Abstract

Deep multi-layer neural networks have many levels of non-linearities allowing them to compactly represent highly non-linear and highly-varying functions. However, until recently it was not clear how to train such deep networks, since gradient-based optimization starting from random initialization often appears to get stuck in poor solutions. Hinton et al. recently proposed a greedy layer-wise unsupervised learning procedure relying on the training algorithm of restricted Boltzmann machines (RBM) to initialize the parameters of a deep belief network (DBN), a generative model with many layers of hidden causal variables. This was followed by the proposal of another greedy layer-wise procedure, relying on the usage of autoassociator networks. In the context of the above optimization problem, we study these algorithms empirically to better understand their success. Our experiments confirm the hypothesis that the greedy layer-wise unsupervised training strategy helps the optimization by initializing weights in a region near a good local minimum, but also implicitly acts as a sort of regularization that brings better generalization and encourages internal distributed representations that are high-level abstractions of the input. We also present a series of experiments aimed at evaluating the link between the performance of deep neural networks and practical aspects of their topology, for example, demonstrating cases where the addition of more depth helps. Finally, we empirically explore simple variants of these training algorithms, such as the use of different RBM input unit distributions, a simple way of combining gradient estimators to improve performance, as well as on-line versions of those algorithms.

Keywords: artificial neural networks, deep belief networks, restricted Boltzmann machines, autoassociators, unsupervised learning

1. Introduction

Training deep multi-layered neural networks is known to be hard. The standard learning strategy—consisting of randomly initializing the weights of the network and applying gradient descent using backpropagation—is known empirically to find poor solutions for networks with 3 or more hidden layers. As this is a negative result, it has not been much reported in the machine learning literature. For that reason, artificial neural networks have been limited to one or two hidden layers.

However, complexity theory of circuits strongly suggests that deep architectures can be much more efficient (sometimes exponentially) than shallow architectures, in terms of computational elements and parameters required to represent some functions (Bengio and Le Cun, 2007; Bengio, 2007). Whereas it cannot be claimed that deep architectures are better than shallow ones on every problem (Salakhutdinov and Murray, 2008; Larochelle and Bengio, 2008), there has been evidence of a benefit when the task is complex enough, and there is enough data to capture that complexity (Larochelle et al., 2007). Hence finding better learning algorithms for such deep networks could be beneficial.

An approach that has been explored with some success in the past is based on constructively adding layers. Each layer in a multi-layer neural network can be seen as a representation of the input obtained through a learned transformation. What makes a good internal representation of the data? We believe that it should disentangle the factors of variation that inherently explain the structure of the distribution. When such a representation is going to be used for unsupervised learning, we would like it to preserve information about the input while being easier to model than the input itself. When a representation is going to be used in a supervised prediction or classification task, we would like it to be such that there exists a "simple" (i.e., somehow easy to learn) mapping from the representation to a good prediction. To constructively build such a representation, it has been proposed to use a *supervised* criterion at each stage (Fahlman and Lebiere, 1990; Lengellé and Denoeux, 1996). However, as we discuss here, the use of a supervised criterion at each stage may be too greedy and does not yield as good generalization as using an unsupervised criterion. Aspects of the input may be ignored in a representation tuned to be immediately useful (with a linear classifier) but these aspects might turn out to be important when more layers are available. Combining unsupervised (e.g., learning about $p(x)$) and supervised components (e.g., learning about $p(y|x)$) can be be helpful when both functions $p(x)$ and $p(y|x)$ share some structure.

The idea of using unsupervised learning at each stage of a deep network was recently put forward by Hinton et al. (2006), as part of a training procedure for the deep belief network (DBN), a generative model with many layers of hidden stochastic variables. Upper layers of a DBN are supposed to represent more "abstract" concepts that explain the input observation $\mathbf{x}$, whereas lower layers extract "low-level features" from $\mathbf{x}$. In other words, this model first learns simple concepts, on which it builds more abstract concepts.

This training strategy has inspired a more general approach to help address the problem of training deep networks. Hinton (2006) showed that stacking restricted Boltzmann machines (RBMs)—that is, training upper RBMs on the distribution of activities computed by lower RBMs—provides a good initialization strategy for the weights of a deep artificial neural network. This approach can be extended to non-linear autoencoders or autoassociators (Saund, 1989), as shown by Bengio et al. (2007), and is found in stacked autoassociators network (Larochelle et al., 2007), and in the deep convolutional neural network (Ranzato et al., 2007b) derived from the convolutional neural network (LeCun et al., 1998). Since then, deep networks have been applied with success not only in classification tasks (Bengio et al., 2007; Ranzato et al., 2007b; Larochelle et al., 2007; Ranzato et al., 2008), but also in regression (Salakhutdinov and Hinton, 2008), dimensionality reduction (Hinton and Salakhutdinov, 2006; Salakhutdinov and Hinton, 2007b), modeling textures (Osindero and Hinton, 2008), information retrieval (Salakhutdinov and Hinton, 2007a), robotics (Hadsell et al., 2008), natural language processing (Collobert and Weston, 2008; Weston et al., 2008), and collaborative filtering (Salakhutdinov et al., 2007).

In this paper, we discuss in detail three principles for training deep neural networks and present experimental evidence that highlight the role of each in successfully training deep networks:

1. Pre-training one layer at a time in a greedy way;

2. using unsupervised learning at each layer in a way that preserves information from the input and disentangles factors of variation;

3. fine-tuning the whole network with respect to the ultimate criterion of interest.

The experiments reported here suggest that this strategy improves on the traditional random initialization of supervised multi-layer networks by providing "hints" to each intermediate layer about the kinds of representations that it should learn, and thus initializing the supervised fine-tuning optimization in a region of parameter space from which a better local minimum (or plateau) can be reached. We also present a series of experiments aimed at evaluating the link between the performance of deep neural networks and aspects of their topology such as depth and the size of the layers. In particular, we demonstrate cases where the addition of depth helps classification error, but too much depth hurts. Finally, we explore simple variants of the aforementioned training algorithms, such as a simple way of combining them to improve their performance, RBM variants for continuous-valued inputs, as well as on-line versions of those algorithms.

2. Notations and Conventions

Before describing the learning algorithms that we will study and experiment with in this paper, we first present the mathematical notation we will use for deep networks.

A deep neural network contains an input layer and an output layer, separated by l layers of hidden units. Given an input sample clamped to the input layer, the other units of the network compute their values according to the activity of the units that they are connected to in the layers below. We will consider a particular sort of topology here, where the input layer is fully connected to the first hidden layer, which is fully connected to the second layer and so on up to the output layer.

Given an input $\mathbf{x}$, the value of the j-th unit in the i-th layer is denoted $\widehat{h}^i_j(\mathbf{x})$, with $i = 0$ referring to the input layer, $i = l + 1$ referring to the output layer (the use of "$\widehat{\ }$" will become clearer in Section 4). We refer to the size of a layer as $|\widehat{\mathbf{h}}^i(\mathbf{x})|$. The default activation level is determined by the internal bias b^i_j of that unit. The set of weights W^i_{jk} between $\widehat{h}^{i-1}_k(\mathbf{x})$ in layer $i-1$ and unit $\widehat{h}^i_j(\mathbf{x})$ in layer i determines the activation of unit $\widehat{h}^i_j(\mathbf{x})$ as follows:

$$\widehat{h}^i_j(\mathbf{x}) = \operatorname{sigm}\left(a^i_j\right) \text{ where } a^i_j(\mathbf{x}) = b^i_j + \sum_k W^i_{jk}\widehat{h}^{i-1}_k(\mathbf{x})\ \forall i \in \{1,\ldots,l\},\text{ with } \widehat{h}^0(\mathbf{x}) = \mathbf{x} \tag{1}$$

where $\operatorname{sigm}(\cdot)$ is the sigmoid squashing function: $\operatorname{sigm}(a) = \frac{1}{1+e^{-a}}$ (alternatively, the sigmoid could be replaced by the hyperbolic tangent). Given the last hidden layer, the output layer is computed similarly by

$$\mathbf{o}(\mathbf{x}) = \widehat{\mathbf{h}}^{l+1}(\mathbf{x}) = f\left(\mathbf{a}^{l+1}(\mathbf{x})\right) \text{ where } \mathbf{a}^{l+1}(\mathbf{x}) = \mathbf{b}^{l+1} + \mathbf{W}^{l+1}\widehat{\mathbf{h}}^l(\mathbf{x})$$

where the activation function $f(\cdot)$ depends on the (supervised) task the network must achieve. Typically, it will be the identity function for a regression problem and the softmax function

$$f_j(\mathbf{a}) = \operatorname{softmax}_j(\mathbf{a}) = \frac{e^{a_j}}{\sum_{k=1}^K e^{a_k}} \tag{2}$$

for a classification problem, in order to obtain a distribution over the K classes.

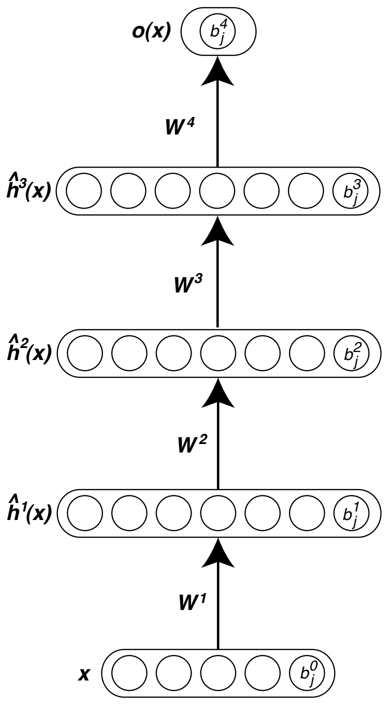

Figure 1: Illustration of a deep network and its parameters.

When an input sample **x** is presented to the network, the application of Equation 1 at each layer will generate a pattern of activity in the different layers of the neural network. Intuitively, we would like the activity of the first layer neurons to correspond to low-level features of the input (e.g., edge orientations for natural images) and to higher level abstractions (e.g., detection of geometrical shapes) in the last hidden layers.

3. Deep Neural Networks

It has been shown that a "shallow" neural network with only one arbitrarily large hidden layer could approximate a function to any level of precision (Hornik et al., 1989). Similarly, any Boolean function can be represented by a two-layer circuit of logic gates. However, most Boolean functions require an exponential number of logic gates (with respect to the input size) to be represented by a two-layer circuit (Wegener, 1987). For example, the parity function, which can be efficiently represented by a circuit of depth $O(\log n)$ (for n input bits) needs $O(2^n)$ gates to be represented by a depth two circuit (Yao, 1985). What about deeper circuits? Some families of functions which can be represented with a depth k circuit are such that they require an exponential number of logic gates to be represented by a depth $k-1$ circuit (Håstad, 1986). Interestingly, an equivalent result has been proved for architectures whose computational elements are not logic gates but linear threshold units (i.e., formal neurons) (Hastad and Goldmann, 1991). The machine learning literature also suggests that shallow architectures can be very inefficient in terms of the number of computational units (e.g., bases, hidden units), and thus in terms of required examples (Bengio and Le Cun, 2007; Bengio et al., 2006). On the other hand, a highly-varying function can sometimes be represented compactly (with fewer parameters) through the composition of many non-linearities, that is, with a deep architecture. When the representation of a concept requires an exponential number of elements (more generally exponential capacity), for example, with a shallow circuit, the number of training examples required to learn the concept may also be impractical. Smoothing the learned function by regularization would not solve the problem here because in these cases the target function itself is complicated and requires exponential capacity just to be represented.

3.1 Difficulty of Training Deep Architectures

Given a particular task, a natural way to train a deep network is to frame it as an optimization problem by specifying a supervised cost function on the output layer with respect to the desired target and use a gradient-based optimization algorithm in order to adjust the weights and biases of the network so that its output has low cost on samples in the training set. Unfortunately, deep networks trained in that manner have generally been found to perform worse than neural networks with one or two hidden layers.

We discuss two hypotheses that may explain this difficulty. The first one is that gradient descent can easily get stuck in poor local minima (Auer et al., 1996) or plateaus of the non-convex training criterion. The number and quality of these local minima and plateaus (Fukumizu and Amari, 2000) clearly also influence the chances for random initialization to be in the basin of attraction (via gradient descent) of a poor solution. It may be that with more layers, the number or the width of such poor basins increases. To reduce the difficulty, it has been suggested to train a neural network in a constructive manner in order to divide the hard optimization problem into several greedy but simpler ones, either by adding one neuron (e.g., see Fahlman and Lebiere, 1990) or one layer (e.g., see Lengellé and Denoeux, 1996) at a time. These two approaches have demonstrated to be very effective for learning particularly complex functions, such as a very non-linear classification problem in 2 dimensions. However, these are exceptionally hard problems, and for learning tasks usually found in practice, this approach commonly overfits.

This observation leads to a second hypothesis. For high capacity and highly flexible deep networks, there actually exists many basins of attraction in its parameter space (i.e., yielding different solutions with gradient descent) that can give low training error but that can have very different generalization errors. So even when gradient descent is able to find a (possibly local) good minimum in terms of training error, there are no guarantees that the associated parameter configuration will provide good generalization. Of course, model selection (e.g., by cross-validation) will partly correct this issue, but if the number of good generalization configurations is very small in comparison to good training configurations, as seems to be the case in practice, then it is likely that the training procedure will not find any of them. But, as we will see in this paper, it appears that the type of unsupervised initialization discussed here can help to select basins of attraction (for the supervised fine-tuning optimization phase) from which learning good solutions is easier both from the point of view of the training set and of a test set.

3.2 Unsupervised Learning as a Promising Paradigm for Greedy Layer-Wise Training

A common approach to improve the generalization performance of a learning algorithm which is motivated by the Occam's razor principle is the use of regularization (such as weight decay) that will favor "simpler" models over more complicated ones. However, using generic priors such as the ℓ^2 norm of the parameters conveys limited information about what the solution to a particular learning task should be. This has motivated researchers to discover more meaningful, data-dependent regularization procedures, which are usually based on unsupervised learning and normally adapted to specific models.

For example, Ando and Zhang (2005) use "auxiliary tasks" designed from unlabelled data and that are appropriate for a particular learning problem, to learn a better regularization term for linear classifiers. Partial least squares (Frank and Friedman, 1993) can also be seen as combining unsupervised and supervised learning in order to learn a better linear regression model when few training data are available or when the input space is very high dimensional.

Many semi-supervised learning algorithms also involve a combination of unsupervised and supervised learning, where the unsupervised component can be applied to additional unlabelled data. This is the case for Fisher-kernels (Jaakkola and Haussler, 1999) which are based on a generative model trained on unlabelled input data and that can be used to solve a supervised problem defined for that input space. In all these cases, unsupervised learning can be seen as adding more constraints on acceptable configurations for the parameters of a model, by asking that it not only describes well the relationship between the input and the target but also contains relevant statistical information about the structure of the input or how it was generated.

Moreover, there is a growing literature on the distinct advantages of generative and discriminative learning. Ng and Jordan (2001) argue that generative versions of discriminative models can be expected to reach their usually higher asymptotic out-of-sample classification error faster (i.e., with less training data), making them preferable in certain situations. Moreover, successful attempts at exploring the space between discriminative and generative learning have been studied (Lasserre et al., 2006; Jebara, 2003; Bouchard and Triggs, 2004; Holub and Perona, 2005).

The deep network learning algorithms that have been proposed recently and that we study in this paper can be seen as combining the ideas of *greedily learning the network* to break down the learning problem into easier steps, *using unsupervised learning* to provide an *effective hint* about what hidden units should learn, bringing along the way a form of regularization that prevents overfitting even in deep networks with many degrees of freedom (which could otherwise overfit). In addition, one should consider the supervised task the network has to solve. The greedy layer-wise unsupervised strategy provides an initialization procedure, after which the neural network is *fine-tuned to the global supervised objective*. The general paradigm followed by these algorithms (illustrated in Figure 2 and detailed in Appendix A) can be decomposed in two phases:

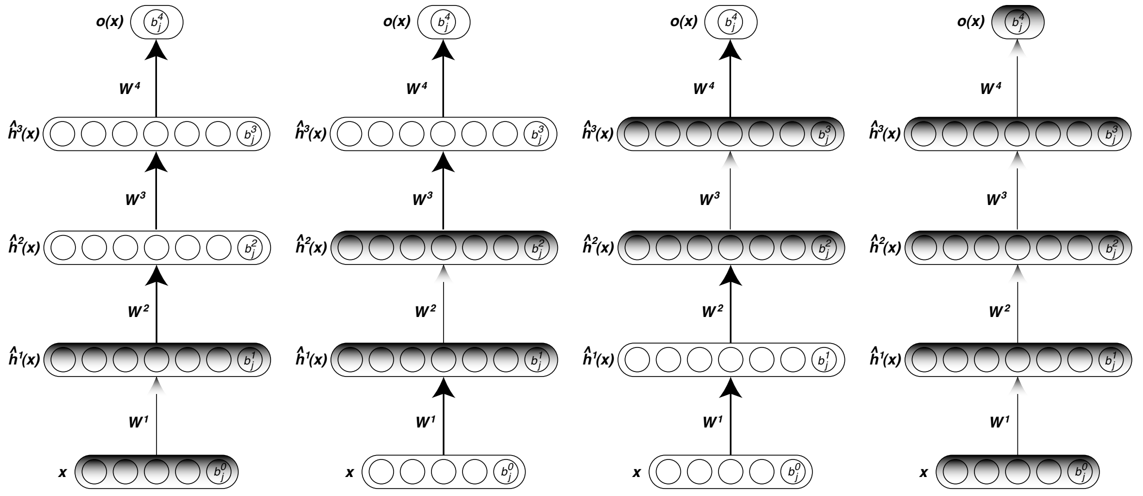
1. In the first phase, greedily train subsets of the parameters of the network using a layer-wise and unsupervised learning criterion, by repeating the following steps for each layer ($i \in \{1, \dots, l\}$)

   Until a stopping criteria is met, iterate through training database by

   (a) mapping input training sample $\mathbf{x}_t$ to representation $\widehat{\mathbf{h}}^{i-1}(\mathbf{x}_t)$ (if $i > 1$) and hidden representation $\widehat{\mathbf{h}}^{i}(\mathbf{x}_t)$,

   (b) updating parameters $\mathbf{b}^{i-1}$, $\mathbf{b}^{i}$ and $\mathbf{W}^{i}$ of layer i using some unsupervised learning algorithm.

   Also, initialize (e.g., randomly) the output layer parameters $\mathbf{b}^{l+1}, \mathbf{W}^{l+1}$.



(a) First hidden layer pre-training (b) Second hidden layer pre-training (c) Third hidden layer pre-training (d) Fine-tuning of whole network

Figure 2: Unsupervised greedy layer-wise training procedure.

2. In the second and final phase, fine-tune all the parameters θ of the network using backpropagation and gradient descent on a global supervised cost function $C(\mathbf{x}_t, y_t, \theta)$, with input $\mathbf{x}_t$ and label y_t, that is, trying to make steps in the direction $E\left[\frac{\partial C(\mathbf{x}_t, y_t, \theta)}{\partial \theta}\right]$.

Regularization is not explicit in this procedure, as it does not come from a weighted term that depends on the complexity of the network and that is added to the global supervised objective. Instead, it is implicit, as the first phase that initializes the parameters of the whole network will ultimately have an impact on the solution found in the second phase (the fine-tuning phase). Indeed, by using an iterative gradual optimization algorithm such as stochastic gradient descent with early-stopping (i.e., training until the error on a validation set reaches a clear minimum), the extent to which the configuration of the network's parameters can be different from the initial configuration given by the first phase is limited. Hence, similarly to using a regularization term on the parameters of the model that constrains them to be close to a particular value (e.g., 0 for weight decay), the first phase here will ensure that the parameter solution for each layer found by fine-tuning will not be far from the solution found by the unsupervised learning algorithm. In addition, the non-convexity of the supervised training criterion means that the choice of initial parameter values can greatly influence the quality of the solution obtained by gradient descent.

In the next two sections, we present a review of the two training algorithms that fall in paradigm presented above and which are empirically studied in this paper, in Section 6.

4. Stacked Restricted Boltzmann Machine Network

Intuitively, a successful learning algorithm for deep networks should be one that discovers a meaningful and possibly complex hidden representation of the data at its top hidden layer. However, learning such non-linear representations is a hard problem. A solution, proposed by Hinton (2006), is based on the learning algorithm of the restricted Boltzmann machine (RBM) (Smolensky, 1986), a generative model that uses a layer of binary variables to explain its input data. In an RBM (see

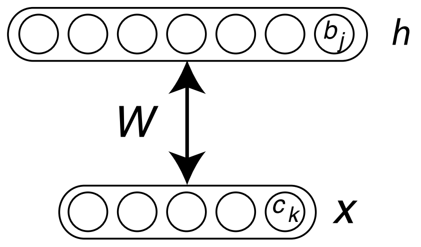


Figure 3: Illustration of a restricted Boltzmann machine and its parameters. **W** is a weight matrix, **b** is a vector of hidden unit biases, and **c** a vector of visible unit biases.

Figure 3 for an illustration), given an input $\mathbf{x}$, it is easy to obtain a hidden representation for that input by computing the posterior $\widehat{\mathbf{h}}(\mathbf{x})$ over the layer of binary hidden variables $\mathbf{h}$ (we use the "$\widehat{\ }$" symbol to emphasize that $\widehat{\mathbf{h}}(\mathbf{x})$ is not a random variable but a deterministic representation of $\mathbf{x}$).

Hinton (2006) argues that this representation can be improved by giving it as input to another RBM, whose posterior over its hidden layer will then provide a more complex representation of the input. This process can be repeated an arbitrary number of times in order to obtain ever more non-linear representations of the input. Finally, the parameters of the RBMs that compute these representations can be used to initialize the parameters of a deep network, which can then be fine-tuned to a particular supervised task. This learning algorithm clearly falls in the paradigm of Section 3.2, where the unsupervised part of the learning algorithm is that of an RBM. We will refer to deep networks trained using this algorithm as stacked restricted Boltzmann machine (SRBM) networks. For more technical details about the SRBM network, and how to train an RBM using the contrastive divergence algorithm (CD-k), see Appendix B.

5. Stacked Autoassociators Network

There are theoretical results about the advantage of stacking many RBMs into a DBN: Hinton et al. (2006) show that this procedure optimizes a bound on the likelihood of the input data when all layers have the same size. An additional hypothesis to explain why this process provides a good initialization for the network is that it makes each hidden layer compute a different, possibly more abstract representation of the input. This is done implicitly, by asking that each layer captures features of the input that help characterize the distribution of values at the layer below. By transitivity, each layer contains some information about the input. However, stacking any unsupervised learning model does not guarantee that the representations learned get increasingly complex or appropriate as we stack more layers. For instance, many layers of linear PCA models could be summarized by only one layer. However, there may be other non-linear, unsupervised learning models that, when stacked, are able to improve the learned representation at the last layer added.

An example of such a non-linear unsupervised learning model is the autoassociator or autoencoder network (Cottrell et al., 1987; Saund, 1989; Hinton, 1989; Baldi and Hornik, 1989; DeMers and Cottrell, 1993). Autoassociators are neural networks that are trained to compute a representation of the input from which it can be reconstructed with as much accuracy as possible. In this paper, we will consider autoassociator networks of only one hidden layer, meaning that the hidden

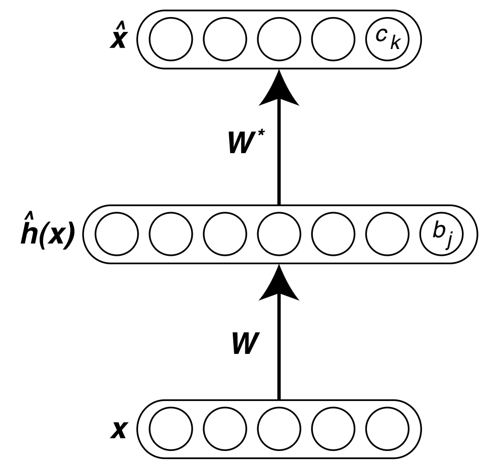

Figure 4: Illustration of an autoassociator and its parameters. $\mathbf{W}$ is the matrix of encoder weights and $\mathbf{W}^*$ the matrix of decoder weights. $\widehat{\mathbf{h}}(\mathbf{x})$ is the code or representation of $\mathbf{x}$.

representation of $\mathbf{x}$ is a code $\widehat{\mathbf{h}}(x)$ obtained from the encoding function

$$\widehat{h}_j(\mathbf{x}) = f(a_j) \text{ where } a_j(\mathbf{x}) = b_j + \sum_k W_{jk} x_k \,. \tag{3}$$

The input's reconstruction is obtained from a decoding function, here a linear transformation of the hidden representation with weight matrix $\mathbf{W}^*$, possibly followed by a non-linear activation function:

$$\widehat{x}_k = g(\widehat{a}_k) \text{ where } \widehat{a}_k = c_k + \sum_j W^*_{jk} \widehat{h}_j(\mathbf{x}) \,.$$

In this work, we used the sigmoid activation function for both $f(\cdot)$ and $g(\cdot)$. Figure 4 shows an illustration of this model.

By noticing the similarity between Equations 3 and 1, we are then able to use the training algorithm for autoassociators as the unsupervised learning algorithm for the greedy layer-wise initialization phase of deep networks. In this paper, stacked autoassociators (SAA) networks will refer to deep networks trained using the procedure of Section 3.2 and the learning algorithm of an autoassociator for each layer, as described in Section 5.1.

Though these neural networks were designed with the goal of dimensionality reduction in mind, the new representation's dimensionality does not necessarily need to be lower than the input's in practice. However, in that particular case, some care must be taken so that the network does not learn a trivial identity function, that is, finds weights that simply "copy" the whole input vector in the hidden layer and then copy it again at the output. For example, a network with small weights W_{jk} between the input and hidden layers (maintaining activations in the linear regime of the activation function f) and large weights W^*_{jk} between the hidden and output layers could encode such an uninteresting identity function. An easy way to avoid such a pathological behavior in the case of continuous inputs is to set the weight matrices $\mathbf{W}^\mathsf{T}$ and $\mathbf{W}^*$ to be the same. This adjustment is motivated by its similarity with the parametrization of the RBM model and by an empirical observation that $\mathbf{W}^\mathsf{T}$ and $\mathbf{W}^*$ tend to be similar up to a multiplicative factor after training. In the case of binary inputs, if the weights are large, the input vector can still be copied (up to a permutation of the elements) to the hidden units, and in turn these used to perfectly reconstruct the input. Weight decay can be useful to prevent such a trivial and uninteresting mapping to be learned, when the inputs are binary. We set $\mathbf{W}^{\mathsf{T}} = \mathbf{W}^*$ in all of our experiments. Vincent et al. (2008) have an improved way of training autoassociators in order to produce interesting, non-trivial features in the hidden layer, by partially corrupting the network's inputs.

The reconstruction error of an autoassociator can be connected to the log-likelihood of an RBM in several ways. Ranzato et al. (2008) connect the log of the numerator of the input likelihood with a form of reconstruction error (where one replaces the sum over hidden unit configurations by a maximization). The denominator is the normalization constant summing over all input configurations the same expression as in the numerator. So whereas maximizing the numerator is similar to minimizing reconstruction error for the training examples, minimizing the denominator means that most input configurations should not be reconstructed well. This can be achieved if the autoassociator is constrained in such a way that it cannot compute the identity function, but only minimizes the reconstruction for training examples.

Another connection between reconstruction error and log-likelihood of the RBM was made in Bengio and Delalleau (2007). They consider a converging series expansion of the log-likelihood gradient and show that whereas CD-k truncates the series by keeping the first $2k$ terms and then approximates expectations by a single sample, reconstruction error is a mean-field approximation of the first term in that series.

5.1 Learning in an Autoassociator Network

Training an autoassociator network is almost identical to training a standard artificial neural network. Given a cost function, backpropagation is used to compute gradients and perform gradient descent. However, autoassociators are "self-supervised", meaning that the target to which the output of the autoassociator is compared is the input that it was fed.

Previous work on autoassociators minimized the squared reconstruction error:

$$C(\widehat{\mathbf{x}}, \mathbf{x}) = \sum_k (\widehat{x}_k - x_k)^2 \ .$$

However, with squared reconstruction error and linear decoder, the "optimal codes" (the implicit target for the encoder, irrespective of the encoder) are in the span of the principal eigenvectors of the input covariance matrix. When we introduce a saturating non-linearity such as the sigmoid, and we want to reconstruct values $[0,1]$, the binomial KL divergence (also known as cross-entropy) seems more appropriate:

$$C(\widehat{\mathbf{x}}, \mathbf{x}) = -\sum_k \left(x_k \log(\widehat{x}_k) + (1 - x_k) \log(1 - \widehat{x}_k) \right) \ . \tag{4}$$

It corresponds to the assumption that $\widehat{\mathbf{x}}$ and $\mathbf{x}$ can be interpreted as factorized distributions over binary units. It is well known that the cross-entropy $-p\log(q) - (1-p)\log(1-q)$ between two binary distributions parametrized by p and q is minimized when $q = p$ (for a fixed p), making it an appropriate cost function to evaluate the quality of a reconstruction. We used this cost function in all the experiments with SAA networks. Appendix C details the corresponding autoassociator training update.

6. Experiments

In this section, we present several experiments set up to evaluate the deep network learning algorithms that fall in the paradigm presented in the Section 3.2 and highlight some of their properties. Unless otherwise stated, stochastic gradient descent was used for layer-wise unsupervised learning (first phase of the algorithm) and global supervised fine-tuning (second phase of the algorithm). The data sets were separated in disjoint training, validation and testing subsets. Model selection consisted of finding the best values for the learning rates of layer-wise unsupervised and global supervised learning as well as the number of unsupervised updates preceding the fine-tuning phase. The number of epochs of fine-tuning was chosen using early-stopping based on the progression of classification error on the validation set. All experiments correspond to classification problems. Hence, to fine-tune the deep networks, we optimized the negative conditional log-likelihood of the training samples' target class (as given by the softmax output of the neural network).

The experiments are based on the MNIST data set[1] (see Figure 5), a benchmark for handwritten digit recognition, as well as variants of this problem where the input distribution has been made more complex by inserting additional factors of variations, such as rotations and background images. The input images are made of 28×28 pixels giving an input dimensionality of 784, the number of classes is 10 (corresponding to the digits from 0 to 9) and the inputs were scaled between 0 and 1.

Successful applications of deep networks have already been presented on a large variety of data, such as images of faces (Salakhutdinov and Hinton, 2008), real-world objects (Ranzato et al., 2007a) as well as text data (Hinton and Salakhutdinov, 2006; Salakhutdinov and Hinton, 2007a; Collobert and Weston, 2008; Weston et al., 2008), and on different types of problems such as regression (Salakhutdinov and Hinton, 2008), information retrieval (Salakhutdinov and Hinton, 2007a), robotics Hadsell et al. (2008), and collaborative filtering (Salakhutdinov et al., 2007).

In Bengio et al. (2007), we performed experiments on two regression data sets, with non-image continuous inputs (UCI Abalone, and a financial data set), demonstrating the use of unsupervised (or partially supervised) pre-training of deep networks on these tasks. In Larochelle et al. (2007), we studied the performance of several architectures on various data sets, including variations of MNIST (with rotations, random background, and image background), and discrimination tasks between wide and tall rectangles, and between convex and non-convex images. On these tasks, deep networks compared favorably to shallow architectures.

Our focus is hence not on demonstrating their usefulness on a wide range of tasks, but on exploring their properties empirically. Such experimental work required several weeks of cumulative CPU time, which restricted the number of data sets we could explore. However, by concentrating on the original MNIST data set and harder versions of it, we were able not only to confirm the good performance of deep networks, but also to study practical variations, to help understand the algorithms, and to discuss the impact on a deep network's performance of stepping to a more complicated problem.

6.1 Validating the Unsupervised Layer-Wise Strategy for Deep Networks

In this section, we evaluate the advantages brought by the unsupervised layer-wise strategy of Section 3.2. We want to separate the different algorithmic concepts behind it, in order to understand their contribution to the whole strategy. In particular, we pursue the following two questions:

1. This data set can be downloaded from `http://yann.lecun.com/expdb/mnist/`.

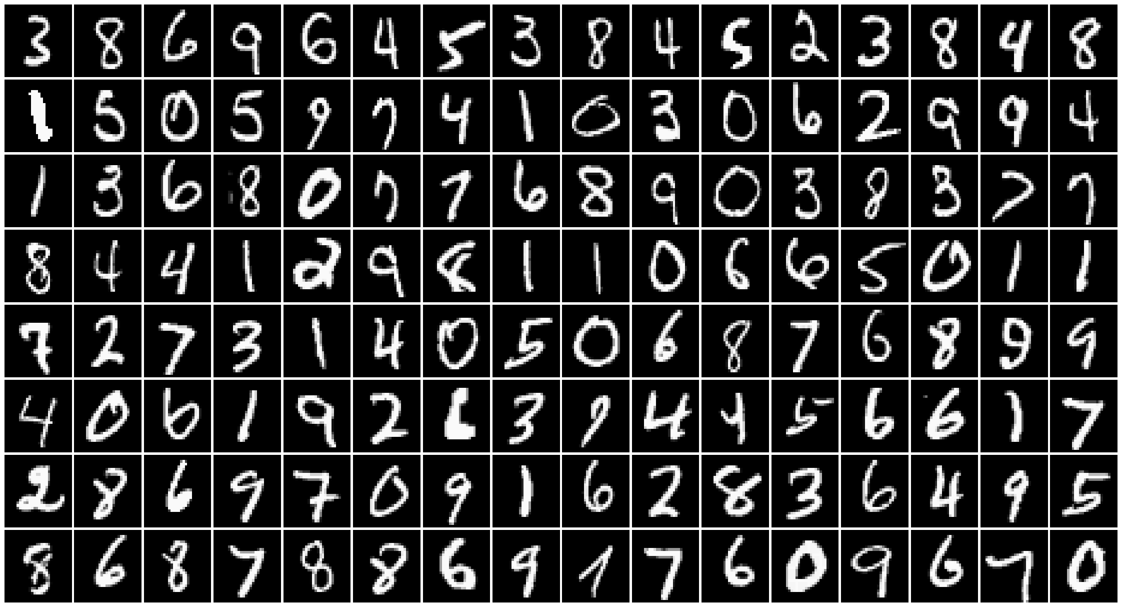

Figure 5: Samples from the MNIST digit recognition data set. Here, a black pixel corresponds to an input value of 0 and a white pixel corresponds to 1 (the inputs are scaled between 0 and 1).

1. To what extent does initializing greedily the parameters of the different layers help?
2. How important is unsupervised learning for this procedure?

To address these two questions, we will compare the learning algorithms for deep networks of Sections 4 and 5 with the following algorithms.

6.1.1 DEEP NETWORK WITHOUT PRE-TRAINING

To address the first question above, we compare the greedy layer-wise algorithm with a more standard way to train neural networks: using standard backpropagation and stochastic gradient descent, and starting at a randomly initialized configuration of the parameters. In other words, this variant simply puts away the pre-training phase of the other deep network learning algorithms.

6.1.2 DEEP NETWORK WITH SUPERVISED PRE-TRAINING

To address the second question, we run an experiment with the following algorithm. We greedily pre-train the layers using a *supervised criterion* (instead of the unsupervised one), before performing as before a final supervised fine-tuning phase. Specifically, when greedily pre-training the parameters $\mathbf{W}^i$ and $\mathbf{b}^i$, we also train another set of weights $\mathbf{V}^i$ and biases $\mathbf{c}^i$ which connect hidden layer $\widehat{\mathbf{h}}^i(\mathbf{x})$ to a temporary output layer as follows:

$$o^i(\mathbf{x}) = f\left(\mathbf{c}^i + \mathbf{V}^i\widehat{\mathbf{h}}^i(\mathbf{x})\right)$$

where $f(\cdot)$ is the softmax function of Equation 2. This output layer can be trained using the same cost as the global supervised cost. However, as this is a greedy procedure, only the parameters $\mathbf{W}^i$, $\mathbf{b}^i$, $\mathbf{V}^i$ and $\mathbf{c}^i$ are updated, that is, the gradient is not propagated to the layers below. When the training of a layer is finished, we can simply discard the parameters $\mathbf{V}^i$ and $\mathbf{c}^i$ and move to pre-training the next hidden layer, having initialized $\mathbf{W}^i$ and $\mathbf{b}^i$.

6.1.3 STACKED LOGISTIC AUTOREGRESSION NETWORK

The second question aims at evaluating to what extent any unsupervised learning can help. We already know that stacking linear PCA models is not expected to help improve generalization. A slightly more complex yet very simple unsupervised model for data in $[0,1]$ is the logistic autoregression model (see also Frey, 1998)

$$\widehat{x}_k = \mathrm{sigm}\left(b_k + \sum_{j \neq k} W_{kj} x_j\right) \tag{5}$$

where the reconstruction $\widehat{\mathbf{x}}$ is log-linear in the input $\mathbf{x}$. The parameters $\mathbf{W}$ and $\mathbf{b}$ can be trained using the same cost used for the autoassociators in Equation 4. This model can be used to initialize the weights $\mathbf{W}^i$ and biases $\mathbf{b}^i$ of the i-th hidden layer of a deep network. However, because $\mathbf{W}$ in Equation 5 is square, the deep network will need to have hidden layers with the same size as the input layer. Also, the weights on the diagonal of $\mathbf{W}$ are not trained in this model, so we initialize them to zero. The stacked logistic autoregression network will refer to deep networks using this unsupervised layer-wise learning algorithm.

6.1.4 RESULTS

The results for all these deep networks are given in Table 1. We also give results for a "shallow", one hidden layer neural network, to validate the utility of deep architectures. Instead of the sigmoid, this network uses hyperbolic tangent squashing functions, which are usually found to work better for one hidden layer neural networks. The MNIST training set was separated into training (50,000) and validation (10,000) sets. The test set has size 10,000. In addition to the hyperparameters mentioned at the beginning of this section, the validation set was used also to select appropriate decrease constants[2] for the learning rates of the greedy and fine-tuning phases. The SRBM and SAA networks had 500, 500 and 2000 hidden units in the first, second and third layers respectively, as in Hinton et al. (2006) and Hinton (2006). In the pre-training phase of the SRBM and SAA networks, when training the parameters of the i-th layer, the down-biases c_k where set to be equal to b_k^{i-1} (although similar results were obtained by using a separate set of biases c_k^{i-1} when the $i-1$-th layer is the down-layer). For the deep networks with supervised or no pre-training, different sizes of hidden layers were compared, including sizes similar to the stacked logistic autoregression network, and to the SRBM and SAA networks. All deep networks had 3 hidden layers.

Overall, the models that use the unsupervised layer-wise procedure of Section 3.2 outperform those that do not. We also observe a slight advantage in the performance of the SRBM network over that of the SAA network (on the MNIST test set, differences of more than 0.1% are statistically significant). The performance difference between the stacked logistic autoregressions network and

2. When using a decrease constant β, the learning rate for the t^{th} update becomes $\frac{\varepsilon_0}{1+t\beta}$, where ε_0 is the initial learning rate.

Models	Train.	Valid.	Test
SRBM (stacked restricted Boltzmann machines) network	0%	1.20%	1.20%
SAA (stacked autoassociators) network	0%	1.31%	1.41%
Stacked logistic autoregressions network	0%	1.65%	1.85%
Deep network with supervised pre-training	0%	1.74%	2.04%
Deep network, no pre-training	0.004%	2.07%	2.40%
Shallow network, no pre-training	0%	1.91%	1.93%

Table 1: Classification error on MNIST training, validation, and test sets, with the best hyperparameters according to validation error.

the deep network with supervised layer-wise pre-training particularly highlights the importance of unsupervised learning. Indeed, even though supervised layer-wise pre-training explicitly trains the hidden layers to capture non-linear information about the input, the overall procedure seems to be too greedy with respect to the supervised task to be learned. On the other hand, even though logistic autoregressions are simple log-linear models and their optimization is blind with respect to the future usage of the weights $\mathbf{W}$ as connections into non-linear hidden layers, the unsupervised nature of training makes them still useful for improving generalization. As a point of comparison, besides the deep networks, the best result on this data set reported for a learning algorithm that does not use any prior knowledge about the task (e.g., image pre-processing like deskewing or subsampling) is that of a support vector machine with a Gaussian kernel,[3] with 1.4% classification error on the test set.

At this point, it is clear that unsupervised layer-wise pre-training improves generalization. However, we could wonder whether it also facilitates the optimization problem of the global fine-tuning. The results of Table 1 do not shed any light on this aspect. Indeed, all the networks, even those without greedy layer-wise pre-training, perform almost perfectly on the training set. The explanatory hypothesis we evaluate here is that, without pre-training, the lower layers are initialized poorly, but still allow the top two layers to learn the training set almost perfectly because the output layer and the last hidden layer form a standard shallow but fat neural network. Consider the top two layers of the deep network *with pre-training*: it presumably takes as input a *better representation*, one that allows for better generalization. Instead, the network *without pre-training* sees a "random" transformation of the input, one that preserves enough information about the input to fit the training set, but that does not help to generalize. To test this hypothesis, we performed a second series of experiments in which we constrain the top hidden layer to be small (20 hidden units).

The results (Table 2) clearly suggest that optimization of the global supervised objective is made easier by greedy layer-wise pre-training. This result for supervised greedy pre-training is also coherent with past experiments on similar greedy strategies (Fahlman and Lebiere, 1990; Lengellé and Denoeux, 1996). Here, we have thus confirmed that it also applies to unsupervised greedy pre-training. With no pre-training, training error degrades significantly when there are only 20 hidden units in the top hidden layer. In addition, the results obtained without pre-training were found to have much larger variance than those with pre-training, indicating high sensitivity to initial

3. See `http://yann.lecun.com/exdb/mnist/` for more details.

Models	Train.	Valid.	Test
SRBM network	0%	1.5%	1.5%
SAA network	0%	1.38%	1.65%
Deep network with supervised pre-training	0%	1.77%	1.89%
Deep network, no pre-training	0.59%	2.10%	2.20%
Shallow network, no pre-training	3.6%	4.77%	5.00%

Table 2: Classification error on MNIST training, validation, and test sets, with the best hyperparameters according to validation error, when the last hidden layer only contains 20 hidden units

conditions: the unsupervised pre-training more consistently puts the parameters in a "good" basin of attraction for the supervised gradient descent procedure.

Figures 6 and 7 show the sorts of first hidden layer features (weights going into different hidden neurons) that are learned by the first (bottom) RBM and autoassociator respectively, before fine-tuning. Both models were trained on the MNIST training set of Section 6.1 for 40 epochs, with 250 hidden units and a learning rate of 0.005. We see that they both learn visual features characterized by local receptive fields, which ought to be useful to recognize more global shapes (though the autoassociator also learns high frequency receptive fields that are spread over the whole image). This is another account of how unsupervised greedy pre-training is able to help the optimization of the network. Even if the supervised fine-tuning gradient at the first hidden layer is weak, we can see that the first hidden layer appears to learn a relevant representation.

6.2 Exploring the Space of Network Architectures

An important practical aspect in using deep network is the choice the architecture or topology of the network. Once we allow ourselves to consider an arbitrary number of hidden layers of arbitrary sizes, some questions naturally arise. First, we would like to know how deep a neural network can be made while still obtaining generalization gains, given a strategy for initializing its parameters (randomly or with unsupervised greedy pre-training). We would also like to know, for a determined depth, what type of architecture is more appropriate. Should the hidden layer's size increase, decrease or stay the same from the first to the last? In this section, we explore those two questions with experiments on the MNIST data set as well as a variant, taken from Larochelle et al. (2007), where the digit images have been randomly rotated. This last data set, noted MNIST-rotation[4] (see Figure 8), contains much more intraclass variability, is much less well described by relatively well separated class-specific clusters and corresponds to a much harder classification problem. The training, validation and test sets contain 10 000, 2 000 and 50 000 examples each. We also generated sets of the same size for the MNIST data set. We refer to this version with a smaller training set by MNIST-small.

4. This data set has been regenerated since Larochelle et al. (2007) and is available here: `http://www.iro.umontreal.ca/~lisa/icml2007`.

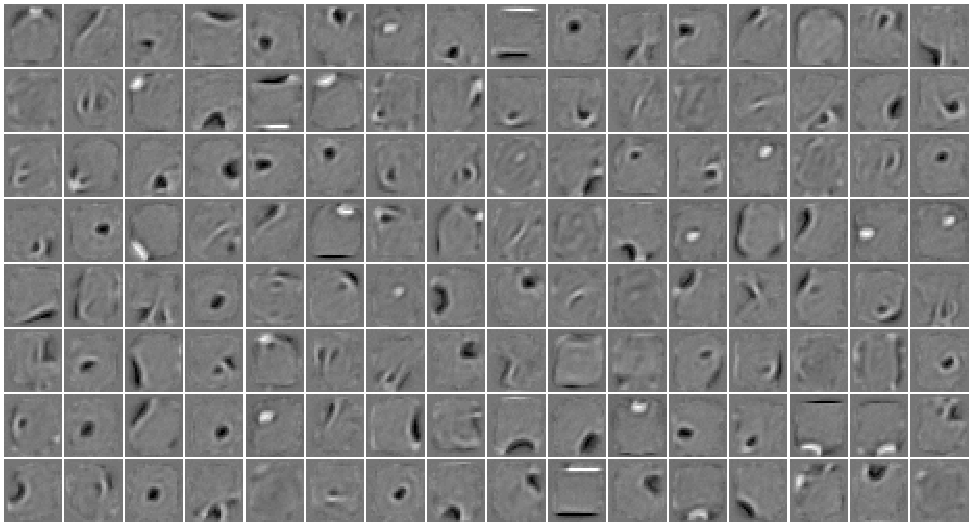

Figure 6: Display of the input weights of a random subset of the hidden units, learned by an RBM when trained on samples from the MNIST data set. The activation of units of the first hidden layer is obtained by a dot product of such a weight "image" with the input image. In these images, a black pixel corresponds to a weight smaller than -3 and a white pixel to a weight larger than 3, with the different shades of gray corresponding to different weight values uniformly between -3 and 3.

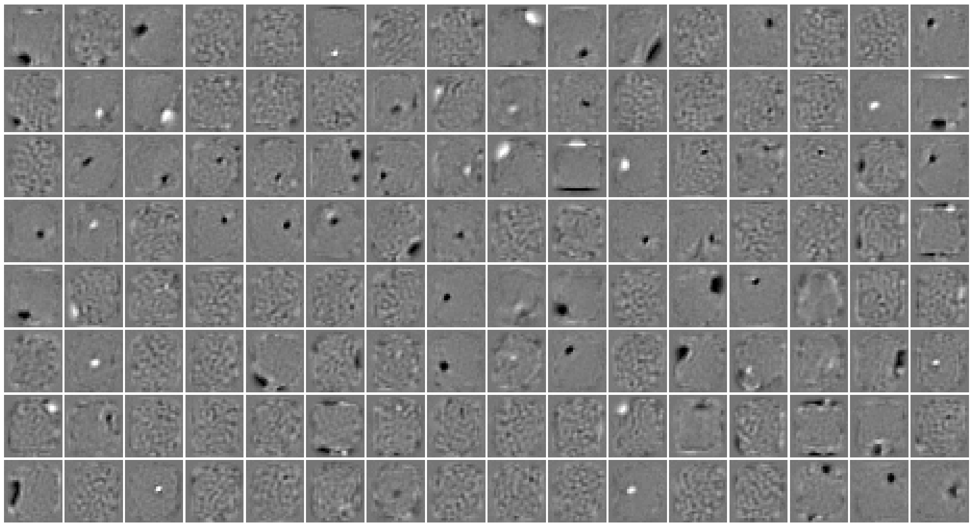

Figure 7: Input weights of a random subset of the hidden units, learned by an autoassociator when trained on samples from the MNIST data set. The display setting is the same as for Figure 6.

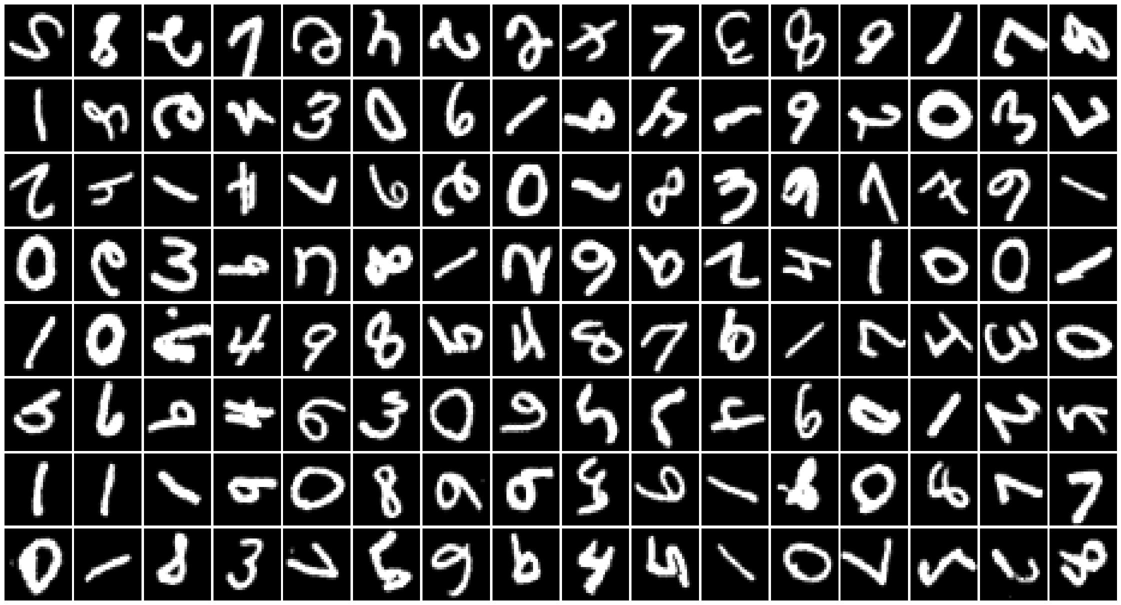

Figure 8: Samples from the MNIST-rotation data set. Here, a black pixel corresponds to an input value of 0 and a white pixel corresponds to 1 (the inputs are scaled between 0 and 1).

6.2.1 NETWORK DEPTH

One can wonder whether a neural network can be made too deep, that is, whether having too many hidden layers can worsen the generalization performance. Of course there are many reasons why this may happen. When a neuron is added, more parameters are inserted in the mathematical formulation of the model, giving it more degrees of freedom to fit the model and hence possibly making it able to overfit. On the other hand, it is less clear to what extent the performance can worsen, since a neuron added at the top layer of a neural network does not increase the capacity the same way a neuron added "in parallel" in a given hidden layer. Also, in the case of an SRBM network, we can imagine that as we stack RBMs, the representation at a hidden layer contains units that correspond to more and more disentangled concepts of the input. Now, consider a hypothetical deep network where the top-level stacked RBM has learned a representation made of units that are mostly independent. An additional RBM stacked on this representation would have no statistical structure to learn. This would initialize the weights of that new RBM to zero, which is particularly troublesome as the representation at this level would then contain no information about the input. It is not clear if this scenario is plausible, unlike in the case of independent component analysis, but if it were approached the result would be detrimental to supervised classification performance. This particular situation is not expected with stacked autoassociators, as it will always learn a representation from which the previous layer can be reconstructed. Another reason why a deeper architecture could produce worse results is simply that our algorithms for training a deep architecture can probably be improved. In particular, note that the only joint training of all layers that we have done in our experiments, if any, is at the supervised fine-tuning stage.

Network		MNIST-small	MNIST-rotation
Type	Depth	classif. test error	classif. test error
Neural network	1	**4.14** % ± 0.17	15.22 % ± 0.31
(random initialization,	2	**4.03** % ± 0.17	**10.63** % ± 0.27
+ fine-tuning)	3	**4.24** % ± 0.18	11.98 % ± 0.28
	4	4.47 % ± 0.18	11.73 % ± 0.29
SAA network	1	3.87 % ± 0.17	11.43% ± 0.28
(autoassociator learning	2	**3.38** % ± 0.16	9.88 % ± 0.26
+ fine-tuning)	3	**3.37** % ± 0.16	**9.22** % ± 0.25
	4	**3.39** % ± 0.16	**9.20** % ± 0.25
SRBM network	1	3.17 % ± 0.15	10.47 % ± 0.27
(CD-1 learning	2	**2.74** % ± 0.14	9.54 % ± 0.26
+ fine-tuning)	3	**2.71** % ± 0.14	**8.80** % ± 0.25
	4	**2.72** % ± 0.14	**8.83** % ± 0.24

Table 3: Classification performance on MNIST-small and MNIST-rotation of different networks for different strategies to initialize parameters, and different depths (number of layers).

Table 3 presents the classification performance obtained by the different deep networks with up to 4 hidden layers on MNIST-small and MNIST-rotation. The hyperparameters of each layer were *separately* selected with the validation set for all hidden layers, using the following greedy strategy: for a network with l hidden layers, only the hyperparameters for the top layer were optimized, the hyperparameters for the layers below being set to those of the best $l-1$ layers deep network according to the validation performance. We settled for this strategy because of the exponential number of possible configurations of hyperparameters. For standard neural networks, we also tested several random initializations of the weights. For SRBM as well as SAA networks, we tuned the unsupervised learning rates and the number of updates. For MNIST-small, we used hidden layers of 500 neurons, since the experiments by Hinton (2006) suggest that it is an appropriate choice. As for MNIST-rotation, the size of each hidden layer had to be validated separately for each layer, and we tested values among 500, 1000, 2000 and 4000.

Table 3 show that there is indeed an optimal number of hidden layers for the deep networks, and that this optimum tends to be larger when unsupervised greedy layer-wise learning is used. For the MNIST-small data set (Table 3), the gain in performance between 2 and 3 hidden layers for SRBM and SAA networks is not statistically significant. However, for the MNIST-rotation data set, the improvement from 2 to 3 hidden layers is clear. This observation is consistent with the increased complexity of the input distribution and classification problem of MNIST-rotation, which should require a more complex model. The improvement remains significant when fixing the network's hidden layers to the same size as in the experiments on MNIST-small, as showed in the results of Table 4 where the number of units per hidden layer was set to 1000. We also compared the performance of shallow and deep SRBM networks with roughly the same number of parameters. With a shallow SRBM network, the best classification error achieved was 10.47%, with 4000 hidden units (around 3.2×10^6 free parameters). With a 3-layers deep SRBM network, we reached 9.38%

Network			**MNIST-rotation**
Type	Depth	Layers width	**classif. test error**
SRBM network	1	1k	12.44 % $\pm$ 0.29
(CD-1 learning	2	1k, 1k	9.98 % $\pm$ 0.26
+ fine-tuning)	3	1k, 1k, 1k	**9.38** % $\pm$ 0.25

Table 4: Classification performance on MNIST-rotation of different networks for different strategies to initialize parameters, and different depths (number of layers). All hidden layers have 1000 units.

classification error with 1000 units in each layer (around 2.8×10^6 parameters): better generalization was achieved with deeper nets having less parameters.

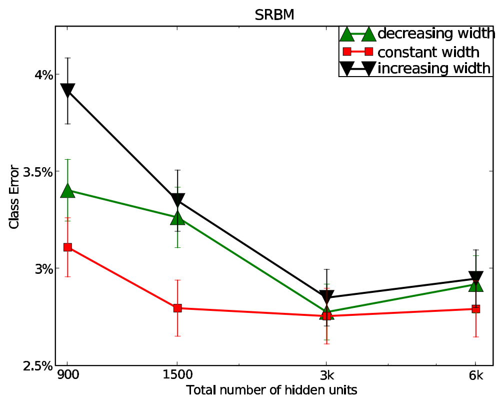
6.2.2 TYPE OF NETWORK ARCHITECTURE

The model selection procedure of Section 6.2.1 works well, but is rather expensive. Every time one wants to train a 4 hidden layer network, networks with 1, 2 and 3 hidden layers effectively have to be trained as well, in order to determine appropriate hyperparameters for the lower hidden layers. These networks can't even be trained in parallel, adding to the computational burden of this model selection procedure. Moreover, the optimal hidden layer size for a 1-hidden layer network could be much bigger than necessary for a 4 hidden layer network, since a shallow network cannot rely on other upper layers to increase its capacity.

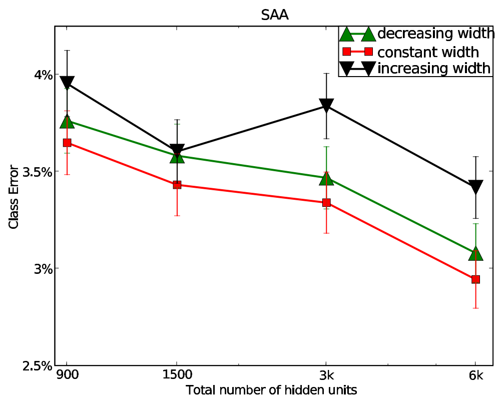
Let us consider the situation where the number of hidden layers of a deep network has already been chosen and good sizes of the different layers must be found. Because the space of such possible choices is exponential in the number of layers, we consider here only three general cases where, as the layer index increases, their sizes either increases (doubles), decreases (halves) or does not change. We conducted experiments for all three cases and varied the total number of hidden neurons in the network. The same hyperparameters as in the experiment of Table 3 had to be selected for each network topologies, however a single unsupervised learning rate and number of updates were chosen for all layers.[5]

We observe in Figures 9 and 10 that the architecture that most often is among the best performing ones across the different sizes of network is the one with equal sizes of hidden layers. It should be noted that this might be a consequence of using the same unsupervised learning hyperparameters for each layer. It might be that the size of a hidden layer has a significant influence on the optimum value for these hyperparameters, and that tying them for all hidden layers induces a bias towards networks with equally-sized hidden layers. However, having untied hyperparameters would make model selection too computationally demanding. Actually, even with tied unsupervised learning hyperparameters, the model selection problem is already complex enough (and prone to overfitting with small data sets), as is indicated by the differences in the validation and test classification errors of Table 3.

5. We imposed this restriction because of the large number of experiments that would otherwise had been required.



(a) SRBM network.



(b) SAA network.

7. Continuous-Valued Inputs

In this section, we wish to emphasize the importance of adapting the unsupervised learning algorithms to the nature of the inputs. We will focus on the SRBM network because they rely on RBMs, which are less simple to work with and adapt to the sorts of visible data we want to model. With the binary units introduced for RBMs and DBNs in Hinton et al. (2006) one can "cheat" and handle continuous-valued inputs by scaling them to the $[0,1]$ interval and considering each input continuous value as the probability for a binary random variable to take the value 1. This has worked well for pixel gray levels, but it may be inappropriate for other kinds of input variables. Previous work on continuous-valued input in RBMs include Chen and Murray (2003), in which noise is added to sigmoidal units, and the RBM forms a special form of diffusion network (Movellan et al., 2002). Welling et al. (2005) also show how to derive RBMs from arbitrary choices of exponential distributions for the visible and hidden layers of an RBM. We show here simple extensions of the RBM framework in which only the energy function and the allowed range of values are changed. As can be seen in Figures 11 and 12 and in the experiment of Section 7.3, such extensions have a very significant impact on nature of the solution learned for the RBM's weights and hence on the initialization of a deep network and its performance.

7.1 Linear Energy: Exponential or Truncated Exponential

Consider a unit with value x_k in an RBM, connected to units $\mathbf{h}$ of the layer above. $p(x_k|\mathbf{h})$ can be obtained by considering the terms in the energy function that contain x_k. These terms can be grouped in $x_k(\mathbf{W}_{\cdot k}^{\mathsf{T}}\mathbf{h}+c_k)$ when the energy function is linear in x_k (as in Equation 7, appendix B), where $\mathbf{W}_{\cdot k}$ is the k-th column of $\mathbf{W}$. If we allow x_k to take any value in interval I, the conditional density of x_k becomes

$$p(x_k|\mathbf{h}) = \frac{e^{x_k(\mathbf{W}_{\cdot j}^{\mathsf{T}}\mathbf{h}+c_k)}\mathbf{1}_{x_k\in I}}{\int_v e^{v(\mathbf{W}_{\cdot j}^{\mathsf{T}}\mathbf{h}+c_k)}\mathbf{1}_{v\in I}dv}\,.$$

When $I=[0,\infty)$, this is an exponential density with parameter $a(\mathbf{h})=\mathbf{W}_{\cdot j}^{\mathsf{T}}\mathbf{h}+c_k$, and the normalizing integral, equal to $\frac{-1}{a(\mathbf{h})}$, only exists if $a(\mathbf{h})<0\ \forall\mathbf{h}$. Computing the density, the expected value ($\frac{-1}{a(\mathbf{h})}$) and sampling would all be easy, but since the density does not always exist it seems more appropriate to let I be a closed interval, yielding a *truncated exponential* density. For simplicity we consider the case $I=[0,1]$ here, for which the normalizing integral, which always exists, is

$$\frac{e^{-a(\mathbf{h})}-1}{a(\mathbf{h})}\,.$$

The conditional expectation of x_k given $\mathbf{h}$ is interesting because it has a sigmoidal-like saturating and monotone non-linearity:

$$E\left[x_k|\mathbf{h}\right] = \frac{1}{1-e^{-a(\mathbf{h})}} - \frac{1}{a(\mathbf{h})}\,.$$

Note that $E\left[x_k|\mathbf{h}\right]$ does not explode for $a(\mathbf{h})$ near 0, but is instead smooth and in the interval $[0,1]$. A sample from the truncated exponential is easily obtained from a uniform sample U, using the inverse cumulative F^{-1} of the conditional density $p(x_k|\mathbf{h})$:

$$F^{-1}(U) = \frac{\log(1-U\times(1-e^{a(\mathbf{h})}))}{a(\mathbf{h})}\,.$$

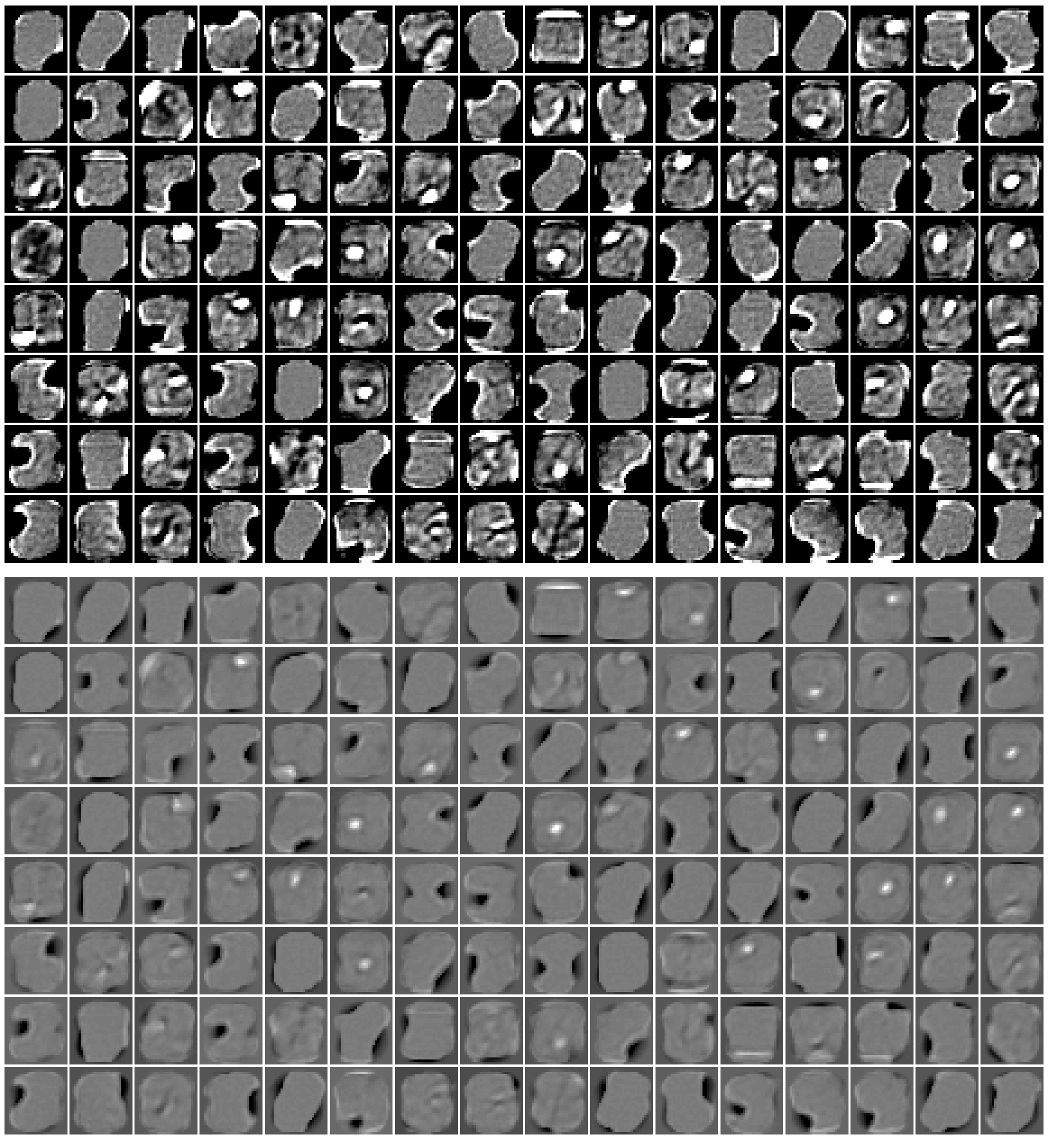

Figure 11: Input weights of a random subset of the hidden units, learned by an RBM with truncated exponential visible units, when trained on samples from the MNIST data set. The top and bottom images correspond to the same filters but with different color scale. On the top, the display setup is the same as for Figures 6 and 7 and, on the bottom, a black and white pixel correspond to weights smaller than -30 and larger than 30 respectively.

The contrastive divergence updates have the same form as for binary units of Equation 11, since the updates only depend on the derivative of the energy with respect to the parameters. Only sampling is changed, according to the unit's conditional density. Figure 11 shows the filters learned by an RBM with truncated exponential visible units, when trained on MNIST samples. Note how these are strikingly different from those obtained with binomial units.

7.2 Quadratic Energy: Gaussian Units

To obtain Gaussian-distributed units, one only needs to add quadratic terms to the energy. Adding $\sum_k d_k^2 x_k^2$ gives rise to a diagonal covariance matrix between units of the same layer, where x_k is the continuous value of a Gaussian unit and d_k^2 is a positive parameter that is equal to the inverse of the variance of x_k. In this case the variance is unconditional, whereas the mean depends on the inputs of the unit: for a visible unit x_k with hidden layer $\mathbf{h}$ and inverse variance d_k^2,

$$E\left[x_k|\mathbf{h}\right] = \frac{a(\mathbf{h})}{2d_k^2} .$$

The contrastive divergence updates are easily obtained by computing the derivative of the energy with respect to the parameters. For the parameters in the linear terms of the energy function $\mathbf{b}$, $\mathbf{c}$ and $\mathbf{W}$, the derivatives have the same form as for the case of binary units. For quadratic parameter $d_k > 0$, the derivative is simply $2d_k x_k^2$. Figure 12 shows the filters learned by an RBM with Gaussian visible units, when trained on MNIST samples.

Gaussian units were previously used as hidden units of an RBM (with multinomial inputs) applied to an information retrieval task (Welling et al., 2005). That same paper also shows how to generalize RBMs to units whose marginal distribution is from any member of the exponential family.

7.3 Impact on Classification Performance

In order to assess the impact of the choice for the visible layer distribution on the ultimate performance of an SRBM network, we trained and compared different deep networks whose first level RBM had binary, truncated exponential or Gaussian input units. These networks all had 3 hidden layers, with 2000 hidden units for each of these layers. The hyperparameters that were optimized are the unsupervised learning rates and number of updates as well as the fine-tuning learning rate. Because the assumption of binary inputs is not unreasonable for the MNIST images, we conducted this experiment on a modified and more challenging version of the data set where the background contains patches of images downloaded from the Internet. Samples from this data set are shown in Figure 13. This data set is part of a benchmark[6] designed by Larochelle et al. (2007). The results are given in Table 5, where we can see that the choice of the input distribution has a significant impact on the classification performance of the deep network. As a comparison, a support vector machine with Gaussian kernel achieves 22.61% error on this data set (Larochelle et al., 2007). Other experimental results with truncated exponential and Gaussian input units are found in Bengio et al. (2007).

8. Generating vs Encoding

Though the SRBM and SAA networks are similar in their motivation, there is a fundamental difference in the type of unsupervised learning used during training. Indeed, the RBM is based on the learning algorithm of a *generative model*, which is trained to be able to generate data similar to those found in the training set. On the other hand, the autoassociator is based on the learning algorithm of an *encoding model* which tries to learn a new representation or code from which the input can be reconstructed without too much loss of information.

6. The benchmark's data sets can be downloaded from `http://www.iro.umontreal.ca/~lisa/icml2007`.

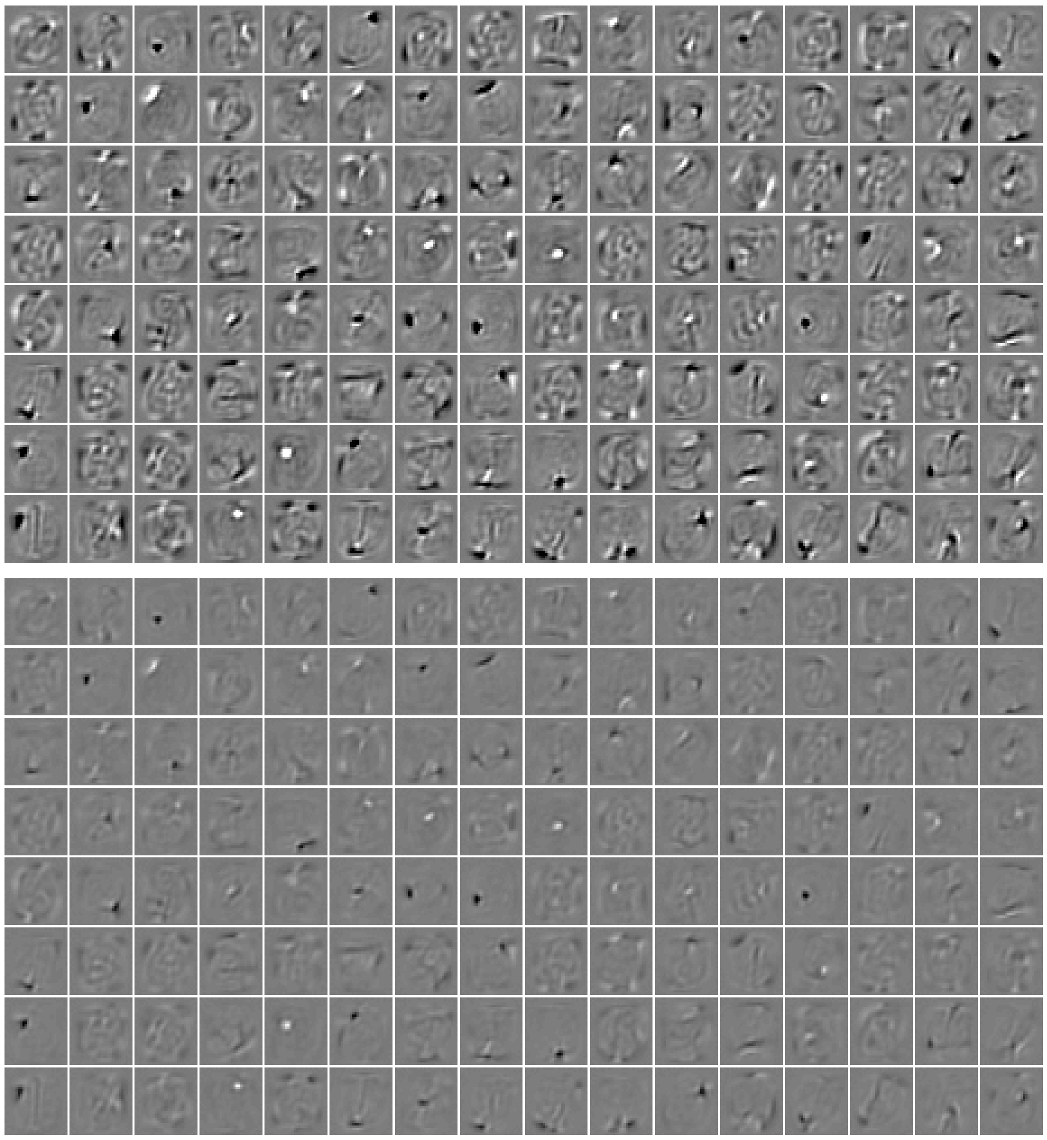

Figure 12: Input weights of a random subset of the hidden units, learned by an RBM with Gaussian visible units, when trained on samples from the MNIST data set. The top and bottom images correspond to the same filters but with different color scale. On top, the display setup is the same as for Figures 6 and 7 and, on the bottom, a black and white pixel correspond to weights smaller than -10 and larger than 10 respectively.

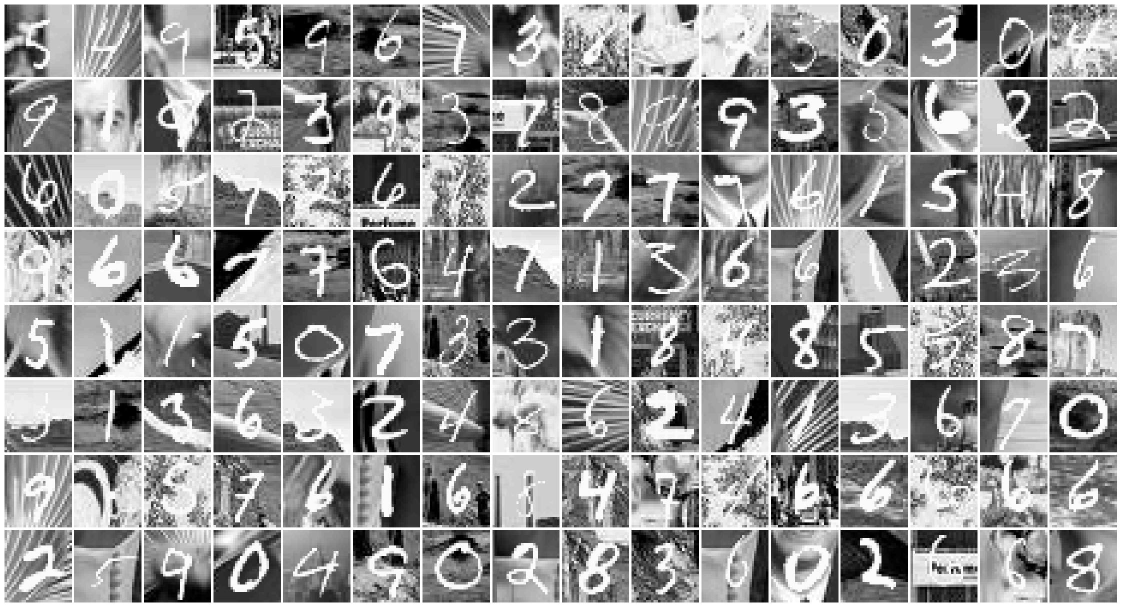

Figure 13: Samples from the modified MNIST digit recognition data set with a background containing image patches. Here, a black pixel corresponds to an input value of 0 and a white pixel corresponds to 1 (the inputs are scaled between 0 and 1).

SRBM input type	Train.	Valid.	Test
Bernoulli	10.50%	18.10%	20.29%
Gaussian	0%	20.50%	21.36%
Truncated exponential	0%	14.30%	14.34%

Table 5: Classification error on MNIST with background containing patches of images (see Figure 13) on the training, validation, and test sets, for different distributions of the input layer for the bottom RBM. The best hyperparameters were selected according to the validation error.

It is not clear which of the two approaches (generating or encoding) is the most appropriate. The advantage of a generative model is that the assumptions that are made are usually clear. However, it is possible that the problem it is trying to solve is harder than it needs to be, since ultimately we are only interested in coming up with good representations or features of the input. For instance, if one is interested in finding appropriate clusters in a very high dimensional space, using a mixture of Gaussians with full covariance matrix can quickly become too computationally intensive, whereas using the simple k-means algorithm might do a good enough job. As for encoding models, they do not require to be interpretable as a generative model and they can be more flexible because any parametric or non-parametric form can be chosen for the encoder and decoder, as long as they are differentiable.

Another interesting connection between reconstruction error in autoassociators and CD in RBMs was mentioned earlier: the reconstruction error can be seen as an estimator of the log-likelihood gradient of the RBM which has more bias but less variance than the CD update rule (Bengio and Delalleau, 2007). In that paper it is shown how to write the RBM log-likelihood gradient as a series expansion where each term is associated with a sample of the contrastive divergence Gibbs chain. Because the terms become smaller and converge to zero, this justifies taking a truncation of the series as an estimator of the gradient. The reconstruction error gradient is a mean-field (i.e., biased) approximation of the first term, whereas CD-1 is a sampling (i.e., high-variance) approximation of the first two terms, and similarly CD-k involves the first $2k$ terms.

This suggests combining the reconstruction error and contrastive divergence for training RBMs. During unsupervised pre-training, we can use the updates given by both algorithms and combine them by associating a coefficient to each of them. This is actually equivalent to applying the updates one after the other but using different learning rates for both. We tested this idea in the MNIST data set split of Section 6.1, where we had to validate separately the learning rates for the RBM and the autoassociator updates. This combination improved on the results of the SRBM and the SAA networks, obtaining 1.02% and 1.09% on the validation and test set respectively. This improvement was confirmed in a more complete experiment on 6 other folds with mutually exclusive test sets of 10 000 examples, where the mixed gradient variant gave on average a statistically significant improvement of 0.1% on a SRBM network. One possible explanation for the improvement brought by this combination is that it uses a better trade-off between bias and variance in estimating the log-likelihood gradient.

Another deterministic alternative to CD is mean-field CD (MF-CD) of Welling and Hinton (2002), and is equivalent to the pseudocode code in Appendix B, with the statements $\mathbf{h}^0 \sim p(\mathbf{h}|\mathbf{x}^0)$ and $\mathbf{v}^1 \sim p(\mathbf{x}|\mathbf{h}^0)$ changed to $\mathbf{h}^0 \leftarrow \mathrm{sigm}(\mathbf{b}+\mathbf{W}\mathbf{v}^0)$ and $\mathbf{v}^1 \leftarrow \mathrm{sigm}(\mathbf{c}+\mathbf{W}^\mathsf{T}\mathbf{h}^0)$ respectively. MF-CD can be used to test another way to change the bias/variance trade-off, either as a gradient estimator alone, or by combining it to the CD-1 gradient estimate (in the same way we combined the autoassociator gradient with CD-1, previous paragraph). On the MNIST split of Section 6.1, SRBM networks with MF-CD and combined CD-1/MF-CD[7] achieved 1.26% and 1.17% on the test set respectively. The improvement brought by combining MF-CD with CD-1 was not found to be statistically significant, based on similar experiments on the 6 other folds.

This suggests that something else than the bias/variance trade-off is at play in the improvements observed when combining CD-1 with the autoassociator gradient. A hypothesis that should be explored is that whereas there is no guarantee that an RBM will encode in its hidden representation all the information in the input vector, an autoassociator is trying to achieve this. In fact an RBM trained by maximum likelihood would be glad to completely ignore the inputs if these were independent of each other. Minimizing the reconstruction error would prevent this, and may be useful in the context where the representations are later used for supervised classification (which is the case here).

9. Continuous Training of all Layers of a Deep Network

The layer-wise training algorithm for networks of depth l actually has $l+1$ separate training phases: first the l phases for the unsupervised training of each layer, and then the final supervised fine-tuning phase to adjust all the parameters simultaneously. One element that we would like to dispense with

7. The weight of the CD-1 and MF-CD gradient estimates was considered as a hyperparameter.

is having to decide the number of unsupervised training iterations for each layer before starting the fine-tuning. One possibility is then to execute all phases simultaneously, that is, train all layers based on both their greedy unsupervised and global supervised gradients. The advantage is that we can now have a single stopping criterion (for the whole network). However, computation time is slightly greater, since we do more computations initially on the upper layers, which might be wasted before the lower layers converge to a decent representation, but time is saved on optimizing hyper-parameters. When this continuous training variant is used on the MNIST data set with the same experimental setup as in Section 6.1, we reach 1.6% and 1.5% error on the test set respectively for the SRBM network and the SAA network, so unsupervised learning still brings better generalization in this setting. This variant may be more appealing for on-line training on very large data sets, where one would never cycle back on the training data.

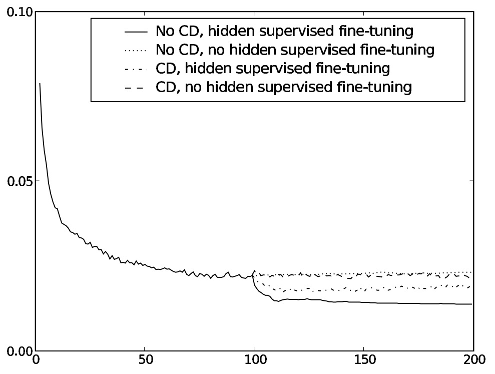
However, there seems to be a price to pay in terms of classification error, with this online variant. In order to investigate what could be the cause, we experimented with a 2-phase algorithm designed to shed some light on the contribution of different factors to this decrease. In the first phase, all layers of networks were simultaneously trained according to their unsupervised criterion *without* fine-tuning. The output layer is still trained according to the supervised criterion, however, unlike in Section 6.1, the gradient is not backpropagated into the rest of the network. This allows us to monitor the discriminative capacity of the top hidden layer. This first phase also enables us to verify whether the use of the supervised gradient too early during training explains the decrease in performance (recall the poor results obtained with purely supervised greedy layer-wise training). Then, in the second phase, 2 options were considered:

1. fine-tune the whole network according to the supervised criterion and stop layer-wise unsupervised learning;
2. fine-tune the whole network and maintain layer-wise unsupervised learning (as in the previous experiment).

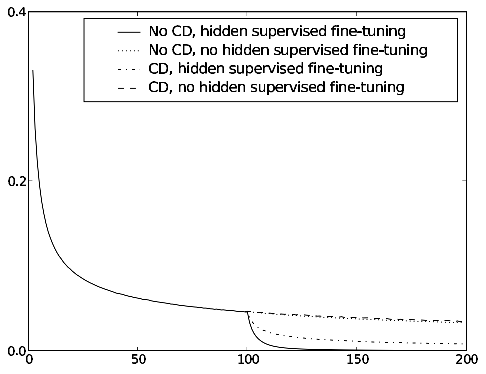
Figures 14(a) and 15(a) show examples of the progression of the test classification error for such an experiment with the SRBM and SAA networks respectively. As a baseline for the second phase, we also give the performance of the networks when unsupervised learning is stopped and only the parameters of the output layer are trained. These specific curves do not correspond to the best values of the hyperparameters, but are representative of the global picture we observed on several runs with different hyperparameter values.

We observe that the best option is to perform fine-tuning without layer-wise unsupervised learning, even when supervised learning is not introduced at the beginning. Also, though performing unsupervised and supervised learning at the same time outperforms unsupervised learning without fine-tuning, it appears to yield over-regularized networks, as indicated by the associated curves of the training negative log-likelihood of the target classes for both networks (see Figures 14(b) and 15(b)). Indeed, we see that by maintaining some unsupervised learning, the networks are not able to optimize as well their supervised training objective. From other runs with different learning rates, we have observed that this effect becomes less visible when the supervised learning rate gets larger, which reduces the relative importance of the unsupervised updates. But then the unsupervised updates usually bring significant instabilities in the learning process, making even the training cost oscillate.

Another interesting observation is that, when layer-wise unsupervised learning is performed, the classification error is less stable in an SRBM network than in an SAA network, as indicated by

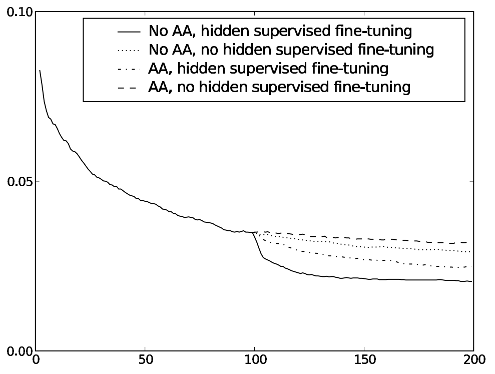


(a) SRBM network, test classification error curves

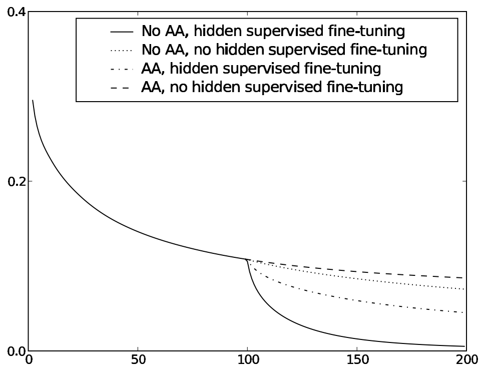


(b) SRBM network, train NLL error curves.

Figure 14: Example of learning curves of the 2-phase experiment of Section 9. During the first half of training, all hidden layers are trained according to CD and the output layer is trained according to the supervised objective, for all curves. In the second phase, all combinations of two possibilities are displayed: CD training is performed at all hidden layers ("CD") or not ("No CD"), and all hidden layers are fine-tuned according to the supervised objective ("hidden supervised fine-tuning") or not ("no hidden supervised fine-tuning").



(a) SAA network, test classification error curves



(b) SAA network, train NLL error curves.

Figure 15: Same as Figure 14, but with autoassociators ("AA") used for layer-wise unsupervised learning.

the dented learning curves in Figure 14(b), whereas the curves in Figure 15(b) are smoother. This may be related to the better performance of the SAA network (1.5%) versus the SRBM network (1.6%) when combining unsupervised and supervised gradients, in the experiment reported at the beginning of this section. Autoassociator learning might hence be more appropriate here, possibly because its training objective, that is, the discovery of a representation that preserves the information in the input, is more compatible with the supervised training objective, which asks that the network discovers a representation that is predictive of the input's class. This hypothesis is related to the one presented at the end of Section 8 regarding the apparent improvement brought by minimizing the reconstruction error in addition to CD-1 updates.

These experiments show that one can eliminate the multiple unsupervised phases: each layer can be pre-trained in a way that simply ignores what the layer above are doing. However, it appears that a final phase involving only supervised gradient yields the best performance. A plausible explanation of these results, and in particular the quick improvement when the unsupervised updates are removed, is that the unsupervised pre-training brings the parameters near a good solution for the supervised criterion, but far enough from that solution to yield a significantly higher classification error. Note that in a setting where there is little labeled data but a lot of unlabelled examples, the additional regularization introduced by maintaining some unsupervised learning might be beneficial (Salakhutdinov and Hinton, 2007b).

10. Conclusion

In this paper, we discussed in detail three principles for training deep neural networks, which are (1) pre-training one layer at a time in a greedy way (2) using unsupervised learning at each layer in a way that preserves information from the input and disentangles factors of variation and (3) fine-tuning the whole network with respect to the ultimate criterion of interest. We also presented experimental evidence that supports the claim that they are key ingredients for reaching good results. Moreover, we presented a series of experimental results that shed some light on many aspects of deep networks: confirming that the unsupervised procedure helps the optimization of the deep architecture, while initializing the parameters in a region near which a good solution of the supervised task can be found. Our experiments showed cases where greater depth clearly helps, but too much depth could be slightly detrimental. We found that CD-1 can be improved by combining it with the gradient of reconstruction error, and that this is not just due to the use of a lower-variance update. We showed that the choice of input distribution in RBMs could be important for continuous-valued input and yielded different types of filters at the first layer. Finally we studied variants more amenable to online learning in which we show that if different training phases can be combined, the best results were obtained with a final fine-tuning phase involving only the supervised gradient.

There are many questions and issues that remain to be addressed and that we intend to investigate in future work. As pointed out in Section 8, the most successful unsupervised learning approach seems to fall in between generative and encoding approaches. This raises questions about what are the properties of a learning algorithm that learns good representations for deep networks. Finding good answers to these questions would have a direct positive impact on the performance of deep networks. Finally, better model selection techniques that would permit to reduce the number of hyperparameters would be beneficial and will need to be developed for deep network learning algorithms to become easier to use.

Acknowledgments

The author are particularly grateful for the inspiration from and constructive discussions with Dan Popovici, Aaron Courville, Olivier Delalleau, James Bergstra, and Dumitru Erhan. The authors also want to thank the editor and reviewers for their helpful comments and suggestions. This research was performed thanks to funding from NSERC, MITACS, and the Canada Research Chairs.

Appendix A. Pseudocode for Greedy Layer-Wise Training Paradigm

```
**Input:** training set $\mathcal{D} = \{(\mathbf{x}_t, y_t)\}_{t=1}^{T}$, pre-training learning rate $\varepsilon_{\text{pre-train}}$ and fine-tuning learning rate $\varepsilon_{\text{fine-tune}}$

Initialize weights $\mathbf{W}^i_{jk} \sim U(-a^{-0.5}, a^{-0.5})$ with $a = \max(|\widehat{\mathbf{h}}^{i-1}|, |\widehat{\mathbf{h}}^i|)$ and set biases $\mathbf{b}^i$ to 0

% Pre-training phase
for $i \in \{1,\ldots,l\}$ do
  while Pre-training stopping criterion is not met do
    Pick input example $\mathbf{x}_t$ from training set
    $\widehat{\mathbf{h}}^0(\mathbf{x}_t) \leftarrow \mathbf{x}_t$
    for $j \in \{1,\ldots,i-1\}$ do
      $\mathbf{a}^j(\mathbf{x}_t) = \mathbf{b}^j + \mathbf{W}^j \widehat{\mathbf{h}}^{j-1}(\mathbf{x}_t)$
      $\widehat{\mathbf{h}}^j(\mathbf{x}_t) = \text{sigm}\left(\mathbf{a}^j(\mathbf{x}_t)\right)$
    end for
    Using $\widehat{\mathbf{h}}^{i-1}(\mathbf{x}_t)$ as input example, update weights $\mathbf{W}^i$ and biases $\mathbf{b}^{i-1}$, $\mathbf{b}^i$ with learning rate $\varepsilon_{\text{pre-train}}$ according to a layer-wise unsupervised criterion (see pseudocodes in appendices B and C)
  end while
end for

% Fine-tuning phase
while Fine-tuning stopping criterion is not met do
  Pick input example $(\mathbf{x}_t, y_t)$ from training set

  % Forward propagation
  $\widehat{\mathbf{h}}^0(\mathbf{x}_t) \leftarrow \mathbf{x}_t$
  for $i \in \{1,\ldots,l\}$ do
    $\mathbf{a}^i(\mathbf{x}_t) = \mathbf{b}^i + \mathbf{W}^i \widehat{\mathbf{h}}^{i-1}(\mathbf{x}_t)$
    $\widehat{\mathbf{h}}^i(\mathbf{x}_t) = \text{sigm}\left(\mathbf{a}^i(\mathbf{x}_t)\right)$
  end for
  $\mathbf{a}^{l+1}(\mathbf{x}_t) = \mathbf{b}^{l+1} + \mathbf{W}^{l+1} \widehat{\mathbf{h}}^l(\mathbf{x}_t)$
  $\mathbf{o}(\mathbf{x}_t) = \widehat{\mathbf{h}}^{l+1}(\mathbf{x}_t) = \text{softmax}\left(\mathbf{a}^{l+1}(\mathbf{x}_t)\right)$

  % Backward gradient propagation and parameter update
  $\frac{\partial \log o_{y_t}(\mathbf{x}_t)}{\partial a^{l+1}_j(\mathbf{x}_t)} \leftarrow \mathbf{1}_{y_t=j} - o_j(\mathbf{x}_t)$ for $j \in \{1,\ldots,K\}$
```

```
    $\mathbf{b}^{l+1} \leftarrow \mathbf{b}^{l+1} + \varepsilon_{\text{fine-tune}} \frac{\partial \log o_{y_t}(\mathbf{x}_t)}{\partial \mathbf{a}^{l+1}(\mathbf{x}_t)}$
    $\mathbf{W}^{l+1} \leftarrow \mathbf{W}^{l+1} + \varepsilon_{\text{fine-tune}} \frac{\partial \log o_{y_t}(\mathbf{x}_t)}{\partial \mathbf{a}^{l+1}(\mathbf{x}_t)} \widehat{\mathbf{h}}^{l}(\mathbf{x}_t)^{\mathsf{T}}$
    for $i \in \{1,\dots,l\}$, in decreasing order do
        $\frac{\partial \log o_{y_t}(\mathbf{x}_t)}{\partial \widehat{\mathbf{h}}^{i}(\mathbf{x}_t)} \leftarrow \left(\mathbf{W}^{i+1}\right)^{\mathsf{T}} \frac{\partial \log o_{y_t}(\mathbf{x}_t)}{\partial \mathbf{a}^{i+1}(\mathbf{x}_t)}$
        $\frac{\partial \log o_{y_t}(\mathbf{x}_t)}{\partial a^{i}_{j}(\mathbf{x}_t)} \leftarrow \frac{\partial \log o_{y_t}(\mathbf{x}_t)}{\partial \widehat{h}^{i}_{j}(\mathbf{x}_t)} \widehat{h}^{i}_{j}(\mathbf{x}_t)\left(1 - \widehat{h}^{i}_{j}(\mathbf{x}_t)\right)$   for $j \in \{1,\dots,|\widehat{\mathbf{h}}^{i}|\}$
        $\mathbf{b}^{i} \leftarrow \mathbf{b}^{i} + \varepsilon_{\text{fine-tune}} \frac{\partial \log o_{y_t}(\mathbf{x}_t)}{\partial \mathbf{a}^{i}}$
        $\mathbf{W}^{i} \leftarrow \mathbf{W}^{i} + \varepsilon_{\text{fine-tune}} \frac{\partial \log o_{y_t}(\mathbf{x}_t)}{\partial \mathbf{a}^{i}} \widehat{\mathbf{h}}^{i-1}(\mathbf{x}_t)^{\mathsf{T}}$
    end for
end while
```

In the first step of the gradient computation, one has to be careful to compute the gradient of the cost with respect to $\mathbf{a}^{l+1}(\mathbf{x}_t)$ at once, in order not to lose numerical precision during the computation. In particular, computing $\frac{\partial \log o_{y_t}(\mathbf{x}_t)}{\partial \mathbf{o}(\mathbf{x}_t)}$ first, then $\frac{\partial \mathbf{o}(\mathbf{x}_t)}{\partial \mathbf{a}^{l+1}(\mathbf{x}_t)}$ and applying chain-rule, leads to numerical instability and sometimes parameter value explosion (NaN).

Appendix B. Restricted Boltzmann Machines and Deep Belief Networks

In this section, we give a brief overview of restricted Boltzmann machines and deep belief networks.

B.1 Restricted Boltzmann Machine

A restricted Boltzmann machine is an energy-based generative model defined over a visible layer $\mathbf{v}$ (sometimes called input) and a hidden layer $\mathbf{h}$ (sometimes called hidden factors or representation). Given an energy function $\text{energy}(\mathbf{v},\mathbf{h})$ on the whole set of visible and hidden units, the joint probability is given by

$$p(\mathbf{v},\mathbf{h}) = \frac{e^{-\text{energy}(\mathbf{v},\mathbf{h})}}{Z} \tag{6}$$

where Z ensures that $p(\mathbf{v},\mathbf{h})$ is a valid distribution and sums to one. See Figure 3 for an illustration of an RBM.

Typically we take $h_i \in \{0,1\}$, but other choices are possible. For now, we consider only binary units, that is, $v_i \in \{0,1\}$ (the continuous case will be discussed in Section 7), where the energy function has the form

$$\text{energy}(\mathbf{v},\mathbf{h}) = -\mathbf{h}^{\mathsf{T}} W \mathbf{v} - c^{\mathsf{T}}\mathbf{v} - b^{\mathsf{T}}\mathbf{h} = -\sum_k c_k v_k - \sum_j b_j h_j - \sum_{jk} W_{jk} v_k h_j \,. \tag{7}$$

When considering the marginal distribution over $\mathbf{v}$, we obtain a mixture distribution

$$p(\mathbf{v}) = \sum_{\mathbf{h}} p(\mathbf{v},\mathbf{h}) = \sum_{\mathbf{h}} p(\mathbf{v}|\mathbf{h}) p(\mathbf{h})$$

with a number of parameters linear in the number of hidden units H, while having a number of components exponential in H. This is because $\mathbf{h}$ can take as many as 2^H possible values. The 2^H distributions $p(\mathbf{v}|\mathbf{h})$ will in general be different, but they are tied. Though computing exactly the marginal $p(\mathbf{v})$ for large values of H is impractical, a good estimator of the log-likelihood gradient have been found with the contrastive divergence algorithm described in the next section. An important property of RBMs is that the posterior distribution over one layer given the other is tractable and fast to compute, as opposed to mixture models with very many components in general. Indeed one can show that

$$p(\mathbf{v}|\mathbf{h}) = \prod_k p(v_k|\mathbf{h}) \quad \text{where} \quad p(v_k = 1|\mathbf{h}) = \text{sigm}(c_k + \sum_j W_{jk}h_j)\ , \tag{8}$$

$$p(\mathbf{h}|\mathbf{v}) = \prod_j p(h_j|\mathbf{v}) \quad \text{where} \quad p(h_j = 1|\mathbf{v}) = \text{sigm}(b_j + \sum_k W_{jk}v_k)\ . \tag{9}$$

Because of the particular parametrization of RBMs, inference of the "hidden factors" **h** given the observed input vector **v** is very easy because those factors are conditionally independent given **v**. On the other hand, unlike in many factor models (such as ICA Jutten and Herault, 1991; Comon, 1994; Bell and Sejnowski, 1995 and sigmoidal belief networks Dayan et al., 1995; Hinton et al., 1995; Saul et al., 1996), these factors are generally not marginally independent (when we integrate **v** out). Notice the similarity between Equations 9 and 1, which makes it possible to relate the weights and biases of an RBM with those of a deep neural network.

B.2 Learning in a Restricted Boltzmann Machine

To train an RBM, we would like to compute the gradient of the negative log-likelihood of the data with respect to the RBM's parameters. However, given an input example $\mathbf{v}_0$, the gradient with respect to a parameter θ in an energy-based model

$$\frac{\partial}{\partial\theta}(-\log p(\mathbf{v}_0)) = E_{p(\mathbf{h}|\mathbf{v}_0)}\left[\frac{\partial \text{energy}(\mathbf{v}_0,\mathbf{h})}{\partial\theta}\right] - E_{p(\mathbf{v},\mathbf{h})}\left[\frac{\partial \text{energy}(\mathbf{v},\mathbf{h})}{\partial\theta}\right] \tag{10}$$

necessitates a sum over all possible assignments for **h** (first expectation of Equation 10) and another sum over all assignments for **v** and **h** (second expectation). The first expectation is not problematic in an RBM because the posterior $p(\mathbf{h}|\mathbf{v}_0)$ and $\frac{\partial \text{energy}(\mathbf{v}_0,\mathbf{h})}{\partial\theta}$ factorize. However, the second expectation requires a prohibitive exponential sum over the possible configurations for **v** or **h**.

Fortunately, there exists an approximation for this gradient given by the contrastive divergence (CD) algorithm (Hinton, 2002), which has been shown to work well empirically (Carreira-Perpiñan and Hinton, 2005). There are two key elements in this approximation. First, consider that in order to estimate the second term of Equation 10, we could replace the expectation by a unique evaluation of the gradient $\frac{\partial \text{energy}(\mathbf{v},\mathbf{h})}{\partial\theta}$ at a particular pair of values $(\mathbf{v},\mathbf{h})$. This pair should ideally be sampled from the distribution $p(\mathbf{v},\mathbf{h})$, which would make the estimation of the gradient unbiased. However, sampling exactly from an RBM distribution is not as easy as in a directed graphical model. Instead, we have to rely on sampling methods such as Markov Chain Monte Carlo methods. For an RBM, we can use Gibbs sampling based on the conditional distributions of Equations 8 and 9, but this method can be costly if the Markov chain mixes slowly. So the second key idea is to run only a few iterations of Gibbs sampling and use the data sample $\mathbf{v}_0$ as the initial state for the chain at the visible layer. It turns out that applying only one iteration of the Markov chain works well in practice. This corresponds to the following sampling procedure:

$$\mathbf{v}_0 \overset{p(\mathbf{h}_0|\mathbf{v}_0)}{\longrightarrow} \mathbf{h}_0 \overset{p(\mathbf{v}_1|\mathbf{h}_0)}{\longrightarrow} \mathbf{v}_1 \overset{p(\mathbf{h}_1|\mathbf{x}_1)}{\longrightarrow} \mathbf{h}_1$$

where $\overset{p(\mathbf{h}_i|\mathbf{v}_i)}{\longrightarrow}$ and $\overset{p(\mathbf{v}_{i+1}|\mathbf{h}_i)}{\longrightarrow}$ represent the operations of sampling from $p(\mathbf{h}_i|\mathbf{v}_i)$ and $p(\mathbf{v}_{i+1}|\mathbf{h}_i)$ respectively. Estimation of the gradient using the above sampling procedure is noted CD-1, with CD-k referring to the contrastive divergence algorithm, performing k iterations of the Markov chain up to $\mathbf{v}_k$. Training with CD-k has been shown to empirically approximate well training with the exact log-likelihood gradient (Carreira-Perpiñan and Hinton, 2005). Furthermore, it can be shown that the CD-k update is an unbiased estimator of the truncation of a series expansion of the log-likelihood gradient (Bengio and Delalleau, 2007), where the truncated part of the series converges to 0 as k increases.

Now let us consider the estimation of the gradient on a weight W_{jk}. We have

$$\frac{\partial \text{energy}(\mathbf{v},\mathbf{h})}{\partial W_{jk}} = -h_j v_k$$

which means that the CD-1 estimate of the gradient becomes

$$-E_{p(\mathbf{h}|\mathbf{v}_0)}\left[h_j v_{0k}\right] + E_{p(\mathbf{h}|\mathbf{v}_1)}\left[h_{1j} v_{1k}\right] = -p(h_j|\mathbf{v}_0)v_{0k} + p(h_j|\mathbf{v}_1)v_{1k}\ . \tag{11}$$

This is similar to what was presented in Hinton et al. (2006) except that we clarify here that we take the expected value of $\mathbf{h}$ given $\mathbf{v}$ instead of averaging over samples. These estimators have the same expected value because

$$E_{p(\mathbf{v},\mathbf{h})}\left[h_j v_k\right] = E_{p(\mathbf{v})}\left[E_{p(\mathbf{h}|\mathbf{v})}\left[h_j v_k\right]\right] = E_{p(\mathbf{v})}\left[p(h_j|\mathbf{v})v_k\right]\ .$$

Using $p(\mathbf{h}|\mathbf{v}_k)$ instead of $\mathbf{h}_k$ is also what is found in the Matlab code distributed with Hinton and Salakhutdinov (2006). Note that it is still necessary to sample $\mathbf{h}_0 \sim p(\mathbf{h}|\mathbf{v}_0)$ in order to sample $\mathbf{v}_1$, but it is not necessary to sample $\mathbf{h}_1$. The above gradient estimator can then be used to perform stochastic gradient descent by iterating through all vectors $\mathbf{v}_0$ of the training set and performing a parameter update using that gradient estimator in an on-line fashion. Gradient estimators for the biases b_k and c_j can as easily be derived from Equation 10.

Notice also that, even if $\mathbf{v}_0$ is not binary, the formula for the CD-1 estimate of the gradient does not change and is still computed essentially in the same way: only the sampling procedure for $p(\mathbf{v}|\mathbf{h})$ changes (see Section 7 for more details about dealing with continuous-valued inputs). The CD-1 training update for a given training input is detailed by the pseudocode in the next section.

In our implementation of the greedy layer-wise initialization phase, we use the deterministic sigmoidal outputs of the previous level as training vector for the next level RBM. By interpreting these real-valued components as probabilities, learning such a distribution for binary inputs can be seen as a crude "mean-field" way of dealing with probabilistic binary inputs (instead of summing or sampling across input configurations).

B.3 Pseudocode for Contrastive Divergence (CD-1) Training Update

```
**Input:** training input $\mathbf{x}$, RBM weights $\mathbf{W}^i$ and biases $\mathbf{b}^{i-1}, \mathbf{b}^i$ and learning rate $\epsilon$
**Notation:** $a \sim p(\cdot)$ means set $a$ equal to a random sample from $p(\cdot)$

% Set RBM parameters
$\mathbf{W} \leftarrow \mathbf{W}^i, \mathbf{b} \leftarrow \mathbf{b}^i, \mathbf{c} \leftarrow \mathbf{b}^{i-1}$
```

```
% Positive phase
$\mathbf{v}^0 \leftarrow \mathbf{x}$
$\widehat{\mathbf{h}}^0 \leftarrow \mathrm{sigm}(\mathbf{b} + \mathbf{W}\mathbf{v}^0)$

% Negative phase
$\mathbf{h}^0 \sim p(\mathbf{h}|\mathbf{v}^0)$ according to Equation 9
$\mathbf{v}^1 \sim p(\mathbf{v}|\mathbf{h}^0)$ according to Equation 8
$\widehat{\mathbf{h}}^1 \leftarrow \mathrm{sigm}(\mathbf{b} + \mathbf{W}\mathbf{v}^1)$

% Update
$\mathbf{W}^i \leftarrow \mathbf{W}^i + \varepsilon \left(\widehat{\mathbf{h}}^0 \left(\mathbf{v}^0\right)^\mathsf{T} - \widehat{\mathbf{h}}^1 \left(\mathbf{v}^1\right)^\mathsf{T}\right)$
$\mathbf{b}^i \leftarrow \mathbf{b}^i + \varepsilon \left(\widehat{\mathbf{h}}^0 - \widehat{\mathbf{h}}^1\right)$
$\mathbf{b}^{i-1} \leftarrow \mathbf{b}^{i-1} + \varepsilon \left(\mathbf{v}^0 - \mathbf{v}^1\right)$
```

B.4 Deep Belief Network

We wish to make a quick remark on the distinction between the SRBM network and the more widely known deep belief network (DBN) (Hinton et al., 2006), which is not a feed-forward neural network but a multi-layer generative model. The SRBM network was initially derived (Hinton et al., 2006) from the DBN, for which stacking RBMs also provides a good initialization.

A DBN is a generative model with several layers of stochastic units. It actually corresponds to a sigmoid belief network (Neal, 1992) of $l-1$ hidden layers, where the prior over its top hidden layer $\mathbf{h}^{l-1}$ (second factor of Equation 12) is an RBM, which itself has a hidden layer $\mathbf{h}^l$. More precisely, it defines a distribution over an input layer $\mathbf{x}$ and l layers of binary stochastic units $\mathbf{h}^i$ as follows:

$$p(\mathbf{x}, \mathbf{h}^1, \dots, \mathbf{h}^l) = \left(\prod_{i=1}^{l-1} p(\mathbf{h}^{i-1}|\mathbf{h}^i)\right) p(\mathbf{h}^{l-1}, \mathbf{h}^l) \tag{12}$$

where hidden units are conditionally independent given the units in the above layer

$$p(\mathbf{h}^{i-1}|\mathbf{h}^i) = \prod_k p(h_k^{i-1}|\mathbf{h}^i)\ .$$

To process binary values, Bernoulli layers can be used, which correspond to equations

$$p(h_k^{i-1} = 1|\mathbf{h}^i) = \mathrm{sigm}\left(b_k^{i-1} + \sum_j W_{jk}^i h_j^i\right)$$

where $\mathbf{h}^0 = \mathbf{x}$ is the input. We also have

$$p(\mathbf{h}^{l-1}, \mathbf{h}^l) \propto e^{\sum_j c_j^{l-1} h_j^{l-1} + \sum_k b_k^l h_k^l + \sum_{jk} W_{jk}^l h_j^{l-1} h_k^l} \tag{13}$$

for the top RBM. Note that Equation 13 can be obtained from Equations 6 and 7, by naming $\mathbf{v}$ as $\mathbf{h}^{l-1}$, and $\mathbf{h}$ as $\mathbf{h}^l$.

We emphasize the distinction between $\mathbf{h}^i$ and $\widehat{\mathbf{h}}^i(\mathbf{x})$, where the former is a random variable and the latter is the representation of an input $\mathbf{x}$ at the i-th hidden layer of the network obtained from the repeated application of Equation 1.

To train such a generative model, Hinton et al. (2006) proposed the pre-training phase of the SRBM network. When all layers of a DBN have the same size, it was actually shown that this initialization improves a lower bound on the likelihood of the data as the DBN is made deeper. After this pre-training phase is over, Hinton et al. (2006) propose a variant of the Wake-Sleep algorithm for sigmoid belief networks (Hinton et al., 1995) to fine-tune the generative model.

By noticing the similarity between the process of approximating the posterior $p(\mathbf{h}^i|\mathbf{x})$ in a deep belief network and computing the hidden layer representation of an input $\mathbf{x}$ in a deep network, Hinton (2006) then proposed the use of the greedy layer-wise pre-training procedure for deep belief networks to initialize a deep feed-forward neural network, which corresponds to the SRBM network described in this paper.

Appendix C. Pseudocode of Autoassociator Training Update

```
**Input:** training input $\mathbf{x}$, autoassociator weights $\mathbf{W}^i$ and biases $\mathbf{b}^{i-1}, \mathbf{b}^i$ and learning rate $\varepsilon$

% Set autoassociator parameters
$\mathbf{W} \leftarrow \mathbf{W}^i, \mathbf{b} \leftarrow \mathbf{b}^i, \mathbf{c} \leftarrow \mathbf{b}^{i-1}$

% Forward propagation
$\mathbf{a}(\mathbf{x}) \leftarrow \mathbf{b} + \mathbf{W}\mathbf{x}$
$\mathbf{h}(\mathbf{x}) \leftarrow \mathrm{sigm}(\mathbf{a}(\mathbf{x}))$
$\widehat{\mathbf{a}}(\mathbf{x}) \leftarrow \mathbf{c} + \mathbf{W}^{\mathsf{T}}\mathbf{h}(\mathbf{x})$
$\widehat{\mathbf{x}} \leftarrow \mathrm{sigm}(\widehat{\mathbf{a}}(\mathbf{x}))$

% Backward gradient propagation
$\frac{\partial C(\widehat{\mathbf{x}},\mathbf{x})}{\partial \widehat{\mathbf{a}}(\mathbf{x})} \leftarrow \widehat{\mathbf{x}} - \mathbf{x}$
$\frac{\partial C(\widehat{\mathbf{x}},\mathbf{x})}{\partial \widehat{h}(\mathbf{x})} \leftarrow \mathbf{W}\frac{\partial C(\widehat{\mathbf{x}},\mathbf{x})}{\partial \widehat{\mathbf{a}}(\mathbf{x})}$
$\frac{\partial C(\widehat{\mathbf{x}},\mathbf{x})}{\partial a_j(\mathbf{x})} \leftarrow \frac{\partial C(\widehat{\mathbf{x}},\mathbf{x})}{\partial \widehat{h}_j(\mathbf{x})}\widehat{h}_j(\mathbf{x})\left(1 - \widehat{h}_j(\mathbf{x})\right)$ **for** $j \in \{1, \ldots, |\widehat{\mathbf{h}}(\mathbf{x})|\}$

% Update
$\mathbf{W}^i \leftarrow \mathbf{W}^i - \varepsilon\left(\frac{\partial C(\widehat{\mathbf{x}},\mathbf{x})}{\partial \mathbf{a}(\mathbf{x})}\mathbf{x}^{\mathsf{T}} + \widehat{\mathbf{h}}(\mathbf{x})\frac{\partial C(\widehat{\mathbf{x}},\mathbf{x})}{\partial \widehat{\mathbf{a}}(\mathbf{x})}^{\mathsf{T}}\right)$
$\mathbf{b}^i \leftarrow \mathbf{b}^i - \varepsilon\frac{\partial C(\widehat{\mathbf{x}},\mathbf{x})}{\partial \mathbf{a}(\mathbf{x})}$
$\mathbf{b}^{i-1} \leftarrow \mathbf{b}^{i-1} - \varepsilon\frac{\partial C(\widehat{\mathbf{x}},\mathbf{x})}{\partial \widehat{\mathbf{a}}(\mathbf{x})}$
```

Abstract

A linear causal model with correlated errors, represented by a DAG with bi-directed edges, can be tested by the set of conditional independence relations implied by the model. A global Markov property specifies, by the d-separation criterion, the set of all conditional independence relations holding in any model associated with a graph. A local Markov property specifies a much smaller set of conditional independence relations which will imply all other conditional independence relations which hold under the global Markov property. For DAGs with bi-directed edges associated with arbitrary probability distributions, a local Markov property is given in Richardson (2003) which may invoke an exponential number of conditional independencies. In this paper, we show that for a class of linear structural equation models with correlated errors, there is a local Markov property which will invoke only a linear number of conditional independence relations. For general linear models, we provide a local Markov property that often invokes far fewer conditional independencies than that in Richardson (2003). The results have applications in testing linear structural equation models with correlated errors.

Keywords: Markov properties, linear causal models, linear structural equation models, graphical models

1. Introduction

Linear causal models called structural equation models (SEMs) are widely used for causal reasoning in social sciences, economics, and artificial intelligence (Goldberger, 1972; Bollen, 1989; Spirtes et al., 2001; Pearl, 2000). One important problem in the applications of linear causal models is testing a hypothesized model against the given data. While the conventional method involves maximum likelihood estimation of the covariance matrix, an alternative approach has been proposed recently which involves testing for the conditional independence relationships implied by the model (Spirtes et al., 1998; Pearl, 1998; Pearl and Meshkat, 1999; Pearl, 2000; Shipley, 2000, 2003). The advantages of using this new test method instead of the traditional global fitting test have been discussed in Pearl (1998), Shipley (2000), McDonald (2002) and Shipley (2003). The method can be applied in small data samples and it can test "local" features of the model.

