 5 is mostly due to the specific implementations used. Furthermore, we would like to note that we decided to plot the speed against the number of edges in the graph instead of the penalty parameter, as the runtime of the algorithm is very closely related to the actual sparseness of the graph.

Overall, when comparing the computation times for the exact algorithms to the approximate algorithms, we can see that the approximate methods are orders of magnitude faster and do not suffer from an exponentially increasing computation time for decreasing sparsity as the exact methods. Therefore, if an exact solution is required, our exact algorithm is preferable. On the other hand, the

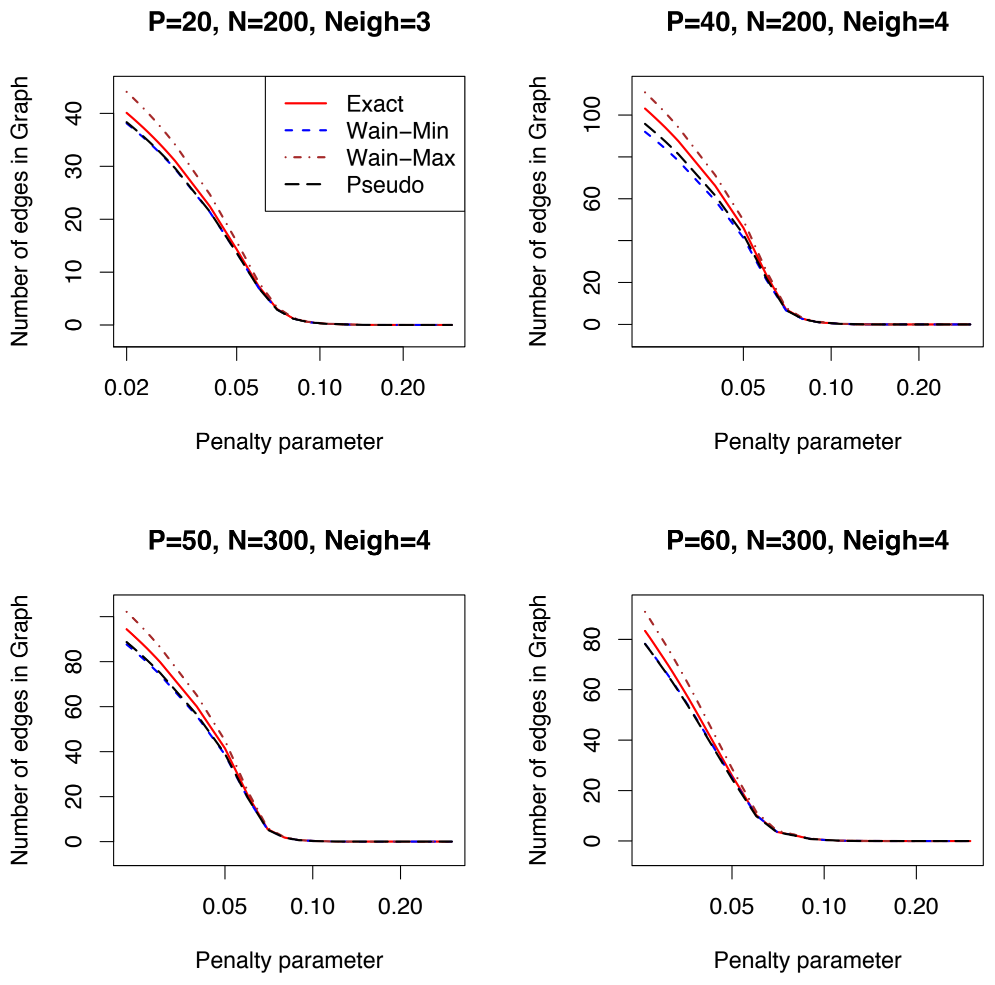

Figure 3: Number of edges in the graph vs. penalty parameter for different problem sizes, averaged over 20 simulations.

superior speed of the pseudo-likelihood and Wainwright et al. (2006) algorithm warrants a closer look at the trade-off with respect to accuracy.

5.3 Accuracy Comparisons

In this subsection we compare the algorithms mentioned above with respect to the accuracy with which they recover the original model. As both our L_1 penalized exact algorithm and the one by Lee, Ganapathi, and Koller (2006a) find the exact maximizer of the L_1-penalized log-likelihood, we only use our algorithm in the comparison. The other 3 methods we compare to are "Wainwright-min", "Wainwright-max" and the pseudo-likelihood.

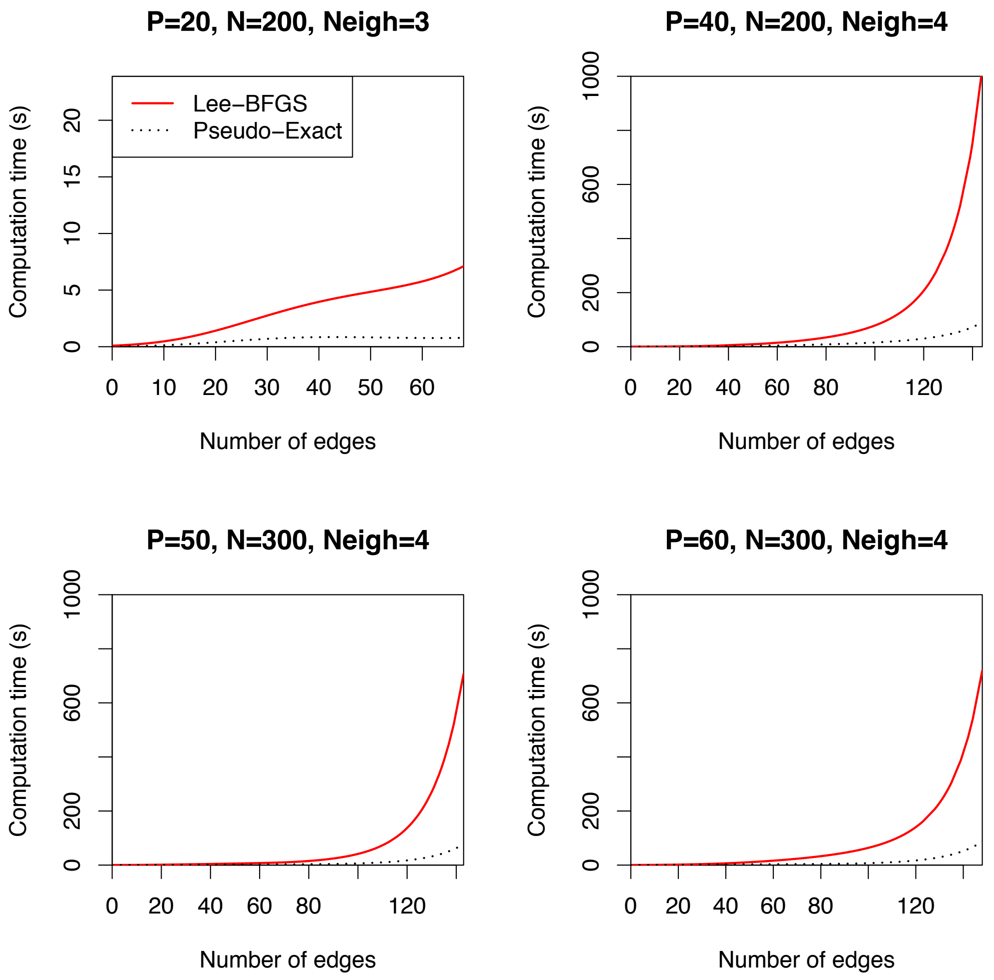

Figure 4: Computation time of the exact algorithms versus the number of non-zero elements in Θ. Values are averages over 20 simulation runs, along with ± 2 standard error curves. Also, p is the number of variables in the model, N the number of observations and *Neigh* is the average number of neighbors per node in the simulated data. Here, Pseudo-Exact refers to the the exact solution algorithm that uses adjusted pseudo-likelihoods as presented in Section 4.

First we investigate how closely the edges in the estimated graph correspond to edges in the true graph. In Figure 6, ROC curves are shown, plotting the false positive (FP) rates against true positive (TP) rates for edge identification, for various problem sizes. Note that only partial ROC curves are shown since our method cannot estimate non-sparse graphs due to very long computation times. Overall, we see that all approximate algorithms match the results of the exact solution very closely and in some of the plots, the curves even lie almost on top of each other.

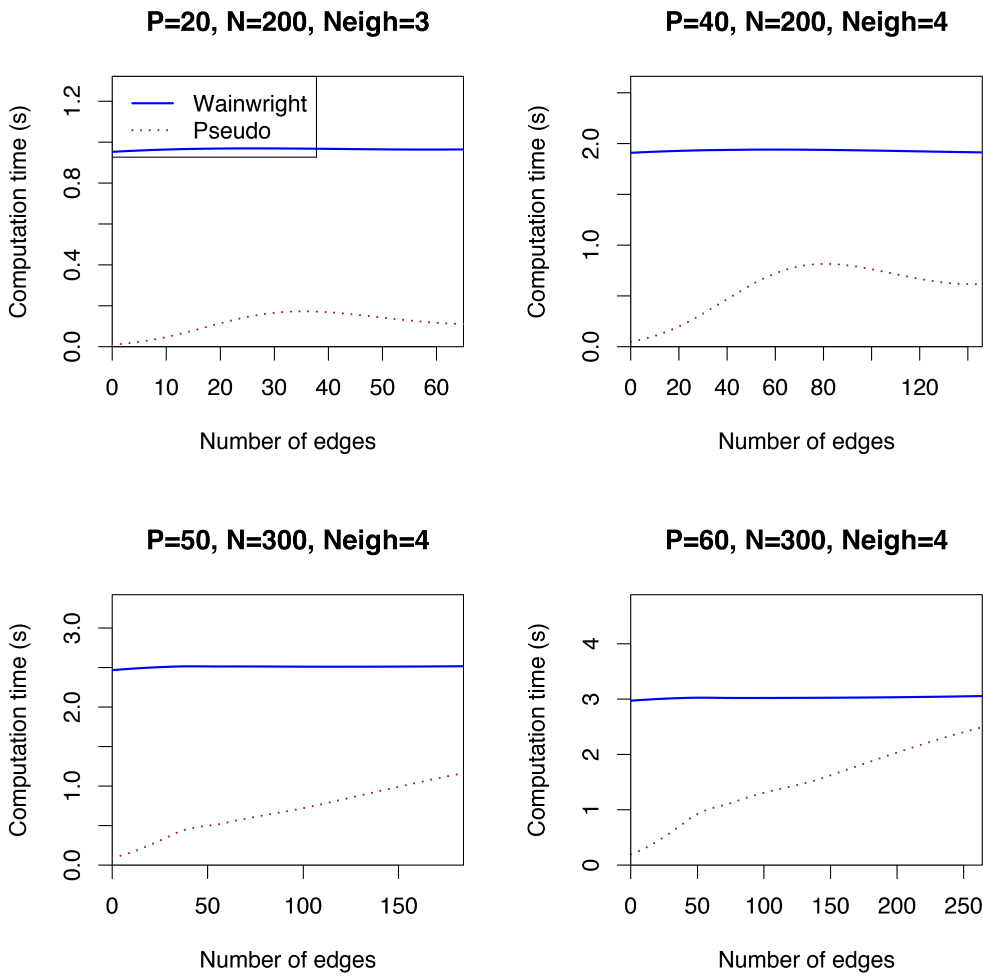

Figure 5: Computation time for the approximate algorithms versus the number of non-zero elements in Θ. Values are averages over 20 simulation runs, along with ± 2 standard error curves. Also, p is the number of variables in the model, N the number of observations and *Neigh* is the average number of neighbors per node in the simulated data.

Apart from the accuracy of edge identification, we also consider other statistics. The unpenalized log-likelihood is a measure of how well the estimated model fits the observed data (higher values are better). Again, the approximate solutions are all very close to the exact solution (see Figure 7) and the differences are always smaller than 2 standard deviations. In Figure 8, we plot the difference of the log-likelihood with respect to the exact solution. Also in this plot, no clear "winner" can be identified.

We also use the Kullback-Leibler divergence $D_{KL}(\mathbb{P}||\mathbb{Q})$, which is a measure of difference between a true probability distribution $\mathbb{P}$ and an arbitrary other distribution $\mathbb{Q}$. Here, for the true

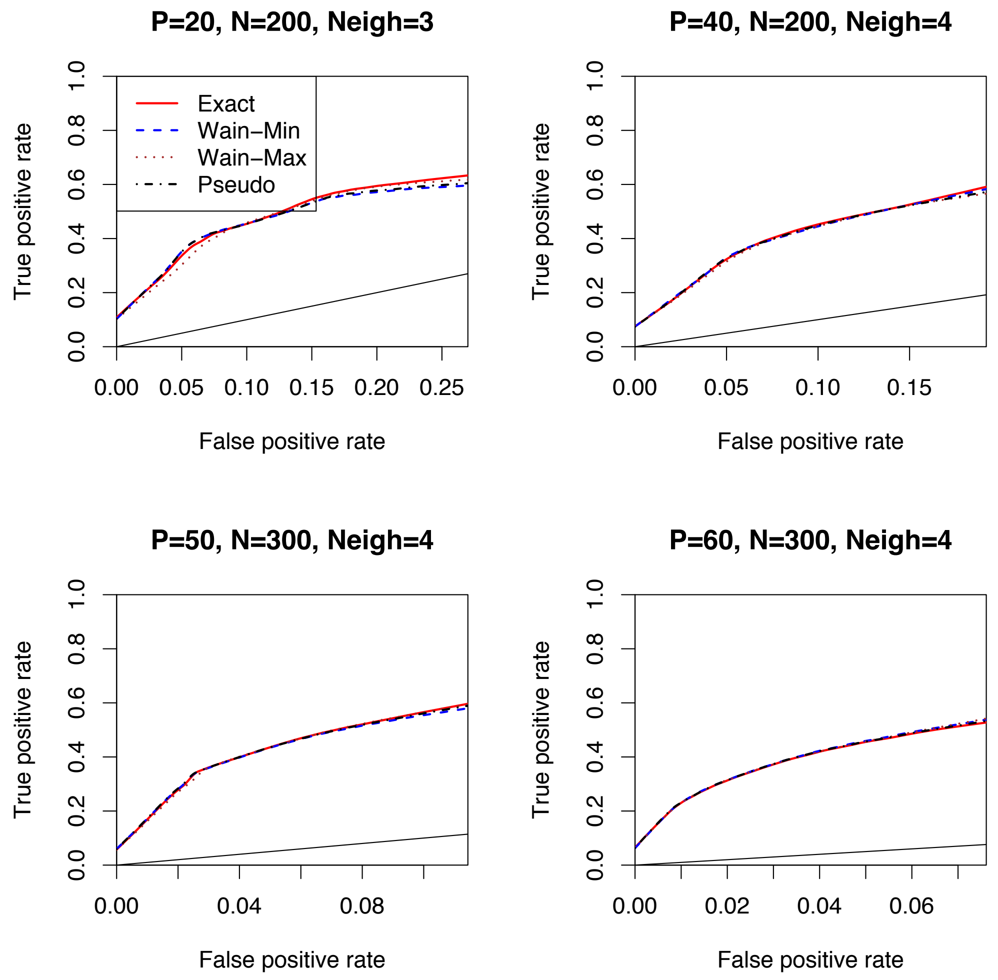

Figure 6: ROC curves: false positive versus true positive rate for edge identification. Values are averages over 20 simulation runs.

probability distribution we use the distribution of the binary Markov network using the true Θ_0-matrix that was used to generate the simulated data. The distribution $\mathbb{Q}$ in our case is the binary Markov network using the estimated $\hat{\Theta}$-matrix. We can compute $D_{KL}(\mathbb{P}||\mathbb{Q})$ as

$$\begin{aligned} D_{KL}(\mathbb{P}||\mathbb{Q}) &= \sum_x \mathbb{P}(x)\log\frac{\mathbb{P}(x)}{\mathbb{Q}(x)} = \Psi(\Theta_0) - \Psi(\hat{\Theta}) + \sum_x \mathbb{P}(x)\operatorname{tr}\left(xx^T(\hat{\Theta}-\Theta_0)\right) = \\ &= \Psi(\Theta_0) - \Psi(\hat{\Theta}) + \operatorname{tr}\left(\mathbb{E}_{\mathbb{P}}(xx^T)(\hat{\Theta}-\Theta_0)\right). \end{aligned}$$

If the distributions $\mathbb{P}$ and $\mathbb{Q}$ are identical, then $D_{KL}(\mathbb{P}||\mathbb{Q}) = 0$. In our simulations, the exact solution has lower KL-divergence than the other methods, however the differences are very small. For a plot of the KL-divergence against the number of edges in the model see Figure 9. Again, all approximate

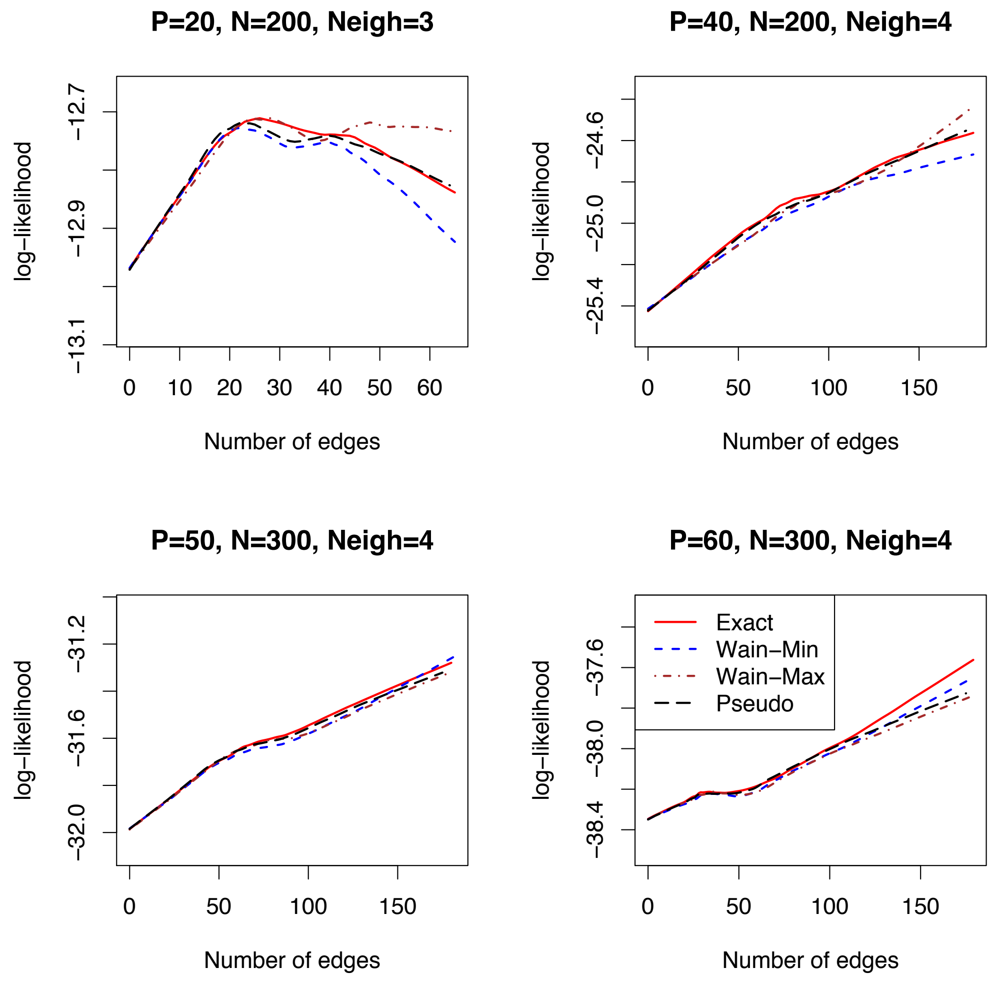

Figure 7: Log-likelihood of the estimated model vs number of edges in the graph for different problem sizes, averaged over 20 simulations.

methods match the exact solution very closely and any differences are well within the 2 standard deviation error band. In Figure 10 the differences of the KL-divergence of the approximate to the exact method can be seen. Again, all methods are very close with the pseudo-likelihood approach performing the best in this case.

6. Discussion

When we embarked on this work, our goal was to find a fast method for maximizing the L_1 penalized log-likelihood of binary-valued Markov networks. We succeeded in doing this, and found that the resulting procedure is faster than competing exact methods. However, in the course of this work,

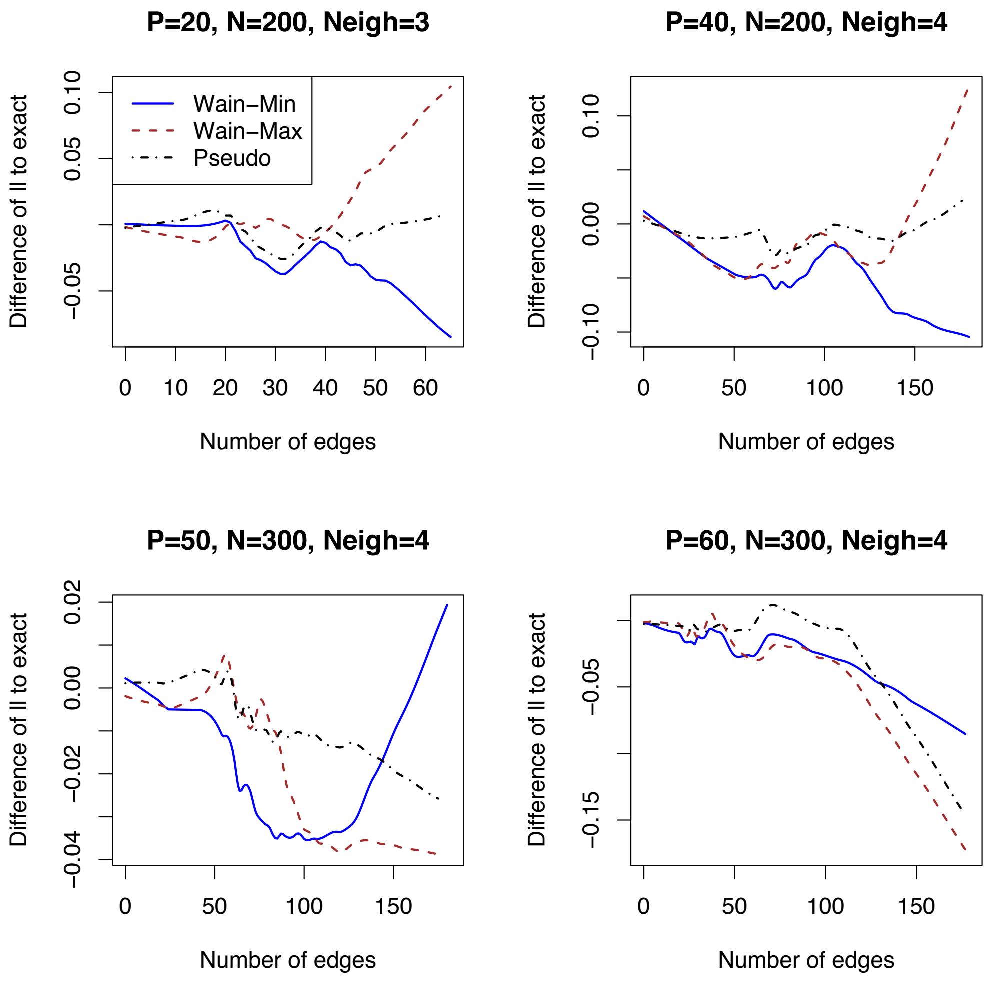

Figure 8: Difference of log-likelihood of the estimated model to the exact model vs number of edges in the graph for different problem sizes, averaged over 20 simulations.

we also learned something surprising: several approximate methods exist that are *much* faster and only slightly less accurate than the exact methods. In addition, when a dense solution is required, the exact methods become infeasible while the approximate methods can still be used. Our implementation of the methods of Wainwright et al. (2006) uses the fast coordinate descent procedure of Friedman, Hastie, and Tibshirani (2008b), a key to its speed. The pseudo-likelihood algorithm also uses similar techniques, which make it very fast as well. We conclude that the Wainwright and pseudo-likelihood methods should be seriously considered for computation in Markov networks.

In this article, we treated the case of pairwise Markov networks with a binary response variable. We think these methods can also be extended to more general cases. With respect to the response variables, a multinomial instead of a binary response could be used. In addition to this, it would

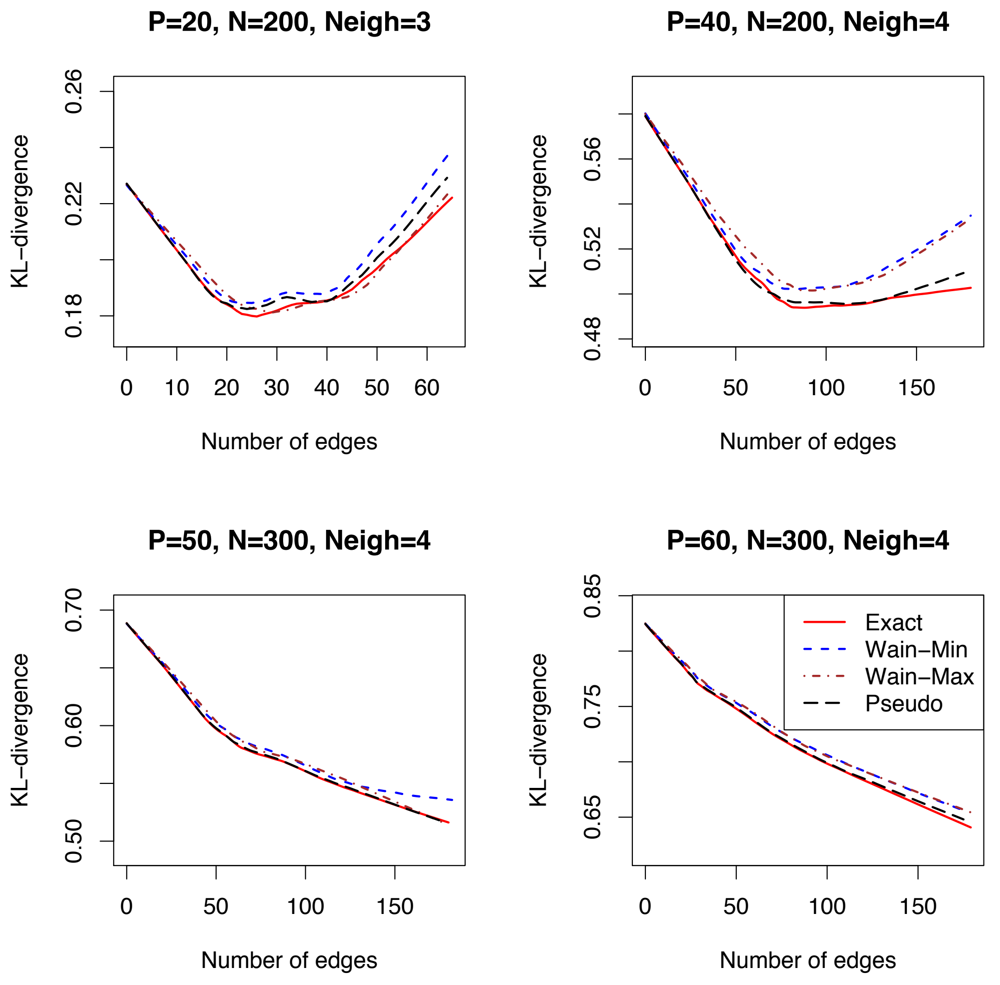

Figure 9: Kullback-Leibler divergence of the estimated model vs. number of edges in the graph for different problem sizes, averaged over 20 simulations.

also be possible to generalize the graph structure by introducing higher order interaction terms. Apart from these extensions, an interesting possibility for future work would also be to prove the theoretical results of Wainwright et al. (2006) for the pseudo-likelihood model. Furthermore, we believe that both the exact and fast approximate methods can also be applied to the learning of multilayer generative models, such as restricted Boltzmann machines (see Hinton, 2007).

An R language package for fitting sparse graphical models, both by exact and approximate methods, will be made available on the authors' websites.

We also want to thank the editor and two anonymous reviewers for their work and helpful reviews.

Appendix A. Proof of Convergence for Penalized Pseudo-likelihood and Penalized Log-likelihood Algorithms

Lee, Lee, Abbeel, and Ng (2006b) gives a proof of convergence for an algorithm that solves an L_1 constrained problem by quadratic approximation of the objective function. Here, we will follow this proof very closely and make few changes to accommodate that we are only using a first order approximation and are working with the Lagrangian form of the L_1 constrained problem instead of the standard form.

Assume that $g(\Theta)$ is a strictly convex function with a global minimum that we want to minimize. Furthermore, let $f_{\Theta_0}(\Theta)$ be a first order approximation of g at Θ_0 and assume that $f_{\Theta_0}(\Theta)$ is strictly convex, has a global optimum and is jointly continuous in (Θ_0, Θ). Here, by first order approximation at Θ_0, we mean that $f_{\Theta_0} - g$ is twice continuously differentiable with derivative 0 at Θ_0. Assume that our algorithm works as follows:

```
initialize $\Theta^{(0)}$;
Set k:=0;
**while** *not converged* **do**
    With current estimate $\Theta^{(k)}$, define local approximation $f_{\Theta^{(k)}}(\Theta)$ to $g$;
    Find solution $\Theta^*$ of $f_{\Theta^{(k)}}(\Theta)$;
    Perform backtracking line search on the line from $\Theta^{(k)}$ to $\Theta^*$ to find $\Theta^{(k+1)}$;
    Set k:=k+1;
**end**
```

Then $\Theta^{(k)}$ converges to the global minimizer of $g(\Theta)$. In order to show this, we first need the following lemma:

Lemma 1 *Let Θ_0 be any point that is not the global optimum. Then there is an open subset S_{Θ_0} and a constant K_{Θ_0} such that for every Φ_0 in S_{Θ_0} every iteration of the algorithm starting at Φ_0 will return a point Φ_1 that improves the objective by at least K_{Θ_0}, that is, $g(\Phi_1) \leq g(\Phi_0) - K_{\Theta_0}$.*

Proof First, let f_{Θ_0} be an approximation to g at Θ_0 with global optimum Θ_1. Then set

$$\delta = f_{\Theta_0}(\Theta_0) - f_{\Theta_0}(\Theta_1)$$

and we know that $\delta > 0$ as Θ_0 is not the global optimum. Now, there exists an $\varepsilon > 0$ such that for $\Phi_0 \in S_{\Theta_0} := \{\Theta : ||\Theta - \Theta_0||_2 < \varepsilon\}$ the following holds:

$$|g(\Theta_0) - g(\Phi_0)| \leq \frac{\delta}{8}$$

and

$$|f_{\Phi_0}(\Phi_1) - f_{\Theta_0}(\Theta_1)| \leq \frac{\delta}{4}$$

where Φ_1 is the global minimum of f_{Φ_0}. The existence of this ε follows from the continuity and convexity of f and g. Then

$$f_{\Phi_0}(\Phi_1) \leq f_{\Theta_0}(\Theta_1) + \frac{\delta}{4} \leq f_{\Theta_0}(\Theta_0) - \frac{3\delta}{4} = \\ = g(\Theta_0) - \frac{3\delta}{4} \leq g(\Phi_0) - \frac{\delta}{2}.$$

With step size $0 < t < 1$ in the line search, and using the previous result, it holds that

$$f_{\Phi_0}(\Phi_0 + t(\Phi_1 - \Phi_0)) \leq (1-t) f_{\Phi_0}(\Phi_0) + t f_{\Phi_0}(\Phi_1) \leq g(\Phi_0) - t\frac{\delta}{2}$$

For the next step observe that the minimizer Φ_1 of f_{Φ_0} is a continuous function of Φ_0 due to the convexity of f in the second argument and the continuity in both arguments. Then, as S_{Θ_0} is a compact set, there exists a compact set T_{Θ_0} with $\Phi_1(\Phi_0) \in T_{\Theta_0}$ for all $\Phi_0 \in S_{\Theta_0}$. Thus, as f_{Θ_0} is a first order approximation of g at Θ_0, there exists a C such that for all $\Theta \in T_{\Theta_0}$

$$g(\Theta) \leq f_{\Theta_0}(\Theta) + C||\Theta - \Theta_0||_2^2.$$

Therefore

$$g(\Phi_0 + t(\Phi_1 - \Phi_0)) \leq g(\Phi_0) - t\frac{\delta}{2} + Ct^2||\Phi_1 - \Phi_0||_2^2 \leq \\ \leq g(\Phi_0) - t\frac{\delta}{2} + t^2 CD^2$$

where D is the diameter of T_{Θ_0}. Now set $t^* = \min\left(1, \frac{\delta}{4CD^2}\right)$ and thus we know that it exists a Φ^* such that

$$g(\Phi^*) \leq g(\Phi_0) - t^*\frac{\delta}{2} + t^{*2}CD^2.$$

Setting $K_{\Theta_0} = t^*\frac{\delta}{2} - t^{*2}CD^2 > 0$ now finishes the proof. ■

Now, using the lemma the rest of the proof is again very similar as in Lee, Lee, Abbeel, and Ng (2006b) and we only repeat it here for completeness.

Theorem 1 *The algorithm converges in a finite number of steps.*

Proof Pick $\delta > 0$ arbitrary. Let Θ^* the global optimum and Θ_0 the starting point of the algorithm. Then there exists a compact set K such that $g(\Theta) > g(\Theta_0)$ for every $\Theta \notin K$. Define $P_\delta = \{\Theta : ||\Theta - \Theta^*|| \geq \delta\} \cap K$. We will show convergence by showing that the algorithm can only spend a finite number of steps in P_δ. For every Θ in P_δ there exists an open set S_Θ. So

$$P_\delta \subseteq \cup_{\Theta \in P_\delta} S_\Theta$$

As P_δ is compact, Heine-Borel guarantees that there is a finite set Q_δ such that

$$P_\delta \subseteq \cup_{\Theta \in Q_\delta} S_\Theta.$$

Furthermore, as Q_δ is finite, define

$$C_\delta = \min_{\Theta \in Q_\delta} K_\Theta.$$

As the lemma guarantees that every step of the algorithm inside P_δ improves the objective by at least C_δ and a global optimum exists by assumption, the algorithm can at most spend a finite number of steps in P_δ. Therefore, the algorithm has to converge in a finite number of steps. ■

For the penalized pseudo-likelihood algorithm, by definition of the approximation it is evident that it is a first order approximation. The situation for the penalized log-likelihood algorithm is a little more complicated and it will be shown in the next section of the appendix that the proposed approximation is to first order and therefore satisfies the assumptions of the proof.

Appendix B. First Order Approximation of Log-likelihood

In Section 4, we defined a function $f_{\Theta^{(k)}}$ to calculate the next estimate $\Theta^{(k+1)}$. The convergence proof in Appendix A requires that $f_{\Theta^{(k)}}$ is a first order approximation of the objective $l(\Theta|\mathbf{X}) - N||\mathbf{R} * \Theta||_1$. Here, we want to show that this is in fact the case. For this, we need to show that $f_{\Theta^{(k)}} - l(\Theta|\mathbf{X}) + N||\mathbf{R} * \Theta||_1$ is twice continuously differentiable with derivative 0 at $\Theta^{(k)}$.

First, inserting $f_{\Theta^{(k)}}$ from Section 4 yields

$$\begin{aligned}
d_{\Theta^{(k)}} &= f_{\Theta^{(k)}} - l(\Theta|\mathbf{X}) + N||\mathbf{R} * \Theta||_1 = \\
&= \frac{1}{2}\Bigg(\tilde{l}(\Theta|\mathbf{X}) + \sum_{s>t}(\theta_{st} - \theta_{st}^{(k)})\left((\hat{\mathbf{p}}(\Theta^{(k)})_s^T \mathbf{X})_t + (\hat{\mathbf{p}}(\Theta^{(k)})_t^T \mathbf{X})_s - 2 \cdot N \cdot w_{st}(\Theta^{(k)})\right) + \\
&\quad + \sum_s (\theta_{ss} - \theta_{ss}^{(k)})\left(\sum_k \hat{p}_{sk}(\Theta^{(k)}) + (\mathbf{X}^T\mathbf{X})_{ss} - 2 \cdot N \cdot w_{ss}(\Theta^{(k)})\right)\Bigg) - \\
&\quad - \sum_{s \geq t} \gamma(\theta_{st} - \theta_{st}^{(k)})^2 - l(\Theta|\mathbf{X})
\end{aligned}$$

which has derivative

$$\begin{aligned}
2\frac{\partial d_{\Theta^{(k)}}}{\partial \theta_{st}} &= 2(\mathbf{X}^T\mathbf{X})_{st} - (\hat{\mathbf{p}}(\Theta)_s^T \mathbf{X})_t - (\hat{\mathbf{p}}(\Theta)_t^T \mathbf{X})_s + (\hat{\mathbf{p}}(\Theta^{(k)})_s^T \mathbf{X})_t + (\hat{\mathbf{p}}(\Theta^{(k)})_t^T \mathbf{X})_s - \\
&\quad - 2 \cdot N \cdot w_{st}(\Theta^{(k)}) - 4\gamma(\theta_{st} - \theta_{st}^{(k)}) - 2(\mathbf{X}^T\mathbf{X})_{st} + 2 \cdot N \cdot w_{st}(\Theta)
\end{aligned}$$

for $s \neq t$ and

$$\begin{aligned}
2\frac{\partial d_{\Theta^{(k)}}}{\partial \theta_{st}} &= (\mathbf{X}^T\mathbf{X})_{ss} - \sum_k \hat{p}_{sk}(\Theta) + \sum_k \hat{p}_{sk}(\Theta^{(k)}) + (\mathbf{X}^T\mathbf{X})_{ss} - 2 \cdot N \cdot w_{ss}(\Theta^{(k)}) - \\
&\quad - 4\gamma(\theta_{ss} - \theta_{ss}^{(k)}) - 2(\mathbf{X}^T\mathbf{X})_{ss} + 2 \cdot N \cdot w_{ss}(\Theta)
\end{aligned}$$

for $s = t$. These are clearly continuous and differentiable. Furthermore, inserting $\Theta = \Theta^{(k)}$ yields that the derivative is 0. Therefore, $f_{\Theta^{(k)}}$ is a first order approximation and our proof holds.

Abstract

Algorithms that list graphs such that no two listed graphs are isomorphic, are important building blocks of systems for mining and learning in graphs. Algorithms are already known that solve this problem efficiently for many classes of graphs of restricted topology, such as trees. In this article we introduce the concept of a dense augmentation schema, and introduce an algorithm that can be used to enumerate any class of graphs with polynomial delay, as long as the class of graphs can be described using a monotonic predicate operating on a dense augmentation schema. In practice this means that this is the first enumeration algorithm that can be applied theoretically efficiently in any frequent subgraph mining algorithm, and that this algorithm generalizes to situations beyond the standard frequent subgraph mining setting.

Keywords: graph mining, enumeration, monotonic graph classes

1. Introduction

Among the most prominent graph mining problems is the problem of finding frequent subgraphs in databases of small graphs of any topology. This is witnessed by the large number of algorithms that have been proposed for this task (Yan and Han, 2002; Borgelt and Berthold, 2002; Kuramochi and Karypis, 2004; Inokuchi et al., 2003; Inokuchi, 2004; Huan et al., 2003; Nijssen and Kok, 2004; Leskovec et al., 2006). A fundamental problem that is addressed in all these works is how to enumerate a set of graphs such that no two graphs in the enumerated set are isomorphic with each other. The main motivation for this focus is that if duplicates would not be avoided, these algorithms would access the data more often than necessary and produce results that are larger than required.

To avoid isomorphic graphs in their output, all these existing graph mining algorithms use a methodology based on canonical codes. A canonical code is a code that uniquely identifies a set of isomorphic graphs. To determine if a graph should be part of the output, its canonical code is computed, and, in some algorithms, compared with the canonical codes of graphs found before.

A fundamental problem with the canonical code based approach, however, is that we essentially need to solve the graph isomorphism problem: if we could compute the canonical code of any graph efficiently, we could compute the codes of two graphs to determine if they are isomorphic. The state of the art is that no polynomial algorithm for the graph isomorphism problem is known. Consequently, it can be shown that when the existing graph mining algorithms are enumerating candidate subgraphs, the *delay* between two enumerated graphs is exponential in the worst case (in terms of the size of the largest graph enumerated).

The contribution of this article is that we introduce a novel algorithm for enumerating graphs that does not use canonical codes, and incrementally maintains data structures that ensure that no two isomorphic graphs are listed. We show that in contrast to other algorithms for enumerating graphs, this new algorithm outputs many classes of graphs, including arbitrary connected graphs, with polynomial delay, which makes this algorithm theoretically more efficient than any other graph enumeration algorithm used in the graph mining literature.

It is important to note that our algorithm works for many classes of graphs. If we would restrict the topology of the graphs, for instance, to only those graphs that are trees, the enumeration problem of frequent graph mining is already known to be more efficiently solvable, and algorithms are known (Wright et al., 1986; Nakano and Uno, 2004) and used in practice (Chi et al., 2005; Horváth et al., 2006).

Even though the frequency constraint is the most popular constraint in the graph mining literature, other constraints have been studied as well. An important property of the frequency constraint is that it is monotonic w.r.t. to subgraph isomorphism: if a graph is frequent, all its subgraphs are also frequent. In our algorithm we exploit this property to maintain data structures incrementally. An interesting question is to what extent enumeration with polynomial delay is feasible when the graphs to enumerate are not monotonic under the subgraph isomorphism relation. To this aim, we developed the concept of an *augmentation schema*. The augmentation schema defines relations between graphs in the space of graphs to enumerate (in the simplest case, the subgraph isomorphism relation). We will show that enumeration with polynomial delay is possible as long as an augmentation schema satisfies certain conditions, and the graphs to enumerate can be specified using a monotonic predicate w.r.t. the augmentation schema. We will specify our algorithm in terms of such augmentation schemas. This makes our method general enough to be applied in settings beyond the traditional frequent subgraph mining setting, and allows us also to enumerate both connected and unconnected graphs. For instance, we can also enumerate hereditary classes of graphs with bounded degree; a class of graphs is called *hereditary* if it is monotonic under the *induced* subgraph relation, instead of the traditional subgraph relation.

The problem of graph enumeration has not only been studied in the graph mining literature. In particular, Goldberg showed in the early nineties that there is a polynomial delay algorithm to list all graphs (Goldberg, 1992). We will provide more details about this algorithm in Section 3, where we will show that this algorithm cannot be used to list graphs that satisfy a monotonic predicate, as required in a graph mining setting. Many algorithms exist for enumerating classes of graphs without taking into account isomorphisms, such as classes of graphs described by first order logic formulas (Goldberg, 1993) and edge-maximal graphs with bounded branchwidth (Paul et al., 2006); it is not known how to list these classes while taking into account isomorphisms. Heuristic implementations exist for enumerating graphs in general (McKay, 1998), but these do not guarantee polynomial delay.

Our algorithm uses similar ideas as the algorithm of Goldberg (1992). In particular, as our algorithm maintains a data structure incrementally, our algorithm requires that all computed subgraphs are stored. In the pattern mining setting, where we are interested in finding these graphs, this is a common assumption.

This article is the full version of a workshop abstract (Ramon and Nijssen, 2007). Compared to the workshop abstract, in this article (1) we show how our method extends to other classes of graphs than connected graphs and (2) we provide full details and proofs.

The article is organized as follows. In Section 2 we introduce the problem of subgraph mining. In Section 3 we show why the algorithm of Goldberg is too limited for applications in graph mining. In Section 4 we introduce the concept of augmentation schemas and formally define the enumeration problems that we are addressing. In Section 5 we state our results. In Section 6 we provide a short introduction to concepts in group theory which we need in Section 7, where we outline our algorithm; Section 8 concludes. The proofs of our claims are given in an appendix.

2. Motivation

The main motivation for our work is the problem of efficiently mining subgraphs under constraints. The most common such problem is the problem of mining frequent subgraphs in a database of small graphs. We will first give a formal definition of this problem.

A graph g is a tuple (V,E) where V is a set of vertices and $E \subseteq V \times V$ is a set of edges. We denote with $V(g)$ the set of vertices and with $E(g)$ the set of edges of a graph g. In this article we restrict ourselves to unlabeled, simple graphs (i.e., undirected, unweighted, no loops, no multiple edges between two nodes). It easy to lift these restrictions. In particular, in frequent subgraph mining it is usually assumed that graphs have labels. However, our discussion is simplified by assuming that we do not have labels; this is not a fundamental restriction of our methodology.

There are many ways in which one can restrict the topology of graphs. For instance, a *path* is a graph in which all nodes have degree 2, except two nodes, which have degree one. A *tree* is a connected graph with k nodes and $k-1$ edges. When we use the word *graph*, we refer to graphs that have no *apriori* restriction on their topology (except being unlabeled and simple).

Between two graphs we can define the graph isomorphism and the subgraph isomorphism relations. Our definitions are as usual in the literature: two graphs g_1 and g_2 are *isomorphic* iff there is a bijection $\varphi : V(g_1) \rightarrow V(g_2)$ such that $(v_1,v_2) \in E(g_1) \Leftrightarrow (\varphi(v_1),\varphi(v_2)) \in E(g_2)$. We denote this by $g_1 \simeq_\varphi g_2$, where φ is the bijection between the graphs. The bijection can be omitted if this is clear from the context.

A graph g_1 is *subgraph isomorphic* to g_2 iff there is a *subgraph* (V',E') with $V' \subseteq V(g_2)$ and $E' \subseteq E(g_2)$, such that g_1 is isomorphic with (V',E'). This is denoted with $g_1 \preceq_\varphi g_2$, where φ is the bijection between the nodes of g_1 and the subset of nodes of g_2. A subgraph (V',E') of g_2 is an *induced subgraph* if for all $v,v' \in V' : \{v,v'\} \in E(g_2) \leftrightarrow \{v,v'\} \in E'$; in other words, all edges in g_2 between nodes in V' are also present in E'. A graph g_1 is *induced subgraph isomorphic* to g_2 iff g_1 is isomorphic with an induced subgraph of g_2.

The graph isomorphism and *sub*graph isomorphism problems should not be confused with each other. The *sub*graph isomorphism problem is known to be NP complete, while the graph isomorphism problem is believed to be in a complexity class of its own. For both problems in general no polynomial algorithm is known (Köbler et al., 1993).

The problem of frequent subgraph mining can now be formalized as follows. Given is a database of graphs, $DB = \{g_1, g_2, \ldots, g_n\}$, and a threshold t. Then we are interested in finding all graphs g for which the support is higher than or equal to t. The *support* of a graph g is the number of graphs in DB with which g is subgraph isomorphic.

This frequent subgraph mining problem can be generalized by replacing the minimum frequency constraint with other predicates. For instance, a predicate could involve an additional maximum size constraint.

A predicate on graphs is called *monotonic* if all subgraphs of a graph that satisfies the predicate, will also all satisfy the predicate.[1] The support constraint and the maximum size constraint are examples of predicates that are monotonic under subgraph isomorphism.

The problem of constraint-based subgraph mining is closely related to the problem of frequent item set mining. Many algorithms have been developed to tackle the frequent item set mining problem, the most well-known being the APRIORI algorithm (Agrawal et al., 1996). Both frequent graph mining algorithms and frequent item set mining algorithms are considered to be constraint-based *pattern* mining algorithms. Constraint-based pattern mining algorithms look for patterns in a pattern language $\mathcal{L}$, and assume that these patterns are ordered using a partial order relation $\leq$ on $\mathcal{L}$. In the case of graph mining, $\leq$ is usually the subgraph isomorphism relation.

Many algorithms for pattern mining are level-wise (breadth-first) enumeration algorithms. These algorithms assume that the *size* of a pattern in the language is well-defined, and look for the patterns by listing them increasing in size. A high-level description of such an algorithm is given in Algorithm 1.

Algorithm 1 Level-Wise Pattern Miner

```
Require: A pattern language $\mathcal{L}$ and a monotonic predicate $p$
Ensure: output all $g \in \mathcal{L}$ with $p(g)$
1: $\mathcal{C}_1 \leftarrow$ patterns of size 1
2: $k \leftarrow 1$
3: while $\mathcal{C}_k \neq \emptyset$ do
4:     $\mathcal{F}_k \leftarrow \{g \in \mathcal{C}_k | p(g)\}$
5:     Generate $\mathcal{C}_{k+1}$ from $\mathcal{F}_k$
6:     $k \leftarrow k+1$
7: end while
8: Output $\bigcup_k \mathcal{F}_k$
```

In this algorithm, $\mathcal{F}_k$ contains the patterns of size k that satisfy the predicate. In line 4 it is determined which candidates of size k satisfy the predicate. In frequent pattern mining, this line requires access to the data, and can be most time consuming. It is therefore essential that $\mathcal{C}_k$ be as small as possible.

The main focus of this article is on the computation that needs to be performed in line 5. In this line new candidates should be generated. This generation should ensure the following:

- by repeatedly generating new candidates we should be able to enumerate all patterns in the pattern space, in our case the space of all unlabeled, simple graphs;
- to ensure that the algorithm is as efficient as possible, we should not insert two patterns in $\mathcal{C}_{k+1}$ that are equivalent with each other; in our case, we should avoid inserting two graphs that are isomorphic;
- we should not insert patterns in $\mathcal{C}_{k+1}$ for which we can know beforehand that p will not be true; in our case, we should exploit the monotonicity of p to avoid inserting graphs of which a subgraph is not included in $\mathcal{F}_k$.

1. We adopt here the terminology most common in graph theory. Some authors in the data mining literature use the term ‘anti-monotonic’.

In the graph mining setting, the second and third requirements are difficult, as the second requirement requires us to solve a graph isomorphism problem, and the third requirement involves a subgraph isomorphism problem.

Algorithm 1 has applications beyond traditional frequent subgraph mining. For instance, if we are interested in computing a decomposition graph kernel between two graphs which counts the number of *non-isomorphic* subgraphs that two graphs have in common, we could compute this kernel by providing algorithm 1 a database of two graphs as input and a threshold of $t = 2$. The size of the output is the desired kernel value.

Similarly, we could be interested in enumerating all *different* graphs that include one node in a network (Leskovec et al., 2006). In this case, the input of Algorithm 1 consists of one graph with all nodes up to a certain threshold distance from the node of interest, and the subgraph isomorphism should be restricted such that only bijections are considered in which at least one node in the pattern is mapped to the special node in the data.

In all cases, the essential problem of enumerating graphs without duplicates remains. Several algorithms have been proposed in the literature to address this graph enumeration problem. The main idea that has been employed, is that for every graph, we can compute a *canonical* code, that is, a code that is unique for all graphs that are isomorphic. The level-wise graph miners AGM (Inokuchi et al., 2003) and FSG (Kuramochi and Karypis, 2004) define a canonical code from adjacency matrices. Essentially, all subgraphs are stored in a data structure that is indexed according to this canonical code, and duplicates are avoided by computing for every candidate the canonical code. The approaches of AGM and FSG differ in their definition of *size*: AGM grows graphs by adding nodes, FSG by adding edges.

Other graph miners search depth-first, but their enumeration strategy can easily be modified for use in a level-wise algorithm (Yan and Han, 2002; Huan et al., 2003; Nijssen and Kok, 2004). Also these algorithms use a canonical code, but do not require the use of an indexed data structure. An algorithm for enumerating graphs surrounding a node in a network was proposed by Leskovec et al. (2006). Again, this algorithm used a canonical code.

Unfortunately, currently no polynomial algorithm is known to compute a canonical code; if one was known, we would be able to solve the graph isomorphism problem in polynomial time. Overall, this means that in all existing graph mining algorithms exponential time can be spent between two graphs that are inserted in the set of candidates.

Enumeration algorithms for which this is not the case, that is, algorithms that solve an enumeration problem such that between any two enumerated solutions polynomial time is spent (in terms of the largest enumerated solution), are known as algorithms with *polynomial delay*. To the best of our knowledge, all algorithms that have been proposed in the graph mining literature for enumerating graphs in general do not have polynomial delay. Only for restricted classes of graphs, such as trees and outerplanar graphs, algorithms with polynomial delay are known (Chi et al., 2005; Horváth et al., 2006).

However, the fact that graph isomorphism is not known to be polynomially computable, does not imply that graph enumeration cannot be solved with polynomial delay. Even though ignored in the data mining and machine learning literature, a polynomial algorithm for enumerating graphs does exist and was proposed by Goldberg (1992).

The problem with this algorithm is that it solves a rather simple enumeration problem: given a bound on the size of the graphs to enumerate, Goldberg's algorithm lists all graphs of this size with polynomial delay. In the case of data mining and machine learning, we are dealing with more complicated monotonic constraints that are data-dependent. We will show in the next section that we can create databases such that the set of graphs to enumerate does not fulfill the basic assumptions that need to be satisfied in Goldberg's algorithm. Even worse, we will see that this type of data is very common.

It should be stressed that this paper only studies the candidate generation of graph mining algorithms; it does not study the frequency evaluation. For general graphs the frequency evaluation also takes exponential time; a general frequent graph miner which uses our enumeration algorithm will still have exponential delay due to the fact that frequency evaluation is still exponential. This article proposes an improvement only of the candidate generation phase. The key insight is that we devised a graph enumeration algorithm which does not use canonical codes to perform this task.

3. Goldberg's Algorithm

In this section we briefly discuss the key points in the algorithm of Goldberg (1992), which shows why this algorithm cannot be used in a pattern mining setting.

Goldberg's algorithm aims at listing all graphs with n nodes, and makes a distinction between easy and hard graphs. Easy is a graph g that satisfies at least one of these two properties:

- g has a vertex with degree $n-1$, that is, at least one vertex is connected to all other vertices;
- g has only one vertex, say v, of maximum degree and $g-v$ is rigid, that is, the graph $g-v$ has only one isomorphism with itself (called the identity automorphism in Section 6).

An example of a graph that is never rigid, is a path.

Let $E(n)$ be the set of easy graphs with n nodes, and $U(n)$ the set of all graphs with n nodes, then it was shown by Goldberg that

$$2|E(n)| \geq |U(n)|.$$

This property implies that a large fraction of the graphs to enumerate are in fact easy. It was then shown that $E(n)$ can be listed with polynomial delay, and that $H(n) = U(n) \setminus E(n)$ can be listed in $O(n^4|U(n)|)$ time steps, where $|U(n)|$ is exponential in n but linear in the number of solutions. The main idea is then to interleave these two methods. The method which lists easy graphs, makes sure that the delay is polynomial. The other method is allowed to spend an exponential number of steps between consecutive graphs, but these steps are spread over several iterations of the method that lists easy graphs. Effectively this gives an algorithm with polynomial delay.

It is clear that this method fundamentally relies on the property that many graphs are 'easy'. This property does not hold for sets of graphs defined by a monotonic predicate. Let us illustrate this for the monotonic constraint that every node in a graph has a degree of at most three. If $n > 3$, it is easily seen that

- as the degree is at most 3, the number of graphs that contain a vertex that is connected to all other vertices is independent of n;
- every graph g that contains a single node v of maximum degree 3, consists, after removal of v, only of a set of (possibly unconnected) paths, hence $g-v$ is not rigid.

Consequently, $E(n)$ is a constant independent of n, while $U(n)$ grows with n. The condition of Goldberg's approach is therefore not satisfied for this class of graphs.

Moreover, to list all graphs in $H(n)$ in time $O(n^4|U(n)|)$, it is assumed that the average size of the automorphism groups of the elements of $U(n)$ is bounded. However, one can find subclasses for which this bound is not polynomial.

The most popular application of graph mining algorithms is in chemistry (Horváth et al., 2006). Most of the graphs in these databases have a degree bounded by four, and a majority of the subgraphs that need to be enumerated have a degree bounded by three. Thus, we do not believe that the conditions for Goldberg's method are satisfied in such data.

4. Problem Statement

Our problem setting has two parameters:

- an augmentation operator, which takes as input a graph, and outputs a set of augmentations of this graph, and whose closure, starting from a given set of graphs, describes a class of graphs;
- a predicate which restricts this class.

For instance, the augmentation operator can be used to describe the class of connected or unconnected graphs, while the boolean predicate can restrict this class further to those graphs that have bounded degree.

More formally, we will denote by $\mathcal{VE}$ the set that contains all pairs (r_V, r_E) where r_V is a set of vertices and r_E a set of edges (not necessarily between vertices in r_V). We will use set operators on elements of $\mathcal{VE}$ to denote the corresponding operations on their components, for example, $(r_V, r_E) \cup (r'_V, r'_E) = (r_V \cup r'_V, r_E \cup r'_E)$. Again, $V(r)$ and $E(r)$ describe the components of an element $r \in \mathcal{VE}$. An augmentation operator ρ^+ is a function that takes as input a graph, and outputs a set of descriptions of possible augmentations. This set is a subset of $\mathcal{VE}$. Every element $r \in \rho^+(g)$ describes a new graph $(V(g) \cup V(r), E(g) \cup E(r))$, abbreviated by $g + r$, that we call a *child* of g.

An example of an augmentation operator is

$$\rho_t^+(g) = \{(\{v_{new}\}, \{\{v, v_{new}\}\}) \mid v \in V(g)\};$$

where v_{new} is a new vertex (not belonging to $V(g)$). This operator adds a new vertex and connects it to an existing vertex. We can use this operator to describe the set of all (connected) trees. The minimal graph on which we apply the operator is in this case the graph with one node $\top_t = (\{v\}, \emptyset)$; in general, when we use one graph as the minimal element, we will denote this initial graph with $\top$.

The following operator enumerates all graphs:

$$\rho_a^+(g) = \{(\{v_{new}\}, \emptyset)\} \cup \{(\emptyset, \{\{v_1, v_2\}\}) | v_1, v_2 \in V(g) \wedge \{v_1, v_2\} \notin E(g)\}. \tag{1}$$

with $\top_a = (\emptyset, \emptyset)$, while the following allows for enumerating all connected graphs:

$$\rho_c^+(g) = \rho_t^+(g) \cup \{(\emptyset, \{\{v_1, v_2\}\}) | v_1, v_2 \in V(g) \wedge \{v_1, v_2\} \notin E(g)\}. \tag{2}$$

with $\top_c = (\{v\}, \emptyset)$.

As we can see in these examples, the vertices occurring in edges $E(r)$ do not have to occur in $V(r)$. Still it is useful to determine the entire set of vertices involved in an augmentation. For this we use the notation V^*, that is, $V^*(r) = V(r) \cup \{v \mid \exists e \in E(r) : v \in e\}$. Observe that the example operators output a number of augmentations that is bounded by a polynomial in the size of g, and that for each r, the size of the set $V^*(r)$ is bounded by a constant.

The class of graphs defined by taking the closure of the augmentation operator on the minimal element is denoted by $\mathcal{L}_{\rho^+}$ (which we shorten further to $\mathcal{L}_a$ and $\mathcal{L}_c$ for the classes defined by ρ_a^+ and ρ_c^+). The operator ρ^+ defines an ancestry relation between the graphs. This relation is a partial order.

The second parameter of our problem setting is a predicate p on graphs. The set of graphs g in $\mathcal{L}_{\rho^+}$ such that $p(g)$ is true is denoted by $\mathcal{L}_{\rho^+,p}$. We only consider predicates that cannot distinguish between isomorphic graphs, that is, if $g \simeq g'$ then $p(g) = p(g')$. We call a predicate *monotonic* w.r.t. an augmentation operator ρ^+ if for every graph $g \in \mathcal{L}_{\rho^+,p}$ it also holds that $g' \in \mathcal{L}_{\rho^+,p}$ for every g' that is an ancestor of g. For instance, the predicate that tests if a graph has bounded degree, is monotonic under ρ_a^+ as defined in (1).

In this article, we consider the following problem.

Problem 1 *Given are an augmentation operator ρ^+ and a predicate p which is monotonic w.r.t. ρ^+. Then, enumerate all elements in $\mathcal{L}_{\rho^+,p}$ such that exactly one representative of every equivalence class under isomorphism of $\mathcal{L}_{\rho^+,p}$ is enumerated.*

In the next section we determine a set of sufficient conditions on the augmentation operator and the monotonic predicate that have to be fulfilled in order to obtain an algorithm with polynomial delay.

5. Main Result

The augmentation operator that we introduced in the previous section, generates the children of a graph. Our algorithm relies on the existence of an operator which can inverse this operator. We call this operator a *reduction operator*. The reduction operator generates the *parents* of a graph.

Formally, the definition of a reduction operator is similar to that of an augmentation operator; the input of a reduction operator ρ^- is a single graph, its output consists of a subset of $\mathcal{VE}$. We call each element $r \in \rho^-(g)$ a reduction of g. It defines a graph $(V(g) \setminus V(r), E(g) \setminus E(r))$, which is abbreviated by $g - r$.

For instance, in the case of connected graphs, we can define the following reduction operator:

$$\begin{aligned}\rho_c^-(g) \quad = \quad & \{r \,|\, r = (\emptyset, \{\{v_1, v_2\}\}) \wedge \{v_1, v_2\} \in E(g) \wedge \{v_1, v_2\} \text{ is in a cycle}\} \\ & \{r \,|\, r = (\{v_1\}, \{\{v_1, v_2\}\}) \wedge \{v_1, v_2\} \in E(g) \wedge v_1 \text{ has degree } 1\} \end{aligned} \qquad (3)$$

Let $\mathcal{L}$ be a class of graphs. Then, an augmentation schema on $\mathcal{L}$ is a pair (ρ^+, ρ^-) of an augmentation operator ρ^+ and a reduction operator ρ^-, such that

- $\forall g \in \mathcal{L}, \forall r \in \rho^+(g) : g + r \in \mathcal{L} \wedge g \cap r = (\emptyset, \emptyset)$, that is, $\rho^+(g)$ contains augmentations that can be added to g to obtain a larger graph (child);
- $\forall g \in \mathcal{L}, \forall r \in \rho^-(g) : g - r \in \mathcal{L} \wedge r \subseteq g$, that is, $\rho^-(g)$ contains reductions that can be removed from g to obtain a parent;
- $\forall g \in \mathcal{L}, \forall r \in \rho^+(g) : r \in \rho^-(g + r)$, that is, the effects of the additions $r \in \rho^+(g)$ can be inverted by a deletion from $\rho^-(g + r)$;

- $\forall g \in \mathcal{L}, \forall r \in \rho^-(g) : \exists r' \in \rho^+(g-r), \exists \varphi : \big((g-r)+r' \simeq_\varphi g\big) \wedge \big(I_{g-r} \subseteq \varphi\big)$, that is, deletions $r \in \rho^-(g)$ can be inverted by additions from $\rho^+(g-r)$. Here $I_{g-r} = \{(v,v) \mid v \in V(g-r)\}$ is the identity permutation over the vertices of $g-r$;

- $\forall g_1, g_2 \in \mathcal{L} : g_1 \simeq_\varphi g_2 \Rightarrow \forall r \in \rho^+(g_1) : \varphi(r) \in \rho^+(g_2)$, that is, ρ^+ (and hence also $\rho^-(g)$) is invariant to isomorphisms.

Given a graph g and two reductions $r_1, r_2 \in \rho^-(g)$, we are interested in applying both r_1 and r_2 to g. However, sometimes this is not possible directly. Consider for instance the class of connected graphs $\mathcal{L}_c$, the graph $g = (\{1,2,3\},\{\{1,2\},\{2,3\},\{3,1\}\})$, and the reductions $r_1 = (\emptyset,\{\{1,2\}\})$ and $r_2 = (\emptyset,\{\{2,3\}\})$. We have $f_1 = g - r_1 = (\{1,2,3\},\{\{2,3\},\{3,1\}\})$. We cannot apply r_2 to f_1 as this would result in a graph which is not in $\mathcal{L}_c$ due to the isolated node 2; r_2 is not an allowed reduction in $g - r_1$. We can however map the reduction r_2 to a reduction that is allowed; instead of r_2 we use $(\{2\},\{\{2,3\}\})$, which is a valid deletion from f_1. This translation of r_2 to the context of $g - r_1$ for ρ_c^- is denoted by $r_2 \uparrow_c^g r_1$. More formally, for connected graphs $\mathcal{L}_c$, we define $r_2 \uparrow_c^g r_1$ to be equal to r_2, except in the case where $r_1 = (\emptyset,\{v,u_1\})$, $r_2 = (\emptyset,\{v,u_2\})$ and v has degree 2, in which case $r_2 \uparrow_c^g r_1 = r_2 \cup (\{v\},\emptyset)$. Then, $(g-r_1) - \big(r_2 \uparrow_c^g r_1\big) = (\{1,3\},\{\{1,3\}\})$.

We now more formally introduce the properties of these reduction translators. A reduction translator is an operator $\cdot \uparrow^{\cdot} \cdot$ mapping graphs g and reductions $r_1, r_2 \in \rho^-(g)$ to a new reduction $r_2 \uparrow^g r_1$ satisfying

$$\forall g, r_1, r_2 : r_2 \subseteq r_2 \uparrow^g r_1, \tag{4}$$

that is, after the translator is applied the reduction can only become larger,

$$\forall g, r_1, r_2 : r_1 \cap (r_2 \uparrow^g r_1) = (\emptyset,\emptyset), \tag{5}$$

that is, no element is removed twice, and

$$\forall g, r_1, r_2 : (r_2 \uparrow^g r_1) \cup r_1 = (r_1 \uparrow^g r_2) \cup r_2, \tag{6}$$

that is, reversing the order does not affect which vertices and edges are removed.

To allow for an efficient enumeration of graphs by our algorithm, we require that the augmentation schema of the class of graphs fulfills a *density* property. This property is based on the *graph of parents*. The graph of parents $GoP_{\rho^-,\uparrow}(g)$ of a graph g is defined as follows:

- $V(GoP_{\rho^-,\uparrow}(g)) = \rho^-(g)$, that is, every reduction for g corresponds to a vertex in its graph of parents.

- For any two $r_1, r_2 \in V(GoP_{\rho^-,\uparrow}(g))$, the graph $GoP_{\rho^-,\uparrow}(g)$ has edge $\{r_1, r_2\}$ iff $(r_1 \uparrow^g r_2) \in \rho^-(g - r_2)$ and $(r_2 \uparrow^g r_1) \in \rho^-(g - r_1)$.

The intuition is that there is an edge between two nodes in the graph of parents, iff it is possible to go from one parent to the other by first applying a reduction, and then applying an augmentation. An example is shown in Figure 1.

We say that $(\rho^+, \rho^-, \uparrow)$ is a dense augmentation schema for $\mathcal{L}$ iff

1. (ρ^+, ρ^-) is an augmentation schema for $\mathcal{L}$ and $\uparrow$ is a reduction translator.

2. for every non-minimal graph $g \in \mathcal{L}$ it holds that either the graph of parents $GoP_{\rho^-,\uparrow}(g)$ is connected, or $g - r$ is a minimal element of $\mathcal{L}$ for all $r \in \rho^-(g)$ (in most cases, $g - r = \top$).

Figure 1: On the bottom-left, a connected graph g is drawn. In the middle, there is the graph of parents $GoP_{\rho_c^-,\uparrow_c}(g)$. For every of its vertices r_i, the corresponding $g - r_i$ of g is drawn. For the edges $\{r_1,r_4\}$ and $\{r_3,r_5\}$, the common (grand)parent is drawn. Note that there is no edge between for example r_3 and r_4 as $(g-r_3)-(r_4 \uparrow^g_c r_3)$ is not a connected graph.

Let us return to the examples of graph classes. For the class of all graphs $\mathcal{L}_a$, we define $r_1 \uparrow^g_a r_2 = r_1$. It is easy to show that $GoP_{\rho_a^-,\uparrow_a}(g)$ is a clique and that $(\rho_a^+,\rho_a^-,\uparrow_a)$ is a dense augmentation schema. We can also prove for connected graphs that $(\rho_c^+,\rho_c^-,\uparrow_c)$ is a dense augmentation schema (see the appendix for a proof).

The main result of this paper is the following:

Theorem 1 *Given an augmentation operator ρ^+ and a predicate p. We can solve problem 1 with polynomial delay if the following conditions are satisfied:*

- *there exists a reduction operator ρ^- and a reduction translator $\uparrow$ such that $(\rho^+,\rho^-,\uparrow)$ is a dense augmentation schema;*
- *the predicate p is monotonic w.r.t. ρ^+ over $\mathcal{L}_{\rho^+}$;*
- *ρ^+, ρ^- and p can be evaluated in polynomial time in their arguments;*
- *the number of vertices in $V^*(r)$ for every possible r resulting from ρ^+ and ρ^- is bounded by a constant.*

There are many classes of graphs for which these conditions are fulfilled. Below we give a non-exhaustive list of examples.

5.1 Monotonic Classes

Any predicate p that is monotonic w.r.t. edge and vertex deletion and that can be evaluated in polynomial time defines a class $\mathcal{L}_{\rho_a^+,p}$ that satisfies the conditions of Theorem 1, as $(\rho_a^+,\rho_a^-,\uparrow_a)$ is a dense augmentation schema, and all operations are polynomial. Hence, our algorithm can efficiently enumerate all these monotonic classes.

An interesting special case are the minor-closed classes of graphs. The minors of a graph can be obtained by deleting edges, vertices, or identifying adjacent vertices into a single new vertex that is adjacent to all vertices that were adjacent to any of the identified original vertices. A class is minor-closed if for any graph g all its minors are also included in the class. Some classes of graphs can be characterized by forbidden minors, that is, minors that none of the graphs are allowed to have. One example is the class of all planar graphs (the forbidden minors being the 5-clique K_5 and the complete bipartite graph $K_{3,3}$). It can be determined in polynomial time if a graph contains a given forbidden minor, and minor-closed classes of graphs are monotonic for ρ_a^+.

5.2 Connected Graphs

It is proven in the appendix that the augmentation schema $(\rho_c^+, \rho_c^-, \uparrow_c)$ is dense and its operators are polynomial. It follows that connected graphs can be enumerated with polynomial delay. Any predicate which is closed under edge and vertex deletion is also monotonic w.r.t. ρ_c^+. Therefore, for any monotonic predicate p, our algorithm can list all connected graphs satisfying p with polynomial delay.

5.3 Hereditary Classes with Bounded Degree

A predicate p is hereditary iff for every graph g_1 such that $p(g_1)$ holds, $p(g_2)$ holds for any *induced* subgraph g_2 of g_1. As pointed out in Section 2, an *induced* subgraph must contain all edges between a selected set of nodes in the original graph. A hereditary predicate is monotonic w.r.t. the following augmentation operator:

$$\rho_h^+(g) = \left\{ \left(\{v_{new}\}, \{\{v_{new}, v'\} | v' \in V\} \right) \;\middle|\; V \subseteq V(g) \right\},$$

where again v_{new} is a new vertex not in $V(g)$. The corresponding reduction operator should remove every single vertex as well as all edges emanating from it. It can be shown that the resulting augmentation schema is dense. However, the augmentation operator ρ_h^+ outputs a number of augmentations exponential in the size of the input. If we restrict ourselves to graphs with bounded degree, however, we can enumerate the resulting class with polynomial delay.

One example is the class of claw-free graphs. A graph is called claw-free if the graph

$$(\{v_1, v_2, v_3, v_4\}, \{\{v_1, v_2\}, \{v_1, v_3\}, \{v_1, v_4\}\})$$

is not one of its induced subgraphs. Claw-freeness is not a monotonic property in $\mathcal{L}_{\rho_a^+}$, as a subgraph of a graph without claws can contain a claw: for instance, consider the clique K_5; this graph does not have a claw as induced subgraph (all its induced subgraphs also being cliques), but many of its (ordinary) subgraphs are claws.

In general, claw-freeness is a hereditary property, as every induced subgraph of a graph without claws, is claw-free. To the best of our knowledge no polynomial algorithm is currently known for enumerating all claw-free graphs even if we do allow for duplicates (Goldberg, 1992). Our algorithm partially solves this problem by allowing for listing all claw-free graphs with bounded degree.

6. Automorphism Groups and Bases

In order to avoid enumerating duplicates, we will use some theory on automorphism groups. In this section, we will briefly review the necessary concepts.

An automorphism of a graph g is an isomorphism between g and itself. We will denote the identity automorphism with I_g. In Figure 2, a graph g^{ex} with 8 vertices is shown, together with

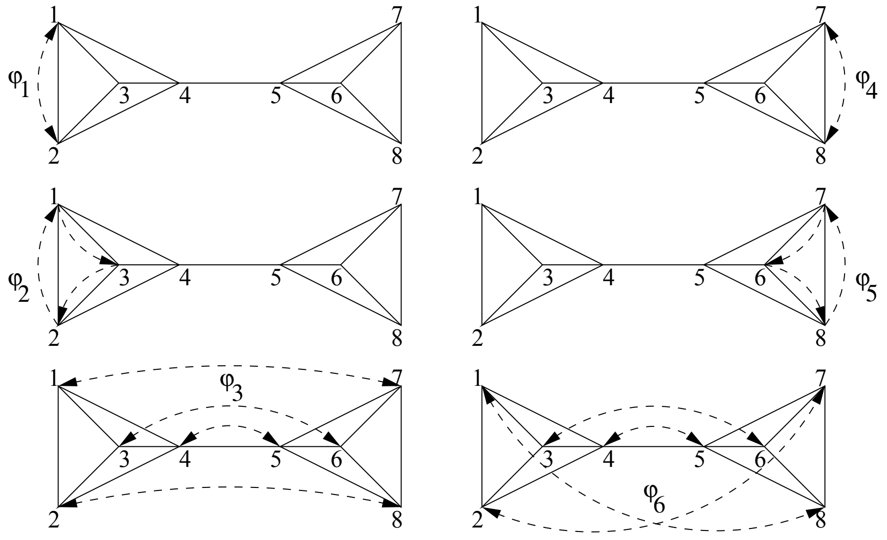

Figure 2: A graph g^{ex} and 6 of its automorphisms.

six of its automorphisms. An automorphism is a permutation of the vertices of g. The set of all automorphisms of g equipped with composition of permutations forms a permutation group acting on $V(g)$. This group is called the automorphism group of g, which we denote with $\mathcal{A}ut(g)$.

Let P be a permutation group and let $S \subseteq P$. We say S is a set of generators of P iff every element of P can be written as a composition of elements of S. We denote this fact with $P = < S >$. For example, in Figure 2, $\{\varphi_1, \varphi_2, \varphi_3, \varphi_5\}$ is a (non-minimal) set of generators of $\mathcal{A}ut(g^{ex})$. Automorphism φ_4 can be composed by $\varphi_4 = \varphi_3 \circ \varphi_1 \circ \varphi_3$. φ_6 can be composed as $\varphi_6 = \varphi_1 \circ \varphi_3 \circ \varphi_1$.

Let P be a permutation group acting on V and let $v \in V$. The stabilizer of v in P is the subgroup $P_v = \{\varphi \in P \mid \varphi(v) = v\}$. Consider for example the automorphism group $P = \mathcal{A}ut(C_5)$ on the 5-cycle graph $C_5 = (\{v_1, v_2, v_3, v_4, v_5\}, \{\{v_1, v_2\}, \{v_2, v_3\}, \{v_3, v_4\}, \{v_4, v_5\}\})$. This group has 10 elements, each of which can be decomposed by (possibly) a mirror permutation $\{(v_1, v_1), (v_2, v_5), (v_5, v_2), (v_3, v_4), (v_4, v_3)\}$ and rotations (0, 1 or more applications of $\{(v_1, v_2), (v_2, v_3), (v_3, v_4), (v_4, v_5), (v_5, v_1)\}$). For any vertex $v \in C_5$, the stabilizer P_v contains precisely 2 elements. E.g., P_{v_3} contains the identity permutation and the mirror $\{(v_3, v_3), (v_4, v_2), (v_2, v_4), (v_1, v_5), (v_5, v_1)\}$

One can apply the definition of stabilizers recursively; we will denote with $P_{v_1,\ldots,v_k}$ the stabilizer of v_k in $P_{v_1,\ldots,v_{k-1}}$. A sequence of points $B = [v_1 \ldots v_n]$ of V is called a *base* for permutation group P iff $P_{v_1,\ldots,v_{n-1}}$ only contains the identity permutation. For example, in Figure 2, $B_1 = [3,1,6,8]$ is a base for g^{ex}. Indeed, only the identity automorphism $I_{g^{ex}}$ leaves all four vertices 1, 3, 6 and 8 fixed. Also $B_2 = [3,1,6,8,2,4,5,7]$ is a base for g^{ex}.

Let P be a permutation group, B a base of P and $S \subseteq P$. S is called a strong generating set related to $B = \{v_1, \ldots, v_k\}$ if it contains generators for all permutations in $P_{v_1,\ldots,v_l}$ for $1 \leq l \leq k$. We will use the abbreviation BSGS for a pair (B, S) where B is a base and S is a strong generating set related to B.

Consider the base $B_1 = [3,1,6,8]$ for the group $\mathcal{A}ut(g^{ex})$ in Figure 2. We can construct a strong generating set by first choosing generators for $\mathcal{A}ut(g^{ex})_{3,1,6,8}$, then choosing generators for $\mathcal{A}ut(g^{ex})_{3,1}$, $\mathcal{A}ut(g^{ex})_{3,1,6}$ and so on until we have generators for $\mathcal{A}ut(g^{ex})$. Each time, we use the generators of the subgroup and extend them to a set of generators for the larger group. In our example, $\{\varphi_4\}$ is a set of generators for $\mathcal{A}ut(g^{ex})_{3,1,6}$, Next, $\{\varphi_4, \varphi_5\}$ is a set of generators for $\mathcal{A}ut(g^{ex})_{3,1}$ and $\{\varphi_4, \varphi_5, \varphi_1\}$ is a set of generators for $\mathcal{A}ut(g^{ex})_3$. Finally, $\{\varphi_4, \varphi_5, \varphi_1, \varphi_3, \varphi_2\}$ is a set of generators for $\mathcal{A}ut(g^{ex})$ and therefore a strong generating set for B.

A BSGS can represent a permutation group acting on n elements using only $O(n\log(n))$ generators. For example, even though in Figure 2, the automorphism group $\mathcal{A}ut(g^{ex})$ contains $2*3*2*3*2 = 72$ elements, only 5 generators are needed to represent it. Moreover, an $O(n^5)$ algorithm exists to transform a BSGS into a BSGS with a different base (Butler, 1991). In Figure 2, consider the BSGS $([3,1,6,8], \{\varphi_4, \varphi_5, \varphi_1, \varphi_3, \varphi_2\})$ and suppose we want a strongly generating set for the base $[3,1,8,6]$. Then, we have to combine the generators of $\mathcal{A}ut(g^{ex})_{3,1,6}$ and $\mathcal{A}ut(g^{ex})_{3,1}$. One possible strongly generating set is $\{\varphi_4 \circ \varphi_5, \varphi_5, \varphi_1, \varphi_3, \varphi_2\}$.

In general, it is easy to see that we can reduce any strong generating set for a permutation group on n elements to at most $n(n-1)/2$ elements. Let $B = \{v_1, \ldots, v_k\}$ be a base ($k \leq n$), and let S_i ($1 \leq i \leq k$) be the subset of the strong generating set containing all generators fixing v_j for all $1 \leq j < i$ but mapping v_i on a different element. Now for all i from 1 to k we can do the following. As long as any S_i has more than $n-i$ elements, there are two permutations $p_1, p_2 \in S_i$ such that $p_1(v_i) = p_2(v_i)$, and we can remove p_2 from S_i and add $p_2 \circ p_1^{-1}$ to S_{i+1}. The permutation group generated by the new strong generating set $\cup_i S_i$ remains the same, as any permutation requiring p_2 in its construction can still be constructed with $p_2 \circ p_1^{-1} \circ p_1$. After performing such replacements until all S_i contain at most $n-i$ elements, we have a strong generating set of size at most $n(n-1)/2$.

An important property is that given a strong generating set for some base, one can efficiently compute a strong generating set for another base. A basic step in such base change is to interchange two vertices, that is, given a strong generating set for $B = \{v_1 \ldots v_n\}$, find a strong generating set for $B' = \{v_1 \ldots v_{l-1}, v_{l+1}, v_l, v_{l+2} \ldots v_n\}$ for some l with $1 \leq l < n$. Let S be a strong generating set with $S = \cup_{i=1}^n S_i$ where S_i contains the generators fixing v_j ($1 \leq j < i$) and not fixing v_i. The only part of S that should be changed when swapping v_l and v_{l+1} in the base are S_l and S_{l+1}. Let $S' = S'_l \cup S'_{l+1} \cup \bigcup_{i \notin \{l,l+1\}} S_i$ be the strong generating set for the new base B', where S'_l fixes v_i ($1 \leq i < l$) and S'_{l+1} fixes v_i ($1 \leq i < l$) and v_{l+1}. One can construct S'_i by ensuring it contains permutations that map v_{i+1} on all its possible images. These images can be found with a so-called reachability graph. This means one starts with a set of possible images $I = \{v_{i+1}\}$, and as long as there is a permutation in $\cup_{i=l}^n S_i$ which maps an element $v \in I$ on an element $v' \notin I$, one adds v' to I; in the mean time, for each element v' one maintains a corresponding permutation. After constructing S'_l, one can construct S'_{l+1} by starting with $S'_{l+1} = S_l \cup S_{l+1}$ and then removing any permutations from it that are redundant. In this way, it is possible to find in polynomial time a strong generating set for a base in which two vertices have been swapped. By iterating this procedure, it is possible to efficiently find a strong generating set for any new base. Note that we here only described one naive strategy. In the literature, much more advanced algorithms have been proposed, which allow to perform these operations significantly more efficiently.

7. Algorithm Outline

Our algorithm enumerates the graph ordered by size, that is, no graph will be output before all its ancestors under ρ^+ are listed. Indeed, we can show that if $(\rho^+, \rho^-, \uparrow)$ is a dense augmentation schema, every graph has a unique size, that is, there is a function *size* that maps every graph to an integer such that for every g in $\mathcal{L}_{\rho^+}$ it holds that $r \in \rho^+(g)$ implies that $size(g+r) = size(g) + 1$. This results allows us to order the graphs that we need to enumerate level-wise.

Superficially, the idea is then as follows. We maintain graphs that we are enumerating in a queue. Initially, this queue contains the graph $\top$. Repeatedly, we pop a graph from the queue, apply the augmentation operator, and those children which are not equivalent to any graph in the queue, are pushed in the queue. Due to the level-wise enumeration, equivalent graphs must be in the queue. We need to address two issues:

- how do we avoid that we insert a child which is equivalent to a child of another graph?
- how do we avoid that we insert two children of the same graph that are equivalent with each other?

To make these computations possible in polynomial time, we also keep all parents of the graphs in the queue in memory. For each graph, both those in the queue and their parents, we store the following information:

- a representation for the graph g
- for each augmentation (and reduction) r of g, we store r together with an isomorphism mapping $\varphi = aug(g,r)$ (resp. $\varphi = red(g,r)$) such that $\varphi(g+r)$ (resp. $\varphi(g-r)$) is the stored representative of the isomorphism class of $g+r$ (resp. $g-r$). Until we assign the $aug(g,r)$ and $red(g,r)$ variables with a value, we will assume them initialized $aug(g,r) =' ?'$ and $red(g,r) =' ?'$. If $p(g+r)$ is false, with p the monotonic predicate of interest, we will assign $aug(g,r)$ the value nil.
- a base and strong generating set (BSGS) $bsgs(g)$ of the automorphism group $\mathcal{A}ut(g)$.

We output a graph when we pop it from the queue. Furthermore, we determine the BSGS at that point. The BSGS allows us to compute for each pair of augmentations of a graph if they result in equivalent graphs, and thus allows us to avoid two equivalent children of the same graph from being pushed in the queue.

To avoid that two different graphs insert children in the queue that are equivalent, we make sure that the first parent of a child marks at least one augmentation in each of the other parents of the child. When this alternative parent is popped from the queue later, it can use this information to avoid pushing this child and all its equivalent children.

To prove that this procedure is polynomial, we need to show that we can compute the BSGS in polynomial time, and that we can find all parents of a child in polynomial time. Let us start with this second point.

One of the conditions of Theorem 1 is that the augmentation schema is dense, that is, that the graph of parents is connected; hence we can compute a spanning tree for the graph of parents. If we create a child, we know the parent that generated this child; by traversing the spanning tree starting from the reduction achieving this parent, we can traverse all possible reductions. At the same time, for every step we take in this spanning tree, we can determine a corresponding stored parent: every step in the graph of parents corresponds to a reduction followed by an augmentation, for which we have stored associated permutations that point to stored representatives.

To compute the BSGS the key observation is that we can incrementally compute the BSGS of a graph from the BSGS of one of its parents, in a similar way to the algorithm of Goldberg (1992). Given a child and its parent, we perform a base change for the parent, such that we obtain permutations in which the vertices contained in the augmentation are stabilized. This gives generators for all vertices in the child, except those contained in the augmentation. By traversing all parents (as computed when the child was created), we can determine permutations and images for these vertices as well. The resulting set of generators can be reduced to a BSGS in polynomial time.

Details of this algorithm, including optimizations and proofs of complexity, can be found in the appendix.

8. Conclusions

We introduced an algorithm for listing graphs that makes sure that no two equivalent graphs are being output. We showed that for a well-defined set of conditions on a class of graphs to enumerate, this algorithm is correct and achieves polynomial delay. Classes of graphs that can be enumerated with low run-time complexity are connected graphs, planar graphs, minor closed graphs, monotonic classes of graphs in general, and hereditary classes with bounded degree. To the best of our knowledge, this is the first algorithm to be general enough to be able to list this range of classes efficiently, and for several of these classes no polynomial delay algorithm was presented before. In the appendix, we show that our algorithm runs with delay $O(n^5)$ for the class of all graphs, which is an improvement over the known method of Goldberg (1992), which achieves a delay of $O(n^6)$, where n is the number of vertices in the largest graph that is listed.

Most pattern mining algorithms consist of a candidate generation part and an interestingness evaluation part. This work contributes to the theory of pattern mining by providing a polynomial-delay algorithm for the first of these two common tasks. Also, our algorithm can be used as a generic candidate pattern generator for a wide range of algorithms for mining structured patterns, avoiding the need to research specialized canonical forms and enumeration strategies.

In contrast to other graph pattern mining systems, our algorithm provides at the same time a data structure in which one can look up a pattern in polynomial time. Indeed: given a pattern g, one can construct g from the empty graph by a sequence of augmentations, and then follow the augmentation pointers through the data structure. Efficient lookup could be very useful when the set of patterns resulting from a pattern mining step is queried by the user or by algorithms taking this set of patterns as input.

Even though its run-time complexity is favorable, the space complexity of our algorithm is an issue. The space required is polynomial in the size of the output; given that the number of listed graphs can be exponential, the storage requirements for large classes of graphs can be exponential. However, in those applications where the listed graphs need to be stored anyway, such as applications in data analysis, this drawback is of minor concern. Moreover, we know of no other general approaches that obtain a better space complexity.

As future work, we conjecture that the run-time complexity of our algorithm can be reduced further, at least to a delay of $O(n^4)$ for the class of all graphs and the class of connected graphs, through the definition of a canonical representation over the graphs. Furthermore, we hope to reduce the space requirements of our algorithm in problem settings where not all listed graphs are required to be stored, and plan to implement it in concrete data mining systems. Finally, relieving the constraint of bounded degree for hereditary classes remains an interesting problem.

Appendix A. Algorithmic Details and Proofs

In this appendix we provide details of our algorithm and proofs for our results.

A.1 Dense Augmentation Schemas

An important property of a dense augmentation schema is the following:

Lemma 2 *Let $\mathcal{L}$ be a class of graphs, and let $(\rho^+, \rho^-, \uparrow)$ be a dense augmentation schema for $\mathcal{L}$. Then, there exists a function size : $\mathcal{L} \rightarrow N$ such that $\forall g \in \mathcal{L}, \forall r \in \rho^+(g) : size(g+r) = size(g)+1$.*

Proof We will say that a graph g can be constructed from $\top$ in n steps if there exists a sequence $\top = g_0, g_1, \ldots, g_n = g$ such that $g_{i+1} = g_i + r_i$ for some $r_i \in \rho^+(g_i)$ for $i = 0 \ldots n-1$.

We first show that there is no graph g which both can be constructed from $\top$ in n_1 steps and can be constructed from $\top$ in n_2 steps for two distinct numbers n_1 and n_2.

Assume that such a graph g exists, and consider a minimal such graph g (according to the order induced by the augmentation schema). Then, there exists a parent $g - r_1'$ of g which can be constructed from $\top$ in $n_1 - 1$ steps, and a parent $g - r_2'$ of g which can be constructed from $\top$ in $n_2 - 1$ steps. As the graph of parents $GoP_{\rho^-,\uparrow}(g)$ of g is connected, there must exist two $r_1, r_2 \in \rho^-(g)$ such that (r_1, r_2) is an edge of $GoP_{\rho^-,\uparrow}(g)$, $g - r_1$ can be constructed from $\top$ in n_1' steps, $g - r_2$ can be constructed from $\top$ in n_2' steps and $n_1' \neq n_2'$. As (r_1, r_2) is an edge of $GoP_{\rho^-,\uparrow}(g)$, $(r_1 \uparrow^g r_2) \in \rho^-(g - r_2)$ and $(r_2 \uparrow^g r_1) \in \rho^-(g - r_1)$, there exists some graph p such that $p \simeq (g - r_2) - (r_1 \uparrow^g r_2)$ and $p \simeq (g - r_2) - (r_2 \uparrow^g r_1)$. Let n_p be the number of steps needed to construct p from $\top$. Then, remembering that augmentation schemas are isomorphism-invariant, we can conclude that both $g - r_1$ and $g - r_2$ can be constructed from $\top$ in $n_p + 1$ steps. Now as $n_1 \neq n_2$ either $n_1 - 1 \neq n_p + 1$ or $n_2 - 1 \neq n_p + 1$. Without loss of generality we can assume $n_1 \neq n_p + 1$. This means that $g - r_1$ can be constructed from $\top$ in both $n_p + 1$ and $n_1 - 1$ steps, which is a contradiction with the assumption that g is a minimal graph for which it holds that it can be constructed from $\top$ in two different numbers of steps.

Therefore, we conclude that no such graph exists. Hence, in order to obtain a function *size* satisfying the requirement, one can define $size(\top)$ to be 0 and for every g, $size(g)$ to be the number of steps in which g can be constructed from $\top$. ■

In Section 5 we stated the following.

Lemma 3 $(\rho_c^+, \rho_c^-, \uparrow_c)$ *is a dense augmentation schema.*

Proof We consider the different elements of the definition of a dense augmentation schema.

First, remember that (ρ_c^+, ρ_c^-) was defined by Equation (2) and (3) (see page 913 and 914). This is clearly an augmentation schema. Also, we defined $r_1 \uparrow_c^g r_2$ to be equal to r_1, except in the case where $r_1 = (\emptyset, \{v, u_1\})$, $r_2 = (\emptyset, \{v, u_2\})$ and v has degree 2. In that case $r_1 \uparrow_c^g r_2 = r_1 \cup (\{v\}, \{\})$. It is easy to see that $\uparrow_c$ satisfies Equations (4), (5) and (6), and hence is a reduction translator.

It remains to be shown that for every non-minimal graph $g \in \mathcal{L}_c$ it holds that either the graph of parents $GoP_{\rho_c^-, \uparrow_c}(g)$ is connected, or $g - r$ is the minimal element of $\mathcal{L}_c$ for all $r \in \rho^-(g)$.

Consider a connected graph g with at least 2 edges. We prove that $GoP_{\rho_c^-, \uparrow_c}(g)$ is connected. If g is a tree, then every reduction in $\rho^-(g)$ removes a leaf and the edge adjacent to it. By the definition of $\uparrow_c$, $r_1 \uparrow_c^g r_2 = r_1$ and $r_1 \in \rho_c^-(g - r_2)$ will hold for any distinct $r_1, r_2 \in \rho_c^-$. So if g is a tree, $GoP_{\rho_c^-, \uparrow_c}(g)$ is a clique.

If g is not a tree it contains at least one simple cycle C. We can partition $\rho_c^-(g)$ into two sets R_1 and R_2 such that R_1 contains all reductions removing an edge from the cycle C, and R_2 contains all other reductions. For any $r_1 \in R_1$ and $r_2 \in R_2$, it holds that removing r_2 from $g - r_1$ does not disconnect g and vice-versa. So such two r_1 and r_2 are adjacent in $GoP_{\rho_c^-, \uparrow_c}(g)$. Therefore, $GoP_{\rho_c^-, \uparrow_c}(g)$ is certainly connected if $\#R_2 \geq 1$. On the other hand, if $\#R_2 = 0$, g is a simple cycle. In that case, two reductions of R_1 are adjacent iff they remove two adjacent edges of the cycle. So in that case, $GoP_{\rho_c^-, \uparrow_c}(g)$ is a cycle and hence connected. ■

A.2 Algorithm

In this section we explain in more detail our algorithm. As stated in Section 7, for each graph, we store the following information:

- a representation for the graph g
- for each augmentation and reduction r of g, we store r together with an isomorphism mapping $aug(g,r)$ (resp. $red(g,r)$) that maps $g+r$ (resp. $g-r$), to the stored representative of their isomorphism class. In the algorithm, we use $aug(g,r)$ and $red(g,r)$ as functions that return the isomorphism. When the isomorphism is not yet computed, $aug(g,r)$ and $red(g,r)$ will return $'?'$. If $p(g+r)$ is false, $aug(g,r)$ returns the value *nil*.
- a base and strong generating set (BSGS) $bsgs(g)$ of the automorphism group $\mathcal{A}ut(g)$.

Algorithm 2 shows the high level algorithm. It repeatedly takes an unprocessed graph $g+r$ and processes it; $g+r$ must be minimal according to the *size* function from Lemma 2. A graph which has been processed remains in memory till it is no longer needed in the computation for one of its ancestors.

As shown by Algorithm 3, the processing of a graph g includes computing a BSGS and the automorphism group of g, computing reachability graphs of $\mathcal{A}ut(g)$ (line 3), finding isomorphic variants of children (lines 8-12), and examining all other children of g including constructing all $red(\cdot,\cdot)$ and some $aug(\cdot,\cdot)$ links (lines 13-24). We will describe each of the steps of the algorithm below.

Let us first consider what is known at the point PROCESS_GRAPH(g,r_0) is called. First, all graphs h for which $p(h)$ and $size(h) < size(g)$ have been processed and outputted, and the values for $aug(h,\cdot)$, $red(h,\cdot)$ and $bsgs(h)$ have been computed. Second, all graphs f for which $p(f)$ and

Algorithm 2 Highlevel algorithm

```
Require: a graph class $\mathcal{L}$, a monotonic predicate $p$ and a dense augmentation schema $(\rho^+, \rho^-, \uparrow)$
Ensure: output all $g \in \mathcal{L}$ with $p(g)$
1: $RefQueue \leftarrow \{(\top, (\emptyset, \emptyset))\}$
2: while $RefQueue \neq \emptyset$ do
3:     Let $(g, r) \in RefQueue$ such that $size(g + r)$ is minimal
4:     $RefQueue \leftarrow RefQueue \setminus \{(g, r)\}$
5:     PROCESS_GRAPH($g$,$r$)
6:     Output $g$
7: end while
```

$size(f) = size(g)$ have either entered $RefQueue$ or are fully processed. In any case, all values $red(f, \cdot)$ have been computed.

Let S_V denote the bound on the number of vertices and edges that can occur at most in any augmentation $r \in \rho^+(g)$ with $g \in \mathcal{L}$. Then we have the following lemma.

Lemma 4 *At line 2 of Algorithm 3 one can compute a BSGS for $\mathcal{Aut}(g)$ in time $O(|V(g)|^5 + |V(g)|^3 \cdot |\rho^-(g)| \cdot S_V!)$.*

Proof The case $g = \top$ is trivial, so we assume $g \neq \top$ and $r_0 \in \rho^-(g)$. A parent $g - r_0$ is known, and so is $bsgs(g - r_0)$ (as $size(g - r_0) = size(g) - 1$ and hence $g - r_0$ has been fully processed). By performing a base change, we can obtain a BSGS for the stabilizer $\mathcal{Aut}(g)_{V^*(r_0)}$ which fixes all elements in $V^*(r_0)$; please note that $V^*(r)$ contains all nodes involved in the reduction. Hence, we compute a base in which all nodes involved in the reduction are fixed. This is possible in time $O(|V(g)|^5)$. We can then extend the set of generators corresponding to this BSGS to a set of generators for $\mathcal{Aut}(g)$ by adding for every coset of $\mathcal{Aut}(g)_{V^*(r_0)}$ in $\mathcal{Aut}(g)$ one representative. Each such representative φ maps r_0 on some different $\varphi(r_0)$. Graphs $g - r_0$ and $g - \varphi(r_0)$ are isomorphic, which is reflected by $red(g, r_0)(g - r_0) = red(g, \varphi(r_0))(g - \varphi(r_0))$; here, $red(g, r_0)$ returns the stored permutation for reduction r_0 on graph g, which after application on the nodes and edges in graph $g - r_0$ yields the same graph as for the equivalent reduction $\varphi(r_0)$. One can therefore find all such representatives by iterating over all $r \in \rho^-(g)$, checking whether $red(g, r_0)(g - r_0) = red(g, r)(g - r)$ (all $red(g, \cdot)$ were computed earlier) and for all of these listing all possibilities to extend $red(g, r)^{-1} \circ aug(g, r_0)$ to an automorphism $(red(g, r)^{-1} \circ aug(g, r_0)) \cup \varphi_0$ (where $\varphi_0 : V(r) \to V(r_0)$). In total, the number of representatives of cosets of $\mathcal{Aut}(g)_{V^*(r_0)}$ is bounded by $|\rho^-(g)| \cdot S_V!$. One can eliminate the redundant automorphisms in this list in time $O(|V(g)|^3 \cdot |\rho^-(g)| \cdot S_V!)$. ■

Line 3 of Algorithm 3 computes reachability graphs Q_i, which are used in line 9 of the algorithm to determine if two augmentations yield isomorphic graphs. These graphs help to exploit the knowledge of the just computed BSGS $bsgs(g)$ of $\mathcal{Aut}(g)$. A reachability graph is computed for the number of nodes of graph g involved in the augmentation. In the case of (un)connected graphs, an augmentation involves either one or two nodes of graph g, and hence a reachability graph is used for $i = 1$ or $i = 2$. Q_i can be computed in time $O(i \cdot |V(g)|^i \cdot |bsgs(g)|)$. As for a reduced BSGS we have $|bsgs(g)| \leq |V(g)|^2$, line 3 can be performed in time $O(S_V \cdot |V(g)|^{S_V+2})$.

Algorithm 3 Processing one graph

```
1: procedure PROCESS_GRAPH($g$,$r_0$)
2:     $bsgs(g) \leftarrow$ Compute_BSGS$(g, r_0)$
3:     Ensure reachability graph $Q_i$ exists for $g$ where $i = |V^*(r_0) \cap V(g)|$,
       $V(Q_i) = (V(g))^i, E(Q_i) = \{(W, \varphi(W)) \mid W \in V(Q_i) \wedge \varphi \in bsgs(g)\}$
4:     $R_{iso+} \leftarrow \{r \in \rho^+(g) \mid aug(g,r) \neq '?'\}$
5:     $done \leftarrow$ FALSE
6:     while $not(done)$ do
7:         if $R_{iso+} \neq \emptyset$ then
8:             Let $r \in R_{iso+}$
9:             for all $r' \in \rho^+(g)$ s.t. $\exists\varphi : (\forall v \in V(g) : \varphi(v) \in V(g)) \wedge g + r \simeq_\varphi g + r'$ do
10:                $aug(g,r') \leftarrow aug(g,r) \circ \varphi^{-1}$
11:                $R_{iso+} \leftarrow R_{iso+} \setminus \{r'\}$
12:            end for
13:        else if $\exists r \in \rho^+(g) : aug(g,r) = '?'$ then
14:            $s = g + r$
15:            $(ok, s\_par\_list) \leftarrow$ SEARCH_PARENTS($g$,$r$,$s$)
16:            if $ok \wedge p(g)$ then
17:                for all $(r', \varphi') \in s\_par\_list$ do
18:                    $f \leftarrow \varphi'(s - r')$ ; $aug(f, \varphi'(r')) = \varphi'^{-1}$ ; $red(s,r') = \varphi'$
19:                $RefQueue = RefQueue \cup \{(s,r)\}$
20:            else
21:                for all $(r', \varphi') \in s\_par\_list$ do
22:                    $aug(\varphi'(s - r'), \varphi'(r')) \leftarrow nil$
23:            end if
24:            $R_{iso+} \leftarrow R_{iso+} \cup \{r\}$
25:        else
26:            $done \leftarrow$ TRUE
27:        end if
28:    end while
29: end procedure
```

It is possible that previous calls of PROCESS_GRAPH have assigned a value already to some of the $aug(g, \cdot)$, and line 4 collects these augmentations so that their isomorphic variants can be computed in lines 8-12.

Next, the while loop at line 6 runs until all $aug(g, \cdot)$ values have been computed. As soon as a new child is identified (either by previous calls to PROCESS_GRAPH (line 4) or by newly examined children (line 24) it is added to R_{iso+}, and in the next iteration all its isomorphic variants are computed. If R_{iso+} is empty, the $r \in \rho^+(g)$ for which $aug(g,r) = '?'$ are isomorphic to none of the r' for which $aug(g,r')$ has already been assigned a value and a new child is considered (lines 13-24).

We will first discuss the computation of isomorphic variants of an $r \in R_{iso+}$ in line 9. Recalling the definition, all r' are searched for which there is a mapping φ such that $(\forall v \in V(g) : \varphi(v) \in V(g)) \wedge g + r \simeq_\varphi g + r'$. One can do this as follows. First, use the reachability graph Q_i (with $i = |V^*(r) \cap V(g)|$) to find all possible images of $V^*(r) \cap V(g)$ under the automorphism group $\mathcal{A}ut(g)$.

Algorithm 4 search_parents

```
1: procedure SEARCH_PARENTS($g$, $r_0$, $s$)
2:     Construct a spanning tree $T$ for $GoP_{\rho^-,\uparrow}(s)$, the graph of parents of $s$
3:     $s\_par\_list \leftarrow \{(r_0, I_g)\}\}$
4:     Perform a depth-first search of $T$, starting at $r_0$
5:     for all edges $(r_1, r_2)$ visited during the depth first search do
6:         $\varphi \leftarrow$ GET_PARENT$(s, r_1, r_2)$
7:         if $\varphi = nil$ then return (FALSE,$s\_par\_list$)
8:         $s\_par\_list \leftarrow s\_par\_list \cup \{(r_2, \varphi)\}$
9:     end for
10:    return (TRUE,$s\_par\_list$)
11: end procedure
```

Algorithm 5 Get one parent

```
1: procedure GET_PARENT($s$,$r_1$,$r_2$)
2:     $\varphi_{f1} \leftarrow ext(s\_par\_list(s, r_1), I_s)$
3:     $f_1 \leftarrow \varphi_{f1}(s - r_1)$
4:     $\varphi_p \leftarrow ext(red(f_1, \varphi_{f1}(r_2 \uparrow^s r_1)), \varphi_{f1})$
5:     $p \leftarrow \varphi_p((s - r_1) - \varphi_{f1}(r_2 \uparrow^s r_1))$
6:     Let $r'_1 \in \rho^+(p)$ and $\varphi_* : V(\varphi_p(r_1 \uparrow^s r_2)) \rightarrow V(r'_1)$ such that $(I_p \cup \varphi_*)(\varphi_p(r_1 \uparrow^s r_2)) = r'_1$
7:     if $aug(p, r'_1) = nil$ then return $nil$
8:     else return $ext(aug(p, r'_1), (I_p \cup \varphi_*) \circ \varphi_p)$
9: end procedure
```

For each of these images of r, one can also compute one automorphism $\varphi_g \in \mathcal{A}ut(g)$ under which $\varphi_g(r)$ corresponds to the image, by following the edges of Q_i. Then, one can check for every $r' \in \rho^+(g)$ whether there is a mapping $\varphi_r : V(r) \rightarrow V(r')$ such that for $\varphi = \varphi_g \cup \varphi_r$ we have $\varphi(r) = r'$. Traversing Q_i and computing the automorphisms φ_g along the way is possible in time $O(|V(g)|^{i+1})$. As $i \leq S_V$ and we do this at most once for every $r \in \rho^+(g)$, the total time spent here is bounded by $O(|V(g)|^{S_V+1}|\rho^+(g)|)$.

Let us now consider the investigation of new children in lines 13-24 of Algorithm 3. For a particular child $s = g + r$, the algorithm first searches the parents $f = s - r'$ for all $r' \in \rho^-(s)$. As we explain below, if all parents of s satisfy the predicate p the algorithm is guaranteed to find all these parents. The $aug(f, r')$ variables have been assigned a value and depending on whether p holds for s itself, the $red(s, r')$ variables have been assigned a value and it is added to the data structures and to $RefQueue$.

Finding other parents of a proposed child $s = g + r$ is detailed in Algorithms 4 and 5. Before analysing this procedure and its consequences, we first explain some basic ideas. The key intuition that enables an efficient enumeration is that we can efficiently identify the (already enumerated) parents f_2 of the candidate graph s together with a suitable isomorphism mapping φ such that $s - r_2 \simeq_\varphi f_2$ for every reduction $r_2 \in \rho^-(s)$ by using the knowledge from Equation (6) that one can obtain $p = (s - r_1) - (r_2 \uparrow^s r_1)$ also by removing the parts in a different order: $p = (s - r_2) - (r_1 \uparrow^s r_2)$. Therefore, in Algorithm 5 we first remove some $r_1 \in \rho^-(s)$ to obtain a known parent f_1 of s, then go to a grand-parent p by removing a (translated) r_2 from f_1, and then go downwards

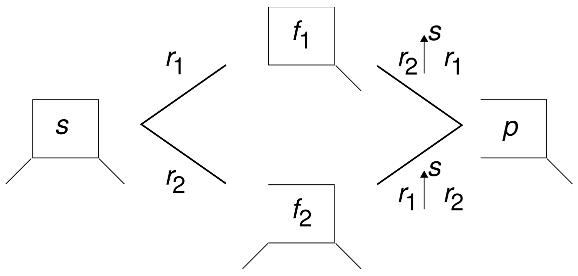

Figure 3: Searching for parents

again from p to the unknown parent f_2 (see Figure 3 for an illustration). In order to construct an isomorphism between $s - r_2$ and f_2, isomorphisms between $s - r_1$ and f_1, between $f_1 - (r_2 \uparrow^s r_1)$ and p and between $p + (r_1 \uparrow^s r_2)$ and f_2 are first extended to cover the full set of vertices of s (the $ext(\cdot,\cdot)$ function), and then composed (line 8).

In Algorithm 5 we have the following notation. Let φ_2 and φ_1 be bijections between sets of vertices. Then, $ext(\varphi_2, \varphi_1)$ is a bijection that maps any x for which $\varphi_1(x)$ is in the domain of φ_2 on $\varphi_2(\varphi_1(x))$ and maps any other x on a new vertex.

Now we return to the details of Algorithms 4 and 5. First, remember that for a dense augmentation schema, the graph of parents of a particular graph is connected. Therefore, it is possible in line 2 of Algorithms 4 to construct a spanning tree for it. Algorithm 4 attempts to construct in *s_par_list* a mapping from reductions $r \in \rho^-(s)$ to isomorphism mappings between the graphs $s - r$ and the representatives of their isomorphism class which were output before. We know already the isomorphism mapping between $s - r_0 = g$ and the representative of its isomorphism class, which is g itself (line 3). Now, if for some $r_1 \in \rho^-(s)$ we know an isomorphism mapping between $s - r_1$ and its representative f_1, and if for some other $r_2 \in \rho^-$, the graph $s - r_2$ satisfies p and has been listed earlier, then Algorithm 5 will provide us with an isomorphism mapping between $s - r_2$ and its representative f_2 as discussed above.

Then there are two possible cases. On the one hand, if there is a parent of s which did not fulfil the predicate p and hence was not listed earlier, we will not find that parent: line 7 of Algorithm 5 will detect this and return *nil*, which will cause also Algorithm 4 to return FALSE. On the other hand, if all parents of s fulfil predicate p, the search along the spanning tree will eventually provide an isomorphism mapping between s and the representatives of $s - r$ for all $r \in \rho^-(s)$.

The complexity of this search can be assessed as follows: Algorithm 5 is executed once for every $r' \in \rho^-(s)$ and contains operations on permutations that can be performed in time $O(|V(s)|)$. Assuming that $\uparrow$ can be performed efficiently, that a good data structure is built on $\rho^+(p)$ in order to be able to perform line 6 of Algorithm 5 efficiently, that $|\rho^-(s)|$ can be bounded by $O(|\rho^-(g)|)$ and that $|V(s)|$ can be bounded by $O(|V(g)|)$, we can therefore conclude that Algorithm 4 can be performed in time $O(|\rho^-(g)| \cdot |V(g)|)$. These assumptions are not very strong and hold for our two example augmentation schemas $(\rho_a^+, \rho_a^-, \uparrow_a)$ and $(\rho_c^+, \rho_c^-, \uparrow_c)$. Algorithm 4 is ran at most once for every $r \in \rho^+(g)$, for a total complexity of $O(|\rho^+(g)| \cdot |V(g)| \cdot |\rho^-(g)|)$.

In summary, this appendix has provided an informal proof of the following.

Theorem 5 *Under the assumptions stated in Theorem 1, Algorithm 2 correctly lists for every isomorphism class of graphs g for which $p(g) =$* TRUE *exactly one representative, and the time needed* *for outputting the next graph g is bounded by* $O(|V(g)|^5 + |V(g)|^3 \cdot |\rho^-(g)| \cdot S_V! + S_V \cdot |V(g)|^{S_V+2} + |V(g)|^{S_V+1}|\rho^+(g)| + |\rho^+(g)| \cdot |V(g)| \cdot |\rho^-(g)|)$.

This bound is polynomial for a constant S_V.

For example, for enumerating connected graphs with the schema $(\rho_c^+, \rho_c^-, \uparrow_c)$, $S_V = 2$. Therefore, this algorithm enumerates classes of connected graphs in time $O(|V(g)|^5)$ for each output graph g in the worst case. A similar result can be shown for enumerating (a monotonic subset of) all graphs with $(\rho_a^+, \rho_a^-, \uparrow_a)$.

Our conjecture is that this complexity can be improved further to $O(|V(g)|^4)$.

Abstract

Java-ML is a collection of machine learning and data mining algorithms, which aims to be a readily usable and easily extensible API for both software developers and research scientists. The interfaces for each type of algorithm are kept simple and algorithms strictly follow their respective interface. Comparing different classifiers or clustering algorithms is therefore straightforward, and implementing new algorithms is also easy. The implementations of the algorithms are clearly written, properly documented and can thus be used as a reference. The library is written in Java and is available from http://java-ml.sourceforge.net/ under the GNU GPL license.

Keywords: open source, machine learning, data mining, java library, clustering, feature selection, classification

1. Introduction

Machine learning techniques are increasingly popular in research fields like bio- and chemo-informatics, text and web mining, as well as many other areas of research and industry. In this paper we present Java-ML: a cross-platform, open source machine learning library written in Java.

Several well-known data mining libraries already exist, including for example, Weka (Witten and Frank, 2005) and Yale/RapidMiner (Mierswa et al., 2006). These programs provide a user-friendly interface and are geared towards interactive use with the user. In contrast to these programs, Java-ML is oriented towards developers that want to use machine learning in their own programs. To this end, Java-ML interfaces are restricted to the essentials, and are very easy to understand. As a result, Java-ML facilitates a broad exploration of different models, is straightforward to integrate into your own source code, and can be easily extended.

Regarding the content of the library, Java-ML also has a different focus than the other libraries. Java-ML contains an extensive set of similarity based techniques, and offers state-of-the-art feature selection techniques. The large number of similarity functions allow for a broad set of clustering and instance based learning techniques, while the feature selection techniques are well suited to deal with high-dimensional domains, such as the ones often encountered in bioinformatics and biomedical applications.

Clustering
K-means-like (7)
Self organizing maps
Density based clustering (3)
Markov chain clustering
Cobweb
Cluster evaluation measures (15)

Classification

Distance measures
Similarity measures (6)
Distance metrics (11)
Correlation measures (2)

Utilities
Cross-validation/evaluation
Data loading (ARFF and CSV)
Weka bridges (2)

Table 1: Overview of the main algorithms included in Java-ML. The number of algorithms for each category is shown in parentheses.

2. Description of the Library

In this section we first describe the software design of Java-ML, we then discuss how to integrate it in your program and finally we cover the documentation.

2.1 Structure of the Library

The library is built around two core interfaces: `Dataset` and `Instance`. These two interfaces have several implementations for different types of samples. The machine learning algorithms implement one of the following interfaces: `Clusterer`, `Classifier`, `FeatureScoring`, `FeatureRanking` or `FeatureSubsetSelection`. Distance, correlation and similarity measures implement the interface `DistanceMeasure`. These distance measures can be used in many algorithms to modify their behavior. Cluster evaluation measures are defined by the `ClusterEvaluation` interface. Manipulation filters either implement `InstanceFilter` or `DatasetFilter`, depending on the level they work on. All implementing classes for each of the interfaces are available from the API documentation that is available on the Java-ML website. Each of these interfaces provides one or two methods that are required to execute the algorithm on a particular data set. Several utility classes make it easy to load data from tab or comma separated files and from ARFF formatted files. An overview of the main algorithms included in Java-ML can be found in Table 1.

The library provides several algorithms that have not been made available before in a bundled form. In particular, clustering algorithms and the accompanying cluster evaluation measures are extensively represented. This includes the adaptive quality-based clustering algorithm, density based methods, self-organizing maps (both as clustering and classification algorithm) and numerous other well-known clustering algorithms. A large number of distance, similarity and correlation measures are included. Feature selection algorithms include traditional algorithms like symmetrical uncertainty, gain ratio, RELIEF, stepwise addition/removal, as well as a number of more recent methods (SVMRFE and random forest attribute evaluation). Also the recently introduced concept of ensemble feature selection techniques (Saeys et al., 2008) is incorporated in the library. We have also implemented a fast and simple random tree algorithm to cope with high dimensional, sparse and ambiguous data. Finally, we provide bridges for classification and clustering in Weka and libsvm (Fan et al., 2005).

2.2 Easy Integration in Your Own Source Code

Including Java-ML algorithms in your own source code is very simple. To illustrate this, we present here two short code fragments that demonstrate the ease to integrate the library. The following lines of code integrate a K-Means clustering algorithm in your own program.

```
Dataset data = FileHandler.loadDataset(new File("iris.data"), 4, ",");
Clusterer km = new KMeans();
Dataset[]clusters=km.cluster(data);
```

The first line uses the FileHandler utility to load data from the iris.data file. In this file, the class label is on the fourth position and the fields are separated by a comma. The second line constructs a new instance of the KMeans clustering algorithm with default values, in this case k=4. The third line uses the KMeans instance to cluster the data that we loaded in the first line. The resulting clusters will be returned as an array of data sets.

The following example illustrates how to perform a cross-validation experiment for a specific dataset and classifier.

```
Dataset data = FileHandler.loadDataset(new File("iris.data"), 4, ",");
Classifier knn = new KNearestNeighbors(5);
CrossValidation cv = new CrossValidation(knn);
Map<Object, PerformanceMeasure> p = cv.crossValidation(data);
```

First we load the iris data set, and construct a K-nearest neighbors classifier, which uses 5 neighbors to classify instances. In the next line, we initialize the cross-validation with our classifier. The last line runs the cross-validation on the loaded data. By default, a 10-fold cross validation will be performed. The result is returned in a map, which maps each class label to its corresponding PerformanceMeasure (`Map<Object,PerformanceMeasure>`). For classification problems, a performance measure is a wrapper around four values: (i) true positives, (ii) true negatives, (iii) false positives and (iv) false negatives. This class also provides a number of derivative measures such as accurracy, error rate, precision, recall and others. More advanced samples are available from the documentation pages on the Java-ML website.

2.3 Documentation

There are a number of resources for documentation about Java-ML. The source code itself is documented thoroughly, always up-to-date, and accessible from the web site through the API documentation. The web site additionally provides a number of tutorials with illustrated code samples for the most common tasks in Java-ML, covering the following topics: installing the library, introducing basic concepts, creating and loading data, creating algorithms and applying them to your data, and more advanced topics for people who would like to contribute to the library. Finally, all code samples as well as the PDF versions of the tutorials are also included in the Java-ML distribution itself.

3. Case Studies

The library described in this manuscript has been used in several studies. Here we highlight two applications which have been recently published.

Initially, the project focused on clustering algorithms and measures to evaluate the quality of a clustering. Our goal was to separate DNA sequences that are likely to contain a promoter (the controlling element of a gene) from other sequences, a well-known task in bioinformatics. The best results were obtained using a clustering algorithm based on self-organizing maps (Abeel et al., 2008).

More recently, the focus has shifted toward feature selection. More specifically, we are looking whether ensemble feature selection (combining different feature selectors) can improve the stability of feature selection in case of high-dimensional data sets with few samples. The improvements in stability were shown not to affect the prediction accuracy. This is ongoing research, but the first results are promising (Saeys et al., 2008).

Acknowledgments

We thank A. De Rijcke for his early contributions to Java-ML, as well as the anonymous reviewers for their valuable comments. TA is funded by IWT-Vlaanderen. YS would like to thank the Research Foundation-Flanders (FWO-Vlaanderen) for funding his research.

Abstract

Positive definite kernels on probability measures have been recently applied to classification problems involving text, images, and other types of structured data. Some of these kernels are related to classic information theoretic quantities, such as (Shannon's) mutual information and the Jensen-Shannon (JS) divergence. Meanwhile, there have been recent advances in nonextensive generalizations of Shannon's information theory. This paper bridges these two trends by introducing nonextensive information theoretic kernels on probability measures, based on new JS-type divergences. These new divergences result from extending the the two building blocks of the classical JS divergence: convexity and Shannon's entropy. The notion of convexity is extended to the wider concept of q-convexity, for which we prove a Jensen q-inequality. Based on this inequality, we introduce Jensen-Tsallis (JT) q-differences, a nonextensive generalization of the JS divergence, and define a k-th order JT q-difference between stochastic processes. We then define a new family of nonextensive mutual information kernels, which allow weights to be assigned to their arguments, and which includes the Boolean, JS, and linear kernels as particular cases. Nonextensive string kernels are also defined that generalize the p-spectrum kernel. We illustrate the performance of these kernels on text categorization tasks, in which documents are modeled both as bags of words and as sequences of characters.

1. Introduction

In kernel-based machine learning (Schölkopf and Smola, 2002; Shawe-Taylor and Cristianini, 2004), there has been recent interest in defining kernels on probability distributions to tackle several problems involving structured data (Desobry et al., 2007; Moreno et al., 2004; Jebara et al., 2004; Hein and Bousquet, 2005; Lafferty and Lebanon, 2005; Cuturi et al., 2005). By defining a parametric family S containing the distributions from which the data points (in the input space X) are assumed to have been generated, and defining a map from X from S (e.g., via maximum likelihood estimation), a distribution in S may be fitted to each datum. Therefore, a kernel that is defined on $S \times S$ automatically induces a kernel on $X \times X$, through map composition. In text categorization, this framework appears as an alternative to the Euclidean geometry inherent to the usual bag-of-words representations. In fact, approaches that map data to statistical manifolds, equipped with well-motivated non-Euclidean metrics (Lafferty and Lebanon, 2005), often outperform support vector machine (SVM) classifiers with linear kernels (Joachims, 2002). Some of these kernels have a natural information theoretic interpretation, establishing a bridge between kernel methods and information theory (Cuturi et al., 2005; Hein and Bousquet, 2005).

The main goal of this paper is to widen that bridge; we do that by introducing a new class of kernels rooted in *nonextensive* information theory, which contains previous information theoretic kernels as particular elements. The Shannon and Rényi entropies (Shannon, 1948; Rényi, 1961) share the *extensivity* property: the joint entropy of a pair of independent random variables equals the sum of the individual entropies. Abandoning this property yields the so-called nonextensive entropies (Havrda and Charvát, 1967; Lindhard, 1974; Lindhard and Nielsen, 1971; Tsallis, 1988), which have raised great interest among physicists in modeling phenomena such as long-range interactions and multifractals, and in constructing nonextensive generalizations of Boltzmann-Gibbs statistical mechanics (Abe, 2006). Nonextensive entropies have also been recently used in signal/image processing (Li et al., 2006) and other areas (Gell-Mann and Tsallis, 2004). The so-called *Tsallis entropies* (Havrda and Charvát, 1967; Tsallis, 1988) form a parametric family of nonextensive entropies that includes the Shannon-Boltzmann-Gibbs entropy as a particular case. Nonextensive generalizations of information theory have been proposed (Furuichi, 2006).

Convexity and Jensen's inequality are key concepts underlying several central results of information theory, for example, the non-negativity of the *Kullback-Leibler (KL) divergence* (or *relative entropy*) (Kullback and Leibler, 1951). Jensen's inequality (Jensen, 1906) also underlies the *Jensen-Shannon (JS) divergence*, a symmetrized and smoothed version of the KL divergence (Lin and Wong, 1990; Lin, 1991), often used in statistics, machine learning, signal/image processing, and physics.

In this paper, we introduce new extensions of JS-type divergences by generalizing its two pillars: *convexity* and *Shannon's entropy*. These divergences are then used to define new information-theoretic kernels between probability distributions. More specifically, our main contributions are:

- The concept of *q-convexity*, generalizing that of convexity, for which we prove a *Jensen q-inequality*. The related concept of *Jensen q-differences*, which generalize Jensen differences, is also proposed. Based on these concepts, we introduce the *Jensen-Tsallis (JT) q-difference*, a nonextensive generalization of the JS divergence, which is also a "mutual information" in the sense of Furuichi (2006).

- Characterization of the JT q-difference, with respect to convexity and extrema, extending work by Burbea and Rao (1982) and by Lin (1991) for the JS divergence.

- Definition of k-th order joint and conditional JT q-differences for families of stochastic processes, and derivation of a chain rule.
- A broad family of (nonextensive information theoretic) positive definite kernels, interpretable as nonextensive mutual information kernels, ranging from the Boolean to the linear kernels, and including the JS kernel proposed by Hein and Bousquet (2005).
- A family of (nonextensive information theoretic) positive definite kernels between stochastic processes, subsuming well-known string kernels (e.g., the p-spectrum kernel) (Leslie et al., 2002).
- Extensions of results of Hein and Bousquet (2005) proving positive definiteness of kernels based on the unbalanced JS divergence. A connection between these new kernels and those studied by Fuglede (2005) and Hein and Bousquet (2005) is also established. In passing, we show that the parametrix approximation of the multinomial diffusion kernel introduced by Lafferty and Lebanon (2005) is *not* positive definite in general.

The paper is organized as follows. Section 2 reviews nonextensive entropies, with emphasis on the Tsallis case. Section 3 discusses Jensen differences and divergences. The concepts of q-differences and q-convexity are introduced in Section 4, where they are used to define and characterize some new divergence-type quantities. In Section 5, we define the Jensen-Tsallis q-difference and derive some of its properties; in that section, we also define k-th order Jensen-Tsallis q-differences for families of stochastic processes. The new family of entropic kernels is introduced and characterized in Section 6, which also introduces nonextensive kernels between stochastic processes. Experiments on text categorization are reported in Section 7. Section 8 concludes the paper and discusses future research.

2. Nonextensive Entropies and Tsallis Statistics

In this section, we start with a brief overview of nonextensive entropies. We then introduce the family of Tsallis entropies, and extend their domain to unnormalized measures.

2.1 Nonextensivity

In what follows, $\mathbb{R}_+$ denotes the nonnegative reals, $\mathbb{R}_{++}$ denotes the strictly positive reals, and

$$\Delta^{n-1} \triangleq \left\{ (x_1, \ldots, x_n) \in \mathbb{R}^n \mid \sum_{i=1}^{n} x_i = 1,\ \forall i\, x_i \geq 0 \right\}$$

denotes the $(n-1)$-dimensional simplex.

Inspired by the axiomatic formulation of Shannon's entropy (Khinchin, 1957; Shannon and Weaver, 1949), Suyari (2004) proposed an axiomatic framework for nonextensive entropies and a uniqueness theorem. Let $q \geq 0$ be a fixed scalar, called the *entropic index*. Suyari's axioms (Appendix A) determine a function $S_{q,\phi} : \Delta^{n-1} \to \mathbb{R}$ of the form

$$S_{q,\phi}(p_1, \ldots, p_n) = \begin{cases} \frac{k}{\phi(q)} \left(1 - \sum_{i=1}^{n} p_i^q\right) & \text{if } q \neq 1 \\ -k \sum_{i=1}^{n} p_i \ln p_i & \text{if } q = 1, \end{cases} \tag{1}$$

where k is a positive constant, and $\phi : \mathbb{R}_+ \to \mathbb{R}$ is a continuous function that satisfies the following three conditions: *(i)* $\phi(q)$ has the same sign as $q-1$; *(ii)* $\phi(q)$ vanishes if and only if $q = 1$; *(iii)* ϕ is differentiable in a neighborhood of 1 and $\phi'(1) = 1$.

Note that $S_{1,\phi} = \lim_{q\to 1} S_{q,\phi}$, thus $S_{q,\phi}(p_1, \dots, p_n)$, seen as a function of q, is continuous at $q = 1$. For any ϕ satisfying these conditions, $S_{q,\phi}$ has the *pseudoadditivity* property: for any two independent random variables A and B, with probability mass functions $p_A \in \Delta^{n_A-1}$ and $p_B \in \Delta^{n_B-1}$, respectively, consider the new random variable $A \otimes B$ defined by the joint distribution $p_A \otimes p_B \in \Delta^{n_A n_B-1}$; then,

$$S_{q,\phi}(A \otimes B) = S_{q,\phi}(A) + S_{q,\phi}(B) - \frac{\phi(q)}{k} S_{q,\phi}(A) S_{q,\phi}(B),$$

where we denote (as usual) $S_{q,\phi}(A) \triangleq S_{q,\phi}(p_A)$.

For $q = 1$, Suyari's axioms recover the Shannon-Boltzmann-Gibbs (SBG) entropy,

$$S_{1,\phi}(p_1, \dots, p_n) = H(p_1, \dots, p_n) = -k \sum_{i=1}^{n} p_i \ln p_i,$$

and pseudoadditivity turns into *additivity*, that is, $H(A \otimes B) = H(A) + H(B)$ holds.

Several proposals for ϕ have appeared in the literature (Havrda and Charvát, 1967; Daróczy, 1970; Tsallis, 1988). In this article, unless stated otherwise, we set $\phi(q) = q - 1$, which yields the *Tsallis entropy*:

$$S_q(p_1, \dots, p_n) = \frac{k}{q-1} \left(1 - \sum_{i=1}^{n} p_i^q \right). \tag{2}$$

To simplify, we let $k = 1$ and write the Tsallis entropy as

$$S_q(X) \triangleq S_q(p_1, \dots, p_n) = - \sum_{x \in X} p(x)^q \ln_q p(x), \tag{3}$$

where $\ln_q(x) \triangleq (x^{1-q} - 1)/(1-q)$ is the *q-logarithm function*, which satisfies $\ln_q(xy) = \ln_q(x) + x^{1-q} \ln_q(y)$ and $\ln_q(1/x) = -x^{q-1} \ln_q(x)$. This notation was introduced by Tsallis (1988).

2.2 Tsallis Entropies

Furuichi (2006) derived some information theoretic properties of Tsallis entropies. Tsallis *joint* and *conditional entropies* are defined, respectively, as

$$S_q(X,Y) \triangleq - \sum_{x,y} p(x,y)^q \ln_q p(x,y)$$

and

$$S_q(X|Y) \triangleq - \sum_{x,y} p(x,y)^q \ln_q p(x|y) = \sum_{y} p(y)^q S_q(X|y), \tag{4}$$

and the chain rule $S_q(X,Y) = S_q(X) + S_q(Y|X)$ holds.

For two probability mass functions $p_X, p_Y \in \Delta^n$, the *Tsallis relative entropy*, generalizing the KL divergence, is defined as

$$D_q(p_X \| p_Y) \triangleq - \sum_{x} p_X(x) \ln_q \frac{p_Y(x)}{p_X(x)}. \tag{5}$$

Finally, the *Tsallis mutual entropy* is defined as

$$I_q(X;Y) \triangleq S_q(X) - S_q(X|Y) = S_q(Y) - S_q(Y|X), \tag{6}$$

generalizing (for $q > 1$) Shannon's mutual information (Furuichi, 2006). In Section 5, we establish a relationship between Tsallis mutual entropy and a quantity called *Jensen-Tsallis q-difference*, generalizing the one between mutual information and the JS divergence (shown, e.g., by Grosse et al. 2002, and recalled below, in Section 3.2).

Furuichi (2006) also mentions an alternative generalization of Shannon's mutual information, defined as

$$\tilde{I}_q(X;Y) \triangleq D_q(p_{X,Y} \| p_X \otimes p_Y), \tag{7}$$

where $p_{X,Y}$ is the true joint probability mass function of (X,Y) and $p_X \otimes p_Y$ denotes their joint probability if they were independent. This alternative definition of a "Tsallis mutual entropy" has also been used by Lamberti and Majtey (2003); notice that $I_q(X;Y) \neq \tilde{I}_q(X;Y)$ in general, the case $q = 1$ being a notable exception. In Section 5, we show that this alternative definition also leads to a nonextensive analogue of the JS divergence.

2.3 Entropies of Measures and Denormalization Formulae

Throughout this paper, we consider functionals that extend the domain of the Shannon-Boltzmann-Gibbs and Tsallis entropies to include unnormalized measures. Although, as shown below, these functionals are completely characterized by their restriction to the normalized probability distributions, the denormalization expressions will play an important role in Section 6 to derive novel positive definite kernels inspired by mutual informations.

In order to keep generality, whenever possible we do not restrict to finite or countable sample spaces. Instead, we consider a measure space $(\mathcal{X}, \mathscr{M}, \nu)$ where $\mathcal{X}$ is Hausdorff and ν is a σ-finite Radon measure. We denote by $M_+(\mathcal{X})$ the set of *finite* Radon ν-absolutely continuous measures on $\mathcal{X}$, and by $M_+^1(\mathcal{X})$ the subset of those which are probability measures. For simplicity, we often identify each measure in $M_+(\mathcal{X})$ or $M_+^1(\mathcal{X})$ with its corresponding nonnegative density; this is legitimated by the Radon-Nikodym theorem, which guarantees the existence and uniqueness (up to equivalence within measure zero) of a density function $f : \mathcal{X} \to \mathbb{R}_+$. In the sequel, Lebesgue-Stieltjes integrals of the form $\int_{\mathcal{A}} f(x) d\nu(x)$ are often written as $\int_{\mathcal{A}} f$, or simply $\int f$, if $\mathcal{A} = \mathcal{X}$. Unless otherwise stated, ν is the Lebesgue-Borel measure, if $\mathcal{X} \subseteq \mathbb{R}^n$ and $\text{int}\mathcal{X} \neq \varnothing$, or the counting measure, if $\mathcal{X}$ is countable. In the latter case integrals can be seen as finite sums or infinite series.

Define $\overline{\mathbb{R}} \triangleq \mathbb{R} \cup \{-\infty, +\infty\}$. For some functional $G : M_+(\mathcal{X}) \to \overline{\mathbb{R}}$, let the set $M_+^G(\mathcal{X}) \triangleq \{f \in M_+(\mathcal{X}) : |G(f)| < \infty\}$ be its effective domain, and $M_+^{1,G}(\mathcal{X}) \triangleq M_+^G(\mathcal{X}) \cap M_+^1(\mathcal{X})$ be its subdomain of probability measures.

The following functional (Cuturi and Vert, 2005), extends the Shannon-Boltzmann-Gibbs entropy from $M_+^{1,H}(\mathcal{X})$ to the unnormalized measures in $M_+^H(\mathcal{X})$:

$$H(f) = -k \int f \ln f = \int \varphi_H \circ f, \tag{8}$$

where $k > 0$ is a constant, the function $\varphi_H : \mathbb{R}_+ \to \mathbb{R}$ is defined as

$$\varphi_H(y) = -k\, y \ln y,$$

and, as usual, $0 \ln 0 \triangleq 0$.

The generalized form of the KL divergence, often called *generalized I-divergence* (Csiszar, 1975), is a directed divergence between two measures $\mu_f, \mu_g \in M_+^H(\mathcal{X})$, such that μ_f is μ_g-absolutely continuous (denoted $\mu_f \ll \mu_g$). Let f and g be the densities associated with μ_f and μ_g, respectively. In terms of densities, this generalized KL divergence is

$$D(f,g) \quad = \quad k \int \left(g - f + f \ln \frac{f}{g} \right). \tag{9}$$

Let us now proceed similarly with the nonextensive entropies. For $q \geq 0$, let $M_+^{S_q}(\mathcal{X}) = \{f \in M_+(\mathcal{X}) : f^q \in M_+(\mathcal{X})\}$ for $q \neq 1$, and $M_+^{S_q}(\mathcal{X}) = M_+^H(\mathcal{X})$ for $q = 1$. The nonextensive counterpart of (8), defined on $M_+^{S_q}(\mathcal{X})$, is

$$S_q(f) = \int \varphi_q \circ f, \tag{10}$$

where $\varphi_q : \mathbb{R}_+ \to \mathbb{R}$ is given by

$$\varphi_q(y) = \begin{cases} \varphi_H(y) & \text{if } q = 1, \\ \frac{k}{\phi(q)}(y - y^q) & \text{if } q \neq 1, \end{cases} \tag{11}$$

and $\phi : \mathbb{R}_+ \to \mathbb{R}$ satisfies conditions *(i)-(iii)* stated following Equation (1). The Tsallis entropy is obtained for $\phi(q) = q - 1$,

$$S_q(f) = -k \int f^q \ln_q f. \tag{12}$$

Similarly, a nonextensive generalization of the generalized KL divergence (9) is

$$D_q(f,g) = -\frac{k}{\phi(q)} \int \left(qf + (1-q)g - f^q g^{1-q} \right),$$

for $q \neq 1$, and $D_1(f,g) \triangleq \lim_{q \to 1} D_q(f,g) = D(f,g)$.

Define $|f| \triangleq \int f = \mu_f(\mathcal{X})$. For $|f| = |g| = 1$, several particular cases are recovered: if $\phi(q) = 1 - 2^{1-q}$, then $D_q(f,g)$ is the Havrda-Charvát relative entropy (Havrda and Charvát, 1967; Daróczy, 1970); if $\phi(q) = q - 1$, then $D_q(f,g)$ is the Tsallis relative entropy (5); finally, if $\phi(q) = q(q-1)$, then $D_q(f,g)$ is the canonical α-divergence defined by Amari and Nagaoka (2001) in the realm of information geometry (with the reparameterization $\alpha = 2q - 1$ and assuming $q > 0$ so that $\phi(q) = q(q-1)$ conforms with the axioms).

Remark 1 *Both functionals S_q and D_q are completely determined by their restriction to the normalized measures. Indeed, the following equalities hold for any $c \in \mathbb{R}_{++}$ and $f, g \in M_+^{S_q}(\mathcal{X})$, with $\mu_f \ll \mu_g$:*

$$\begin{aligned} S_q(cf) &= c^q S_q(f) + |f| \varphi_q(c), \\ D_q(cf, cg) &= c D_q(f,g), \\ D_q(cf, g) &= c^q D_q(f,g) - q \varphi_q(c)|f| + \frac{k}{\phi(q)}(q-1)(1-c^q)|g|. \end{aligned} \tag{13}$$

For any $f \in M_+^{S_q}(\mathcal{X})$ and $g \in M_+^{S_q}(\mathcal{Y})$,

$$S_q(f \otimes g) = |g| S_q(f) + |f| S_q(g) - \frac{\phi(q)}{k} S_q(f) S_q(g).$$

If $|f| = |g| = 1$, we recover the pseudo-additivity property of nonextensive entropies:

$$S_q(f \otimes g) = S_q(f) + S_q(g) - \frac{\phi(q)}{k} S_q(f) S_q(g).$$

For $\phi(q) = q-1$, D_q is the Tsallis relative entropy and (13) *reduces to*

$$D_q(cf, g) = c^q D_q(f,g) - q\varphi_q(c)|f| + k(1-c^q)|g|.$$

By taking the limit $q \to 1$, we obtain the following formulae for H and D:

$$\begin{aligned} H(cf) &= cH(f) + |f|\, \varphi_H(c), \\ D(cf, cg) &= cD(f,g), \\ D(cf, g) &= cD(f,g) - |f|\, \varphi_H(c) + k\,(1-c)\,|g|. \end{aligned}$$

Consider $f \in M_+^H(\mathcal{X})$ and $g \in M_+^H(\mathcal{Y})$, and define $f \otimes g \in M_+^H(\mathcal{X} \times \mathcal{Y})$ as $(f \otimes g)(x,y) \triangleq f(x)g(y)$. Then,

$$H(f \otimes g) = |g|\, H(f) + |f|\, H(g).$$

If $|f| = |g| = 1$, we recover the additivity property of the Shannon-Boltzmann-Gibbs entropy, $H(f \otimes g) = H(f) + H(g)$.

3. Jensen Differences and Divergences

In this section, we review the concept of Jensen difference. We then discuss three particular cases: the Jensen-Shannon, Jensen-Rényi, and Jensen-Tsallis divergences.

3.1 The Jensen Difference

Jensen's inequality (Jensen, 1906) is at the heart of many important results in information theory. Let $E[.]$ denote the expectation operator. Jensen's inequality states that if Z is an integrable random variable taking values in a set $\mathcal{Z}$, and f is a measurable convex function defined on the convex hull of $\mathcal{Z}$, then

$$f(E[Z]) \leq E[f(Z)].$$

Burbea and Rao (1982) considered the scenario where $\mathcal{Z}$ is finite, and took $f \triangleq -H_\varphi$, where $H_\varphi : [a,b]^n \to \mathbb{R}$ is a concave function, called a *φ-entropy*, defined as

$$H_\varphi(z) \triangleq -\sum_{i=1}^{n} \varphi(z_i), \tag{14}$$

where $\varphi : [a,b] \to \mathbb{R}$ is convex. They studied the Jensen difference

$$J_\varphi^\pi(y_1, \ldots, y_m) \triangleq H_\varphi\left(\sum_{t=1}^{m} \pi_t\, y_t\right) - \sum_{t=1}^{m} \pi_t\, H_\varphi(y_t),$$

where $\pi \triangleq (\pi_1, \dots, \pi_m) \in \Delta^{m-1}$, and each $y_1, \dots, y_m \in [a,b]^n$.

We consider here a more general scenario, involving two measure sets $(\mathcal{X}, \mathscr{M}, \nu)$ and $(\mathcal{T}, \mathscr{T}, \tau)$, where the second is used to index the first.

Definition 2 *Let $\mu \triangleq (\mu_t)_{t\in\mathcal{T}} \in [M_+(\mathcal{X})]^{\mathcal{T}}$ be a family of finite Radon measures on $\mathcal{X}$, indexed by $\mathcal{T}$, and let $\omega \in M_+(\mathcal{T})$ be a finite Radon measure on $\mathcal{T}$. Define:*

$$J_\Psi^\omega(\mu) \quad \triangleq \quad \Psi\left(\int_{\mathcal{T}} \omega(t)\mu_t \, d\tau(t)\right) - \int_{\mathcal{T}} \omega(t)\Psi(\mu_t)\, d\tau(t) \tag{15}$$

where:

(i) Ψ *is a concave functional such that* $\operatorname{dom}\Psi \subseteq M_+(\mathcal{X})$*;*

(ii) $\omega(t)\mu_t(x)$ *is* τ*-integrable, for all* $x \in \mathcal{X}$*;*

(iii) $\int_{\mathcal{T}} \omega(t)\mu_t d\tau(t) \in \operatorname{dom}\Psi$*;*

(iv) $\mu_t \in \operatorname{dom}\Psi$*, for all* $t \in \mathcal{T}$*;*

(v) $\omega(t)\Psi(\mu_t)$ *is* τ*-integrable.*

If $\omega \in M_+^1(\mathcal{T})$*, we still call* (15) *a Jensen difference.*

In the following subsections, we consider several instances of Definition 2, leading to several Jensen-type divergences.

3.2 The Jensen-Shannon Divergence

Let p be a random probability distribution taking values in $\{p_t\}_{t\in\mathcal{T}}$ according to a distribution $\pi \in M_+^1(\mathcal{T})$. (In classification/estimation theory parlance, π is called the prior distribution and $p_t \triangleq p(.|t)$ the likelihood function.) Then, (15) becomes

$$J_\Psi^\pi(p) = \Psi(E[p]) - E[\Psi(p)], \tag{16}$$

where the expectations are with respect to π.

Let now $\Psi = H$, the Shannon-Boltzmann-Gibbs entropy. Consider the random variables T and X, taking values respectively in $\mathcal{T}$ and $\mathcal{X}$, with densities $\pi(t)$ and $p(x) \triangleq \int_{\mathcal{T}} p(x|t)\pi(t)$. Using standard notation of information theory (Cover and Thomas, 1991),

$$\begin{aligned} J^\pi(p) \triangleq J_H^\pi(p) &= H\left(\int_{\mathcal{T}} \pi(t)p_t\right) - \int_{\mathcal{T}} \pi(t)H(p_t) \\ &= H(X) - \int_{\mathcal{T}} \pi(t)H(X|T=t) \\ &= H(X) - H(X|T) \\ &= I(X;T), \end{aligned} \tag{17}$$

where $I(X;T)$ is the mutual information between X and T. (This relationship between JS divergence and mutual information was pointed out by Grosse et al. 2002.) Since $I(X;T)$ is also equal to the

KL divergence between the joint distribution and the product of the marginals (Cover and Thomas, 1991), we have

$$J^{\pi}(p) = H(E[p]) - E[H(p)] = E[D(p\|E[p])]. \tag{18}$$

When $\mathcal{X}$ and $\mathcal{T}$ are finite with $|\mathcal{T}| = m$, $J^{\pi}_{H}(p_1,\ldots,p_m)$ is called the *Jensen-Shannon (JS) divergence* of $p_1,\ldots,p_m$, with weights $\pi_1,\ldots,\pi_m$ (Burbea and Rao, 1982; Lin, 1991). Equality (18) allows two interpretations of the JS divergence:

- the Jensen difference of the Shannon entropy of p;
- the expected KL divergence from p to the expectation of p.

A remarkable fact is that $J^{\pi}(p) = \min_r E[D(p\|r)]$, that is, $r^* = E[p]$ is a minimizer of $E[D(p\|r)]$ with respect to r. It has been shown that this property together with Equality (18) characterize the so-called *Bregman divergences*: they hold not only for $\Psi = H$, but for any concave Ψ and the corresponding Bregman divergence, in which case J^{π}_{Ψ} is the *Bregman information* (Banerjee et al., 2005).

When $|\mathcal{T}| = 2$ and $\pi = (1/2, 1/2)$, p may be seen as a random distribution whose value on $\{p_1, p_2\}$ is chosen by tossing a fair coin. In this case, $J^{(1/2,1/2)}(p) = JS(p_1, p_2)$, where

$$\begin{aligned} JS(p_1,p_2) &\triangleq H\left(\frac{p_1+p_2}{2}\right) - \frac{H(p_1)+H(p_2)}{2} \\ &= \frac{1}{2}D\left(p_1\middle\|\frac{p_1+p_2}{2}\right) + \frac{1}{2}D\left(p_2\middle\|\frac{p_1+p_2}{2}\right), \end{aligned}$$

as introduced by Lin (1991). It has been shown that $\sqrt{JS}$ satisfies the triangle inequality (hence being a metric) and that, moreover, it is a Hilbertian metric[1] (Endres and Schindelin, 2003; Topsøe, 2000), which has motivated its use in kernel-based machine learning (Cuturi et al., 2005; Hein and Bousquet, 2005) (see Section 6).

3.3 The Jensen-Rényi Divergence

Consider again the scenario above (Section 3.2), with the Rényi q-entropy

$$R_q(p) = \frac{1}{1-q}\ln\int p^q$$

replacing the Shannon-Boltzmann-Gibbs entropy. It is worth noting that the Rényi and Tsallis q-entropies are monotonically related through $R_q(p) = \ln\left([1+(1-q)S_q(p)]^{\frac{1}{1-q}}\right)$, or, using the q-logarithm function,

$$S_q(p) = \ln_q \exp R_q(p).$$

The Rényi q-entropy is concave for $q \in [0,1)$ and has the Shannon-Boltzmann-Gibbs entropy as the limit when $q \to 1$. Letting $\Psi = R_q$, (16) becomes

$$J^{\pi}_{R_q}(p) = R_q(E[p]) - E[R_q(p)]. \tag{19}$$

1. A metric $d : \mathcal{X}\times\mathcal{X} \to \mathbb{R}$ is Hilbertian if there is some Hilbert space $\mathcal{H}$ and an isometry $f : \mathcal{X} \to \mathcal{H}$ such that $d^2(x,y) = \langle f(x) - f(y), f(x) - f(y)\rangle_{\mathcal{H}}$ holds for any $x, y \in \mathcal{X}$ (Hein and Bousquet, 2005).

Unlike in the JS divergence case, there is no counterpart of equality (18) based on the Rényi q-divergence

$$D_{R_q}(p_1\|p_2) = \frac{1}{q-1}\ln\int p_1^q\, p_2^{1-q}.$$

When $\mathcal{X}$ and $\mathcal{T}$ are finite, we call $J^{\pi}_{R_q}$ in (19) the *Jensen-Rényi (JR) divergence*. Furthermore, when $|\mathcal{T}| = 2$ and $\pi = (1/2, 1/2)$, we write $J^{\pi}_{R_q}(p) = JR_q(p_1, p_2)$, where

$$JR_q(p_1, p_2) = R_q\left(\frac{p_1+p_2}{2}\right) - \frac{R_q(p_1)+R_q(p_2)}{2}.$$

The JR divergence has been used in several signal/image processing applications, such as registration, segmentation, denoising, and classification (Ben-Hamza and Krim, 2003; He et al., 2003; Karakos et al., 2007). In Section 6, we show that the JR divergence is (like the JS divergence) a Hilbertian metric, which is relevant for its use in kernel-based machine learning.

3.4 The Jensen-Tsallis Divergence

Burbea and Rao (1982) have defined Jensen-type divergences of the form (16) based on the Tsallis q-entropy S_q, defined in (12). Like the Shannon-Boltzmann-Gibbs entropy, but unlike the Rényi entropies, the Tsallis q-entropy, for finite $\mathcal{T}$, is an instance of a φ-entropy (see Equation 14). Letting $\Psi = S_q$, (16) becomes

$$J^{\pi}_{S_q}(p) = S_q(E[p]) - E[S_q(p)]. \tag{20}$$

Again, as in Section 3.3, if we consider the Tsallis q-divergence,

$$D_q(p_1\|p_2) = \frac{1}{1-q}\left(1 - \int {p_1}^q\, {p_2}^{1-q}\right),$$

there is no counterpart of the Equality (18).

When $\mathcal{X}$ and $\mathcal{T}$ are finite, $J^{\pi}_{S_q}$ in (20) is called the *Jensen-Tsallis (JT) divergence* and it has also been applied in image processing (Ben-Hamza, 2006). Unlike the JS divergence, the JT divergence lacks an interpretation as a mutual information. Despite this, for $q \in [1,2]$, it exhibits joint convexity (Burbea and Rao, 1982). In the next section, we propose an alternative to the JT divergence which, among other features, is interpretable as a nonextensive mutual information (in the sense of Furuichi 2006) and is jointly convex, for $q \in [0,1]$.

4. q-Convexity and q-Differences

This section introduces a novel class of functions, termed *Jensen q-differences*, which generalize Jensen differences. Later (in Section 5), we will use these functions to define the *Jensen-Tsallis q-difference*, which we will propose as an alternative nonextensive generalization of the JS divergence, instead of the JT divergence discussed in Section 3.4. We begin by recalling the concept of q-expectation (Tsallis, 1988).

Definition 3 *The unnormalized* q-expectation *of a random variable* X*, with probability density* p*, is*

$$E_q[X] \triangleq \int x\, p(x)^q.$$

Of course, $q=1$ corresponds to the standard notion of expectation. For $q \neq 1$, the q-expectation does not match the intuitive meaning of average/expectation (e.g., $E_q[1] \neq 1$, in general). The q-expectation is a convenient concept in nonextensive information theory; for example, it yields a very compact form for the Tsallis entropy: $S_q(X) = -E_q[\ln_q p(X)]$.

4.1 q-Convexity

We now introduce the novel concept of q-convexity and use it to derive a set of results, namely the *Jensen q-inequality*.

Definition 4 *Let $q \in \mathbb{R}$ and $\mathcal{X}$ be a convex set. A function $f : \mathcal{X} \to \mathbb{R}$ is* q-convex *if for any $x, y \in \mathcal{X}$ and $\lambda \in [0,1]$,*

$$f(\lambda x + (1-\lambda)y) \leq \lambda^q f(x) + (1-\lambda)^q f(y). \tag{21}$$

If $-f$ is q-convex, f is said to be q-concave.

Of course, 1-convexity is the usual notion of convexity. Many properties of 1-convex functions do not have q-analogues. For example, for $q \neq 1$, any q-convex function must be either nonnegative (if $q < 1$) or nonpositive (if $q > 1$); this simple fact can be shown through *reductio ad absurdum* by setting $x = y$ in (21). However, other properties remain: the next proposition states the Jensen q-inequality.

Proposition 5 *If $f : \mathcal{X} \to \mathbb{R}$ is q-convex, then for any $n \in \mathbb{N}$, $x_1, \ldots, x_n \in \mathcal{X}$ and $\pi = (\pi_1, \ldots, \pi_n) \in \Delta^{n-1}$,*

$$f\left(\sum_{i=1}^{n} \pi_i x_i\right) \leq \sum_{i=1}^{n} \pi_i^q f(x_i).$$

Moreover, if f is continuous, the above still holds for countably many points $(x_i)_{i \in \mathbb{N}}$.

Proof In the finite case, the proof can be carried out by induction, as in the proof of the standard Jensen inequality (Cover and Thomas, 1991). Assuming that the inequality holds for $n \in \mathbb{N}$, then, from the definition of q-convexity, it will also hold for $n+1$:

$$\begin{aligned} f\left(\sum_{i=1}^{n+1} \pi_i x_i\right) &= f\left(\sum_{i=1}^{n} \pi_i x_i + \pi_{n+1} x_{n+1}\right) \\ &= f\left((1-\pi_{n+1}) \sum_{i=1}^{n} \pi'_i x_i + \pi_{n+1} x_{n+1}\right) \\ &\leq (1-\pi_{n+1})^q f\left(\sum_{i=1}^{n} \pi'_i x_i\right) + \pi_{n+1}^q f(x_{n+1}) \\ &\leq \sum_{i=1}^{n} \pi_i^q f(x_i) + \pi_{n+1}^q f(x_{n+1}) \;=\; \sum_{i=1}^{n+1} \pi_i^q f(x_i), \end{aligned}$$

where we used the fact that $\pi_{n+1} = 1 - \sum_{i=1}^{n} \pi_i$, and we defined $\pi'_i \triangleq \pi_i/(1-\pi_{n+1})$ (note that $\sum_{i=1}^{n} \pi'_i = 1$.) Furthermore, if f is continuous, it commutes with taking limits, thus

$$f\left(\sum_{i=1}^{\infty}\pi_i x_i\right) = f\left(\lim_{n\to\infty}\sum_{i=1}^{n}\pi_i x_i\right) = \lim_{n\to\infty} f\left(\sum_{i=1}^{n}\pi_i x_i\right) \le \lim_{n\to\infty}\sum_{i=1}^{n}\pi_i^q f(x_i) = \sum_{i=1}^{\infty}\pi_i^q f(x_i).$$

■

Proposition 6 *Let $f \ge 0$ and $q \ge r \ge 0$; then,*

$$f \text{ is } q\text{-convex} \quad \Rightarrow \quad f \text{ is } r\text{-convex} \tag{22}$$

$$f \text{ is } r\text{-concave} \quad \Rightarrow \quad f \text{ is } q\text{-concave}. \tag{23}$$

Proof Implication (22) results from

$$f(\lambda x + (1-\lambda)y) \ \le\ \lambda^q f(x) + (1-\lambda)^q f(y) \ \le\ \lambda^r f(x) + (1-\lambda)^r f(y),$$

where the first inequality states the q-convexity of f and the second one is valid because $f(x), f(y) \ge 0$ and $t^r \ge t^q \ge 0$, for any $t \in [0,1]$ and $q \ge r$. The proof of (23) is similar. ■

4.2 Jensen q-Differences

We now generalize Jensen differences, formalized in Definition 2, by introducing the concept of Jensen q-differences.

Definition 7 *Let $\mu \triangleq (\mu_t)_{t\in\mathcal{T}} \in [M_+(\mathcal{X})]^{\mathcal{T}}$ be a family of finite Radon measures on $\mathcal{X}$, indexed by $\mathcal{T}$, and let $\omega \in M_+(\mathcal{T})$ be a finite Radon measure on $\mathcal{T}$. For $q \ge 0$, define*

$$T^{\omega}_{q,\Psi}(\mu) \ \triangleq\ \Psi\left(\int_{\mathcal{T}} \omega(t)\,\mu_t\, d\tau(t)\right) - \int_{\mathcal{T}} \omega(t)^q\, \Psi(\mu_t)\, d\tau(t), \tag{24}$$

where:

(i) *Ψ is a concave functional such that* $\mathrm{dom}\,\Psi \subseteq M_+(\mathcal{X})$*;*

(ii) *$\omega(t)\mu_t(x)$ is τ-integrable for all $x \in \mathcal{X}$;*

(iii) *$\int_{\mathcal{T}} \omega(t)\mu_t\, d\tau(t) \in \mathrm{dom}\,\Psi$;*

(iv) *$\mu_t \in \mathrm{dom}\,\Psi$, for all $t \in \mathcal{T}$;*

(v) *$\omega(t)^q\, \Psi(\mu_t)$ is τ-integrable.*

If $\omega \in M^1_+(\mathcal{T})$, we call the function defined in (24) *a* Jensen q-difference.

Burbea and Rao (1982) established necessary and sufficient conditions on φ for the Jensen difference of a φ-entropy (see Equation 14) to be convex. The following proposition generalizes that result, extending it to Jensen q-differences.

Proposition 8 *Let $\mathcal{T}$ and $\mathcal{X}$ be finite sets, with $|\mathcal{T}| = m$ and $|\mathcal{X}| = n$, and let $\pi \in M^1_+(\mathcal{T})$. Let $\varphi : [0,1] \to \mathbb{R}$ be a function of class C^2 and consider the (φ-entropy, Burbea and Rao, 1982) function $\Psi : [0,1]^n \to \mathbb{R}$ defined as $\Psi(z) \triangleq -\sum_{i=1}^{n}\varphi(z_i)$. Then, the q-difference $T^{\pi}_{q,\Psi} : [0,1]^{nm} \to \mathbb{R}$ is convex if and only if φ is convex and $-1/\varphi''$ is $(2-q)$-convex.*

The proof is rather long, thus it is relegated to Appendix B.

5. The Jensen-Tsallis q-Difference

This section introduces the Jensen-Tsallis q-difference, a nonextensive generalization of the Jensen-Shannon divergence. After deriving some properties concerning the convexity and extrema of these functionals, we introduce the notion of joint and conditional Jensen-Tsallis q-difference, a contrast measure between stochastic processes. We end the section with a brief asymptotic analysis for the extensive case.

5.1 Definition

As in Section 3.2, let p be a random probability distribution taking values in $\{p_t\}_{t\in\mathcal{T}}$ according to a distribution $\pi \in M_+^1(\mathcal{T})$. Then, we may write

$$T^{\pi}_{q,\Psi}(p) = \Psi(E[p]) - E_q[\Psi(p)],$$

where the expectations are with respect to π. Hence Jensen q-differences may be seen as deformations of the standard Jensen differences (16), in which the second expectation is replaced by a q-expectation.

Let $\Psi = S_q$, the nonextensive Tsallis q-entropy. Introducing the random variables T and X, with values respectively in $\mathcal{T}$ and $\mathcal{X}$, with densities $\pi(t)$ and $p(x) \triangleq \int_{\mathcal{T}} p(x|t)\pi(t)$, we have (writing T^{π}_{q,S_q} simply as T^{π}_q)

$$\begin{aligned} T^{\pi}_q(p) &= S_q(E[p]) - E_q[S_q(p)] \\ &= S_q(X) - \int_{\mathcal{T}} \pi(t)^q S_q(X|T=t) \\ &= S_q(X) - S_q(X|T) \\ &= I_q(X;T), \end{aligned} \tag{25}$$

where $S_q(X|T)$ is the Tsallis conditional entropy (4), and $I_q(X;T)$ is the Tsallis mutual information (6), as defined by Furuichi (2006). Observe that (25) is a nonextensive analogue of (17). Since, in general, $I_q \neq \tilde{I}_q$ (see Equation 7), unless $q=1$ (in that case, $I_1 = \tilde{I}_1 = I$), there is no counterpart of (18) in terms of q-differences. Nevertheless, Lamberti and Majtey (2003) have proposed a non-logarithmic version of the JS divergence, which corresponds to using $\tilde{I}_q$ for the Tsallis mutual q-entropy (although this interpretation is not explicitly mentioned).

When $\mathcal{X}$ and $\mathcal{T}$ are finite with $|\mathcal{T}| = m$, we call the quantity $T^{\pi}_q(p_1,\ldots,p_m)$ the *Jensen-Tsallis (JT) q-difference* of $p_1,\ldots,p_m$ with weights $\pi_1,\ldots,\pi_m$. Although the JT q-difference is a generalization of the JS divergence, for $q \neq 1$, the term "divergence" would be misleading in this case, since T^{π}_q may take negative values (if $q<1$) and does not vanish in general if p is deterministic.

When $|\mathcal{T}| = 2$ and $\pi = (1/2, 1/2)$, define $T_q \triangleq T_q^{1/2,1/2}$,

$$T_q(p_1,p_2) = S_q\left(\frac{p_1+p_2}{2}\right) - \frac{S_q(p_1)+S_q(p_2)}{2^q}.$$

Notable cases arise for particular values of q:

- For $q=0$, $S_0(p) = -1 + \nu(\mathrm{supp}(p))$, where $\nu(\mathrm{supp}(p))$ denotes the measure of the support of p (recall that p is defined on the measure space $(\mathcal{X},\mathscr{M},\nu)$). For example, if $\mathcal{X}$ is finite and

ν is the counting measure, $\nu(\mathrm{supp}(p)) = \|p\|_0$ is the so-called *0-norm* (although it is not a norm) of vector p, that is, its number of nonzero components. The Jensen-Tsallis 0-difference is thus

$$\begin{aligned} T_0(p_1,p_2) &= -1+\nu\left(\mathrm{supp}\left(\frac{p_1+p_2}{2}\right)\right)+1-\nu(\mathrm{supp}(p_1))+1-\nu(\mathrm{supp}(p_2)) \\ &= 1+\nu(\mathrm{supp}(p_1)\cup\mathrm{supp}(p_2))-\nu(\mathrm{supp}(p_1))-\nu(\mathrm{supp}(p_2)) \\ &= 1-\nu(\mathrm{supp}(p_1)\cap\mathrm{supp}(p_2)); \qquad (26) \end{aligned}$$

if $\mathcal{X}$ is finite and ν is the counting measure, this becomes

$$T_0(p_1,p_2) = 1 - \|p_1 \odot p_2\|_0,$$

where $\odot$ denotes the Hadamard-Schur (i.e., elementwise) product. We call T_0 the *Boolean difference*.

- For $q = 1$, since $S_1(p) = H(p)$, T_1 is the JS divergence,

$$T_1(p_1,p_2) = JS(p_1,p_2).$$

- For $q = 2$, $S_2(p) = 1 - \langle p,p\rangle$, where $\langle a,b\rangle = \int_{\mathcal{X}} a(x)\,b(x)\,d\nu(x)$ is the inner product between a and b (which reduces to $\langle a,b\rangle = \sum_i a_i b_i$ if $\mathcal{X}$ is finite and ν is the counting measure). Consequently, the Tsallis 2-difference is

$$T_2(p_1,p_2) = \frac{1}{2} - \frac{1}{2}\langle p_1,p_2\rangle,$$

which we call the *linear difference*.

5.2 Properties of the JT q-Difference

This subsection presents results regarding convexity and extrema of the JT q-difference, for certain values of q, extending known properties of the JS divergence ($q = 1$). Some properties of the JS divergence are lost in the transition to nonextensivity; for example, while the former is nonnegative and vanishes if and only if all the distributions are identical, this is not true in general with the JT q-difference. Nonnegativity of the JT q-difference is only guaranteed if $q \geq 1$, which explains why some authors (e.g., Furuichi 2006) only consider values of $q \geq 1$, when looking for nonextensive analogues of Shannon's information theory. Moreover, unless $q = 1$, it is not generally true that $T_q^{\pi}(p,\ldots,p) = 0$ or even that $T_q^{\pi}(p,\ldots,p,p') \geq T_q^{\pi}(p,\ldots,p,p)$. For example, the solution of the optimization problem

$$\min_{p_1\in\Delta^n} T_q(p_1,p_2), \qquad (27)$$

is, in general, different from p_2, unless $q = 1$. Instead, this minimizer is closer to the uniform distribution if $q \in [0,1)$, and closer to a degenerate distribution for $q \in (1,2]$ (see Fig. 1). This is not so surprising: recall that $T_2(p_1,p_2) = \frac{1}{2} - \frac{1}{2}\langle p_1,p_2\rangle$; in this case, (27) becomes a linear program, and the solution is not $p_1^* = p_2$, but $p_1^* = \delta_j$, where $j = \arg\max_i p_{2i}$.

At this point, we should also remark that, when $\mathcal{X}$ is a finite set, the uniform distribution maximizes the Tsallis entropy for any $q \geq 0$, which is in fact one of the Suyari axioms underlying the Tsallis entropy (see Axiom A2 in Appendix A).

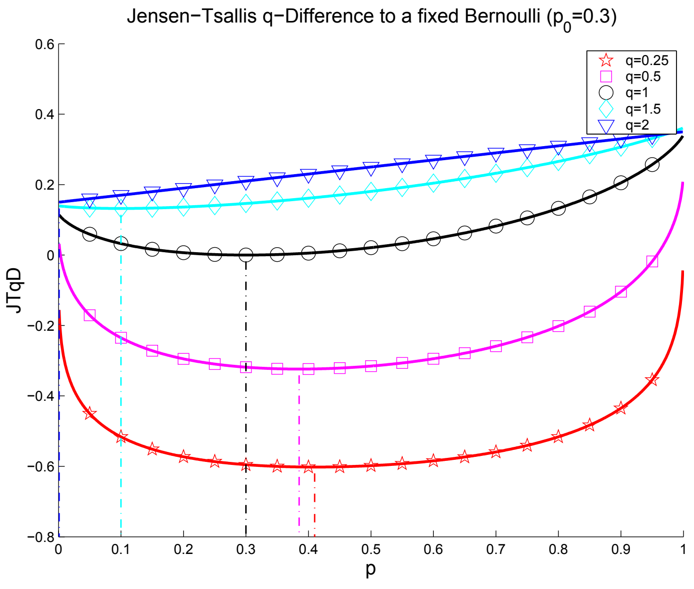

Figure 1: Jensen-Tsallis q-difference between two Bernoulli distributions, $p_1 = (0.3, 0.7)$ and $p_2 = (p, 1-p)$, for several values of the entropic index q. Observe that, for $q \in [0,1)$, the minimizer of the JT q-difference approaches the uniform distribution $(0.5, 0.5)$ as q approaches 0; for $q \in (1,2]$, this minimizer approaches the degenerate distribution, as $q \to 2$.

We start with the following corollary of Proposition 8, which establishes the joint convexity of the JT q-difference, for $q \in [0,1]$. (Interestingly, this "complements" the joint convexity of the JT divergence (20), for $q \in [1,2]$, proved by Burbea and Rao 1982.)

Corollary 9 *Let $\mathcal{T}$ and $\mathcal{X}$ be finite sets with cardinalities m and n, respectively. For $q \in [0,1]$, the JT q-difference is a jointly convex function on $M_+^{1,S_q}(\mathcal{X})$. Formally, let $\{p_t^{(i)}\}_{t\in\mathcal{T}}$, and $i = 1,\ldots,l$, be a collection of l sets of probability distributions on $\mathcal{X}$; then, for any $(\lambda_1,\ldots,\lambda_l) \in \Delta^{l-1}$,*

$$T_q^\pi\left(\sum_{i=1}^l \lambda_i p_1^{(i)}, \ldots, \sum_{i=1}^l \lambda_i p_m^{(i)}\right) \le \sum_{i=1}^l \lambda_i T_q^\pi(p_1^{(i)}, \ldots, p_m^{(i)}).$$

Proof Observe that the Tsallis entropy (3) of a probability distribution $p_t = \{p_{t1}, ..., p_{tn}\}$ can be written as

$$S_q(p_t) = -\sum_{i=1}^n \varphi(p_{ti}), \quad \text{where} \quad \varphi_q(x) = \frac{x - x^q}{1-q};$$

thus, from Proposition 8, T_q^π is convex if and only if φ_q is convex and $-1/\varphi_q''$ is $(2-q)$-convex. Since $\varphi_q''(x) = q x^{q-2}$, φ_q is convex for $x \ge 0$ and $q \ge 0$. To show the $(2-q)$-convexity of $-1/\varphi_q''(x) = -(1/q)x^{2-q}$, for $x_t \ge 0$, and $q \in [0,1]$, we use a version of the power mean inequality (Steele, 2006),

$$-\left(\sum_{i=1}^l \lambda_i x_i\right)^{2-q} \le -\sum_{i=1}^l (\lambda_i x_i)^{2-q} = -\sum_{i=1}^l \lambda_i^{2-q} x_i^{2-q},$$

thus concluding that $-1/\varphi_q''$ is in fact $(2-q)$-convex. ■

A consequence of Corollary 9 is that, for finite $\mathcal{X}$ and any $q \in [0,1]$, the JT q-difference is upper bounded, namely $T_q^\pi(p_1,\ldots,p_m) \leq S_q(\pi)$. Indeed, since T_q^π is convex and its domain is the Cartesian product of m simplices (a convex polytope), its maximum must occur on a vertex, that is, when each argument p_t is a degenerate distribution at x_t, denoted δ_{x_t}. In particular, if $|\mathcal{X}| \geq |\mathcal{T}|$, this maximum occurs at a vertex corresponding to disjoint degenerate distributions, that is, such that $x_i \neq x_j$ if $i \neq j$. At this maximum,

$$\begin{aligned} T_q^\pi(\delta_{x_1},\ldots,\delta_{x_m}) &= S_q\left(\sum_{t=1}^m \pi_t \delta_{x_t}\right) - \sum_{t=1}^m \pi_t S_q(\delta_{x_t}) \\ &= S_q\left(\sum_{t=1}^m \pi_t \delta_{x_t}\right) \qquad (28) \\ &= S_q(\pi) \end{aligned}$$

where the equality in (28) results from $S_q(\delta_{x_t}) = 0$. (Notice that this maximum may not be achieved if $|\mathcal{X}| < |\mathcal{T}|$.) The next proposition provides a stronger result: it establishes upper and lower bounds for the JT q-difference to any non-negative q and to countable $\mathcal{X}$ and $\mathcal{T}$.

Proposition 10 *Let $\mathcal{T}$ and $\mathcal{X}$ be countable sets. For $q \geq 0$,*

$$T_q^\pi((p_t)_{t\in\mathcal{T}}) \leq S_q(\pi), \qquad (29)$$

and, if $|\mathcal{X}| \geq |\mathcal{T}|$, the maximum of T_q^π is reached for a set of disjoint degenerate distributions. This maximum may not be attained if $|\mathcal{X}| < |\mathcal{T}|$.

For $q \geq 1$,

$$T_q^\pi((p_t)_{t\in\mathcal{T}}) \geq 0,$$

and the minimum of T_q^π is attained in the purely deterministic case, that is, when all distributions are equal to the same degenerate distribution.

For $q \in [0,1]$ and $\mathcal{X}$ a finite set with $|\mathcal{X}| = n$,

$$T_q^\pi((p_t)_{t\in\mathcal{T}}) \geq S_q(\pi)[1-n^{1-q}]. \qquad (30)$$

This lower bound (which is zero or negative) is attained when all distributions are uniform.

Proof The proof is given in Appendix C. ■

Finally, the next proposition characterizes the convexity/concavity of the JT q-difference on each argument.

Proposition 11 *Let $\mathcal{T}$ and $\mathcal{X}$ be countable sets. The JT q-difference is convex in each argument, for $q \in [0,2]$, and concave in each argument, for $q \geq 2$.*

Proof Notice that the JT q-difference can be written as $T_q^\pi(p_1,\ldots,p_m) = \sum_j \psi(p_{1j},\ldots,p_{mj})$, with

$$\psi(y_1,\ldots,y_m) = \frac{1}{q-1}\left[\sum_i (\pi_i - \pi_i^q)y_i + \sum_i \pi_i^q y_i^q - \left(\sum_i \pi_i y_i\right)^q\right].$$

It suffices to consider the second derivative of ψ with respect to y_1. Introducing $z = \sum_{i=2}^m \pi_i y_i$,

$$\begin{aligned}\frac{\partial^2\psi}{\partial y_1^2} &= q\left[\pi_1^q y_1^{q-2} - \pi_1^2(\pi_1 y_1 + z)^{q-2}\right] \\ &= q\pi_1^2\left[(\pi_1 y_1)^{q-2} - (\pi_1 y_1 + z)^{q-2}\right]. \qquad (31)\end{aligned}$$

Since $\pi_1 y_1 \le (\pi_1 y_1 + z) \le 1$, the quantity in (31) is nonnegative for $q \in [0,2]$ and non-positive for $q \ge 2$. ■

5.3 Joint and Conditional JT q-Differences and a Chain Rule

This subsection introduces joint and conditional JT q-differences, which will later be used as a contrast measure between stochastic processes. A chain rule is derived that relates conditional and joint JT q-differences.

Definition 12 *Let $\mathcal{X}$, $\mathcal{Y}$ and $\mathcal{T}$ be measure spaces. Let $(p_t)_{t\in\mathcal{T}} \in [M_+^1(\mathcal{X}\times\mathcal{Y})]^{\mathcal{T}}$ be a family of measures in $M_+^1(\mathcal{X}\times\mathcal{Y})$ indexed by $\mathcal{T}$, and let p be a random probability distribution taking values in $\{p_t\}_{t\in\mathcal{T}}$ according to a distribution $\pi \in M_+^1(\mathcal{T})$. Consider also:*

- *for each $t\in\mathcal{T}$, the marginals $p_t(Y) \in M_+^1(\mathcal{Y})$,*
- *for each $t\in\mathcal{T}$ and $y\in\mathcal{Y}$, the conditionals $p_t(X|Y=y) \in M_+^1(\mathcal{X})$,*
- *the mixture $r(X,Y) \triangleq \int_{\mathcal{T}} \pi(t)\, p_t(X,Y) \in M_+^1(\mathcal{X}\times\mathcal{Y})$,*
- *the marginal $r(Y) \in M_+^1(\mathcal{Y})$,*
- *for each $y\in\mathcal{Y}$, the conditionals $r(X|Y=y) \in M_+^1(\mathcal{X})$.*

For notational convenience, we also append a subscript to p to emphasize its joint or conditional dependency of the random variables X and Y, that is, $p_{XY} \triangleq p$, and $p_{X|Y}$ denotes a random conditional probability distribution taking values in $\{p_t(.|Y)\}_{t\in\mathcal{T}}$ according to the distribution π.

For $q \ge 0$, we refer to the joint JT q-difference *of p_{XY} by*

$$T_q^\pi(p_{XY}) \triangleq T_q^\pi(p) = S_q(r) - E_{q,T\sim\pi(T)}[S_q(p_t)]$$

and to the conditional JT q-difference *of $p_{X|Y}$ by*

$$T_q^\pi(p_{X|Y}) \triangleq E_{q,Y\sim r(Y)}[S_q(r(.|Y=y))] - E_{q,T\sim\pi(T)}\left[E_{q,Y\sim p_t(Y)}[S_q(p_t(.|Y=y))]\right], \qquad (32)$$

where we appended the random variables being used in each q-expectation, for the sake of clarity.

Note that the joint JT q-difference is just the usual JT q-difference of the joint random variable $X \times Y$, which equals (cf. 25)

$$T_q^\pi(p_{XY}) \;=\; S_q(X,Y) - S_q(X,Y|T) \;=\; I_q(X \times Y; T), \tag{33}$$

and the conditional JT q-difference is simply the usual JT q-difference with all entropies replaced by conditional entropies (conditioned on Y). Indeed, expression (32) can be rewritten as:

$$T_q^\pi(p_{X|Y}) \;=\; S_q(X|Y) - S_q(X|T,Y) \;=\; I_q(X;T \mid Y), \tag{34}$$

that is, the conditional JT q-difference may also interpreted as a Tsallis mutual information, as in (25), but now *conditioned* on the random variable Y.

Note also that, for the extensive case $q = 1$, (32) may also be rewritten in terms of the conditional KL divergences,

$$\begin{aligned} J^\pi(p_{X|Y}) \triangleq T_1^\pi(p_{X|Y}) \;&=\; E_{Y\sim r(Y)}\left[H(r(.|Y=y))\right] - E_{T\sim\pi(T)}\left[E_{Y\sim p_t(Y)}\left[H(p_t(.|Y=y))\right]\right] \\ &=\; E_{T\sim\pi(T)}\left[E_{Y\sim r(Y)}\left[D(p_t(.|Y=y)\|r(.|Y=y))\right]\right]. \end{aligned}$$

Proposition 13 *The following chain rule holds:*

$$T_q^\pi(p_{XY}) = T_q^\pi(p_{X|Y}) + T_q^\pi(p_Y)$$

Proof Writing the joint/conditional JT q-differences as joint/conditional mutual informations (33–34) and invoking the chain rule provided by (4), we have that

$$\begin{aligned} I_q(X;T|Y) + I_q(Y;T) \;&=\; S_q(X|T,Y) - S_q(X|Y) + S_q(Y|T) - S_q(Y) \\ &=\; S_q(X,Y|T) - S_q(X,Y), \end{aligned}$$

which is the joint JT q-difference associated with the random variable $X \times Y$. ■

Let us now turn our attention to the case where $Y = X^k$ for some $k \in \mathbb{N}$. In the following, the notation $(A_n)_{n\in\mathbb{N}}$ denotes a stationary ergodic process with values on some finite alphabet $\mathcal{A}$.

Definition 14 *Let $\mathcal{X}$ and $\mathcal{T}$ be measure spaces, with $\mathcal{X}$ finite, and let $\mathscr{F} = [(X_n)_{n\in\mathbb{N}}]^{\mathcal{T}}$ be a family of stochastic processes (taking values on the alphabet $\mathcal{X}$) indexed by $\mathcal{T}$. The k-*th order JT q-difference *of $\mathscr{F}$ is defined, for $k = 1,\ldots,n$, as*

$$T_{q,k}^{\text{joint},\pi}(\mathscr{F}) \triangleq T_q^\pi(p_{X^k})$$

*and the k-*th order conditional JT q-difference *of $\mathscr{F}$ is defined, for $k = 1,\ldots,n$, as*

$$T_{q,k}^{\text{cond},\pi}(\mathscr{F}) \triangleq T_q^\pi(p_{X|X^k}),$$

and, for $k = 0$, as $T_{q,0}^{\text{cond},\pi}(\mathscr{F}) \triangleq T_{q,1}^{\text{joint},\pi}(\mathscr{F}) = T_q^\pi(p_X)$.

Proposition 15 *The joint and conditional k-th order JT q-differences are related through:*

$$T_{q,k}^{\text{joint},\pi}(\mathscr{F}) = \sum_{i=0}^{k-1} T_{q,i}^{\text{cond},\pi}(\mathscr{F}) \tag{35}$$

Proof Use Proposition 13 and induction. ■

5.4 Asymptotic Analysis in the Extensive Case

We now focus on the extensive case ($q = 1$) for a brief asymptotic analysis of the k-th order joint and conditional JT 1-differences (or *conditional Jensen-Shannon divergences*) when k goes to infinity.

The conditional Jensen-Shannon divergence was introduced by El-Yaniv et al. (1998) to address the *two-sample problem* for strings emitted by Markovian sources. Given two strings s and t, the goal is to decide whether they were emitted by the same source or by different sources. Under some fair assumptions, the most likely k-th order Markovian joint source of s and t is governed by a distribution $\hat{r}$ given by

$$\hat{r} = \arg\min_{r} \lambda D(\hat{p}_s \| r) + (1-\lambda) D(\hat{p}_t \| r). \tag{36}$$

where $D(.\|.)$ are conditional KL divergences, $\hat{p}_s$ and $\hat{p}_t$ are the empirical $(k-1)$-th order conditionals associated with s and t, respectively, and $\lambda = |s|/(|s|+|t|)$ is the length ratio. The solution of the optimization problem is

$$\hat{r}(a|c) = \frac{\lambda \hat{p}_s(c)}{\lambda \hat{p}_s(c) + (1-\lambda)\hat{p}_t(c)}\, \hat{p}_s(a|c) + \frac{(1-\lambda)\hat{p}_t(c)}{\lambda \hat{p}_s(c) + (1-\lambda)\hat{p}_t(c)}\, \hat{p}_t(a|c),$$

where $a \in \mathcal{A}$ is a symbol and $c \in \mathcal{A}^{k-1}$ is a context; this can be rewritten as $\hat{r}(a,c) = \lambda \hat{p}_s(a,c) + (1-\lambda)\hat{p}_t(a,c)$; that is, the optimum in (36) is a mixture of $\hat{p}_s$ and $\hat{p}_t$ weighted by the string lengths. Notice that, at the minimum, we have

$$\lambda D(\hat{p}_s \| \hat{r}) + (1-\lambda) D(\hat{p}_t \| \hat{r}) = JS_k^{\text{cond},(\lambda,1-\lambda)}(\hat{p}_s, \hat{p}_t).$$

It is tempting to investigate the asymptotic behavior of the conditional and joint JS divergences when $k \to \infty$; however, unlike other asymptotic information theoretic quantities, like the entropy or cross entropy rates, this behavior fails to characterize the sources s and t. Intuitively, this is justified by the fact that observing more and more symbols drawn from the mixture of the two sources rapidly decreases the uncertainty about which source generated the sample. Indeed, from the asymptotic equipartition property of stationary ergodic sources (Cover and Thomas, 1991), we have that $\lim_{k\to\infty} \frac{1}{k} H(p_{X_k}) = \lim_{k\to\infty} H(p_{X|X_k})$, which implies

$$\lim_{k\to\infty} JS_k^{\text{cond},\pi} \;=\; \lim_{k\to\infty} \frac{1}{k} JS_k^{\text{joint},\pi} \;\leq\; \lim_{k\to\infty} \frac{1}{k} H(\pi) \;=\; 0,$$

where we used the fact that the JS divergence is upper-bounded by the entropy of the mixture $H(\pi)$ (see Proposition 10). Since the conditional JS divergence must be non-negative, we therefore conclude that $\lim_{k\to\infty} JS_k^{\text{cond},\pi} = 0$, pointwise.

6. Nonextensive Mutual Information Kernels

In this section we consider the application of extensive and nonextensive entropies to define kernels on measures; since kernels involve pairs of measures, throughout this section $|\mathcal{T}| = 2$. Based on the denormalization formulae presented in Section 2.3, we devise novel kernels related to the JS divergence and the JT q-difference; these kernels allow setting a weight for each argument, thus will be called *weighted Jensen-Tsallis kernels*. We also introduce kernels related to the JR divergence (Section 3.3) and the JT divergence (Section 3.4), and establish a connection between the Tsallis kernels and a family of kernels investigated by Hein et al. (2004) and Fuglede (2005), placing those kernels under a new information-theoretic light. After that, we give a brief overview of string kernels, and using the results of Section 5.3, we devise k-th order Jensen-Tsallis kernels between stochastic processes that subsume the well-known p-spectrum kernel of Leslie et al. (2002).

6.1 Positive and Negative Definite Kernels

We start by recalling basic concepts from kernel theory (Schölkopf and Smola, 2002); in the following, $\mathcal{X}$ denotes a nonempty set.

Definition 16 *Let $\varphi : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$ be a symmetric function, that is, a function satisfying $\varphi(y,x) = \varphi(x,y)$, for all $x, y \in \mathcal{X}$. φ is called a* positive definite *(pd) kernel if and only if*

$$\sum_{i=1}^{n} \sum_{j=1}^{n} c_i c_j \varphi(x_i, x_j) \geq 0$$

for all $n \in \mathbb{N}$, $x_1, \ldots, x_n \in \mathcal{X}$ and $c_1, \ldots, c_n \in \mathbb{R}$.

Definition 17 *Let $\psi : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$ be symmetric. ψ is called a* negative definite *(nd) kernel if and only if*

$$\sum_{i=1}^{n} \sum_{j=1}^{n} c_i c_j \psi(x_i, x_j) \leq 0$$

for all $n \in \mathbb{N}$, $x_1, \ldots, x_n \in \mathcal{X}$ and $c_1, \ldots, c_n \in \mathbb{R}$, satisfying the additional constraint $c_1 + \ldots + c_n = 0$. In this case, $-\psi$ is called conditionally *pd; obviously, positive definiteness implies conditional positive definiteness.*

The sets of pd and nd kernels are both closed under pointwise sums/integrations, the former being also closed under pointwise products; moreover, both sets are closed under pointwise convergence. While pd kernels "correspond" to inner products via embedding in a Hilbert space, nd kernels that vanish on the diagonal and are positive anywhere else, "correspond" to squared Hilbertian distances. These facts, and the following propositions and lemmas, are shown in Berg et al. (1984).

Proposition 18 *Let $\psi : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$ be a symmetric function, and $x_0 \in \mathcal{X}$. Let $\varphi : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$ be given by*

$$\varphi(x,y) = \psi(x, x_0) + \psi(y, x_0) - \psi(x,y) - \psi(x_0, x_0).$$

Then, φ is pd if and only if ψ is nd.

Proposition 19 *The function $\psi : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$ is a nd kernel if and only if $\exp(-t\psi)$ is pd for all $t > 0$.*

Proposition 20 *The function $\psi : \mathcal{X} \times \mathcal{X} \to \mathbb{R}_+$ is a nd kernel if and only if $(t + \psi)^{-1}$ is pd for all $t > 0$.*

Lemma 21 *If ψ is nd and nonnegative on the diagonal, that is, $\psi(x,x) \geq 0$ for all $x \in \mathcal{X}$, then ψ^α, for $\alpha \in [0,1]$, and $\ln(1 + \psi)$, are also nd.*

Lemma 22 *If $f : \mathcal{X} \to \mathbb{R}$ satisfies $f \geq 0$, then, for $\alpha \in [1,2]$, the function $\psi_\alpha(x,y) = -(f(x)+f(y))^\alpha$ is a nd kernel.*

The following definition (Berg et al., 1984) has been used in a machine learning context by Cuturi and Vert (2005).

Definition 23 *Let $(\mathcal{X}, \oplus)$ be a semigroup.*[2] *A function $\varphi : \mathcal{X} \to \mathbb{R}$ is called pd (in the semigroup sense) if $k : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$, defined as $k(x,y) = \varphi(x \oplus y)$, is a pd kernel. Likewise, φ is called nd if k is a nd kernel. Accordingly, these are called* semigroup kernels.

6.2 Jensen-Shannon and Tsallis Kernels

The basic result that allows deriving pd kernels based on the JS divergence and, more generally, on the JT q-difference, is the fact that the denormalized Tsallis q-entropies (10) are nd functions on $(M_+^{S_q}(\mathcal{X}), +)$, for $q \in [0,2]$. Of course, this includes the denormalized Shannon-Boltzmann-Gibbs entropy (8) as a particular case, corresponding to $q = 1$. Although part of the proof was given by Berg et al. (1984) (and by Topsøe 2000 and Cuturi and Vert 2005 for the Shannon entropy case), we present a complete proof here.

Proposition 24 *For $q \in [0,2]$, the denormalized Tsallis q-entropy S_q is a nd function on $(M_+^{S_q}(\mathcal{X}), +)$.*

Proof Since nd kernels are closed under pointwise integration, it suffices to prove that φ_q (see Equation 11) is nd on $(\mathbb{R}_+, +)$. For $q \neq 1$, $\varphi_q(y) = (q-1)^{-1}(y - y^q)$. Let us consider two cases separately: if $q \in [0,1)$, $\varphi_q(y)$ equals a positive constant times $-\iota + \iota^q$, where $\iota(y) = y$ is the identity map defined on $\mathbb{R}_+$. Since the set of nd functions is closed under sums, we only need to show that both $-\iota$ and ι^q are nd. Both ι and $-\iota$ are nd, as can easily be seen from the definition; besides, since ι is nd and nonnegative, Lemma 21 guarantees that ι^q is also nd. For the second case, where $q \in (1,2]$, $\varphi_q(y)$ equals a positive constant times $\iota - \iota^q$. It only remains to show that $-\iota^q$ is nd for $q \in (1,2]$: Lemma 22 guarantees that the kernel $k(x,y) = -(x+y)^q$ is nd; therefore $-\iota^q$ is a nd function.

For $q = 1$, we use the fact that,

$$\varphi_1(x) = \varphi_H(x) = -x \ln x = \lim_{q \to 1} \frac{x - x^q}{q-1} = \lim_{q \to 1} \varphi_q(x),$$

where the limit is obtained by L'Hôpital's rule; since the set of nd functions is closed under limits, $\varphi_1(x)$ is nd. ■

The following lemma, proved in Berg et al. (1984), will also be needed below.

Lemma 25 *The function $\zeta_q : \mathbb{R}_{++} \to \mathbb{R}$, defined as $\zeta_q(y) = y^{-q}$ is pd, for $q \in [0,1]$.*

We are now in a position to present the main contribution of this section, which is a family of *weighted Jensen-Tsallis kernels*, generalizing the JS-based (and other) kernels in two ways: (i) they allow using unnormalized measures; equivalently, they allow using different weights for each of the two arguments; (ii) they extend the mutual information feature of the JS kernel to the nonextensive scenario.

2. Recall that $(\mathcal{X}, \oplus)$ is a *semigroup* if $\oplus$ is a binary operation in $\mathcal{X}$ that is associative and has an identity element.

Definition 26 (weighted Jensen-Tsallis kernels) *The kernel* $\widetilde{k}_q : M_+^{S_q}(\mathcal{X}) \times M_+^{S_q}(\mathcal{X}) \to \mathbb{R}$ *is defined as*

$$\begin{aligned} \widetilde{k}_q(\mu_1,\mu_2) &\triangleq \widetilde{k}_q(\omega_1 p_1, \omega_2 p_2) \\ &= \left(S_q(\pi) - T_q^{\pi}(p_1,p_2)\right)(\omega_1+\omega_2)^q, \end{aligned}$$

where $p_1 = \mu_1/\omega_1$ *and* $p_2 = \mu_2/\omega_2$ *are the normalized counterparts of* μ_1 *and* μ_2*, with corresponding masses* $\omega_1, \omega_2 \in \mathbb{R}_+$*, and* $\pi = (\omega_1/(\omega_1+\omega_2), \omega_2/(\omega_1+\omega_2))$.

The kernel $k_q : \left(M_+^{S_q}(\mathcal{X}) \setminus \{0\}\right)^2 \to \mathbb{R}$ *is defined as*

$$k_q(\mu_1,\mu_2) \triangleq k_q(\omega_1 p_1, \omega_2 p_2) = S_q(\pi) - T_q^{\pi}(p_1,p_2).$$

Recalling (25), notice that $S_q(\pi) - T_q^{\pi}(p_1,p_2) = S_q(T) - I_q(X;T) = S_q(T|X)$ can be interpreted as the *Tsallis posterior conditional entropy*. Hence, k_q can be seen (in Bayesian classification terms) as a nonextensive expected measure of uncertainty in correctly identifying the class, given the prior $\pi = (\pi_1, \pi_2)$, and a sample from the mixture $\pi_1 p_1 + \pi_2 p_2$. The more similar the two distributions are, the greater this uncertainty.

Proposition 27 *The kernel* $\widetilde{k}_q$ *is pd, for* $q \in [0,2]$*. The kernel* k_q *is pd, for* $q \in [0,1]$.

Proof With $\mu_1 = \omega_1 p_1$ and $\mu_2 = \omega_2 p_2$ and using the denormalization formula of Remark 1, we obtain $\widetilde{k}_q(\mu_1,\mu_2) = -S_q(\mu_1+\mu_2) + S_q(\mu_1) + S_q(\mu_2)$. Now invoke Proposition 18 with $\psi = S_q$ (which is nd by Proposition 24), $x = \mu_1$, $y = \mu_2$, and $x_0 = 0$ (the null measure). Observe now that $k_q(\mu_1,\mu_2) = \widetilde{k}_q(\mu_1,\mu_2)(\omega_1+\omega_2)^{-q}$. Since the product of two pd kernels is a pd kernel and (Proposition 25) $(\omega_1+\omega_2)^{-q}$ is a pd kernel, for $q \in [0,1]$, we conclude that k_q is pd. ■

As we can see, the weighted Jensen-Tsallis kernels have two inherent properties: they are parameterized by the entropic index q and they allow their arguments to be unbalanced, that is, to have different weights ω_i. We now mention some instances of kernels where each of these degrees of freedom is suppressed. We start with the following subfamily of kernels, obtained by setting $q = 1$.

Definition 28 (weighted Jensen-Shannon kernels) *The kernel* $\widetilde{k}_{WJS} : (M_+^H(\mathcal{X}))^2 \to \mathbb{R}$ *is defined as* $\widetilde{k}_{WJS} \triangleq \widetilde{k}_1$*, that is,*

$$\begin{aligned} \widetilde{k}_{WJS}(\mu_1,\mu_2) &= \widetilde{k}_{WJS}(\omega_1 p_1, \omega_2 p_2) \\ &= \left(H(\pi) - J^{\pi}(p_1,p_2)\right)(\omega_1+\omega_2), \end{aligned}$$

where $p_1 = \mu_1/\omega_1$ *and* $p_2 = \mu_2/\omega_2$ *are the normalized counterpart of* μ_1 *and* μ_2*, and* $\pi = (\omega_1/(\omega_1+\omega_2), \omega_2/(\omega_1+\omega_2))$.

Analogously, the kernel $k_{WJS} : \left(M_+^H(\mathcal{X}) \setminus \{0\}\right)^2 \to \mathbb{R}$ *is simply* $k_{WJS} \triangleq k_1$*, that is,*

$$k_{WJS}(\mu_1,\mu_2) = k_{WJS}(\omega_1 p_1, \omega_2 p_2) = H(\pi) - J^{\pi}(p_1,p_2).$$

Corollary 29 *The weighted Jensen-Shannon kernels* $\widetilde{k}_{WJS}$ *and* k_{WJS} *are pd.*

Proof Invoke Proposition 27 with $q = 1$. ■

The following family of *weighted exponentiated JS kernels*, generalize the so-called *exponentiated JS* kernel, that has been used, and shown to be pd, by Cuturi and Vert (2005).

Definition 30 (Exponentiated JS kernel) *The kernel $k_{EJS} : M_+^1(\mathcal{X}) \times M_+^1(\mathcal{X}) \to \mathbb{R}$ is defined, for $t > 0$, as*

$$k_{EJS}(p_1, p_2) = \exp\left[-t\, JS(p_1, p_2)\right].$$

Definition 31 (Weighted exponentiated JS kernels) *The kernel $k_{WEJS} : M_+^H(\mathcal{X}) \times M_+^H(\mathcal{X}) \to \mathbb{R}$ is defined, for $t > 0$, as*

$$\begin{aligned} k_{WEJS}(\mu_1, \mu_2) &= \exp[t\, k_{WJS}(\mu_1, \mu_2)] \\ &= \exp(t\, H(\pi)) \exp\left[-tJ^\pi(p_1, p_2)\right]. \end{aligned} \tag{37}$$

Corollary 32 *The kernels k_{WEJS} are pd. In particular, k_{EJS} is pd.*

Proof Results from Proposition 19 and Corollary 29. Notice that although k_{WEJS} is pd, none of its two exponential factors in (37) is pd. ■

We now keep $q \in [0, 2]$ but consider the weighted JT kernel family restricted to normalized measures, $k_q|_{(M_+^1(\mathcal{X}))^2}$. This corresponds to setting uniform weights ($\omega_1 = \omega_2 = 1/2$); note that in this case $\widetilde{k}_q$ and k_q collapse into the same kernel,

$$\widetilde{k}_q(p_1, p_2) = k_q(p_1, p_2) = \ln_q(2) - T_q(p_1, p_2).$$

Proposition 27 guarantees that these kernels are pd for $q \in [0, 2]$. Remarkably, we recover three well-known particular cases for $q \in \{0, 1, 2\}$. We start with the Jensen-Shannon kernel, introduced and shown to be pd by Hein et al. (2004); it is a particular case of a weighted Jensen-Shannon kernel in Definition 28.

Definition 33 (Jensen-Shannon kernel) *The kernel $k_{JS} : M_+^1(\mathcal{X}) \times M_+^1(\mathcal{X}) \to \mathbb{R}$ is defined as*

$$k_{JS}(p_1, p_2) = \ln 2 - JS(p_1, p_2).$$

Corollary 34 *The kernel k_{JS} is pd.*

Proof k_{JS} is the restriction of k_{WJS} to $M_+^1(\mathcal{X}) \times M_+^1(\mathcal{X})$. ■

Finally, we study two other particular cases of the family of Tsallis kernels: the Boolean and linear kernels.

Definition 35 (Boolean kernel) *Let the kernel $k_{\text{Bool}} : M_+^{S_0,1}(\mathcal{X}) \times M_+^{S_0,1}(\mathcal{X}) \to \mathbb{R}$ be defined as $k_{\text{Bool}} = k_0$, that is,*

$$k_{\text{Bool}}(p_1, p_2) = \nu\left(\text{supp}(p_1) \cap \text{supp}(p_2)\right),$$

that is, $k_{\text{Bool}}(p_1, p_2)$ equals the measure of the intersection of the supports (cf. Equation 26). In particular, if $\mathcal{X}$ is finite and ν is the counting measure, the above may be written as

$$k_{\text{Bool}}(p_1, p_2) = \|p_1 \odot p_2\|_0.$$

Definition 36 (Linear kernel) *Let the kernel $k_{\text{lin}} : M_+^{S_2,1}(\mathcal{X}) \times M_+^{S_2,1}(\mathcal{X}) \to \mathbb{R}$ be defined as*

$$k_{\text{lin}}(p_1, p_2) = \frac{1}{2} \langle p_1, p_2 \rangle.$$

Corollary 37 *The kernels k_{Bool} and k_{lin} are pd.*

Proof Invoke Proposition 27 with $q = 0$ and $q = 2$. Notice that, for $q = 2$, we just recover the well-known property of the inner product kernel (Schölkopf and Smola, 2002), which is equal to k_{lin} up to a scalar. ■

In conclusion, the Boolean kernel, the Jensen-Shannon kernel, and the linear kernel are simply particular elements of the much wider family of Jensen-Tsallis kernels, continuously parameterized by $q \in [0,2]$. Furthermore, the Jensen-Tsallis kernels are a particular subfamily of the even wider set of weighted Jensen-Tsallis kernels.

One of the key features of our generalization is that the kernels are defined on unnormalized measures, with arbitrary mass. This is relevant, for example, in applications of kernels on empirical measures (e.g., word counts, pixel intensity histograms); instead of the usual step of normalization Hein et al. 2004, we may leave these empirical measures unnormalized, thus allowing objects of different size (e.g., total number of words in a document, total number of image pixels) to be weighted differently. Another possibility opened by our generalization is the explicit inclusion of weights: given two normalized measures, they can be multiplied by arbitrary (positive) weights before being fed to the kernel function.

6.3 Other Kernels Based on Jensen Differences and q-Differences

It is worthwhile to note that the Jensen-Rényi and the Jensen-Tsallis divergences also yield positive definite kernels, albeit there are not any obvious "weighted generalizations" like the ones presented above for the Tsallis kernels.

Proposition 38 (Jensen-Rényi and Jensen-Tsallis kernels) *For any $q \in [0,2]$, the kernel*

$$(p_1, p_2) \mapsto S_q\left(\frac{p_1 + p_2}{2}\right)$$

and the (unweighted) Jensen-Tsallis divergence J_{S_q} (20) are nd kernels on $M_+^1(\mathcal{X}) \times M_+^1(\mathcal{X})$.

Also, for any $q \in [0,1]$, the kernel

$$(p_1, p_2) \mapsto R_q\left(\frac{p_1 + p_2}{2}\right)$$

and the (unweighted) Jensen-Rényi divergence J_{R_q} (19) are nd kernels on $M_+^1(\mathcal{X}) \times M_+^1(\mathcal{X})$.

Proof The fact that $(p_1, p_2) \mapsto S_q(\frac{p_1+p_2}{2})$ is nd results from the embedding $x \mapsto x/2$ and Proposition 24. Since $(p_1, p_2) \mapsto \frac{S_q(p_1)+S_q(p_2)}{2}$ is trivially nd, we have that J_{S_q} is a sum of nd functions, which turns it nd. To prove the negative definiteness of the kernel $(p_1, p_2) \mapsto R_q\left(\frac{p_1+p_2}{2}\right)$, notice first that the kernel $(x,y) \mapsto (x+y)/2$ is clearly nd. From Lemma 21 and integrating, we have that $(p_1,p_2) \mapsto \int \left(\frac{p_1+p_2}{2}\right)^q$ is nd for $q \in [0,1]$. From the same lemma we have that $(p_1,p_2) \mapsto \ln\left(t + \int \left(\frac{p_1+p_2}{2}\right)^q\right)$ is nd for any $t > 0$. Since $\int \left(\frac{p_1+p_2}{2}\right)^q > 0$, the nonnegativity of $(p_1,p_2) \mapsto R_q\left(\frac{p_1+p_2}{2}\right)$ follows by taking the limit $t \to 0$. By the same argument as above, we conclude that J_{R_q} is nd. ■

As a consequence, we have from Lemma 19 that the following kernels are pd for any $q \in [0,1]$ and $t > 0$:

$$\tilde{k}_{\text{EJR}}(p_1,p_2) = \exp\left(-tR_q\left(\frac{p_1+p_2}{2}\right)\right) = \left(\int \left(\frac{p_1+p_2}{2}\right)^q\right)^{-\frac{t}{1-q}},$$

and its "normalized" counterpart,

$$k_{\text{EJR}}(p_1,p_2) = \exp(-tJ_{R_q}(p_1,p_2)) = \left(\frac{\int \left(\frac{p_1+p_2}{2}\right)^q}{\sqrt{\int p_1^q \int p_2^q}}\right)^{-\frac{t}{1-q}}.$$

Although we could have derived its positive definiteness without ever referring to the Rényi entropy, the latter has in fact a suggestive interpretation: it corresponds to an exponentiation of the Jensen-Rényi divergence; it generalizes the case $q = 1$ which corresponds to the exponentiated Jensen-Shannon kernel.

Finally, we point out a relationship between the Jensen-Tsallis divergences (Section 3.4) and a family of difference kernels introduced by Fuglede (2005),

$$\psi_{\alpha,\beta}(x,y) = \left(\frac{x^\alpha + y^\alpha}{2}\right)^{1/\alpha} - \left(\frac{x^\beta + y^\beta}{2}\right)^{1/\beta}.$$

Fuglede (2005) derived the negative definiteness of the above family of kernels provided $1 \le \alpha \le \infty$ and $1/2 \le \beta \le \alpha$; he went further by providing representations for these kernels. Hein et al. (2004) used the fact that the integral $\int \psi_{\alpha,\beta}(x(t),y(t))d\tau(t)$ is also nd to derive a family of pd kernels for probability measures that included the Jensen-Shannon kernel (see Def. 33).

We start by noting the following property of the extended Tsallis entropy, which is very easy to establish:

$$S_q(\mu) = q^{-1}S_{1/q}(\mu^q)$$

As a consequence, by making the substitutions $r \triangleq q^{-1}$, $x_1 \triangleq y_1^q$ and $x_2 \triangleq y_2^q$, we have that

$$\begin{aligned} J_{S_q}(y_1,y_2) &= S_q\left(\frac{y_1+y_2}{2}\right) - \left(\frac{S_q(y_1)+S_q(y_2)}{2}\right) \\ &= r\left[S_r\left(\left(\frac{x_1^r+x_2^r}{2}\right)^{1/r}\right) - \frac{S_r(x_1)+S_r(x_2)}{2}\right] \\ &\triangleq r\tilde{J}_{S_r}(x_1,x_2) \end{aligned}$$

where we introduced

$$\begin{aligned}\tilde{J}_{S_r}(x_1,x_2) &= S_r\left(\left(\frac{x_1^r+x_2^r}{2}\right)^{1/r}\right)-\frac{S_r(x_1)+S_r(x_2)}{2}\\ &= (r-1)^{-1}\int\left[\left(\frac{x_1^r+x_2^r}{2}\right)^{1/r}-\frac{x_1+x_2}{2}\right]. \end{aligned}\tag{38}$$

Since J_{S_q} is nd for $q\in[0,2]$, we have that $\tilde{J}_{S_r}$ is nd for $r\in[1/2,\infty]$.

Notice that while J_{S_q} may be interpreted as "the difference between the Tsallis q-entropy of the mean and the mean of the Tsallis q-entropies," $\tilde{J}_{S_q}$ may be interpreted as "the difference between the Tsallis q-entropy of the q-power mean and the mean of the Tsallis q-entropies."

From (38) we have that

$$\int\psi_{\alpha,\beta}(x,y)=(\alpha-1)\tilde{J}_{S_\alpha}(x,y)-(\beta-1)\tilde{J}_{S_\beta}(x,y),$$

so the family of probabilistic kernels studied in Hein et al. (2004) can be written in terms of Jensen-Tsallis divergences.

6.4 *k*-th Order Jensen-Tsallis String Kernels

This subsection introduces a new class of string kernels inspired by the k-th order JT q-difference introduced in Section 5.3. Although we refer to them as "string kernels," they are more generally kernels between stochastic processes.

Several string kernels (i.e., kernels operating on the space of strings) have been proposed in the literature (Haussler, 1999; Lodhi et al., 2002; Leslie et al., 2002; Vishwanathan and Smola, 2003; Shawe-Taylor and Cristianini, 2004; Cortes et al., 2004). These are kernels defined on $\mathcal{A}^*\times\mathcal{A}^*$, where $\mathcal{A}^*$ is the Kleene closure of a finite alphabet $\mathcal{A}$ (i.e., the set of all finite strings formed by characters in $\mathcal{A}$ together with the empty string ε). The *p-spectrum kernel* (Leslie et al., 2002) is associated with a feature space indexed by $\mathcal{A}^p$ (the set of length-p strings). The feature representation of a string s, $\Phi^p(s)\triangleq(\phi_u^p(s))_{u\in\mathcal{A}^p}$, counts the number of times each $u\in\mathcal{A}^p$ occurs as a substring of s,

$$\phi_u^p(s)=|\{(v_1,v_2):s=v_1uv_2\}|.$$

The p-spectrum kernel is then defined as the standard inner product in $\mathbb{R}^{|\mathcal{A}|^p}$

$$k_{\mathrm{SK}}^p(s,t)=\langle\Phi^p(s),\Phi^p(t)\rangle.\tag{39}$$

A more general kernel is the *weighted all-substrings kernel* (Vishwanathan and Smola, 2003), which takes into account the contribution of all the substrings weighted by their length. This kernel can be viewed as a conic combination of p-spectrum kernels and can be written as

$$k_{\mathrm{WASK}}(s,t)=\sum_{p=1}^{\infty}\alpha_p k_{\mathrm{SK}}^p(s,t),\tag{40}$$

where α_p is often chosen to decay exponentially with p and truncated; for example, $\alpha_p=\lambda^p$, if $p_{\min}\le p\le p_{\max}$, and $\alpha_p=0$, otherwise, where $0<\lambda<1$ is the decaying factor.

Both k_{SK}^{p} and k_{WASK} are trivially positive definite, the former by construction and the latter because it is a conic combination of positive definite kernels. A remarkable fact is that both kernels may be computed in $O(|s|+|t|)$ time (i.e., with cost that is linear in the length of the strings), as shown by Vishwanathan and Smola (2003), by using data structures such as suffix trees or suffix arrays (Gusfield, 1997). Moreover, with s fixed, any kernel $k(s,t)$ may be computed in time $O(|t|)$, which is particularly useful for classification applications.

We will now see how Jensen-Tsallis kernels may be used as string kernels. In Section 5.3, we have introduced the concept of *joint* and *conditional* JT q-differences. We have seen that joint JT q-differences are just JT q-differences in a product space of the form $\mathcal{X} = \mathcal{X}_1 \times \mathcal{X}_2$; for k-th order joint JT q-differences this product space is of the form $\mathcal{A}^k = \mathcal{A} \times \mathcal{A}^{k-1}$. Therefore, they still yield positive definite kernels as those introduced in Definition 26, where $\mathcal{X} = \mathcal{A}^k$. The next definition and proposition summarize these statements.

Definition 39 (k-th order weighted JT kernels) *Let $\mathscr{S}(\mathcal{A})$ be the set of stationary and ergodic stochastic processes that take values on the alphabet $\mathcal{A}$. For $k \in \mathbb{N}$ and $q \in [0,2]$, let the kernel $\widetilde{k}_{q,k} : (\mathbb{R}_+ \times \mathscr{S}(\mathcal{A}))^2 \to \mathbb{R}$ be defined as*

$$\begin{aligned} \widetilde{k}_{q,k}((\omega_1,s_1),(\omega_2,s_2)) &\triangleq \widetilde{k}_q(\omega_1 p_{s_1,k}, \omega_2 p_{s_2,k}) \\ &= \left(S_q(\pi) - T_{q,k}^{\mathrm{joint},\pi}(s_1,s_2)\right)(\omega_1+\omega_2)^q, \end{aligned} \tag{41}$$

where $p_{s_1,k}$ and $p_{s_2,k}$ are the k-th order joint probability functions associated with the stochastic sources s_1 and s_2, and $\pi = (\omega_1/(\omega_1+\omega_2), \omega_2/(\omega_1+\omega_2))$.

Let the kernel $k_{q,k} : (\mathbb{R}_{++} \times \mathscr{S}(\mathcal{A}))^2 \to \mathbb{R}$ be defined as

$$\begin{aligned} k_{q,k}((\omega_1,s_1),(\omega_2,s_2)) &\triangleq k_q(\omega_1 p_{s_1,k}, \omega_2 p_{s_2,k}) \\ &= \left(S_q(\pi) - T_{q,k}^{\mathrm{joint},\pi}(s_1,s_2)\right), \end{aligned} \tag{42}$$

Proposition 40 *The kernel $\widetilde{k}_{q,k}$ is pd, for $q \in [0,2]$. The kernel $k_{q,k}$ is pd, for $q \in [0,1]$.*

Proof Define the map $g : \mathbb{R}_+ \times \mathscr{S}(\mathcal{A}) \to \mathbb{R}_+ \times M_+^{1,S_q}(\mathcal{A}^k)$ as $(\omega, s) \mapsto g(\omega,s) = (\omega, p_{s,k})$. From Proposition 27, the kernel $\widetilde{k}_q(g(\omega_1,s_1), g(\omega_2,s_2))$ is pd and therefore so is $\widetilde{k}_{q,k}((\omega_1,s_1),(\omega_2,s_2))$; proceed analogously for $k_{q,k}$. ■

At this point, one might wonder whether the "k-th order conditional JT kernel" $\widetilde{k}_{q,k}^{\mathrm{cond}}$ that would be obtained by replacing $T_{q,k}^{\mathrm{joint},\pi}$ with $T_{q,k}^{\mathrm{cond},\pi}$ in (41–42) is also pd. Formula (35) shows that such "conditional JT kernel" is a difference between two joint JT kernels, which is inconclusive. The following proposition shows that $\widetilde{k}_{q,k}^{\mathrm{cond}}$ and $k_{q,k}^{\mathrm{cond}}$ are not pd in general. The proof, which is in Appendix D, proceeds by building a counterexample.

Proposition 41 *Let $\widetilde{k}_{q,k}^{\mathrm{cond}}$ be defined as $\widetilde{k}_{q,k}^{\mathrm{cond}}(s_1,s_2) \triangleq \left(S_q(\pi) - T_{q,k}^{\mathrm{cond},\pi}(s_1,s_2)\right)(\omega_1+\omega_2)^q$; and $k_{q,k}^{\mathrm{cond}}$ be defined as $k_{q,k}^{\mathrm{cond}}(s_1,s_2) \triangleq \left(S_q(\pi) - T_{q,k}^{\mathrm{cond},\pi}(s_1,s_2)\right)$. It holds that $\widetilde{k}_{q,k}^{\mathrm{cond}}$ and $k_{q,k}^{\mathrm{cond}}$ are not pd in general.*

Despite the negative result in Proposition 41, the chain rule in Proposition 15 still allows us to define pd kernels by combining conditional JT q-differences.

Proposition 42 *Let $(\beta_k)_{k\in\mathbb{N}}$ be a non-increasing infinitesimal sequence, that is, satisfying*

$$\beta_0 \geq \beta_1 \geq \ldots \geq \beta_n \to 0$$

Any kernel of the form

$$\sum_{k=0}^{\infty} \beta_k \, \widetilde{k}_{q,k}^{\text{cond}} \tag{43}$$

is pd for $q \in [0,2]$; and any kernel of the form

$$\sum_{k=0}^{\infty} \beta_k \, k_{q,k}^{\text{cond}}$$

is pd for $q \in [0,1]$, provided both series above converge pointwise.

Proof From the chain rule, we have that (defining the 0-th order joint JT q-difference as $\widetilde{k}_{q,0} \triangleq 0$)

$$\sum_{k=0}^{\infty} \beta_k \widetilde{k}_{q,k}^{\text{cond}} = \sum_{k=0}^{\infty} \beta_k \,(\widetilde{k}_{q,k+1} - \widetilde{k}_{q,k}) = \lim_{n\to\infty} \sum_{k=1}^{n} \alpha_k \, \widetilde{k}_{q,k} + \beta_n \, \widetilde{k}_{q,n+1} = \sum_{k=1}^{\infty} \alpha_k \, \widetilde{k}_{q,k} \tag{44}$$

with $\alpha_k = \beta_{k-1} - \beta_k$ (the term $\lim \beta_n \widetilde{k}_{q,n+1}$ was dropped because $\beta_n \to 0$ and $\widetilde{k}_{q,n+1}$ is bounded). Since $(\beta_k)_{k\in\mathbb{N}}$ is non-increasing, we have that $(\alpha_k)_{k\in\mathbb{N}\setminus\{0\}}$ is non-negative, which makes (44) the pointwise limit of a conic combination of pd kernels, and therefore a pd kernel. The proof for $\sum_{k=0}^{\infty} \beta_k k_{q,k}^{\text{cond}}$ is analogous. ■

Notice that if we set $\beta_0 = \ldots = \beta_{k-1} = 1$ and $\beta_j = 0$, $\forall j \geq k$, in the above proposition, we recover the k-th order joint JT q-difference.

Finally, notice that, in the same way that the linear kernel is a special case of a JT kernel when $q = 2$ (see Cor. 37), the p-spectrum kernel (39) is a particular case of a p-th order joint JT kernel, and the weighted all substrings kernel (40) is a particular case of a combination of joint JT kernels in the form (43), both obtained when we set $q = 2$ and the weights ω_1 and ω_2 equal to the length of the strings. Therefore, we conclude that the JT string kernels introduced in this section subsume these two well-known string kernels.

7. Experiments

We illustrate the performance of the proposed nonextensive information theoretic kernels, in comparison with common kernels, for SVM-based text classification. We performed experiments with two standard data sets: *Reuters-21578*[3] and *WebKB*.[4] Since our objective was to evaluate the kernels, we considered a simple binary classification task that tries to discriminate among the two largest categories of each data set; this led us to the *earn-vs-acq* classification task for the first data set, and *stud-vs-fac* (students' *vs.* faculty webpages) in the second data set. Two different frameworks were considered: modeling documents as bags of words, and modeling them as strings of characters. Therefore, both bags of words kernels and string kernels were employed for each task.

3. Available at `www.daviddlewis.com/resources/testcollections`.
4. Available at `www.cs.cmu.edu/afs/cs.cmu.edu/project/theo-20/www/data`.

7.1 Documents as Bags of Words

For the bags of words framework, after the usual preprocessing steps of stemming and stop-word removal, we mapped text documents into probability distributions over words using the bag-of-words model and maximum likelihood estimation; this corresponds to normalizing the *term frequencies* (tf) using the ℓ_1-norm, and is referred to as *tf* (Joachims, 2002; Baeza-Yates and Ribeiro-Neto, 1999). We also used the *tf-idf* (term frequency-inverse document frequency) representation, which penalizes terms that occur in many documents (Joachims, 2002; Baeza-Yates and Ribeiro-Neto, 1999). To weight the documents for the Tsallis kernels, we tried four strategies: uniform weighting, word counts, square root of the word counts, and one plus the logarithm of the word counts; however, for both tasks, uniform weighting revealed the best strategy, which may be due to the fact that documents in both collections are usually short and do not differ much in size.

As baselines, we used the linear kernel with ℓ_2 normalization, commonly used for this task (Joachims, 2002), and the heat kernel approximation introduced by Lafferty and Lebanon (2005):

$$k_{\text{heat}}(p_1,p_2) = (4\pi t)^{-\frac{n}{2}} \exp\left(-\frac{1}{4t}\, d_g^2(p_1,p_2)\right),$$

where $t > 0$ and $d_g(p_1,p_2) = 2\arccos\left(\sum_i \sqrt{p_{1i}p_{2i}}\right)$. Although Lafferty and Lebanon (2005) provide empirical evidence that the heat kernel outperforms the linear kernel, it is not guaranteed to be pd for an arbitrary choice of t, as we show in Appendix E. This parameter and the SVM C parameter were tuned by cross-validation over the training set. The SVM-Light package (available at `http://svmlight.joachims.org/`) was used to solve the SVM quadratic optimization problem.

Figures 2–3 summarize the results. We report the performance of the Tsallis kernels as a function of the entropic index q. For comparison, we also plot the performance of an instance of a Tsallis kernel with q tuned by cross-validation. For the first task, this kernel and the two baselines exhibit similar performance for both the *tf* and the *tf-idf* representations; differences are not statistically significant. In the second task, the Tsallis kernel outperformed the ℓ_2-normalized linear kernel for both representations, and the heat kernel for *tf-idf*; the differences are statistically significant (using the unpaired t test at the 0.05 level). Regarding the influence of the entropic index, we observe that in both tasks, the optimal value of q is usually higher for *tf-idf* than for *tf*.

The results on these two problems are representative of the typical relative performance of the kernels considered: in almost all tested cases, both the heat kernel and the Tsallis kernels (for a suitable value of q) outperform the ℓ_2-normalized linear kernel; the Tsallis kernels are competitive with the heat kernel.

7.2 Documents as Strings

In the second set of experiments, each document is mapped into a probability distribution over character p-grams, using maximum likelihood estimation; we did experiments for $p = 3,4,5$. To weight the documents for the p-th order joint Jensen-Tsallis kernels, four strategies were attempted: uniform weighting, document lengths (in characters), square root of the document lengths, and one plus the logarithm of the document lengths. For the *earn-vs-acq* task, all strategies performed similarly, with a slight advantage for the square root and logarithm of the document lengths; for the *stud-vs-fac* task, uniform weighting revealed the best strategy. For simplicity, all experiments reported here use uniform weighting.

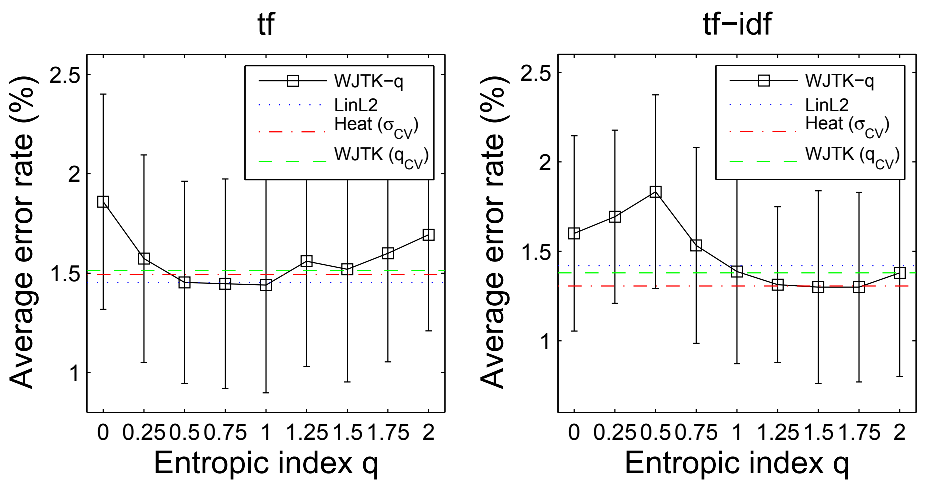

Figure 2: Results for *earn-vs-acq* using *tf* and *tf-idf* representations. The error bars represent ± 1 standard deviation on 30 runs. Training (resp. testing) with 200 (resp. 250) samples per class.

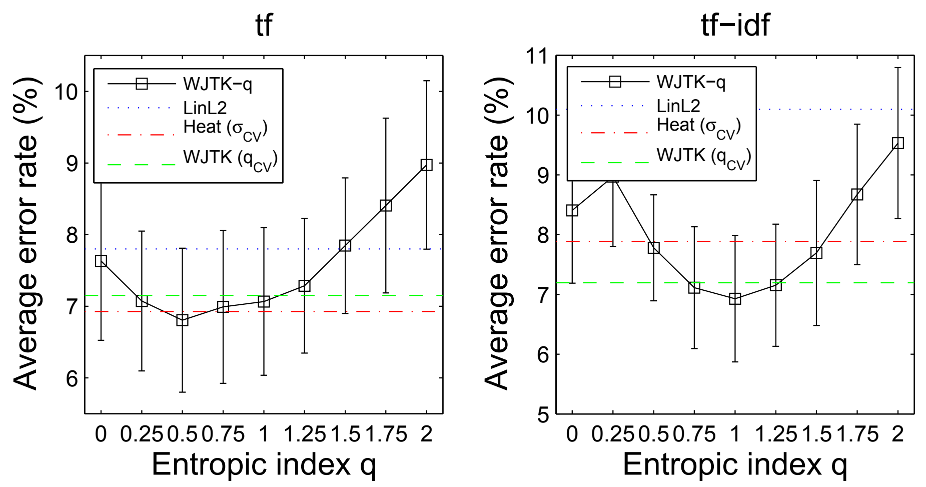

Figure 3: Results for *stud-vs-fac* using *tf* and *tf-idf* representations. The error bars represent ± 1 standard deviation on 30 runs. Training (resp. testing) with 200 (resp. 250) samples per class.

As baselines, we used the p-spectrum kernel (PSK, see 39) for the values of p referred above, and the weighted all substrings kernel (WASK, see 40) with decaying factor tuned to $\lambda = 0.75$ (which yielded the best results), with $p_{\min} = p$ set to the values above, and $p_{\max} = \infty$. The SVM C parameter was tuned by cross-validation over the training set.

Figures 4–5 summarize the results.

For the first task, the JT string kernel and the WASK outperformed the PSK (with statistical significance for $p = 3$), all kernels performed similarly for $p = 4$, and the JT string kernel outperformed the WASK for $p = 5$; all other differences are not statiscally significant. In the second task, the JT string kernel outperformed both the WASK and the PSK (and the WASK outperformed the PSK), with statistical significance for $p = 3,4,5$. Furthermore, by comparing Figures 3 and 5, we

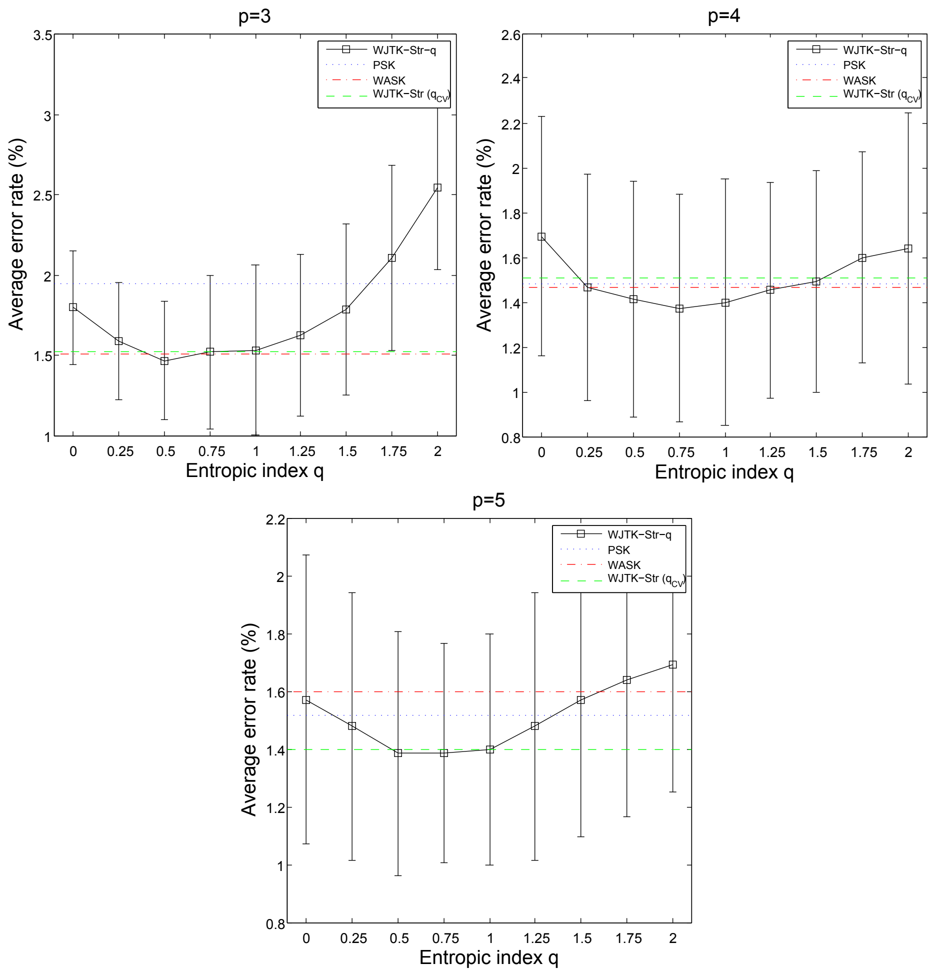

Figure 4: Results for *earn-vs-acq* using string kernels and $p = 3, 4, 5$. The error bars represent ± 1 standard deviation on 15 runs. Training (resp. testing) with 200 (resp. 250) samples per class.

also observe that the 5-th order JT string kernel remarkably outperforms all bags of words kernels for the *stud-vs-fac* task, even though it does not use or build any sort of language model at the word level.

8. Conclusions

In this paper we have introduced a new family of positive definite kernels between measures, which includes previous information-theoretic kernels on probability measures as particular cases. One of the key features of the new kernels is that they are defined on unnormalized measures (not necessarily normalized probabilities). This is relevant, for example, for kernels on empirical measures (such as word counts, pixel intensity histograms); instead of the usual step of normalization (Hein et al., 2004), we may leave these empirical measures unnormalized, thus allowing objects of different sizes (e.g., documents of different lengths, images with different sizes) to be weighted differently. Another possibility is the explicit inclusion of weights: given two normalized measures, they can

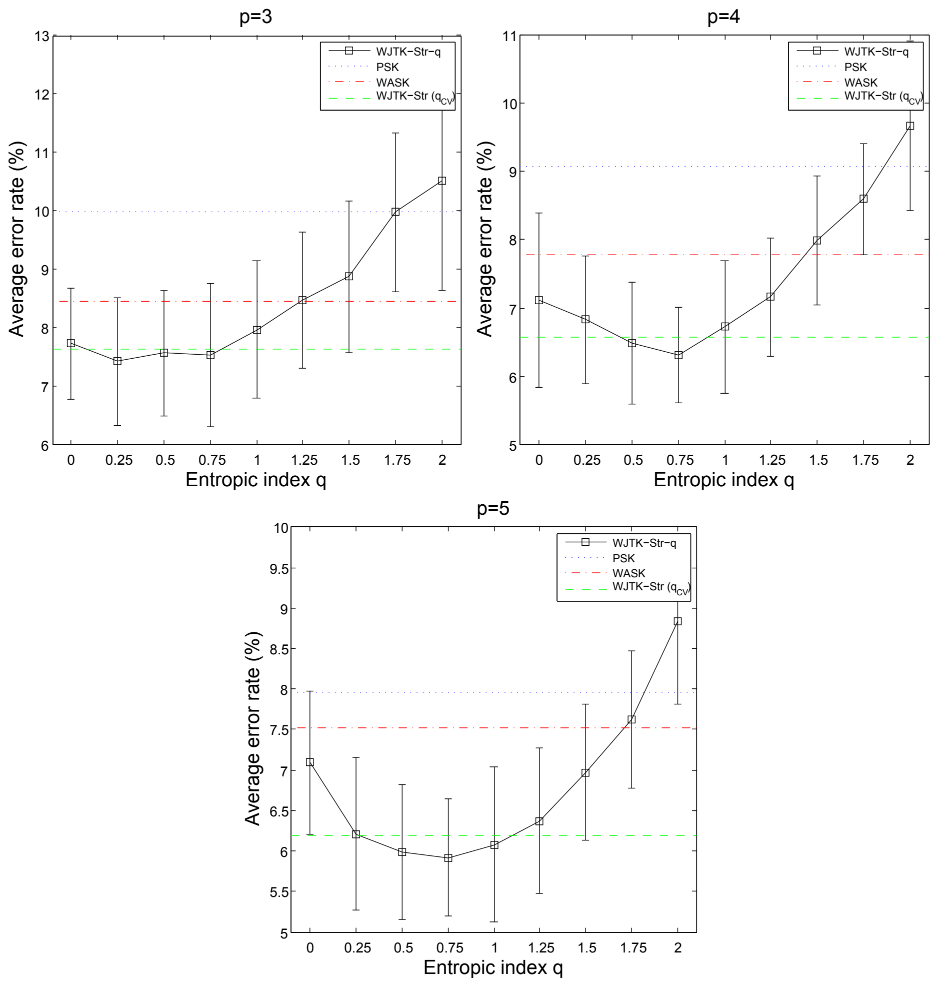

Figure 5: Results for *stud-vs-fac* using string kernels and $p = 3, 4, 5$. The error bars represent ± 1 standard deviation on 15 runs. Training (resp. testing) with 200 (resp. 250) samples per class.

be multiplied by arbitrary (positive) weights before being fed to the kernel function. In addition, we define positive definite kernels between stochastic processes that subsume well-known string kernels.