To apply this test method, one needs to be able to identify the conditional independence relationships implied by an SEM. This can be achieved by representing the SEM with a graph called a path diagram (Wright, 1934) and then reading independence relations from the path diagram. For a linear SEM without correlated errors, the corresponding path diagram is a directed acyclic graph (DAG). The set of all conditional independence relations holding in any model associated with a

DAG, often called a global Markov property for the DAG, can be read by the d-separation criterion (Pearl, 1988). However, it is not necessary to test for all the independencies implied by the model as a subset of those independencies may imply all others. A local Markov property specifies a much smaller set of conditional independence relations which will imply (using the laws of probability) all other conditional independence relations that hold under the global Markov property. A well-known local Markov property for DAGs is that each variable is conditionally independent of its non-descendants given its parents (Lauritzen et al., 1990; Lauritzen, 1996). Based on this local Markov property, Pearl and Meshkat (1999) and Shipley (2000) proposed testing methods for linear SEMs without correlated errors that involve at most one conditional independence test for each pair of variables.

On the other hand, the path diagrams for linear SEMs with correlated errors are DAGs with bi-directed edges ($\leftrightarrow$) where bi-directed edges are used to represent correlated errors. A DAG with bi-directed edges is called an *acyclic directed mixed graph (ADMG)* in Richardson (2003). The set of all conditional independence relations encoded in an ADMG can still be read by (a natural extension of) the d-separation criterion (called m-separation in Richardson, 2003) which provides the global Markov property for ADMGs (Spirtes et al., 1998; Koster, 1999; Richardson, 2003). A local Markov property for ADMGs is given in Richardson (2003), which, in the worst case, may invoke an exponential number of conditional independence relations, a sharp difference with the local Markov property for DAGs, where only one conditional independence relation is associated with each variable. Shipley (2003) suggested a method for testing linear SEMs with correlated errors but the method may or may not, depending on the actual models, be able to find a subset of conditional independence relations that imply all others.

In this paper, we seek to improve the local Markov property given in Richardson (2003) for linear SEMs with correlated errors. The local Markov property in Richardson (2003) is applicable for ADMGs associated with arbitrary probability distributions. Specifically, only semi-graphoid axioms which must hold in all probability distributions (Pearl, 1988) are used in showing that the set of conditional independence relations specified by the local Markov property will imply all those specified by the global Markov property. On the other hand, in linear SEMs, variables are assumed to have normal distributions, and it is known that normal distributions also satisfy the so-called composition axiom. Therefore, in this paper, we look for local Markov properties for ADMGs associated with probability distributions that satisfy the composition axiom. We will show that for a class of ADMGs, the local Markov property will invoke only one conditional independence relation for each variable, and therefore testing for the corresponding linear SEMs will involve at most one conditional independence test for each pair of variables. For general ADMGs, we provide a procedure that reduces the number of conditional independencies invoked by the local Markov property given in Richardson (2003), and therefore reduces the complexity of testing linear SEMs with correlated errors.

In the test of conditional independence relations, the efficiency of the test is influenced by the size of the conditioning set (that is, the number of conditioning variables) with a small conditioning set having advantage over a large one. The conditional independence relations invoked by the standard local Markov property for DAGs use a parent set as the conditioning set. Pearl and Meshkat (1999) have shown for linear SEMs without correlated errors how to find a set of conditional independence relations that may involve fewer conditioning variables. In this paper, we also generalize this result to linear SEMs with correlated errors.

The paper is organized as follows. In Section 2, we introduce linear SEMs, give basic notation and definitions, and present the local Markov property developed in Richardson (2003). In Section 3, we show that for a class of ADMGs, there is a local Markov property for probability distributions satisfying the composition axiom that invokes only a linear number of conditional independence relations. We also show a local Markov property that may involve fewer conditioning variables. In Section 4, we consider general ADMGs (for probability distributions satisfying the composition axiom) and show a local Markov property that invokes fewer conditional independencies than that in Richardson (2003). Section 5 concludes the paper.

2. Preliminaries and Motivation

In this section, we give basic definitions and introduce some relevant concepts.

2.1 Linear Causal Models

The SEM technique was developed by geneticists (Wright, 1934) and economists (Haavelmo, 1943) for assessing cause-effect relationships from a combination of statistical data and qualitative causal assumptions. It is an important causal analysis tool widely used in social sciences, economics, and artificial intelligence (Goldberger, 1972; Duncan, 1975; Bollen, 1989; Spirtes et al., 2001). For a review of SEMs and causality we refer to Pearl (1998).

In an SEM, the causal relationships among a set of variables are often assumed to be linear and expressed by linear equations. Each equation describes the dependence of one variable in terms of the others. For example, an equation

$$Y = aX + \varepsilon \tag{1}$$

represents that X may have a *direct* causal influence on Y and that no other variables have (direct) causal influences on Y except those factors (represented by the error term ε traditionally assumed to have normal distribution) that are omitted from the model. The parameter a quantifies the (direct) causal effect of X on Y. An equation like (1) with a causal interpretation represents an autonomous causal mechanism and is said to be *structural*.

As an example, consider the following model from Pearl (2000) that concerns the relations between smoking (X) and lung cancer (Y), mediated by the amount of tar (Z) deposited in a person's lungs:

$$\begin{aligned} X &= \varepsilon_1, \\ Z &= aX + \varepsilon_2, \\ Y &= bZ + \varepsilon_3. \end{aligned}$$

The model assumes that the amount of tar deposited in the lungs depends on the level of smoking (and external factors) and that the production of lung cancer depends on the amount of tar in the lungs but smoking has no effect on lung cancer except as mediated through tar deposits. To fully specify the model, we also need to decide whether those omitted factors (ε_1, ε_2, ε_3) are correlated or not. We may assume that no other factor that affects tar deposit is correlated with the omitted factors that affect smoking or lung cancer ($Cov(\varepsilon_1, \varepsilon_2) = Cov(\varepsilon_2, \varepsilon_3) = 0$). However, there might be unobserved factors (say some unknown carcinogenic genotype) that affect both smoking and lung

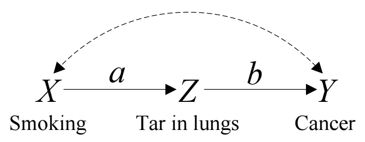

Figure 1: Causal diagram illustrating the effect of smoking on lung cancer

cancer ($Cov(\varepsilon_1, \varepsilon_3) \neq 0$), but the genotype nevertheless has no effect on the amount of tar in the lungs except indirectly (through smoking). Often, it is illustrative to express our qualitative causal assumptions in terms of a graphical representation, as shown in Figure 1.

We now formally define the model that we will consider in this paper. A *linear causal model* (or *linear SEM*) over a set of random variables $V = \{V_1, \ldots, V_n\}$ is given by a set of structural equations of the form

$$V_j = \sum_i c_{ji} V_i + \varepsilon_j, \; j = 1, \ldots, n, \tag{2}$$

where the summation is over the variables in V judged to be immediate causes of V_j. c_{ji}, called a *path coefficient*, quantifies the direct causal influence of V_i on V_j. ε_j's represent "error" terms due to omitted factors and are assumed to have normal distribution. We consider recursive models and assume that the summation in (2) is for $i < j$, that is, $c_{ji} = 0$ for $i \geq j$.

We denote the covariances between observed variables $\sigma_{ij} = Cov(V_i, V_j)$, and between error terms $\psi_{ij} = Cov(\varepsilon_i, \varepsilon_j)$. We denote the following matrices, $\Sigma = [\sigma_{ij}]$, $\Psi = [\psi_{ij}]$, and $C = [c_{ij}]$. The parameters of the model are the non-zero entries in the matrices C and Ψ. A parameterization of the model assigns a value to each parameter in the model, which then determines a unique covariance matrix Σ given by (see, for example, Bollen, 1989)

$$\Sigma = (I - C)^{-1} \Psi ((I - C)^t)^{-1}.$$

The structural assumptions encoded in the model are the zero path coefficients and zero error covariances. The model structure can be represented by a DAG G with (dashed) bi-directed edges (an ADMG), called a *causal diagram* (or *path diagram*), as follows: the nodes of G are the variables $V_1, \ldots, V_n$; there is a directed edge from V_i to V_j in G if V_i appears in the structural equation for V_j, that is, $c_{ji} \neq 0$; there is a bi-directed edge between V_i and V_j if the error terms ε_i and ε_j have non-zero correlation. For example, the smoking-and-lung-cancer SEM is represented by the causal diagram in Figure 1, in which each directed edge is annotated by the corresponding path coefficient.

We note that linear SEMs are often used without explicit causal interpretation. A linear SEM in which error terms are uncorrelated consists of a set of regression equations. Note that an equation as given by (2) is a regression equation if and only if ε_j is uncorrelated with each V_i ($Cov(V_i, \varepsilon_j) = 0$). Hence, an equation in an SEM with correlated errors may not be a regression equation. Linear SEMs provide a more powerful way to model data than the regression models taking into account correlated error terms.

2.2 Model Testing and Markov Properties

One important task in the applications of linear SEMs is to test a model against data. One approach for this task is to test for the conditional independence relationships implied by the model, which can be read from the causal diagram by the d-separation criterion as defined in the following.[1] A *path* between two vertices V_i and V_j in an ADMG consists of a sequence of consecutive edges of any type (directed or bi-directed). A vertex V_i is said to be an *ancestor* of a vertex V_j if there is a path $V_i \to \cdots \to V_j$. A non-endpoint vertex W on a path is called a *collider* if two arrowheads on the path meet at W, that is, $\to W \leftarrow$, $\leftrightarrow W \leftrightarrow$, $\leftrightarrow W \leftarrow$, $\to W \leftrightarrow$; all other non-endpoint vertices on a path are *non-colliders*, that is, $\leftarrow W \to$, $\leftarrow W \leftarrow$, $\to W \to$, $\leftrightarrow W \to$, $\leftarrow W \leftrightarrow$. A path between vertices V_i and V_j in an ADMG is said to be *d-connecting given a set* of vertices Z if

1. every non-collider on the path is not in Z, and
2. every collider on the path is an ancestor of a vertex in Z.

If there is no path d-connecting V_i and V_j given Z, then V_i and V_j are said to be *d-separated* given Z. Sets X and Y are said to be *d-separated* given Z, if for every pair V_i, V_j, with $V_i \in X$ and $V_j \in Y$, V_i and V_j are d-separated given Z. Let $I(X,Z,Y)$ denote that X is conditionally independent of Y given Z. The set of all the conditional independence relations encoded by a causal diagram G is specified by the following global Markov property.

Definition 1 (The Global Markov Property (GMP)) *A probability distribution P is said to satisfy the global Markov property for G if for arbitrary disjoint sets X,Y,Z with X and Y being nonempty,*

$$\text{(GMP)} \qquad X \text{ is d-separated from } Y \text{ given } Z \text{ in } G \Longrightarrow I(X,Z,Y).$$

The global Markov property typically involves a vast number of conditional independence relations and it is possible to test for a subset of those independencies that will imply all others. A local Markov property specifies a much smaller set of conditional independence relations which will imply by the laws of probability all other conditional independence relations that hold under the global Markov property. For example, a well-known local Markov property for DAGs is that each variable is conditionally independent of its non-descendants given its parents. The causal diagram for a linear SEM with correlated errors is an ADMG and a local Markov property for ADMGs is given in Richardson (2003).

Note that in linear SEMs, the conditional independence relations will correspond to zero partial correlations (Lauritzen, 1996):

$$\rho_{V_iV_j.Z} = 0 \Longleftrightarrow I(\{V_i\},Z,\{V_j\}).$$

As an example, for the linear SEM with the causal diagram in Figure 2, if we use the local Markov property in Richardson (2003), then we need to test for the vanishing of the following set of partial correlations (for ease of notation, we write $\rho_{ij.Z}$ to denote $\rho_{V_iV_j.Z}$):

$$\{\rho_{21}, \rho_{32.1}, \rho_{43.2}, \rho_{41.2}, \rho_{54.3}, \rho_{52.3}, \rho_{51.3}, \rho_{64.53}, \rho_{62.53}, \rho_{61.53}, \rho_{64.3}, \rho_{62.3}, \rho_{61.3}, \rho_{72.6543}, \rho_{71.6543}, \rho_{72.643}, \rho_{71.643}, \rho_{75.4}, \rho_{73.4}, \rho_{72.4}, \rho_{71.4}\}. \tag{3}$$

The local Markov property in Richardson (2003) is valid for any probability distributions. In fact, the equivalence of the global and local Markov properties is proved using the following so-called *semi-graphoid axioms* (Pearl, 1988) that probabilistic conditional independencies must satisfy:

1. The d-separation criterion was originally defined for DAGs (Pearl, 1988) but can be naturally extended for ADMGs and is called m-separation in Richardson (2003).

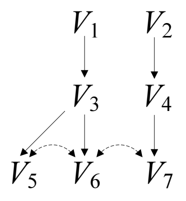

Figure 2: A causal diagram

- Symmetry
$$I(X,Z,Y) \Longleftrightarrow I(Y,Z,X).$$
- Decomposition
$$I(X,Z,Y\cup W) \Longrightarrow I(X,Z,Y)\ \&\ I(X,Z,W).$$
- Weak Union
$$I(X,Z,Y\cup W) \Longrightarrow I(X,Z\cup W,Y).$$
- Contraction
$$I(X,Z,Y)\ \&\ I(X,Z\cup Y,W) \Longrightarrow I(X,Z,Y\cup W).$$

where X, Y, Z, and W are disjoint sets of variables.

On the other hand, in linear SEMs the variables are assumed to have normal distributions, and normal distributions also satisfy the following *composition* axiom:

- Composition
$$I(X,Z,Y)\ \&\ I(X,Z,W) \Longrightarrow I(X,Z,Y\cup W).$$

Therefore, we expect a local Markov property for linear SEMs to invoke fewer conditional independence relations than that for arbitrary distributions. In this paper, we will derive reduced local Markov properties for linear SEMs by making use of the composition axiom. As an example, for the linear SEM in Figure 2, a local Markov property which we will present in this paper (see Section 3.3) says that we only need to test for the vanishing of the following set of partial correlations:

$$\{\rho_{21},\rho_{32},\rho_{43},\rho_{41},\rho_{54},\rho_{52},\rho_{51.3},\rho_{64},\rho_{62},\rho_{61.3},\rho_{75},\rho_{73},\rho_{71},\rho_{72.4}\}.$$

The number of tests needed and the size of the conditioning set Z are both substantially reduced compared with (3), thus leading to a more economical way of testing the given model.

2.3 A Local Markov Property for ADMGs

In this section, we describe the local Markov property for ADMGs associated with arbitrary probability distributions presented in Richardson (2003). In this paper, this Markov property will be used as an important tool to prove the equivalence of our local Markov properties and the global Markov property.

First, we define some graphical notations. For a vertex X in an ADMG G, $\text{pa}_G(X) \equiv \{Y|Y \to X$ in $G\}$ is the set of *parents* of X. $\text{sp}_G(X) \equiv \{Y|Y \leftrightarrow X$ in $G\}$ is the set of *spouses* of X. $\text{an}_G(X) \equiv$

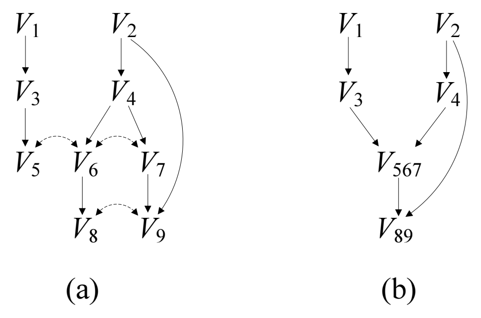

Figure 3: An ADMG and its compressed graph

$\{Y|Y \rightarrow \cdots \rightarrow X$ in G or $Y = X\}$ is the set of *ancestors* of X. And $\mathrm{de}_G(X) \equiv \{Y|Y \leftarrow \cdots \leftarrow X$ in G or $Y = X\}$ is the set of *descendants* of X. These definitions will be applied to sets of vertices, so that, for example, $\mathrm{pa}_G(A) \equiv \cup_{X\in A}\mathrm{pa}_G(X)$, $\mathrm{sp}_G(A) \equiv \cup_{X\in A}\mathrm{sp}_G(X)$, etc.

Definition 2 (C-component) *A c-component of G is a maximal set of vertices in G such that any two vertices in the set are connected by a path on which every edge is of the form $\leftrightarrow$; a vertex that is not connected to any bi-directed edge forms a c-component by itself.*

For example, the ADMG in Figure 3 (a) is composed of 6 c-components $\{V_1\}$, $\{V_2\}$, $\{V_3\}$, $\{V_4\}$, $\{V_5,V_6,V_7\}$ and $\{V_8,V_9\}$. The *district* of X in G is the c-component of G that includes X. Thus,

$$\mathrm{dis}_G(X) \equiv \{Y|Y \leftrightarrow \cdots \leftrightarrow X \text{ in } G \text{ or } Y = X\}.$$

For example, in Figure 3 (a), we have $\mathrm{dis}_G(V_5) = \{V_5,V_6,V_7\}$ and $\mathrm{dis}_G(V_8) = \{V_8,V_9\}$. A set A is said to be *ancestral* if it is closed under the ancestor relation, that is, if $\mathrm{an}_G(A) = A$. Let G_A denote the induced subgraph of G on the vertex set A, formed by removing from G all vertices that are not in A, and all edges that do not have both endpoints in A.

Definition 3 (Markov Blanket)[2] *If A is an ancestral set in an ADMG G, and X is a vertex in A that has no children in A then the* Markov blanket of vertex X with respect to the induced subgraph on A*, denoted* $\mathrm{mb}(X,A)$ *is defined to be*

$$\mathrm{mb}(X,A) \equiv \mathrm{pa}_{G_A}(\mathrm{dis}_{G_A}(X)) \cup (\mathrm{dis}_{G_A}(X) \setminus \{X\}).$$

For example, for an ancestral set $A = \mathrm{an}_G(\{V_5,V_6\}) = \{V_1,V_2,V_3,V_4,V_5,V_6\}$ in Figure 3 (a), we have

$$\mathrm{mb}(V_5,A) = \{V_3,V_4,V_6\}.$$

An ordering ($\prec$) on the vertices of G is said to be consistent with G if $X \prec Y \Rightarrow Y \notin \mathrm{an}_G(X)$. Given a consistent ordering $\prec$, let $\mathrm{pre}_{G,\prec}(X) \equiv \{Y|Y \prec X$ or $Y = X\}$.

Definition 4 (The Ordered Local Markov Property (LMP,$\prec$)) *A probability distribution P satisfies the ordered local Markov property for G with respect to a consistent ordering $\prec$, if, for any X and ancestral set A such that $X \in A \subseteq \mathrm{pre}_{G,\prec}(X)$,*

$$\text{(LMP,}\prec\text{)} \qquad I(\{X\},\mathrm{mb}(X,A),A \setminus (\mathrm{mb}(X,A) \cup \{X\})). \qquad (4)$$

2. The definition of Markov blanket here follows that in Richardson (2003) and is compatible with that in Pearl (1988).

Theorem 5 (Richardson, 2003) *If G is an ADMG and $\prec$ is a consistent ordering, then a probability distribution P satisfies the ordered local Markov property for G with respect to $\prec$ if and only if P satisfies the global Markov property for G.*

We will write (GMP) $\Longleftrightarrow$ (LMP,$\prec$) to denote the equivalence of the two Markov properties. Therefore the (smaller) set of conditional independencies specified in the ordered local Markov property will imply all other conditional independencies which hold under the global Markov property. It is possible to further reduce the number of conditional independence relations in the ordered local Markov property. An ancestral set A, with $X \in A \subseteq \mathrm{pre}_{G,\prec}(X)$ is said to be *maximal with respect to the Markov blanket* $\mathrm{mb}(X,A)$ if, whenever there is a set B such that $A \subseteq B \subseteq \mathrm{pre}_{G,\prec}(X)$ and $\mathrm{mb}(X,A) = \mathrm{mb}(X,B)$, then $A = B$. For example, suppose that we are given an ordering $\prec$: $V_1 \prec V_2 \prec V_3 \prec V_4 \prec V_5 \prec V_6 \prec V_7 \prec V_8 \prec V_9$ for the graph G in Figure 3 (a). While an ancestral set $A = \mathrm{an}_G(\{V_3,V_6,V_7\}) = \{V_1,V_2,V_3,V_4,V_6,V_7\}$ is maximal with respect to the Markov blanket $\mathrm{mb}(V_7,A) = \{V_4,V_6\}$, an ancestral set $A' = \mathrm{an}_G(\{V_6,V_7\}) = \{V_2,V_4,V_6,V_7\}$ is not. It was shown that we only need to consider ancestral sets A which are maximal with respect to $\mathrm{mb}(X,A)$ in the ordered local Markov property (Richardson, 2003). Thus, we will consider only maximal ancestral sets A when we discuss (LMP,$\prec$) for the rest of this paper. The following lemma characterizes maximal ancestral sets.

Lemma 6 (Richardson, 2003) *Let X be a vertex and A an ancestral set in G with consistent ordering $\prec$ such that $X \in A \subseteq \mathrm{pre}_{G,\prec}(X)$. The set A is maximal with respect to the Markov blanket* mb*(X,A) if and only if*

$$A = \mathrm{pre}_{G,\prec}(X) \setminus \mathrm{de}_G(\mathrm{h}(X,A))$$

where

$$\mathrm{h}(X,A) \equiv \mathrm{sp}_G\Big(\mathrm{dis}_{G_A}(X)\Big) \setminus \Big(\{X\} \cup \mathrm{mb}(X,A)\Big).$$

Even though we only consider maximal ancestral sets, the ordered local Markov property may still invoke an exponential number of conditional independence relations. For example, for a vertex X, if $\mathrm{dis}_G(X) \subseteq \mathrm{pre}_{G,\prec}(X)$ and $\mathrm{dis}_G(X)$ has a clique of n vertices joined by bi-directed edges, then there are at least $O(2^{n-1})$ different Markov blankets.

It should be noted that only the semi-graphoid axioms were used to prove Theorem 5 on the equivalence of the two Markov properties and no assumptions about probability distributions were made. Next we will show that the ordered local Markov property can be further reduced if we use the composition axiom in addition to the semi-graphoid axioms. The local Markov properties we obtained (in Sections 3 and 4) are not restricted to linear causal models in that they are actually valid for any probability distributions that satisfy the composition axiom.

3. Markov Properties for ADMGs without Directed Mixed Cycles

In this section, we introduce three local Markov properties for a class of ADMGs and show that they are equivalent to the global Markov property. Also, we discuss related work in maximal ancestral graphs and chain graphs. First, we give some definitions.

Definition 7 (Directed Mixed Cycle) *A path is said to be a directed mixed path from X to Y if it contains at least one directed edge and every edge on the path is either of the form $Z \leftrightarrow W$, or $Z \rightarrow W$ with W between Z and Y. A directed mixed path from X to Y together with an edge $Y \rightarrow X$ or $Y \leftrightarrow X$ is called a directed mixed cycle.*

$$\begin{tikzcd}
X \arrow[d] \arrow[r, leftrightarrow, dashed, bend left] & Y \\
Z \arrow[r, leftrightarrow, dashed, bend left] & W \arrow[u]
\end{tikzcd}$$

Figure 4: Directed mixed cycles

For example, the path $X \to Z \leftrightarrow W \to Y \leftrightarrow X$ in the graph in Figure 4 forms a directed mixed cycle. In this section, we will consider only ADMGs without directed mixed cycles.

Definition 8 (Compressed Graph) *Let G be an ADMG. The compressed graph of G is defined to be the graph $G' = (V', E')$, $V' = \{V_C \mid C$ is a c-component of $G\}$, $E' = \{V_{C_i} \to V_{C_j} \mid$ there is an edge $X \to Y$ in G such that $X \in C_i, Y \in C_j\}$.*

Figure 3 shows an ADMG and its compressed graph. If there exists a directed mixed cycle in an ADMG G, there will be a cycle or a self-loop in the compressed graph of G. For example, if for two vertices X and Y in a c-component C of G there exists an edge $X \to Y$, then the compressed graph of G contains a self-loop $\overset{\curvearrowright}{V_C}$. The following proposition holds.

Proposition 9 *Let G be an ADMG. The compressed graph of G is a DAG if and only if G has no directed mixed cycles.*

3.1 The Reduced Local Markov Property

In this section, we introduce a local Markov property for ADMGs without directed mixed cycles which only invokes a linear number of conditional independence relations and show that it is equivalent to the global local Markov property.

Definition 10 (The Reduced Local Markov Property (RLMP)) *Let G be an ADMG without directed mixed cycles. A probability distribution P is said to satisfy the reduced local Markov property for G if*

$$\text{(RLMP)} \qquad \forall X \in V, \quad I(\{X\}, \mathrm{pa}_G(X), V \setminus \mathrm{f}(X,G)) \tag{5}$$

where $\mathrm{f}(X,G) \equiv \mathrm{pa}_G(X) \cup \mathrm{de}_G(\{X\} \cup \mathrm{sp}_G(X))$.

The reduced local Markov property states that *a variable is independent of the variables that are neither its descendants nor its spouses' descendants given its parents.*

Theorem 11 *If a probability distribution P satisfies the composition axiom and an ADMG G has no directed mixed cycles, then*

$$\text{(GMP)} \Longleftrightarrow \text{(RLMP)}.$$

Proof: (GMP) $\Longrightarrow$ (RLMP)
We need to prove that any variable X is d-separated from $V \setminus \mathrm{f}(X,G)$ given $\mathrm{pa}_G(X)$ in G with no directed mixed cycle. Consider a vertex $\alpha \in V \setminus \mathrm{f}(X,G)$. We will show that there is no path d-connecting X and α given $\mathrm{pa}_G(X)$. There are four possible cases for any path between X and α.

1. $X \leftarrow \beta \cdots \alpha$
2. $X \rightarrow \cdots \rightarrow \delta \leftarrow\!\!* \cdots \alpha$
3. $X \leftrightarrow \gamma \leftarrow\!\!* \cdots \alpha$
4. $X \leftrightarrow \gamma \rightarrow \cdots \rightarrow \delta \leftarrow\!\!* \cdots \alpha$

A symbol $*$ serves as a wildcard for an end of an edge. For example, $\leftarrow\!\!*$ represents both $\leftarrow$ and $\leftrightarrow$. In case 1, $\beta \in \mathrm{pa}_G(X)$. In case 2, the collider δ is not an ancestor of a vertex in $\mathrm{pa}_G(X)$ (otherwise, there would be a cycle). In cases 3 and 4, neither γ nor δ is an ancestor of a vertex in $\mathrm{pa}_G(X)$ (otherwise, there would be directed mixed cycles). In any case, the path is not d-connecting given $\mathrm{pa}_G(X)$. ■

Proof: (RLMP) $\Longrightarrow$ (GMP)
We will show that for some consistent ordering $\prec$, (RLMP) $\Longrightarrow$ (LMP, $\prec$). Then, by Theorem 5, we have (RLMP) $\Longrightarrow$ (GMP).

We construct a consistent ordering with the desired property as follows.

1. Construct the compressed graph G' of G.
2. Let $\prec'$ be any consistent ordering on G'. Construct a consistent ordering $\prec$ from $\prec'$ by replacing each V_C (corresponding to each c-component C of G) in $\prec'$ with the vertices in C (the ordering of the vertices in C is arbitrary).

We now prove that (RLMP) $\Longrightarrow$ (LMP,$\prec$). Assume that a probability distribution P satisfies (RLMP). Consider the set of conditional independence relations invoked by (LMP,$\prec$) for each variable X given in (4). First, observe that for any vertex Y in $\mathrm{dis}_{G_A}(X)$, we have

$$A \setminus (\mathrm{pa}_G(Y) \cup \{Y\} \cup \mathrm{sp}_G(Y)) \subseteq V \setminus \mathrm{f}(Y,G),$$

since

$$\begin{aligned} & A \setminus (\mathrm{pa}_G(Y) \cup \{Y\} \cup \mathrm{sp}_G(Y)) \\ & = A \setminus \Big(\big(\mathrm{pa}_G(Y) \cup \{Y\} \cup \mathrm{sp}_G(Y)\big) \cup \big(\mathrm{de}_G(\{Y\} \cup \mathrm{sp}_G(Y)) \setminus (\{Y\} \cup \mathrm{sp}_G(Y))\big) \Big) \qquad (6) \\ & = A \setminus \mathrm{f}(Y,G). \end{aligned}$$

The equality (6) holds since the vertices in $\mathrm{de}_G(\{Y\} \cup \mathrm{sp}_G(Y)) \setminus (\{Y\} \cup \mathrm{sp}_G(Y))$ do not appear in A (because of the way $\prec$ is constructed, no descendant of $\mathrm{dis}_{G_A}(X)$ is in A). Thus, by (5), for all Y in $\mathrm{dis}_{G_A}(X)$, we have

$$I(\{Y\}, \mathrm{pa}_G(Y), A \setminus (\mathrm{pa}_G(Y) \cup \{Y\} \cup \mathrm{sp}_{G_A}(Y))).$$

Let $S_1 = \mathrm{pa}_G(\mathrm{dis}_{G_A}(X)) \setminus \mathrm{pa}_G(Y)$ and $S_2 = A \setminus (\mathrm{mb}(X,A) \cup \{X\})$. It follows that

$$\begin{aligned} & S_1 \subseteq A \setminus (\mathrm{pa}_G(Y) \cup \{Y\} \cup \mathrm{sp}_G(Y)) \text{ and} \\ & S_2 \subseteq A \setminus (\mathrm{pa}_G(Y) \cup \{Y\} \cup \mathrm{sp}_G(Y)). \end{aligned}$$

Also, we have

$$S_1 \cap S_2 = \emptyset,$$

since $S_1 \subseteq \mathrm{mb}(X,A)$. Therefore, for $Y \in \mathrm{dis}_{G_A}(X)$,

$$\begin{array}{ll}
I(\{Y\},\mathrm{pa}_G(Y),S_1 \cup S_2) & \text{by decomposition} \\
I(\{Y\},\mathrm{pa}_G(Y) \cup S_1,S_2) & \text{by weak union} \\
I(\mathrm{dis}_{G_A}(X),\mathrm{pa}_G(\mathrm{dis}_{G_A}(X)),A \setminus (\mathrm{mb}(X,A) \cup \{X\})) & \text{by composition} \\
I(\{X\},\mathrm{pa}_G(\mathrm{dis}_{G_A}(X)) \cup (\mathrm{dis}_{G_A}(X) \setminus \{X\}), & \\
\quad A \setminus (\mathrm{mb}(X,A) \cup \{X\})) & \text{by weak union.}
\end{array}$$

Thus, we have

$$I(\{X\},\mathrm{mb}(X,A),A \setminus (\mathrm{mb}(X,A) \cup \{X\}))$$

by the definition of the Markov blanket of X with respect to A. ■

As an example, consider the ADMG G in Figure 3 (a) which has no directed mixed cycles. The graph in Figure 3 (b) is the compressed graph G' of G described in the proof. From the ordering $\prec'$: $V_1 \prec V_2 \prec V_3 \prec V_4 \prec V_{567} \prec V_{89}$, we obtain the ordering $\prec$: $V_1 \prec V_2 \prec V_3 \prec V_4 \prec V_5 \prec V_6 \prec V_7 \prec V_8 \prec V_9$. The ordered local Markov property (LMP,$\prec$) involves the following conditional independence relations:

$$\begin{array}{ll}
I(\{V_2\},\emptyset,\{V_1\}), & I(\{V_3\},\{V_1\},\{V_2\}), \\
I(\{V_4\},\{V_2\},\{V_1,V_3\}), & I(\{V_5\},\{V_3\},\{V_1,V_2,V_4\}), \\
I(\{V_6\},\{V_3,V_4,V_5\},\{V_1,V_2\}), & I(\{V_6\},\{V_4\},\{V_1,V_2,V_3\}), \\
I(\{V_7\},\{V_3,V_4,V_5,V_6\},\{V_1,V_2\}), & I(\{V_7\},\{V_4,V_6\},\{V_1,V_2,V_3\}), \\
I(\{V_7\},\{V_4\},\{V_1,V_2,V_3,V_5\}), & I(\{V_8\},\{V_6\},\{V_1,V_2,V_3,V_4,V_5,V_7\}), \\
I(\{V_9\},\{V_2,V_6,V_7,V_8\},\{V_1,V_3,V_4,V_5\}), & I(\{V_9\},\{V_2,V_7\},\{V_1,V_3,V_4,V_5,V_6\}).
\end{array} \tag{7}$$

(RLMP) invokes the following conditional independence relations:

$$\begin{array}{ll}
I(\{V_1\},\emptyset,\{V_2,V_4,V_6,V_7,V_8,V_9\}), & I(\{V_2\},\emptyset,\{V_1,V_3,V_5\}), \\
I(\{V_3\},\{V_1\},\{V_2,V_4,V_6,V_7,V_8,V_9\}), & I(\{V_4\},\{V_2\},\{V_1,V_3,V_5\}), \\
I(\{V_5\},\{V_3\},\{V_1,V_2,V_4,V_7,V_9\}), & I(\{V_6\},\{V_4\},\{V_1,V_2,V_3\}), \\
I(\{V_7\},\{V_4\},\{V_1,V_2,V_3,V_5\}), & I(\{V_8\},\{V_6\},\{V_1,V_2,V_3,V_4,V_5,V_7\}), \\
I(\{V_9\},\{V_2,V_7\},\{V_1,V_3,V_4,V_5,V_6\}) &
\end{array} \tag{8}$$

which, by Theorem 11, imply all the conditional independence relations in (7).

For the special case of graphs containing only bi-directed edges,[3] Kauermann (1996) provides a local Markov property for probability distributions obeying the composition axiom as follows:

$$\forall X \in V, \quad I(\{X\},\emptyset,V \setminus (\{X\} \cup \mathrm{sp}_G(X))). \tag{9}$$

3. Kauermann (1996) actually used undirected graphs with dashed edges which are Markov equivalent to graphs with only bi-directed edges (see Richardson, 2003, for discussions).

Since a graph containing only bi-directed edges is a special case of ADMGs without directed mixed cycles, the reduced local Markov property (RLMP) is applicable, and it turns out that (RLMP) reduces to (9) for graphs containing only bi-directed edges. Therefore (RLMP) includes the local Markov property given in Kauermann (1996) as a special case.

3.2 The Ordered Reduced Local Markov Property

The set of zero partial correlations corresponding to a conditional independence relation $I(X,Z,Y)$ is

$$\{\rho_{V_iV_j.Z} = 0 \mid V_i \in X, V_j \in Y\}.$$

Although (RLMP) gives only a linear number of conditional independence relations, the number of zero partial correlations may be larger than that invoked by (LMP,$\prec$) in some cases. For example, 12 conditional independence relations in (7) involve 37 zero partial correlations while 9 conditional independence relations in (8) involve 41 zero partial correlations. In this section, we will show an ordered local Markov property such that at most one zero partial correlation is invoked for each pair of variables.

Definition 12 (C-ordering) *Let G be an ADMG. A consistent ordering $\prec$ on the vertices of G is said to be a c-ordering if all the vertices in each c-component of G are consecutively ordered in $\prec$.*

For example, the ordering $V_1 \prec V_2 \prec V_3 \prec V_4 \prec V_5 \prec V_6 \prec V_7 \prec V_8 \prec V_9$ is a c-ordering on the vertices of G in Figure 3 (a). The following holds.

Proposition 13 *There exists a c-ordering on the vertices of G if G does not have directed mixed cycles.*

We can easily construct a c-ordering from the compressed graph of G. We introduce the following Markov property.

Definition 14 (The Ordered Reduced Local Markov Property (RLMP,$\prec_c$)) *Let G be an ADMG without directed mixed cycles and $\prec_c$ be a c-ordering on the vertices of G. A probability distribution P is said to satisfy the ordered reduced local Markov property for G with respect to $\prec_c$ if*

$$\text{(RLMP,}\prec_c\text{)} \qquad \forall X \in V,\ I(\{X\}, \text{pa}_G(X), \text{pre}_{G,\prec_c}(X) \setminus (\{X\} \cup \text{pa}_G(X) \cup \text{sp}_G(X))). \qquad (10)$$

The ordered reduced local Markov property states that *a variable is independent of its predecessors, excluding its spouses, in a c-ordering given its parents*. We now establish the equivalence of (GMP) and (RLMP,$\prec_c$).

Theorem 15 *If a probability distribution P satisfies the composition axiom and an ADMG G has no directed mixed cycles, then for a c-ordering $\prec_c$ on the vertices of G,*

$$\text{(GMP)} \Longleftrightarrow \text{(RLMP,}\prec_c\text{)}.$$

Proof: (GMP) $\implies$ (RLMP,$\prec_c$)
The set $\mathrm{pre}_{G,\prec_c}(X)$ does not include any descendant of $\mathrm{dis}_G(X)$ since $\prec_c$ is a c-ordering. We have

$$\begin{aligned}
&\mathrm{pre}_{G,\prec_c}(X)\setminus(\{X\}\cup\mathrm{pa}_G(X)\cup\mathrm{sp}_G(X))\\
&=\mathrm{pre}_{G,\prec_c}(X)\setminus\Big(\Big(\{X\}\cup\mathrm{pa}_G(X)\cup\mathrm{sp}_G(X)\Big)\cup\Big(\mathrm{de}_G(\{X\}\cup\mathrm{sp}_G(X))\setminus(\{X\}\cup\mathrm{sp}_G(X))\Big)\Big)\\
&=\mathrm{pre}_{G,\prec_c}(X)\setminus\mathrm{f}(X,G)\\
&\subseteq V\setminus\mathrm{f}(X,G).
\end{aligned}$$

Hence, (RLMP,$\prec_c$) follows from (RLMP). ■

Proof: (RLMP,$\prec_c$) $\implies$ (GMP)
We will show that (RLMP,$\prec_c$) $\implies$ (LMP,$\prec_c$). Assume that a probability distribution P satisfies (RLMP,$\prec_c$). Let $\mathrm{g}(Y)=\mathrm{pre}_{G,\prec_c}(Y)\setminus(\{Y\}\cup\mathrm{pa}_G(Y)\cup\mathrm{sp}_G(Y))$. Consider the set of conditional independence relations invoked by (LMP,$\prec_c$) for each variable X given in (4) where A is maximal. By (10), for all Y in $\mathrm{dis}_{G_A}(X)$, we have

$$I(Y,\mathrm{pa}_G(Y),\mathrm{g}(Y)). \tag{11}$$

Let $S_1=\mathrm{pa}_G(\mathrm{dis}_{G_A}(X))\setminus\mathrm{pa}_G(Y)$ and $S_2=A\setminus(\mathrm{mb}(X,A)\cup\{X\})$. We have that

$$S_1\subseteq\mathrm{g}(Y).$$

Note that $S_2\setminus\mathrm{g}(Y)$ may be non-empty. Let $S_3=S_2\setminus\mathrm{g}(Y)$. It suffices to show that

$$I(Y,\mathrm{pa}_G(Y),S_3),$$

which implies $I(Y,\mathrm{pa}_G(Y),S_2)$ by composition. Then, the rest of the proof would be identical to that of Theorem 11.

We first characterize the vertices in S_3. We will show that

$$S_3=(\mathrm{pre}_{G,\prec_c}(X)\setminus\mathrm{pre}_{G,\prec_c}(Y))\setminus\mathrm{sp}_G(\mathrm{dis}_{G_A}(X)). \tag{12}$$

By Lemma 6, we have

$$S_2=\mathrm{pre}_{G,\prec_c}(X)\setminus\Big(\mathrm{de}_G(\mathrm{h}(X,A))\cup\mathrm{mb}(X,A)\cup\{X\}\Big).$$

Since $\prec_c$ is a c-ordering, no descendant of $\mathrm{dis}_G(X)$ will appear in A. Hence,

$$S_2=\mathrm{pre}_{G,\prec_c}(X)\setminus\Big(\mathrm{sp}_G(\mathrm{dis}_{G_A}(X))\cup\mathrm{pa}_G(\mathrm{dis}_{G_A}(X))\Big).$$

To identify some common elements of S_2 and $\mathrm{g}(Y)$, we will reformulate S_2 and $\mathrm{g}(Y)$ as follows.

$$\begin{aligned}
S_2&=\Big(B\setminus\mathrm{pa}_G(\mathrm{dis}_{G_A}(X))\Big)\cup\Big((\mathrm{dis}_G(X)\cap\mathrm{pre}_{G,\prec_c}(X))\setminus\mathrm{sp}_G(\mathrm{dis}_{G_A}(X))\Big),\\
\mathrm{g}(Y)&=\Big(B\setminus\mathrm{pa}_G(Y)\Big)\cup\Big((\mathrm{dis}_G(X)\cap\mathrm{pre}_{G,\prec_c}(Y))\setminus(\{Y\}\cup\mathrm{sp}_G(Y))\Big)
\end{aligned}$$

where $B = \mathrm{pre}_{G,\prec_c}(X) \setminus \mathrm{dis}_G(X)$. This can be verified by noting that $A_1 = A_2 \setminus (A_3 \cup A_4) = (A_{11} \setminus A_2) \cup (A_{12} \setminus A_3)$ if $A_1 = A_{11} \cup A_{12}, A_{11} \cap A_{12} = \emptyset, A_2 \subseteq A_{11}, A_3 \subseteq A_{12}$. From $\mathrm{pa}_G(Y) \subseteq \mathrm{pa}_G(\mathrm{dis}_{G_A}(X))$, it follows that $B \setminus \mathrm{pa}_G(\mathrm{dis}_{G_A}(X)) \subseteq B \setminus \mathrm{pa}_G(Y)$ and

$$\begin{aligned} S_3 =& S_2 \setminus \mathrm{g}(Y) \\ =& \Big((\mathrm{dis}_G(X) \cap \mathrm{pre}_{G,\prec_c}(X)) \setminus \mathrm{sp}_G(\mathrm{dis}_{G_A}(X)) \Big) \\ & \setminus \Big((\mathrm{dis}_G(X) \cap \mathrm{pre}_{G,\prec_c}(Y)) \setminus (\{Y\} \cup \mathrm{sp}_G(Y)) \Big). \end{aligned}$$

We can rewrite the first part of this expression as follows.

$$\begin{aligned} & (\mathrm{dis}_G(X) \cap \mathrm{pre}_{G,\prec_c}(X)) \setminus \mathrm{sp}_G(\mathrm{dis}_{G_A}(X)) \\ =& \Big((\mathrm{dis}_G(X) \cap \mathrm{pre}_{G,\prec_c}(Y)) \setminus \mathrm{sp}_G(\mathrm{dis}_{G_A}(X)) \Big) \\ & \cup \Big((\mathrm{pre}_{G,\prec_c}(X) \setminus \mathrm{pre}_{G,\prec_c}(Y)) \setminus \mathrm{sp}_G(\mathrm{dis}_{G_A}(X)) \Big). \end{aligned}$$

From $(\mathrm{dis}_G(X) \cap \mathrm{pre}_{G,\prec_c}(Y)) \setminus \mathrm{sp}_G(\mathrm{dis}_{G_A}(X)) \subseteq (\mathrm{dis}_G(X) \cap \mathrm{pre}_{G,\prec_c}(Y)) \setminus (\{Y\} \cup \mathrm{sp}_G(Y))$, (12) follows. Thus, the vertices in S_3 are those in the set $\mathrm{pre}_{G,\prec_c}(X) \setminus \mathrm{pre}_{G,\prec_c}(Y)$ and not in the set $\mathrm{sp}_G(\mathrm{dis}_{G_A}(X))$.

Now we are ready to prove $I(Y, \mathrm{pa}_G(Y), S_3)$. For any $Z \in S_3$, we have $Y \prec Z$ and $Z \notin \mathrm{sp}_G(Y)$. Hence,

$$\begin{array}{ll} I(\{Z\}, \mathrm{pa}_G(Z), \mathrm{g}(Z)), & \\ I(\{Z\}, \mathrm{pa}_G(Z), \{Y\} \cup (\mathrm{pa}_G(Y) \setminus \mathrm{pa}_G(Z))) & \text{by decomposition,} \\ I(\{Z\}, \mathrm{pa}_G(Z) \cup \mathrm{pa}_G(Y), \{Y\}) & \text{by weak union,} \\ I(\{Y\}, \mathrm{pa}_G(Y), \mathrm{pa}_G(Z) \setminus \mathrm{pa}_G(Y)) & \text{by } \mathrm{pa}_G(Z) \setminus \mathrm{pa}_G(Y)) \subseteq \mathrm{g}(Y), (11) \\ \quad \text{and decomposition,} & \\ I(\{Y\}, \mathrm{pa}_G(Y), \{Z\}) & \text{by contraction and decomposition.} \end{array}$$

Therefore, by composition, $I(Y, \mathrm{pa}_G(Y), S_3)$ holds. ■

(RLMP,$\prec_c$) invokes one zero partial correlation for each pair of nonadjacent variables. For example, for the ADMG G in Figure 3 (a) and a c-ordering $\prec_c$: $V_1 \prec V_2 \prec V_3 \prec V_4 \prec V_5 \prec V_6 \prec V_7 \prec V_8 \prec V_9$, (RLMP,$\prec_c$) invokes the following conditional independence relations:

$$\begin{array}{ll} I(\{V_2\}, \emptyset, \{V_1\}), & I(\{V_3\}, \{V_1\}, \{V_2\}), \\ I(\{V_4\}, \{V_2\}, \{V_1, V_3\}), & I(\{V_5\}, \{V_3\}, \{V_1, V_2, V_4\}), \\ I(\{V_6\}, \{V_4\}, \{V_1, V_2, V_3\}), & I(\{V_7\}, \{V_4\}, \{V_1, V_2, V_3, V_5\}), \\ I(\{V_8\}, \{V_6\}, \{V_1, V_2, V_3, V_4, V_5, V_7\}), & I(\{V_9\}, \{V_2, V_7\}, \{V_1, V_3, V_4, V_5, V_6\}) \end{array} \tag{13}$$

which involve 25 zero partial correlations while (7) involve 37 zero partial correlations.

3.3 The Pairwise Markov Property

In this section, we give a pairwise Markov property which specifies conditional independence relations between pairs of variables and show that it is equivalent to the global Markov property. In previous sections, we focused on minimizing the number of zero partial correlations. We now take into account the size of the conditioning set Z in each zero partial correlation $\rho_{XY.Z}$. When the size of $\mathrm{pa}_G(X)$ for a vertex X in (RLMP,$\prec_c$) is large, it might be advantageous to use a different conditioning set with smaller size (if the equivalence of the Markov properties still holds). Pearl and Meshkat (1999) introduced a pairwise Markov property for DAGs (without bi-directed edges) which may involve fewer conditioning variables and thus lead to more economical tests. The result can be easily generalized to ADMGs with no directed mixed cycles.

Let $d(X,Y)$ denote the shortest distance between two vertices X and Y, that is, the number of edges in the shortest path between X and Y. Two vertices X and Y are nonadjacent if X and Y are not connected by a directed nor a bi-directed edge.

Definition 16 (The Pairwise Markov Property (PMP,$\prec_c$)) *Let G be an ADMG without directed mixed cycles and $\prec_c$ be a c-ordering on the vertices of G. A probability distribution P is said to satisfy the pairwise Markov property for G with respect to $\prec_c$ if for any two nonadjacent vertices $V_i, V_j, V_j \prec_c V_i$*

$$\text{(PMP,}\prec_c\text{)} \qquad\qquad I(\{V_i\}, Z_{ij}, \{V_j\})$$

where Z_{ij} is any set of vertices such that Z_{ij} d-separates V_i from V_j and $\forall Z \in Z_{ij}, d(V_i,Z) < d(V_i,V_j)$.

Note that, in ADMGs with no directed mixed cycles, there always exists such a Z_{ij} for any two nonadjacent vertices. For example, the parent set of V_i always satisfies the condition for Z_{ij}. If the empty set d-separates V_i from V_j, then the empty set is defined to satisfy the condition for Z_{ij}. Therefore we can always choose a Z_{ij} with the smallest size, providing a more economical way to test zero partial correlations.

Theorem 17 *If a probability distribution P satisfies the composition axiom and an ADMG G has no directed mixed cycles, then*

$$\text{(GMP)} \Longleftrightarrow \text{(PMP,}\prec_c\text{)}.$$

Proof: Noting that two vertices X and Y are adjacent if $X \leftarrow Y$, $X \rightarrow Y$ or $X \leftrightarrow Y$, the proof of Theorem 1 by Pearl and Meshkat (1999) is directly applicable to ADMGs and it effectively proves that (RLMP,$\prec_c$) $\Longleftrightarrow$ (PMP,$\prec_c$). We do not reproduce the proof here. ■

As an example, for the ADMG G in Figure 3 (a) and a c-ordering $\prec_c$: $V_1 \prec V_2 \prec V_3 \prec V_4 \prec V_5 \prec V_6 \prec V_7 \prec V_8 \prec V_9$, the following conditional independence relations (for convenience, we combine the relations for each vertex that have the same conditioning set) can be given by (PMP,$\prec_c$):

$$\begin{array}{ll}
I(\{V_2\},\emptyset,\{V_1\}), & I(\{V_3\},\emptyset,\{V_2\}), \\
I(\{V_4\},\emptyset,\{V_3,V_1\}), & I(\{V_5\},\emptyset,\{V_4,V_2\}), \\
I(\{V_5\},\{V_3\},\{V_1\}), & I(\{V_6\},\emptyset,\{V_3,V_1\}), \\
I(\{V_6\},\{V_4\},\{V_2\}), & I(\{V_7\},\emptyset,\{V_5,V_3,V_1\}), \\
I(\{V_7\},\{V_4\},\{V_2\}), & I(\{V_8\},\{V_6\},\{V_7,V_5,V_4,V_2\}), \\
I(\{V_8\},\emptyset,\{V_3,V_1\}), & I(\{V_9\},\{V_2,V_7\},\{V_6,V_4\}), \\
I(\{V_9\},\emptyset,\{V_5,V_3,V_1\}) &
\end{array}$$

which involve the same number of zero partial correlations as (13) but involve smaller conditioning sets than those in (13).

3.4 Relation to Other Work

In this section, we contrast the class of ADMGs without directed mixed cycles to maximal ancestral graphs and chain graphs in terms of Markov properties.

3.4.1 MAXIMAL ANCESTRAL GRAPHS

It is easy to see that an ADMG without directed mixed cycles is a *maximal ancestral graph (MAG)* (Richardson and Spirtes, 2002). An ADMG is said to be *ancestral* if, for any edge $X \leftrightarrow Y$, X is not an ancestor of Y (and vice versa). Note that an edge $X \leftrightarrow Y$ and a directed path from X to Y (or Y to X) form a directed mixed cycle. Hence, an ADMG without directed mixed cycles is ancestral. An ancestral graph is said to be *maximal* if, for any pair of nonadjacent vertices X and Y, there exists a set $Z \subseteq V \setminus \{X,Y\}$ that d-separates X from Y. From Theorem 17, it follows that an ADMG without directed mixed cycles is maximal. On the other hand, there exist MAGs which have directed mixed cycles (see Figure 4). Thus, the class of ADMGs without directed mixed cycles is a strict subclass of MAGs.

Richardson and Spirtes (2002, p.979) showed the following pairwise Markov property for a MAG G:

$$I(\{V_i\}, \mathrm{an}_G(\{V_i,V_j\}) \setminus \{V_i,V_j\}, \{V_j\})$$

for any two nonadjacent vertices V_i and V_j. Richardson and Spirtes (2002) proved that this pairwise Markov property implies the global Markov property assuming a Gaussian parametrization. This does not trivially imply our results in Section 3.3 and our results cannot be considered as a special case of the results on MAGs. The two pairwise Markov properties involve two different forms of conditioning sets. The pairwise Markov property for MAGs involves considerably larger conditioning sets than our pairwise Markov property: the conditioning set includes all ancestors of V_i and V_j, which is undesirable for our purpose of using the zero partial correlations to test a model.

Also, it should be stressed that our results do not depend on a specific parameterization. We only require the composition axiom to be satisfied. In contrast, Richardson and Spirtes (2002) consider only Gaussian parameterizations. It requires further study whether the pairwise Markov property for MAGs can be generalized to the class of distributions satisfying the composition axiom.

In the next section, we consider general ADMGs and try to eliminate redundant conditional independence relations from (LMP,$\prec$). The class of MAGs is clearly a (strict) subclass of ADMGs. Hence, given a MAG, we have two options: either we use the result in the next section or the pairwise Markov property for MAGs. Although the pairwise Markov property for MAGs gives fewer zero partial correlations (one for each nonadjacent pair of vertices), it is possible that in some cases we are better off using the result in the next section (because of the cost incurred by the large conditioning sets in the pairwise Markov property for MAGs). An example of this situation will be given in the next section.

Richardson and Spirtes (2002) also proved that for a Gaussian distribution encoded by a MAG all the constraints on the distribution (that is, on the covariance matrix) are implied by the vanishing partial correlations given by the global Markov property. Hence, this also holds in a linear SEM represented by an ADMG without directed mixed cycles which is a special type of MAG.

3.4.2 CHAIN GRAPHS

The graph that results from replacing bi-directed edges with undirected edges in an ADMG without directed mixed cycles is a *chain graph*. The class of chain graphs has been studied extensively (see Lauritzen, 1996, for a review).

Some Markov properties have been proposed for chain graphs. The first Markov property for chain graphs has been proposed by Lauritzen and Wermuth (1989) and Frydenberg (1990). Andersson et al. (2001) have introduced another Markov property. These two Markov properties do not correspond to the Markov property for ADMGs. Let G be an ADMG without directed mixed cycles and G' be the chain graph obtained by replacing bi-directed edges with undirected edges. In general, the set of conditional independence relations given by the Markov property for G is not equivalent to that given by either of the two Markov properties for chain graphs. However, there are other Markov properties for chain graphs that correspond to the Markov property for ADMGs without directed mixed cycles (Cox and Wermuth, 1993; Wermuth and Cox, 2001, 2004).[4]

4. Markov Properties for General ADMGs

When an ADMG G has directed mixed cycles, (RLMP), (RLMP,$\prec_c$), and (PMP,$\prec_c$) are no longer equivalent to (GMP) while (LMP,$\prec$) still is. In this section, we show that the number of conditional independence relations given by (LMP,$\prec$) for an arbitrary ADMG that might have directed mixed cycles can still be reduced. We introduce a procedure to reduce (LMP,$\prec$). We then give an example to illustrate the procedure.

4.1 Reducing the Ordered Local Markov Property

First, we introduce a lemma that gives a condition by which a conditional independence relation renders another conditional independence relation redundant.

Lemma 18 *Given an ADMG G, a consistent ordering $\prec$ on the vertices of G and a vertex X, assume that a probability distribution P satisfies the global Markov property for $G_{\mathrm{pre}_{G,\prec}(X)\setminus\{X\}}$. Let $A = \mathrm{pre}_{G,\prec}(X)$ and A' be a maximal ancestral set with respect to $\mathrm{mb}(X,A')$ such that $X \in A' \subset A$, $A' \cap \mathrm{dis}_{G_A}(X) = \mathrm{dis}_{G_{A'}}(X)$ and $\mathrm{pa}_G(\mathrm{dis}_{G_A}(X) \setminus \mathrm{dis}_{G_{A'}}(X)) \subseteq \mathrm{mb}(X,A')$. Then,*

$$I(\{X\}, \mathrm{mb}(X,A), A \setminus (\mathrm{mb}(X,A) \cup \{X\})) \tag{14}$$

implies

$$I(\{X\}, \mathrm{mb}(X,A'), A' \setminus (\mathrm{mb}(X,A') \cup \{X\})).$$

We define $\mathrm{rd}_{G,\prec}(X)$ to be the set of all A' satisfying this condition.

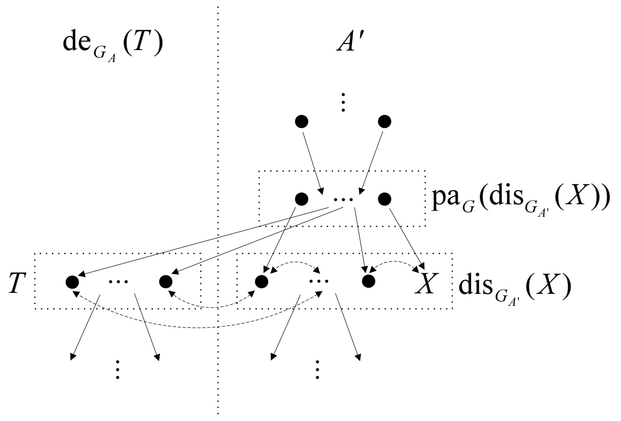
Proof: First, we show the relationships among $A, \mathrm{dis}_{G_A}(X)$, $\mathrm{mb}(X,A)$ and $A', \mathrm{dis}_{G_{A'}}(X)$, $\mathrm{mb}(X,A')$. By Lemma 6, we have

$$A' = A \setminus \mathrm{de}_{G_A}(\mathrm{h}(X,A')) \tag{15}$$

where

$$\mathrm{h}(X,A') \equiv \mathrm{sp}_{G_A}\Big(\mathrm{dis}_{G_{A'}}(X)\Big) \setminus \Big(\{X\} \cup \mathrm{mb}(X,A')\Big).$$

4. In their terminology, ADMGs without directed mixed cycles correspond to chain graphs with dashed arrows and dashed edges.



$\mathrm{de}_{G_A}(T)$
A'
$\mathrm{pa}_G(\mathrm{dis}_{G_{A'}}(X))$
T
X
$\mathrm{dis}_{G_{A'}}(X)$

Figure 5: The relationship between A and A' that satisfy the conditions in Lemma 18. The induced subgraph G_A is shown. The vertices of G_A are decomposed into two disjoint subsets $\mathrm{de}_{G_A}(T)$ and A'.

$\mathrm{dis}_{G_{A'}}(X)$ and $\mathrm{h}(X,A')$ are subsets of $\mathrm{dis}_{G_A}(X)$. Since $\mathrm{dis}_{G_{A'}}(X) \subseteq \{X\} \cup \mathrm{mb}(X,A')$ (by the definition of the Markov blanket), $\mathrm{dis}_{G_{A'}}(X) \cap \mathrm{h}(X,A') = \emptyset$. Thus, we can decompose the set $\mathrm{dis}_{G_A}(X)$ into 3 disjoint subsets as follows.

$$\mathrm{dis}_{G_A}(X) = \mathrm{dis}_{G_{A'}}(X) \cup \mathrm{h}(X,A') \cup B \tag{16}$$

where

$$B \equiv \mathrm{dis}_{G_A}(X) \setminus \Big(\mathrm{dis}_{G_{A'}}(X) \cup \mathrm{h}(X,A')\Big).$$

We have

$$\begin{aligned} A' \cap \mathrm{dis}_{G_A}(X) &= A' \cap \Big(\mathrm{dis}_{G_{A'}}(X) \cup \mathrm{h}(X,A') \cup B\Big) \\ &= \mathrm{dis}_{G_{A'}}(X) \cup B \end{aligned}$$

since $\mathrm{dis}_{G_{A'}}(X) \subseteq A', B \subseteq A'$ and $A' \cap \mathrm{h}(X,A') = \emptyset$. From the assumption in Lemma 18 that $A' \cap \mathrm{dis}_{G_A}(X) = \mathrm{dis}_{G_{A'}}(X)$, it follows that $B = \emptyset$. Thus, from (16), we have

$$\mathrm{dis}_{G_A}(X) \setminus \mathrm{dis}_{G_{A'}}(X) = \mathrm{h}(X,A'). \tag{17}$$

Let $T = \mathrm{dis}_{G_A}(X) \setminus \mathrm{dis}_{G_{A'}}(X) = \mathrm{h}(X,A')$. Then,

$$\begin{aligned} \mathrm{mb}(X,A) &= \mathrm{mb}(X,A') \cup T \cup \mathrm{pa}_G(T) \\ &= \mathrm{mb}(X,A') \cup T \end{aligned} \tag{18}$$

since $\mathrm{pa}_G(T) \subseteq \mathrm{mb}(X,A')$ by our assumption. Thus A decomposes into

$$A = A' \cup \mathrm{de}_{G_A}(T) \tag{19}$$

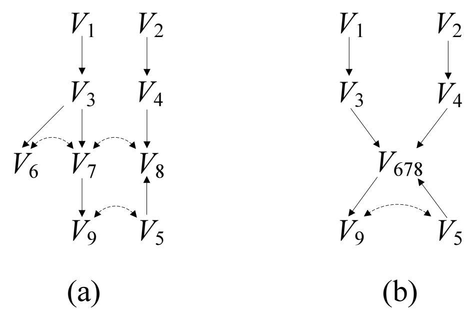


Figure 6: (a) An ADMG with directed mixed cycles (b) Illustration of the procedure **GetOrdering**. The modified graph after the first step is shown.

since $\mathrm{de}_{G_A}(T) \subseteq A$ and (15).

The key relationships among $A, \mathrm{dis}_{G_A}(X), \mathrm{mb}(X,A)$ and $A', \mathrm{dis}_{G_{A'}}(X), \mathrm{mb}(X,A')$ are given by (17)–(19). Figure 5 shows these relationships. We are now ready to prove that $I(\{X\}, \mathrm{mb}(X,A'), A' \setminus (\mathrm{mb}(X,A') \cup \{X\}))$ can be derived from $I(\{X\}, \mathrm{mb}(X,A), A \setminus (\mathrm{mb}(X,A) \cup \{X\}))$. From (18) and (19), it follows that

$$A \setminus (\mathrm{mb}(X,A) \cup \{X\}) = (A' \cup \mathrm{de}_{G_A}(T)) \setminus (\mathrm{mb}(X,A') \cup \{X\} \cup T).$$

Since $A' \cap \mathrm{de}_{G_A}(T) = \emptyset, (\mathrm{mb}(X,A') \cup \{X\}) \cap T = \emptyset, \mathrm{mb}(X,A') \cup \{X\} \subseteq A'$ and $T \subseteq \mathrm{de}_{G_A}(T)$, we have

$$A \setminus (\mathrm{mb}(X,A) \cup \{X\}) = \Big(A' \setminus (\mathrm{mb}(X,A') \cup \{X\})\Big) \cup \Big(\mathrm{de}_{G_A}(T) \setminus T\Big). \tag{20}$$

Plugging (18) and (20) into (14), we get

$$I\Big(\{X\}, \mathrm{mb}(X,A') \cup T, \Big(A' \setminus (\mathrm{mb}(X,A') \cup \{X\})\Big) \cup \Big(\mathrm{de}_{G_A}(T) \setminus T\Big)\Big).$$

From the decomposition axiom, it follows that

$$I(\{X\}, \mathrm{mb}(X,A') \cup T, A' \setminus (\mathrm{mb}(X,A') \cup \{X\})). \tag{21}$$

The last step is to remove T from the conditioning set to obtain $I(\{X\}, \mathrm{mb}(X,A'), A' \setminus (\mathrm{mb}(X,A') \cup \{X\}))$. We claim that

$$I(T, \mathrm{mb}(X,A'), A' \setminus (\mathrm{mb}(X,A') \cup \{X\})). \tag{22}$$

We first argue that T is d-separated from $A' \setminus (\mathrm{mb}(X,A') \cup \{X\})$ given $\mathrm{mb}(X,A')$. Consider a vertex $t \in T$ and a vertex $\alpha \in A' \setminus (\mathrm{mb}(X,A') \cup \{X\})$. Note that for any bi-directed edge $t \leftrightarrow \beta$ in G_A, β is either in T or $\mathrm{dis}_{G_{A'}}(X)$. There are only four possible cases for any path in G_A from t to α.

1. $t \leftarrow \gamma \cdots \alpha$

2. $t \rightarrow \cdots \rightarrow \gamma \leftarrow\!\ast \cdots \alpha$

3. $t \leftrightarrow \leftrightarrow \cdots \leftrightarrow \delta \leftarrow \gamma \cdots \alpha$

4. $t \leftrightarrow \leftrightarrow \cdots \leftrightarrow \delta \rightarrow \cdots \rightarrow \gamma \leftarrow\!\!* \cdots \alpha$

In case 1, $\gamma \in \text{mb}(X,A')$ since $\text{pa}_G(T) \subseteq \text{mb}(X,A')$. Thus, the path is not d-connecting. In case 2, γ is a descendant of t. Since $\text{mb}(X,A')$ does not contain any descendant of t, the path is not d-connecting. Case 3 is similar to case 1, but there are one or more bi-directed edges after t. δ is either in T or $\text{dis}_{G_{A'}}(X)$. It follows that $\gamma \in \text{mb}(X,A')$, so the path is not d-connecting. Case 4 is similar to case 2, but there are one or more bi-directed edges after t. If δ is in T, the argument for case 2 can be applied. If δ is in $\text{dis}_{G_{A'}}(X)$, then $\delta \in \text{mb}(X,A')$, which implies that the path is not d-connecting. This establishes that T is d-separated from $A' \setminus (\text{mb}(X,A') \cup \{X\})$ given $\text{mb}(X,A')$. By the assumption that P satisfies the global Markov property for $G_{\text{pre}_{G,\prec}(X)\setminus\{X\}}$, (22) holds. Finally, from (21),(22) and the contraction axiom, it follows that $I(\{X\}, \text{mb}(X,A'), A' \setminus (\text{mb}(X,A') \cup \{X\}))$. ■

For example, consider the ADMG G in Figure 2 and a consistent ordering $V_1 \prec V_2 \prec V_3 \prec V_4 \prec V_5 \prec V_6 \prec V_7$. Assume that the global Markov property for $G_{\text{pre}_{G,\prec}(V_6)}$ is satisfied. Let $A = \{V_1,V_2,V_3,V_4,V_5,V_6,V_7\}$ and $A' = \{V_1,V_2,V_3,V_4,V_6,V_7\}$. Then, $\text{dis}_{G_A}(V_7) = \{V_5,V_6,V_7\}$, $\text{dis}_{G_{A'}}(V_7) = \{V_6,V_7\}$, $A' \cap \text{dis}_{G_A}(V_7) = \{V_6,V_7\} = \text{dis}_{G_{A'}}(V_7)$ and $\text{pa}_G(\text{dis}_{G_A}(V_7) \setminus \text{dis}_{G_{A'}}(V_7)) = \{V_3\} \subseteq \{V_3,V_4,V_6\} = \text{mb}(V_7,A')$. Thus, $I(\{V_7\},\{V_3,V_4,V_6\},\{V_1,V_2\})$ follows from $I(\{V_7\},\{V_3,V_4,V_5,V_6\},\{V_1,V_2\})$. Note that in the proof of Lemma 18, the composition axiom is not used. Thus, Lemma 18 can be used to reduce the ordered local Markov property for ADMGs associated with an arbitrary probability distribution. Also, note that the condition that P satisfies the global Markov property for $G_{\text{pre}_{G,\prec}(X)\setminus\{X\}}$ is always satisfied in a recursive application of this lemma in Theorem 21.

We now introduce a key concept in eliminating redundant conditional independence relations from (LMP,$\prec$).

Definition 19 (C-ordered Vertex) *Given a consistent ordering $\prec$ on the vertices of an ADMG G, a vertex X is said to be c-ordered in $\prec$ if*

1. *all vertices in $\text{dis}_G(X) \cap \text{pre}_{G,\prec}(X)$ are consecutive in $\prec$ and*

2. *for any two vertices Y and Z in $\text{dis}_G(X) \cap \text{pre}_{G,\prec}(X)$, there is no directed edge between Y and Z.*

If no bi-directed edge is connected to X, then X is defined to be c-ordered. For example, consider the ADMG G in Figure 6 (a). $\prec$: $V_1 \prec V_2 \prec V_3 \prec V_4 \prec V_5 \prec V_6 \prec V_7 \prec V_8 \prec V_9$ is a consistent ordering on the vertices of G. $V_1,V_2,\ldots,V_8$ are c-ordered in $\prec$ but V_9 is not since V_5 and V_9 are not consecutive in $\prec$.

The key observation, which will be proved, is that c-ordered vertices contribute to eliminating many redundant conditional independence relations invoked by the ordered local Markov property (LMP,$\prec$). We provide two procedures. The first procedure **ReduceMarkov** in Figure 7 constructs a list of conditional independence relations in which some redundant conditional independence relations from (LMP,$\prec$) are not included (all the conditional independence relations identified by Lemma 18 are not included). **ReduceMarkov** takes as input a fixed ordering $\prec$. The second procedure **GetOrdering** in Figure 9 gives a good ordering that might have many c-ordered vertices.

We first describe the procedure **ReduceMarkov**. Given an ADMG G and a consistent ordering $\prec$, **ReduceMarkov** gives a set of conditional independence relations which will be shown to be

```
procedure ReduceMarkov
INPUT: An ADMG $G$ and a consistent ordering $\prec$ on the vertices of $G$
OUTPUT: A set of conditional independence relations $S$
$S \leftarrow \emptyset$
for $i = 1, \ldots, n$ do
  $I_i \leftarrow \emptyset$
  if $V_i$ is c-ordered in $\prec$ then

Figure 7: A procedure to generate a reduced set of conditional independence relations for an ADMG G and a consistent ordering $\prec$

equivalent to the global Markov property for G. For each vertex V_i, **ReduceMarkov** generates a set of conditional independence relations. If V_i is c-ordered, the relations that correspond to the pairwise Markov property are generated. Otherwise, the relations that correspond to the ordered local Markov property are generated, and Lemma 18 is used to remove some redundant relations. The output $S = \textbf{ReduceMarkov}(G, \prec)$ can be described as follows:

$$S = \bigcup_{X : X \text{ is c-ordered in } \prec} \Big(\bigcup_{Y : Y \prec X} I(\{X\}, Z_{XY}, \{Y\}) \Big) \bigcup \bigcup_{X : X \text{ is not c-ordered in } \prec} \Big(\bigcup_{\substack{\text{all maximal sets } A \\ \text{with respect to mb}(X,A): \\ X \in A \subseteq \text{pre}_{G,\prec}(X), \\ A \notin \text{rd}_{G,\prec}(X)}} I(\{X\}, \text{mb}(X,A), A \setminus (\text{mb}(X,A) \cup \{X\})) \Big) \tag{23}$$

where Z_{XY} is any set of vertices such that Z_{XY} d-separates X from Y and $\forall Z \in Z_{XY}$, $d(X,Z) < d(X,Y)$.

If a vertex X is c-ordered, $O(n)$ conditional independence relations (or zero partial correlations) are added to S. Otherwise, $O(2^n)$ conditional independence relations may be added to S and $O(n2^n)$ zero partial correlations may be invoked. Furthermore, a c-ordered vertex typically involves a smaller conditioning set. $I(\{X\}, Z_{XY}, \{Y\})$ has the conditioning set $|Z_{XY}| \leq |\text{pa}_G(X)|$ while $I(\{X\}, \text{mb}(X,A), A \setminus (\text{mb}(X,A) \cup \{X\}))$ has the conditioning set $|\text{mb}(X,A)| \geq |\text{pa}_G(X)|$.

We now prove that the conditional independence relations produced by **ReduceMarkov** can derive all the conditional independence relations invoked by the global Markov property.

Definition 20 **(S-Markov Property (S-MP,$\prec$))** *Let G be an ADMG and $\prec$ be a consistent ordering on the vertices of G. Let S be the set of conditional independence relations given by* ***ReduceMarkov****$(G,\prec)$. A probability distribution P is said to satisfy the S-Markov property for G with respect to $\prec$, if*

(S-MP,$\prec$) *P satisfies all the conditional independence relations in S.*

Theorem 21 *Let G be an ADMG and $\prec$ be a consistent ordering on the vertices of G. Let S be the set of conditional independence relations given by* ***ReduceMarkov****$(G,\prec)$. If a probability distribution P satisfies the composition axiom, then*

$$\text{(GMP)} \Longleftrightarrow (S\text{-MP},\prec).$$

Proof: (GMP) $\Longrightarrow$ (S-MP,$\prec$) since every conditional independence relation in (S-MP,$\prec$) corresponds to a valid d-separation. We show (S-MP,$\prec$) $\Longrightarrow$ (GMP). Without any loss of generality, let $\prec$: $V_1 \prec \ldots \prec V_n$. The proof is by induction on the sequence of ordered vertices. Suppose that (S-MP,$\prec$) $\Longrightarrow$ (GMP) holds for $V_1,\ldots V_{i-1}$. Let $S_{i-1} = I_1 \cup \ldots \cup I_{i-1}$. Then, by the induction hypothesis, S_{i-1} contains all the conditional independence relations invoked by (LMP,$\prec$) for $V_1,\ldots V_{i-1}$. If V_i is not c-ordered, $I_i = I(\{V_i\}, \mathrm{mb}(V_i,A), A \setminus (\mathrm{mb}(V_i,A) \cup \{V_i\}))$ for all maximal ancestral sets A such that $V_i \in A \subseteq \mathrm{pre}_{G,\prec}(V_i)$, $A \notin \mathrm{rd}_{G,\prec}(V_i)$. The conditional independence relations invoked by (LMP,$\prec$) with respect to V_i and any $A \in \mathrm{rd}_{G,\prec}(V_i)$ can be derived from other conditional independence relations by Lemma 18. Thus, $S_i = S_{i-1} \cup I_i$ contains all the conditional independence relations invoked by (LMP,$\prec$) for $V_1,\ldots V_i$, which implies (GMP). If V_i is c-ordered, applying the arguments in the proof of (GMP) $\Longleftrightarrow$ (PMP,$\prec_c$), we have

$$I(\{V_i\}, \mathrm{pa}_G(V_i), \mathrm{pre}_{G,\prec}(V_i) \setminus (\{V_i\} \cup \mathrm{pa}_G(V_i) \cup \mathrm{sp}_G(V_i))).$$

By the induction hypothesis and the definition of a c-ordered vertex, we have for all $V_j \in \mathrm{dis}_G(V_i) \cap \mathrm{pre}_{G,\prec}(V_i)$

$$I(\{V_j\}, \mathrm{pa}_G(V_j), \mathrm{pre}_{G,\prec}(V_j) \setminus (\{V_j\} \cup \mathrm{pa}_G(V_j) \cup \mathrm{sp}_G(V_j))).$$

By the arguments in the proof of (GMP) $\Longleftrightarrow$ (RLMP,$\prec_c$), we have for all maximal ancestral sets A such that $V_i \in A \subseteq \mathrm{pre}_{G,\prec}(V_i)$

$$I(\{V_i\}, \mathrm{mb}(V_i,A), A \setminus (\mathrm{mb}(V_i,A) \cup \{V_i\})).$$

Therefore, $S_i = S_{i-1} \cup I_i$ derives all the conditional independence relations invoked by (GMP). ■

As we have seen earlier, the number of zero partial correlations critically depends on the number of c-ordered vertices in a given ordering. This motivates us to find the ordering with the most c-ordered vertices. An obvious way of finding this ordering is to explore the space of all the consistent orderings. However, this exhaustive search may become infeasible as the number of vertices grows. We propose a greedy algorithm to get an ordering that has a large number of c-ordered vertices. The basic idea is to first find a large c-component in which many vertices can be c-ordered and place the vertices consecutively in the ordering, then repeating this until we cannot find a set of vertices that can be c-ordered. To describe the algorithm, we define the following notion, which identifies the largest subset of a c-component that can be c-ordered.

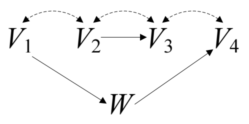

Figure 8: The c-component $\{V_1,V_2,V_3,V_4\}$ has the root set $\{V_1,V_2\}$

Definition 22 (Root Set) *The root set of a c-component C, denoted* $\mathrm{rt}(C)$ *is defined to be the set* $\{V_i \in C \mid \textit{there is no } V_j \in C \textit{ such that a directed path } V_j \to \ldots \to V_i \textit{ exists in } G\}$.

For example, the c-component $\{V_1,V_2,V_3,V_4\}$ in Figure 8 has the root set $\{V_1,V_2\}$. V_3 and V_4 are not in the root set since there are paths $V_2 \to V_3$ and $V_1 \to W \to V_4$. The root set has the following properties.

Proposition 23 *Let $\prec$ be a consistent ordering on the vertices of an ADMG G and C be a c-component of G. If the vertices in* $\mathrm{rt}(C)$ *are consecutive in $\prec$, then all the vertices in* $\mathrm{rt}(C)$ *are c-ordered in $\prec$.*

Proof: Assume that the vertices in $\mathrm{rt}(C)$ are consecutive in $\prec$. Then, for $X \in \mathrm{rt}(C)$, $\mathrm{dis}_G(X) \cap \mathrm{pre}_{G,\prec}(X) \subseteq \mathrm{rt}(C)$. Thus, there is no directed edge between any two vertices in $\mathrm{dis}_G(X) \cap \mathrm{pre}_{G,\prec}(X)$. ■

Proposition 24 *Let $\prec$ be a consistent ordering on the vertices of an ADMG G and C be a c-component of G. If a vertex X in C is c-ordered in $\prec$, then $X \in$* $\mathrm{rt}(C)$.

Proof: Assume that X is c-ordered in $\prec$. Suppose for a contradiction that $X \notin \mathrm{rt}(C)$. Then, there exists an ancestor Y of X in C. If there exists a vertex Z such that $Z \notin C$, $Y \to \cdots \to Z \to \cdots \to X$. Then, the first condition of a c-ordered vertex is violated. Otherwise, the second condition is violated. ■

Proposition 23 and 24 imply that the root set of a c-component is the largest subset of the c-component that can be c-ordered in a consistent ordering. If G does not have directed mixed cycles, $\mathrm{rt}(C) = C$ for every c-component C.

The procedure **GetOrdering** in Figure 9 is our proposed greedy algorithm that generates a good consistent ordering for G. In Step 1, it searches for the largest root set M and then merges all the vertices in M to one vertex V_M modifying edges accordingly. Then, it repeats the same operation for the modified graph until there is no root set that contains more than one vertex. Since the vertices in a root set are merged at each iteration, the modified graph is acyclic as otherwise there would be a directed path between two vertices in the root set, which contradicts the condition of a root set. After Step 1, we can easily obtain a consistent ordering for the original graph from the modified graph.

4.2 An Example

We show the application of the procedures **ReduceMarkov** and **GetOrdering** by considering the ADMG G in Figure 6 (a). First, we apply **GetOrdering** to get a consistent ordering on the vertices V of G. In Step 1, we first look for the largest root set. The c-component $\{V_6,V_7,V_8\}$ has the largest

```
procedure GetOrdering
INPUT: An ADMG $G$
OUTPUT: A consistent ordering $\prec$ on $V$
Step 1:
$G' \leftarrow G$ ($V'$ is the set of vertices of $G$)
while (there is a c-component $C$ of $G'$ such that $|\mathrm{rt}(C)| > 1$) do
  $M \leftarrow \emptyset$
  for each c-component $C$ of $G'$ do
    if $|\mathrm{rt}(C)| > |M|$ then
      $M \leftarrow \mathrm{rt}(C)$
    end if
  end for
  Add a vertex $V_M$ to $G'_{V' \setminus M}$
  Draw an edge $V_M \leftarrow X$ (respectively $V_M \rightarrow X, V_M \leftrightarrow X$) if there is
  $Y \leftarrow X$ (respectively $Y \rightarrow X, Y \leftrightarrow X$) in $G'$ such that $Y \in M, X \in V' \setminus M$
  Let $G'$ be the resulting graph
end while
Step 2:
Let $\prec'$ be any consistent ordering on $V'$. Construct a consistent ordering $\prec$ from $\prec'$ by replacing
each $V_S \in V' \setminus V$ with the vertices in $S$ (the ordering of the vertices in $S$ is arbitrary)
```

Figure 9: A greedy algorithm to generate a good consistent ordering on the vertices of an ADMG G

root set $\{V_6, V_7, V_8\}$. Then, the vertices in $\{V_6, V_7, V_8\}$ are merged into a vertex V_{678}. Figure 6 (b) shows the modified graph G' after the first iteration of the while loop. In the next iteration, we find that every c-component has the root set of size 1. Note that for $C = \{V_5, V_9\}$, $\mathrm{rt}(C) = \{V_5, V_9\}$ in G but $\mathrm{rt}(C) = \{V_5\}$ in G'. Thus, Step 1 ends. In Step 2, from G' in Figure 6 (b), we can obtain an ordering $\prec'$: $V_1 \prec V_2 \prec V_3 \prec V_4 \prec V_5 \prec V_{678} \prec V_9$. This is converted to a consistent ordering $\prec$: $V_1 \prec V_2 \prec V_3 \prec V_4 \prec V_5 \prec V_6 \prec V_7 \prec V_8 \prec V_9$ for G.

With the ordering $\prec$, we now apply **ReduceMarkov** to obtain a set of conditional independence relations that can derive those invoked by the global Markov property. It is easy to see that the vertices $V_1, \ldots, V_8$ are c-ordered in $\prec$. Thus, the following conditional independence relations corresponding to the pairwise Markov property are added to the set S (initially empty).

$$\begin{aligned}
&I(\{V_2\}, \emptyset, \{V_1\}), && I(\{V_3\}, \emptyset, \{V_2\}),\\
&I(\{V_4\}, \emptyset, \{V_3, V_1\}), && I(\{V_5\}, \emptyset, \{V_4, V_3, V_2, V_1\}),\\
&I(\{V_6\}, \emptyset, \{V_5, V_4, V_2\}), && I(\{V_6\}, \{V_3\}, \{V_1\}),\\
&I(\{V_7\}, \emptyset, \{V_5, V_4, V_2\}), && I(\{V_7\}, \{V_3\}, \{V_1\}),\\
&I(\{V_8\}, \emptyset, \{V_6, V_3, V_1\}), && I(\{V_8\}, \{V_4\}, \{V_2\}).
\end{aligned} \tag{24}$$

V_9 is not c-ordered in $\prec$ since V_5 is not adjacent in $\prec$. Thus, we use the ordered local Markov property (LMP,$\prec$) for V_9. The maximal ancestral sets that we need to consider are

$$A_1 = \text{an}_G(\{V_6,V_8,V_9\}) = \{V_1,V_2,V_3,V_4,V_5,V_6,V_7,V_8,V_9\} \text{ and}$$
$$A_2 = \text{an}_G(\{V_4,V_6,V_9\}) = \{V_1,V_2,V_3,V_4,V_6,V_7,V_9\}.$$

The corresponding conditional independence relations are

$$I(\{V_9\},\{V_7,V_5\},\{V_8,V_6,V_4,V_3,V_2,V_1\}), \tag{25}$$
$$I(\{V_9\},\{V_7\},\{V_6,V_4,V_3,V_2,V_1\}). \tag{26}$$

However, it turns out that $A_2 \in \text{rd}_{G,\prec}(V_9)$ and (26) is not added to S. We check the condition of Lemma 18. The global Markov property for $G_{\text{pre}_{G,\prec}(V_8)}$ is satisfied by (24). Also,

$$\text{dis}_{G_{A_1}}(V_9) = \{V_5,V_9\},$$
$$\text{dis}_{G_{A_2}}(V_9) = \{V_9\},$$
$$A_2 \cap \text{dis}_{G_{A_1}}(V_9) = \{V_9\} = \text{dis}_{G_{A_2}}(V_9),$$
$$\text{pa}_G(\text{dis}_{G_{A_1}}(V_9) \setminus \text{dis}_{G_{A_2}}(V_9)) = \emptyset \subseteq \{V_7\} = \text{mb}(V_9,A_2).$$

Therefore, the condition of Lemma 18 is satisfied and it follows that (26) is redundant. To see how much we reduced the testing requirements, the conditional independence relations invoked by (LMP,$\prec$) are shown below.

$$\begin{array}{ll}
I(\{V_2\},\emptyset,\{V_1\}), & I(\{V_3\},\{V_1\},\{V_2\}),\\
I(\{V_4\},\{V_2\},\{V_3,V_1\}), & I(\{V_5\},\emptyset,\{V_4,V_3,V_2,V_1\}),\\
I(\{V_6\},\{V_3\},\{V_5,V_4,V_2,V_1\}), & I(\{V_7\},\{V_3\},\{V_5,V_4,V_2,V_1\}),\\
I(\{V_7\},\{V_6,V_3\},\{V_5,V_4,V_2,V_1\}), & I(\{V_8\},\{V_5,V_4\},\{V_6,V_3,V_2,V_1\}),\\
I(\{V_8\},\{V_7,V_5,V_4,V_3\},\{V_2,V_1\}), & I(\{V_8\},\{V_7,V_6,V_5,V_4,V_3\},\{V_2,V_1\}),\\
I(\{V_9\},\{V_7\},\{V_6,V_4,V_3,V_2,V_1\}), & I(\{V_9\},\{V_7,V_5\},\{V_8,V_6,V_4,V_3,V_2,V_1\}).
\end{array} \tag{27}$$

S invokes 26 zero partial correlations while (LMP,$\prec$) invokes 39. Also, S involves much smaller conditioning sets. We have at most one vertex in each conditioning set in (24) and two vertices in (25) while 23 zero partial correlations in (27) involve more than 2 vertices in the conditioning set.

The ADMG G in this example turns out to be a MAG. As we discussed in Section 3.4.1, we have two options: either we use the constraints in (24) and (25) or the constraints given by the pairwise Markov property for MAGs. In this example, both sets of constraints involve the same number of zero partial correlations. However, the pairwise Markov property for MAGs involves much larger conditioning sets. For example, the pairwise Markov property for MAGs gives the following conditional independence relation for the pair V_6 and V_8: $I(\{V_8\},\{V_5,V_4,V_3,V_2,V_1\},\{V_6\})$. Our method uses an empty set as the conditioning set for the pair. Hence, in this example, we are better off using the constraints in (24) and (25).

4.3 Comparison of (LMP,$\prec$) and (S-MP,$\prec$)

From (23), it is clear that (S-MP,$\prec$) invokes fewer conditional independence relations than (LMP,$\prec$) if there are c-ordered vertices in $\prec$. But how much more economical is (S-MP,$\prec$) than (LMP,$\prec$) and for what type of graphs is the reduction large?

For simplicity, we will compare the number of conditional independence relations rather than zero partial correlations and ignore the reduction done by Lemma 18. For now assume

$$S = \bigcup_{X:X \text{ is c-ordered in } \prec} I(\{X\}, \mathrm{pa}_G(X), \mathrm{pre}_{G,\prec}(X) \setminus (\{X\} \cup \mathrm{pa}_G(X) \cup \mathrm{sp}_G(X))) \bigcup$$
$$\bigcup_{X:X \text{ is not c-ordered in } \prec} \Big(\bigcup_{\substack{\text{all maximal sets } A \\ \text{with respect to } \mathrm{mb}(X,A): \\ X \in A \subseteq \mathrm{pre}_{G,\prec}(X)}} I\big(\{X\}, \mathrm{mb}(X,A), A \setminus (\mathrm{mb}(X,A) \cup \{X\})\big)\Big).$$

Let $\mathrm{M}(X,\prec)$ be the number of different Markov blankets of a vertex X, that is, $\mathrm{M}(X,\prec) = \Big|\{\mathrm{dis}_{G_A}(X) \mid A \text{ is an ancestral set such that } X \in A \subseteq \mathrm{pre}_{G,\prec}(X)\}\Big|$, and $\mathrm{C}(\prec)$ be the set of vertices that are c-ordered in $\prec$. Then, (LMP,$\prec$) lists $\sum_{X \in V} \mathrm{M}(X,\prec)$ conditional independence relations and (S-MP,$\prec$) lists $|\mathrm{C}(\prec)| + \sum_{X \notin \mathrm{C}(\prec)} \mathrm{M}(X,\prec)$ conditional independence relations. Hence, the difference in the number of conditional independence relations between (LMP,$\prec$) and (S-MP,$\prec$) is

$$\sum_{X \in \mathrm{C}(\prec)} \Big(\mathrm{M}(X,\prec) - 1\Big).$$

This difference is large when $|\mathrm{C}(\prec)|$ or $\mathrm{M}(X,\prec)$ for each X is large.

The size of $\mathrm{C}(\prec)$ depends on the number of directed mixed cycles. From Definition 19, it follows that $\mathrm{C}(\prec)$ is large if there are a small number of directed mixed cycles. Note that a directed mixed cycle such as that in Figure 4 induces the violation of the first condition in Definition 19 and a directed mixed cycle of the form $\alpha \overset{\leftrightarrow}{\rightarrow} \beta$ induces the violation of the second condition in Definition 19.

$\mathrm{M}(X,\prec)$ depends on the structure of $\mathrm{dis}_G(X) \cap \mathrm{pre}_{G,\prec}(X)$. We will reformulate $\mathrm{M}(X,\prec)$ to show the properties that affect $\mathrm{M}(X,\prec)$. Let $G_{\leftrightarrow,\mathrm{dis}}(X,\prec) = (V', E')$ where $V' = \mathrm{dis}_G(X) \cap \mathrm{pre}_{G,\prec}(X)$ and $E' = \{V_i \leftrightarrow V_j \mid V_i \leftrightarrow V_j \text{ in } G_{V'}\}$. For example, for an ADMG G in Figure 8 and an ordering $V_1 \prec V_2 \prec V_3 \prec V_4$, $G_{\leftrightarrow,\mathrm{dis}}(V_3,\prec)$ is $V_1 \leftrightarrow V_2 \leftrightarrow V_3$. Let $G_{\leftrightarrow,\mathrm{dis}}(X,\prec)_S$ be the induced subgraph of $G_{\leftrightarrow,\mathrm{dis}}(X,\prec)$ on a set $S \subseteq \mathrm{dis}_G(X) \cap \mathrm{pre}_{G,\prec}(X)$. Then, $\mathrm{M}(X,\prec) = \Big|\{S \mid S \subseteq \mathrm{dis}_G(X) \cap \mathrm{pre}_{G,\prec}(X)$ such that $G_{\leftrightarrow,\mathrm{dis}}(X,\prec)_S$ is a *connected component* of $G_{\leftrightarrow,\mathrm{dis}}(X,\prec)_{S \cup (\mathrm{an}_G(S) \cap \mathrm{dis}_G(X) \cap \mathrm{pre}_{G,\prec}(X))}\}\Big|$ that is, $\mathrm{M}(X,\prec)$ corresponds to a set of subsets S of $\mathrm{dis}_G(X) \cap \mathrm{pre}_{G,\prec}(X)$ satisfying two conditions: (i) $G_{\leftrightarrow,\mathrm{dis}}(X,\prec)_S$ is connected; and (ii) for all $Y \in \Big(\mathrm{an}_G(S) \cap \mathrm{dis}_G(X) \cap \mathrm{pre}_{G,\prec}(X)\Big) \setminus S$, there is no path from Y to any vertices in S. The condition (i) implies that $\mathrm{M}(X,\prec)$ will be large if the vertices in $\mathrm{dis}_G(X) \cap \mathrm{pre}_{G,\prec}(X)$ are connected by many bi-directed edges. The condition (ii) implies that $\mathrm{M}(X,\prec)$ will be large if there are few directed mixed cycles. Note that for ADMGs without directed mixed cycles, (ii) trivially holds since $\Big(\mathrm{an}_G(S) \cap \mathrm{dis}_G(X) \cap \mathrm{pre}_{G,\prec}(X)\Big) \setminus S = \emptyset$. For example, consider a subset of vertices $\{V_1, \ldots, V_k\}$ in an ADMG with edges $V_i \leftrightarrow V_k, i = 1, \ldots, k-1$, which has no directed mixed cycles. Then, for an ordering $V_1 \prec \ldots \prec V_k$, $\mathrm{M}(V_k,\prec) = 2^{k-1}$. Also, consider a subset of vertices $\{V_1, \ldots, V_k\}$ in an ADMG with edges $V_1 \overset{\leftrightarrow}{\rightarrow} V_2 \overset{\leftrightarrow}{\rightarrow} \cdots \overset{\leftrightarrow}{\rightarrow} V_k$, which has $k-1$ directed mixed cycles. Then, $\mathrm{M}(V_k,\prec) = 1$. Hence, it is clear that $\mathrm{M}(X,\prec)$ is large if

1. the set $\mathrm{dis}_G(X) \cap \mathrm{pre}_{G,\prec}(X)$ is large,

2. there are many bi-directed edges connecting vertices in $\mathrm{dis}_G(X) \cap \mathrm{pre}_{G,\prec}(X)$, and

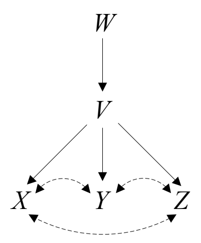

Figure 10: An example ADMG for which using (S-MP,$\prec$) is most beneficial. There is no directed mixed cycle and each c-component is a clique joined by bi-directed edges.

3. there are few directed mixed cycles.

Thus, (LMP,$\prec$) will invoke a large number of conditional independence relations for an ADMG with few directed mixed cycles and large c-components with many bi-directed edges. For such an ADMG, $\sum_{X\in \mathrm{C}(\prec)}\Big(\mathrm{M}(X,\prec)-1\Big)$, the reduction made by (S-MP,$\prec$), is also large. An extreme case is an ADMG that has no directed mixed cycles and each c-component of which is a clique joined by bi-directed edges. An example of such an ADMG is given in Figure 10. For this ADMG and an ordering $W \prec V \prec X \prec Y \prec Z$, (LMP,$\prec$) invokes $\mathrm{M}(W,\prec)+\mathrm{M}(V,\prec)+\mathrm{M}(X,\prec)+\mathrm{M}(Y,\prec)+\mathrm{M}(Z,\prec) = 1+1+1+2+4 = 9$ conditional independence relations while (S-MP,$\prec$) invokes $|\mathrm{C}(\prec)| = n = 5$ conditional independence relations. If we enlarge the clique joined by bi-directed edges such that it contains k vertices, then (LMP,$\prec$) invokes $2+\sum_{i=0}^{k-1}2^i = 1+2^k$ conditional independence relations while (S-MP,$\prec$) invokes $k+2$.

In general, although (S-MP,$\prec$) greatly reduces (LMP,$\prec$), it may still invoke an exponential number of conditional independence relations if there exist directed mixed cycles.

5. Conclusion and Discussion

We present local Markov properties for ADMGs representing linear SEMs with correlated errors. The results have applications in testing linear SEMs against the data by testing for zero partial correlations implied by the model. For general linear SEMs with correlated errors, we provide a procedure that lists a subset of zero partial correlations that will imply all other zero partial correlations implied by the model. In particular, for a class of models whose corresponding path diagrams contain no directed mixed cycles, this subset invokes one zero partial correlation for each pair of variables.

In general, our procedure may invoke an exponential number of zero partial correlations if the path diagram G satisfies all of the following properties: (i) G has large c-components; (ii) the vertices in each c-component are heavily connected by bi-directed edges; and (iii) G has directed mixed cycles. If one of these properties is not satisfied, then the number of zero partial correlations derived by our method is typically not exponential.

For the class of MAGs, which is a strict superclass of ADMGs without directed mixed cycles, one might use the pairwise Markov property for MAGs given in Richardson and Spirtes (2002) instead of our results in Section 4. However, when the two approaches give a similar number of constraints, it may be better to use our approach since it may use smaller conditioning sets as shown in the example in Section 4.2.

The potential advantages of testing linear SEMs based on vanishing partial correlations over the classical test method based on maximum likelihood estimation of the covariance matrix have been discussed in Pearl (1998), Shipley (2000), McDonald (2002) and Shipley (2003). The results presented in this paper provide a theoretical foundation for the practical applications of this test method in linear SEMs with correlated errors. How to implement this test method in practice still needs further study as it requires multiple testing of hypotheses about zero partial correlations (Shipley, 2000; Drton and Perlman, 2007). We also note that, in linear SEMs *without* correlated errors, all the constraints on the covariance matrix are implied by vanishing partial correlations. This also holds in linear SEMs *with* correlated errors that are represented by ADMGs *without* directed mixed cycles. However, it is possible that linear SEMs *with* correlated errors represented by ADMGs *with* directed mixed cycles may imply constraints on the covariance matrix that are not implied by zero partial correlations.

Although the intended application is in linear SEMs, the local Markov properties presented in the paper are valid for ADMGs associated with any probability distributions that satisfy the composition axiom. For example, any probability distribution that is faithful[5] to some DAG or undirected graph (and the marginals of the distribution) satisfies the composition axiom.

Model debugging for ADMGs using vanishing partial correlations is another area of current research. In this model debugging problem, the goal is to modify a graph based on the pattern of rejected hypotheses. The properties of ADMGs presented in this paper may facilitate the development of a new model debugging method.

Abstract

The problem of obtaining the maximum *a posteriori* estimate of a general discrete Markov random field (i.e., a Markov random field defined using a discrete set of labels) is known to be NP-hard. However, due to its central importance in many applications, several approximation algorithms have been proposed in the literature. In this paper, we present an analysis of three such algorithms based on convex relaxations: (i) LP-S: the linear programming (LP) relaxation proposed by Schlesinger (1976) for a special case and independently in Chekuri et al. (2001), Koster et al. (1998), and Wainwright et al. (2005) for the general case; (ii) QP-RL: the quadratic programming (QP) relaxation of Ravikumar and Lafferty (2006); and (iii) SOCP-MS: the second order cone programming (SOCP) relaxation first proposed by Muramatsu and Suzuki (2003) for two label problems and later extended by Kumar et al. (2006) for a general label set.

We show that the SOCP-MS and the QP-RL relaxations are equivalent. Furthermore, we prove that despite the flexibility in the form of the constraints/objective function offered by QP and SOCP, the LP-S relaxation *strictly dominates* (i.e., provides a better approximation than) QP-RL and SOCP-MS. We generalize these results by defining a large class of SOCP (and equivalent QP) relaxations which is dominated by the LP-S relaxation. Based on these results we propose some novel SOCP relaxations which define constraints using random variables that form cycles or cliques in the graphical model representation of the random field. Using some examples we show that the new SOCP relaxations strictly dominate the previous approaches.

Keywords: probabilistic models, MAP estimation, discrete MRF, convex relaxations, linear programming, second-order cone programming, quadratic programming, dominating relaxations

1. Introduction

Discrete random fields are a powerful tool to obtain a probabilistic formulation for various applications in computer vision and related areas (Boykov et al., 2001; Cohen, 1986). Hence, developing accurate and efficient algorithms for performing inference on a given discrete random field is of fundamental importance. In this work, we will focus on the problem of maximum a posteriori (MAP) estimation. MAP estimation is a key step in obtaining the solutions to many applications such as stereo, image stitching and segmentation (Szeliski et al., 2006). Furthermore, it is closely related to many important Combinatorial Optimization problems such as MAXCUT (Goemans and Williamson, 1995), multi-way cut (Dalhaus et al., 1994), metric labelling (Boykov et al., 2001; Kleinberg and Tardos, 1999) and 0-extension (Boykov et al., 2001; Karzanov, 1998).

Given data $\mathbf{D}$, a discrete random field models the distribution (i.e., either the joint or the conditional probability) of a labelling for a set of random variables. Each of these variables $\mathbf{v} = \{v_0, v_1, \cdots, v_{n-1}\}$ can take a label from a discrete set $\mathbf{l} = \{l_0, l_1, \cdots, l_{h-1}\}$. A particular labelling of variables $\mathbf{v}$ is specified by a function f whose domain corresponds to the indices of the random variables and whose range is the index of the label set, that is,

$$f : \{0, 1, \cdots, n-1\} \rightarrow \{0, 1, \cdots, h-1\}.$$

In other words, random variable v_a takes label $l_{f(a)}$. For convenience, we assume the model to be a Markov random field (MRF) while noting that all the results of this paper also apply to conditional random fields (CRF).

An MRF specifies a neighbourhood relationship $\mathcal{E}$ between the random variables, that is, $(a,b) \in \mathcal{E}$ if, and only if, v_a and v_b are neighbouring random variables. Within this framework, the joint probability of a labelling f given data $\mathbf{D}$ is specified as

$$\Pr(f, \mathbf{D}|\theta) = \frac{1}{Z(\theta)} \exp(-Q(f, \mathbf{D}; \theta)).$$

Here θ represents the parameters of the MRF and $Z(\theta)$ is a normalization constant which ensures that the probability sums to one (known as the partition function). Assuming a pairwise MRF (i.e., an MRF with maximum clique size of 2 according to the neighbourhood relationship $\mathcal{E}$), the energy $Q(f, \mathbf{D}; \theta)$ is given by

$$Q(f, \mathbf{D}; \theta) = \sum_{v_a \in \mathbf{v}} \theta^1_{a;f(a)} + \sum_{(a,b) \in \mathcal{E}} \theta^2_{ab;f(a)f(b)}.$$

The term $\theta^1_{a;f(a)}$ is called a unary potential since its value depends on the labelling of one random variable at a time. Similarly, $\theta^2_{ab;f(a)f(b)}$ is called a pairwise potential as it depends on a pair of random variables. Note that the assumption of pairwise MRF is not a severe restriction as any MRF can be converted into an equivalent (i.e., representing the same probability distribution) pairwise MRF, for example, see Yedidia et al. (2001). For further simplicity of notation, we assume that $\theta^2_{ab;f(a)f(b)} = w(a,b)d(f(a), f(b))$ where $w(a,b)$ is the weight that indicates the strength of the pairwise relationship between variables v_a and v_b, with $w(a,b) = 0$ if $(a,b) \notin \mathcal{E}$, and $d(\cdot,\cdot)$ is a distance function on the labels.[1] As will be seen later, this formulation of the pairwise potentials would allow us to concisely describe our results.

1. The pairwise potentials for any MRF can be represented in the form $\theta^2_{ab;ij} = w(a,b)d(i,j)$. This can be achieved by using a larger set of labels $\hat{\mathbf{l}} = \{l_{0;0}, \cdots, l_{0;h_1}, \cdots, l_{n-1;h_1}\}$ such that the unary potential of v_a taking label $l_{b;i}$ is $\theta^1_{a;i}$ if

We note that a subclass of this problem where $w(a,b) \geq 0$ and the distance function $d(\cdot,\cdot)$ is a semi-metric or a metric has been well-studied in the literature (Boykov et al., 2001; Chekuri et al., 2001; Kleinberg and Tardos, 1999). However, we will focus on the general MAP estimation problem. In other words, unless explicitly stated, we do not place any restriction on the form of the unary and pairwise potentials.

The problem of MAP estimation for a discrete MRF is well known to be NP-hard in general. Since it plays a central role in several applications, many approximate algorithms have been proposed in the literature. In this work, we analyze three such algorithms which are based on convex relaxations. Specifically, we consider: (i) LP-S, the linear programming (LP) relaxation of Chekuri et al. (2001), Koster et al. (1998), Schlesinger (1976), and Wainwright et al. (2005); (ii) QP-RL, the quadratic programming (QP) relaxation of Ravikumar and Lafferty (2006); and (iii) SOCP-MS, the second order cone programming (SOCP) relaxation of Kumar et al. (2006) and Muramatsu and Suzuki (2003). In order to provide an outline of these relaxations, we formulate the problem of MAP estimation as an Integer Program (IP).

1.1 Integer Programming Formulation

We define a binary variable vector $\mathbf{x}$ of length nh. We denote the element of $\mathbf{x}$ at index $a \cdot h + i$ as $x_{a;i}$ where $v_a \in \mathbf{v}$ and $l_i \in \mathbf{l}$. These elements $x_{a;i}$ specify a labelling f such that

$$x_{a;i} = \begin{cases} 1 & \text{if} \quad f(a) = i, \\ -1 & \text{otherwise.} \end{cases}$$

We say that the variable $x_{a;i}$ *belongs to* variable v_a since it defines whether the variable v_a takes the label l_i. Let $\mathbf{X} = \mathbf{x}\mathbf{x}^\top$. We refer to the $(a \cdot h + i, b \cdot h + j)^{th}$ element of the matrix $\mathbf{X}$ as $X_{ab;ij}$ where $v_a, v_b \in \mathbf{v}$ and $l_i, l_j \in \mathbf{l}$. Clearly the sum of the unary potentials for a labelling specified by $\mathbf{x}$ is given by

$$\sum_{v_a, l_i} \theta^1_{a;i} \frac{(1 + x_{a;i})}{2}.$$

Similarly the sum of the pairwise potentials for a labelling $\mathbf{x}$ is given by

$$\sum_{(a,b) \in \mathcal{E}, l_i, l_j} \theta^2_{ab;ij} \frac{(1 + x_{a;i})}{2} \frac{(1 + x_{b;j})}{2} = \sum_{(a,b) \in \mathcal{E}, l_i, l_j} \theta^2_{ab;ij} \frac{(1 + x_{a;i} + x_{b;j} + X_{ab;ij})}{4}.$$

Hence, the following IP finds the labelling with the minimum energy, that is, it is equivalent to the MAP estimation problem:

$$\begin{aligned} \text{IP:} \quad & \mathbf{x}^* = \arg\min_{\mathbf{x}} \textstyle\sum_{v_a, l_i} \theta^1_{a;i} \frac{(1+x_{a;i})}{2} + \sum_{(a,b) \in \mathcal{E}, l_i, l_j} \theta^2_{ab;ij} \frac{(1+x_{a;i}+x_{b;j}+X_{ab;ij})}{4} \\ \text{s.t.} \quad & \mathbf{x} \in \{-1, 1\}^{nh}, & (1) \\ & \textstyle\sum_{l_i \in \mathbf{l}} x_{a;i} = 2 - h, & (2) \\ & \mathbf{X} = \mathbf{x}\mathbf{x}^\top. & (3) \end{aligned}$$

$a = b$ and ∞ otherwise. In other words, a variable v_a can only take labels from the set $\{l_{a;0}, \cdots, l_{a;h-1}\}$ since all other labels will result in an energy value of ∞. The pairwise potential for variables v_a and v_b taking labels $l_{a;i}$ and $l_{b;j}$ respectively can then be represented in the form $w(a,b)d(a;i,b;j)$ where $w(a,b) = 1$ and $d(a;i,b;j) = \theta^2_{ab;ij}$. Note that using a larger set of labels $\hat{\mathbf{l}}$ will increase the time complexity of MAP estimation algorithms, but does not affect the analysis presented in this paper.

Constraints (1) and (3) specify that the variables $\mathbf{x}$ and $\mathbf{X}$ are binary such that $X_{ab;ij} = x_{a;i}x_{b;j}$. We will refer to them as the *integer constraints*. Constraint (2), which specifies that each variable should be assigned only one label, is known as the *uniqueness constraint*. Note that one uniqueness constraint is specified for each variable v_a. Solving the above IP is in general NP-hard. It is therefore common practice to obtain an approximate solution using convex relaxations. We describe four such convex relaxations below.

1.2 Linear Programming Relaxation

The LP relaxation, proposed by Schlesinger (1976) for a special case (where the pairwise potentials specify a hard constraint, that is, they are either 0 or ∞) and independently in Chekuri et al. (2001), Koster et al. (1998), and Wainwright et al. (2005) for the general case, is given as follows:

$$\begin{aligned}
\text{LP-S:}\quad & \mathbf{x}^* = \arg\min_{\mathbf{x}} \textstyle\sum_{v_a,l_i} \theta^1_{a;i}\frac{(1+x_{a;i})}{2} + \sum_{(a,b)\in\mathcal{E},l_i,l_j}\theta^2_{ab;ij}\frac{(1+x_{a;i}+x_{b;j}+X_{ab;ij})}{4} \\
\text{s.t.}\quad & \mathbf{x}\in[-1,1]^{nh}, \mathbf{X}\in[-1,1]^{nh\times nh}, \\
& \textstyle\sum_{l_i\in\mathbf{l}} x_{a;i} = 2-h, \\
& \textstyle\sum_{l_j\in\mathbf{l}} X_{ab;ij} = (2-h)x_{a;i}, \qquad (4)\\
& X_{ab;ij} = X_{ba;ji}, \qquad (5)\\
& 1+x_{a;i}+x_{b;j}+X_{ab;ij} \geq 0. \qquad (6)
\end{aligned}$$

In the above relaxation, which we call LP-S, only those elements $X_{ab;ij}$ of $\mathbf{X}$ are used for which $(a,b)\in\mathcal{E}$ and $l_i,l_j\in\mathbf{l}$. Unlike the IP, the feasibility region of the above problem is relaxed such that the variables $x_{a;i}$ and $X_{ab;ij}$ lie in the interval $[-1,1]$. Further, the constraint (3) is replaced by Equation (4) which is called the *marginalization constraint* (Wainwright et al., 2005). One marginalization constraint is specified for each $(a,b)\in\mathcal{E}$ and $l_i\in\mathbf{l}$. Constraint (5) specifies that $\mathbf{X}$ is symmetric. Constraint (6) ensures that $\theta^2_{ab;ij}$ is multiplied by a number between 0 and 1 in the objective function. These constraints (5) and (6) are defined for all $(a,b)\in\mathcal{E}$ and $l_i,l_j\in\mathbf{l}$. The formulation of the LP-S relaxation presented here uses a slightly different notation to the ones described in Kolmogorov (2006) and Wainwright et al. (2005). However, it can easily be shown that the two formulations are equivalent by using the variables $\mathbf{y}$ and $\mathbf{Y}$ instead of $\mathbf{x}$ and $\mathbf{X}$ such that $y_{a;i} = \frac{1+x_{a;i}}{2}, Y_{ab;ij} = \frac{1+x_{a;i}+x_{b;j}+X_{ab;ij}}{4}$. Throughout this paper, we will make use of the variables $\mathbf{x}$ and $\mathbf{X}$ instead of $\mathbf{y}$ and $\mathbf{Y}$. As will be seen in the subsequent sections, this would allow us to concisely describe our results. Note that the above constraints are not exhaustive, that is, it is possible to specify other constraints for the problem of MAP estimation (e.g., see § 1.3 and 1.5).

1.2.1 PROPERTIES OF THE LP-S RELAXATION

- Since the LP-S relaxation specifies a linear program it can be solved in polynomial time. A labelling f can then be obtained by rounding the (possibly fractional) solution of the LP-S.

- Using the rounding scheme of Kleinberg and Tardos (1999), the LP-S provides a multiplicative bound[2] of 2 when the pairwise potentials form a Potts model (Chekuri et al., 2001).

2. Consider a set of optimization problems $\mathcal{A}$ and a relaxation scheme defined over this set $\mathcal{A}$. In other words, for every optimization problem A $\in\mathcal{A}$, the relaxation scheme provides a relaxation B $\in\mathcal{B}$ of A. Let e^A denote the optimal value of the optimization problem A. Further, let $\hat{e}^A$ denote the value of the objective function of A at the point obtained

- Using the rounding scheme of Chekuri et al. (2001), LP-S obtains a multiplicative bound of $2+\sqrt{2}$ for truncated linear pairwise potentials.
- LP-S provides a multiplicative bound of 1 when the energy function $Q(\cdot,\mathbf{D};\theta)$ of the MRF is submodular (Schlesinger and Flach, 2000) (also see Ishikawa 2003 and Schlesinger and Flach 2006 for the st-MINCUT graph construction for minimizing submodular energy functions).
- The LP-S relaxation provides the same optimal solution for all reparameterizations $\overline{\theta}$ of θ (Kolmogorov, 2006; Werner, 2007).[3]

We note here that, although the LP-S relaxation can be solved in polynomial time, the state of the art Interior Point algorithms can only handle up to a few thousand variables and constraints. In order to overcome this deficiency several efficient algorithms have been proposed in the literature for (approximately) solving the Lagrangian dual of LP-S (Kolmogorov, 2006; Komodakis et al., 2007; Schlesinger and Giginyak, 2007a,b; Wainwright et al., 2005; Werner, 2007). Recently, efficient methods have also been devised for solving the primal problem directly (Ravikumar et al., 2008).

1.3 Quadratic Programming Relaxation

We now describe the QP relaxation for the MAP estimation IP which was proposed by Ravikumar and Lafferty (2006). To this end, it would be convenient to reformulate the objective function of the IP using a vector of unary potentials of length nh (denoted by $\hat{\theta}^1$) and a matrix of pairwise potentials of size $nh \times nh$ (denoted by $\hat{\theta}^2$). The element of the unary potential vector at index $(a\cdot h+i)$ is defined as

$$\hat{\theta}^1_{a;i} = \theta^1_{a;i} - \sum_{v_c\in\mathbf{v}}\sum_{l_k\in\mathbf{l}} |\theta^2_{ac;ik}|,$$

where $v_a \in \mathbf{v}$ and $l_i \in \mathbf{l}$. The $(a\cdot h+i, b\cdot h+j)^{th}$ element of the pairwise potential matrix $\hat{\theta}^2$ is defined such that

$$\hat{\theta}^2_{ab;ij} = \begin{cases} \sum_{v_c\in\mathbf{v}}\sum_{l_k\in\mathbf{l}} |\theta^2_{ac;ik}|, & \text{if} \quad a=b, i=j, \\ \theta^2_{ab;ij} & \text{otherwise}, \end{cases}$$

where $v_a, v_b \in \mathbf{v}$ and $l_i, l_j \in \mathbf{l}$. In other words, the potentials are modified by defining a pairwise potential $\hat{\theta}^2_{aa;ii}$ and subtracting the value of that potential from the corresponding unary potential $\theta^1_{a;i}$. The advantage of this reformulation is that the matrix $\hat{\theta}^2$ is guaranteed to be positive semidefinite, that is, $\hat{\theta}^2 \succeq 0$. This can be seen by observing that for any vector $\mathbf{z}\in\mathbb{R}^{nh}$ the following holds true:

$$\begin{aligned} \mathbf{z}^\top\hat{\theta}^2\mathbf{z} &= \sum_{(a,b)\in\mathcal{E}}\sum_{l_i,l_j\in\mathbf{l}} \left(|\theta^2_{ab;ij}|z^2_{a;i} + |\theta^2_{ab;ij}|z^2_{b;j} + 2\theta^2_{ab;ij}z_{a;i}z_{b;j}\right), \\ &= \sum_{(a,b)\in\mathcal{E}}\sum_{l_i,l_j\in\mathbf{l}} \left(|\theta^2_{ab;ij}|\left(z_{a;i} + \frac{\theta^2_{ab;ij}}{|\theta^2_{ab;ij}|}z_{b;j}\right)^2\right), \\ &\geq 0. \end{aligned}$$

by rounding the optimal solution of its relaxation B. The relaxation scheme is said to provide a multiplicative bound of ρ for the set $\mathcal{A}$ if, and only if, the following condition is satisfied: $E(\hat{e}^A) \le \rho e^A, \forall A \in \mathcal{A}$, where $E(\cdot)$ denotes the expectation of its argument under the rounding scheme employed.

3. A parameter $\overline{\theta}$ is called a reparameterization of θ (denoted by $\overline{\theta}\equiv\theta$) if and only if $Q(f,\mathbf{D};\theta) = Q(f,\mathbf{D};\overline{\theta})$ for all labellings f.

Using the fact that for $x_{a;i} \in \{-1,1\}$,

$$\left(\frac{1+x_{a;i}}{2}\right)^2 = \frac{1+x_{a;i}}{2},$$

it can be shown that the following is equivalent to the MAP estimation problem (Ravikumar and Lafferty, 2006):

$$\begin{aligned}
\text{QP-RL:} \quad & \mathbf{x}^* = \arg\min_{\mathbf{x}} \left(\tfrac{\mathbf{1}+\mathbf{x}}{2}\right)^\top \hat{\theta}^1 + \left(\tfrac{\mathbf{1}+\mathbf{x}}{2}\right)^\top \hat{\theta}^2 \left(\tfrac{\mathbf{1}+\mathbf{x}}{2}\right), && (7)\\
\text{s.t.} \quad & \textstyle\sum_{l_i \in \mathbf{l}} x_{a;i} = 2-h, \forall v_a \in \mathbf{v}, && (8)\\
& \mathbf{x} \in \{-1,1\}^{nh}, && (9)
\end{aligned}$$

where $\mathbf{1}$ is a vector of appropriate dimensions whose elements are all equal to 1. It is worth noting that, although $\hat{\theta}^1$ and $\hat{\theta}^2$ define the same energy for a labelling f as the original parameter θ, they are not a valid reparameterization of θ since they contain non-zero pairwise potentials of the form $\hat{\theta}^2_{aa;ii}$. By relaxing the feasibility region of the above problem to $\mathbf{x} \in [-1,1]^{nh}$, the resulting QP can be solved in polynomial time since $\hat{\theta}^2 \succeq 0$ (i.e., the relaxation of the QP (7)-(9) is convex). We call the above relaxation QP-RL. Note that in Ravikumar and Lafferty (2006), the QP-RL relaxation was described using the variable $\mathbf{y} = \frac{\mathbf{1}+\mathbf{x}}{2}$. However, the above formulation can easily be shown to be equivalent to the one presented in Ravikumar and Lafferty (2006).

In Ravikumar and Lafferty (2006), the authors proposed a rounding scheme for QP-RL (different from the ones used in Chekuri et al. 2001 and Kleinberg and Tardos 1999) that provides an additive bound[4] of $\frac{S}{4}$ for the MAP estimation problem, where

$$S = \sum_{(a,b)\in\mathcal{E}} \sum_{l_i,l_j \in \mathbf{l}} |\theta^2_{ab;ij}|,$$

that is, S is the sum of the absolute values of all pairwise potentials (Ravikumar and Lafferty, 2006). Under their rounding scheme, this bound can be shown to be tight[5] using a random field defined over two random variables which specifies uniform unary potentials and Ising model pairwise potentials (see Fig. 2(a)). Further, they also proposed an efficient iterative procedure for solving the QP-RL relaxation approximately. However, unlike LP-S, no multiplicative bounds have been established for the QP-RL formulation for special cases of the MAP estimation problem.

1.4 Semidefinite Programming Relaxation

The SDP relaxation of the MAP estimation problem replaces the non-convex constraint $\mathbf{X} = \mathbf{x}\mathbf{x}^\top$ by the convex semidefinite constraint $\mathbf{X} - \mathbf{x}\mathbf{x}^\top \succeq 0$ (de Klerk et al., 2004; Goemans and Williamson, 1995; Lasserre, 2001) which can be expressed as

$$\begin{pmatrix} 1 & \mathbf{x}^\top \\ \mathbf{x} & \mathbf{X} \end{pmatrix} \succeq 0,$$

4. A relaxation scheme defined over the set of optimization problems $\mathcal{A}$ is said to provide an additive bound of σ for $\mathcal{A}$ if, and only if, the following holds true: $E(\hat{e}^A) \leq e^A + \sigma, \forall \text{A} \in \mathcal{A}$. Here e^A is the optimal value of A and $\hat{e}^A$ is the value obtained by rounding the solution of B.

5. The multiplicative bound specified by a relaxation scheme defined over the set of optimization problems $\mathcal{A}$ is said to be *tight* if, and only if, there exists an $\text{A} \in \mathcal{A}$ such that $E(\hat{e}^A) = \rho e^A$. Similarly, the additive bound specified by a relaxation scheme defined over $\mathcal{A}$ is said to be tight if, and only if, there exists an $\text{A} \in \mathcal{A}$ such that $E(\hat{e}^A) = e^A + \sigma$.

using Schur's complement (Boyd and Vandenberghe, 2004). Further, like LP-S, it relaxes the integer constraints by allowing the variables $x_{a;i}$ and $X_{ab;ij}$ to lie in the interval $[-1,1]$ with $X_{aa;ii} = 1$ for all $v_a \in \mathbf{v}, l_i \in \mathbf{l}$. Note that the value of $X_{aa;ii}$ is derived using the fact that $X_{aa;ii} = x_{a;i}^2$. Since $x_{a;i}$ can only take the values -1 or 1 in the MAP estimation IP, it follows that $X_{aa;ii} = 1$. The SDP relaxation is a well-studied approach which provides accurate solutions for the MAP estimation problem (e.g., see Wainwright and Jordan 2004). However, due to its computational inefficiency, it is not practically useful for large scale problems with $nh > 1000$. See however Olsson et al. (2007), Schellewald and Schnorr (2003) and Torr (2003).

1.5 Second Order Cone Programming Relaxation

We now describe the SOCP relaxation that was proposed by Muramatsu and Suzuki (2003) for the MAXCUT problem (i.e., MAP estimation with $h = 2$) and later extended for a general label set (Kumar et al., 2006). This relaxation, which we call SOCP-MS, is based on the technique of Kim and Kojima (2000). For completeness we first describe the general technique of Kim and Kojima (2000) and later show how SOCP-MS can be derived using it.

1.5.1 SOCP RELAXATIONS

In Kim and Kojima (2000), the authors observed that the SDP constraint $\mathbf{X} - \mathbf{x}\mathbf{x}^\top \succeq 0$ can be further relaxed to second order cone (SOC) constraints. Their technique uses the fact that the Frobenius inner product of two semidefinite matrices is non-negative. For example, consider the inner product of a fixed matrix $\mathbf{C} = \mathbf{U}\mathbf{U}^\top \succeq 0$ with $\mathbf{X} - \mathbf{x}\mathbf{x}^\top$ (which, by the SDP constraint, is also positive semidefinite). The non-negativity of this inner product can be expressed as an SOC constraint as follows:

$$\begin{aligned} \mathbf{C} \bullet (\mathbf{X} - \mathbf{x}\mathbf{x}^\top) &\geq 0, \\ \Rightarrow \|(\mathbf{U})^\top \mathbf{x}\|^2 &\leq \mathbf{C} \bullet \mathbf{X}. \end{aligned}$$

Hence, by using a set of matrices $\mathcal{S} = \{\mathbf{C}^k | \mathbf{C}^k = \mathbf{U}^k(\mathbf{U}^k)^\top \succeq 0, k = 1,2,\ldots,n_C\}$, the SDP constraint can be further relaxed to n_C SOC constraints,that is,

$$\Rightarrow \|(\mathbf{U}^k)^\top \mathbf{x}\|^2 \leq \mathbf{C}^k \bullet \mathbf{X}, k = 1, \cdots, n_C.$$

It can be shown that, for the above set of SOC constraints to be equivalent to the SDP constraint, $n_C = \infty$. However, in practice, we can only specify a finite set of SOC constraints. Each of these constraints may involve some or all variables $x_{a;i}$ and $X_{ab;ij}$. For example, if $C^k_{ab;ij} = 0$, then the k^{th} SOC constraint will not involve $X_{ab;ij}$ (since its coefficient will be 0).

1.5.2 THE SOCP-MS RELAXATION

Consider a pair of neighbouring variables v_a and v_b, that is, $(a,b) \in \mathcal{E}$, and a pair of labels l_i and l_j. These two pairs define the following variables: $x_{a;i}$, $x_{b;j}$, $X_{aa;ii} = X_{bb;jj} = 1$ and $X_{ab;ij} = X_{ba;ji}$ (since $\mathbf{X}$ is symmetric). For each such pair of variables and labels, the SOCP-MS relaxation specifies two SOC constraints which involve only the above variables (Kumar et al., 2006; Muramatsu and Suzuki, 2003). In order to specify the exact form of these SOC constraints, we need the following definitions.

Using the variables v_a and v_b (where $(a,b) \in \mathcal{E}$) and labels l_i and l_j, we define the submatrices $\mathbf{x}^{(a,b,i,j)}$ and $\mathbf{X}^{(a,b,i,j)}$ of $\mathbf{x}$ and $\mathbf{X}$ respectively as:

$$\mathbf{x}^{(a,b,i,j)} = \begin{pmatrix} x_{a;i} \\ x_{b;j} \end{pmatrix}, \mathbf{X}^{(a,b,i,j)} = \begin{pmatrix} X_{aa;ii} & X_{ab;ij} \\ X_{ba;ji} & X_{bb;jj} \end{pmatrix}.$$

The SOCP-MS relaxation specifies SOC constraints of the form:

$$||(\mathbf{U}^k_{MS})^\top \mathbf{x}^{(a,b,i,j)}||^2 \leq \mathbf{C}^k_{MS} \bullet \mathbf{X}^{(a,b,i,j)}, \tag{10}$$

for all pairs of neighbouring variables $(a,b) \in \mathcal{E}$ and labels $l_i, l_j \in \mathbf{l}$. To this end, it uses the following two matrices:

$$\mathbf{C}^1_{MS} = \begin{pmatrix} 1 & 1 \\ 1 & 1 \end{pmatrix}, \mathbf{C}^2_{MS} = \begin{pmatrix} 1 & -1 \\ -1 & 1 \end{pmatrix}.$$

In other words SOCP-MS specifies a total of $2|\mathcal{E}|h^2$ SOC constraints. Note that both the matrices $\mathbf{C}^1_{MS}$ and $\mathbf{C}^2_{MS}$ defined above are positive semidefinite, and hence can be written as $\mathbf{C}^1_{MS} = \mathbf{U}^1_{MS}(\mathbf{U}^1_{MS})^\top$ and $\mathbf{C}^2_{MS} = \mathbf{U}^2_{MS}(\mathbf{U}^2_{MS})^\top$ where

$$\mathbf{U}^1_{MS} = \begin{pmatrix} 0 & 1 \\ 0 & 1 \end{pmatrix} \text{ and } \mathbf{U}^2_{MS} = \begin{pmatrix} 0 & -1 \\ 0 & 1 \end{pmatrix},$$

Substituting these matrices in inequality (10) we see that the constraints defined by the SOCP-MS relaxation are given by

$$\begin{aligned}
& ||(\mathbf{U}^1_{MS})^\top \mathbf{x}^{(a,b,i,j)}||^2 \leq \mathbf{C}^1_{MS} \bullet \mathbf{X}^{(a,b,i,j)}, \\
& ||(\mathbf{U}^2_{MS})^\top \mathbf{x}^{(a,b,i,j)}||^2 \leq \mathbf{C}^2_{MS} \bullet \mathbf{X}^{(a,b,i,j)}, \\
\Rightarrow \quad & \left|\left|\begin{pmatrix} 0 & 0 \\ 1 & 1 \end{pmatrix}\begin{pmatrix} x_{a;i} \\ x_{b;j} \end{pmatrix}\right|\right|^2 = \begin{pmatrix} 1 & 1 \\ 1 & 1 \end{pmatrix} \bullet \begin{pmatrix} X_{aa;ii} & X_{ab;ij} \\ X_{ba;ji} & X_{bb;jj} \end{pmatrix}, \\
& \left|\left|\begin{pmatrix} 0 & 0 \\ -1 & 1 \end{pmatrix}\begin{pmatrix} x_{a;i} \\ x_{b;j} \end{pmatrix}\right|\right|^2 = \begin{pmatrix} 1 & -1 \\ -1 & 1 \end{pmatrix} \bullet \begin{pmatrix} X_{aa;ii} & X_{ab;ij} \\ X_{ba;ji} & X_{bb;jj} \end{pmatrix}, \\
\Rightarrow \quad & (x_{a;i} + x_{b;j})^2 \leq X_{aa;ii} + X_{bb;jj} + X_{ab;ij} + X_{ba;ji}, \\
& (x_{a;i} - x_{b;j})^2 \leq X_{aa;ii} + X_{bb;jj} - X_{ab;ij} - X_{ba;ji}, \\
\Rightarrow \quad & (x_{a;i} + x_{b;j})^2 \leq 2 + 2X_{ab;ij}, \\
& (x_{a;i} - x_{b;j})^2 \leq 2 - 2X_{ab;ij}.
\end{aligned}$$

The last expression is obtained using the fact that $\mathbf{X}$ is symmetric and $X_{aa;ii} = 1$, for all $v_a \in \mathbf{v}$ and $l_i \in \mathbf{l}$. Hence, in the SOCP-MS formulation, the MAP estimation IP is relaxed to

$$\begin{aligned}
\text{SOCP-MS:} \quad & \mathbf{x}^* = \arg\min_{\mathbf{x}} \textstyle\sum_{v_a,l_i} \theta^1_{a;i} \frac{(1+x_{a;i})}{2} + \sum_{(a,b)\in\mathcal{E},l_i,l_j} \theta^2_{ab;ij} \frac{(1+x_{a;i}+x_{b;j}+X_{ab;ij})}{4} \\
\text{s.t.} \quad & \mathbf{x} \in [-1,1]^{nh}, \mathbf{X} \in [-1,1]^{nh \times nh}, \\
& \textstyle\sum_{l_i \in \mathbf{l}} x_{a;i} = 2 - h, \\
& (x_{a;i} - x_{b;j})^2 \leq 2 - 2X_{ab;ij}, && (11) \\
& (x_{a;i} + x_{b;j})^2 \leq 2 + 2X_{ab;ij}, && (12) \\
& X_{ab;ij} = X_{ba;ji}. && (13)
\end{aligned}$$

We refer the reader to Kumar et al. (2006) and Muramatsu and Suzuki (2003) for details. The SOCP-MS relaxation yields the supremum and infimum for the elements of the matrix $\mathbf{X}$ using constraints (11) and (12) respectively, that is,

$$\frac{(x_{a;i}+x_{b;j})^2}{2} - 1 \leq X_{ab;ij} \leq 1 - \frac{(x_{a;i}-x_{b;j})^2}{2}.$$

These constraints are specified for all $(a,b) \in \mathcal{E}$ and $l_i, l_j \in \mathbf{l}$. When the objective function of SOCP-MS is minimized, one of the two inequalities would be satisfied as an equality. This can be proved by assuming that the value for the vector $\mathbf{x}$ has been fixed. Hence, the elements of the matrix $\mathbf{X}$ should take values such that it minimizes the objective function subject to the constraints (11) and (12). Clearly, the objective function would be minimized when $X_{ab;ij}$ equals either its supremum or infimum value, depending on the sign of the corresponding pairwise potential $\theta^2_{ab;ij}$, that is,

$$X_{ab;ij} = \begin{cases} \frac{(x_{a;i}+x_{b;j})^2}{2} - 1 & \text{if} \quad \theta^2_{ab;ij} > 0, \\ 1 - \frac{(x_{a;i}-x_{b;j})^2}{2} & \text{otherwise.} \end{cases}$$

Similar to the LP-S and QP-RL relaxations defined above, the SOCP-MS relaxation can also be solved in polynomial time. To the best our knowledge, no bounds have been established for the SOCP-MS relaxation in earlier work. Our recent work (Kumar and Torr, 2008) provides an efficient approach for solving general SOCP relaxations of the MAP estimation problem for discrete MRF.

2. Comparing Relaxations

In order to compare the relaxations described above, we require the following definitions. We say that a relaxation A *dominates* (Chekuri et al., 2001) the relaxation B (alternatively, B is dominated by A) if and only if

$$\min_{(\mathbf{x},\mathbf{X})\in\mathcal{F}(\text{A})} e(\mathbf{x},\mathbf{X};\theta) \geq \min_{(\mathbf{x},\mathbf{X})\in\mathcal{F}(\text{B})} e(\mathbf{x},\mathbf{X};\theta), \forall\theta,$$

where $\mathcal{F}(\text{A})$ and $\mathcal{F}(\text{B})$ are the feasibility regions of the relaxations A and B respectively. The term $e(\mathbf{x},\mathbf{X};\theta)$ denotes the value of the objective function at $(\mathbf{x},\mathbf{X})$ (i.e., the energy of the possibly fractional labelling $(\mathbf{x},\mathbf{X})$) for the MAP estimation problem defined over the MRF with parameter θ. Thus the optimal value of the dominating relaxation A is always greater than or equal to the optimal value of relaxation B. We note here that the concept of domination has been used previously by Chekuri et al. (2001) (to compare LP-S with the linear programming relaxation of Kleinberg and Tardos 1999).

Relaxations A and B are said to be *equivalent* if A dominates B and B dominates A, that is, their optimal values are equal to each other for all MRFs. A relaxation A is said to *strictly dominate* relaxation B if A dominates B but B does not dominate A. In other words there exists at least one MRF with parameter θ such that

$$\min_{(\mathbf{x},\mathbf{X})\in\mathcal{F}(\text{A})} e(\mathbf{x},\mathbf{X};\theta) > \min_{(\mathbf{x},\mathbf{X})\in\mathcal{F}(\text{B})} e(\mathbf{x},\mathbf{X};\theta).$$

Note that, by definition, the optimal value of any relaxation would always be less than or equal to the energy of the optimal (i.e., the MAP) labelling. Hence, the optimal value of a strictly dominating relaxation A is closer to the optimal value of the MAP estimation IP compared to that of relaxation

B. In other words, A provides a tighter lower bound for MAP estimation than B and, in that sense, is a better relaxation than B. It is worth noting that the concept of domination (or strict domination) does not apply to the final solutions obtained by rounding the possibly fractional solutions of the relaxation. In other words, it is possible for a relaxation B which is strictly dominated by a relaxation A to provide a better final (integer) solution than A. However, the concept of domination provides an intuitive measure for comparing relaxations. One may also argue that if a dominating relaxation provides worse final solutions, then the deficiency of the method may be rooted in the rounding technique used.

We now describe two special cases of domination which are used extensively in the remainder of this paper.

Case I: Consider two relaxations A and B which share a common objective function. For example, the objective functions of the LP-S and the SOCP-MS relaxations described in the previous section have the same form. Further, let A and B differ in the constraints that they specify such that $\mathcal{F}(\text{A}) \subseteq \mathcal{F}(\text{B})$, that is, the feasibility region of A is a subset of the feasibility region of B.

Given two such relaxations, we claim that A dominates B. This can be proved by contradiction: assume that A does not dominate B then, by definition of domination, there exists at least one parameter θ for which B provides a greater value of the objective function than A. Let an optimal solution of A be $(\mathbf{x}_A, \mathbf{X}_A)$. Similarly, let $(\mathbf{x}_B, \mathbf{X}_B)$ be an optimal solution of B. By our assumption, the following holds true:

$$e(\mathbf{x}_A, \mathbf{X}_A; \theta) < e(\mathbf{x}_B, \mathbf{X}_B; \theta). \tag{14}$$

However, since $\mathcal{F}(\text{A}) \subseteq \mathcal{F}(\text{B})$ it follows that $(\mathbf{x}_A, \mathbf{X}_A) \in \mathcal{F}(\text{B})$. Hence, from Equation (14), we see that $(\mathbf{x}_B, \mathbf{X}_B)$ cannot be an optimal solution of B. This proves our claim.

We can also consider a case where $\mathcal{F}(\text{A}) \subset \mathcal{F}(\text{B})$, that is, the feasibility region of A is a strict subset of the feasibility region of B. Using the above argument we see that A dominates B. Further, assume that there exists a parameter θ such that the intersection of the set of all optimal solutions of A and the set of all optimal solutions of B is null. In other words if $(\mathbf{x}_B, \mathbf{X}_B)$ is an optimal solution of B then $(\mathbf{x}_B, \mathbf{X}_B) \notin \mathcal{F}(\text{A})$. Clearly, if such a parameter θ exists then A strictly dominates B.

Note that the converse is not true, that is, if A dominates (or strictly dominates) B it does not necessarily imply that $\mathcal{F}(\text{A}) \subseteq \mathcal{F}(\text{B})$ (or $\mathcal{F}(\text{A}) \subset \mathcal{F}(\text{B})$). In other words, the concept of domination is related to the value of the objective function and not to the feasibility region. In Section 5, we will consider some examples of relaxations which can be related through the concept of domination despite the fact that their feasibility regions are not subsets (or supersets) of each other.

Case II: Consider two relaxations A and B such that they share a common objective function. Further, let the constraints of B be a subset of the constraints of A. We claim that A dominates B. This follows from the fact that $\mathcal{F}(\text{A}) \subseteq \mathcal{F}(\text{B})$ and the argument used in Case I above.

2.1 Our Results

We prove that LP-S strictly dominates SOCP-MS (see Section 3). Further, in Section 4, we show that QP-RL is equivalent to SOCP-MS. This implies that LP-S strictly dominates the QP-RL relaxation. In Section 5 we generalize the above results by proving that a large class of SOCP (and equivalent QP) relaxations is dominated by LP-S. Based on these results, we propose a novel set of constraints which result in SOCP relaxations that dominate LP-S, QP-RL and SOCP-MS. These relaxations introduce SOC constraints on cycles and cliques formed by the neighbourhood relationship of the MRF.

A preliminary version of this article has appeared as Kumar et al. (2007).

3. LP-S vs. SOCP-MS

We now show that for the MAP estimation problem the linear constraints of LP-S, that is,

$$\mathbf{x} \in [-1,1]^{nh}, \mathbf{X} \in [-1,1]^{nh \times nh}, \tag{15}$$
$$\textstyle\sum_{l_i \in \mathbf{l}} x_{a;i} = 2-h, \tag{16}$$
$$\textstyle\sum_{l_j \in \mathbf{l}} X_{ab;ij} = (2-h)x_{a;i}, \tag{17}$$
$$X_{ab;ij} = X_{ba;ji}, \tag{18}$$
$$1 + x_{a;i} + x_{b;j} + X_{ab;ij} \geq 0. \tag{19}$$

are stronger than the SOCP-MS constraints, that is,

$$\mathbf{x} \in [-1,1]^{nh}, \mathbf{X} \in [-1,1]^{nh \times nh},$$
$$\textstyle\sum_{l_i \in \mathbf{l}} x_{a;i} = 2-h,$$
$$(x_{a;i} - x_{b;j})^2 \leq 2 - 2X_{ab;ij}, \tag{20}$$
$$(x_{a;i} + x_{b;j})^2 \leq 2 + 2X_{ab;ij}, \tag{21}$$
$$X_{ab;ij} = X_{ba;ji}.$$

In other words the feasibility region of LP-S is a strict subset of the feasibility region of SOCP-MS (i.e., $\mathcal{F}(\text{LP-S}) \subset \mathcal{F}(\text{SOCP-MS})$). This in turn would allow us to prove the following Theorem.

Theorem 1: The LP-S relaxation strictly dominates the SOCP-MS relaxation.

Proof: The LP-S and the SOCP-MS relaxations differ only in the way they relax the non-convex constraint $\mathbf{X} = \mathbf{x}\mathbf{x}^\top$. While LP-S relaxes $\mathbf{X} = \mathbf{x}\mathbf{x}^\top$ using the marginalization constraint (17), SOCP-MS relaxes it to constraints (20) and (21). The SOCP-MS constraints provide the supremum and infimum of $X_{ab;ij}$ as

$$\frac{(x_{a;i} + x_{b;j})^2}{2} - 1 \leq X_{ab;ij} \leq 1 - \frac{(x_{a;i} - x_{b;j})^2}{2}.$$

Consider a pair of neighbouring variables v_a and v_b and a pair of labels l_i and l_j. Recall that SOCP-MS specifies the constraints (20) and (21) for all such pairs of random variables and labels, that is, for all $x_{a;i}, x_{b;j}, X_{ab;ij}$ such that $(a,b) \in \mathcal{E}$ and $l_i, l_j \in \mathbf{l}$. In order to prove this Theorem we use the following two Lemmas.

Lemma 3.1: If $x_{a;i}$, $x_{b;j}$ and $X_{ab;ij}$ satisfy the LP-S constraints, that is, constraints (15)-(19), then

$$|x_{a;i} - x_{b;j}| \leq 1 - X_{ab;ij}.$$

The above result holds true for all $(a,b) \in \mathcal{E}$ and $l_i, l_j \in \mathbf{l}$.

Proof: From the LP-S constraints, we get

$$\frac{1 + x_{a;i}}{2} = \sum_{l_k \in \mathbf{l}} \frac{1 + x_{a;i} + x_{b;k} + X_{ab;ik}}{4},$$
$$\frac{1 + x_{b;j}}{2} = \sum_{l_k \in \mathbf{l}} \frac{1 + x_{a;k} + x_{b;j} + X_{ab;kj}}{4}. \tag{22}$$

Therefore,

$$\begin{aligned} |x_{a;i} - x_{b;j}| &= 2\left|\tfrac{1+x_{a;i}}{2} - \tfrac{1+x_{b;j}}{2}\right|, \\ &= 2\left|\left(\tfrac{1+x_{a;i}}{2} - \tfrac{1+x_{a;i}+x_{b;j}+X_{ab;ij}}{4}\right) - \left(\tfrac{1+x_{b;j}}{2} - \tfrac{1+x_{a;i}+x_{b;j}+X_{ab;ij}}{4}\right)\right|, \\ &\leq 2\left(\tfrac{1+x_{a;i}}{2} - \tfrac{1+x_{a;i}+x_{b;j}+X_{ab;ij}}{4}\right) + 2\left(\tfrac{1+x_{b;j}}{2} - \tfrac{1+x_{a;i}+x_{b;j}+X_{ab;ij}}{4}\right), \\ &= 1 - X_{ab;ij}. \end{aligned}$$

Note that the inequality holds since both the expressions in the parentheses, that is,

$$\left(\frac{1+x_{a;i}}{2} - \frac{1+x_{a;i}+x_{b;j}+X_{ab;ij}}{4}\right), \left(\frac{1+x_{b;j}}{2} - \frac{1+x_{a;i}+x_{b;j}+X_{ab;ij}}{4}\right),$$

are non-negative, as follows from equations (19) and (22). ∎

Using the above Lemma, we get

$$(x_{a;i} - x_{b;j})^2 \leq (1 - X_{ab;ij})(1 - X_{ab;ij}), \quad (23)$$
$$\Rightarrow \quad (x_{a;i} - x_{b;j})^2 \leq 2(1 - X_{ab;ij}), \quad (24)$$
$$\Rightarrow \quad (x_{a;i} - x_{b;j})^2 \leq 2 - 2X_{ab;ij}. \quad (25)$$

Inequality (24) is obtained using the fact that $-1 \leq X_{ab;ij} \leq 1$ and hence, $1 - X_{ab;ij} \leq 2$. Using inequality (23), we see that the necessary condition for the equality to hold true is $(1 - X_{ab;ij})(1 - X_{ab;ij}) = 2 - 2X_{ab;ij}$, that is, $X_{ab;ij} = -1$. Note that inequality (25) is equivalent to the SOCP-MS constraint (20). Thus LP-S provides a smaller supremum of $X_{ab;ij}$ when $X_{ab;ij} > -1$.

Lemma 3.2: If $x_{a;i}, x_{b;j}$ and $X_{ab;ij}$ satisfy the LP-S constraints then

$$|x_{a;i} + x_{b;j}| \leq 1 + X_{ab;ij}.$$

This holds true for all $(a,b) \in \mathcal{E}$ and $l_i, l_j \in \mathbf{l}$.

Proof: According to constraint (19),

$$-(x_{a;i} + x_{b;j}) \leq 1 + X_{ab;ij}. \quad (26)$$

Using Lemma 3.1, we get the following set of inequalities:

$$|x_{a;i} - x_{b;k}| \leq 1 - X_{ab;ik}, l_k \in \mathbf{l}, k \neq j.$$

Adding the above set of inequalities, we get

$$\begin{aligned} & \textstyle\sum_{l_k \in \mathbf{l}, k \neq j} |x_{a;i} - x_{b;j}| \leq \sum_{l_k \in \mathbf{l}, k \neq j} (1 - X_{ab;ik}), \\ \Rightarrow \quad & \textstyle\sum_{l_k \in \mathbf{l}, k \neq j} (x_{a;i} - x_{b;k}) \leq \sum_{l_k \in \mathbf{l}, k \neq j} (1 - X_{ab;ik}), \\ \Rightarrow \quad & (h-1)x_{a;i} - \textstyle\sum_{l_k \in \mathbf{l}, k \neq j} x_{b;k} \leq (h-1) - \sum_{l_k \in \mathbf{l}, k \neq j} X_{ab;ik}, \\ \Rightarrow \quad & (h-1)x_{a;i} + (h-2) + x_{b;j} \leq (h-1) + (h-2)x_{a;i} + X_{ab;ij}. \end{aligned}$$

The last step is obtained using constraints (16) and (17), that is,

$$\sum_{l_k \in \mathbf{l}} x_{b;k} = (2-h), \sum_{l_k \in \mathbf{l}} X_{ab;ik} = (2-h)x_{a;i}.$$

Rearranging the terms, we get

$$(x_{a;i} + x_{b;j}) \leq 1 + X_{ab;ij}. \tag{27}$$

Thus, according to inequalities (26) and (27)

$$|x_{a;i} + x_{b;j}| \leq 1 + X_{ab;ij}. \quad \blacksquare$$

Using the above Lemma, we obtain

$$\begin{aligned} & (x_{a;i} + x_{b;j})^2 \leq (1 + X_{ab;ij})(1 + X_{ab;ij}), \\ \Rightarrow \quad & (x_{a;i} + x_{b;j})^2 \leq 2 + 2X_{ab;ij}. \end{aligned}$$

where the necessary condition for the equality to hold true is $1 + X_{ab;ij} = 2$ (i.e., $X_{ab;ij} = 1$). Note that the above constraint is equivalent to the SOCP-MS constraint (21). Together with inequality (25), this proves that the LP-S relaxation provides smaller supremum and larger infimum of the elements of the matrix $\mathbf{X}$ than the SOCP-MS relaxation. Thus, $\mathcal{F}(\text{LP-S}) \subset \mathcal{F}(\text{SOCP-MS})$.

One can also construct a parameter θ for which the set of all optimal solutions of SOCP-MS do not lie in the feasibility region of LP-S. In other words the optimal solutions of SOCP-MS belong to the non-empty set $\mathcal{F}(\text{SOCP-MS}) - \mathcal{F}(\text{LP-S})$, for example, see Fig. 1. Using the argument of Case I in Section 2, this implies that LP-S strictly dominates SOCP-MS. $\blacksquare$

Note that the above Theorem does not apply to the variation of SOCP-MS described in Kumar et al. (2006) and Muramatsu and Suzuki (2003) which include *triangular inequalities* (Chopra and Rao, 1993). However, since triangular inequalities are linear constraints, LP-S can be extended to include them. The resulting LP relaxation would strictly dominate the SOCP-MS relaxation with triangular inequalities.

4. QP-RL vs. SOCP-MS

We now prove that QP-RL and SOCP-MS are equivalent (i.e., their optimal values are equal for MAP estimation problems defined over all MRFs). Specifically, we consider a vector $\mathbf{x}$ which lies in the feasibility regions of the QP-RL and SOCP-MS relaxations, that is, $\mathbf{x} \in [-1,1]^{nh}$. For this vector, we show that the values of the objective functions of the QP-RL and SOCP-MS relaxations are equal. This would imply that if $\mathbf{x}^*$ is an optimal solution of QP-RL for some MRF with parameter θ then there exists an optimal solution $(\mathbf{x}^*, \mathbf{X}^*)$ of the SOCP-MS relaxation. Further, if e^Q and e^S are the optimal values of the objective functions obtained using the QP-RL and SOCP-MS relaxation, then $e^Q = e^S$.

Theorem 2: The QP-RL relaxation and the SOCP-MS relaxation are equivalent.

Proof: Recall that the QP-RL relaxation is defined as follows:

$$\begin{aligned} \text{QP-RL:} \quad & \mathbf{x}^* = \arg\min_{\mathbf{x}} \left(\tfrac{\mathbf{1}+\mathbf{x}}{2}\right)^\top \hat{\theta}^1 + \left(\tfrac{\mathbf{1}+\mathbf{x}}{2}\right)^\top \hat{\theta}^2 \left(\tfrac{\mathbf{1}+\mathbf{x}}{2}\right), \\ \text{s.t.} \quad & \textstyle\sum_{l_i \in \mathbf{l}} x_{a;i} = 2 - h, \forall v_a \in \mathbf{v}, \\ & \mathbf{x} \in \{-1,1\}^{nh}, \end{aligned}$$

where the unary potential vector $\hat{\theta}^1$ and the pairwise potential matrix $\hat{\theta}^2 \succeq 0$ are defined as

$$\hat{\theta}^1_{a;i} = \theta^1_{a;i} - \sum_{v_c \in \mathbf{v}} \sum_{l_k \in \mathbf{l}} |\theta^2_{ac;ik}|, \tag{28}$$

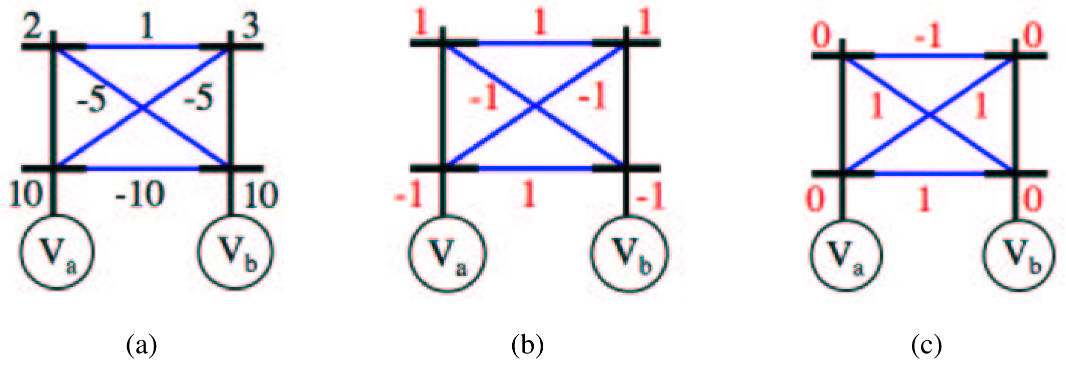

Figure 1: **(a)** An example MRF defined using two neighbouring random variables. Note that the observed nodes are not shown for the sake of clarity of the image. Each random variable can take one of two labels, represented by the branches (i.e., the horizontal lines) of the trellises (i.e., the vertical lines) on top of the variables. The value of the unary potential $\theta^1_{a;i}$ is shown next to the i^{th} branch of the trellis on top of v_a. For example, $\theta^1_{a;0} = 10$ (shown next to the lower branch of the trellis on top of v_a) and $\theta^1_{b;1} = 3$ (shown next to the upper branch of the trellis on top of v_b). The pairwise potential $\theta^2_{ab;ij}$ is shown next to the connection between the i^{th} and j^{th} branches of the trellises on top of v_a and v_b respectively. For example, $\theta^2_{ab;00} = -10$ (shown next to the bottom-most connection between the two trellises) and $\theta^2_{ab;01} = -5$ (shown next to the diagonal connection between the two trellises). **(b)** The optimal solution obtained using the LP-S relaxation. The value of $x_{a;i}$ is shown next to the i^{th} branch of the trellis on top of v_a. Similarly, the value of $X_{ab;ij}$ is shown next to the connection between the i^{th} and j^{th} branches of the trellises on top of v_a and v_b respectively. Note that the value of the objective function for the optimal solution is 6. **(c)** A feasible solution of the SOCP-MS relaxation which does not belong to the feasibility region of LP-S and has an objective function value of 2. It follows that the optimal solution of SOCP-MS would lie in $\mathcal{F}(\text{SOCP-MS}) - \mathcal{F}(\text{LP-S})$ and have a value of at most 2. Together with Lemmas 3.1 and 3.2, this proves that LP-S strictly dominates SOCP-MS.

$$\hat{\theta}^2_{ab;ij} = \begin{cases} \sum_{v_c \in \mathbf{v}} \sum_{l_k \in \mathbf{l}} |\theta^2_{ac;ik}|, & \text{if} \quad a = b, i = j, \\ \theta^2_{ab;ij} & \text{otherwise}. \end{cases} \tag{29}$$

Here, the terms $\theta^1_{a;i}$ and $\theta^2_{ac;ik}$ are the (original) unary potentials and pairwise potentials for the given MRF. Consider a feasible solution $\mathbf{x}$ of the QP-RL and the SOCP-MS relaxations. Further, let $\mathbf{X}$ be the solution obtained when minimizing the objective function of the SOCP-MS relaxation whilst keeping $\mathbf{x}$ fixed. We prove that the value of the objective functions for both relaxations at the above feasible solution is the same by equating the coefficient of $\theta^1_{a;i}$ and $\theta^2_{ab;ij}$ for all $v_a \in \mathbf{v}$, $(a,b) \in \mathcal{E}$ and $l_i, l_j \in \mathbf{l}$ in both formulations. Using Equation (28), we see that $\theta^1_{a;i}$ is multiplied by $\frac{1+x_{a;i}}{2}$ in the objective function of the QP-RL. Similarly, $\theta^1_{a;i}$ is multiplied by $\frac{1+x_{a;i}}{2}$ in the SOCP-MS relaxation. Therefore the coefficients of $\theta^1_{a;i}$ in both relaxations are equal for all $v_a \in \mathbf{v}$ and $l_i \in \mathbf{l}$.

We now consider the pairwise potentials, that is, $\theta^2_{ab;ij}$ and show that their coefficients are the same when obtaining the minimum of the objective function. We consider the following two cases.

Case I: Let $\theta^2_{ab;ij} = \theta^2_{ba;ji} \geq 0$. Using Equation (29) we see that, in the QP-RL relaxation, $\theta^2_{ab;ij} + \theta^2_{ba;ji}$ is multiplied by the following term:

$$\left(\frac{1+x_{a;i}}{2}\right)^2 + \left(\frac{1+x_{b;j}}{2}\right)^2 + 2\left(\frac{1+x_{a;i}}{2}\right)\left(\frac{1+x_{b;j}}{2}\right) - \frac{1+x_{a;i}}{2} - \frac{1+x_{b;j}}{2}. \tag{30}$$

In the case of SOCP-MS relaxation, since $\theta^2_{ab;ij} \geq 0$, the minimum of the objective function is obtained by using the minimum value that $X_{ab;ij}$ would take given the SOC constraints. Since $\mathbf{X}$ is symmetric, we see that $\theta^2_{ab;ij} + \theta^2_{ba;ji}$ is multiplied by the following term:

$$\begin{aligned} & \frac{1+x_{a;i}+x_{b;j}+\inf\{X_{ab;ij}\}}{2} \\ = & \frac{1+x_{a;i}+x_{b;j}+(x_{a;i}+x_{b;j})^2/2-1}{2}, \end{aligned} \tag{31}$$

where the infimum of $X_{ab;ij}$ is defined by constraint (21) in the SOCP-MS relaxation. It can easily be verified that the terms (30) and (31) are equal.

Case II: Now consider the case where $\theta^2_{ab;ij} = \theta^2_{ba;ji} < 0$. In the QP-RL relaxation, the term $\theta^2_{ab;ij} + \theta^2_{ba;ji}$ is multiplied by

$$\frac{1+x_{a;i}}{2} + \frac{1+x_{b;j}}{2} + 2\left(\frac{1+x_{a;i}}{2}\right)\left(\frac{1+x_{b;j}}{2}\right) - \left(\frac{1+x_{a;i}}{2}\right)^2 - \left(\frac{1+x_{b;j}}{2}\right)^2. \tag{32}$$

In order to obtain the minimum of the objective function, the SOCP-MS relaxation uses the maximum value that $X_{ab;ij}$ would take given the SOC constraints. Thus, $\theta^2_{ab;ij} + \theta^2_{ba;ji}$ is multiplied by

$$\begin{aligned} & \frac{1+x_{a;i}+x_{b;j}+\sup\{X_{ab;ij}\}}{2} \\ = & \frac{1+x_{a;i}+x_{b;j}+1-(x_{a;i}-x_{b;j})^2/2}{2}, \end{aligned} \tag{33}$$

where the supremum of $X_{ab;ij}$ is defined by constraint (20). Again, the terms (32) and (33) can be shown to be equivalent. ∎

Theorems 1 and 2 prove that the LP-S relaxation strictly dominates the QP-RL and SOCP-MS relaxations. A natural question that now arises is whether the additive bound of QP-RL (proved by Ravikumar and Lafferty 2006) is applicable to the LP-S and SOCP-MS relaxations. Our next Theorem answers this question in an affirmative. To this end, we use the rounding scheme proposed by Ravikumar and Lafferty (2006) to obtain the labelling f for all the random variables of the given MRF. This rounding scheme is summarized below:

- Pick a variable v_a which has not been assigned a label.
- Assign the label l_i to v_a (i.e., f(a) = i) with probability $\frac{1+x_{a;i}}{2}$.
- Continue till all variables have been assigned a label.

Recall that $\sum_{i=0}^{h-1} \frac{1+x_{a;i}}{2} = 1$ for all $v_a \in \mathbf{v}$. Hence, once v_a is picked it is guaranteed to be assigned a label. In other words the above rounding scheme terminates after $n = |\mathbf{v}|$ steps. To the best of our knowledge, this additive bound was previously known only for the QP-RL relaxation (Ravikumar and Lafferty, 2006).

Theorem 3: For the above rounding scheme, LP-S and SOCP-MS provide the same additive bound as the QP-RL relaxation of Ravikumar and Lafferty (2006), that is, $\frac{S}{4}$ where $S = \sum_{(a,b)\in\mathcal{E}} \sum_{l_i,l_j\in\mathbf{l}} |\theta^2_{ab;ij}|$ (i.e., the sum of the absolute values of all pairwise potentials). Furthermore, this bound is tight.

Proof: The QP-RL and SOCP-MS relaxations are equivalent. Thus the above Theorem holds true for SOCP-MS. We now consider the LP-S relaxation (Chekuri et al., 2001; Koster et al., 1998; Schlesinger, 1976; Wainwright et al., 2005). We denote the energy of the optimal labelling as e^*. Recall that e^L denotes the optimal value of the LP-S which is obtained using possibly fractional variables $(\mathbf{x}^*, \mathbf{X}^*)$. Clearly, $e^L \leq e^*$. The energy of the labelling $\hat{\mathbf{x}}$, obtained after rounding the solution of the LP-S relaxation, is represented by the term $\hat{e}^L$,

Using the above notation, we now show that the LP-S relaxation provides an additive bound of $\frac{S}{4}$ for the above rounding scheme. We first consider the unary potentials and observe that

$$E\left(\theta^1_{a;i}\left(\frac{1+\hat{x}_{a;i}}{2}\right)\right) = \theta^1_{a;i}\left(\frac{1+x^*_{a;i}}{2}\right),$$

where $E(\cdot)$ denotes the expectation of its argument under the above rounding scheme. Similarly, for the pairwise potentials,

$$E\left(\theta^2_{ab;ij}\left(\frac{1+\hat{x}_{a;i}}{2}\right)\left(\frac{1+\hat{x}_{b;j}}{2}\right)\right) = \theta^2_{ab;ij}\left(\frac{1+x^*_{a;i}+x^*_{b;ij}+x^*_{a;i}x^*_{b;j}}{4}\right).$$

We analyze the following two cases:

(i) $\theta^2_{ab;ij} \geq 0$: Using the fact that $X^*_{ab;ij} \geq |x^*_{a;i}+x^*_{b;j}| - 1$ (see Lemma 3.2), we get

$$\begin{array}{cc} & 1+x^*_{a;i}+x^*_{b;j}+x^*_{a;i}x^*_{b;j} - (1+x^*_{a;i}+x^*_{b;j}+X^*_{ab;ij}) \\ = & x^*_{a;i}x^*_{b;j} - X^*_{ab;ij} \\ \leq & x^*_{a;i}x^*_{b;j} + 1 - |x^*_{a;i}+x^*_{b;j}| \\ \leq & 1, \end{array}$$

where the equality holds when $x^*_{a;i} = x^*_{b;j} = 0$. Therefore,

$$E\left(\theta^2_{ab;ij}\left(\frac{1+\hat{x}_{a;i}}{2}\right)\left(\frac{1+\hat{x}_{b;j}}{2}\right)\right) \leq \theta^2_{ab;ij}\frac{(1+x^*_{a;i}+x^*_{b;ij}+X^*_{ab;ij})}{4} + \frac{|\theta^2_{ab;ij}|}{4}.$$

(ii) $\theta^2_{ab;ij} < 0$: Using the fact that $X^*_{ab;ij} \leq 1 - |x^*_{a;i} - x^*_{b;j}|$ (see Lemma 3.1), we get

$$\begin{array}{cc} & 1+x^*_{a;i}+x^*_{b;j}+x^*_{a;i}x^*_{b;j} - (1+x^*_{a;i}+x^*_{b;j}+X^*_{ab;ij}) \\ \geq & x^*_{a;i}x^*_{b;j} - 1 + |x^*_{a;i}-x^*_{b;j}| \\ \geq & -1, \end{array}$$

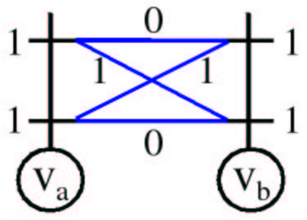
where the equality holds when $x^*_{a;i} = x^*_{b;j} = 0$. Therefore,

$$E\left(\theta^2_{ab;ij}\left(\frac{1+\hat{x}_{a;i}}{2}\right)\left(\frac{1+\hat{x}_{b;j}}{2}\right)\right) \leq \theta^2_{ab;ij}\frac{(1+x^*_{a;i}+x^*_{b;ij}+X^*_{ab;ij})}{4} + \frac{|\theta^2_{ab;ij}|}{4}.$$

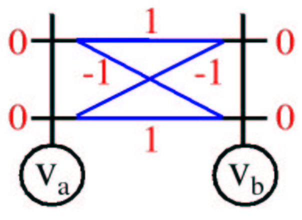
Summing the expectation of the unary and pairwise potentials for all $v_a \in \mathbf{v}$, $(a,b) \in \mathcal{E}$ and $l_i, l_j \in \mathbf{l}$, we get

$$e^* \leq E(\hat{e}^L) \leq e^L + \frac{S}{4} \leq e^* + \frac{S}{4},$$

which proves the additive bound for LP-S.



(a)



(b)

Figure 2: An example MRF for proving the tightness of the LP-S additive bound of $\frac{S}{4}$. **(a)** The MRF consisting of two random variables v_a and v_b. The potentials are shown similar to Fig. 1. Note that the unary potentials are uniform while the pairwise potentials form an Ising model. **(b)** An optimal solution of the LP-S relaxation for the MRF shown in (a). The values of the variables $x_{a;i}$ are shown next to the i^{th} branch of the trellis of v_a. Note that all variables $x_{a;i}$ have been assigned to 0. The values of the variables $X_{ab;ij}$ are shown next to the connection between the i^{th} and j^{th} branch of the trellises of v_a and v_b. Note that $X_{ab;ij} = -1$ if $\theta^2_{ab;ij} > 0$ and $X_{ab;ij} = 1$ otherwise.

This additive bound can indeed be shown to be tight by using the following simple example. Consider an instance of the MAP estimation problem for an MRF defined on two variables $\mathbf{v} = \{v_a, v_b\}$ each of which can take one of two labels from the set $\mathbf{l} = \{l_0, l_1\}$. Let the unary and pairwise potentials be as defined in Fig. 2(a), that is, the unary potentials are uniform and the pairwise potentials follow the Ising model. Note that this MRF is a chain of size 2 and can thus, be solved exactly using the LP-S relaxation (Chekuri et al., 2001; Wainwright and Jordan, 2003) (i.e., the optimal value of the objective function of the LP-S relaxation is exactly equal to the energy of the MAP estimate). However, our aim is to show that for a particular randomized rounding scheme the MRF in Fig. 2(a) offers an example of tightness for the additive bound.

An optimal solution of the LP-S relaxation is given in Fig. 2(b). Clearly, $e^* = 2$ (e.g., for the labelling $f = \{0,0\}$ or $f = \{1,1\}$) while $E(\hat{e}^L) = 2 + \frac{2}{4} = e^* + \frac{S}{4}$. Thus the additive bounds obtained for the LP-S, QP-RL and SOCP-MS algorithms are the same. In fact, one can construct arbitrarily large MRFs (i.e., MRF defined over a large number of variables) with uniform unary potentials and Ising model pairwise potentials for which the bound can be shown to be tight. ■

The above bound was proved for the case of binary variables (i.e., h = 2) by Hammer and Kalantari (1987) using a slightly different rounding scheme. Our result can be viewed as a generalization of this for any arbitrary number of labels. The above Theorem proves a tight additive bound using a simple rounding scheme. However, using this rounding scheme in practical applications may not be desirable as it generates an independent random number for rounding the fractional labelling of each random variable. We note here that better bounds can be obtained for some special cases of the MAP estimation problem using the LP-S relaxation together with more clever rounding schemes (such as those described in Chekuri et al. 2001 and Kleinberg and Tardos 1999).

5. QP and SOCP Relaxations over Trees and Cycles

We now generalize the results of Theorem 1 by defining a large class of SOCP relaxations which is dominated by LP-S. Specifically, we consider the SOCP relaxations which relax the non-convex constraint $\mathbf{X} = \mathbf{x}\mathbf{x}^\top$ using a set of second order cone (SOC) constraints of the form

$$||(\mathbf{U}^k)^\top \mathbf{x}|| \leq \mathbf{C}^k \bullet \mathbf{X}, k = 1, \cdots, n_C \tag{34}$$

where $\mathbf{C}^k = \mathbf{U}^k(\mathbf{U}^k)^\top \succeq 0$, for all $k = 1, \cdots, n_C$. In order to make the proofs of the subsequent Theorems easier, we make two assumptions. However, the Theorems would hold true even without these assumptions as discussed below.

Assumption 1: We assume that the integer constraints

$$\mathbf{x} \in \{-1, +1\}^{nh}, \mathbf{X} \in \{-1, +1\}^{nh \times nh}, \tag{35}$$

are relaxed to

$$\mathbf{x} \in [-1, +1]^{nh}, \mathbf{X} \in [-1, +1]^{nh \times nh}, \tag{36}$$

with $X_{aa;ii} = 1$, for all $v_a \in \mathbf{v}, l_i \in \mathbf{l}$. The constraints (36) provide the convex hull for all the points defined by the integer constraints (35). Recall that the convex hull of a set of points is the smallest convex set which contains all the points. We now discuss how the above assumption is not restrictive with respect to the results that follow. Let A be a relaxation which contains constraints (36). Using A it is possible to obtain another relaxation B by substituting constraints (36) by some other relaxation of the integer constraints. By the definition of convex hull, it would follow that $\mathcal{F}(\text{A}) \subset \mathcal{F}(\text{B})$. In other words A dominates B (see Case I in Section 2). Hence, if A is dominated by the LP-S relaxation, then LP-S would also dominate B.

Assumption 2: We assume that the set of constraints (34) contains all the constraints specified in the SOCP-MS relaxation. Recall that for a given pair of neighbouring random variables, that is, $(a,b) \in \mathcal{E}$, and a pair of labels $l_i, l_j \in \mathbf{l}$, SOCP-MS specifies SOC constraints using two matrices (say $\mathbf{C}^1$ and $\mathbf{C}^2$) which are 0 everywhere except for the following 2×2 submatrices:

$$\begin{pmatrix} C^1_{aa;ii} & C^1_{ab;ij} \\ C^1_{ba;ji} & C^1_{bb;jj} \end{pmatrix} = \begin{pmatrix} 1 & 1 \\ 1 & 1 \end{pmatrix}, \begin{pmatrix} C^2_{aa;ii} & C^2_{ab;ij} \\ C^2_{ba;ji} & C^2_{bb;jj} \end{pmatrix} = \begin{pmatrix} 1 & -1 \\ -1 & 1 \end{pmatrix}. \tag{37}$$

In the case where a given relaxation A does not contain the SOCP-MS constraints, we can define a new relaxation B. This new relaxation B is obtained by adding all the SOCP-MS constraints to A. By definition, B dominates A (although not necessarily strictly, see Case II in Section 2). Hence, if B is dominated by the LP-S relaxation then it follows that LP-S would also dominate A. Hence, our assumption about including the SOCP-MS constraints is not restrictive for the results presented in this section.

Note that each SOCP relaxation belonging to this class would not include the marginalization constraints. Hence, it would define an equivalent QP relaxation (similar to the equivalent QP-RL relaxation defined by the SOCP-MS relaxation). By definition of equivalent relaxations, all these QP relaxations will also be dominated by LP-S. Before we begin to describe our results in detail, we need to set up some notation as follows.

5.1 Notation

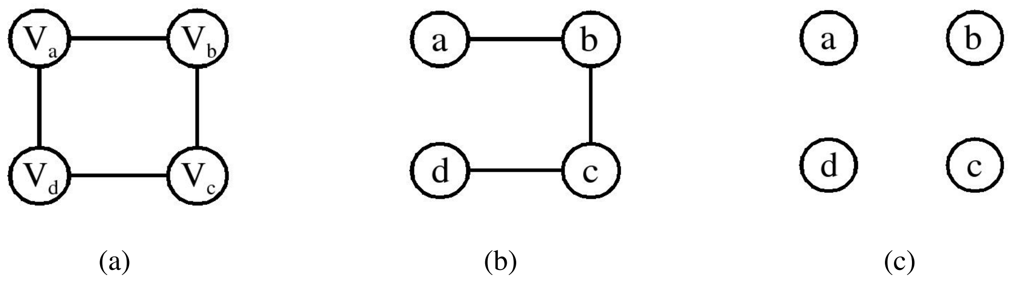


Figure 3: **(a)** An example MRF defined over four variables which form a cycle. **(b)** The set E^k specified by the matrix $\mathbf{C}^k$ shown in Equation (39), that is, $E^k = \{(a,b),(b,c),(c,d)\}$. **(c)** The set $V^k = \{a,b,c,d\}$. See text for definitions of these sets.

We consider an SOC constraint which is of the form described in Equation (34), that is,

$$||(\mathbf{U}^k)^\top \mathbf{x}|| \leq \mathbf{C}^k \bullet \mathbf{X}, \tag{38}$$

where $k \in \{1,\cdots,n_C\}$. In order to help the reader understand the notation better, we use an example MRF shown in Fig. 3(a). This MRF is defined over four variables $\mathbf{v} = \{v_a, v_b, v_c, v_d\}$ (connected to form a cycle of length 4), each of which take a label from the set $\mathbf{l} = \{l_0, l_1\}$. For this MRF we specify a constraint using a matrix $\mathbf{C}^k \succeq 0$ which is 0 everywhere, except for the following 4×4 submatrix:

$$\begin{pmatrix} C^k_{aa;00} & C^k_{ab;00} & C^k_{ac;00} & C^k_{ad;00} \\ C^k_{ba;00} & C^k_{bb;00} & C^k_{bc;00} & C^k_{bd;00} \\ C^k_{ca;00} & C^k_{cb;00} & C^k_{cc;00} & C^k_{cd;00} \\ C^k_{da;00} & C^k_{db;00} & C^k_{dc;00} & C^k_{dd;00} \end{pmatrix} = \begin{pmatrix} 2 & 1 & 1 & 0 \\ 1 & 2 & 1 & 1 \\ 1 & 1 & 2 & 1 \\ 0 & 1 & 1 & 2 \end{pmatrix}. \tag{39}$$

Using the SOC constraint shown in Equation (38) we define the following sets:

- The set E^k is defined such that $(a,b) \in E^k$ if, and only if, it satisfies the following conditions:

$$(a,b) \in \mathcal{E},$$
$$\exists l_i, l_j \in \mathbf{l} \text{ such that } C^k_{ab;ij} \neq 0.$$

  Recall that $\mathcal{E}$ specifies the neighbourhood relationship for the given MRF. In other words E^k is the subset of the edges in the graphical model of the MRF such that $\mathbf{C}^k$ specifies constraints for the random variables corresponding to those edges. For the example MRF (shown in Fig. 3(a)) and $\mathbf{C}^k$ matrix (in Equation 39), the set E^k obtained is shown in Fig. 3(b).

- The set V^k is defined as $a \in V^k$ if, and only if, there exists a $v_b \in \mathbf{v}$ such that $(a,b) \in E^k$. In other words V^k is the subset of hidden nodes in the graphical model of the MRF such that $\mathbf{C}^k$ specifies constraints for the random variables corresponding to those hidden nodes. Fig. 3(c) shows the set V^k for our example SOC constraint.

- The set $\mathcal{T}^k$ consists of elements $a;i \in \mathcal{T}^k$ which satisfy

$$a \in V^k, l_i \in \mathbf{l},$$
$$\exists b \in V^k, l_j \in \mathbf{l}, \text{ such that } C^k_{ab;ij} \neq 0.$$

In other words the set $\mathcal{T}^k$ consists of the set of indices for the vector $\mathbf{x}$ which are constrained by inequality (38), that is, the coefficient of $x_{a;i}$ where $a;i \in \mathcal{T}^k$ are non-zero in the LHS of inequality (38). Note that in Equation (39) the constraint is specified using only the label l_0 for all the random variables $\mathbf{v}$. Thus the set $\mathcal{T}^k$ is given by

$$\mathcal{T}^k = \{(a;0),(b;0),(c;0),(d;0)\}.$$

For each set $\mathcal{T}^k$ we define three disjoint subsets of $\mathcal{T}^k \times \mathcal{T}^k$ as follows.

- The set $\mathcal{T}^k_0$ is defined as

$$\mathcal{T}^k_0 = \{(a;i,b;j)|(a;i,b;j) \in \mathcal{T}^k \times \mathcal{T}^k, (a,b) \in \mathcal{E}, (a,b) \notin E^k\}.$$

Note that by definition $C^k_{ab;ij} = 0$ if $(a;i,b;j) \in \mathcal{T}^k_0$. Thus $\mathcal{T}^k_0$ indexes the elements of matrix $\mathbf{X}$ which are not constrained by inequality (38) but are present in the set $\mathcal{T}^k \times \mathcal{T}^k$. For the matrix $\mathbf{C}^k$ in Equation (39), the set $\mathcal{T}^k_0$ is given by

$$\mathcal{T}^k_0 = \{(a;0,d;0)\}.$$

- The set $\mathcal{T}^k_1$ is defined as

$$\mathcal{T}^k_1 = \{(a;i,b;j)|(a;i,b;j) \in \mathcal{T}^k \times \mathcal{T}^k, (a,b) \notin \mathcal{E}\}.$$

In other words the set $\mathcal{T}^k_1$ indexes the elements of matrix $\mathbf{X}$ which are constrained by inequality (38) but do not belong to any pair of neighbouring random variables. Note that the variables $X_{ab;ij}$ such that $(a;i,b;j) \in \mathcal{T}^k_1$ were not present in the LP-S relaxation. For the matrix $\mathbf{C}^k$ in Equation (39), the set $\mathcal{T}^k_1$ is given by

$$\mathcal{T}^k_1 = \{(a;0,c;0),(b;0,d;0)\}.$$

- The set $\mathcal{T}^k_2$ is defined as

$$\mathcal{T}^k_2 = \{(a;i,b;j)|(a;i,b;j) \in \mathcal{T}^k \times \mathcal{T}^k, (a,b) \in E^k\}.$$

In other words the set $\mathcal{T}^k_2$ indexes the elements of matrix $\mathbf{X}$ which are constrained by inequality (38) and belong to a pair of neighbouring random variables. For the matrix $\mathbf{C}^k$ in Equation (39), the set $\mathcal{T}^k_2$ is given by

$$\mathcal{T}^k_2 = \{(a;0,b;0),(b;0,c;0)(c;0,d;0)\}.$$

Note that $\mathcal{T}^k_0 \bigcup \mathcal{T}^k_1 \bigcup \mathcal{T}^k_2 = \mathcal{T}^k \times \mathcal{T}^k$. For a given set of pairwise potentials $\theta^2_{ab;ij}$ we define two disjoint sets of $\mathcal{T}^k_2$ as follows.

- The set $\mathcal{T}^k_{2+}$ corresponds to non-negative pairwise potentials, that is,

  $$\mathcal{T}^k_{2+} = \{(a;i,b;j) | (a;i,b;j) \in \mathcal{T}^k_2, \theta^2_{ab;ij} \geq 0\},$$

  Thus the set $\mathcal{T}^k_{2+}$ indexes the elements of matrix $\mathbf{X}$ which belong to $\mathcal{T}^k_2$ and are multiplied by a non-negative pairwise potential in the objective function of the relaxation.

- The set $\mathcal{T}^k_{2-}$ corresponds to negative pairwise potentials, that is,

  $$\mathcal{T}^k_{2-} = \{(a;i,b;j) | (a;i,b;j) \in \mathcal{T}^k_2, \theta^2_{ab;ij} < 0\},$$

  Thus the set $\mathcal{T}^k_{2-}$ indexes the elements of matrix $\mathbf{X}$ which belong to $\mathcal{T}^k_2$ and are multiplied by a negative pairwise potential in the objective function of the relaxation. Note that $\mathcal{T}^k_2 = \mathcal{T}^k_{2+} \bigcup \mathcal{T}^k_{2-}$. For the purpose of illustration let us assume that, for the example MRF in Fig. 3(a), $\theta^2_{ab;00} \geq 0$ while $\theta^2_{bc;00} < 0$ and $\theta^2_{cd;00} < 0$. Then,

  $$\mathcal{T}^k_{2+} = \{(a;0,b;0)\},$$
  $$\mathcal{T}^k_{2-} = \{(b;0,c;0),(c;0,d;0)\},$$

We also define a weighted graph $G^k = (V^k, E^k)$ whose vertices are specified by the set V^k and whose edges are specified by the set E^k. The weight of an edge $(a,b) \in E^k$ is given by $w(a,b)$. Recall that $w(a,b)$ specifies the strength of the pairwise relationship between two neighbouring variables v_a and v_b. Thus, for our example SOC constraint, the vertices of this graph are given in Fig. 3(c) while the edges are shown in Fig. 3(b). This graph can be viewed as a subgraph of the graphical model representation for the given MRF.

Further, we define the submatrices $\mathbf{x}^k_T$ and $\mathbf{X}^k_T$ of $\mathbf{x}$ and $\mathbf{X}$ respectively such that

$$\mathbf{x}^k_T = \{x_{a;i} | a;i \in \mathcal{T}^k\},$$
$$\mathbf{X}^k_T = \{X_{ab;ij} | (a;i,b;j) \in \mathcal{T}^k \times \mathcal{T}^k\}.$$

For our example, these submatrices will be given by

$$\mathbf{x}^k_T = \begin{pmatrix} x_{a;0} \\ x_{b;0} \\ x_{c;0} \\ x_{d;0} \end{pmatrix}, \mathbf{X}^k_T = \begin{pmatrix} X_{aa;00} & X_{ab;00} & X_{ac;00} & X_{ad;00} \\ X_{ba;00} & X_{bb;00} & X_{bc;00} & X_{bd;00} \\ X_{ca;00} & X_{cb;00} & X_{cc;00} & X_{cd;00} \\ X_{da;00} & X_{db;00} & X_{dc;00} & X_{dd;00} \end{pmatrix}.$$

Using the above notation, we are now ready to describe our results in detail.

5.2 QP and SOCP Relaxations over Trees

We begin by considering those relaxations where the SOC constraints are defined such that the graphs $G^k = (V^k, E^k)$ form trees. For example, the graph G^k defined by the SOC constraint in Equation (39) forms a tree as shown in Fig. 3(b). We denote such a relaxation, which specifies SOC constraints only over trees, by SOCP-T. Note that SOCP-MS (and hence, QP-RL) can be considered a special case of this class of relaxations where the number of vertices in each tree is equal to two (since the constraints are defined for all $(a,b) \in \mathcal{E}$).

We will remove this restriction by allowing the number of vertices in each tree to be arbitrarily large (i.e., between 1 and n). We consider one such tree $G = (V,E)$. Note that for a given relaxation SOCP-T, there may be several SOC constraints defined using this tree G (or its subtrees). Without loss of generality, we assume that the constraints

$$||(\mathbf{U}^k)^\top \mathbf{x}|| \leq \mathbf{C}^k \bullet \mathbf{X}, k = 1, \cdots, n'_C,$$

are defined on the tree G. In other words,

$$G^k \subseteq G, k = 1, \cdots, n'_C,$$

where $G^k \subseteq G$ implies that G^k is a subtree of G. In order to make the notation less cluttered, **we will drop the superscript *k* from the sets defined in the previous section** (since we will consider only one tree G in our analysis).

We will now show that SOCP-T is dominated by the LP-S relaxation. This result is independent of the choice of the tree G and matrices $\mathbf{C}^k$. To this end, we define the term $e_1(\mathbf{x}_T)$ for a given value of $\mathbf{x}_T$ as

$$e_1(\mathbf{x}_T) = \sum_{(a;i)\in\mathcal{T}} \left(\theta^1_{a;i} + \sum_{(b;j)\in\mathcal{T}} \frac{\theta^2_{ab;ij}}{2} \right) x_{a;i}.$$

Further, for a fixed $\mathbf{x}_T$ we also define the following two terms:

$$\begin{aligned} e^S_2(\mathbf{x}_T) &= \min_{(\mathbf{x}_T,\mathbf{X}_T)\in\mathcal{F}(\text{SOCP-T})} \sum_{(a;i,b;j)\in\mathcal{T}_2} \theta^2_{ab;ij} X_{ab;ij}, \\ e^L_2(\mathbf{x}_T) &= \min_{(\mathbf{x}_T,\mathbf{X}_T)\in\mathcal{F}(\text{LP-S})} \sum_{(a;i,b;j)\in\mathcal{T}_2} \theta^2_{ab;ij} X_{ab;ij}, \end{aligned}$$

where $\mathcal{F}$(SOCP-T) and $\mathcal{F}$(LP-S) are the feasibility regions of SOCP-T and LP-S respectively. We use the notation $(\mathbf{x}_T,\mathbf{X}_T) \in \mathcal{F}$(SOCP-T) loosely to mean that we can obtain a feasible solution $(\mathbf{x},\mathbf{X})$ of SOCP-T such that the values of the variables $x_{a;i}$ where $a;i \in \mathcal{T}$ and $X_{ab;ij}$ where $(a;i,b;j) \in \mathcal{T}\times\mathcal{T}$ are equal to the values specified by $\mathbf{x}_T$ and $\mathbf{X}_T$. The notation $(\mathbf{x}_T,\mathbf{X}_T) \in \mathcal{F}$(LP-S) is used similarly. Note that for a given $\mathbf{x}_T$ the possible values of $\mathbf{X}_T$ are constrained such that $(\mathbf{x}_T,\mathbf{X}_T) \in \mathcal{F}$(SOCP-T) and $(\mathbf{x}_T,\mathbf{X}_T) \in \mathcal{F}$(LP-S) (in the case of SOCP-T and LP-S respectively). Hence different values of $\mathbf{x}_T$ will provide different values of $e^S_2(\mathbf{x}_T)$ and $e^L_2(\mathbf{x}_T)$.

The contribution of the tree G to the objective function of SOCP-T and LP-S is given by

$$\begin{aligned} e^S &= \min_{\mathbf{x}_T} \frac{e_1(\mathbf{x}_T)}{2} + \frac{e^S_2(\mathbf{x}_T)}{4}, \\ e^L &= \min_{\mathbf{x}_T} \frac{e_1(\mathbf{x}_T)}{2} + \frac{e^L_2(\mathbf{x}_T)}{4}, \end{aligned}$$

respectively. Assuming that the trees G do not overlap, the total value of the objective function would simply be the sum of e^S (for SOCP-T) or e^L (for LP-S) over all trees G. However, since we use an arbitrary parameter θ in our analysis, it follows that the results do not depend on this assumption of non-overlapping trees. In other words if two trees G^1 and G^2 share an edge $(a,b) \in \mathcal{E}$ then we can simply consider two MAP estimation problems defined using arbitrary parameters θ_1 and θ_2 such that $\theta_1 + \theta_2 = \theta$. We can then add the contribution of G_1 for the MAP estimation problem with parameter θ_1 to the contribution of G_2 for the MAP estimation problem with parameter θ_2. This would then provide us with the total contribution of G_1 and G_2 for the original MAP estimation defined using parameter θ.

Using the above argument it follows that if, for all G and for all θ, the following holds true:

$$\begin{aligned} & \frac{e_1(\mathbf{x}_T)}{2} + \frac{e_2^S(\mathbf{x}_T)}{4} \leq \frac{e_1(\mathbf{x}_T)}{2} + \frac{e_2^L(\mathbf{x}_T)}{4}, \forall \mathbf{x}_T \in [-1,1]^{|\mathcal{T}|} \\ \Rightarrow \quad & e_2^S(\mathbf{x}_T) \leq e_2^L(\mathbf{x}_T), \forall \mathbf{x}_T \in [-1,1]^{|\mathcal{T}|}, \end{aligned} \tag{40}$$

then LP-S dominates SOCP-T (since this would imply that $e^S \leq e^L$, for all G and for all θ). This is the condition that we will use to prove that LP-S dominates all SOCP relaxations whose constraints are defined over trees. To this end, we define a vector $\omega = \{\omega_k, k = 1, \cdots, n'_C\}$ of non-negative real numbers such that

$$\sum_k \omega_k C^k_{ab;ij} = \theta^2_{ab;ij}, \forall (a;i,b;j) \in \mathcal{T}_2.$$

Due to the presence of the matrices $\mathbf{C}^k$ defined in Equation (37) (which result in the SOCP-MS constraints for all $(a,b) \in \mathcal{E}$ and $l_i, l_j \in \mathbf{l}$), such a vector ω would always exist for any MRF parameter θ. We denote the matrix $\sum_k \omega_k \mathbf{C}^k$ by $\mathbf{C}$. Clearly, $\mathbf{C} \succeq 0$, and hence can be written as $\mathbf{C} = \mathbf{U}\mathbf{U}^\top$.

Using the constraints $||(\mathbf{U}^k)^\top \mathbf{x}||^2 \leq \mathbf{C}^k \bullet \mathbf{X}_T$ together with the fact that $\omega_k \geq 0$, we get the following inequality:[6]

$$\begin{aligned} & \textstyle\sum_k \omega_k ||(\mathbf{U}^k)^\top \mathbf{x}||^2 \leq \sum_k \omega_k \mathbf{C}^k \bullet \mathbf{X}, \\ \Rightarrow \quad & ||\mathbf{U}^\top \mathbf{x}||^2 \leq \mathbf{C} \bullet \mathbf{X}, \\ \Rightarrow \quad & ||\mathbf{U}^\top \mathbf{x}||^2 \leq \textstyle\sum_{a;i \in \mathcal{T}} C_{aa;ii} X_{aa;ii} + \sum_{(a;i,b;j) \in \mathcal{T}_1} C_{ab;ij} X_{ab;ij} + \sum_{(a;i,b;j) \in \mathcal{T}_2} C_{ab;ij} X_{ab;ij}, \\ \Rightarrow \quad & ||\mathbf{U}^\top \mathbf{x}||^2 - \textstyle\sum_{a;i \in \mathcal{T}} C_{aa;ii} - \sum_{(a;i,b;j) \in \mathcal{T}_1} C_{ab;ij} X_{ab;ij} \leq \sum_{(a;i,b;j) \in \mathcal{T}_2} \theta^2_{ab;ij} X_{ab;ij}, \end{aligned} \tag{41}$$

where the last expression is obtained using the fact that $C_{ab;ij} = \theta^2_{ab;ij}$ for all $(a;i,b;j) \in \mathcal{T}_2$ and $X_{aa;ii} = 1$ for all $v_a \in \mathbf{v}$ and $l_i \in \mathbf{l}$. Note that the above inequality provides a lower bound of $e_2^S(\mathbf{x}_T)$. Another lower bound of $e_2^S(\mathbf{x}_T)$ is provided by the constraints that $-1 \leq X_{ab;ij} \leq 1$ for all $(a;i,b;j) \in \mathcal{T}_2$. Since the objective function being minimized contains $e_2^S(\mathbf{x}_T)$, it follows that in the absence of any other constraints (which is our assumption) $e_2^S(\mathbf{x}_T)$ would be equal to the maximum of the two lower bounds, that is,

$$\max \left\{ \sum_{(a;i,b;j) \in \mathcal{T}_2} -|\theta^2_{ab;ij} X_{ab;ij}|, ||\mathbf{U}^\top \mathbf{x}||^2 - \sum_{a;i \in \mathcal{T}} C_{aa;ii} - \sum_{(a;i,b;j) \in \mathcal{T}_1} C_{ab;ij} X_{ab;ij} \right\}.$$

The first expression is obtained by substituting the following values for $X_{ab;ij}$ where $(a;i,b;j) \in \mathcal{T}_2$:

$$X_{ab;ij} = \begin{cases} -1 & \text{if} \quad \theta^2_{ab;ij} \geq 0, \\ 1 & \text{otherwise}, \end{cases}$$

while the second expression is the LHS of inequality (41). Clearly, if $e_2^S(\mathbf{x}_T)$ is equal to the first expression then $e_2^L(\mathbf{x}_T) \geq e_2^S(\mathbf{x}_T)$, that is, LP-S dominates SOCP-T. In what follows, we will only

6. Note that there are no terms corresponding to $(a;i,b;j) \in \mathcal{T}_0$ in inequality (41) since $C_{ab;ij} = 0$ if $(a;i,b;j) \in \mathcal{T}_0$. In other words, $X_{ab;ij}$ vanishes from the above inequality if $(a;i,b;j) \in \mathcal{T}_0$.

consider the non-trivial case when

$$\begin{aligned} e_2^S(\mathbf{x}_T) &= \min \sum_{(a;i,b;j)\in\mathcal{T}_2} \theta^2_{ab;ij} X_{ab;ij}, \\ &= \|\mathbf{U}^\top \mathbf{x}\|^2 - \sum_{a;i\in\mathcal{T}} C_{aa;ii} - \sum_{(a;i,b;j)\in\mathcal{T}_1} C_{ab;ij} X_{ab;ij}. \end{aligned} \tag{42}$$

For the LP-S relaxation, from Lemmas 3.1 and 3.2, we obtain the following value of $e_2^L(\mathbf{x}_T)$:

$$\begin{aligned} & |x_{a;i}+x_{b;j}|-1 \leq X_{ab;ij} \leq 1-|x_{a;i}-x_{b;j}|, \\ \Rightarrow \quad & e_2^L(\mathbf{x}_T) = \min \textstyle\sum_{(a;i,b;j)\in\mathcal{T}_2} \theta^2_{ab;ij} X_{ab;ij}, \\ & = \textstyle\sum_{(a;i,b;j)\in\mathcal{T}_{2+}} \theta^2_{ab;ij}(|x_{a;i}+x_{b;j}|) - \sum_{(a;i,b;j)\in\mathcal{T}_{2-}} \theta^2_{ab;ij}(|x_{a;i}-x_{b;j}|) - \\ & \textstyle\sum_{(a;i,b;j)\in\mathcal{T}_2} |\theta^2_{ab;ij}|. \end{aligned} \tag{43}$$

We are now ready to prove one of our main results which generalizes Theorems 1 and 2. However, before proceeding with the proof, we note that our result can also be obtained using the *moment constraints* of Wainwright and Jordan (2003) (which imply that LP-S provides the exact solution for the MAP estimation problems defined over tree-structured random fields). However, as will be seen shortly, the proof presented here allows us to generalize our results to certain cycles.

Theorem 4: SOCP relaxations (and the equivalent QP relaxations) which define constraints only using graphs $G=(V,E)$ which form (arbitrarily large) trees are dominated by the LP-S relaxation.

Proof: We begin by assuming that $d(i,j)\geq 0$ for all $l_i, l_j \in \mathbf{l}$ and later drop this constraint on the distance function.[7] We will show that for any arbitrary tree G and any matrix $\mathbf{C}$, the value of $e_2^L(\mathbf{x}_T)$ is greater than the value of $e_2^S(\mathbf{x}_T)$ for all $\mathbf{x}_T$. This would prove inequality (40) which in turn would show that the LP-S relaxation dominates SOCP-T (and the equivalent QP relaxation which we call QP-T) whose constraints are defined over trees.

It is assumed that we do not specify any additional constraints for all the variables $X_{ab;ij}$ where $(a;i,b;j)\in\mathcal{T}_1$ (i.e., for $X_{ab;ij}$ not belonging to any of our trees). In other words these variables $X_{ab;ij}$ are bounded only by the relaxation of the integer constraint, that is, $-1\leq X_{ab;ij}\leq +1$. Thus in Equation (42) the minimum value of the RHS (which is equal to the value of $e_2^S(\mathbf{x}_T)$) is obtained by using the following value of $X_{ab;ij}$ where $(a;i,b;j)\in\mathcal{T}_1$:

$$X_{ab;ij} = \begin{cases} 1 & \text{if} \quad C_{ab;ij}\geq 0, \\ -1 & \text{otherwise.} \end{cases}$$

Substituting these values in Equation (42) we get

$$\begin{aligned} & e_2^S(\mathbf{x}_T) = ||\mathbf{U}^\top \mathbf{x}||^2 - \textstyle\sum_{a;i\in\mathcal{T}} C_{aa;ii} - \sum_{(a;i,b;j)\in\mathcal{T}_1} |C_{ab;ij}|, \\ \Rightarrow \quad & e_2^S(\mathbf{x}_T) = \textstyle\sum_{a;i\in\mathcal{T}} C_{aa;ii} x^2_{a;i} + \sum_{(a;i,b;j)\in\mathcal{T}_1} C_{ab;ij} x_{a;i} x_{b;j} + \sum_{(a;i,b;j)\in\mathcal{T}_2} \theta^2_{ab;ij} x_{a;i} x_{b;j} \\ & \qquad - \textstyle\sum_{a;i\in\mathcal{T}} C_{aa;ii} - \sum_{(a;i,b;j)\in\mathcal{T}_1} |C_{ab;ij}|, \end{aligned}$$

where the last expression is obtained using the fact that $\mathbf{C}=\mathbf{U}^\top\mathbf{U}$. Consider the term $\sum_{(a;i,b;j)\in\mathcal{T}_1} C_{ab;ij} x_{a;i} x_{b;j}$ which appears in the RHS of the above equation. For this term, clearly

7. Recall that $d(\cdot,\cdot)$ is a distance function on the labels. Together with the weights $w(\cdot,\cdot)$ defined over neighbouring random variables, it specifies the pairwise potentials as $\theta^2_{ab;ij} = w(a,b)d(i,j)$.

the following holds true

$$\sum_{(a;i,b;j)\in\mathcal{T}_1} C_{ab;ij}x_{a;i}x_{b;j} \le \sum_{(a;i,b;j)\in\mathcal{T}_1} \frac{|C_{ab;ij}|}{2}(x_{a;i}^2+x_{b;j}^2), \tag{44}$$

since for all $(a;i,b;j)\in\mathcal{T}_1$

$$\begin{aligned} C_{ab;ij} &\le |C_{ab;ij}|, \\ x_{a;i}x_{b;j} &\le \tfrac{(x_{a;i}^2+x_{b;j}^2)}{2}. \end{aligned}$$

Inequality (44) provides us with an upper bound on the value of $e_2^S(\mathbf{x}_T)$ as follows:

$$\begin{aligned} e_2^S(\mathbf{x}_T) \le \textstyle\sum_{a;i\in\mathcal{T}} C_{aa;ii}x_{a;i}^2 + \sum_{(a;i,b;j)\in\mathcal{T}_1} \frac{|C_{ab;ij}|}{2}(x_{a;i}^2+x_{b;j}^2) + \sum_{(a;i,b;j)\in\mathcal{T}_2} \theta^2_{ab;ij}x_{a;i}x_{b;j} \\ -\textstyle\sum_{a;i\in\mathcal{T}} C_{aa;ii} - \sum_{(a;i,b;j)\in\mathcal{T}_1}|C_{ab;ij}|. \end{aligned} \tag{45}$$

Note that in order to prove inequality (40), that is,

$$e_2^S(\mathbf{x}_T) \le e_2^L(\mathbf{x}_T), \forall \mathbf{x}_T \in [-1,1]^{|\mathcal{T}|},$$

it would be sufficient to show that $e_2^L(\mathbf{x}_T)$ specified in Equation (43) is greater than the RHS of inequality (45) (since the RHS of inequality (45) is greater than $e_2^S(\mathbf{x}_T)$). We now simplify the two infimums $e_2^L(\mathbf{x}_T)$ and $e_2^S(\mathbf{x}_T)$ as follows.

LP-S Infimum: Let $z_{a;i} = \sqrt{|x_{a;i}|(1-|x_{a;i}|)}$. From Equation (43), we see that the infimum provided by the LP-S relaxation is given by

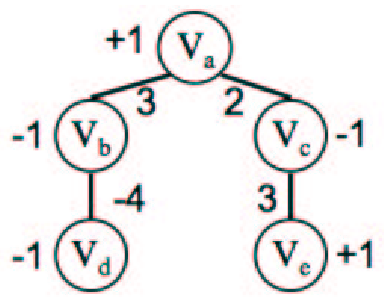
$$\begin{aligned} &\textstyle\sum_{(a;i,b;j)\in\mathcal{T}_{2+}} \theta^2_{ab;ij}(|x_{a;i}+x_{b;j}|) - \sum_{(a;i,b;j)\in\mathcal{T}_{2-}} \theta^2_{ab;ij}(|x_{a;i}-x_{b;j}|) - \sum_{(a;i,b;j)\in\mathcal{T}_2}|\theta^2_{ab;ij}| \\ &= -\textstyle\sum_{(a;i,b;j)\in\mathcal{T}_{2+}} |\theta^2_{ab;ij}|(1-|x_{a;i}+x_{b;j}|+x_{a;i}x_{b;j}) \\ &\quad -\textstyle\sum_{(a;i,b;j)\in\mathcal{T}_{2-}} |\theta^2_{ab;ij}|(1-|x_{a;i}-x_{b;j}|-x_{a;i}x_{b;j}) \\ &\quad +\textstyle\sum_{(a;i,b;j)\in\mathcal{T}_2} \theta^2_{ab;ij}x_{a;i}x_{b;j} \\ &\ge -\textstyle\sum_{(a;i,b;j)\in\mathcal{T}_2} |\theta^2_{ab;ij}|(1-|x_{a;i}|)(1-|x_{b;j}|) - 2\sum_{(a;i,b;j)\in\mathcal{T}_2}|\theta^2_{ab;ij}|z_{a;i}z_{b;j} + \\ &\quad +\textstyle\sum_{(a;i,b;j)\in\mathcal{T}_2} \theta^2_{ab;ij}x_{a;i}x_{b;j}. \end{aligned} \tag{46}$$

The last expression is obtained using the fact that

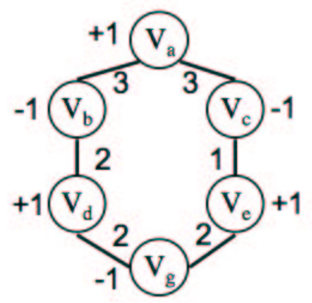
$$\begin{aligned} (1-|x_{a;i}+x_{b;j}|+x_{a;i}x_{b;j}) &\le (1-|x_{a;i}|)(1-|x_{b;j}|)+2z_{a;i}z_{b;j}, \\ (1-|x_{a;i}-x_{b;j}|-x_{a;i}x_{b;j}) &\le (1-|x_{a;i}|)(1-|x_{b;j}|)+2z_{a;i}z_{b;j}. \end{aligned}$$

SOCP Infimum: From inequality (45), we see that the infimum provided by the SOCP-T relaxation is given by

$$\begin{aligned} &\textstyle\sum_{a;i\in\mathcal{T}} C_{aa;ii}x_{a;i}^2 + \sum_{(a;i,b;j)\in\mathcal{T}_1} \frac{|C_{ab;ij}|}{2}(x_{a;i}^2+x_{b;j}^2) + \sum_{(a;i,b;j)\in\mathcal{T}_2}\theta^2_{ab;ij}x_{a;i}x_{b;j} \\ &\quad -\textstyle\sum_{a;i\in\mathcal{T}} C_{aa;ii} - \sum_{(a;i,b;j)\in\mathcal{T}_1}|C_{ab;ij}| \\ =&\quad -\textstyle\sum_{a;i\in\mathcal{T}} C_{aa;ii}(1-x_{a;i}^2) - \sum_{(a;i,b;j)\in\mathcal{T}_1}|C_{ab;ij}|(1-\frac{x_{a;i}^2}{2}-\frac{x_{b;j}^2}{2}) \\ &\quad +\textstyle\sum_{(a;i,b;j)\in\mathcal{T}_2}\theta^2_{ab;ij}x_{a;i}x_{b;j} \\ \le&\quad -\textstyle\sum_{a;i\in\mathcal{T}} C_{aa;ii}(1-|x_{a;i}|)^2 - \sum_{(a;i,b;j)\in\mathcal{T}_1}|C_{ab;ij}|(1-|x_{a;i}|)(1-|x_{b;j}|) \\ &\quad -2\textstyle\sum_{a;i\in\mathcal{T}} C_{aa;ii}z_{a;i}^2 - 2\sum_{(a;i,b;j)\in\mathcal{T}_1}|C_{ab;ij}|z_{a;i}z_{b;j} \\ &\quad +\textstyle\sum_{(a;i,b;j)\in\mathcal{T}_2}\theta^2_{ab;ij}x_{a;i}x_{b;j}. \end{aligned} \tag{47}$$



(a)



(b)

Figure 4: **(a)** An example subgraph G which forms a tree. The weights of the edges and corresponding elements of the vector $\mathbf{m}$ are also shown. **(b)** An example subgraph G which forms an even cycle where all weights are positive. The elements of $\mathbf{s}$ are defined using the $\{+1,-1\}$ assignments of the vertices.

The last expression is obtained using

$$1 - x_{a;i}^2 \geq (1-|x_{a;i}|)^2 + 2z_{a;i}^2,$$
$$1 - \frac{x_{a;i}^2}{2} - \frac{x_{b;j}^2}{2} \geq (1-|x_{a;i}|)(1-|x_{b;j}|) + 2z_{a;i}z_{b;j}.$$

In order to prove the Theorem, we use the following two Lemmas.

Lemma 5.1: The following inequality holds true for any matrix $\mathbf{C} \succeq 0$:

$$\sum_{a;i\in\mathcal{T}} C_{aa;ii}(1-|x_{a;i}|)^2 + \sum_{(a;i,b;j)\in\mathcal{T}_1} |C_{ab;ij}|(1-|x_{a;i}|)(1-|x_{b;j}|)$$
$$\geq \sum_{(a;i,b;j)\in\mathcal{T}_2} |\theta^2_{ab;ij}|(1-|x_{a;i}|)(1-|x_{b;j}|).$$

In other words, the first term in the RHS of inequality (46) exceeds the sum of the first two terms in the RHS of inequality (47).

Proof: The proof relies on the fact that $\mathbf{C}$ is positive semidefinite. We construct a vector $\mathbf{m} = \{m_a, a = 1,\cdots,n\}$ where n is the number of variables. Let $p(a)$ denote the parent of a non-root vertex a of tree G (where the root vertex can be chosen arbitrarily). The vector $\mathbf{m}$ is defined such that

$$m_a = \begin{cases} 0 & \text{if } \ a \text{ does not belong to tree } G, \\ 1 & \text{if } \ a \text{ is the root vertex of } G, \\ -m_{p(a)} & \text{if } \ w(a,p(a)) > 0, \\ m_{p(a)} & \text{if } \ w(a,p(a)) < 0. \end{cases}$$

Here $w(\cdot,\cdot)$ are the weights provided for a given MRF. Fig. 4(a) shows an example of a graph which forms a tree together with the corresponding elements of $\mathbf{m}$. Using the vector $\mathbf{m}$, we define a vector $\mathbf{s}$ of length nh (where $h = |\mathbf{l}|$) such that $s_{a;i} = 0$ if $a;i \notin \mathcal{T}$ and $s_{a;i} = m_a(1-|x_{a;i}|)$ otherwise. Since

$\mathbf{C}$ is positive semidefinite, we get

$$\begin{aligned}
& \mathbf{s}^\top \mathbf{C}\mathbf{s} \geq 0 \\
\Rightarrow\quad & \textstyle\sum_{a;i\in\mathcal{T}} C_{aa;ii}(1-|x_{a;i}|)^2 + \sum_{(a;i,b;j)\in\mathcal{T}_1} m_a m_b C_{ab;ij}(1-|x_{a;i}|)(1-|x_{b;j}) \\
& \quad + \textstyle\sum_{(a;i,b;j)\in\mathcal{T}_2} m_a m_b \theta^2_{ab;ij}(1-|x_{a;i}|)(1-|x_{b;j}) \geq 0, \\
\Rightarrow\quad & \textstyle\sum_{a;i\in\mathcal{T}} C_{aa;ii}(1-|x_{a;i}|)^2 + \sum_{(a;i,b;j)\in\mathcal{T}_1} m_a m_b C_{ab;ij}(1-|x_{a;i}|)(1-|x_{b;j}) \\
& \quad \geq \textstyle\sum_{(a;i,b;j)\in\mathcal{T}_2} |\theta^2_{ab;ij}|(1-|x_{a;i}|)(1-|x_{b;j}), \\
\Rightarrow\quad & \textstyle\sum_{a;i\in\mathcal{T}} C_{aa;ii}(1-|x_{a;i}|)^2 + \sum_{(a;i,b;j)\in\mathcal{T}_1} |C_{ab;ij}|(1-|x_{a;i}|)(1-|x_{b;j}|) \\
& \quad \geq \textstyle\sum_{(a;i,b;j)\in\mathcal{T}_2} |\theta^2_{ab;ij}|(1-|x_{a;i}|)(1-|x_{b;j}|). \quad \blacksquare
\end{aligned}$$

Lemma 5.2: The following inequality holds true for any matrix $\mathbf{C} \succeq 0$:

$$\sum_{a;i\in\mathcal{T}} C_{aa;ii} z_{a;i}^2 + \sum_{(a;i,b;j)\in\mathcal{T}_1} |C_{ab;ij}| z_{a;i} z_{b;j} \geq \sum_{(a;i,b;j)\in\mathcal{T}_2} |\theta^2_{ab;ij}| z_{a;i} z_{b;j}.$$

In other words the second term in the RHS of inequality (46) exceeds the sum of the third and fourth terms in inequality (47).

Proof: Similar to Lemma 5.1, we construct a vector $\mathbf{s}$ of length nh such that $s_{a;i} = 0$ if $a;i \notin \mathcal{T}$ and $s_{a;i} = m_a z_{a;i}$ otherwise. The proof follows by observing that $\mathbf{s}^\top\mathbf{C}\mathbf{s} \geq 0$. $\blacksquare$

Using the above two Lemmas, we see that the sum of the first two terms of inequality (46) exceed the sum of the first four terms of inequality (47). Further, the third and the fifth terms of inequalities (46) and (47) are the same. Since inequality (46) provides the lower limit of $e_2^L(\mathbf{x}_T)$ and inequality (47) provides the upper limit of $e_2^S(\mathbf{x}_T)$, it follows that $e_2^L(\mathbf{x}_T) \geq e_2^S(\mathbf{x}_T)$ for all $\mathbf{x}_T \in [-1,1]^{|\mathcal{T}|}$. Using condition (40), this proves the Theorem. $\blacksquare$

The proofs of Lemmas 5.1 and 5.2 make use of the fact that for any neighbouring random variables v_a and v_b (i.e., $(a,b) \in \mathcal{E}$), the pairwise potentials $\theta^2_{ab;ij}$ have the same sign for all $l_i, l_j \in \mathbf{l}$. This follows from the non-negativity property of the distance function. However, Theorem 4 can be extended to the case where the distance function does not obey the non-negativity property. To this end, we define a parameter $\overline{\theta}$ which satisfies the following condition:

$$Q(f,\mathbf{D};\overline{\theta}) = Q(f,\mathbf{D};\theta), \forall f.$$

Such a parameter $\overline{\theta}$ is called the reparameterization of θ (i.e., $\overline{\theta} \equiv \theta$). Note that there exist several reparameterizations of any parameter θ. We are interested in a parameter $\overline{\theta}$ which satisfies

$$\sum_{l_i,l_j\in\mathbf{l}} |\overline{\theta}^2_{ab;ij}| = |\sum_{l_i,l_j\in\mathbf{l}} \theta^2_{ab;ij}|, \forall (a,b) \in \mathcal{E}. \tag{48}$$

It can easily be shown that such a reparameterization always exists. Specifically, consider the general form of reparameterization described by Kolmogorov (2006), that is,

$$\begin{aligned}
\overline{\theta}^1_{a;i} &= \theta^1_{a;i} + M_{ba;i}, \\
\overline{\theta}^2_{ab;ij} &= \theta^2_{ab;ij} - M_{ba;i} - M_{ab;j}.
\end{aligned}$$

Clearly one can set the values of the terms $M_{ba;i}$ and $M_{ab;j}$ such that Equation (48) is satisfied. Further, the optimal value of LP-S for the parameter $\overline{\theta}$ is equal to its optimal value obtained using θ.

For details, we refer the reader to Kolmogorov (2006). Using this parameter $\overline{\theta}$, we obtain an LP-S infimum which is similar in form to the inequality (46) for any distance function (i.e., without the positivity constraint $d(i,j) \geq 0$ for all $l_i, l_j \in \mathbf{l}$). This LP-S infimum can then be easily compared to the SOCP-T infimum of inequality (47) (using slight extensions of Lemmas 5.1 and 5.2), thereby proving the results of Theorem 4 for a general distance function. We omit details.

As an upshot of the above Theorem, we see that the feasibility region of LP-S is always a subset of the feasibility region of SOCP-T (for any general set of trees and SOC constraints), that is, $\mathcal{F}(\text{LP-S}) \subset \mathcal{F}(\text{SOCP-T})$. This implies that $\mathcal{F}(\text{LP-S}) \subset \mathcal{F}(\text{QP-T})$, where QP-T is the equivalent QP relaxation defined by SOCP-T.

We now show how the above proof can be generalized to certain cycles. To the best of our knowledge, the alternative proof in Wainwright and Jordan (2003) cannot be trivially extended to these cases.

5.3 QP and SOCP Relaxations over Cycles

We now prove that the above result also holds true when the graph G forms an *even cycle*, that is, cycles with even number of vertices, whose weights are all non-negative or all non-positive provided $d(i,j) \geq 0$, for all $l_i, l_j \in \mathbf{l}$.

Theorem 5: When $d(i,j) \geq 0$ for all $l_i, l_j \in \mathbf{l}$, the SOCP relaxations which define constraints only using non-overlapping graphs G which form (arbitrarily large) even cycles with all positive or all negative weights are dominated by the LP-S relaxation.

Proof: It is sufficient to show that Lemmas 5.1 and 5.2 hold for a graph $G = (V,E)$ which forms an even cycle. We first consider the case where $\theta^2_{ab;ij} > 0$. Without loss of generality, we assume that $V = \{1,2,\ldots,t\}$ (where t is even) such that $(i,i+1) \in E$ for all $i = 1,\cdots,t-1$. Further, $(t,1) \in E$ thereby forming an even cycle. We construct a vector $\mathbf{m}$ of size n such that $m_a = -1^a$ if $a \in V$ and $m_a = 0$ otherwise. When $\theta^2_{ab;ij} < 0$, we define a vector $\mathbf{m}$ such that $m_a = 1$ if $a \in V$ and $m_a = 0$ otherwise. Fig. 4(b) shows an example of a graph G which forms an even cycle together with the corresponding elements of $\mathbf{m}$. Using $\mathbf{m}$, we construct a vector $\mathbf{s}$ of length nh (similar to the proofs of Lemmas 5.1 and 5.2). Lemmas 5.1 and 5.2 follow from the fact that $\mathbf{s}^\top \mathbf{C} \mathbf{s} \geq 0$. We omit details. ∎

It is worth noting that the feasibility region of the above SOCP relaxation (with SOC constraints defined using some special form of cycles) is not a subset of the LP-S relaxation. However, we are still able to show that LP-S dominates such an SOCP relaxation. The above Theorem helps illustrate the difference between comparing the feasibility regions of relaxations and the employing the concept of domination. Specifically, if the feasibility region of relaxation A is a subset of the feasibility region of relaxation B, then B dominates A. However, the converse of the above statement is not true.

Theorem 5 can be proved for cycles of any length whose weights are all negative by a similar construction. Further, it also holds true for *odd cycles* (i.e., cycles of odd number of variables) which have only one positive or only one negative weight. However, as will be seen in the next section, unlike trees it is not possible to extend these results for any general cycle.

6. Some Useful SOC Constraints

We now describe two SOCP relaxations which include all the marginalization constraints specified in LP-S. Note that the marginalization constraints can be incorporated within the SOCP framework but not in the QP framework.

6.1 The SOCP-C Relaxation

The SOCP-C relaxation (where C denotes cycles) defines second order cone (SOC) constraints using positive semidefinite matrices $\mathbf{C}$ such that the graph G (defined in § 5.1) form cycles. Let the variables corresponding to vertices of one such cycle G of length c be denoted as $\mathbf{v}_C = \{v_b | b \in \{a_1, a_2, \cdots, a_c\}\}$. Further, let $\mathbf{l}_C = \{l_j | j \in \{i_1, i_2, \cdots, i_c\}\} \in \mathbf{l}^c$ be a set of labels for the variables $\mathbf{v}_C$. The SOCP-C relaxation specifies the following constraints:

- The marginalization constraints, that is,

$$\sum_{l_j \in \mathbf{l}} X_{ab;ij} = (2-h)x_{a;i}, \forall (a,b) \in \mathcal{E}, l_i \in \mathbf{l}.$$

- A set of SOC constraints

$$||\mathbf{U}^\top \mathbf{x}|| \leq \mathbf{C} \bullet \mathbf{X}, \tag{49}$$

  such that the graph G defined by the above constraint forms a cycle. The matrix $\mathbf{C}$ is 0 everywhere except the following elements:

$$C_{a_k,a_l,i_k,i_l} = \begin{cases} \lambda_c & \text{if} \quad k = l, \\ D_c(k,l) & \text{otherwise}. \end{cases}$$

  Here $\mathbf{D}_c$ is a $c \times c$ matrix which is defined as follows:

$$D_c(k,l) = \begin{cases} 1 & \text{if} \quad |k-l| = 1, \\ (-1)^{c-1} & \text{if} \quad |k-l| = c-1, \\ 0 & \text{otherwise}, \end{cases}$$

  and λ_c is the absolute value of the smallest eigenvalue of $\mathbf{D}_c$.

In other words the submatrix of $\mathbf{C}$ defined by $\mathbf{v}_C$ and $\mathbf{l}_C$ has diagonal elements equal to λ_c and off-diagonal elements equal to the elements of $\mathbf{D}_c$. As an example we consider two cases when $c = 3$ and $c = 4$. In these cases the matrix $\mathbf{D}_c$ is given by

$$\mathbf{D}_3 = \begin{pmatrix} 0 & 1 & 1 \\ 1 & 0 & 1 \\ 1 & 1 & 0 \end{pmatrix} \text{ and } \mathbf{D}_4 = \begin{pmatrix} 0 & 1 & 0 & -1 \\ 1 & 0 & 1 & 0 \\ 0 & 1 & 0 & 1 \\ -1 & 0 & 0 & 1 \end{pmatrix},$$

respectively, while $\lambda_3 = 1$ and $\lambda_4 = \sqrt{2}$. Clearly, $\mathbf{C} = \mathbf{U}^\top \mathbf{U} \succeq 0$ since its only non-zero submatrix $\lambda_c I + \mathbf{D}_c$ (where I is a $c \times c$ identity matrix) is positive semidefinite. This allows us to define a valid SOC constraint as shown in inequality (49). We choose to define the SOC constraint (49) for only those set of labels $\mathbf{l}_C$ which satisfy the following:

$$\sum_{(a_k,a_l) \in \mathcal{E}} D_c(k,l) \theta^2_{a_k a_l; i_k i_l} \geq \sum_{(a_k,a_l) \in \mathcal{E}} D_c(k,l) \theta^2_{a_k a_l; j_k j_l}, \forall \{j_1, j_2, \cdots, j_c\}.$$

Note that this choice is motivated by the fact that the variables $X_{a_k a_l;i_k i_l}$ corresponding to these sets $\mathbf{v}_C$ and $\mathbf{l}_C$ are assigned trivial values by the LP-S relaxation in the presence of non-submodular terms (see example below), that is,

$$X_{a_k a_l;i_k i_l} = \begin{cases} -1 & \text{if} \quad \theta^2_{a_k a_l;i_k i_l} \geq 0, \\ 1 & \text{otherwise.} \end{cases}$$

In order to avoid this trivial solution, we impose the SOC constraint (49) on them.

Since marginalization constraints are included in the SOCP-C relaxation, the value of the objective function obtained by solving this relaxation would at least be equal to the value obtained by the LP-S relaxation (i.e., SOCP-C dominates LP-S, see Case II in Section 2). We can further show that in the case where $|\mathbf{l}| = 2$ and the constraint (49) is defined over a frustrated cycle[8] SOCP-C strictly dominates LP-S. One such example is given below. Note that if the given MRF contains no frustrated cycle, then it can be solved exactly using the method described by Hammer et al. (1984).

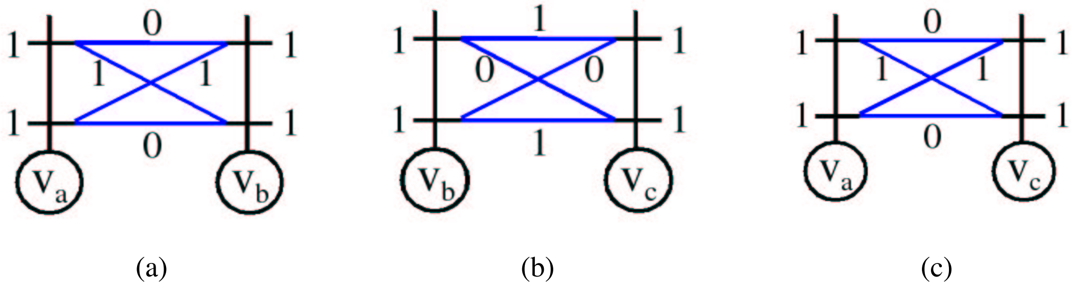


Figure 5: An example MRF defined over three random variables $\mathbf{v} = \{v_a, v_b, v_c\}$ shown as unfilled circles. Each of these variables can take one of two labels from the set $\mathbf{l} = \{l_0, l_1\}$ which are shown as branches (i.e., the horizontal lines) of trellises (i.e., the vertical lines) on top of the random variables. The unary potentials are shown next to the corresponding branches. The pairwise potentials are shown next to the edges connecting the branches of two neighbouring variables. Note that the pairwise potentials defined for (a,b) and (a,c) form a submodular Ising model (in **(a)** and **(b)** respectively). The pairwise potentials defined for (b,c) are non-submodular (in **(c)**). In other words, the above MRF defines a frustrated cycle.

Example: We consider a frustrated cycle and show that SOCP-C strictly dominates LP-S. Specifically, we consider an MRF with $\mathbf{v} = \{v_a, v_b, v_c\}$ and $\mathbf{l} = \{l_0, l_1\}$. The neighbourhood of this MRF is defined such that the variables form a cycle of length 3, that is, $\mathcal{E} = \{(a,b),(b,c),(c,a)\}$. We define a frustrated cycle which consists of all 3 variables of this MRF using the unary and pairwise potentials shown in Fig. 5, that is, the unary potentials are uniform and the pairwise potentials define only one non-submodular term (between the vertices b and c). Clearly, the energy of the optimal labelling for the above problem is 4. The value of the objective function obtained by solving the LP-S relaxation is 3 at an optimal solution shown in Fig. 6.

8. A cycle is called frustrated if it contains an odd number of non-submodular terms.

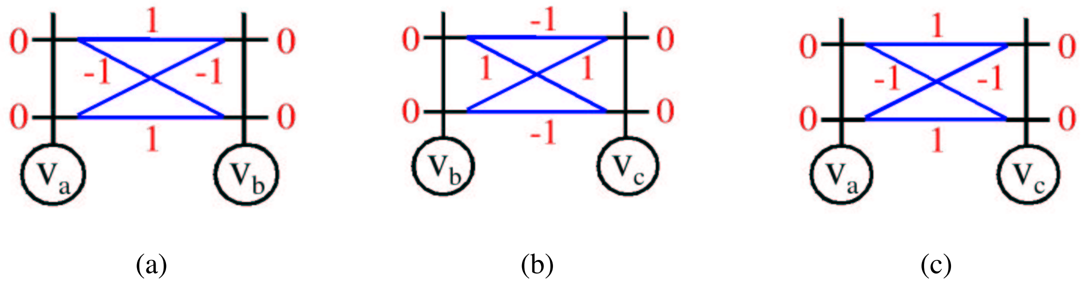

Figure 6: An optimal solution provided by the LP-S relaxation for the MRF shown in Fig. 5. The value of variable $x_{a;i}$ is shown next to the i^{th} branch of the trellis on top of v_a. In this optimal solution, all such variables $x_{a;i}$ are equal to 0. The value of the variable $X_{ab;ij}$ is shown next to the connection joining the i^{th} and the j^{th} branch of the trellises on top of v_a and v_b respectively. Note that $X_{ab;ij} = -1$ when $\theta^2_{ab;ij} > 0$ and $X_{ab;ij} = 1$ otherwise. This provides us with the minimum value of the objective function of LP-S, that is, 3.

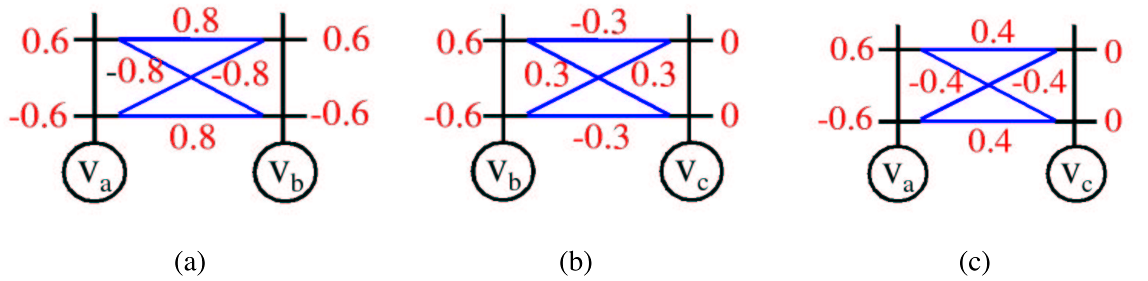

Figure 7: An optimal solution provided by the SOCP-C relaxation for the MRF shown in Fig. 5. This optimal solution provides us with the optimal value of 3.75 which greater than the LP-S optimal value for the solution shown in Fig. 6. Note that the optimal solution of LP-S does not belong to the feasibility region of SOCP-C as it violates constraint (50). This example proves that SOCP-C strictly dominates LP-S.

The LP-S optimal solution is no longer feasible when the SOCP-C relaxation is used. Specifically, the constraint

$$(x_{a;0} + x_{b;1} + x_{c;1})^2 \leq 3 + 2(X_{ab;01} + X_{ac;01} + X_{bc;11}), \tag{50}$$

is violated. In fact, the value of the objective function obtained using the SOCP-C relaxation is 3.75. Fig. 7 shows an optimal solution of the SOCP-C relaxation for the MRF in Fig. 5. The above example can be generalized to a frustrated cycle of any length. This proves that SOCP-C strictly dominates the LP-S relaxation (and hence, the QP-RL and SOCP-MS relaxations).

The constraint defined in Equation (49) is similar to the (linear) cycle inequality constraints (Chopra and Rao, 1993) which are given by

$$\sum_{k,l} D_c(k,l) X_{a_k a_l; i_k i_l} \geq 2 - c.$$

We believe that the feasibility region defined by cycle inequalities is a strict subset of the feasibility region defined by Equation (49). In other words a relaxation defined by adding cycle inequalities to LP-S would strictly dominate SOCP-C. We are not aware of a formal proof for this. We now describe the SOCP-Q relaxation.

6.2 The SOCP-Q Relaxation

In the previous section we saw that LP-S dominates SOCP relaxations whose constraints are defined on trees. However, the SOCP-C relaxation, which defines its constraints using cycles, strictly dominates LP-S. This raises the question whether matrices $\mathbf{C}$, which result in more complicated graphs G, would provide an even better relaxation for the MAP estimation problem. In this section, we answer this question in an affirmative. To this end, we define an SOCP relaxation which specifies constraints such that the resulting graph G form a clique. We denote this relaxation by SOCP-Q (where Q indicates cliques).

The SOCP-Q relaxation contains the marginalization constraint and the cycle inequalities (defined above). In addition, it also defines SOC constraints on graphs G which form a clique. We denote the variables corresponding to the vertices of clique G as $\mathbf{v}_Q = \{v_b | b \in \{a_1, a_2, \cdots, a_q\}\}$. Let $\mathbf{l}_Q = \{l_j | j \in \{i_1, i_2, \cdots, i_q\}\}$ be a set of labels for these variables $\mathbf{v}_Q$. Given this set of variables $\mathbf{v}_Q$ and labels $\mathbf{l}_Q$, we define an SOC constraint using a matrix $\mathbf{C}$ of size $nh \times nh$ which is zero everywhere except for the elements $C_{a_k a_l; i_k i_l} = 1$. Clearly, $\mathbf{C}$ is a rank 1 matrix with eigenvalue 1 and eigenvector $\mathbf{u}$ which is zero everywhere except $u_{a_k; i_k} = 1$ where $v_{a_k} \in \mathbf{v}_Q$ and $l_{i_k} \in \mathbf{l}_Q$. This implies that $\mathbf{C} \succeq 0$, which enables us to obtain the following SOC constraint:

$$\left(\sum_k x_{a_k; i_k}\right)^2 \leq q + \sum_{k,l} X_{a_k a_l; i_k i_l}. \tag{51}$$

We choose to specify the above constraint only for the set of labels $\mathbf{l}_Q$ which satisfy the following condition:

$$\sum_{(a_k, a_l) \in \mathcal{E}} \theta^2_{a_k a_l; i_k i_l} \geq \sum_{(a_k, a_l) \in \mathcal{E}} \theta^2_{a_k a_l; j_k j_l}, \forall \{j_1, j_2, \cdots, j_q\}.$$

Again, this choice is motivated by the fact that the variables $X_{a_k a_l; i_k i_l}$ corresponding to these sets $\mathbf{v}_Q$ and $\mathbf{l}_Q$ are assigned trivial values by the LP-S relaxation in the presence of non-submodular pairwise potentials.

When the clique contains a frustrated cycle, it can be shown that SOCP-Q dominates the LP-S relaxation (similar to SOCP-C). Further, using a counter-example, it can proved that the feasibility region given by cycle inequalities is not a subset of the feasibility region defined by constraint (51). One such example is given below.

Example: We present an example to prove that the feasibility region given by cycle inequalities is not a subset of the feasibility region defined by the SOC constraint

$$\left(\sum_k x_{a_k; i_k}\right)^2 \leq q + \sum_{k,l} X_{a_k a_l; i_k i_l}, \tag{52}$$