The new kernels and the proofs of positive definiteness rely on other main contributions of this paper: the new concept of q-convexity, for which we proved a *Jensen q-inequality*; the concept of *Jensen-Tsallis q-difference*, a nonextensive generalization of the Jensen-Shannon divergence; denormalization formulae for several entropies and divergences.

We have reported experiments in which these new kernels were used in support vector machines for text classification tasks. Although the reported experiments do not lead to strong conclusions, they show that the new kernels are competitive with the state-of-the-art, in some cases yielding a significant performance improvement.

Future research will concern applying Jensen-Tsallis q-differences to other learning problems, like clustering, possibly exploiting the fact that they accept more than two arguments.

Acknowledgments

The authors would like to thank the reviewers for their valuable comments, and Guy Lebanon for the fruitful discussions regarding the heat kernel approximation. Appendix A. Suyari's Axioms for Nonextensive Entropies

Suyari (2004) proposed the following set of axioms (above referred as Suyari's axioms) that determine nonextensive entropies of the form stated in (1). Below, $q \geq 0$ is any fixed scalar and f_q is a function defined on $\cup_{n=1}^{\infty} \Delta^{n-1}$.

(A1) *Continuity*: $f_q|_{\Delta^{n-1}}$ is continuous, for any $n \in \mathbb{N}$;

(A2) *Maximality*: For any $n \in \mathbb{N}$ and $(p_1, \ldots, p_n) \in \Delta^{n-1}$,

$$f_q(p_1, \ldots, p_n) \leq S_q(1/n, \ldots, 1/n);$$

(A3) *Generalized additivity*: For $i = 1, \ldots, n$, $j = 1, \ldots, m_i$, $p_{ij} \geq 0$, and $p_i = \sum_{j=1}^{m_i} p_{ij}$,

$$\begin{aligned} f_q(p_{11}, \ldots, p_{nm_n}) &= f_q(p_1, \ldots, p_n) + \\ & \sum_{i=1}^{n} p_i^q f_q\left(\frac{p_{i1}}{p_i}, \ldots, \frac{p_{im_i}}{p_i}\right); \end{aligned}$$

(A4) *Expandability*: $f_q(p_1, \ldots, p_n, 0) = f_q(p_1, \ldots, p_n)$.

Appendix B. Proof of Proposition 8

Proof The case $q = 1$ corresponds to the Jensen difference and was proved by Burbea and Rao (1982) (Theorem 1). Our proof extends that to $q \neq 1$. Let $y = (y_1, \ldots, y_m)$, where $y_t = (y_{t1}, \ldots, y_{tn})$. Thus

$$\begin{aligned} T_{q,\Psi}^{\pi}(y) &= \Psi\left(\sum_{t=1}^{m} \pi_t y_t\right) - \sum_{t=1}^{m} \pi_t^q \, \Psi(y_t) \\ &= \sum_{i=1}^{n} \left[\sum_{t=1}^{m} \pi_t^q \varphi(y_{ti}) - \varphi\left(\sum_{t=1}^{m} \pi_t y_{ti}\right)\right], \end{aligned}$$

showing that it suffices to consider $n = 1$, where each $y_t \in [0, 1]$, that is,

$$T_{q,\Psi}^{\pi}(y_1, \ldots, y_m) = \sum_{t=1}^{m} \pi_t^q \varphi(y_t) - \varphi\left(\sum_{t=1}^{m} \pi_t y_t\right);$$

this function is convex on $[0,1]^m$ if and only if, for every fixed $a_1,\dots,a_m \in [0,1]$, and $b_1,\dots,b_m \in \mathbb{R}$, the function

$$f(x) = T^{\pi}_{q,\Psi}(a_1 + b_1 x, \dots, a_m + b_m x)$$

is convex in $\{x \in \mathbb{R} : a_t + b_t x \in [0,1], t = 1,\dots,m\}$. Since f is C^2, it is convex if and only if $f''(t) \geq 0$.

We first show that convexity of f (equivalently of $T^{\pi}_{q,\Psi}$) implies convexity of φ. Letting $c_t = a_t + b_t x$,

$$f''(x) = \sum_{t=1}^{m} \pi_t^q b_t^2 \varphi''(c_t) - \left(\sum_{t=1}^{m} \pi_t b_t\right)^2 \varphi''\left(\sum_{t=1}^{m} \pi_t c_t\right). \tag{45}$$

By choosing $x = 0$, $a_t = a \in [0,1]$, for $t = 1,...,m$, and $b_1,\dots,b_m$ satisfying $\sum_t \pi_t b_t = 0$ in (45), we get

$$f''(0) = \varphi''(a) \sum_{t=1}^{m} \pi_t^q b_t^2,$$

hence, if f is convex, $\varphi''(a) \geq 0$ thus φ is convex.

Next, we show that convexity of f also implies $(2-q)$-convexity of $-1/\varphi''$. By choosing $x = 0$ (thus $c_t = a_t$) and $b_t = \pi_t^{1-q}(\varphi''(a_t))^{-1}$, we get

$$\begin{aligned} f''(0) &= \sum_{t=1}^{m} \frac{\pi_t^{2-q}}{\varphi''(a_t)} - \left(\sum_{t=1}^{m} \frac{\pi_t^{2-q}}{\varphi''(a_t)}\right)^2 \varphi''\left(\sum_{t=1}^{m} \pi_t a_t\right) \\ &= \left[\frac{1}{\varphi''\left(\sum_{t=1}^{m} \pi_t a_t\right)} - \sum_{t=1}^{m} \frac{\pi_t^{2-q}}{\varphi''(a_t)}\right] \left(\sum_{t=1}^{m} \frac{\pi_t^{2-q}}{\varphi''(a_t)}\right) \varphi''\left(\sum_{t=1}^{m} \pi_t a_t\right), \end{aligned}$$

where the expression inside the square brackets is the Jensen $(2-q)$-difference of $1/\varphi''$ (see Definition 7). Since $\varphi''(x) \geq 0$, the factor outside the square brackets is non-negative, thus the Jensen $(2-q)$-difference of $1/\varphi''$ is also nonnegative and $-1/\varphi''$ is $(2-q)$-convex.

Finally, we show that if φ is convex and $-1/\varphi''$ is $(2-q)$-convex, then $f'' \geq 0$, thus $T^{\pi}_{q,\Psi}$ is convex. Let $r_t = (q\pi_t^{2-q}/\varphi''(c_t))^{1/2}$ and $s_t = b_t(\pi_t^q \varphi''(c_t)/q)^{1/2}$; then, non-negativity of f'' results from the following chain of inequalities/equalities:

$$\begin{aligned} 0 &\leq \left(\sum_{t=1}^{m} r_t^2\right)\left(\sum_{t=1}^{m} s_t^2\right) - \left(\sum_{t=1}^{m} r_t s_t\right)^2 && (46) \\ &= \sum_{t=1}^{m} \frac{\pi_t^{2-q}}{\varphi''(c_t)} \sum_{t=1}^{m} b_t^2 \pi_i^q \varphi''(c_t) - \left(\sum_{t=1}^{m} b_t \pi_t\right)^2 && (47) \\ &\leq \frac{1}{\varphi''\left(\sum_{t=1}^{m} \pi_t c_t\right)} \sum_{t=1}^{m} b_t^2 \pi_t^q \varphi''(c_t) - \left(\sum_{t=1}^{m} b_t \pi_t\right)^2 && (48) \\ &= \frac{1}{\varphi''\left(\sum_{t=1}^{m} \pi_t c_t\right)} \cdot f''(t), && (49) \end{aligned}$$

where: (46) is the Cauchy-Schwarz inequality; Equality (47) results from the definitions of r_t and s_t and from the fact that $r_t s_t = b_t \pi_t$; Inequality (48) states the $(2-q)$-convexity of $-1/\varphi''$; equality (49) results from (45). ■

Appendix C. Proof of Proposition 10

Proof The proof of (29), for $q \geq 0$, results from

$$\begin{aligned} T_q^\pi(p_1,\ldots,p_m) &= \frac{1}{q-1}\left[1-\sum_{j=1}^n\left(\sum_{t=1}^m \pi_t p_{tj}\right)^q - \sum_{t=1}^m \pi_t^q\left(1-\sum_{j=1}^n p_{tj}^q\right)\right] \\ &= S_q(\pi)+\frac{1}{q-1}\sum_{j=1}^n\left[\sum_{t=1}^m(\pi_t p_{tj})^q-\left(\sum_{t=1}^m \pi_t p_{tj}\right)^q\right] \\ &\leq S_q(\pi), \end{aligned}$$

where the inequality holds since, for $y_i \geq 0$: if $q \geq 1$, then $\sum_i y_i^q \leq (\sum_i y_i)^q$; if $q \in [0,1]$, then $\sum_i y_i^q \geq (\sum_i y_i)^q$.

The proof that $T_q^\pi \geq 0$ for $q \geq 1$, uses the notion of q-convexity. Since $\mathcal{X}$ is countable, the Tsallis entropy is as in (2), thus $S_q \geq 0$. Since $-S_q$ is 1-convex, then, by Proposition 6, it is also q-convex for $q \geq 1$. Consequently, from the q-Jensen inequality (Proposition 5), for finite $\mathcal{T}$, with $|\mathcal{T}| = m$,

$$T_q^\pi(p_1,\ldots,p_m) = S_q\left(\sum_{t=1}^m \pi_t p_t\right) - \sum_{t=1}^m \pi_t^q S_q(p_t) \geq 0.$$

Since S_q is continuous, so is T_q^π, thus the inequality is valid in the limit as $m \to \infty$, which proves the assertion for $\mathcal{T}$ countable. Finally, $T_q^\pi(\delta_1,\ldots,\delta_1,\ldots) = 0$, where δ_1 is some degenerate distribution.

Finally, to prove (30), for $q \in [0,1]$ and $\mathcal{X}$ finite,

$$\begin{aligned} T_q^\pi(p_1,\ldots,p_m) &= S_q\left(\sum_{t=1}^m \pi_t p_t\right) - \sum_{t=1}^m \pi_t^q S_q(p_t) \\ &\geq \sum_{t=1}^m \pi_t S_q(p_t) - \sum_{t=1}^m \pi_t^q S_q(p_t) \qquad (50) \\ &= \sum_{t=1}^m (\pi_t - \pi_t^q) S_q(p_t) \\ &\geq S_q(U)\sum_{t=1}^m(\pi_t-\pi_t^q) \qquad (51) \\ &= S_q(\pi)[1-n^{1-q}]. \end{aligned}$$

where the Inequality (50) results from S_q being concave, and the Inequality (51) holds since $\pi_t - \pi_t^q \leq 0$, for $q \in [0,1]$, and the uniform distribution U maximizes S_q, with $S_q(U) = (1-n^{1-q})/(q-1)$. ■

Appendix D. Proof of Proposition 41

Proof We show a counterexample with $q = 1$ (the extensive case), $\pi = (1/2, 1/2)$ and $k = 1$, that discards both cases. It suffices to show that $\sqrt{JS_1^{\text{cond}}} \triangleq \sqrt{T_{1,1}^{\text{cond},(1/2,1/2)}}$ violates the triangle inequality for some choice of stochastic processes s_1, s_2, s_3 and therefore is a not a squared distance;

this in turn implies that $\sqrt{JS_1^{\text{cond}}}$ is not nd and, from Proposition 18, that the above two kernels are not pd. We define s_1, s_2, s_3 to be stationary first order Markov processes in a binary alphabet $\mathcal{A} = \{0,1\}$ defined by the following transition matrices, respectively:

$$S_1 = \lim_{\varepsilon \to 0} \begin{bmatrix} 1-\varepsilon & \varepsilon \\ 1/4 & 3/4 \end{bmatrix} = \begin{bmatrix} 1 & 0 \\ 1/4 & 3/4 \end{bmatrix},$$

$$S_2 = \lim_{\varepsilon \to 0} \begin{bmatrix} 3/4 & 1/4 \\ \varepsilon & 1-\varepsilon \end{bmatrix} = \begin{bmatrix} 3/4 & 1/4 \\ 0 & 1 \end{bmatrix},$$

and

$$S_3 = \lim_{\varepsilon \to 0} \begin{bmatrix} \varepsilon & 1-\varepsilon \\ 1/4 & 3/4 \end{bmatrix} = \begin{bmatrix} 0 & 1 \\ 1/4 & 3/4 \end{bmatrix},$$

whose stationary distributions are

$$\sigma_1 = \lim_{\varepsilon \to 0} \frac{1}{1+4\varepsilon} \begin{bmatrix} 1 \\ 4\varepsilon \end{bmatrix} = \begin{bmatrix} 1 \\ 0 \end{bmatrix},$$

$$\sigma_2 = \lim_{\varepsilon \to 0} \frac{1}{1+4\varepsilon} \begin{bmatrix} 4\varepsilon \\ 1 \end{bmatrix} = \begin{bmatrix} 0 \\ 1 \end{bmatrix},$$

and

$$\sigma_3 = \lim_{\varepsilon \to 0} \frac{1}{5-4\varepsilon} \begin{bmatrix} 1 \\ 4-4\varepsilon \end{bmatrix} = \begin{bmatrix} 1/5 \\ 4/5 \end{bmatrix}.$$

The matrix of first order conditional JT 1-differences (or first order conditional Jensen-Shannon divergences) is

$$\begin{bmatrix} 0 & 0 & \frac{3}{5}H(\frac{5}{6}) \\ * & 0 & \frac{9}{10}H(\frac{8}{9}) - \frac{2}{5}H(\frac{1}{4}) \\ * & * & 0 \end{bmatrix} \approx \begin{bmatrix} 0 & 0 & 0.390 \\ * & 0 & 0.128 \\ * & * & 0 \end{bmatrix}, \tag{52}$$

which fails to be negative definite, since

$$\sqrt{JS_1^{\text{cond}}(s_1,s_2)} + \sqrt{JS_1^{\text{cond}}(s_2,s_3)} < \sqrt{JS_1^{\text{cond}}(s_1,s_3)},$$

which violates the triangle inequality required for $\sqrt{JS_1^{\text{cond}}}$ to be a metric.

Interestingly, the 0-th order conditional Jensen-Shannon divergence matrix (this one ensured to be negative definite because it equals a standard Jensen-Shannon divergence matrix) is

$$\begin{bmatrix} 0 & 1 & H(\frac{2}{5}) - \frac{1}{2}H(\frac{1}{5}) \\ * & 0 & H(\frac{1}{10}) - \frac{1}{2}H(\frac{1}{5}) \\ * & * & 0 \end{bmatrix} \approx \begin{bmatrix} 0 & 1 & 0.610 \\ * & 0 & 0.108 \\ * & * & 0 \end{bmatrix}. \tag{53}$$

From the chain rule (35), we have that the sum of the matrices (52) and (53) is the second order joint Jensen-Shannon divergence, and therefore is also guaranteed to be negative definite. ■

Appendix E. The Heat Kernel Approximation

The diffusion kernel for statistical manifolds, recently proposed by Lafferty and Lebanon (2005), is grounded in information geometry (Amari and Nagaoka, 2001). It models the diffusion of "information" over a statistical manifold according to the heat equation. Since in the case of the multinomial manifold (the relative interior of Δ^n), the diffusion kernel has no closed form, the authors adopt the so-called "first-order parametrix expansion," which resembles the Gaussian kernel replacing the Euclidean distance by the geodesic distance that is induced when the manifold is endowed with a Riemannian structure given by the Fisher information (we refer to Lafferty and Lebanon 2005 for further details). The resulting heat kernel approximation is

$$k_{\text{heat}}(p_1, p_2) = (4\pi t)^{-\frac{n}{2}} \exp\left(-\frac{1}{4t}\, d_g^2(p_1, p_2)\right),$$

where $t > 0$ and $d_g(p_1, p_2) = 2 \arccos\left(\sum_i \sqrt{p_{1i} p_{2i}}\right)$. Whether k_{heat} is pd has been an open problem (Hein et al., 2004; Zhang et al., 2005). Let $\mathbb{S}_+^n$ be the positive orthant of the n-dimensional sphere, that is,

$$\mathbb{S}_+^n = \left\{ (x_1, \ldots, x_{n+1}) \in \mathbb{R}^{n+1} \mid \sum_{i=1}^{n+1} x_i^2 = 1,\ \forall i\, x_i \geq 0 \right\}.$$

The problem can be restated as follows: is there an isometric embedding from $\mathbb{S}_+^n$ to some Hilbert space? In this section we answer that question in the negative.

Proposition 43 *Let $n \geq 2$. For sufficiently large t, the kernel k_{heat} is* not *pd.*

Proof From Proposition 19, k_{heat} is pd, for all $t > 0$, if and only if d_g^2 is nd. We provide a counterexample, using the following four points in Δ^2: $p_1 = (1,0,0)$, $p_2 = (0,1,0)$, $p_3 = (0,0,1)$ and $p_4 = (1/2, 1/2, 0)$. The squared distance matrix $[D_{ij}] = [d_g^2(p_i, p_j)]$ is

$$D = \frac{\pi^2}{4} \cdot \begin{bmatrix} 0 & 4 & 4 & 1 \\ 4 & 0 & 4 & 1 \\ 4 & 4 & 0 & 4 \\ 1 & 1 & 4 & 0 \end{bmatrix}.$$

Taking $c = (-4, -4, 1, 7)$ we have $c^T D c = 2\pi^2 > 0$, showing that D is not nd. Although p_1, p_2, p_3, p_4 lie on the boundary of Δ^2, continuity of d_g^2 implies that it is not nd on the relative interior of Δ^2. The case $n > 2$ follows easily, by appending zeros to the four vectors above. ■

On Uniform Deviations of General Empirical Risks with Unboundedness, Dependence, and High Dimensionality

Editor: Gábor Lugosi

Abstract

The statistical learning theory of risk minimization depends heavily on probability bounds for uniform deviations of the empirical risks. Classical probability bounds using Hoeffding's inequality cannot accommodate more general situations with unbounded loss and dependent data. The current paper introduces an inequality that extends Hoeffding's inequality to handle these more general situations. We will apply this inequality to provide probability bounds for uniform deviations in a very general framework, which can involve discrete decision rules, unbounded loss, and a dependence structure that can be more general than either martingale or strong mixing. We will consider two examples with high dimensional predictors: autoregression (AR) with ℓ_1-loss, and ARX model with variable selection for sign classification, which uses both lagged responses and exogenous predictors.

Keywords: dependence, empirical risk, probability bound, unbounded loss, uniform deviation

1. Introduction

In machine learning, a problem of central importance is to bound a probability of uniform deviation $P[\sup_{b\in B}|n^{-1}\sum_{t=1}^{n}\rho(\omega_t,b)-n^{-1}\sum_{t=1}^{n}E\rho(\omega_t,b)|>\delta]$, where $\delta>0$ is a positive deviation (which can be allowed to depend on n and characterize a convergence rate), b is a parameter in a parameter space B (which is typically a Borel measurable subset of an Euclidean space), $D=(\omega_1,...,\omega_n)$ form the data set of n random observations, $\rho(\cdot,\cdot)$ is a loss function (measurable to a certain product σ-field), $\hat{R}(b)=n^{-1}\sum_{t=1}^{n}\rho(\omega_t,b)$ is an empirical risk, and $R(b)=n^{-1}\sum_{t=1}^{n}E\rho(\omega_t,b)$ is its expectation.[1]

Such a probability is of interest since it is well known to bound the performance $R(\hat{b})$ of an empirical risk minimizer $\hat{b}=\arg\min_{b\in B}\hat{R}(b)$, relative to the optimal performance $\inf_{b\in B}R(b)$ over B:

$$P[R(\hat{b})-\inf_{b\in B}R(b)>2\delta]\le P[\sup_{b\in B}|\hat{R}(b)-R(b)|>\delta],$$

due to, for example, Lemma 8.2 (Devroye, Györfi and Lugosi, 1996). Recently, Jiang and Tanner (2007, 2008) indicate that the probability of uniform deviation is also of central importance in

1. In this paper, we will not be concerned about the measurability problem that may be involved in quantities such as $\sup_{b\in B}|\hat{R}(b)-R(b)|$. Works on 'universal measurability' described in, for example, Yu (1994, Appendix) and Davidson (1994, Section 21.1) imply that this is not a problem for all our examples later where B is a Borel measurable subset of a compact metric space. Alternatively we could consider P as the 'outer probability' as in Newey (1991).

studying the performance of a Bayesian approach of empirical risk minimization considered in, for example, Zhang (2006), when b is generated randomly according to a Gibbs posterior $\pi_{b|D}(db) \propto e^{-n\psi\hat{R}(b)}\pi_b(db)$ where $\pi_b(db)$ is a prior distribution on B and $\psi^{-1} > 0$ is a 'temperature parameter'. This includes the usual Bayesian posterior as a special case when $\psi = 1$ and when $-n\hat{R}$ is the log-likelihood function. A straightforward application of Jiang and Tanner (2008, Proposition 6) renders

$$P[R(b) - \inf_{b\in B} R(b) > 5\delta] \leq P[\sup_{b\in B} |\hat{R}(b) - R(b)| > \delta] + e^{-2n\psi\delta}/\pi_b[R(b) - \inf_{b\in B} R(b) < \delta],$$

when $b|D \sim \pi_{b|D}$ and D is generated from a true distribution. This again shows the dependence of the risk performance on the probability of uniform deviation.

The probability of uniform deviation is treated in the standard machine learning text such as Devroye, Györfi and Lugosi (1996) by the Vapnik-Chervonenkis theory using a Hoeffding's inequality on the probability of pointwise deviation $P[|n^{-1}\sum_{t=1}^n \rho(\omega_t, b) - n^{-1}\sum_{t=1}^n E\rho(\omega_t, b)| > \delta]$, which typically assumes that ω_t's are iid (independent and identically distributed), and that the loss function ρ is bounded. The goal of this paper is to generalize in several directions, so that ρ can be unbounded and ω_t's can be dependent. In addition, we will allow b to have a possibly high dimension that can increase with n in certain ways. When ρ has sufficiently thin tail in the distribution and when ω_t's have certain kind of decaying dependence over t, we derive bounds of the form

$$P[\sup_{b\in B} |n^{-1}\sum_{t=1}^n \rho(\omega_t, b) - n^{-1}\sum_{t=1}^n E\rho(\omega_t, b)| > n^{-0.5+\gamma_1}] = O(e^{-c_1 n^{c_2}}),$$

for any small positive γ_1, where c_1, c_2 are some positive constants depending on γ_1. Such a result indicates uniform convergence of the empirical risk at a near 'parametric' rate (close to $O_P(n^{-0.5})$) despite high dimensionality in b, dependence in ω_t, and unbounded loss function ρ.

Such results are obtained using a very general 'pointwise' inequality that generalizes Hoeffding's inequality, which will be introduced in Section 2. This allows unbounded loss and a framework of dependence that is more general than strong mixing, which is therefore more general than previous works using strong mixing (e.g., Vidyasagar, 2005; Zou and Li, 2007) or β-mixing (e.g., Yu, 1994; Lozano, Kulkarni and Schapire, 2006). The 'uniform aspect' is then treated in a very general framework in Section 3 allowing both continuity and discontinuity of ρ in b. Examples of applications of this general framework are given in Sections 4 and 5.

2. An Inequality

We first introduce an inequality that is more general than Hoeffding's inequality (Hoeffding, 1963). This inequality may be called a 'triplex inequality' since its right hand side has three parts. In addition to a term that is of an exponential form as in the Hoeffding's inequality, it also includes a term to gauge the dependence, and a term to control the unboundedness of the random variables. The result is therefore almost assumption free and generally applicable: it does not assume independence or boundedness of the random variables.

Theorem 1 *(A triplex inequality.) let $\{\mathcal{F}_t\}_{-\infty}^{\infty}$ be an increasing sequence of σ-fields and ρ_t be a random variable that is $\mathcal{F}_t$-measurable for each t. Then for any $\varepsilon, C > 0$ and positive integers n, m,* *we have*

$$P[|\sum_{t=1}^{n}(\rho_t - E\rho_t)| > n\varepsilon] \leq 2me^{-n\varepsilon^2/(288m^2C^2)}$$
$$+(6/\varepsilon)n^{-1}\sum_{t=1}^{n} E|E(\rho_t|\mathcal{F}_{t-m}) - E\rho_t|$$
$$+(15/\varepsilon)n^{-1}\sum_{t=1}^{n} E|\rho_t|I(|\rho_t| > C),$$

as long as the right hand side exists and does not exceed one.

2.1 Remarks

1. The bound is not necessarily very tight; the constants appearing in the theorem may be improved. However, these typically do not affect the convergence rates in the later applications of this inequality.

2. In later applications, the choices of m and C can be made to depend on n so that the combination of all three terms converge to zero as $n \to \infty$.

3. The last term will be called the 'tail term' since it is related to the tail behavior of ρ_t. This often can be bounded by techniques similar to the Markov inequalities. Note that for nonnegative $X = |\rho_t|$, $EXI(X > C) \leq EX^{k+1}C^{-k}$ and $EXI(X > C) \leq \sqrt{EX^2}\sqrt{P(X > C)} \leq \sqrt{EX^2}\sqrt{Ee^{\theta X}}e^{-\theta C/2}$, for $k, \theta > 0$. So existence of moments of X will imply a power law and existence of the moment generating function in a neighborhood of zero will imply an exponential law for the decay of the 'tail term' in C.

4. The second term will be called the 'dependence term' since it is related to the dependence described in the framework of L_1-mixingale (see, e.g., Chapter 16, Davidson, 1994), which is more general than either martingale or strong mixing. When $\{\rho_t\}$ is a sequence of martingale differences, the dependence term vanishes. If $\{\rho_t\}$ is strong mixing with coefficients α_m, and has bounded L_q norms ($q > 1$), then Theorem 14.2 of Davidson (1994) would imply that the dependence term decreases according to order $O(\alpha_m^{1-1/q})$ as m increases.

5. The mixingale formulation of the dependence term can also handle a process ρ_t that is *not* strong mixing. We will provide an example below when ρ_t is not strong mixing but is *approximable* to a strong mixing process, where we can still make the dependence term small for large m. Such an extension from 'strong mixing' to 'approximable by strong mixing', although seemingly a small improvement, is very significant. The problem of strong mixing is that a function of a mixing sequence (even an independent sequence) that depends on an infinite number of lags is not generally mixing. This is regarded as a 'serious drawback from the viewpoint of applications in time-series modelling' (Davidson, 1994, p.261), and has led to the 'approximability' framework summarized in Davidson (1994, Chapter 17), which is popular in modern time series study but has not been paid much attention to by the machine learning society. Our work can incorporate this approximability concept and provide a 'bridge' introducing this framework to our field.

2.2 An Example for the Dependence Term

Suppose that $\{\rho_t\}_{t=-\infty}^{\infty}$ can be approximated in an L_1-sense by a strong mixing sequence $\{\rho_{t,k}\}_{t=-\infty}^{\infty}$ as k increases (where $\rho_{t,k}$ is measurable -$\mathcal{F}_t$ for each t):

$$n^{-1}\sum_{t=1}^{n} E|\rho_t - \rho_{t,k}| \le c_1\nu_k,$$

where $c_1 > 0$ and $\nu_k > 0$ are nonstochastic and ν_k decreases to zero as $k \to \infty$. Suppose the qth moment $||\rho_{t,k}||_q \equiv (E|\rho_{t,k}|^q)^{1/q} \le c_2$ for some constants $q > 1$, $c_2 > 0$. Then Theorem 14.2 of Davidson (1994) implies that

$$n^{-1}\sum_{t=1}^{n} E|E(\rho_{t,k}|\mathcal{F}_{t-m}) - E\rho_{t,k}| \le 6c_2\alpha_m(\{\rho_{t,k}\}_{t=-\infty}^{\infty})^{1-1/q}.$$

Then apply the triangular inequality and note that the dependence term is proportional to

$$\begin{aligned} n^{-1}\sum_{t=1}^{n} E|E(\rho_t|\mathcal{F}_{t-m}) - E\rho_t| &\le n^{-1}\sum_{t=1}^{n} E|E(\rho_{t,k}|\mathcal{F}_{t-m}) - E\rho_{t,k}| + 2n^{-1}\sum_{t=1}^{n} E|\rho_t - \rho_{t,k}| \\ &\le 6c_2\alpha_m(\{\rho_{t,k}\}_{t=-\infty}^{\infty})^{1-1/q} + 2c_1\nu_k. \end{aligned}$$

We may be able to choose $k = k(m)$ to increase with m somehow so that both terms above are small for large m. Such a choice $k(m)$ depends on the mechanism of approximation. When k indicates the number of lags involved as in the following example, one can choose $k(m) \approx m/2$.

For example, consider an $MA(\infty)$ process $\rho_t = \sum_{j=0}^{\infty}\theta_j V_{t-j}$ where $\{V_t\}_{-\infty}^{\infty}$ is a zero-mean, L_q-bounded sequence (i.e., $\sup_t ||V_t||_q < \infty$) for some $q > 1$. (We can take $\mathcal{F}_t$ to be the σ-field generated by $\{V_s\}_{s=-\infty}^{t}$.) Then ρ_t is not necessarily strong mixing even when V_t's are independent innovations, even when $|\theta_j|$ decreases very rapidly, due to the infinitely many lags involved (see, e.g., Section 14.3, Davidson 1994). On the other hand, when $|\theta|_1 \equiv \sum_1^{\infty}|\theta_j| < \infty$, we can define 'finite-lag' approximators $\rho_{t,k} = \sum_{j=0}^{k}\theta_j V_{t-j}$ so that $E|\rho_t - \rho_{t,k}| = E|\sum_{k+1}^{\infty}\theta_j V_{t-j}| \le \sup_t ||V_t||_1 \sum_{k+1}^{\infty}|\theta_j|$ which is of the form $c_1\nu_k$ where $\nu_k = \sum_{k+1}^{\infty}|\theta_j| \to 0$ as $k \to \infty$.

Suppose V_t is strong mixing (e.g., when innovations are independent) with mixing coefficient $\alpha_m(\{V_t\}_{-\infty}^{\infty})$. Then the strong mixing coefficient of $\rho_{t,k}$ satisfies

$$\alpha_m(\{\rho_{t,k}\}_{t=-\infty}^{\infty}) \le \alpha_{m-k}(\{V_t\}_{-\infty}^{\infty}),$$

since the $\rho_{t,k}$ depends on lags $V_t, V_{t-1}, ..., V_{t-k}$. Note that $||\rho_{t,k}||_q \le \sum_{j=0}^{k}|\theta_j|\sup_t ||V_{t-k}||_q \le |\theta|_1 \sup_t ||V_t||_q$ which can be taken as the constant c_2.

Now note that the dependence term of interest is proportional to

$$\begin{aligned} & n^{-1}\sum_{t=1}^{n} E|E(\rho_t|\mathcal{F}_{t-m}) - E\rho_t| \\ & \le 6c_2\alpha_m(\{\rho_{t,k}\}_{t=-\infty}^{\infty})^{1-1/q} + 2c_1\nu_k \\ & \le 6c_2\alpha_{m-k}(\{V_t\}_{-\infty}^{\infty})^{1-1/q} + 2c_1\nu_k. \end{aligned}$$

Then one can take, for example, $k = \lceil m/2 \rceil$ (the integer part of $m/2$) and make the upperbound small for large m.

This shows that the current formulation of the inequality can handle dependence that is more general than strong mixing.

2.3 Proving the Triplex Inequality

The idea behind an upperbound with a decomposition into such three terms has appeared in econometric literature. For example, de Jong and Woutersen (2004) used this idea to treat an unbounded sum appearing in the binary choice models. The idea of our proof is related to a mixingale treatment seen in, for example, Chapter 16 of Davidson (1994). Since the specific form of the current inequality is not seen in these literatures, we will provide a proof below for completeness. The following Lemma will be used in the proof.

Lemma 1 *let $\{\mathcal{F}_t\}_{-\infty}^{\infty}$ be an increasing sequence of σ-fields. Let X_t be a random variable that is $\mathcal{F}_t$-measurable and is bounded so that $|X_t| \leq C$ for some constant C for each t. Then for any $\varepsilon > 0$ and positive integers n, m, we have*

$$P[|\sum_{t=1}^{n} X_t - E\sum_{t=1}^{n} X_t| > n\varepsilon] \leq 2me^{-n\varepsilon^2/(32m^2C^2)} + (2/\varepsilon)n^{-1}\sum_{t=1}^{n} E|E(X_t|\mathcal{F}_{t-m}) - EX_t|, \tag{1}$$

as long as the right hand side exists.

Proof for Lemma 1 Consider $U_n \equiv \sum_{t=1}^{n} X_t - E\sum_{t=1}^{n} X_t$, which can be 'telescoped' into $U_n = U_{1,n} + U_{2,n} + ... + U_{m,n} + V_n$ where $U_{1,n} = \{X_1 - E(X_1|\mathcal{F}_{1-1})\} + ... + \{X_n - E(X_n|\mathcal{F}_{n-1})\}$, $U_{2,n} = \{E(X_1|\mathcal{F}_{1-1}) - E(X_1|\mathcal{F}_{1-2})\} + ... + \{E(X_n|\mathcal{F}_{n-1}) - E(X_n|\mathcal{F}_{n-2})\}$,..., $U_{m,n} = \{E(X_1|\mathcal{F}_{1-(m-1)}) - E(X_1|\mathcal{F}_{1-m})\} + ... + \{E(X_n|\mathcal{F}_{n-(m-1)}) - E(X_n|\mathcal{F}_{n-m})\}$, $V_n = \{E(X_1|\mathcal{F}_{1-m}) - EX_1\} + ... + \{E(X_n|\mathcal{F}_{n-m}) - EX_n\}$. Then a union bound leads to

$$\begin{aligned}
&P[|U_n| > n\varepsilon] \\
&\leq P[|U_{1,n}| > n\varepsilon/(2m)] + P[|U_{2,n}| > n\varepsilon/(2m)] + ... + P[|U_{m,n}| > n\varepsilon/(2m)] \\
&+P[|V_n| > n\varepsilon/2].
\end{aligned} \tag{2}$$

Note that $U_{1,n}$ is a sum of n martingale differences each bounded in magnitude by $2C$. So $P[|U_{1,n}| > n\varepsilon/(2m)] \leq 2e^{-n\varepsilon^2/(32m^2C^2)}$ by applying a generalization of the Hoeffding's inequality to the martigale differences (see, e.g., Theorem 15.20, Davidson, 1994, or Theorem 9.1, Devroye, Györfi and Lugosi, 1996). Similarly is $P[|U_{j,n}| > n\varepsilon/(2m)] \leq 2e^{-n\varepsilon^2/(32m^2C^2)}$ for all $j = 1,...,m$. Now $P[|V_n| > n\varepsilon/2] \leq (2/\varepsilon)n^{-1}E|V_n| \leq (2/\varepsilon)n^{-1}\sum_{t=1}^{n} E|E(X_t|\mathcal{F}_{t-m}) - EX_t|$ using the Markov inequality and the triangular inequalities. Combining these upperbounds for the terms on the right hand side of (2) leads to the proof. Q.E.D.

The inequality appearing in the current lemma holds without assumption of a dependence structure. It still assumes a bounded X_t. Next we remove the boundedness assumption by incorporating a term related to the 'tail behavior' of a random variable ρ_t, which is now possibly unbounded.

Proof for Theorem 1 We will decompose $\rho_t = X_t + Y_t$ where $X_t = \rho_t I[|\rho_t| \leq C]$ and $Y_t = \rho_t I[|\rho_t| > C]$. Then $|\sum(\rho_t - E\rho_t)| \leq |\sum(X_t - EX_t)| + \sum|Y_t| + \sum E|Y_t|$ by using triangular inequalities. Then $P[\sum_1^n(\rho_t - E\rho_t)| > n\varepsilon] \leq P[|\sum_1^n(X_t - EX_t)| > n\varepsilon/3] + P[\sum_1^n |Y_t| > n\varepsilon/3] + P[\sum_1^n E|Y_t| > n\varepsilon/3]$ The first term is bounded by the preceding lemma by

$$2me^{-n\varepsilon^2/(288m^2C^2)} + (6/\varepsilon)n^{-1}\sum_{t=1}^{n} E|E(X_t|\mathcal{F}_{t-m}) - EX_t|.$$

The second term is bounded above by $(3/\varepsilon)n^{-1}\sum_1^n E|Y_t|$. The third term is a probability of a deterministic event, which is zero if the righthand side of the triplex inequality in Theorem 1 does not exceed one. Therefore $P[\sum_1^n(\rho_t - E\rho_t)| > n\varepsilon] \leq 2me^{-n\varepsilon^2/(288m^2C^2)} + (6/\varepsilon)n^{-1}\sum_{t=1}^n E|E(X_t|\mathcal{F}_{t-m}) - EX_t| + (3/\varepsilon)n^{-1}\sum_1^n E|Y_t|$. Now note that $|E|E(X_t|\mathcal{F}_{t-m}) - EX_t| - E|E(\rho_t|\mathcal{F}_{t-m}) - E\rho_t|| \leq E|E(Y_t|\mathcal{F}_{t-m}) - EY_t| \leq 2E|Y_t|$ using the triangular inequalities and the Jensen's inequality. Then $E|E(X_t|\mathcal{F}_{t-m}) - EX_t| \leq E|E(\rho_t|\mathcal{F}_{t-m}) - E\rho_t| + 2E|Y_t|$ and $P[\sum_1^n(\rho_t - E\rho_t)| > n\varepsilon] \leq 2me^{-n\varepsilon^2/(288m^2C^2)}$ $+(6/\varepsilon)n^{-1}\sum_{t=1}^n\{E|E(\rho_t|\mathcal{F}_{t-m}) - E\rho_t| + 2E|Y_t|\} + (3/\varepsilon)n^{-1}\sum_1^n E|Y_t|$ which leads to the proof of the theorem. Q.E.D.

3. Uniform Deviation

The above inequality (in Theorem 1) can be used to bound the probability of a large (pointwise) deviation $T_n(b) = \hat{R}(b) - R(b)$, where b is a parameter, $\hat{R}(b)$ is a sample average $\hat{R}(b) = n^{-1}\sum_{t=1}^n \rho(\omega_t, b)$ (where for each t, ω_t is measurable -$\mathcal{F}_t$ from an increasing sequence of σ-fields), and $R(b)$ is its expectation $R(b) = E\hat{R}(b)$. It is often of interest to bound the probability of a large *uniform* deviation $\sup_{b\in B}|T_n(b)|$ over a parameter space B for b.

The connection between the pointwise and uniform deviations can be obtained by covering B with many (say, Γ) smaller sets B_i's, so that $B \subset \cup_{i=1}^{\Gamma} B_i$. Choose b_i to be some parameter located in B_i for each i. Note that $\sup_{b\in B}|T_n(b)| \leq \max_{i=1}^{\Gamma}|T_n(b_i)| + \max_{i=1}^{\Gamma}\sup_{b\in B_i}|T_n(b) - T_n(b_i)|$. Then a union bound leads to:

Proposition 1 *For any nonstochastic* $\delta > 0$ *and any positive integer n,*

$$P[\sup_{b\in B}|T_n(b)| > 2\delta] \leq \sum_{i=1}^{\Gamma} P[|T_n(b_i)| > \delta] + \sum_{i=1}^{\Gamma} P[\sup_{b\in B_i}|T_n(b) - T_n(b_i)| > \delta]. \tag{3}$$

This is the basis for us to bound the probability of uniform large deviation. The first term involves pointwise deviations and can be bounded by the inequality derived before. The second term can be bounded when $T_n(b)$ 'often changes little' in a small set B_i. This can often achieved by assuming a Lipshitz condition for the summand $\rho(\omega_t, b)$ in argument b (see, e.g., Newey, 1991).

In machine learning, however, we often encounter summand $\rho(\omega_t, b)$ that is discontinuous in b. For example, the classification error can be written as $\rho(\omega_t, b) = |y_t - I[x_t'b > 0]|$, which is discontinuous in b, when a linear boundary (in predictor x_t) is used to classify a $\{0,1\}$ valued label y_t. (Here $\omega_t = (y_t, x_t)$.)

We will use a quite general framework that allows some continuous cases and some discontinuous cases as well as some 'mixed' cases. Let $\rho(\omega_t, b)$ be of the form $\rho(\omega_t, b) = f_t(b, A_t(b))$ where $f_t(\cdot,\cdot)$ is continuous in the first argument, but the second argument $A_t(b) = I[g(\omega_t, b) > 0]$ for some fixed function g that determines a decision boundary. The function f_t depends on t through observation ω_t. This framework can then include the following examples:

- (continuous) L_1-loss: $\rho = |y_t - x_t'b|$ (when $f_t(b,\cdot)$ is constant);
- (discontinuous) classification loss: $\rho = |y_t - I[x_t'b > 0]|$ (when $f_t(\cdot, A_t(b))$ is constant);
- 'mixed' loss such as $\rho = (1 - y_t)\alpha(x_t'b)I[\alpha(x_t'b) > 0]$, which may result from a loan decision of lending out amount $\alpha(x_t'b)$ (according to a continuous parametric model α) when $100y_t\%$ of the loan is paid back.

Under this framework we will bound the deviation $\sup_{b\in B_i}|T_n(b)-T_n(b_i)|$. This is summarized in the following Proposition, the proof of which is included in the Appendix.

Proposition 2 *For each parameter b in a convex set B_i that contains b_i, denote $T_n(b)=\hat{R}(b)-E\hat{R}(b)$, where $\hat{R}(b)=n^{-1}\sum_{t=1}^{n}\rho(\omega_t,b)$ and for each t, ω_t is measurable -$\mathcal{F}_t$ (from an increasing sequence of σ-fields). Assume that ρ has the form $\rho(\omega_t,b)=f_t(b,A_t(b))$ where $A_t(b)=I[g(\omega_t,b)>0]$ for some fixed function g that determines a decision boundary.*

Define S_i as the 'boundary set' $S_i=\cup_{b\in B_i}\{\omega_t : g(\omega_t,b)=0\}$. Assume that:

(A1): $g(\omega_t,b)$ is continuous in b and measurable in ω_t;

(A2): (Lipshitz condition) $\sup_{a=0,1}|f_t(b,a)-f_t(b^*,a))|\le N_{it}|b-b^*|_q$ for some $q>0$, for any $b,b^*\in B_i$;[2]

(A3): (Small boundary condition) The boundary set S_i is measurable and $n^{-1}\sum_{t=1}^{n}EI(\omega_t\in S_i)\le\delta/(12C)$ for some constants $\delta,C>0$.

Denote $\lambda=\sup_{b,b^*\in B_i}|b-b^*|_q$ and $M_{it}=|f_t(b_i,1)-f_t(b_i,0)|$.

For any constants $\delta,C>0$ and positive integers n,m, if (A3) holds, then we have:

$$\begin{aligned}
&P[\sup_{b\in B_i}|T_n(b)-T_n(b_i)|>\delta]\\
&\le(6\lambda/\delta)n^{-1}\sum_{t=1}^{n}E(N_{it}+EN_{it})I[N_{it}+EN_{it}>\delta/(6\lambda)]\\
&+(6/\delta)n^{-1}\sum_{t=1}^{n}EM_{it}I(M_{it}>C)\\
&+2me^{-n\delta^2/(1152m^2C^2)}+(12C/\delta)n^{-1}\sum_{t=1}^{n}E|E(I(\omega_t\in S_i)|\mathcal{F}_{t-m})-EI(\omega_t\in S_i)|,
\end{aligned}$$

as long as the right hand side exists.

3.1 Remarks

6. In the 'continuous case', $f_t(b,a)$ is constant in $a\in\{0,1\}$. We can then drop the last three terms in the above bound. This is because $M_{it}=0$ in this case and we can take $C\to 0$. In the 'discontinuous case', $f_t(b,a)$ is constant in b and we can drop the first term in the above bound, since the Lipshitz constant N_{it} can be taken as 0. The result above holds also for the more general 'mixed case' when $f_t(b,a)$ varies with both b and a.

7. Assumption A2 can often be validated by bounding the partial derivative of $f_t(b,a)$ on the first argument. In a later example with L_1 loss we will use a triangular inequality to validate this assumption.

8. Assumption A3 is related to $P(\omega_t\in S_i)$, the probability of an observation falling in the 'boundary set' S_i corresponding to a parameter set B_i. When B_i is small enough, we expect that the 'boundary set' will have small probability and A3 can be satisfied. The situation is clarified when $\omega_t=(y_t,x_t)$, $g(\omega_t,b)$ depends on ω_t only through predictor x_t, and $x_t=(w_t,v_t')'$ has a

2. For a vector v with component v_j's, define the ℓ_q norm as $|v|_q=(\sum_{j=1}^{\dim(v)}|v_j|^q)^{1/q}$ for $q\in(0,\infty)$, and $|v|_\infty=\sup_{j=1}^{\dim(v)}|v_j|$. We will also formally denote $|v|_0=\sum_{j=1}^{\dim(v)}I[|v_j|>0]$.

scalar component w_t and other components v_t, so that the decision boundary $[g(\omega_t, b) = 0]$ 'can be solved' as $[w_t = w(v_t, b)]$ for some fixed function w. In this case the boundary set $S_i = \{(w_t, v_t) : w_t = w(v_t, b), b \in B_i\} = [\inf_{b \in B_i} w(v_t, b) \le w_t \le \sup_{b \in B_i} w(v_t, b)]$ if B_i is compact and $w(v_t, b)$ is continuous in b. Suppose we use the ℓ_∞ norm and define $\lambda = \sup_{b,b^* \in B_i} |b - b^*|_\infty$. Denote $d_0 = \sup_{b,b^* \in B_i} |b - b^*|_0$. Then in the Appendix we will show that

$$P(\omega_t \in S_i) \le E_{\mathcal{V}_t}\{\sup_{w_t} p(w_t|\mathcal{V}_t) \sup_{b \in B_i} |\partial_b w(v_t, b)|_\infty\}\lambda d_0. \tag{4}$$

Here $\partial_b w(v_t, b)$ denotes a partial derivative of w, $\mathcal{V}_t$ is some σ-field such that v_t is measurable -$\mathcal{V}_t$ for each t, and $p(w_t|\mathcal{V}_t)$ denotes the conditional density. In the 'linear case'[3] assuming $\lambda < 2$, $g(\omega_t, b) = \pm w_t + v_t' b_v$ (so A1 is satisfied), we can take $w(v_t, b) = \mp v_t' b_v$ and $\sup_{b \in B_i} |\partial_b w(v_t, b)|_\infty = |v_t|_\infty$. If the conditional density is bounded above by constant c, then (4) becomes $P(\omega_t \in S_i) \le cE|v_t|_\infty \lambda d_0$. The assumption A3 will be satisfied for choosing $\lambda \le \delta/(12Cc \sup_t E|v_t|_\infty d_0)$, which restricts the size of B_i.

9. It is also noted that in this paper, we will consider 'boundary sets' of the 'solvable' form $S_i = [\inf_{b \in B_i} w(v_t, b) \le w_t \le \sup_{b \in B_i} w(v_t, b)]$ which is assumed to be measurable. In our later examples we will focus on 'linear solvable type' described above, with decision boundary $[w_t = \mp v_t' b_v]$, and B_i being a closed ℓ_∞ ball centered at b_i and with radius $h = \lambda/2 > 0$. Then $S_i = [\mp v_t'(b_i)_v - h|v_t|_1 \le w_t \le \mp v_t'(b_i)_v + h|v_t|_1]$ which is indeed measurable. [More generally, when $\sup_{b \in B_i} w(v_t, b)$ and $\inf_{b \in B_i} w(v_t, b)$ are both continuous in v_t, S_i is measurable.]

We will analyze the bound in Proposition 2 term by term in the later examples. The terms $E(N_{it} + EN_{it})I[N_{it} + EN_{it} > \delta/(6\lambda)]$ and $EM_{it}I(M_{it} > C)$ are tail terms. We can choose sufficiently small λ and sufficiently large C to make them small.

The dependence term $E|E(I(\omega_t \in S_i)|\mathcal{F}_{t-m}) - EI(\omega_t \in S_i)|$ will be small for large m when ω_t can be approximated by strong mixing sequences in some sense.

The exponential term $2me^{-n\delta^2/(1152m^2C^2)}$ can be made small by choosing m and C to depend on n in certain ways. We can allow δ to depend on n also, which will lead to convergence rates.

4. A Continuous Example

Consider $\rho_t = \rho(\omega_t, b) = |Y_t - b_1 Y_{t-1} - \ldots - b_r Y_{t-r}|$ (where $\omega_t = (Y_t, \ldots, Y_{t-r})$ and $b = (b_1, \ldots, b_r)$), which represents predicting Y_t by r of its own lags under an L_1 loss. We will allow r to increase with n later to allow high dimensionality. We will bound the probability of a large uniform deviation $\sup_{b \in B} |n^{-1} \sum_{t=1}^n \rho_t - n^{-1} \sum_{t=1}^n E\rho_t|$ over an ℓ_∞ ball $B = [|b|_\infty \le C_b]$ with a constant radius $C_b > 0$.

Suppose the true model for Y_t follows an $MA(\infty)$ model $Y_t = \sum_{j=0}^\infty \theta_j Z_{t-j}$, where θ_j's are fixed coefficients with a finite ℓ_1 norm $|\theta|_1 = \sum_0^\infty |\theta_j| < \infty$, and Z_j's are 'innovations', which are assumed to be iid (independent and identically distributed) with zero mean and finite variance. Although we have assumed Y_t to be centered to have mean zero and that there is no intercept term used in the L_1 loss, this is only for convenience and similar results can be obtained without this assumption.

We will consider a case of exponentially decaying θ_j's, but each θ_j can be nonzero:

3. In the 'linear case' the decision rule $[g(\omega_t, b) > 0]$ has the form $[w_t b_w + v_t' b_v > 0]$. We can always rescale the coefficients $b = (b_w, b_v')'$ by a scalar multiple. One such standardization used in Horowitz (1992) is such that $|b_w| = 1$ or $b_w \in \{-1, +1\}$. Note that for small enough set B_i with $\lambda = \sup_{b,b' \in B_i} |b - b'|_\infty < 2$, b_w is constant in B_i and takes a common sign. We can pick either sign to proceed.

Condition (B1): $\sum_{j=k}^{\infty}|\theta_j| < \nu^k$ *for all large enough* k*, for some* $\nu \in (0,1)$.

This is a situation when Y_t can have a dependence structure that is not strong mixing, since it involves the infinite past of Z_{t-j}'s (see, e.g., Davidson, 1994, Section 14.3). On the other hand, the dependence term in Theorem 1 can be bounded by L_1 approximation of strong mixing and we have the following result (proved in Appendix, where $\mathcal{F}_t$ is the σ-field generated by $\{Z_s\}_{s=-\infty}^{t}$ for each t):

$$E|E(\rho_t|\mathcal{F}_{t-m}) - E\rho_t| \le 2(r+1)(C_b+1)E|Z_1| \sum_{j=k+1}^{\infty}|\theta_j| \text{ for any positive integer } k < m-r. \quad (5)$$

In order to bound the tail term in Theorem 1, we use, for some finite constants $u, C_u > 0$,

$$E|\rho_t|I(|\rho_t| > C) \le (r+1)^2(C_b+1)||Z_1||_2|\theta|_1 C_u e^{-uC(C_b+1)^{-1}(r+1)^{-1}/2}, \quad (6)$$

which is proved in the Appendix assuming an additional condition:
Condition (B2): For innovation Z_1*, the cumulant generating function* $K(u) = \ln Ee^{Z_1 u}$ *is continuously differentiable at* 0. *(E.g.,* Z_1 *can be a Gaussian innovation.)*

Now we apply Proposition 2, where only the first term of the bound is relevant in this continuous case due to Remark 6. The Lipshitz constant N_{it} can be obtained from the triangular inequality $|\rho(\omega_t,b) - \rho(\omega_t,b^*)| \le |b_1 - b_1^*||Y_{t-1}| + \dots + |b_r - b_r^*||Y_{t-r}| \le (|Y_{t-1}| + \dots + |Y_{t-r}|)|b-b^*|_\infty$. So we can take $N_{it} = |Y_{t-1}| + \dots + |Y_{t-r}|$ (using ℓ_∞ norm). We have

$$E(N_{it} + EN_{it})I(N_{it} + EN_{it} > \delta/(6\lambda)) \le (2r^2|\theta|_1||Z_1||_2)C_u e^{-u\psi/2}, \quad (7)$$

for some finite constants $u, C_u > 0$, where $\psi = \delta/(6r\lambda) - E|Z_1||\theta|_1$, which is proved in the Appendix.

Now we apply (3), Theorem 1 and Proposition 2 and combine all terms together (using (5), (6) and (7)) to obtain:

For any positive integers $k < m-r$, m, n, and positive C, δ, we have

$$\begin{aligned}
&P[\sup_{b\in B}|n^{-1}\sum_{t=1}^{n}(\rho_n - E\rho_t)| > 2\delta] \\
&\le \Gamma 2me^{-n\delta^2/(288m^2C^2)} \\
&+\Gamma(6/\delta)2(r+1)(C_b+1)E|Z_1|\sum_{j=k+1}^{\infty}|\theta_j| \\
&+\Gamma(15/\delta)(r+1)^2(C_b+1)||Z_1||_2|\theta|_1 C_u e^{-uC(C_b+1)^{-1}(r+1)^{-1}/2} \\
&+\Gamma(6\lambda/\delta)(2r^2|\theta|_1||Z_1||_2)C_u e^{-u(\delta/(6r\lambda)-E|Z_1||\theta|_1)/2}. \quad (8)
\end{aligned}$$

Here $B = [|b|_\infty \le C_b] = [-C_b, C_b]^r$ for some constant radius $C_b > 0$. We will consider a high dimensional case where the number of lags can increase with sample size n:
Condition (B3): $r = O((\ln n)^M)$ *for some power* $M > 0$.

Note that we can take $B_1, \dots, B_\Gamma$ to be Γ closed ℓ_∞ balls of radius $\lambda/2$ to cover B, where $\Gamma \le (2C_b/\lambda + 1)^r$.

We will let $\delta = n^{-0.5+\gamma_1}/2$ for some small $\gamma_1 > 0$, $m = C = \lceil n^{\gamma_1/4}\rceil$, $\lambda = n^{-1}$, $k = m - 2r$. Then under conditions (B1) to (B3), $\ln\Gamma = O((\ln n)^{M_1})$ for some $M_1 > 0$ and all four terms in the above inequality (8) are $O(e^{-c_1 n^{c_2}})$ for some $c_1, c_2 > 0$ dependent on γ_1. Therefore we have:

Proposition 3 *Under Conditions (B1) to (B3), for any small* $\gamma_1 > 0$,

$$P[\sup_{b \in B} |n^{-1} \sum_{t=1}^{n} (\rho_t - E\rho_t)| > n^{-0.5+\gamma_1}] = O(e^{-c_1 n^{c_2}}).$$

The rate of uniform convergence remains nearly 'parametric' $O_P(n^{-0.5})$ in this case, despite the high dimensionality of set B.

5. A Discontinuous Example

Let $\omega_t = (y_t, x_t)$, where y_t is a real-valued response at t and $x_t = (1, y_{t-1}, ..., y_{t-r}, z_t')'$ is a vector of predictors that can include r lags of y as well as a vector of exogenous variable z_t. Suppose we are interested in predicting the sign of y_t by using a discontinuous loss $\rho_t = |I(y_t > 0) - I(x_t' b > 0)|$. We will bound the probability of a large uniform deviation $\sup_{b \in B} |n^{-1} \sum_{t=1}^{n} (\rho_t - E\rho_t)|$ over a set of 'variable selection' $B = [|b|_0 \leq v, |b|_\infty \leq C_b, |b_{r+2}| = 1]$, where $|b|_0 \equiv \sum_{j=1}^{\dim(b)} I|b_j| > 0]$ counts the number of selected x-components, $|b|_\infty \leq C_b$ bounds the parameter space, and $|b_{r+2}| = 1$ is due to a standardization for the coefficient of the first component of z_t (see Footnote 2). Later we will allow v (maximal number of selected variables), r (number of lags allowed) and $K \equiv \dim(z_t)$ to increase with n in certain ways for high dimensional variable selection.

The true model of y_t is assumed to be an $MA(\infty)$ transform of a strong mixing process: $y_t = \sum_{j=0}^{\infty} \theta_j f_j(z_{t-j}, \varepsilon_{t-j})$, where f_j is some fixed measurable function for each j so that $\sup_{t,j} ||f_j(z_t, \varepsilon_t)||_1 < \infty$, and ε_t is a stochastic sequence independent of z_t called the 'innovation'. We assume that:

Condition (C1): $\{z_t, \varepsilon_t\}$ *is strong mixing with mixing coefficient* α_m *decreasing exponentially fast in* m.

Condition (C2): $\sum_{j=k+1}^{\infty} |\theta_j|$ *decreases exponentially fast in* k.

Note that y_t itself may no longer be strong mixing due to its dependence on the infinite past. These assumptions are satisfied in many situations. For example, in an ARX model $y_t = \varphi y_{t-1} + z_t' \beta + \varepsilon_t$ ($|\varphi| < 1$), an $MA(\infty)$ representation gives $y_t = \sum_{j=0}^{\infty} \varphi^j (z_{t-j}' \beta + \varepsilon_{t-j})$. Here, ε_t does not have to be iid; it can be an 'exponential' strong (or β-) mixing process such as a GARCH process (see, e.g., Francq and Zakoïan, 2006) when y_t follows an ARX-GARCH model.

In the Appendix, we show that under some additional conditions (C3 and C4) on the underlying process $\{z_t, \varepsilon_t\}$, we have, for any positive integer $k < m - r$,

$$E|E(\rho_t|\mathcal{F}_{t-m}) - E\rho_t| \leq 6\alpha_{m-r-k} + 8(\sqrt{2M_y} + \sqrt{2M_x r C_b}) \sqrt{\sup_{t,l} ||f_l(z_t, \varepsilon_t)||_1 \sum_{j>k} |\theta_j|}. \qquad (9)$$

Here M_x, M_y are constants appearing in these additional conditions:

Condition (C3): y_t *follows a model of the form* $y_t = F_t + \varepsilon_t$ *where* F_t *depends on the history* $(\{z_s\}_{\infty}^{t}, \{\varepsilon_s\}_{-\infty}^{t-1})$ *and* ε_t *is an innovation that has a conditional density* $p(\varepsilon_t | \{z_s\}_{\infty}^{t}, \{\varepsilon_s\}_{-\infty}^{t-1})$ *bounded above by a constant* M_y *(which is satisfied, for example, by* $N(0, \sigma^2)$ *innovations).*

Condition (C4): The conditional density $p(z_{t,1} | z_{t,2}, ..., z_{t,K}, \{z_s, \varepsilon_s\}_{-\infty}^{t-1})$ *is bounded above by a constant* M_x.

We can cover B by Γ sets $B_i \subset B$, $i = 1, ..., \Gamma$, with each B_i being a closed ℓ_∞ ball centered at some b_i, with radius $h = \lambda/2 > 0$, and with dimension at most $v - 1$. This is explained in the Appendix, where we also show that we can take

$$\Gamma \leq 2v(K + r)^{v-1} (2C_b/\lambda + 1)^{v-1} \qquad (10)$$

as an upperbound obtained from a combinatorial argument. Now we try to apply Proposition 2.

Assumption (A1) is obviously satisfied since $g(\omega_t, b) = x_t'b$. We will show that assumption (A3) holds for all large n in the Appendix, with an additional condition (C5) and with suitable choices of δ, λ (the ℓ_∞ diameter of B_i), r (the number of lags) and v (the maximal number of selected variables) to be specified later. This additional condition is:

Condition (C5): The exogenous variables are bounded above by a finite constant: $|z_t|_\infty \leq C_z$.

Assumption (A2) is satisfied with $N_{it} = 0$ due to this 'discrete' situation (see Remark 6). So the first term of the bound in Proposition 2 is zero. We can take $M_{it} = ||I(y_t > 0) - 1| - |I(y_t > 0) - 0|| = 1$ and $C = 1$ so the second term of the bound is zero also.

In the Appendix we evaluate the last term which is determined by $E|E(I(\omega_t \in S_i)|\mathcal{F}_{t-m}) - EI(\omega_t \in S_i)|$. Assuming (C4), we have, for any positive integer $k < m - r$,

$$E|E(I(\omega_t \in S_i)|\mathcal{F}_{t-m}) - EI(\omega_t \in S_i)| \leq 6\alpha_{m-r-k} + 4\sqrt{r\sum_{j>k}|\theta_j|\sup_{t,l}||f_l(z_t,\varepsilon_t)||_1(2M_x 2(1+C_b+h))}. \tag{11}$$

Now combine the applications of (3), Theorem 1 (with $C = 1$, or just use Lemma 1), and Proposition 2, apply Equations (9) and (11) and we obtain:

For any positive integers $k < m - r$, m, n, and positive δ,

$$\begin{aligned}
&P[\sum_{b\in B}|n^{-1}\sum_{t=1}^{n}(\rho_t - E\rho_t)| > 2\delta] \\
&\leq \Gamma 2me^{-n\delta^2/(32m^2)} \\
&+\Gamma(2/\delta)\left\{6\alpha_{m-r-k} + 8(\sqrt{2M_y} + \sqrt{2M_x rC_b})\sqrt{\sup_{t,l}||f_l(z_t,\varepsilon_t)||_1\sum_{j>k}|\theta_j|}\right\} \\
&+\Gamma 2me^{-n\delta^2/(1152m^2)} \\
&+\Gamma(12/\delta)\left\{6\alpha_{m-r-k} + 4\sqrt{r\sum_{j>k}|\theta_j|\sup_{t,l}||f_l(z_t,\varepsilon_t)||_1(2M_x 2(1+C_b+\lambda/2))}\right\}.
\end{aligned} \tag{12}$$

Now choose parameters to make the bound small. Note that we can take $\Gamma \leq 2v(K+r)^{v-1}(2C_b/\lambda + 1)^{v-1}$. We have assumed exponential decay for α_k and $\sum_{j>k}|\theta_j|$ in k.

Let $C_b > 0$ be a constant in n. Assume the following condition on the various dimension parameters:

Condition (C6): The number of lags $r = O((\ln n)^{M_1})$ for some power $M_1 > 0$; the number of exogenous variables $K = O(n^{M_2})$ for some power $M_2 > 0$, which can form a very-high dimensional candidate predictor, with dimension possibly large than sample size n; the number of selected variables $v = O((\ln n)^{M_3})$ for some power $M_3 > 0$.

We will let $\delta = n^{-0.5+\gamma_1}/2$ for some small $\gamma_1 > 0$, $m = \lceil n^{\gamma_1/4}\rceil$, $\lambda = n^{-1}$, $k = \lceil(m-r)/2\rceil$. Then $\ln\Gamma = O((\ln n)^{M_4})$ for some $M_4 > 0$ and all four terms in the above inequality (12) are $O(e^{-c_1 n^{c_2}})$ (for some $c_1, c_2 > 0$ dependent on γ_1), when Conditions (C1) to (C6) are assumed. Therefore we have:

Proposition 4 *Under conditions (C1) to (C6), for any small $\gamma_1 > 0$,*

$$P[\sup_{b\in B}|n^{-1}\sum_{t=1}^{n}(\rho_n - E\rho_t)| > n^{-0.5+\gamma_1}] = O(e^{-c_1 n^{c_2}}).$$

The rate of uniform convergence remains nearly 'parametric' $O_P(n^{-0.5})$ in this case, despite the high dimensionality of set B.

6. Discussion

This paper presents a very general inequality that generalizes Hoeffding's inequality to dependent and unbounded summands. The inequality may not be very tight, but it involves few assumptions and can be very useful in deriving convergence rates of pointwise and uniform deviations in a number of situations that cannot be dealt with before. We gave two examples here, one with L_1 loss and another on sign classification. There are other examples that may be worked out (e.g., with L_2 loss or with log-likelihood) which are not considered here. We hope that the current work can serve as a probablistic foundation to the theory of empirical risk minimization for many situations with dependent data and unbounded loss.

The current results involve a high dimensional parameter b; near-parametric convergence rates are obtained in examples with exponentially small 'unboundedness' (characterized by existence of some moment generating function) and with certain kinds of exponentially decaying temporal dependence. We expect that slower convergence rates may be obtained with more severe 'unboundedness', or with a slower decay of temporal dependence, using the same techniques.

Although the number of selected variables is restricted to $O((\log n)^M)$, we can allow these variables to be selected from a much higher number of candidate regressors of dimension up to n^M for any finite positive M, and still maintain a near-parametric convergence rate. This is demonstrated in Section 5 and is also true if we add in regressors and make an ARX model for Section 4. (In fact it is also possible to allow a higher number of selected variables such as n^a for some $a \in (0,1)$, but this will correspond to a slower convergence rate.)

It is noted that there exists much previous work in addressing the problems considered in this paper, in addition to the related work mentioned in the Introduction (we thank the reviewers for bringing our attention to these additional references). In the direction of unbounded loss, Meir and Zhang (2003) consider uniform deviations for iid data using a bound of the Rademaker complexity. Various ratios of empirical processes can also be used to handle unboundedness (see, e.g., Haussler, 1992; Pollard, 1995; Bartlett and Lugosi, 1999; Bercu, Gassiat and Rio, 2002). Bercu, Gassiat and Rio (2002) present a ratio-type result that can relax the assumption on the 'unboundedness' while proving exponential concentration for iid data. In the direction of dependence, McDiarmid (1998, e.g., Theorem 3.8) uses the method of bounded differences and includes a term related to a 'bad set' of events involving a large variance. Uniform inequalities have also been obtained for martingales (see, e.g., van de Geer, 2000, Theorem 8.13). In the direction of high dimensionality, typical uniform deviation results deal with infinite-dimensional function space (see, e.g, good summaries in Bousquet, Boucheron, and Lugosi, 2003 and van de Geer, 2000).

In comparison, our method addresses the three aspects (unboundedness, dependence, high dimensionality) simultaneously with a relative simple approach. While the additional references can sometimes handle one aspect better, they typically do not address the other aspects in the same time. For example, McDiarmid (1998, e.g., Theorem 3.8) can potentially handle data that are dependent 'in multi-dimensions' (such as random graph or spatial dependence), while our method only addresses 'one-dimensional' dependence (i.e., a time series). On the other hand, McDiarmid's method also requires bounded differences which would require some kind of boundedness (e.g., bounded summands in the case of an iid average) while we do not need this assumption. In addition, we note that the 'bad set' term bounding the probability of a large variance will often require applying a large deviation inequality again, while our triplex inequality is one in closed form.

Many of these additional references do not treat dependence to the same degree of generality as the current paper. For example, traditional treatments with symmetrization and Rademaker average such as Meir and Zhang (2003) are suitable only for iid data. Ratio-type results such as Bercu, Gassiat, Rio (2002) can relax the assumption on the 'unboundedness' while proving exponential concentration for iid data, but it is not clear how this can be extended to general dependent situations. The chaining technique described in, for example, van de Geer (2000, Section 3.2) and Bousquet, Boucheron and Lugosi (2003, Section 5) may be used to improve the convergence rate by a $\log n$ factor in the finite dimensional case. However, most applications of this technique are for independent data or martingales. Our dependence term, on the other hand, is put in the framework of mixingale, which is more general than martingales as discussed in Remark 4.

Typical uniform deviation results deal with infinite-dimensional function spaces. Our formulation is for a somewhat less general situation where the functions are parameterized, and we formulated uniform convergence on a high dimensional parameter space. Although it may be possible to formulate uniform convergence on function spaces directly for dependent data (see, e.g., Yu, 1994 for beta-mixing and Vidyasagar, 2005 for alpha-mixing), we choose the parametric covering framework which is less abstract and easier to understand, and demonstrates the convergence rates more clearly. The result of such a formulation is that a reader with an elementary background on probability and real analysis can follow the development easily, and arrive at such advanced results as the convergence rates with high dimensional variable selection. Although the formulation is deliberately elementary, the results are powerful enough to handle such complicated dependent situations as the sign prediction for an ARX process with GARCH error in Section 5.

Appendix A.

Proof of Proposition 2 Note that for any $b \in B_i$, $|T_n(b) - T_n(b_i)| = |n^{-1}\sum_{t=1}^n \{f_t(b, A_t(b)) - f_t(b_i, A_t(b_i))\} - n^{-1}\sum_{t=1}^n E\{f_t(b, A_t(b)) - f_t(b_i, A_t(b_i))\}|$. We therefore investigate the differences of the form $f_t(b, A_t(b)) - f_t(b_i, A_t(b_i)) = \{f_t(b, A_t(b)) - f_t(b_i, A_t(b))\} + \{f_t(b_i, A_t(b)) - f_t(b_i, A_t(b_i))\}$.

Note that $|f_t(b_i, A_t(b)) - f_t(b_i, A_t(b_i))| = M_{it}|A_t(b) - A_t(b_i)|$ where $M_{it} = |f_t(b_i, 1) - f_t(b_i, 0)|$, and $|f_t(b, A_t(b)) - f_t(b_i, A_t(b))| \le \sup_{b,b^* \in B_i}\sup_{a=0,1}|f_t(b,a) - f_t(b^*,a))| \le N_{it}\lambda$, where $\lambda \equiv \sup_{b,b^* \in B_i}|b - b^*|_q$, if we assume a Lipshitz condition $\sup_{a=0,1}|f_t(b,a) - f_t(b^*,a))| \le N_{it}|b - b^*|_q$ under an ℓ_q-norm for some $q > 0$.

We then combine the statements before and apply the triangular inequalities to obtain $|T_n(b) - T_n(b_i)| \le n^{-1}\sum_{t=1}^n N_{it}\lambda + n^{-1}\sum_{t=1}^n M_{it}|A_t(b) - A_t(b_i)| + n^{-1}\sum_{t=1}^n EN_{it}\lambda + n^{-1}\sum_{t=1}^n EM_{it}|A_t(b) - A_t(b_i)|$.

Now note that $|A_t(b) - A_t(b_i)| \le I(\omega_t \in S_i)$ where S_i is the 'boundary set $S_i = \cup_{b \in B_i}\{\omega_t : g(\omega_t, b) = 0\}$. This is true when we assume that $g(\omega_t, b)$ is continuous in b and B_i is convex.

[The difference $|A_t(b)-A_t(b_i)|$ is $\{0,1\}$ valued and takes value 1 only when only one of $g(\omega_t,b)$ and $g(\omega_t,b_i)$ is positive. This would imply $g(\omega_t,b^*)=0$ at some intermediate point b^* on the line segment between b and b_i, which must fall in B_i due to its convexity. A similar technique is used in Jiang and Tanner (2007) for a binary choice model with $g(\omega_t,b)$ linear in b.]

The above statements hold for any $b\in B_i$. Therefore

$$\begin{aligned}
&\sup_{b\in B_i}|T_n(b)-T_n(b_i)|\\
&\le n^{-1}\sum_{t=1}^n N_{it}\lambda+n^{-1}\sum_{t=1}^n M_{it}I(\omega_t\in S_i)+n^{-1}\sum_{t=1}^n EN_{it}\lambda+n^{-1}\sum_{t=1}^n EM_{it}I(\omega_t\in S_i)\\
&\le n^{-1}\sum_{t=1}^n (N_{it}+EN_{it})\lambda+n^{-1}\sum_{t=1}^n CI(\omega_t\in S_i)+n^{-1}\sum_{t=1}^n CEI(\omega_t\in S_i)\\
&+n^{-1}\sum_{t=1}^n\{M_{it}I(M_{it}>C)+EM_{it}I(M_{it}>C)\},
\end{aligned}$$

by noting that $M_{it}I(\omega_t\in S_i)\le CI(\omega_t\in S_i)+M_{it}I(M_{it}>C)$ for any constant $C>0$.

Then

$$\begin{aligned}
&P[\sup_{b\in B_i}|T_n(b)-T_n(b_i)|>\delta]\\
&\le P[n^{-1}\sum_{t=1}^n(N_{it}+EN_{it})\lambda>\delta/3]\\
&+P[n^{-1}\sum_{t=1}^n CI(\omega_t\in S_i)+n^{-1}\sum_{t=1}^n CEI(\omega_t\in S_i)>\delta/3]\\
&+P[n^{-1}\sum_{t=1}^n\{M_{it}I(M_{it}>C)+EM_{it}I(M_{it}>C)\}>\delta/3]\\
&\le P[n^{-1}\sum_{t=1}^n(N_{it}+EN_{it})\lambda>\delta/3]\\
&+(6/\delta)n^{-1}\sum_{t=1}^n EM_{it}I(M_{it}>C)\\
&+P[n^{-1}\sum_{t=1}^n\{I(\omega_t\in S_i)-EI(\omega_t\in S_i)\}>\delta/(3C)-2n^{-1}\sum_{t=1}^n EI(\omega_t\in S_i)]\\
&\le(6\lambda/\delta)n^{-1}\sum_{t=1}^n E(N_{it}+EN_{it})I[N_{it}+EN_{it}>\delta/(6\lambda)]\\
&+(6/\delta)n^{-1}\sum_{t=1}^n EM_{it}I(M_{it}>C)\\
&+P[n^{-1}\sum_{t=1}^n\{CI(\omega_t\in S_i)-CEI(\omega_t\in S_i)\}>\delta/6],
\end{aligned}$$

where in the last step we assume that $n^{-1}\sum_{t=1}^n EI(\omega_t\in S_i)\le\delta/(12C)$ and have used $P[n^{-1}\sum_{t=1}^n X_t>2Q]\le Q^{-1}n^{-1}\sum_{t=1}^n EX_tI[X_t>Q]$ for nonnegative $X=N_{it}+EN_{it}$ and constant $Q=\delta/(6\lambda)$. [Note that $n^{-1}\sum_{t=1}^n X_t=n^{-1}\sum_{t=1}^n X_tI[X_t>Q]+n^{-1}\sum_{t=1}^n X_tI[X_t\le Q]\le Q+n^{-1}\sum_{t=1}^n X_tI[X_t>Q]$ and use Markov inequality.]

Now apply the pointwise inequality (1) on the last term and we obtain Proposition 2. Q.E.D.

Proof of Equation (4) in Remark 8

$$\begin{aligned}
&P(\omega_t \in S_i) = P[w_t \in [\inf_{b\in B_i} w(v_t,b), \sup_{b\in B_i} w(v_t,b)]] \\
&\leq E_{\mathcal{V}_t} \sup_{w_t} p(w_t|\mathcal{V}_t)|\sup_{b\in B_i} w(v_t,b) - \inf_{b\in B_i} w(v_t,b)| \\
&\leq E_{\mathcal{V}_t} \sup_{w_t} p(w_t|\mathcal{V}_t) \sup_{b,b^*\in B_i} |w(v_t,b) - w(v_t,b^*)| \\
&\leq E_{\mathcal{V}_t} \{\sup_{w_t} p(w_t|\mathcal{V}_t) \sup_{b\in B_i} |\partial_b w(v_t,b)|_\infty\} \sup_{b,b^*\in B_i} |b-b^*|_\infty \sup_{b,b^*\in B_i} |b-b^*|_0 \\
&= E_{\mathcal{V}_t} \{\sup_{w_t} p(w_t|\mathcal{V}_t) \sup_{b\in B_i} |\partial_b w(v_t,b)|_\infty\} \lambda d_0.
\end{aligned}$$

Q.E.D.

Proof of Equation (5) Define $Y_{t,k} = \sum_{j=0}^{k} \theta_j Z_{t-j}$ and $\rho_{t,k} = |Y_{t,k} - b_1 Y_{t-1,k} - \dots - b_r Y_{t-r,k}|$, which are strong mixing due to dependence on finite number of lags. We then have the L_1 approximation error $E|\rho_t - \rho_{t,k}| \leq (C_b+1)E(|Y_t - Y_{t,k}| + \dots + |Y_{t-r} - Y_{t-r,k}|) \leq (r+1)(C_b+1)E|Z_1|\sum_{j=k+1}^{\infty}|\theta_j|$. Then the technique in Section 2.2 implies that $E|E(\rho_t|\mathcal{F}_{t-m}) - E\rho_t| \leq 6\sup_{t,k}||\rho_{t,k}||_2 \alpha_{m-k-r}(\{Z_t\})^{1/2}$ $+2(r+1)(C_b+1)E|Z_1|\sum_{j=k+1}^{\infty}|\theta_j|$.

Note that $\alpha_{m-k-r}(\{Z_t\}) = 0$ for $m > k+r$, We have (5). Q.E.D.

Proof of Equation (6) We note that $|\rho_t| \leq (C_b+1)(|Y_t| + \dots + |Y_{t-r}|)$ and therefore $E|\rho_t|I(|\rho_t| > C) \leq (C_b+1)E(|Y_t| + \dots + |Y_{t-r}|)\sum_{s=0}^{r} I(|Y_{t-s}| > C(C_b+1)^{-1}(r+1)^{-1}) \leq (1+r)^2(C_b+1)\sup_{t,s} E|Y_t|I(|Y_s| > C(C_b+1)^{-1}(r+1)^{-1})$. Note that for $\eta = C(C_b+1)^{-1}(r+1)^{-1}$, we have

$$\begin{aligned}
&E|Y_t|I(|Y_s| > \eta) \\
&\leq ||Y_t||_2 ||I(|Y_s| > \eta)||_2 \\
&\leq (\sum_{j=0}^{\infty} |\theta_j| ||Z_{t-j}||_2) \sqrt{(Ee^{u|Y_s|})e^{-u\eta}} \\
&= ||Z_1||_2 |\theta|_1 \sqrt{(Ee^{u|Y_1|})} e^{-u\eta/2} \\
&\leq ||Z_1||_2 |\theta|_1 C_u e^{-u\eta/2}
\end{aligned}$$

for some positive u and C_u such that $Ee^{u|Y_s|} \leq C_u^2 < \infty$. This is achieved for some small enough u since

$$\begin{aligned}
&Ee^{\pm uY_s} = \exp\{\sum_{j=0}^{\infty} \ln Ee^{\pm u\theta_j Z_1}\} = \exp\{\sum_{j=0}^{\infty} K(\pm u\theta_j)\} \\
&\leq \exp\{\sum_{j=0}^{\infty} \sup_{|v|\leq u|\theta|_1} |K'(v)||u\theta_j|\} \leq \exp\{\sup_{|v|\leq u|\theta|_1} |K'(v)|u|\theta|_1\}.
\end{aligned}$$

Then

$$Ee^{u|Y_s|} \leq Ee^{uY_s} + Ee^{-uY_s} \leq 2\exp\{\sup_{|v|\leq u|\theta|_1} |K'(v)|u|\theta|_1\} \equiv C_u^2 < \infty$$

for some small enough u, due to continuous differentiability of $K(\cdot)$ at 0, which is assumed in Condition (B2). These lead to (6). Q.E.D.

Proof of Equation (7) Note that $EN_{it} = rE|Y_1| \leq rE|Z_1||\theta|_1$, and

$$\begin{aligned}
&E(N_{it}+EN_{it})I(N_{it}+EN_{it} > \delta/(6\lambda)) \\
&\leq E(|Y_{t-1}|+...+|Y_{t-r}|+rE|Y_1|)I(|Y_{t-1}|+...+|Y_{t-r}| > \delta/(6\lambda) - rE|Z_1||\theta|_1) \\
&\leq E(|Y_{t-1}|+...+|Y_{t-r}|+rE|Y_1|)\sum_{s=1}^{r} I(|Y_{t-s}| > \delta/(6r\lambda) - E|Z_1||\theta|_1) \\
&\leq |||Y_{t-1}|+...+|Y_{t-r}|+rE|Y_1|||_2||\sum_{s=1}^{r} I(|Y_{t-s}| > \delta/(6r\lambda) - E|Z_1||\theta|_1)||_2 \\
&\leq (2r||Y_1||_2)r\sqrt{Ee^{u|Y_1|}}e^{-u\psi/2} \\
&\leq (2r^2|\theta|_1||Z_1||_2)C_u e^{-u\psi/2}
\end{aligned}$$

for some small enough $u > 0$, where $\psi = \delta/(6r\lambda) - E|Z_1||\theta|_1$, and C_u is defined in Proof of Equation (6). Q.E.D.

Proof of Equation (9) We notice the process (y_t, x_t) can be approximated by strong mixing processes. This is because if we define $y_{t,k} = \sum_{j=0}^{k}\theta_j f_j(z_{t-j}, \varepsilon_{t-j})$, and $x_{t,k} = (1, y_{t-1,k}, ..., y_{t-r,k}, z_t')'$ then $||y_t - y_{t,k}||_1 \leq \sum_{j>k}|\theta_j|\sup_{t,l}||f_l(z_t,\varepsilon_t)||_1$ and $||x_t - x_{t,k}||_1 \equiv E|x_t - x_{t,k}|_1 = \sum_{s=t-1}^{t-r}||y_s - y_{s,k}||_1 \leq r\sum_{j>k}|\theta_j|\sup_{t,l}||f_l(z_t,\varepsilon_t)||_1$, both of which will decrease exponentially fast with k. On the other hand, $(y_{t,k}, x_{t,k})$ is a measurable transform of $(z_t, ..., z_{t-r-k}, \varepsilon_t, ..., \varepsilon_{t-r-k})$ and is therefore strong mixing with mixing coefficient α_{m-r-k} for $m > r+k$.

Now define $\rho_{t,k} = |I(y_{t,k} > 0) - I(x_{t,k}'b > 0)|$. The technique in Section 2.2 implies that $E|E(\rho_t|\mathcal{F}_{t-m}) - E\rho_t| \leq E|E(\rho_{t,k}|\mathcal{F}_{t-m}) - E\rho_{t,k}| + 2E|\rho_t - \rho_{t,k}|$ where $\mathcal{F}_t$ represents the σ-field generated by $(z_s, \varepsilon_s)_{-\infty}^{t}$. The first term is bounded by $6\alpha_{m-r-k}$ by using Theorem 14.2, Davidson (1994).

Applying the triangular inequalities, the second term is at most $2||I(y_t > 0) - I(y_{t,k} > 0)||_1 + 2||I(x_t'b > 0) - I(x_{t,k}'b > 0)||_1$. We will assume that (†) $P[|y_t| \leq \Delta] \leq M_y(2\Delta)$ for any small $\Delta > 0$, for some constant $M_y < \infty$. This is true under Condition (C3).

We will also assume that (‡) $P[|x_t'b| \leq \Delta] \leq M_x(2\Delta)$ for any small $\Delta > 0$, for some constant $M_x < \infty$. Notice that $x_t'b$ is of the form "$\pm z_{t,1} +$ *a linear combination of* $y_{t-1}, ..., y_{t-r}, z_{t,2}, ..., z_{t,K}$" due to the standardization of the coefficient of $z_{t,1}$. Then it is obvious that (‡) holds under Condition (C4).

Now notice that for two random variables W and W^*,

$$||I(W > 0) - I(W^* > 0)||_1 \leq 4\sqrt{2M}\sqrt{||W - W^*||_1}, \tag{13}$$

if $P(|W| \leq \Delta) \leq M(2\Delta)$ for $\Delta = \sqrt{||W - W^*||_1}/\sqrt{2M}$. This is proved by noting

$$EI(W > 0, W^* \leq 0)$$

$$
\begin{aligned}
&\le EI(W>0, W^* \le 0, |W-W^*| \le \Delta) + EI(|W-W^*| > \Delta) \\
&\le P[|W| \le \Delta] + E|W-W^*|/\Delta \\
&\le M(2\Delta) + E|W-W^*|/\Delta \\
&= 2\sqrt{2M}\sqrt{||W-W^*||_1}.
\end{aligned}
$$

Similarly $EI(W^*>0, W \le 0) \le 2\sqrt{2M}\sqrt{||W-W^*||_1}$. Now $||I(W>0)-I(W^*>0)||_1 = EI(W>0, W^* \le 0) + EI(W^*>0, W \le 0)$ leads to (13).

Now apply (13) and we obtain

$$
\begin{aligned}
&2||I(y_t>0)-I(y_{t,k}>0)||_1 + 2||I(x_t'b>0)-I(x_{t,k}'b>0)||_1 \\
&\le 8\sqrt{2M_y}\sqrt{||y_t-y_{t,k}||_1} + 8\sqrt{2M_x}\sqrt{||x_t'b-x_{t,k}'b||_1} \\
&\le 8\sqrt{2M_y}\sqrt{||y_t-y_{t,k}||_1} + 8\sqrt{2M_x|b|_\infty}\sqrt{||x_t-x_{t,k}||_1} \\
&\le 8\sqrt{2M_y}\sqrt{\sum_{j>k}|\theta_j|\sup_{t,l}||f_l(z_t,\varepsilon_t)||_1} + 8\sqrt{2M_xC_b}\sqrt{r\sum_{j>k}|\theta_j|\sup_{t,l}||f_l(z_t,\varepsilon_t)||_1},
\end{aligned}
$$

and therefore we have (9). Q.E.D.

Proof of Equation (10) Note that the $B = B_+ \cup B_-$ where $B_\pm = \{b \in B : b_{r+1} = \pm 1\}$ represents the two halfs of B with $b_{r+1} = \pm 1$, respectively. Note that $B_\pm$ can be written as a union $B_\pm = \cup_\gamma B_\pm(\gamma)$, where γ represents the subset of 'selected indices' in addition to $r+2$, and the union is taken over all subsets γ of $\{1,...,K+r+1\}\backslash\{r+2\}$ with card$(\gamma) \le v-1$. Here $B_\pm(\gamma) = \{b \in \Re^{K+r+1} : b_{r+2} = \pm 1, |b_j| \le C_b, \forall j \in \gamma; |b_j| = 0, \forall j \notin \gamma \cup \{r+2\}\}$. Each $B_\pm(\gamma)$ can be covered by at most $(2C_b/\lambda+1)^{\text{card}(\gamma)}$ sets B_i's of the form $B_i = \{b \in \Re^{K+r+1} : b_{r+2} = \pm 1, |b_j - (b_i)_j| \le \lambda/2, \forall j \in \gamma; |b_j-(b_i)_j| = 0, \forall j \notin \gamma \cup \{r+2\}\}$ for some $b_i \in B_\pm(\gamma)$, where card$(\gamma) \le v-1$. So a combinatorial argument leads to upperbound (10). Q.E.D.

Proof of Assumption (A3) for the example in Section 5 Assume Condition (C5), so that $|z_t|_\infty \le C_z < \infty$.

We can apply the arguments in Remark 8 by identifying $w_t = z_{t,1}$, $v_t = (1, y_{t-1}, ..., y_{t-r}, z_{t,2}, ..., z_{t,K})'$. Note that $d_0 \le v$ and we can choose $\mathcal{V}_t$ as the σ-field generated by $\{z_s, \varepsilon_s\}_{-\infty}^{t-1}$ and $z_{t,2}, ..., z_{t,K}$. Then A3 is satisfied if (C4) holds [the conditional density $p(w_t|\mathcal{V}_t)$ is bounded above by c (=M_x)] and if

$$\lambda \le \delta/(12vCc(1+C_z+r|\theta|_1\sup_{t,l}||f_l(z_t,\varepsilon_t)||_1)), \tag{14}$$

which would then be $\le \delta/(12vCc(1+C_z+r\sup_t||y_t||_1)) \le \delta/(12d_0Cc\sup_t E|v_t|_\infty)$. This inequality (14) is satisfied for all large n, when we take $\delta = n^{-0.5+\gamma_1}/2$ for any $\gamma_1 > 0$, and $\lambda = n^{-1}$ (the ℓ_∞-diameter of B_i), and assume that the number of lags r and the maximal number of selected variables v follow condition (C6). Q.E.D.

Proof of Equation (11) Similar to the approximation argument used before in Proof of Equation (9), we define $\omega_{t,k} = (y_{t,k}, x_{t,k})$ and obtain $E|E(I(\omega_t \in S_i)|\mathcal{F}_{t-m}) - EI(\omega_t \in S_i)| \le E|E(I(\omega_{t,k} \in S_i)|\mathcal{F}_{t-m}) - EI(\omega_{t,k} \in S_i)| + 2E|I(\omega_t \in S_i) - I(\omega_{t,k} \in S_i)|$, where the first term is bounded above by

$6\alpha_{m-r-k}$ for $m > r+k$, due to a treatment similar to the one used in Proof of Equation (9). Now we try to bound $E|I(\omega_t \in S_i) - I(\omega_{t,k} \in S_i)| \equiv ED$ in the second term, where $S_i \equiv \cup_{b \in B_i}[x_t' b = 0]$ will be computed below.

For our vector $x_t = (1, y_{t-1}, ..., y_{t-r}, z_{t,1}, z_{t,2}, ..., z_{t,K})'$, we here identify $w_t = z_{t,1} = (x_t)_{r+2}$, and $v_t = (1, y_{t-1}, ..., y_{t-r}, z_{t,2}, ..., z_{t,K})'$ including all $\{(x_t)_j\}_{j \neq r+2}$, for applying Remarks 8 and 9. Note that according to Remark 9, $S_i = [w^-(v_t) \le w_t \le w^+(v_t)]$ where $w^\pm(v_t) = v_t'(b_i)_v \pm h|v_t|_1$. [We have picked a sign $b_{r+2} = -1$ to proceed. The other sign is similar. To be more precise, here $|v_t|_1 = \sum_{j \in \gamma} |(x_t)_j|$ where γ is a subset of 'selected indices' in addition to $r+2$, when B_i is as described in Proof of Equation (10).]

Now $D \equiv |I(\omega_t \in S_i) - I(\omega_{t,k} \in S_i)| = 1$ implies that only one of the two points $\{x_t, x_{t,k}\} = \{(v_t', w_t)', \ (v_{t,k}', w_{t,k})'\}$ can lie in S_i, so there must be an intermediate point lying on a boundary of S_i, either on the upper boundary and denoted as $x^+ = ((v^+)', w^+(v^+))'$, or on the lower boundary and denoted as $x^- = ((v^-)', w^-(v^-))'$. [Here we have re-ordered the components of the vectors. For examples, for vector x_t, its component $(x_t)_{r+2} = w_t$ is now placed behind other components (denoted as v_t).]

If in addition, we also have a small distance $|x_t - x_{t,k}|_1 \le \eta$, then one of the following two events must happen (with $\pm$ option depending on whether the intermediate point falls on the upper or lower boundary of S_i):

$$\begin{aligned}
&|w_t - w^\pm(v_t)| \\
&\le |w_t - w^\pm(v^\pm)| + |w^\pm(v^\pm) - w^\pm(v_t)| \\
&\le |w_t - w^\pm(v^\pm)| + (C_b + h)|v_t - v^\pm|_1 \\
&\le |(1 + C_b + h)|x_t - x^\pm|_1 \\
&\le (1 + C_b + h)|x_t - x_{t,k}|_1 \le (1 + C_b + h)\eta.
\end{aligned}$$

Now we can bound

$$\begin{aligned}
ED &\le P[D = 1, |x_t - x_{t,k}|_1 \le \eta] + P[|x_t - x_{t,k}|_1 > \eta] \\
&\le P[\cup |w_t - w^\pm(v_t)| \le (1 + C_b + h)\eta] + P[|x_t - x_{t,k}|_1 > \eta] \\
&\overset{(a)}{\le} 2c2(1 + C_b + h)\eta + E|x_t - x_{t,k}|_1/\eta \\
&\le 2c2(1 + C_b + h)\eta + r\sum_{j>k} |\theta_j| \sup_{t,l} ||f_l(z_t, \varepsilon_t)||_1/\eta.
\end{aligned}$$

Now take $\eta = \sqrt{r\sum_{j>k} |\theta_j| \sup_{t,l} ||f_l(z_t, \varepsilon_t)||_1 / (2c2(1 + C_b + h))}$ and obtain

$$ED \le 2\sqrt{r\sum_{j>k} |\theta_j| \sup_{t,l} ||f_l(z_t, \varepsilon_t)||_1 (2c2(1 + C_b + h))}.$$

As in the previous Proof of Assumption (A3), we identify $c = M_x$. We have assumed Condition (C4) for the inequality (a) above. Therefore we have (11). Q.E.D.

Abstract

Permutations are ubiquitous in many real-world problems, such as voting, ranking, and data association. Representing uncertainty over permutations is challenging, since there are $n!$ possibilities, and typical compact and factorized probability distribution representations, such as graphical models, cannot capture the mutual exclusivity constraints associated with permutations. In this paper, we use the "low-frequency" terms of a Fourier decomposition to represent distributions over permutations compactly. We present *Kronecker conditioning*, a novel approach for maintaining and updating these distributions directly in the Fourier domain, allowing for polynomial time bandlimited approximations. Low order Fourier-based approximations, however, may lead to functions that do not correspond to valid distributions. To address this problem, we present a quadratic program defined directly in the Fourier domain for projecting the approximation onto a relaxation of the polytope of legal marginal distributions. We demonstrate the effectiveness of our approach on a real camera-based multi-person tracking scenario.

Keywords: identity management, permutations, approximate inference, group theoretical methods, sensor networks

1. Introduction

Probability distributions over permutations arise in a diverse variety of real world problems. While they were perhaps first studied in the context of gambling and card games, they have now been found to be applicable to many important problems such as multi-object tracking, information retrieval, webpage ranking, preference elicitation, and voting. Probabilistic reasoning problems over permutations, however, are not amenable to the typical representations afforded by machine learning such as Bayesian networks and Markov random fields. This paper explores an alternative representation and inference algorithms based on Fourier analysis for dealing with permutations.

As an example, consider the problem of tracking n people based on a set of noisy measurements of identity and position. A typical tracking system might attempt to manage a set of n tracks along

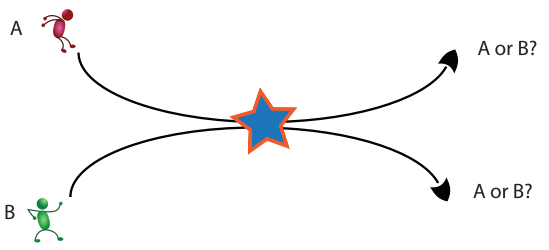

Figure 1: When two persons pass near each other, their identities can get confused.

with an identity corresponding to each track, in spite of ambiguities arising from imperfect identity measurements. When the people are well separated, the problem is easily decomposed and measurements about each individual can be clearly associated with a particular track. When people pass near each other, however, confusion can arise as their signal signatures may mix; see Figure 1. After the individuals separate again, their positions may be clearly distinguishable, but their identities can still be confused, resulting in identity uncertainty which must be propagated forward in time with each person, until additional observations allow for disambiguation. This task of maintaining a belief state for the correct association between object tracks and object identities while accounting for local mixing events and sensor observations, was introduced in Shin et al. (2003) and is called the *identity management problem*.

The identity management problem poses a challenge for probabilistic inference because it needs to address the fundamental combinatorial challenge that there is a factorial number of associations to maintain between tracks and identities. Distributions over the space of all permutations require storing at least $n! - 1$ numbers, an infeasible task for all but very small n. Moreover, typical compact representations, such as graphical models, cannot efficiently capture the mutual exclusivity constraints associated with permutations.

While there have been many approaches for coping with the factorial complexity of maintaining a distribution over permutations, most attack the problem using one of two ideas—storing and updating a small subset of likely permutations, or, as in our case, restricting consideration to a tractable subspace of possible distributions. Willsky (1978) was the first to formulate the probabilistic filtering/smoothing problem for group-valued random variables. He proposed an efficient FFT based approach of transforming between primal and Fourier domains so as to avoid costly convolutions, and provided efficient algorithms for dihedral and metacyclic groups. Kueh et al. (1999) show that probability distributions on the group of permutations are well approximated by a small subset of Fourier coefficients of the actual distribution, allowing for a principled tradeoff between accuracy and complexity. The approach taken in Shin et al. (2005), Schumitsch et al. (2005), and Schumitsch et al. (2006) can be seen as an algorithm for maintaining a particular fixed subset of Fourier coefficients of the log density. Most recently, Kondor et al. (2007) allow for a general set of Fourier coefficients, but assume a restrictive form of the observation model in order to exploit an efficient FFT factorization.

In the following, we outline our main contributions and provide a roadmap of the sections ahead.[1]

1. A much shorter version this work appeared in *NIPS* 2007 (Huang et al., 2007). We provide a more complete discussion of our Fourier based methods in this extended paper.

- In Sections 4 and 5, we provide a gentle introduction to the theory of group representations and noncommutative Fourier analyis. While none of the results of these sections are novel, and have indeed been studied by mathematicians for decades (Diaconis, 1989; Terras, 1999; Willsky, 1978; Chen, 1989), noncommutative Fourier analysis is still fairly new to the machine learning community, which has just begun to discover some of its exciting applications (Huang et al., 2007, 2009; Kondor et al., 2007; Kondor and Borgwardt, 2008). Our tutorial sections are targeted specifically at the machine learning community and describe its connections to probabilistic inference problems that involve permutations.

- In Section 6, we discuss performing probabilistic inference operations in the Fourier domain. In particular, we present Fourier theoretic algorithms for two ubiquitous operations which appear in filtering applications and beyond: prediction/rollup and conditioning with Bayes rule. Our main contribution in this section is a novel and conceptually simple algorithm, called *Kronecker Conditioning*, which performs all conditioning operations completely in the Fourier domain, allowing for a principled tradeoff between computational complexity and approximation accuracy. Our approach generalizes upon previous work in two ways—first, in the sense that it can address any transition model or likelihood function that can be represented in the Fourier domain, and second, in the sense that many of our results hold for arbitrary finite groups.

- In Section 7, we analyze the errors which can be introduced by bandlimiting a probability distribution and show how they propagate with respect to inference operations. We argue that approximate conditioning based on bandlimited distributions can sometimes yield Fourier coefficients which do not correspond to any valid distribution, even returning negative "probabilities" on occasion. We address possible negative and inconsistent probabilities by presenting a method for projecting the result back into the polytope of coefficients which correspond to nonnegative and consistent marginal probabilities using a simple quadratic program.

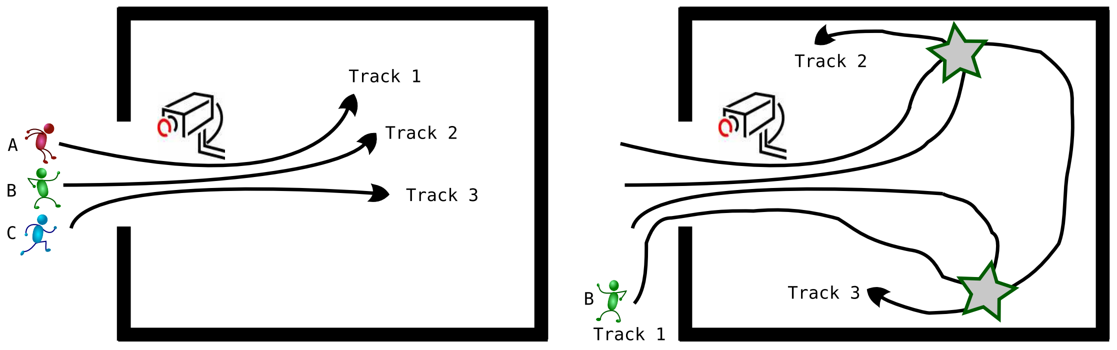
- In Section 8, we present a collection of general techniques for efficiently computing the Fourier coefficients of probabilistic models that might be useful in practical inference problems, and give a variety of examples of such computations for probabilistic models that might arise in identity management or ranking scenarios.

- Finally in Section 10, we empirically evaluate the accuracy of approximate inference on simulated data drawn from our model and further demonstrate the effectiveness of our approach on a real camera-based multi-person tracking scenario.

2. Filtering Over Permutations

As a prelude to the general problem statement, we begin with a simple identity management problem on three tracks (illustrated in Figure 2) which we will use as a running example. In this problem, we observe a stream of localization data from three people walking inside a room. Except for a camera positioned at the entrance, however, there is no way to distinguish between identities once they are inside. In this example, an internal tracker declares that two tracks have 'mixed' whenever they get too close to each other and announces the identity of any track that enters or exits the room.

In our particular example, three people, Alice, Bob and Cathy, enter a room separately, walk around, and we observe Bob as he exits. The events for our particular example in the figure are



(a) *Before* (b) *After*

Figure 2: Identity Management example. Three people, Alice, Bob and Charlie enter a room and we receive a position measurement for each person at each time step. With no way to observe identities inside the room, however, we are confused whenever two tracks get too close. In this example, track 1 crosses with track 2, then with track 3, then leaves the room, at which point it is observed that the identity at Track 1 is in fact Bob.

recorded in Table 1. Since Tracks 2 and 3 never mix, we know that Cathy cannot be in Track 2 in the end, and furthermore, since we observe Bob to be in Track 1 when he exits, we can deduce that Cathy must have been in Track 3, and therefore Alice must have been in Track 2. Our simple example illustrates the combinatorial nature of the problem—in particular, reasoning about the mixing events allows us to exactly decide where Alice and Cathy were even though we only made an observation about Bob at the end.

Event #	*Event Type*
1	*Tracks 1 and 2 mixed*
2	*Tracks 1 and 3 mixed*
3	*Observed Identity Bob at Track 1*

Table 1: Table of Mixing and Observation events logged by the tracker.

In identity management, a permutation σ represents a joint assignment of identities to internal tracks, with $\sigma(i)$ being the track belonging to the ith identity. When people walk too closely together, their identities can be confused, leading to uncertainty over σ. To model this uncertainty, we use a *Hidden Markov Model (HMM)* on permutations, which is a joint distribution over latent permutations $\sigma^{(1)},\dots,\sigma^{(T)}$, and observed variables $z^{(1)},\dots,z^{(T)}$ which factors as:

$$P(\sigma^{(1)},\dots,\sigma^{(T)},z^{(1)},\dots,z^{(T)}) = P(\sigma^{(1)})P(z^{(1)}|\sigma^{(1)})\prod_{t=2}^{T} P(z^t|\sigma^{(t)})\cdot P(\sigma^{(t)}|\sigma^{(t-1)}).$$

The conditional probability distribution $P(\sigma^{(t)}|\sigma^{(t-1)})$ is called the *transition model*, and might reflect, for example, that the identities belonging to two tracks were swapped with some probability by a mixing event. The distribution $P(z^{(t)}|\sigma^{(t)})$ is called the *observation model*, which might, for example, capture a distribution over the color of clothing for each individual.

We focus on *filtering*, in which one queries the HMM for the posterior at some time step, conditioned on all past observations. Given the distribution $P(\sigma^{(t)}|z^{(1)},\dots,z^{(t)})$, we recursively compute $P(\sigma^{(t+1)}|z^{(1)},\dots,z^{(t+1)})$ in two steps: a *prediction/rollup* step and a *conditioning* step. Taken together, these two steps form the well known *Forward Algorithm* (Rabiner, 1989). The prediction/rollup step multiplies the distribution by the transition model and marginalizes out the previous time step:

$$P(\sigma^{(t+1)}|z^{(1)},\dots,z^{(t)}) = \sum_{\sigma^{(t)}} P(\sigma^{(t+1)}|\sigma^{(t)})P(\sigma^{(t)}|z^{(1)},\dots,z^{(t)}).$$

The conditioning step conditions the distribution on an observation $z^{(t+1)}$ using Bayes rule:

$$P(\sigma^{(t+1)}|z^{(1)},\dots,z^{(t+1)}) \propto P(z^{(t+1)}|\sigma^{(t+1)})P(\sigma^{(t+1)}|z^{(1)},\dots,z^{(t)}).$$

Since there are $n!$ permutations, a single iteration of the algorithm requires $O((n!)^2)$ flops and is consequently intractable for all but very small n. The approach that we advocate is to maintain a compact approximation to the true distribution based on the Fourier transform. As we discuss later, the Fourier based approximation is equivalent to maintaining a set of low-order marginals, rather than the full joint, which we regard as being analogous to an *Assumed Density Filter* (Boyen and Koller, 1998).

Although we use hidden Markov models and filtering as a running example, the approach we describe is useful for other probabilistic inference tasks over permutations, such as ranking objects and modeling user preferences. For example, operations such as marginalization and conditioning are fundamental and are widely applicable. In particular, conditioning using Bayes rule, one of the main topics of our paper, is one of the most fundamental probabilistic operations, and we provide a completely general formulation.

3. Probability Distributions over the Symmetric Group

A permutation on n elements is a one-to-one mapping of the set $\{1,\dots,n\}$ into itself and can be written as a tuple,

$$\sigma = [\sigma(1)\ \sigma(2)\ \dots\ \sigma(n)],$$

where $\sigma(i)$ denotes where the ith element is mapped under the permutation (called *one line notation*). For example, $\sigma = [2\ 3\ 1\ 4\ 5]$ means that $\sigma(1) = 2$, $\sigma(2) = 3$, $\sigma(3) = 1$, $\sigma(4) = 4$, and $\sigma(5) = 5$. The set of all permutations on n elements forms a group under the[2] operation of function composition—that is, if σ_1 and σ_2 are permutations, then

$$\sigma_1\sigma_2 = [\sigma_1(\sigma_2(1))\ \sigma_1(\sigma_2(2))\ \dots\ \sigma_1(\sigma_2(n))]$$

is itself a permutation. The set of all $n!$ permutations is called the *symmetric group*, or just S_n.

We will actually notate the elements of S_n using the more standard *cycle notation*, in which a *cycle* $(i,j,k,\dots,\ell)$ refers to the permutation which maps i to j, j to k, $\dots$, and finally ℓ to i. Though not every permutation can be written as a single cycle, any permutation can always be written as a product of disjoint cycles. For example, the permutation $\sigma = [2\ 3\ 1\ 4\ 5]$ written in cycle notation is $\sigma = (1,2,3)(4)(5)$. The number of elements in a cycle is called the *cycle length* and we typically drop the length 1 cycles in cycle notation when it creates no ambiguity—in our

2. See Appendix A for a list of the basic group theoretic definitions used in this paper.

example, $\sigma = (1,2,3)(4)(5) = (1,2,3)$. We refer to the identity permutation (which maps every element to itself) as ε.

A probability distribution over permutations can be thought of as a joint distribution on the n random variables $(\sigma(1),\dots,\sigma(n))$ subject to the *mutual exclusivity constraints* that $P(\sigma : \sigma(i) = \sigma(j)) = 0$ whenever $i \neq j$. For example, in the identity management problem, Alice and Bob cannot both be in Track 1 simultaneously. Due to the fact that all of the $\sigma(i)$ are coupled in the joint distribution, graphical models, which might have otherwise exploited an underlying conditional independence structure, are ineffective. Instead, our Fourier based approximation achieves compactness by exploiting the *algebraic structure* of the problem.

3.1 Compact Summary Statistics

While continuous distributions like Gaussians are typically summarized using moments (like mean and variance), or more generally, expected features, it is not immediately obvious how one might, for example, compute the 'mean' of a distribution over permutations. There is a simple method that might spring to mind, however, which is to think of the permutations as *permutation matrices* and to average the matrices instead.

Example 1 *For example, consider the two permutations* $\varepsilon, (1,2) \in S_3$ *(*ε *is the identity and* $(1,2)$ *swaps 1 and 2). We can associate the identity permutation* ε *with the* 3×3 *identity matrix, and similarly, we can associate the permutation* $(1,2)$ *with the matrix:*

$$(1,2) \mapsto \begin{bmatrix} 0 & 1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 1 \end{bmatrix}.$$

The 'average' of ε *and* $(1,2)$ *is therefore:*

$$\frac{1}{2}\begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix} + \frac{1}{2}\begin{bmatrix} 0 & 1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 1 \end{bmatrix} = \begin{bmatrix} 1/2 & 1/2 & 0 \\ 1/2 & 1/2 & 0 \\ 0 & 0 & 1 \end{bmatrix}.$$

As we will later show, computing the 'mean' (as described above) of a distribution over permutations, P, compactly summarizes P by storing a marginal distribution over each of $\sigma(1), \sigma(2), \dots, \sigma(n)$, which requires storing only $O(n^2)$ numbers rather than the full $O(n!)$ for the exact distribution. As an example, one possible summary might look like:

$$\widehat{P} = \left[\begin{array}{c|ccc} & \text{Alice} & \text{Bob} & \text{Cathy} \\ \hline \text{Track 1} & 2/3 & 1/6 & 1/6 \\ \text{Track 2} & 1/3 & 1/3 & 1/3 \\ \text{Track 3} & 0 & 1/2 & 1/2 \end{array}\right].$$

Such doubly stochastic "first-order summaries" have been studied in various settings (Shin et al., 2003; Helmbold and Warmuth, 2007). In identity management (Shin et al., 2003),[3] first-order sum-

3. Strictly speaking, a map from identities to tracks is not a permutation since a permutation always maps a set into itself. In fact, the set of all such identity-to-track assignments does not actually form a group since there is no way to compose any two such assignments to obtain a legitimate group operation. We abuse the notation by referring to these assignments as a group, but really the elements of the group here should be thought of as the 'deviation' from the original identity-to-track assignment (where only the tracks are permuted, for example, when they are confused). In the group theoretic language, there is a faithful group action of S_n on the set of all identity-to-track assignments.

maries maintain, for example,

$$P(\text{Alice is at Track 1}) = 2/3,$$
$$P(\text{Bob is at Track 3}) = 1/2.$$

What cannot be captured by first-order summaries however, are the higher order statements like:

$$P(\text{Alice is in Track 1 } \textit{and} \text{ Bob is in Track 2}) = 0.$$

Over the next two sections, we will show that the first-order summary of a distribution $P(\sigma)$ can equivalently be viewed as the lowest frequency coefficients of the Fourier transform of $P(\sigma)$, and that by considering higher frequencies, we can capture higher order marginal probabilities in a principled fashion. Furthermore, the Fourier theoretic perspective, as we will show, provides a natural framework for formulating inference operations with respect to our compact summaries. In a nutshell, we will view the prediction/rollup step as a convolution and the conditioning step as a pointwise product—then we will formulate the two inference operations in the Fourier domain as a pointwise product and convolution, respectively.

4. The Fourier Transform on Finite Groups

Over the last fifty years, the Fourier Transform has been ubiquitously applied to everything digital, particularly with the invention of the Fast Fourier Transform (Cooley and Tukey, 1965; Rockmore, 2000). On the real line, the Fourier Transform is a well-studied method for decomposing a function into a sum of sine and cosine terms over a spectrum of frequencies. Perhaps less familiar to the machine learning community though, is its group theoretic generalization. In this section we review group theoretic generalizations of the Fourier transform with an eye towards approximating functions on S_n. None of the results stated in this section or the next are original. Noncommutative generalizations of the Fourier transform have been studied quite extensively throughout the last century from both the mathematics (Lang, 1965) and physics communities (Chen, 1989). Applications to permutations were first pioneered by Persi Diaconis who studied problems in card shuffling and since then, there have been many papers on related topics in probability and statistics. For further information, see Diaconis (1988) and Terras (1999).

4.1 Group Representation Theory

The generalized definition of the Fourier Transform relies on the theory of group representations, which formalize the concept of associating permutations with matrices and are used to construct a complete basis for the space of functions on a group G, thus also playing a role analogous to that of sinusoids on the real line.

Definition 1 *A* representation *of a group G is a map ρ from G to a set of invertible $d_\rho \times d_\rho$ (complex) matrix operators ($\rho : G \to \mathbb{C}^{d_\rho \times d_\rho}$) which preserves algebraic structure in the sense that for all $\sigma_1, \sigma_2 \in G$, $\rho(\sigma_1\sigma_2) = \rho(\sigma_1) \cdot \rho(\sigma_2)$. The matrices which lie in the image of ρ are called the* representation matrices*, and we will refer to d_ρ as the* degree *of the representation.*

The requirement that $\rho(\sigma_1\sigma_2) = \rho(\sigma_1) \cdot \rho(\sigma_2)$ is analogous to the property that $e^{i(\theta_1+\theta_2)} = e^{i\theta_1} \cdot e^{i\theta_2}$ for the conventional sinusoidal basis. Each matrix entry, $\rho_{ij}(\sigma)$ defines some function over S_n:

$$\rho(\sigma) = \begin{bmatrix} \rho_{11}(\sigma) & \rho_{12}(\sigma) & \cdots & \rho_{1d_\rho}(\sigma) \\ \rho_{21}(\sigma) & \rho_{22}(\sigma) & \cdots & \rho_{2d_\rho}(\sigma) \\ \vdots & \vdots & \ddots & \vdots \\ \rho_{d_\rho 1}(\sigma) & \rho_{d_\rho 2}(\sigma) & \cdots & \rho_{d_\rho d_\rho}(\sigma) \end{bmatrix},$$

and consequently, each representation ρ simultaneously defines a set of d_ρ^2 functions over S_n. We will eventually think of group representations as the set of Fourier basis functions onto which we can project arbitrary functions.

Before moving onto examples, we make several remarks about the generality of this paper. First, while our paper is primarily focused on the symmetric group, many of its results hold for arbitrary finite groups. For example, there are a variety of finite groups that have been studied in applications, like metacyclic groups (Willsky, 1978), wreath product groups (Foote et al., 2004), etc. However, while some of these results will even extend with minimal effort to more general cases, such as locally compact groups, the assumption in all of the following results will be that G is finite, even if it is not explicitly stated. Specifically, most of the results in Sections 4, 6, and Appendix D.2 are intended to hold over any finite group, while the results of the remaining sections are specific to probabilistic inference over the symmetric group. Secondly, given an arbitrary finite group G, some of the algebraic results that we use require that the underlying field be the complex numbers. For the particular case of the symmetric group, however, we can in fact assume that the representations are real-valued matrices. Thus, throughout the paper, we will explicitly assume that the representations are real-valued.[4]

Example 2 *We begin by showing three examples of representations on the symmetric group.*

1. *The simplest example of a representation is called the* trivial representation $\rho_{(n)} : S_n \to \mathbb{R}^{1\times 1}$, *which maps each element of the symmetric group to 1, the multiplicative identity on the real numbers. The trivial representation is actually defined for every group, and while it may seem unworthy of mention, it plays the role of the constant basis function in the Fourier theory.*

2. *The* first-order permutation representation *of S_n, which we alluded to in Example 1, is the degree n representation, $\tau_{(n-1,1)}$ (we explain the terminology in Section 5) , which maps a permutation σ to its corresponding permutation matrix given by $[\tau_{(n-1,1)}(\sigma)]_{ij} = \mathbb{1}\{\sigma(j) = i\}$. For example, the first-order permutation representation on S_3 is given by:*

$$\tau_{(2,1)}(\varepsilon) = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix} \qquad \tau_{(2,1)}(1,2) = \begin{bmatrix} 0 & 1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 1 \end{bmatrix} \qquad \tau_{(2,1)}(2,3) = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 0 & 1 \\ 0 & 1 & 0 \end{bmatrix}$$

$$\tau_{(2,1)}(1,3) = \begin{bmatrix} 0 & 0 & 1 \\ 0 & 1 & 0 \\ 1 & 0 & 0 \end{bmatrix} \qquad \tau_{(2,1)}(1,2,3) = \begin{bmatrix} 0 & 0 & 1 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \end{bmatrix} \qquad \tau_{(2,1)}(1,3,2) = \begin{bmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \\ 1 & 0 & 0 \end{bmatrix}$$

4. To recover similar results for more complex-valued representations, one would have to replace matrix transposes by adjoints, etc.

3. *The* alternating representation *of S_n, maps a permutation σ to the determinant of $\tau_{(n-1,1)}(\sigma)$, which is $+1$ if σ can be equivalently written as the composition of an even number of pairwise swaps, and -1 otherwise. We write the alternating representation as $\rho_{(1,\ldots,1)}$ with n 1's in the subscript. For example, on S_4, we have:*

$$\rho_{(1,1,1,1)}((1,2,3)) = \rho_{(1,1,1,1)}((13)(12)) = +1.$$

The alternating representation can be interpreted as the 'highest frequency' basis function on the symmetric group, intuitively due to its high sensitivity to swaps. For example, if $\tau_{(1,\ldots,1)}(\sigma) = 1$, then $\tau_{(1,\ldots,1)}((12)\sigma) = -1$. In identity management, it may be reasonable to believe that the joint probability over all n identity labels should only change by a little if just two objects are mislabeled due to swapping—in this case, ignoring the basis function corresponding to the alternating representation should still provide an accurate approximation to the joint distribution.

In general, a representation corresponds to an overcomplete set of functions and therefore does not constitute a valid basis for any subspace of functions. For example, the set of nine functions on S_3 corresponding to $\tau_{(2,1)}$ span only four dimensions, because there are six normalization constraints (three on the row sums and three on the column sums), of which five are independent—and so there are five redundant dimensions. To find a valid complete basis for the space of functions on S_n, we will need to find a family of representations whose basis functions are independent, and span the entire $n!$-dimensional space of functions.

In the following two definitions, we will provide two methods for constructing a new representation from old ones such that the set of functions on S_n corresponding to the new representation is linearly *dependent* on the old representations. Somewhat surprisingly, it can be shown that dependencies which arise amongst the representations can always be recognized in a certain sense, to come from the two possible following sources (Serre, 1977).

Definition 2

1. ***Equivalence.*** *Given a representation ρ_1 and an invertible matrix C, one can define a new representation ρ_2 by "changing the basis" for ρ_1:*

$$\rho_2(\sigma) \triangleq C^{-1} \cdot \rho_1(\sigma) \cdot C. \tag{1}$$

We say, in this case, that ρ_1 and ρ_2 are equivalent *as representations (written $\rho_1 \equiv \rho_2$, as opposed to $\rho_1 = \rho_2$), and the matrix C is known as the* intertwining operator. *Note that $d_{\rho_1} = d_{\rho_2}$.*

It can be checked that the functions corresponding to ρ_2 can be reconstructed from those corresponding to ρ_1. For example, if C is a permutation matrix, the matrix entries of ρ_2 are exactly the same as the matrix entries of ρ_1, only permuted.

2. ***Direct Sum.*** *Given two representations ρ_1 and ρ_2, we can always form a new representation, which we will write as $\rho_1 \oplus \rho_2$, by defining:*

$$\rho_1 \oplus \rho_2(\sigma) \triangleq \left[\begin{array}{c|c} \rho_1(\sigma) & 0 \\ \hline 0 & \rho_2(\sigma) \end{array}\right].$$

$\rho_1 \oplus \rho_2$ *is called the* direct sum representation. *For example, the direct sum of two copies of the trivial representation is:*

$$\rho_{(n)} \oplus \rho_{(n)}(\sigma) = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix},$$

with four corresponding functions on S_n, each of which is clearly dependent upon the trivial representation itself.

Most representations can be seen as being equivalent to a direct sum of strictly smaller representations. Whenever a representation ρ can be decomposed as $\rho \equiv \rho_1 \oplus \rho_2$, we say that ρ is *reducible*. As an example, we now show that the first-order permutation representation is a reducible representation.

Example 3 *Instead of using the standard basis vectors $\{e_1, e_2, e_3\}$, the first-order permutation representation for S_3, $\tau_{(2,1)} : S_3 \to \mathbb{C}^{3\times 3}$, can be equivalently written with respect to a new basis $\{v_1, v_2, v_3\}$, where:*

$$v_1 = \frac{e_1 + e_2 + e_3}{|e_1 + e_2 + e_3|},$$
$$v_2 = \frac{-e_1 + e_2}{|-e_1 + e_2|},$$
$$v_3 = \frac{-e_1 - e_2 + 2e_3}{|-e_1 - e_2 + 2e_3|}.$$

To 'change the basis', we write the new basis vectors as columns in a matrix C:

$$C = \begin{bmatrix} | & | & | \\ v_1 & v_2 & v_3 \\ | & | & | \end{bmatrix} = \begin{bmatrix} \frac{1}{\sqrt{3}} & -\frac{\sqrt{2}}{2} & -\frac{1}{\sqrt{6}} \\ \frac{1}{\sqrt{3}} & \frac{\sqrt{2}}{2} & -\frac{1}{\sqrt{6}} \\ \frac{1}{\sqrt{3}} & 0 & \frac{2}{\sqrt{6}} \end{bmatrix},$$

and conjugate the representation $\tau_{(2,1)}$ by C (as in Equation 1) to obtain the equivalent representation $C^{-1} \cdot \tau_{(2,1)}(\sigma) \cdot C$:

$$C^{-1} \cdot \tau_{(2,1)}(\varepsilon) \cdot C = \left[\begin{array}{c|cc} 1 & 0 & 0 \\ \hline 0 & 1 & 0 \\ 0 & 0 & 1 \end{array}\right] \qquad C^{-1} \cdot \tau_{(2,1)}(1,2) \cdot C = \left[\begin{array}{c|cc} 1 & 0 & 0 \\ \hline 0 & -1 & 0 \\ 0 & 0 & 1 \end{array}\right]$$

$$C^{-1} \cdot \tau_{(2,1)}(2,3) \cdot C = \left[\begin{array}{c|cc} 1 & 0 & 0 \\ \hline 0 & 1/2 & \sqrt{3}/2 \\ 0 & \sqrt{3}/2 & -1/2 \end{array}\right] \qquad C^{-1} \cdot \tau_{(2,1)}(1,3) \cdot C = \left[\begin{array}{c|cc} 1 & 0 & 0 \\ \hline 0 & 1/2 & -\sqrt{3}/2 \\ 0 & -\sqrt{3}/2 & -1/2 \end{array}\right]$$

$$C^{-1} \cdot \tau_{(2,1)}(1,2,3) \cdot C = \left[\begin{array}{c|cc} 1 & 0 & 0 \\ \hline 0 & -1/2 & -\sqrt{3}/2 \\ 0 & \sqrt{3}/2 & -1/2 \end{array}\right] \qquad C^{-1} \cdot \tau_{(2,1)}(1,3,2) \cdot C = \left[\begin{array}{c|cc} 1 & 0 & 0 \\ \hline 0 & -1/2 & \sqrt{3}/2 \\ 0 & -\sqrt{3}/2 & -1/2 \end{array}\right]$$

The interesting property of this particular basis is that the new representation matrices all appear to be the direct sum of two smaller representations, a trivial representation, $\rho_{(3)}$ as the top left block, and a degree 2 representation in the bottom right which we will refer to as $\rho_{(2,1)}$.

Geometrically, the representation $\rho_{(2,1)}$ *can also be thought of as the group of rigid symmetries of the equilateral triangle with vertices:*

$$P_1 = \begin{bmatrix} \sqrt{3}/2 \\ 1/2 \end{bmatrix}, P_2 = \begin{bmatrix} -\sqrt{3}/2 \\ 1/2 \end{bmatrix}, P_3 = \begin{bmatrix} 0 \\ -1 \end{bmatrix}.$$

The matrix $\rho_{(2,1)}(1,2)$ *acts on the triangle by reflecting about the x-axis, and* $\rho_{(2,1)}(1,2,3)$ *by a* $\pi/3$ *counter-clockwise rotation.*

In general, there are infinitely many reducible representations. For example, given any dimension d, there is a representation which maps every element of a group G to the $d \times d$ identity matrix (the direct sum of d copies of the trivial representation). However, for any finite group, there exists a finite collection of atomic representations which can be used to build up any other representation (up to equivalence) using the direct sum operation. These representations are referred to as the *irreducibles* of a group, and they are defined simply to be the collection of representations (up to equivalence) which are not reducible. It can be shown that any (complex) representation of a finite group G is equivalent to a direct sum of irreducibles (Diaconis, 1988), and hence, for any representation τ, there exists a matrix C for which

$$C^{-1} \cdot \tau \cdot C = \bigoplus_{\rho} \bigoplus_{j=1}^{z_\rho} \rho, \tag{2}$$

where ρ ranges over all distinct irreducible representations of the group G, and the inner $\oplus$ refers to some finite number (z_ρ) of copies of each irreducible ρ.

As it happens, there are only three irreducible representations of S_3 (Diaconis, 1988), up to equivalence: the trivial representation $\rho_{(3)}$, the degree 2 representation $\rho_{(2,1)}$, and the alternating representation $\rho_{(1,1,1)}$. The complete set of irreducible representation matrices of S_3 are shown in the Table 2. Unfortunately, the analysis of the irreducible representations for $n > 3$ is far more complicated and we postpone this more general discussion for Section 5.

4.2 The Fourier Transform

The link between group representation theory and Fourier analysis is given by the celebrated *Peter-Weyl theorem* (Diaconis, 1988; Terras, 1999; Sagan, 2001) which says that the matrix entries of the irreducibles of G form a *complete* set of *orthogonal* basis functions on G.[5] The space of functions on S_3, for example, is orthogonally spanned by the 3! functions $\rho_{(3)}(\sigma)$, $[\rho_{(2,1)}(\sigma)]_{1,1}$, $[\rho_{(2,1)}(\sigma)]_{1,2}$, $[\rho_{(2,1)}(\sigma)]_{2,1}$, $[\rho_{(2,1)}(\sigma)]_{2,2}$ and $\rho_{(1,1,1)}(\sigma)$, where $[\rho(\sigma)]_{ij}$ denotes the (i,j) entry of the matrix $\rho(\sigma)$.

As a replacement for projecting a function f onto a complete set of sinusoidal basis functions (as one would do on the real line), the Peter-Weyl theorem suggests instead to project onto the basis provided by the irreducibles of G. As on the real line, this projection can be done by computing the inner product of f with each element of the basis, and we define this operation to be the generalized form of the Fourier Transform.

5. Technically the Peter-Weyl result, as stated here, is only true if all of the representation matrices are unitary. That is, $\rho(\sigma)^*\rho(\sigma) = I$ for all $\sigma \in S_n$, where the matrix A^* is the conjugate transpose of A. For the case of real-valued (as opposed to complex-valued) matrices, however, the definitions of unitary and orthogonal matrices coincide.

While most representations are not unitary, there is a standard result from representation theory which shows that for *any* representation of G, there exists an equivalent unitary representation.

σ	$\rho_{(3)}$	$\rho_{(2,1)}$	$\rho_{(1,1,1)}$
ε	1	$\begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}$	1
$(1,2)$	1	$\begin{bmatrix} -1 & 0 \\ 0 & 1 \end{bmatrix}$	-1
$(2,3)$	1	$\begin{bmatrix} 1/2 & \sqrt{3}/2 \\ \sqrt{3}/2 & -1/2 \end{bmatrix}$	-1
$(1,3)$	1	$\begin{bmatrix} 1/2 & -\sqrt{3}/2 \\ -\sqrt{3}/2 & -1/2 \end{bmatrix}$	-1
$(1,2,3)$	1	$\begin{bmatrix} -1/2 & -\sqrt{3}/2 \\ \sqrt{3}/2 & -1/2 \end{bmatrix}$	1
$(1,3,2)$	1	$\begin{bmatrix} -1/2 & \sqrt{3}/2 \\ -\sqrt{3}/2 & -1/2 \end{bmatrix}$	1

Table 2: The irreducible representation matrices of S_3.

Definition 3 *Let $f : G \to \mathbb{R}$ be any function on a group G and let ρ be any representation on G. The* Fourier Transform *of f at the representation ρ is defined to be the matrix of coefficients:*

$$\hat{f}_\rho = \sum_\sigma f(\sigma)\rho(\sigma).$$

The collection of Fourier Transforms at all irreducible representations of G form the Fourier Transform of f.

There are two important points which distinguish this Fourier Transform from its familiar formulation on the real line—first, the outputs of the transform are matrix-valued, and second, the inputs to $\hat{f}$ are *representations* of G rather than real numbers. As in the familiar formulation, the Fourier Transform is invertible and the inversion formula is explicitly given by the Fourier Inversion Theorem.

Theorem 4 (Fourier Inversion Theorem)

$$f(\sigma) = \frac{1}{|G|} \sum_\lambda d_{\rho_\lambda} Tr \left[\hat{f}^T_{\rho_\lambda} \cdot \rho_\lambda(\sigma) \right], \tag{3}$$

where λ indexes over the collection of irreducibles of G.

Note that the trace term in the inverse Fourier Transform is just the 'matrix dot product' between $\hat{f}_{\rho_\lambda}$ and $\rho_\lambda(\sigma)$, since $\mathrm{Tr}\left[A^T \cdot B\right] = \langle \mathrm{vec}(A), \mathrm{vec}(B) \rangle$, where by vec we mean mapping a matrix to a vector on the same elements arranged in column-major order.

We now provide several examples for intuition. For functions on the real line, the Fourier Transform at zero frequency gives the DC component of a signal. The same holds true for functions on a group; If $f : G \to \mathbb{R}$ is any function, then since $\rho_{(n)} = 1$, the Fourier Transform of f at the trivial representation is constant, with $\hat{f}_{\rho_{(n)}} = \sum_\sigma f(\sigma)$. Thus, for any probability distribution P, we have $\hat{P}_{\rho_{(n)}} = 1$. If P were the uniform distribution, then $\hat{P}_\rho = 0$ at every irreducible ρ except at the trivial representation.

The Fourier Transform at $\tau_{(n-1,1)}$ also has a simple interpretation:

$$[\hat{f}_{\tau_{(n-1,1)}}]_{ij} = \sum_{\sigma\in S_n} f(\sigma)[\tau_{(n-1,1)}(\sigma)]_{ij} = \sum_{\sigma\in S_n} f(\sigma)\mathbb{1}\{\sigma(j)=i\} = \sum_{\sigma:\sigma(j)=i} f(\sigma).$$

The set $\Delta_{ij} = \{\sigma : \sigma(j) = i\}$ is the set of the $(n-1)!$ possible permutations which map element j to i. In identity management, Δ_{ij} can be thought of as the set of assignments which, for example, have Alice at Track 1. If P is a distribution, then $\hat{P}_{\tau_{(n-1,1)}}$ is a matrix of *first-order* marginal probabilities, where the (i,j)-th element is the marginal probability that a random permutation drawn from P maps element j to i.

Example 4 *Consider the following probability distribution on S_3:*

σ	ε	$(1,2)$	$(2,3)$	$(1,3)$	$(1,2,3)$	$(1,3,2)$
$P(\sigma)$	$1/3$	$1/6$	$1/3$	0	$1/6$	0

The set of all first order marginal probabilities is given by the Fourier transform at $\tau_{(2,1)}$:

$$\widehat{P}_{\tau_{(2,1)}} = \left[\begin{array}{c|ccc} & \mathbf{A} & \mathbf{B} & \mathbf{C} \\ \hline \mathbf{1} & 2/3 & 1/6 & 1/6 \\ \mathbf{2} & 1/3 & 1/3 & 1/3 \\ \mathbf{3} & 0 & 1/2 & 1/2 \end{array}\right].$$

In the above matrix, each column j represents a marginal distribution over the possible tracks that identity j can map to under a random draw from P. We see, for example, that Alice is at Track 1 with probability 2/3, or at Track 2 with probability 1/3. Simultaneously, each row i represents a marginal distribution over the possible identities that could have been mapped to track i under a random draw from P. In our example, Bob and Cathy are equally likely to be in Track 3, but Alice is definitely not in Track 3. Since each row and each column is itself a distribution, the matrix $\widehat{P}_{\tau_{(2,1)}}$ must be doubly stochastic. We will elaborate on the consequences of this observation later.

The Fourier transform of the same distribution at all irreducibles is:

$$\widehat{P}_{\rho_{(3)}} = 1, \quad \widehat{P}_{\rho_{(2,1)}} = \begin{bmatrix} 1/4 & \sqrt{3}/4 \\ \sqrt{3}/4 & 1/4 \end{bmatrix}, \quad \widehat{P}_{\rho_{(1,1,1)}} = 0.$$

The first-order permutation representation, $\tau_{(n-1,1)}$, captures the statistics of how a random permutation acts on a single object irrespective of where all of the other $n-1$ objects are mapped, and in doing so, compactly summarizes the distribution with only $O(n^2)$ numbers. Unfortunately, as mentioned in Section 3, the Fourier transform at the first-order permutation representation cannot capture more complicated statements like:

$$P(\text{Alice and Bob occupy Tracks 1 and 2}) = 0.$$

To avoid collapsing away so much information, we might define richer summary statistics that might capture 'higher-order' effects. We define the *second-order unordered permutation representation* by:

$$[\tau_{(n-2,2)}(\sigma)]_{\{i,j\},\{k,\ell\}} = \mathbb{1}\left\{\sigma(\{k,\ell\}) = \{i,j\}\right\},$$

where we index the matrix rows and columns by unordered pairs $\{i,j\}$. The condition inside the indicator function states that the representation captures whether the pair of objects $\{k,\ell\}$ maps to the pair $\{i,j\}$, but is indifferent with respect to the ordering; that is, either $k \mapsto i$ and $\ell \mapsto j$, *or*, $k \mapsto j$ and $\ell \mapsto i$.

Example 5 *For $n=4$, there are six possible unordered pairs: $\{1,2\}$,$\{1,3\}$,$\{1,4\}$,$\{2,3\}$,$\{2,4\}$, and $\{3,4\}$. The matrix representation of the permutation $(1,2,3)$ is:*

$$\tau_{(2,2)}(1,2,3) = \left[\begin{array}{c|cccccc} & \{1,2\} & \{1,3\} & \{1,4\} & \{2,3\} & \{2,4\} & \{3,4\} \\ \hline \{1,2\} & 0 & 0 & 0 & 1 & 0 & 0 \\ \{1,3\} & 1 & 0 & 0 & 0 & 0 & 0 \\ \{1,4\} & 0 & 0 & 0 & 0 & 1 & 0 \\ \{2,3\} & 0 & 1 & 0 & 0 & 0 & 0 \\ \{2,4\} & 0 & 0 & 0 & 0 & 0 & 1 \\ \{3,4\} & 0 & 0 & 1 & 0 & 0 & 0 \end{array}\right].$$

The *second order ordered permutation representation*, $\tau_{(n-2,1,1)}$, is defined similarly:

$$[\tau_{(n-2,1,1)}(\sigma)]_{(i,j),(k,\ell)} = \mathbb{1}\left\{\sigma((k,\ell)) = (i,j)\right\},$$

where (k,ℓ) denotes an *ordered* pair. Therefore, $[\tau_{(n-2,1,1)}(\sigma)]_{(i,j),(k,\ell)}$ is 1 if and only if σ maps k to i *and* ℓ to j.

As in the first-order case, the Fourier transform of a probability distribution at $\tau_{(n-2,2)}$, returns a matrix of marginal probabilities of the form: $P(\sigma : \sigma(\{k,\ell\}) = \{i,j\})$, which captures statements like, "Alice and Bob occupy Tracks 1 and 2 with probability 1/2". Similarly, the Fourier transform at $\tau_{(n-2,1,1)}$ returns a matrix of marginal probabilities of the form $P(\sigma : \sigma((k,\ell)) = (i,j))$, which captures statements like, "Alice is in Track 1 *and* Bob is in Track 2 with probability 9/10".

We can go further and define third-order representations, fourth-order representations, and so on. In general however, the permutation representations as they have been defined above are reducible, intuitively due to the fact that it is possible to recover lower order marginal probabilities from higher order marginal probabilities. For example, one can recover the normalization constant (corresponding to the trivial representation) from the first order matrix of marginals by summing across either the rows or columns, and the first order marginal probabilities from the second order marginal probabilities by summing across appropriate matrix entries. To truly leverage the machinery of Fourier analysis, it is important to understand the Fourier transform at the irreducibles of the symmetric group, and in the next section, we show how to derive the irreducible representations of the Symmetric group by first defining permutation representations, then "subtracting off the lower-order effects".

5. Representation Theory on the Symmetric Group

In this section, we provide a brief introduction to the representation theory of the Symmetric group. Rather than giving a fully rigorous treatment of the subject, our goal is to give some intuition about the kind of information which can be captured by the irreducible representations of S_n. Roughly speaking, we will show that Fourier transforms on the Symmetric group, instead of being indexed by frequencies, are indexed by *partitions* of n (tuples of numbers which sum to n), and certain partitions correspond to more complex basis functions than others. For proofs, we point the reader to consult: Diaconis (1989), James and Kerber (1981), Sagan (2001) and Vershik and Okounkov (2006).

Instead of the singleton or pairwise marginals which were described in the previous section, we will now focus on using the Fourier coefficients of a distribution to query a much wider class of marginal probabilities. As an example, we will be able to compute the following (more complicated) marginal probability on S_6 using Fourier coefficients:

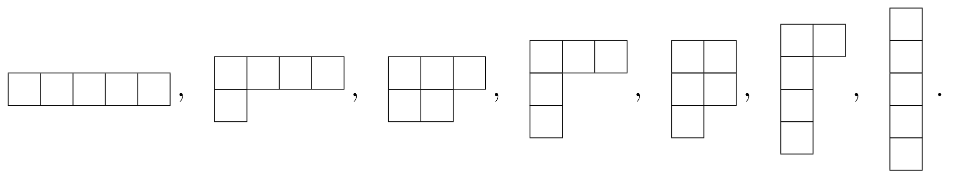
$$P\left(\sigma : \sigma\left(\left\{\begin{ytableau} 1 & 2 & 3 \\ 4 & 5 \\ 6 \end{ytableau}\right\}\right) = \left\{\begin{ytableau} 1 & 2 & 6 \\ 4 & 5 \\ 3 \end{ytableau}\right\}\right), \tag{4}$$

which we interpret as the joint marginal probability that the rows of the diagram on the left map to corresponding rows on the right as unordered sets. In other words, Equation 4 is the joint probability that *unordered* set $\{1,2,3\}$ maps to $\{1,2,6\}$, the unordered pair $\{4,5\}$ maps to $\{4,5\}$, and the singleton $\{6\}$ maps to $\{3\}$.

The diagrams in Equation 4 are known as *Ferrer's diagrams* and are commonly used to visualize *partitions* of n, which are defined to be unordered tuples of positive integers, $\lambda = (\lambda_1, \dots, \lambda_\ell)$, which sum to n. For example, $\lambda = (3,2)$ is a partition of $n = 5$ since $3+2 = 5$. Usually we write partitions as weakly decreasing sequences by convention, so the partitions of $n = 5$ are:

$$(5),\ (4,1),\ (3,2),\ (3,1,1),\ (2,2,1),\ (2,1,1,1),\ (1,1,1,1,1),$$

and their respective Ferrers diagrams are:



A *Young tabloid* is an assignment of the numbers $\{1,\dots,n\}$ to the boxes of a Ferrers diagram for a partition λ, where each row represents an unordered set. There are 6 Young tabloids corresponding to the partition $\lambda = (2,2)$, for example:

$$\left\{\begin{ytableau} 1 & 2 \\ 3 & 4 \end{ytableau}\right\}, \left\{\begin{ytableau} 1 & 3 \\ 2 & 4 \end{ytableau}\right\}, \left\{\begin{ytableau} 1 & 4 \\ 2 & 3 \end{ytableau}\right\}, \left\{\begin{ytableau} 2 & 3 \\ 1 & 4 \end{ytableau}\right\}, \left\{\begin{ytableau} 2 & 4 \\ 1 & 3 \end{ytableau}\right\}, \left\{\begin{ytableau} 3 & 4 \\ 1 & 2 \end{ytableau}\right\}.$$

The Young tabloid, $\begin{ytableau} 1 & 2 \\ 3 & 4 \end{ytableau}$, for example, represents the two underordered sets $\{1,2\}$ and $\{3,4\}$, and if we were interested in computing the joint probability that $\sigma(\{1,2\}) = \{3,4\}$ and $\sigma(\{3,4\}) = \{1,2\}$, then we could write the problem in terms of Young tabloids as:

$$P\left(\sigma : \sigma\left(\left\{\begin{ytableau} 1 & 2 \\ 3 & 4 \end{ytableau}\right\}\right) = \left\{\begin{ytableau} 3 & 4 \\ 1 & 2 \end{ytableau}\right\}\right).$$

In general, we will be able to use the Fourier coefficients at irreducible representations to compute the marginal probabilities of Young tabloids. As we shall see, with the help of the *James Submodule theorem* (James and Kerber, 1981), the marginals corresponding to “simple” partitions will require very few Fourier coefficients to compute, which is one of the main strengths of working in the Fourier domain.

Example 6 *Imagine three separate rooms containing two tracks each, in which Alice and Bob are in room 1 occupying Tracks 1 and 2; Cathy and David are in room 2 occupying Tracks 3 and 4; and Eric and Frank are in room 3 occupying Tracks 5 and 6, but we are not able to distinguish which person is at which track in any of the rooms. Then*

$$P\left(\sigma : \left(\left\{\begin{array}{|c|c|}\hline A & B \\ \hline C & D \\ \hline E & F \\ \hline\end{array}\right\}\right) \to \left\{\begin{array}{|c|c|}\hline 1 & 2 \\ \hline 3 & 4 \\ \hline 5 & 6 \\ \hline\end{array}\right\}\right) = 1.$$

It is in fact, possible to recast the first-order marginals which were described in the previous section in the language of Young tabloids by noticing that, for example, if 1 maps to 1, then the unordered set $\{2,\ldots,n\}$ must map to $\{2,\ldots,n\}$ since permutations are one-to-one mappings. The marginal probability that $\sigma(1) = 1$, then, is equal to the marginal probability that $\sigma(1) = 1$ *and* $\sigma(\{2,\ldots,n\}) = \{2,\ldots,n\}$. If $n = 6$, then the marginal probability written using Young tabloids is:

$$P\left(\sigma : \sigma\left(\left\{\begin{array}{|c|c|c|c|c|}\hline 2 & 3 & 4 & 5 & 6 \\ \hline 1 \\ \cline{1-1}\end{array}\right\}\right) = \left\{\begin{array}{|c|c|c|c|c|}\hline 2 & 3 & 4 & 5 & 6 \\ \hline 1 \\ \cline{1-1}\end{array}\right\}\right).$$

The first-order marginal probabilities correspond, therefore, to the marginal probabilities of Young tabloids of shape $\lambda = (n-1,1)$.

Likewise, the second-order unordered marginals correspond to Young tabloids of shape $\lambda = (n-2,2)$. If $n = 6$ again, then the marginal probability that $\{1,2\}$ maps to $\{2,4\}$ corresponds to the following marginal probability for tabloids:

$$P\left(\sigma : \sigma\left(\left\{\begin{array}{|c|c|c|c|}\hline 3 & 4 & 5 & 6 \\ \hline 1 & 2 \\ \cline{1-2}\end{array}\right\}\right) = \left\{\begin{array}{|c|c|c|c|}\hline 1 & 3 & 5 & 6 \\ \hline 2 & 4 \\ \cline{1-2}\end{array}\right\}\right).$$

The second-order *ordered* marginals are captured at the partition $\lambda = (n-2,1,1)$. For example, the marginal probability that $\{1\}$ maps to $\{2\}$ *and* $\{2\}$ maps to $\{4\}$ is given by:

$$P\left(\sigma : \sigma\left(\left\{\begin{array}{|c|c|c|c|}\hline 3 & 4 & 5 & 6 \\ \hline 1 \\ \cline{1-1} 2 \\ \cline{1-1}\end{array}\right\}\right) = \left\{\begin{array}{|c|c|c|c|}\hline 1 & 3 & 5 & 6 \\ \hline 2 \\ \cline{1-1} 4 \\ \cline{1-1}\end{array}\right\}\right).$$

And finally, we remark that the $(1,\ldots,1)$ partition of n recovers all original probabilities since it asks for a joint distribution over $\sigma(1),\ldots,\sigma(n)$. The corresponding matrix of marginals has $n! \times n!$ entries (though there will only be $n!$ distinct probabilities.

To see how the marginal probabilities of Young tabloids of shape λ can be thought of as Fourier coefficients, we will define a representation (which we call the *permutation representation*) associated with λ and show that the Fourier transform of a distribution at a permutation representation gives marginal probabilities. We begin by fixing an ordering on the set of possible Young tabloids, $\{t_1\}, \{t_2\}, \ldots$, and define the permutation representation $\tau_\lambda(\sigma)$ to be the matrix:

$$[\tau_\lambda(\sigma)]_{ij} = \begin{cases} 1 & \text{if } \sigma(\{t_j\}) = \{t_i\} \\ 0 & \text{otherwise} \end{cases} .$$

It can be checked that the function τ_λ is indeed a valid representation of the Symmetric group, and therefore we can compute Fourier coefficients at τ_λ. If $P(\sigma)$ is a probability distribution, then

$$\begin{aligned} \left[\widehat{P}_{\tau_\lambda}\right]_{ij} &= \sum_{\sigma \in S_n} P(\sigma)\,[\tau_\lambda(\sigma)]_{ij}, \\ &= \sum_{\{\sigma:\sigma(\{t_j\})=\{t_i\}\}} P(\sigma), \\ &= P(\sigma:\ \sigma(\{t_j\}) = \{t_i\}), \end{aligned}$$

and therefore, *the matrix of marginals corresponding to Young tabloids of shape* λ *is given* exactly *by the Fourier transform at the representation* τ_λ.

As we showed earlier, the simplest marginals (the zeroth order normalization constant), correspond to the Fourier transform at $\tau_{(n)}$, while the first-order marginals correspond to $\tau_{(n-1,1)}$, and the second-order unordered marginals correspond to $\tau_{(n-2,2)}$. The list goes on and on, with the marginals getting more complicated. At the other end of the spectrum, we have the Fourier coefficients at the representation $\tau_{(1,1,\ldots,1)}$ which exactly recover the original probabilities $P(\sigma)$.

We use the word 'spectrum' suggestively here, because the different levels of complexity for the marginals are highly reminiscent of the different frequencies for real-valued signals, and a natural question to ask is how the partitions might be ordered with respect to the 'complexity' of the corresponding basis functions. In particular how might one characterize this vague notion of complexity for a given partition?

The 'correct' characterization, as it turns out, is to use the *dominance ordering* of partitions, which, unlike the ordering on frequencies, is not a linear order, but rather, a partial order.

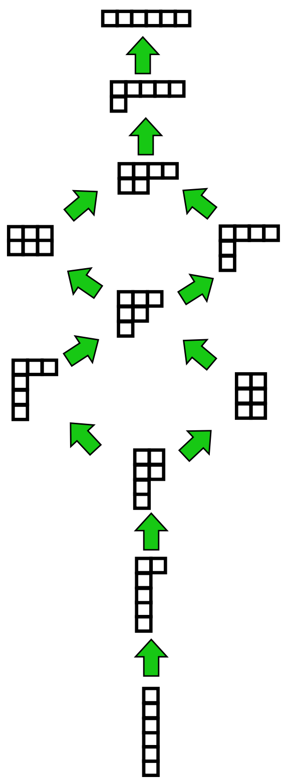
Definition 5 (Dominance Ordering) *Let* λ,μ *be partitions of* n. *Then* $\lambda \trianglerighteq \mu$ *(we say* λ dominates μ*), if for each* i, $\sum_{k=1}^{i} \lambda_k \geq \sum_{k=1}^{i} \mu_k$.

For example, $(4,2) \trianglerighteq (3,2,1)$ since $4 \geq 3$, $4+2 \geq 3+2$, and $4+2+0 \geq 3+2+1$. However, $(3,3)$ and $(4,1,1)$ cannot be compared with respect to the dominance ordering since $3 \leq 4$, but $3+3 \geq 4+1$. The ordering over the partitions of $n=6$ is depicted in Figure 3(a).

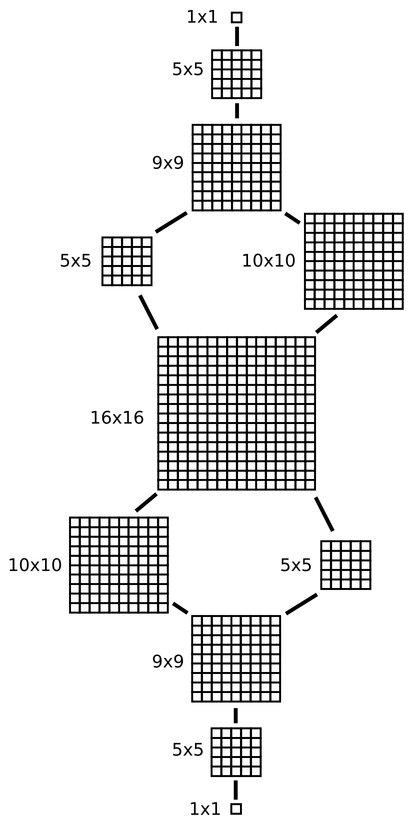
Partitions with fat Ferrers diagrams tend to be greater (with respect to dominance ordering) than those with skinny Ferrers diagrams. Intuitively, representations corresponding to partitions which are *high* in the dominance ordering are 'low frequency', while representations corresponding to partitions which are *low* in the dominance ordering are 'high frequency.'[6]

Having defined a family of intuitive permutation representations over the Symmetric group, we can now ask whether the permutation representations are irreducible or not: the answer in general, is to the negative, due to the fact that it is often possible to reconstruct lower order marginals by summing over the appropriate higher order marginal probabilities. However, it is possible to show

6. The direction of the ordering is slightly counterintuitive given the frequency interpretation, but is standard in the literature.



(a) Dominance ordering for $n = 6$.



(b) Fourier coefficient matrices for S_6.

Figure 3: The dominance order for partitions of $n = 6$ are shown in the left diagram (a). Fat Ferrer's diagrams tend to be higher in the order and long, skinny diagrams tend to be lower. The corresponding Fourier coefficient matrices for each partition (at irreducible representations) are shown in the right diagram (b). Note that since the Fourier basis functions form a complete basis for the space of functions on the Symmetric group, there must be exactly $n!$ coefficients in total.

that, for each permutation representation τ_λ, there exists a corresponding irreducible representation ρ_λ, which, loosely, captures all of the information at the 'frequency' λ which was not already captured at lower frequency irreducibles. Moreover, it can be shown that there exists no irreducible representation besides those indexed by the partitions of n. These remarkable results are formalized in the *James Submodule Theorem*, which we state here without proof (see Diaconis 1988, James and Kerber 1981 and Sagan 2001).

Theorem 6 (James' Submodule Theorem)

1. *(Uniqueness) For each partition, λ, of n, there exists an irreducible representation, ρ_λ, which is unique up to equivalence.*
2. *(Completeness) Every irreducible representation of S_n corresponds to some partition of n.*

3. *There exists a matrix C_λ associated with each partition λ, for which*

$$C_\lambda^T \cdot \tau_\lambda(\sigma) \cdot C_\lambda = \bigoplus_{\mu \trianglerighteq \lambda} \bigoplus_{\ell=1}^{K_{\lambda\mu}} \rho_\mu(\sigma), \quad \textit{for all } \sigma \in S_n. \tag{5}$$

4. $K_{\lambda\lambda} = 1$ *for all partitions* λ.

In plain English, part (3) of the James Submodule theorem says that we can always reconstruct marginal probabilities of λ-tabloids using the Fourier coefficients at irreducibles which lie *at* λ *and above* in the dominance ordering, if we have knowledge of the matrix C_λ (which can be precomputed using methods detailed in Appendix D), and the multiplicities $K_{\lambda\mu}$. In particular, combining Equation 5 with the definition of the Fourier transform, we have that

$$\hat{f}_{\tau_\lambda} = C_\lambda \cdot \left[\bigoplus_{\mu \trianglerighteq \lambda} \bigoplus_{\ell=1}^{K_{\lambda\mu}} \hat{f}_{\rho_\mu} \right] \cdot C_\lambda^T, \tag{6}$$

and so to obtain marginal probabilities of λ-tabloids, we simply construct a block diagonal matrix using the appropriate irreducible Fourier coefficients, and conjugate by C_λ. The multiplicities $K_{\lambda\mu}$ are known as the *Kostka numbers* and can be computed using Young's rule (Sagan, 2001). To illustrate using a few examples, we have the following decompositions:

$$\begin{aligned}
\tau_{(n)} &\equiv \rho_{(n)}, \\
\tau_{(n-1,1)} &\equiv \rho_{(n)} \oplus \rho_{(n-1,1)}, \\
\tau_{(n-2,2)} &\equiv \rho_{(n)} \oplus \rho_{(n-1,1)} \oplus \rho_{(n-2,2)}, \\
\tau_{(n-2,1,1)} &\equiv \rho_{(n)} \oplus \rho_{(n-1,1)} \oplus \rho_{(n-1,1)} \oplus \rho_{(n-2,2)} \oplus \rho_{(n-2,1,1)}, \\
\tau_{(n-3,3)} &\equiv \rho_{(n)} \oplus \rho_{(n-1,1)} \oplus \rho_{(n-2,2)} \oplus \rho_{(n-3,3)}, \\
\tau_{(n-3,2,1)} &\equiv \rho_{(n)} \oplus \rho_{(n-1,1)} \oplus \rho_{(n-1,1)} \oplus \rho_{(n-2,2)} \oplus \rho_{(n-2,2)} \oplus \rho_{(n-2,1,1)} \oplus \rho_{(n-3,3)} \oplus \rho_{(n-3,2,1)}.
\end{aligned}$$

Intuitively, the irreducibles at a partition λ reflect the "pure" λ^{th}-order effects of the underlying distribution. In other words, the irreducibles at λ form a basis for functions that have "interesting" λ^{th}-order marginal probabilities, but uniform marginals at all partitions μ such that $\mu \triangleright \lambda$.

Example 7 *As an example, we demonstrate a "preference" function which is "purely" second-order (unordered) in the sense that its Fourier coefficients are equal to zero at all irreducible representations except* $\rho_{(n-2,2)}$ *(and the trivial representation). Consider the function* $f : S_n \to \mathbb{R}$ *defined by:*

$$f(\sigma) = \begin{cases} 1 & \textit{if } |\sigma(1) - \sigma(2)| \equiv 1 \ (\textit{mod } n) \\ 0 & \textit{otherwise} \end{cases}.$$

Intuitively, imagine seating n people at a round table with n chairs, but with the constraint that the first two people, Alice and Bob, are only happy if they are allowed to sit next to each other. In this case, f can be thought of as the indicator function for the subset of seating arrangements (permutations) which make Alice and Bob happy.

Since f depends only on the destination of the unordered pair $\{1,2\}$*, its Fourier transform is zero at all partitions* μ *such that* $\mu \triangleleft (n-2,2)$ $(\hat{f}_\mu = 0)$*. On the other hand, Alice and Bob*

λ	(n)	$(n-1,1)$	$(n-2,2)$	$(n-2,1,1)$	$(n-3,3)$	$(n-3,2,1)$
$\dim \rho_\lambda$	1	$n-1$	$\frac{n(n-3)}{2}$	$\frac{(n-1)(n-2)}{2}$	$\frac{n(n-1)(n-5)}{6}$	$\frac{n(n-2)(n-4)}{3}$

Table 3: Dimensions of low-order irreducible representation matrices.

have no individual preferences for seating, so the first-order "marginals" of f are uniform, and hence, $\hat{f}_{(n-1,1)} = 0$. The Fourier coefficients at irreducibles can be obtained from the second-order (unordered) "marginals" using Equation 5.

$$C^T_{(n-2,2)} \cdot \hat{P}_{\tau_{(n-2,2)}} \cdot C_{(n-2,2)} = \begin{bmatrix} \boxed{Z} & & \\ & \boxed{0} & \\ & & \boxed{\hat{f}_{\rho_{(n-2,2)}}} \end{bmatrix}.$$

The sizes of the irreducible representation matrices are typically much smaller than their corresponding permutation representation matrices. In the case of $\lambda = (1, \dots, 1)$ for example, $\dim \tau_\lambda = n!$ while $\dim \rho_\lambda = 1$. There is a simple combinatorial algorithm, known as the *Hook Formula* (Sagan, 2001), for computing the dimension of ρ_λ. While we do not discuss it, we provide a few dimensionality computations here (Table 3) to facilitate a dicussion of complexity later. Despite providing polynomial sized function approximations, the Fourier coefficient matrices can grow quite fast, and roughly, one would need $O(n^{2k})$ storage to maintain kth order marginals. For example, we would need to store $O(n^8)$ elements to maintain fourth-order marginals. It is worth noting that since the Fourier transform is invertible, there must be $n!$ Fourier coefficients in total, and so $\sum_\rho d_\rho^2 = |G| = n!$. See Figure 3(b) for an example of what the matrices of a complete Fourier transform on S_6 would look like.

In practice, since the irreducible representation matrices are determined only up to equivalence, it is necessary to choose a basis for the irreducible representations in order to explicitly construct the representation matrices. As in Kondor et al. (2007), we use the *Gel'fand-Tsetlin basis* which has several attractive properties, two advantages being that the matrices are real-valued and orthogonal. See Appendix B for details on constructing irreducible matrix representations with respect to the Gel'fand-Tsetlin basis.

6. Inference in the Fourier Domain

What we have shown thus far is that there is a principled method for compactly summarizing distributions over permutations based on the idea of bandlimiting—saving only the low-frequency terms of the Fourier transform of a function, which, as we discussed, is equivalent to maintaining a set of low-order marginal probabilities. We now turn to the problem of performing probabilistic inference using our compact summaries. One of the main advantages of viewing marginals as Fourier coefficients is that it provides a natural principle for formulating polynomial time approximate inference algorithms, which is to rewrite all inference related operations with respect to the Fourier domain, then to perform the Fourier domain operations ignoring high-order terms.

The idea of bandlimiting a distribution is ultimately moot, however, if it becomes necessary to transform back to the primal domain each time an inference operation is called. Naively, the Fourier Transform on S_n scales as $O((n!)^2)$, and even the fastest Fast Fourier Transforms for functions on S_n are no faster than $O(n^2 \cdot n!)$ (see Maslen 1998 for example). To resolve this issue, we present a formulation of inference which operates solely in the Fourier domain, allowing us to avoid a costly transform. We begin by discussing exact inference in the Fourier domain, which is no more tractable than the original problem because there are $n!$ Fourier coefficients, but it will allow us to discuss the bandlimiting approximation in the next section. There are two operations to consider: prediction/rollup, and conditioning. While we have motivated both of these operations in the familiar context of hidden Markov models, they are fundamental and appear in many other settings. The assumption for the rest of this section is that the Fourier transforms of the transition and observation models are known. We discuss methods for obtaining the models in Section 8. The main results of this section (excluding the discussions about complexity) extend naturally to other finite groups besides S_n.

6.1 Fourier Prediction/Rollup

We will consider one particular class of transition models—that of random walks over a group, which assumes that $\sigma^{(t+1)}$ is generated from $\sigma^{(t)}$ by drawing a random permutation $\pi^{(t)}$ from some distribution $Q^{(t)}$ and setting $\sigma^{(t+1)} = \pi^{(t)}\sigma^{(t)}$.[7] In our identity management example, $\pi^{(t)}$ represents a random identity permutation that might occur among tracks when they get close to each other (what we call a *mixing event*). For example, $Q(1,2) = 1/2$ means that Tracks 1 and 2 swapped identities with probability 1/2. The random walk model also appears in many other applications such as modeling card shuffles (Diaconis, 1988).

The motivation behind the random walk transition model is that it allows us to write the prediction/rollup operation as a *convolution* of distributions on a group. The extension of the familiar notion of convolution to groups simply replaces additions and subtractions by analogous group operations (function composition and inverse, respectively):

Definition 7 *Let Q and P be probability distributions on a group G. Define the* convolution[8] *of Q and P to be the function* $[Q * P](\sigma_1) = \sum_{\sigma_2} Q(\sigma_1\sigma_2^{-1})P(\sigma_2)$.

Using Definition 7, we see that the prediction/rollup step can be written as:

$$\begin{aligned} P(\sigma^{(t+1)}) &= \sum_{\sigma^{(t)}} P(\sigma^{(t+1)}|\sigma^{(t)}) \cdot P(\sigma^{(t)}), \\ &= \sum_{\{(\sigma^{(t)},\pi^{(t)})\,:\,\sigma^{(t+1)}=\pi^{(t)}\cdot\sigma^{(t)}\}} Q^{(t)}(\pi^{(t)}) \cdot P(\sigma^{(t)}), \end{aligned}$$

7. We place π on the left side of the multiplication because we want it to permute tracks and not identities. Had we defined π to map from tracks to identities (instead of identities to tracks), then π would be multiplied from the right. Besides left versus right multiplication, there are no differences between the two conventions.

8. Note that this definition of convolution on groups is *strictly* a generalization of convolution of functions on the real line, and is a non-commutative operation for non-Abelian groups. Thus the distribution $P * Q$ is not necessarily the same as $Q * P$.

$$\begin{aligned}
&\text{(Right-multiplying both sides of } \sigma^{(t+1)} = \pi^{(t)}\sigma^{(t)} \\
&\qquad \text{by } (\sigma^{(t)})^{-1}\text{, we see that } \pi^{(t)} \text{ can be replaced by } \sigma^{(t+1)}(\sigma^{(t)})^{-1}), \\
&= \sum_{\sigma^{(t)}} Q^{(t)}(\sigma^{(t+1)} \cdot (\sigma^{(t)})^{-1}) \cdot P(\sigma^{(t)}), \\
&= \left[Q^{(t)} * P\right](\sigma^{(t+1)}).
\end{aligned}$$

As with Fourier transforms on the real line, the Fourier coefficients of the convolution of distributions P and Q on groups can be obtained from the Fourier coefficients of P and Q individually, using the *convolution theorem* (see also Diaconis 1988):

Proposition 8 (Convolution Theorem) *Let Q and P be probability distributions on a group G. For any representation ρ,*

$$\left[\widehat{Q * P}\right]_\rho = \widehat{Q}_\rho \cdot \widehat{P}_\rho,$$

where the operation on the right side is matrix multiplication.

Therefore, assuming that the Fourier transforms $\widehat{P}^{(t)}_\rho$ and $\widehat{Q}^{(t)}_\rho$ are given, the prediction/rollup update rule is simply:

$$\widehat{P}^{(t+1)}_\rho \leftarrow \widehat{Q}^{(t)}_\rho \cdot \widehat{P}^{(t)}_\rho.$$

Note that the update only requires knowledge of $\hat{P}$ and does not require P. Furthermore, the update is *pointwise* in the Fourier domain in the sense that the coefficients at the representation ρ affect $\widehat{P}^{(t+1)}_\rho$ *only* at ρ. Consequently, prediction/rollup updates in the Fourier domain never increase the representational complexity. For example, if we maintain third-order marginals, then a single step of prediction/rollup called at time t returns the *exact* third-order marginals at time $t+1$, and nothing more.

Example 8 *We run the prediction/rollup routines on the first two time steps of the example in Figure 2, first in the primal domain, then in the Fourier domain. At each mixing event, two tracks, i and j, swap identities with some probability. Using a mixing model given by:*

$$Q(\pi) = \begin{cases} 3/4 & \textit{if } \pi = \varepsilon \\ 1/4 & \textit{if } \pi = (i,j) \\ 0 & \textit{otherwise} \end{cases},$$

we obtain results shown in Tables 4 and 5.

6.1.1 COMPLEXITY OF PREDICTION/ROLLUP

We will discuss complexity in terms of the dimension of the largest maintained irreducible Fourier coefficient matrix, which we will denote by d_{max} (see Table 3 for irreducible dimensions). If we maintain 2^{nd} order marginals, for example, then $d_{max} = O(n^2)$, and if we maintain 3^{rd} order marginals, then $d_{max} = O(n^3)$.

Performing a single prediction/rollup step in the Fourier domain involves performing a single matrix multiplication for each irreducible and thus requires $O(d_{max}^3)$ time using the naive multiplication algorithm.

σ	$P^{(0)}$	$Q^{(1)}$	$P^{(1)}$	$Q^{(2)}$	$P^{(2)}$
ε	1	3/4	3/4	3/4	9/16
$(1,2)$	0	1/4	1/4	0	3/16
$(2,3)$	0	0	0	0	0
$(1,3)$	0	0	0	1/4	3/16
$(1,2,3)$	0	0	0	0	1/16
$(1,3,2)$	0	0	0	0	0

Table 4: Primal domain prediction/rollup example.

	$\widehat{P}^{(0)}$	$\widehat{Q}^{(1)}$	$\widehat{P}^{(1)}$	$\widehat{Q}^{(2)}$	$\widehat{P}^{(2)}$
$\rho_{(3)}$	1	1	1	1	1
$\rho_{(2,1)}$	$\begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}$	$\begin{bmatrix} 1/2 & 0 \\ 0 & 1 \end{bmatrix}$	$\begin{bmatrix} 1/2 & 0 \\ 0 & 1 \end{bmatrix}$	$\begin{bmatrix} 7/8 & -\sqrt{3}/8 \\ -\sqrt{3}/8 & 5/8 \end{bmatrix}$	$\begin{bmatrix} 7/16 & -\sqrt{3}/8 \\ -\sqrt{3}/16 & 5/8 \end{bmatrix}$
$\rho_{(1,1,1)}$	1	1/2	1/2	1/2	1/4

Table 5: Fourier domain prediction/rollup example.

In certain situations, faster updates can be achieved. For example, in the pairwise mixing model of Example 8, the Fourier transform of Q distribution takes the form: $\hat{Q}_{\rho_\lambda} = \alpha I_{d_\lambda} + \beta \rho_\lambda(i,j)$, where I_{d_λ} is the $d_\lambda \times d_\lambda$ identity matrix (see also Section 8). As it turns out, the matrix $\rho_\lambda(i,j)$ can be factored into a product of $O(n)$ sparse matrices each with at most $O(d_\lambda)$ nonzero entries. To see why, recall the elementary fact that the transposition (i,j) factors into a sequence of $O(n)$ adjacent transpositions:

$$(i,j) = (i,i+1)(i+1,i+2)\cdots(j-1,j)(j-2,j-1)\cdot(i+1,i+2)(i,i+1).$$

If we use the Gel'fand-Tsetlin basis adapted to the subgroup chain $S_1 \subset \cdots S_n$ (see Appendix B), then we also know that the irreducible representation matrices evaluated at adjacent transpositions are sparse with no more than $O(d_{max}^2)$ nonzero entries. Thus by carefully exploiting sparsity during the prediction/rollup algorithm, one can achieve an $O(nd_{max}^2)$ update, which is faster than $O(d_{max}^3)$ as long as one uses more than first-order terms.

6.1.2 LIMITATIONS OF RANDOM WALK MODELS

While the random walk assumption captures a rather general family of transition models, there do exist certain models which cannot be written as a random walk on a group. In particular, one limitation is that the prediction/rollup update for a random walk model can only increase the entropy of the distribution. As with Kalman filters, localization is thus impossible without making observations.[9] Shin et al. (2005) show that the entropy must increase for a certain kind of random walk on S_n (where π could be either the identity or the transposition (i,j)), but in fact, the result is easily generalized for any random walk mixing model and for any finite group.

Proposition 9

$$H\left[P^{(t+1)}(\sigma^{(t+1)})\right] \geq \max\left\{H\left[Q^{(t)}(\tau^{(t)})\right], H\left[P^{(t)}(\sigma^{(t)})\right]\right\},$$

where $H[P(\sigma)]$ denotes the statistical entropy functional, $H[P(\sigma)] = -\sum_{\sigma\in G} P(\sigma)\log P(\sigma)$.

Proof We have:

$$\begin{aligned} P^{(t+1)}(\sigma^{(t+1)}) &= \left[Q^{(t)} * P^{(t)}\right](\sigma^{(t+1)}) \\ &= \sum_{\sigma^{(t)}} Q(\sigma^{(t+1)}\cdot(\sigma^{(t)})^{-1})P^{(t)}(\sigma^{(t)}) \end{aligned}$$

Applying the Jensen Inequality to the entropy function (which is concave) yields:

$$\begin{aligned} H\left[P^{(t+1)}(\sigma^{(t+1)})\right] &\geq \sum_{\sigma^{(t)}} P^{(t)}(\sigma^{(t)})H\left[Q^{(t)}(\sigma\cdot(\sigma^{(t)})^{-1})\right], && \text{(Jensen's inequality)} \\ &= \sum_{\sigma^{(t)}} P^{(t)}(\sigma^{(t)})H\left[Q^{(t)}(\sigma)\right], && \text{(translation invariance of entropy)} \\ &= H\left[Q^{(t)}(\sigma)\right], && \text{(since } \textstyle\sum_{\sigma^{(t)}} P^{(t)}(\sigma^{(t)}) = 1). \end{aligned}$$

The proof that $H\left[P^{(t+1)}(\sigma^{(t+1)})\right] \geq H\left[P^{(t)}(\sigma^{(t)})\right]$ is similar with the exception that we must rewrite the convolution so that the sum ranges over $\tau^{(t)}$.

$$\begin{aligned} P^{(t+1)}(\sigma^{(t+1)}) &= \left[Q^{(t)} * P^{(t)}\right](\sigma^{(t+1)}), \\ &= \sum_{\tau^{(t)}} Q^{(t)}(\tau^{(t)})P^{(t)}((\tau^{(t)})^{-1}\cdot\sigma^{(t+1)}). \end{aligned}$$

■

Example 9 *This example is based on one from Diaconis (1988). Consider a deck of cards numbered $\{1,\ldots,n\}$. Choose a random permutation of cards by first picking two cards independently, and swapping (a card might be swapped with itself), yielding the following probability distribution over S_n:*

$$Q(\pi) = \begin{cases} \frac{1}{n} & \text{if } \pi = \varepsilon \\ \frac{2}{n^2} & \text{if } \pi \text{ is a transposition} \\ 0 & \text{otherwise} \end{cases}. \tag{7}$$

9. In general, if we are not constrained to using linear Gaussian models, it *is* possible to localize with no observations. Consider a robot walking along the unit interval on the real line (which is not a group). If the position of the robot is unknown, one easy localization strategy might be to simply drive the robot to the right, with the knowledge that given ample time, the robot will slam into the ‘wall’, at which point it will have been localized. With random walk based models on groups however, these strategies are impossible—imagine the same robot walking around the unit circle—since, in some sense, the group structure prevents the existence of ‘walls’.

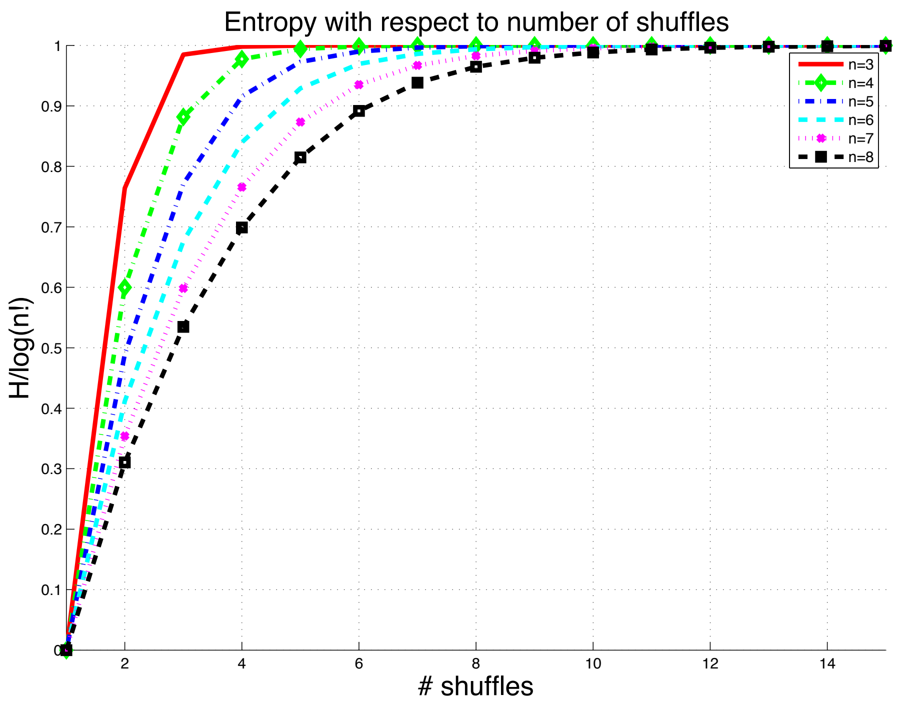


Figure 4: We start with a deck of cards in sorted order, and perform fifteen consecutive shuffles according to the rule given in Equation 7. The plot shows the entropy of the distribution over permutations with respect to the number of shuffles for $n = 3, 4, \ldots, 8$. When $H(P)/\log(n!) = 1$, the distribution has become uniform.

Repeating the above process for generating random permutations π gives a transition model for a hidden Markov model over the symmetric group. We can also see (Figure 4) that the entropy of the deck increases monotonically with each shuffle, and that repeated shuffles with $Q(\pi)$ eventually bring the deck to the uniform distribution.

6.2 Fourier Conditioning

In contrast with the prediction/rollup operation, conditioning can potentially increase the representational complexity. As an example, suppose that we know the following first-order marginal probabilities:

$$P(\text{Alice is at Track 1 or Track 2}) = .9, \text{ and}$$

$$P(\text{Bob is at Track 1 or Track 2}) = .9.$$

If we then make the following first-order observation:

$$P(\text{Cathy is at Track 1 or Track 2}) = 1,$$

then it can be inferred that Alice and Bob cannot *both* occupy Tracks 1 and 2 at the same time, that is,

$$P(\{\text{Alice,Bob}\} \text{ occupy Tracks } \{1{,}2\}) = 0,$$

demonstrating that after conditioning, we are left with knowledge of second-order (unordered) marginals despite the fact that the prior and likelihood functions were only known up to first-order. Intuitively, the example shows that conditioning "smears" information from low-order Fourier coefficients to high-order coefficients, and that one cannot hope for a pointwise operation as was afforded by prediction/rollup. We now show precisely how irreducibles of different complexities "interact" with each other in the Fourier domain during conditioning.

An application of Bayes rule to find a posterior distribution $P(\sigma|z)$ after observing some evidence z requires two steps: a *pointwise product* of likelihood $P(z|\sigma)$ and prior $P(\sigma)$, followed by a normalization step:

$$P(\sigma|z) = \eta \cdot P(z|\sigma) \cdot P(\sigma).$$

For notational convenience, we will refer to the likelihood function as $L(z|\sigma)$ henceforth. We showed earlier that the normalization constant $\eta^{-1} = \sum_\sigma L(z|\sigma) \cdot P(\sigma)$ is given by the Fourier transform of $\widehat{L^{(t)}P^{(t)}}$ at the trivial representation—and therefore the normalization step of conditioning can be implemented by simply dividing each Fourier coefficient by the scalar $\left[\widehat{L^{(t)}P^{(t)}}\right]_{\rho_{(n)}}$.

The pointwise product of two functions f and g, however, is trickier to formulate in the Fourier domain. For functions on the real line, the pointwise product of functions can be implemented by convolving the Fourier coefficients of $\hat{f}$ and $\hat{g}$, and so a natural question is: can we apply a similar operation for functions over general groups? Our answer to this is that there is an analogous (but more complicated) notion of convolution in the Fourier domain of a general finite group. We present a convolution-based conditioning algorithm which we call *Kronecker Conditioning*, which, in contrast to the pointwise nature of the Fourier Domain prediction/rollup step, and much like convolution, smears the information at an irreducible ρ_ν to other irreducibles.

6.2.1 FOURIER TRANSFORM OF THE POINTWISE PRODUCT

Our approach to computing the Fourier transform of the pointwise product in terms of $\hat{f}$ and $\hat{g}$ is to manipulate the function $f(\sigma)g(\sigma)$ so that it can be seen as the result of an inverse Fourier transform (Equation 3). Hence, the goal will be to find matrices R_ν (as a function of $\hat{f}, \hat{g}$) such that for any $\sigma \in G$,

$$f(\sigma) \cdot g(\sigma) = \frac{1}{|G|} \sum_\nu d_{\rho_\nu} \mathrm{Tr}\left(R_\nu^T \cdot \rho_\nu(\sigma)\right), \tag{8}$$

after which we will be able to read off the Fourier transform of the pointwise product as $\left[\widehat{fg}\right]_{\rho_\nu} = R_\nu$.

For any $\sigma \in G$, we can write the pointwise product in terms of $\hat{f}$ and $\hat{g}$ using the inverse Fourier transform:

$$\begin{aligned} f(\sigma) \cdot g(\sigma) &= \left[\frac{1}{|G|} \sum_\lambda d_{\rho_\lambda} \mathrm{Tr}\left(\hat{f}_{\rho_\lambda}^T \cdot \rho_\lambda(\sigma)\right)\right] \cdot \left[\frac{1}{|G|} \sum_\mu d_{\rho_\mu} \mathrm{Tr}\left(\hat{g}_{\rho_\mu}^T \cdot \rho_\mu(\sigma)\right)\right] \\ &= \left(\frac{1}{|G|}\right)^2 \sum_{\lambda,\mu} d_{\rho_\lambda} d_{\rho_\mu} \left[\mathrm{Tr}\left(\hat{f}_{\rho_\lambda}^T \cdot \rho_\lambda(\sigma)\right) \cdot \mathrm{Tr}\left(\hat{g}_{\rho_\mu}^T \cdot \rho_\mu(\sigma)\right)\right]. \end{aligned} \tag{9}$$

1. If A and B are square, $\mathrm{Tr}\,(A \otimes B) = (\mathrm{Tr}A) \cdot (\mathrm{Tr}B)$.
2. $(A \otimes B) \cdot (C \otimes D) = AC \otimes BD$.
3. Let A be an $n \times n$ matrix, and C an invertible $n \times n$ matrix. Then $\mathrm{Tr}A = \mathrm{Tr}\left(C^{-1}AC\right)$.
4. Let A be an $n \times n$ matrix and B_i be matrices of size $m_i \times m_i$ where $\sum_i m_i = n$. Then $\mathrm{Tr}\,(A \cdot (\bigoplus_i B_i)) = \sum_i \mathrm{Tr}\,(A_i \cdot B_i)$, where A_i is the block of A corresponding to block B_i in the matrix $(\bigoplus_i B_i)$.

Table 6: Matrix Identities used in Proposition 10.

Now we want to manipulate this product of traces in the last line to be just one trace (as in Equation 8), by appealing to some properties of the *Kronecker Product*. The Kronecker product of an $n \times n$ matrix $U = (u_{i,j})$ by an $m \times m$ matrix V, is defined to be the $nm \times nm$ matrix

$$U \otimes V = \begin{pmatrix} u_{1,1}V & u_{1,2}V & \dots & u_{1,n}V \\ u_{2,1}V & u_{2,2}V & \dots & u_{2,n}V \\ \vdots & \vdots & \ddots & \vdots \\ u_{n,1}V & u_{n,2}V & \dots & u_{n,n}V \end{pmatrix}.$$

We summarize some important matrix properties in Table 6. The connection to our problem is given by matrix property 1. Applying this to Equation 9, we have:

$$\begin{aligned} \mathrm{Tr}\left(\hat{f}^T_{\rho_\lambda} \cdot \rho_\lambda(\sigma)\right) \cdot \mathrm{Tr}\left(\hat{g}^T_{\rho_\mu} \cdot \rho_\mu(\sigma)\right) &= \mathrm{Tr}\left(\left(\hat{f}^T_{\rho_\lambda} \cdot \rho_\lambda(\sigma)\right) \otimes \left(\hat{g}^T_{\rho_\mu} \cdot \rho_\mu(\sigma)\right)\right) \\ &= \mathrm{Tr}\left(\left(\hat{f}_{\rho_\lambda} \otimes \hat{g}_{\rho_\mu}\right)^T \cdot \left(\rho_\lambda(\sigma) \otimes \rho_\mu(\sigma)\right)\right), \end{aligned}$$

where the last line follows by Property 2. The term on the left, $\hat{f}_{\rho_\lambda} \otimes \hat{g}_{\rho_\mu}$, is a matrix of coefficients. The term on the right, $\rho_\lambda(\sigma) \otimes \rho_\mu(\sigma)$, itself happens to be a representation, called the *Kronecker (or Tensor) Product Representation*. In general, the Kronecker product representation is reducible, and so it can be decomposed into a direct sum of irreducibles. In particular, if ρ_λ and ρ_μ are any two irreducibles of G, there exists a similarity transform $C_{\lambda\mu}$ such that, for any $\sigma \in G$,

$$C^{-1}_{\lambda\mu} \cdot \left[\rho_\lambda \otimes \rho_\mu\right](\sigma) \cdot C_{\lambda\mu} = \bigoplus_{\nu} \bigoplus_{\ell=1}^{z_{\lambda\mu\nu}} \rho_\nu(\sigma). \tag{10}$$

The $\oplus$ symbols here refer to a matrix direct sum as in Equation 2, ν indexes over all irreducible representations of S_n, while ℓ indexes over a number of *copies* of ρ_ν which appear in the decomposition. We index blocks on the right side of this equation by pairs of indices (ν, ℓ). The number of copies of each ρ_ν (for the tensor product pair $\rho_\lambda \otimes \rho_\mu$) is denoted by the integer $z_{\lambda\mu\nu}$, the collection of which, taken over all triples (λ, μ, ν), are commonly referred to as the *Clebsch-Gordan series*. Note that we allow the $z_{\lambda\mu\nu}$ to be zero, in which case ρ_ν does not contribute to the direct sum. The matrices $C_{\lambda\mu}$ are known as the *Clebsch-Gordan coefficients*. The *Kronecker Product Decomposition* problem is that of finding the irreducible components of the Kronecker product representation, and thus to find the Clebsch-Gordan series/coefficients for each pair of irreducible representations (ρ_λ, ρ_μ).

Decomposing the Kronecker product inside Equation 10 using the Clebsch-Gordan series and coefficients yields the desired Fourier transform, which we summarize in the form of a proposition. In the case that f and g are defined over an Abelian group, we will show that the following formulas reduce to the familiar form of convolution.

Proposition 10 *Let $\hat{f}, \hat{g}$ be the Fourier transforms of functions f and g respectively, and for each ordered pair of irreducibles (ρ_λ, ρ_μ), define: $A_{\lambda\mu} \triangleq C_{\lambda\mu}^{-1} \cdot \left(\hat{f}_{\rho_\lambda} \otimes \hat{g}_{\rho_\mu}\right) \cdot C_{\lambda\mu}$. Then the Fourier transform of the pointwise product fg is:*

$$\left[\widehat{fg}\right]_{\rho_\nu} = \frac{1}{d_{\rho_\nu}|G|} \sum_{\lambda\mu} d_{\rho_\lambda} d_{\rho_\mu} \sum_{\ell=1}^{z_{\lambda\mu\nu}} A_{\lambda\mu}^{(\nu,\ell)}, \tag{11}$$

where $A_{\lambda\mu}^{(\nu,\ell)}$ is the block of $A_{\lambda\mu}$ corresponding to the (ν,ℓ) block in $\bigoplus_\nu \bigoplus_{\ell=1}^{z_{\lambda\mu\nu}} \rho_\nu$ from Equation 10.

Proof We use the fact that $C_{\lambda\mu}$ is an orthogonal matrix for all pairs (ρ_λ, ρ_μ), that is, $C_{\lambda\mu}^T \cdot C_{\lambda\mu} = I$.

$$\begin{aligned}
f(\sigma) \cdot g(\sigma) &= \left[\frac{1}{|G|} \sum_\lambda d_{\rho_\lambda} \mathrm{Tr}\left(\hat{f}_{\rho_\lambda}^T \cdot \rho_\lambda(\sigma)\right)\right] \cdot \left[\frac{1}{|G|} \sum_\mu d_{\rho_\mu} \mathrm{Tr}\left(\hat{g}_{\rho_\mu}^T \cdot \rho_\mu(\sigma)\right)\right] \\
&= \left(\frac{1}{|G|}\right)^2 \sum_{\lambda,\mu} d_{\rho_\lambda} d_{\rho_\mu} \left[\mathrm{Tr}\left(\hat{f}_{\rho_\lambda}^T \cdot \rho_\mu(\sigma)\right) \cdot \mathrm{Tr}\left(\hat{g}_{\rho_\mu}^T \cdot \rho_\mu(\sigma)\right)\right] \\
\text{(by Property 1)} &= \left(\frac{1}{|G|}\right)^2 \sum_{\lambda,\mu} d_{\rho_\lambda} d_{\rho_\mu} \left[\mathrm{Tr}\left(\left(\hat{f}_{\rho_\lambda}^T \cdot \rho_\lambda(\sigma)\right) \otimes \left(\hat{g}_{\rho_\mu}^T \cdot \rho_\mu(\sigma)\right)\right)\right] \\
\text{(by Property 2)} &= \left(\frac{1}{|G|}\right)^2 \sum_{\lambda,\mu} d_{\rho_\lambda} d_{\rho_\mu} \mathrm{Tr}\left(\left(\hat{f}_{\rho_\lambda} \otimes \hat{g}_{\rho_\mu}\right)^T \cdot \left(\rho_\lambda(\sigma) \otimes \rho_\mu(\sigma)\right)\right) \\
\text{(by Property 3)} &= \left(\frac{1}{|G|}\right)^2 \sum_{\lambda,\mu} d_{\rho_\lambda} d_{\rho_\mu} \mathrm{Tr}\Big(C_{\lambda\mu}^T \cdot \left(\hat{f}_{\rho_\lambda} \otimes \hat{g}_{\rho_\mu}\right)^T \cdot C_{\lambda\mu} \\
&\qquad \cdot C_{\lambda\mu}^T \cdot \left(\rho_\lambda(\sigma) \otimes \rho_\mu(\sigma)\right) \cdot C_{\lambda\mu}\Big) \\
\text{(by definition of } C_{\lambda\mu} \text{ and } A_{\lambda\mu}) &= \left(\frac{1}{|G|}\right)^2 \sum_{\lambda,\mu} d_{\rho_\lambda} d_{\rho_\mu} \mathrm{Tr}\left(A_{\lambda\mu}^T \cdot \left(\bigoplus_\nu \bigoplus_{\ell=1}^{z_{\lambda\mu\nu}} \rho_\nu(\sigma)\right)\right) \\
\text{(by Property 4)} &= \frac{1}{|G|^2} \sum_{\lambda\mu} d_{\rho_\lambda} d_{\rho_\mu} \sum_\nu d_{\rho_\nu} \sum_{\ell=1}^{z_{\lambda\mu\nu}} \mathrm{Tr}\left(\left(d_{\rho_\nu}^{-1} A_{\lambda\mu}^{(\nu,\ell)}\right)^T \rho_\nu(\sigma)\right) \\
\text{(rearranging terms)} &= \frac{1}{|G|} \sum_\nu d_{\rho_\nu} \mathrm{Tr}\left[\left(\sum_{\lambda\mu} \sum_{\ell=1}^{z_{\lambda\mu\nu}} \frac{d_{\rho_\lambda} d_{\rho_\mu}}{d_{\rho_\nu}|G|} A_{\lambda\mu}^{(\nu,\ell)}\right)^T \rho_\nu(\sigma)\right].
\end{aligned}$$

Recognizing the last expression as an inverse Fourier transform completes the proof. ■

The Clebsch-Gordan series, $z_{\lambda\mu\nu}$, plays an important role in Equation 11, which says that the (ρ_λ, ρ_μ) cross-term contributes to the pointwise product at ρ_ν *only* when $z_{\lambda\mu\nu} > 0$. In the simplest case, we have that

$$z_{(n),\mu,\nu} = \begin{cases} 1 & \text{if } \mu = \nu \\ 0 & \text{otherwise} \end{cases},$$

which is true since $\rho_{(n)}(\sigma) = 1$ for all $\sigma \in S_n$. As another example, it is known that:

$$\rho_{(n-1,1)} \otimes \rho_{(n-1,1)} \equiv \rho_{(n)} \oplus \rho_{(n-1,1)} \oplus \rho_{(n-2,2)} \oplus \rho_{(n-2,1,1)},$$

or equivalently,

$$z_{(n-1,1),(n-1,1),\nu} = \begin{cases} 1 & \text{if } \nu \text{ is one of } (n),(n-1,1),(n-2,2), \text{ or } (n-2,1,1) \\ 0 & \text{otherwise} \end{cases}.$$

So if the Fourier transforms of the likelihood and prior are zero past the first two irreducibles ((n) and $(n-1,1)$), then a single conditioning step results in a Fourier transform which, in general, carries second-order information at $(n-2,2)$ and $(n-2,1,1)$, but is guaranteed to be zero past the first four irreducibles (n), $(n-1,1)$, $(n-2,2)$ and $(n-2,1,1)$.

As far as we know, there are no analytical formulas for finding the entire Clebsch-Gordan series or coefficients, and in practice, acquiring the coefficients requires considerable precomputation. We emphasize however, that as fundamental constants related to the irreducibles of the Symmetric group, they need only be computed *once and for all* (like the digits of π, for example) and can be stored in a table for all future reference. For a detailed discussion of techniques for computing the Clebsch-Gordan series/coefficients, see Appendix D. We have made a set of precomputed coefficients available on our lab website,[10] but we will assume throughout the rest of the paper that both the series and coefficients have been made available as a lookup table.

As a final remark, note that Proposition 10 can be rewritten somewhat more intuitively by absorbing the scalars and submatrices of the Clebsch-Gordan coefficients into projection matrices $P^{(\nu,\ell)}_{\lambda\mu}$.

Proposition 11 *Let $\hat{f}, \hat{g}$ be the Fourier transforms of functions f and g respectively. For each triple of partitions (λ,μ,ν) there exists a positive integer $z_{\lambda,\mu,\nu}$ and projection operators $P^{(\nu,\ell)}_{\lambda\mu}$ for each $\ell \in \{1,2,\ldots,z_{\lambda\mu\nu}\}$ such that the Fourier transform of the pointwise product fg is:*

$$\left[\widehat{fg}\right]_{\rho_\nu} = \sum_{\lambda,\mu}\sum_{\ell=1}^{z_{\lambda\mu\nu}} (P^{(\nu,\ell)}_{\lambda\mu})^T \cdot \left(\hat{f}_{\rho_\lambda} \otimes \hat{g}_{\rho_\mu}\right) \cdot P^{(\nu,\ell)}_{\lambda\mu}. \quad (12)$$

When f and g are functions on an Abelian group G, then it is a well known fact that all irreducible representations are one-dimensional, and so Equation 12 reduces to $\left[\widehat{fg}\right]_{\rho_\nu} = \sum_{\lambda,\mu}\left(\hat{f}_{\rho_\lambda} \cdot \hat{g}_{\rho_\mu}\right)$, where all the tensor products have simply become scalar multiplications and the familiar definition of convolution is recovered.

6.2.2 COMPLEXITY OF CONDITIONING

The complexity of (bandlimited) conditioning (assuming precomputed Clebsch-Gordan series/coefficients) depends on the order of the coefficients maintained for both the prior and the

10. See `http://www.select.cs.cmu.edu/data/index.html`.

observation model. However, it is difficult to state a general complexity bound for arbitrary finite groups due to our limited understanding of the Clebsch-Gordan series. Here we consider conditioning only on the symmetric group of order n with the assumption that the number of irreducibles maintained is very small (and in particular, not allowed to grow with respect to n). Our assumption is realistic in practice since for moderately large n, it is impractical to consider maintaining higher than, say, third-order terms. If we denote the dimension of the largest maintained irreducibles of the prior and likelihood by d_{max}^{prior} and d_{max}^{obs}, respectively, then the complexity of conditioning is dominated by the step that forms a matrix $C^T \cdot (A \otimes B) \cdot C$, where the matrices $A \otimes B$ and C are each $(d_{max}^{prior} \cdot d_{max}^{obs})$-dimensional. Note, however, that since we are only interested in certain blocks of $C^T \cdot (A \otimes B) \cdot C$, the full matrix need not be computed. In particular, the largest extracted block has size d_{max}^{prior}, and so the complexity of conditioning is $O\left((d_{max}^{obs})^2 (d_{max}^{prior})^3\right)$ using the naive matrix multiplication algorithm.

In some situations (see Section 8), the observation model is fully specified by first-order Fourier terms. In such cases, $d_{max}^{obs} = O(n)$ and we can perform conditioning in the Fourier domain in $O(n^2 \cdot (d_{max}^{prior})^3)$ time. If a model is fully specified by second-order terms, for example, then the update requires $O(n^4 \cdot (d_{max}^{prior})^3)$ time.

To speed up conditioning, one can often exploit matrix sparsity in two ways. First, we observe that the Clebsch-Gordan coefficient matrices are often sparse (we cannot yet prove this, see Figure 10.1) and so we can save a conjectured factor of $(d_{max}^{prior} \cdot d_{max}^{obs})$ in practice. Secondly, for certain coset-based observation models (see Section 8), we can show that (under an appropriate relabeling of identities and tracks), the Fourier coefficient matrices of the observation model are sparse (with $O(d_{max}^{obs})$ or sometimes even $O(1)$ nonzero entries for $\hat{L}_\lambda$). For the simplest observations which take the form ("Identity j is at track j"), for example, we can obtain $O((d_{max}^{prior})^3)$ running time (without accounting for the conjectured sparsity of the Clebsch-Gordan coefficients), which matches the time required for the prediction/rollup update. See Appendix B for details.

We now conclude our section on inference with a fully worked example of Kronecker conditioning.

Example 10 *For this example, refer to Table 2 for the representations of S_3. Given functions $f, g : S_3 \to \mathbb{R}$, we will compute the Fourier transform of the pointwise product $f \cdot g$.*

Since there are three irreducibles, there are nine tensor products $\rho_\lambda \otimes \rho_\mu$ to decompose, six of which are trivial either because they are one-dimensional, or involve tensoring against the trivial representation. The nontrivial tensor products to consider are $\rho_{(2,1)} \otimes \rho_{(1,1,1)}$, $\rho_{(1,1,1)} \otimes \rho_{(2,1)}$ and $\rho_{(2,1)} \otimes \rho_{(2,1)}$. The Clebsch-Gordan series for the nontrivial tensor products are:

	$z_{(2,1),(1,1,1),\nu}$	$z_{(1,1,1),(2,1),\nu}$	$z_{(2,1),(2,1),\nu}$
$\nu = (3)$	*0*	*0*	*1*
$\nu = (2,1)$	*1*	*1*	*1*
$\nu = (1,1,1)$	*0*	*0*	*1*

The Clebsch-Gordan coefficients for the nontrivial tensor products are given by the following orthogonal matrices:

$$C_{(2,1)\otimes(1,1,1)} = \begin{bmatrix} 0 & 1 \\ -1 & 0 \end{bmatrix}, \quad C_{(1,1,1)\otimes(2,1)} = \begin{bmatrix} 0 & -1 \\ 1 & 0 \end{bmatrix}, \quad C_{(2,1)\otimes(2,1)} = \frac{\sqrt{2}}{2} \begin{bmatrix} 1 & 0 & -1 & 0 \\ 0 & -1 & 0 & 1 \\ 0 & -1 & 0 & -1 \\ 1 & 0 & 1 & 0 \end{bmatrix}.$$

As in Proposition 10, define:

$$A_{(2,1)\otimes(1,1,1)} = C^T_{(2,1)\otimes(1,1,1)}\left(\hat{f}_{(2,1)}\otimes\hat{g}_{(1,1,1)}\right)C_{(2,1)\otimes(1,1,1)}, \tag{13}$$

$$A_{(1,1,1)\otimes(2,1)} = C^T_{(1,1,1)\otimes(2,1)}\left(\hat{f}_{(1,1,1)}\otimes\hat{g}_{(2,1)}\right)C_{(1,1,1)\otimes(2,1)}, \tag{14}$$

$$A_{(2,1)\otimes(2,1)} = C^T_{(2,1)\otimes(2,1)}\left(\hat{f}_{(2,1)}\otimes\hat{g}_{(2,1)}\right)C_{(2,1)\otimes(2,1)}, \tag{15}$$

Then Proposition 10 gives the following formulas:

$$\widehat{f\cdot g}_{\rho_{(3)}} = \frac{1}{3!}\cdot\left[\hat{f}_{\rho_{(3)}}\cdot\hat{g}_{\rho_{(3)}} + \hat{f}_{\rho_{(1,1,1)}}\cdot\hat{g}_{\rho_{(1,1,1)}} + 4\cdot\left[A_{(2,1)\otimes(2,1)}\right]_{1,1}\right], \tag{16}$$

$$\widehat{f\cdot g}_{\rho_{(2,1)}} = \frac{1}{3!}\cdot\Big[\hat{f}_{\rho_{(2,1)}}\cdot\hat{g}_{\rho_{(3)}} + \hat{f}_{\rho_{(3)}}\cdot\hat{g}_{\rho_{(2,1)}} + A_{(1,1,1)\otimes(2,1)} + A_{(2,1)\otimes(1,1,1)} + 2\cdot\left[A_{(2,1)\otimes(2,1)}\right]_{2:3,2:3}\Big], \tag{17}$$

$$\widehat{f\cdot g}_{\rho_{(1,1,1)}} = \frac{1}{3!}\cdot\left[\hat{f}_{\rho_{(3)}}\cdot\hat{g}_{\rho_{(1,1,1)}} + \hat{f}_{\rho_{(1,1,1)}}\cdot\hat{g}_{\rho_{(3)}} + 4\cdot\left[A_{(2,1)\otimes(2,1)}\right]_{4,4}\right], \tag{18}$$

where the notation $[A]_{a:b,c:d}$ denotes the block of entries in A between rows a and b, and between columns c and d (inclusive).

Using the above formulas, we can continue on Example 8 and compute the last update step in our identity management problem (Figure 2). At the final time step, we observe that Bob is at track 1 with 100% certainty. Our likelihood function is therefore nonzero only for the permutations which map Bob (the second identity) to the first track:

$$L(\sigma) \propto \begin{cases} 1 & \textit{if } \sigma = (1,2) \textit{ or } (1,3,2) \\ 0 & \textit{otherwise} \end{cases}.$$

The Fourier transform of the likelihood function is:

$$\widehat{L}_{\rho_{(3)}} = 2, \quad \widehat{L}_{\rho_{(2,1)}} = \begin{bmatrix} -3/2 & \sqrt{3}/2 \\ -\sqrt{3}/2 & 1/2 \end{bmatrix}, \quad \widehat{L}_{\rho_{(1,1,1)}} = 0. \tag{19}$$

Plugging the Fourier transforms of the prior distribution ($\widehat{P}^{(2)}$ from Table 5) and likelihood (Equation 19) into Equations 13, 14, 15, we have:

$$A_{(2,1)\otimes(1,1,1)} = \begin{bmatrix} 0 & 0 \\ 0 & 0 \end{bmatrix}, \; A_{(1,1,1)\otimes(2,1)} = \frac{1}{8}\begin{bmatrix} 1 & \sqrt{3} \\ -\sqrt{3} & -3 \end{bmatrix}, \; A_{(2,1)\otimes(2,1)} = \frac{1}{32}\begin{bmatrix} -7 & -\sqrt{3} & 11 & 5\sqrt{3} \\ -2\sqrt{3} & -10 & -6\sqrt{3} & -14 \\ 20 & 22\sqrt{3} & -4 & 4\sqrt{3} \\ -11\sqrt{3} & -23 & -\sqrt{3} & -13 \end{bmatrix}$$

To invoke Bayes rule in the Fourier domain, we perform a pointwise product using Equations 16, 17, 18, and normalize by dividing by the trivial coefficient, which yields the Fourier transform of the posterior distribution as:

$$\left[\widehat{P(\sigma|z)}\right]_{\rho_{(3)}} = 1, \quad \left[\widehat{P(\sigma|z)}\right]_{\rho_{(2,1)}} = \begin{bmatrix} -1 & 0 \\ 0 & 1 \end{bmatrix}, \quad \left[\widehat{P(\sigma|z)}\right]_{\rho_{(1,1,1)}} = -1. \tag{20}$$

Finally, we can see that the result is correct by recognizing that the Fourier transform of the posterior (Equation 20) corresponds exactly to the distribution which is 1 at $\sigma = (1,2)$ and 0 everywhere else. Bob is therefore at Track 1, Alice at Track 2 and Cathy at Track 3.

7. Approximate Inference by Bandlimiting

We now consider the consequences of performing inference using the Fourier transform at a reduced set of coefficients. Important issues include understanding how error can be introduced into the system, and when our algorithms are expected to perform well as an approximation. Specifically, we fix a bandlimit λ^{MIN} and maintain the Fourier transform of P only at irreducibles which are at λ^{MIN} or above in the dominance ordering:

$$\Lambda = \{\rho_\lambda \, : \, \lambda \trianglerighteq \lambda^{MIN}\}.$$

For example, when $\lambda^{MIN} = (n-2,1,1)$, Λ is the set $\left\{\rho_{(n)}, \rho_{(n-1,1)}, \rho_{(n-2,2)}, \text{ and } \rho_{(n-2,1,1)}\right\}$, which corresponds to maintaining second-order (ordered) marginal probabilities of the form $P(\sigma((i,j)) = (k,\ell))$. During inference, we follow the procedure outlined in the previous section but discard the higher order terms which can be introduced during the conditioning step. Pseudocode for bandlimited prediction/rollup and Kronecker conditioning is given in Algorithms 1 and 2. We note that it is not necessary to maintain the same number of irreducibles for both prior and likelihood during the conditioning step. The first question to ask is: when should one expect a bandlimited approximation to be close to $P(\sigma)$ as a function? Qualitatively, if a distribution is relatively smooth, then most of its

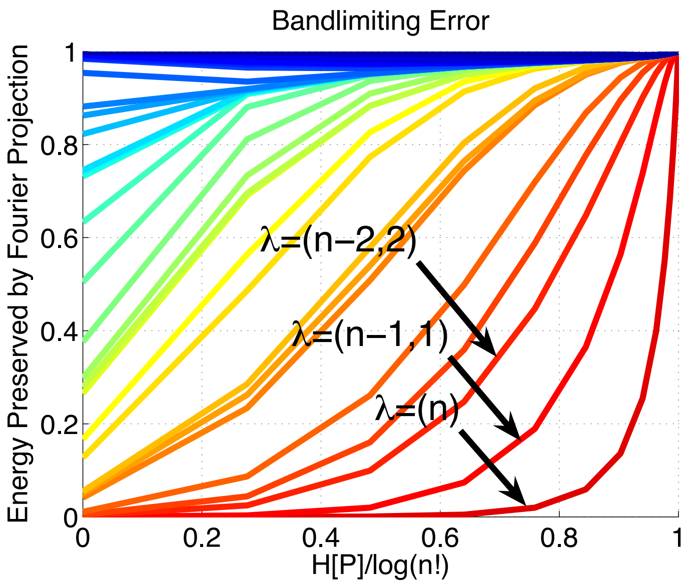

Figure 5: In general, smoother distributions are well approximated by low-order Fourier projections. In this graph, we show the approximation quality of the Fourier projections on distributions with different entropies, starting from sharply peaked delta distributions on the left side of the graph, which get iteratively smoothed until they becomes the maximum entropy uniform distribution on the right side. On the y-axis, we measure how much *energy* is preserved in the bandlimited approximation, which we define to be $\frac{|P'|^2}{|P|^2}$, where P' is the bandlimited approximation to P. Each line represents the approximation quality using a fixed number of Fourier coefficients. At one extreme, we achieve perfect signal reconstruction by using all Fourier coefficients, and at the other, we perform poorly on "spiky" distributions, but well on high-entropy distributions, by storing a single Fourier coefficient.

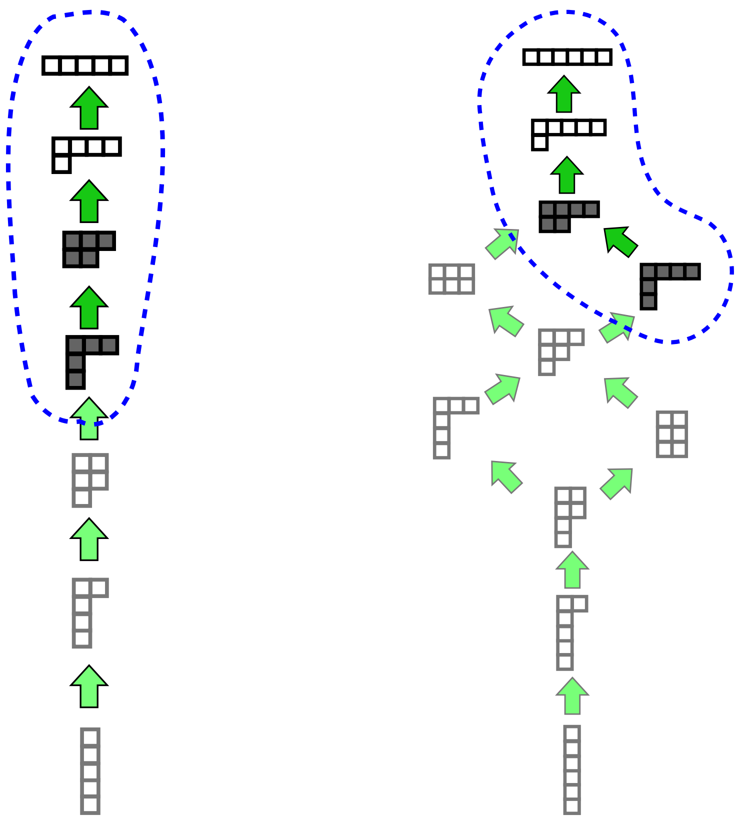
energy is stored in the low-order Fourier coefficients. However, in a phenomenon quite reminiscent of the Heisenberg uncertainty principle from quantum mechanics, it is exactly when the distribution is sharply concentrated at a small subset of permutations, that the Fourier projection is unable to faithfully approximate the distribution. We illustrate this uncertainty effect in Figure 5 by plotting the accuracy of a bandlimited distribution against the entropy of a distribution.

Even though the bandlimited distribution is sometimes a poor approximation to the true distribution, the marginals maintained by our algorithm are often sufficiently accurate. And so instead of considering the approximation accuracy of the bandlimited Fourier transform to the true joint distribution, we consider the accuracy only at the marginals which are maintained by our method.

7.1 Sources of Error During Inference

We now analyze the errors incurred during our inference procedures with respect to the accuracy at maintained marginals. It is immediate that the Fourier domain prediction/rollup operation is *exact* due to its pointwise nature in the Fourier domain. For example, if we have the second order



(a) $n = 5$ (b) $n = 6$

Figure 6: We show the dominance ordering for partitions of $n = 5$ and $n = 6$ again. By setting $\lambda^{MIN} = (3,1,1)$ and $(4,1,1)$ respectively, we keep the irreducibles corresponding to the partitions in the dotted regions. If we call Kronecker Conditioning with a first-order observation model, then according to Theorem 12, we can expect to incur some error at the Fourier coefficients corresponding to $(3,1,1)$ and $(3,2)$ for $n = 5$, and $(4,1,1)$ and $(4,2)$ for $n = 6$ (shown as shaded tableaux), but to be exact at first-order coefficients.

marginals at time $t = 0$, then we can find the exact second order marginals at all $t > 0$ if we only perform prediction/rollup operations. Instead, the errors in inference are only committed by Kronecker conditioning, where they are implicitly introduced at coefficients outside of Λ (by effectively setting the coefficients of the prior and likelihood at irreducibles outside of Λ to be zero), then propagated inside to the irreducibles of Λ.

In practice, we observe that the errors introduced at the low-order irreducibles during inference are small if the prior and likelihood are sufficiently diffuse, which makes sense since the high-frequency Fourier coefficients are small in such cases. We can sometimes show that the update is *exact* at low order irreducibles if we maintain *enough* coefficients.

Theorem 12 *If* $\lambda^{MIN} = (n-p, \lambda_2, \ldots)$*, and the Kronecker conditioning algorithm is called with a likelihood function whose Fourier coefficients are nonzero only at* ρ_μ *when* $\mu \trianglerighteq (n-q, \mu_2, \ldots)$*, then* *the approximate Fourier coefficients of the posterior distribution are exact at the set of irreducibles:*

$$\Lambda_{EXACT} = \{\rho_\lambda : \lambda \trianglerighteq (n - |p-q|, \dots)\}.$$

Proof See Appendix D. ■

For example, if we call Kronecker conditioning by passing in third-order terms of the prior and first-order terms of the likelihood, then all first and second-order (unordered and ordered) marginal probabilities of the posterior distribution can be reconstructed without error.

7.2 Projecting to the Marginal Polytope

Despite the encouraging result of Theorem 12, the fact remains that consecutive conditioning steps can propagate errors to all levels of the bandlimited Fourier transform, and in many circumstances, result in a Fourier transform whose "marginal probabilities" correspond to no consistent joint distribution over permutations, and are sometimes negative. To combat this problem, we present a method for projecting to the space of coefficients corresponding to consistent joint distributions (which we will refer to as the *marginal polytope*) during inference.

We begin by discussing the first-order version of the marginal polytope projection problem. Given an $n \times n$ matrix, M, of real numbers, how can we decide whether there exists some probability distribution which has M as its matrix of first-order marginal probabilities? A necessary and sufficient condition, as it turns out, is for M to be *doubly stochastic*. That is, all entries of M must be nonnegative and all rows and columns of M must sum to one (the probability that Alice is at *some track* is 1, and the probability that *some identity* is at Track 3 is 1). The double stochasticity condition comes from the *Birkhoff-von Neumann* theorem (van Lint and Wilson, 2001) which states that a matrix is doubly stochastic *if and only if* it can be written as a convex combination of permutation matrices.

To "renormalize" first-order marginals to be doubly stochastic, some authors (Shin et al., 2003, 2005; Balakrishnan et al., 2004; Helmbold and Warmuth, 2007) have used the *Sinkhorn iteration*, which alternates between normalizing rows and columns independently until convergence is obtained. Convergence is guaranteed under mild conditions and it can be shown that the limit is a nonnegative doubly stochastic matrix which is closest to the original matrix in the sense that the Kullback-Leibler divergence is minimized (Balakrishnan et al., 2004).

There are several problems which cause the Sinkhorn iteration to be an unnatural solution in our setting. First, since the Sinkhorn iteration only works for nonnegative matrices, we would have to first cap entries to lie in the appropriate range, $[0,1]$. More seriously, even though the Sinkhorn iteration would guarantee a doubly stochastic higher order matrix of marginals, there are several natural constraints which are violated when running the Sinkhorn iteration on higher-order marginals. For example, with second-order (ordered) marginals, it seems that we should at least enforce the following symmetry constraint:

$$P(\sigma : \sigma(k,\ell) = (i,j)) = P(\sigma : \sigma(\ell,k) = (j,i)),$$

which says, for example, that the marginal probability that Alice is in Track 1 and Bob is in Track 2 is the same as the marginal probability that Bob is in Track 2 and Alice is in Track 1. Another natural constraint that can be broken is what we refer to as *low-order marginal consistency*. For example, it should always be the case that:

$$P(j) = \sum_i P(i,j) = \sum_k P(j,k).$$

It should be noted that the doubly stochastic requirement is a special case of lower-order marginal consistency—we require that higher-order marginals be consistent on the 0^{th} order marginal.

While compactly describing the constraints of the marginal polytope exactly remains an open problem, we propose a method for projecting onto a *relaxed* form of the marginal polytope which addresses both symmetry and low-order consistency problems by operating directly on irreducible Fourier coefficients instead of on the matrix of marginal probabilities. After each conditioning step, we apply a 'correction' to the approximate posterior $P^{(t)}$ by finding the bandlimited function in the relaxed marginal polytope which is closest to $P^{(t)}$ in an L_2 sense. To perform the projection, we employ the Plancherel Theorem (Diaconis, 1988) which relates the L_2 distance between functions on S_n to a distance metric in the Fourier domain.

Proposition 13 (Plancherel Theorem)

$$\sum_\sigma (f(\sigma)-g(\sigma))^2 \quad = \quad \frac{1}{|G|}\sum_\nu d_{\rho_\nu} Tr\left(\left(\hat{f}_{\rho_\nu}-\hat{g}_{\rho_\nu}\right)^T \cdot \left(\hat{f}_{\rho_\nu}-\hat{g}_{\rho_\nu}\right)\right). \tag{21}$$

To find the closest bandlimited function in the relaxed marginal polytope, we formulate a quadratic program whose objective is to minimize the right side of Equation 21, and whose sum is taken only over the set of maintained irreducibles, Λ, subject to the set of constraints which require all marginal probabilities to be nonnegative. We thus refer to our correction step as *Plancherel Projection*. Our quadratic program can be written as:

$$\begin{aligned}
&\text{minimize}_{\hat{f}^{proj}} && \sum_{\lambda\in\Lambda} d_\lambda \mathrm{Tr}\left[\left(\hat{f}-\hat{f}^{proj}\right)^T_{\rho_\lambda}\left(\hat{f}-\hat{f}^{proj}\right)_{\rho_\lambda}\right] \\
&\text{subject to:} && \left[\hat{f}^{proj}\right]_{(n)} = 1, \\
& && \left[C_{\lambda^{MIN}}\cdot\left(\bigoplus_{\mu\trianglerighteq\lambda^{MIN}}\bigoplus_{\ell=1}^{K_{\lambda^{MIN},\mu}}\hat{f}^{proj}_{\rho_\mu}\right)\cdot C^T_{\lambda^{MIN}}\right]_{ij} \geq 0, \qquad \text{for all } (i,j),
\end{aligned}$$

where $K_{\lambda^{MIN}}$ and $C_{\lambda^{MIN}}$ are the precomputed constants from Equation 6. We remark that even though the projection will produce a Fourier transform corresponding to nonnegative marginals which are consistent with each other, there might not necessarily exist a joint probability distribution on S_n consistent with those marginals except in the special case of first-order marginals.

Example 11 *In Example 10, we ran the Kronecker conditioning algorithm using all of the Fourier coefficients. If only the first-order coefficients are available, however, then the expressions for zeroth and first order terms of the posterior (Equations 16,17) become:*

$$\begin{aligned}
\widehat{f\cdot g}_{\rho_{(3)}} &= \frac{1}{3!}\cdot\left[\hat{f}_{\rho_{(3)}}\cdot\hat{g}_{\rho_{(3)}} + 4\cdot\left[A_{(2,1)\otimes(2,1)}\right]_{1,1}\right], \\
\widehat{f\cdot g}_{\rho_{(2,1)}} &= \frac{1}{3!}\cdot\left[\hat{f}_{\rho_{(2,1)}}\cdot\hat{g}_{\rho_{(3)}} + \hat{f}_{\rho_{(3)}}\cdot\hat{g}_{\rho_{(2,1)}} + 2\cdot\left[A_{(2,1)\otimes(2,1)}\right]_{2:3,2:3}\right],
\end{aligned}$$

Plugging in the same numerical values from Example 10 and normalizing appropriately yields the approximate Fourier coefficients of the posterior:

$$\left[\widehat{P(\sigma|z)}\right]_{\rho_{(3)}} = 1 \qquad \left[\widehat{P(\sigma|z)}\right]_{\rho_{(2,1)}} = \begin{bmatrix} -10/9 & -77/400 \\ 77/400 & 4/3 \end{bmatrix},$$

which correspond to the following first-order marginal probabilities:

$$\hat{P}_{\tau_{(2,1)}} \left[\begin{array}{c|ccc} & A & B & C \\ \hline \textit{Track 1} & 0 & 11/9 & -2/9 \\ \textit{Track 2} & 1 & 0 & 0 \\ \textit{Track 3} & 0 & -2/9 & 11/9 \end{array}\right].$$

In particular, we see that the approximate matrix of 'marginals' contains negative numbers. Applying the Plancherel projection step, we obtain the following marginals:

$$\hat{P}_{\tau_{(2,1)}} \left[\begin{array}{c|ccc} & A & B & C \\ \hline \textit{Track 1} & 0 & 1 & 0 \\ \textit{Track 2} & 1 & 0 & 0 \\ \textit{Track 3} & 0 & 0 & 1 \end{array}\right],$$

which happen to be exactly the true posterior marginals. It should be noted however, that rounding the 'marginals' to be in the appropriate range would have worked in this particular example as well.

8. Probabilistic Models of Mixing and Observations

While the algorithms presented in the previous sections are general in the sense that they work on all mixing and observation models, it is not always obvious how to compute the Fourier transform of a given model. In this section, we discuss a collection of useful models for which we *can* efficiently compute low-order Fourier coefficients or even provide a closed-form expression. See Table 7 for a summary of the various models covered in this section.

We consider both *mixing* and *observation* models. In multiobject tracking, a mixing model might account for the fact that two tracks may have swapped identities with some probability. Or in card shuffling, a mixing model might reflect that a card has been inserted somewhere into the deck. In multiobject tracking, an observation model might tell us that Alice is at some track with probability one. Or it might reflect the fact that some subset of identities occupies some subset of tracks with no order information, as in the case of the *bluetooth model*. In ranking applications, an observation model might, for example, reflect that some object is ranked higher than, or preferred over some other object.

This section is divided into three parts, each describing a different approach to computing the Fourier coefficients of a model, with some being simpler or more efficient to implement in certain situations than others. In *direct constructions*, we naively apply the definition of the Fourier transform to obtain the Fourier coefficients of some model. In *marginal based constructions*, we first compute the low-order 'marginals' of some probabilistic model, then project the result onto the irreducible Fourier basis. Finally, in *coset-based constructions*, we introduce a family of 'atomic' indicator functions of subgroups of the form $S_k \subset S_n$ which are then combined using

Mixing Model	Example Semantics	Relevant Subgroup
Pairwise mixing	Identity confusion at tracks 1 and 2	S_2
k-subset mixing	Identity confusion at tracks in $\{1,2,4,6\}$	S_k
Insertion mixing	Insert top card somewhere in the deck	n/a

Observation Model	Example Semantics	Relevant Subgroup
Single track observation	Alice is at Track 1	S_{n-1}
Multitrack observation	Alice is at Track 1, Bob is at Track 2, etc.	S_{n-k}
Bluetooth observation	The girls occupy tracks $\{1,2,6,8\}$	$S_k \times S_{n-k}$
Pairwise ranking observation	Apples are better than oranges	S_{n-2}

Table 7: Several useful types of mixing and observation models are summarized in the above table. In many of these cases, computing the appropriate Fourier transform reduces to computing the Fourier transform of the indicator function of some related subgroup of S_n, and so we also mention the relevant subgroup in the second column. In the third column we provide an example illustrating the semantics of each model.

scale/shift/convolution operations to form more complex models. As we discuss in Section 11, there also remains the open possibility of learning models *directly* in the Fourier domain. For the sake of succinctness, many of the results in this section will be stated without proof.

8.1 Direct Construction

In some applications we are fortunate enough to have a model that can be "directly" transformed efficiently using the definition of the Fourier transform (Definition 3). We provide two examples.

8.1.1 Pairwise Mixing

The simplest mixing model for identity management assumes that with probability p, nothing happens, and that with probability $(1-p)$, the identities for tracks i and j are swapped. The probability distribution for the *pairwise mixing model* is therefore:

$$Q_{ij}(\pi) = \begin{cases} p & \text{if } \pi = \varepsilon \\ 1-p & \text{if } \pi = (i,j) \\ 0 & \text{otherwise} \end{cases} . \tag{22}$$

Since Q_{ij} is such a sparse distribution (in the sense that $Q_{ij}(\pi) = 0$ for most π), it is possible to directly compute $\widehat{Q}_{ij}$ using Definition 3:

$$\left[\widehat{Q}_{ij}\right]_{\rho_\lambda} = pI + (1-p)\rho_\lambda((i,j)),$$

where I refers to the $d_\lambda \times d_\lambda$ identity matrix (since any representation must map the identity element ε to an identity matrix), and $\rho_\lambda((i,j))$ is the irreducible representation matrix ρ_λ evaluated at the transposition (i,j) (which can be computed using the algorithms from Appendix C).

8.1.2 INSERTION MIXING

As another example, we can consider the *insertion mixing model* (also called the *top-in shuffle* Diaconis 1988) in which we take the top card in some deck of n cards, and with uniform probability, insert it *somewhere* in the deck, preserving all other original relative orderings. Insertions can be useful in ranking applications where we might wish to add a new item into consideration without disturbing the marginal probabilities over relative rankings of existing items. The distribution for the insertion mixing model is given by:

$$Q^{insertion}(\pi) = \begin{cases} \frac{1}{n} & \text{if } \pi \text{ is a cycle of the form } (j, j-1, \ldots, 1) \text{ for some } j \in \{1, \ldots, n\} \\ 0 & \text{otherwise} \end{cases}.$$

Since the insertion mixing model is supported on n permutations, it is again simple to directly construct the Fourier transform from the definition. We have:

$$\widehat{Q}^{insertion}_{\rho_\lambda} = \frac{1}{n} \sum_{j=1}^{n} \rho_\lambda(j, j-1, \ldots, 1).$$

8.2 Marginal Based Construction

In *marginal based constructions*, we first compute the low-order 'marginals'[11] of some probabilistic model, then project the result onto the irreducible Fourier basis. Thus given a function $f : S_n \to \mathbb{R}$, we compute, for example, the first-order marginals $\hat{f}_{\tau_{(n-1,1)}}$, and conjugate by an intertwining operator (Equation 6) to obtain the Fourier coefficients at (n) and $(n-1,1)$. Sometimes when the Fourier transform of f is provably non-zero *only* at low-order terms, a marginal based construction might be the easiest method to obtain Fourier coefficients.

8.2.1 COLOR HISTOGRAM OBSERVATION

The simplest model assumes that we can get observations of the form: 'track ℓ is color k' (which is essentially the model considered by Kondor et al. 2007). The probability of seeing color k at track ℓ given data association σ is

$$L(\sigma) = P(z_\ell = k|\sigma) = \alpha_{\sigma^{-1}(\ell),k},$$

where $\sum_k \alpha_{\sigma^{-1}(\ell),k} = 1$. For each identity, the likelihood $L(\sigma) = P(z_\ell = k|\sigma)$ depends, for example, on a histogram over all possible colors. If the number of possible colors is K, then the likelihood model can be specified by an $n \times K$ matrix of probabilities. For example,

$$\alpha_{\sigma(\ell),k} = \left[\begin{array}{c|cccc} & k = \text{Red} & k = \text{Orange} & k = \text{Yellow} & k = \text{Green} \\ \hline \sigma(\text{Alice}) = \ell & 1/2 & 1/4 & 1/4 & 0 \\ \sigma(\text{Bob}) = \ell & 1/4 & 0 & 0 & 3/4 \\ \sigma(\text{Cathy}) = \ell & 0 & 1/2 & 1/2 & 0 \end{array} \right]. \quad (23)$$

Since the observation model only depends on a single identity, the first-order terms of the Fourier transform suffice to describe the likelihood exactly. To compute the first-order Fourier coefficients

11. The word 'marginals' is technically appropriate only when the function in question is a legal probability distribution (as opposed to likelihood functions, for example), however we use it to refer to similar summary statistics for general functions.

at irreducibles, we proceed by computing the first-order Fourier coefficients at the first-order permutation representation (the first-order “marginals”), then transforming to irreducible coefficients. The Fourier transform of the likelihood at the first-order permutation representation is given by:

$$\left[\widehat{L}_{\tau_{(n-1,1)}}\right]_{ij} = \sum_{\{\sigma:\sigma(j)=i\}} P(z_\ell = k|\sigma) = \sum_{\{\sigma:\sigma(j)=i\}} \alpha_{\sigma^{-1}(\ell),k}.$$

To compute the ij-term, there are two cases to consider.

1. If $i = \ell$ (that is, if Track i is the same as the track that was observed), then the coefficient $\widehat{L}_{ij}$ is proportional to the probability that Identity j is color k.

$$\widehat{L}_{ij} = \sum_{\{\sigma:\sigma(j)=i\}} \alpha_{j,k} = (n-1)! \cdot \alpha_{j,k}. \tag{24}$$

2. If, on the other hand, $i \neq \ell$ (Track i is not the observed track)), then the coefficient $\hat{L}_{ij}$ is proportional to the sum over

$$\widehat{L}_{ij} = \sum_{\{\sigma:\sigma(j)=i\}} \alpha_{\sigma^{-1}(\ell),k} = \sum_{m\neq j} \sum_{\{\sigma:\sigma(j)=i \text{ and } \sigma(m)=\ell\}} \alpha_{\sigma^{-1}(\ell),k} = \sum_{m\neq j} (n-2)! \cdot \alpha_{m,k}. \tag{25}$$

Example 12 *We will compute the first-order marginals of the likelihood function on S_3 which arises from observing a "Red blob at Track 1". Plugging the values from the “Red” column of the α matrix (Equation 23) into Equation 24 and 25 yields the following matrix of first-order coefficients (at the $\tau_{(n-1,1)}$ permutation representation):*

$$\left[\hat{L}_{(n-1,1)}\right]_{ij} = \left[\begin{array}{c|ccc} & \textit{Track 1} & \textit{Track 2} & \textit{Track 3} \\ \hline \textit{Alice} & 1/4 & 1/2 & 3/4 \\ \textit{Bob} & 1/4 & 1/2 & 3/4 \\ \textit{Cathy} & 1 & 1/2 & 0 \end{array}\right].$$

The corresponding coefficients at the irreducible representations are:

$$\hat{L}_{(3)} = 1.5, \qquad \hat{L}_{(2,1)} = \begin{bmatrix} 0 & 0 \\ -\sqrt{3}/4 & -3/4 \end{bmatrix}, \qquad \hat{L}_{(1,1,1)} = 0.$$

8.2.2 UNORDERED SUBSET (BLUETOOTH) OBSERVATION

We sometimes receive measurements in the form of unordered lists. For example, the *bluetooth model* is the likelihood function that arises if tracks $\{1,\ldots,k\}$ are within range of a bluetooth detector and we receive a measurement that identities $\{1,\ldots,k\}$ are in range. In sports, we might observe that the first k tracks belong to the red team and that the last $n-k$ tracks belong to the blue team. And finally, in *approval voting*, one specifies a subset of approved candidates rather than, for example, picking a single favorite.

We consider two options for bluetooth-type situations. In the first option, we allow for some error-tolerance by setting the likelihood to be proportional to the number of tracks that are correctly returned in the measurement:

$$P^{bluetooth}(z_{\{t_1,\ldots,t_k\}} = \{i_1,\ldots,i_k\}|\sigma) \propto |\{t_1,\ldots,t_k\} \cap \sigma(\{i_1,\ldots,i_k\})| + U(\sigma), \tag{26}$$

where $U(\sigma)$ is a constant function on S_n allowing for noisy observations. Our first bluetooth model can be expressed using only first order terms (intuitively because each track makes a linear contribution) and thus $\hat{P}_\lambda^{bluetooth}$ is nonzero only at the first two partitions $\lambda = (n), (n-1,1)$. For simplicity, we consider the Fourier transform of the function: $f(\sigma) = |\sigma(\{1,\dots,k\}) \cap \{1,\dots,k\}|$. The first-order 'marginals' of f are covered in the following four cases:

- *($j \leq k$ and $i \leq k$)*: $L_{ij} = \sum_{\sigma:\sigma(j)=i} f(\sigma) = (k-1)^2(n-2)! + (n-1)!$
- *($j \leq k$ and $i > k$)*: $L_{ij} = \sum_{\sigma:\sigma(j)=i} f(\sigma) = k(k-1)(n-2)!$
- *($j > k$ and $i \leq k$)*: $L_{ij} = \sum_{\sigma:\sigma(j)=i} f(\sigma) = k(k-1)(n-2)!$
- *($j > k$ and $i > k$)*: $L_{ij} = \sum_{\sigma:\sigma(j)=i} f(\sigma) = k^2(n-2)!$

We discuss the second bluetooth-type model after discussing coset based constructions.

8.3 Coset-Based Construction

Most of the time, realistic models are not supported on only a handful of permutations. The approach we take now is to use a collection of 'primitive' functions to form more interesting models via scale/shift/convolution operations. In particular, we will make use of indicator functions of subsets of the form $S_{X,Y} \subset S_n$, where $X = (x_1,\dots,x_k)$ and $Y = (y_1,\dots,y_k)$ are ordered k-tuples with $\{x_1,\dots,x_k\} \subset \{1,\dots,n\}$, $\{y_1,\dots,y_k\} \subset \{1,\dots,n\}$ and no repetitions are allowed. $S_{X,Y}$ denotes the set of elements in S_n which are constrained to map each x_i to y_i:

$$S_{X,Y} \equiv \{\sigma \in S_n \ : \ \sigma(x_i) = y_i, \text{for each i=1,\dots,k}\}. \qquad (27)$$

The $S_{X,Y}$ can also be thought of as two-sided cosets associated with subgroups of the form $S_{n-k} \subset S_n$. For example, if $X = (1,2)$ and $Y = (3,4)$ with $n = 4$, then $S_{X,Y}$ is simply the set of all permutations that map $1 \mapsto 3$ and $2 \mapsto 4$. Thus, $S_{X,Y} = \{(1,3)(2,4), (1,3,2,4)\}$. Since $|X| = |Y| = k$, then $|S_{X,Y}| = (n-k)!$, and in the special case that $X = Y$, we have that $S_{X,Y}$ is in fact a subgroup isomorphic to S_{n-k}.

As we show in Appendix C, the Fourier transform of the indicator $\delta_{S_{X,Y}}$ takes a particularly simple (and low rank) form and can be efficiently computed. The method described in Appendix C is based on the FFT and exploits the same structure of the symmetric group that is used by Kondor et al. (2007). It is thus possible to understand why some observation models afford faster conditioning updates based on sparsity in Fourier domain.

The functions $\delta_{S_{X,Y}}$ can be viewed as a set of function primitives for constructing more complicated models via shift/scale/convolution operations in the Fourier domain. We now discuss the remaining models in Table 7 with the assumption that there exists some blackbox function which constructs the Fourier coefficients of the indicator function of (two-sided) cosets of the form $S_{X,Y} \subset S_n$ (see Algorithm 5 in Appendix D).

8.3.1 k-SUBSET MIXING

It is not always appropriate to mix only two people at once (as in Equation 22) and so we would like to formulate a mixing model which occurs over a subset of tracks, $X = \{t_1,\dots,t_k\} \subset \{1,\dots,n\}$. One way to 'mimic' the desired effect is to repeatedly draw pairs (i,j) from $\{t_1,\dots,t_k\}$ and to convolve against the pairwise mixing models Q_{ij}. A better alternative is to directly construct the Fourier coefficient matrices for the *k-subset mixing model*, in which we allow the tracks in X to be randomly permuted with uniform probability. In the following, $\bar{X}$ denotes some fixed ordering of the complement of X. For example, if $n = 5$, with $X = \{1,2,4\}$, then $\bar{X}$ is either $(3,5)$ or $(5,3)$. The k-subset mixing model is defined as:

$$Q_X(\pi) = \begin{cases} \frac{1}{k!} & \text{if } \pi \in S_{\bar{X},\bar{X}} \subset S_n \\ 0 & \text{otherwise} \end{cases}. \tag{28}$$

Note that $S_{\bar{X},\bar{X}}$ is isomorphic to S_k and that the pairwise mixing model is the special case where $k = 2$. Intuitively, Equation 28 fixes all of the tracks outside of X and says that with uniform probability, the set of tracks in X experience some permutation of their respective identities. Equation 28 can also be written as $Q_X(\pi) = \frac{1}{k!}\delta_{S_{\bar{X},\bar{X}}}(\pi)$, and thus the mixing model is simply a multiple of the indicator function of $S_{\bar{X},\bar{X}}$.

8.3.2 SINGLE/MULTI-TRACK OBSERVATION

In the *single track observation model* (used in Shin et al. 2005, Schumitsch et al. 2005 and Kondor et al. 2007, for example), we acquire an identity measurement z_j at track j. In the simplest version of the model, we write the likelihood function as:

$$P(z_i = j|\sigma) = \begin{cases} \pi & \text{if } \sigma(j) = i \\ \frac{1-\pi}{n-1} & \text{otherwise} \end{cases}, \tag{29}$$

where j ranges over all n possible identities. $P(z_i|\sigma)$ can also be written as a weighted sum of a uniform distribution U, and an indicator function:

$$P(z_i = j|\sigma) = \left(\frac{\pi n - 1}{n-1}\right)\delta_{S_{j,i}}(\sigma) + \left(\frac{1-\pi}{n-1}\right)U(\sigma).$$

Equation 29 is useful when we receive measurements directly as single identities ("Alice is at Track 1 with such and such probability"). It is, however, far more common to receive lower level measurements that *depend* only upon a single identity, which we formalize with the following conditional independence assumption:

$$P(z_i|\sigma) = P(z_i|\sigma(j)).$$

For example, as in Equation 23, we might have a color histogram over each individual ("Alice loves to wear green") and observe a single color per timestep. Or we might acquire observations in the form of color histograms and choose to model a distribution over all possible color histograms. If for each identity j, $P(z_i|\sigma(j) = i) = \alpha_j$, then we can write the likelihood function as a weighted linear combination of n indicators,

$$L(\sigma) = P(z_i|\sigma) = \sum_j \alpha_j \delta_{S_{j,i}}(\sigma),$$

and by the linearity of the Fourier transform, we can obtain the Fourier coefficients of L:

$$\hat{L}_\lambda = \sum_j \alpha_j \left[\widehat{\delta_{S_{j,i}}}\right]_\lambda.$$

Finally, the single-track observations can be generalized to handle joint observations of multiple tracks at once with a higher-order model:

$$P(z_{(t_1,\dots,t_k)} = (i_1,\dots,i_k)|\sigma) = \begin{cases} \pi & \text{if } \sigma(i_\ell) = t_\ell \text{ for each } \ell \in \{1,\dots,k\} \\ \frac{1-\pi}{\frac{n!}{(n-k)!}-1} & \text{otherwise} \end{cases} . \quad (30)$$

Unsurprisingly, while the Fourier coefficients of Equation 29 can be expressed exactly using first-order terms, the Fourier coefficients of the multi-track observation model, Equation 30, requires kth-order terms. It is important to note that joint multi-track observations are distinct from making k independent identity observations at the same timestep—we can handle the latter case by calling the Kronecker conditioning algorithm with a single-track observation model k times. Depending upon the specific sensor setup, one model may be more natural than the other.

8.3.3 BLUETOOTH OBSERVATION

In contrast with the first bluetooth model (Equation 26), our second bluetooth-type model handles a higher-order form of measurement. Like the single/multi-track observation models, it says that with some probability we receive the correct unordered list, and with some probability, we receive some other list drawn uniformly at random:

$$P^{bluetooth2}(z_{\{t_1,\dots,t_k\}} = \{i_1,\dots,i_k\}|\sigma) = \begin{cases} \pi & \text{if } \sigma(\{i_1,\dots,i_k\}) = \{t_1,\dots,t_k\} \\ \frac{1-\pi}{\binom{n}{k}-1} & \text{otherwise} \end{cases} .$$

As with the single/multi-track observation models, the bluetooth model can be written as a weighted linear combination of a uniform distribution and the indicator function of an $S_k \times S_{n-k}$-coset, where:

$$S_k \times S_{n-k} = \{\sigma \in S_n \,:\, \sigma(\{1,\dots,k\}) = \{1,\dots,k\}\}.$$

To compute the Fourier transform of $P^{bluetooth2}$, it is enough to note that the indicator function of $S_k \times S_{n-k}$ can be thought of as a convolution of indicator functions of S_k and S_{n-k} in a certain sense. More precisely.

Proposition 14 *Let $X = (1,\dots,k)$ and $Y = (k+1,\dots,n)$. Then:* $\delta_{S_k \times S_{n-k}} = \delta_{S_{X,X}} * \delta_{S_{Y,Y}}$.

Invoking the convolution theorem (Proposition 8) shows that the Fourier coefficient matrices of $\delta_{S_k\times S_{n-k}}$ can be constructed by first computing the Fourier coefficients of $S_{X,X}$ and $S_{Y,Y}$, and pointwise multiplying corresponding coefficient matrices. We have:

$$\left[\widehat{\delta}_{S_k\times S_{n-k}}\right]_\lambda = \left[\widehat{\delta}_{S_{X,X}}\right]_\lambda \cdot \left[\widehat{\delta}_{S_{Y,Y}}\right]_\lambda, \text{ for all partitions } \lambda.$$

An interesting fact about the bluetooth model is that its Fourier terms are zero at all partitions with more than two rows.

Proposition 15 *Without loss of generality, assume that $k \le \frac{n}{2}$. The Fourier transform of the bluetooth model, $\hat{P}^{bluetooth2}_\lambda$ is nonzero only at partitions of the form $(n-s,s)$ where $s \le k$.*

8.3.4 PAIRWISE RANKING OBSERVATION

Finally in the *pairwise ranking model*, we consider observations of the form "object j is ranked higher than object i" which can appear in various forms of voting and preference elicitation ("I like candidate x better than candidate y") or webpage/advertisement ranking. Here we think of σ as a mapping from objects to ranks. Our pairwise ranking model simply assigns higher probability to observations which agree with the ordering of i and j in σ.

$$P^{rank}(z_{k\ell}|\sigma) = \begin{cases} \pi & \text{if } \sigma(k) < \sigma(\ell) \\ 1-\pi & \text{otherwise} \end{cases} .$$

When $k = n-1$, $\ell = n$ and $\pi = 1$, we have:

$$\begin{aligned} P^{rank}(z_{k\ell}|\sigma) &= \begin{cases} 1 & \text{if } \sigma(n-1) < \sigma(n) \\ 0 & \text{otherwise} \end{cases} \\ &= \sum_{i<j} \delta_{S_{(n-1,n),(i,j)}}(\sigma). \end{aligned}$$

Perhaps unsurprisingly, pairwise ranking models can be sufficiently captured by first-order and second-order (ordered) Fourier coefficients[12].

Proposition 16 *The Fourier coefficients of the pairwise ranking model, $\hat{P}^{rank}_{\lambda}$, are nonzero only at three partitions: $\lambda = (n)$, $(n-1,1)$, and $(n-2,1,1)$.*

9. Related Work

Rankings and permutations have recently become an active area of research in machine learning due to their importance in information retrieval and preference elicitation. Rather than considering full distributions over permutations, many approaches, like RankSVM (Joachims, 2002) and RankBoost (Freund et al., 2003), have instead focused on learning a single 'optimal' ranking with respect to some objective function.

There are also several authors (from both the statistics and machine learning communities) who have studied distributions over permutations/rankings (Mallows, 1957; Critchlow, 1985; Fligner and Verducci, 1986; Meila et al., 2007; Taylor et al., 2008; Lebanon and Mao, 2008). Taylor et al. (2008) consider distributions over S_n which are induced by the rankings of n independent draws from n individually centered Gaussian distributions with equal variance. They compactly summarize their distributions using an $O(n^2)$ matrix which is conceptually similar to our first-order summaries and apply their techniques to ranking web documents. Most other previous approaches at directly modeling distributions on S_n, however, have relied on distance based exponential family models. For example, the Mallows model (Mallows, 1957) defines a Gaussian-like distribution over permutations as:

$$P(\sigma; c, \sigma_0) \propto \exp\left(-cd(\sigma, \sigma_0)\right),$$

where the function $d(\sigma, \sigma_0)$ is the *Kendall's tau distance* which counts the number of adjacent swaps that are required to bring σ^{-1} to σ_0^{-1}.

12. Additionally, $\hat{P}^{rank}_{(n-1,1)}$ and $\hat{P}^{rank}_{(n-2,1,1)}$ are known to be rank 1 matrices, a fact which can potentially be exploited for faster conditioning updates in practice.

Distance based exponential family models have the advantage that they can compactly represent distributions for very large n, and admit conjugate prior distributions (Meila et al., 2007). Estimating parameters has been a popular problem for statisticians—recovering the optimal σ_0 from data is known as the *consensus ranking* or *rank aggregation* problem and is known to be *NP*-hard (Bartholdi et al., 1989). Many authors have focused on approximation algorithms instead.

Like Gaussian distributions, distance based models also tend to lack flexibility, and so Lebanon and Mao (2008) propose a nonparametric model of ranked (and partially ranked) data based on placing weighted Mallows kernels on top of training examples, which, as they show, can realize a far richer class of distributions, and can be learned efficiently. However, they do not address the inference problem, and it is not clear if one can efficiently perform inference operations like marginalization and conditioning in such models.

As we have shown in this paper, Fourier based methods (Diaconis, 1988; Kondor et al., 2007; Huang et al., 2007) offer a principled alternative method for compactly representing distributions over permutations and performing efficient probabilistic inference operations. Our work draws from two strands of research—one from the data association/identity management literature, and one from a more theoretical area on Fourier analysis in statistics. In the following, we review several of the works which have led up to our current Fourier based approach.

9.1 Previous Work in Identity Management

The identity management problem has been addressed in a number of previous works, and is closely related to, but not identical with, the classical data association problem of maintaining correspondences between tracks and observations. Both problems need to address the fundamental combinatorial challenge that there is a factorial or exponential number of associations to maintain between tracks and identities, or between tracks and observations respectively. A vast literature already exists on the the data association problem, beginning with the *multiple hypothesis testing* approach (MHT) of Reid (1979). The MHT is a 'deferred logic' method in which past observations are exploited in forming new hypotheses when a new set of observations arises. Since the number of hypotheses can grow exponentially over time, various heuristics have been proposed to help cope with the complexity blowup. For example, one can choose to maintain only the *k best* hypotheses for some parameter k (Cox and Hingorani, 1994), using Murty's algorithm (Murty, 1968). But for such an approximation to be effective, k may still need to scale exponentially in the number of objects. A slightly more recent filtering approach is the *joint probabilistic data association filter* (JPDA) (Bar-Shalom and Fortmann, 1988), which is a suboptimal single-stage approximation of the optimal Bayesian filter. JPDA makes associations sequentially and is unable to correct erroneous associations made in the past (Poore, 1995). Even though the JPDA is more efficient than the MHT, the calculation of the JPDA association probabilities is still a #P-complete problem (Collins and Uhlmann, 1992), since it effectively must compute matrix permanents. Polynomial approximation algorithms to the JPDA association probabilities have recently been studied using Markov chain Monte Carlo (MCMC) methods (Oh et al., 2004; Oh and Sastry, 2005).

The identity management problem was first explicitly introduced in Shin et al. (2003). Identity management differs from the classical data association problem in that its observation model is not concerned with the low-level tracking details but instead with high level information about object identities. Shin et al. (2003) introduced the notion of the *belief matrix* approximation of the association probabilities, which collapses a distribution over all possible associations to just its first-order marginals. In the case of n tracks and n identities, the belief matrix B is an $n \times n$ doubly-stochastic matrix of non-negative entries b_{ij}, where b_{ij} is the probability that identity i is associated with track j. As we already saw in Section 4, the belief matrix approximation is equivalent to maintaining the zeroth- and first-order Fourier coefficients. Thus our current work is a strict generalization and extension of those previous results.

An alternative representation that has also been considered is an information theoretic approach (Shin et al., 2005; Schumitsch et al., 2005, 2006) in which the density is parameterized as:

$$P(\sigma;\Omega) \propto \exp \mathrm{Tr}\left(\Omega^T \cdot \tau_{(n-1,1)}(\sigma)\right).$$

In our framework, the information form approach can be viewed as a method for maintaining the Fourier transform of the *log* probability distribution at only the first two irreducibles. The information matrix approach is especially attractive in a distributed sensor network setting, since, if the columns of the information matrix are distributed to leader nodes tracking the respective targets, then the observation events become entirely local operations, avoiding the more expensive Kronecker conditioning algorithm in our setting. On the other hand, the information matrix coefficients do not have the same intuitive marginals interpretation afforded in our setting, and moreover, prediction/rollup steps cannot be performed analytically in the information matrix form. As in many classical data structures problems there are representation trade-off issues: some operations are less expensive in one representation and some operations in the the other. The best choice in any particular scenario will depend on the ratio between observation and mixing events.

9.2 Previous Work on Fourier-Based Approximations

The concept of using Fourier transforms to study probability distributions on groups is not new, with the earliest papers in this area having been published in the 1960s (Grenander, 1963). Willsky (1978) was the first to formulate the exact filtering problem in the Fourier domain for finite and locally compact Lie groups and contributed the first noncommutative Fast Fourier Transform algorithm (for Metacyclic groups). However, he does not address approximate inference, suggesting instead to always transform to the appropriate domain for which either the prediction/rollup or conditioning operations can be accomplished using a pointwise product. While providing significant improvements in complexity for smaller groups, his approach is still infeasible for our problem given the factorial order of the Symmetric group.

Diaconis (1988) used the Fourier transform to analyze probability distributions on the Symmetric group in order to study card shuffling and ranking problems. His work laid the ground for much of the progress made over the last two decades on probabilistic group theory and noncommutative FFT algorithms (Clausen and Baum, 1993; Rockmore, 2000).

Kondor et al. (2007) was the first to show that the data association problem could be efficiently approximated using FFT factorizations. In contrast to our framework where every model is assumed to be have been specified in the Fourier domain, they work with an observation model which can be written as the indicator function of cosets of subgroups of the form $S_k \subset S_n$.

Conceptually, one might imagine formulating a conditioning algorithm which applies the Inverse Fast Fourier Transform (IFFT) to the prior distribution, conditions in the primal domain using pointwise multiplication, then transforms back up to the Fourier domain using the FFT to obtain posterior Fourier coefficients. While such a procedure would ordinarily be intractable because of the factorial number of permutations, Kondor et al. (2007) elegantly shows that for certain coset-based observation models, it is not necessary to perform the full FFT recursion to do a pointwise product. They exploit this observation to formulate an efficient conditioning algorithm whose running time depends on the complexity of the observation model (which can roughly be measured by the number of irreducibles required to fully specify it).

Our work generalizes the conditioning formulation from Kondor et al. (2007) in the sense that it can work for *any* observation model and extends easily to similar filtering problems over any finite group. In the case that the observation model is specified at sufficiently many irreducibles, our conditioning algorithm (prior to the projection step) returns the same approximate probabilities as the FFT-based algorithm. For example, we can show that the observation model given in Equation 29 is fully specified by two Fourier components, and that both algorithms have identical output. Additionally, Kondor et al. (2007) do not address the issue of projecting onto legal distributions, which, as we show in our experimental results is fundamental in practice.

10. Experimental Results

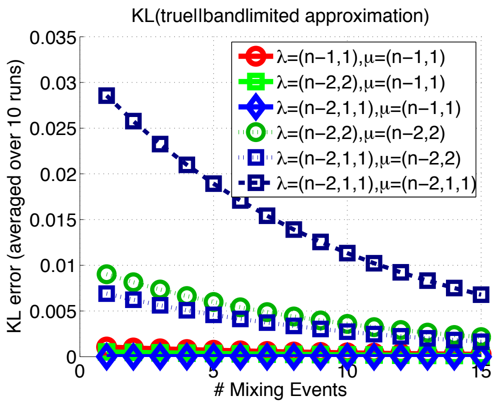
In this section we present the results of several experiments to validate our algorithm. We evaluate performance first by measuring the quality of our approximation for problems where the true distribution is known. Instead of measuring a distance between the true distribution and the inverse Fourier transform of our approximation, it makes more sense in our setting to measure error only at the marginals which are maintained by our approximation. In the results reported below, we measure the L_1 error between the true matrix of marginals and the approximation. If nonnegative marginal probabilities are guaranteed, it also makes sense to measure KL-divergence.

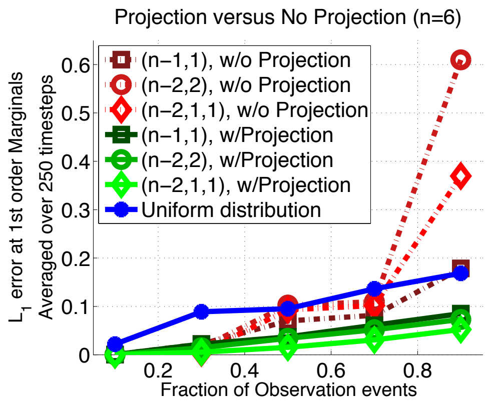
10.1 Simulated Data

We first tested the accuracy of a single Kronecker conditioning step by calling some number of pairwise mixing events (which can be thought roughly as a measure of entropy), followed by a single first-order observation. In the y-axis of Figure 7(a), we plot the Kullback-Leibler divergence between the true first-order marginals and approximate first-order marginals returned by Kronecker conditioning. We compared the results of maintaining first-order, and second-order (unordered and ordered) marginals. As shown in Figure 7(a), Kronecker conditioning is more accurate when the prior is smooth and unsurprisingly, when we allow for higher order Fourier terms. As guaranteed by Theorem 12, we also see that the first-order terms of the posterior are exact when we maintain second-order (ordered) marginals.

To understand how our algorithms perform over many timesteps (where errors can propagate to all Fourier terms), we compared to exact inference on synthetic data sets in which tracks are drawn at random to be observed or swapped. As a baseline, we show the accuracy of a uniform distribution. We observe that the Fourier approximation is better when there are either more mixing events (the fraction of conditioning events is smaller), or when more Fourier coefficients are maintained, as shown in Figure 7(b). We also see that the Plancherel Projection step is fundamental, especially when mixing events are rare.

Figures 10(a) and 10(b) show the per-timeslice accuracy of two typical runs of the algorithm. The fraction of conditioning events is 50% in Figure 10(a), and 70% in Figure 10(b). What we typically observe is that while the projected and nonprojected accuracies are often quite similar, the nonprojected marginals can perform significantly worse during certain segments.





(a) Kronecker Conditioning Accuracy—we measure the accuracy of a single Kronecker conditioning operation after some number of mixing events.

(b) HMM Accuracy—we measure the average accuracy of posterior marginals over 250 timesteps, varying the proportion of mixing and observation events

Figure 7: Simulation results.

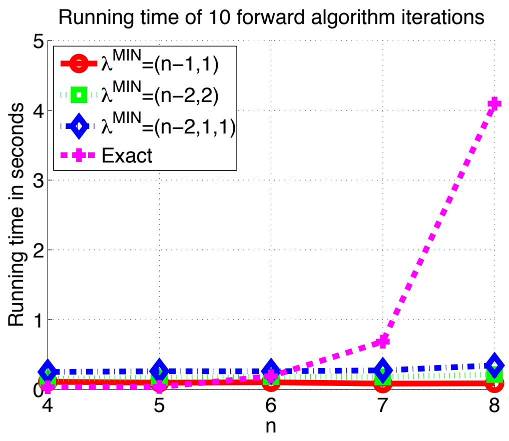


Figure 8: Running times: We compared running times of our polynomial time bandlimited inference algorithms against an exact algorithm with $O(n^3 n!)$ time complexity

Finally, we compared running times against an exact inference algorithm which performs prediction/rollup in the Fourier domain and conditioning in the primal domain. While the prediction/rollup step for pairwise mixing models can be implemented in $O(n!)$ time (linear in the size of the symmetric group), we show running times for the more general mixing models. Instead of the naive $O((n!)^2)$ complexity, its running time is a more efficient $O(n^3 n!)$ due to the Fast Fourier Transform (Clausen and Baum, 1993). It is clear that our algorithm scales gracefully compared to the exact solution (Figure 10.1), and in fact, we could not run exact inference for $n > 8$ due to memory constraints. In Figure 10.1, we show empirically that the Clebsch-Gordan coefficients are indeed sparse, supporting a faster conjectured runtime.

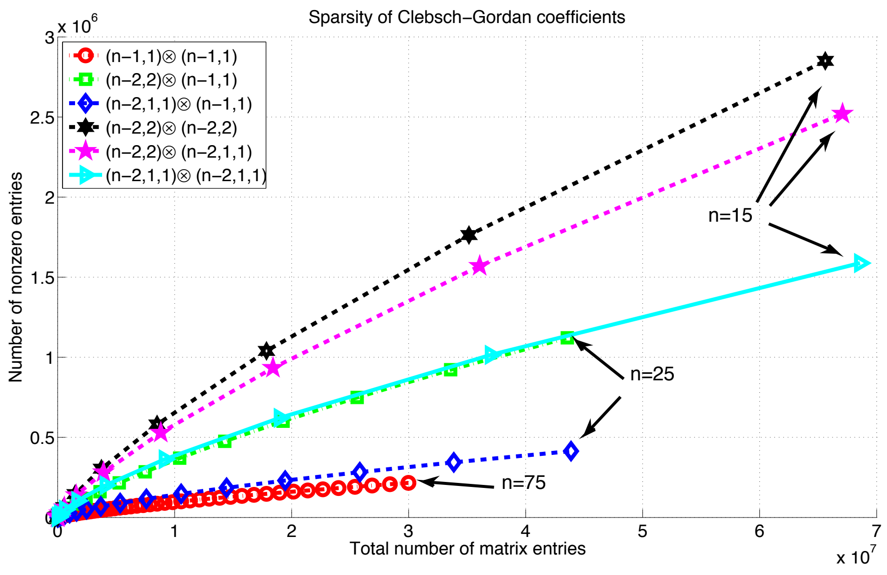

Figure 9: Clebsch-Gordan Sparsity: We measured the sparsity of the Clebsch-Gordan coefficients matrices by plotting the number of nonzero coefficients in a Clebsch-Gordan coefficient matrix against the number of total entries in the matrix for various n and pairs of irreducibles. For each fixed tensor product pair, we see that the number of nonzero entries scales sublinearly with respect to the total number of matrix elements.

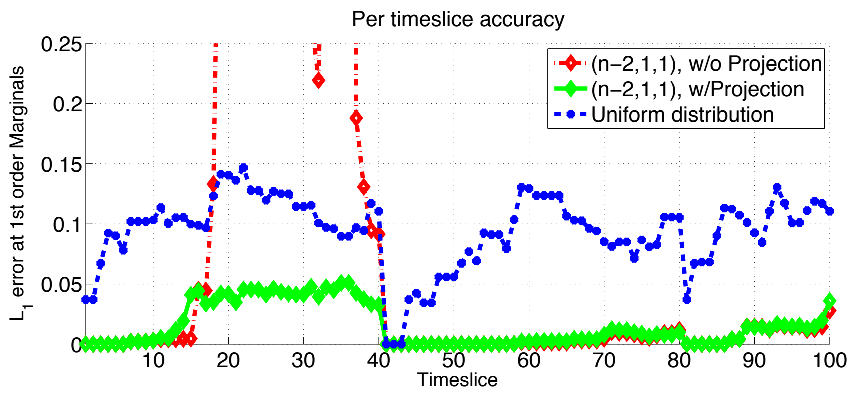
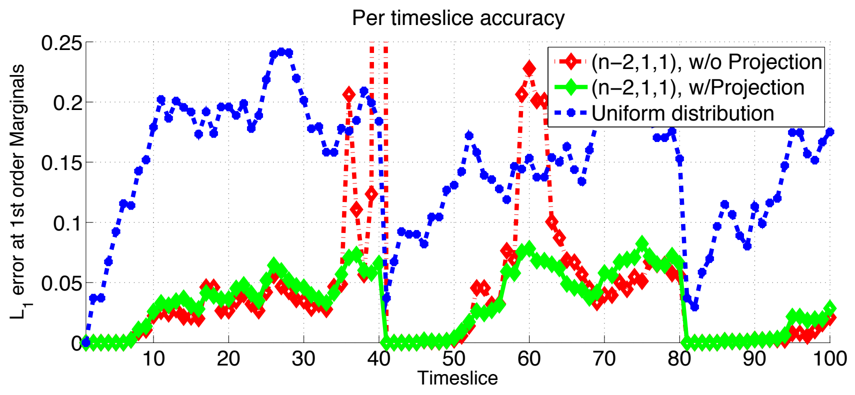
10.2 Real Camera Network

We also evaluated our algorithm on data taken from a real network of eight cameras (Fig. 11(a)). In the data, there are $n = 11$ people walking around a room in fairly close proximity. To handle the fact that people can freely leave and enter the room, we maintain a list of the tracks which are external to the room. Each time a new track leaves the room, it is added to the list and a mixing event is called to allow for m^2 pairwise swaps amongst the m external tracks.

The number of mixing events is approximately the same as the number of observations. For each observation, the network returns a color histogram of the blob associated with one track. The task after conditioning on each observation is to predict identities for all tracks which are inside the room, and the evaluation metric is the fraction of accurate predictions. We compared against a baseline approach of predicting the identity of a track based on the most recently observed histogram at that track. This approach is expected to be accurate when there are many observations and discriminative appearance models, neither of which our problem afforded. As Figure 11(b) shows, both the baseline and first order model(without projection) fared poorly, while the projection step dramatically boosted the prediction accuracy for this problem. To illustrate the difficulty of predicting based on appearance alone, the rightmost bar reflects the performance of an *omniscient* tracker who knows the result of each mixing event and is therefore left only with the task of distinguishing between appearances. We conjecture that the performance of our algorithm (with projection) is near optimal.



(a) $n = 6$ with 50% mixing events and 50% observations



(b) $n = 6$ with 30% mixing events and 70% observations

Figure 10: Accuracy as a function of time on two typical runs.

11. Future Research

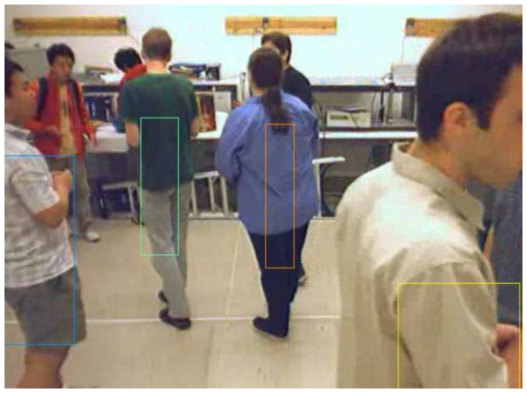
There remain several possible extensions to the current work stemming from both practical and theoretical considerations. We list a few open questions and extensions in the following.

11.1 Adaptive Filtering

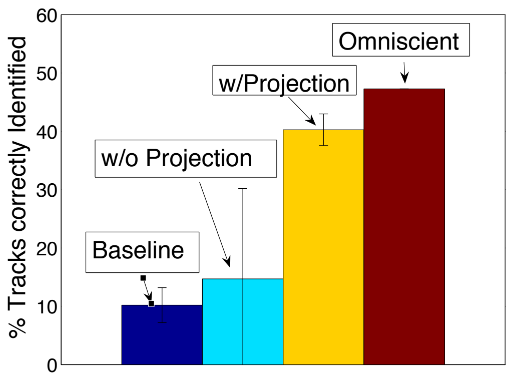
While our current algorithms easily beat exact inference in terms of running time, they are still limited by a relatively high (though polynomial) time complexity. In practice however, it seems reasonable to believe that the "difficult" identity management problems typically involve only a small subset of people at a time. A useful extension of our work would be to devise an *adaptive* version of the algorithm which allocates more Fourier coefficients towards the identities which require higher order reasoning. We believe that this kind of extension would be the appropriate way to scale our algorithm to handling massive numbers of objects at a time.

11.2 Characterizing the Marginal Polytope

In our paper, we presented a projection of the bandlimited distribution to a certain polytope, which is exactly the marginal polytope for first-order bandlimited distributions, but strictly an outer bound



(a) Sample Image



(b) Accuracy for Camera Data

Figure 11: Evaluation on data set from a real camera network. In this experiment, there are $n = 11$ people walking in a room begin tracked by 8 cameras.

for higher orders. An interesting project would be to generalize the Birkhoff-von Neumann theorem by exactly characterizing the marginal polytope at higher order marginals. We conjecture that the marginal polytope for low order marginals can be described with polynomially many constraints.

11.3 Learning in the Fourier Domain

Another interesting problem is whether we can learn bandlimited mixing and observation models *directly in the Fourier domain*. Given fully observed permutations $\sigma_1, \dots, \sigma_m$, drawn from a distribution $P(\sigma)$, a naive method for estimating $\hat{P}_\rho$ at low-order ρ is to simply observe that:

$$\hat{P}_\rho = \mathbb{E}_{\sigma \sim P}[\rho(\sigma)],$$

and so one can estimate the Fourier transform by simply averaging $\rho(\sigma_i)$ over all σ_i. However, since we typically do not observe full permutations in real applications like ranking or identity management, it would be interesting to estimate Fourier transforms using partially observed data. In the case of Bayesian learning, it may be possible to apply some of the techniques discussed in this paper.

11.4 Probabilistic Inference on Other Groups

The Fourier theoretic framework presented in this paper is not specific to the symmetric group - in fact, the prediction/rollup and conditioning formulations, as well as most of the results from Appendix D hold over any finite or compact Lie group. As an example, the noncommutative group of rotation operators in three dimensions, $SO(3)$, appears in settings which model the pose of a three dimensional object. Elements in $SO(3)$ might be used to represent the pose of a robot arm in robotics, or the orientation of a mesh in computer graphics; In many settings, it would be useful to have a compact representation of uncertainty over poses. We believe that there are many other application domains with algebraic structure where similar probabilistic inference algorithms might apply, and in particular, that noncommutative settings offer a particularly challenging but exciting opportunity for machine learning research.

12. Conclusions

In this paper, we have presented a Fourier theoretic framework for compactly summarizing distributions over permutations. We showed that common probabilistic inference operations can be performed completely in the Fourier domain and that, using the low-order terms of the Fourier expansion of a distribution, one can obtain polynomial time inference algorithms. Fourier theoretic summaries are attractive because they have tuneable approximation quality, have intuitive interpretations in terms of low-order marginals, and have allowed us to leverage results and insights from noncommutative Fourier analysis to formulate our algorithms.

The main contributions of our paper include methods for performing general probabilistic inference operations completely in the Fourier domain. In particular, we developed the Kronecker conditioning algorithm, which conditions a distribution on evidence using Bayes rule while operating only on Fourier coefficients. While prediction/rollup operations can be written as pointwise products in the Fourier domain, we showed that conditioning operations can be written, in dual fashion, as generalized convolutions in the Fourier domain. Our conditioning algorithm is general in two senses: first, one can use Kronecker conditioning to handle any observation model which can be written in the Fourier domain, and second, the same algorithm can be applied to condition distributions over arbitrary finite groups. Due to this generality, we are able to efficiently compute the Fourier transforms of a wide variety of probabilistic models which may potentially be useful in different applications.

We presented an analysis of the errors which can accumulate in bandlimited inference and argued that Fourier based approaches work well when the underlying distributions are diffuse and are thus well approximated by low-frequency basis functions. During inference, errors in high-order terms due to bandlimiting can be propagated to lower-order terms and bandlimited conditioning can, on occasion, result in Fourier coefficients which correspond to no valid distribution. We showed, however, that the problem can be remedied by projecting to a relaxation of the marginal polytope.

Finally, our evaluation on data from a camera network shows that our methods perform well when compared to the optimal solution in small problems, or to an omniscient tracker in large problems. Furthermore, we demonstrated that our projection step is fundamental in obtaining these high-quality results.

Algebraic methods have recently enjoyed a surge of interest in the machine learning community. We believe that our unified approach for performing probabilistic inference over permutations, as well as our gentle exposition of group representation theory and noncommutative Fourier analysis will significantly lower the barrier of entry for machine learning researchers who are interested in using or further developing algebraically inspired algorithms which are useful for real-world problems.

Robert Hough, Emre Oto and Risi Kondor for helpful and insightful discussions. We would like to thank the reviewers for providing thoughtful and detailed feedback.

Appendix A. Groups

This section is intended as a quick glossary for the group theoretic definitions used in the paper. Groups are a generalization of many of the spaces that we typically work with, such as the real numbers, integers, vector spaces, and matrices. The definition of a group unifies all of these spaces under a handful of axioms.

Definition 17 (Group) *A* group *is a set G together with a binary operation $\cdot : G \times G \to G$ (called the* group operation*) such that the following* group axioms *hold:*

1. *(Associativity) The group operation is* associative*. That is, for any group elements $g_1, g_2, g_3 \in G$, we have:*
$$(g_1 \cdot g_2) \cdot g_3 = g_1 \cdot (g_2 \cdot g_3), \text{ for all } g_1, g_2, g_3 \in G.$$
2. *(Identity) There exists an* identity *element (denoted by ε) such that $g \cdot \varepsilon = \varepsilon \cdot g = g$ for any $g \in G$.*
3. *(Inverses) For every $g \in G$, there exists an* inverse element *g^{-1} such that $g \cdot g^{-1} = g^{-1} \cdot g = \varepsilon$.*

Definition 18 (Abelian Group) *If, for any group elements $g_1, g_2 \in G$, we have $g_1 \cdot g_2 = g_2 \cdot g_1$, then G is called an* Abelian *or* commutative *group.*

Perhaps the most familiar group is the set of integers, $\mathbb{Z}$, with respect to the addition operation. It is well known that for any integers $a, b, c \in \mathbb{Z}$, $a + (b + c) = (a + b) + c$. The identity element in the integers is zero, and every element has an additive inverse ($a + (-a) = (-a) + a = 0$). Additionally, the integers are an Abelian group since $a + b = b + a$ for any $a, b \in \mathbb{Z}$. Note that the natural numbers $\mathbb{N} = \{0, 1, 2, 3, \ldots\}$ do not form a group with respect to addition because inverses do not exist.

The main example of a group in this paper, of course, is the symmetric group, the set of permutations of $\{1, \ldots, n\}$. The group operation on permutations is function composition, which is associative, and we discussed inverses and the identity element in Section 3.

Example 13 *There are many groups besides the integers and the symmetric group. The following are several examples.*

- *The positive real numbers $\mathbb{R}^+$ form a group with respect to multiplication. The identity element of $\mathbb{R}^+$ is the multiplicative identity, 1, and given a real number x, there exists an inverse element $\frac{1}{x}$.*
- *As an example of a finite group, the* integers modulo *n, $\mathbb{Z}/n\mathbb{Z}$, form a group with respect to addition modulo n.*
- *The invertible $n \times n$ matrices over the reals, $GL_n(\mathbb{R})$, form a group with respect to matrix multiplication. The $n \times n$ identity matrix serves as the identity element in $GL_n(\mathbb{R})$, and by assumption, every matrix in $GL_n(\mathbb{R})$ is invertible.*

The group axioms impose strong structural constraints on G, and one of the ways that structure is manifested in groups is in the existence of *subgroups*.

Definition 19 (Subgroup) *If G is a group (with group operation $\cdot$), a subset $H \subset G$ is called a* subgroup *if it is itself a group with respect to the same group operation. H is called a* trivial subgroup *if it is either all of G or consists only of a single element.*

Example 14 *We have the following examples of subgroups.*

- *The even integers, $2\mathbb{Z}$, form a subgroup of the integers since the sum of any two even integers is an even integer, and the inverse (negative) of an even integer is again even. However, the odd integers do* not *form a subgroup since the sum of two odd integers is not odd.*
- *The special orthogonal matrices (orthogonal matrices with determinant $+1$) form a subgroup of the group of $n \times n$ matrices, $GL_n(\mathbb{R})$. This can be seen by using the facts (1), that $(\det A)(\det B) = \det(AB)$ and (2), that the inverse of any orthogonal matrix is also orthogonal.*

Appendix B. Constructing Irreducible Representation Matrices

In this section, we present (without proof) some standard algorithms for constructing the irreducible representation matrices with respect to the *Gel'fand-Tsetlin (GZ) basis* (constructed with respect to the subgroup chain $S_1 \subset S_2 \subset \cdots \subset S_n$).[13] None of the techniques in Appendix B are novel. For a more elaborate discussion, see, for example, Kondor (2006), Chen (1989) and Vershik and Okounkov (2006). There are several properties which make the irreducible representation matrices, written with respect to the GZ basis, fairly useful in practice. They are guaranteed to be, for example, real-valued and orthogonal. And as we will show, the matrices have certain useful sparsity properties that can be exploited in implementation.

We begin by introducing a few concepts relating to *Young tableaux* which are like Young tabloids with the distinction that the rows are considered as *ordered tuples* rather than *unordered sets*. For example, the following two diagrams are distinct as Young *tableaux*, but not as Young *tabloids*:

$$\begin{array}{|c|c|c|}\hline 1&2&3\\\hline 4&5\\\cline{1-2}\end{array} \neq \begin{array}{|c|c|c|}\hline 1&3&2\\\hline 5&4\\\cline{1-2}\end{array} \qquad \text{(as Young tableaux).}$$

A Young Tableau t is said to be *standard* if its entries are increasing to the right along rows and down columns. For example, the set of all standard Young Tableaux of shape $\lambda = (3,2)$ is:

$$\left\{ \begin{array}{|c|c|c|}\hline 1&3&5\\\hline 2&4\\\cline{1-2}\end{array},\ \begin{array}{|c|c|c|}\hline 1&2&5\\\hline 3&4\\\cline{1-2}\end{array},\ \begin{array}{|c|c|c|}\hline 1&3&4\\\hline 2&5\\\cline{1-2}\end{array},\ \begin{array}{|c|c|c|}\hline 1&2&4\\\hline 3&5\\\cline{1-2}\end{array},\ \begin{array}{|c|c|c|}\hline 1&2&3\\\hline 4&5\\\cline{1-2}\end{array} \right\}. \tag{31}$$

Given a permutation $\sigma \in S_n$, one can always apply σ to a Young tableau t to get a new Young tableau, which we denote by $\sigma \circ t$, by permuting the labels within the tableau. For example,

$$(1,2) \circ \begin{array}{|c|c|c|}\hline \mathbf{1}&\mathbf{2}&3\\\hline 4&5\\\cline{1-2}\end{array} = \begin{array}{|c|c|c|}\hline \mathbf{2}&\mathbf{1}&3\\\hline 4&5\\\cline{1-2}\end{array}.$$

Note, however, that even if t is a standard tableau, $\sigma \circ t$ is not guaranteed to be standard.

The significance of the standard tableaux is that the set of all standard tableaux of shape λ can be used to index the set of GZ basis vectors for the irreducible representation ρ_λ. Since there are

13. The irreducible representation matrices in this Appendix are also sometimes referred to as *Young's Orthogonal Representation (YOR)*.

five total standard tableaux of shape $(3,2)$, we see, for example, that the irreducible corresponding to the partition $(3,2)$ is 5-dimensional. There is a simple recursive procedure for enumerating the set of all standard tableaux of shape λ, which we illustrate for $\lambda = (3,2)$.

Example 15 *If $\lambda = (3,2)$, there are only two possible boxes that the label 5 can occupy so that both rows and columns are increasing. They are:*

$$\begin{array}{|c|c|c|}\hline \; & \; & 5 \\ \hline \; & \; \\ \cline{1-2}\end{array}, \textit{ and } \begin{array}{|c|c|c|}\hline \; & \; & \; \\ \hline \; & 5 \\ \cline{1-2}\end{array}.$$

To enumerate the set of all standard tableaux of shape $(3,2)$, we need to fill the empty boxes in the above partially filled tableaux with the labels $\{1,2,3,4\}$ so that both rows and columns are increasing. Enumerating the standard tableaux of shape $(3,2)$ thus reduces to enumerating the set of standard tableaux of shapes $(2,2)$ and $(3,1)$, respectively. For $(2,2)$, the set of standard tableaux (which, in implementation would be computed recursively) is:

$$\left\{ \begin{array}{|c|c|}\hline 1 & 3 \\ \hline 2 & 4 \\ \hline\end{array}, \begin{array}{|c|c|}\hline 1 & 2 \\ \hline 3 & 4 \\ \hline\end{array} \right\},$$

and for $(3,1)$, the set of standard tableaux is:

$$\left\{ \begin{array}{|c|c|c|}\hline 1 & 3 & 4 \\ \hline 2 \\ \cline{1-1}\end{array}, \begin{array}{|c|c|c|}\hline 1 & 2 & 4 \\ \hline 3 \\ \cline{1-1}\end{array}, \begin{array}{|c|c|c|}\hline 1 & 2 & 3 \\ \hline 4 \\ \cline{1-1}\end{array} \right\}.$$

The entire set of standard tableaux of shape $(3,2)$ is therefore:

$$\left\{ \begin{array}{|c|c|c|}\hline 1 & 3 & \mathbf{5} \\ \hline 2 & 4 \\ \cline{1-2}\end{array}, \begin{array}{|c|c|c|}\hline 1 & 2 & \mathbf{5} \\ \hline 3 & 4 \\ \cline{1-2}\end{array} \right\} \bigcup \left\{ \begin{array}{|c|c|c|}\hline 1 & 3 & 4 \\ \hline 2 & \mathbf{5} \\ \cline{1-2}\end{array}, \begin{array}{|c|c|c|}\hline 1 & 2 & 4 \\ \hline 3 & \mathbf{5} \\ \cline{1-2}\end{array}, \begin{array}{|c|c|c|}\hline 1 & 2 & 3 \\ \hline 4 & \mathbf{5} \\ \cline{1-2}\end{array} \right\}.$$

Before explicitly constructing the representation matrices, we must define a signed distance on Young Tableaux called the *axial distance*.

Definition 20 *The* axial distance, *$d_t(i,j)$, between entries i and j in tableau t, is defined to be:*

$$d_t(i,j) \equiv (col(t,j) - col(t,i)) - (row(t,j) - row(t,i)),$$

where $row(t,i)$ denotes the row of label i in tableau t, and $col(t,i)$ denotes the column of label i in tableau t.

Intuitively, the axial distance between $i-1$ and i in a standard tableau t is equal to the (signed) number of steps that are required to travel from $i-1$ to i, if at each step, one is allowed to traverse a single box in the tableau in one of the four cardinal directions. For example, the axial distance from 3 to 4 with respect to tableau: $t = \begin{array}{|c|c|c|}\hline 1 & 2 & 3 \\ \hline 4 & 5 \\ \cline{1-2}\end{array}$ is:

$$\begin{aligned} d_t(3,4) &= \left(col\left(\begin{array}{|c|c|c|}\hline 1 & 2 & 3 \\ \hline 4 & 5 \\ \cline{1-2}\end{array}, 4 \right) - col\left(\begin{array}{|c|c|c|}\hline 1 & 2 & 3 \\ \hline 4 & 5 \\ \cline{1-2}\end{array}, 3 \right) \right) - \left(row\left(\begin{array}{|c|c|c|}\hline 1 & 2 & 3 \\ \hline 4 & 5 \\ \cline{1-2}\end{array}, 4 \right) - row\left(\begin{array}{|c|c|c|}\hline 1 & 2 & 3 \\ \hline 4 & 5 \\ \cline{1-2}\end{array}, 3 \right) \right) \\ &= (1-3) - (2-1) = -3 \end{aligned}$$

B.1 Constructing Representation Matrices for Adjacent Transpositions

In the following discussion, we will consider a fixed ordering, $t_1, \ldots, t_{d_\lambda}$, on the set of standard tableaux of shape λ and refer to both standard tableaux and columns of $\rho_\lambda(\sigma)$ interchangeably. Thus t_1 refers to first column, t_2 refers to the second column and so on. And we will index elements in $\rho_\lambda(\sigma)$ using pairs of standard tableau, (t_j, t_k).

To explicitly define the representation matrices with respect to the GZ basis, we will first construct the matrices for adjacent transpositions (i.e., permutations of the form $(i-1,i)$), and then we will construct arbitrary representation matrices by combining the matrices for the adjacent transpositions. The rule for constructing the matrix coefficient $[\rho_\lambda(i-1,i)]_{t_j,t_k}$ is as follows.

1. Define the (t_j, t_k) coefficient of $\rho_\lambda(i-1,i)$ to be zero if it is (1), off-diagonal ($j \neq k$) and (2), not of the form $(t_j, (i-1,i) \circ t_k)$.
2. If (t_j, t_k) is a diagonal element, (i.e., of the form (t_j, t_j)), define:
$$[\rho_\lambda(i-1,i)]_{t_j,t_j} = 1/d_{t_j}(i-1,i),$$
where $d_{t_j}(i-1,i)$ is the axial distance which we defined earlier in the section.
3. If (t_j, t_k) can be written as $(t_j, (i-1,i) \circ t_j)$ define:
$$[\rho_\lambda(i-1,i)]_{t_j, \sigma \circ t_j} = \sqrt{1 - 1/d_{t_j}^2(i-1,i)}.$$

Note that the only time that off-diagonal elements can be nonzero under the above rules is when $(i-i,i) \circ t_j$ happens to also be a standard tableau. If we apply an adjacent transposition, $\sigma = (i-1,i)$ to a standard tableau t, then $\sigma \circ t$ is guaranteed to be standard if and only if $i-1$ and i were neither in the same row nor column of t. This can be seen by examining each case separately.

1. **$i-1$ and i are in the same row or same column of t.** If i and $i-1$ are in the same row of t, then $i-1$ lies to the left of i. Applying $\sigma \circ t$ swaps their positions so that i lies to the left of $i-1$, and so we see that $\sigma \circ t$ cannot be standard. For example,
$$(3,4) \circ \begin{array}{|c|c|c|}\hline 1 & 2 & 5 \\ \hline \mathbf{3} & \mathbf{4} \\ \cline{1-2} \end{array} = \begin{array}{|c|c|c|}\hline 1 & 2 & 5 \\ \hline \mathbf{4} & \mathbf{3} \\ \cline{1-2} \end{array}.$$
Similarly, we see that if i and $i-1$ are in the same column of t, $\sigma \circ t$ cannot be standard. For example,
$$(3,4) \circ \begin{array}{|c|c|c|}\hline 1 & \mathbf{3} & 5 \\ \hline 2 & \mathbf{4} \\ \cline{1-2} \end{array} = \begin{array}{|c|c|c|}\hline 1 & \mathbf{4} & 5 \\ \hline 2 & \mathbf{3} \\ \cline{1-2} \end{array}.$$
2. **$i-1$ and i are neither in the same row nor column of t.** In the second case, $\sigma \circ t$ can be seen to be a standard tableau due to the fact that $i-1$ and i are adjacent indices. For example,
$$(3,4) \circ \begin{array}{|c|c|c|}\hline 1 & 2 & \mathbf{3} \\ \hline \mathbf{4} & 5 \\ \cline{1-2} \end{array} = \begin{array}{|c|c|c|}\hline 1 & 2 & \mathbf{4} \\ \hline \mathbf{3} & 5 \\ \cline{1-2} \end{array}.$$

Therefore, to see if $(i-1,i) \circ t$ is standard, we need only check to see that $i-1$ and i are in different rows and columns of the tableau t. The pseudocode for constructing the irreducible representation matrices for adjacent swaps is summarized in Algorithm 3. Note that the matrices constructed in the algorithm are sparse, with no more than two nonzero elements in any given column.

Algorithm 3: Pseudocode for computing irreducible representations matrices with respect to the Gel'fand-Tsetlin basis at adjacent transpositions.

```
ADJACENTRHO
input : $i \in \{2,\ldots,n\}, \lambda$
output: $\rho_\lambda(i-1,i)$
1  $\rho \leftarrow \mathbf{0}_{d_\lambda \times d_\lambda}$;
2  foreach standard tableaux $t$ of shape $\lambda$ do
3      $d \leftarrow (col(t,i) - col(t,i-1)) - (row(t,i) - row(t,i-1))$;
4      $\rho(t,t) \leftarrow 1/d$;
5      if $i-1$ and $i$ are in different rows and columns of $t$ then
6          $\rho((i-1,i) \circ (t), t) \leftarrow \sqrt{1-1/d^2}$;
7  return $\rho$ ;
```

Example 16 *We compute the representation matrix of* $\rho_{(3,2)}$ *evaluated at the adjacent transposition* $\sigma = (i-1,i) = (3,4)$. *For this example, we will use the enumeration of the standard tableaux of shape* $(3,2)$ *given in Equation 31.*

For each $(3,2)$*-tableau* t_j, *we identify whether* $\sigma \circ t_j$ *is standard and compute the axial distance from* 3 *to* 4 *on the tableau* t_j.

j	*1*	*2*	*3*	*4*	*5*
t_j	$\begin{array}{\|c\|c\|c\|}\hline 1&\mathbf{3}&5\\\hline 2&\mathbf{4}\\\cline{1-2}\end{array}$	$\begin{array}{\|c\|c\|c\|}\hline 1&2&5\\\hline \mathbf{3}&\mathbf{4}\\\cline{1-2}\end{array}$	$\begin{array}{\|c\|c\|c\|}\hline 1&\mathbf{3}&\mathbf{4}\\\hline 2&5\\\cline{1-2}\end{array}$	$\begin{array}{\|c\|c\|c\|}\hline 1&2&\mathbf{4}\\\hline \mathbf{3}&5\\\cline{1-2}\end{array}$	$\begin{array}{\|c\|c\|c\|}\hline 1&2&\mathbf{3}\\\hline \mathbf{4}&5\\\cline{1-2}\end{array}$
$(3,4)\circ t_j$	$\begin{array}{\|c\|c\|c\|}\hline 1&\mathbf{4}&5\\\hline 2&\mathbf{3}\\\cline{1-2}\end{array}$	$\begin{array}{\|c\|c\|c\|}\hline 1&2&5\\\hline \mathbf{4}&\mathbf{3}\\\cline{1-2}\end{array}$	$\begin{array}{\|c\|c\|c\|}\hline 1&\mathbf{4}&\mathbf{3}\\\hline 2&5\\\cline{1-2}\end{array}$	$\begin{array}{\|c\|c\|c\|}\hline 1&2&\mathbf{3}\\\hline \mathbf{4}&5\\\cline{1-2}\end{array}$	$\begin{array}{\|c\|c\|c\|}\hline 1&2&\mathbf{4}\\\hline \mathbf{3}&5\\\cline{1-2}\end{array}$
$(3,4)\circ t_j$ *Standard?*	*No*	*No*	*No*	*Yes*	*Yes*
axial distance ($d_{t_j}(3,4)$)	*-1*	*1*	*1*	*3*	*-3*

Putting the results together in a matrix yields:,

$$\rho_{(3,2)}(3,4) = \left[\begin{array}{c|ccccc} & t_1 & t_2 & t_3 & t_4 & t_5 \\ \hline t_1 & -1 & & & & \\ t_2 & & 1 & & & \\ t_3 & & & 1 & & \\ t_4 & & & & \frac{1}{3} & \sqrt{\frac{8}{9}} \\ t_5 & & & & \sqrt{\frac{8}{9}} & -\frac{1}{3} \end{array}\right],$$

where all of the empty entries are zero.

B.2 Constructing Representation Matrices for General Permutations

To construct representation matrices for general permutations, it is enough to observe that all permutations can be factored into a sequence of adjacent swaps. For example, the permutation $(1,2,5)$ can be factored into:

$$(1,2,5) = (4,5)(3,4)(1,2)(2,3)(3,4)(4,5),$$

Algorithm 4: Pseudocode for computing irreducible representation matrices for arbitrary permutations.

```
GETRHO
input  : $\sigma \in S_n, \lambda$
output: $\rho_\lambda(\sigma)$ (a $d_\lambda \times d_\lambda$ matrix)
1  //Use Bubblesort to factor $\sigma$ into a product of transpositions
2  $k \leftarrow 0$ ;
3  $factors \leftarrow \emptyset$;
4  for $i = 1, 2, \ldots, n$ do
5      for $j = n, n-1, \ldots, i+1$ do
6          if $\sigma(j) < \sigma(j-1)$ then
7              Swap($\sigma(j-1), \sigma(j)$) ;
8              $k \leftarrow k+1$ ;
9              $factors(k) \leftarrow j$ ;
10 //Construct representation matrix using adjacent transpositions
11 $\rho_\lambda(\sigma) \leftarrow I_{d_\lambda \times d_\lambda}$ ;
12 $m \leftarrow length(factors)$;
13 for $j = 1, \ldots, m$ do
14     $\rho_\lambda(\sigma) \leftarrow$ GETADJACENTRHO $(factors(j), \lambda) \cdot \rho_\lambda(\sigma)$ ;
```

and hence, for any partition λ,

$$\rho_\lambda(1,2,5) = \rho_\lambda(4,5) \cdot \rho_\lambda(3,4) \cdot \rho_\lambda(1,2) \cdot \rho_\lambda(2,3) \cdot \rho_\lambda(3,4) \cdot \rho_\lambda(4,5),$$

since ρ_λ is a group representation. Algorithmically, factoring a permutation into adjacent swaps looks very similar to the Bubblesort algorithm, and we show the pseudocode in Algorithm 4.

Appendix C. Fourier Transforming the Indicator Function $\delta_{S_{X,Y}}$

In this section, we derive the Fourier transform of the indicator function of the two-sided coset $S_{X,Y} \subset S_n$ (see Equation 27). To do so, we will need to understand the Gel'fand-Tsetlin basis at a slightly deeper level. For example, the fact that the basis elements are indexed by standard tableaux has not been motivated and may seem unintuitive. We begin this section by motivating the standard tableaux from the perspective of the *branching rule*, a standard fact taken from the representation theory of the symmetric group. We then show how the branching rule leads to a method for computing the desired indicator functions.

C.1 Standard Tableaux and the Gel'fand-Tsetlin Basis

It is straightforward to see that any irreducible representation ρ_λ of S_n, can also be seen as a representation of S_{n-1} when restricted to permutations in S_{n-1} (the set of elements which fix n). We will denote the restricted representation by $\rho_\lambda \downarrow^{S_n}_{S_{n-1}}$. However, the irreducibility property may not be preserved by restriction, which is to say that, as a representation of S_{n-1}, ρ_λ is not necessarily irreducible and might decompose as Equation 2 would dictate. Thus, for all $\sigma \in S_{n-1}$ (or more precisely, $\sigma \in S_n$ such that $\sigma(n) = n$), there exists C_λ and multiplicities $z_{\lambda\mu}$ such that:

$$C_\lambda^{-1} \cdot \rho_\lambda(\sigma) \cdot C_\lambda = \bigoplus_{\mu} \bigoplus_{j=1}^{z_{\lambda\mu}} \rho_\mu(\sigma),$$

where μ ranges over the partitions of $n-1$.

The *branching rule* allows us to state the decomposition even more precisely. Given any partition λ of n, let λ^- index over the set of partitions of $n-1$ whose Ferrers diagrams differ from λ in a single box.

Theorem 21 (Branching Rule, see Vershik and Okounkov (2006) for a proof) *For each irreducible representation ρ_λ of S_n, there exists a matrix C_λ such that:*

$$C_\lambda^{-1} \cdot \rho_\lambda(\sigma) \cdot C_\lambda = \bigoplus_{\lambda^-} \rho_{\lambda^-}(\sigma)$$

holds for any $\sigma \in S_{n-1}$.

Example 17 *If $\lambda = (3,2)$, then its corresponding Ferrers diagram is:* *, and the Ferrers diagrams corresponding to partitions of 4 which differ from λ in a single box are:*

, .

Thus, λ^- indexes over the set $\{(2,2),(3,1)\}$. The branching rule states that given an irreducible matrix representation $\rho_{(3,2)}$ of S_5, then there is a matrix $C_{(3,2)}$ such that, for any permutation $\sigma \in S_5$ such that $\sigma(5) = 5$,

$$C_\lambda^{-1} \cdot \rho_{(3,2)}(\sigma) \cdot C_\lambda = \left[\begin{array}{c|c} \rho_{(2,2)}(\sigma) & 0 \\ \hline 0 & \rho_{(3,1)}(\sigma) \end{array}\right].$$

The Gel'fand-Tsetlin basis is constructed such that the branching rule holds with all $C_\lambda = I$. Thus the irreducible representation matrices constructed with respect to the GZ basis have the property that the equation:

$$\rho_\lambda(\sigma) = \bigoplus_{\lambda^-} \rho_{\lambda^-}(\sigma)$$

holds identically for all $\sigma \in S_{n-1}$. We now can show how the branching rule naturally leads to indexing the basis elements by standard tableaux. First observe that the branching rule allows us to associate each column of the irreducible ρ_λ with some partition of $n-1$.

If we recursively apply the branching rule again (thus restricting to S_{n-2}), we see that the following decomposition holds:

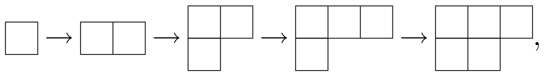
$$\rho_\lambda(\sigma) = \bigoplus_{\lambda^-} \left[\bigoplus_{\lambda^{--}} \rho_{\lambda^{--}}(\sigma) \right],$$

where λ^{--} indexes over partitions which differ from λ^- by a single box. Thus each column can be associated with a partition of $n-1$ *and* a partition of $n-2$. Taking this logic even further, we can restrict to S_{n-3}, S_{n-4}, and so on until we can restrict no further, associating each column with a sequence of partitions[14] $\mu_1 \vdash 1, \mu_2 \vdash 2 \ldots, \mu_n \vdash n$, where each partition μ_i can be obtained by adding

14. Here we use the $\lambda \vdash n$ notation to denote the relation that λ is a partition of n. For example, $(3,2,1) \vdash 6$.

a single box to the Ferrers diagram of μ_{i-1}, and $\mu_n = \lambda$. We will refer to such a sequence as a *branching sequence*. Since the branching rule guarantees multiplicity-free decompositions (that is, $z_{\lambda\mu} = 1$ for all pairs (λ, μ)), it turns out that each column of ρ_λ is *uniquely* specified by a branching sequence.

Example 18 *A possible branching sequence is:*



or written as partitions, $[(1) \to (2) \to (2,1) \to (3,1) \to (3,2)]$.

The set of all possible branching sequences ending in λ can be visualized using a *branching tree* (shown for $\lambda = (3,2)$ in Figure 12(a)), where each branching sequence is a path between the root and some leaf node. We will denote the branching tree corresponding to the partition λ by $\mathcal{T}^\lambda$ and the set of nodes at the r^{th} level of $\mathcal{T}^\lambda$ by $\mathcal{T}^\lambda_r$ (where the root node forms the zeroth level by convention). We can rephrase the branching rule in terms of the branching tree.

Proposition 22 *Let ρ_λ be an irreducible matrix representation of S_n (constructed with respect to the Gel'fand-Tsetlin basis). For any $\sigma \in S_k \subset S_n$, $\rho_\lambda(\sigma)$ decomposes as:*

$$\rho_\lambda(\sigma) = \bigoplus_{\mu \in \mathcal{T}^\lambda_{n-k}} \rho_\mu(\sigma).$$

Example 19 *As an example, consider applying Proposition 22 to $\rho_{(3,2)}$ with $k = 3$. The $(n-k)$th (second) level of the branching tree for $\lambda = (3,2)$, $\mathcal{T}_2^{(3,2)}$ consists of two copies of the partition $(2,1)$ and a single copy of the partition (3). Thus for any element $\sigma \in S_5$ which fixes 4 and 5 ($\sigma(4) = 4$, $\sigma(5) = 5$), we have:*

$$\rho_{(3,2)}(\sigma) = \left[\begin{array}{c|c|c} \rho_{(2,1)}(\sigma) & & \\ \hline & \rho_{(2,1)}(\sigma) & \\ \hline & & \rho_{(3)}(\sigma) \end{array}\right].$$

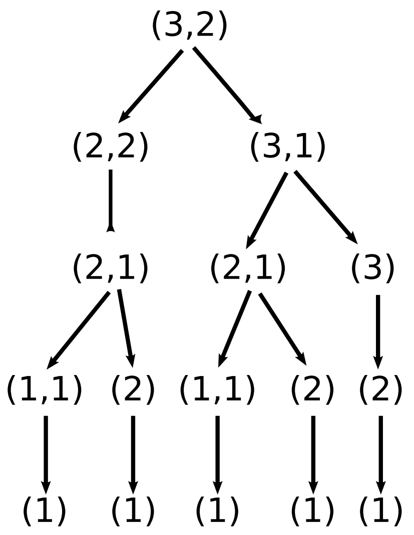
As a final remark, observe that branching sequences can be compactly represented as *standard tableaux*, where the number in each box indicates the point in the sequence at which the box was added. For example, the following standard tableau and sequence of partitions are equivalent:

$$\begin{array}{|c|c|c|} \hline 1 & 2 & 4 \\ \hline 3 & 5 \\ \cline{1-2} \end{array} \qquad \longleftrightarrow \qquad [(1) \to (2) \to (2,1) \to (3,1) \to (3,2)].$$

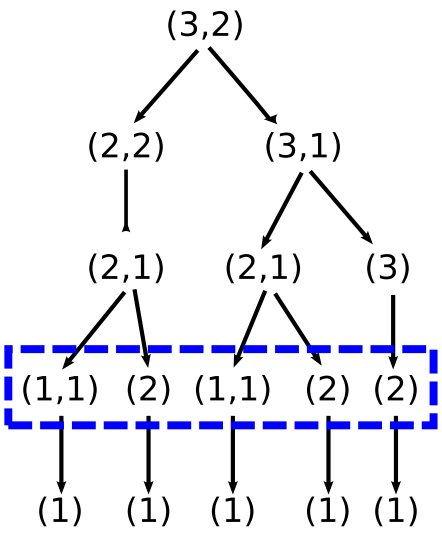
To summarize, the GZ basis (adapted to the subgroup chain $S_1 \subset \cdots \subset S_n$) is defined so that the branching rule holds as a matrix identity (with no need of a change of basis matrix), and furthermore, each basis vector of the representation space for ρ_λ can be associated with a branching sequence, or equivalently, a standard tableau.

C.2 Fourier Transforming $\delta_{S_{X,Y}}$

We are now in a position to compute the Fourier transform of indicators of the form $\delta_{S_{X,Y}}$. First, as a corollary of the branching rule, we see that we can decompose the Fourier transform of functions that are supported on $S_{n-1} \subset S_n$.



(a) $\mathcal{T}^{(3,2)}$



(b) $\mathcal{T}_3^{(3,2)}$

Figure 12: (a) The branching tree for $\lambda = (3,2)$. (b) The 3rd level of $\mathcal{T}^{(3,2)}$ (outlined) is denoted by $\mathcal{T}_3^{(3,2)}$ and consists of two copies of the partition $(1,1)$ and three copies of the partition (2).

Corollary 23 *If $f : S_n \to \mathbb{R}$ is supported on the subgroup S_{n-1}, then for each partition λ, the Fourier transform of f (with respect to the Gel'fand-Tsetlin basis adapted $S_1 \subset S_2 \subset \cdots \subset S_n$) decomposes into a direct sum of Fourier transforms on S_{n-1}. Specifically, we have:*

$$\hat{f}_\lambda = \bigoplus_{\lambda^-} \left[\hat{f} \downarrow^n_{n-1}\right]_{\lambda^-},$$

where $f \downarrow^n_{n-1}$ is defined to be the restriction of f to S_{n-1}.

Consider the Fourier transform of the indicator function of $S_k \subset S_n$:

$$\delta_{S_k}(\sigma) = \begin{cases} 1 & \text{if } \sigma(j) = j \text{ for } j \in \{k+1, \dots, n\} \\ 0 & \text{otherwise} \end{cases}.$$

We now apply the branching rule $n-k$ times to the indicator function δ_{S_k}. Since δ_{S_k} is supported on $S_k \subset S_n$, the Fourier transform of δ_{S_k} at the irreducible ρ_λ can be written as a direct sum of Fourier coefficient matrices at the irreducibles which appear in the $n-k$th level of the branching tree corresponding to λ.

$$\left[\hat{\delta}_{S_k}\right]_\lambda = \bigoplus_{\mu \in \mathcal{T}^\lambda_{n-k}} \left[\hat{\delta}_{S_k} \downarrow^n_k\right]_\mu$$

Furthermore, since the restriction of δ_{S_k} to the subgroup S_k is a constant function, we see that all of the nontrivial irreducible summands are zero (since the Fourier transform of a constant function is zero at all nontrivial terms) and that the trivial terms are exactly $k!$. Because the trivial representation is one-dimensional, only a subset of the diagonal elements of $\left[\hat{\delta}_{S_k}\right]_\lambda$ can be nonzero.

Algorithm 5: Pseudocode for computing the Fourier transform of the indicator function of $S_k \subset S_n$ at the partition λ.

```
$S_k$-INDICATOR
input  : $k, n, \lambda$ (a partition of $n$)
output: $\left[\widehat{\delta_{S_k}}\right]_\lambda$
1  $\left[\widehat{\delta_{S_k}}\right]_\lambda \leftarrow \mathbf{0}_{d_\lambda \times d_\lambda}$ ;
2  foreach standard tableaux $t$ of shape $\lambda$ do
3      if $t \downarrow^n_k = \boxed{1}\boxed{2}\boxed{3}\boxed{\cdots}\boxed{k}$ then
4          $\left[\widehat{\delta_{S_k}}\right]_\lambda (t,t) \leftarrow k!$;
```

Algorithmically we can construct the Fourier transform of δ_{S_k} at λ by enumerating all of the branching sequences for λ and setting the (j, j) diagonal element of $\left[\hat{\delta}_{S_k}\right]_\lambda$ to be $k!$ if the corresponding jth branching sequence contains the partition (k). Alternatively, we can state the procedure in terms of standard tableaux. First, we define a restriction operation on a standard tableau t.

Definition 24 *Given a standard tableau t with n boxes and a positive integer $k < n$, we define the* restriction *of t to S_k (denoted by $t \downarrow^n_k$) to be the standard tableau t after removing boxes containing labels $k+1, \ldots, n$.*

To construct the Fourier transform of δ_{S_k} at λ, we iterate through the standard tableaux of shape λ, and set the (j, j) diagonal element of $\left[\hat{\delta}_{S_k}\right]_\lambda$ to be $k!$ if the restriction of the jth tableau to S_k, $t_j \downarrow^n_k$, takes the form $\boxed{1}\boxed{2}\boxed{3}\boxed{\cdots}\boxed{k}$. See Algorithm 5.

Example 20 *We compute $\left[\hat{\delta}_{S_2}\right]_{(3,2)}$ as an example. The branching sequences for $\lambda = (3,2)$ are:*

$$\begin{array}{|c|c|c|}\hline 1&3&5\\\hline 2&4\\\cline{1-2}\end{array} \longleftrightarrow [(1) \to (1,1) \to (2,1) \to (2,2) \to (3,2)],$$

$$\begin{array}{|c|c|c|}\hline 1&2&5\\\hline 3&4\\\cline{1-2}\end{array} \longleftrightarrow [(1) \to (\mathbf{2}) \to (2,1) \to (2,2) \to (3,2)],$$

$$\begin{array}{|c|c|c|}\hline 1&3&4\\\hline 2&5\\\cline{1-2}\end{array} \longleftrightarrow [(1) \to (1,1) \to (2,1) \to (3,1) \to (3,2)],$$

$$\begin{array}{|c|c|c|}\hline 1&2&4\\\hline 3&5\\\cline{1-2}\end{array} \longleftrightarrow [(1) \to (\mathbf{2}) \to (2,1) \to (3,1) \to (3,2)],$$

$$\begin{array}{|c|c|c|}\hline 1&2&3\\\hline 4&5\\\cline{1-2}\end{array} \longleftrightarrow [(1) \to (\mathbf{2}) \to (3) \to (3,1) \to (3,2)].$$

Since there are only three sequences which contain the partition (2), only those three basis elements have nonzero entries. And finally, noting that the appropriate normalization constant here *is simply* $|S_2| = 2! = 2$*, we see that:*

$$\left[\hat{\delta}_{S_2}\right]_{(3,2)} = \left[\begin{array}{c|ccccc} & \begin{array}{|c|c|c|}\hline 1&3&5\\ \hline 2&4\\ \cline{1-2}\end{array} & \begin{array}{|c|c|c|}\hline \mathbf{1}&\mathbf{2}&5\\ \hline 3&4\\ \cline{1-2}\end{array} & \begin{array}{|c|c|c|}\hline 1&3&4\\ \hline 2&5\\ \cline{1-2}\end{array} & \begin{array}{|c|c|c|}\hline \mathbf{1}&\mathbf{2}&4\\ \hline 3&5\\ \cline{1-2}\end{array} & \begin{array}{|c|c|c|}\hline \mathbf{1}&\mathbf{2}&3\\ \hline 4&5\\ \cline{1-2}\end{array} \\ \hline \begin{array}{|c|c|c|}\hline 1&3&5\\ \hline 2&4\\ \cline{1-2}\end{array} & 0 & 0 & 0 & 0 & 0 \\ \begin{array}{|c|c|c|}\hline \mathbf{1}&\mathbf{2}&5\\ \hline 3&4\\ \cline{1-2}\end{array} & 0 & 2 & 0 & 0 & 0 \\ \begin{array}{|c|c|c|}\hline 1&3&4\\ \hline 2&5\\ \cline{1-2}\end{array} & 0 & 0 & 0 & 0 & 0 \\ \begin{array}{|c|c|c|}\hline \mathbf{1}&\mathbf{2}&4\\ \hline 3&5\\ \cline{1-2}\end{array} & 0 & 0 & 0 & 2 & 0 \\ \begin{array}{|c|c|c|}\hline \mathbf{1}&\mathbf{2}&3\\ \hline 4&5\\ \cline{1-2}\end{array} & 0 & 0 & 0 & 0 & 2 \end{array}\right].$$

Our discussion has been focused on the indicator function δ_{S_k}, but computing $\delta_{S_{X,Y}}$ with $|X| = |Y| = n-k$ can be accomplished by first constructing the Fourier coefficient matrices for δ_{S_k}, then relabeling the tracks and identities using a change of basis. More precisely, suppose that, to achieve this relabeling, we must permute the X (identities) using a permutation π_1 and the Y (tracks) using π_2. The *Shift Theorem* (see Diaconis 1988) can be applied to reorder the Fourier coefficients according to these new labels.

Proposition 25 (Shift Theorem) *Given* $f : S_n \to \mathbb{R}$*, define* $f' : S_n \to \mathbb{R}$ *by* $f'(\sigma) = f(\pi_1\sigma\pi_2)$ *for some fixed* $\pi_1, \pi_2 \in S_n$*. The Fourier transforms of* f *and* f' *are related as:* $\widehat{f'}_\lambda = \rho_\lambda(\pi_1)\cdot\widehat{f}_\lambda\cdot\rho_\lambda(\pi_2)$.

We conclude with a comment on sparsity. It is clear from Algorithm 5 that the coefficient matrices of $\left[\hat{\delta}_{S_{X,Y}}\right]_\lambda$ are all, up to an appropriate relabeling of identities and tracks, diagonal matrices with at most $O(d_\lambda)$ nonzero entries. In fact, we can sometimes show that a given model has $O(1)$ nonzero entries.

Consider, for example, the indicator function $\delta_{S_{n-1}}$, corresponding to observations of the form ("Identity j is at track i"), which is nonzero only at the first two partitions, (n), and $(n-1,1)$. The zeroth-order term is, $\left[\hat{\delta}_{S_{n-1}}\right]_{(n)} = (n-1)!$. The first-order Fourier coefficient matrix, $\left[\hat{\delta}_{S_{n-1}}\right]_{(n-1,1)}$, is a matrix of all zeroes except for a single element on the diagonal, $\left[\hat{\delta}_{S_{n-1}}\right]_{(n-1,1)}(t,t)$, where $t = \begin{array}{|c|c|c|c|}\hline 1&2&3&\cdots\\ \hline n\\ \cline{1-1}\end{array}$, which takes on the value $(n-1)!$.

Appendix D. Decomposing the Tensor Product Representation

We now turn to the *Tensor Product Decomposition* problem, which is that of finding the irreducible components of the typically reducible tensor product representation. If ρ_λ and ρ_μ are irreducible representations of S_n, then there exists an intertwining operator $C_{\lambda\mu}$ such that:

$$C_{\lambda\mu}{}^{-1}\cdot(\rho_\lambda\otimes\rho_\mu(\sigma))\cdot C_{\lambda\mu} = \bigoplus_\nu\bigoplus_{\ell=1}^{z_{\lambda\mu\nu}}\rho_\nu(\sigma). \qquad (32)$$

In this section, we will present a set of numerical methods for computing the Clebsch-Gordan series ($z_{\lambda\mu\nu}$) and Clebsch-Gordan coefficients ($C_{\lambda\mu}$) for a pair of irreducible representations $\rho_\lambda \otimes \rho_\mu$. We begin by discussing two methods for computing the Clebsch-Gordan series. In the second section, we provide a general algorithm for computing the intertwining operators which relate two equivalent representations and discuss how it can be applied to computing the Clebsch-Gordan coefficients (Equation 32) and the matrices which relate marginal probabilities to irreducible Fourier coefficients (Equation 6). The results of Appendix D.1 are specific to the symmetric group, while the results of Appendix D.2 can be applied to arbitrary finite groups.

D.1 Computing the Clebsch-Gordan Series

We begin with a simple, well-known algorithm based on *group characters* for computing the Clebsch-Gordan series that turns out to be computationally intractable, but yields several illuminating theoretical results. See Serre (1977) for proofs of the theoretical results cited in this section.

One of the main results of representation theory was the discovery that there exists a relatively compact way of encoding any representation up to equivalence with a vector which we call the *character* of the representation. If ρ is a representation of a group G, then the character of the representation ρ, is defined simply to be the trace of the representation at each element $\sigma \in G$:

$$\chi_\rho(\sigma) = \mathrm{Tr}\left(\rho(\sigma)\right).$$

The reason characters have been so extensively studied is that they uniquely characterize a representation up to equivalence in the sense that two characters χ_{ρ_1} and χ_{ρ_2} are equal if and only if ρ_1 and ρ_2 are equivalent as representations. Even more surprising is that the space of possible group characters is orthogonally spanned by the characters of the irreducible representations. To make this precise, we first define an inner product on functions from G.

Definition 26 *Let ϕ, ψ be two real-valued functions on G. The* inner product *of ϕ and ψ is defined to be:*

$$\langle \phi, \psi \rangle \equiv \frac{1}{|G|} \sum_{\sigma \in G} \phi(\sigma)\psi(\sigma)$$

With respect to the above inner product, we have the following important result which allows us to test a given representation for irreducibility, and to test two irreducibles for equivalence.

Proposition 27 *Let χ_{ρ_1} and χ_{ρ_2} be characters corresponding to irreducible representations. Then*

$$\langle \chi_{\rho_1}, \chi_{\rho_2} \rangle = \begin{cases} 1 & \textit{if } \rho_1 \equiv \rho_2 \\ 0 & \textit{otherwise} \end{cases}.$$

Proposition 27 shows that the irreducible characters form an orthonormal set of functions. The next proposition says that the irreducible characters *span* the space of all possible characters.

Proposition 28 *Suppose ρ is any representation of G and which decomposes into irreducibles as:*

$$\rho \equiv \bigoplus_{\lambda} \bigoplus_{\ell=1}^{z_\lambda} \rho_\lambda,$$

where λ indexes over all irreducibles of G. Then:

1. *The character of* ρ *is a linear combination of irreducible characters* ($\chi_\rho = \sum_\lambda z_\lambda \chi_{\rho_\lambda}$),
2. *and the multiplicity of each irreducible,* z_λ, *can be recovered using* $\langle \chi_\rho, \chi_{\rho_\lambda} \rangle = z_\lambda$.

A simple way to decompose any group representation ρ, is given by Proposition 28, which says that we can take inner products of χ_ρ against the basis of irreducible characters to obtain the irreducible multiplicities z_λ. To treat the special case of finding the Clebsch-Gordan series, one observes that the character of the tensor product is simply the pointwise product of the characters of each tensor product factor.

Theorem 29 *Let* ρ_λ *and* ρ_μ *be irreducible representations with characters* χ_λ, χ_μ *respectively. Let* $z_{\lambda\mu\nu}$ *be the number of copies of* ρ_ν *in* $\rho_\lambda \otimes \rho_\mu$ *(hence, one term of the Clebsch-Gordan series). Then:*

1. *The character of the tensor product representation is given by:*
$$\chi_{\rho_\lambda \otimes \rho_\mu} = \chi_\lambda \cdot \chi_\mu = \sum_\nu z_{\lambda\mu\nu} \chi_\nu.$$
2. *The terms of the Clebsch-Gordan series can be computed using:*
$$z_{\lambda\mu\nu} = \frac{1}{|G|} \sum_{g \in G} \chi_\lambda(g) \cdot \chi_\mu(g) \cdot \chi_\nu(g),$$
and satisfy the following symmetry:
$$z_{\lambda\mu\nu} = z_{\lambda\nu\mu} = z_{\mu\lambda\nu} = z_{\mu\nu\lambda} = z_{\nu\lambda\mu} = z_{\nu\mu\lambda}. \tag{33}$$

Dot products for characters on the symmetric group can be done in $O(\#(n))$ time where $\#(n)$ is the number of partitions of the number n, instead of the naive $O(n!)$ time. In practice however, $\#(n)$ also grows too quickly for the character method to be tractable.

D.1.1 MURNAGHAN'S FORMULAS

A theorem by Murnaghan (1938) gives us a 'bound' on which representations can appear in the tensor product decomposition on S_n.

Theorem 30 *Let* ρ_1, ρ_2 *be the irreducibles corresponding to the partition* $(n-p, \lambda_2, \dots)$ *and* $(n-q, \mu_2, \dots)$ *respectively. Then the product* $\rho_1 \otimes \rho_2$ *does not contain any irreducibles corresponding to a partition whose first term is less than* $n-p-q$.

In view of the connection between the Clebsch-Gordan series and convolution of Fourier coefficients, Theorem 30 is analogous to the fact that for functions over the reals, the convolution of two compactly supported functions is also compactly supported.

We can use Theorem 30 to show that Kronecker conditioning is exact at certain irreducibles.
Proof [of Theorem 12] Let Λ denote the set of irreducibles at which our algorithm maintains Fourier coefficients. Since the errors in the prior come from setting coefficients outside of Λ to be zero, we see that Kronecker conditioning returns an approximate posterior which is exact at the irreducibles in
$$\Lambda_{EXACT} = \{\rho_\nu \,:\, z_{\lambda\mu\nu} = 0, \text{ where } \lambda \notin \Lambda \text{ and } \mu \trianglerighteq (n-q, \mu_2, \dots)\}.$$

Combining Theorem 30 with Equation 33: if $z_{\lambda\mu\nu} > 0$, with $\lambda = (n-p,\lambda_2,\lambda_3,\dots),\mu = (n-q,\mu_2,\mu_3,\dots)$ and $\nu = (n-r,\nu_2,\nu_3,\dots)$, then we have that: $r \leq p+q, p \leq q+r$, and $q \leq p+r$. In particular, it implies that $r \geq p-q$ and $r \geq q-p$, or more succinctly, $r \geq |p-q|$. Hence, if $\nu = (n-r,\nu_2,\dots)$, then $\rho_\nu \in \Lambda_{EXACT}$ whenever $r \leq |p-q|$, which proves the desired result. ■

The same paper (Murnaghan, 1938) derives several general Clebsch-Gordan series formulas for pairs of low-order irreducibles in terms of n, and in particular, derives the Clebsch-Gordan series for many of the Kronecker product pairs that one would likely encounter in practice. For example,

- $\rho_{(n-1,1)} \otimes \rho_{(n-1,1)} \equiv \rho_{(n)} \oplus \rho_{(n-1,1)} \oplus \rho_{(n-2,2)} \oplus \rho_{(n-2,1,1)}$
- $\rho_{(n-1,1)} \otimes \rho_{(n-2,2)} \equiv \rho_{(n-1,1)} \oplus \rho_{(n-2,2)} \oplus \rho_{(n-2,1,1)} \oplus \rho_{(n-3,3)} \oplus \rho_{(n-3,2,1)}$
- $\rho_{(n-1,1)} \otimes \rho_{(n-2,1,1)} \equiv \rho_{(n-1,1)} \oplus \rho_{(n-2,2)} \oplus \rho_{(n-2,1,1)} \oplus \rho_{(n-3,2,1)} \oplus \rho_{(n-3,1,1,1)}$
- $\rho_{(n-1,1)} \otimes \rho_{(n-3,3)} \equiv \rho_{(n-2,2)} \oplus \rho_{(n-3,3)} \oplus \rho_{(n-3,2,1)} \oplus \rho_{(n-4,4)} \oplus \rho_{(n-4,3,1)}$

D.2 Computing the Clebsch-Gordan Coefficients

In this section, we consider the general problem of finding an orthogonal operator which decomposes an arbitrary complex representation, $X(\sigma)$, of a finite group G.[15] Unlike the Clebsch-Gordan series which are basis-independent, intertwining operators must be recomputed if we change the underlying basis by which the irreducible representation matrices are constructed. However, for a fixed basis, we remind the reader that these intertwining operators need only be computed once and for all and can be stored in a table for future reference. Let X be any degree d group representation of G, and let Y be an equivalent direct sum of irreducibles, for example,

$$Y(\sigma) = \bigoplus_{\nu} \bigoplus_{\ell=1}^{z_\nu} \rho_\nu(\sigma), \tag{34}$$

where each irreducible ρ_ν has degree d_ν. We would like to compute an invertible (and orthogonal) operator C, such that $C \cdot X(\sigma) = Y(\sigma) \cdot C$, for all $\sigma \in G$. Throughout this section, we will assume that the multiplicities z_ν are known. To compute Clebsch-Gordan coefficients, for example, we would set $X = \rho_\lambda \otimes \rho_\mu$, and the multiplicities would be given by the Clebsch-Gordan series (Equation 32). To find the matrix which relates marginal probabilities to irreducible coefficients, we would set $X = \tau_\lambda$, and the multiplicities would be given by the Kostka numbers (Equation 6).

We will begin by describing an algorithm for computing a basis for the space of all possible intertwining operators which we denote by:

$$\mathrm{Int}_{[X;Y]} = \{C \in \mathbb{R}^{d\times d} \ : \ C \cdot X(\sigma) = Y(\sigma) \cdot C, \ \ \forall \sigma \in G\}.$$

We will then discuss some of the theoretical properties of $\mathrm{Int}_{[X;Y]}$ and show how to efficiently select an *orthogonal* element of $\mathrm{Int}_{[X;Y]}$.

15. Though the fundamental ideas in this section hold for a general finite group, we will continue to index irreducible by partitions and think of representations as being real-valued. To generalize the results, one can simply replace all transposes in this section by adjoints and think of η as indexing over the irreducibles of G rather than partitions.

Our approach is to naively[16] view the task of finding elements of $\mathrm{Int}_{[X;Y]}$ as a similarity matrix recovery problem, with the twist that the similarity matrix must be consistent over all group elements. To the best of our knowledge, the technique presented in this section is original. We first cast the problem of recovering a similarity matrix as a nullspace computation.

Proposition 31 *Let A,B,C be matrices and let $K_{AB} = I \otimes A - B^T \otimes I$. Then $AC = CB$ if and only if $vec(C) \in Nullspace(K_{AB})$.*

Proof A well known matrix identity (van Loan, 2000) states that if A,B,C are matrices, then $\mathrm{vec}(ABC) = \left(C^T \otimes A\right)\mathrm{vec}(B)$. Applying the identity to $AC = CB$, we have:

$$\mathrm{vec}(ACI) = \mathrm{vec}(ICB),$$

and after some manipulation:

$$\left(I \otimes A - B^T \otimes I\right)\mathrm{vec}(C) = 0,$$

showing that $\mathrm{vec}(C) \in \mathrm{Nullspace}(K_{AB})$. ■

For each $\sigma \in G$, the nullspace of the matrix $K(\sigma)$ constructed using the above proposition as:

$$K(\sigma) = I \otimes Y(\sigma) - X(\sigma) \otimes I, \tag{35}$$

where I is a $d \times d$ identity matrix, corresponds to the space of matrices C_σ such that

$$C_\sigma \cdot X(\sigma) = Y(\sigma) \cdot C, \qquad \text{for all } \sigma \in G.$$

To find the space of intertwining operators which are consistent across all group elements, we need to find the intersection:

$$\bigcap_{\sigma \in G} Nullspace(K(\sigma)).$$

At first glance, it may seem that computing the intersection might require examining $n!$ nullspaces if $G = S_n$, but as luck would have it, most of the nullspaces in the intersection are extraneous, as we now show.

Definition 32 *We say that a finite group G is* generated *by a set of* generators $S = \{g_1, \ldots, g_m\}$ *if every element of G can be written as a finite product of elements in S.*

For example, the following three sets are all generators for S_n:

- $\{(1,2),(1,3),\ldots,(1,n)\}$,
- $\{(1,2),(2,3),(3,4),\ldots,(n-1,n)\}$, and
- $\{(1,2),(1,2,3,\ldots,n)\}$.

To ensure a consistent similarity matrix for all group elements, we use the following proposition which says that it suffices to be consistent on any set of generators of the group.

16. In implementation, we use a more efficient algorithm for computing intertwining operators known as the *Eigenfunction Method* (EFM) (Chen, 1989). Unfortunately, the EFM is too complicated for us to describe in this paper. The method which we describe in this appendix is conceptually simpler than the EFM and generalizes easily to groups besides S_n.

Proposition 33 *Let X and Y be representations of finite group G and suppose that G is generated by the elements $\sigma_1, \ldots, \sigma_m$. If there exists an invertible linear operator C such that $C \cdot X(\sigma_i) = Y(\sigma_i) \cdot C$ for each $i \in \{1, \ldots, m\}$, then X and Y are equivalent as representations with C as the intertwining operator.*

Proof We just need to show that C is a similarity transform for any other element of G as well. Let π be any element of G and suppose π can be written as the following product of generators: $\pi = \prod_{i=1}^{n} \sigma_i$. It follows that:

$$\begin{aligned} C^{-1} \cdot Y(\pi) \cdot C &= C^{-1} \cdot Y\left(\prod_i \sigma_i\right) \cdot C = C^{-1} \cdot \left(\prod_i Y(\sigma_i)\right) \cdot C \\ &= (C^{-1} \cdot Y(\sigma_1) \cdot C)(C^{-1} \cdot Y(\sigma_2) \cdot C) \cdots (C^{-1} \cdot Y(\sigma_m) \cdot C) \\ &= \prod_i \left(C^{-1} \cdot Y(\sigma_i) \cdot C\right) = \prod_i X(\sigma_i) = X\left(\prod_i \sigma_i\right) = X(\pi). \end{aligned}$$

Since this holds for every $\pi \in G$, we have shown C to be an intertwining operator between the representations X and Y. ■

The good news is that despite having $n!$ elements, S_n can be generated by just two elements, namely, $(1,2)$ and $(1,2,\ldots,n)$, and so the problem reduces to solving for the intersection of two nullspaces, $(K(1,2) \cap K(1,2,\ldots,n))$, which can be done using standard numerical methods. Typically, the nullspace is multidimensional, showing that, for example, the Clebsch-Gordan coefficients for $\rho_\lambda \otimes \rho_\mu$ are not unique even up to scale.

Because $\mathrm{Int}_{[X;Y]}$ contains singular operators (the zero matrix is a member of $\mathrm{Int}_{[X;Y]}$, for example), not every element of $\mathrm{Int}_{[X;Y]}$ is actually a legitimate intertwining operator as we require invertibility. In practice, however, since the singular elements correspond to a measure zero subset of $\mathrm{Int}_{[X;Y]}$, one method for reliably selecting an operator from $\mathrm{Int}_{[X;Y]}$ that "works" is to simply select a random element from the nullspace to be C. It may, however, be desirable to have an *orthogonal* matrix C which works as an intertwining operator. In the following, we discuss an object called the *Commutant Algebra* which will lead to several insights about the space $\mathrm{Int}_{[X;Y]}$, and in particular, will lead to an algorithm for 'modifying' any invertible intertwining operator C to be an *orthogonal* matrix.

Definition 34 *The* Commutant Algebra *of a representation Y is defined to be the space of operators which commute with Y:*[17]

$$Com_Y = \{S \in \mathbb{R}^{d \times d} \ : \ S \cdot Y(\sigma) = Y(\sigma) \cdot S, \ \forall \sigma \in G\}.$$

The elements of the Commutant Algebra of Y can be shown to always take on a particular constrained form (shown using Schur's Lemma in Sagan 2001). In particular, every element of Com_Y takes the form

$$S = \bigoplus_\nu \left(M_{z_\nu} \otimes I_{d_\nu}\right), \tag{36}$$

where M_{z_ν} is some $z_\nu \times z_\nu$ matrix of coefficients and I_{d_ν} is the $d_\nu \times d_\nu$ identity (recall that the z_ν are the multiplicities from Equation 34). Moreover, it can be shown that every matrix of this form must necessarily be an element of the Commutant Algebra.

17. Notice that the definition of the Commutant Algebra does not involve the representation X.

The link between Com_Y and our problem is that the space of intertwining operators can be thought of as a 'translate' of the Commutant Algebra.

Lemma 35 *There exists a vector space isomorphism between $Int_{[X;Y]}$ and Com_Y.*

Proof Let R be any invertible element of $\text{Int}_{[X;Y]}$ and define the linear map $f : \text{Com}_Y \to \mathbb{R}^{d\times d}$ by: $f : S \mapsto (S\cdot R)$. We will show that the image of f is exactly the space of intertwining operators. Consider any element $\sigma \in G$:

$$\begin{aligned}(S\cdot R)\cdot X(\sigma)\cdot(S\cdot R)^{-1} &= S\cdot R\cdot X(\sigma)\cdot R^{-1}\cdot S^{-1},\\ &= S\cdot Y(\sigma)\cdot S^{-1} \quad (\text{since } R\in \text{Int}_{[X;Y]}),\\ &= Y(\sigma) \quad (\text{since } S\in\text{Com}_Y).\end{aligned}$$

We have shown that $S\cdot R\in \text{Int}_{[X;Y]}$, and since f is linear and invertible, we have that $\text{Int}_{[X;Y]}$ and Com_Y are isomorphic as vector spaces. ■

Using the lemma, we can see that the dimension of $\text{Int}_{[X;Y]}$ must be the same as the dimension of Com_Y, and therefore we have the following expression for the dimension of $\text{Int}_{[X;Y]}$.

Proposition 36

$$\dim Int_{[X;Y]} = \sum_\nu z_\nu^2.$$

Proof To compute the dimension of $\text{Int}_{[X;Y]}$, we need to compute the dimension of Com_Y, which can be accomplished simply by computing the number of free parameters in Equation 36. Each matrix M_{z_ν} is free and yields z_ν^2 parameters, and summing across all irreducibles ν yields the desired dimension. ■

To select an orthogonal intertwining operator, we will assume that we are given some invertible $R\in\text{Int}_{[X;Y]}$ which is not necessarily orthogonal (such as a random element of the nullspace of K , Equation 35). To find an orthogonal element, we will 'modify' R to be an orthogonal matrix by applying an appropriate rotation, such that $R\cdot R^T = I$. We begin with a simple observation about $R\cdot R^T$.

Lemma 37 *If both X and Y are orthogonal representations and R is an invertible member of $Int_{[X;Y]}$, then the matrix $R\cdot R^T$ is an element of Com_Y.*

Proof Consider a fixed $\sigma\in G$. Since $R\in\text{Int}_{[X;Y]}$, we have that:

$$X(\sigma) = R^{-1}\cdot Y(\sigma)\cdot R.$$

It is also true that:

$$X(\sigma^{-1}) = R^{-1}\cdot Y(\sigma^{-1})\cdot R. \tag{37}$$

Since $X(\sigma)$ and $Y(\sigma)$ are orthogonal matrices by assumption, Equation 37 becomes:

$$X^T(\sigma) = R^{-1}\cdot Y^T(\sigma)\cdot R.$$

Algorithm 6: Pseudocode for computing an orthogonal intertwining operators

```
INTXY
input : A degree $d$ orthogonal matrix representation $X$ evaluated at permutations $(1,2)$ and
        $(1,\dots,n)$, and the multiplicity $z_\nu$, of the irreducible $\rho_\nu$ in $X$
output: A matrix $C_\nu$ with orthogonal rows such that $C_\nu^T \cdot \oplus^{z_\nu}\rho_\nu \cdot C_\nu = X$
1 $K_1 \leftarrow I_{d\times d} \otimes (\oplus^{z_\nu}\rho_\nu(1,2)) - X(1,2) \otimes I_{d\times d}$;
2 $K_2 \leftarrow I_{d\times d} \otimes (\oplus^{z_\nu}\rho_\nu(1,\dots,n)) - X(1,\dots,n) \otimes I_{d\times d}$;
3 $K \leftarrow [K_1; K_2]$;   //Stack $K_1$ and $K_2$
4 $v \leftarrow \text{SparseNullspace}\big(K, z_\nu^2\big)$;   //Find the $d_\nu^2$-dimensional nullspace
5 $R \leftarrow \text{Reshape}(v; z_\nu d_\nu, d)$;   //Reshape $v$ into a $(z_\nu d_\nu)\times d$ matrix
6 $M \leftarrow \text{KroneckerFactors}(R\cdot R^T)$;   //Find $M$ such that $R\cdot R^T = M\otimes I_{d_\nu}$
7 $S_\nu \leftarrow \text{Eigenvectors}(M)$ ;
8 $C_\nu \leftarrow S_\nu^T \cdot R$ ;
9 NormalizeRows$(C_\nu)$;
```

Taking transposes,

$$X(\sigma) = R^T \cdot Y(\sigma)\cdot (R^{-1})^T.$$

We now multiply both sides on the left by R, and on the right by R^T,

$$\begin{aligned} R\cdot X(\sigma)\cdot R^T &= R\cdot R^T \cdot Y(\sigma)\cdot (R^{-1})^T\cdot R^T \\ &= R\cdot R^T\cdot Y(\sigma). \end{aligned}$$

Since $R \in \text{Int}_{[X;Y]}$,

$$Y(\sigma)\cdot R\cdot R^T = R\cdot R^T\cdot Y(\sigma),$$

which shows that $R\cdot R^T \in \text{Com}_Y$. ■

We can now state and prove our orthogonalization procedure, which works by diagonalizing the matrix $R\cdot R^T$. Due to its highly constrained form, the procedure is quite efficient.

Theorem 38 *Let X be any orthogonal group representation of G and Y an equivalent orthogonal irreducible decomposition (As in Equation 34). Then for any invertible element $R \in Int_{[X;Y]}$, there exists an (efficiently computable) orthogonal matrix T such that the matrix $T\cdot R$ is an element of $Int_{[X;Y]}$ and is* orthogonal.

Proof Lemma 37 and Equation 36 together imply that the matrix $R\cdot R^T$ can always be written in the form

$$R\cdot R^T = \oplus_\nu \left(M_{z_\nu}\otimes I_{d_\nu}\right)$$

Since $R\cdot R^T$ is symmetric, each of the matrices M_{z_ν} is also symmetric and must therefore possess an orthogonal basis of eigenvectors. Define the matrix S_{z_ν} to be the matrix whose columns are the eigenvectors of M_{z_ν}.

The matrix $S = \oplus_\nu(S_{z_\nu}\otimes I_{d_\nu})$ has the following two properties:

1. $(S^T \cdot R)(S^T \cdot R)^T$ is a diagonal matrix:

   Each column of S is an eigenvector of $R \cdot R^T$ by standard properties of the direct sum and Kronecker product. Since each of the matrices, S_{z_ν}, is orthogonal, the matrix S is also orthogonal. We have:

$$\begin{aligned}(S^T \cdot R)(S^T \cdot R)^T &= S^T \cdot R \cdot R^T \cdot S,\\ &= S^{-1} \cdot R \cdot R^T \cdot S,\\ &= D,\end{aligned}$$

   where D is a diagonal matrix of eigenvalues of $R \cdot R^T$.

2. $S^T \cdot R \in \mathrm{Int}_{[X;Y]}$:

   By Equation 36, a matrix is an element of Com_Y if and only if it takes the form $\oplus_\nu (S_{z_\nu} \otimes I_{d_\nu})$. Since S can be written in the required form, so can S^T. We see that $S^T \in \mathrm{Com}_Y$, and by the proof of Lemma 35, we see that $S^T \cdot R \in \mathrm{Int}_{[X;Y]}$.

Finally, setting $T = D^{1/2} \cdot S^T$ makes the matrix $T \cdot R$ orthogonal (and does not change the fact that $T \cdot R \in \mathrm{Int}_{[X;Y]}$). ■

We see that the complexity of computing T is dominated by the eigenspace decomposition of M_{z_ν}, which is $O\left(z_\nu^3\right)$. Pseudocode for computing orthogonal intertwining operators is given Algorithm 6.

Abstract

We present a sound and complete graphical criterion for reading dependencies from the minimal undirected independence map G of a graphoid M that satisfies weak transitivity. Here, complete means that it is able to read all the dependencies in M that can be derived by applying the graphoid properties and weak transitivity to the dependencies used in the construction of G and the independencies obtained from G by vertex separation. We argue that assuming weak transitivity is not too restrictive. As an intermediate step in the derivation of the graphical criterion, we prove that for any undirected graph G there exists a strictly positive discrete probability distribution with the prescribed sample spaces that is faithful to G. We also report an algorithm that implements the graphical criterion and whose running time is considered to be at most $O(n^2(e+n))$ for n nodes and e edges. Finally, we illustrate how the graphical criterion can be used within bioinformatics to identify biologically meaningful gene dependencies.

Keywords: graphical models, vertex separation, graphoids, weak transitivity, bioinformatics

1. Introduction

A minimal undirected independence map G of an independence model M is used to read independencies that hold in M. Sometimes, however, G can also be used to read dependencies holding in M. For instance, if M is a graphoid that is faithful to G then, by definition, lack of vertex separation is a sound and complete graphical criterion for reading dependencies from G, where complete means

*. Also at the Department of Medicine, Karolinska Institutet, SE-17176 Stockholm, Sweden.

that it is able to read all the dependencies in M. If M is simply a graphoid, then Bouckaert (1995) proposes a sound and complete graphical criterion for reading dependencies from G. In this case, complete means that it is able to read all the dependencies in M that can be derived by applying the graphoid properties to the dependencies used in the construction of G and the independencies obtained from G by vertex separation.

In this paper, we introduce a sound and complete graphical criterion for reading dependencies from G under the assumption that M is a graphoid that satisfies weak transitivity. Here, complete means that it is able to read all the dependencies in M that can be derived by applying the graphoid properties and weak transitivity to the dependencies used in the construction of G and the independencies obtained from G by vertex separation. Our criterion allows reading more dependencies than the criterion in Bouckaert (1995) when the graphoid at hand satisfies weak transitivity. We show that there exist important families of probability distributions that are graphoids and satisfy weak transitivity. These include, for instance, the regular Gaussian probability distributions.

We think that the work presented in this paper can be of great interest for the machine learning community. Graphs are one of the most commonly used metaphors for representing knowledge because they appeal to human intuition (Pearl, 1988). Furthermore, graphs are parsimonious models because they trade off accuracy for simplicity. Consider, for instance, representing the independence model induced by a probability distribution as a graph. Though this graph is typically less accurate than the probability distribution (the graph may not represent all the (in)dependencies and those that are represented are not quantified), it also requires less space to be stored and less time to be communicated than the probability distribution, which may be desirable features in some applications. Thus, it seems sensible developing tools for reasoning with graphs. Our criterion is one such a tool: As vertex separation makes the discovery of independencies amenable to human reasoning by enabling to read independencies off G without numerical calculation (Pearl, 1988), so does our criterion with respect to the discovery of dependencies. There are fields where discovering dependencies is more important than discovering independencies. It is in these fields where we believe that our criterion has greater potential. In bioinformatics, for instance, the nodes of G represent (the expression levels of) some genes under study. Bioinformaticians are typically more interested in discovering gene dependencies than independencies, because the former provide contexts in which the expression level of some genes is informative about that of some other genes, which may lead to hypothesize dependencies, functional relations, causal relations, the effects of manipulation experiments, etc. As we will illustrate at the end of the paper, our criterion can be very helpful in such a scenario. Our criterion also clarifies a misconception that may exist among some bioinformaticians, namely that two genes are dependent if there exists a path in G between them. We will see that there must exist exactly one path to draw such a conclusion. Hence, the importance of developing a formal criterion like ours to prevent drawing erroneous conclusions. Of course, the conclusions drawn by our criterion may be misleading if G is learnt from a sample, which is most likely the case in bioinformatics. However, this has nothing to do with the correctness of our criterion, which we prove in subsequent sections, but with the fact that G is an estimate.

The rest of the paper is organized as follows. We start by reviewing some concepts in Section 2. We show in Section 3 that assuming weak transitivity is not too restrictive. We prove in Section 4 that for any undirected graph G there exists a strictly positive discrete probability distribution with the prescribed sample spaces that is faithful to G. This is an important result in itself as well as for proving the completeness of the graphical criterion that we present in Section 5. An algorithmic implementation of the graphical criterion is described in Section 6. We illustrate in Section 7 how the graphical criterion works in practice with a real world example taken from bioinformatics. Finally, we close with some discussion in Section 8.

2. Preliminaries

The definitions and results in this section are taken from Lauritzen (1996), Pearl (1988) and Studený (2005). We use the juxtaposition $\mathbf{XY}$ to denote $\mathbf{X} \cup \mathbf{Y}$, and X to denote the singleton $\{X\}$. We use upper-case letters to denote random variables and the same letters in lower-case to denote their states. We use $Val(\mathbf{X})$ to denote the set of possible states of a random variable $\mathbf{X}$. Let $\mathbf{U}$ denote a set of random variables. Unless otherwise stated, all the probability distributions, independence models and graphs in this paper are defined over $\mathbf{U}$. Let $\mathbf{X}, \mathbf{Y}, \mathbf{Z}$ and $\mathbf{W}$ denote four mutually disjoint subsets of $\mathbf{U}$. An independence model M is a set of independencies of the form $\mathbf{X}$ is independent of $\mathbf{Y}$ given $\mathbf{Z}$. We represent that an independence is in M by $\mathbf{X} \perp\!\!\!\perp \mathbf{Y} | \mathbf{Z}$ and that an independence is not in M by $\mathbf{X} \not\perp\!\!\!\perp \mathbf{Y} | \mathbf{Z}$. In the latter case, we may equivalently say that the dependence $\mathbf{X} \not\perp\!\!\!\perp \mathbf{Y} | \mathbf{Z}$ is in M. An independence model is a graphoid when it satisfies the following five properties:

- Symmetry $\mathbf{X} \perp\!\!\!\perp \mathbf{Y} | \mathbf{Z} \Rightarrow \mathbf{Y} \perp\!\!\!\perp \mathbf{X} | \mathbf{Z}$.
- Decomposition $\mathbf{X} \perp\!\!\!\perp \mathbf{YW} | \mathbf{Z} \Rightarrow \mathbf{X} \perp\!\!\!\perp \mathbf{Y} | \mathbf{Z}$.
- Weak union $\mathbf{X} \perp\!\!\!\perp \mathbf{YW} | \mathbf{Z} \Rightarrow \mathbf{X} \perp\!\!\!\perp \mathbf{Y} | \mathbf{ZW}$.
- Contraction $\mathbf{X} \perp\!\!\!\perp \mathbf{Y} | \mathbf{ZW} \wedge \mathbf{X} \perp\!\!\!\perp \mathbf{W} | \mathbf{Z} \Rightarrow \mathbf{X} \perp\!\!\!\perp \mathbf{YW} | \mathbf{Z}$.
- Intersection $\mathbf{X} \perp\!\!\!\perp \mathbf{Y} | \mathbf{ZW} \wedge \mathbf{X} \perp\!\!\!\perp \mathbf{W} | \mathbf{ZY} \Rightarrow \mathbf{X} \perp\!\!\!\perp \mathbf{YW} | \mathbf{Z}$.

The independence model induced by any strictly positive probability distribution is a graphoid. Hereinafter, for the sake of simplicity, we do not make any distinction between a probability distribution and the independence model induced by it and, thus, we always refer to the former. For instance, instead of saying that the independence model of a probability distribution p is a graphoid, we simply say that p is a graphoid. In this paper, we pay particular attention to strictly positive discrete probability distributions and regular Gaussian probability distributions, that is, those whose covariance matrices are positive definite. For the strictly positive discrete probability distributions, we assume that each random variable in $\mathbf{U}$ has a finite sample space with at least two possible states. Note that if p is a strictly positive discrete probability distribution, then $p(\mathbf{X})$ and $p(\mathbf{X}|\mathbf{Y}=\mathbf{y})$ are uniquely defined, strictly positive and discrete. Likewise, if p is a regular Gaussian probability distribution, then $p(\mathbf{X})$ and $p(\mathbf{X}|\mathbf{Y}=\mathbf{y})$ are uniquely determined (by a convention) and regular Gaussian. Moreover, any regular Gaussian probability distribution satisfies composition $\mathbf{X} \perp\!\!\!\perp \mathbf{Y} | \mathbf{Z} \wedge \mathbf{X} \perp\!\!\!\perp \mathbf{W} | \mathbf{Z} \Rightarrow \mathbf{X} \perp\!\!\!\perp \mathbf{YW} | \mathbf{Z}$.

A path between X_1 and X_n in a graph G is a sequence of distinct nodes $X_1, \ldots, X_n$ $(1 \leq n)$ such that there exists an edge in G between every two consecutive nodes in the sequence. Given a path $X_1, \ldots, X_n$ in a directed and acyclic graph (DAG) G, a node X_i $(1 < i < n)$ is a collider in the path if $X_{i-1} \rightarrow X_i \leftarrow X_{i+1}$ in G. Let $sep(\mathbf{X}, \mathbf{Y}|\mathbf{Z})$ denote that $\mathbf{X}$ is separated from $\mathbf{Y}$ given $\mathbf{Z}$ in a graph G. Specifically, $sep(\mathbf{X}, \mathbf{Y}|\mathbf{Z})$ holds when every path in G between $\mathbf{X}$ and $\mathbf{Y}$ is blocked by $\mathbf{Z}$. If G is an undirected graph (UG), then a path in G between $\mathbf{X}$ and $\mathbf{Y}$ is blocked by $\mathbf{Z}$ when there exists some $Z \in \mathbf{Z}$ in the path. If G is a DAG, then a path in G between $\mathbf{X}$ and $\mathbf{Y}$ is blocked by $\mathbf{Z}$ when there exists a node Z in the path such that

- either Z is not a collider in the path and $Z \in \mathbf{Z}$, or
- Z is a collider in the path and neither Z nor any of its descendants in G is in $\mathbf{Z}$.

An independence model M is faithful to an UG or DAG G when $\mathbf{X} \perp\!\!\!\perp \mathbf{Y} | \mathbf{Z}$ iff $sep(\mathbf{X}, \mathbf{Y} | \mathbf{Z})$. Any independence model that is faithful to some UG or DAG is a graphoid. An UG (resp. DAG) G is an undirected (resp. directed) independence map of an independence model M when $\mathbf{X} \perp\!\!\!\perp \mathbf{Y} | \mathbf{Z}$ if $sep(\mathbf{X}, \mathbf{Y} | \mathbf{Z})$. Moreover, an UG G is a minimal undirected independence (MUI) map of M when

(i) G is an undirected independence map of M, and

(ii) no proper subgraph of G satisfies (i).

A Markov boundary of $X \in \mathbf{U}$ in an independence model M is any subset $MB(X)$ of $\mathbf{U} \setminus X$ such that

(i) $X \perp\!\!\!\perp \mathbf{U} \setminus X \setminus MB(X) | MB(X)$, and

(ii) no proper subset of $MB(X)$ satisfies (i).

If M is a graphoid, then

(i) $MB(X)$ is unique for each $X \in \mathbf{U}$,

(ii) the MUI map G of M is unique, and

(iii) two nodes X and Y are adjacent in G iff $X \in MB(Y)$ iff $Y \in MB(X)$ iff $X \not\perp\!\!\!\perp Y | \mathbf{U} \setminus (XY)$.

A Bayesian network (BN) is a pair (G, p) where G is a DAG and p is a discrete probability distribution that factorizes as $p = \prod_{X \in \mathbf{U}} q(X | Pa(X))$, where $q(X | Pa(X))$ denotes a conditional discrete probability distribution of X given the parents of X in G, $Pa(X)$. Recall that a node Y is called a parent of X if $Y \to X$ is in G. We denote by $\mathcal{D}(G)^+$ all the strictly positive discrete probability distributions that can be represented by a BN with DAG G, that is, those that factorize according to G as indicated.

3. Weak Transitivity Graphoids

Let $\mathbf{X}$, $\mathbf{Y}$ and $\mathbf{Z}$ denote three mutually disjoint subsets of $\mathbf{U}$. We define a weak transitivity (WT) graphoid as a graphoid that satisfies weak transitivity $\mathbf{X} \perp\!\!\!\perp \mathbf{Y} | \mathbf{Z} \wedge \mathbf{X} \perp\!\!\!\perp \mathbf{Y} | \mathbf{Z}V \Rightarrow \mathbf{X} \perp\!\!\!\perp V | \mathbf{Z} \vee V \perp\!\!\!\perp \mathbf{Y} | \mathbf{Z}$ with $V \in \mathbf{U} \setminus (\mathbf{XYZ})$. There exist important families of probability distributions that are WT graphoids and, thus, we believe that WT graphoids are worth studying: For instance, any probability distribution that is regular Gaussian or faithful to some UG or DAG is a WT graphoid (Pearl, 1988; Studený, 2005). Other interesting families of probability distributions that are WT graphoids are presented in this section.

We say that a strictly positive discrete probability distribution p has context-specific dependencies if there exists some $\mathbf{W} \subseteq \mathbf{U}$ such that $p(\mathbf{U} \setminus \mathbf{W} | \mathbf{W} = \mathbf{w})$ does not have the same (in)dependencies for all $\mathbf{w}$. The theorem below proves that for any DAG G, in a measure-theoretic sense (Halmos, 1966), almost all the probability distributions in $\mathcal{D}(G)^+$ have no context-specific dependencies. This result is not only relative to the DAG G, but also to the measure considered, the

Lebesgue measure in our case, as well as to the dimension of $\mathcal{D}(G)^+$. For this purpose, we discuss first how we parameterize the probability distributions in $\mathcal{D}(G)^+$. Since each probability distribution p in $\mathcal{D}(G)^+$ factorizes as $p = \prod_{X \in \mathbf{U}} q(X|Pa(X))$, p can be parameterized by parameterizing each probability table $q(X|Pa(X))$. Let $Val(X) = \{x_1, \ldots, x_{n(X)}\}$ denote the $n(X)$ possible states of the random variable X. Let $\theta_{x_i,\mathbf{pa}}$ $(1 \leq i \leq n(X))$ denote the parameter corresponding to $q(X = x_i|Pa(X) = \mathbf{pa})$ with $\mathbf{pa} \in Val(Pa(X))$. Note that the parameters are linearly dependent because $\sum_{i=1}^{n(X)} q(X = x_i|Pa(X) = \mathbf{pa}) = 1$. In order to introduce properly the parameter space for $\mathcal{D}(G)^+$ and the Lebesgue measure on it, we make the convention that $\theta_{x_{n(X)},\mathbf{pa}}$ is linearly dependent on the remaining parameters $\theta_{x_i,\mathbf{pa}}$ with $1 \leq i < n(X)$. Therefore, the number of linearly independent parameters for p is $n = \sum_{X \in \mathbf{U}}(n(X) - 1)(\prod_{Y \in Pa(X)} n(Y))$. Let Δ_d denote the simplex $\{(s_1, \ldots, s_d) \in \mathbb{R}^d : s_i \geq 0 \; (1 \leq i \leq d), \sum_{i=1}^d s_i \leq 1\}$. The Lebesgue measure of Δ_d wrt $\mathbb{R}^d$ is $1/d!$ (Stein, 1966). Let Δ_d^+ denote the set $\{(s_1, \ldots, s_d) \in \mathbb{R}^d : s_i > 0 \; (1 \leq i \leq d), \sum_{i=1}^d s_i < 1\}$. The Lebesgue measure of Δ_d^+ wrt $\mathbb{R}^d$ is also $1/d!$, because the difference between Δ_d and Δ_d^+ has Lebesgue measure zero. Then, the parameter space for $\mathcal{D}(G)^+$ is $\times_{X \in \mathbf{U}} \times_{\mathbf{pa} \in Val(Pa(X))} \Delta^+_{n(X)-1}$, whose Lebesgue measure wrt $\mathbb{R}^n$ is $\prod_{X \in \mathbf{U}} \prod_{\mathbf{pa} \in Val(Pa(X))} 1/(n(X) - 1)!$.

Theorem 1 *Let G be a DAG. $\mathcal{D}(G)^+$ has non-zero Lebesgue measure wrt $\mathbb{R}^n$, where n is the number of linearly independent parameters in the parametrization of the probability distributions in $\mathcal{D}(G)^+$ described above. The probability distributions in $\mathcal{D}(G)^+$ that are not faithful to G or have context-specific dependencies have zero Lebesgue measure wrt $\mathbb{R}^n$.*

Proof First, we prove that there is a one-to-one correspondence between the elements of the parameter space for $\mathcal{D}(G)^+$ and the probability distributions in $\mathcal{D}(G)^+$. This will allow us later to compute the Lebesgue measure wrt $\mathbb{R}^n$ of a subset of $\mathcal{D}(G)^+$ as the Lebesgue measure wrt $\mathbb{R}^n$ of the corresponding subset of the parameter space for $\mathcal{D}(G)^+$. Obviously, different probability distributions in $\mathcal{D}(G)^+$ must correspond to different elements of the parameter space for $\mathcal{D}(G)^+$. On the other hand, different elements of the parameter space for $\mathcal{D}(G)^+$ correspond to different probability distributions in $\mathcal{D}(G)^+$, because the values of the parameters $\theta_{x_i,\mathbf{pa}}$ defining a probability distribution p coincide with the values of the conditional probabilities $p(X = x_i|Pa(X) = \mathbf{pa})$ that are computed from p (Pearl, 1988).

To prove the first statement in the theorem it suffices to note that, as discussed right before the theorem, the parameter space for $\mathcal{D}(G)^+$ has non-zero Lebesgue measure wrt $\mathbb{R}^n$. This implies that $\mathcal{D}(G)^+$ also has non-zero Lebesgue measure wrt $\mathbb{R}^n$ because, as proven above, there is a one-to-one correspondence between the elements of the parameter space for $\mathcal{D}(G)^+$ and the probability distributions in $\mathcal{D}(G)^+$.

To prove the second statement in the theorem, we first prove that the probability distributions in $\mathcal{D}(G)^+$ that have context-specific dependencies have zero Lebesgue measure wrt $\mathbb{R}^n$. The proof basically proceeds in the same way as that of Theorem 7 in Meek (1995). We start by showing that for a probability distribution in $\mathcal{D}(G)^+$ to have context-specific dependencies, some polynomials in the parameters in the parametrization of the probability distributions in $\mathcal{D}(G)^+$ must be satisfied. Specifically, these polynomials are real polynomials in real variables that we interpret as real functions on a real Euclidean space that includes the parameter space for $\mathcal{D}(G)^+$. Let $\mathbf{W} \subseteq \mathbf{U}$ and let $\mathbf{X}$, $\mathbf{Y}$ and $\mathbf{Z}$ denote three disjoint subsets of $\mathbf{U} \setminus \mathbf{W}$. Since G is a directed independence map of any probability distribution $p \in \mathcal{D}(G)^+$ (Neapolitan, 2003), for a constraint such as $\mathbf{X} \perp\!\!\!\perp \mathbf{Y}|\mathbf{Z}$ to be true in $p(\mathbf{U} \setminus \mathbf{W}|\mathbf{W} = \mathbf{w})$ but false in $p(\mathbf{U} \setminus \mathbf{W}|\mathbf{W} = \mathbf{w}')$, two conditions must be met. First, $sep(\mathbf{X}, \mathbf{Y}|\mathbf{Z}\mathbf{W})$

must not hold in G and, second, the following equations must be satisfied:

$$p(\mathbf{X}=\mathbf{x},\mathbf{Y}=\mathbf{y},\mathbf{Z}=\mathbf{z},\mathbf{W}=\mathbf{w})p(\mathbf{Z}=\mathbf{z},\mathbf{W}=\mathbf{w})-$$

$$p(\mathbf{X}=\mathbf{x},\mathbf{Z}=\mathbf{z},\mathbf{W}=\mathbf{w})p(\mathbf{Y}=\mathbf{y},\mathbf{Z}=\mathbf{z},\mathbf{W}=\mathbf{w})=0 \tag{1}$$

for all $\mathbf{x}$, $\mathbf{y}$ and $\mathbf{z}$. Each equation is a polynomial in the parameters in the parametrization of the probability distributions in $\mathcal{D}(G)^+$, because each term $p(\mathbf{V}=\mathbf{v})$ in the equations is a polynomial in the parameters: $p(\mathbf{V}=\mathbf{v})=\sum_{\mathbf{v}'}p(\mathbf{V}=\mathbf{v},\mathbf{U}\setminus\mathbf{V}=\mathbf{v}')$ where each term $p(\mathbf{V}=\mathbf{v},\mathbf{U}\setminus\mathbf{V}=\mathbf{v}')$ is a polynomial in the parameters, since $p=\prod_{X\in\mathbf{U}}q(X|Pa(X))$. Let each variable in the polynomials take values in $\mathbb{R}$. Then, each polynomial in Equation (1) is non-trivial, that is, not all the values of the variables are solutions to the polynomial. To prove this, it suffices to prove that there exists a probability distribution $p'\in\mathcal{D}(G)^+$ for which the polynomial does not hold. Consider the polynomial for $\mathbf{x}, \mathbf{y}$ and $\mathbf{z}$. Note that there exists a probability distribution $p''\in\mathcal{D}(G)^+$ that is faithful to G (Meek, 1995) and, thus, $\mathbf{X}\not\perp\mathbf{Y}|\mathbf{ZW}$ is in p'' because $sep(\mathbf{X},\mathbf{Y}|\mathbf{ZW})$ does not hold in G. Then, there is some instantiation $\mathbf{x}''\mathbf{y}''\mathbf{z}''\mathbf{w}''$ of $\mathbf{XYZW}$ such that

$$p''(\mathbf{X}=\mathbf{x}'',\mathbf{Y}=\mathbf{y}'',\mathbf{Z}=\mathbf{z}'',\mathbf{W}=\mathbf{w}'')p''(\mathbf{Z}=\mathbf{z}'',\mathbf{W}=\mathbf{w}'')-$$

$$p''(\mathbf{X}=\mathbf{x}'',\mathbf{Z}=\mathbf{z}'',\mathbf{W}=\mathbf{w}'')p''(\mathbf{Y}=\mathbf{y}'',\mathbf{Z}=\mathbf{z}'',\mathbf{W}=\mathbf{w}'')\neq 0.$$

Then, by permuting the states of the random variables in $\mathbf{X}$, $\mathbf{Y}$, $\mathbf{Z}$ and $\mathbf{W}$, we can transform p'' into the desired p'. Let $\mathbf{V}\equiv\mathbf{XYZW}$, $\mathbf{v}\equiv\mathbf{xyzw}$, and $\mathbf{v}''\equiv\mathbf{x}''\mathbf{y}''\mathbf{z}''\mathbf{w}''$. One can introduce a permutation π_X on the set of possible states of X for each $X\in\mathbf{U}$: For $X\in\mathbf{V}$, it is the transposition of the states of X in $\mathbf{v}$ and $\mathbf{v}''$, and the identical mapping for $X\in\mathbf{U}\setminus\mathbf{V}$. These random variable permutations together define a permutation π of the joint sample space of $\mathbf{U}$. Then, p'' can be transformed by π to $p'\equiv p''\circ\pi$. Note that $p'\in\mathcal{D}(G)^+$ because $p''\in\mathcal{D}(G)^+$, and that the parameter values of p' are obtained from the parameter values of p'' by local permutations. Finally, note that $p'(\mathbf{V}=\mathbf{v})=p''(\mathbf{V}=\mathbf{v}'')$ and, thus, the polynomial in Equation (1) for $\mathbf{x}$, $\mathbf{y}$ and $\mathbf{z}$ does not hold for p'.

Let $sol(\mathbf{x},\mathbf{y},\mathbf{z},\mathbf{w})$ denote the set of solutions to the polynomial in Equation (1) for $\mathbf{x}$, $\mathbf{y}$ and $\mathbf{z}$. Then, $sol(\mathbf{x},\mathbf{y},\mathbf{z},\mathbf{w})$ has zero Lebesgue measure wrt $\mathbb{R}^n$ because it consists of the solutions to a non-trivial polynomial in real variables (Okamoto, 1973). Let $sol=\bigcup_{\mathbf{X},\mathbf{Y},\mathbf{Z},\mathbf{W}}\bigcup_{\mathbf{w}}\bigcap_{\mathbf{x},\mathbf{y},\mathbf{z}}sol(\mathbf{x},\mathbf{y},\mathbf{z},\mathbf{w})$ and recall from above that the outer-most union only involves those cases for which $sep(\mathbf{X},\mathbf{Y}|\mathbf{ZW})$ does not hold in G. Then, sol has zero Lebesgue measure wrt $\mathbb{R}^n$, because the finite union and intersection of sets of zero Lebesgue measure has zero Lebesgue measure too. Consequently, the probability distributions in $\mathcal{D}(G)^+$ that have context-specific dependencies correspond to a set of elements of the parameter space for $\mathcal{D}(G)^+$ that has zero Lebesgue measure wrt $\mathbb{R}^n$ because it is contained in sol. Since, as proven above, this correspondence is one-to-one, the probability distributions in $\mathcal{D}(G)^+$ that have context-specific dependencies also have zero Lebesgue measure wrt $\mathbb{R}^n$.

To finish the proof of the second statement, it suffices to note that (i) the probability distributions in $\mathcal{D}(G)^+$ that are not faithful to G have zero Lebesgue measure wrt $\mathbb{R}^n$, because they are a subset of the probability distributions that factorize according to G but are not faithful to G, and these have zero Lebesgue measure wrt $\mathbb{R}^n$ (Meek, 1995), (ii) the probability distributions in $\mathcal{D}(G)^+$ that have context-specific dependencies have zero Lebesgue measure wrt $\mathbb{R}^n$ as proven above, and (iii) the union of the probability distributions in (i) and (ii) has zero Lebesgue measure wrt $\mathbb{R}^n$, because the finite union of sets of zero Lebesgue measure has zero Lebesgue measure too. ■

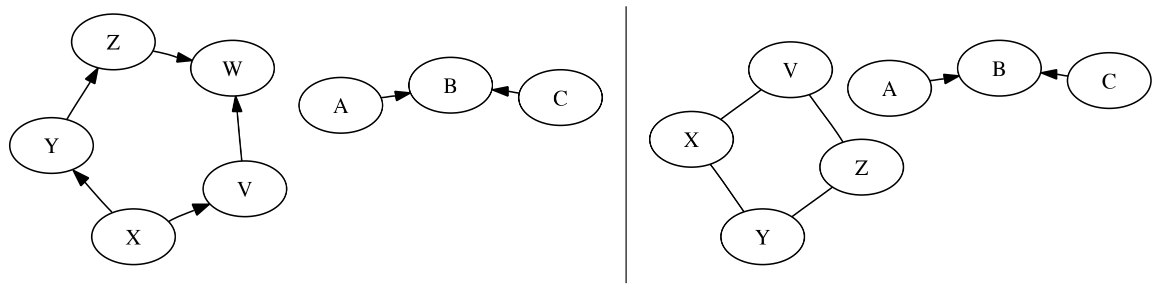

Figure 1: Chain graphs in Example 1.

The theorem below proves that the marginals and conditionals of a strictly positive discrete probability distribution that is a WT graphoid and has no context-specific dependencies are WT graphoids too.

Theorem 2 *Let p be a strictly positive discrete probability distribution that is a WT graphoid. Then, $p(\mathbf{U} \setminus \mathbf{W})$ for any $\mathbf{W} \subseteq \mathbf{U}$ is a WT graphoid. If p has no context-specific dependencies, then $p(\mathbf{U} \setminus \mathbf{W}|\mathbf{W} = \mathbf{w})$ for any $\mathbf{w}$ and $\mathbf{W} \subseteq \mathbf{U}$ is a WT graphoid.*

Proof Let $\mathbf{X}$, $\mathbf{Y}$ and $\mathbf{Z}$ denote three mutually disjoint subsets of $\mathbf{U} \setminus \mathbf{W}$. Then, $\mathbf{X} \perp\!\!\!\perp \mathbf{Y}|\mathbf{Z}$ is in $p(\mathbf{U} \setminus \mathbf{W})$ iff $\mathbf{X} \perp\!\!\!\perp \mathbf{Y}|\mathbf{Z}$ is in p and, thus, $p(\mathbf{U} \setminus \mathbf{W})$ satisfies the WT graphoid properties because p satisfies them. Now, note that $p(\mathbf{U} \setminus \mathbf{W}|\mathbf{W} = \mathbf{w})$ is uniquely defined because p is strictly positive. Furthermore, if p has no context-specific dependencies, then $\mathbf{X} \perp\!\!\!\perp \mathbf{Y}|\mathbf{Z}$ is in $p(\mathbf{U} \setminus \mathbf{W}|\mathbf{W} = \mathbf{w})$ iff $\mathbf{X} \perp\!\!\!\perp \mathbf{Y}|\mathbf{Z}\mathbf{W}$ is in p. Then, $p(\mathbf{U} \setminus \mathbf{W}|\mathbf{W} = \mathbf{w})$ satisfies the WT graphoid properties because p satisfies them. ■

In a nutshell, Theorem 1 proves that for any DAG G, in the measure-theoretic sense explained above, almost all the probability distributions in $\mathcal{D}(G)^+$ are faithful to G and, thus, are WT graphoids (Pearl, 1988). On the other hand, the combination of Theorems 1 and 2 proves that, in the measure-theoretic sense explained above, all the marginals and conditionals of almost all the probability distributions in $\mathcal{D}(G)^+$ are WT graphoids. Finally, we give an example that shows that not all the probability distributions that are WT graphoids are either regular Gaussian or faithful to some UG or DAG.

Example 1 *Let p be a strictly positive discrete probability distribution that is faithful to the DAG in the left-hand side of Figure 1 and that has no context-specific dependencies. Such a probability distribution exists due to Theorem 1 and, moreover, it is a WT graphoid (Pearl, 1988). Then, $p(X,Y,Z,V,A,B,C|W = w)$ for any w, which is uniquely defined because p is strictly positive, is a WT graphoid by Theorem 2. However, this conditional probability distribution is neither regular Gaussian nor faithful to any UG or DAG, because it is discrete and faithful to the chain graph in the right-hand side of Figure 1 (Chickering and Meek, 2002; Peña et al., 2006).*

4. Reading Independencies

By definition, *sep* is sound for reading independencies from the MUI map G of a WT graphoid M, that is, it only identifies independencies in M. In the regular Gaussian case, *sep* in G is also complete in the sense that it identifies all the independencies in M that are shared by all the WT graphoids for which G is the MUI map, because (i) it is proven in Lněnička and Matúš (2007) that there exist regular Gaussian probability distributions that are faithful to G, and (ii) such probability distributions are WT graphoids (Studený, 2005), G is their MUI map, and they only have the independencies that *sep* identifies from G. In this section, we extend this result to the case where $\mathbf{U}$ is discrete. Specifically, we prove that there exist strictly positive discrete probability distributions that are faithful to G for any sample spaces (with at least two possible states) of the random variables in $\mathbf{U}$. Again, such probability distributions are WT graphoids (Pearl, 1988), G is their MUI map, and they only have the independencies that *sep* identifies from G. Therefore, when $\mathbf{U}$ is discrete *sep* in G is also complete in the sense that it identifies all the independencies in M that are shared by all the WT graphoids for which G is the MUI map. These completeness results, in addition to being important in themselves, are crucial for reading as many dependencies as possible from G, as we will see in the next section.

Theorem 3 *Let G be an UG. Let us assume that the sample space of each random variable in* $\mathbf{U}$ *is prescribed and has at least two possible states. Then, there exists a strictly positive discrete probability distribution with the prescribed sample spaces for the random variables in* $\mathbf{U}$ *that is faithful to G.*

Proof Create an extended DAG H of G as follows. For each edge $X - Y$ in G, create an auxiliary discrete random variable W_{XY}. Let $\mathbf{W}$ denote all the auxiliary random variables created. Let H be a DAG over $\mathbf{UW}$ with no edges. For each edge $X - Y$ in G add $X \rightarrow W_{XY} \leftarrow Y$ to H. No more edges are added to H. It is easy to see that for any three mutually disjoint subsets $\mathbf{X}$, $\mathbf{Y}$ and $\mathbf{Z}$ of $\mathbf{U}$, $sep(\mathbf{X},\mathbf{Y}|\mathbf{ZW})$ in H iff $sep(\mathbf{X},\mathbf{Y}|\mathbf{Z})$ in G.

Let $p(\mathbf{U},\mathbf{W})$ denote any strictly positive discrete probability distribution in $\mathcal{D}(H)^+$ that is faithful to H and has no context-specific dependencies. Such a probability distribution exists by Theorem 1. Now, fix any $\mathbf{w}$ and note that $p(\mathbf{U}|\mathbf{W}=\mathbf{w})$ is uniquely defined because $p(\mathbf{U},\mathbf{W})$ is strictly positive. Let $\mathbf{X}$, $\mathbf{Y}$ and $\mathbf{Z}$ denote three mutually disjoint subsets of $\mathbf{U}$. Then, $\mathbf{X}\perp\!\!\!\perp\mathbf{Y}|\mathbf{Z}$ is in $p(\mathbf{U}|\mathbf{W}=\mathbf{w})$ iff $\mathbf{X}\perp\!\!\!\perp\mathbf{Y}|\mathbf{ZW}$ is in $p(\mathbf{U},\mathbf{W})$ iff $sep(\mathbf{X},\mathbf{Y}|\mathbf{ZW})$ in H iff $sep(\mathbf{X},\mathbf{Y}|\mathbf{Z})$ in G. Then, $p(\mathbf{U}|\mathbf{W}=\mathbf{w})$ is faithful to G. Obviously, $p(\mathbf{U}|\mathbf{W}=\mathbf{w})$ is strictly positive and discrete. ■

Note that the theorem above proves that there exists a strictly positive discrete probability distribution that is faithful to G for any sample spaces (with at least two possible states) of the random variables in $\mathbf{U}$. This result is therefore stronger than Theorem 11 in Geiger and Pearl (1993), which proves that there exists a strictly positive discrete probability distribution that is faithful to G for some sample spaces (with at least two possible states) of the random variables in $\mathbf{U}$.

The theorem above proves that, when $\mathbf{U}$ is discrete, *sep* in the MUI map G of a WT graphoid M is complete for any sample spaces of the random variables in $\mathbf{U}$, where complete means that it is able to identify all the independencies in M that are shared by all the WT graphoids for which G is the MUI map. However, *sep* in G is not complete if this is understood as being able to identify all the independencies in M. Actually, no sound criterion for reading independencies from G is complete in the latter sense. An example follows.

Example 2 *Let p be a discrete probability distribution that is faithful to the DAG $\{X \rightarrow Z, Y \rightarrow Z\}$. Such a probability distribution exists (Meek, 1995). Let G denote the MUI map of p, namely the* *complete UG. Note that p is not faithful to G. However, by Theorem 3, there exists a discrete probability distribution p' that is faithful to G. As proven in Pearl (1988), p and p' are WT graphoids. Let us assume that we are dealing with p. Then, no sound criterion can conclude $X \perp\!\!\!\perp Y|\emptyset$ by just studying G because this independence does not hold in p', and it is impossible to know whether we are dealing with p or p' on the sole basis of G.*

5. Reading Dependencies

In this section, we propose a sound and complete criterion for reading dependencies from the MUI map G of a WT graphoid. Here, complete means that it is able to read all the dependencies that can be derived by applying the WT graphoid properties to the dependencies used in the construction of G and the independencies obtained from G by *sep*.

We define the dependence base of an independence model M, denoted $bas(M)$, as the set of dependencies $X \not\perp\!\!\!\perp Y|\mathbf{U} \setminus (XY)$ with $X, Y \in \mathbf{U}$. Recall from Section 2 that X and Y are adjacent in the MUI map of M iff $X \not\perp\!\!\!\perp Y|\mathbf{U} \setminus (XY)$. If M is a WT graphoid, then additional dependencies in M can be derived from $bas(M)$ via the WT graphoid properties. For this purpose, we rephrase the WT graphoid properties as follows. Let $\mathbf{X}$, $\mathbf{Y}$, $\mathbf{Z}$ and $\mathbf{W}$ denote four mutually disjoint subsets of $\mathbf{U}$. Symmetry $\mathbf{Y} \not\perp\!\!\!\perp \mathbf{X}|\mathbf{Z} \Rightarrow \mathbf{X} \not\perp\!\!\!\perp \mathbf{Y}|\mathbf{Z}$. Decomposition $\mathbf{X} \not\perp\!\!\!\perp \mathbf{Y}|\mathbf{Z} \Rightarrow \mathbf{X} \not\perp\!\!\!\perp \mathbf{YW}|\mathbf{Z}$. Weak union $\mathbf{X} \not\perp\!\!\!\perp \mathbf{Y}|\mathbf{ZW} \Rightarrow \mathbf{X} \not\perp\!\!\!\perp \mathbf{YW}|\mathbf{Z}$. Contraction $\mathbf{X} \not\perp\!\!\!\perp \mathbf{YW}|\mathbf{Z} \Rightarrow \mathbf{X} \not\perp\!\!\!\perp \mathbf{Y}|\mathbf{ZW} \vee \mathbf{X} \not\perp\!\!\!\perp \mathbf{W}|\mathbf{Z}$ is problematic for deriving new dependencies because it contains a disjunction in the right-hand side and, thus, it should be split into two properties: Contraction1 $\mathbf{X} \not\perp\!\!\!\perp \mathbf{YW}|\mathbf{Z} \wedge \mathbf{X} \perp\!\!\!\perp \mathbf{Y}|\mathbf{ZW} \Rightarrow \mathbf{X} \not\perp\!\!\!\perp \mathbf{W}|\mathbf{Z}$, and contraction2 $\mathbf{X} \not\perp\!\!\!\perp \mathbf{YW}|\mathbf{Z} \wedge \mathbf{X} \perp\!\!\!\perp \mathbf{W}|\mathbf{Z} \Rightarrow \mathbf{X} \not\perp\!\!\!\perp \mathbf{Y}|\mathbf{ZW}$. Likewise, intersection $\mathbf{X} \not\perp\!\!\!\perp \mathbf{YW}|\mathbf{Z} \Rightarrow \mathbf{X} \not\perp\!\!\!\perp \mathbf{Y}|\mathbf{ZW} \vee \mathbf{X} \not\perp\!\!\!\perp \mathbf{W}|\mathbf{ZY}$ gives rise to intersection1 $\mathbf{X} \not\perp\!\!\!\perp \mathbf{YW}|\mathbf{Z} \wedge \mathbf{X} \perp\!\!\!\perp \mathbf{Y}|\mathbf{ZW} \Rightarrow \mathbf{X} \not\perp\!\!\!\perp \mathbf{W}|\mathbf{ZY}$, and intersection2 $\mathbf{X} \not\perp\!\!\!\perp \mathbf{YW}|\mathbf{Z} \wedge \mathbf{X} \perp\!\!\!\perp \mathbf{W}|\mathbf{ZY} \Rightarrow \mathbf{X} \not\perp\!\!\!\perp \mathbf{Y}|\mathbf{ZW}$. Note that intersection1 and intersection2 are equivalent and, thus, we refer to them simply as intersection. Finally, weak transitivity $\mathbf{X} \not\perp\!\!\!\perp V|\mathbf{Z} \wedge V \not\perp\!\!\!\perp \mathbf{Y}|\mathbf{Z} \Rightarrow \mathbf{X} \not\perp\!\!\!\perp \mathbf{Y}|\mathbf{Z} \vee \mathbf{X} \not\perp\!\!\!\perp \mathbf{Y}|\mathbf{Z}V$ with $V \in \mathbf{U} \setminus (\mathbf{XYZ})$ gives rise to weak transitivity1 $\mathbf{X} \not\perp\!\!\!\perp V|\mathbf{Z} \wedge V \not\perp\!\!\!\perp \mathbf{Y}|\mathbf{Z} \wedge \mathbf{X} \perp\!\!\!\perp \mathbf{Y}|\mathbf{Z} \Rightarrow \mathbf{X} \not\perp\!\!\!\perp \mathbf{Y}|\mathbf{Z}V$, and weak transitivity2 $\mathbf{X} \not\perp\!\!\!\perp V|\mathbf{Z} \wedge V \not\perp\!\!\!\perp \mathbf{Y}|\mathbf{Z} \wedge \mathbf{X} \perp\!\!\!\perp \mathbf{Y}|\mathbf{Z}V \Rightarrow \mathbf{X} \not\perp\!\!\!\perp \mathbf{Y}|\mathbf{Z}$. The independence in the left-hand side of any of the properties above holds if the corresponding *sep* statement holds in the MUI map G of M. This is the best solution we can hope for because, as discussed in Section 4, *sep* in G is sound and complete in the sense that it identifies all and only the independencies in M that are shared by all the WT graphoids for which G is the MUI map. Moreover, this solution does not require more information about M than what it is available, because G can be constructed from $bas(M)$. We denote by $sep(G)$ all the *sep* statements holding in the MUI map G. We define the WT graphoid closure of $bas(M)$ wrt $sep(G)$, denoted $WT_{bas(M)}^{sep(G)}$, as the set of dependencies in $bas(M)$ plus those that can be derived from it and $sep(G)$ by applying the WT graphoid properties. We now introduce our criterion for reading dependencies from the MUI map of a WT graphoid.

Definition 4 *Let $\mathbf{X}$, $\mathbf{Y}$ and $\mathbf{Z}$ denote three mutually disjoint subsets of $\mathbf{U}$. Let $con(\mathbf{X}, \mathbf{Y}|\mathbf{Z})$ denote that $\mathbf{X}$ is connected to $\mathbf{Y}$ given $\mathbf{Z}$ in an UG G. Specifically, $con(\mathbf{X}, \mathbf{Y}|\mathbf{Z})$ holds when there exist some $X_1 \in \mathbf{X}$ and $X_n \in \mathbf{Y}$ such that there exists **exactly one** path in G between X_1 and X_n that is not blocked by $(\mathbf{X} \setminus X_1)(\mathbf{Y} \setminus X_n)\mathbf{Z}$.*

As an illustrative example of *con*, consider the UG in Figure 2. Some *con* statements holding in that graph are $con(A, B|CD)$, $con(AC, BD|\emptyset)$, $con(A, BCD|\emptyset)$ and $con(A, BD|\emptyset)$ because in each of these statement there exists a single path between A and B or D that is not blocked by the rest of

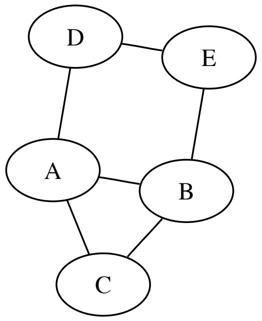

Figure 2: UG to illustrate the definition of *con*: $con(A,B|CD)$, $con(AC,BD|\emptyset)$, $con(A,BCD|\emptyset)$ and $con(A,BD|\emptyset)$ hold in the graph, whereas $con(A,B|\emptyset)$ and $con(A,B|D)$ do not hold.

the nodes in the statement. On the other hand, some *con* statements that do not hold in the graph under consideration are $con(A,B|\emptyset)$ and $con(A,B|D)$, because in both cases there exist several paths between A and B that are not blocked by the rest of the nodes in the statement. Note that the place the nodes take in the statement matters: For instance, $con(A,BD|\emptyset)$ holds but $con(A,B|D)$ does not.

We now prove that *con* is sound for reading dependencies from the MUI map G of a WT graphoid M, that is, it only identifies dependencies in M. Actually, it only identifies dependencies in $WT_{bas(M)}^{sep(G)}$. Hereinafter, we abbreviate a path $X_1,\dots,X_n$ in an UG as $X_{1:n}$.

Theorem 5 *Let M be a WT graphoid and G its MUI map. Then, con in G only identifies dependencies in $WT_{bas(M)}^{sep(G)}$.*

Proof We first prove that if $X_{1:n}$ is the only path in G between X_1 and X_n that is not blocked by $\mathbf{Y} \subseteq \mathbf{U} \setminus X_{1:n}$, then $X_1 \not\perp X_n|\mathbf{Y}$ is in $WT_{bas(M)}^{sep(G)}$. In other words, we prove that $X_1 \not\perp X_n|\mathbf{Y}$ can be derived from $bas(M)$ and $sep(G)$ using the WT graphoid properties. We prove it by induction over n. We first prove it for $n = 2$. Let $\mathbf{W}$ denote all the nodes in $\mathbf{U} \setminus X_{1:2} \setminus \mathbf{Y}$ that are not separated from X_1 given $X_2\mathbf{Y}$ in G. Since X_1 and X_2 are adjacent in G, $X_1 \not\perp X_2|\mathbf{U} \setminus X_{1:2}$ and, thus, $X_1\mathbf{W} \not\perp X_2(\mathbf{U} \setminus X_{1:2} \setminus \mathbf{Y} \setminus \mathbf{W})|\mathbf{Y}$ due to weak union and symmetry. This together with $sep(X_1\mathbf{W}, \mathbf{U} \setminus X_{1:2} \setminus \mathbf{Y} \setminus \mathbf{W}|X_2\mathbf{Y})$, which follows from the definition of $\mathbf{W}$, implies $X_1\mathbf{W} \not\perp X_2|\mathbf{Y}$ due to contraction1. Note that if $\mathbf{U} \setminus X_{1:2} \setminus \mathbf{Y} \setminus \mathbf{W} = \emptyset$, then $X_1\mathbf{W} \not\perp X_2(\mathbf{U} \setminus X_{1:2} \setminus \mathbf{Y} \setminus \mathbf{W})|\mathbf{Y}$ directly implies $X_1\mathbf{W} \not\perp X_2|\mathbf{Y}$. In any case, this dependence together with $sep(\mathbf{W}, X_2|X_1\mathbf{Y})$, because otherwise there exist several unblocked paths in G between X_1 and X_2 which contradicts the definition of $\mathbf{Y}$, implies $X_1 \not\perp X_2|\mathbf{Y}$ due to contraction1 and symmetry. Note that if $\mathbf{W} = \emptyset$, then $X_1\mathbf{W} \not\perp X_2|\mathbf{Y}$ directly implies $X_1 \not\perp X_2|\mathbf{Y}$.

Let us assume as induction hypothesis that the statement that we are proving holds for all $n < m$. We now prove it for $n = m$. Since the paths $X_{1:2}$ and $X_{2:m}$ contain less than m nodes and $\mathbf{Y}$ blocks all the other paths in G between X_1 and X_2 and between X_2 and X_m, because otherwise there exist several unblocked paths in G between X_1 and X_m which contradicts the definition of $\mathbf{Y}$, then $X_1 \not\perp X_2|\mathbf{Y}$ and $X_2 \not\perp X_m|\mathbf{Y}$ due to the induction hypothesis. This together with $sep(X_1, X_m|\mathbf{Y}X_2)$, which follows from the definition of $X_{1:m}$ and $\mathbf{Y}$, implies $X_1 \not\perp X_m|\mathbf{Y}$ due to weak transitivity2.

Let $\mathbf{X}$, $\mathbf{Y}$ and $\mathbf{Z}$ denote three mutually disjoint subsets of $\mathbf{U}$. If $con(\mathbf{X}, \mathbf{Y}|\mathbf{Z})$ holds in G, then there exist some $X_1 \in \mathbf{X}$ and $X_n \in \mathbf{Y}$ such that $X_1 \not\perp X_n|(\mathbf{X} \setminus X_1)(\mathbf{Y} \setminus X_n)\mathbf{Z}$ is in $WT_{bas(M)}^{sep(G)}$ due to the paragraph above and, thus, $\mathbf{X} \not\perp \mathbf{Y}|\mathbf{Z}$ is also in $WT_{bas(M)}^{sep(G)}$ due to weak union and symmetry. ■

We now prove that *con* is complete for reading dependencies from the MUI map G of a WT graphoid M, in the sense that it identifies all the dependencies in M that follow from the information about M that is available, namely the dependencies in $bas(M)$, the independencies in $sep(G)$, and the fact that M is a WT graphoid.

Theorem 6 *Let M be a WT graphoid and G its MUI map. Then, con in G identifies all the dependencies in $WT_{bas(M)}^{sep(G)}$.*

Proof It suffices to prove (i) that all the dependencies in $bas(M)$ are identified by *con* in G, and (ii) that *con* satisfies the WT graphoid properties. Since the first point is trivial, we only prove the second point. Let $\mathbf{X}, \mathbf{Y}, \mathbf{Z}$ and $\mathbf{W}$ denote four mutually disjoint subsets of $\mathbf{U}$.

- Symmetry $con(\mathbf{Y}, \mathbf{X}|\mathbf{Z}) \Rightarrow con(\mathbf{X}, \mathbf{Y}|\mathbf{Z})$. Trivial.

- Decomposition $con(\mathbf{X}, \mathbf{Y}|\mathbf{Z}) \Rightarrow con(\mathbf{X}, \mathbf{YW}|\mathbf{Z})$. Trivial if $\mathbf{W}$ contains no node in the path $X_{1:n}$ in $con(\mathbf{X}, \mathbf{Y}|\mathbf{Z})$. If $\mathbf{W}$ contains some node in $X_{1:n}$, then let X_m denote the closest node to X_1 that is in $X_{1:n}$ and $\mathbf{W}$. Then, the path $X_{1:m}$ ensures $con(\mathbf{X}, \mathbf{YW}|\mathbf{Z})$ because $(\mathbf{X} \setminus X_1)(\mathbf{YW} \setminus X_m)\mathbf{Z}$ blocks all the other paths in G between X_1 and X_m, since $(\mathbf{X} \setminus X_1)(\mathbf{Y} \setminus X_n)\mathbf{Z}$ blocks all the paths in G between X_1 and X_m except $X_{1:m}$ because otherwise there exist several unblocked paths in G between X_1 and X_n, which contradicts $con(\mathbf{X}, \mathbf{Y}|\mathbf{Z})$.

- Weak union $con(\mathbf{X}, \mathbf{Y}|\mathbf{ZW}) \Rightarrow con(\mathbf{X}, \mathbf{YW}|\mathbf{Z})$. Trivial because $\mathbf{W}$ contains no node in the path $X_{1:n}$ in $con(\mathbf{X}, \mathbf{Y}|\mathbf{ZW})$.

- Contraction1 $con(\mathbf{X}, \mathbf{YW}|\mathbf{Z}) \wedge sep(\mathbf{X}, \mathbf{Y}|\mathbf{ZW}) \Rightarrow con(\mathbf{X}, \mathbf{W}|\mathbf{Z})$. Since $\mathbf{ZW}$ blocks all the paths in G between $\mathbf{X}$ and $\mathbf{Y}$, then the path $X_{1:n}$ in $con(\mathbf{X}, \mathbf{YW}|\mathbf{Z})$ must be between $\mathbf{X}$ and $\mathbf{W}$. To prove that $X_{1:n}$ ensures $con(\mathbf{X}, \mathbf{W}|\mathbf{Z})$, we have to prove that this is the only path in G between X_1 and X_n that is not blocked by $(\mathbf{X} \setminus X_1)(\mathbf{W} \setminus X_n)\mathbf{Z}$. Assume to the contrary that there is a second such path in G. This second path cannot contain any node in $\mathbf{Y}$ for $sep(\mathbf{X}, \mathbf{Y}|\mathbf{ZW})$ to hold. Then, this second path is not blocked by $(\mathbf{X} \setminus X_1)\mathbf{Y}(\mathbf{W} \setminus X_n)\mathbf{Z}$ either. However, this contradicts $con(\mathbf{X}, \mathbf{YW}|\mathbf{Z})$, because we have found two paths in G between X_1 and X_n that are not blocked by $(\mathbf{X} \setminus X_1)\mathbf{Y}(\mathbf{W} \setminus X_n)\mathbf{Z}$.

- Contraction2 $con(\mathbf{X}, \mathbf{YW}|\mathbf{Z}) \wedge sep(\mathbf{X}, \mathbf{W}|\mathbf{Z}) \Rightarrow con(\mathbf{X}, \mathbf{Y}|\mathbf{ZW})$. Since $\mathbf{Z}$ blocks all the paths in G between $\mathbf{X}$ and $\mathbf{W}$, the path $X_{1:n}$ in $con(\mathbf{X}, \mathbf{YW}|\mathbf{Z})$ must be between $\mathbf{X}$ and $\mathbf{Y}$ and, thus, it ensures $con(\mathbf{X}, \mathbf{Y}|\mathbf{ZW})$.

- Intersection $con(\mathbf{X}, \mathbf{YW}|\mathbf{Z}) \wedge sep(\mathbf{X}, \mathbf{Y}|\mathbf{ZW}) \Rightarrow con(\mathbf{X}, \mathbf{W}|\mathbf{ZY})$. Since $\mathbf{ZW}$ blocks all the paths in G between $\mathbf{X}$ and $\mathbf{Y}$, the path $X_{1:n}$ in $con(\mathbf{X}, \mathbf{YW}|\mathbf{Z})$ must be between $\mathbf{X}$ and $\mathbf{W}$ and, thus, it ensures $con(\mathbf{X}, \mathbf{W}|\mathbf{ZY})$.

- Weak transitivity2 $con(\mathbf{X}, X_m|\mathbf{Z}) \wedge con(X_m, \mathbf{Y}|\mathbf{Z}) \wedge sep(\mathbf{X}, \mathbf{Y}|\mathbf{Z}X_m) \Rightarrow con(\mathbf{X}, \mathbf{Y}|\mathbf{Z})$ with $X_m \in \mathbf{U} \setminus (\mathbf{XYZ})$. Let $X_{1:m}$ and $X_{m:n}$ denote the paths in $con(\mathbf{X}, X_m|\mathbf{Z})$ and $con(X_m, \mathbf{Y}|\mathbf{Z})$, respectively. For $con(\mathbf{X}, X_m|\mathbf{Z})$ to hold, $X_{1:m}$ cannot contain any node in $(\mathbf{X} \setminus X_1)\mathbf{Z}$. For $con(X_m, \mathbf{Y}|\mathbf{Z})$ to hold, $X_{m:n}$ cannot contain any node in $(\mathbf{Y} \setminus X_n)\mathbf{Z}$. For $sep(\mathbf{X}, \mathbf{Y}|\mathbf{Z}X_m)$ to hold, neither $X_{1:m}$

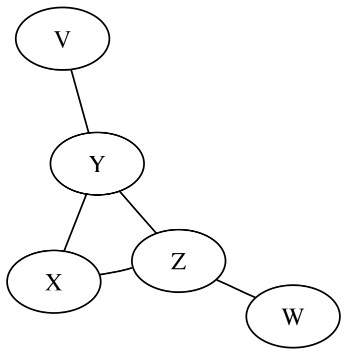

Figure 3: UG in Example 4.

can contain a node in $\mathbf{Y}$, nor $X_{m:n}$ can contain a node in $\mathbf{X}$. Consequently, neither $X_{1:m}$ nor $X_{m:n}$ is blocked by $(\mathbf{X} \setminus X_1)(\mathbf{Y} \setminus X_n)\mathbf{Z}$.

Furthermore, $X_{1:m}$ and $X_{m:n}$ only intersect on X_m. To see this, assume the contrary. Let X_l ($X_l \neq X_m$) denote the closest node to X_1 that is in $X_{1:m}$ and $X_{m:n}$. Then, it follows from the paragraph above that neither $X_{1:l}$ and $X_{l:n}$ contain a node in $\mathbf{Z}X_m$. However, this contradicts $sep(\mathbf{X}, \mathbf{Y}|\mathbf{Z}X_m)$. Consequently, $X_{1:m}$ followed by $X_{m:n}$ is a path in G between X_1 and X_n that, as shown above, is not blocked by $(\mathbf{X} \setminus X_1)(\mathbf{Y} \setminus X_n)\mathbf{Z}$. It remains to prove that this path is unique. Assume to the contrary that there exists a second such path in G. For $sep(\mathbf{X}, \mathbf{Y}|\mathbf{Z}X_m)$ to hold, this second path must pass through X_m. However, this implies that either there exists a second path in G between X_1 and X_m that is not blocked by $(\mathbf{X} \setminus X_1)\mathbf{Z}$, or there exists a second path in G between X_m and X_n that is not blocked by $(\mathbf{Y} \setminus X_n)\mathbf{Z}$. This contradicts $con(\mathbf{X}, X_m|\mathbf{Z})$ or $con(X_m, \mathbf{Y}|\mathbf{Z})$.

- Weak transitivity1 $con(\mathbf{X}, X_m|\mathbf{Z}) \wedge con(X_m, \mathbf{Y}|\mathbf{Z}) \wedge sep(\mathbf{X}, \mathbf{Y}|\mathbf{Z}) \Rightarrow con(\mathbf{X}, \mathbf{Y}|\mathbf{Z}X_m)$ with $X_m \in \mathbf{U} \setminus (\mathbf{XYZ})$. Trivial because the antecedent involves a contradiction: It follows from the proof of weak transitivity2 that $con(\mathbf{X}, X_m|\mathbf{Z})$ and $con(X_m, \mathbf{Y}|\mathbf{Z})$ imply the existence of a path in G between some $X_1 \in \mathbf{X}$ and $X_n \in \mathbf{Y}$ that is not blocked by $(\mathbf{X} \setminus X_1)(\mathbf{Y} \setminus X_n)\mathbf{Z}$, which contradicts $sep(\mathbf{X}, \mathbf{Y}|\mathbf{Z})$.

■

We devote the rest of this section to some remarks on the two theorems above. Note that *con* in G is not complete if this is understood as being able to identify all the dependencies in M. Actually, no sound criterion for reading dependencies from G alone is complete in this sense. Example 2 illustrates this point. Let us now assume that we are dealing with p' instead of with p. Then, no sound criterion can conclude $X \not\perp\!\!\!\perp Y|\emptyset$ by just studying G because this dependence does not hold in p, and it is impossible to know whether we are dealing with p or p' on the sole basis of G.

It seems natural to expect that assuming further independence properties will result in more dependencies being readable from the MUI map of an independence model and, thus, in the necessity of developing a new graphical criterion that identifies them. However, this is not always the case as the following example shows. First, let us define a weak transitivity and composition (WTC) graphoid as a WT graphoid that satisfies composition.

Example 3 *The graphical criterion con is still sound and complete for reading dependencies from the MUI map G of a WTC graphoid M. Here, complete means that it is able to read all the dependencies in M that can be derived from bas(M) and sep(G) by applying the WTC graphoid properties. The reason is that every dependence that follows from composition also follows from contraction1. In other words, when rephrased to derive dependencies, composition looks like* $\mathbf{X}\not\perp\!\!\!\perp\mathbf{YW}|\mathbf{Z} \wedge \mathbf{X}\perp\!\!\!\perp\mathbf{Y}|\mathbf{Z} \Rightarrow \mathbf{X}\not\perp\!\!\!\perp\mathbf{W}|\mathbf{Z}$*. As before, the independence in the left-hand side holds if the corresponding sep statement holds in G. However, if* $sep(\mathbf{X},\mathbf{Y}|\mathbf{Z})$ *then* $sep(\mathbf{X},\mathbf{Y}|\mathbf{ZW})$*. Thus, when composition applies so does contraction1, and both imply the same consequent. Any probability distribution that is regular Gaussian or faithful to some UG or DAG is a WTC graphoid (Pearl, 1988; Studený, 2005). Moreover, similarly to Theorem 2, the marginals and conditionals of a strictly positive discrete probability distribution that is a WTC graphoid and has no context-specific dependencies are WTC graphoids (Chickering and Meek, 2002; Peña et al., 2006).*

A sensible question to ask is whether the definition of complete in Theorem 6 coincides with the definition of complete as able to identify all the dependencies shared by all the WT graphoids for which G is the MUI map. Currently, we do not have an answer to this question, though we incline to think that the definition in the theorem above is weaker than the alternative one. For instance, if we limit ourselves to WTC graphoids, then *con* in G may not identify every dependency shared by all the WTC graphoids for which G is the MUI map, as the following example illustrates.

Example 4 *Consider any regular Gaussian probability distribution whose MUI map is the UG in Figure 3. Such probability distributions exist (Lněnička and Matúš, 2007). Recall that any regular Gaussian probability distribution is a WTC graphoid. Then,* $X\not\perp\!\!\!\perp Y|\emptyset$ *or* $X\not\perp\!\!\!\perp Z|\emptyset$ *because otherwise* $X\perp\!\!\!\perp YZ|\emptyset$ *by composition, which is a contradiction as* $con(X,YZ|\emptyset)$ *holds in G and thus* $X\not\perp\!\!\!\perp YZ|\emptyset$ *by Theorem 5.*

Assume $X\not\perp\!\!\!\perp Y|\emptyset$*. Furthermore,* $con(Y,V|\emptyset)$ *holds in G and thus* $Y\not\perp\!\!\!\perp V|\emptyset$ *by Theorem 5. Furthermore,* $sep(X,V|Y)$ *holds in G and thus* $X\perp\!\!\!\perp V|Y$*. Consequently,* $X\not\perp\!\!\!\perp V|\emptyset$ *by weak transitivity2. Likewise,* $X\not\perp\!\!\!\perp W|\emptyset$ *when assuming* $X\not\perp\!\!\!\perp Z|\emptyset$*. Then,* $X\not\perp\!\!\!\perp V|\emptyset$ *or* $X\not\perp\!\!\!\perp W|\emptyset$ *and, thus,* $X\not\perp\!\!\!\perp VW|\emptyset$ *by decomposition. However,* $con(X,VW|\emptyset)$ *does not hold in G.*

At the beginning of this section, we have defined *bas*(M) as the set of dependencies $X\not\perp\!\!\!\perp Y|\mathbf{U}\setminus(XY)$ with $X,Y\in\mathbf{U}$. However, Theorems 5 and 6 remain valid if we redefine *bas*(M) as the set of dependencies $X\not\perp\!\!\!\perp Y|MB(X)\setminus Y$ with $X\in\mathbf{U}$ and $Y\in MB(X)$. A proof follows. Moreover, recall from Section 2 that X and Y are adjacent in the MUI map of M iff $Y\in MB(X)$.

Proof It suffices to prove that, when *bas*(M) consists of the dependencies in the first definition, $WT^{sep(G)}_{bas(M)}$ includes the dependencies in the second definition, and vice versa. If $X\not\perp\!\!\!\perp Y|\mathbf{U}\setminus(XY)$, then $X\not\perp\!\!\!\perp Y(\mathbf{U}\setminus(XY)\setminus(MB(X)\setminus Y))|MB(X)\setminus Y$ due to weak union. This together with $sep(X,\mathbf{U}\setminus(XY)\setminus(MB(X)\setminus Y)|Y(MB(X)\setminus Y))$ implies $X\not\perp\!\!\!\perp Y|MB(X)\setminus Y$ due to contraction1. On the other hand, if $X\not\perp\!\!\!\perp Y|MB(X)\setminus Y$, then $X\not\perp\!\!\!\perp Y(\mathbf{U}\setminus(XY)\setminus(MB(X)\setminus Y))|MB(X)\setminus Y$ due to decomposition. This together with $sep(X,\mathbf{U}\setminus(XY)\setminus(MB(X)\setminus Y)|Y(MB(X)\setminus Y))$ implies $X\not\perp\!\!\!\perp Y|\mathbf{U}\setminus(XY)$ due to intersection. ■

It is proven in Becker et al. (2000) that if M is a WT graphoid whose MUI map is a forest G, then M is faithful to G. The soundness of *con* allows us to give an alternative proof of this result.

Proof Assume to the contrary that M is not faithful to G. Since G is the MUI map of M, the previous assumption is equivalent to assume that there exists three mutually disjoint subsets of $\mathbf{U}$, say $\mathbf{X}$,

```
FirstPath(X, Y, Z, L)

1   CreatePointers(L)
2   for each node W in L do
3     if $W \in \mathbf{Z}$ then
4       $C[W] = 0$
5     else
6       $C[W] = 1$
7   $P = \emptyset$
8   Push(X, P)
9   $C[X] = 0$
10  while $P \neq \emptyset$ and $Top(P) \neq Y$ do
11    $W = NextAdj(Top(P), L)$
12    if $W = \emptyset$ then
13      Pop(P)
14    else
15      if $C[W] = 1$ then
16        Push(W, P)
17        $C[W] = 0$
18  return P
```

Table 1: $FirstPath(X,Y,\mathbf{Z},L)$.

$\mathbf{Y}$ and $\mathbf{Z}$, such that $\mathbf{X} \perp\!\!\!\perp \mathbf{Y}|\mathbf{Z}$ is in M but $sep(\mathbf{X},\mathbf{Y}|\mathbf{Z})$ does not hold in G. However, if $sep(\mathbf{X},\mathbf{Y}|\mathbf{Z})$ does not hold in G, then there must exist a path in G between some $X_1 \in \mathbf{X}$ and $X_n \in \mathbf{Y}$ that is not blocked by $(\mathbf{X}\setminus X_1)(\mathbf{Y}\setminus X_n)\mathbf{Z}$. Furthermore, since G is a forest, that must be the only path in G between X_1 and X_n that is not blocked by $(\mathbf{X}\setminus X_1)(\mathbf{Y}\setminus X_n)\mathbf{Z}$. Consequently, $con(\mathbf{X},\mathbf{Y}|\mathbf{Z})$ holds in G and, thus, $\mathbf{X} \not\perp\!\!\!\perp \mathbf{Y}|\mathbf{Z}$ is in M due to Theorem 5. This is a contradiction and, thus, M is faithful to G. ■

Finally, we note that the following graphical criterion, denoted *bou* here, for reading dependencies from the MUI map G of a graphoid M is introduced in Bouckaert (1995): Let $\mathbf{X}$, $\mathbf{Y}$ and $\mathbf{Z}$ denote three mutually disjoint subsets of $\mathbf{U}$, then $bou(\mathbf{X},\mathbf{Y}|\mathbf{Z})$ holds when there exist some $X_1 \in \mathbf{X}$ and $X_n \in \mathbf{Y}$ such that $X_1 \in MB(X_n)$ and either $MB(X_1)\setminus X_n \subseteq (\mathbf{X}\setminus X_1)(\mathbf{Y}\setminus X_n)\mathbf{Z}$ or $MB(X_n)\setminus X_1 \subseteq (\mathbf{X}\setminus X_1)(\mathbf{Y}\setminus X_n)\mathbf{Z}$. The criterion is proven to be sound and complete, where complete means that it is able to identify all the dependencies in M that can be derived from $bas(M)$ and $sep(G)$ by applying the graphoid properties. It is clear that *con* identifies a superset of the dependencies identified by *bou* when M satisfies weak transitivity. In such a case, then, *con* represents an advantage over *bou*. As discussed in Section 3, there are important families of probability distributions that are graphoids and satisfy weak transitivity.

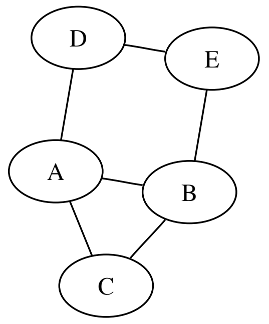
6. An Algorithm for Reading (In)Dependencies

In this section, we present an algorithm that jointly implements *sep* and *con*. We first describe in Table 1 the algorithm $FirstPath(X,Y,\mathbf{Z},L)$ which returns a path in an UG G between X and Y that is not blocked by $\mathbf{Z}$, if such a path exists. We assume that G is represented as a set of adjacency lists L, that is, each node in G has an associated ordered list containing the nodes that are adjacent to it in G. In the algorithm, the function $CreatePointers(L)$ creates a pointer for each adjacency list in L. Each pointer points to the first element of the corresponding list. If the list is empty, the pointer is NULL. The function $NextAdj(W,L)$ returns the element that is pointed by the pointer created by $CreatePointers(L)$ for the adjacency list associated to the node W and, then, moves the pointer to the next element in the list. If there is no next element, the pointer takes value NULL. $NextAdj(W,L)$ returns $\emptyset$ if the pointer is NULL. In the algorithm, P is a stack storing the path currently being explored. The function $Top(P)$ returns the element on the top of P. The function $Pop(P)$ removes the element on the top of P from P. The function $Push(W,P)$ adds the node W to the top of P. Finally, C is an array containing a binary entry for each node in G indicating whether the node should (1) or should not (0) be considered to extend P. The algorithm sets $C[W]$ to 0 iff W is in $\mathbf{Z}$ or W was considered before and the algorithm already found a path from X to W that is not blocked by $\mathbf{Z}$ (see lines 4 and 17). A node considered before should not be considered again because either it is still in P or if it is not in P then it does not lead to Y. To see the latter point, note that the algorithm works in a depth-first fashion: It extends P with a node W that is adjacent to the top element of P if W is not in the blocking set $\mathbf{Z}$ and has not been considered before (see lines 11, 15 and 16). When P cannot be extended further, the algorithm backtracks by removing the top element of P from P and exploring an alternative extension (see lines 12 and 13). The algorithm ends when P is empty, meaning that all the paths in G starting with X were explored and none of them reached Y without visiting $\mathbf{Z}$, or when the top element of P is Y, meaning that a path in G between X and Y that is not blocked by $\mathbf{Z}$ was found and stored in P.

$FirstPath(X,Y,\mathbf{Z},L)$ is considered to run in at most $O(e+n)$ time where e and n are the number of edges and nodes in G, respectively. To see it, note that thanks to the use of C each node is pushed into P at most once. For each node V pushed into P, the algorithm performs as many iterations of lines 10-17 as adjacent nodes V has plus one last iteration when $W=\emptyset$. These iterations need not be consecutive. So, the number of iterations of lines 10-17 that the algorithm performs is bounded from above by $2e+n$. Additionally, the algorithm performs n iterations of lines 2-6 to initialize C. As described in the paragraph above, $CreatePointers(L)$ is considered to run in $O(n)$ time whereas any other operation or function in the algorithm is considered to run in $O(1)$ time. Consequently, $FirstPath(X,Y,\mathbf{Z},L)$ is considered to require at most $O(e+n)$ time.

Recall from above that we assume that G is represented as a set of adjacency lists L and that each of these lists is ordered. Let us now reverse the order of the elements in each of these lists and let L' denote the resulting set of adjacency lists. Our premise is that producing L' from L takes $O(e)$ time. Obviously, L' is also an adjacency list representation of G. However, $FirstPath(X,Y,\mathbf{Z},L)$ and $FirstPath(X,Y,\mathbf{Z},L')$ return the same path iff that is the only path in G between X and Y that is not blocked by $\mathbf{Z}$. We formally prove this assertion below, but first we give an example. Let G, L and L' be as shown in Table 2. Then, $FirstPath(A,B,\emptyset,L)$ returns the path A,B whereas $FirstPath(A,B,\emptyset,L')$ returns the path A,D,E,B.

Proof First, we introduce a total order for the paths between X and Y in G that are not blocked by $\mathbf{Z}$. For this purpose, we associate to each such path a sequence of length $n-1$ of natural numbers



Adjacency lists L

Node	Adjacency list
A	B, C, D
B	A, C, E
C	A, B
D	A, E
E	B, D

Adjacency lists L'

Node	Adjacency list
A	D, C, B
B	E, C, A
C	B, A
D	E, A
E	D, B

Table 2: Example where $FirstPath(A,B,\emptyset,L)$ and $FirstPath(A,B,\emptyset,L')$ return different paths.

between 0 and $n-1$, where n is the number of nodes in G. For a path $X = X_1,\ldots,X_k = Y$, the sequence is $[o_1,\ldots,o_{k-1},0,\ldots,0]$, where o_i is the position of X_{i+1} in the adjacency list associated to X_i. We order the sequences lexicographically, which results in the desired order.

We now prove that if there exists a path between X and Y in G that is not blocked by $\mathbf{Z}$, then $FirstPath(X,Y,\mathbf{Z},L)$ returns the first such a path in the order described above. Let $X = X_1,\ldots,X_k = Y$ denote the first such a path. It suffices to prove that at some point P contains (from the bottom to the top) the nodes $X_1,\ldots,X_j$ for any $1 \leq j \leq k$. We prove the result by induction over j.

The result is immediate for $j = 1$. Assume as induction hypothesis that the result holds for all $i < j$. We now prove the result for j. By the induction hypothesis, at some point t, P contains (from the bottom to the top) the nodes $X_1,\ldots X_{j-1}$. Pushing into P a node that is adjacent to X_{j-1} and appears before X_j in the adjacency list associated to X_{j-1} cannot lead to a path between X_1 and X_k, because that would contradict the assumption that $X = X_1,\ldots,X_k = Y$ is the first path between X and Y in G that is not blocked by $\mathbf{Z}$. Therefore, the algorithm will eventually pop from P every element pushed after time t and, then, X_j will be pushed into P.

Finally, note that if we reverse the order of the nodes in each adjacency list in L, then we also reverse the order of the paths described above. Consequently, $X = X_1,\ldots,X_k = Y$ is the last path in the order considered by $FirstPath(X,Y,\mathbf{Z},L')$. Thus, $FirstPath(X,Y,\mathbf{Z},L')$ does not return $X = X_1,\ldots,X_k = Y$ unless that is the only path between X and Y in G that is not blocked by $\mathbf{Z}$. ■

The algorithm that jointly implements sep and con is as follows. If $FirstPath(X,Y,(\mathbf{X}\setminus X)(\mathbf{Y}\setminus X)\mathbf{Z},L)$ and $FirstPath(X,Y,(\mathbf{X}\setminus X)(\mathbf{Y}\setminus X)\mathbf{Z},L')$ return the same path for some $X \in \mathbf{X}$ and $Y \in \mathbf{Y}$, then $con(\mathbf{X},\mathbf{Y}|\mathbf{Z})$. On the other hand, if $FirstPath(X,Y,(\mathbf{X}\setminus X)(\mathbf{Y}\setminus X)\mathbf{Z})$ returns no path for all $X \in \mathbf{X}$ and $Y \in \mathbf{Y}$, then $sep(\mathbf{X},\mathbf{Y}|\mathbf{Z})$. Finally, if neither of the two previous conditions is met, then neither $con(\mathbf{X},\mathbf{Y}|\mathbf{Z})$ nor $sep(\mathbf{X},\mathbf{Y}|\mathbf{Z})$. The algorithm is considered to require at most $O(n^2(e+n))$ time.

7. An Application to Bioinformatics

Our end-goal is to apply the results in this paper to our project on atherosclerosis gene expression data analysis in order to learn dependencies between genes. We believe that it is not unrealistic to assume that the probability distribution underlying our data satisfies strict positivity and weak transitivity and, thus, that it is a WT graphoid. We base this belief on the following argument. The cell is the functional unit of all the organisms and includes all the information necessary to regulate its function. This information is encoded in the DNA of the cell, which is divided into a set of genes, each coding for one or more proteins. Proteins are required for practically all the functions in the cell. The amount of protein produced depends on the expression level of the coding gene which, in turn, depends on the amount of proteins produced by other genes. Therefore, a dynamic BN seems to be a relatively accurate model of the cell: The nodes represent the genes and proteins, and the edges and parameters represent the causal relations between the gene expression levels and the protein amounts. As a matter of fact, dynamic BNs have become very popular models of gene networks for the last few years (Bernard and Hartemink, 2005; Friedman et al., 1998; Husmeier, 2003; Kim et al., 2003; Murphy and Mian, 1999; Ong et al., 2002; Perrin et al., 2003; Zou and Conzen, 2005). It is important that the BN is dynamic because a gene can regulate some of its regulators and even itself with some time delay. Since the technology for measuring the state of the protein nodes is not widely available yet, the data in most projects on gene expression data analysis is a finite sample of the probability distribution represented by the dynamic BN after marginalizing the protein nodes out. The probability distribution with no node marginalized out is, in the measure-theoretic sense discussed in Section 3, almost surely faithful to the dynamic BN (Meek, 1995) and, thus, it satisfies weak transitivity (Pearl, 1988) and, thus, so does the probability distribution after marginalizing the protein nodes out (see Theorem 2). The assumption that the probability distribution sampled is strictly positive is justified because measuring the state of the gene nodes involves a series of complex wet-lab and computer-assisted steps that introduces noise in the measurements (Sebastiani et al., 2003). Obviously, the reasoning above can be extended to include any other molecules that, in addition to proteins, regulate gene expression but are not measured.

In the rest of this section we focus on Gaussian graphical models (GGMs) of gene networks, which have received increasing attention from the bioinformatics community as a means to gain insight into gene networks (Castelo and Roverato, 2006; Dobra et al., 2004; Kishino and Waddell, 2000; Li and Gui, 2006; Schäfer and Strimmer, 2005a,b; Toh and Horimoto, 2002; Waddell and Kishino, 2000; Wang et al., 2003; Wu et al., 2003). Assume that each random variable in $\mathbf{U}$ represents (the expression level of) a gene in the network under study. Assume also that $\mathbf{U}$ follows a regular Gaussian probability distribution $\mathcal{N}(\mu, \Sigma)$. This is a ubiquitous assumption in bioinformatics. The GGM of the gene network is nothing else but the MUI map of $\mathcal{N}(\mu, \Sigma)$ (Lauritzen, 1996; Whittaker, 1990). Therefore, two genes X and Y are adjacent in the GGM iff $X \not\perp\!\!\!\perp Y | \mathbf{U} \setminus (XY)$ or, equivalently, iff $(\Sigma^{-1})_{XY} \neq 0$ (Lauritzen, 1996). In practice, Σ is unknown and the only information about it that is available is a finite sample from $\mathcal{N}(\mu, \Sigma)$. The usual way of proceeding in practice consists of two steps: First, estimating Σ from the sample and, then, making two genes adjacent in the GGM iff the corresponding entry in the inverse of the estimate of Σ significantly differs from zero. We refer the interested reader to the works cited above for different solutions to these two steps. Recall that regular Gaussian probability distributions are WT graphoids and, thus, that the results obtained in the previous sections of this paper apply to GGMs of gene networks.

The GGM of a gene network is a powerful tool for discovering gene independencies, because *sep* is sound and complete (in the sense discussed in Section 4) for reading independencies from it. However, bioinformaticians are typically more interested in discovering gene dependencies, because these provide contexts in which the expression level of some genes is informative about that of some other genes which, in some cases, can lead to hypothesize dependencies, functional

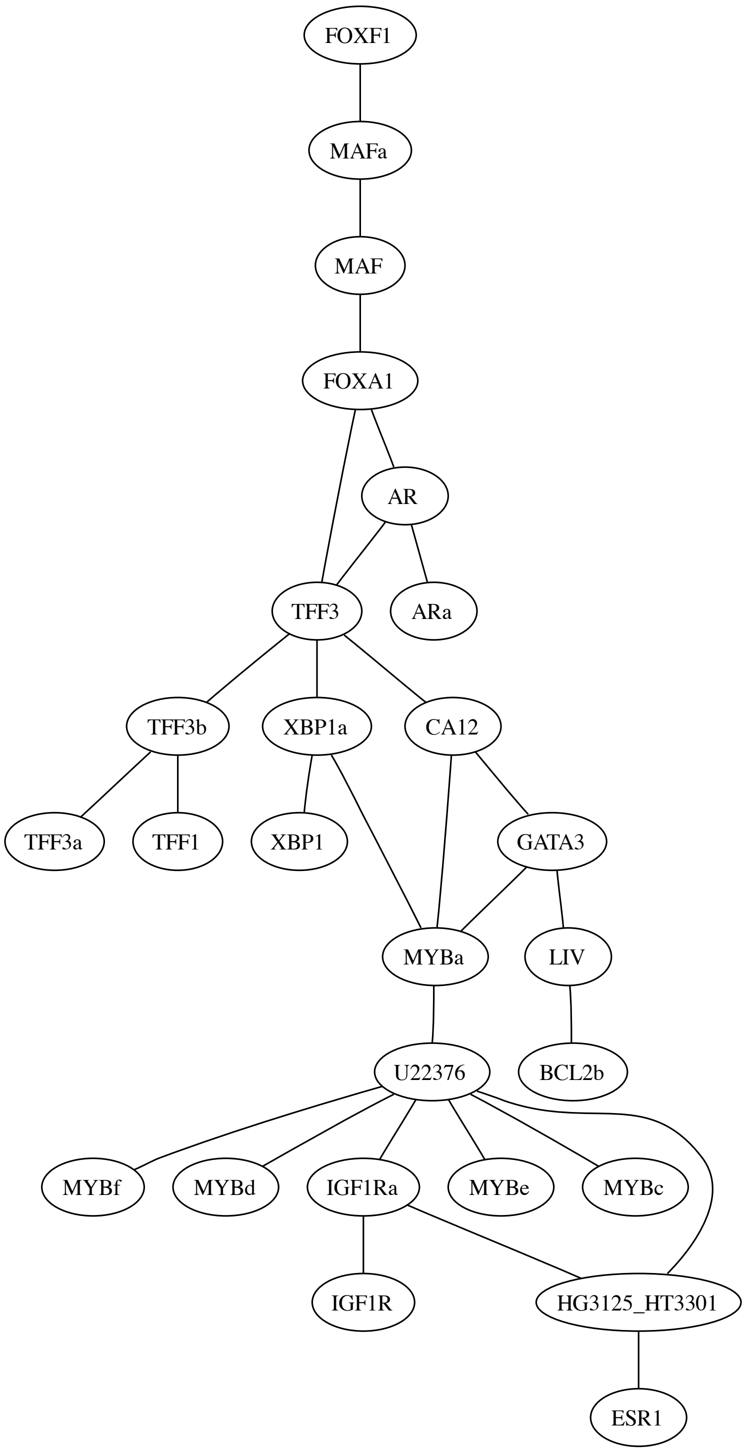


Figure 4: Estrogen receptor pathway.

relations, causal relations, the effects of manipulation experiments, etc. Thanks to *con*, which is sound and complete (in the sense discussed in Section 5) for reading dependencies from the GGM of a gene network, such a model is now a powerful tool for discovering gene dependencies too. We illustrate this with a real world example. In Dobra et al. (2004), a GGM over 12558 nodes is learnt from 158 breast cancer samples. Unfortunately, the GGM is neither reported in the paper nor available from the authors. However, the authors do report in the paper the subgraph of the GGM that is induced by some genes that are known to be related to the estrogen receptor (ER) and TFF1 genes. ER is a transcription factor that plays a key role in breast cancer, and TFF1 is a target of ER. This subgraph, depicted in Figure 4, suffices for our illustrative purposes. Note that the graph in the figure is not necessarily the GGM over the nodes in the graph. It is also worth mentioning that the nodes in the subgraph do not correspond to genes but to probe sets. A probe set is a collection of probes designed to measure the abundance of a particular DNA sequence. Since this sequence is for technical reasons usually shorter than that of a gene, a gene may have several probe sets associated with it, each measuring the abundance of a different subsequence of the gene. This aims at measuring gene expression more accurately. The following genes have multiple probe sets (nodes) in Figure 4: ER (ESR1, HG3125-HT3301), MYB (U22376, MYBa, MYBc, MYBd, MYBe, MYBf), AR (AR, ARa), c-MAF (MAF, MAFa), TFF3 (TFF3, TFF3a, TFF3b), XBP (XBP1, XBP1a), and IGF1R (IGF1R, IGF1Ra). According to Dobra et al. (2004), it is known that ER regulates TFF1, FOXA1 regulates TFF1, GATA3 possibly regulates TFF1, AR regulates ER, MAF inhibits MYB, FOXF1 possibly interacts with ER, and AR regulates IGF1R. Had these relations been unknown, we could have obtained principled clues about them by just applying *con* to the subgraph in Figure 4. For instance, if $\mathbf{U}$ denotes all the 12558 probe sets in the GGM, then *con* enables us to conclude that the following gene dependencies hold in the underlying probability distribution: ER is conditionally dependent on TFF1 since $con(\text{HG3125-HT3301}, \text{TFF1}|\mathbf{U} \setminus \{\text{HG3125-HT3301}, \text{U22376}, \text{MYBa}, \text{XBP1a}, \text{TFF3}, \text{TFF3b}, \text{TFF1}\})$, FOXA1 is conditionally dependent on TFF1 since $con(\text{FOXA1}, \text{TFF1}|\mathbf{U} \setminus \{\text{FOXA1}, \text{TFF3}, \text{TFF3b}, \text{TFF1}\})$, GATA3 is conditionally dependent on TFF1 since $con(\text{GATA3}, \text{TFF1}|\mathbf{U} \setminus \{\text{GATA3}, \text{CA12}, \text{TFF3}, \text{TFF3b}, \text{TFF1}\})$, AR is conditionally dependent on ER since $con(\text{AR}, \text{HG3125-HT3301}|\mathbf{U} \setminus \{\text{AR}, \text{TFF3}, \text{CA12}, \text{MYBa}, \text{U22376}, \text{HG3125-HT3301}\})$, MAF is conditionally dependent on MYB since $con(\text{MAF}, \text{MYBa}|\mathbf{U} \setminus \{\text{MAF}, \text{FOXA1}, \text{TFF3}, \text{CA12}, \text{MYBa}\})$, FOXF1 is conditionally dependent on ER since $con(\text{FOXF1}, \text{HG3125-HT3301}|\mathbf{U} \setminus \{\text{FOXF1}, \text{MAFa}, \text{MAF}, \text{FOXA1}, \text{TFF3}, \text{CA12}, \text{MYBa}, \text{U22376}, \text{HG3125-HT3301}\})$, and AR is conditionally dependent on IGF1R since $con(\text{AR}, \text{IGF1Ra}|\mathbf{U} \setminus \{\text{AR}, \text{TFF3}, \text{CA12}, \text{MYBa}, \text{U22376}, \text{IGF1Ra}\})$. Furthermore, *con* also enables us to conclude that $X \not\perp\!\!\!\perp Y|\mathbf{U} \setminus \{X, \text{U22376}, Y\}$ with $X, Y \in \{\text{MYBa}, \text{MYBc}, \text{MYBd}, \text{MYBe}, \text{MYBf}\}$ and $X \neq Y$, and that $\text{TFF3} \not\perp\!\!\!\perp \text{TFF3a} \,|\mathbf{U} \setminus \{\text{TFF3}, \text{TFF3b}, \text{TFF3a}\}$. These dependencies make sense as they are between different probe sets of the same gene. Note that none of the dependencies discussed above was used in the construction of the GGM. Note also that each of the dependencies discussed above involves a conditioning set of maximum size. It is very likely that these dependencies also hold for smaller conditioning sets, but we cannot confirm this point without seeing the complete GGM the subgraph in Figure 4 is part of which, as discussed above, is not available. In any case, it is clear that *con* improves the current interpretation of GGMs of gene networks by allowing reading biologically meaningful gene dependencies.

8. Discussion

The MUI map G of an independence model M is typically used to identify independencies that hold in M via vertex separation. However, lack of vertex separation in G does not necessarily imply dependency in M. In this paper, we have studied when lack of vertex separation does imply dependency. This should be relevant for those interested in graphical models, as it allows to infer from MUI maps (i.e., without numerical calculation) not only independencies but also dependencies. Specifically, in this paper we have introduced a graphical criterion called *con* for reading dependencies from G when M is a WT graphoid, that is, a graphoid that satisfies weak transitivity. Specifically, $con(\mathbf{X},\mathbf{Y}|\mathbf{Z})$ holds when there exist some $X_1 \in \mathbf{X}$ and $X_n \in \mathbf{Y}$ such that there exists exactly one path in G between X_1 and X_n that is not blocked by $(\mathbf{X} \setminus X_1)(\mathbf{Y} \setminus X_n)\mathbf{Z}$. We have proven that the criterion is sound and complete, where complete means that it is able to read all the dependencies in M that can be derived by applying the WT graphoid properties to the dependencies used in the construction of G and the independencies obtained from G by vertex separation. Note that our criterion remains inconclusive if there are several unblocked paths between any node in $\mathbf{X}$ and any node in $\mathbf{Y}$, though $\mathbf{X}$ and $\mathbf{Y}$ may be dependent given $\mathbf{Z}$ in M. However, we have shown in Section 5 that neither our criterion nor any other sound criterion can identify all the dependencies in M.

Note that our criterion is antimonotone in the following sense: If some edges are added to G then some *con* statements may not longer hold, whereas if some edges are removed from G then some new *con* statements may hold. This antimonotone property should be taken into account if one is to remove "weak" edges from G to make it sparser, because this may result in false dependencies being identified. However, this has nothing to do with the correctness of our criterion, something that we have proved, but with the fact that after removing "weak" edges G is an approximation to the true MUI map. One may consider to extend our work with a measure of confidence in the dependencies identified by our criterion. Such a measure could be a function of the confidence in the dependencies used in the construction of G. We have not pursued this idea further.

A work that is closely related to ours is Bouckaert (1995), which introduces the following graphical criterion, denoted *bou* here, for reading dependencies from the MUI map G of a graphoid M: $bou(\mathbf{X},\mathbf{Y}|\mathbf{Z})$ holds when there exist some $X_1 \in \mathbf{X}$ and $X_n \in \mathbf{Y}$ such that $X_1 \in MB(X_n)$ and either $MB(X_1) \setminus X_n \subseteq (\mathbf{X} \setminus X_1)(\mathbf{Y} \setminus X_n)\mathbf{Z}$ or $MB(X_n) \setminus X_1 \subseteq (\mathbf{X} \setminus X_1)(\mathbf{Y} \setminus X_n)\mathbf{Z}$. In other words, $bou(\mathbf{X},\mathbf{Y}|\mathbf{Z})$ holds when there exist two nodes, one in $\mathbf{X}$ and the other in $\mathbf{Y}$, that are neighbors in G and, moreover, the rest of the neighbors of one of them are among the rest of the nodes in the statement. The criterion is proven to be sound and complete, where complete means that it is able to identify all the dependencies in M that can be derived by applying the graphoid properties to the dependencies used in the construction of G and the independencies obtained from G by vertex separation.

Although *bou* is tailored to the case where M is a graphoid, it can obviously be applied when M is a WT graphoid. However, there are two main differences between *bou* and our criterion that make the latter more powerful when M is a WT graphoid. First, our criterion does not require that X_1 is adjacent to X_n in G, that is, there can be a path of length greater than one between X_1 and X_n. Second, our criterion does not require than all the nodes adjacent to either X_1 or X_n in G are among $\mathbf{XYZ}$, that is, all the paths between X_1 and X_n but one can be blocked by nodes that are neither adjacent to X_1 nor X_n. Consequently, our criterion represents an advantage over *bou* when M is a WT graphoid, as it allows us to identify a superset of the dependencies identified by *bou*. Interestingly, WT graphoids are a rich subclass of graphoids, including any regular Gaussian distribution, any probability distribution that is faithful to some UG or DAG, and all the marginals and conditionals of almost all the strictly positive discrete probability distributions that factorize according to a DAG. We believe that these probability distributions are encountered in many applications and, thus, that the work presented in this paper is of interest to the machine learning community. For instance, regular Gaussian distributions are ubiquitous. Likewise, it is rather usual to assume that the probability distribution underlying the domain at hand is strictly positive and faithful to some DAG, though one may be forced to work with a marginal of it because only a subset of the nodes in the DAG are observable. The strict positivity assumptions is usually justified by measurement errors, whereas the DAG faithfulness assumption is usually justified by the fact that many domains have a causality structure. For a more concrete case example, recall our discussion on bioinformatics applications in Section 7.

A problem that remains open is whether our criterion is complete in the sense that it identifies all the dependencies shared by all the WT graphoids for which G is the MUI map. This is a problem that we are currently studying though, as we have argued in Section 5, we incline to think that our criterion only identifies a proper subset of those dependencies. To the best of our knowledge, there has not been any attempt to solve this problem. As a matter of fact, one can think of an analogous problem for *bou* and the graphoids for which G is the MUI map. However, such a problem is not even mentioned in Bouckaert (1995).

Another problem we are currently working on is the development of a graphical criterion for reading dependencies from the minimal directed independence maps of WT graphoids. As a first step, we have derived such a criterion for the case where the minimal directed independence maps are polytrees (Peña, 2007).

Finally, it is worth recalling that, as an intermediate step in the derivation of our criterion, we have proved that for any UG G there exists a strictly positive discrete probability distribution that is faithful to G for any sample spaces (with at least two possible states) of the random variables in $\mathbf{U}$. For any DAG, an analogous result follows from Meek (1995). Both results are subsumed by our recent work in Peña (2009), which proves an analogous result for chain graphs. Note that such a result is stronger than Theorem 7.2 in Studený and Bouckaert (1998), which proves the result for some sample spaces (with at least two possible states) of the random variables in $\mathbf{U}$ but not for any such sample spaces.

Abstract

We propose a novel framework for supervised learning of discrete concepts. Since the 1970's, the standard computational primitive has been to find the most consistent hypothesis in a given complexity class. In contrast, in this paper we propose a new basic operation: for each pair of input instances, count how many concepts of bounded complexity contain both of them.

Our approach maps instances to a Hilbert space, whose metric is induced by a universal kernel coinciding with our computational primitive, and identifies concepts with half-spaces. We prove that all concepts are linearly separable under this mapping. Hence, given a labeled sample and an oracle for evaluating the universal kernel, we can efficiently compute a linear classifier (via SVM, for example) and use margin bounds to control its generalization error. Even though exact evaluation of the universal kernel may be infeasible, in various natural situations it is efficiently approximable.

Though our approach is general, our main application is to regular languages. Our approach presents a substantial departure from current learning paradigms and in particular yields a novel method for learning this fundamental concept class. Unlike existing techniques, we make no structural assumptions on the corresponding unknown automata, the string distribution or the completeness of the training set. Instead, given a labeled sample our algorithm outputs a classifier with guaranteed distribution-free generalization bounds; to our knowledge, the proposed framework is the only one capable of achieving the latter. Along the way, we touch upon several fundamental questions in complexity, automata, and machine learning.

Keywords: grammar induction, regular language, finite state automaton, maximum margin hyperplane, kernel approximation

1. Introduction

We begin by describing the basic problem setting and outlining our approach.

1.1 Background

Perhaps the most fundamental problem in learning from labeled data is to construct a classifier with guaranteed small generalization error. Typically, given labeled data there exists a nested sequence of candidate concept classes with increasing complexity. Of course, a classifier from a rich concept class can easily achieve a low or even zero training error, but is likely to overfit the data and have a poor generalization performance. Hence, a major challenge is to choose the hypothesis class with appropriate complexity. This issue also arises in classical statistics, where it is known as the *model selection* problem (Rissanen, 1989). In Vapnik (1982), the structural risk minimization (SRM) principle was proposed to solve this problem, by quantifying the bias-variance tradeoff between fit to the data and model complexity, as captured by the VC-dimension.

The basic computational primitive in the SRM framework is finding the most consistent hypothesis in a given concept class. Although SRM resolves the information theoretic problem of model selection, it offers no method for finding such a hypothesis. Moreover, for discrete concept classes, finding this hypothesis may be infeasible, as this computational primitive typically requires solving a hard combinatorial optimization problem.

An important instance of this scenario is the problem of learning a regular language from labeled examples. Supervised language learning from examples is one of the most fundamental problems in learning theory, and as such has fascinated philosophers, linguists, computer scientists and mathematicians as a quintessential problem of induction. Insofar as the PAC model (Valiant, 1984) is a natural formalization of learning and the regular languages are the simplest nontrivial class of formal languages, the vast amount of literature devoted to learning regular languages is well justified (see Rivest and Schapire 1987 and de la Higuera 2005 and the references therein).

Applying the standard SRM principle to learning a regular language requires finding the smallest automaton consistent with the given labeled sample. However, it was realized early on that this task is computationally very difficult. Finding the smallest automaton consistent with a set of accepted and rejected strings was shown to be NP-complete by Angluin (1978) and Gold (1978); this was further strengthened in the hardness of approximation result of Pitt and Warmuth (1993), where it was proven that even finding a DFA with a number of states polynomial in the number of states of the minimum solution is NP-complete.

To make matters worse, it turns out that under cryptographic assumptions the class of regular languages is inherently hard to learn, regardless of representation. Thus, assuming the average-case difficulty of the Discrete Cube Root problem, Theorem 7.6 of Kearns and Vazirani (1997) shows how to construct small automata over $\{0,1\}$ and distributions over $\{0,1\}^n$ for which it is intractable to discover a hypothesis with error less than $1/2 - 1/p(n)$, for any fixed polynomial p. A similar construction shows that this task is also at least as hard as factoring.

Nevertheless, a number of positive learnability results were obtained under various restricted settings. Trakhtenbrot and Barzdin (1973) showed that the smallest finite automaton consistent with the input data can be learned exactly from a complete sample of all strings up to a given length. The worst case complexity of their algorithm is exponential in automaton size, but a better average-case complexity can be obtained assuming that the topology and the labeling are selected randomly or even that the topology is selected adversarially (Freund et al., 1993). In a different model of learnability—"identification in the limit" (Gold, 1967)—positive results were obtained for the k-reversible languages (Angluin, 1982) and subsequential transducers (Oncina et al., 1993). Some restricted classes of probabilistic automata such as acyclic probabilistic automata were also shown to be efficiently learnable by Ron et al. (1998). In a modified model of PAC, and with additional language complexity constraints, Clark and Thollard (2004) showed a class of probabilistic finite state automata to be learnable; see also literature review therein.

In light of the strong negative results mentioned above, the prevailing paradigm in formal language learning has been to make structural regularity assumptions about the family of languages and/or the sampling distribution in question and to employ a state-merging heuristic. Indeed, over the years a number of clever and sophisticated combinatorial approaches have been proposed for learning DFAs. Typically, an initial automaton or prefix tree consistent with the sample is first created. Then, starting with the trivial partition with one state per equivalence class, classes are merged while preserving an invariant congruence property. The automaton learned is obtained by merging states according to the resulting classes. Thus, the choice of the congruence determines the algorithm and generalization bounds are obtained from the structural regularity assumptions. This rough summary broadly characterizes the techniques of Angluin (1982); Oncina and Garcia (1992); Ron et al. (1998); Clark and Thollard (2004) and until recently, this appears to have been the only general-purpose technique available for learning finite automata.

Finally, despite the fact that the problems of inducing a regular language, and specifically finding the smallest automaton consistent with a given sample were proven to be theoretically computationally hard, in recent years various heuristic search methods have been developed with reported considerable success in solving these problems for moderately sized DFAs, see for example Lang (1992), and Oliveira and Silva (2001) and Bugalho and Oliveira (2005). Of course, these heuristic methods find some automaton consistent with the given sample, but provide no generalization bounds on its expected performance on new samples.

1.2 Learning Languages Via Hyperplanes

In this paper we propose a novel framework for learning a regular language from a finite sample of positive and negative labeled strings. Rather than attempting to find a *single* small consistent automaton, we embed the strings in a Hilbert space and compute a maximum margin hyperplane, which becomes our classifier for new strings. Hence, we effectively convert a difficult combinatorial problem into a (high dimensional) geometric one, amenable to efficient techniques using linear algebra and convex optimization. In particular, our resulting classifier is a linear combination of potentially smaller automata, each of which is typically not consistent with the training data.

Since the advent of Support Vector Machines (SVMs), maximum margin classifiers have flourished in the machine learning community (Schölkopf and Smola, 2002). Within the context of grammatical inference, the first work to apply this methodology was Kontorovich et al. (2006), where a kernel was used to learn a specific family of regular languages (the piecewise-testable ones). The authors embed the set of all strings onto a high-dimensional space and achieve language induction by constructing a maximum-margin hyperplane. This hinges on every language in a family of interest being *linearly separable* under the embedding, and on the efficient computability of the kernel. This line of research is continued in Cortes et al. (2007), where linear separability properties of rational kernels are investigated.

In this paper, we build upon the approach suggested in Kontorovich (2007), where a *universal* kernel is given that renders *all* regular languages linearly separable. We prove that any linearly separable language necessarily has a positive margin, so standard margin-based generalization guarantees apply. A by-product of this result is a novel characterization of the regular languages as precisely those that are linearly separable under our kernel. A drawback of this kernel is that a brute-force computation is infeasible, while an efficient one is currently unknown (and conjectured not to exist unless P= #P). However, we propose a simple randomized scheme for efficiently obtaining an ε-approximation to our universal kernel. We show that the approximate kernel preserves the distances with low distortion, and therefore may be used as a surrogate for the original one. Random sampling of embedding features to evaluate otherwise intractable kernels seems to first have been employed in Kontorovich (2007); Rahimi and Recht (2007) used a similar idea in a somewhat different setting. Also related are the approaches of Garg et al. (2002) and Balcan et al. (2006), where classifiers and their generalization performance are computed based on low-dimensional random projections. Note the marked difference between our method and theirs: we take a random subset of the embedding features as opposed to projecting the embedding space onto a random subspace; in fact, the setting we consider does not seem to allow the use of random projections. Also, note that in general, projecting the sample onto a low-dimensional subspace does not guarantee linear separability; a somewhat delicate margin analysis is needed, as described in Section 5.

From a practical standpoint, our resulting classifier is the sign of a weighted linear combination of possibly many random DFAs. The fact that a complicated DFA with many states may be written as a weighted sum of much simpler DFAs is illustrated below and provides additional motivation for our approach. Our methodology is intimately connected to boosting (see, for example, Bartlett et al. 1998), since our resulting classifier can also be viewed as a weighted sum of weak classifiers—each being one of the random DFAs. Furthermore, our approach has a natural interpretation in the structural risk minimization (SRM) framework, where we trade the computational problem of finding a small consistent hypothesis for the problem of counting the number of small concepts accepting a given instance. The advantage of the latter is that it admits an efficient approximation in many cases of interest, including the case of DFAs.

In summary, our proposed algorithm is efficient, simple to implement, comes with strong theoretical guarantees, and readily generalizes to many other learning settings, such as context-free languages. We also present preliminary empirical results as a proof of concept. To our knowledge, the framework we propose is the only one capable of inducing unrestricted regular languages from labeled samples, without imposing additional structural assumptions—modulo standard cryptographic limitations. Some of the results in this paper first appeared in the conference version (Kontorovich, 2007).

1.3 Outline of Paper

This paper is organized as follows. In Section 2 we set down the notation and definitions used throughout the paper. The notion of linearly separable concept classes is defined in Section 3, and a general theorem regarding their existence via a canonical embedding is proved in Section 4. In Section 5, the universal kernel oracle is used to obtain an efficient generic learning algorithm, and in Section 6 an efficient approximation scheme is given for computing the universal kernel, with a corresponding learning algorithm. In Section 7, these results are applied to the case of the regular languages, with some experimental results presented in Section 8. Some inherent limitations of such kernel-based techniques are discussed in Section 9, and concluding remarks are made in Section 10.

2. Preliminaries

We refer the reader to Kearns and Vazirani (1997) for standard learning-theoretic definitions such as *instance space* and *concept class*. We likewise use standard set-theoretic terminology, with $|\cdot|$ denoting set cardinalities and $\mathbb{1}_{\{\cdot\}}$ representing the 0-1 truth value of the predicate inside the brackets. We blur the distinctions between subsets $c \subset \mathcal{X}$ and binary functions $c : \mathcal{X} \to \{0,1\}$; when we wish to make the distinction explicit, we will use a $\{\pm 1\}$-valued characteristic function:

$$\chi_c(x) := 2\mathbb{1}_{\{x \in c\}} - 1.$$

Recall that if A and B are two sets, B^A represents the collection of all functions from A to B. For countable sets A, we will consider the vector space $\mathbb{R}^A$ and often index $x \in \mathbb{R}^A$ by elements of A as opposed to by the naturals. For example, for $x, y \in \mathbb{R}^A$, we define their *inner product* as

$$\langle x, y \rangle \quad = \quad \sum_{a \in A} [x]_a [y]_a,$$

whenever the latter sum is well-defined. Square brackets may be omitted from the indexing notation for readability.

For any $x \in \mathbb{R}^{\mathbb{N}}$, we define its *support* to be the set of its nonzero coordinates:

$$\operatorname{supp}(x) \quad = \quad \{i \in \mathbb{N} : x_i \neq 0\}.$$

We define the quasinorm $\|\cdot\|_0$ to be the number of the nonzero coordinates:

$$\|x\|_0 \quad = \quad |\operatorname{supp}(x)|,$$

and the standard ℓ_2 norm by $\|x\|_2^2 = \langle x, x \rangle$.

If V_1 and V_2 are two inner product spaces over $\mathbb{R}$, we define their *direct product* $V_1 \otimes V_2$ to be the vector space

$$V_1 \otimes V_2 \quad = \quad \{(x, y) : x \in V_1, y \in V_2\}$$

which naturally inherits vector addition and scalar multiplication from V_1 and V_2, and whose inner product is defined by

$$\left\langle (x, y), (x', y') \right\rangle \quad = \quad \left\langle x, x' \right\rangle + \left\langle y, y' \right\rangle.$$

We will also write $(x, y) \in V_1 \otimes V_2$ as $x \otimes y$. Note that $\|x \otimes y\|_0 = \|x\|_0 + \|y\|_0$.

3. Linearly Separable Concept Classes

Our main results are actually quite general and most of them make no use of the properties of regular languages and automata. The only property we use is the *countability* of the instance space $\mathcal{X}$ and of the concept class $\mathcal{C}$. Henceforth, $\mathcal{X}$ and $\mathcal{C}$ are always assumed to be (at most) countable, unless noted otherwise. Let $\mathcal{C}$ be a concept class defined over an instance space $\mathcal{X}$; thus, $\mathcal{C} \subseteq 2^{\mathcal{X}}$. Any $c \in \mathcal{C}$ is thus a classifier or a function that induces a $\{0, 1\}$ labeling on the instance space $\mathcal{X}$. Note that a concept $c \subset \mathcal{X}$ may contain infinitely many instances, and an instance $x \in \mathcal{X}$ may belong to an infinite number of concepts.

We will say that a concept $c \in \mathcal{C}$ is *finitely linearly separable* if there exists a mapping $\phi : \mathcal{X} \to \{0, 1\}^{\mathbb{N}}$ and a weight vector $w \in \mathbb{R}^{\mathbb{N}}$, both with *finite support*, that is, $\|w\|_0 < \infty$ and $\|\phi(x)\|_0 < \infty$ for all $x \in \mathcal{X}$, such that

$$c = \{x \in \mathcal{X} : \langle w, \phi(x) \rangle > 0\}.$$

The concept class $\mathcal{C}$ is said to be *finitely linearly separable* if all $c \in \mathcal{C}$ are finitely linearly separable under the *same* mapping ϕ.

Note that the condition $\|\phi(\cdot)\|_0 < \infty$ is important; otherwise, we could define the *embedding by concept* $\phi : \mathcal{X} \to \{0,1\}^{\mathcal{C}}$

$$[\phi(x)]_c \quad = \quad \mathbb{1}_{\{x \in c\}}, \qquad c \in \mathcal{C}$$

and for any target $\hat{c} \in \mathcal{C}$,

$$[w]_c \quad = \quad \mathbb{1}_{\{c = \hat{c}\}}.$$

This construction trivially ensures that

$$\langle w, \phi(x) \rangle \quad = \quad \mathbb{1}_{\{x \in \hat{c}\}}, \qquad x \in \mathcal{X},$$

but may not satisfy $\|\phi(\cdot)\|_0 < \infty$ since certain $x \in \mathcal{X}$ may belong to an infinite number of concepts.

Similarly, we disallow $\|w\|_0 = \infty$ due to the algorithmic impossibility of storing infinitely many numbers and also because it leads to the trivial construction, via *embedding by instance* $\phi : \mathcal{X} \to \{0,1\}^{\mathcal{X}}$

$$[\phi(x)]_u \quad = \quad \mathbb{1}_{\{x = u\}}, \qquad u \in \mathcal{X},$$

whereby for any target $\hat{c} \in \mathcal{C}$, the corresponding vector

$$[w]_u \quad = \quad \mathbb{1}_{\{u \in \hat{c}\}}$$

ensures $\langle w, \phi(x) \rangle = \mathbb{1}_{\{x \in \hat{c}\}}$ without doing anything interesting or useful.

An additional important reason to insist on finite linear separability is that it ensures that for each $c \in \mathcal{C}$ there is a "separability dimension" $D(c) < \infty$ such that c is linearly separable in $\{0,1\}^{D(c)}$ under ϕ (in particular, if w defines a separating hyperplane for c then $D(c) \le \|w\|_0$). Now any linearly separable partition of $\{0,1\}^D$ must necessarily be separable with a strictly positive margin; this is true on any discrete finite space (but false in $\{0,1\}^\infty$). The latter in turn provides generalization guarantees, as spelled out in Section 5. Finally, any embedding ϕ induces a kernel K via

$$K(x,y) \quad = \quad \langle \phi(x), \phi(y) \rangle \tag{1}$$

for $x, y \in \mathcal{X}$. The finite support of ϕ automatically guarantees that K is everywhere well-defined; otherwise, additional assumptions are needed.

In light of the discussion above, from now on the only kind of linear separability we shall consider is in the strong sense defined above, where both the embedding $\phi(\cdot)$ and the hyperplane vector w have finite support. The modifiers "countable" (for instance spaces and concept classes), "finitely" (for linear separability) and "finite support" (for embeddings and hyperplanes) will be implicitly assumed throughout. Since an embedding $\phi : \mathcal{X} \to \{0,1\}^{\mathbb{N}}$ induces a kernel K as in (1), and any positive definite[1] kernel $K : \mathcal{X}^2 \to \mathbb{R}$ induces an embedding $\phi : \mathcal{X} \to \{0,1\}^{\mathcal{X}}$ via

$$\phi(x) \quad = \quad K(x, \cdot)$$

(see Schölkopf and Smola 2002), we shall speak of linear separability by ϕ or by K interchangeably, as dictated by convenience.

An immediate question is whether, under our conventions, every concept class is linearly separable. A construction of the requisite ϕ given any $\mathcal{X}$ and $\mathcal{C}$ would provide a positive answer; an example of $\mathcal{X}$ and $\mathcal{C}$ for which no such embedding exists would resolve the question negatively.

1. In the sense that for any finite set $\{x_i \in \mathcal{X} : 1 \le i \le m\}$, the $m \times m$ matrix $G = (g_{ij})$ given by $g_{ij} = K(x_i, x_j)$ is always positive definite.

4. Every Concept Class is Linearly Separable

The question raised in Section 3 turns out to have an affirmative answer, as we prove in the following theorem.

Theorem 1 *Every countable concept class $\mathcal{C}$ over a countable instance space $\mathcal{X}$ is finitely linearly separable.*

Proof We present a constructive proof, by describing an explicit mapping $\phi : \mathcal{X} \to \{0,1\}^{\mathbb{N}}$ under which all concepts $c \in C$ are finitely linearly separable. Recall that both the embedding by concept and embedding by instance, described in the previous section, rendered all concepts linearly separable, but were possibly not finitely supported. Hence, the "trick" in our construction is the introduction of *size functions* that measure the *complexity* of both individual instances and individual concepts, thus providing a notion of capacity control and adaptive regularization, and leading to finite separability.

We thus begin by defining the notion of a *size function* $f : \mathcal{A} \to \mathbb{N}$, mapping any countable set $\mathcal{A}$ to the naturals. We require a size function to have finite level sets:

$$\left|f^{-1}(n)\right| \quad < \quad \infty, \qquad \forall n \in \mathbb{N}.$$

In words, f assigns at most finitely many elements of $\mathcal{A}$ to any fixed size. Any countable $\mathcal{A}$ has such a size function (in fact, there are infinitely many size functions on $\mathcal{A}$). We denote by $|\cdot|$ and $\|\cdot\|$ some fixed choices of size functions on $\mathcal{X}$ and $\mathcal{C}$, respectively.

Recall that our goal is to construct an embedding $\phi : \mathcal{X} \to \{0,1\}^{\mathbb{N}}$ with $\|\phi(x)\|_0 < \infty$ for all $x \in \mathcal{X}$ such that for all $c \in \mathcal{C}$ there is a $w = w(c) \in \mathbb{R}^{\mathbb{N}}$ with $\|w\|_0 < \infty$ such that

$$c = \{x \in \mathcal{X} : \langle w, \phi(x) \rangle > 0\}.$$

We will construct the requisite *canonical* embedding ϕ as the direct product of two auxiliary embeddings, α and β,

$$\phi(x) = \alpha(x) \otimes \beta(x). \tag{2}$$

First, we define the *embedding by instance* $\alpha : \mathcal{X} \to \{0,1\}^{\mathcal{X}}$ by

$$[\alpha(x)]_u \quad = \quad \mathbb{1}_{\{u=x\}}, \qquad u \in \mathcal{X};$$

obviously, $\|\alpha(x)\|_0 = 1$ for all $x \in \mathcal{X}$ (recall our vector-indexing conventions, set down in Section 2). Second, using the size function as notion of complexity, we define a *regularized embedding by concept* $\beta : \mathcal{X} \to \{0,1\}^{\mathcal{C}}$ by

$$[\beta(x)]_c \quad = \quad \mathbb{1}_{\{x \in c\}} \mathbb{1}_{\{\|c\| \le |x|\}}, \qquad c \in \mathcal{C}; \tag{3}$$

since size functions have finite level sets, in contrast to the standard embedding by concept, we have $\|\beta(x)\|_0 < \infty$ for any $x \in \mathcal{X}$.

We now show that the embedding (2) renders all concepts $c \in \mathcal{C}$ finitely linearly separable, by explicitly constructing hyperplane vectors $w^{\alpha} \in \mathbb{R}^{\mathcal{X}}$ and $w^{\beta} \in \mathbb{R}^{\mathcal{C}}$ corresponding to the mappings α and β, respectively. To this end, it is helpful to keep in mind the dual roles of $\mathcal{X}$ and $\mathcal{C}$.

Pick any $\hat{c} \in C$. Since the embedding α involved no regularization, we introduce a complexity restriction in the corresponding hyperplane vector $w^{\alpha} \in \mathbb{R}^{\mathcal{X}}$ as follows

$$[w^{\alpha}]_u \quad = \quad \mathbb{1}_{\{u \in \hat{c}\}} \mathbb{1}_{\{|u| < \|\hat{c}\|\}}, \qquad u \in \mathcal{X};$$

since size functions have finite level sets, we have $\|w^\alpha\|_0 < \infty$. Thus,

$$\begin{aligned}\langle w^\alpha, \alpha(x)\rangle &= \sum_{u\in\mathcal{X}} [w^\alpha]_u [\alpha(x)]_u \\ &= \sum_{u\in\mathcal{X}} \mathbb{1}_{\{u\in\hat{c}\}} \mathbb{1}_{\{|u|<\|\hat{c}\|\}} \mathbb{1}_{\{x=u\}} \\ &= \mathbb{1}_{\{x\in\hat{c}\}} \mathbb{1}_{\{|x|<\|\hat{c}\|\}}. \end{aligned} \tag{4}$$

For the second embedding β, no further regularization is needed, and we define its corresponding hyperplane vector $w^\beta \in \mathbb{R}^{\mathcal{C}}$ by

$$[w^\beta]_c = \mathbb{1}_{\{c=\hat{c}\}}, \qquad c \in \mathcal{C};$$

note that $\left\|w^\beta\right\|_0 = 1$. Now

$$\begin{aligned}\left\langle w^\beta, \beta(x)\right\rangle &= \sum_{c\in\mathcal{C}} [w^\beta]_c [\beta(x)]_c \\ &= \sum_{c\in\mathcal{C}} \mathbb{1}_{\{c=\hat{c}\}} \mathbb{1}_{\{x\in c\}} \mathbb{1}_{\{\|c\|\le|x|\}} \\ &= \mathbb{1}_{\{x\in\hat{c}\}} \mathbb{1}_{\{|x|\ge\|\hat{c}\|\}}. \end{aligned} \tag{5}$$

Since ϕ is the direct product of the two embeddings α and β, the corresponding hyperplane is the direct product of the two hyperplanes:

$$w = w^\alpha \otimes w^\beta.$$

Note that by construction, both ϕ and w are finite:

$$\|\phi(x)\|_0 = \|\alpha(x)\|_0 + \|\beta(x)\|_0 < \infty \quad \text{and} \quad \|w\|_0 = \|w^\alpha\|_0 + \|w^\beta\|_0 < \infty.$$

Combining (4) and (5), we get

$$\begin{aligned}\langle w, \phi(x)\rangle &= \langle w^\alpha, \alpha(x)\rangle + \left\langle w^\beta, \beta(x)\right\rangle \\ &= \mathbb{1}_{\{x\in\hat{c}\}} \mathbb{1}_{\{|x|<\|\hat{c}\|\}} + \mathbb{1}_{\{x\in\hat{c}\}} \mathbb{1}_{\{|x|\ge\|\hat{c}\|\}} \\ &= \mathbb{1}_{\{x\in\hat{c}\}} \end{aligned}$$

which shows that w is indeed a linear separator (with finite support) for $\hat{c}$. ■

Next, we observe that linearly separable concepts may be described by finitely many instances, via the following "representer theorem". Note that this result holds for *any* separating embedding—not just the canonical one constructed in Theorem 1.

Theorem 2 *If a concept class $\mathcal{C}$ over an instance space $\mathcal{X}$ is linearly separable under ϕ (equivalently, under the induced kernel $K(x,y) = \langle\phi(x), \phi(y)\rangle$), there are $s_i \in \mathcal{X}$ and $\alpha_i \in \mathbb{R}$, $i = 1, \ldots, m$, such that*

$$c = \left\{ x \in \mathcal{X} : \sum_{i=1}^{m} \alpha_i K(s_i, x) > 0 \right\}.$$

Proof Suppose a concept $c \in \mathcal{C}$ is linearly separable with vector w, that is, $c = \{x \in \mathcal{X} : \langle w, \phi(x) \rangle > 0\}$. It follows that c is also separable under the finite dimensional embedding $\phi_D : \mathcal{X} \to \{0,1\}^D$ where $D = \max\{i : w_i \neq 0\}$ and ϕ_D is the truncation of ϕ by D:

$$[\phi_D(x)]_i \quad = \quad [\phi(x)]_i, \qquad i = 1, \ldots, D.$$

Define the equivalence relation $\equiv_D$ on $\mathcal{X}$ via

$$x \equiv_D y \quad \Leftrightarrow \quad \phi_D(x) = \phi_D(y)$$

and notice that $\equiv_D$ partitions $\mathcal{X}$ into finitely many equivalence classes. Let $x_1, x_2, \ldots, x_m$ be chosen arbitrarily, one from each equivalence class, and define $y_i := \chi_c(x_i)$. Let w' be the maximum-margin hyperplane for the labeled sample $(x_i, y_i)_{i=1}^m$ (see (9) for the definition of margin). This construction ensures that w' is a linear separator for c. By the representer theorem of Kimeldorf and Wahba (1971), it follows that w' admits a representation of the form

$$w' = \sum_{i=1}^{m} \alpha_i \phi(x_i),$$

and the claim follows. ■

A few remarks regarding Theorem 1 are in order. First, note that the construction of the canonical embedding depends on the choice of the size functions $|\cdot|$ and $\|\cdot\|$ on $\mathcal{X}$ and $\mathcal{C}$. These size functions induce a natural notion of complexity for instances $x \in \mathcal{X}$ and concepts $c \in \mathcal{C}$. Hence, our construction has analogies to various settings where classifier complexity can adaptively grow with the sample, such as structural risk minimization (SRM) in machine learning (Vapnik, 1982), and minimum description length (MDL) and other information theoretic criteria in statistics (Rissanen, 1989). We shall have more to say about SRM in particular, below.

Observe that any nondecreasing transformation $f : \mathbb{N} \to \mathbb{N}$ of a size function $|\cdot|$ produces another valid size function $|x|' := f(|x|)$. These affect the embedding in the following way. Consider a canonical embedding ϕ induced by $(|\cdot|, \|\cdot\|)$, and consider a transformed embedding ϕ' induced by $(f(|\cdot|), \|\cdot\|)$. If f is a very rapidly growing function then the truncation in (3) becomes ineffective, and in the limit of $f(\cdot) \equiv \infty$, ϕ' essentially becomes a pure embedding by concept. In the other extreme of a very slowly increasing f, the truncation in (3) becomes too restrictive. In the limit of $f(\cdot) \equiv$ const, ϕ' effectively becomes an embedding by instance.

A final note is that the separability result does not preclude the trivial scenario where the only coordinate separating a concept is the concept itself. To parse the last statement, recall that Theorem 1 states that under the canonical embedding, for each concept $c \in \mathcal{C}$ there is a finite $N = N(c)$ such that c is separable in $\{0,1\}^N$. However, it may be the case that the separator w is trivial, in the sense that $w_i \equiv \mathbb{1}_{\{i=c\}}$. In other words, the separability result implies that for each $c \in \mathcal{C}$ there is a finite collection of $\{c_i \in \mathcal{C} : \|c_i\| \leq \|c\|, 1 \leq i \leq m\}$ with coefficients $\alpha_i \in \mathbb{R}$ such that

$$c \quad = \quad \sum_{i=1}^{m} \alpha_i c_i, \tag{6}$$

where the relation above is symbolic shorthand for the statement that

$$c \quad = \quad \{x \in \mathcal{X} : \sum_{i=1}^{m} \alpha_i \mathbb{1}_{\{x \in c_i\}} > 0\}.$$

When a relation of type (6) holds, we say that c is *linearly decomposable* into the concepts $\{c_i\}$. No claims of uniqueness are made, and certainly any concept c is trivially decomposable into the singleton $\{c\}$. However, in many situations, concepts indeed decompose. As a simple example, define the concept c_{10} to be the set of all binary numbers, written as strings in $\{0,1\}^*$, divisible by ten, and define c_1, c_2 and c_5 analogously. Then it is straightforward to verify that

$$c_{10} = c_2 + c_5 - c_1,$$

in the sense of (6), since a number is divisible by 10 iff it is divisible by both 2 and 5.

As far as implications for learnability, Theorem 1 is most relevant when the target concept is linearly decomposable into a *small* collection of *simpler* concepts, as illustrated in the last example. In such cases, our approach can offer a substantial advantage over existing methods.

We may formalize the latter observation as a "universal learnability" theorem:

Theorem 3 *Let $\mathcal{C}$ be a concept class over $\mathcal{X}$, both countable, with size functions $\|\cdot\|$ and $|\cdot|$, respectively. Define the family of kernels:*

$$K_n(x,y) \quad = \quad \sum_{c:\|c\|\le n} \mathbb{1}_{\{x\in c\}}\mathbb{1}_{\{y\in c\}} \tag{7}$$

for $n \in \mathbb{N}$. Then, given an oracle for computing K_n, we can efficiently learn $\mathcal{C}$ from labeled examples.

More explicitly, let $c \in \mathcal{C}$ be a fixed concept, and let S be a sequence of m instances independently sampled from an arbitrary distribution P, and labeled according to c.

There is an efficient algorithm `UnivLearn`*, which inputs a labeled sample and outputs a classifier $\hat{f} : \mathcal{X} \to \{-1,1\}$ which, with probability at least $1-\delta$, achieves a small generalization error:*

$$P\{\hat{f}(x) \ne \chi_c(x)\} \quad \le \quad \frac{2}{m}\left(R(c)\log(8em)\log(32m)+\log(8m/\delta)\right), \quad \text{for } m \ge \theta^{-1}(\|c\|), \tag{8}$$

where $R(c)$ does not depend on the distribution P and $\theta, \theta^{-1} : \mathbb{N} \to \mathbb{N}$ are fixed monotone increasing functions with polynomial growth.

We defer the proof of Theorem 3 to Section 5, as it requires some preliminary definitions and results. The regularization function θ is chosen by the learner and represents his desired tradeoff between computational complexity and generalization error; this is further elucidated in Remark 7. We stress that the size of the target concept, $\|c\|$, is unknown to the learner—otherwise regularization would not be necessary. Finally, Remarks 4 and 5 below point out the non-trivial nature of Theorem 3; we are not aware of any way to obtain it as an immediate corollary of known results.

Remark 4 *We emphasize that the bound in Theorem 3 is distribution-free and recall that a distribution-dependent "learning" bound is trivial to obtain. Define $\hat{f}$ to be the rote memorizer: $\hat{f}(x) = y(x)$ if the example x appears in the sample S with label y and $\hat{f}(x) = -1$ otherwise. In this case, we have*

$$P\{\hat{f}(x) \ne \chi_c(x)\} \le P(x \notin S) = P(\mathcal{X} \setminus S),$$

and the latter quantity clearly tends to 0 as $m \to \infty$. All this bound says is that when we have observed a large enough portion of the world, we can be sure that most test examples will simply be recycled training examples. However, for any concept containing infinitely many instances, one can find an adversarial distribution P so that $P(\mathcal{X} \setminus S)$ will tend to zero arbitrarily slowly.

Remark 5 *The dependence of the required number of samples on the unknown concept c in the generalization bound (8) is inevitable whenever $\mathcal{C}$ has infinite VC-dimension. As a simple example, note that to learn an n-state DFA, one needs to observe at least n strings (at least one string ending at each state).*

5. Margin Bounds

In this section, we recall some classic margin bounds and their implications for learnability. Let $\mathcal{C}$ be a concept class over the instance space $\mathcal{X}$. Suppose there is some family of embeddings $\phi_d : \mathcal{X} \to \{0,1\}^{N_d}$; at this point, we assume nothing about the relationship between $\{\phi_d\}$ and $\mathcal{C}$. Let $S \subset \mathcal{X}$ be a finite sample with labels $Y \in \{-1,1\}^S$ consistent with some $c \in \mathcal{C}$, that is, $Y_x = \chi_c(x) = 2\mathbb{1}_{\{x\in c\}} - 1$ for all $x \in S$.

We define the *sample margin* of (S,Y) under ϕ_d as follows:

$$\hat{\gamma}_d(S,Y) \quad := \quad \sup_{w\in B(N_d)} \min_{x\in S} Y_x \langle w, \phi_d(x)\rangle \tag{9}$$

where $B(k) := \{x \in \mathbb{R}^k : \|x\|_2 \leq 1\}$. The *sample radius* of S under ϕ_d is defined to be

$$\hat{\rho}_d(S) \quad := \quad \max_{x\in S} \|\phi_d(x)\|_2 .$$

Analogously, define the *intrinsic margin* of c under ϕ_d to be

$$\gamma_d(c) \quad = \quad \sup_{w\in B(N_d)} \inf_{x\in \mathcal{X}} \chi_c(x) \langle w, \phi_d(x)\rangle$$

and the *radius* of ϕ_d to be

$$\rho_d \quad = \quad \sup_{x\in \mathcal{X}} \|\phi_d(x)\|_2 .$$

The case where γ_d or $\hat{\gamma}_d$ is negative is not excluded; it arises when ϕ_d fails to separate the given concept or sample. Note that since for $A \subset B$, we have $\inf_A f \geq \inf_B f$ and $\sup_A f \leq \sup_B f$, the relation $S \subset \mathcal{X}$ implies that

$$\hat{\gamma}_d(S,Y) \geq \gamma_d(c) \quad \text{and} \quad \hat{\rho}_d(S) \leq \rho_d . \tag{10}$$

The following theorem is a slight rewording of Shawe-Taylor et al. (1998, Theorem 4.5):

Theorem 6 (Shawe-Taylor et al. 1998) *Suppose m instances are drawn independently from a distribution whose support is contained in a ball in $\mathbb{R}^n$ centered at the origin, of radius ρ. If we succeed in correctly classifying all of them by a hyperplane through the origin with margin γ, then with confidence $1-\delta$ the generalization error will be bounded from above by*

$$\frac{2}{m}\left(R\log(8em/R)\log(32m) + \log(8m/\delta)\right), \tag{11}$$

where $R = R(\rho,\gamma) = \lfloor 577\rho^2/\gamma^2 \rfloor$.