which is used in SOCP-Q. Note that it would be sufficient to provide a set of variables $(\mathbf{x}, \mathbf{X})$ which satisfy the cycle inequalities but not constraint (52).

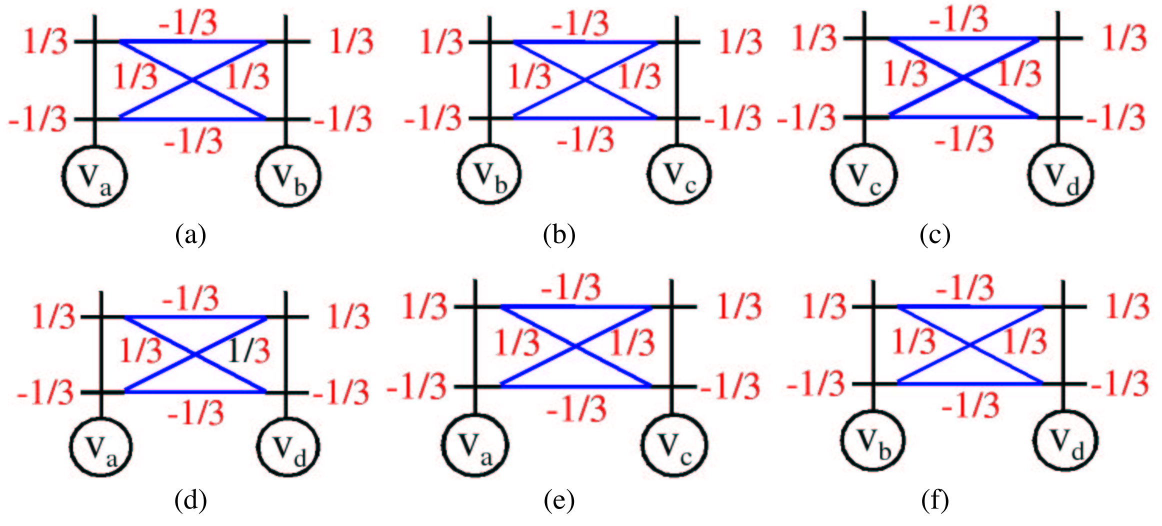

Figure 8: An infeasible solution for SOCP-Q. The value of the variable $x_{a;i}$ is shown next to the i^{th} branch of the trellis on top of v_a. The value of $X_{ab;ij}$ is shown next to the connection between the i^{th} and the j^{th} branches of the trellises on top of v_b and v_b respectively. It can easily be verified that these variables satisfy all cycle inequalities. However, they do not belong to the feasibility region of SOCP-Q since they violate constraint (53).

To this end, we consider an MRF defined over the random variables $\mathbf{v} = \{v_a, v_b, v_c, v_d\}$ which form a clique of size 4 with respect to the neighbourhood relationship $\mathcal{E}$, that is,

$$\mathcal{E} = \{(a,b), (b,c), (c,d), (a,d), (a,c), (b,d)\}.$$

Each of these variables takes a label from the set $\mathbf{l} = \{l_0, l_1\}$. Consider the set of variables $(\mathbf{x}, \mathbf{X})$ shown in Fig. 8 which do not belong to the feasibility region of SOCP-Q. It can be easily shown that these variables satisfy all the cycle inequalities (together with all the constraints of the LP-S relaxation). However, $(\mathbf{x}, \mathbf{X})$ defined in Fig. 8 does not belong to the feasibility region of the SOCP-Q relaxation since it does not satisfy the following SOC constraint:

$$\left(\sum_{v_a \in \mathbf{v}} x_{a;0} \right)^2 \leq 4 + 2 \left(\sum_{(a,b) \in \mathcal{E}} X_{ab;00} \right). \tag{53}$$

7. Discussion

We presented an analysis of approximate algorithms for MAP estimation which are based on convex relaxations. The surprising result of our work is that despite the flexibility in the form of the objective function/constraints offered by QP and SOCP, the LP-S relaxation dominates a large class of QP and SOCP relaxations. It appears that the authors who have previously used SOCP relaxations in the combinatorial optimization literature (Muramatsu and Suzuki, 2003) and those who have reported QP relaxation in the machine learning literature (Ravikumar and Lafferty, 2006) were unaware of this result. **However, our results do not discourage future research on SOCP based relaxations**.

On the contrary, we have proposed two new SOCP relaxations (SOCP-C and SOCP-Q) and presented some examples to prove that they provide a better approximation than LP-S. We also believe that SOC constraints are easier to obtain (using the method of Kim and Kojima 2000) than LP constraints. An interesting direction for future research would be to determine the best SOC constraints for a given MAP estimation problem (e.g., with truncated linear/quadratic pairwise potentials).

Editor: John Shawe-Taylor

Abstract

We continue our recent study on constructing a *refinement kernel* for a given kernel so that the reproducing kernel Hilbert space associated with the refinement kernel contains that with the original kernel as a subspace. To motivate this study, we first develop a refinement kernel method for learning, which gives an efficient algorithm for updating a learning predictor. Several characterizations of refinement kernels are then presented. It is shown that a nontrivial refinement kernel for a given kernel always exists if the input space has an infinite cardinal number. Refinement kernels for translation invariant kernels and Hilbert-Schmidt kernels are investigated. Various concrete examples are provided.

Keywords: reproducing kernels, reproducing kernel Hilbert spaces, learning with kernels, refinement kernels, translation invariant kernels, Hilbert-Schmidt kernels

1. Introduction

In our recent work (Xu and Zhang, 2007), we studied characterizations of a refinable kernel which offers a convenient way of enlarging its reproducing kernel Hilbert space (RKHS). Appropriately expanding a given RKHS is needed in learning theory when the given space is not adequate for a specific purpose. We will discuss this point in depth later. With a refinable kernel, a wavelet-like kernel or a *kernellet* was introduced in Xu and Zhang (2007). As pointed out there, the refinable kernel leaves out two important classes of kernels. Neither the Gaussian kernels nor kernels having finite dimensional feature spaces are refinable. Due to important applications of these classes of kernels, there is a need to develop a general method of enlarging a RKHS besides the particular one given by a refinable kernel. It is this need that leads to the study presented in this paper of *refinement* kernels for a given kernel.

We first review necessary notions related to kernels. Let X be a nonempty prescribed set called an input space. For $n \in \mathbb{N}$, we let $\mathbb{N}_n := \{1, 2, \dots, n\}$. A *kernel* K on X is a function from $X \times X$ to the field $\mathbb{C}$ of complex numbers such that for any finite set of inputs $\mathbf{x} := \{x_j : j \in \mathbb{N}_n\} \subseteq X$ the matrix

$$K[\mathbf{x}] := [K(x_j, x_k) : j, k \in \mathbb{N}_n] \tag{1}$$

is hermitian and positive semi-definite. Kernels are important in learning theory as they are used to measure the similarity between inputs in X (Evgeniou et al., 2000; Schölkopf and Smola, 2002; Shawe-Taylor and Cristianini, 2004; Vapnik, 1998). A *reproducing kernel Hilbert space* (RKHS) on

X is a Hilbert space of functions on X for which point evaluations are continuous linear functionals (Aronszajn, 1950).

There is a bijective correspondence between the set of kernels on X and that of reproducing kernel Hilbert spaces (RKHS) on X. In particular, for each kernel K on X there is a unique RKHS $\mathcal{H}_K$ such that

$$K(\cdot,x) \in \mathcal{H}_K, \ \text{ for all } x \in X \tag{2}$$

and for all $f \in \mathcal{H}_K$ there holds

$$f(x) = (f, K(\cdot,x))_{\mathcal{H}_K}, \ \ x \in X, \tag{3}$$

where $(\cdot,\cdot)_{\mathcal{H}_K}$ denotes the inner product on $\mathcal{H}_K$. Moreover, the linear span of $\{K(\cdot,x) : x \in X\}$ is dense in $\mathcal{H}_K$, namely,

$$\mathcal{H}_K = \overline{\operatorname{span}}\{K(\cdot,x) : x \in X\}, \tag{4}$$

and the inner product on $\mathcal{H}_K$ is determined by

$$(K(\cdot,y), K(\cdot,x))_{\mathcal{H}_K} = K(x,y), \ \ x,y \in X. \tag{5}$$

Conversely, for each RKHS $\mathcal{H}$ on X there exists exactly one kernel K on X such that (2) and (3) hold true with $\mathcal{H}_K$ replaced by $\mathcal{H}$. Equation (3) is interpreted as that a function in $\mathcal{H}_K$ can be *reproduced* through its inner product with the kernel K. For this reason, K is often called the *reproducing kernel* of $\mathcal{H}_K$.

The main purpose of this study is to investigate kernels K and G on X so that

$$\mathcal{H}_K \preceq \mathcal{H}_G \tag{6}$$

in the sense that $\mathcal{H}_K \subseteq \mathcal{H}_G$ and for all $f,g \in \mathcal{H}_K$, $(f,g)_{\mathcal{H}_K} = (f,g)_{\mathcal{H}_G}$. For an existing kernel K, we call a kernel G satisfying (6) a *refinement kernel* for K. If in addition, $\mathcal{H}_G$ contains $\mathcal{H}_K$ as a proper subspace, then we call G a *nontrivial* refinement kernel for K. The inclusion (6) was first considered by Aronszajn (1950). It was proved there that (6) holds true if and only if $L := G - K$ remains a kernel on X and $\mathcal{H}_K \cap \mathcal{H}_L = \{0\}$.

Our interest in refinement kernels is motivated by the widely used regularized learning algorithm, which and its variations have attracted much attention in the literature (see, for example, Bousquet and Elisseeff, 2002; Cucker and Smale, 2002; Micchelli and Pontil, 2005a,b; Mukherjee et al., 2006; Schölkopf and Smola, 2002; Smale and Zhou, 2003; Steinwart and Scovel, 2005; Vapnik, 1998; Wahba, 1999; Walder et al., 2006; Ying and Zhou, 2007; Zhang, 2004, and the references cited therein). The algorithm aims at inferring from a finite set of training data $\mathbf{z} := \{(x_j, y_j) : j \in \mathbb{N}_m\} \subseteq X \times \mathbb{C}$ a function f_0 on X so that $f_0(x)$ would yield a meaningful output of an input $x \in X$. For a positive regularization parameter μ and the norm $\|\cdot\|_{\mathcal{H}_K}$ on $\mathcal{H}_K$, we set for each $f \in \mathcal{H}_K$

$$\mathcal{E}_{K,\mu}(f) := \sum_{j \in \mathbb{N}_m} |f(x_j) - y_j|^2 + \mu \|f\|_{\mathcal{H}_K}^2.$$

The learning algorithm then outputs a predictor f_0 as the minimizer of an error functional:

$$f_0 = \min_{f \in \mathcal{H}_K} \mathcal{E}_{K,\mu}(f). \tag{7}$$

The behavior of the predictor f_0 depends on the choice of the regularization parameter μ and as well as the RKHS. We will not consider the choice of μ in this paper. Rather, we will focus on the issue of expanding the RKHS associated with the original kernel K.

There are two possible situations where one may desire to find a nontrivial refinement kernel G for K in (7). The first happens when the predictor f_0 obtained from (7) does not work in a satisfactory way. One may hence be forced to replace K with a kernel G hoping that the corresponding learning algorithm would yield a better predictor. This is possible only if $\mathcal{H}_G$ is larger than $\mathcal{H}_K$. In other words, if the current RKHS underfits, then a refinement kernel may lead to a better predictor. The second situation occurs when the old training data $\mathbf{z}$ is expanded to be a new training data by adding to $\mathbf{z}$ more new samples from $X \times \mathbb{C}$. Since more information is available as the training data is increased, it is reasonable for people to expect a better predictor, which could be achieved by searching in a larger RKHS. This accounts for another reason one might want to find a refinement kernel for K.

In a recent paper (Xu and Zhang, 2007), we introduced a method of updating kernels via a composition of the kernel with a bijective mapping γ of the input space. Specifically, with a selected positive constant λ, we define for a kernel K on X a new kernel

$$G(x,y) := \lambda K(\gamma(x),\gamma(y)), \quad x,y \in X \tag{8}$$

and call K a γ-*refinable kernel* if (8) gives a nontrivial refinement kernel G for K. Various characterizations and many examples of refinable kernels were provided in Xu and Zhang (2007). The work was motivated by refinable functions in the context of wavelet analysis (Daubechies, 1992). As mentioned earlier, a purpose of the current study is to resolve two remaining questions in Xu and Zhang (2007). One is that a kernel is never refinable if it has a finite dimensional feature space. The other is that the commonly used Gaussian kernels are not refinable either. On the other hand, we know that kernels with a finite dimensional feature space, such as finite dot-product kernels (FitzGerald et al., 1995), and Gaussian kernels are important in learning (Micchelli and Pontil, 2005a; Schölkopf and Smola, 2002; Steinwart and Scovel, 2005; Walder et al., 2006). We would like to find nontrivial refinement kernels for them by considering general methods of updating kernels besides the particular one (8).

We organize this paper in six sections. Before delving into technical analysis of refinement kernels, we further motivate our study by proposing a refinement kernel method for learning in the next section. In Section 3, we present three basic characterizations of a refinement kernel. The first characterization is due to Aronszajn (1950), the second comes from a modification of a result in Xu and Zhang (2007) and the third result which is completely new serves as a base for further study in the remaining sections. We discuss in Section 4 the existence of a refinement kernel, and desired properties of kernels preserved by a refinement process. In particular, it will be shown that a nontrivial refinement kernel always exists if the input space contains infinite elements. In Sections 5 and 6, we study refinement kernels for translation invariant kernels and Hilbert-Schmidt kernels, respectively.

2. A Refinement Kernel Method for Learning

This section is devoted to development of learning algorithms based on refinement kernels. Suppose that a learning algorithm with kernel K has been given, that is, we have had a minimizer in the RKHS $\mathcal{H}_K$. But somehow we find that the minimizer is not good enough for a specific purpose. We then want to make a new search for a new minimizer in a larger RKHS $\mathcal{H}_G$, where G is a refinement kernel for K. We will demonstrate how a new search is done by making use of the previously computed results for the kernel K and the corresponding minimizer. We will refer to the methods described in this section as *refinement kernel methods* for learning.

For simplicity of presentation, we work only with real numbers in this section. Let K be a kernel on the input space X and $\mathbf{z} := \{(x_j, y_j) : j \in \mathbb{N}_m\} \subseteq X \times \mathbb{R}$ a finite set of sample data. We return to the learning algorithm described in the introduction which has the form

$$\min_{f \in \mathcal{H}_K} \left\{ \sum_{j \in \mathbb{N}_m} |f(x_j) - y_j|^2 + \mu \|f\|^2_{\mathcal{H}_K} \right\}. \tag{9}$$

The *representer theorem* (Kimeldorf and Wahba, 1971; Schölkopf et al., 2001; Schölkopf and Smola, 2002) in learning theory ensures that the minimizer $f_0 \in \mathcal{H}_K$ of (9) has the form

$$f_0 = \sum_{j \in \mathbb{N}_m} c_j K(\cdot, x_j).$$

In the above equation the vector $\mathbf{c} := [c_j : j \in \mathbb{N}_m]^T$ satisfies the linear system

$$(\mu I_m + K[\mathbf{x}])\mathbf{c} = \mathbf{y}, \tag{10}$$

where I_m denotes the $m \times m$ identity matrix, $\mathbf{x} := [x_j : j \in \mathbb{N}_m]^T$ and $\mathbf{y} := [y_j : j \in \mathbb{N}_m]^T$.

Suppose that the minimizer f_0 is not satisfactory and we need to have a new search in a larger RKHS. We assume that a refinement kernel G for K has been chosen and the training data $\mathbf{z}$ has been expanded to $\mathbf{z} \cup \mathbf{z}'$, where $\mathbf{z}' := \{(x'_k, y'_k) : k \in \mathbb{N}_q\} \subseteq X \times \mathbb{R}$. A new predictor can be obtained as the minimizer of

$$\min_{g \in \mathcal{H}_G} \left\{ \sum_{j \in \mathbb{N}_m} |g(x_j) - y_j|^2 + \sum_{k \in \mathbb{N}_q} |g(x'_k) - y'_k|^2 + \mu \|g\|^2_{\mathcal{H}_G} \right\}. \tag{11}$$

The purpose of this section is to develop an algorithm for efficiently solving (11) by using the existing information of the original minimization (9).

We proceed it in two steps.

2.1 Fixed Training Data

In this subsection, we assume that the training data set remains unchanged. Suppose that f_0 has been obtained, that is, linear system (10) has been solved, and one wishes to refine the kernel K in (9) to improve the predictor f_0. We consider a refinement kernel G for K for which the orthogonal complement of $\mathcal{H}_K$ in $\mathcal{H}_G$ is finite dimensional. We see from Aronszajn (1950) that there exist linearly independent functions ψ_j, $j \in \mathbb{N}_p$, on X, none of which lies in $\mathcal{H}_K$ such that the kernel $L := G - K$ has the form

$$L(x,y) := \sum_{j \in \mathbb{N}_p} \psi_j(x)\psi_j(y), \quad x, y \in X.$$

For instance, if K is the Gaussian kernel on $\mathbb{R}^d$ then L can be chosen as a finite dot-product kernel

$$\sum_{n \in \mathbb{Z}_+} a_n (x,y)^n, \quad x, y \in \mathbb{R}^d$$

or a *finite complex sinusoid kernel*

$$\sum_{n\in\mathbb{Z}^d} b_n e^{i(n,x-y)}, \ \ x,y\in\mathbb{R}^d,$$

where a and b are a nonnegative function on $\mathbb{Z}_+ := \mathbb{N}\cup\{0\}$ and $\mathbb{Z}^d$, respectively, with finite supports.

Using the refinement kernel G, we shall obtain a new predictor g_0 in a larger RKHS $\mathcal{H}_G$ that is the minimizer of

$$\min_{g\in\mathcal{H}_G}\left\{\sum_{j\in\mathbb{N}_m}|g(x_j)-y_j|^2+\mu\|g\|^2_{\mathcal{H}_G}\right\}.$$

By the representer theorem, the predictor g_0 is of the form

$$g_0=\sum_{j\in\mathbb{N}_m} d_j G(\cdot,x_j),$$

where $\mathbf{d} := [d_j : j\in\mathbb{N}_m]^T$ satisfies

$$(\mu I_m + K[\mathbf{x}] + L[\mathbf{x}])\mathbf{d} = \mathbf{y}. \tag{12}$$

Suppose that the computational results in solving (10) have been stored. Since in general $K[\mathbf{x}]$ is a dense positive semi-definite matrix, linear system (10) is usually solved by the Cholesky factorization method (Golub and van Loan, 1996). The method works at a cost of $O(m^3)$ multiplications of real numbers. We hence assume that we have obtained the Cholesky factorization of $\mu I_m + K[\mathbf{x}]$. The decomposition (12) enables us to solve a linear system whose coefficient matrix is $\mu I_m + K[\mathbf{x}]$ using only $O(m^2)$ multiplications.

Now we have to solve the new linear system (12). Instead of spending another $O(m^3)$ multiplications, we wish to make use of the stored computational results from solving (10) to reduce the computational complexity in solving (12). Specifically, for each $j\in\mathbb{N}_p$, we let $\psi_j(\mathbf{x}) := [\psi_j(x_k) : k\in\mathbb{N}_m]^T$ and let $\mathbf{e}_j$ denote the vector satisfying

$$(\mu I_m + K[\mathbf{x}])\mathbf{e}_j = \psi_j(\mathbf{x}). \tag{13}$$

We also need the vector

$$\beta := [-\psi_j(\mathbf{x})^T\mathbf{c} : j\in\mathbb{N}_p] \tag{14}$$

and the $p\times p$ matrix B defined by

$$B_{jk} := \psi_j(\mathbf{x})^T\mathbf{e}_k, \ \ j,k\in\mathbb{N}_p. \tag{15}$$

Since by (13) there holds for each $j,k\in\mathbb{N}_p$ that $B_{jk} = \mathbf{e}_j^T(\mu I_m + K[\mathbf{x}])\mathbf{e}_k$ and $\mu I_m + K[\mathbf{x}]$ is symmetric and strictly positive definite, B is symmetric and positive semi-definite. As a consequence, $I_p + B$ is invertible and we are allowed to introduce another vector $\alpha := [\alpha_j : j\in\mathbb{N}_p]^T\in\mathbb{R}^p$ as the unique solution of

$$(I_p + B)\alpha = \beta. \tag{16}$$

Proposition 1 *If vectors $\mathbf{e}_j\in\mathbb{R}^m$, $j\in\mathbb{N}_p$ are defined by (13), $\mathbf{c}\in\mathbb{R}^m$ by (10) and $\alpha\in\mathbb{R}^p$ by (16), then the solution $\mathbf{d}$ of linear system (12) is given by*

$$\mathbf{d} = \mathbf{c} + \sum_{j\in\mathbb{N}_p}\alpha_j\mathbf{e}_j. \tag{17}$$

If $\mathcal{N}(\mathbf{d})$ denotes the number of multiplications required for computing $\mathbf{d}$*, then*

$$\mathcal{N}(\mathbf{d}) = O(pm^2 + p^2m + p^3).$$

Proof Let $\mathbf{d}' := \mathbf{d} - \mathbf{c}$. It is clear by (10) and (12) that $\mathbf{d}$ satisfies (12) if and only if

$$(\mu I_m + K[\mathbf{x}])\mathbf{d}' + L[\mathbf{x}]\mathbf{d} = 0. \tag{18}$$

To prove the first statement of this proposition, it suffices to show that the vector $\mathbf{d}$ defined by (17) satisfies Equation (18). We denote by δ the left-hand side of (18). Substituting (17) into the left-hand side of (18) and noting that $L[\mathbf{x}] = \sum_{j\in\mathbb{N}_p}\psi_j(\mathbf{x})\psi_j(\mathbf{x})^T$, we obtain that

$$\delta = \sum_{j\in\mathbb{N}_p}\alpha_j\psi_j(\mathbf{x}) + \sum_{j\in\mathbb{N}_p}\psi_j(\mathbf{x})[\psi_j(\mathbf{x})^T\mathbf{c} + \sum_{k\in\mathbb{N}_p}\alpha_k\psi_j(\mathbf{x})^T\mathbf{e}_k].$$

By using (14) and (15), we have that

$$\delta = \sum_{j\in\mathbb{N}_p}\psi_j(\mathbf{x})\left[\alpha_j - \beta_j + \sum_{k\in\mathbb{N}_p}B_{jk}\alpha_k\right]. \tag{19}$$

Noting that α satisfies linear system (16) we observe for all $j\in\mathbb{N}_p$ that

$$\alpha_j - \beta_j + \sum_{k\in\mathbb{N}_p}B_{jk}\alpha_k = 0.$$

Combining this equation with (19) yields that $\delta = 0$. That is, the vector $\mathbf{d}$ defined by (17) satisfies Equation (18).

To prove the second statement, we make use of the assumption that the result of the Cholesky factorization of $\mu I_m + K[\mathbf{x}]$ has been computed and stored and we enumerate the additional number of multiplications required for computing the solution $\mathbf{d}$. Solving p linear systems (13) needs $O(pm^2)$ number of multiplications. Computing vector β and matrix B requires pm and $\frac{p(p+1)}{2}m$ multiplications respectively. Solving (16) costs $O(p^3)$ multiplications and finally, computing $\mathbf{d}$ by (17) requires pm multiplications. Summing these costs together yields the number of multiplications required to solve (12). ■

We remark that in applications, the number m of sample data is much larger than the number p of the dimension of the difference space $\mathcal{H}_L$. Therefore, under the condition $p \ll m$, we know from Proposition 1 that computing the solution $\mathbf{d}$ of the linear system (12) requires $O(m^2)$ additional number of multiplications. This is a big saving in comparison to $O(m^3)$ number of multiplications if the linear system (12) is solved directly by the Cholesky factorization without using the refinement kernel method. In other words, the use of the refinement kernel method reduces the number of multiplications from $O(m^3)$ to $O(m^2)$.

Moreover, we observe that most of the computational costs are used for solving (13), which is clearly independent of the output $\mathbf{y}$. Therefore, if $\mathbf{x}$ remains fixed for different applications, which is the case in many practical scenarios such as image analysis and processing of signals of the same size, then (13) can be calculated in advance and stored for repeated use. Taking this advantage, we only need $O(m)$ additional number of multiplications to solve (12) in order to obtain an updated predictor.

2.2 Expanded Training Data

We assume in this subsection that the training data $\mathbf{z}$ has been expanded to $\mathbf{z}\cup\mathbf{z}'$ while the kernel K remains the same. A new predictor $f_1 \in \mathcal{H}_K$ is obtained by solving the minimization problem

$$\min_{f\in\mathcal{H}_K} \sum_{j\in\mathbb{N}_m} |f(x_j)-y_j|^2 + \sum_{k\in\mathbb{N}_q} |f(x'_k)-y'_k|^2 + \mu\|f\|^2_{\mathcal{H}_K}. \tag{20}$$

The predictor f_1 can be written in terms of the kernel K. To this end, we introduce two vectors

$$\mathbf{x}' := [x'_k : k\in\mathbb{N}_q]^T,\ \ \mathbf{y}' := [y'_k : k\in\mathbb{N}_q]^T,$$

and matrices

$$K[\mathbf{x},\mathbf{x}'] := [K(x_j,x'_k) : j\in\mathbb{N}_m, k\in\mathbb{N}_q],\ \ K[\mathbf{x}',\mathbf{x}] := K[\mathbf{x},\mathbf{x}']^T.$$

For notational simplicity, we also set $A := \mu I_m + K[\mathbf{x}]$, $B := \mu I_q + K[\mathbf{x}']$ and $C := K[\mathbf{x},\mathbf{x}']$. By the representer theorem, the minimizer f_1 of (20) is given by

$$f_1 = \sum_{j\in\mathbb{N}_m} d_j K(\cdot,x_j) + \sum_{k\in\mathbb{N}_q} d'_k K(\cdot,x'_k),$$

where $\mathbf{d} := [d_j : j\in\mathbb{N}_m]^T$ and $\mathbf{d}' := [d'_k : k\in\mathbb{N}_q]^T$ satisfy

$$\begin{bmatrix} A & C \\ C^T & B \end{bmatrix}\begin{bmatrix} \mathbf{d} \\ \mathbf{d}' \end{bmatrix} = \begin{bmatrix} \mathbf{y} \\ \mathbf{y}' \end{bmatrix}. \tag{21}$$

The above linear system generally cost $O((m+q)^3)$ number of multiplications to solve by using the Cholesky factorization. With the known Cholesky factorization of $\mu I_m + K[\mathbf{x}]$, we propose a method to solve system (21) with reduction in the computational costs.

To solve system (21), we first find the $m\times q$ matrix M that satisfies

$$AM = C. \tag{22}$$

Note that

$$\begin{bmatrix} A & 0 \\ 0 & B-C^TM \end{bmatrix} = \begin{bmatrix} I_m & 0 \\ -C^TA^{-1} & I_q \end{bmatrix}\begin{bmatrix} A & C \\ C^T & B \end{bmatrix}\begin{bmatrix} I_m & -A^{-1}C \\ 0 & I_q \end{bmatrix}.$$

Thus $B-C^TM$ is symmetric and strictly positive definite. Consequently, we can solve the following system for a unique vector $\eta\in\mathbb{R}^q$

$$(B-C^TM)\eta = C^T\mathbf{c}-\mathbf{y}' \tag{23}$$

by using again the Cholesky factorization.

Proposition 2 *The solution* $\mathbf{d}$, $\mathbf{d}'$ *for linear system (21) is given as*

$$\mathbf{d} := \mathbf{c}+M\eta,\ \mathbf{d}' := -\eta. \tag{24}$$

Moreover, if $\mathcal{N}(\mathbf{d},\mathbf{d}')$ *denotes the number of multiplications required for computing both* $\mathbf{d}$ *and* $\mathbf{d}'$*, then*

$$\mathcal{N}(\mathbf{d},\mathbf{d}') = O(qm^2+q^2m+q^3).$$

Proof The first statement of this theorem follows by a direct computation using (10), (21), (22) and (23).

We now count the number of multiplications used for computing both $\mathbf{d}$ and $\mathbf{d}'$. Computing matrix M by solving the matrix Equation (22) needs $O(qm^2)$ number of multiplications. Finding η from the system (23) takes up $O(q^2m+q^3)$ number of multiplications. Computing $\mathbf{d}$ and $\mathbf{d}'$ by using (24) costs $O(qm)$ number of multiplications. Summing all these costs up proves the second part of this proposition. ■

We remark that under the assumption that $q \ll m$, we only need additional $O(m^2)$ number of multiplications to solve system (21) based on the known Cholesky factorization of matrix A from solving (10). Since (22) is independent of outputs, making use of this feature, if the inputs $\mathbf{x}$, $\mathbf{x}'$ remain unchanged in different applications, the computational costs can be further reduced as we have mentioned at the end of the last subsection.

2.3 The General Case

We now return to the general case where we have both a refinement kernel G for K such that $\mathcal{H}_{G-K}$ is p-dimensional, and an expanded training data $\mathbf{z}\cup\mathbf{z}'$. To make use of the computational result in solving (10) to compute the minimizer of (11), we divide the updating process into two steps. In step one, we fix the training data to be $\mathbf{z}$ and refine the kernel K to G. We then solve the system using the method described in Section 2.1. In step two, we fix the kernel to be G and expand $\mathbf{z}$ to $\mathbf{z}\cup\mathbf{z}'$ and solve the problem described in Section 2.2 with K replaced by G. Under reasonable hypotheses, the number of multiplications is $O(m^2)$. We state this result in the next proposition.

Proposition 3 *If $p \ll m$ and $q \ll m$ then the number of multiplications required for computing the minimizer of (11) using the algorithm described above is given by $O(m^2)$.*

The refinement kernel learning method allows us to reduce the number of multiplications from $O(m^3)$ to $O(m^2)$ by using the known Cholesky factorization of the matrix corresponding to the old kernel K.

Here we focus on the computational complexity of the refinement kernel method for the regularized learning algorithm in order to motivate the study of the refinement kernel. Although convergence and consistency of the refinement kernel method, and extensions of the method to other learning algorithms such as support vector machines are important, they are not the focus of this paper. They will be addressed in different occasions. The rest of this paper will be devoted to theoretical analysis of refinement kernels such as characterizations, existence and constructions.

3. Characterizations of Refinement Kernels

We present in this section several characterizations of refinement kernels. We begin with a review of a well-known characterization from Aronszajn (1950).

Lemma 4 *Let K,G be kernels on X. Then G is a refinement kernel for K if and only if $L := G-K$ is a kernel on X and $\mathcal{H}_K \cap \mathcal{H}_L = \{0\}$. If G is a refinement kernel for K then $\mathcal{H}_L$ is the orthogonal complement of $\mathcal{H}_K$ in $\mathcal{H}_G$, and G is a nontrivial refinement kernel for K if and only if L is not the zero kernel.*

Proof This is a direct consequence of Property 7 on page 345 and the theorem on page 353 of Aronszajn (1950). ■

In general, the conditions in the characterization presented in Lemma 4 are not easy to verify. Aiming at a characterization convenient for use, we next characterize refinement kernels in terms of feature maps for kernels, since most kernels are identified with their feature maps. A *feature map* for a kernel K on X is a mapping Φ from X to a Hilbert space $\mathcal{W}$ over $\mathbb{C}$ such that

$$K(x,y)=(\Phi(x),\Phi(y))_{\mathcal{W}},\ \ x,y\in X. \tag{25}$$

The Hilbert space $\mathcal{W}$ is called a *feature space* for K. It is well-known that K is a kernel on X if and only if it can be represented as (25) for some mapping $\Phi:X\to\mathcal{W}$ (Schölkopf and Smola, 2002). We denote by $\Phi(X)$ the image of X under the mapping Φ, by $\overline{\operatorname{span}}\Phi(X)$ the closure of the linear span of $\Phi(X)$ in $\mathcal{W}$, and by P_Φ the orthogonal projection from $\mathcal{W}$ to $\overline{\operatorname{span}}\Phi(X)$. There is a well-known characterization (Micchelli and Pontil, 2005a; Opfer, 2006; Schölkopf and Smola, 2002; Shawe-Taylor and Cristianini, 2004; Xu and Zhang, 2007) of the RKHS $\mathcal{H}_K$ of K in terms of its feature maps.

Lemma 5 *If K is a kernel on X represented as (25) by a feature map Φ from X to $\mathcal{W}$, then $\mathcal{H}_K=\{(\Phi(\cdot),u)_{\mathcal{W}}:u\in\mathcal{W}\}$ with the inner product*

$$((\Phi(\cdot),u)_{\mathcal{W}},(\Phi(\cdot),v)_{\mathcal{W}})_{\mathcal{H}_K}=(P_\Phi v,P_\Phi u)_{\mathcal{W}},\ \ u,v\in\mathcal{W}. \tag{26}$$

We shall always assume in the application of Lemma 5 that

$$\overline{\operatorname{span}}\Phi(X)=\mathcal{W} \tag{27}$$

since (25) remains valid if we replace $\mathcal{W}$ there with $\overline{\operatorname{span}}\Phi(X)$. Convenience which results from this assumption is that P_Φ in (26) would become the identity operator on $\mathcal{W}$.

We next state a characterization of refinement kernels in terms of their feature maps. Recall that we call a linear operator T from Hilbert space $\mathcal{W}_1$ to Hilbert space $\mathcal{W}_2$ *isometric* if for each $u\in\mathcal{W}_1$, $\|Tu\|_{\mathcal{W}_2}=\|u\|_{\mathcal{W}_1}$. A linear operator T from Hilbert space $\mathcal{W}_1$ to Hilbert space $\mathcal{W}_2$ is called an *isomorphism* if it is a bijective isometric linear mapping from $\mathcal{W}_1$ to $\mathcal{W}_2$. If there is an isomorphism from $\mathcal{W}_1$ to $\mathcal{W}_2$, we say that $\mathcal{W}_1$ is *isomorphic* to $\mathcal{W}_2$.

Theorem 6 *Suppose that K is a kernel on X with a feature map $\Phi:X\to\mathcal{W}$ satisfying (27) and G is a kernel on X with a feature map $\Phi':X\to\mathcal{W}'$ that satisfies*

$$\overline{\operatorname{span}}\Phi'(X)=\mathcal{W}'.$$

Then G is a refinement kernel for K if and only if there exists a bounded linear operator $T:\mathcal{W}'\to\mathcal{W}$ such that

$$T\Phi'(x)=\Phi(x),\ \ x\in X \tag{28}$$

and the adjoint operator $T^*:\mathcal{W}\to\mathcal{W}'$ of T is isometric. Moreover, G is a nontrivial refinement kernel for K if and only if T in (28) is not injective.

Proof The proof for the case when $\mathcal{W}' = \mathcal{W}$ and G is given by (8) can be found in Xu and Zhang (2007) (see Theorems 6, 7 therein). Based on Lemma 5, the arguments used there can be extended in a direct way to prove the general result described here. ■

We now explain how the general context of Theorem 6 allows us to refine kernels with a finite dimensional feature space while the refinement approach (8) does not. Suppose that K has the feature map representation (25) and G is given by (8). Then it can be seen that G has the form

$$G(x,y) = (\lambda^{1/2}\Phi(\gamma(x)), \lambda^{1/2}\Phi(\gamma(y)))_{\mathcal{W}},\ \ x,y \in X$$

with the feature space $\mathcal{W}$. By Theorem 6, G is a nontrivial refinement kernel for K if and only if there exists a bounded linear operator $T : \mathcal{W} \to \mathcal{W}$ such that

$$\lambda^{1/2} T\Phi(\gamma(x)) = \Phi(x),\ \ x \in X,$$

its adjoint T^* is isometric from $\mathcal{W}$ to $\mathcal{W}$, and T is not injective. By the latter two conditions, $\mathcal{W}$ must be isomorphic to a proper subspace of itself. This is impossible if $\mathcal{W}$ is finite dimensional. Therefore, we can not get a nontrivial refinement kernel by (8) if $\mathcal{W}$ is of finite dimension. On the other hand, by considering a general refinement process

$$G(x,y) = (\Phi'(x), \Phi'(y))_{\mathcal{W}'},\ \ x,y \in X,$$

we have the freedom to choose $\mathcal{W}'$ different from $\mathcal{W}$. The fact that $\mathcal{W}$ is finite dimensional actually makes it easier to find $\mathcal{W}'$ such that $\mathcal{W}$ is isomorphic to a proper subspace of $\mathcal{W}'$. Examples of nontrivial refinement kernels for kernels with a finite dimensional feature space will be provided in Section 6.

Our next task is to present a characterization of refinement kernels in terms of their feature spaces defined by finite positive Borel measures. This result is crucial for our discussion later on translation invariant kernels and Hilbert-Schmidt kernels. Suppose that Y is a topological space and denote by $\mathcal{B}(Y)$ the set of finite positive Borel measures on Y. For each $\rho \in \mathcal{B}(Y)$ and $p \in [1, +\infty)$ we let $L^p(Y, \rho)$ denote the space of Borel measurable functions f on Y such that

$$\int_Y |f(\xi)|^p d\rho(\xi) < +\infty.$$

In particular, $L^2(Y, \rho)$ is a Hilbert space with the inner product

$$(f,g)_{L^2(Y,\rho)} := \int_Y f(\xi)\overline{g(\xi)} d\rho(\xi),\ \ f,g \in L^2(Y,\rho).$$

For two measures $\rho_1, \rho_2 \in \mathcal{B}(Y)$, ρ_1 is said to be *absolutely continuous* with respect to ρ_2, denoted as $\rho_1 \ll \rho_2$, if for each Borel subset $V \subseteq Y$ with $\rho_2(V) = 0$, we have $\rho_1(V) = 0$. By the Radon-Nikodym theorem (see, for example, Rudin, 1987, page 121), if $\rho_1 \ll \rho_2$ then there exists a nonnegative $h \in L^1(Y, \rho_2)$ such that there holds for each Borel subset $V \subseteq Y$

$$\rho_1(V) = \int_Y h(\xi)\chi_V(\xi) d\rho_2(\xi),$$

where χ_V denotes the characteristic function of V. We sometimes write the function h satisfying the above equation as $d\rho_1/d\rho_2$.

For $\mu,\nu \in \mathcal{B}(Y)$, we let

$$\omega := \frac{\mu+\nu}{2} + \frac{|\mu-\nu|}{2},$$

where $|\mu-\nu|$ denotes the *total variation measure* of $\mu-\nu$. For the definition and properties of total variations of signed measures, see Rudin (1987, page 116). We remark that $|\mu-\nu| \in \mathcal{B}(Y)$ and $\mu(V),\nu(V) \le \omega(V)$ for all Borel subsets V of Y. It follows that μ,ν are absolutely continuous with respect to ω. We assume that a function $\phi : X \times Y \to \mathbb{C}$ has the property that for each $x \in X$, $\phi(x,\cdot) \in L^2(Y,\omega)$ and

$$\overline{\operatorname{span}}\{\phi(x,\cdot) : x \in X\} = L^2(Y,\omega). \tag{29}$$

Lemma 7 *If $\phi : X \times Y \to \mathbb{C}$ satisfies $\phi(x,\cdot) \in L^2(Y,\omega)$ for each $x \in X$ and condition (29), then $\phi(x,\cdot)$ lies in $L^2(Y,\mu)$ and $L^2(Y,\nu)$ for all $x \in X$, and* span $\{\phi(x,\cdot) : x \in X\}$ *is dense in $L^2(Y,\mu)$ and $L^2(Y,\nu)$.*

Proof We present only the case for μ since the case for ν can be similarly handled. Since $\mu \ll \omega$, we may introduce a function $h_\mu := d\mu/d\omega$. By the fact that $\mu(V) \le \omega(V)$ for each Borel $V \subseteq Y$, h_μ is less than or equal to 1 almost everywhere on Y with respect to ω. For $x \in X$, the assumption that $\phi(x,\cdot) \in L^2(Y,\omega)$ implies that it is Borel measurable. We also verify that

$$\int_Y |\phi(x,\xi)|^2 d\mu(\xi) = \int_Y |\phi(x,\xi)|^2 h_u(\xi) d\omega(\xi) \le \int_Y |\phi(x,\xi)|^2 d\omega(\xi) < +\infty.$$

This yields that $\phi(x,\cdot) \in L^2(Y,\mu)$ for all $x \in X$.

Now we assume that $f \in L^2(Y,\mu)$ is orthogonal to $\phi(x,\cdot)$ for each $x \in X$, that is,

$$\int_Y \phi(x,\xi)\overline{f(\xi)} d\mu(\xi) = 0, \ \ x \in X.$$

In the above equation, we substitute $d\mu(\xi) = h_\mu(\xi) d\omega(\xi)$ to obtain that

$$\int_Y \phi(x,\xi)\overline{f(\xi)} h_\mu(\xi) d\omega(\xi) = 0, \ \ x \in X. \tag{30}$$

The function fh_μ belongs to $L^2(Y,\omega)$ since h_μ is less than or equal to 1 almost everywhere on Y with respect to ω. Thus, by condition (29), Equation (30) implies that $fh_\mu = 0$ with respect to ω. We then observe for each Borel subset $V \subseteq Y$ that

$$\int_V |f(\xi)| d\mu(\xi) = \int_V |f(\xi)| h_\mu(\xi) d\omega(\xi) = 0.$$

This ensures that f vanishes almost everywhere on Y with respect to μ. We conclude that span $\{\phi(x,\cdot) : x \in X\}$ is dense in $L^2(Y,\mu)$. ■

By virtue of the above lemma, we introduce two kernels K_μ, K_ν by setting for all $x,y \in X$

$$K_\mu(x,y) := (\phi(x,\cdot),\phi(y,\cdot))_{L^2(Y,\mu)}, \ \ K_\nu(x,y) := (\phi(x,\cdot),\phi(y,\cdot))_{L^2(Y,\nu)}. \tag{31}$$

By Lemmas 5 and 7, functions in $\mathcal{H}_\mu := \mathcal{H}_{K_\mu}$ have the form

$$f_{\phi,\mu}(x) := (\phi(x,\cdot), f)_{L^2(Y,\mu)}, \ \ x \in X, \ \ f \in L^2(Y,\mu)$$

and the inner product on $\mathcal{H}_\mu$ is given by

$$(f_{\phi,\mu}, g_{\phi,\mu})_{\mathcal{H}_\mu} = (g, f)_{L^2(Y,\mu)}, \ \ f, g \in L^2(Y,\mu).$$

Similar results hold for $\mathcal{H}_\nu := \mathcal{H}_{K_\nu}$.

We shall characterize the relation $\mathcal{H}_\mu \preceq \mathcal{H}_\nu$ in terms of a relation of the measures μ, ν. To this end, we write $\mu \preceq \nu$ to indicate that $\mu \ll \nu$, and $d\mu/d\nu$ equals 0 or 1 almost everywhere with respect to ν, that is,

$$\nu\left(Y \setminus \left\{x \in Y : \frac{d\mu}{d\nu}(x) = 0 \text{ or } 1\right\}\right) = 0.$$

Note that $\mu \preceq \nu$ if and only if there exists a Borel subset $E \subseteq Y$ such that $\mu(Y \setminus E) = 0$ and for each Borel subset $V \subseteq E, \mu(V) = \nu(V)$.

Theorem 8 *Suppose that $\phi : X \times Y \to \mathbb{C}$ satisfies (29) and K_μ, K_ν are defined by (31). Then $\mathcal{H}_\mu \preceq \mathcal{H}_\nu$ if and only if $\mu \preceq \nu$. If $\mu \preceq \nu$ then K_ν is a nontrivial refinement kernel for K_μ if and only if*

$$\nu(Y) - \mu(Y) > 0.$$

Proof Suppose that $\mathcal{H}_\mu \preceq \mathcal{H}_\nu$. Hence, by Lemma 5, for each $f \in L^2(Y,\mu)$ there exists some $g \in L^2(Y,\nu)$ such that

$$\int_Y \phi(x,\xi)\overline{f(\xi)}d\mu(\xi) = \int_Y \phi(x,\xi)\overline{g(\xi)}d\nu(\xi) \tag{32}$$

and

$$\int_Y |f(\xi)|^2 d\mu(\xi) = \int_Y |g(\xi)|^2 d\nu(\xi). \tag{33}$$

With the derivatives $h_u := d\mu/d\omega$ and $h_\nu := d\nu/d\omega$, Equation (32) is rewritten as

$$\int_Y \phi(x,\xi)\overline{f(\xi)}h_\mu(\xi)d\omega(\xi) = \int_Y \phi(x,\xi)\overline{g(\xi)}h_\nu(\xi)d\omega(\xi).$$

This together with the density condition (29) implies that $fh_\mu = gh_\nu$ almost everywhere on Y with respect to ω. Thus for each $f \in L^2(Y,\mu)$ there exists some $g \in L^2(Y,\nu)$ satisfying for all Borel $V \subseteq Y$ that

$$\int_V f(\xi)d\mu(\xi) = \int_V f(\xi)h_\mu(\xi)d\omega(\xi) = \int_V g(\xi)h_\nu(\xi)d\omega(\xi) = \int_V g(\xi)d\nu(\xi). \tag{34}$$

We claim that $\mu \ll \nu$. We assume to the contrary that there exists a Borel set $V \subseteq Y$ for which $\nu(V) = 0$ and $\mu(V) > 0$. Letting $f = \chi_V$ in (34) yields $\mu(V) = 0$, a contradiction. Set $h := d\mu/d\nu$. By (34), the function g satisfying (32) and (33) can be taken as $g := fh$. With this choice, we obtain from (33) for each $f \in L^2(Y,\mu)$ that

$$\int_Y |f(\xi)|^2 h(\xi)d\nu(\xi) = \int_Y |f(\xi)|^2 h^2(\xi)d\nu(\xi).$$

The above equation implies that h equals 1 or 0 almost everywhere on Y with respect to ν. Consequently, $\mu \preceq \nu$.

Conversely, we suppose that $\mu \preceq \nu$ and proceed the proof by using Theorem 6. To this end, we set $E := \{x \in Y : \frac{d\mu}{d\nu}(x) = 1\}$ and introduce a linear operator $T : L^2(Y,\nu) \to L^2(Y,\mu)$ by

$$Tf := f\chi_E, \ \ f \in L^2(Y,\nu).$$

By the hypothesis $\mu \preceq \nu$, we have that $\mu(Y \setminus E) = 0$. This guarantees that for each $x \in X$, $T\phi(x,\cdot) = \phi(x,\cdot)$ in $L^2(Y,\mu)$. Note that for $g \in L^2(Y,\mu)$ and $f \in L^2(Y,\nu)$,

$$\begin{aligned}\int_Y g(\xi)\overline{(Tf)(\xi)}d\mu(\xi) &= \int_Y g(\xi)\overline{f(\xi)\chi_E(\xi)}d\mu(\xi) = \int_E g(\xi)\overline{f(\xi)}d\mu(\xi)\\ &= \int_E g(\xi)\overline{f(\xi)}d\nu(\xi) = \int_Y g(\xi)\chi_E(\xi)\overline{f(\xi)}d\nu(\xi).\end{aligned}$$

This ensures that the adjoint $T^* : L^2(Y,\mu) \to L^2(Y,\nu)$ of T is given by $T^*g = g\chi_E$, for $g \in L^2(Y,\mu)$. Moreover, it can be verified that

$$\int_Y |(T^*g)(\xi)|^2 d\nu(\xi) = \int_Y |g(\xi)\chi_E(\xi)|^2 d\nu(\xi) = \int_E |g(\xi)|^2 d\nu(\xi).$$

Since $d\mu/d\nu = 1$ on E and $\mu(Y \setminus E) = 0$, we get that

$$\int_E |g(\xi)|^2 d\nu(\xi) = \int_E |g(\xi)|^2 \frac{d\mu}{d\nu}(\xi) d\nu(\xi) = \int_E |g(\xi)|^2 d\mu(\xi) = \int_Y |g(\xi)|^2 d\mu(\xi).$$

Combining the above two equations yields that T^* is isometric. By Theorem 6, K_ν is a refinement kernel for K_μ.

If $\mu \preceq \nu$ then K_ν is a nontrivial refinement kernel for K_μ if and only if the operator T is not injective, that is, there exists $f \in L^2(Y,\nu)$ such that

$$\|f\|_{L^2(Y,\nu)} > 0 \ \text{ but } \ \|Tf\|_{L^2(Y,\mu)} = 0.$$

This is equivalent to that

$$\int_Y |f(\xi)|^2 d\nu(\xi) > 0 \ \text{ but } \ \int_E |f(\xi)|^2 d\nu(\xi) = 0.$$

Clearly, such an f exists if and only if $\nu(Y \setminus E) > 0$. Because

$$\nu(Y) - \mu(Y) = \nu(Y) - \mu(E) = \nu(Y) - \nu(E) = \nu(Y \setminus E),$$

we conclude the second statement of the theorem. ■

4. Existence of Refinement Kernels

With characterizations in Lemma 4 and Theorem 6, we shall consider existence of nontrivial refinement kernels and properties of kernels preserved by the refinement process. We let $\mathbb{C}^X$ denote the space of all the complex-valued functions on X.

Lemma 9 *A kernel K on X does not have a nontrivial refinement kernel if and only if $\mathcal{H}_K = \mathbb{C}^X$.*

Proof If $\mathcal{H}_K = \mathbb{C}^X$ then since for all kernels G on X, $\mathcal{H}_G \subseteq \mathbb{C}^X$, K does not have a nontrivial refinement kernel. Conversely, if $\mathcal{H}_K \neq \mathbb{C}^X$ then we choose an arbitrary function $\varphi \in \mathbb{C}^X \setminus \mathcal{H}_K$ and define the kernel

$$G(x,y) := K(x,y) + \varphi(x)\overline{\varphi(y)}, \ \ x,y \in X.$$

It is clear that $L := G - K$ is a kernel on X since it has a feature map $\varphi : X \to \mathbb{C}$. Moreover, $\mathcal{H}_L = \operatorname{span}\{\varphi\}$, which does not have a nontrivial intersection with $\mathcal{H}_K$. By Lemma 4, G is a nontrivial refinement kernel for K. ■

According to Lemma 9, one may expect that every kernel has a nontrivial refinement kernel since in general it should be impossible to impose an inner product on $\mathbb{C}^X$ so that it becomes a RKHS. Our next two results confirm this expectation.

Proposition 10 *If the input space X has a finite cardinality, then a kernel K on X has a nontrivial refinement kernel if and only if $K[X]$ is singular.*

Proof By Lemma 9, it suffices to show that $\mathcal{H}_K = \mathbb{C}^X$ if and only if the matrix $K[X]$ is invertible. Suppose that the cardinality of X is n and $X = \{x_j : j \in \mathbb{N}_n\}$. Assume that $K[X]$ is invertible. Then for each function $\varphi \in \mathbb{C}^X$ there exists a unique vector $[c_j : j \in \mathbb{N}_n] \in \mathbb{C}^n$ such that

$$\sum_{k\in\mathbb{N}_n} c_k K(x_j, x_k) = \varphi(x_j), \quad j \in \mathbb{N}_n,$$

which implies that $\varphi = \sum_{k\in\mathbb{N}_n} c_k K(\cdot, x_k)$. By (4), we have $\varphi \in \mathcal{H}_K$, thereby proving that $\mathcal{H}_K = \mathbb{C}^X$. Conversely, suppose that $\mathcal{H}_K = \mathbb{C}^X$. For each $j \in \mathbb{N}_n$, we introduce a function $\varphi_j \in \mathbb{C}^X$ by setting for each $l \in \mathbb{N}_n$, $\varphi_j(x_l) := \delta_{j,l}$, where δ denotes the Kronecker delta function. By (4) and the assumption that $\mathcal{H}_K = \mathbb{C}^X$, there exists a vector $[c_{j,k} : k \in \mathbb{N}_n] \in \mathbb{C}^n$ such that

$$\sum_{k\in\mathbb{N}_n} c_{j,k} K(x_l, x_k) = \varphi_j(x_l) = \delta_{j,l}, \quad j, l \in \mathbb{N}_n.$$

That is, $[c_{j,k} : j, k \in \mathbb{N}_n]$ is the inverse of the transpose of $K[X]$. Therefore, the matrix $K[X]$ is invertible. The proof is complete. ■

Theorem 11 *If the input space X has an infinite cardinality, then every kernel on it has a nontrivial refinement kernel.*

Proof According to Lemma 9, it suffices to show that there does not exist a kernel K on X such that $\mathcal{H}_K$ contains every function on X. We prove this by contradiction. Assume that there were a kernel K on X such that $\mathcal{H}_K = \mathbb{C}^X$. Since X has a countable subset of distinct points $x_n, n \in \mathbb{N}$, we may define a fixed function $f \in \mathbb{C}^X$ by setting $f(x_j) := j$ for each $j \in \mathbb{N}$ and $f(x) := 0$ for $x \in X \setminus \{x_j : j \in \mathbb{N}\}$. By (3), we would have for each $n \in \mathbb{N}$ that

$$n = |f(x_n)| = |(f, K(\cdot, x_n))_{\mathcal{H}_K}| \le \|f\|_{\mathcal{H}_K} \|K(\cdot, x_n)\|_{\mathcal{H}_K}. \tag{35}$$

Note that

$$\|K(\cdot, x_n)\|_{\mathcal{H}_K} = \sqrt{K(x_n, x_n)}, \quad n \in \mathbb{N}. \tag{36}$$

Combining (35) and (36) yields that

$$\lim_{n\to\infty} K(x_n, x_n) = +\infty. \tag{37}$$

However, again by (3) for the function $g \in \mathbb{C}^X$ defined by $g(x) := K(x,x)$, $x \in X$, we observe for each $n \in \mathbb{N}$ that

$$\begin{aligned} K(x_n,x_n) &= |g(x_n)| = |(g, K(\cdot,x_n))_{\mathcal{H}_K}| \\ &\le \|g\|_{\mathcal{H}_K}\|K(\cdot,x_n)\|_{\mathcal{H}_K} = \|g\|_{\mathcal{H}_K}\sqrt{K(x_n,x_n)}. \end{aligned}$$

This implies that

$$K(x_n,x_n) \le \|g\|^2_{\mathcal{H}_K}, \ \ n \in \mathbb{N},$$

which contradicts (37). The contradiction proves the desired result. ■

In the rest of this section, we show that the refinement process preserves the strictly positive definiteness, the continuity and the universality of the original kernel. A kernel K on X is said to be *strictly positive definite* if for any finite inputs $\mathbf{x} := \{x_j : j \in \mathbb{N}_n\} \subseteq X$ the matrix $K[\mathbf{x}]$ defined by (1) is strictly positive definite. Strictly positive definite kernels are important to the minimum norm interpolation in RKHS.

Proposition 12 *If K is a strictly positive definite kernel on X and G is a refinement kernel for K, then G is also strictly positive definite.*

Proof By Lemma 4, if G is a refinement kernel for K then $G-K$ remains a kernel on X. As a consequence, we have for all $\mathbf{x} := \{x_j : j \in \mathbb{N}_n\} \subseteq X$ that

$$G[\mathbf{x}] = K[\mathbf{x}] + (G-L)[\mathbf{x}].$$

Since $K[\mathbf{x}]$ is strictly positive definite and $(G-L)[\mathbf{x}]$ is positive semi-definite, $G[\mathbf{x}]$ is strictly positive definite. ■

The next kernel property that we consider is continuity. Suppose that the input space X is a topological space. We call a kernel on X a *continuous kernel* if it is at the same time a continuous function on $X \times X$. Given a continuous kernel K on X, can we find a nontrivial refinement kernel G for K that is also continuous? Assuming that X is a metric space with an infinite cardinality, the answer to this question is positive. Recall the Tietze extension theorem in topology (see, for example, Munkres, 2000, page 219), which states that a continuous function defined on a closed subspace of X can be extended to a continuous function on X.

Theorem 13 *If X is a metric space with an infinite cardinality, then every continuous kernel on X has a nontrivial continuous refinement kernel.*

Proof If the topology on X is discrete then any function on X is continuous. In this case, the result holds true by Theorem 11.

Now we suppose that X has an accumulation point x_0. In other words, there exists a sequence of distinct points $x_n \in X$, $n \in \mathbb{N}$ that converges to x_0 and none of the points is the same as x_0. By the arguments used in the proof of Lemma 9, it suffices to prove that there is not a continuous kernel K on X for which $\mathcal{H}_K$ contains all the continuous functions on X. Suppose to the contrary that there is such a kernel K. Then we introduce a sequence of nonnegative numbers by setting

$$c_n := \|K(\cdot,x_n) - K(\cdot,x_{n+1})\|_{\mathcal{H}_K}, \ \ n \in \mathbb{N}.$$

For each $n \in \mathbb{N}$, we define a function φ_n on the closed set $\{x_n, x_{n+1}\}$ as $\varphi_n(x_n) := 1, \varphi_n(x_{n+1}) := 0$. The function φ_n is continuous on $\{x_n, x_{n+1}\}$. Therefore, by the Tietze extension theorem, it can be extended to a continuous function on X. As a consequence, for each $n \in \mathbb{N}$, c_n is positive since otherwise we would get by (3) for each $f \in C(X) \subseteq \mathcal{H}_K$ that $f(x_n) = f(x_{n+1})$. By (5), we have that

$$c_n = \sqrt{K(x_n, x_n) + K(x_{n+1}, x_{n+1}) - K(x_n, x_{n+1}) - K(x_{n+1}, x_n)}, \ \ n \in \mathbb{N}.$$

Since K is continuous and x_n converges to x_0, c_n converges to zero as n tends to infinity.

Set $\mathcal{Z} := \{x_n : n \in \mathbb{N}\} \cup \{x_0\}$. Then $\mathcal{Z}$ is a closed subspace of X. We define a continuous function f on $\mathcal{Z}$ by

$$f(x) := \begin{cases} \sqrt{c_{2n-1}}, & x = x_{2n-1},\ n \in \mathbb{N}, \\ 0, & \text{otherwise}. \end{cases}$$

By the Tietze extension theorem, f can be extended to a continuous function on X, which we still denote by f. By the assumption that $C(X) \subseteq \mathcal{H}_K$, $f \in \mathcal{H}_K$. We now obtain by the reproducing property (3) for each $n \in \mathbb{N}$ that

$$\begin{aligned} \sqrt{c_{2n-1}} &= |f(x_{2n-1}) - f(x_{2n})| = |(f, K(\cdot, x_{2n-1}) - K(\cdot, x_{2n}))_{\mathcal{H}_K}| \\ &\leq \|f\|_{\mathcal{H}_K} \|K(\cdot, x_{2n-1}) - K(\cdot, x_{2n})\|_{\mathcal{H}_K} = \|f\|_{\mathcal{H}_K} c_{2n-1}. \end{aligned}$$

Thus we get that

$$\|f\|_{\mathcal{H}_K} \geq \frac{1}{\sqrt{c_{2n-1}}}, \ \ n \in \mathbb{N},$$

which contradicts the fact that c_n converges to zero. This contradiction implies that $\mathcal{H}_K$ can not contain the space $C(X)$. ■

The result in Theorem 13 remains valid if we only assume that X is a *normal* topological space (see, Munkres, 2000, page 195).

The last kernel property with which we are concerned is universality (Micchelli et al., 2003, 2006; Steinwart, 2001). Suppose that X is a locally compact Hausdorff space. We say that a function $K : X \times X \to \mathbb{C}$ is a *universal kernel* if it is a continuous kernel on X and for all compact subsets $\mathcal{Z} \subseteq X$, span$\{K(\cdot, x) : x \in \mathcal{Z}\}$ is dense in the Banach space $C(\mathcal{Z})$ of the continuous functions on $\mathcal{Z}$. Universal kernels were extensively studied in Micchelli et al. (2006). They are those kernels that can be used to approximate any continuous target function uniformly on a compact input space.

Proposition 14 *If K is a universal kernel on X, then any continuous refinement kernel for K is universal.*

Proof Suppose that K is a universal kernel on X and G is a continuous refinement kernel for K. Assume that K and G have feature maps $\Phi : X \to \mathcal{W}$ and $\Phi' : X \to \mathcal{W}'$, respectively. By Theorem 4 in Micchelli et al. (2006), G is universal if and only if for all compact $\mathcal{Z} \subseteq X$, span$\{(\Phi'(\cdot), u')_{\mathcal{W}'} : u' \in \mathcal{W}'\}$ is dense in $C(\mathcal{Z})$. Let $\mathcal{Z}$ be a compact subset of X. Since K is universal, Theorem 4 in Micchelli et al. (2006) ensures that

$$\overline{\text{span}}\{(\Phi(\cdot), u)_{\mathcal{W}} : u \in \mathcal{W}\} = C(\mathcal{Z}). \tag{38}$$

By Theorem 6, there exists a bounded linear operator $T : \mathcal{W}' \to \mathcal{W}$ that satisfies (28). We hence get for each $u \in \mathcal{W}$ that

$$(\Phi(\cdot), u)_{\mathcal{W}} = (T\Phi'(\cdot), u)_{\mathcal{W}} = (\Phi'(\cdot), T^* u)_{\mathcal{W}'}.$$

Therefore, there holds

$$\{(\Phi(\cdot), u)_{\mathcal{W}} : u \in \mathcal{W}\} \subseteq \{(\Phi'(\cdot), u')_{\mathcal{W}'} : u' \in \mathcal{W}'\}.$$

The above inclusion together with (38) proves that G is also universal. ■

By Theorems 11 and 13, it is reasonable to conjecture that there exist nontrivial refinement kernels for most kernels used in machine learning. To verify this conjecture and present concrete examples, we shall discuss refinement kernels for translation invariant kernels and Hilbert-Schmidt kernels in the next two sections.

5. Refinement of Translation Invariant Kernels

In this section, we specify our input space as $\mathbb{R}^d$, $d \in \mathbb{N}$ and investigate refinement kernels for translation invariant kernels on $\mathbb{R}^d$. The presentation of this section is organized into six subsections. We discuss in the first subsection the notion of translation invariant kernels. In Section 5.2 we establish various characterizations of refinement for general translation invariant kernels. We then consider several types of specific translation invariant kernels. Specifically, refinement of B-spline kernels, radial kernels and periodic kernels is studied in Sections 5.3, 5.4 and 5.5, respectively. Finally in Section 5.6, we deal with refinement through an expanding matrix.

5.1 Translation Invariant Kernels

A kernel K on $\mathbb{R}^d$ is said to be *translation invariant* if for all $a \in \mathbb{R}^d$,

$$K(x-a, y-a) = K(x,y), \ \ x, y \in \mathbb{R}^d. \tag{39}$$

For each $a \in \mathbb{R}^d$ we introduce the translation operator τ_a by setting for all functions f on $\mathbb{R}^d$

$$\tau_a f := f(\cdot - a).$$

It can be seen by (3) and (39) that a translation invariant kernel K on $\mathbb{R}^d$ satisfies for all $a, b, x, y \in \mathbb{R}^d$ that

$$\tau_a K(\cdot, x) = K(\cdot - a, x) = K(\cdot, x + a) \tag{40}$$

and

$$(\tau_a K(\cdot, y), \tau_b K(\cdot, x))_{\mathcal{H}_K} = (K(\cdot, y+a), K(\cdot, x+b))_{\mathcal{H}_K} = K(x+b, y+a). \tag{41}$$

Recall that $\mathcal{B}(\mathbb{R}^d)$ denotes the set of all the finite positive Borel measures on $\mathbb{R}^d$. It was established by Bochner in Bochner (1959) that K is a continuous translation invariant kernel on $\mathbb{R}^d$ if and only if there exists a $\mu \in \mathcal{B}(\mathbb{R}^d)$ such that

$$K(x,y) = \int_{\mathbb{R}^d} e^{i(x-y,\xi)} d\mu(\xi), \ \ x, y \in \mathbb{R}^d,$$

where $(\cdot,\cdot)$ denotes the standard inner product on $\mathbb{R}^d$. This result is referred to as the Bochner theorem. We present below a characterization of translation invariant kernels in terms of their RKHS. To this end, we call a linear operator from a Hilbert space $\mathcal{W}$ to itself an *isomorphism* on $\mathcal{W}$ if it is isomorphic from $\mathcal{W}$ to $\mathcal{W}$.

Proposition 15 *A kernel K on $\mathbb{R}^d$ is translation invariant if and only if for each $a \in \mathbb{R}^d$, τ_a is an isomorphism on $\mathcal{H}_K$.*

Proof Suppose that K is a translation invariant kernel on $\mathbb{R}^d$. Set $a \in \mathbb{R}^d$, $f \in \mathcal{H}_K$ and $\mathcal{H} := \operatorname{span}\{K(\cdot,x) : x \in \mathbb{R}^d\}$. By (4), $\mathcal{H}$ is a dense subspace of $\mathcal{H}_K$. Thus there exists a sequence of functions $f_n \in \mathcal{H}$, $n \in \mathbb{N}$ that converges to f in $\mathcal{H}_K$. By (40) and (41), $\tau_a f_n \in \mathcal{H}$ and $\|\tau_a f_n\|_{\mathcal{H}_K} = \|f_n\|_{\mathcal{H}_K}$ for each $n \in \mathbb{N}$. The latter implies that $\tau_a f_n$ form a Cauchy sequence in $\mathcal{H}_K$. Let g be their limit in $\mathcal{H}_K$. We have that $\|g\|_{\mathcal{H}_K} = \|f\|_{\mathcal{H}_K}$. To prove that τ_a is isometric on $\mathcal{H}_K$, it remains to prove that $g = \tau_a f$. To this end, we verify for each $x \in \mathbb{R}^d$ by (3), (40) and (41) that

$$\begin{aligned} g(x) &= (g, K(\cdot,x))_{\mathcal{H}_K} = \lim_{n\to\infty} (\tau_a f_n, K(\cdot,x))_{\mathcal{H}_K} \\ &= \lim_{n\to\infty} (f_n, K(\cdot,x-a))_{\mathcal{H}_K} = (f, K(\cdot,x-a))_{\mathcal{H}_K} = f(x-a). \end{aligned}$$

Similarly, it can be proved that $\tau_{-a} f_n$ converges to $\tau_{-a} f$, implying that $\tau_{-a} f \in \mathcal{H}_K$. Since $\tau_a \tau_{-a} f = f$, τ_a is surjective from $\mathcal{H}_K$ to $\mathcal{H}_K$. This together with τ_a being isometric shows that it is an isomorphism on $\mathcal{H}_K$.

Conversely, suppose that for each $a \in \mathbb{R}^d$, τ_a is an isomorphism on $\mathcal{H}_K$. This implies that the adjoint operator τ_a^* of τ_a is identified with τ_{-a} (see, Conway, 1990, page 32). It follows for each $x,y \in \mathbb{R}^d$ that $\tau_a K(\cdot,y), \tau_{-a} K(\cdot,x) \in \mathcal{H}_K$ and

$$\begin{aligned} (\tau_a K(\cdot,y), K(\cdot,x))_{\mathcal{H}_K} &= (K(\cdot,y), \tau_{-a} K(\cdot,x))_{\mathcal{H}_K} \\ &= (K(\cdot,y), K(\cdot + a, x))_{\mathcal{H}_K} = K(x, y+a). \end{aligned}$$

On the other hand, we have by (5) that

$$(\tau_a K(\cdot,y), K(\cdot,x))_{\mathcal{H}_K} = (K(\cdot - a, y), K(\cdot,x))_{\mathcal{H}_K} = K(x-a, y).$$

Combining the above two equations, we obtain that $K(x-a,y) = K(x,y+a)$ for all $a,x,y \in \mathbb{R}^d$. Replacing y with $y-a$ yields (39). ■

5.2 Characterizations

Suppose that K is a continuous translation invariant kernel on $\mathbb{R}^d$. We are interested in constructing refinement kernels for K that are continuous and translation invariant as well. Specifically, with a different measure $\mu' \in \mathcal{B}(\mathbb{R}^d)$ we introduce a new kernel

$$G(x,y) := \int_{\mathbb{R}^d} e^{i(x-y,\xi)} d\mu'(\xi), \ \ x,y \in \mathbb{R}^d$$

and characterize G being a refinement kernel for K in terms of a relation between μ and μ'.

Theorem 16 *There holds $\mathcal{H}_K \preceq \mathcal{H}_G$ if and only if $\mu \preceq \mu'$. Moreover, if $\mu \preceq \mu'$ then G is a nontrivial refinement kernel for K if and only if*

$$\mu'(\mathbb{R}^d) - \mu(\mathbb{R}^d) > 0.$$

Proof We prove this result by employing Theorem 8 with $Y := \mathbb{R}^d$. To this end, we introduce a mapping $\phi : \mathbb{R}^d \times \mathbb{R}^d \to \mathbb{C}$ by setting $\phi(x,\xi) := e^{i(x,\xi)}$, for $x,\xi \in \mathbb{R}^d$. One can see that K can be represented by

$$K(x,y) = \int_{\mathbb{R}^d} \phi(x,\xi)\overline{\phi(y,\xi)}d\mu(\xi), \;\; x,y \in \mathbb{R}^d$$

and likewise

$$G(x,y) = \int_{\mathbb{R}^d} \phi(x,\xi)\overline{\phi(y,\xi)}d\mu'(\xi), \;\; x,y \in \mathbb{R}^d.$$

Note also that for any $\omega \in \mathcal{B}(\mathbb{R}^d)$, span $\{\phi(x,\cdot) : x \in \mathbb{R}^d\}$ is dense in $L^2(\mathbb{R}^d,\omega)$. Thus, the result of this theorem is an immediate consequence of Theorem 8. ■

We next characterize the inclusion $\mathcal{H}_K \preceq \mathcal{H}_G$ by using the structure of $\mathcal{H}_K$ and $\mathcal{H}_G$. Let us prepare for this analysis by recalling some basic facts about Borel measures on $\mathbb{R}^d$. Suppose $\nu,\omega \in \mathcal{B}(\mathbb{R}^d)$. If there is a Borel subset $V \subseteq \mathbb{R}^d$ such that for each Borel $U \subseteq \mathbb{R}^d$, $\nu(U) = \nu(U \cap V)$, we say that ν is *concentrated* on V. We call ν a *singular* measure with respect to ω if there exist disjoint Borel subsets U,V of $\mathbb{R}^d$ such that ω is concentrated on U and ν is concentrated on V. The Lebesgue decomposition theorem (see, for example, Rudin, 1987, page 121) asserts that for two measures $\nu,\omega \in \mathcal{B}(\mathbb{R}^d)$, there exist two unique measures $\nu_c,\nu_s \in \mathcal{B}(\mathbb{R}^d)$ with ν_c being absolutely continuous with respect to ω and ν_s being singular with respect to ω such that ν has the Lebesgue decomposition with respect to ω

$$\nu = \nu_c + \nu_s.$$

The Lebesgue decomposition of measures with respect to the Lebesgue measure leads to a decomposition of the corresponding continuous translation invariant kernel. Specifically, for a continuous translation invariant kernel K on $\mathbb{R}^d$, we have the *Lebesgue decomposition*

$$K = K_c + K_s, \tag{42}$$

where

$$K_c(x,y) = \int_{\mathbb{R}^d} e^{i(x-y,\xi)}d\mu_c(\xi), \;\; K_s(x,y) = \int_{\mathbb{R}^d} e^{i(x-y,\xi)}d\mu_s(\xi), \;\; x,y \in \mathbb{R}^d.$$

Likewise, for a continuous translation invariant kernel G on $\mathbb{R}^d$, we also have its Lebesgue decomposition

$$G = G_c + G_s, \tag{43}$$

where

$$G_c(x,y) = \int_{\mathbb{R}^d} e^{i(x-y,\xi)}d\mu'_c(\xi), \;\; G_s(x,y) = \int_{\mathbb{R}^d} e^{i(x-y,\xi)}d\mu'_s(\xi), \;\; x,y \in \mathbb{R}^d.$$

In the above equations, the measures μ_c,μ'_c are absolutely continuous with respect to the Lebesgue measure and μ_s,μ'_s are singular with respect to the Lebesgue measure. By the Radon-Nikodym theorem, there exist nonnegative functions $k,g \in L^1(\mathbb{R}^d)$ such that

$$K_c(x,y) = \int_{\mathbb{R}^d} e^{i(x-y,\xi)}k(\xi)d\xi, \; G_c(x,y) = \int_{\mathbb{R}^d} e^{i(x-y,\xi)}g(\xi)d\xi, \;\; x,y \in \mathbb{R}^d. \tag{44}$$

The next task is to characterize $\mathcal{H}_K \preceq \mathcal{H}_G$ in terms of k, g, μ_s, μ'_s. We start with a simple observation. We associate with each $\psi \in L^1(\mathbb{R}^d)$ a finite Borel measure μ_ψ on $\mathbb{R}^d$ defined on each Borel subset $V \subseteq \mathbb{R}^d$ by

$$\mu_\psi(V) := \int_V \psi(\xi) d\xi.$$

Lemma 17 *If L is a continuous translation invariant kernel on $\mathbb{R}^d$ with a Lebesgue decomposition $L = L_c + L_s$, then $\mathcal{H}_L$ is equal to the orthogonal direct sum of $\mathcal{H}_{L_c}$ and $\mathcal{H}_{L_s}$, namely, $\mathcal{H}_L = \mathcal{H}_{L_c} \bigoplus \mathcal{H}_{L_s}$.*

Proof By Lemma 4, it suffices to show that $\mathcal{H}_{L_c} \cap \mathcal{H}_{L_s} = \{0\}$. We assume that

$$L_c(x,y) = \int_{\mathbb{R}^d} e^{i(x-y,\xi)} l(\xi) d\xi,\ L_s(x,y) = \int_{\mathbb{R}^d} e^{i(x-y,\xi)} d\rho(\xi),\ \ x,y \in \mathbb{R}^d,$$

where $l \in L^1(\mathbb{R}^d)$ is nonnegative and $\rho \in \mathcal{B}(\mathbb{R}^d)$ is singular with respect to the Lebesgue measure. Suppose that $f \in \mathcal{H}_{L_c} \cap \mathcal{H}_{L_s}$. By Lemma 5, there exists $g \in L^2(\mathbb{R}^d, \mu_l)$ and $h \in L^2(\mathbb{R}^d, \rho)$ such that

$$f(x) = \int_{\mathbb{R}^d} e^{i(x,\xi)} g(\xi) l(\xi) d\xi = \int_{\mathbb{R}^d} e^{i(x,\xi)} h(\xi) d\rho(\xi),\ \ x \in \mathbb{R}^d.$$

Define the Borel measure $\mu_{h,\rho}$ on each Borel set $V \subseteq \mathbb{R}^d$ by

$$\mu_{h,\rho}(V) := \int_V h(\xi) d\rho(\xi).$$

By the uniqueness of Fourier transforms (Grafakos, 2004), the two Borel measures μ_{gl}, $\mu_{h,\rho}$ are identical. However, μ_{gl} is absolutely continuous with respect to the Lebesgue measure while $\mu_{h,\rho}$ is singular with respect to the Lebesgue measure. Therefore, we must have $\mu_{gl} = \mu_{h,\rho} = 0$. Consequently, $f = 0$. The proof is complete. ■

The next result allows us to identify the inclusion $\mathcal{H}_K \preceq \mathcal{H}_G$ with two independent inclusions $\mathcal{H}_{K_c} \preceq \mathcal{H}_{G_c}$ and $\mathcal{H}_{K_s} \preceq \mathcal{H}_{G_s}$.

Proposition 18 *Suppose that K and G are continuous translation invariant kernels on $\mathbb{R}^d$ defined by (42) and (43). Then $\mathcal{H}_K \preceq \mathcal{H}_G$ if and only if $\mathcal{H}_{K_c} \preceq \mathcal{H}_{G_c}$ and $\mathcal{H}_{K_s} \preceq \mathcal{H}_{G_s}$.*

Proof Suppose that $\mathcal{H}_{K_c} \preceq \mathcal{H}_{G_c}$ and $\mathcal{H}_{K_s} \preceq \mathcal{H}_{G_s}$. Let f be an arbitrary function in $\mathcal{H}_K$. By Lemma 17, there exists $f_c \in \mathcal{H}_{K_c}$ and $f_s \in \mathcal{H}_{K_s}$ such that $f = f_c + f_s$ and

$$\|f\|^2_{\mathcal{H}_K} = \|f_c\|^2_{\mathcal{H}_{K_c}} + \|f_s\|^2_{\mathcal{H}_{K_s}}.$$

By the assumption, $f_c \in \mathcal{H}_{G_c}$, $f_s \in \mathcal{H}_{G_s}$ and

$$\|f_c\|_{\mathcal{H}_{G_c}} = \|f_c\|_{\mathcal{H}_{K_c}},\ \|f_s\|_{\mathcal{H}_{G_s}} = \|f_s\|_{\mathcal{H}_{K_s}}.$$

Lemma 17 asserts that $\mathcal{H}_G = \mathcal{H}_{G_c} \bigoplus \mathcal{H}_{G_s}$. As a result, we get that $f \in \mathcal{H}_G$ and

$$\|f\|^2_{\mathcal{H}_G} = \|f_c\|^2_{\mathcal{H}_{G_c}} + \|f_s\|^2_{\mathcal{H}_{G_s}} = \|f_c\|^2_{\mathcal{H}_{K_c}} + \|f_s\|^2_{\mathcal{H}_{K_s}} = \|f\|^2_{\mathcal{H}_K}.$$

Therefore, we have proved that $\mathcal{H}_K \preceq \mathcal{H}_G$.

Conversely, we assume that G is a refinement kernel for K. Suppose that $f \in \mathcal{H}_{K_c}$. By Lemma 17, $f \in \mathcal{H}_K$ and $\|f\|_{\mathcal{H}_K} = \|f\|_{\mathcal{H}_{K_c}}$. By the assumption and Lemma 17, there exist two functions $g_c \in \mathcal{H}_{G_c}$ and $g_s \in \mathcal{H}_{G_s}$ such that $f = g_c + g_s$ and

$$\|f\|^2_{\mathcal{H}_K} = \|f\|^2_{\mathcal{H}_G} = \|g_c\|^2_{\mathcal{H}_{G_c}} + \|g_s\|^2_{\mathcal{H}_{G_s}}.$$

To obtain that $f \in \mathcal{H}_{G_c}$ and $\|f\|_{\mathcal{H}_{K_c}} = \|f\|_{\mathcal{H}_{G_c}}$, it suffices to show that $g_s = 0$. Arguments similar to those used in the proof of Lemma 17 serve this purpose. Since f is an arbitrary function in $\mathcal{H}_{K_c}$, we obtain that $\mathcal{H}_{K_c} \preceq \mathcal{H}_{G_c}$. Likewise, one can show that $\mathcal{H}_{K_s} \preceq \mathcal{H}_{G_s}$. The proof is thus complete. ∎

We next consider $\mathcal{H}_{K_c} \preceq \mathcal{H}_{G_c}$. For a nonnegative function f on $\mathbb{R}^d$, we let $\Omega_f := \{x \in \mathbb{R}^d : f(x) > 0\}$. We write $k \preceq g$ to mean that $g = k$ almost everywhere on Ω_k with respect to the Lebesgue measure.

Theorem 19 *There holds $\mathcal{H}_{K_c} \preceq \mathcal{H}_{G_c}$ if and only if $k \preceq g$. Moreover, if $k \preceq g$ then G_c is a nontrivial refinement kernel for K_c if and only if*

$$\int_{\mathbb{R}^d} (g(\xi) - k(\xi))d\xi > 0. \tag{45}$$

Proof The proof for this result when G_c has the form $\lambda K_c(2\cdot, 2\cdot)$ for some positive constant λ was provided in Xu and Zhang (2007), Theorem 23. Arguments similar to those in Xu and Zhang (2007) can prove the general result described here. We give a different proof below based on Theorem 16.

By Theorem 16, $\mathcal{H}_{K_c} \preceq \mathcal{H}_{G_c}$ if and only if $\mu_k \ll \mu_g$ and $d\mu_k/d\mu_g$ equals 1 almost everywhere on Ω_k and equals 0 almost everywhere elsewhere. Therefore, $\mathcal{H}_{K_c} \preceq \mathcal{H}_{G_c}$ if and only if for each Borel $V \subseteq \Omega_k$

$$\int_V k(\xi)d\xi = \int_V g(\xi)d\xi.$$

Clearly, the above equation holds for all Borel $V \subseteq \Omega_k$ if and only if $k \preceq g$. The second statement of the result follows from the observation that the right hand side of (45) is equal to $\mu_g(\mathbb{R}^d) - \mu_k(\mathbb{R}^d)$. ∎

We are ready to present a characterization of $\mathcal{H}_K \preceq \mathcal{H}_G$ in terms of conditions on k, g, μ_s, μ'_s.

Theorem 20 *Let K and G be continuous translation invariant kernels on $\mathbb{R}^d$ defined by (42) and (43). Then $\mathcal{H}_K \preceq \mathcal{H}_G$ if and only if $k \preceq g$ and $\mu_s \preceq \mu'_s$. The refinement kernel G is nontrivial for K if and only if there holds (45) or $\mu'_s(\mathbb{R}^d) - \mu_s(\mathbb{R}^d) > 0$.*

Proof The result of this theorem follows directly from Proposition 18 and Theorems 19, 16. ∎

The next result is a direct consequence of Theorem 19. Suppose that $k \in L^1(\mathbb{R}^d)$ is positive almost everywhere on $\mathbb{R}^d$ and define

$$K(x,y) := \int_{\mathbb{R}^d} e^{i(x-y,\xi)} k(\xi)d\xi, \ \ x, y \in \mathbb{R}^d. \tag{46}$$

Corollary 21 *For $k \in L^1(\mathbb{R}^d)$ positive almost everywhere on $\mathbb{R}^d$, define K as in (46). Suppose that G is a continuous translation invariant kernel on $\mathbb{R}^d$ with a Lebesgue decomposition (43). Then $\mathcal{H}_K \preceq \mathcal{H}_G$ if and only if $G_c = K$. The kernel G is a nontrivial refinement kernel for K if and only if $G_c = K$ and $G_s \neq 0$.*

5.3 B-spline Kernels

Our next example is concerned with the B-spline kernel. For a nontrivial compactly supported function $f_0 \in L^2(\mathbb{R}^d)$ such that

$$\overline{f_0(-x)} = f_0(x), \ \ x \in \mathbb{R}^d, \tag{47}$$

we define recursively

$$f_n(x) := \int_{\mathbb{R}^d} f_{n-1}(x-y) f_0(y) dy, \ \ x \in \mathbb{R}^d, \ \ n \in \mathbb{N}.$$

For each odd integer $p \in \mathbb{N}$, we let

$$K(x,y) := f_p(x-y), \ \ x,y \in \mathbb{R}^d. \tag{48}$$

In the next proposition, we show that K is a kernel on $\mathbb{R}^d$ and characterize refinement kernels for K. To this end, we need the Fourier transform $\hat{f}$ of a function $f \in L^1(\mathbb{R}^d)$ defined as

$$\hat{f}(\xi) := \int_{\mathbb{R}^d} f(x) e^{-i(x,\xi)} dx, \ \ \xi \in \mathbb{R}^d.$$

By a standard approximation process (Grafakos, 2004), the Fourier transform can be extended to be a bounded operator on $L^2(\mathbb{R}^d)$.

Proposition 22 *For each odd integer $p \in \mathbb{N}$, K defined by (48) is a kernel on $\mathbb{R}^d$. Moreover, suppose that G is a continuous translation invariant kernel on $\mathbb{R}^d$ with a Lebesgue decomposition (43). Then G is a refinement kernel for K if and only if $G_c = K$.*

Proof Since f_0 is compactly supported, $f_0 \in L^1(\mathbb{R}^d)$. By the Schwartz inequality and by induction, we have that $f_p \in L^1(\mathbb{R}^d)$. By the Fourier transform of convolutions, we know that

$$(f_p)\hat{} = ((f_0)\hat{})^{p+1}.$$

Condition (47) ensures that $(f_0)\hat{}$ is real on $\mathbb{R}^d$. Since p is odd, $(f_p)\hat{}$ is nonnegative. By the Bochner theorem, to prove that K is a kernel on $\mathbb{R}^d$, it suffices to show that $((f_0)\hat{})^{p+1} \in L^1(\mathbb{R}^d)$. This is clear since $((f_0)\hat{})^2 \in L^1(\mathbb{R}^d)$ and $(f_0)\hat{}$ is bounded.

Since f_0 is compactly supported, by the Paley-Wiener theorem (see, for example, Gasquet and Witomski, 1999, page 293), $(f_0)\hat{}$ is real-analytic on $\mathbb{R}^d$. Also, it is nontrivial since f_0 is assumed to be nontrivial. By Corollary 21, to conclude our second statement it suffices to point out the well-known fact that the zeros of a nontrivial real-analytic function on $\mathbb{R}^d$ form a set of Lebesgue measure zero in $\mathbb{R}^d$. ■

A particular example of (48) are the *B-spline kernels* (see, for example, Schölkopf and Smola, 2002, page 98, and the references therein), which are defined as (48) by f_0 that is the characteristic function of a ball in $\mathbb{R}^d$ centered at the origin.

5.4 Radial Kernels

We next turn to the *radial* kernels on $\mathbb{R}^d$. They are kernels of the form

$$K(x,y) := r(\|x-y\|), \ \ x,y \in \mathbb{R}^d, \tag{49}$$

where r is a function on $\mathbb{R}_+ := [0,+\infty)$ and $\|\cdot\|$ denotes the standard Euclidean norm on $\mathbb{R}^d$. It was proved in Schoenberg (1938) that the function K in the form (49) with a continuous function r on $\mathbb{R}_+$ defines a kernel on $\mathbb{R}^d$ for all $d \in \mathbb{N}$ if and only if there exists some $\mu \in \mathcal{B}(\mathbb{R}_+)$ such that

$$r(t) := \int_{\mathbb{R}_+} e^{-\sigma t^2} d\mu(\sigma), \ \ t \in \mathbb{R}_+. \tag{50}$$

Theorem 23 *Suppose that K is a nontrivial radial kernel defined by (49), (50) with $\mu(\{0\}) = 0$. Then a continuous translation invariant kernel G on $\mathbb{R}^d$ with a Lebesgue decomposition (43) is a refinement kernel for K if and only if $G_c = K$.*

Proof We prove this theorem by applying Corollary 21 with identifying the function $k \in L^1(\mathbb{R}^d)$ that is positive almost everywhere.

Recalling that for all $\sigma > 0$ there holds

$$\exp\left(-\sigma\|x-y\|^2\right) = \frac{1}{(2\pi)^d}\int_{\mathbb{R}^d}\left(\frac{\pi}{\sigma}\right)^{d/2} e^{i(x-y,\xi)} e^{-\frac{\|\xi\|^2}{4\sigma}} d\xi, \ \ x,y \in \mathbb{R}^d,$$

by the hypothesis that $\mu(\{0\}) = 0$, we have for all $x,y \in \mathbb{R}^d$ that

$$K(x,y) = \int_{(0,+\infty)} \frac{1}{(2\pi)^d}\int_{\mathbb{R}^d}\left(\frac{\pi}{\sigma}\right)^{d/2} e^{i(x-y,\xi)} e^{-\frac{\|\xi\|^2}{4\sigma}} d\xi d\mu(\sigma).$$

Define

$$k(\xi) := \int_{(0,+\infty)} \frac{1}{(2\pi)^d}\left(\frac{\pi}{\sigma}\right)^{d/2} e^{-\frac{\|\xi\|^2}{4\sigma}} d\mu(\sigma), \ \ \xi \in \mathbb{R}^d.$$

It can be verified by the Fubini theorem (see, Rudin, 1987, page 164) that

$$\int_{\mathbb{R}^d} k(\xi)d\xi = \int_{(0,+\infty)} d\mu(\sigma)\int_{\mathbb{R}^d}\frac{1}{(2\pi)^d}\left(\frac{\pi}{\sigma}\right)^{d/2} e^{-\frac{\|\xi\|^2}{4\sigma}} d\xi = \int_{(0,+\infty)} d\mu(\sigma) = \mu(\mathbb{R}_+).$$

Therefore, k is a nontrivial function in $L^1(\mathbb{R}^d)$. Again, by the Fubini theorem we get that

$$K(x,y) = \int_{\mathbb{R}^d} e^{i(x-y,\xi)} k(\xi)d\xi, \ \ x,y \in \mathbb{R}^d.$$

Thus, to conclude the result of this theorem by Corollary 21, it remains to show that k is positive almost everywhere on $\mathbb{R}^d$. To this end, we observe that the function

$$\varphi(t) := \int_{(0,+\infty)} \frac{1}{(2\pi)^d}\left(\frac{\pi}{\sigma}\right)^{d/2} e^{-\frac{t}{4\sigma}} d\mu(\sigma), \ \ t > 0$$

belongs to $C^\infty(0,+\infty)$ and satisfies for each nonnegative integer j that $(-1)^j\varphi^{(j)}(t) > 0$, for $t > 0$. In other words, φ is *completely monotonic* in $(0,+\infty)$ and is hence real-analytic on the interval (see, Widder, 1941, pages 145–146). Consequently, $k = \varphi(\|\cdot\|^2)$ is real-analytic on $\mathbb{R}^d \setminus \{0\}$. This together with $\|k\|_{L^1(\mathbb{R}^d)} > 0$ proves that k is almost everywhere positive on $\mathbb{R}^d$. The proof is complete. ■

We remark that if $\mu(\{0\}) > 0$ then K is the sum of a constant kernel and a radial kernel satisfying the hypothesis of the last theorem. Note that a constant kernel is defined by a singular Borel measure. Therefore, by Theorems 20 and 23, a continuous kernel G with a Lebesgue decomposition (43) is a refinement kernel for K if and only if $G_c = K - \mu(\{0\})$ and $\mu_s'(\{0\}) = \mu(\{0\})$ since μ_s' and μ must agree at the origin.

As a direct consequence of Theorem 23, we have the following result about the Gaussian kernels

$$\mathcal{G}_\sigma(x,y) := \exp\left(-\sigma\|x-y\|^2\right), \ \ x,y \in \mathbb{R}^d, \ \ \sigma > 0.$$

Corollary 24 *A continuous translation invariant kernel G on $\mathbb{R}^d$ with a Lebesgue decomposition (43) is a refinement kernel for the Gaussian kernel $\mathcal{G}_\sigma$ if and only if $G_c = \mathcal{G}_\sigma$. It is a nontrivial refinement kernel for $\mathcal{G}_\sigma$ if and only if $G_c = \mathcal{G}_\sigma$ and $G_s \neq 0$.*

The corollary above suggests that we may refine the Gaussian kernel $\mathcal{G}_\sigma$ by adding to it a kernel G_s defined by a singular measure on $\mathbb{R}^d$. The RKHS for a Gaussian kernel has been well understood (see, for example, Walder et al., 2006). In particular, we can see by Lemma 5 that

$$\mathcal{H}_{\mathcal{G}_\sigma} := \left\{ f \in L^2(\mathbb{R}^d) : \int_{\mathbb{R}^d} |\hat{f}(\xi)|^2 e^{\frac{\|\xi\|^2}{4\sigma}} d\xi < +\infty \right\}, \tag{51}$$

and the inner product on $\mathcal{H}_{\mathcal{G}_\sigma}$ is given as

$$(f,g)_{\mathcal{H}_{\mathcal{G}_\sigma}} = \frac{1}{(2\pi)^d}\left(\frac{\sigma}{\pi}\right)^{d/2} \int_{\mathbb{R}^d} \hat{f}(\xi)\overline{\hat{g}(\xi)} e^{\frac{\|\xi\|^2}{4\sigma}} d\xi.$$

By (51), $\mathcal{H}_{\mathcal{G}_\sigma} \subseteq \mathcal{H}_{\mathcal{G}_{\sigma'}}$ for $\sigma < \sigma'$. However, since functions with a continuous compactly supported Fourier transform are contained in $\mathcal{H}_{\mathcal{G}_\sigma}$ and are dense in $\mathcal{H}_{\mathcal{G}_{\sigma'}}$, $\mathcal{H}_{\mathcal{G}_\sigma}$ is dense in $\mathcal{H}_{\mathcal{G}_{\sigma'}}$. But, $\mathcal{H}_{\mathcal{G}_\sigma}$ is not closed under the norm of $\mathcal{H}_{\mathcal{G}_{\sigma'}}$. Therefore, there does not exist σ' with $\sigma < \sigma'$ such that $\mathcal{G}_{\sigma'}$ is a refinement kernel for $\mathcal{G}_\sigma$.

5.5 Periodic Kernels

We now investigate kernels defined by continuous periodic functions and their refinement. For this purpose, we recall the Fourier coefficients of a function $f \in L^2([0,2\pi]^d)$ which are defined by setting for each $n \in \mathbb{Z}^d$

$$c_n(f) := \frac{1}{(2\pi)^d} \int_{[0,2\pi]^d} f(x) e^{-i(n,x)} dx.$$

A function f on $\mathbb{R}^d$ is called 2π-*periodic* if for all $n \in \mathbb{Z}^d$, $f = f(\cdot + 2\pi n)$.

Proposition 25 *Let f be a continuous 2π-periodic function on $\mathbb{R}^d$. Then $K(x,y) := f(x-y)$ defines a kernel on $\mathbb{R}^d$ if and only if $\mathbf{f} := [c_n(f) : n \in \mathbb{Z}^d] \in \ell^1(\mathbb{Z}^d)$ and $\mathbf{f} \geq 0$.*

Proof If $\mathbf{f} \in \ell^1(\mathbb{Z}^d)$ and $\mathbf{f} \geq 0$, then we define the Borel measure μ that is supported on $\mathbb{Z}^d$ with $\mu(n) := c_n(f)$, $n \in \mathbb{Z}^d$. By the Fourier series expansion of f, we get that

$$K(x,y) = f(x-y) = \sum_{n \in \mathbb{Z}^d} c_n(f) e^{i(n,x-y)} = \int_{\mathbb{R}^d} e^{i(x-y,\xi)} d\mu(\xi), \;\; x,y \in \mathbb{R}^d.$$

By the Bochner theorem, K is a kernel on $\mathbb{R}^d$.

Conversely, if K is a kernel on $\mathbb{R}^d$, then again by the Bochner theorem, there is a $\mu \in \mathcal{B}(\mathbb{R}^d)$ such that

$$f(x) = \int_{\mathbb{R}^d} e^{i(x,\xi)} d\mu(\xi), \;\; x \in \mathbb{R}^d. \tag{52}$$

Since f is 2π-periodic, we have for each $n \in \mathbb{Z}^d$ that

$$\int_{\mathbb{R}^d} e^{i(x,\xi)} d\mu(\xi) = \int_{\mathbb{R}^d} e^{i(x,\xi)} e^{i2\pi(n,\xi)} d\mu(\xi), \;\; x \in \mathbb{R}^d.$$

By the uniqueness of Fourier transforms, there holds for almost every $\xi \in \mathbb{R}^d$ with respect to μ that $e^{i2\pi(n,\xi)} = 1$, for $n \in \mathbb{Z}^d$. Note that this equation holds for all $n \in \mathbb{Z}^d$ if and only if $\xi \in \mathbb{Z}^d$. Therefore, $\mu(\mathbb{R}^d \setminus \mathbb{Z}^d) = 0$. Consequently, by (52) we obtain that

$$f(x) = \sum_{n \in \mathbb{Z}^d} \mu(\{n\}) e^{i(n,x)}, \;\; x \in \mathbb{R}^d.$$

It is implied that $c_n(f) = \mu(\{n\})$, $n \in \mathbb{Z}^d$. Since μ is finite and positive, $\mathbf{f} \in \ell^1(\mathbb{Z}^d)$ and $\mathbf{f} \geq 0$. ■

By the last proposition, for $c := [c_n : n \in \mathbb{Z}^d] \in \ell^1(\mathbb{Z}^d)$ with $c_n \geq 0$ for each $n \in \mathbb{Z}^d$, we introduce kernel

$$f_c(x-y) := \sum_{n \in \mathbb{Z}^d} c_n e^{i(n,x-y)}, \;\; x,y \in \mathbb{R}^d, \tag{53}$$

and set $\Omega_c := \{n \in \mathbb{Z}^d : c_n > 0\}$. The function $c \in \ell^1(\mathbb{Z}^d)$ will be viewed at the same time as a Borel measure on $\mathbb{Z}^d$ whose measure on $n \in \mathbb{Z}^d$ is defined to be c_n.

Proposition 26 *Suppose that $a, b \in \ell^1(\mathbb{Z}^d)$ with $a_n, b_n \geq 0$ for each $n \in \mathbb{Z}^d$ and define f_a, f_b as in (53). Then $\mathcal{H}_{f_a} \preceq \mathcal{H}_{f_b}$ if and only if*

$$\Omega_a \subseteq \Omega_b \;\; \textit{and for all} \;\; n \in \Omega_a, \;\; a_n = b_n. \tag{54}$$

If $\mathcal{H}_{f_a} \preceq \mathcal{H}_{f_b}$ then f_b is a nontrivial refinement kernel for f_a if and only if Ω_a is a proper subset of Ω_b.

Proof By Theorem 20, $\mathcal{H}_{f_a} \preceq \mathcal{H}_{f_b}$ if and only if $a \preceq b$. We now show that $a \preceq b$ is equivalent to (54).

Suppose that condition (54) holds. By $\Omega_a \subseteq \Omega_b$ we have that $a \ll b$. The derivative $c := da/db$ is given by

$$c_n := \begin{cases} \dfrac{a_n}{b_n}, & n \in \Omega_a, \\ 0, & \text{otherwise.} \end{cases} \tag{55}$$

Therefore, $a \preceq b$.

Conversely, suppose that $a \preceq b$. Since $a \ll b$, we have $\Omega_a \subseteq \Omega_b$. Also, since the derivative $c := da/db$ given by (55) is equal to 1 or 0 almost everywhere with respect to b, we have $a_n = b_n$ for each $n \in \Omega_a$. Hence, (54) holds. ■

5.6 Refinement via an Expanding Matrix

To close this section, we consider a special refinement process in the sense of refinable kernels introduced in Xu and Zhang (2007). The translation invariant kernels K_c defined by (44) via a non-negative function $k \in L^1(\mathbb{R}^d)$ are of special interest. We call them translation invariant kernels of continuous type. Next, we consider updating kernels of this type through an expanding matrix. Let D be a $d \times d$ real matrix with determinant $\det D$ bigger than 1. Such a matrix is called expanding. Refinable functions with respect to an expanding matrix and the corresponding wavelets were studied by many authors (see, for example, Chen et al., 2003, 2007; Daubechies, 1992; Goodman and Lee, 1994; Jia, 1999; Jia et al., 1999; Micchelli and Sauer, 1997; Micchelli and Xu, 1994; Wang, 2002, and the references cited therein). In particular, the interesting relation between wavelets and tiling was investigated in Wang (2002). For a continuous translation invariant kernel K_c defined by (44), we consider a refinement kernel G_c having the form

$$G_c(x,y) = \lambda K_c(Dx, Dy), \;\; x, y \in \mathbb{R}^d. \tag{56}$$

We are interested in characterizing $\mathcal{H}_{K_c} \preceq \mathcal{H}_{G_c}$ in terms of k, λ and D. A special case of this problem when D is the dilation matrix $2I$ was studied in Xu and Zhang (2007).

Theorem 27 *Suppose that K_c is defined by (44) via a nonnegative $k \in L^1(\mathbb{R}^d)$ and G_c is given by (56). Then, $\mathcal{H}_{K_c} \preceq \mathcal{H}_{G_c}$ if and only if for almost every $\xi \in \Omega_k$,*

$$k(\xi) = \frac{\lambda}{\det D} k((D^T)^{-1}\xi).$$

If $\mathcal{H}_{K_c} \preceq \mathcal{H}_{G_c}$ then G_c is a nontrivial refinement kernel for K_c if and only if

$$\int_{\Omega_k \setminus (D^T)^{-1}\Omega_k} k(\xi) d\xi > 0. \tag{57}$$

Proof Through a change of variables, we obtain from (56) that

$$G_c(x,y) = \frac{\lambda}{\det D} \int_{\mathbb{R}^d} e^{i(x-y,\xi)} k((D^T)^{-1}\xi) d\xi, \;\; x, y \in \mathbb{R}^d.$$

We then identify the nonnegative function $g \in L^1(\mathbb{R}^d)$ in the definition (44) of the translation invariant kernel G_c of continuous type as follows

$$g(\xi) = \frac{\lambda}{\det D} k((D^T)^{-1}\xi), \;\; \xi \in \mathbb{R}^d.$$

The first statement of this theorem now follows directly from the first statement of Theorem 19.

If $\mathcal{H}_{K_c} \preceq \mathcal{H}_{G_c}$, by the first statement of this theorem, we have that

$$\int_{\mathbb{R}^d} g(\xi)d\xi = \int_{\mathbb{R}^d} k(\xi)d\xi + \int_{\mathbb{R}^d\setminus\Omega_k} \frac{\lambda}{\det D} k((D^T)^{-1}\xi)d\xi.$$

Using this identity, we observe that inequality (45) is equivalent to inequality

$$\int_{\mathbb{R}^d\setminus\Omega_k} k((D^T)^{-1}\xi)d\xi > 0.$$

By a change of variables, we find that the inequality above is equivalent to inequality (57). ■

Along this direction, we present a corollary to Proposition 26.

Corollary 28 *Let D be an invertible matrix in $\mathbb{Z}^{d\times d}$, f_a a kernel defined as in (53) and G defined as $G(x,y) = \lambda f_a(Dx - Dy)$ for some positive constant λ. Then G is a refinement kernel for f_a if and only if $\Omega_a \subseteq D^T\Omega_a$ and for each $n \in \Omega_a$, $a_n = \lambda a_{(D^T)^{-1}n}$.*

We shall see in the next section that Proposition 26 and Corollary 28 are special instances of refinement of Hilbert-Schmidt kernels.

6. Refinement of Hilbert-Schmidt Kernels

We characterize in this section refinement kernels for two types of Hilbert-Schmidt kernels. As special examples, we study refinement of the Bergman kernels, the Szegö kernels, the Schoenberg kernels, and kernels having finite dimensional feature spaces.

Let a be a nonnegative function on $\mathbb{N}$ and set $a_n := a(n)$, $n \in \mathbb{N}$. We denote by $\ell_a^2(\mathbb{N})$ the set of functions f on $\mathbb{N}$ such that $\sum_{n\in\mathbb{N}} a_n|f_n|^2 < +\infty$. It is a Hilbert space with the inner product

$$(f,g)_{\ell_a^2(\mathbb{N})} := \sum_{n\in\mathbb{N}} a_n f_n \overline{g_n}, \ \ f,g \in \ell_a^2(\mathbb{N}).$$

Suppose that we have a sequence of functions ϕ_n on the input space X, $n \in \mathbb{N}$ such that for each $x \in X$ the function $\Phi(x)$ on $\mathbb{N}$ defined as

$$\Phi(x)(n) := \phi_n(x), \ \ n \in \mathbb{N} \tag{58}$$

belongs to $\ell_a^2(\mathbb{N})$. The *Hilbert-Schmidt kernel* K_a associated with a is given as

$$K_a(x,y) := (\Phi(x),\Phi(y))_{\ell_a^2(\mathbb{N})} = \sum_{n\in\mathbb{N}} a_n\phi_n(x)\overline{\phi_n(y)}, \ \ x,y \in X. \tag{59}$$

The Mercer theorem (see, for example, Cucker and Smale, 2002; Hochstadt, 1973; Mercer, 1909; Sun, 2005) in the theory of reproducing kernels indicates that (59) represents a large class of kernels. Hilbert-Schmidt kernels are a key element of recent studies Opfer (2006) and Rakotomamonjy and Canu (2005).

The support of a function a on $\mathbb{N}$, denoted as $\operatorname{supp} a$, is the set of $n \in \mathbb{N}$ for which $a_n \neq 0$. Let a,b be two nonnegative functions on $\mathbb{N}$. Set $c := \max\{a,b\}$ and assume that the sequence ϕ_n satisfies for each $x \in X$ that $\Phi(x) \in \ell_c^2(\mathbb{N})$ and

$$\overline{\operatorname{span}}\{\Phi(x) : x \in X\} = \ell_c^2(\mathbb{N}).$$

We shall consider the inclusion $\mathcal{H}_{K_a} \preceq \mathcal{H}_{K_b}$. For this purpose, we make the convention that whenever we write $a \preceq b$ for two functions a, b on $\mathbb{N}$, it means that $\operatorname{supp} a \subseteq \operatorname{supp} b$ and $a_n = b_n$ for each $n \in \operatorname{supp} a$.

Theorem 29 *There holds $\mathcal{H}_{K_a} \preceq \mathcal{H}_{K_b}$ if and only if $a \preceq b$. Moreover, if $a \preceq b$ then K_b is a nontrivial refinement kernel for K_a if and only if* $\operatorname{supp} a$ *is a proper subset of* $\operatorname{supp} b$.

Proof This theorem is proved by using Theorem 8 with an identification of measures μ and ν. We introduce three nonnegative functions $\tilde{a}, \tilde{b}, \tilde{c}$ in $\ell^1(\mathbb{N})$ by setting for $n \in \mathbb{N}$

$$\tilde{a}_n := \begin{cases} \frac{a_n}{n^2 c_n}, & n \in \operatorname{supp} a, \\ 0, & \text{otherwise}, \end{cases} \quad \tilde{b}_n := \begin{cases} \frac{b_n}{n^2 c_n}, & n \in \operatorname{supp} b, \\ 0, & \text{otherwise}, \end{cases}$$

and

$$\tilde{c}_n := \begin{cases} \frac{1}{n^2}, & n \in \operatorname{supp} c, \\ 0, & \text{otherwise}. \end{cases}$$

We also define a function $\phi : X \times \mathbb{N} \to \mathbb{C}$ by

$$\phi(x,n) := n\sqrt{c_n}\phi_n(x), \ \ x \in X, \ n \in \mathbb{N}.$$

It is observed that $\tilde{c} = (\tilde{a}+\tilde{b})/2 + |\tilde{a}-\tilde{b}|/2$, $\phi(x,\cdot) \in \ell^2_{\tilde{c}}(\mathbb{N})$ for all $x \in X$ and $\operatorname{span}\{\phi(x,\cdot) : x \in X\}$ is dense in $\ell^2_{\tilde{c}}(\mathbb{N})$. Moreover,

$$K_a(x,y) = (\phi(x,\cdot), \phi(y,\cdot))_{\ell^2_{\tilde{a}}(\mathbb{N})}, \ K_b(x,y) = (\phi(x,\cdot), \phi(y,\cdot))_{\ell^2_{\tilde{b}}(\mathbb{N})}, \ \ x, y \in X.$$

Let $Y := \mathbb{N}$. We identify measures $\mu, \nu \in \mathcal{B}(Y)$ with $\tilde{a}$ and $\tilde{b}$, respectively, such that

$$K_a(x,y) = \int_Y \phi(x,\xi)\overline{\phi(y,\xi)}d\mu(\xi), \ \ K_b(x,y) = \int_Y \phi(x,\xi)\overline{\phi(y,\xi)}d\nu(\xi), \ \ x, y \in X.$$

Note that $\mu \preceq \nu$ is equivalent to $a \preceq b$. The result of this theorem now follows immediately from Theorem 8. ■

One can see that Proposition 26 may be viewed as a corollary of Theorem 29. We next present two more concrete applications of Theorem 29.

For the first example, we assume $R \in (0, +\infty]$ and specify our input space X to be $\{z \in \mathbb{C} : |z| < R^{1/2}\}$. Here we make the convention that if $R = +\infty$ then $X := \mathbb{C}$. For two nonnegative functions a, b defined on $\mathbb{N}$ satisfying

$$\max\left\{\limsup_{n\to\infty} \sqrt[n]{a_n}, \ \limsup_{n\to\infty} \sqrt[n]{b_n}\right\} \leq \frac{1}{R}, \tag{60}$$

we define the kernels

$$\mathcal{K}_a(\xi,\eta) := \sum_{n\in\mathbb{N}} a_n \xi^{n-1}\overline{\eta}^{n-1}, \ \mathcal{K}_b(\xi,\eta) := \sum_{n\in\mathbb{N}} b_n \xi^{n-1}\overline{\eta}^{n-1}, \ \ \xi, \eta \in X. \tag{61}$$

Classical kernels such as the Bergman kernels and the Szegö kernels (see, for example, Saitoh, 1988) have the above form.

Proposition 30 *Suppose that a, b are nonnegative functions defined on $\mathbb{N}$ satisfying (60) and kernels $\mathcal{K}_a, \mathcal{K}_b$ are defined in (61). Then $\mathcal{H}_{\mathcal{K}_a} \preceq \mathcal{H}_{\mathcal{K}_b}$ if and only if $a \preceq b$, and the refinement is nontrivial if and only if* $\operatorname{supp} a$ *is a proper subset of* $\operatorname{supp} b$.

Proof We define a sequence of functions $\phi_n, n \in \mathbb{N}$ on the input space X by setting

$$\phi_n(\xi) := \xi^{n-1}, \ \ \xi \in X.$$

Let $c := \max\{a, b\}$. Condition (60) ensures that Φ defined by (58) with the ϕ_n defined above satisfies the condition that $\Phi(\xi) \in \ell^2_c(\mathbb{N})$ for each $\xi \in X$. It is clear that $\operatorname{span}\{\Phi(\xi) : \xi \in X\}$ is dense in $\ell^2_c(\mathbb{N})$. The result of this proposition follows directly from Theorem 29. ■

Our second example concerns the *Schoenberg kernels* (Schoenberg, 1942) on the unit sphere $\mathbb{S}^d$ in $\mathbb{R}^{d+1}$. We shall need the ultraspherical polynomials $P^d_n, n \in \mathbb{Z}_+$. When $d = 1, P^1_n$ is the Chebyshev polynomial of degree n (Rivlin, 1990) and for $d > 1, P^d_n$ is determined by

$$\frac{1}{(1-2zt+z^2)^{(d-1)/2}} = \sum_{n \in \mathbb{Z}_+} P^d_n(t) z^n, \ \ |z| < 1, \ t \in [-1, 1].$$

For a nonnegative function h defined on $\mathbb{N}$ satisfying the conditions

$$\sum_{n \in \mathbb{N}} h_n P^d_{n-1}(1) < +\infty, \tag{62}$$

we introduce a Schoenberg kernel on $\mathbb{S}^d$ by setting

$$\mathcal{S}_h(x, y) := \sum_{n \in \mathbb{N}} h_n P^d_{n-1}((x, y)), \ \ x, y \in \mathbb{S}^d, \tag{63}$$

where $(\cdot, \cdot)$ denotes the inner product on $\mathbb{R}^{d+1}$.

Theorem 31 *Suppose that a and b are two nonnegative functions defined on $\mathbb{N}$ satisfying the condition (62) and $\mathcal{S}_a$ and $\mathcal{S}_b$ are the corresponding Schoenberg kernels on $\mathbb{S}^d$ defined as in (63). Then, $\mathcal{H}_{\mathcal{S}_a} \preceq \mathcal{H}_{\mathcal{S}_b}$ if and only if $a \preceq b$. If $a \preceq b$ then $\mathcal{S}_b$ is a nontrivial refinement kernel for $\mathcal{S}_a$ if and only if* $\operatorname{supp} a$ *is a proper subset of* $\operatorname{supp} b$.

Proof We shall write the kernels $\mathcal{S}_a, \mathcal{S}_b$ in the form of Hilbert-Schmidt kernels and then apply Theorem 29. To this end, we recall some basic facts of *spherical harmonics* (Stein and Weiss, 1971). For each $n \in \mathbb{Z}_+$ we let $\mathcal{H}_n$ be the set of all homogeneous harmonic polynomials of total degree n on $\mathbb{R}^{d+1}$ restricted to $\mathbb{S}^d$. We consider $\mathcal{H}_n$ as a subspace of $L^2(\mathbb{S}^d, \omega)$ where ω is the Lebesgue measure on $\mathbb{S}^d$. Let d_n denote the dimension of $\mathcal{H}_n$ and $\{Y^n_j : j \in \mathbb{N}_{d_n}\}$ an orthonormal basis for $\mathcal{H}_n$. If $n \neq n'$ then $\mathcal{H}_n$ is orthogonal to $\mathcal{H}_{n'}$ (Stein and Weiss, 1971). For each $n \in \mathbb{Z}_+$, there exists a positive constant c_n such that

$$P^d_n((x, y)) = c_n \sum_{j \in \mathbb{N}_{d_n}} Y^n_j(x) Y^n_j(y), \ \ x, y \in \mathbb{S}^d. \tag{64}$$

By Equations (63) and (64), we have that

$$\mathcal{S}_a(x, y) = \sum_{n \in \mathbb{N}} a_n c_{n-1} \sum_{j \in \mathbb{N}_{d_{n-1}}} Y^{n-1}_j(x) Y^{n-1}_j(y), \ \ x, y \in \mathbb{S}^d$$

and

$$\mathcal{S}_b(x,y) = \sum_{n\in\mathbb{N}} b_n c_{n-1} \sum_{j\in\mathbb{N}_{d_{n-1}}} Y_j^{n-1}(x) Y_j^{n-1}(y), \ \ x,y\in\mathbb{S}^d.$$

The result of this theorem hence follows immediately from Theorem 29 and the orthogonality of Y_j^n. ■

We now return to general Hilbert-Schmidt kernels defined by a sequence of functions ϕ_n on X and investigate the case when ϕ_n's are coupled. We shall work in the Hilbert space $\ell^2(\mathbb{N})$ under the assumption that $\Phi(x)\in\ell^2(\mathbb{N})$ for each $x\in X$ and

$$\overline{\operatorname{span}}\{\Phi(x): x\in X\} = \ell^2(\mathbb{N}). \tag{65}$$

For each bounded, positive, and self-adjoint linear operator C on $\ell^2(\mathbb{N})$, we denote by $\ell^2_C(\mathbb{N})$ the Hilbert space completed upon the linear space $\ell^2(\mathbb{N})$ under the inner product

$$(u,v)_{\ell^2_C(\mathbb{N})} := (Cu,v)_{\ell^2(\mathbb{N})}, \ \ u,v\in\ell^2(\mathbb{N}).$$

Note that $\ell^2_C(\mathbb{N})$ is a Hilbert space of equivalent classes. In other words, two elements $u,v\in\ell^2(\mathbb{N})$ are identical in $\ell^2_C(\mathbb{N})$ if and only if $u-v\in\ker C := \{x\in\ell^2(\mathbb{N}): Cx=0\}$. For two bounded, positive and self-adjoint linear operators A,B from $\ell^2(\mathbb{N})$ to itself, we introduce two kernels by setting

$$K_A(x,y) := (\Phi(x),\Phi(y))_{\ell^2_A(\mathbb{N})}, \ K_B(x,y) := (\Phi(x),\Phi(y))_{\ell^2_B(\mathbb{N})}, \ \ x,y\in X.$$

Before delving into conditions equivalent to $\mathcal{H}_{K_A}\preceq\mathcal{H}_{K_B}$, we review necessary results from functional analysis. For each bounded, positive and self-adjoint linear operator C on $\ell^2(\mathbb{N})$, we let $P_{C,\perp}$ denote the orthogonal projection from $\ell^2(\mathbb{N})$ to the orthogonal complement $(\ker C)^\perp$ of $\ker C$. Note that $u\in\ell^2(\mathbb{N})$ satisfies $(Cu,u)_{\ell^2(\mathbb{N})}=0$ if and only if $u\in\ker C$. Moreover, for each $u\in\ell^2(\mathbb{N})$ there holds that

$$(Cu,u)_{\ell^2(\mathbb{N})} = (CP_{C,\perp}u, P_{C,\perp}u)_{\ell^2(\mathbb{N})}.$$

Thus C is a bijective mapping from $(\ker C)^\perp$ to $\operatorname{ran} C$. We denote by $\tilde{C}^{-1}$ its inverse from $\operatorname{ran} C$ to $(\ker C)^\perp$.

Our characterization of $\mathcal{H}_{K_A}\preceq\mathcal{H}_{K_B}$ is as follows.

Theorem 32 *Suppose that A,B are bounded, positive and self-adjoint linear operators from $\ell^2(\mathbb{N})$ to itself. Then, $\mathcal{H}_{K_A}\preceq\mathcal{H}_{K_B}$ if and only if $\operatorname{ran} A\subseteq\operatorname{ran} B$ and for each $v\in\operatorname{ran} A$,*

$$P_{A,\perp}\tilde{B}^{-1}v = \tilde{A}^{-1}v. \tag{66}$$

Proof By Lemma 5, $\mathcal{H}_{K_A}\preceq\mathcal{H}_{K_B}$ if and only if for each $u\in\ell^2(\mathbb{N})$ there exists $v\in\ell^2(\mathbb{N})$ such that

$$(\Phi(x),Au)_{\ell^2(\mathbb{N})} = (\Phi(x),Bv)_{\ell^2(\mathbb{N})}, \ \ x\in X \tag{67}$$

and

$$(Au,u)_{\ell^2(\mathbb{N})} = (Bv,v)_{\ell^2(\mathbb{N})}. \tag{68}$$

By the density assumption (65), (67) is equivalent to that

$$Au = Bv. \tag{69}$$

Suppose that $\mathcal{H}_{K_A} \preceq \mathcal{H}_{K_B}$. Then for each $u \in \ell^2(\mathbb{N})$ there exists $v \in \ell^2(\mathbb{N})$ satisfying (68) and (69). By (69), we have that $\operatorname{ran} A \subseteq \operatorname{ran} B$. Let $u \in (\ker A)^\perp$. Then v in (69) can be taken as $\tilde{B}^{-1}Au$. Similarly, if we choose $u' \in (\ker A)^\perp$ and let $v' := \tilde{B}^{-1}Au'$ then (67) and (69) hold true with u, v replaced by u', v'. Since $\mathcal{H}_{K_A}$ is a subspace of $\mathcal{H}_{K_B}$, we have

$$\begin{aligned}(Au', u)_{\ell^2(\mathbb{N})} &= ((\Phi(x), Au)_{\ell^2(\mathbb{N})}, (\Phi(x), Au')_{\ell^2(\mathbb{N})})_{\mathcal{H}_{K_A}} \\ &= ((\Phi(x), Bv)_{\ell^2(\mathbb{N})}, (\Phi(x), Bv')_{\ell^2(\mathbb{N})})_{\mathcal{H}_{K_B}} \\ &= (Bv', v)_{\ell^2(\mathbb{N})}.\end{aligned}$$

By the above equation and (69), we get that

$$(Au', P_{A,\perp}\tilde{B}^{-1}Au)_{\ell^2(\mathbb{N})} = (Au', \tilde{B}^{-1}Au)_{\ell^2(\mathbb{N})} = (Bv', v)_{\ell^2(\mathbb{N})} = (Au', u)_{\ell^2(\mathbb{N})}.$$

Note that the above equation is true for all $u, u' \in (\ker A)^\perp$. Thus there must hold

$$P_{A,\perp}\tilde{B}^{-1}Au = u = \tilde{A}^{-1}Au.$$

Since A is surjective from $(\ker A)^\perp$ onto $\operatorname{ran} A$, we obtain (66) for each $v \in \operatorname{ran} A$.

Conversely, suppose that $\operatorname{ran} A \subseteq \operatorname{ran} B$ and there holds for each $v \in \operatorname{ran} A$ Equation (66). Therefore, for each $u \in (\ker A)^\perp$ there exists $v \in \ell^2(\mathbb{N})$ satisfying (69). Moreover, we calculate by (66) that

$$\begin{aligned}(Bv, v)_{\ell^2(\mathbb{N})} &= (Bv, P_{B,\perp}v)_{\ell^2(\mathbb{N})} = (Bv, \tilde{B}^{-1}Au)_{\ell^2(\mathbb{N})} = (Au, \tilde{B}^{-1}Au)_{\ell^2(\mathbb{N})} \\ &= (Au, P_{A,\perp}\tilde{B}^{-1}Au)_{\ell^2(\mathbb{N})} = (Au, \tilde{A}^{-1}Au)_{\ell^2(\mathbb{N})} = (Au, u)_{\ell^2(\mathbb{N})}.\end{aligned}$$

Thus (68) holds true. We hence prove that $\mathcal{H}_{K_A} \preceq \mathcal{H}_{K_B}$. ■

To close this section, as an application of Theorem 32, we consider kernels of finite dimensional feature spaces. Let $n \le m$ be two positive integers and A, B hermitian and strictly positive definite matrices of sizes $n \times n$ and $m \times m$, respectively. Suppose that ϕ_j, $j \in \mathbb{N}_m$ form a sequence of linearly independent functions on X. The kernels we consider are

$$G_A(x,y) := \sum_{j,k \in \mathbb{N}_n} A_{jk}\phi_k(x)\overline{\phi_j(y)},\ G_B(x,y) := \sum_{j,k \in \mathbb{N}_m} B_{jk}\phi_k(x)\overline{\phi_j(y)},\ \ x, y \in X. \tag{70}$$

We remark that a kernel has a finite dimensional feature space if and only if its RKHS has finite dimension. It was proven in Aronszajn (1950) that a RKHS is finite dimensional if and only if its reproducing kernel has the form of (70). The following corollary is a direct consequence of Theorem 32.

Corollary 33 *Let kernels G_A, G_B be defined by (70). Then $\mathcal{H}_{G_A} \preceq \mathcal{H}_{G_B}$ if and only if B^{-1} is an augmentation of A^{-1}, namely, $B^{-1}_{jk} = A^{-1}_{jk}$, $j, k \in \mathbb{N}_n$. In particular, if G_A, G_B have the form*

$$G_A(x,y) := \sum_{j \in \mathbb{N}_n} a_j\phi_j(x)\overline{\phi_j(y)},\ G_B(x,y) := \sum_{k \in \mathbb{N}_m} b_k\phi_k(x)\overline{\phi_k(y)},\ \ x, y \in X$$

for some positive constants a_j, b_k then $\mathcal{H}_{G_A} \preceq \mathcal{H}_{G_B}$ if and only if $a_j = b_j$ for each $j \in \mathbb{N}_n$. In both cases, if $\mathcal{H}_{G_A} \preceq \mathcal{H}_{G_B}$ then G_B is a nontrivial refinement kernel for G_A if and only if $m > n$.

Abstract

Subgroup analysis is an integral part of comparative analysis where assessing the treatment effect on a response is of central interest. Its goal is to determine the heterogeneity of the treatment effect across subpopulations. In this paper, we adapt the idea of recursive partitioning and introduce an interaction tree (IT) procedure to conduct subgroup analysis. The IT procedure automatically facilitates a number of objectively defined subgroups, in some of which the treatment effect is found prominent while in others the treatment has a negligible or even negative effect. The standard CART (Breiman et al., 1984) methodology is inherited to construct the tree structure. Also, in order to extract factors that contribute to the heterogeneity of the treatment effect, variable importance measure is made available via random forests of the interaction trees. Both simulated experiments and analysis of census wage data are presented for illustration.

Keywords: CART, interaction, subgroup analysis, random forests

1. Introduction

In comparative studies where two or more treatments are compared, subgroup analysis emerges after the overall assessment of the treatment effect and plays an important role in determining whether and how the treatment effect (i.e., comparison among treatments) varies across subgroups induced by covariates. In designed clinical trials, for example, practitioners and regulatory agencies are keen to know if there are subgroups of trial participants who are more (or less) likely to be helped (or harmed) by the intervention under investigation. Subgroup analysis helps explore the heterogeneity of the treatment effect and extract the maximum amount of information from the available data. According to a survey conducted by Assmann et al. (2000), 70% of trials published over a three-month period in four leading medical journals involved subgroup analyses.

The research questions in subgroup analysis can be either pre-planned or raised in a post-hoc manner. If there is a prior hypothesis of the treatment effect being different in particular subgroups, then this hypothesis and its assessment should be part of the planned study design (CPMP, 1995). At the same time, subgroup analysis is also often used for post-hoc exploratory identification of unusual or unexpected results (Chow and Liu, 2004). Suppose, for example, that it is of interest to investigate whether the treatment effect is consistent among three age groups: young, middle-aged, and older individuals. The evaluation is formally approached by means of an interaction test between treatment and age. If the resulting test is significant, multiple comparisons are then used to find out further details about the magnitude and direction of the treatment effect within each age group. To ensure a valid experimentwise false positive rate, adjustment methods such as Bonferroni typed correction are often applied.

Limitations of traditional subgroup analysis have been extensively noted (see, e.g., Assmann et al., 2000, Sleight, 2000, and Lagakos, 2006). First of all, the subgroups themselves, as well as the number of subgroups to be examined, are specified by the investigator beforehand in the current practice of subgroup analysis, which renders subgroup analysis a highly subjective process. Even for the field expert, it is a daunting task to determine which specific subgroups should be used in subgroup analysis. The subjectivity may lead directly to dubious results and willful manipulations. For example, one may fail to identify a subgroup of great prospective interest or intentionally avoid reporting subgroups where the investigational treatment is found unsuccessful or even potentially harmful. Reliance on such analyses is likely to be erroneous and harmful. Moreover, significance testing is the main approach in subgroup analysis. Because there is no general guideline for selecting the number of subgroups, one has to examine numerous plausible possibilities to have a thorough assessment of the treatment effect. However, a large number of subgroups inevitably causes concerns related to multiplicity and lack of power.

In this paper, we propose a data-driven tree procedure, labelled as "interaction trees" (IT), to explore the heterogeneity structure of the treatment effect across a number of subgroups that are objectively defined in a post hoc manner. The tree method, also called recursive partitioning, was first proposed by Morgan and Sonquist (1963). By recursively bisecting the predictor space, the hierarchical tree structure partitions the data into meaningful groups and makes available a piecewise approximation of the underlying relationship between the response and its associated predictors. The applications of tree models have been greatly advanced in various fields especially since the development of CART (classification and regression trees) by Breiman et al. (1984). Their pruning idea for tree size selection has become and remains the current standard in constructing tree models.

The remainder of the paper is organized as follows. In Section 2, the IT procedure is presented in detail. Section 3 contains simulation studies designed for assessing the proposed method. In Section 4, we apply the IT procedure to analyze a wage data set, in which the goal is to determine whether or not women are underpaid or overpaid as compared to their male counterparts and, if so, by what amount. Section 5 concludes the paper with a brief discussion.

2. Tree-Structured Subgroup Analysis

We consider a study designed to assess a binary treatment effect on a continuous response or output while adjusting or controlling for a number of covariates. Suppose that the data available contain n i.i.d. observations $\{(y_i, \text{trt}_i, \mathbf{x}_i) : i = 1, \ldots, n\}$, where y_i is the continuous response; trt_i is the binary treatment indicator taking values 1 or 0; and $\mathbf{x}_i = (x_{i1}, \ldots, x_{ip})'$ is the associated p-dimensional covariate vector where its components can be of mixed types, that is, categorical or continuous. Our goal in subgroup analysis is to find out whether there exist subgroups of individuals in which the treatment shows heterogeneous effects, and if so, how the treatment effect varies across them.

Applying a tree procedure to guide the subgroup analysis is rather intuitive. First, subgroup analysis essentially involves the interaction between the treatment and the covariates. The tree algorithm is known as an excellent tool for exploring interactions. As a matter of fact, the first implementation of decision trees is referred to as Automatic Interaction Detection (AID; Morgan and Sonquist, 1963). However, tree methods handle interactions *implicitly*. It is often hard to determine whether or not interaction really exists among variables for a given tree structure. We shall seeks ways that enable us to *explicitly* assess the interaction between the treatment and the covariates. Secondly, the hierarchical binary tree structure naturally groups data in an optimal way. By recursively partitioning the data into two subgroups that show the greatest heterogeneity in treatment effect, we are able to optimize the subgroup analysis and make it more efficient in representing the heterogeneity structure of the treatment effect. Thirdly, the tree procedure is objective, data-driven, and automated. The grouping strategy and the number of subgroups are automatically determined by the procedure. The proposed method would result in a set of objectively recognized and mutually exclusive subgroups, ranking from the most effective to the least effective in terms of treatment effect. To the best of our knowledge, Negassa et al. (2005) and Su et al. (2008), who studied tree-structured subgroup analysis in the context of censored survival data, are the only previous works along similar lines to our proposal.

To construct the IT model, we follow the CART (Breiman et al., 1984) convention, which consists of three major steps: (1) growing a large initial tree; (2) a pruning algorithm; and (3) a validation method for determining the best tree size. Once a final tree structure is obtained, the subgroups are naturally induced by its terminal nodes. To achieve better efficiency, an amalgamation algorithm is used to merge terminal nodes that show homogenous treatment effects. In addition, we adopt the variable importance technique in the context of random forest to extract covariates that exhibit important interactions with the treatment.

2.1 Growing a Large Initial Tree

We start with a single split, say s, of the data. This split is induced by a threshold on a predictor X. If X is continuous, then the binary question whether $X \leq c$ is considered. Observations answering "yes" go to the left child node t_L and observations answering "no" go to the right child node t_R. If X is nominal with r distinct categories $C = \{c_1, \ldots, c_r\}$, then the binary question becomes "Is $X \in A$?" for any subset $A \subset C$. When X has many distinct categories, one may place them into order according to the treatment effect estimate within each category and then proceed as if X is ordinal. This strategy helps reduce the computational burden. A theoretical justification is provided by Theorem 1 in the appendix.

For a given node t, a split s yields the following 2×2 table:

	child node							
treatment	t_L				t_R			
1	μ_1^L	$\bar{y}_1^L$	s_1^2	n_1	μ_1^R	$\bar{y}_1^R$	s_2^2	n_2
0	μ_0^L	$\bar{y}_0^L$	s_3^2	n_3	μ_0^R	$\bar{y}_0^R$	s_4^2	n_4

Here, $\{\mu_1^L, \bar{y}_1^L, s_1^2, n_1\}$ are the population mean, the sample mean, the sample variance, and the sample size for the treatment 1 group in the left child node t_L, respectively. Similar notation applies to the other quantities. To evaluate the heterogeneity of the treatment effect between t_L and t_R, we compare $(\mu_1^L - \mu_0^L)$ with $(\mu_1^R - \mu_0^R)$ so that the interaction between split s and treatment is under investigation.

A natural measure for assessing the interaction is given by

$$t(s) = \frac{(\bar{y}_1^L - \bar{y}_0^L) - (\bar{y}_1^R - \bar{y}_0^R)}{\hat{\sigma} \cdot \sqrt{1/n_1 + 1/n_2 + 1/n_3 + 1/n_4}}, \tag{1}$$

where $\hat{\sigma}^2 = \sum_{i=1}^4 w_i s_i^2$ is a pooled estimator of the constant variance, and $w_i = (n_i - 1)/\sum_{j=1}^4 (n_j - 1)$. For a given split s, $G(s) = t^2(s)$ converges to a $\chi^2(1)$ distribution. We will use $G(s)$ as the splitting statistic, while remaining aware that the sign of $t(s)$ supplies useful information regarding the direction of the comparison.

The best split $s^\star$ is the one that yields the maximum G statistic among all permissible splits. That is,

$$G(s^\star) = \max_s G(s).$$

The data in node t are then split according to the best split $s^\star$. The same procedure is applied to split both child nodes: t_L and t_R. Recursively doing so results in a large initial tree, denoted by T_0.

Remark 1: It can be easily seen that $t(s)$ given in (1) is equivalent to the t test for testing $H_0 : \gamma = 0$ in the following threshold model

$$y_i = \beta_0 + \beta_1 \cdot \text{trt}_i + \delta \cdot z_i^{(s)} + \gamma \cdot \text{trt}_i \cdot z_i^{(s)} + \varepsilon_i, \tag{2}$$

where $z_i^{(s)} = 1_{\{X_i \le c\}}$ is the binary variable associated with split s. This observation sheds light on extensions of the proposed method to situations involving different types of responses and multi-level treatments. Note that inclusion of both trt_i and $z_i^{(s)}$ in model (2) is important to assure the correspondence between the regression coefficient γ and the interaction, that is, $\gamma = (\mu_1^L - \mu_0^L) - (\mu_1^R - \mu_0^R)$.

Remark 2: In constructing the large initial tree T_0, a terminal node is declared when any one of the following conditions is met: the node gets pure in the sense that all the covariates have the same values; the total number of observations in the node is less than some preset minimum node size; the depth of the node is greater than some preset maximum tree depth; for all permissible splits, the minimum of (n_1, n_2, n_3, n_4) is below some preset threshold. The last condition is particularly useful in preventing the "end-cut preference" problem as discussed in CART (Breiman et al., 1984, pp. 313–317). For this purpose, the threshold can be set adaptively with respect to the depth of the node, following the suggestion of Torgo (2001).

2.2 Pruning

The final tree could be any subtree of T_0. To narrow down the choices, Breiman et al. (1984) proposed a pruning algorithm which results in a sequence of optimally pruned subtrees by iteratively truncating the "weakest link" of T_0. In the following, we briefly describe an interaction-complexity pruning procedure, which is analogous to the split-complexity pruning algorithm in LeBlanc and Crowley (1993). We refer the reader to their paper for a detailed description.

To evaluate the performance of an interaction tree T, we define an interaction-complexity measure:

$$G_\lambda(T) = G(T) - \lambda \cdot \mid T - \widetilde{T} \mid, \tag{3}$$

where $G(T) = \sum_{h \in T - \widetilde{T}} G(h)$ measures the overall amount of interaction in T; the total number of internal nodes $|T - \widetilde{T}|$ corresponds to the complexity of the tree; and the complexity parameter $\lambda \geq 0$ acts as a penalty for each added split. Given a fixed λ, a tree with larger $G_\lambda(T)$ is preferable.

Start with T_0. For any internal node h of T_0, calculate $g(h) = G(T_h)/ \mid T_h - \widetilde{T_h} \mid$, where T_h is the branch with h as root and $|T_h - \widetilde{T_h}|$ denotes the number of internal nodes of T_h. Then, the node $h^\star$ with smallest $g(h^\star)$ is the "weakest link," in the sense that $h^\star$ becomes ineffective first as λ increases. Next, let T_1 be the subtree after pruning off the branch $T_{h^\star}$ from T_0, and subsequently apply the same procedure to prune T_1. Repeating this procedure yields a nested sequence of subtrees $T_M \prec \cdots \prec T_m \prec T_{m-1} \prec \cdots \prec T_1 \prec T_0$, where T_M is the null tree with the root node only and $\prec$ means "is a subtree of".

2.3 Selecting the Best-Sized Subtree

The final tree will be selected from the nested subtree sequence $\{T_m : m = 0, 1, \ldots, M\}$, again, based on the maximum interaction-complexity measure $G_\lambda(T_m)$ given in (3). For tree size determination purposes, λ is suggested to be fixed within the range $2 \leq \lambda \leq 4$, where $\lambda = 2$ is in the spirit of the Akaike information criterion (AIC; Akaike, 1973) and $\lambda = 4$ corresponds roughly to the 0.05 significance level on the $\chi^2(1)$ curve. Another choice is $\lambda = \ln(n)$, citing the Bayesian information criterion (BIC; Schwarz, 1978).

To overcome the over-optimism due to greedy search, an "honest" estimate of the goodness-of-split measure $G(T_m)$ is needed. This can be achieved by a validation method. If the sample size is large, $G(T_m)$ can be recalculated using an independent subset of the data (termed the validation sample). If the sample size is small or moderate, one has to resort to techniques such as v-fold cross-validation or bootstrapping methods in order to validate $G(T_m)$. The bootstrap method used in LeBlanc and Crowley (1993), for example, can be readily adapted to interaction trees.

Remark 3: As another alternative, one referee suggested the use of in-sample BIC to determine the optimally-sized subtree, which can be promising, although further research effort is needed to determine the effective degrees of freedom (see, e.g., Ye, 1998, and Tibshirani and Knight, 1999) associated with interaction trees.

2.4 Summarizing the Terminal Nodes

The total number of subgroups, which could be further reduced, corresponds to the automatically selected best tree size. Existence of the overall interaction between the treatment and the covariates can be roughly assessed by inspecting whether a null final tree structure is obtained. Unlike conventional subgroup analysis, the subgroups obtained from the IT procedure are mutually exclusive. Due to the subjectivity in determining the subgroups and multiplicity emerging from significance testings across subgroups, it is generally agreed that subgroup analysis should be regarded as exploratory and hypothesis-generating. As recommended by Lagakos (2006), it is best not to present p-values for within-subgroup comparisons, but rather to give an estimate of the magnitude of the treatment difference. To summarize the terminal nodes, one can compute the average responses for both treatments within each terminal node, as well as their relative differences or ratios and the associated standard errors. If, however, one would like to perform some formal statistical testings, then it is important to conduct these tests based on yet another independent sample. To do so, one partitions the data into three sets: the learning sample $\mathcal{L}_1$, the validation sample $\mathcal{L}_2$, and the test sample $\mathcal{L}_3$. The best IT structure will be developed using $\mathcal{L}_1$ and $\mathcal{L}_2$, and then reconfirmed using the test sample $\mathcal{L}_3$.

It happens often that the treatment shows homogeneous effects for entirely different causal reasons in terminal nodes stemming from different branches. In this case, a merging scheme analogous to the approach of Ciampi et al. (1986) can be useful to further bring down the number of final subgroups. A smaller number of subgroups are easier to summarize and comprehend and more efficient to represent the heterogeneity structure for the treatment effect. It also ameliorates the multiplicity issue in within-subgroup comparisons. In this scheme, one computes the t statistic in equation (1) between every pair of the terminal nodes. The pair showing the least heterogeneity in treatment effect are then merged together. The same procedure is executed iteratively until all the remaining subgroups display outstanding heterogeneity. In the end, one can sort the final subgroups based on the strength of the treatment effect, from the most effective to the least effective.

Remark 4: The hierarchical tree structure is appealing mainly because of its easy interpretability. Apparently the merging scheme would invalidate the tree structure, yet lead to better interpretations. It is noteworthy that this merging scheme contributes additional optimism to the results. Thus, we suggest that amalgamation be executed with data $(\mathcal{L}_1 + \mathcal{L}_2)$ that pool the learning sample $\mathcal{L}_1$ and the validation sample $\mathcal{L}_2$ together, so that the resultant subgroups can be validated using the test sample $\mathcal{L}_3$. We shall illustrate this scheme with an example presented in Section 4.

2.5 Variable Importance Measure via Random Forests

Variable importance measure is another attractive feature offered by recursive partitioning. In the context of subgroup analysis, a covariate is called an *effect-modifier* of the treatment if it strongly interacts with the treatment. Variable importance measure helps answer questions such as which features or predictors are important in modifying the treatment effect. This issue cannot be fully addressed by simply examining the splitting variables shown in a single final IT structure, as an important variable can be completely masked by other correlated ones. While there are many methods available for extracting variable importance information, we propose an algorithm analogous to the procedure used in random forests (Breiman, 2001), which is among the newest and most promising developments in this regards.

Algorithm 1: Computing Variable Importance Measure via Random Forests.