We are now in a position to prove the "universal learnability" theorem:

Proof [of Theorem 3] Recall that (S,Y) is our finite labeled sample consistent with some unknown target concept c. For each $n \in \mathbb{N}$, let $\phi_n : \mathcal{X} \to \{0,1\}^{N_n}$ be the embedding associated with K_n, defined in (7), where

$$N_n = |\mathcal{C}_n| = |\{c \in \mathcal{C} : \|c\| \le n\}|.$$

Let the margins $\gamma_n(c), \hat{\gamma}_n(S,Y)$ and radii $\rho_n, \hat{\rho}_n(S)$ be as defined above. Define the *normalized margins*

$$\Delta_n(c) := \frac{\gamma_n(c)}{\rho_n}, \quad \text{and} \quad \hat{\Delta}_n(S,Y) := \frac{\hat{\gamma}_n(S,Y)}{\hat{\rho}_n(S)}.$$

Additionally, define $n_0 = n_0(c)$ to be the smallest n for which K_n linearly separates c:

$$n_0(c) := \min\{n \in \mathbb{N} : \gamma_n(c) > 0\} \tag{12}$$

and define

$$\Delta_0(c) := \Delta_{n_0(c)}(c).$$

The algorithm `UnivLearn` requires some fixed monotone increasing function $\theta : \mathbb{N} \to \mathbb{N}$, as mentioned in the statement of the theorem (for a concrete choice, one may take $\theta(m) = \lceil m^{1/2} \rceil$). Recall the theorem's condition that $m \ge \theta^{-1}(\|c\|)$ which (by Theorem 1) implies that $K_{\theta(m)}$ indeed separates the unknown concept c. The algorithm proceeds by computing the normalized sample margins $\hat{\Delta}_n(S,Y)$ for $n = 1, \ldots, \theta(m)$ and sets

$$\hat{\Delta}_*(S,Y) := \max\{\hat{\Delta}_n(S,Y) : 1 \le n \le \theta(m),\ \hat{\gamma}_n(S,Y) > 0\}$$

with corresponding $n_* \in \{1, \ldots, \theta(m)\}$. The condition $m \ge \theta^{-1}(\|c\|)$ ensures that the latter is well defined.

By (10) we have that $\hat{\Delta}_n(S,Y) \ge \Delta_n(c)$ for all $\{n \in \mathbb{N} : \gamma_n(c) > 0\}$. In addition, the condition $m \ge \theta^{-1}(\|c\|)$ combined with Theorem 1 ensure that

$$n_0(c) \le \|c\| \le \theta(m).$$

Therefore, we have

$$\hat{\Delta}_*(S,Y) \ge \Delta_0(c). \tag{13}$$

The classifier $\hat{f} : \mathcal{X} \to \{-1,1\}$ which `UnivLearn` outputs is the maximum-margin hyperplane under the embedding ϕ_{n_*}. It follows from Theorem 6 that the bound in (8) holds with $R(c) = \lfloor 577/\Delta_0(c)^2 \rfloor$. Note that in (8) we have opted for a slightly coarser but simpler bounds.

■

Remark 7 *To explain the role of the function $\theta(m)$, let us attempt to simplify the algorithm* `UnivLearn`. *Recall the definition of n_0 in (12), and define $\hat{n}_0$ to be the first n for which we perfectly classify the training set, that is, $\hat{n}_0 = \min_n\{\hat{\gamma}_n(S,Y) > 0\}$ and let $\hat{\Delta}_0(S,Y) := \hat{\Delta}_{\hat{n}_0}(S,Y)$. If it were the case that*

$$\hat{\Delta}_0(S,Y) \ge \Delta_0(c), \tag{14}$$

then the maximum-margin classifier $\hat{f}$ corresponding to $\phi_{\hat{n}_0}$ would satisfy the desired bound in (8). Unfortunately, the assertion in (14) is generally false, since it is possible for a small sample to be separable under K_n with $n < n_0$ and margin $\hat{\gamma}_n(S,Y) \ll \gamma_{n_0}(c)$. Because of this potentially very small margin, stopping prematurely at this n would render our theorem false. There seems to be no way around requiring the learner to try every $n \in \mathbb{N}$. To make the algorithm terminate in finite time for each given sample, we cut off the search at $n = \theta(m)$. Note that the theorem is only claimed to hold for sufficiently large sample sizes (namely, $m \geq \theta^{-1}(\|c\|)$)—but this is a feature of many bounds, especially where the complexity of the target concept is unknown (cf. Theorem 8). Since θ is a monotonically increasing function, we are guaranteed that eventually the sample size m will attain $\theta^{-1}(\|c\|)$, which is what the claim in (13) hinges upon. If θ grows too quickly (say, $\theta(\cdot) = \Omega(\exp(\cdot))$), the algorithm will take too long to run. If θ grows too slowly (say, $\theta(\cdot) = O(\log(\cdot))$), the generalization bound will only hold for huge sample sizes. The suggested rate of $\theta(m) = \lceil m^{1/2} \rceil$) seems a reasonable compromise.

Theorem 3 has a natural interpretation in the structural risk minimization (SRM) framework (Vapnik, 1982). Let us quote a well-known result, as it appears in Shawe-Taylor et al. (1996); for a detailed discussion of VC-dimension, see Vapnik's books (Vapnik, 1982, 1998) or any standard reference on learning theory such as Kearns and Vazirani (1997).

Theorem 8 (Shawe-Taylor et al. 1996) *Let H_i, $i = 1,2,\ldots$ be a sequence of hypothesis classes mapping $\mathcal{X}$ to $\{0,1\}$ such that $\mathrm{VCdim}(H_i) = i$ and let P be a probability distribution on $\mathcal{X}$. Let p_d be any set of positive numbers satisfying $\sum_{d=1}^{\infty} p_d = 1$. With probability $1-\delta$ over m independent examples drawn according to P, for any d for which the learner finds a consistent hypothesis h in H_d, the generalization error of h is bounded above by*

$$\varepsilon(m,d,\delta) = \frac{4}{m}\left(d\log\left(\frac{2em}{d}\right) + \log\left(\frac{1}{p_d}\right) + \log\left(\frac{4}{\delta}\right)\right),$$

provided $m \geq d$.

As a concrete choice of p_d, one may always take $p_d = 2^{-d}$. Viewing Theorems 3 and 8 through a computational lens, the two approaches may be contrasted by their "computational primitives". The SRM approach requires one to find a consistent hypothesis in a given complexity class (if one exists). Whenever the latter problem is efficiently solvable, SRM is quite satisfactory as a learning paradigm. In many interesting cases, however, the latter problem is intractable—as is the case for DFAs, for example (see Introduction). Our approach in Theorem 3 is to consider a different computational primitive—namely, the generic kernel

$$K_n(x,y) = |\{c \in \mathcal{C} : \|c\| \leq n, x \in c, y \in c\}|.$$

The margin-based bound may be significantly sharper than the generic SRM bound since it is sensitive to the target concept and its intrinsic margin. Additionally, the SRM bound is not directly applicable to our setting since the VC-dimension of linear combinations of functions may grow linearly with the number of terms (Anthony and Bartlett, 1999). The roles of θ in Theorem 3 and $\{p_d\}$ in Theorem 8 are analogous in that both encode a prior belief regarding hypothesis complexity.

The performance of `UnivLearn` is readily quantified:

Corollary 9 *If a labeled sample of size m is consistent with some concept $c \in \mathcal{C}$, and there is an oracle for computing $K_n(x,y)$ in time $O(1)$, then there is an algorithm with running time $O(m^2\theta(m))$ that achieves, with probability $1-\delta$, a generalization error of at most*

$$\frac{2}{m}\left(R(c)\log(8em)\log(32m)+\log(8m/\delta)\right),$$

for $m \geq \theta^{-1}(\|c\|)$.

Proof Using the oracle, the nth Gram matrix, defined by $(G_n)_{ij} = K_n(x_i,x_j)$, for $x_i, x_j \in S$, is computable in time $O(m^2)$. For a given Gram matrix, the margin may be computed in time $O(m)$ by a primal algorithm such as Pegasos (Shalev-Shwartz et al., 2007). The different Gram matrices and margins are computed $\theta(m)$ times. ■

Of course, at this point we have simply traded the generally intractable problem of finding a consistent $h \in H_d$ for the problem of evaluating $K_n(x,y)$. The latter is unlikely to have an efficient solution in general, and may well be intractable in many cases of interest. However, as we shall see below, under natural assumptions K_n admits an efficient stochastic approximation $\tilde{K}_n$ and Corollary 9 has a suitable extension in terms of $\tilde{K}_n$.

6. Approximating K_n

In the previous section we showed that the generic kernel family K_n renders all concepts $c \in \mathcal{C}$ linearly separable. However, exact evaluation of this kernel involves the summation in (7), which may contain a super-exponential number of terms. For example, a natural size function on DFAs is the number of states. Since the VC-dimension of n-state DFAs is $\Theta(n\log n)$ (Ishigami and Tani, 1997), there are $2^{\Theta(n\log n)}$ such concepts. Hence, a direct brute-force evaluation of the corresponding K_n is out of the question. Though we consider the complexity of computing K_n for DFAs to be a likely candidate for #P-complete, we have no proof of this; there is also the possibility that some symmetry in the problem will enable a clever efficient computation.

Instead, we propose an efficient randomized approximation to the generic K_n. All we require are oracles for computing $|\mathcal{C}_n|$ and for uniform sampling from $\mathcal{C}_n$, where

$$\mathcal{C}_n := \{c \in \mathcal{C} : \|c\| \leq n\}: \tag{15}$$

Assumption 10

(i) There is a sampling algorithm with running time $T_{\text{SAM}}(\mathcal{C},n) = O(\text{poly}(n))$ that outputs random concepts $c \in \mathcal{C}_n$, each with probability $|\mathcal{C}_n|^{-1}$. Additionally, k distinct concepts may be drawn (i.e., without replacement) in expected time $O(kT_{\text{SAM}}(\mathcal{C},n))$.

(ii) There is an algorithm that computes $|\mathcal{C}_n|$, in time $O(1)$.

We make an additional assumption regarding the time complexity of instance/concept membership queries:

Assumption 11 *For each $x \in \mathcal{X}$ and $c \in \mathcal{C}$, the characteristic function $\chi_c(x) = 2\mathbb{1}_{\{x\in c\}} - 1$ is computable in time $O(|x|)$.*

Note that sampling without replacement is a mild condition. Collisions are likely to occur when sampling from small sets, in which case one could simply enumerate the elements of $\mathcal{C}_n$. When the latter is large, however, uniform sampling is rather unlikely to generate collisions, and various hashing schemes can be employed to ensure this in practice.

For the purpose of approximating the kernel, it is convenient to normalize it as follows:

$$\bar{K}_n(x,y) := |\mathcal{C}_n|^{-1} K_n(x,y), \tag{16}$$

Note that the margin bounds of Section 5 are invariant under rescaling of the kernel by any constant.

Having stated our basic assumptions, we are ready to prove some results. The first one deals with efficient approximation of the generic kernel:

Theorem 12 *Let $S \subset \mathcal{X}$ be a sample of size m and the normalized generic kernel $\bar{K}_n$ be defined as in (16). Then, for any $0 < \varepsilon, \delta < 1$, there is a randomized algorithm with deterministic running time*

$$T \quad = \quad O\left(\frac{1}{\varepsilon^2} T_{\text{SAM}}(\mathcal{C}, n) \log\left(\frac{m}{\delta}\right)\right),$$

that produces a (random) kernel $\tilde{K}_n$ with the following properties

(a) $\tilde{K}_n$ is a positive semidefinite function on $\mathcal{X}^2$

(b)

$$\mathbf{E}[\tilde{K}_n(x,y)] \quad = \quad \bar{K}_n(x,y)$$

for all $x, y \in \mathcal{X}$

(c) with probability at least $1 - \delta$,

$$\left|\bar{K}_n(x,y) - \tilde{K}_n(x,y)\right| \quad \leq \quad \varepsilon,$$

for all $x, y \in S$,

(d) for all $x, y \in \mathcal{X}$, $\tilde{K}_n(x,y)$ is computable in deterministic time

$$O\left(\frac{1}{\varepsilon^2} \log\left(\frac{m}{\delta}\right)(|x| + |y|)\right).$$

Proof The approximation algorithm amounts to sampling T concepts, $\{c_i : 1 \leq i \leq T\}$ uniformly at random (without replacement) from $\mathcal{C}_n$, where Assumption 10 ensures that the latter sampling scheme is computationally feasible.

The random concepts $\{c_i : 1 \leq i \leq T\}$ are used to define the random kernel $\tilde{K}_n$:

$$\tilde{K}_n(x,y) \quad = \quad \frac{1}{T} \sum_{i=1}^{T} \mathbb{1}_{\{x \in c_i\}} \mathbb{1}_{\{y \in c_i\}}, \qquad x, y \in \mathcal{X}. \tag{17}$$

Since $\tilde{K}_n$ is constructed as a (semi) inner product, it is non-negative but still not strictly positive definite, as it may fail to separate distinct points. Hence, (a) is proved.

To prove (b), fix $x, y \in \mathcal{X}$ and define $D_{xy} \subset \mathcal{C}_n$ by

$$D_{xy} \quad = \quad \{c \in \mathcal{C}_n : x, y \in c\};$$

this is the set of those $c \in \mathcal{C}$ with $\|c\| \leq n$ which contain both x and y. Since any c drawn uniformly from $\mathcal{C}_n$ contains both x and y with probability $|D_{xy}| \, / \, |\mathcal{C}_n|$ it follows that the approximate kernel

$$\tilde{K}_n(x,y) = \frac{1}{T} \sum_{i=1}^{T} \mathbb{1}_{\{c_i \in D_{xy}\}} \tag{18}$$

is an unbiased estimator for

$$\bar{K}_n(x,y) \quad = \quad |\mathcal{C}_n|^{-1} \sum_{c \in \mathcal{C}_n} \mathbb{1}_{\{c \in D_{xy}\}} \quad = \quad \frac{|D_{xy}|}{|\mathcal{C}_n|};$$

this proves (b).

Our arguments show that the random variable $\mathbb{1}_{\{c_i \in D_{xy}\}}$ has a Bernoulli distribution with mean $\bar{K}_n(x,y)$. Hence, applying Hoeffding's bound (Hoeffding, 1963), which also holds for variables sampled without replacement, to (18) yields

$$\mathbf{P}\left\{ \left| \tilde{K}_n(x,y) - \bar{K}_n(x,y) \right| > \varepsilon \right\} \quad \leq \quad 2\exp(-2T\varepsilon^2). \tag{19}$$

The latter can be inverted to make the claim in (c) hold for a given x, y whenever $T > (2\varepsilon^2)^{-1} \log(2/\delta)$. Applying the union bound to (19), we have established (c), with

$$T \quad = \quad \frac{1}{2\varepsilon^2} \log\left(\frac{m^2 + m}{\delta} \right).$$

Finally, (d) holds by Assumptions 10 and 11. ■

Our next observation is that perturbing a kernel pointwise by a small additive error preserves linear separability:

Theorem 13 *Let $K : \mathcal{X}^2 \to \mathbb{R}$ be a kernel, and $S \subset \mathcal{X}$ be a finite sample with labels $Y \in \{-1, 1\}^S$. Assume that (S, Y) is separable under the kernel K with margin γ, that is,*

$$\sup_{w \in \mathbb{R}^{\mathbb{N}}} \min_{s \in S} \frac{Y_s \langle w, \phi(s) \rangle}{\|w\|_2} \quad \geq \quad \gamma > 0,$$

where ϕ is the embedding associated with K. Let K' be another kernel, which is uniformly close to K on S:

$$\left| K(s,t) - K'(s,t) \right| \leq \varepsilon \qquad \forall s, t \in S. \tag{20}$$

Then, for $\varepsilon < \gamma^2$, the sample (S, Y) is also separable under K', with a positive margin.

Proof Let $f(x)$ be the maximum-margin hyperplane classifier corresponding to the training set S, under the kernel K. By the representer theorem, it can written as

$$f(x) = \langle \phi(x), w \rangle = \sum_{s \in S} \alpha_s K(x,s).$$

Since (S,Y) is linearly separable, $f(x)$ satisfies the constraint

$$Y_s f(s) \geq 1 \qquad \forall s \in S.$$

By the KKT conditions (Schölkopf and Smola, 2002), its margin is given by

$$\gamma^{-2} \;\; = \;\; \sum_s |\alpha_s|.$$

We now consider the following linear classifier, obtained by replacing K by K':

$$f'(x) = \sum_{s \in S} \alpha_s K'(x,s).$$

By (20), for each $x, s \in S$,

$$K'(x,s) = K(x,s) + \varepsilon\, \eta_{x,s}$$

where $|\eta_{x,s}| \leq 1$. Hence, for all $x \in S$,

$$f'(x) = f(x) + \varepsilon \sum_{s \in S} \eta_{x,s} \alpha_s.$$

Therefore,

$$Y_s f'(s) \geq 1 - \varepsilon \sum_s |\alpha_s| = 1 - \frac{\varepsilon}{\gamma^2},$$

which shows that f' is a linear separator for (S,Y) as long as $\varepsilon < \gamma^2$. ■

The next result quantifies the amount by which the margin may shrink when an approximate kernel is constructed using a random subset of the features:

Theorem 14 *Let a labeled sample (S,Y) be given, with $S \subset \mathcal{X}$. Let the kernel K be induced by the embedding $\phi : \mathcal{X} \to \{0,1\}^F$, where F is a finite feature set, as follows:*

$$K(s,t) := \frac{1}{|F|} \langle \phi(s), \phi(t) \rangle .$$

Consider a feature subset $F' \subset F$. Define $\phi' : \mathcal{X} \to \{0,1\}^{F'}$ to be the restriction of ϕ to $\{0,1\}^{F'}$ and K' to be corresponding kernel:

$$K'(s,t) := \frac{1}{|F'|} \langle \phi'(s), \phi'(t) \rangle .$$

Suppose that (S,Y) is linearly separable under K with margin $\gamma > 0$. If K' is ε-close to K on S in the sense of (20) with $\varepsilon < \gamma^2$, then (S,Y) is linearly separable under the kernel K', with margin γ' bounded from below by

$$\gamma' \geq \frac{|F'|}{|F|} \left(\gamma - \frac{\varepsilon}{\gamma} \right).$$

Proof Let $f : \mathcal{X} \to \mathbb{R}$ be the maximum-margin separator under K:

$$f(x) = \sum_{s \in S} \alpha_s K(x,s) = \frac{1}{|F|} \sum_{s \in S} \alpha_s \langle \phi(x), \phi(s) \rangle = \langle w, \phi(x) \rangle .$$

Let us define f' as f with K replaced by K':

$$f'(x) = \sum_{s \in S} \alpha_s K'(x,s) = \frac{1}{|F'|} \sum_{s \in S} \alpha_s \left\langle \phi'(x), \phi'(s) \right\rangle .$$

By Theorem 13 we have that f' is a linear separator for (S,Y), satisfying

$$Y_s f'(s) \geq 1 - \varepsilon \sum_s \alpha_s = 1 - \frac{\varepsilon}{\gamma^2}, \qquad s \in S.$$

Observe that

$$f'(x) = \frac{|F|}{|F'|} \left\langle w|_{F'}, \phi'(x) \right\rangle$$

where $w|_{F'}$ is the restriction of w to $\mathbb{R}^{F'}$. Thus, letting

$$w' := \frac{|F|}{|F'|} \left(1 - \frac{\varepsilon}{\gamma^2} \right)^{-1} w|_{F'},$$

we have that

$$f''(x) := \left\langle w', \phi'(x) \right\rangle$$

linearly separates S and satisfies and $Y_s f''(s) \geq 1$ for $s \in S$. Since the margin attained by the hyperplane w is given by $1/\|w\|$ (Schölkopf and Smola, 2002), the claim follows. ■

Our final result for this section—and perhaps the highlight of the paper—is the following "approximate" version of Corollary 9:

Theorem 15 *Let $\mathcal{C}$ be a concept class over $\mathcal{X}$. Let $S \subset \mathcal{X}$ be a sequence of m instances sampled independently from an arbitrary distribution P, and labeled according to some unknown $c \in \mathcal{C}$. For any $\delta > 0$, there is a randomized algorithm* `ApproxUnivLearn`*, which outputs a classifier $\hat{f} : \mathcal{X} \to \{-1,1\}$ such that with probability at least $1-\delta$ it achieves a small generalization error,*

$$P\{\hat{f}(x) \neq \chi_c(x)\} \quad \leq \quad \frac{2}{m}\left(4R(c)\log(8em)\log(32m) + \log(16m/\delta)\right) \tag{21}$$

for

$$m \geq \max\{\theta^{-1}(\|c\|), D(c)/2, R(c)^2/8.4 \times 10^4\}, \tag{22}$$

where $0 < D(c), R(c) < \infty$ are constants that depend only on c, and $\theta : \mathbb{N} \to \mathbb{N}$ is discussed in Remark 7.

Furthermore, `ApproxUnivLearn` *has deterministic polynomial complexity, with running time*

$$O\left(m\theta(m)\log(m/\delta)(\ell_{\max} m^2 + T_{\text{SAM}}(\mathcal{C}, \theta(m)))\right),$$

where $\ell_{\max} := \max\{|s| : s \in S\})$.

Proof Let (S,Y) denote a training set consisting of m samples, labeled consistently with the target concept $c \in \mathcal{C}$. We define

$$\begin{aligned} n_0 &:= \min\{n \in \mathbb{N} : \gamma_n(c) > 0\}, \\ \gamma_0(c) &:= \gamma_{n_0}(c), \end{aligned}$$

and

$$\begin{aligned} R(c) &:= \left\lfloor 577/\gamma_0(c)^2 \right\rfloor, \\ D(c) &:= |\mathcal{C}_{n_0}|, \end{aligned}$$

where $\mathcal{C}_n$ is defined in (15) as the set of concepts with complexity at most n.

Given the training set (S,Y), our algorithm constructs $\theta(m)$ different classifiers. According to Theorem 12, each of these classifiers is constructed as follows: For $1 \le n \le \theta(m)$, we randomly sample T features, construct the respective approximate kernel, and calculate its resulting max-margin hyperplane, with sample margin $\tilde{\gamma}_n(S,Y)$. Finally, our algorithm chooses the kernel with the largest empirical margin

$$\tilde{\gamma}_* := \max\{\tilde{\gamma}_n(S,Y) : 1 \le n \le \theta(m), \tilde{\gamma}_n(S,Y) > 0\}. \tag{23}$$

If the latter set is empty, we leave $\tilde{\gamma}_*$ undefined (however, our analysis below will show that under the conditions of the theorem, this is a highly unlikely event).

To prove the theorem, we need to show that with high probability,

$$\tilde{\gamma}_* \ge \text{Const} \times \gamma_0(c). \tag{24}$$

If this equation holds (whp), then the standard margin bound (11) proves the theorem. There are two ways in which the theorem's generalization bound (21) may fail to hold. The first is due to a particularly unlucky sample whereas the second is due to a bad kernel approximation so that (24) does not hold. Hence, we split the confidence parameter δ so that each of these kinds of failure occurs with probability at most $\delta/2$.

The first step is to note that by definition $\tilde{\gamma}_* \ge \tilde{\gamma}_{n_0}$. The next step is to lower bound the approximate sample margin, constructed with a random approximate kernel, in terms of the true sample margin corresponding to the exact kernel. Such a bound is provided by Theorem 14:

$$\tilde{\gamma}_{n_0}(S,Y) \ge \frac{\min\{T, D(c)\}}{D(c)} \left(\hat{\gamma}_{n_0}(S,Y) - \frac{\varepsilon}{\hat{\gamma}_{n_0}(S,Y)} \right).$$

Note that by condition (22) we have

$$m \quad \ge \quad 4/\gamma_0(c)^4 \ge 4/\hat{\gamma}_{n_0}(S,Y)^4, \tag{25}$$

since $\hat{\gamma}_{n_0}(S,Y) \ge \gamma_0(c)$, as in (10).

Furthermore, in constructing the approximate kernels, we set the precision to be $\varepsilon = 1/\sqrt{m}$. This condition, combined with (25) gives

$$\tilde{\gamma}_* \ge \frac{1}{2} \frac{\min\{T, D(c)\}}{D(c)} \hat{\gamma}_{n_0}(S,Y) \ge \frac{1}{2} \frac{\min\{T, D(c)\}}{D(c)} \gamma_0(c).$$

The last step is to bound the factor multiplying $\gamma_0(c)$ in the last equation. To this end, recall that according to Theorem 12, under the condition $\varepsilon = 1/\sqrt{m}$, the number of random concepts T drawn from $\mathcal{C}_n$ is

$$T \;=\; \frac{1}{2\varepsilon^2}\log\left(\frac{m^2+m}{\delta/2}\right) = \frac{m}{2}\log\left(\frac{m^2+m}{\delta/2}\right) > m.$$

Combining this with (22), we have

$$T > m \geq D(c)/2.$$

Hence, $\tilde{\gamma}_* \geq \gamma_0(c)/4$, and applying (11) proves the generalization bound.

It remains to analyze the complexity of `ApproxUnivLearn`. The main loop is executed $\theta(m)$ times. To compute each approximate kernel we sample $O(\varepsilon^{-2}\log(m/\delta))$ concepts from $\mathcal{C}_n$, and evaluate the summation in (17) for each $x,y \in S$. Since $\varepsilon = m^{-1/2}$, the nth Gram matrix is computable in time $O\left(m\log(m/\delta)(\ell_{\max}m^2 + T_{\text{SAM}}(\mathcal{C},n))\right)$. For a given Gram matrix, the margin may be computed in time $O(m)$ by a primal algorithm such as Pegasos (Shalev-Shwartz et al., 2007), which gets absorbed into the preceding $O(m^3\theta(m)\log(m))$ bound.

■

Remark 16 *For* $\theta(m) = \lceil m^{1/2}\rceil$, `ApproxUnivLearn` *has a running time of* $O(m^{3.5}\log m)$. *This may be brought down to* $m^{2+\alpha}$ *for any* $\alpha > 0$*, at the expense of increased sample complexity in (21), by choosing* $\varepsilon = m^{-\beta}$ *with* $\beta \ll 1$. *The role of* $\theta(m)$ *in the tradeoff between running time and sample complexity is discussed in Remark 7;* $\varepsilon(m)$*, taken to be* $m^{-1/2}$ *in the proof above, has an analogous role.*

7. Universal Regular Kernel, New Characterization of Regular Languages

Having developed some general tools for learning countable concept classes, we now apply these to regular languages. For the remainder of the paper, we follow standard formal-language terminology. Thus, Σ will denote a fixed finite alphabet and Σ^* is the free monoid over Σ. Its elements are called *strings* (or *words*) and the length of $x \in \Sigma^*$ is denoted by $|x|$. The latter will be our default size function on Σ^*.

Our definition of a Deterministic Finite-state Automaton (DFA) is a slight modification of the standard one. We define the latter to be a tuple $A = (\Sigma, Q, F, \delta)$ where

- Σ is a finite alphabet
- $Q = \{1,2,\ldots,n\}$ is a finite set of states
- $F \subset Q$ is the set of the accepting states
- $\delta : Q \times \Sigma \to Q$ is the deterministic transition function.

The only difference between our definition and the common one is that we take the initial state q_0 to be fixed at $q_0 = 1$, while most authors allow it to be an arbitrary $q_0 \in Q$. We write $L(A)$ for the language accepted by the automaton A, and denote the number of states in A by size(A) or $\|A\|$, interchangeably.

Recall that a language $L \subseteq \Sigma^*$ is *regular* if and only if it is recognized by some DFA. Lewis and Papadimitriou (1981) and Sipser (2005) are among the standard introductory texts on automata and formal languages.

In order to apply our results to regular languages, we begin by defining the instance space $\mathcal{X} = \Sigma^*$ and concept class $\mathcal{C} = \cup_{n \geq 1} \mathrm{DFA}(n)$, where $\mathrm{DFA}(n)$ is the set of all DFAs on n states; both are countable. Once the size functions on $\mathcal{X}$ and $\mathcal{C}$ have been specified, Theorem 1 furnishes an embedding $\phi : \mathcal{X} \to \{0,1\}^{\mathbb{N}}$ that renders all regular languages linearly separable. It is instructive to verify that the construction of the canonical embedding yields the following kernel, which we call a *universal regular kernel*:

$$\begin{aligned} K_{\mathrm{REG}}(x,y) &= \langle \phi(x), \phi(y) \rangle \\ &= \mathbb{1}_{\{x=y\}} + \sum_{n=1}^{\min\{|x|,|y|\}} \sum_{A \in \mathrm{DFA}(n)} \mathbb{1}_{\{x \in L(A)\}} \mathbb{1}_{\{y \in L(A)\}}. \end{aligned}$$

In fact, we obtain a novel characterization of the regular languages:

Theorem 17 *A language $L \subseteq \Sigma^*$ is regular if and only if there exists a finite set of strings, $s_i \in \Sigma^*$ with corresponding weights $\alpha_i \in \mathbb{R}$, $i = 1, \ldots, m$ such that*

$$L = \left\{ x \in \Sigma^* : \sum_{i=1}^{m} \alpha_i K_{\mathrm{REG}}(s_i, x) > 0 \right\}. \tag{26}$$

Proof Theorem 1 provides an embedding $\phi : \Sigma^* \to \{0,1\}^{\mathbb{N}}$ such that for any regular language L there is a $D \in \mathbb{N}$ so that the sets $\phi_D(L)$ and $\phi_D(\Sigma^* \setminus L)$ are separable by a hyperplane in $\{0,1\}^D$, where ϕ_D is the restriction of ϕ to $\{0,1\}^D$. Thus, by Theorem 2, (26) holds for some finite collection of strings s_i and weights α_i. Conversely, suppose that $L \subseteq \Sigma^*$ is expressible as in (26). Writing $w = \sum_{i=1}^{m} \alpha_i \phi_D(x_i) \in \mathbb{R}^D$, consider the function $f : \Sigma^* \to \mathbb{R}$ defined by

$$f(x) = \sum_{j=1}^{D} w_j [\phi_D(x)]_j$$

and note that $L = \{x : f(x) > 0\}$. Observe that f can only take on finitely many real values $\{r_k : k = 1, \ldots, k_f\}$. Let $L_{r_k} \subseteq \Sigma^*$ be defined by

$$L_{r_k} = f^{-1}(r_k).$$

A subset $I \subseteq \{1, 2, \ldots, N\}$ is said to be *r_k-acceptable* if $\sum_{i \in I} w_i = r_k$. Any such r_k-acceptable set corresponds to a set of strings $L_I \subseteq \Sigma^*$ such that

$$L_I = \left(\bigcap_{i \in I} [\phi_D]_i^{-1}(1) \right) \setminus \left(\bigcup_{i \in \{1,\ldots,N\} \setminus I} [\phi_D]_i^{-1}(1) \right).$$

It remains to show that each $[\phi_D]_i^{-1}(1) \subseteq \Sigma^*$ is a regular language, but this follows immediately from Theorem 1 and our choice of size functions $|\cdot|$ and $\|\cdot\|$. Now each L_{r_k} is the union of finitely many r_k-acceptable L_I's, and L is the union of the L_{r_k} for $r_k > 0$. This means that L is a finite Boolean combination of regular languages and is therefore itself regular. ■

The result above is mainly of theoretical interest. In order to obtain an efficient learning algorithm with generalization bounds, we must stratify K_{REG} into a regularized kernel family $\{K_n\}$ and show that these are efficiently computable (or approximable).

For our purposes, $A \in \text{DFA}(n)$ is a directed multigraph on n labeled vertices (states), with edges labeled by elements in Σ, and some of the vertices designated as accepting. Note that a given regular language has infinitely many representations as various DFAs; we make no attempt to minimize automata or identify isomorphic ones, nor do we exclude degenerate or disconnected ones.

The first order of business is to verify that Assumptions 10 and 11 hold for the present choice of $\mathcal{X}$ and $\mathcal{C}$, with the specified size functions:

Lemma 18 *Let*

$$\mathcal{C}_n = \bigcup_{k=1}^{n} \text{DFA}(k).$$

Then

(i) There is a sampling algorithm with running time $T_{\text{SAM}}(\mathcal{C}, n) = O(|\Sigma| n)$ that outputs random automata $A \in \mathcal{C}_n$, each with probability $|\mathcal{C}_n|^{-1}$

(ii) $|\mathcal{C}_n|$ is computable in time $O(1)$

(iii) for each $x \in \mathcal{X}$ and $A \in \text{DFA}(k)$, the characteristic function $\chi_A(x) = 2\mathbb{1}_{\{x \in L(A)\}} - 1$ is computable in time $O(|x|)$.

Proof Under our definition of $\text{DFA}(k)$, each member is specified by a vertex-labeled directed graph. Equivalently, $A \in \text{DFA}(k)$ is described by the matrix $\delta \in Q^{Q \times \Sigma}$, where $Q = \{1, 2, \ldots, k\}$, and by the set of accepting states $F \subseteq Q$. This immediately implies that

$$|\,\text{DFA}(k)| = 2^k k^{|\Sigma| k}$$

and $|\mathcal{C}_n| = \sum_{k=1}^{n} |\,\text{DFA}(k)|$; thus (ii) is proved. To sample a δ uniformly from $Q^{Q \times \Sigma}$, we may independently draw each $\delta(q, \sigma)$ uniformly at random from Q. Since the latter is achievable in constant time, we have that δ may be sampled in time $O(|\Sigma| k)$. Additionally, for each $q \in Q$ we may flip a fair coin to determine whether $q \in F$; this amounts to a uniform sampling of F. We've established that $A \in \text{DFA}(k)$ may be uniformly sampled in time $O(|\Sigma| k)$.

To sample uniformly from $\mathcal{C}_n$, define first the distribution π on $\{1, \ldots, n\}$ by

$$\pi_k = \frac{|\text{DFA}(k)|}{|\mathcal{C}_n|} = \frac{2^k k^{|\Sigma| k}}{\sum_{i=1}^{n} 2^i i^{|\Sigma| i}}.$$

Sampling a $k \in \{1, \ldots, n\}$ according to π can be done in time $O(n)$ and then A is drawn uniformly from $\text{DFA}(k)$ as described above. The resulting automaton is a uniform draw from $\mathcal{C}_n$, which took $O(|\Sigma| n)$ steps to perform; this proves (i).

To prove (iii) we simply recall that an automaton evaluates a string by reading it from beginning to end, each time evolving from state to state as prescribed by δ. ■

We now state our main learnability result for regular languages. The theorem below is a direct consequence of Theorem 15, where $\theta(m) := \lceil m^{1/2} \rceil$ and $T_{\text{SAM}}(\mathcal{C}, n) = O(n)$, as per Lemma 18:

Theorem 19 *Let $L \subseteq \Sigma^*$ be a regular language and suppose that $S \subset \Sigma^*$ is a sequence of m instances sampled independently from an arbitrary distribution P, and labeled according to L. For any $\delta > 0$, there is a randomized algorithm* `RegLearn`*, which outputs a classifier $\hat{f} : \Sigma^* \to \{-1, 1\}$ such that with probability at least $1 - \delta$ it achieves a small generalization error,*

$$\begin{aligned} P\{\hat{f}(x) \neq \chi_L(x)\} \quad &\leq \quad \frac{2}{m}\left(4R(L)\log(8em)\log(32m) + \log(16m/\delta)\right) \\ &\qquad \textit{for } m > \max\{\text{size}(L)^2, D(L)/2, R(L)^2/8.3 \times 10^4\}, \end{aligned}$$

where $\text{size}(L)$ *is the number of states in the smallest automaton recognizing L and $D(L)$, $R(L)$ are constants depending only on L.*

Furthermore, `RegLearn` *has deterministic polynomial complexity, with running time*

$$O\left(\ell_{\max} m^{5/2} \log(m/\delta)\right),$$

where $\ell_{\max} := \max\{|s| : s \in S\}$).

8. Empirical Results

In this section we present some preliminary empirical results that provide a proof of concept for our approach. We performed several types of experiments.

8.1 Proof of Concept, Comparisons

In this basic setup, we draw a sample S of $m = 300$ strings in $\{0,1\}^*$ uniformly with mean Poisson length 15 (that is, the string length ℓ is a Poisson random variable with mean 15 and the string x is drawn uniformly from $\{0,1\}^\ell$). The target DFA A is uniformly drawn at random from DFA(n) as described in Lemma 18, where its size is chosen uniformly in the interval $3 \leq n \leq 50$. This DFA is then minimized, so that its number of states represents its "true" complexity. The automaton A is run on the sample S to produce the label vector $Y \in \{-1,1\}^S$.

For the learning process, we randomly sample a fixed number $T = 1000$ of "feature" automata A_i, from the set DFA$(1:18) = \cup_{n=1}^{18}$ DFA(n), where we chose $\theta(m) = \sqrt{m}$ (note that $18 \approx \sqrt{300}$). For each $s \in S$, we compute the embedding vector $\phi(s) \in \{0,1\}^T$ by

$$[\phi(s)]_i = \mathbb{1}_{\{s \in L(A_i)\}}$$

and arrange the $\{\phi(s)\}_{s \in S}$ into the columns of the $T \times m$ matrix Φ. Now that (Φ, Y) corresponds to m labeled points in $\mathbb{R}^T$, we can apply some standard classification algorithms:

- `SVM` finds the maximum-margin hyperplane separating the positive and negative examples
- `AdaBoost` (Freund and Schapire, 1996) uses the feature automata $\{A_i : 1 \leq i \leq T\}$ as weak classifiers and combines them into a weighted sum

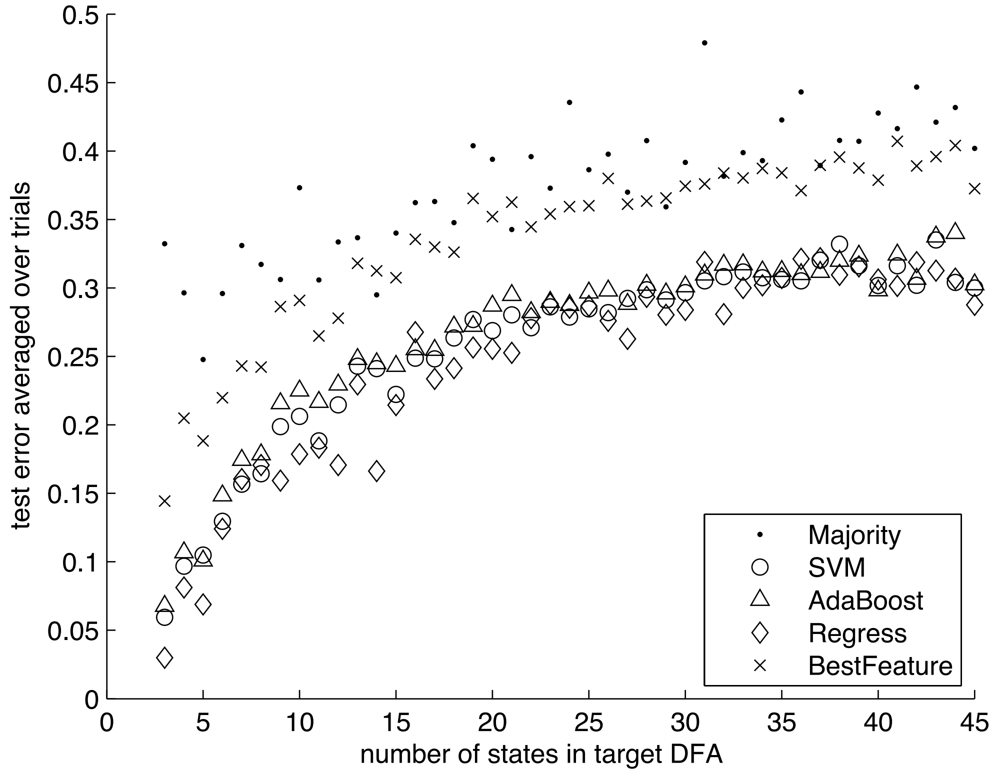

Figure 1: Performance plots of different linear threshold classifiers (sample size = 300, number of features = 1000)

- `Regress` labels a new string $x \in \{0,1\}^*$ as follows:

$$y = \operatorname{sgn}(\phi(x)(\Phi\Phi^{\mathsf{T}})^{-1}\Phi Y)$$

  where $\cdot^{\mathsf{T}}$ denotes the matrix transpose

as well as two "baseline" classifiers:

- `Majority` labels every unseen string $x \in \{0,1\}^*$ by the majority vote of the training labels, disregarding the actual training strings:

$$y = \operatorname{sgn}\left(\sum_{s \in S} Y_s\right)$$

- `BestFeature` picks the single feature automaton A_i with the best empirical performance.

A test set of 100 strings is drawn from the same distribution as S, and the performance of each classifier is compared against the true labels given by A. The results are summarized in Figure 1, averaged over several hundred trials.

As expected, since in this experiment the sample size is kept fixed, the performance degrades with increasing automaton complexity. Furthermore, `SVM`, `AdaBoost` and `Regress` have a similar performance. While the first two methods are margin driven with guaranteed performance bounds, the success of `Regress` is somewhat surprising. We currently have no explanation for why such a seemingly naive approach should work so well. Unsurprisingly, `BestFeature` and `Majority` trail behind the other methods significantly. However, even the latter simplistic approaches perform quite better than chance on moderately sized automata.

Despite the rather pessimistic impossibility results for learning general automata, our results seem to indicate that random automata are efficiently learnable. This is in line with the empirical observations of Lang (1992) and others that random automata are "easy" to learn in practice.

8.2 Role of Adaptive Feature Set

In the second experiment, we demonstrate the importance of having an adaptive feature set. Here, we chose a single fixed target DFA on 20 states, and study the generalization performance of two schemes, one with a fixed number of features T, and one where T is chosen adaptively as a function of sample size. The training and test strings are sampled according to the same scheme as described above. The sample size m varies from 10 to 400; the test set is fixed at 100. In the fixed T scheme we set $T \equiv 500$ while in the adaptive one $T = m \log m$. As expected, the adaptive scheme eventually outperforms the fixed one (see Figure 2).

8.3 Case Study: Parity Languages

For $I = \{i_1 < i_2 \ldots < i_k\} \subset \mathbb{N}$, define the language $L[I] \subset \{0,1\}^*$ by

$$L[I] = \{x \in \{0,1\}^* : |x| \geq i_k, x_{i_1} \oplus x_{i_2} \oplus \ldots \oplus x_{i_k} = 1\}$$

where $\oplus$ is addition modulo 2. Then $L[I]$ is called a *parity language*. The following facts are easily verified

Claim 20 *For $I \subset \mathbb{N}$ and $L[I]$, we have*

(a) the language $L[I]$ is regular

(b) the minimal DFA accepting $L[\{1,k\}]$ has size $2k+1$.

The minimal DFA for the language

$$L[\{1,2\}] = \{x \in \{0,1\}^* : x_1 \oplus x_2 = 1\}$$

is shown in Figure 3. We describe the results of some empirical investigations with parity languages.

8.3.1 EXACT RECOVERY

Recall that the learner is presented with a labeled sample (S,Y), which is consistent with some target language $L_0 \subset \{0,1\}^*$. PAC learning entails producing a hypothesis $\hat{L}$ whose predictions on new strings will be statistically similar to those of L_0. *Exact recovery* is a more stringent demand: we are required to produce a hypothesis that is identical to the target language.

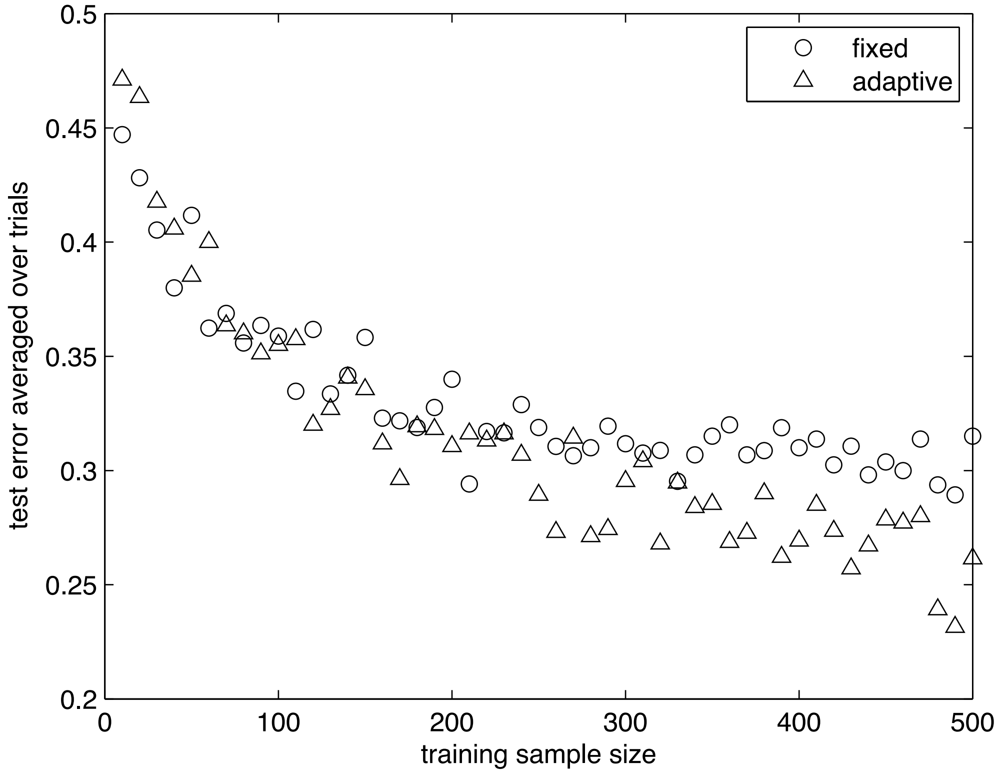

Figure 2: Performance in the fixed and adaptive settings

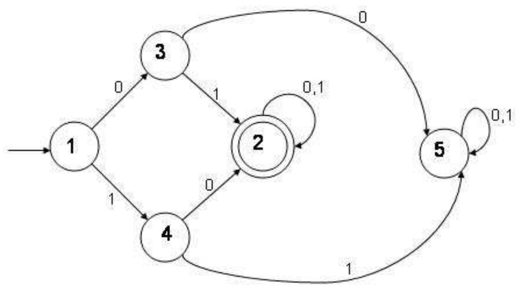

Figure 3: The minimal DFA for the parity language $L[\{1,2\}]$

Note that the output of our algorithm is not an explicit automaton. Instead, we output a collection of DFAs $\{A_1, A_2, \ldots, A_T\}$ with corresponding weights $\alpha_t \in \mathbb{R}$, with the hypothesis language $\hat{L}$ given by

$$\hat{L} = \left\{ x \in \{0,1\}^* : \sum_{t=1}^{T} \alpha_t \mathbb{1}_{\{x \in L(A_t)\}} > 0 \right\}. \tag{27}$$

An interesting question is the relation between $\hat{L}$ and the true unknown language L_0. In principle, the DFA for $\hat{L}$ can be recovered exactly, using the algorithmic construction given in the proof of Theorem 17. However, this procedure has exponential complexity in T and is certainly infeasible for $T \sim 100$. Thus, rather than recovering the *exact* DFA corresponding to $(\{A_t\}, \{\alpha_t\})$, we implement Angluin's algorithm for learning DFAs from membership and equivalence queries (Angluin, 1982). Testing whether a string x belongs to $\hat{L}$ is achievable in time $O(T|x|)$, so membership queries pose no problem. As discussed above, testing whether Angluin's hypothesis language L_{ANGL} is equivalent to $\hat{L}$ is infeasible (at least using the brute-force construction; we do not exclude the possibility of some clever efficient approach). Instead, we only compare L_{ANGL} and $\hat{L}$ on the labeled sample (S, Y). If $\chi_{L_{\text{ANGL}}}(x) = Y_x$ for all $x \in S$, we declare the two equal; otherwise, the first string on which the two disagree is fed as a counterexample into Angluin's algorithm.

We drew a sample of 300 strings in $\{0,1\}^*$ uniformly with mean Poisson length 10, as described in Section 8.1. These strings were labeled consistently with $L[\{1,2\}]$. On this labeled sample we ran the algorithm `RegLearn`, as defined in Theorems 15, and 19, which outputs the language $\hat{L}$, as given in (27). The hypothesis $\hat{L}$ attained an accuracy of 91% on unseen strings and our adaptation of Angluin's algorithm recovered $L[\{1,2\}]$ *exactly* 88% of the time. When this experiment was repeated on $L[\{1,3\}]$, whose minimal DFA has 7 states, prediction accuracy of `RegLearn` dropped to 86% while the target automaton was recovered exactly only 1% of the time. It seems that relatively large sample sizes are needed for exact recovery, though we are not able to quantify (or even conjecture) a rate at this point.

8.3.2 EMPIRICAL MARGIN

We took the "complete" sample $S = \{0,1\}^{\leq 7}$ (i.e., $|S| = 255$) and labeled it with $L[\{1,k\}]$, for $k = 2,3,4,5$. The algorithm `RegLearn` (as a special case of `UnivLearn`) finds the optimal empirical margin $\tilde{\gamma}_*$ as defined in (23). We repeated this experiment a few dozen times—since the kernel is random, the margins obtained are also random. The results are presented in Figure 4, but should be interpreted with caution. As expected, the margin is decreasing with automaton size (the latter given by $2k+1$, as per Claim 20(b)). It is difficult to discern a trend (polynomial/exponential decay) from four points, and extending the experiment for moderate-sized k is computationally expensive.

8.3.3 LONG INPUT STRINGS

One of the claimed advantages of our method is that long training strings do not significantly affect hypothesis complexity. To test this claim empirically, we fixed the target language at $L[\{1,2\}]$ and let the mean string length λ vary from 10 to 100 in increments of 10. For each value of λ, we drew a sample S of 300 strings in $\{0,1\}^*$ uniformly with mean Poisson length λ (as described in Section 8.1) and labeled S consistently with $L[\{1,2\}]$. On this labeled sample we ran the algorithm `RegLearn`, and tested its prediction accuracy on 100 new strings. The results are displayed in Figure 5 and show a graceful degradation of performance. In particular, for strings of mean length

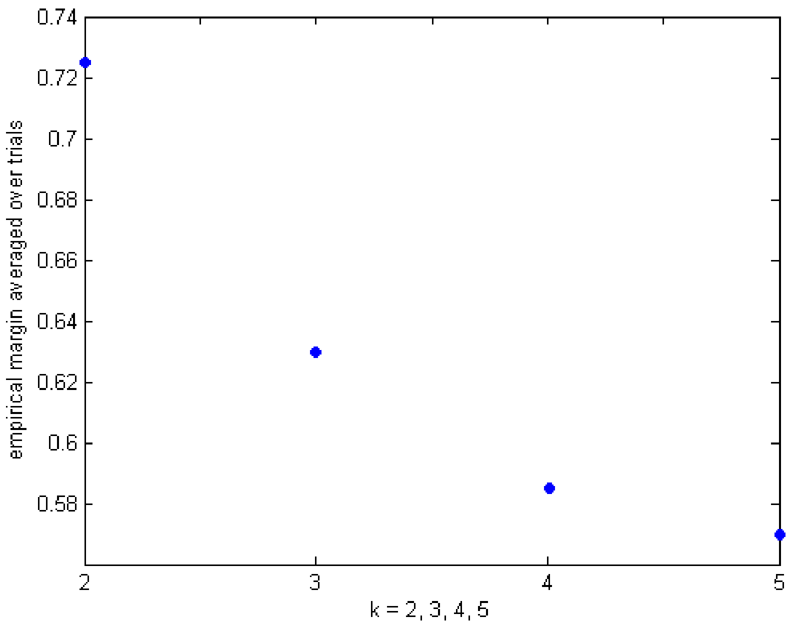

Figure 4: Empirical margins of $L[\{1,k\}]$, for $k = 2,3,4,5$

100, the learner performs significantly better than chance—even though learning parity languages from long strings entails high-dimensional feature selection. This example illustrates the tradeoff between information and computational complexity. If we had unbounded resources, exhaustive enumeration over all automata would most likely find the correct automaton. It is not clear how standard methods, such as the RPNI algorithm (Oncina and Garcia, 1992) would process input strings of such length.

9. Inherent Limitations

An immediate question is, How does the "margin learning rate" $R(\cdot)$ appearing in Theorems 3 and 15 relate to the target concept complexity (say, as measured by $\|\cdot\|$)? One might hope for a bound of the type

$$R(c) \quad = \quad O(\text{poly}(\|c\|)).$$

Unfortunately, under standard cryptographic assumptions this cannot hold in general, as we demonstrate for the case of DFAs. For reference, let us state the Discrete Cube Root (DCR) assumption as it appears in Kearns and Vazirani (1997). In what follows, $N = pq$ is an n-bit number and p,q are randomly chosen primes so that 3 does not divide $(p-1)(q-1)$. The multiplicative group modulo N is denoted by $\mathbb{Z}_N^*$ and x is chosen uniformly random in $\mathbb{Z}_N^*$. DCR states that for every polynomial r, there is no algorithm with running time $r(n)$ that on input N and $y = x^3 \bmod N$ outputs x with probability exceeding $1/r(n)$ (the probability is taken over p,q,x, and the algorithm's internal randomization).

The following theorem is implicit in chapters 6 and 7 of Kearns and Vazirani (1997), and is a combination of results in Pitt and Warmuth (1990) and Kearns and Valiant (1994):

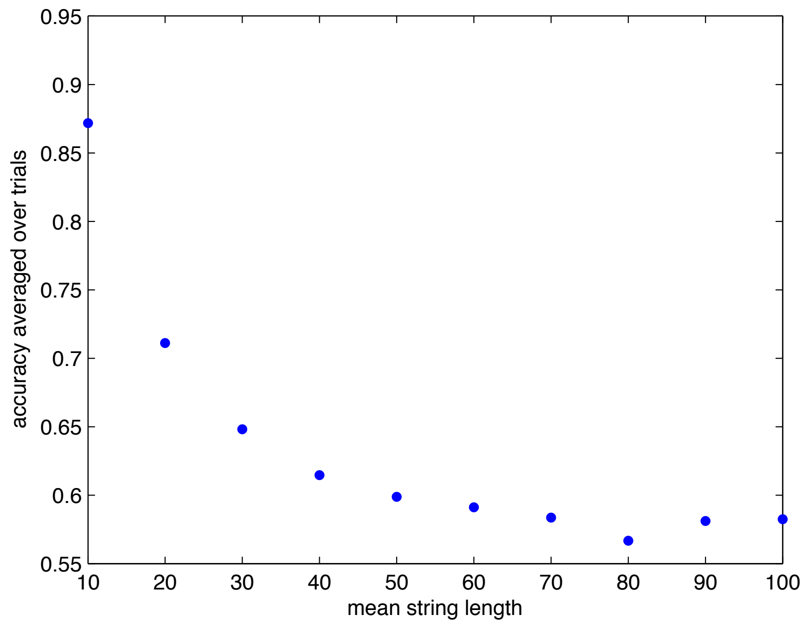

Figure 5: Prediction accuracy when training on long strings

Theorem 21 *For every polynomial p, there is a sequence of distributions P_n on $\{0,1\}^n$ and finite state automata A_n, with $\mathrm{size}(A_n) = \mathrm{poly}(n)$ such that assuming DCR, there is no algorithm with running time $p(n)$ that produces a hypothesis that agrees with A_n on more than $1/2 + 1/p(n)$ of P_n.*

We will refer to the concept-dependent quantity $R(c)$ appearing in theorems 3, 15, and 19 as the *margin-based rate* and the parameter $D(c)$ appearing in Theorems 15, and 19 as the *intrinsic dimension*. Under the DCR assumption, these quantities cannot both grow polynomially in the target automaton size for *all* automata:

Corollary 22 *If DCR is true, there is no efficiently computable (or approximable) universal regular kernel K and polynomial p such that for every finite state automaton A, we have $\max\{R(A), D(A)\} \leq p(\mathrm{size}(A))$ under K.*

Proof We argue by contradiction. Suppose K is an efficiently computable universal regular kernel, and that for some polynomial p we have the margin-based rate $R(A) \leq p(\mathrm{size}(A))$ under K, for every DFA A. Then by Theorem 3, a sample of size $p(\mathrm{size}(A))^2$ suffices to guarantee (with high probability) the existence of a classifier with polynomially small generalization error, and there is an efficient algorithm (e.g., SVM) to discover such a classifier. This contradicts Theorem 21. A similar contradiction is obtained via Theorem 15 if K is efficiently approximable. ■

Still focusing on the special case of DFAs, another natural line of inquiry is the relationship between the true target language L and the hypothesis language $\hat{L}$ induced by our learning algorithm (note that $\hat{L}$ is necessarily regular, by Theorem 17). In particular, it would be desirable to have a handle on the complexity of the minimal DFA accepting $\hat{L}$ in terms of the corresponding minimal

DFA for L. To be more concrete, suppose we have observed a finite sample $S \subset \Sigma^*$ with labels $Y \in \{-1,1\}^S$. We compute a maximum-margin hyperplane (i.e., a set of weights $\alpha \in \mathbb{R}^S$) for this sample, and consider the resulting language

$$L(S,\alpha) \quad = \quad \{x \in \mathcal{X} : \sum_{s \in S} \alpha_s \tilde{K}(s,x) > 0\}$$

where $\tilde{K}$ is the approximate kernel constructed by the algorithm of Theorem 15; note that $L(S,\alpha)$ is regular. Let $A_0(S,Y)$ be the smallest DFA consistent with the labeled sample (S,Y) and let $A_0(S,\alpha)$ denote the smallest DFA recognizing $L(S,\alpha)$. Now approximately recovering $A_0(S,\alpha)$ is feasible via active learning (see Chapter 8 of Kearns and Vazirani 1997). Given a hyperplane representation for a regular language one may efficiently query the resulting classifier on any string in $x \in \Sigma^*$ to see if $x \in L(S,\alpha)$. Using membership and equivalence queries, Angluin's algorithm (Angluin, 1987) recovers $A_0(S,\alpha)$ exactly. If only membership queries are allowed, we can draw enough strings $x \in \Sigma^*$ according to a distribution P to simulate an equivalence query efficiently, to arbitrary P-accuracy. Note that $L(A)$ and $L(A')$ can differ by only one (very long) word, while the two automata may be of exponentially different size. We do not currently have either (a) an efficient method of exactly recovering $A_0(S,\alpha)$ nor can we claim that (b)

$$\mathrm{size}(A_0(S,\alpha)) \quad \leq \quad \mathrm{poly}(\mathrm{size}(A_0(S,Y)));$$

note that if both (a) and (b) were true, that would imply P=NP via the Pitt and Warmuth (1993) hardness of approximation result.

Another limitation of our approach is the possibility of a "Boolean-independent" concept class $\mathcal{C}$, in which no $c \in \mathcal{C}$ may be expressed as a finite Boolean combination of other concepts. One way to construct such a concept class is by taking $\mathcal{X} = \mathbb{N}$ and $\mathcal{C} = \{c_p : p \text{ is prime}\}$, where

$$x \in c_p \quad \Leftrightarrow \quad x \equiv 0 \pmod{p}.$$

That $\mathcal{C}$ is Boolean-independent is seen by taking k distinct primes $\{p_i : 1 \leq i \leq k\}$ and an arbitrary $b \in \{0,1\}^k$. Then the number

$$N_b := \prod_{i=1}^{k} (p_i + b_i)$$

is divisible by p_i iff $b_i = 0$; thus the divisibility of N by $p_1, p_2, \ldots, p_{k-1}$ gives no information regarding its divisibility by p_k. In a Boolean-independent class, no concept may be expressed as a finite linear combination of other concepts (the contrapositive of this claim is established while proving the "if" direction of Theorem 17). Alas, Boolean independence is an inevitable feature of nontrivial concept classes:

Theorem 23 *Any infinite concept class $\mathcal{C}$ contains an infinite Boolean-independent subset.*

Proof Suppose $\mathcal{C}$ contains no infinite Boolean-independent subsets. This means that every $c \in \mathcal{C}$ may be expressed as a finite Boolean combination of elements $\{e_i\}$ from some finite $E \subset \mathcal{C}$. But the Boolean closure of a finite collection of sets is finite, so $\mathcal{C}$ must be finite. ■

The moral of this section is that our approach is certainly vulnerable to the same classical computational hardness reductions as other discrete concept-learning methodologies. One must keep in mind, however, that the hardness reductions are pessimistic, based on carefully contrived target concepts and distributions. As noted in Section 8, "typical" or "random" concepts are often much easier to learn than their worst-case cousins (which is unsurprising given the numerous NP-hard but easy-on-average problems; see, for example Chvátal and Szemerédi 1988 or Flaxman 2003).

10. Discussion

We have presented a new generic technique for learning general countable concept classes and applied it to regular languages. Aside from its generality and ease of implementation, our approach offers certain advantages over existing techniques. Observe that the complexity of the classifier constructed in Theorem 15 does not directly depend on the input string lengths. For the case of learning regular languages, it means that the training string lengths do not affect hypothesis complexity. This is not the case for the methods surveyed in the Introduction, which build a prefix tree acceptor in the initial phase. As already mentioned, we make no structural assumptions on the target automaton (such as acyclic or nearly so), or on the sampling distribution (such as the sample being "structurally complete").

In practice, given m samples, our approach attempts to fit the labeled data by a linear combination of concepts with bounded complexity, $\|c\| \leq \theta(m)$. This method may fail for two possible reasons: Either we don't have sufficient number of samples to learn the unknown target concept, or we got unlucky - this specific concept has a very small margin. Note that these sample size restrictions are inherent also in the SRM framework, for example in Theorem 8.

The experiments presented in Section 8 provide support for our approach. Our basic method could be easily adapted to learning context-free and other grammars. There are obvious computability limitations—thus, if our concept class is all Turing-recognizable languages, the corresponding universal kernel is provably uncomputable (Blocki, 2007). Modulo these limitations, any concept class satisfying the efficient sampling and membership evaluation assumptions (Assumptions 10 and 11) is amenable to our approach.

Our work naturally raises some interesting questions—in particular, regarding learning regular languages. We conclude the paper with a few of them.

1. Can K_{REG} be efficiently computed? Is it a #P-complete problem? Is there *any* efficiently computable universal regular kernel?

2. Can $A_0(S,\alpha)$ be efficiently recovered from its hyperplane representation? Can $\text{size}(A_0(S,\alpha))$ be nontrivially bounded in terms of $\text{size}(A_0(S,Y))$? (The notation is from the previous section.)

3. Corollary 22 seems to thwart attempts to bound the margin-based rate for a regular language in terms of the size of its minimal DFA. Is there a different natural complexity measure for regular languages which does allow a polynomial bound on the margin-based rate?

4. The intractability results in Theorem 21 are highly pessimistic, in that both the automaton and the training/testing distribution are contrived to be pathological. What about the complexity of learning "typical" automata—say, those drawn uniformly from $\text{DFA}(n)$? What can be said

about the margin distribution of such automata? Similarly, what about their sample margin, under some natural class of distributions on the strings Σ^*?

Acknowledgments

AK's work at Carnegie Mellon took place under the guidance of John Lafferty, with part of the support from NSF ITR grant IIS-0205456. The research continued at the Weizmann Institute, where AK is being hosted by Gideon Schechtman, and supported in part by the Israel Science Foundation. BN was supported by the Lord Sieff of Brimpton Memorial fund. Various key concepts were crystallized during AK's many valuable discussions with Corinna Cortes and Mehryar Mohri. Abstract

We consider the problem of multi-task reinforcement learning (MTRL) in multiple partially observable stochastic environments. We introduce the regionalized policy representation (RPR) to characterize the agent's behavior in each environment. The RPR is a parametric model of the conditional distribution over current actions given the history of past actions and observations; the agent's choice of actions is directly based on this conditional distribution, without an intervening model to characterize the environment itself. We propose off-policy batch algorithms to learn the parameters of the RPRs, using episodic data collected when following a behavior policy, and show their linkage to policy iteration. We employ the Dirichlet process as a nonparametric prior over the RPRs across multiple environments. The intrinsic clustering property of the Dirichlet process imposes sharing of episodes among similar environments, which effectively reduces the number of episodes required for learning a good policy in each environment, when data sharing is appropriate. The number of distinct RPRs and the associated clusters (the sharing patterns) are automatically discovered by exploiting the episodic data as well as the nonparametric nature of the Dirichlet process. We demonstrate the effectiveness of the proposed RPR as well as the RPR-based MTRL framework on various problems, including grid-world navigation and multi-aspect target classification. The experimental results show that the RPR is a competitive reinforcement learning algorithm in partially observable domains, and the MTRL consistently achieves better performance than single task reinforcement learning.

Keywords: reinforcement learning, partially observable Markov decision processes, multi-task learning, Dirichlet processes, regionalized policy representation

1. Introduction

Planning in a partially observable stochastic environment has been studied extensively in the fields of operations research and artificial intelligence. Traditional methods are based on partially observable Markov decision processes (POMDPs) and assume that the POMDP models are given (Sondik, 1971; Smallwood and Sondik, 1973). Many POMDP planning algorithms (Sondik, 1971, 1978; Cheng, 1988; Lovejoy, 1991; Hansen, 1997; Kaelbling et al., 1998; Poupart and Boutilier, 2003; Pineau et al., 2003; Spaan and Vlassis, 2005; Smith and Simmons, 2005; Li et al., 2006a,b) have been proposed, addressing problems of increasing complexity as the algorithms become progressively more efficient. However, the assumption of knowing the underlying POMDP model is often difficult to meet in practice. In many cases the only knowledge available to the agent are experiences, that is, the observations and rewards, resulting from interactions with the environment, and the agent must learn the behavior policy based on such experience. This problem is known as reinforcement learning (RL) (Sutton and Barto, 1998). Reinforcement learning methods generally fall into two broad categories: model-based and model-free. In model-based methods, one first builds a POMDP model based on experiences and then exploits the existing planning algorithms to find the POMDP policy. In model-free methods, one directly infers the policy based on experiences. The focus of this paper is on the latter, trying to find the policy for a partially observable stochastic environment without the intervening stage of environment-model learning.

In model-based approaches, when the model is updated based on new experiences gathered from the agent-environment interaction, one has to solve a new POMDP planing problem. Solving a POMDP is computationally expensive, which is particularly true when one takes into account the model uncertainty; in the latter case the POMDP state space grows fast, often making it inefficient to find even an approximate solution (Wang et al., 2005). Recent work (Ross et al., 2008) gives a relatively efficient approximate model-based method, but still the computation time grows exponentially with the planning horizon. By contrast, model-free methods update the policy directly, without the need to update an intervening POMDP model, thus saving time and eliminating the errors introduced by approximations that may be made when solving the POMDP.

Model-based methods suffer particular computational inefficiency in multi-task reinforcement learning (MTRL), the problem being investigated in this paper, because one has to repeatedly solve multiple POMDPs due to frequent experience-updating arising from the communications among different RL tasks. The work in Wilson et al. (2007) assumes the environment states are perfectly observable, reducing the POMDP in each task to a Markov decision process (MDP); since a MDP is relatively efficient to solve, the computational issue is not serious there. In the present paper, we assume the environment states are partially observable, thus manifesting a POMDP associated with each environment. If model-based methods are pursued, one would have to solve multiple POMDPs for each update of the task clusters, which entails a prohibitive computational burden.

Model-free methods are consequently particularly advantageous for MTRL in partially observable domains. The regionalized policy representation (RPR) proposed in this paper, which yields an efficient parametrization for the policy governing the agent's behavior in each environment, lends itself naturally to a Bayesian formulation and thus furnishes a posterior distribution of the policy. The policy posterior allows the agent to reason and plan under uncertainty about the policy itself. Since the ultimate goal of reinforcement learning is the policy, the policy's uncertainty is more direct and relevant to the learning goal than the POMDP model's uncertainty as considered in Ross et al. (2008).

The MTRL problem considered in this paper shares similar motivations as the work in Wilson et al. (2007)—that is, in many real-world settings there may be multiple environments for which policies are desired. For example, a single agent may have collected experiences from previous environments and wishes to borrow from previous experience when learning the policy for a new environment. In another case, multiple agents are distributed in multiple environments, and they wish to communicate with each other and share experiences such that their respective performances are enhanced. In either case the experiences in one environment should be properly exploited to benefit the learning in another (Guestrin et al., 2003). Appropriate experience sharing among multiple environments and joint learning of multiple policies save resources, improve policy quality, and enhance generalization to new environments, especially when the experiences from each individual environment are scarce (Thrun, 1996). Many problems in practice can be formulated as an MTRL problem, with one example given in Wilson et al. (2007). The application we consider in the experiments (see Section 6.2.3) is another example, in which we make the more realistic assumption that the states of the environments are partially observable.

To date there has been much work addressing the problem of inferring the sharing structure between general learning tasks. Most of the work follows a hierarchical Bayesian approach, which assumes that the parameters (models) for each task are sampled from a common prior distribution, such as a Gaussian distribution specified by unknown hyper-parameters (Lawrence and Platt, 2004; Yu et al., 2003). The parameters as well as the hyper-parameters are estimated simultaneously in the learning phase. In Bakker and Heskes (2003) a single Gaussian prior is extended to a Gaussian mixture; each task is given a corresponding Gaussian prior and related tasks are allowed to share a common Gaussian prior. Such a formulation for information sharing is more flexible than a single common prior, but still has limitations: the form of the prior distribution must be specified *a priori*, and the number of mixture components must also be pre-specified.

In the MTRL framework developed in this paper, we adopt a nonparametric approach by employing the Dirichlet process (DP) (Ferguson, 1973) as our prior, extending the work in Yu et al. (2004) and Xue et al. (2007) to model-free policy learning. The nonparametric DP prior does not assume a specific form, therefore it offers a rich representation that captures complicated sharing patterns among various tasks. A nonparametric prior drawn from the DP is almost surely discrete, and therefore a prior distribution that is drawn from a DP encourages task-dependent parameter clustering. The tasks in the same cluster share information and are learned collectively as a group. The resulting MTRL framework automatically learns the number of clusters, the members in each cluster as well as the associated common policy.

The nonparametric DP prior has been used previously in MTRL (Wilson et al., 2007), where each task is a Markov decision process (MDP) assuming perfect state observability. To the authors' knowledge, this paper represents the first attempt to apply the DP prior to reinforcement learning in multiple partially observable stochastic environments. Another distinction is that the method here is model-free, with information sharing performed directly at the policy level, without having to learn a POMDP model first; the method in Wilson et al. (2007) is based on using MDP models.

This paper contains several technical contributions. We propose the regionalized policy representation (RPR) as an efficient parametrization of stochastic policies in the absence of a POMDP model, and develop techniques of learning the RPR parameters based on maximizing the sum of discounted rewards accrued during episodic interactions with the environment. An analysis of the techniques is provided, and relations are established to the expectation-maximization algorithm and the POMDP policy improvement theorem. We formulate the MTRL framework by placing multiple RPRs in a Bayesian setting and employ a draw from the Dirichlet process as their common nonparametric prior. The Dirichlet process posterior is derived, based on a nonconventional application of Bayes law. Because the DP posterior involves large mixtures, Gibbs sampling analysis is inefficient. This motivates a hybrid Gibbs-variational algorithm to learn the DP posterior. The proposed techniques are evaluated on four problem domains, including the benchmark Hallway2 (Littman et al., 1995), its multi-task variants, and a remote sensing application. The main theoretical results in the paper are summarized in the form of theorems and lemmas, the proofs of which are all given in the Appendix.

The RPR formulation in this paper is an extension of the work in Li (2006) and Liao et al. (2007). All other content in the paper is extended from the work in Li (2006).

2. Partially Observable Markov Decision Processes

The partially observable Markov decision process (POMDP) (Sondik, 1971; Lovejoy, 1991; Kaelbling et al., 1998) is a mathematical model for the optimal control of an agent situated in a partially observable stochastic environment. In a POMDP the state dynamics of the agent are governed by a Markov process, and the state of the process is not completely observable but is inferred from observations; the observations are probabilistically related to the state. Formally, the POMDP can be described as a tuple $(\mathcal{S}, \mathcal{A}, T, O, \Omega, R)$, where $\mathcal{S}$, $\mathcal{A}$, O respectively denote a finite set of states, actions, and observations; T are state-transition matrices with $T_{ss'}(a)$ the probability of transiting to state s' by taking action a in state s; Ω are observation functions with $\Omega_{s'o}(a)$ the probability of observing o after performing action a and transiting to state s'; and R is a reward function with $R(s,a)$ the expected immediate reward received by taking action a in state s.

The optimal control of a POMDP is represented by a policy for choosing the best action at any time such that the future expected reward is maximized. Since the state in a POMDP is only partially observable, the action choice is based on the belief state, a sufficient statistic defined as the probability distribution of the state s given the history of actions and observations (Sondik, 1971). It is important to note that computation of the belief state requires knowing the underlying POMDP model.

The belief state constitutes a continuous-state Markov process (Smallwood and Sondik, 1973). Given that at time t the belief state is b and the action a is taken, and the observation received at time $t+1$ is o, then the belief state at time $t+1$ is computed by Bayes rule

$$b_o^a(s') = \frac{\sum_{s\in\mathcal{S}} b(s) T_{ss'}^a \Omega_{s'o}^a}{p(o|b,a)}, \tag{1}$$

where the superscript a and the subscript o are used to indicate the dependence of the new belief state on a and o, and

$$p(o|b,a) = \sum_{s'\in\mathcal{S}} \sum_{s\in\mathcal{S}} b(s) T_{ss'}^a \Omega_{s'o}^a \tag{2}$$

is the probability of transiting from b to b' when taking action a.

Equations (1) and (2) imply that, for any POMDP, there exists a corresponding Markov decision process (MDP), the state of which coincides with the belief state of the POMDP (hence the term "belief-state MDP"). Although the belief state is continuous, their transition probabilities are discrete : from any given b, one can only make a transition to a finite number of new belief states $\{b_o^a : a \in \mathcal{A}, o \in O\}$, assuming $\mathcal{A}$ and O are discrete sets with finite alphabets. For any action $a \in \mathcal{A}$, the belief state transition probabilities are given by

$$p(b'|b,a) = \begin{cases} p(o|b,a), & \text{if } b' = b_o^a \\ 0, & \text{otherwise} \end{cases} . \tag{3}$$

The expected reward of the belief-state MDP is given by

$$R(b,a) = \sum_{s\in\mathcal{S}} b(s) R(s,a). \tag{4}$$

In summary, the belief-state MDP is completely defined by the action set $\mathcal{A}$, the space of belief state

$$\mathcal{B} = \left\{ b \in \mathbb{R}^{|\mathcal{S}|} : b(s) \geq 0, \sum_{s\in\mathcal{S}} b(s) = 1 \right\},$$

along with the belief state transition probabilities in (3) and the reward function in (4).

The optimal control of the POMDP can be found by solving the corresponding belief-state MDP. Assume that at any time there are infinite steps remaining for the POMDP (infinite horizon), the future rewards are discounted exponentially with a factor $0 < \gamma < 1$, and the action is drawn from $p^{\Pi}(a|b)$, then the expected reward accumulated over the infinite horizon satisfies the Bellman equation (Bellman, 1957; Smallwood and Sondik, 1973)

$$V^{\Pi}(b) = \sum_{a \in \mathcal{A}} p^{\Pi}(a|b) \left[R(b,a) + \gamma \sum_{o \in \mathcal{O}} p(o|b,a) V^{\Pi}(b_o^a) \right],$$

where $V^{\Pi}(b)$ is called the value function. Sondik (1978) showed that, for a finite-transient deterministic policy,[1] there exists a Markov partition $\mathcal{B} = \mathcal{B}_1 \cup \mathcal{B}_2 \cup \cdots$ satisfying the following two properties :

(a) There is a unique optimal action a_i associated with subset $\mathcal{B}_i$, $i = 1, 2, \cdots$. This implies that the optimal control is represented by a deterministic mapping from the Markov partition to the set of actions.

(b) Each subset maps completely into another (or itself), that is, $\{b_o^a : b \in \mathcal{B}_i, a = \Pi(b), o \in \mathcal{O}\} \subseteq \mathcal{B}_j$ (i may equal j).

The Markov partition yields an equivalent representation of the finite-transient deterministic policy. Sondik noted that an arbitrary policy Π is not likely to be finite-transient, and for it one can only construct a partition where one subset maps partially into another (or itself), that is, there exists $b \in \mathcal{B}_i$ and $o \in \mathcal{O}$ such that $b_o^{\Pi(b)} \notin \mathcal{B}_j$. Nevertheless, the Markov partition provides an approximate representation for non-finite-transient policies and Sondik gave an error bound of the difference between the true value function and approximate value function obtained by the Markov partition. Based on the Markov partition, Sondik also proposed a policy iteration algorithm for POMDPs, which was later improved by Hansen (1997) and the improved algorithm is referred to as finite state controller (the partition is finite).

3. Regionalized Policy Representation

We are interested in model-free policy learning, that is, we assume the model of the POMDP is *unknown* and aim to learn the policy directly from the experiences (data) collected from agent-environment interactions. One may argue that we do in fact learn a model, but our model is directly at the policy level, constituting a *probabilistic* mapping from the space of action-observation histories to the action space.

Although the optimal control of a POMDP can be obtained via solving the corresponding belief-state MDP, this is not true when we lack an underlying POMDP model. This is because, as indicated above, the observability of the belief-state depends on the availability of the POMDP model. When the model is unknown, one does not have access to the information required to compute the belief state, making the belief state *unobservable*.

1. Let Π be a deterministic policy, that is, $p^{\Pi}(a|b) = \begin{cases} 1, & \text{if } a = \Pi(b) \\ 0, & \text{otherwise} \end{cases}$. Let S_{Π}^n be the set of all possible belief-states when Π has been followed for n consecutive steps by starting from any initial belief-state. The Π is finite transient if and only if there exists $n < \infty$ such that S_{Π}^n is disjoint with $\{b : \Pi(b) \text{ is discontinuous at } b\}$ (Sondik, 1978).

In this paper, we treat the belief-state as a hidden (latent) variable and marginalize it out to yield a stochastic POMDP policy that is purely dependent on the observable history, that is, the sequence of previous actions and observations. The belief-state dynamics, as well as the optimal control in each state, is learned empirically from experiences, instead of being computed from an underlying POMDP model. Although it may be possible to learn the dynamics and control in the continuous space of belief state, the exposition in this paper is restricted to the discrete case, that is, the case for which the continuous belief-state space is quantized into a finite set of disjoint regions. The quantization can be viewed as a stochastic counterpart of the Markov partition (Sondik, 1978), discussed at the end of Section 2. With the quantization, we learn the dynamics of belief regions and the local optimal control in each region, both represented stochastically. The stochasticity manifests the uncertainty arising from the belief quantization (the policy is parameterized in terms of latent belief *regions*, not the precise belief state). The stochastic policy reduces to a deterministic one when the policy is finitely transient, in which case the quantization becomes a Markov partition. The resulting framework is termed *regionalized policy representation* to reflect the fact that the policy of action selection is expressed through the dynamics of belief regions as well as the local controls in each region. We also use *decision state* as a synonym of *belief region*, in recognition of the fact that each belief region is an elementary unit to encode the decisions of action selection.

3.1 Formal Framework

Definition 1 *A* regionalized policy representation *(RPR) is a tuple $\langle \mathcal{A}, \mathcal{O}, \mathcal{Z}, W, \mu, \pi \rangle$ specified as follows. The $\mathcal{A}$ and $\mathcal{O}$ are respectively a finite set of actions and observations. The $\mathcal{Z}$ is a finite set of decision states (belief regions). The W are decision-state transition matrices with $W(z,a,o',z')$ denoting the probability of transiting from z to z' when taking action a in decision state z results in observing o'. The μ is the initial distribution of decision states with $\mu(z)$ denoting the probability of initially being in decision state z. The π are state-dependent* stochastic *policies with $\pi(z,a)$ denoting the probability of taking action a in decision state z.*

The stochastic formulation of W and π in Definition 1 is fairly general and subsumes two special cases.

1. If z shrinks down to a single belief-state b, $z = b$ becomes a sufficient statistic of the POMDP (Smallwood and Sondik, 1973) and there is a unique action associated with it, thus $\pi(z,a)$ is deterministic and the local policy can be simplified as $a = \pi(b)$.

2. If the belief regions form a Markov partition of the belief-state space (Sondik, 1978), that is, $\mathcal{B} = \cup_{z \in \mathcal{Z}} \mathcal{B}_z$, then the action choice in each region is constant and one region transits completely to another (or itself). In this case, both W and π are deterministic and, moreover, the policy yielded by the RPR (see (8)) is finite transient deterministic. In fact this is the same case as considered in Hansen (1997).

In both of the two special cases, each z has one action choice $a = \pi(z)$ associated with it, and one can write $W(z,a,o',z') = W(z,\pi(z),o',z')$, thus the transition of z is driven solely by o. In general, each z represents multiple individual belief-states, and the belief region transition is driven jointly by a and o. The action-dependency captures the state dynamics of the POMDP, and the observation-dependency reflects the partial observability of the state (perception aliasing).

To make notation simple, the following conventions are observed throughout the paper:

- The elements of $\mathcal{A}$ are enumerated as $\mathcal{A} = \{1,2,\cdots,|\mathcal{A}|\}$, where $|\mathcal{A}|$ denotes the cardinality of $\mathcal{A}$. Similarly, $\mathcal{O} = \{1,2,\cdots,|\mathcal{O}|\}$ and $\mathcal{Z} = \{1,2,\cdots,|\mathcal{Z}|\}$.
- A sequence of actions $(a_0,a_1,\cdots,a_T)$ is abbreviated as $a_{0:T}$, where the subscripts index discrete time steps. Similarly a sequence of observations $(o_1,o_2,\cdots,o_T)$ is abbreviated as $o_{1:T}$, and a sequence of decision states $(z_0,z_1,\cdots,z_T)$ is abbreviated as $z_{0:T}$, etc.
- A history h_t is the set of actions executed and observation received up to time step t, that is, $h_t = \{a_{0:t-1}, o_{1:t}\}$.

Let $\Theta = \{\pi,\mu,W\}$ denote the parameters of the RPR. Given a history of actions and observations, $h_t = (a_{0:t-1}, o_{1:t})$, collected up to time step t, the RPR yields a joint probability distribution of $z_{0:t}$ and $a_{0:t}$

$$p(a_{0:t}, z_{0:t}|o_{1:t},\Theta) = \mu(z_0)\pi(z_0,a_0)\prod_{\tau=1}^{t} W(z_{\tau-1},a_{\tau-1},o_\tau,z_\tau)\pi(z_\tau,a_\tau), \tag{5}$$

where application of local controls $\pi(z_t,a_t)$ at every time step implies that $a_{0:t}$ are all drawn according to the RPR. The decision states $z_{0:t}$ in (5) are hidden variables and we marginalize them to get

$$p(a_{0:t}|o_{1:t},\Theta) = \sum_{z_0,\cdots,z_t=1}^{|\mathcal{Z}|}\left[\mu(z_0)\pi(z_0,a_0)\prod_{\tau=1}^{t} W(z_{\tau-1},a_{\tau-1},o_\tau,z_\tau)\pi(z_\tau,a_\tau)\right]. \tag{6}$$

It follows from (6) that

$$\begin{aligned} p(a_{0:t-1}|o_{1:t},\Theta) &= \sum_{a_t=1}^{|\mathcal{A}|} p(a_{0:t}|o_{1:t},\Theta) \\ &= \sum_{z_0,\cdots,z_{t-1}=1}^{|\mathcal{Z}|}\left[\mu(z_0)\pi(z_0,a_0)\prod_{\tau=1}^{t-1} W(z_{\tau-1},a_{\tau-1},o_\tau,z_\tau)\pi(z_\tau,a_\tau)\right] \\ &\qquad \times \underbrace{\sum_{a_t=1}^{|\mathcal{A}|}\sum_{z_t=1}^{|\mathcal{Z}|} W(z_{t-1},a_{t-1},o_t,z_t)\pi(z_t,a_t)}_{=1} \\ &= p(a_{0:t-1}|o_{1:t-1},\Theta), \end{aligned} \tag{7}$$

which implies that observation o_t does not influence the actions before t, in agreement with expectations. From (6) and (7), we can write the history-dependent distribution of action choices

$$p(a_\tau|h_\tau,\Theta) = p(a_\tau|a_{0:\tau-1},o_{1:\tau},\Theta) = \frac{p(a_{0:\tau}|o_{1:\tau},\Theta)}{p(a_{0:\tau-1}|o_{1:\tau},\Theta)} = \frac{p(a_{0:\tau}|o_{1:\tau},\Theta)}{p(a_{0:\tau-1}|o_{1:\tau-1},\Theta)}, \tag{8}$$

which gives a stochastic RPR policy for choosing the action a_t, given the historical actions and observations. The policy is purely history-dependent, with the unobservable belief regions z integrated out.

The history h_t forms a Markov process with transitions driven by actions and observations: $h_t = h_{t-1} \cup \{a_{t-1}, o_t\}$. Applying this recursively, we get $h_t = \cup_{\tau=1}^{t}\{a_{\tau-1},o_\tau\}$, and therefore

$$\prod_{\tau=0}^{t} p(a_\tau|h_\tau,\Theta) = \left[\prod_{\tau=0}^{t-2} p(a_\tau|h_\tau,\Theta)\right] p(a_{t-1}|h_{t-1},\Theta)p(a_t|h_{t-1},a_{t-1},o_t,\Theta)$$

$$\begin{aligned}
&= \left[\prod_{\tau=0}^{t-2} p(a_\tau|h_\tau,\Theta)\right] p(a_{t-1:t}|h_{t-1},o_t,\Theta) \\
&= \left[\prod_{\tau=0}^{t-3} p(a_\tau|h_\tau,\Theta)\right] p(a_{t-2}|h_{t-2},\Theta)p(a_{t-1:t}|h_{t-2},a_{t-2},o_{t-1},o_t,\Theta) \\
&= \left[\prod_{\tau=0}^{t-3} p(a_\tau|h_\tau,\Theta)\right] p(a_{t-2:t}|h_{t-2},o_{t-1:t},\Theta) \\
&\vdots \\
&= p(a_{0:t}|h_0,o_{1:t},\Theta) \\
&= p(a_{0:t}|o_{1:t},\Theta), \qquad (9)
\end{aligned}$$

where we have used $p(a_\tau|h_\tau,o_{\tau+1:t}) = p(a_\tau|h_\tau)$ and $h_0 = \text{null}$. The rightmost side of (9) is the observation-conditional probability of joint action-selection at multiple time steps $\tau = 0,1,\cdots,t$. Equation (9) can be verified directly by multiplying (8) over $\tau = 0,1,\cdots,t$

$$\begin{aligned}
&\prod_{\tau=0}^{t} p(a_\tau|h_\tau,\Theta) \\
&= p(a_0|\Theta)\frac{p(a_{0:1}|o_1,\Theta)}{p(a_0|\Theta)}\frac{p(a_{0:2}|o_{1:2},\Theta)}{p(a_{0:1}|o_1,\Theta)}\cdots\frac{p(a_{0:t-1}|o_{1:t-1},\Theta)}{p(a_{0:t-2}|o_{1:t-2},\Theta)}\frac{p(a_{0:t}|o_{1:t},\Theta)}{p(a_{0:t-1}|o_{1:t-1},\Theta)} \\
&= p(a_{0:t}|o_{1:t},\Theta). \qquad (10)
\end{aligned}$$

It is of interest to point out the difference between the RPR and previous reinforcement learning algorithms for POMDPs. The reactive policy and history truncation (Jaakkola et al., 1995; Baxter and Bartlett, 2001) condition the action only upon the immediate observation or a truncated sequence of observations, without using the full history, and therefore these are clearly different from the RPR. The U-tree (McCallum, 1995) stores historical information along the branches of decision trees, with the branches split to improve the prediction of future return or utility. The drawback is that the tree may grow intolerably fast with the episode length. The finite policy graphs (Meuleau et al., 1999), finite state controllers (Aberdeen and Baxter, 2002), and utile distinction HMMs (Wierstra and Wiering, 2004) use internal states to memorize the full history, however, their state transitions are driven by observations only. In contrast, the dynamics of decision states in the RPR are driven jointly by actions and observations, the former capturing the dynamics of world-states and the latter reflecting the perceptual aliasing. Moreover, none of the previous algorithms is based on Bayesian learning, and therefore they are intrinsically not amenable to the Dirichlet process framework that is used in the RPR for multi-task examples.

3.2 The Learning Objective

We are interested in empirical learning of the RPR, based on a set of episodes defined as follows.

Definition 2 *(Episode) An episode is a sequence of agent-environment interactions terminated in an absorbing state that transits to itself with zero rewards (Sutton and Barto, 1998). An episode is denoted by* $(a_0^k r_0^k o_1^k a_1^k r_1^k \cdots o_{T_k}^k a_{T_k}^k r_{T_k}^k)$*, where the subscripts are discrete times, k indexes the episodes, and o, a, and r are respectively observations, actions, and immediate rewards.*

Definition 3 *(Sub-episode) A sub-episode is an episode truncated at a particular time step and retaining the immediate reward only at the time step where truncation occurs. The t-th sub-episode of episode $(a_0^k r_0^k o_1^k a_1^k r_1^k \cdots o_{T_k}^k a_{T_k}^k r_{T_k}^k)$ is defined as $(a_0^k o_1^k a_1^k \cdots o_t^k a_t^k r_t^k)$, which yields a total of $T_k + 1$ sub-episodes for this episode.*

The learning objective is to maximize the optimality criterion given in Definition 4. Theorem 5 introduced below establishes the limit of the criterion when the number of episodes approaches infinity.

Definition 4 *(The RPR Optimality Criterion) Let $\mathcal{D}^{(K)} = \{(a_0^k r_0^k o_1^k a_1^k r_1^k \cdots o_{T_k}^k a_{T_k}^k r_{T_k}^k)\}_{k=1}^K$ be a set of episodes obtained by an agent interacting with the environment by following policy Π to select actions, where Π is an arbitrary stochastic policy with action-selecting distributions $p^\Pi(a_t|h_t) > 0$, $\forall$ action a_t, $\forall$ history h_t. The RPR optimality criterion is defined as*

$$\widehat{V}(\mathcal{D}^{(K)};\Theta) \overset{def.}{=} \frac{1}{K}\sum_{k=1}^{K}\sum_{t=0}^{T_k}\frac{\gamma^t r_t^k}{\prod_{\tau=0}^{t} p^\Pi(a_\tau^k|h_\tau^k)}\prod_{\tau=0}^{t} p(a_\tau^k|h_\tau^k,\Theta), \tag{11}$$

where $h_t^k = a_0^k o_1^k a_1^k \cdots o_t^k$ is the history of actions and observations up to time t in the k-th episode, $0 < \gamma < 1$ is the discount, and Θ denotes the parameters of the RPR.

Theorem 5 *Let $\widehat{V}(\mathcal{D}^{(K)};\Theta)$ be as defined in Definition 4, then $\lim_{K\to\infty}\widehat{V}(\mathcal{D}^{(K)};\Theta)$ is the expected sum of discounted rewards within the environment under test by following the RPR policy parameterized by Θ, over an infinite horizon.*

Theorem 5 shows that the optimality criterion given in Definition 4 is the expected sum of discounted rewards in the limit, when the number of episodes approaches infinity. Throughout the paper, we call $\lim_{K\to\infty}\widehat{V}(\mathcal{D}^{(K)};\Theta)$ the value function and $\widehat{V}(\mathcal{D}^{(K)};\Theta)$ the empirical value function. The Θ maximizing the (empirical) value function is the best RPR policy (given the episodes).

It is assumed in Theorem 5 that the behavior policy Π used to collect the episodic data is an arbitrary policy that assigns nonzero probability to any action given any history, that is, Π is required to be a soft policy (Sutton and Barto, 1998). This premise assures a complete exploration of the actions that might lead to large immediate rewards given any history, that is, the actions that might be selected by the optimal policy.

4. Single-Task Reinforcement Learning (STRL) with RPR

We develop techniques to maximize the empirical value function in (11) and the Θ resulting from value maximization is called a Maximum-Value (MV) estimate (related to maximum *likelihood*). An MV estimate of the RPR is preferred when the number of episodes is large, in which case the empirical value function approaches the true value function and the estimate is expected to approach the optimal (assuming the algorithm is not trapped in a local minima). The episodes $\mathcal{D}^{(K)}$ are assumed to have been collected in a single partially observable stochastic environment, which may correspond to a single physical environment or a pool of multiple identical/similar physical environments. As a result, the techniques developed in this section are for single-task reinforcement learning (STRL).

By substituting (6) and (9) into (11), we rewrite the empirical value function

$$\widehat{V}(\mathcal{D}^{(K)};\Theta) = \frac{1}{K}\sum_{k=1}^{K}\sum_{t=0}^{T_k}\tilde{r}_t^k \sum_{z_0^k,\cdots,z_t^k=1}^{|\mathcal{Z}|} p(a_{0:t}^k, z_{0:t}^k | o_{1:t}^k, \Theta), \tag{12}$$

where

$$\tilde{r}_t^k = \frac{\gamma^t r_t^k}{\prod_{\tau=0}^{t} p^{\Pi}(a_\tau^k | h_\tau^k)}$$

is the discounted immediate reward $\gamma^t r_t^k$ weighted by the inverse probability that the behavior policy Π has generated r_t^k. The weighting is a result from importance sampling (Robert and Casella, 1999), and reflects the fact that r_t^k is obtained by following Π but the Monte Carlo integral (i.e., the empirical value function) is with respect to the RPR policy Θ. For simplicity, $\tilde{r}_t^k$ is also referred to as discounted immediate reward or simply reward throughout the paper.

We assume $r_t \geq 0$ (and hence $\widetilde{r}_t \geq 0$), which can always be achieved by adding a constant to r_t; this results in a constant added to the value function (the value function of a POMDP is linear in immediate reward) and does not influence the policy.

Theorem 6 *(Maximum Value Estimation) Let*

$$q_t^k(z_{0:t}^k|\Theta^{(n)}) = \frac{\tilde{r}_t^k}{\widehat{V}(\mathcal{D}^{(K)};\Theta^{(n)})} p(a_{0:t}^k, z_{0:t}^k | o_{1:t}^k, \Theta^{(n)}), \tag{13}$$

for $z_t^k = 1,2,\cdots,|\mathcal{Z}|$, $t = 1,2,\cdots,T_k$, *and* $k = 1,2,\cdots,K$. *Let*

$$\Theta^{(n+1)} = \arg\max_{\widehat{\Theta}\in\mathcal{F}} \frac{1}{K}\sum_{k=1}^{K}\sum_{t=0}^{T_k}\sum_{z_0^k,\cdots,z_t^k=1}^{|\mathcal{Z}|} q_t^k(z_{0:t}^k|\Theta^{(n)}) \ln \frac{\tilde{r}_t^k p(a_{0:t}^k, z_{0:t}^k | o_{1:t}^k, \widehat{\Theta})}{q_t^k(z_{0:t}^k|\Theta^{(n)})}, \tag{14}$$

where

$$\mathcal{F} = \left\{ \Theta = (\mu,\pi,W): \sum_{j=1}^{|\mathcal{Z}|}\widehat{\mu}(j) = 1, \sum_{a=1}^{|\mathcal{A}|}\widehat{\pi}(i,a) = 1, \sum_{j=1}^{|\mathcal{Z}|}\widehat{W}(i,a,o,j) = 1, \right.$$
$$\left. i = 1,2,\cdots,|\mathcal{Z}|, a = 1,2,\cdots,|\mathcal{A}|, o = 1,2,\cdots,|\mathcal{O}| \right\}$$

is the set of feasible parameters for the RPR in question. Let $\{\Theta^{(0)}\Theta^{(1)}\cdots\Theta^{(n)}\cdots\}$ *be a sequence yielded by iteratively applying (13) and (14), starting from* $\Theta^{(0)}$. *Then*

$$\lim_{n\to\infty}\widehat{V}(\mathcal{D}^{(K)};\Theta^{(n)})$$

exists and the limit is a maxima of $\widehat{V}(\mathcal{D}^{(K)};\Theta)$.

To gain a better understanding of Theorem 6, we rewrite (13) to get

$$q_t^k(z_{0:t}^k|\Theta) \quad = \quad \frac{\sigma_t^k(\Theta)}{\widehat{V}(\mathcal{D}^{(K)};\Theta)} p(z_{0:t}^k | a_{0:t}^k, o_{1:t}^k, \Theta), \tag{15}$$

where $p(z_{0:t}^k|a_{0:t}^k,o_{1:t}^k,\Theta)$ is an standard posterior distribution of the latent decision states given the Θ updated in the most recent iteration (the superscript $^{(n)}$ indicating the iteration number has been dropped for simplicity), and

$$\sigma_t^k(\Theta) \overset{Def.}{=} \tilde{r}_t^k p(a_{0:t}^k|o_{1:t}^k,\Theta) \tag{16}$$

is called the *re-computed reward* at time step t in the k-th episode. The re-computed reward represents the discounted immediate reward $\tilde{r}_t^k$ *weighted* by the probability that the action sequence yielding this reward is generated by the RPR policy parameterized by Θ, therefore $\sigma_t^k(\Theta)$ is a function of Θ. The re-computed reward reflects the update of the RPR policy which, if allowed to re-interact with the environment, is expected to accrue larger rewards than in the previous iteration. Recall that the algorithm does not assume real re-interactions with the environment so the episodes themselves cannot update. However, by recomputing the rewards as in (16), the agent is allowed to generate an *internal* set of episodes in which the immediate rewards are modified. The internal episodes represent the *new* episodes that would be collected if the agent followed the updated RPR to *really* re-interact with the environment. In this sense, the reward re-computation can be thought of as virtual re-interactions with the environment.

By (15), $q_t^k(z_{0:t}^k)$ is a weighted version of the standard posterior of $z_{0:t}^k$, with the weight given by the reward recomputed by the RPR in the previous iteration. The normalization constant $\widehat{V}(\mathcal{D}^{(K)};\Theta)$, which is also the empirical value function in (11), can be expressed as the recomputed rewards averaged over all episodes at all time steps,

$$\widehat{V}(\mathcal{D}^{(K)};\Theta) = \frac{1}{K}\sum_{k=1}^{K}\sum_{t=0}^{T_k}\sigma_t^k(\Theta), \tag{17}$$

which ensures

$$\frac{1}{K}\sum_{k=1}^{K}\sum_{t=0}^{T_k}\sum_{z_0^k,\cdots,z_t^k=1}^{|\mathcal{Z}|} q_t^k(z_{0:t}^k|\Theta) = 1.$$

The maximum value (MV) algorithm based on alternately applying (13) and (14) in Theorem 6 bears strong resemblance to the expectation-maximization (EM) algorithms (Dempster et al., 1977) widely used in statistics, with (13) and (14) respectively corresponding to the E-step and M-step in EM. However, the goal in standard EM algorithms is to maximize a likelihood function, while the goal of the MV algorithm is to maximize an empirical value function. This causes significant differences between the MV and the EM. It is helpful to compare the MV algorithm in Theorem 6 to the EM algorithm for maximum likelihood (ML) estimation in hidden Markov models (Rabiner, 1989), since both deal with sequences or episodes. The sequences in an HMM are treated as uniformly important, therefore parameter updating is based solely on the frequency of occurrences of latent states. Here the episodes are not equally important because they have different rewards associated with them, which determine their importance relative to each other. As seen in (15), the posterior of $z_{0:t}^k$ is weighted by the recomputed reward σ_t^k, which means that the contribution of episode k (at time t) to the update of Θ is not solely based on the frequency of occurrences of $z_{0:t}^k$ but also based on the associated σ_t^k. Thus the new parameters $\widehat{\Theta}$ will be adjusted in such a way that the episodes earning large rewards have more "credits" recorded into $\widehat{\Theta}$ and, as a result, the policy parameterized by $\widehat{\Theta}$ will more likely generate actions that lead to high rewards.

The objective function being maximized in (14) enjoys some interesting properties due to the fact that $q_t^k(z_{0:t}^k)$ is a weighted posterior of $z_{0:t}^k$. These properties not only establish a more formal connection between the MV algorithm here and the traditional ML algorithm based on EM, they also shed light on the close relations between Theorem 6 and the policy improvement theorem of POMDP (Blackwell, 1965). To show these properties, we rewrite the objective function in (14) (with the subscript $^{(n)}$ dropped for simplicity) as

$$\begin{aligned}\mathrm{LB}(\widehat{\Theta}|\Theta) &\overset{Def.}{=} \frac{1}{K}\sum_{k=1}^{K}\sum_{t=0}^{T_k}\sum_{z_0^k,\cdots,z_t^k=1}^{|Z|} q_t^k(z_{0:t}^k|\Theta)\ln\frac{\tilde{r}_t^k p(a_{0:t}^k, z_{0:t}^k|o_{1:t}^k,\widehat{\Theta})}{q_t^k(z_{0:t}^k|\Theta)} \\ &= \frac{1}{K}\sum_{k=1}^{K}\sum_{t=0}^{T_k}\frac{\sigma_t^k(\Theta)}{\widehat{V}(\mathcal{D}^{(K)};\Theta)}\sum_{z_0^k,\cdots,z_t^k=1}^{|Z|} p(z_{0:t}^k|a_{0:t}^k,o_{1:t}^k,\Theta)\ln\frac{\tilde{r}_t^k p(a_{0:t}^k, z_{0:t}^k|o_{1:t}^k,\widehat{\Theta})}{\frac{\sigma_t^k(\Theta)}{\widehat{V}(\mathcal{D}^{(K)};\Theta)}p(z_{0:t}^k|a_{0:t}^k,o_{1:t}^k,\Theta)},\end{aligned} \tag{18}$$

where the second equation is obtained by substituting (15) into the left side of it. Since $\frac{1}{K}\sum_{k=1}^{K}\sum_{t=0}^{T_k}\frac{\sigma_t^k(\Theta)}{\widehat{V}(\mathcal{D}^{(K)};\Theta)} = 1$ and $\sum_{z_0^k,\cdots,z_t^k=1}^{|Z|} p(z_{0:t}^k|a_{0:t}^k,o_{1:t}^k,\Theta) = 1$, one can apply Jensen's inequality *twice* to the rightmost side of (18) to obtain two inequalities

$$\begin{aligned}\mathrm{LB}(\widehat{\Theta}|\Theta) &\le \frac{1}{K}\sum_{k=1}^{K}\sum_{t=0}^{T_k}\frac{\sigma_t^k(\Theta)}{\widehat{V}(\mathcal{D}^{(K)};\Theta)}\ln\frac{\tilde{r}_t^k p(a_{0:t}^k|o_{1:t}^k,\widehat{\Theta})}{\frac{\sigma_t^k(\Theta)}{\widehat{V}(\mathcal{D}^{(K)};\Theta)}} \overset{Def.}{=} \Upsilon(\widehat{\Theta}|\Theta) \\ &\le \ln\left[\frac{1}{K}\sum_{k=1}^{K}\sum_{t=0}^{T_k}\tilde{r}_t^k p(a_{0:t}^k|o_{1:t}^k,\widehat{\Theta})\right] = \ln\widehat{V}(\mathcal{D}^{(K)};\widehat{\Theta}),\end{aligned} \tag{19}$$

where the first inequality is with respect to $p(z_{0:t}^k|a_{0:t}^k,o_{1:t}^k,\Theta)$ while the second inequality is with respect to $\left\{\frac{\sigma_t^k(\Theta)}{\widehat{V}(\mathcal{D}^{(K)};\Theta)} : t = 1,\cdots,T_k, k = 1,\cdots,K\right\}$. Each inequality yields a lower bound to the logarithmic empirical value function $\ln\widehat{V}(\mathcal{D}^{(K)};\widehat{\Theta})$. It is not difficult to verify from (18) and (19) that both of the two lower bounds are tight (the respective equality can be reached), that is,

$$\mathrm{LB}(\Theta|\Theta) = \ln\widehat{V}(\mathcal{D}^{(K)};\Theta) = \Upsilon(\Theta|\Theta). \tag{20}$$

The equations in (20) along with the inequalities in (19) show that any $\widehat{\Theta}$ satisfying $\mathrm{LB}(\Theta|\Theta) < \mathrm{LB}(\widehat{\Theta}|\Theta)$ or $\Upsilon(\Theta|\Theta) < \Upsilon(\widehat{\Theta}|\Theta)$ also satisfies $\widehat{V}(\mathcal{D}^{(K)};\Theta) < \widehat{V}(\mathcal{D}^{(K)};\widehat{\Theta})$. Thus one can choose to maximize either of the two lower bounds, $\mathrm{LB}(\widehat{\Theta}|\Theta)$ or $\Upsilon(\widehat{\Theta}|\Theta)$, when trying to improve the empirical value of $\widehat{\Theta}$ over that of Θ. In either case, the maximization is with respect to $\widehat{\Theta}$.

The two alternatives, though both yielding an improved RPR, are quite different in the manner the improvement is achieved. Suppose one has obtained $\Theta^{(n)}$ by applying (13) and (14) for n iterations, and is seeking $\Theta^{(n+1)}$ satisfying $\widehat{V}(\mathcal{D}^{(K)};\Theta^{(n)}) < \widehat{V}(\mathcal{D}^{(K)};\Theta^{(n+1)})$. Maximization of the first lower bound gives $\Theta^{(n+1)} = \arg\max_{\widehat{\Theta}\in\mathcal{F}}\mathrm{LB}(\widehat{\Theta}|\Theta^{(n)})$, which has an analytic solution that will be given in Section 4.2. Maximization of the second lower bound yields

$$\Theta^{(n+1)} = \arg\max_{\widehat{\Theta}\in\mathcal{F}}\Upsilon(\widehat{\Theta}|\Theta^{(n)}). \tag{21}$$

The definition of Υ in (19) is substituted into (21) to yield

$$\Theta^{(n+1)} = \arg\max_{\widehat{\Theta}\in\mathcal{F}}\frac{1}{K}\sum_{k=1}^{K}\sum_{t=0}^{T_k}\frac{\sigma_t^k(\Theta^{(n)})}{\widehat{V}(\mathcal{D}^{(K)};\Theta^{(n)})}\ln\frac{\tilde{r}_t^k p(a_{0:t}^k|o_{1:t}^k,\widehat{\Theta})}{\frac{\sigma_t^k(\Theta^{(n)})}{\widehat{V}(\mathcal{D}^{(K)};\Theta^{(n)})}}$$

$$= \quad \arg\max_{\widehat{\Theta}\in\mathcal{F}} \sum_{k=1}^{K}\sum_{t=0}^{T_k} \sigma_t^k(\Theta^{(n)}) \ln p(a_{0:t}^k|o_{1:t}^k,\widehat{\Theta}), \tag{22}$$

which shows that maximization of the second lower bound is equivalent to maximizing a weighted sum of the log-likelihoods of $\{a_{0:t}^k\}$, with the weights being the rewards recomputed by $\Theta^{(n)}$. Through (22), the connection between the maximum value algorithm in Theorem 6 and the traditional ML algorithm is made more formal and clearer: with the recomputed rewards given and fixed, the MV algorithm is a weighted version of the ML algorithm, with $\Upsilon(\widehat{\Theta}|\Theta^{(n)})$ a weighted log-likelihood function of $\widehat{\Theta}$.

The above analysis also sheds light on the relations between Theorem 6 and the policy improvement theorem in POMDP (Blackwell, 1965). By (19), (20), and (22), we have

$$\begin{aligned}\ln V(\mathcal{D}^{(K)};\Theta^{(n)}) = \Upsilon(\Theta^{(n)}|\Theta^{(n)}) &\leq \Upsilon(\Theta^{(n+1)}|\Theta^{(n)}) \\ &\leq \ln V(\mathcal{D}^{(K)};\Theta^{(n+1)}).\end{aligned}$$

The first inequality, achieved by the weighted likelihood maximization in (22), represents the policy improvement on the old episodes collected by following the previous policy. The second inequality ensures that, if the improved policy is followed to collect new episodes in the environment, the expected sum of newly accrued rewards is no less than that obtained by following the previous policy. This is similar to policy evaluation. Note that the update of episodes is simulated by reward computation. The actual episodes are collected by a fixed behavior policy Π and do not change.

The maximization in (22) can be performed using any optimization techniques. As long as the maximization is achieved, the policy is improved as guaranteed by Theorem 6. Since the latent z variables are involved, it is natural to employ EM to solve the maximization. The EM solution to (22) is obtained by solving a sequence of maximization problems: starting from $\Theta^{(n)(0)} = \Theta^{(n)}$, one successively solves

$$\Theta^{(n)(j)} = \arg\max_{\widehat{\Theta}\in\mathcal{F}} \mathrm{LB}(\widehat{\Theta}|\Theta^{(n)(j-1)}) \text{ subject to } \sigma_t^k(\Theta^{(n)(j-1)}) = \sigma_t^k(\Theta^{(n)}),\ \forall t,k, \tag{23}$$
$$j = 1,2,\cdots,$$

where in each problem one maximizes the first lower bound with an updated posterior of $\{z_t^k\}$ but with the recomputed rewards fixed at $\{\sigma_t^k(\Theta^{(n)})\}$; upon convergence, the solution of (23) is the solution to (22). The EM solution here is almost the same as the likelihood maximization of sequences for hidden Markov models (Rabiner, 1989). The only difference is that here we have a weighted log-likelihood function, but with the weights given and fixed. The posterior of $\{z_t^k\}$ can be updated by employing the dynamical programming techniques similar to those used in HMM, as we discuss below.

It is interesting to note that, with standard EM employed to solve (22), the overall maximum value algorithm is a "double-EM" algorithm, since reward computation constitutes an outer EM-like loop.

4.1 Calculating the Posterior of Latent Belief Regions

To allocate the weights or recomputed rewards and update the RPR as in (14), we do not need to know the full distribution of $z_{0:t}^k$. Instead, a small set of marginals of $p(z_{0:t}^k|a_{0:t}^k,o_{1:t}^k,\Theta)$ are necessary for the purpose, in particular,

$$\xi^k_{t,\tau}(i,j) = p(z^k_\tau = i, z^k_{\tau+1} = j | a^k_{0:t}, o^k_{1:t}, \Theta), \tag{24}$$
$$\phi^k_{t,\tau}(i) = p(z^k_\tau = i | a^k_{0:t}, o^k_{1:t}, \Theta). \tag{25}$$

Lemma 7 *(Factorization of the ξ and ϕ Variables) Let*

$$\begin{aligned} \alpha^k_\tau(i) &= p(z^k_\tau = i | a^k_{0:\tau}, o^k_{1:\tau}, \Theta) \\ &= \frac{p(z^k_\tau = i, a^k_{0:\tau} | o^k_{1:\tau}, \Theta)}{\prod_{\tau'=0}^{\tau} p(a^k_{\tau'} | h^k_{\tau'}, \Theta)}, \end{aligned} \tag{26}$$
$$\beta^k_{t,\tau}(i) = \frac{p(a^k_{\tau+1:t} | z^k_\tau = i, a^k_\tau, o^k_{\tau+1:t}, \Theta)}{\prod_{\tau'=\tau}^{t} p(a^k_{\tau'} | h^k_{\tau'}, \Theta)}. \tag{27}$$

Then

$$\xi^k_{t,\tau}(i,j) = \alpha^k_\tau(i) W(z^k_\tau = i, a^k_\tau, o^k_{\tau+1}, z^k_{\tau+1} = j) \pi(z^k_{\tau+1} = j, a^k_{\tau+1}) \beta^k_{t,\tau+1}(j), \tag{28}$$
$$\phi^k_{t,\tau}(i) = \alpha^k_\tau(i) \beta^k_{t,\tau}(i) p(a^k_\tau | h^k_\tau). \tag{29}$$

The α and β variables in the Lemma 7 are similar to the scaled forward variables and backward variables in hidden Markov models (HMM) (Rabiner, 1989). The scaling factors here are $\prod_{\tau'=0}^{\tau} p(a^k_{\tau'} | h^k_{\tau'}, \Theta)$, which is equal to $p(a^k_{0:\tau} | o^k_{1:\tau}, \Theta)$ as shown in (9) and (10). Recall from Definition 3 that one episode of length T has $T+1$ sub-episodes with each having a different ending time step. For this reason, one must compute the β variables for each sub-episode separately, since the β variables depend on the ending time step. For α variables, one needs to compute them once per episode, since it does not involve the ending time step.

Similar to the forward variables and backward variables in HMM models, the α and β variables can be computed recursively, via dynamical programming,

$$\alpha^k_\tau(i) = \begin{cases} \dfrac{\mu(z^k_0 = i)\pi(z^k_0 = i, a^k_0)}{p(a^k_0 | h^k_0, \Theta)}, & \tau = 0 \\ \dfrac{\sum_{j=1}^{|Z|} \alpha^k_{\tau-1}(j) W(z^k_{\tau-1} = j, a^k_{\tau-1}, o^k_\tau, z^k_\tau = i) \pi(z^k_\tau = i, a^k_\tau)}{p(a^k_\tau | h^k_\tau, \Theta)}, & \tau > 0 \end{cases}, \tag{30}$$
$$\beta^k_{t,\tau}(i) = \begin{cases} \dfrac{1}{p(a^k_t | h^k_t, \Theta)}, & \tau = t \\ \dfrac{\sum_{j=1}^{|Z|} W(z^k_\tau = i, a^k_\tau, o^k_{\tau+1}, z^k_{\tau+1} = j) \pi(z^k_{\tau+1} = j, a^k_{\tau+1}) \beta^k_{t,\tau+1}(j)}{p(a^k_\tau | h^k_\tau, \Theta)}, & \tau < t \end{cases}, \tag{31}$$

for $t = 0, \cdots, T_k$ and $k = 1, \cdots, K$. Since $\sum_{i=1}^{|Z|} \alpha^k_\tau(i) = 1$, it follows from (30) that

$$p(a^k_\tau | h^k_\tau, \Theta) = \begin{cases} \displaystyle\sum_{i=1}^{|Z|} \mu(z^k_0 = i) \pi(z^k_0 = i, a^k_0), & \tau = 0 \\ \displaystyle\sum_{i=1}^{|Z|} \sum_{j=1}^{|Z|} \alpha^k_{\tau-1}(j) W(z^k_{\tau-1} = j, a^k_{\tau-1}, o^k_\tau, z^k_\tau = i) \pi(z^k_\tau = i, a^k_\tau), & \tau > 0 \end{cases}. \tag{32}$$

4.2 Updating the Parameters

We rewrite the lower bound in (18),

$$\begin{aligned}\mathrm{LB}(\widehat{\Theta}|\Theta) &= \frac{1}{K}\sum_{k=1}^{K}\sum_{t=0}^{T_k}\sum_{z_0^k,\cdots,z_t^k=1}^{|\mathcal{Z}|} q_t^k(z_{0:t}^k|\Theta^{(n)})\ln\frac{\tilde{r}_t^k p(a_{0:t}^k,z_{0:t}^k|o_{1:t}^k,\widehat{\Theta})}{q_t^k(z_{0:t}^k|\Theta^{(n)})}\\ &= \frac{1}{K}\sum_{k=1}^{K}\sum_{t=0}^{T_k}\sum_{z_0^k,\cdots,z_t^k=1}^{|\mathcal{Z}|} q_t^k(z_{0:t}^k|\Theta^{(n)})\ln p(a_{0:t}^k,z_{0:t}^k|o_{1:t}^k,\widehat{\Theta})+\text{constant},\end{aligned}$$

where the "constant" collects all the terms irrelevant to $\widehat{\Theta}$. Substituting (5) and (15) gives

$$\begin{aligned}\mathrm{LB}(\widehat{\Theta}|\Theta) &= \frac{1}{K}\sum_{k=1}^{K}\sum_{t=0}^{T_k}\frac{\sigma_t^k}{\widehat{V}(\mathcal{D}^{(K)};\Theta)}\Bigg\{\sum_{i=1}^{|\mathcal{Z}|}\phi_{t,0}^k(i)\ln\widehat{\mu}(i)+\sum_{\tau=0}^{t}\sum_{i=1}^{|\mathcal{Z}|}\phi_{t,\tau}^k(i)\ln\widehat{\pi}(i,a_\tau^k)\\ &\qquad +\sum_{\tau=1}^{t}\sum_{i,j=1}^{|\mathcal{Z}|}\xi_{t,\tau}^k(i,j)\ln\widehat{W}(i,a_{\tau-1}^k,o_\tau^k,j)\Bigg\}+\text{constant}.\end{aligned}$$

It is not difficult to show that $\widehat{\Theta}=\arg\max_{\widehat{\Theta}\in\mathcal{F}}\mathrm{LB}(\widehat{\Theta}|\Theta)$ is given by

$$\widehat{\mu}(i) = \frac{\sum_{k=1}^{K}\sum_{t=0}^{T_k}\sigma_t^k\phi_{t,0}^k(i)}{\sum_{i=1}^{|\mathcal{Z}|}\sum_{k=1}^{K}\sum_{t=0}^{T_k}\sigma_t^k\phi_{t,0}^k(i)}, \tag{33}$$

$$\widehat{\pi}(i,a) = \frac{\sum_{k=1}^{K}\sum_{t=0}^{T_k}\sigma_t^k\sum_{\tau=0}^{t}\phi_{t,\tau}^k(i)\,\delta(a_\tau^k,a)}{\sum_{a=1}^{|\mathcal{A}|}\sum_{k=1}^{K}\sum_{t=0}^{T_k}\sigma_t^k\sum_{\tau=0}^{t}\phi_{t,\tau}^k(i)\,\delta(a_\tau^k,a)}, \tag{34}$$

$$\widehat{W}(i,a,o,j) = \frac{\sum_{k=1}^{K}\sum_{t=0}^{T_k}\sigma_t^k\sum_{\tau=1}^{t-1}\xi_{t,\tau}^k(i,j)\,\delta(a_\tau^k,a)\,\delta(o_{\tau+1}^k,o)}{\sum_{j=1}^{|\mathcal{Z}|}\sum_{k=1}^{K}\sum_{t=0}^{T_k}\sigma_t^k\sum_{\tau=1}^{t-1}\xi_{t,\tau}^k(i,j)\,\delta(a_\tau^k,a)\,\delta(o_{\tau+1}^k,o)}, \tag{35}$$

for $i,j=1,2,\cdots,|\mathcal{Z}|$, $a=1,\cdots,|\mathcal{A}|$, and $o=1,\cdots,|O|$, where $\delta(a,b)=\begin{cases}1, & a=b\\ 0, & a\neq b\end{cases}$, and σ_t^k is the recomputed reward as defined in (16). In computing σ_t^k one employs the equation $p(a_{0:t}^k|o_{1:t}^k,\Theta)=\prod_{\tau=0}^{t}p(a_\tau^k|h_\tau^k,\Theta)$ established in (9) and (10), to get

$$\sigma_t^k(\Theta)\overset{Def.}{=}\tilde{r}_t^k\prod_{\tau=0}^{t}p(a_\tau^k|h_\tau^k,\Theta), \tag{36}$$

with $p(a_\tau^k|h_\tau^k,\Theta)$ computed from the α variables by using (32). Note that the normalization constant, which is equal to the empirical value $\widehat{V}(\mathcal{D}^{(K)};\Theta)$, is now canceled in the update formulae of $\widehat{\Theta}$.

4.3 The Complete Value Maximization Algorithm for Single-Task RPR Learning

The complete value maximization algorithm for single-task RPR learning is summarized in Table 1. In earlier discussions regarding the relations of the algorithm to EM, we have mentioned that reward computation constitutes an outer EM-like loop; the standard EM employed to solve (22) is embedded in the outer loop and constitutes an inner EM loop. The double EM loops are not explicitly shown in Table 1. However, one may separate these two loops by keeping $\{\sigma_t^k\}$ fixed

```
Input: $\mathcal{D}^{(K)}$, $\mathcal{A}$, $\mathcal{O}$, $|\mathcal{Z}|$.
Output: $\Theta = \{\mu, \pi, W\}$.

1. Initialize $\Theta$, $\ell = []$, iteration $= 1$.
2. Repeat
   2.1 Dynamical programming:
       Compute $\alpha$ and $\beta$ variables with Equations (30)-(32).
   2.2 Reward re-computation:
       Calculate $\{\sigma_t^k\}$ using (36) and (32).
   2.3 Convergence check:
       Compute $\ell(\text{iteration}) = \widehat{V}(\mathcal{D}^{(K)};\Theta)$ using (17).
       If the sequence of $\ell$ converges
           Stop the algorithm and exit.
       Else
           iteration := iteration $+ 1$
   2.4 Posterior update for $z$:
       Compute the $\xi$ and $\phi$ variables using Equations (28)-(29).
   2.5 Update of $\Theta$:
       Compute the updated $\Theta$ using (33), (34), and (35).
```

Table 1: The value maximization algorithm for single-task RPR learning

when updating Θ and the posterior of z's, until the empirical value converges; see (23) for details. Once $\{\sigma_t^k\}$ are updated, the empirical value will further increase by continuing updating Θ and the posterior of z's. Note that the $\{\sigma_t^k\}$ used in the convergence check are always updated at each iteration, even though the new $\{\sigma_t^k\}$ may not be used for updating Θ and the posterior of z's.

Given a history of actions and observations $(a_{0:t-1}, o_{1:t})$ collected up to time step t, the single RPR yields a distribution of a_t as given by (8). The optimal choice for a_t can be obtained by either sampling from this distribution or taking the action that maximizes the probability.

4.3.1 TIME COMPLEXITY ANALYSIS

We quantify the time complexity by the number of real number multiplications performed per iteration and present it in the Big-O notation. Since there is no compelling reason for the number of iterations to depend on the size of the input,[2] the complexity per iteration also represents the complexity of the complete algorithm. A stepwise analysis of the time complexity of the value maximization algorithm in Table 1 is given as follows.

- Computation of the α variables with (30) and (32) runs in time $O(|\mathcal{Z}|^2 \sum_{k=1}^K T_k)$.
- Computation of β's with (31) and (32) runs in time $O(|\mathcal{Z}|^2 \sum_{k=1}^K \sum_{t=0, r_t^k \neq 0}^{T_k} (t+1))$, which depends on the degree of sparsity of the immediate rewards $\{r_0^k r_2^k \cdots r_{T_k}^k\}_{k=1}^K$. In the worst case

2. The number of iterations usually depends on such factors as initialization of the algorithm and the required accuracy, etc.

the time is $O(|\mathcal{Z}|^2 \sum_{k=1}^{K} \sum_{t=0}^{T_k}(t+1)) = O(|\mathcal{Z}|^2 \sum_{k=1}^{K} T_k^2)$, which occurs when the immediate reward in each episode is nonzero at every time step. In the best case the time is $O(|\mathcal{Z}|^2 \sum_{k=1}^{K} T_k)$, which occurs when the immediate reward in each episode is nonzero only at a fixed number of time steps (only at the last time step, for example, as is the case of the benchmark problems presented in Section 6).

- The reward re-computation using (36) and (32) requires time $O(\sum_{k=1}^{K} T_k)$ in the worst case and $O(K)$ in the best case, where the worse/best cases are as defined above.

- Update of Θ using (33), (34), and (35), as well as computation of the ξ and ϕ variables using (28) and (29), runs in time $O(|\mathcal{Z}|^2 \sum_{k=1}^{K} T_k^2)$ in the worst case and $O(|\mathcal{Z}|^2 \sum_{k=1}^{K} T_k)$ in the best case, where the worse/best cases are defined above.

Since $\sum_{k=1}^{K} T_k \gg |\mathcal{A}||O|$ in general, the overall complexity of the value maximization algorithm is $O(|\mathcal{Z}|^2 \sum_{k=1}^{K} T_k^2)$ in the worst case and $O(|\mathcal{Z}|^2 \sum_{k=1}^{K} T_k)$ in the best case, depending on the degree of sparsity of the immediate rewards. Therefore the algorithm scales linearly with the number of episodes and to the square of the number of belief regions. The time dependency on the lengths of episodes is between linear and square. The sparser the immediate rewards are, the more the time is towards being linear in the lengths of episodes.

Note that in many reinforcement problems, the agent does not receive immediate rewards at every time step. For the benchmark problems and maze navigation problems considered in Section 6, the agent receives rewards only when the goal state is reached, which makes the value maximization algorithm scale linearly with the lengths of episodes.

5. Multi-Task Reinforcement Learning (MTRL) with RPR

We formulate our MTRL framework by placing multiple RPRs in a Bayesian setting and develop techniques to learn the posterior of each RPR within the context of all other RPRs.

Several notational conventions are observed in this section. The posterior of Θ is expressed in terms of probability density functions. The notation $G_0(\Theta)$ is reserved to denote the density function of a parametric prior distribution, with the associated probability measure denoted by G_0 without a parenthesized Θ beside it. For the Dirichlet process (which is a nonparametric prior), G_0 denotes the base measure and $G_0(\Theta)$ denotes the corresponding density function. The twofold use of G_0 is for notational simplicity; the difference can be easily discerned by the presence or absence of a parenthesized Θ. The δ is a Dirac delta for continuous arguments and a Kronecker delta for discrete arguments. The notation δ_{Θ_j} is the Dirac measure satisfying $\delta_{\Theta_j}(d\Theta_m) = \begin{cases} 1, & \Theta_j \in d\Theta_m \\ 0, & \text{otherwise} \end{cases}$.

5.1 Basic Bayesian Formulation of RPR

Consider M partially observable and stochastic environments indexed by $m = 1, 2 \cdots, M$, each of which is apparently different from the others but may actually share fundamental common characteristics with some other environments. Assume we have a set of episodes collected from each environment, $\mathcal{D}_m^{(K_m)} = \left\{ (a_0^{m,k} r_0^{m,k} o_1^{m,k} a_1^{m,k} r_1^{m,k} \cdots o_{T_{m,k}}^{m,k} a_{T_{m,k}}^{m,k} r_{T_{m,k}}^{m,k}) \right\}_{k=1}^{K_m}$, for $m = 1, 2, \cdots, M$, where $T_{m,k}$ represents the length of episode k in environment m. Following the definitions in Section 3, we write the empirical value function of the m-th environment as

$$\widehat{V}(\mathcal{D}_m^{(K_m)};\Theta_m) = \frac{1}{K_m}\sum_{k=1}^{K_m}\sum_{t=0}^{T_{m,k}} \tilde{r}_t^{m,k} p(a_{0:t}^{m,k}|o_{1:t}^{m,k},\Theta_m), \tag{37}$$

for $m = 1,2,\cdots,M$, where $\Theta_m = \{\pi_m,\mu_m,W_m\}$ are the RPR parameters for the m-th individual environment.

Let $G_0(\Theta_m)$ represent the prior of Θ_m, where $G_0(\Theta)$ is assumed to be the density function of a probability distribution. We define the posterior of Θ_m as

$$p(\Theta_m|\mathcal{D}_m^{(K_m)},G_0) \overset{Def.}{=} \frac{\widehat{V}(\mathcal{D}_m^{(K_m)};\Theta_m)G_0(\Theta_m)}{\widehat{V}_{G_0}(\mathcal{D}_m^{(K_m)})}, \tag{38}$$

where the inclusion of G_0 in the left hand side is to explicitly indicate that the prior being used is G_0, and $\widehat{V}_{G_0}(\mathcal{D}_m^{(K_m)})$ is a normalization constant

$$\widehat{V}_{G_0}(\mathcal{D}_m^{(K_m)}) \overset{Def.}{=} \int \widehat{V}(\mathcal{D}_m^{(K_m)};\Theta_m)G_0(\Theta_m)d\Theta_m, \tag{39}$$

which is also referred to as the *marginal empirical value*,[3] since the parameters Θ_m are integrated out (marginalized). The marginal empirical value $\widehat{V}_{G_0}(\mathcal{D}_m^{(K_m)})$ represents the accumulated discounted reward in the episodes, averaged over infinite RPR policies independently drawn from G_0.

Equation (38) is literally a normalized product of the empirical value function and a prior $G_0(\Theta_m)$. Since $\int p(\Theta_m|\mathcal{D}_m^{(K_m)},G_0)d\Theta_m = 1$, (38) yields a valid probability density, which we call the posterior of Θ_m given the episodes $\mathcal{D}_m^{(K_m)}$. It is noted that (38) would be the Bayes rule if $\widehat{V}(\mathcal{D}_m^{(K_m)};\Theta_m)$ were a likelihood function. Since $\widehat{V}(\mathcal{D}_m^{(K_m)};\Theta_m)$ is a value function in our case, (38) is a somewhat non-standard use of Bayes rule. However, like the classic Bayes rule, (38) indeed gives a posterior whose shape incorporates both the prior information about Θ_m and the empirical information from the episodes.

Equation (38) has another interpretation that may be more meaningful from the perspective of standard probability theory. To see this we substitute (37) into (38) to obtain

$$\begin{aligned} p(\Theta_m|\mathcal{D}_m^{(K_m)},G_0) &= \frac{\frac{1}{K_m}\sum_{k=1}^{K_m}\sum_{t=0}^{T_{m,k}} \tilde{r}_t^{m,k} p(a_{0:t}^{m,k}|o_{1:t}^{m,k},\Theta_m)G_0(\Theta_m)}{\widehat{V}_{G_0}(\mathcal{D}_m^{(K_m)})} && (40)\\ &= \frac{\frac{1}{K_m}\sum_{k=1}^{K_m}\sum_{t=0}^{T_{m,k}} \zeta_t^{m,k} p(\Theta_m|a_{0:t}^{m,k},o_{1:t}^{m,k},G_0)}{\widehat{V}_{G_0}(\mathcal{D}_m^{(K_m)})}, && (41)\end{aligned}$$

where

$$\begin{aligned} \zeta_t^{m,k} &= \tilde{r}_t^{m,k} p(a_{0:t}^{m,k}|o_{1:t}^{m,k},G_0)\\ &= \tilde{r}_t^{m,k} \int p(a_{0:t}^{m,k}|o_{1:t}^{m,k},\Theta_m)G_0(\Theta_m)d\Theta_m\\ &= \int \sigma_t^{m,k}(\Theta_m)G_0(\Theta_m)d\Theta_m, && (42)\end{aligned}$$

3. The term "marginal" is borrowed from the probability theory. Here we use it to indicate that the dependence of the value on the parameter is removed by integrating out the parameter.

with $\sigma_t^{m,k}$ the re-computed reward as defined in (16) and therefore $\zeta_t^{m,k}$ is the averaged re-computed reward, obtained by taking the expectation of $\sigma_t^{m,k}(\Theta_m)$ with respect to $G_0(\Theta_m)$.

In arriving (41), we have used the fact the RPR parameters are independent of the observations, which is true due to the following reasons: RPR is a policy concerning generation of the actions, employing as input the observations (which themselves are generated by the unknown environment); therefore, observations carry no information about the RPR parameters, that is, $p(\Theta|\text{observations}) = p(\Theta) \equiv G_0(\Theta)$.

It is noted that $p(\Theta_m|a_{0:t}^{m,k}, o_{1:t}^{m,k}, G_0)$ in (41) is the standard posterior of Θ_m given the action sequence $a_{0:t}^{m,k}$, and $p(\Theta_m|\mathcal{D}_m^{(K_m)}, G_0)$ is a mixture of these posteriors with the mixing proportion given by $\zeta_t^{m,k}$. The meaning of (40) is fairly intuitive: each action sequence affects the posterior of Θ_m in proportion to its re-evaluated reward. This is distinct from the posterior in the classic hidden Markov model (Rabiner, 1989) where sequences are treated as equally important.

Since $p(\Theta_m|\mathcal{D}_m^{(K_m)}, G_0)$ integrates to one, the normalization constant $\widehat{V}_{G_0}(\mathcal{D}_m^{(K_m)})$ is

$$\widehat{V}_{G_0}(\mathcal{D}_m^{(K_m)}) = \frac{1}{K_m} \sum_{k=1}^{K_m} \sum_{t=0}^{T_{m,k}} \zeta_t^{m,k}. \tag{43}$$

We obtain a more convenient form of the posterior by substituting (6) into (41) to expand the summation over the latent z variables, yielding

$$p(\Theta_m|\mathcal{D}_m^{(K_m)}, G_0) = \frac{\frac{1}{K_m} \sum_{k=1}^{K_m} \sum_{t=0}^{T_{m,k}} \tilde{r}_t^{m,k} \sum_{z_0^{m,k},\cdots,z_t^{m,k}=1}^{|\mathcal{Z}|} p(a_{0:t}^{m,k}, z_{0:t}^{m,k}|o_{1:t}^{m,k}, \Theta_m) G_0(\Theta_m)}{\widehat{V}_{G_0}(\mathcal{D}_m^{(K_m)})}. \tag{44}$$

To obtain an analytic posterior, we let the prior be conjugate to $p(a_{0:t}^{m,k}, z_{0:t}^{m,k}|o_{1:t}^{m,k}, \Theta_m)$. As shown by (5), $p(a_{0:t}^{m,k}, z_{0:t}^{m,k}|o_{1:t}^{m,k}, \Theta_m)$ is a product of multinomial distributions, and hence we choose the prior as a product of Dirichlet distributions, with each Dirichlet representing an independent prior for a subset of parameters in Θ. The density function of such a prior is given by

$$\begin{aligned}
G_0(\Theta_m) &= p(\mu^m|\upsilon)p(\pi^m|\rho)p(W^m|\omega), && (45)\\
p(\mu^m|\upsilon) &= \mathrm{Dir}\Big(\mu^m(1), \cdots, \mu^m(|\mathcal{Z}|)\Big|\upsilon\Big), && (46)\\
p(\pi^m|\rho) &= \prod_{i=1}^{|\mathcal{Z}|} \mathrm{Dir}\Big(\pi^m(i,1), \cdots, \pi^m(i,|\mathcal{A}|)\Big|\rho_i\Big), && (47)\\
p(W^m|\omega) &= \prod_{a=1}^{|\mathcal{A}|}\prod_{o=1}^{|\mathcal{O}|}\prod_{i=1}^{|\mathcal{Z}|} \mathrm{Dir}\Big(W^m(i,a,o,1), \cdots, W^m(i,a,o,|\mathcal{Z}|)\Big|\omega_{i,a,o}\Big), && (48)
\end{aligned}$$

where $\upsilon = \{\upsilon_1, \ldots, \upsilon_{|\mathcal{Z}|}\}$, $\rho = \{\rho_1, \ldots, \rho_{|\mathcal{Z}|}\}$ with $\rho_i = \{\rho_{i,1}, \ldots, \rho_{i,|\mathcal{A}|}\}$, and $\omega = \{\omega_{i,a,o} : i = 1 \ldots |\mathcal{Z}|, a = 1 \ldots |\mathcal{A}|, o = 1 \ldots |\mathcal{O}|\}$ with $\omega_{i,a,o} = \{\omega_{i,a,o,1}, \ldots, \omega_{i,a,o,|\mathcal{Z}|}\}$. Substituting the expression of G_0 into (44), one gets

$$\begin{aligned}
&p(\Theta_m|\mathcal{D}_m^{(K_m)}, G_0)\\
&= \frac{\frac{1}{K_m} \sum_{k=1}^{K_m} \sum_{t=0}^{T_{m,k}} \sum_{z_0^{m,k},\cdots,z_t^{m,k}=1}^{|\mathcal{Z}|} \zeta_t^{m,k}(z_{0:t}^{m,k})\, p(\Theta_m|a_{0:t}^{m,k}, o_{1:t}^{m,k}, z_{0:t}^{m,k}, G_0)}{\widehat{V}_{G_0}(\mathcal{D}_m^{(K_m)})},
\end{aligned}$$

where

$$\begin{aligned}\zeta_t^{m,k}(z_{0:t}^{m,k}) &= \tilde{r}_t^{m,k}\int p(a_{0:t}^{m,k},z_{0:t}^{m,k}|o_{1:t}^{m,k},\Theta_m)G_0(\Theta_m)d\Theta_m\\ &= \tilde{r}_t^{m,k}\frac{\prod_i\Gamma(\widehat{\upsilon}_i^{m,k,t})}{\Gamma(\sum_i\widehat{\upsilon}_i^{m,k,t})}\frac{\Gamma(\sum_i\upsilon_i^{m,k,t})}{\prod_i\Gamma(\upsilon_i^{m,k,t})}\frac{\prod_i\prod_a\Gamma(\widehat{\rho}_{i,a}^{m,k,t})}{\prod_i\Gamma(\sum_a\widehat{\rho}_{i,a}^{m,k,t})}\frac{\prod_i\Gamma(\sum_a\rho_{i,a}^{m,k,t})}{\prod_i\prod_a\Gamma(\rho_{i,a}^{m,k,t})}\\ &\quad\times\frac{\prod_a\prod_o\prod_i\prod_j\Gamma(\widehat{\omega}_{i,a,o,j}^{m,k,t})}{\prod_a\prod_o\prod_i\Gamma(\sum_j\widehat{\omega}_{i,a,o,j}^{m,k,t})}\frac{\prod_a\prod_o\prod_i\Gamma(\sum_j\omega_{i,a,o,j}^{m,k,t})}{\prod_a\prod_o\prod_i\prod_j\Gamma(\omega_{i,a,o,j}^{m,k,t})}\end{aligned}\tag{49}$$

represents the averaged recomputed reward over a given z sequence $z_{0:t}^{m,k}$, and

$$p(\Theta_m|a_{0:t}^{m,k},o_{1:t}^{m,k},z_{0:t}^{m,k},G_0) = p(\mu^m|\widehat{\upsilon}^{m,k,t})p(\pi^m|\widehat{\rho}^{m,k,t})p(W^m|\widehat{\omega}^{m,k,t})$$

is the density of a product of Dirichlet distributions and has the same form as $G_0(\Theta)$ in (45) but with υ,ρ,ω respectively replaced by $\widehat{\upsilon}^{m,k,t}$, $\widehat{\rho}^{m,k,t}$, $\widehat{\omega}^{m,k,t}$ as given by

$$\widehat{\upsilon}_i^{m,k,t} = \upsilon_i^m+\delta(z_0^{m,k}-i),\tag{50}$$

$$\widehat{\rho}_{i,a}^{m,k,t} = \rho_{i,a}^m+\sum_{\tau=0}^{t}\delta(z_\tau^{m,k}-i)\delta(a_\tau^{m,k}-a),\tag{51}$$

$$\widehat{\omega}_{i,a,o,j}^{m,k,t} = \omega_{i,a,o,j}^m+\sum_{\tau=1}^{t}\delta(z_{\tau-1}^{m,k}-i)\delta(a_{\tau-1}^{m,k}-a)\delta(o_\tau^{m,k}-o)\delta(z_\tau^{m,k}-j).\tag{52}$$

The normalization constant $\widehat{V}_{G_0}(\mathcal{D}_m^{(K_m)})$ (which is also the marginal empirical value) can now be expressed as

$$\widehat{V}_{G_0}(\mathcal{D}_m^{(K_m)}) = \frac{1}{K_m}\sum_{k=1}^{K_m}\sum_{t=0}^{T_{m,k}}\sum_{z_0^{m,k},\cdots,z_t^{m,k}=1}^{|\mathcal{Z}|}\zeta_t^{m,k}(z_{0:t}^{m,k}).\tag{53}$$

5.2 The Dirichlet Process Prior

In order to identify related tasks and introduce sharing mechanisms for multi-task learning, we employ the Dirichlet process (Ferguson, 1973; Blackwell and MacQueen, 1973; Antoniak, 1974; Sethuraman, 1994) as a nonparametric prior that is shared by Θ_m, $m=1,2,\cdots,M$. A draw from a DP has the nice property of being almost surely discrete (Blackwell and MacQueen, 1973), which is known to promote clustering (West et al., 1994); therefore, related tasks (as judged by the empirical value function) are encouraged to be placed in the same group and be learned simultaneously by sharing the episodic data across all tasks in the same group. Assuming the prior of Θ_m, $m=1,2,\cdots,M$, is drawn from a Dirichlet process with base measure G_0 and precision α, we have

$$\begin{aligned}\Theta_m|G &\sim G,\\ G|\alpha,G_0 &\sim DP(\alpha,G_0),\end{aligned}$$

where the precision α provides an expected number of dominant clusters, with this driven by the number of samples (West, 1992). It usually suffices to set the precision α using the rule in West (1992). If desired, however, one may also put a Gamma prior on α and draw from its posterior

(Escobar and West, 1995), which yields greater model flexibility. Note the DP precision is denoted by the same symbol as the α variables in (26). The difference is easy to recognize, since the former is a single quantity bearing neither superscripts and nor subscripts while the latter represent a set of variables and always bear superscripts and subscripts.

By marginalizing out G, one obtains the Polya-urn representation of DP (Blackwell and MacQueen, 1973), expressed in terms of density functions,[4]

$$p(\Theta_m|\Theta_{-m},\alpha,G_0)=\frac{\alpha}{\alpha+M-1}G_0(\Theta_m)+\frac{1}{\alpha+M-1}\sum_{\substack{j=1\\j\neq m}}^{M}\delta(\Theta_m-\Theta_j),\;\; m=1,\cdots,M, \tag{54}$$

where the probability is conditioned on $\Theta_{-m}=\{\Theta_1,\Theta_2,\cdots,\Theta_M\}\setminus\{\Theta_m\}$. The Polya-urn representation in (54) gives a set of full conditionals for the joint prior $p(\Theta_1,\Theta_2,\cdots,\Theta_M)$.

The fact that $G\sim DP(\alpha,G_0)$ is almost surely discrete implies that the set $\{\Theta_1,\,\Theta_2,\,\cdots,\,\Theta_M\}$, which are iid drawn from G, can have duplicate elements and the number of distinct elements N cannot exceed M, the total number of environments. It is useful to consider an equivalent representation of (54) based on the distinct elements (Neal, 1998). Let $\overline{\Theta}=\{\overline{\Theta}_1,\overline{\Theta}_2,\cdots,\overline{\Theta}_N\}$ represent the set of distinct elements of $\{\Theta_1,\Theta_2,\cdots,\Theta_M\}$, with $N\le M$. Let $c=\{c_1,c_2,\ldots,c_M\}$ denote the vector of indicator variables defined by $c_m=n$ iff $\Theta_m=\overline{\Theta}_n$ and $c_{-m}=\{c_1,c_2,\cdots,c_M\}\setminus\{c_m\}$. The prior conditional distribution $p(c_m|c_{-m})$ that arises from the Polya-urn representation of the Dirichlet process is as follows (MacEachern, 1994)

$$p(c_m|c_{-m},\alpha)=\frac{\alpha}{\alpha+M-1}\delta(c_m)+\sum_{n=1}^{N}\frac{l_{-m,n}}{\alpha+M-1}\delta(c_m-n), \tag{55}$$

where $l_{-m,n}$ denotes the number of elements in $\{i:c_i=n,i\neq m\}$ and $c_m=0$ indicates a new sample is drawn from the base G_0. Given c_m and $\overline{\Theta}$, the density of Θ_m is given by

$$p(\Theta_m|c_m,\overline{\Theta},G_0)=\delta(c_m)G_0(\Theta_m)+\sum_{n=1}^{N}\delta(c_m-n)\delta(\Theta_m-\overline{\Theta}_n). \tag{56}$$

5.3 The Dirichlet Process Posterior

We take two steps to derive the posterior based on the representation of the DP prior given by (55) and (56). First we write the conditional posterior of c_m, $\forall\, m\in\{1,\cdots,M\}$,

$$p(c_m|c_{-m},\overline{\Theta},\mathcal{D}_m^{(K_m)},\alpha,G_0)=\frac{\int\widehat{V}(\mathcal{D}_m^{(K_m)};\Theta_m)p(\Theta_m|c_m,\overline{\Theta},G_0)p(c_m|c_{-m},\alpha)d\Theta_m}{\sum_{c_m=0}^{N}\int\widehat{V}(\mathcal{D}_m^{(K_m)};\Theta_m)p(\Theta_m|c_m,\overline{\Theta},G_0)p(c_m|c_{-m},\alpha)d\Theta_m},$$

which is rewritten, by substituting (55) and (56) into the righthand side, to yield an algorithmically more meaningful expression

$$p(c_m|c_{-m},\overline{\Theta},\mathcal{D}_m^{(K_m)},\alpha,G_0)=\frac{\alpha\widehat{V}_{G_0}(\mathcal{D}_m^{(K_m)})\,\delta(c_m)+\sum_{n=1}^{N}l_{-m,n}\widehat{V}(\mathcal{D}_m^{(K_m)};\overline{\Theta}_n)\,\delta(c_m-n)}{\alpha\widehat{V}_{G_0}(\mathcal{D}_m^{(K_m)})+\sum_{j=1}^{N}l_{-m,j}\widehat{V}(\mathcal{D}_m^{(K_m)};\overline{\Theta}_j)}, \tag{57}$$

4. The corresponding expression in terms of probability measures (Escobar and West, 1995) is given by

$$\Theta_m|\Theta_{-m},\alpha,G_0\sim\frac{\alpha}{\alpha+M-1}G_0+\frac{1}{\alpha+M-1}\textstyle\sum_{j=1,j\neq m}^{M}\delta_{\Theta_j},\;\; m=1,\cdots,M,$$

where δ_{Θ_j} is the Dirac measure.

where the $\widehat{V}_{G_0}(\mathcal{D}_m^{(K_m)})$ is the marginal empirical value defined in (39) and its expression is given by (53) when the DP base has a density function as specified in (45).

It is observed from (57) that the indicator c_m tends to equal n if $\widehat{V}(\mathcal{D}_m^{(K_m)};\overline{\Theta}_n)$ is large, which occurs when the n-th distinct RPR produces a high empirical value in the m-th environment. If none of the other RPRs produces a high empirical value in the m-th environment, c_m will tend to be equal to zero, which means a new cluster will be generated to account for the novelty. The merit of generating a new cluster is measured by the empirical value weighted by α and averaged with respect to G_0. Therefore the number of distinct RPRs is jointly dictated by the DP prior and the episodes.

Given the indicator variables c, the clusters are formed. Let $I_n(c) = \{m : c_m = n\}$ denote the indices of the environments that have been assigned to the n-th cluster. Given the clusters, we now derive the conditional posterior of $\overline{\Theta}_n, \forall\, n \in \{1,\cdots,N\}$. If $I_n(c)$ is an empty set, there is no empirical evidence available for it to obtain a posterior, therefore one simply removes this cluster. If $I_n(c)$ is nonempty, the density function of the conditional posterior of $\overline{\Theta}_n$ is given by

$$p(\overline{\Theta}_n|\textstyle\bigcup_{m\in I_n(c)}\mathcal{D}_m^{(K_m)},G_0) = \dfrac{\sum_{m\in I_n(c)}\widehat{V}(\mathcal{D}_m^{(K_m)};\overline{\Theta}_n)G_0(\overline{\Theta}_n)}{\int\sum_{m\in I_n(c)}\widehat{V}(\mathcal{D}_m^{(K_m)};\overline{\Theta}_n)G_0(\overline{\Theta}_n)\,d\overline{\Theta}_n} \tag{58}$$

$$= \dfrac{\sum_{m\in I_n(c)}\frac{1}{K_m}\sum_{k=1}^{K_m}\sum_{t=0}^{T_{m,k}}\tilde{r}_t^{m,k}\sum_{z_0^{m,k},\cdots,z_t^{m,k}=1}^{|\mathcal{Z}|}p(a_{0:t}^{m,k},z_{0:t}^{m,k}|o_{1:t}^{m,k},\overline{\Theta}_n)G_0(\overline{\Theta}_n)}{\sum_{m\in I_n(c)}\widehat{V}_{G_0}(\mathcal{D}_m^{(K_m)})}, \tag{59}$$

where (59) results from substituting (12) into the righthand side of (58). Note that $\overline{\Theta}_n$, which represents the set of parameters of the n-th distinct RPR, is conditioned on all episodes aggregated across all environments in the n-th cluster. The posterior in (58) has the same form as the definition in (38) and it is obtained by applying Bayes law to the empirical value function constructed from the aggregated episodes. As before, the Bayes law is applied in a nonstandard manner, treating the value function as if it were a likelihood function.

A more concrete expression of (59) can be obtained by letting the DP base G_0 have a density function as in (45),

$$\begin{aligned}&p(\overline{\Theta}_n|\textstyle\bigcup_{m\in I_n(c)}\mathcal{D}_m^{(K_m)},G_0)\\ &= \dfrac{\sum_{m\in I_n(c)}\frac{1}{K_m}\sum_{k=1}^{K_m}\sum_{t=0}^{T_{m,k}}\tilde{r}_t^{m,k}\sum_{z_0^{m,k},\cdots,z_t^{m,k}=1}^{|\mathcal{Z}|}\zeta_t^{m,k}(z_{0:t}^{m,k})\;p(\overline{\Theta}_n|a_{0:t}^{m,k},o_{1:t}^{m,k},z_{0:t}^{m,k},G_0)}{\sum_{m\in I_n(c)}\widehat{V}_{G_0}(\mathcal{D}_m^{(K_m)})},\end{aligned} \tag{60}$$

where $\widehat{V}_{G_0}(\mathcal{D}_m^{(K_m)})$ is the marginal empirical value given in (53), $\zeta_t^{m,k}(z_{0:t}^{m,k})$ is the average recomputed reward as given in (49), and

$$p(\overline{\Theta}_n|a_{0:t}^{m,k},o_{1:t}^{m,k},z_{0:t}^{m,k},G_0) \quad = \quad p(\overline{\mu}^n|\widehat{\upsilon}^{m,k,t})p(\overline{\pi}^n|\widehat{\rho}^{m,k,t})p(\overline{W}^n|\widehat{\omega}^{m,k,t})$$

is the density of a product of Dirichlet distributions and has the same form as $G_0(\Theta)$ in (45) but with υ,ρ,ω respectively replaced by $\widehat{\upsilon}^{m,k,t}$, $\widehat{\rho}^{m,k,t}$, $\widehat{\omega}^{m,k,t}$ as given by (50), (51), and (52).

It is noted that, conditional on the indicator variables c and the episodes across all environments, the distinct RPRs are independent of each other. The indicator variables cluster the M environments into $N \le M$ groups, each of which is associated with a distinct RPR. Given the clusters, the environments in the n-th group merge their episodes to form a pool, and the posterior of $\overline{\Theta}_n$ is derived based on this pool. Existing clusters may become empty and be removed, and new clusters may be introduced when novelty is detected, thus the pools change dynamically. The dynamic changes are implemented inside the algorithm presented below. Therefore, the number of distinct RPRs is not fixed but is allowed to vary.

5.4 Challenges for Gibbs Sampling

The DP posterior as given by (57) and (60) may be analyzed using the technique of Gibbs sampling (Geman and Geman, 1984; Gelfand and Smith, 1990). The Gibbs sampler successively draws the indicator variables $c_1, c_2, \cdots, c_M$ and the distinct RPRs $\overline{\Theta}_1, \overline{\Theta}_2, \cdots, \overline{\Theta}_N$ according to (57) and (60). The samples are expected to represent the posterior when the Markov chain produced by the Gibbs sampler reaches the stationary distribution. However, the convergence of Gibbs sampling can be slow and a long sequence of samples may be required before the stationary distribution is reached. The slow convergence can generally be attributed to the fact that the Gibbs sampler implements message-passing between dependent variables through the use of samples, instead of sufficient statistics (Jordan et al., 1999). Variational methods have been suggested as a replacement for Gibbs sampling (Jordan et al., 1999). Though efficient, variational methods are known to suffer from bias. A good trade-off is to combine the two, which is the idea of hybrid variational/Gibbs inference in Welling et al. (2008).

In our present case, Gibbs sampling is further challenged by the particular form of the conditional posterior of $\overline{\Theta}_n$ in (60), which is seen to be a large mixture resulting from the summation over environment m, episode k, time step t, and latent z variables. Thus it has a total of $\sum_{m \in I_n} \sum_{k=1}^{K_m} \sum_{t=0}^{T_{m,k}} |\mathcal{Z}|^t$ components and each component is uniquely associated with a single sub-episode and a specific instantiation of latent z variables. To sample from this mixture, one first makes a draw to decide a component and then draws $\overline{\Theta}_n$ from this component. Obviously, any particular draw of $\overline{\Theta}_n$ makes use of one single sub-episode only, instead of simultaneously employing all sub-episodes in the n-th cluster as one would wish.

In essence, mixing with respect to (m,k,t) effectively introduces additional latent indicator variables, that is, those for locating environment m, episode k, and time step t. It is important to note that these new indicator variables play a different role than z's in affecting the samples of $\overline{\Theta}_n$. In particular, the z's are intrinsic latent variables inside the RPR model, while the new ones are extrinsic latent variables resulting from the particular form of the empirical value function in (37). Each realization of the new indicators is uniquely associated with a distinct sub-episode while each realization of z's is uniquely associated specific decision states. Therefore, the update of $\overline{\Theta}_n$ based on one realization of the new indicators employs a single sub-episode, but the update based on one realization of z's employs all sub-episodes.

5.5 The Gibbs-Variational Algorithm for Learning the DP Posterior

The fact that the Gibbs sampler cannot update the posterior RPR samples by using more than one sub-episode motivates us to develop a hybrid Gibbs-variational algorithm for learning the posterior.

We restrict the joint posterior of the latent z variables and the RPR parameters to the variational Bayesian (VB) approximation that assumes a factorized form. This restriction yields a variational approximation to $p(\overline{\Theta}_n | \bigcup_{m \in I_n(c)} \mathcal{D}_m^{(K_m)}, G_0)$ that is a single product of Dirichlet density functions, where the terms associated with different episodes are collected and added up. Therefore, updating of the variational posterior of $\overline{\Theta}_n$ in each Gibbs-variational iteration is based on simultaneously employing all sub-episodes in the n-th cluster. In addition, the variational method yields an approximation of the marginal empirical value $\widehat{V}_{G_0}(\mathcal{D}_m^{(K_m)})$ as given in (39).

The overall Gibbs-variational algorithm is an iterative procedure based on the DP posterior represented by (57) and (58). At each iteration one successively performs the following for $m = 1, 2, \cdots, M$. First, the cluster indicator variable c_m is drawn according to (57), where $\widehat{V}_{G_0}(\mathcal{D}_m^{(K_m)})$ is replaced by its variational Bayesian approximation; accordingly the clusters $I_n = \{m : c_m = n\}, n = 1, \ldots, N$ are updated. For each nonempty cluster n, the associated distinct RPR is updated by drawing from, or finding the mode of, the variational Bayesian approximation of $p(\overline{\Theta}_n | \bigcup_{m \in I_n(c)} \mathcal{D}_m^{(K_m)}, G_0)$. The steps are iterated until the variational approximation of $\sum_{n=1}^{N} \widehat{V}_{G_0}(\bigcup_{m \in I_n(c)} \mathcal{D}_m^{(K_m)})$ converges. Note that the number of clusters is not fixed but changes with the iteration, since existing clusters may become empty and be removed and new clusters may be added in.

5.5.1 VARIATIONAL BAYESIAN APPROXIMATION OF $\widehat{V}_{G_0}(\mathcal{D}^{(K)})$ AND $p(\Theta|\mathcal{D}^{(K)}, G_0)$

In this subsection we drop the variable dependence on environment m, for notational simplicity. The discussion assumes a set of episodes $\mathcal{D}^{(K)} = \{(a_0^k r_0^k o_1^k a_1^k r_1^k \cdots o_{T_k}^k a_{T_k}^k r_{T_k}^k)\}_{k=1}^{K}$, which may come from a single environment or a conglomeration of several environments.

We now derive the variational Bayesian approximation of the marginal empirical value function $\widehat{V}_{G_0}(\mathcal{D}^{(K)})$ as defined in (39). We begin by rewriting (39), using (6) and (37), as

$$\widehat{V}_{G_0}(\mathcal{D}^{(K)}) \quad = \quad \frac{1}{K} \sum_{k=1}^{K} \sum_{t=0}^{T_k} \tilde{r}_t^k \sum_{z_0^k, \cdots, z_t^k = 1}^{|\mathcal{Z}|} \int p(a_{0:t}^k, z_{0:t}^k | o_{1:t}^k, \Theta) G_0(\Theta)\, d\Theta.$$

We follow the general variational Bayesian approach (Jordan et al., 1999; Jaakkola, 2001; Beal, 2003)[5] to find a variational lower bound to $\ln \widehat{V}_{G_0}(\mathcal{D}^{(K)})$, and the variational Bayesian approximation of $\widehat{V}_{G_0}(\mathcal{D}^{(K)})$ is obtained as the exponential of the lower bound. The lower bound is a functional of a set of factorized forms $\{q_t^k(z_{0:t}^k) g(\Theta) : z_t^k \in \mathcal{Z}, t = 1 \ldots T_k, k = 1 \ldots K\}$ that satisfies the following normalization constraints:

$$\sum_{k=1}^{K} \sum_{t=1}^{T_k} \sum_{z_0^k, \cdots, z_t^k = 1}^{|\mathcal{Z}|} q_t^k(z_{0:t}^k) = K \;\text{ and }\; q_t^k(z_{0:t}^k) \geq 0 \, \forall z_{0:t}^k, t, k,$$
$$\int g(\Theta) d\Theta = 1 \;\text{ and }\; g(\Theta) \geq 0 \, \forall \Theta.$$

The lower bound is maximized with respect to $\{q_t^k(z_{0:t}^k) g(\Theta)\}$. As will come clear below, maximization of the lower bound is equivalent to minimization of the Kullback-Leibler (KL) distance between the factorized forms and *weighted* true joint posterior of z's and Θ. In this sense, the optimal $g(\Theta)$ is a variational Bayesian approximation to the posterior $p(\Theta|\mathcal{D}^{(K)}, G_0)$. It should be noted that, as before, the weights result from the empirical value function and are not a part of standard VB (as applied to likelihood functions).

The variational lower bound is obtained by applying Jensen's inequality to $\ln \widehat{V}_{G_0}(\mathcal{D}^{(K)})$,

$$\ln \widehat{V}_{G_0}(\mathcal{D}^{(K)})$$

5. The standard VB applies to a likelihood function. Since we are using a value function instead of a likelihood function, the VB derivation here is not a standard one, just as the Bayes rule in (38) is non-standard.

$$\begin{aligned}
&= \ln \frac{1}{K}\sum_{k=1}^{K}\sum_{t=0}^{T_k}\sum_{z_0^k,\cdots,z_t^k=1}^{|\mathcal{Z}|}\int q_t^k(z_{0:t}^k)g(\Theta)\frac{\tilde{r}_t^k G_0(\Theta)p(a_{0:t}^k,z_{0:t}^k|o_{1:t}^k,\Theta)}{q_t^k(z_{0:t}^k)g(\Theta)}\,d\Theta \\
&\geq \frac{1}{K}\sum_{k=1}^{K}\sum_{t=0}^{T_k}\sum_{z_0^k,\cdots,z_t^k=1}^{|\mathcal{Z}|}\int q_t^k(z_{0:t}^k)g(\Theta)\ln\frac{\tilde{r}_t^k G_0(\Theta)p(a_{0:t}^k,z_{0:t}^k|o_{1:t}^k,\Theta)}{q_t^k(z_{0:t}^k)g(\Theta)}\,d\Theta \\
&= \ln\widehat{V}_{G_0}(\mathcal{D}^{(K)}) - \mathrm{KL}\left(\left\{q_t^k(z_{0:t}^k)g(\Theta)\right\}\Big\|\left\{\frac{\zeta_t^k}{\widehat{V}_{G_0}(\mathcal{D}^{(K)})}p(z_{0:t}^k,\Theta|a_{0:t}^k,o_{1:t}^k)\right\}\right) \\
&\overset{Def.}{=} \mathrm{LB}\left(\left\{q_t^k\right\},g(\Theta)\right), \qquad (61)
\end{aligned}$$

where ζ_t^k is the average recomputed reward as given in (42), and

$$\begin{aligned}
&\mathrm{KL}\left(\left\{q_t^k(z_{0:t}^k)g(\Theta)\right\}\Big\|\left\{\frac{\zeta_t^k}{\widehat{V}_{G_0}(\mathcal{D}^{(K)})}p(z_{0:t}^k,\Theta|a_{0:t}^k,o_{1:t}^k)\right\}\right) \\
&= \frac{1}{K}\sum_{k=1}^{K}\sum_{t=0}^{T_k}\sum_{z_0^k,\cdots,z_t^k=1}^{|\mathcal{Z}|}\int q_t^k(z_{0:t}^k)g(\Theta)\ln\frac{q_t^k(z_{0:t}^k)g(\Theta)}{\frac{\zeta_t^k}{\widehat{V}_{G_0}(\mathcal{D}^{(K)})}p(z_{0:t}^k,\Theta|a_{0:t}^k,o_{1:t}^k)}\,d\Theta,
\end{aligned}$$

with $\mathrm{KL}(q||p)$ denoting the Kullback-Leibler distance.

For any set $\left\{q_t^k(z_{0:t}^k)g(\Theta) : z_t^k \in \mathcal{Z}, t = 1\ldots T_k, k = 1\ldots K\right\}$ satisfying the above normalization constraints, the inequality in (61) holds. In order to obtain the lower bound that is closest to $\ln\widehat{V}(\mathcal{D}^{(K)})$, one maximizes the lower bound by optimizing $\left(\left\{q_t^k\right\},g(\Theta)\right)$ subject to the normalization constraints. Since $\ln\widehat{V}_{G_0}(\mathcal{D}^{(K)})$ is independent of Θ and $\{q_t^k\}$, it is clear that maximization of the lower bound $\mathrm{LB}\left(\left\{q_t^k\right\},g(\Theta)\right)$ is equivalent to minimization of the KL distance between $\left\{q_t^k(z_{0:t}^k)g(\Theta)\right\}$ and the weighted posterior $\left\{\frac{\zeta_t^k}{\widehat{V}_{G_0}(\mathcal{D}^{(K)})}p(z_{0:t}^k,\Theta|a_{0:t}^k,o_{1:t}^k)\right\}$, where the weight for episode k at time step t is $\frac{\zeta_t^k}{\widehat{V}_{G_0}(\mathcal{D}^{(K)})} = K\frac{\zeta_t^k}{\sum_{k=1}^{K}\sum_{t=0}^{T_k}\zeta_t^k}$ (the equation results directly from (43)), that is, K times the fraction that the average recomputed reward ζ_t^k occupies in the total average recomputed reward. Therefore the factorized form $\left\{q_t^k(z_{0:t}^k)g(\Theta)\right\}$ represents an approximation of the weighted posterior when the lower bound reaches the maximum, and the corresponding $g(\Theta)$ is called the approximate variational posterior of Θ.

The lower bound maximization is accomplished by solving $\left\{q_t^k(z_{0:t}^k)\right\}$ and $q(\Theta)$ alternately, keeping one fixed while solving for the other, as shown in Theorem 8.

Theorem 8 *Iteratively applying the following two equations produces a sequence of monotonically increasing lower bounds* $\mathrm{LB}\left(\left\{q_t^k\right\},g(\Theta)\right)$*, which converges to a maxima,*

$$q_t^k(z_{0:t}^k) = \frac{\tilde{r}_t^k}{C_z}\exp\left\{\int g(\Theta)\ln p(a_{0:t}^k,z_{0:t}^k|o_{1:t}^k,\Theta)\,d\Theta\right\}, \qquad (62)$$

$$g(\Theta) = \frac{G_0(\Theta)}{C_\Theta}\exp\left\{\frac{1}{K}\sum_{k=1}^{K}\sum_{t=0}^{T_k}\sum_{z_0^k,\cdots,z_t^k=1}^{|\mathcal{Z}|}q_t^k(z_{0:t}^k)\ln\tilde{r}_t^k p(a_{0:t}^k,z_{0:t}^k|o_{1:t}^k,\Theta)\right\}, \qquad (63)$$

where C_z and C_Θ are normalization constants such that $\int g(\Theta)d\Theta = 1$ and $\sum_{k=1}^{K}\sum_{t=0}^{T_k}\sum_{z_0^k,\cdots,z_t^k=1}^{|\mathcal{Z}|}q_t^k(z_{0:t}^k) = K$.

It is seen from (63) that the variational posterior $g(\Theta)$ takes the form of a product, where each term in the product is uniquely associated with a sub-episode. As will be clear shortly, the terms are properly collected and the associated sub-episodes simultaneously employed in the posterior. We now discuss the computations involved in Theorem 8.

Calculation of $\left\{q_t^k(z_{0:t}^k)\right\}$ We uses the prior of Θ as specified by (45). It is not difficult to verify from (63) that the variational posterior $g(\Theta)$ takes the same form as the prior, that is,

$$g(\Theta) \quad = \quad p(\mu|\widehat{\upsilon})p(\pi|\widehat{\rho})p(W|\widehat{\omega}), \tag{64}$$

where the three factors respectively have the forms of (46),(47), and (48); we have put a hat $\widehat{}$ above the hyper-parameters of $g(\Theta)$ to indicate the difference from those of the prior.

Substituting (5) and (64) into (62), we obtain

$$\begin{aligned}
&q_t^k(z_{0:t}^k)\\
&=\frac{\tilde{r}_t^k}{C_z}\exp\left\{\sum_{\tau=0}^{t}\left\langle\ln\pi(z_\tau^k,a_\tau^k)\right\rangle_{p(\pi|\widehat{\rho})}+\left\langle\ln\mu(z_0^k)\right\rangle_{p(\mu|\widehat{\upsilon})}+\sum_{\tau=1}^{t}\left\langle\ln W(z_{\tau-1}^k,a_{\tau-1}^k,o_\tau^k,z_\tau^k)\right\rangle_{p(W|\widehat{\omega})}\right\}\\
&=\frac{\tilde{r}_t^k}{C_z}\widetilde{\mu}(z_0^k)\widetilde{\pi}(z_0^k,a_0^k)\prod_{\tau=1}^{t}\widetilde{W}(z_{\tau-1}^k,a_{\tau-1}^k,o_\tau^k,z_\tau^k)\widetilde{\pi}(z_\tau^k,a_\tau^k),
\end{aligned}\tag{65}$$

where $\langle\cdot\rangle_{p(\pi|\widehat{\rho})}$ denotes taking expectation with respect to $p(\pi|\widehat{\rho})$, and

$$\begin{aligned}
\widetilde{\mu}(j) &= \exp\left\{\left\langle\ln\mu(j)\right\rangle_{p(\mu|\widehat{\upsilon})}\right\}\\
&= \exp\left\{\psi(\widehat{\upsilon}_j)-\psi(\sum_{j'=1}^{|\mathcal{Z}|}\widehat{\upsilon}_{j'})\right\}, \quad j=1\ldots|\mathcal{Z}|, &(66)\\
\widetilde{\pi}(i,m) &= \exp\left\{\left\langle\ln\pi(i,m)\right\rangle_{p(\pi|\widehat{\rho})}\right\}\\
&= \exp\left\{\psi(\widehat{\rho}_{i,m})-\psi(\sum_{m'=1}^{|\mathcal{A}|}\widehat{\rho}_{i,m'})\right\}, \quad m=1\ldots|\mathcal{A}|, &(67)\\
\widetilde{W}(i,a,o,j) &= \exp\left\{\left\langle\ln W(i,a,o,j)\right\rangle_{p(W|\widehat{\omega})}\right\}\\
&= \exp\left\{\psi(\widehat{\omega}_{i,a,o,j})-\psi(\sum_{j'=1}^{|\mathcal{Z}|}\widehat{\omega}_{i,a,o,j'})\right\}, \quad j=1\ldots|\mathcal{Z}|, &(68)
\end{aligned}$$

each of which is a finite set of nonnegative numbers with a sum less than one. Such a finite set is called under-normalized probabilities in Beal (2003) and used there to perform variational Bayesian learning of hidden Markov models (HMM). The $\psi(\cdot)$ is the digamma function.

It is interesting to note that the product $\widetilde{\mu}(z_0^k)\widetilde{\pi}(z_0^k,a_0^k)\prod_{\tau=1}^{t}\widetilde{W}(z_{\tau-1}^k,a_{\tau-1}^k,o_\tau^k,z_\tau^k)\widetilde{\pi}(z_\tau^k,a_\tau^k)$ on the left side of (65) has exactly the same form as the expression of $p(a_{0:t}^k,z_{0:t}^k|o_{1:t}^k,\Theta)$ in (5), except that the Θ is replaced by $\widetilde{\Theta}=\{\widetilde{\mu},\widetilde{\pi},\widetilde{W}\}$. Therefore, one can nominally rewrite (65) as

$$q_t^k(z_{0:t}^k) \quad = \quad \frac{\tilde{r}_t^k}{C_z}p(a_{0:t}^k,z_{0:t}^k|o_{1:t}^k,\widetilde{\Theta}),$$

with the normalization constant given by

$$C_z = \frac{1}{K}\sum_{k=1}^{K}\sum_{t=0}^{T_k}\sum_{z_0^k,\cdots,z_t^k=1}^{|\mathcal{Z}|} \tilde{r}_t^k p(a_{0:t}^k, z_{0:t}^k | o_{1:t}^k, \widetilde{\Theta}),$$

such that the constraint $\sum_{k=1}^{K}\sum_{t=0}^{T_k}\sum_{z_0^k,\cdots,z_t^k=1}^{|\mathcal{Z}|} q_t^k(z_{0:t}^k) = K$ is satisfied. One may also find that the normalization constant C_z is a nominal empirical value function that has the same form as the empirical value function in (12). The only difference is that the normalized Θ is replaced by the under-normalized $\widetilde{\Theta}$. Therefore, one may write

$$C_z = \widehat{V}(\mathcal{D}^{(K)};\widetilde{\Theta}). \tag{69}$$

Since $\widetilde{\Theta} = \{\widetilde{\mu}, \widetilde{\pi}, \widetilde{W}\}$ are under-normalized, $p(a_{0:t}^k, z_{0:t}^k | o_{1:t}^k, \widetilde{\Theta})$ is not a proper probability distribution. However, one may still write $p(a_{0:t}^k, z_{0:t}^k | o_{1:t}^k, \widetilde{\Theta}) = p(a_{0:t}^k | o_{1:t}^k, \widetilde{\Theta}) p(z_{0:t}^k | a_{0:t}^k, o_{1:t}^k, \widetilde{\Theta})$, where $p(a_{0:t}^k | o_{1:t}^k, \widetilde{\Theta}) = \sum_{z_0^k,\cdots,z_t^k=1}^{|\mathcal{Z}|} p(a_{0:t}^k, z_{0:t}^k | o_{1:t}^k, \widetilde{\Theta})$ and $p(z_{0:t}^k | a_{0:t}^k, o_{1:t}^k, \widetilde{\Theta}) = \frac{p(a_{0:t}^k, z_{0:t}^k | o_{1:t}^k, \widetilde{\Theta})}{p(a_{0:t}^k | o_{1:t}^k, \widetilde{\Theta})}$. Note that $p(z_{0:t}^k | a_{0:t}^k, o_{1:t}^k, \widetilde{\Theta})$ is a proper probability distribution. Accordingly, $q_t^k(z_{0:t}^k)$ can be rewritten as

$$q_t^k(z_{0:t}^k) = \frac{\sigma_t^k(\widetilde{\Theta})}{\widehat{V}(\mathcal{D}^{(K)};\widetilde{\Theta})} p(z_{0:t}^k | a_{0:t}^k, o_{1:t}^k, \widetilde{\Theta}), \tag{70}$$

where

$$\begin{aligned}\sigma_t^k(\widetilde{\Theta}) &= \tilde{r}_t^k p(a_{0:t}^k | o_{1:t}^k, \widetilde{\Theta}) \\ &= \tilde{r}_t^k \prod_{\tau=0}^{t} p(a_\tau^k | h_\tau^k, \widetilde{\Theta})\end{aligned} \tag{71}$$

is called variational re-computed reward, which has the same form as the re-computed reward given in (16) but with Θ replaced by $\widetilde{\Theta}$. The second equality in (71) is based on the equation $p(a_{0:t}^k | o_{1:t}^k, \Theta) = \prod_{\tau=0}^{t} p(a_\tau^k | h_\tau^k, \Theta)$ established in (9) and (10). The nominal empirical value function $\widehat{V}(\mathcal{D}^{(K)};\widetilde{\Theta})$ can now be expressed in terms of $\sigma_t^k(\widetilde{\Theta})$,

$$\widehat{V}(\mathcal{D}^{(K)};\widetilde{\Theta}) = \frac{1}{K}\sum_{k=1}^{K}\sum_{t=0}^{T_k} \sigma_t^k(\widetilde{\Theta}). \tag{72}$$

Equation (70) shows that $q_t^k(z_{0:t}^k)$ is a weighted posterior of $z_{0:t}^k$. The weights, using (72), can be equivalently expressed as $\frac{\sigma_t^k(\widetilde{\Theta})}{\widehat{V}(\mathcal{D}^{(K)};\widetilde{\Theta})} = K\eta_t^k(\widetilde{\Theta})$ where

$$\eta_t^k(\widetilde{\Theta}) \overset{Def.}{=} \frac{\sigma_t^k(\widetilde{\Theta})}{\sum_{k=1}^{K}\sum_{t=0}^{T_k} \sigma_t^k(\widetilde{\Theta})}. \tag{73}$$

The weighted posterior has the same form as (15) used in single-task RPR learning. Therefore we can borrow the techniques developed there to compute the marginal distributions of $p(z_{0:t}^k | a_{0:t}^k, o_{1:t}^k, \widetilde{\Theta})$, particularly those defined in (24) and (25). For clarity, we rewrite these marginal distributions below without re-deriving them, with Θ replaced by $\widetilde{\Theta}$,

$$\xi_{t,\tau}^k(i,j) = p(z_\tau^k = i, z_{\tau+1}^k = j | a_{0:t}^k, o_{1:t}^k, \widetilde{\Theta}), \tag{74}$$

$$\phi_{t,\tau}^k(i) = p(z_\tau^k = i | a_{0:t}^k, o_{1:t}^k, \widetilde{\Theta}). \tag{75}$$

These marginals along with the $\{\eta_t^k(\widetilde{\Theta})\}$ defined in (73) will be used below to compute the variational posterior $g(\Theta)$.

Calculation of the Variational Posterior $g(\Theta)$ To compute $g(\Theta)$, one substitutes (5) and (70) into (63) and performs summation over the latent z variables. Most z variables are summed out, leaving only the marginals in (74) and (75). Employing these marginals and taking into account the weights $\{K\eta_t^k(\widetilde{\Theta})\}$, the variational posterior (with $\eta_t^k(\widetilde{\Theta})$ abbreviated as η_t^k for notational simplicity) is obtained as

$$\begin{aligned} g(\Theta) &= \frac{G_0(\Theta)}{C_\Theta}\exp\left\{\frac{1}{K}\sum_{k=1}^{K}\sum_{t=0}^{T_k}K\eta_t^k\left[\sum_{i=1}^{|\mathcal{Z}|}\phi_{t,0}^k(i)\ln\mu(i)\right.\right.\\ &\quad\left.\left.+\sum_{\tau=1}^{t}\sum_{i=1}^{|\mathcal{Z}|}\phi_{t,\tau}^k(i)\ln\pi(i,a_\tau^k)+\sum_{\tau=1}^{t}\sum_{i,j=1}^{|\mathcal{Z}|}\xi_{t,\tau}^k(i,j)\ln W(i,a_{\tau-1}^k,o_\tau^k,j)\right]\right\}\\ &= \frac{G_0(\Theta)}{C_\Theta}\prod_{k=1}^{K}\prod_{t=0}^{T_k}\left\{\prod_{i=1}^{|\mathcal{Z}|}\left[\mu(i)\right]^{\eta_t^k\phi_{t,0}^k(i)}\prod_{\tau=1}^{t}\prod_{i=1}^{|\mathcal{Z}|}\left[\pi(i,a_\tau^k)\right]^{\eta_t^k\phi_{t,\tau}^k(i)}\right.\\ &\quad\left.\times\prod_{\tau=1}^{t}\prod_{i,j=1}^{|\mathcal{Z}|}\left[W(i,a_{\tau-1}^k,o_\tau^k,j)\right]^{\eta_t^k\xi_{t,\tau-1}^k(i,j)}\right\}\\ &= p(\mu|\widehat{\upsilon})p(\pi|\widehat{\rho})p(W|\widehat{\omega}), \end{aligned}$$

where $p(\mu|\widehat{\upsilon})$, $p(\pi|\widehat{\rho})$, $p(W|\widehat{\omega})$ have the same forms as in (46), (47), and (48), respectively, but with the hyper-parameters replaced by

$$\widehat{\upsilon}_i = \upsilon_i+\sum_{k=1}^{K}\sum_{t=0}^{T_k}\eta_t^k\phi_{t,0}^k(i), \tag{76}$$

$$\widehat{\rho}_{i,a} = \rho_{i,a}+\sum_{k=1}^{K}\sum_{t=0}^{T_k}\sum_{\tau=0}^{t}\eta_t^k\phi_{t,\tau}^k(i)\delta(a_\tau^k,a), \tag{77}$$

$$\widehat{\omega}_{i,a,o,j} = \omega_{i,a,o,j}+\sum_{k=1}^{K}\sum_{t=0}^{T_k}\sum_{\tau=1}^{t}\eta_t^k\xi_{t,\tau-1}^k(i,j)\delta(a_{\tau-1}^k,a)\delta(o_\tau^k,o), \tag{78}$$

for $i,j=1,\ldots,|\mathcal{Z}|$, $a=1,\ldots,|\mathcal{A}|$, $o=1,\ldots,|\mathcal{O}|$. Note that, for simplicity, we have used $\{\widehat{\upsilon},\widehat{\rho},\widehat{\omega}\}$ to denote the hyper-parameters of $g(\Theta)$ for both before and after the updates in (76)-(78) are made. It should be kept in mind that the η's, ϕ's, and ξ's are all based on the numerical values of $\{\widehat{\upsilon},\widehat{\rho},\widehat{\omega}\}$ before the updates in (76)-(78) are made, that is, they are based on the $\{\widehat{\upsilon},\widehat{\rho},\widehat{\omega}\}$ updated in the previous iteration.

It is clear from (76)-(78) that the update of the variational posterior is based on using all episodes at all time steps (i.e., all sub-episodes). The η_t^k can be thought of as a variational soft count at time t of episode k, which is appended to the hyper-parameters (initial Dirichlet counts) of the prior. Each decision state z receives η_t^k in the amount that is proportional to the probability specified by the posterior marginals $\{\phi_{t,\tau}^k\}$ and $\{\xi_{t,\tau-1}^k\}$.

Computation of the Lower Bound To compute the lower bound $\text{LB}(\{q_t^k\},g(\Theta))$ given in (61), one first takes the logarithm of (62) to obtain

$$\begin{aligned} \ln q_t^k(z_{0:t}^k) &= \ln C_z^{-1}\tilde{r}_t^k\exp\left\{\int g(\Theta)\ln p(a_{0:t}^k,z_{0:t}^k|o_{1:t}^k,\Theta)\,d\Theta\right\}\\ &= -\ln C_z+\int g(\Theta)\ln\tilde{r}_t^k p(a_{0:t}^k,z_{0:t}^k|o_{1:t}^k,\Theta)\,d\Theta, \end{aligned}$$

which is then substituted into the right side of (82) in the Appendix to cancel the first term, yielding

$$\begin{aligned}\mathrm{LB}\left(\left\{q_t^k\right\},g(\Theta)\right) &= \ln C_z - \int g(\Theta)\ln\frac{g(\Theta)}{G_0(\Theta)}\,d\Theta \\ &= \ln C_z - \mathrm{KL}\Big(g(\Theta)\|G_0(\Theta)\Big) \\ &= \ln\widehat{V}(\mathcal{D}^{(K)};\widetilde{\Theta}) - \mathrm{KL}\Big(g(\Theta)\|G_0(\Theta)\Big), \end{aligned} \tag{79}$$

where the last equality follows from (69).

The lower bound yields a variational approximation to the logarithm of the marginal empirical value. As variational Bayesian learning proceeds, the lower bound monotonically increases, as guaranteed by Theorem 8, and eventually reaches a maxima, at which point one obtains the best (assuming the maxima is global) variational approximation. By taking exponential of the best lower bound, one gets the approximated marginal empirical value. The lower bound also provides a quantitative measure for monitoring the convergence of variational Bayesian learning.

5.5.2 THE COMPLETE GIBBS-VARIATIONAL LEARNING ALGORITHM

A detailed algorithmic description of the complete Gibbs-variational algorithm is given in Table 2. The algorithm calls the variational Bayesian (VB) algorithm in Table 3 as a sub-routine, to find the variational Bayesian approximations to intractable computations. In particular, the marginal empirical value $\widehat{V}_{G_0}(\mathcal{D}_m^{(K_m)})$ in (57) is approximated by the exponential of the variational lower bound returned from the VB algorithm by feeding the episodes $\mathcal{D}_m^{(K_m)}$. The conditional posterior $p(\overline{\Theta}_n|\bigcup_{m\in I_n(c)}\mathcal{D}_m^{(K_m)},G_0)$ in (58) is approximated by the variational posterior $g(\overline{\Theta}_n)$ returned from the VB algorithm by feeding the episodes $\bigcup_{m\in I_n(c)}\mathcal{D}_m^{(K_m)}$. The variational approximation of $\widehat{V}_{G_0}(\mathcal{D}_m^{(K_m)})$ need be computed only once for each environment m, before the main loop begins, since it solely depends on the DP base G_0 and the episodes, which are assumed given and fixed. The variational posterior $g(\overline{\Theta}_n)$ and $\widehat{V}_{G_0}\left(\bigcup_{m\in I_n(c)}\mathcal{D}_m^{(K_m)}\right)$, however, need be updated inside the main loop, because the clusters $\{I_n(c)\}$ keep changing from iteration to iteration.

Upon convergence of the algorithm, one obtains variational approximations to the posteriors of distinct RPRs $\{g(\overline{\Theta}_n)\}_{n=1}^N$, which along with the cluster indicators $\{c_1,c_2,\cdots,c_M\}$ give the variational posterior $g(\Theta_m)$ for each individual environment m. By simple post-processing of the posterior, we obtain the mean or mode of each Θ_m, which gives a single RPR for each environment and yields the history-dependent policy as given by (8). Alternatively, one may draw samples from the variational posterior and use them to produce an ensemble of RPRs for each environment. The RPR ensemble gives multiple history-dependent policies, that are marginalized (averaged) to yield the final choice for the action.

It should be noted that the VB algorithm in Table 3 can also be used as a stand-alone algorithm to find the variational posterior of the RPR of each environment independently of the RPRs of other environments. In this respect the VB is a Bayesian counterpart of the maximum value (MV) algorithm for single-task reinforcement learning (STRL), presented in Section 4 and Table 1.

Time Complexity Analysis The time complexity of the VB algorithm in Table 3 is given as follows where, as in Section 4.3.1, the complexity is quantified by the number of real number multiplications in each iteration and is presented in the Big-O notation. For the reasons stated in Section 4.3.1, the complexity per iteration also represents the complexity of the complete algorithm.

```
Input: ${\{\mathcal{D}_m^{(K_m)}\}_{m=1}^M}$, $\mathcal{A}$, $\mathcal{O}$, $|\mathcal{Z}|$, $\{\upsilon,\rho,\omega\}$, $\alpha$
Output: $\{\widehat{\upsilon}_n,\widehat{\rho}_n,\widehat{\omega}_n\}_{n=1}^N$ with $N \le M$ and $\{c_1,c_2,\cdots,c_M\}$.

1. Computing the variational approximations of $\{\widehat{V}_{G_0}(\mathcal{D}_m^{(K_m)})\}$:
  1.1 for $m=1$ to $M$
        Call the algorithm in Table 3, with the inputs $\mathcal{D}_m^{(K_m)}$, $\mathcal{A}$, $\mathcal{O}$, $|\mathcal{Z}|$,
        $\{\upsilon,\rho,\omega\}$. Record the returned hyper-parameters as $\{\widehat{\upsilon}_m,\widehat{\rho}_m,\widehat{\omega}_m\}$ and the
        approximate $\widehat{V}_{G_0}(\mathcal{D}_m^{(K_m)})$.
2. Initializations: Let $j=1$, N=M, $\ell=0$.
        Let $\overline{\upsilon}_n=\widehat{\upsilon}_n$, $\overline{\rho}_n=\widehat{\rho}_n$, $\overline{\omega}_n=\widehat{\omega}_n$, for $n=1,\cdots,N$.
3. Repeat
  3.1 For $n=1$ to $N$
        Update $\overline{\Theta}_n$ by drawing from, or finding the mode of, the $G_0$ with hyper-
        parameters $\{\overline{\upsilon}_n,\overline{\rho}_n,\overline{\omega}_n\}$.
  3.2 For $m=1$ to $M$
        Let $c_m^{\text{old}}=c_m$ and draw $c_m$ according to (57).
        If $c_m \neq c_m^{\text{old}}$
          If $c_m=0$, start a new cluster $I_{N+1}(c)=\{m\}$.
          Elseif $c_m \neq 0$, move the element $m$ from $I_{c_m^{\text{old}}}(c)$ to $I_{c_m}(c)$.
          For $n=\{c_m^{\text{old}},c_m\}$
            If $I_n(c)$ is an empty set
              Delete the $n$-th cluster.
            Elseif $I_n(c)$ contain a single element (let it be denoted by $m'$)
              Let $\overline{\upsilon}_n=\widehat{\upsilon}_{m'}$, $\overline{\rho}_n=\widehat{\rho}_{m'}$, $\overline{\omega}_n=\widehat{\omega}_{m'}$. Add $\frac{K_{m'}}{\sum_{i=1}^M K_i}\widehat{V}_{G_0}(\mathcal{D}_{m'}^{(K_{m'})})$ to $\ell(j)$.
            Else
              Call the algorithm in Table 3, with the inputs $\bigcup_{i\in I_n(c)}\mathcal{D}_i^{(K_i)}$,
              $\mathcal{A}$, $\mathcal{O}$, $|\mathcal{Z}|$, $\{\upsilon,\rho,\omega\}$. Record the returned hyper-parameters as
              $\{\overline{\upsilon}_n,\overline{\rho}_n,\overline{\omega}_n\}$. Scale the returned $\widehat{V}_{G_0}\big(\bigcup_{i\in I_n(c)}\mathcal{D}_i^{(K_i)}\big)$
              by $\frac{\sum_{i\in I_n(c)}K_i}{\sum_{i=1}^M K_i}$ and add the result to $\ell(j)$.
            If $I_n(c)$ is not empty
              Draw $\overline{\Theta}_n$ drawn from $G_0$ with hyper-parameters $\{\overline{\upsilon}_n,\overline{\rho}_n,\overline{\omega}_n\}$.
  3.3 Updating $N$:
        Let $N$ be the number of nonempty clusters and renumber the
        nonempty clusters so that their indices are in $\{1,2,\cdots,N\}$.
  3.4 Convergence check:
        If the sequence of $\ell$ converges
          stop the algorithm and exit.
        Otherwise
          Set $j:=j+1$ and $\ell(j)=0$.
```

Table 2: The Gibbs-variational algorithm for learning the DP posterior

```
Input: $\mathcal{D}^{(K)}$, $\mathcal{A}$, $\mathcal{O}$, $|\mathcal{Z}|$, $\{\upsilon, \rho, \omega\}$.
Output: $\{\widehat{\upsilon}, \widehat{\rho}, \widehat{\omega}\}$, $\widehat{V}_{G_0}(\mathcal{D}^{(K)}) \approx \mathrm{LB}(\{q_t^k\}, g(\Theta))$.

1. Initialize $\widehat{\upsilon} = \upsilon$, $\widehat{\rho} = \rho$, $\widehat{\omega} = \omega$, $\ell = []$, iteration $= 1$.
2. Repeat
  2.1 Computing $\widetilde{\Theta}$:
      Compute the set of under-normalized probabilities $\widetilde{\Theta}$ using
      Equations (66)-(68).
  2.2 Dynamical programming:
      Compute $\alpha$ and $\beta$ variables with (30), (31), and (32), with $\Theta$
      replaced by $\widetilde{\Theta}$ in these equations.
  2.3 Reward re-computation:
      Calculate the variational recomputed reward $\{\sigma_t^k(\widetilde{\Theta})\}$ using
      (71) and (32) and compute the weight $\{\eta_t^k(\widetilde{\Theta})\}$ using (73).
  2.4 Lower bound computation:
      Calculate the variational lower bound $\mathrm{LB}(\{q_t^k\}, g(\Theta))$ using
      (79) and (72).
  2.5 Convergence check:
      Let $\ell(\text{iteration}) = \mathrm{LB}(\{q_t^k\}, g(\Theta))$.
      If the sequence of $\ell$ converges
          Stop the algorithm and exit.
      Else
          Set iteration := iteration + 1.
  2.6 Posterior update for $z$:
      Compute the $\xi$ and $\phi$ variables using Equations (28)-(29).
  2.7 Update of hyper-paramters:
      Compute the updated $\{\widehat{\upsilon}, \widehat{\rho}, \widehat{\omega}\}$ using (76), (77), and (78).
```

Table 3: The variational Bayesian learning algorithm for RPR

- The computation of $\widetilde{\Theta}$ based on Equations (66)-(68) runs in time $O(|\mathcal{Z}|)$, $O(|\mathcal{A}||\mathcal{Z}|)$, and $O(|\mathcal{A}||\mathcal{O}||\mathcal{Z}|^2)$, respectively.
- Computation of the α variables with (30) and (32) (with Θ replaced by $\widetilde{\Theta}$) runs in time $O(|\mathcal{Z}|^2 \sum_{k=1}^K T_k)$.
- Computation of the β variables with (31) and (32) (with Θ replaced by $\widetilde{\Theta}$) runs in time $O(|\mathcal{Z}|^2 \sum_{k=1}^K \sum_{t=0, r_t^k \neq 0}^{T_k} (t+1))$, which is $O(|\mathcal{Z}|^2 \sum_{k=1}^K T_k^2)$ in the worst case and is $O(|\mathcal{Z}|^2 \sum_{k=1}^K T_k)$ in the best case, where the worst and best cases are distinguished by the sparseness of immediate rewards, as discussed in Section 4.3.1.
- The reward re-computation using (71), (32), and (73) requires time $O(\sum_{k=1}^K T_k)$ in the worst case and $O(K)$ in the best case.
- Computation of the lower bound using (72) and (79) requires time $O(|\mathcal{A}||\mathcal{O}||\mathcal{Z}|^2)$.

- Update of the hyper-parameters using (76), (77), and (78), as well as computation of the ξ and ϕ variables using (28) and (29), runs in time $O(|\mathcal{Z}|^2 \sum_{k=1}^{K} T_k^2)$ in the worst case and $O(|\mathcal{Z}|^2 \sum_{k=1}^{K} T_k)$ in the best case.

The overall complexity of the VB algorithm is seen to be $O(|\mathcal{Z}|^2 \sum_{k=1}^{K} T_k^2)$ in the worst case and $O(|\mathcal{Z}|^2 \sum_{k=1}^{K} T_k)$ in the best case, based on the fact that $\sum_{k=1}^{K} T_k \gg |\mathcal{A}||\mathcal{O}|$ in general. Thus the VB algorithm has the same time complexity as the value maximization algorithm in Table 1. Note that the time dependency on the lengths of episodes is dictated by the sparseness of the immediate rewards; for most problems considered in Section 6, the agent receives rewards only when the goal state is reached, in which case the VB algorithm scales linearly with the lengths of episodes.

The complexity of the Gibbs-variational algorithm can be easily obtained based on the complexity analysis above for the VB algorithm. At the beginning and before entering the main loop, the Gibbs-variational algorithm calls the VB to compute the variational approximation of the marginal empirical value $\{\widehat{V}_{G_0}(\mathcal{D}_m^{(K_m)})\}$ for each environment m, by feeding the associated episodes $\mathcal{D}_m^{(K_m)}$. These computations are performed only once. For each environment the VB runs until convergence, with a time complexity between $O(|\mathcal{Z}|^2 \sum_{k=1}^{K_m} T_{m,k})$ and $O(|\mathcal{Z}|^2 \sum_{k=1}^{K_m} T_{m,k}^2)$ per iteration, depending on the sparseness of the immediate rewards. Inside the main loop, the Gibbs-variational algorithm calls the VB to compute the variational posterior of distinct RPR for each cluster n, by feeding the merged episodes $\bigcup_{m \in I_n(c)} \mathcal{D}_m^{(K_m)}$. These computations are performed each time the clusters are updated, with a time complexity between $O(|\mathcal{Z}|^2 \sum_{m\in I_n(c)} \sum_{k=1}^{K_m} T_{m,k})$ and $O(|\mathcal{Z}|^2 \sum_{m\in I_n(c)} \sum_{k=1}^{K_m} T_{m,k}^2)$ per iteration for cluster n.

6. Experimental Results

We compare the performance of RPR in multi-task reinforcement learning (MTRL) versus single-task reinforcement learning (STRL), and demonstrate the advantage of MTRL. The RPR for MTRL is implemented by the Gibbs-variational algorithm in Table 2 and the RPR for STRL is implemented by the maximum-value (MV) algorithm in Table 1. The variational Bayesian (VB) algorithm in Table 3, which is a Bayesian counterpart of the MV algorithm, generally performs similar to the MV for STRL and is thus excluded in the comparisons.

Since the MV algorithm is a new technique developed in this paper, we evaluate the performance of the MV before proceeding to the comparison of MTRL and STRL. We also compare the MV to the method of first learning a POMDP model from the episodes and then finding the optimal policy for the POMDP.

6.1 Performance of RPR in Single-Task Reinforcement Learning (STRL)

We consider the benchmark example Hallway2, introduced in Littman et al. (1995). The Hallway2 problem was originally designed to test algorithms based on a given POMDP model, and it has recently been employed as a benchmark for testing model-free reinforcement algorithms (Bakker, 2004; Wierstra and Wiering, 2004).

Hallway2 is a navigation problem where an agent is situated in a maze consisting of a number of rooms and walls that are connected to each other and the agent navigates in the maze with the objective of reaching the goal within a minimum number of steps. The maze is characterized by 92 states, each representing one of four orientations (south, north, east, west) in any of 23 rectangle areas, and four of the states (corresponding to a single rectangle area) represent the goal. The observations consist of $2^4 = 16$ combinations of presence/absence of a wall as viewed when standing in a rectangle facing one of the four orientations, and there is an observation uniquely associated with the goal. There are five different actions that the agent can take: $\{$*stay in place*, *move forward*, *turn right*, *turn left*, *turn around*$\}$. Both state transitions and observations are very noisy (uncertain), except that the goal is fully identified by the unique observation associated with it. The reward function is defined in such a way that a large reward is received when the agent enters the goal from the adjacent states, and zero reward is received otherwise. Thus the reward structure is highly sparse and both the MTRL and STRL algorithms scale linearly with the lengths of episodes in this case, as discussed in Sections 4.3.1 and 5.5.2.

6.1.1 PERFORMANCE AS A FUNCTION OF NUMBER OF EPISODES

We investigate the performance of the RPR, as a function of K the number of episodes used in the learning. For each given K, we learn a RPR from a set of K episodes $\mathcal{D}^{(K)}$ that are generated by following the behavior policy Π, and the learning follows the procedures described in Section 4.

The conditions for the policy Π, as given in Theorem 5, are very mild, and are satisfied by a uniformly random policy. However, a uniformly random agent may take a long time to reach the goal, which makes the learning very slow. To accelerate learning, we use a semi-random policy Π, which is simulated by the rule that, with probability p_{query}, Π chooses an action suggested by the PBVI algorithm (Pineau et al., 2003) and, with probability $1 - p_{\text{query}}$, Π chooses an action uniformly sampled from $\mathcal{A}$. The use of PBVI here is similar to the meta-queries used in Doshi et al. (2008), where a meta-query consults a domain expert (who is assumed to have access to the true POMDP model) for the optimal action at a particular time step. The meta-queries correspond to human-robot interactions in robotics applications. It should be noted that, by implementing the reward re-computation in RPR online, the behavior policy in each iteration simply becomes the RPR in the previous iteration, in which case the use of an external policy like PBVI is eliminated.

In principle, the number of decision states (belief regions) $|\mathcal{Z}|$ can be selected by maximizing the marginal empirical value $\widehat{V}_{G_0}(\mathcal{D}^{(K)}) = \int \widehat{V}(\mathcal{D}^{(K)}) G_0(\Theta) d\Theta$ with respect to $|\mathcal{Z}|$, where an approximation of $\widehat{V}(\mathcal{D}^{(K)})$ can be found by the VB algorithm in Table 3. Because the MV does not employ a prior, we make a nominal prior $G_0(\Theta)$ by letting it take the form of (45) but with all hyper-parameters uniformly set to one. This leads to $G_0(\Theta) \equiv C_{\text{mv}}$, where C_{mv} is a normalization constant. Therefore maximization of $\widehat{V}_{G_0}(\mathcal{D}^{(K)})$ is equivalent to maximization of $\int \widehat{V}(\mathcal{D}^{(K)}; \Theta) d\Theta$, which serves as an evidence of how good the choice of $|\mathcal{Z}|$ fits to the episodes in terms of empirical value. According to the Occam Razor principle (Beal, 2003), the minimum $|\mathcal{Z}|$ fitting the episodes has the best generalization. In practice, letting $|\mathcal{Z}|$ be a multiple of the number of actions is usually a good choice (here $|\mathcal{Z}| = 4 \times 5 = 20$) and we find that the performance of the RPR is quite robust to the choice of $|\mathcal{Z}|$. This may be attributed to the fact that learning of the RPR is a process of allocating counts to the decision states—when more decision states are included, they simply share the counts that otherwise would have been allocated to a single decision state. Provided the sharing of counts is consistent among μ, π, and W, the policy will not change much.

The performance of the RPR is compared against EM-PBVI, the method that first learns a predictive model as in Chrisman (1992) and then learns the policy based on the predictive model. Here the predictive model is a POMDP learned by expectation maximization (EM) based on $\mathcal{D}^{(K)}$ and the PBVI (Pineau et al., 2003) is employed to find the policy given the POMDP. To examine the effect of the behavior policy Π on the RPR's performance, we consider three different Π's, which respectively have a probability $p_{\text{query}} = 5\%, 30\%, 50\%$ of choosing the actions suggested by PBVI, where p_{query} corresponds to the rate of meta-query in Doshi et al. (2008). The episodes used to learn EM-PBVI are collected by the behavior policy with $p_{\text{query}} = 50\%$, which is the highest query rate considered here. Therefore the experiments are biased favorably towards the EM-PBVI, in terms of the number of expert-suggested actions that are employed to generate the training episodes.

The performance of each RPR, as well as that of EM-PBVI, is evaluated on Hallway2 by following the standard testing procedure as set up in Littman et al. (1995). For each policy, a total of 251 independent trials are performed and each trial is terminated when either the goal is reached or a maximum budget of 251 steps is consumed. Three performance measures are computed based on the 251 trials: (a) the discounted accumulative reward (i.e., the sum of exponentially discounted rewards received over the $N_{\text{te}} \leq 251$ steps) averaged over the 251 trials; (b) the goal rate, that is, the percentage of the 251 trials in which the agent has reached the goal; (c) the number of steps that the agent has actually taken, averaged over the 251 trials.

The results on Hallway2 are summarized in Figure 1, where we present each of the three performance measures plus the learning time, as a function of $\log_{10}$ of the number of episodes K used in the learning. The four curves in each figure correspond to the EM-PBVI, and the three RPRs with a rate of PBVI query 5%, 30%, and 50%, respectively. Each curve results from an average over 20 independently generated $\mathcal{D}^{(K)}$ and the error bars show the standard deviations. For simplicity, the error bars are shown only for the RPR with a 50% query rate.

As shown in Figure 1 the performance of the RPR improves as the number of episodes K used to learn it increases, regardless of the behavior policy Π. As recalled from Theorem 5, the empirical value function $\widehat{V}(\mathcal{D}^{(K)};\Theta)$ approaches the exact value function as K goes to infinity. Assuming the RPR has enough memory (decision states) and the algorithm finds the global maxima, the RPR will approach the optimal policy as K increases. Therefore, Figure 1 serves as an experimental verification of Theorem 5. The CPU time shown in Figure 1(d) is exponential in $\log_{10} K$ or, equivalently, is linear in K. The linear time is consistent with the complexity analysis in Section 4.3.1.

The error bars of goal rate exhibits quick shrinkage with K and those of the median number of steps also shrinks relatively fast. In contrast, the discounted accumulative reward has a very slow shrinkage rate for its error bars. The different shrinkage rates show that it is much easier to reach the goal within the prescribed number of steps (251 here) than to reach the goal in relatively less steps. Note that, when the goal is reached at the t-th step, the number of steps is t but the discounted accumulative reward is $\gamma^{-t} r_{\text{goal}}$, where r_{goal} is the reward of entering the goal state. The exponential discounting explains the difference between the number of steps and the discounted accumulative reward regarding the shrinkage rates of error bars.

A comparison of the three RPR curves in Figure 1 shows that the rate at which the behavior policy Π uses or queries PBVI influences the RPR's performance and the influence depends on K. When K is small, increasing the query rate significantly improves the performance; whereas, when K gets larger, the influence decreases until it eventually vanishes. The decreased influence is most easily seen between the curves of 30% and 50% query rates. To make the performance not degrade when the query rate decreases to as low as 5%, a much larger K may be required. These experimental results confirm that random actions can accomplish a good exploration of available rewards (the goal state here) by collecting a large number of (lengthy) episodes and the RPR learned from these episodes perform competitively. With a small number of episodes, however, random actions achieve limited exploration and the resulting RPR performs poorly. In the latter case, queries to experts like PBVI plays an important role in improving the exploration and the RPR's performance.

(d) Learning time

Figure 1: Performance comparison on the Hallway2 problem. The horizontal axis is $\log_{10}$ of the number of episodes K used in learning the RPR. The horizontal axis in each sub-figure is (a) Goal rate (b) Discounted accumulative reward (c) Number of steps to reach the goal (d) Time in seconds for learning the RPR. The four curves in each figure correspond to the EM-PBVI and the RPR based on a behavior policy Π that queries PBVI with a probability $p_{\text{query}} = 5\%, 30\%, 50\%$, respectively. The EM-PBVI employs EM to learn a POMDP model based on the episodes collected by Π with $p_{\text{query}} = 50\%$ and then uses the PBVI (Pineau et al., 2003) to find the optimal policy based on the learned POMDP. Each curve results from an average over 20 independent runs and, for simplicity, the error bars are shown only for the RPR with a 50% query rate. The performance measures in (a)-(c) are explained in greater detail in text.

It is also seen from Figure 1 that the performance of EM-PBVI is not satisfactory and grows slowly with K. The poor performance is strongly related to insufficient exploration of the environment by the limited episodes. For EM-PBVI, the required amount of episodes is more demanding because the initial objective is to build a POMDP model instead of learning a policy. This is because policy learning is concerned with exploring the reward structure but building a POMDP requires exploration of all aspects of the environment. This demonstrates the drawback of methods that rely on learning an intervening POMDP model, with which a policy is designed subsequently.

6.2 Performance of RPR in Multi-task Reinforcement Learning (MTRL)

We investigate the performance of RPR on three MTRL problems. The first two are robotic navigation in mazes and the last one is multi-aspect classification.

6.2.1 MAZE NAVIGATION

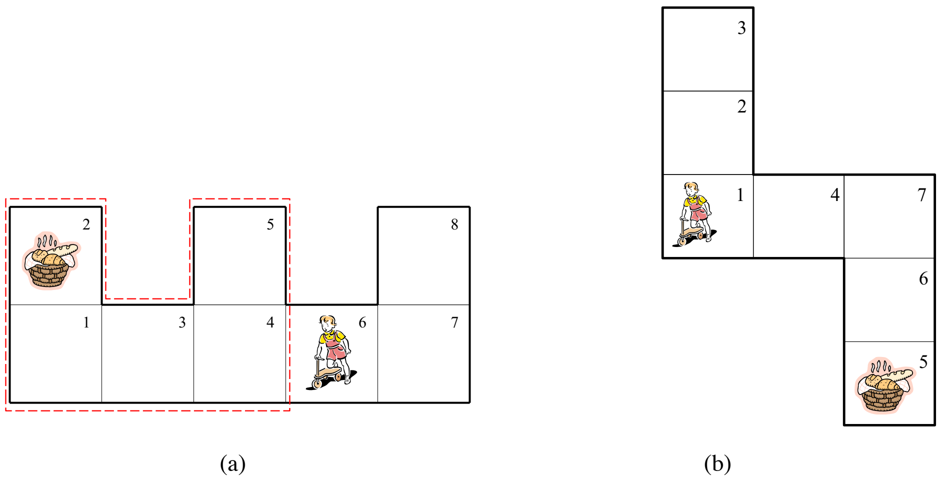
In this problem, there are $M = 10$ environments and each environment is a grid-world, that is, an array of rectangular cells. Of the ten environments, three are distinct and are shown in Figure 2, the remaining are duplicated from the three distinct ones. Specifically, the first three environments are duplicated from the first distinct one, the following three environments are duplicated from the second distinct one, and the last four environments are duplicates from the third distinct one. We assume 10 sets of episodes, with the m-th set collected from the m-th environment.

In each of the distinct environments shown in Figure 2, the agent can take five actions $\{$*move forward*, *move backward*, *move left*, *move right*, *stay*$\}$. In each cell of the grid-world environments, the agent can only observe the openness of the cell in the four directions. The agent then has a total of 16 possible observations indicating the $2^4 = 16$ different combinations of the openness of a cell in the four orientations. The actions (except the action *stay*) taken by the agent are not accurate and have some noise. The probability of arriving at the correct cell by taking a *move* action is 0.7 and the probability of arriving at other neighboring cells is 0.3. The perception is noisy, with a probability 0.8 of correctly observing the openness and the probability 0.2 of making a mistaken observation. The agent receives a unit reward when the goal (indicated by a basket of food in the figures) is reached and zero reward otherwise. The agent does not know the model of any of the environments but only has access to the episodes, that is, sequences of actions, observations, and rewards.

Algorithm Learning and Evaluation For each environment $m = 1, 2, \cdots, 10$, there is a set of K episodes $\mathcal{D}_m^{(K)}$, collected by simulating the agent-environment interaction using the models described above and a behavior policy Π that the agent follows to determine his actions. The behavior policy is the semi-random policy described in Section 6.1, with a probability $p_{\text{query}} = 0.5$ of taking the actions suggested by PBVI.

Reinforcement learning (RL) based on the ten sets of episodes $\{\mathcal{D}_m^{(K)}\}_{m=1}^{10}$ leads to ten RPRs, each associated with one of the ten environments. We consider three paradigms of learning: the MTRL in which the Gibbs-variational algorithm in Table 2 is applied to the ten sets of episodes jointly, the STRL in which the MV algorithm in Table 1 is applied to each of the ten episode sets separately, and pooling in which the MV algorithm is applied to the union of the ten episode sets. The number of decision states is chosen as $|\mathcal{Z}| = 6$ for all environments and all learning paradigms. Other larger $|\mathcal{Z}|$ give similar results and, if desired, the selection of decision states can be accomplished by maximizing the marginal empirical value with respect to $|\mathcal{Z}|$, as discussed above.

The RPR policy learned by any paradigm for any environment is evaluated by executing the policy 1000 times independently, each time starting randomly from a grid cell in the environment and taking a maximum of 15 steps. The performance of the policy is evaluated by two performance



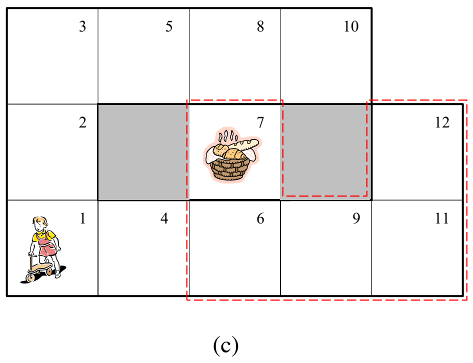


Figure 2: The three distinct grid-world environments, where the goal is designated by the basket of food, each block indicates a cell in the grid world, and the two gray cells are occupied by a wall. The red dashed lines in (a) and (c) indicate the *similar* parts in the two environments. The agent locates himself by observing the openness of a cell in the four orientations. Both the motion and the observation are noisy.

measures: (a) the average success rate at which the agent reaches the goal within 15 steps, and (b) the average number of steps that the agent takes to reach the goal. When the agent does not reach the goal within 15 steps, the number of steps is 15. Each performance measure is computed from the 1000 instances of policy execution, and is averaged over 20 independent trials.

We examine the performance of each learning paradigm for various choices of K, the number of episodes per environment. Specifically we consider 16 different choices: $K = 3,4,5,6,7,8,9,10,11,12,24,60,120,240$. The performances of the three learning paradigms, averaged over 20 independent trials, are plotted in Figure 3 as a function of K. Figures 3(c) and 3(d) are respectively duplicates of Figures 3(a) and 3(b), with the horizontal axis displayed in a logarithmic scale. By (57), the choice of the precision parameter α in Dirichlet process influences the probability of sampling a new cluster; it hence influences the resulting number of distinct RPR parameters $\overline{\Theta}$. According to West (1992), the choice of α is governed by the posterior $p(\alpha|K,N) \propto p(N|K,\alpha)p(\alpha)$, where N is the number of clusters updated in the most recent iteration of the Gibbs-variational algorithm. One

may choose α by sampling from the posterior or finding the mean. When K is large and $N \ll K$ and the prior $p(\alpha)$ is a Gamma distribution, the posterior $p(\alpha|K,N)$ is approximately a Gamma distribution with the mean $\mathbb{E}(\alpha) = O(N\log(K))$. For the different choices of K considered above, we choose $\alpha = 3n$, with $n = 2,3,\ldots,15$ respectively. These choices are based on approximations of $\mathbb{E}(\alpha)$ obtained by fixing N at an initial guess $N = 8$. We find that the results are relatively robust to the initial guess provided the logarithmic dependence on K is employed. The density of the DP base G_0 is of the form in (45), with all hyper-parameters set to one, making the base non-informative.

Figures 3(a) and 3(b) show that the performance of MTRL is generally much better than that of STRL and pooling. The improvement is attributed to the fact that MTRL automatically identifies and enforces appropriate sharing among the ten environments to ensure that information transfer is positive. The improvement over STRL indicates that the number of episodes required for finding the correct sharing is generally smaller that that required for finding the correct policies.

The identification of appropriate sharing is based on information from the episodes. When the number of episodes is very small (say, less than 25 in the examples here), the sharing found by MTRL may not be accurate; in this case, simply pooling the episodes across all ten environments may be a more reasonable alternative. When the number of episodes increases, however, pooling begins to show disadvantages since the environments are not all the same and forcing them to share leads to negative information transfer. The seemingly degraded performance of pooling at the first two points in Figure 3(c) may not be accurate since the results have large variations when the episodes are extremely scarce; much more Monte Carlo runs may be required to obtain accurate results in these cases.

The performance of STRL is poor when the number of episodes is small, because a small set of episodes do not provide enough information for learning a good RPR. However, the STRL performance improves significantly with the increase of episodes, which whittles down the advantage brought about by information transfer and allows STRL to eventually catch up with MTRL in performance.

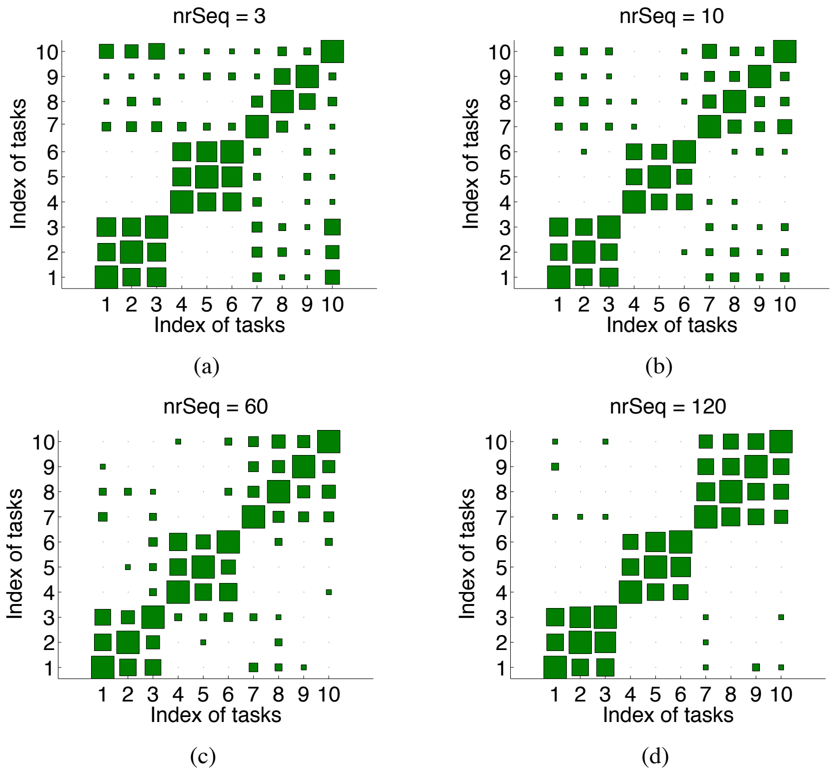

Figure 4: Hinton diagrams of the between-task similarity matrix inferred by the MTRL for the problem of multiple stochastic environments 2. The number of episodes per environment is (a) 3 (b) 10 (c) 60 (d) 120.

Analysis of the Sharing Mechanism We investigate the sharing mechanism of the MTRL by plotting Hinton diagrams. The Hinton diagram (Hinton and Sejnowski, 1986) is a quantitative way of displaying the elements of a data matrix. Each element is represented by a square whose size is proportional to the magnitude. In our case here, the data matrix is the between-task similarity matrix (Xue et al., 2007) learned by the MTRL; it is defined as follows: the between-task similarity matrix is a symmetric matrix of size $M \times M$ (where M denotes the number of tasks and $M = 10$ in the present experiment), the (i, j)-th element measuring the frequency that task i and task j belong to the same cluster (i.e., they result in the same distinct RPR). In order to avoid the bias due to any specific set of episodes, we perform 20 independent trials and average the similarity matrix over the 20 trials. In each trial, if tasks i and j belong to one cluster upon convergence of the Gibbs-variational algorithm, we add one at (i,j) and (j,i) of the matrix. We compute the between-task similarity matrices when the number of episodes is respectively $K = 3, 10, 60, 120$, which represent the typical sharing patterns inferred by the MTRL for the present maze navigation problem. The Hinton diagrams for these four matrices are plotted in Figure 4.

The Hinton diagrams in Figures 4(a) and 4(b) show that when the number of episodes is small, environments 1, 2, 3, 7, 8, 9, 10 have a higher frequency of sharing the same RPR. This sharing can be intuitively justified by first recalling that these environments are duplicates of Figures 2(a) and 2(c), and then noting that the parts circumscribed by red dashed lines in Figures 2(a) and 2(c) are quite similar. Meanwhile the Hinton diagrams also show a weak sharing between environments 4,5,6,7,8,9,10, which are duplicates of Figures 2(b) and 2(c). This is probably because the episodes are very few at this stage, and pooling episodes from environments that are not so relevant to each other could also be helpful. This explains why, in Figure 3(a), the performance of pooling is as good as that of the MTRL when the number of episodes is small.

As the number of episodes progressively increases, the ability of MTRL to identify the correct sharing improves and, as seen in Figures 4(b) and 4(c), only those episodes from relevant environments are pooled together to enhance the performance—a simple pooling of all episodes together deteriorates the performance. This explains why the MTRL outperforms pooling with the increase of episodes. Meanwhile, the STRL does not perform well for limited episodes. However, when there are more episodes from each environment, the STRL learns and performs steadily better until it outperforms the pooling and becomes comparable to the MTRL.

6.2.2 MAZE NAVIGATION 2

We consider six environments, each of which results from modifying the benchmark maze problem Hallway2 (Littman et al., 1995) in the following manner. First the goal state is displaced to a new grid cell and then the unique observation associated with the goal is changed accordingly. For each environment the location of the goal state is shown in Figure 5 as a numbered circle, where the number indicates the index of the environment. Of the six environments the first one is the original Hallway2. It is seen that environments $1,2,3$ have their goal states near the lower right corner while environments $4,5,6$ have their goal states near the upper left corner. Thus we expect that the environments are grouped into two clusters.

For each environment, a set of K episodes are collected by following a semi-random behavior policy Π that executes the actions suggested by PBVI with probability $p_{\text{query}} = 0.3$. As in Section 6.2.1 three versions of RPR are obtained for each environment, based respectively on three paradigms, namely MTRL, STRL, and pooling. The α is chosen as $5\log(K)$ with 5 corresponding to an initial guess of N and G_0 is of the form of (45) with all hyper-parameters close to one (thus the prior is non-informative). The number of decision states is $|\mathcal{Z}| = 20$ as in Section 6.1.1. The performance comparison, in terms of discounted accumulative reward and averaged over 20 independent trials, is summarized in Figure 6, as a function of the number of episodes per environment.

Figure 6(a) shows that the MTRL maintains the overall best performance regardless of the number of episodes K. The STRL and the pooling are sensitive to K, with the pooling outperforming the STRL when $K < 540$ but outperformed by the STRL when $K > 540$. In either case, however, the

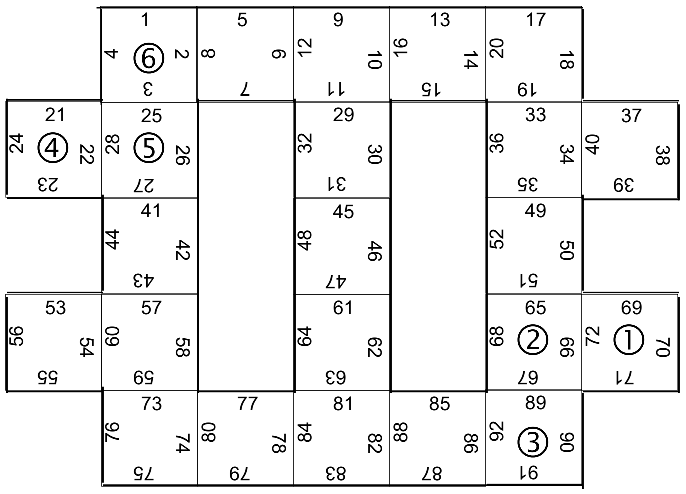

Figure 5: Displacements of goal state in the six environments considered in Maze Navigation 2. Each environment is a variant of the benchmark Hallway2 (Littman et al., 1995) with the goal displaced to a new grid cell designated by a numbered circle and the number indicating the index of the environment. The unique observation associated with the goal is also changed accordingly in each variant.

(*b*)

Figure 6: Performance comparison on the six environments modified from the benchmark problem Hallway2 (Littman et al., 1995). (a) Discounted accumulative reward averaged over the six environments (b) Discounted accumulative reward in the first environment, which is the original Hallway2.

MTRL performs no worse than both. The MTRL consistently performs well because it adaptively adjusts the sharing among tasks as K changes, such that the sharing is appropriate regardless of K. The adaptive sharing can be seen from Figure 7, which shows the Hinton diagram of the between-task similarity matrix learned by the MTRL, for various instances of K. When K is small there is a strong sharing among all tasks, in which case the MTRL reduces to the pooling, explaining why the

MTRL performs similar to the pooling when $K \leq 250$. When K is large, the sharing becomes weak between any two tasks, which reduces the MTRL to the STRL, explaining why the two perform similarly when $K \geq 700$. As the number of episodes approaches to $K = 540$, the performances of the STRL and the pooling tend to become closer and more comparable until they eventually meet at $K = 540$. The range of K near this intersection is also the area in which the MTRL yields the most significant margin of improvements over the STRL and the pooling. This is so because, for this range of K, the correct between-task sharing is complicated (as shown in Figure 7(b)), which can be accurately characterized by the fine sharing patterns provided by the MTRL, but cannot be characterized by the pooling or the STRL.

Figure 6(a) plots the overall performance comparison taking all environments into consideration. As an example of the performances in individual environments, we show in Figure 6(a) the performance comparison in the first environment, which is also the original Hallway2 problem. The change of magnitude in the vertical axis is due to the fact the first environment has the goal in a room (instead in the hallway), which makes it more difficult to reach the goal.

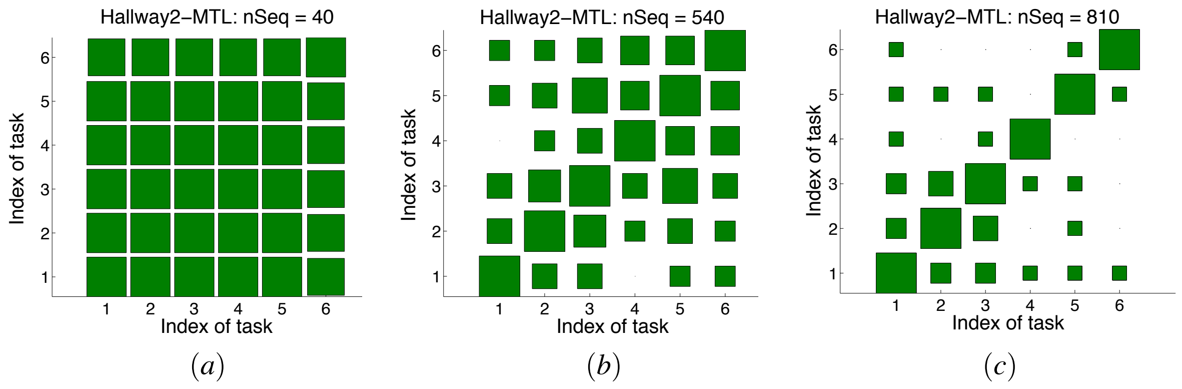

Figure 7: Hinton diagrams of the between-task similarity matrix learned by the MTRL from the six environments modified from the benchmark problem Hallway2 (Littman et al., 1995). The number of episodes is is (a) $K = 40$ (b) $K = 540$ (c) $K = 810$.

6.2.3 MULTI-ASPECT CLASSIFICATION

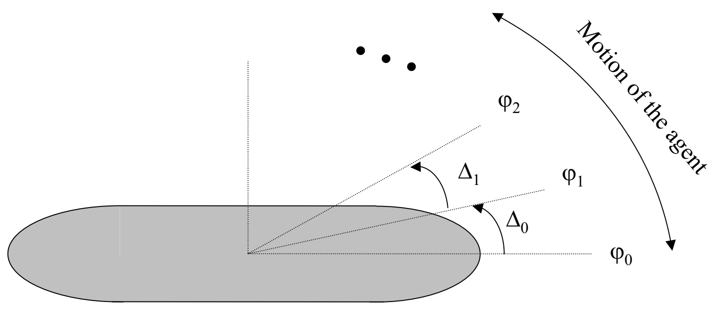

Figure 8: A typical configuration of multi-aspect classification of underwater objects.

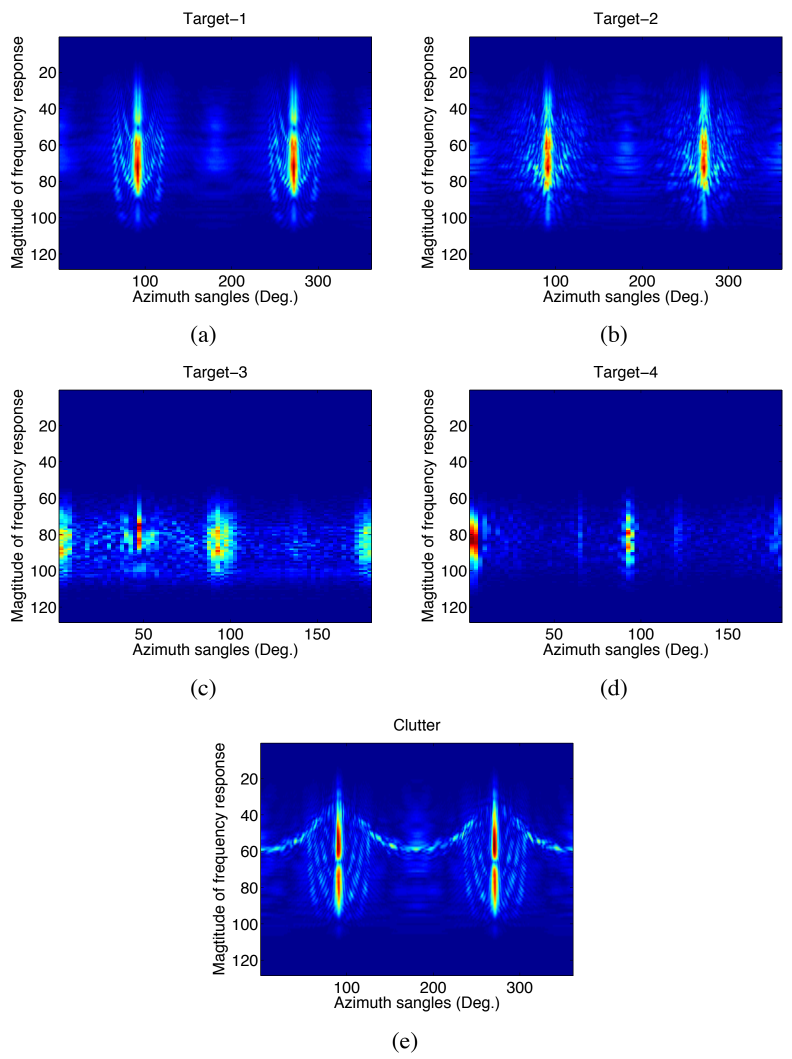

Figure 9: Frequency-domain acoustic responses of the five underwater objects (a) Target-1 (b) Target-2 (c) Target-3 (d) Target-4 (e) Clutter.

Multi-aspect classification refers to the problem of identifying the class label of an object using observations from a sequence of viewing angles. This problem is generally found in applications where the object responds to interrogations in a angle-dependent manner. In such cases, an observation at a single viewing angle carries the information specific to only that angle and the nearby angles, and one requires observations at many viewing angles to fully characterize the object.

More importantly, the observations at different viewing angles are not independent of each other, and are correlated in a complicated and yet useful way. The specific form of the angle-dependency is dictated by the physical constitution of the object as well as the nature of the interrogator—typically electromagnetic or acoustic waves. By carefully collecting and processing observations sampled at densely spaced angles, it is possible to form an image, based on which classification can be performed. An alternative approach is to treat the observations as a sequence and characterize the angle-dependency by a hidden Markov model (HMM) (Runkle et al., 1999).

In this section we consider multi-aspect classification of underwater objects based on acoustic responses of the objects. Figure 8 shows a typical configuration of the problem. The cylinder represents an underwater object of unknown identity y. We assume that the object belongs to a finite set of categories $\mathcal{Y}$ (i.e., $y \in \mathcal{Y}$). The agent aims to discover the unknown y by moving around the object and interrogating it at multiple viewing angles φ. We assume the angular motion is one-dimensional, that is, the agent moves clockwise or counterclockwise on the page, but does not move out of the page. The set of angles that can be occupied by the agent is then $[0°, 360°]$, which in practice is discretized into a finite number of angular sectors denoted by $\mathcal{S}_\varphi$.