```
Initialize all $V_j$'s to 0.
For $b = 1, 2, \ldots, B$, do
    • Generate bootstrap sample $\mathcal{L}_b$ and obtain the out-of-bag sample $\mathcal{L} - \mathcal{L}_b$.
    • Based on $\mathcal{L}_b$, grow a large IT tree $T_b$ by searching over $m_0$ randomly selected
    covariates at each split.
    • Send $\mathcal{L} - \mathcal{L}_b$ down $T_b$ to compute $G(T_b)$.
    • For all covariates $X_j$, $j = 1, \ldots, p$, do
        ◦ Permute the values of $X_j$ in $\mathcal{L} - \mathcal{L}_b$.
        ◦ Send the permuted $\mathcal{L} - \mathcal{L}_b$ down to $T_b$ to compute $G_j(T_b)$.
        ◦ Update $V_j \leftarrow V_j + \frac{G(T_b) - G_j(T_b)}{G(T_b)}$.
    • End do.
End do.
Average $V_j \leftarrow V_j / B$.
```

Let V_j denote the importance measure of the j-th covariate or feature X_j for $j = 1, \ldots, p$. We construct random forests of IT trees by taking B bootstrap samples $\mathcal{L}_b$, $b = 1, \ldots, B$. This is done by searching over only a subset of randomly selected m_0 covariates at each split. For each IT tree T_b, the b-th out-of-bag sample (denoted as $\mathcal{L} - \mathcal{L}_b$), which contains all observations that are not in $\mathcal{L}_b$, is sent down T_b to compute the interaction measure $G(T_b)$. Next, the values of the j-th covariate in $\mathcal{L} - \mathcal{L}_b$ are randomly permuted. The permuted out-of-bag sample is then sent down T_b to recompute $G_j(T_b)$. The relative difference between $G(T_b)$ and $G_j(T_b)$ is recorded. The procedure is repeated for B bootstrap samples. As a result, the importance measure V_j is the average of the relative differences over all B bootstrap samples. The whole procedure is summarized in Algorithm 1.

The variable importance technique in random forests has been increasingly studied in its own right and applied as a tool for variable selection in various fields. This method generally belongs to the "cost-of-exclusion" (Kononenko and Hong, 1997) feature selection category, in which the importance or relevance of a feature is determined by the difference in some model performance measure with and without the given feature included in the modeling process. In Algorithm 1, random forests make available a flexible modeling process while exclusion of a given feature is carried out by permutating its values.

3. Simulated Studies

This section contains simulated experiments designed to investigate the performance of the IT procedure. We generate data from six models outlined in Table 1. Each data set consists of a continuous response Y, a binary treatment, and four covariates X_1–X_4 simulated from a discrete uniform distribution over $(0.02, 0.04, \ldots, 1.00)$. However, only a subset of the covariates interact with the treatment.

Model	Form	Error Distribution
A	$Y = 2 + 2 \cdot \mathrm{trt} + 2Z_1 + 2Z_2 + \varepsilon$	$\mathcal{N}(0,1)$
B	$Y = 2 + 2 \cdot \mathrm{trt} + 2Z_1 + 2Z_2 + 2 \cdot \mathrm{trt} \cdot Z_1 Z_2 + \varepsilon$	$\mathcal{N}(0,1)$
C	$Y = 2 + 2 \cdot \mathrm{trt} + 2Z_1 + 2Z_2 + 2 \cdot \mathrm{trt} \cdot Z_1 + 2 \cdot \mathrm{trt} \cdot Z_2 + \varepsilon$	$\mathcal{N}(0,1)$
D	$Y = 10 + 10 \cdot \mathrm{trt} \cdot \exp\{(X_1 - 0.5)^2 + (X_2 - 0.5)^2\} + \varepsilon$	$\mathcal{N}(0,1)$
E	$Y = 2 + 2 \cdot \mathrm{trt} + 2Z_1 + 2Z_2 + 2 \cdot \mathrm{trt} \cdot Z_1 + 2 \cdot \mathrm{trt} \cdot Z_2 + \varepsilon$	$\mathrm{Unif}(-\sqrt{3}, \sqrt{3})$
F	$Y = 2 + 2 \cdot \mathrm{trt} + 2Z_1 + 2Z_2 + 2 \cdot \mathrm{trt} \cdot Z_1 + 2 \cdot \mathrm{trt} \cdot Z_2 + \varepsilon$	$\exp(1)$

Table 1: Models used for assessing the performance of the IT procedure. Note that $Z_1 = 1_{\{X_1 \leq 0.5\}}$ and $Z_2 = 1_{\{X_2 \leq 0.5\}}$.

Specifically, Model A is a plain additive model with no interaction. It helps assess the type I error or false positive rate when using the IT procedure. Model B involves a second-order interaction between the treatment and two terms of thresholds, both at 0.5, on X_1 and X_2. If the IT procedure works, a tree structure with three terminal nodes should be selected. In Model C, the two thresholds, each interacting with the treatment, are present in an additive manner. Model D involves interaction of complex forms other than cross-products. A large tree is expected in order to represent the interaction structure in this case. Models E and F are similar to Model C, but with different error distributions. They are useful in evaluating the robustness of the IT procedure to deviations from normality.

Only one set of sample sizes is reported: 800 observations in the learning sample $\mathcal{L}_1$ and 400 observations in the validation sample $\mathcal{L}_2$. Each model is examined for 200 simulation runs and four choices of λ, $\{2, 3, 4, \ln(400)\}$, are considered for determining the best tree structure. The relative frequencies of the final tree sizes selected by the IT procedure are presented in Table 2. The expected final tree size for each model is highlighted in boldface. Note that both X_1 and X_2, but neither X_3 nor X_4, are actually involved in models B-F. To address the variable selection issue, we count the frequency of "hits" (i.e., the final tree selected by the IT procedure is split by X_1 and X_2 and only by them). The results are presented in the last column of Table 2.

We first examine the results for Model A, which involves no interaction. The IT procedure correctly selects the null tree structure at least 83.5% of the time. When $\lambda = \ln(n)$, the percentage of correct selections becomes 98.5%. The 98.5% of correct selections yields an empirical size of 100%-98.5% = 1.5%, which is well within the acceptable level. This implies that the chance for the IT procedure to extract an unsolicited interactions is really small. For models B-F, the IT procedure also successfully identifies the true final tree structure and selects the desired splitting variables a majority of the time. Moreover, from results for models E and F, it seems rather robust against deviations from normality. When comparing different complexity parameters, we see that $\lambda = \ln(n)$ provides the best selection. This is mainly because of the large sample size and relatively strong signals considered in our simulation configuration (see, e.g., McQuarrie and Tsai, 1998).

To evaluate the proposed variable importance technique, we generate a data set containing 1,200 observations from each model. Then a total number of 500 random interaction trees with $m_0 = 1$ are used to compute the variable importance. In Figure 1, graphs A-I, B-I, ..., F-I display the resultant importance scores for models A-F, respectively. For comparison, we also apply a simple feature

	Complexity	Final Tree Size

Table 2: Relative frequencies (in percentages) of the final tree size identified by the interaction tree (IT) procedure in 200 runs.

selection approach, in which the importance of a covariate, say, X, is determined by the p-value for testing $H_0 : \beta_3 = 0$ in the interaction model $y = \beta_0 + \beta_1 x + \beta_2 \,\mathrm{trt} + \beta_3 \,\mathrm{trt} \cdot x + \varepsilon$. In Figure 1, graphs A-II, B-II, ..., F-II depict the resulting logworths for models A-F, where the logworth is defined as minus base 10 logarithm of the p-value. Both methods are able to pick up important variables in many cases. Nevertheless, the latter approach is focused on cross-product and first-order interactions only, which accounts for its failure in models B and D. In Figure B-II, it fails to identify X_1

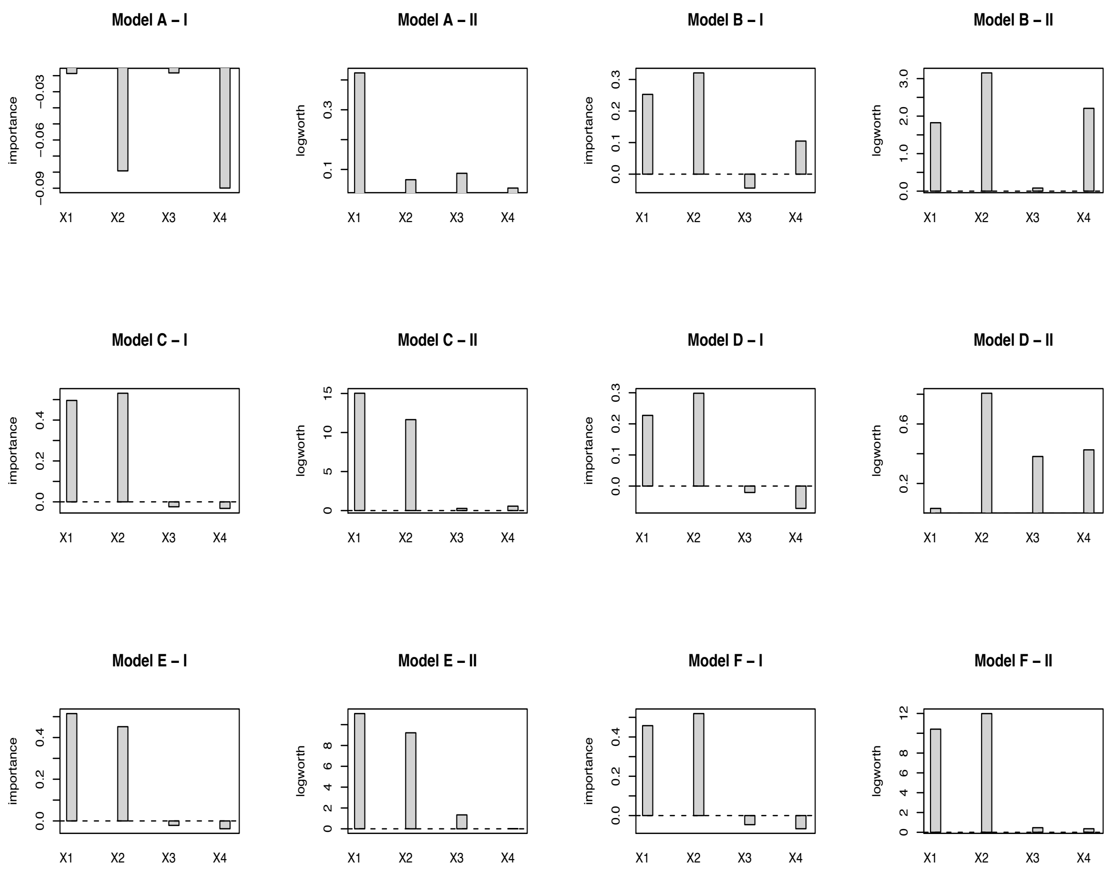

Figure 1: Variable Importance via Random Forests and Feature Selection for the Six Simulation Models. With a data set consisting of 1200 observations generated from Model A, Graph A-I plots the variable importance score computed from 500 random interaction trees while Graph A-II plots the logworth of the p-value from the simple feature selection method. Note that logworth $= -\log_{10}$(p-value). Similar methods were used to make other graphs.

and mistakenly selects X_4. In Figure D-II, none of the covariates are found important.

Remark 5: Comparatively, the random forest approach facilitates better comprehensive evaluation by automatically taking into consideration interactions of higher orders and complex forms. As pointed out by an anonymous reviewer, some other feature selection methods such as the wrapper and/or embedded algorithms can be adopted to detect interactions. It would be interesting in future research to have a more comprehensive study in comparing various algorithms with the variable importance measure obtained from random forests.

	Name	Type	Levels	Description
X_1	`age`	continuous	70	age

[3]The specific levels for `household.sum` (X_{11}): 1 - Child 18 or older; 2 - Child under 18 never married; 3 - Group Quarters, Secondary individual; 4 - Householder; 5 - Nonrelative of householder; 6 - Other relative of householder; 7 - Spouse of householder.

Table 3: Variable Description for the Census Wage Data.

4. An Example - The CPS Data

Society has long been arguing for pay equality between women and men. Although the pay gap has narrowed, according to current statistics, gaps between the two sexes still exist. For example, the Bureau of Labor Statistics of the U.S. Department of Labor, in 2004, the most recent year for which statistics are available, reported that women's median weekly earnings were only 80 percent that of men. This represents an improvement over 1979, when women brought home only 62 percent of earnings compared to their male counterparts. A public policy advocate would be very interested in specific subgroups of the working population where the pay gap between sexes is still dominant. Traditional statistical methods consider simple cross tabulations according to a number of variables.

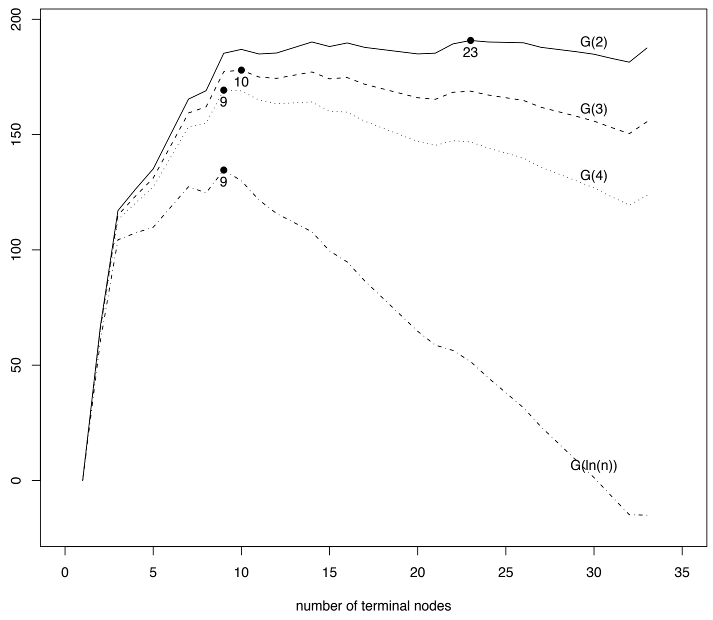

Figure 2: Tree size selection for the CPS data (the plot of $G_\lambda(T_m)$ vs. tree size).

The quest becomes complicated when there are a large number of classification variables to choose from, which motivates the IT procedure.

We extract data from the Current Population Survey (CPS) database, which can be accessed at (`http://www.census.gov/cps/`). The CPS is a national monthly survey of approximately 60,000 households conducted by the U.S. Census Bureau for the Bureau of Labor Statistics. Information collected in the survey includes employment status, hours worked and income from work as well as a number of demographic characteristics of the household members. From the CPS 1995 March Supplement, we compile a data set, which contains 16,602 individuals with no missing value involved. We use hourly wages in U.S. dollars as a measure of pay. Besides gender, there are a total of 16 demographical covariates included. A brief description for these covariates is given in Table 3. Several of them are nominal with many levels. We only list detailed codings for those variables appearing in the final tree structure.

To apply IT, we take a logarithmic transformation on wage. Then, we randomly divide the entire data (denoted as $\mathcal{L}$) into three sets with a ratio of approximately 2: 1: 1. A large initial tree with 33 terminal nodes is constructed and pruned using data in $\mathcal{L}_1$. Sending the validation sample $\mathcal{L}_2$ down each subtree, Figure 2 depicts the resultant $G_\lambda(T_m)$ score versus the subtree size. It can be seen that the four choices of complexity parameter $\lambda = 2, 3, 4$, and $\ln(n)$ yield the best tree sizes of 23, 10, 9, and 9, respectively. For the sake of illustration, the best tree structure with 9 terminal nodes as well as some related summary statistics are given in Figure 3. To merge those terminal nodes among which the wage discrepancies due to gender are not significantly different, we run the amalgamation algorithm with the pooled data $(\mathcal{L}_1 + \mathcal{L}_2)$. It results in four final subgroups, which are then ranked as I-IV according to the ratio of women versus men in terms of average wage. In Group

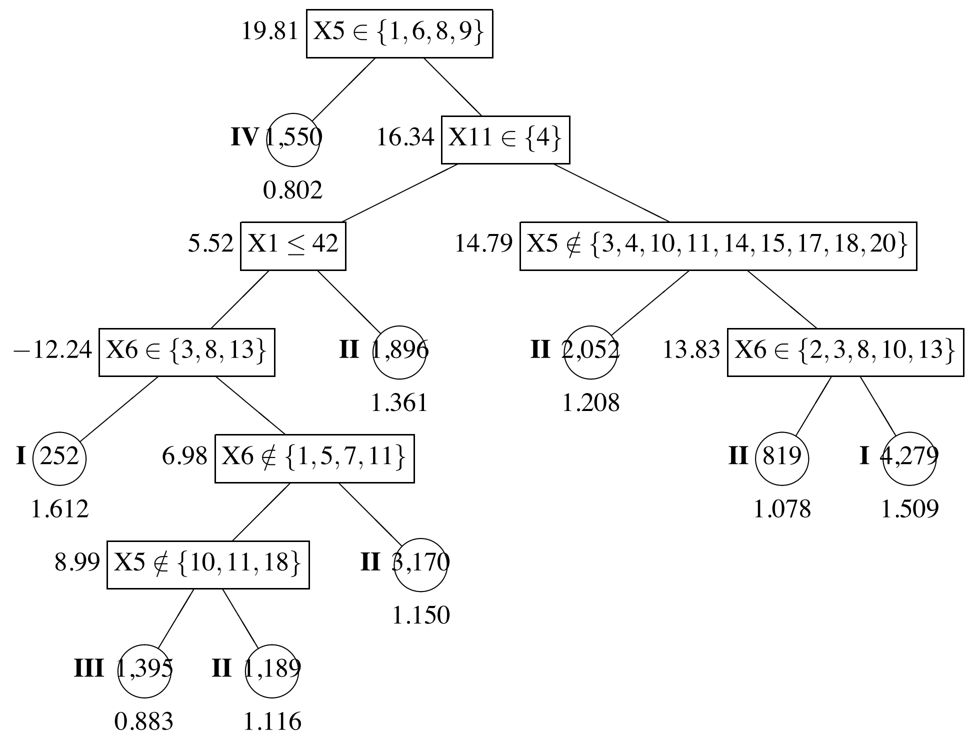

Figure 3: The best-sized interaction tree for the CPS data selected by BIC. For each internal node denoted by a box, the splitting rule is given inside the box. Observations satisfying the condition go to the left node while observations not satisfying the condition go the right node. To the left of each internal node is the $t(s)$ test statistic recomputed using $\mathcal{L}_3$. Terminal nodes are denoted by circles and ranked with Roman numerals on the left. The node size (i.e., number of individuals) is given inside the circle and the ratio of average wages for males versus females is given underneath, both based on the entire data set $\mathcal{L}$.

I, women are most underpaid compared to men. In Group II, women are somewhat underpaid, etc. This specification was also made available to each terminal node in Figure 3.

Table 4 summarizes the final four subgroups. For each subgroup, the number of men and women, as well as their average wages, are computed based on the whole data $\mathcal{L}$. The two-sample t test for comparing the average wages between men and women is also presented. This test was computed by using the test sample $\mathcal{L}_3$. Since there are four tests performed, one may compare the resultant p-values with $0.05/4 = 0.0125$ by applying the Bonferroni-typed adjustment to the joint significant level $\alpha = 0.05$. As a result, Groups I, II, and IV, each marked with an asterisk, show significant differences in wage between men and women.

Figure 3 indicates that the wage disparity between men and women varies with their occupation (X_5), industry of the job (X_6), household compositional situation (X_{11}), and age (X_1). For both Groups I and II, which constitute the majority of the population, women are paid significantly less than men. It is particularly pronounced in Group I, where the average wage of men is \$12.29 per

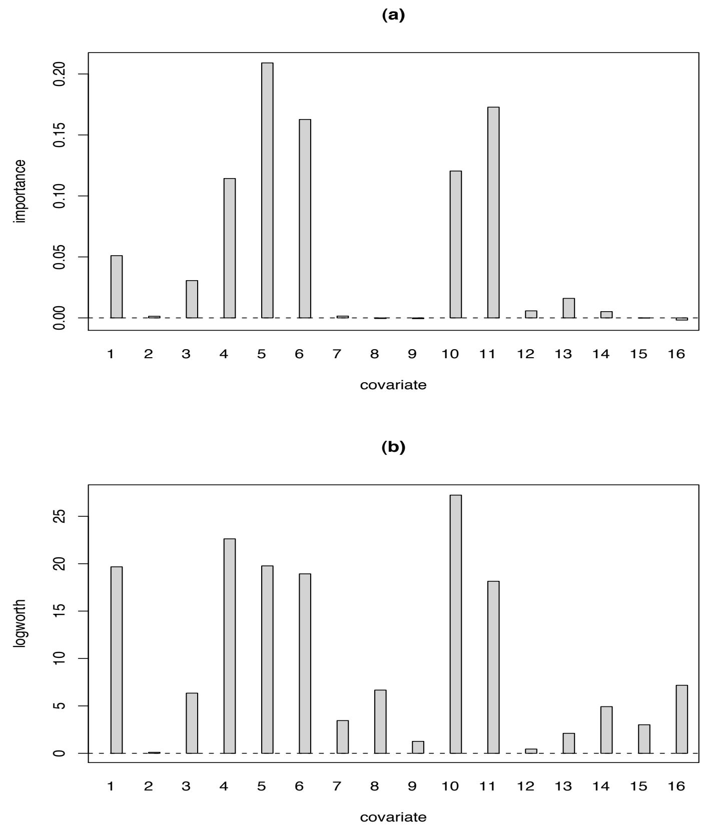

Figure 4: Variable importance measures for the CPS Data: (a), via random forests of interaction trees; (b), based on the p-value associated with the interaction terms in an interaction model that includes the treatment and the covariate only. Note that the logworth is $-\log_{10}$(p-value). The sixteen covariates are `age` (X_1), `workclass` (X_2), `education` (X_3), `marital` (X_4), `industry` (X_5), `occupation` (X_6), `race` (X_7), `union` (X_8), `fulltime` (X_9), `tax.status` (X_{10}), `household.sum` (X_{11}), `n.employee` (X_{12}), `country.birth` (X_{13}), `citizenship` (X_{14}), `self.employed` (X_{15}), and `weeks.worked` (X_{16}).

hour while the average wage of women is only \$8.03 per hour. Interestingly the IT tree has also identified a subgroup, Group IV, in which men are underpaid compared to women. This occurs in the following industries (X_5): 1 - Agriculture; 6 - Entertainment; 8 - Forestry and fisheries; 9 - Hospital services.

Finally, Figure 4(a) displays the computed variance importance scores for each of the 16 covariates. In this calculation, $B = 2,000$ bootstrap samples are used and the number of randomly selected variables, m_0, is set at 4 when splitting data. It can be seen that `industry` (X_5) and `household.sum` (X_{11}) stand out as the most important factors that contribute to the pay gap between males and females, followed by `occupation` (X_6), `tax.status` (X_{10}), `marital` (X_4), and then `age` X_1. This finding is consistent with the tree structure in Figure 3, except for that `tax.status` (X_{10}) and `marital`

	Male		Female		Two-Sample t Test (computed from the test sample)	
	size	average	size	average		
Node	(n_1)	wage $(\bar{y}_1)$	(n_0)	wage $(\bar{y}_0)$	t	p-value
I	3220	12.29	1311	8.03	13.449	$< 0.0001^\star$
II	3800	10.11	5326	8.25	7.678	$< 0.0001^\star$
III	449	8.08	946	9.15	−0.306	0.7598
IV	501	9.43	1049	11.76	−5.560	$< 0.0001^\star$

Table 4: Summary statistics for the four final subgroups of the CPS data. Note that $(n_1, \bar{y}_1, n_0, \bar{y}_0)$ are computed using the whole data. The two-sample t test statistics are calculated from the test sample $\mathcal{L}_3$. The associated p-values are obtained for two-sided tests.

(X_4) have been masked out. The simple feature selection technique is also used to determine the importance of each covariate. Figure 4(b) depicts the resulting logworths. While both plots show some similarities, one should keep in mind that evaluation based on the latter approach is rather restrictive.

5. Discussion

In data analysis, it is important to distinguish two types of interactions. If there is no directional change in terms of the comparison, that is, $(\mu_1^L - \mu_0^L) \cdot (\mu_1^R - \mu_0^R) > 0$, the interaction is said to be *quantitative*; otherwise, it is termed as *qualitative*. The presence of qualitative interactions causes more concerns than quantitative ones (see, e.g., Gail and Simon, 1985). The results from the IT procedure can help to address this issue. For instance, the qualitative interaction in the the CPS example is obviously present among the final four subgroups.

The proposed IT procedure is applicable to a number of different areas. For example, the IT structure can help identify the most and least effective subgroups for the investigational medicine. If the new medicine shows an overall effect that is significant, and, if even in the least effective subgroup under examination, it does not present any harmful side effects, then its release may be endorsed without reservation. In trials where the proposed compound is not found to be significantly effective, the tree-structured subgroup analysis may identify sub-populations that contribute to the failure of the compound. Information gained in this manner could provide the basis for establishing inclusion/exclusion criteria in future trials, and as such, could be of considerable value to the existing efforts in synthesizing compounds to fight deadly diseases such as cancer and HIV/AIDS. We believe that efforts along these lines make subgroup analysis an efficient and valuable tool for research in many application fields.

Appendix A. Categorical Splits

The following theorem provides motivation and justification for the computationally efficient strategy of "ordinalizing" categorical covariates in interaction trees as discussed in Section 2.1. It is analogous to Theorem 9.6 of CART (Breiman et al., 1984, pp. 274–278) yet makes a stronger statement.

Consider splits based on a categorical covariate X, whose possible values range over a finite set $C = \{c_1, \ldots, c_r\}$. Then any subset $A \subset C$, together with its complement $A' = C - A$, induces a partition of the data into $t_L = \{(y_i, \text{trt}_i, \mathbf{x}_i) : x_{il} \in A\}$ and $t_R = \{(y_i, \text{trt}_i, \mathbf{x}_i) : x_{il} \in A'\}$. In the setting of interaction trees, the splitting rule seeks an optimal partition $(A + A')$ to maximize the difference in treatment effect between two child nodes $\left\{(\mu_1^L - \mu_0^L) - (\mu_1^R - \mu_0^R)\right\}^2$, where $\mu_1^L = \mu_{A1} = E\left(y \,|\, x_{il} \in A, \text{trt}_i = 1\right)$ denotes the treatment mean in the left child node, and a similar definition applies for the other μ's. For the sake of convenience, we assume $(\mu_1^L - \mu_0^L) > (\mu_1^R - \mu_0^R)$ so that an optimal split maximizes $(\mu_1^L - \mu_0^L) - (\mu_1^R - \mu_0^R)$.

Theorem 1. *Let $\mu_{ck} = E(y \,|\, X = c, trt = k)$ for any element $c \in C$ and $k = 0, 1$. If $(A + A')$ forms an optimal partition of C, then we have*

$$\mu_{c_1 1} - \mu_{c_1 0} \geq \mu_{c_2 1} - \mu_{c_2 0},$$

for any element $c_1 \in A$ and $c_2 \in A'$. ■

Proof. Define

$$d_1 = \min_{c \in A} (\mu_{c1} - \mu_{c0}) \quad \text{and} \quad d_2 = \max_{c \in A'} (\mu_{c1} - \mu_{c0}).$$

Accordingly, it suffices to show that $d_1 \geq d_2$.

To proceed, let

$$\begin{aligned} A_1 &= \{c \in A : \mu_{c1} - \mu_{c0} = d_1\} \\ A_2 &= \left\{c \in A' : \mu_{c1} - \mu_{c0} = d_2\right\} \\ A_3 &= \{c \in A : \mu_{c1} - \mu_{c0} > d_1\} \\ A_4 &= \left\{c \in A' : \mu_{c1} - \mu_{c0} < d_2\right\}. \end{aligned}$$

Thus $A = A_1 + A_3$ and $A' = A_2 + A_4$. We reserve a generic notation $d = \mu_1 - \mu_0$ for the treatment effect. Define

$$\begin{aligned} d_i &= \sum_{c \in A_i} (\mu_{c1} - \mu_{c0}) \Pr\{X_j = c\}, \\ d_{ij} &= \sum_{c \in A_i \cup A_j} (\mu_{c1} - \mu_{c0}) \Pr\{X_j = c\}, \\ d_{ijk} &= \sum_{c \in A_i \cup A_j \cup A_k} (\mu_{c1} - \mu_{c0}) \Pr\{X_j = c\}. \end{aligned}$$

for $i \neq j \neq k = 1, 2, 3, 4$. We also introduce notation $Q_i = \Pr\{X_j \in A_i\}$ for $i = 1, 2, 3, 4$. It can be verified that

$$d_{ij} = \frac{d_i Q_i + d_j Q_j}{Q_{ij}} \text{ with } Q_{ij} = Q_i + Q_j$$

and

$$d_{ijk} = \frac{d_i Q_i + d_j Q_j + d_k Q_k}{Q_{ijk}} \text{ with } Q_{ijk} = Q_i + Q_j + Q_k.$$

Since partition $(A + A')$ provides an optimal partition, $d_{13} - d_{24} > 0$ reaches the maximum among all possible partitions. In particular, for partition $(A_3 + A_3')$, we have $d_{13} - d_{24} \geq d_3 - d_{124}$, which can be shown equivalent to

$$d_1 \geq (1 - Q_3)\, d_{13} + Q_3\, d_{24}, \tag{4}$$

by first plugging in the following two relationships

$$\begin{aligned} d_3 &= \frac{Q_{13} d_{13} - Q_1 d_1}{Q_3} \\ d_{124} &= \frac{Q_{24} d_{24} + d_1 Q_1}{Q_{124}} \end{aligned}$$

and then simplifying. Similarly, for partition $(A_4' + A_4)$, we can establish

$$Q_4\, d_{13} + (1 - Q_4)\, d_{24} \geq d_2 \tag{5}$$

starting with $d_{13} - d_{24} \geq d_{123} - d_4$.

Now suppose that $d_2 \geq d_1$. It follows from (5) and (4) that

$$\begin{aligned} & Q_4\, d_{13} + (1 - Q_4)\, d_{24} \geq d_2 \geq d_1 \geq (1 - Q_3)\, d_{13} + Q_3\, d_{24} \\ \Longrightarrow\ & \{Q_4\, d_{13} + (1 - Q_4)\, d_{24}\} - \{(1 - Q_3)\, d_{13} + Q_3\, d_{24}\} \ \geq\ d_2 - d_1 \\ \Longrightarrow\ & Q_{12}(d_{24} - d_{13}) \ \geq\ d_2 - d_1, \text{ since } 1 - Q_3 - Q_4 = Q_1 + Q_2 = Q_{12}. \end{aligned}$$

However, $0 > d_{24} - d_{13}$ leads to $0 > d_2 - d_1$, which contradicts the condition $d_1 \leq d_2$. Thus we must have $d_1 > d_2$.

The theorem also holds in extreme cases such as $d_1 = d_3$ or $d_2 = d_4$, etc. The proofs are omitted.

Abstract

In this paper, we introduce PEBL, a Python library and application for learning Bayesian network structure from data and prior knowledge that provides features unmatched by alternative software packages: the ability to use interventional data, flexible specification of structural priors, modeling with hidden variables and exploitation of parallel processing.
PEBL is released under the MIT open-source license, can be installed from the Python Package Index and is available at `http://pebl-project.googlecode.com`.

Keywords: Bayesian networks, python, open source software

1. Introduction

Bayesian networks (BN) have become a popular methodology in many fields because they can model nonlinear, multimodal relationships using noisy, inconsistent data. Although learning the structure of BNs from data is now common, there is still a great need for high-quality open-source software that can meet the needs of various users. End users require software that is easy to use; supports learning with different data types; can accommodate missing values and hidden variables; and can take advantage of various computational clusters and grids. Researchers require a framework for developing and testing new algorithms and translating them into usable software. We have developed the Python Environment for Bayesian Learning (PEBL) to meet these needs.

2. PEBL Features

PEBL provides many features for working with data and BNs; some of the more notable ones are listed below.

2.1 Structure Learning

PEBL can load data from tab-delimited text files with continuous, discrete and class variables and can perform maximum entropy discretization. Data collected following an intervention is important for determining causality but requires an altered scoring procedure (Pe’er et al., 2001; Sachs et al., 2002). PEBL uses the BDe metric for scoring networks and handles interventional data using the method described by Yoo et al. (2002).