In the HMM approach (Runkle et al., 1999), $\mathcal{S}_\varphi$ constitutes the set of hidden states, and the state transitions can be computed using simple geometry (Runkle et al., 1999), under the assumptions that each time the agent moves by a constant angular step and that the specific angles occupied by the agent are uniformly distributed within any given state. Refinement of state transitions and estimation of state emissions can be achieved by maximizing the likelihood function constructed from the training sequences. In the training phase, one trains an HMM for each $y \in \mathcal{Y}$. For an unknown object, one collects a sequence of observations (sensor data) and submit it to the HMM for each $y \in \mathcal{Y}$; the y yielding the maximum likelihood is then declared to be the identity of the unknown object. Obviously the agent must follow a common protocol to collect the data sequences in both the training and test phases, to ensure that their statistics are consistent. Since such a protocol is not part of the HMMs, a question arises as to how to specify the protocol.

From the perspective of sequential decision-making, multi-aspect classification can be formulated as a reinforcement learning problem, with a state space $\mathcal{S} = \mathcal{S}_\varphi \times \mathcal{Y}$, where $\times$ is a Cartesian product. Both $\mathcal{S}_\varphi$ and $\mathcal{Y}$ are only partially observable (through sensor data). The RL approach possesses several conspicuous advantages over the HMM approach. First, the sensor data are now collected in an active manner, under the control of agent actions. When two data sequences are collected by following the same policy of choosing actions, they are automatically ensured to be consistent in statistics, hence there is no need to specify a separate common protocol for collecting the sequential data. Second, unlike maximizing the data likelihood (under a given data collection protocol), the agent is now free to choose a more flexible learning objective by setting an appropriate reward structure. Third, unlike building a HMM for each $y \in \mathcal{Y}$, the different categories are now coalesced into a single RPR (details are presented below), making the RL a discriminative approach vis-a-via the generative HMM approach.

In our experiment, there are a total of five objects, four of them are targets of interest and one of them represents the clutter. The frequency-domain acoustic responses of these objects are shown in Figure 9, for a full coverage of angles from 0° to 360°; the data are real measurements as described in Runkle et al. (1999). We aim to distinguish each target from clutter and this gives four tasks, where task i is defined by the problem of distinguishing target-i from clutter, $i = 1, 2, 3, 4$, and the targets and clutter are as shown in Figure 9. Each task is a multi-aspect classification problem.[6] From the data in Figure 9 targets 1 and 2 have similar angle-dependent scattering phenomena, and therefore Tasks 1 and 2 are expected to be related. Targets 3 and 4 also appear to have similar angle-dependent scattering characteristics, and therefore Tasks 3 and 4 are expected to also be related. In fact, although the target details are too involved to detail here, targets 1 and 2 are both of a cylindrical form (like those in Runkle et al., 1999), while targets 3 and 4 are more irregular in shape.

6. The data are available at `http://www.ee.duke.edu/~lcarin/ShellData.zip`.

The RPR for Multi-aspect Classification In applying the RPR to multi-aspect classification, our approach is distinct from an HMM construction (Runkle et al., 1999) in two important respects. First, the RPR is a control model and it aims to optimize the value function, instead of the likelihood function. Since the RPR takes into account a reward structure, it can be more flexible in specifying the learning objective. Second, the RPR embraces all objects in the same representation, instead of having a separate model for each individual object. As a result, it is a discriminative model instead of a generative model (this may be viewed as a discriminative extension of the traditional generative HMM).

The RPR does not manipulate the angular states—it works directly with observations. Since classification is treated as a control problem in the RPR, we need two extra components, actions and rewards, to complete the specification. We consider four actions, that is, $\mathcal{A}=\{$*declare as target*, *declare as clutter*, *move clockwise and sense*, *move counterclockwise and sense*$\}$. When the agent takes action *move clockwise and sense*, it moves 5° clockwise and collects an observation; when the agent takes action *move counterclockwise and sense*, it moves 5° counterclockwise and collects an observation. The reward structure is specified as follows. A correct declaration receives a reward of 5 units, a false declaration receives a reward of -5, and the actions *move clockwise and sense* and *move counterclockwise and sense* each receives a reward of zero units. The objective, therefore, is to correctly classify the target with the minimal number of sensing actions.

The episodes used in learning the RPR consist of a number of observation sequences, each observation is associated with the action *move clockwise and sense* or *move counterclockwise and sense* and the terminal action in each episode is the correct declaration. The correction declaration is available because the episodes in this problem are the training data in standard classification, hence the ground truth of class labels is known. Note that the training episodes always terminate with a correct declaration, thus the agent never actually receives the penalty -5 during the training phase. Alternatively, one may split each episode into two, respectively terminated with the correct and the false declaration. Recall the false declaration receives the minimum reward which, after an offset of 5 to make all rewards non-negative, is converted to zero. Since a zero reward received at the end of an episode nullifies the entire episode, such an alternative is equivalent to excluding the penalized episodes.

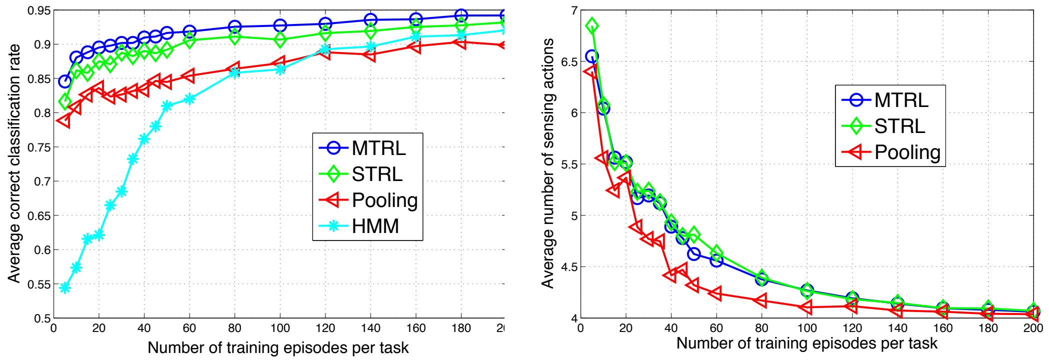
Classification Results The raw data are shown in Figure 9, for the five objects we are considering. Each datum is the response of an object measured at a particular angle and the data set for an object consists of measurements collected at $0^\circ, 1^\circ, \cdots, 359^\circ$. Each raw datum is converted into a feature vector using matching pursuit (McClure and Carin, 1997), and the feature vectors are further discretized by vector quantization (Gersho and Gray, 1992) to produce a finite code-book. As mentioned earlier, we have a total of four tasks, each task being to distinguish each of the four respective targets from the clutter.

Four methods are compared: the MTRL, the STRL, the pooling, and the hidden Markov models (HMM), where the first three are as described in Section 6.2.1 and the last one is the standard hidden Markov model (Rabiner, 1989). The four methods yield four corresponding agents, each following the policy resulting from one of the algorithms.

When the agents collect episodes during the training phase, they start from angles that are uniformly drawn from $\{1^\circ, 2^\circ, \cdots, 360^\circ\}$. For each starting angle, two episodes are collected: the first is obtained by moving clockwise to collect an observation at every 5° and terminating upon the 10-th observation, and the other is the same as the first but the agent moves counterclockwise.

During the testing phase, both the RPR agents and the HMM agent start from angles uniformly drawn from $\{1^\circ, 2^\circ, \cdots, 360^\circ\}$; however, the RPR agents follow one of the three policies (resulting respectively from the MTRL, the STRL, and the pooling) to choose an action from $\mathcal{A}$, while the HMM agent collects n observations by moving consistently clockwise or counterclockwise (either direction is chosen with a probability of 0.5) and then makes a declaration, where n is adaptively set to the *maximum* of the numbers of observations used by the three RPR agents starting from the same angle.

Figure 10 summarizes the performance as a function of the number of training episodes K, where the performance is evaluated by the correct classification rate as well as the average number of sensing actions (i.e., the average number of observations collected) before a declaration is made. Each point in the figures is an average from 20 independent trials.



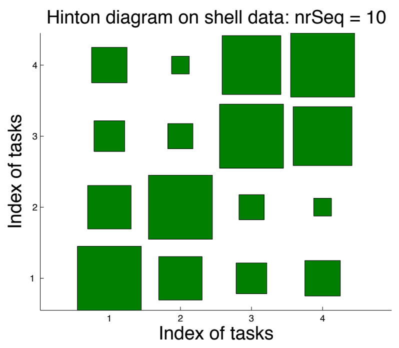
(a) Classification rate

(b) Average number of sensing steps

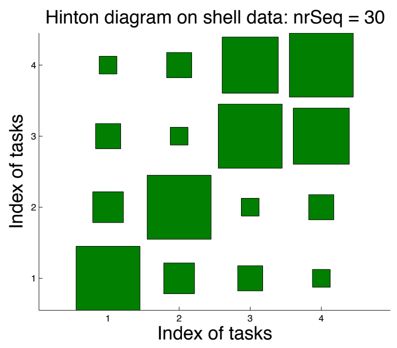
Figure 10: Performance comparison on multi-aspect classification of underwater targets (a) Average classification rate as a function of the number of training episodes per task (b) Average number of sensing actions (average number of observations collected) before a declaration is made, as a function of the number of training episodes per task.

It is seen from Figure 10(a) that the MTRL achieves the highest classification rate regardless of the number of training episodes K. The pooling performs worse than the STRL and the poor performance persists even when K is small. The latter is in contrast with the results on the maze navigation problems in Sections 6.2.1 and 6.2.2, where the pooling performs better than the STRL with a small K. The reason for this will be clear below from the sharing-mechanism analysis. It is noted that all three RPR algorithms perform much better than the HMM, demonstrating the superiority of discriminative models over generative models in classification problems.

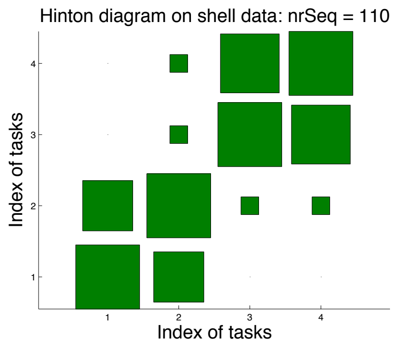
As shown by Figure 10(b), pooling takes the least number of sensing actions, which may be attributed to the over-confidence arising from an abundant set of training data, noting that the pooling agent learns its policy by using the episodes accumulated over all tasks. In contrast, the STRL agent takes the most number of actions. Considering that the STRL agent bases policy learning on the episodes collected from a single task, which may contain inadequate information, it is reasonable that the STRL agent is less confident and would make more observations before coming to a conclusion. The sensing steps taken by the MTRL agent lies in between, since it relies on related tasks, but not all tasks, to provide the episodes for policy learning.



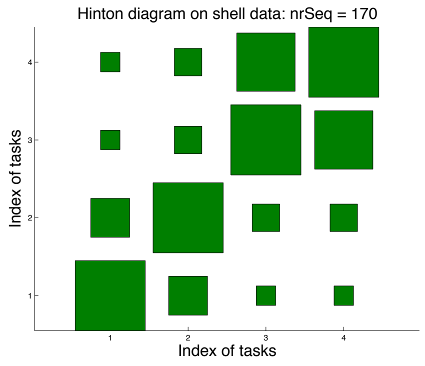
(a)



(b)



(c)



(d)

Figure 11: Sharing mechanism for multi-aspect classification of underwater targets. Each figure is the Hinton diagram of the between similarity matrix, with the number of training episodes per task: (a) 10 (b) 30 (c) 110 (d) 170.

Analysis of the Sharing Mechanism The Hinton diagram of the between-task similarity matrix is shown in Figures 11(a), 11(b), 11(c), 11(d), for the cases when the number of training episodes K is equal to 10, 30, 110, 170, respectively.

It is seen that the sharing patterns are dominated by two clusters, the first consisting of Task 1 and Task 2 and the second consisting of Task 3 and Task 4. The second cluster remains unchanged regardless of K. The first cluster tends to break when $K = 30$, but is resumed later on. The two clusters are consistent with Figure 9 which shows that targets 1 and 2 are similar and so are targets 3 and 4. The fact the two clusters are persistent through the entire range of K implies that the tasks from different clusters are weakly related even when the episodes are scarce, as a result pooling the episodes across all tasks yields poor policies. This explains the poor performance of the pooling in Figure 10(a).

To understand the reason why the cluster of tasks 1 and 2 is less stable, one need delve into some details of the targets. Target 1 and Target 2 both have a cylindrical shape while Task 3 and Task 4 are more irregular in shape. Similar geometry puts Targets 1 and 2 in one cluster and Targets 3 and 4 in another cluster. Moreover, the measurements of Targets 3 and 4 are more noisy than the measurements of Targets 1 and 2, because they are collected under different conditions. The low signal to noise ratio (SNR) increases the similarity between Targets 3 and 4 since their distinctive features are buried in the noise. The more noise-free measurements of Target 1 and 2 yields a more faithful representation of these targets, which tends to magnify their differences and make them appear less similar.

7. Conclusions

We have presented a multi-task reinforcement learning (MTRL) framework for *partially observable* stochastic environments. To our knowledge, this is the first framework proposed for MTRL in the partially observable domain.

A key element in our MTRL framework is the regionalized policy representation (RPR), which yields a history-dependent stochastic policy for environments characterized by a partially observable Markov decision process (POMDP). Learning of the RPR is based on episodic experiences collected from the environment, without requiring the environment's model. We have developed two algorithms for learning the RPR, one based on maximum-value estimation and the other based on the variational Bayesian paradigm. The latter offers the ability for selecting the number of decision states based on the Occam Razor principle and the possibility of transferring experience between related environments.

Built upon the basic RPR, the proposed MTRL framework consists of multiple RPRs, each for an environment, coupled by a common Dirichlet process (DP) that is used to produce the nonparametric prior over all RPRs. By virtue of the discreteness of the nonparametric prior, the environments are clustered into groups, with each group consisting of a subset of environments that are related in some manner. The number of groups as well as the associated environments are automatically identified, and the experiences are shared among the related environments to increase their respective exploration. A hybrid Gibbs-variational algorithm is presented for learning multiple RPRs simultaneously under the unified MTRL framework, based on selective use of the experiences collected across all environments.

Experimental results demonstrate that the proposed MTRL consistently yields superior performance regardless of the amount of experiences used in learning. The two competitors, one based on single-task reinforcement learning (STRL) and other based on simple pooling, are shown to be sensitive to the amount of experiences. The superior performance is attributed to the ability of the MTRL to automatically identify useful experiences from related environments to enhance the exploration. The MTRL adaptively adjusts sharing patterns to offset the changes in the experience and hence has addressed the problem of how to positively transfer the experience from one environment to the benefit of improving learning in another. In addition, we have also presented experimental results on benchmark problems demonstrating the RPR as a powerful stand-alone algorithm for single-task reinforcement learning.

The work presented in this paper mainly focuses on off-policy batch learning, assuming the learning is based on a fixed set of episodic experiences collected by following an external behavior policy. In the off-policy batch learning mode, the policy improvement is implemented without actually re-interacting with the environment; instead the improvement is implemented through virtual "reward re-computation" (discussed after (15)), which simulates the re-interaction with the environment. By taking reward re-computation out of the algorithm and implementing it via real re-interaction, we can learn the RPRs in an on-policy online manner. In this case, the need for an external behavior policy is eliminated and the previous version RPR is employed as the behavior policy. In the next phase of this work, we will focus on on-policy online learning of RPRs and investigate how each environment can be better explored via multi-task reinforcement learning. In this on-policy MTRL setting, multi-task learning will have two aspects: co-exploitation (already addressed in the present paper) and co-exploration (not explicitly addressed here). It is of interest to investigate how much benefit can be gained by simultaneous co-exploitation and co-exploration.

Although the experiments considered in the paper mainly involve robot navigation in grid-worlds, there are many other interesting practical problems to which the proposed algorithms are immediately applicable. The multi-aspect classification serves as a preliminary example of such applications. Other examples include using RPRs as policies to control and coordinate a set of sub-models such that the collective performance is optimized and more advanced tasks could be accomplished than by any single sub-model.

For the work presented here, the DP prior is placed directly on Θ. Because of the discrete nature of G, this implies that when parameters Θ are shared between different environments, they are shared exactly. This may be too restrictive for some problems; for two environments that are similar, we may desire the associated parameters to be similar, but not exactly the same. This may be accommodated, for example, via the following modification to the DP prior

$$\begin{aligned}\Theta_m|\Psi_m &\sim H(\Theta_m|\Psi_m),\\ \Psi_m|G &\sim G,\\ G|\alpha,G_0 &\sim DP(\alpha,G_0).\end{aligned}$$

This formulation results in an infinite mixture model for Θ, where each component is of the form H. When two environments share, their parameters share a component of this infinite mixture, but the specific draws will generally differ from each other—this can provide greater flexibility. The above modification brings some challenges to the inference. Recall that Θ is set of probability mass functions (pmf), it is natural to require H to be a product of Dirichlets. The difficulty now lies in choosing G that provides a conjugate prior for the parameters of H, which seems not easy. If G is properly specified, however, the inference should be a straightforward extension of the techniques developed in this paper. An alternative to the above modification that may avoid the inference difficulty is to follow the approach in Liu et al. (2008) to impose soft sharing by replacing the Dirac delta with its soft version.

Acknowledgments

The authors would like to thank Prof. Ronald Parr of Duke University for pointing out the drawback of an early version of the RPR optimality criterion, and for the insightful counter-examples and the long discussions that eventually lead to the optimality criterion defined in Definition 4.

We would also like to thank the anonymous reviewers for their valuable comments and suggestions, which help to improve the paper significantly.

Appendix A. Proof of Theorem 5

According to Kaelbling et al. (1998), the expected sum of exponentially discounted reward (value function) over an infinite horizon can be written as

$$V = \mathbb{E}\left[\sum_{t=0}^{\infty}\gamma^t r_t\right]$$

where $0 < \gamma < 1$ is the discount factor. Let E denote the environment in question and $\mathscr{P}_E$ the corresponding probabilistic model (POMDP). Let Θ be the parameters specifying the RPR, the expectation in our situation here is $\mathbb{E}_{\text{episodes}|E,\Theta}$. Thus

$$\begin{aligned}
V &= \mathbb{E}_{\text{episodes}|E,\Theta}\left[\sum_{t=0}^{\infty}\gamma^t r_t\right] \\
&= \sum_{a_0 r_0 o_1 a_1 r_1 \cdots} p(a_0 r_0 o_1 a_1 r_1 o_2 \cdots | E, \Theta)\left[\sum_{t=0}^{\infty}\gamma^t r_t\right] \\
&= \sum_{a_0 a_1 \cdots} p(a_0 a_1 \cdots|\Theta)\mathbb{E}_{r_0 o_1 r_1 o_2 r_2 \cdots | a_0 a_1 \cdots \sim \mathscr{P}_E}\left[\sum_{t=0}^{\infty}\gamma^t r_t\right] \\
&= \sum_{a_0 a_1 \cdots} p^{\Pi}(a_0 a_1 \cdots)\frac{p(a_0 a_1 \cdots|\Theta)}{p^{\Pi}(a_0 a_1 \cdots)}\mathbb{E}_{r_0 o_1 r_1 o_2 r_2 \cdots | a_0 a_1 \cdots \sim \mathscr{P}_E}\left[\sum_{t=0}^{\infty}\gamma^t r_t\right] \\
&\quad \text{(Importance sampling Robert and Casella, 1999)} \\
&= \sum_{a_0 a_1 \cdots} p^{\Pi}(a_0 a_1 \cdots)\mathbb{E}_{r_0 o_1 r_1 o_2 r_2 \cdots | a_0 a_1 \cdots \sim \mathscr{P}_E}\left[\sum_{t=0}^{\infty}\frac{\gamma^t r_t}{\prod_{\tau=0}^{t} p^{\Pi}(a_\tau|h_\tau)}\prod_{\tau=0}^{t} p(a_\tau|h_\tau,\Theta)\right] \\
&= \mathbb{E}_{a_0 a_1 \cdots \sim p^{\Pi}}\mathbb{E}_{r_0 o_1 r_1 o_2 r_2 \cdots | a_0 a_1 \cdots \sim \mathscr{P}_E}\left[\sum_{t=0}^{\infty}\frac{\gamma^t r_t}{\prod_{\tau=0}^{t} p^{\Pi}(a_\tau|h_\tau)}\prod_{\tau=0}^{t} p(a_\tau|h_\tau,\Theta)\right] \\
&= \lim_{K\to\infty}\frac{1}{K}\sum_{k=1}^{K}\left[\sum_{t=0}^{\infty}\frac{\gamma^t r_t^k}{\prod_{\tau=0}^{t} p^{\Pi}(a_\tau^k|h_\tau^k)}\prod_{\tau=0}^{t} p(a_\tau^k|h_\tau^k,\Theta)\right] \\
&\quad \left(a_0^k a_1^k \cdots \sim p^{\Pi},\ r_0^k o_1^k r_1^k o_2^k r_2^k \cdots | a_0^k a_1^k \cdots \sim \mathscr{P}_E\right) \\
&= \lim_{K\to\infty}\frac{1}{K}\sum_{k=1}^{K}\left[\sum_{t=0}^{T_k}\frac{\gamma^t r_t^k}{\prod_{\tau=0}^{t} p^{\Pi}(a_\tau^k|h_\tau^k)}\prod_{\tau=0}^{t} p(a_\tau^k|h_\tau^k,\Theta)\right] \\
&= \lim_{K\to\infty}\widehat{V}(\mathcal{D}^{(K)};\Theta)
\end{aligned}$$

where the sum over $0 \le t < \infty$ is equal to the sum over $0 \le t \le T_k$ because $r_t^k = 0$ for $t > T_k$ according to Definition 2. Q.E.D.

Appendix B. Proof of Theorem 6

We begin our derivation by writing the empirical value function in its logarithm

$$\begin{aligned}
\ln\widehat{V}(\mathcal{D}^{(K)};\Theta) &= \ln\frac{1}{K}\sum_{k=1}^{K}\sum_{t=0}^{T_k}\tilde{r}_t^k\sum_{z_0^k,\cdots,z_t^k=1}^{|\mathcal{Z}|} p(a_{0:t}^k, z_{0:t}^k|o_{1:t}^k,\Theta) \\
&= \ln\sum_{k=1}^{K}\sum_{t=0}^{T_k}\sum_{z_0^k,\cdots,z_t^k=1}^{|\mathcal{Z}|}\frac{q_t^k(z_{0:t}^k)}{K}\frac{\tilde{r}_t^k p(a_{0:t}^k, z_{0:t}^k|o_{1:t}^k,\Theta)}{q_t^k(z_{0:t}^k)},
\end{aligned} \tag{80}$$

where

$$\begin{aligned}
q_t^k(z_{0:t}^k) &\ge 0, \\
\frac{1}{K}\sum_{k=1}^{K}\sum_{t=0}^{T_k}\sum_{z_0^k,\cdots,z_t^k=1}^{|\mathcal{Z}|} q_t^k(z_{0:t}^k) &= 1.
\end{aligned}$$

Applying Jensen's inequality to (80), we obtain

$$\ln \widehat{V}(\mathcal{D}^{(K)};\Theta) \quad \geq \quad \sum_{k=1}^{K}\sum_{t=0}^{T_k}\sum_{z_0^k,\cdots,z_t^k=1}^{|\mathcal{Z}|} \frac{q_t^k(z_{0:t}^k)}{K} \ln \frac{\tilde{r}_t^k p(a_{0:t}^k, z_{0:t}^k | o_{1:t}^k, \Theta)}{q_t^k(z_{0:t}^k)}. \tag{81}$$

The lower bound is maximized when

$$q_t^k(z_{0:t}^k) \quad = \quad q_t^k(z_{0:t}^k|\Theta) \overset{Def.}{=} \frac{\tilde{r}_t^k}{\widehat{V}(\mathcal{D}^{(K)};\Theta)} p(a_{0:t}^k, z_{0:t}^k | o_{1:t}^k, \Theta),$$

which turns the inequality in into an equality. Define

$$\mathrm{LB}(\widehat{\Theta}|\Theta) = \frac{1}{K}\sum_{k=1}^{K}\sum_{t=0}^{T_k}\sum_{z_0^k,\cdots,z_t^k=1}^{|\mathcal{Z}|} q_t^k(z_{0:t}^k|\Theta) \ln \frac{\tilde{r}_t^k p(a_{0:t}^k, z_{0:t}^k | o_{1:t}^k, \widehat{\Theta})}{q_t^k(z_{0:t}^k|\Theta)}.$$

By (81), $\mathrm{LB}(\widehat{\Theta}|\Theta) \leq \mathrm{LB}(\widehat{\Theta}|\widehat{\Theta}) = \ln \widehat{V}(\mathcal{D}^{(K)};\widehat{\Theta})$ holds for any Θ and $\widehat{\Theta}$. Therefore, when $\widehat{\Theta} = \arg\max_{\widehat{\Theta}\in\mathcal{F}} \mathrm{LB}(\widehat{\Theta}|\Theta)$, we have

$$\ln \widehat{V}(\mathcal{D}^{(K)};\Theta) = \mathrm{LB}(\Theta|\Theta) \leq \mathrm{LB}(\widehat{\Theta}|\Theta) \leq \mathrm{LB}(\widehat{\Theta}|\widehat{\Theta}) = \ln \widehat{V}(\mathcal{D}^{(K)};\widehat{\Theta}).$$

Starting from $\Theta^{(0)}$ we compute

$$\begin{aligned}
\Theta^{(1)} &= \arg\max_{\widehat{\Theta}\in\mathcal{F}} \mathrm{LB}(\widehat{\Theta}|\Theta^{(0)}),\\
\Theta^{(2)} &= \arg\max_{\widehat{\Theta}\in\mathcal{F}} \mathrm{LB}(\widehat{\Theta}|\Theta^{(1)}),\\
&\ \ \vdots \qquad \vdots
\end{aligned}$$

which satisfy $\widehat{V}(\mathcal{D}^{(K)};\Theta^{(0)}) \leq \widehat{V}(\mathcal{D}^{(K)};\Theta^{(1)}) \leq \widehat{V}(\mathcal{D}^{(K)};\Theta^{(2)}) \leq \cdots$. Since the value function is upper bounded, this monotonically increasing sequence must converge, which happens at a maxima of $\widehat{V}(\mathcal{D}^{(K)};\Theta)$. Q.E.D.

Appendix C. Proof of Lemma 7

Substituting (26) and (27), we have

$$\text{Right side of (28)} = \frac{p(z_\tau^k = i, z_{\tau+1}^k = j, a_{0:t}^k | o_{1:t}^k, \Theta)}{\prod_{\tau'=0}^{t} p(a_{\tau'}^k | h_{\tau'}^k)}.$$

Since the denominator is equal to $p(a_{0:t}^k | o_{1:t}^k, \Theta)$ by (9), we have

$$\text{Right side of (28)} = p(z_\tau^k = i, z_{\tau+1}^k = j | a_{0:t}^k, o_{1:t}^k, \Theta) = \xi_{t,\tau}^k(i,j).$$

Similarly,

$$\begin{aligned}
\text{Right side of (29)} &= \frac{p(z_\tau^k = i, a_{0:t}^k | o_{1:t}^k, \Theta)}{\prod_{\tau'=0}^{t} p(a_{\tau'}^k | h_{\tau'}^k)} = \frac{p(z_\tau^k = i, a_{0:t}^k | o_{1:t}^k, \Theta)}{p(a_{0:t}^k | o_{1:t}^k, \Theta)}\\
&= p(z_\tau^k = i | a_{0:t}^k, o_{1:t}^k, \Theta)\\
&= \phi_{t,\tau}^k(i).
\end{aligned}$$

Q.E.D.

Appendix D. Proof of Theorem 8

We rewrite the lower bound in (61) as

$$\begin{aligned}\mathrm{LB}\left(\left\{q_t^k\right\}, g(\Theta)\right) = \frac{1}{K}\sum_{k=1}^{K}\sum_{t=0}^{T_k}\sum_{z_0^k,\cdots,z_t^k=1}^{|\mathcal{Z}|} \int q_t^k(z_{0:t}^k) g(\Theta) \ln \tilde{r}_t^k p(a_{0:t}^k, z_{0:t}^k | o_{1:t}^k, \Theta)\, d\Theta \\ -\frac{1}{K}\sum_{k=1}^{K}\sum_{t=0}^{T_k}\sum_{z_0^k,\cdots,z_t^k=1}^{|\mathcal{Z}|} q_t^k(z_{0:t}^k) \ln q_t^k(z_{0:t}^k) - \int g(\Theta) \ln \frac{g(\Theta)}{G_0(\Theta)}\, d\Theta. \qquad (82)\end{aligned}$$

We alternatively find the $\{q_t^k\}$ and $g(\Theta)$ that maximizes the lower bound, keeping one fixed while finding the other.

Keeping $g(\Theta)$ fixed, we solve $\max_{\{q_t^k\}} \mathrm{LB}\left(\left\{q_t^k\right\}, g(\Theta)\right)$ subject to the normalization constraint for $\{q_t^k\}$. We construct the Lagrangian

$$\ell_q = \mathrm{LB}\left(\left\{q_t^k\right\}, g(\Theta)\right) - \lambda\left(K - \sum_{k=1}^{K}\sum_{t=1}^{T_k}\sum_{z_0^k,\cdots,z_t^k=1}^{|\mathcal{Z}|} q_t^k(z_{0:t}^k)\right),$$

where λ is the Lagrangian multiplier. Differentiating ℓ_q with respect to $q_t^k(z_{0:t}^k)$ and setting the result to zero, we obtain

$$\frac{\partial \ell_q}{\partial\left(q_t^k(z_{0:t}^k)\right)} = \frac{1}{K}\int g(\Theta)\ln \tilde{r}_t^k p(a_{0:t}^k, z_{0:t}^k | o_{1:t}^k, \Theta)\, d\Theta - \frac{1}{K}\ln q_t^k(z_{0:t}^k) - \frac{1}{K} + \lambda = 0,$$

which is solved to give

$$q_t^k(z_{0:t}^k) = e^{K\lambda - 1}\tilde{r}_t^k \exp\left\{\int g(\Theta)\ln p(a_{0:t}^k, z_{0:t}^k | o_{1:t}^k, \Theta)\, d\Theta\right\}.$$

Using the constraint $\sum_{k=1}^{K}\sum_{t=1}^{T_k}\sum_{z_0^k,\cdots,z_t^k=1}^{|\mathcal{Z}|} q_t^k(z_{0:t}^k) = K$, (62) is arrived with $e^{1-K\lambda} = C_z$.

Keeping $\{q_t^k\}$ fixed, we solve $\max_{g(\Theta)} \mathrm{LB}\left(\left\{q_t^k\right\}, g(\Theta)\right)$ subject to the normalization constraint that $\int g(\Theta) d\Theta = 1$. Construct the Lagrangian

$$\ell_g = \mathrm{LB}\left(\left\{q_t^k\right\}, g(\Theta)\right) - \lambda\left(1 - \int g(\Theta) d\Theta\right),$$

where λ is the Lagrangian multiplier. Differentiating ℓ_g with respect to $g(\Theta)$ and setting the result to zero, we obtain

$$\frac{\partial \ell_g}{\partial\left(g(\Theta)\right)} = \frac{1}{K}\sum_{k=1}^{K}\sum_{t=0}^{T_k}\sum_{z_0^k,\cdots,z_t^k=1}^{|\mathcal{Z}|} q_t^k(z_{0:t}^k)\ln \tilde{r}_t^k p(a_{0:t}^k, z_{0:t}^k | o_{1:t}^k, \Theta) - 1 - \ln\frac{g(\Theta)}{G_0(\Theta)} + \lambda = 0,$$

which is solved to give

$$g(\Theta) = \frac{G_0(\Theta)}{e^{1-\lambda}} \exp\left\{\frac{1}{K}\sum_{k=1}^{K}\sum_{t=0}^{T_k}\sum_{z_0^k,\cdots,z_t^k=1}^{|\mathcal{Z}|} q_t^k(z_{0:t}^k)\ln \tilde{r}_t^k p(a_{0:t}^k, z_{0:t}^k | o_{1:t}^k, \Theta)\right\}.$$

By using the constraint $\int g(\Theta) d\Theta = 1$, we arrive at (63) with $e^{1-\lambda} = C_\Theta$. Q.E.D.

Abstract

Directed acyclic graphs (DAGs) have been widely used as a representation of conditional independence in machine learning and statistics. Moreover, hidden or latent variables are often an important component of graphical models. However, DAG models suffer from an important limitation: the family of DAGs is not closed under marginalization of hidden variables. This means that in general we cannot use a DAG to represent the independencies over a subset of variables in a larger DAG. Directed mixed graphs (DMGs) are a representation that includes DAGs as a special case, and overcomes this limitation. This paper introduces algorithms for performing Bayesian inference in Gaussian and probit DMG models. An important requirement for inference is the specification of the distribution over parameters of the models. We introduce a new distribution for covariance matrices of Gaussian DMGs. We discuss and illustrate how several Bayesian machine learning tasks can benefit from the principle presented here: the power to model dependencies that are generated from hidden variables, but without necessarily modeling such variables explicitly.

Keywords: graphical models, structural equation models, Bayesian inference, Markov chain Monte Carlo, latent variable models

1. Contribution

The introduction of graphical models (Pearl, 1988; Lauritzen, 1996; Jordan, 1998) changed the way multivariate statistical inference is performed. Graphical models provide a suitable language to decompose many complex real-world processes through conditional independence constraints.

Different families of independence models exist. The directed acyclic graph (DAG) family is a particularly powerful representation. Besides providing a language for encoding causal statements (Spirtes et al., 2000; Pearl, 2000), it is in a more general sense a family that allows for non-monotonic independence constraints: that is, models where some independencies can be destroyed by conditioning on new information (also known as the "explaining away" effect — Pearl, 1988), a feature to be expected in many real problems.

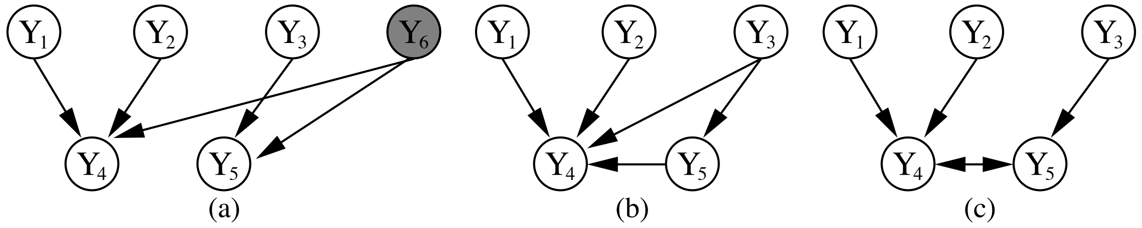

Figure 1: Consider the DAG in (a). Suppose we want to represent the marginal dependencies and independencies that result after marginalizing out Y_6. The simplest resulting DAG (i.e., the one with fewest edges) is depicted in (b). However, notice that this graph does not encode some of the independencies of the original model. For instance, Y_3 and Y_4 are no longer marginally independent in the modified DAGs. A different family of graphical models, encoded with more than one type of edge (directed and *bi-directed*), is the focus of this paper. The graph in (c) depicts the solution using this "mixed" representation.

However, DAG independence models have an undesirable feature: they are not closed under marginalization, as we will illustrate. Consider the regression problem where we want to learn the effect of a cocktail of two drugs for blood pressure, while controlling for a chemotherapy treatment of liver cancer. We refer to Y_1, Y_2 as the dosage for the blood pressure drugs, Y_3 as a measure of chemotherapy dosage, Y_4 as blood pressure, and Y_5 as an indicator of liver status. Moreover, let Y_6 be an hidden physiological factor that affects both blood pressure and liver status. It is assumed that the DAG corresponding to this setup is given by Figure 1(a).

In this problem, predictions concerning Y_6 are irrelevant: what we care is the marginal for $\{Y_1,\dots,Y_5\}$. Ideally, we want to take such irrelevant hidden variables out of the loop. Yet the set of dependencies within the marginal for $\{Y_1,\dots,Y_5\}$ cannot be efficiently represented as a DAG model. If we remove the edge $Y_3 \rightarrow Y_4$ from Figure 1(b), one can verify this will imply a model where Y_3 and Y_4 are independent given Y_5, which is not true in our original model. To avoid introducing unwanted independence constraints, a DAG such as the one in Figure 1(b) will be necessary. Notice that in general this will call for extra dependencies that did not exist originally (such as Y_3 and Y_4 now being marginally dependent). Not only learning from data will be more difficult due to the extra dependencies, but specifying prior knowledge on the parameters becomes less intuitive and therefore more error prone.

In general, it will be the case that variables of interest have hidden common causes. This puts the researcher using DAGs in a difficult position: if she models only the marginal comprising the variables of interest, the DAG representation might not be suitable anymore. If she includes all hidden variables for the sake of having the desirable set of independencies, extra assumptions about hidden variables will have to be taken into account. In this sense, the DAG representation is flawed. There is a need for a richer family of graphical models, for which *mixed graphs* are an answer.

Directed mixed graphs (DMGs) are graphs with directed and bi-directed edges. In particular, acyclic directed mixed graphs (ADMGs) have no directed cycle, that is, no sequence of directed edges $X \rightarrow \cdots \rightarrow X$ that starts and ends on the same node. Such a representation encodes a set of conditional independencies among random variables, which can be read off a graph by using a

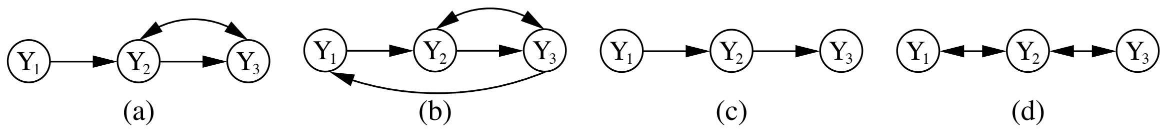

Figure 2: Different examples of directed mixed graphs. The graph in (b) is cyclic, while all others are acyclic. A subgraph of two variables where both edges $Y_1 \rightarrow Y_2$ and $Y_1 \leftrightarrow Y_2$ are present is sometimes known as a "bow pattern" (Pearl, 2000) due to its shape.

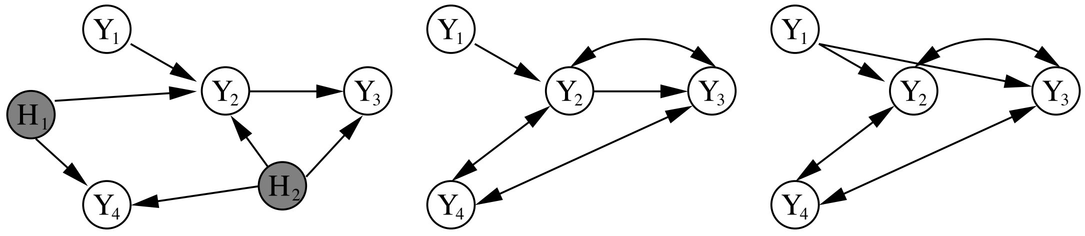

Figure 3: After marginalizing variables H_1 and H_2 from the DAG on the left, one possible DMG representation of the same dependencies is shown by the graph in the middle. Notice that there are multiple DMGs within a same Markov equivalence class, that is, encoding the same set of conditional independencies (Richardson and Spirtes, 2002). The two last graphs above are on the same class.

criterion known as m-separation, a natural extension of the d-separation criterion used for directed acyclic graphs (Richardson, 2003).

In a ADMG, two adjacent nodes might be connected by up to two edges, where in this case one has to be bi-directed and the other directed. A cyclic model can in principle allow for two directed edges of opposite directions. Figure 2 provides a few examples of DMGs. The appeal of this graphical family lies on the representation of the marginal independence structure among a set of observed variables, assuming they are part of a larger DAG structure that includes hidden variables. This is illustrated in Figure 3.[1] More details on DMGs are given in Sections 2 and 8. In our blood pressure\liver status multiple regression problem, the suitable directed mixed graph is depicted in Figure 1(c).

The contribution of this paper is how to perform Bayesian inference on two different families of mixed graph models: Gaussian and probit. Markov chain Monte Carlo (MCMC) and variational approximations will be discussed. Current Bayesian inference approaches for DMG models have limitations, as discussed in Section 2, despite the fact that such models are widely used in several sciences.

The rest of the paper is organized as follows. Section 3 describes a special case of Gaussian mixed graph models, where only bi-directed edges are allowed. Priors and a Monte Carlo algorithm are described. This case will be a building block for subsequent sections, such as Section 4, where

1. Notice that it is not necessarily the case that the probability model itself is closed under marginalization. This will happen to some models, including the Gaussian model treated in this paper. But the basic claim of closure concerns the graph, that is, the representation of independence constraints.

Gaussian DMG models are treated. Section 5 covers a type of discrete distribution for binary and ordinal data that is Markov with respect to an acyclic DMG. In Section 6 we discuss more sophisticated algorithms that are useful for scaling up Bayesian learning to higher-dimensional problems. Section 7 presents several empirical studies. Since the use of mixed graph models in machine learning applications is still in its early stages, we briefly describe in Section 8 a variety of possible uses of such graphs in machine learning applications.

2. Basics of DMGs, Gaussian Models and Related Work

In this section, we describe the Gaussian DMG model and how it complements latent variable models. At the end of the section, we also discuss a few alternative approaches for the Bayesian inference problem introduced in this paper.

2.1 Notation and Terminology

In what follows, we will use standard notions from the graphical modeling literature, such as vertex (node), edge, parent, child, ancestor, descendant, DAG, undirected graph, induced subgraph, Markov condition and d-separation. Refer to Pearl (1988) and Lauritzen (1996) for the standard definitions if needed. Less standard definitions will be given explicitly when appropriate. A useful notion is that of m-separation (Richardson, 2003) for reading off which independencies are entailed by a DMG representation. This can be reduced to d-separation (Pearl, 1988) by the following trick: for each bi-directed edge $Y_i \leftrightarrow Y_j$, introduce a new hidden variable X_{ij} and the edges $X_{ij} \rightarrow Y_i$ and $X_{ij} \rightarrow Y_j$. Remove then all bi-directed edges and apply d-separation to the resulting directed graph.

As usual, we will refer to vertices (nodes) in a graph and the corresponding random variables in a distribution interchangeably. Data points are represented by vectors with an upper index, such as $\mathbf{Y}^{(1)}, \mathbf{Y}^{(2)}, \ldots, \mathbf{Y}^{(n)}$. The variable corresponding to node Y_i in data point $\mathbf{Y}^{(j)}$ is represented by $Y_i^{(j)}$.

2.2 Gaussian Parameterization

The origins of mixed graph models can be traced back to Sewall Wright (Wright, 1921), who used special cases of mixed graph representations in genetic studies. Generalizing Wright's approach, many scientific fields such as psychology, social sciences and econometrics use linear mixed graph models under the name of *structural equation models* (Bollen, 1989). Only recently the graphical and parametrical aspects of mixed graph models have been given a thorough theoretical treatment (Richardson and Spirtes, 2002; Richardson, 2003; Kang and Tian, 2005; Drton and Richardson, 2008a). In practice, many structural equation models today are Gaussian models. We will work under this assumption unless stated otherwise.

For a DMG $\mathcal{G}$ with a set of vertices $\mathbf{Y}$, a standard parameterization of the Gaussian model is given as follows. For each variable Y_i with a (possibly empty) parent set $\{Y_{i1}, ..., Y_{ik}\}$, we define a "structural equation"

$$Y_i = \alpha_i + b_{i1}Y_{i1} + b_{i2}Y_{i2} + \cdots + b_{ik}Y_{ik} + \varepsilon_i$$

where ε_i is a Gaussian random variable with zero mean and variance v_{ii}. Notice that this parameterization allows for cyclic models.

Unlike in standard Gaussian DAG models, the error terms $\{\varepsilon_i\}$ are not necessarily mutually independent. Independence is asserted by the graphical structure: given two vertices Y_i and Y_j, the respective error terms ε_i and ε_j are marginally independent if Y_i and Y_j are not connected by a bi-directed edge.

By this parameterization, each directed edge $Y_i \leftarrow Y_j$ in the graph corresponds to a parameter b_{ij}. Each bi-directed edge $Y_i \leftrightarrow Y_j$ in the graph is associated with a covariance parameter v_{ij}, the covariance of ε_i and ε_j. Each vertex Y_j in the graph is associated with variance parameter v_{jj}, the variance of ε_j. Algebraically, let $\mathbf{B}$ be a $m \times m$ matrix, m being the number of observed variables. This matrix is such that $(\mathbf{B})_{ij} = b_{ij}$ if $Y_i \leftarrow Y_j$ exists in the graph, and 0 otherwise. Let $\mathbf{V}$ be a $m \times m$ matrix, where $(\mathbf{V})_{ij} = v_{ij}$ if $i = j$ or if $Y_i \leftrightarrow Y_j$ is in the graph, and 0 otherwise. Let $\mathbf{Y}$ be the column vector of observed variables, α the column vector of intercept parameters, and ε be the corresponding vector of error terms. The set of structural equations can be given in matrix form as

$$\begin{aligned} & \mathbf{Y} = \mathbf{BY} + \alpha + \varepsilon \Rightarrow \mathbf{Y} = (\mathbf{I} - \mathbf{B})^{-1}(\varepsilon + \alpha) \\ \Rightarrow \quad & \Sigma(\Theta) = (\mathbf{I} - \mathbf{B})^{-1}\mathbf{V}(\mathbf{I} - \mathbf{B})^{-\mathsf{T}} \end{aligned} \tag{1}$$

where $\mathbf{A}^{-\mathsf{T}}$ is the transpose of $\mathbf{A}^{-1}$ and $\Sigma(\Theta)$ is the *implied covariance matrix* of the model, $\Theta \equiv \{\mathbf{B}, \mathbf{V}, \alpha\}$.

2.2.1 COMPLETENESS OF PARAMETERIZATION AND ANCESTRAL GRAPHS

An important class of ADMGs is the directed ancestral graph. Richardson and Spirtes (2002) provide the definition and a thorough account of the Markov properties of ancestral graphs. One of the reasons for the name "ancestral graph" is due to one of its main properties: if there is a directed path $Y_i \rightarrow \cdots \rightarrow Y_j$, that is, if Y_i is an ancestor of Y_j, then there is no bi-directed edge $Y_i \leftrightarrow Y_j$. Thus directed ancestral graphs are ADMGs with this constraint.[2]

In particular, they show that any Gaussian distribution that is Markov with respect to a given ADMG can be represented by some Gaussian ancestral graph model that is parameterized as above. For the ancestral graph family, the given parameterization is *complete*: that is, for each Markov equivalence class, it is always possible to choose an ancestral graph where the resulting parameterization imposes no further constraints on the distribution besides the independence constraints of the class. Since the methods described in this paper apply to general DMG models, they also apply to directed ancestral graphs.

In principle, it is possible to define and parameterize a Gaussian DAG model that entails exactly the same independence constraints encoded in an directed ancestral graph. One possibility, as hinted in the previous Section, is to replace each bi-directed edge $Y_i \leftrightarrow Y_j$ by a new path $Y_i \leftarrow X_{ij} \rightarrow Y_j$. Variables $\{X_{ij}\}$ are "ancillary" hidden variables, in the sense that they are introduced for the sake of obtaining the same independence constraints of an ancestral graph. Standard Bayesian methodology can then be applied to perform inference in this Gaussian DAG model.

However, this parameterization might have undesirable consequences, as discussed in Section 8.6 of Richardson and Spirtes (2002). Moreover, when Markov chain Monte Carlo algorithms are applied to compute posteriors, the "ancillary" hidden variables will have to be integrated out numerically. The resulting Markov chain can suffer from substantial autocorrelation when compared to a model with no ancillary variables. We illustrate this behavior in Section 7.

Further constraints beyond independence constraints are certainly desirable depending on the context. For instance, general ADMGs that are not ancestral graphs may impose other constraints (Richardson and Spirtes, 2002), and such graphs can still be sensible models of, for example, the

2. Notice this rules out the possibility of having both edges $Y_i \rightarrow Y_j$ and $Y_i \leftrightarrow Y_j$ in the same ancestral graph.

causal processes for the problem at hand. When many observed variables are confounded by a same hidden common cause, models based on factor analysis are appropriate (Silva et al., 2006). However, it is useful to be able to build upon independence models that are known to have a complete parameterization. In any case, even the latent variables in any model might have dependencies that arise from other latent variables that were marginalized, and a latent variable ADMG model will be necessary. When it comes to solving a problem, it is up to the modeler (or learning algorithm) to decide if some set of latent variables should be included, or if they should be implicit, living their hidden life through the marginals.

Richardson and Spirtes (2002) provide further details on the advantages of a complete parameterization. Drton and Richardson (2004) provide an algorithm for fitting Gaussian ancestral graph models by maximum likelihood.

2.3 Bayesian Inference

The literature on Bayesian structural equation models is extensive. Scheines et al. (1999) describe one of the first approaches, including ways of testings such models. Lee (2007) provides details on many recent advances. Standard Bayesian approaches for Gaussian DMG models rely on either attempting to reduce the problem to inference with DAG models, or on using rejection sampling.

In an application described by Dunson et al. (2005), the "ancillary latent" trick is employed, and Gibbs sampling for Gaussian DAG models is used. This parameterization has the disadvantages mentioned in the previous section. Scheines et al. (1999) use the complete parameterization, with a single parameter corresponding to each bi-directed edge. However, the global constraint of positive-definiteness in the covariance matrix is enforced only by rejection sampling, which might be inefficient in models with moderate covariance values. The prior is setup in an indirect way. A Gaussian density function is independently defined for each error covariance v_{ij}. The actual prior, however, is the result of multiplying all of such functions and the indicator function that discards non-positive definite matrices, which is then renormalized.

In contrast, the Bayesian approach delineated in the next sections uses the complete parameterization, does not appeal to rejection sampling, makes use of a family of priors which we believe is the natural choice for the problem, and leads to convenient ways of computing marginal likelihoods for model selection. We will also see that empirically they lead to much better behaved Markov chain Monte Carlo samplers when compared to DAGs with ancillary latent variables.

3. Gaussian Models of Marginal Independence

This section concerns priors and sampling algorithms for zero-mean Gaussian models that are Markov with respect to a bi-directed graph, that is, a DMG with no directed edges. Focusing on bi-directed graphs simplifies the presentation, while providing a convenient starting point to solve the full DMG case in the sequel.

Concerning the notation: the distribution we introduce in this section is a distribution over covariance matrices. In the interest of generality, we will refer to the random matrix as Σ. In the context of the previous section, $\Sigma \equiv \Sigma(\Theta) = \mathbf{V}$, since we are assuming $\mathbf{B} = 0, \alpha = 0$.

3.1 Priors

Gaussian bi-directed graph models are sometimes called *covariance graph models*. Covariance graphs are models of marginal independence: each edge corresponds to a single parameter in the covariance matrix (the corresponding covariance); the absence of an edge $Y_i \leftrightarrow Y_j$ is a statement that $\sigma_{Y_iY_j} = 0$, σ_{XY} being the covariance of random variables X and Y. More precisely, if Σ is a random covariance matrix generated by a covariance model, a distribution of Σ is the distribution over the (non-repeated) entries corresponding to variances and covariances of adjacent nodes.[3]

In a model with a fully connected bi-directed graph, this reduces to a space of unrestricted covariance matrices. A common distribution for covariance matrices is the inverse Wishart $IW(\delta, \mathbf{U})$. In this paper, we adopt the following inverse Wishart parameterization:

$$p(\Sigma) \propto |\Sigma|^{-(\delta+2m)/2} \exp\left\{-\frac{1}{2}tr(\Sigma^{-1}\mathbf{U})\right\}, \Sigma \text{ positive definite,}$$

$p(\cdot)$ being the density function, $tr(\cdot)$ the trace function, and m the number of variables (nodes) in our model.[4] We will overload the symbol $p(\cdot)$ wherever it is clear from the context which density function we are referring to. It is assumed that $\delta > 0$ and $\mathbf{U}$ is positive definite.

Following Atay-Kayis and Massam (2005), let $M^+(\mathcal{G})$ be the cone of positive definite matrices such that, for a given bi-directed graph $\mathcal{G}$ and $\Sigma \in M^+(\mathcal{G})$, $\sigma_{ij} = 0$ if nodes Y_i and Y_j are not adjacent in $\mathcal{G}$. It is convenient to choose a distribution that is conjugate to the Gaussian likelihood function, since one can use the same algorithms for performing inference both in the prior and posterior. In a zero-mean Gaussian model, the likelihood function for a fixed data set $\mathcal{D} = \{\mathbf{Y}^{(1)}, \mathbf{Y}^{(2)}, \dots, \mathbf{Y}^{(n)}\}$ is defined by the sufficient statistic $\mathbf{S} = \sum_{d=1}^{n}(\mathbf{Y}^{(d)})(\mathbf{Y}^{(d)})^{\mathsf{T}}$ as follows:

$$\mathcal{L}(\Sigma; \mathcal{D}) = (2\pi)^{-nm/2}|\Sigma|^{-n/2} \exp\left\{-\frac{1}{2}tr(\Sigma^{-1}\mathbf{S})\right\}. \tag{2}$$

We extend the inverse Wishart distribution to the case of constrained covariance matrices in order to preserve conjugacy. This define the following distribution:

$$p(\Sigma) = \frac{1}{I_{\mathcal{G}}(\delta, \mathbf{U})}|\Sigma|^{-(\delta+2m)/2} \exp\left\{-\frac{1}{2}tr(\Sigma^{-1}\mathbf{U})\right\}, \Sigma \in M^+(\mathcal{G}) \tag{3}$$

which is basically a re-scaled inverse Wishart prior with a different support and, consequently, different normalizing constant $I_{\mathcal{G}}(\delta, \mathbf{U})$. An analogous concept exists for undirected graphs, where $\Sigma^{-1} \in M^+(\mathcal{G})$ is given a Wishart-like prior: the "$\mathcal{G}$-Wishart" distribution (Atay-Kayis and Massam, 2005). We call the distribution with density function defined as in Equation (3) the *$\mathcal{G}$-Inverse Wishart* distribution ($\mathcal{G}$-*IW*). It will be the basis of our framework. There are no analytical formulas for the normalizing constant.

3. As such, the density function for Σ is defined with respect to the Lebesgue measure of the non-zero, independent elements of this matrix.
4. We adopt this non-standard parameterization of the inverse Wishart because it provides a more convenient reparameterization used in the sequel. Notice this is the parameterization used by Brown et al. (1993) and Atay-Kayis and Massam (2005), which developed other distributions for covariance matrices.

3.2 The Normalizing Constant

We now derive a Monte Carlo procedure to compute $I_{\mathcal{G}}(\delta, \mathbf{U})$. In the sequel, this will be adapted into an importance sampler to compute functionals of a $\mathcal{G}$-*IW* distribution. The core ideas are also used in a Gibbs sampler to obtain samples from its posterior.

The normalizing constant is essential for model selection of covariance graphs. By combining the likelihood equation (2) with the prior (3), we obtain the joint

$$p(\mathcal{D}, \Sigma \mid \mathcal{G}) = (2\pi)^{-\frac{nm}{2}} I_{\mathcal{G}}(\delta, \mathbf{U})^{-1} \times |\Sigma|^{-\frac{\delta+2m+n}{2}} \exp\left\{-\frac{1}{2} tr[\Sigma^{-1}(\mathbf{S}+\mathbf{U})]\right\}$$

where we make the dependency on the graphical structure $\mathcal{G}$ explicit. By the definition of $I_{\mathcal{G}}$, integrating Σ out of the above equation implies the following marginal likelihood:

$$p(\mathcal{D} \mid \mathcal{G}) = \frac{1}{(2\pi)^{\frac{nm}{2}}} \frac{I_{\mathcal{G}}(\delta + n, \mathbf{S}+\mathbf{U})}{I_{\mathcal{G}}(\delta, \mathbf{U})}$$

from which a posterior $\mathcal{P}(\mathcal{G} \mid \mathcal{D})$ can be easily derived as a function of quantities of the type $I_{\mathcal{G}}(\cdot, \cdot)$.

The normalizing constant $I_{\mathcal{G}}(\delta, \mathbf{U})$ is given by the following integral:[5]

$$I_{\mathcal{G}}(\delta, \mathbf{U}) = \int_{M^+(\mathcal{G})} |\Sigma|^{-\frac{\delta+2m}{2}} \exp\left\{-\frac{1}{2} tr(\Sigma^{-1}\mathbf{U})\right\} d\Sigma. \tag{4}$$

The space $M^+(\mathcal{G})$ can be described as the space of positive definite matrices conditioned on the event that each matrix has zero entries corresponding to non-adjacent nodes in graph $\mathcal{G}$. We will reduce the integral (4) to an integral over random variables we know how to sample from. The given approach follows the framework of Atay-Kayis and Massam (2005) using the techniques of Drton and Richardson (2003).

Atay-Kayis and Massam (2005) show how to compute the marginal likelihood of non-decomposable undirected models by reparameterizing the precision matrix through the Cholesky decomposition. The zero entries in the inverse covariance matrix of this model correspond to constraints in this parameterization, where part of the parameters can be sampled independently and the remaining parameters calculated from the independent ones.

We will follow a similar framework but with a different decomposition. It turns out that the Cholesky decomposition does not provide an easy reduction of (4) to an integral over canonical, easy to sample from, distributions. We can, however, use Bartlett's decomposition to achieve this reduction.

3.2.1 Bartlett's Decomposition

Before proceeding, we will need a special notation for describing sets of indices and submatrices.

Let $\{i\}$ represent the set of indices $\{1, 2, \ldots, i\}$. Let $\Sigma_{i,\{i-1\}}$ be the row vector containing the covariance between Y_i and all elements of $\{Y_1, Y_2, \ldots, Y_{i-1}\}$. Let $\Sigma_{\{i-1\},\{i-1\}}$ be the marginal covariance matrix of $\{Y_1, Y_2, \ldots, Y_{i-1}\}$. Let σ_{ii} be the variance of Y_i. Define the mapping

$$\Sigma \rightarrow \Phi \equiv \{\gamma_1, \mathcal{B}_2, \gamma_2, \mathcal{B}_3, \gamma_3, \ldots, \mathcal{B}_m, \gamma_m\},$$

5. Notice this integral is always finite for any choice of $\delta > 0$ and positive definite $\mathbf{U}$, since it is no greater than the normalizing constant of the inverse Wishart.

such that $\mathcal{B}_i$ is a row vector with $i-1$ entries, γ_i is a scalar, and

$$\begin{array}{rcll} \gamma_1 & = & \sigma_{11}, & \\ \mathcal{B}_i & = & \Sigma_{i,\{i-1\}}\Sigma^{-1}_{\{i-1\},\{i-1\}}, & i>1, \\ \gamma_i & = & \sigma_{ii.\{i-1\},\{i-1\}} \equiv \sigma_{ii} - \Sigma_{i,\{i-1\}}\Sigma^{-1}_{\{i-1\},\{i-1\}}\Sigma_{\{i-1\},i}, & i>1. \end{array} \tag{5}$$

The set Φ provides a parameterization of Σ, in the sense that the mapping (5) is bijective. Given that $\sigma_{11} = \gamma_1$, the inverse mapping is defined recursively by

$$\begin{array}{rcl} \Sigma_{i,\{i-1\}} & = & \mathcal{B}_i\Sigma_{\{i-1\},\{i-1\}},\ i>1, \\ \sigma_{ii} & = & \gamma_i + \mathcal{B}_i\Sigma_{\{i-1\},i},\ i>1. \end{array} \tag{6}$$

We call the set $\Phi \equiv \{\gamma_1, \mathcal{B}_2, \gamma_2, \mathcal{B}_3, \gamma_3, \dots, \mathcal{B}_m, \gamma_m\}$ the *Bartlett parameters* of Σ, since the decomposition (6) is sometimes known as Bartlett's decomposition (Brown et al., 1993).

For a random inverse Wishart matrix, Bartlett's decomposition allows the definition of its density function by the joint density of $\{\gamma_1, \mathcal{B}_2, \gamma_2, \mathcal{B}_3, \gamma_3, \dots, \mathcal{B}_m, \gamma_m\}$. Define $\mathbf{U}_{\{i-1\},\{i-1\}}$, $\mathbf{U}_{\{i-1\},i}$ and $u_{ii.\{i-1\},\{i-1\}}$ in a way analogous to the Σ definitions. The next lemma follows directly from Lemma 1 of Brown et al. (1993):

Lemma 1 *Suppose Σ is distributed as $IW(\delta, \mathbf{U})$. Then the distribution of the corresponding Bartlett parameters $\Phi \equiv \{\gamma_1, \mathcal{B}_2, \gamma_2, \mathcal{B}_3, \gamma_3, \dots, \mathcal{B}_m, \gamma_m\}$ is given by:*

1. *γ_i is independent of $\Phi \backslash \{\gamma_i, \mathcal{B}_i\}$*
2. *$\gamma_i \sim IG((\delta+i-1)/2, u_{ii.\{i-1,i-1\}}/2)$, where $IG(\alpha,\beta)$ is the inverse gamma distribution*
3. *$\mathcal{B}_i \mid \gamma_i \sim N(\mathbf{U}^{-1}_{\{i-1\},\{i-1\}}\mathbf{U}_{\{i-1\},i}, \gamma_i\mathbf{U}^{-1}_{\{i-1\},\{i-1\}})$, where $N(\mathbf{M},\mathbf{C})$ is a multivariate Gaussian distribution and $\mathbf{U}^{-1}_{\{i-1\},\{i-1\}} \equiv (\mathbf{U}_{\{i-1\},\{i-1\}})^{-1}$.*

3.2.2 BARTLETT'S DECOMPOSITION OF MARGINAL INDEPENDENCE MODELS

What is interesting about Bartlett's decomposition is that it provides a simple parameterization of the inverse Wishart distribution with variation independent parameters. This decomposition allows the derivation of new distributions. For instance, Brown et al. (1993) derive a "Generalized Inverted Wishart" distribution that allows one to define different degrees of freedom for different submatrices of an inverse Wishart random matrix. For our purposes, Bartlett's decomposition can be used to reparameterize the $\mathcal{G}$-*IW* distribution. For that, one needs to express the independent elements of Σ in the space of Bartlett parameters.

The original reparameterization maps Σ to $\Phi \equiv \{\gamma_1, \mathcal{B}_2, \gamma_2, \mathcal{B}_3, \gamma_3, \dots, \mathcal{B}_d, \gamma_d\}$. To impose the constraint that Y_i and Y_j are uncorrelated, for $i > j$, is to set $\left(\mathcal{B}_i\Sigma_{\{i-1\},\{i-1\}}\right)_j = \sigma_{Y_iY_j}(\Phi) = 0$. For a fixed $\Sigma_{\{i-1\},\{i-1\}}$, this implies a constraint on $(\mathcal{B}_i)_j \equiv \beta_{ij}$.

Following the terminology used by Richardson and Spirtes (2002), let a *spouse* of node Y in a mixed graph be any node adjacent to Y by a bi-directed edge. The set of spouses of Y_i is denoted by $sp(i)$. The set of spouses of Y_i *according to order* $Y_1, Y_2, \dots, Y_m$ is defined by $sp_\prec(i) \equiv sp(i) \cap \{Y_1, \dots, Y_{i-1}\}$. The set of non-spouses of Y_i is denoted by $nsp(i)$. Analogously, $nsp_\prec(i) \equiv \{Y_1, \dots, Y_{i-1}\} \backslash sp_\prec(i)$. Let $\mathcal{B}_{i,sp_\prec(i)}$ be the subvector of $\mathcal{B}_i$ corresponding to the the respective spouses of Y_i. Define $\mathcal{B}_{i,nsp_\prec(i)}$ analogously.

Given the constraint $\mathcal{B}_i \Sigma_{\{i-1\},nsp_{\prec}(i)} = 0$, it follows that

$$\mathcal{B}_{i,sp_{\prec}(i)}\Sigma_{sp_{\prec}(i),nsp_{\prec}(i)} + \mathcal{B}_{i,nsp_{\prec}(i)}\Sigma_{nsp_{\prec}(i),nsp_{\prec}(i)} = 0 \Rightarrow$$

$$\mathcal{B}_{i,nsp_{\prec}(i)} = -\mathcal{B}_{i,sp_{\prec}(i)}\Sigma_{sp_{\prec}(i),nsp_{\prec}(i)}\Sigma^{-1}_{nsp_{\prec}(i),nsp_{\prec}(i)}. \tag{7}$$

Identity (7) was originally derived by Drton and Richardson (2003). A property inherited from the original decomposition for unconstrained matrices is that $\mathcal{B}_{i,sp_{\prec}(i)}$ is functionally independent of $\Sigma_{\{i-1\},\{i-1\}}$. From (7), we obtain that the free Bartlett parameters of Σ are $\Phi_{\mathcal{G}} \equiv \{\gamma_1, \mathcal{B}_{2,sp_{\prec}(2)}, \gamma_2, \mathcal{B}_{3,sp_{\prec}(3)}, \gamma_3, \dots, \mathcal{B}_{m,sp_{\prec}(m)}, \gamma_m\}$.

Notice that, according to (5), Φ corresponds to the set of parameters of a fully connected, zero-mean, Gaussian DAG model. In such a DAG, Y_i is a child of $\{Y_1, \dots, Y_{i-1}\}$, and

$$Y_i = \mathcal{B}_i \mathbf{Y}_{i-1} + \zeta_j, \qquad \zeta_j \sim N(0, \gamma_j)$$

where $\mathbf{Y}_{i-1}$ is the $(i-1)\times 1$ vector corresponding to $\{Y_1, \dots, Y_{i-1}\}$.

As discussed by Drton and Richardson (2003), this interpretation along with Equation (7) implies

$$Y_i = \mathcal{B}_{i,sp_{\prec}(i)}\mathbf{Z}_i + \zeta_j \tag{8}$$

where the entries in $\mathbf{Z}_i$ are the corresponding residuals of the regression of $sp_{\prec}(i)$ on $nsp_{\prec}(i)$.

The next step in solving integral (4) is to find the Jacobian $J(\Phi_{\mathcal{G}})$ of the transformation $\Sigma \rightarrow \Phi_{\mathcal{G}}$. This is given by the following Lemma:

Lemma 2 *The determinant of the Jacobian for the change of variable $\Sigma \rightarrow \Phi_{\mathcal{G}}$ is*

$$|J(\Phi_{\mathcal{G}})| = \prod_{i=2}^{m}|R_i| = \frac{1}{\prod_{i=2}^{m}|\Sigma_{nsp_{\prec(i)},nsp_{\prec(i)}}|}\prod_{i=1}^{m-1}\gamma_i^{m-i}$$

where $R_i \equiv \Sigma_{sp_{\prec(i)},sp_{\prec(i)}} - \Sigma_{sp_{\prec(i)},nsp_{\prec(i)}}\Sigma^{-1}_{nsp_{\prec(i)},nsp_{\prec(i)}}\Sigma_{nsp_{\prec(i)},sp_{\prec(i)}}$, that is, the covariance matrix of the respective residual $\mathbf{Z}_i$ (as parameterized by $\Phi_{\mathcal{G}}$). If $nsp_{\prec(i)} = \emptyset$, R_i is defined as $\Sigma_{sp_{\prec(i)},sp_{\prec(i)}}$ and $|\Sigma_{nsp_{\prec(i)},nsp_{\prec(i)}}|$ is defined as 1.

The proof of this Lemma is in Appendix C. A special case is the Jacobian of the unconstrained covariance matrix (i.e., when the graph has no missing edges):

$$|J(\Phi)| = \prod_{i=1}^{m-1}\gamma_i^{m-i}. \tag{9}$$

Now that we have the Jacobian, the distribution over Bartlett's parameters given by Lemma 1, and the identities of Drton and Richardson (2003) given in Equation (7), we have all we need to provide a Monte Carlo algorithm to compute the normalizing constant of a $\mathcal{G}$-*IW* with parameters $(\delta, \mathbf{U})$.

Let $\Sigma(\Phi_{\mathcal{G}})$ be the implied covariance matrix given by our set of parameters $\Phi_{\mathcal{G}}$. We start from the integral in (4), and rewrite it as a function of $\Phi_{\mathcal{G}}$. This can be expressed by substituting Σ for $\Sigma(\Phi_{\mathcal{G}})$ and multiplying the integrand by the determinant of the Jacobian. Notice that the parameters in $\Sigma(\Phi_{\mathcal{G}})$ are variation independent: that is, their joint range is given by the product of their individual ranges (positive reals for the γ variables and the real line for the β coefficients). This range will replace the original $M^+(\mathcal{G})$ space, which we omit below for simplicity of notation:

$$I_{\mathcal{G}}(\delta,\mathbf{U}) = \int |J(\Phi_{\mathcal{G}})||\Sigma(\Phi_{\mathcal{G}})|^{-\frac{\delta+2m}{2}} \exp\left\{-\frac{1}{2}tr(\Sigma(\Phi_{\mathcal{G}})^{-1}\mathbf{U})\right\} d\Phi_{\mathcal{G}}.$$

We now multiply and divide the above expression by the normalizing constant of an inverse Wishart $(\delta,\mathbf{U})$, which we denote by $I_{IW}(\delta,\mathbf{U})$:

$$I_{\mathcal{G}}(\delta,\mathbf{U}) = I_{IW}(\delta,\mathbf{U}) \int |J(\Phi_{\mathcal{G}})| \times I_{IW}^{-1}(\delta,\mathbf{U})|\Sigma(\Phi_{\mathcal{G}})|^{-\frac{\delta+2m}{2}} \exp\left\{-\frac{1}{2}tr(\Sigma(\Phi_{\mathcal{G}})^{-1}\mathbf{U})\right\} d\Phi_{\mathcal{G}}. \quad (10)$$

The expression

$$I_{IW}^{-1}(\delta,\mathbf{U})|\Sigma|^{-\frac{\delta+2m}{2}} \exp\left\{-\frac{1}{2}tr(\Sigma^{-1}\mathbf{U})\right\}$$

corresponds to the density function of an inverse Wishart Σ. Lemma 1 allows us to rewrite the inverse Wishart density function as the density of Bartlett parameters, but this is assuming no independence constraints. We can easily reuse the result of Lemma 1 as follows:

1. write the density of the inverse Wishart as the product of gamma-normal densities given in Lemma 1;

2. this expression contains the original Jacobian determinant $|J(\Phi)|$. We have to remove it, since we are plugging in our own Jacobian determinant. Hence, we divide the reparameterized density by the expression in Equation (9).

   This ratio $|J(\Phi_{\mathcal{G}})|/|J(\Phi)|$ can be rewritten as

   $$\frac{|J(\Phi_{\mathcal{G}})|}{|J(\Phi)|} = \prod_{i=1}^{m} \frac{|R_i|}{\gamma_i^{m-i}} = \frac{1}{\prod_{i=2}^{m} |\Sigma_{nsp_{\prec(i)},nsp_{\prec(i)}}|}$$

   where $|\Sigma_{nsp_{\prec(i)},nsp_{\prec(i)}}| \equiv 1$ if $nsp_{\prec}(i) = \emptyset$;

3. substitute each vector $\mathcal{B}_{i,nsp_{\prec}(i)}$, which is not a free parameter, by the corresponding expression $-\mathcal{B}_{i,sp_{\prec}(i)}\Sigma_{sp_{\prec}(i),nsp_{\prec}(i)}\Sigma^{-1}_{nsp_{\prec}(i),nsp_{\prec}(i)}$.

This substitution takes place into the original factors given by Bartlett's decomposition, as introduced in Lemma 1:

$$\begin{array}{rcl} p(\mathcal{B}_i,\gamma_i) & = & (2\pi)^{-(i-1)/2}\gamma_i^{-(i-1)/2}|\mathbf{U}_{\{i-1\},\{i-1\}}|^{1/2} \\ & \times & \exp\left(-\frac{1}{2\gamma_i}(\mathcal{B}_i^{\mathsf{T}} - \mathbf{M}_i)^{\mathsf{T}}\mathbf{U}_{\{i-1\},\{i-1\}}(\mathcal{B}_i^{\mathsf{T}} - \mathbf{M}_i)\right) \\ & \times & \dfrac{(u_{ii.\{i-1\},\{i-1\}}/2)^{(\delta+i-1)/2}}{\Gamma((\delta+i-1)/2)}\gamma_i^{-\left(\frac{\delta+i-1}{2}+1\right)} \exp\left(-\frac{1}{2\gamma_i}u_{ii.\{i-1\},\{i-1\}}\right) \end{array} \quad (11)$$

where $\mathbf{M}_i \equiv \mathbf{U}^{-1}_{\{i-1\},\{i-1\}}\mathbf{U}_{\{i-1\},i}$. Plugging in this in (10) results in

$$I_{\mathcal{G}}(\delta, \mathbf{U}) = I_{IW}(\delta, \mathbf{U}) \int \frac{1}{\prod_{i=2}^{m} |\Sigma_{nsp_{\prec}(i), nsp_{\prec}(i)}|} \times p(\gamma_1) \prod_{i=2}^{m} p(\mathcal{B}_i, \gamma_i)\, d\Phi_{\mathcal{G}}.$$

However, after substitution, each factor $p(\mathcal{B}_i, \gamma_i)$ is not in general a density function for $\{\mathcal{B}_{i,sp_{\prec}(i)}, \gamma_i\}$ and will include also parameters $\{\mathcal{B}_{j,sp_{\prec}(j)}, \gamma_j\}, j < i$. Because of the non-linear relationships that link Bartlett parameters in a marginal independence model, we cannot expect to reduce this expression to a tractable distribution we can easily sample from. Instead, we rewrite each original density factor $p(\mathcal{B}_i, \gamma_i)$ such that it includes all information about $\mathcal{B}_{i,sp_{\prec}(i)}$ and γ_i within a canonical density function. That is, factorize $p(\mathcal{B}_i, \gamma_i)$ as

$$p(\mathcal{B}_i, \gamma_i | \Phi_{i-1}) = p_b(\mathcal{B}_{i,sp_{\prec}(i)} | \gamma_i, \Phi_{i-1}) p_g(\gamma_i | \Phi_{i-1}) \times f_i(\Phi_{i-1}) \tag{12}$$

where we absorb any occurrence of $\mathcal{B}_{i,sp_{\prec}(i)}$ within the sampling distribution and factorize the remaining dependence on previous parameters $\Phi_{i-1} \equiv \{\gamma_1, \gamma_2, \mathcal{B}_{2,sp_{\prec}(2)}, \dots, \gamma_{i-1}, \mathcal{B}_{i-1,sp_{\prec}(i-1)}\}$ into a separate function.[6] We derive the functions $p_b(\cdot), p_g(\cdot)$ and $f_i(\cdot)$ in Appendix A. The result is as follows.

The density $p_b(\mathcal{B}_{i,sp_{\prec}(i)} | \gamma_i, \Phi_{i-1})$ is the density of a Gaussian $N(\mathbf{K}_i \mathbf{m}_i, \gamma_i \mathbf{K}_i)$ such that

$$\begin{aligned}
\mathbf{m}_i &= (\mathbf{U}_{ss} - \mathbf{A}_i \mathbf{U}_{ns}) \mathbf{M}_{sp_{\prec}(i)} + (\mathbf{U}_{sn} - \mathbf{A}_i \mathbf{U}_{nn}) \mathbf{M}_{nsp_{\prec}(i)}, \\
\mathbf{K}_i^{-1} &= \mathbf{U}_{ss} - \mathbf{A}_i \mathbf{U}_{ns} - \mathbf{U}_{sn} \mathbf{A}_i^{\mathsf{T}} + \mathbf{A}_i \mathbf{U}_{nn} \mathbf{A}_i^{\mathsf{T}}, \\
\mathbf{A}_i &= \Sigma_{sp_{\prec}(i), nsp_{\prec}(i)} \Sigma^{-1}_{nsp_{\prec}(i), nsp_{\prec}(i)}
\end{aligned} \tag{13}$$

where

$$\begin{bmatrix} \mathbf{U}_{ss} & \mathbf{U}_{sn} \\ \mathbf{U}_{ns} & \mathbf{U}_{nn} \end{bmatrix} \equiv \begin{bmatrix} \mathbf{U}_{sp_{\prec}(i), sp_{\prec}(i)} & \mathbf{U}_{sp_{\prec}(i), nsp_{\prec}(i)} \\ \mathbf{U}_{nsp_{\prec}(i), sp_{\prec}(i)} & \mathbf{U}_{nsp_{\prec}(i), nsp_{\prec}(i)} \end{bmatrix}. \tag{14}$$

The density $p_g(\gamma_i | \Phi_{i-1})$ is the density of an inverse gamma $IG(g_1, g_2)$ such that

$$\begin{aligned}
g_1 &= \frac{\delta + i - 1 + \#nsp_{\prec}(i)}{2}, \\
g_2 &= \frac{u_{ii.\{i-1\},\{i-1\}} + \mathcal{U}_i}{2}, \\
\mathcal{U}_i &= \mathbf{M}_i^{\mathsf{T}} \mathbf{U}_{\{i-1\},\{i-1\}} \mathbf{M}_i - \mathbf{m}_i^{\mathsf{T}} \mathbf{K}_i \mathbf{m}_i.
\end{aligned}$$

where $u_{ii.\{i-1\},\{i-1\}}$ was originally defined in Section 3.2.1.

Finally,

$$\begin{aligned}
f_i(\Phi_{i-1}) \equiv\ & (2\pi)^{-\frac{(i-1)-\#sp_{\prec}(i)}{2}} |\mathbf{K}_i|^{1/2} |\mathbf{U}_{\{i-1\},\{i-1\}}|^{1/2} \\
\times\ & \frac{(u_{ii.\{i-1\},\{i-1\}}/2)^{(\delta+i-1)/2}}{\Gamma((\delta+i-1)/2)} \frac{\Gamma((\delta+i-1+\#nsp_{\prec}(i))/2)}{((u_{ii.\{i-1\},\{i-1\}} + \mathcal{U}_i)/2)^{(\delta+i-1+\#nsp_{\prec}(i))/2}}.
\end{aligned}$$

6. A simpler decomposition was employed by Silva and Ghahramani (2006) (notice however that paper used an incorrect expression for the Jacobian). The following derivation, however, can be adapted with almost no modification to define a Gibbs sampling algorithm, as we show in the sequel.

Density function $p_b(\mathcal{B}_{i,sp_{\prec}(i)}|\cdot,\cdot)$ and determinant $|\mathbf{K}_i|^{1/2}$ are defined to be 1 if $sp_{\prec}(i) = \emptyset$. $\mathcal{U}_i$ is defined to be zero if $nsp_{\prec}(i) = \emptyset$, and $\mathcal{U}_i = \mathbf{M}_i^{\mathsf{T}}\mathbf{U}_{\{i-1\},\{i-1\}}\mathbf{M}_i$ if $sp_{\prec}(i) = \emptyset$.

The original normalizing constant integral is the expected value of a function of $\Phi_{\mathcal{G}}$ over a factorized inverse gamma-normal distribution. The density function of this distribution is given below:

$$p_{I(\delta,\mathbf{U})}(\Phi_{\mathcal{G}}) = \left(\prod_{i=1}^{m} p_g(\gamma_i|\Phi_{i-1})\right)\left(\prod_{i=2}^{m} p_b(\mathcal{B}_{i,sp_{\prec}(i)}|\gamma_i,\Phi_{i-1})\right).$$

We summarize the main result of this section through the following theorem:

Theorem 3 *Let $\langle f(\mathbf{X})\rangle_{p(\mathbf{X})}$ be the expected value of $f(\mathbf{X})$ where $\mathbf{X}$ is a random vector with density $p(\mathbf{X})$. The normalizing constant of a $\mathcal{G}$-Inverse Wishart with parameters $(\delta,\mathbf{U})$ is given by*

$$I_{\mathcal{G}}(\delta,\mathbf{U}) = I_{IW}(\delta,\mathbf{U}) \times \left\langle \prod_{i=1}^{m} \frac{f_i(\Phi_{i-1})}{|\Sigma_{nsp_{\prec}(i),nsp_{\prec}(i)}|} \right\rangle_{p_{I(\delta,\mathbf{U})}(\Phi_{\mathcal{G}})}.$$

This can be further simplified to

$$I_{\mathcal{G}}(\delta,\mathbf{U}) = \left\langle \prod_{i=1}^{m} \frac{f'_i(\Phi_{i-1})}{|\Sigma_{nsp_{\prec}(i),nsp_{\prec}(i)}|} \right\rangle_{p_{I(\delta,\mathbf{U})}(\Phi_{\mathcal{G}})} \tag{15}$$

where

$$f'_i(\Phi_{i-1}) \equiv (2\pi)^{\frac{\#sp_{\prec}(i)}{2}} |\mathbf{K}_i(\Phi_{i-1})|^{1/2} \frac{\Gamma((\delta+i-1+\#nsp_{\prec}(i))/2)}{((u_{ii.\{i-1\},\{i-1\}}+\mathcal{U}_i)/2)^{(\delta+i-1+\#nsp_{\prec}(i))/2}}$$

which, as expected, reduces $I_{\mathcal{G}}(\delta,\mathbf{U})$ to $I_{IW}(\delta,\mathbf{U})$ when the graph is complete.

A Monte Carlo estimate of $I_{\mathcal{G}}(\delta,\mathbf{U})$ is then given from (15) by obtaining samples $\{\Phi_{\mathcal{G}}^{(1)},\Phi_{\mathcal{G}}^{(2)},\ldots,\Phi_{\mathcal{G}}^{(M)}\}$ according to $p_{I(\delta,\mathbf{U})}(\cdot)$ and computing:

$$I_{\mathcal{G}}(\delta,\mathbf{U}) \approx \frac{1}{M}\sum_{s=1}^{M}\prod_{i=1}^{m} \frac{f'_i(\Phi_{i-1}^{(s)})}{|\Sigma_{nsp_{\prec}(i),nsp_{\prec}(i)}(\Phi_{i-1}^{(s)})|}$$

where here we emphasize that $\Sigma_{nsp_{\prec}(i),nsp_{\prec}(i)}$ is a function of $\Phi_{\mathcal{G}}$ as given by (6).

3.3 General Monte Carlo Computation

If $\mathbf{Y}$ follows a Gaussian $N(0,\Sigma)$ where Σ is given a $\mathcal{G}$-$IW(\delta,\mathbf{U})$ prior, then from a sample $\mathcal{D} = \{\mathbf{Y}^{(1)},\ldots,\mathbf{Y}^{(n)}\}$ with sufficient statistic $\mathbf{S} = \sum_{d=1}^{n}(\mathbf{Y}^{(d)})(\mathbf{Y}^{(d)})^{\mathsf{T}}$, the posterior distribution for Σ given $\mathbf{S}$ will be a $\mathcal{G}$-$IW(\delta+n,\mathbf{U}+\mathbf{S})$. In order to obtain samples from the posterior or to compute its functionals, one can adapt the algorithm for computing normalizing constants. We describe an importance sampler for computing functionals, followed by a Gibbs sampling algorithm that also provides samples from the posterior.

```
Algorithm SAMPLEGIW-1
Input: a $m \times m$ matrix $\mathbf{U}$, scalar $\delta$, bi-directed graph $\mathcal{G}$, an ordering $\prec$

 1. Let $\Sigma$ be a $m \times m$ matrix
 2. Define functions $sp_{\prec}(\cdot), nsp_{\prec}(\cdot)$ according to $\mathcal{G}$ and ordering $\prec$
 3. Sample $\sigma_{11}$ from $IG(\delta/2, u_{11}/2)$
 4. For $i = 2, 3, \dots, m$
 5.     Sample $\gamma_i \sim IG((\delta + i - 1 + \#nsp_{\prec}(i))/2, (u_{ii.\{i-1\},\{i-1\}} + \mathcal{U}_i)/2)$
 6.     Sample $\mathcal{B}_{i,sp_{\prec}(i)} \sim N(\mathbf{K}_i\mathbf{m}_i, \gamma_i\mathbf{K}_i)$
 7.     Set $\mathcal{B}_{i,nsp_{\prec}(i)} = -\mathcal{B}_{i,sp_{\prec}(i)}\Sigma_{sp_{\prec}(i),nsp_{\prec}(i)}\Sigma^{-1}_{nsp_{\prec}(i),nsp_{\prec}(i)}$
 8.     Set $\Sigma^{\mathsf{T}}_{\{i-1\},i} = \Sigma_{i,\{i-1\}} = \mathcal{B}_i\Sigma_{\{i-1\},\{i-1\}}$
 9.     Set $\sigma_{ii} = \gamma_i + \mathcal{B}_i\Sigma_{i,\{i-1\}}$
10. Set $w = \prod_{i=1}^{m} f_i'(\Phi_{i-1})/|\Sigma_{nsp_{\prec}(i),nsp_{\prec}(i)}|$
11. Return $(w, \Sigma)$.
```

Figure 4: A procedure for generating an importance sample Σ and importance weight w for computing functionals of a $\mathcal{G}$-Inverse Wishart distribution. Variables $\{\mathbf{M}_i, \mathbf{m}_i, \mathbf{K}_i, \mathcal{U}_i\}$ and function $f_i'(\Phi_{i-1})$ are defined in Section 3.2.2.

3.3.1 THE IMPORTANCE SAMPLER

One way of computing functionals of the $\mathcal{G}$-IW distribution, that is, functions of the type

$$g(\delta, \mathbf{U}; \mathcal{G}) \equiv \int_{M^+(\mathcal{G})} g(\Sigma)p(\Sigma \mid \delta, \mathbf{U}, \mathcal{G})\, d\Sigma$$

is through the numerical average

$$g(\delta, \mathbf{U}; \mathcal{G}) \approx \frac{\sum_{s=1}^{M} w_s g(\Sigma^{(s)})}{\sum_{s=1}^{M} w_s},$$

where weights $\{w_1, w_2, \dots, w_M\}$ and samples $\{\Sigma^{(1)}, \Sigma^{(2)}, \dots, \Sigma^{(M)}\}$ are generated by an importance sampler. The procedure for computing normalizing constants can be readily adapted for this task using $p_{I(\delta,\mathbf{U})}(\cdot)$ as the importance distribution and the corresponding weights from the remainder factors. The sampling algorithm is shown in Figure 4.

3.3.2 THE GIBBS SAMPLER

While the importance sampler can be useful to compute functionals of the distribution, we will need a Markov chain Monte Carlo procedure to sample from the posterior. In the Gibbs sampling

```
Algorithm SAMPLEGIW-2
Input: a $m \times m$ matrix $\mathbf{U}$, scalar $\delta$, bi-directed graph $\mathcal{G}$, a $m \times m$ matrix $\Sigma^{start}$

 1. Let $\Sigma$ be a copy of $\Sigma^{start}$
 2. Define functions $sp(\cdot), nsp(\cdot)$ according to $\mathcal{G}$
 3. For $i = 1, 2, 3, \dots, m$
 4.     Sample $\gamma_i \sim IG((\delta + (m-1) + \#nsp(i))/2, (u_{ii.\{\backslash i\},\{\backslash i\}} + \mathcal{U}_{\backslash i})/2)$
 5.     Sample $\mathcal{B}_{i,sp(i)}$ from a $N(\mathbf{K}_{\backslash i}\mathbf{m}_{\backslash i}, \gamma_i \mathbf{K}_{\backslash i})$
 6.     Set $\mathcal{B}_{i,nsp(i)} = -\mathcal{B}_{i,sp(i)}\Sigma_{sp(i),nsp(i)}\Sigma^{-1}_{nsp(i),nsp(i)}$
 7.     Set $\Sigma^{\mathsf{T}}_{\{\backslash i\},i} = \Sigma_{i,\{\backslash i\}} = \mathcal{B}_i \Sigma_{\{\backslash i\},\{\backslash i\}}$
 8.     Set $\sigma_{ii} = \gamma_i + \mathcal{B}_i \Sigma_{i,\{\backslash i\}}$
 9. Return $\Sigma$.
```

Figure 5: A procedure for generating a sampled Σ within a Gibbs sampling procedure.

procedure, we sample the whole i-th row of Σ, for each $1 \leq i \leq m$, by conditioning on the remaining independent entries of the covariance matrix as obtained on the previous Markov chain iteration.

The conditional densities required by the Gibbs sampler can be derived from (12), which for a particular ordering $\prec$ implies

$$p(\Sigma; \delta, \mathbf{U}, \mathcal{G}) \propto p_g(\gamma_1) \prod_{i=2}^{m} p_b(\mathcal{B}_{i,sp_{\prec}(i)} | \gamma_i, \Phi_{i-1}) p_g(\gamma_i | \Phi_{i-1}) f_i(\Phi_{i-1}).$$

By an abuse of notation, we used Σ in the left-hand side and the Bartlett parameters in the righ-hand side.

The conditional density of $\{\mathcal{B}_{m,sp_{\prec}(m)}, \gamma_m\}$ given all other parameters is therefore

$$p(\mathcal{B}_{m,sp_{\prec}(m)}, \gamma_m | \Phi_{\mathcal{G}} \backslash \{\mathcal{B}_{m,sp_{\prec}(m)}, \gamma_m\}) = p_b(\mathcal{B}_{m,sp_{\prec}(m)} | \gamma_m, \Phi_{m-1}) p_g(\gamma_m | \Phi_{m-1})$$

from which we can reconstruct a new sample of the m-th row/column of Σ after sampling $\{\mathcal{B}_{m,sp_{\prec}(m)}, \gamma_m\}$. Sampling other rows can be done by redefining a new order where the corresponding target variable is the last one.

More precisely: let $\{\backslash i\}$ denote the set $\{1, 2, \dots, i-1, i+1, \dots, m\}$. The Gibbs algorithm is analogous to the previous algorithms. Instead of $sp_{\prec}(i)$ and $nsp_{\prec}(i)$, we refer to the original $sp(i)$ and $nsp(i)$. Matrices $\Sigma_{\{\backslash i\},\{\backslash i\}}$ and $\mathbf{U}_{\{\backslash i\},\{\backslash i\}}$ are defined by deleting the respective i-th row and i-th columns. Row vector $\Sigma_{i,\{\backslash i\}}$ and scalar $u_{ii.\{\backslash i\}}$ are defined accordingly, as well as any other vector and matrix originally required in the marginal likelihood/importance sampling procedure. The algorithm is described in Figure 5. The procedure can be interpreted as calling a modification of the importance sampler with a dynamic ordering $\prec_i$ which, at every step, moves Y_i to the end of the global ordering $\prec$.

3.4 Remarks

The importance sampler suffers from the usual shortcomings in high-dimensional problems, where a few very large weights dominate the procedure (MacKay, 1998). This can result in unstable estimates of functionals of the posterior and the normalizing constant.

The stability of the importance sampler is not a simple function of the number of variables in the domain. For large but sparse graphs, the number of parameters might be small. For large but fairly dense graphs, the importance distribution might be a good match to the actual distribution since there are few constraints. In Section 7, we performe some experiments to evaluate the sampler.

When used to compute functionals, the Gibbs sampler is more computationally demanding considering the cost per step, but we expect it to be more robust in high-dimensional problems. In problems that require repeated calculations of functionals (such as the variational optimization procedure of Section 4.3), it might be interesting to run a few preliminary comparisons between the estimates of the two samplers, and choose the (cheaper) importance sampler if the estimates are reasonably close.

Naïvely, the Gibbs sampler costs $O(m^4)$ per iteration, since for each step we have to invert the matrix $\Sigma_{nsp\{\backslash i\},nsp\{\backslash i\}}$, which is of size $O(m)$ for sparse graphs. However, this inversion can cost much less than $O(m^3)$ if sparse matrix inversion methods are used. Still, the importance sampler can be even more optimized by using the methods of Section 6.

4. Gaussian Directed Mixed Graph Models

As discussed in Section 2, Gaussian directed mixed graph models are parameterized by the set with parameters $\Theta = \{\mathbf{V}, \mathbf{B}, \alpha\}$. Our prior takes the form $p(\Theta) = p(\mathbf{B})p(\alpha)p(\mathbf{V})$. We assign priors for the parameters of directed edges (non-zero entries of matrix $\mathbf{B}$) in a standard way: each parameter b_{ij} is given a Gaussian $N(c^B_{ij}, s^B_{ij})$ prior, where all parameters are marginally independent in the prior, that is, $p(\mathbf{B}) = \prod_{ij} p(b_{ij})$. The prior for intercept parameters α is analogous, with α_i being a Gaussian $N(c^\alpha_i, s^\alpha_i)$.

Recall from Equation (1) that the implied covariance of the model is given by the matrix $\Sigma(\Theta) = (\mathbf{I}-\mathbf{B})^{-1}\mathbf{V}(\mathbf{I}-\mathbf{B})^{-\mathsf{T}}$. Similarly, we have the implied mean vector $\mu(\Theta) \equiv (\mathbf{I}-\mathbf{B})^{-1}\alpha$. The likelihood function for data set $\mathcal{D} = \{\mathbf{Y}^{(1)}, \mathbf{Y}^{(2)}, \dots, \mathbf{Y}^{(n)}\}$ is defined as

$$\begin{aligned}\mathcal{L}(\Theta;\mathcal{D}) &= |\Sigma(\Theta)|^{-n/2}\textstyle\prod_{d=1}^n \exp\left(-\frac{1}{2}(\mathbf{Y}^{(d)}-\mu(\Theta))^{\mathsf{T}}\Sigma(\Theta)^{-1}(\mathbf{Y}^{(d)}-\mu(\Theta))\right)\\ &= \left\{|(\mathbf{I}-\mathbf{B})^{-1}||\mathbf{V}||(\mathbf{I}-\mathbf{B})^{-\mathsf{T}}|\right\}^{-n/2}\left\{\exp\left(-\frac{1}{2}tr(\mathbf{V}^{-1}(\mathbf{I}-\mathbf{B})\mathbf{S}(\mathbf{I}-\mathbf{B})^{\mathsf{T}})\right)\right\},\end{aligned}$$

where now $\mathbf{S} \equiv \sum_{d=1}^n (\mathbf{Y}^{(d)}-\mu(\Theta))(\mathbf{Y}^{(d)}-\mu(\Theta))^{\mathsf{T}}$.

Given a prior $\mathcal{G}$-$IW(\delta, \mathbf{U})$ for $\mathbf{V}$, it immediately follows that the posterior distribution of $\mathbf{V}$ given the data and other parameters is

$$\mathbf{V} \mid \{\mathbf{B}, \alpha, \mathcal{D}\} \sim \mathcal{G}\text{-}IW(\delta+n, \mathbf{U}+(\mathbf{I}-\mathbf{B})\mathbf{S}(\mathbf{I}-\mathbf{B})^{\mathsf{T}}).$$

Therefore it can be sampled using the results from the previous section. Notice this holds even if the directed mixed graph $\mathcal{G}$ is cyclic.

Sampling α_i given $\{\mathcal{D}, \Theta\backslash\{\alpha_i\}\}$ can also be done easily for both cyclic and acyclic models: the posterior is given by a normal $N(c^{\alpha'}_i/s^{\alpha'}_i, 1/s^{\alpha'}_i)$ where

$$\begin{aligned} s_i^{\alpha'} &\equiv \frac{1}{s_i^{\alpha}} + n(\mathbf{V}^{-1})_{ii}, \\ c_i^{\alpha'} &\equiv \frac{c_i^{\alpha}}{s_i^{\alpha}} - n\sum_{t=1,t\neq i}^{m}(\mathbf{V}^{-1})_{it}\alpha_t + \sum_{d=1}^{n}\sum_{t=1}^{m}(\mathbf{V}^{-1})_{it}\left(Y_t^{(d)} - \sum_{p_t} b_{tp_t}Y_{p_t}^{(d)}\right), \end{aligned}$$

with p_t being an index running over the parents of Y_t in $\mathcal{G}$.

However, sampling the non-zero entries of $\mathbf{B}$ results in two different cases depending whether $\mathcal{G}$ is cyclic or not. We deal with them separately.

4.1 Sampling from the Posterior: Acyclic Case

The acyclic case is simplified by the fact that $\mathbf{I}-\mathbf{B}$ can be rearranged in a way it becomes lower triangular, with each diagonal element being 1. This implies the identity $|(\mathbf{I}-\mathbf{B})^{-1}||\mathbf{V}||(\mathbf{I}-\mathbf{B})^{-\mathsf{T}}| = |\mathbf{V}|$, with the resulting log-likelihood being a quadratic function of the non-zero elements of $\mathbf{B}$. Since the prior for coefficient b_{ij} is Gaussian, its posterior given the data and all other parameters will be the Gaussian $N(c_{ij}^{b'}/s_{ij}^{b'}, 1/s_{ij}^{b'})$ where

$$\begin{aligned} s_{ij}^{b'} &\equiv \frac{1}{s_{ij}^{b}} + (\mathbf{V}^{-1})_{ii}\sum_{d=1}^{n}(Y_j^{(d)})^2, \\ c_{ij}^{b'} &\equiv \frac{c_{ij}^{b}}{s_{ij}^{b}} + \sum_{d=1}^{n}Y_j^{(d)}\sum_{t=1}^{m}(\mathbf{V}^{-1})_{it}\left(Y_t^{(d)} - \sum_{p_t,(t,p_t)\neq(i,j)} b_{tp_t}Y_{p_t}^{(d)} - \alpha_t\right). \end{aligned} \tag{16}$$

As before, p_t runs over the indices of the parents of Y_t in $\mathcal{G}$. Notice that in the innermost summation we exclude $b_{ij}Y_j^{(d)}$. We can then sample b_{ij} accordingly.

It is important to notice that, in practice, better mixing behavior can be obtained by sampling the coefficients (and intercepts) jointly. The joint distribution is Gaussian and can be obtained in a way similar to the above derivation. The derivation of the componentwise conditionals is nevertheless useful in the algorithm for cyclic networks.

4.2 Sampling from the Posterior: Cyclic Case

Cyclic directed graph models have an interpretation in terms of causal systems in equilibrium. The simultaneous presence of directed paths $Y_i \rightarrow \cdots \rightarrow Y_j$ and $Y_j \rightarrow \cdots \rightarrow Y_i$ can be used to parameterize instantaneous causal effects in a feedback loop (Spirtes, 1995). This model appears also in the structural equation modeling literature (Bollen, 1989). In terms of cyclic graphs as families of conditional independence constraints, methods for reading off constraints in linear systems also exist (Spirtes et al., 2000).

The computational difficulty in the cyclic case is that the determinant $|\mathbf{I}-\mathbf{B}|$ is no longer a constant, but a multilinear function of coefficients $\{b_{ij}\}$. Because b_{ij} will appear outside the exponential term, its posterior will no longer be Gaussian.

From the definition of the implied covariance matrix $\Sigma(\Theta)$, it follows that $|\Sigma(\Theta)|^{-n/2} = (|\mathbf{I}-\mathbf{B}||\mathbf{V}|^{-1}|\mathbf{I}-\mathbf{B}|)^{n/2}$. As a function of coefficient b_{ij},

$$|\mathbf{I}-\mathbf{B}| = (-1)^{i+j+1}C_{ij}b_{ij} + \sum_{k=1,k\neq j}^{k=m}(-1)^{i+k+1}C_{ik}b_{ik},$$

where C_{ij} is the determinant of respective co-factor of $\mathbf{I}-\mathbf{B}$, $b_{ik} \equiv 0$ if there is no edge $Y_i \leftarrow Y_k$, and $b_{ii} \equiv -1$. The resulting density function of b_{ij} given $\mathcal{D}$ and $\Theta\backslash\{b_{ij}\}$ is

$$p(b_{ij}|\Theta\backslash\{b_{ij}\}, \mathcal{D}) \propto |b_{ij} - \kappa_{ij}|^n \exp\left\{-\frac{(b_{ij} - c_{ij}^{b'}/s_{ij}^{b'})^2}{2s_{ij}^{b'}}\right\},$$

where

$$\kappa_{ij} \equiv C_{ij}^{-1} \sum_{k=1, k\neq j}^{k=m} (-1)^{k-j+1} C_{ik} b_{ik}$$

and $\{c_{ij}^{b'}, s_{ij}^{b'}\}$ are defined as in Equation (16). Standard algorithms such as Metropolis-Hastings can be applied to sample from this posterior within a Gibbs procedure.

4.3 Marginal Likelihood: A Variational Monte Carlo Approach

While model selection of bi-directed graphs can be performed using a simple Monte Carlo procedure as seen in the previous Section, the same is not true in the full Gaussian DMG case. Approaches such as nested sampling (Skilling, 2006) can in principle be adapted to deal with the full case. For problems where there are many possible candidates to be evaluated, such a computationally demanding sampling procedure might be undesirable (at least for an initial ranking of graphical structures). As an alternative, we describe an approximation procedure for the marginal likelihood $p(\mathcal{D}|\mathcal{G})$ by combining variational bounds (Jordan et al., 1998) with the $\mathcal{G}$-Inverse Wishart samplers, and therefore avoiding a Markov chain over the joint model of coefficients and error covariances. This is described for acyclic DMGs only.

We adopt the following approximation in our variational approach, accounting also for possible latent variables $\mathbf{X}$:

$$p(\mathbf{V}, \mathbf{B}, \alpha, \mathbf{X}|\mathcal{D}) \approx q(\mathbf{V})q(\mathbf{B}, \alpha) \prod_{d=1}^{n} q(\mathbf{X}^{(d)}) \equiv q(\mathbf{V})q(\mathbf{B}, \alpha)q(\mathbf{X})$$

with $q(\mathbf{B}, \alpha)$ being a multivariate Gaussian density of the non-zero elements of $\mathbf{B}$ and α. Function $q(\mathbf{X}^{(d)})$ is also a Gaussian density, and function $q(\mathbf{V})$ is a $\mathcal{G}$-Inverse Wishart density.

From Jensen's inequality, we obtain the following lower-bound (Beal, 2003, p. 47):

$$\begin{array}{rcl} \ln p(\mathcal{D}|\mathcal{G}) & = & \ln \int p(\mathbf{Y}, \mathbf{X}|\mathbf{V}, \mathbf{B}, \alpha)p(\mathbf{V}, \mathbf{B}, \alpha)\, d\mathbf{X}\, d\mathbf{B}\, d\mathbf{V}\, d\alpha \\ & \geq & \langle \ln p(\mathbf{Y}, \mathbf{X}|\mathbf{V}, \mathbf{B}, \alpha)\rangle_{q(\mathbf{V})q(\mathbf{B},\alpha)q(\mathbf{X})} \\ & & + \langle \ln p(\mathbf{V})/q(\mathbf{V})\rangle_{q(\mathbf{V})} \\ & & + \langle \ln p(\mathbf{B}, \alpha)/q(\mathbf{B}, \alpha)\rangle_{q(\mathbf{B},\alpha)} - \langle \ln q(\mathbf{X})\rangle_{q(\mathbf{X})} \end{array} \quad (17)$$

where this lower bound can be optimized with respect to functions $q(\mathbf{V})$, $q(\mathbf{B})$, $q(\mathbf{X})$. This can be done by iterative coordinate ascent, maximizing the bound with respect to a single $q(\cdot)$ function at a time.

The update of $q(\mathbf{V})$ is given by

$$q^{new}(\mathbf{V}) = p_{\mathcal{G}\text{-}IW}(\delta + d, \mathbf{U} + \left\langle (\mathbf{I}-\mathbf{B})\mathbf{S}(\mathbf{I}-\mathbf{B})^{\mathsf{T}} \right\rangle_{q(\mathbf{X})q(\mathbf{B},\alpha)})$$

where $p_{\mathcal{G}\text{-}IW}(\cdot)$ is the density function for a $\mathcal{G}$-Inverse Wishart, and $\mathbf{S}$ is the empirical second moment matrix summed over the completed data set $(\mathbf{X}, \mathbf{Y})$ (hence the expectation over $q(\mathbf{X})$) centered at $\mu(\Theta)$.

The updates for $q(\mathbf{B}, \alpha)$ and $q(\mathbf{X})$ are tedious but straightforward derivations, and described in Appendix B. The relevant fact about these updates is that they are functions of $\langle \mathbf{V}^{-1} \rangle_{q(\mathbf{V})}$. Fortunately, we pay a relatively small cost to obtain these inverses using the Monte Carlo sampler of Figure 4: from the Bartlett parameters, define a lower triangular $m \times m$ matrix $\mathcal{B}$ (by placing on the ith line the row vector $\mathcal{B}_i$, followed by zeroes) and a diagonal matrix Γ from the respective vector of γ_i's. The matrix $\mathbf{V}^{-1}$ can be computed from $(\mathbf{I} - \mathcal{B})^{\mathsf{T}}\Gamma^{-1}(\mathbf{I} - \mathcal{B})$, and the relevant expectation computed according to the importance sampling procedure. For problems of moderate dimensionality,[7] the importance sampler might not be recommended, but the Gibbs sampler can be used.

At the last iteration of the variational maximization, the (importance or posterior) samples from $q(\mathbf{V})$ can then be used to compute the required averages in (17), obtaining a bound on the marginal log-likelihood of the model. Notice that the expectation $\langle \ln p(\mathbf{V})/q(\mathbf{V}) \rangle_{q(\mathbf{V})}$ contains the entropy of $q(\mathbf{V})$, which will require the computation of $\mathcal{G}$-inverse Wishart normalizing constants.

For large problems, the cost of this approximation might still be prohibitive. An option is to partially parameterize $\mathbf{V}$ in terms of ancillary latents and another submatrix distributed as a $\mathcal{G}$-inverse Wishart, but details on how to best do this partition are left as future work (this approximation will be worse but less computationally expensive if ancillary latents are independent of the coefficient parameters in the variational density function $q(\cdot)$). Laplace approximations might be an alternative, which have been successfully applied to undirected non-decomposable models (Roverato, 2002).

We emphasize that the results present in this section are alternatives that did not exist before in previous approaches for learning mixed graph structures through variational methods (e.g., Silva and Scheines, 2006). It is true that the variational approximation for marginal likelihoods will tend to underfit the data, that is, generate models simpler than the true model in simulations. Despite the bias introduced by the method, this is less of a problem for large data sets (Beal and Ghahramani, 2006) and the method has been shown to be useful in model selection applications (Silva and Scheines, 2006), being consistently better than standard scores such as BIC when hidden variables are present (Beal and Ghahramani, 2006). An application in prediction using the variational posterior instead of MCMC samples is discussed by Silva and Ghahramani (2006). It is relevant to explore other approaches for marginal likelihood evaluation of DMG models using alternative methods such as annealed importance sampling (Neal, 2001) and nested sampling (Skilling, 2006), but it is unrealistic to expect that such methods can be used to evaluate a large number of candidate models. A pre-selection by approximations such as variational methods might be essential.

5. Discrete Models: The Probit Case

Constructing a discrete mixed graph parameterization is not as easy as in the Gaussian case. Advances in this area are described by Drton and Richardson (2008a), where a complete parameterization of binary bi-directed graph models is given. In our Bayesian context, inference with the mixed graph discrete models of Drton and Richardson would not to be any computationally easier than the case for Markov random fields, which has been labeled as *doubly-intractable* (Murray et al., 2006).

7. We observed a high ratio of the highest importance weight divided by the median weight in problems with dimensionality as low as 15 nodes. However, notice that in practice the error covariance matrix $\mathbf{V}$ has a block diagonal structure, and only the size of the largest block is relevant. This is explained in more detail in Section 6.

Instead, in this paper we will focus on a class of discrete models that has been widely used in practice: the probit model (Bartholomew and Knott, 1999). This model is essentially a projection of a Gaussian distribution into a discrete space. It also allows us to build on the machinery developed in the previous sections. We will describe the parameterization of the model for acyclic DMGs, and then proceed to describe algorithms for sampling from the posterior distribution.

5.1 Parameterizing Models of Observable Independencies

A probit model for the conditional probability of discrete variable Y_i given a set of variables $\{Y_{i1}, \ldots, Y_{ik}\}$ can be described by the two following relationships:

$$\begin{array}{rcl} Y_i^\star & = & \alpha_i + b_{i1}Y_{i1} + b_{i2}Y_{i2} + \cdots + b_{ik}Y_{ik} + \varepsilon_i \\ \mathcal{P}(Y_i = v_l^i \mid Y_i^\star) & = & 1(\tau_{l-1}^i \leq Y_i^\star < \tau_l^i) \end{array} \tag{18}$$

where $\mathcal{P}(\cdot)$ is the probability mass function of a given random variable, as given by the context, and $1(\cdot)$ is the indicator function. Y_i assumes values in $\{v_1^i, v_1^i, \ldots, v_{\kappa(i)}^i\}$. Thresholds $\{\tau_0^i = -\infty < \tau_1^i < \tau_2^i < \cdots < \tau_{\kappa(i)}^i = \infty\}$ are used to define the mapping from continuous $Y_i^\star$ to discrete Y_i. This model has a sensible interpretation for ordinal and binary values as the discretization of some *underlying latent variable* (UV) $Y_i^\star$. Such a UV is a conditionally Gaussian random variable, which follows by assuming normality of the error term ε_i. This formulation, however, is not appropriate for general discrete variables, which are out of the scope of this paper. Albert and Chib (1993) describe alternative Bayesian treatments of discrete distributions not discussed here.

Given this binary/ordinal regression formulation, the natural step is how to define a graphical model accordingly. As a matter of fact, the common practice does not strictly follow the probit regression model. Consider the following example: for a given graph $\mathcal{G}$, a respective graphical representation of a probit model can be built by first replicating $\mathcal{G}$ as a graph $\mathcal{G}^\star$, where each vertex Y_i is relabeled as $Y_i^\star$. Those vertices represent continuous underlying latent variables (UVs). To each vertex $Y_i^\star$ in $\mathcal{G}^\star$, we then add a single child Y_i. We call this the *Type-I UV model*. Although there are arguments for this approach (see, for instance, the arguments by Webb and Forster (2006) concerning stability to ordinal encoding), this is a violation of the original modeling assumption as embodied by $\mathcal{G}$: if the given graph is a statement of conditional independence constraints, it is expected that such independencies will be present in the actual model. The Type-I formulation does not fulfill this basic premise: by construction there are no conditional independence constraints among the set of variables $\mathbf{Y}$ (the marginal independencies are preserved, though). This is illustrated by Figure 6(b), where the conditional independence of Y_1 and Y_3 given Y_2 disappears.

An alternative is illustrated in Figure 6(c). Starting from the original graph $\mathcal{G}$ (as in Figure 6(a)), the probit graph model $\mathcal{G}^\star$ shown in the Figure is built from $\mathcal{G}$ by the following algorithm:

1. add to empty graph $\mathcal{G}^\star$ the vertices $\mathbf{Y}$ of $\mathcal{G}$, and for each $Y_i \in \mathbf{Y}$, add a respective UV $Y_i^\star$ and the edge $Y_i^\star \rightarrow Y_i$;

2. for each $Y_i \rightarrow Y_j$ in $\mathcal{G}$, add edge $Y_i \rightarrow Y_j^\star$ to $\mathcal{G}^\star$;

3. for each $Y_i \leftrightarrow Y_j$ in $\mathcal{G}$, add edge $Y_i^\star \leftrightarrow Y_j^\star$ to $\mathcal{G}^\star$;

We call this the *Type-II UV model*, which has the following property (the proof is in Appendix C):

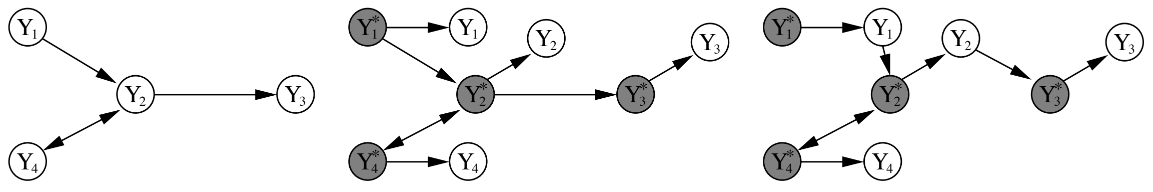

Figure 6: The model in (a) has at least two main representations as a probit network. In (b), the original structure is given to the underlying variables, with observed variables being children of their respective latents. In (c), the underlying variable inherits the parents of the original variable and the underlying latents of the spouses.

Theorem 4 *Suppose $\mathcal{G}$ is acyclic with vertex set* $\mathbf{Y}$. *Y_i and Y_j are m-separated given $\mathbf{Z} \subseteq \mathbf{Y}\backslash\{Y_i, Y_j\}$ in $\mathcal{G}$ if and only if Y_i and Y_j are m-separated given $\mathbf{Z}$ in $\mathcal{G}^\star$.*

The parameterization of the Type-II UV model follows from the definition of probit regression: the conditional distribution Y_i given its parents in $\{Y_{i1}, ..., Y_{ik}\}$ in $\mathcal{G}$ is given as in Equation (18), while the error terms $\{\varepsilon_1, \varepsilon_2, \dots, \varepsilon_m\}$ follow the multivariate Gaussian $N(0, \mathbf{V})$. The entry corresponding to the covariance of ε_i and ε_j is assumed to be zero if there is no bi-directed edge $Y_i \leftrightarrow Y_j$ in $\mathcal{G}$.

In what follows, we discuss algorithms for Type-II models. The approach here described can be easily adapted to cover Type-I models. We say that Type-II models are models of *observable independencies*, since independencies hold even after marginalizing all UVs.

5.2 Algorithm

As before, we provide a Gibbs sampling scheme to sample parameters $\Theta = \{\alpha, \mathbf{B}, \mathbf{V}, \mathcal{T}\}$ from the posterior distribution given data set $\mathcal{D} = \{\mathbf{Y}^{(1)}, \mathbf{Y}^{(2)}, \dots, \mathbf{Y}^{(n)}\}$. The set $\mathcal{T} = \{\mathcal{T}_i\}$ is the set of threshold parameters, $\mathcal{T}_i = \{\tau^i_0 = -\infty < \tau^i_1 < \tau^i_2 < \cdots < \tau^i_{\kappa(i)} = \infty\}$ for each random variable Y_i with $\kappa(i)$ different values. We will not discuss priors and algorithms for sampling $\mathcal{T}$ given the other parameters: this can be done by standard approaches (e.g., Albert and Chib, 1993).[8]

For the purposes of the Gibbs procedure, we augment the data set with the underlying variables $\mathcal{D}^\star = \{\mathbf{Y}^{\star(1)}, \mathbf{Y}^{\star(2)}, \dots, \mathbf{Y}^{\star(n)}\}$ at each sampling step.

From the set of structural equations

$$\mathbf{Y}^{\star(d)} = \alpha + \mathbf{B}\mathbf{Y}^{(d)} + \varepsilon$$

it follows that the conditional distribution of $\mathbf{Y}^{\star(d)}$ given the $\mathcal{D} \cup \Theta$ is a truncated Gaussian with mean $\alpha + \mathbf{B}\mathbf{Y}^{(d)}$ and covariance matrix $\mathbf{V}$. The truncation levels are given by the thresholds and observed data $\mathbf{Y}^{(d)}$: for each $Y^{(d)}_i = v^i_l$, the range for $Y^{\star(d)}_i$ becomes $[\tau^i_{l-1}, \tau^i_l)$. Sampling from a truncated Gaussian is a standard procedure. We used the algorithm of Kotecha and Djuric (1999) in our implementation.

To sample $\mathbf{V}$ from its conditional, we will rely on the following result.

8. In Section 7, we perform experiments with binary data only. In this case, the thresholds are set to fixed values: $\{\tau^i_0 = -\infty, \tau^i_1 = 0, \tau^i_2 = \infty\}$ for all $0 \leq i \leq m$.

Proposition 5 *Let $\mathcal{G}$ be an acyclic DMG, and $(\alpha, \mathbf{B}, \mathbf{V}, \mathcal{T})$ be the respective set of parameters that defines the probit model. For a fixed $(\alpha, \mathbf{B}, \mathcal{T})$, there is a bijective function $f_{\mathbf{B}\alpha\mathcal{T}}(\cdot)$ mapping $\mathbf{Y}^\star$ to ε. This is not true in general if $\mathcal{G}$ is cyclic.*

Proof: If the graph is acyclic, this follows directly by recursively solving the model equations, starting from those corresponding to $Y_j^\star$ vertices with no parents. This results in $\varepsilon = \mathbf{Y}^\star - \alpha - \mathbf{B}\mathbf{Y}$, as expected.

For cyclic graphs, the following model provides a counter-example. Let the graph be $Y_1^\star \rightarrow Y_1 \rightarrow Y_2^\star \rightarrow Y_2 \rightarrow Y_1^\star$. Let the model be $Y_1^\star = Y_2 + \varepsilon_1, Y_2^\star = Y_1 + \varepsilon_2$, that is, $b_{12} = b_{21} = 1$ and $\alpha = 0$. Let the variables be binary, with a threshold at zero ($Y_i = 1$ if and only if $Y_i^\star \geq 0$). Then the two instantiations $(Y_1^\star = -0.8, Y_2^\star = 0)$, $(Y_1^\star = 0.2, Y_2^\star = 1)$ imply the same pair $(\varepsilon_1 = -0.8, \varepsilon_2 = 0)$. $\square$

The negative result for discrete models with cycles is the reason why such models are out of the scope of the paper.

Let $\mathcal{D}_\varepsilon^\star = \{\varepsilon^{(1)}, \dots, \varepsilon^{(n)}\}$, where $\varepsilon^{(d)} = f_{\mathbf{B}\alpha\mathcal{T}}(\mathbf{y}^{(d)\star})$. Due to this bijection (and the determinism mapping $\mathbf{Y}^\star$ to $\mathbf{Y}$), the density $p(\mathbf{V} \mid \Theta\backslash\mathbf{V}, \mathcal{D}, \mathcal{D}^\star) = p(\mathbf{V} \mid \Theta\backslash\mathbf{V}, \mathcal{D}^\star) = p(\mathbf{V} \mid \Theta\backslash\mathbf{V}, \mathbf{y}^{(1)\star}, \dots, \mathbf{y}^{(d)\star})$ is equivalent to

$$\begin{aligned} p(\mathbf{V} \mid \Theta\backslash\mathbf{V}, \mathcal{D}^\star) &= p(\mathbf{V} \mid \alpha, \mathbf{B}, \mathcal{T}, \mathcal{D}^\star, \mathcal{D}_\varepsilon^\star) \\ &= p(\mathbf{V} \mid \alpha, \mathbf{B}, \mathcal{T}, \mathcal{D}_\varepsilon^\star) \\ &\propto p(\mathbf{V} \mid \alpha, \mathbf{B}, \mathcal{T}) p(\mathcal{D}_\varepsilon^\star \mid \alpha, \mathbf{B}, \mathcal{T}, \mathbf{V}) \\ &\propto p(\mathbf{V}) \textstyle\prod_{d=1}^n p(\varepsilon^{(d)} \mid \mathbf{V}). \end{aligned}$$

For the given data set $\mathcal{D} \cup \mathcal{D}^\star$, define $\mathbf{S}^\star$ as the sum of $(\mathbf{Y}^{\star(d)} - \alpha - \mathbf{B}\mathbf{Y}^{(d)})(\mathbf{Y}^{\star(d)} - \alpha - \mathbf{B}\mathbf{Y}^{(d)})^\mathsf{T}$ over all $d \in \{1, 2, \dots, n\}$. Since $p(\varepsilon \mid \mathbf{V})$ is normal with zero mean and covariance matrix $\mathbf{V}$, the posterior for $\mathbf{V}$ given all other parameters and variables is

$$\mathbf{V} \mid \ \{\Theta\backslash\mathbf{V}, \mathcal{D}, \mathcal{D}^\star\} \sim \mathcal{G}\text{-}IW(\delta + n, \mathbf{U} + \mathbf{S}^\star).$$

Sampling $\mathbf{B}$ and α is analogous to the Gaussian case, except that we have to consider that the left-hand side of the structural equations now refer to $\mathbf{Y}^\star$. We give the explicit conditional for α_i, with the conditional for b_{ij} being similarly adapted from Section 4. The posterior for α_i is given by a normal $N((s_i')^{-1} m_i', s_i')$ where

$$\begin{aligned} s_i^{\alpha'} &= \frac{1}{s_i^\alpha} + n(\mathbf{V}^{-1})_{ii}, \\ c_i^{\alpha'} &= \frac{c_i^\alpha}{s_i^\alpha} - n \sum_{t=1, t\neq i}^m (\mathbf{V}^{-1})_{it} \alpha_t + \sum_{d=1}^n \sum_{t=1}^m (\mathbf{V}^{-1})_{it} \left(Y_t^{\star(d)} - \sum_{p_t} b_{tp_t} Y_{p_t}^{(d)} \right). \end{aligned}$$

5.3 A Note on Identifiability

The scale of the underlying latent variables in the probit model is arbitrary. As such, it has been often suggested that such latents should have constant (e.g., unity) variance (Pitt et al., 2006). There are two usual arguments for fixing the variance: improving the interpretability of the model, and improving the mixing of the Markov chain. The interpretability argument is not particularly appealing within the Bayesian setting with proper priors, such as the one proposed in this paper: the posterior distribution of the parameters is well-defined by the prior uncertainty and the data.

The goal of improving the mixing of the chain might be important: if some parameters can assume arbitrary values and still allow for the same model over the observables, then fixing such parameters may help sampling by eliminating largely flat regions from the posterior (which will happen for large data sets and broad priors). In practice, however, scaling UVs might not be advantageous. In some cases it might increase the computational cost of each sampling step, while sampling from the non-scaled model might work just fine. Many MCMC algorithms work well on highly unidentifiable models such as multilayer perceptrons (Neal, 1996). In our experiments, we do not use any scaling.

5.4 Remarks

It is clear that the given approach can be generalized to other generalized linear models by changing the link function that maps underlying latent variables (UVs) to observables. For instance, a model containing discrete and continuous variables can be constructed by using the identity link function instead of probit for the continuous variables. Notice that the continuous variables will not necessarily be marginally Gaussian if some of its parents are discrete. Other link functions will have different parameters besides thresholds, such as in multivalued ("polychotomous") discrete distributions. A Bayesian account of Gaussian copula models is given by Pitt et al. (2006), to which a DMG-based family could in principle be defined. For continuous, marginally non-Gaussian, variables joined by a Gaussian copula, it is possible that all link functions are invertible. In this case, it is easier in principle to define cyclic models through Type-I UV models (e.g., Figure 6(b)) while preserving the observable independencies.

It is important to point out that Type-II probit models with Markov equivalent graphs will not, in general, be likelihood equivalent. A simple example is given by the two-node graphs $Y_1 \rightarrow Y_2$ and $Y_1 \leftrightarrow Y_2$: if Y_1 is binary, then the marginal for Y_2 in the first case is equivalent to having an underlying latent variable that follows a mixture of two Gaussians. While some of these issues can be solved by adopting a mixture of Gaussians marginal independence model to account for bi-directed edges (Silva and Ghahramani, 2009), details need to be worked out. When the goal of model selection is to find causal structures (Spirtes et al., 2000), the usual guarantees of search methods based on Markov equivalence classes do not hold. However, it remains to be seen whether the parametric constraints implied by the Type-II formulation will allow for other consistent approaches for causal discovery, as shown in the case of non-linearities with additive noise (Hoyer et al., 2008).

6. Scaling Up: Factorizations and Perfect Sequences

Each Monte Carlo sampling step for the given mixed graph models is theoretically tractable, but not necessarily practical when the dimensionality m of the data is high. By using clever factorizations of the graph and ordering of the variables, it is possible to sometimes scale to high-dimensional problems. In this section, we describe approaches to minimize the run-time of the marginal likelihood computation for bi-directed graphs, which is also important for computing variational bounds for DMG models. We start, however, with a discussion on factorizations of the posterior density for coefficient parameters $\mathbf{B}$. The context is the Gibbs sampler for acyclic models.

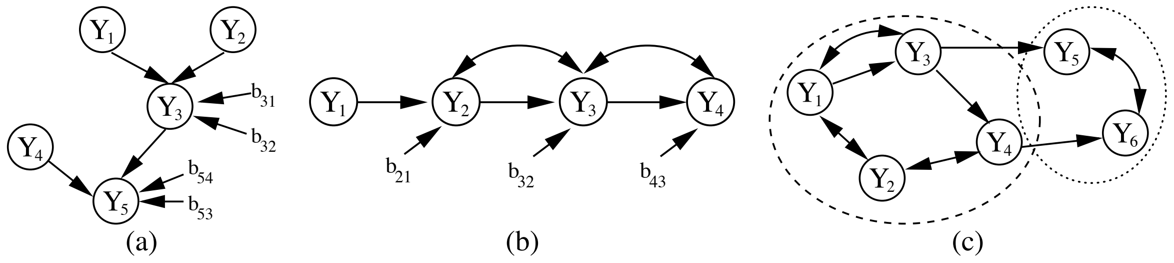

Figure 7: The coefficients b_{31} and b_{32}, represented as nodes in (a), become dependent after conditioning on $\mathbf{Y}$. However, they are still independent of b_{54}. This a general property of DAG models. In DMG models, a sequence of bi-directed edges will connect extra coefficients. In graph (b), coefficients b_{21}, b_{32} and b_{43} will all be dependent given $\mathbf{Y}$. Coefficients into nodes in different districts will still be independent. The graph in (c) has districts $\{Y_1, Y_2, Y_3, Y_4\}$ and $\{Y_5, Y_6\}$.

6.1 Factorizations

Our prior for coefficients $\{b_{ij}\}$ is fully factorized. In directed acyclic graphs, this is particularly advantageous: coefficients corresponding to edges into different nodes are independent in the posterior.[9] One can then jointly sample a whole set of $\{b_{ij}\}$ coefficients with same i index, with no concern for the other coefficients. Figure 7(a) illustrates this factorization. This means that, in Equation (16), the summation over t does not go over all variables, but only for $t = i$. This also follows from the fact that $(\mathbf{V})^{-1}_{it} = 0$ unless $i = t$, since $\mathbf{V}$ is diagonal.

In ADMGs, however, this is not true anymore. For any pair of vertices linked by a path of bi-directed edges, for example, $Y_i \leftrightarrow Y_{i+1} \leftrightarrow \cdots \leftrightarrow Y_t$, one will have in general that $(\mathbf{V})^{-1}_{it} \neq 0$. This can be shown by using the graphical properties of the model when conditioning on some arbitrary datapoint $\mathbf{Y}$:

Proposition 6 *Let $\mathcal{G}$ be an acyclic DMG with vertex set $\mathbf{Y}$, and $\mathcal{G}'$ the DMG obtained by augmenting $\mathcal{G}$ with a vertex for each parameter b_{ij} and a respective edge $b_{ij} \rightarrow Y_i$. Then if there is a bi-directed path $Y_i \leftrightarrow \cdots \leftrightarrow Y_t$ in $\mathcal{G}$, $\{b_{ij}, b_{tv}\}$ are not m-separated given $\mathbf{Y}$ in $\mathcal{G}'$.*

Proof: The joint model for $\{\mathbf{Y}, \mathbf{B}\}$ with independent priors on the non-zero entries of $\mathbf{B}$ is Markov with respect to $\mathcal{G}'$. The sequence of bi-directed edges between Y_i and Y_t implies a path between b_{ij} and b_{tv} where every vertex but the endpoints is a collider in this path. Since every collider is in $\mathbf{Y}$, this path is active. $\Box$

This Proposition is illustrated by Figure 7(b). The practical implication is as follows: m-connection means that there is no further graphical property that would entail $(\mathbf{V})^{-1}_{it} = 0$ (i.e., only particular cancellations on the expression of the inverse, unlikely to happen in practice, would happen to generate such zeroes).

9. Sampling in Gaussian DAG models is still necessary if the model includes latent variables (Dunson et al., 2005).

Consider the maximal sets of vertices in an ADMG such that each pair of elements in this set is connected by a path of bi-directed edges. Following Richardson (2003), we call this a *district*.[10] It follows that is not possible in general to factorize the posterior of $\mathbf{B}$ beyond the set of districts of $\mathcal{G}$. Figure 7(c) illustrates a factorization. Fortunately, for many DMG models with both directed and bi-directed edges found in practical applications (e.g., Bollen, 1989), the maximum district size tends to be considerably smaller than the dimensionality of the problem.

6.2 Perfect Sequences

It is still important to speed up marginal likelihood (or variational bound) computations for models with districts of moderate size, particularly if many models are to be evaluated.

Without loss of generality, assume our graph $\mathcal{G}$ is a bi-directed graph with a single district, since the problem can be trivially separated into the disjoint bi-directed components. We will consider the case where the bi-directed graph is sparse: otherwise there is little to be gained by exploring the graphical structure. In that case, we will assume that the largest number of spouses of any node in $\mathcal{G}$ is bounded by a constant κ that is independent of the total number of nodes, m. The goal is to derive algorithms that are of lower complexity in m than the original algorithms.

The bottleneck of our procedure is the computation of the $\Sigma^{-1}_{nsp_{\prec}(i),nsp_{\prec}(i)}$ matrices, required in the mapping between independent and dependent Bartlett parameters (Equation 7), as well as computing the determinants $|\Sigma_{nsp_{\prec}(i),nsp_{\prec}(i)}|$. Since in sparse districts $nsp_{\prec}(i)$ grows linearly with m, the cost of a naïve algorithm for a single sampling step is $O(m^3)$ per node. Iterating over all nodes implies a cost of $O(m^4)$ for a Monte Carlo sweep. Therefore, our goal is to find a procedure by which such mappings can be computed in less than $O(m^3)$ time. The general framework is reusing previous inverses and determinants instead of performing full matrix inversion and determinant calculation for each Y_i. The difficulty on applying low-rank updates when we traverse the covariance matrix according to $\prec$ is that the sets of non-spouses $nsp_{\prec}(i)$ and $nsp_{\prec}(i+1)$ might differ arbitrarily. We want sensible orderings where such sets vary slowly and allow for efficient low-rank updates, if any.

The foundation of many scaling-up procedures for graphical models is the graph decomposition by clique separators (Tarjan, 1985), usually defined for undirected graphs. The definition for bi-directed graphs is analogous. Such a decomposition identifies overlapping *prime subgraphs* $\{\mathcal{G}_{P(1)}, \mathcal{G}_{P(2)}, \dots, \mathcal{G}_{P(k)}\}$ of the original graph $\mathcal{G}$. A prime graph is a graph that cannot be partitioned into a triple $(\mathbf{Y}', \mathbf{S}, \mathbf{Y}'')$ of non-empty sets such that $\mathbf{S}$ is a complete separator (i.e., $\mathbf{S}$ is a clique and removing $\mathbf{S}$ disconnects the graph). Notice that a clique is also a prime subgraph.

The prime components of a graph can be ordered in a *perfect sequence* $\{\mathbf{Y}_{P(1)}, \dots, \mathbf{Y}_{P(k)}\}$ of subsets of $\mathbf{Y}$ (Roverato, 2002; Lauritzen, 1996). Define $\mathbf{H}_j \equiv \mathbf{Y}_{P(1)} \cup \cdots \cup \mathbf{Y}_{P(j)}$ as the *history* of the perfect sequence up to the j-th subgraph. Let $\mathbf{R}_j \equiv \mathbf{Y}_{P(j)} \backslash \mathbf{H}_{j-1}$ be the *residual* of this history (with $\mathbf{R}_1 \equiv \mathbf{Y}_{P(1)}$), and $\mathbf{S}_j \equiv \mathbf{H}_{j-1} \cap \mathbf{Y}_{P(j)}$ the separator. In a perfect sequence, the triple $(\mathbf{H}_{j-1} \backslash \mathbf{S}_j, \mathbf{S}_j, \mathbf{R}_j)$ forms a decomposition of the subgraph of $\mathcal{G}$ induced by the vertex set $\mathbf{H}_j$.

Surprisingly, although bi-directed and undirected graph models have very different Markov properties (in undirected models, conditioning removes dependencies; in bi-directed models, it adds dependencies), perfect prime graph sequences prove to be also useful, but in an entirely different

10. Kang and Tian (2005) call such structures *c-components* and reserve the word "district" to refer to the function mapping a vertex to its respective c-component, as originally introduced by Richardson (2003). We choose to overload the word and call "district" both the structure and the mapping.

$\mathcal{V}_2 = \{Y_4, Y_5\}$
$\mathcal{V}_3 = \{Y_6\}$

Figure 8: On the left, we have a bi-directed graph of 7 vertices arranged and ordered such that nodes are numbered by a depth-first numbering starting from "root" Y_7, with $\{Y_1, Y_2, Y_4, Y_6\}$ being leaves. Vertices $\{Y_1, Y_2, \dots, Y_6\}$ can be partitioned as the union $\cup_{t=1}^{3} \mathcal{V}_t$, as illustrated on the right.

way. The next subsection describes the use of prime graph decompositions in a particularly interesting class of bi-directed graphs: the decomposable case. The general case is treated in the sequel.

6.2.1 DECOMPOSABLE MODELS

In a recursively decomposable graph, all prime subgraphs are cliques. We will assume that any perfect sequence in this case contains all and only the (maximal) cliques of the graph. The resulting decomposition can be interpreted as a hypergraph where nodes are the maximal cliques of the original graph, and edges correspond to the separators. In the statistics literature, a decomposable model is defined as a model that is Markov with respect to a recursively decomposable undirected graph (Lauritzen, 1996). Its widespread presence on applications of Markov random fields is due to nice computational properties, with tree-structured distributions being a particular case. Our definition of bi-directed decomposable models is analogous: a model Markov with respect to a recursively decomposable bi-directed graph.

Given the residual sequence $\{\mathbf{R}_1, \mathbf{R}_2, \dots, \mathbf{R}_k\}$ obtained through a perfect sequence of maximal cliques of $\mathcal{G}$, we define a *perfect ordering* $\prec$ by numbering nodes in $\mathbf{R}_t$ before nodes in $\mathbf{R}_1, \dots, \mathbf{R}_{t-1}$, $1 < t \leq k$ and ordering nodes according to this numbering.[11] Any ordering that satisfies this restriction is a perfect ordering. Such an ordering has the following property.

Theorem 7 *Let $\mathcal{G}$ be a recursively decomposable bi-directed graph such that the indexing of its vertices $\mathbf{Y} = \{Y_1, Y_2, \dots, Y_m\}$ follows a perfect ordering $\prec$. Then for each $1 < i \leq m$, the set $\{Y_1, Y_2, \dots, Y_{i-1}\}$ can be partitioned as $\cup_{t=1}^{K(i)} \mathcal{V}_t$ such that:*

1. *each $\mathcal{V}_t$ induces a connected subgraph of $\mathcal{G}$, and for each $Y_t \in \mathcal{V}_t$ and $Y_{t'} \in \mathcal{V}_{t'}$, $t \neq t'$, Y_t is not adjacent to $Y_{t'}$ in $\mathcal{G}$;*

11. Lauritzen (1996) describes other uses of perfect sequences in undirected graphs. Notice that the notion of perfect numbering described by Lauritzen (1996) is not equivalent to our notion of perfect ordering, which is always derived from a perfect sequence of prime graphs.

2. *for each* $\{Y_p, Y_q\} \subseteq \mathcal{V}_t^i$*, if* Y_p *is a spouse of* Y_i*, and* Y_q *is a non-spouse of* Y_i*, then* $p > q$*;*

The proof is in Appendix C. This result is easier to visualize in trees. One can take as a perfect ordering some depth-first ordering for a given choice of root. Then for each vertex Y_i, the set $\{Y_1, Y_2, \dots, Y_{i-1}\}$ is partitioned according to the different branches "rooted" at Y_i. The starting point of each branch is a spouse of Y_i, and all other vertices are non-spouses of Y_i. The ordering result then follows directly from the definition of depth-first traversal, as illustrated in Figure 8.

Let Σ be the covariance matrix of a bi-directed decomposable model with graph $\mathcal{G}$, where Σ follows a $\mathcal{G}$-inverse Wishart distribution. Let $\prec$ be a perfect ordering for $\mathcal{G}$. By the construction of Bartlett's decomposition, mapping between parameters is given by

$$\Sigma_{sp_\prec(i), nsp_\prec(i)} \Sigma^{-1}_{nsp_\prec(i), nsp_\prec(i)},$$

the computational bottleneck being the inversion. Notice this corresponds to the multiple regression coefficients of $sp_\prec(i)$ on $nsp_\prec(i)$. But according to Theorem 7, using a perfect ordering implies that within each $\mathcal{V}_s^i$ for a fixed Y_i, all preceding non-spouses of Y_i are ordered before the preceding spouses. Elements $\{Y_p, Y_q\}$ in different $\mathcal{V}_s^i$ are marginally independent given $\{Y_1, \dots, Y_{i-1}\} \backslash \{Y_p, Y_q\}$. This implies that the regression coefficient of spouse Y_p on non-spouse Y_q will be zero if Y_p and Y_q are on different components $\mathcal{V}_s^i$, and will be identical to the previously computed $\mathcal{B}_{p,q}$ if they are in the same component. Splitting the set $\{Y_1, Y_2, \dots Y_{i-1}\}$ into preceding spouses $\mathbf{Y}_{sp_\prec(i)}$ and non-spouses $\mathbf{Y}_{nsp_\prec(i)}$, we have

$$\begin{aligned}
\mathbf{Y}_{sp_\prec(i)} &= \mathcal{B}_{sp_\prec(i), sp_\prec(i)} \mathbf{Y}_{sp_\prec(i)} + \mathcal{B}_{sp_\prec(i), nsp_\prec(i)} \mathbf{Y}_{nsp_\prec(i)} + \varepsilon_{sp_\prec(i)} \Rightarrow \\
\mathbf{Y}_{sp_\prec(i)} &= (\mathbf{I} - \mathcal{B}_{sp_\prec(i), sp_\prec(i)})^{-1} (\mathcal{B}_{sp_\prec(i), nsp_\prec(i)} \mathbf{Y}_{nsp_\prec(i)} + \varepsilon_{sp_\prec(i)})
\end{aligned}$$

where each ε_j is an independent Gaussian with variance γ_j, and each element (p, q) in $\mathcal{B}_{sp_\prec(i), nsp_\prec(i)}$ corresponds to the known (i.e., previously computed) regression coefficient of the spouse Y_p on the non-spouse Y_q. Matrix $\mathcal{B}_{sp_\prec(i), sp_\prec(i)}$ is defined analogously. Hence, the regression coefficients of $\mathbf{Y}_{sp_\prec(i)}$ on $\mathbf{Y}_{nsp_\prec(i)}$ are given by

$$\Sigma_{sp_\prec(i), nsp_\prec(i)} \Sigma^{-1}_{nsp_\prec(i), nsp_\prec(i)} = (\mathbf{I} - \mathcal{B}_{sp_\prec(i), sp_\prec(i)})^{-1} \mathcal{B}_{sp_\prec(i), nsp_\prec(i)}. \tag{19}$$

No inversion of $\Sigma_{nsp_\prec(i), nsp_\prec(i)}$ is ever necessary. Moreover, the determinant $|\Sigma_{nsp_\prec(i), nsp_\prec(i)}|$ is given by $\prod_{\{q \text{ s.t. } Y_q \in nsp_\prec(i)\}} \gamma_q$, since all non-spouses precede the spouses (which means their marginal covariance matrix is given by the previously computed Bartlett parameters).

Hence, calculating $\mathcal{B}_{i, nsp_\prec(i)}$ for all $1 \leq i \leq m$ according to a perfect ordering has as a bottleneck the inversion (of a triangular matrix) and multiplication in Equation (19), with a cost of $O(\kappa^2 + m\kappa^2)$, κ being the maximum number of spouses for any given node. The cost of the remaining operations for the i-th stage in the importance sampler is $O(\kappa^3)$. As a function of m, the cost of the parameter sampling step falls from $O(m^3)$ to $O(m)$. The cost of computing the weights is dominated by the computation of $\mathbf{K}_i$ from Equation (13), which is $O(\kappa^3 + \kappa m^2) = O(m^2)$. Figure 9 illustrates the derivation of the new ordering in a tree-structured model.

6.2.2 NON-DECOMPOSABLE MODELS

In a non-decomposable model, some prime graphs $\mathbf{Y}_{P(t)}$ will no longer be cliques. In what follows, we once again assume that $\prec$ is a perfect ordering. Unlike in the decomposable case, the product

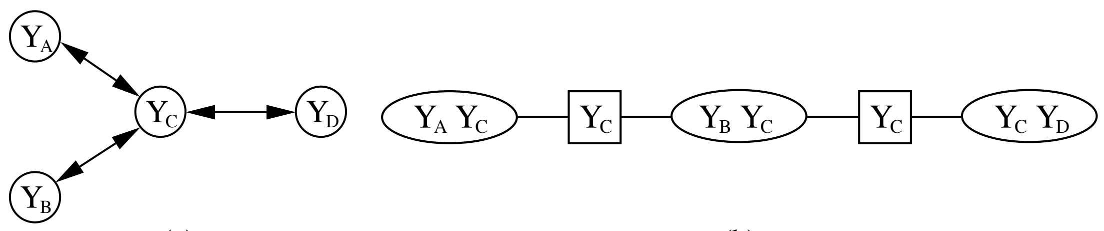

Figure 9: The tree-structured (i.e., cycle-free) bi-directed graph in (a) has as maximal cliques the adjacent pairs. Such cliques can be ordered in a perfect sequence as shown in (b), where rectangles indicate the separators. Notice that $\mathbf{R}_1 = \{Y_A, Y_C\}, \mathbf{R}_2 = \{Y_B\}, \mathbf{R}_3 = \{Y_D\}$. One possible perfect ordering is $\{Y_D, Y_B, Y_C, Y_A\}$.

$\Sigma_{sp_{\prec}(i),nsp_{\prec}(i)}\Sigma^{-1}_{nsp_{\prec}(i),nsp_{\prec}(i)}$ does not simplify in general. Instead we will focus only on fast methods to compute $\Sigma^{-1}_{nsp_{\prec}(i),nsp_{\prec}(i)}$.

As we shall see, the function of the perfect sequence is now to provide a sensible choice of which inverse submatrices $\{\Sigma^{-1}_{\mathbf{W},\mathbf{W}}\}$, $\mathbf{W} \subseteq \mathbf{Y}$, to cache and reuse when computing $\Sigma^{-1}_{nsp_{\prec}(i),nsp_{\prec}(i)}$. The same can be done to compute determinants $|\Sigma_{nsp_{\prec}(i),nsp_{\prec}(i)}|$.

A simple way of reusing the results from the previous section is by triangulating the non-decomposable graph $\mathcal{G}$, transforming it into a decomposable one, $\mathcal{G}'$, which is then used to generate the perfect sequence. We need to distinguish between the "true" spouses of a node Y_i in $\mathcal{G}$ and the artificial spouses in $\mathcal{G}'$ that result from the extra edges added.

Let $nsp_{\prec\mathcal{G}'}(i)$ be the non-spouses of Y_i in $\mathcal{G}'$ that precede it according to $\prec$: by construction, these are also non-spouses of Y_i in $\mathcal{G}$. Let $sp_{\Delta\prec\mathcal{G}'}(i)$ be the spouses of Y_i in $\mathcal{G}'$ that are *not* spouses of Y_i in $\mathcal{G}$. That is, the set of preceding non-spouses of Y_i in $\mathcal{G}$ is given by $nsp_{\prec}(i) = nsp_{\prec\mathcal{G}'}(i) \cup sp_{\Delta\prec\mathcal{G}'}(i)$.

Recall that the inverse of a partitioned matrix can be given by the following identity:

$$\begin{pmatrix} \mathbf{A} & \mathbf{B} \\ \mathbf{C} & \mathbf{D} \end{pmatrix}^{-1} = \begin{pmatrix} \mathbf{A}^{-1} + \mathbf{A}^{-1}\mathbf{B}(\mathbf{D} - \mathbf{C}\mathbf{A}^{-1}\mathbf{B})^{-1}\mathbf{C}\mathbf{A}^{-1} & -\mathbf{A}^{-1}\mathbf{B}(\mathbf{D} - \mathbf{C}\mathbf{A}^{-1}\mathbf{B})^{-1} \\ -(\mathbf{D} - \mathbf{C}\mathbf{A}^{-1}\mathbf{B})^{-1}\mathbf{C}\mathbf{A}^{-1} & (\mathbf{D} - \mathbf{C}\mathbf{A}^{-1}\mathbf{B})^{-1} \end{pmatrix}. \quad (20)$$

In order to compute $\Sigma^{-1}_{nsp_{\prec}(i),nsp_{\prec}(i)}$, we consider its partitioned version

$$\Sigma^{-1}_{nsp_{\prec}(i),nsp_{\prec}(i)} = \begin{pmatrix} \Sigma_{nsp_{\prec\mathcal{G}'}(i),nsp_{\prec\mathcal{G}'}(i)} & \Sigma_{nsp_{\prec\mathcal{G}'}(i),sp_{\Delta\prec\mathcal{G}'}(i)} \\ \Sigma_{sp_{\Delta\prec\mathcal{G}'}(i),nsp_{\prec\mathcal{G}'}(i)} & \Sigma_{sp_{\Delta\prec\mathcal{G}'}(i),sp_{\Delta\prec\mathcal{G}'}(i)} \end{pmatrix}^{-1}. \quad (21)$$

Let κ_{nsp} be the maximum number of non-spouses among all Y_i within any prime subgraph induced by $\mathbf{Y}_{P(t)}$. By using relation (20), where we assume for now that we know $\mathbf{A}^{-1} \equiv \Sigma^{-1}_{nsp_{\prec\mathcal{G}'}(i),nsp_{\prec\mathcal{G}'}(i)}$, the cost of computing (21) is $O(m^2\kappa_{nsp}) + O(\kappa^3_{nsp}) = O(m^2\kappa_{nsp})$ (the cost of computing $\mathbf{D} - \mathbf{C}\mathbf{A}^{-1}\mathbf{B}$ is $O(m^2\kappa_{nsp}) + O(\kappa^2_{nsp}) = O(m^2\kappa_{nsp})$, while the cost of inverting it is $O(\kappa^3_{nsp})$). Treating κ_{nsp} as a constant, this reduces the complexity of sampling the i-th row of Σ from $O(m^3)$ to $O(m^2)$. A similar procedure applies to the computation of the determinant $|\Sigma_{nsp_{\prec}(i),nsp_{\prec}(i)}|$, using in this case the relationship (26).

The advantage of using the perfect sequence is to allow for the computation of all $\mathbf{A}^{-1} \equiv \Sigma^{-1}_{nsp_{\prec \mathcal{G}'}(i), nsp_{\prec \mathcal{G}'}(i)}$ at a total cost, across all nodes, of $O(m^3)$: each set $nsp_{\prec \mathcal{G}'}(i)$ is guaranteed to be equal to $\{Y_1, Y_2, \dots, Y_{lns}\}$ where Y_{lns} is the last non-spouse of Y_i in $\mathcal{G}'$ that antecedes Y_i. This follows from the result in the previous section, since all non-spouses of a node in a decomposable graph precede its spouses. Therefore, if we store the inverse covariance matrices for $\{Y_1, Y_2, \dots, Y_i\}$, $1 \leq i \leq m$, we can obtain the required matrices $\mathbf{A}^{-1}$. This requires the storage of $O(m)$ matrices, and each matrix can be obtained by the previous one by a low-rank update (20) with a $O(m^2)$ cost.

Arbitrary orderings do not guarantee such an incremental pattern and, hence, no efficient low-rank updates. Notice that depending on the problem, many of such inverse matrices can be dynamically removed from memory if they are not used by any node placed after a particular position.

6.3 Remarks

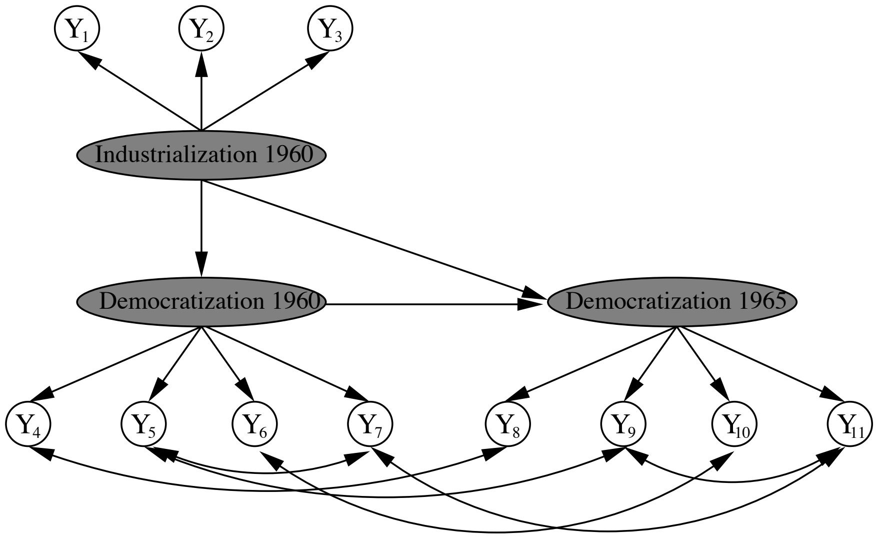
In Gaussian undirected models, the problem of covariance matrix sampling can also be reduced to sampling within each prime graph at the cost of $O(|\mathcal{P}|^4)$, $|\mathcal{P}|$ being the size of the largest prime component (Atay-Kayis and Massam, 2005). Since both κ and κ_{nsp} are $O(|\mathcal{P}|)$, our procedure costs $O(m^2|\mathcal{P}|^2 + |\mathcal{P}|^4)$ per prime graph, plus a cost of $O(m^2)$ per node to compute the importance weights. Considering a number of $m/|\mathcal{P}|$ prime graphs and $|\mathcal{P}| < m$, the total cost is $O(m^3|\mathcal{P}|)$, down from $O(m^4)$. For undirected models, the corresponding cost by sampling step using the perfect ordering decomposition is $O(m|\mathcal{P}|^3)$. The higher-order dependency on m in bi-directed models is to be expected, since the Markov blanket of any node Y_t in a connected bi-directed graph is $\mathbf{V}\backslash\{Y_t\}$. It is clear that inference with a given bi-directed graph model will never scale at the same rate of a undirected model with the same adjacencies, but this does not justify adopting an undirected representation if it is ill-suited to the problem at hand. One has also to consider that in problems with directed and bi-directed edges, the actual maximum district size might be much smaller than the number of variables. For large problems, however, further approximation schemes will be necessary. Drton and Richardson (2008b) describe some reduction techniques for transforming bi-directed edges into directed edges such that the resulting Gaussian model remains the same. As future work, such methods could be adapted to the $\mathcal{G}$-inverse Wishart sampling procedures and combined with the ordering techniques developed here into a single framework. It will also be interesting to develop similar schemes for the Gibbs sampler.

7. Experiments

We now evaluate the advantages of the Gaussian and probit models in Bayesian inference on real problems.

7.1 Industrialization and Democratization Study

Bollen (1989) describes a structural equation model of political and democratization factors within nations. “Democratization” and “industrialization” levels are abstract notions, but nevertheless of clearly observable impact. They are tied to empirical observations through different sets of *indicators*. For instance, an indicator of industrialization level is the gross national product. Hence, democratization and industrialization levels are here defined as scalar latent variables never observed directly, while the observed data is composed of indicators. In this model, there is a total of three indicators of industrialization, and four indicators of democratization. Democratization is



1. Gross national product (GNP) 1960
2. Energy consumption per capita 1960
3. Percentage of labor force in industry 1960
4. Freedom of press 1960
5. Freedom of opposition 1960
6. Fairness of elections 1960
7. Elective nature of legislative body 1960
8. Freedom of press 1965
9. Freedom of opposition 1965
10. Fairness of elections 1965
11. Elective nature of legislative body 1965

Figure 10: A directed mixed graph representing dependencies between 11 observed political and economical indicators and three latent concepts (shaded nodes) (Dunson et al., 2005; Bollen, 1989).

measured in a longitudinal study, where data was collected in two years (1960 and 1965). The indicators of democratization are pooled expert opinions summarized in an ordinal number scaled from 1 to 10. Following Bollen, we will treat the model as multivariate Gaussian, which provides an excellent fit (a p-value greater than 0.3 using a chi-square test) for a sample of 75 countries.

The corresponding mixed graph is depicted in Figure 10, along with a description of all indicators. The graph is taken from Bollen (1989). Other hidden common causes affect the democratization indicators over time, but the nature of such hidden variables is irrelevant to the problem at hand: that is, the bi-directed edges are motivated by unmeasured causes of variability in the observed indicators that exist over time. For instance, the records of freedom of press in 1960 (Y_4) and 1965 (Y_8) co-vary due to other unmeasured factors not accounted by democratization factors.

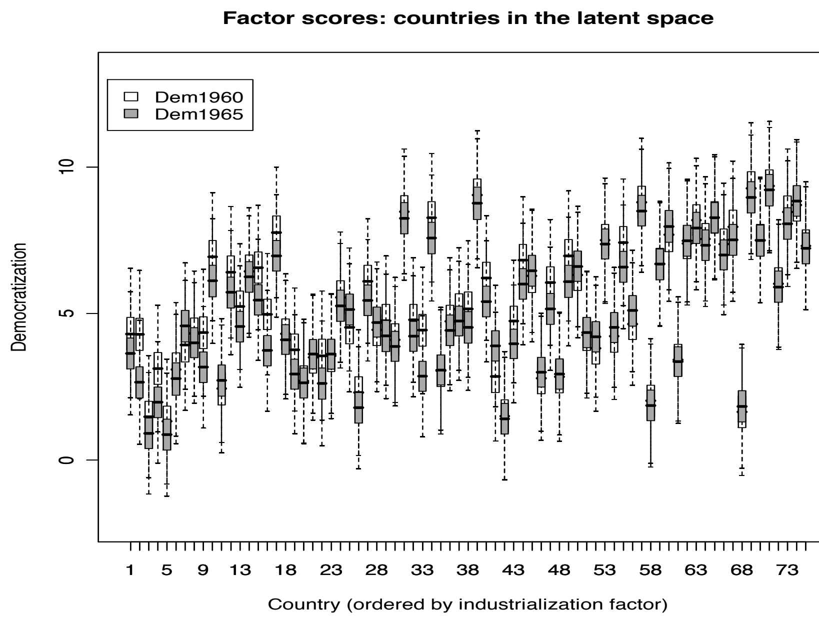


Figure 11: An embedding of 75 countries in a two-dimensional latent space: democratization level in 1960 and 1965. Boxplots of the Bayesian posterior distribution of the projection in the two dimensions are depicted in the vertical axis. Countries are arranged in the horizontal axis by the increasing order of their posterior expected industrialization level. Figure adapted from Dunson et al. (2005).

An example of Bayesian inference application is shown in Figure 11. Boxplots of the posterior values of *Democratization Level 1960* and *Democratization Level 1965* are generated. Dunson et al. (2005) use this information to, for instance, find clusters of countries in the latent space. An example of a cluster is the one formed by the bottom 16 countries in the industrialization level ranking: the growing trend of democratization levels after the first 16 countries is interrupted. This type of analysis might provide new insights to a polical scientist, for example, by revealing particular characteristics for such a group of nations.

7.1.1 EVALUATING THE MCMC ALGORITHM FOR DIFFERENT MODELS

In our analysis, we fix to unity the coefficients corresponding to the edges *Industrialization 1960* $\rightarrow Y_1$, *Democratization 1960* $\rightarrow Y_4$ and *Democratization 1965* $\rightarrow Y_8$, since the scale and sign of the latent variables is arbitrary. The intercept terms of the equations for Y_1, Y_4 and Y_8 are set to zero, since the mean of the latents is also arbitrary. The resulting model is identifiable.

We apply the Gibbs sampling procedure to three different models. The Gaussian DMG model as described in this paper, and two modified DAG models. The first DAG model is the one described by Dunson et al. (2005), where each bi-directed edge is substituted by an “ancillary” latent (as mentioned in Section 2.3). For instance, the pathway corresponding to $Y_4 \leftrightarrow Y_8$ is substituted by the chain $Y_4 \leftarrow D_{48} \rightarrow Y_8$, where D_{48} is unobserved. Dunson et al. further assume that all covariances due to such ancillary latents are positive. As such, the coefficients from D_{ij} into $\{Y_i, Y_j\}$ are set

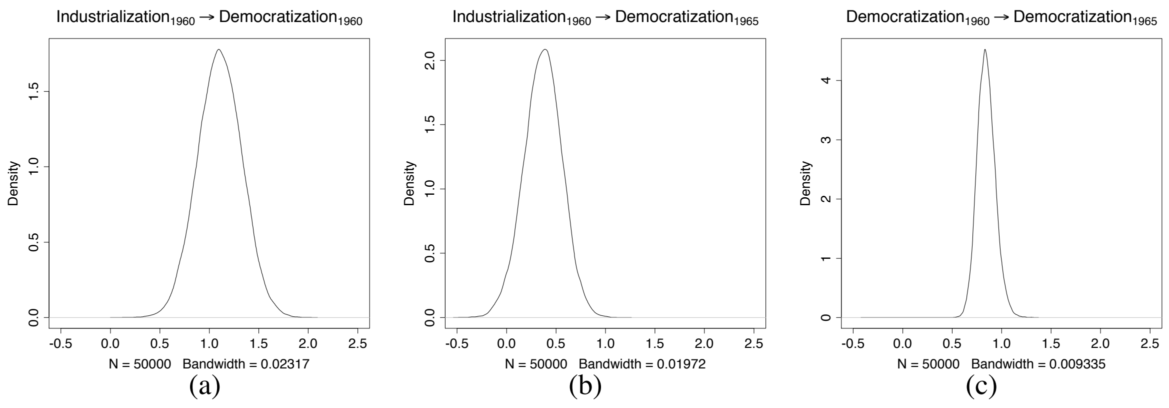

Figure 12: Posterior distribution of parameters associated with the respective edges in the industrialization/democratization domain. Smoothed posterior obtained using the output of our Gibbs sampler and the DENSITY function of R 2.6.0.

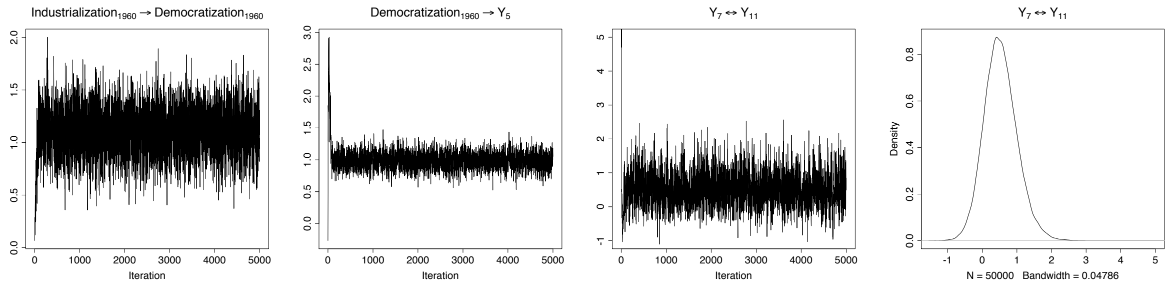

Figure 13: The first three plots show the initial 5,000 iterations of a run of the Gibbs sampling algorithm for the DMG model for three different parameters associated with edges in the graph. The last plot depicts the posterior distribution the error covariance associated with the edge $Y_7 \leftrightarrow Y_{11}$ (smoothed with the kernel density estimator from the statistical software R).

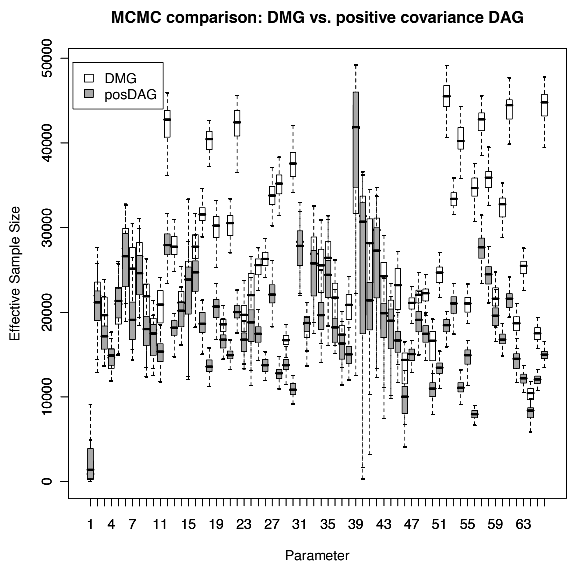
to unity, with the variance of D_{ij} corresponding to the residual covariance of $\{Y_i, Y_j\}$ given their parents. Means of ancillary latents are fixed at zero.

However, even for covariance matrices with positive covariances, this parameterization is not complete. This result is evident from the fact that the variances of Y_i and Y_j will both be larger than their covariance, which is not true of covariance matrices in general. For this particular problem, however, this extra restriction provides no measurable difference in terms of fitness. It does serve as a reminder, however, that "intuitive" parameterizations might hide undesirable constraints.

The second DAG model is an extension of the DAG model suggested by Dunson et al., the only difference being that the coefficients corresponding to edges $D_{ij} \rightarrow Y_i, i < j$, are free to vary (instead of being fixed to 1). In general, there are Gaussian DMG models that cannot be parameterized this way (Richardson and Spirtes, 2002). Notice also that because of chains such as *Democratization 1960* $\rightarrow Y_4 \leftrightarrow Y_8 \leftarrow$ *Democratization 1965*, the set of independence constraints in this graph can only be represented by a DAG if we include the ancillary latents D_{ij}. That is, there is no DAG with



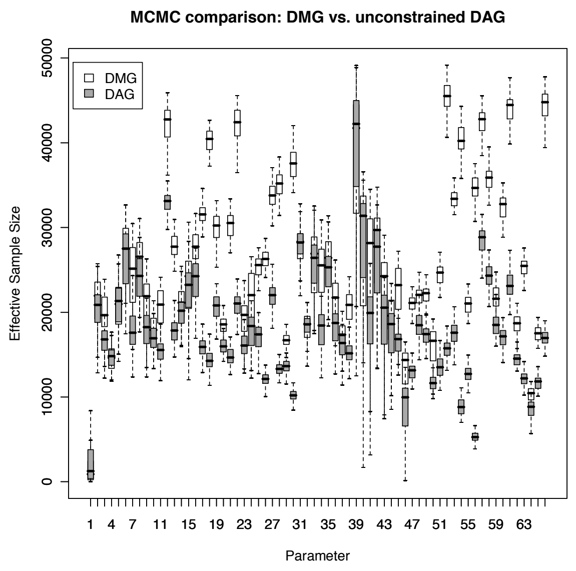


Figure 14: Comparison of the effective sample size of the MCMC algorithm applied to the three models, DMG, DAG with positive covariances (posDAG) and general DAG, as explained in the main text. The horizontal axis is the boxplot for each independent entry of the observed covariance matrix, 66 in total. The boxplots are obtained from 80 independent chains initialized randomly, where each chain runs for 50,000 iterations.

exactly the same set of independence constraints as the given DMG, unless ancillary latent variables are added.

We study the behavior of the MCMC algorithm for these three models.[12] It turns out that the mixing properties of the chain are considerably affected by the choice of model. Recall that, in the Gibbs sampling algorithm for the DMG model, a whole row of the error covariance matrix is sampled jointly conditioning on the other parameters. For the DAG models all entries of the error covariance matrix are independent and can be sampled jointly, but this requires *conditioning* on the ancillary latents, which do not exist in the DMG model and have to be sampled only in the DAG case.

For the majority of the covariance entries, the MCMC procedure mixed quite well, as illustrated in Figure 13. Notice how about 12% of the sampled DMG error covariances for $Y_7 \leftrightarrow Y_{11}$ were under zero, which could raise suspicion over the assumption of positive covariances. Autocorrelation is

12. A few technical notes: we used the priors suggested in Dunson et al. (2005), except that we changed the confidence in the prior of the covariance of the error terms $\mathbf{V}$ to be smaller (in order to minimize the influence of the priors in the models, since in this particular problem the DMG and DAG models are nearly likelihood equivalent but not posterior distribution equivalent – the priors belong to different families). We used 1 degree of freedom in our $\mathcal{G}$-Inverse Wishart, with the matrix parameter being the expected value of Dunson et al.'s prior. For the DAG models, we also used the $\mathcal{G}$-inverse Wishart prior for the error terms, but where all error terms are independent. For the DAG model with a free coefficient per ancillary latent, we assigned a standard Gaussian prior to such coefficients. The chains were initialized randomly by sampling standard Gaussians for the coefficients and latent variables. Error covariance matrices were initialized to diagonal matrices with diagonal entries sampled uniformly in $[1,2]$. Coefficient parameters were sampled jointly given the error covariance matrix and latent variables. Latent variables were also sampled jointly, given the parameters.

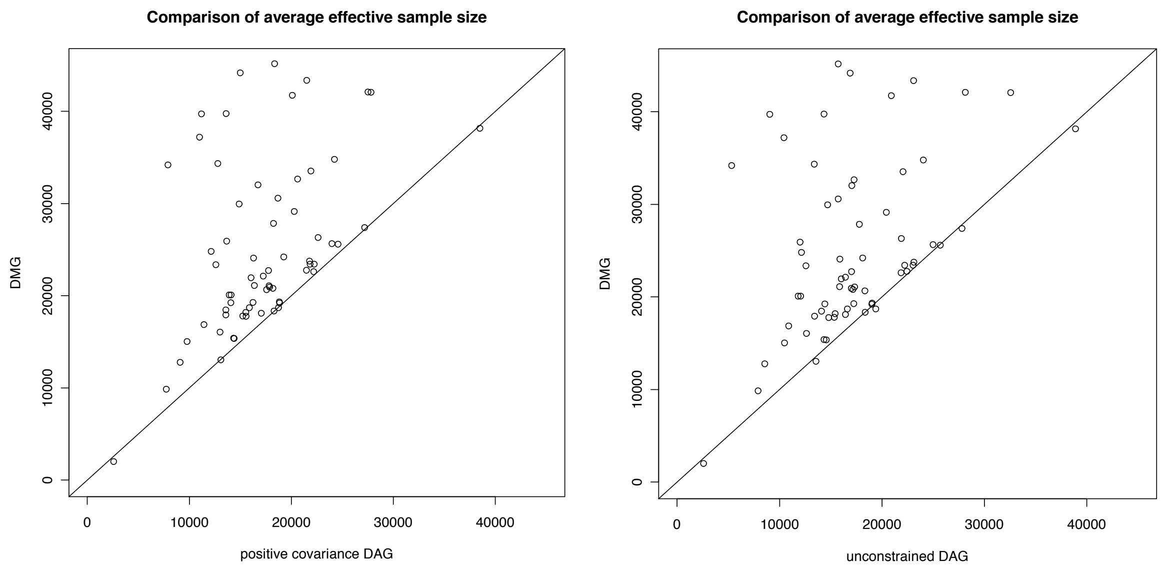

Figure 15: Comparison of the effective sample size of the MCMC algorithm applied to the three models. Here we plot the average effective sample sizes over 80 trials of 50,000 samples for each of the 66 entries of the covariance matrix. Points over the line indicate parameters where the DMG approach performed better.

essentially zero for most parameters at a lag of 50. The degree of autocorrelation, however, varied significantly between the DMG model and each DAG model. The chains for the DMG model mixed considerably better. To summarize such behavior, we calculated the effective sample size of the samples obtained from several chains. The parameters of interest in this comparison are the independent entries in the 11×11 dimensional observed covariance matrix. This is a total of 66 parameters. The effective sample size statistics were obtained by 80 independent chains of 50,000 samples each, for the three models. For each chain and each parameter, we compute the desired statistic using the EFFECTIVESIZE function implemented in the R package CODA, freely available in the Internet.

Results are summarized by boxplots in Figure 14. Parameters are ordered in the x-axis following the upper triangular covariance matrix, scanning it in the order $\{\sigma_{Y_1Y_1}, \sigma_{Y_1Y_2}, \dots, \sigma_{Y_1Y_{11}}, \sigma_{Y_2Y_2}, \dots, \sigma_{Y_{11}Y_{11}}\}$. White boxplots correspond to the distribution of effective sample size statistics with the DMG model across the 80 independent chains. Gray boxplots correspond to the two DAG variants. There is no significant difference between the behaviour of the Gibbs sampling procedure for the two DAG models. The procedure with the DMG model is clearly better behaved. As a summary statistic, the average effective sample size over 80 trials was steadly larger in the DMG outcome than in the positive DAG outcome (61 out of 66 parameters) and unconstrained DAG (59 out of 66). The comparison of averages is illustrated by Figure 15.

By caching the sufficient statistics of the data and factorizing the sampling procedure according to the districts of the graph, the running time for generating 50,000 samples out of the DMG model was of 34 seconds in a dual core Pentium IV 2.0 GHz. Depending on the connectivity of the bi-directed components of the graph and on the implementation of matrix inversion, sampling from the

DAG model might be faster than sampling from the DMG. In this particular study, sampling from the DAG models was substantially slower, an approximate average of 60 seconds for both variants. This can be explained by the fact that sampling latent variables is very expensive, especially considering that in the given DAG models all ancillary latents become dependent when conditioning on the data. To summarize, the DMG approach allowed for a complete parameterization with significantly better mixing properties, while still resulting in a faster MCMC procedure.

7.2 Structure Learning Applications

When trying to find a point estimate of graphical structures (i.e., returning a single graph that explains the data well), simple approaches such as testing for marginal independencies are reasonable learning algorithms under the Gaussian assumption. The Bayesian approach, however, allows one to compute odds and distributions over graphs and graph statistics, for example, the joint probability of small substructures (Friedman and Koller, 2003). Moreover, it is not clear how the independence test procedure controls for the predictive ability of the model, which is not a straightforward function of the edges that are selected due to the quantitative aspects of the dependencies.

We evaluate our Bayesian model selection contribution, focusing on the Monte Carlo sampler for bi-directed models. Jones et al. (2005) propose the following priors for graphs:

$$\mathcal{P}(\mathcal{G}|\beta) = \beta^{|E|}(1-\beta)^{0.5m(m-1)-|E|}$$

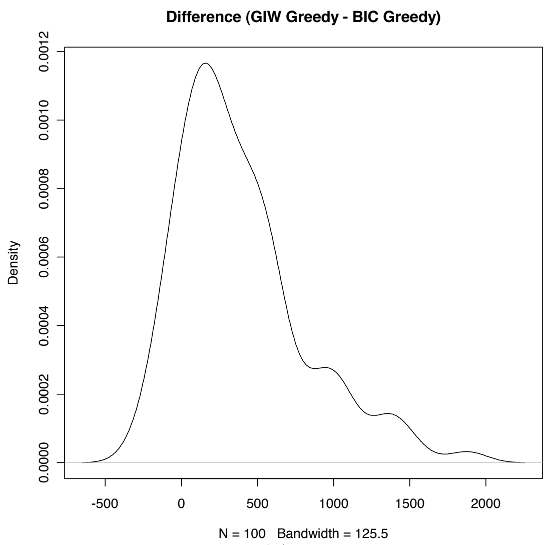
where β is a hyperparameter, $|E|$ is the number of edges in $\mathcal{G}$, and m is the number of nodes. As suggested by Jones et al., we choose $\beta = 0.5/(m-1)$, which puts more mass on graphs with $O(m)$ edges than the uniform prior.

We start with a brief synthetic study to compare the approach against a simple but effective approach based on the BIC approximation.[13] An experiment with gene expression data closes this subsection.

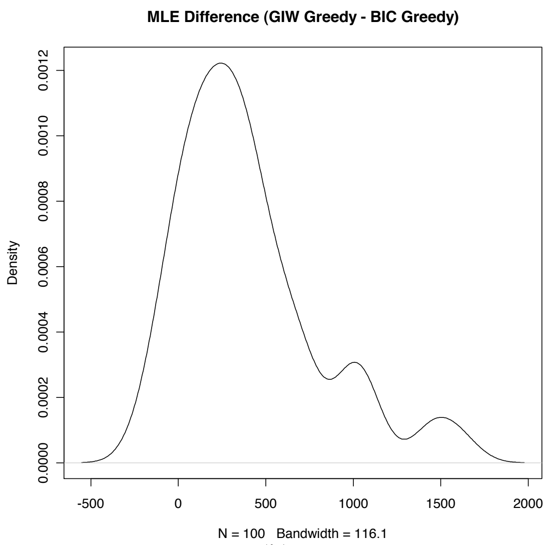
7.2.1 SYNTHETIC STUDIES

As a sanity check for the procedure, we generate synthetic 10-dimensional Gaussian data from models that are Markov with respect to a bi-directed graph. One hundred data sets of 50 datapoints each are generated, each coming from a different model.[14] We initially find a structure by marginal independence tests using the Fisher's Z statistic at a 0.05 level. From this starting point, we perform two searches: one using the BIC score, and the other using the marginal likelihood with a $\mathcal{G}$-*IW* prior.[15] Given the best model for each procedure, we evaluate the predictive log-likelihood on a test set of 2,000 points which are independently sampled for each of the 100 models.

13. The BIC approach is an asymptotically consistent score for selecting the maximum a posteriori Gaussian bi-directed graph model (Richardson and Spirtes, 2002).
14. The details of the simulated data are as follows: we start with DAG with no edges, with observed nodes $\{Y_1, Y_2, \dots, Y_{10}\}$ and hidden nodes $\{X_1, X_2, X_3, X_4\}$. Each individual edge $X_i \rightarrow Y_j$ is added with probability 0.35, and no other edges are allowed. We reject graphs with fewer than 10 edges. All coefficient parameters are sampled from a standard Gaussian, and variances from an uniform distribution in $[0,1]$. The model over $\mathbf{Y}$ corresponds to a bi-directed graph, where the edge $Y_i \leftrightarrow Y_j$ exists if and only if Y_i and Y_j have a common latent parent X_k in the DAG. We then store 50 samples for the $\mathbf{Y}$ variables in a data set. The procedure is repeated 100 times with different parameters and graphical structures each time. The average number of edges in the resulting simulation was of 18.4 edges per graph.
15. In both cases, we center the data at the empirical mean of the training set and assume the data to have been generated from a zero-mean Gaussian. The $\mathcal{G}$-Inverse Wishart is an empirical prior: a diagonal matrix with the training variance



(a)



(b)

Figure 16: The differente in predictive log-likelihood with models learned with the $\mathcal{G}$-*IW* prior and the best BIC models found by greedy search. Although the difference per point is small, it reflects a persistent advantage of the full Bayesian approach. Figure (a) shows the estimated density of the distribution of differences when predicting points using the Bayesian predictive log-likelihood. Since the BIC search method does not atempt to maximize the finite sample posterior distribution, we provide Figure (b) for completeness: in this case, the predictive log-likelihood for the BIC model was calculated using the maximum likelihood estimator. The difference hardly changes, and the fully Bayesian model still wins (density estimates produced by the DENSITY$(\cdot)$ function of R 2.6.0.).

The average difference in log-likelihood prediction[16] between the structure learned with the Bayesian prior and the BIC-induced model is depicted in Figure 16(a). This is computed by conditioning on the learned structures (fully Bayesian vs. BIC maximum a posteriori graphs) and marginalizing over the posterior of the parameters. The parameter priors are those used for the structure learning step. This might be unfair for the BIC procedure, since it is not designed to maximize the finite sample posterior: hence we also show in Figure 16(b) the results obtained when the predictions given the BIC model are obtained by using the maximum likelihood estimators of the

of each variable used as the diagonal. The number of degrees of freedom is set to 1. The search is a standard greedy procedure: we evaluate the marginal log-likelihood or BIC score for each graph that differs from the current candidate by one edge (i.e., graphs with one more or one fewer edge) and pick the one with the highest score. We stop when no improvement is possible.

16. In terms of incorrect edge additions and deletions, the procedures behave about the same: an average of one third of the edges is missed, and 7% of edges are incorrectly added (individual percentages are with respect to total number of possible mistakes in each graph). Unlike BIC, however, our procedure allows for different trade-offs by using different priors. It should also be pointed out that counting edge errors is just one possible measure. A more global quantitative score such as predictive log-likelihood takes into account, indirectly, the magnitude of the errors—although it is not a direct measure of model fitness.

parameters. The average difference in the first case is 400.07, and only slightly less for the second case (389.63). Most of the mass of the difference distribution is positive (85 out of 100 for the first case, 89 out of 100 in the second case), which passes a sign test at a 0.05 level. The difference is still relatively small, suggesting that informative prior knowledge might be necessary to produce substantially better predictions.

7.2.2 GENE EXPRESSION ANALYSIS

To illustrate the use of Bayesian model selection approaches, we analyse the gene expression data previously studied by Drton and Perlman (2007), also as Gaussian bi-directed models. As before, our goal will be to compare the predictive power of models learned by greedy search with BIC and greedy search with the Bayesian posterior.

The data consists of 13 gene expression measurements from a metabolic network. A total of 118 points is available. Using all data, the BIC-induced graph has 39 edges, while the finite sample posterior graph had 44. The same procedure used in the synthetic studies, for initializing graphs and choosing priors and centering the data, was applied in this case with two choices of degrees of freedom δ for the $\mathcal{G}$-*IW* prior: $\delta = 1$ and $\delta = 5$. Preliminary experiments where 90% of the samples are assigned to the training set showed a negligible difference between methods. We then generate 10 random splits of the data, 50% of them assigned to the training set. Predictive results using the MCMC method for evaluating the Bayesian predictions (with half a million samples) are shown in Table 1. The BIC graphs are by definition the same in the three sets of evaluation, but parameters are learned in three different ways (maximum likelihood point estimation and Bayesian averaging with two different priors). There is a steady advantage for the Bayesian approach, although a small one. Notice that using Bayesian averaging over parameters given the BIC graph improves prediction when compared to using the maximum likelihood point estimate, despite the simplistic choice of prior in this study. Notice also that the cases where the Monte Carlo method has small or no advantage over the BIC method were the ones where the maximum likelihood estimators produced their best results.

7.2.3 REMARKS

The procedure based on the sampler is doable for reasonably sized problem on the order of a few dozen variables in desktop machines. Further improvements are necessary for larger problems. One aspect that was not explored here was re-using previous computations when calculating the probability of a new candidate, in a way similar to the local updates in DAG models (Chickering, 2002). How to combine local updates with the ordering-based improved sampler of Section 6 is left as future research. Several practical variations can also be implemented, such as vetoing the inclusion of edges associated with high p-values in the respective independence tests. Such tabu lists can significantly shrink the search space.

It is important to evaluate how the Monte Carlo procedure for computing normalizing constants behaves in practice. For all practical purposes, the procedure is an importance sampler and as such is not guaranteed to work within a reasonable amount of time for problems of high dimensionality (MacKay, 1998). We can, however, exploit the nature of the problem for our benefit. Notice that the procedure depends upon a choice of ordering $\prec$ for the variables. Different orderings correspond in general to *different importance distributions*. We can play with this feature to choose an suitable ordering. Consider the following algorithm for choosing an ordering given a bi-directed graph $\mathcal{G}$:

	MLE	$\delta = 1$		$\delta = 5$	
Folder	BIC	BIC	MC	BIC	MC
1	-6578.44	-6382.45	-6308.19	-6342.82	**-6296.14**

Table 1: Results for the 10 random splits of the gene expression data, with 50% of the points assigned to the training set. The first column shows the predictive log-likelihood for the graph learned with the BIC criterion and parameters fit by maximum likelihood. The next two columns show predictive log-likelihood results for the graphs learned with BIC and the Monte Carlo (MC) marginal likelihood method using a $\mathcal{G}$-*IW* prior with degrees of freedom $\delta = 1$. The last two columns are the results of a prior where $\delta = 5$. Best results in bold.

1. Let $\prec$ be an empty queue.
2. Let $\mathcal{G}'$ be the graph complement of $\mathcal{G}$, that is, the graph where $\{Y_i, Y_j\}$ are neighbors if and only if they are not adjacent in $\mathcal{G}$.
3. Let $\mathcal{C}$ be an arbitrary maximum clique of $\mathcal{G}'$. Add all elements of $\mathcal{C}$ to the end of $\prec$ in any arbitrary order.
4. For each pair $\{Y_i, Y_j\}$, not intersecting $\mathcal{C}$, such that the path $Y_i \leftrightarrow Y_k \leftrightarrow Y_j$ exists in $\mathcal{G}$ and $Y_k \in \mathcal{C}$, add the edge $Y_i \leftrightarrow Y_j$ to $\mathcal{G}$.
5. Remove all elements $Y_k \in \mathcal{C}$ from $\mathcal{G}$, including any edge into Y_k.
6. Iterate Steps 2-5 until $\mathcal{G}$ is an empty graph.

The resulting queue $\prec$ is an ordering that attempts to maximize the number of variables that are marginally independent given their common predecessors. This is just one possibility to simplify the importance sampling distribution: perfect orderings and the approaches for simplifying maximum likelihood estimation described by Drton and Richardson (2008b) could be adapted to provide even better orderings, but we leave this as future work.[17]

17. In our actual implementation used in the experiments in this Section, we implemented an even simpler approach: instead of finding maximum cliques, we start to build a clique from a particular node, "greedily" adding other nodes to the clique according to the column order of the data set. Each node generates a candidate clique, and we pick an arbitrary clique of maximal size to be our new set $\mathcal{C}$.

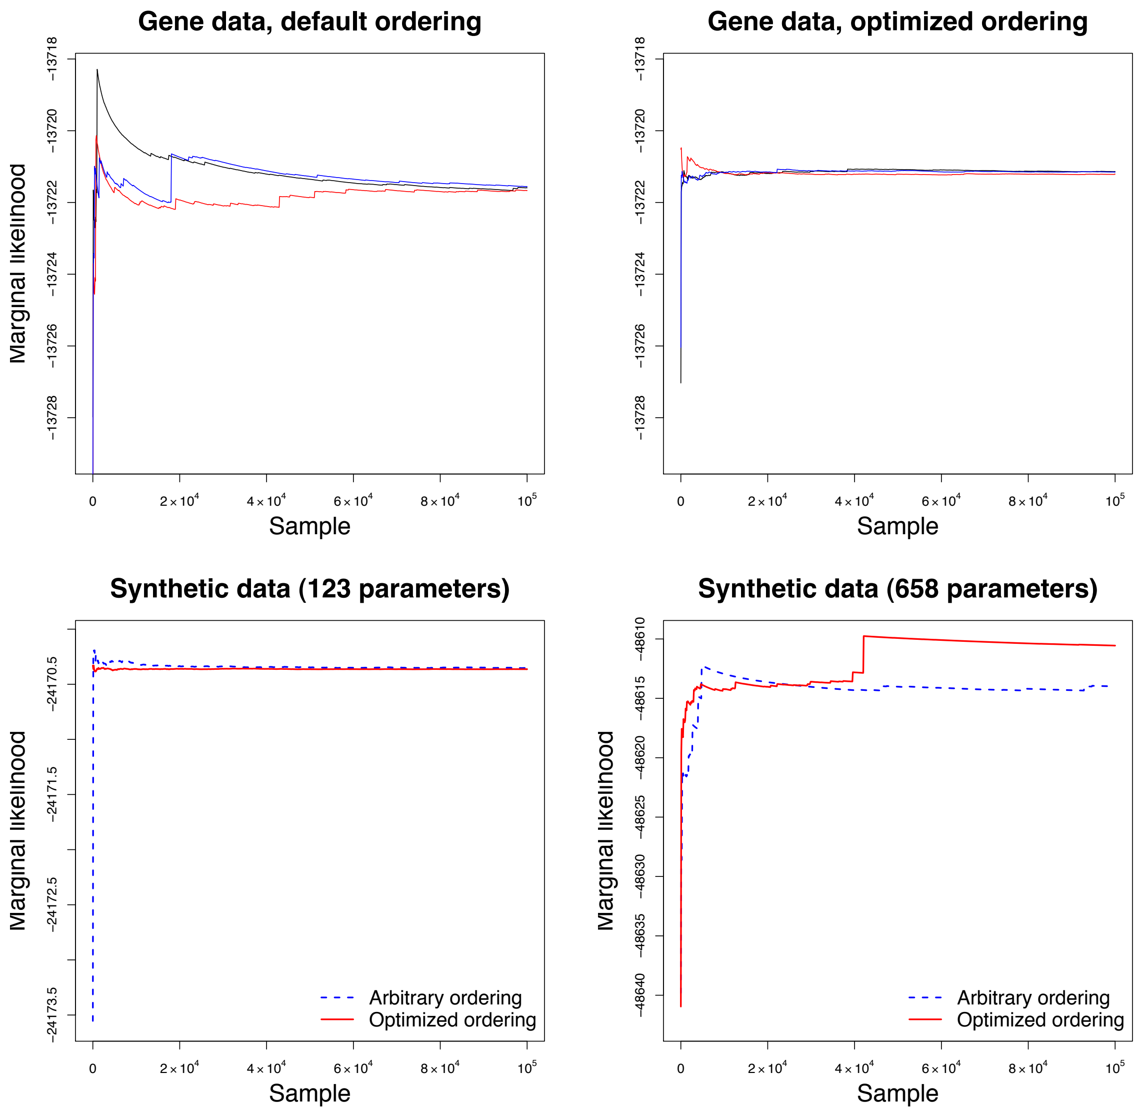

Figure 17: An evaluation on the stability of the Monte Carlo normalizing function procedure. The top row depicts the marginal likelihood estimates for the gene problem using two different distributions implied by two different orderings, as explained in the text. Experiments with synthetic data are shown in the bottom, and the bottom-right figure illustrates major differences.

Figure 17 illustrates the difference that a smart choice of ordering can make. The top left graph in Figure 17 depicts the progress of the marginal likelihood Monte Carlo estimator for the gene expression problem using the graph given by the hypothesis testing procedure. The model has 55 parameters. We obtain three estimates, each using a sample of 100,000 points, which allows us to observe how the estimates change at the initial stages. The variable ordering in this case is the ordering present in the original database (namely, DXPS1, DXPS2, DXPS3, DXR, MCT, CMK, MECPS, HDS, HDR, IPPI1, GPPS, PPDS1 and PPDS2). The top right graph shows three runs using the optimized ordering criterion. Convergence is much faster in this case, and both samplers agree on the normalizing constant estimate.

As an illustration of the power of the procedure and its limitations, we generated a synthetic sample of 1,000 training points from a graph with 25 nodes, using the same procedure of Section 7.2.1. A run of two different samplers is shown at the bottom left of Figure 17. They are seemingly well-behaved, the ratio between the largest and median weight being at the order of one hundred in the "optimally" ordered case. In contrast, the bottom right corner of Figure 17 illustrates the method with a covariance matrix of 50 random variables and 1,000 training points. Notice this is a particularly dense graph. Much bigger jumps are observed in this case and there is no clear sign of convergence at 100,000 iterations.

While there is no foolproof criterion to evaluate the behavior of an importance sampler, the relationship between orderings provides a complementary technique: if the normalizing constant estimators vary substantially for a given set of random permutations of the variables, then the outcomes are arguably not to be trusted even if the respective estimators appear to have converged.

Concerning the choice of priors, in this Section we exploited empirical priors. The $\mathcal{G}$-Inverse Wishart matrix hyperparameter is a diagonal matrix where variance entries are the sample variances. While this adds an extra bias towards diagonal matrices, at least in our experiments we performed close to or better than other approaches—it is however not clear whether we could have done much better. It is still an open question which practical "default" hyperparameters will prove useful for the $\mathcal{G}$-IW. Elicitation of subjective priors in the context of structural equation models can benefit from pre-existing work on Bayesian regression, although again practical matters might be different for the $\mathcal{G}$-IW. Dunson et al. (2005) describe some limitations of default priors for structural equation models. A thorough evaluation of methods for eliciting subjective priors is out of the context of this work, but existing work on inverse Wishart elicitation provides a starting point (Al-Awadhi and Garthwaite, 1998). As in the case of the inverse Wishart, the $\mathcal{G}$-Inverse Wishart has a single hyperparameter for specifying degrees of freedom, a limitation which might motivate new types of priors (Brown et al., 1993).

7.3 Discrete Data Applications

We now show results on learning a discrete distribution that factorizes according to a mixed graph. Drton and Richardson (2008a) describe applications on real-world binary data modeled according to bi-directed graphs. The empirical contingency tables for two studies can be found in the corresponding technical report (Drton and Richardson, 2005). Drton and Richardson used a complete parameterization for bi-directed binary models and a maximum likelihood estimation procedure. In this section, we analyze these two data sets to illustrate the behavior of our Bayesian procedure using the probit model. Our model imposes probit constraints that are not enforced by Drton and Richardson, but it allows us to obtain Bayesian credible intervals and predictions.

The graphs used in the two studies are depicted in Figure 18. The first problem is a study on the dependence between alcoholism and depression, as shown in Figure 18(a). A data point is collected for a given pair of mono-zygotic twins. For each sibling S_i, it is recorded whether S_i is/is not alcoholic (A_i), and whether S_i suffers/does not suffer from depression (D_i). The hypothesis encoded by the graph is that alcoholism and depression do not share a common genetic cause, despite A and

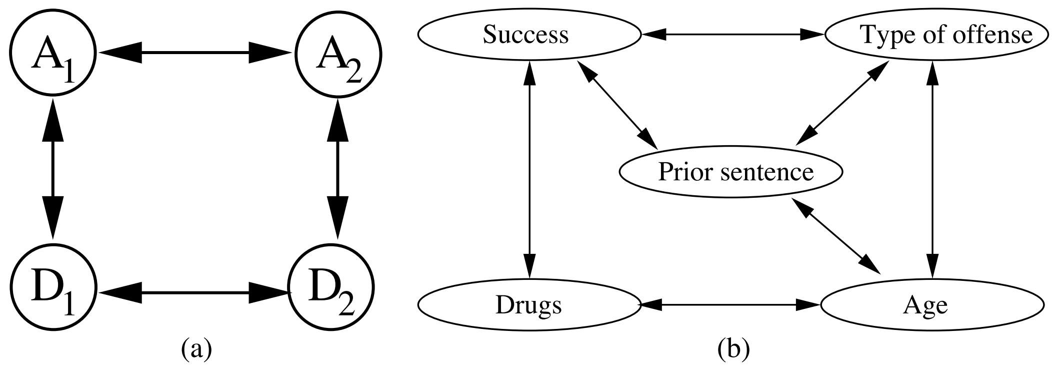

Figure 18: Two learning problems with discrete data. In (a), the graph shows dependencies concerning alcoholism (A_i) and depression (D_i) symptoms for paired twins $\{1,2\}$. In (b), a model for dependencies among features of a study on parole appeals, including the success of the parole, if the type of offense was a person offense or not, and if the offender had a dependency on drugs and was over 25 years old. All variables in these studies are binary and further details and references are provided by Drton and Richardson (2008a).

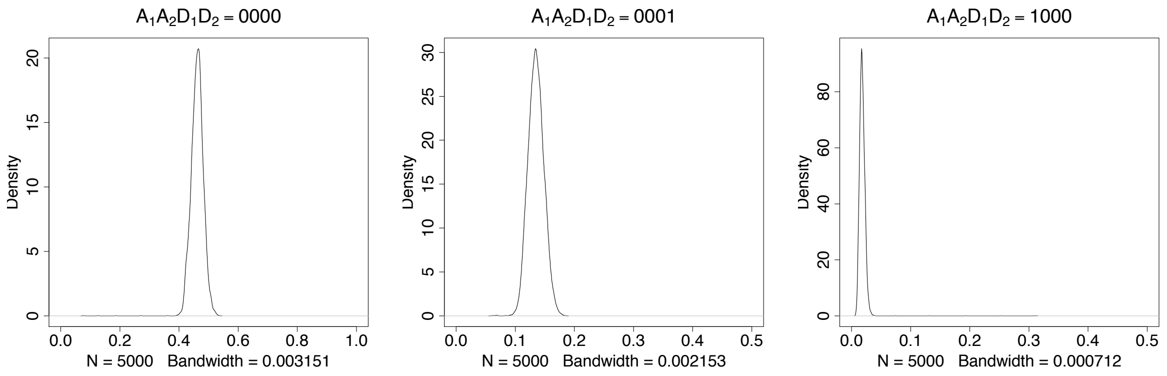

Figure 19: Posterior distribution of some of the marginal contingency table entries for the twin model.

D having some hidden (but different) genetic causes. If A and D did have genetic common causes, one would expect that the edges $A_1 \leftrightarrow D_2$ and $A_2 \leftrightarrow D_1$ would be also required. The compounded hypothesis of marginal independencies for A_i and D_j, $i \neq j$, can be tested jointly by testing a bi-directed model. Notice that no reference to particular genetic hidden causes of alcoholism and depression is necessary, which again illustrates the power of modeling by marginalizing out latent variables.

The second study, as shown in Figure 18(b), concerns the dependencies among several variables in an application for parole. The model implies, for instance, that the success of a parole application (*Success* node, in the Figure) is independent of the age of the offender being under 25 (*Age* node). However, if it is known that the offender had a prior sentence, these two variables become dependent (through the path *Success* $\leftrightarrow$ *Prior sentence* $\leftrightarrow$ *Age*). As reported by Drton and Richardson, their

Figure 20: The posterior expected value of the 16 entries in the twin study table ($E[\Theta|\mathcal{D}]$). Results generated with a chain of 5,000 points. We also show the maximum likelihood estimates of Drton and Richardson (MLE) and the maximum likelihood values obtained using an unconstrained model (uMLE). Despite the probit parameterization, in this particular study there is a reasonable agreement between the Bayesian estimator and the estimator of Drton and Richardson.

binary bi-directed model passes a significance test. Drton and Richardson also attempted to learn an undirected (Markov) network structure with this data, but the outcome was a fully connected graph. This is expected, since Markov networks cannot represent marginal independencies unless the graph is disconnected, which would introduce all sorts of other independencies and possibly not fit the data well. If many marginal independencies exist in the data generating process, Markov networks might be a bad choice of representation. For problems with symmetries such as the twin study, DAGs are not a natural choice either.

7.3.1 RESULTS

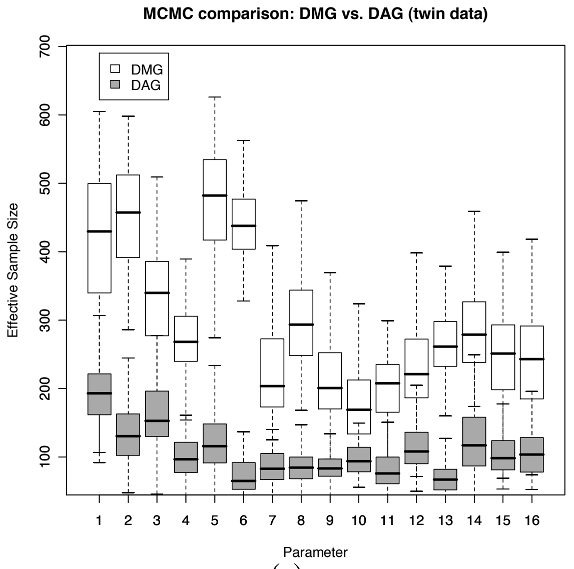
For the twin data problem, we used a simple prior for the covariance matrix of the underlying latent variables: a $\mathcal{G}$-inverse Wishart with 1 degree of freedom and a complete covariance with a value of 2 for each element in the diagonal and 1 outside the diagonals. Thresholds are fixed at zero, since we have binary data. We present the expected posterior values of the contingency table entries in Figure 20. The outcome is essentially identical to the maximum likelihood estimates of Drton and Richardson despite the probit parameterization. Moreover, with our procedure we are able to generate Bayesian confidence intervals, as illustrated in Figure 19. The results are very stable for a chain of 1,000 points.

For the parole data, we used a $\mathcal{G}$-inverse Wishart prior for the covariance matrix of underlying variables $\mathbf{Y}^\star$ with 1 degree of freedom and the identity matrix as hyperparameters. We compare the effective sample size of the Gibbs sampler for our DMG model and the DAG model obtained by using the ancillary latent parameterization of Section 7.1 for the underlying latent variable covariance matrix.[18] Boxplots for the 16 contingency table entries of the twin network and the 32 entries of the parole study are shown in Figure 21. The setup is the same as in the democratization and

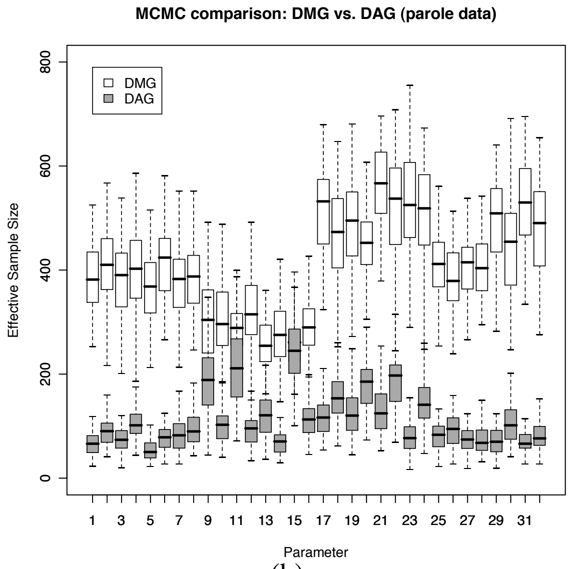
18. The priors used are as follows: the ancillary representation was given a prior with mean 1 and variance 1 for the coefficients $X_{ij} \rightarrow Y_j^\star$, for $j > i$, and set constant to 1, if $i < j$. The means of the ancillary latents were fixed at

industrialization experiment, where we run 80 independent chains and plot the distribution of the effective sample sizes to measure the mixing time. We ran a shorter chain of 2,000 points, since computing the contingency table entries is expensive.

There is a substantial difference in effective sample size for the parole study. Notice that we are comparing MCMC samples for the entries in the contingency table, which in the DAG case requires integrating out not only the underlying latent variables implicit in the probit parameterization, but also the ancillary latents that account for the bi-directed edges. This hierarchy of latent variables, which does not exist in the DMG case, causes a considerable increase on autocorrelation of the chain compared to the DMG model. The standard DMG parameterization can be seen as a way of obtaining a collapsed Gibbs sampler, where the parameterization by construction reflects latent variables that were analytically marginalized.



(a)



(b)

Figure 21: Comparison of effective sample sizes for the twin data (a) and parole data (b). 80 independent chains of 2,000 points were obtained using the Gibbs sampling algorithm, and the respective box-plots shown above. The Markov chain with the DMG approach easily dominates the DAG one. For the parole data, the average effective sample size for the DAG was as low as 60 points.

8. Conclusion

Directed mixed graph models are a generalization of directed graph models. Whenever a machine learning application requires directed graphs, one should first consider whether directed mixed graphs are a better choice of representation instead. DMGs represent conditional independencies of DAGs where hidden variables have been marginalized out. Given that in most applications it is

0. Variance parameters were given $(0.5,0.5)$ inverse gamma priors, which approximately matches the priors in the DMG model.

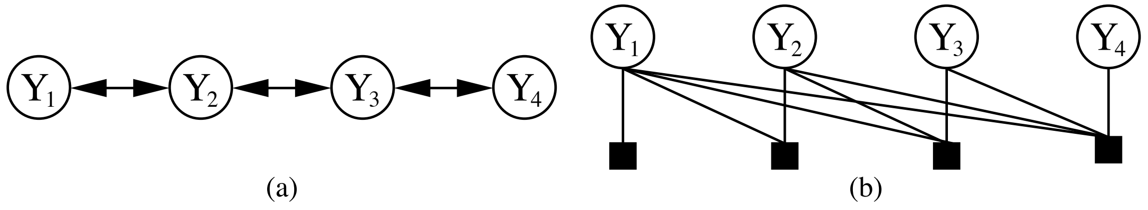


Figure 22: In (a), a simple bi-directed chain with four random variables. In (b), the respective factor graph that is obtained from a Bartlett parameterization using the ordering $\prec \equiv \{Y_1, Y_2, Y_3, Y_4\}$. In this case, the factors are $p(Y_1) \times p(Y_2|Y_1) \times p(Y_3|Y_1, Y_2) \times p(Y_4|Y_1, Y_2, Y_3)$. A different choice of ordering (e.g., the perfect ordering) could provide simpler factors on average, but the presence of a factor linked to all variables is unavoidable.

unlikely that all relevant variables are known, DMGs are a natural representation to use. In this paper, we introduced priors and inference algorithms for Bayesian learning with two popular families of mixed graph models: Gaussian and probit. We discussed some implementations and approximations to scale up algorithms. We showed examples of applications with real data, and demonstrated that Bayesian inference in Gaussian and probit DMG models using MCMC can have substantially faster mixing than in comparable DAGs.

It is part of the machine learning folklore that factor graphs can subsume directed networks. In an important sense, this is known not to be true: undirected and factor graphs only allow for monotonic independence models, where explaining away is ruled out. This excludes a vast number of realistic, non-monotonic, models. While factor graphs are perhaps the *data structures* of choice for general message-passing algorithms (e.g., Yedidia et al., 2005), they are far from being universal *modeling languages* for independencies.

What is true is that for any distribution that is Markov with respect to a DAG or DMG there is at least one corresponding factor graph model, but this is a vacuous claim of little interest: any distribution can be represented by a single-factor model involving all variables. Some will *require* a factor with all variables, even under the presence of a large number of independence constraints. For instance, a factor graph corresponding to any given bi-directed chain will necessarily include a factor node adjacent to all variable nodes, as illustrated in Figure 22. When parameterizing a distribution with many marginal independencies (e.g., a bi-directed tree), the respective factor graph would be no more than an unhelpful drawing. A better strategy for solving real-world problems is to define a family of models according to the (directed/undirected/factor) graphs of choice, and let the inference algorithm decide which re-expression of the model suits the problem. This has been traditional in graphical modeling literature (Lauritzen, 1996). The strategy adopted in this paper followed this spirit.

An alternative has been recently introduced by Huang and Frey (2008). This paper discusses graphical families of marginal independence constraints (essentially identical to bi-directed graphs, although other types of constraints might implicitly follow from the parameterization). Models are parameterized using a very different strategy. The idea is to parameterize cumulative distribution functions (CDFs) instead of densities or probability mass functions. A simple factorization criterion can be defined in the space of CDFs, but densities have to be computed by a novel message-passing scheme. The particular application discussed by Huang and Frey (2008) could in principle be approached using the Gaussian bi-directed probit model of Section 5, but the parameterization in Huang and Frey (2008) does not need to rely on Gaussian distributions. It is not clear, however, how to efficiently perform Bayesian inference in this case and which constraints are implicitly implied by the different choices of parameterization. The different perspective given by products of CDFs is novel and promising. It should point out to new directions in mixed graph modeling.

The structural equation modeling literature also describes several pragmatic ways of specifying non-linearities in the structural equations (Lee, 2007). Less common is the specification of non-Gaussian models for the joint density of the error terms. Silva and Ghahramani (2009) introduce a flexible mixture of Gaussians approach for models of marginal independence. There is a need on how to combine this approach with flexible families of structural equations in a computationally efficient way. Also, models with non-additive error terms remain to be explored.

Current interest in estimating sparse statistical models has lead to approaches that estimate structured covariance matrices (e.g., Bickel and Levina, 2008). This development could also lead to new families of priors. In particular, different matrix decompositions have motivated different ways of specifying priors on covariance matrices. For instance, Chen and Dunson (2003) propose a modified Cholesky decomposition for the covariance matrix of random effect parameters: standard deviations are parameterized separately with a prior that puts positive mass on zero variances (effectively allowing the random effect to be neutralized). Wong et al. (2003) describe a prior for inverse correlation matrices that is uniform conditioned on the number of structural zeros. Metropolis-Hastings schemes are necessary in this case.

Shrinkage methods have also been applied to the estimation of covariance matrices. A common approach, shrinkage towards a diagonal matrix (e.g., Daniels and Kass, 1999), could be generalized towards some sparse matrix corresponding to a bi-directed graph. Although shrinkage will not generate structural zeros in the resulting matrix, allowing for sparse shrinkage matrices other than the identity matrix could be interesting in prediction problems.

Some approaches can exploit an ordering for the variables, which is natural in some domains such as time-series analysis. While the $\mathcal{G}$-Inverse Wishart is invariant to a permutation of the variables, new types of priors that exploit a natural variable ordering should be of interest, as in the original work of Brown et al. (1993) that motivated our approach.

Other directions and applications are suggested by recent papers:

- **learning measurement models:** the industrialization and democratization problem of Section 7.1 provides an example of a measurement model. In such a family of problems, observed variables are children of latent variables, and connections from latents to observables define the measurement model. Sparsity in the measurement can be exploited to allow for more general dependencies connecting latent variables. One role of the bi-directed component is to allow for extra dependencies connecting observed variables that are not accounted by the explicit latent variables in the model. Silva et al. (2006) describes a learning algorithm for mixed graph measurement models using the "ancillary" parameterization. The natural question is which alternative optimization strategies could be used and how to scale them up;

- **structural and relational learning:** in prediction problems where given an input vector $\mathbf{X}$ we have to predict an output vector $\mathbf{Y}$, the dependence structure of $\mathbf{Y}$ given $\mathbf{X}$ can also lie within the directed mixed graph family. Silva et al. (2007) introduces mixed graph models within the context of relational classification, where $\mathbf{Y}$ are labels of different data points not independently distributed. In such a class of problems, novel kinds of parameterization are necessary since the dimensionality of the covariance matrix increases with the sample size. Structural features of the graph are used to propose different parameterizations of the dependencies, and many other alternatives are possible;

- **causal inference:** mixed graphs have been consistently used as a language for representing causal dependencies under unmeasured confounding. Zhang (2008) describes recent advances in identifying causal effects with ancestral graphs. Algorithms for learning mixed graph structures are described by Spirtes et al. (2000) and the recent advances in parameterizing such models should result in new algorithms;

Many challenges remain. For instance, more flexible models for DMG discrete models are being developed (Drton and Richardson, 2008a), but for large graphs they pose a formidable computational problem. An important question is which other less flexible, but more tractable, parameterizations could be used, and which approximation algorithms to develop. The probit family discussed here was a choice among many. The parameterization by Drton and Richardson (2008a) could be a starting point for trading-off flexibility and computational effort. And while it is true that Gaussian copula models (Pitt et al., 2006) can be adapted to generalize the approach introduced here, it remains to be seen if other copula parameterizations easily lead to DMG models.

Acknowledgments

We thank the anonymous reviewers for their suggestions, Kenneth Bollen for providing us with the industrialization and democratization data set, and Robert Gramacy for helpful discussions. An earlier version of this paper (Silva and Ghahramani, 2006) appeared in the proceedings of the Uncertainty in Artificial Intelligence conference. Appendix A. Deriving the Sampling Distribution for the Monte Carlo Computation of Normalizing Constants

We give here the details on how to derive the sampling distribution used for computing normalizing constants $I_{\mathcal{G}}(\delta, \mathbf{U})$, as described in Section 3.2.2.

Let $\mathbf{A}_i \equiv \Sigma_{sp_{\prec}(i),nsp_{\prec}(i)}\Sigma^{-1}_{nsp_{\prec}(i),nsp_{\prec}(i)}$. Recall from Equation (7) that $\mathcal{B}_{i,nsp_{\prec}(i)} = -\mathcal{B}_{i,sp_{\prec}(i)}\mathbf{A}_i$. The original density $p(\mathcal{B}_i \mid \gamma_i)$, as given by Lemma 1, is a multivariate Gaussian with the following kernel:

$$\exp\left(-\frac{1}{2\gamma_i}\left[\begin{array}{c}\mathcal{B}^{\mathsf{T}}_{i,sp_{\prec}(i)} - \mathbf{M}_{sp_{\prec}(i)} \\ \mathcal{B}^{\mathsf{T}}_{i,nsp_{\prec}(i)} - \mathbf{M}_{nsp_{\prec}(i)}\end{array}\right]^{\mathsf{T}}\left[\begin{array}{cc}\mathbf{U}_{ss} & \mathbf{U}_{sn} \\ \mathbf{U}_{ns} & \mathbf{U}_{nn}\end{array}\right]\left[\begin{array}{c}\mathcal{B}^{\mathsf{T}}_{i,sp_{\prec}(i)} - \mathbf{M}_{sp_{\prec}(i)} \\ \mathcal{B}^{\mathsf{T}}_{i,nsp_{\prec}(i)} - \mathbf{M}_{nsp_{\prec}(i)}\end{array}\right]\right) \tag{22}$$

where $\mathbf{U}_{\{i-1\},\{i-1\}}$ in Lemma 1 was rearranged above as the partitioned matrix in (14). The pair $\{\mathbf{M}_{sp_{\prec}(i)}, \mathbf{M}_{nsp_{\prec}(i)}\}$ corresponds to the respective partition of the mean vector $\mathbf{M}_i$. Plugging in the expression for $\mathcal{B}_{i,nsp_{\prec}(i)}$ in (22), we obtain the modified kernel

$$\exp\left(-\frac{1}{2\gamma_i}\left[\begin{array}{c}\mathcal{B}_{i,sp_{\prec}(i)}^{\mathsf{T}}-\mathbf{M}_{sp_{\prec}(i)}\\ -\mathbf{A}_i^{\mathsf{T}}\mathcal{B}_{i,sp_{\prec}(i)}^{\mathsf{T}}-\mathbf{M}_{nsp_{\prec}(i)}\end{array}\right]^{\mathsf{T}}\left[\begin{array}{cc}\mathbf{U}_{ss} & \mathbf{U}_{sn}\\ \mathbf{U}_{ns} & \mathbf{U}_{nn}\end{array}\right]\left[\begin{array}{c}\mathcal{B}_{i,sp_{\prec}(i)}^{\mathsf{T}}-\mathbf{M}_{sp_{\prec}(i)}\\ -\mathbf{A}_i^{\mathsf{T}}\mathcal{B}_{i,sp_{\prec}(i)}^{\mathsf{T}}-\mathbf{M}_{nsp_{\prec}(i)}\end{array}\right]\right) \qquad (23)$$

which can be rewritten as

$$\begin{array}{rcl} p_b(\mathcal{B}_{i,sp_{\prec}(i)};\mathbf{K}_i\mathbf{m}_i,\gamma_i\mathbf{K}_i) & \times & (2\pi)^{\#sp_{\prec}(i)/2}|\gamma_i|^{\#sp_{\prec}(i)/2}|\mathbf{K}_i(\Phi_{i-1})|^{1/2}\\ & \times & \exp\left\{-\frac{1}{2}\gamma_i^{-1}\mathcal{U}_i\right\}\end{array} \qquad (24)$$

where $\#sp_{\prec}(i)$ is the size of set $sp_{\prec}(i)$, $p_b(\cdot;\alpha,\Sigma)$ is the density function of a multivariate Gaussian distribution with mean α and covariance Σ, $\mathbf{K}_i(\Phi_{i-1})\equiv\mathbf{K}_i$ to emphasize the contribution of previous parameters, and

$$\begin{array}{rcl} \mathbf{m}_i & = & (\mathbf{U}_{ss}-\mathbf{A}_i\mathbf{U}_{ns})\mathbf{M}_{sp_{\prec}(i)}+(\mathbf{U}_{sn}-\mathbf{A}_i\mathbf{U}_{nn})\mathbf{M}_{nsp_{\prec}(i)},\\ \mathbf{K}_i^{-1} & = & \mathbf{U}_{ss}-\mathbf{A}_i\mathbf{U}_{ns}-\mathbf{U}_{sn}\mathbf{A}_i^{\mathsf{T}}+\mathbf{A}_i\mathbf{U}_{nn}\mathbf{A}_i^{\mathsf{T}},\\ \mathcal{U}_i & = & \mathbf{M}_i^{\mathsf{T}}\mathbf{U}_{\{i-1\},\{i-1\}}\mathbf{M}_i-\mathbf{m}_i^{\mathsf{T}}\mathbf{K}_i\mathbf{m}_i.\end{array}$$

If $sp_{\prec}(i)=\emptyset$, it follows that $\mathcal{B}_i=\mathcal{B}_{i,nsp_{\prec}(i)}=0$. The kernel (23) reduces to $\exp(-0.5\mathcal{U}_i/\gamma_i)$, and $\mathcal{U}_i\equiv\mathbf{M}_i^{\mathsf{T}}\mathbf{U}_{\{i-1\},\{i-1\}}\mathbf{M}_i$. If $nsp_{\prec}(i)=\emptyset$, then the expression for the kernel does not change ($\mathcal{U}_i\equiv 0$), and Equation (24) corresponds to the original kernel in Equation (11).

Inserting the re-expressed kernel into the original function (11), we obtain

$$p_b(\mathcal{B}_{i,sp_{\prec}(i)};\mathbf{K}_i\mathbf{m}_i,\gamma_i\mathbf{K}_i)p_g\left(\gamma_i;\frac{\delta+i-1+\#nsp_{\prec}(i)}{2},\frac{u_{ii.\{i-1\},\{i-1\}}+\mathcal{U}_i}{2}\right)f_i(\Phi_{i-1})$$

where $p_g(\cdot;\alpha,\beta)$ is an inverse gamma density function and

$$\begin{array}{rcl} f_i(\Phi_{i-1}) & \equiv & (2\pi)^{-\frac{(i-1)-\#sp_{\prec}(i)}{2}}|\mathbf{K}_i(\Phi_{i-1})|^{1/2}|\mathbf{U}_{\{i-1\},\{i-1\}}|^{1/2}\\ & \times & \dfrac{(u_{ii.\{i-1\},\{i-1\}}/2)^{(\delta+i-1)/2}}{\Gamma((\delta+i-1)/2)}\dfrac{\Gamma((\delta+i-1+\#nsp_{\prec}(i))/2)}{((u_{ii.\{i-1\},\{i-1\}}+\mathcal{U}_i)/2)^{(\delta+i-1+\#nsp_{\prec}(i))/2}}.\end{array}$$

Appendix B. Variational Updates for Gaussian Mixed Graph Models

The variational updates for the coefficient and intercept parameters are essentially identical to their joint conditional distribution given $\mathbf{V}$ and $\mathbf{X}$, where occurrences of $\mathbf{V}$ and $\mathbf{X}$ are substituted by expectations $\langle\mathbf{V}^{-1}\rangle_{q(\mathbf{V})}$ and $\langle\mathbf{X}\rangle_{q(\mathbf{X})}$, respectively. Let $\mathcal{V}_{ij}$ be the ij-th entry of $\langle\mathbf{V}^{-1}\rangle_{q(\mathbf{V})}$. The covariance matrix of $(\mathbf{B},\alpha)$ is the covariance matrix of the vector $vec(\mathbf{B},\alpha)$. Such vector is constructed using all (non-zero) coefficients and intercepts. We denote this covariance matrix by $\Sigma_{\mathbf{B},\alpha}$. For simplicity of notation, we will treat α_i as the coefficient $b_{i(m+1)}$, m being the number of variables. We will also adopt the notation $Y_{m+1}^{(d)}\equiv 1$ in the following derivations. As an abuse of notation, let $\mathbf{Y}$ also refer to latent variables. In this case, if Y_i and Y_j refer to latent variables X_{h_i} and X_{h_j}, then define $Y_i \equiv \langle X_{h_i} \rangle_{q(\mathbf{X})}$, and $Y_iY_j \equiv \left\langle X_{h_i}X_{h_j} \right\rangle_{q(\mathbf{X})}$.

Let b_{ij} and b_{tv} be the r-th and s-th entries of $vec(\mathbf{B}, \alpha)$, respectively. The rs-th entry of the inverse matrix $\Sigma_{\mathbf{B}\alpha}^{-1}$ is given by

$$(\Sigma_{\mathbf{B}\alpha}^{-1})_{rs} \quad = \quad \mathcal{V}_{it} \sum_{d=1}^{n} Y_j^{(d)} Y_v^{(d)} + 1(i = t)1(j = v)\frac{c_{ij}^b}{s_{ij}^b}$$

where $b_{xp_x} \equiv 0$ if no edge $Y_x \leftarrow Y_{p_x}$ exists in the graph, $1(\cdot)$ is the indicator function, and c_{ij}^b, s_{ij}^b are the given prior parameters defined in Section 4. Similarly to the factorization criterion explained in Section 6, the matrix $q(\mathbf{V})$ will in general be block-diagonal, and this summation can be highly simplified.

Define now a vector $\mathbf{c}^b$ analogous to the Gibbs sampling case, where

$$c_r^b \quad = \quad \sum_{t=1}^{m} \mathcal{V}_{it} \sum_{d=1}^{n} Y_j^{(d)} Y_t^{(d)} + \frac{c_{ij}^b}{s_{ij}^b}.$$

The variational distribution $q(\mathbf{B}, \alpha)$ is then a $N(\Sigma_{\mathbf{B},\alpha}\mathbf{c}, \Sigma_{\mathbf{B},\alpha})$. The variational distribution for the latent variables will exactly the same as the Gibbs distribution, except that references to $\mathbf{B}, \alpha, \mathbf{V}^{-1}$ are substituted by $\langle \mathbf{B} \rangle_{q(\mathbf{B},\alpha)}$, $\langle \alpha \rangle_{q(\mathbf{B},\alpha)}$ and $\left\langle \mathbf{V}^{-1} \right\rangle_{q(\mathbf{V})}$.

Appendix C. Proofs

Proof of Lemma 2: Arrange the columns of the Jacobian such that their order corresponds to the sequence $\sigma_{11}, \sigma_{21}, \sigma_{22}, \sigma_{31}, \sigma_{32}, \sigma_{33}, \ldots, \sigma_{mm}$, excluding the entries σ_{ij} that are identically zero by construction. Arrange the rows of the Jacobian such that their order corresponds to the sequence $\gamma_1, \beta_{21}, \gamma_2, \beta_{31}, \beta_{32}, \ldots, \gamma_m$, excluding the entries β_{ij} that are not in $\Phi_{\mathcal{G}}$ (i.e., exclude any β_{ij} corresponding to a pair $\{Y_i, Y_j\}$ that is not adjacent in the graph).

By the definition of Bartlett's decomposition, $\Sigma_{\{i\},\{i\}}$ and β_{st} are functionally independent for $s > i$. The same holds for $\Sigma_{\{i\},\{i\}}$ and γ_s. As such, $\partial\sigma_{ij}/\partial\beta_{st} = 0$ and $\partial\sigma_{ij}/\partial\gamma_s = 0$ for $s > i$. This implies that $J(\Phi_{\mathcal{G}})$ is a (lower) block triangular matrix of $2m - 1$ blocks: for k odd, the k-th block is the singleton $\partial\sigma_{ii}/\partial\gamma_i = 1$, where $i = (k + 1)/2$. For k even, the k-th block is the Jacobian $\partial\Sigma_{i,sp_{\prec(i)}}/\partial\mathcal{B}_{i,sp_{\prec(i)}}$, where $i = 1 + k/2$ and $\Sigma_{i,sp_{\prec(i)}}$ is the vector of covariances of Y_i and its preceding spouses.

From the interpretation given by Equation (8), it follows that $\mathcal{B}_{i,sp_{\prec}(i)}$ can also be defined by the regression of Y_i on $\mathbf{Z}_i$. That is

$$\mathcal{B}_{i,sp_{\prec}(i)} = \Sigma_{Y_i,\mathbf{Z}_i}\Sigma_{\mathbf{Z}_i,\mathbf{Z}_i}^{-1} \equiv \Sigma_{Y_i,\mathbf{Z}_i}R_i^{-1}. \tag{25}$$

However, $\Sigma_{Y_i,\mathbf{Z}_i} = \Sigma_{i,sp_{\prec}(i)}$, since Y_i is independent of its non-spouses. From (25) we get $\Sigma_{i,sp_{\prec}(i)} = \mathcal{B}_{i,sp_{\prec}(i)}R_i$, and as such the submatrix $\partial\Sigma_{i,sp_{\prec(i)}}/\partial\mathcal{B}_{i,sp_{\prec(i)}}$ turns out to be R_i.

Since the determinant of the block triangular Jacobian $J(\Phi_{\mathcal{G}})$ is given by the determinant of the blocks, this implies

$$|J(\Phi_{\mathcal{G}})| = \prod_{i=2}^{m} |R_i|.$$

By the matrix identity

$$\left|\begin{array}{cc}\mathbf{A} & \mathbf{B}\\ \mathbf{C} & \mathbf{D}\end{array}\right| = |\mathbf{A}||\mathbf{D}-\mathbf{C}\mathbf{A}^{-1}\mathbf{B}|, \tag{26}$$

$|\Sigma_{\{i-1\},\{i-1\}}| = |\Sigma_{nsp_{\prec(i)},nsp_{\prec(i)}}||\Sigma_{sp_{\prec(i)},sp_{\prec(i)}} - \Sigma_{sp_{\prec(i)},nsp_{\prec(i)}}\Sigma^{-1}_{nsp_{\prec(i)},nsp_{\prec(i)}}\Sigma_{nsp_{\prec(i)},sp_{\prec(i)}}| \equiv |\Sigma_{nsp_{\prec(i)},nsp_{\prec(i)}}||R_i|$. Since $|\Sigma_{\{i-1\},\{i-1\}}| = \prod_{t=1}^{i-1}\gamma_t$, the second equality holds. □

Proof of Theorem 4: We first describe a mapping from each path in $\mathcal{G}$ to a path in $\mathcal{G}^\star$, and vice-versa (such mappings are not inverse functions of each other, since the number of paths in $\mathcal{G}^\star$ is larger than in $\mathcal{G}$). By construction, all bi-directed edges in $\mathcal{G}^*$ have two UVs as endpoints, with an one-to-one mapping between each $Y_s^\star \leftrightarrow Y_t^\star$ in $\mathcal{G}^\star$ and each $Y_s \leftrightarrow Y_t$ in $\mathcal{G}$. All directed edges in $\mathcal{G}^\star$ are of two types: $Y_s \rightarrow Y_t^\star$, with $s \neq t$, or $Y_s^\star \rightarrow Y_s$. Therefore, one can define an unique path P in $\mathcal{G}$ as a function of a path $P^\star$ in $\mathcal{G}^\star$, obtained by relabeling each $Y^\star$ as Y, and by collapsing any $Y \rightarrow Y$ edges that might result from this relabeling into a single vertex Y. A mapping in the opposite direction is analogous as given by the construction rule of Type-II models.

A collider in a path is any vertex within a head-to-head collision in the path, that is, any vertex Y_t where the preceding and the next vertex in the path are connected to Y_t with an edge (directed or bi-directed) into Y_t. Y_i and Y_j are m-separated by $\mathbf{Z}$ in an acyclic DMG if and only if there is no active path connecting Y_i and Y_j. Like in d-separation, a path is active if all of its colliders have some descendant in $\mathbf{Z}$, and none of its non-colliders is in $\mathbf{Z}$ (Richardson, 2003). The mappings between paths P and $P^\star$ are such that Y_t is a collider in P if and only if Y_t is in $P^\star$ and is a collider, or $Y_t^\star$ is in $P^\star$ and is a collider. Since by construction any $Y_t^\star$ will have the same $\mathbf{Y}$-descendants in $\mathcal{G}^\star$ as Y_t has in $\mathcal{G}$, and $\mathbf{Z} \subset \mathbf{Y}$, the result follows. □

Proof of Theorem 7: The first of the two claims of the theorem trivially holds, since connectivity is a transitive property and as such this partition will always exist (where $K(i) = 1$ is a possibility). We will prove the validity of the second claim by induction. Let $\{\mathbf{R}_1, \dots, \mathbf{R}_k\}$ be the perfect sequence that generated our perfect ordering. The second claim automatically holds for all vertices in $\mathbf{R}_k$, since $\mathbf{R}_k$ is a clique.

Assume the second claim holds for the subsequence $\{\mathbf{R}_{l+1}, \mathbf{R}_{l+2}, \dots, \mathbf{R}_k\}$. Let Y_i be an element of $\mathbf{R}_l$. Assume there is some non-spouse Y_q of Y_i in $\mathbf{R}_{l'}$, and some spouse Y_p of Y_i in $\mathbf{R}_{l''}$, such that $l < l' \leq l''$. We will assume that both Y_q and Y_p belong to the same component $\mathcal{V}_t^i$ and show this leads to a contradiction.

Without loss of generality, we can assume that Y_q and Y_p are adjacent: otherwise, the fact that Y_q and Y_p are in the connected set $\mathcal{V}_t^i$ will imply there is a path connecting Y_q and Y_p in the subgraph induced by $\{\mathbf{R}_{l+1}, \dots, \mathbf{R}_k\}$. We can redefine $\{Y_q, Y_p\}$ to be the endpoints of the first edge in the path containing a non-spouse and a spouse of Y_i. It will still be the case that $q > p$, by the induction hypothesis.

Since $Y_p \in \mathbf{R}_{l''}$, there is a separator $\mathbf{S}_{l''}$ between $\mathbf{H}_{l''} \backslash \mathbf{S}_{l''}$ and $\mathbf{R}_{l''}$. But $Y_i \in \mathbf{H}_{l''}$, and Y_i is adjacent to Y_p, which implies $Y_i \in \mathbf{S}_{l''}$. If $l' < l''$, this will also imply that $Y_q \in \mathbf{S}_{l''}$, which is a contradiction, since $\mathbf{S}_{l''}$ is a complete set. If $l' = l''$, this implies that Y_i and Y_q are both in $\mathbf{Y}_{P(l'')}$, which is also a contradiction since $\mathbf{Y}_{P(l'')}$ is a clique. □

Abstract

Incorporating prior knowledge of a particular task into the architecture of a learning algorithm can greatly improve generalization performance. We study here a case where we know that the function to be learned is non-decreasing in its two arguments and convex in one of them. For this purpose we propose a class of functions similar to multi-layer neural networks but (1) that has those properties, (2) is a universal approximator of Lipschitz[1] functions with these and other properties. We apply this new class of functions to the task of modelling the price of call options. Experiments show improvements on regressing the price of call options using the new types of function classes that incorporate the *a priori* constraints.

Keywords: neural networks, universal approximation, monotonicity, convexity, call options

1. Introduction

Incorporating *a priori* knowledge of a particular task into a learning algorithm helps reduce the necessary complexity of the learner and generally improves performance, if the incorporated knowledge is relevant to the task and brings enough information about the unknown generating process of the data. In this paper we consider prior knowledge on the positivity of some first and second derivatives of the function to be learned. In particular such constraints have applications to modelling

1. A function f is Lipschitz in Ω if $\exists c > 0,\ \forall x, y \in \Omega,\ |f(y) - f(x)| \leq c|y - x|$ (Delfour and Zolésio, 2001).

the price of stock options. Based on the Black-Scholes formula, the price of a call stock option is monotonically increasing in both the "moneyness" and time to maturity of the option, and it is convex in the "moneyness". Section 4 better explains these terms and stock options. For a function $f(x_1,x_2)$ of two real-valued arguments, this corresponds to the following properties:

$$f \geq 0, \qquad \frac{\partial f}{\partial x_1} \geq 0, \qquad \frac{\partial f}{\partial x_2} \geq 0, \qquad \frac{\partial^2 f}{\partial x_1^2} \geq 0. \tag{1}$$

The mathematical results of this paper (Section 2) are the following: first we introduce a class of one-argument functions that is positive, non-decreasing and convex in its argument. Second, we use this new class of functions as a building block to design another class of functions that is a universal approximator for functions with positive outputs. Third, once again using the first class of functions, we design a third class that is a universal approximator to functions of two or more arguments, with the set of arguments partitioned in two groups: those arguments for which the second derivative is known positive and those arguments for which we have no prior knowledge on the second derivative. The first derivative is positive for any argument. The universality property of the third class rests on additional constraints on cross-derivatives, which we illustrate below for the case of two arguments:

$$\frac{\partial^2 f}{\partial x_1 \partial x_2} \geq 0, \quad \frac{\partial^3 f}{\partial x_1^2 \partial x_2} \geq 0. \tag{2}$$

Thus, we assume that $f \in \mathcal{C}^3$, the set of functions three times continuously differentiable. Comparative experiments on these new classes of functions were performed on stock option prices, showing improvements when using these new classes rather than ordinary feedforward neural networks. The improvements appear to be non-stationary but the new class of functions shows the most stable behavior in predicting future prices. Detailed experimental results are presented in section 6.