```
from pebl import data, result
from pebl.learner.greedy import GreedyLearner
from pebl.taskcontroller.xgrid import XgridController

dataset = data.fromfile('mydata.txt')
runner = XgridController('grid.com', 'pass')
learners = [GreedyLearner(dataset) for i in range(10)]
results = runner.run(learners)
result.merge(results).tohtml('./myoutput')
```

(a) Python script

```
[data]
filename = mydata.txt
[learner]
type = greedy.GreedyLearner
numtasks = 10
[taskcontroller]
type=xgrid.XgridController
[xgrid]
controller = grid.com
password = pass
[result]
output = ./myoutput
```

(b) PEBL configuration file

Figure 1: Two ways of using PEBL: with a Python script and a configuration file. Both methods create 10 greedy learners with default parameters and run them on an Apple Xgid. The Python script can be typed in an interactive shell, run as a script or included as part of a larger application.

PEBL can handle missing values and hidden variables using exact marginalization and Gibbs sampling (Heckerman, 1998). The Gibbs sampler can be resumed from a previously suspended state, allowing for interactive inspection of preliminary results or a manual strategy for determining satisfactory convergence.

A key strength of Bayesian analysis is the ability to use prior knowledge. PEBL supports structural priors over edges specified as 'hard' constraints or 'soft' energy matrices (Imoto et al., 2003) and arbitrary constraints specified as Python functions or lambda expressions.

PEBL includes greedy hill-climbing and simulated annealing learners and makes writing custom learners easy. Efficient implementaion of learners requires careful programming to eliminate redundant computation. PEBL provides components to alter, score and rollback changes to BNs in a simple, transactional manner and with these, efficient learners look remarkably similar to pseudocode.

2.2 Convenience and Scalability

PEBL includes both a library and a command line application. It aims for a balance between ease of use, extensibility and performance. The majority of PEBL is written in Python, a dynamically-typed programming language that runs on all major operating systems. Critical sections use the numpy library (Ascher et al., 2001) for high-performance matrix operations and custom extensions written in ANSI C for portability and speed.

PEBL's use of Python makes it suitable for both programmers and domain experts. Python provides interactive shells and notebook interfaces and includes an extensive standard library and many third-party packages. It has a strong presence in the scientific computing community (Oliphant, 2007). Figure 1 shows a script and configuration file example that showcase the ease of using PEBL.

[3] Only constraints/hard-priors supported.

Table 1: Comparing the features of popular Bayesian network structure learning software.

While many tasks related to Bayesian learning are embarrassingly parallel in theory, few software packages take advantage of it. PEBL can execute learning tasks in parallel over multiple processors or CPU cores, an Apple Xgrid,[1] an IPython cluster[2] or the Amazon EC2 platform.[3] The EC2 platform is especially attractive for scientists because it allows one to rent processing power on an on-demand basis and execute PEBL tasks on them.

With appropriate configuration settings and the use of parallel execution, PEBL can be used for large learning tasks. Although PEBL has been tested successfully with data sets with 10000 variables and samples, BN structure learning is a known NP-Hard problem (Chickering et al., 1994) and analysis using data sets with more than a few hundred variables is likely to result in poor results due to poor coverage of the search space.

3. PEBL Development

The benefits of open source software derive not just from the freedoms afforded by the software license but also from the open and collaborative development model. PEBL's source code repository and issue tracker are hosted at Google Code and freely available to all. Additionally, PEBL includes over 200 automated unit tests and mandates that every source code submission and resolved error be accompanied with tests.

4. Related Software

While there are many software tools for working with BNs, most focus on parameter learning and inference rather than structure learning. Of the few tools for structure learning, few are open-source and none provide the set of features included in PEBL. As shown in Table 1, the ability to handle interventional data, model with missing values and hidden variables, use soft and arbitrary priors and exploit parallel platforms are unique to PEBL. PEBL, however, does not currently provide any

1. Grid computing solution by Apple, Inc. `http://www.apple.com/server/macosx/technology/xgrid.html`.
2. Cluster of Python interpreters (`http://ipython.scipy.org`).
3. A pay-per-use, on-demand computing platform by Amazon, Inc. (`http://aws.amazon.com`).

features for inference or learning Dynamic Bayesian Networks (DBN). Despite its use of optimized matrix libraries and custom C extension modules, PEBL can be an order of magnitude or more slower than software written in Java or C/C++; the ability to use a wider range of data and priors, the parallel processing features and the ease-of-use, however, should make it an attractive option for many users.

5. Conclusion and Future Work

We have developed a library and application for learning BNs from data and prior knowledge. The set of features found in PEBL is unmatched by alternative packages and we hope that our open development model will convince others to use PEBL as a platform for BN algorithms research.

Editor: Rocco Servedio

Abstract

We study the properties of the agnostic learning framework of Haussler (1992) and Kearns, Schapire, and Sellie (1994). In particular, we address the question: is there any situation in which membership queries are useful in agnostic learning?

Our results show that the answer is negative for distribution-independent agnostic learning and positive for agnostic learning with respect to a specific marginal distribution. Namely, we give a simple proof that any concept class learnable agnostically by a distribution-independent algorithm with access to membership queries is also learnable agnostically without membership queries. This resolves an open problem posed by Kearns et al. (1994). For agnostic learning with respect to the uniform distribution over $\{0,1\}^n$ we show a concept class that is learnable with membership queries but computationally hard to learn from random examples alone (assuming that one-way functions exist).

Keywords: agnostic learning, membership query, separation, PAC learning

1. Introduction

The agnostic framework (Haussler, 1992; Kearns et al., 1994) is a natural generalization of Valiant's PAC learning model (Valiant, 1984). In this model no assumptions are made on the labels of the examples given to the learning algorithm, in other words, the learning algorithm has no prior beliefs about the target concept (and hence the name of the model). The goal of the agnostic learning algorithm for a concept class $\mathcal{C}$ is to produce a hypothesis h whose error on the target concept is close to the best possible by a concept from $\mathcal{C}$. This model reflects a common empirical approach to learning, where few or no assumptions are made on the process that generates the examples and a limited space of candidate hypothesis functions is searched in an attempt to find the best approximation to the given data.

Designing algorithms that learn efficiently in this model is notoriously hard and very few positive results are known (Kearns et al., 1994; Lee et al., 1995; Goldman et al., 2001; Gopalan et al., 2008; Kalai et al., 2008a,b). Furthermore, strong computational hardness results are known for agnostic learning of even the simplest classes of functions such as parities, monomials and halfspaces (Håstad, 2001; Feldman, 2006; Feldman et al., 2006; Guruswami and Raghavendra, 2006) (albeit only for *proper* learning). Reductions from long-standing open problems for PAC learning to ag-

nostic learning of simple classes of functions provide another indication of the hardness of agnostic learning (Kearns et al., 1994; Kalai et al., 2008a; Feldman et al., 2006).

A membership oracle allows a learning algorithm to obtain the value of the unknown target function f on any point in the domain. It can be thought of as modeling the access to an expert or ability to conduct experiments. Learning with membership queries in both PAC and Angluin's exact models (Angluin, 1988) was studied in numerous works. For example monotone DNF formulas, finite automata and decision trees are only known to be learnable with membership queries (Valiant, 1984; Angluin, 1988; Bshouty, 1995). It is well-known and easy to prove that the PAC model with membership queries is strictly stronger than the PAC model without membership queries (if one-way functions exist).

Membership queries are also used in several agnostic learning algorithms. The first one is the famous algorithm of Goldreich and Levin (1989) introduced in a cryptographic context (even before the definition of the agnostic learning model). Their algorithm learns parities agnostically with respect to the uniform distribution using membership queries. Kushilevitz and Mansour (1993) used this algorithm to PAC learn decision trees and it has since found numerous other significant applications. More efficient versions of this algorithm were also given by Levin (1993), Bshouty, Jackson, and Tamon (2004) and Feldman (2007). Recently, Gopalan, Kalai, and Klivans (2008) gave an elegant algorithm that learns decision trees agnostically over the uniform distribution and uses membership queries.

1.1 Our Contribution

In this work we study the power of membership queries in the agnostic learning model. The question of whether or not membership queries can aid in agnostic learning was first asked by Kearns et al. (1994) who conjectured that the answer is no. To the best of our knowledge, the question has not been addressed prior to our work. We present two results on this question. In the first result we prove that every concept class learnable agnostically with membership queries is also learnable agnostically without membership queries (see Th. 6 for a formal statement). This proves the conjecture of Kearns et al. (1994). The reduction we give modifies the distribution of examples and therefore is only valid for distribution-independent learning, that is, when a single learning algorithm is used for every distribution over the examples. The simple proof of this result explains why the known distribution-independent agnostic learning algorithm do not use membership queries (Kearns et al., 1994; Kalai et al., 2008a,b).

The proof of this result also shows equivalence of two standard agnostic models: the one in which examples are labeled by an unrestricted function and the one in which examples come from a joint distribution over the domain and the labels.

Our second result is a proof that there exists a concept class that is agnostically learnable with membership queries over the uniform distribution on $\{0,1\}^n$ but hard to learn in the same setting without membership queries (see Th. 8 for a formal statement). This result is based on the most basic cryptographic assumption, namely the existence of one-way functions. Note that an unconditional separation of these two models would imply $\mathsf{NP} \neq \mathsf{P}$. Cryptographic assumptions are essential for numerous other hardness results in learning theory (cf., Kearns and Valiant, 1994; Kharitonov, 1995). Our construction is based on the use of pseudorandom function families, list-decodable codes and a variant of an idea from the work of Elbaz, Lee, Servedio, and Wan (2007). Sections 4.1 and 4.2 describe the technique and its relation to prior work in more detail.

This results is, perhaps, unsurprising since agnostic learning of parities with respect to the uniform distribution from random examples only is commonly considered hard and is known to be equivalent to learning of parities with random noise (Feldman et al., 2006), a long standing open problem which itself is equivalent to decoding of random linear codes, a long-standing open problem in coding theory. The best known algorithm for this problem runs in time $O(2^{n/\log n})$ (Blum et al., 2003; Feldman et al., 2006). If one assumes that learning of parities with noise is intractable then it immediately follows that membership queries are provably helpful in agnostic learning over the uniform distribution on $\{0,1\}^n$. The goal of our result is to replace this assumption by a possibly weaker and more general cryptographic assumption. It is known that if learning of parities with noise is hard then one-way functions exist (Blum et al., 1993) but, for all we know, it is possible that the converse is not true. The proof of our result however is substantially less straightforward than one might expect (and than the analogous separation for PAC learning). Here the main obstacle is the same as in proving positive results for agnostic learning: the requirements of the model impose severe limits on concept classes for which the agnostic guarantees can be provably satisfied.

1.2 Organization

Following the preliminaries, our first result is described in Section 3. The second result appears in Section 4.

2. Preliminaries

Let X denote the domain or the *input space* of a learning problem. The domain of the problems that we study is $\{0,1\}^n$, or the n-dimensional *Boolean hypercube*. A *concept* over X is a $\{-1,1\}$ function over the domain and a *concept class* $\mathcal{C}$ is a set of concepts over X. The unknown function $f \in \mathcal{C}$ that a learning algorithm is trying to learn is referred to as the *target concept*.

A parity function is a function equal to the *XOR* of some subset of variables. For a Boolean vector $a \in \{0,1\}^n$ we define the parity function $\chi_a(x) = (-1)^{a\cdot x} = (-1)^{\oplus_{i\le n} a_i x_i}$. We denote the concept class of parity functions $\{\chi_a \mid a \in \{0,1\}^n\}$ by PAR. A *k-junta* is a function that depends only on k variables.

A *representation class* is a concept class defined by providing a specific way to represent each function in the concept class. In fact all the classes of functions that we discuss are representation classes. We often refer to a representation class simply as concept class when the representation is implicit in the description of the class. For a representation class $\mathcal{F}$, we say that an algorithm outputs $f \in \mathcal{F}$ if the algorithm outputs f in the representation associated with $\mathcal{F}$.

2.1 PAC Learning Model

The learning models discussed in this work are based on Valiant's well-known PAC model (Valiant, 1984). In this model, for a concept f and distribution D over X, an *example oracle* $\mathrm{EX}(D,f)$ is the oracle that, upon request, returns an example $\langle x, f(x)\rangle$ where x is chosen randomly with respect to D. For $\varepsilon \ge 0$ we say that a function g ε-approximates a function f with respect to distribution D if $\mathbf{Pr}_D[f(x) = g(x)] \ge 1-\varepsilon$. In the PAC learning model the learner is given access to $\mathrm{EX}(D,f)$ where f is assumed to belong to a fixed concept class $\mathcal{C}$.

Definition 1 *For a representation class $\mathcal{C}$, we say that an algorithm* `Alg` PAC learns $\mathcal{C}$*, if for every $\varepsilon > 0$, $\delta > 0$, $f \in \mathcal{C}$, and distribution D over X,* `Alg`*, given access to $EX(D, f)$, outputs, with probability at least $1 - \delta$, a hypothesis h that ε-approximates f.*

The learning algorithm is *efficient* if its running time and the time to evaluate h are polynomial in $1/\varepsilon, 1/\delta$ and the *size* σ of the learning problem. Here by the size we refer to the maximum description length of an element in X (e.g., n when $X = \{0,1\}^n$) plus the maximum description length of an element in $\mathcal{C}$ in the representation associated with $\mathcal{C}$.

An algorithm is said to *weakly* learn $\mathcal{C}$ if it produces a hypothesis h that $(\frac{1}{2} - \frac{1}{p(\sigma)})$-approximates f for some polynomial $p(\cdot)$.

2.2 Agnostic Learning Model

The *agnostic* learning model was introduced by Haussler (1992) and Kearns et al. (1994) in order to model situations in which the assumption that examples are labeled by some $f \in \mathcal{C}$ does not hold. In its least restricted version the examples are generated from some unknown distribution A over $X \times \{-1,1\}$. The goal of an agnostic learning algorithm for a concept class $\mathcal{C}$ is to produce a hypothesis whose error on examples generated from A is close to the best possible by a concept from $\mathcal{C}$. Class $\mathcal{C}$ is referred to as the *touchstone* class in this setting. More generally, the model allows specification of the assumptions made by a learning algorithm by describing a set $\mathcal{A}$ of distributions over $X \times \{-1,1\}$ that restricts the distributions over $X \times \{-1,1\}$ seen by a learning algorithm. Such $\mathcal{A}$ is referred to as the *assumption class*. Any distribution A over $X \times \{-1,1\}$ can be described uniquely by its marginal distribution D over X and the expectation of b given x. That is, we refer to a distribution A over $X \times \{-1,1\}$ by a pair (D_A, ϕ_A) where $D_A(z) = \mathbf{Pr}_{\langle x,b\rangle \sim A}[x = z]$ and

$$\phi_A(z) = \mathbf{E}_{\langle x,b\rangle \sim A}[b \mid z = x].$$

Formally, for a Boolean function h and a distribution $A = (D, \phi)$ over $X \times \{-1,1\}$, we define

$$\Delta(A,h) = \mathbf{Pr}_{\langle x,b\rangle \sim A}[h(x) \neq b] = \mathbf{E}_D[|\phi(x) - h(x)|/2] \ .$$

Similarly, for a concept class $\mathcal{C}$, define

$$\Delta(A,\mathcal{C}) = \inf_{h \in \mathcal{C}} \{\Delta(A,h)\} \ .$$

Kearns et al. (1994) define agnostic learning as follows.

Definition 2 *An algorithm* `Alg` agnostically *learns a representation class $\mathcal{C}$ by a representation class $\mathcal{H}$ assuming $\mathcal{A}$ if for every $\varepsilon > 0, \delta > 0, A \in \mathcal{A}$,* `Alg` *given access to examples drawn randomly from A, outputs, with probability at least $1 - \delta$, a hypothesis $h \in \mathcal{H}$ such that $\Delta(A,h) \leq \Delta(A,\mathcal{C}) + \varepsilon$.*

The learning algorithm is *efficient* if it runs in time polynomial $1/\varepsilon, \log(1/\delta)$ and σ (the size of the learning problem). If $\mathcal{H} = \mathcal{C}$ then, by analogy with the PAC model, the learning is referred to as *proper*. We drop the reference to $\mathcal{H}$ to indicate that $\mathcal{C}$ is learnable by some representation class.

A number of special cases of the above definition are commonly considered (and often referred to as *the* agnostic learning model). In fully agnostic learning $\mathcal{A}$ is the set of all distributions over $X \times \{-1,1\}$. Another version assumes that examples are labeled by an unrestricted function. That is, the set $\mathcal{A}$ contains distribution $A = (D, f)$ for every Boolean function f and distribution D. Note that access to random examples from $A = (D, f)$ is equivalent to access to $\mathrm{EX}(D, f)$. Following Kearns et al. (1994), we refer to this version as *agnostic PAC learning*. Theorem 6 implies that these versions are essentially equivalent. In *distribution-specific* versions of this model for every $(D, \phi) \in \mathcal{A}$, D equals to some fixed distribution known in advance.

We also note that the agnostic PAC learning model can also be thought of as a model of adversarial classification noise. By definition, a Boolean function g differs from some function $f \in \mathcal{C}$ on $\Delta(g, \mathcal{C})$ fraction of the domain. Therefore g can be thought of as f corrupted by noise of rate $\Delta_D(f, \mathcal{C})$. Unlike in the random classification noise model, the points on which a concept can be corrupted are unrestricted and therefore the noise is referred to as adversarial.

2.2.1 UNIFORM CONVERGENCE

A natural approach to agnostic learning is to first draw a sample of fixed size and then choose a hypothesis that best fits the observed labels. The conditions in which this approach is successful were studied in works of Dudley (1978), Pollard (1984), Haussler (1992), Vapnik (1998) and others. They give a number of conditions on the hypothesis class $\mathcal{H}$ that guarantee *uniform convergence* of empirical error to the true error. That is, existence of a function $m_{\mathcal{H}}(\varepsilon, \delta)$ such that for every distribution A over examples, every $h \in \mathcal{H}$, $\varepsilon > 0$, $\delta > 0$, the empirical error of h on sample of $m_{\mathcal{H}}(\varepsilon, \delta)$ examples randomly chosen from A is, with probability at least $1 - \delta$, within ε of $\Delta(A, h)$. We denote the empirical error of h on sample S by $\Delta(S, h)$. In the Boolean case, the following result of Vapnik and Chervonenkis (1971) will be sufficient for our purposes.

Theorem 3 *Let $\mathcal{H}$ be a concept class over X of VC dimension d. Then for every distribution A over $X \times \{-1, 1\}$, every $h \in \mathcal{H}$, $\varepsilon > 0$, $\delta > 0$, and sample S of size $m = O((d \log(d/\varepsilon) + \log(1/\delta))/\varepsilon^2)$ randomly drawn with respect to A,*

$$\mathbf{Pr}[|\Delta(A, h) - \Delta(S, h)| \geq \varepsilon] \leq \delta.$$

In fact a simple uniform convergence result based on the cardinality of the function class follows easily from Chernoff bounds (Haussler, 1992). That is Theorem 3 holds for $m = O(\log|\mathcal{H}|/\varepsilon^2 \cdot \log(1/\delta))$. This result would also be sufficient for our purposes but might give somewhat weaker bounds.

2.3 Membership Queries

A membership oracle for a function f is the oracle that, given any point $z \in \{0, 1\}^n$, returns the value $f(z)$ (Valiant, 1984). We denote it by $\mathrm{MEM}(f)$. We refer to agnostic PAC learning with access to $\mathrm{MEM}(f)$, where f is the unknown function that labels the examples, as *agnostic PAC+MQ* learning. Similarly, one can extend the definition of a membership oracle to fully agnostic learning. For a distribution A over $X \times \{-1, 1\}$, let $\mathrm{MEM}(A)$ be the oracle that, upon query z, returns $b \in \{-1, 1\}$ with probability $\mathbf{Pr}_A[(x, b) \mid x = z]$. We say that $\mathrm{MEM}(A)$ is *persistent* if given the same query the oracle responds with the same label. When learning with persistent membership queries the learning algorithm is allowed to fail with some negligible probability over the answers of $\mathrm{MEM}(A)$. This is necessary to account for probability that the answers of $\mathrm{MEM}(A)$ might be not "representative" of A (a more formal argument can be found for example in the work of Goldman et al. 2001).

2.4 List-Decodable Codes

As we have mentioned earlier, agnostic learning can be seen as recovery of an unknown concept from possibly malicious errors. Therefore, encoding of information that allows recovery from errors, or error-correcting codes, can be useful in the design of agnostic learning algorithms. In our construction we will use binary list-decodable error-correcting codes. A list-decodable code is a code that allows recovery from errors when the number of errors is larger than the distance of the code, and hence there is more than one valid way to decode the corrupted encoding, each giving a different message (see for example the book of van Lint 1998). List-decoding of the code gives the list of all the messages corresponding to the valid ways to decode the corrupt encoding. Formally, let $C : \{0,1\}^u \to \{0,1\}^v$ be a binary code of message length u and block length v. Our construction requires efficient encoding and efficient list-decoding from $1/2-\gamma$ fraction of errors for a $\gamma > 0$ that we will define later. Specifically,

- Efficient encoding algorithm. For any $z \in \{0,1\}^u$ and $j \le v$, $C(z)_j$ (the j^{th} bit of $C(z)$) is computable in time polynomial in u and $\log v$.
- Efficient list-decoding from $(1/2-\gamma')v$ errors in time polynomial in u and $1/\gamma'$ for any $\gamma' \ge \gamma$. That is, an algorithm that given oracle access to the bits of string $y \in \{0,1\}^v$, produces the list of all messages z such that $\mathbf{Pr}_{j\in[v]}[C(z)_j \ne y_j] \le 1/2-\gamma'$ (in time polynomial in u and $1/\gamma'$).

Our main result is achieved using the Reed-Solomon code concatenated with the Hadamard code for which the list-decoding algorithm was given by Guruswami and Sudan (2000). Their code has the desired properties for $v = O(u^2/\gamma^4)$. In the description of our construction, for simplicity, we use the more familiar but exponentially longer Hadamard code.

2.4.1 HADAMARD CODE

The Hadamard code encodes a vector $a \in \{0,1\}^n$ as the values of the parity function χ_a on all the points in $\{0,1\}^n$ (that is the length of the encoding is 2^n). It is convenient to describe list-decoding of the Hadamard code using Fourier analysis over $\{0,1\}^n$ that is commonly used in the context of learning with respect to the uniform distribution (Linial, Mansour, and Nisan, 1993). We now briefly review a number of simple facts on the Fourier representation of functions over $\{0,1\}^n$ and refer the reader to a survey by Mansour (1994) for more details. In the discussion below all probabilities and expectations are taken with respect to the uniform distribution U unless specifically stated otherwise.

Define an inner product of two real-valued functions over $\{0,1\}^n$ to be $\langle f,g\rangle = \mathbf{E}_x[f(x)g(x)]$. The technique is based on the fact that the set of all parity functions $\{\chi_a(x)\}_{a\in\{0,1\}^n}$ forms an orthonormal basis of the linear space of real-valued functions over $\{0,1\}^n$ with the above inner product. This fact implies that any real-valued function f over $\{0,1\}^n$ can be uniquely represented as a linear combination of parities, that is $f(x) = \sum_{a\in\{0,1\}^n} \hat{f}(a)\chi_a(x)$. The coefficient $\hat{f}(a)$ is called Fourier coefficient of f on a and equals $\mathbf{E}_x[f(x)\chi_a(x)]$; a is called the *index* of $\hat{f}(a)$. We say that a Fourier coefficient $\hat{f}(a)$ is θ-heavy if $|\hat{f}(a)| \ge \theta$. Let $L_2(f) = E_x[(f(x))^2]^{1/2}$. Parseval's identity states that

$$(L_2(f))^2 = \mathbf{E}_x[(f(x))^2] = \sum_a \hat{f}^2(a) .$$

Let $A = (U,\phi)$ be a distribution over $\{0,1\}^n \times \{-1,1\}$ with uniform marginal distribution over $\{0,1\}^n$. Fourier coefficient $\hat{\phi}(a)$ can be easily related to the error of $\chi_a(x)$ on A. That is,

$$\mathbf{Pr}_{\langle x,b\rangle\sim A}[b \ne \chi_a(x)] = (1-\hat{\phi}(a))/2. \tag{1}$$

Therefore, both list-decoding of the Hadamard code and agnostic learning of parities amount to finding the largest (within 2ϵ) Fourier coefficient of $\phi(x)$. The first algorithm for this task was given by Goldreich and Levin (1989). Given access to a membership oracle, for every $\epsilon > 0$ their algorithm can efficiently find all ϵ-heavy Fourier coefficients.

Theorem 4 (Goldreich and Levin, 1989) *There exists an algorithm* GL *that for every distribution* $A = (U, \phi)$ *and every* $\epsilon, \delta > 0$, *given access to MEM*(A), $\mathtt{GL}(\epsilon, \delta)$ *returns, with probability at least* $1 - \delta$, *a set of indices* $T \subseteq \{0,1\}^n$ *that contains all a such that* $|\hat{\phi}(a)| \geq \epsilon$ *and for all* $a \in T$, $|\hat{\phi}(a)| \geq \epsilon/2$. *Furthermore, the algorithm runs in time polynomial in n,*$1/\epsilon$ *and* $\log(1/\delta)$.

Note that by Parseval's identity, the condition $|\hat{\phi}(a)| \geq \epsilon/2$ implies that there are at most $4/\epsilon^2$ elements in T.

2.5 Pseudo-random Function Families

A key part of our construction in Section 4 will be based on the use of pseudorandom functions families defined by Goldreich, Goldwasser, and Micali (1986).

Definition 5 *A function family* $\mathcal{F} = \{F_n\}_{n=1}^{\infty}$ *where* $F_n = \{\pi_z\}_{z \in \{0,1\}^n}$ *is a* pseudorandom function family *of Boolean functions over* $\{0,1\}^n$ *if*

- *There exists a polynomial time algorithm that for every n, given* $z \in \{0,1\}^n$ *and* $x \in \{0,1\}^n$ *computes* $\pi_z(x)$.
- *Any adversary M whose resources are bounded by a polynomial in n can distinguish between a function* π_z *(where* $z \in \{0,1\}^n$ *is chosen randomly and kept secret) and a totally random function from* $\{0,1\}^n$ *to* $\{-1,1\}$ *only with negligible probability. That is, for every probabilistic polynomial time M with an oracle access to a function from* $\{0,1\}^n$ *to* $\{-1,1\}$ *there exists a negligible function* $\nu(n)$,

$$|\mathbf{Pr}[M^{\pi_z}(1^n) = 1] - \mathbf{Pr}[M^{\rho}(1^n) = 1]| \leq \nu(n),$$

where π_z *is a function randomly and uniformly chosen from* F_n *and* ρ *is a randomly chosen function from* $\{0,1\}^n$ *to* $\{-1,1\}$. *The probability is taken over the random choice of* π_z *or* ρ *and the coin flips of M.*

Results of Håstad et al. (1999) and Goldreich et al. (1986) give a construction of pseudorandom function families based on the existence of one-way functions.

3. Distribution-Independent Agnostic Learning

In this section we show that in distribution-independent agnostic learning membership queries do not help. In addition, we prove that fully agnostic learning is equivalent to agnostic PAC learning. Our proof is based on two simple observations about agnostic learning via empirical error minimization. Values of the unknown function on points outside of the sample can be set to any value without changing the best fit by a function from the touchstone class. Therefore membership queries do not make empirical error minimization easier. In addition, points with contradicting labels do not influence the complexity of empirical error minimization since any function has the same error on pairs of contradicting labels. We will now provide the formal statement of this result.

Theorem 6 *Let* `Alg` *be an algorithm that agnostically PAC+MQ learns a concept class $\mathcal{C}$ in time $T(\sigma,\varepsilon,\delta)$ and outputs a hypothesis in a representation class $\mathcal{H}(\sigma,\varepsilon)$. Then $\mathcal{C}$ is (fully) agnostically learnable by $\mathcal{H}(\sigma,\varepsilon/2)$ in time $T(\sigma,\varepsilon/2,\delta/2)+O(d\cdot\log(d/\varepsilon)+\log(1/\delta))/\varepsilon^2)$, where d is the VC dimension of $\mathcal{H}(\sigma,\varepsilon/2)\cup\mathcal{C}$.*

Proof Let $A=(D,\phi)$ be a distribution over $X\times\{-1,1\}$. Our reduction works as follows. Start by drawing m examples from A for m to be defined later. Denote this sample by S. Let S' be S with all contradicting pairs of examples removed, that is for each example $\langle x,1\rangle$ we remove it together with one example $\langle x,-1\rangle$. Every function has the same error rate of $1/2$ on examples in $S\setminus S'$. Therefore for every function h,

$$\Delta(S,h)=\frac{\Delta(S',h)|S'|+|S\setminus S'|/2}{|S|}=\Delta(S',h)\frac{|S'|}{m}+\frac{m-|S'|}{2m} \tag{2}$$

and hence

$$\Delta(S,\mathcal{C})=\Delta(S',\mathcal{C})\frac{|S'|}{m}+\frac{m-|S'|}{2m}. \tag{3}$$

Let $f(x)$ denote the function equal to b if $\langle x,b\rangle\in S'$ and equal to 1 otherwise. Let $U_{S'}$ denote the uniform distribution over S'. Given the sample S' we can easily simulate the example oracle $\mathrm{EX}(U_{S'},f)$ and $\mathrm{MEM}(f)$. We run `Alg`$(\varepsilon/2,\delta/2)$ with theses oracles and denote its output by h. Note, that this simulates $\mathcal{A}$ in the agnostic PAC+MQ setting over distribution $(U_{S'},f)$.

By the definition of $U_{S'}$, for any Boolean function $g(x)$,

$$\mathbf{Pr}_{U_{S'}}[f(x)\neq g(x)]=\frac{1}{|S'|}\left|\{x\in S'\mid f(x)\neq g(x)\}\right|=\Delta(S',g)\ .$$

That is, the error of any function g on $U_{S'}$ is exactly the empirical error of g on sample S'. Thus $\Delta((U_{S'},f),h)=\Delta(S',h)$ and $\Delta((U_{S'},f),\mathcal{C})=\Delta(S',\mathcal{C})$. By the correctness of `Alg`, with probability at least $1-\delta/2$, $\Delta(S',h)\leq\Delta(S',\mathcal{C})+\varepsilon/2$. By Equations (2) and (3) we thus obtain that

$$\Delta(S,h)=\Delta(S',h)\frac{|S'|}{m}+\frac{m-|S'|}{2m}\leq(\Delta(S',\mathcal{C})+\frac{\varepsilon}{2})\frac{|S'|}{m}+\frac{m-|S'|}{2m}=\Delta(S,\mathcal{C})+\frac{\varepsilon}{2}\frac{|S'|}{m}.$$

Therefore $\Delta(S,h)\leq\Delta(S,\mathcal{C})+\varepsilon/2$. We can apply the VC dimension-based uniform convergence results for $\mathcal{H}(\sigma,\varepsilon/2)\cup\mathcal{C}$ (Theorem 3) to conclude that for

$$m(\varepsilon/4,\delta/4)=O\left(\frac{d\log(d/\varepsilon)+\log(1/\delta)}{\varepsilon^2}\right),$$

with probability at least $1-\delta/2$, $\Delta(A,h)\leq\Delta(S,h)+\frac{\varepsilon}{4}$ and $\Delta(S,\mathcal{C})+\frac{\varepsilon}{4}\leq\Delta(A,\mathcal{C})$. Finally, we obtain that with probability at least $1-\delta$,

$$\Delta(A,h)\leq\Delta(S,h)+\frac{\varepsilon}{4}\leq\Delta(S,\mathcal{C})+\frac{3\varepsilon}{4}\leq\Delta(A,\mathcal{C})+\varepsilon.$$

It easy to verify that the running time and hypothesis space of this algorithm are as claimed. ■

Note that if `Alg` is efficient then $d(\sigma,\varepsilon/2)$ is polynomial in σ and $1/\varepsilon$ and, in particular, the obtained algorithm is efficient. In addition, in place of VC-dim one can use the uniform convergence result based on the cardinality of the hypothesis space. The description length of a hypothesis output by `Alg` is polynomial in σ and $1/\varepsilon$ and hence in this case a polynomial number of samples will be required to simulate `Alg`.

Remark 7 *We note that while this proof is given for the strongest version of agnostic learning in which the error of an agnostic algorithm is bounded by $\Delta(A,\mathcal{C})+\varepsilon$, it can be easily extended to weaker forms of agnostic learning, such as algorithms that only guarantee error bounded by $\alpha\cdot\Delta(A,\mathcal{C})+\beta+\varepsilon$ for some $\alpha\geq 1$ and $\beta\geq 0$. This is true since the reduction adds at most $\varepsilon/2$ to the error of the original algorithm.*

4. Learning with Respect to the Uniform Distribution

In this section we show that when learning with respect to the uniform distribution over $\{0,1\}^n$, membership queries are helpful. Specifically, we show that if one-way functions exist, then there exists a concept class $\mathcal{C}$ that is not agnostically PAC learnable (even weakly) with respect to the uniform distribution but is agnostically learnable over the uniform distribution given membership queries. Our agnostic learning algorithm is successful only when $\varepsilon\geq 1/p(n)$ for a polynomial p fixed in advance (the definition of $\mathcal{C}$ depends on p). While this is slightly weaker than required by the definition of the model it still exhibits the gap between agnostic learning with and without membership queries. We remark that a number of known PAC and agnostic learning algorithms are efficient only for restricted values of ε (O'Donnell and Servedio, 2006; Gopalan et al., 2008; Kalai et al., 2008a).

Theorem 8 *For every polynomial $p(\cdot)$, there exists a concept class $\mathcal{C}^p$ over $\{0,1\}^n$ such that,*

1. *there exists no efficient algorithm that weakly PAC learns $\mathcal{C}^p$ with respect to the uniform distribution over $\{0,1\}^n$;*
2. *there exists a randomized algorithm* `AgnLearn` *that for every distribution $A=(U,\phi)$ over $\{0,1\}^n\times\{-1,1\}$ and every $\varepsilon\geq 1/p(n),\delta>0$, given access to MEM$(A)$, with probability at least $1-\delta$, finds h such that $\Delta(A,h)\leq\Delta(A,\mathcal{C}^p_n)+\varepsilon$. The probability is taken over the coin flips of MEM(A) and* `AgnLearn`. `AgnLearn` *runs in time polynomial in n and $\log(1/\delta)$.*

4.1 Background

We first show why some of the known separation results will not work in the agnostic setting. It is well-known that the PAC model with membership queries is strictly stronger than the PAC model without membership queries (under the same cryptographic assumption). The separation result is obtained by using a concept class $\mathcal{C}$ that is not PAC learnable and augmenting each concept $f\in\mathcal{C}$ with the encoding of f in a fixed part of the domain. This encoding is readable using membership queries and therefore an MQ algorithm can "learn" the augmented $\mathcal{C}$ by querying the points that contain the encoding. On the other hand, with overwhelming probability this encoding will not be observed in random examples and therefore does not help learning from random examples. This simple approach would fail in the agnostic setting. The unknown function might be random on the part of the domain that contains the encoding and equal to a concept from $\mathcal{C}$ elsewhere. The agreement of the unknown function with a concept from $\mathcal{C}$ is almost 1 but membership queries on the points of encoding will not yield any useful information.

A similar problem arises with encoding schemes used in the separation results of Elbaz et al. (2007) and Feldman and Shah (2009). There too the secret encoding can be rendered unusable by a function that agrees with a concept in $\mathcal{C}$ on a significant fraction of the domain.

4.2 Outline

We start by presenting some of the intuition behind our construction. As in most other separation results our goal is to create a concept class that is not learnable from uniform examples but includes an encoding of the unknown function that is readable using membership queries. We first note that in order for this approach to work in the agnostic setting the secret encoding has to be "spread" over at least $1-2\varepsilon$ fraction of $\{0,1\}^n$. To see this let f be a concept and let $S \subseteq \{0,1\}^n$ be the subset of the domain where the encoding of f is contained. Assume, for simplicity, that without the encoding the learning algorithm cannot predict f on $\overline{S} = \{0,1\}^n \setminus S$ with any significant advantage over random guessing. Let f' be a function equal to f on $\overline{S}$ and truly random on S. Then

$$\mathbf{Pr}[f = f'] \approx (|\overline{S}| + |S|/2)/2^n = 1/2 + \frac{|\overline{S}|}{2^{n+1}} .$$

On the other hand, f' does not contain any information about the encoding of f and therefore, by our assumption, no efficient algorithm can produce a hypothesis with advantage significantly higher than $1/2$ on both S and $\overline{S}$. This means that the error of any efficient algorithm will be higher by at least $|\overline{S}|/2^{n+1}$ than the best possible. To ensure that $|\overline{S}|/2^{n+1} \leq \varepsilon$, we need $|S| \geq (1-2\varepsilon)2^n$.

Another requirement that the construction has to satisfy is that the encoding of the secret has to be resilient to almost any amount of noise. In particular, since the encoding is a part of the function, we also need to be able to reconstruct an encoding that is close to the best possible. An encoding with this property is in essence a list-decodable binary code. In order to achieve the strongest separation result we will use the code of Guruswami and Sudan (2000) that is the concatenation of Reed-Solomon code with the binary Hadamard code. However, to simplify the presentation, we will use the more familiar binary Hadamard code in our construction. In Section 4.6 we provide the details on the use of the Guruswami-Sudan code in place of the Hadamard code.

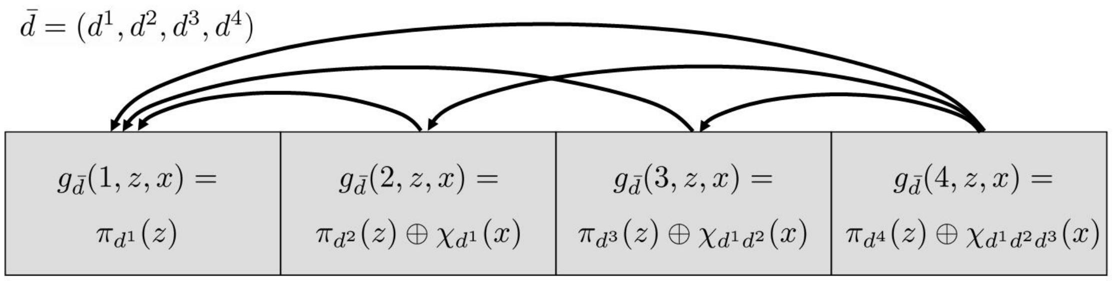
The Hadamard code is equivalent to encoding a vector $a \in \{0,1\}^n$ as the values of the parity function χ_a on all points in $\{0,1\}^n$. That is, n bit vector a is encoded into 2^n bits given by $\chi_a(x)$ for every $x \in \{0,1\}^n$. This might appear quite inefficient since a learning algorithm will not be able to read all the bits of the encoding. However the Goldreich-Levin algorithm provides an efficient way to recover the indices of all the parities that agree with a given function with probability significantly higher than $1/2$ (Goldreich and Levin, 1989). Therefore the Hadamard code can be decoded by reading the code in only a polynomial number of (appropriately-chosen) locations.

The next problem that arises is that the encoding should not be readable from random examples. As we have observed earlier, we cannot simply "hide" it on a negligible fraction of the domain. Specifically, we need to make sure that our Hadamard encoding is not recoverable from random examples. Our solution to this problem is to use a pseudo-random function to make values on random examples indistinguishable from random coin flips in the following manner. Let $a \in \{0,1\}^n$ be the vector we want to encode and let $\pi_d : \{0,1\}^n \to \{-1,1\}$ be a pseudo-random function from some pseudorandom function family $\mathcal{F} = \{\pi_b\}_{b \in \{0,1\}^n}$. We define a function $g : \{0,1\}^n \times \{0,1\}^n \to \{-1,1\}$ as

$$g(z,x) = \pi_d(z) \oplus \chi_a(x)$$

($\oplus$ is simply the product in $\{-1,1\}$). The label of a random point $(z,x) \in \{0,1\}^{2n}$ is a XOR of a pseudorandom bit with an independent bit and therefore is pseudorandom. Values of a pseudorandom function b on any polynomial set of distinct points are pseudorandom and therefore random points will have pseudorandom labels as long as their z parts are distinct. In a sample of polynomial in n size of random and uniform points from $\{0,1\}^{2n}$ this happens with overwhelming probability and therefore $g(z,x)$ is not learnable from random examples. On the other hand, for a fixed z, $\pi_d(z) \oplus \chi_a(x)$ gives a Hadamard encoding of a or its negation. Hence it is possible to find a using membership queries with the same prefix. A construction based on a similar idea was used by Elbaz et al. (2007) in their separation result.

Finally, the problem with the construction we have so far is that while a membership query learning algorithm can find the secret a, it cannot predict $g(z,x)$ without knowing d. This means that we also need to provide d to the learning algorithm. It is tempting to use the Hadamard code to encode d together with a. However, a bit of the encoding of d is no longer independent of π_d, and therefore the previous argument does not hold. We are unaware of any constructions of pseudorandom functions that would remain pseudorandom when the value of the function is "mixed" with the description of the function (see the work of Halevi and Krawczyk (2007) for a discussion of this problem). An identical problem also arises in the construction of Elbaz et al. (2007). They used another pseudorandom function π_{d^1} to "hide" the encoding of d, then used another pseudorandom function π_{d^2} to "hide" the encoding of d^1 and so on. The fraction of the domain used up for the encoding of d^i is becoming progressively smaller as i grows. In their construction a PAC learning algorithm can recover as many of the encodings as is required to reach accuracy ε. This method would not be effective in our case. First, in the agnostic setting all the encodings but the one using the largest fraction of the domain can be "corrupted". This makes the largest encoding unrecoverable and implies that the best ε achievable is at most half of the fraction of the domain used by the largest encoding. In addition, in the agnostic setting the encoding of d^i for every odd i can be completely "corrupted" making all the other encodings unrecoverable. To solve these problems in our construction we split the domain into p equal parts and on part i we use a pseudorandom function π_{d^i} to "hide" the encoding of d^j for all $j < i$. In Figure 1 we provide a schematic view of a concept that we construct (for $p = 4$).



$\bar{d} = (d^1, d^2, d^3, d^4)$
$g_{\bar{d}}(1,z,x) = \pi_{d^1}(z)$
$g_{\bar{d}}(2,z,x) = \pi_{d^2}(z) \oplus \chi_{d^1}(x)$
$g_{\bar{d}}(3,z,x) = \pi_{d^3}(z) \oplus \chi_{d^1 d^2}(x)$
$g_{\bar{d}}(4,z,x) = \pi_{d^4}(z) \oplus \chi_{d^1 d^2 d^3}(x)$

Figure 1: Structure of a concept in $\mathcal{C}_n^p$ for $p = 4$. Arrow from part i to part j indicates that the secret key to part j is encoded using the Hadamard code in part i.

The crucial property of this construction is that the unknown concept can be "recovered" on all but one part of the domain. Specifically, the only part where the unknown concept cannot be "recovered" agnostic is the part i such for all $j > i$ agreement of the target function with every $g_{\bar{d}} \in \mathcal{C}_n^p$ on part j is close to $1/2$ and hence d^j cannot be recovered. Therefore, by making the number of parts p larger than $1/\varepsilon$, we can make sure that there exists an efficient algorithm that finds a hypothesis with the error within ε of the optimum.

4.3 The Construction

We will now describe the construction formally and give a proof of its correctness. Let $p = p(n)$ be a polynomial, let $\ell = \log p(n)$ (we assume for simplicity that $p(n)$ is a power of 2) and let $m = \ell + n \cdot p$. We refer to an element of $\{0,1\}^m$ by triple $(k, z, \bar{x})$ where $k \in [p]$, $z \in \{0,1\}^n$, and

$$\bar{x} = (x^1, x^2, \dots, x^{p-1}) \in \{0,1\}^{n \times (p-1)}.$$

Here k indexes the encodings, z is the input to the k-th pseudorandom function and $\bar{x}$ is the input to a parity function on $n(p-1)$ variables that encodes the secret keys for all pseudorandom functions used for encodings 1 through $k-1$. Formally, let

$$\overline{d} = (d^1, d^2, \dots, d^{p-1})$$

be a vector in $\{0,1\}^{n \times (p-1)}$ (where each $d^i \in \{0,1\}^n$) and for $k \in [p]$ let

$$\overline{d}(k) = (d^1, d^2, \dots, d^{k-1}, 0^n, \dots, 0^n).$$

Let $\mathcal{F} = \{\pi_y\}_{y \in \{0,1\}^*}$ be a pseudorandom function family (Definition 5). We define $g_{\overline{d}} : \{0,1\}^m \to \{-1,1\}$ as follows:

$$g_{\overline{d}}(k, z, \bar{x}) = \pi_{d^k}(z) \oplus \chi_{\overline{d}(k)}(\bar{x}) \ .$$

Finally, we define

$$\mathcal{C}_n^p = \left\{ g_{\overline{d}} \mid \overline{d} \in \{0,1\}^{n \times (p-1)} \right\} \ .$$

4.4 Hardness of Learning $\mathcal{C}_n^p$ From Random Examples

We start by showing that $\mathcal{C}_n^p$ is not agnostically learnable from random and uniform examples only. In fact, we will show that it is not even weakly PAC learnable. Our proof is similar to the proof by Elbaz et al. (2007) who show that the same holds for the concept class they define.

Theorem 9 *There exists no efficient algorithm that weakly PAC learns $\mathcal{C}_n^p$ with respect to the uniform distribution over $\{0,1\}^m$.*

Proof In order to prove the claim we show that a weak PAC learning algorithm for $\mathcal{C}_n^p$ can be used to distinguish a pseudorandom function family from a truly random function. A weak learning algorithm for $\mathcal{C}_n^p$ implies that every function in $\mathcal{C}_n^p$ can be distinguished from a truly random function on $\{0,1\}^m$. If, on the other hand, in the computation of $g_{\overline{d}}(k, z, \bar{x})$ we used a truly random function in place of each $\pi_{d^k}(z)$ then the resulting labels would be truly random and, in particular, unpredictable.

Formally, let `Alg` be a weak learning algorithm for $\mathcal{C}_n^p$ that, with probability at least $1-\delta$, produces a hypothesis with error of at most $1/2 - 1/q(m)$ and runs in time $t(m, 1/\delta)$ for some polynomials $t(\cdot,\cdot)$ and $q(\cdot)$. Our concept class $\mathcal{C}_n^p$ uses numerous pseudorandom functions from F_n and therefore we use a so-called "hybrid" argument to show that one can replace a single $\pi_{d^k}(z)$ with a truly random function to cause `Alg` to fail.

For $0 \le i \le p$, let $\mathbb{O}(i)$ denote an oracle randomly chosen according to the following procedure. First choose randomly and uniformly $\pi_{d^1}, \pi_{d^2}, \dots, \pi_{d^i} \in F_n$ and then choose randomly and uniformly $\rho_{i+1}, \rho_{i+2}, \dots, \rho_p$ from the set of all Boolean functions over $\{0,1\}^n$. Upon request such an oracle returns an example $\langle (k, z, \bar{x}), b \rangle$ where $(k, z, \bar{x})$ is chosen randomly and uniformly from $\{0,1\}^m$ and

$$b = \begin{cases} \pi_{d^k}(z) \oplus \chi_{\overline{d}(k)}(\bar{x}) & 0 \le k \le i, \\ \rho_k(z) & i < k \le p. \end{cases}$$

We note that in order to simulate such an oracle it is not needed to explicitly choose $\rho_{i+1}, \rho_{i+2}, \ldots, \rho_p$ (and, indeed that would not be possible in polynomial time). Instead their values can be generated upon request by flipping a fair coin. This means that for every i, $\mathbb{O}(i)$ can be chosen and then simulated in time polynomial in m and the number of examples requested. Let $M(i)$ denote the algorithm that performs the following steps.

- Choose $\mathbb{O}(i)$ randomly according to the above procedure.
- Simulate `Alg` with random examples from $\mathbb{O}(i)$ and $\delta = 1/2$. Let h be the output of `Alg`.
- Produce an estimate $\tilde{e_h}$ of the error of h on distribution defined by $\mathbb{O}(i)$ that, with probability at least $7/8$, is within $1/(3q(m))$ of the true error. Chernoff bounds imply that this can be done using an empirical estimate on $O(q^2(m))$ random samples.
- Output 1 if $\tilde{e_h} \leq 1/2 - 2/(3q(m))$ and 0 otherwise.

We denote by δ_i the probability that $M(i)$ outputs 1. The probability is taken over all the random choices made by $M(i)$: the random choice and simulation of $\mathbb{O}(i)$, the coin flips of `Alg` and the estimation of the error of h.

Claim 10 $\delta_p - \delta_0 \geq 1/4$.

Proof To see this we first observe that $\mathbb{O}(0)$ is defined using p truly random functions and therefore, the probability that there exists a hypothesis of size at most $t(m,2)$ that has error less than $1/2 - 1/3q(m)$ is some negligible function $\nu(n)$. In particular, the error of the hypothesis produced by `Alg` is at least $1/2 - 1/3q(m)$ (with probability at least $1 - \nu(n)$). This means that $\tilde{e_h} \leq 1/2 - 2/(3q(m))$ only if the estimation fails. By the definition of our error estimation procedure, this happens with probability at most $1/8$ and therefore $\delta_0 \leq 1/8 + \nu(n)$. On the other hand, $\mathbb{O}(p)$ is equivalent to $\mathrm{EX}(U, g_{\bar{d}})$ for some randomly chosen $\bar{d}$. This implies that with probability at least $1/2$, `Alg` outputs a hypothesis with error of at most $1/2 - 1/q(m)$. With probability at least $7/8$, $\tilde{e_h} \leq 1/2 - 2/(3q(m))$, and hence $\delta_p \geq 7/16$. This implies our claim. ■

We now describe our distinguisher M^π, where π denotes the function given to M as an oracle. Let $\mathbb{O}^\pi(i)$ denote the example oracle generated by using π in place of π_{d^i} in the definition of $\mathbb{O}(i)$. That is, first choose randomly and uniformly $\pi_{d^1}, \pi_{d^2}, \ldots, \pi_{d^{i-1}} \in F_n$ and then choose randomly and uniformly $\rho_{i+1}, \rho_{i+2}, \ldots, \rho_p$ from the set of all Boolean functions over $\{0,1\}^n$. Upon request $\mathbb{O}^\pi(i)$ returns an example $\langle (k,z,\bar{x}), b\rangle$ where $(k,z,\bar{x})$ is chosen randomly and uniformly from $\{0,1\}^m$ and

$$b = \begin{cases} \pi_{d^k}(z) \oplus \chi_{\bar{d}(k)}(\bar{x}) & k < i, \\ \pi(z) \oplus \chi_{\bar{d}(k)}(\bar{x}) & k = i, \\ \rho_k(z) & k > i. \end{cases}$$

Similarly, we denote by $M^\pi(i)$ the algorithm that is the same as $M(i)$ but chooses a random $\mathbb{O}^\pi(i)$ in place of $\mathbb{O}(i)$. The distinguishing test M^π chooses a random $i \in [p]$ and runs $M^\pi(i)$.

We first observe that if π is chosen randomly from F_n then choosing and simulating a random $\mathbb{O}^\pi(i)$ is equivalent to choosing and simulating a random $\mathbb{O}(i)$. Therefore for every $i \in [p]$, $M^\pi(i)$ is equivalent to $M(i)$. This implies that in this case M^π will output 1 with probability

$$\frac{1}{p}\sum_{i \in [p]} \delta_i .$$

On the other hand, if π is chosen randomly from the set of all Boolean function over $\{0,1\}^n$ then $\mathbb{O}^{\pi}(i)$ is equivalent to $\mathbb{O}(i-1)$. Therefore in this case M^{π} will output 1 with probability

$$\frac{1}{p}\sum_{i\in[p]}\delta_{i-1}.$$

Therefore, by Claim 10 this implies that the difference in the probability that M outputs 1 in these two cases is

$$\frac{1}{p}\sum_{i\in[p]}\delta_i - \frac{1}{p}\sum_{i\in[p]}\delta_{i-1} = \frac{1}{p}(\delta_p - \delta_0) \geq 1/(4p),$$

that is, non-negligible.

The efficiency of M follows readily from the efficiency of `Alg` and the efficiency of the steps we described. This gives us the contradiction to the pseudorandomness property of function family $\mathcal{F}$. ∎

4.5 Agnostic Learning of $\mathcal{C}_n^p$ with Membership Queries

We now describe a (fully) agnostic learning algorithm for $\mathcal{C}_n^p$ that uses membership queries and is successful for any $\varepsilon \geq 1/p(n)$.

Theorem 11 *There exists a randomized algorithm* `AgnLearn` *that for every distribution $A = (U,\phi)$ over $\{0,1\}^m \times \{-1,1\}$ and every $\varepsilon \geq 1/p(n), \delta > 0$, given access to MEM$(A)$, with probability at least $1-\delta$, finds h such that $\Delta(A,h) \leq \Delta(A,\mathcal{C}_n^p)+\varepsilon$. The probability is taken over the coin flips of MEM(A) and* `AgnLearn`. `AgnLearn` *runs in time polynomial in m and $\log(1/\delta)$.*

Proof Let $g_{\overline{e}}$ for $\overline{e} = (e^1,e^2,\ldots,e^{p-1}) \in \{0,1\}^{(p-1)\times n}$ be the function for which $\Delta(A,g_{\overline{e}}) = \Delta(A,\mathcal{C}_n^p)$. The goal of our algorithm is to find the largest j such that on random examples from the j-th part of the domain (i.e., for $k=j$) A agrees with the encoding of $\overline{e}(j) = (e^1,e^2,\ldots,e^{j-1},0^n,\ldots,0^n)$ with probability at least $1/2+\varepsilon/4$. Using Goldreich-Levin algorithm such j can be used to recover $\overline{e}(j)$ and therefore will allow us to reconstruct $g_{\overline{e}}$ on all points $(k,z,\overline{x})$ for $k<j$. For points with $k \geq j$, our hypothesis will be either constant 1 or constant -1, whichever has the higher agreement with A. This guarantees that the error on this part is at most $1/2$. By the definition of j, $g_{\overline{e}}$ has error of at least $1/2-\varepsilon/4-1/(2p) \geq 1/2-\varepsilon$ on this part of the domain and therefore our hypothesis has error close to that of $g_{\overline{e}}$.

We now describe `AgnLearn` formally. For every $i\in[p]$ and $y\in\{0,1\}^n$, let $A_{i,y}$ be A restricted to points in $\{0,1\}^m$ with prefix i,y. That is $A = (U_{(p-1)\times n}, \phi_{i,y})$ where $\phi_{i,y}(\overline{x}) \equiv \phi(i,y,\overline{x})$ and $U_{(p-1)\times n}$ is the uniform distribution over $\{0,1\}^{(p-1)\times n}$. Note that MEM$(A_{i,y})$ can be simulated using MEM(A): when queried on a point $\overline{x} \in \{0,1\}^{(p-1)\times n}$ MEM$(A_{i,y})$ returns the answer of MEM(A) on point $(i,y,\overline{x})$. Further, for each vector $\overline{d} \in \{0,1\}^{(p-1)\times n}$ and $b\in\{-1,1\}$, let $h_{\overline{d},i,b}$ be defined as

$$h_{\overline{d},i,b}(k,z,\overline{x}) = \begin{cases} \pi_{d^k}(z) \oplus \chi_{\overline{d}(k)}(\overline{x}) & k<i, \\ b & k \geq i. \end{cases} \tag{4}$$

(Here π_{d^k} is an element of the pseudorandom function family F_n used in the construction.)

`AgnLearn` performs the following steps.

1. Initializes $H = \{h_1, h_{-1}\}$, where $h_1 \equiv 1$ and $h_{-1} \equiv -1$.
2. For each $2 \leq i \leq p$:
   (a) Chooses r independent random and uniform points in $\{0,1\}^n$, for r to be defined later. Denote the obtained set of points by Y_i.
   (b) For each $y \in Y_i$:
      i. Runs `GL`$(\varepsilon/4, 1/2)$ over $\{0,1\}^{(p-1)\times n}$ using MEM$(A_{i,y})$. Let T denote the set of indices of heavy Fourier coefficients returned by `GL`.
      ii. For each vector $\overline{d} \in T$ and $b \in \{-1,1\}$ adds $h_{\overline{d},i,b}$ to the set of hypotheses H.
3. For each $h \in H$, estimates $\Delta(A,h)$ to within accuracy $\varepsilon/8$ and with overall confidence $1-\delta/2$ using the empirical error on random samples from A. Chernoff bounds imply that this can be done using samples of size $O(\log(|H|/\delta)/\varepsilon^2)$. Denote the estimate obtained for a hypothesis $h_{\overline{d},i,b} \in H$ by $\tilde{\Delta}_{\overline{d},i,b}$.
4. Returns $h \in H$ with the lowest empirical error.

Claim 12 *For $r = O(\log(1/\delta)/\varepsilon)$, with probability at least $1-\delta$,* `AgnLearn` *returns h such that $\Delta(A,h) \leq \Delta(A, \mathcal{C}_n^p) + \varepsilon$.*

Proof We show that in the set H of hypotheses considered by `AgnLearn` there will be a hypothesis h' such that $\Delta(A,h') \leq \Delta(A, g_{\overline{e}}) + 3\varepsilon/4$ (with sufficiently high probability). The estimates of the error of each hypothesis are within $\varepsilon/8$ of the true error and therefore the hypothesis h with the smallest empirical error will satisfy

$$\Delta(A,h) \leq \Delta(A,h') + \varepsilon/4 \leq \Delta(A, g_{\overline{e}}) + \varepsilon \ .$$

For $i \in [p]$, denote

$$\Delta_i = \mathbf{Pr}_A[b \neq g_{\overline{e}}(k,z,\overline{x}) \mid k = i]$$

(here and below by probability with respect to A we mean that a labeled example $\langle (k,z,\overline{x}), b\rangle$ is chosen randomly according to A). By the definition,

$$\frac{1}{p}\sum_{i\in[p]} \Delta_i = \Delta(A, g_{\overline{e}}). \tag{5}$$

Let j be the largest $i \in [p]$ that satisfies $\Delta_i \leq 1/2 - \varepsilon/4$. If j is undefined (when no i satisfies the condition) then by Equation (5), $\Delta(A, g_{\overline{e}}) > 1/2 - \varepsilon/4$. Either h_1 or h_{-1} has error of at most $1/2$ on A and therefore there exists $h' \in H$ such that $\Delta(A,h') \leq \Delta(A, g_{\overline{e}}) + 3\varepsilon/4$.

We can now assume that j is well-defined. For $i \in [p]$ and $y \in \{0,1\}^n$ denote

$$\Delta_{i,y} = \mathbf{Pr}_A[b \neq g_{\overline{e}}(k,z,\overline{x}) \mid k = i,\ z = y] = \mathbf{Pr}_{\langle \overline{x},b\rangle \sim A_{i,y}}[b \neq g_{\overline{e}}(i,y,\overline{x})].$$

The function $g_{\overline{e}}(j,y,\overline{x})$ equals $\pi_{d^j}(y) \cdot \chi_{\overline{e}(j)}(\overline{x})$. If $\pi_{d^j}(y) = 1$ then by Equation (1) and the definition of $A_{j,y}$,

$$\Delta_{j,y} = \frac{1 - \widehat{\phi_{j,y}}(\overline{e}(j))}{2} \ ,$$

and therefore $\widehat{\phi_{j,y}}(\bar{e}(j)) = 1 - 2\Delta_{j,y}$. If $\pi_{d^j}(y) = -1$ then

$$\Delta_{j,y} = 1 - \frac{1 - \widehat{\phi_{j,y}}(\bar{e}(j))}{2} = \frac{1 + \widehat{\phi_{j,y}}(\bar{e}(j))}{2}$$

and thus $\widehat{\phi_{j,y}}(\bar{e}(j)) = -(1 - 2\Delta_{j,y})$. In either case

$$|\widehat{\phi_{j,y}}(\bar{e}(j))| \geq 1 - 2\Delta_{j,y}. \tag{6}$$

By the definition,

$$\mathbf{E}_{y\in\{0,1\}^n}[\Delta_{i,y}] = \Delta_i.$$

This implies that for a randomly and uniformly chosen y, with probability at least $\varepsilon/4$, $\Delta_{j,y} \leq 1/2 - \varepsilon/8$. This is true since otherwise

$$\Delta_j \geq (1 - \frac{\varepsilon}{4})(\frac{1}{2} - \frac{\varepsilon}{8}) > \frac{1}{2} - \frac{\varepsilon}{4},$$

contradicting the choice of j.

Together with Equation (6) we obtain that for a randomly chosen y, with probability at least $\varepsilon/4$, $|\widehat{\phi_{j,y}}(\bar{e}(j))| \geq \varepsilon/4$. In this case, by Theorem 4, $\texttt{GL}(\varepsilon/4, 1/2)$ with access to $\mathrm{MEM}(A_{j,y})$ will return $\bar{e}(j)$ with probability at least $1/2$ (possibly, among other vectors). This means that $\bar{e}(j)$ will be found with probability at least $\varepsilon/8$. By taking $r = 8\ln(2/\delta)/\varepsilon$ we ensure that `AgnLearn` finds $\bar{e}(j)$ with probability at least $1 - \delta/2$.

Now let b_j be the constant with the lowest error on examples from A for which $k \geq j$, that is

$$b_j = \texttt{sign}(\mathbf{E}_A[b \mid k \geq j]).$$

Clearly, the error of b_j on A when $k \geq j$ is at most $1/2$. By the definition of $h_{\bar{e}(j),j,b_j}$ (Equation 4), $h_{\bar{e}(j),j,b_j}$ equals $g_{\bar{e}}$ on points for which $k < j$ and equals b_j on the rest of the domain. Therefore

$$\begin{aligned}\Delta(A, h_{\bar{e}(j),j,b_j}) &= \frac{j-1}{p}\mathbf{Pr}_A[b \neq g_{\bar{e}}(k,z,\bar{x}) \mid k < j] + \frac{p-j+1}{p}\mathbf{Pr}_A[b \neq b_j \mid k \geq j] \\ &\leq \frac{1}{p}\left(\sum_{i<j}\Delta_i + \frac{p-j+1}{2}\right).\end{aligned}$$

On the other hand, by the properties of j, for all $i > j$, $\Delta_i \geq 1/2 - \varepsilon/4$ and thus

$$\Delta(A, g_{\bar{e}}) = \frac{1}{p}\left(\sum_{i\in[p]}\Delta_i\right) \geq \frac{1}{p}\left(\sum_{i<j}\Delta_i + (p-j)\left(\frac{1}{2} - \frac{\varepsilon}{4}\right)\right).$$

By combining these equations we obtain that

$$\Delta(A, h_{\bar{e}(j),j,b_j}) - \Delta(A, g_{\bar{e}}) \leq \frac{1}{2p} + \frac{\varepsilon}{4} \leq \frac{3\varepsilon}{4}.$$

As noted before, this implies the claim. ∎

Given Claim 12, we only need to check that the running time of `AgnLearn` is polynomial in m and $\log(1/\delta)$. By Parseval's identity there are $O(1/\varepsilon^2)$ elements in each set of vectors returned by `GL` and $r = 8\ln(2/\delta)/\varepsilon$. Therefore the efficiency of `GL` implies that H is found in polynomial time and the size of H is $O(p \cdot \log(1/\delta)/\varepsilon^3)$. This implies that the error estimation step of `AgnLearn` takes polynomial time. ■

Remark 13 *In Theorem 11 we assumed that MEM(A) is not persistent. If MEM(A) is persistent then executions of* `GL` *for different y's are not completely independent and* `GL` *might fail with some negligible probability. A simple and standard modification of the analysis (as in the work of Bshouty et al. (2004) for example) can be used to show that the probability of failure of* `AgnLearn` *in this case is negligible. This implies that* `AgnLearn` *agnostically learns C_n^p from persistent membership queries.*

4.6 Bounds on ε

In Theorem 11 C_n^p is defined over $\{0,1\}^m$ for $m = n \cdot p(n) + \log p(n)$ and is learnable agnostically for any $\varepsilon \geq 1/p(n)$. This means that this construction cannot achieve dependence on ε beyond $1/m$. To improve this dependence we use a more efficient list-decodable code in place of the Hadamard code. Specifically, we need a list-decodable code $C : \{0,1\}^u \rightarrow \{0,1\}^v$ that can be list-decoded from $(1/2 - \gamma')v$ errors in time polynomial in u and $1/\gamma'$ for any $\gamma' \geq \varepsilon/8$. Guruswami and Sudan (2000) gave a list-decoding algorithm for the Reed-Solomon code concatenated with the Hadamard code that has the desired properties for $v = O(u^2/\varepsilon^4)$. Note that this is exponentially more efficient than the Hadamard code for which $v = 2^u$. In fact for this code we can afford to read the whole corrupt message in polynomial time. This means that we can assume that the output of the list-decoding algorithm is exact (and not approximate as in the case of list-decoding using the Hadamard code using the Goldreich-Levin algorithm).

In our construction $u = n(p(n) - 1)$. To apply the above code we index a position in the code using $\log v = O(\log(n/\varepsilon))$ bits. Further we can use pseudorandom functions over $\{0,1\}^{n/2}$ instead of $\{0,1\}^n$ in the definition of C_n^p. We would then obtain that the dimension of C_n^p is $m = n/2 + \log v + \log p(n) \leq n$ for any polynomial $p(n)$ and $\varepsilon \geq 1/p(n)$. This implies that our learning algorithm is successful for every $\varepsilon \geq 1/p(n) \geq 1/p(m)$. It is easy to verify that Theorems 9 and 11 still hold for this variant of the construction and imply Theorem 8.

5. Discussion

Our results clarify the role of membership queries in agnostic learning. They imply that in order to extract any meaningful information from membership queries the learner needs to have significant prior knowledge about the distribution of examples. Specifically, either the set of possible classification functions has to be restricted (as in the PAC model) or the set of possible marginal distributions (as in distribution-specific agnostic learning).

A interesting result in this direction would be a demonstration that membership queries are useful for distribution-specific agnostic learning of a natural concept class such as halfspaces.

Finally, we would be interested to see a proof that membership queries are useful in distribution-specific agnostic learning that places no restriction on ε.

Abstract

Most classification methods assume that the samples are drawn independently and identically from an unknown data generating distribution, yet this assumption is violated in several real life problems. In order to relax this assumption, we consider the case where batches or groups of samples may have internal correlations, whereas the samples from different batches may be considered to be uncorrelated. This paper introduces three algorithms for classifying all the samples in a batch jointly: one based on a probabilistic formulation, and two based on mathematical programming analysis. Experiments on three real-life *computer aided diagnosis* (CAD) problems demonstrate that the proposed algorithms are significantly more accurate than a naive support vector machine which ignores the correlations among the samples.

Keywords: batch-wise classification, support vector machine, linear programming, machine learning, statistical methods, unconstrained optimization

1. Introduction

Most classification systems assume that the data used to train and test the classifier are drawn from an independent and identically distributed underlying distribution. For example, samples are classified one at a time in a *support vector machine* (SVM), thus the classification of a particular test sample does not depend on the features from any other test sample. Nevertheless, this assumption

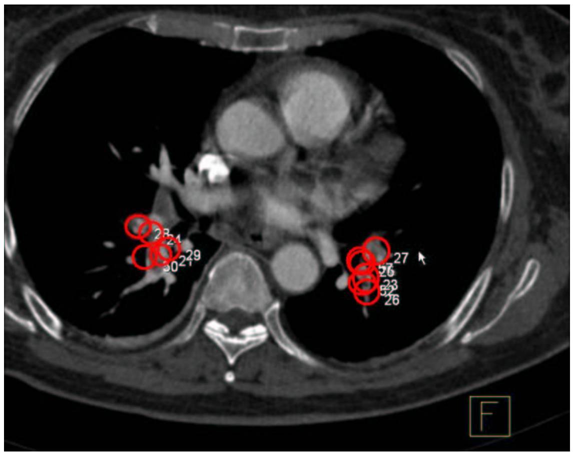

Figure 1: Two pulmonary emboli (blood clots) as they are detected by the Candidate Generation algorithm in a CT image. The candidates are shown as five circles for the left embolus & six circles for the right embolus. The disease status of spatially overlapping or proximate candidates is highly correlated.

is commonly violated in many real-life problems where sub-groups of samples have a high degree of correlation amongst both their features and their labels.

A sample problem with the characteristics described above is *computer aided diagnosis* (CAD), where the goal is to detect structures of interest to physicians in medical images: for example, to identify potentially malignant tumors in computed tomography (CT) scans, X-ray images, etc. In an almost universal paradigm for CAD algorithms, this problem is addressed by a three-stage system: (1) identification of potentially unhealthy candidates *regions of interest* (ROI) from a medical image, (2) computation of descriptive features for each candidate, and (3) classification of each candidate (e.g., normal or diseased) based on its features.

Figure 1 displays a CT image of a lung showing circular marks that point to potential diseased candidate regions that are detected by a CAD algorithm. There are five candidates on the left and six candidates on the right (marked by circles) in Figure 1. Descriptive features are extracted for each candidate and each candidate region is classified as normal or abnormal. In this setting, correlations exist among the candidates belonging to the same batch (image, in the case of CAD) both in the training data set and in the unseen testing data. Further, the level of correlation is a function of the pairwise distance between candidates: the disease status (class-label) of a candidate is highly correlated with the status of other spatially proximate candidates, but the correlations decrease as the distance is increased. Most conventional CAD algorithms classify one candidate at a time, ignoring the correlations amongst the candidates in an image. By explicitly accounting for the correlation structure between the labels of the test samples, classification accuracy can be improved.

In this paper, we present two large margin classifiers and a batch-wise version of logistic regression that take into account the local correlations among samples in a batch. We use the term *batch-wise classification* to mean training and testing classifiers in *batches* or groups (i.e., samples in the same batch are learned and classified collectively). Our experiments on three real CAD problems show that indeed incorporating the local dependencies among samples within a batch improve the classification accuracy significantly compared to standard SVMs.

Beyond the domain of CAD applications, our algorithms are quite general and may be used for batch-wise classification problems in many other contexts. In general, the proposed classifiers can be used whenever data samples are presented in independent batches. In the CAD example, a batch corresponds to an image and strong correlations among candidate samples are based on spatial proximity within an image. A similar relationship structure is true with geographical classification of regions in satellite images; an image would be a batch and spatial proximity corresponds to correlations among the pixel instances. In other contexts, a batch may correspond to data from the same hospital, the patients treated by the same doctor or nurse, etc. In non-medical contexts, a batch can be transactions from the same person, or documents from the same author. Another example is in credit card transaction approval where a single transaction has to be classified by taking into account both the entire set of available training transactions and other transactions made by the same person recently during the testing phase. In this credit card example, it might be preferable to test the recent transaction of this same person as a batch collectively rather than singly.

1.1 Related Work

We are not aware of previous work that exploit internal correlations among the samples to improve the performance of standard classifiers (such as, SVM). However, there exist classification algorithms that incorporate special relationships among the samples (the Markov property) into their model formulation. In natural language processing (NLP), *conditional random fields* (CRF) (Lafferty et al., 2001) and recently *maximum margin Markov* (MMM) networks (Taskar et al., 2004) are used to identify part-of-speech information about words by using the context of nearby words. CRF are also used in similar applications in spoken word recognition. For images, Markov random fields (MRF) (Besag, 1974; Geman and Geman, 1984) are applied to capture correlation among neighborhood pixels.

However, while these Markov models are also fairly general algorithms, they are both computationally demanding and are not easy to implement for problems where the relationship structure among the samples is in any form other than a linear chain (as in the text and speech processing applications). Certainly, their application would be difficult in many large-scale medical applications where run time requirements would be quite severe. For example, in the CAD applications shown in our experiments, the run-time of the testing phase usually has to be less than a second in order that the end user's (radiologist's) time would not be wasted.

Our algorithm is also related to the *multiple instance learning* (MIL) problem, where one is given bags (batches) of samples; class labels are provided only for the bags, not for the individual samples. A bag is labeled positive if we know that at least one sample from it is positive, and a negative bag is known to not contain any positive sample. In this manner, the MIL problem also encodes a form of prior knowledge about correlations between the labels of the training instances.

There are two differences between our algorithm and MIL. First, we want to classify each instance (candidate) in our algorithm; unlike MIL, we are not only trying to label a bag of related instances. Second, unlike the MIL problem which treats all the instances in a bag as equally related to each other, we account for more fine grained differences in the level of correlation between samples (via the similarity matrix $\mathbf{R}$).

Local learning algorithms such as, Wu and Schlkopf (2007) and Bottou and Vapnik (1992), also capture the correlation among data points. However, one major difference between our method and local learning based methods is that our methods build a global classifier that combines the global information extracted from the entire training data with the additional side-information extracted from correlations in the same batch, whereas the local learning algorithms rely on the local information only. Another major difference is that local learning algorithms classify a particular point based on its neighbors in the feature space, therefore the captured correlation is limited to the neighbors of that particular point. On the other hand, the methods that we propose in this paper can incorporate *any* type of correlation information that is not fully encoded in the features. The same difference is also valid between our method and semi-supervised algorithms such as, Vural et al. (2008) and Zhou et al. (2003) that exploit the idea of using local information in semi-supervised learning. The graph based semi-supervised algorithms such as, Krishnapuram et al. (2005) and Zhu et al. (2003), can be considered to be related to the methods introduced in this paper in the sense that they build weighted graphs based on the correlation among data points. However, the targeted problems in semi-supervised learning and this paper are substantially different. In semi-supervised learning problems, the goal is to make use of unlabeled data to improve classification accuracy. In our methods, on the other hand, we investigate the relations among the data points that are in the same batch only. These data points may not constitute a neighborhood in the feature space and every data point is labeled in our problem.

1.2 Organization of the Paper

After briefly describing the notation in Section 2, we build two SVM based methods for classifying batches of correlated samples in Section 3. We also provide a probabilistic interpretation of our approach in Section 4.

Unlike the previous methods such as CRF, MMM and MRF, the proposed algorithms are easy to implement for arbitrary relationships between samples, and further we are able to run these fast enough to be viable in commercial CAD products. In Section 5, we provide experimental evidence from three different CAD problems to show that the proposed algorithms are more accurate in terms of the metrics appropriate to CAD as compared to a naive SVM which is routinely used for these problems as the state-of-the-art in the current literature and commercial products. We conclude with a review of our contributions in Section 6.

2. Notations

Throughout this paper, we will use the following notations. The capital letters shown in bold font represent matrices whereas lower case letters in bold correspond to vectors. The notation $\mathbf{A} \in \mathbb{R}^{m \times n}$ will signify a real $m \times n$ matrix. For such a matrix, $\mathbf{A}'$ will denote the transpose of $\mathbf{A}$ and $\mathbf{A}_i$ will denote the i-th row of $\mathbf{A}$. All vectors will be column vectors.

For $\mathbf{x} \in \mathbb{R}^n$, $\|\mathbf{x}\|_p$ denotes the p-norm, $p = 1, 2, \infty$. A vector of ones in a real space of arbitrary dimension will be denoted by $\mathbf{e}$. Thus, for $\mathbf{e} \in \mathbb{R}^m$ and $\mathbf{y} \in \mathbb{R}^m$, $\mathbf{e}'\mathbf{y}$ is the sum of the components of $\mathbf{y}$. A vector of zeros in a real space of arbitrary dimension will be denoted by 0. The identity matrix of arbitrary dimension will be denoted by $\mathbf{I}$. A *separating hyperplane*, with respect to two given point sets $\mathbf{A}$ and $\mathbf{B}$, is a plane that attempts to separate $\mathbb{R}^n$ into two half spaces such that each open half space contains points mostly of $\mathbf{A}$ or $\mathbf{B}$.

3. A Mathematical Programming Approach

In this section, we formulate the problem of learning for batch-wise prediction as an SVM-like mathematical program.

3.1 Standard Support Vector Machine

In a standard SVM hyperplane classifier, $f(\mathbf{x}) = \mathbf{x}'\mathbf{w} - \gamma$ is learned from the training instances individually, ignoring the correlations among them. Consider the problem of classifying m points in the n-dimensional real space $\mathbb{R}^n$, represented by the $m \times n$ matrix $\mathbf{A}$, according to class membership of each point $\mathbf{x}_i$ (i^{th} row of $\mathbf{A}$) in the classes $\mathbf{A}+$, $\mathbf{A}-$ as specified by a given $m \times m$ diagonal matrix $\mathbf{D}$ with $+1$ or -1 along its diagonal. The standard 1-norm support vector machine with a linear kernel (Vapnik, 1995; Bradley and Mangasarian, 1998) is given by the following linear program with parameter $\nu > 0$:

$$\begin{aligned} \min_{(\mathbf{w},\gamma,\xi,\mathbf{v})\in\mathbb{R}^{n+1+m+n}} \quad & \nu\mathbf{e}'\xi + \mathbf{e}'\mathbf{v} \\ \text{s.t.} \quad \mathbf{D}(\mathbf{A}\mathbf{w} - \mathbf{e}\gamma) + \xi &\geq \mathbf{e} \\ \mathbf{v} \geq \mathbf{w} &\geq -\mathbf{v} \\ \xi &\geq 0 \end{aligned} \tag{1}$$

where, $\xi \in \mathbb{R}^m$ is a vector of slack variables, ν is the cost parameter, and at a solution, $\mathbf{v} = |\mathbf{w}|$ is the absolute value of $\mathbf{w}$. We used the 1-norm linear programming formulation instead of the more popular 2-norm quadratic programming (QP) formulation since the 1-norm formulation is known to produce solutions that depend on fewer features. In other words, by solving the 1-norm formulation, an implicit feature selection is obtained automatically. This is an advantage in CAD applications because the initial pool typically contains a large set of experimental features, although often only a small subset of these features is typically found to be very useful for the classification task at the end of design (i.e., training) stage. It is important to note that all the batch-based classification approaches presented in this paper are equally applicable even when the standard QP SVM formulation is considered.

3.2 Batch Support Vector Machine

The idea in our model is to encode that the classification of any sample (i.e., data point) depends on two factors: (a) the features that encode information about each candidate sample in a batch; and (b) additional side-information—not already fully encoded in the features—that is available to describe the level of correlations among the set of samples within a batch.[1]

Let the covariance matrix $\mathbf{R}^j$ represent the correlations among the samples withing the j^{th} batch. As mentioned above, in CAD applications, $\mathbf{R}^j$ can be defined in terms of $\mathbf{S^j}$, the matrix of Euclidean distances between candidates inside a medical image (from a patient) as:

1. We define a batch to be a set of possibly correlated samples that occur together naturally, for example, the set of all candidate locations from the image of the same patient.

$$\mathbf{R}^j_{pq} = \begin{cases} 0 & ,p=q \\ \exp(-\alpha \mathbf{S}^j_{pq}) & ,o.w. \end{cases}$$

with $\alpha > 0$ as a model parameter. Accordingly, $\mathbf{B}^j \in \mathbb{R}^{m_j \times n}$ represents the m_j training points that belong to the j^{th} batch and the labels of these training points are represented by the $m_j \times m_j$ diagonal matrix $\mathbf{D}^j$ with positive or negative ones along its diagonal. Using the new notations, the standard SVM set of constraints: $\mathbf{D}(\mathbf{Aw} - \mathbf{e}\gamma) + \xi \geq \mathbf{e}$ can be presented as:

$$\mathbf{D}^j(\mathbf{B}^j\mathbf{w} - \mathbf{e}\gamma) + \xi^j \geq \mathbf{e}, \text{ for } j = 1, \ldots, k. \tag{2}$$

Here, k is defined as the number of batches in $\mathbf{A}$ and the vector of slack variables, ξ, in Equation (1) corresponds to $\xi = [\xi^{1'}, \xi^{2'}, \ldots, \xi^{k'}]'$. In Equation (2), every data point in $\mathbf{B}^j$ sets a constraint on $\mathbf{w}$ and γ *independently*, that is, the i^{th} constraint is set by only the i^{th} data point, $\mathbf{B}^j_i$, ignoring the correlations between $\mathbf{B}^j_i$ and the rest of the samples in $\mathbf{B}^j$. Therefore, we modify the standard SVM set of constraints in order to take into account the correlations among samples in the same batches, using the $\mathbf{R}^j$ matrix as:

$$\mathbf{D}^j\left[\left(\mathbf{I} + \theta\mathbf{R}^j\right)\left(\mathbf{B}^j\mathbf{w} - \mathbf{e}\gamma\right)\right] + \xi^j \geq \mathbf{e}, \text{ for } j = 1, \ldots, k. \tag{3}$$

Here, θ is a parameter that helps us control the contribution of the correlation information encoded by $\mathbf{R}^j$. We can find the optimum value of θ by tuning over a validation set. However, we also present a method where we can learn θ automatically in Section 3.3.

In Equation (3), the class membership prediction for any single sample in batch j is a weighted average of the batch members' prediction vector $\mathbf{B}^j\mathbf{w} - \mathbf{e}\gamma$, and the weighting coefficients depend on the pairwise similarity between samples. Using constraints (3) in the SVM formulation (1), we obtain the optimization problem for learning *BatchSVM* with parameters ν and θ:

$$\begin{aligned} \min_{(\mathbf{w},\gamma,\xi,\mathbf{v}) \in \mathbb{R}^{n+1+m+n}} \quad & \nu\mathbf{e}'\xi + \mathbf{e}'\mathbf{v} \qquad (4) \\ \text{s.t.} \quad \mathbf{D}^j\left[\left(\theta\mathbf{R}^j + \mathbf{I}\right)\left(\mathbf{B}^j\mathbf{w} - \mathbf{e}\gamma\right)\right] + \xi^j \geq \mathbf{e}, & \quad \text{for } j = 1, \ldots, k \\ \mathbf{v} \geq \mathbf{w} \geq -\mathbf{v} & \\ \xi \geq 0. & \end{aligned}$$

When $\theta = 0$, the constraints in Equation (4) become standard SVM constraints. Therefore, if the information provided in $\mathbf{R}^j$ matrix does not help our algorithm improve the accuracy performance of SVM, we expect our method to turn into the standard SVM.

Unlike standard SVMs, the hyperplane ($f(\mathbf{x}) = \mathbf{w}'\mathbf{x} - \gamma$) produced by *BatchSVM* is *not* the final decision function. We refer to $f(\mathbf{x})$ as a pre-classifier that will be used in the next stage to make the final decision on a batch of instances. While testing an arbitrary data point $\mathbf{x}^j_i$ in batch $\mathbf{B}^j$, the *BatchSVM* algorithm accounts for the pre-classifier prediction $\mathbf{w}'\mathbf{x}^j_p - \gamma$ for every member in the batch. The final prediction $\hat{f}(\mathbf{x}^j_i)$ is given by:

$$sign(\hat{f}(\mathbf{x}^j_i)) = sign(\mathbf{w}'\mathbf{x}^j_i - \mathbf{e}\gamma + \theta\mathbf{R}^j_i\left[\mathbf{B}^j\mathbf{w} - \mathbf{e}\gamma\right]). \tag{5}$$

Consider the two dimensional example in Figure 2, showing batches of training points. The data points that belong to the same batch are indicated by the elliptical boundaries in the figure. Figure 2b displays the correlations amongst the training points given in Figure 2a using an edge.

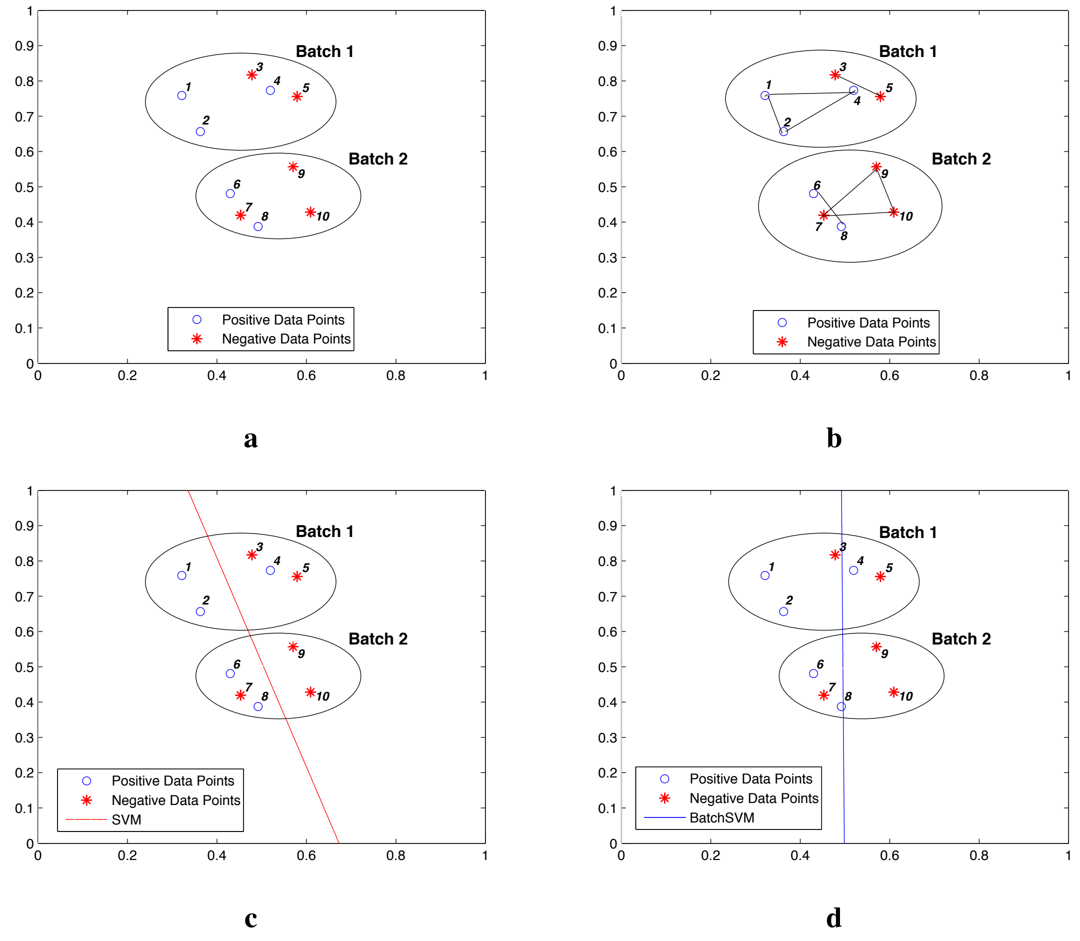

Figure 2: An illustrative example for batch learning. **a**) Training data points are displayed in batches. **b**) Relations within training points are displayed as a linked graph. **c**) Classifier produced by SVM. **d**) Pre-classifier produced by $BatchSVM$. Unlike standard SVMs, the hyperplane, $f(\mathbf{x})$, produced by $BatchSVM$ (preclassifier) is not the decision function. Instead, the decision of each test sample $\mathbf{x}_i$, is based on a weighted average of the $f(\mathbf{x})$ values for the points linked to $\mathbf{x}_i$.

In Figure 2c, the hyperplane $f_{svm}(\mathbf{x})$ is the final decision function for standard SVM and gives the results displayed in Table 1 where we observe that the fourth and the seventh instances are misclassified. In Figure 2d, the pre-classifier produced by $BatchSVM$, $f_{batch}(\mathbf{x})$ gives the results displayed in the fifth column of Table 1 for the training data. If this pre-classifier were to be considered as the decision function, then three training points would be misclassified. However, during batch-testing (Equation 5), the predictions of those points are corrected as seen in the sixth column of Table 1.

Point	Batch	Label	SVM	Pre-classifier	Final classifier
1	1	+	0.2826	0.1723	0.1918
2	1	+	0.2621	0.1315	0.2122
3	1	-	-0.2398	**0.0153**	-0.0781
4	1	+	**-0.3188**	**-0.0259**	0.2909

Table 1: Outputs of the classifier produced by SVM, pre-classifier and the final classifier produced by *BatchSVM*. The outputs are calculated for the data points presented in Figure 2. The first column of the table indicates the order of the data points as they are presented in Figure 2a and the second column specifies the corresponding labels. Misclassified points are displayed in bold. Notice that the combination of the pre-classifier outputs at the final stage corrects the mistakes.

3.3 A Faster Proximal Batch Approach

Support vector machines are known to be slow to train. In Fung and Mangasarian (2001), Fung and Mangasarian introduced proximal support vector machine which is a fast and simple algorithm for generating a linear or nonlinear classifier that merely requires the solution of a single system of linear equations. To yield a faster training method, we present a batch approach to proximal support vector machine in this section.

Similar to the proximal support vector machine formulation (PSVM) in Fung and Mangasarian (2001), we can slightly modify the set of inequalities (3) and consider a Gaussian prior (instead of a Laplacian) for both the error vector ξ and the regularization term, to obtain the following unconstrained formulation:

$$\min_{(\mathbf{w},\gamma)\in\mathbb{R}^{n+1}} \nu\frac{1}{2}\sum_{j=1}^{k} \|\mathbf{e}-\mathbf{D}^j\left[\left(\theta\mathbf{R}^j+\mathbf{I}\right)\left(\mathbf{B}^j\mathbf{w}-\mathbf{e}\gamma\right)\right]\|^2+\frac{1}{2}(\mathbf{w}'\mathbf{w}+\gamma^2). \tag{6}$$

Note that formulation (6) is a strongly convex (quadratic) unconstrained optimization problem and it has a unique solution. Then, obtaining the solution to formulation (6) requires only solving a single system of linear equations; therefore, it should be substantially faster than the linear programming approach of the standard QP approach while maintaining approximate accuracy results (Fung and Mangasarian, 2001). Moreover, this simple formulation allows us to introduce a very small modification to learn the parameter θ in a very simple but effective manner:

$$\min_{(\mathbf{w},\gamma,\theta)\in\mathbb{R}^{n+1+1}} \nu\frac{1}{2}\sum_{j=1}^{k} \|\mathbf{e}-\mathbf{D}^j\left[\left(\theta\mathbf{R}^j+\mathbf{I}\right)\left(\mathbf{B}^j\mathbf{w}-\mathbf{e}\gamma\right)\right]\|^2+\frac{1}{2}(\mathbf{w}'\mathbf{w}+\gamma^2+\theta^2). \tag{7}$$

This formulation is strongly convex in all its variables $(\mathbf{w}, \gamma, \theta)$ and it has a unique solution as well. The optimization problem (7) can be solved in many different ways, however we chose to use an alternating optimization approach similar to the one used in Fung et al. (2004), since it suits the structure of the problem perfectly and it converged rapidly in our experiments. It took nine iterations on average for the algorithm to converge in our experiments. The alternate optimization method used can be summarized as follows:

0 *initialization*: Given an initial θ_0, the parameter ν, the training data $A = \bigcup_{j=1}^{k} \mathbf{B}^j$ and the corresponding labels $\mathbf{D}$.

1. Solve optimization problem (6) for $\theta = \theta^{i-1}$ obtain $\mathbf{w}^i$ and γ^i.

2. For the obtained $\mathbf{w}^i$ and γ^i, solve the following linear system of equations:

$$\theta^i = \frac{-\sum_{j=1}^{k} M^j}{2\sum_{j=1}^{k} N^j}$$

where

$$M^j \quad = \mathbf{S}^{j\prime}\mathbf{Z}_j\mathbf{S}^j + 2\mathbf{e}'\mathbf{D}^j\mathbf{R}^j\mathbf{S}^j \text{ , for } \mathbf{S}^j = \left(\mathbf{B}^j\mathbf{w} - \mathbf{e}\gamma\right) \text{ and } \mathbf{Z}_j = (\mathbf{R}^{j\prime} + \mathbf{R}^j),$$

$$N^j \quad = \mathbf{Y}^{j\prime}\mathbf{Y}^j + \tfrac{1}{\nu} \text{ , for } \mathbf{Y}^j = \mathbf{R}^j\left(\mathbf{B}^j\mathbf{w} - \mathbf{e}\gamma\right).$$

This is an iterative method with two steps. At the first step, it finds the optimum values of $\mathbf{w}$ and γ ($\mathbf{w}_{opt}, \gamma_{opt}$) for a given θ. At the second step, for the given $\mathbf{w}_{opt}$ and γ_{opt}, it finds the optimum value of θ (θ_{opt}), which will be used at the first leg of the next iteration. Appendix A.2 provides a derivation of the update equations. Initially, we assign a random value for θ, the procedure is repeated until it converges to the global optimum solution for $\mathbf{w}$, γ and θ.

4. A Probabilistic Batch Classification Model

Let $\mathbf{x}_i^j \in \mathbb{R}^n$ represent the n features for the i^{th} candidate in the j^{th} image, and let $\mathbf{w} \in \mathbb{R}^n$ be the weight parameters and $\gamma \in \mathbb{R}^1$ be the offset of some hyperplane classifier. Traditionally, classifiers label samples one at a time (i.e., independently) based only on the features that describe a given sample $\mathbf{x}_i^j$:

$$z_i^j \quad = \mathbf{w}'\mathbf{x}_i^j - \gamma \quad = (\mathbf{x}_i^j)'\mathbf{w} - \gamma \quad , z_i^j \in \mathbb{R}^1.$$

For example, in logistic regression, the posterior probability of the sample $\mathbf{x}_i^j$ belonging to class $+1$ is obtained using the sigmoid function $P(y_i^j = 1|\mathbf{x}_i^j) = \frac{1}{1+\exp(-\mathbf{w}'\mathbf{x}_i^j+\gamma)}$.

We claim that z_i^j is only a noisy observation of the underlying, unobserved variable $u_i^j \in \mathbb{R}^1$ that actually influences classification (as opposed to the traditional classification approach, where classification directly depends on z_i^j). Beside the features $\mathbf{x}_i^j$ that are available to influence the classification of a sample point (via u_i^j), we have side information about the extent of correlation amongst the quantities u_i^j. We mathematically model the side information as an a-priori guess or intuition about u_i^j even before we observe any $\mathbf{x}_i^j$ (therefore before z_i^j).

For example, in the context of CAD, features describe the shape, size, texture, and intensity profile of a candidate (sample) in an image. However, besides the above information encoded in the form of features that describe each candidate, we also know that correlation amongst the samples in an image (batch) purely based on the proximity of the spatial locations of samples in the j^{th} image. In CAD applications, this spatial adjacency induces correlations in the predictions for the labels, but in other applications the nature of side-information that accounts for the correlations would be different. Nevertheless, in general (in a domain independent way) we model this side-information as a Gaussian prior on u_i^j.

$$P(\mathbf{u}^j \in \mathbb{R}^{n_j}) \quad = N(\mathbf{u}^j | 0, \mathbf{R}^j) \tag{8}$$

where n_j is the number of the candidates in the j^{th} image, and the covariance matrix $\mathbf{R}^j$ encodes the correlations. As mentioned above, in CAD applications, $\mathbf{R}^j$ can be defined in terms of $\mathbf{S}$, the matrix of Euclidean distances between candidates inside a medical image (from a patient) as $\mathbf{R}^j = \exp(-\alpha\mathbf{S})$, with $\alpha > 0$ as a model parameter.

Having defined a prior, next we define the likelihood as follows:

$$P(z_i^j | u_i^j) \quad = N(z_i^j | u_i^j, \sigma^2). \tag{9}$$

After observing $\mathbf{x}_i^j$ and therefore z_i^j, we can modify our prior intuition about $\mathbf{u}^j$ in (8), based on our observations from (9) to obtain the Bayesian posterior:

$$P(\mathbf{u}^j | \mathbf{z}^j) \quad = N\left(\mathbf{u}^j | (\mathbf{R}^{j^{-1}}\sigma^2 + \mathbf{I})^{-1}\mathbf{z}^j; (\mathbf{R}^{j^{-1}} + \tfrac{1}{\sigma^2}\mathbf{I})^{-1}\right) \tag{10}$$

The class-membership prediction for the i^{th} candidate in the j^{th} image is controlled exclusively by u_i^j. Let $\mathbf{B}^j \in \mathbb{R}^{m_j \times n}$ represent the m_j training points that belong to the j^{th} batch. Exact computation of the integral required for $P(\mathbf{y}^j = 1 | \mathbf{B}^j, \mathbf{w}, \gamma, \alpha, \sigma^2)$ is analytically infeasible because of the nonlinear sigmoid terms. However, by using the *maximum-a-posteriori* (MAP) estimate of u_i^j, the prediction probability for class label, y_i^j is then determined approximately as:

$$\begin{gathered} P(y_i^j = 1 | \mathbf{B}^j, \mathbf{w}, \gamma, \alpha, \sigma^2) \approx 1/\left(1 + \exp\left(-\mathbf{V}_i^j[\mathbf{B}^j\mathbf{w} - \mathbf{e}\gamma]\right)\right), \\ \text{where} \\ \mathbf{V}^j = \left[\mathbf{R}^{j^{-1}}\sigma^2 + \mathbf{I}\right]^{-1}. \end{gathered} \tag{11}$$

Note, however, that for each batch j, the probabilistic method requires calculating two matrix inversions to compute $\left(\mathbf{R}^{j^{-1}}\sigma^2 + \mathbf{I}\right)^{-1}$. Hence, training and testing using this method can be time consuming for large batch sizes. On the other hand, $\left(\mathbf{R}^j\theta + \mathbf{I}\right)$ that we introduced in Equation (3) is relatively less time consuming to compute.

In general, $\left(\mathbf{R}^{j^{-1}}\sigma^2 + \mathbf{I}\right)^{-1} \neq \left(\mathbf{R}^j\theta + \mathbf{I}\right)$. However, the intuition behind both are similar: *the class prediction for each sample is a weighted sum of the prediction values of the test sample and the samples that are correlated with the test instance*. In the appendix A.1, we show that when σ is small and we are considering a least squared loss function as in Section 3.3, the constraint (3) results in an approximation to the following constraint:

$$\mathbf{D}^j \left[\left(\mathbf{R}^{j^{-1}}\sigma^2 + \mathbf{I}\right)^{-1}(\mathbf{B}^j\mathbf{w} - \mathbf{e}\gamma)\right] + \xi^j \geq \mathbf{e}, \ \text{ for } j = 1, \ldots, k \tag{12}$$

when the sum of the labels of neighboring data points according to each row of $\mathbf{R}^j$ is the same or they have similar values. Note that, this is particularly true when $\mathbf{R}^j$ only contains information about correlations for a constant number of nearest neighbors for each sample (k-nearest neighbors) and when the assumption that neighboring segments should have similar labels holds.

4.1 Learning in this Model

For batch-wise prediction using (11), $\mathbf{w}, \alpha$ and σ^2 can be learned from a set of N training images via *maximum-a-posteriori* (MAP) estimation of $\mathbf{w}$ and *maximum-likelihood* estimation of α, σ^2 as follows:

$$[\hat{\mathbf{w}}, \hat{\gamma}, \hat{\alpha}, \hat{\sigma^2}] \quad = \arg\max_{\mathbf{w},\gamma,\alpha,\sigma^2} P(\mathbf{w}) \prod_{j=1}^{N} P(\mathbf{y}^j | \mathbf{B}^j, \mathbf{w}, \gamma, \alpha, \sigma^2)$$

where, $P(\mathbf{y}^j | \mathbf{B}^j, \mathbf{w}, \gamma, \alpha, \sigma^2)$ is defined as in (11) and $P(\mathbf{w})$ may be assumed to be Gaussian $N(\mathbf{w}|0, \lambda)$. The regularization parameter λ is typically chosen by cross-validation. General purpose numerical optimizers such as conjugate gradient algorithms may be used for the above optimization problem.

4.2 Intuition about Batch Classification

Equations (10) and (11) imply that $\mathbb{E}[\mathbf{u}^j | \mathbf{z}^j] = (\mathbf{R}^{j^{-1}} \sigma^2 + \mathbf{I})^{-1} \mathbf{z}^j$. In other words, the class membership prediction for any single sample is a weighted average of the noisy prediction quantity $\mathbf{z}^j$ (distance to the hyperplane), where the weighting coefficients depend on the pairwise Euclidean distances between samples. Hence, the intuition presented above is that we predict the classes for all the n_j candidates in the j^{th} image together, as a function of the features for all the candidates in the batch (here a batch corresponds to an image from a patient). In every test image, *each* of the candidates is classified using the features from *all* the samples in the image. Note that although we classify each instance in a batch at the same time, our algorithm outputs a class for each instance and the class membership for these samples need not be the same.

5. Experiments

In this section, we compare regular SVM, probabilistic batch learning (*BatchProb*), and *BatchSVM*. Note that in order to make the comparison consistent, *BatchProb* was implemented by using the same linear programming formulation as *BatchSVM* but using Equation (12) instead of Equation (3). We also compare PSVM based techniques introduced in Section 3: (1) the proximal version of batch learning presented in (6) where θ is determined as a parameter via cross-validation ($BatchPSVM - cv$), and (2) the alternating optimization method presented in (7), where θ is learned automatically ($BatchPSVM - learned$).

5.1 Implementation Details

We present the details of the similarity function that we used in our experiments and how we tuned the parameters of our methods in the next sections.

5.1.1 THE SIMILARITY FUNCTION

As mentioned earlier, the matrix $\mathbf{R}^j$ represents the level of correlation between all pairs of candidates from a batch (an image in our case) and it is a function of the pairwise-similarity between the candidates. One needs to produce the $\mathbf{R}^j$ matrix using the appropriate similarity metric that represents the pairwise-similarities the best for a particular application.

In our CAD applications, we have used the Euclidean distances between candidates inside a medical image as our similarity metric to define the covariance matrix $\mathbf{R}^j$. Let $\mathbf{r}_p$ and $\mathbf{r}_q$ represent the coordinates of two candidates, $\mathbf{B}_p^j$ and $\mathbf{B}_q^j$ on the j^{th} image. For our experiments, we used the Euclidean distance between $\mathbf{r}_p$ and $\mathbf{r}_q$ to define the pairwise-similarity, $s(p,q)$, between $\mathbf{B}_p^j$ and $\mathbf{B}_q^j$ as following:

$$s(p,q) = e^{-\frac{\|\mathbf{r}_p - \mathbf{r}_q\|^2}{\varsigma^2}}.$$

If the matrices $s(p,q)$ are sparse, it aids the computational efficiency of our algorithms, both in terms of memory use and speed of implementation. Note also that the matrix is naturally sparse, due to the rapid decrease of the exponential function. Nevertheless, to make the implementation stable and memory efficient (by avoiding storing all the elements of these matrices), we found it useful to discretize the continuous similarity function, $s(p,q)$ to the binary similarity function, $s^*(p,q)$ by applying a threshold as following:

$$s^*(p,q) = \begin{cases} 0 & s(p,q) < e^{-4}, \\ 1 & s(p,q) \geq e^{-4}. \end{cases} \tag{13}$$

In all experiments, we set the threshold at e^{-4} to provide us with a similarity of one if the neighbor is at a 95% confidence level of belonging to the same density as the candidate assuming that the neighborhood is a Gaussian distribution with mean equal to the candidate and variance $\varsigma^2 = \frac{1}{\alpha}$. Each element of the matrix $\mathbf{R}$ is given by:

$$\mathbf{R}_{pq} = s^*(p,q).$$

In order to observe the effects of binarization of the $\mathbf{R}$ matrix, we also run experiments on *BatchSVM* without applying the threshold in Equation (13), that is, $\mathbf{R} = s(p,q)$. We refer to this version of *BatchSVM* as $BatchSVM_{cont}$ in our experiments.

5.1.2 PARAMETER TUNING

All our parameters in these experiments are tuned by 10-fold patient cross-validation on the training data (i.e., the training data is split into ten folds). During cross-validation, a range of parameters $(\theta, \sigma, \varsigma)$ were evaluated for the proposed methods. In $BatchPSVM - learned$, the parameter θ is learned automatically through equation (7).

5.2 Evaluation Method

As we explained earlier, $\mathbf{R}$ used in the proposed methods is produced from the spatial locations of the candidates. These spatial locations can be considered as extra information provided to our methods. In order to make fair comparisons between our methods and standard SVM and PSVM, we added the spatial locations (x,y,z coordinates of the candidates in 3D image) to the feature vectors of the candidates.

Receiver Operating Characteristic (ROC) plots are used to study the classification accuracy of these techniques on three CAD applications for detecting pulmonary embolism, colon cancer, and

Table 2: Training and testing times for each classifier are displayed in seconds.

lung cancer. In clinical practice, CAD systems are evaluated on the basis of a somewhat domain-specific metric: to maximize the fraction of *positives* that are correctly identified by the system while displaying at most a clinically acceptable number of false-marks per image. We report this domain-specific metric in an ROC plot, where the y-axis is a measure of sensitivity and the x-axis is the number of false-marks per patient (in our case, per image is also per patient). Sensitivity is the number of patients diagnosed as having the disease divided by the number of patients that has the disease. High sensitivity and low false-marks are desired. All classification algorithms are trained on a training data set and evaluated on a sequestered (held-out) test set.

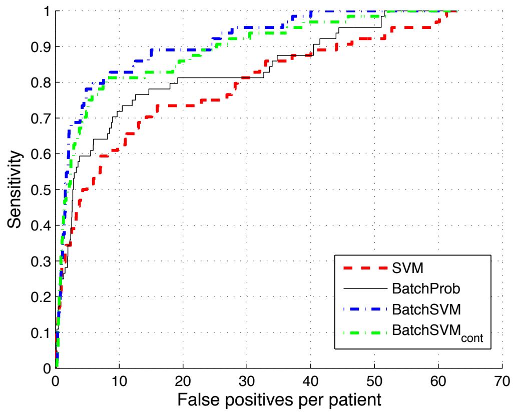
The area under the ROC curve is a commonly used criteria to evaluate the performance of an algorithm. Table 3 displays the area under the ROC curve of each classifier. It is important to note that the areas under the curve presented in Table 3 are calculated considering the entire false positive range which tends to underestimate the superiority of our proposed approach with respect to traditional approaches around the range of false positives acceptable for CAD applications.

PSVM, $BatchPSVM-cv$ and $BatchPSVM-learned$ algorithms require solving a set of linear equations while training, therefore we expect them to be faster than the other methods mentioned in this paper, namely SVM, $BatchProb$ and $BatchSVM$. In order to compare the time performances of the methods, we measured the CPU time consumed by each classifier. Table 2, displays the training and testing times required by the algorithms. The training times obtained for the parametric methods (SVM, $BatchProb$, $BatchSVM$, PSVM and $BatchPSVM-cv$) are the total times divided by the number of cross-validations to find the best value of θ. On the other hand, the training time for $BatchPSVM-learned$ is the total time divided by the number of iterations that $BatchPSVM-learned$ required while converging to the optimum value of θ. We measured the training times this way to be able to make a fair comparison between the algorithms.

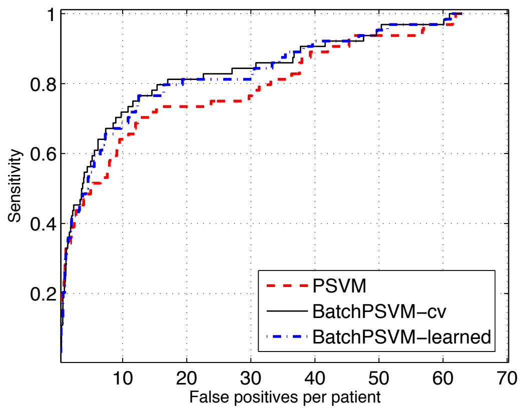
We ran our experiments on an Intel Pentium 4 CPU with 2.8 GHz clock frequency and 1GB RAM and the algorithms were implemented in Matlab.

5.3 Data Sources and Domain Description

When searching for descriptive features, researchers often deploy a large amount of experimental image features to describe the identified candidates, which consequently introduces irrelevant or redundant features. The initial large set of features is based on medically relevant characteristics:



a



b

Figure 3: Experimental results for PE data. ROC curves obtained by (a) SVM, *BatchProb*, *BatchSVM* and $BatchSVM_{cont}$ (b) PSVM, $BatchPSVM-cv$ and $BatchPSVM-learned$

the pixel intensity descriptive statistics, texture, contrast, 2D and 3D shape descriptors, and the location of the corresponding structure.

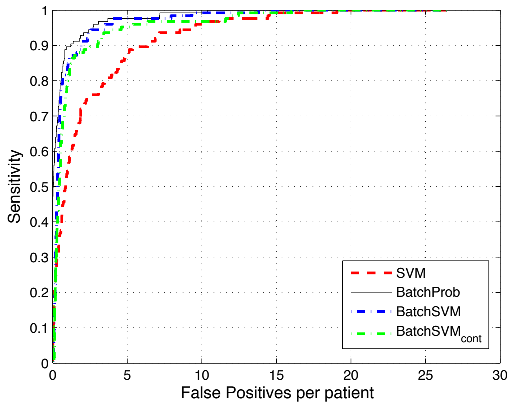
5.3.1 EXAMPLE: PULMONARY EMBOLISM

Pulmonary embolism (PE), a potentially life-threatening condition, is a result of underlying venous thromboembolic disease. An early and accurate diagnosis is the key to survival. Computed tomography angiography (CTA) has emerged as an accurate diagnostic tool for PE. However, there are hundreds of CT slices in each CTA study. Manual reading is laborious, time consuming and complicated by various PE look-alikes (false positives) including respiratory motion artifact, flow-related artifact, streak artifact, partial volume artifact, stair step artifact, lymph nodes, vascular bifurcation among many others (Masutani et al., 2002; Wittram et al., 2004). Several CAD systems are developed to assist radiologists in this process by helping them detect and characterize emboli in an accurate, efficient and reproducible way (Quist et al., 2004; Zhou et al., 2003).

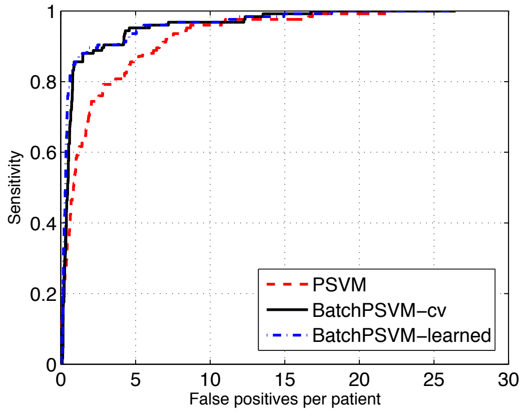
We have collected 72 cases with 242 PEs marked by expert chest radiologists at four different institutions (two North American sites and two European sites). For our experiments, they were randomly divided into two sets: a training and a testing set. The training set was used to train and validate the classifiers and consists of 48 cases with 173 PEs and a total of 3655 candidates. The testing set consists of 24 cases with 69 true PEs out of a total of 1857 candidates. This set was only used to evaluate the performance of the final system. A combined total of 70 features were extracted to describe the shape, texture, size and intensity profile of each candidate.

5.3.2 EXAMPLE: COLON CANCER DETECTION

Colorectal cancer is the third most common cancer in both men and women. It is estimated that in 2004, nearly 147,000 cases of colon and rectal cancer will be diagnosed in the US, and more than 56,730 people would die from colon cancer (Jemal et al., 2004). In over 90% of the cases colon



a



b

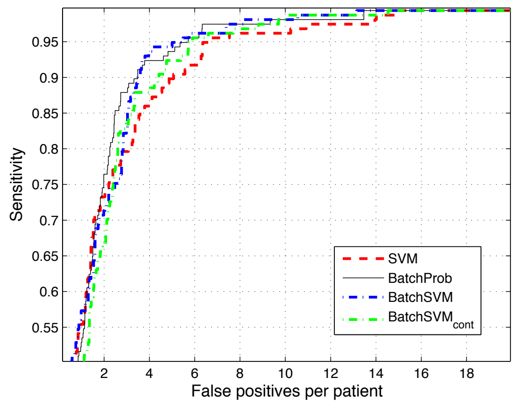
Figure 4: Experimental results for Colon Cancer data. ROC curves obtained by (a) SVM, $BatchProb$, $BatchSVM$ and $BatchSVM_{cont}$ (b) PSVM, $BatchPSVM-cv$ and $BatchPSVM-learned$

cancer progressed rapidly is from local (polyp adenomas) to advanced stages (colorectal cancer), which has very poor survival rates. However, identifying (and removing) lesions (polyp) when still in a local stage of the disease, has very high survival rates, thus illustrating the critical need for early diagnosis. The sizes of a polyp in the colon can vary from 1mm all the way up to 10cm. Most polyps no matter how small they are, are represented by two candidates; one obtained from the prone view and the other one from the supine view. Moreover, for large polyps or so called masses a typical candidate generation algorithm generates several candidates across the polyp surface. Therefore most polyps in the training data are inherently represented by multiple candidates.

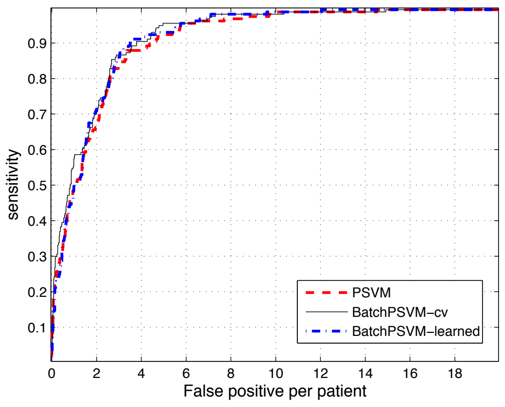
For the sake of clinical acceptability, it is sufficient to detect one of these candidates during classification. Unlike a standard classification algorithm where the emphasis is to accurately classify each and every candidate, here we seek to classify at least one of the candidates representing a polyp accurately. The database of high-resolution CT images used in this study were obtained from seven different sites across US, Europe and Asia. The 188 patients were randomly partitioned into a training and a test set. The training set consists of 65 cases containing 127 volumes. Fifty polyps were identified in this set out of a total of 6748 candidates. The testing set consists of 123 cases containing 237 volumes. There are 103 polyps in this set from a total of 12984 candidates. A total of 75 features were extracted to describe the shape, size, texture and intensity profile of each candidate.

5.3.3 EXAMPLE: LUNG CANCER

LungCAD is a computer aided detection system for detecting potentially cancerous pulmonary nodules from thin slice multi-detector computed tomography (CT) scans. The final output of LungCAD is provided by a classifier that classifies a set of candidates as positive or negative. This is a very hard classification problem: most patient lung CTs contain a few thousand structures (candidates),



a



b

Figure 5: Experimental results for Lung Cancer data. ROC curves obtained by (a) SVM, $BatchProb$, $BatchSVM$ and $BatchSVM_{cont}$ (b) PSVM, $BatchPSVM-cv$ and $BatchPSVM-learned$

and only a few (≤ 5 on average) of which are potential nodules that should be identified as positive by LungCAD, all within the run-time requirements of completing the classification on-line during the time the physician completes their manual review.

The training set consists of 60 patients. The number of candidates labeled as nodules in the training set are 157 and the total number of candidates is 9987. The testing set consists of 26 patients. In this testing set, there are 79 candidates labeled as nodules out of 6159 generated candidates. A total of 15 features were used to describe the shape, size, texture and intensity profile of each candidate region.

5.4 Discussion and Results

In our experiments, we would like to find out whether the batch methods are better than the standard SVM, whether $BatchSVM$ is better than $BatchProb$ in terms of accuracy and speed, whether B$atchPSVM$ is as accurate as $BatchSVM$, whether $BatchPSVM$ is faster than $BatchSVM$, and whether the automated tuning works by comparing $BatchPSVM-learned$ with $BatchPSVM-cv$.

5.4.1 SVM versus Batch Methods

Figures 3, 4, and 5 show the ROC curves for pulmonary embolism, colon cancer, and lung cancer data respectively. In our medical applications high-sensitivity is critical as early detection of lung and colon cancer is believed to greatly improve the chances of successful treatment (Bogoni et al., 2005). Furthermore, high specificity is also critical, as a large number of false positives will vastly increase physician load and lead (ultimately) to loss of physician confidence.

In Figure 3a, corresponding to the comparison of the ROC curves on the PE data set, we observe that standard SVM can only achieve 53% sensitivity for six false positives. However, $BatchSVM$ achieves 80% with a remarkable improvement of 27%. $BatchProb$ also outperforms SVM with a

	PE	Colon	Lung
SVM	0.79	0.91	0.98
BatchProb	0.83	**0.98**	**0.99**
BatchSVM	**0.89**	0.96	**0.99**
$BatchSVM_{cont}$	0.88	0.95	**0.99**
PSVM	0.77	0.91	**0.99**
$BatchPSVM-cv$	0.82	0.96	**0.99**
$BatchPSVM-learned$	0.83	0.96	**0.99**

Table 3: Area under the ROC curves for each classifier. (Best in bold).

64% sensitivity. As seen from the figure, the two proposed methods are substantially more accurate than standard SVMs at any specificity level. When we compare the performances of PSVM and $BatchPSVM-learned$ in Figure 3b, we observe that the proposed batch method ($BatchPSVM-learned$) dominates over PSVM. However, they do not improve the accuracy of PSVM as much as *BatchProb* and *BatchSVM* do.

Colon cancer data is a relatively easier data set than pulmonary embolism since standard SVM can achieve 54.5% sensitivity at one false positive level as illustrated in Figure 4a. However, *BatchSVM* improved SVM's performance to 84% sensitivity for the same number of false positives. Note that *BatchProb* improved the sensitivity further, giving 89.6% for the same specifity. In one to ten false positives region which constitutes the region of interest in our applications, our proposed methods outperform standard SVM significantly. PSVM's performance is substantially worse than that of our proposed batch methods, $BatchPSVM-cv$ and $BatchPSVM-learned$.

Although SVM is very accurate for the lung cancer application, Figure 5a shows that *BatchProb* and *BatchSVM* could still improve SVM's performance further. *BatchProb* method is superior to the other methods at two and three false positives per image. Both *BatchProb* and *BatchSVM* outperform SVM in the 2-6 false positives per image region, which is the region of interest for commercial clinical lung CAD systems. All three of the methods are comparable at other specificity levels. On the other hand, we observe in Figure 5b that $BatchPSVM-cv$ and $BatchPSVM-learned$ methods did not achieve significant improvements, yet they are still comparable to PSVM.

When we consider the area under the ROC curve for each of the methods in Table 3, we observe that our proposed methods are better than SVM and PSVM in every case except one where PSVM performs the same as our proposed methods in the lung cancer data.

In order to understand if the proposed methods are statistically significantly better than standard SVM and PSVM, we applied Z-test to compare the areas under the ROC curves derived from the same set of patients as explained in Hanley and McNeil (1983). The corresponding P-values that indicate the level of confidence of the paired comparisons are presented in Table 4. The smaller the P-values, the higher the level of confidence. Looking at the results in Table 4, we can say that the improvements provided by the proposed methods are statistically significant for PE and Colon data sets.

	SVM vs *BatchProb*	SVM vs *BatchSVM*	PSVM vs *BatchPSVM − cv*	PSVM vs *BatchPSVM − learned*
PE	0.05	0.01	0.06	0.05
Colon	0.01	0.01	0.05	0.05
Lung	0.81	0.81	1	1

Table 4: P-values that indicate the confidence level of significance when the proposed algorithms are compared to SVM and PSVM in terms of the area under the ROC curves.

5.4.2 *BatchSVM* VERSUS *BatchProb*

As we discussed in Section 3, *BatchProb* requires calculating two matrix inversions, which can be time consuming for large sizes of batches, whereas *BatchSVM* avoids matrix inversions, therefore *BatchSVM* should be faster than *BatchProb* in both training and testing. As expected, our experiments show us that *BatchSVM* is faster than *BatchProb* in every case. Note that the difference in run times is significant for testing in PE and Colon data sets, where *BatchSVM* is twenty times faster than *BatchProb*. On the other hand, *BatchProb* produced a better ROC curve in Colon data set. Therefore, although *BatchProb* is slow compared to *BatchSVM*, it may be preferable with respect to accuracy depending on the application.

5.4.3 *BatchPSVM − learned* VERSUS *BatchPSVM − cv*

BatchPSVM − cv requires cross-validated tuning over the parameter θ to achieve the optimum accuracy. One problem with tuning is that we can only tune the parameter in a limited range. Therefore a good guess of the range of the parameter values is crucial. Another problem is that we can only tune the parameter over discrete values which may not include the best parameter value. One way to obtain a close approximation of the best parameter value is to divide the range of the parameter into small steps. However this method will increase the training time since cross-validation will be repeated as many times as the possible parameter values (in our experiments, we cross-validated θ over 21 values). On the other hand, automated tuning (*BatchPSVM − learned*) is quite feasible and avoids the problems stated above. In our experiments, *BatchPSVM − learned* was able to automatically converge to the optimum value of θ in only nine iterations on average while producing comparable ROC plots with cross-validated tuning (*BatchPSVM − cv*) as seen in Figures 3b, 4b and 5b. The optimum θ values obtained by cross-validated tuning and automated tuning are presented in Table 5. As observed in the table, the optimum θ values found by both algorithms are very similar.

When we compare the two methods with respect to training times, we observe that *BatchPSVM − cv* is faster than *BatchPSVM − learned* for a fixed value of θ. However, since we repeated cross-validation 21 times for *BatchPSVM − cv* and *BatchPSVM − learned* required nine iterations on average, *BatchPSVM − learned* is actually faster than *BatchPSVM − cv* in overall while training.

5.4.4 *BatchPSVM* VERSUS *BatchSVM*

BatchSVM results in a linear programming problem, whereas *BatchPSVM* requires solving a set of linear equations. Therefore, we expect *BatchPSVM* to be faster than *BatchSVM* while training. Experimental results on training times displayed in Table 2 confirm that it takes less time for

	PE	Colon	Lung
$BatchPSVM-cv$	1	0.6	0.1
$BatchPSVM-learned$	1.11	0.68	0.03

Table 5: θ values obtained by $BatchPSVM-cv$ and $BatchPSVM-learned$.

$BatchPSVM$ in the training phase. However, despite the training time performance, $BatchSVM$ produced better ROC curves than that of $BatchPSVM$ in PE and lung cancer data sets as illustrated in Figures 3 and 5 respectively. The area under the ROC curve produced by $BatchSVM$ is also better than $BatchPSVM$ for these two data sets. For Colon data set, in Figure 4b, we observe that $BatchPSVM-cv$ and $BatchSVM$ performed slightly better than $BatchSVM-learned$ where both achieve 86% sensitivity at one false positive level. Furthermore, the total area under the ROC curves produced by $BatchSVM$ and $BatchPSVM$ are the same (0.96). From the experimental results, we can draw the conclusion that $BatchPSVM$ is a fast alternative to $BatchSVM$ and can be preferable in some applications.

6. Conclusions

Three related algorithms have been proposed for classifying batches of correlated data samples. Although primarily motivated by real-life CAD applications, the problem occurs commonly in many situations; our algorithms are sufficiently general to be applied in other contexts. Experimental results indicate that the proposed method can substantially improve the diagnosis of (a) early stage cancer in the Lung & Colon, and (b) pulmonary embolisms (which may result in strokes). With the increasing adoption of these systems in routine clinical practice, these experimental results demonstrate the potential of our methods to impact a large cross-section of the population.

In this paper, we validated the improvement in diagnosis sensitivity that batch-wise classification provides to CAD problems. The algorithms presented here are general and can be applied to other domains. In other domains, one may apply other similarity metric appropriate for the application. For data with no clear batch information, clustering can be performed to create the batches. Extending the batch algorithms to other data and automatically learning the similarity metric are topics for future work.

Appendix A.

In this section, we present the connection between Equations (3) and (12), and the derivation steps for automatically tuning the parameters in BatchPSVM.

A.1 Connection between Equations (3) and (12)

We will show the connection between the optimization problems that result by considering the constraints (3) and (12) by proving that the resulting objective functions are closely related to each other.

First, let us show that the inverse $\left(\mathbf{I}+\mathbf{R}^{j^{-1}}\sigma^2\right)^{-1}$ that appears in Equation (12) can be approximated by the expression $\mathbf{I}-\sigma^2\mathbf{R}^{j^{-1}}$.

By replacing $\mathbf{A}=\sigma^2\mathbf{R}^{j^{-1}}$, in the identity:

$$(\mathbf{I}+\mathbf{A})^{-1}=\mathbf{I}-\mathbf{A}+\mathbf{A}^2-\mathbf{A}^3+\ldots+,\forall\mathbf{A}$$

we have:

$$\left(\mathbf{I}+\mathbf{R}^{j^{-1}}\sigma^2\right)^{-1}=\mathbf{I}-\sigma^2\mathbf{R}^{j^{-1}}+\sigma^4\mathbf{R}^{j^{-1}}\mathbf{R}^{j^{-1}}-\ldots$$

where the terms $\sigma^4\mathbf{R}^{j^{-1}}\mathbf{R}^{j^{-1}}-\sigma^6\mathbf{R}^{j^{-1}}\mathbf{R}^{j^{-1}}\mathbf{R}^{j^{-1}}+\ldots$ can be ignored if σ is sufficiently small.

Then, we have:

$$\begin{aligned}\left(\mathbf{I}+\mathbf{R}^{j^{-1}}\sigma^2\right)^{-1} &\cong \mathbf{I}-\sigma^2\mathbf{R}^{j^{-1}}\\ &= -\sigma^2\mathbf{R}^{j^{-1}}\left(\mathbf{I}+\theta\mathbf{R}^j\right)\end{aligned}\tag{14}$$

where $\theta=\frac{-1}{\sigma^2}$ provided that $\sigma\neq 0$.

Let us recall that the quadratic unconstrained objective function that results from the constraint (12) is:

$$\min_{(\mathbf{w},\gamma,\theta)\in\mathbb{R}^{n+1+1}}\nu\frac{1}{2}\sum_{j=1}^{k}\left\|\mathbf{e}-\mathbf{D}^j\left[\left(\sigma^2\mathbf{R}^{j^{-1}}+\mathbf{I}\right)^{-1}(\mathbf{B}^j\mathbf{w}-\mathbf{e}\gamma)\right]\right\|^2+\frac{1}{2}(\mathbf{w}'\mathbf{w}+\gamma^2+\theta^2)\tag{15}$$

and that the quadratic unconstrained objective function that results from the constraint (3) is given by:

$$\min_{(\mathbf{w},\gamma,\theta)\in\mathbb{R}^{n+1+1}}\nu\frac{1}{2}\sum_{j=1}^{k}\left\|\mathbf{e}-\mathbf{D}^j\left[\left(\theta\mathbf{R}^j+\mathbf{I}\right)(\mathbf{B}^j\mathbf{w}-\mathbf{e}\gamma)\right]\right\|^2+\frac{1}{2}(\mathbf{w}'\mathbf{w}+\gamma^2+\theta^2).\tag{16}$$

Next, we will show that the objective functions (15) and (16) are related to each other under certain assumptions. In order to ease the notation, let's now define

$$g(\mathbf{w},\gamma)=\sum_{j=1}^{k}\left\|\mathbf{e}-\mathbf{D}^j\left[\left(\sigma^2\mathbf{R}^{j^{-1}}+\mathbf{I}\right)^{-1}(\mathbf{B}^j\mathbf{w}-\mathbf{e}\gamma)\right]\right\|^2.$$

Then if σ^2 is small we have from (14) that:

$$\begin{aligned}g(\mathbf{w},\gamma) &\approx \textstyle\sum_{j=1}^{k}\left\|\mathbf{e}-\mathbf{D}^j\left[-\sigma^2\mathbf{R}^{j^{-1}}\left(\theta\mathbf{R}^j+\mathbf{I}\right)(\mathbf{B}^j\mathbf{w}-\mathbf{e}\gamma)\right]\right\|^2\\ &= \textstyle\sum_{j=1}^{k}\left\|\left(-\sigma^2\mathbf{R}^{j^{-1}}\right)\left(\left(-\frac{1}{\sigma^2}\mathbf{R}^j\right)\mathbf{e}-\mathbf{D}^j\left[\left(\theta\mathbf{R}^j+\mathbf{I}\right)(\mathbf{B}^j\mathbf{w}-\mathbf{e}\gamma)\right]\right)\right\|^2\\ &\leq \textstyle\sum_{j=1}^{k}\left\|\sigma^2\mathbf{R}^{j^{-1}}\right\|^2\left\|\left(-\frac{1}{\sigma^2}\mathbf{R}^j\right)\mathbf{e}-\mathbf{D}^j\left[\left(\theta\mathbf{R}^j+\mathbf{I}\right)(\mathbf{B}^j\mathbf{w}-\mathbf{e}\gamma)\right]\right\|^2\\ &\leq \Psi\textstyle\sum_{j=1}^{k}\left\|-\frac{1}{\sigma^2}\mathbf{R}^j\mathbf{e}-\mathbf{D}^j\left[\left(\theta\mathbf{R}^j+\mathbf{I}\right)(\mathbf{B}^j\mathbf{w}-\mathbf{e}\gamma)\right]\right\|^2=f(\mathbf{w},\gamma)\end{aligned}$$

where $\Psi = max_j\{\left\|\sigma^2\mathbf{R}^{j^{-1}}\right\|^2\}$, then, if σ is small we can conclude that $f(\mathbf{w},\gamma)$ is approximately a "good" upper bound for $g(\mathbf{w},\gamma)$. Furthermore if $h(\mathbf{w},\gamma,\theta) = \mathbf{w}'\mathbf{w}+\gamma^2+\theta^2$,then $F(\mathbf{w},\gamma,\theta) = \nu\frac{1}{2}f(\mathbf{w},\gamma)+\frac{1}{2}h(\mathbf{w},\gamma,\theta)$ is also a "good" upper bound for $G(\mathbf{w},\gamma,\theta) = \nu\frac{1}{2}g(\mathbf{w},\gamma)+\frac{1}{2}h(\mathbf{w},\gamma,\theta)$.

So intuitively, since $G(\mathbf{w},\gamma,\theta)$ and $F(\mathbf{w},\gamma,\theta)$ are non-negative convex quadratic functions, minimizing $F(\mathbf{w},\gamma,\theta)$ should provide good approximate solutions to the problem of minimizing $G(\mathbf{w},\gamma,\theta)$.

Let us assume now that the number of neighboring points that affect the classification for every point is more or less constant. This is true when $\mathbf{R}$ is binary and calculated only for the k nearest neighbors or when the rows of $\mathbf{R}$ are normalized and approximately true when $\mathbf{R}$ is defined as in (13). This is equivalent to assuming that the summation of all the rows of $\mathbf{R}$ is constant, or equivalently, for every batch j:

$$-\frac{1}{\sigma^2}\mathbf{R}^j\mathbf{e} \approx k\mathbf{e}$$

where k is a constant. hence:

$$f(\mathbf{w},\gamma) = \sum_{j=1}^{k}\left\|k\mathbf{e}-\mathbf{D}^j\left[\left(\theta\mathbf{R}^j+\mathbf{I}\right)\left(\mathbf{B}^j\mathbf{w}-\mathbf{e}\gamma\right)\right]\right\|^2.$$

Then, solving the problem:

$$min_{\mathbf{w},\gamma,\theta}F(\mathbf{w},\gamma,\theta)$$

is equivalent to solving the proximal batch formulation presented in Equation (7) for some $\nu = \bar{\nu}$ (the constant k only rescales the problem in the variables w and γ).

A.2 Derivation for Automatically Tuning the Parameters in BatchPSVM

The optimization problem in (7) is a bi-convex problem and can be solved in an iterative fashion with two steps. At the first step, we find the optimum values of $\mathbf{w}$ and γ ($\mathbf{w}_{opt},\gamma_{opt}$) for a given θ. At the second step, for $\mathbf{w}_{opt}$ and γ_{opt} held fixed, we find the optimum value of θ (θ_{opt}), which will be used at the first leg of the next iteration.

A.2.1 OPTIMIZING FOR w AND γ WITH θ FIXED

Given θ is held fixed, we can optimize (7) with respect to $\mathbf{w}$ and γ, and rewrite the equation as follows:

$$\min_{(\mathbf{w},\gamma)\in\mathbb{R}^{n+1}}\frac{1}{2}\mu\sum_{j=1}^{k}\mathbf{x}'\mathbf{P}^j\mathbf{x}+\mathbf{q}^j\mathbf{x}+K_1,$$

where

$$\mathbf{x} = \begin{bmatrix}\mathbf{w}\\ \gamma\end{bmatrix},$$

$$\mathbf{P}^j = \begin{bmatrix}\frac{1}{\mu}\mathbf{I}+\theta^2\mathbf{B}^{j\prime}\mathbf{R}^{j\prime}\mathbf{R}^j\mathbf{B}^j+\theta\mathbf{B}^{j\prime}(\mathbf{R}^{j\prime}+\mathbf{R}^j)\mathbf{B}^j+\mathbf{B}^{j\prime}\mathbf{B}^j & -\theta^2\mathbf{B}^{j\prime}\mathbf{R}^{j\prime}\mathbf{R}^j\mathbf{e}-\theta\mathbf{B}^{j\prime}(\mathbf{R}^{j\prime}+\mathbf{R}^j)\mathbf{e}-\mathbf{B}^{j\prime}\mathbf{e}\\ -\theta^2\mathbf{e}'\mathbf{R}^{j\prime}\mathbf{R}^j\mathbf{B}^j-\theta\mathbf{e}'(\mathbf{R}^{j\prime}+\mathbf{R}^j)\mathbf{B}^j-\mathbf{e}'\mathbf{B}^j & \theta^2\mathbf{e}'\mathbf{R}^{j\prime}\mathbf{R}^j\mathbf{e}+\theta\mathbf{e}'(\mathbf{R}^{j\prime}+\mathbf{R}^j)\mathbf{e}+\mathbf{e}'\mathbf{e}+\frac{1}{\mu}\end{bmatrix},$$

$$\mathbf{q}^j = 2\begin{bmatrix}-\theta\mathbf{e}'\mathbf{D}^j\mathbf{R}^j\mathbf{B}^j-\mathbf{e}'\mathbf{D}^j\mathbf{B}^j\\ -\theta\mathbf{e}'\mathbf{D}^j\mathbf{R}^j\mathbf{e}+\mathbf{e}'\mathbf{D}^j\mathbf{e}\end{bmatrix}$$

and K_1 is a constant term with respect to $\mathbf{w}$ and γ.

After taking the derivative of the objective function with respect to $\mathbf{x}$ and equating to zero, we can obtain the solution as following:

$$x = -(\sum_{j=1}^{k} \mathbf{P}^j)^{-1}(\sum_{j=1}^{k} \mathbf{q}^j)$$

A.2.2 OPTIMIZING FOR θ WITH $\mathbf{w}$ AND γ FIXED

When $\mathbf{w}$ and γ have fixed values, we can rewrite Equation (7) considering θ is the only variable as following:

$$\min_{(\mathbf{w},\gamma)\in\mathbb{R}^{n+1}} \frac{1}{2}\mu \sum_{j=1}^{k} \theta^2 N^j + \theta M^j + K_2$$

where K_2 is a constant with respect to θ and

$$N^j = \quad \mathbf{w}'\mathbf{B}^{j'}\mathbf{R}^{j'}\mathbf{R}^j\mathbf{B}^j\mathbf{w} - \mathbf{w}'\mathbf{B}^{j'}\mathbf{R}^{j'}\mathbf{R}^j\mathbf{e}\gamma - \gamma\mathbf{e}'\mathbf{R}^{j'}\mathbf{R}^j\mathbf{B}^j\mathbf{w} + \gamma^2\mathbf{e}'\mathbf{R}^{j'}\mathbf{R}^j\mathbf{e} + \frac{1}{\mu}$$

and

$$\begin{aligned} M^j = \quad & -\mathbf{e}'\mathbf{D}^j\mathbf{R}^j\mathbf{B}^j\mathbf{w} + \mathbf{e}'\mathbf{D}^j\mathbf{R}^j\mathbf{e}\gamma - \mathbf{w}'\mathbf{B}^{j'}\mathbf{R}^{j'}\mathbf{D}^{j'}\mathbf{e} + \mathbf{w}'\mathbf{B}^{j'}\mathbf{R}^{j'}\mathbf{B}^j\mathbf{w} - \mathbf{w}'\mathbf{B}^{j'}\mathbf{R}^{j'}\mathbf{e}\gamma \\ & +\gamma\mathbf{e}'\mathbf{R}^{j'}\mathbf{D}^{j'}\mathbf{e} - \gamma\mathbf{e}'\mathbf{R}^{j'}\mathbf{B}^j\mathbf{w} + \gamma\mathbf{e}'\mathbf{R}^{j'}\mathbf{e}\gamma + \mathbf{w}'\mathbf{B}^{j'}\mathbf{R}^j\mathbf{B}^j\mathbf{w} - \mathbf{w}'\mathbf{B}^{j'}\mathbf{R}^j\mathbf{e}\gamma \\ & -\gamma\mathbf{e}'\mathbf{R}^j\mathbf{B}^j\mathbf{w} + \gamma\mathbf{e}'\mathbf{R}^j\mathbf{e} \end{aligned} .$$

M^j can be further simplified as:

$$\begin{aligned} M^j = \quad & \mathbf{w}'\mathbf{B}^{j'}(\mathbf{R}^{j'} + \mathbf{R}^j)\mathbf{B}^j\mathbf{w} - \mathbf{w}'\mathbf{B}^{j'}(\mathbf{R}^{j'} + \mathbf{R}^j)\mathbf{e}\gamma - \gamma\mathbf{e}'(\mathbf{R}^{j'} + \mathbf{R}^j)\mathbf{B}^j\mathbf{w} \\ & +\gamma\mathbf{e}'(\mathbf{R}^{j'} + \mathbf{R}^j)\mathbf{e}\gamma - 2\mathbf{e}'\mathbf{D}^j\mathbf{R}^j\mathbf{B}^j\mathbf{w} + 2\mathbf{e}'\mathbf{D}^j\mathbf{R}^j\mathbf{e}\gamma \end{aligned}$$

using the property that $A' = A$, if A is a scalar.

Abstract

The accuracy of k-nearest neighbor (kNN) classification depends significantly on the metric used to compute distances between different examples. In this paper, we show how to learn a Mahalanobis distance metric for kNN classification from labeled examples. The Mahalanobis metric can equivalently be viewed as a global linear transformation of the input space that precedes kNN classification using Euclidean distances. In our approach, the metric is trained with the goal that the k-nearest neighbors always belong to the same class while examples from different classes are separated by a large margin. As in support vector machines (SVMs), the margin criterion leads to a convex optimization based on the hinge loss. Unlike learning in SVMs, however, our approach requires no modification or extension for problems in multiway (as opposed to binary) classification. In our framework, the Mahalanobis distance metric is obtained as the solution to a semidefinite program. On several data sets of varying size and difficulty, we find that metrics trained in this way lead to significant improvements in kNN classification. Sometimes these results can be further improved by clustering the training examples and learning an individual metric within each cluster. We show how to learn and combine these local metrics in a globally integrated manner.

Keywords: convex optimization, semi-definite programming, Mahalanobis distance, metric learning, multi-class classification, support vector machines

1. Introduction

One of the oldest and simplest methods for pattern classification is the k-nearest neighbors (kNN) rule (Cover and Hart, 1967). The kNN rule classifies each unlabeled example by the majority label of its k-nearest neighbors in the training set. Despite its simplicity, the kNN rule often yields competitive results and in certain domains, when cleverly combined with prior knowledge, it has significantly advanced the state-of-the-art (Belongie et al., 2002; Simard et al., 1993).

By the very nature of its decision rule, the performance of kNN classification depends crucially on the way that distances are computed between different examples. When no prior knowledge is available, most implementations of kNN compute simple Euclidean distances (assuming the examples are represented as vector inputs). Unfortunately, Euclidean distances ignore any statistical regularities that might be estimated from a large training set of labeled examples. Ideally, one would like to adapt the distance metric to the application at hand. Suppose, for example, that we are using kNN to classify images of faces by age and gender. It can hardly be optimal to use the same distance metric for age and gender classification, even if in both tasks, distances are computed between the same sets of extracted features (e.g., pixels, color histograms).

Motivated by these issues, a number of researchers have demonstrated that kNN classification can be greatly improved by learning an appropriate distance metric from labeled examples (Chopra et al., 2005; Goldberger et al., 2005; Shalev-Shwartz et al., 2004; Shental et al., 2002). This is the so-called problem of *distance metric learning*. Recently, it has been shown that even a simple linear transformation of the input features can lead to significant improvements in kNN classification (Goldberger et al., 2005; Shalev-Shwartz et al., 2004). Our work builds in a novel direction on the success of these previous approaches.

In this paper, we show how to learn a Mahalanobis distance metric for kNN classification. The algorithm that we propose was described at a high level in earlier work (Weinberger et al., 2006) and later extended in terms of scalability and accuracy (Weinberger and Saul, 2008). Intuitively, the algorithm is based on the simple observation that the kNN decision rule will correctly classify an example if its k-nearest neighbors share the same label. The algorithm attempts to increase the number of training examples with this property by learning a linear transformation of the input space that precedes kNN classification using Euclidean distances. The linear transformation is derived by minimizing a loss function that consists of two terms. The first term penalizes large distances between examples in the same class that are desired as k-nearest neighbors, while the second term penalizes small distances between examples with non-matching labels. Minimizing these terms yields a linear transformation of the input space that increases the number of training examples whose k-nearest neighbors have matching labels. The Euclidean distances in the transformed space can equivalently be viewed as Mahalanobis distances in the original space. We exploit this equivalence to cast the problem of distance metric learning as a problem in convex optimization.

Our approach is largely inspired by recent work on neighborhood component analysis (Goldberger et al., 2005) and metric learning in energy-based models (Chopra et al., 2005). Despite similar goals, however, our method differs significantly in the proposed optimization. We formulate the problem of distance metric learning as an instance of semidefinite programming. Thus, the optimization is convex, and its global minimum can be efficiently computed. There have been other studies in distance metric learning based on eigenvalue problems (Shental et al., 2002; De Bie et al., 2003) and semidefinite programming (Globerson and Roweis, 2006; Shalev-Shwartz et al., 2004; Xing et al., 2002). These previous approaches, however, essentially attempt to learn distance metrics that cluster together *all* similarly labeled inputs, even those that are not k-nearest neighbors. This objective is far more difficult to achieve than what we propose. Moreover, it does not leverage the full power of kNN classification, whose accuracy does not require that all similarly labeled inputs be tightly clustered.

There are many parallels between our method and classification by support vector machines (SVMs)—most notably, a convex objective function based on the hinge loss, and the potential to work in nonlinear feature spaces by using the "kernel trick". In light of these parallels, we describe our approach as *large margin nearest neighbor* (LMNN) classification. Our framework can be viewed as the logical counterpart to SVMs in which kNN classification replaces linear classification.

Our framework contrasts with classification by SVMs, however, in one intriguing respect: it requires no modification for multiclass problems. Extensions of SVMs to multiclass problems typically involve combining the results of many binary classifiers, or they require additional machinery that is elegant but non-trivial (Crammer and Singer, 2001). In both cases the training time scales at least linearly in the number of classes. By contrast, our framework has no explicit dependence on the number of classes.

We also show how to extend our framework to learn multiple Mahalanobis metrics, each of them associated with a different class label and/or region of the input space. The multiple metrics are trained simultaneously by minimizing a single loss function. While the loss function couples metrics in different parts of the input space, the optimization remains an instance of semidefinite programming. The globally integrated training of local distance metrics distinguishes our approach from earlier work on discriminant adaptive kNN classification (Hastie and Tibshirani, 1996)

Our paper is organized as follows. Section 2 introduces the general problem of distance metric learning for *k*NN classification and reviews previous approaches that motivated our work. Section 3 describes our model for LMNN classification and formulates the required optimization as an instance of semidefinite programming. Section 4 presents experimental results on several data sets. Section 5 discusses several extensions to LMNN classification, including iterative re-estimation of target neighbors, locally adaptive Mahalanobis metrics in different parts of the input space, and "kernelization" of the basic algorithm. Section 6 describes faster implementations for training and testing in LMNN classification using ball trees. Section 7 concludes by summarizing our main contributions and sketching several directions of ongoing research. Finally, appendix A describes the special-purpose solver that we implemented for large scale problems in LMNN classification.

2. Background

In this section, we introduce the general problem of distance metric learning (section 2.1) and review a number of previously studied approaches. Broadly speaking, these approaches fall into three categories: eigenvector methods based on second-order statistics (section 2.2), convex optimizations over the space of positive semidefinite matrices (section 2.3), and fully supervised algorithms that directly attempt to optimize *k*NN classification error (section 2.4) .

2.1 Distance Metric Learning

We begin by reviewing some basic terminology. A mapping $D : \mathcal{X} \times \mathcal{X} \rightarrow \Re_0^+$ over a vector space $\mathcal{X}$ is called a **metric** if for all vectors $\forall \vec{x}_i, \vec{x}_j, \vec{x}_k \in \mathcal{X}$, it satisfies the properties:

1. $D(\vec{x}_i,\vec{x}_j) + D(\vec{x}_j,\vec{x}_k) \geq D(\vec{x}_i,\vec{x}_k)$ (triangular inequality).
2. $D(\vec{x}_i,\vec{x}_j) \geq 0$ (non-negativity).
3. $D(\vec{x}_i,\vec{x}_j) = D(\vec{x}_j,\vec{x}_i)$ (symmetry).
4. $D(\vec{x}_i,\vec{x}_j) = 0 \iff \vec{x}_i = \vec{x}_j$ (distinguishability).

Strictly speaking, if a mapping satisfies the first three properties but not the fourth, it is called a **pseudometric**. However, to simplify the discussion in what follows, we will often refer to pseudometrics as metrics, pointing out the distinction only when necessary.

We obtain a family of metrics over $\mathcal{X}$ by computing Euclidean distances after performing a linear transformation $\vec{x}' = \mathbf{L}\vec{x}$. These metrics compute squared distances as:

$$D_{\mathbf{L}}(\vec{x}_i,\vec{x}_j) = \|\mathbf{L}(\vec{x}_i - \vec{x}_j)\|_2^2, \tag{1}$$

where the linear transformation in Eq. (1) is parameterized by the matrix $\mathbf{L}$. It is simple to show that Eq. (1) defines a valid metric if $\mathbf{L}$ is full rank and a valid pseudometric otherwise.

It is common to express squared distances under the metric in Eq. (1) in terms of the square matrix:

$$\mathbf{M} = \mathbf{L}^\top \mathbf{L}. \tag{2}$$

Any matrix $\mathbf{M}$ formed in this way from a real-valued matrix $\mathbf{L}$ is guaranteed to be positive semidefinite (i.e., to have no negative eigenvalues). In terms of the matrix $\mathbf{M}$, we denote squared distances by

$$\mathcal{D}_{\mathbf{M}}(\vec{x}_i, \vec{x}_j) = (\vec{x}_i - \vec{x}_j)^\top \mathbf{M} (\vec{x}_i - \vec{x}_j), \tag{3}$$

and we refer to pseudometrics of this form as **Mahalanobis** metrics. Originally, this term was used to describe the quadratic forms in Gaussian distributions, where the matrix $\mathbf{M}$ played the role of the inverse covariance matrix. Here we allow $\mathbf{M}$ to denote any positive semidefinite matrix. The distances in Eq. (1) and Eq. (3) can be viewed as generalizations of Euclidean distances. In particular, Euclidean distances are recovered by setting $\mathbf{M}$ to be equal to the identity matrix.

A Mahalanobis distance metric can be parameterized in terms of the matrix $\mathbf{L}$ or the matrix $\mathbf{M}$. Note that the matrix $\mathbf{L}$ uniquely defines the matrix $\mathbf{M}$, while the matrix $\mathbf{M}$ defines $\mathbf{L}$ up to rotation (which does not affect the computation of distances). This equivalence suggests two different approaches to distance metric learning. In particular, we can either estimate a linear transformation $\mathbf{L}$, or we can estimate a positive semidefinite matrix $\mathbf{M}$. Note that in the first approach, the optimization is unconstrained, while in the second approach, it is important to enforce the constraint that the matrix $\mathbf{M}$ is positive semidefinite. Though generally more complicated to solve a constrained optimization, this second approach has certain advantages that we explore in later sections.

Many researchers have proposed ways to estimate Mahalanobis distance metrics for the purpose of computing distances in *k*NN classification. In particular, let $\{(\vec{x}_i, y_i)\}_{i=1}^n$ denote a training set of n labeled examples with inputs $\vec{x}_i \in \Re^d$ and discrete (but not necessarily binary) class labels $y_i \in \{1, 2, \ldots, \mathcal{C}\}$. For *k*NN classification, one seeks a linear transformation such that nearest neighbors computed from the distances in Eq. (1) share the same class labels. We review several previous approaches to this problem in the following section.

2.2 Eigenvector Methods

Eigenvector methods have been widely used to discover informative linear transformations of the input space. As discussed in section 2.1, these linear transformations can be viewed as inducing a Mahalanobis distance metric. Popular eigenvector methods for linear preprocessing are principal component analysis, linear discriminant analysis, and relevant component analysis. These methods differ in the way that they use labeled or unlabeled data to derive linear transformations of the input space. These methods can also be "kernelized" to work in a nonlinear feature space (Müller et al., 2001; Schölkopf et al., 1998; Tsang et al., 2005), though we do not discuss such formulations here.

2.2.1 PRINCIPAL COMPONENT ANALYSIS

We briefly review principal component analysis (PCA) (Jolliffe, 1986) in the context of distance metric learning. Essentially, PCA computes the linear transformation $\vec{x}_i \rightarrow \mathbf{L}\vec{x}_i$ that projects the training inputs $\{\vec{x}_i\}_{i=1}^n$ into a variance-maximizing subspace. The variance of the projected inputs can be written in terms of the covariance matrix:

$$\mathbf{C} = \frac{1}{n}\sum_{i=1}^{n}(\vec{x}_i - \vec{\mu})^\top(\vec{x}_i - \vec{\mu}),$$

where $\vec{\mu} = \frac{1}{n}\sum_i \vec{x}_i$ denotes the sample mean. The linear transformation $\mathbf{L}$ is chosen to maximize the variance of the projected inputs, subject to the constraint that $\mathbf{L}$ defines a projection matrix. In terms of the input covariance matrix, the required optimization is given by:

$$\max_{\mathbf{L}} \mathrm{Tr}(\mathbf{L}^\top \mathbf{C}\mathbf{L}) \text{ subject to: } \mathbf{L}\mathbf{L}^\top = \mathbf{I}. \tag{4}$$

The optimization in Eq. (4) has a closed-form solution; the standard convention equates the rows of $\mathbf{L}$ with the leading eigenvectors of the covariance matrix. If $\mathbf{L}$ is a rectangular matrix, the linear transformation projects the inputs into a lower dimensional subspace. If $\mathbf{L}$ is a square matrix, then the transformation does not reduce the dimensionality, but this solution still serves to rotate and re-order the input coordinates by their respective variances.

Note that PCA operates in an unsupervised setting without using the class labels of training inputs to derive informative linear projections. Nevertheless, PCA still has certain useful properties as a form of linear preprocessing for kNN classification. For example, PCA can be used for "de-noising": projecting out the components of the bottom eigenvectors often reduces kNN error rate. PCA can also be used to accelerate neighbor nearest computations in large data sets. The linear preprocessing from PCA can significantly reduce the amount of computation either by explicitly reducing the dimensionality of the inputs, or simply by re-ordering the input coordinates in terms of their variance (as discussed further in section 6).

2.2.2 LINEAR DISCRIMINANT ANALYSIS

We briefly review linear discriminant analysis (LDA) (Fisher, 1936) in the context of distance metric learning. Let Ω_c denote the set of indices of examples in the cth class (with $y_i = c$). Essentially, LDA computes the linear projection $\vec{x}_i \to \mathbf{L}\vec{x}_i$ that maximizes the amount of between-class variance relative to the amount of within-class variance. These variances are computed from the between-class and within-class covariance matrices, defined by:

$$\begin{aligned} \mathbf{C}_b &= \frac{1}{\mathcal{C}}\sum_{c=1}^{\mathcal{C}} \vec{\mu}_c \vec{\mu}_c^\top, \\ \mathbf{C}_w &= \frac{1}{n}\sum_{c=1}^{\mathcal{C}}\sum_{i\in\Omega_c}(\vec{x}_i - \vec{\mu}_c)(\vec{x}_i - \vec{\mu}_c)^\top, \end{aligned} \tag{5}$$

where $\vec{\mu}_c$ denotes the sample mean of the c^{th} class; we also assume that the data is globally centered. The linear transformation $\mathbf{L}$ is chosen to maximize the ratio of between-class to within-class variance, subject to the constraint that $\mathbf{L}$ defines a projection matrix. In terms of the above covariance matrices, the required optimization is given by:

$$\max_{\mathbf{L}} \mathrm{Tr}\left(\frac{\mathbf{L}^\top \mathbf{C}_b \mathbf{L}}{\mathbf{L}^\top \mathbf{C}_w \mathbf{L}}\right) \text{ subject to: } \mathbf{L}\mathbf{L}^\top = \mathbf{I}. \tag{6}$$

The optimization in Eq. (6) has a closed-form solution; the standard convention equates the rows of $\mathbf{L}$ with the leading eigenvectors of $\mathbf{C}_w^{-1}\mathbf{C}_b$.

LDA is widely used as a form of linear preprocessing for pattern classification. Unlike PCA, LDA operates in a supervised setting and uses the class labels of the inputs to derive informative linear projections. Note that the between-class covariance matrix $\mathbf{C}_b$ in Eq. (5) has at most rank $\mathcal{C}$, where $\mathcal{C}$ is the number of classes. Thus, up to $\mathcal{C}$ linear projections can be extracted from the eigenvalue problem in LDA. Because these projections are based on second-order statistics, they work well to separate classes whose conditional densities are multivariate Gaussian. When this assumption does not hold, however, LDA may extract spurious features that are not well suited to kNN classification.

2.2.3 RELEVANT COMPONENT ANALYSIS

Finally, we briefly review relevant component analysis (RCA) (Shental et al., 2002; Bar-Hillel et al., 2006) in the context of distance metric learning. RCA is intermediate between PCA and LDA in its use of labeled data. Specifically, RCA makes use of so-called "chunklet" information, or subclass membership assignments. A chunklet is essentially a subset of a class. Inputs in the same chunklet belong to the same class, but inputs in different chunklets do not necessarily belong to different classes. Essentially, RCA computes the linear projection $\vec{x}_i \longrightarrow \mathbf{L}\vec{x}_i$ that "whitens" the data with respect to the averaged within-chunklet covariance matrix. In particular, let Ω_ℓ denote the set of indices of examples in the ℓth chunklet, and let $\vec{\mu}_\ell$ denote the mean of these examples. The averaged within-chunklet covariance matrix is given by:

$$\mathbf{C}_w = \frac{1}{n}\sum_{l=1}^{L}\sum_{i\in\Omega_l}(\vec{x}_i - \vec{\mu}_l)(\vec{x}_i - \vec{\mu}_l)^\top .$$

RCA uses the linear transformation $\vec{x}_i \longrightarrow \mathbf{L}\vec{x}_i$ with $\mathbf{L} = \mathbf{C}_w^{-1/2}$. This transformation acts to normalize the within-chunklet variance. An unintended side effect of this transformation may be to amplify noisy directions in the data. Thus, it is recommended to de-noise the data by PCA before computing the within-chunklet covariance matrix.

2.3 Convex Optimization

Recall that the goal of distance metric learning can be stated in two ways: to learn a linear transformation $\vec{x}_i \longrightarrow \mathbf{L}\vec{x}_i$ or, equivalently, to learn a Mahalanobis metric $\mathbf{M} = \mathbf{L}\mathbf{L}^\top$. It is possible to formulate certain types of distance metric learning as convex optimizations over the cone of positive semidefinite matrices $\mathbf{M}$. In this section, we review two previous approaches based on this idea.

2.3.1 MAHALANOBIS METRIC FOR CLUSTERING

A convex objective function for distance metric learning was first proposed by Xing et al. (2002). The goal of this work was to learn a Mahalanobis metric for clustering (MMC) with side-information. MMC shares a similar goal as LDA: namely, to minimize the distances between similarly labeled inputs while maximizing the distances between differently labeled inputs. MMC differs from LDA in its formulation of distance metric learning as an convex optimization problem. In particular, whereas LDA solves the eigenvalue problem in Eq. (6) to compute the linear transformation $\mathbf{L}$, MMC solves a convex optimization over the matrix $\mathbf{M} = \mathbf{L}^\top\mathbf{L}$ that directly represents the Mahalanobix metric itself.

To state the optimization for MMC, it is helpful to introduce further notation. From the class labels y_i, we define the $n \times n$ binary association matrix with elements $y_{ij} = 1$ if $y_i = y_j$ and $y_{ij} = 0$ otherwise. In terms of this notation, MMC attempts to maximize the distances between pairs of inputs with different labels ($y_{ij} = 0$), while constraining the sum over squared distances of pairs of similarly labeled inputs ($y_{ij} = 1$). In particular, MMC solves the following optimization:

$$\boxed{\begin{array}{l} \textbf{Maximize } \sum_{ij}(1-y_{ij})\sqrt{\mathcal{D}_{\mathbf{M}}(\vec{x}_i,\vec{x}_j)} \textbf{ subject to:} \\ \quad\quad \textbf{(1) } \sum_{ij} y_{ij}\mathcal{D}_{\mathbf{M}}(\vec{x}_i,\vec{x}_j) \ \leq\ 1 \\ \quad\quad \textbf{(2) } \mathbf{M} \succeq 0\textbf{.} \end{array}}$$

The first constraint is required to make the problem feasible and bounded; the second constraint enforces that $\mathbf{M}$ is a positive semidefinite matrix. The overall optimization is convex. The square root in the objective function ensures that MMC leads to generally different results than LDA.

MMC was designed to improve the performance of iterative clustering algorithms such as k-means. In these algorithms, clusters are generally modeled as normal or unimodal distributions. MMC builds on this assumption by attempting to minimize distances between all pairs of similarly labeled inputs; this objective is only sensible for unimodal clusters. For this reason, however, MMC is not especially appropriate as a form of distance metric learning for kNN classification. One of the major strengths of kNN classification is its non-parametric framework. Thus a different objective for distance metric learning is needed to preserve this strength of kNN classification—namely, that it does not implicitly make parametric (or other limiting) assumptions about the input distributions.

2.3.2 ONLINE LEARNING OF MAHALANOBIS DISTANCES

Convex optimizations over the cone of positive semidefinite matrices have also been proposed for perceptron-like approaches to distance metric learning. The Pseudometric Online Learning Algorithm (POLA) (Shalev-Shwartz et al., 2004) combines ideas from convex optimization and large margin classification. Like LDA and MMC, POLA attempts to learn a metric that shrinks distances between similarly labeled inputs and expands distances between differently labeled inputs. POLA differs from LDA and MMC, however, in explicitly encouraging a finite margin that separates differently labeled inputs. POLA was also conceived in an online setting.

The online version of POLA works as follows. At time t, the learning environment presents a tuple $(\vec{x}_t, \vec{x}'_t, y_t)$, where the binary label y_t indicates whether the two inputs $\vec{x}_t$ and $\vec{x}'_t$ belong to the same ($y_t = 1$) or different ($y_t = -1$) classes. From streaming tuples of this form, POLA attempts to learn a Mahalanobis metric $\mathbf{M}$ and a scalar threshold b such that similarly labeled inputs are *at most* a distance of $b - 1$ apart, while differently labeled inputs are *at least* a distance of $b + 1$ apart. These constraints can be expressed by the single inequality:

$$y_t \left[b - \left(\vec{x}_t - \vec{x}'_t\right)^{\top} \mathbf{M} \left(\vec{x}_t - \vec{x}'_t\right) \right] \geq 1. \tag{7}$$

The distance metric $\mathbf{M}$ and threshold b are updated after each tuple $(\vec{u}_t, \vec{v}_t, y_t)$ to correct any violation of this inequality. In particular, the update computes a positive semidefinite matrix $\mathbf{M}$ that satisfies (7). The required optimization can be performed by an alternating projection algorithm, similar to the one described in appendix A. The algorithm extends naturally to problems with more than two classes.

POLA can also be implemented on a data set of fixed size. In this setting, pairs of inputs are repeatedly processed until no pair violates its margin constraints by more than some constant $\beta > 0$. Moreover, as in perceptron learning, the number of iterations over the data set can be bounded above (Shalev-Shwartz et al., 2004).

In many ways, POLA exhibits the same strengths and weaknesses as MMC. Both algorithms are based on convex optimizations that do not have spurious local minima. On the other hand, both algorithms make implicit assumptions about the distributions of inputs and class labels. The margin constraints enforced by POLA are designed to learn a distance metric under which all pairs of similarly labeled inputs are closer than all pairs of differently labeled inputs. This type of learning may often be unrealizable, however, even in situations where *k*NN classification is able to succeed. For this reason, a different framework is required to learn distance metrics for *k*NN classification.

2.4 Neighborhood Component Analysis

Recently, Goldberger et al. (2005) considered how to learn a Mahalnobis distance metric especially for *k*NN classification. They proposed a novel supervised learning algorithm known as *Neighborhood Component Analysis* (NCA). The algorithm computes the expected leave-one-out classification error from a stochastic variant of *k*NN classification. The stochastic classifier uses a Mahalanobis distance metric parameterized by the linear transformation $\vec{x} \rightarrow \mathbf{L}\vec{x}$ in Eqs. (1–3). The algorithm attempts to estimate the linear transformation $\mathbf{L}$ that minimizes the expected classification error when distances are computed in this way.

The stochastic classifier in NCA is used to label queries by the majority vote of nearby training examples, but not necessarily the k nearest neighbors. In particular, for each query, the reference examples in the training set are drawn from a softmax probability distribution that favors nearby examples over faraway ones. The probability of drawing $\vec{x}_j$ as a reference example for $\vec{x}_i$ is given by:

$$p_{ij} = \begin{cases} \frac{\exp\left(-\|\mathbf{L}x_i - \mathbf{L}x_j\|^2\right)}{\sum_{k\neq i}\exp\left(-\|\mathbf{L}x_i - \mathbf{L}x_k\|^2\right)} & \text{if } i \neq j \\ 0 & \text{if } i = j. \end{cases} \tag{8}$$

Note that there is no free parameter k for the number of nearest neighbors in this stochastic classifier. Instead, the scale of $\mathbf{L}$ determines the size of neighborhoods from which nearby training examples are sampled. On average, though, this sampling procedure yields similar results as a deterministic *k*NN classifier (for some value of k) with the same Mahalanobis distance metric.

Under the softmax sampling scheme in Eq. (8), it is simple to compute the expected leave-one-out classification error on the training examples. As in section 2.3.1, we define the $n \times n$ binary matrix with elements $y_{ij} = 1$ if $y_i = y_j$ and $y_{ij} = 0$ otherwise. The expected error computes the fraction of training examples that are (on average) misclassified:

$$\varepsilon_{\text{NCA}} = 1 - \frac{1}{n}\sum_{ij} p_{ij} y_{ij}. \tag{9}$$

The error in Eq. (9) is a continuous, differentiable function of the linear transformation $\mathbf{L}$ used to compute Mahalanobis distances in Eq. (8).

Note that the differentiability of Eq. (9) depends on the stochastic neighborhood assignment of the NCA decision rule. By contrast, the leave-one-out error of a deterministic *k*NN classifier is neither continuous nor differentiable in the parameters of the distance metric. For distance metric learning, the differentiability of Eq. (9) is a key advantage of stochastic neighborhood assignment, making it possible to minimize this error measure by gradient descent. It would be much more difficult to minimize the leave-one-out error of its deterministic counterpart.

The objective function for NCA differs in one important respect from other algorithms reviewed in this section. Though continuous and differentiable with respect to the parameters of the distance metric, Eq. (9) is not convex, nor can it be minimized using eigenvector methods. Thus, the optimization in NCA can suffer from spurious local minima. In practice, the results of the learning algorithm depend on the initialization of the distance metric.

The linear transformation in NCA can also be used to project the inputs into a lower dimensional Euclidean space. Eqs. (8–9) remain valid when $\mathbf{L}$ is a rectangular as opposed to square matrix. Lower dimensional projections learned by NCA can be used to visualize class structure and/or to accelerate *k*NN search.

Recently, Globerson and Roweis (2006) proposed a related model known as Metric Learning by Collapsing Classes (MLCC). The goal of MLCC is to find a distance metric that (like LDA) shrinks the within-class variance while maintaining the separation between different classes. MLCC uses a similar rule as NCA for stochastic classification, so as to yield a differentiable objective function. Compared to NCA, MLCC has both advantages and disadvantages for distance metric learning. The main advantage is that distance metric learning in MLCC can be formulated as a convex optimization over the space of positive semidefinite matrices. The main disadvantage is that MLCC implicitly assumes that the examples in each class have a unimodal distribution. In this sense, MLCC shares the same basic strengths and weaknesses of the methods described in section 2.3.

3. Model

The model we propose for distance metric learning builds on the algorithms reviewed in section 2. In common with all of them, we attempt to learn a Mahalanobis distance metric of the form in Eqs. (1–3). Other key aspects of our model build on the particular strengths of individual approaches. As in MMC (see section 2.3.1), we formulate the parameter estimation in our model as a convex optimization over the space of positive semidefinite matrices. As in POLA (see section 2.3.2), we attempt to maximize the margin by which the model correctly classifies labeled examples in the training set. Finally, as in NCA (see section 2.4), our model was conceived specifically to learn a Mahalanobis distance metric that improves the accuracy of *k*NN classification. Indeed, the three essential ingredients of our model are (i) its convex loss function, (ii) its goal of margin maximization, and (iii) the constraints on the distance metric imposed by accurate *k*NN classification.

3.1 Intuition and Terminology

Our model is based on two simple intuitions (and idealizations) for robust *k*NN classification: first, that each training input $\vec{x}_i$ should share the same label y_i as its k nearest neighbors; second, that training inputs with different labels should be widely separated. We attempt to learn a linear transformation of the input space such that the training inputs satisfy these properties. In fact, these objectives are neatly balanced by two competing terms in our model's loss function. Specifically, one term penalizes large distances between nearby inputs with the same label, while the other term penalizes small distances between inputs with different labels. To make precise these relative notions of "large" and "small", however, we first need to introduce some new terminology.

Learning in our framework requires auxiliary information beyond the label y_i of each input $\vec{x}_i$ in the training set. Recall that the goal of learning is to estimate a distance metric under which each input $\vec{x}_i$ has k nearest neighbors that share its same label y_i. We facilitate this goal by identifying *target neighbors* for each input $\vec{x}_i$ at the outset of learning. The target neighbors of $\vec{x}_i$ are those that we desire to be closest to $\vec{x}_i$; in particular, we attempt to learn a linear transformation of the input space such that the resulting nearest neighbors of $\vec{x}_i$ are indeed its target neighbors. We emphasize that target neighbors are fixed a priori and do not change during the learning process. This step significantly simplifies the learning process by specifying a priori which similarly labeled inputs to cluster together. In many applications, there may be prior knowledge or auxiliary information (e.g., a similarity graph) that naturally identifies target neighbors. In the absence of prior knowledge, the simplest prescription is to compute the k nearest neighbors with the same class label, as determined by Euclidean distance. This was done for all the experiments in this paper. We use the notation $j \rightsquigarrow i$ to indicate that input $\vec{x}_j$ is a target neighbor of input $\vec{x}_i$. Note that this relation is not symmetric: $j \rightsquigarrow i$ does not imply $i \rightsquigarrow j$.

For kNN classification to succeed, the target neighbors of each input $\vec{x}_i$ should be closer than all differently labeled inputs. In particular, for each input $\vec{x}_i$, we can imagine the target neighbors as establishing a perimeter that differently labeled inputs should not invade. We refer to the differently labeled inputs in the training set that invade this perimeter as *impostors*; the goal of learning (roughly speaking) is to minimize the number of impostors.

In fact, to increase the robustness of kNN classification, we adopt an even more stringent goal for learning—namely to maintain a large (finite) distance between impostors and the perimeters established by target neighbors. By maintaining a *margin* of safety around the kNN decision boundaries, we ensure that the model is robust to small amounts of noise in the training inputs. This robustness criterion also gives rise to the name of our approach: *large margin nearest neighbor* (LMNN) classification.

In mathematical terms, impostors are defined by a simple inequality. For an input $\vec{x}_i$ with label y_i and target neighbor $\vec{x}_j$, an impostor is any input $\vec{x}_l$ with label $\vec{y}_l \neq \vec{y}_i$ such that

$$\|\mathbf{L}(\vec{x}_i - \vec{x}_l)\|^2 \leq \|\mathbf{L}(\vec{x}_i - \vec{x}_j)\|^2 + 1. \tag{10}$$

In other words, an impostor $\vec{x}_l$ is any differently labeled input that invades the perimeter plus unit margin defined by any target neighbor $\vec{x}_j$ of the input $\vec{x}_i$.

Figure 1 illustrates the main idea behind LMNN classification. Before learning, a training input has both target neighbors and impostors in its local neighborhood. During learning, the impostors are pushed outside the perimeter established by the target neighbors. After learning, there exists a finite margin between the perimeter and the impostors. The figure shows the idealized scenario where kNN classification errors in the original input space are corrected by learning an appropriate linear transformation.

3.2 Loss Function

With the intuition and terminology from the previous section, we can now construct a loss function for LMNN classification. The loss function consists of two terms, one which acts to *pull* target neighbors closer together, and another which acts to *push* differently labeled examples further apart.

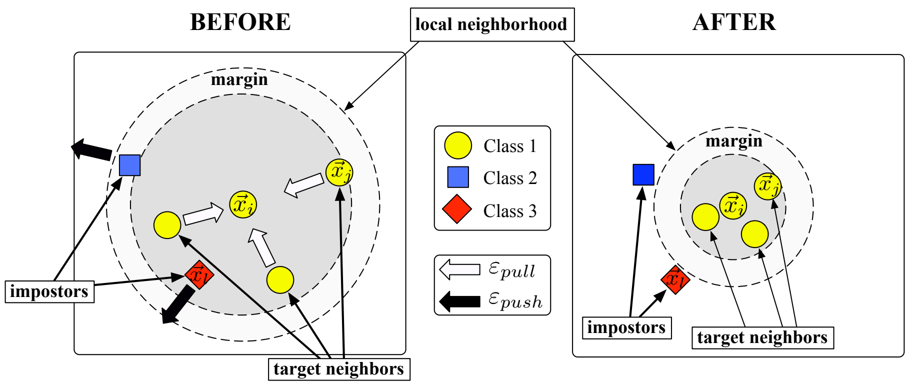

Figure 1: Schematic illustration of one input's neighborhood before training (*left*) versus after training (*right*). The distance metric is optimized so that: (i) its $k=3$ target neighbors lie within a smaller radius after training; (ii) differently labeled inputs lie outside this smaller radius by some finite margin. Arrows indicate the gradients on distances arising from different terms in the cost function.

These two terms have competing effects, since the first is reduced by shrinking the distances between examples while the second is generally reduced by magnifying them. We discuss each term in turn.

The first term in the loss function penalizes large distances between each input and its target neighbors. In terms of the linear transformation $\mathbf{L}$ of the input space, the sum of these squared distances is given by:

$$\varepsilon_{\text{pull}}(\mathbf{L}) = \sum_{j \rightsquigarrow i} \|\mathbf{L}(\vec{x}_i - \vec{x}_j)\|^2. \tag{11}$$

The gradient of this term generates a pulling force that attracts target neighbors in the linearly transformed input space. It is important that Eq. (11) only penalizes large distances between inputs and their *target neighbors*; in particular, it does not penalize large distances between all similarly labeled inputs. We purposefully do not penalize the latter because accurate kNN classification does not require that all similarly labeled inputs be tightly clustered. Our approach is distinguished in this way from many previous approaches to distance metric learning; see section 2. By only penalizing large distances between neighbors, we build models that leverage the full power of kNN classification.

The second term in the loss function penalizes small distances between differently labeled examples. In particular, the term penalizes violations of the inequality in Eq. (10). To simplify notation, we introduce a new indicator variable $y_{il}=1$ if and only if $y_i=y_l$, and $y_{il}=0$ otherwise. In terms of this notation, the second term of the loss function ε_{push} is given by:

$$\varepsilon_{\text{push}}(\mathbf{L}) = \sum_{i,j \rightsquigarrow i} \sum_{l} (1-y_{il}) \left[1 + \|\mathbf{L}(\vec{x}_i - \vec{x}_j)\|^2 - \|\mathbf{L}(\vec{x}_i - \vec{x}_l)\|^2\right]_+ \tag{12}$$

where the term $[z]_+ = \max(z, 0)$ denotes the standard hinge loss. The hinge loss monitors the inequality in Eq. (10). If the inequality does not hold (i.e., the input $\vec{x}_l$ lies a safe distance away from $\vec{x}_i$), then its hinge loss has a negative argument and makes no contribution to the overall loss function. The (sub-)gradient of Eq. (12) generates a pushing force that repels imposters away from the perimeter established by each example's k nearest (similarly labeled) neighbors; see Fig. 1.

The choice of unit margin is an arbitrary convention that sets the scale for the linear transformation $\mathbf{L}$ (which enters every other term in the loss function). If a margin $c > 0$ was enforced instead of the unit margin, the loss function would be minimized by the same linear transformation up to an overall scale factor $\sqrt{c}$.

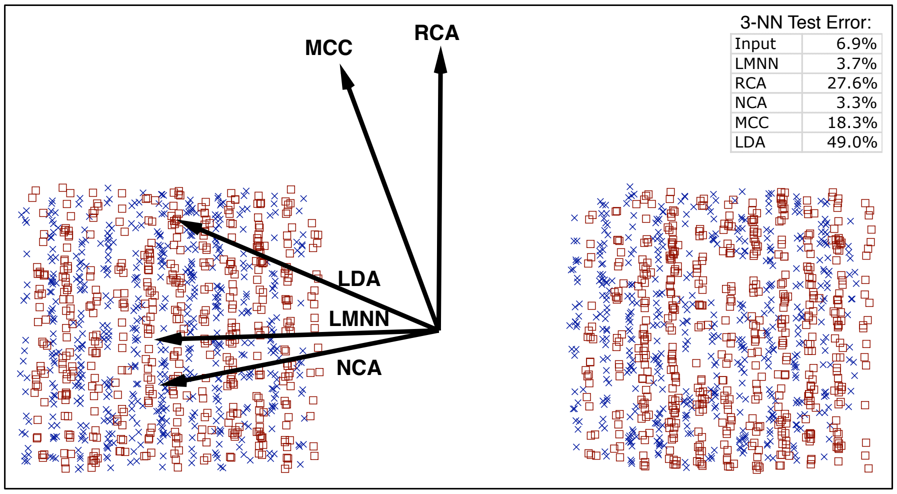
Finally, we combine the two terms $\varepsilon_{\text{pull}}(\mathbf{L})$ and $\varepsilon_{\text{push}}(\mathbf{L})$ into a single loss function for distance metric learning. The two terms can have competing effects—to attract target neighbors on one hand, to repel impostors on the other. A weighting parameter $\mu \in [0,1]$ balances these goals:

$$\varepsilon(\mathbf{L}) = (1-\mu)\,\varepsilon_{pull}(\mathbf{L}) + \mu\,\varepsilon_{push}(\mathbf{L}). \tag{13}$$

Generally, the parameter μ can be tuned via cross validation, though in our experience, the results from minimizing the loss function in Eq. (13) did not depend sensitively on the value of μ. In practice, the value $\mu = 0.5$ worked well.

The competing terms in Eq. (13) are analogous to those in the loss function for learning in SVMs (Schölkopf and Smola, 2002). In both loss functions, one term penalizes the norm of the "parameter" vector (i.e., the weight vector of the maximum margin hyperplane, or the linear transformation in the distance metric), while the other incurs the hinge loss. Just as the hinge loss in SVMs is only triggered by examples near the decision boundary, the hinge loss in Eq. (13) is only triggered by differently labeled examples that invade each other's neighborhoods. Both loss functions in SVMs and LMNN can be rewritten to depend on the input vectors only through their inner products. Working with the inner product matrix directly allows the application of the *kernel trick*; see section 5.3. Finally, as in SVMs, we can formulate the minimization of the loss function in Eq. (13) as a convex optimization. This last point will be developed further in section 3.4.

Our framework for distance metric learning provides an alternative to the earlier approach of NCA (Goldberger et al., 2005) described in section 2.4. We briefly compare the two approaches at a high level. Both LMNN and NCA are designed to learn a Mahalanobis distance metric over the input space that improves kNN classification at test time. Though test examples are not available during training, the learning algorithms for LMNN and NCA are based on training in "simulated" test conditions. Neither approach directly minimizes the leave-one-out error[1] for kNN classification over the training set. The leave-one-out error is a piecewise constant but non-smooth function of the linear transformation $\mathbf{L}$, making it difficult to minimize directly. NCA uses stochastic neighborhood assignment to construct a smooth loss function, thus circumventing this problem. LMNN uses the hinge loss to construct an upper bound on the leave-one-out error for kNN classification; this upper bound is continuous and similarly well behaved for standard gradient-based methods. In NCA, it is not necessary to select a fixed number k of target neighbors in advance of the optimization. Because the objective function for NCA is not convex, however, the initial conditions for the Mahalanobis metric implicitly favor the preservation of certain neighborhoods over others. By contrast, in LMNN, the target neighborhoods must be explicitly specified. A potential advantage of LMNN is that the required optimization can be formulated as an instance of semidefinite programming.



3-NN Test Error:

Input	6.9%
LMNN	3.7%
RCA	27.6%
NCA	3.3%
MCC	18.3%
LDA	49.0%

Figure 2: A toy data set for distance metric learning, with $n = 2000$ data points sampled from a bi-modal distribution. Within each mode, examples from two classes are distributed in alternating vertical stripes. The figure shows the dominant axis extracted by several different algorithms for distance metric learning. Only NCA and LMNN reduce the 1-NN classification error on this data set; the other algorithms actually increase the error by focusing on global versus local distances.

3.3 Local Versus Global Distances

We emphasize that the loss function for LMNN classification only penalizes large distances between target neighbors as opposed to all examples in the same class. The toy data set in Fig. 2 illustrates the potential advantages of this approach. The data was generated by sampling $n = 2000$ data points from two classes in a zebra striped pattern; additionally, the data for each class was generated in two sets of stripes displaced by a large horizontal offset. As a result, this data set has the property that within-class variance is much larger in the horizontal direction than the vertical direction; however, local class membership is much more reliably predicted by examples that are nearby in the vertical direction.

Algorithms such as LMNN and NCA perform very differently on this data set than algorithms such as LDA, RCA, and MCC. In particular, LMNN and NCA adapt to the local striped structure in the data set and learn distance metrics that significantly reduce the *k*NN error rate. By contrast, LDA, RCA, and MCC attempt to shrink distances between all examples in the same class and actually increase the *k*NN error rate as a result. Though this data set is especially contrived, it illustrates in general the problems posed by classes with multimodal support. Such classes violate a basic assumption behind metric learning algorithms that attempt to shrink global distances between all similarly labeled examples.

1. This is the number of training examples that *would have* been mislabeled by *k*NN classification if their label was in fact unknown.

3.4 Convex Optimization

The loss function in Eq. (13) is not convex in the matrix elements of the linear transformation $\mathbf{L}$. To minimize this loss function, one straightforward approach is gradient descent in the elements of $\mathbf{L}$. However, such an approach is prone to being trapped in local minima. The results of this form of gradient descent will depend in general on the initial estimates for $\mathbf{L}$. Thus they may not be reproducible across different problems and applications.

We can overcome these difficulties by reformulating the optimization of Eq. (13) as an instance of semidefinite programming (Boyd and Vandenberghe, 2004). A semidefinite program (SDP) is a linear program that incorporates an additional constraint on a symmetric matrix whose elements are linear in the unknown variables. This additional constraint requires the matrix to be positive semidefinite, or in other words, to only have nonnegative eigenvalues. This matrix constraint is nonlinear but convex, so that the overall optimization remains convex. There exist provably efficient algorithms to solve SDPs (with polynomial time convergence guarantees).

We begin by reformulating Eq. (13) as an optimization over positive semidefinite matrices. Specifically, as described in Eq. (2), we work in terms of the new variable $\mathbf{M} = \mathbf{L}^\top\mathbf{L}$. With this change of variable, we can rewrite the squared distances that appear in the loss function using Eq. (3). Recall that $\mathcal{D}_\mathbf{M}(\vec{x}_i,\vec{x}_j)$ denotes the squared distance with respect to the Mahalanobis metric $\mathbf{M}$. As shown in section 2.1, this distance is equivalent to the Euclidean distance after the mapping $\vec{x}_i \to \mathbf{L}\vec{x}_i$. Substituting Eq. (3) into Eq. (13), we obtain the loss function:

$$\varepsilon(\mathbf{M}) = (1-\mu)\sum_{i,j\rightsquigarrow i}\mathcal{D}_\mathbf{M}(\vec{x}_i,\vec{x}_j) + \mu\sum_{i,j\rightsquigarrow i}\sum_{l}(1-y_{il})\left[1+\mathcal{D}_\mathbf{M}(\vec{x}_i,\vec{x}_j)-\mathcal{D}_\mathbf{M}(\vec{x}_i,\vec{x}_l)\right]_+ . \tag{14}$$

With this substitution, the loss function is now expressed over positive semidefinite matrices $\mathbf{M} \succeq 0$, as opposed to real-valued matrices $\mathbf{L}$. Note that the constraint $\mathbf{M} \succeq 0$ must be added to the optimization to ensure that we learn a well-defined pseudometric.

The loss function in Eq. (14) is a piecewise linear, convex function of the elements in the matrix $\mathbf{M}$. In particular, the first term in the loss function (penalizing large distances between target neighbors) is linear in the elements of $\mathbf{M}$, while the second term (penalizing impostors) is derived from the convex hinge loss. To formulate the optimization of Eq. (14) as an SDP, however, we need to convert it into a more standard form.

An SDP is obtained by introducing slack variables which mimic the effect of the hinge loss. In particular, we introduce nonnegative slack variables $\{\xi_{ijl}\}$ for all triplets of target neighbors ($j \rightsquigarrow i$) and impostors $\vec{x}_l$. The slack variable $\xi_{ijl} \geq 0$ is used to measure the amount by which the large margin inequality in Eq. (10) is violated. Using the slack variables to monitor these margin violations, we obtain the SDP:

Minimize $(1-\mu)\sum_{i,j\rightsquigarrow i}(\vec{x}_i-\vec{x}_j)^\top\mathbf{M}(\vec{x}_i-\vec{x}_j) + \mu\sum_{i,j\rightsquigarrow i,l}(1-y_{il})\xi_{ijl}$ **subject to:**

(1) $(\vec{x}_i-\vec{x}_l)^\top\mathbf{M}(\vec{x}_i-\vec{x}_l) - (\vec{x}_i-\vec{x}_j)^\top\mathbf{M}(\vec{x}_i-\vec{x}_j) \;\geq\; 1-\xi_{ijl}$

(2) $\xi_{ijl} \geq 0$

(3) $\mathbf{M} \succeq 0$**.**

While SDPs in this form can be solved by standard solver packages, general-purpose solvers tend to scale poorly in the number of constraints. For this work, we implemented our own special-purpose solver, exploiting the fact that most of the slack variables $\{\xi_{ijl}\}$ never attain positive values. The slack variables $\{\xi_{ijl}\}$ are sparse because most inputs $\vec{x}_i$ and $\vec{x}_l$ are well separated relative to the distance between $\vec{x}_i$ and any of its target neighbors $\vec{x}_j$. Such triplets do not incur a positive hinge loss, resulting in very few *active* constraints in the SDP. Thus, a great speedup can be achieved by solving an SDP that only monitors a fraction of the margin constraints, then using the resulting solution as a starting point for the actual SDP of interest.

Our solver was based on a combination of sub-gradient descent in both the matrices **L** and **M**, the latter used mainly to verify that we had reached the global minimum. We projected updates in **M** back onto the positive semidefinite cone after each step. Alternating projection algorithms provably converge (Vandenberghe and Boyd, 1996), and in this case our implementation[2] worked much faster than generic solvers. For a more detailed description of the solver please see appendix A.

3.5 Energy Based Classification

The matrix **M** that minimizes the loss function in Eq. (14) can be used as a Mahalanobis distance metric for *k*NN classification. However, it is also possible to use the loss function directly as a so-called "energy-based" classifier. This use is inspired by previous work on energy-based models (Chopra et al., 2005).

Energy-based classification of a test example is done by considering it as an extra training example and computing the loss function in Eq. (14) for every possible label y_t. In particular, for a test example $\vec{x}_t$ with hypothetical label y_t, we locate k (similarly labeled) target neighbors (as determined by Euclidean distance to $\vec{x}_t$ or other a priori considerations) and then compute both terms in Eq. (14) given the already estimated Mahalanobis metric **M**. For the first term, we accumulate the squared distances to the k target neighbors of $\vec{x}_t$. For the second term, we accumulate the hinge loss over all impostors (i.e., differently labeled examples) that invade the perimeter around $\vec{x}_t$ as determined by its target neighbors; we also accumulate the hinge loss for differently labeled examples whose perimeters are invaded by $\vec{x}_t$. Finally, the test example is classified by the hypothetical label that minimizes the combination of these terms:

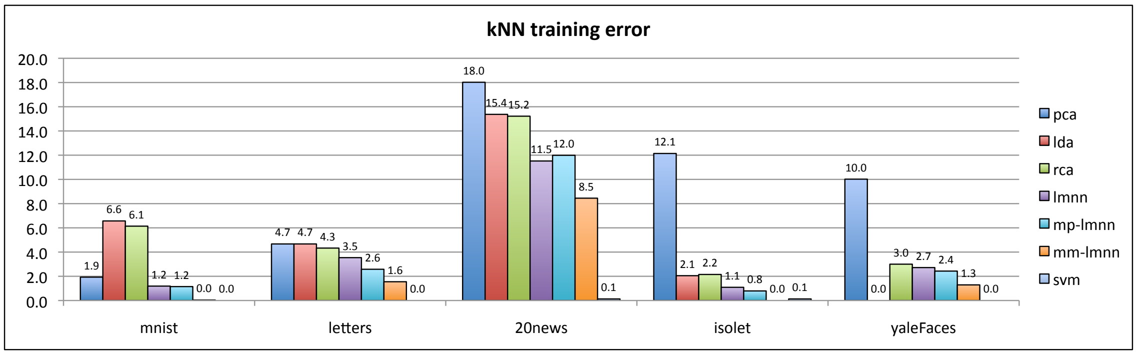
$$\begin{aligned} y_t \;=\; \operatorname{argmin}_{y_t} \Bigg\{ & (1-\mu) \sum_{j \rightsquigarrow t} \mathcal{D}_{\mathbf{M}}(\vec{x}_t, \vec{x}_j) + \mu \sum_{j \rightsquigarrow t, l} (1 - y_{tl}) \left[1 + \mathcal{D}_{\mathbf{M}}(\vec{x}_t, \vec{x}_j) - \mathcal{D}_{\mathbf{M}}(\vec{x}_t, \vec{x}_l)\right]_+ \\ & + \mu \sum_{i, j \rightsquigarrow i} (1 - y_{it}) \left[1 + \mathcal{D}_{\mathbf{M}}(\vec{x}_i, \vec{x}_j) - \mathcal{D}_{\mathbf{M}}(\vec{x}_i, \vec{x}_t)\right]_+ \Bigg\}. \end{aligned} \tag{15}$$

Note that the relation $j \rightsquigarrow t$ in this criterion depends on the value of y_t. As shown in Fig. 3, energy-based classification with this assignment rule generally leads to further improvements in test error rates. Often these improvements are significantly beyond those already achieved by adopting the Mahalanobis distance metric **M** for *k*NN classification.

4. Results

We evaluated LMNN classification on nine data sets of varying size and difficulty. Some of these data sets were derived from collections of images, speech, and text, yielding very high dimensional inputs. In these cases, we used PCA to reduce the dimensionality of the inputs before training LMNN classifiers. Pre-processing the inputs with PCA helped to reduce computation time and avoid overfitting. Table 1 compares the different data sets in detail.

2. A matlab implementation is currently available at `http://www.weinbergerweb.net/Downloads/LMNN.html`.



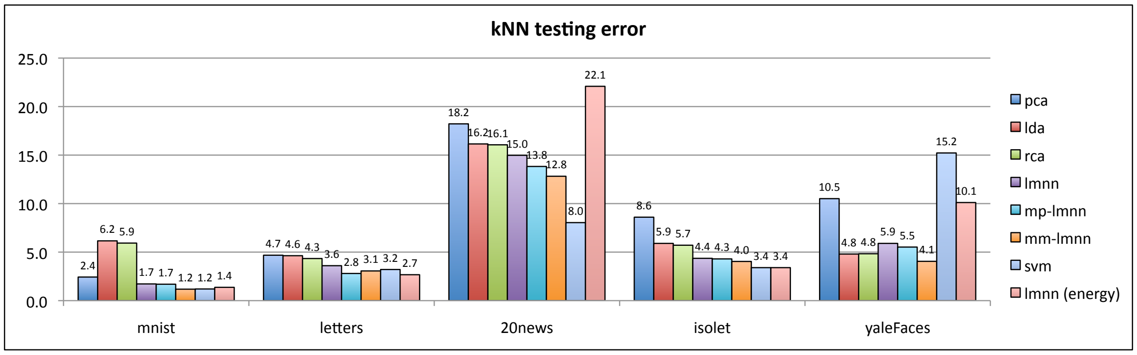


Figure 3: Training and test results on the five largest data sets, preprocessed in different ways, and using different variants of kNN classification. We compared principal component analysis (pca), linear discriminant analysis (lda), relevant component analysis (rca), large margin nearest neighbor classification (lmnn), lmnn with multiple passes (mp-lmnn), lmnn with multiple metrics (mm-lmnn), multi-class support vector machines (svm), lmnn classification with the energy based decision rule (lmnn (energy)). All variations of lmnn, rca and lda were applied after pre-processing with pca for general noise reduction. See text and Table 1 for details. The lmnn results consistently outperform pca and lda. The multiple metrics version of lmnn (mm-lmnn) is comparable with multiclass svm on most data sets (with 20news and yaleFaces as only exceptions).

Experimental results were obtained by averaging over multiple runs on randomly generated 70/30 splits of each data set. This procedure was followed with two exceptions: no averaging was done for the Isolet and MNIST data sets, which have pre-defined training/test splits. For all experiments reported in this paper, the number of target neighbors k was set to $k = 3$, and the weighting parameter μ in Eqs. (14-15) was set to $\mu = 0.5$. Though we experimented with different settings, the results from LMNN classification appeared fairly insensitive to the values of these parameters.

The main results on the five largest data sets are shown in Fig. 3. (See Table 1 for a complete listing of results, including those for various extensions of LMNN classification described in section 5.) All training error rates reported are leave-one-out estimates. To break ties among different classes from the *k*NN decision rule, we repeatedly reduced the neighborhood size, ultimately classifying (if necessary) by just the $k = 1$ nearest neighbor. We begin by reporting overall trends, then discuss the results on individual data sets in more detail.

The first general trend is that LMNN classification using Mahalanobis distances consistently improves on *k*NN classification using Euclidean distances. In general, the Mahalanobis metrics learned by semidefinite programming led to significant improvements in *k*NN classification, both in training and testing.

A second general trend is that the energy-based decision rule described in section 3.5 leads to further improvements over the (already improved) results from *k*NN classification using Mahalanobis distances. In particular, better performance was observed on most of the large data sets. The results are shown in Fig. 3.

A third general trend is that LMNN classification works better with PCA than LDA when some form of dimensionality reduction is required for preprocessing. Table 1 shows the results of LMNN classification on inputs whose dimensionality was reduced by LDA. While pre-processing by LDA helps on some data sets (e.g., wine, yale faces), it generally leads to worse results than pre-processing by PCA. On some data sets, moreover, it leads to drastically worse results (e.g., olivetti faces, MNIST). Consequently we used PCA as a pre-processing step for all subsequent experiments throughout this paper.

A fourth general trend is that LMNN classification yields larger improvements on larger data sets. Though we do not have a formal analysis that accounts for this observation, we can provide the following intuitive explanation. One crucial aspect of the optimization in LMNN classification is the choice of the *target neighbors*. In all of our experiments, we chose the target neighbors based on Euclidean distance in the input space (after dimensionality reduction by PCA or LDA). This choice was a simple heuristic used in the absence of prior knowledge. However, the quality of this choice presumably depends on the sample density of the data set. In particular, as the sample density increases, we suspect that more reliable discriminative signals can be learned from target neighbors chosen in this way. The experimental results bear this out.

Finally, we compare our results to those of competing methods. We take multi-class SVMs (Crammer and Singer, 2001) as providing a fair representation of the state-of-the-art. On each data set (except MNIST), we trained multi-class SVMs using linear, polynomial and RBF kernels and chose the best kernel with cross validation. On MNIST, we used a non-homogeneous polynomial kernel of degree four, which gave us our best results, as also reported in LeCun et al. (1995). The results of the energy-based LMNN classifier are very close to those of state-of-the-art multi-class SVMs: better on some data sets, worse on others. However, consistent improvement over multi-class SVMs was obtained by a multiple-metric variant of LMNN, discussed in section 5.2. This multi-metric extension outperformed SVMs on three of the five large data sets; see Fig. 3. On the only data set with a large performance difference, 20-newsgroups, the multi-class SVMs benefited from training in the original $d = 20000$ dimensional input space, whereas the LMNN classifiers were trained only on the input's leading $d = 200$ principal components. Based on these results, in section 7, we suggest some applications that seem particularly well suited to LMNN classification, though poorly suited to SVMs. These are applications with moderate input dimensionality, but large numbers of classes.

To compare with previous work, we also evaluated RCA (Shental et al., 2002), LDA (Fisher, 1936) and NCA (Goldberger et al., 2005) on the same data sets. For NCA and RCA, we used the code provided by the authors; however, the NCA code ran out of memory on the larger data sets.

Table 1 shows the results of all algorithms on small and larger data sets. LMNN outperforms these other methods for distance metric learning on the four largest data sets. In terms of running times, RCA is by far the fastest method (since its projections can be computed in closed form), while NCA is the slowest, mainly due to the $O(n^2)$ normalization of its softmax probability distributions. Although the optimization in LMNN naively scales as $O(n^2)$, in practice it can be accelerated by various efficiency measures: Appendix A discusses our semidefinite programming solver in detail. We did also include the results of MCC (Xing et al., 2002); however, the code provided by the authors could only handle a few of the small data sets. As shown in Table 1, on those data sets it resulted in classification rates generally higher than NCA.

The results of experiments on particular data sets provide additional insight into the performance of LMNN classification versus competing methods. We give a more detailed overview of these experiments in what follows.

4.1 Small Data Sets with Few Classes

The wine, iris, and bal data sets are small in size, with less than 500 training examples. Each of these data sets has three classes. The data sets are available from the UCI Machine Learning Repository.[3] On data sets of this size, a distance metric can be learned in a matter of seconds. The results in Table 1 were averaged over 100 experiments with different random 70/30 splits of each data set.

On these data sets, LMNN classification improves on kNN classification with a Euclidean distance metric. These results could potentially be improved further with better measures against overfitting (such as regularization). Table 1 also compares the results from LMNN classification to other competing methods. Here, the results are somewhat variable; compared to NCA, RCA, LDA, and multiclass SVMs, LMNN fares better in some cases, worse in others. We mainly report these results to facilitate direct comparisons with previously published work. However, the small size of these data sets makes it difficult to assess the significance of these results. Moreover, these data sets do not represent the regime in which we expect LMNN classification to be most useful.

4.2 Face Recognition

The Olivetti face recognition data set[4] contains 400 grayscale images of 40 subjects in 10 different poses. We downsampled the images to 38×31 pixels and used PCA to further reduce the dimensionality, projecting the images into the subspace spanned by the first 200 eigenfaces (Turk and Pentland, 1991). Training and test sets were created by randomly sampling 7 images of each subject for training and 3 images for testing. The task involved 40-way classification—essentially, recognizing a face from an unseen pose. Table 1 shows the improvements due to LMNN classification. Fig. 4 illustrates the improvements more graphically by showing how the $k=3$ nearest neighbors change as a result of learning a Mahalanobis metric. (Although the algorithm operated on downsampled, projected images, for clarity the figure shows the original images.)

The (extended) Yale face data set contains $n = 2414$ frontal images of 38 subjects. For each subject, there are 64 images taken under extreme illumination conditions. (A few subjects are represented with fewer images.) As for the Olivetti data set, we preprocessed the images by downsampling and projecting them onto their leading 200 principal components. To reduce the impact of the very high variance in illumination, we followed the standard practice of discarding the leading 5

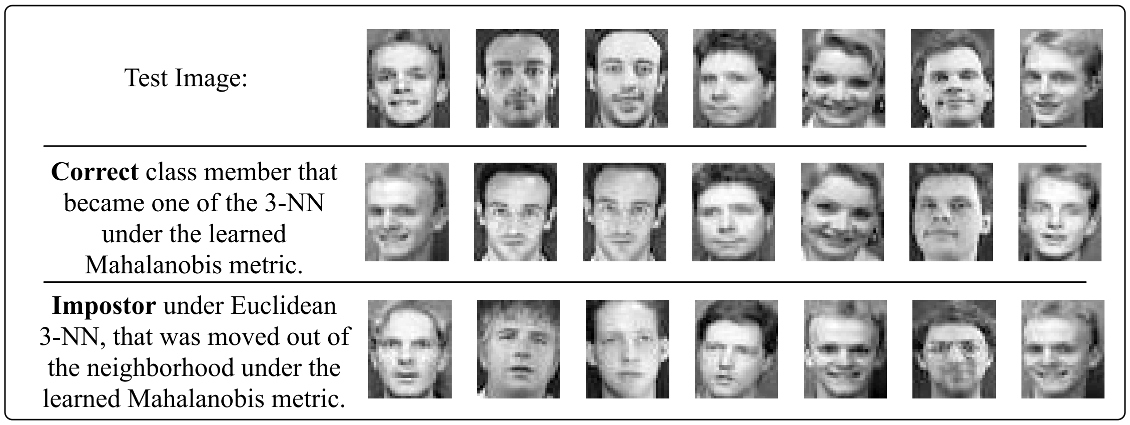
eigenvectors. Results from LMNN classification were averaged over 10 runs of 70/30 splits. Each split was obtained by randomly selecting 45 images of each subject for training and 19 images for testing. This protocol ensured that the training examples were evenly distributed across the relatively large number of classes. To guard against overfitting, we employed a validation set consisting of 30% of the training data and stopped the training early when the lowest classification error on the validation set was reached. On this data set, Fig. 3 shows that the LMNN metric outperforms the Euclidean metric and even improves on multiclass SVMs. (Particularly effective on this data set, though, is the simple strategy of LDA.)



Test Image:
Correct class member that became one of the 3-NN under the learned Mahalanobis metric.
Impostor under Euclidean 3-NN, that was moved out of the neighborhood under the learned Mahalanobis metric.

Figure 4: Test images from the Olivetti face recognition data set (*top row*). The middle row shows images from the same class that were among the 3-NN under the learned Mahalanobis metric (after training) but not among the original 3-NN under the Euclidean metric (before training). The bottom row shows impostors under the Euclidean metric that were no longer inside the local neighborhoods under the Mahalanobis metric.

4.3 Spoken Letter Recognition

The Isolet data set from the UCI Machine Learning Repository contains 6238 examples and 26 classes corresponding to letters of the alphabet. We reduced the input dimensionality (originally at 617) by projecting the data onto its leading 172 principal components—enough to account for 95% of its total variance. On this data set, Dietterich and Bakiri report test error rates of 4.2% using nonlinear backpropagation networks with 26 output units (one per class) and 3.3% using nonlinear backpropagation networks with a 30-bit error correcting code (Dietterich and Bakiri, 1995). LMNN with energy-based classification obtains a test error rate of 3.4%.

4.4 Letter Recognition

The letter recognition data set was also taken from the UCI Machine Learning Repository. It contains randomly distorted images of the 26 letters in the English alphabet in 20 different fonts. The features consist of 16 attributes, such as height, width, correlations of axes and others.[5] It is inter-

4.5 Text Categorization

The 20-newsgroups data set consists of posted articles from 20 newsgroups, with roughly 1000 articles per newsgroup. We used the 18828-version of the data set[6] in which cross-postings are removed and some headers stripped out. The data set was tokenized using the rainbow package (McCallum, 1996). Each article was initially represented by a word-count vector for the 20,000 most common words in the vocabulary. These word-count vectors were then reduced in dimensionality by projecting them onto their leading 200 principal components. The results in Fig. 3 were obtained by averaging over 10 runs with 70/30 splits for training and test data. The best result for LMMN on this data set improved significantly over *k*NN classification using Euclidean distances and PCA (with 14.98% versus 48.57% and 18.22% test error rates). LMNN was outperformed by multiclass SVM (Crammer and Singer, 2001), which obtained a 8.0% test error rate using a linear kernel and 20000 dimensional inputs.[7]

4.6 Handwritten Digit Recognition

The MNIST data set of handwritten digits[8] has been extensively benchmarked (LeCun et al., 1995). We deskewed the original 28×28 grayscale images, then reduced their dimensionality by projecting them onto their leading 164 principal components (enough to capture 95% of the data's overall

Table 1: Results and statistics from all experiments. The data sets are sorted by largest to smallest from left to right. The table shows data statistics and error rates from different variants of LMNN training (single-pass, multi-pass, multi-metric), testing (*k*NN decision rule, energy-based classification), and preprocessing (PCA, LDA). Results from RCA, NCA and multiclass support vector machines (SVMs) are also provided for comparison. See section 5 for discussion of multi-pass and multi-metric LMNN training.

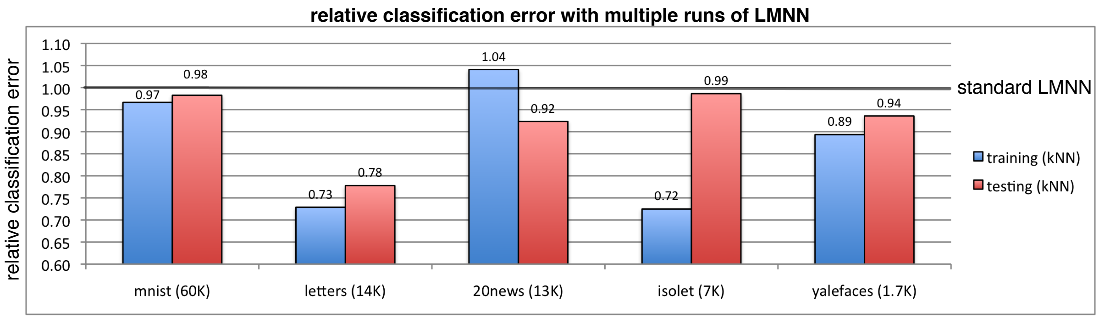

Figure 6: The relative change of the 3-NN classification error after multiple runs of LMNN over a single run of LMNN.

variance). Energy-based LMNN classification yielded a test error rate at 1.4%, cutting the baseline *k*NN error rate by over one-third. Other comparable benchmarks (LeCun et al., 1995) (not exploiting additional prior knowledge) include multilayer neural nets at 1.6% and SVMs at 1.2%. Fig. 5 shows some digits whose nearest neighbor changed as a result of learning, from a mismatch using Euclidean distances to a match using Mahalanobis distances. Table 1 reveals that the LMNN error can be further reduced by learning a different distance metric for each digit class. This is discussed further in section 5.2.

5. Extensions

In this section, we investigate four extensions designed to improve LMNN classification. Section 5.1 examines the impact of multiple consecutive applications of LMNN on one data set. Section 5.2 shows how to learn multiple (locally linear) metrics instead of a single global metric. Section 5.3 discusses how to "kernelize" the algorithm for LMNN classification and reviews complementary work by Torresani and Lee (2007). Finally, section 5.4 investigates the use of LMNN as a method for supervised dimensionality reduction.

5.1 Multi-pass LMNN

One potential weakness of LMNN is that target neighbors must be a priori specified. In the absence of prior knowledge, a default choice is to use Euclidean distances to determine target nearest neighbors. While the target nearest neighbors are fixed during learning, however, the actual nearest neighbors may change as a result of the linear transformation of the input space. These changes suggest an iterative approach, in which the Mahalanobis distances learned in one application (or "pass") of LMNN are used to determine the target nearest neighbors in a subsequent run of the algorithm. More formally, let $\mathbf{L}_p$ be the transformation matrix obtained from the p^{th} pass of LMNN. For the $(p+1)^{th}$ pass, we can assign target neighbors using the Euclidean distance metric after the linear transformation $\vec{x}_i \rightarrow \mathbf{L}_p\mathbf{L}_{p-1}...\mathbf{L}_1\mathbf{L}_0\vec{x}_i$ (with $\mathbf{L}_0 = \mathbf{I}$).

To evaluate this approach, we performed multiple passes of LMNN on all the data sets from Table 1. The parameter k was set to $k = 3$. Figure 6 shows the relative improvements in *k*NN classi-

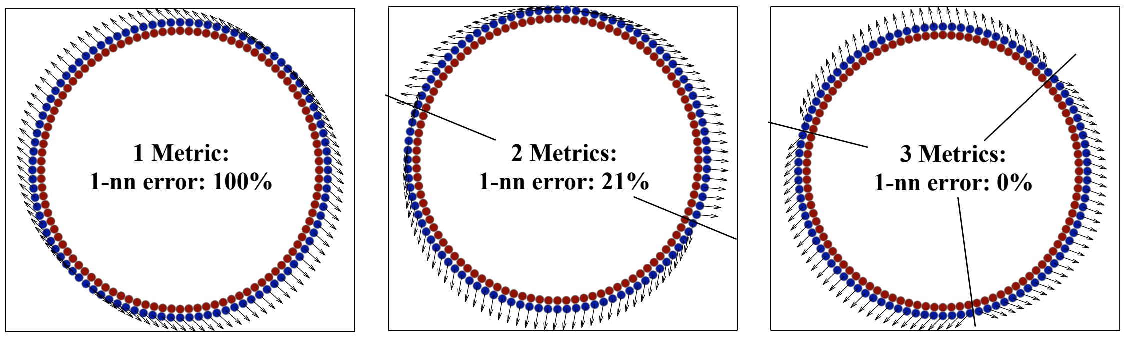

Figure 7: A synthetic data set to illustrate the potential of multiple metrics. The data set consists of inputs sampled from two concentric circles, each of which defines a different class membership. LMNN training was used to estimate one global metric, as well as multiple local metrics. *Left:* a single linear metric cannot model the non-linear decision boundary. The leave-one-out (LOO) error is 100%. *Middle:* if the data set is divided into two clusters (by k-means), and a local metric learned within each cluster, the error rate drops drastically. *Right:* the use of three metrics reduces the LOO-error on the training set to zero. The principal directions of individual distance metrics are indicated by arrows.

fication error rates on the five largest data sets. (Here, a value of one indicates that multiple passes of LMNN did not change the error rate, while a value less than one indicates an improvement.) On these data sets, multiple passes of LMMN were generally helpful, sometimes significantly improving the results. On smaller data sets, though, the multi-pass strategy seemed prone to overfit. Table 1 shows the absolute results on all data sets from multiple passes of LMNN (indicated by MP-LMNN).

A better strategy for choosing target neighbors remains an open question. This aspect of LMNN classification differs significantly from NCA, which does not require the choice of target neighbors. In fact, NCA also determines the effective neighborhood size as part of its optimization. On the other hand, the optimization in NCA is not convex; as such, the initial conditions implicitly specify a basin of attraction that determines the final result. In LMNN classification, the target neighbors are fixed in order to obtain a convex optimization. This trade-off is reminiscent of other convex relaxations of computationally hard problems in machine learning.

5.2 Multi-metric LMNN

On some data sets, a global linear transformation of the input space may not be sufficiently powerful to improve *k*NN classification. Figure 7 shows an example of a synthetic data set for which a single metric is not sufficient. The data set consists of inputs sampled from two concentric circles, each of which defines a different class membership. Global linear transformations cannot improve the accuracy of kNN classification of this data set. In general, highly nonlinear multiclass decision boundaries may not be well modeled by a single Mahalanobis distance metric.

In these situations, one useful extension of LMNN is to learn multiple locally linear transformations instead of a single global linear transformation. In this section, we show how to learn different Mahalanobis distance metrics for different examples in the input space. The idea of learning locally linear distance metrics for kNN classification is at least a decade old (Hastie and Tibshirani, 1996). It has also been explored more recently in the context of metric learning for semi-supervised clustering (Bilenko et al., 2004). The novelty of our approach lies in learning these metrics specifically to maximize the margin of correct kNN classification. As a first step, we partition the training data into disjoint clusters using k-means, spectral clustering (Shi and Malik, 2000), or label information. (In our experience, the latter seems to work best.) We then learn a Mahalanobis distance metric for each cluster. While the training procedure couples the distance metrics in different clusters, the optimization remains a convex problem in semidefinite programming. The globally integrated training of local distance metrics also distinguishes our approach from earlier work (Hastie and Tibshirani, 1996).

Before developing this idea more formally, we first illustrate its potential in a toy setting—namely, on the data set in Fig. 7. For this data set, LMNN training was used to estimate one global metric, as well as multiple local metrics (as described below). Cluster boundaries in the input space were determined by the k-means algorithm. We measured the leave-one-out (LOO) training error (with $k=1$ nearest neighbors) after learning one, two and three metrics. With one metric, the error was 100%; with two metrics, it dropped to 21%; finally, with three metrics, it vanished altogether. The figure illustrates how the multiple metrics adapt to the local structure of the class decision boundaries.

In order to learn different Mahalanobis metrics in different parts of the input space, we minimize a variation of the objective function in Eq. (14). We denote the different metrics by $\mathbf{M}^1,\ldots,\mathbf{M}^c$, where c is the number of clusters. If we partition the training examples by their class labels, then c also coincides with the number of classes; this was done for the remaining experiments in this section. In this case, as the cluster that contains $\vec{x}_i$ is indexed by its label y_i, we can refer to its metric as $\mathbf{M}^{y_i}$. We further define the cluster-dependent distance between two vectors $\vec{x}_i$ and $\vec{x}_j$ as:

$$\hat{\mathcal{D}}(\vec{x}_i,\vec{x}_j) = (\vec{x}_i-\vec{x}_j)^\top \mathbf{M}^{y_j}(\vec{x}_i-\vec{x}_j). \tag{16}$$

Note that this cluster-dependent measure of distance $\hat{\mathcal{D}}(\vec{x}_i,\vec{x}_j)$ is not symmetric with respect to its input arguments. In a slight abuse of terminology, however, we will continue to refer to Eq. (16) as a distance metric; the symmetry is not required for its use in kNN classification. To learn these metrics from data, we solve a modified version of the original SDP:

Minimize $(1-\mu)\sum_{i,j\rightsquigarrow i}(\vec{x}_i-\vec{x}_j)^\top \mathbf{M}^{y_j}(\vec{x}_i-\vec{x}_j)+\mu\sum_{j\rightsquigarrow i,l}(1-y_{il})\xi_{ijl}$
subject to:
(1) $(\vec{x}_i-\vec{x}_l)^\top \mathbf{M}^{y_l}(\vec{x}_i-\vec{x}_l)-(\vec{x}_i-\vec{x}_j)^\top \mathbf{M}^{y_j}(\vec{x}_i-\vec{x}_j) \;\geq\; 1-\xi_{ijl}$
(2) $\xi_{ijl}\geq 0$
(3) $\mathbf{M}^i\succeq 0$ **for** $i=1,\ldots,c$**.**

Note that all the matrices $\mathbf{M}^i$ are learned simultaneously by solving a single SDP. This approach ensures the consistency of distance computations in different clusters: for example, the distance from a test example to training examples with different labels. The integrated learning of different metrics is necessary to calibrate these distances on the same scale; if the metrics were learned independently, then the distances computed by different metrics could not be meaningfully compared—obviously, a crucial requirement for *k*NN classification.

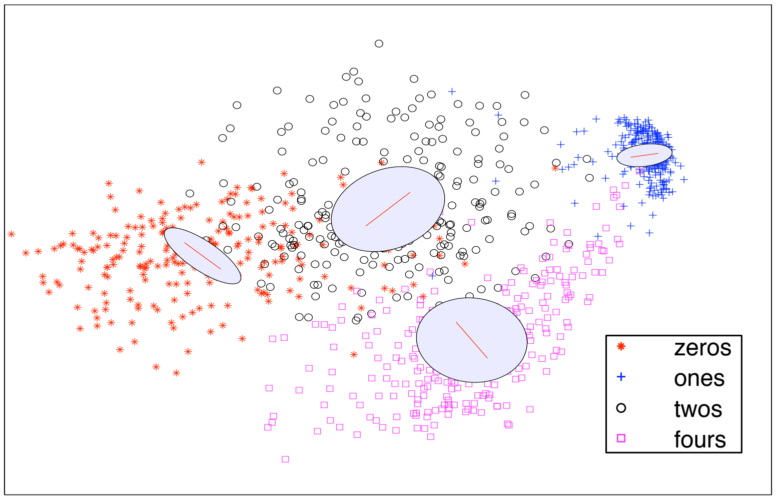

Figure 8: Multiple local distance metrics learned for a data set consisting of handwritten digits *four*, *two*, *one* and *zero*.

Fig. 8 illustrates the multiple metrics learned from an image data set of four different handwritten digits: *zero*, *one*, *four*, and *two*. The plot shows the first two principal components of the data. Only these principal components were used in training in order to yield an easily visualized solution. The solution can be visualized by illustrating the metrics as ellipsoids centered at the class means. The ellipsoids show the effect on a unit circle of each local linear transformation learned by LMNN. The line inside each ellipsoid indicates its principal axis.

We experimented with this multi-metric version of LMNN on all of the data sets from section 4. To avoid overfitting, we held out 30% of each data set's training examples and used them as a validation set. We learned one metric per class. To speed up training, we initialized the multi-metric optimization by setting each class-dependent metric to the solution from LMNN classification with a single global distance metric. Table 1 reports the error rates and other results from all these experiments (under "MM-LMNN"). The training times for MM-LMNN include the time required to compute the initial metric settings from the optimization in Eq. (14).

Fig. 9 shows the relative improvement in 3-NN classification error rates from multi-metric LMNN over standard LMNN on the five largest data sets. The multiple metrics variant improves over standard LMNN on every data set. The best result occurs on the MNIST handwritten digits data set, where MM-LMNN obtained a 1.18% *k*NN classification error rate, slightly outperforming multi-class SVMs. However, the improvement from multi-metric LMNN is not as consistently observed when the energy-based decision rule is used for classification.

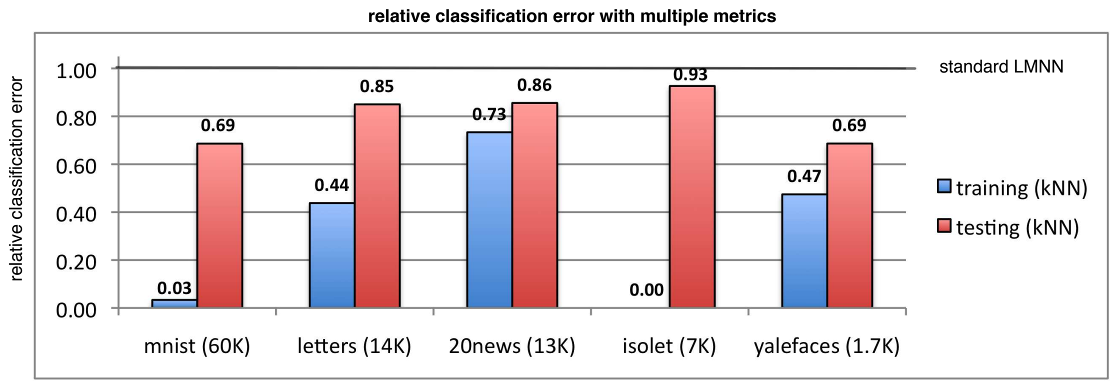

Figure 9: Relative improvement in $k-$NN classification error rates using multiple metrics over error rates using a single metric.

5.3 Kernel Version

LMNN can also be extended by using kernel methods (Schölkopf and Smola, 2002) to work in a nonlinear feature space, as opposed to the original input space. The idea of learning a kernel matrix has been explored in other contexts (Kwok and Tsang, 2003; Lanckriet et al., 2004; Varma and Ray, 2007), particularly large margin classification by support vector machines. This idea for LMNN has been investigated in detail by Torresani and Lee (2007). The "kernel trick" is used to map the inputs $\vec{x}_i$ into higher (possibly infinite) dimensional feature vectors $\Phi(\vec{x}_i)$. To avoid the computational cost of working directly with these feature vectors, they are only accessed through their inner products, which are pre-computed and stored in the kernel matrix:

$$\mathbf{K}_{ij} = \Phi(\vec{x}_i)^\top \Phi(\vec{x}_j).$$

Note how in Eq. (14), the inputs $\vec{x}_i$ are only accessed in terms of the distances in Eq. (3). Torresani and Lee (2007) considered Mahalanobis metrics of the form $\mathbf{M} = \sum_{lm} \mathbf{A}_{lm} \Phi(\vec{x}_l)\Phi(\vec{x}_m)^\top$, where the matrix $\mathbf{A}$ is constrained to be positive semidefinite. They showed that the gradient of Eq. (14) with respect to the matrix $\mathbf{A}$ can be written entirely in terms of the elements of the kernel matrix. Thus, a "kernelized" version of LMNN can be implemented efficiently in the same way as kernel PCA (Schölkopf et al., 1998), without ever working directly in the high dimensional feature space.

Torresani and Lee (2007) show that the kernelized version of LMNN can lead to significant further improvements, but at the cost of increased computation. The increased computation is due to the size of the matrix that must be learned in this setting: the matrix $\mathbf{A}$ has $O(n^2)$ elements instead of $O(d^2)$. (However, the kernel version could require less computation in applications where $n < d$.) More details on the kernelized version of LMNN can be found in their paper.

5.4 Dimensionality Reduction

Often it is useful to generate low dimensional representations of high dimensional data. These representations can be used to visualize the data and/or to accelerate algorithms whose time complexity scales with the input dimensionality. In section 6, for example, we will investigate how to accelerate the *k*NN search in LMNN classification by mapping the training data into a low dimensional subspace.

Low dimensional representations of inputs can be derived from the linear transformation $\vec{x}_i \rightarrow \mathbf{L}\vec{x}_i$ in LMNN classification. This can be done in two ways. The first way is to project the *transformed* inputs onto their leading principal components. Note that if the inputs are whitened prior to optimizing Eq. (13), then these principal components are given simply by the leading eigenvectors of the square matrix $\mathbf{L}$. Another way to derive low dimensional representations is to build this goal explicitly into the optimization for LMNN classification. In particular, we can attempt to minimize Eq. (13) with respect to $\mathbf{L}$ (rather than with respect to $\mathbf{M} = \mathbf{L}^\top \mathbf{L}$) and constrain $\mathbf{L}$ to be rectangular of size $r \times d$, where r is the desired output dimensionality (presumed to be much smaller than the input dimensionality, d). The optimization in terms of $\mathbf{L}$ is not convex, but in practice (Torresani and Lee, 2007), it does not appear to suffer from very poor local minima. In the following section, we use and compare both these methods to build efficient tree data structures for LMNN classification.

6. Metric Trees

One inherent disadvantage of *k*NN search is its relatively high computational complexity at test time. The simplest brute-force way to locate a test example's nearest neighbors is to compute its distance to all the training examples. Such a naïve implementation has a test time-complexity of $O(nd)$, where n is the number of training examples, and d is the input dimensionality.

One way to accelerate *k*NN search is to rotate the input space such that the coordinate axes are aligned with the data's principal components. Such a rotation sorts the input coordinates by decreasing variance; see Section 2.2.1. This ordering can be used to prune unnecessary computations in *k*NN search. In particular, for any test example, a nearest neighbor query consists of computing the distance to each training example and comparing this distance to the k closest examples already located. The distance computation to a particular training example can be aborted upon determining that it lies further away than the k closest examples already located. When the coordinate axes are aligned with the principal components, this determination can often be made after examining just a few of the leading, load-bearing dimensions. We have used this optimization in our baseline implementation of *k*NN search.

Generally there are two major approaches to gain additional speed-ups. The first approach is to reduce the input dimensionality d. The Johnson-Lindenstrauss Lemma (Dasgupta and Gupta, 1999) states that n points can be mapped into a space of dimensionality $O(\frac{\log(n)}{\varepsilon^2})$ such that the distances between any two points changes only by a factor of $(1 \pm \varepsilon)$. Thus we can often reduce the dimensionality of the input data without distorting the nearest neighbor relations. (Note also that for *k*NN classification, we may tolerate inexact nearest neighbor computations if they do not lead to significant errors in classification.) The second approach to speed up *k*NN search is to build a sophisticated tree-based data structure for storing training examples. Such a data structure can reduce the nearest neighbor test time complexity in practice to $O(d \log n)$ (Beygelzimer et al., 2006). This latter method works best for low dimensional data. Fig. 10 compares a baseline implementation of *k*NN search versus one based on ball trees (Liu et al., 2005; Omohundro, 1987). Note how the speed-up from the ball trees is magnified by dimensionality reduction of the inputs.

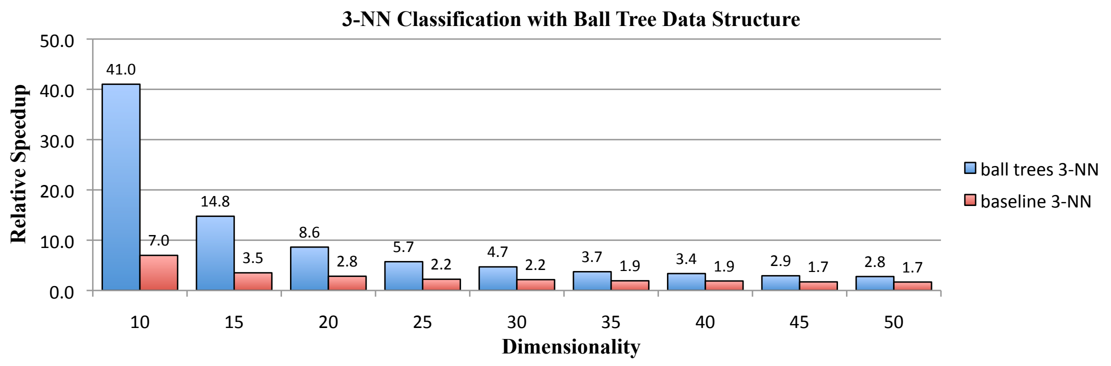

Figure 10: Relative speed-up for 3NN classification obtained from different orthogonal projections of MNIST handwritten digits onto their leading principal components. For these experiments, the $d = 784$ dimensional inputs from the raw images were projected onto the number of principal components shown on the x-axis. The figure compares the speed-ups when ball trees are used (blue) versus when ball trees are not used (red) in the lower dimensional space. Note how the gains from ball trees diminish with increasing dimensionality. All the NN computations in these experiments were accelerated by aligning the coordinate axes along principal components, as described in section 6.

In this section, we explore the use of ball trees for LMNN classification and dimensionality reduction. We find that ball trees can be used for both faster training and testing of LMNN classifiers.

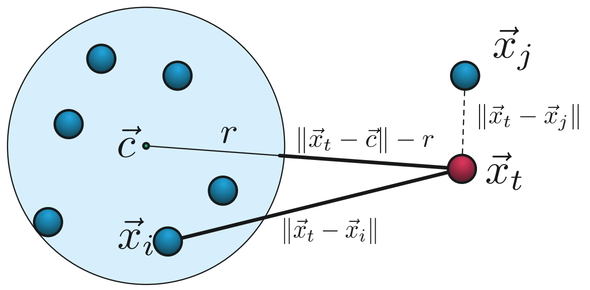
6.1 Review of Ball Trees

Several authors have proposed tree-based data structures to speed up *k*NN search. Examples are kd-trees (Friedman et al., 1977), ball trees (Liu et al., 2005; Omohundro, 1987) and cover-trees (Beygelzimer et al., 2006). All these data structures exploit the same idea: to partition the input space data into hierarchically nested bounding regions. The bounding regions are set up to guarantee that the distance from a test example to a training example inside the bounding region is at least as large as the distance from the test example's to the region's boundary. Thus, for each test example, the training examples inside the bounding region can be ruled out as k nearest neighbors if k training examples have already been found that are closer than the region's boundary. In this case, the *k*NN search can proceed without explicitly computing the distances to training examples in the bounding region. This "pruning" of distance computations often leads to a significant speedup in *k*NN computation time.

We experimented with ball trees (Liu et al., 2005), in which the bounding regions are hyperspheres. Fig. 11 illustrates the basic idea behind ball trees. If a set S of training examples is encapsulated inside a ball with center $\vec{c}$ and radius r, such that $\forall \vec{x} \in S:\ \|\vec{x}-\vec{c}\| \leq r$, then for any test example $\vec{x}_t$ we can bound the distance to any training example inside the ball by the following expression:

$$\forall \vec{x}_i \in S \quad \|\vec{x}_t - \vec{x}_i\| \geq \max(\|\vec{x}_t - \vec{c}\|_2 - r, 0). \tag{17}$$

Ball trees exploit this inequality to build a hierarchical data structure. The data structure is based



$\vec{x}_j$
$\|\vec{x}_t - \vec{x}_j\|$
$\vec{c}$
r
$\|\vec{x}_t - \vec{c}\| - r$
$\vec{x}_t$
$\vec{x}_i$
$\|\vec{x}_t - \vec{x}_i\|$

Figure 11: The basic idea behind ball trees: for any training example $\vec{x}_i$ inside the ball we can bound the distance $\|\vec{x}_t - \vec{x}_i\|_2$ from below using (17). If another training example $\vec{x}_j$ outsider the ball is already known to be closer than this bound to the test example $\vec{x}_t$, then the training examples inside the ball can be ruled out as nearest neighbors.

on recursively splitting the training examples into two disjoint sets. The sets are encapsulated by hyperspheres (or "balls") which may be partially overlapping. The training examples are recursively divided into smaller and smaller sets until no leaf set contains more than some predefined number of examples.

From this hierarchical data structure, the k-nearest neighbors of a test example can be found by a standard depth-first tree-based search. Recall that each node in the tree has an associated hypersphere that encloses the training examples stored by its descendants. The kNN search proceeds by traversing the tree and computing a test example's distance to the center of each node's hypersphere. The tree is traversed by greedily descending sub-trees in order of this distance. Before descending a subtree, however, Eq. (17) is checked to determine whether training examples in the subtree lie further away than the currently estimated k-nearest neighbors. If this is true, the sub-tree is pruned from the search without further computation. When a leaf node is reached, all the training examples at the leaf node are compared to the currently estimated k-nearest neighbors, and the estimates are updated as necessary. Note that ball trees support exact queries for kNN search.

As pointed out earlier, and as illustrated by Fig. 10, ball trees yield the largest gains in kNN search time for low dimensional data. When the data is high dimensional, the search is plagued by the so-called "curse of dimensionality" (Indyk and Motwani, 1998). In particular, the distances between high dimensional points tend to be more uniform, thereby reducing the opportunities for pruning subtrees in the depth-first search.

6.2 Ball Trees for LMNN Training

The most computationally intensive part of LMNN training is computing the gradient of the penalty for margin violations in Eq. (12). The gradient computation requires a search over all pairs of differently labeled examples to determine if any of them are "impostors" (see section 3.1) that incur margin violations. The solver described in appendix A reduces the number of these searches by maintaining an active list of previous margin violations. Nevertheless, this search scales $O(n^2d)$, which is very computationally intensive for large data sets.

Ball trees can be used to further speed up the search for impostors. Recall how impostors were defined in section 3.1. For any training example $\vec{x}_i$, and for any similarly labeled example $\vec{x}_j$ that

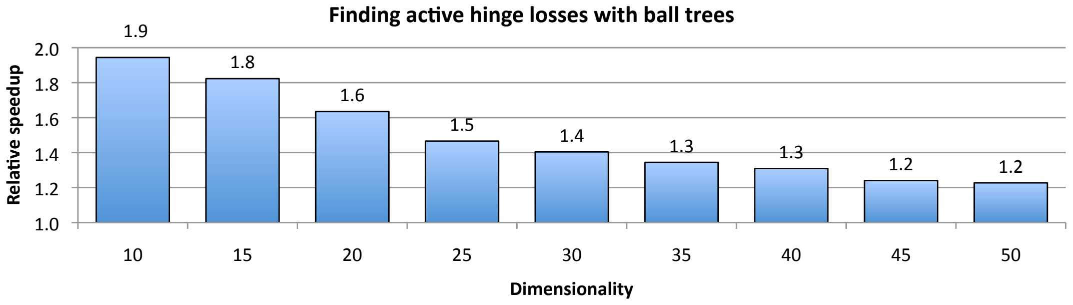


Figure 12: The relative speed-up obtained using ball trees to search for margin violations. The speed-up was measured on the MNIST data set of handwritten digits, with inputs of varying dimensionality derived from PCA. Note how the gains from ball trees diminish with increasing input dimensionality.

is one of its target k-nearest neighbors (with $j \rightsquigarrow i$), the impostors consist of all differently labeled examples $\vec{x}_l$ (with $y_{il} = 0$) that satisfy Eq. (10). Ball trees can be used to search for all training examples that meet this criterion. As in their use for kNN search, many subtrees in the depth-first search for impostors can be pruned: if for some ball the lower bound distances between examples is already greater than the right hand side of Eq. (10), then all the examples stored in the subtree can be ruled out as impostors. Note that for each training example $\vec{x}_i$, we only need to search for impostors among other training examples $\vec{x}_l$ that have a different class label (with $y_{il} = 0$). Thus, we build one ball tree data structure per class and perform a separate search for impostors in each class.

Fig. 12 shows the relative speed-up when ball trees are used to search for margin violations in LMNN classification. The figure shows results from experiments with the MNIST images of handwritten digits. For these experiments, the images were projected into subspaces of varying dimensionality using PCA. The gains from ball trees in this context are significant, though not as dramatic as those in Fig. 10 for simple kNN search. The lesser gains for LMNN classification can be attributed to the minimum enforced margin of unit distance, which sometimes causes a high number of sub-trees to be traversed. This effect is controlled by the relative magnitude of the unit margin; it can be partially offset by scaling the input data by a constant factor before training.

6.3 Ball Trees for LMNN Testing

Ball trees can also be used to accelerate kNN search at test time. We have observed earlier, though, that the speed-up from ball trees diminishes quickly as the input dimensionality increases; see Fig. 10. If very fast kNN classification using ball trees is desired on a large data set, then often it is necessary to work with a lower dimensional representation of the training examples.

The most commonly used methods for dimensionality reduction in ball trees are random projections and PCA. Neither of these methods, however, is especially geared to preserve the accuracy of kNN classification. There is an inherent trade-off between dimensionality reduction and nearest

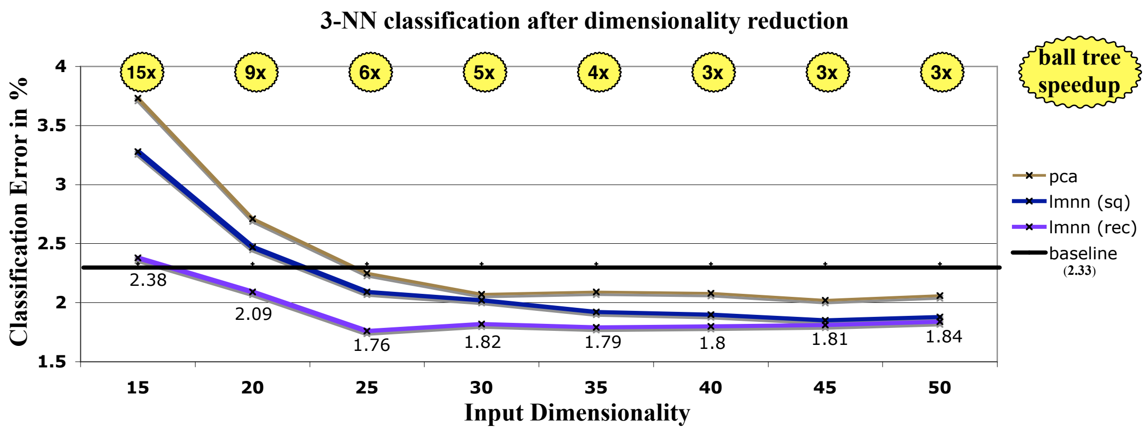

Figure 13: Graph of *k*NN classification error (with $k = 3$) on different low dimensional representations of the MNIST data set; see text for details. The speed-up from ball-trees is shown at the top of the graph.

neighbor preservation. Nearest neighbor relationships can change when the training examples are projected into a lower dimensional space, resulting in significantly worse *k*NN classification.

In this section, we explore how the distance metric learned for LMNN classification can be used for more effective dimensionality reduction in ball trees. In section 5.4, we described two different ways to derive low dimensional representations for LMNN classification. The first computed a low-rank approximation to the (generally full rank) matrix $\mathbf{L}$; the second directly learned a low-rank rectangular matrix $\mathbf{L}$ by optimizing the non-convex loss function in Eq. (13). For shorthand, we refer to these approaches for dimensionality reduction as LMNN-S and LMNN-R, denoting whether a square (S) or rectangular (R) matrix is learned to minimize the LMNN cost function. Fig. 13 shows the results of *k*NN classification from both these methods on the MNIST data set of handwritten digits. For these experiments, the raw MNIST images (of size 28×28) were projected onto their 350 leading principal components before any training for LMNN classification. Also shown in the figure are the results from further dimensionality reduction using PCA, as well as the baseline *k*NN error rate in the original (high dimensional) input space. The square matrix in LMNN-S was of size 350×350, and for dimensionality reduction, the data was projected onto the r leading eigenvectors of linear transformation $\mathbf{L}$. The rectangular matrix in LMNN-R was of size $r \times 350$, where r varied from 15 to 50. The speed-up from ball trees is shown at the top of the graph. The amount of speed-up depends significantly on the amount of dimensionality reduction, but very little on the particular method of dimensionality reduction.

The results show that LMNN can be used effectively for dimensionality reduction. For example, LMNN-R achieves a *k*NN test error rate of 2.38% in 15 dimensions, only slightly higher than the baseline error rate of 2.33% in the original input space. In this space, moreover, ball trees yield a 15x speedup over baseline *k*NN search. In 25 dimensions, the LMNN-R error rate drops further to 1.76% while still yielding a 5.7x speed-up. Of the three methods compared in Fig. 13, LMNN-R is the most effective. In fact, though working in many fewer dimensions, LMNN-R obtains results very close to the best results reported in section 4. It is interesting that LMNN-R outperforms LMNN-S, though (as expected) their results converge as the rectangular matrix in LMNN-R becomes more square. These results show that aggressive dimensionality reduction can be combined with highly accurate *k*NN classification.

7. Discussion

In this paper, we have introduced a new framework for large margin nearest neighbor (LMNN) classification. From labeled training examples, we have shown how to learn a Mahalanobis distance metric for *k*NN classification. The required optimization was formulated as an instance of semidefinite programming. Our framework makes no parametric assumptions about the structure or distribution of the data and scales naturally to problems with large number of classes. On multiple data sets, we have demonstrated that we can significantly improve the accuracy of *k*NN classification by learning a metric in this way. We have also shown that an alternative energy-based decision rule typically leads to further improvements over traditional *k*NN classification.

Beyond the basic framework for LMNN classification, we described several useful and complementary extensions. These included: iterative re-estimation of target neighbor assignments, globally integrated learning of multiple locally linear metrics, kernel methods for LMNN classification, low-rank distance metrics for dimensionality reduction, and ball trees for more efficient gradient computations (in training) and *k*NN search (in testing). These extensions can be adapted and combined to meet the demands of particular applications. For example, to build a highly accurate classifier without regard to the actual computation at test time, our results suggest to train multiple locally linear metrics. At the other extreme, to build a *k*NN classifier that is as fast as possible at test time, our results suggest to combine low-rank distance metrics with ball trees.

Taken as a whole, our results demonstrate the promise and widespread applicability of LMNN classification. Perhaps the greatest promise lies in problems with very large numbers of classes, such as face and identity recognition. The number of classes in these problems can be in the hundreds, thousands, or more. Nearest neighbor methods handle this regime more transparently than other leading methods, such as SVMs. The ideas behind LMNN classification have also been extended by others in various ways (Torresani and Lee, 2007; Kumar et al., 2007). In the appendix, we describe a simple solver that scales well to problems with tens of thousands of examples. A MATLAB implementation of the algorithm is also freely available with this paper.

Future work will concentrate on several open problems. The improved performance with multiple metrics suggests that LMNN classification could benefit from even more adaptive transformations of the input space. It would also be useful to study LMMN classification in the semi-supervised, transductive setting, where only a few labeled inputs are available for training but the unlabeled test set is known in advance. Finally, for many real-world applications in computer vision and information retrieval, the data sets can be much larger than the ones we have studied. For very large data sets, our current implementation for LMNN does not scale as well as simpler eigenvector methods such as PCA, LDA, and RCA. It remains an interesting challenge to scale LMNN to even larger data sets with millions or more training examples.

Acknowledgments

We especially thank John C. Blitzer for his many suggestions to improve the algorithm and his generous help with various data sets. We also thank Koby Crammer for many useful comments and suggestions. This work was supported by NSF Award 0238323.

Appendix A. Solver

We implemented our own special-purpose solver for large-scale problems in LMNN classification. Our solver was designed to exploit the particular structure of the cost function in Eq. (13). The solver iteratively re-estimates the Mahalanobis distance metric as it attempts to minimize the cost function for LMNN classification. The amount of computation is minimized by careful book-keeping from one iteration to the next. The speed-ups from these optimizations enabled us to work comfortably on data sets with up to $n = 60,000$ training examples.

Our solver implements an iterative sub-gradient projection method to optimize Eq. (14) in terms of the positive semidefinite matrix $\mathbf{M}$. We refer to the Mahalanobis distance metric at the tth iteration as $\mathbf{M}_t$ and to its squared Mahalanobis distance in Eq. (3) as $\mathcal{D}_t$. At each iteration, the optimization takes a step along the sub-gradient to reduce the loss function and then projects $\mathbf{M}_t$ onto the feasible set. In our case, the feasible set is the cone of all positive semidefinite matrices $\mathcal{S}_+$. The following sections derive the gradient and describe the projection onto $\mathcal{S}_+$.

It is worth emphasizing that although we can phrase the optimization of Eq. (14) as a semidefinite program (by introducing nonnegative slack variables to model the hinge loss), in practice our large-scale solver works directly to minimize Eq. (14). The hinge losses that appear in this loss function are not differentiable at all points. Nevertheless, because the loss function is convex, we can compute its sub-gradient and use standard hill-climbing algorithms to find its minimum. It has been shown that such sub-gradient methods converge to the correct solution, provided that the gradient step-size is sufficiently small (Boyd and Vandenberghe, 2004).

A.1 Gradient Computation

The gradient computation can be done most efficiently by careful book-keeping from one iteration to the next. As simplifying notation, let $\mathbf{C}_{ij} = (\vec{x}_i - \vec{x}_j)(\vec{x}_i - \vec{x}_j)^\top$. It is straightforward to express the distances, as defined in Eq. (3), in terms of this notation. In particular, at the tth iteration, we have $\mathcal{D}_t(\vec{x}_i, \vec{x}_j) = \mathrm{tr}(\mathbf{M}_t\mathbf{C}_{ij})$. Consequently, we can rewrite the loss function in Eq. (14) as:

$$\varepsilon(\mathbf{M}_t) \;=\; (1-\mu)\sum_{i,j\rightsquigarrow i}\mathrm{tr}(\mathbf{M}_t\mathbf{C}_{ij}) + \mu\sum_{j\rightsquigarrow i,l}(1-y_{il})\left[1+\mathrm{tr}(\mathbf{M}_t\mathbf{C}_{ij}) - \mathrm{tr}(\mathbf{M}_t\mathbf{C}_{il})\right]_+ \tag{18}$$

Note that Eq. (18) is piecewise linear with respect to $\mathbf{M}_t$. Let us define a set of triples $\mathcal{N}^t$, such that $(i,j,l) \in \mathcal{N}^t$ if and only if the indices (i,j,l) trigger the hinge loss in the second part of Eq. (18). With this definition, we can write the gradient $\mathbf{G}_t$ of $\varepsilon(\mathbf{M}_t)$ as:

$$\mathbf{G}_t = \frac{\partial\varepsilon}{\mathbf{M}_t} = (1-\mu)\sum_{i,j\rightsquigarrow i}\mathbf{C}_{ij} + \mu\sum_{(i,j,l)\in\mathcal{N}^t}(\mathbf{C}_{ij} - \mathbf{C}_{il}).$$

Computing the gradient requires computing the outer products in $\mathbf{C}_{ij}$; it thus scales quadratically in the input dimensionality. As the set $\mathcal{N}_t$ is potentially very large, a naïve computation of the gradient would be extremely expensive. However, we can exploit the fact that the gradient contribution from each active triplet (i,j,l) does not depend on the degree of its margin violation. Thus, the changes in the gradient from one iteration to the next are determined entirely by the differences between the sets $\mathcal{N}_t$ and $\mathcal{N}_{t+1}$. We can use this fact to derive an extremely efficient update that relates the gradient $\mathbf{G}_{t+1}$ at iteration $t+1$ from the gradient $\mathbf{G}_t$ at iteration t. The update simply subtracts the contributions from triples that are no longer active and adds the contributions of those that just became active:

$$\mathbf{G}_{t+1} = \mathbf{G}_t - \mu \sum_{(i,j,l)\in\mathcal{N}_t - \mathcal{N}_{t+1}} (\mathbf{C}_{ij} - \mathbf{C}_{il}) + \mu \sum_{(i,j,l)\in\mathcal{N}_{t+1} - \mathcal{N}_t} (\mathbf{C}_{ij} - \mathbf{C}_{il}). \tag{19}$$

For small gradient step sizes, the set $\mathcal{N}_t$ changes very little from one iteration to the next. In this case, computing the right hand side of Eq. (19) is extremely fast.

To accelerate the solver even further, we adopt an active set method. Note that computing the set $\mathcal{N}_t$ at each iteration requires checking every triplet (i,j,l) with $j \rightsquigarrow i$ for a potential margin violation. This computation scales as $O(nd^2 + kn^2d)$, making it impractical for large data sets. To avoid this computational burden, we exploit the fact that the great majority of triples do not incur margin violations: in particular, for each training example, only a very small fraction of differently labeled examples typically lie nearby in the input space. Consequently, a useful approximation is to check only a subset of likely triples for margin violations per gradient computation. We initialize the training procedure by checking all triples and maintaining an active list of those with margin violations; however, a full re-check is only made every 10-20 iterations, depending on fluctuations of the set $\mathcal{N}_t$. For intermediate iterations, we only check for margin violations from among those active triples accumulated over previous iterations. When the optimization converges, we verify that the working set $\mathcal{N}_t$ does contain all active triples that incur margin violations. This final check is needed to ensure convergence to the correct minimum. If the check is not satisfied, the optimization restarts with the newly expanded active set.

A.2 Projection

The minimization of Eq. (18) must enforce the constraint that the matrix $\mathbf{M}_t$ remains positive semidefinite. To enforce this constraint, we project $\mathbf{M}_t$ onto the cone of all positive semidefinite matrices $\mathcal{S}_+$ after each gradient step. This projection is computed from the diagonalization of $\mathbf{M}_t$. Let $\mathbf{M}_t = \mathbf{V}\Delta\mathbf{V}^\top$ denote the eigendecomposition of $\mathbf{M}_t$, where $\mathbf{V}$ is the orthonormal matrix of eigenvectors and Δ is the diagonal matrix of corresponding eigenvalues. We can further decompose $\Delta = \Delta^- + \Delta^+$, where $\Delta^+ = \max(\Delta, 0)$ contains all the positive eigenvalues and $\Delta^- = \min(\Delta, 0)$ contains all the negative eigenvalues. The projection of $\mathbf{M}_t$ onto the cone of positive semidefinite matrices is given by:

$$\mathcal{P}_{\mathcal{S}}(\mathbf{M}_t) = \mathbf{V}\Delta^+\mathbf{V}^\top. \tag{20}$$

The projection effectively truncates any negative eigenvalues from the gradient step, setting them equal to zero.

A.3 Algorithm

Our gradient projection algorithm combined the update rules for the gradient in Eq. (19) and the projection in Eq. (20). A simplified pseudo-code implementation is shown in Algorithm 1. We denote the gradient step-size by $\alpha > 0$. In practice, it worked best to start with a small value of α. Then, at each iteration, we increased α by a factor of 1.01 if the loss function decreased and decreased α by a factor of 0.5 if the loss function increased.

Algorithm 1 A simple gradient projection pseudo-code implementation.