2. Theory

Definition 1 *A class of functions $\hat{\mathcal{F}}$ from $\mathbb{R}^n$ to $\mathbb{R}$ is a* **universal approximator** *for a class of functions $\mathcal{F}$ from $\mathbb{R}^n$ to $\mathbb{R}$ if for any $f \in \mathcal{F}$, any compact domain $D \subset \mathbb{R}^n$, and any positive ε, one can find a $\hat{f} \in \hat{\mathcal{F}}$ with* $\sup_{x \in D} |f(x) - \hat{f}(x)| \leq \varepsilon$.

It has already been shown that the class of artificial neural networks with one hidden layer:

$$\hat{\mathcal{N}} = \left\{ f(x) = w_0 + \sum_{i=1}^{H} w_i \cdot h\left(b_i + \sum_j v_{ij} x_j\right) \right\}, \tag{3}$$

for example, with a sigmoid activation function $h(s) = 1/(1+e^{-s})$, is a universal approximator of continuous functions (Cybenko, 1988, 1989; Hornik et al., 1989; Barron, 1993). Furthermore, Leshno et al. (1993) have shown that any non-polynomial activation function will suffice for universal approximation. The number of hidden units H of the neural network is a hyper-parameter that controls the accuracy of the approximation and it should be chosen to balance the trade-off (see also Moody, 1994) between accuracy (bias of the class of functions) and variance (due to the finite sample used to estimate the parameters of the model). Because of this trade-off, in the finite sample case, it may be advantageous to consider a “simpler” class of functions that is appropriate to the task.

Since the sigmoid h is monotonically increasing ($h'(s) = h(s)(1-h(s)) > 0$), it is easy to force the first derivatives with respect to x to be positive by forcing the weights to be positive, for example with the exponential function:

$$\hat{\mathcal{N}}_{+} = \left\{ f(x) = e^{w_0} + \sum_{i=1}^{H} e^{w_i} \cdot h\left(b_i + \sum_j e^{v_{ij}} x_j \right) \right\}. \tag{4}$$

Note that the positivity of $f(x)$ and $f'(x)$ is not affected by the values of the $\{b_i\}$ parameters. Since the sigmoid h has a positive first derivative, its primitive, which we call *softplus*, is convex:

$$\boxed{\zeta(s) = \ln(1+e^s)}$$

where $\ln(\cdot)$ is the natural logarithm operator. Note that $d\zeta(s)/ds = h(s) = 1/(1+e^{-s})$.

2.1 Universality for Functions with Positive Outputs

Using the softplus function introduced above, we define a new class of functions, all of which have positive outputs:

$$\hat{\mathcal{N}}_{>0} = \{f(x) = \zeta(g(x)), g(x) \in \hat{\mathcal{N}}\}.$$

Theorem 2 *Within the set of continuous functions from $\mathbb{R}^n$ to $\mathbb{R}_+ = \{x : x \in \mathbb{R}, x > 0\}$, the class $\hat{\mathcal{N}}_{>0}$ is a universal approximator.*

Proof Consider a positive function $f(x)$, which we want to approximate arbitrarily well. Consider $g(x) = \zeta^{-1}(f(x)) = \ln(e^{f(x)} - 1)$, the inverse softplus transform of $f(x)$. Choose $\hat{g}(x)$ from $\hat{\mathcal{N}}$ such that $\sup_{x \in D} |g(x) - \hat{g}(x)| \le \varepsilon$, where D is any compact domain over $\mathbb{R}^n$ and ε is any positive real number. The existence of $\hat{g}(x)$ is ensured by the universality property of $\hat{\mathcal{N}}$. Set $\hat{f}(x) = \zeta(\hat{g}(x)) = \ln(1+e^{\hat{g}(x)})$. Consider any particular x and define $a = \min(\hat{g}(x), g(x))$ and $b = \max(\hat{g}(x), g(x))$. Since $b - a \le \varepsilon$, we have,

$$\begin{aligned} |\hat{f}(x) - f(x)| &= \ln(1+e^b) - \ln(1+e^a) \\ &= \ln\left(1 + (e^b - e^a)/(1+e^a)\right) \\ &\le \ln\left(1 + (e^\varepsilon - 1)e^a/(1+e^a)\right) \\ &< \varepsilon. \end{aligned}$$

□

Thus, the use of the softplus function to transform the output of a regular one hidden layer artificial neural network ensures the positivity of the final output without hindering the universality property.

2.2 The Class ${}_{c,n}\hat{\mathcal{N}}_{++}$

In this section, we use the softplus function, in order to define a new class of functions with positive outputs, positive first derivatives w.r.t. all input variables and positive second derivatives w.r.t.

some of the input variables. The basic idea is to replace the sigmoid of a sum by a product of either softplus or sigmoid functions over each of the dimensions (using the softplus over the convex dimensions and the sigmoid over the others):

$$ {}_{c,n}\hat{\mathcal{N}}_{++} = \left\{ f(x) = e^{w_0} + \sum_{i=1}^{H} e^{w_i} \left(\prod_{j=1}^{c} \zeta(b_{ij} + e^{v_{ij}} x_j) \right) \left(\prod_{j=c+1}^{n} h(b_{ij} + e^{v_{ij}} x_j) \right) \right\}. \quad (5) $$

One can readily check that the output is necessarily positive, the first derivatives w.r.t. x_j are positive, and the second derivatives w.r.t. x_j for $j \le c$ are positive. However, this class of functions has other properties that are summarized by the following:

$$ \begin{aligned} \frac{\partial^m f}{\partial^{m_1} x_1 \partial^{m_2} x_2 \cdots \partial^{m_n} x_n} &\geq 0, \quad (6) \\ m_j &\in \begin{cases} \{0,1,2\} & 1 \le j \le c \\ \{0,1\} & c+1 \le j \le n, \end{cases} \\ \sum_{j=1}^{n} m_j &= m. \end{aligned} $$

Here, we have assumed that $f \in \mathcal{C}^{c+n}$, the set of functions that are $c+n$ times continuously differentiable. We will also restrict ourselves to Lispschitz functions since the proof of the theorem relies on the fact that the derivative of the function is bounded. The set of functions that respect these derivative conditions will be referred to as ${}_{c,n}\hat{\mathcal{F}}_{++}$. Note that, as special cases we find that f is positive ($m = 0$), and that it is monotonically increasing w.r.t. any of its inputs ($m = 1$), and convex w.r.t. the first c inputs ($m = 2, \exists j : m_j = 2$). Also note that, when applied to our particular case where $n = 2$ and $c = 1$, this set of equations corresponds to Equations (1) and (2). We now state the main universality theorem:

Theorem 3 *Within the set ${}_{c,n}\hat{\mathcal{F}}_{++}$ of Lipschitz functions from $\mathbb{R}^n$ to $\mathbb{R}$ whose set of derivatives as specified by Equation* (6) *are non-negative, the class ${}_{c,n}\hat{\mathcal{N}}_{++}$ is a universal approximator.*

The proof of the theorem is given in Section A.

2.3 Parameter Optimization

In our experiments, conjugate gradient descent was used to optimize the parameters of the model. The backpropagation equations are obtained as the derivatives of $f \in {}_{c,n}\hat{\mathcal{N}}_{++}$ (Equation 5) w.r.t. to its parameters. Let $z_{i,j} = b_{ij} + e^{v_{ij}} x_j$, $u_i = e^{w_i}(\prod_{j=1}^{c} \zeta(z_{i,j}))(\prod_{j=c+1}^{n} h(z_{ij}))$ and $f = e^{w_0} + \sum_{i=1}^{H} u_i$. Then, we have

$$ \begin{aligned} \partial f / \partial w_0 &= e^{w_0}, \\ \partial f / \partial w_i &= u_i, \\ \partial f / \partial b_{i,k} &= \begin{cases} u_i \cdot h(z_{i,k}) / \zeta(z_{i,k}) & 1 \le k \le c \\ u_i \cdot (1 - h(z_{i,k})) & c+1 \le k \le n, \end{cases} \quad (7) \\ \partial f / \partial v_{i,k} &= e^{v_{ik}} x_k \cdot \partial f / \partial b_{i,k}. \end{aligned} $$

Except for terms $h(z_{i,k})$, $k \le c$ of Equation (7), all values are computed through the forward phase, that is, while computing the value of f. Error backpropagation can thus be performed efficiently if careful attention is paid, during the forward phase, to store the values to be reused in the backpropagation phase.

Software implementing parameter optimization of the proposed architecture and the numerical experiments of the following section is available on-line.[2] Code was written using the "R" statistical software package.[3]

3. Experiments with Artificial Data

In this section, we present a series of controlled experiments in order to assess the potential improvements that can be gained from using the proposed architecture in cases where some derivatives of the target function are known to be positive. The emphasis is put on analyzing the evolution of the model bias and model variance values w.r.t. various noise levels and training set sizes.

The function we shall attempt to learn is

$$\begin{aligned} f(\vec{x}) &= \zeta(x_1)\zeta(x_2)\zeta(x_3)h(x_4), \\ y &= f(\vec{x}) + \xi, \end{aligned}$$

where $\zeta(\cdot)$ is the softplus function defined above and $h(\cdot)$ is the sigmoid function. The input values are drawn from a uniform distribution over the [0,1] interval, that is, $x_i \sim \mathcal{U}(0,1)$. The noise term ξ is added to the true function $f(\vec{x})$ to generate the target value y. Finally, $\xi \sim \mathcal{N}(0, \sigma^2)$, that is, we used additive Gaussian noise. Different values for σ have been tested.

For each combination of noise level ($\sigma \in \{$1e-2, 3e-2, 1e-1$\}$) and training set size (25, 50, 100, 200, 400), we chose the best performing combination of number of hidden units and weight decay. In order to perform model selection, 100 models were trained using different random training sets, for each combination. Based on validation set performance, 50 models were retained and their validation set performances were averaged. The best performing combination was chosen based on this average validation performance. Bias and variance were measured using these 50 selected models when applied on another testset of 10000 examples. In each case, the number of training epochs was 10000. The process was repeated for two architectures: the proposed architecture of products of softplus and sigmoid functions over input dimensions with constrained weights (CPSD) and regular unconstrained multi-layered perceptrons with a single hidden layer (UMLP).

In order to compute the bias and variance values, we first computed, for each test example, the average of the $N_D = 50$ model outputs:

$$\bar{g}(\vec{x}_i) = \frac{1}{N_D} \sum_{j=1}^{N_D} g_j(\vec{x}_i),$$

where $g_j(\vec{x}_i)$ is the output of the j^{th} model associated to the i^{th} input vector $\vec{x}_i$.

The variance was unbiasedly approximated as the average over all test examples ($N_i = 10000$), of the sample variance of model outputs $g_j(\vec{x}_i)$ w.r.t. the corresponding mean output $\bar{g}(\vec{x}_i)$:

$$\begin{aligned} \hat{v}(\vec{x}_i) &= \frac{1}{N_D - 1} \sum_{j=1}^{N_D} (g_j(\vec{x}_i) - \bar{g}(\vec{x}_i))^2, \\ \hat{v} &= \frac{1}{N_i} \sum_i \hat{v}(\vec{x}_i). \end{aligned}$$

2. Software can be found at `http://www.dms.umontreal.ca/~dugas/convex/`.
3. Code found at `http://www.r-project.org/`.

The bias was unbiasedly estimated as the average over all test examples, of the squared deviation of the mean output $\bar{g}(\vec{x}_i)$ w.r.t. the known true function value $f(\vec{x}_i)$, less a variance term:

$$\begin{aligned} \hat{b}(\vec{x}_i) &= (\bar{g}(\vec{x}_i) - f(\vec{x}_i))^2 - \hat{v}(\vec{x}_i)/N_D, \\ \hat{b} &= \frac{1}{N_i}\sum_i \hat{b}(\vec{x}_i). \end{aligned}$$

Let $b(\vec{x}_i) = (E_G(g(\vec{x}_i)) - f(\vec{x}_i))^2$ be the true bias, at point $\vec{x}_i$ where $E_G()$ denotes expectation taken over training set distribution, which induces a distribution of the function g produced by the learning algorithm. Let us show that $E_G(\hat{b}(\vec{x}_i)) = b(\vec{x}_i)$:

$$\begin{aligned} E_G(\hat{b}(\vec{x}_i)) &= E_G[(\bar{g}(\vec{x}_i) - f(\vec{x}_i))^2 - \hat{v}(\vec{x}_i)/N_D], \\ &= E_G[(\bar{g}(\vec{x}_i) - g(\vec{x}_i) + g(\vec{x}_i) - f(\vec{x}_i))^2] - v(\vec{x}_i)/N_D, \\ &= E_G[(\bar{g}(\vec{x}_i) - g(\vec{x}_i))^2] + E_G[(g(\vec{x}_i) - f(\vec{x}_i))^2] - v(\vec{x}_i)/N_D, \\ &= v(\vec{x}_i)/N_D + b(\vec{x}_i) - v(\vec{x}_i)/N_D, \\ &= b(\vec{x}_i). \end{aligned}$$

Table 1 reports the results for these simulations. In all cases, the bias and variance are lower for the proposed architecture than for a regular neural network architecture, which is the result we expected. The variance reduction is easy to understand because of the appropriate constraints on the class of functions. The bias reduction, we conjecture to be a side effect of the bias-variance tradeoff being performed by the model selection on the validation set: to achieve a lower validation error, a larger bias is needed with the unconstrained artificial neural network. The improvements are generally more important for smaller sample sizes. A possible explanation is that the proposed architecture helps reduce the variance of the estimator. With small sample sizes, this is very beneficial and becomes less important as the number of points increases.

4. Estimating Call Option Prices

An option is a contract between two parties that entitles the buyer to a claim at a future date T that depends on the future price, S_T of an underlying asset whose price at current time t is S_t. In this paper we consider the very common European call options, in which the buyer (holder) of the option obtains the right to buy the asset at a fixed price K called the strike price. This purchase can only occur at maturity date (time T). Thus, if at maturity, the price of the asset S_T is above the strike price K, the holder of the option can *exercise* his option and buy the asset at price K, then sell it back on the market at price S_T, thus making a profit of $S_T - K$. If, on the other hand, the price of the asset at maturity S_T is below the strike price K, then the holder of the option has no interest in exercising his option (and does not have to) and the option simply expires worthless and unexercised. For this reason, the option is considered to be worth $\max(0, S_T - K)$ at maturity and our goal is to estimate C_t, the value of that worth at current time t.

In the econometric literature, the call function is often expressed in terms of the primary economic variables that influence its value: the actual market price of the security (S_t), the strike price (K), the remaining time to maturity ($\tau = T - t$), the risk free interest rate (r), and the volatility of the return (σ). One important result is that under mild conditions, the call option function is homogeneous of degree one with respect to the strike price and so we can perform dimensionality reduction

Table 1: Comparison of the bias and variance values for two neural network architectures, three levels of noise, and five sizes of training sets (Ntrain), using artificial data. In bold, the best performance between the two models.

by letting our approximating function depend on the "moneyness" ratio ($M = S_t/K$) instead of the current asset price S_t and the strike price K independently. We must then modify the target to be the price of the option divided by the strike price: C_t/K.

Most of the research on call option modelling relies on strong parametric assumptions of the underlying asset price dynamics. Any misspecification of the stochastic process for the asset price will lead to systematic mispricings for any option based on the asset (Hutchinson et al., 1994). The well-known Black-Scholes formula (Black and Scholes, 1973) is a consequence of such specifications and other assumptions:

$$f(M,\tau,r,\sigma) \quad = \quad M\Phi(d_1) - e^{-r\tau}\Phi(d_2),$$

where $\Phi(\cdot)$ is the cumulative Gaussian function evaluated in points

$$d_1, d_2 \quad = \quad \frac{\ln M + (r \pm \sigma^2/2)\tau}{\sigma\sqrt{\tau}},$$

that is, $d_1 = d_2 + \sigma\sqrt{\tau}$. In particular, two assumptions on which this formula relies have been challenged by empirical evidence: the assumed lognormality of returns on the asset and the assumed constance of volatility over time.

On the other hand, nonparametric models such as neural networks do not rely on such strong assumptions and are therefore robust to model specification errors and their consequences on option modelling and this motivates research in the direction of applying nonparametric techniques for option modelling.

Analyzing the primary economic variables that influence the call option price, we note that the risk free interest rate (r) needs to be somehow extracted from the term structure of interest rates and the volatility (σ) needs to be forecasted. This latter task is a field of research in itself. Dugas et al. (2000) have previously tried to feed in neural networks with estimates of the volatility using historical averages but the gains have remained insignificant. We therefore drop these two features and rely on the ones that can be observed (S_t, K, τ) to obtain the following:

$$C_t/K \quad = \quad f(M,\tau).$$

The novelty of our approach is to account for properties of the call option function as stated in Equation (1). These properties derive from simple arbitrage pricing theory.[4] Now even though we know the call option function to respect these properties, we do not know if it does respect the additional cross derivative properties of Equation (2). In order to gain some insight in this direction, we confront the Black-Scholes formula to our set of constraints:

$$\frac{\partial f}{\partial M} \quad = \quad \Phi(d_1), \tag{8}$$

$$\frac{\partial^2 f}{\partial M^2} \quad = \quad \frac{\phi(d_1)}{\sqrt{\tau}M\sigma}, \tag{9}$$

$$\frac{\partial f}{\partial \tau} \quad = \quad e^{-r\tau}\left(\frac{\phi(d_2)\sigma}{2\sqrt{\tau}} + r\Phi(d_2)\right), \tag{10}$$

$$\frac{\partial^2 f}{\partial M \partial \tau} \quad = \quad \frac{\phi(d_1)}{2\sigma\tau^{3/2}}\left((r+\sigma^2/2)\tau - \ln M\right), \tag{11}$$

$$\frac{\partial^3 f}{\partial M^2 \partial \tau} \quad = \quad \frac{\phi(d_1)}{2M\sigma^3\tau^{5/2}}\left(\ln^2 M - \sigma^2\tau - (r+\sigma^2/2)^2\tau^2\right), \tag{12}$$

where $\phi(\cdot)$ is the Gaussian density function. Equations (8), (9) and (10) confirm that the Black-Scholes formula is in accordance with our prior knowledge of the call option function: all three

4. The convexity of the call option w.r.t. the moneyness is a consequence of the butterfly spread strategy (Garcia and Gençay, 1998).

derivatives are positive. Equations (11) and (12) are the cross derivatives which will be positive for any function chosen from ${}_{1,2}\hat{\mathcal{N}}_{++}$. When applied to the Black-Scholes formula, it is less clear whether these values are positive, too. In particular, one can easily see that both cross derivatives can not be simultaneously positive. Thus, the Black-Scholes formula is not within the set ${}_{1,2}\hat{\mathcal{F}}_{++}$. Then again, it is known that the Black-Scholes formula does not adequately represent the market pricing of options, but it is considered as a useful guide for evaluating call option prices. So, we do not know if these constraints on the cross derivatives are present in the true price function.

Nonetheless, even if these additional constraints are not respected by the true function on all of its domain, one can hope that the increase in the bias of the estimator due to the constraints will be offset (because we are searching in a smaller function space) by a decrease in the variance of that estimator and that overall, the mean-squared error will decrease. This strategy has often been used successfully in machine learning (e.g., regularization, feature selection, smoothing).

5. Experimental Setup

As a reference model, we use a simple multi-layered perceptron with one hidden layer (Equation 3). For **UMLP models**, weights are left unconstrained whereas for **CMLP models**, weights are constrained, through exponentiation, to be positive. We also compare our results with a recently proposed model (Garcia and Gençay, 1998) that closely resembles the Black-Scholes formula for option pricing (i.e., another way to incorporate possibly useful prior knowledge):

$$\begin{aligned} y &= \alpha + M \cdot \sum_{i=1}^{n_h} \beta_{1,i} \cdot h(\gamma_{i,0} + \gamma_{i,1} \cdot M + \gamma_{i,2} \cdot \tau) \\ &+ e^{-r\tau} \cdot \sum_{i=1}^{n_h} \beta_{2,i} \cdot h(\gamma_{i,3} + \gamma_{i,4} \cdot M + \gamma_{i,5} \cdot \tau), \end{aligned} \tag{13}$$

with inputs M, τ, parameters r, α, β, γ and hyperparameter n_h (number of hidden units). We shall refer to Equation (13) as the **UBS models**. Constraining the weights of Equation (13) through exponentiation leads to a different architecture we refer to as the **CBS models**.

We evaluate two new architectures incorporating all of the constraints defined in Equation (6). The proposed architecture involves the product of softplus and sigmoid functions over input dimensions, hence the **UPSD models** and **CPSD models** labels for an unconstrained version of the proposed architecture and the proposed constrained architecture, respectively. Finally, we also tested another architecture derived from the proposed one by simply summing, instead of multiplying, softplus and sigmoid functions. For that last architecture (with constrained weights), positivity, monotonicity and convexity properties are respected but in that case, cross-derivatives are all equal to zero. We do not have a universality proof for that specific class of functions. The unconstrained and constrained architectures are labelled as **USSD models** and **CSSD models**, respectively.

We used European call option data from 1988 to 1993. A total of 43518 transaction prices on European call options on the S&P500 index were used. In Section 6, we report results on 1988 data. In each case, we used the first two quarters of 1988 as a training set (3434 examples), the third quarter as a validation set (1642 examples) for model selection and the fourth quarter as a test set (each with around 1500 examples) for final generalization error estimation. In tables 2 and 3, we present results for networks with unconstrained weights on the left-hand side, and weights constrained to positive and monotone functions through exponentiation of parameters on the right-hand side. For each model, the number of hidden units varies from one to nine. The mean squared error results reported were obtained as follows: first, we randomly sampled the parameter space 1000 times. We picked the best (lowest training error) model and trained it up to 1000 more epochs. Repeating this procedure 10 times, we selected and averaged the performance of the best of these 10 models (those with training error no more than 10% worse than the best out of 10). In figure 1, we present tests of the same models on each quarter up to and including 1993 (20 additional test sets) in order to assess the persistence (conversely, the degradation through time) of the trained models.

6. Forecasting Results

As can be seen in tables 2 and 3, unconstrained architectures obtain better training, validation and testing (test 1) results but fail in the extra testing set (test 2). A possible explanation is that constrained architectures capture more fundamental relationships between variables and are more robust to nonstationarities of the underlying process. Constrained architectures therefore seem to give better generalization when considering longer time spans.

The importance in the difference in performance between constrained and unconstrained architectures on the second test set lead us to look even farther into the future and test the selected models on data from later years. In Figure 1, we see that the Black-Scholes similar constrained model performs slightly better than other models on the second test set but then fails on later quarters. All in all, at the expense of slightly higher initial errors our proposed architecture allows one to forecast with increased stability much farther in the future. This is a very welcome property as new derivative products have a tendency to lock in values for much longer durations (up to 10 years) than traditional ones.

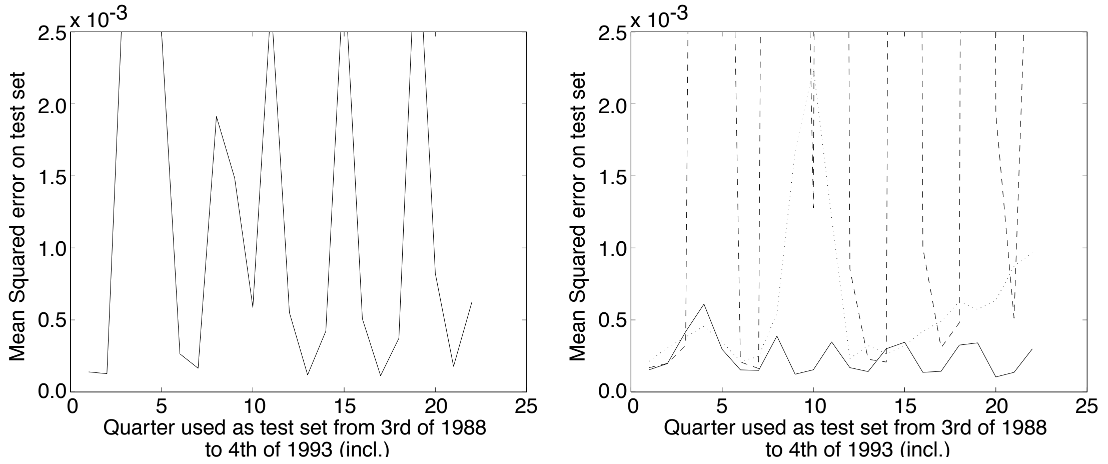

Figure 1: Out-of-sample results from the third quarter of 1988 to the fourth of 1993 (incl.) for models with best validation results. Left: unconstrained models; results for the UBS models. Other unconstrained models exhibit similar swinging result patterns and levels of errors. Right: constrained models. The proposed CPSD architecture (solid) does best. The model with sums over dimensions (CSSD) obtains similar results. Both CMLP (dotted) and CBS (dashed) models obtain poorer results. (dashed).

Table 2: Left: the parameters are free to take on negative values. Right: parameters are constrained through exponentiation so that the resulting function is both positive and monotone increasing everywhere w.r.t. both inputs as in Equation (4). Top: regular feedforward artificial neural networks. Bottom: neural networks with an architecture resembling the Black-Scholes formula as defined in Equation (13). The number of hidden units varies from 1 to 9 for each network architecture. The first two quarters of 1988 were used for training, the third of 1988 for validation and the fourth of 1988 for testing. The first quarter of 1989 was used as a second test set to assess the persistence of the models through time (figure 1). In bold: test results for models with best validation results.

In another series of experiments, we tested the unconstrained multi-layered perceptron against the proposed constrained products of softplus convex architecture using data from years 1988 through 1993 incl. For each year, the first two quarters were used for training, the third quarter for model selection (validation) and the fourth quarter for testing. We trained neural networks for 50000 epochs and with a number of hidden units ranging from 1 through 10. In Table 4, we report training, validation and test results for the two chosen architectures. Model selection was performed using the validation set in order to choose the best number of hidden units, learning rate, learning rate decrease and weight decay. In all cases, except for 1988, the proposed architecture outperformed the multi-layered perceptron model. This might explain why the proposed architecture did

not perform as well as other architectures on previous experiments using only data from 1988. Also note that the MSE obtained in 1989 is much higher. This is a possible explanation for the bad results obtained in tables 2 and 3 on the second test set. A hypothesis is that the process was undergoing nonstationarities that affected the forecasting performances. This shows that performance can vary by an order of magnitude from year to year and that forecasting in the presence of nonstationary processes is a difficult task.

7. Conclusions

Motivated by prior knowledge on the positivity of the derivatives of the function that gives the price of European options, we have introduced new classes of functions similar to multi-layer neural networks that have those properties. We have shown universal approximation properties for these classes. On simulation experiments, using artificial data sets, we have shown that these classes of functions lead to a reduction in the variance and the bias of the associated estimators. When applied

We also report the number of units chosen by the model selection process.

in empirical tests of option pricing, we showed that the architecture from the proposed constrained classes usually generalizes better than a standard artificial neural network.

Appendix A. Proof of the Universality Theorem for Class ${}_{c,n}\hat{\mathcal{N}}_{++}$

In this section, we prove theorem 2.2. In order to help the reader through the formal mathematics, we first give an outline of the proof, that is, a high-level informal overview of the proof, in Section A.1. Then, in Section A.2, we make use of two functions namely, the threshold $\theta(x) = I_{x\geq 0}$ and positive part $x_+ = \max(0,x)$ functions. These two functions are part of the closure of the set ${}_{c,n}\hat{\mathcal{N}}_{++}$ since

$$\begin{aligned} \theta(x) &= \lim_{t\to\infty} h(tx), \\ x_+ &= \lim_{t\to\infty} \zeta(tx). \end{aligned}$$

This extended class of functions that includes $\theta(x)$ and x_+ shall be referred to as ${}_{c,n}\hat{\mathcal{N}}^{\infty}_{++}$. In Section A.3, we give an illustration of the constructive algorithm used to prove universal approximation. Now the proof, as it is stated in Section A.2, only involves functions $\theta(x)$ and x_+, that is, the limit cases of the class ${}_{c,n}\hat{\mathcal{N}}^{\infty}_{++}$ which are actually not part of class ${}_{c,n}\hat{\mathcal{N}}_{++}$. Functions $\theta(x)$ and x_+ assume the use of parameters of infinite value, making the proof without any practical bearing. For this reason, in Section A.4, we broaden the theorem's application from ${}_{c,n}\hat{\mathcal{N}}^{\infty}_{++}$ to ${}_{c,n}\hat{\mathcal{N}}_{++}$, building upon the proof of Section A.2.

A.1 Outline of the Proof

The proof of the first main part (Section A.2) works by construction: we start by setting the approximating function equal to a constant function. Then, we build a grid over the domain of interest and scan through it. At every point of the grid we add a term to the approximating function. This term is a function itself that has zero value at every point of the grid that has already been visited. Thus, this term only affects the current point being visited and some of the points to be visited. The task is therefore to make sure the term being added is such that the approximating function matches the actual function at the point being visited. The functions to be added are chosen from the set ${}_{c,n}\hat{\mathcal{N}}^{\infty}_{++}$ so that each of them individually respects the constraints on the derivatives. The bulk of the work in the proof is to show that, throughout the process, at each scanned point, we need to add a positive term to match the approximating function to the true function. For illustrative purposes, we consider the particular case of call options of Section A.3.

In the second part (Section A.4), we build upon the proof of the first part. The same constructive algorithm is used with the same increment values. We simply consider sigmoidal and softplus functions that are greater or equal, in every point, than their limit counterparts, used in the first part. Products of these softplus and sigmoidal functions are within ${}_{c,n}\hat{\mathcal{N}}_{++}$. Consequently, the function built here is always greater than or equal to its counterpart of the first main part. The main element of the second part is that the difference between these two functions, *at gridpoints*, is capped. This is done by setting the sigmoid and softplus parameter values appropriately. Universality of approximation follows from (1) the capped difference, at gridpoints, between the functions obtained in the first and second parts, (2) the exact approximation obtained at gridpoints in the first part and (3) the bounded function variation between gridpoints.

A.2 Proof of the Universality Theorem for Class ${}_{c,n}\hat{\mathcal{N}}^{\infty}_{++}$

Let D be the compact domain over which we wish to obtain an approximation error below ε in every point. Suppose the existence of an oracle allowing us to evaluate the function in a certain number of points. Let T be the smallest hyperrectangle encompassing D. Let us partition T in hypercubes with sides of length L so that the variation of the function between two arbitrary points of any hypercube is bounded by $\varepsilon/2$. For example, given s, an upper bound on the derivative of the function in any direction, setting $L \leq \frac{\varepsilon}{2s\sqrt{n}}$ would do the trick. Since we have assumed the function to be approximated is Lipschitz, then its derivative is bounded and s does exist. The number of gridpoints is N_1+1 over the x_1 axis, N_2+1 over the x_2 axis, ..., N_n+1 over the x_n axis. Thus, the number of points on the grid formed within T is $H=(N_1+1)\cdot(N_2+1)\cdot\ldots\cdot(N_n+1)$. We define gridpoints $\vec{a}=(a_1,a_2,\cdots,a_n)$ and $\vec{b}=(b_1,b_2,\cdots,b_n)$ as the innermost (closest to origin) and outermost corners of T, respectively. Figure 2 illustrates these values. The points of the grid are defined as:

$$\begin{aligned}
\vec{p}_1 &= a, \\
\vec{p}_2 &= (a_1, a_2, \ldots, a_n + L), \\
\vec{p}_{N_n+1} &= (a_1, a_2, \ldots, b_n), \\
\vec{p}_{N_n+2} &= (a_1, a_2, \ldots a_{n-1} + L, a_n), \\
\vec{p}_{N_n+3} &= (a_1, a_2, \ldots a_{n-1} + L, a_n + L), \ldots, \\
\vec{p}_{(N_n+1)(N_{n-1}+1)} &= (a_1, a_2, \ldots, a_{n-2}, b_{n-1}, b_n), \\
\vec{p}_{(N_n+1)(N_{n-1}+1)+1} &= (a_1, a_2, \ldots, a_{n-2} + L, a_{n-1}, a_n), \ldots, \\
\vec{p}_H &= b. \qquad (14)
\end{aligned}$$

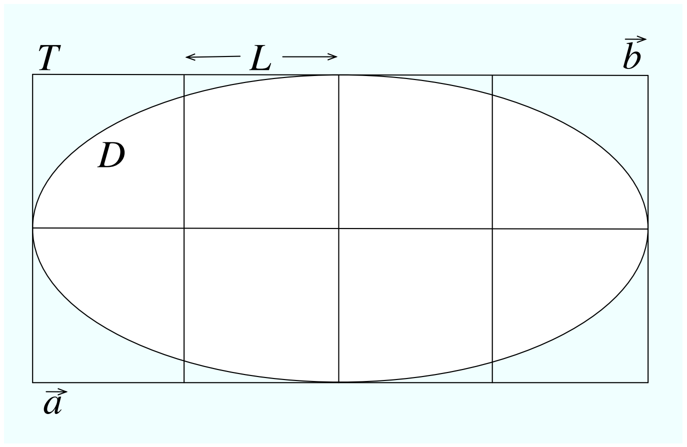

Figure 2: Two dimensional illustration of the proof of universality: ellipse D corresponds to the domain of observation over which we wish to obtain a universal approximator. Rectangle T encompasses D and is partitioned in squares of length L. Points $\vec{a}$ and $\vec{b}$ are the innermost (closest to origin) and outermost corners of T, respectively.

We start with an approximating function $\hat{f}_0 = f(\vec{a})$, that is, the function $\hat{f}_0$ is initially set to a constant value equal to $f(\vec{a})$ over the entire domain. Note that, for the remainder of the proof, notations $\hat{f}_h$, f_h, $\hat{g}_h$, without any argument, refer to the functions themselves. When an argument is present, such as in $f_h(\vec{p})$, we refer to the value of the function f_h evaluated at point $\vec{p}$.

After setting $\hat{f}_0$ to its initial value, we scan the grid according to the order defined in Equation (14). At each point along the grid, we add a term ($\hat{g}_h$, a function) to the current approximating function so that it becomes exact at point $\{\vec{p}_h\}$:

$$\begin{aligned}
\hat{f}_h &= \hat{g}_h + \hat{f}_{h-1}, \\
&= \sum_{k=0}^{h} \hat{g}_k,
\end{aligned}$$

where we have set $\hat{g}_0 = \hat{f}_0$.

The functions $\hat{f}_h$, $\hat{g}_h$ and $\hat{f}_{h-1}$ are defined over the whole domain and the increment function $\hat{g}_h$ must be such that at point $\vec{p}_h$, we have $\hat{f}_h(\vec{p}_h) = f(\vec{p}_h)$. We compute the constant term δ_h as the difference between the value of the function evaluated at point $\vec{p}_h$, $f(\vec{p}_h)$, and the value of the currently accumulated approximating function at the same point $\hat{f}_{h-1}(\vec{p}_h)$:

$$\delta_h = f(\vec{p}_h) - \hat{f}_{h-1}(\vec{p}_h).$$

Now, the function $\hat{g}_h$ must not affect the value of the approximating function at gridpoints that have already been visited. According to our sequencing of the gridpoints, this corresponds to having $\hat{g}_h(\vec{p}_k) = 0$ for $0 < k < h$. Enforcing this constraint ensures that $\forall k \leq h$, $\hat{f}_h(\vec{p}_k) = \hat{f}_k(\vec{p}_k) = f(\vec{p}_k)$. We define

$$\hat{\beta}_h(\vec{p}_k) = \prod_{j=1}^{c} (p_k(j) - p_h(j) + L)_+ / L \cdot \prod_{j=c+1}^{n} \theta(p_k(j) - p_h(j)), \tag{15}$$

where $p_k(j)$ is the j^{th} coordinate of $\vec{p}_k$ and similarly for $\vec{p}_h$. We have assumed, without loss of generality, that the convex dimensions are the first c ones. One can readily verify that $\hat{\beta}_h(\vec{p}_k) = 0$ for $0 < k < h$ and $\hat{\beta}_h(\vec{p}_h) = 1$. We can now define the incremental function as:

$$\hat{g}_h(\vec{p}) = \delta_h \hat{\beta}_h(\vec{p}), \tag{16}$$

so that after all gridpoints have been visited, our final approximation is

$$\hat{f}_H(\vec{p}) = \sum_{h=0}^{H} \hat{g}_h(\vec{p}),$$

with $f(\vec{p}) = \hat{f}_H(\vec{p})$ for all gridpoints.

So far, we have devised a way to approximate the target function as a sum of terms from the set ${}_{c,n}\hat{\mathcal{N}}_{++}^{\infty}$. We know our approximation to be exact in every point of a grid and that the grid is tight enough so that the approximation error is bounded above by $\varepsilon/2$ anywhere within T (thus within D): take any point $\vec{q}$ within a hypercube. Let $\vec{q}_1$ and $\vec{q}_2$ be the innermost (closest to origin) and outermost gridpoints of $\vec{q}$'s hypercube, respectively. Then, we have $f(\vec{q}_1) \leq f(\vec{q}) \leq f(\vec{q}_2)$ and, *assuming* $\delta_h \geq 0\ \forall h$, $f(\vec{q}_1) = \hat{f}_H(\vec{q}_1) \leq \hat{f}_H(\vec{q}) \leq \hat{f}_H(\vec{q}_2) = f(\vec{q}_2)$. Thus, $|\hat{f}_H(\vec{q}) - f(\vec{q})| \leq |f(\vec{q}_2) - f(\vec{q}_1)| \leq Ls\sqrt{n} \leq \varepsilon/2$, since we have set $L \leq \frac{\varepsilon}{2s\sqrt{n}}$. And there remains to be shown that, effectively, $\delta_h \geq 0\ \forall h$. In order to do so, we will express the target function at gridpoint $\vec{p}_h$, $f(\vec{p}_h)$ in terms of the δ_k coefficients ($0 < k \leq h$), then solve for δ_h and show that it is necessarily positive.

First, let $p_k(j) = a(j) + \vec{\iota}_k(j)L$ and define $\vec{\iota}_k = (i_k(1), i_k(2), \ldots, i_k(n))$ so that $\vec{p}_k = \vec{a} + L \cdot \vec{\iota}_k$. Now, looking at Equations (15) and (16), we see that $\hat{g}_k(\vec{p})$ is equal to zero if, for any j, $p_k(j) > p(j)$. Conversely, $\hat{g}_k(\vec{p})$ can only be different from zero if $p_k(j) \leq p(j), \forall j$ or, equivalently, if $i_k(j) \leq i(j), \forall j$.

Next, in order to facilitate the derivations to come, it will be convenient to define some subsets of $\{1, 2, \ldots, H\}$, the indices of the gridpoints of T. Given index h, define $Q_{h,l} \subset \{1, 2, \ldots, H\}$ as

$$Q_{h,l} = \{k : i_k(j) \leq i_h(j) \text{ if } j \leq l \text{ and } i_k(j) = i_h(j) \text{ if } j > l\}.$$

In particular, $Q_{h,n} = \{k : i_k(j) \le i_h(j) \forall j\}$ and $Q_{h,0} = \{h\}$. Thus, we have

$$\begin{aligned}
f(\vec{p}_h) &= \hat{f}_H(\vec{p}_h) \\
&= \sum_{k \in Q_{h,n}} \hat{g}_k(\vec{p}_h) \\
&= \sum_{k \in Q_{h,n}} \delta_k \prod_{j=1}^{c} (i_h(j) - i_k(j) + 1)_+ \prod_{j=c+1}^{n} \theta(i_h(j) - i_k(j)) \\
&= \sum_{k \in Q_{h,n}} \delta_k \prod_{j=1}^{c} (i_h(j) - i_k(j) + 1). && (17)
\end{aligned}$$

Now, let us define the finite difference of the function along the l^{th} axis as

$$\Delta_l f(\vec{p}_h) \quad = \quad f(\vec{p}_h) - f(\vec{p}_{h_l}), \qquad (18)$$

where $\vec{p}_{h_l}$ is the neighbor of $\vec{p}_h$ on T with all coordinates equal except along the l^{th} axis where $i_{h_l}(l) = i_h(l) - 1$. The following relationship shall be useful:

$$\begin{aligned}
Q_{h,l} \backslash Q_{h_l,l} &= \{k : i_k(j) \le i_h(j) \text{ if } j < l, i_k(l) \le i_h(l) \text{ and } i_k(j) = i_h(j) \text{ if } j > l\} \backslash \\
&\quad \{k : i_k(j) \le i_h(j) \text{ if } j < l, i_k(l) < i_h(l) \text{ and } i_k(j) = i_h(j) \text{ if } j > l\} \\
&= \{k : i_k(j) \le i_h(j) \text{ if } j \le l-1 \text{ and } i_k(j) = i_h(j) \text{ if } j > l-1\} \\
&= Q_{h,l-1}. && (19)
\end{aligned}$$

We now have the necessary tools to solve for δ_h by differentiating the target function. Using Equations (17), (18) and (19) we get:

$$\begin{aligned}
\Delta_n f(\vec{p}_h) &= \sum_{k \in Q_{h,n}} \delta_k \prod_{j=1}^{c} (i_h(j) - i_k(j) + 1) \\
&\quad - \sum_{k \in Q_{h_n,n}} \delta_k \prod_{j=1}^{c} (i_{h_n}(j) - i_k(j) + 1).
\end{aligned}$$

Since $i_{h_n}(j) = i_h(j)$ for $j \le c$, then

$$\Delta_n f(\vec{p}_h) \quad = \quad \sum_{k \in Q_{h,n-1}} \delta_k \prod_{j=1}^{c} (i_h(j) - i_k(j) + 1).$$

This process is repeated for non-convex dimensions $n-1, n-2, \ldots, c+1$ until we obtain

$$\Delta_{c+1} \ldots \Delta_n f(\vec{p}_h) \quad = \quad \sum_{k \in Q_{h,c}} \delta_k \prod_{j=1}^{c} (i_h(j) - i_k(j) + 1),$$

at which point we must consider differentiating with respect to convex dimensions:

$$\begin{aligned}\Delta_c \ldots \Delta_n f(\vec{p}_h) &= \sum_{k \in Q_{h,c}} \delta_k \prod_{j=1}^{c} (i_h(j) - i_k(j) + 1) \\ &\quad - \sum_{k \in Q_{h_c,c}} \delta_k \prod_{j=1}^{c} (i_{h_c}(j) - i_k(j) + 1) \\ &= \sum_{k \in Q_{h,c}} \delta_k (i_h(c) - i_k(c) + 1) \prod_{j=1}^{c-1} (i_h(j) - i_k(j) + 1) \\ &\quad - \sum_{k \in Q_{h_c,c}} \delta_k (i_h(c) - i_k(c)) \prod_{j=1}^{c-1} (i_h(j) - i_k(j) + 1).\end{aligned}$$

According to Equation (19), $Q_{h,c} \backslash Q_{h_c,c} = Q_{h,c-1}$ and by definition $i_k(c) - i_h(c) = 0 \; \forall k \in Q_{h,c-1}$. Using this, we subtract a sum of zero terms from the last equation in order to simplify the result:

$$\begin{aligned}\Delta_c \ldots \Delta_n f(\vec{p}_h) &= \sum_{k \in Q_{h,c}} \delta_k (i_h(c) - i_k(c) + 1) \prod_{j=1}^{c-1} (i_h(j) - i_k(j) + 1) \\ &\quad - \sum_{k \in Q_{h_c,c}} \delta_k (i_h(c) - i_k(c)) \prod_{j=1}^{c-1} (i_h(j) - i_k(j) + 1) \\ &\quad - \sum_{k \in Q_{h,c-1}} \delta_k (i_h(c) - i_k(c)) \prod_{j=1}^{c-1} (i_h(j) - i_k(j) + 1) \\ &= \sum_{k \in Q_{h,c}} \delta_k (i_h(c) - i_k(c) + 1) \prod_{j=1}^{c-1} (i_h(j) - i_k(j) + 1) \\ &\quad - \sum_{k \in Q_{h,c}} \delta_k (i_h(c) - i_k(c)) \prod_{j=1}^{c-1} (i_h(j) - i_k(j) + 1) \\ &= \sum_{k \in Q_{h,c}} \delta_k \prod_{j=1}^{c-1} (i_h(j) - i_k(j) + 1).\end{aligned}$$

Differentiating once again with respect to dimension c:

$$\begin{aligned}\Delta_c^2 \ldots \Delta_n f(\vec{p}_h) &= \sum_{k \in Q_{h,c}} \delta_k \prod_{j=1}^{c-1} (i_h(j) - i_k(j) + 1) \\ &\quad - \sum_{k \in Q_{h_c,c}} \delta_k \prod_{j=1}^{c-1} (i_{h_c}(j) - i_k(j) + 1).\end{aligned}$$

and since $i_{h_c}(j) = i_h(c) \forall j \leq c-1$, then

$$\Delta_c^2 \ldots \Delta_n f(\vec{p}_h) = \sum_{k \in Q_{h,c-1}} \delta_k \prod_{j=1}^{c-1} (i_h(j) - i_k(j) + 1).$$

This process of differentiating twice is repeated for all convex dimensions so that

$$\begin{aligned}\Delta_1^2 \dots \Delta_c^2 \Delta_{c+1} \dots \Delta_n f(\vec{p}_h) &= \sum_{k \in Q_{h,0}} \delta_k. \\ &= \delta_h\end{aligned}$$

Now, by definition of the integral operator,

$$\Delta f = \tfrac{f(b)-f(a)}{b-a} = \frac{1}{b-a} \int_a^b f' \, dx,$$

so that if $f' \geq 0$ over the range $[a,b]$, then consequently, $\Delta f \geq 0$. Since, according to Equation (6), we have

$$\frac{\partial^{n+c} f(p_h)}{\partial x_1^2 \partial x_2^2 \dots \partial x_c^2 \partial x_{c+1} \dots \partial x_n} \geq 0,$$

then $\Delta_1^2 \dots \Delta_c^2 \Delta_{c+1} \dots \Delta_n f(\vec{p}_h) \geq 0$ and $\delta_h \geq 0$.

For gridpoints with either $i_h(j) = 1$ for any j or with $i_h(j) = 2$ for any $j \leq c$, solving for δ_h requires fewer than $n+c$ differentiations. Since the positivity of the derivatives of f corresponding to these lower order differentiations are covered by Equation (6), then we also have that $\delta_h \geq 0$ for these gridpoints laying at or near some of the boundaries of T. Thus, ${}_{c,n}\hat{\mathcal{N}}_{++}^{\infty}$ is a universal approximator of ${}_{c,n}\hat{\mathcal{F}}_{++}$.

$\square$

A.3 Illustration of the Constructive Algorithm

In order to give the reader a better intuition regarding the constructive algorithm and as how to solve for δ_h, we apply the developments of the previous subsection to ${}_{1,2}\hat{\mathcal{N}}_{++}$, the set of functions that include call price functions, that is, positive convex w.r.t. the first variable and monotone increasing w.r.t. both variables. Figure 3 illustrates the two dimensional setting of our example with the points of the grid labelled in the order in which they are scanned according the constructive procedure. Here, we will solve δ_6.

For the set ${}_{1,2}\hat{\mathcal{N}}_{++}$, we have,

$$f(\vec{p}_h) = \sum_{k=1}^{H} \delta_k \cdot (p_h(1) - p_k(1) + L)_+ \cdot \theta(p_h(2) - p_k(2)).$$

Applying this to the six gridpoints of Figure 3, we obtain $f(\vec{p}_1) = \delta_1$, $f(\vec{p}_2) = (\delta_1 + \delta_2)$, $f(\vec{p}_3) = (2\delta_1 + \delta_3)$, $f(\vec{p}_4) = (2\delta_1 + 2\delta_2 + \delta_3 + \delta_4)$, $f(\vec{p}_5) = (3\delta_1 + 2\delta_3 + \delta_5)$, $f(\vec{p}_6) = (3\delta_1 + 3\delta_2 + 2\delta_3 + 2\delta_4 + \delta_5 + \delta_6)$.

Differentiating w.r.t. the second variable, then the first, we have:

$$\begin{aligned}\Delta_2 f(\vec{p}_6) &= f(\vec{p}_6) - f(\vec{p}_5) \\ \Delta_1 \Delta_2 f(\vec{p}_6) &= (f(\vec{p}_6) - f(\vec{p}_5)) - (f(\vec{p}_4) - f(\vec{p}_3)) \\ \Delta_1^2 \Delta_2 f(\vec{p}_6) &= (f(\vec{p}_6) - f(\vec{p}_5)) - (f(\vec{p}_4) - f(\vec{p}_3)) \\ &\quad - (f(\vec{p}_4) - f(\vec{p}_3)) + (f(\vec{p}_2) - f(\vec{p}_1)) \\ &= \delta_6.\end{aligned}$$

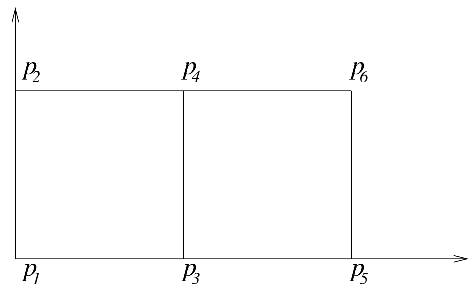

Figure 3: Illustration in two dimensions of the constructive proof. The points are labelled according to the order in which they are visited. The function is known to be convex w.r.t. to the first variable (abscissa) and monotone increasing w.r.t. both variables.

The conclusion associated with this result is that the third finite difference of the function must be positive in order for δ_6 to be positive as well. As stated above, enforcing the corresponding derivative to be positive is a stronger condition which is respected by all element functions of ${}_{c,n}\hat{\mathcal{N}}_{++}$. In the illustration above, other increment terms (δ_1 through δ_5) can be solved for with fewer differentiations. As mention in the previous subsection, derivatives associated to these lower order differentiations are all positive.

A.4 Proof of the Universality Theorem for Class ${}_{c,n}\hat{\mathcal{N}}_{++}$

In Section A.2, we obtained an approximating function $\hat{f}_H \in {}_{c,n}\hat{\mathcal{N}}^{\infty}_{++}$ such that $|\hat{f}_H - f| \leq \varepsilon/2$. Here, we will build a function $\tilde{f}_H \in {}_{c,n}\hat{\mathcal{N}}_{++}$ everywhere greater or equal to $\hat{f}_H$, but we will show how the difference between the two functions can be bounded so that $\tilde{f}_H - \hat{f}_H \leq \varepsilon/2$ at all gridpoints.

We start with an approximating function $\tilde{f}_0 = \hat{f}_0 = f(\vec{a})$, that is, $\tilde{f}_0$ is initially set to a constant value equal to $f(\vec{a})$ over the entire domain. Then, we scan the grid in an orderly manner, according to the definition of the set of points $\{\vec{p}_h\}$. At each point $\vec{p}_h$ along the grid, we add a term $\tilde{g}_h$ (a function) to the current approximating function $\tilde{f}_{h-1}$:

$$\begin{aligned}\tilde{f}_h &= \tilde{g}_h + \tilde{f}_{h-1}\\ &= \sum_{k=1}^{h} \tilde{g}_k\\ &= \sum_{k=1}^{h} \delta_k \tilde{\beta}_k,\end{aligned}$$

where the δ_k are kept equal to the ones found in Section A.2 and we define the set of $\tilde{\beta}_k$ functions as a product of sigmoid and softplus functions, one for each input dimension:

$$\tilde{\beta}_h(\vec{p}) = \prod_{j=1}^{n} \tilde{\beta}_{h,j}(\vec{p}).$$

For each of the convex coordinates, we set:

$$\tilde{\beta}_{h,j}(\vec{p}) = \frac{1}{\alpha}\zeta(\alpha \cdot (p(j) - p_h(j) + L)). \tag{20}$$

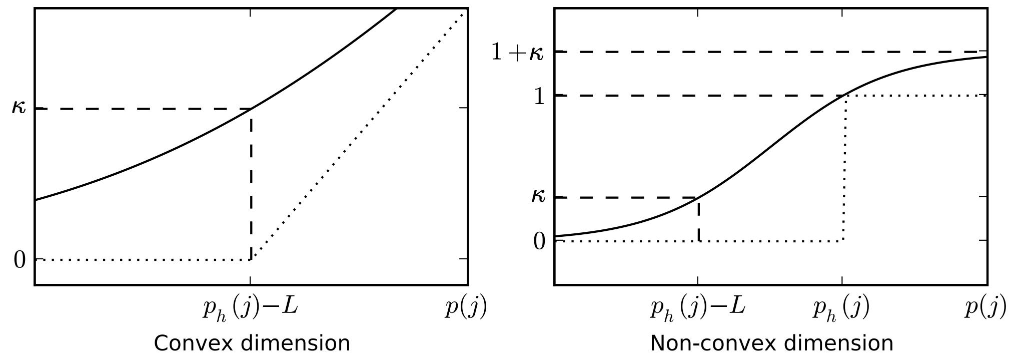

Figure 4: Illustration of the difference between $\tilde{\beta}_{h,j}$ (solid) and $\hat{\beta}_{h,j}$ (dotted) for convex (left) and non-convex (right) dimensions.

where $\alpha > 0$. Now, note that κ, the maximum of the difference between the softplus function of Equation (20) and the positive part function $\hat{\beta}_{h,j}(\vec{p}) = (p(j) - p_h(j) + L)_+$, is attained for $p(j) = p_h(j) - L$ where the difference is $\ln 2/\alpha$. Thus, in order to cap the difference resulting from the approximation along the convex dimensions, we simply need to set κ (α) to a small (large) enough value which we shall soon define. Let us now turn to the non-convex dimensions where we set:

$$\tilde{\beta}_{h,j}(\vec{p}) \quad = \quad (1+\kappa)\, h(\gamma \cdot p(j) + \eta)$$

and add two constraints:

$$\begin{aligned} h(\gamma(p_h(j) - L) + \eta) &= \frac{\kappa}{1+\kappa}, \\ h(\gamma \cdot p_h(j) + \eta) &= \frac{1}{1+\kappa}. \end{aligned}$$

Solving for γ and η, we obtain:

$$\gamma \quad = \quad -\frac{2}{L}\ln\kappa, \tag{21}$$

$$\eta \quad = \quad \left(\frac{2p_h(j)}{L} - 1\right)\ln\kappa. \tag{22}$$

For non-convex dimensions, we have $\hat{\beta}_{h,j}(\vec{p}) = \theta(p(j) - p_h(j))$. Thus, for values of $p(j)$ such that $p_h(j) - L < p(j) < p_h(j)$, we have a maximum difference $\tilde{\beta}_{h,j} - \hat{\beta}_{h,j}$ of 1. For other values of $p(j)$, the difference is capped by κ. In particular, the difference is bounded above by κ for all gridpoints and is zero for gridpoints with $p(j) = p_h(j)$. These values are illustrated in Figure 4.

We now compare incremental terms. Our goal is to cap the difference between $\tilde{g}_h$ and $\hat{g}_h$ by $\varepsilon/2H$. This will lead us to bound the value of κ. At gridpoints, $\hat{\beta}_h$ is equal to

$$\hat{\beta}_h \quad = \quad \prod_{j=1}^{n} m_j,$$

where $m_j \in \{0,1\}$ along non-convex dimensions and m_j is equal to a non-negative integer along the convex dimensions. Also, since $\tilde{\beta}_{h,j} - \hat{\beta}_{h,j} \leq \kappa$ at gridpoints, then

$$\tilde{\beta}_h \leq \prod_{j=1}^{n}(m_j+\kappa).$$

In order find a bound on the value of κ, we need to consider two cases. First, consider the case where $m_j > 0 \,\forall j$:

$$\begin{aligned}
\tilde{g}_h - \hat{g}_h &\leq \delta_h\left(\prod_{j=1}^{n}(m_j+\kappa) - \prod_{j=1}^{n} m_j\right)\\
&\leq \delta_h\left(\prod_{j=1}^{n} m_j(1+\kappa) - \prod_{j=1}^{n} m_j\right)\\
&= \delta_h((1+\kappa)^n - 1)\prod_{j=1}^{n} m_j\\
&\leq \delta_h((1+\kappa)^n - 1)\prod_{j=1}^{n}(N_j+1)\\
&\leq \varepsilon((1+\kappa)^n - 1)H.
\end{aligned}$$

In that case, we have $\tilde{g}_h - \hat{g}_h < \varepsilon/2H$ if

$$\kappa \leq (1/2H^2+1)^{1/n} - 1. \tag{23}$$

Now, consider cases where $\exists j : m_j = 0$. Let $d = \#\{j : m_j = 0\}$. Then,

$$\begin{aligned}
\tilde{g}_h - \hat{g}_h &\leq \delta_h\left(\prod_{j=1}^{n}(m_j+\kappa) - \prod_{j=1}^{n} m_j\right)\\
&\leq \delta_h\kappa^d \prod_{m_j\neq 0}(N_j+1)(1+\kappa)\\
&\leq \delta_h\kappa^d(1+\kappa)^{n-d}H\\
&\leq \varepsilon\kappa^d 2^{n-d}H\\
&\leq \varepsilon\kappa 2^{n-1}H,
\end{aligned}$$

so that here, the bound on κ is:

$$\kappa \leq \frac{1}{2^n H^2}. \tag{24}$$

Depending on the relative values of n and H, one of the two bounds may be effective so that both values of Equations (23) and (24) must be considered in order to set an upper bound on κ:

$$\kappa \leq \min\left((1/2H^2+1)^{1/n} - 1, \frac{1}{2^n H^2}\right).$$

Values for $\alpha = \ln 2/\kappa, \gamma$, and η (Equations 21 and 22) are derived accordingly.

Thus, for any gridpoint, we have:

$$\begin{aligned} \tilde{f}_h - \hat{f}_h &= \sum_{k=1}^{H} \tilde{g}_h - \hat{g}_h \\ &\leq H \cdot \varepsilon/2H \\ &= \varepsilon/2. \end{aligned}$$

In Section A.2, we developed an algorithm such that $\hat{f} = f$ for any gridpoint. In this present subsection, we showed that softplus and sigmoid parameters could be chosen such that $\hat{f} \leq \tilde{f} \leq \hat{f} + \varepsilon/2$ for any gridpoint. Note that $f, \hat{f}$, and $\tilde{f}$ are increasing along each input dimension.

As in Section A.2, consider any point $\vec{q} \in D$. Let $\vec{q}_1$ and $\vec{q}_2$ be the innermost and outermost gridpoints of $\vec{q}$'s encompassing hypercube of side length L. In Section A.2, we showed how a grid could be made tight enough so that $f(\vec{q}_2) - f(\vec{q}_1) \leq \varepsilon/2$.

With these results at hand, we can set upper and lower bounds on $\tilde{f}(\vec{q})$. First, observe that $\tilde{f}_H(\vec{q}) \geq \tilde{f}_H(\vec{q}_1) \geq \hat{f}_H(\vec{q}_1) = f(\vec{q}_1)$, which provides us with a lower bound on $\tilde{f}_H(\vec{q})$. Next, for the upper bound we have: $\tilde{f}_H(\vec{q}) \leq \tilde{f}_H(\vec{q}_2) \leq \hat{f}_H(\vec{q}_2) + \varepsilon/2 = f(\vec{q}_2) + \varepsilon/2 \leq f(\vec{q}_1) + \varepsilon$. Thus, $\tilde{f}_H(\vec{q}) \in [f(\vec{q}_1), f(\vec{q}_1) + \varepsilon]$ and $f(\vec{q}) \in [f(\vec{q}_1), f(\vec{q}_1) + \varepsilon/2] \subset [f(\vec{q}_1), f(\vec{q}_1) + \varepsilon]$. Since both $f(\vec{q})$ and $\tilde{f}(\vec{q})$ are within a range of length ε, then $|\tilde{f}(\vec{q}) - f(\vec{q})| \leq \varepsilon$.

$\square$

Abstract

Bayesian inference is intractable for many interesting models, making deterministic algorithms for approximate inference highly desirable. Unlike stochastic methods, which are exact in the limit, the accuracy of these approaches cannot be reasonably judged. In this paper we show how low order perturbation corrections to an expectation-consistent (EC) approximation can provide the necessary tools to ameliorate inference accuracy, and to give an indication of the quality of approximation without having to resort to Monte Carlo methods. Further comparisons are given with variational Bayes and parallel tempering (PT) combined with thermodynamic integration on a Gaussian mixture model. To obtain practical results we further generalize PT to temper from arbitrary distributions rather than a prior in Bayesian inference.

Keywords: Bayesian inference, mixture models, expectation propagation, expectation consistent, perturbation correction, variational Bayes, parallel tempering, thermodynamic integration

1. Introduction

Approximate methods for Bayesian inference have recently enjoyed a limelight of attention. These methods can be either deterministic or stochastic. Deterministic methods, which typically turn integration and summation problems of Bayesian marginalization into optimization problems, include the Laplace approximation, mean field (or variational) methods like variational Bayes (VB), expectation propagation (EP), and expectation consistent (EC) and Bethe/Kikuchi approximations (also known as loopy belief propagation or generalized belief propagation). Their attraction lies in the precise but tractable inferences that they typically provide, but their drawback is the lack of a built-in sanity check, as we cannot assess the approximation error. Stochastic methods like Markov chain Monte Carlo (MCMC) algorithms, which give exact estimates in a large enough sample limit, lie orthogonal to deterministic methods. They are normally much slower than their deterministic counterparts, but given a skilled user and enough computational resources stochastic methods are capable of giving more precise answers. Whether inference errors (of unknown size) are acceptable of course depends on the application in question. In statistical applications one might prefer simple models which allow for exact inferences, whereas in communication systems intractability is an inherent property of communication channels and to counter this, one instead designs fault tolerant error-correcting protocols.

The problem under consideration can be stated in general terms: We are presented with a data set of N independent and identically distributed (i.i.d.) examples $\mathcal{D} = \{x_n\}_{n=1}^N$, which we model by a generative model specified by the distribution $p(x|\theta)$, such that $p(\mathcal{D}|\theta) = \prod_n p(x_n|\theta)$. In Bayesian inference we introduce a prior distribution $p(\theta)$ over model parameters θ, and to infer unobserved random variables we compute different averages over the posterior distribution

$$p(\theta|\mathcal{D}) = \frac{1}{Z} p(\mathcal{D}|\theta)p(\theta) \quad \text{with} \quad Z = \int d\theta \, p(\mathcal{D}|\theta)p(\theta) \; . \tag{1}$$

In model selection or model averaging the normalizer (marginal likelihood) $Z = p(\mathcal{D})$ needs to be computed for different models under consideration, that is, $p(\mathcal{D}|\mathcal{M}_m)$, $m = 1, \ldots, |\mathcal{M}|$. Another central inference is about the density at a new (test) example, the so-called predictive density (or distribution):

$$p(x|\mathcal{D}) = \int d\theta \, p(x|\theta)p(\theta|\mathcal{D}) \; . \tag{2}$$

This paper mostly specializes to modelling the density with a mixture model

$$p(x|\theta) = \sum_{k=1}^{K} p(k)p(x|\theta_k)$$

such that mixing proportions $p(k)$ sum to one, and $\theta = \{p(k), \theta_k\}_{k=1}^K$. A mixture of Gaussians (MoG) corresponds to $p(x|\theta_k)$ being Gaussian. The prior distribution and the likelihood term for each component term $p(k)p(x|\theta_k)$ are chosen to be conjugate, such that their product is in the same distribution family as the prior and thus tractable. Intractability for the mixture model arises not because integration is intractable, but because the number of terms in the marginal likelihood is K^N.

This paper starts from the vantage point of an expectation consistent (EC) approximation (Opper and Winther, 2005) (and its algorithmic realisation by expectation propagation (EP) Minka 2001a) and substantiates these main contributions and findings:

1. We express the exact posterior distribution by an approximating distribution which is given by EC plus a series of error terms with increasing complexity. When low order corrections are small, one might hope that the remaining contributions will also decrease with the order, suggesting that the approximation can be improved by retaining only the lowest orders in the series. One can thus expect corrections to improve an already good approximation, but not a poor one. On the other hand, large lower order terms may indicate a poor approximation, providing an error check on the approximation without having to resort to Monte Carlo methods.

2. We derive corrections both for the marginal likelihood and the predictive distribution in the form of an expansion in terms of "clusters" of likelihood terms of the posterior. This expansion resembles the loop series expansions which were derived for correcting loopy belief propagation (LBP) (Chertkov and Chernyak, 2006, Gómez et al., 2007, Sudderth et al.,

2008).[1] All these methods hold in common that the correction terms are expressed as averages over the approximating solution and can thus be calculated *after* the convergence of the EP or LBP iterative scheme.

3. We show that our first order correction to the posterior can be simply expressed by quantities already computed by the EP algorithm. No further averages are needed. In contrast, the lowest non-trivial correction to the marginal likelihood is of second order, with the number of terms growing as $O(N^2)$. Corrections to the marginal likelihood can be tractably computed, for example, for models where the likelihood is a mixture distribution. Each of error terms contains the original K-component mixture, such that a correction up to order j requires the computation of $O((NK)^j)$ terms.

4. When the true distribution is multi-modal, EP will in most cases provide a local (single) mode approximation, with lower-order corrections also being local. One such example is the $K!$-fold labelling symmetry of the latent space of mixture models, which may cause $O(K!)$ separated modes in the posterior distribution. While the predictive distribution is invariant to this symmetry, the log marginal likelihood usually has to be further corrected by a factor of $O(\log K!)$, a correction that is typically much larger than a low-order perturbation correction.

5. Thorough empirical tests of EP validate its precision, and show errors that do not scale with N. The perturbation corrected predictions are almost uniformly more precise than EP. As a tool for improving inference accuracy, we show in a practical example that the first nontrivial correction term to the marginal likelihood approximation can make a clear difference in predicting which K maximizes the marginal likelihood, compared to when the correction was not used.

In this paper EC or EP and its resulting corrections are compared with variational Bayes (VB), Minka's α-divergence message passing scheme, and a gold standard benchmark of parallel tempering (PT) and thermodynamic integration (TI). PT is a Markov chain Monte Carlo (MCMC) method whose Markov chain operates on a "tempered posterior" and has very good convergence properties. Contrary to more standard Monte Carlo methods (for example Metropolis-Hastings or Gibbs sampling) it can also provide estimates of the marginal likelihood by TI, which interpolates the expected value of the log likelihood between the prior and the posterior. To increase the stability of estimates obtained by TI, we give a novel generalization of PT, which allows interpolation of the value of the log likelihood between *any* choice of distribution and the posterior. A good choice may also improve sampling when the tempered posterior exhibits phase transition-like properties. This choice might be obtained by some deterministic approximation, and although not investigated in this paper, provides a springboard for combining deterministic and stochastic inference algorithms.

As a further example it is also shown how the "cluster" perturbation expansion can be applied to Gaussian Process classification models, where the evaluation of integrals for Bayesian marginalization are not analytically tractable.

The rest of the paper follows with a description of EC and EP in Section 2. Section 3 shows an example of corrections for a marginal distribution in a Gaussian Process classification model.

1. An information geometrical expansion for LBP is given by Ikeda et al. (2004), and for EP by Matsui and Tanaka (2008). LBP can also be improved with a message passing algorithm that corrects for the influence of loops (Mooij et al., 2007).

In Section 4 an inference algorithm is presented for mixture weights, that is, a mixture model with fixed component densities, while Appendix D treats the fully multivariate MoG. Section 5 contains short descriptions of PT with TI and a generalization suitable for statistical inference. Results are presented for real world examples in Section 6, and we conclude in Section 7.

2. Expectation Consistent Inference

The *expectation consistent* approximation provides a framework for finding a surrogate distribution $q(\theta)$ for $p(\theta|\mathcal{D})$ in Bayesian inference (Opper and Winther, 2005).[2] The message passing scheme of *expectation propagation* gives rise to an identical marginal likelihood approximation, and the following interpretation sheds light on both methods by looking at them as a set of self-consistent approximations to marginal or predictive distributions. The outline presented here allows for further *perturbation corrections* to be derived.

For the purpose of this paper the EC approximation rests on the observation that the predictive density $p(x|\mathcal{D})$ in (2) can be fairly precisely approximated without averaging over the actual posterior. The entire posterior can be replaced with a simpler distribution $q(\theta)$ *if* it produces the correct statistics for this average, that is,

$$p(x|\mathcal{D}) = \int d\theta\, p(x|\theta)p(\theta|\mathcal{D}) \approx \int d\theta\, p(x|\theta)q(\theta)\ .$$

It is sufficient for $q(\theta)$ to share some key properties, namely low order statistics, with $p(\theta|\mathcal{D})$. This is an ambitious demand that is generally not realizable, but we can transfer the principle of moment matching to the "cavity" posteriors $p(\theta|\mathcal{D}_{\setminus n})$, which correspond to reduced training sets $\mathcal{D}_{\setminus n}$ where the n^{th} example has been left out. By introducing a similar approximation to the "cavity" predictive distributions

$$p(x_n|\mathcal{D}_{\setminus n}) = \int d\theta\, p(x_n|\theta)p(\theta|\mathcal{D}_{\setminus n}) \approx \int d\theta\, p(x_n|\theta)q_{\setminus n}(\theta)$$

for each x_n in the training set, a computationally efficient approximation can be derived. We shall now *rather* require $q(\theta)$ to share key properties, namely lower order statistics, with *each* of the distributions $q_n(\theta) \propto p(x_n|\theta)q_{\setminus n}(\theta)$; this is explored in the next section.

2.1 EC and EP with Exponential Families

EC defines a tractable approximation $q(\theta)$ through expectation consistency with each $q_n(\theta)$. Our view of EC shall be narrowed to models factorizing in likelihood terms $p(x_n|\theta)$, and an exponential family prior

$$p(\theta) = \frac{1}{Z_0} \exp\left(\Lambda_0^T \phi(\theta)\right) h(\theta)\ ,$$

where Z_0 is the normalizing constant, $\phi(\theta)$ is a fixed vector of the corresponding sufficient statistics—for example for a univariate Gaussian we can choose $\phi(\theta) = \left(\theta, -\theta^2/2\right)$, Λ_0 is the associated parameter vector and the fixed function $h(\theta)$ encodes additional constraints (positivity, normalizations, etc.). The desired quality of approximation, and the possible convenience of obtaining tractable moments, typically guide the choice of $\phi(\theta)$.

2. A more general interpretation is possible, but for clarity we show the approximation for the generative model in (1).

The posterior will be approximated with a tractable density of the same exponential family as the prior,

$$q(\theta) = \frac{1}{Z(\Lambda,0)} \exp\left(\Lambda^T \phi(\theta)\right) p(\theta) \; . \tag{3}$$

By adding the condition $\Lambda = \sum_n \Lambda_n$, we allow each likelihood factor $p(x_n|\theta)$ of the posterior in (1) to correspond to simpler factor proportional to $\Lambda_{\setminus n} = \Lambda - \Lambda_n$ in (3): the Λ_n's therefore parameterize the likelihood term contributions to the approximation.[3] We here introduced a definition for normalization as

$$Z(\Lambda,a) = \int d\theta \prod_n \left[p(x_n|\theta)\right]^{a_n} \exp\left(\Lambda^T \phi(\theta)\right) p(\theta) \; ,$$

with a being a vector with elements a_n. The cavity posterior $p(\theta|\mathcal{D}_{\setminus n})$ should then be approximated by a member of the same exponential family

$$q_{\setminus n}(\theta) \propto \exp\left(\Lambda_{\setminus n}^T \phi(\theta)\right) p(\theta) \; ,$$

where $\Lambda_{\setminus n} = \Lambda - \Lambda_n$. This is obtained from (3) by removing a single likelihood approximation and renormalizing.

Let 1_n be a unit-vector in the n^{th} direction. We can now formalize our concluding remark: $q(\theta)$ is required to share lower order statistics with the *tilted* distributions

$$q_n(\theta) = \frac{1}{Z(\Lambda - \Lambda_n, 1_n)} p(x_n|\theta) \exp\left((\Lambda - \Lambda_n)^T \phi(\theta)\right) p(\theta) \; , \tag{4}$$

each of which are obtained from the posterior $p(\theta|\mathcal{D})$ by replacing the cavity posterior by its approximation. We therefore require consistency of the generalized moments, that is,

$$\left\langle \phi(\theta) \right\rangle_q = \left\langle \phi(\theta) \right\rangle_{q_n} \; , \qquad n = 1, \ldots, N \; .$$

One can also show that the corresponding marginal likelihood approximation is given by

$$Z_{\text{EC}} = Z(\Lambda,0) \prod_n \frac{Z(\Lambda - \Lambda_n, 1_n)}{Z(\Lambda,0)} \tag{5}$$

(Minka, 2005, Opper and Winther, 2005). In Appendix A we relate this approximation to variational bounds on the marginal likelihood.

2.1.1 EXPECTATION PROPAGATION

The final expression for the EC partition function in (5) depends upon the partition functions for two distributions q and q_n in (3) and (4), and consistency on the statistics $\phi(\theta)$ determines the Λ_n parameters. This moment consistency can be achieved via a message passing framework called EP, which appear, together with VB,[4] as special cases of a more generic message passing framework recently

3. In this context the likelihood terms (factors) are sometimes referred to as *sites*, and hence the Λ_n's as *site parameters* of *site functions* that are proportional to $\exp(\Lambda_n^T \phi(\theta))$ (Seeger, 2003).

4. VB finds its approximation $q(\theta)$ by lower-bounding the log marginal likelihood with Jensen's inequality (Jordan et al., 1999), giving $\log Z_{\text{VB}} \leq \log p(\mathcal{D})$. By writing

$$\log Z_{\text{VB}} = -\text{KL}(q(\theta) \| p(\theta|\mathcal{D})) + \log p(\mathcal{D})$$

the bound can be made as tight as possible by adjusting $q(\theta)$; this is achieved by minimizing the KL-divergence between $q(\theta)$ and $p(\theta|\mathcal{D})$.

Algorithm 1 EP message passing (Minka, 2001a)

```
1: initialize: Set all $\Lambda_n$ to zero, $\Lambda_n \leftarrow 0$, $n = 1, \ldots, N$. This choice corresponds to initializing in
   the prior, setting the sufficient statistics to $\mu \leftarrow \langle \phi(\theta) \rangle_{p(\theta)}$.
2: repeat
3:    Randomly choose example $n$, and make the following update steps:
4:    Update sufficient statistics
          $\mu \leftarrow \left\langle \phi(\theta) \right\rangle_{q_n(\theta;\Lambda_n)}$ .
5:    Determine $q(\theta;\Lambda)$ from $\mu$, that is, solve
          $\left\langle \phi(\theta) \right\rangle_{q(\theta;\Lambda')} = \mu$
      with respect to $\Lambda'$ and update
          $\Delta\Lambda \leftarrow \Lambda' - \Lambda$ followed by $\Lambda \leftarrow \Lambda + \Delta\Lambda$ .
      The EP updates can also be damped by $\gamma \in [0,1]$ through $\Delta\Lambda \leftarrow \gamma(\Lambda' - \Lambda)$.
6:    Update $q_n(\theta;\Lambda_n)$:
          $\Lambda_n \leftarrow \Lambda_n + \Delta\Lambda$ .
      This update ensures that $\Lambda = \sum_n \Lambda_n$; $q$ and $q_n$ are therefore in the forms of (3) and (4). We
      have no guarantee in this step that $q_n$ stays a proper distribution. A robust heuristic is to skip
      any update that makes $q_n$ improper.
7: until expectation consistency $\langle \phi(\theta) \rangle_{q_n(\theta;\Lambda_n)} = \langle \phi(\theta) \rangle_{q(\theta;\Lambda)} = \mu$ holds for $n = 1, \ldots, N$.
```

proposed by Minka (2005). EP defines a specific message algorithm which iteratively refines each Λ_n by minimising local Kullback-Leibler divergences $\mathrm{KL}(q_n(\theta)\|q(\theta))$; in other words it iteratively performs the required moment matching $\langle \phi(\theta) \rangle_q = \langle \phi(\theta) \rangle_{q_n}$. EP is presented in Algorithm 1 for our choice of q and q_n, and we shall henceforth use the terms EP and EC interchangeably.

If EP converges we will have expectation consistency $\langle \phi(\theta) \rangle_{q_n(\theta)} = \langle \phi(\theta) \rangle_{q(\theta)} = \mu$ because of the moment matching in lines 4 and 5 of Algorithm 1. Line 6 ensures that q and q_n follow the forms in (3) and (4). Solving for q in line 5 is analytical for most of the parameters as long as q is in the exponential family. (In the mixture of Gaussian examples in this paper, one has to solve two independent scalar non-linear equations for Dirichlet and Wishart densities. All other vector and matrix parameters can be found analytically.)

EP is not guaranteed to converge, in which case double-loop algorithms may be used. It has been observed by Heskes and Zoeter (2002) that when EP does not converge to a stable fixed point, even when considerable damping (choosing γ small in Algorithm 1) is used, the corresponding double-loop algorithm has a Hessian with a significantly negative eigenvalue(s). It has been suggested that the failure of convergence of canonical EP usually implies an inaccurate solution, with the choice of approximating family not being rich enough (Minka, 2001a).

2.2 Perturbation Corrections

The goal of this section is to derive formal expressions for the errors of the EC approximation to the marginal likelihood and the predictive distribution and to discuss ways of how this error can be computed using a formal perturbation expansion. In order to expand the EC approximation we use (4) to express each likelihood term by the approximating densities as

$$p(x_n|\theta) = \frac{Z(\Lambda - \Lambda_n, 1_n)}{Z(\Lambda, 0)} \frac{q_n(\theta)}{q(\theta)} \exp\left(\Lambda_n^T \phi(\theta)\right) ,$$

to find that

$$p(\theta)\prod_n p(x_n|\theta) = Z_{\mathrm{EC}}\, q(\theta) \prod_n \left(\frac{q_n(\theta)}{q(\theta)}\right) . \tag{6}$$

If we define

$$\varepsilon_n(\theta) = \frac{q_n(\theta) - q(\theta)}{q(\theta)}$$

such that $\frac{q_n(\theta)}{q(\theta)} = 1 + \varepsilon_n(\theta)$, we should expect $\varepsilon_n(\theta)$ to be on average small over a suitable measure when the EC approximation works well. Bearing this definition in mind, the exact posterior and the exact marginal likelihood can be written as

$$p(\theta|\mathcal{D}) = \frac{1}{R}\, q(\theta) \prod_n (1 + \varepsilon_n(\theta)) \qquad \text{and} \qquad Z = Z_{\mathrm{EC}}\, R , \tag{7}$$

with

$$R = \int d\theta\, q(\theta) \prod_n (1 + \varepsilon_n(\theta)) .$$

We expect that an expansion of posterior and Z in terms of $\varepsilon_n(\theta)$ truncated at low orders might give the dominant corrections to EC. Hence, we get the (2^N term finite) expansion

$$R = 1 + \sum_{n_1 < n_2} \left\langle \varepsilon_{n_1}(\theta)\varepsilon_{n_2}(\theta) \right\rangle_q + \sum_{n_1 < n_2 < n_3} \left\langle \varepsilon_{n_1}(\theta)\varepsilon_{n_2}(\theta)\varepsilon_{n_3}(\theta) \right\rangle_q + \ldots , \tag{8}$$

showing that EC is correct to the first order as the term $\sum_n \langle \varepsilon_n(\theta) \rangle_q = 0$ vanishes. The posterior in (7) can be similarly expanded with

$$p(\theta|\mathcal{D}) = \frac{q(\theta)\, \left(1 + \sum_n \varepsilon_n(\theta) + \sum_{n_1<n_2} \varepsilon_{n_1}(\theta)\varepsilon_{n_2}(\theta) + \ldots\right)}{1 + \sum_{n_1<n_2} \langle \varepsilon_{n_1}(\theta)\varepsilon_{n_2}(\theta) \rangle_q + \ldots} , \tag{9}$$

where we should keep as many terms in the numerator as in the denominator in order to keep the resulting density normalized to one.

The corresponding predictive distribution is

$$\begin{aligned} p(x|\mathcal{D}) &= \int d\theta\, p(x|\theta)\, p(\theta|\mathcal{D}) \\ &= \frac{\int d\theta\, q(\theta)\, p(x|\theta)\, \left(1 + \sum_n \varepsilon_n(\theta) + \sum_{n_1<n_2} \varepsilon_{n_1}(\theta)\varepsilon_{n_2}(\theta) + \ldots\right)}{1 + \sum_{n_1<n_2} \langle \varepsilon_{n_1}(\theta)\varepsilon_{n_2}(\theta) \rangle_q + \ldots} , \end{aligned} \tag{10}$$

where again as many terms in the numerator as in the denominator should be kept to ensure proper normalization.

If the expansions in (9) and (10) are truncated, the approximations are not guaranteed to be valid probability distributions, since as functional approximations they may be negative. Nevertheless, the quality of EC approximation is still improved, as is illustrated in Figures 1, 8, 12, and Table 1.

2.3 Tractability of Corrections

For the case where q_n is just a finite *mixture* of K simpler densities from the exponential family to which q belongs, then the number of mixture components in the j-th term of the expansion of R is just of the order $O(K^j)$ and an evaluation of low order terms is tractable and can be computed in $O((KN)^j)$ after q has been found.

In other cases, an exact computation of even the low order terms may be analytically intractable. If the dimensionality of necessary integrations is proportional to the order of the correction one may still resort to numerical quadratures. A different approach would be to re-expand each term ε_n in a different "measure of closeness" of densities which takes into account the moments $\phi(\theta)$ of the densities. This can be for example achieved in the case where $q(\theta)$ is Gaussian and the statistics $\phi(\theta)$ denote just the set of all first and a subset of second moments (or cumulants) of the random variable θ. Then we could resort to the use of characteristic functions $\chi(\kappa)$ and $\chi_n(\kappa)$ defined through

$$q(\theta) = \int d\kappa\, e^{i\kappa^T\theta}\chi(\kappa), \qquad q_n(\theta) = \int d\kappa\, e^{i\kappa^T\theta}\chi_n(\kappa)$$

for all n. The coefficients in a formal multivariate Taylor expansion of $\log\chi_n(\kappa)$ in powers of the vector κ define (up to a factor) the *cumulants* of q_n. Hence, the multivariate Taylor expansion of $r_n(\kappa) \equiv \log\chi_n(\kappa) - \log\chi(\kappa)$ in powers of κ contains only those cumulants in which q_n and q *differ*. Thus, we may write

$$\begin{aligned} q_n(\theta) - q(\theta) &= \int d\kappa\, e^{i\kappa^T\theta}\chi(\kappa)\left(1 - e^{\log\left(\frac{\chi_n(\kappa)}{\chi(\kappa)}\right)}\right) = \int d\kappa\, e^{i\kappa^T\theta}\chi(\kappa)\left(1 - e^{r_n(\kappa)}\right) \\ &= -\int d\kappa\, e^{i\kappa^T\theta}\chi(\kappa)\left(r_n(\kappa) + \frac{1}{2}r_n^2(\kappa) + \dots\right) . \end{aligned} \tag{11}$$

Hence, when the statistics $\phi(\theta)$ contain *all* first and *all* second moments of θ, the integral is expressed through cumulants of order 3 and higher. In this way the error of the EC approximation can be expressed in terms of higher order cumulants.

If we expand r_n in powers of κ, it is possible to express the integral (11) explicitly in a series containing derivatives of increasing order of the Gaussian $q(\theta) = \int d\kappa\, e^{i\kappa^T\theta}\chi(\kappa)$ with respect to θ. This is because each such derivative creates a factor κ in the Fourier integral via differentiations of the exponential $e^{i\kappa^T\theta}$. Finally, each term $\varepsilon_n(\theta) = \frac{q_n(\theta)-q(\theta)}{q(\theta)}$ can then be expressed by a series of Hermite polynomials in a standard way. This alternative expansion is introduced by Opper et al. (2008); its details and applications will be presented in a future paper.

2.4 First Order Correction

We have seen that in general, higher order correction terms require the computation of extra expectations. Remarkably, in contrast, the first order correction to the EC posterior (9) is obtained as simple sum of terms which where already computed in the EC approximation. Hence, it provides a simple and efficiently computable quantity to improve on EC/EP or judge its validity. A straightforward calculation gives

$$p(\theta|\mathcal{D}) \approx \sum_n q_n(\theta) - (N-1)q(\theta) . \tag{12}$$

The first order correction does *not* change the moments which are consistent in EC, but provides an approximation to nontrivial higher cumulants, which, for example, in the case of a Gaussian $q(\theta)$ would be *zero* in EC.

3. Gaussian Process Classification

The cluster expansion can be applied in a limited setting to non-parametric models with a Gaussian process prior. This section provides as an introductory case a correction to the marginal distribution, illustrating that a lower-order correction can be very accurate. For this family of models corrections to other quantities of interest, for example the log marginal likelihood and predictive distribution, have to rely on cumulant expansions (Opper et al., 2008), and will be treated in detail a companion paper.

A Gaussian process prior forms the cornerstone of many popular non-parametric Bayesian methods. It has been used to great effect on various regression and classification problems. A Gaussian prior is placed on an N-dimensional unobserved variable f, for example

$$p(f) = \mathcal{N}(f\,; 0, K) \ ,$$

where each f_n is associated with an input vector x_n, and K is a kernel matrix with entries $k(x_n, x_{n'})$ (Rasmussen and Williams, 2005). A binary classification task attaches a class label $y_n \in \{-1, +1\}$ to each input x_n, and a typical prediction would be the class of a new input x_* given the data $\mathcal{D} = \{x_n, y_n\}_{n=1}^{N}$. It is common to use the cumulative Normal distribution function $\Phi(\cdot)$ as a likelihood for correctly classifying a data point (Opper and Winther, 2000). The likelihood is dependent on the unobserved f_n associated with x_n, and hence

$$p(y_n|f_n) = \Phi(y_n f_n) \ .$$

The posterior distribution of f is therefore

$$p(f|\mathcal{D}) = \frac{1}{Z} \prod_{n=1}^{N} p(y_n|f_n)\, \mathcal{N}(f\,; 0, K) \ .$$

With this factorization the site functions are chosen to depend on only f_n such that the posterior is approximated by the same exponential family distribution (Gaussian) as the prior,

$$q(f) \propto \prod_{n=1}^{N} \exp\left(\tilde{\nu}_n f_n - \frac{1}{2}\tilde{s}_n f_n^2\right) \mathcal{N}(f\,; 0, K) \ .$$

The notation in this section is deliberately chosen to be consistent with that of Rasmussen and Williams (2005, chapter 3), and we refer the reader to the reference for an example EP algorithm. We assume that a fixed point of EP has been reached. Let $\tilde{S}$ be a diagonal matrix containing $\tilde{s}_n$, and $\tilde{\nu}$ be a vector containing $\tilde{\nu}_n$. The posterior approximation is therefore $q(f) = \mathcal{N}(f; \mu, \Sigma)$, with $\Sigma = (K^{-1} + \tilde{S})^{-1}$ and $\mu = \Sigma\tilde{\nu}$.

The cavity posterior approximations $q_{\setminus n}(f) = \mathcal{N}(f; \mu_{\setminus n}, \Sigma_{\setminus n})$ arise from setting $\tilde{\nu}_n = \tilde{s}_n = 0$ (giving diagonal matrix $\tilde{S}_{\setminus n}$ and vector $\tilde{\nu}_{\setminus n}$), where $\Sigma_{\setminus n}$ can be determined with a rank one update of Σ. The tilted distributions are therefore $q_n(f) \propto q_{\setminus n}(f)\,\Phi(y_n f_n)$.

The first order correction (12) can be applied to compute a correction to the marginal distribution of f_*, the latent function associated with a novel input x_*. Integrating $p(f_*|f)$ with (12) yields

$$p(f_*|\mathcal{D}) \approx \sum_{n=1}^{N} q_n(f_*) - (N-1) q(f_*) \ . \tag{13}$$

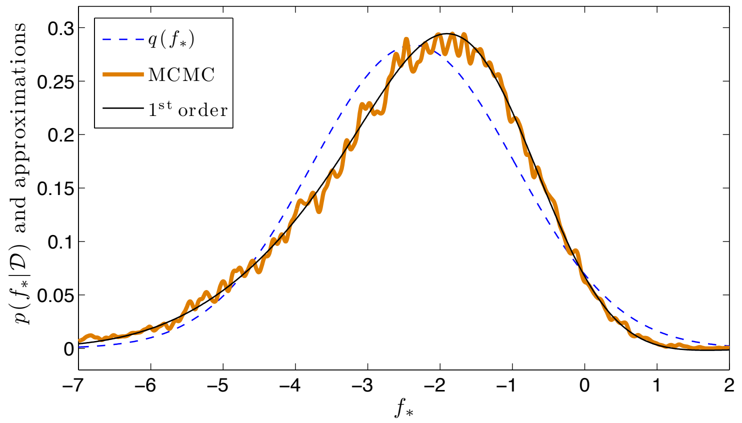

Figure 1: The first-order correction (13) is shown in black, with $q(f_*)$ in blue. Full details about the data set in question, as well as the individual terms in (13), are illustrated in Figure 13 in Appendix B. An MCMC estimate for the true marginal is overlayed in orange, and comes from averaging $p(f_*|f)$ over 20,000 MCMC samples from the posterior of $p(f|\mathcal{D})$. The "spikiness" is a result of the variance of $p(f_*|f)$ being very narrow: if the "noise-free" latent f is given, then f_* is highly correlated with f and well determined for this example. The first-order correction gives an excellent approximation.

Notice that corrections for the predictive distribution and log marginal likelihood cannot be expressed analytically in this way. Hence numerical quadrature or an expansion in terms of cumulants (Opper et al., 2008) is required. Higher-order terms of the above correction are also analytically intractable.

The detailed derivation of the correction is presented in Appendix B. Figure 1 provides a summary comparison of a first-order correction, $q(f_*)$, and a MCMC estimate of $p(f_*|\mathcal{D})$. The correction is very accurate and provides a much better fit than EC or EP at a negligible additional computational cost. Figure 13 in Appendix B gives further illustrations to accompany Figure 1. In Section 2.4 it was noted that the first order correction provides an approximation to nontrivial higher cumulants which would otherwise be *zero* in EC, even though the moments which are consistent in EC are not changed. Figure 2 illustrates this observation, showing an accurate approximation of the third cumulant for various distributions $p(f_*|\mathcal{D})$.

4. Mixture of Gaussians

We shall empirically examine the corrections to EP approximations through a multivariate mixture of Gaussians (MoG). Mixture models provide a more challenging testbed for EP than the Gaussian Process model illustrated in Section 3, as the posterior is multi-modal with many symmetries, and the site distributions are not log-concave. For clarity we relegate the MoG derivations to Appendix D, favouring a simpler but similar model here. As an outline to deriving an algorithm for a MoG we

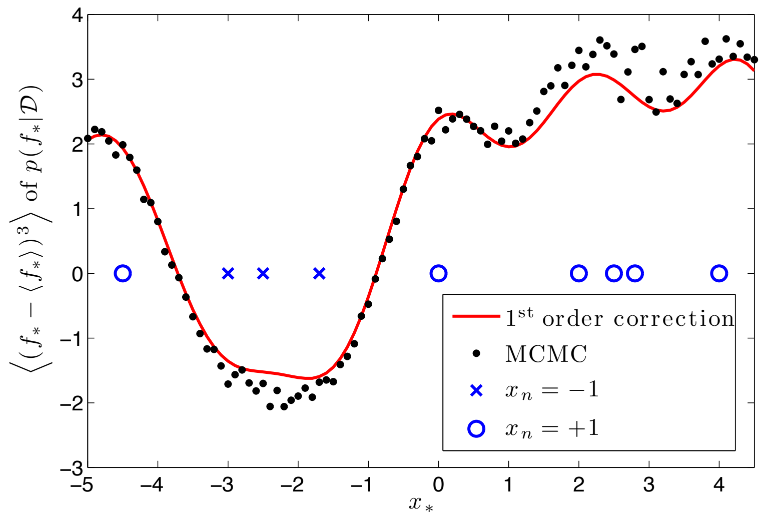

Figure 2: For different inputs x_*—and hence latent function f_*—the *third* cumulant of the first-order correction (13) is shown in red. It closely matches the true third cumulant of $p(f_*|f)$, which is plotted in black. The EC approximation $q(f_*)$'s higher cumulants are all zero. Figure 1 shows the particular approximations at $x_* = -2$, with further details appearing in Figure 13 and Appendix B.

consider the task of inferring the mixing proportions $\pi_k = p(k)$ in a model of the form

$$p(x|\theta) = \sum_k \pi_k p(x|k) \ ,$$

with $p(x|k)$ being fixed (Minka, 2001b). Since the mixing proportions should sum to one a Dirichlet prior for π is is a natural choice, and Appendix C gives a detailed description of all its properties needed in this context. We give the explicit EP message passing updates for the mixing proportions with fixed component densities in Algorithm 2 (this scheme is generalized to adaptive components in a straightforward way in Appendix D). Details for the required computations in Algorithm 2 are given below.

4.1 Variational and Predictive Distributions

The prior—and thus also the q-distribution in (3)—are Dirichlet,

$$q(\pi) = \mathcal{D}(\pi;\lambda) \ ,$$

with $\mathcal{D}(\pi;\lambda)$ given in Appendix C by (23). The parameters of q are $\lambda_k = \lambda_{k,0} + \sum_n \lambda_{k,n}$ (here λ_0 are the parameters of the prior, which we include into λ for simplicity).

We can also get the EC approximation to the predictive distribution both for new datum x, $p(x|\mathcal{D})$ and the cavity predictive distribution: $p(x_n|\mathcal{D}_{\setminus n})$. For the new datum x the approximation is straightforward using $q(\pi)$ as an approximate posterior:

$$p(x|\mathcal{D}) \approx \int d\pi\, p(x|\pi)\, q(\pi) = \sum_k \left\langle \pi_k \right\rangle_q p(x|k) \,, \tag{14}$$

with the mean value being

$$\left\langle \pi_k \right\rangle_q = \frac{\lambda_k}{\sum_{k'} \lambda_{k'}} \,.$$

For the "within data set" version we introduce the cavity distribution $q_{\setminus n}(\pi) = \mathcal{D}(\pi;\lambda_{\setminus n})$, using $\lambda_{k\setminus n} = \lambda_k - \lambda_{k,n}$, and derive a result that is very similar to the one above:

$$p(x_n|\mathcal{D}_{\setminus n}) \approx \sum_k \left\langle \pi_k \right\rangle_{q_{\setminus n}} p(x_n|k) \,. \tag{15}$$

For message passing we also need expectations of $q_n(\pi)$ from (4):

$$q_n(\pi) = \frac{1}{Z_n(\lambda_{\setminus n}, 1_n)} e^{\sum_{k'} (\lambda_{k'\setminus n} - 1) \log \pi_{k'}}\, \delta\left(\sum_{k'} \pi_{k'} - 1 \right) \sum_k \pi_k p(x_n|k) \,.$$

The above normalizer can easily be found by noting that

$$q_n(\pi) = \frac{Z(\lambda_{\setminus n}, 0)}{Z_n(\lambda_{\setminus n}, 1_n)} q_{\setminus n}(\pi) \sum_k \pi_k p(x_n|k) \,,$$

such that

$$Z_n(\lambda_{\setminus n}, 1_n) = Z(\lambda_{\setminus n}, 0) \sum_k \left\langle \pi_k \right\rangle_{q_{\setminus n}} p(x_n|k) \,.$$

In this simple case we have $Z(\lambda_{\setminus n}, 0) = Z_{\mathcal{D}}(\lambda_{\setminus n})$, with the normalization $Z_{\mathcal{D}}$ of the Dirichlet being given by (24) in Appendix C.

4.2 Expectations

When updating $\mu \leftarrow \langle \phi(\theta) \rangle_{q_n(\theta;\Lambda_n)}$ in Algorithm 2 the sufficient statistics can be computed using $\log Z_n(\lambda_{\setminus n})$ as a generating function:

$$\left\langle \log \pi_k \right\rangle_{q_n} = \frac{d \log Z_n(\lambda_{\setminus n})}{d\lambda_{k\setminus n}} = \left\langle \log \pi_k \right\rangle_{q_{\setminus n}} + \frac{r_{nk}}{\lambda_{k\setminus n}} - \frac{1}{\sum_{k'} \lambda_{k'\setminus n}} \,, \tag{16}$$

where the expression for $\langle \log \pi_k \rangle_{q_{\setminus n}}$ is given by (25) in Appendix C with $\lambda \to \lambda_{\setminus n}$, and the "responsibility" r_{nk} was introduced as

$$r_{nk} = \frac{\lambda_{k\setminus n} p(x_n|k)}{\sum_{k'} \lambda_{k'\setminus n} p(x_n|k')} \,.$$

Algorithm 2 Message Passing for Mixing Proportions

```
1: initialize: Set $\lambda_{k,n} \leftarrow 0$, for $n = 1,\dots,N$ and $k = 1,\dots,K$, initializing $q(\pi)$ to the prior. Set $\mu_k \leftarrow \langle \log \pi_k \rangle_{p(\pi)} = \psi(\pi_{k,0}) - \psi(\sum_k \pi_{k,0})$, where the digamma function $\psi(x)$ is defined as $\log \Gamma(x)/dx$.
2: repeat
3:    Randomly choose example $n$, and make the following update steps:
4:    Update the sufficient statistics
          $$\mu_k \leftarrow \left\langle \log \pi_k \right\rangle_{q_n(\pi;\lambda_n)} = \psi(\lambda_k - \lambda_{k,n}) - \psi\left(\sum_k (\lambda_k - \lambda_{k,n})\right) .$$
5:    Determine $q(\pi;\lambda')$ from $\mu$, that is, by solving $\langle \log \pi_k \rangle_{q(\pi;\lambda')} = \mu_k$ with respect to $\lambda'$. As shown in Appendix C, this involves solving for $\alpha \equiv \psi(\sum_k \psi^{-1}(\mu_k + \alpha))$, followed by with $\lambda'_k = \psi^{-1}(\mu_k + \alpha)$. Update
          $$\Delta\lambda_k \leftarrow \lambda'_k - \lambda_k \quad \text{and} \quad \lambda_k \leftarrow \lambda'_k .$$
6:    Update $q_n(\pi;\lambda_n)$ with
          $$\lambda_{k,n} \leftarrow \lambda_{k,n} + \Delta\lambda_k ,$$
      ensuring that $\lambda_k = \lambda_{k,0} + \sum_n \lambda_{k,n}$.
7: until expectation consistency $\langle \log \pi_k \rangle_{q_n(\pi;\lambda_n)} = \langle \log \pi_k \rangle_{q(\pi;\lambda)} = \mu$ holds $\forall n, k$.
8: Compute $\log Z_{\mathrm{EC}}$ from (5) with
          $$\log Z_{\mathrm{EC}} = \sum_n \log Z(\lambda - \lambda_0 - \lambda_n, 1_n) - (N-1) \log Z(\lambda - \lambda_0, 0)$$
          $$= \sum_n \log \left[ \frac{Z_{\mathcal{D}}(\lambda_{\setminus n})}{Z_{\mathcal{D}}(\lambda)} p(x_n | \mathcal{D}_{\setminus n}) \right] + \log Z_{\mathcal{D}}(\lambda_0) + \log Z_{\mathcal{D}}(\lambda) ,$$
   where $p(x_n|\mathcal{D}_{\setminus n})$ signifies the "cavity" predictive distribution from (15).
```

5. Parallel Tempering and Thermodynamic Integration

Having considered deterministic inference algorithms, the last bit of machinery that we shall need is a stochastic method to provide exact estimates in a large enough sample limit. Parallel tempering (PT) and thermodynamic integration (TI) are ideal for our purposes: PT is an efficient method of combining separate Monte Carlo simulations to sample across different modes of a target distribution and, as a by-product, TI can be used to estimate the normalizing constant or log marginal likelihood.

We conclude this section with a new practical generalization of PT and TI, which can in principle be used to combine stochastic and approximate methods. A further novel extension to the generalization is given in Appendix E.2.

5.1 Parallel Tempering (Replica Exchange)

A single MCMC simulation may run into difficulties if the target distribution is multimodal. The chain may get stuck in a local mode, and fail to fully explore other areas of the parameter space that have significant probability. A conceptual solution to this problem is to create a series of progressively flatter distributions through an inverse temperature parameter β, which ranges from zero to one. This gives a "tempered" posterior

$$p(\theta|\mathcal{D},\beta) = \frac{1}{Z(\beta)} p(\mathcal{D}|\theta)^{\beta} p(\theta) \ , \tag{17}$$

where the normalizing constant (partition function) is $Z(\beta) = \int d\theta \, p(\mathcal{D}|\theta)^{\beta} p(\theta)$. The prior is recaptured with $\beta = 0$, and the posterior with $\beta = 1$. We now simulate N_β replicas of (17) in parallel, each using a $\beta \in \{\beta_i\}_{i=1}^{N_\beta}$. Let the set $\{\beta_i\}$ be ordered as a ladder with $\beta_i < \beta_{i+1}$. The parameter space is replicated N_β times to $\{\theta_i\}_{i=1}^{N_\beta}$, and the full target distribution that is being sampled from is

$$p(\{\theta_i\}) = \prod_{i=1}^{N_\beta} \frac{1}{Z(\beta_i)} \exp\Big(\beta_i \log p(\mathcal{D}|\theta_i)\Big) p(\theta_i) \ .$$

We run the N_β chains independently to sample from distributions $p(\theta|\mathcal{D},\beta_i)$, and add an additional *replica-exchange* Metropolis-Hastings move to swap two β's, or equivalently two parameters, between chains. Let $\{\theta_i\}^{\text{new}}$ be a parameter set with θ_i and θ_j swapped. The acceptance probability of the move is $p(\text{accept}) = \min(1, p(\{\theta_i\}^{\text{new}})/p(\{\theta_i\}))$, and the acceptance ratio simplifies to

$$\frac{p(\{\theta_i\}^{\text{new}})}{p(\{\theta_i\})} = \exp\Big((\beta_i - \beta_j)\big(\log p(\mathcal{D}|\theta_j) - \log p(\mathcal{D}|\theta_i)\big)\Big) \ . \tag{18}$$

The temperatures of the two replica i and j have to be close to ensure non-negligible acceptance rates; neighboring pairs are typically taken as candidates. To fully satisfy detailed balance, pairs $\{i, i+1\}$ can be uniformly chosen, for example. With this formulation the states of the replicas are effectively propagated between chains, and the mixing of the Markov chain is facilitated by the fast relaxation at small β's.

From (18), the acceptance probability depends on the difference between $\log p(\mathcal{D}|\theta_i)$ and $\log p(\mathcal{D}|\theta_{i+1})$, and for some swaps to be accepted this difference should not be "too big"; there should be an *overlap* of some of the log likelihood evaluations of adjacent chains, as illustrated in Figure 3. For a simulation at inverse temperature β, define the mean evaluation of the log likelihood as

$$\big\langle \log p(\mathcal{D}|\theta) \big\rangle_\beta = \int d\theta \, \log p(\mathcal{D}|\theta) \, p(\theta|\mathcal{D},\beta) \ .$$

If we knew the variance in chain β, $\sigma_\beta^2 = \langle [\log p(\mathcal{D}|\theta)]^2 \rangle_\beta - \langle \log p(\mathcal{D}|\theta) \rangle_\beta^2$, then it can be shown that temperatures should be chosen according to the density $Q(\beta) \propto \sigma_\beta$ (Iba, 2001). This is obviously difficult, as σ_β^2 is not known in advance, and has to be estimated. Good results can be achieved under the assumption $\sigma_\beta^2 \propto 1/\beta^2$ (the equivalent of assuming a *constant* heat capacity in a physical system), giving a *geometric* progression, hence choosing β_i/β_{i+1} constant (Kofke, 2002).

5.2 Thermodynamic Integration

The samples from parallel tempering can be used for model comparison (Gregory, 2005, Skilling, 1998), as the marginal likelihood can be obtained from tempering. Firstly, notice that the integral

$$\int_0^1 d \log Z(\beta) = \int_0^1 d\beta \, \frac{d \log Z(\beta)}{d\beta} = \log Z(1) - \log Z(0) = \log Z(1) = \log p(\mathcal{D})$$

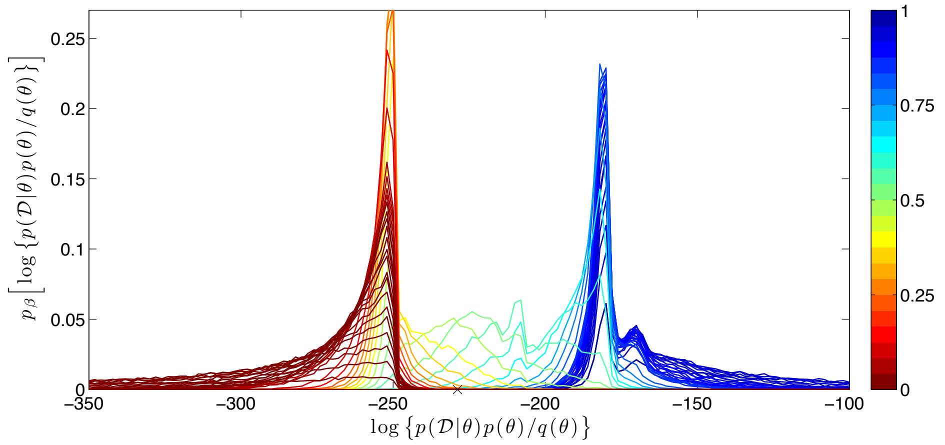

Figure 3: The density of $\log\{p(\mathcal{D}|\theta)p(\theta)/q(\theta)\}$ under replicas at different temperatures, $p(\theta|\mathcal{D},\beta)$, defined in (20). These densities correspond to "energy histograms," and following (18) there should be an overlap between adjacent replicas at different temperatures, so that acceptance of configuration or parameter swaps is allowed for. For interest, the log marginal likelihood $\log p(\mathcal{D})$ is indicated with a $\times$. The color bar indicates the inverse temperature β. This illustration comes from the **galaxy** data set with $K = 3$ components.

is equal to the log marginal likelihood, as $\beta = 0$ gives the prior, which integrates to one. We therefore have to determine the derivative $\frac{d}{d\beta}\log Z(\beta)$. By taking the derivative of the log normalizer (log partition function), we see that it evaluates as an average over the posterior

$$\frac{d\log Z(\beta)}{d\beta} = \frac{1}{Z(\beta)}\int d\theta \log p(\mathcal{D}|\theta) \times p(\mathcal{D}|\theta)^{\beta} p(\theta) = \left\langle \log p(\mathcal{D}|\theta)\right\rangle_{\beta} .$$

The log marginal likelihood equals

$$\log p(\mathcal{D}) = \int_0^1 d\beta \left\langle \log p(\mathcal{D}|\theta)\right\rangle_{\beta} \tag{19}$$

and can be numerically estimated from the Markov chain samples. If $\{\theta_i^{(t)}\}$ represents the samples for tempering parameter β_i, then the expectation is approximated with

$$\left\langle \log p(\mathcal{D}|\theta)\right\rangle_{\beta_i} \approx \frac{1}{T}\sum_{t=1}^{T} \log p(\mathcal{D}|\theta_i^{(t)}) .$$

We assume that a burn-in sample is discarded in the sum over t. As a set of chains are run in parallel at different inverse temperatures $0 = \beta_1 < \cdots < \beta_{N_\beta} = 1$, the integral can be evaluated numerically by interpolating the N_β expectations between zero and one (say with a piecewise cubic Hermite interpolation, available as part of `Matlab` and other standard software packages), and using for example the trapesium rule to obtain the desired result. Figure 4 illustrates how $\log p(\mathcal{D})$ is estimated.

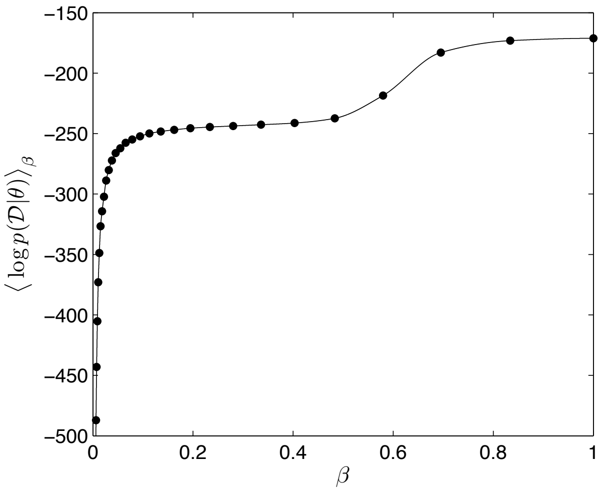

Figure 4: The log likelihood averages $\langle \log p(\mathcal{D}|\theta)\rangle_\beta$ are estimated from each of the MCMC simulations at temperatures $\{\beta_i\}$, and interpolated, so that Equation (19)'s integral can be evaluated numerically. This illustration comes from the **galaxy** data set with $K = 3$ components.

Parallel tempering can be done *complementary* to any Monte Carlo method at a single temperature. Appendix E presents Gibbs sampling to sample from $p(\theta|\mathcal{D},\beta)$ for the MoG problem.

5.3 A Practical Generalization of Parallel Tempering

The success of the interpolation obtaining $\langle \log p(\mathcal{D}|\theta)\rangle_\beta$, illustrated in Figure 4, is dependent on the slope

$$\frac{d\langle \log p(\mathcal{D}|\theta)\rangle_\beta}{d\beta} = \frac{d^2 \log Z(\beta)}{d\beta^2} = \sigma_\beta^2$$

at $\beta \approx 0$. Consider the following thought exercise: Imagine a non-informative (infinitely wide) prior at $\beta = 0$. Samples from this prior will strictly speaking have an infinite variance σ_0^2. With $\beta \approx 0$ we introduce the likelihood, practically infinitely decreasing the variance of our samples, causing $\langle \log p(\mathcal{D}|\theta)\rangle_\beta$ to asymptotically diverge at zero. As we narrow our prior the change in this mean should be less rapid, and this motivates a generalization of PT and TI such that we get a more stable interpolation.

We introduce a new distribution $q(\theta)$, which might be a narrower version of the prior, and modify (17) to

$$p(\theta|\mathcal{D},\beta) = \frac{1}{Z(\beta)} \left[p(\mathcal{D}|\theta) \frac{p(\theta)}{q(\theta)} \right]^\beta q(\theta) \; . \tag{20}$$

The log marginal likelihood can, as before, be determined with

$$\log p(\mathcal{D}) = \int_0^1 d\beta \left\langle \log p(\mathcal{D}|\theta) + \log \frac{p(\theta)}{q(\theta)} \right\rangle_\beta \; .$$

It is evident that setting $q(\theta) = p(\theta|\mathcal{D})$ gives an integral over a constant function, $\log p(\mathcal{D}) = \int_0^1 d\beta \, \langle \log p(\mathcal{D}) \rangle_\beta$. This suggests a wealth of possibilities of approximating $p(\theta|\mathcal{D})$ with $q(\theta)$ to effectively combine deterministic methods of inference with Markov chains. This comes with a cautionary note as VB, for example, may give a $q(\theta)$ that captures (lower-bounds) a mode of a possibly multimodal posterior, causing PT to lose its pleasing property of fast relaxation at high temperatures. In our results presented in Section 6, we have found it completely adequate to use a narrower version of the prior where necessary. Appendix E concludes with a short generalization to sample from (20) for the MoG problem.

6. Results

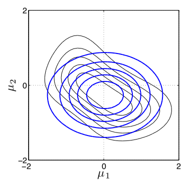
Low order corrections provide the tools to both improve inference accuracy, and to give an indication of the quality of approximate solutions. We illustrate and elaborate on these claims, with comparisons between various deterministic and stochastic methods, through this practical discussion. Data is viewed as being observed from a mixture model $p(x|\theta) = \sum_{k=1}^K \pi_k \, \mathcal{N}(x; \mu_k, \Gamma_k^{-1})$, as is discussed in Appendices D, E, and F. A Dirichlet prior is placed on π, and Normal-Wishart priors on μ_k and Γ_k; the approximating distribution $q(\theta) = q(\pi) \prod_k q(\mu_k, \Gamma_k)$ follows the same distribution as the prior.

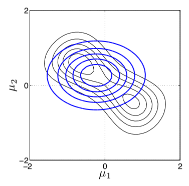
6.1 Modes and Symmetries

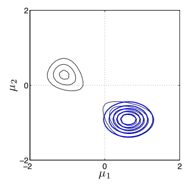
Mixture models are invariant under component relabelling, with a $K!$ growth in the number of permutations also manifesting itself in symmetries in the posterior density. In aid of interpreting later results, we present some basic understanding of VB, EP, and low order corrections under this property. Our aim in this section is to use simple toy posteriors to facilitate discussion on the behavior of q under various scenarios and discuss how that might affect the estimation of the marginal likelihood and predictive distribution.

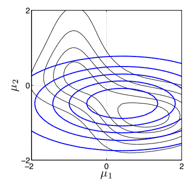
The labelling of hidden units of a two-layer neural network gives rise to symmetries similar to those observed in mixture models. For neural networks a statistical mechanics analysis shows that for small N the posterior is uni-modal and "star-like," as convex combinations of parameters with high posterior value which are equivalent under permutations will also have high density (Engel et al., 1992). The symmetry is broken into equivalent disconnected modes for large N.

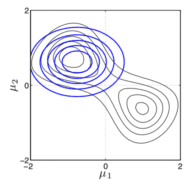
For mixture models we can analyze the situation where q is restricted to approximate the posterior in one of the symmetric modes, as what will typically be the solution for both VB and EP/C when N is large. Minimizing the KL-divergence $\mathrm{KL}(q\|p)$ leads to a solution where q is proportional to p within the mode (and by construction zero otherwise). If there are $K!$ modes contributing equally to the normalizer and q is restricted to one of them, then q's normalizer is a factor of $K!$ smaller than p's and consequently $\mathrm{KL}(q\|p) = \log K!$ at the minimum (Bishop, 2006, page 484). However, *groups* of equivalent modes are often present. A simple example is a 3-component mixture with three "clusters" of data. If each component is associated with a cluster, there are 3! labelling symmetries. Another VB or EP fixed point may prune one mixture component (see MacKay 2001 for VB and Figure 11 for EP), leaving one component to cover two clusters of data, and one component the other; this solution has *yet another* 3! labelling symmetries, albeit possibly with a lesser contribution to the normalizer. In effect the correction is rather $O(\log K!)$, as illustrated in Figure 9. A useful approximation would be to correct the marginal likelihood estimate by a factor of $K!$ when N is large. The predictive distribution is invariant under the symmetry and will thus

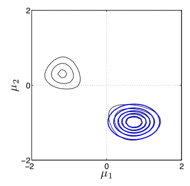
$N = 7$	$N = 14$	$N = 40$	$N = 7$	$N = 14$	$N = 40$
narrower prior: 			broader prior: 												


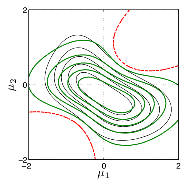


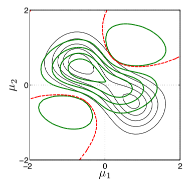


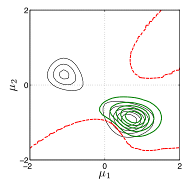


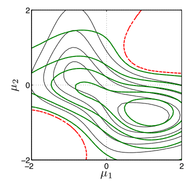


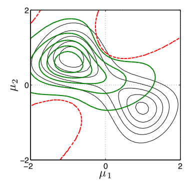












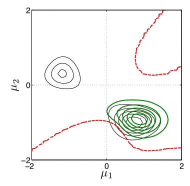


Table 1: A comparison between the VB (top row), and EC (middle row) approximations $q(\theta)$, and a first order correction to the EC approximation (bottom row). Data is assumed to come from a two-component mixture with *only* the means $\theta = \{\mu_1, \mu_2\}$ unknown. Under various priors and data set sizes we show the posterior $p(\theta|\mathcal{D})$ in thin black lines, with the VB, EC, and first-order corrected approximations overlaid in thicker lines. The first order correction integrates to one but is not guaranteed to be nonnegative (bottom row); dashed red lines are used to demarcate the regions of parameter space where the correction dips below zero.

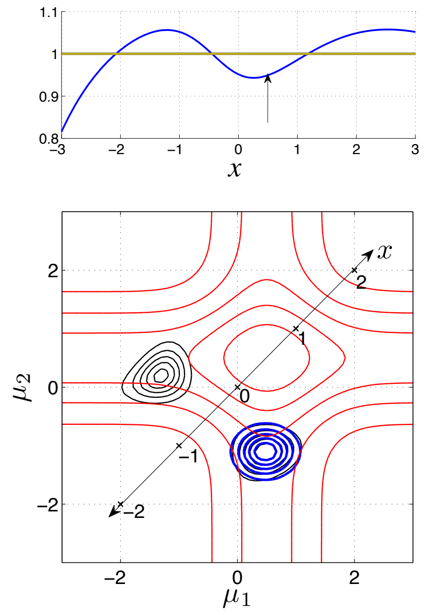

Figure 5: Symmetries and averages: The likelihood $p(x|\{\mu_1,\mu_2\}) = 0.4\mathcal{N}(x;\mu_1,1)+0.6\mathcal{N}(x;\mu_2,1)$ is plotted as red contours for the novel observation $x=\frac{1}{2}$ at the arrow in the top figure. Observing x centres the likelihood function at (x,x) along the μ_1–μ_2 axis in the bottom figure. The *predictive density* $p(x|\mathcal{D})$ is average of the likelihood over the *bi-modal* posterior (black contours), while the *approximate* predictive density is the average of the likelihood function over the *uni-modal* EC approximation (overlaid in blue). The near-symmetry of the posterior implies that each mode contributes approximately *half* its mass. When the EC approximation puts *all* its mass on one mode, and the modes are well separated, the two predictive densities are therefore similar. The top figure shows the ratio between the true and approximate $p(x|\mathcal{D})$; the discrepancy at negative x is due to the fact that the posterior is not perfectly symmetrical (e.g., when $x=-2$ its likelihood is centred at (-2,-2) and overlaps less with the EC mode).

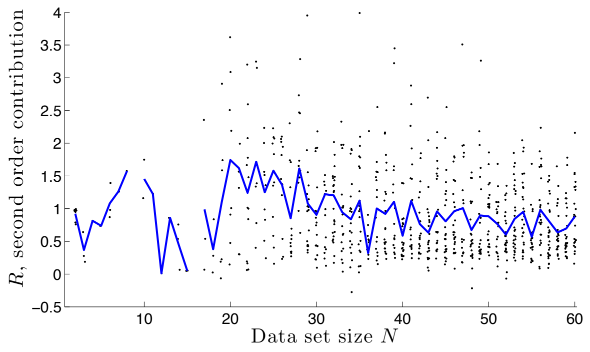
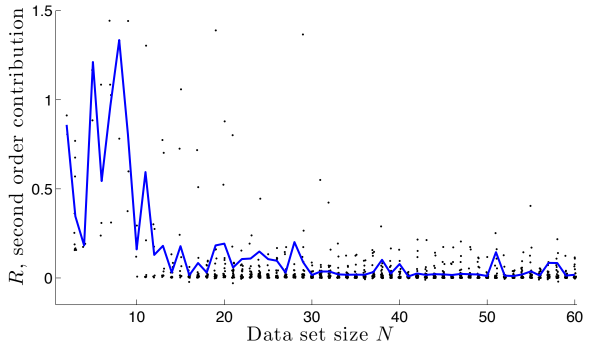
not be greatly affected by q approximating only one mode, as is shown in Figure 5. For small to intermediate values of N the situation is less clear, as the following example illustrates.

In Table 1 we illustrate a number of posterior distributions, with the VB and EC approximations overlaid. We also overlay the first order correction to $q(\theta)$, given from (12) by $p(\theta|\mathcal{D}) \approx \sum_n q_n(\theta) - (N-1)q(\theta)$. For Table 1 all parameters but the means were kept fixed, such that with $K=2$ the approximation $q(\theta)=q(\mu_1)q(\mu_2)$ is a factorised Gaussian. Both component variances were equal, and we used $(\pi_1,\pi_2)=(0.4,0.6)$. The modes are thus not completely symmetric but this set-up still illustrates the points made above well. We chose the component variances (set to one) such that the posterior modes overlap when N is small, with bimodality arising as N increases. We will see in the following sections that even though q is a rather crude approximation to the posterior the predictions for the predictive distribution are fairly precise.

The correction given by (12) integrates to one but is not guaranteed to be nonnegative, as it follows from discarding the higher order terms in (7). The first order correction to the predictive



(a) With overlapping mixture components, damped EP does not necessarily converge for small N (e.g., EP failed, in the sense that the 2nd order correction cannot be computed, on all 30 random data sets of size 8). The corrections are on average (blue line) large for broadly overlapping posterior modes, as EP does not necessarily lock onto one of them.



(b) With well separated clusters the 2nd order corrections indicate for which N, on average, EP prefers a modal solution. Note the better convergence of EP for larger N, with on average stabler fixed points than Figure 6(a). This is reflected in the corrections being close to zero.

Figure 6: The second order term of (8) on 3600 random data sets.

density, however, usually remains nonnegative because it is an *average* of $p(x|\theta)$ over (12). This underlines the fact that average properties will not be strongly affected by imprecision in approximating distributions.

Other local minima that we did not show in Table 1 was for N small, where $q(\mu_1)$ remains as broad as the prior and the component is effectively pruned, while $q(\mu_2)$, on the other hand, caters for both mixture components (MacKay, 2001).

6.2 Corrections

The illustrations in Table 1 suggest that the lowest nontrivial corrections can provide insight into the quality of approximation, as we expect corrections to be small for good approximations. To illustrate this claim, 30 random data sets $\mathcal{D}_N$ were drawn for each size $N = 1, \ldots, 60$ according to $\mathcal{D}_N \sim p(x)$, with $p(x)$ being a three-component mixture with $\pi = (0.2, 0.3, 0.5)$ and $\mu = (-2, 0, 2)$. Two cases were used for the variance: firstly, $\Gamma_k^{-1} = 0.5$ provides a model with overlapping mixture

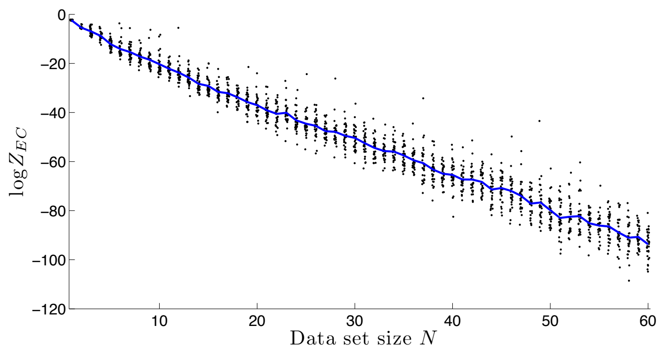


Figure 7: The growth of $\log Z_{\text{EC}}$ for the random data sets $\mathcal{D}_N$ used to obtain Figure 6(b).

components; secondly, $\Gamma_k^{-1} = 0.1$ gives a model with components that are further separated. EP was run with damping $\gamma = 0.5$, and the second order corrections to the log marginal likelihood approximations were computed where possible (i.e., EP converged, etc.); see Appendices D and F.

Figures 6(a) and 6(b) illustrate the "overlapping" and "separate" examples, showing that when N is small compared to $\log K!$, and the posterior is "starlike" and comparatively unimodal, EP often fails, and the nature of the problem is reflected in the large corrections. When N becomes large EP often converges (to one of $K!$ equivalent modes); small corrections immediately tell us that solution is close to exact, apart from here a $\log K!$ correction to the marginal likelihood.

We also observe that the corrections do not scale with N, whereas the free energy $\log Z_{\text{EC}}$ does, as shown in Figure 7. This is an important property, as it means that the quality of approximation does not deteriorate with increasing N.

When the observations $\mathcal{D}_N \sim p(x)$ are i.i.d. we expect that $\log Z_{\text{EC}}/N$, by its form as an empirical average over N terms, should converge to a non-random c_Z as $N \to \infty$. In fact a linear scaling $\log Z_{\text{EC}} \to c_Z N$ is observed in Figure 7. When and whether the expected correction $\langle \log R \rangle_{\mathcal{D}_N} = c_R(N) \to 0$ as $N \to \infty$ (and hence EP becomes exact) is an open question. This does not seem true for Figure 6(a): If the the posterior modes were well-separated then for large N, a change in one mean parameter in a factorized approximation will not greatly affect the other. If, in this case, the means are close compared to the standard deviations of the normal densities, the mean parameters will stay correlated also for large data sets, and the corrections will persistently stay bigger for large N.

6.3 Toy Example

To illustrate the difference between EC and VB, and show additional gains from perturbation corrections, we generated a small data set ($N = 7$) from a mixture of two Gaussians. The hyperparameters followed that of Section 6.4.

Under two model assumptions we show in Figure 8 that EC or EP (labeled "EC/P") gives a predictive density that is generally closer to the truth than that given by VB. Each example in the toy data set was duplicated (see Figure 8(b)) to show that this gain decreases under larger data sets; this decrease is due to the predictive density being an average of $p(x|\theta)$ over now more concentrated VB and EC posterior approximations. Secondly, meaningful improvements can be achieved through perturbation corrections. Figure 8(d) shows a second order correction to the log marginal likelihoods

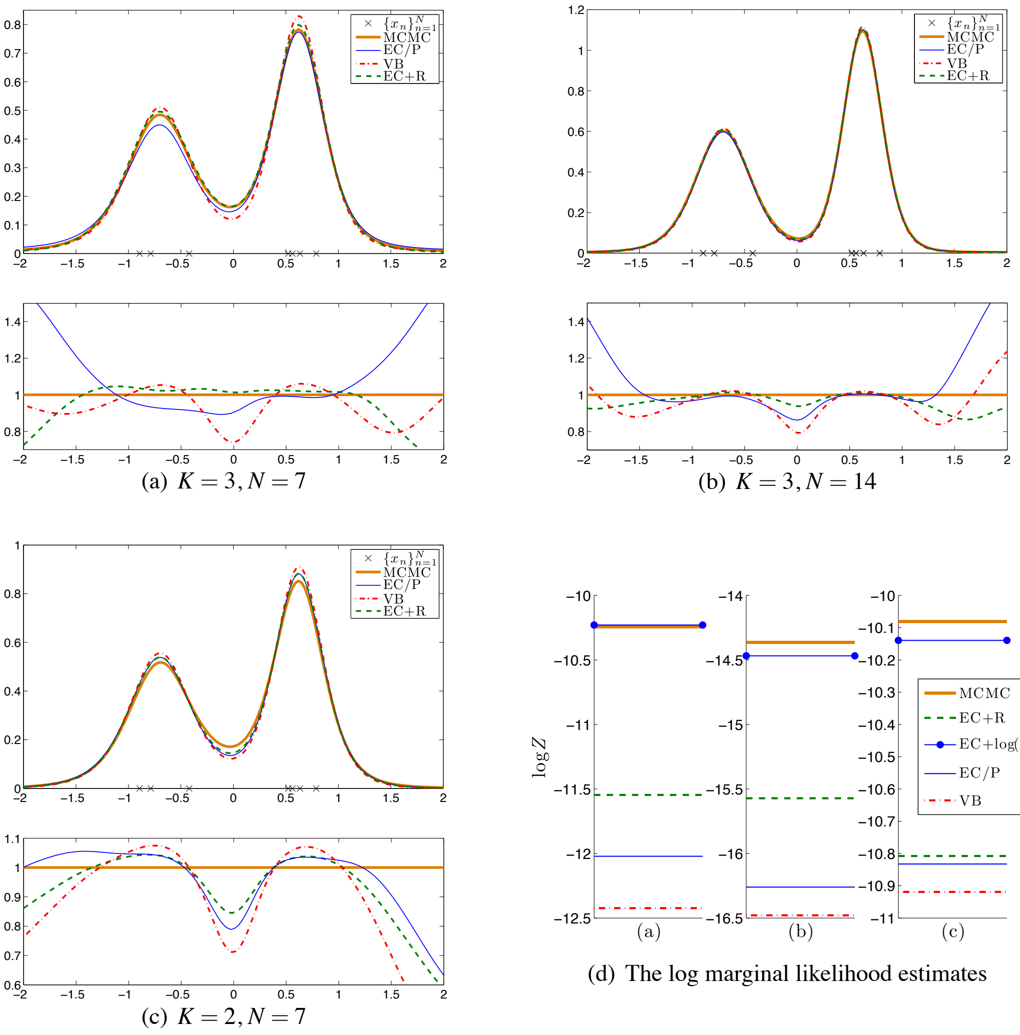

Figure 8: Predictive densities $p(x|\mathcal{D}, \mathcal{M}_K)$ given by VB, EC, and a perturbation correction (EC+R), with accompanying log marginal likelihood estimates and MCMC "truth" baselines. Note that if we "correct" with a factor $\log K!$ we get very close to the "truth" for VB and to a even higher degree for EC. EC+R overshoots in two cases but that might be because the perturbation corrected posterior is actually multi-modal. The lower figures in 8(a) to 8(c) show the *ratio* between each of the approximate predictive densities and the "truth."

of the examples in question, labeled "EC+R" (see Appendix F). A lower bound to the log marginal likelihood is provided by VB. The improvement is also visible when we are concerned with the predictive density, for which we show a first order correction.

6.4 A Practical Comparison

In this section we draw a comparison between the approximate log marginal likelihoods and predictive distributions given by VB, EP, and various corrections, and use estimations given by PT and TI as a benchmark. For interest we also include results from an implementation of $\alpha = \frac{1}{2}$ in Minka's general α-divergence message passing scheme for this problem, but refer the interested reader to Minka (2005) for further details. Finding a VB approximation follows directly from the expectation maximisation algorithm given by Attias (2000), with a slightly different parameterization of the Wishart distribution.

From the results that follow, we observe that the growth of $\log Z$, as a function of model size, gives a characteristic "Ockham hill" (defined in more detail later in this section), where the "peak" of the hill indicates the model with highest approximate $\log p(\mathcal{D})$. This graph can be used for model comparison or selection, as its form closely matches the MCMC evaluation of $\log p(\mathcal{D})$. We will also see that, following Section 6.1's discussion, the discrepancy between a $\log Z$ estimate and the true $\log p(\mathcal{D})$ grows as the model size is increased. Furthermore, the EC approximation gives a predictive distribution that is closer to the truth than VB, with the gain decreasing with increasing N. We will show that a principled algorithm initialization can circumvent many spurious local minima in the log marginal likelihood estimate. If completely arbitrary initialization schemes are implemented, one may note that the number of local solutions is influenced by the width of the prior distribution, with *more* local minima arising under broader prior distributions.

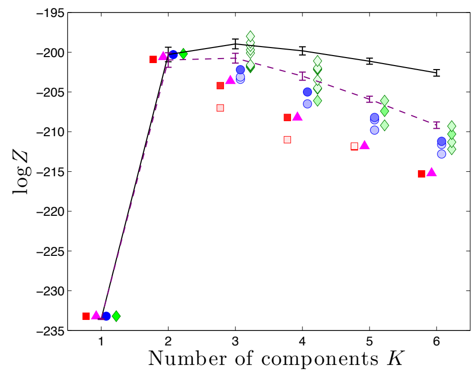
The data sets under investigation have been well studied, for example, by Richardson and Green (1997) for a reversible jump MCMC, and by Corduneanu and Bishop (2001) for variational Bayesian model selection: the **galaxy** data set contains the velocities (in 1000s of km/second) of 82 galaxies, diverging from our own, in the Corona Borealis region; the **acidity** data set contains the log measured acid neutralizing capacity indices for 155 lakes in North-central Wisconsin (USA); the **enzyme** data set contains enzymatic activity measurements, for an enzyme involved in the metabolism of carcinogenic substances, taken from 245 unrelated individuals; the **old faithful** data set contains 222 observation pairs consisting of eruption time and waiting time to the next eruption, from the Old Faithful Geyser in the Yellowstone National Park.

6.4.1 THE APPROXIMATE LOG MARGINAL LIKELIHOOD

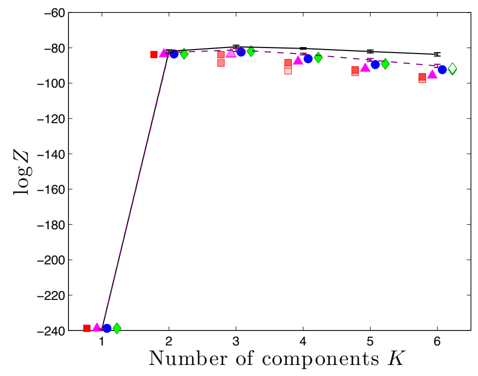
Ockham hills are useful for visualizing log marginal likelihood estimates for a set of plausible models with increasing explanatory power, for example, mixture models with increasing K. The largest estimates of $\log Z$ for the various models typically form a hill, peaking at the "optimal" model. As models become *less* complex, the hill falls steeply due to a poorer explanation of the data. For *more* complex models the plots show a slower downward trend, as an improvement in data fit is counterbalanced by a penalty from a larger parameter space in Bayesian marginalization. For mixture models this downward trend is even slower when the true log marginal is considered; this is mainly due to the number of modes in the true posterior increasing with the number of components, with an approximation possibly only capturing one of them.[5]

In the case of VB, the $\log Z$ approximation provides a lower bound to the marginal likelihood $p(\mathcal{D}|\mathcal{M})$, and this quantity is often used for model selection (Beal and Ghahramani, 2003, Bishop and Svensén, 2003, Corduneanu and Bishop, 2001). The model with the largest bound is typically kept, although the bound can also be used for model averaging. Regardless of our method of

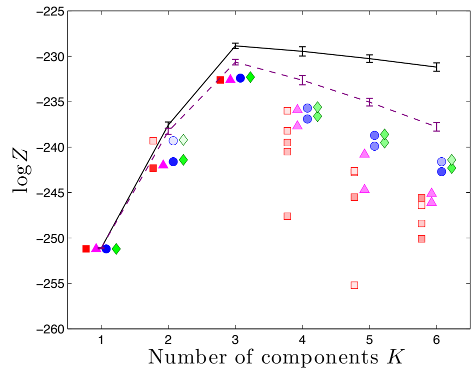
5. Rasmussen and Ghahramani (2001) present an account which includes "Ockham plateaus."



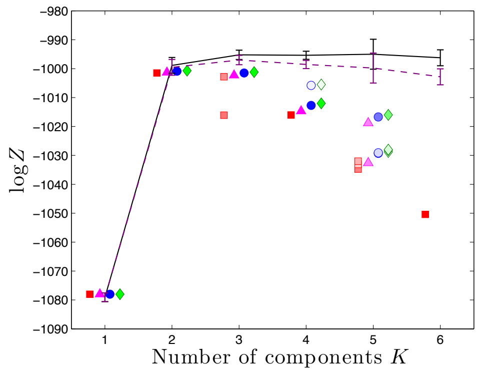
(a) **acidity** data set



(b) **enzyme** data set



(c) **galaxy** data set



(d) **old faithful** data set

Figure 9: Ockham hills for various data sets. VB is shown as red squares, $\alpha = \frac{1}{2}$ as magenta triangles, EC/P as blue circles, and EC+R as green diamonds. An estimate of $\log p(\mathcal{D}|\mathcal{M}_K)$ found by PT and TI is shown as a line. The effect of an $O(\log K!)$ correction on any of the approximate solutions can be seen by comparing them against the dashed-line plot of $\log p(\mathcal{D}|\mathcal{M}_K) - \log K!$. (For Figure 9(d)'s $K = 6$ the EP and $\alpha = \frac{1}{2}$ schemes did not converge.)

approximation, poor local minima in the objective function have to be avoided in order to obtain meaningful results.

Figure 9 shows such hills for the marginal likelihood approximations for different data sets for VB, $\alpha = \frac{1}{2}$ message passing, EP, and a second-order perturbation correction. The prior hyperparameters were $\lambda_{k,0} = 1$, $m_{k,0} = 0$, $\nu_{k,0} = 10^{-2}$, $a_{k,0} = 1$ and $B_{k,0} = 0.11$. For Figure 9(d) we took $B_{k,0} = [0.11, 0.01; 0.01, 0.11]$. For each of the models $\mathcal{M}_K$, with K mixture components, the figures show twenty approximations for each method, with the colour intensity of each plot corresponding to the frequency of reaching different approximations for $\log Z$. Each plot is complemented with estimates of $\log p(\mathcal{D}|\mathcal{M}_K)$. The estimates—shown as lines—were obtained form an average over ten PT and TI simulations, with two standard deviation error bars also being shown.

Finally, it is evident that the "true peak" in Figure 9(a) does not match the peak obtained by approximate inference. Without having to resort to MCMC and TI, the second order correction for $K = 3$ already confirms that the approximation might be inadequate.

6.4.2 THE EFFECT OF A GOOD INITIALIZATION

Finding the best VB/EP solution is strongly seed-dependent in the problem considered here. In this council of despair an educated guess may take us a long way: many inferior local minima in the VB/EP objective functions can be suppressed with a good algorithm initialization.

We base our factor initializations around a scaled version of the solution obtained by the VB expectation maximisation algorithm,

$$\exp(\Lambda_n^T \phi(\theta)) \propto \exp\left(\int dz_n \, q(z_n) \log p(x_n, z_n|\theta) \right) ,$$

which was seeded with a data clustering based on the k-means algorithm.[6] This is illustrated in Figure 9.

When using an "out of the box" EP scheme, starting with a slight asymmetric prior that is later corrected for, many lower minima are also found. The same behavior arises when the VB parameters are randomly initialized. Figure 10 shows more local minima than Figure 9(c), and the results in Bishop (2006, chapter 10), where the same principled initial guess for VB was used.[7]

The canonical EP scheme (and indeed $\alpha = \frac{1}{2}$) sometimes did not converge to a fixed point. This is evident in Figure 10 and has been observed in practice (Minka, 2001a): when EP does not converge, the reason can be traced back to the approximating family being a poor match to the exact posterior distribution.

6.4.3 THE PREDICTIVE DISTRIBUTION

Given a specific model $\mathcal{M}$, the predictive distribution can be approximated by using $p(x|\mathcal{D}) \approx \int d\theta \, p(x|\theta) q(\theta)$, as is shown for example in Figure 11. The final predictive distribution strongly depends on whether or not a global minimum in the objective function in (5) has been found, as is clear from Figure 11. To illustrate how much the approximate predictive distribution differs from the true predictive distribution, the figures show $p(x|\mathcal{D})$ obtained from an average over ten thousand $\beta = 1$ samples from a parallel tempered Markov chain. Figure 12 shows the gain achieved by EC/P over VB, and in turn the further improvement from a perturbation correction to the EC approximation (see Appendix F).

7. Conclusion and Outlook

In this paper we presented a method for computing systematic corrections to EC approximations in Bayesian inference. These corrections are useful not only in improving estimates like log marginal likelihood and predictive density approximations, but can also provide insight into the quality of an approximation in polynomial time. When the corrections are large the EC approximation may be

6. Similar to Appendix E, z indicates latent variables, with $p(\theta, z|\mathcal{D})$ approximated by $q(\theta)q(z)$. We point the interested reader to Attias (2000).
7. Markus Svensén, personal communication.

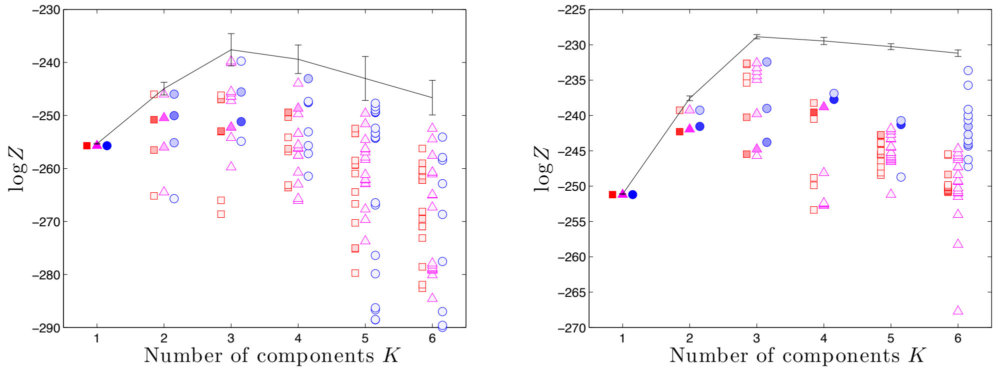


Figure 10: The effect of random algorithm initializations using the **galaxy** data set: For the *left* figure a broader prior with $\nu_{k,0} = 10^{-6}$, and for the *right* figure a much narrower prior with $\nu_{k,0} = 10^{-2}$, was used. Compared to Figure 9(c), note for example the additional local maxima at $K = 3$, and the greater number of local minima under a broader prior. (For $K = 6$ the EP scheme failed to converge without a sensible initialization.)

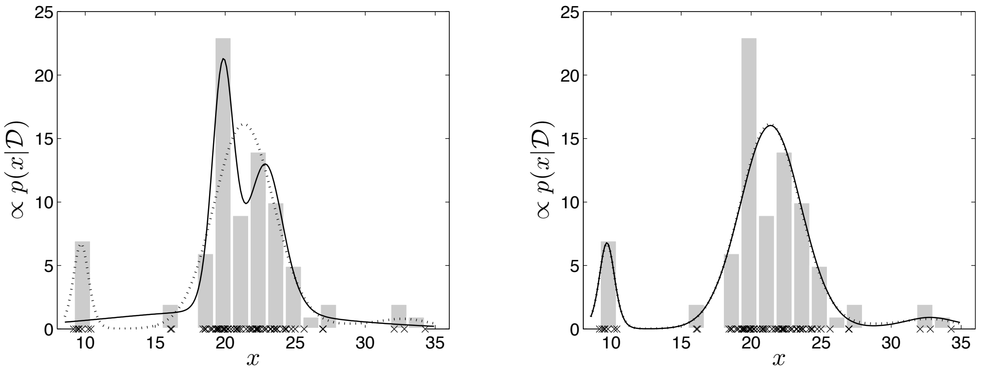

Figure 11: EP can have more than one stable fixed point: The predictive distribution $p(x|\mathcal{D}, \mathcal{M}_3)$, from two *different* approximations for the **galaxy** data set. For $K = 3$ under narrower prior in Figure 10, we see three local maxima of the EC objective function in (5): the predictive distribution shown on the *left* coincided with $\log Z_{\text{EC}} = -243.8$, whereas the approximation on the *right* coincided with a much higher $\log Z_{\text{EC}} = -232.4$. The true predictive distribution, obtained from an average over a PT MCMC sample, is shown with a dotted line.

questioned or discarded, and we hope to address the question of how it is done in practice in future work.

A juxtaposition of VB, EC and EP, PT with TI, and EC with corrections, was given in the context of Gaussian mixture models. We argued that EC can give improvements over VB, and can in turn be improved through a perturbation expansion. Throughout the paper our "gold standard" was given by PT, and we presented possible ways of improving it. We would like to include better

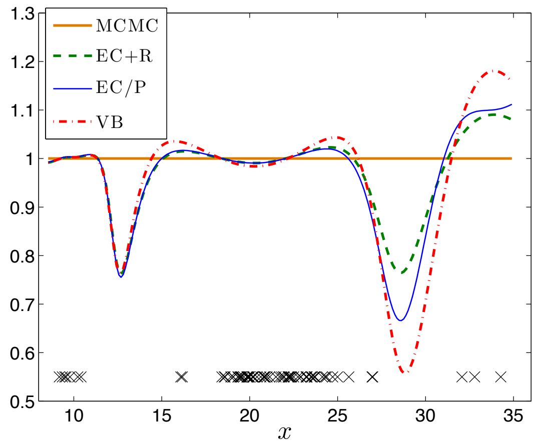

Figure 12: The ratio between each of the approximate predictive densities and the MCMC "truth" of $p(x|\mathcal{D},\mathcal{M}_3)$ for the **galaxy** data set. This figure corresponds to Figure 11 (right).

MCMC algorithms in this rich tapestry of methods: PT is not the best choice for near first-order phase transitions. In Figure 3 the high probability regions are very different above and below the transition at $\beta \approx 0.5$, suggesting multicanonical sampling as a viable alternative, since it aims at sampling from a distribution that is flat in the log likelihood and will therefore not have this "bottle-neck."

The choice of a unimodal $q(\theta)$ to capture the characteristics of a typically multimodal $p(\theta|\mathcal{D})$ also leads to various questions. When there are symmetries in the parameter space, with overlapping modes, we may ask whether or not we would achieve a better predictive density with EC, say, if the approximation is restricted to one mode. In the case where $p(\theta|\mathcal{D})$ is multimodal (large N) then fairly general arguments suggest that we should correct the marginal likelihood estimate by a factor of $K!$—higher order corrections may clarify for which N and under which conditions this transition will typically take place.

One way be improve the approximation is to generalize $q(\theta)$ for example by including a small fraction of the data points (similar to the proposed generalization of PT). However, that poses an additional problem an the matching of moments step in EP message passing gets much more complicated.

Finally, we focused on a MoG where the lower order terms in the correction R are tractable. For models where this is not the case, R can be expanded in terms of the higher order cumulants of $q_n(\theta)$ and $q(\theta)$. This approach will be presented in a companion paper.

Acknowledgments

We thank Zoubin Ghahramani for suggesting the generalization presented in Appendix E.2. We thank Tom Minka, Markus Svensén, and Neil Lawrence for helpful discussions and comments, and the anonymous reviewers for their comments.

Appendix A. Bounds on the Marginal Likelihood

It is interesting to compare the marginal likelihood approximation (5) with the one given by a variational approximation. Here one would use the fact that the relative entropy $\left\langle \log \frac{q(\theta)}{p(\theta|\mathcal{D})} \right\rangle_q \geq 0$ to approximate the free energy $-\log Z$ by the upper bound

$$-\log Z \leq \left\langle \log \left(\frac{q(\theta)}{p(\theta) \prod_n p(x_n|\theta)} \right) \right\rangle_q .$$

To compare with (5) we use the definition (3) to get

$$\frac{Z(\Lambda - \Lambda_n, 1_n)}{Z(\Lambda, 0)} = \left\langle p(x_n|\theta) \exp\left(-\Lambda_n^T \phi(\theta) \right) \right\rangle_q .$$

After inserting this expression into (5), taking logs and applying Jensen's inequality we arrive at

$$-\log Z_{\text{EC}} \leq \left\langle \log \left(\frac{\exp\left(\sum_n \Lambda_n^T \phi(\theta) \right)}{\prod_n p(x_n|\theta)} \right) \right\rangle_q - \log Z(\Lambda, 0) = \left\langle \log \left(\frac{q(\theta)}{p(\theta) \prod_n p(x_n|\theta)} \right) \right\rangle_q ,$$

where in the last step we have used $\sum_n \Lambda_n = \Lambda$. This shows that if one would use the distribution $q(\theta)$ derived from EC within the variational approximation, the EC approximation achieves a lower free energy. Since approximating densities in the variational approximation will usually differ from the EC result (by the way they are optimised) this does not imply that variational free energies are always higher than the EC counterpart. Also we cannot draw any conclusion about the relation to the true free energy.

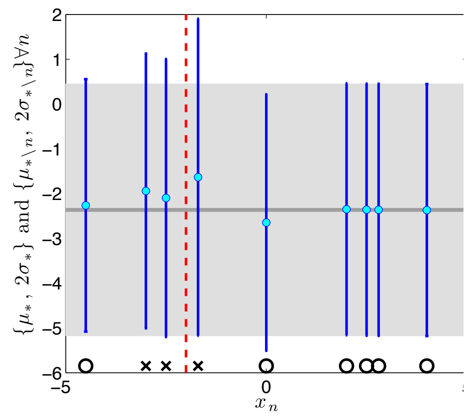
Appendix B. Gaussian Process Classification

This appendix provides the details of the derivation of first order correction to marginal distribution $p(f_*|\mathcal{D})$ for Gaussian process classification, as introduced in Section 3. Let k_* be the kernel vector with entries $k(x_*, x_n)$ for all n, and $\kappa_* = k(x_*, x_*)$. It is well-established that

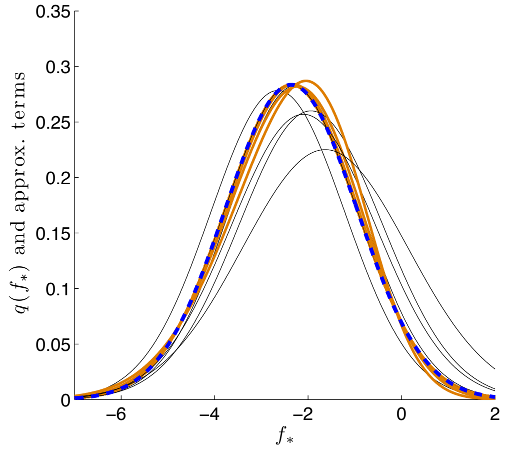
$$\begin{aligned} q(f_*) &= \mathcal{N}(f_*; \mu_*, \sigma_*^2), \\ \mu_* &= k_*^T K^{-1} \mu, \\ \sigma_*^2 &= \kappa_* - k_*^T (K + \tilde{S}^{-1})^{-1} k_* \end{aligned} \tag{21}$$

where $p(f_*|f) = \mathcal{N}(f_*; k_*^\top K^{-1} f, \kappa_* - k_*^\top K^{-1} k_*)$ was averaged over $q(f)$. To determine $q_n(f_*)$, we have to average $p(f_*|f)$ over $q_n(f)$: a lengthy derivation shows that the required integral $q_n(f_*) = \int df \, p(f_*|f) \, q_n(f)$ simplifies to

$$\begin{aligned} q_n(f_*) &= \Phi\left(\frac{y_n m_n(f_*)}{\sqrt{1 + V_n}} \right) \Big/ \Phi\left(\frac{y_n \mu_{\setminus n;n}}{\sqrt{1 + \Sigma_{\setminus n;n,n}}} \right) \times \mathcal{N}(f_*; \mu_{*\setminus n}, \sigma_{*\setminus n}^2), \\ \mu_{*\setminus n} &= k_*^T K^{-1} \mu_{\setminus n}, \\ \sigma_{*\setminus n}^2 &= \kappa_* - k_*^T (K + \tilde{S}_{\setminus n}^{-1})^{-1} k_* . \end{aligned} \tag{22}$$



(a) The mean μ_* and 2 standard deviations $2\sigma_*$ of the marginal $q(f_*)$ is shown as a gray error bar for a *novel* data point at $x_* = -2$ (dashed red line). Positive examples x_n are indicated with a $\circ$, and negative examples with a $\times$. At each x_n an error bar from $\mathcal{N}(f_*\,;\mu_{*\backslash n},\,\sigma^2_{*\backslash n})$ in (22) is shown for comparison. An exclusion of a negative example brings the density of the mean function f_* closer to zero; an exclusion of the the positive example at $x_n = 0$ increases the certainty about the class of x_*.



(b) The distributions $q(f_*)$ and each of the $q_n(f_*)$'s (which are not Gaussian) used in (13) are respectively shown in dashed blue and (thick solid) orange. These distributions are accumulated into the correction shown in Figure 1. To observe the influence of the non-linear "weight-function" of f_* in (22), the distributions $\mathcal{N}(f_*\,;\mu_{*\backslash n},\,\sigma^2_{*\backslash n})$ which are shown in Figure 13(a) are plotted as (thin) black lines.

Figure 13: An illustration of all the terms occurring in the first-order correction in (13) for an example data set.

This "tilted" predictive marginal in (22) has exactly the same form as $q(f_*)$ in (21), except[8] for its use of $\mu_{\backslash n}$ and $\tilde{S}_{\backslash n}$, and the nonlinear "weight" that is still a function of f_*, so that $q_n(f_*)$ is ultimately non-Gaussian. $\Sigma_{\backslash n;n,n}$ and $\mu_{\backslash n;n}$ denote elements (n,n) and n in $\Sigma_{\backslash n}$ and $\mu_{\backslash n}$.

In the ratio of cumulative Normals in (22) we have

$$V_n = \Sigma_{\backslash n;n,n} - \frac{\eta^2}{\sigma^2_{*\backslash n}},$$

$$m_n(f_*) = \mu_{\backslash n;n} + \frac{\eta(f_* - \mu_{*\backslash n})}{\sigma^2_{*\backslash n}},$$

where we define $\eta = k_*^T K^{-1} c_n$, with c_n being column n of $\Sigma_{\backslash n}$.

When comparing V_n and $\Sigma_{\backslash n;n,n}$ in the numerator and denominator in (22), we see that V_n is close to $\Sigma_{\backslash n;n,n}$ whenever η is small compared to $\sigma_{*\backslash n}$. Function $m_n(f_*)$ adjusts $\mu_{\backslash n;n}$ with a term *linear* in how far f_* differs from the Gaussian mean in (22), and is similarly close to $\mu_{\backslash n;n}$ when η is small compared to $\sigma^2_{*\backslash n}$.

Figure 13 provides an illustration of how the correction in (13) works. A squared exponential kernel $k(x_n, x_{n'}) = a\exp(-\frac{1}{2}\|x_n - x_{n'}\|^2/\ell^2)$ was used, with a being the (positive) amplitude, and ℓ

8. This representation is chosen for simplicity, although $\tilde{S}_{\backslash n}$ contains a zero on its diagonal.

the characteristic length-scale of the latent function. In Figure 13 the marginals $q(f_*)$ and $q_n(f_*)$ are shown, leading to the first-order correction originally shown in Figure 1.

Appendix C. Useful Distributions in the Exponential Family

In this paper we use the Dirichlet, Normal-Gamma and Normal-Wishart distributions for the MoG problem. For these distribution have to 1) compute their sufficient statistics, 2) for message passing solve the inverse problem: given the sufficient statistics we must solve for the parameters of the distribution and 3) for the predictions with the mixture models compute their predictive distribution.

C.1 Dirichlet

The Dirichlet distribution over the probability simplex π, $\sum_k \pi_k = 1$, is commonly used in two contexts: here as a prior over mixing proportions in the mixture model, and as a prior/posterior for the parameters of multinomial distribution. We denote the Dirichlet with parameters λ_k by

$$\mathcal{D}(\pi;\lambda) = \frac{1}{Z_{\mathcal{D}}(\lambda)} e^{\sum_k (\lambda_k - 1)\log \pi_k} \delta\left(\sum_k \pi_k - 1\right) , \tag{23}$$

$$Z_{\mathcal{D}}(\lambda) = \frac{\prod_k \Gamma(\lambda_k)}{\Gamma(\sum_k \lambda_k)} . \tag{24}$$

C.1.1 SUFFICIENT STATISTICS

The sufficient statistic of the Dirichlet is

$$\langle \log \pi_k \rangle = \frac{\partial \log Z_{\mathcal{D}}(\lambda)}{\partial \lambda_k} = \psi(\lambda_k) - \psi\left(\sum_k \lambda_k\right) , \tag{25}$$

where ψ is the digamma-function $d \log \Gamma(x)/dx$.

C.1.2 INVERSE

In line 5 of the Algorithms 1 and 2 we have to solve the inverse problem: given the statistics $m_k = \langle \log \pi_k \rangle$ find the parameters λ. This can be done effectively by first solving for

$$\alpha \equiv \psi\left(\sum_k \lambda_k\right) = \psi\left(\sum_k \psi^{-1}(m_k + \alpha)\right)$$

by Newton's method, and then setting $\lambda_k := \psi^{-1}(m_k + \alpha)$.

C.1.3 PREDICTIVE DISTRIBUTION

The Dirichlet can also be used as a prior for the parameters of the multinomial distribution. This distribution is used multi-category either counts or sequence data. For counts, $x = (x_1, \ldots, x_d)$ is a vector of counts for each of the possible d outcomes. For sequence data x is an indicator variable being one for the outcome and zero in all other entries. The multinomial distribution is:

$$p(x|\pi) = \frac{(\sum_k x_k)!}{x_1! \ldots x_d!} \prod_{k=1}^{d} \pi_k^{x_k} ,$$

where the combinatorial prefactor goes away in the sequence case. The predictive distribution for multinomial data and Dirichlet distributed posterior is straightforward to calculate using the result for the normalizer of the Dirichlet:

$$p(x|\lambda) = \int d\pi p(x|\pi) \mathcal{D}(\pi;\lambda) = \frac{(\sum_l x_l)!}{x_1! \dots x_d!} \frac{Z_{\mathcal{D}}(x+\lambda)}{Z_{\mathcal{D}}(\lambda)} \ .$$

C.2 Normal-Gamma

The Normal-Gamma (or Gauss-Gamma) model is use for a joint distribution of one dimensional mean and precision (inverse variance) variables:

$$\mathcal{NG}(\mu,\gamma;m,\nu,a,b) = \frac{1}{Z_{\mathcal{NG}}(m,\nu,a,b)} \exp\left[\begin{pmatrix} m\nu \\ -\frac{1}{2}\nu \\ -b-\frac{1}{2}\nu m^2 \\ a-\frac{1}{2} \end{pmatrix}^T \begin{pmatrix} \mu\gamma \\ \mu^2\gamma \\ \gamma \\ \log\gamma \end{pmatrix} \right] ,$$

$$Z_{\mathcal{NG}}(m,\nu,a,b) = \sqrt{\frac{2\pi}{\nu}} \frac{\Gamma(a)}{b^a} \ ,$$

where this distribution is obtained by multiplying the Normal and Gamma distributions:

$$\mathcal{N}(\mu;m,(\nu\gamma)^{-1}) = \sqrt{\frac{\nu\gamma}{2\pi}} \exp\left(-\frac{1}{2}(\mu-m)^2\nu\gamma\right) ,$$

$$\mathcal{G}(\gamma;a,b) = \frac{b^a}{\Gamma(a)} \exp((a-1)\log\gamma - b\gamma) \ ,$$

where a and b must be positive.

C.2.1 SUFFICIENT STATISTICS

The sufficient statistics are obtained by using $\log Z_{\mathcal{NG}}(m,\nu,a,b)$ as a generating function for the sufficient statistic. By taking derivatives of $\log Z_{\mathcal{NG}}$ with respect to the parameters $\{m,\nu,a,b\}$,

$$\begin{aligned} \nu\langle\mu\gamma\rangle - \nu m\langle\gamma\rangle &= 0, \\ m\langle\mu\gamma\rangle - \frac{1}{2}\langle\mu^2\gamma\rangle - m^2\langle\gamma\rangle &= -\frac{1}{2\nu}, \\ \langle\log\gamma\rangle &= \psi(a) - \log b, \\ -\langle\gamma\rangle &= -a/b \ , \end{aligned}$$

we can solve for $\langle\mu\gamma\rangle$, $\langle\mu^2\gamma\rangle$, $\langle\gamma\rangle$ and $\langle\log\gamma\rangle$.

C.2.2 INVERSE

We can use these expressions to solve for the parameters in terms of the sufficient statistics in the same fashion as above. We get closed form expressions for three of parameters

$$m = \frac{\langle\mu\gamma\rangle}{\langle\gamma\rangle} \ , \quad \nu = \frac{1}{\langle\mu^2\gamma\rangle - m^2\langle\gamma\rangle} \ , \quad b = \frac{a}{\langle\gamma\rangle} \ ,$$

and a should be found from

$$\psi(a) - \log a = \langle \log \gamma \rangle - \log \langle \gamma \rangle$$

by for example Newton's method.

C.2.3 PREDICTIVE DISTRIBUTION

The predictive distribution can be calculated straightforwardly from the normalizer and is a univariate Student-t distribution:

$$\begin{aligned} p(x|m,\nu,a,b) &= \frac{1}{\sqrt{2\pi}} \frac{Z_{\mathcal{NG}}\left(\frac{x+\nu m}{\nu+1}, \nu+1, a+\frac{1}{2}, b+\frac{\nu}{\nu+1}(x-m)^2\right)}{Z_{\mathcal{NG}}(m,\nu,a,b)} \\ &= \mathcal{T}\left(x;\ m,\ \frac{b}{a}\frac{\nu+1}{\nu},\ 2a\right) , \end{aligned}$$

where $\mathcal{T}\left(x;\mu,\sigma^2,d_{\mathrm{f}}\right)$ is a Student-t distribution with mean μ, variance σ^2 and d_{f} degrees of freedom:

$$\begin{aligned} \mathcal{T}\left(x;\mu,\sigma^2,d_{\mathrm{f}}\right) &= \frac{1}{Z_{\mathcal{T}}(\mu,\sigma^2,d_{\mathrm{f}})} \exp\left[-\frac{d_{\mathrm{f}}+1}{2}\log\left(1+\frac{1}{d_{\mathrm{f}}}\left(\frac{x-\mu}{\sigma}\right)^2\right)\right], \\ Z_{\mathcal{T}}(\mu,\sigma^2,d_{\mathrm{f}}) &= \sqrt{2\pi\sigma^2}\sqrt{\frac{d_{\mathrm{f}}}{2}} \frac{\Gamma\left(\frac{d_{\mathrm{f}}}{2}\right)}{\Gamma\left(\frac{d_{\mathrm{f}}+1}{2}\right)} . \end{aligned}$$

C.3 Normal-Wishart

The Normal-Wishart is the multidimensional generalization of the Normal-Gamma. We will write the Wishart distribution over positive definite symmetric matrices in the same form as the Gamma distribution:

$$\mathcal{W}(\Gamma;a,B) \propto \exp\left(\left(a-\frac{d+1}{2}\right)\log\det\Gamma - \mathrm{tr}B\Gamma\right) ,$$

where the degrees of freedom $2a$ should be greater than $d-1$ for the distribution to be normalizable. The Normal-Wishart is given by

$$\begin{aligned} \mathcal{NW}(\mu,\Gamma;m,\nu,a,B) &= \frac{1}{Z_{\mathcal{NW}}(m,\nu,a,B)} \\ &\quad \exp\left[\begin{pmatrix} \nu m \\ -\frac{1}{2}\nu \\ a-\frac{d}{2} \end{pmatrix}^T \begin{pmatrix} \Gamma\mu \\ \mu^T\Gamma\mu \\ \log\det\Gamma \end{pmatrix} - \mathrm{tr}(B+\frac{1}{2}\nu m m^T)\Gamma\right] , \\ Z_{\mathcal{NW}}(m,\nu,a,B) &= \pi^{d(d-1)/4}\left(\frac{2\pi}{\nu}\right)^{d/2}\prod_{l=1}^{d}\Gamma\left(a+\frac{1-l}{2}\right)e^{-a\log\det B} . \end{aligned}$$

C.3.1 SUFFICIENT STATISTICS

The sufficient statistics follow from a straightforward generalization of the results from the Normal-Gamma model:

$$\langle \Gamma \rangle = aB^{-1},$$

$$\begin{aligned}
\langle \Gamma\mu \rangle &= \langle \Gamma \rangle m, \\
\langle \mu^T \Gamma \mu \rangle &= \frac{d}{\nu} + m^T \langle \Gamma \rangle m, \\
\langle \log\det\Gamma \rangle &= \sum_{l=1}^{d} \psi\left(a + \frac{1-l}{2}\right) - \log\det B \ .
\end{aligned}$$

C.3.2 INVERSE

From the sufficient statistics we can get closed form expressions for the parameters

$$m = \langle \Gamma \rangle^{-1} \langle \Gamma\mu \rangle \ , \quad \nu = \frac{d}{\langle \mu^T \Gamma \mu \rangle - m^T \langle \Gamma \rangle m} \ , \quad B = a \langle \Gamma \rangle^{-1} \ ,$$

whereas a should be found from

$$\sum_{l=1}^{d} \psi\left(a + \frac{1-l}{2}\right) - d \log a = \langle \log\det\Gamma \rangle - \log\det\langle \Gamma \rangle \ .$$

C.3.3 PREDICTIVE DISTRIBUTION

A generalization of the result for the predictive distribution in one dimension to the multivariate case gives:

$$p(x|m,\nu,a,b) = \mathcal{T}\left(x;\ m,\ \frac{2B}{2a-d+1}\frac{\nu+1}{\nu},\ 2a-d+1\right) \ ,$$

where $\mathcal{T}(x;\mu,\Sigma,d_{\mathrm{f}})$ is the d-dimensional multivariate Student-t distribution with mean μ, covariance Σ and d_{f} degrees of freedom:

$$\begin{aligned}
\mathcal{T}(x;\mu,\Sigma,d_{\mathrm{f}}) &= \frac{1}{Z_{\mathcal{T}}(\mu,\Sigma,d_{\mathrm{f}})} \exp\left[-\frac{d_{\mathrm{f}}+d}{2} \log\left(1 + \frac{1}{d_{\mathrm{f}}}(x-\mu)^T \Sigma^{-1} (x-\mu)\right)\right], \\
Z_{\mathcal{T}}(\mu,\sigma^2,d_{\mathrm{f}}) &= \sqrt{\det(2\pi\Sigma)} \left(\frac{d_{\mathrm{f}}}{2}\right)^{d/2} \frac{\Gamma\left(\frac{d_{\mathrm{f}}}{2}\right)}{\Gamma\left(\frac{d_{\mathrm{f}}+d}{2}\right)} \ .
\end{aligned}$$

Appendix D. Inference for a Mixture of Gaussians

When we have unconstrained d-dimensional data we can model this with a Normal (or Gaussian) distribution,

$$p(x|\mu,\Gamma) = \mathcal{N}(x;\mu,\Gamma^{-1}) = \sqrt{\frac{\det\Gamma}{(2\pi)^d}} \exp\left(-\frac{1}{2}(x-\mu)^T \Gamma (x-\mu)\right) \ ,$$

where μ and Γ are respectively the mean vector and precision (or inverse covariance) matrix. The conjugate prior for the mean and precision is the Normal-Wishart distribution, which we describe in appendix C. In the following we choose Gaussians $p(x|\mu_k,\Gamma_k)$ as components densities $p(x|k)$ in the mixture.

D.1 Variational and Predictive Distributions

The q distribution follows the prior and is conveniently chosen to factorise over mixture components:

$$q(\theta) = q(\pi)\prod_k q(\mu_k, \Gamma_k)$$

with $q(\mu_k, \Gamma_k | m_k, \nu_k, a_k, B_k)$ being a Normal-Wishart distribution; see Appendix C. We can use the same machinery as Section 4 to derive the EC approximation to the predictive distribution and the statistics needed for message passing.

The predictive distribution $p(x|\mathcal{D})$ is again approximated by the form given in (14), with $p(x|k)$ replaced by

$$p(x|k) \equiv p(x|m_k, \nu_k, a_k, B_k) = \mathcal{T}\left(x;\ m_k,\ \frac{2B_k}{2a_k - d + 1}\frac{\nu_k + 1}{\nu_k},\ 2a_k - d + 1\right) . \tag{26}$$

Here $\mathcal{T}$ is a Student-t distribution, which we describe in greater detail in Appendix C.

Likewise, the within data set predictive distribution $p(x_n|\mathcal{D}_{\backslash n})$ follows (15); only now $p(x_n|k)$ is replaced with $p(x_n|k\backslash n)$, which takes the same form as (26) above, with Λ replaced by $\Lambda_{\backslash n}$. The Dirichlet cavity parameters are again $\lambda_{k\backslash n} = \lambda_{k,0} + \sum_{n' \neq n} \lambda_{k,n'}$. The other cavity parameters are similarly defined in terms of the appropriate parameter vector components, for instance $\nu_{k\backslash n} m_{k\backslash n} = \nu_{k,0} m_{k,0} + \sum_{n' \neq n} \nu_{k,n'} m_{k,n'}$.

We can again use the cavity parameters to write q_n in terms of $q_{\backslash n}$:

$$q_n(\theta) = \frac{Z(\Lambda_{\backslash n}, 0)}{Z_n(\Lambda_{\backslash n}, 1_n)} q_{\backslash n}(\theta) \sum_k \pi_k p(x_n | \mu_k, \Gamma_k) .$$

The normalizer is given by

$$Z_n(\Lambda_{\backslash n}, 1_n) = Z(\Lambda_{\backslash n}, 0) \sum_k \langle \pi_k \rangle_{q_{\backslash n}} p(x_n | k\backslash n) , \tag{27}$$

where the explicit form of $Z(\Lambda_{\backslash n}, 0)$ is

$$Z(\Lambda_{\backslash n}, 0) = Z_{\mathcal{D}}(\lambda_{\backslash n}) \prod_k Z_{\mathcal{NW}}(m_{k\backslash n}, \nu_{k\backslash n}, a_{k\backslash n}, B_{k\backslash n}) .$$

D.2 Expectations

The statistics of $q_n(\theta)$ for the mixture of Gaussians are computed by using $\log Z_n(\Lambda_{\backslash n})$ from (27) as a generating function. To simplify the derivative with respect to the predictive distribution $p(x_n|k\backslash n)$, we introduce another component-specific Normal-Wishart distribution

$$q_{k,n}(\mu_k, \Gamma_k) \propto p(x_n|\mu_k, \Gamma_k) q_{\backslash n}(\mu_k, \Gamma_k) ,$$

and write the predictive distribution as a ratio between the normalizers of $q_{k,n}$ and $q_{\backslash n}$:

$$p(x_n|k\backslash n) = \frac{(2\pi)^{-d/2} Z_{\mathcal{NW}}\left(\frac{\nu_{k\backslash n} m_{k\backslash n} + x_n}{\nu_{k\backslash n} + 1}, \nu_{k\backslash n} + 1, a_{k\backslash n} + \frac{1}{2}, B_{k\backslash n} + \frac{1}{2}\frac{\nu_{k\backslash n}}{\nu_{k\backslash n} + 1}(x_n - m_{k\backslash n})(x_n - m_{k\backslash n})^T\right)}{Z_{\mathcal{NW}}(m_{k\backslash n}, \nu_{k\backslash n}, a_{k\backslash n}, B_{k\backslash n})} .$$

For example, for $\langle \Gamma_k \mu_k \rangle$ we get

$$\left\langle \Gamma_k \mu_k \right\rangle_{q_n} = \frac{1}{\nu_{k\backslash n}} \frac{d \log Z_n(\Lambda_{\backslash n})}{d m_{k\backslash n}} = (1 - r_{nk}) \left\langle \Gamma_k \mu_k \right\rangle_{q_{\backslash n}} + r_{nk} \left\langle \Gamma_k \mu_k \right\rangle_{q_{k,n}} , \tag{28}$$

where the "responsibility" (the probability of example n being generated by the kth mixture component) is defined as

$$r_{nk} = \frac{\lambda_{k\backslash n} p(x_n | k\backslash n)}{\sum_{k'} \lambda_{k'\backslash n} p(x_n | k'\backslash n)} . \tag{29}$$

The expectation in (28) is expressed as a weighed sum of a "prior" expectation over the cavity distribution $q_{\backslash n}(\mu_k, \Gamma_k)$, and a "posterior" expectation over $q_{k,n}(\mu_k, \Gamma_k)$. The other moments $\langle \Gamma_k \rangle$, $\langle \mu_k^T \Gamma_k \mu_k \rangle$ and $\langle \log \det \Gamma_k \rangle$ can be expressed as weighed sums similar to (28):

$$\begin{aligned}
\left\langle \Gamma_k \right\rangle_{q_n} &= (1 - r_{nk}) \left\langle \Gamma_k \right\rangle_{q_{\backslash n}} + r_{nk} \left\langle \Gamma_k \right\rangle_{q_{k,n}}, \\
\left\langle \mu_k^T \Gamma_k \mu_k \right\rangle_{q_n} &= (1 - r_{nk}) \left\langle \mu_k^T \Gamma_k \mu_k \right\rangle_{q_{\backslash n}} + r_{nk} \left\langle \mu_k^T \Gamma_k \mu_k \right\rangle_{q_{k,n}}, \\
\left\langle \log \det \Gamma_k \right\rangle_{q_n} &= (1 - r_{nk}) \left\langle \log \det \Gamma_k \right\rangle_{q_{\backslash n}} + r_{nk} \left\langle \log \det \Gamma_k \right\rangle_{q_{k,n}} .
\end{aligned}$$

The explicit expressions for the $q_{k,n}$ are given below, whereas those for $q_{\backslash n}$ can be obtained from Appendix C:

$$\begin{aligned}
\left\langle \Gamma_k \right\rangle_{q_{k,n}} &= \left(a_{k\backslash n} + \frac{1}{2} \right) \left[B_{k\backslash n} + \frac{1}{2} \frac{\nu_{k\backslash n}}{\nu_{k\backslash n} + 1} (x_n - m_{k\backslash n})(x_n - m_{k\backslash n})^T \right]^{-1} , \\
\left\langle \Gamma_k \mu_k \right\rangle_{q_{k,n}} &= \left\langle \Gamma_k \right\rangle_{q_{k,n}} \frac{\nu_{k\backslash n} m_{k\backslash n} + x_n}{\nu_{k\backslash n} + 1}, \\
\left\langle \mu_k^T \Gamma_k \mu_k \right\rangle_{q_{k,n}} &= \frac{d}{\nu_{k\backslash n} + 1} + \left(\frac{\nu_{k\backslash n} m_{k\backslash n} + x_n}{\nu_{k\backslash n} + 1} \right)^T \left\langle \Gamma_k \right\rangle_{q_{k,n}} \left(\frac{\nu_{k\backslash n} m_{k\backslash n} + x_n}{\nu_{k\backslash n} + 1} \right), \\
\left\langle \log \det \Gamma_k \right\rangle_{q_{k,n}} &= \sum_{i=1}^{d} \psi \left(a_{k\backslash n} + \frac{1}{2} + \frac{1 - i}{2} \right) \\
&\qquad - \log \det \left(B_{k\backslash n} + \frac{1}{2} \frac{\nu_{k\backslash n}}{\nu_{k\backslash n} + 1} (x_n - m_{k\backslash n})(x_n - m_{k\backslash n})^T \right) .
\end{aligned}$$

We have already seen how to solve for $\langle \log \pi_k \rangle_{q_n}$, the only difference being r_{nk} in (16), which we now take from (29).

Appendix E. Gibbs Sampling for Parallel Tempering

Parallel tempering of a mixture of Gaussian distributions $p(x_n|\theta) = \sum_{k=1}^{K} \pi_k \mathcal{N}(x_n; \mu_k, \Gamma_k^{-1})$ requires a Monte Carlo simulation at inverse temperature β. We can either sample from $p(\theta|\mathcal{D}, \beta)$ using a Metropolis-Hastings (MH) method, or augment the parameter space with latent allocation variables z so that we can sample from $p(\theta, z|\mathcal{D}, \beta)$ with Gibbs sampling. We may also define $p(z|\mathcal{D}, \beta) = \int d\theta \, p(\theta, z|\mathcal{D}, \beta)$, and devise a MH scheme on this distribution by making random assignment changes to z.

The road of Gibbs sampling is pathed with tractable conditional distributions of $p(\theta, z|\mathcal{D}, \beta)$, and it is the one we choose. We extend the parameter space to include a binary latent allocation vector z_n

for each data point n to indicate which mixture component was responsible for generating it (Diebolt and Robert, 1994); consequently $z_{nk} \in \{0,1\}$, and $\sum_k z_{nk} = 1$. The complete joint distribution is therefore

$$p(\mathcal{D}, z|\theta)p(\theta) = \prod_n \prod_k \left[\pi_k \mathcal{N}(x_n; \mu_k, \Gamma_k^{-1})\right]^{z_{nk}} p(\theta) \ .$$

We can write the complete data likelihood as $p(\mathcal{D}, z|\theta) = p(\mathcal{D}|z,\theta)p(z|\theta)$, and in this form the likelihood, to the power β, multiplied by the prior over z and θ, is

$$p(\mathcal{D}|z,\theta)^\beta \times p(z,\theta) = \prod_n \prod_k \mathcal{N}(x_n; \mu_j, \Gamma_k^{-1})^{\beta z_{nk}} \times \prod_n \prod_k \pi_k^{z_{nk}} p(\theta) \ .$$

(Note that the introduction of z moves π to the prior.) With inverse temperature parameter β the tempered posterior distribution is $p(\theta, z|\mathcal{D}, \beta) \propto p(\mathcal{D}|z,\theta)^\beta p(z,\theta)$, and can be treated as any missing-value Gibbs sampling problem. The allocation variables are sampled with

$$z_{nk}|\pi, \mu, \Gamma \sim \frac{\pi_k \mathcal{N}(x_n; \mu_k, \Gamma_k^{-1})^\beta}{\sum_{k'} \pi_{k'} \mathcal{N}(x_n; \mu_{k'}, \Gamma_{k'}^{-1})^\beta} \ .$$

Given the allocation variables, we define

$$r_{nk} = \beta z_{nk}, \qquad \bar{x}_k = \frac{1}{N_k} \sum_n r_{nk} x_n,$$
$$N_k = \sum_n r_{nk} \qquad \Sigma_k, = \frac{1}{N_k} \sum_n r_{nk} (x_n - \bar{x}_k)(x_n - \bar{x}_k)^T \ ,$$

to give the conditional distributions needed for sampling the mixture parameters as

$$\begin{aligned} \pi|z &\sim \mathcal{D}\big(\pi; \lambda_{1,0} + \tfrac{1}{\beta}N_1, \ldots, \lambda_{K,0} + \tfrac{1}{\beta}N_K\big), \\ \mu_k, \Gamma_k|z &\sim \mathcal{NW}\big(\mu_k, \Gamma_k; m, \nu, a, B\big) \ , \end{aligned} \tag{30}$$

with

$$\begin{aligned} m &= \frac{\nu_{k,0} m_{k,0} + N_k \bar{x}_k}{\nu_{k,0} + N_k}, \\ \nu &= \nu_{k,0} + N_k, \\ a &= a_{k,0} + N_k/2, \\ B &= B_{k,0} + \frac{1}{2} N_k \Sigma_k + \frac{1}{2} \frac{N_k \nu_{k,0} (\bar{x}_k - m_{k,0})(\bar{x}_k - m_{k,0})^T}{\nu_{k,0} + N_k} \ . \end{aligned} \tag{31}$$

As $p(\mathcal{D}) = \int d\theta dz\, p(\mathcal{D}, \theta, z)$, we use the samples over θ and z to estimate the average log likelihood. If $\{\{\pi_{k,i}^{(t)}, \mu_{k,i}^{(t)}, \Gamma_{k,i}^{(t)}\}_{k=1}^K, \{z_{n,i}^{(t)}\}_{n=1}^N\}_{t=1}^T$ indicates the samples of chain i (after a burn-in period), then

$$\langle \log p(\mathcal{D}|\theta, z) \rangle_{\beta_i} \approx \frac{1}{T} \sum_t \sum_n \sum_k z_{nk,i}^{(t)} \log \mathcal{N}\big(x_n; \mu_{k,i}^{(t)}, \Gamma_{k,i}^{(t)\,-1}\big) \ . \tag{32}$$

Notice that the samples of the mixing weights $\pi_{k,i}^{(t)}$ are not used in estimating the log likelihood average over the posterior, but occur in the prior.

E.1 A Practical Generalization (I)

The generalization of PT and TI from Section 5.3 can be made by writing the tempered posterior distribution as

$$p(\theta, z|\mathcal{D}, \beta) \propto \prod_n \prod_k \mathcal{N}(x_n; \mu_k, \Gamma_k^{-1})^{\beta z_{nk}} \pi_k^{z_{nk}} p(\theta)^\beta q(\theta)^{1-\beta} ,$$

where $\prod_{n,k} \pi_k^{z_{nk}} = p(z|\theta)^\beta q(z|\theta)^{1-\beta}$ follows from $p(z|\theta) = q(z|\theta)$. To do Gibbs sampling as before, we have to determine the parameters of the "effective" prior in the above scenario. Here we let $q(\theta)$ be in the same family—for example a narrower version—of the prior. If superscripts p and q now differentiate between the parameters of $p(\theta)$ and $q(\theta)$, we use

$$\begin{aligned}
\lambda_0 &= \beta\lambda_0^p + (1-\beta)\lambda_0^q, \\
m_{k,0} &= \frac{\beta\nu_{k,0}^p m_{k,0}^p + (1-\beta)\nu_{k,0}^q m_{k,0}^q}{\beta\nu_{k,0}^p + (1-\beta)\nu_{k,0}^q}, \\
\nu_{k,0} &= \beta\nu_{k,0}^p + (1-\beta)\nu_{k,0}^q, \\
a_{k,0} &= \beta a_{k,0}^p + (1-\beta)a_{k,0}^q, \\
B_{k,0} &= \beta B_{k,0}^p + (1-\beta)B_{k,0}^q + \frac{1}{2}\frac{\beta\nu_{k,0}^p(1-\beta)\nu_{k,0}^q}{\beta\nu_{k,0}^p + (1-\beta)\nu_{k,0}^q}(m_{k,0}^p - m_{k,0}^q)(m_{k,0}^p - m_{k,0}^q)^T
\end{aligned}$$

as substitute for the usual prior in (30) and (31). The empirical expectation given in (32) should be generalized—simplifying the left hand side below with $p(z,\theta)/q(z,\theta) = p(\theta)/q(\theta)$—to

$$\left\langle \log p(\mathcal{D}|\theta, z) + \log\frac{p(\theta)}{q(\theta)} \right\rangle_{\beta_i} \approx \frac{1}{T}\sum_t \Bigg[\log p(\pi_i^{(t)}) - \log q(\pi_i^{(t)}) + \sum_k \Big[\log p(\mu_{k,i}^{(t)}, \Gamma_{k,i}^{(t)}) \\ - \log q(\mu_{k,i}^{(t)}, \Gamma_{k,i}^{(t)}) + \sum_n z_{nk,i}^{(t)} \log\mathcal{N}\big(x_n; \mu_{k,i}^{(t)}, {\Gamma_{k,i}^{(t)}}^{-1}\big)\Big]\Bigg] .$$

E.2 A Practical Generalization (II)

We implemented a further possible generalization, which arises from choosing $q(\theta) = p(\theta|\mathcal{D}')$, where $\mathcal{D}'$ contains a small subset of data points from $\mathcal{D}$. This sensibly restricts q to parameter space closer to the posterior, with the benefit that the normalizer of q needs to be calculated only once. With $|\mathcal{D}'|$ being small, q can be evaluated analytically without feeling the effect of the exponentially expanding number of terms. This brings an interesting tradeoff, as setting $\mathcal{D}' \leftarrow \mathcal{D}$ solves our original (difficult) problem. (Figure 3 used this choice of surrogate prior, with $\mathcal{D}'$ containing 3 out of a possible 82 data points.)

We can construct $q(\theta)$ as follows: Let $N' = |\mathcal{D}'|$ be the number of data points in $\mathcal{D}'$, so that $q(\theta)$ expands as a sum over $(N')^K$ terms. Allow $1, \ldots, K$ to be the digit set of a number system in base K. Make a list $\mathcal{S}$ of the first $(N')^K$ numbers in base K, such that each number s consists of N' digits, and each $x_{n'} \in \mathcal{D}'$ can be associated with a corresponding digit *position*. Each $s \in \mathcal{S}$ therefore defines a unique allocation for all $x_{n'} \in \mathcal{D}'$ to clusters $1, \ldots, K$ ($x_{n'}$'s digit *value*). We shall use the shorthand $\mathcal{D}'_s$ to indicate a data set with a data point to cluster allocation given by s.

The surrogate prior is a weighted sum of various posteriors

$$q(\theta) = p(\theta|\mathcal{D}') = \sum_{s\in\mathcal{S}} w_s p(\pi|\mathcal{D}'_s) \prod_k p(\mu_k, \Gamma_k|\mathcal{D}'_s) .$$

If $Z_s = \int d\theta\, p(\theta, \mathcal{D}'_s)$, the weights are determined with $w_s = Z_s / \sum_{s'} Z_{s'}$.

Instead of merely raising q to the power $1 - \beta$, we first turn q into a product amenable to Gibbs sampling by augmenting it with binary indicator variables $y = \{y_s\}_{s \in \mathcal{S}}$ that pick a particular component of q; $\sum_s y_s = 1$. With $q(y) = p(y) = \prod_s w_s^{y_s}$, the surrogate prior now takes the form $q(z|\theta)q(\theta|y)q(y)$; the prior becomes $p(z|\theta)p(\theta)p(y)$. The empirical expectation in (32) generalizes to

$$\left\langle \log p(\mathcal{D}|\theta, z) + \log \frac{p(\theta)}{q(\theta|y)} \right\rangle_{\beta_i} \approx \frac{1}{T} \sum_t \Bigg[\log p(\pi_i^{(t)}) - \sum_s y_{s,i}^{(t)} \log p(\pi_i^{(t)}|\mathcal{D}'_s) + \sum_k \Big[\log p(\mu_{k,i}^{(t)}, \Gamma_{k,i}^{(t)}) - \sum_s y_{s,i}^{(t)} \log p(\mu_{k,i}^{(t)}, \Gamma_{k,i}^{(t)}|\mathcal{D}'_s) + \sum_n z_{nk,i}^{(t)} \log \mathcal{N}\big(x_n; \mu_{k,i}^{(t)}, {\Gamma_{k,i}^{(t)}}^{-1}\big) \Big] \Bigg] .$$

Appendix F. Perturbation Corrections for Mixture of Gaussians

In this appendix we show how to compute the second-order terms of (8),

$$R = 1 + \sum_{n_1 < n_2} \Big\langle \varepsilon_{n_1}(\theta)\varepsilon_{n_2}(\theta) \Big\rangle_q + \sum_{n_1 < n_2 < n_3} \Big\langle \varepsilon_{n_1}(\theta)\varepsilon_{n_2}(\theta)\varepsilon_{n_3}(\theta) \Big\rangle_q + \dots , \tag{33}$$

and the first-order term in the numerator of (10),

$$p(x|\mathcal{D}) = \frac{\int d\theta\, q(\theta)\, p(x|\theta)\, \left(1 + \sum_n \varepsilon_n(\theta) + \sum_{n_1<n_2} \varepsilon_{n_1}(\theta)\varepsilon_{n_2}(\theta) + \dots\right)}{1 + \sum_{n_1<n_2} \langle \varepsilon_{n_1}(\theta)\varepsilon_{n_2}(\theta) \rangle_q + \dots} . \tag{34}$$

The sum in the second order term runs over all distinct pairs and the complexity thus grows as $O(N^2)$. However, one would expect that the largest contribution comes from nearby points, or more precisely points that belong to the same component, as indicated by a large responsibility for the same component. Although not done here, it is plausible to restrict the summation to only include these pairs without sacrificing much precision.

Let $\Lambda = \{\lambda, \{m_k, v_k, a_k, B_k\}_{k=1}^K\}$ be the parameters that solve the EC equations. We also have access to the parameters of each of the cavity distributions $\Lambda_{\setminus n}$.

For each n the parameters of $q_n(\theta)$ is given by the parameters of $p(x_n|\theta)q_{\setminus n}(\theta)$, which expands as a sum over the K mixture components. Each element k in the sum contains a product of a Dirichlet density and K Normal-Wishart densities. The Dirichlet parameter vector will have element k incremented by one, and as x_n is associated with component k, it will affect only the parameters of the kth Normal-Wishart. Therefore, apart from the cavity parameters $\Lambda_{\setminus n}$, we will also need for each $k = 1, \dots, K$:

$$\begin{aligned}
\lambda^*_{k\setminus n} &= \lambda_{k\setminus n} + 1 \quad \text{and} \quad \lambda^*_{k'\setminus n} = \lambda_{k'\setminus n} \text{ for } k' \neq k, \\
v^*_{k\setminus n} &= v_{k\setminus n} + 1, \\
m^*_{k\setminus n} &= \frac{v_{k\setminus n} m_{k\setminus n} + x_n}{v_{k\setminus n} + 1}, \\
a^*_{k\setminus n} &= a_{k\setminus n} + \tfrac{1}{2},
\end{aligned}$$

$$B^*_{k\setminus n} = B_{k\setminus n} + \frac{1}{2}\frac{v_{k\setminus n}}{v_{k\setminus n}+1}(m_{k\setminus n} - x_n)(m_{k\setminus n} - x_n)^T \; . \tag{35}$$

The normalizer of $q_n(\theta)$ follows from (27) to be $\int d\theta' p(x_n|\theta')q_{\setminus n}(\theta') = \sum_k \langle \pi_k \rangle_{q_{\setminus n}} p(x_n|k\setminus n) = Z_n$.

F.1 Corrections for the Marginal Likelihood

A single second-order term in (33) can be evaluated with

$$\begin{aligned}
\Big\langle \varepsilon_{n_1}(\theta)\varepsilon_{n_2}(\theta)\Big\rangle_q &= \int d\theta \, \frac{q_{n_1}(\theta)q_{n_2}(\theta)}{q(\theta)} - 1 \\
&= -1 + \frac{1}{Z_{n_1}}\frac{1}{Z_{n_2}}(2\pi)^{-d}\sum_{k=1}^{K}\sum_{l=1}^{K}\left\{ \frac{Z_{\mathcal{D}}(\lambda)\,Z_{\mathcal{D}}(\lambda^{(k,l)})}{Z_{\mathcal{D}}(\lambda_{\setminus n_1})\,Z_{\mathcal{D}}(\lambda_{\setminus n_2})} \right. \\
&\quad \cdots \times \left. \prod_{j=1}^{K} \frac{Z_{\mathcal{NW}}(m_j, v_j, a_j, B_j)\,Z_{\mathcal{NW}}(m_j^{(k,l)}, v_j^{(k,l)}, a_j^{(k,l)}, B_j^{(k,l)})}{Z_{\mathcal{NW}}(m_{j\setminus n_1}, v_{j\setminus n_1}, a_{j\setminus n_1}, B_{j\setminus n_1})\,Z_{\mathcal{NW}}(m_{j\setminus n_2}, v_{j\setminus n_2}, a_{j\setminus n_2}, B_{j\setminus n_2})} \right\} .
\end{aligned}$$

The above sum over k relates x_{n_1} to coming from a particular mixture component k, while the sum over l does the same for x_{n_2}. For a particular element in the sum over k and l we need parameters relating to each of the $j = 1, \ldots, K$ mixture components. For the Dirichlet normalizer the parameters $\lambda_j^{(k,l)}$ depend on whether $k = l$, implying that both x_{n_1} and x_{n_2} were generated from the same mixture component, or whether $k \neq l$, implying that x_{n_1} and x_{n_2} came from different mixture components. The elements of $\lambda^{(k,l)}$ are:

$$\lambda_j^{(k,l)} = \lambda_{j\setminus n_1} + \lambda_{j\setminus n_2} - \lambda_j \qquad \text{for } j \neq k, l \; .$$

When $k \neq l$ two indices j remain to be defined; if $k = l$ we will have one remaining index to take care of:

$$\begin{aligned}
\lambda_j^{(k,l)} &= \lambda^*_{j\setminus n_1} + \lambda_{j\setminus n_2} - \lambda_j && \text{for } j = k \text{ and } k \neq l, \\
\lambda_j^{(k,l)} &= \lambda_{j\setminus n_1} + \lambda^*_{j\setminus n_2} - \lambda_j && \text{for } j = l \text{ and } k \neq l, \\
\lambda_j^{(k,l)} &= \lambda^*_{j\setminus n_1} + \lambda^*_{j\setminus n_2} - \lambda_j && \text{for } j = k = l \; .
\end{aligned}$$

For each element in the sum over k and l the Normal-Wishart parameters are similarly defined. When $j \neq k, l$ we have:

$$\begin{aligned}
v_j^{(k,l)} &= v_{j\setminus n_1} + v_{j\setminus n_2} - v_j, \\
m_j^{(k,l)} &= \frac{v_{j\setminus n_1} m_{j\setminus n_1} + v_{j\setminus n_2} m_{j\setminus n_2} - v_j m_j}{v_{j\setminus n_1} + v_{j\setminus n_2} - v_j}, \\
a_j^{(k,l)} &= a_{j\setminus n_1} + a_{j\setminus n_2} - a_j, \\
B_j^{(k,l)} &= B_{j\setminus n_1} + \frac{1}{2} v_{j\setminus n_1} m_{j\setminus n_1} m^T_{j\setminus n_1} + B_{j\setminus n_2} + \frac{1}{2} v_{j\setminus n_2} m_{j\setminus n_2} m^T_{j\setminus n_2} \\
&\quad \cdots - B_j - \frac{1}{2} v_j m_j m_j^T - \frac{1}{2} v_j^{(k,l)} m_j^{(k,l)} m_j^{(k,l)T} \; .
\end{aligned}$$

As was seen for the mixture weights, we will need further definitions: when $j = k$ and $k \neq l$ we shall use $v_j^{(k,l)} = v^*_{j\backslash n_1} + v_{j\backslash n_2} - v_j$; a similar definition follows when $j = l$. Finally, when $j = k = l$ we find that $v_j^{(k,l)} = v^*_{j\backslash n_1} + v^*_{j\backslash n_2} - v_j$. The other Normal-Wishart parameters follow the same route. The correction evaluates in $O(N^2K^2)$ complexity.

F.2 Corrections for the Predictive Distribution

From (34) we can compute a first-order correction to the predictive distribution with $p(x|\mathcal{D}) \approx \int d\theta\, q(\theta)p(x|\theta)(1 + \sum_n \varepsilon_n(\theta))$, which we rewrite as

$$p(x|\mathcal{D}) \approx \sum_n \int d\theta\, p(x|\theta)q_n(\theta) - (N-1)\int d\theta\, p(x|\theta)q(\theta)\ .$$

Each predictive density in the above equation simplifies as

$$\int d\theta\, p(x|\theta)q_n(\theta) = \frac{1}{Z_n}\sum_k \sum_l \begin{cases} \dfrac{\lambda_{k\backslash n}\lambda_{l\backslash n}}{(\sum_{k'}\lambda_{k'\backslash n}+1)\sum_{k'}\lambda_{k'\backslash n}} p(x_n|k\backslash n)\, p(x|l\backslash n) & \text{if } k \neq l \\[2ex] \dfrac{(\lambda_{k\backslash n}+1)\lambda_{k\backslash n}}{(\sum_{k'}\lambda_{k'\backslash n}+1)\sum_{k'}\lambda_{k'\backslash n}} p(x_n|k\backslash n)\, p(x|x_n, k\backslash n) & \text{if } k = l. \end{cases}$$

We have seen how to compute $p(x_n|k\backslash n)$ in (26) and the discussion that followed it; we similarly define $p(x|l\backslash n)$. Density $p(x|x_n, k\backslash n)$ is again the Student-t distribution of (26), but now Λ is replaced with $\Lambda^*_{\backslash n}$ from (35). The correction evaluates in $O(NK^2)$ complexity.

Abstract

Process discovery is the automated construction of structured process models from information system event logs. Such event logs often contain positive examples only. Without negative examples, it is a challenge to strike the right balance between recall and specificity, and to deal with problems such as expressiveness, noise, incomplete event logs, or the inclusion of prior knowledge. In this paper, we present a configurable technique that deals with these challenges by representing process discovery as a multi-relational classification problem on event logs supplemented with Artificially Generated Negative Events (AGNEs). This problem formulation allows using learning algorithms and evaluation techniques that are well-know in the machine learning community. Moreover, it allows users to have a declarative control over the inductive bias and language bias.

Keywords: graph pattern discovery, inductive logic programming, Petri net, process discovery, positive data only

1. Introduction

Learning descriptive or predictive models from sequence data is an important data mining task with applications in Web usage mining, fraud detection, bio-informatics, and process discovery. The learning task can be formulated as follows: given a sequence database that contains a finite number of sequences, find a useful generative model that describes or predicts its spatio-temporal properties. Depending on the application domain, a variety of sequence models and corresponding learning algorithms are available. For instance, probabilistic generative models such as (hidden) Markov models have been successfully applied in speech analysis, and bio-informatics (Durbin et al., 1998), whereas deterministic models such as partial orders have been applied in domains such as Web usage mining (Mannila and Meek, 2000; Pei et al., 2006). In this paper, we focus on the problem of process discovery, the discovery of business process models from event-based data generated by information systems. Process models typically contain structures such as sequences, or-splits, and-splits (parallel threads), or-joins, and-joins, loops (iterations), non-local, non-free, history-dependent or-splits, and duplicate activities. Because Petri nets can represent these con-

structs, they are known to be a convenient process modeling language (van der Aalst, 1998; Alves de Medeiros, 2006) provides a detailed overview of how these structures can be represented with Petri nets.

The motivation for process discovery is the abundant availability of information system event logs. The analysis of such event logs can provide insight into how processes *actually* take place, and to what extent actual processes deviate from a normative process model. Information system events keep track of, among others, the completion of an activity of a particular activity type. For example, an event can report that a particular activity of type ‘apply for license’ has completed. The goal of process discovery is to construct a useful process model that *describes* the event sequences recorded in the event log. Example 1, illustrates the learning problem for a fictitious driver’s license application process. Given the event sequence database in Example 1, a useful process models is to be conceived.

Example 1 *DriversLicenseI—discovery of a driver’s license application process with loop. The transitions correspond to activity types that have the following meaning: a start, b apply for license, c attend classes cars, d attend classes motor bikes, e obtain insurance, f theoretical exam, g practical exam cars, h practical exam motor bikes, i get result, j receive license, and k end.*

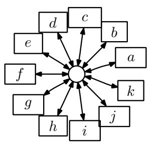
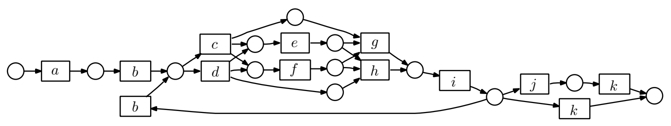
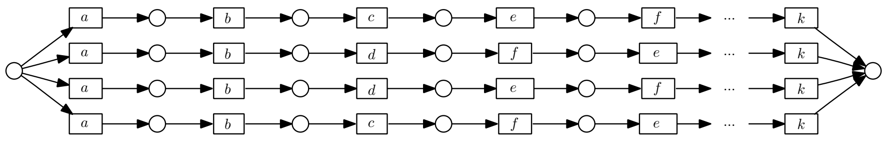
(a) sequences



(b) general



(c) specific and general



(d) over-specific

The construction of useful process models from an event log is subjected to many challenging problems. An inherent difficulty is that process discovery is limited to a setting of unsupervised learning. Event logs rarely contain negative information about state transitions that were prevented from taking place. Such negative information can be useful to discover the discriminating properties of the underlying process. In the absence of negative information, it is necessary to provide a learner with a particular *inductive bias*, to accurately strike the right balance between generality and specificity. The absence of negative information, makes the learning task aim at accurately summarizing an event log such that the discovered process model allows the observed behavior (recall) but does not include unintended, random behavior that is not present in the event log (specificity). In addition to accuracy, the learning problem faces challenges such as expressiveness, noise, incomplete event logs, and the inclusion of prior knowledge:

- **accuracy**: accuracy refers to the extent to which the induced model fits the behavior in the event log. Accuracy necessitates a tradeoff between specificity and recall. The Petri net in

Example 1, called a flower model, is capable of parsing every sequence in the event log. However, it can be considered to be overly general as it allows any activity to occur in any order. In contrast, the Petri net in Example 1 is overly specific, as it provides a mere enumeration of the different sequences in the event log. The Petri net in Example 1 is likely to be the more suitable process model. It is well-structured, and strikes a reasonable balance between specificity and generality, allowing for instance an unseen sequence *abcefgik*, but disallowing random behavior. An additional difficulty is that in the absence of negative information, the specificity of a learned process model is difficult to quantify.

- **expressiveness**: expressiveness relates to the ability to comprehensively summarize an event log using a rich palette of structures such as sequences, or-splits, and-splits (parallel threads), or-joins, and-joins, loops (iterations), history-dependent or-splits, and duplicate activities.
- **noise**: human-centric processes are prone to exceptions and logging errors. This causes additional low-frequent behavior to be present in the event log that is unwanted in the process model to be learned. Process discovery algorithms face the challenge of not overfitting this noise.
- **incomplete logs**: incomplete event logs do not contain the complete set of sequences that occur according to the underlying, real-life process. This is particularly the case for processes that portray a large amount of concurrent and recurrent behavior. In this case, process discovery algorithms must be capable of generalizing beyond the observed behavior.
- **prior knowledge**: the problem of consolidating the knowledge extracted from the data with the knowledge representing the experience of domain experts, is called the knowledge fusion problem (Dybowski et al., 2003). Prior knowledge constrains the hypothesis space of a sequence mining algorithm. In the context of process discovery, prior knowledge might refer to knowledge about concurrency (parallelism), locality, or exclusivity of activities. When a learner produces a process model that is not in line with the prior knowledge of a domain expert, the expert might refuse using the discovered process model. For instance, a domain expert might refuse a process model in which a pair of activities cannot take place concurrently, whereas in reality such parallelism is actually allowed.

In this paper, these challenges addressed by representing process discovery as an ILP classification learning problem on event logs supplemented with artificially generated negative events (AGNEs). The AGNEs technique is capable of constructing Petri net models from event logs and has been implemented as a mining plugin in the ProM framework. A benchmark experiment with 34 artificial event logs and comparison to four state-of-the-art process discovery algorithms indicate that the technique is expressive, robust to noise, and capable of dealing with incomplete event logs. A second contribution of the paper is the definition of a new metric for quantifying the specificity of an induced process model, based on these artificially generated negative events.

The remainder of this paper is structured as follows. Section 2 introduces some preliminaries and notations about inductive logic programming, event logs, and Petri nets. Section 3 explains the rationale for generating artificial negative events and provides a detailed description of the used algorithms. Section 4 discusses the process discovery technique. Section 5 introduces the new specificity metric that is based on negative events. Sections 6 and 7 provide both an experimental and practical evaluation of the process discovery technique. Finally, Section 8 provides an overview of the work in the area of process discovery and outlines the contributions made.

2. Preliminaries

This section introduces the most important concepts and notations that are used in the remainder of this paper.

2.1 Inductive Logic Programming

Inductive Logic Programming (ILP) (Muggleton, 1990; Džeroski and Lavrač, 1994, 2001; Džeroski, 2003) is a research domain in machine learning involving learners that use logic programming to represent data, background knowledge, the hypothesis space, and the learned hypothesis. ILP learners are called multi-relational learners and extend classical, uni-relational learners in the sense that they can not only learn patterns that occur within single tuples (within rows), but can also find patterns that may range over different tuples of different relations (between multiple rows of a single or multiple tables). For process discovery, this multi-relational property is much desired, as it allows discovering patterns that relate the occurrence of an event to the occurrence of any other event in the event log.

Within ILP, *concept learning* is an important learning task. An ILP classification learner will search for a hypothesis H in a hypothesis space $\mathcal{S}$ that best discriminates between the positive P and negative examples N ($E = P \cup N$) in combination with some given background knowledge B. A particularly salient feature of such learners is that they have a highly configurable language bias. The language bias $\mathcal{L}$ specifies the hypothesis space $\mathcal{S}$ of logic programs H that can be considered. In addition, users of ILP learners can specify background knowledge B as a logic program. Such background knowledge is a more parsimonious encoding of knowledge that is true about every example, than is the case for the attribute-value encoding of propositional learners. In addition to their multi-relational capabilities, the power of ILP concept learners lies with the configurability of their language bias $\mathcal{L}$ and background knowledge B. The effectiveness by which an ILP learner can be applied to a learning task depends on the choices that are made in representing the examples E, the background knowledge B and the language bias $\mathcal{L}$.

In this text, we make use of TILDE (Blockeel and De Raedt, 1998), a first-order decision tree learner available in the ACE-ilProlog data mining system (Blockeel et al., 2002). Blockeel (1998) formalizes the learning task of TILDE as follows:
given:

- a set of classes C
- a set of classified examples E, each example $(e, c) \in E$ is an independent logic program for which the predicate $Class(c)$ denotes that e is classified into class c.
- a logic program B that represents the background knowledge
- a language bias $\mathcal{L}$ that specifies a hypothesis space $\mathcal{S}$ of logic programs.

find: a hypothesis $H \in \mathcal{S}$ (a logic program) such that for all labeled examples $(e, c) \in E$,

- $\forall e \in E : H \wedge e \wedge B \vDash Class(c)$
- $\forall e \in E, \forall c' \in C \backslash \{c\} : H \wedge e \wedge B \nvDash Class(c')$.

TILDE is a first-order generalization of the well-known C4.5 algorithm for decision tree induction (Quinlan, 1993). Like C4.5, TILDE (Blockeel and De Raedt, 1998; Blockeel et al., 2002) obtains classification rules by recursively partitioning the data set according to logical conditions that can be represented as nodes in a tree. This top-down induction of logical decision trees (TILDE) is driven by refining the node criteria according to the provided language bias $\mathcal{L}$. Unlike C4.5, TILDE is capable of inducing first-order logical decision trees (FOLDT). A FOLDT is a tree that holds logical formula containing variables instead of propositions. Blockeel and De Raedt (1998) show how each FOLDT can be converted into a logic program.

2.2 Event Logs

In process discovery, an event log is a database of event sequences. Each event reports an instantaneous state change of an activity of a particular activity type. Activities and events that pertain to the same process instance are identified by a so-called case identifier. In process discovery, the MXML format for event logs (van Dongen and van der Aalst, 2005a) is the commonly accepted format for event logs. To use event logs with TILDE event logs have to be represented as a logical program. Let X be a set of event identifiers, P a set of case identifiers, the alphabet A a set of activity types, and $E = \{completed, completeRejected\}$ a set of event types. An event predicate is a quintuple $Event(x, p, a, e, t)$, where $x \in X$ is the event identifier, $p \in P$ is the case identifier, $a \in A$ the activity type, $e \in E$ the event type, and $t \in \mathbb{N}$ the time of occurrence of the event. The function $Case \in X \cup L \rightarrow P$ denotes the case identifier of an event or a sequence. The function $AT \in X \rightarrow A$ denotes the activity type of an event. The function $ET \in X \rightarrow E$ denotes the event type of an event. The function $Time \in X \rightarrow \mathbb{N}$ denotes the time of occurrence of an event. The set X of identifiers has a complete ordering, such that $\forall x, y \in X : x < y \vee y < x$ and $\forall x, y \in L : x < y \Rightarrow Time(x) \leq Time(y)$. The event types $E = \{completed, completeRejected\}$ respectively indicate the completion of a particular activity or that the completion of a particular activity could not take place, a negative event.

Let an event log L be a set of sequences σ. Let $\sigma \in L$ be an event sequence, an ordered set of event identifiers $x \in X$ of events pertaining to the same process instance as denoted by the case id; $\sigma = \{x \mid x \in X \wedge Case(x) = Case(\sigma)\}$. The function $Position \in X \times L \rightarrow \mathbb{N}_0$ denotes the position of an event with identifier $x \in X$ in the sequence $\sigma \in L$. Two subsequent event identifiers within a sequence σ can be represented as a sequence $x.y \subseteq \sigma$. We define the .-predicate as follows

$$x.y \Leftrightarrow \exists x, y \in \sigma : x < y \wedge \nexists z \in \sigma : x < z < y.$$

In the text, this predicate is used within the context of a single sequence σ which is therefore left implicit. Given that $AT(x) = a, AT(y) = b$ the information in the sequence can be further abbreviated as *ab*, because the order of the activity types in a sequence is the most important information for the purpose of process discovery. This notation is used to represent the event log in Example 1. Each row σ_i in the event log represents a different execution sequence that corresponds to a particular process instance.

2.3 Petri Nets

Example 1 is a Petri net representation of a simplified driver's license application process. Petri nets represent a graphical language with a formal semantics that has been used to represent, analyze, verify, and simulate dynamic behavior (Murata, 1989). Petri nets consist of places, tokens, and arcs. *Places* (drawn as circles) can contain *tokens* and are a distributed representation of state.

Each different distribution of tokens over the places of a Petri net indicate a different state. Such a state is called a *marking*. *Transitions* (drawn as rectangles) can consume and produce tokens and represent a state change. *Arcs* (drawn as arrows) connect places and transitions and represent a flow relationship. More formally, a marked Petri net is a pair $((P,T,F),s)$ where,

- P is a finite set of places,
- T is a finite set of transitions such that $P \cap T = \emptyset$, and
- $F \subseteq (P \times T) \cup (T \times P)$ is a finite set of direct arcs, and
- $s \in P \to \mathbb{N}$ is a bag over P denoting the marking of the net (van der Aalst, 1997, 1998).

Petri nets are bipartite directed graphs, that means that each arc must connect a transition to a place or a place to a transition. The transitions in a Petri net can be labeled or not. Transitions that are not labeled are called *silent transitions*. Different transitions that bear the same label are called *duplicate transitions*.

The behavior of a Petri net is determined by the *firing rule*. A transition t is *enabled* iff each input place p of t contains at least one token. When a transition is enabled it can *fire*. When a transition fires, it brings about a state change in the Petri net. In essence, it consumes one token from each input place p and produces one token in each output place p of t. To evaluate the extent to which a Petri net is capable of parsing an event sequence, transitions might be forced to fire. A transition that is not enabled, can be *forced to fire*. When a transition is forced to fire, it consumes one token from each input place that contains a token—if any—and produces one token in each output place. Petri nets are capable of representing structures such as sequences, or-splits, and-splits (parallel threads), or-joins, and-joins, loops (iterations), history-dependent or-splits, and duplicate activities that are typical for organizational processes.

3. Artificial Negative Events

Event logs generally contain sequences of positive events only. To make a tradeoff between overly general or overly specific process models, learners make additional assumptions about the given event sequences. Such assumptions are part of the inductive bias of a learner. Process discovery algorithms generally include the assumption that event logs portray the complete behavior of the underlying process and implicitly use this completeness assumption to make a tradeoff between overly general and overly specific process models. Our technique makes this completeness assumption explicit by inducing artificial negative information from the event log in a configurable way.

For processes that contain a lot of recurrent and concurrent behavior, the completeness assumption can become problematic. For example, a process containing five parallel activities (ten parallel pairs) that are placed in a loop, has $\sum_{i=1}^{n}(5!)^i$ different possible execution sequences (n being the maximum number of allowed loops).

The more recurrent behavior a process has, the more different kinds of event sequences a process can produce. This makes a given event log less likely to contain all possible behavior. The problem of recurrent behavior is addressed by restricting the window size (parameter: *windowSize*). Window size is the number of events in the subsequence one hopes to detect at least once in the sequence database. The larger the window size, the less probable that a similar subsequence is contained by the other sequences in the event log. A limited window size can be advantageous in the presence of loops (recurrent behavior) in the underlying process. Limiting the window size to a smaller subsequence of the event log, makes the completeness assumption less strict. An unlimited window size ($windowSize = -1$) results in the most strict completeness assumption.

The problem of concurrent behavior is addressed by exploiting some available parallelism information, discovered by induction or provided as prior knowledge by a domain expert. Given a subsequence and parallelism information, all parallel variants of the subsequence can be calculated. Taking into account the parallel variants of a subsequence makes the completeness assumption less strict.The function $AllParallelVariants(\tau)$ returns the set of all parallel variants that can be obtained by permuting the activities in each sub-sequence of τ while preserving potential dependency relationships among non-parallel activities.

Negative events record that at a particular position in an event sequence, a particular event cannot occur. At each position k in each event sequence τ_i, it is examined which negative events can be induced for this position. Algorithm 1 gives an overview of the negative event induction and is discussed in the next paragraphs. In a first step, the event log is made more compact, by grouping process instances $\sigma \in L$ that have identical sequences into grouped process instances $\tau \in M$ (line 1). By grouping similar process instances, searching for similar behavior in the event log can be performed more efficiently.

In the next step, all negative events are induced for each grouped process instance (lines 2–12). Making a completeness assumption about an event log boils down to assuming that behavior that does not occur in the event log, should not occur in the process model to be learned. Negative examples can be introduced in grouped process instances τ_i by checking at any given positive event $x_k \in \tau_i$ at position $k = Position(x_k, \tau_i)$ whether another event of interest z_k of activity type $b \in A \backslash \{AT(x_k)\}$ also could occur. For each event $x_k \in \tau_i$, it is tested whether there exists a similar sequence $\tau_j^{\|} \in AllParallelVariants(\tau_j) : \tau_j \neq \tau_i$ in the event log in which at that point a state transition y_k has taken place that is similar to z_k (line 6). If such a state transition does not occur in any other sequence, such behavior is not present in the event log L. This means under the completeness assumption that the state transition cannot occur. Consequently, z_k can be added as a negative event at this point k in the event sequence τ_i (lines 7–8). On the other hand, if a similar sequence is found with this behavior, no negative event is generated.

Finally, the negative events in the grouped process instances are used to induce negative events into the similar non-grouped sequences. If a grouped sequence τ contains negative events at position k, then the ungrouped sequence σ contains corresponding negative events at position k. At each position, a large number of negative events can generally be generated. To avoid an imbalance in the proportion of negative versus positive events the addition of negative events can be manipulated with a negative event injection probability π (line 13). π is a parameter that influences the probability that a corresponding negative event is recorded in an ungrouped trace σ. The smaller π, the less negative events are generated at each position in the ungrouped event sequences. A value of $\pi = 1.0$ means that every induced negative event for a grouped sequence is included in every similar, corresponding, non-grouped sequence. A value of $\pi = 0$ will result in no negative events being induced for any of the corresponding, non-grouped sequences.

Example 2 illustrates how in an event log of two (grouped) sequences τ_1 and τ_2 artificial negative events can be generated. The event sequences originate from a simplified driver's license process, depicted at the bottom. Given the parallelism information, $Parallel(e, f)$, the event sequences each have two parallel variants. When generating negative events into event sequence τ_1, it is examined whether instead of the first event b the events $c, d, e, f, g, h,$ or i could also have occurred at the

```

first position. Because there is no similar sequence $\tau_j^{\|}$ in which c, d, e, f, g, h, or i occur at this position, it can be concluded that they are negative events. Consequently $\neg c, \neg d, \neg e, \neg f, \neg g, \neg h$, and $\neg i$ are added as negative events at this position. Other artificial negative events are generated in a similar fashion. Notice that history-dependent processes generally will require a larger window size to correctly detect all non-local dependencies. In Example 2, an unlimited window size is used. Should the window size be limited to 1, for instance, then it would no longer be possible to take into account the non-local dependency between the activity pairs *c*–*g* and *d*–*h*. In the experiments at the end of this paper, an unlimited window size has been used (parameter value -1).

4. Process Discovery

Having an algorithm to artificially generate negative events, it becomes possible to represent process discovery as a binary classification problem, that learns the conditions that discriminate between the occurrence of an activity (a positive event), or the non-occurrence of an activity (a negative event). Algorithm 2 outlines four major steps in the AGNEs process discovery procedure. These four steps are addressed this section.

4.1 Step 1: Induce Parallelism and Locality Information

The starting point is the gathering of information about local dependency ($Local(a,b)$), and parallelism relationships ($Parallel(a,b)$, or $Serial(a,b)$) that exist between pairs of activities $a, b \in A$ in an event log L. Locality information is used in the language bias of the classification learner, to constrain the hypothesis space to locally discriminating preconditions when required. Without locality information, the classification learner is likely also to come up with non-local dependencies

3: step 3: learn the preconditions of each activity type
4: step 4: transform the preconditions into a Petri net
```

that cannot easily be transformed into a graphical model. Parallelism information is used to prevent the construction of sequential models, where in reality concurrency is expected.

This information is either gathered by the analysis of frequent temporal constraints that hold in the event log or by means of user-specified prior knowledge. Frequent temporal constraints are temporal constraints that hold in a sufficient number of sequences σ within an event log L. Goedertier (2008), defines a number of temporal constraints and shows how local dependency and parallelism information can be derived from it.

Additionally, the end-user can also specify locality and parallelism information in terms of prior knowledge. In particular, the following predicates can be used: *PriorParallel*(a,b), *PriorSerial*(a,b), *PriorLocal*(a,b), and *PriorNonLocal*(a,b). Information specified using these predicates defeats any inference about locality or parallelism made on the basis of the information gathered from frequent temporal constraints.

4.2 Step 2: Generate Artificial Negative Events

A second step in the process discovery technique is the induction of artificial negative events, as described in Section 3. The inferred information about parallel activity pairs can be used for parallel variant calculation. Furthermore, the induction of negative events is dependent on the window size *windowSize*, and negative event injection probability π parameters.

4.3 Step 3: Learn the Preconditions of each Activity Type

It is now possible to represent process discovery as a multiple, first-order classification learning problem that learns the preconditions that discriminate between the occurrence of either a positive or a negative completion event for each activity type. In our experiments, we make use of TILDE, an existing multi-relational classification learner, to perform the actual classification learning.

The motivation for representing process discovery as a classification problem is that it allows using classification learning and evaluation techniques that are well-known in the machine learning community. Furthermore, classification learners have the potential to deal with so-called **duplicate tasks**. Duplicate tasks refer to the reoccurrence of identically labeled transitions, homonyms, in different contexts within the event logs. Classification learning can detect the different execution contexts for these transitions and derive different preconditions for them. Transforming these preconditions into graphs will eventually result in duplicate, homonymic activities in the graph model that correspond to the different usage contexts. Techniques for process discovery, such as heuristics miner and genetic miner, which have causal matrices as internal representation (Weijters et al., 2006; Alves de Medeiros et al., 2007), are unable to discover duplicate activities. Alves de Medeiros (2006), however, presents a non-trivial extension of the genetic miner that includes duplicate tasks.

The motivation for using a multi-relational, first-order representation is that first-order learning allows relating the occurrence of an event to the occurrence of any other event. This enables the detection of patterns that involve non-local, historic, dependencies between events. Alternatively, the history of each event could in part be represented as extra propositions, for instance by including all preceding positive events as extra columns in the event log. This propositional representation would have many difficulties.

Being able to detect non-local, historic patterns in an event log can also produce counter-intuitive results. A non-local relationship might have more discriminating power than a local one and can therefore be preferred by a learner. Unfortunately, an excess of non-local patterns makes it more difficult to generate a graphical model, a Petri net, containing local connections. Because TILDE allows specifying a language bias with dynamic refinement (Blockeel and De Raedt, 1998), it becomes possible to constrain the hypothesis space to locally discriminating patterns whenever necessary. One technique is the dynamic generation of constants, that can be used to constrain the combinations of activity type constants that are to be considered for a particular language bias construct. Additionally, it is also possible to constrain the occurrence of particular literals in a hypothesis $\mathcal{H}$, given the presence or absence of other literals that are already part of the hypothesis.

The classification task of TILDE is to predict whether for a given activity type $a \in A$, at a given time point $t \in \mathbb{N}$ in a given sequence $\sigma \in L$, a positive or a negative event takes place. In the case of a positive event, the target predicate evaluates to $Class(a, \sigma, t, completed)$. In the case of a negative event, the target predicate evaluates to $Class(a, \sigma, t, completeRejected)$. In the language bias, the target activity, indicated by a, will be used for dynamically constraining the combinations of activity type constants generated.

The primary objective of AGNEs being the construction of a graphical model from an event log, the language bias consists of a logical predicate that can represent the conditions under which a Petri net place contains a token. This predicate is called the “no-sequel” predicate, $NS(a_1, a, \sigma, t)$. Let

$a_1, a \in A$ be activity types, $\sigma \in L$ the sequence of a process instance, and t the time of observation. The *NS* predicate is defined as follows:

$$\forall a_1, a \in A, t \in \mathbb{N} : \exists x \in \sigma : AT(x) = a_1 \ \wedge\ Time(x) < t \\ \wedge\ \nexists y \in \sigma : AT(y) = a \ \wedge\ Time(x) < Time(y) < t \quad \Rightarrow NS(a_1, a, \sigma, t).$$

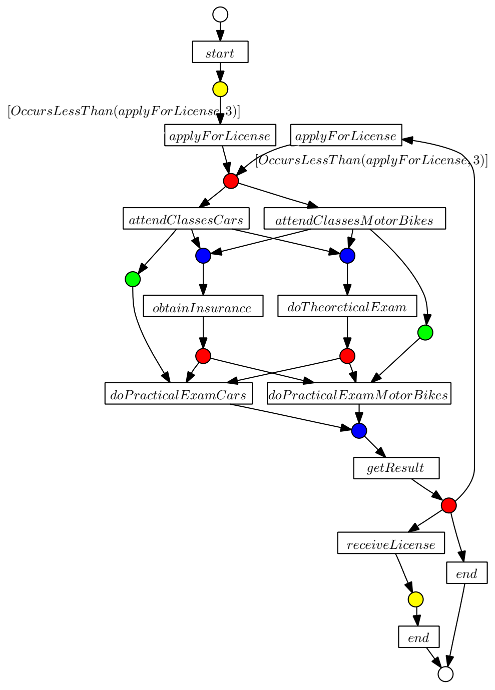
In the remainder of this text, the arguments σ and t will be implicitly assumed and therefore left out. The predicate $NS(a_1, a)$ evaluates to true when at the time of observation, an activity a_1 has completed, but has not (yet) been followed by an activity a. In combination with conjunction ($\wedge$), disjunction ($\vee$) and negation-as-failure ($\sim$), the $NS(a_1, a)$ predicate makes it possible to learn fragments of Petri nets using a multi-relational classification learner.

Example 3 shows how the preconditions in the Petri net can be represented as conjunctions and disjunctions of *NS* atoms. This representation accounts for the different contexts in which the activities *applyForLicense* and *end* can take place and derives different preconditions for these activities. In addition, it can represent the non-local, non-free, history-dependent choice construct between the activities *attendClassesCars–doPracticalExamCars* and *attendClassesMotorBikes–doPracticalExamMotorBikes* and the maximum recurrence of the activity *applyForLicense*. The Petri net fragments included in the language bias of AGNEs are enumerated in Figure 1 and are briefly discussed in the remainder of this section.

Example 3 *(Continued from example 2) DriversLicenseI—A Petri net in terms of NS preconditions*

	activity	*precondition*
a	*start*	*true*
b	*applyForLicense*	$NS(a,b)$
b	*applyForLicense*	$(NS(i,b) \wedge NS(i,j) \wedge NS(i,k))$ $\wedge\ OccursLessThan(b,3)$
c	*attendClassesCars*	$NS(b,c) \wedge NS(b,d)$
d	*attendClassesMotorBikes*	$NS(b,c) \wedge NS(b,d)$
e	*obtainInsurance*	$NS(c,e) \vee NS(d,e)$
f	*doTheoreticalExam*	$NS(c,f) \vee NS(d,f)$
g	*doPracticalExamCars*	$(NS(f,g) \wedge NS(f,h)) \wedge$ $(NS(e,g) \wedge NS(e,h)) \wedge NS(c,g)$
h	*doPracticalExamMtrBikes*	$(NS(f,g) \wedge NS(f,h)) \wedge$ $(NS(e,g) \wedge NS(e,h)) \wedge NS(d,h)$
i	*getResult*	$NS(g,i) \vee NS(h,i)$
j	*receiveLicense*	$NS(i,b) \wedge NS(i,j) \wedge NS(i,k)$
k	*end*	$NS(j,k)$
k	*end*	$NS(i,b) \wedge NS(i,j) \wedge NS(i,k)$

(a) DriversLicenseI—activity preconditions



(b) DriversLicenseI—Petri net

Figure 1(a) shows a graphical representation of the local sequence predicate that is part of the language bias. A local sequence of two transitions labeled $a_1, a \in A$ in a Petri net can be represented by $NS(a_1, a)$. In the language bias, the following constraints apply:

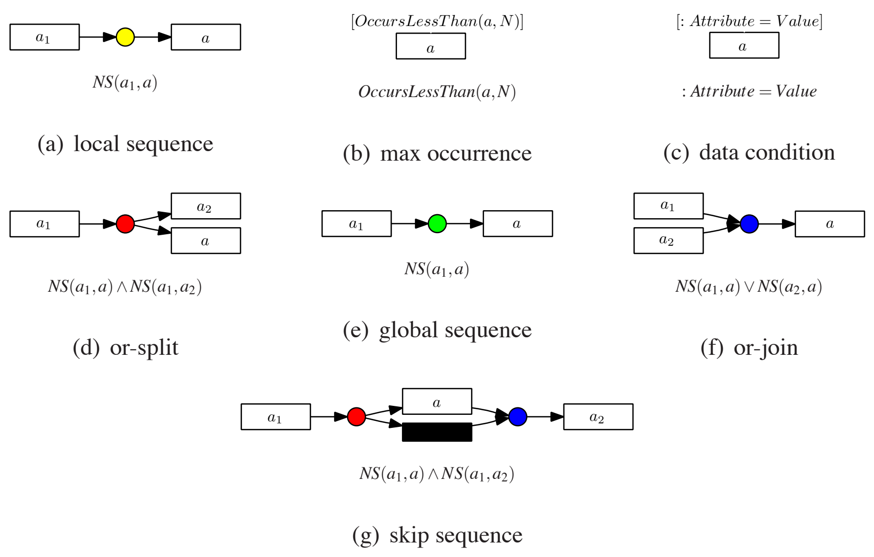


Figure 1: Petri net patterns in the language bias

sequence	$NS(a_1,a)$	
constraints:	$Local(a_1,a)$.	(1)
	$\nexists l \in \mathcal{H} : l = [NS(\_,a_1)]$.	(2)

The conversion from *NS*-based preconditions into Petri nets requires the conditions to refer to local, immediately preceding events as much as possible. Therefore, constraint (1) requires to restrict the generation of constants a_1 to constants that are local to a. In constraint (1) we do not require a_1 and a to be different activity types. This is sufficient for the discovery of length-one loops. Graphically, a conjunction of *NS* constructs can be considered to be the logical counterpart of a single Petri net place. Besides the case of length-one loops—that can be expressed with a single *NS* construct—there is no reason for a Petri net place to contain both an input and an output arc that is connected to the same transition. Constraint (2) has been put in place to keep a multi-relational learner from constructing such useless hypotheses. The constraint stipulates that the construct $NS(a_1,a)$ can only be added to the current hypothesis $\mathcal{H}$, if $\mathcal{H}$ does not already contain a logical condition that boils down to an output arc towards a_1.

The same $NS(a_1,a)$ construct, with different constraints, can be used to keep track of a global sequence (see Figure 1(e)). Global sequences are used to represent non-local, non-free choice constructs. We require TILDE only to consider global sequence between activity types for which both a precedence and a response relationship has been detected from the event log, this is expressed as a language bias constraint. Because we assume that any transition must be locally connected, that is connected to other transitions to which it is local in the event log, we require as an additional constraint that the global sequence construct must not be added first to any hypothesis. The other Petri net based language constructs depicted in Figure 1 have similar definitions and are described in detail by Goedertier (2008).

The language bias of TILDE is limited to conjunctions and disjunctions of *NS* constructs of length two and three. Or-splits and or-joins that involve more activity types are obtained by grouping conjunctions and disjunctions of *NS* constructs into larger conjunctions and disjunctions in step 4. However, this limitation in length sometimes leads to TILDE make inadequate refinements. Solving this language bias issue, requires constructing a proprietary ILP classification algorithm that during each refinement step allows considering conjunctions of *NS* constructs of variable lengths. We leave this improvements to future work.

4.4 Step 4: Transform the Preconditions into a Petri Net

In the previous step, TILDE has learned preconditions for each activity type independently. In a Petri net, the preconditions for each activity type are nonetheless interrelated. Therefore, the logic programs of activity preconditions are submitted to several rule-level pruning steps, to make sure that they do not produce redundant duplicate places in the Petri net to be constructed. These pruning steps occur among the conditions within a single precondition, within a set of preconditions to the same activity type and among preconditions of activity types that pertain to the same or-split. Given a pruned rule set of preconditions for each activity type, the construction of a Petri net is fairly straightforward. Each induced precondition corresponds to a different transition in a Petri net to be constructed. Because AGNEs may produce several preconditions for an activity type, the constructed Petri net may contain duplicate transitions. Algorithm 3 provides an overview of these procedures. In the remainder of this section, these different pruning steps will be discussed and illustrated for a sample of rules from the DriversLicenseI example.

The logic programs constructed by TILDE contain rules that classify the occurrence of either a positive or a negative event. By construction, the language bias of AGNEs is such that TILDE will never consider a negation of an *NS* construct to be explanatory for the occurrence of a positive event. Therefore, TILDE will never construct a tree in which a right leaf predicts a positive event. The latter entails that, in equivalent the logic program, the rules with a $class(a,\sigma,t,comleted)$ rule head can be taken from the logic programs without loss of information (line 1). Example 4 depicts the preconditions that are induced by TILDE for the apply for license and end activities in the DriversLicenseI example.

In a second step, a number of intra-rule pruning operations take place (lines 2–6). The top-down refinement of hypotheses, can result in the derivation of logically redundant conditions. These logical redundancies are removed for each rule (line 3). Each rule in the logic program consists of conjunctions of groups of *NS* constructs. A conjunction of a pair of or-split constructs that originate from the same activity a_1 can be combined into a larger or-split (line 4). Likewise, a conjunction of a pair of or-joins can be combined into a larger or-join (line 5). Example 4 illustrates intra-rule pruning for the DriversLicenseI example.

In a third step, a number of inter-rule pruning operations are performed for the preconditions that pertain to each activity type. In particular, a precondition that subsumes another precondition for the same activity type, is redundant and thus removed from consideration (lines 10–12). Furthermore, it is examined whether a more specific or-join can be constructed out of the groups of *NS* constructs within the different preconditions of the same rule (lines 13–15). Finally, all rules are examined to find the most specific or-split condition from the preconditions extracted by TILDE (lines 18–26). Example 4 illustrates this pruning for the DriversLicenseI example.

Example 4 *(Continued from example 3.) DriversLicensel—pruning*

rules induced by TILDE		:

b apply for license	$(NS(a,b))$. *(lines 10–12)*	
k end	$(NS(j,k))$.	
k end	$(NS(i,b) \wedge NS(i,j) \wedge NS(i,k))$. *(lines 18–26)*	

5. Evaluation Metrics

Discovered process models preferably allow the behavior in the event log (recall) but no other, unobserved, random behavior (specificity). Having formulated process discovery as a binary classification problem on event logs supplemented with artificial negative events, it becomes possible to use the true positive and true negative rate from classification learning theory to quantify the recall and specificity of a process model:

- **true positive rate** TP_{rate} or **recall**: the percentage of correctly classified positive events in the event log. This probability can be estimated as follows: $TP_{rate} = \frac{TP}{TP+FN}$, where TP is the amount of correctly classified positive events and FN is the amount of incorrectly classified positive events.

- **true negative rate** TN_{rate} or **specificity**: the percentage of correctly classified negative events in the event log. This probability can be estimated as follows: $TN_{rate} = \frac{TN}{TN+FP}$, where TN is the amount of correctly classified negative events and FP is the amount of incorrectly classified negative events.

Accuracy is the sum of the true positive and true negative rate, weighted by the respective class distributions. The fact that accuracy is relative to the underlying class distributions can lead to unintuitive interpretations. Moreover, in process discovery, these class distributions can be quite different and have no particular meaning. In order to make abstraction of the proportion of negative and positive events, we propose, from a practical viewpoint to attach equal importance to both recall and specificity: $acc = \frac{1}{2}recall + \frac{1}{2}specificity$. According to this definition, the accuracy of a majority-class predictor is $\frac{1}{2}$. Flower models, such as the one in Example 1(b), are an example of such a majority-class predictors. Because a flower model represents random behavior, it has a perfect recall of the all behavior in the event log but it also has much *additional* behavior compared to the event log. Because of the latter fact, the flower model has zero specificity, and an accuracy of $\frac{1}{2}$. Any useful process model should have an accuracy higher than $\frac{1}{2}$.

Algorithm 3 Rule-level pruning

```
1:  $R^+ = \{r \in R \mid r$ has rule head $class(a,\sigma,t,comleted)$ $\}$.
    // intra-rule pruning:
2:  for all $r \in R^+$ do
3:      reduce $r$ according to $(NS_1 \vee NS_2) \wedge NS_1 \equiv NS_1$.
4:      group or-splits: $NS(a_1,a) \wedge NS(a_1,a_2) \in r$ and $NS(a_1,a) \wedge NS(a_1,a_3) \in r$ into $NS(a_1,a) \wedge$
        $NS(a_1,a_2) \wedge NS(a_1,a_3)$.
5:      group or-joins: $NS(a_1,a) \vee NS(a_2,a) \in r$ and $NS(a_3,a) \vee NS(a_4,a) \in r$ into $NS(a_1,a) \vee$
        $NS(a_2,a) \vee NS(a_3,a) \vee NS(a_4,a)$.
6:  end for
    //inter-rule pruning:
7:  for all $a \in A$ do
8:      $R_a^+ = \{r \in R^+ \mid r$ is a precondition of $a\}$
9:      for all $r \in R_a^+$ do
10:         if $\exists s \in R_a^+$ : $s$ is more specific than $r$ then
11:             remove $r$.
12:         end if
13:         if $\exists s \in R_a^+$ : $s$ combined with $r$ lead to a more specific or-join than $r$ then
14:             replace the or-join in $r$ with the more specific or-join.
15:         end if
16:     end for
17: end for
    //keep the most specific or-split:
18: for all $a \in A$ do
19:     $R_a^{split} = \{r \in R^+ \mid r$ contains an or-split going out $a$ $\}$.
20:     $s$ = the most specific or-split by combining the or-splits going out $a$ in $R_a^{split}$.
21:     for all $r \in R_a^{split}$ do
22:         if $s$ is more specific than $r$ then
23:             replace the or-split in $r$ with the or-split in $s$.
24:         end if
25:     end for
26: end for
```

The metrics that are introduced in this section will be used to evaluate the performance of AGNEs in the following sections. They have been defined and implemented for Petri nets. However, they can also be applied to other generative models.

5.1 Existing Metrics

Weijters et al. (2006) define a metric that has a somewhat similar interpretation as TP_{rate}: the parsing measure PM. The measure is defined as follows:

- **parsing measure** PM: the number of sequences in the event log that are correctly parsed by the process model, divided by the total number of sequences in the event log. For efficiency, the similar sequences in the event log are grouped. Let k represent the number of grouped sequences, n_i the number of process instances in a grouped sequence i, c_i a variable that is equal to 1 if grouped sequence i can be parsed correctly, and 0 if grouped sequence i cannot be parsed correctly. The parsing measure can be defined as follows Weijters et al. (2006):

$$PM = \frac{\sum_{i=1}^{k} n_i c_i}{\sum_{i=1}^{k} n_i}.$$

PM is a coarse-grained metric. A single missing arc in a Petri net can result in parsing failure for all sequences. A process model with a single point of failure is generally better than a process model with more points of failure. This is not quantified by the parsing measure PM.

Rozinat and van der Aalst (2008) define two metrics that have a somewhat similar interpretation as TP_{rate} and TN_{rate}: the fitness metric f and the advanced behavioral appropriateness metric $a_B^{'}$:

- **fitness** f: Fitness is a metric that is obtained by trying whether each (grouped) sequence in the event log can be reproduced by the generative model. This procedure is called *sequence replay*. The metric assumes the generative model to be a Petri net. At the start of the sequence replay, f has an initial value of one. During replay, the transitions in the Petri net will produce and consume tokens to reflect the state transitions. However, the proportion of tokens that must additionally be created in the marked Petri net, so as to *force* a transition to fire, is subtracted from this initial value. Likewise, the fitness measure f punishes for extra behavior by subtracting the proportion of remaining tokens relative to the total number of produced tokens from this initial value. Let k represent the number of grouped sequences, n_i the number of process instances, c_i the number of tokens consumed, m_i the number of missing tokens, p_i the number of produced tokens, and r_i the number of remaining tokens for each grouped sequence i $(1 \leq i \leq k)$. The fitness metric can be defined as follows (Rozinat and van der Aalst, 2008):

$$f = \frac{1}{2}\left(1 - \frac{\sum_{i=1}^{k} n_i m_i}{\sum_{i=1}^{k} n_i c_i}\right) + \frac{1}{2}\left(1 - \frac{\sum_{i=1}^{k} n_i r_i}{\sum_{i=1}^{k} n_i p_i}\right).$$

- **behavioral appropriateness** $a_B^{'}$: Behavioral appropriateness is a metric that is obtained by an exploration of the state space of a Petri net and by comparing the different types of *follows* and *precedes* relationships that occur in the state space with the different types of *follows* and *precedes* relationships that occur in the event log. The metric is defined as the proportion of number of *follows* and *precedes* relationships that the Petri net has in common with the event log vis-à-vis the number of relationships allowed by the Petri net. Let S_F^m be the S_F relation and S_P^m be the S_P relation for the process model, and S_F^l the S_F relation and S_P^l the S_P relation for the event log. The advanced behavioral appropriateness metric $a_B^{'}$ is defined as follows (Rozinat and van der Aalst, 2008):

$$a_B^{'} = \left(\frac{|S_F^l \cap S_F^m|}{2.|S_F^m|} + \frac{|S_P^l \cap S_P^m|}{2.|S_P^m|}\right).$$

Rozinat and van der Aalst (2008) also report a solution to two non-trivial problems that are encountered when replaying Petri nets with silent steps and duplicate activities. In the presence of silent steps (or invisible tasks) it is non-trivial to determine whether there exist a suitable firing sequence of invisible tasks such that the right activities become enabled for the Petri net to optimally replay a given sequence of events. Likewise, in the presence of multiple enabled duplicate activities, it is a non-trivial problem of determining the optimal firing, as the firing of one duplicate activity affects the ability of the Petri net to replay the remaining events in a given sequence of events. Rozinat and van der Aalst (2008) present two local approaches that are based on heuristics involving the next activity event in the given sequence of events.

Fitness f and behavioral appropriateness $a_B^{'}$ are particularly useful measures to evaluate the performance of a discovered process model. Moreover, these metrics have been implemented in the ProM framework. However, the interpretation of the fitness measure requires some attention: although it accounts for recall as it punishes for the number of missing tokens that had to be created, it also punishes for the number of tokens that remain in a Petri net after log replay. The latter can be considered *extra* behavior. Therefore, the fitness metric f also has a specificity semantics attached to it. Furthermore, it is to be noted that the behavioral appropriateness $a_B^{'}$ metric is not guaranteed to account for all non-local behavior in the event log (for instance, a non-local, non-free, history-dependent choice construct that is part of a loop will not be detected by the measure). In addition, the $a_B^{'}$ metric requires an analysis of the state space of the process model or a more or less exhaustive simulation to consider all allowable sequences by the model.

5.2 New Metrics

The availability of an event log supplemented with artificial negative events, allows for the definition of a new specificity metric that does not require a state space analysis. Instead, specificity can be calculated by parsing the (grouped) sequences, supplemented with negative events. We therefore define:

- **behavioral recall r_B^p**: The behavioral recall r_B^p metric is obtained by parsing each grouped event sequence. The values for *TP* and *FN* are initially zero. Starting from the initial marking, each sequence is parsed. Whenever an enabled transitions fires, the value for *TP* is increased by one. Whenever a transition is not enabled, but must be forced to fire the value for *FN* is increased. As an optimization, identical sequences are only replayed once. Let k represent the number of grouped sequences, n_i the number of process instances, TP_i number of events that are correctly parsed, and FN_i the number events for which a transition was forced to fire for each grouped sequence i $(1 \leq i \leq k)$. At the end of the sequence replay, r_B^p is obtained as follows:

$$r_B^p = \left(\frac{\sum_{i=1}^{k} n_i TP_i}{\sum_{i=1}^{k} n_i TP_i + \sum_{i=1}^{k} n_i FN_i} \right).$$

  In the case of multiple enabled duplicate transitions, sequence replay fires the transition of which the succeeding transition is the next positive event (or makes a random choice). In the case of multiple enabled silent transitions, log replay fires the transition of which the succeeding transition is the next positive event (or makes a random choice). Unlike the fitness metric f, r_B^p does not punish for remaining tokens. Whenever after replaying a sequence tokens remaining tokens cause *additional behavior* by enabling particular transitions, this is punished by our behavioral specificity metric s_B^n.

- **behavioral specificity s_B^n**: The behavioral specificity s_B^n metric can be obtained during the same replay as r_B^p. The values for *TN* and *TP* are initially zero. Whenever during replay, a negative event is encountered for which no transitions are enabled, the value for *TN* is increased by one. In contrast, whenever a negative event is encountered during sequence replay for which there is a corresponding transition enabled in the Petri net, the value for *FP* is increased by one. As an optimization, identical sequences only are to be replayed once. Let k represent the number of grouped sequences, n_i the number of process instances, TN_i number of negative events for which no transition was enabled, and FP_i the number negative events for which a transition was enabled during the replay of each grouped sequence i $(1 \leq i \leq k)$. At the end of the sequence replay, s_B^n is obtained as follows:

$$s_B^n = \left(\frac{\sum_{i=1}^{k} n_i TN_i}{\sum_{i=1}^{k} n_i TN_i + \sum_{i=1}^{k} n_i FP_i} \right).$$

Because the behavioral specificity metric s_B^n checks whether the Petri net recalls negative event, it is inherently dependent on the way in which these negative events are generated. For the moment, the negative event generation procedure is configurable by the negative event injection probability π, and whether or not it must account for the parallel variants of the given sequences of positive events. For the purpose of uniformity, negative events are generated in the test sets with π equal to 1.0 and account for parallel variants = true.

6. Experimental Evaluation

AGNEs has been implemented in Prolog. In particular, the frequent temporal constraint induction, the artificial negative event generation, the language bias constraints, and the pruning and graph construction algorithms all have been written in Prolog. As mentioned before, AGNEs makes use of TILDE, an existing multi-relational classifier (Blockeel and De Raedt, 1998), available in the ACE-ilProlog data mining system (Blockeel et al., 2002). To be able to benefit from the facilities of the ProM framework, a plugin was written that makes AGNEs accessible in ProM.[1] Figure 3 depicts a screen shot of AGNEs in ProM.

In this section the results of an experimental evaluation of AGNEs are presented. First we will discuss the properties of the event logs and the parameter settings that have been used. Then, in Section 6.1, we analyse the expressiveness of AGNEs and benchmark the ability of AGNEs to generalize from incomplete event logs. In Section 6.2, we analyze the results of a number of noise experiments with different types and levels of noise that have been carried out to test how the learning algorithm behaves in the presence of noise.

In order to evaluate and compare the performance of AGNEs, a benchmark experiment with 34 event logs has been set up. These event logs have previously been used by Alves de Medeiros (2006) and Alves de Medeiros et al. (2007) to evaluate the genetic miner algorithm. Table 1 describes the properties of the underlying artificial process models of the event logs. The number of different process instance sequences (column "$\neq$ process inst.") gives an indication of the amount of different behavior that is present in the event log. This number is to be compared with the total number of process instances in the event logs. In general, the presence of loops and parallelism exponentially increases the amount of different behavior that can be produced by a process. Therefore, the number of activity types that are pairwise parallel and the number and type of loops have been reported in Table 1. In correspondence with the naming conventions used by Alves de Medeiros, nfc stands for

1. The AGNEs plugin is available from `http://www.processintelligence.be/AGNEs.php`.

non-free-choice, l1l and l2l stands for the presence of a length-one and length-two loop respectively, and st and unst stands for structured and unstructured loops. Furthermore, the presences of special structures such as skip activities and (parallel or serial) duplicate activities have been indicated. For most of the event logs in the experiment, a reference model was available that can be assumed to represent the behavior in the event log. Columns "r_B^p reference model" and "s_B^n reference model" indicate the behavioral recall and specificity of the reference models with respect to the original event logs.

In the experiments, the performance of AGNEs is compared to the performance of four state-of-the-art process discovery algorithms: α^+ (van der Aalst et al., 2004; Alves de Medeiros et al., 2004), α^{++} (Wen et al., 2007), genetic miner (Alves de Medeiros et al., 2007) and heuristics miner (Weijters et al., 2006). Being the first large-scale, comparative benchmark study in the literature of process discovery, we have chosen to include algorithms that already have appeared as journal publications (α^+, α^{++}, and genetic miner) or that are much referenced in the literature (heuristics miner).

During all experiments, the algorithms were run with the same, standard parameter settings of their ProM 4.2 implementation, as reported in Table 2. These parameter settings coincide with the ones used to run similar experiments by the authors of the algorithms. To enable a comparison on the same terms, AGNEs was not provided with prior knowledge regarding parallelism or locality of activity types. In particular, the thresholds used to induce frequent temporal patterns have been given the following values ($t_{absence} = 0.9$, $t_{chain} = 0.08$, $t_{succ} = 0.8$, $t_{ordering} = 0.08$, $t_{triple} = 0.10$). In practice, a good threshold depends on the amount of low-frequent behavior (noise) one is willing to accept within the discovered process model. The negative event injection probability π influences the proportion of artificially generated negative events in an event log. A strong imbalance of this proportion may bias a classification learner towards a majority class prediction, without deriving any useful preconditions for a particular activity type. As a rule of thumb, it is a good idea to set this parameter value as low as possible, without the learner making a majority class prediction. In the experiments π has been given a default value of 0.08. Ex-post, AGNEs warns the user when too low a value for π has led to a majority-class prediction. TILDE's C4.5 gain metric was used as a heuristic for selecting the best branching criterion. In addition, TILDE's C4.5 post pruning method was used with a standard confidence level of 0.25. Furthermore, TILDE is forced to stop node splitting when the number of process instances in a tree node drops below 5. The same parameter settings have been used on all 34 data sets. Empirical validation has shown the parameter settings to work well across all data sets.

The AGNEs technique, has run times in between 20 seconds and 2 hours for the data sets in the experiments on a Pentium 4, 2.4 Ghz machine with 1GB internal memory. These processing times are well in excess of the processing times of α^+, α^{++} and heuristics miner. In comparison to the run times of the genetic miner algorithm, processing times are considerably shorter. Most of the time is required by TILDE to learn the preconditions for each activity type. The generation of negative events also can take up some time. As process discovery generally is not a real-time data mining application, less attention has been given to computation times.

6.1 Zero-noise, Cross Validation Experiment

To evaluate AGNEs' expressiveness and ability to generalize, a 10-fold cross-validation experiment has been set up. In the literature on process discovery, cross-validation has only been considered by

Table 1: Event log properties

Goedertier et al. (2008) and Rozinat et al. (2007). The reason for the absence of cross-validation experiments, is that process discovery is an inherently *descriptive* learning task rather than a *predictive* one. The primary intent of process discovery is to produce a model that accurately describes the event log at hand. Nonetheless, it is interesting to test the *predictive* ability of process discovery algorithms in an experimental setting. To apply cross-validation, a randomization routine has been

Table 2: Parameter settings

written in SWI-Prolog that groups similar sequences, randomly partitions the grouped event log in $n = 10$ uniform subgroups, and produces n pairs of training and test event logs. Training event logs are used for the purpose of process discovery. Test event logs are used for evaluation, this is for calculating the specificity and recall metrics. For the purpose of this experiment, no noise was added to the event logs.

Specificity metrics must be calculated based on the combination of training and test event logs, the entire event log. Although this might seem unintuitive, specificity and specificity metrics make a completeness assumption as well, as they account for the amount of *extra* behavior in a process model vis-à-vis the event log (Rozinat and van der Aalst, 2008). To correctly evaluate the proposed learning technique, it is important that the negative events in the test set accurately indicate the state transitions that are not present in the event log. For this reason, the negative events in the test log are created with information from the entire event log. Should the negative event generation be based on training set instances only, it is possible that additional, erroneous negative events are injected because it is possible that some behavior is not present in the test set. In short, the experiment applies the above-described partitioning, after having generated negative events for each grouped process instance. Intended to be used by the evaluation metric, the negative events have been generated with an injection probability π equal to 1, an infinite window size, and by considering parallel variants. Evidently, the thus generated negative events were not retained in the training set. For training purposes, negative events have been calculated based on the information in the training set only. For the same reasons, the behavioral appropriateness metric a'_B has also been calculated based on the whole of training and test set data.

In the experiment, only 19 out of the 34 event logs were retained, as the other event logs have less than 10 different sequences. Table 3 shows the aggregated, average results of the 10-fold cross validation experiment over 190 event logs. The **best** average performance over the 34 event logs is underlined and denoted in bold face for each metric. We then use a paired t-test to test the significance of the performance differences (Van Gestel et al., 2004). Performances that are **not significantly different at the 5% level** from the top-ranking performance with respect to a one-tailed paired t-test are tabulated in bold face. Statistically *significant underperformances at the 1% level* are emphasized in italics. Performances significantly different at the 5% level but not at the 1% level are reported in normal font. For the *PM* measure, no paired t-tests could be performed, because the metric could not be calculated on some of the process models discovered by α^+ and α^{++}. The latter is the case when the discovered process models have disconnected elements.

From the results for the parsing measure *PM*, the fitness measure f, and behavioral recall measures r_B^p, it can be concluded that genetic miner scores slightly better on the recall requirement. Moreover, the behavioral specificity metric s_B^n shows genetic miner and heuristics miner to produce slightly more specific models.

		PM	f	a'_B	acc	r_B^p	s_B^n	acc_B^{pn}
zero_noise	α^+	0.72	*0.96*	**0.96**	**0.96**	*0.97*	*0.83*	*0.90*

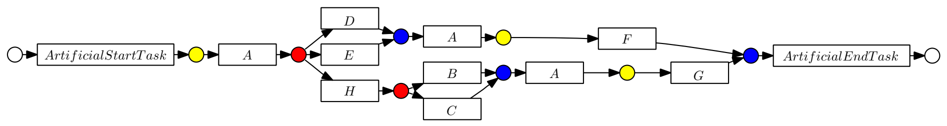
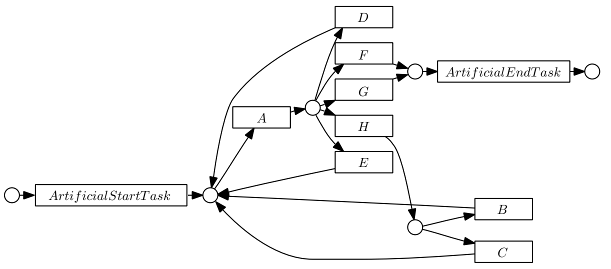
	heuristics	0.79	*0.97*	*0.85*	*0.91*	0.97	**0.93**	**0.95**

Table 3: 10-fold cross validation experiment - aggregated results

From the cross-validation experiment, we conclude that AGNEs portrays similar generalization behavior to other process discovery algorithms. The reason that it is not sensitive to incomplete event logs can be attributed to the following. Given an incomplete event log, AGNEs is likely to generate a proportion of incorrect negative events. However, this proportion of negative events is relatively small, as the negative event injection parameter π is not required to be excessively large. More importantly, the coarse-grained language bias that combines *NS* constructs into larger structures, prevents TILDE from overfitting the incomplete event log and allows it to generalize, to some extent, beyond the observed behavior. The additional incorporation of process knowledge expressed by a domain expert would only add to this benefit. Finally, the negative event injection procedure takes into account parallelism and window size. Concurrent and recurrent behavior are the root causes of incomplete event logs. The ability to include information about parallel variants and window size, gives our learning technique a configurable inductive bias, with different strategies to account for incompleteness.



(a) AGNEs result



(b) heuristics miner result

Figure 2: herbstFig6p33: AGNEs detects the duplicate activity *A*

The metrics r_B^p and s_B^n do not indicate a large or significant difference for the performance of α^{++}, AGNEs, genetic miner, and heuristics miner. Only by looking at the individual process models, the expressiveness of AGNEs with respect to the detection of non-local, non-free choice constructs or the discovery of duplicate tasks becomes apparent. Example 3, discussed in Section 4.3, shows how AGNEs is capable of detecting non-local, non-free choice constructs, even within the loop of the DriversLicensel reference problem. AGNEs is also particularly suited for the detection of duplicate activities. In the herbstFig6p33 event log, the activity *A* occurs in three different contexts and AGNEs draws three different, identically labeled transitions correspondingly. Figure 2 compares the results of heuristics miner and AGNEs on this event log.

The goal of process discovery is to give an idea of how the processes recorded in the event log *actually* have taken place. This goal makes process discovery an inherently *descriptive* learning task. To evaluate the accuracy of the discovered process model, it is therefore justified to compare the learned process models on the same sequence the process models are learned from. In the process discovery literature, this training-log-based evaluation has been the dominant evaluation paradigm (Alves de Medeiros et al., 2007; Weijters et al., 2006). Consequently, the remaining experiments of this paper use training-log-based evaluation.

6.2 Training-log-based Noise Experiment

In these experiments we have stirred up the 34 event logs with artificial noise. In the literature, six artificial noise types have been described (Maruster, 2003; Alves de Medeiros et al., 2007): (1) *missing head*: the removal of the head of a sequence, (2) *missing body*: the removal of the mid section of a sequence, (3) *missing tail*: the removal of the end section of a sequence, (4) *swap tasks*: the interchange of two random events in a sequence, (5) *remove task*: the removal of a random event in a sequence, and (6) *mix all*: a combination of all of the above. The noise has been added with the AddNoiseLogFilter event log filter available in the ProM framework. This filter has been applied after ungrouping the 34 event logs. To keep the size of the experiment under control, we have limited the noise types used in our experiments to *mix all* and *swap tasks*. For both noise types, the used noise levels of 5%, 10%, 20% and 50% are applied.

Table 4 reports the average results of the discovered process models over the all 34 corresponding zero noise event logs. As is known from the literature, heuristics miner is resilient to noise, whereas the formal approaches of α^+ and α^{++} and the genetic miner are known to overfit the noise in event logs. On 11 event logs from the bn1, bn2, and bn3 processes, the α^{++} implementation was incapable of producing an outcome. These missing values resulted in a score of 0 for each measure. Furthermore, the state space analysis required to calculate the behavioral appropriateness measure $a_B^{'}$ produces invalid outcomes that occur 27 times for the results of the genetic miner algorithm out of a total of 272 (34 x 8) experiments, the reported results for the genetic miner are less suitable for comparison. For this reason, we only indicate the significance of the r_B^p and s_B^n outcomes with respect to the top ranking performance. For the PM, f, and $a_B^{'}$ metrics, the algorithm that has obtained the <u>best</u> average score, is underlined. For every noise level, AGNEs obtains accuracy results that are robust and not significantly different from the results obtained by heuristics miner. This is a remarkable result, as AGNEs is a more expressive algorithm than heuristics miner, also capable of detecting more complex structures such as non-local dependencies and duplicate activities.

To calibrate the metrics, we also report their evaluation of the so-called flower model for the zero-noise case. Because the flower model parses every possible sequence, it has a perfect recall but zero specificity. These properties are to some extent reflected in the metrics in Table 4. The fitness measure f and the behavioral recall measure r_B^p are both 1.0, whereas the behavioral specificity metric s_B^n amounts to 0. The behavioral appropriateness measure $a_B^{'}$ does not really seem to quantify the lack of specificity of the flower model.

The reasons why AGNEs is robust to noise can be put down to the following. First of all, the generation of negative events is not invalidated by the presence of noise. Noise is *additional* low-frequent behavior that will result in less negative events being generated by AGNEs. However, the presence of noisy positive events does not lead to the generation of noisy negative ones. Another property that adds to robustness, is that the constraints in AGNEs ’ language bias allows it to come up with structured patterns and to some extent prevents the construction of arbitrary connections between transitions, while remaining expressive with regard to short loops, duplicate tasks and non-local behavior. Finally, the formulation of process discovery as a classification allows for the application of an already robust classification algorithm (TILDE). Like many classification learners, TILDE takes into account the frequency of an anomaly, when constructing the preconditions for each activity type. Moreover, TILDE applies the same tree-level pruning method as C4.5 (Quinlan, 1993).

7. A Case Study

This section shows the result of the AGNEs process discovery algorithm applied to an event log of customer-initiated processes, recorded by a European telecom provider. The goal of the case study was to investigate whether AGNEs can be usefully applied to map the routing choices that are made between queues of a workflow management system (WfMS). With 18721 process instances and 127 queues, the obtained log file has a size of over 130 megabytes in the form of a comma-separated text file. The case study gives an idea of the scalability of the algorithm towards large event logs and the usefulness of the AGNEs process discovery algorithm on realistic, real-life processes.

Table 4: noise experiments - average, zero-noise training-log-based results

The event log consists of events about customer-initiated processes that are handled at three different locations by the employees of the telecom provider. The handling of cases is organized in a first line and a second line. First-line operators are junior operators that deal with frequent customer requests for which standardized procedures have been put in place. When a first-line operator cannot process a case, it is routed to a queue of the second line. Second-line case handling is operated by senior experts who have the authority to make decisions to solve the more involved cases. The

Figure 3: AGNEs in ProM 4.2

second-line processes are coordinated and supported by means of a workflow management system (WfMS). The obtained event log consists of these second-line case handling events. The second-line WfMS is organized as a system of 127 logical queues. Each queue corresponds to a number of similar types of activities that are to be carried out. At any given moment each active case resides in exactly one queue. Employees can process a case by taking it out of the queue into their personal work bin. Every evolution of a case is documented by adding notes. Moreover, employees can classify the nature of the case according to a number of data fields. In addition, a worker or dispatcher has the ability to reroute cases to different queues whenever this is necessary. The system imposes no restrictions with regard to the routing of cases. Queues represent a work distribution system and are akin to roles in WfMS. For the purpose of this analysis, queues are considered to be activity types. The 40 most frequently occurring queues were retained for further analysis. Nine process instances that did not involve at least one of these 40 queues were retained from the event log.

We compare the mining results of AGNEs, genetic miner, and heuristics miner. Some parameter settings that are different from the experimental evaluation in the previous section. In particular, AGNEs was provided with the prior knowledge that no activity can occur concurrently: $\forall a, b \in A$:

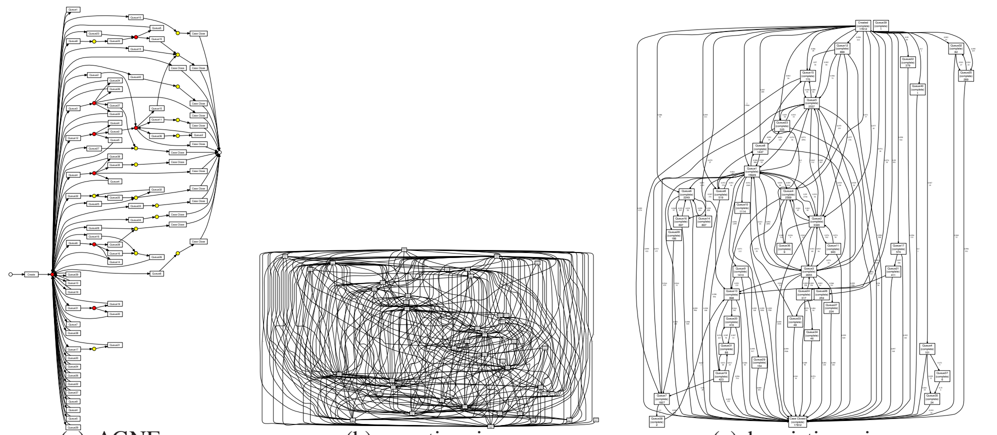
	PM	f	$a_B^{'}$	acc	r_B^p	s_B^n	acc_B^{pn}
AGNEs	0.06	0.94	0.67	0.80	0.93	0.67	0.80
genetic	0.03	x.xx	x.xx	x.xx	0.83	0.62	0.73
heuristics	$\underline{0.80}$	$\underline{0.97}$	$\underline{0.72}$	$\underline{0.85}$	$\underline{0.96}$	$\underline{0.88}$	$\underline{0.92}$
flower model	0.00	1.00	0.76	0.88	1.00	0.00	0.50

Table 5: telecom—training-log-based results

$PriorSerial(a,b)$. This prior knowledge is justifiable, as no case can be routed to or reside in several queues at the same time. Genetic miner has been running for 5000 generations, with a population size of 10. These parameter settings correspond to the parameter settings in the case study described by Alves de Medeiros et al. (2007). To account for the prior knowledge that no concurrent behavior is contained in the event log, heuristics miner needs to have an infinite AND threshold. In general AGNEs allows to provide a-priori locality and parallelism information for individual pairs of activity types. This fine-grained a-priori knowledge cannot be provided by fine-tuning the AND threshold with heuristics miner. Currently, it is not possible to constrain the search space of genetic miner with this a-priori knowledge.

The results of applying these process discovery algorithms on the filtered event log are displayed in Figure 4. Table 5 gives an overview of the metrics that compare the discovered process models to the original event log. As the purpose of the case study is to provide the most accurate description of the event log, the use of training data for evaluation is justified. To calibrate the metrics, we also report their evaluation of the so-called flower model. Because the flower model represents random behavior, it has a perfect recall of the all behavior in the event log but it also has much *additional* behavior compared to the event log. Because of the latter fact, the flower model has zero specificity. These properties are to some extent reflected in the metrics in Table 5. The fitness measure f and the behavioral recall measure r_B^p are both 1.0, whereas the behavioral specificity metric s_B^n amounts to 0. The table also indicates the usefulness of the metrics proposed in this paper. The parsing measure PM does not reflect the recall of the flower model. Furthermore, the behavioral appropriateness measure $a_B^{'}$ does not really seem to quantify the lack of specificity of the flower model. For the genetic miner mining result, the ProM implementations of f, and $a_B^{'}$ did not produce an outcome. To calculate these metrics, a conversion of the heuristics nets into Petri nets is required. The resulting Petri nets, which have many invisible transitions, are seemingly too complex to calculate the metric. These results are an indication of the usefulness of the new specificity metric proposed in this paper.

Comparing the available r_B^p and s_B^n outcomes, it can be observed that AGNEs performs better than genetic miner, but worse than heuristics miner on the obtained event log. The discovered process model by AGNEs has an accuracy of 80%, whereas the models discovered by genetic miner and heuristics miner have an accuracy of 73% and 92% respectively. This case study brings forward that human-centric processes contained in the event log can take place in a less structured fashion than often is assumed by process discovery algorithms. In this particular case, for instance, it seems that OR-splits and OR-joins can involve a rather high number of outgoing or incoming activities. In the current implementation, the language bias of TILDE is limited to conjunctions and disjunctions of *NS* constructs of length two and three. This imposes limitations on the hypotheses that can be learned by AGNEs. As indicated in Section 4.3, solving this language bias issue, requires construct-



(a) AGNEs (b) genetic miner (c) heuristics miner

Figure 4: telecom—mining results

ing a proprietary ILP classification algorithm that during each refinement step allows considering conjunctions of *NS* constructs of variable lengths. In this regard, the language bias of Heuristics Miner seems to be less limiting, although Heuristics Miner does not have many of the declarative properties of AGNEs. Another outcome of the case study, is that the proposed measures for behavioral recall r_B^p and behavioral specificity s_B^n in practice turn out to be valuable metrics for assessing the accuracy of a discovered process model.

8. Related Work

Process discovery can be seen as an application of the machine learning of grammars from positive data, of which Angluin and Smith (1983) provide an overview. Gold (1967) has shown that important classes of recursively enumerable languages cannot be *identified in the limit* from a finite number of positive examples only. Instead, both positive and negative examples are required for grammar learning to distinguish the right hypothesis among an infinite number of grammars that fit the positive examples. Whereas Gold's negative learnability result applies to the learning of grammars with perfect accuracy, process discovery is more concerned with the ability to discover process models that have *only* a good recall and specificity. Learning grammars from only positive examples requires a tradeoff between overly general and overly specific hypotheses. Muggleton (1996) shows that in a Bayesian framework, logic programs are learnable with arbitrarily low error from positive examples only. Bayes' theorem allows to formulate this tradeoff as a tradeoff between size and generality of the hypotheses and learning can be considered to maximization the posterior probability over all hypotheses. In this paper, a new approach for making the tradeoff between generality and specificity is proposed, by inducing artificial negative events using a (highly configurable) assumption about the completeness of the behavior displayed by the positive examples in the event log. Another difference with grammar learning is that in grammar learning, the hypothesis space is often expressed as production rules, automata or regular expressions, whereas process discovery uses formalisms that can represent the concurrency and synchronization concerns of processes more elegantly.

Process models are in general deterministic. In the literature, there are many formalisms to represent and learn the probability distributions of *stochastic*, generative grammars over sequences of observed characters and unobserved state variables. Historically, techniques like Markov models, hidden Markov models, factorial hidden Markov models, and dynamic Bayesian networks have been first applied to speech recognition, and bio-informatics (Durbin et al., 1998). Each representation has its own particular modeling features that makes it more or less suited for representing the human-centric behavior of business processes. Factorial hidden Markov models, for instance, have a distributed state representation that allows for the modeling of concurrent behavior (Ghahramani and Jordan, 1997). Hidden Markov models have furthermore been provided with a first-order, extension that allows for the representation of sequences of logical atoms rather than alphabets of flat characters (Kersting et al., 2006). Other authors describe learning mixture models to identify meaningful clusters of (hidden) Markov models (Smyth, 1997; Cadez et al., 2003). Whereas stochastic models provide useful information, their probabilistic nature tends to compromise the comprehensibility of discovered process models. Business processes have well-defined start, end, split, and synchronization nodes. The network structure of stochastic models does not visualize this. For instance, although hidden states could be useful in representing duplicate activities—the same activity label is logged in different contexts—a hidden Markov model is unlikely to be capable of comprehensively representing its different usage contexts.

In contrast, Mannila and Meek (2000) describe a technique to learn two-component mixture models of global partial orders that provide an understandable, global view of the sequential data. The authors assume the presence of one dominant, global partial order and consider a generic partial order with random behavior to deal with low-frequent variations (noise) from the former model. Silva et al. (2005) describe a probabilistic model and algorithm for process discovery that discovers so-called and/or graphs in polynomial time. These and/or graphs are comprehensible, directed acyclic graphs that have the advantage over global partial order representations that they can differentiate between parallel and serial split and join points. Pei et al. (2006) describe a scalable technique for discovering the complete set of frequent, closed partial orders from sequential data. The three aforementioned techniques assume each item to occur only once within a sequence, and do not consider recurrent behavior (cycles), nor duplicate activities.

The term process discovery was coined by Cook and Wolf (1998), who apply it in the field of software engineering. Their Markov algorithm can only discover sequential patterns as Markov chains cannot elegantly represent concurrent behavior. The idea of applying process discovery in the context of workflow management systems stems from Agrawal et al. (1998) and Lyytinen et al. (1998). The value of process discovery for the general purpose of process mining (van der Aalst et al., 2007) is well illustrated by the plugins within the ProM framework. In analogy with the WEKA toolset for data mining (Witten and Frank, 2000), the ProM Framework consists of a large number of plugins for the analysis of event logs (Process Mining Group, TU/Eindhoven, 2008). The *Conformance Checker* plugin (Rozinat and van der Aalst, 2008), for instance, allows identifying the discrepancies between an idealized process model and an event log. Moreover, with a model that accurately describes the event log, it becomes possible to use the time-information in an event log for the purpose of performance analysis, using, for instance, the *Performance Analysis with Petri nets* plugin.

Table 6 provides a chronological overview of process discovery algorithms that have been applied to the context of workflow management systems. The α algorithm can be considered to be a theoretical learner for which van der Aalst et al. (2004) prove that it can learn an important class of workflow nets, called structured workflow nets, from complete event logs. The α algorithm assumes event logs to be complete with respect to all allowable binary sequences and assumes that the event log does not contain any noise. Therefore, the α algorithm is sensitive to noise and incompleteness of event logs. Moreover, the original α algorithm was incapable of discovering short loops or non-local, non-free choice constructs. Alves de Medeiros et al. (2004) have extended the α algorithm to mine short loops and called it α^+. Wen et al. (2007) made an extension for detecting implicit dependencies, for detecting non-local, non-free choice constructs. None of the algorithms can detect duplicate activities. The main reason why the α algorithms are sensitive to noise, is that they does not take into account the frequency of binary sequences that occur in event logs. Weijters and van der Aalst (2003) and Weijters et al. (2006) have developed a robust, heuristic-based method for process discovery, called heuristics miner, that is known to be noise resilient. Heuristics miner can discover short loops, and non-local, non-free choice as it can consider non-local dependencies within an event log. However, heuristics miner cannot detect duplicate activities.

Algorithm (Ref.)	**Summary**
global partial orders (Mannila and Meek, 2000)	Learns a two-component mixture model of a dominant series-parallel partial order and a trivial partial order by searching for the dominant partial order that yields the highest probability for generating the observed sequence database.
little thumb, **heuristics miner** (Weijters and van der Aalst, 2003) (Weijters et al., 2006)	Extends the α algorithm by taking into account the frequency of the follows relationship, to calculate dependency/frequency tables from the event log and uses heuristics to convert this information into a heuristics net.
α, α^+ (van der Aalst et al., 2004) (Alves de Medeiros et al., 2004)	Derives a Petri net from local, binary ordering relations detected within an event log.
splitpar—InWoLvE (Herbst and Karagiannis, 2004)	Derives a so-called stochastic activity graph and converts it into a structured process model in the Adonis Modeling language.
multi-phase miner (van Dongen and van der Aalst, 2005b)	Constructs a process model for every sequence in the log and aggregates the model into an event-driven process chain.
α^{++} (Wen et al., 2007)	Extends the α algorithm to discover non-local, non-free choice constructs.
– (Silva et al., 2005)	A probabilistic approach to process discovery.
frecpo (Pei et al., 2006)	A scalable technique for discovering the complete set of frequent, closed partial orders from sequential data.
FSM/Petrify miner (van der Aalst et al., 2006)	Derives a highly configurable finite state machine from the event log and folds the finite state machine into regions using the theory of regions.
– (Ferreira and Ferreira, 2006)	Learns the case data preconditions and effects of activities with ILP classification techniques and user-supplied negative events.
genetic miner (Alves de Medeiros et al., 2007)	A genetic algorithm that selects the more complete and precise heuristics nets over generations of nets.
DecMiner (Lamma et al., 2007)	A classification technique that learns the preconditions of activities with the ICL ILP learner from event logs with user-supplied negative sequences.
fuzzy miner (Günther and van der Aalst, 2007)	An adaptive simplification and visualization technique based on significance and correlation measures to visualize unstructured processes.

Table 6: Chronological overview of process discovery algorithms

van Dongen and van der Aalst (2005b) present a multi-phase approach to process mining that starts from the individual process sequences, constructs so-called instance graphs for each sequence that account for parallelism, and then aggregates these instance graphs according to previously detected binary relationships between activity types. Interestingly, the aggregation ensures that every discovered process model has a perfect recall, but generally scores less on specificity. Herbst and Karagiannis (2004) describe the working of the splitpar algorithm that is part of the InWoLvE framework for process analysis. This algorithm derives a so-called stochastic activity graph and converts it into a structured process model. The splitpar algorithm is capable of detecting duplicate activities, but it is not able to discover non-local dependencies.

Alves de Medeiros et al. (2007) describe a genetic algorithm for process discovery. The fitness function of this genetic algorithm incorporates both a recall and a specificity measure that drives the genetic algorithm towards suitable models. The genetic miner is capable of detecting non-local patterns in the event log and is described to be fairly robust to noise. In her PhD, Alves de Medeiros (2006) describes an extension to this algorithm for the discovery of duplicate tasks.

van der Aalst et al. (2006) present a two-phase approach to process discovery that allows to configure when states or state transitions are considered to be similar. The ability to manipulate similarity is a good approach to deal with incomplete event logs. In particular, several criteria can be considered for defining similarity of behavior and states: the inclusion of future or past events, the maximum horizon, the activities that determine state, whether ordering matters, the activities that visibly can bring about state changes, etcetera. Using these criteria, a configurable finite state machine can be constructed from the event log. In a second phase, the finite state machine is folded into regions using the existing theory of regions (Cortadella et al., 1998). For the moment, the second phase of the algorithm still poses difficulties with respect to constructing suitable process models. The approach presented in this paper considers window size (maximum horizon) and parallel variants as similarity criteria when generating artificial negative events.

Günther and van der Aalst (2007) present an adaptive simplification and visualization technique based on significance and correlation measures to visualize the behavior in event logs at various levels of abstraction. The contribution of this approach is that it can also be applied to less structured, or unstructured processes of which the event logs cannot easily be summarized in concise, structured process models.

Several authors have used classification techniques for the purpose of process discovery. Maruster et al. (2006), for instance, were among the first to investigate the use of rule-induction to predict dependency relationships between activities from a corpus of reference logs that portray various levels of noise and imbalance. To this end, the authors use a propositional rule induction technique, the uni-relational classification learner RIPPER (Cohen, 1995), on a table of direct metrics for each process task in relation to each other process task, which is generated in a pre-processing step.

Ferreira and Ferreira (2006) apply a combination of ILP learning and partial-order planning techniques to process mining. Rather than generating artificial negative events, negative examples are collected from the users who indicate whether a proposed execution plan is feasible or not. By iteratively combining planning and learning, a process model is discovered that is represented in terms of the case data preconditions and effects of its activities. In addition to this new process mining technique, the contribution of this work is in the truly integrated BPM life cycle of process generation, execution, re-planning and learning. Lamma et al. (2007) also describe the use of ILP to process mining. The authors assume the presence of negative sequences to guide the search algorithm. Unlike the approach of Ferreira and Ferreira, who use partial-order planning to present the user with an execution plan to accept or reject (a negative example), this approach does not provide an immediate answer to the origin of the negative events. Contrary to our approach, the latter two approaches are not concerned with the construction of a graphical, control-flow based process model and do not consider the generation of artificial negative events.

9. Conclusion

Process discovery aims at accurately summarizing an event log in a structured process model. So far, the discovery of structured processes by supplementing event logs with *artificial* negative events has not been considered in the literature. The advantage is that it allows representing process discovery as a multi-relational classification problem to which existing classification learners can be applied. In this paper, the generation of artificial negative events gives rise to a new process discovery algorithm and to new metrics for quantifying the recall and specificity of a process model vis-à-vis an event log.

Process discovery algorithms must deal with challenges such as expressiveness, noise, incomplete event logs and the inclusion of prior knowledge. Dealing with one challenge sometimes leads to poor performance with respect to another. The technique presented in this paper, simultaneously addresses many of these challenges. This can be concluded from the results of a large benchmark study applied to AGNEs and four state-of-the art process discovery algorithms. A comparative benchmark study of this scale is the first in the field of process discovery. The benchmark experiments indicate that our technique can discover complex structures such as short loops, duplicate activities, and non-free choice constructs, while remaining robust to noise. In addition, our technique has a new, declarative way of dealing with incomplete event logs that diminishes the effects of concurrent and recurrent behavior on the generation of artificial negative events. Finally, our technique is capable of having prior knowledge constrain the hypothesis space during process discovery. These declarative aspects—the inclusion of prior knowledge, the configurability of the negative event generation procedure and the language bias—potentially make it very useful in practical applications. Another outcome of the benchmark study is the usefulness of the new specificity metric, which in contrast to existing metrics can always be calculated and produces intuitive results.

Acknowledgments

We extend our gratitude to the guest editors, the anonymous reviewers, and the production editor, as their many constructive and detailed remarks certainly contributed much to the quality of this paper. Further, we would like to thank the Flemish Research Council for financial support (FWO postdoctoral research grant, Odysseus grant B.0915.09).

Abstract

Predictive models benefit from a compact, non-redundant subset of features that improves interpretability and generalization. Modern data sets are wide, dirty, mixed with both numerical and categorical predictors, and may contain interactive effects that require complex models. This is a challenge for filters, wrappers, and embedded feature selection methods. We describe details of an algorithm using tree-based ensembles to generate a compact subset of non-redundant features. Parallel and serial ensembles of trees are combined into a mixed method that can uncover masking and detect features of secondary effect. Simulated and actual examples illustrate the effectiveness of the approach.

Keywords: trees, resampling, importance, masking, residuals

1. Introduction

Large data sets are becoming the norm and traditional methods designed for data sets with a modest number of features will struggle in the new environment. This problem area was described by Guyon and Elisseeff (2003) along with other publications in the same issue, and it has increased in importance since then. Additional comments and examples have been provided by Liu and Yu (2005) in a recent survey article.

1.1 Feature Selection

There are three major categories of feature selection methods. Filter methods score variables, typically individually, and eliminate some before a model is constructed. The filter needs to be generated carefully to relate well to the requirements of the modeling task. In particular, the filter may not consider the value of one variable in the presence of others. For example, the widely-used value difference metric (VDM) (Stanfill and Waltz, 1986) and its modified version (MVDM) (Cost and Salzberg, 1993) consider the conditional probability distribution of the response at a predictor value. Such a measure is not sensitive to the effects of some predictors in a model with others present even though interactions among predictors might be critical for an effective subset. A sequential, subset search is sometimes implemented to improve the performance when interactions are important, although a greedy search also has disadvantages in the presence of interactions. Several common filter methods such as ReliefF (Robnik-Sikonja and Kononenko, 2003), CFS (Hall, 2000), and FOCUS (Almuallin and Dietterich, 1994) were modified with sequential search and compared by Yu and Liu (2004).

Wrapper methods form a second group of feature selection methods. The prediction accuracy (or the change in accuracy) of a model directly measures the value of a feature set. Although effective, the exponential number of possible subsets places computational limits for the wide data sets that are the focus of this work.

Embedded methods form a third group for feature selection. These methods use all the variables to generate a model and then analyze the model to infer the importance of the variables. Consequently, they directly link variable importance to the learner used to model the relationship.

1.2 Subset Feature Selection

Fundamentally, the goal of feature selection is to model a target response (or output) variable y, with a subset of the (important) predictor variables (inputs). This is a general goal and several more specific objectives can be identified. Each can lead to different strategies and algorithms. In *filtering* the interest is to remove irrelevant variables. Another objective is *variable ranking* where the interest is in obtaining relative relevance for all input variables with respect to the target. Finally, we might be interested in a compact, yet effective model, where the goal is to identify the smallest subset of independent features with the most predictive power, although a few alternative groups might be reasonable. An important concept here is *the masking relationships* among the predictor variables. Masking occurs when one variable can effectively represent others in a model. Along with the related issue of masking, this paper focuses on the subset selection.

1.3 Contributions of this Paper

Existing tree ensembles such as random forest (Breiman, 2001) or gradient boosting trees (Friedman, 1999) were developed primarily for predictive modeling. In addition, they can provide an importance ranking of the features, but this information has been considered an ad hoc benefit. Random forest (RF) is a random subspace method, and is capable of efficiently ranking features for large data sets. We exploit this property of RF, augment the original data with *artificial contrast variables* constructed independently from the target, and use their ranking for removal of irrelevant variables from the original set. The tree construction method is also modified to produce a more reliable variable ranking in the presence of high cardinality variables. A variable masking measure is then introduced that incorporates surrogate variable scores from ensembles of trees. This forms the basis for *redundancy elimination*. Residual effects are calculated to enable the method to detect variables of secondary importance. These elements are integrated into an efficient algorithm for subset selection called ACE (artificial contrasts with ensembles).

The structure of this paper is as follows. In Section 2 we describe previous work and outline directions taken in this paper. Section 3 describes variable importance measures defined through tree ensembles and explains how they could be used to remove irrelevant features using random, artificial features. Next, we introduce a masking measure and use it for redundancy elimination. Section 4 describes the details of the ACE algorithm to generate the selected subset, and compares ACE with its closest competitors in detail. Section 5 provides results from experiments. Section 6 provides conclusions.

2. Background

This section defines the problem of finding the best susbset of features, discusses previous approaches, and outlines our solution.

2.1 Markov Boundaries

Let F be a full set of features. A feature selection solution can be described in terms of a Markov blanket (Koller and Sahami, 1996). Given a target feature Y, let $M \subset F$ and $Y \notin M$. M is said to be a Markov blanket for Y if $Y \perp (F - M) | M$. That is, Y is conditionally independent of other features given M. A minimal Markov blanket is referred to as Markov boundary (MB) and such a subset might be considered a feature selection solution. However, an important issue is that a MB need not be unique. Redundant features can replace others in a feature subset. Usually feature redundancy is defined in terms of feature correlation (Hall, 2000). For example, two features are redundant to each other if their values are completely correlated. In reality, it is not so straightforward to determine feature redundancy if a feature is partially correlated to a set of features.

Our goal is to focus on the important case with redundant features and obtain at least one MB. In most real-life problems exactly determining the MB or measuring feature relevance is very difficult because of a limited sample size, high time complexity, and noise in the data. Furthermore, evaluation of the distribution of the input variables and the response always relies on some model (linear, support vector machine, frequency tables, trees, etc.). In practice, most algorithms just try to remove irrelevant features and then apply some heuristics that remove “possibly” redundant variables.

2.2 Existing Approaches in Feature Selection

The nature of real life data sets provides strong restrictions for model fitting and feature selection methods. First, data sets may be very large both in terms of the number of predictors and in the number of samples (tens of thousands $\times$ tens of millions). Second, the predictors and the response can be of mixed type (both numeric and categoric), and can contain missing values. Lastly and also very importantly, dependency of the response on predictors can be highly non-linear, noisy and multivariate.

This leaves most existing methods out of scope for such problems. For example, wrapper methods (forward selection or backward elimination) are simply computationally unfeasible when dealing with thousands of predictors. Filter methods are also useless for the minimal subset selection problem, as they do not deal with the notion of redundancy and most of them are inherently univariate. However, there are filters that use a“local” feature importance measure (like RELIEF) that can be considered multivariate (Kira and Rendell, 1992), but still they do not deal with redundancy giving just a ranked list of features instead of a selected minimal subset.

Subset evaluation filter methods such as CFS (Hall, 2000) are neither suitable because they do not deal explicitly with redundancy, and have to iterate over many feature subsets incurring a high time complexity. For example, the time complexity of the CFS is at least quadratic in the number of features and linear in number of samples. Also CFS is highly sensitive to outliers as it uses correlations between features.

Many embedded methods that use a built-in feature relevance measurement, such as SVM-RFE (Guyon et al., 2002) and linear regression with backward feature elimination are heavily dependent on the model (linear or SVM), that can fail to fit the data well. These methods have at least quadratic complexity in the number of samples for fitting an SVM and at least cubic complexity in the number of features ($O(nm^2+m^3)$, where m is the number of features, and n is number of samples) for fitting a regression model. Data sets with tens of thousands of features or samples become very time consuming and impractical to handle. For example, SVM-RFE involves retraining the SVM after features with smallest relevance are removed, thus incurring at least cubic complexity in number of samples ($O(max(m,n)n^2)$).

An issue that discourages using regression methods and methods that rely on some kind of distance measure between observations (linear regression, SVM, Kernel-based methods, RELIEF) is the difficulty of dealing with outliers in the input (predictor) space. Also, selection of important model parameters (kernel width and type, feature relevance thresholds, etc) is non-obvious, and the results of feature selection depend heavily on them.

Most methods return just a ranked list of features instead of an optimal subset. These methods include RELIEF, Koller's Markov blanket based backward elimination (referred to here as MBBE) (Koller and Sahami, 1996), and SVM-RFE. Some methods such as FCBS use a relevance threshold that is not clear how to adjust (Yu and Liu, 2004). In reality, the user also obtains a number of feature subsets corresponding to different values of parameters without a hint of how to choose the best subset.

Many methods work with frequency tables. They can thus deal well with categorical inputs only. For numerical inputs, they require discretization. Such methods are not always able to deal with interacting variables and have great difficulties with multivariate dependencies on numerical inputs. Examples of such methods are FCBS and MBBE. These two algorithms need discretization because they use an entropy measure computed on frequency tables. If the number of categories is large, or if we use frequency tables with more than two inputs, the tables can be sparse and may not represent the data distribution well. Another issue for MBBE is computational complexity. Considering all feature pairs incurs a quadratic complexity on the number of features.

Hence we see that most methods at hand are either not applicable at all to the best subset selection problem, or have some major problems. The most useful methods in such a setting (that appeared to be applicable to the examples of large “real-life” data in the challenge data sets discussed in Sec. 5.3) are methods based on backward feature elimination using an approximate Markov blanket concept (Koller and Sahami, 1996; Yu and Liu, 2004). Our method approximates the optimal Markov blanket redundancy elimination procedure, but without most of the drawbacks of previous methods.

2.3 Towards Efficient and Approximately Optimal Feature Selection

We propose a method that uses an idea similar to those proposed by Koller and Sahami (1996) and Yu and Liu (2004) that tries to overcome their limitations. It does not have quadratic time complexity in the number of features, can deal with thousands of predictors, uses a model (ensembles of trees) that can be applied to mixed variable types, thus eliminating need for discretization of numeric inputs, does not require imputation of missing values, captures local information (like RELIEF), is invariant to a monotone transformation of inputs, thus not very sensitive to noise and outliers, and deals well with multivariate dependencies.

It is well known that trees and especially ensembles of trees can provide robust and accurate models in "real-life" data settings. They handle mixed and noisy data, and are scale insensitive. Ensembles of trees have high predictive power and are resistant to over-fitting (Breiman, 2001). Our approach relies heavily on ensembles of trees.

First, we find irrelevant features that are conditionally independent of the response given the rest of the features. It is accomplished by comparing the relevance of the original variables with the relevance of random, artificial features (appended to the original data) constructed from the same distribution, but independently from the response. These features are referred to as artificial contrasts. We measure feature relevance as variable importance in random forests with a modified robust splitting criteria. We assume that if an original variable had a relevance score not statistically higher than that of an artificial probe (independent from the target by construction) then it is also independent from the target, irrelevant, and should be removed. Note that we try to remove irrelevant features by directly assessing conditional independence without searching for a MB, the existence of which is a much stronger requirement. Although the idea of artificial contrasts was already used by other researchers in simple filter methods with success (Stoppiglia et al., 2003), its application to tree ensembles is novel and promising. Actually, our approach can be considered as non-parametric because all parameters in our algorithm can be assigned reasonable default values that work well for wide range of problems.

Then the redundant feature elimination step is performed. Redundancy between features is measured using surrogate scores. The variable with the largest impurity reduction score at a node is the primary splitter. If surrogate variables (ones that partition the node in same way as the primary variable) are present, these surrogate variables are considered as "masked". Masking scores between all pairs of important variables are computed and evaluated using a statistical test, and variables masked by more important variables ("approximately redundant") are removed iteratively.

Finally, after a set of non-redundant relevant features has been found, our method removes the influence of the found subset with an ensemble and proceeds. Because redundancy elimination is approximate in nature this iterative approach is another advantage of our method. It allows one to recover variables with small importance and to reduce the chance to lose important variables during redundancy elimination.

3. Tree Ensembles for Feature Selection

For our embedded method, we focus on ensembles of decision trees for the following reasons. Trees can be applied in ubiquitous scenarios so that they provide a good entry point for feature selection for interdisciplinary, wide data sets. They apply to either a numerical or a categorical response. They are nonlinear, simple and fast learners that handle also both numerical and categorical predictors well. They are scale invariant and robust to missing values. A simple decision tree also provides an embedded measure of variable importance that can be obtained from the number and the quality of splits that are generated from a predictor variable. However, a single tree is produced by a greedy algorithm that generates an unstable model. A small change to the data can result in a very different model. Consequently, ensemble methods have been used to counteract the instability of a single tree.

Supervised ensemble methods construct a set of simple models, called base learners, and use their weighted outcome (or vote) to predict new data. That is, ensemble methods combine outputs from multiple base learners to form a committee with improved performance. Numerous empirical studies confirm that ensemble methods often outperform any single base learner (Freund and Schapire, 1996; Bauer and Kohavi, 1999; Dietterich, 2000a). The improvement can be dramatic when a base algorithm is unstable. More recently, a series of theoretical developments (Bousquet and Elisseeff, 2001; Poggio et al., 2002; Mukherjee et al., 2006; Poggio et al., 2004) also confirmed the fundamental role of stability for the generalization of a learning algorithm. More comprehensive overviews of ensemble methods were presented by Dietterich (2000b) and Valentini and Masulli (2002). There are two primary approaches to ensemble construction: parallel and serial.

A parallel ensemble combines independently constructed and diverse base learners. That is, different base learners should make different errors on new data. An ensemble of such base learners can outperform any single one of its components since diverse errors cancel out (Hansen and Salamon, 1990; Amit and Geman, 1997). Parallel ensembles are variance-reduction techniques, and in most cases, they are applied to unstable, high-variance algorithms (such as trees). Also, Valentini and Dietterich (2003) showed that ensembles of low-bias support vector machines (SVMs) often outperformed a single, best-tuned, canonical SVM (Boser et al., 1992).

Random forest (RF) is an exemplar for parallel ensembles (Breiman, 2001). It is an improved bagging method (Breiman, 1996) that extends the "random subspace" method (Ho, 1998). It grows a forest of random decision trees on bagged samples showing excellent results comparable with the best known classifiers. A RF can be summarized as follows: (1) Grow each tree on a bootstrap sample of the training set to maximum depth, (2) Given M predictors, select at random $m < M$ variables at each node, and (3) Use the best split selected from the possible splits on these m variables. Note that for every tree grown in RF, about one-third of the cases are out-of-bag (out of the bootstrap sample). The out-of-bag (OOB) samples can serve as a test set for the tree grown on the non-OOB data. We discuss later how OOB samples can be used for feature selection.

In serial ensembles, every new learner relies on previously built learners so that the weighted combination forms an accurate model. A serial ensemble algorithm is often more complex. It is targeted to reduce both bias and variance. A serial ensemble results in an additive model built by a forward-stagewise algorithm. The *adaboost* algorithm was introduced by Freund and Schapire (1996). At every step of ensemble construction the boosting scheme adds a new base learner that is forced (by iteratively reweighting the training data) to concentrate on the training observations that are misclassified by the previous sequence. Boosting showed dramatic improvement in accuracy even with very weak base learners (like decision stumps, single split trees). Breiman (1998) and Friedman et al. (2000) showed that the adaboost algorithm is a form of gradient optimization in functional space, and is equivalent to a forward-stagewise, additive algorithm with the exponential loss function $\Psi(y, F(\mathbf{x})) = \exp(-yF(\mathbf{x}))$ referred to as a gradient boosted tree (GBT).

3.1 Relative Variable Importance Metrics

A single decision tree partitions the input space into a set of disjoint regions, and assigns a response value to each corresponding region. It uses a greedy, top-down recursive partitioning strategy. At every step an exhaustive search is used to test all variables and split points to achieve the maximum reduction in impurity. Therefore, the tree constructing process itself can be considered as a type of variable selection (a kind of forward selection, embedded algorithm), and the impurity reduction due to a split on a specific variable indicates the relative importance of that variable to the tree model (Breiman et al., 1984). For ensembles, the metric is averaged over the collection of base learners. Note, that this relative importance automatically incorporates variable interaction effects thus being very different from the relevance measured by a univariate filter method.

For a single decision tree the measure of variable importance is

$$VI(X_i,T) = \sum_{t \in T} \Delta I(X_i,t), \tag{1}$$

where $\Delta I(X_i,t)$ is the decrease in impurity due to an actual (or potential) split on variable X_i at a node t of the optimally pruned tree T (Breiman et al., 1984). Node impurity $I(t)$ for regression is defined as $\sum_{i\in t}(y_i - \bar{y})^2/N(t)$ where the sum and mean are taken over all observations i in node t, and $N(t)$ is the number of observations in node t. For classification $I(t) = Gini(t)$ where $Gini(t)$ is the Gini index of node t defined as

$$Gini(t) = \sum_{i \neq j} p_i^t p_j^t,$$

and p_i^t is the proportion of observations in t whose response label equals i ($y = i$) and i, j run through all response class numbers. The Gini index is in the same family of functions as *cross-entropy* $= -\sum_i p_i^t log(p_i^t)$, and measures node impurity. It is zero when t has observations only from one class, and is maximum when classes are perfectly mixed. The decrease $\Delta I(X_i,t)$ computes the impurity at the node t and the weighted average of impurities at each child node of t. The weights are proportional to the number of observations that are assigned to each child from the split at node t so that $\Delta I(X_i,t) = I(t) - p_L I(t_L) - p_R I(t_R)$.

For an ensemble of M trees this importance measure is easily generalized. It is simply averaged over the trees

$$E(X_i) = \frac{1}{M}\sum_{m=1}^{M} VI(X_i,T_m). \tag{2}$$

The averaging makes this measure more reliable.

This split weight measure $\Delta I(X_i,t)$ in Equation (1) can be improved if OOB samples are used. The split value for a variable is calculated using the training data as usual. However, the variable selected as the primary splitter uses only the OOB samples. Also, the variable importance measure is calculated from only the OOB samples. This provides a more accurate and unbiased estimate of variable importance in each tree and improves the filtering of noise variables.

Breiman (2001) also proposed a *sensitivity* based measure of variable relevance evaluated by a RF. For a classification problem it is summarized as follows: (1) Classify the OOB cases and count the number of votes cast for the correct class in every tree grown in the forest, (2) randomly permute the values of variable m in the OOB cases and classify these cases down the tree, (3) Subtract the number of votes for the correct class in the variable-m-permuted OOB data from the original OOB data, and (4) Average this number over all trees in the forest to obtain the raw importance score for variable m. Similar ideas were presented by Parmanto et al. (1996) and a similar resampling strategy was successfully used in a more traditional model by Wisnowski et al. (2003). The sensitivity measure is computationally expensive. Furthermore, it does not account for masking, nor does it consider an iterative process with residuals (that we describe in Sec. 4.2). Experiments by Tuv (2006) demonstrated that weaker but independent predictors can rank higher than stronger, but related predictors. Also, related predictors can all be identified as important. Neither of these results are desirable for a best subset model and a more effective algorithm is described in Sec. 4.

With the importance measure (2) we can thus merely rank the variables. The following two subsections discuss how to amend the ranking so that irrelevant variables can be reliably detected, and how the redundancies among the remaining relevant variables can then be handled.

3.2 Removing Irrelevant Features by Artificial Contrasts

Although an ensemble can be used to calculate a relative feature ranking from the variable importance score in (2) the metric does not separate relevant features from irrelevant. Only a list of importance values is produced without a clear indication which variables to include, and which to discard. Also, trees tend to split on variables with more distinct values. This effect is more pronounced for categorical predictors with many levels. It often makes a less relevant (or completely irrelevant) input variable more “attractive” for a split only because it has high cardinality.

The variable importance score in (2) is based on the relevance of an input variable to the target. Consequently, any stable feature ranking method should favor a relevant input X_i over an artificially generated variable with the same distribution as X_i but generated to be irrelevant to the target. That is, a higher variable importance score is expected from a true relevant variable than from an artificially generated contrast variable. With sufficient replicates in an analysis one can select important variables from those that have statistically significantly higher variable importance scores than the contrast variables (Tuv et al., 2006). Here, these contrast variables are integrated into a subset algorithm. We discuss this in detail in Section 4.

Also, artificial contrasts can be applied to masking discussed in the next subsection. Given a selected subset of relevant variables, one computes the masking scores of all variables by elements of this subset, and the masking of contrast variables by this subset. Masking scores statistically higher than the contrast variables are considered to be real masking. Variables that are masked are dropped from the relevant subset list over a sequence of iterations of the algorithm.

3.3 Masking Measures

An important issue for variable importance in tree-based models is how to evaluate or rank variables that were masked by others with slightly higher splitting scores, but could provide as accurate a model if used instead. One early approach in the CART methodology used surrogate splits (Breiman et al., 1984). The predictive association of a surrogate variable X^s for the best splitter X^* at a tree node T is defined through the probability that X^s predicts the action of X^* correctly and this is estimated as

$$p(X^s, X^*) = p_L(X^s, X^*) + p_R(X^s, X^*),$$

where $p_L(X^s, X^*)$ and $p_R(X^s, X^*)$ define the estimated probabilities that both X^s and X^* send a case in T left (right). The predictive measure of association $\lambda(X^*|X^s)$ between split X^s and primary split X^* is defined as

$$\lambda(X^*|X^s) = \frac{\min(\pi_L, \pi_R) - [1 - p(X^s, X^*)]}{\min(\pi_L, \pi_R)},$$

where π_L, π_R are the proportions of cases sent to the left(or right) by X^*. It measures the relative reduction in error $(1 - p(X^s, X^*))$ due to using X^s to predict X^* as compared with the "naive" rule that matches the action with $\max(\pi_L, \pi_R)$ (with error $\min(\pi_L, \pi_R)$). If $\lambda(X^*|X^s) < 0$ then X^s is disregarded as a surrogate for X^*. Sometimes a small, nonnegative threshold is used instead. The variable importance sum in Equation (1) is taken over all internal tree nodes where X_i is a primary splitter or a surrogate variable ($\lambda(X^*|X_i) > 0$ for a primary splitter X^*). Often a variable that does not appear as a primary splitter in a tree is still ranked high on the variable importance list constructed using surrogate variables.

We extend the surrogate concept to define a masking score as follows. Variable i is said to mask variable j in a tree, if there is a split in variable i in a tree with a surrogate on variable j. We define the masking measure for a pair of variables i, j in tree T as

$$M_{ij}(T) = \sum_{\{t \in T | \text{split on } X_i\}} w(X_i, t) \lambda(X_i | X_j),$$

where $w(X_i, t) = \Delta I(X_i, t)$ is the decrease in impurity from the primary split on variable X_i, and summation is done over the nodes where primary split was made on variable X_i. Here we take into account both the similarity between variables X_i, X_j at the node, and the contribution of the actual split of variable X_i to the model. For an ensemble the masking measure is simply averaged over the trees. Note that in general the measure is not symmetric in the variables. One variable may mask several others, but for a single selected masked variable the reverse may not be true.

4. Algorithm: Ensemble-Based Feature Selection with Artificial Variables and Redundancy Elimination

We now integrate the previously described concepts and metrics into a subset selection algorithm. The fundamental steps outlined in Section 2.3 consist of using the advantages of a parallel ensemble to detect important variables among potentially a very large feature set, using the advantages of a serial ensemble to de-mask the important variables, and calculating residuals and repeating in order to recover variables of secondary importance.

Within the algorithm, artificial contrast variables are re-generated a number of times. Then the significance from a paired t-test over the replicates is used to identify important variables and masked variables. Essentially the t-test is used to define thresholds for selection and masking. These thresholds could also be set as tunable parameters. An advantage of the statistical test is that the significance of selected variables relative to noise can be quantified.

4.1 Algorithm Details

1. **Identify Important Variables:** Artificially generated noise variables are used to determine a threshold to test for statistically significant variable importance scores. The test is used to remove irrelevant variables. Details are presented in the displayed algorithms and further described as follows.

   In each replicate $r, r = 1, 2, \ldots, R$ artificial variables are constructed as follows. For every real variable X_j $j = 1, 2, \ldots, M$ a corresponding artificial variable Z_j is generated from a random permutation. Then in each replicate a small RF is trained and variable importance scores are computed for real and artificial variables. The scores from each replicate r are compiled into the rth row of a matrix $\mathbf{V}$ $R \times 2M$. Furthermore, the $1-\alpha$ percentile of the importance scores in replicate r is calculated from only the artificial variables. This is denoted as v_r and the vector of percentiles over the R replicates is $\mathbf{v}$ $R \times 1$. For each real variable X_j a paired t-test compares importance scores for X_j (obtained from the jth column of $\mathbf{V}$) to the vector of scores $\mathbf{v}$. A test that results in statistical significance identifies an important variable.

Significance is evaluated through a suitably small p-value. The use of a p-value requires a feature to consistently score higher than the artificial variables over multiple replicates. Furthermore, this statistical testing framework also allows any method to control false selections to be applied. We routinely use the Bonferroni adjustment, but a false discovery rate approach is also reasonable. Each replicate uses a RF with $L =$ 20-50 trees to score the importance of the original and artificial noise variables. Also, the split weight calculation for variable importance in (2) only uses OOB samples as described previously.

2. **Calculate Masking Scores:** A masking matrix is computed from independent replicates in order to evaluate the statistical significance of masking results. Suppose there are m important variables from step 1. For similar reasons as in the previous step, replicates and noise variables are used to detect masking among the relevant variables. These are currently the same replicates that are used for variable importance. A set of R independent GBT models are generated each with $L =$ 10-50 trees. Note that all variables are tested in each node in each tree in a serial ensemble. Therefore, richer, more effective masking information is obtained from a serial ensemble than from a random subspace method like RF. In these calculations, the surrogate scores and the split weights are calculated from the OOB samples as in the previous step. Let $M_{i,j}^r$ denote the masking score for variables X_i and X_j from the ensemble in replicate r, for $r = 1, 2, \ldots, R$. Also, let $M_{i,\alpha}^r$ denote the $(1-\alpha)$-percentile of the masking score in replicate r from the distribution of scores between variable X_i and the noise variables. That is, $M_{i,\alpha}^r$ denotes the $(1-\alpha)$-percentile of $M_{i,j}^r$ for $j = m+1, \ldots, 2m$. Similar to the check for variable importance, a paired t-test compares the masking score between variables (X_i, X_j) with masking score $M_{i,\alpha}^r$ computed from the noise variables. There is a significant masking between variables (X_i, X_j) if the paired t-test is significant. Variable X_j is masked by variable X_i if the test is significant.

3. **Eliminate Masked Variables:** Masked variables are removed from the list of important variables as follows. Given a list of important variables upon entry to this step, the variables are sorted by the importance score calculated in step 2. The most important variable is added to an exit list, and dropped from the entry list. Assume this is variable X_i. All variables that are masked by X_i are dropped from the entry list. This is repeated until the entry list is empty. The exit list represents the unmasked important variables.

4. **Generate Residuals for Incremental Adjustment:** An iteration is used to enhance the ability of the algorithm to detect variables that are important, but possibly weaker than a primary set. Given a current subset of important variables, only this subset is used to predict the target. Residuals are calculated and form a new target. For a numerical target the residuals are simply the actual minus the predicted values. For a classification problem residuals are calculated from a multiclass logistic regression procedure (Friedman et al., 2000). We predict the log-odds of class probabilities for each class (typically GBT is used), and then take

pseudo residuals as summarized in the following multi-class logistic regression algorithm. The algorithms are described using the notation in Table 1.

The iterations are similar to those used in forward selection. See, for example, Stoppiglia et al. (2003). The Gram-Schmidt procedure first selects the variable with highest correlation with the target. To remove the information from this variable the remaining predictors and the target are othogonalized with respect to the selected variable. This provides residuals from the fit of the target to the first selected variable. In the feature selection method here we do not require orthogonal predictors, but we adjust the target for the variables already selected through residuals. We also can select more than a single variable in each iteration. The method also uses a conservative selection criterion (Bonferroni adjustment) and the residuals allow a variable to enter on another iteration. There are similar procedures used elsewhere in regression model building. Least angle regression (Efron et al., 2004) and projection pursuit methods (Friedman et al., 1981) are well known examples that use residuals in forward-stagewise modeling.

The algorithm returns to step 1 and continues until no variables with statistically significant importance scores remain. The current subset of important variables is used for the prediction model. Whenever step 1 is calculated, all variables are used to build the ensembles—not only the currently important ones. This approach allows the algorithm to recover partially masked variables that still contribute predictive power to the model. This can occur after the effect of a masking variable is completely removed, and the partial masking is eliminated. The algorithms for numerical (regression) and categorical (classification) targets are presented as algorithms 1 and 2. A separate algorithm 3 describes the variable masking calculations.

Algorithm 1: Ensemble-Based Feature Selection, Regression

```
1.  Set $\Phi \leftarrow \{\}$; set $F \leftarrow \{X_1,\ldots,X_M\}$; set $W = 0$ $(|W| = M)$.
2.  for $r = 1,\ldots,R$ do
3.      $\{Z_1,\ldots,Z_M\} \leftarrow$ permute$\{X_1,\ldots,X_M\}$
4.      set $F_P \leftarrow F \cup \{Z_1,\ldots,Z_M\}$
5.      $r^{th}$ row of $\mathbf{V} = \mathbf{V}_{r.} = g_I(F_P, Y)$;
    endfor
6.  $R \times 1$ vector (element wise) $\mathbf{v} = Percentile_{1-\alpha}(\mathbf{V}[\cdot, M+1,\ldots,2M])$
7.  Set $\hat{\Phi}$ to those $\{X_j\}$ for which element wise $\mathbf{V}_{.j} > \mathbf{v}$
    with specified paired t-test significance (0.05)
8.  Set $\hat{\Phi} = RemoveMasked(\hat{\Phi}, W + g_I(F_P, Y))$
9.  If $\hat{\Phi}$ is empty, then quit.
10. $\Phi \leftarrow \Phi \cup \hat{\Phi}$;
11. $Y = Y - g_Y(\hat{\Phi}, Y)$
12. $W(\hat{\Phi}) = W(\hat{\Phi}) + g_I(\hat{\Phi}, Y)$
13. Go to 2.
```

Algorithm 2: Ensemble-Based Feature Selection, Classification

```
1.   set $\Phi \leftarrow \{\}$; $G_k(F) = 0, W_k = 0$
2.   for $k = 1, \ldots, K$ do
3.     set $V = 0$.
4.     for $r = 1, \ldots, R$ do
         $\{Z_1, \ldots, Z_M\} \leftarrow$ permute$\{X_1, \ldots, X_M\}$
         set $F \leftarrow X \cup \{Z_1, \ldots, Z_M\}$
         Compute class proportion $p_k(x) = exp(G_k(x)) / \sum_{l=1}^{K} exp(G_l(x))$
         Compute pseudo-residuals $Y_i^k = I(Y_i = k) - p_k(x_i)$
         $\mathbf{V}_{r.} = \mathbf{V}_{r.} + g_I(F, Y^k)$;
       endfor
5.     Element wise $\mathbf{v} = Percentile_{1-\alpha}(\mathbf{V}[\cdot, M+1, \ldots, 2M])$
6.     Set $\hat{\Phi}_k$ to those $\{X_k\}$ for which $\mathbf{V}_{.k} > \mathbf{v}$
       with specified paired t-test significance (0.05)
7.     Set $\hat{\Phi}_k = RemoveMasked(\hat{\Phi}_k, W_k + g_I(F, Y^k))$
8.     $\Phi \leftarrow \Phi \cup \hat{\Phi}_k$;
       for $k = 1, \ldots, K$ do
9.       $G_k(F) = G_k(F) + g_Y(\hat{\Phi}_k, Y^k)$
10.      $W_k(\hat{\Phi}_k) = W_k(\hat{\Phi}_k) + g_I(\hat{\Phi}_k, Y^k)$
       endfor
     endfor
11.  If $\hat{\Phi}_k$ for all $k = 1, \ldots, K$ is empty, then quit.
12.  Go to 2.
```

4.2 Comparison to Previous Work

Two earlier methods are closely related to ACE, FCBS (Yu and Liu, 2004) and MBBE (Koller and Sahami, 1996). We compare our method in detail to these two methods. Because we use a multivariate model (tree) instead of frequency tables, our method fits in the category of embedded methods. This is unlike FCBS and MBBE that can be considered as correlation filters, although Koller works with frequency tables of 2-5 variables.

FCBS first sorts features by correlation with the response using a symmetric uncertainty, optionally removing the bottom of the list by a user-specified threshold, then

1. The feature most correlated to the response is selected.

2. All features that have correlation with the selected feature higher than it's correlation with response are considered redundant and removed. The feature is added to the minimal subset (and this is an approximate heuristic for Markov blanket filtering).

3. Return to 1).

FCBS is similar in structure to our method, with the following important differences.

Algorithm 3: RemoveMasked(F,W)

```
1    Let $m = |F|$.
2.   for $r = 1, \dots, R$ do
3.       $\{Z_1, \dots, Z_m\} \leftarrow$ permute$\{X_1, \dots, X_m\}$
4.       set $F_P \leftarrow F \cup \{Z_1, \dots, Z_m\}$
5.       Build GBT model $G_r = GBT(F_P)$.
6.       Calculate masking matrix $M^r = M(G_r)$ ($2m \times 2m$ matrix).
     endfor
7.   Set $M^r_{i,\alpha_m} = Percentile_{1-\alpha_m}(M^r[i, m+1, \dots, 2m]),\ r = 1, \dots, R$
8.   Set $M^*_{ij} = 1$ for those $i, j = 1 \dots m$ for which $M^r_{ij} > M^r_{i,\alpha_m},\ r = 1, \dots, R$
     with specified paired t-test significance (0.05), otherwise set $M^*_{ij} = 0$
9.   Set $L = F, L^* = \{\}$.
10.  Move $X_i \in L$ with $i = \operatorname{argmax}_i W_i$ to $L^*$.
11.  Remove all $X_j \in L$ from $L$, for which $M^*_{ij} = 1$.
12.  Return to step 10 if $L \neq \{\}$.
```

1. We use tree importance instead of univariate correlation with the response. This makes ACE much more robust and accurate.

2. We use a surrogate masking measure instead of correlation. This takes the response into account, not only the correlations between inputs. No arbitrary thresholds for correlation are used.

3. We compute residuals to find smaller effects reducing the chance to drop a non-redundant feature.

Koller's MBBE works as follows:

1. For each feature X_i, find the set M_i of K features ($K = 1-4$) that are most correlated to it. (That is, which provide little information on the response when added to the selected feature in frequency table models.) Additional information is measured as KL-distance (Kullback and Liebler, 1951) $D(P(y|X_i, X_j), P(y|X_i))$. The set M_i is called the approximate Markov blanket for feature X_i. The authors state that $K = 1-2$ gives the best results.

2. For each feature compute the relevance score $\delta_i = D(P(y|M_i, X_i), P(y|M_i))$. This represents the additional information it brings when added to its approximate Markov blanket, and remove features that have the smallest relevance scores (i.e., most redundant).

3. Repeat (1,2) until all features are ranked in the order they are deleted. This method returns a ranked list of features rather than one subset.

Our ACE algorithm works more like FCBS as it uses only one feature as an approximate MB for each feature (as does the MBBE algorithm with $K = 1$). Furthermore, it filters features by relevance before computing redundancy between the features, and reports a final minimum feature subset.

K	Number of classes (if classification problem)
X	set of original variables
Y	target variable
M	Number of variables
R	Number of replicates for t-test
α	quantile used for variable importance estimation
α_m	quantile used for variable masking estimation
Z	permuted versions of X
W	cumulative variable importance vector.
W_k	cumulative variable importance vector for k-th class in classification.
F	current working set of variables
Φ	set of important variables
$\mathbf{V}$	variable importance matrix $(R \times 2M)$
$\mathbf{V}_{r.}$	rth row of variable importance matrix $\mathbf{V}$, $r = 1 \dots R$
$\mathbf{V}_{.j}$	jth column of matrix $\mathbf{V}$
$g_I(F,Y)$	function that trains an ensemble of L trees based on variables F and target Y, and returns a row vector of importance for each variable in F
$g_Y(F,Y)$	function that trains an ensemble based on variables F and target Y, and returns a prediction of Y
$G_k(F)$	current predictions for log-odds of k-th class
$GBT(F)$	GBT model built on variable set F
$M(G)$	Masking measure matrix calculated from model G
M^k	Masking matrix for k-th GBT ensemble G_t.
M^*	Masking flags matrix

Table 1: Notation in Algorithms 1-3

However, the major difference is that our redundancy measure approximates KL-distance taking the response into account and uses local information. Thus, it can deal with multivariate dependencies. MBBE for $K > 1$ will incur three (or more) dimensional frequency tables that are hard to deal with if number of categories is large.

The learner $g(.,.)$ in the ACE algorithms is an ensemble of trees. Any classifier/regressor function can be used, from which the variable importance from all variable interactions can be derived. To our knowledge, only ensembles of trees can provide this conveniently.

The computational complexity of the algorithm is of the same order as the maximal complexity of a RF on the whole feature set and a GBT model on the selected important feature subset. A GBT model is usually more complex, because all surrogate splits at every tree node are computed. However, a smaller tree depth setting for the GBT model reduces the calculations in this part of the algorithm. The complexity is proportional to

$$(Fsel + Fimpvar) * N * logN * Ntrees * Nensembles * Niter + Niter * Fimpvar^2,$$

where the variables are defined as follows: *Niter* is the number of iterations of the ACE algorithm (for example, for the challenge discussed in Sec. 5.3 this was always less than 10 and usually 3-4); *Nensembles* is the number of replicates for t-tests (equal to 20 in the challenge); *Ntrees* is the number of trees in the RF or ensemble (equal to 20-100 in the challenge); N is the number of samples; *Fsel* is the number of selected variables per tree split in RF (equal to the square root of the total number features or less); *Fimpvar* is the number of selected important variables (for example, for the challenge data set NOVA discussed in Section 5.3 this was approximately 400-800 depending on parameters). The algorithm is very fast with approximately a minute for one feature selection iteration on the challenge NOVA data set with 16K variables with 20 replicates with 70 trees on a Windows XP-based four-processor Xeon (2 x HT) 3.4GHz workstation.

5. Experiments

In order to evaluate the goodness of feature selection algorithms, two options have been used in the literature. The first is not to evaluate the actual feature selection performance at all, but the performance of a subsequent learner in some task. This facilitates the use of any data set in the "evaluation" but does not give much useful information at all in characterizing the actual feature selection. The second option is to directly evaluate the feature selection performance without using a subsequent proxy task. The latter dictates the need to know the ground truth behind the data, which typically means that the data must be artificially generated, either completely, or by adding some redundant and/or irrelevant features to some known data.

As the topic of the paper at hand is a method for the subset feature selection, the first evaluation method is affected by the choice of the classifier. The effects of feature selection are mixed in with how well the learner is able to handle redundant or irrelevant features. The results would thus depend on the choice of learners and on the choice of data sets. Therefore we will mainly describe experiments with two types of simulated data with known ground truth.

Experiments on data with linear relationships are presented first. Then a nonlinear data generator is used to study the sensitivity to multiple variable interactions with nonlinear relations. Further results are from the 2007 International Joint Conference on Neural Networks (IJCNN), "Agnostic learning vs. prior knowledge challenge & data representation discovery workshop". The algorithm described here had the second best performance in the agnostic track. Here we demonstrate the effect of the subset to predictor performance as compared to the full set of features. Also, an actual manufacturing data set as well as a comparison to a previous analysis of the well known Hepatitis data are also presented in terms of predictive power of the resulting feature set.

5.1 Generated Data with Linear Relationships

The data in this experiment has an additive structure with one numeric response variable and 203 input variables. Inputs $x_1,\ldots,x_{100}$ are highly correlated with one another, and they are all reasonably predictive of the response (regression $R^2 \sim 0.5$). But a,b, and c are independent variables that are much weaker predictors (regression $R^2 \sim 0.1$). Further $u_1,\ldots,u_{100}$ are i.i.d. $N(0,1)$ variables that are unrelated to the target. The target variable was generated as an additive model with additional noise using $y = x_1 + a + b + c + \varepsilon$, where $\varepsilon \sim N(0,1)$. This structure is chosen because it is well known that linear (oblique) relationships are not optimal for a tree representation. However, they are ideal for correlation-based methods. Thus we have here the worst possible case for ACE and the best possible case for CFS. The methods were evaluated on 50 data sets of size 400 samples.

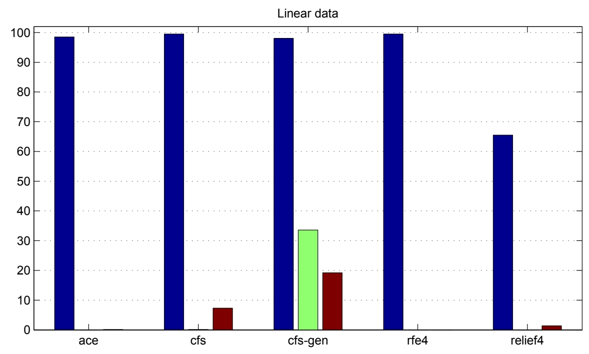

Figure 1: Artificial data with linear relationships. Subset discovery methods (ACE, CFS, CFS-gen) and methods finding a subset of predefined size four (RFE4, Relief4) are compared. The results for each method consist of three bars. The first is the percentage of relevant variables detected (out of four), the second is the percentage of redundant variables detected (out of 100), and the third is the percentage of irrelevant variables detected (out of 100). The results are averages over 50 data sets.

Figure 1 depicts the performance of ACE against methods that also discover the subsets (CFS with best-first search, CFS with genetic search), as well as against some subset ranking methods (RFE, Relief).

RFE and Relief are ranking methods. In this experiment they were given the advantage of knowing the number of relevant features beforehand, that is, their task was to “find the best possible four variable subset” (RFE4, Relief4), whereas ACE and CFS had to also find the number themselves. A further advantage was given to RFE by matching the underlying support vector regressor to the problem with a linear kernel (using the standard RBF kernel produced inferior results). This experiment demonstrates one aspect of the advantages of ACE. In a task ideal for correlation-based methods but hard for trees, we show equal performance.

5.2 Generated Nonlinear Data

Next, experiments were conducted using a well-known data generator (Friedman, 1999), which produces data sets with multiple non-linear interactions between input variables. The true model can be designed with relevant, redundant, and noise inputs. We selected 10 relevant inputs plus random, uniform (0, 1) noise. Also, 20 redundant inputs were used. Each was a random linear combination of three inputs plus random, uniform noise. Finally, 40 noise inputs were added, so that 70 features were available to the full model. The target function was generated as a weighted sum of 10 multidimensional Gaussians, each Gaussian at a time involving about four input variables randomly drawn from the relevant 10 variables. Thus all of the relevant 10 input variables are involved in the target, to a varying degree. The Gaussian functions also have a random mean vector and a random covariance matrix as described by Friedman (1999). Weights for the Gaussians were randomly drawn from $U[-1,1]$.

The data generator produces continuous-valued variables. Thus the data sets can be used as such for regression problems. Data sets of two different sizes were generated, 1000 and 4000 samples. In order to generate classification problems, the target variable was discretized to two levels. Mixed-type data was generated by randomly discretizing half of the variables, each to a random number of levels drawn from $U[2,32]$. There are thus eight different experiments altogether. For each experiment, 50 data sets were generated with different seeds. Figure 2 presents the results for each case as average percentages of features selected in each group (relevant, redundant, or noise) over the 50 generated data sets.

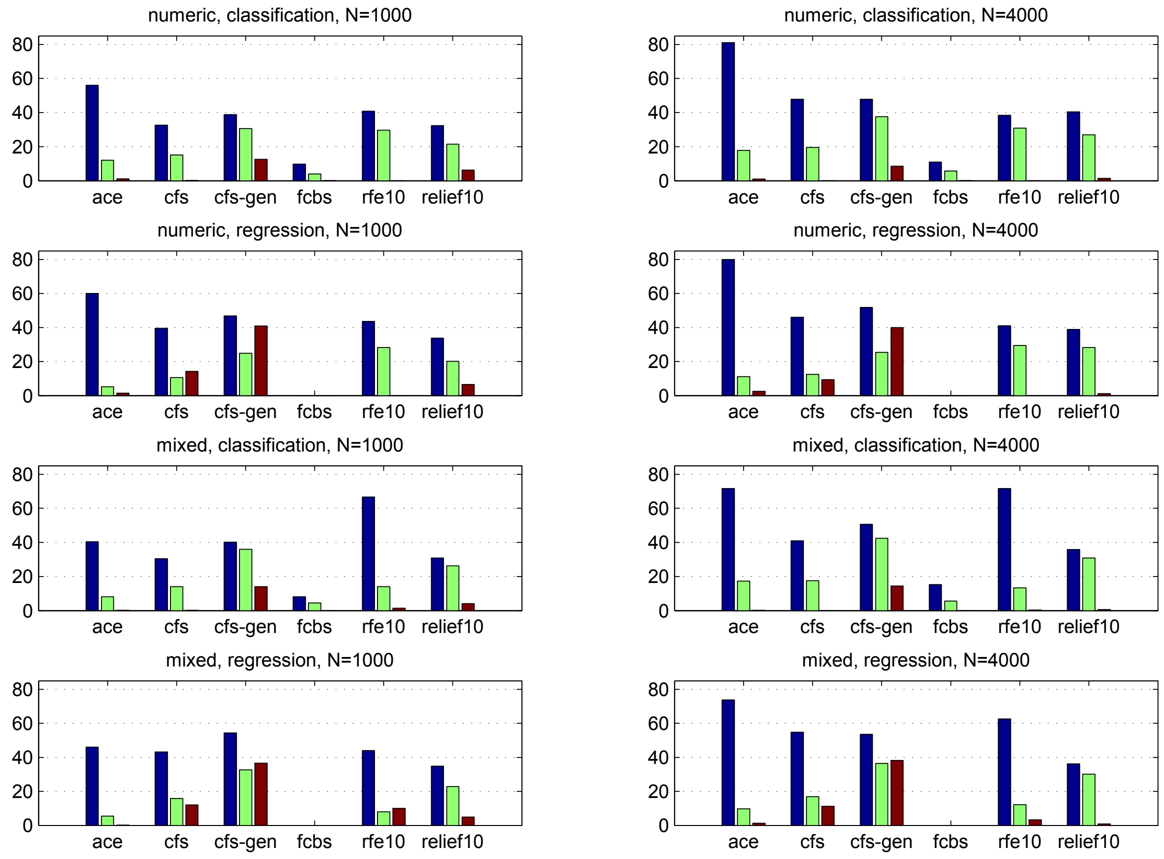

Figure 2: Artificial data with nonlinear relationships. Subset discovery methods (ACE, CFS, CFS-gen, FCBS) and methods finding a subset of predefined size 10 (RFE10, Relief10) are compared. FCBS works only in classification problems. The results for each method consist of three bars. The first is the percentage of relevant variables detected (out of 10), the second is the percentage of redundant variables detected (out of 20), and the third is the percentage of irrelevant variables detected (out of 40). The results are averages over 50 data sets.

RFE and Relief were again given the advantage of knowing the number of relevant features beforehand, that is, their task was to “find the best possible ten-variable subset”, whereas ACE, CFS, and FCBS had to also find the number by themselves. A further advantage was given to RFE by matching the underlying support vector classifier to the problem with an RBF kernel. Using a linear kernel produced inferior results.

The notable failure of FCBS on this data can be explained as follows. Most numerical important variables are dropped at the discretization step of FCBS, because MDL discretization works as a filter method, and it cannot deal with the multivariate dependency from Friedmans's generator. It works well with discrete variables only when the number of categories is small and the response is categorical with a small number of categories.

This experiment demonstrates another aspect of the universality of ACE. The only case where another method (RFE10) showed a superior result was a classification problem with a smaller sample size and mixed type inputs. Again RFE10 was given the advantage of knowing the number of relevant features and an appropriate kernel beforehand.

5.3 IJCNN 2007 Agnostic Learning vs. Prior Knowledge Challenge

In this experiment we show the effect of the selected subset within various classification tasks. The ACE feature selection algorithm was applied to the data sets in the Agnostic Learning Challenge. The number of training/validation/testing instances and the number of features are shown in the following list:

- ADA, Marketing, 4147/415/41471, 48 features
- GINA, Handwriting recognition, 3153/315/31532, 970 features
- HIVA, Drug discovery, 3845/384/38449, 1617 features
- NOVA, Text, 1754/175/17537, 16969 features
- SYLVA, Ecology, 13086/1309/130857, 216 features

For feature selection with ACE, the number of trees, importance and masking quantiles were parameters that were optimized. Next GBT with embedded feature selection (to prevent overfitting) (Borisov et al., 2006) was built on the subset. The following parameters of GBT were optimized: number of trees, tree depth, shrinkage, number of selected features per tree node, and the importance adjustment rate for embedded feature selection, stratified sampling for 0/1 class proportions, and priors. The optimization strategy (manual) was to set reasonable parameter values, and then try to adjust each parameter sequentially, so that the test error decreased. The model was trained on 60% of the training data during parameter optimization. Several passes over all the GBT parameters were used, and one for the feature selection parameters. Priors were selected using cross validation. Feature selection and GBT were used on K partitions of the data and then optimal priors were selected on the remaining part.

Table 2 shows the results before and after subset selection for the five challenge data sets. The CV-error was either preserved or reduced through a good subset. The overall results were the second best in the agnostic learning challenge. Redundancy elimination was applied on ADA, HIVA, SYLVA, and feature selection without redundancy elimination was used on NOVA and GINA.

5.4 TIED Data Set

A data set with multiple Markov boundaries was generated by Statnikov and Aliferis (2009). The data was obtained from a discrete Bayesian network with 1000 variables and a target variable with four classes. A training set was constructed with 750 instances simulated from the network.

Original	Features	CV-error from all features	Best subset size	CV-error from selected subset
Ada	47	0.1909	16	0.1855
Gina	970	0.0527	75	0.0506
Hiva	1617	0.2847	221	0.2559
Nova	12993	0.0591	400	0.0518
Sylva	212	0.0133	69	0.0129

Table 2: IJCNN 2007 Agnostic Learning vs. Prior Knowledge Challenge results.

Variable	p-value	Importance Score
3	0	100.0%
2	0	98.4%
10	0	96.4%
1	1.E-10	96.4%
11	3.E-07	83.3%
12	2.E-07	83.3%
13	5.E-07	79.1%

19	2.E-07	67.5%
15	2.E-07	41.4%
20	2.E-06	39.5%
29	2.E-06	29.8%
8	3.E-06	26.2%
14	1.E-08	11.6%
4	8.E-06	9.5%
9	6.E-06	8.3%

Table 3: Feature selection scores for the TIED data set. Variables in any Markov boundary are recovered as significant with three false alarms.

The network contained 72 Markov boundaries. Each boundary contained five variables (one from each of the following subsets):(1)$\{X_9\}$, (2) $\{X_4, X_8\}$, (3)$\{X_{11}, X_{12}, X_{13}\}$, (4) $\{X_{18}, X_{19}, X_{20}\}$, and (5) $\{X_1, X_2, X_3, X_{10}\}$.

The ACE feature selection method described here was used to remove irrelevant features. After three iterations of the residual calculations described previously the algorithm stopped with the important variables (and p-values from the artificial contrasts) shown in Table 3. The list of statistically significant variables reproduces all the variables in any of the Markov boundaries listed above, with false alarms from variables X_{14}, X_{15}, and X_{29}.

Although ACE recovered the variables in the Markov boundaries, there are limitations with the masking methods for a multi-class target. The GBT ensembles model each class (versus the rest) with a binary logistic function and averages variable masking scores over the binary models. Consequently, some attenuation of the importance scores are expected. Redundancy elimination did not effectively eliminate masking in the TIED data. However, we used the TIED network and TIED data for binary problems with each class versus the rest. For example, for class 1 versus the rest the TIED network generates the same collection of 72 Markov boundaries. The results from ACE without redundancy elimination for the binary target are shown in Table 4. The list of statistically significant variables reproduces all the variables in any of the Markov boundaries, with no false alarms.

Variable	Importance Score
4	100.0%
8	100.0%
19	88.1%
18	88.1%
20	88.1%
9	64.8%
13	39.5%
12	39.5%
11	39.5%
10	21.9%
2	21.9%
3	21.9%
1	21.9%
6	0.0%

Table 4: Variable importance for TIED data modified for a binary target (class 1 versus the rest). All variables in the true Markov boundaries are identified with no false alarms.

As the importance scores are arranged in decreasing order in Table 4, groups of variables with similar scores become noticeable and these groups correspond to the subsets (equivalence classes) in the cross-product that defines the Markov boundaries. That is, the most important variables in Table 4 are those in the subset $\{X_4, X_8\}$ in the Markov boundaries and the last group matches the subset $\{X_1, X_2, X_3, X_{10}\}$. The equivalent groups are clear from their importance scores in this case.

The analysis with redundancy elimination generated the list of significantly significant variables in Table 5. One equivalent variable from the subset $\{X_1, X_2, X_3, X_{10}\}$ was missed in the recovery of a Markov boundary. The contribution from this subset was, however, small. The predictive performance of a tree ensemble on the recovered variables is nearly identical to a model on a true Markov boundary. In addition, the three variables $\{X_{18}, X_{20}, X_4\}$ are identified in Table 5 as important, but they are redundant in the true network. Although these comprise false alarms, the magnitudes of the importance scores indicate that the last three variables are much less important than the others. Similar results (not shown here) were obtained for the binary target class 2 (versus the rest). Results without any errors were obtained for classes 0 and 3 (each versus the rest). Specifically, for class 0 the Markov boundaries from the TIED network consist of one element from $\{X_1, X_2, X_3, X_{10}\}$. In this case the ACE analysis without redundancy elimination recovered these four variables without false alarms. The analysis with redundancy elimination correctly recovered a single variable from this set. Similarly for class 3, without redundancy elimination all variables in the Markov boundaries $\{X_{12}, X_{13}, X_{14}\}$ were recovered, and only one variable from this set was recovered with redundancy elimination.

Variable	Importance Score
8	100.0%
9	61.3%
19	43.8%
1	10.2%
18	2.6%
20	0.9%
4	0.3%

Table 5: Variable importance for TIED data modified for a binary target (class 1 versus the rest) with redundancy elimination.

5.5 Manufacturing Data

In multiple real world applications collecting unnecessary variables is a cost issue and finding a suitable subset is critical in terms of cost-efficiency. As an example we present manufacturing data from a process that contained approximately 10K rows and consisted of 35 predictors that were all numerical, continuous measurements. The target was a binary response and approximately 20% of the data belonged in the rare class. Because the data is actual manufacturing data, the specific variable names are not provided. The data was analyzed extensively with traditional regression methods (the response was coded as 0 and 1) and models obtained were complex and not accurate. A list of the results from our algorithm is shown in Table 6. It is not unusual for manufacturing data to consist of related predictors. Without redundancy elimination, 20 variables were identified as related to the target. However, after masking scores were used to remove redundant predictors the final subset model consisted of only five predictors.

The predictive accuracy for the binary target was nearly identical using a GBT model with these 5 predictors to the full set of 35 predictors. Table 6 also compares other subset selection algorithms to ACE in terms of their predictive accuracy and the size of the selected feature set.

A previous analysis of this data by Berrado and Runger (2007) used association rules applied after the predictors were discretized with simple equal-frequency discretization. Only rules with consequent equal to the rare target class were considered. A total of 25 rules were detected that met the minimum support threshold. These rules contained 14 variables and 13 out of 14 are listed in the Table 6. Although the objectives of the association analysis were different, the relatively high proportion of important variables is consistent with the results in Table 6.

5.6 Hepatitis Data

The hepatitis data available from the UC-Irvine repository has been widely analyzed. There are 155 patients and 19 predictors and the response is a binary survival result. Breiman (2001) considered this data and cited a previous analysis from the Stanford Medical School and another analysis by Diaconis and Efron (1983). The analysis from the medical school concluded that the important variables were 6, 12, 14, 19. But Breiman (2001) concluded after a set of analyses that number 12 or 17 provided predictive power nearly equivalent to the full set of variables, and that these masked each other. A notable difficulty is the small sample size in this example.

Variables	ACE without redundancy elim.	ACE with redundancy elim.	CFS	CFS-gen	FCBS

Table 6: Manufacturing data with a binary target with redundancy elimination excludes many variables. Only a smaller subset of the relevant predictors remain. We compare the extracted variables to other subset selection algorithms (selected variables are marked as '1' in the table). The error rate for the full set of variables was 0.146.

We confirmed the strong masking between variables 12 and 17 (and vice versa) from our masking matrix. We also obtained a subset model that consists of variables 6, 17, 14, 19, and 11, similar to medical school. Variable 11 was also identified in unpublished lecture notes by Breiman. The subset selected by our algorithm has the lowest cross-validation error using logistic regression.

6. Conclusions

We have presented an efficient method for feature subset selection that builds upon the known strengths of the tree ensembles and is designed explicitly to discover a non-redundant, effective subset of features in large, dirty, and complex data sets.

Our method attempts to eliminate irrelevant variables using statistical comparisons with artificial contrasts to obtain a threshold for importance estimated from the parallel ensembles of trees capable of scoring very large number of variables.

It uses serial ensembles to discover significant masking effects for redundancy elimination. Furthermore we have showed that the redundancy elimination based on feature masking approximates the Markov blanket redundancy filtering. It also uses an iterative strategy to allow for weaker predictors to be identified after stronger contributors.

A Parameter-Free Classification Method for Large Scale Learning

Marc Boullé MARC.BOULLE@ORANGE-FTGROUP.COM

Editor: Soeren Sonnenburg

Abstract

With the rapid growth of computer storage capacities, available data and demand for scoring models both follow an increasing trend, sharper than that of the processing power. However, the main limitation to a wide spread of data mining solutions is the non-increasing availability of skilled data analysts, which play a key role in data preparation and model selection.

In this paper, we present a parameter-free scalable classification method, which is a step towards fully automatic data mining. The method is based on Bayes optimal univariate conditional density estimators, naive Bayes classification enhanced with a Bayesian variable selection scheme, and averaging of models using a logarithmic smoothing of the posterior distribution. We focus on the complexity of the algorithms and show how they can cope with data sets that are far larger than the available central memory. We finally report results on the Large Scale Learning challenge, where our method obtains state of the art performance within practicable computation time.

Keywords: large scale learning, naive Bayes, Bayesianism, model selection, model averaging

1. Introduction

Data mining is "the non-trivial process of identifying valid, novel , potentially useful, and ultimately understandable patterns in data" (Fayyad et al., 1996). Several industrial partners have proposed to formalize this process using a methodological guide named CRISP-DM, for CRoss Industry Standard Process for Data Mining (Chapman et al., 2000). The CRISP-DM model provides an overview of the life cycle of a data mining project, which consists in the following phases: business understanding, data understanding, data preparation, modeling, evaluation and deployment. Practical data mining projects involve a large variety of constraints, like scalable training algorithms, understandable models, easy and fast deployment. In a large telecommunication companies like France Telecom, data mining applies to many domains: marketing, text mining, web mining, traffic classification, sociology, ergonomics. The available data is heterogeneous, with numerical and categorical variables, target variables with multiple classes, missing values, noisy unbalanced distributions, and with numbers of instances or variables which can vary over several orders of magnitude. The most limiting factor which slows down the spread of data mining solutions is the data preparation phase, which consumes 80% of the process (Pyle, 1999; Mamdouh, 2006) and requires skilled data analysts. In this paper, we present a method[1] (Boullé, 2007) which aims at automatizing the data preparation and modeling phases of a data mining project, and which performs well on a large variety of problems. The interest of the paper, which extends the workshop abstract (Boullé, 2008), is

1. The method is available as a shareware, downloadable at `http://perso.rd.francetelecom.fr/boulle/`.

to introduce the algorithmic extensions of the method to large scale learning, when data does not fit into memory, and to evaluate them in an international challenge.

The paper is organized as follows. Section 2 summarizes the principles of our method and Section 3 focuses on its computational complexity, with a detailed description of the extensions introduced for large scale learning. Section 4 reports the results obtained on the Large Scale Learning challenge (Sonnenburg et al., 2008). Finally, Section 5 gives a summary and discusses future work.

2. A Parameter-Free Classifier

Our method, introduced in Boullé (2007), extends the naive Bayes classifier owing to an optimal estimation of the class conditional probabilities, a Bayesian variable selection and a compression-based model averaging.

2.1 Optimal Discretization

The naive Bayes classifier has proved to be very effective on many real data applications (Langley et al., 1992; Hand and Yu, 2001). It is based on the assumption that the variables are independent within each output class, and solely relies on the estimation of univariate conditional probabilities. The evaluation of these probabilities for numerical variables has already been discussed in the literature (Dougherty et al., 1995; Liu et al., 2002). Experiments demonstrate that even a simple equal width discretization brings superior performance compared to the assumption using a Gaussian distribution. In the MODL approach (Boullé, 2006), the discretization is turned into a model selection problem and solved in a Bayesian way. First, a space of discretization models is defined. The parameters of a specific discretization are the number of intervals, the bounds of the intervals and the output frequencies in each interval. Then, a prior distribution is proposed on this model space. This prior exploits the hierarchy of the parameters: the number of intervals is first chosen, then the bounds of the intervals and finally the output frequencies. The choice is uniform at each stage of the hierarchy. Finally, the multinomial distributions of the output values in each interval are assumed to be independent from each other. A Bayesian approach is applied to select the best discretization model, which is found by maximizing the probability $p(Model|Data)$ of the model given the data. Owing to the definition of the model space and its prior distribution, the Bayes formula is applicable to derive an exact analytical criterion to evaluate the posterior probability of a discretization model. Efficient search heuristics allow to find the most probable discretization given the data sample. Extensive comparative experiments report high performance.

The case of categorical variables is treated with the same approach in Boullé (2005), using a family of conditional density estimators which partition the input values into groups of values.

2.2 Bayesian Approach for Variable Selection

The naive independence assumption can harm the performance when violated. In order to better deal with highly correlated variables, the selective naive Bayes approach (Langley and Sage, 1994) exploits a wrapper approach (Kohavi and John, 1997) to select the subset of variables which optimizes the classification accuracy. Although the selective naive Bayes approach performs quite well on data sets with a reasonable number of variables, it does not scale on very large data sets with hundreds of thousands of instances and thousands of variables, such as in marketing applications or text mining. The problem comes both from the search algorithm, whose complexity is quadratic in the number of variables, and from the selection process which is prone to overfitting. In Boullé (2007), the overfitting problem is tackled by relying on a Bayesian approach, where the best model is found by maximizing the probability of the model given the data. The parameters of a variable selection model are the number of selected variables and the subset of variables. A hierarchic prior is considered, by first choosing the number of selected variables and second choosing the subset of selected variables. The conditional likelihood of the models exploits the naive Bayes assumption, which directly provides the conditional probability of each label. This allows an exact calculation of the posterior probability of the models. Efficient search heuristic with super-linear computation time are proposed, on the basis of greedy forward addition and backward elimination of variables.

2.3 Compression-Based Model Averaging

Model averaging has been successfully exploited in Bagging (Breiman, 1996) using multiple classifiers trained from re-sampled data sets. In this approach, the averaged classifier uses a voting rule to classify new instances. Unlike this approach, where each classifier has the same weight, the Bayesian Model Averaging (BMA) approach (Hoeting et al., 1999) weights the classifiers according to their posterior probability. In the case of the selective naive Bayes classifier, an inspection of the optimized models reveals that their posterior distribution is so sharply peaked that averaging them according to the BMA approach almost reduces to the maximum a posteriori (MAP) model. In this situation, averaging is useless. In order to find a trade-off between equal weights as in bagging and extremely unbalanced weights as in the BMA approach, a logarithmic smoothing of the posterior distribution, called compression-based model averaging (CMA), is introduced in Boullé (2007). Extensive experiments demonstrate that the resulting compression-based model averaging scheme clearly outperforms the Bayesian model averaging scheme.

3. Complexity Analysis

In this section, we first recall the algorithmic complexity of the algorithms detailed in Boullé (2005, 2006, 2007) in the case where all the data fits in central memory, then introduce the extension of the algorithms when data exceeds the central memory.

3.1 When Data Fits into Central Memory

The algorithm consists in three phases: data preprocessing using discretization or value grouping, variable selection and model averaging.

3.1.1 PREPROCESSING

In the case of numerical variables, the discretization Algorithm 1 exploits a greedy-heuristic. It first sorts the input values, then starts with initial single value intervals and searches for the best merge between adjacent intervals. This merge is performed if the cost (evaluation) of the discretization decreases after the merge and the process is reiterated until no further merge can decrease the discretization cost. With a straightforward implementation of the algorithm, the method runs in $O(N^3)$ time, where N is the number of instances. However, the method can be optimized in $O(N \log N)$ time owing to the additivity of the discretization cost with respect to the intervals and using a maintained sorted list of the evaluated merges (such as an AVL binary search tree for example).

Algorithm 1 Discretization

```
Input: $X_k$    // Numerical input variable
Output: $D$    // Best discretization
 1: // Initialization
 2: Sort the input values
 3: $D$ = Elementary discretization with one interval per value value
 4: // Optimization
 5: $cost_{best} = cost(D), m_{best} = \emptyset$
 6: repeat
 7:   for all merge $m$ between adjacent intervals do
 8:     if $(cost(D \cup m) < cost_{best})$ then
 9:       $cost_{best} = cost(D \cup m), m_{best} = m$
10:     end if
11:   end for
12:   if $(cost_{best} = cost(D))$ then
13:     $D = D \cup m_{best}$
14:   end if
15: until no improvement
```

The case of categorical variables is handled using a similar greedy heuristic. Overall, the preprocessing phase is super-linear in time and requires $O(KN\log N)$ time, where K is the number of variables and N the number of instances.

3.1.2 VARIABLE SELECTION

In the variable selection Algorithm 2, the method alternates fast forward and backward variable selection steps based on randomized reorderings of the variables, and repeats the process several times in order to better explore the search space and reduce the variance caused by the dependence over the order of the variables.

Evaluating one variable selection for the naive Bayes classifier requires $O(KN)$ time, since the conditional probabilities, which are linear in the number of variables, require $O(K)$ time per instance. Updating the evaluation of a variable subset by adding or dropping one single variable requires only $O(1)$ time per instance and thus $O(N)$ time for all the instances. Therefore, one loop of fast forward or backward variable selection, which involves $O(K)$ adds or drops of variables, can be evaluated in $O(KN)$ time.

In order to bound the time complexity, each succession of fast forward and backward variable selection is repeated only twice ($MaxIter = 2$ in algorithm 2), which is sufficient in practice to be close to convergence within a small computation time.

The number of repeats of the outer loop is fixed to $\log_2 N + \log_2 K$, so that the overall time complexity of the variable selection algorithm is $O(KN(\log K + \log N))$, which is comparable to that of the preprocessing phase.

Algorithm 2 Variable Selection

```
Input: $X = (X_1, X_2, \ldots X_K)$ // Set of input variables
Output: $B$ // Best subset of variables
 1: $B = \emptyset$ // Start with an empty subset of variables
 2: for Step=1 to $\log_2 KN$ do
 3:   // Fast forward backward selection
 4:   $S = \emptyset$ // Initialize an empty subset of variables
 5:   $Iter = 0$
 6:   repeat
 7:     $Iter = Iter + 1$
 8:     $X' = \text{Shuffle}(X)$ // Randomly reorder the variables to add
 9:     // Fast forward selection
10:     for $X_k \in X'$ do
11:       if $(cost(S \cup \{X_k\}) < cost(S))$ then
12:         $S = S \cup \{X_k\}$
13:       end if
14:     end for
15:     $X' = \text{Shuffle}(X)$ // Randomly reorder the variables to remove
16:     // Fast backward selection
17:     for $X_k \in X'$ do
18:       if $(cost(S - \{X_k\}) < cost(S))$ then
19:         $S = S - \{X_k\}$
20:       end if
21:     end for
22:   until no improvement or $Iter \geq MaxIter$
23:   // Update best subset of variables
24:   if $(cost(S) < cost(B))$ then
25:     $B = S$
26:   end if
27: end for
```

3.1.3 MODEL AVERAGING

The model averaging algorithm consists in collecting all the models evaluated in the variable selection phase and averaging then according to a logarithmic smoothing of their posterior probability, with no overhead on the time complexity.

Overall, the preprocessing, variable selection and model averaging have a time complexity of $O(KN(\log K + \log N))$ and a space complexity of $O(KN)$.

3.2 When Data Exceeds Central Memory

Whereas standard scalable approaches, such as data sampling or online learning, cannot process all the data simultaneously and have to consider simpler models, our objective is to enhance the scalability of our algorithm without sacrificing the quality of the results.

With the $O(KN)$ space complexity, large data sets cannot fit into central memory and training time becomes impracticable as soon as memory pages have to be swapped between disk and central memory.[2] To avoid this strong limitation, we enhance our algorithm with a specially designed chunking strategy.

3.2.1 CHUNKING STRATEGY

First of all, let us consider the access time from central *m*emory (t_m) and from sequential *r*ead (t_r) or random disk *a*ccess (t_a). In modern personal computers (year 2008), t_m is in the order of 10 nanoseconds. Sequential read from disk is so fast (based on 100 Mb/s transfer rates) that t_r is in the same order as t_m: CPU is sometimes a limiting factor, when parsing operations are involved. Random disk access t_a is in the order of 10 milliseconds, one million times slower than t_m or t_r. Therefore, the only way to manage very large amounts of memory space is to exploit disk in a sequential manner.

Let S=$O(KN)$ be the size of the data set and M the size of the central memory. Our chunking strategy consists in minimizing the number of exchanges between disk and central memory. The overhead of the scalable version of the algorithms will be expressed in terms of sequential disk read time t_r.

3.2.2 PREPROCESSING

For the preprocessing phase of our method, each variable is analyzed once after being loaded into central memory. The discretization Algorithm 1 extensively accesses the values of the analyzed variable, both in the initialization step (values are sorted) and in the optimization step. We partition the set of input variables into $C = \lceil S/M \rceil$ chunks of $K_1, \ldots, K_C$ variables, such that each chunk can be loaded into memory ($K_c N < M, 1 \leq c \leq C$). The preprocessing phase loops on the C subsets, and at each step of the loop, reads the data set, parses and loads the chunk variables only, as shown in Figure 1. Each memory chunk is preprocessed as in Algorithm 1, in order to induce conditional probability tables (CPT) for the chunk variables.

After the preprocessing, the chunk variables are recoded by replacing the input values by their index in the related CPT. The recoded chunk of variables are stored in C files of integer indexes, as shown in Figure 2. These recoded chunks are very fast to load, since the chunk variables only need to be read, without any parsing (integer indexes are directly transfered from disk to central memory).

The scalable version of the preprocessing algorithm is summarized in Algorithm 3. Each input variable is read C times, but parsed and loaded only once as in the standard case. The overhead in terms of disk read time is $O((C-1)KNt_r)$ time for the load steps. In the recoding step, each variable is written once on disk, which involves an overhead of $O(KNt_r)$ (disk sequential write time is similar to disk sequential read time). Overall, the overhead is $O(CKNt_r)$ time.

This could be improved by first splitting the input data file into C initial disk chunks (without parsing), with an overall overhead of only $O(3KNt_r)$ time (read and write all the input data before preprocessing, and write recoded chunks after preprocessing). However, this involves extra disk space and the benefit is small in practice, since even C read steps are not time expensive compared to the rest of the algorithm.

2. On 32 bits CPU, central memory is physically limited to 4 Go, or even to 2 Go on Windows PCs.

Algorithm 3 Scalable preprocessing

```
Input: input data on disk
Output: recoded data on several recoded disk chunks, conditional probability tables
 1: // Compute chunking parameters
 2: estimate input data size $S$ and available central memory size $M$
 3: compute number of chunks: $C = \lceil S/M \rceil$
 4: partition the set of variables into $C$ balanced chunks of variables
 5: // Main loop
 6: for all chunk do
 7:     // Load chunk into central memory
 8:     for all variable do
 9:         read input data
10:         if (variable in current chunk) then
11:             parse and load variable
12:         end if
13:     end for
14:     // Preprocessing
15:     for all variable in memory chunk do
16:         call the discretization or value grouping algorithm
17:         keep the conditional probability table (CPT) into memory
18:     end for
19:     // Recoding
20:     for all variable in memory chunk do
21:         write a recoded chunk by replacing each input value by its index in the CPT
22:     end for
23: end for
```

3.2.3 VARIABLE SELECTION

In the variable selection phase, the algorithm performs $\mathrm{O}(\log K + \log N)$ steps of fast forward backward variable selection, based on random reordering of the variables. Each step evaluates the add or drop of one variable at a time, so that the whole input data has to be read.

In the scalable version of the variable selection phase, we exploit the recoded chunks of variables as shown in Figure 3: one single chunk is loaded in memory at a time. Instead of reordering randomly all the variables, we first reorder randomly the list of recoded chunks, then reorder randomly the subset of variables in the recoded chunk currently loaded in memory. This "double stage" reordering is the only place where the scalable algorithm does not exactly mirror the behavior of the standard algorithm.

Each step of fast forward backward variable selection involves reading each recoded chunk $\mathrm{O}(1)$ times (exactly $2 * MaxIter$ times with $MaxIter = 2$), thus implies an overhead of $\mathrm{O}(KNt_r)$ read time.

Overall, the algorithmic overhead consists of additional steps for reading the input data: $C \approx S/M$ steps for the preprocessing phase and $(\log K + \log N)$ read for variable selection phase, with an overhead of $\mathrm{O}(KN(S/M + \log K + \log N)t_r)$ time. Since sequential disk read time t_s is comparable to memory access time, we expect that the scalable version of the algorithm has a practicable computation time.

4. Results on the Large Scale Learning Challenge

In this section, we summarize the Pascal Large Scale Learning Challenge (Sonnenburg et al., 2008) and describe our submission. We then analyze the advantages and limitations of our non-parametric modeling approach on large scale learning and evaluate our chunking strategy. We finaly report the challenge results.

4.1 Challenge Data Sets and Protocol

The challenge is designed to enable a direct comparison of learning methods given limited resource. The data sets, summarized in Table 1 represent a variety of domains and contain up to millions of instances, thousands of variables and tens of gigabytes of disk space.

The challenge data sets are a convenient way to evaluate the scalability of our offline method, when data set size is larger than the central memory by one order of magnitude (on computers with 32 bit CPU). In the Wild Competition Track of the challenge, the participants are "free to do anything that leads to more efficient, more accurate methods, for example, perform feature selection, find effective data representations, use efficient program-code, tune the core algorithm etc". The method have to be trained on subsets of the train data set of increasing size, with sizes $10^2, 10^3, 10^4, 10^5, \ldots$ up to the maximum number of train examples.

For all the training sessions, the accuracy is estimated using the area over the precision recall curve (aoPRC) criterion. The training time is estimated by the organizer in the final evaluation by a re-run of the algorithm on a single CPU Linux machine, 32 Gb RAM. It is noteworthy that the evaluated training time is the computation time for the optimal parameter settings, excluding data loading times and any kind of data preparation or model selection time.

Data set	Domain	Training	Validation	Dimensions	Best aoPRC	Our aoPRC
alpha	artificial	500000	100000	500	0.1345	0.2479
beta	artificial	500000	100000	500	0.4627	**0.4627**
gamma	artificial	500000	100000	500	0.0114	**0.0114**
delta	artificial	500000	100000	500	0.0798	**0.0798**
epsilon	artificial	500000	100000	2000	0.0343	0.0625
zeta	artificial	500000	100000	2000	0.0118	0.0305
fd	face detection	5469800	532400	900	0.1829	**0.1829**
ocr	character recognition	3500000	670000	1156	0.1584	0.1637
dna	dna split point detection	50000000	1000000	200	0.8045	0.8645
webspam	webspam detection	350000	50000	variable	0.0004	0.0031

Table 1: Challenge data sets and final best vs our results for the aoPRC criterion.

The overall results are summarized based on performance figures: displaying training time vs. test error, data set size vs. test error and data set size vs. training time. A final ranking is computed by aggregating a set of performance indicators computed from these figures.

4.2 Our Submission

We made one fully automatic submission, using the raw representation of the data sets, which is numerical for all the data sets except for dna where the variables are categorical.

For the two image-based data sets (fd and ocr), we also studied the impact of initial representation using centered reduced rows, and finally chose the representation leading to the best results: raw for ocr and centered-reduced for fd.

The webspam data set is represented using a tri-gram representation, which implies 16 millions of potential variables ($K = 256^3 \approx 16 * 10^6$). Although this is a sparse data set, our algorithm exploits a dense representation and cannot manage such a large number of variables. We applied a simple dimensionality reduction method inspired from the random projection technique (Vempala, 2004). We choose to build a compact representation, using a set of $K' = 10007$ (first prime number beyond 10000) constructed variables: each constructed feature is the sum of the initial variables having the same index modulo K':

$$\forall k', 0 \leq k' < K', Var_{k'} = \sum_{k, k \bmod K' = k'} Var_k.$$

As our method is available as a scoring tool for Windows end users, it is implemented for 32 bits CPUs and limited to 2 Gb RAM, thus does not benefit from the 32 Gb RAM allowed in the challenge. The algorithmic extensions presented in Section 3.2 are thus extensively exploited for the largest training sessions.

4.3 Non-Parametric Modeling with Large Data Sets

In Boullé (2007), we have analyzed the accuracy performance of our method using extensive experiments. In the section, we give new insights on our non-parametric approach and its impact on large scale learning. Actually, the MODL method considers a space of discretization models which grows with the size of the training data set. The number of intervals is taken between 1 to N intervals, where N is the number of training instances, the boundaries come from the input data and the class conditional parameters per interval are confined to a finite number of frequencies (rather than continuous distributions in [0, 1]), on the basis on instance counts in the data. Both the space of discretization models and the prior distribution on the model parameters are data-dependent. More precisely, they depends on the input data, and the best model, with the maximum a posteriori probability, is selected using the output data.

To illustrate this, we chose the delta data set and exploit the 500000 labeled instances for our experiment. We use training sets of increasing sizes 100, 1000, 10000, 100000 and 400000, and keep the last 100000 instances as a test set. The best variable according to the MODL criterion is Var150 for all data set sizes above 1000. In Figure 4, we draw the discretization (with boundaries and conditional probability of the positive class) of Var150, using the MODL method and the unsupervised equal frequency method with 10 intervals, as a baseline. For data set size 100, the empirical class distribution is noisy, and the MODL method selects a discretization having one single interval, leading to the elimination of the variable. When the data set size increases, the MODL discretizations contain more and more intervals, with up to 12 intervals in the case of data set size 400000. Compared to the fixed size equal frequency discretization, the MODL method builds discretizations which are both more accurate and robust and obtain a good approximation of the underlying class distribution.

This also demonstrates how the univariate MODL preprocessing method behaves as a variable ranking method with a clear threshold: any input variable discretized into one single interval does not contain any predictive information and can be eliminated. In Figure 5, we report the number of selected variables per data set size, which goes from 6 for data set size 100 to about 350 for data set size 400000. Figure 5 also report the test AUC (area under the ROC curve (Fawcett, 2003)), which significantly improves with the data set size and exhibits a clear correlation with the number of selected variables.

One drawback of this approach is that all the training data have to be exploited simultaneously to unable a deep optimization of the model parameters and fully benefit from their expressiveness. Although learning with very large data sets is possible, as shown in this paper, the approach is limited to offline learning and does not apply to the one-pass learning paradigm or to learning on stream.

Overall, our non-parametric approach build models of increasing complexity with the size of the training data set, in order to better approximate the underlying class distribution. Small training data sets lead to simple models, which are fast to deploy (few selected variables with simple discretization), whereas large training data sets allow more accurate models at the expense of more training time and deployment time.

4.4 Impact of the Chunking Strategy

In Section 3.2, we have proposed a chunking strategy that allows to learn with training data sets which size is far larger than central memory. The only difference with the standard algorithm is the “double stage” random reordering of the variables, which is performed prior to each step of fast forward or backward variable selection in Algorithm 2. In this section, we evaluate our chunking strategy and its impact on training time and test AUC.

We exploit the delta data set with trainings sets of increasing sizes 100, 1000, 10000, 10000, 400000, and a test set of 100000 instances. The largest training size fits into central memory on our

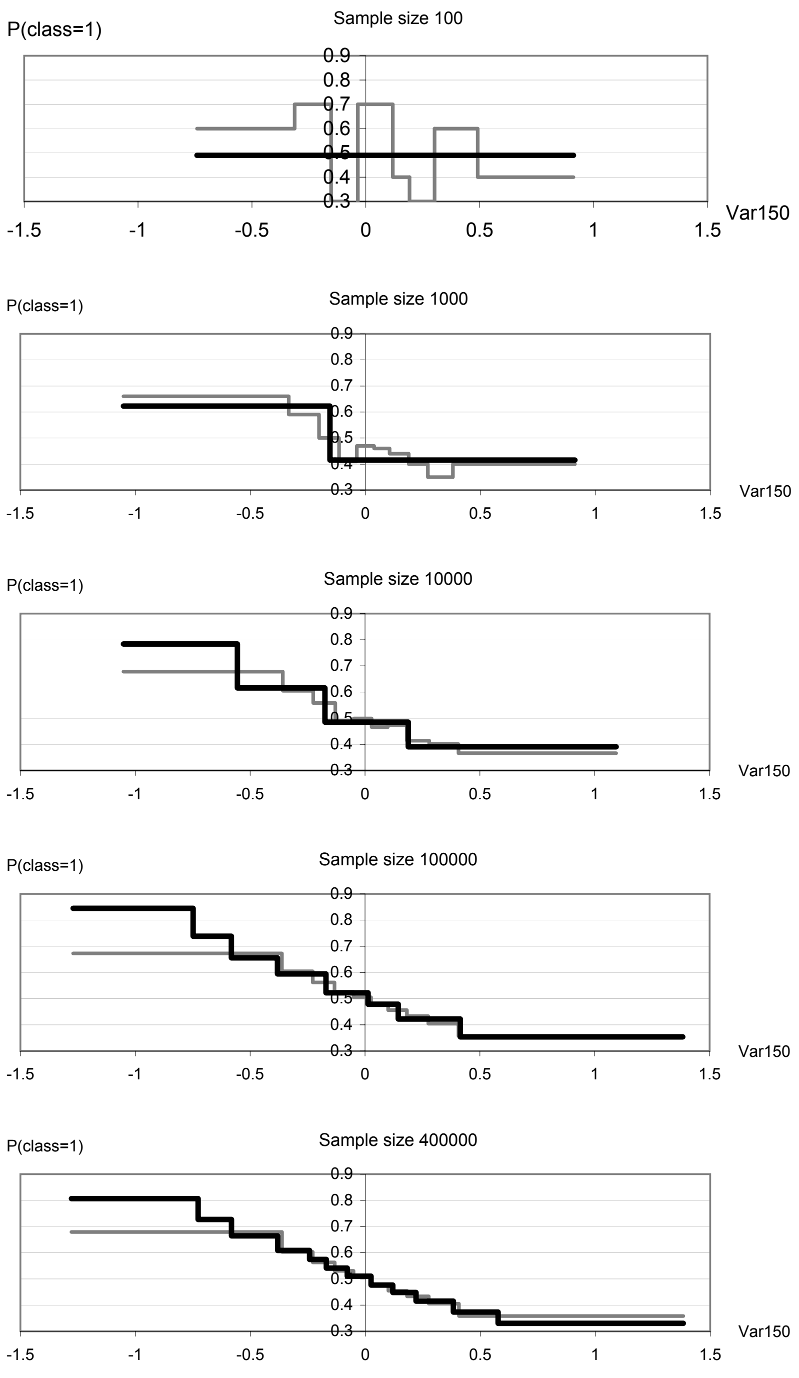

Figure 4: Discretization of Var150 for the delta data set, using the MODL method (in black) and the 10 equal frequency method (in gray).

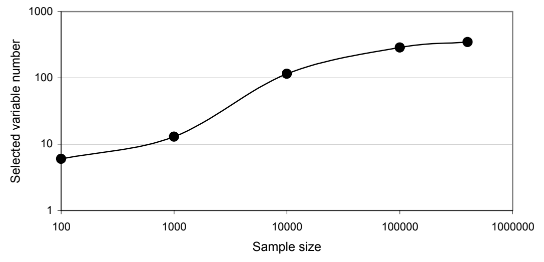

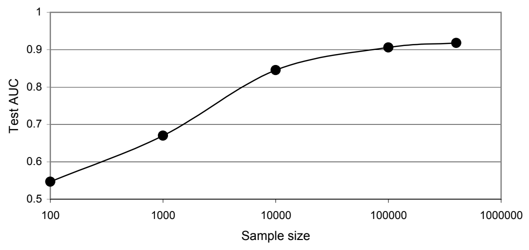

Figure 5: Data set size versus selected variable number and test AUC for the delta data set.

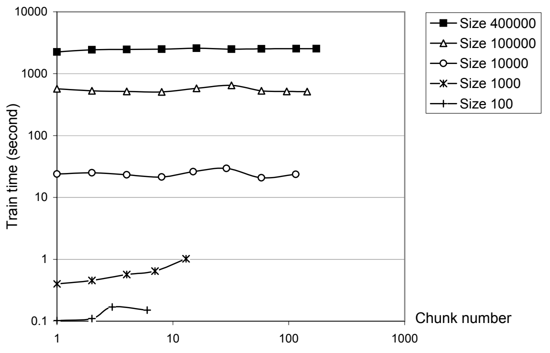
machine (Pentium 4, 3.2 Ghz, 2 Go RAM, Windows XP), which allows to compare the standard algorithm with the chunking strategy. In Figure 6, we report the wall-clock variable selection training time and the test AUC for the standard algorithm (chunk number = 1) and the chunking strategy, for various numbers of chunks.



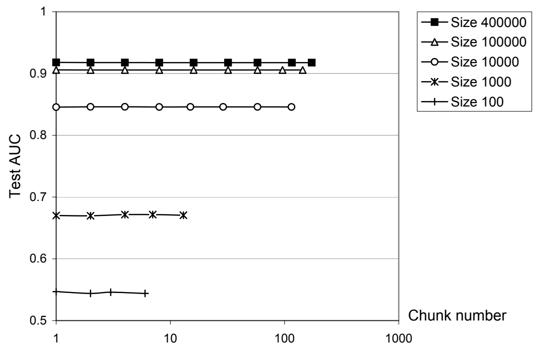


Figure 6: Impact on the chunking strategy on the wall-clock variable selection training time and the test AUC for the delta data set.

The results show that the impact on test AUC is insignificant: the largest differences go from 0.003 for data set size 100 to 0.0004 for data set size 400000. The variable selection training time is almost constant with the number of chunks. Compared to the standard algorithm, the time overhead is only 10% (for data set size above 10000), whatever be the number of chunks. Actually, as analyzed in Section 3.2, the recoded chunks of variables are extremely quick to load into memory, resulting in just a slight impact on training time.

We perform another experiment using the fd data set, with up to 5.5 millions of instances and 900 variables, which is one order of magnitude larger than our central memory resources. Figure 7 reports the wall-clock full training time, including load time, preprocessing and variable selection. When the size of the data sets if far beyond the size of the central memory, the overhead in wall-clock time is by only a factor two. This overhead mainly comes from the preprocessing phase of the algorithm (see Algorithm 3), which involves several reads of the initial training data set. Overall, the wall-clock training time is about one hour per analyzed gigabyte.

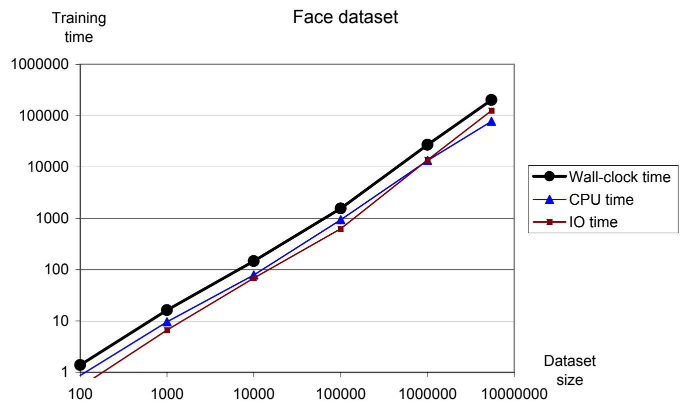

Figure 7: Training time for the fd data set.

Table 2: Challenge final ranking.

4.5 Challenge Results

The challenge attracted 49 participants who registered, for a total of 44 submissions. In the final evaluation, our submission is ranked 5^{th} using the the aggregated performance indicator of the organizers, as shown in Table 2. To go beyond this aggregated indicator and analyze the intrinsic multi-criterion nature of the results, we now report and comment separately the training time and accuracy performance of our method.

4.5.1 TRAINING TIME

Most of the other competitors exploit linear SVM, using for example Newton based optimization in the primal (Chapelle, 2007), Sequential Dual Method optimization (Hsieh et al., 2008) or stochastic gradient optimization (Bordes and Bottou, 2008). These method were applied using a specific data preparation per data set, such as 0-1, L1 or L2 normalization, and the model parameters were tuned using most of the available training data, even for the smallest training sessions. They exploit incremental algorithms, similar to online learning methods: they are very fast and need only a few passes on the data to reach convergence.

We report in Figure 8 the training time vs data set size performance curves (in black for our results).[3] As far as the computation time only is considered, our offline training time is much longer than that of the online methods of the other competitors, by about two orders of magnitude. However, when the overall process is accounted for, with data preparation, model selection and data loading time, our training time becomes competitive, with about one hour of training time per analyzed gigabyte.

4.5.2 ACCURACY

Table 1 reports our accuracy results in the challenge for the area over the precision recall curve (aoPRC) criterion in the final evaluation of the challenge. The detailed results are presented in Figure 9, using the data set size vs accuracy performance curves.

On the webspam data set, the linear SVM submissions of Keerthi obtain excellent performance, which confirms the effectiveness of SVM for text categorization (Joachims, 1998). On the alpha data set, our method (based on the naive Bayes assumption) fails to exploit the quadratic nature of this artificial data set and obtains poor results. Except for this data set, our method always ranks among the first competitors and obtains the 1^{st} place with a large margin on four data sets: beta, gamma, delta and fd. This is a remarkable performance for a fully automatic method, which exploits the limited naive Bayes assumption.

Overall, our method is highly scalable and obtains competitive performance fully automatically, without tuning any parameter.

5. Conclusion

We have presented a parameter-free classification method that exploits the naive Bayes assumption. It estimates the univariate conditional probabilities using the MODL method, with Bayes optimal discretizations and value groupings for numerical and categorical variables. It searches for a subset of variables consistent with the naive Bayes assumption, using an evaluation based on a Bayesian model selection approach and efficient add-drop greedy heuristics. Finally, it combines all the evaluated models using a compression-based averaging schema. In this paper, we have introduced a carefully designed chunking strategy, such that our method is no longer limited to data sets that fit into central memory.

Our classifier is aimed at automatically producing competitive predictions in a large variety of data mining contexts. Our results in the Large Scale Learning Challenge demonstrates that our method is highly scalable and automatically builds state-of-the art classifiers. When the data set size is larger than the available central memory by one order of magnitude, our method exploits an efficient chunking strategy, with a time overhead of only a factor two.

Compared to alternative methods, our method requires all the data simultaneously to fully exploit the potential of our non-parametric preprocessing: it is thus dedicated to offline learning, not to online learning. Another limitation is our selective naive Bayes assumption. Although this is often leveraged in practice when large number of features can be constructed using domain knowledge, alternative methods might be more effective when their bias fit the data. Overall, our approach is

3. For readability reasons in this paper, we have represented our results in black and the others in gray, which allows to present our performance relatively to the distribution of all the results. On the challenge website, Figures 8 and 9 come in color, which allows to discriminate the performance of each method.

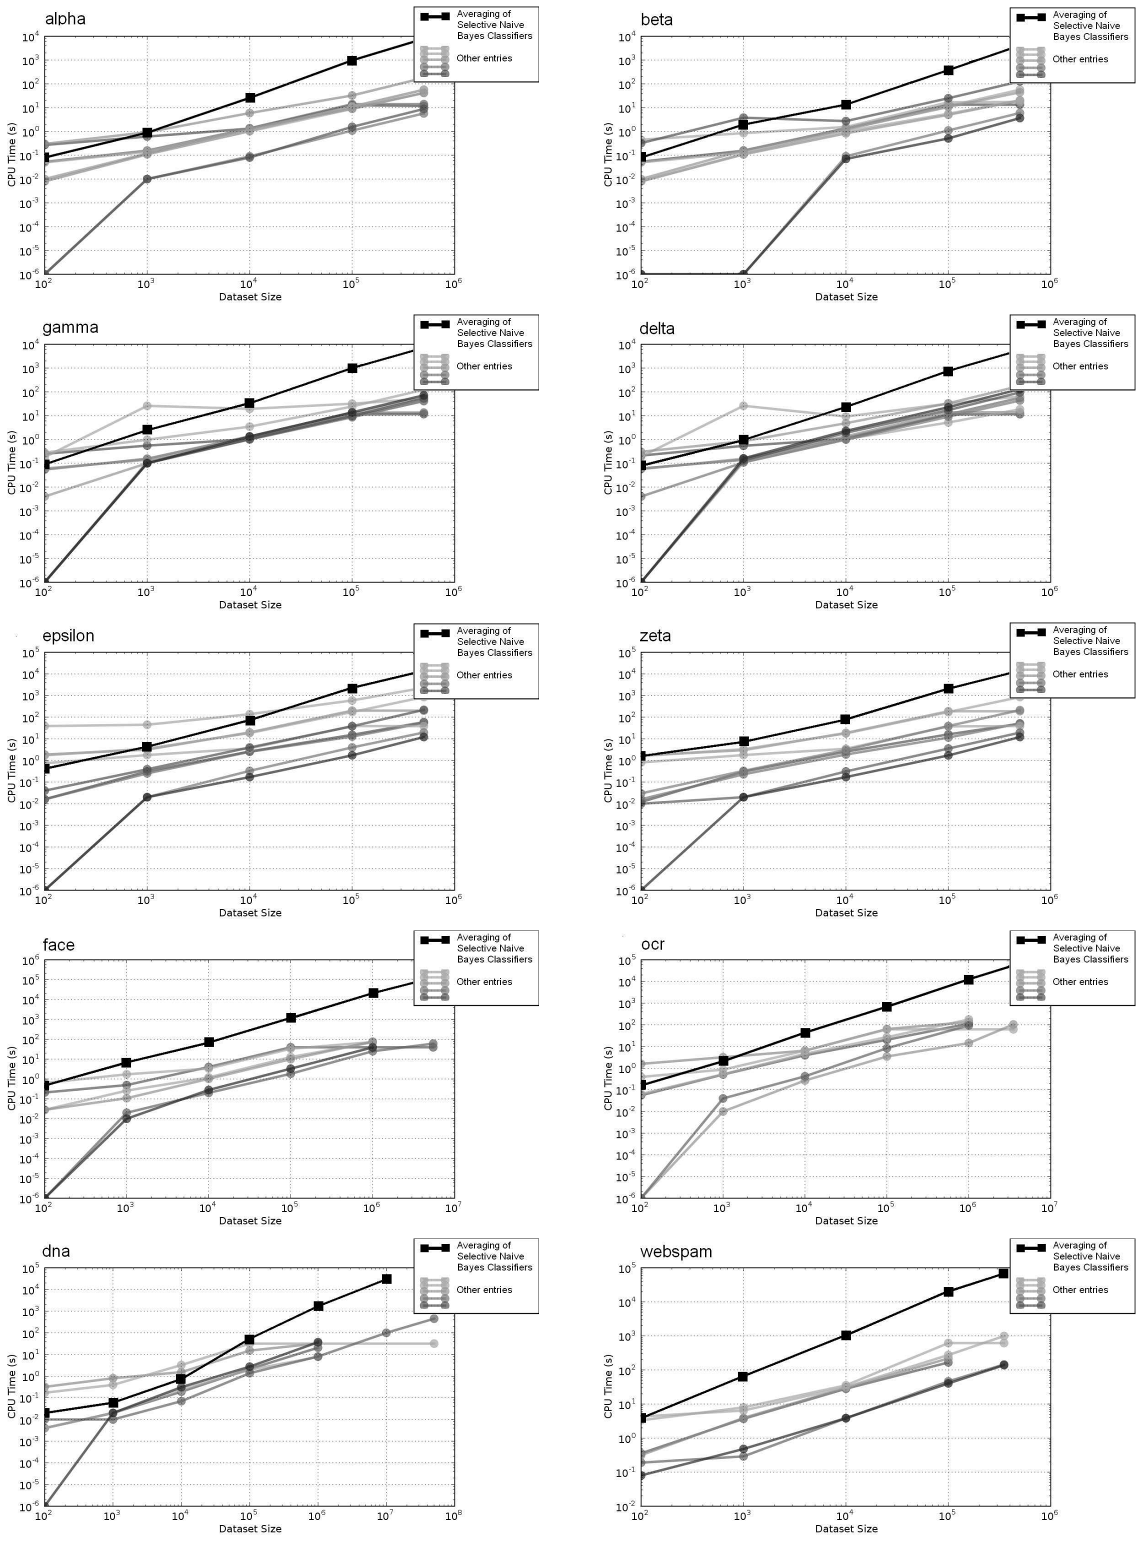

Figure 8: Final training time results: data set size versus training time (excluding data loading).

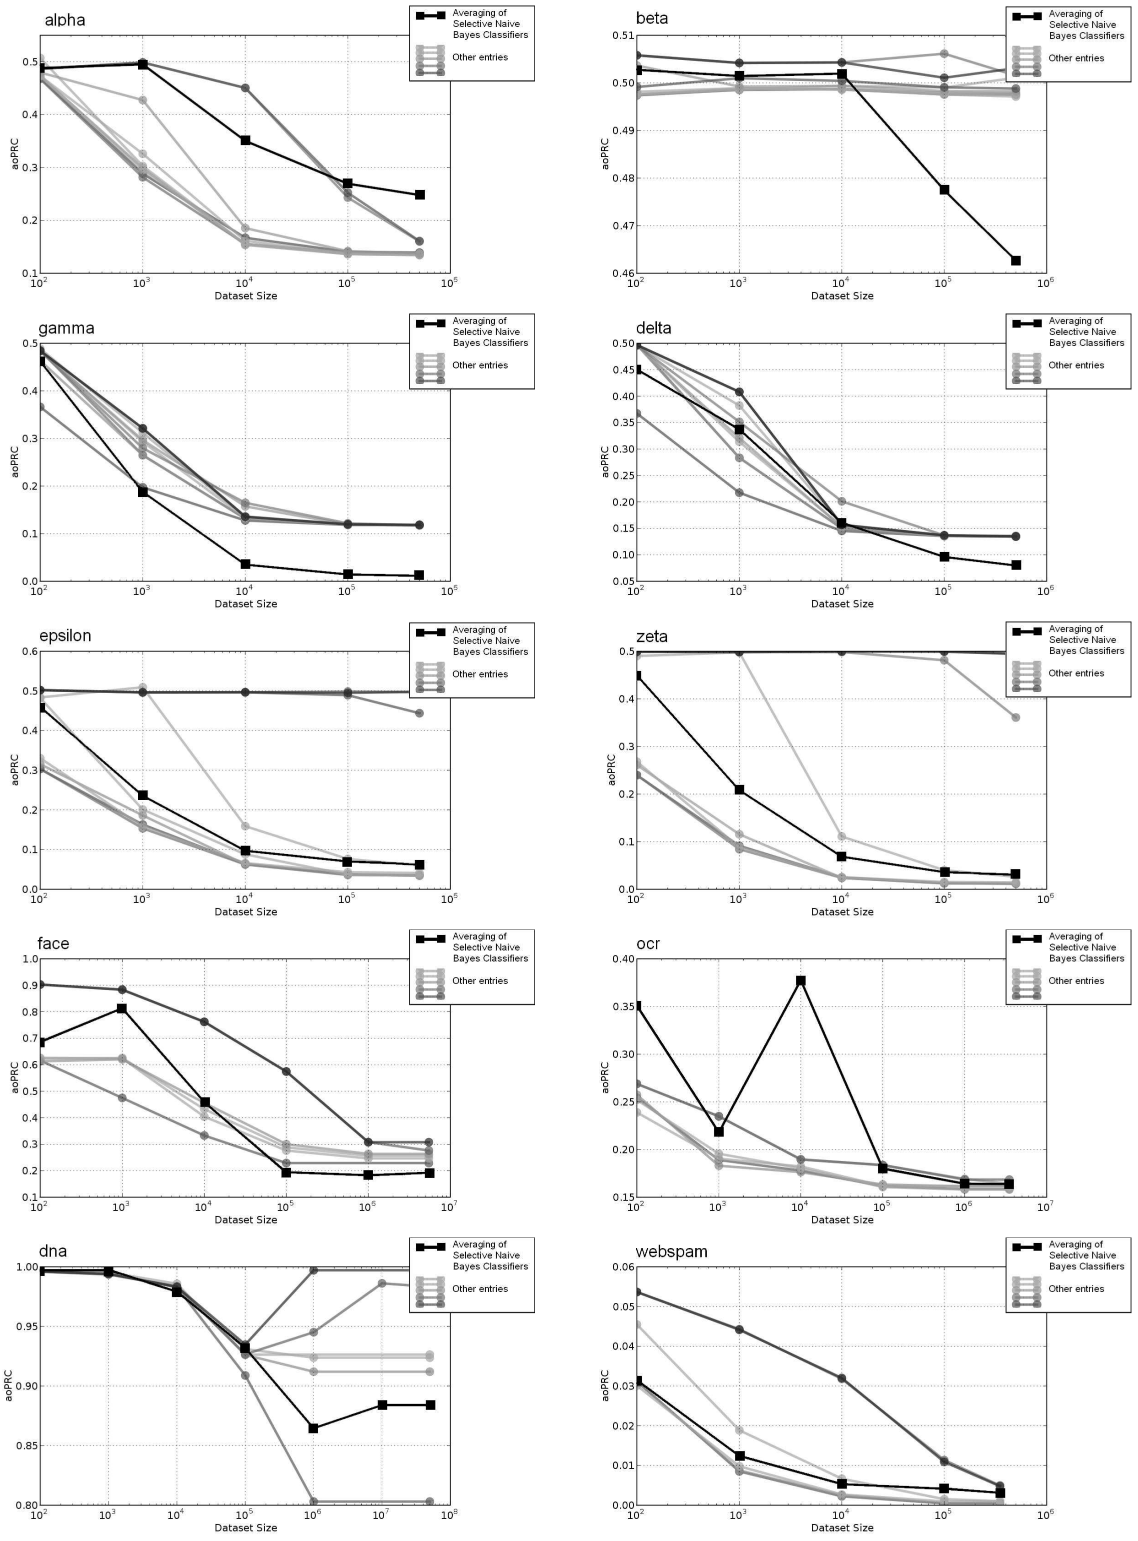

Figure 9: Final accuracy results: data set size versus test error.

of great interest for automatizing the data preparation and modeling phases of data mining, and exploits as much as possible all the available training data in its initial representation.

In future work, we plan to further improve the method and extend it to classification with large number of class values and to regression.

Acknowledgments

I am grateful to Bruno Guerraz, who got the initial Windows code to work under Linux. I would also like to thank the organizers of the Large Scale Learning Challenge for their valuable initiative.

Editor: Soeren Sonenberg

Abstract

This paper presents Model Monitor (M^2), a Java toolkit for robustly evaluating machine learning algorithms in the presence of changing data distributions. M^2 provides a simple and intuitive framework in which users can evaluate classifiers under hypothesized shifts in distribution and therefore determine the best model (or models) for their data under a number of potential scenarios. Additionally, M^2 is fully integrated with the WEKA machine learning environment, so that a variety of commodity classifiers can be used if desired.

Keywords: machine learning, open-source software, distribution shift, scenario analysis

1. Introduction

Most work in machine learning implicitly assumes a *stationary distribution*, meaning that the population from which our data is drawn does not change over time. However, a number of real-world applications present the challenge of a drift in distribution between training and testing (Quiñonero et al., 2008). At the same time, the prevalent evaluation paradigm does not take into account the effect of changing distributions on the performance of the models being compared. We posit that it is important to effectively evaluate the generalization capacity of models or classifiers on a range of distribution divergences. We propose M^2, a Java toolkit that is designed to help researchers and practitioners grapple with potential shifts in data distribution. The fundamental issues that we address in this toolkit are: a) which of several competing models is most robust to changing distributions? b) when, why, and how may the learned model fail? Specifically, it carries the following fundamental capabilities.

1. Detection of distribution shift: M^2 contains methods for isolating features whose distribution has changed significantly between training and testing sets. This allows for following: a) sensitivity/fragility analysis on features with respect to distributional shifts; b) if a testing set is available, determination of features that change significantly between the training and testing sets; and c) if an effective model is beginning to degrade in performance, problematic features can be isolated and the model can be updated before its performance gets worse.

2. Exploration of hypothetical scenarios: If a user is building a model on new data and expects the distribution to change over time, he or she can inject these changes into the test data and

determine which classifiers[1] (trained on current data) perform best on both the current and hypothetical future distributions.

3. Empirical comparison of classifiers: M^2 can compare classifiers on performance across several data sets and distribution shifts. This capability allows researchers to objectively evaluate the robustness of the classifiers under distribution shift. This can guide the selection of a classifier that is more robust to distributional drifts. Various cross-validation schemes are available, and we implement statistical tests, so that the user knows whether the observed differences are statistically significant.

M^2 is, to our knowledge, the only publicly-available software to tackle the important problem of learning under changing distributions. At present, it is designed mainly for two-class problems. Most of the currently-implemented performance measures will compare the performance of the positive class (i.e., class 1) against the performance on all other classes.

The current version is available on `mloss.org`, and its distribution package contains a user's guide, developer's guide, JavaDoc documentation, and examples. To afford flexibility to the user M^2 fully integrates with WEKA (Witten et al., 1999), but also provides support for interfacing with arbitrary custom classifiers. Input data can either be in the WEKA format or the comma-delimited format of traditional UCI repository data sets (often called C4.5 style).

2. Implementation

M^2 is implemented in Java and is therefore fully cross-platform. It provides a Swing graphical user interface, and implements several different distribution shifts, methods of evaluation such as 10-fold, 5x2 CV, etc., performance measures, and statistical measures for the comparison of classifiers. Each of these critical components has been validated by a series of automated unit tests to insure correct operation and protect against regression.

2.1 Performance Measures

In addition to the standard performance measures (*Accuracy*, *AUROC*, *Precision*, *Recall*, F_1*-Measure*), we have implemented other performance and loss measures commonly used for binary classification tasks, including *Brier Score* and *Negative Cross Entropy*. For any of the tasks described above, M^2 supports all of the standard validation measures including *cross-validation* (5-by-2 and 10-fold from the GUI, arbitrary configurations otherwise), splitting a data set into training and testing, and specifying an entirely separate file of test data.

2.2 Distribution Shifts

M^2 can introduce a number of different changes in distribution, including *missing at random*, *missing not at random*, *random noise*, *mean shift*, *variance change*, and a *prior probability shift*. Specific details on how each of the distribution shifts are implemented is available in the user's guide.

1. Model and classifier will be used inter-changeably in this paper.

2.3 Statistical Measures

The bulk of the implementation has to do with methods for detecting and evaluating the effect of shifts in distribution. For detecting shifts in distribution, we provide both *Hellinger distance* and the *Kolmogorov-Smirnov* (KS) test. Recent work by Cieslak and Chawla (2007) has shown that systematic shifts in distribution tend to cause significant changes in Hellinger distance. The KS test helps to distinguish between changes caused by random fluctuation and changes caused by systematic bias.

For comparing the performance of multiple classifiers, we have implemented the *Friedman test* and the *Bonferroni-Dunn test*. The average performance of several classifiers, across multiple data sets is compared with the Friedman test, as suggested by Demšar (2006), and if a significant difference in performance is found, the Bonferroni-Dunn test determines the classifiers or sets of classifiers between which the significant difference exists.

3. Functionality

Here we provide a quick overview of the toolkit's major functionality. Each feature is described in greater detail in the user's guide.

3.1 Detecting Distribution Shift

When a user starts M^2, he or she can load any data set in either C4.5 names/data format or the WEKA ARFF format. The user then specifies a test set (either by selecting hold-out or cross-validation or by choosing a separate test file).

At this point, the user can begin evaluating the training and test data sets for shifts in distribution. Each attribute in the data set is automatically displayed, and selecting it will produce a histogram of both distributions so that any differences can be visually inspected. Additionally M^2 automatically calculates the Hellinger distance for each feature between the training and test sets. If a feature's distribution fails the KS test (at the $\alpha = 0.05$ confidence level), the Hellinger distance for that feature is highlighted. In this way, users can quickly locate features whose distribution may have changed. A simple example appears in Figure 1(a).

3.2 Exploration of Hypothetical Scenarios

After loading a data set, the user has the opportunity to introduce any of a number of distribution shifts into the test data. Upon doing so, the histograms displayed on the screen will be updated, and new Hellinger distances and KS-test p-values are calculated. The user can then quickly evaluate any classifier on both the original and new ("biased") test sets to compare the results. WEKA classifiers can be chosen from a GUI chooser, whereas for general classifiers, a commandline must be specified.

For more sophisticated sensitivity analysis, the user may specify a range of distribution shifts. In this case, he or she provides a set of increasingly severe biases, and then the tool evaluates the classifier's performance under each one. The results are presented to the user both graphically (plotting classifier preformance against severity of shift) and in tabular form, to facilitate further offline processing.

3.3 Empirical Comparison of Classifiers

Finally, users may test any one classifier against several others across multiple data sets and distribution shifts. For each specified distribution shift, the software will evaluate each classifier on all the data sets. It ranks the classifiers on each data set, calculates the average rank for each classifier, and then performs the Friedman test for analysis of variance on the resulting table of ranks. If the Friedman test determines (again at the 0.05 level) that there is a significant difference between the classifiers, we run the Bonferroni-Dunn test to determine exactly which classifiers are different from the specified reference classifier.

In addition to producing an annotated table of ranks containing the statistical test information, this step produces all the same output that the other portions of the program produce. Taken together, these results provide a complete picture of the classifiers' relative performance in the relevant scenarios.

Acknowledgments

The authors would like to acknowledge Ryan Lichtenwalter, Dave Cieslak, and Karsten Steinhaeuser for helpful discussions on both implementation and user interface issues.

Abstract

We address the problem of estimating the ratio of two probability density functions, which is often referred to as the *importance*. The importance values can be used for various succeeding tasks such as *covariate shift adaptation* or *outlier detection*. In this paper, we propose a new importance estimation method that has a closed-form solution; the leave-one-out cross-validation score can also be computed analytically. Therefore, the proposed method is computationally highly efficient and simple to implement. We also elucidate theoretical properties of the proposed method such as the convergence rate and approximation error bounds. Numerical experiments show that the proposed method is comparable to the best existing method in accuracy, while it is computationally more efficient than competing approaches.

Keywords: importance sampling, covariate shift adaptation, novelty detection, regularization path, leave-one-out cross validation

1. Introduction

In the context of *importance sampling* (Fishman, 1996), the ratio of two probability density functions is called the *importance*. The problem of estimating the importance is attracting a great deal of attention these days since the importance can be used for various succeeding tasks such as *covariate shift adaptation* or *outlier detection*.

> **Covariate Shift Adaptation:** Covariate shift is a situation in supervised learning where the distributions of inputs change between the training and test phases but the conditional distribution of outputs given inputs remains unchanged (Shimodaira, 2000; Quiñonero-Candela et al., 2008). Covariate shift is conceivable in many real-world

$*$. A MATLAB® or R implementation of the proposed importance estimation algorithm, *unconstrained Least-Squares Importance Fitting* (uLSIF), is available from `http://sugiyama-www.cs.titech.ac.jp/∼sugi/software/uLSIF/`.

applications such as bioinformatics (Baldi and Brunak, 1998; Borgwardt et al., 2006), brain-computer interfaces (Wolpaw et al., 2002; Sugiyama et al., 2007), robot control (Sutton and Barto, 1998; Hachiya et al., 2008), spam filtering (Bickel and Scheffer, 2007), and econometrics (Heckman, 1979). Under covariate shift, standard learning techniques such as maximum likelihood estimation or cross-validation are biased and therefore unreliable—the bias caused by covariate shift can be compensated by weighting the loss function according to the importance (Shimodaira, 2000; Zadrozny, 2004; Sugiyama and Müller, 2005; Sugiyama et al., 2007; Huang et al., 2007; Bickel et al., 2007).

Outlier Detection: The outlier detection task addressed here is to identify irregular samples in a validation data set based on a model data set that only contains regular samples (Schölkopf et al., 2001; Tax and Duin, 2004; Hodge and Austin, 2004; Hido et al., 2008). The values of the importance for regular samples are close to one, while those for outliers tend to be significantly deviated from one. Thus the values of the importance could be used as an index of the degree of outlyingness.

Below, we refer to the two sets of samples as the *training* set and the *test* set.

A naive approach to estimating the importance is to first estimate the training and test density functions from the sets of training and test samples separately, and then take the ratio of the estimated densities. However, density estimation is known to be a hard problem particularly in high-dimensional cases if we do not have simple and good parametric density models (Vapnik, 1998; Härdle et al., 2004). In practice, such an appropriate parametric model may not be available and therefore this naive approach is not so effective.

To cope with this problem, direct importance estimation methods which do not involve density estimation have been developed recently. The *kernel mean matching* (KMM) method (Huang et al., 2007) directly gives estimates of the importance at the training inputs by matching the two distributions efficiently based on a special property of *universal reproducing kernel Hilbert spaces* (Steinwart, 2001). The optimization problem involved in KMM is a convex quadratic program, so the unique global optimal solution can be obtained using a standard optimization software. However, the performance of KMM depends on the choice of tuning parameters such as the kernel parameter and the regularization parameter. For the kernel parameter, a popular heuristic of using the median distance between samples as the Gaussian width could be useful in some cases (Schölkopf and Smola, 2002; Song et al., 2007). However, there seems no strong justification for this heuristic and the choice of other tuning parameters is still open.

A probabilistic classifier that separates training samples from test samples can be used for directly estimating the importance, for example, a *logistic regression* (LogReg) classifier (Qin, 1998; Cheng and Chu, 2004; Bickel et al., 2007). Maximum likelihood estimation of LogReg models can be formulated as a convex optimization problem, so the unique global optimal solution can be obtained. Furthermore, since the LogReg-based method only involves a standard supervised classification problem, the tuning parameters such as the kernel width and the regularization parameter can be optimized based on the standard cross-validation procedure. This is a very useful property in practice.

The *Kullback-Leibler importance estimation procedure* (KLIEP) (Sugiyama et al., 2008b; Nguyen et al., 2008) also directly gives an estimate of the importance function by matching the two distributions in terms of the Kullback-Leibler divergence (Kullback and Leibler, 1951). The optimization problem involved in KLIEP is convex, so the unique global optimal solution—which tends to be sparse—can be obtained, when linear importance models are used. In addition, the tuning parameters in KLIEP can be optimized based on a variant of cross-validation.

As reviewed above, LogReg and KLIEP are more advantageous than KMM since the tuning parameters can be objectively optimized based on cross-validation. However, optimization procedures of LogReg and KLIEP are less efficient in computation than KMM due to high non-linearity of the objective functions to be optimized—more specifically, exponential functions induced by the LogReg model or the log function induced by the Kullback-Leibler divergence. The purpose of this paper is to develop a new importance estimation method that is equipped with a build-in model selection procedure as LogReg and KLIEP and is computationally more efficient than LogReg and KLIEP.

Our basic idea is to formulate the direct importance estimation problem as a least-squares function fitting problem. This formulation allows us to cast the optimization problem as a convex quadratic program, which can be efficiently solved using a standard quadratic program solver. Cross-validation can be used for optimizing the tuning parameters such as the kernel width or the regularization parameter. We call the proposed method *least-squares importance fitting* (LSIF). We further show that the solutions of LSIF is piecewise linear with respect to the ℓ_1-regularization parameter and the entire regularization path (that is, all solutions for different regularization parameter values) can be computed efficiently based on the *parametric optimization technique* (Best, 1982; Efron et al., 2004; Hastie et al., 2004). Thanks to this regularization path tracking algorithm, LSIF is computationally efficient in model selection scenarios. Note that in the regularization path tracking algorithm, we can trace the solution path without a quadratic program solver—we just need to compute matrix inverses.

LSIF is shown to be efficient in computation, but it tends to share a common weakness of regularization path tracking algorithms, that is, *accumulation of numerical errors* (Scheinberg, 2006). The numerical problem tends to be severe if there are many change points in the regularization path. To cope with this problem, we develop an approximation algorithm in the same least-squares framework. The approximation version of LSIF, which we call *unconstrained LSIF* (uLSIF), allows us to obtain the closed-form solution that can be computed just by solving a system of linear equations. Thus uLSIF is numerically stable when regularized properly. Moreover, the leave-one-out cross-validation score for uLSIF can also be computed analytically (cf. Wahba, 1990; Cawley and Talbot, 2004), which significantly improves the computational efficiency in model selection scenarios. We experimentally show that the accuracy of uLSIF is comparable to the best existing method while its computation is faster than other methods in covariate shift adaptation and outlier detection scenarios.

Our contributions in this paper are summarized as follows. A proposed density-ratio estimation method, LSIF, is equipped with cross-validation (which is an advantage over KMM) and is computationally efficient thanks to regularization path tracking (which is an advantage over KLIEP and LogReg). Furthermore, uLSIF is computationally even more efficient since its solution and leave-one-out cross-validation score can be computed analytically in a stable manner. The proposed methods, LSIF and uLSIF, are similar in spirit to KLIEP, but the loss functions are different: KLIEP uses the log loss while LSIF and uLSIF use the squared loss. The difference of the log functions allows us to improve computational efficiency significantly.

The rest of this paper is organized as follows. In Section 2, we propose a new importance estimation procedure based on least-squares fitting (LSIF) and show its theoretical properties. In

Section 3, we develop an approximation algorithm (uLSIF) which can be computed efficiently. In Section 4, we illustrate how the proposed methods behave using a toy data set. In Section 5, we discuss the characteristics of existing approaches in comparison with the proposed methods and show that uLSIF could be a useful alternative to the existing methods. In Section 6, we experimentally compare the performance of uLSIF and existing methods. Finally in Section 7, we summarize our contributions and outline future prospects. Those who are interested in practical implementation may skip the theoretical analyses in Sections 2.3, 3.2, and 3.3.

2. Direct Importance Estimation

In this section, we propose a new method of direct importance estimation.

2.1 Formulation and Notation

Let $\mathcal{D} \subset (\mathbb{R}^d)$ be the data domain and suppose we are given independent and identically distributed (i.i.d.) training samples $\{x_i^{\mathrm{tr}}\}_{i=1}^{n_{\mathrm{tr}}}$ from a training distribution with density $p_{\mathrm{tr}}(x)$ and i.i.d. test samples $\{x_j^{\mathrm{te}}\}_{j=1}^{n_{\mathrm{te}}}$ from a test distribution with density $p_{\mathrm{te}}(x)$:

$$\{x_i^{\mathrm{tr}}\}_{i=1}^{n_{\mathrm{tr}}} \overset{i.i.d.}{\sim} p_{\mathrm{tr}}(x),$$
$$\{x_j^{\mathrm{te}}\}_{j=1}^{n_{\mathrm{te}}} \overset{i.i.d.}{\sim} p_{\mathrm{te}}(x).$$

We assume that the training density is strictly positive, that is,

$$p_{\mathrm{tr}}(x) > 0 \text{ for all } x \in \mathcal{D}.$$

The goal of this paper is to estimate the *importance* $w(x)$ from $\{x_i^{\mathrm{tr}}\}_{i=1}^{n_{\mathrm{tr}}}$ and $\{x_j^{\mathrm{te}}\}_{j=1}^{n_{\mathrm{te}}}$:

$$w(x) = \frac{p_{\mathrm{te}}(x)}{p_{\mathrm{tr}}(x)},$$

which is non-negative by definition. Our key restriction is that we want to avoid estimating densities $p_{\mathrm{te}}(x)$ and $p_{\mathrm{tr}}(x)$ when estimating the importance $w(x)$.

2.2 Least-squares Approach to Direct Importance Estimation

Let us model the importance $w(x)$ by the following linear model:

$$\widehat{w}(x) = \sum_{\ell=1}^{b} \alpha_\ell \varphi_\ell(x), \tag{1}$$

where $\alpha = (\alpha_1, \alpha_2, \ldots, \alpha_b)^\top$ are parameters to be learned from data samples, $^\top$ denotes the transpose of a matrix or a vector, and $\{\varphi_\ell(x)\}_{\ell=1}^{b}$ are basis functions such that

$$\varphi_\ell(x) \geq 0 \text{ for all } x \in \mathcal{D} \text{ and for } \ell = 1, 2, \ldots, b.$$

Note that b and $\{\varphi_\ell(x)\}_{\ell=1}^{b}$ could be dependent on the samples $\{x_i^{\mathrm{tr}}\}_{i=1}^{n_{\mathrm{tr}}}$ and $\{x_j^{\mathrm{te}}\}_{j=1}^{n_{\mathrm{te}}}$, for example, *kernel* models are also allowed. We explain how the basis functions $\{\varphi_\ell(x)\}_{\ell=1}^{b}$ are chosen in Section 2.5.

We determine the parameters $\{\alpha_\ell\}_{\ell=1}^b$ in the model $\widehat{w}(x)$ so that the following squared error J_0 is minimized:

$$\begin{aligned}
J_0(\alpha) &= \frac{1}{2}\int \left(\widehat{w}(x) - w(x)\right)^2 p_{\mathrm{tr}}(x)dx \\
&= \frac{1}{2}\int \widehat{w}(x)^2 p_{\mathrm{tr}}(x)dx - \int \widehat{w}(x)w(x)p_{\mathrm{tr}}(x)dx + \frac{1}{2}\int w(x)^2 p_{\mathrm{tr}}(x)dx \\
&= \frac{1}{2}\int \widehat{w}(x)^2 p_{\mathrm{tr}}(x)dx - \int \widehat{w}(x)p_{\mathrm{te}}(x)dx + \frac{1}{2}\int w(x)^2 p_{\mathrm{tr}}(x)dx,
\end{aligned}$$

where in the second term the probability density $p_{\mathrm{tr}}(x)$ is canceled with that included in $w(x)$. The squared loss $J_0(\alpha)$ is defined as the expectation under the probability of training samples. In covariate shift adaptation (see Section 6.2) and outlier detection (see Section 6.3), the importance values on the training samples are used. Thus, the definition of $J_0(\alpha)$ well agrees with our goal.

The last term of $J_0(\alpha)$ is a constant and therefore can be safely ignored. Let us denote the first two terms by J:

$$\begin{aligned}
J(\alpha) &= \frac{1}{2}\int \widehat{w}(x)^2 p_{\mathrm{tr}}(x)dx - \int \widehat{w}(x)p_{\mathrm{te}}(x)dx \\
&= \frac{1}{2}\sum_{\ell,\ell'=1}^{b} \alpha_\ell\alpha_{\ell'}\left(\int \varphi_\ell(x)\varphi_{\ell'}(x)p_{\mathrm{tr}}(x)dx\right) - \sum_{\ell=1}^{b}\alpha_\ell\left(\int \varphi_\ell(x)p_{\mathrm{te}}(x)dx\right) \\
&= \frac{1}{2}\alpha^\top H\alpha - h^\top\alpha, \qquad (2)
\end{aligned}$$

where H is the $b\times b$ matrix with the (ℓ,ℓ')-th element

$$H_{\ell,\ell'} = \int \varphi_\ell(x)\varphi_{\ell'}(x)p_{\mathrm{tr}}(x)dx, \qquad (3)$$

and h is the b-dimensional vector with the ℓ-th element

$$h_\ell = \int \varphi_\ell(x)p_{\mathrm{te}}(x)dx.$$

Approximating the expectations in J by empirical averages, we obtain

$$\begin{aligned}
\widehat{J}(\alpha) &= \frac{1}{2n_{\mathrm{tr}}}\sum_{i=1}^{n_{\mathrm{tr}}}\widehat{w}(x_i^{\mathrm{tr}})^2 - \frac{1}{n_{\mathrm{te}}}\sum_{j=1}^{n_{\mathrm{te}}}\widehat{w}(x_j^{\mathrm{te}}) \\
&= \frac{1}{2}\sum_{\ell,\ell'=1}^{b}\alpha_\ell\alpha_{\ell'}\left(\frac{1}{n_{\mathrm{tr}}}\sum_{i=1}^{n_{\mathrm{tr}}}\varphi_\ell(x_i^{\mathrm{tr}})\varphi_{\ell'}(x_i^{\mathrm{tr}})\right) - \sum_{\ell=1}^{b}\alpha_\ell\left(\frac{1}{n_{\mathrm{te}}}\sum_{j=1}^{n_{\mathrm{te}}}\varphi_\ell(x_j^{\mathrm{te}})\right) \\
&= \frac{1}{2}\alpha^\top\widehat{H}\alpha - \widehat{h}^\top\alpha,
\end{aligned}$$

where $\widehat{H}$ is the $b\times b$ matrix with the (ℓ,ℓ')-th element

$$\widehat{H}_{\ell,\ell'} = \frac{1}{n_{\mathrm{tr}}}\sum_{i=1}^{n_{\mathrm{tr}}}\varphi_\ell(x_i^{\mathrm{tr}})\varphi_{\ell'}(x_i^{\mathrm{tr}}), \qquad (4)$$

and $\widehat{h}$ is the b-dimensional vector with the ℓ-th element

$$\widehat{h}_\ell = \frac{1}{n_{\mathrm{te}}} \sum_{j=1}^{n_{\mathrm{te}}} \varphi_\ell(x_j^{\mathrm{te}}). \tag{5}$$

Taking into account the non-negativity of the importance function $w(x)$, we can formulate our optimization problem as follows.

$$\min_{\alpha \in \mathbb{R}^b} \left[\frac{1}{2} \alpha^\top \widehat{H} \alpha - \widehat{h}^\top \alpha + \lambda 1_b^\top \alpha \right] \quad \text{subject to } \alpha \geq 0_b, \tag{6}$$

where 0_b and 1_b are the b-dimensional vectors with all zeros and ones, respectively; the vector inequality $\alpha \geq 0_b$ is applied in the element-wise manner, that is, $\alpha_\ell \geq 0$ for $\ell = 1, 2, \ldots, b$. In Eq. (6), we included a penalty term $\lambda 1_b^\top \alpha$ for regularization purposes, where λ (≥ 0) is a regularization parameter. The above is a convex quadratic programming problem and therefore the unique global optimal solution can be computed efficiently by a standard optimization package. We call this method *Least-Squares Importance Fitting* (LSIF).

We can also use the ℓ_2-regularizer $\alpha^\top \alpha$ instead of the ℓ_1-regularizer $1_b^\top \alpha$ without changing the computational property. However, using the ℓ_1-regularizer would be more advantageous since the solution tends to be sparse (Williams, 1995; Tibshirani, 1996; Chen et al., 1998). Furthermore, as shown in Section 2.6, the use of the ℓ_1-regularizer allows us to compute the entire regularization path efficiently (Best, 1982; Efron et al., 2004; Hastie et al., 2004). The ℓ_2-regularization method will be used for theoretical analysis in Section 3.3.

2.3 Convergence Analysis of LSIF

Here, we theoretically analyze the convergence property of the solution $\widehat{\alpha}$ of the LSIF algorithm; practitioners may skip this theoretical analysis.

Let $\widehat{\alpha}(\lambda)$ be the solution of the LSIF algorithm with regularization parameter λ, and let $\alpha^*(\lambda)$ be the optimal solution of the 'ideal' problem:

$$\min_{\alpha \in \mathbb{R}^b} \left[\frac{1}{2} \alpha^\top H \alpha - h^\top \alpha + \lambda 1_b^\top \alpha \right] \quad \text{subject to } \alpha \geq 0_b. \tag{7}$$

Below, we theoretically investigate the *learning curve* (Amari et al., 1992) of LSIF, that is, we elucidate the relation between $J(\widehat{\alpha}(\lambda))$ and $J(\alpha^*(\lambda))$ in terms of the expectation over all possible training and test samples as a function of the number of samples.

Let $\mathbb{E}$ be the expectation over all possible training samples of size n_{tr} and all possible test samples of size n_{te}. Let $\mathcal{A} \subset \{1, 2, \ldots, b\}$ be the set of *active* indices (Boyd and Vandenberghe, 2004), that is,

$$\mathcal{A} = \{\ell \mid \alpha_\ell^*(\lambda) = 0,\ \ell = 1, 2, \ldots, b\}.$$

For the active set $\mathcal{A} = \{j_1, j_2, \ldots, j_{|\mathcal{A}|}\}$ with $j_1 < j_2 < \cdots < j_{|\mathcal{A}|}$, let E be the $|\mathcal{A}| \times b$ indicator matrix with the (i, j)-th element

$$E_{i,j} = \begin{cases} 1 & j = j_i, \\ 0 & \text{otherwise.} \end{cases}$$

Similarly, let $\widehat{\mathcal{A}}$ be the active set of $\widehat{\alpha}(\lambda)$:

$$\widehat{\mathcal{A}} = \{\ell \mid \widehat{\alpha}_\ell(\lambda) = 0,\ \ell = 1,2,\ldots,b\}.$$

For the active set $\widehat{\mathcal{A}} = \{\widehat{j}_1, \widehat{j}_2, \ldots, \widehat{j}_{|\widehat{\mathcal{A}}|}\}$ with $\widehat{j}_1 < \widehat{j}_2 < \cdots < \widehat{j}_{|\widehat{\mathcal{A}}|}$, let $\widehat{E}$ be the $|\widehat{\mathcal{A}}| \times b$ indicator matrix with the (i,j)-th element similarly defined by

$$\widehat{E}_{i,j} = \begin{cases} 1 & j = \widehat{j}_i, \\ 0 & \text{otherwise.} \end{cases} \tag{8}$$

First, we show the optimality condition of (6) which will be used in the following theoretical analyses. The *Lagrangian* of the optimization problem (6) is given as

$$L(\alpha,\xi) = \frac{1}{2}\alpha^\top \widehat{H}\alpha - \widehat{h}^\top \alpha + \lambda 1_b^\top \alpha - \xi^\top \alpha,$$

where ξ is the b-dimensional *Lagrange multiplier* vector. Then the *Karush-Kuhn-Tucker (KKT) conditions* (Boyd and Vandenberghe, 2004) are expressed as follows:

$$\begin{align} &\widehat{H}\alpha - \widehat{h} + \lambda 1_b - \xi = 0_b, \tag{9}\\ &\alpha \geq 0_b, \notag\\ &\xi \geq 0_b, \notag\\ &\xi_\ell \alpha_\ell = 0 \text{ for } \ell = 1,2,\ldots,b. \tag{10} \end{align}$$

Let $\widehat{\xi}'(\lambda)$ be the $|\widehat{\mathcal{A}}|$-dimensional vector with the i-th element being the $\widehat{j}_i$-th element of $\widehat{\xi}(\lambda)$:

$$\widehat{\xi}'_i(\lambda) = \widehat{\xi}_{\widehat{j}_i}(\lambda), \qquad i = 1,\ldots,|\widehat{\mathcal{A}}|. \tag{11}$$

We assume that $\widehat{\xi}'(\lambda)$ only contains non-zero elements of $\widehat{\xi}(\lambda)$. Let $\widehat{G}$ be

$$\widehat{G} = \begin{pmatrix} \widehat{H} & -\widehat{E}^\top \\ -\widehat{E} & O_{|\widehat{\mathcal{A}}|\times|\widehat{\mathcal{A}}|} \end{pmatrix},$$

where $O_{|\widehat{\mathcal{A}}|\times|\widehat{\mathcal{A}}|}$ is the $|\widehat{\mathcal{A}}| \times |\widehat{\mathcal{A}}|$ matrix with all zeros. Then Eqs. (9) and (10) are together expressed in a matrix form as

$$\widehat{G}\begin{pmatrix} \widehat{\alpha}(\lambda) \\ \widehat{\xi}'(\lambda) \end{pmatrix} = \begin{pmatrix} \widehat{h} - \lambda 1_b \\ 0_{|\widehat{\mathcal{A}}|} \end{pmatrix}. \tag{12}$$

Regarding the matrix $\widehat{G}$, we have the following lemma:

Lemma 1 *The matrix $\widehat{G}$ is invertible if $\widehat{H}$ is invertible.*

The proof of the above lemma is given in Appendix A. Below, we assume that $\widehat{H}$ is invertible. Then the inverse of $\widehat{G}$ exists and multiplying $\widehat{G}^{-1}$ from the left-hand side of Eq. (12) yields

$$\begin{pmatrix} \widehat{\alpha}(\lambda) \\ \widehat{\xi}'(\lambda) \end{pmatrix} = \widehat{G}^{-1}\begin{pmatrix} \widehat{h} - \lambda 1_b \\ 0_{|\widehat{\mathcal{A}}|} \end{pmatrix}. \tag{13}$$

The following inversion formula holds for block matrices (Petersen and Pedersen, 2007):

$$\begin{pmatrix} M_1 & M_2 \\ M_3 & M_4 \end{pmatrix}^{-1} = \begin{pmatrix} M_1^{-1} + M_1^{-1} M_2 M_0^{-1} M_3 M_1^{-1} & -M_1^{-1} M_2 M_0^{-1} \\ -M_0^{-1} M_3 M_1^{-1} & M_0^{-1} \end{pmatrix}, \tag{14}$$

where

$$M_0 = M_4 - M_3 M_1^{-1} M_2.$$

Applying Eq. (14) to Eq. (13), we have

$$\widehat{\alpha}(\lambda) = \widehat{A}(\widehat{h} - \lambda 1_b), \tag{15}$$

where $\widehat{A}$ is defined by

$$\widehat{A} = \widehat{H}^{-1} - \widehat{H}^{-1} \widehat{E}^\top (\widehat{E} \widehat{H}^{-1} \widehat{E}^\top)^{-1} \widehat{E} \widehat{H}^{-1}. \tag{16}$$

When the Lagrange multiplier vector satisfies

$$\xi^*_\ell(\lambda) > 0 \text{ for all } \ell \in \mathcal{A}, \tag{17}$$

we say that the *strict complementarity condition* is satisfied (Bertsekas et al., 2003). An important consequence of strict complementarity is that the optimal solution and the Lagrange multipliers of convex quadratic problems are uniquely determined. Then we have the following theorem.

Theorem 2 *Let P be the probability over all possible training samples of size n_{tr} and test samples of size n_{te}. Let $\xi^*(\lambda)$ be the Lagrange multiplier vector of the problem* (7) *and suppose $\xi^*(\lambda)$ satisfies the strict complementarity condition* (17). *Then, there exists a positive constant $c > 0$ and a natural number N such that for $\min\{n_{\mathrm{tr}}, n_{\mathrm{te}}\} \geq N$,*

$$P(\widehat{\mathcal{A}} \neq \mathcal{A}) < e^{-c \min\{n_{\mathrm{tr}}, n_{\mathrm{te}}\}}.$$

The proof of the above theorem is given in Appendix B. Theorem 2 shows that the probability that the active set $\widehat{\mathcal{A}}$ of the empirical problem (6) is different from the active set $\mathcal{A}$ of the ideal problem (7) is exponentially small. Thus we may regard $\widehat{\mathcal{A}} = \mathcal{A}$ in practice.

Let A be the 'ideal' counterpart of $\widehat{A}$:

$$A = H^{-1} - H^{-1} E^\top (E H^{-1} E^\top)^{-1} E H^{-1},$$

and let $C_{w,w'}$ be the $b \times b$ covariance matrix with the (ℓ, ℓ')-th element being the covariance between $w(x)\varphi_\ell(x)$ and $w'(x)\varphi_{\ell'}(x)$ under $p_{\mathrm{tr}}(x)$. Let

$$w^*(x) = \sum_{\ell=1}^{b} \alpha^*_\ell(\lambda) \varphi_\ell(x),$$

$$v(x) = \sum_{\ell=1}^{b} [A 1_b]_\ell \varphi_\ell(x).$$

Let

$$f(n) = \omega(g(n))$$

denote that $f(n)$ asymptotically dominates $g(n)$; more precisely, for all $C > 0$, there exists n_0 such that

$$|Cg(n)| < |f(n)| \quad \text{for all } n > n_0.$$

Then we have the following theorem.

Theorem 3 *Assume that*

(a) *The optimal solution of the problem* (7) *satisfies the strict complementarity condition* (17).

(b) n_{tr} *and* n_{te} *satisfy*

$$n_{\mathrm{te}} = \omega(n_{\mathrm{tr}}^2). \tag{18}$$

Then, for any $\lambda \geq 0$*, we have*

$$\mathbb{E}[J(\widehat{\alpha}(\lambda))] = J(\alpha^*(\lambda)) + \frac{1}{2n_{\mathrm{tr}}}\mathrm{tr}(A(C_{w^*,w^*} - 2\lambda C_{w^*,v})) + o\left(\frac{1}{n_{\mathrm{tr}}}\right). \tag{19}$$

The proof of the above theorem is given in Appendix C. This theorem elucidates the learning curve of LSIF up to the order of n_{tr}^{-1}. In Section 2.4.1, we discuss practical implications of this theorem.

2.4 Model Selection for LSIF

The practical performance of LSIF depends on the choice of the regularization parameter λ and basis functions $\{\varphi_\ell(x)\}_{\ell=1}^b$ (which we refer to as a *model*). Since our objective is to minimize the cost function J defined in Eq. (2), it is natural to determine the model such that J is minimized.

However, the value of the cost function J is inaccessible since it includes the expectation over unknown probability density functions $p_{\mathrm{tr}}(x)$ and $p_{\mathrm{te}}(x)$. The value of the empirical cost $\widehat{J}$ may be regarded as an estimate of J, but this is not useful for model selection purposes since it is heavily biased—the bias is caused by the fact that the same samples are used twice for learning the parameter α and estimating the value of J. Below, we give two practical methods of estimating the value of J in more precise ways.

2.4.1 INFORMATION CRITERION

In the same way as Theorem 3, we can obtain an asymptotic expansion of the empirical cost $\mathbb{E}\left[\widehat{J}(\widehat{\alpha}(\lambda))\right]$ as follows:

$$\mathbb{E}[\widehat{J}(\widehat{\alpha}(\lambda))] = J(\alpha^*(\lambda)) - \frac{1}{2n_{\mathrm{tr}}}\mathrm{tr}(A(C_{w^*,w^*} + 2\lambda C_{w^*,v})) + o\left(\frac{1}{n_{\mathrm{tr}}}\right). \tag{20}$$

Combining Eqs. (19) and (20), we have

$$\mathbb{E}[J(\widehat{\alpha}(\lambda))] = \mathbb{E}[\widehat{J}(\widehat{\alpha}(\lambda))] + \frac{1}{n_{\mathrm{tr}}}\mathrm{tr}(AC_{w^*,w^*}) + o\left(\frac{1}{n_{\mathrm{tr}}}\right).$$

From this, we can immediately obtain an *information criterion* (Akaike, 1974; Konishi and Kitagawa, 1996) for LSIF:

$$\widehat{J}^{(\mathrm{IC})} = \widehat{J}(\widehat{\alpha}(\lambda)) + \frac{1}{n_{\mathrm{tr}}}\mathrm{tr}(\widehat{A}\widehat{C}_{\widehat{w},\widehat{w}}),$$

where $\widehat{A}$ is defined by Eq. (16). $\widehat{E}$ is defined by Eq. (8) and $\widehat{C}_{w,w'}$ is the $b \times b$ covariance matrix with the (ℓ, ℓ')-th element being the covariance between $w(x)\varphi_\ell(x)$ and $w'(x)\varphi_{\ell'}(x)$ over $\{x_i^{\mathrm{tr}}\}_{i=1}^{n_{\mathrm{tr}}}$. Since $\widehat{A}$ and $\widehat{C}_{\widehat{w},\widehat{w}}$ are consistent estimators of A and C_{w^*,w^*}, the above information criterion is unbiased up to the order of n_{tr}^{-1}.

Note that the term $\mathrm{tr}(\widehat{A}\widehat{C}_{\widehat{w},\widehat{w}})$ may be interpreted as the *effective dimension* of the model (Moody, 1992). Indeed, when $\widehat{w}(x) = 1$, we have $\widehat{H} = \widehat{C}_{\widehat{w},\widehat{w}}$ and thus

$$\mathrm{tr}(\widehat{A}\widehat{C}_{\widehat{w},\widehat{w}}) = \mathrm{tr}(I_b) - \mathrm{tr}(E\widehat{C}_{\widehat{w},\widehat{w}}^{-1}E^\top(E\widehat{C}_{\widehat{w},\widehat{w}}^{-1}E^\top)^{-1}) = b - |\widehat{\mathcal{A}}|,$$

which is the dimension of the *face* on which $\widehat{\alpha}(\lambda)$ lies.

2.4.2 CROSS-VALIDATION

Although the information criterion derived above is more accurate than just a naive empirical estimator, its accuracy is guaranteed only asymptotically. Here, we employ cross-validation for estimating $J(\widehat{\alpha})$, which has an accuracy guarantee for finite samples.

First, the training samples $\{x_i^{\mathrm{tr}}\}_{i=1}^{n_{\mathrm{tr}}}$ and test samples $\{x_j^{\mathrm{te}}\}_{j=1}^{n_{\mathrm{te}}}$ are divided into R disjoint subsets $\{\mathcal{X}_r^{\mathrm{tr}}\}_{r=1}^{R}$ and $\{\mathcal{X}_r^{\mathrm{te}}\}_{r=1}^{R}$, respectively. Then an importance estimate $\widehat{w}_{\mathcal{X}_r^{\mathrm{tr}},\mathcal{X}_r^{\mathrm{te}}}(x)$ is obtained using $\{\mathcal{X}_j^{\mathrm{tr}}\}_{j\neq r}$ and $\{\mathcal{X}_j^{\mathrm{te}}\}_{j\neq r}$ (that is, without $\mathcal{X}_r^{\mathrm{tr}}$ and $\mathcal{X}_r^{\mathrm{te}}$), and the cost J is approximated using the held-out samples $\mathcal{X}_r^{\mathrm{tr}}$ and $\mathcal{X}_r^{\mathrm{te}}$ as

$$\widehat{J}^{(\mathrm{CV})}_{\mathcal{X}_r^{\mathrm{tr}},\mathcal{X}_r^{\mathrm{te}}} = \frac{1}{2|\mathcal{X}_r^{\mathrm{tr}}|}\sum_{x^{\mathrm{tr}}\in\mathcal{X}_r^{\mathrm{tr}}} \widehat{w}_{\mathcal{X}_r^{\mathrm{tr}},\mathcal{X}_r^{\mathrm{te}}}(x^{\mathrm{tr}})^2 - \frac{1}{|\mathcal{X}_r^{\mathrm{te}}|}\sum_{x^{\mathrm{te}}\in\mathcal{X}_r^{\mathrm{te}}} \widehat{w}_{\mathcal{X}_r^{\mathrm{tr}},\mathcal{X}_r^{\mathrm{te}}}(x^{\mathrm{te}}).$$

This procedure is repeated for $r = 1,2,\ldots,R$ and its average $\widehat{J}^{(\mathrm{CV})}$ is used as an estimate of J:

$$\widehat{J}^{(\mathrm{CV})} = \frac{1}{R}\sum_{r=1}^{R}\widehat{J}^{(\mathrm{CV})}_{\mathcal{X}_r^{\mathrm{tr}},\mathcal{X}_r^{\mathrm{te}}}.$$

We can show that $\widehat{J}^{(\mathrm{CV})}$ gives an almost unbiased estimate of the true cost J, where the ‘almost’-ness comes from the fact that the number of samples is reduced in the cross-validation procedure due to data splitting (Luntz and Brailovsky, 1969; Wahba, 1990; Schölkopf and Smola, 2002).

Cross-validation would be more accurate than the information criterion for finite samples. However, it is computationally more expensive than the information criterion since the learning procedure should be repeated R times.

2.5 Heuristics of Basis Function Design for LSIF

A good model may be chosen by cross-validation or the information criterion, given that a family of promising model candidates is prepared. As model candidates, we propose using a Gaussian kernel model centered at the *test* points $\{x_j^{\mathrm{te}}\}_{j=1}^{n_{\mathrm{te}}}$, that is,

$$\widehat{w}(x) = \sum_{\ell=1}^{n_{\mathrm{te}}}\alpha_\ell K_\sigma(x, x_\ell^{\mathrm{te}}),$$

where $K_\sigma(x,x')$ is the Gaussian kernel with kernel width σ:

$$K_\sigma(x,x') = \exp\left(-\frac{\|x-x'\|^2}{2\sigma^2}\right). \tag{21}$$

The reason why we chose the test points $\{x_j^{\mathrm{te}}\}_{j=1}^{n_{\mathrm{te}}}$ as the Gaussian centers, not the training points $\{x_i^{\mathrm{tr}}\}_{i=1}^{n_{\mathrm{tr}}}$, is as follows (Sugiyama et al., 2008b). By definition, the importance $w(x)$ tends to take large values if the training density $p_{\mathrm{tr}}(x)$ is small and the test density $p_{\mathrm{te}}(x)$ is large; conversely, $w(x)$ tends to be small (that is, close to zero) if $p_{\mathrm{tr}}(x)$ is large and $p_{\mathrm{te}}(x)$ is small. When a function is approximated by a Gaussian kernel model, many kernels may be needed in the region where the output of the target function is large; on the other hand, only a small number of kernels would be enough in the region where the output of the target function is close to zero. Following this heuristic, we allocate many kernels at high *test* density regions, which can be achieved by setting the Gaussian centers at the test points $\{x_j^{\mathrm{te}}\}_{j=1}^{n_{\mathrm{te}}}$.

Alternatively, we may locate $(n_{\mathrm{tr}}+n_{\mathrm{te}})$ Gaussian kernels at both $\{x_i^{\mathrm{tr}}\}_{i=1}^{n_{\mathrm{tr}}}$ and $\{x_j^{\mathrm{te}}\}_{j=1}^{n_{\mathrm{te}}}$. However, in our preliminary experiments, this did not further improve the performance, but just slightly increased the computational cost. When n_{te} is large, just using all the test points $\{x_j^{\mathrm{te}}\}_{j=1}^{n_{\mathrm{te}}}$ as Gaussian centers is already computationally rather demanding. To ease this problem, we practically propose using a subset of $\{x_j^{\mathrm{te}}\}_{j=1}^{n_{\mathrm{te}}}$ as Gaussian centers for computational efficiency, that is,

$$\widehat{w}(x) = \sum_{\ell=1}^{b} \alpha_\ell K_\sigma(x, c_\ell), \tag{22}$$

where $c_\ell,\ \ell = 1, 2, \ldots, b$ are template points randomly chosen from $\{x_j^{\mathrm{te}}\}_{j=1}^{n_{\mathrm{te}}}$ without replacement and $b\ (\leq n_{\mathrm{te}})$ is a prefixed number. In the rest of this paper, we usually fix the number of template points at

$$b = \min(100, n_{\mathrm{te}}),$$

and optimize the kernel width σ and the regularization parameter λ by cross-validation with grid search.

2.6 Entire Regularization Path for LSIF

We can show that the LSIF solution $\widehat{\alpha}$ is piecewise linear with respect to the regularization parameter λ (see Appendix D). Therefore, the *regularization path* (that is, solutions for all λ) can be computed efficiently based on the *parametric optimization technique* (Best, 1982; Efron et al., 2004; Hastie et al., 2004).

A basic idea of regularization path tracking is to check violation of the KKT conditions—which are necessary and sufficient for optimality of convex programs—when the regularization parameter λ is changed. The KKT conditions of LSIF are summarized in Section 2.3. The strict complementarity condition (17) assures the uniqueness of the optimal solution for a fixed λ, and thus the uniqueness of the regularization path. A pseudo code of the regularization path tracking algorithm for LSIF is described in Figure 1—its detailed derivation is summarized in Appendix D. Thanks to the regularization path algorithm, LSIF is computationally efficient in model selection scenarios.

The pseudo code implies that we no longer need a quadratic programming solver for obtaining the solution of LSIF—just computing matrix inverses is enough. Furthermore, the regularization path algorithm is computationally more efficient when the solution is sparse, that is, most of the elements are zero since the number of change points tends to be small for such sparse solutions.

Even though the regularization path tracking algorithm is computationally efficient, it tends to be numerically unreliable, as we experimentally show in Section 4. This numerical instability is caused by near singularity of the matrix $\widehat{G}$. When $\widehat{G}$ is nearly singular, it is not easy to accurately obtain the solutions u, v in Figure 1, and therefore the change point $\lambda_{\tau+1}$ cannot be accurately computed. As a result, we cannot accurately update the active set of the inequality constraints and thus

```
**Input:** $\widehat{H}$ and $\widehat{h}$    % see Eqs. (4) and (5) for the definitions
**Output:** entire regularization path $\widehat{\alpha}(\lambda)$ for $\lambda \geq 0$

$\tau \longleftarrow 0$;
$k \longleftarrow \mathrm{argmax}_i\{\widehat{h}_i \mid i = 1,2,\ldots,b\}$;
$\lambda_\tau \longleftarrow \widehat{h}_k$;
$\widehat{\mathcal{A}} \longleftarrow \{1,2,\ldots,b\}\backslash\{k\}$;
$\widehat{\alpha}(\lambda_\tau) \longleftarrow 0_b$;    % the vector with all zeros
While $\lambda_\tau > 0$
    $\widehat{E} \longleftarrow O_{|\widehat{\mathcal{A}}|\times b}$;    % the matrix with all zeros
    For $i = 1,2,\ldots,|\widehat{\mathcal{A}}|$
        $\widehat{E}_{i,\widehat{j}_i} \longleftarrow 1$;  % $\widehat{\mathcal{A}} = \{\widehat{j}_1, \widehat{j}_2, \ldots, \widehat{j}_{|\widehat{\mathcal{A}}|} \mid \widehat{j}_1 < \widehat{j}_2 < \cdots < \widehat{j}_{|\widehat{\mathcal{A}}|}\}$
    end
    $\widehat{G} \longleftarrow \begin{pmatrix} \widehat{H} & -\widehat{E}^\top \\ -\widehat{E} & O_{|\widehat{\mathcal{A}}|\times|\widehat{\mathcal{A}}|} \end{pmatrix}$;
    $u \longleftarrow \widehat{G}^{-1}\begin{pmatrix} \widehat{h} \\ 0_{|\widehat{\mathcal{A}}|} \end{pmatrix}$;
    $v \longleftarrow \widehat{G}^{-1}\begin{pmatrix} 1_b \\ 0_{|\widehat{\mathcal{A}}|} \end{pmatrix}$;
    If $v \leq 0_{b+|\widehat{\mathcal{A}}|}$   % the final interval
        $\lambda_{\tau+1} \longleftarrow 0$;
        $\widehat{\alpha}(\lambda_{\tau+1}) \longleftarrow (u_1, u_2, \ldots, u_b)^\top$;
    else   % an intermediate interval
        $k \longleftarrow \mathrm{argmax}_i\{u_i/v_i \mid v_i > 0,\ i = 1,2,\ldots,b+|\widehat{\mathcal{A}}|\}$;
        $\lambda_{\tau+1} \longleftarrow \max\{0, u_k/v_k\}$;
        $\widehat{\alpha}(\lambda_{\tau+1}) \longleftarrow (u_1, u_2, \ldots, u_b)^\top - \lambda_{\tau+1}(v_1, v_2, \ldots, v_b)^\top$;
        If $1 \leq k \leq b$
            $\widehat{\mathcal{A}} \longleftarrow \widehat{\mathcal{A}} \cup \{k\}$;
        else
            $\widehat{\mathcal{A}} \longleftarrow \widehat{\mathcal{A}}\backslash\{\widehat{j}_{k-b}\}$;
        end
    end
    $\tau \longleftarrow \tau + 1$;
end
$\widehat{\alpha}(\lambda) \longleftarrow \begin{cases} 0_b & \text{if } \lambda \geq \lambda_0 \\ \frac{\lambda_{\tau+1}-\lambda}{\lambda_{\tau+1}-\lambda_\tau}\widehat{\alpha}(\lambda_\tau) + \frac{\lambda-\lambda_\tau}{\lambda_{\tau+1}-\lambda_\tau}\widehat{\alpha}(\lambda_{\tau+1}) & \text{if } \lambda_{\tau+1} \leq \lambda \leq \lambda_\tau \end{cases}$
```

Figure 1: Pseudo code for computing the entire regularization path of LSIF. When the computation of $\widehat{G}^{-1}$ is numerically unstable, we may add small positive diagonals to $\widehat{H}$ for stabilization purposes.

the obtained solution $\widehat{\alpha}(\lambda)$ becomes unreliable; furthermore, such numerical error tends to be accumulated through the path-tracking process. This instability issue seems to be a common pitfall of solution path tracking algorithms in general (see Scheinberg, 2006).

When the Gaussian width σ is very small or very large, the matrix $\widehat{H}$ tends to be nearly singular and thus the matrix $\widehat{G}$ also becomes nearly singular. On the other hand, when the Gaussian width σ is not too small or too large compared with the dispersion of samples, the matrix $\widehat{G}$ is well-conditioned and therefore the path-following algorithm would be stable and reliable.

3. Approximation Algorithm

Within the quadratic programming formulation, we have proposed a new importance estimation procedure LSIF and showed its theoretical properties. We also gave a regularization path tracking algorithm that can be computed efficiently. However, as we experimentally show in Section 4, it tends to suffer from a numerical problem and therefore is not practically reliable. In this section, we give a practical alternative to LSIF which gives an approximate solution to LSIF in a computationally efficient and reliable manner.

3.1 Unconstrained Least-squares Formulation

The approximation idea we introduce here is very simple: we ignore the non-negativity constraint of the parameters in the optimization problem (6). This results in the following unconstrained optimization problem.

$$\min_{\beta \in \mathbb{R}^b} \left[\frac{1}{2}\beta^\top \widehat{H}\beta - \widehat{h}^\top \beta + \frac{\lambda}{2}\beta^\top \beta \right]. \tag{23}$$

In the above, we included a quadratic regularization term $\beta^\top\beta/2$, instead of the linear one $1_b^\top \beta$ since the linear penalty term does not work as a regularizer without the non-negativity constraint. Eq. (23) is an unconstrained convex quadratic program, so the solution can be analytically computed as

$$\widetilde{\beta}(\lambda) = (\widehat{H} + \lambda I_b)^{-1}\widehat{h},$$

where I_b is the b-dimensional identity matrix. Since we dropped the non-negativity constraint $\beta \geq 0_b$, some of the learned parameters could be negative. To compensate for this approximation error, we modify the solution by

$$\widehat{\beta}(\lambda) = \max(0_b, \widetilde{\beta}(\lambda)),$$

where the 'max' operation for a pair of vectors is applied in the element-wise manner. This is the solution of the approximation method we propose in this section.

An advantage of the above unconstrained formulation is that the solution can be computed just by solving a system of linear equations. Therefore, its computation is stable when λ is not too small. We call this method *unconstrained LSIF* (uLSIF). Due to the ℓ_2 regularizer, the solution tends to be close to 0_b to some extent. Thus, the effect of ignoring the non-negativity constraint may not be so strong—later, we analyze the approximation error both theoretically and experimentally in more detail in Sections 3.3 and 4.5.

Note that LSIF and uLSIF differ only in parameter learning. Thus, the basis design heuristic of LSIF given in Section 2.5 is also valid for uLSIF.

3.2 Convergence Analysis of uLSIF

Here, we theoretically analyze the convergence property of the solution $\widehat{\beta}(\lambda)$ of the uLSIF algorithm; practitioners may skip Sections 3.2 and 3.3.

Let $\beta^{\circ}(\lambda)$ be the optimal solution of the 'ideal' version of the problem (23):

$$\min_{\beta \in \mathbb{R}^b} \left[\frac{1}{2}\beta^\top H \beta - h^\top \beta + \frac{\lambda}{2}\beta^\top \beta \right].$$

Then the ideal solution $\beta^*(\lambda)$ is given by

$$\begin{aligned} \beta^*(\lambda) &= \max(0_b, \beta^{\circ}(\lambda)), \\ \beta^{\circ}(\lambda) &= B_\lambda^{-1} h, \\ B_\lambda &= H + \lambda I_b. \end{aligned} \tag{24}$$

Below, we theoretically investigate the learning curve of uLSIF.

Let $\mathcal{B} \subset \{1, 2, \ldots, b\}$ be the set of negative indices of $\beta^{\circ}(\lambda)$, that is,

$$\mathcal{B} = \{\ell \mid \beta^{\circ}_\ell(\lambda) < 0,\ \ell = 1, 2, \ldots, b\},$$

and $\widetilde{\mathcal{B}} \subset \{1, 2, \ldots, b\}$ be the set of negative indices of $\widetilde{\beta}(\lambda)$, that is,

$$\widetilde{\mathcal{B}} = \{\ell \mid \widetilde{\beta}_\ell(\lambda) < 0,\ \ell = 1, 2, \ldots, b\}.$$

Then we have the following theorem.

Theorem 4 *Assume that $\beta^{\circ}_\ell(\lambda) \neq 0$ for $\ell = 1, 2, \ldots, b$. Then, there exists a positive constant c and a natural number N such that for $\min\{n_{\mathrm{tr}}, n_{\mathrm{te}}\} \geq N$,*

$$P(\mathcal{B} \neq \widetilde{\mathcal{B}}) < e^{-c \min\{n_{\mathrm{tr}}, n_{\mathrm{te}}\}}.$$

The proof of the above theorem is given in Appendix E. The assumption that $\beta^{\circ}_\ell(\lambda) \neq 0$ for $\ell = 1, 2, \ldots, b$ corresponds to the strict complementarity condition (17) in LSIF. Theorem 4 shows that the probability that $\widetilde{\mathcal{B}}$ is different from $\mathcal{B}$ is exponentially small. Thus we may regard $\widetilde{\mathcal{B}} = \mathcal{B}$ in practice.

Let D be the b-dimensional diagonal matrix with the ℓ-th diagonal element

$$D_{\ell,\ell} = \begin{cases} 0 & \ell \in \mathcal{B}, \\ 1 & \text{otherwise.} \end{cases}$$

Let

$$\begin{aligned} w^{\circ}(x) &= \sum_{\ell=1}^{b} \beta^{\circ}_\ell(\lambda) \varphi_\ell(x), \\ u(x) &= \sum_{\ell=1}^{b} [B_\lambda^{-1} D (H\beta^*(\lambda) - h)]_\ell \varphi_\ell(x). \end{aligned}$$

Then we have the following theorem.

Theorem 5 *Assume that*

(a) $\beta^{\circ}_{\ell}(\lambda) \neq 0$ *for* $\ell = 1, 2, \ldots, b$.

(b) n_{tr} *and* n_{te} *satisfy Eq.* (18).

Then, for any $\lambda \geq 0$, *we have*

$$\mathbb{E}[J(\widehat{\beta}(\lambda))] = J(\beta^*(\lambda)) + \frac{1}{2n_{\mathrm{tr}}}\mathrm{tr}(B_{\lambda}^{-1}DHDB_{\lambda}^{-1}C_{w^{\circ},w^{\circ}} + 2B_{\lambda}^{-1}C_{w^{\circ},u}) + o\left(\frac{1}{n_{\mathrm{tr}}}\right). \tag{25}$$

The proof of the above theorem is given in Appendix F. Theorem 5 elucidates the learning curve of uLSIF up to the order of n_{tr}^{-1}. An information criterion may be obtained in the same way as Section 2.4.1. However, as shown in Section 3.4, we can have a closed-form expression of the leave-one-out cross-validation score for uLSIF, which would be practically more useful. For this reason, we do not go into the detail of information criterion.

3.3 Approximation Error Bounds for uLSIF

The uLSIF method is introduced as an approximation of LSIF. Here, we theoretically evaluate the difference between the uLSIF solution $\widehat{\beta}(\lambda)$ and the LSIF solution $\widehat{\alpha}(\lambda)$. More specifically, we use the following normalized L_2-norm on the training samples as the difference measure and derive its upper bounds:

$$\mathrm{diff}(\lambda) = \frac{\inf_{\lambda' \geq 0}\sqrt{\frac{1}{n_{\mathrm{tr}}}\sum_{i=1}^{n_{\mathrm{tr}}}\left(\widehat{w}(x_i^{\mathrm{tr}};\widehat{\alpha}(\lambda')) - \widehat{w}(x_i^{\mathrm{tr}};\widehat{\beta}(\lambda))\right)^2}}{\sum_{i=1}^{n_{\mathrm{tr}}}\widehat{w}(x_i^{\mathrm{tr}};\widehat{\beta}(\lambda))}, \tag{26}$$

where the importance function $\widehat{w}(x;\alpha)$ is given by

$$\widehat{w}(x;\alpha) = \sum_{\ell=1}^{b}\alpha_{\ell}\varphi_{\ell}(x).$$

In the theoretical analysis below, we assume

$$\sum_{i=1}^{n_{\mathrm{tr}}}\widehat{w}(x_i^{\mathrm{tr}};\widehat{\beta}(\lambda)) \neq 0.$$

For $p \in \mathbb{N} \cup \{\infty\}$, let $\|\cdot\|_p$ be the L_p-norm, and let $\|\alpha\|_{\widehat{H}}$ be

$$\|\alpha\|_{\widehat{H}} = \sqrt{\alpha^{\top}\widehat{H}\alpha}, \tag{27}$$

where $\widehat{H}$ is the $b \times b$ matrix defined by Eq. (4). Then we have the following theorem.

Theorem 6 (Norm bound) *Assume that all basis functions satisfy*

$$0 < \varphi_{\ell}(x) \leq 1.$$

Then we have

$$\begin{aligned} \mathrm{diff}(\lambda) &\le \frac{\|\widehat{\beta}(\lambda)\|_{\widehat{H}}}{\sum_{i=1}^{n_{\mathrm{tr}}} \widehat{w}(x_i^{\mathrm{tr}};\widehat{\beta}(\lambda))} && (28)\\ &\le b^2\left(1+\frac{b}{\lambda}\right)\frac{1}{\min_\ell \sum_{i=1}^{n_{\mathrm{tr}}}\varphi_\ell(x_i^{\mathrm{tr}})}\cdot\frac{n_{\mathrm{te}}}{\min_\ell \sum_{j=1}^{n_{\mathrm{te}}}\varphi_\ell(x_j^{\mathrm{te}})}, && (29)\end{aligned}$$

where b is the number of basis functions. The upper bound (29) *is reduced as the regularization parameter λ increases. For the Gaussian basis function model* (22)*, the upper bound (29) is reduced as the Gaussian width σ increases.*

The proof of the above theorem is given in Appendix G. We call Eq. (28) the *norm bound* since it is governed by the norm of $\widehat{\beta}$. Intuitively, the approximation error of uLSIF would small if λ is large since $\widetilde{\beta} \ge 0$ may not be severely violated due to the strong regularization effect. The upper bound (29) justifies this intuitive claim since the error bound tends to be small if the regularization parameter λ is large. Furthermore, the upper bound (29) shows that for the Gaussian basis function model (22), the error bound tends to be small if the Gaussian width σ is large. This is also intuitive since the Gaussian basis functions are nearly flat when the Gaussian width σ is large—a difference in parameters does not cause a significant change in the learned importance function $\widehat{w}(x)$. From the above theorem, we expect that uLSIF is a nice approximation of LSIF when λ is large and σ is large. In Section 4.5, we numerically investigate this issue.

Below, we give a more sophisticated bound on $\mathrm{diff}(\lambda)$. To this end, let us introduce an intermediate optimization problem defined by

$$\begin{aligned} &\min_{\gamma\in\mathbb{R}^b}\left[\frac{1}{2}\gamma^\top\widehat{H}\gamma - \widehat{h}^\top\gamma + \frac{\lambda}{2}\gamma^\top\gamma\right] \\ &\text{subject to } \gamma \ge 0_b, \qquad (30)\end{aligned}$$

which we refer to as *LSIF with quadratic penalty* (LSIFq). LSIFq bridges LSIF and uLSIF since the 'goodness-of-fit' part is the same as LSIF but the 'regularization' part is the same as uLSIF. Let $\widehat{\gamma}(\lambda)$ be the optimal solution of LSIFq (30). Based on the solution of LSIFq, we have the following upper bound.

Theorem 7 (Bridge bound) *For any $\lambda \ge 0$, the following inequality holds:*

$$\mathrm{diff}(\lambda) \le \frac{\sqrt{\lambda\left(\|\widehat{\gamma}(\lambda)\|_1\cdot\|\widehat{\gamma}(\lambda)\|_\infty - \|\widehat{\gamma}(\lambda)\|_2^2\right)} + \|\widehat{\gamma}(\lambda)-\widehat{\beta}(\lambda)\|_{\widehat{H}}}{\sum_{i=1}^{n_{\mathrm{tr}}}\widehat{w}(x_i^{\mathrm{tr}};\widehat{\beta}(\lambda))}. \qquad (31)$$

The proof of the above theorem is given in Appendix H. We call the above bound the *bridge bound* since the bridged estimator $\widehat{\gamma}(\lambda)$ plays a central role in the bound. Note that, in the bridge bound, the inside of the square root is assured to be non-negative due to Hölder's inequality (see Appendix H for detail). The bridge bound is generally much sharper than the norm bound (28), but not always (see Section 4.5 for numerical examples).

3.4 Efficient Computation of Leave-one-out Cross-validation Score for uLSIF

A practically important advantage of uLSIF over LSIF is that the score of leave-one-out cross-validation (LOOCV) can be computed analytically—thanks to this property, the computational complexity for performing LOOCV is the same order as just computing a single solution.

In the current setup, we are given two sets of samples, $\{x_i^{\mathrm{tr}}\}_{i=1}^{n_{\mathrm{tr}}}$ and $\{x_j^{\mathrm{te}}\}_{j=1}^{n_{\mathrm{te}}}$, which generally have different sample size. For simplicity, we assume that $n_{\mathrm{tr}} < n_{\mathrm{te}}$ and the i-th training sample x_i^{tr} and the i-th test sample x_i^{te} are held out at the same time; the test samples $\{x_j^{\mathrm{te}}\}_{j=n_{\mathrm{tr}}+1}^{n_{\mathrm{te}}}$ are always used for importance estimation. Note that this assumption is only for the sake of simplicity; we can change the order of test samples without sacrificing the computational advantages.

Let $\widehat{w}^{(i)}(x)$ be an estimate of the importance obtained without the i-th training sample x_i^{tr} and the i-th test sample x_i^{te}. Then the LOOCV score is expressed as

$$\mathrm{LOOCV} = \frac{1}{n_{\mathrm{tr}}} \sum_{i=1}^{n_{\mathrm{tr}}} \left[\frac{1}{2} (\widehat{w}^{(i)}(x_i^{\mathrm{tr}}))^2 - \widehat{w}^{(i)}(x_i^{\mathrm{te}}) \right]. \tag{32}$$

Our approach to efficiently computing the LOOCV score is to use the *Sherman-Woodbury-Morrison formula* (Golub and Loan, 1996) for computing matrix inverses: for an invertible square matrix A and vectors u and v such that $v^\top A^{-1} u \neq -1$,

$$(A + uv^\top)^{-1} = A^{-1} - \frac{A^{-1} u v^\top A^{-1}}{1 + v^\top A^{-1} u}. \tag{33}$$

Efficient approximation schemes of LOOCV have often been investigated under asymptotic setups (Stone, 1974; Hansen and Larsen, 1996). On the other hand, we provide the exact LOOCV score of uLSIF, which follows the same line as that of ridge regression (Hoerl and Kennard, 1970; Wahba, 1990).

A pseudo code of uLSIF with LOOCV-based model selection is summarized in Figure 2—its detailed derivation is described in Appendix I. Note that the basis-function design heuristic given in Section 2.5 is used in the pseudo code, but the analytic form of the LOOCV score is available for any basis functions.

4. Illustrative Examples

In this section, we illustrate the behavior of LSIF and uLSIF using a toy data set.

4.1 Setup

Let the dimension of the domain be $d = 1$ and the training and test densities be

$$p_{\mathrm{tr}}(x) = \mathcal{N}(x; 1, (1/2)^2),$$
$$p_{\mathrm{te}}(x) = \mathcal{N}(x; 2, (1/4)^2),$$

where $\mathcal{N}(x; \mu, \sigma^2)$ denotes the Gaussian density with mean μ and variance σ^2. These densities are depicted in Figure 3. The task is to estimate the importance $w(x) = p_{\mathrm{te}}(x)/p_{\mathrm{tr}}(x)$.

```
Input: $\{x_i^{\mathrm{tr}}\}_{i=1}^{n_{\mathrm{tr}}}$ and $\{x_j^{\mathrm{te}}\}_{j=1}^{n_{\mathrm{te}}}$
Output: $\widehat{w}(x)$

$b \longleftarrow \min(100, n_{\mathrm{te}})$;    $n \longleftarrow \min(n_{\mathrm{tr}}, n_{\mathrm{te}})$;
Randomly choose $b$ centers $\{c_\ell\}_{\ell=1}^{b}$ from $\{x_j^{\mathrm{te}}\}_{j=1}^{n_{\mathrm{te}}}$ without replacement;
For each candidate of Gaussian width $\sigma$
    $\widehat{H}_{\ell,\ell'} \longleftarrow \frac{1}{n_{\mathrm{tr}}}\sum_{i=1}^{n_{\mathrm{tr}}}\exp\left(-\frac{\|x_i^{\mathrm{tr}}-c_\ell\|^2+\|x_i^{\mathrm{tr}}-c_{\ell'}\|^2}{2\sigma^2}\right)$ for $\ell,\ell'=1,2,\ldots,b$;
    $\widehat{h}_\ell \longleftarrow \frac{1}{n_{\mathrm{te}}}\sum_{j=1}^{n_{\mathrm{te}}}\exp\left(-\frac{\|x_j^{\mathrm{te}}-c_\ell\|^2}{2\sigma^2}\right)$ for $\ell=1,2,\ldots,b$;
    $X_{\ell,i}^{\mathrm{tr}} \longleftarrow \exp\left(-\frac{\|x_i^{\mathrm{tr}}-c_\ell\|^2}{2\sigma^2}\right)$ for $i=1,2,\ldots,n$ and $\ell=1,2,\ldots,b$;
    $X_{\ell,i}^{\mathrm{te}} \longleftarrow \exp\left(-\frac{\|x_i^{\mathrm{te}}-c_\ell\|^2}{2\sigma^2}\right)$ for $i=1,2,\ldots,n$ and $\ell=1,2,\ldots,b$;
    For each candidate of regularization parameter $\lambda$
        $\widehat{B} \longleftarrow \widehat{H}+\frac{\lambda(n_{\mathrm{tr}}-1)}{n_{\mathrm{tr}}}I_b$;
        $B_0 \longleftarrow \widehat{B}^{-1}\widehat{h}1_n^\top+\widehat{B}^{-1}X^{\mathrm{tr}}\,\mathrm{diag}\left(\frac{\widehat{h}^\top\widehat{B}^{-1}X^{\mathrm{tr}}}{n_{\mathrm{tr}}1_n^\top-1_b^\top(X^{\mathrm{tr}}*\widehat{B}^{-1}X^{\mathrm{tr}})}\right)$;
        $B_1 \longleftarrow \widehat{B}^{-1}X^{\mathrm{te}}+\widehat{B}^{-1}X^{\mathrm{tr}}\,\mathrm{diag}\left(\frac{1_b^\top(X^{\mathrm{te}}*\widehat{B}^{-1}X^{\mathrm{tr}})}{n_{\mathrm{tr}}1_n^\top-1_b^\top(X^{\mathrm{tr}}*\widehat{B}^{-1}X^{\mathrm{tr}})}\right)$;
        $B_2 \longleftarrow \max\left(O_{b\times n},\ \frac{n_{\mathrm{tr}}-1}{n_{\mathrm{tr}}(n_{\mathrm{te}}-1)}(n_{\mathrm{te}}B_0-B_1)\right)$;
        $w_{\mathrm{tr}} \longleftarrow (1_b^\top(X^{\mathrm{tr}}*B_2))^\top$;    $w_{\mathrm{te}} \longleftarrow (1_b^\top(X^{\mathrm{te}}*B_2))^\top$;
        $\mathrm{LOOCV}(\sigma,\lambda) \longleftarrow \frac{w_{\mathrm{tr}}^\top w_{\mathrm{tr}}}{2n}-\frac{1_n^\top w_{\mathrm{te}}}{n}$;
    end
end
$(\widehat{\sigma},\widehat{\lambda}) \longleftarrow \mathrm{argmin}_{(\sigma,\lambda)}\mathrm{LOOCV}(\sigma,\lambda)$;
$\widetilde{H}_{\ell,\ell'} \longleftarrow \frac{1}{n_{\mathrm{tr}}}\sum_{i=1}^{n_{\mathrm{tr}}}\exp\left(-\frac{\|x_i^{\mathrm{tr}}-c_\ell\|^2+\|x_i^{\mathrm{tr}}-c_{\ell'}\|^2}{2\widehat{\sigma}^2}\right)$ for $\ell,\ell'=1,2,\ldots,b$;
$\widetilde{h}_\ell \longleftarrow \frac{1}{n_{\mathrm{te}}}\sum_{j=1}^{n_{\mathrm{te}}}\exp\left(-\frac{\|x_j^{\mathrm{te}}-c_\ell\|^2}{2\widehat{\sigma}^2}\right)$ for $\ell=1,2,\ldots,b$;
$\widehat{\alpha} \longleftarrow \max(0_b,(\widetilde{H}+\widehat{\lambda}I_b)^{-1}\widetilde{h})$;
$\widehat{w}(x) \longleftarrow \sum_{\ell=1}^{b}\widehat{\alpha}_\ell\exp\left(-\frac{\|x-c_\ell\|^2}{2\widehat{\sigma}^2}\right)$;
```

Figure 2: Pseudo code of uLSIF algorithm with LOOCV. $B*B'$ denotes the element-wise multiplication of matrices B and B' of the same size, that is, the (i,j)-th element is given by $B_{i,j}B'_{i,j}$. For n-dimensional vectors b and b', $\mathrm{diag}\left(\frac{b}{b'}\right)$ denotes the $n\times n$ diagonal matrix with i-th diagonal element b_i/b'_i. A MATLAB® or R implementation of uLSIF is available from `http://sugiyama-www.cs.titech.ac.jp/~sugi/software/uLSIF/`.

4.2 Importance Estimation

First, we illustrate the behavior of LSIF and uLSIF in importance estimation. We set the number of training and test samples at $n_{\mathrm{tr}} = 200$ and $n_{\mathrm{te}} = 1000$, respectively. We use the Gaussian kernel model (22), and the number of basis functions is set at $b = 100$. The centers of the kernel function are randomly chosen from the test points $\{x_i^{\mathrm{te}}\}_{j=1}^{n_{\mathrm{te}}}$ without replacement (see Section 2.5).

We test different Gaussian widths σ and different regularization parameters λ. The following two setups are examined:

(A) λ is fixed at $\lambda = 0.2$ and σ is changed as $0.1 \leq \sigma \leq 1.0$,

(B) σ is fixed at $\sigma = 0.3$ and λ is changed as $0 \leq \lambda \leq 0.5$.

Figure 4 depicts the true importance and its estimates obtained by LSIF and uLSIF, where all importance functions are normalized so that $\int w(x)dx = 1$ for better comparison. Figures 4(a) and 4(b) show that the estimated importance $\widehat{w}(x)$ tends to be too peaky when the Gaussian width σ is small, while it tends to be overly smoothed when σ is large. If the Gaussian width is chosen appropriately, both LSIF and uLSIF seem to work reasonably well. As shown in Figures 4(c) and 4(d), the solutions of LSIF and uLSIF also significantly change when different regularization parameters λ are used. Again, given that the regularization parameter is chosen appropriately, both LSIF and uLSIF tend to perform well.

From the graphs, we also observe that model selection based on cross-validation works reasonably well for both LSIF (5-fold) and uLSIF (leave-one-out) to choose appropriate values of the Gaussian width or the regularization parameter; this will be analyzed in more detail in Section 4.4.

4.3 Regularization Path

Next, we illustrate how the regularization path tracking algorithm for LSIF behaves. We set the number of training and test samples at $n_{\mathrm{tr}} = 50$ and $n_{\mathrm{te}} = 100$, respectively. For better illustration, we set the number of basis functions at a small value as $b = 30$ in the Gaussian kernel model (22) and use the Gaussian kernels centered at equidistant points in $[0, 3]$ as basis functions.

We use the algorithm described in Figure 1 for regularization path tracking. Theoretically, the inequality $\lambda_{\tau+1} < \lambda_\tau$ is assured. In numerical computation, however, the inequality is occasionally violated. In order to avoid this numerical problem, we slightly regularize $\widehat{H}$ for stabilization (see also the caption of Figure 1).

Figure 5 depicts the values of the estimated coefficients $\{\alpha_\ell\}_{\ell=1}^{b}$ as functions of $\|\alpha\|_1$ for $\sigma = 0.1, 0.3$, and 0.5. Note that small $\|\alpha\|_1$ corresponds to large λ. The figure indicates that the regularization parameter λ works as a sparseness controlling factor of the solution, that is, the larger (smaller) the value of λ ($\|\alpha\|_1$) is, the sparser the solution is.

The path following algorithm is computationally efficient and therefore practically very attractive. However, as the above experiments illustrate, the path following algorithm is numerically rather unstable. Modification of $\widehat{H}$ can ease to solve this problem, but this in turn results in accumulating numerical errors through the path tracking process. Consequently, the solutions for small λ tend to be inaccurate. This problem becomes prominent if the number of change points in the regularization path is large.

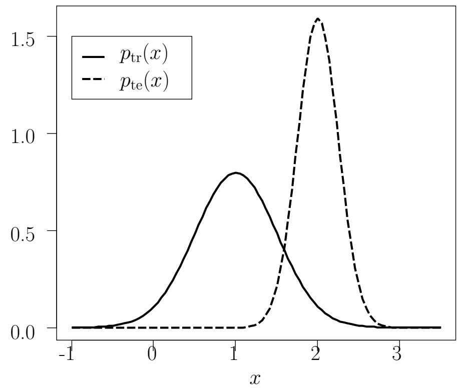

Figure 3: The solid line is the probability density of training data, and the dashed line is the probability density of test data.