```
 1: $\mathbf{M}_0 := \mathbf{I}$ {Initialize with the identity matrix}
 2: $t := 0$ {Initialize counter}
 3: $\mathcal{N}^{(0)}, \mathcal{N}_0 := \{\}$ {Initialize active sets}
 4: $\mathbf{G}_0 := (1-\mu)\sum_{i,j\rightsquigarrow i}\mathbf{C}_{ij}$ {Initialize gradient}
 5: while (not converged) do
 6:     if mod$(t, someconstant) = 0 \vee$ (almost converged){we used $someconstant$=10} then
 7:         compute $\mathcal{N}_{t+1}$ exactly
 8:         $\mathcal{N}^{(t+1)} := \mathcal{N}^{(t)} \cup \mathcal{N}_{t+1}$ {Update active set}
 9:     else
10:         compute $\mathcal{N}_{t+1} \approx \mathcal{N}_{t+1} \cap \mathcal{N}^{(t)}$ { Only search active set}
11:         $\mathcal{N}^{(t+1)} := \mathcal{N}^{(t)}$ {Keep active set untouched}
12:     end if
13:     $\mathbf{G}_{t+1} := \mathbf{G}_t - \mu\sum_{(i,j,l)\in\mathcal{N}_t - \mathcal{N}_{t+1}}(\mathbf{C}_{ij} - \mathbf{C}_{il}) + \mu\sum_{(i,j,l)\in\mathcal{N}_{t+1} - \mathcal{N}_t}(\mathbf{C}_{ij} - \mathbf{C}_{il})$
14:     $\mathbf{M}_{t+1} := \mathcal{P}_{\mathcal{S}}(\mathbf{M}_t - \alpha\mathbf{G}_{t+1})$ {Take gradient step and project onto SDP cone}
15:     $t := t + 1$
16: end while
17: Output $\mathbf{M}_t$
```

Abstract

Penalization procedures often suffer from their dependence on multiplying factors, whose optimal values are either unknown or hard to estimate from data. We propose a completely data-driven calibration algorithm for these parameters in the least-squares regression framework, without assuming a particular shape for the penalty. Our algorithm relies on the concept of minimal penalty, recently introduced by Birgé and Massart (2007) in the context of penalized least squares for Gaussian homoscedastic regression. On the positive side, the minimal penalty can be evaluated from the data themselves, leading to a data-driven estimation of an optimal penalty which can be used in practice; on the negative side, their approach heavily relies on the homoscedastic Gaussian nature of their stochastic framework.

The purpose of this paper is twofold: stating a more general heuristics for designing a data-driven penalty (the *slope heuristics*) and proving that it works for penalized least-squares regression with a random design, even for heteroscedastic non-Gaussian data. For technical reasons, some exact mathematical results will be proved only for regressogram bin-width selection. This is at least a first step towards further results, since the approach and the method that we use are indeed general.

Keywords: data-driven calibration, non-parametric regression, model selection by penalization, heteroscedastic data, regressogram

1. Introduction

In the last decades, model selection has received much interest, commonly through penalization. In short, penalization chooses the model minimizing the sum of the empirical risk (how well the algorithm fits the data) and of some measure of complexity of the model (called penalty); see FPE (Akaike, 1970), AIC (Akaike, 1973), Mallows' C_p or C_L (Mallows, 1973). Many other penalization procedures have been proposed since, among which Rademacher complexities (Koltchinskii, 2001; Bartlett et al., 2002), local Rademacher complexities (Bartlett et al., 2005; Koltchinskii, 2006), bootstrap penalties (Efron, 1983), resampling and V-fold penalties (Arlot, 2008b,c).

Model selection can target two different goals. On the one hand, a procedure is *efficient* (or asymptotically optimal) when its quadratic risk is asymptotically equivalent to the risk of the oracle.

On the other hand, a procedure is *consistent* when it chooses the smallest true model asymptotically with probability one. This paper deals with *efficient* procedures, without assuming the existence of a true model.

A huge amount of literature exists about efficiency. First Mallows' C_p, Akaike's FPE and AIC are asymptotically optimal, as proved by Shibata (1981) for Gaussian errors, by Li (1987) under suitable moment assumptions on the errors, and by Polyak and Tsybakov (1990) under sharper moment conditions, in the Fourier case. Non-asymptotic oracle inequalities (with some leading constant $C > 1$) have been obtained by Barron et al. (1999) and by Birgé and Massart (2001) in the Gaussian case, and by Baraud (2000, 2002) under some moment assumptions on the errors. In the Gaussian case, non-asymptotic oracle inequalities with leading constant C_n tending to 1 when n tends to infinity have been obtained by Birgé and Massart (2007).

However, from the practical point of view, both AIC and Mallows' C_p still present serious drawbacks. On the one hand, AIC relies on a strong asymptotic assumption, so that for small sample sizes, the optimal multiplying factor can be quite different from one. Therefore, corrected versions of AIC have been proposed (Sugiura, 1978; Hurvich and Tsai, 1989). On the other hand, the optimal calibration of Mallows' C_p requires the knowledge of the noise level σ^2, assumed to be constant. When real data are involved, σ^2 has to be estimated separately and independently from any model, which is a difficult task. Moreover, the best estimator of σ^2 (say, with respect to the quadratic error) quite unlikely leads to the most efficient model selection procedure. Contrary to Mallows' C_p, the data-dependent calibration rule defined in this article is not a "plug-in" method; it focuses directly on efficiency, which can improve significantly the performance of the model selection procedure.

Existing penalization procedures present similar or stronger drawbacks than AIC and Mallows' C_p, often because of a gap between theory and practice. For instance, oracle inequalities have only been proved for (global) Rademacher penalties multiplied by a factor two (Koltchinskii, 2001), while they are used without this factor (Lozano, 2000). As proved by Arlot (2007, Chapter 9), this factor is necessary in general. Therefore, the optimal calibration of these penalties is really an issue. The calibration problem is even harder for local Rademacher complexities: theoretical results hold only with large calibration constants, particularly the multiplying factor, and no optimal values are known. One of the purposes of this paper is to address the issue of optimizing the multiplying factor for general-shape penalties.

Few automatic calibration algorithms are available. The most popular ones are certainly cross-validation methods (Allen, 1974; Stone, 1974), in particular V-fold cross-validation (Geisser, 1975), because these are general-purpose methods, relying on a widely valid heuristics. However, their computational cost can be high. For instance, V-fold cross-validation requires the entire model selection procedure to be performed V times for each candidate value of the constant to be calibrated. For penalties proportional to the dimension of the models, such as Mallows' C_p, alternative calibration procedures have been proposed by George and Foster (2000) and by Shen and Ye (2002).

A completely different approach has been proposed by Birgé and Massart (2007) for calibrating dimensionality-based penalties. Since this article extends their approach to a much wider range of applications, let us briefly recall their main results. In Gaussian homoscedastic regression with a fixed design, assume that each model is a finite-dimensional vector space. Consider the penalty $\mathrm{pen}(m) = KD_m$, where D_m is the dimension of the model m and $K > 0$ is a positive constant, to be calibrated. First, there exists a *minimal* constant $K_{\min}$, such that the ratio between the quadratic risk of the chosen estimator and the quadratic risk of the oracle is asymptotically infinite if $K < K_{\min}$, and finite if $K > K_{\min}$. Second, when $K = K^\star := 2K_{\min}$, the penalty KD_m yields an efficient model selection procedure. In other words, *the optimal penalty is twice the minimal penalty*. This relationship characterizes the "slope heuristics" of Birgé and Massart (2007).

A crucial fact is that the minimal constant $K_{\min}$ can be estimated from the data, since large models are selected if and only if $K < K_{\min}$. This leads to the following strategy for choosing K from the data. For every $K \geq 0$, let $\widehat{m}(K)$ be the model selected by minimizing the empirical risk penalized by $\operatorname{pen}(D_m) = KD_m$. First, compute $K_{\min}$ such that $D_{\widehat{m}(K)}$ is "huge" for $K < K_{\min}$ and "reasonably small" when $K \geq K_{\min}$; explicit values for "huge" and "small" are proposed in Section 3.3. Second, define $\widehat{m} := \widehat{m}(2K_{\min})$. Such a method has been successfully applied for multiple change points detection by Lebarbier (2005).

From the theoretical point of view, the issue for understanding and validating this approach is the existence of a minimal penalty. This question has been addressed for Gaussian homoscedastic regression with a fixed design by Birgé and Massart (2001, 2007) when the variance is known, and by Baraud et al. (2007) when the variance is unknown. Non-Gaussian or heteroscedastic data have never been considered. This article contributes to fill this gap in the theoretical understanding of penalization procedures.

The calibration algorithm proposed in this article relies on a generalization of Birgé and Massart's slope heuristics (Section 2.3). In Section 3, the algorithm is defined in the least-squares regression framework, for general-shape penalties. The shape of the penalty itself can be estimated from the data, as explained in Section 3.4.

The theoretical validation of the algorithm is provided in Section 4, from the *non-asymptotic point of view*. Non-asymptotic means in particular that the collection of models is allowed to depend on n: in practice, it is usual to allow the number of explanatory variables to increase with the number of observations. Considering models with a large number of parameters (for example of the order of a power of the sample size n) is also necessary to approximate functions belonging to a general approximation space. Thus, the non-asymptotic point of view allows us not to assume that the regression function is described with a small number of parameters.

The existence of minimal penalties for *heteroscedatic regression with a random design* (Theorem 2) is proved in Section 4.3. In Section 4.4, by proving that twice the minimal penalty has some optimality properties (Theorem 3), we extend the so-called slope heuristics to heteroscedatic regression with a random design. Moreover, neither Theorem 2 nor Theorem 3 assume the data to be Gaussian; only mild moment assumptions are required.

For proving Theorems 2 and 3, each model is assumed to be the vector space of piecewise constant functions on some partition of the feature space. This is indeed a restriction, but we conjecture that it is mainly technical, and that the slope heuristics remains valid at least in the general least-squares regression framework. We provide some evidence for this by proving two key concentration inequalities without the restriction to piecewise constant functions. Another argument supporting this conjecture is that recently several simulation studies have shown that the slope heuristics can be used in several frameworks: mixture models (Maugis and Michel, 2008), clustering (Baudry, 2007), spatial statistics (Verzelen, 2008), estimation of oil reserves (Lepez, 2002) and genomics (Villers, 2007). Although the slope heuristics has not been formally validated in these frameworks, this article is a first step towards such a validation, by proving that the slope heuristics can be applied whatever the shape of the ideal penalty.

This paper is organized as follows. The framework and the slope heuristics are described in Section 2. The resulting algorithm is defined in Section 3. The main theoretical results are stated in Section 4. All the proofs are given in Appendix A.

2. Framework

In this section, we describe the framework and the general slope heuristics.

2.1 Least-squares Regression

Suppose we observe some data $(X_1,Y_1),\dots(X_n,Y_n) \in \mathcal{X} \times \mathbb{R}$, independent with common distribution P, where the feature space $\mathcal{X}$ is typically a compact set of $\mathbb{R}^d$. The goal is to predict Y given X, where $(X,Y) \sim P$ is a new data point independent of $(X_i,Y_i)_{1 \leq i \leq n}$. Denoting by s the regression function, that is $s(x) = \mathbb{E}[Y \mid X = x]$ for every $x \in \mathcal{X}$, we can write

$$Y_i = s(X_i) + \sigma(X_i)\varepsilon_i \tag{1}$$

where $\sigma : \mathcal{X} \mapsto \mathbb{R}$ is the heteroscedastic noise level and ε_i are i.i.d. centered noise terms, possibly dependent on X_i, but with mean 0 and variance 1 conditionally to X_i.

The quality of a predictor $t : \mathcal{X} \mapsto \mathcal{Y}$ is measured by the (quadratic) prediction loss

$$\mathbb{E}_{(X,Y)\sim P}[\gamma(t,(X,Y))] =: P\gamma(t) \qquad \text{where} \quad \gamma(t,(x,y)) = (t(x) - y)^2$$

is the least-squares contrast. The minimizer of $P\gamma(t)$ over the set of all predictors, called Bayes predictor, is the regression function s. Therefore, the excess loss is defined as

$$\ell(s,t) := P\gamma(t) - P\gamma(s) = \mathbb{E}_{(X,Y)\sim P}(t(X) - s(X))^2 \quad .$$

Given a particular set of predictors S_m (called a *model*), we define the best predictor over S_m as

$$s_m := \arg\min_{t \in S_m} \{ P\gamma(t) \} \quad ,$$

with its empirical counterpart

$$\widehat{s}_m := \arg\min_{t \in S_m} \{ P_n\gamma(t) \}$$

(when it exists and is unique), where $P_n = n^{-1} \sum_{i=1}^n \delta_{(X_i,Y_i)}$. This estimator is the well-known *empirical risk minimizer*, also called least-squares estimator since γ is the least-squares contrast.

2.2 Ideal Model Selection

Let us assume that we are given a family of models $(S_m)_{m \in \mathcal{M}_n}$, hence a family of estimators $(\widehat{s}_m)_{m \in \mathcal{M}_n}$ obtained by empirical risk minimization. The model selection problem consists in looking for some data-dependent $\widehat{m} \in \mathcal{M}_n$ such that $\ell(s, \widehat{s}_{\widehat{m}})$ is as small as possible. For instance, it would be convenient to prove some oracle inequality of the form

$$\ell(s, \widehat{s}_{\widehat{m}}) \leq C \inf_{m \in \mathcal{M}_n} \{ \ell(s, \widehat{s}_m) \} + R_n$$

in expectation or on an event of large probability, with leading constant C close to 1 and $R_n = o(n^{-1})$.

General penalization procedures can be described as follows. Let $\mathrm{pen} : \mathcal{M}_n \mapsto \mathbb{R}^+$ be some penalty function, possibly data-dependent, and define

$$\widehat{m} \in \arg\min_{m \in \mathcal{M}_n} \{ \mathrm{crit}(m) \} \qquad \text{with} \qquad \mathrm{crit}(m) := P_n\gamma(\widehat{s}_m) + \mathrm{pen}(m) \quad . \tag{2}$$

Since the ideal criterion $\operatorname{crit}(m)$ is the true prediction error $P\gamma\left(\widehat{s}_m\right)$, the *ideal penalty* is

$$\operatorname{pen}_{\mathrm{id}}(m) := P\gamma(\widehat{s}_m) - P_n\gamma(\widehat{s}_m) \enspace .$$

This quantity is unknown because it depends on the true distribution P. A natural idea is to choose $\operatorname{pen}(m)$ as close as possible to $\operatorname{pen}_{\mathrm{id}}(m)$ for every $m \in \mathcal{M}_n$. We will show below, in a general setting, that when pen is a good estimator of the ideal penalty $\operatorname{pen}_{\mathrm{id}}$, then $\widehat{m}$ satisfies an oracle inequality with leading constant C close to 1.

By definition of $\widehat{m}$,

$$\forall m \in \mathcal{M}_n, \quad P_n\gamma(\widehat{s}_{\widehat{m}}) \leq P_n\gamma(\widehat{s}_m) + \operatorname{pen}(m) - \operatorname{pen}(\widehat{m}) \enspace .$$

For every $m \in \mathcal{M}_n$, we define

$$p_1(m) = P\left(\gamma(\widehat{s}_m) - \gamma(s_m)\right) \quad p_2(m) = P_n\left(\gamma(s_m) - \gamma(\widehat{s}_m)\right) \quad \delta(m) = (P_n - P)\left(\gamma(s_m)\right)$$

so that

$$\begin{aligned} & \operatorname{pen}_{\mathrm{id}}(m) = p_1(m) + p_2(m) - \delta(m) \\ \text{and} \qquad & \ell\left(s, \widehat{s}_m\right) = P_n\gamma(\widehat{s}_m) + p_1(m) + p_2(m) - \delta(m) - P\gamma(s) \enspace . \end{aligned}$$

Hence, for every $m \in \mathcal{M}_n$,

$$\ell\left(s, \widehat{s}_{\widehat{m}}\right) + (\operatorname{pen} - \operatorname{pen}_{\mathrm{id}})(\widehat{m}) \leq \ell\left(s, \widehat{s}_m\right) + (\operatorname{pen} - \operatorname{pen}_{\mathrm{id}})(m) \enspace . \tag{3}$$

Therefore, in order to derive an oracle inequality from (3), it is sufficient to show that for every $m \in \mathcal{M}_n$, $\operatorname{pen}(m)$ is close to $\operatorname{pen}_{\mathrm{id}}(m)$.

2.3 The Slope Heuristics

If the penalty is too big, the left-hand side of (3) is larger than $\ell\left(s, \widehat{s}_{\widehat{m}}\right)$ so that (3) implies an oracle inequality, possibly with large leading constant C. On the contrary, if the penalty is too small, the left-hand side of (3) may become negligible with respect to $\ell\left(s, \widehat{s}_{\widehat{m}}\right)$ (which would make C explode) or—worse—may be nonpositive. In the latter case, no oracle inequality may be derived from (3). We shall see in the following that $\ell\left(s, \widehat{s}_{\widehat{m}}\right)$ blows up if and only if the penalty is smaller than some “minimal penalty”.

Let us consider first the case $\operatorname{pen}(m) = p_2(m)$ in (2). Then, $\mathbb{E}\left[\operatorname{crit}(m)\right] = \mathbb{E}\left[P_n\gamma\left(s_m\right)\right] = P\gamma\left(s_m\right)$, so that $\widehat{m}$ approximately minimizes its bias. Therefore, $\widehat{m}$ is one of the more complex models, and the risk of $\widehat{s}_{\widehat{m}}$ is large. Let us assume now that $\operatorname{pen}(m) = Kp_2(m)$. If $0 < K < 1$, $\operatorname{crit}(m)$ is a decreasing function of the complexity of m, so that $\widehat{m}$ is again one of the more complex models. On the contrary, if $K > 1$, $\operatorname{crit}(m)$ increases with the complexity of m (at least for the largest models), so that $\widehat{m}$ has a small or medium complexity. This argument supports the conjecture that the “minimal amount of penalty” required for the model selection procedure to work is $p_2(m)$.

In many frameworks such as the one of Section 4.1, it turns out that

$$\forall m \in \mathcal{M}_n, \qquad p_1(m) \approx p_2(m) \enspace .$$

Hence, the ideal penalty $\operatorname{pen}_{\mathrm{id}}(m) \approx p_1(m) + p_2(m)$ is close to $2p_2(m)$. Since $p_2(m)$ is a “minimal penalty”, the optimal penalty is close to twice the minimal penalty:

$$\operatorname{pen}_{\mathrm{id}}(m) \approx 2\operatorname{pen}_{\min}(m) \enspace .$$

This is the so-called "slope heuristics", first introduced by Birgé and Massart (2007) in a Gaussian homoscedastic setting. Note that a formal proof of the validity of the slope heuristics has only been given for Gaussian homoscedastic least-squares regression with a fixed design (Birgé and Massart, 2007); up to the best of our knowledge, the present paper yields the second theoretical result on the slope heuristics.

This heuristics has some applications because the minimal penalty can be estimated from the data. Indeed, when the penalty smaller than $\mathrm{pen}_{\min}$, the selected model $\widehat{m}$ is among the more complex. On the contrary, when the penalty is larger than $\mathrm{pen}_{\min}$, the complexity of $\widehat{m}$ is much smaller. This leads to the algorithm described in the next section.

3. A Data-driven Calibration Algorithm

Now, a data-driven calibration algorithm for penalization procedures can be defined, generalizing a method proposed by Birgé and Massart (2007) and implemented by Lebarbier (2005).

3.1 The General Algorithm

Assume that the shape $\mathrm{pen}_{\mathrm{shape}} : \mathcal{M}_n \mapsto \mathbb{R}^+$ of the ideal penalty is known, from some prior knowledge or because it had first been estimated, see Section 3.4. Then, the penalty $K^\star \mathrm{pen}_{\mathrm{shape}}$ provides an approximately optimal procedure, for some unknown constant $K^\star > 0$. The goal is to find some $\widehat{K}$ such that $\widehat{K}\,\mathrm{pen}_{\mathrm{shape}}$ is approximately optimal.

Let D_m be some known complexity measure of the model $m \in \mathcal{M}_n$. Typically, when the models are finite-dimensional vector spaces, D_m is the dimension of S_m. According to the "slope heuristics" detailed in Section 2.3, the following algorithm provides an optimal calibration of the penalty $\mathrm{pen}_{\mathrm{shape}}$.

Algorithm 1 (Data-driven penalization with slope heuristics)

1. *Compute the selected model $\widehat{m}(K)$ as a function of $K > 0$*

$$\widehat{m}(K) \in \arg\min_{m \in \mathcal{M}_n} \left\{ P_n\gamma(\widehat{s}_m) + K\,\mathrm{pen}_{\mathrm{shape}}(m) \right\} \quad .$$

2. *Find $\widehat{K}_{\min} > 0$ such that $D_{\widehat{m}(K)}$ is "huge" for $K < \widehat{K}_{\min}$ and "reasonably small" for $K > \widehat{K}_{\min}$.*

3. *Select the model $\widehat{m} := \widehat{m}\left(2\widehat{K}_{\min}\right)$.*

A computationally efficient way to perform the first step of Algorithm 1 is provided in Section 3.2. The accurate definition of $\widehat{K}_{\min}$ is discussed in Section 3.3, including explicit values for "huge" and "reasonably small"). Then, once $P_n\gamma(\widehat{s}_m)$ and $\mathrm{pen}_{\mathrm{shape}}(m)$ are known for every $m \in \mathcal{M}_n$, the complexity of Algorithm 1 is $O(\mathrm{Card}(\mathcal{M}_n)^2)$ (see Algorithm 2 and Proposition 1). This can be a decisive advantage compared to cross-validation methods, as discussed in Section 4.6.

3.2 Computation of $(\widehat{m}(K))_{K \geq 0}$

Step 1 of Algorithm 1 requires to compute $\widehat{m}(K)$ for every $K \in (0, +\infty)$. A computationally efficient way to perform this step is described in this subsection.

We start with some notations:

$$\forall m \in \mathcal{M}_n, \qquad f(m) = P_n\gamma(\widehat{s}_m) \qquad\qquad g(m) = \mathrm{pen}_{\mathrm{shape}}(m)$$
$$\text{and} \qquad \forall K \geq 0, \qquad \widehat{m}(K) \in \arg\min_{m\in\mathcal{M}_n} \{ f(m) + Kg(m) \} \enspace .$$

Since the latter definition can be ambiguous, let us choose any total ordering $\preceq$ on $\mathcal{M}_n$ such that g is non-decreasing, which is always possible if $\mathcal{M}_n$ is at most countable. Then, $\widehat{m}(K)$ is defined as the smallest element of

$$E(K) := \arg\min_{m\in\mathcal{M}_n} \{ f(m) + Kg(m) \}$$

for $\preceq$. The main reason why the whole trajectory $(\widehat{m}(K))_{K\geq 0}$ can be computed efficiently is its particular shape.

Indeed, the proof of Proposition 1 shows that $K \mapsto \widehat{m}(K)$ is piecewise constant, and non-increasing for $\preceq$. Then, the whole trajectory $(\widehat{m}(K))_{K\geq 0}$ can be summarized by

- the number of jumps $i_{\max} \in \{0,\dots,\mathrm{Card}(\mathcal{M}_n)-1\}$,
- the location of the jumps: an increasing sequence of nonnegative reals $(K_i)_{0\leq i\leq i_{\max}+1}$, with $K_0 = 0$ and $K_{i_{\max}+1} = +\infty$,
- a non-increasing sequence of models $(m_i)_{0\leq i\leq i_{\max}}$,

$$\text{with} \qquad \forall i \in \{0,\dots,i_{\max}\}, \quad \forall K \in [K_i, K_{i+1}), \qquad \widehat{m}(K) = m_i \enspace .$$

Algorithm 2 (Step 1 of Algorithm 1) *For every $m \in \mathcal{M}_n$, define $f(m) = P_n\gamma(\widehat{s}_m)$ and $g(m) = \mathrm{pen}_{\mathrm{shape}}(m)$. Choose $\preceq$ any total ordering on $\mathcal{M}_n$ such that g is non-decreasing.*

- *Init: $K_0 := 0$, $m_0 := \arg\min_{m\in\mathcal{M}_n}\{f(m)\}$ (when this minimum is attained several times, m_0 is defined as the smallest one with respect to $\preceq$).*
- *Step i, $i \geq 1$: Let*

$$G(m_{i-1}) := \{ m \in \mathcal{M}_n \text{ s.t. } f(m) > f(m_{i-1}) \quad \text{and} \quad g(m) < g(m_{i-1}) \} \enspace .$$

If $G(m_{i-1}) = \emptyset$, then put $K_i = +\infty$, $i_{\max} = i-1$ and stop. Otherwise,

$$K_i := \inf\left\{ \frac{f(m) - f(m_{i-1})}{g(m_{i-1}) - g(m)} \text{ s.t. } m \in G(m_{i-1}) \right\} \tag{4}$$
$$\text{and} \qquad m_i := \min_{\preceq} F_i \qquad \text{with} \quad F_i := \arg\min_{m\in G(m_{i-1})} \left\{ \frac{f(m) - f(m_{i-1})}{g(m_{i-1}) - g(m)} \right\} \enspace .$$

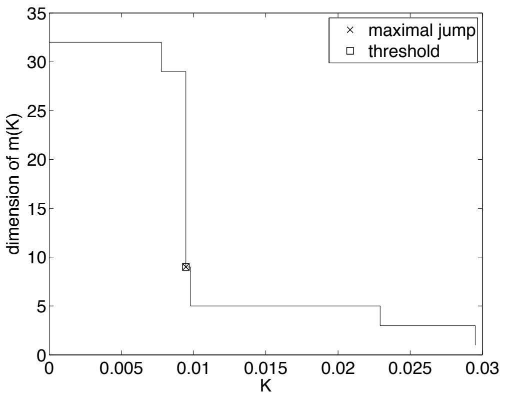
Proposition 1 (Correctness of Algorithm 2) *If $\mathcal{M}_n$ is finite, Algorithm 2 terminates and $i_{\max} \leq \mathrm{Card}(\mathcal{M}_n) - 1$. With the notations of Algorithm 2, let $\widehat{m}(K)$ be the smallest element of*

$$E(K) := \arg\min_{m\in\mathcal{M}_n} \{ f(m) + Kg(m) \} \qquad \text{with respect to } \preceq .$$

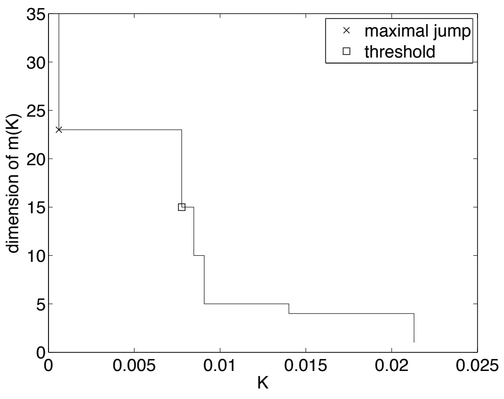
Then, $(K_i)_{0\leq i\leq i_{\max}+1}$ is increasing and $\forall i \in \{0,\dots,i_{\max}-1\}$, $\forall K \in [K_i, K_{i+1})$, $\widehat{m}(K) = m_i$.

It is proved in Section A.2. In the change-point detection framework, a similar result has been proved by Lavielle (2005).

Proposition 1 also gives an upper bound on the computational complexity of Algorithm 2; since the complexity of each step is $O(\mathrm{Card}\,\mathcal{M}_n)$, Algorithm 2 requires less than $O(i_{\max}\,\mathrm{Card}\,\mathcal{M}_n) \leq O((\mathrm{Card}\,\mathcal{M}_n)^2)$ operations. In general, this upper bound is pessimistic since $i_{\max} \ll \mathrm{Card}\,\mathcal{M}_n$.



(a) One clear jump.



(b) Two jumps, two values for $\widehat{K}_{\min}$.

Figure 1: $D_{\widehat{m}(K)}$ as a function of K for two different samples. Data are simulated according to (1) with $n = 200$, $X_i \sim \mathcal{U}([0,1])$, $\varepsilon_i \sim \mathcal{N}(0,1)$, $s(x) = \sin(\pi x)$ and $\sigma \equiv 1$. The models $(S_m)_{m \in \mathcal{M}_n}$ are the sets of piecewise constant functions on regular partitions of $[0,1]$, with dimensions between 1 and $n/(\ln(n))$. The penalty shape is $\mathrm{pen}_{\mathrm{shape}}(m) = D_m$ and the dimension threshold is $D_{\mathrm{thresh}} = 19 \approx n/(2\ln(n))$. See experiment S1 by Arlot (2008c, Section 6.1) for details.

3.3 Definition of $\widehat{K}_{\min}$

Step 2 of Algorithm 1 estimates $\widehat{K}_{\min}$ such that $\widehat{K}_{\min}\,\mathrm{pen}_{\mathrm{shape}}$ is the minimal penalty. The purpose of this subsection is to define properly $\widehat{K}_{\min}$ as a function of $(\widehat{m}(K))_{K>0}$.

According to the slope heuristics described in Section 2.3, $\widehat{K}_{\min}$ corresponds to a "complexity jump". If $K < \widehat{K}_{\min}$, $\widehat{m}(K)$ has a large complexity, whereas if $K > \widehat{K}_{\min}$, $\widehat{m}(K)$ has a small or medium complexity. Therefore, the two following definitions of $\widehat{K}_{\min}$ are natural.

Let D_{thresh} be the largest "reasonably small" complexity, meaning the models with larger complexities should not be selected. When D_m is the dimension of S_m as a vector space, $D_{\mathrm{thresh}} \propto n/(\ln(n))$ or $n/(\ln(n))^2$ are natural choices since the dimension of the oracle is likely to be of order n^{α} for some $\alpha \in (0,1)$. Then, define

$$\widehat{K}_{\min} := \inf\left\{ K > 0 \text{ s.t. } D_{\widehat{m}(K)} \leq D_{\mathrm{thresh}} \right\} \quad . \tag{5}$$

With this definition, Algorithm 2 can be stopped as soon as the threshold is reached.

Another idea is that $\widehat{K}_{\min}$ should match with the largest complexity jump:

$$\widehat{K}_{\min} := K_{i_{\mathrm{jump}}} \quad \text{with} \quad i_{\mathrm{jump}} = \arg \max_{i \in \{0,\dots,i_{\max}-1\}} \left\{ D_{m_{i+1}} - D_{m_i} \right\} \quad . \tag{6}$$

In order to ensure that there is a clear jump in the sequence $(D_{m_i})_{i \geq 0}$, it may be useful to add a few models of large complexity.

As an illustration, we compared the two definitions above (5 and 6) on 1 000 simulated samples. The exact simulation framework is described below Figure 1. Three cases occured:

1. There is one clear jump. Both definitions give the same value for $\widehat{K}_{\min}$. This occured for about 85% of the samples; an example is given on Figure 1a.

2. There are several jumps corresponding to close values of K. Definitions (5) and (6) give slightly different values for $\widehat{K}_{\min}$, but the selected models $\widehat{m}\left(2\widehat{K}_{\min}\right)$ are equal. This occured for about 8.5% of the samples.

3. There are several jumps corresponding to distant values of K. Definitions (5) and (6) strongly disagree, giving different selected models $\widehat{m}\left(2\widehat{K}_{\min}\right)$ at final. This occured for about 6.5% of the samples; an example is given on Figure 1b.

The only problematic case is the third one, in which an arbitrary choice has to be made between definitions (5) and (6).

With the same simulated data, we have compared the prediction errors of the two methods by estimating the constant C_{or} that would appear in some oracle inequality,

$$C_{\text{or}} := \frac{\mathbb{E}\left[\ell\left(s, \widehat{s}_{\widehat{m}}\right)\right]}{\mathbb{E}\left[\inf_{m \in \mathcal{M}_n}\left\{\ell\left(s, \widehat{s}_m\right)\right\}\right]} \quad .$$

With definition (5) $C_{\text{or}} \approx 1.88$; with definition (6) $C_{\text{or}} \approx 2.01$. For both methods, the standard error of the estimation is 0.04. As a comparison, Mallows' C_p with a classical estimator of the variance σ^2 has an estimated performance $C_{\text{or}} \approx 1.93$ on the same data.

The overall conclusion of this simulation experiment is that Algorithm 1 can be competitive with Mallows' C_p in a framework where Mallows' C_p is known to be optimal. Definition (5) for $\widehat{K}_{\min}$ seems slightly more efficient than (6), but without convincing evidence. Indeed, both definitions depend on some arbitrary choices: the value of the threshold D_{thresh} in (5), the maximal complexity among the collection of models $(S_m)_{m \in \mathcal{M}_n}$ in (6). When n is small, say $n = 200$, choosing D_{thresh} is tricky since $n/(2\ln(n))$ and $\sqrt{n}$ are quite close. Then, the difference between (5) and (6) is likely to come mainly from the particular choice $D_{\text{thresh}} = 19$ than from basic differences between the two definitions.

In order to estimate $\widehat{K}_{\min}$ as automatically as possible, we suggest to combine the two definitions; when the selected models $\widehat{m}(2\widehat{K}_{\min})$ differ, send a warning to the final user advising him to look at the curve $K \mapsto D_{\widehat{m}(K)}$ himself; otherwise, remain confident in the automatic choice of $\widehat{m}(2\widehat{K}_{\min})$.

3.4 Penalty Shape

For using Algorithm 1 in practice, it is necessary to know *a priori*, or at least to estimate, the optimal shape $\text{pen}_{\text{shape}}$ of the penalty. Let us explain how this can be achieved in different frameworks.

The first example that comes to mind is $\text{pen}_{\text{shape}}(m) = D_m$. It is valid for homoscedastic least-squares regression on linear models, as shown by several papers mentioned in Section 1. Indeed, when $\text{Card}(\mathcal{M}_n)$ is smaller than some power of n, Mallows' C_p penalty—defined by $\text{pen}(m) = 2\mathbb{E}\left[\sigma^2(X)\right] n^{-1} D_m$—is well known to be asymptotically optimal. For larger collections $\mathcal{M}_n$, more elaborate results (Birgé and Massart, 2001, 2007) have shown that a penalty proportional to $\ln(n)\mathbb{E}\left[\sigma^2(X)\right] n^{-1} D_m$ and depending on the size of $\mathcal{M}_n$ is asymptotically optimal.

Algorithm 1 then provides an alternative to plugging an estimator of $\mathbb{E}\left[\sigma^2(X)\right]$ into the above penalties. Let us detail two main advantages of our approach. First, we avoid the difficult task of estimating $\mathbb{E}\left[\sigma^2(X)\right]$ without knowing in advance some model to which the true regression function belongs. Algorithm 1 provides a model-free estimation of the factor multiplying the penalty. Second, the estimator $\widehat{\sigma^2}$ of $\mathbb{E}\left[\sigma^2(X)\right]$ with the smallest quadratic risk is certainly far from being the optimal one for model selection. For instance, underestimating the multiplicative factor is well-known to lead to poor performances, whereas overestimating the multiplicative factor does not increase much the prediction error in general. Then, a good estimator of $\mathbb{E}\left[\sigma^2(X)\right]$ for model selection should overestimate it with a probability larger than $1/2$. Algorithm 1 satisfies this property automatically because $\widehat{K}_{\min}$ so that the selected model cannot be too large.

In short, *Algorithm 1 with* $\mathrm{pen}_{\mathrm{shape}}(m) = D_m$ *is quite different from a simple plug-in version of Mallows' C_p*. It leads to a really *data-dependent penalty, which may perform better in practice than the best deterministic penalty $K^\star D_m$*.

In a more general framework, Algorithm 1 allows to choose a different shape of penalty $\mathrm{pen}_{\mathrm{shape}}$. For instance, in the heteroscedastic least-squares regression framework of Section 2.1, the optimal penalty is no longer proportional to the dimension D_m of the models. This can be shown from computations made by (Arlot, 2008c, Proposition 1) when S_m is assumed to be the vector space of piecewise constant functions on a partition $(I_\lambda)_{\lambda \in \Lambda_m}$ of $\mathcal{X}$:

$$\mathbb{E}\left[\mathrm{pen}_{\mathrm{id}}(m)\right] = \mathbb{E}\left[(P - P_n)\gamma(\widehat{s}_m)\right] \approx \frac{2}{n} \sum_{\lambda \in \Lambda_m} \mathbb{E}\left[\sigma(X)^2 \,\middle|\, X \in I_\lambda\right] \quad . \tag{7}$$

An exact result has been proved by Arlot (2008c, Proposition 1). Moreover, Arlot (2008a) gave an example of model selection problem in which no penalty proportional to D_m can be asymptotically optimal.

A first way to estimate the shape of the penalty is simply to use (7) to compute $\mathrm{pen}_{\mathrm{shape}}$, when both the distribution of X and the shape of the noise level σ are known. In practice, one has seldom such a prior knowledge.

We suggest in this situation to use *resampling penalties* (Efron, 1983; Arlot, 2008c), or *V-fold penalties* (Arlot, 2008b) which have much smaller computational costs. Up to a multiplicative factor (automatically estimated by Algorithm 1), these penalties should estimate correctly $\mathbb{E}\left[\mathrm{pen}_{\mathrm{id}}(m)\right]$ in any framework. In particular, resampling and V-fold penalties are asymptotically optimal in the heteroscedastic least-squares regression framework (Arlot, 2008b,c).

3.5 The General Prediction Framework

Section 2 and definition of Algorithm 1 have restricted ourselves to the least-squares regression framework. Actually, this is not necessary at all to make Algorithm 1 well-defined, so that it can naturally be extended to the general prediction framework. More precisely, the (X_i, Y_i) can be assumed to belong to $\mathcal{X} \times \mathcal{Y}$ for some general $\mathcal{Y}$, and $\gamma : S \times (\mathcal{X} \times \mathcal{Y}) \mapsto [0; +\infty)$ any contrast function. In particular, $\mathcal{Y} = \{0, 1\}$ leads to the binary classification problem, for which a natural contrast function is the 0–1 loss $\gamma(t; (x, y)) = \mathbb{1}_{t(x) \neq y}$. In this case, the shape of the penalty $\mathrm{pen}_{\mathrm{shape}}$ can for instance be estimated with the global or local Rademacher complexities mentioned in Section 1.

However, a natural question is whether the slope heuristics of Section 2.3, upon which Algorithm 1 relies, can be extended to the general framework. Several concentration results used to prove the validity of the slope heuristics in the least-squares regression framework in this article are valid in a general setting including binary classification. Even if the factor 2 coming from the closeness of $\mathbb{E}[p_1]$ and $\mathbb{E}[p_2]$ (see Section 2.3) may not be universally valid, we conjecture that Algorithm 1 can be used in other settings than least-squares regression. Moreover, as already mentioned at the end of Section 1, empirical studies have shown that Algorithm 1 can be successfully applied to several problems, with different shapes for the penalty. To our knowledge, to give a formal proof of this fact remains an interesting open problem.

4. Theoretical Results

Algorithm 1 mainly relies on the "slope heuristics", developed in Section 2.2. The goal of this section is to provide a theoretical justification of this heuristics.

It is split into two main results. First, Theorem 2 provides lower bounds on $D_{\widehat{m}}$ and the risk of $\widehat{s}_{\widehat{m}}$ when the penalty is smaller than $\mathrm{pen}_{\min}(m) := \mathbb{E}[p_2(m)]$. Second, Theorem 3 is an oracle inequality with leading constant almost one when $\mathrm{pen}(m) \approx 2\mathbb{E}[p_2(m)]$, relying on (3) and the comparison $p_1 \approx p_2$.

In order to prove both theorems, two probabilistic results are necessary. First, p_1, p_2 and δ concentrate around their expectations; for p_2 and δ, it is proved in a general framework in Appendix A.6. Second, $\mathbb{E}[p_1(m)] \approx \mathbb{E}[p_2(m)]$ for every $m \in \mathcal{M}_n$. The latter point is quite hard to prove in general, so that we must make an assumption on the models. Therefore, in this section, we restrict ourselves to the regressogram case, assuming that for every $m \in \mathcal{M}_n$, S_m is the set of piecewise constant functions on some fixed partition $(I_\lambda)_{\lambda\in\Lambda_m}$ of $\mathcal{X}$. This framework is described precisely in the next subsection. Although we do not consider regressograms as a final goal, the theoretical results proved for regressograms help to understand better how to use Algorithm 1 in practice.

4.1 Regressograms

Let S_m be the the set of piecewise constant functions on some partition $(I_\lambda)_{\lambda\in\Lambda_m}$ of $\mathcal{X}$. The empirical risk minimizer $\widehat{s}_m$ on S_m is called a *regressogram*. S_m is a vector space of dimension $D_m = \mathrm{Card}(\Lambda_m)$, spanned by the family $(\mathbb{1}_{I_\lambda})_{\lambda\in\Lambda_m}$. Since this basis is orthogonal in $L^2(\mu)$ for any probability measure μ on $\mathcal{X}$, computations are quite easy. In particular, we have:

$$s_m = \sum_{\lambda\in\Lambda_m} \beta_\lambda \mathbb{1}_{I_\lambda} \quad \text{and} \quad \widehat{s}_m = \sum_{\lambda\in\Lambda_m} \widehat{\beta}_\lambda \mathbb{1}_{I_\lambda} \enspace ,$$

where

$$\beta_\lambda := \mathbb{E}_P[Y \mid X \in I_\lambda] \qquad \widehat{\beta}_\lambda := \frac{1}{n\widehat{p}_\lambda} \sum_{X_i\in I_\lambda} Y_i \qquad \widehat{p}_\lambda := P_n(X \in I_\lambda) \enspace .$$

Note that $\widehat{s}_m$ is uniquely defined if and only if each I_λ contains at least one of the X_i. Otherwise, $\widehat{s}_m$ is not uniquely defined and we consider that the model m cannot be chosen.

4.2 Main Assumptions

In this section, we make the following assumptions. First, each model S_m is a set of piecewise constants functions on some fixed partition $(I_\lambda)_{\lambda\in\Lambda_m}$ of $\mathcal{X}$. Second, the family $(S_m)_{m\in\mathcal{M}_n}$ satisfies:

(**P1**) Polynomial complexity of $\mathcal{M}_n$: $\mathrm{Card}(\mathcal{M}_n) \leq c_{\mathcal{M}} n^{\alpha_{\mathcal{M}}}$.

(**P2**) Richness of $\mathcal{M}_n$: $\exists m_0 \in \mathcal{M}_n$ s.t. $D_{m_0} \in [\sqrt{n}, c_{\mathrm{rich}}\sqrt{n}]$.

Assumption (**P1**) is quite classical for proving the asymptotic optimality of a model selection procedure; it is for instance implicitly assumed by Li (1987) in the homoscedastic fixed-design case. Assumption (**P2**) is merely technical and can be changed if necessary; it only ensures that $(S_m)_{m\in\mathcal{M}_n}$ does not contain only models which are either too small or too large.

For any penalty function pen : $\mathcal{M}_n \mapsto \mathbb{R}^+$, we define the following model selection procedure:

$$\widehat{m} \in \arg \min_{m \in \mathcal{M}_n,\, \min_{\lambda \in \Lambda_m} \{ \widehat{p}_\lambda \} > 0} \{ P_n \gamma(\widehat{s}_m) + \operatorname{pen}(m) \} \quad . \tag{8}$$

Moreover, the data $(X_i, Y_i)_{1 \le i \le n}$ are assumed to be i.i.d. and to satisfy:

($\mathbf{Ab}$) The data are bounded: $\|Y_i\|_\infty \le A < \infty$.

($\mathbf{An}$) Uniform lower-bound on the noise level: $\sigma(X_i) \ge \sigma_{\min} > 0$ a.s.

($\mathbf{Ap_u}$) The bias decreases as a power of D_m: there exist some $\beta_+, C_+ > 0$ such that

$$\ell(s, s_m) \le C_+ D_m^{-\beta_+} \quad .$$

($\mathbf{Ar}_\ell^{\mathbf{X}}$) Lower regularity of the partitions for $\mathcal{L}(X)$: $D_m \min_{\lambda \in \Lambda_m} \{ \mathbb{P}(X \in I_\lambda) \} \ge c_{\mathrm{r},\ell}^X$.

Further comments are made in Sections 4.3 and 4.4 about these assumptions, in particular about their possible weakening.

4.3 Minimal Penalties

Our first result concerns the existence of a minimal penalty. In this subsection, ($\mathbf{P2}$) is replaced by the following strongest assumption:

($\mathbf{P2}+$) $\exists c_0, c_{\mathrm{rich}} > 0$ s.t. $\forall l \in [\sqrt{n}, c_0 n / (c_{\mathrm{rich}} \ln(n))]$, $\exists m \in \mathcal{M}_n$ s.t. $D_m \in [l, c_{\mathrm{rich}} l]$.

The reason why ($\mathbf{P2}$) is not sufficient to prove Theorem 2 below is that at least one model of dimension of order $n/\ln(n)$ should belong to the family $(S_m)_{m \in \mathcal{M}_n}$; otherwise, it may not be possible to prove that such models are selected by penalization procedures beyond the minimal penalty.

Theorem 2 *Suppose all the assumptions of Section 4.2 are satisfied. Let $K \in [0;1)$, $L > 0$, and assume that an event of probability at least $1 - Ln^{-2}$ exists on which*

$$\forall m \in \mathcal{M}_n, \quad 0 \le \operatorname{pen}(m) \le K \mathbb{E}[P_n(\gamma(s_m) - \gamma(\widehat{s}_m))] \quad . \tag{9}$$

Then, there exist two positive constants K_1, K_2 such that, with probability at least $1 - K_1 n^{-2}$,

$$D_{\widehat{m}} \ge K_2 n \ln(n)^{-1} \quad ,$$

where $\widehat{m}$ is defined by (8). *On the same event,*

$$\ell(s, \widehat{s}_{\widehat{m}}) \ge \ln(n) \inf_{m \in \mathcal{M}_n} \{ \ell(s, \widehat{s}_m) \} \quad . \tag{10}$$

The constants K_1 and K_2 may depend on K, L and constants in ($\mathbf{P1}$), ($\mathbf{P2}+$), ($\mathbf{Ab}$), ($\mathbf{An}$), ($\mathbf{Ap_u}$) *and* ($\mathbf{Ar}_\ell^{\mathbf{X}}$)*, but do not depend on n.*

This theorem thus validates the first part of the heuristics of Section 2.3, proving that a minimal amount of penalization is required; when the penalty is smaller, the selected dimension $D_{\widehat{m}}$ and the quadratic risk of the final estimator $\ell(s, \widehat{s}_{\widehat{m}})$ blow up. This coupling is quite interesting, since the dimension $D_{\widehat{m}}$ is known in practice, contrary to $\ell(s, \widehat{s}_{\widehat{m}})$. It is then possible to detect from the data whether the penalty is too small, as proposed in Algorithm 1.

The main interest of this result is its combination with Theorem 3 below. Nevertheless Theorem 2 is also interesting by itself for understanding the theoretical properties of penalization procedures. Indeed, it generalizes the results of Birgé and Massart (2007) on the existence of minimal penalties to heteroscedastic regression with a random design, even if we have to restrict to regressograms. Moreover, we have a general formulation for the minimal penalty

$$\mathrm{pen}_{\min}(m) := \mathbb{E}\left[P_n \left(\gamma(s_m) - \gamma(\widehat{s}_m) \right) \right] = \mathbb{E}\left[p_2(m) \right] \quad ,$$

which can be used in frameworks situations where it is not proportional to the dimension D_m of the models (see Section 3.4 and references therein).

In addition, assumptions $(\mathbf{Ab})$ and $(\mathbf{An})$ on the data are much weaker than the Gaussian homoscedastic assumption. They are also much more realistic, and moreover can be strongly relaxed. Roughly speaking, boundedness of data can be replaced by conditions on moments of the noise, and the uniform lower bound $\sigma_{\min}$ is no longer necessary when σ satisfies some mild regularity assumptions. We refer to Arlot (2008c, Section 4.3) for detailed statements of these assumptions, and explanations on how to adapt proofs to these situations.

Finally, let us comment on conditions $(\mathbf{Ap_u})$ and $(\mathbf{Ar}_{\ell}^{\mathbf{X}})$. The upper bound $(\mathbf{Ap_u})$ on the bias occurs in the most reasonable situations, for instance when $\mathcal{X} \subset \mathbb{R}^k$ is bounded, the partition $(I_\lambda)_{\lambda \in \Lambda_m}$ is regular and the regression function s is α-Hölderian for some $\alpha > 0$ (β_+ depending on α and k). It ensures that medium and large models have a significantly smaller bias than smaller ones; otherwise, the selected dimension would be allowed to be too small with significant probability. On the other hand, $(\mathbf{Ar}_{\ell}^{\mathbf{X}})$ is satisfied at least for "almost regular" partitions $(I_\lambda)_{\lambda \in \Lambda_m}$, when X has a lower bounded density w.r.t. the Lebesgue measure on $\mathcal{X} \subset \mathbb{R}^k$.

Theorem 2 is stated with a general formulation of $(\mathbf{Ap_u})$ and $(\mathbf{Ar}_{\ell}^{\mathbf{X}})$, instead of assuming for instance that s is α-Hölderian and X has a lower bounded density w.r.t Leb, in order to point out the *generality* of the "minimal penalization" phenomenon. It occurs as soon as the models are not too much pathological. In particular, we do not make any assumption on the distribution of X itself, but only that the models are not too badly chosen according to this distribution. Such a condition can be checked in practice if some prior knowledge on $\mathcal{L}(X)$ is available; if part of the data are unlabeled—a usual case,—classical density estimation procedures can be applied for estimating $\mathcal{L}(X)$ from unlabeled data (Devroye and Lugosi, 2001).

4.4 Optimal Penalties

Algorithm 1 relies on a link between the minimal penalty pointed out by Theorem 2 and some optimal penalty. The following result is a formal proof of this link in the framework we consider: penalties close to twice the minimal penalty satisfy an oracle inequality with leading constant approximately equal to one.

Theorem 3 *Suppose all the assumptions of Section 4.2 are satisfied together with*

(**Ap**) *The bias decreases like a power of D_m: there exist $\beta_- \geq \beta_+ > 0$ and $C_+, C_- > 0$ such that*

$$C_- D_m^{-\beta_-} \leq \ell(s, s_m) \leq C_+ D_m^{-\beta_+} \ .$$

Let $\delta \in (0,1)$, $L > 0$, and assume that an event of probability at least $1 - Ln^{-2}$ exists on which for every $m \in \mathcal{M}_n$,

$$(2-\delta)\mathbb{E}[P_n(\gamma(s_m) - \gamma(\widehat{s}_m))] \leq \mathrm{pen}(m) \leq (2+\delta)\mathbb{E}[P_n(\gamma(s_m) - \gamma(\widehat{s}_m))] \ . \tag{11}$$

Then, for every $0 < \eta < \min\{\beta_+; 1\}/2$, there exist a constant K_3 and a sequence ε_n tending to zero at infinity such that, with probability at least $1 - K_3 n^{-2}$,

$$\begin{aligned} & D_{\widehat{m}} \leq n^{1-\eta} \\ \text{and} \qquad & \ell(s, \widehat{s}_{\widehat{m}}) \leq \left(\frac{1+\delta}{1-\delta} + \varepsilon_n \right) \inf_{m \in \mathcal{M}_n} \{ \ell(s, \widehat{s}_m) \} \ , \end{aligned} \tag{12}$$

where $\widehat{m}$ is defined by (8)*. Moreover, we have the oracle inequality*

$$\mathbb{E}[\ell(s, \widehat{s}_{\widehat{m}})] \leq \left(\frac{1+\delta}{1-\delta} + \varepsilon_n \right) \mathbb{E}\left[\inf_{m \in \mathcal{M}_n} \{ \ell(s, \widehat{s}_m) \} \right] + \frac{A^2 K_3}{n^2} \ .$$

The constant K_3 may depend on L, δ, η and the constants in (**P1**)*,* (**P2**)*,* (**Ab**)*,* (**An**)*,* (**Ap**) *and* ($\mathbf{Ar}_\ell^{\mathbf{X}}$)*, but not on n. The term ε_n is smaller than $\ln(n)^{-1/5}$; it can be made smaller than $n^{-\delta}$ for any $\delta \in (0; \delta_0(\beta_-, \beta_+))$ at the price of enlarging K_3.*

This theorem shows that twice the minimal penalty $\mathrm{pen}_{\min}$ pointed out by Theorem 2 satisfies an oracle inequality with leading constant almost one. In other words, the slope heuristics of Section 2.3 is valid. The consequences of the *combination* of Theorems 2 and 3 are detailed in Section 4.5.

The oracle inequality (12) remains valid when the penalty is only close to twice the minimal one. In particular, *the shape of the penalty can be estimated by resampling* as suggested in Section 3.4.

Actually, Theorem 3 above is a corollary of a more general result stated in Appendix A.3, Theorem 5. If

$$\mathrm{pen}(m) \approx K\mathbb{E}[P_n(\gamma(s_m) - \gamma(\widehat{s}_m))] \tag{13}$$

instead of (11), under the same assumptions, an oracle inequality with leading constant $C(K) + \varepsilon_n$ instead of $1 + \varepsilon_n$ holds with large probability. The constant $C(K)$ is equal to $(K-1)^{-1}$ when $K \in (1,2]$ and to $C(K) = K - 1$ when $K > 2$. Therefore, for every $K > 1$, the penalty defined by (13) is efficient up to a multiplicative constant. This result is new in the heteroscedastic framework.

Let us comment the additional assumption (**Ap**), that is the lower bound on the bias. Assuming $\ell(s, s_m) > 0$ for every $m \in \mathcal{M}_n$ is classical for proving the asymptotic optimality of Mallows' C_p (Shibata, 1981; Li, 1987; Birgé and Massart, 2007). (**Ap**) has been made by Stone (1985) and Burman (2002) in the density estimation framework, for the same technical reasons as ours. Assumption (**Ap**) is satisfied in several frameworks, such as the following: $(I_\lambda)_{\lambda \in \Lambda_m}$ is "regular", X has a lower-bounded density w.r.t. the Lebesgue measure on $\mathcal{X} \subset \mathbb{R}^k$, and s is non-constant and α-hölderian (w.r.t. $\|\cdot\|_\infty$), with

$$\beta_1 = k^{-1} + \alpha^{-1} - (k-1)k^{-1}\alpha^{-1} \qquad \text{and} \qquad \beta_2 = 2\alpha k^{-1} \ .$$

We refer to Arlot (2007, Section 8.10) for a complete proof.

When the lower bound in (**Ap**) is no longer assumed, (12) holds with two modifications in its right-hand side (for details, see Arlot, 2008c, Remark 9): the inf is restricted to models of dimension larger than $\ln(n)^{\gamma_1}$, and there is a remainder term $\ln(n)^{\gamma_2} n^{-1}$, where $\gamma_1, \gamma_2 > 0$ are numerical constants. This is equivalent to (12), unless there is a model of small dimension with a small bias. The lower bound in (**Ap**) ensures that it cannot happen. Note that if there is a small model close to s, it is hopeless to obtain an oracle inequality with a penalty which estimates $\mathrm{pen}_{\mathrm{id}}$, simply because deviations of $\mathrm{pen}_{\mathrm{id}}$ around its expectation would be much larger than the excess loss of the oracle. In such a situation, BIC-like methods are more appropriate; for instance, Csiszár (2002) and Csiszár and Shields (2000) showed that BIC penalties are minimal penalties for estimating the order of a Markov chain.

4.5 Main Theoretical and Practical Consequences

The slope heuristics and the correctness of Algorithm 1 follow from the combination of Theorems 2 and 3.

4.5.1 OPTIMAL AND MINIMAL PENALTIES

For the sake of simplicity, let us consider the penalty $K\mathbb{E}[p_2(m)]$ with any $K > 0$; any penalty close to this one satisfies similar properties. At first reading, one can think of the homoscedastic case where $\mathbb{E}[p_2(m)] \approx \sigma^2 D_m n^{-1}$; one of the novelties of our results is that the general picture is quite similar.

According to Theorem 3, the penalization procedure associated with $K\mathbb{E}[p_2(m)]$ satisfies an oracle inequality with leading constant $C_n(K)$ as soon as $K > 1$, and $C_n(2) \approx 1$. Moreover, results proved by Arlot (2008b) imply that $C_n(K) \geq C(K) > 1$ as soon as K is not close to 2. Therefore, $K = 2$ *is the optimal multiplying factor* in front of $\mathbb{E}[p_2(m)]$.

When $K < 1$, Theorem 2 shows that no oracle inequality can hold with leading constant $C_n(K) < \ln(n)$. Since $C_n(K) \leq (K-1)^{-1} < \ln(n)$ as soon as $K > 1 + \ln(n)^{-1}$, $K = 1$ *is the minimal multiplying factor* in front of $\mathbb{E}[p_2(m)]$. More generally, $\mathrm{pen}_{\min}(m) := \mathbb{E}[p_2(m)]$ is proved to be a *minimal penalty*.

In short, Theorems 2 and 3 prove the slope heuristics described in Section 2.3:

$$\text{“optimal” penalty} \approx 2 \times \text{“minimal” penalty} \enspace .$$

Birgé and Massart (2007) have proved the validity of the slope heuristics in the Gaussian homoscedastic framework. This paper extends their result to a non-Gaussian and heteroscedastic setting.

4.5.2 DIMENSION JUMP

In addition, Theorems 2 and 3 prove the existence of a crucial phenomenon: there exists a “dimension jump”—complexity jump in the general framework—around the minimal penalty. Let us consider again the penalty $K\mathbb{E}[p_2(m)]$. As in Algorithm 1, let us define

$$\widehat{m}(K) \in \arg\min_{m \in \mathcal{M}_n} \left\{ P_n \gamma(\widehat{s}_m) + K\mathbb{E}[p_2(m)] \right\} \enspace .$$

A careful look at the proofs of Theorems 2 and 3 shows that there exist constants $K_4, K_5 > 0$ and an event of probability $1 - K_4 n^{-2}$ on which

$$\forall 0 < K < 1 - \frac{1}{\ln(n)}, D_{\widehat{m}(K)} \geq \frac{K_5 n}{(\ln(n))^2} \text{ and } \forall K > 1 + \frac{1}{\ln(n)}, D_{\widehat{m}(K)} \leq n^{1-\eta} \ . \tag{14}$$

Therefore, the dimension $D_{\widehat{m}(K)}$ of the selected model jumps around the minimal value $K = 1$, from values of order $n(\ln(n))^{-2}$ to $n^{1-\eta}$.

Let us know explain why Algorithm 1 is correct, assuming that $\mathrm{pen}_{\mathrm{shape}}(m)$ is close to $\mathbb{E}[p_2(m)]$. With definition (5) of $\widehat{K}_{\min}$ and a threshold $D_{\mathrm{thresh}} \propto n(\ln(n))^{-3}$, (14) ensures that

$$1 - \frac{1}{\ln(n)} \leq \widehat{K}_{\min} \leq 1 + \frac{1}{\ln(n)}$$

with a large probability. Then, according to Theorem 3, the output of Algorithm 1 satisfies an oracle inequality with leading constant C_n tending to one as n tends to infinity.

4.6 Comparison with Data-splitting Methods

Tuning parameters are often chosen by cross-validation or by another data-splitting method, which suffer from some drawbacks compared to Algorithm 1.

First, V-fold cross-validation, leave-p-out and repeated learning-testing methods require a larger computation time. Indeed, they need to perform the empirical risk minimization process for each model several times, whereas Algorithm 1 only needs to perform it once.

Second, V-fold cross-validation is asymptotically suboptimal when V is fixed, as shown by (Arlot, 2008b, Theorem 1). The same suboptimality result is valid for the hold-out, when the size of the training set is not asymptotically equivalent to the sample size n. On the contrary, Theorems 2 and 3 prove that Algorithm 1 is asymptotically optimal in a framework including the one used by (Arlot, 2008b, Theorem 1) for proving the suboptimality of V-fold cross-validation. Hence, the quadratic risk of Algorithm 1 should be smaller, within a factor $\kappa > 1$.

Third, hold-out with a training set of size $n_t \sim n$, for instance $n_t = n - \sqrt{n}$ or $n_t = n(1 - \ln(n)^{-1})$, is known to be unstable. The final output $\widehat{m}$ strongly depends on the choice of a particular split of the data. According to the simulation study of Section 3.3, Algorithm 1 is far more stable.

To conclude, compared to data splitting methods, Algorithm 1 is either faster to compute, more efficient in terms of quadratic risk, or more stable. Then, Algorithm 1 should be preferred each time it can be used. Another approach is to use aggregation techniques, instead of selecting one model. As shown by several results (see for instance Tsybakov, 2004; Lecué, 2007), aggregating estimators built upon a training simple of size $n_t \sim n$ can have an optimal quadratic risk. Moreover, aggregation requires approximately the same computation time as Algorithm 1, and is much more stable than the hold-out. Hence, it can be an alternative to model selection with Algorithm 1.

5. Conclusion

This paper provides mathematical evidence that the method introduced by Birgé and Massart (2007) for designing data-driven penalties remains efficient in a non-Gaussian framework. The purpose of this conclusion is to relate the slope heuristics developed in Section 2 to the well known Mallows' C_p and Akaike's criteria and to the unbiased estimation of the risk principle.

Let us come come back to Gaussian model selection in order to explain how to guess what is the right penalty from the data themselves. Let γ_n be some empirical criterion (for instance the least-squares criterion as in this paper, or the log-likelihood criterion), $(S_m)_{m\in\mathcal{M}_n}$ be a collection of models and for every $m \in \mathcal{M}_n$ s_m be some minimizer of $t \mapsto \mathbb{E}[\gamma_n(t)]$ over S_m (assuming that such a point exists). Minimizing some penalized criterion

$$\gamma_n(\widehat{s}_m) + \mathrm{pen}(m)$$

over $\mathcal{M}_n$ amounts to minimize

$$\widehat{b}_m - \widehat{v}_m + \mathrm{pen}(m) \ ,$$
$$\text{where} \quad \forall m \in \mathcal{M}_n,\ \widehat{b}_m = \gamma_n(s_m) - \gamma_n(s) \text{ and } \widehat{v}_m = \gamma_n(s_m) - \gamma_n(\widehat{s}_m) \ .$$

The point is that $\widehat{b}_m$ is an unbiased estimator of the bias term $\ell(s, s_m)$. Having concentration arguments in mind, minimizing $\widehat{b}_m - \widehat{v}_m + \mathrm{pen}(m)$ can be conjectured approximately equivalent to minimize

$$\ell(s, s_m) - \mathbb{E}[\widehat{v}_m] + \mathrm{pen}(m) \ .$$

Since the purpose of model selection is to minimize the risk $\mathbb{E}[\ell(s, \widehat{s}_m)]$, an ideal penalty would be

$$\mathrm{pen}(m) = \mathbb{E}[\widehat{v}_m] + \mathbb{E}[\ell(s_m, \widehat{s}_m)] \ .$$

In Gaussian least-squares regression with a fixed design, the models S_m are linear and $\mathbb{E}[\widehat{v}_m] = \mathbb{E}[\ell(s_m, \widehat{s}_m)]$ is explicitly computable if the noise level is constant and known; this leads to Mallows' C_p penalty. When γ_n is the log-likelihood,

$$\mathbb{E}[\widehat{v}_m] \approx \mathbb{E}[\ell(s_m, \widehat{s}_m)] \approx \frac{D_m}{2n}$$

asymptotically, where D_m stands for the number of parameters defining model S_m; this leads to Akaike's Information Criterion (AIC). Therefore, both Mallows' C_p and Akaike's criterion are based on the unbiased (or asymptotically unbiased) risk estimation principle.

This paper goes further in this direction, using that $\mathbb{E}[\widehat{v}_m] \approx \mathbb{E}[\ell(s_m, \widehat{s}_m)]$ remains a valid approximation in a non-asymptotic framework. Then, a good penalty becomes $2\mathbb{E}[\widehat{v}_m]$ or $2\widehat{v}_m$, having in mind concentration arguments. Since $\widehat{v}_m$ is the minimal penalty, this explains the slope heuristics (Birgé and Massart, 2007) and connects it to Mallows' C_p and Akaike's heuristics.

The second main idea developed in this paper is that the minimal penalty can be estimated from the data; Algorithm 1 uses the jump of complexity which occurs around the minimal penalty, as shown in Sections 3.3 and 4.5.2. Another way to estimate the minimal penalty when it is (at least approximately) of the form αD_m is to estimate α by the *slope* of the graph of $\gamma_n(\widehat{s}_m)$ for large enough values of D_m; this method can be extended to other shapes of penalties, simply by replacing D_m by some (known!) function $f(D_m)$.

The slope heuristics can even be combined with resampling ideas, by taking a function f built from a randomized empirical criterion. As shown by Arlot (2008a), this approach is much more efficient than the rougher choice $f(D_m) = D_m$ for heteroscedastic regression frameworks. The question of the optimality of the slope heuristics in general remains an open problem; nevertheless, we believe that this heuristics can be useful in practice, and that proving its efficiency in this paper helps to understand it better.

Let us finally mention that contrary to Birgé and Massart (2007), we assume in this paper that the collection of models $\mathcal{M}_n$ is "small", that is $\mathrm{Card}(\mathcal{M}_n)$ grows at most like a power of n. For several problems, such that complete variable selection, larger collections of models have to be considered; then, it is known from the homoscedastic case that the minimal penalty is much larger than $\mathbb{E}[p_2(m)]$. Nevertheless, Émilie Lebarbier has used the slope heuristics with $f(D_m) = D_m \left(2.5 + \ln \left(\frac{n}{D_m} \right) \right)$ for multiple change-points detection from n noisy data, using the results by Birgé and Massart (2007) in the Gaussian case.

Let us now explain how we expect to generalize the slope heuristics to the non-Gaussian heteroscedastic case when $\mathcal{M}_n$ is large. First, group the models according to some complexity index C_m such as their dimensions D_m; for $C \in \{1, \dots, n^k\}$, define $\widetilde{S_C} = \bigcup_{C_m = C} S_m$. Then, replace the model selection problem with the family $(S_m)_{m \in \mathcal{M}_n}$ by a "complexity selection problem", that is model selection with the family $\left(\widetilde{S_C}\right)_{1 \le C \le n^k}$. We conjecture that this grouping of the models is sufficient to take into account the richness of $\mathcal{M}_n$ for the optimal calibration of the penalty. A theoretical justification of this point could rely on the extension of our results to any kind of model, since $\widetilde{S_C}$ is not a vector space in general.

Acknowledgments

The authors gratefully acknowledge the anonymous referees for several suggestions and references. The first author was financed by Univ Paris-Sud (Laboratoire de Mathematiques, CNRS - UMR 8628, Orsay, F-91405). The second author is also affiliated to INRIA Saclay, Projet Select.

Appendix A. Proofs

This appendix is devoted to the proofs of the results stated in the paper. Proposition 1 is proved in Section A.2; Theorem 3 is proved in Sections A.3 and A.4; Theorem 2 is proved in Section A.5; the remaining sections are devoted to probabilistic results used in the main proofs and technical proofs.

A.1 Conventions and Notations

In the rest of the paper, L denotes a universal constant, not necessarily the same at each occurrence. When L is not universal, but depends on $p_1, \dots, p_k$, it is written $L_{p_1, \dots, p_k}$. Similarly, $L_{(\mathbf{SH2})}$ (resp. $L_{(\mathbf{SH5})}$) denotes a constant allowed to depend on the parameters of the assumptions made in Theorem 2 (resp. Theorem 5), including (**P1**) and (**P2**). We also make use of the following notations:

- $\forall a, b \in \mathbb{R}$, $a \wedge b$ is the minimum of a and b, $a \vee b$ is the maximum of a and b, $a_+ = a \vee 0$ is the positive part of a and $a_- = a \wedge 0$ is its negative part.
- $\forall I_\lambda \subset \mathcal{X}$, $p_\lambda := P(X \in I_\lambda)$ and $\sigma_\lambda^2 := \mathbb{E}\left[(Y - s_m(X))^2 \,\middle|\, X \in I_\lambda \right]$.
- Since $\mathbb{E}[p_1(m)]$ is not well-defined (because of the event $\{\min_{\lambda \in \Lambda_m} \{\widehat{p_\lambda}\} = 0\}$), we have to take the following convention

$$p_1(m) = \widetilde{p_1}(m) := \sum_{\lambda \in \Lambda_m \text{ s.t. } \widehat{p_\lambda} > 0} p_\lambda \left(\beta_\lambda - \widehat{\beta_\lambda} \right)^2 + \sum_{\lambda \in \Lambda_m \text{ s.t. } \widehat{p_\lambda} = 0} p_\lambda \sigma_\lambda^2 \ .$$

Remark that $p_1(m) = \widetilde{p}_1(m)$ when $\min_{\lambda \in \Lambda_m} \{ \widehat{p}_\lambda \} > 0$), so that this convention has no consequences on the final results (Theorems 2 and 5).

A.2 Proof of Proposition 1

First, since $\mathcal{M}_n$ is finite, the infimum in (4) is attained as soon as $G(m_{i-1}) \neq \emptyset$, so that m_i is well defined for every $i \leq i_{\max}$. Moreover, by construction, $g(m_i)$ decreases with i, so that all the $m_i \in \mathcal{M}_n$ are different; hence, Algorithm 2 terminates and $i_{\max} + 1 \leq \mathrm{Card}(\mathcal{M}_n)$. We now prove by induction the following property for every $i \in \{0, \dots, i_{\max}\}$:

$$\mathcal{P}_i : \qquad K_i < K_{i+1} \quad \text{and} \quad \forall K \in [K_i, K_{i+1}), \quad \widehat{m}(K) = m_i \ .$$

Notice also that K_i can always be defined by (4) with the convention $\inf \emptyset = +\infty$.

A.2.1 $\mathcal{P}_0$ HOLDS TRUE

By definition of K_1, it is clear that $K_1 > 0$ (it may be equal to $+\infty$ if $G(m_0) = \emptyset$). For $K = K_0 = 0$, the definition of m_0 is the one of $\widehat{m}(0)$, so that $\widehat{m}(K) = m_0$. For $K \in (0, K_1)$, Lemma 4 shows that either $\widehat{m}(K) = \widehat{m}(0) = m_0$ or $\widehat{m}(K) \in G(0)$. In the latter case, by definition of K_1,

$$\frac{f(\widehat{m}(K)) - f(m_0)}{g(m_0) - g(\widehat{m}(K))} \geq K_1 > K$$

hence

$$f(\widehat{m}(K)) + K g(\widehat{m}(K)) > f(m_0) + K g(m_0)$$

which is contradictory with the definition of $\widehat{m}(K)$. Therefore, $\mathcal{P}_0$ holds true.

A.2.2 $\mathcal{P}_i \Rightarrow \mathcal{P}_{i+1}$ FOR EVERY $i \in \{0, \dots, i_{\max} - 1\}$

Assume that $\mathcal{P}_i$ holds true. First, we have to prove that $K_{i+2} > K_{i+1}$. Since $K_{i_{\max}+1} = +\infty$, this is clear if $i = i_{\max} - 1$. Otherwise, $K_{i+2} < +\infty$ and m_{i+2} exists. Then, by definition of m_{i+2} and K_{i+2} (resp. m_{i+1} and K_{i+1}), we have

$$f(m_{i+2}) - f(m_{i+1}) = K_{i+2}(g(m_{i+1}) - g(m_{i+2})) \tag{15}$$

$$f(m_{i+1}) - f(m_i) = K_{i+1}(g(m_i) - g(m_{i+1})) \ . \tag{16}$$

Moreover, $m_{i+2} \in G(m_{i+1}) \subset G(m_i)$, and $m_{i+2} \prec m_{i+1}$ (because g is non-decreasing). Using again the definition of K_{i+1}, we have

$$f(m_{i+2}) - f(m_i) > K_{i+1}(g(m_i) - g(m_{i+2})) \tag{17}$$

(otherwise, we would have $m_{i+2} \in F_{i+1}$ and $m_{i+2} \prec m_{i+1}$, which is not possible). Combining the difference of (17) and (16) with (15), we have

$$K_{i+2}(g(m_{i+1}) - g(m_{i+2})) > K_{i+1}(g(m_{i+1}) - g(m_{i+2})) \ ,$$

hence $K_{i+2} > K_{i+1}$, since $g(m_{i+1}) > g(m_{i+2})$.

Second, we prove that $\widehat{m}(K_{i+1}) = m_{i+1}$. From $\mathcal{P}_i$, we know that for every $m \in \mathcal{M}_n$, for every $K \in [K_i, K_{i+1})$, $f(m_i) + K g(m_i) \leq f(m) + K g(m)$. Taking the limit when K tends to K_{i+1}, it follows that $m_i \in E(K_{i+1})$. By (16), we then have $m_{i+1} \in E(K_{i+1})$. On the other hand, if $m \in E(K_{i+1})$, Lemma 4 shows that either $f(m) = f(m_i)$ and $g(m) = g(m_i)$ or $m \in G(m_i)$. In the first case, $m_{i+1} \prec m$ (because g is non-decreasing). In the second one, $m \in F_{i+1}$, so $m_{i+1} \preceq m$. Since $\widehat{m}(K_{i+1})$ is the smallest element of $E(K_{i+1})$, we have proved that $m_{i+1} = \widehat{m}(K_{i+1})$.

Last, we have to prove that $\widehat{m}(K) = m_{i+1}$ for every $K \in (K_1, K_2)$. From the last statement of Lemma 4, we have either $\widehat{m}(K) = \widehat{m}(K_1)$ or $\widehat{m}(K_1) \in G(\widehat{m}(K))$. In the latter case (which is only possible if $K_{i+2} < \infty$), by definition of K_{i+2},

$$\frac{f(\widehat{m}(K)) - f(m_{i+1})}{g(m_{i+1}) - g(\widehat{m}(K))} \geq K_{i+2} > K$$

so that

$$f(\widehat{m}(K)) + Kg(\widehat{m}(K)) > f(m_{i+1}) + Kg(m_{i+1})$$

which is contradictory with the definition of $\widehat{m}(K)$. ■

Lemma 4 *With the notations of Proposition 1 and its proof, if* $0 \leq K < K'$, $m \in E(K)$ *and* $m' \in E(K')$, *then one of the two following statements holds true:*

(a) $f(m) = f(m')$ *and* $g(m) = g(m')$.

(b) $f(m) < f(m')$ *and* $g(m) > g(m')$.

In particular, either $\widehat{m}(K) = \widehat{m}(K')$ *or* $\widehat{m}(K') \in G(\widehat{m}(K))$.

Proof By definition of $E(K)$ and $E(K')$,

$$f(m) + Kg(m) \leq f(m') + Kg(m') \tag{18}$$
$$f(m') + K'g(m') \leq f(m) + K'g(m) \ . \tag{19}$$

Summing (18) and (19) gives $(K' - K)g(m') \leq (K' - K)g(m)$ so that

$$g(m') \leq g(m) \ . \tag{20}$$

Since $K \geq 0$, (18) and (20) give $f(m) + Kg(m) \leq f(m') + Kg(m)$, that is

$$f(m) \leq f(m') \ . \tag{21}$$

Moreover, (21) and (19) imply $g(m) = g(m')$, hence $f(m') \leq f(m)$, that is $f(m) = f(m')$ by (21). Similarly, (18) and (20) show that $f(m) = f(m')$ imply $g(m) = g(m')$. In both cases, (a) is satisfied. Otherwise, $f(m) < f(m')$ and $g(m) > g(m')$, that is the (b) statement.

The last statement follows by taking $m = \widehat{m}(K)$ and $m' = \widehat{m}(K')$, because g is non-decreasing, so that the minimum of g in $E(K)$ is attained by $\widehat{m}(K)$. ■

A.3 A General Oracle Inequality

First of all, let us state a general theorem, from which Theorem 3 is an obvious corollary.

Theorem 5 *Suppose all the assumptions of Section 4.2 are satisfied together with*

(**Ap**) *The bias decreases like a power of D_m: there exist $\beta_- \geq \beta_+ > 0$ and $C_+, C_- > 0$ such that*

$$C_- D_m^{-\beta_-} \leq \ell(s, s_m) \leq C_+ D_m^{-\beta_+} \quad .$$

Let $L, \xi, c_1, C_1, C_2 \geq 0$, $c_2 > 1$ and assume that an event of probability at least $1 - Ln^{-2}$ exists on which, for every $m \in \mathcal{M}_n$ such that $D_m \geq \ln(n)^{\xi}$,

$$\begin{aligned} &\mathbb{E}\left[c_1 P(\gamma(\widehat{s}_m) - \gamma(s_m)) + c_2 P_n(\gamma(s_m) - \gamma(\widehat{s}_m)) \right] \\ &\quad \leq \mathrm{pen}(m) \leq \mathbb{E}\left[C_1 P(\gamma(\widehat{s}_m) - \gamma(s_m)) + C_2 P_n(\gamma(s_m) - \gamma(\widehat{s}_m)) \right] \quad . \end{aligned} \tag{22}$$

Then, for every $0 < \eta < \min\{\beta_+; 1\}/2$, there exist a constant K_3 and a sequence ε_n tending to zero at infinity such that, with probability at least $1 - K_3 n^{-2}$,

$$\begin{aligned} & D_{\widehat{m}} \leq n^{1-\eta} \\ \textit{and} \qquad & \ell(s, \widehat{s}_{\widehat{m}}) \leq \left[\frac{1 + (C_1 + C_2 - 2)_+}{(c_1 + c_2 - 1) \wedge 1} + \varepsilon_n \right] \inf_{m \in \mathcal{M}_n} \{ \ell(s, \widehat{s}_m) \} \end{aligned} \tag{23}$$

where $\widehat{m}$ is defined by (8). Moreover, we have the oracle inequality

$$\mathbb{E}[\ell(s, \widehat{s}_{\widehat{m}})] \leq \left[\frac{1 + (C_1 + C_2 - 2)_+}{(c_1 + c_2 - 1) \wedge 1} + \varepsilon_n \right] \mathbb{E}\left[\inf_{m \in \mathcal{M}_n} \{ \ell(s, \widehat{s}_m) \} \right] + \frac{A^2 K_3}{n^2} \quad . \tag{24}$$

The constant K_3 may depend on L, η, ξ, c_1, c_2, C_1, C_2 and constants in (**P1**), (**P2**), (**Ab**), (**An**), (**Ap**) *and* ($\mathbf{Ar}_\ell^{\mathbf{X}}$)*, but not on n. The term ε_n is smaller than $\ln(n)^{-1/5}$; it can be made smaller than $n^{-\delta}$ for any $\delta \in (0; \delta_0(\beta_-, \beta_+))$ at the price of enlarging K_3.*

The particular form of condition (22) on the penalty is motivated by the fact that the ideal shape of penalty $\mathbb{E}[\mathrm{pen}_{\mathrm{id}}(m)]$ (or equivalently $\mathbb{E}[2p_2(m)]$) is unknown in general. Then, it has to be estimated from the data, for instance by resampling. Under the assumptions of Theorem 5, Arlot (2008b,c) has proved that resampling and V-fold penalties satisfy condition (22) with constants $c_1 + c_2 = 2 - \delta_n$, $C_1 + C_2 = 2 + \delta_n$ (for some absolute sequence δ_n tending to zero at infinity), and some numerical constant $\xi > 0$. Then, Theorem 5 shows that such a penalization procedure satisfies an oracle inequality with leading constant tending to 1 asymptotically.

The rationale behind Theorem 5 is that if $\mathrm{pen}(m)$ is close to $c_1 p_1(m) + c_2 p_2(m)$, then $\mathrm{crit}(m) \approx \ell(s, s_m) + c_1 p_1(m) + (c_2 - 1) p_2(m)$. When $c_1 = c_2 = 1$, this is exactly the ideal criterion $\ell(s, \widehat{s}_m)$. When $c_1 + c_2 = 2$ with $c_1 \geq 0$ and $c_2 > 1$, we obtain the same result because $p_1(m)$ and $p_2(m)$ are quite close, at least when D_m is large enough. The closeness between p_1 and p_2 is the keystone of the slope heuristics. Notice that if $\max_{m \in \mathcal{M}_n} D_m \leq K_3'(\ln(n))^{-1} n$ (for some constant K_3' depending only on the assumptions of Theorem 3, as K_3), one can replace the condition $c_2 > 1$ by $c_1 + c_2 > 1$ and $c_1, c_2 \geq 0$.

A.4 Proof of Theorem 5

This proof is similar to the one of Arlot (2008c, Theorem 1). We give it for the sake of completeness.

From (3), we have for each $m \in \mathcal{M}_n$ such that $A_n(m) := \min_{\lambda \in \Lambda_m} \{ n\widehat{p}_\lambda \} > 0$

$$\ell(s, \widehat{s}_{\widehat{m}}) - \left(\mathrm{pen}'_{\mathrm{id}}(\widehat{m}) - \mathrm{pen}(\widehat{m}) \right) \leq \ell(s, \widehat{s}_m) + \left(\mathrm{pen}(m) - \mathrm{pen}'_{\mathrm{id}}(m) \right) \quad . \tag{25}$$

with $\mathrm{pen}'_{\mathrm{id}}(m) := p_1(m) + p_2(m) - \overline{\delta}(m) = \mathrm{pen}(m) + (P - P_n)\gamma(s)$ and $\overline{\delta}(m) := (P_n - P)(\gamma(s_m) - \gamma(s))$. It is sufficient to control $\mathrm{pen} - \mathrm{pen}'_{\mathrm{id}}$ for every $m \in \mathcal{M}_n$.

We will thus use the concentration inequalities of Section A.6 with $x = \gamma \ln(n)$ and $\gamma = 2 + \alpha_{\mathcal{M}}$. Define $B_n(m) = \min_{\lambda \in \Lambda_m} \{ np_\lambda \}$, and Ω_n the event on which

- for every $m \in \mathcal{M}_n$, (22) holds
- for every $m \in \mathcal{M}_n$ such that $B_n(m) \geq 1$, (31) and (32) hold:

$$\widetilde{p}_1(m) \geq \mathbb{E}[\widetilde{p}_1(m)] - L_{(\mathbf{SH5})} \left[\frac{\ln(n)^2}{\sqrt{D_m}} + e^{-LB_n(m)} \right] \mathbb{E}[p_2(m)]$$
$$\widetilde{p}_1(m) \leq \mathbb{E}[\widetilde{p}_1(m)] + L_{(\mathbf{SH5})} \left[\frac{\ln(n)^2}{\sqrt{D_m}} + \sqrt{D_m} e^{-LB_n(m)} \right] \mathbb{E}[p_2(m)]$$

- for every $m \in \mathcal{M}_n$ such that $B_n(m) > 0$, (33), (30) and 28 hold:

$$\widetilde{p}_1(m) \geq \left(\frac{1}{2 + (\gamma+1)B_n(m)^{-1}\ln(n)} - \frac{L_{(\mathbf{SH5})}\ln(n)^2}{\sqrt{D_m}} \right) \mathbb{E}[p_2(m)]$$
$$|p_2(m) - \mathbb{E}[p_2(m)]| \leq \frac{L_{(\mathbf{SH5})}\ln(n)}{\sqrt{D_m}} [\ell(s, s_m) + \mathbb{E}[p_2(m)]]$$
$$\left| \overline{\delta}(m) \right| \leq \frac{\ell(s, s_m)}{\sqrt{D_m}} + L_{(\mathbf{SH5})} \frac{\ln(n)}{\sqrt{D_m}} \mathbb{E}[p_2(m)]$$

From Proposition 11 (for $\widetilde{p}_1$), Proposition 10 (for p_2) and Proposition 8 (for $\overline{\delta}(m)$),

$$\mathbb{P}(\Omega_n) \geq 1 - L \sum_{m \in \mathcal{M}_n} n^{-2-\alpha_{\mathcal{M}}} \geq 1 - L_{c_{\mathcal{M}}} n^{-2} \quad .$$

For every $m \in \mathcal{M}_n$ such that $D_m \leq L_{c^X_{\mathrm{r},\ell}} n \ln(n)^{-1}$, $(\mathbf{Ar}^{\mathbf{X}}_\ell)$ implies that $B_n(m) \geq L^{-1}\ln(n) \geq 1$. As a consequence, on Ω_n, if $\ln(n)^7 \leq D_m \leq L_{c^X_{\mathrm{r},\ell}} n \ln(n)^{-1}$:

$$\max\left\{ |\widetilde{p}_1(m) - \mathbb{E}[\widetilde{p}_1(m)]|, |p_2(m) - \mathbb{E}[p_2(m)]|, \left| \overline{\delta}(m) \right| \right\} \leq \frac{L_{(\mathbf{SH5})}\mathbb{E}[\ell(s, s_m) + p_2(m)]}{\ln(n)}$$

Using (34) (in Proposition 12) and the fact that $B_n(m) \geq L^{-1}\ln(n)$,

$$\frac{(c_1 + c_2)\left(1 - \widetilde{\delta}_n\right)}{2} \leq \mathbb{E}[\mathrm{pen}(m)] \leq \frac{(C_1 + C_2)\left(1 + \widetilde{\delta}_n\right)}{2} \mathbb{E}[\widetilde{p}_1(m) + p_2(m)]$$

with $0 \leq \widetilde{\delta_n} \leq L \ln(n)^{-1/4}$. We deduce: if $n \geq L_{(\mathbf{SH5})}$, for every $m \in \mathcal{M}_n$ such that $\ln(n)^7 \leq D_m \leq L_{c^X_{\mathrm{r},\ell}} n \ln(n)^{-1}$, on Ω_n,

$$\left[(c_1 + c_2 - 2)_- - \frac{L_{(\mathbf{SH5})}}{\ln(n)^{1/4}} \right] p_1(m) \leq (\mathrm{pen} - \mathrm{pen}'_{\mathrm{id}})(m)$$
$$\leq \left[(C_1 + C_2 - 2)_+ + \frac{L_{(\mathbf{SH5})}}{\ln(n)^{1/4}} \right] p_1(m) \enspace .$$

We need to assume that n is large enough in order to upper bound $\mathbb{E}[p_2(m)]$ in terms of $p_1(m)$, since we only have

$$p_1(m) \geq \left[1 - \frac{L_{(\mathbf{SH5})}}{\ln(n)^{1/4}} \right]_+ \mathbb{E}[p_2(m)]$$

in general. Combined with (25), this gives: if $n \geq L_{(\mathbf{SH5})}$,

$$\ell(s, \widehat{s}_{\widehat{m}}) \mathbb{1}_{\ln(n)^5 \leq D_{\widehat{m}} \leq L_{c^X_{\mathrm{r},\ell}} n \ln(n)^{-1}} \leq \left[\frac{1 + (C_1 + C_2 - 2)_+}{(c_1 + c_2 - 1) \wedge 1} + \frac{L_{(\mathbf{SH5})}}{\ln(n)^{1/4}} \right]$$
$$\times \inf_{m \in \mathcal{M}_n \text{ s.t. } \ln(n)^7 \leq D_m \leq L_{\alpha_{\mathcal{M}}, c^X_{\mathrm{r},\ell}} n \ln(n)^{-1}} \{ \ell(s, \widehat{s}_m) \} \enspace .$$

We now use Lemmas 6 and 7 below to control on Ω_n the dimensions of the selected model $\widehat{m}$ and the oracle model $m^\star \in \arg\min_{m \in \mathcal{M}_n} \{ \ell(s, \widehat{s}_m) \}$.

The result follows since $L_{(\mathbf{SH5})} \ln(n)^{-1/4} \leq \varepsilon_n = \ln(n)^{-1/5}$ for $n \geq L_{(\mathbf{SH5})}$. We finally remove the condition $n \geq n_0 = L_{(\mathbf{SH5})}$ by choosing $K_3 = L_{(\mathbf{SH5})}$ such that $K_3 n_0^{-2} \geq 1$.

A.4.1 CLASSICAL ORACLE INEQUALITY

Since (23) holds true on Ω_n,

$$\mathbb{E}[\ell(s, \widehat{s}_{\widehat{m}})] = \mathbb{E}[\ell(s, \widehat{s}_{\widehat{m}}) \mathbb{1}_{\Omega_n}] + \mathbb{E}\left[\ell(s, \widehat{s}_{\widehat{m}}) \mathbb{1}_{\Omega_n^c}\right]$$
$$\leq [2\eta - 1 + \varepsilon_n] \mathbb{E}\left[\inf_{m \in \mathcal{M}_n} \{ \ell(s, \widehat{s}_m) \} \right] + A^2 K_3 \mathbb{P}(\Omega_n^c)$$

which proves (24). ■

Lemma 6 (Control on the dimension of the selected model) *Let $c > 0$ and $\alpha > (1 - \beta_+)_+ / 2$. Then, if $n \geq L_{(\mathbf{SH5}), c, \alpha}$, on the event Ω_n defined in the proof of Theorem 5,*

$$\ln(n)^7 \leq D_{\widehat{m}} \leq n^{1/2 + \alpha} \leq c n \ln(n)^{-1} \enspace .$$

Lemma 7 (Control on the dimension of the oracle model) *Define the oracle model $m^\star \in \arg\min_{m \in \mathcal{M}_n} \{ \ell(s, \widehat{s}_m) \}$. Let $c > 0$ and $\alpha > (1 - \beta_+)_+ / 2$. Then, if $n \geq L_{(\mathbf{SH5}), c, \alpha}$, on the event Ω_n defined in the proof of Theorem 5,*

$$\ln(n)^7 \leq D_{m^\star} \leq n^{1/2 + \alpha} \leq c n \ln(n)^{-1} \enspace .$$

A.4.2 PROOF OF LEMMA 6

By definition, $\widehat{m}$ minimizes $\operatorname{crit}(m)$ over $\mathcal{M}_n$. It thus also minimizes

$$\operatorname{crit}'(m) = \operatorname{crit}(m) - P_n\gamma(s) = \ell(s, s_m) - p_2(m) + \overline{\delta}(m) + \operatorname{pen}(m)$$

over $\mathcal{M}_n$.

1. Lower bound on $\operatorname{crit}'(m)$ for small models: let $m \in \mathcal{M}_n$ such that $D_m < (\ln(n))^7$. We then have

$$\begin{aligned} \ell(s, s_m) &\geq C_- (\ln(n))^{-7\beta_-} && \text{from } (\mathbf{Ap}) \\ \operatorname{pen}(m) &\geq 0 \\ p_2(m) &\leq L_{(\mathbf{SH5})}\sqrt{\frac{\ln(n)}{n}} + L_{(\mathbf{SH5})}\frac{D_m}{n} \leq L_{(\mathbf{SH5})}\sqrt{\frac{\ln(n)}{n}} && \text{from (29)} \end{aligned}$$

   and from (28) (in Proposition 8),

$$\overline{\delta}(m) \geq -L_A\sqrt{\frac{\ell(s, s_m)\ln(n)}{n}} + L_A\frac{\ln(n)}{n} \geq -L_A\sqrt{\frac{\ln(n)}{n}} \quad .$$

   We then have
$$\operatorname{crit}'(m) \geq L_{(\mathbf{SH5})}(\ln(n))^{-L_{\beta_-}} \quad .$$

2. Lower bound for large models: let $m \in \mathcal{M}_n$ such that $D_m \geq n^{1/2+\alpha}$. From (22) and (29) (in Proposition 10),

$$\begin{aligned} \operatorname{pen}(m) - p_2(m) &\geq (c_2 - 1)\mathbb{E}[p_2(m)] - L_A\sqrt{\frac{\ln(n)}{n}} \\ &\geq \frac{(c_2-1)\sigma_{\min}^2 D_m}{n} - L_A\sqrt{\frac{\ln(n)}{n}} \end{aligned}$$

   and from (26),
$$\overline{\delta}(m) \geq -L_{(\mathbf{SH5})}\sqrt{\frac{\ln(n)}{n}} \quad .$$

   Hence, if $D_m \geq n^{1/2+\alpha}$ and $n \geq L_{(\mathbf{SH5}),\alpha}$

$$\operatorname{crit}'(m) \geq \operatorname{pen}(m) + \overline{\delta}(m) - p_2(m) \geq L_{(\mathbf{SH5}),\alpha} n^{-1/2+\alpha} \quad .$$

3. There exists a better model for $\operatorname{crit}(m)$: from $(\mathbf{P2})$, there exists $m_0 \in \mathcal{M}_n$ such that $\sqrt{n} \leq D_{m_0} \leq c_{\mathrm{rich}}\sqrt{n}$. If moreover $n \geq L_{c_{\mathrm{rich}},\alpha}$, then

$$\ln(n)^7 \leq \sqrt{n} \leq D_{m_0} \leq c_{\mathrm{rich}}\sqrt{n} \leq n^{1/2+\alpha} \quad .$$

   By (35) in Lemma 13, $A_n(m_0) \geq 1$ with probability at least $1 - Ln^{-2}$.
   Using $(\mathbf{Ap})$,
$$\ell(s, s_{m_0}) \leq C_+ c_{\mathrm{rich}}^{\beta_+} n^{-\beta_+/2}$$

so that, when $n \geq L_{(\mathbf{SH5})}$,

$$\begin{aligned}\operatorname{crit}'(m_0) &\leq \ell(s, s_{m_0}) + \left|\overline{\delta}(m)\right| + \operatorname{pen}(m) \\ &\leq L_{(\mathbf{SH5})}\left(n^{-\beta_+/2} + n^{-1/2}\right) \quad .\end{aligned}$$

If $n \geq L_{(\mathbf{SH5}),\alpha}$, this upper bound is smaller than the previous lower bounds for small and large models. ■

A.4.3 PROOF OF LEMMA 7

Recall that $m^\star$ minimizes $\ell(s, \widehat{s}_m) = \ell(s, s_m) + p_1(m)$ over $m \in \mathcal{M}_n$, with the convention $\ell(s, \widehat{s}_m) = \infty$ if $A_n(m) = 0$.

1. Lower bound on $\ell(s, \widehat{s}_m)$ for small models: let $m \in \mathcal{M}_n$ such that $D_m < (\ln(n))^7$. From (**Ap**), we have
$$\ell(s, \widehat{s}_m) \geq \ell(s, s_m) \geq C_-(\ln(n))^{-7\beta_-} \quad .$$

2. Lower bound on $\ell(s, \widehat{s}_m)$ for large models: let $m \in \mathcal{M}_n$ such that $D_m > n^{1/2+\alpha}$. From (33), for $n \geq L_{(\mathbf{SH5}),\alpha}$,
$$\widetilde{p}_1(m) \geq \left(\frac{1}{2 + (\gamma+1)\left(c_{\mathrm{r},\ell}^X\right)^{-1}\ln(n)} - \frac{L_{(\mathbf{SH5}),\alpha}}{n^{1/4}}\right)\mathbb{E}\left[\widetilde{p}_2(m)\right]$$
$$\text{so that} \quad \ell(s, \widehat{s}_m) \geq \widetilde{p}_1(m) \geq L_{(\mathbf{SH5}),\alpha} n^{-1/2+\alpha} \quad .$$

3. There exists a better model for $\ell(s, \widehat{s}_m)$: let $m_0 \in \mathcal{M}_n$ be as in the proof of Lemma 6 and assume that $n \geq L_{c_{\mathrm{rich}},\alpha}$. Then,
$$p_1(m_0) \leq L_{(\mathbf{SH5})}\mathbb{E}\left[p_2(m)\right] \leq L_{(\mathbf{SH5})} n^{-1/2}$$
and the arguments of the previous proof show that
$$\ell(s, \widehat{s}_{m_0}) \leq L_{(\mathbf{SH5})}\left(n^{-\beta_+/2} + n^{-1/2}\right)$$
which is smaller than the previous upper bounds for $n \geq L_{(\mathbf{SH5}),\alpha}$. ■

A.5 Proof of Theorem 2

Similarly to the proof of Theorem 5, we consider the event Ω'_n, of probability at least $1 - L_{c_{\mathcal{M}}} n^{-2}$, on which:

- for every $m \in \mathcal{M}_n$, (9) (for pen), (33) (for $\widetilde{p}_1$), (29)–(30) (for p_2, with $x = \gamma\ln(n)$ and $\theta = \sqrt{\ln(n)/n}$) and (26)–(28) (for $\overline{\delta}$, with $x = \gamma\ln(n)$ and $\eta = \sqrt{\ln(n)/n}$) hold true.

- for every $m \in \mathcal{M}_n$ such that $B_n(m) \geq 1$, (31) and (32) hold (for $\widetilde{p}_1$).

A.5.1 LOWER BOUND ON $D_{\widehat{m}}$

By definition, $\widehat{m}$ minimizes

$$\operatorname{crit}'(m) = \operatorname{crit}(m) - P_n\gamma(s) = \ell(s, s_m) - p_2(m) + \overline{\delta}(m) + \operatorname{pen}(m)$$

over $m \in \mathcal{M}_n$ such that $A_n(m) \geq 1$. As in the proof of Theorem 5, we define $c = L_{c^X_{\mathrm{r},\ell}} > 0$ such that for every model of dimension $D_m \leq cn\ln(n)^{-1}$, $B_n(m) \geq L^{-1}\ln(n) \geq 1$. Let $c' = \min(c, c_0)$ and $d \in (0,1)$ a constant to be chosen later.

1. Lower bound on $\operatorname{crit}'(m)$ for "small" models: assume that $m \in \mathcal{M}_n$ and $D_m \leq dc'n\ln(n)^{-1}$. Then, $\ell(s, s_m) + \operatorname{pen}(m) \geq 0$ and from (26),

   $$\overline{\delta}(m) \geq -L_A\sqrt{\frac{\ln(n)}{n}} \enspace .$$

   If $D_m \geq \ln(n)^4$, (30) implies that

   $$p_2(m) \leq \left(1 + \frac{L_{(\mathbf{SH2})}}{\ln(n)}\right)\mathbb{E}\left[p_2(m)\right] \leq \frac{L_{(\mathbf{SH2})}D_m}{n} \leq \frac{c'dL_{(\mathbf{SH2})}}{\ln(n)} \enspace .$$

   On the other hand, if $D_m < \ln(n)^4$, (29) implies that

   $$p_2(m) \leq L_{(\mathbf{SH2})}\sqrt{\frac{\ln(n)}{n}} \enspace .$$

   We then have

   $$\operatorname{crit}'(m) \geq -dL_{(\mathbf{SH2})}\left(\ln(n)\right)^{-1} \enspace .$$

2. There exists a better model for $\operatorname{crit}(m)$: let $m_1 \in \mathcal{M}_n$ such that

   $$\ln(n)^4 \leq \frac{c'dn}{c_{\mathrm{rich}}\ln(n)} \leq D_{m_1} \leq \frac{c'n}{\ln(n)} \leq n \enspace .$$

   From (**P2**+), this is possible as soon as $n \geq L_{c_{\mathrm{rich}},c',d}$. By (35) in Lemma 13, $A_n(m_0) \geq 1$ with probability at least $1 - Ln^{-2}$.
   We then have

   $$\begin{aligned}
   \ell(s, s_{m_1}) &\leq L_{(\mathbf{SH2}),c'}\ln(n)^{\beta_+}n^{-\beta_+} && \text{by } (\mathbf{Ap})\\
   p_2(m_1) &\geq \left(1 - \frac{L_{(\mathbf{SH2})}}{\ln(n)}\right)\mathbb{E}\left[p_2(m_1)\right] && \text{by (30)}\\
   \operatorname{pen}(m_1) &\leq K\mathbb{E}\left[p_2(m_1)\right] && \text{by (9)}\\
   \left|\overline{\delta}(m_1)\right| &\leq L_A\sqrt{\frac{\ln(n)}{n}} && \text{by (26)}
   \end{aligned}$$

   so that

   $$\begin{aligned}
   \operatorname{crit}'(m_1) &\leq L_{(\mathbf{SH2}),c'}\ln(n)^{\beta_+}n^{-\beta_+} + \left(K - 1 + \frac{L_{(\mathbf{SH2})}}{\ln(n)}\right)\mathbb{E}\left[p_2(m_1)\right] + L_A\sqrt{\frac{\ln(n)}{n}}\\
   &\leq \frac{(K - 1 + L_{(\mathbf{SH2})}(\ln(n))^{-1})\sigma_{\min}^2 c'}{2\ln(n)}
   \end{aligned}$$

if $n \geq L_{(\mathbf{SH2}),c'}$.

We now choose d such that the constant $dL_{(\mathbf{SH2})}$ appearing in the lower bound on $\mathrm{crit}'(m)$ for "small" models is smaller than $(1-K-L_{(\mathbf{SH2})}(\ln(n))^{-1})\sigma_{\min}^2 c'/2$, that is $d \leq L_{(\mathbf{SH2}),c'}$. Then, we assume that $n \geq n_0 = L_{(\mathbf{SH2}),c',d} = L_{(\mathbf{SH2})}$. Finally, we remove this condition as before by enlarging K_1.

A.5.2 RISK OF $D_{\widehat{m}}$

The proof of (10) is quite similar to the one of Lemma 7. First, for every model $m \in \mathcal{M}_n$ such that $A_n(m) \geq 1$ and $D_m \geq K_2 n \ln(n)^{-1}$, we have

$$\ell(s, \widehat{s}_m) \geq \widetilde{p}_1(m) \geq L_{(\mathbf{SH2})} K_2 \ln(n)^{-2} \qquad \text{by (33)} \ .$$

Then, the model $m_0 \in \mathcal{M}_n$ defined previously satisfies $A_n(m) \geq 1$, and

$$\ell(s, \widehat{s}_{m_0}) \leq L_{(\mathbf{SH2})} \left(n^{-\beta_+/2} + n^{-1/2} \right) \ .$$

If $n \geq L_{(\mathbf{SH2})}$, the ratio between these two bounds is larger than $\ln(n)$, so that (10) holds. ■

A.6 Concentration Inequalities Used in the Main Proofs

In this section, we no longer assume that each model is the set of piecewise constant functions on some partition of $\mathcal{X}$. First, we control $\overline{\delta}(m)$ with general models and bounded data.

Proposition 8 *Assume that $\|Y\|_\infty \leq A < \infty$. Then for all $x \geq 0$, on an event of probability at least $1-2e^{-x}$:*

$$\forall \eta > 0, \quad \left|\overline{\delta}(m)\right| \leq \eta \ell(s, s_m) + \left(\frac{4}{\eta} + \frac{8}{3}\right) \frac{A^2 x}{n} \ . \tag{26}$$

If moreover

$$Q_m^{(p)} := \frac{n \mathbb{E}[p_2(m)]}{D_m} > 0 \ , \tag{27}$$

on the same event,

$$\left|\overline{\delta}(m)\right| \leq \frac{\ell(s, s_m)}{\sqrt{D_m}} + \frac{20}{3} \frac{A^2}{Q_m^{(p)}} \frac{\mathbb{E}[p_2(m)]}{\sqrt{D_m}} x \ . \tag{28}$$

Remark 9 (Regressogram case) *If S_m is the set of piecewise constant functions on some partition $(I_\lambda)_{\lambda \in \Lambda_m}$ of $\mathcal{X}$,*

$$Q_m^{(p)} = \frac{1}{D_m} \sum_{\lambda \in \Lambda_m} \sigma_\lambda^2 \geq (\sigma_{\min})^2 > 0 \ .$$

Then, we derive a concentration inequality for $p_2(m)$ in the regressogram case from a general result by Boucheron and Massart (2008).

Proposition 10 *Let S_m be the model of piecewise constant functions associated with the partition $(I_\lambda)_{\lambda \in \Lambda_m}$. Assume that $\|Y\|_\infty \leq A$ and define $p_2(m) = P_n(\gamma(s_m) - \gamma(\widehat{s}_m))$.*

Then, for every $x \geq 0$, there exists an event of probability at least $1 - e^{1-x}$ on which for every $\theta \in (0;1)$,

$$|p_2(m) - \mathbb{E}[p_2(m)]| \leq L \left[\theta \ell(s, s_m) + \frac{A^2 \sqrt{D_m} \sqrt{x}}{n} + \frac{A^2 x}{\theta n} \right] \tag{29}$$

for some absolute constant L. If moreover $\sigma(X) \geq \sigma_{\min} > 0$ a.s., we have on the same event:

$$|p_2(m) - \mathbb{E}[p_2(m)]| \leq \frac{L}{\sqrt{D_m}} \left[\ell(s, s_m) + \frac{A^2 \mathbb{E}[p_2(m)]}{\sigma_{\min}^2} \left(\sqrt{x} + x \right) \right] \quad . \tag{30}$$

Finally, we recall a concentration inequality for $p_1(m)$ proved by (Arlot, 2008b, Proposition 9). Its proof is particular to the regressogram case.

Proposition 11 (Proposition 9, Arlot 2008b) *Let $\gamma > 0$ and S_m be the model of piecewise constant functions associated with the partition $(I_\lambda)_{\lambda \in \Lambda_m}$. Assume that $\|Y\|_\infty \leq A < \infty$, $\sigma(X) \geq \sigma_{\min} > 0$ a.s. and $\min_{\lambda \in \Lambda_m} \{ n p_\lambda \} \geq B_n > 0$. Then, if $B_n \geq 1$, on an event of probability at least $1 - L n^{-\gamma}$,*

$$\widetilde{p_1}(m) \geq \mathbb{E}[\widetilde{p_1}(m)] - L_{A,\sigma_{\min},\gamma} \left[\frac{\ln(n)^2}{\sqrt{D_m}} + e^{-L B_n} \right] \mathbb{E}[p_2(m)] \tag{31}$$

$$\widetilde{p_1}(m) \leq \mathbb{E}[\widetilde{p_1}(m)] + L_{A,\sigma_{\min},\gamma} \left[\frac{\ln(n)^2}{\sqrt{D_m}} + \sqrt{D_m} e^{-L B_n} \right] \mathbb{E}[p_2(m)] \quad . \tag{32}$$

If we only have a lower bound $B_n > 0$, then, with probability at least $1 - L n^{-\gamma}$,

$$\widetilde{p_1}(m) \geq \left(\frac{1}{2 + (\gamma+1) B_n^{-1} \ln(n)} - \frac{L_{A,\sigma_{\min},\gamma} \ln(n)^2}{\sqrt{D_m}} \right) \mathbb{E}[p_2(m)] \quad . \tag{33}$$

A.7 Additional Results Needed

A crucial result in the proofs of Theorems 5 and 2 is that $p_1(m)$ and $p_2(m)$ are close in expectation; the following proposition was proved by Arlot (2008b, Lemma 7).

Proposition 12 (Lemma 7, Arlot 2008b) *Let S_m be a model of piecewise constant functions adapted to some partition $(I_\lambda)_{\lambda \in \Lambda_m}$. Assume that $\min_{\lambda \in \Lambda_m} \{ n p_\lambda \} \geq B > 0$. Then,*

$$\begin{aligned} \left(1 - e^{-B}\right)^2 \mathbb{E}[p_2(m)] &\leq \mathbb{E}[\widetilde{p_1}(m)] \\ &\leq \left[2 \wedge \left(1 + 5.1 \times B^{-1/4} \right) + (B \vee 1) e^{-(B \vee 1)} \right] \mathbb{E}[p_2(m)] \quad . \end{aligned} \tag{34}$$

Finally, we need the following technical lemma in the proof of the main theorems.

Lemma 13 *Let $(p_\lambda)_{\lambda \in \Lambda_m}$ be non-negative real numbers of sum 1, $(n \widehat{p}_\lambda)_{\lambda \in \Lambda_m}$ a multinomial vector of parameters $(n; (p_\lambda)_{\lambda \in \Lambda_m})$. Then, for all $\gamma > 0$,*

$$\min_{\lambda \in \Lambda_m} \{ n \widehat{p}_\lambda \} \geq \frac{\min_{\lambda \in \Lambda_m} \{ n p_\lambda \}}{2} - 2(\gamma+1) \ln(n) \tag{35}$$

with probability at least $1 - 2n^{-\gamma}$.

Proof By Bernstein inequality (Massart, 2007, Proposition 2.9), for all $\lambda \in \Lambda_m$,

$$\mathbb{P}\left(n\widehat{p}_\lambda \geq (1-\theta) n p_\lambda - \sqrt{2npx} - \frac{x}{3} \right) \geq 1 - e^{-x} \ .$$

Take $x = (\gamma+1)\ln(n)$ above, and remark that $\sqrt{2npx} \leq \frac{np}{2} + x$. The union bound gives the result since $\operatorname{Card}(\Lambda_m) \leq n$. ■

A.8 Proof of Proposition 8

Since $\|Y\|_\infty \leq A$, we have $\|s\|_\infty \leq A$ and $\|s_m\|_\infty \leq A$. In fact, everything happens as if $S_m \cup \{s\}$ was bounded by A in L^∞.

We have

$$\overline{\delta}(m) = \frac{1}{n} \sum_{i=1}^{n} \left(\gamma(s_m, (X_i,Y_i)) - \gamma(s,(X_i,Y_i)) - \mathbb{E}\left[\gamma(s_m,(X_i,Y_i)) - \gamma(s,(X_i,Y_i)) \right] \right)$$

and assumptions of Bernstein inequality (Massart, 2007, Proposition 2.9) are fulfilled with

$$c = \frac{8A^2}{3n} \quad \text{and} \quad v = \frac{8A^2 \ell(s,s_m)}{n}$$

since

$$\left\| \gamma(s_m,(X_i,Y_i)) - \gamma(s,(X_i,Y_i)) - \mathbb{E}\left[\gamma(s_m,(X_i,Y_i)) - \gamma(s,(X_i,Y_i)) \right] \right\|_\infty \leq 8A^2$$

and

$$\begin{aligned} \operatorname{var}\left(\gamma(s_m,(X_i,Y_i)) - \gamma(s,(X_i,Y_i)) \right) &\leq \mathbb{E}\left[\left(\gamma(s_m,(X_i,Y_i)) - \gamma(s,(X_i,Y_i)) \right)^2 \right] \\ &\leq 8A^2 \ell(s,s_m) \end{aligned}$$

because $\|s_m - s\|_\infty \leq 2A$ and

$$\begin{aligned} (\gamma(t,\cdot) - \gamma(s,\cdot))^2 &= (t(X) - s(X))^2 \left(2(Y - s(X)) - t(X) + s(X) \right)^2 \\ \text{and} \quad \mathbb{E}\left[(Y - s(X))^2 \,\middle|\, X \right] &\leq \frac{(2A)^2}{4} = A \ . \end{aligned}$$

We obtain that, with probability at least $1 - 2e^{-x}$,

$$\left| \overline{\delta}(m) \right| \leq \sqrt{2vx} + c = \sqrt{\frac{16A^2 \ell(s,s_m) x}{n}} + \frac{8A^2 x}{3n}$$

and (26) follows since $2\sqrt{ab} \leq a\eta + b\eta^{-1}$ for all $\eta > 0$. Taking $\eta = D_m^{-1/2} \leq 1$ and using $Q_m^{(p)}$ defined by (27), we deduce (28). ■

A.9 Proof of Proposition 10

We apply here a result by Boucheron and Massart (2008, Theorem 2.2 in a preliminary version), in which it is only assumed that γ takes its values in $[0;1]$. This is satisfied when $\|Y\|_\infty \leq A = 1/2$. When $A \neq 1/2$, we apply this result to $(2A)^{-1}Y$ and recover the general result by homogeneity.

First, we recall this result in the bounded least-squares regression framework. For every $t : \mathcal{X} \mapsto \mathbb{R}$ and $\varepsilon > 0$, we define

$$d^2(s,t) = 2\ell(s,t) \qquad \text{and} \qquad w(\varepsilon) = \sqrt{2}\varepsilon \ .$$

Let ϕ_m belong to the class of nondecreasing and continuous functions $f : \mathbb{R}^+ \mapsto \mathbb{R}^+$ such that $x \mapsto f(x)/x$ is nonincreasing on $(0;+\infty)$ and $f(1) \geq 1$. Assume that for every $u \in S_m$ and $\sigma > 0$ such that $\phi_m(\sigma) \leq \sqrt{n}\sigma^2$,

$$\sqrt{n}\mathbb{E}\left[\sup_{t \in S_m, d(u,t) \leq \sigma} |\overline{\gamma}_n(u) - \overline{\gamma}_n(t)|\right] \leq \phi_m(\sigma) \ . \tag{36}$$

Let $\varepsilon_{\star,m}$ be the unique positive solution of the equation

$$\sqrt{n}\varepsilon_{\star,m}^2 = \phi_m(w(\varepsilon_{\star,m})) \ .$$

Then, there exists some absolute constant L such that for every real number $q \geq 2$ one has

$$\|p_2(m) - \mathbb{E}[p_2(m)]\|_q \leq \frac{L}{\sqrt{n}}\left[\sqrt{2q}\left(\sqrt{\ell(s,s_m)} \vee \varepsilon_{\star,m}\right) + q\frac{2}{\sqrt{n}}\right] \ . \tag{37}$$

Using now that S_m is the set of piecewise constant functions on some partition $(I_\lambda)_{\lambda \in \Lambda_m}$ of $\mathcal{X}$, we can take

$$\phi_m(\sigma) = 3\sqrt{2}\sqrt{D_m} \times \sigma \qquad \text{in (36).} \tag{38}$$

The proof of this statement is made below. Then, $\varepsilon_{\star,m} = 6\sqrt{D_m}n^{-1/2}$.

Combining (37) with the classical link between moments and concentration (see for instance Arlot, 2007, Lemma 8.9), the first result follows. The second result is obtained by taking $\theta = D_m^{-1/2}$, as in Proposition 8. ■

A.9.1 PROOF OF (38)

Let $u \in S_m$ and $d(u,t) = \sqrt{2}\|u(X) - t(X)\|_2$ for every $t : \mathcal{X} \mapsto \mathbb{R}$. Define $\psi : \mathbb{R}^+ \mapsto \mathbb{R}^+$ by

$$\psi(\sigma) = \mathbb{E}\left[\sup_{d(u,t) \leq \sigma, t \in S_m} |(P_n - P)(\gamma(u,\cdot) - \gamma(t,\cdot))|\right] \ .$$

We are looking for some nondecreasing and continuous function $\phi_m : \mathbb{R}^+ \mapsto \mathbb{R}^+$ such that $\phi_m(x)/x$ is nonincreasing, $\phi_m(1) \geq 1$ and for every $u \in S_m$,

$$\forall \sigma > 0 \quad \text{such that} \quad \phi_m(\sigma) \leq \sqrt{n}\sigma^2 \ , \qquad \phi_m(\sigma) \geq \sqrt{n}\psi(\sigma) \ .$$

We first look at a general upperbound on ψ.

Assume that $u = s_m$. If this is not the case, the triangular inequality shows that $\psi_{\text{general } u} \leq 2\psi_{u=s_m}$. Let us write

$$t = \sum_{\lambda \in \Lambda_m} t_\lambda \mathbb{1}_{I_\lambda} \qquad u = s_m = \sum_{\lambda \in \Lambda_m} \beta_\lambda \mathbb{1}_{I_\lambda} \ .$$

A.9.2 COMPUTATION OF $P(\gamma(t,\cdot)-\gamma(s_m,\cdot))$

for some general $t \in S_m$:

$$\begin{aligned}
P(\gamma(t,\cdot)-\gamma(s_m,\cdot)) &= \mathbb{E}\left[(t(X)-Y)^2-(s_m(X)-Y)^2\right] \\
&= \mathbb{E}\left[(t(X)-s_m(X))^2\right]+2\mathbb{E}\left[(t(X)-s_m(X))(s_m(X)-s(X))\right] \\
&= \mathbb{E}\left[(t(X)-s_m(X))^2\right] \\
&= \sum_{\lambda\in\Lambda_m} p_\lambda (t_\lambda-\beta_\lambda)^2
\end{aligned}$$

since for every $\lambda \in \Lambda_m, \mathbb{E}[s(X) \mid X\in I_\lambda] = \beta_\lambda$.

A.9.3 COMPUTATION OF $P_n(\gamma(t,\cdot)-\gamma(s_m,\cdot))$

for some general $t \in S_m$: with $\eta_i = Y_i - s_m(X_i)$, we have

$$\begin{aligned}
P_n(\gamma(t,\cdot)-\gamma(s_m,\cdot)) &= \frac{1}{n}\sum_{i=1}^n \left[(t(X_i)-Y_i)^2-(u(X_i)-Y_i)^2\right] \\
&= \frac{1}{n}\sum_{i=1}^n (t(X_i)-u(X_i))^2 - \frac{2}{n}\sum_{i=1}^n \left[(t(X_i)-u(X_i))\eta_i\right] \\
&= \frac{1}{n}\sum_{i=1}^n \sum_{\lambda\in\Lambda_m} (t_\lambda-u_\lambda)^2 \mathbb{1}_{X_i\in I_\lambda} - \frac{2}{n}\sum_{i=1}^n \sum_{\lambda\in\Lambda_m} (t_\lambda-u_\lambda)\mathbb{1}_{X_i\in I_\lambda}\eta_i \quad .
\end{aligned}$$

A.9.4 BACK TO $(P_n - P)$

We sum the two inequalities above and use the triangular inequality:

$$\begin{aligned}
\left|(P_n-P)(\gamma(t,\cdot)-\gamma(u,\cdot))\right| &\leq \left|\frac{1}{n}\sum_{i=1}^n\sum_{\lambda\in\Lambda_m}(t_\lambda-u_\lambda)^2(\mathbb{1}_{X_i\in I_\lambda}-p_\lambda)\right| \\
&\quad + \left|\frac{2}{n}\sum_{i=1}^n\sum_{\lambda\in\Lambda_m}(t_\lambda-u_\lambda)\mathbb{1}_{X_i\in I_\lambda}\eta_i\right| \\
&\leq \frac{2A}{n}\sum_{\lambda\in\Lambda_m}\left[\left(\sqrt{p_\lambda}\,|t_\lambda-u_\lambda|\right)\frac{\left|\sum_{i=1}^n(\mathbb{1}_{X_i\in I_\lambda}-p_\lambda)\right|}{\sqrt{p_\lambda}}\right] \\
&\quad + \frac{2}{n}\sum_{\lambda\in\Lambda_m}\left[\left(\sqrt{p_\lambda}\,|t_\lambda-u_\lambda|\right)\frac{\left|\sum_{i=1}^n\mathbb{1}_{X_i\in I_\lambda}\eta_i\right|}{\sqrt{p_\lambda}}\right]
\end{aligned}$$

since $|t_\lambda-u_\lambda|\leq 2A$ for every $t\in S_m$.

We now assume that $d(u,t)\leq\sigma$ for some $\sigma>0$, that is

$$d(u,t)^2 = 2\sum_{\lambda\in\Lambda_m} p_\lambda(t_\lambda-u_\lambda)^2 \leq \sigma^2 \quad .$$

From Cauchy-Schwarz inequality, we obtain for every $t \in S_m$ such that $d(u,t) \leq \sigma$

$$|(P_n - P)(\gamma(t,\cdot) - \gamma(u,\cdot))| \leq \frac{2A\sigma}{\sqrt{2}n} \sqrt{\sum_{\lambda \in \Lambda_m} \frac{\left(\sum_{i=1}^n (\mathbb{1}_{X_i \in I_\lambda} - p_\lambda)\right)^2}{p_\lambda}} + \frac{\sqrt{2}\sigma}{n} \sqrt{\sum_{\lambda \in \Lambda_m} \frac{\left(\sum_{i=1}^n \mathbb{1}_{X_i \in I_\lambda} \eta_i\right)^2}{p_\lambda}}$$

A.9.5 BACK TO ψ

The upper bound above does not depend on t, so that the left-hand side of the inequality can be replaced by a supremum over $\{t \in S_m \text{ s.t. } d(u,t) \leq \sigma\}$. Taking expectations and using Jensen's inequality ($\sqrt{\cdot}$ being concave), we obtain an upper bound on ψ:

$$\psi(\sigma) \leq \frac{2A\sigma}{\sqrt{2}n} \sqrt{\sum_{\lambda \in \Lambda_m} \mathbb{E}\left[\frac{\left(\sum_{i=1}^n (\mathbb{1}_{X_i \in I_\lambda} - p_\lambda)\right)^2}{p_\lambda}\right]} + \frac{\sqrt{2}\sigma}{n} \sqrt{\sum_{\lambda \in \Lambda_m} \mathbb{E}\left[\frac{\left(\sum_{i=1}^n \mathbb{1}_{X_i \in I_\lambda} \eta_i\right)^2}{p_\lambda}\right]} \tag{39}$$

For every $\lambda \in \Lambda_m$, we have

$$\mathbb{E}\left(\sum_{i=1}^n (\mathbb{1}_{X_i \in I_\lambda} - p_\lambda)\right)^2 = \sum_{i=1}^n \mathbb{E}\left(\mathbb{1}_{X_i \in I_\lambda} - p_\lambda\right)^2 = np_\lambda(1 - p_\lambda) \tag{40}$$

which simplifies the first term. For the second term, notice that

$$\begin{aligned} \forall i \neq j, \qquad & \mathbb{E}\left[\mathbb{1}_{X_i \in I_\lambda} \mathbb{1}_{X_j \in I_\lambda} \eta_i \eta_j\right] = \mathbb{E}\left[\mathbb{1}_{X_i \in I_\lambda} \eta_i\right] \mathbb{E}\left[\mathbb{1}_{X_j \in I_\lambda} \eta_j\right] \\ \text{and} \quad \forall i, \qquad & \mathbb{E}\left[\mathbb{1}_{X_i \in I_\lambda} \eta_i\right] = \mathbb{E}\left[\mathbb{1}_{X_i \in I_\lambda} \mathbb{E}\left[\eta_i \mid \mathbb{1}_{X_i \in I_\lambda}\right]\right] = 0 \end{aligned}$$

since η_i is centered conditionally to $\mathbb{1}_{X_i \in I_\lambda}$. Then,

$$\mathbb{E}\left(\sum_{i=1}^n \mathbb{1}_{X_i \in I_\lambda} \eta_i\right)^2 = \sum_{i=1}^n \mathbb{E}\left[\mathbb{1}_{X_i \in I_\lambda} \eta_i^2\right] \leq np_\lambda \|\eta\|_\infty^2 \leq np_\lambda (2A)^2 \ . \tag{41}$$

Combining (39) with (40) and (41), we deduce that

$$\psi(\sigma) \leq \frac{2A\sigma}{\sqrt{2}\sqrt{n}} \sqrt{D_m - 1} + \frac{2\sqrt{2}A\sigma}{\sqrt{n}} \sqrt{D_m} \leq 3A\sqrt{2} \frac{\sqrt{D_m}}{\sqrt{n}} \times \sigma \ .$$

As already noticed, we have to multiply this bound by 2 so that it is valid for every $u \in S_m$ and not only $u = s_m$.

The resulting upper bound (multiplied by $\sqrt{n}$) has all the desired properties for ϕ_m since $6A\sqrt{2}\sqrt{D_m} = 3\sqrt{2D_m} \geq 1$. The result follows. ■

Abstract

We start by showing that in an active learning setting, the Perceptron algorithm needs $\Omega(\frac{1}{\varepsilon^2})$ labels to learn linear separators within generalization error ε. We then present a simple active learning algorithm for this problem, which combines a modification of the Perceptron update with an adaptive filtering rule for deciding which points to query. For data distributed uniformly over the unit sphere, we show that our algorithm reaches generalization error ε after asking for just $\tilde{O}(d \log \frac{1}{\varepsilon})$ labels. This exponential improvement over the usual sample complexity of supervised learning had previously been demonstrated only for the computationally more complex query-by-committee algorithm.

Keywords: active learning, perceptron, label complexity bounds, online learning

1. Introduction

In many machine learning applications, unlabeled data is abundant but labeling is expensive. This distinction is not captured in standard models of supervised learning, and has motivated the field of *active learning*, in which the labels of data points are initially hidden, and the learner must pay for each label it wishes revealed. If query points are chosen randomly, the number of labels needed to reach a target generalization error ε, at a target confidence level $1-\delta$, is similar to the sample complexity of supervised learning. The hope is that there are alternative querying strategies which require significantly fewer labels.

An early dramatic demonstration of the potential of active learning was Freund et al.'s analysis of the query-by-committee (QBC) learning algorithm (Freund et al., 1997). The analysis is with respect to the *selective sampling* model: the learner observes a stream of unlabeled data and makes spot decisions about whether or not to ask for each point's label. The paper showed that if the data is drawn uniformly from the surface of the unit sphere in $\mathbb{R}^d$, and the hidden labels correspond perfectly to a homogeneous (i.e., through the origin) linear separator from this same distribution, then it is possible to achieve generalization error ε after seeing $\tilde{O}(\frac{d}{\varepsilon}\log\frac{1}{\varepsilon})$ points and requesting just $\tilde{O}(d\log\frac{1}{\varepsilon})$ labels:[1] an exponential improvement over the usual $\tilde{O}(\frac{d}{\varepsilon})$ sample complexity of learning linear separators in a supervised setting. (An $\Omega(d\log\frac{1}{\varepsilon})$ label complexity can be seen to be optimal by counting the number of spherical caps of radius ε that can be packed onto the surface of the unit sphere in $\mathbb{R}^d$.) This remarkable result is tempered somewhat by the complexity of the QBC algorithm, which involves random sampling from intermediate version spaces; the complexity of the update step scales (polynomially) with the number of updates performed.

In this paper, we show how a simple modification of the perceptron update can be used to achieve the same sample complexity bounds (within $\tilde{O}$ factors), under the same streaming model and the same uniform input distribution. Unlike QBC, we do not assume a distribution over target hypotheses, and our algorithm does not need to store previously seen data points, only its current hypothesis. Moreover, in addition to requiring only one-at-a-time access to examples (as opposed to batch data access), neither our algorithm's memory usage, nor its computation time per example, scales with the number of seen examples.[2]

Our algorithm has the following structure.