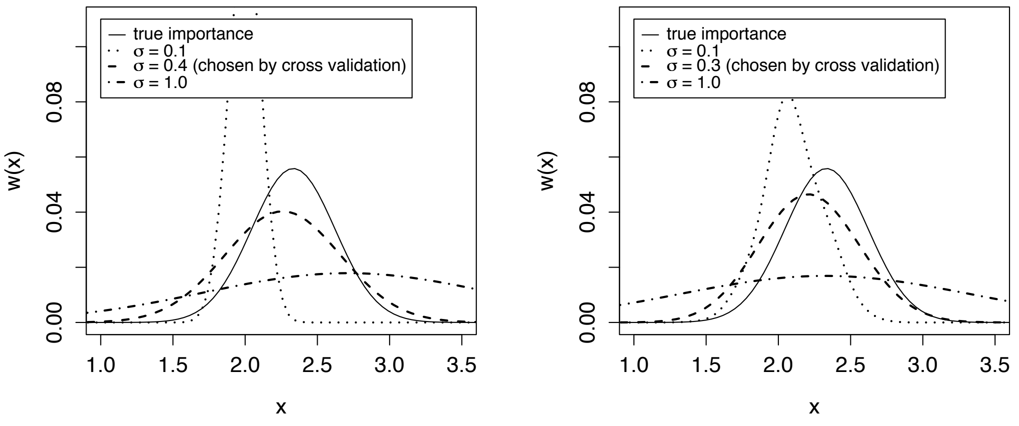
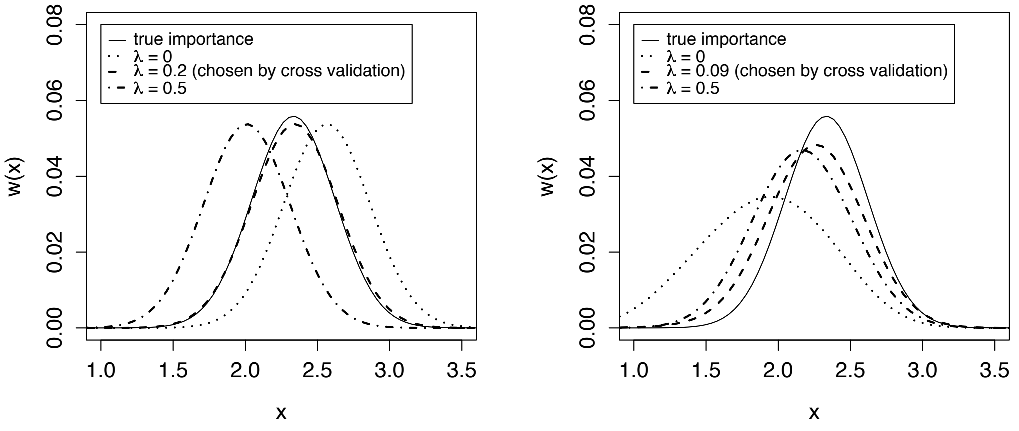


(a) LSIF for $\lambda = 0.2, \sigma = 0.1, 0.4, 1.0$.

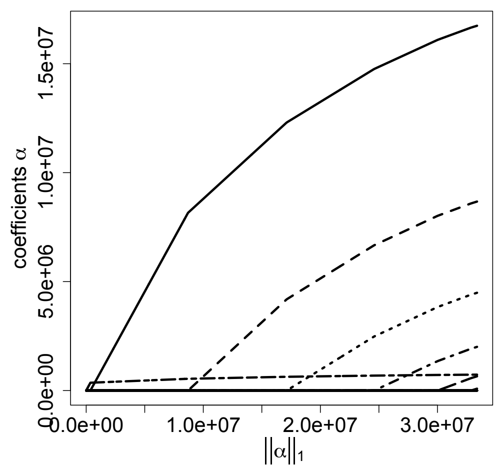
(b) uLSIF for $\lambda = 0.2, \sigma = 0.1, 0.3, 1.0$.



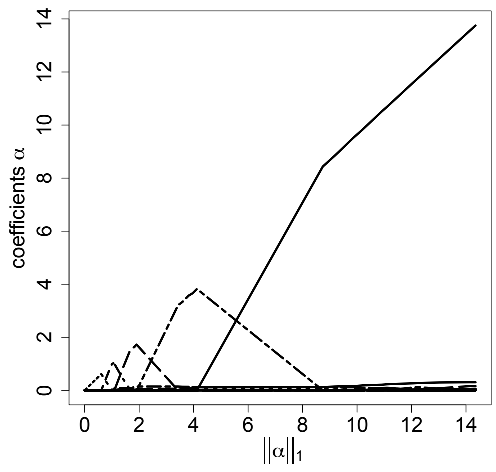
(c) LSIF for $\sigma = 0.3, \lambda = 0, 0.2, 0.5$.

(d) uLSIF for $\sigma = 0.3, \lambda = 0, 0.09, 0.5$.

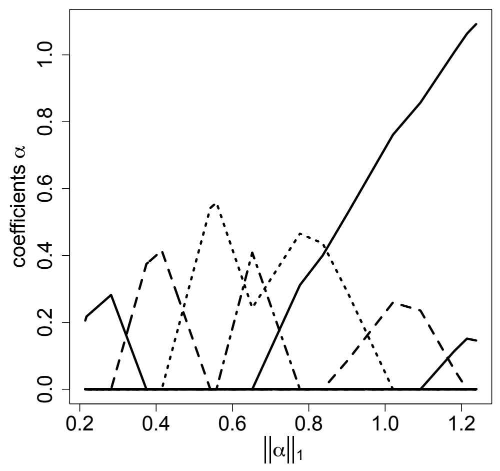
Figure 4: True and estimated importance functions obtained by LSIF and uLSIF for various different Gaussian widths σ and regularization parameters λ.



(a) $\sigma = 0.1$.



(b) $\sigma = 0.3$.

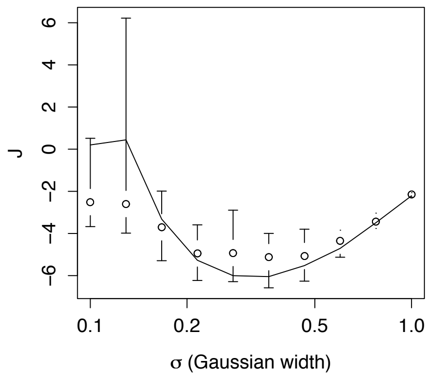


(c) $\sigma = 0.5$.

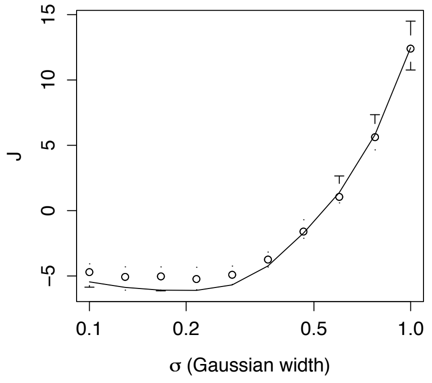
Figure 5: Regularization path of LSIF: the values of the estimated coefficients $\{\alpha_\ell\}_{\ell=1}^{b}$ are depicted as functions of the L_1-norm of the estimated parameter vector for $\sigma = 0.1, 0.3$, and 0.5. Small $\|\alpha\|_1$ corresponds to large λ.

4.4 Cross-validation

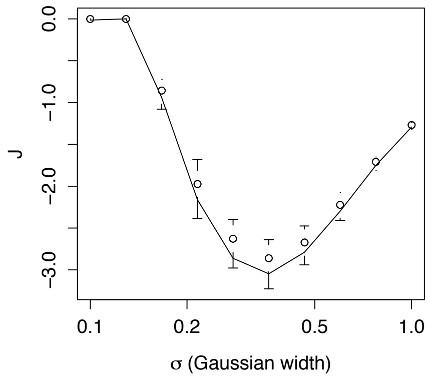
Here we illustrate the behavior of the cross-validation scores of LSIF and uLSIF. We set the number of training and test samples at $n_{\mathrm{tr}} = 200$ and $n_{\mathrm{te}} = 1000$, respectively. The number of template points is $b = 100$ and the Gaussian kernel model (22) is used. The centers of the kernel functions are randomly chosen from the test points as described in Section 4.2. The left column of Figure 6 depicts the expectation of the true cost $J(\widehat{\alpha})$ over 50 runs for LSIF and its estimate by 5-fold CV (25, 50, and 75 percentiles are plotted in the figure) as functions of the Gaussian width σ for $\lambda = 0.2, 0.5$, and 0.8. We used the regularization path tracking algorithm for computing the solutions of LSIF.



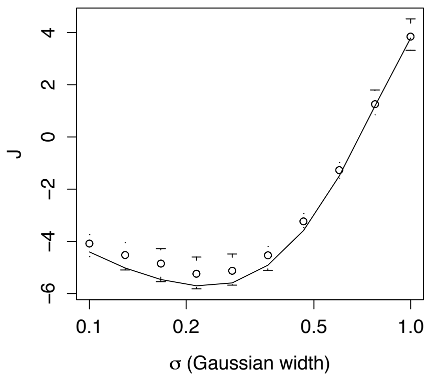
(a) LSIF with 5CV ($\lambda = 0.2$).



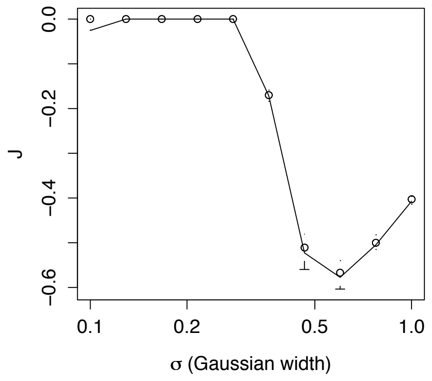
(b) uLSIF with LOOCV ($\lambda = 0.2$).



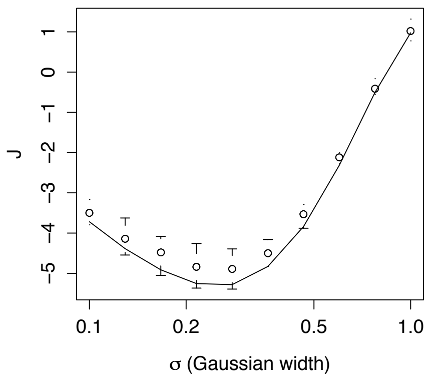
(c) LSIF with 5CV ($\lambda = 0.5$).



(d) uLSIF with LOOCV ($\lambda = 0.5$).



(e) LSIF with 5CV ($\lambda = 0.8$).



(f) uLSIF with LOOCV ($\lambda = 0.8$).

Figure 6: The true cost J and its cross-validation estimate as functions of Gaussian width σ for different values of λ. The solid line denotes the expectation of the true cost J over 50 runs, while '$\circ$' and error bars denote the 25, 50, and 75 percentiles of the cross-validation score.

The right column shows the expected true cost and its LOOCV estimates for uLSIF in the same manner.

The graphs show that overall CV gives reasonably good approximations of the expected cost, although CV for LSIF with small λ and small σ is rather inaccurate due to numerical problems—the solution path of LSIF is computed from $\lambda = \infty$ to $\lambda = 0$, and the numerical error is accumulated as the tracking process approaches to $\lambda = 0$. This phenomenon seems problematic when σ is small.

4.5 Difference between LSIF and uLSIF

In Section 3.3, we analyzed the approximation error of uLSIF against LSIF. Here we numerically investigate the behavior of the approximation error (26) as well as the norm bound (28) and the bridge bound (31). We set the number of training and test samples at $n_{\mathrm{tr}} = 200$ and $n_{\mathrm{te}} = 1000$, respectively. The number of template points in the Gaussian kernel model (22) is set at $b = 100$. The centers of the kernel functions are randomly chosen from the test points (see Section 4.2).

Figure 7 depicts the true approximation error as well as its upper bounds as functions of the regularization parameter λ; λ is varied from 0.001 to 10 and the three Gaussian widths $\sigma = 0.1, 0.5, 1.0$ are tested. The graphs show that when λ and σ are large, the approximation error tends to be small; this is in good agreement with the theoretical analysis given in Section 3.3. The bridge bound is fairly tight in the entire range and is sharper than the norm bound except when σ is small and λ is large.

4.6 Summary

Through the numerical examples, we overall found that LSIF and uLSIF give qualitatively similar results. However, the computation of the solution-path tracking algorithm for LSIF tends to be numerically unstable, which can result in unreliable model selection performance. On the other hand, only a system of linear equations needs to be solved in uLSIF, which turned out to be much more stable than LSIF. Thus, uLSIF would be practically more reliable than LSIF.

Based on the above findings, we will focus on uLSIF in the rest of this paper.

5. Relation to Existing Methods

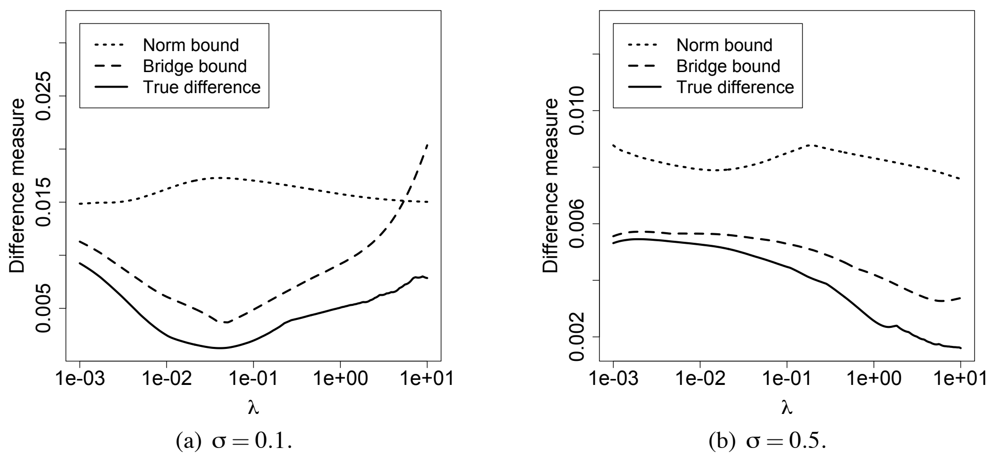
In this section, we discuss the characteristics of existing approaches in comparison with the proposed methods.

5.1 Kernel Density Estimator

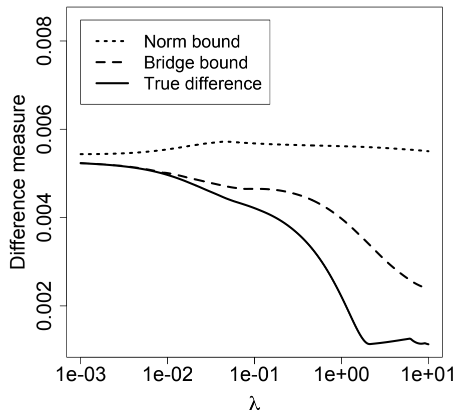
The *kernel density estimator* (KDE) is a non-parametric technique to estimate a probability density function $p(x)$ from its i.i.d. samples $\{x_k\}_{k=1}^{n}$. For the Gaussian kernel (21), KDE is expressed as

$$\widehat{p}(x) = \frac{1}{n_{\mathrm{tr}}(2\pi\sigma^2)^{d/2}} \sum_{k=1}^{n} K_{\sigma}(x, x_k).$$

The performance of KDE depends on the choice of the kernel width σ. The kernel width σ can be optimized by *likelihood cross-validation* (LCV) as follows (Härdle et al., 2004): First, divide the samples $\{x_i\}_{i=1}^{n}$ into R disjoint subsets $\{\mathcal{X}_r\}_{r=1}^{R}$. Then obtain a density estimate $\widehat{p}_{\mathcal{X}_k}(x)$ from



(a) $\sigma = 0.1$. (b) $\sigma = 0.5$.



(c) $\sigma = 1.0$.

Figure 7: The approximation error of uLSIF against LSIF as functions of the regularization parameter λ for different Gaussian width σ. Its upper bounds are also plotted in the graphs.

$\{\mathcal{X}_r\}_{r \neq k}$ (i.e., without $\mathcal{X}_k$) and compute its log-likelihood for $\mathcal{X}_k$:

$$\frac{1}{|\mathcal{X}_k|} \sum_{x \in \mathcal{X}_k} \log \widehat{p}_{\mathcal{X}_k}(x).$$

Repeat this procedure for $r = 1, 2, \ldots, R$ and choose the value of σ such that the average of the above hold-out log-likelihood over all r is maximized. Note that the average hold-out log-likelihood is an almost unbiased estimate of the Kullback-Leibler divergence from $p(x)$ to $\widehat{p}(x)$, up to an irrelevant constant.

KDE can be used for importance estimation by first obtaining density estimators $\widehat{p}_{\mathrm{tr}}(x)$ and $\widehat{p}_{\mathrm{te}}(x)$ separately from $\{x_i^{\mathrm{tr}}\}_{i=1}^{n_{\mathrm{tr}}}$ and $\{x_j^{\mathrm{te}}\}_{j=1}^{n_{\mathrm{te}}}$, and then estimating the importance by $\widehat{w}(x) = \widehat{p}_{\mathrm{te}}(x)/\widehat{p}_{\mathrm{tr}}(x)$. A potential limitation of this approach is that KDE suffers from the *curse of dimensionality* (Vapnik, 1998; Härdle et al., 2004), that is, the number of samples needed to maintain the same approximation quality grows exponentially as the dimension of the domain increases. This is critical when the number of available samples is limited. Therefore, the KDE-based approach may not be reliable in high-dimensional problems.

5.2 Kernel Mean Matching

The *kernel mean matching* (KMM) method allows us to directly obtain an estimate of the importance values at training points without going through density estimation (Huang et al., 2007). The basic idea of KMM is to find $\widehat{w}(x)$ such that the mean discrepancy between nonlinearly transformed samples drawn from $p_{\mathrm{te}}(x)$ and $p_{\mathrm{tr}}(x)$ is minimized in a *universal reproducing kernel Hilbert space* (Steinwart, 2001). The Gaussian kernel (21) is an example of kernels that induce universal reproducing kernel Hilbert spaces and it has been shown that the solution of the following optimization problem agrees with the true importance:

$$\min_{w(x)} \left\| \int K_\sigma(x,\cdot)p_{\mathrm{te}}(x)dx - \int K_\sigma(x,\cdot)w(x)p_{\mathrm{tr}}(x)dx \right\|^2_{\mathcal{H}}$$
$$\text{subject to } \int w(x)p_{\mathrm{tr}}(x)dx = 1 \text{ and } w(x) \geq 0,$$

where $\|\cdot\|_{\mathcal{H}}$ denotes the norm in the Gaussian reproducing kernel Hilbert space and $K_\sigma(x,x')$ is the Gaussian kernel (21).

An empirical version of the above problem is reduced to the following quadratic program:

$$\min_{\{w_i\}_{i=1}^{n_{\mathrm{tr}}}} \left[\frac{1}{2} \sum_{i,i'=1}^{n_{\mathrm{tr}}} w_i w_{i'} K_\sigma(x_i^{\mathrm{tr}}, x_{i'}^{\mathrm{tr}}) - \sum_{i=1}^{n_{\mathrm{tr}}} w_i \kappa_i \right]$$
$$\text{subject to } \left| \sum_{i=1}^{n_{\mathrm{tr}}} w_i - n_{\mathrm{tr}} \right| \leq n_{\mathrm{tr}}\varepsilon \text{ and } 0 \leq w_1, w_2, \ldots, w_{n_{\mathrm{tr}}} \leq B,$$

where

$$\kappa_i = \frac{n_{\mathrm{tr}}}{n_{\mathrm{te}}} \sum_{j=1}^{n_{\mathrm{te}}} K_\sigma(x_i^{\mathrm{tr}}, x_j^{\mathrm{te}}).$$

B (≥ 0) and ε (≥ 0) are tuning parameters that control the regularization effects. The solution $\{\widehat{w}_i\}_{i=1}^{n_{\mathrm{tr}}}$ is an estimate of the importance at the training points $\{x_i^{\mathrm{tr}}\}_{i=1}^{n_{\mathrm{tr}}}$.

Since KMM does not involve density estimation, it is expected to work well even in high dimensional cases. However, the performance is dependent on the tuning parameters B, ε, and σ, and they cannot be simply optimized, for example, by CV since estimates of the importance are available only at the training points. A popular heuristic is to use the median distance between samples as the Gaussian width σ, which is shown to be useful (Schölkopf and Smola, 2002; Song et al., 2007). However, there seems no strong justification for this heuristic. For the choice of ε, a theoretical result given in Huang et al. (2007) could be used as guidance, although it is still hard to determine the best value of ε in practice.

5.3 Logistic Regression

Another approach to directly estimating the importance is to use a probabilistic classifier. Let us assign a selector variable $\eta = -1$ to training samples and $\eta = 1$ to test samples, that is, the training and test densities are written as

$$p_{\mathrm{tr}}(x) = p(x|\eta = -1),$$
$$p_{\mathrm{te}}(x) = p(x|\eta = 1).$$

Note that η is regarded as a random variable.

Application of the Bayes theorem yields that the importance can be expressed in terms of η as follows (Qin, 1998; Cheng and Chu, 2004; Bickel et al., 2007):

$$w(x) = \frac{p(\eta = -1)}{p(\eta = 1)} \frac{p(\eta = 1|x)}{p(\eta = -1|x)}.$$

The probability ratio of test and training samples may be simply estimated by the ratio of the numbers of samples:

$$\frac{p(\eta = -1)}{p(\eta = 1)} \approx \frac{n_{\mathrm{tr}}}{n_{\mathrm{te}}}.$$

The conditional probability $p(\eta|x)$ could be approximated by discriminating test samples from training samples using a *logistic regression* (LogReg) classifier, where η plays the role of a class variable. Below we briefly explain the LogReg method.

The LogReg classifier employs a parametric model of the following form for expressing the conditional probability $p(\eta|x)$:

$$\widehat{p}(\eta|x) = \frac{1}{1 + \exp\left(-\eta \sum_{\ell=1}^{m} \zeta_\ell \phi_\ell(x)\right)},$$

where m is the number of basis functions and $\{\phi_\ell(x)\}_{\ell=1}^{m}$ are fixed basis functions. The parameter ζ is learned so that the negative regularized log-likelihood is minimized:

$$\widehat{\zeta} = \underset{\zeta}{\mathrm{argmin}} \left[\sum_{i=1}^{n_{\mathrm{tr}}} \log\left(1 + \exp\left(\sum_{\ell=1}^{m} \zeta_\ell \phi_\ell(x_i^{\mathrm{tr}})\right)\right) \right.$$
$$\left. + \sum_{j=1}^{n_{\mathrm{te}}} \log\left(1 + \exp\left(-\sum_{\ell=1}^{m} \zeta_\ell \phi_\ell(x^{\mathrm{te}})\right)\right) + \lambda \zeta^\top \zeta \right].$$

Since the above objective function is convex, the global optimal solution can be obtained by standard nonlinear optimization methods such as Newton's method, the conjugate gradient method, and the BFGS method (Minka, 2007). Then the importance estimate is given by

$$\widehat{w}(x) = \frac{n_{\mathrm{tr}}}{n_{\mathrm{te}}} \exp\left(\sum_{\ell=1}^{m} \zeta_\ell \phi_\ell(x)\right). \tag{34}$$

An advantage of the LogReg method is that model selection (that is, the choice of the basis functions $\{\phi_\ell(x)\}_{\ell=1}^{m}$ as well as the regularization parameter λ) is possible by standard CV since the learning problem involved above is a standard supervised classification problem.

5.4 Kullback-Leibler Importance Estimation Procedure

The *Kullback-Leibler importance estimation procedure* (KLIEP) (Sugiyama et al., 2008a) also directly gives an estimate of the importance function without going through density estimation by matching the two distributions in terms of the Kullback-Leibler divergence (Kullback and Leibler, 1951).

Let us model the importance $w(x)$ by the linear model (1). An estimate of the test density $p_{\mathrm{te}}(x)$ is given by using the model $\widehat{w}(x)$ as

$$\widehat{p}_{\mathrm{te}}(x) = \widehat{w}(x) p_{\mathrm{tr}}(x).$$

In KLIEP, the parameters α are determined so that the Kullback-Leibler divergence from $p_{\mathrm{te}}(x)$ to $\widehat{p}_{\mathrm{te}}(x)$ is minimized:

$$\begin{aligned}\mathrm{KL}[p_{\mathrm{te}}(x)\|\widehat{p}_{\mathrm{te}}(x)] &= \int_{\mathcal{D}} p_{\mathrm{te}}(x) \log \frac{p_{\mathrm{te}}(x)}{\widehat{w}(x)p_{\mathrm{tr}}(x)} dx \\ &= \int_{\mathcal{D}} p_{\mathrm{te}}(x) \log \frac{p_{\mathrm{te}}(x)}{p_{\mathrm{tr}}(x)} dx - \int_{\mathcal{D}} p_{\mathrm{te}}(x) \log \widehat{w}(x) dx. \end{aligned} \tag{35}$$

The first term is a constant, so it can be safely ignored. Since $\widehat{p}_{\mathrm{te}}(x)$ $(= \widehat{w}(x)p_{\mathrm{tr}}(x))$ is a probability density function, it should satisfy

$$1 = \int_{\mathcal{D}} \widehat{p}_{\mathrm{te}}(x) dx = \int_{\mathcal{D}} \widehat{w}(x) p_{\mathrm{tr}}(x) dx. \tag{36}$$

Then the KLIEP optimization problem is given by replacing the expectations in Eqs. (35) and (36) with empirical averages as follows:

$$\begin{aligned}&\max_{\{\alpha_\ell\}_{\ell=1}^{b}} \left[\sum_{j=1}^{n_{\mathrm{te}}} \log \left(\sum_{\ell=1}^{b} \alpha_\ell \varphi_\ell(x_j^{\mathrm{te}}) \right) \right] \\ &\qquad \text{subject to } \sum_{\ell=1}^{b} \alpha_\ell \left(\sum_{i=1}^{n_{\mathrm{tr}}} \varphi_\ell(x_i^{\mathrm{tr}}) \right) = n_{\mathrm{tr}} \text{ and } \alpha_1, \alpha_2, \ldots, \alpha_b \geq 0.\end{aligned}$$

This is a convex optimization problem and the global solution—which tends to be sparse (Boyd and Vandenberghe, 2004)—can be obtained, for example, by simply performing gradient ascent and feasibility satisfaction iteratively. Model selection of KLIEP is possible by LCV.

Properties of KLIEP-type algorithms have been theoretically investigated in Nguyen et al. (2008) and Sugiyama et al. (2008b) (see also Qin, 1998; Cheng and Chu, 2004). Note that the importance model of KLIEP is the linear model (1), while that of LogReg is the log-linear model (34). A variant of KLIEP for log-linear models has been studied in Tsuboi et al. (2008).

5.5 Discussions

Table 1 summarizes properties of proposed and existing methods.

KDE is efficient in computation since no optimization is involved, and model selection is possible by LCV. However, KDE may suffer from the curse of dimensionality due to the difficulty of density estimation in high dimensions.

Methods	Density estimation	Model selection	Optimization	Out-of-sample prediction
KDE	Necessary	**Available**	**Analytic**	**Possible**
KMM	**Not necessary**	Not available	Convex quadratic program	Not possible
LogReg	**Not necessary**	**Available**	Convex non-linear	**Possible**
KLIEP	**Not necessary**	**Available**	Convex non-linear	**Possible**
LSIF	**Not necessary**	**Available**	Convex quadratic program	**Possible**
uLSIF	**Not necessary**	**Available**	**Analytic**	**Possible**

Table 1: Relation between proposed and existing methods.

KMM can potentially overcome the curse of dimensionality by directly estimating the importance. However, there is no objective model selection method. Therefore, model parameters such as the Gaussian width need to be determined by hand, which is highly unreliable unless we have strong prior knowledge. Furthermore, the computation of KMM is rather demanding since a quadratic programming problem has to be solved.

LogReg and KLIEP also do not involve density estimation, but different from KMM, they give an estimate the entire importance function, not only the values of the importance at training points. Therefore, the values of the importance at unseen points can be estimated by LogReg and KLIEP. This feature is highly useful since it enables us to employ CV for model selection, which is a significant advantage over KMM. However, LogReg and KLIEP are computationally rather expensive since non-linear optimization problems have to be solved. Note that the LogReg method is slightly different in motivation from other methods, but has some similarity in computation and implementation, for example, the LogReg method also involves a kernel smoother.

The proposed LSIF method is qualitatively similar to LogReg and KLIEP, that is, it can avoid density estimation, model selection is possible, and non-linear optimization is involved. LSIF is advantageous over LogReg and KLIEP in that it is equipped with a regularization path tracking algorithm. Thanks to this, model selection of LSIF is computationally much more efficient than LogReg and KLIEP. However, the regularization path tracking algorithm tends to be numerically unstable.

The proposed uLSIF method inherits good properties of existing methods such as no density estimation involved and a build-in model selection method equipped. In addition to these preferable properties, the solution of uLSIF can be computed in an efficient and numerically stable manner. Furthermore, thanks to the availability of the closed-form solution of uLSIF, the LOOCV score can be analytically computed without repeating hold-out loops, which highly contributes to reducing the computation time in the model selection phase.

In the next section, we experimentally show that uLSIF is computationally more efficient than existing direct importance estimation methods, while its estimation accuracy is comparable to the best existing methods.

6. Experiments

In this section, we compare the experimental performance of the proposed and existing methods.

6.1 Importance Estimation

Let the dimension of the domain be d and

$$p_{\mathrm{tr}}(x) = \mathcal{N}(x;(0,0,\ldots,0)^\top, I_d),$$
$$p_{\mathrm{te}}(x) = \mathcal{N}(x;(1,0,\ldots,0)^\top, I_d).$$

The task is to estimate the importance at training points:

$$w_i = w(x_i^{\mathrm{tr}}) = \frac{p_{\mathrm{te}}(x_i^{\mathrm{tr}})}{p_{\mathrm{tr}}(x_i^{\mathrm{tr}})} \quad \text{for } i = 1,2,\ldots,n_{\mathrm{tr}}.$$

We compare the following methods:

KDE(CV): The Gaussian kernel (21) is used, where the kernel widths of the training and test densities are separately optimized based on 5-fold LCV.

KMM(med): The performance of KMM is dependent on B, ε, and σ. We set $B = 1000$ and $\varepsilon = (\sqrt{n_{\mathrm{tr}}} - 1)/\sqrt{n_{\mathrm{tr}}}$ following the original paper (Huang et al., 2007), and the Gaussian width σ is set at the median distance between samples within the training set and the test set (Schölkopf and Smola, 2002; Song et al., 2007).

LogReg(CV): The Gaussian kernel model (22) are used as basis functions. The kernel width σ and the regularization parameter λ are chosen based on 5-fold CV.[1]

KLIEP(CV): The Gaussian kernel model (22) is used. The kernel width σ is selected based on 5-fold LCV.

uLSIF(CV): The Gaussian kernel model (22) is used. The kernel width σ and the regularization parameter λ are determined based on LOOCV.

All the methods are implemented using the *MATLAB*® environment, where the *CPLEX*® optimizer is used for solving quadratic programs in KMM and the *LIBLINEAR* implementation is used for LogReg (Lin et al., 2007).

We fixed the number of test points at $n_{\mathrm{te}} = 1000$ and consider the following two setups for the number n_{tr} of training samples and the input dimensionality d:

(a) n_{tr} is fixed at $n_{\mathrm{tr}} = 100$ and d is changed as $d = 1,2,\ldots,20$,

(b) d is fixed at $d = 10$ and n_{tr} is changed as $n_{\mathrm{tr}} = 50,60,\ldots,150$.

We run the experiments 100 times for each d, each n_{tr}, and each method, and evaluate the quality of the importance estimates $\{\widehat{w}_i\}_{i=1}^{n_{\mathrm{tr}}}$ by the *normalized mean squared error* (NMSE):

$$\mathrm{NMSE} = \frac{1}{n_{\mathrm{tr}}} \sum_{i=1}^{n_{\mathrm{tr}}} \left(\frac{\widehat{w}_i}{\sum_{i'=1}^{n_{\mathrm{tr}}} \widehat{w}_{i'}} - \frac{w_i}{\sum_{i'=1}^{n_{\mathrm{tr}}} w_{i'}} \right)^2 .$$

1. In Sugiyama et al. (2008b) where KLIEP has been proposed, the performance of LogReg has been experimentally investigated in the same setup. In that paper, however, LogReg was not regularized since KLIEP was not also regularized. On the other hand, we use a regularized LogReg method and choose the regularization parameter in addition to the Gaussian kernel width by CV here. Thanks to the regularization effect, the results of LogReg in the current paper tends to be better than that reported in Sugiyama et al. (2008b).

In practice, the scale of the importance is not significant and the relative magnitude among w_i is important. Thus the above NMSE would be a suitable error metric for evaluating the performance of each method.

NMSEs averaged over 100 trials (a) as a function of input dimensionality d and (b) as a function of the training sample size n_{tr} are plotted in log scale in Figure 8. Error bars are omitted for clear visibility—instead, the best method in terms of the mean error and comparable ones based on the t-test at the significance level 1% are indicated by '$\circ$'; the methods with significant difference from the best methods are indicated by '$\times$'.

Figure 8(a) shows that the error of KDE(CV) sharply increases as the input dimensionality grows, while LogReg, KLIEP, and uLSIF tend to give much smaller errors than KDE. This would be the fruit of directly estimating the importance without going through density estimation. KMM tends to perform poorly, which is caused by an inappropriate choice of the Gaussian kernel width. On the other hand, model selection in LogReg, KLIEP, and uLSIF seems to work quite well. Figure 8(b) shows that the errors of all methods tend to decrease as the number of training samples grows. Again LogReg, KLIEP, and uLSIF tend to give much smaller errors than KDE and KMM.

Next we investigate the computation time. Each method has a different model selection strategy, that is, KMM does not involve CV, KDE and KLIEP involve CV over the kernel width, and LogReg and uLSIF involve CV over both the kernel width and the regularization parameter. Thus the naive comparison of the total computation time is not so meaningful. For this reason, we first investigate the computation time of each importance estimation method after the model parameters are fixed.

The average CPU computation time over 100 trials are summarized in Figure 9. Figure 9(a) shows that the computation time of KDE, KLIEP, and uLSIF is almost independent of the input dimensionality, while that of KMM and LogReg is rather dependent on the input dimensionality. Note that LogReg for $d \leq 3$ is slow due to some convergence problem of the LIBLINEAR package. Among them, the proposed uLSIF is one of the fastest methods. Figure 9(b) shows that the computation time of LogReg, KLIEP, and uLSIF is nearly independent of the number of training samples, while that of KDE and KMM sharply increase as the number of training samples increases.

Both LogReg and uLSIF have high accuracy and their computation time after model selection is comparable. Finally, we compare the entire computation time of LogReg and uLSIF including CV, which is summarized in Figure 10. We note that the Gaussian width σ and the regularization parameter λ are chosen over the 9×9 grid in this experiment for both LogReg and uLSIF. Therefore, the comparison of the entire computation time is fair. Figures 10(a) and 10(b) show that uLSIF is approximately 5 times faster than LogReg.

Overall, uLSIF is shown to be comparable to the best existing method (LogReg) in terms of the accuracy, but is computationally more efficient than LogReg.

6.2 Covariate Shift Adaptation in Regression and Classification

Next, we illustrate how the importance estimation methods could be used in *covariate shift adaptation* (Shimodaira, 2000; Zadrozny, 2004; Sugiyama and Müller, 2005; Huang et al., 2007; Bickel and Scheffer, 2007; Bickel et al., 2007; Sugiyama et al., 2007). Covariate shift is a situation in supervised learning where the input distributions change between the training and test phase but the conditional distribution of outputs given inputs remains unchanged. Under covariate shift, standard learning techniques such as maximum likelihood estimation or cross-validation are biased—the bias

caused by covariate shift can be asymptotically canceled by weighting the loss function according to the importance.

In addition to training input samples $\{x_i^{\mathrm{tr}}\}_{i=1}^{n_{\mathrm{tr}}}$ drawn from a training input density $p_{\mathrm{tr}}(x)$ and test input samples $\{x_j^{\mathrm{te}}\}_{j=1}^{n_{\mathrm{te}}}$ drawn from a test input density $p_{\mathrm{te}}(x)$, suppose that we are given training *output* samples $\{y_i^{\mathrm{tr}}\}_{i=1}^{n_{\mathrm{tr}}}$ at the training input points $\{x_i^{\mathrm{tr}}\}_{i=1}^{n_{\mathrm{tr}}}$. The task is to predict the outputs for test inputs $\{x_j^{\mathrm{te}}\}_{j=1}^{n_{\mathrm{te}}}$ based on the input-output training samples $\{(x_i^{\mathrm{tr}}, y_i^{\mathrm{tr}})\}_{i=1}^{n_{\mathrm{tr}}}$.

We use the following kernel model for function learning:

$$\widehat{f}(x;\theta) = \sum_{\ell=1}^{t} \theta_\ell K_h(x, m_\ell),$$

where $K_h(x,x')$ is the Gaussian kernel (21) and m_ℓ is a template point randomly chosen from $\{x_j^{\mathrm{te}}\}_{j=1}^{n_{\mathrm{te}}}$ without replacement. We set the number of kernels at $t = 50$. We learn the parameter θ by *importance weighted regularized least-squares* (IWRLS) (Evgeniou et al., 2000; Sugiyama and Müller, 2005):

$$\widehat{\theta}_{\mathrm{IWRLS}} \equiv \operatorname*{argmin}_{\theta} \left[\sum_{i=1}^{n_{\mathrm{tr}}} \widehat{w}(x_i^{\mathrm{tr}}) \left(\widehat{f}(x_i^{\mathrm{tr}};\theta) - y_i^{\mathrm{tr}} \right)^2 + \gamma \|\theta\|^2 \right]. \tag{37}$$

It is known that IWRLS is consistent when the true importance $w(x_i^{\mathrm{tr}})$ is used as weights—unweighted RLS is not consistent due to covariate shift, given that the true learning target function $f(x)$ is not realizable by the model $\widehat{f}(x)$ (Shimodaira, 2000).

The solution $\widehat{\theta}_{\mathrm{IWRLS}}$ is analytically given by

$$\widehat{\theta}_{\mathrm{IWRLS}} = (K^\top \widehat{W} K + \gamma I_b)^{-1} K^\top \widehat{W} y^{\mathrm{tr}},$$

where

$$\begin{aligned} K_{i,\ell} &= K_h(x_i^{\mathrm{tr}}, m_\ell), \\ \widehat{W} &= \mathrm{diag}\left(\widehat{w}(x_1^{\mathrm{tr}}), \widehat{w}(x_2^{\mathrm{tr}}), \ldots, \widehat{w}(x_{n_{\mathrm{tr}}}^{\mathrm{tr}}) \right), \\ y^{\mathrm{tr}} &= (y_1^{\mathrm{tr}}, y_2^{\mathrm{tr}}, \ldots, y_{n_{\mathrm{tr}}}^{\mathrm{tr}})^\top. \end{aligned}$$

$\mathrm{diag}\,(a,b,\ldots,c)$ denotes the diagonal matrix with the diagonal elements $a,b,\ldots,c$.

The kernel width h and the regularization parameter γ in IWRLS (37) are chosen by *importance weighted CV* (IWCV) (Sugiyama et al., 2007). More specifically, we first divide the training samples $\{z_i^{\mathrm{tr}} \mid z_i^{\mathrm{tr}} = (x_i^{\mathrm{tr}}, y_i^{\mathrm{tr}})\}_{i=1}^{n_{\mathrm{tr}}}$ into R disjoint subsets $\{\mathcal{Z}_r^{\mathrm{tr}}\}_{r=1}^{R}$. Then a function $\widehat{f}_r(x)$ is learned using $\{\mathcal{Z}_j^{\mathrm{tr}}\}_{j \neq r}$ by IWRLS and its mean test error for the remaining samples $\mathcal{Z}_r^{\mathrm{tr}}$ is computed:

$$\frac{1}{|\mathcal{Z}_r^{\mathrm{tr}}|} \sum_{(x,y) \in \mathcal{Z}_r^{\mathrm{tr}}} \widehat{w}(x) \mathrm{loss}\left(\widehat{f}_r(x), y \right),$$

where

$$\mathrm{loss}\,(\widehat{y}, y) = \begin{cases} (\widehat{y} - y)^2 & \text{(Regression)}, \\ \frac{1}{2}(1 - \mathrm{sign}\{\widehat{y} y\}) & \text{(Classification)}. \end{cases}$$

We repeat this procedure for $r = 1, 2, \ldots, R$ and choose the kernel width h and the regularization parameter γ so that the average of the above mean test error over all r is minimized. We set the number of folds in IWCV at $R = 5$. IWCV is shown to be an (almost) unbiased estimator of the

Table 2: Mean test error averaged over 100 trials for covariate shift adaptation in regression and classification. The numbers in the brackets are the standard deviation. All the error values are normalized by that of 'Uniform' (uniform weighting, or equivalently no importance weighting). For each data set, the best method in terms of the mean error and comparable ones based on the *Wilcoxon signed rank test* at the significance level 1% are described in bold face. The upper half corresponds to regression data sets taken from DELVE (Rasmussen et al., 1996), while the lower half correspond to classification data sets taken from IDA (Rätsch et al., 2001). All the methods are implemented using the *MATLAB*® environment, where the *CPLEX*® optimizer is used for solving quadratic programs in KMM and the *LIBLINEAR* implementation is used for LogReg (Lin et al., 2007).

generalization error, while unweighted CV with misspecified models is biased due to covariate shift (Zadrozny, 2004; Sugiyama et al., 2007).

The data sets provided by DELVE (Rasmussen et al., 1996) and IDA (Rätsch et al., 2001) are used for performance evaluation. Each data set consists of input/output samples $\{(x_k, y_k)\}_{k=1}^{n}$. We normalize all the input samples $\{x_k\}_{k=1}^{n}$ into $[0,1]^d$ and choose the test samples $\{(x_j^{\mathrm{te}}, y_j^{\mathrm{te}})\}_{j=1}^{n_{\mathrm{te}}}$ from the pool $\{(x_k, y_k)\}_{k=1}^{n}$ as follows. We randomly choose one sample (x_k, y_k) from the pool and accept this with probability $\min(1, 4(x_k^{(c)})^2)$, where $x_k^{(c)}$ is the c-th element of x_k and c is randomly determined and fixed in each trial of the experiments. Then we remove x_k from the pool regardless of its rejection or acceptance, and repeat this procedure until n_{te} samples are accepted. We choose the training samples $\{(x_i^{\mathrm{tr}}, y_i^{\mathrm{tr}})\}_{i=1}^{n_{\mathrm{tr}}}$ uniformly from the rest. Thus, in this experiment, the test input density tends to be lower than the training input density when $x_k^{(c)}$ is small. We set the number of samples at $n_{\mathrm{tr}} = 100$ and $n_{\mathrm{te}} = 500$ for all data sets. Note that we only use $\{(x_i^{\mathrm{tr}}, y_i^{\mathrm{tr}})\}_{i=1}^{n_{\mathrm{tr}}}$ and $\{x_j^{\mathrm{te}}\}_{j=1}^{n_{\mathrm{te}}}$ for training regressors or classifiers; the test output values $\{y_j^{\mathrm{te}}\}_{j=1}^{n_{\mathrm{te}}}$ are used only for evaluating the generalization performance.

We run the experiments 100 times for each data set and evaluate the *mean test error*:

$$\frac{1}{n_{\mathrm{te}}} \sum_{j=1}^{n_{\mathrm{te}}} \mathrm{loss}\left(\widehat{f}(x_j^{\mathrm{te}}), y_j^{\mathrm{te}}\right).$$

The results are summarized in Table 2, where 'Uniform' denotes uniform weights (or equivalently, no importance weight). The numbers in the brackets are the standard deviation. All the error values are normalized so that the mean error of Uniform is one. For each data set, the best method in terms of the mean error and comparable ones based on the *Wilcoxon signed rank test* at the significance level 1% are described in bold face. The upper half of the table corresponds to regression data sets taken from DELVE (Rasmussen et al., 1996), while the lower half correspond to classification data sets taken from IDA (Rätsch et al., 2001). All the methods are implemented using the *MATLAB*® environment, where the *CPLEX*® optimizer is used for solving quadratic programs in KMM and the *LIBLINEAR* implementation is used for LogReg (Lin et al., 2007).

The table shows that the generalization performance of uLSIF tends to be better than that of Uniform, KDE, KMM, and LogReg, while it is comparable to the best existing method (KLIEP). The mean computation time over 100 trials is described in the bottom row of the table, where the value is normalized so that the computation time of uLSIF is one. This shows that the computation time of uLSIF is much shorter than KLIEP. Thus, uLSIF is overall shown to be useful in covariate shift adaptation.

6.3 Outlier Detection

Finally, we apply importance estimation methods in outlier detection.

Here, we consider an outlier detection problem of finding irregular samples in a data set ("evaluation data set") based on another data set ("model data set") that only contains regular samples. Defining the importance over two sets of samples, we can see that the importance values for regular samples are close to one, while those for outliers tend to be significantly deviated from one. Thus the importance values could be used as an index of the degree of outlyingness in this scenario. Since the evaluation data set has wider support than the model data set, we regard the evaluation data set as the training set $\{x_i^{\mathrm{tr}}\}_{i=1}^{n_{\mathrm{tr}}}$ (that is, the denominator in the importance) and the model data set as the test set $\{x_j^{\mathrm{te}}\}_{j=1}^{n_{\mathrm{te}}}$ (that is, the numerator in the importance). Then outliers tend to have smaller importance values (that is, close to zero).

We again test KMM(med), LogReg(CV), KLIEP(CV), and uLSIF(CV) for importance estimation; in addition, we include native outlier detection methods for comparison purposes. The outlier detection problem that the native methods used below solve is to find outliers in a single data set $\{x_k\}_{k=1}^{n}$—the native methods can be employed in the current scenario just by finding outliers from all samples:

$$\{x_k\}_{k=1}^{n} = \{x_i^{\mathrm{tr}}\}_{i=1}^{n_{\mathrm{tr}}} \cup \{x_j^{\mathrm{te}}\}_{j=1}^{n_{\mathrm{te}}}.$$

One-class support vector machine (OSVM): The *support vector machine* (SVM) (Vapnik, 1998; Schölkopf and Smola, 2002) is one of the most successful classification algorithms in machine learning. The core idea of SVM is to separate samples in different classes by the maximum margin hyperplane in a kernel-induced feature space.

OSVM is an extension of SVM to outlier detection (Schölkopf et al., 2001). The basic idea of OSVM is to separate data samples $\{x_k\}_{k=1}^{n}$ into outliers and inliers by a hyperplane in a Gaussian reproducing kernel Hilbert space. More specifically, the solution of OSVM is given as the solution of the following convex quadratic programming problem:

$$\min_{\{w_k\}_{k=1}^{n}} \frac{1}{2}\sum_{k,k'=1}^{n} w_k w_{k'} K_\sigma(x_k, x_{k'})$$
$$\text{subject to} \sum_{k=1}^{n} w_k = 1 \text{ and } 0 \le w_1, w_2, \ldots, w_n \le \frac{1}{\nu n},$$

where ν ($0 \le \nu \le 1$) is the maximum fraction of outliers.

We use the inverse distance of a sample from the separating hyperplane as an outlier score. The OSVM solution is dependent on the outlier ratio ν and the Gaussian kernel width σ, and there seems to be no systematic method to determine the values of these tuning parameters. Here we use the median distance between samples as the Gaussian width, which is a popular heuristic (Schölkopf and Smola, 2002; Song et al., 2007). The value of ν is fixed at the true output ratio, that is, the ideal optimal value. Thus the simulation results below should be slightly in favor of OSVM.

Local outlier factor (LOF): LOF is the score to detect a local outlier which lies relatively far from the nearest dense region (Breunig et al., 2000). For a prefixed natural number k, the LOF value of a sample x is defined by

$$\mathrm{LOF}_R(x) = \frac{1}{k}\sum_{i=1}^{k} \frac{\mathrm{imd}_k(\mathrm{nearest}_i(x))}{\mathrm{imd}_k(x)},$$

where $\mathrm{nearest}_i(x)$ denotes the i-th nearest neighbor of x and $\mathrm{imd}_k(x)$ denotes the inverse mean distance from x to its k nearest neighbors:

$$\mathrm{imd}_k(x) = \frac{1}{\frac{1}{k}\sum_{i=1}^{k} \|x - \mathrm{nearest}_i(x)\|}.$$

If x alone is apart from a cloud of points, $\mathrm{imd}_k(x)$ tends to become smaller than than $\mathrm{imd}_k(\mathrm{nearest}_i(x))$ for all i. Then the LOF value gets large and therefore such a point is regarded as an outlier. The performance of LOF depends on the choice of the parameter k and there seems no systematic way to find an appropriate value of k. Here we test several different values of k.

Kernel density estimator (KDE'): A naive density estimation of all data samples $\{x_k\}_{k=1}^{n}$ can also be used for outlier detection since the density value itself could be regarded as an outlier score. We use KDE with the Gaussian kernel (21) for density estimation, where the kernel width is determined based on 5-fold LCV.

All the methods are implemented using the R environment—we use the *ksvm* routine in the *kernlab* package for OSVM (Karatzoglou et al., 2004) and the *lofactor* routine in the *dprep* package for LOF (Fernandez, 2005).

The data sets provided by IDA (Rätsch et al., 2001) are used for performance evaluation. These data sets are binary classification data sets consisting of positive/negative and training/test samples. We allocate all positive training samples for the "model" set, while all positive test samples and a fraction ρ $(= 0.01, 0.02, 0.05)$ of negative test samples are assigned in the "evaluation" set. Thus, we regard the positive samples as regular and the negative samples as irregular.

In the evaluation of the performance of outlier detection methods, it is important to take into account both the detection rate (the amount of true outliers an outlier detection algorithm can find) and the detection accuracy (the amount of true inliers that an outlier detection algorithm misjudges as outliers). Since there is a trade-off between the detection rate and the detection accuracy, we adopt the area under the ROC curve (AUC) as our error metric (Bradley, 1997).

The mean AUC values over 20 trials as well as the computation time are summarized in Table 3, showing that uLSIF works fairly well. KLIEP works slightly better than uLSIF, but uLSIF is computationally much more efficient. LogReg overall works reasonably well, but it performs poorly for some data sets and the average AUC performance is not as good as uLSIF or KLIEP. KMM and OSVM are not comparable to uLSIF in AUC and they are computationally inefficient. Note that we also tested KMM and OSVM with several different Gaussian widths and experimentally found that the heuristic of using the median sample distance as the Gaussian kernel width works reasonably well in this experiment. Thus the AUC values of KMM and OSVM are close to optimal. LOF with large k is shown to work well, although it is not clear whether the heuristic of simply using large k is always appropriate or not. The computational cost of LOF is high since nearest neighbor search is computationally expensive. KDE' works reasonably well, but its performance is not as good as uLSIF and KLIEP.

Overall, uLSIF is shown to work well with low computational costs.

7. Conclusions

The importance is useful in various machine learning scenarios such as covariate shift adaptation and outlier detection. In this paper, we proposed a new method of importance estimation that can avoid solving a substantially more difficult task of density estimation. We formulated the importance estimation problem as least-squares function fitting and casted the optimization problem as a convex quadratic program (we referred to it as LSIF). We theoretically elucidated the convergence property of LSIF and showed that the entire regularization path of LSIF can be efficiently computed based on a parametric optimization technique. We further developed an approximation algorithm (we called it uLSIF), which allows us to obtain the closed-form solution. We showed that the leave-one-out cross-validation score can be computed analytically for uLSIF—this makes the computation of uLSIF highly efficient. We carried out extensive simulations in covariate shift adaptation and outlier detection, and experimentally confirmed that the proposed uLSIF is computationally more efficient than existing approaches, while the accuracy of uLSIF is comparable to the best existing methods. Thanks to the low computational cost, uLSIF would be highly scalability to large data sets, which is very important in practical applications.

We have given convergence proofs for LSIF and uLSIF. A possible future direction to pursue along this line is to show the convergence of LSIF and uLSIF in non-parametric cases, for example, following Nguyen et al. (2008) and Sugiyama et al. (2008b). We are currently exploring various possible applications of important estimation methods beyond covariate shift adaptation or outlier detection, for example, feature selection, conditional distribution estimation, independent component analysis, and dimensionality reduction—we believe that importance estimation could be used as a new versatile tool in statistical machine learning.

Table 3: Mean AUC values for outlier detection over 20 trials for the benchmark data sets. All the methods are implemented using the R environment, where quadratic programs in KMM are solved by the *ipop* optimizer (Karatzoglou et al., 2004), the *ksvm* routine is used for OSVM (Karatzoglou et al., 2004), and the *lofactor* routine is used for LOF (Fernandez, 2005).

Acknowledgments

The authors wish to thank Issei Sato for fruitful discussion and helpful comments. The authors would also like to thank the anonymous referees whose comments helped to improve the paper further. This work was supported by MEXT (20680007), SCAT, and AOARD.

Appendix A. Existence of the Inverse Matrix of $\widehat{G}$

Here we prove Lemma 1.

Let us consider the following system of linear equations:

$$\begin{pmatrix} \widehat{H} & -\widehat{E}^\top \\ -\widehat{E} & O_{|\widehat{\mathcal{A}}|\times|\widehat{\mathcal{A}}|} \end{pmatrix} \begin{pmatrix} x \\ y \end{pmatrix} = \begin{pmatrix} 0_b \\ 0_{|\widehat{\mathcal{A}}|} \end{pmatrix}, \tag{38}$$

where x and y are b- and $|\widehat{\mathcal{A}}|$-dimensional vectors, respectively. From the upper half of Eq. (38), we have

$$x = \widehat{H}^{-1}\widehat{E}^\top y.$$

Substituting this into the lower half of Eq. (38), we have

$$\widehat{E}\widehat{H}^{-1}\widehat{E}^\top y = 0_{|\widehat{\mathcal{A}}|}.$$

From the definition, the rank of the matrix $\widehat{E}$ is $|\widehat{\mathcal{A}}|$, that is, $\widehat{E}$ is a row-full rank matrix. As a result, the matrix $\widehat{E}\widehat{H}^{-1}\widehat{E}^\top$ is invertible. Therefore, Eq. (38) has the unique solution $x = 0_b$ and $y = 0_{|\widehat{\mathcal{A}}|}$. This implies that $\widehat{G}$ is invertible.

Appendix B. Active Set of LSIF

Here, we prove Theorem 2.

We prove that the active set $\mathcal{A}$ does not change under the infinitesimal shift of H and h if the strict complementarity condition is satisfied. We regard the pair of a symmetric matrix and a vector (H', h') as an element in the $(\frac{b(b+1)}{2} + b)$-dimensional Euclidean space. We consider the following linear equation:

$$\begin{pmatrix} \alpha' \\ \xi' \end{pmatrix} = \begin{pmatrix} H' & -E^\top \\ -E & O_{|\mathcal{A}|\times|\mathcal{A}|} \end{pmatrix}^{-1} \begin{pmatrix} h' - \lambda 1_b \\ 0_{|\mathcal{A}|} \end{pmatrix},$$

where E is the $|\mathcal{A}| \times b$ indicator matrix determined from the active set $\mathcal{A}$ (see Section 2.3 for the detailed definition). If $H' = H$ and $h' = h$ hold, the solution $(\alpha', \xi') = (\alpha^*(\lambda), \xi^*(\lambda))$ satisfies

$$\begin{aligned} \alpha'_\ell = 0,\ \xi'_\ell > 0,\ \ {}^\forall \ell \in \mathcal{A}, \\ \alpha'_\ell > 0,\ \xi'_\ell = 0,\ \ {}^\forall \ell \notin \mathcal{A}, \end{aligned} \tag{39}$$

because of the strict complementarity condition. On the other hand, if the norm of $(H', h') - (H, h)$ is infinitesimal, the solution (α', ξ') also satisfies Eq. (39) because of the continuity of the relation between (H', h') and (α', ξ').

As a result, there exists an ε-ball B_ε in $\mathbb{R}^{\frac{b(b+1)}{2}+b}$ such that the equality $\mathcal{A} = \{\ell \mid \alpha'_\ell = 0\}$ holds for any $(H', h') \in B_\varepsilon$. Therefore, we have $P(\mathcal{A} \neq \widehat{\mathcal{A}}) \leq P((\widehat{H}, \widehat{h}) \notin B_\varepsilon)$. Due to the large deviation principle (Dembo and Zeitouni, 1998), there is a positive constant c such that

$$-\frac{1}{\min\{n_{\mathrm{tr}}, n_{\mathrm{te}}\}} \log P((\widehat{H}, \widehat{h}) \notin B_\varepsilon) > c > 0,$$

if $\min\{n_{\mathrm{tr}}, n_{\mathrm{te}}\}$ is large enough. Thus, asymptotically $P(\widehat{\mathcal{A}} \neq \mathcal{A}) < e^{-c\min\{n_{\mathrm{tr}}, n_{\mathrm{te}}\}}$ holds.

Appendix C. Learning Curve of LSIF

Here, we prove Theorem 3.

Let us consider the ideal problem (7). Let $\alpha^*(\lambda)$ and $\xi^*(\lambda)$ be the optimal parameter and Lagrange multiplier (that is, the KKT conditions are fulfilled; see Section 2.3) and let $\xi^{*\prime}(\lambda)$ be the vector of non-zero elements of $\xi^*(\lambda)$ defined in the same way as Eq. (11). Then $\alpha^*(\lambda)$ and $\xi^{*\prime}(\lambda)$ satisfy

$$G \begin{pmatrix} \alpha^*(\lambda) \\ \xi^{*\prime}(\lambda) \end{pmatrix} = \begin{pmatrix} h - \lambda 1_b \\ 0_{|\mathcal{A}|} \end{pmatrix}, \tag{40}$$

where

$$G = \begin{pmatrix} H & -E^\top \\ -E & O_{|\mathcal{A}|\times|\mathcal{A}|} \end{pmatrix}.$$

From the central limit theorem and the assumption (18), we have

$$\widehat{h} = h + O_p\left(\frac{1}{\sqrt{n_{\mathrm{te}}}}\right) = h + o_p\left(\frac{1}{n_{\mathrm{tr}}}\right), \tag{41}$$

where O_p and o_p denote the asymptotic order in probability. The assumption (a) implies that the equality

$$\widehat{E} = E \tag{42}$$

holds with exponentially high probability due to Theorem 2. Note that $\widehat{G}$ is the same size as G if $\widehat{E} = E$. Thus we have

$$\widehat{G} = G + \delta G,$$

where

$$\delta G = \begin{pmatrix} \delta H & O_{b\times|\mathcal{A}|} \\ O_{|\mathcal{A}|\times b} & O_{|\mathcal{A}|\times|\mathcal{A}|} \end{pmatrix},$$

$$\delta H = \widehat{H} - H. \tag{43}$$

Combining Eqs. (12), (40), (41), and (42), we have

$$\begin{pmatrix} \widehat{\alpha}(\lambda) \\ \widehat{\xi}'(\lambda) \end{pmatrix} = \widehat{G}^{-1} G \begin{pmatrix} \alpha^*(\lambda) \\ \xi^{*\prime}(\lambda) \end{pmatrix} + o_p\left(\frac{1}{n_{\mathrm{tr}}}\right). \tag{44}$$

The matrix Taylor expansion (Petersen and Pedersen, 2007) yields

$$\widehat{G}^{-1} = G^{-1} - G^{-1}\delta G G^{-1} + G^{-1}\delta G G^{-1}\delta G G^{-1} - \cdots, \tag{45}$$

and the central limit theorem asserts that

$$\delta H = O_p\left(\frac{1}{\sqrt{n_{\mathrm{tr}}}}\right). \tag{46}$$

Combining Eqs. (44), (45), (14), and (46), we have

$$\begin{aligned}\delta\alpha &= \widehat{\alpha}(\lambda) - \alpha^*(\lambda) &(47)\\ &= -A\delta H\alpha^*(\lambda) + A\delta HA\delta H\alpha^*(\lambda) + o\left(\frac{1}{n_{\mathrm{tr}}}\right). &(48)\end{aligned}$$

Through direct calculation, we can confirm that

$$AHA = A. \tag{49}$$

Similar to Eq. (15), it holds that

$$\alpha^*(\lambda) = A(h - \lambda 1_b). \tag{50}$$

From Eqs. (49) and (50), we have

$$A(H\alpha^*(\lambda) - h) = -\lambda A 1_b. \tag{51}$$

Eqs. (43), (4), and (3) imply

$$\mathbb{E}[\delta H] = O_{b\times b}. \tag{52}$$

From Eqs. (2) and (47), we have

$$J(\widehat{\alpha}(\lambda)) = J(\alpha^*(\lambda)) + \frac{1}{2}\delta\alpha^\top H\delta\alpha + (H\alpha^*(\lambda) - h)^\top\delta\alpha. \tag{53}$$

From Eqs. (46), (48), and (49), we have

$$\begin{aligned}\mathbb{E}\left[\delta\alpha^\top H\delta\alpha\right] &= \mathrm{tr}(H\,\mathbb{E}\left[\delta\alpha\delta\alpha^\top\right])\\ &= \mathrm{tr}(AHA\,\mathbb{E}\left[(\delta H\alpha^*(\lambda))(\delta H\alpha^*(\lambda))^\top\right]) + o\left(\frac{1}{n_{\mathrm{tr}}}\right)\\ &= \mathrm{tr}(A\,\mathbb{E}\left[(\delta H\alpha^*(\lambda))(\delta H\alpha^*(\lambda))^\top\right]) + o\left(\frac{1}{n_{\mathrm{tr}}}\right). &(54)\end{aligned}$$

From Eqs. (48), (51), and (52), we have

$$\begin{aligned}\mathbb{E}\left[\delta\alpha^\top(H\alpha^*(\lambda) - h)\right] &= -\,\mathbb{E}\left[(\delta H\alpha^*(\lambda) - \delta HA\delta H\alpha^*(\lambda))^\top A(H\alpha^*(\lambda) - h)\right] + o\left(\frac{1}{n_{\mathrm{tr}}}\right)\\ &= \mathbb{E}\left[(\delta H\alpha^*(\lambda) - \delta HA\delta H\alpha^*(\lambda))^\top\lambda A 1_b\right] + o\left(\frac{1}{n_{\mathrm{tr}}}\right)\\ &= -\,\lambda\mathrm{tr}(A\,\mathbb{E}\left[(\delta H\alpha^*(\lambda))(\delta HA1_b)^\top\right]) + o\left(\frac{1}{n_{\mathrm{tr}}}\right). &(55)\end{aligned}$$

Combining Eqs. (53), (54), and (55), we have

$$\begin{aligned}\mathbb{E}\left[J(\widehat{\alpha}(\lambda))\right] =& J(\alpha^*(\lambda)) + \frac{1}{2n_{\mathrm{tr}}}\mathrm{tr}(A\,\mathbb{E}\left[(\sqrt{n_{\mathrm{tr}}}\delta H\alpha^*(\lambda))(\sqrt{n_{\mathrm{tr}}}\delta H\alpha^*(\lambda))^\top\right]) \\ &- \frac{\lambda}{n_{\mathrm{tr}}}\mathrm{tr}(A\,\mathbb{E}\left[(\sqrt{n_{\mathrm{tr}}}\delta H\alpha^*(\lambda))(\sqrt{n_{\mathrm{tr}}}\delta HA1_b)^\top\right]) + o\left(\frac{1}{n_{\mathrm{tr}}}\right).\end{aligned}$$

According to the central limit theorem, $\sqrt{n_{\mathrm{tr}}}\delta H_{i,j}$ asymptotically follows the normal distribution with mean zero and variance

$$\int \varphi_i^2(x)\varphi_j^2(x)p_{\mathrm{tr}}(x)dx - H_{i,j}^2,$$

and the asymptotic covariance between $\sqrt{n_{\mathrm{tr}}}\delta H_{i,j}$ and $\sqrt{n_{\mathrm{tr}}}\delta H_{i',j'}$ is given by

$$\int \varphi_i(x)\varphi_j(x)\varphi_{i'}(x)\varphi_{j'}(x)p_{\mathrm{tr}}(x)dx - H_{i,j}H_{i',j'}.$$

Then we have

$$\begin{aligned}\lim_{n_{\mathrm{tr}}\to\infty}\mathbb{E}\left[(\sqrt{n_{\mathrm{tr}}}\delta H\alpha^*(\lambda))(\sqrt{n_{\mathrm{tr}}}\delta H\alpha^*(\lambda))^\top\right] &= C_{w^*,w^*},\\ \lim_{n_{\mathrm{tr}}\to\infty}\mathbb{E}\left[(\sqrt{n_{\mathrm{tr}}}\delta H\alpha^*(\lambda))(\sqrt{n_{\mathrm{tr}}}\delta HA1_b)^\top\right] &= C_{w^*,v},\end{aligned}$$

where $C_{w,w'}$ is the $b\times b$ covariance matrix with the (ℓ,ℓ')-th element being the covariance between $w(x)\varphi_\ell(x)$ and $w'(x)\varphi_{\ell'}(x)$ under $p_{\mathrm{tr}}(x)$. Then we obtain Eq. (19).

Appendix D. Regularization Path of LSIF

Here, we derive the regularization path tracking algorithm given in Figure 1.

When λ is greater than or equal to $\max_k \widehat{h}_k$, the solution of the KKT conditions (9)–(10) is provided as $\alpha = 0_b$, $\xi = \lambda 1_b - \widehat{h} \geq 0_b$. Therefore, the initial value of λ_0 is $\max_k \widehat{h}_k$, and the corresponding optimal solution is $\widehat{\alpha}(\lambda_0) = 0_b$.

Since $\widehat{\xi}'(\lambda)$ corresponds to non-zero elements of $\widehat{\xi}(\lambda)$ as shown in Eq. (11), we have

$$\widehat{\xi}_j(\lambda) = \begin{cases}\widehat{\xi}_i'(\lambda) & \text{if } j = \widehat{j}_i,\\ 0 & \text{otherwise.}\end{cases} \tag{56}$$

When λ is decreased, the solutions $\widehat{\alpha}(\lambda)$ and $\widehat{\xi}(\lambda)$ still satisfy Eqs. (12) and (56) as long as the active set $\widehat{\mathcal{A}}$ remains unchanged. Change points of the active set can be found by examining the non-negativity conditions of $\widehat{\alpha}(\lambda)$ and $\widehat{\xi}(\lambda)$ as follows. Suppose λ is decreased and the non-negativity condition

$$\begin{pmatrix}\widehat{\alpha}(\lambda)\\ \widehat{\xi}(\lambda)\end{pmatrix} \geq 0_{2b}$$

is violated at $\lambda = \lambda'$. That is, both $\widehat{\alpha}(\lambda') \geq 0_b$ and $\widehat{\xi}(\lambda') \geq 0_b$ hold, and either $\widehat{\alpha}(\lambda' - \varepsilon) \geq 0_b$ or $\widehat{\xi}(\lambda' - \varepsilon) \geq 0_b$ is violated for any $\varepsilon > 0$. If $\widehat{\alpha}_j(\lambda') = 0$ for $j \notin \widehat{\mathcal{A}}$, j should be added to the active set

$\widehat{\mathcal{A}}$; on the other hand, if $\widehat{\xi}_j(\lambda') = 0$ for some $j \in \widehat{\mathcal{A}}$, $\widehat{\alpha}_j(\lambda')$ will take a positive value and therefore j should be removed from the active set $\widehat{\mathcal{A}}$. Then, for the updated active set, we compute the solutions by Eqs. (12) and (56). Iterating this procedure until λ reaches zero, we can obtain the entire regularization path.

Note that we omitted some minor exceptional cases for the sake of simplicity—treatments for all possible exceptions and the rigorous convergence property are exhaustively studied in Best (1982).

Appendix E. Negative Index Set of $\beta^\circ(\lambda)$

Here we prove Theorem 4.

As explained in Appendix B, we regard the pair of a symmetric matrix and a vector (H', h') as an element in the $(\frac{b(b+1)}{2} + b)$-dimensional Euclidean space.

We consider the linear equation

$$\beta' = (H' + \lambda I_b)^{-1} h'.$$

Due to the assumption, for $H' = H$ and $h' = h$, we have

$$\beta'_\ell \neq 0, \ \ell = 1, 2, \ldots, b. \tag{57}$$

On the other hand, if the norm of $(H', h') - (H, h)$ is infinitesimal, the solution β' also satisfies Eq. (57), and the sign of β'_ℓ is same as that of β_ℓ for $\ell = 1, 2, \ldots, b$, because of the continuity of the relation between (H', h') and β'.

As a result, there exists an ε-ball B_ε in $\mathbb{R}^{\frac{b(b+1)}{2}+b}$ such that the equality $\mathcal{B} = \widetilde{\mathcal{B}}$ holds for any $(H', h') \in B_\varepsilon$. Therefore, we have $P(\mathcal{B} \neq \widetilde{\mathcal{B}}) \leq P((\widehat{H}, \widehat{h}) \notin B_\varepsilon)$. Due to the large deviation principle (Dembo and Zeitouni, 1998), there is a positive constant c such that

$$-\frac{1}{\min\{n_{\mathrm{tr}}, n_{\mathrm{te}}\}} \log P((\widehat{H}, \widehat{h}) \notin B_\varepsilon) > c > 0,$$

if $\min\{n_{\mathrm{tr}}, n_{\mathrm{te}}\}$ is large enough. Thus, asymptotically $P(\mathcal{B} \neq \widetilde{\mathcal{B}}) < e^{-c \min\{n_{\mathrm{tr}}, n_{\mathrm{te}}\}}$ holds.

Appendix F. Learning Curve of uLSIF

Here, we prove Theorem 5.

Let

$$\widehat{B}_\lambda = \widehat{H} + \lambda I_b.$$

The matrix Taylor expansion (Petersen and Pedersen, 2007) yields

$$\widehat{B}_\lambda^{-1} = B_\lambda^{-1} - B_\lambda^{-1} \delta H B_\lambda^{-1} + B_\lambda^{-1} \delta H B_\lambda^{-1} \delta H B_\lambda^{-1} - \cdots. \tag{58}$$

Let $\widetilde{\mathcal{B}} \subset \{1, 2, \ldots, b\}$ be the set of negative indices of $\widetilde{\beta}(\lambda)$, that is,

$$\widetilde{\mathcal{B}} = \{\ell \mid \widetilde{\beta}_\ell(\lambda) < 0, \ \ell = 1, 2, \ldots, b\}.$$

Let $\widehat{D}$ be the b-dimensional diagonal matrix with the ℓ-th diagonal element

$$\widehat{D}_{\ell,\ell} = \begin{cases} 0 & \ell \in \widetilde{\mathcal{B}}, \\ 1 & \text{otherwise.} \end{cases}$$

The assumption (a) implies that the equality

$$\widehat{D} = D \tag{59}$$

holds with exponentially high probability due to Theorem 4. Combining Eqs. (59), (41), (58), and (24), we have

$$\begin{aligned}\delta\beta &= \widehat{\beta}(\lambda) - \beta^*(\lambda)\\ &= \widehat{D}\widehat{B}_\lambda^{-1}\widehat{h} - DB_\lambda^{-1}h\\ &= -DB_\lambda^{-1}\delta H\beta^\circ(\lambda) + DB_\lambda^{-1}\delta HB_\lambda^{-1}\delta H\beta^\circ(\lambda) + o\left(\frac{1}{n_{\mathrm{tr}}}\right).\end{aligned} \tag{60}$$

From Eqs. (46) and (60), we have

$$\mathbb{E}\left[\delta\beta^\top H\delta\beta\right] = \mathrm{tr}(B_\lambda^{-1}DHDB_\lambda^{-1}\,\mathbb{E}\left[(\delta H\beta^\circ(\lambda))(\delta H\beta^\circ(\lambda))^\top\right]) + o\left(\frac{1}{n_{\mathrm{tr}}}\right). \tag{61}$$

From Eqs. (52) and (24), we have

$$\begin{aligned}\mathbb{E}\left[\delta\beta^\top(H\beta^*(\lambda)-h)\right] =&\mathbb{E}\left[(-\delta H\beta^\circ(\lambda) + \delta HB_\lambda^{-1}\delta H\beta^\circ(\lambda))^\top B_\lambda^{-1}D(H\beta^*(\lambda)-h)\right]\\ &+ o\left(\frac{1}{n_{\mathrm{tr}}}\right)\\ =&\mathbb{E}\left[\mathrm{tr}(B_\lambda^{-1}(\delta H\beta^\circ(\lambda))(\delta HB_\lambda^{-1}D(H\beta^*(\lambda)-h))^\top)\right]\\ &+ o\left(\frac{1}{n_{\mathrm{tr}}}\right).\end{aligned} \tag{62}$$

Combining Eqs. (53), (61), and (62), we have

$$\begin{aligned}\mathbb{E}\left[J(\widehat{\beta}(\lambda))\right] =&J(\beta^*(\lambda)) + \frac{1}{2n_{\mathrm{tr}}}\mathrm{tr}(B_\lambda^{-1}DHDB_\lambda^{-1}\,\mathbb{E}[(\sqrt{n_{\mathrm{tr}}}\delta H\beta^\circ(\lambda))(\sqrt{n_{\mathrm{tr}}}\delta H\beta^\circ(\lambda))^\top)\\ &+ \frac{1}{n_{\mathrm{tr}}}\mathrm{tr}(B_\lambda^{-1}\,\mathbb{E}[(\sqrt{n_{\mathrm{tr}}}\delta H\beta^\circ(\lambda))(\sqrt{n_{\mathrm{tr}}}\delta HB_\lambda^{-1}D(H\beta^*(\lambda)-h))^\top) + o\left(\frac{1}{n_{\mathrm{tr}}}\right).\end{aligned}$$

According to the central limit theorem, we have

$$\begin{aligned}\lim_{n_{\mathrm{tr}}\to\infty}\mathbb{E}[(\sqrt{n_{\mathrm{tr}}}\delta H\beta^\circ(\lambda))(\sqrt{n_{\mathrm{tr}}}\delta H\beta^\circ(\lambda))^\top] &= C_{w^\circ,w^\circ},\\ \lim_{n_{\mathrm{tr}}\to\infty}\mathbb{E}[(\sqrt{n_{\mathrm{tr}}}\delta H\beta^\circ(\lambda))(\sqrt{n_{\mathrm{tr}}}\delta HB_\lambda^{-1}D(H\beta^*(\lambda)-h))^\top] &= C_{w^\circ,u}.\end{aligned}$$

Then we obtain Eq. (25).

Appendix G. 'Norm' Upper Bound of Approximation Error for uLSIF

Here we prove Theorem 6.

Using the weighted norm (27), we can express diff(λ) as

$$\mathrm{diff}(\lambda) = \frac{\inf_{\lambda'\geq 0}\|\widehat{\alpha}(\lambda') - \widehat{\beta}(\lambda)\|_{\widehat{H}}}{\sum_{i=1}^{n_{\mathrm{tr}}}\widehat{w}(x_i^{\mathrm{tr}};\widehat{\beta}(\lambda))}.$$

As shown in Appendix D, $\widehat{\alpha}(\lambda') = 0_b$ holds for some large λ'. Then we immediately have

$$\mathrm{diff}(\lambda) \le \frac{\|\widehat{\beta}(\lambda)\|_{\widehat{H}}}{\sum_{i=1}^{n_{\mathrm{tr}}} \widehat{w}(x_i^{\mathrm{tr}}; \widehat{\beta}(\lambda))},$$

which proves Eq. (28). Let $\kappa_{\max}$ be the largest eigenvalue of $\widehat{H}$. Then $\|\widehat{\beta}(\lambda)\|_{\widehat{H}}$ can be upper bounded as

$$\|\widehat{\beta}(\lambda)\|_{\widehat{H}} \le \sqrt{\kappa_{\max}} \|\widehat{\beta}(\lambda)\|_2 \le \sqrt{\kappa_{\max}} \|\widetilde{\beta}(\lambda)\|_2,$$

where the first inequality may be confirmed by eigen-decomposing $\widehat{H}$ and the second inequality is clear from the definitions of $\widehat{\beta}(\lambda)$ and $\widetilde{\beta}(\lambda)$. Let $\kappa_{\min}$ be the smallest eigenvalue of $\widehat{H}$. Then an upper bound of $\|\widetilde{\beta}(\lambda)\|_2^2$ is given as

$$\|\widetilde{\beta}(\lambda)\|_2^2 = \widehat{h}^\top (\widehat{H} + \lambda I_b)^{-2} \widehat{h} \le \frac{1}{(\kappa_{\min} + \lambda)^2} \|\widehat{h}\|_2^2 \le \frac{1}{\lambda^2} \|\widehat{h}\|_2^2,$$

where the last inequality follows from $\kappa_{\min} > 0$.

Now we have

$$\begin{aligned} \frac{\|\widehat{\beta}(\lambda)\|_{\widehat{H}}}{\sum_{i=1}^{n_{\mathrm{tr}}} w(x_i^{\mathrm{tr}}; \widehat{\beta}(\lambda))} &\le \frac{1}{\sum_{i=1}^{n_{\mathrm{tr}}} w(x_i^{\mathrm{tr}}; \widehat{\beta}(\lambda))} \frac{\sqrt{\kappa_{\max}} \|\widehat{h}\|_2}{\lambda} \\ &= \frac{1}{\sum_{i=1}^{n_{\mathrm{tr}}} \sum_{\ell=1}^{b} \varphi_\ell(x_i^{\mathrm{tr}}) \widehat{\beta}_\ell(\lambda) / \|\widehat{\beta}(\lambda)\|_1} \frac{\sqrt{\kappa_{\max}} \|\widehat{h}\|_2}{\lambda \|\widehat{\beta}(\lambda)\|_1}. \end{aligned}$$

For the denominator of the above expression, we have

$$\sum_{i=1}^{n_{\mathrm{tr}}} \sum_{\ell=1}^{b} \varphi_\ell(x_i^{\mathrm{tr}}) \frac{\widehat{\beta}_\ell(\lambda)}{\|\widehat{\beta}(\lambda)\|_1} \ \ge \ \min_{\ell'} \Big(\sum_{i=1}^{n_{\mathrm{tr}}} \varphi_{\ell'}(x_i^{\mathrm{tr}}) \Big) \cdot \sum_{\ell=1}^{b} \frac{\widehat{\beta}_\ell(\lambda)}{\|\widehat{\beta}(\lambda)\|_1} \ = \ \min_{\ell} \sum_{i=1}^{n_{\mathrm{tr}}} \varphi_\ell(x_i^{\mathrm{tr}}),$$

where the last equality follows from the non-negativity of $\widehat{\beta}_\ell(\lambda)$. The reciprocal of $\|\widehat{h}\|_2 / \|\widehat{\beta}(\lambda)\|_1$ is lower bounded as follows:

$$\frac{\|\widehat{\beta}(\lambda)\|_1}{\|\widehat{h}\|_2} \ = \ \left\| \max\left\{ \frac{\widetilde{\beta}(\lambda)}{\|\widehat{h}\|_2}, 0 \right\} \right\|_1 \ \ge \ \left\| \max\left\{ \frac{\widetilde{\beta}(\lambda)}{\|\widehat{h}\|_2}, 0 \right\} \right\|_\infty \ = \ \max_\ell \frac{\widetilde{\beta}_\ell(\lambda)}{\|\widehat{h}\|_2},$$

where the last equality follows from the fact that there is an ℓ such that $\widetilde{\beta}_\ell(\lambda) > 0$; otherwise, we have $\sum_{i=1}^{n_{\mathrm{tr}}} w(x_i^{\mathrm{tr}}; \widehat{\beta}) = 0$ which contradicts to the assumption of the theorem. Let us put

$$\kappa e = \frac{\widetilde{\beta}(\lambda)}{\|\widehat{h}\|_2},$$

where $\kappa > 0$ and $e \in \mathbb{R}^b$ such that $\|e\|_2 = 1$. Then we have

$$(\kappa_{\max} + \lambda)^{-1} \le \kappa \text{ and } e^\top \widehat{h} > 0.$$

Note that there exists an ℓ such that $e_\ell > 0$. Then, we have

$$\begin{aligned}\max_\ell \frac{\widetilde{\beta}_\ell(\lambda)}{\|\widehat{h}\|_2} &= \max_\ell \kappa e_\ell = \kappa \max_\ell e_\ell \geq \frac{1}{\kappa_{\max}+\lambda} \max_\ell e_\ell \\ &\geq \frac{1}{\kappa_{\max}+\lambda} \min_e \{\max_\ell e_\ell \mid e^\top e = 1, e^\top \widehat{h}/\|\widehat{h}\|_1 > 0\}.\end{aligned}$$

Now we prove the following lemma.

Lemma 8 *Let $p_1, p_2, \ldots, p_b \, (b \geq 2)$ be positive numbers such that*

$$\sum_{\ell=1}^b p_\ell = 1,$$

and let

$$\varepsilon = \frac{1}{\sqrt{b}} \min_\ell \frac{p_\ell}{1-p_\ell}.$$

Then, there exists no $e = (e_1, e_2, \ldots, e_b) \in \mathbb{R}^b$ such that the three conditions,

$$\sum_{\ell=1}^b e_\ell^2 = 1, \ \sum_{\ell=1}^b p_\ell e_\ell > 0, \text{ and } e_\ell < \varepsilon \text{ for } \ell = 1, 2, \ldots, b$$

are satisfied at the same time.

Proof We suppose that $e \in \mathbb{R}^b$ satisfies the three conditions. If $\min_\ell p_\ell/(1-p_\ell) > 1$, we have $p_\ell > 1/2$ for all ℓ. However, this is contradictory to $\sum_{\ell=1}^b p_\ell = 1$. Therefore, we have

$$\min_\ell p_\ell/(1-p_\ell) \leq 1,$$

from which we have

$$\varepsilon \leq 1/\sqrt{b}.$$

The equality constraint $\sum_{\ell=1}^b e_\ell^2 = 1$ implies the condition that there exists an e_i such that $|e_i| \geq 1/\sqrt{b}$. Moreover, we have $e_1, e_2, \ldots, e_b < \varepsilon \leq 1/\sqrt{b}$, and thus there is an e_i such that $e_i \leq -1/\sqrt{b}$. Hence, we have

$$\frac{p_i}{\sqrt{b}} \leq -p_i e_i < \sum_{\ell \neq i} p_\ell e_\ell < \sum_{\ell \neq i} p_\ell \frac{1}{\sqrt{b}} \min_k \frac{p_k}{1-p_k} = (1-p_i)\frac{1}{\sqrt{b}} \min_k \frac{p_k}{1-p_k} \leq \frac{p_i}{\sqrt{b}}.$$

This results in contradiction. ■

Let $p_\ell = \widehat{h}_\ell/\|\widehat{h}\|_1$ and we use Lemma 8. Note that any element of $\widehat{h}$ is positive. Then, we have

$$\frac{\|\widehat{\beta}(\lambda)\|_1}{\|\widehat{h}\|_2} \geq \frac{1}{\kappa_{\max}+\lambda} \cdot \frac{1}{\sqrt{b}} \min_\ell \frac{p_\ell}{\sum_{i \neq \ell} p_i}.$$

Moreover, we have

$$\min_\ell \frac{p_\ell}{\sum_{i \neq \ell} p_i} \geq \frac{\min_\ell \widehat{h}_\ell}{\sum_{\ell'=1}^b \widehat{h}_{\ell'}} = \frac{\min_\ell \sum_{j=1}^{n_{\mathrm{te}}} \varphi_\ell(x_j^{\mathrm{te}})}{\sum_{\ell'=1}^b \sum_{j=1}^{n_{\mathrm{te}}} \varphi_{\ell'}(x_j^{\mathrm{te}})} \geq \frac{\min_\ell \sum_{j=1}^{n_{\mathrm{te}}} \varphi_\ell(x_j^{\mathrm{te}})}{n_{\mathrm{te}} b},$$

where the last inequality follows from the assumption $0 < \varphi_\ell(x) \leq 1$. Therefore, we have the inequality

$$\begin{aligned}
&\frac{1}{\sum_{i=1}^{n} w(x_i^{\mathrm{tr}}; \widehat{\beta}(\lambda))} \frac{\sqrt{\kappa_{\max}} \|\widehat{h}\|_2}{\lambda} \\
&\leq b\sqrt{b\kappa_{\max}} \left(1 + \frac{\kappa_{\max}}{\lambda}\right) \frac{1}{\min_\ell \sum_{i=1}^{n_{\mathrm{tr}}} \varphi_\ell(x_i^{\mathrm{tr}})} \cdot \frac{n_{\mathrm{te}}}{\min_{\ell'} \sum_{j=1}^{n_{\mathrm{te}}} \varphi_{\ell'}(x_j^{\mathrm{te}})}. \qquad (63)
\end{aligned}$$

An upper bound of $\kappa_{\max}$ is given as follows. For all $a \in \mathbb{R}^b$, the inequality

$$-\sum_{\ell=1}^{b} |a_\ell| \varphi_\ell(x) \leq \sum_{\ell=1}^{b} a_\ell \varphi_\ell(x) \leq \sum_{\ell=1}^{b} |a_\ell| \varphi_\ell(x) \qquad (64)$$

holds because of the positivity of $\varphi_\ell(x)$. Let us define $\bar{a} \in \mathbb{R}^b$ for given $a \in \mathbb{R}^b$ as

$$\bar{a} = (|a_1|, |a_2|, \ldots, |a_b|)^\top.$$

Note that $\|\bar{a}\|_2 = \|a\|_2$ holds. Then, using Eq. (64), we obtain the inequality

$$a^\top \widehat{H} a = \frac{1}{n_{\mathrm{tr}}} \sum_{i=1}^{n_{\mathrm{tr}}} \left(\sum_{\ell=1}^{b} a_\ell \varphi_\ell(x_i^{\mathrm{tr}}) \right)^2 \leq \frac{1}{n_{\mathrm{tr}}} \sum_{i=1}^{n_{\mathrm{tr}}} \left(\sum_{\ell=1}^{b} |a_\ell| \varphi_\ell(x_i^{\mathrm{tr}}) \right)^2 = \bar{a}^\top \widehat{H} \bar{a},$$

for any $a \in \mathbb{R}^b$. Therefore, we obtain

$$\max_{\|a\|_2=1} a^\top \widehat{H} a \leq \max_{\|a\|_2=1} \bar{a}^\top \widehat{H} \bar{a} = \max_{\|a\|_2=1,\, a \geq 0_b} a^\top \widehat{H} a, \qquad (65)$$

where the last equality is derived from the relation,

$$\{\bar{a} \mid \|a\|_2 = 1,\ a \in \mathbb{R}^b\} = \{a \mid \|a\|_2 = 1,\ a \geq 0_b,\ a \in \mathbb{R}^b\}.$$

On the other hand, due to the additional constraint $a \geq 0_b$, the inequality

$$\max_{\|a\|_2=1,\, a \geq 0_b} a^\top \widehat{H} a \leq \max_{\|a\|_2=1} a^\top \widehat{H} a \qquad (66)$$

holds. From Eqs. (65) and (66), we have

$$\kappa_{\max} = \max_{\|a\|_2=1} a^\top \widehat{H} a = \max_{\|a\|_2=1, a \geq 0_b} a^\top \widehat{H} a = \max_{\|a\|_2=1,\, a \geq 0_b} \frac{1}{n_{\mathrm{tr}}} \sum_{i=1}^{n_{\mathrm{tr}}} \left(\sum_{\ell=1}^{b} a_\ell \varphi_\ell(x_i^{\mathrm{tr}}) \right)^2.$$

Using the assumption $0 < \varphi_\ell(x) \leq 1$, we have

$$\begin{aligned}
\kappa_{\max} &= \max_{\|a\|_2=1,\, a \geq 0_b} \frac{1}{n_{\mathrm{tr}}} \sum_{i=1}^{n_{\mathrm{tr}}} \left(\sum_{\ell=1}^{b} a_\ell \varphi_\ell(x_i^{\mathrm{tr}}) \right)^2 \leq \max_{\|a\|_2=1,\, a \geq 0_b} \frac{1}{n_{\mathrm{tr}}} \sum_{i=1}^{n_{\mathrm{tr}}} \left(\sum_{\ell=1}^{b} a_\ell \right)^2 \\
&= \max_{\|a\|_2=1,\, a \geq 0_b} \left(\sum_{\ell=1}^{b} a_\ell \right)^2 \leq \max_{\|a\|_2=1,\, a \geq 0_b} b \cdot \sum_{\ell=1}^{b} a_\ell^2 \\
&= b, \qquad (67)
\end{aligned}$$

where the Schwarz inequality for a and 1_b is used in the last inequality. The inequalities (63) and (67) lead to the inequality (29).

It is clear that the upper bound (29) is a decreasing function of λ (> 0). For the Gaussian basis function, $\varphi_\ell(x)$ is an increasing function with respect to the Gaussian width σ. Thus, Eq. (29) is a decreasing function of σ.

Appendix H. 'Bridge' Upper Bound of Approximation Error for uLSIF

Here we prove Theorem 7.

From the triangle inequality, we obtain

$$\mathrm{diff}(\lambda) \leq \frac{\inf_{\lambda' \geq 0} \|\widehat{\alpha}(\lambda') - \widehat{\gamma}(\lambda)\|_{\widehat{H}} + \|\widehat{\gamma}(\lambda) - \widehat{\beta}(\lambda)\|_{\widehat{H}}}{\sum_{i=1}^{n_{\mathrm{tr}}} \widehat{w}(x_i^{\mathrm{tr}}; \widehat{\beta}(\lambda))}. \tag{68}$$

We derive an upper bound of the first term.

First, we show that the LSIF optimization problem (6) is equivalently expressed as

$$\min_{\alpha \in \mathbb{R}^b} \left[\frac{1}{2} \alpha^\top \widehat{H} \alpha - \widehat{h}^\top \alpha \right]$$
$$\text{subject to } \alpha \geq 0_b, \;\; 1_b^\top \alpha \leq c,$$

which we refer to as LSIF$'$. The KKT conditions of LSIF (6) are given as

$$\begin{cases} \widehat{H}\alpha - \widehat{h} + \lambda 1_b - \mu = 0_b, \\ \alpha \geq 0_b, \;\; \mu \geq 0_b, \;\; \alpha^\top \mu = 0, \end{cases}$$

where μ is the Lagrange multiplier vector. Similarly, the KKT conditions of LSIF$'$ are given as

$$\begin{cases} \widehat{H}\alpha - \widehat{h} + \mu_0 1_b - \mu = 0_b, \\ \alpha \geq 0_b, \;\; \mu \geq 0_b, \;\; \alpha^\top \mu = 0, \\ 1_b^\top \alpha - c \leq 0, \; \mu_0 \geq 0, \;\; (1_b^\top \alpha - c)\mu_0 = 0, \end{cases} \tag{69}$$

where μ and μ_0 are the Lagrange multipliers. Let $(\widehat{\alpha}(\lambda), \widehat{\mu}(\lambda))$ be the solution of the KKT conditions of LSIF. Then, we find that $(\alpha, \mu, \mu_0) = (\widehat{\alpha}(\lambda), \widehat{\mu}(\lambda), \lambda)$ is the solution of Eq. (69) with $c = 1_b^\top \widehat{\alpha}(\lambda)$. Note that LSIF$'$ is a strictly convex optimization problem, and thus $\widehat{\alpha}(\lambda)$ is the unique optimal solution. Conversely, when the solution of Eq. (69) is provided as $(\widehat{\alpha}, \widehat{\mu}, \mu_0)$, LSIF with $\lambda = \mu_0$ has the same optimal solution $\widehat{\alpha}$.

When the optimal solution of LSIFq is $\widehat{\gamma}(\lambda)$, the KKT conditions of LSIFq (30) are given as

$$\widehat{H}\widehat{\gamma}(\lambda) - \widehat{h} + \lambda\widehat{\gamma}(\lambda) - \widehat{\eta} = 0_b, \tag{70}$$

$$\widehat{\gamma}(\lambda) \geq 0_b, \;\; \widehat{\eta} \geq 0_b, \;\; \widehat{\gamma}(\lambda)^\top \widehat{\eta} = 0, \tag{71}$$

where $\widehat{\eta}$ is the Lagrange multiplier vector.

Let $\widehat{\alpha}(\lambda_1)$ be the optimal solution of LSIF$'$ with $c = 1_b^\top \widehat{\gamma}(\lambda)$, and suppose that the solution $\widehat{\alpha}(\lambda_1)$ coincides with that of LSIF with $\lambda = \lambda_1$. Then, from Eq. (69), we have

$$\widehat{H}\widehat{\alpha}(\lambda_1) - \widehat{h} + \lambda_1 1_b - \widehat{\mu}(\lambda_1) = 0_b, \tag{72}$$

$$\widehat{\alpha}(\lambda_1) \geq 0_b, \;\; \widehat{\mu}(\lambda_1) \geq 0_b, \;\; \widehat{\alpha}(\lambda_1)^\top \widehat{\mu}(\lambda_1) = 0, \tag{73}$$

$$1_b^\top \widehat{\alpha}(\lambda_1) - 1_b^\top \widehat{\gamma}(\lambda) \leq 0, \;\; \lambda_1 \geq 0, \;\; (1_b^\top \widehat{\alpha}(\lambda_1) - 1_b^\top \widehat{\gamma}(\lambda))\lambda_1 = 0. \tag{74}$$

From Eqs. (70) and (72), we obtain

$$\widehat{H}(\widehat{\alpha}(\lambda_1) - \widehat{\gamma}(\lambda)) = -\lambda_1 1_b + \lambda\widehat{\gamma}(\lambda) + \widehat{\mu}(\lambda_1) - \widehat{\eta}. \tag{75}$$

Applying Eqs. (71), (73), (74), and (75), we have

$$\begin{aligned}\inf_{\lambda'\geq 0}\|\widehat{\alpha}(\lambda')-\widehat{\gamma}(\lambda)\|_{\widehat{H}}^2 &\leq (\widehat{\alpha}(\lambda_1)-\widehat{\gamma}(\lambda))^\top\widehat{H}(\widehat{\alpha}(\lambda_1)-\widehat{\gamma}(\lambda))\\ &= -\lambda_1(\widehat{\alpha}(\lambda_1)-\widehat{\gamma}(\lambda))^\top 1_b+\lambda(\widehat{\alpha}(\lambda_1)-\widehat{\gamma}(\lambda))^\top\widehat{\gamma}(\lambda)\\ &\quad +(\widehat{\alpha}(\lambda_1)-\widehat{\gamma}(\lambda))^\top(\widehat{\mu}(\lambda_1)-\widehat{\eta})\\ &= \lambda(\widehat{\alpha}(\lambda_1)^\top\widehat{\gamma}(\lambda)-\|\widehat{\gamma}(\lambda)\|_2^2)-\widehat{\alpha}(\lambda_1)^\top\widehat{\eta}-\widehat{\gamma}(\lambda)^\top\widehat{\mu}(\lambda_1)\\ &\leq \lambda(\widehat{\alpha}(\lambda_1)^\top\widehat{\gamma}(\lambda)-\|\widehat{\gamma}(\lambda)\|_2^2). \end{aligned} \tag{76}$$

From $\widehat{\alpha}(\lambda_1)\geq 0_b, \widehat{\gamma}(\lambda)\geq 0_b$, and $1_b^\top\widehat{\alpha}(\lambda_1)\leq 1_b^\top\widehat{\gamma}(\lambda)$, we have

$$\|\widehat{\alpha}(\lambda_1)\|_1 = 1_b^\top\widehat{\alpha}(\lambda_1)\leq 1_b^\top\widehat{\gamma}(\lambda)\leq\|\widehat{\gamma}(\lambda)\|_1.$$

Then we have the following inequality:

$$\begin{aligned}\widehat{\alpha}(\lambda_1)^\top\widehat{\gamma}(\lambda) &\leq \widehat{\alpha}(\lambda_1)^\top(\|\widehat{\gamma}(\lambda)\|_\infty 1_b)\\ &= \|\widehat{\alpha}(\lambda_1)\|_1\cdot\|\widehat{\gamma}(\lambda)\|_\infty\leq\|\widehat{\gamma}(\lambda)\|_1\cdot\|\widehat{\gamma}(\lambda)\|_\infty.\end{aligned} \tag{77}$$

For p and q such that $1/p+1/q=1$ and $1\leq p,q\leq\infty$, Hölder's inequality states that

$$\|\alpha*\beta\|_1\leq\|\alpha\|_p\cdot\|\beta\|_q,$$

where $\alpha*\beta$ denotes the element-wise product of α and β. Setting $p=1, q=\infty$, and $\alpha=\beta=\widehat{\gamma}(\lambda)$ in Hölder's inequality, we have

$$\|\widehat{\gamma}(\lambda)\|_1\cdot\|\widehat{\gamma}(\lambda)\|_\infty-\|\widehat{\gamma}(\lambda)\|_2^2\geq 0. \tag{78}$$

Combining Eqs. (68), (76), (77), and (78), we obtain

$$\mathrm{diff}(\lambda)\ \leq\ \frac{\sqrt{\lambda(\|\widehat{\gamma}(\lambda)\|_1\cdot\|\widehat{\gamma}(\lambda)\|_\infty-\|\widehat{\gamma}(\lambda)\|_2^2)}+\|\widehat{\gamma}(\lambda)-\widehat{\beta}(\lambda)\|_{\widehat{H}}}{\sum_{i=1}^{n_{\mathrm{tr}}}\widehat{w}(x_i^{\mathrm{tr}};\widehat{\beta}(\lambda))}.$$

Appendix I. Closed Form of LOOCV Score for uLSIF

Here we derive a closed form expression of the LOOCV score for uLSIF (see Figure 2 for the pseudo code).

Let

$$\varphi(x)=(\varphi_1(x),\varphi_2(x),\ldots,\varphi_b(x))^\top.$$

Then the matrix $\widehat{H}$ and the vector $\widehat{h}$ are expressed as

$$\widehat{H}=\frac{1}{n_{\mathrm{tr}}}\sum_{i=1}^{n_{\mathrm{tr}}}\varphi(x_i^{\mathrm{tr}})\varphi(x_i^{\mathrm{tr}})^\top,$$

$$\widehat{h}=\frac{1}{n_{\mathrm{te}}}\sum_{j=1}^{n_{\mathrm{te}}}\varphi(x_j^{\mathrm{te}}),$$

and the coefficients $\widetilde{\beta}(\lambda)$ can be computed by

$$\widetilde{\beta}(\lambda) = \widehat{B}_{\lambda}^{-1}\widehat{h}.$$

Let $\widehat{\beta}^{(i)}$ be the estimator obtained without the i-th training sample x_i^{tr} and the i-th test sample x_i^{te}. Then the estimator has the following closed form:

$$\widehat{\beta}^{(i)}(\lambda) = \max(0_b, \widetilde{\beta}^{(i)}(\lambda)),$$
$$\widetilde{\beta}^{(i)}(\lambda) = \left(\frac{1}{n_{\mathrm{tr}}-1}(n_{\mathrm{tr}}\widehat{H} - \varphi(x_i^{\mathrm{tr}})\varphi(x_i^{\mathrm{tr}})^\top) + \lambda I_b\right)^{-1} \frac{1}{n_{\mathrm{te}}-1}(n_{\mathrm{te}}\widehat{h} - \varphi(x_j^{\mathrm{te}})).$$

Let $\widehat{B} = \widehat{H} + \frac{\lambda(n_{\mathrm{tr}}-1)}{n_{\mathrm{tr}}} I_b$ and $\widetilde{\beta} = \widehat{B}^{-1}\widehat{h}$ in the following calculation. Using the Sherman-Woodbury-Morrison formula (33), we can simplify the expression of $\widetilde{\beta}^{(i)}(\lambda)$ as follows:

$$\begin{aligned}
\widetilde{\beta}^{(i)}(\lambda) =& \frac{n_{\mathrm{tr}}-1}{n_{\mathrm{tr}}}\left(\widehat{B} - \frac{1}{n_{\mathrm{tr}}}\varphi(x_i^{\mathrm{tr}})\varphi(x_i^{\mathrm{tr}})^\top\right)^{-1}\left(\frac{n_{\mathrm{te}}}{n_{\mathrm{te}}-1}\widehat{h} - \frac{1}{n_{\mathrm{te}}-1}\varphi(x_i^{\mathrm{te}})\right) \\
=& \frac{n_{\mathrm{tr}}-1}{n_{\mathrm{tr}}}\left(\widehat{B}^{-1} + \frac{1}{n_{\mathrm{tr}} - \varphi(x_i^{\mathrm{tr}})^\top \widehat{B}^{-1}\varphi(x_i^{\mathrm{tr}})}\widehat{B}^{-1}\varphi(x_i^{\mathrm{tr}})\varphi(x_i^{\mathrm{tr}})^\top\widehat{B}^{-1}\right) \\
&\times\left(\frac{n_{\mathrm{te}}}{n_{\mathrm{te}}-1}\widehat{h} - \frac{1}{n_{\mathrm{te}}-1}\varphi(x_i^{\mathrm{te}})\right) \\
=& \frac{(n_{\mathrm{tr}}-1)n_{\mathrm{te}}}{n_{\mathrm{tr}}(n_{\mathrm{te}}-1)}\left(\widetilde{\beta} + \frac{\varphi(x_i^{\mathrm{tr}})^\top\widetilde{\beta}}{n_{\mathrm{tr}} - \varphi(x_i^{\mathrm{tr}})^\top\widehat{B}^{-1}\varphi(x_i^{\mathrm{tr}})}\widehat{B}^{-1}\varphi(x_i^{\mathrm{tr}})\right) \\
&- \frac{(n_{\mathrm{tr}}-1)}{n_{\mathrm{tr}}(n_{\mathrm{te}}-1)}\left(\widehat{B}^{-1}\varphi(x_i^{\mathrm{te}}) + \frac{\varphi(x_i^{\mathrm{tr}})^\top\widehat{B}^{-1}\varphi(x_i^{\mathrm{te}})}{n_{\mathrm{tr}} - \varphi(x_i^{\mathrm{tr}})^\top\widehat{B}^{-1}\varphi(x_i^{\mathrm{tr}})}\widehat{B}^{-1}\varphi(x_i^{\mathrm{tr}})\right).
\end{aligned}$$

Thus the matrix inversion required for computing $\widetilde{\beta}^{(i)}(\lambda)$ for all $i = 1, 2, \ldots, n_{\mathrm{tr}}$ is only $\widehat{B}$. Applying this to Eq. (32) and rearrange the formula, we can compute the LOOCV score analytically.

Abstract

This paper considers binary classification algorithms generated from Tikhonov regularization schemes associated with general convex loss functions and varying Gaussian kernels. Our main goal is to provide fast convergence rates for the excess misclassification error. Allowing varying Gaussian kernels in the algorithms improves learning rates measured by regularization error and sample error. Special structures of Gaussian kernels enable us to construct, by a nice approximation scheme with a Fourier analysis technique, uniformly bounded regularizing functions achieving polynomial decays of the regularization error under a Sobolev smoothness condition. The sample error is estimated by using a projection operator and a tight bound for the covering numbers of reproducing kernel Hilbert spaces generated by Gaussian kernels. The convexity of the general loss function plays a very important role in our analysis.

Keywords: reproducing kernel Hilbert space, binary classification, general convex loss, varying Gaussian kernels, covering number, approximation

1. Introduction

In this paper we study binary classification algorithms generated from Tikhonov regularization schemes associated with general convex loss functions and varying Gaussian kernels.

Let X be a compact subset of $\mathbb{R}^n$ (input space) and $Y = \{1, -1\}$ (representing the two classes). Classification algorithms produce *binary classifiers* $\mathcal{C} : X \to Y$. The misclassification error is used to measure the prediction power of a classifier $\mathcal{C}$. If ρ is a probability distribution on $Z := X \times Y$, then the *misclassification error* of $\mathcal{C}$ is defined by

$$\mathcal{R}(\mathcal{C}) = \text{Prob}\{\mathcal{C}(x) \neq y\} = \int_X P(y \neq \mathcal{C}(x)|x) d\rho_X.$$

Here ρ_X is the marginal distribution of ρ on X and $P(y|x)$ is the conditional distribution at $x \in X$. The classifier minimizing the misclassification error is called the Bayes rule f_c and is given by

$$f_c(x) = \begin{cases} 1, & \text{if } P(y = 1|x) \geq P(y = -1|x), \\ -1, & \text{otherwise.} \end{cases}$$

The performance of a classifier $\mathcal{C}$ can be measured by the *excess misclassification error* $\mathcal{R}(\mathcal{C}) - \mathcal{R}(f_c)$.

The classifiers considered here are induced by real-valued functions $f : X \to \mathbb{R}$ as $\mathcal{C}_f = \text{sgn}(f)$ which is defined by $\text{sgn}(f)(x) = 1$ if $f(x) \geq 0$ and $\text{sgn}(f)(x) = -1$ otherwise. The real-valued functions are generated from Tikhonov regularization schemes associated with general convex loss functions and varying Gaussian kernels.

Definition 1 *We say that* $\phi : \mathbb{R} \to \mathbb{R}_+$ *is a classifying loss (function) if it is convex, differentiable at* 0 *with* $\phi'(0) < 0$*, and the smallest zero of* ϕ *is* 1.

Examples of classifying loss functions include the least-square loss $\phi_{ls}(t) = (1-t)^2$, the hinge loss $\phi_h(t) = (1-t)_+ = \max\{1-t, 0\}$ for support vector machine (SVM) algorithms, and the r-norm SVM loss with $1 \le r < \infty$ defined by $\phi_r(t) = (\phi_h(t))^r$.

The *Gaussian kernel* with variance $\sigma > 0$ is the function on $X \times X$ given by

$$K^\sigma(x, x') = \exp\Big\{ -\frac{|x - x'|^2}{2\sigma^2} \Big\}. \tag{1}$$

It defines (Aronszajn, 1950) a reproducing kernel Hilbert space (RKHS) $\mathcal{H}_\sigma$.

With the loss ϕ and Gaussian kernel K^σ, the *Tikhonov regularization scheme* is defined (Wahba, 1990; Evgeniou et al., 2000; Cristianini and Shawe-Taylor, 2000) with a sample $\mathbf{z} = \{(x_i, y_i)\}_{i=1}^m \in Z^m$ as the solution $f_{\mathbf{z}} = f^{\phi}_{\mathbf{z},\sigma,\lambda}$ to the following minimization problem

$$f_{\mathbf{z}} = \arg\min_{f \in \mathcal{H}_\sigma} \Big\{ \frac{1}{m} \sum_{i=1}^m \phi(y_i f(x_i)) + \lambda \|f\|^2_{\mathcal{H}_\sigma} \Big\}. \tag{2}$$

Here λ is a positive constant called the *regularization parameter*. Throughout the paper we assume that the sample $\mathbf{z}$ is drawn independently according to the distribution ρ.

The purpose of this paper is to estimate the excess misclassification error $\mathcal{R}(\mathrm{sgn}(f_{\mathbf{z}})) - \mathcal{R}(f_c)$ as $m \to \infty$. Convergence rates will be derived under the choice of the parameters

$$\lambda = \lambda(m) = m^{-\gamma}, \quad \sigma = \sigma(m) = \lambda^{\zeta} = m^{-\gamma\zeta} \tag{3}$$

for some $\gamma, \zeta > 0$ and conditions on the distribution ρ and the loss ϕ. This has been done for the SVM in Steinwart and Scovel (2007) with the loss ϕ_h. Here we consider the error analysis with a general loss function ϕ (De Vito et al., 2004).

Let us demonstrate our main results by stating learning rates for the least-square loss $\phi = \phi_{ls}$. The rates will be proved in Section 4. They are given by means of a Tsybakov noise condition (Tsybakov, 2004) and a function smoothness condition stated in terms of Sobolev spaces. Since $\phi_{ls}(yf(x)) = (1 - yf(x))^2 = (y - f(x))^2$ for $y \in Y$, a minimizer of $\int_Z \phi_{ls}(yf(x)) d\rho$ is the *regression function* defined by

$$f_\rho(x) = \int_Y y d\rho(y|x) = P(y = 1|x) - P(y = -1|x), \qquad x \in X. \tag{4}$$

Definition 2 *Let* $0 \le q \le \infty$. *We say that* ρ *satisfies the Tsybakov noise condition with exponent* q *if there exists a constant* $C_q > 0$ *such that*

$$\rho_X(\{x \in X : |f_\rho(x)| \le C_q t\}) \le t^q, \qquad \forall t > 0. \tag{5}$$

Note that (5) always holds for $q = 0$ with $C_q = 1$. So setting the index $q = 0$ in (5) is the same as removing the Tsybakov noise condition. The case $q = \infty$ means $|f_\rho(x)| \geq C_q$ for almost every $x \in (X, \rho_X)$.

Recall the Sobolev space $H^s(\mathbb{R}^n)$ with index $s > 0$ consisting of all functions in $L^2(\mathbb{R}^n)$ with the semi-norm $|f|_{H^s(\mathbb{R}^n)} = \left\{(2\pi)^{-n} \int_{\mathbb{R}^n} |\xi|^{2s} |\hat{f}(\xi)|^2 d\xi\right\}^{\frac{1}{2}}$ finite where $\hat{f}$ is the Fourier transform of f defined for $f \in L^1(\mathbb{R}^n)$ as $\hat{f}(\xi) = \int_{\mathbb{R}^n} f(x) e^{-ix\cdot\xi}\, dx$.

Theorem 1 *Let $\phi = \phi_{ls}$. Assume (5) for some $q \in [0, \infty]$ and $\frac{d\rho_X}{dx} \in L^2(X)$. If for some $s > 0$, f_ρ equals the restriction onto X of some function in $H^s(\mathbb{R}^n) \cap L^\infty(\mathbb{R}^n)$, then by taking $\sigma = \lambda^\zeta$ with $0 < \zeta \leq \frac{1}{n+s}$ and $\lambda = m^{-\frac{1}{\zeta(s+2n+2)}}$, for any $0 < \delta < 1$, with confidence $1 - \delta$, we have*

$$\mathcal{R}(sgn(f_{\mathbf{z}})) - \mathcal{R}(f_c) \leq \widetilde{C}_{\rho,s,q,n} m^{-\theta_{ls}} \log\frac{2}{\delta} \qquad \textit{with} \quad \theta_{ls} = \frac{(q+1)s}{(q+2)(s+2n+2)}, \tag{6}$$

where $\widetilde{C}_{\rho,s,q,n}$ is a constant independent of m or δ.

When Tsybakov noise condition (5) is not assumed, we can still use Theorem 1 by setting $q = 0$ and obtain learning rate (6) with $\theta_{ls} = \frac{s}{2s+4n+4}$.

When q tends to infinity, the power index θ_{ls} in (6) has the limit $\frac{s}{s+2n+2}$ which can be very close to 1 for large s. So the learning rate can be $O(m^{\varepsilon-1})$ for arbitrarily small $\varepsilon > 0$ when q and s are large enough. To be more specific, for $0 < \varepsilon < 1$, when $q > \frac{1}{\varepsilon} - 2$ and $s \geq (2n+2)(q+2)\frac{1-\varepsilon}{\varepsilon(q+2)-1}$, we have $\theta_{ls} \geq 1 - \varepsilon$.

Remark 1 *We show that the power index θ_{ls} for learning rate (6) can be $1 - \varepsilon$ for arbitrarily small $\varepsilon > 0$. This result is new for scheme (2) associated with $\phi = \phi_{ls}$ and a single Gaussian kernel with changing variance $\sigma = \sigma(m)$. The same learning rates are achieved in the literature in two different settings: one is for the same least square regularization scheme associated with a single fixed Gaussian kernel, but under the much stronger condition that f_ρ lies in the range of powers of an integral operator associated with a fixed Gaussian kernel, requiring $f_\rho \in C^\infty$ (Zhang, 2004; De Vito et al., 2005; Smale and Zhou, 2007). The other setting is to allow flexible variances of Gaussians in (2), see Ying and Zhou (2007) and Wu et al. (2007).*

When the decision boundary $\{x \in X : f_\rho(x) = 0\}$ has measure zero and $\frac{d\rho_X}{dx} \in L^2(X)$, the smoothness condition for an extension of f_ρ implies (5) for some $q > 0$. In general, noise condition (5) does not require smoothness of f_ρ in domains away from the decision boundary.

Note that as $t \to -\infty$, the hinge loss ϕ_h for the SVM studied in Steinwart and Scovel (2007) increases slowly: $\phi_h(t) = O(|t|)$, while the least-square loss ϕ_{ls} in Theorem 1 increases moderately with $\phi_{ls}(t) = O(|t|^2)$. Difficulty arises for the error analysis with a general loss ϕ when $\phi(t)$ increases fast such as $\phi = \phi_r$ with very large r or the *exponential-hinge loss* we introduce in this paper as

$$\phi_{eh}(t) = \max\{e^{1-t} - 1, 0\} = \begin{cases} e^{1-t} - 1, & \text{if } t \leq 1, \\ 0, & \text{otherwise.} \end{cases}$$

The reason is random variables of form $\xi = \phi(yf(x))$ with $(x, y) = z \in (Z, \rho)$ are involved and large norms $\|f\|_{L^\infty(X)}$ would lead to large bounds for ξ. We shall use special properties of Gaussian kernels and construct functions $f_{\sigma,\lambda}$ which are uniformly bounded and have powerful approximation ability (see (9) and (10) below). With this construction, we can do the analysis well for the general loss ϕ by dealing with uniformly bounded random variables in an error decomposition approach (see (13) below). In particular, explicit learning rates will be given in Section 4 for the r-norm SVM loss ϕ_r (Theorem 4) and the exponential-hinge loss ϕ_{eh} (Theorem 5). Comparing with Theorem 1, we shall provide at the end of Section 4 an approximation theory viewpoint to the effect of various loss functions for learning algorithm (2): the exponential-hinge loss has some advantages over ϕ_{ls} and ϕ_r, the r-norm SVM loss ϕ_r may have worse performance when $r > 2$.

We list key notations used in the paper in a table given in Appendix B.

2. Two Special Properties of Gaussians and Key Bounds

The novelty in our approach for general ϕ and kernels K^σ arises from two special properties of the Gaussian kernels with changing variance $\sigma > 0$: nice approximation scheme and low capacity of the RKHS, described in Sections 2.1 and 2.3.

2.1 Regularizing Functions Generated by Gaussians

A data-free limit of (2) is a function $\widetilde{f}_{\sigma,\lambda}$ defined in terms of the *generalization error* $\mathcal{E}^\phi$ as

$$\widetilde{f}_{\sigma,\lambda} := \arg\min_{f\in\mathcal{H}_\sigma}\{\mathcal{E}^\phi(f)+\lambda\|f\|^2_{\mathcal{H}_\sigma}\}, \text{ where } \mathcal{E}^\phi(f)=\int_Z \phi(yf(x))\,d\rho. \tag{7}$$

This is the regularizing function used in the literature (De Vito et al., 2005; Yao, 2008; Zhang, 2004). It works well for the error analysis when the loss ϕ increases slowly or moderately (as $t\to-\infty$) such as $\phi=\phi_h$ or ϕ_{ls}.

In this paper we consider a general loss ϕ. When $\phi(t)$ increases fast (as $t\to-\infty$), applying the regularizing function $\widetilde{f}_{\sigma,\lambda}$ in the error analysis (described in Section 2.2) may lead to a random variable $\phi(y\widetilde{f}_{\sigma,\lambda}(x))$ of large bound.

The first novelty of this paper is to construct a function $f_{\sigma,\lambda}$ (which plays the role of a regularizing function in an error decomposition approach discussed in subsection 2.2) by special approximation ability of Gaussian kernels. The constructed function has two advantages. On one hand, it is uniformly bounded (with respect to both λ and σ) so that the random variable $\phi(yf_{\sigma,\lambda}(x))$ involved in the error analysis is bounded. On the other hand, it plays the same role as $\widetilde{f}_{\sigma,\lambda}$ in achieving nice bounds for the approximation error. The construction of the explicit approximation scheme for $f_{\sigma,\lambda}$ is done under a Sobolev smoothness condition of a measurable function f^ϕ_ρ minimizing $\mathcal{E}^\phi$, that is, for a. e. $x\in X$,

$$f^\phi_\rho(x)=\arg\min_{t\in\mathbb{R}}\int_Y \phi(yt)\,d\rho(y|x)=\arg\min_{t\in\mathbb{R}}\{\phi(t)P(y=1|x)+\phi(-t)P(y=-1|x)\}.$$

Theorem 2 *Assume that for some* $s>0$,

$$f^\phi_\rho=\tilde{f}^\phi_\rho|_X \text{ for some } \tilde{f}^\phi_\rho\in H^s(\mathbb{R}^n)\cap L^\infty(\mathbb{R}^n) \text{ and } \frac{d\rho_X}{dx}\in L^2(X). \tag{8}$$

Then we can find functions $\{f_{\sigma,\lambda}\in\mathcal{H}_\sigma : 0<\sigma\le 1,\lambda>0\}$ *such that*

$$\|f_{\sigma,\lambda}\|_{L^\infty(X)} \le \widetilde{B}, \tag{9}$$

$$\mathcal{D}(\sigma,\lambda):=\mathcal{E}^\phi(f_{\sigma,\lambda})-\mathcal{E}^\phi(f^\phi_\rho)+\lambda\|f_{\sigma,\lambda}\|^2_{\mathcal{H}_\sigma} \le \widetilde{B}(\sigma^s+\lambda\sigma^{-n}) \tag{10}$$

for $0 < \sigma \leq 1, \lambda > 0$*, where* $\widetilde{B} \geq 1$ *is a constant independent of* σ *or* λ.

Theorem 2 will be proved in Appendix A in a more general form as Theorem 6 where the constant $\widetilde{B}$ is given explicitly.

Remark 2 *A usual assumption in the literature (Zhang, 2004) for deriving learning rates is that for some* $0 < \beta \leq 1$ *and* $C_\beta > 0$,

$$\widetilde{\mathcal{D}}(\lambda) = \min_{f \in \mathcal{H}_\sigma} \{\mathcal{E}^\phi(f) - \mathcal{E}^\phi(f_\rho^\phi) + \lambda \|f\|^2_{\mathcal{H}_\sigma}\} \leq C_\beta \lambda^\beta \qquad \forall \lambda > 0. \tag{11}$$

This is hardly satisfied for a single fixed K^σ *due to the analyticity of the Gaussian kernel (Smale and Zhou, 2003; Cucker and Zhou, 2007). When we choose a changing Gaussian kernel with* $\sigma = \lambda^\zeta$ *for some* $\zeta > 0$*, decay (11) of the approximation error is valid in many cases (as shown in Theorem 2). Under assumption (11), one has the bound*

$$\|\widetilde{f}_{\sigma,\lambda}\|_{L^\infty(X)} \leq \|\widetilde{f}_{\sigma,\lambda}\|_{\mathcal{H}_\sigma} \leq \sqrt{\widetilde{\mathcal{D}}(\lambda)/\lambda} \leq \sqrt{C_\beta} \lambda^{\frac{\beta-1}{2}}.$$

Hence a natural bound for the random variable $\phi_{eh}(y\widetilde{f}_{\sigma,\lambda}(x))$ *would be* $\exp\{\sqrt{C_\beta}\lambda^{\frac{\beta-1}{2}}\}$ *which increases exponentially fast as* $\lambda \to 0$ *(polynomially fast with degree* $\frac{r(1-\beta)}{2}$ *for* $\phi = \phi_r$ *when r is very large). This shows difficulty in choosing* $\widetilde{f}_{\sigma,\lambda}$ *and demonstrates novelty in choosing the function* $f_{\sigma,\lambda}$ *from Theorem 2 for the error analysis with a general loss* ϕ.

When $\sigma = \lambda^\zeta$ for some $0 < \zeta < \frac{1}{n}$, (10) of Theorem 2 tells us that the function $f_{\sigma,\lambda}$ yields an approximation order similar to (11) while (9) ensures the uniform boundedness of $\phi(yf_{\sigma,\lambda}(x))$, better than the function $\widetilde{f}_{\sigma,\lambda}$ for the error decomposition described below.

2.2 Error Decomposition and Projection Operator

The excess misclassification error $\mathcal{R}(\text{sgn}(f)) - \mathcal{R}(f_c)$ for the classifier $\text{sgn}(f)$ can be bounded by means of the *excess generalization error* $\mathcal{E}^\phi(f)) - \mathcal{E}^\phi(f_\rho^\phi)$ according to some comparison theorems (Zhang, 2004; Chen et al., 2004; Bartlett et al., 2006). For example, it was proved in Zhang (2004) that for $\phi = \phi_h$ and any measurable function $f : X \to \mathbb{R}$, we have

$$\mathcal{R}(\text{sgn}(f)) - \mathcal{R}(f_c) \leq \mathcal{E}^{\phi_h}(f) - \mathcal{E}^{\phi_h}(f_c).$$

For a classifying loss ϕ with $\phi''(0) > 0$, it was proved in Chen et al. (2004) and Bartlett et al. (2006) that for some $c_\phi > 0$,

$$\mathcal{R}(\text{sgn}(f)) - \mathcal{R}(f_c) \leq c_\phi \sqrt{\mathcal{E}^\phi(f) - \mathcal{E}^\phi(f_\rho^\phi)}. \tag{12}$$

For the least square loss and ρ satisfying the Tsybakov noise condition, a comparison theorem improving (12) will be given in Section 4 and will be used to prove Theorem 1.

Classifiers in this paper are obtained by taking signs of real-valued functions. Since the smallest zero of ϕ is 1, we can take $f_\rho^\phi(x) \in [-1, 1]$ for each $x \in X$, which we shall assume throughout the paper. We may improve the error estimates (Chen et al., 2004) by replacing values of f by projections onto $[-1, 1]$.

Definition 3 *The projection operator π on the space of functions on X is defined by*

$$\pi(f)(x) = \begin{cases} 1 & \text{if } f(x) > 1, \\ -1 & \text{if } f(x) < -1, \\ f(x) & \text{if } -1 \le f(x) \le 1. \end{cases}$$

Trivially $\operatorname{sgn}(\pi(f)) = \operatorname{sgn}(f)$. Then we can use (12) with $f = \pi(f_{\mathbf{z}})$ to bound the excess misclassification error $\mathcal{R}(\operatorname{sgn}(f_{\mathbf{z}})) - \mathcal{R}(f_c)$ by means of the excess generalization error $\mathcal{E}^{\phi}(\pi(f_{\mathbf{z}})) - \mathcal{E}^{\phi}(f_{\rho}^{\phi})$ which in turn can be estimated by an error decomposition technique (Wu and Zhou, 2006). Define the *empirical error* associated with the loss ϕ as

$$\mathcal{E}_{\mathbf{z}}^{\phi}(f) = \frac{1}{m}\sum_{i=1}^{m} \phi(y_i f(x_i)) \qquad \text{for } f : X \to \mathbb{R}.$$

Then we have the following error decomposition which will be proved in Section 3.

Lemma 1 *Let ϕ be a classifying loss, $f_{\mathbf{z}}$ be defined by (2) and $f_{\sigma,\lambda} \in \mathcal{H}_{\sigma}$. Then*

$$\mathcal{E}^{\phi}(\pi(f_{\mathbf{z}})) - \mathcal{E}^{\phi}(f_{\rho}^{\phi}) \le \mathcal{D}(\sigma,\lambda) + \mathcal{S}_{\mathbf{z}}(f_{\sigma,\lambda}) - \mathcal{S}_{\mathbf{z}}(\pi(f_{\mathbf{z}})), \tag{13}$$

where the quantity $\mathcal{S}_{\mathbf{z}}(f)$ is defined for $f \in C(X)$ by

$$\mathcal{S}_{\mathbf{z}}(f) = [\mathcal{E}_{\mathbf{z}}^{\phi}(f) - \mathcal{E}_{\mathbf{z}}^{\phi}(f_{\rho}^{\phi})] - [\mathcal{E}^{\phi}(f) - \mathcal{E}^{\phi}(f_{\rho}^{\phi})].$$

When we use the regularizing function $f_{\sigma,\lambda}$ given in Theorem 2, the bound (10) deals with $\mathcal{D}(\sigma,\lambda)$, the first term of (13). The uniform bound (9) for $\|f_{\sigma,\lambda}\|_{L^{\infty}(X)}$ ensures that the second term $\mathcal{S}_{\mathbf{z}}(f_{\sigma,\lambda})$ of (13), which can be expressed as $\frac{1}{m}\sum_{i=1}^{m} \xi(z_i) - \mathbf{E}(\xi)$ with the random variable $\xi(z) = \phi(y f_{\sigma,\lambda}(x)) - \phi(y f_{\rho}^{\phi}(x))$, can be easily handled. The crucial remaining term $\mathcal{S}_{\mathbf{z}}(\pi(f_{\mathbf{z}}))$ of (13) involves the set of functions $\{f_{\mathbf{z}}\}_{\mathbf{z}\in Z^m}$ and can be treated by various empirical process techniques such as Rademacher average and entropy integral. Here we use the specialty of the Gaussians that the RKHS has low capacity, hence the last term of (13) can be estimated efficiently and simply by means of covering numbers.

2.3 Applying Tight Bounds for Covering Numbers

The second novelty of this paper is to make full use of the special low capacity property of the Gaussian kernels that a tight bound for covering numbers of the unit ball of the RKHS $\mathcal{H}_{\sigma}$ leads to nice estimates for the last term $\mathcal{S}_{\mathbf{z}}(\pi(f_{\mathbf{z}}))$ of (13) for the error analysis.

Definition 4 *For a subset S of $C(X)$ and $\eta > 0$, the covering number $\mathcal{N}(S,\eta)$ is the minimal integer $l \in \mathbb{N}$ such that there exist l disks with radius η covering S.*

The covering numbers of unit balls of classical function spaces have been well studied in the literature (Edmunds and Triebel, 1996). As an example, take $X = [0,1]^n$ and $s > 0$. The covering numbers of the unit ball $B_1(C^s(X))$ of the space $C^s(X)$ has the asymptotic behavior

$$c_s'\left(\frac{1}{\eta}\right)^{n/s} \le \log \mathcal{N}(B_1(C^s(X)),\eta) \le c_s''\left(\frac{1}{\eta}\right)^{n/s}, \tag{14}$$

where the positive constants c'_s, and c''_s are independent of $0 < \eta < 1$. In particular, since a Gaussian kernel K^σ is C^∞, an embedding result from Zhou (2003) tells us that $\log \mathcal{N}(B_1, \eta) \leq C''_s(\frac{1}{\eta})^{n/s}(\frac{1}{\sigma})^{2n}$ where $s > 0$ can be arbitrarily large but the constant C''_s depends on s. Here $B_1 = B_{1,\sigma} = \{f \in \mathcal{H}_\sigma : \|f\|_{\mathcal{H}_\sigma} \leq 1\}$ is the unit ball of $\mathcal{H}_\sigma$ and is regarded as a compact subset of $C(X)$. A crucial improved bound for the covering number of B_1 was given in Zhou (2002) with $(\frac{1}{\eta})^{n/s}$ replaced by $(\log \frac{1}{\eta})^{n+1}$ as follows.

Proposition 1 *There exists a constant* $C_0 > 0$ *depending only on* X *and* n *such that*

$$\log \mathcal{N}(B_1, \eta) \leq C_0 \Big((\log \frac{1}{\eta})^{n+1} + \frac{1}{\sigma^{2(n+1)}} \Big) \qquad \forall\, 0 < \eta < 1, 0 < \sigma \leq 1. \tag{15}$$

The constant C_0 can be taken as $(124n)^{n+2}$ when $X = [0,1]^n$. Bound (15) is almost sharp in the sense that for some $C'_0 > 0$ given in Zhou (2003),

$$\log \mathcal{N}(B_1, \eta) \geq C'_0 \Big((\log \frac{1}{\eta})^{n/2} + \frac{1}{\sigma^n} \Big).$$

The logarithmic term $(\log \frac{1}{\eta})^{n+1}$ appearing in the tight bound (15) is better than the polynomial term $(\frac{1}{\eta})^{n/s}$ in (14). This enables us to derive efficient error bounds for the algorithm (2) involving Gaussian kernels, by a simple covering number argument without other empirical process techniques or iteration techniques used in Steinwart and Scovel (2007) and Wu et al. (2007). To demonstrate explicitly why tight bound (15) helps, we state the following result which is needed for estimating confidence and will be proved in Appendix B.

Lemma 2 *Let* $0 \leq \tau \leq 1$ *and* $C_1 > 0$. *Let* $0 < \delta < 1$ *and* λ, σ *take form (3) with some* $\gamma > 0$ *and* $0 < \zeta < \frac{1}{2\gamma(n+1)}$. *Denote* $\varepsilon^*(m, \lambda, \sigma, \delta/2)$ *as the smallest positive number* ε *satisfying*

$$1 - \mathcal{N}\Big(B_1, \frac{\lambda \varepsilon}{\sqrt{\phi(0)}|\phi'_+(-1)|}\Big) \exp\left\{ -\frac{m\varepsilon^{2-\tau}}{2C_1 + \frac{2}{3}\phi(-1)\varepsilon^{1-\tau}} \right\} \geq 1 - \frac{\delta}{2}. \tag{16}$$

Then we have

$$\varepsilon^*(m, \lambda, \sigma, \delta/2) \leq C_2 m^{-\frac{1-2\gamma\zeta(n+1)}{2-\tau}} \log \frac{2}{\delta}, \tag{17}$$

where C_2 *is the constant independent of* m, λ, σ *or* δ.

2.4 Key Bounds

We are in a position to present our key bounds for the excess generalization error $\mathcal{E}^\phi(\pi(f_{\mathbf{z}})) - \mathcal{E}^\phi(f^\phi_\rho)$ which will be used to get rates for the excess misclassification error $\mathcal{R}(\mathrm{sgn}(f_{\mathbf{z}})) - \mathcal{R}(f_c)$. To achieve tight bounds, we need the following definition.

Definition 5 *A variancing power* $\tau = \tau_{\phi,\rho}$ *of the pair* (ϕ, ρ) *is a number* τ *in* $[0,1]$ *such that for any* $\widetilde{B} \geq 1$, *there exists some constant* $C_1 = C_1(\widetilde{B}) > 0$ *satisfying*

$$\mathbf{E}\Big\{ \Big[\phi(yf(x)) - \phi(yf^\phi_\rho(x))\Big]^2 \Big\} \leq C_1 \Big[\mathcal{E}^\phi(f) - \mathcal{E}^\phi(f^\phi_\rho)\Big]^\tau \qquad \forall\, f : X \to [-\widetilde{B}, \widetilde{B}]. \tag{18}$$

Remark 3 *For $\phi = \phi_{ls}$, we can take $\tau = 1$, see Evgeniou et al. (2000) and Cucker and Zhou (2007). For $\phi = \phi_h$, we can take $\tau = 0$, and an improved power $\tau = \frac{q}{q+1}$ if the Tsybakov noise condition (5) is satisfied (Steinwart and Scovel, 2007; Wu and Zhou, 2005). In general, $\tau_{\phi,\rho}$ depends on the strong convexity of ϕ and noise conditions for ρ.*

Theorem 3 *Let $\sigma = \lambda^{\zeta}$ and $\lambda = m^{-\gamma}$ for some $0 < \zeta < \frac{1}{n}$ and $0 < \gamma < \frac{1}{2\zeta(n+1)}$. If (8) is valid for some $s > 0$, then for any $0 < \delta < 1$, with confidence $1 - \delta$ we have*

$$\mathcal{E}^{\phi}(\pi(f_{\mathbf{z}})) - \mathcal{E}^{\phi}(f_{\rho}^{\phi}) \leq \widetilde{C} m^{-\theta} \log \frac{2}{\delta} \tag{19}$$

where

$$\theta = \min\left\{ s\zeta\gamma, \gamma(1-n\zeta), \frac{1-2\gamma\zeta(n+1)}{2-\tau} \right\}, \tag{20}$$

and $\widetilde{C}$ is a constant independent of m and δ.

Theorem 3 will be proved in the next section and the constant $\widetilde{C}$ will be given explicitly.

3. Error Analysis

In this section we derive the key error bounds stated in Theorem 3 by estimating the right-hand side of (13) in Lemma 1 (which is proved here).

3.1 Proof of Lemma 1

Write the regularized excess generalization error as

$$\begin{aligned} \mathcal{E}^{\phi}(\pi(f_{\mathbf{z}})) - \mathcal{E}^{\phi}(f_{\rho}^{\phi}) + \lambda \|f_{\mathbf{z}}\|_{\mathcal{H}_{\sigma}}^2 &= \left\{ \mathcal{E}^{\phi}(\pi(f_{\mathbf{z}})) - \mathcal{E}_{\mathbf{z}}^{\phi}(\pi(f_{\mathbf{z}})) \right\} \\ &+ \left\{ \left[\mathcal{E}_{\mathbf{z}}^{\phi}(\pi(f_{\mathbf{z}})) + \lambda \|f_{\mathbf{z}}\|_{\mathcal{H}_{\sigma}}^2 \right] - \left[\mathcal{E}_{\mathbf{z}}^{\phi}(f_{\sigma,\lambda}) + \lambda \|f_{\sigma,\lambda}\|_{\mathcal{H}_{\sigma}}^2 \right] \right\} \\ &+ \left\{ \mathcal{E}_{\mathbf{z}}^{\phi}(f_{\sigma,\lambda}) - \mathcal{E}^{\phi}(f_{\sigma,\lambda}) \right\} + \left\{ \mathcal{E}^{\phi}(f_{\sigma,\lambda}) - \mathcal{E}^{\phi}(f_{\rho}^{\phi}) + \lambda \|f_{\sigma,\lambda}\|_{\mathcal{H}_{\sigma}}^2 \right\}. \end{aligned}$$

Since ϕ is convex and its smallest zero is 1, we find a special property of the projection operator that $\phi(y\pi(f)(x)) \leq \phi(yf(x))$ for any function f on X. Hence $\mathcal{E}_{\mathbf{z}}^{\phi}(\pi(f)) \leq \mathcal{E}_{\mathbf{z}}^{\phi}(f)$. This in connection with the definition of $f_{\mathbf{z}}$ tells us that the second term on the right-hand side above is at most zero. By subtracting and adding $\mathcal{E}^{\phi}(f_{\rho}^{\phi})$ in the first and third terms we see $\mathcal{E}^{\phi}(\pi(f_{\mathbf{z}})) - \mathcal{E}^{\phi}(f_{\rho}^{\phi})$ is bounded as in (13). This proves Lemma 1. ■

Let us turn to estimate $\mathcal{E}^{\phi}(\pi(f_{\mathbf{z}})) - \mathcal{E}^{\phi}(f_{\rho}^{\phi})$ by (13). We first bound $\mathcal{S}_{\mathbf{z}}(f_{\sigma,\lambda})$, the term involving $f_{\sigma,\lambda}$. It can be written as $\frac{1}{m}\sum_{i=1}^{m} \xi(z_i) - \mathbf{E}(\xi)$ with ξ the random variable on (Z,ρ) given by $\xi(z) = \phi(yf_{\sigma,\lambda}(x)) - \phi(yf_{\rho}^{\phi}(x))$.

Lemma 3 *Let $\tau = \tau_{\phi,\rho}$ and $f_{\sigma,\lambda} \in \mathcal{H}_{\sigma}$ satisfy (9). For any $0 < \delta < 1$, with confidence $1 - \frac{\delta}{2}$, the term $\mathcal{S}_{\mathbf{z}}(f_{\sigma,\lambda})$ of (13) can be bounded as*

$$\mathcal{S}_{\mathbf{z}}(f_{\sigma,\lambda}) \leq 2(\|\phi\|_{C[-\widetilde{B},\widetilde{B}]} + C_1) \log \frac{2}{\delta} m^{-\frac{1}{2-\tau}} + \mathcal{E}^{\phi}(f_{\sigma,\lambda}) - \mathcal{E}^{\phi}(f_{\rho}^{\phi}).$$

Proof Consider the random variable $\xi(z) = \phi(yf_{\sigma,\lambda}(x)) - \phi(yf_\rho^\phi(x))$ on (Z,ρ). It satisfies $-\phi(-1) \le \xi \le \|\phi\|_{C[-\widetilde{B},\widetilde{B}]}$. Hence $|\xi - \mathbf{E}(\xi)| \le 2\|\phi\|_{C[-\widetilde{B},\widetilde{B}]}$. We apply the one side Bernstein inequality and know that

$$\text{Prob}_{\mathbf{z}\in Z^m}\Big\{\frac{1}{m}\sum_{i=1}^m \xi(z_i) - \mathbf{E}(\xi) > \varepsilon\Big\} \le \exp\Big\{-\frac{m\varepsilon^2}{2(\sigma^2(\xi) + \frac{2}{3}\|\phi\|_{C[-\widetilde{B},\widetilde{B}]}\varepsilon)}\Big\} \qquad \forall \varepsilon > 0.$$

Here $\sigma^2(\xi)$ is the variance of ξ. Solving the quadratic equation for ε by setting the above probability bound to be $\delta/2$, we see that with confidence at least $1-\delta/2$,

$$\frac{1}{m}\sum_{i=1}^m \xi(z_i) - \mathbf{E}(\xi) \le \frac{4\|\phi\|_{C[-\widetilde{B},\widetilde{B}]}\log\frac{2}{\delta}}{3m} + \frac{\sqrt{2m\sigma^2(\xi)\log\frac{2}{\delta}}}{m}.$$

Using (18) involving the variancing power $\tau = \tau_{\phi,\rho}$ in Definition 5, we have $\sigma^2(\xi) \le \mathbf{E}(\xi^2) \le C_1(\mathbf{E}(\xi))^\tau$. This in connection with Young's inequality implies

$$\frac{\sqrt{2m\sigma^2(\xi)\log\frac{2}{\delta}}}{m} \le \sqrt{\frac{2\log\frac{2}{\delta}C_1(\mathbf{E}(\xi))^\tau}{m}} \le (1-\frac{\tau}{2})\Big(\frac{2\log\frac{2}{\delta}C_1}{m}\Big)^{\frac{1}{2-\tau}} + \frac{\tau}{2}\mathbf{E}(\xi).$$

Therefore, with confidence at least $1-\delta/2$,

$$\frac{1}{m}\sum_{i=1}^m \xi(z_i) - \mathbf{E}(\xi) \le \frac{4\|\phi\|_{C[-\widetilde{B},\widetilde{B}]}\log\frac{2}{\delta}}{3m} + \Big(\frac{2\log\frac{2}{\delta}C_1}{m}\Big)^{\frac{1}{2-\tau}} + \mathbf{E}(\xi).$$

Since $\mathbf{E}(\xi) = \mathcal{E}^\phi(f_{\sigma,\lambda}) - \mathcal{E}^\phi(f_\rho^\phi)$, our conclusion follows. ∎

The sample error term $-\mathcal{S}_\mathbf{z}(\pi(f_\mathbf{z}))$ in (13) can be expressed as $\int \xi_\mathbf{z} d\rho - \frac{1}{m}\sum_{i=1}^m \xi_\mathbf{z}(z_i)$ with $\xi_\mathbf{z}(z) = \phi(yf_\mathbf{z}(x)) - \phi(yf_\rho^\phi(x))$. However, $\xi_\mathbf{z}$ is not a single random variable since $\mathbf{z}$ is a random sample itself. This is the essential difficulty. Here we use the specialty of low capacity of the RKHS $\mathcal{H}_\sigma$ and overcome the difficulty by a simple covering number argument over a ball of $\mathcal{H}_\sigma$ where $f_\mathbf{z}$ lies.

Lemma 4 *For any $\lambda > 0$ and $\mathbf{z} \in Z^m$, there holds*

$$\|f_\mathbf{z}\|_{\mathcal{H}_\sigma} \le \sqrt{\phi(0)/\lambda}.$$

The proof follows easily by taking $f = 0$ in the definition of $f_\mathbf{z}$ as in De Vito et al. (2005), De Vito et al. (2004) and Hardin et al. (2004).

Let ξ be a random variable on Z with mean $\mu \ge 0$ and variance $\sigma^2 \le c\mu^\tau$ for some $0 \le \tau \le 2$ and $c \ge 0$. If $|\xi - \mu| \le B$ almost surely for some $B \ge 0$, then the one-side Bernstein inequality implies

$$\text{Prob}_{\mathbf{z}\in Z^m}\Big\{\frac{\mu - \frac{1}{m}\sum_{i=1}^m \xi(z_i)}{\sqrt{\mu^\tau + \varepsilon^\tau}} > \varepsilon^{1-\frac{\tau}{2}}\Big\} \le \exp\Big\{-\frac{m\varepsilon^{2-\tau}}{2(c + \frac{1}{3}B\varepsilon^{1-\tau})}\Big\} \qquad \forall\ \varepsilon > 0.$$

Applying this probability inequality to random variables of type $\xi(z) = \phi(y(\pi f)(x)) - \phi(yf_\rho^\phi(x))$ and using a standard argument (Wu et al., 2007; Yao, 2008; Ying, 2007) with covering numbers for the ball $\{f \in \mathcal{H}_\sigma : \|f\|_{\mathcal{H}_\sigma} \le \sqrt{\phi(0)/\lambda}\}$ of the RKHS $\mathcal{H}_\sigma$, we find the following bound.

Lemma 5 *Let* $\tau = \tau_{\phi,\rho}$ *satisfy (18) with* $\widetilde{B}$ *being* 1. *For any* $\varepsilon > 0$, *we have*

$$\mathrm{Prob}_{\mathbf{z}\in Z^m}\Big\{\sup_{\|f\|_{\mathcal{H}_\sigma}\le\sqrt{\phi(0)/\lambda}}\frac{[\mathcal{E}^\phi(\pi(f))-\mathcal{E}^\phi(f_\rho^\phi)]-[\mathcal{E}_{\mathbf{z}}^\phi(\pi(f))-\mathcal{E}_{\mathbf{z}}^\phi(f_\rho^\phi)]}{\sqrt{(\mathcal{E}^\phi(\pi(f))-\mathcal{E}^\phi(f_\rho^\phi))^\tau+\varepsilon^\tau}}\le 4\varepsilon^{1-\frac{\tau}{2}}\Big\}$$
$$\ge 1-\mathcal{N}\Big(B_1,\frac{\sqrt{\lambda}\varepsilon}{\sqrt{\phi(0)}|\phi'_+(-1)|}\Big)\exp\Big\{-\frac{m\varepsilon^{2-\tau}}{2C_1+\frac{2}{3}\phi(-1)\varepsilon^{1-\tau}}\Big\}.$$

Recall the definition of $\varepsilon^*(m,\lambda,\sigma,\delta/2)$ in Lemma 2. It satisfies (16) which means that the probability in Lemma 5 is bounded by $1-\frac{\delta}{2}$ from below when $\varepsilon = \varepsilon^*(m,\lambda,\sigma,\delta/2)$.

Proposition 2 *Let* $f_{\sigma,\lambda}\in\mathcal{H}_\sigma$ *satisfy (9). For any* $0<\delta<1$, *with confidence at least* $1-\delta$, *we have*

$$\mathcal{E}^\phi(\pi(f_{\mathbf{z}}))-\mathcal{E}^\phi(f_\rho^\phi)\le 4\mathcal{D}(\sigma,\lambda)+40\varepsilon^*(m,\lambda,\sigma,\delta/2)+4(\|\phi\|_{C[-\widetilde{B},\widetilde{B}]}+C_1)\log\frac{2}{\delta}m^{-\frac{1}{2-\tau}}.$$

Proof Applying Lemma 3, we know that there is a subset V_1 of Z^m with measure at least $1-\frac{\delta}{2}$ such that for $\mathbf{z}\in V_1$,

$$\mathcal{S}_{\mathbf{z}}(f_{\sigma,\lambda})\le 2(\|\phi\|_{C[-\widetilde{B},\widetilde{B}]}+C_1)\log\frac{2}{\delta}m^{-\frac{1}{2-\tau}}+\mathcal{D}(\sigma,\lambda).$$

By Lemma 5 and Lemma 4, taking $\varepsilon=\varepsilon^*(m,\lambda,\sigma,\delta/2)$, we see that there exists another subset V_2 of Z^m with measure at least $1-\frac{\delta}{2}$ such that for $\mathbf{z}\in V_2$,

$$\begin{aligned}
-\mathcal{S}_{\mathbf{z}}(\pi(f_{\mathbf{z}})) &= [\mathcal{E}^\phi(\pi(f_{\mathbf{z}}))-\mathcal{E}^\phi(f_\rho^\phi)]-[\mathcal{E}_{\mathbf{z}}^\phi(\pi(f_{\mathbf{z}}))-\mathcal{E}_{\mathbf{z}}^\phi(f_\rho^\phi)]\\
&\le 4[\varepsilon^*(m,\lambda,\sigma,\delta/2)]^{1-\frac{\tau}{2}}\sqrt{\Big[\mathcal{E}^\phi(\pi(f_{\mathbf{z}}))-\mathcal{E}^\phi(f_\rho^\phi)\Big]^\tau+[\varepsilon^*(m,\lambda,\sigma,\delta/2)]^\tau}\\
&\le \Big(1-\frac{\tau}{2}\Big)4^{\frac{2}{2-\tau}}\varepsilon^*(m,\lambda,\sigma,\delta/2)+\frac{\tau}{2}[\mathcal{E}^\phi(\pi(f_{\mathbf{z}}))-\mathcal{E}^\phi(f_\rho^\phi)]+4\varepsilon^*(m,\lambda,\sigma,\delta/2).
\end{aligned}$$

Here we have used the elementary inequality $\sqrt{a+b}\le\sqrt{a}+\sqrt{b}$ and Young's inequality.

Adding the above two bounds and observing that $0\le\tau\le 1$ implies $\frac{1}{1-\tau/2}\le 2$ we know from Lemma 1 that for $\mathbf{z}\in V_1\cap V_2$,

$$\mathcal{E}^\phi(\pi(f_{\mathbf{z}}))-\mathcal{E}^\phi(f_\rho^\phi)\le 4\mathcal{D}(\sigma,\lambda)+40\varepsilon^*(m,\lambda,\sigma,\delta/2)+4(\|\phi\|_{C[-\widetilde{B},\widetilde{B}]}+C_1)\log\frac{2}{\delta}m^{-\frac{1}{2-\tau}}.$$

Since the measure of $V_1\cap V_2$ is at least $1-\delta$, our conclusion holds true. ∎

Now we are in a position to prove Theorem 3.

3.2 Proof of Theorem 3

From condition (8) and the parameter form $\sigma=\lambda^\zeta$ with $0<\zeta<\frac{1}{n}$, we know by Theorem 2 that

$$\mathcal{D}(\sigma,\lambda)\le\widetilde{B}\lambda^{\min\{s\zeta,1-n\zeta\}}.$$

Putting bound (17) for $\varepsilon^*(m,\lambda,\sigma,\delta/2)$ from Lemma 2 into Proposition 2, we see from the parameter form $\lambda = m^{-\gamma}$ that with confidence at least $1-\delta$,

$$\begin{aligned}\mathcal{E}^\phi(\pi(f_{\mathbf{z}})) - \mathcal{E}^\phi(f_\rho^\phi) &\leq 4\widetilde{B}\lambda^{\min\{s\zeta,1-n\zeta\}} + 40C_2 m^{-\frac{1-2\gamma\zeta(n+1)}{2-\tau}}\log\frac{2}{\delta} \\ &\quad +4(\|\phi\|_{C[-\widetilde{B},\widetilde{B}]}+C_1)\log\frac{2}{\delta}m^{-\frac{1}{2-\tau}} \leq \widetilde{C}m^{-\theta}\log\frac{2}{\delta}.\end{aligned}$$

Here θ is given by (20) and $\widetilde{C}$ is the constant independent of m and δ given by

$$\widetilde{C} = 4\widetilde{B} + 40C_2 + 4(\|\phi\|_{C[-\widetilde{B},\widetilde{B}]} + C_1).$$

This proves (19) and hence Theorem 3. ■

4. Deriving Learning Rates

In this section we apply Theorem 3 to derive learning rates with various loss functions. For the least square loss, to prove Theorem 1 we need the following comparison theorem improving (12).

Proposition 3 *If $\phi = \phi_{ls}$ and ρ satisfies noise condition (5) for some $q \in [0,\infty]$, then for every measurable function $f : X \to \mathbb{R}$, we have*

$$\mathcal{R}(sgn(f)) - \mathcal{R}(f_c) \leq 2C_q^{-\frac{q}{q+2}}\left\{\mathcal{E}^{\phi_{ls}}(f) - \mathcal{E}^{\phi_{ls}}(f_\rho)\right\}^{\frac{q+1}{q+2}}.$$

Proof Denote $X_f = \{x \in X : \mathrm{sgn}(f)(x) \neq f_c(x)\}$. It is known that $\mathcal{R}(\mathrm{sgn}(f)) - \mathcal{R}(f_c) = \int_{X_f}|f_\rho(x)|d\rho_X$. See, for example, Equation (9.14) of Cucker and Zhou (2007).

When $q < \infty$, take $t = \left(\|f-f_\rho\|_{L^2_{\rho_X}}/C_q\right)^{\frac{2}{q+2}} > 0$. We separate the set X_f into two parts, one with $|f_\rho(x)| \leq C_q t$ and the other with $|f_\rho(x)| > C_q t$ where $|f_\rho(x)| \leq |f_\rho(x)|^2/(C_q t) \leq |f(x) - f_\rho(x)|^2/(C_q t)$. We find from (5) that

$$\begin{aligned}\int_{X_f}|f_\rho(x)|d\rho_X &\leq \int_{\{x\in X_f:\ |f_\rho(x)|\leq C_q t\}} C_q t d\rho_X + \int_{\{x\in X_f:\ |f_\rho(x)|>C_q t\}}|f(x)-f_\rho(x)|^2/(C_q t)d\rho_X \\ &\leq C_q t\rho_X(\{x\in X : |f_\rho(x)|\leq C_q t\}) + \|f-f_\rho\|^2_{L^2_{\rho_X}}/(C_q t) \\ &\leq C_q t^{q+1} + \|f-f_\rho\|^2_{L^2_{\rho_X}}/(C_q t) = 2C_q\left(\|f-f_\rho\|_{L^2_{\rho_X}}/C_q\right)^{\frac{2q+2}{q+2}}.\end{aligned}$$

This gives the desired bound for the case $q<\infty$ since $\|f-f_\rho\|^2_{L^2_{\rho_X}} = \mathcal{E}^{\phi_{ls}}(f) - \mathcal{E}^{\phi_{ls}}(f_\rho)$.

When $q = \infty$, noise condition (5) means $|f_\rho(x)| \geq C_q$ and hence $|f_\rho(x)| \leq |f_\rho(x)|^2/C_q$ for almost every $x \in (X,\rho_X)$. So $\int_{X_f}|f_\rho(x)|d\rho_X \leq \int_{X_f}|f(x)-f_\rho(x)|^2/C_q d\rho_X = \|f-f_\rho\|^2_{L^2_{\rho_X}}/C_q$ which is what we want. ■

Now we can derive learning rates with the least square loss.

4.1 Proof of Theorem 1

The assumptions on $\frac{d\rho_X}{dx}$ and f_ρ verify condition (8). Then by Theorem 2 with $\phi = \phi_{ls}$, we find functions $f_{\sigma,\lambda}$ satisfying (9) and (10) for $0 < \sigma \leq 1, \lambda > 0$.

The choice $\sigma = \lambda^\zeta$ with $0 < \zeta \leq \frac{1}{n+s} < \frac{1}{n}$ and $\lambda = m^{-\gamma}$ with $\gamma = \frac{1}{\zeta(s+2n+2)}$ tell us that $0 < \gamma < \frac{1}{2\zeta(n+1)}$. Therefore all conditions of Theorem 3 are valid. Moreover, a specialty of the least square loss is $\tau = 1$ in (18). So by Theorem 3, for any $0 < \delta < 1$, with confidence $1-\delta$, (19) holds with

$$\theta = \min\left\{\frac{s}{s+2n+2}, \frac{1-n\zeta}{\zeta(s+2n+2)}, 1 - \frac{2(n+1)}{s+2n+2}\right\} = \frac{s}{s+2n+2}.$$

This bound for the excess generalization error $\mathcal{E}^\phi(\pi(f_{\mathbf{z}})) - \mathcal{E}^\phi(f_\rho^\phi)$ together with Proposition 3 yields the desired bound (6) for the excess misclassification error $\mathcal{R}(\text{sgn}(f_{\mathbf{z}})) - \mathcal{R}(f_c)$ with the constant $\widetilde{C}_{\rho,s,q,n} = 2C_q^{-\frac{q}{q+2}} \widetilde{C}^{\frac{q+1}{q+2}}$. The proof of Theorem 1 is complete. ■

Let us derive learning rates with the r-norm SVM loss $\phi = \phi_r$ $(1 < r < \infty)$ for which we have (Chen et al., 2004)

$$f_\rho^\phi(x) = f_\rho^{\phi_r}(x) = \frac{(1+f_\rho(x))^{1/(r-1)} - (1-f_\rho(x))^{1/(r-1)}}{(1+f_\rho(x))^{1/(r-1)} + (1-f_\rho(x))^{1/(r-1)}}, \qquad x \in X. \tag{21}$$

Theorem 4 *Let $\phi = \phi_r$ with $1 < r < \infty$. Assume (8) for some $s > 0$. Take $\sigma = \lambda^\zeta$ with $0 < \zeta \leq \frac{1}{n+s}$ and $\lambda = m^{-\gamma}$ with $\gamma = \frac{1}{\zeta(s+2n+2)}$ for $1 < r \leq 2$ and $\gamma = \frac{1}{\zeta(2s(1-1/r)+2n+2)}$ for $2 < r < \infty$. Then for any $0 < \delta < 1$, with confidence $1-\delta$, we have*

$$\mathcal{R}(sgn(f_{\mathbf{z}})) - \mathcal{R}(f_c) \leq \widetilde{C}_{\rho,r} m^{-\theta_r} \log\frac{2}{\delta} \quad \textit{with } \theta_r = \begin{cases} \frac{s}{2(s+2n+2)}, & \textit{if } 1 < r \leq 2, \\ \frac{s}{4(s(1-1/r)+n+1)}, & \textit{if } 2 < r < \infty. \end{cases} \tag{22}$$

Proof The convexity of ϕ_r gives the variancing power (Bartlett et al., 2006) as

$$\tau = \tau_{\phi_r,\rho} = \begin{cases} 1, & \text{if } 1 < r \leq 2, \\ \frac{2}{r}, & \text{if } 2 < r < \infty. \end{cases}$$

Take $\sigma = \lambda^\zeta$ with $0 < \zeta \leq \frac{1}{n+s} < \frac{1}{n}$ and choose $\lambda = m^{-\gamma}$ with $\gamma = \frac{1}{\zeta((2-\tau)s+2n+2)}$. We see that $0 < \gamma < \frac{1}{2\zeta(n+1)}$. Hence all conditions of Theorem 3 are valid and we conclude that for any $0 < \delta < 1$, with confidence $1-\delta$, (19) holds with $\theta = \frac{s}{(2-\tau)s+2n+2}$. This bound for the excess generalization error together with comparison relation (12) caused by $\phi_r''(0) = r(r-1) > 0$ yields the desired bound (22) for the excess misclassification error with the constant $\widetilde{C}_{\rho,r} = c_{\phi_r}\sqrt{\widetilde{C}}$. The proof of Theorem 4 is complete. ■

When $\phi = \phi_{eh}$, a simple computation shows that the function f_ρ^ϕ is given by

$$f_\rho^{\phi_{eh}}(x) = \begin{cases} \frac{1}{2}\log\frac{1+f_\rho(x)}{1-f_\rho(x)}, & \text{if } -(e^2-1)/(e^2+1) \leq f_\rho(x) \leq (e^2-1)/(e^2+1), \\ 1, & \text{if } f_\rho(x) > (e^2-1)/(e^2+1), \\ -1, & \text{if } f_\rho(x) < -(e^2-1)/(e^2+1). \end{cases} \tag{23}$$

Theorem 5 *Let $\phi = \phi_{eh}$. Assume (8) for some $s > 0$. Take $\sigma = \lambda^{\zeta}$ with $0 < \zeta \leq \frac{1}{n+s}$ and $\lambda = m^{-\frac{1}{\zeta(2s+2n+2)}}$. Then for any $0 < \delta < 1$, with confidence $1 - \delta$, we have*

$$\mathcal{R}(sgn(f_{\mathbf{z}})) - \mathcal{R}(f_c) \leq \widetilde{C}_{\rho,eh} m^{-\theta_{eh}} \log \frac{2}{\delta} \qquad with \quad \theta_{eh} = \frac{s}{4s+4n+4}. \tag{24}$$

Proof Take $\tau = 0$ and $\sigma = \lambda^{\zeta}$ with $0 < \zeta \leq \frac{1}{n+s} < \frac{1}{n}$. Choose $\lambda = m^{-\gamma}$ with $\gamma = \frac{1}{\zeta(2s+2n+2)}$ in Theorem 3. We see that for any $0 < \delta < 1$, with confidence $1 - \delta$, (19) holds with $\theta = \frac{s}{2s+2n+2}$. This bound together with comparison relation (12) again (as $\phi''_{eh}(0) = e > 0$) yields the desired bound (24) with $\widetilde{C}_{\rho,eh} = c_{\phi_{eh}} \sqrt{\widetilde{C}}$. This proves Theorem 5. ∎

Remark 4 *When $s \leq \frac{1}{r-1}$, the extension condition of f_ρ stated in Theorem 1 implies assumption (8) of $f_\rho^{\phi_r}$ required in Theorem 4. In fact, the extension of the function $f_\rho^{\phi_r}$ onto $\mathbb{R}^n$ can be defined by taking values of the extended function of f_ρ in (21). After composing with the function $t \to t^{1/(r-1)}$ on $\mathbb{R}$, smoothness of functions in the Sobolev space H^s is kept for $s \leq \frac{1}{r-1}$. When $s \leq 1$, the same condition for f_ρ implies assumption (8) of $f_\rho^{\phi_{eh}}$ needed for Theorem 5, as seen from expression (23).*

It is possible to refine learning rates (22) and (24) by improving comparison relation (12) when Tsybakov noise condition (5) is satisfied. We omit the discussion here.

Error analysis with $\phi = \phi_r$ was done in Chen et al. (2004) under assumption (11). Our learning rates in Theorem 4 are new since our assumption on Sobolev smoothness is weaker. The learning rates for $\phi = \phi_{eh}$ in Theorem 5 are also new.

We are in a position to get from Theorems 1, 4 and 5 some theoretical clues on the effect of various loss functions for learning algorithm (2). We know from Smale and Zhou (2003) that when $\phi = \phi_{ls}$ the approximation error and hence learning rates can essentially be characterized by regularities of the function f_ρ. So here we give some comparisons under the same regularity assumption (8) for the function f_ρ^{ϕ} with some $s > 0$. Under this assumption (removing the Tsybakov noise condition by taking $q = 0$ in Theorem 1), the learning rates derived in Theorems 1, 4 and 5 for $\phi = \phi_{ls}, \phi_r, \phi_{eh}$ take the same form $\mathcal{R}(\text{sgn}(f_{\mathbf{z}})) - \mathcal{R}(f_c) = O(m^{-\theta} \log \frac{2}{\delta})$ with the power index θ very close, all lying in the range $[\frac{s}{4s+4n+4}, \frac{s}{2s+4n+4}]$. However, the index s in regularity assumption (8) for the function f_ρ^{ϕ} might vary dramatically, leading to varying power index θ for the learning rates.

Note that the function f_ρ^{ϕ} with $\phi = \phi_r, \phi_{eh}$ depends explicitly on the regression function f_ρ corresponding the least-square loss. The dependence of the function $f_\rho^{\phi_{eh}}$ on f_ρ has an advantage of ignoring any irregularity appearing in the domain where $|f_\rho(x)| > (e^2 - 1)/(e^2 + 1)$. This can be seen from the following example where f_ρ has a singularity at 0 while $f_\rho^{\phi_{eh}} \equiv 1$ is C^{∞}.

Example 1 *Let $X = [-1, 1]$, $0 < \alpha < \frac{1}{14}$ and ρ be the distribution given by $d\rho_X = \frac{1}{2}dx$ and $f_\rho(x) = 1 - \frac{1}{5}|x|^{\alpha}$ which means $P(y = 1|x) = 1 - \frac{1}{10}|x|^{\alpha}$. It is well known that the function $|x|^{\alpha}$ lies in the Sobolev space $H^s(X)$ if and only if $s < \alpha + \frac{1}{2}$. So regularity assumption (8) is satisfied for ϕ_{ls} if and only if $s < \alpha + \frac{1}{2}$. Then from Theorem 1, we see the learning rate $\mathcal{R}(sgn(f_{\mathbf{z}})) - \mathcal{R}(f_c) = O(m^{-\theta_{ls}} \log \frac{2}{\delta})$ with $\theta_{ls} = \frac{s}{s+2+2}$ arbitrarily close to $\frac{1+2\alpha}{9+2\alpha} < \frac{1}{8}$. However, for the exponential-hinge loss ϕ_{eh}, we have $f_\rho^{\phi_{eh}} \equiv 1$ which follows from expression (23) and the definition $f_\rho(x) = 1 - \frac{1}{5}|x|^{\alpha} \geq$*

$1-\frac{1}{5} > (e^2-1)/(e^2+1)$ on X. Therefore, regularity assumption (8) is satisfied for an arbitrarily large s and Theorem 5 yields the learning rate $\mathcal{R}(sgn(f_{\mathbf{z}})) - \mathcal{R}(f_c) = O(m^{-\theta_{eh}} \log \frac{2}{\delta})$ with θ_{eh} arbitrarily close to $\frac{1}{4}$. Thus for learning algorithm (2), the exponential-hinge loss has some advantages over ϕ_{ls} (and ϕ_r as shown in the next example).

The dependence of the function $f_\rho^{\phi_r}$ on f_ρ involves a power function $u \to u^{1/(r-1)}$ which might cause irregularity. This is demonstrated by the following example where the singularity of the function f_ρ at 0 is worsened for the function $f_\rho^{\phi_r}$ when r is large.

Example 2 *Let X and ρ be as in Example 1. When $\phi = \phi_r$ with $r > 2$, the function $f_\rho^{\phi_r}$ in (21) equals*

$$f_\rho^{\phi_r}(x) = \frac{(2-\frac{1}{5}|x|^\alpha)^{1/(r-1)} - (\frac{1}{5}|x|^\alpha)^{1/(r-1)}}{(2-\frac{1}{5}|x|^\alpha)^{1/(r-1)} + (\frac{1}{5}|x|^\alpha)^{1/(r-1)}}.$$

Regularity assumption (8) is satisfied for ϕ_r if and only if $s < \frac{\alpha}{r-1} + \frac{1}{2}$. Then Theorem 4 yields the learning rate $\mathcal{R}(sgn(f_{\mathbf{z}})) - \mathcal{R}(f_c) = O(m^{-\theta_r} \log \frac{2}{\delta})$ with $\theta_r = \frac{s}{4(s(1-1/r)+1+1)}$ arbitrarily close to $\frac{r(2\alpha+r-1)}{4(5r+2\alpha-1)(r-1)}$. This power index is always less than that of ϕ_{ls} or ϕ_{eh}. It shows that the loss ϕ_r has worse performance than ϕ_{ls} and ϕ_{eh}, at least for some distributions.

5. Further Discussion

Let us discuss further generalizations and connections briefly here. More details will be provided in our future study.

The first extension is to a manifold setting. If X is a connected compact C^∞ submanifold of $\mathbb{R}^n$ without boundary and its dimension is $d \le n$, then the covering number estimate (15) holds with n replaced by the manifold dimension d. Proposition 2 and Lemma 2 are still valid with n replaced by d. Learning rates in Theorems 1, 4 and 5 can be improved with n replaced by d if approximation error estimates similar to Theorem 2 can be established in the manifold setting. One can use ideas for convolution type approximation schemes on $\mathbb{R}^n$ (Pan, et al., 2008) to define higher order operators on manifolds and then get estimates for the regularization error.

The second connection is to multi-kernel regularization schemes (Wu et al., 2007; Argyriou et al., 2006; Chapelle et al., 2002) defined as

$$f_{\mathbf{z},\lambda}^{\phi} = \arg \min_{0<\sigma<\infty} \min_{f\in\mathcal{H}_\sigma} \left\{ \frac{1}{m}\sum_{i=1}^{m} \phi(y_i f(x_i)) + \lambda \|f\|_{\mathcal{H}_\sigma}^2 \right\}.$$

In this scheme the variance parameter σ is chosen automatically while the learning rate derived in Ying and Zhou (2007) is at most $O(m^{-1/6})$. It would be interesting to investigate how to choose the parameter σ in (2).

The last questions is about more general loss functions. In our analysis we assume that the convex loss ϕ has a zero which excludes the logistic loss $\phi(t) = \log(1+e^{-t})$. One might generalize our analysis to get some error bounds for the scheme with loss functions without zero by using a general projection operator π_M with level $M > 0$ given by

$$\pi_M(f)(x) = \begin{cases} M & \text{if } f(x) > M, \\ -M & \text{if } f(x) < -M, \\ f(x) & \text{if } -M \le f(x) \le M. \end{cases}$$

Appendix A. Approximation Scheme by Gaussians

This appendix provides a proof of Theorem 2 which is a corollary of the following more general theorem. The approximation error is estimated by means of a convolution type scheme constructed by Gaussians with a Fourier analysis technique (Schaback and Werner, 2006; Steinwart and Scovel, 2007; Steinwart et al. , 2006).

Theorem 6 *Assume that for some $s>0$, f_ρ^ϕ is the restriction of some $\tilde{f}_\rho^\phi \in H^s(\mathbb{R}^n)$ onto X, and the density function $g=\frac{d\rho_X}{dx}$ exists and lies in $L^2(X)$.*

(1) If $\tilde{f}_\rho^\phi \in L^\infty(\mathbb{R}^n)$, then we can find a set of functions $\{f_{\sigma,\lambda}\in\mathcal{H}_\sigma\}_{0\le\sigma\le 1,\lambda>0}$ such that

$$\begin{aligned} \|f_{\sigma,\lambda}\|_{L^\infty(X)} &\le \widetilde{B}, && (25)\\ \mathcal{D}(\sigma,\lambda) &\le \widetilde{B}(\sigma^s+\lambda\sigma^{-n}), \quad \forall\, 0<\sigma\le 1, \lambda>0, && (26)\end{aligned}$$

where $\widetilde{B}$ is a constant independent of σ or λ.

(2) If for some $r\ge 1$ and $C_\phi>0$,

$$|\phi'_+(t)|\le C_\phi |t|^{r-1} \qquad \forall |t|\ge 1. \tag{27}$$

then we can find $\{f_{\sigma,\lambda}\in\mathcal{H}_\sigma\}$ such that

$$\begin{aligned} \|f_{\sigma,\lambda}\|_{L^\infty(X)} &\le \widetilde{B}'\sigma^{-\frac{n}{2}}, && (28)\\ \mathcal{D}(\sigma,\lambda) &\le \widetilde{B}'(\sigma^{s-\frac{n(r-1)}{2}}+\lambda\sigma^{-n}), \quad \forall\, 0<\sigma\le 1, \lambda>0, && (29)\end{aligned}$$

where $\widetilde{B}'$ is a constant independent of σ or λ.

Proof Take some trigonometric polynomial $\tilde{a}(\xi)=\sum_{j\in J} a_j e^{-ij\cdot\xi}$ on $\mathbb{R}^n$ with a finite subset J of $\mathbb{Z}^n$ such that for some $C_s>0$ depending only on s and n, we have

$$|e^{-\frac{|\xi|^2}{2}}\tilde{a}(\xi)-1|\le C_s|\xi|^s \quad \forall\, \xi\in\mathbb{R}^n.$$

This can be done by choosing the coefficients $(a_j)_{j\in J}$ of $\tilde{a}$ satisfying the linear system

$$\tilde{a}(0)=1 \quad \text{and} \quad D^\alpha(e^{-\frac{|\xi|^2}{2}}\tilde{a}(\xi))(0)=0, \qquad \alpha\in\mathbb{Z}^n, 0<|\alpha|<s.$$

So J and $(a_j)_{j\in J}$ depend only on s and n.

Define

$$\tilde{f}_\sigma(x)=\Big(\frac{1}{\sqrt{2\pi}\sigma}\Big)^n\int_{\mathbb{R}^n} K^\sigma(x,y)\sum_{j\in J} a_j \tilde{f}_\rho^\phi(y-\sigma j)\,dy, \quad x\in\mathbb{R}^n.$$

We first estimate $\|\tilde{f}_\sigma - \tilde{f}_\rho^\phi\|_{L^2(\mathbb{R}^n)}$.

Define a function $\tilde{k}^\sigma$ on $\mathbb{R}^n$ by $\tilde{k}^\sigma(x) = \left(\frac{1}{\sqrt{2\pi}\sigma}\right)^n e^{-\frac{|x|^2}{2\sigma^2}}$, we know that $\hat{\tilde{k}^\sigma}(\xi) = e^{-\frac{|\sigma\xi|^2}{2}}$ and $\tilde{f}_\sigma(x) = \tilde{k}^\sigma * \left(\sum_{j\in J} a_j \tilde{f}_\rho^\phi(\cdot - \sigma j)\right)$. This in connection with the fact that the Fourier transform of $\tilde{f}_\rho^\phi(\cdot - \sigma j)$ equals $e^{-i\sigma j\cdot\xi}\hat{\tilde{f}}_\rho^\phi(\xi)$ implies

$$\hat{\tilde{f}}_\sigma(\xi) = \hat{\tilde{k}^\sigma}(\xi) \sum_{j\in J} a_j e^{-i\sigma j\cdot\xi} \hat{\tilde{f}}_\rho^\phi(\xi) = e^{-\frac{|\sigma\xi|^2}{2}} \tilde{a}(\sigma\xi) \hat{\tilde{f}}_\rho^\phi(\xi).$$

It follows that

$$\begin{aligned} \|\tilde{f}_\sigma - \tilde{f}_\rho^\phi\|^2_{L^2(\mathbb{R}^n)} &= (2\pi)^{-n} \|\hat{\tilde{f}}_\sigma - \hat{\tilde{f}}_\rho^\phi\|^2_{L^2(\mathbb{R}^n)} = (2\pi)^{-n} \int_{\mathbb{R}^n} |e^{-\frac{|\sigma\xi|^2}{2}} \tilde{a}(\sigma\xi) - 1|^2 |\hat{\tilde{f}}_\rho^\phi(\xi)|^2 \, d\xi \\ &\leq (2\pi)^{-n} C_s^2 \int_{\mathbb{R}^n} |\sigma\xi|^{2s} |\hat{\tilde{f}}_\rho^\phi(\xi)|^2 \, d\xi \leq C_s^2 \sigma^{2s} (2\pi)^{-n} \int_{\mathbb{R}^n} |\xi|^{2s} |\hat{\tilde{f}}_\rho^\phi(\xi)|^2 \, d\xi. \end{aligned}$$

That is,

$$\|\tilde{f}_\sigma - \tilde{f}_\rho^\phi\|_{L^2(\mathbb{R}^n)} \leq C_s \|\tilde{f}_\rho^\phi\|_{H^s(\mathbb{R}^n)} \sigma^s. \tag{30}$$

Then we bound $\|\tilde{f}_\sigma\|_{\mathcal{H}_\sigma(\mathbb{R}^n)}$. Here $\mathcal{H}_\sigma(\mathbb{R}^n)$ is the RKHS generated by the Mercer kernel $K^\sigma(x,y)$ on $\mathbb{R}^n$. By the inner product in $\mathcal{H}_\sigma(\mathbb{R}^n)$, we know that $\langle K^\sigma(\cdot,y), K^\sigma(\cdot,z)\rangle_{\mathcal{H}_\sigma(\mathbb{R}^n)} = K^\sigma(y,z)$. So we have

$$\|\tilde{f}_\sigma\|^2_{\mathcal{H}_\sigma(\mathbb{R}^n)} = \left(\frac{1}{\sqrt{2\pi}\sigma}\right)^{2n} \int_{\mathbb{R}^n} \int_{\mathbb{R}^n} K^\sigma(y,z) \sum_{j\in J} a_j \tilde{f}_\rho^\phi(y - \sigma j) \, dy \sum_{l\in J} a_l \tilde{f}_\rho^\phi(z - \sigma l) \, dz.$$

By the elementary inequality $|uv| \leq \frac{u^2+v^2}{2}$ and $\int_{\mathbb{R}^n} K^\sigma(y,z) \, dz = (\sqrt{2\pi}\sigma)^n$, we see that

$$\begin{aligned} \|\tilde{f}_\sigma\|^2_{\mathcal{H}_\sigma(\mathbb{R}^n)} &\leq \left(\frac{1}{\sqrt{2\pi}\sigma}\right)^{2n} \sum_{j\in J} \sum_{l\in J} |a_j||a_l| \int_{\mathbb{R}^n} \int_{\mathbb{R}^n} K^\sigma(y,z) \frac{|\tilde{f}_\rho^\phi(y-\sigma j)|^2 + |\tilde{f}_\rho^\phi(z-\sigma l)|^2}{2} \, dydz \\ &= \left(\frac{1}{\sqrt{2\pi}\sigma}\right)^{2n} \sum_{j,l\in J} |a_j||a_l| (\sqrt{2\pi}\sigma)^n \|\tilde{f}_\rho^\phi\|^2_{L^2(\mathbb{R}^n)}. \end{aligned}$$

That is,

$$\|\tilde{f}_\sigma\|_{\mathcal{H}_\sigma(\mathbb{R}^n)} \leq C_s' \|\tilde{f}_\rho^\phi\|_{L^2(\mathbb{R}^n)} (\sqrt{2\pi}\sigma)^{-\frac{n}{2}}$$

where $C_s' := \sum_{j\in J} |a_j|$ is a constant depending only on s and n.

Take $f_{\sigma,\lambda} = \tilde{f}_\sigma|_X$, the restriction of $\tilde{f}_\sigma$ onto X. By basic facts about RKHS (Aronszajn, 1950), we know that $f_{\sigma,\lambda} = \tilde{f}_\sigma|_X \in \mathcal{H}_\sigma$ and

$$\|f_{\sigma,\lambda}\|_{\mathcal{H}_\sigma} \leq \|\tilde{f}_\sigma\|_{\mathcal{H}_\sigma(\mathbb{R}^n)} \leq C_s' \|\tilde{f}_\rho^\phi\|_{L^2(\mathbb{R}^n)} (\sqrt{2\pi}\sigma)^{-\frac{n}{2}}. \tag{31}$$

Now we can derive the desired bounds.

(1) When $\tilde{f}_\rho^\phi \in L^\infty(\mathbb{R}^n)$, for any $x \in \mathbb{R}^n$, we have

$$|\tilde{f}_\sigma(x)| \leq \sum_{j\in J} |a_j| \left(\frac{1}{\sqrt{2\pi}\sigma}\right)^n \int_{\mathbb{R}^n} e^{-\frac{|x-y|^2}{2\sigma^2}} \, dy \|\tilde{f}_\rho^\phi\|_{L^\infty(\mathbb{R}^n)} = C_s' \|\tilde{f}_\rho^\phi\|_{L^\infty(\mathbb{R}^n)}.$$

It follows that (25) holds true and

$$\begin{aligned}\mathcal{E}^{\phi}(f_{\sigma,\lambda})-\mathcal{E}^{\phi}(f_{\rho}^{\phi}) &\leq \int_X\int_Y \sup\left\{|\phi_+'(\xi)|:|\xi|\leq \max\{C_s'\|\tilde{f}_\rho^\phi\|_{L^\infty(\mathbb{R}^n)},\|f_\rho^\phi\|_{L^\infty(X)}\}\right\}\\ &\quad |f_{\sigma,\lambda}(x)-f_\rho^\phi(x)|d\rho(y|x)g(x)dx.\end{aligned}$$

By the Schwarz inequality we see that

$$\mathcal{E}^{\phi}(f_{\sigma,\lambda})-\mathcal{E}^{\phi}(f_{\rho}^{\phi})\leq \sup\{|\phi_+'(\xi)|:|\xi|\leq (C_s'+1)\|\tilde{f}_\rho^\phi\|_{L^\infty(\mathbb{R}^n)}\}\|f_{\sigma,\lambda}-f_\rho^\phi\|_{L^2(X)}\|g\|_{L^2(X)}.$$

This bound in connection with (30) and (31) implies (26) with the constant $\widetilde{B}$ given by

$$\begin{aligned}\widetilde{B} &= \max\Big\{C_s'\|\tilde{f}_\rho^\phi\|_{L^\infty(\mathbb{R}^n)},(C_s')^2\|\tilde{f}_\rho^\phi\|^2_{L^2(\mathbb{R}^n)}(2\pi)^{-\frac{n}{2}},\\ &\quad \sup\{|\phi_+'(\xi)|:|\xi|\leq (C_s'+1)\|\tilde{f}_\rho^\phi\|_{L^\infty(\mathbb{R}^n)}\}C_s\|\tilde{f}_\rho^\phi\|_{H^s(\mathbb{R}^n)}\|g\|_{L^2(X)},\Big\}.\end{aligned}$$

(2) Without the condition $\tilde{f}_\rho^\phi\in L^\infty(\mathbb{R}^n)$, we bound $\|f_{\sigma,\lambda}\|_{L^\infty(X)}$ directly from the expression of $\tilde{f}_\sigma$. For $x\in\mathbb{R}^n$, we have

$$\begin{aligned}|\tilde{f}_\sigma(x)| &\leq \sum_{j\in J}|a_j|\Big(\frac{1}{\sqrt{2\pi}\sigma}\Big)^n\Big\{\int_{\mathbb{R}^n}(K^\sigma(x,y))^2\,dy\Big\}^{\frac12}\Big\{\int_{\mathbb{R}^n}|\tilde{f}_\rho^\phi(y-\sigma j)|^2\,dy\Big\}^{\frac12}\\ &= \sum_{j\in J}|a_j|(2\sqrt{\pi}\sigma)^{-\frac{n}{2}}\|\tilde{f}_\rho^\phi\|_{L^2(\mathbb{R}^n)}.\end{aligned}$$

It follows that $\|f_{\sigma,\lambda}\|_{L^\infty(X)}\leq C_s'(2\sqrt{\pi})^{-\frac{n}{2}}\|\tilde{f}_\rho^\phi\|_{L^2(\mathbb{R}^n)}\sigma^{-\frac{n}{2}}$.

To derive the bound for the excess generalization error, we notice from (27) that

$$\begin{aligned}&\mathcal{E}^{\phi}(f_{\sigma,\lambda})-\mathcal{E}^{\phi}(f_{\rho}^{\phi})=\int_X\int_Y(\phi(yf_{\sigma,\lambda}(x))-\phi(yf_\rho^\phi(x)))\,d\rho(y|x)d\rho_X(x)\\ &\leq \int_X\int_Y\sup\left\{|\phi_+'(\xi)|:|\xi|\leq\max\{C_s'(2\sqrt{\pi}\sigma)^{-\frac{n}{2}}\|\tilde{f}_\rho^\phi\|_{L^2(\mathbb{R}^n)},\|f_\rho^\phi\|_{L^\infty(X)}\}\right\}\\ &\qquad |f_{\sigma,\lambda}(x)-f_\rho^\phi(x)|d\rho(y|x)g(x)dx.\end{aligned}$$

If we denote $C_s''=\max\{C_\phi,C_\phi\|f_\rho^\phi\|^{r-1}_{L^\infty(X)},C_\phi[C_s'(2\sqrt{\pi})^{-\frac{n}{2}}\|\tilde{f}_\rho^\phi\|_{L^2(\mathbb{R}^n)}]^{r-1}\}$, then

$$\mathcal{E}^{\phi}(f_{\sigma,\lambda})-\mathcal{E}^{\phi}(f_{\rho}^{\phi})\leq C_s''\sigma^{-\frac{n(r-1)}{2}}\|f_{\sigma,\lambda}-f_\rho^\phi\|_{L^2(X)}\|g\|_{L^2(X)}\leq C_s''\|g\|_{L^2(X)}C_s\|\tilde{f}_\rho^\phi\|_{H^s(\mathbb{R}^n)}\sigma^{s-\frac{n(r-1)}{2}}.$$

Therefore,

$$\mathcal{D}(\sigma,\lambda)\leq C_s''\|g\|_{L^2(X)}C_s\|\tilde{f}_\rho^\phi\|_{H^s(\mathbb{R}^n)}\sigma^{s-\frac{n(r-1)}{2}}+\lambda(C_s')^2\|\tilde{f}_\rho^\phi\|^2_{L^2(\mathbb{R}^n)}(\sqrt{2\pi}\sigma)^{-n}.$$

This verifies (28) and (29) by taking

$$\widetilde{B}'=\max\left\{C_s'(2\sqrt{\pi})^{-\frac{n}{2}}\|\tilde{f}_\rho^\phi\|_{L^2(\mathbb{R}^n)},C_s''\|g\|_{L^2(X)}C_s\|\tilde{f}_\rho^\phi\|_{H^s(\mathbb{R}^n)},(C_s')^2\|\tilde{f}_\rho^\phi\|^2_{L^2(\mathbb{R}^n)}(2\pi)^{-n/2}\right\}.$$

The proof of Theorem 6 is complete. ■

In our main results, only part (1) of Theorem 6, that is, Theorem 2 is used. A main assumption, condition (8), gives the restriction $\widetilde{f}_\rho^\phi \in H^s(\mathbb{R}^n)\cap L^\infty(\mathbb{R}^n)$. When we do not know whether f_ρ^ϕ can be extended to a uniformly bounded function on $\mathbb{R}^n$, we can use part (2) of Theorem 6. This might be the case when $\phi = \phi_h$, as mentioned in the following.

A geometric noise condition was introduced in Steinwart and Scovel (2007). This condition with exponent $\alpha > 0$ means

$$\int_X |f_\rho(x)| \exp\left\{-\frac{\tau_x^2}{t}\right\} d\rho_X(x) = O\left(t^{\frac{\alpha n}{2}}\right) \tag{32}$$

where

$$\tau_x = \begin{cases} \inf_{f_\rho(u)\geq 0} |x-u|, & \text{if } f_\rho(x) < 0, \\ \inf_{f_\rho(u)\leq 0} |x-u|, & \text{if } f_\rho(x) > 0, \\ 0, & \text{otherwise.} \end{cases}$$

It does not assume smoothness of functions. An interesting result in Steinwart and Scovel (2007) asserts that when $\phi = \phi_h$, geometric noise condition (32) with exponent $0 < \alpha < \infty$ leads to $\mathcal{D}(\sigma,\lambda) \leq \widetilde{B}'''(\sigma^{\alpha n} + \lambda\sigma^{-n})$. With this estimate, under Tsybakov noise condition (5), learning rates are obtained in Steinwart and Scovel (2007). For example, when $\alpha > \frac{q+2}{2q}$, for an arbitrarily small $\varepsilon > 0$, with confidence $1-\delta$,

$$\mathcal{R}(sgn(f_{\mathbf{z}})) - \mathcal{R}(f_c) \leq \widetilde{C}_\varepsilon \left(\log\frac{4}{\delta}\right)^2 \left(\frac{1}{m}\right)^{\frac{2\alpha(q+1)}{2\alpha(q+2)+3q+4}-\varepsilon}. \tag{33}$$

Since no Sobolev smoothness is assumed for $f_\rho^{\phi_h} = f_c$ (Wahba, 1990), we need to use the regularizing function $\widetilde{f}_{\sigma,\lambda}$ defined by (7) and derive by some detailed computations that with confidence $1-\delta$,

$$\mathcal{R}(sgn(f_{\mathbf{z}})) - \mathcal{R}(f_c) \leq \widetilde{C}_{\rho,h} \log\frac{4}{\delta}\left(\frac{1}{m}\right)^{\frac{(q+1)\alpha n}{(q+2)\alpha n+2(q+1)(n+1)}}.$$

This rate is slightly worse than (33), though the estimate for the confidence is slightly better. It raises the question of improving Theorem 6 under various noise conditions.

Appendix B. Role of Tight Bounds for Covering Numbers

In this appendix we prove Lemma 2 which shows a special role of the tight bound (15) for covering numbers concerning Gaussian kernels. In fact, we have the following more general result.

Proposition 4 *Let $\Delta \geq 1$ be arbitrary. Then $\varepsilon^*(m,\lambda,\sigma,\delta/2)$ defined by (16) satisfies*

$$\varepsilon^*(m,\lambda,\sigma,\delta/2) \leq \widetilde{C}_2\left(\frac{\log\frac{2}{\delta} + \sigma^{-2(n+1)/(2-\tau)} + (\log m)^{(n+1)/(2-\tau)}}{m^{\frac{1}{2-\tau}}} + \frac{\sigma^{-2(n+1)}}{m} + \frac{\sqrt{\phi(0)}}{\sqrt{\lambda}m^\Delta}\right),$$

where $\widetilde{C}_2$ is the constant depending on $C_0, C_1, \tau, \phi'_+(-1), \phi(-1), \Delta$ and is given by

$$\widetilde{C}_2 = \max\left\{|\phi'_+(-1)|, (4C_1)^{\frac{1}{2-\tau}}, 2(4C_0C_1)^{\frac{1}{2-\tau}}\Delta^{n+1}, 2\phi(-1)(1+C_0+C_0\Delta^{n+1})\right\}.$$

Proof Observe from (15) that as a function on $(0,+\infty)$, the logarithm of the middle term of (16) is bounded by

$$h(\varepsilon) := C_0\Big(\Big(\log\frac{\sqrt{\phi(0)}|\phi'_+(-1)|}{\sqrt{\lambda}\varepsilon}\Big)^{n+1} + \frac{1}{\sigma^{2(n+1)}}\Big) - g(\varepsilon),$$

where g is the strictly increasing function on $(0,\infty)$ defined by

$$g(\varepsilon) = \frac{m\varepsilon^{2-\tau}}{2C_1 + \frac{2}{3}\phi(-1)\varepsilon^{1-\tau}}.$$

Set

$$\begin{aligned}\mathcal{B} &= \frac{\sqrt{\phi(0)}|\phi'_+(-1)|}{\sqrt{\lambda}m^{\Delta}} + \left(\frac{4C_1(\log\frac{2}{\delta} + \frac{C_0}{\sigma^{2(n+1)}}) + 4C_0C_1(\Delta\log m)^{n+1}}{m}\right)^{\frac{1}{2-\tau}} \\ &\quad + \frac{4\phi(-1)}{3m}\left(\log\frac{2}{\delta} + \frac{C_0}{\sigma^{2(n+1)}} + C_0(\Delta\log m)^{n+1}\right).\end{aligned}$$

If $\frac{2}{3}\phi(-1)\mathcal{B}^{1-\tau} \le 2C_1$, then

$$g(\mathcal{B}) \ge \frac{m\mathcal{B}^{2-\tau}}{4C_1} \ge \log\frac{2}{\delta} + \frac{C_0}{\sigma^{2(n+1)}} + C_0(\Delta\log m)^{n+1}.$$

If $\frac{2}{3}\phi(-1)\mathcal{B}^{1-\tau} > 2C_1$, then

$$g(\mathcal{B}) \ge \frac{m\mathcal{B}^{2-\tau}}{\frac{4}{3}\phi(-1)\mathcal{B}^{1-\tau}} = \frac{m\mathcal{B}}{\frac{4}{3}\phi(-1)} \ge \log\frac{2}{\delta} + \frac{C_0}{\sigma^{2(n+1)}} + C_0(\Delta\log m)^{n+1}.$$

Thus in either case we have

$$g(\mathcal{B}) \ge \log\frac{2}{\delta} + \frac{C_0}{\sigma^{2(n+1)}} + C_0(\Delta\log m)^{n+1}.$$

On the other hand, since $\mathcal{B} \ge \frac{\sqrt{\phi(0)}|\phi'_+(-1)|}{\sqrt{\lambda}m^{\Delta}}$, we also see that $\log\frac{\sqrt{\phi(0)}|\phi'_+(-1)|}{\mathcal{B}\sqrt{\lambda}} \le \Delta\log m$. It follows that

$$h(\mathcal{B}) \le C_0(\Delta\log m)^{n+1} - \log\frac{2}{\delta} - C_0(\Delta\log m)^{n+1} = \log\frac{\delta}{2}.$$

But the function h is strictly decreasing. So $\varepsilon^*(m,\lambda,\sigma,\delta/2) \le \mathcal{B}$. The the desired bound for $\varepsilon^*(m,\lambda,\sigma,\delta/2)$ follows with the constant $\widetilde{C_2}$. The proof of Proposition 4 is complete. ■

Now we can prove Lemma 2 by the special form of λ,σ.

B.1 Proof of Lemma 2

Take $\Delta = \frac{\gamma}{2} + 1$ in Proposition 4. Then we know from the special form (3) of λ and σ that

$$\varepsilon^*(m,\lambda,\sigma,\delta/2) \le \widetilde{C_2}\left\{\frac{\log\frac{2}{\delta}}{m^{\frac{1}{2-\tau}}} + \Big(\frac{1}{m}\Big)^{\frac{1-2\gamma\zeta(n+1)}{2-\tau}} + \Big(\frac{(\log m)^{n+1}}{m}\Big)^{\frac{1}{2-\tau}} + \frac{\sqrt{\phi(0)}}{m}\right\}.$$

$\tau = \tau_{\phi,\rho}$	variancing power defined in Definition 5	1453, 1454, 1456, 1458

Table 1: NOTATIONS

Observe the elementary inequality (Yao, 2008; Ye and Zhou, 2007)

$$\exp\{-cx\} \leq (\frac{a}{ec})^a x^{-a} \quad \forall x, c, a > 0.$$

Taking $x = \log m$, $a = n+1$ and $c = 2\gamma\zeta(n+1)$, we have

$$(\log m)^{n+1} \leq (\frac{1}{2e\gamma\zeta})^{n+1} m^{2\gamma\zeta(n+1)}.$$

Hence (17) holds true with the constant $C_2 = \widetilde{C}_2(4 + 2\sqrt{\phi(0)})$. The proof of Lemma 2 is complete.

Abstract

We present a procedure for effective estimation of entropy and mutual information from small-sample data, and apply it to the problem of inferring high-dimensional gene association networks. Specifically, we develop a James-Stein-type shrinkage estimator, resulting in a procedure that is highly efficient statistically as well as computationally. Despite its simplicity, we show that it outperforms eight other entropy estimation procedures across a diverse range of sampling scenarios and data-generating models, even in cases of severe undersampling. We illustrate the approach by analyzing *E. coli* gene expression data and computing an entropy-based gene-association network from gene expression data. A computer program is available that implements the proposed shrinkage estimator.

Keywords: entropy, shrinkage estimation, James-Stein estimator, "small n, large p" setting, mutual information, gene association network

1. Introduction

Entropy is a fundamental quantity in statistics and machine learning. It has a large number of applications, for example in astronomy, cryptography, signal processing, statistics, physics, image analysis neuroscience, network theory, and bioinformatics—see, for example, Stinson (2006), Yeo and Burge (2004), MacKay (2003) and Strong et al. (1998). Here we focus on *estimating* entropy from small-sample data, with applications in genomics and gene network inference in mind (Margolin et al., 2006; Meyer et al., 2007).

To define the Shannon entropy, consider a categorical random variable with alphabet size p and associated cell probabilities $\theta_1, \dots, \theta_p$ with $\theta_k > 0$ and $\sum_k \theta_k = 1$. Throughout the article, we assume that p is fixed and known. In this setting, the Shannon entropy in natural units is given by[1]

$$H = -\sum_{k=1}^{p} \theta_k \log(\theta_k). \tag{1}$$

In practice, the underlying probability mass function are unknown, hence H and θ_k need to be *estimated* from observed cell counts $y_k \geq 0$.

A particularly simple and widely used estimator of entropy is the maximum likelihood (ML) estimator

$$\hat{H}^{\text{ML}} = -\sum_{k=1}^{p} \hat{\theta}_k^{\text{ML}} \log(\hat{\theta}_k^{\text{ML}})$$

constructed by plugging the ML frequency estimates

$$\hat{\theta}_k^{\text{ML}} = \frac{y_k}{n} \tag{2}$$

into Equation **1**, with $n = \sum_{k=1}^{p} y_k$ being the total number of counts.

In situations with $n \gg p$, that is, when the dimension is low and when there are many observation, it is easy to infer entropy reliably, and it is well-known that in this case the ML estimator is optimal. However, in high-dimensional problems with $n \ll p$ it becomes extremely challenging to estimate the entropy. Specifically, in the "small n, large p" regime the ML estimator performs very poorly and severely underestimates the true entropy.

While entropy estimation has a long history tracing back to more than 50 years ago, it is only recently that the specific issues arising in high-dimensional, undersampled data sets have attracted attention. This has lead to two recent innovations, namely the NSB algorithm (Nemenman et al., 2002) and the Chao-Shen estimator (Chao and Shen, 2003), both of which are now widely considered as benchmarks for the small-sample entropy estimation problem (Vu et al., 2007).

Here, we introduce a novel and highly efficient small-sample entropy estimator based on James-Stein shrinkage (Gruber, 1998). Our method is fully analytic and hence computationally inexpensive. Moreover, our procedure simultaneously provides estimates of the entropy *and* of the cell frequencies suitable for plugging into the Shannon entropy formula (Equation 1). Thus, in comparison the estimator we propose is simpler, very efficient, and at the same time more versatile than currently available entropy estimators.

2. Conventional Methods for Estimating Entropy

Entropy estimators can be divided into two groups: i) methods, that rely on estimates of cell frequencies, and ii) estimators, that directly infer entropy without estimating a compatible set of θ_k. Most methods discussed below fall into the first group, except for the Miller-Madow and NSB approaches.

1. In this paper we use the following conventions: log denotes the natural logarithm (*not* base 2 or base 10), and we define $0 \log 0 = 0$.

2.1 Maximum Likelihood Estimate

The connection between observed counts y_k and frequencies θ_k is given by the multinomial distribution

$$\text{Prob}(y_1,\ldots,y_p;\theta_1,\ldots,\theta_p) = \frac{n!}{\prod_{k=1}^{p} y_k!}\prod_{k=1}^{p}\theta_k^{y_k}. \tag{3}$$

Note that $\theta_k > 0$ because otherwise the distribution is singular. In contrast, there may be (and often are) zero counts y_k. The ML estimator of θ_k maximizes the right hand side of Equation **3** for fixed y_k, leading to the observed frequencies $\hat{\theta}_k^{\text{ML}} = \frac{y_k}{n}$ with variances $\text{Var}(\hat{\theta}_k^{\text{ML}}) = \frac{1}{n}\theta_k(1-\theta_k)$ and $\text{Bias}(\hat{\theta}_k^{\text{ML}}) = 0$ as $E(\hat{\theta}_k^{\text{ML}}) = \theta_k$.

2.2 Miller-Madow Estimator

While $\hat{\theta}_k^{\text{ML}}$ is unbiased, the corresponding plugin entropy estimator $\hat{H}^{\text{ML}}$ is not. First order bias correction leads to

$$\hat{H}^{\text{MM}} = \hat{H}^{\text{ML}} + \frac{m_{>0}-1}{2n},$$

where $m_{>0}$ is the number of cells with $y_k > 0$. This is known as the Miller-Madow estimator (Miller, 1955).

2.3 Bayesian Estimators

Bayesian regularization of cell counts *may* lead to vast improvements over the ML estimator (Agresti and Hitchcock, 2005). Using the Dirichlet distribution with parameters $a_1, a_2, \ldots, a_p$ as prior, the resulting posterior distribution is also Dirichlet with mean

$$\hat{\theta}_k^{\text{Bayes}} = \frac{y_k + a_k}{n + A},$$

where $A = \sum_{k=1}^{p} a_k$. The flattening constants a_k play the role of pseudo-counts (compare with Equation 2), so that A may be interpreted as the *a priori* sample size.

Some common choices for a_k are listed in Table **1**, along with references to the corresponding plugin entropy estimators,

$$\hat{H}^{\text{Bayes}} = -\sum_{k=1}^{p}\hat{\theta}_k^{\text{Bayes}}\log(\hat{\theta}_k^{\text{Bayes}}).$$

a_k	Cell frequency prior	Entropy estimator
0	no prior	maximum likelihood
$1/2$	Jeffreys prior (Jeffreys, 1946)	Krichevsky and Trofimov (1981)
1	Bayes-Laplace uniform prior	Holste et al. (1998)
$1/p$	Perks prior (Perks, 1947)	Schürmann and Grassberger (1996)
$\sqrt{n}/p$	minimax prior (Trybula, 1958)	

Table 1: Common choices for the parameters of the Dirichlet prior in the Bayesian estimators of cell frequencies, and corresponding entropy estimators.

While the multinomial model with Dirichlet prior is standard Bayesian folklore (Gelman et al., 2004), there is no general agreement regarding which assignment of a_k is best as noninformative prior—see for instance the discussion in Tuyl et al. (2008) and Geisser (1984). But, as shown later in this article, choosing inappropriate a_k can easily cause the resulting estimator to perform *worse* than the ML estimator, thereby defeating the originally intended purpose.

2.4 NSB Estimator

The NSB approach (Nemenman et al., 2002) avoids overrelying on a particular choice of a_k in the Bayes estimator by using a more refined prior. Specifically, a Dirichlet mixture prior with infinite number of components is employed, constructed such that the resulting prior over the entropy is uniform. While the NSB estimator is one of the best entropy estimators available at present in terms of statistical properties, using the Dirichlet mixture prior is computationally expensive and somewhat slow for practical applications.

2.5 Chao-Shen Estimator

Another recently proposed estimator is due to Chao and Shen (2003). This approach applies the Horvitz-Thompson estimator (Horvitz and Thompson, 1952) in combination with the Good-Turing correction (Good, 1953; Orlitsky et al., 2003) of the empirical cell probabilities to the problem of entropy estimation. The Good-Turing-corrected frequency estimates are

$$\hat{\theta}_k^{\text{GT}} = (1 - \frac{m_1}{n})\hat{\theta}_k^{\text{ML}},$$

where m_1 is the number of singletons, that is, cells with $y_k = 1$. Used jointly with the Horvitz-Thompson estimator this results in

$$\hat{H}^{CS} = -\sum_{k=1}^{p} \frac{\hat{\theta}_k^{\text{GT}} \log \hat{\theta}_k^{\text{GT}}}{(1 - (1 - \hat{\theta}_k^{\text{GT}})^n)},$$

an estimator with remarkably good statistical properties (Vu et al., 2007).

3. A James-Stein Shrinkage Estimator

The contribution of this paper is to introduce an entropy estimator that employs James-Stein-type shrinkage at the level of cell frequencies. As we will show below, this leads to an entropy estimator that is highly effective, both in terms of statistical accuracy and computational complexity.

James-Stein-type shrinkage is a simple analytic device to perform regularized high-dimensional inference. It is ideally suited for small-sample settings - the original estimator (James and Stein, 1961) considered sample size $n = 1$. A general recipe for constructing shrinkage estimators is given in *Appendix A*. In this section, we describe how this approach can be applied to the specific problem of estimating cell frequencies.

James-Stein shrinkage is based on averaging two very different models: a high-dimensional model with low bias and high variance, and a lower dimensional model with larger bias but smaller variance. The intensity of the regularization is determined by the relative weighting of the two models. Here we consider the convex combination

$$\hat{\theta}_k^{\text{Shrink}} = \lambda t_k + (1 - \lambda)\hat{\theta}_k^{\text{ML}}, \tag{4}$$

where $\lambda \in [0,1]$ is the shrinkage intensity that takes on a value between 0 (no shrinkage) and 1 (full shrinkage), and t_k is the shrinkage target. A convenient choice of t_k is the uniform distribution $t_k = \frac{1}{p}$. This is also the maximum entropy target. Considering that $\text{Bias}(\hat{\theta}_k^{\text{ML}}) = 0$ and using the unbiased estimator $\widehat{\text{Var}}(\hat{\theta}_k^{\text{ML}}) = \frac{\hat{\theta}_k^{\text{ML}}(1-\hat{\theta}_k^{\text{ML}})}{n-1}$ we obtain (cf. *Appendix A*) for the shrinkage intensity

$$\hat{\lambda}^\star = \frac{\sum_{k=1}^p \widehat{\text{Var}}(\hat{\theta}_k^{\text{ML}})}{\sum_{k=1}^p (t_k - \hat{\theta}_k^{\text{ML}})^2} = \frac{1 - \sum_{k=1}^p (\hat{\theta}_k^{\text{ML}})^2}{(n-1)\sum_{k=1}^p (t_k - \hat{\theta}_k^{\text{ML}})^2}. \tag{5}$$

Note that this also assumes a non-stochastic target t_k. The resulting plugin shrinkage entropy estimate is

$$\hat{H}^{\text{Shrink}} = -\sum_{k=1}^{p} \hat{\theta}_k^{\text{Shrink}} \log(\hat{\theta}_k^{\text{Shrink}}). \tag{6}$$

Remark 1 *There is a one to one correspondence between the shrinkage and the Bayes estimator. If we write $t_k = \frac{a_k}{A}$ and $\lambda = \frac{A}{n+A}$, then $\hat{\theta}_k^{Shrink} = \hat{\theta}_k^{Bayes}$. This implies that the shrinkage estimator is an empirical Bayes estimator with a data-driven choice of the flattening constants—see also Efron and Morris (1973). For every choice of A there exists an equivalent shrinkage intensity λ. Conversely, for every λ there exist an equivalent $A = n\frac{\lambda}{1-\lambda}$.*

Remark 2 *Developing $A = n\frac{\lambda}{1-\lambda} = n(\lambda + \lambda^2 + \ldots)$ we obtain the approximate estimate $\hat{A} = n\hat{\lambda}$, which in turn recovers the "pseudo-Bayes" estimator described in Fienberg and Holland (1973).*

Remark 3 *The shrinkage estimator assumes a fixed and known p. In many practical applications this will indeed be the case, for example, if the observed counts are due to discretization (see also the data example). In addition, the shrinkage estimator appears to be robust against assuming a larger p than necessary (see scenario 3 in the simulations).*

Remark 4 *The shrinkage approach can easily be modified to allow multiple targets with different shrinkage intensities. For instance, using the Good-Turing estimator (Good, 1953; Orlitsky et al., 2003), one could setup a different uniform target for the non-zero and the zero counts, respectively.*

4. Comparative Evaluation of Statistical Properties

In order to elucidate the relative strengths and weaknesses of the entropy estimators reviewed in the previous section, we set to benchmark them in a simulation study covering different data generation processes and sampling regimes.

4.1 Simulation Setup

We compared the statistical performance of all nine described estimators (maximum likelihood, Miller-Madow, four Bayesian estimators, the proposed shrinkage estimator (Equations 4–6), NSB und Chao-Shen) under various sampling and data generating scenarios:

- The dimension was fixed at $p = 1000$.
- Samples size n varied from 10, 30, 100, 300, 1000, 3000, to 10000. That is, we investigate cases of dramatic undersampling ("small n, large p") as well as situations with a larger number of observed counts.

The true cell probabilities $\theta_1, \dots, \theta_{1000}$ were assigned in four different fashions, corresponding to rows 1-4 in Figure **1**:

1. Sparse and heterogeneous, following a Dirichlet distribution with parameter $a = 0.0007$,
2. Random and homogeneous, following a Dirichlet distribution with parameter $a = 1$,
3. As in scenario 2, but with half of the cells containing structural zeros, and
4. Following a Zipf-type power law.

For each sampling scenario and sample size, we conducted 1000 simulation runs. In each run, we generated a new set of true cell frequencies and subsequently sampled observed counts y_k from the corresponding multinomial distribution. The resulting counts y_k were then supplied to the various entropy and cell frequencies estimators and the squared error $\sum_{i=k}^{1000}(\theta_k - \hat{\theta}_k)^2$ was computed. From the 1000 repetitions we estimated the mean squared error (MSE) of the cell frequencies by averaging over the individual squared errors (except for the NSB, Miller-Madow, and Chao-Shen estimators). Similarly, we computed estimates of MSE and bias of the inferred entropies.

4.2 Summary of Results from Simulations

Figure **1** displays the results of the simulation study, which can be summarized as follows:

- Unsurprisingly, all estimators perform well when the sample size is large.
- The maximum likelihood and Miller-Madow estimators perform worst, except for scenario 1. Note that these estimators are inappropriate even for moderately large sample sizes. Furthermore, the bias correction of the Miller-Madow estimator is not particularly effective.
- The minimax and $1/p$ Bayesian estimators tend to perform slightly better than maximum likelihood, but not by much.
- The Bayesian estimators with pseudocounts $1/2$ and 1 perform very well even for small sample sizes in the scenarios 2 and 3. However, they are less efficient in scenario 4, and completely fail in scenario 1.
- Hence, the Bayesian estimators can perform better or worse than the ML estimator, depending on the choice of the prior and on the sampling scenario.
- The NSB, the Chao-Shen and the shrinkage estimator all are statistically very efficient with small MSEs in all four scenarios, regardless of sample size.
- The NSB and Chao-Shen estimators are nearly unbiased in scenario 3.

The three top-performing estimators are the NSB, the Chao-Shen and the prosed shrinkage estimator. When it comes to estimating the entropy, these estimators can be considered identical for practical purposes. However, the shrinkage estimator is the only one that simultaneously estimates cell frequencies suitable for use with the Shannon entropy formula (Equation 1), and it does so with high accuracy even for small samples. In comparison, the NSB estimator is by far the slowest method: in our simulations, the shrinkage estimator was faster by a factor of 1000.

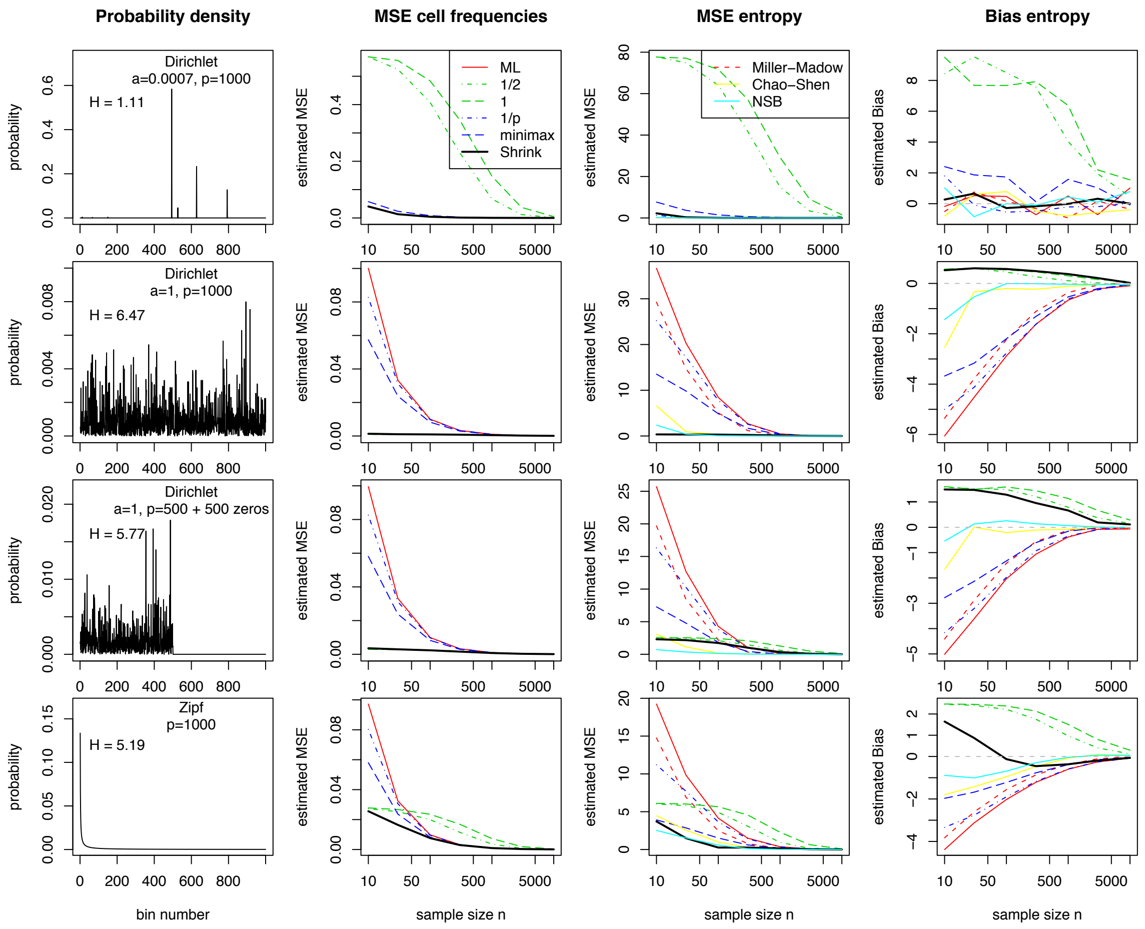

Figure 1: Comparing the performance of nine different entropy estimators (maximum likelihood, Miller-Madow, four Bayesian estimators, the proposed shrinkage estimator, NSB und Chao-Shen) in four different sampling scenarios (rows 1 to 4). The estimators are compared in terms of MSE of the underlying cell frequencies (except for Miller-Madow, NSB, Chao-Shen) and according to MSE and Bias of the estimated entropies. The dimension is fixed at $p = 1000$ while the sample size n varies from 10 to 10000.

5. Application to Statistical Learning of Nonlinear Gene Association Networks

In this section we illustrate how the shrinkage entropy estimator can be applied to the problem of inferring regulatory interactions between genes through estimating the nonlinear association network.

5.1 From Linear to Nonlinear Gene Association Networks

One of the aims of systems biology is to understand the interactions among genes and their products underlying the molecular mechanisms of cellular function as well as how disrupting these interactions may lead to different pathologies. To this end, an extensive literature on the problem of gene regulatory network "reverse engineering" has developed in the past decade (Friedman, 2004). Starting from gene expression or proteomics data, different statistical learning procedures have been proposed to infer associations and dependencies among genes. Among many others, methods have been proposed to enable the inference of large-scale correlation networks (Butte et al., 2000) and of high-dimensional partial correlation graphs (Dobra et al., 2004; Schäfer and Strimmer, 2005a; Meinshausen and Bühlmann, 2006), for learning vector-autoregressive (Opgen-Rhein and Strimmer, 2007a) and state space models (Rangel et al., 2004; Lähdesmäki and Shmulevich, 2008), and to reconstruct directed "causal" interaction graphs (Kalisch and Bühlmann, 2007; Opgen-Rhein and Strimmer, 2007b).

The restriction to linear models in most of the literature is owed at least in part to the already substantial challenges involved in estimating linear high-dimensional dependency structures. However, cell biology offers numerous examples of threshold and saturation effects, suggesting that linear models may not be sufficient to model gene regulation and gene-gene interactions. In order to relax the linearity assumption and to capture nonlinear associations among genes, entropy-based network modeling was recently proposed in the form of the ARACNE (Margolin et al., 2006) and MRNET (Meyer et al., 2007) algorithms.

The starting point of these two methods is to compute the mutual information $\mathrm{MI}(X,Y)$ for all pairs of genes X and Y, where X and Y represent the expression levels of the two genes for instance. The mutual information is the Kullback-Leibler distance from the joint probability density to the product of the marginal probability densities:

$$\mathrm{MI}(X,Y) = E_{f(x,y)}\left\{\log\frac{f(x,y)}{f(x)f(y)}\right\}. \tag{7}$$

The mutual information (MI) is always non-negative, symmetric, and equals zero only if X and Y are independent. For normally distributed variables the mutual information is closely related to the usual Pearson correlation,

$$\mathrm{MI}(X,Y) = -\frac{1}{2}\log(1-\rho^2).$$

Therefore, mutual information is a natural measure of the association between genes, regardless whether linear or nonlinear in nature.

5.2 Estimation of Mutual Information

To construct an entropy network, we first need to *estimate* mutual information for all pairs of genes. The entropy representation

$$\mathrm{MI}(X,Y) = H(X) + H(Y) - H(X,Y), \tag{8}$$

shows that MI can be computed from the joint and marginal entropies of the two genes X and Y. Note that this definition is equivalent to the one given in Equation **7** which is based on the Kullback-Leibler divergence. From Equation **8** it is also evident that $\mathrm{MI}(X,Y)$ is the information shared between the two variables.

For gene expression data the estimation of MI and the underlying entropies is challenging due to the small sample size, which requires the use of a regularized entropy estimator such as the shrinkage approach we propose here. Specifically, we proceed as follows:

- As a prerequisite the data must be discrete, with each measurement assuming one of K levels. If the data are not already discretized, we propose employing the simple algorithm of Freedman and Diaconis (1981), considering the measurements of all genes simultaneously.
- Next, we estimate the $p = K^2$ cell frequencies of the $K \times K$ contingency table for each pair X and Y using the shrinkage approach (Eqs. 4 and 5). Note that typically the sample size n is much smaller than K^2, thus simple approaches such as ML are not valid.
- Finally, from the estimated cell frequencies we calculate $H(X)$, $H(Y)$, $H(X,Y)$ and the desired $\mathrm{MI}(X,Y)$.

5.3 Mutual Information Network for *E. Coli* Stress Response Data

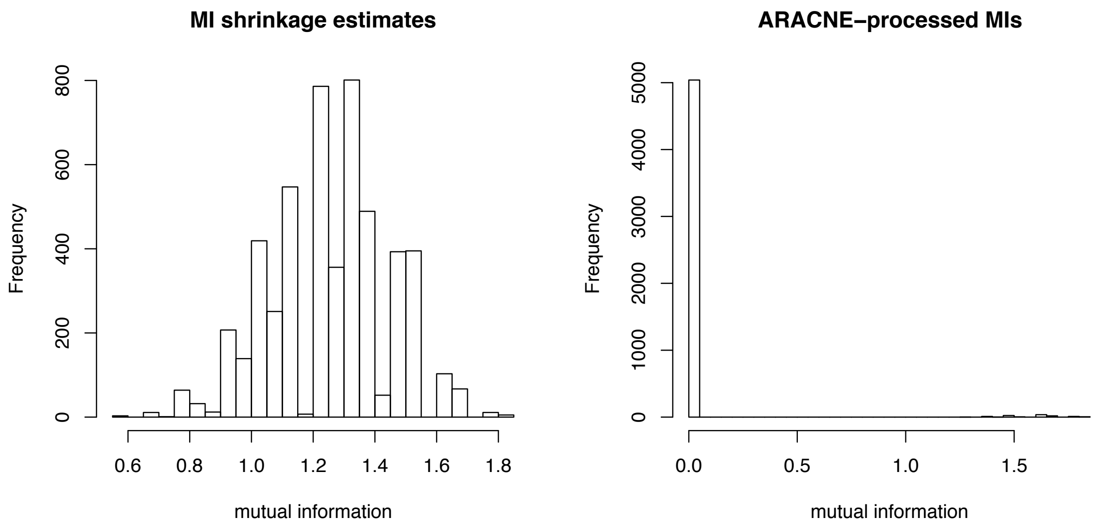

Figure 2: Left: Distribution of estimated mutual information values for all 5151 gene pairs of the *E. coli* data set. Right: Mutual information values after applying the ARACNE gene pair selection procedure. Note that the most MIs have been set to zero by the ARACNE algorithm.

For illustration, we now analyze data from Schmidt-Heck et al. (2004) who conducted an experiment to observe the stress response in *E. Coli* during expression of a recombinant protein. This data set was also used in previous linear network analyzes, for example, in Schäfer and Strimmer (2005b). The raw data consist of 4289 protein coding genes, on which measurements were taken at 0, 8, 15, 22, 45, 68, 90, 150, and 180 minutes. We focus on a subset of $G = 102$ differentially expressed genes as given in Schmidt-Heck et al. (2004).

Discretization of the data according to Freedman and Diaconis (1981) yielded $K = 16$ distinct gene expression levels. From the $G = 102$ genes, we estimated MIs for 5151 pairs of genes. For each pair, the mutual information was based on an estimated 16×16 contingency table, hence $p = 256$. As the number of time points is $n = 9$, this is a strongly undersampled situation which requires the use of a regularized estimate of entropy and mutual information.

The distribution of the shrinkage estimates of mutual information for all 5151 gene pairs is shown in the left side of Figure **2**. The right hand side depicts the distribution of mutual information values after applying the ARACNE procedure, which yields 112 gene pairs with nonzero MIs.

The model selection provided by ARACNE is based on applying the information processing inequality to all gene triplets. For each triplet, the gene pair corresponding to the smallest MI is discarded, which has the effect to remove gene-gene links that correspond to indirect rather than direct interactions. This is similar to a procedure used in graphical Gaussian models where correlations are transformed into partial correlations. Thus, both the ARACNE and the MRNET algorithms can be considered as devices to approximate the conditional mutual information (Meyer et al., 2007). As a result, the 112 nonzero MIs recovered by the ARACNE algorithm correspond to statistically detectable direct associations.

The corresponding gene association network is depicted in Figure **3**. The most striking feature of the graph are the "hubs" belonging to genes hupB, sucA and nuoL. hupB is a well known DNA-binding transcriptional regulator, whereas both nuoL and sucA are key components of the *E. coli* metabolism. Note that a Lasso-type procedure (that implicitly limits the number of edges that can connect to each node) such as that of Meinshausen and Bühlmann (2006) cannot recover these hubs.

6. Discussion

We proposed a James-Stein-type shrinkage estimator for inferring entropy and mutual information from small samples. While this is a challenging problem, we showed that our approach is highly efficient both statistically and computationally despite its simplicity.

In terms of versatility, our estimator has two distinct advantages over the NSB and Chao-Shen estimators. First, in addition to estimating the entropy, it also provides the underlying multinomial frequencies for use with the Shannon formula (Equation 1). This is useful in the context of using mutual information to quantify non-linear pairwise dependencies for instance. Second, unlike NSB, it is a fully analytic estimator.

Hence, our estimator suggests itself for applications in large scale estimation problems. To demonstrate its application in the context of genomics and systems biology, we have estimated an entropy-based gene dependency network from expression data in *E. coli*. This type of approach may prove helpful to overcome the limitations of linear models currently used in network analysis.

In short, we believe the proposed small-sample entropy estimator will be a valuable contribution to the growing toolbox of machine learning and statistics procedures for high-dimensional data analysis.

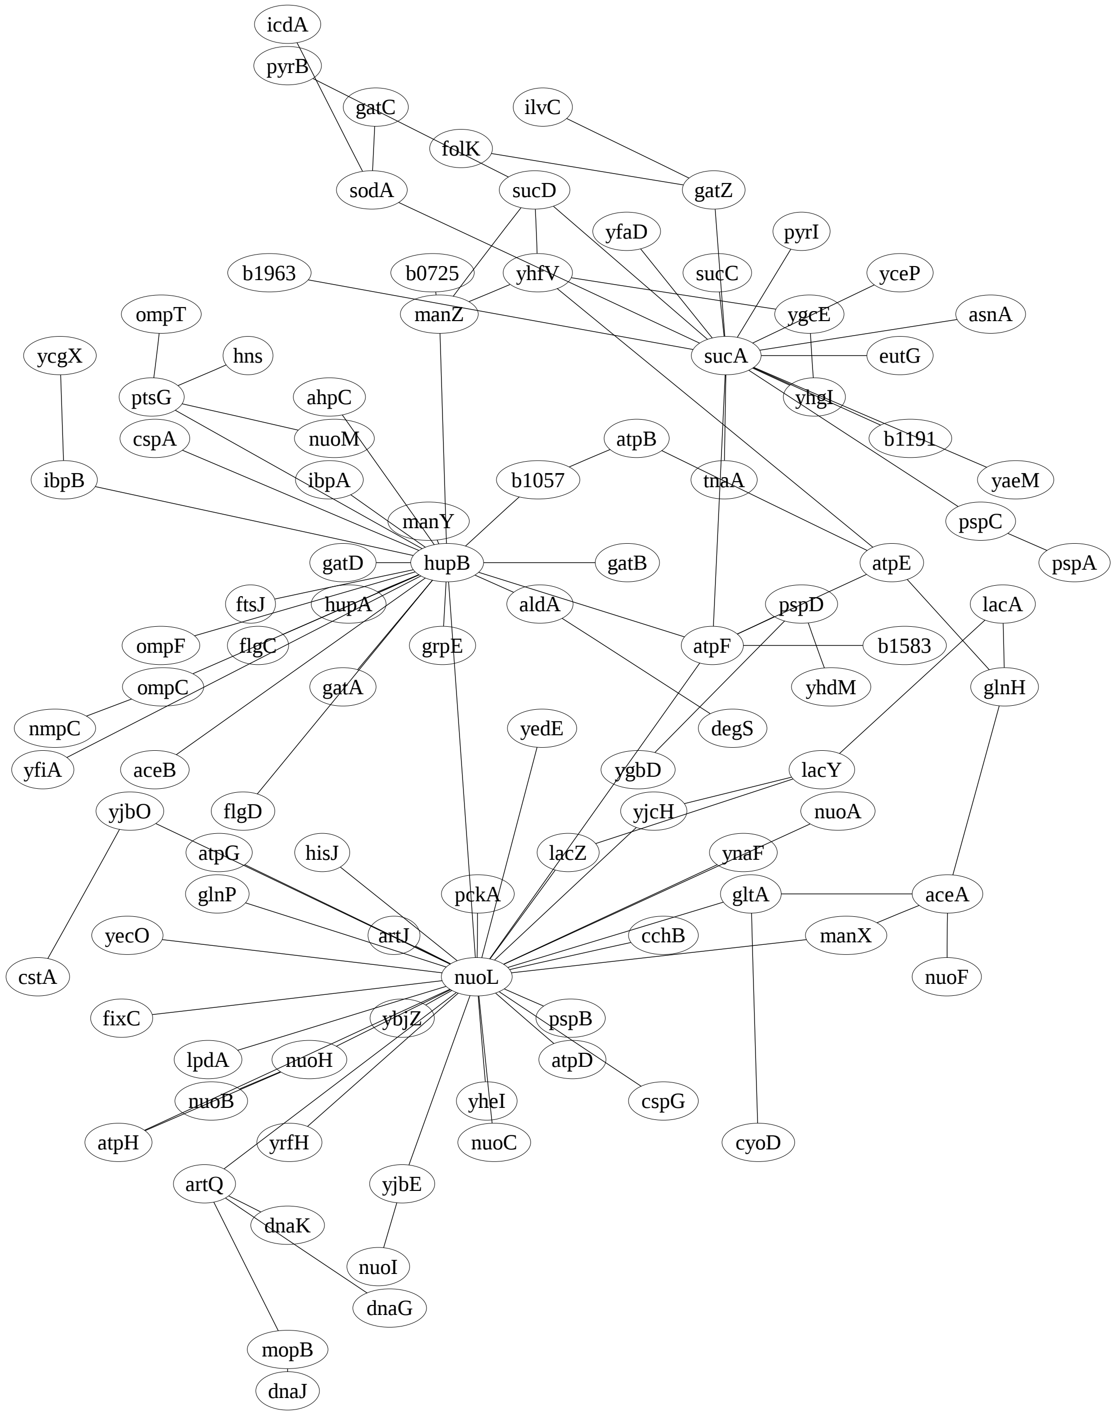

Figure 3: Mutual information network for the *E. coli* data inferred by the ARACNE algorithm based on shrinkage estimates of entropy and mutual information.

Appendix A. Recipe For Constructing James-Stein-type Shrinkage Estimators

The original James-Stein estimator (James and Stein, 1961) was proposed to estimate the mean of a multivariate normal distribution from a single ($n = 1!$) vector observation. Specifically, if x is a sample from $N_p(\mu, I)$ then James-Stein estimator is given by

$$\hat{\mu}_k^{\text{JS}} = (1 - \frac{p-2}{\sum_{k=1}^p x_k^2}) x_k.$$

Intriguingly, this estimator outperforms the maximum likelihood estimator $\hat{\mu}_k^{\text{ML}} = x_k$ in terms of mean squared error if the dimension is $p \geq 3$. Hence, the James-Stein estimator dominates the maximum likelihood estimator.

The above estimator can be slightly generalized by shrinking towards the component average $\bar{x} = \sum_{k=1}^p x_k$ rather than to zero, resulting in

$$\hat{\mu}_k^{\text{Shrink}} = \hat{\lambda}^\star \bar{x} + (1 - \hat{\lambda}^\star) x_k$$

with estimated shrinkage intensity

$$\hat{\lambda}^\star = \frac{p-3}{\sum_{k=1}^p (x_k - \bar{x})^2}.$$

The James-Stein shrinkage principle is very general and can be put to to use in many other high-dimensional settings. In the following we summarize a simple recipe for constructing James-Stein-type shrinkage estimators along the lines of Schäfer and Strimmer (2005b) and Opgen-Rhein and Strimmer (2007a).

In short, there are two key ideas at work in James-Stein shrinkage:

i) regularization of a high-dimensional estimator $\hat{\theta}$ by linear combination with a lower-dimensional target estimate $\hat{\theta}^{\text{Target}}$, and

ii) adaptive estimation of the shrinkage parameter λ from the data by quadratic risk minimization.

A general form of a James-Stein-type shrinkage estimator is given by

$$\hat{\theta}^{\text{Shrink}} = \lambda \hat{\theta}^{\text{Target}} + (1 - \lambda) \hat{\theta}. \tag{9}$$

Note that $\hat{\theta}$ and $\hat{\theta}^{\text{Target}}$ are two very different estimators (for the same underlying model!). $\hat{\theta}$ as a high-dimensional estimate with many independent components has low bias but for small samples a potentially large variance. In contrast, the target estimate $\hat{\theta}^{\text{Target}}$ is low-dimensional and therefore is generally less variable than $\hat{\theta}$ but at the same time is also more biased. The James-Stein estimate is a weighted average of these two estimators, where the weight is chosen in a data-driven fashion such that $\hat{\theta}^{\text{Shrink}}$ is improved in terms of mean squared error relative to *both* $\hat{\theta}$ and $\hat{\theta}^{\text{Target}}$.

A key advantage of James-Stein-type shrinkage is that the optimal shrinkage intensity $\lambda^\star$ can be calculated analytically and without knowing the true value θ, via

$$\lambda^\star = \frac{\sum_{k=1}^{p} \text{Var}(\hat{\theta}_k) - \text{Cov}(\hat{\theta}_k, \hat{\theta}_k^{\text{Target}}) + \text{Bias}(\hat{\theta}_k) E(\hat{\theta}_k - \hat{\theta}_k^{\text{Target}})}{\sum_{k=1}^{p} E[(\hat{\theta}_k - \hat{\theta}_k^{\text{Target}})^2]}. \tag{10}$$

A simple estimate of $\lambda^\star$ is obtained by replacing all variances and covariances in Equation **10** with their empirical counterparts, followed by truncation of $\hat{\lambda}^\star$ at 1 (so that $\hat{\lambda}^\star \leq 1$ always holds).

Equation **10** is discussed in detail in Schäfer and Strimmer (2005b) and Opgen-Rhein and Strimmer (2007a). More specialized versions of it are treated, for example, in Ledoit and Wolf (2003) for unbiased $\hat{\theta}$ and in Thompson (1968) (unbiased, univariate case with deterministic target). A very early version (univariate with zero target) even predates the estimator of James and Stein, see Goodman (1953). For the multinormal setting of James and Stein (1961), Equation **9** and Equation **10** reduce to the shrinkage estimator described in Stigler (1990).

James-Stein shrinkage has an empirical Bayes interpretation (Efron and Morris, 1973). Note, however, that only the first two moments of the distributions of $\hat{\theta}^{\text{Target}}$ and $\hat{\theta}$ need to be specified in Equation **10**. Hence, James-Stein estimation may be viewed as a *quasi-empirical Bayes* approach (in the same sense as in quasi-likelihood, which also requires only the first two moments).

Appendix B. Computer Implementation

The proposed shrinkage estimators of entropy and mutual information, as well as all other investigated entropy estimators, have been implemented in R (R Development Core Team, 2008). A corresponding R package "entropy" was deposited in the R archive CRAN and is accessible at the URL `http://cran.r-project.org/web/packages/entropy/` under the GNU General Public License.