```
Set initial hypothesis $v_0 \in \mathbb{R}^d$.
For $t = 0, 1, 2, \ldots$.
  Receive unlabeled point $x_t$.
  Make a prediction SGN($v_t \cdot x_t$).
  *Filtering step:* Decide whether to ask for $x_t$'s label.
  If label $y_t$ is requested:
    *Update step:* Set $v_{t+1}$ based on $v_t, x_t, y_t$.
    Adjust filtering rule.
  else:   $v_{t+1} = v_t$.
```

UPDATE STEP.

The regular perceptron update, whose convergence behavior was first analyzed by Rosenblatt (1958), consists of the following simple rule:

$$\text{if } (x_t, y_t) \text{ is misclassified, then } v_{t+1} = v_t + y_t x_t.$$

It turns out that this update cannot yield an error rate better than $\Omega(1/\sqrt{l_t})$, where l_t is the number of labels queried up to time t, no matter what filtering scheme is used.

Theorem 1 *Consider any sequence of data points $x_0, x_1, x_2, \ldots \in \mathbb{R}^d$ which is perfectly classified by some linear separator $u \in \mathbb{R}^d$. Suppose that perceptron updates are used, starting with an initial hypothesis v_0. Let k_t be the number of updates performed upto time t, let v_t be the hypothesis at time t, and let θ_t be the angle between u and v_t. Then for any $t \geq 0$, if $\theta_{t+1} \leq \theta_t$ then $\sin\theta_t \geq 1/(5\sqrt{k_t + \|v_0\|^2})$.*

This holds regardless of how the data is produced. When the points are distributed uniformly over the unit sphere, $\theta_t \geq \sin\theta_t$ (for $\theta_t \leq \frac{\pi}{2}$) is proportional to the error rate of v_t. In other words, the

1. In this paper, the $\tilde{O}$ notation is used to suppress multiplicative terms in $\log d, \log\log\frac{1}{\varepsilon}$ and $\log\frac{1}{\delta}$.
2. See Monteleoni (2006) for an extended discussion of learning with online constraints.

error rate is $\Omega(1/\sqrt{k_t})$, which in turn is $\Omega(1/\sqrt{l_t})$, since each update must be triggered by a label. As we will shortly see, the reason for this slow rate is that the magnitude of the perceptron update is too large for points near the decision boundary of the current hypothesis.

So instead we use a *variant* of the update rule, originally due to Motzkin and Schoenberg (1954):

$$\text{if } (x_t, y_t) \text{ is misclassified, then } v_{t+1} = v_t - 2(v_t \cdot x_t)x_t$$

(where x_t is assumed normalized to unit length). Note that the update can also be written as $v_{t+1} = v_t + 2y_t|v_t \cdot x_t|x_t$, since updates are only made on mistakes, in which case $y_t \neq \texttt{SGN}(v_t \cdot x_t)$, by definition. Thus we are scaling the standard perceptron's additive update by a factor of $2|v_t \cdot x_t|$ to avoid oscillations caused by points close to the half-space represented by the current hypothesis. Motzkin and Schoenberg (1954) introduced this rule, in the context of solving linear inequalities, and called it the "Reflexion" method, due to certain geometric properties it has, which we will discuss later. Hampson and Kibler (1999) subsequently applied it to learning linear separators, in an analysis framework that differs from ours. The same rule, but without the factor of two, has been used in previous work (Blum et al., 1996) on learning linear classifiers from noisy data, in a batch setting. We are able to show that our formulation has the following generalization performance in a supervised (non-active) setting.

Theorem 2 *Pick any* $\delta, \varepsilon > 0$. *Consider a stream of data points* x_t *drawn uniformly at random from the surface of the unit sphere in* $\mathbb{R}^d$, *and corresponding labels* y_t *that are consistent with some linear separator. When the modified Perceptron algorithm (Figure 2) is applied to this stream of data, then with probability* $1 - \delta$, *after* $O(d(\log \frac{1}{\varepsilon} + \log \frac{1}{\delta}))$ *mistakes, its generalization error is at most* ε.

This contrasts favorably with the $\tilde{O}(\frac{d}{\varepsilon^2})$ mistake bound of the Perceptron algorithm, and a more recent variant, on the same distribution (Baum, 1997; Servedio, 1999). Meanwhile, in terms of lower bounds, Theorem 1 also applies in the supervised case, and gives a lower bound on the number of mistakes (updates) made by the standard perceptron. Finally, there is the question of how many samples are needed in the supervised setting (as opposed to the number of mistakes). For data distributed uniformly over the unit sphere, this is known to be $\tilde{\Theta}(\frac{d}{\varepsilon})$ (lower bound, Long, 1995, and upper bound, Long, 2003).

FILTERING STEP.

Given the limited information the algorithm keeps, a natural filtering rule is to query points x_t when $|v_t \cdot x_t|$ is less than some threshold s_t. The choice of s_t is crucial. If it is too large, then only a miniscule fraction of the points queried will actually be misclassified (and thus trigger updates)—almost all labels will be wasted. On the other hand, if s_t is too small, then the waiting time for a query might be prohibitive, and when an update is actually made, the magnitude of this update might be tiny.

Therefore, we set the threshold adaptively: we start s_t high, and keep dividing it by two until we reach a level where there are enough misclassifications amongst the points queried. By wrapping this filtering strategy around the modified Perceptron update, we get an active learning algorithm (Figure 4) with the following label complexity guarantee.

Theorem 3 *Pick any* $\delta, \varepsilon > 0$. *Consider a stream of data points* x_t *drawn uniformly at random from the surface of the unit sphere in* $\mathbb{R}^d$, *and corresponding labels* y_t *that are consistent with some linear* *separator. With probability* $1-\delta$*, if the active modified Perceptron algorithm (Figure 4) is given a stream of* $\tilde{O}(\frac{d}{\varepsilon}\log\frac{1}{\varepsilon})$ *such unlabeled points, it will request* $\tilde{O}(d\log\frac{1}{\varepsilon})$ *labels, make* $\tilde{O}(d\log\frac{1}{\varepsilon})$ *errors (on all points, labeled or not), and have final error* $\leq \varepsilon$.

The proofs of Theorems 1 through 3 are in Sections 4 through 6, respectively.

2. Related Work

Much of the early theory work on active learning was in the *query learning* model, in which the learner has the ability to synthesize arbitrary data points and request their labels. See Angluin (2001) for an excellent survey of this area. In this paper, we consider a different setting, in which (1) there is an underlying joint distribution over data points and labels, (2) the learner has access to (unlabeled) data points drawn at random from this distribution, and (3) the learner is able to request labels only for points obtained in this way, not for arbitrary points. This framework for active learning was originally introduced by Cohn, Atlas, and Ladner (1994),[3] along with a simple and elegant querying algorithm. Unless we specify otherwise, we will use the term selective sampling to denote the framework. In this work, we focus on the *realizable* setting: the hypothesis class which we consider for learning contains a classifier with zero error on the data distribution.[4] Our contribution to active learning is for online learning of linear separators through the origin, under the uniform distribution.

Several methods for learning linear separators (or their probabilistic analogues) in the selective sampling framework, have been proposed in the literature. Some have been shown to work reasonably well in practice, for example Lewis and Gale's sequential algorithm for text classification (Lewis and Gale, 1994), which has batch access to the remaining unlabeled data points at each iteration. Several of these are similar in spirit to our approach, in that they query points with small margins, such as Tong and Koller's active learning algorithms that use a support vector machine (SVM) as the underlying classifier (Tong and Koller, 2001).

On the theoretical side, there have been some encouraging upper bounds on label complexity; however, some of the schemes achieving them have not yet been proven efficient. Dasgupta (2005) provided a result for learning general hypothesis classes, in a non-Bayesian, realizable setting. For homogeneous half-spaces with data distributed uniformly on the sphere, this result implies an upper bound on label complexity of $\tilde{O}(d\log^2(\frac{1}{\varepsilon}))$. Balcan, Beygelzimer, and Langford (2006) provided a technique for learning general hypothesis classes, in a non-Bayesian, agnostic setting, for which they showed a label complexity upper bound of $\tilde{O}(d^2\log\frac{1}{\varepsilon})$ for learning linear separators under the uniform input distribution.[5] Both of these results rely on schemes that are computationally prohibitive, requiring exponential storage and/or computation.

The literature contains several active learning algorithms that are both feasible to implement (at least in special cases) and have label complexity guarantees, although none of them is quite as simple as the algorithm we present in this paper. We have already discussed the label complexity upper bound attained by Freund et al. (1997) for the Query By Committee algorithm of Seung et al. (1992). More recently, it was shown how to efficiently implement this scheme for linear separators under certain prior distributions, and the empirical results were encouraging (Gilad-Bachrach et al.,

3. The conference version dates back to NIPS 1989, with a superset of the coauthors.
4. The *agnostic* setting removes this assumption.
5. This bound was further tightened to $\tilde{O}(d^{1.5}\log\frac{1}{\varepsilon})$, in Balcan et al. (2007), and this scheme has also been analyzed by Hanneke (2007), who introduced a new label complexity measure.

2005). Cesa-Bianchi et al. (2003) provided regret bounds on a selective sampling algorithm for learning linear thresholds from a stream of iid examples corrupted by random class noise whose rate scales with the examples' margins. For half-spaces under the uniform input distribution, in the realizable setting, the algorithm of Balcan et al. (2006) can be implementated efficiently, as shown by Balcan et al. (2007), which analyzed various margin-based techniques for active learning, matching our label complexity bound in the same setting. Dasgupta, Hsu, and Monteleoni (2007) recently gave an active learning algorithm for general concept classes in the non-Bayesian, agnostic setting (a generalization of the original selective sampling algorithm of Cohn et al. 1994) which, for half-spaces under the uniform input distribution, in the realizable case, has a label complexity upper bound of $\tilde{O}(d^{1.5} \log \frac{1}{\varepsilon})$.

Cesa-Bianchi et al. (2004) analyzed an algorithm which conforms to roughly the same template as ours but differs in both the update and filtering rule—it uses the regular perceptron update and it queries points x_t according to a fixed, randomized rule which favors small $|v_t \cdot x_t|$. The authors make no distributional assumptions on the input and they show that in terms of worst-case hinge-loss bounds, their algorithm does about as well as one which queries *all* labels. The actual fraction of points queried varies from data set to data set. In contrast, our objective is to achieve a target generalization error with minimum label complexity, although we also obtain a mistake bound (on both labeled and unlabeled points) under our distributional assumption.

It is known that active learning does not always give a large improvement in the sample complexity of learning linear separators. For instance, in our setting, in which data is distributed uniformly over the unit sphere, Dasgupta (2004) showed that if the target linear separator is allowed to be non-homogeneous, then the number of labels required to reach error ε is $\Omega(\frac{1}{\varepsilon})$, no matter what active learning scheme is used. This lower bound also applies to learning homogeneous linear separators with respect to an arbitrary distribution. In the fully agnostic setting, Kääriäinen (2006) provided a lower bound of $\Omega(\frac{\eta^2}{\varepsilon^2})$, where η is the error rate of the best hypothesis in the concept class.

3. Preliminaries

In our model, all data x_t lie on the surface of the unit ball in $\mathbb{R}^d$, which we denote by S:

$$S = \left\{ x \in \mathbb{R}^d \;\middle|\; \|x\| = 1 \right\}.$$

Their labels y_t are either -1 or $+1$, and the target function is a half-space $u \cdot x \geq 0$ represented by a unit vector $u \in \mathbb{R}^d$ which classifies all points perfectly, that is, $y_t(u \cdot x_t) > 0$ for all t, with probability one.

For any vector $v \in \mathbb{R}^d$, we define $\hat{v} = \frac{v}{\|v\|}$ to be the corresponding unit vector.

Our lower bound (Theorem 1) is distribution-free; thereafter we will assume that the data points x_t are drawn independently from the uniform distribution over S.

Under the uniform input distribution, any hypothesis $v \in \mathbb{R}^d$ has error

$$\varepsilon(v) = P_{x \in S}[\texttt{SGN}(v \cdot x) \neq \texttt{SGN}(u \cdot x)] = \frac{\arccos(u \cdot \hat{v})}{\pi}.$$

We will refer to the error rate of a hypothesis v as its *generalization error*, since in the realizable case the target itself has zero error.

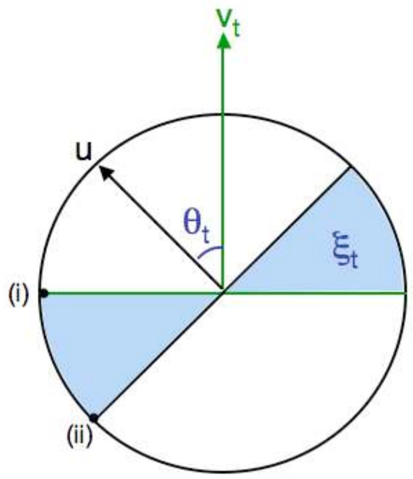

Figure 1: The projection of the error region ξ_t onto the plane defined by u and v_t.

For a hypothesis v_t, we will denote the angle between u and v_t by θ_t, and we will define the error region of v_t as $\xi_t = \{x \in S \,|\, \mathtt{SGN}(v_t \cdot x) \neq \mathtt{SGN}(u \cdot x)\}$. Figure 1 provides a schematic of the projection of the error region onto the plane defined by u and v_t.

We will use the term *margin*, in the context of learning half-spaces, to denote simply the distance from an example to the separator in question, as opposed to the standard use of this term (as the minimum over examples of this distance with respect to the target separator). For example, we will denote the margin of x with respect to v as $|x \cdot v|$.

We will use a few useful inequalities for θ on the interval $(0, \frac{\pi}{2}]$.

$$\frac{4}{\pi^2} \leq \frac{1-\cos\theta}{\theta^2} \leq \frac{1}{2}, \tag{1}$$

$$\frac{2}{\pi}\theta \leq \sin\theta \leq \theta. \tag{2}$$

Equation (1) can be verified by checking that for θ in this interval, $\frac{1-\cos\theta}{\theta^2}$ is a decreasing function, and evaluating it at the endpoints.

We will also make use of the following lemma.

Lemma 4 *For any fixed unit vector a and any $\gamma \leq 1$,*

$$\frac{\gamma}{4} \leq P_{x \in S}\left[|a \cdot x| \leq \frac{\gamma}{\sqrt{d}}\right] \leq \gamma.$$

The proof is deferred to the appendix.

4. A Lower Bound for the Perceptron Update

Consider an algorithm of the following form:

```
Pick some $v_0 \in \mathbb{R}^d$.
Repeat for $t = 0, 1, 2, \ldots$:
  Get some $(x, y)$ for which $y(v_t \cdot x) \le 0$.
  $v_{t+1} = v_t + yx$
```

On any update,

$$v_{t+1} \cdot u = v_t \cdot u + y(x \cdot u). \tag{3}$$

Thus, if we assume for simplicity that $v_0 \cdot u \geq 0$ (we can always just start count when this first occurs) then $v_t \cdot u \geq 0$ always, and θ_t, the angle between u and v_t is always acute. Since $\|u\| = 1$, the following holds:

$$\|v_t\| \cos\theta_t = v_t \cdot u.$$

The update rule also implies

$$\|v_{t+1}\|^2 = \|v_t\|^2 + 1 + 2y(v_t \cdot x). \tag{4}$$

Thus $\|v_t\|^2 \leq t + \|v_0\|^2$ for all t. In particular, this means that Theorem 1 is an immediate consequence of the following lemma.

Lemma 5 *Assume $v_0 \cdot u \geq 0$ (i.e., start count when this first occurs). Then*

$$\theta_{t+1} \leq \theta_t \;\;\Rightarrow\;\; \sin\theta_t \geq \min\left\{\frac{1}{3}, \frac{1}{5\|v_t\|}\right\}.$$

Proof Figure 1 shows the unit circle in the plane defined by u and v_t. The dot product of any point $x \in \mathbb{R}^d$ with either u or v_t depends only upon the projection of x into this plane. The point is misclassified when its projection lies in the shaded region. For such points, $y(u \cdot x)$ is at most $\sin\theta_t$ (point (i)) and $y(v_t \cdot x)$ is at least $-\|v_t\| \sin\theta_t$ (point (ii)).

Combining this with Equations (3) and (4), we get

$$\begin{array}{rcl} v_{t+1} \cdot u & \leq & v_t \cdot u + \sin\theta_t, \\ \|v_{t+1}\|^2 & \geq & \|v_t\|^2 + 1 - 2\|v_t\| \sin\theta_t. \end{array}$$

To establish the lemma, we first assume $\theta_{t+1} \leq \theta_t$ and $\sin\theta_t \leq \frac{1}{5\|v_t\|}$, and then conclude that $\sin\theta_t \geq \frac{1}{3}$.

$\theta_{t+1} \leq \theta_t$ implies

$$\cos^2\theta_t \;\leq\; \cos^2\theta_{t+1} \;=\; \frac{(u \cdot v_{t+1})^2}{\|v_{t+1}\|^2} \;\leq\; \frac{(u \cdot v_t + \sin\theta_t)^2}{\|v_t\|^2 + 1 - 2\|v_t\| \sin\theta_t}.$$

The final denominator is positive since $\sin\theta_t \leq \frac{1}{5\|v_t\|}$. Rearranging,

$$(\|v_t\|^2 + 1 - 2\|v_t\| \sin\theta_t) \cos^2\theta_t \;\leq\; (u \cdot v_t)^2 + \sin^2\theta_t + 2(u \cdot v_t) \sin\theta_t,$$

and using $\|v_t\| \cos\theta_t = (u \cdot v_t)$:

$$(1 - 2\|v_t\| \sin\theta_t) \cos^2\theta_t \;\leq\; \sin^2\theta_t + 2\|v_t\| \sin\theta_t \cos\theta_t.$$

```
Inputs: dimensionality $d$ and budget on number of updates
(mistakes) $M$.
  Let $v_1 = x_1 y_1$ for the first example $(x_1, y_1)$.
  For $t = 1$ to $M$:
    Let $(x_t, y_t)$ be the next example with $y(x \cdot v_t) < 0$.
    $v_{t+1} = v_t - 2(v_t \cdot x_t) x_t$
```

Figure 2: The (non-active) modified Perceptron algorithm. The standard Perceptron update, $v_{t+1} = v_t + y_t x_t$, is in the same direction (note $y_t = -\texttt{SGN}(v_t \cdot x_t)$) but different magnitude (scaled by a factor of $2|v_t \cdot x_t|$).

Again, since $\sin\theta_t \le \frac{1}{5\|v_t\|}$, it follows that $(1 - 2\|v_t\|\sin\theta_t) \ge \frac{3}{5}$ and that $2\|v_t\|\sin\theta_t\cos\theta_t \le \frac{2}{5}$. Using $\cos^2 = 1 - \sin^2$, we then get

$$\frac{3}{5}(1 - \sin^2\theta_t) \;\le\; \sin^2\theta_t + \frac{2}{5},$$

which works out to $\sin^2\theta_t \ge \frac{1}{8}$, implying $\sin\theta_t > \frac{1}{3}$. ■

The problem is that the perceptron update can be too large. In $\mathbb{R}^2$ (e.g., Figure 1), when θ_t is tiny, the update will cause v_{t+1} to overshoot the mark and swing too far to the other side of u, unless $\|v_t\|$ is very large: to be precise, we need $\|v_t\| = \Omega(\frac{1}{\sin\theta_t})$. But $\|v_t\|$ grows slowly, at best at a rate of $\sqrt{t}$. If $\sin\theta_t$ is proportional to the error of v_t, as in the case of data distributed uniformly over the unit sphere, this means that the perceptron update cannot stably maintain an error rate $\le \varepsilon$ until $t = \Omega(\frac{1}{\varepsilon^2})$.

5. The Modified Perceptron Update

We now describe a modified Perceptron algorithm. Unlike the standard Perceptron, it ensures that $v_t \cdot u$ is increasing, that is, the error of v_t is monotonically decreasing. Another difference from the standard update (and other versions) is that the magnitude of the current hypothesis, $\|v_t\|$, is always 1, which is convenient for the analysis.

The modified Perceptron algorithm is shown in Figure 2. We now show that the norm of v_t stays at one. Note that $\|v_1\| = 1$ and

$$\|v_{t+1}\|^2 = \|v_t\|^2 + 4(v_t \cdot x_t)^2\|x_t\|^2 - 4(v_t \cdot x_t)^2 = 1$$

by induction. In contrast, for the standard perceptron update, the magnitude of v_t increases steadily.

With the modified update, the error can only decrease, because $v_t \cdot u$ only increases:

$$v_{t+1} \cdot u = v_t \cdot u - 2(v_t \cdot x_t)(x_t \cdot u) = v_t \cdot u + 2|v_t \cdot x_t||x_t \cdot u|. \quad (5)$$

The second equality follows from the fact that v_t misclassified x_t. Thus $v_t \cdot u$ is increasing, and the increase can be bounded from below by showing that $|v_t \cdot x_t||x_t \cdot u|$ is large. This is a different approach from previous analyses.

Hampson and Kibler (1999) previously used this update for learning linear separators, calling it the "Reflection" method, based on the "Reflexion" method due to Motzkin and Schoenberg (1954). These names are likely due to the following geometric property of this update:

$$x_t \cdot v_{t+1} = x_t \cdot v_t - 2(x_t \cdot v_t)(x_t \cdot x_t) = -(x_t \cdot v_t).$$

In general, one can consider modified updates of the form $v_{t+1} = v_t - \alpha(v_t \cdot x_t)x_t$, which corresponds to the "Relaxation" method of solving linear inequalities (Agmon, 1954; Motzkin and Schoenberg, 1954). When $\alpha \neq 2$, the vectors v_t no longer remain of fixed length; however, one can verify that their corresponding unit vectors $\hat{v}_t$ satisfy

$$\hat{v}_{t+1} \cdot u = (\hat{v}_t \cdot u + \alpha|\hat{v}_t \cdot x_t||x_t \cdot u|)/\sqrt{1 - \alpha(2-\alpha)(\hat{v}_t \cdot x_t)^2},$$

and thus any choice of $\alpha \in [0,2]$ guarantees non-increasing error. Blum et al. (1996) used $\alpha = 1$ to guarantee progress in the denominator (their analysis did not rely on progress in the numerator) as long as $\hat{v}_t \cdot u$ and $(\hat{v}_t \cdot x_t)^2$ were bounded away from 0. Their approach was used in a batch setting as one piece of a more complex algorithm for noise-tolerant learning. In our sequential framework, we can bound $|\hat{v}_t \cdot x_t||x_t \cdot u|$ away from 0 in expectation, under the uniform distribution, and hence the choice of $\alpha = 2$ is most convenient, but $\alpha = 1$ would work as well. Although we do not further optimize our choice of the constant α, this choice itself may yield interesting future work, perhaps by allowing it to be a function of the dimension.

5.1 Analysis of (Non-Active) Modified Perceptron

How large do we expect $|v_t \cdot x_t|$ and $|u \cdot x_t|$ to be for an error (x_t, y_t)? As we shall see, in d dimensions, one expects each of these terms to be on the order of $d^{-1/2} \sin\theta_t$, where $\sin\theta_t = \sqrt{1-(v_t \cdot u)^2}$. Hence, we might expect their product to be about $(1-(v_t \cdot u)^2)/d$, which is how we prove the following lemma.

Note, we have made little effort to optimize constant factors.

Lemma 6 *For any v_t, with probability at least $\frac{1}{3}$,*

$$1 - v_{t+1} \cdot u \leq (1 - v_t \cdot u)\left(1 - \frac{1}{50d}\right).$$

There exists a constant $c > 0$, such that with probability at least $\frac{63}{64}$, for any v_t,

$$1 - v_{t+1} \cdot u \leq (1 - v_t \cdot u)\left(1 - \frac{c}{d}\right).$$

Proof We show only the first part of the lemma. The second part is quite similar. We will argue that each of $|v_t \cdot x_t|$,$|u \cdot x_t|$ is "small" with probability at most 1/3. This means, by the union bound, that with probability at least 1/3, they are both sufficiently large.

The error rate of v_t is θ_t/π, where $\cos\theta_t = v_t \cdot u$. Also define the error region $\xi_t = \{x \in S | \texttt{SGN}(v_t \cdot x) \neq \texttt{SGN}(u \cdot x)\}$. By Lemma 4, for an x drawn uniformly from the sphere,

$$P_{x \in S}\left[|v_t \cdot x| \leq \frac{\theta_t}{3\pi\sqrt{d}}\right] \leq \frac{\theta_t}{3\pi}.$$

Using $P[A|B] \le P[A]/P[B]$, we have,

$$P_{x\in S}\left[|v_t\cdot x| \le \frac{\theta_t}{3\pi\sqrt{d}} \;\middle|\; x\in\xi_t\right] \le \frac{P_{x\in S}[|v_t\cdot x|\le \frac{\theta_t}{3\pi\sqrt{d}}]}{P_{x\in S}[x\in\xi_t]} \le \frac{\theta_t/(3\pi)}{\theta_t/\pi} = \frac{1}{3}.$$

Similarly for $|u\cdot x|$, and by the union bound the probability that $x\in\xi_t$ is within margin $\frac{\theta}{3\pi\sqrt{d}}$ from either u or v is at most $\frac{2}{3}$. Since the updates only occur if x is in the error region, we now have a lower bound on the expected magnitude of $|v_t\cdot x||u\cdot x|$:

$$P_{x\in S}\left[|v_t\cdot x||u\cdot x| \ge \frac{\theta_t^2}{(3\pi\sqrt{d})^2}\middle| x\in\xi_t\right] \ge \frac{1}{3}.$$

Hence, we know that with probability at least 1/3, $|v_t\cdot x||u\cdot x| \ge \frac{1-(v_t\cdot u)^2}{100d}$, since $\theta_t^2 \ge \sin^2\theta_t = 1-(v_t\cdot u)^2$ and $(3\pi)^2 < 100$. In this case,

$$\begin{aligned} 1-v_{t+1}\cdot u &\le 1-v_t\cdot u - 2|v_t\cdot x_t||u\cdot x_t| \\ &\le 1-v_t\cdot u - \frac{1-(v_t\cdot u)^2}{50d} \\ &= (1-v_t\cdot u)\left(1-\frac{1+v_t\cdot u}{50d}\right), \end{aligned}$$

where the first inequality is by application of (5). ■

Finally, we give a high-probability bound, that is, Theorem 2, stated here with proof.

Theorem 7 *With probability* $1-\delta$ *with respect to the uniform distribution on the unit sphere, in the supervised, realizable setting, after* $M = O(d(\log\frac{1}{\varepsilon}+\log\frac{1}{\delta}))$ *mistakes, the generalization error of the modified Perceptron algorithm is at most* ε.

Proof By the above lemma, we can conclude that, for any vector v_t,

$$E[1-v_{t+1}\cdot u] \le (1-v_t\cdot u)\left(1-\frac{1}{3(50d)}\right).$$

This is because with $\ge 1/3$ probability it goes down by a factor of $1-\frac{1}{50d}$ and with the remaining $\le 2/3$ probability it does not increase. Hence, after M mistakes,

$$E[1-v_M\cdot u] \le (1-v_1\cdot u)\left(1-\frac{1}{150d}\right)^M \le \left(1-\frac{1}{150d}\right)^M,$$

since $v_1\cdot u \ge 0$. By Markov's inequality,

$$P\left[1-v_M\cdot u \ge \left(1-\frac{1}{150d}\right)^M \delta^{-1}\right] \le \delta.$$

Finally, using (1) and $\cos\theta_M = v_M\cdot u$, we see $P[\frac{4}{\pi^2}\theta_M^2 \ge (1-\frac{1}{150d})^M\delta^{-1}] \le \delta$. Using $M = 150d\log\frac{1}{\varepsilon\delta}$ gives $P[\frac{\theta_M}{\pi}\ge\varepsilon]\le\delta$, as required. ■

The additional factor of $\frac{1}{\varepsilon}$ in the bound on unlabeled samples ($\tilde{O}(\frac{d}{\varepsilon}\log\frac{1}{\varepsilon})$) follows by upper bounding the number of unlabeled samples until an update: when the hypothesis has error rate ε, the waiting time (in samples) until an update is $\frac{1}{\varepsilon}$, in expectation.

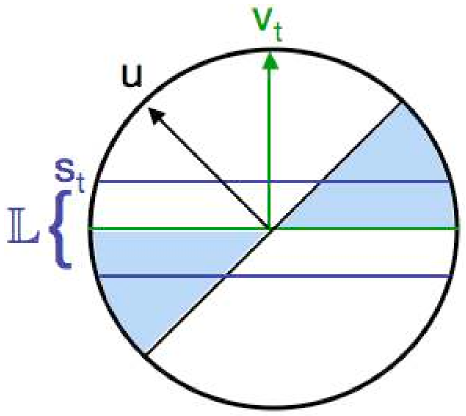

Figure 3: The active learning rule is to query for labels on points x in $\mathbb{L}$ which is defined by the threshold s_t on $|v_t \cdot x|$.

6. An Active Modified Perceptron

The ideal objective in designing an active learning rule that minimizes label complexity would be to query for labels only on points in the error region, ξ_t. However without knowledge of u, the algorithm is unaware of the location of ξ_t. The intuition behind our active learning rule is to approximate the error region, given the information the algorithm does have: v_t. As shown in Figure 3, the labeling region $\mathbb{L}$ is simply formed by thresholding the margin of a candidate example with respect to v_t.

The active version of the modified Perceptron algorithm is shown in Figure 4. The algorithm is similar to the algorithm of the previous section, in its update step. For its filtering rule, we maintain a threshold s_t and we only ask for labels of examples with $|v_t \cdot x| \leq s_t$. Approximating the error region is achieved by choosing the threshold, s_t, adaptively, so as to manage the tradeoff between $\mathbb{L}$ being too large, causing many labels to be wasted without hitting ξ_t (and thus yielding updates), and $\mathbb{L}$ only containing points with very small margins with respect to v_t, since our update step will make very small updates on such points. We decrease the threshold adaptively over time, starting at $s_1 = 1/\sqrt{d}$ and reducing it by a factor of two whenever we have a run of labeled examples on which we are correct.

For Theorem 3, we select values of R, L that yield ε error with probability at least $1-\delta$. The idea of the analysis is as follows:

Definition 7 *We say the tth update is "good" if,*

$$1 - v_{t+1} \cdot u \leq (1 - v_t \cdot u)\left(1 - \frac{c}{d}\right).$$

(The constant c is from Lemma 6.)

1. (Lemma 8) First, we argue that s_t is not too small (we do not decrease s_t too quickly). Assuming this is the case, then 2 and 3 hold.

2. (Lemma 10) We query for labels on at least an expected 1/32 of all *errors*. In other words, some errors may go undetected because we do not ask for their labels, but the number of

```
Inputs: Dimensionality $d$, maximum number of labels $L$,
and patience $R$.
  $v_1 = x_1 y_1$ for the first example $(x_1, y_1)$.
  $s_1 = 1/\sqrt{d}$
  **For** $t = 1$ **to** $L$:
    Wait for the next example $x$ : $|x \cdot v_t| \leq s_t$ and query its label.
    Call this labeled example $(x_t, y_t)$.
    **If** $(x_t \cdot v_t) y_t < 0$, **then**:
      $v_{t+1} = v_t - 2(v_t \cdot x_t) x_t$
      $s_{t+1} = s_t$
    **else**:
      $v_{t+1} = v_t$
      **If** predictions were correct on $R$ consecutive labeled
      examples (i.e., $(x_i \cdot v_i) y_i \geq 0 \ \forall i \in \{t-R+1, t-R+2, \ldots, t\}$),
      **then** set $s_{t+1} = s_t/2$, **else** $s_{t+1} = s_t$.
```

Figure 4: An active version of the modified Perceptron algorithm.

mistakes total should not be much more than 32 times the number of updates we actually perform.

3. (Lemma 11) Each update is *good* (Definition 7) with probability at least $1/2$.

4. (Theorem 3) Finally, we conclude that we cannot have too many label queries, updates, or total errors, because half of our updates are good, 1/32 of our errors are updates, and about $1/R$ of our labels are updates.

We first lower-bound s_t with respect to our error, showing that, with high probability, the threshold s_t is never too small.

Lemma 8 *With probability at least* $1 - L\left(\frac{3}{4}\right)^R$*, we have:*

$$s_t \geq \sqrt{\frac{1-(u \cdot v_t)^2}{16d}} \text{ for } t = 1, 2, \ldots, L, \text{ simultaneously.} \qquad (6)$$

Before proving this lemma, it will be helpful to show the following lemma. As before, let us define $\xi_t = \{x \in S | (x \cdot v_t)(x \cdot u) < 0\}$.

Lemma 9 *For any* $\gamma \in \left(0, \sqrt{\frac{1-(u \cdot v_t)^2}{4d}}\right]$,

$$P_{x_t \in S}\left[x_t \in \xi_t \;\middle|\; |x_t \cdot v_t| < \gamma\right] \geq \frac{1}{4}.$$

Proof Let x be a random example from S such that $|x \cdot v_t| < \gamma$ and, without loss of generality, suppose that $0 \leq x \cdot v_t \leq \gamma$. Then we want to calculate the probability we err, that is, $u \cdot x < 0$. We can decompose $x = x' + (x \cdot v_t)v_t$ where $x' = x - (x \cdot v_t)v_t$ is the component of x orthogonal to v_t, that is, $x' \cdot v_t = 0$. Similarly for $u' = u - (u \cdot v_t)v_t$. Hence,

$$u \cdot x = (u' + (u \cdot v_t)v_t) \cdot (x' + (x \cdot v_t)v_t) = u' \cdot x' + (u \cdot v_t)(x \cdot v_t).$$

In other words, we err iff $u' \cdot x' < -(u \cdot v_t)(x \cdot v_t)$. Using $u \cdot v_t \in [0,1]$ and since $x \cdot v_t \in [0, \sqrt{(1-(u \cdot v_t)^2)/(4d)}]$, we conclude that if

$$u' \cdot x' < -\sqrt{\frac{1-(u \cdot v_t)^2}{4d}}, \tag{7}$$

then we must err. Also, let $\hat{x}' = \frac{x'}{\|x'\|}$ be the unit vector in the direction of x'. It is straightforward to check that $\|x'\| = \sqrt{1-(x \cdot v_t)^2}$. Similarly, for u we define $\hat{u}' = \frac{u'}{\sqrt{1-(u \cdot v_t)^2}}$. Substituting these into (7), we must err if, $\hat{u}' \cdot \hat{x}' < -1/\sqrt{4d(1-(x \cdot v_t))^2}$, and since $\sqrt{1-(x \cdot v_t)^2} \geq \sqrt{1-1/(4d)}$, it suffices to show that,

$$P_{x \in S}\left[\hat{u}' \cdot \hat{x}' < \frac{-1}{\sqrt{4d(1-1/(4d))}} \;\middle|\; 0 \leq x \cdot v_t \leq \gamma\right] \geq \frac{1}{4}.$$

What is the probability that this happens? Well, one way to pick $x \in S$ would be to first pick $x \cdot v_t$ and then to pick $\hat{x}'$ uniformly at random from the set $S' = \{\hat{x}' \in S | \hat{x}' \cdot v_t = 0\}$, which is a unit sphere in one fewer dimensions. Hence the above probability does not depend on the conditioning. By Lemma 4, for any unit vector $a \in S'$, the probability that $|\hat{u}' \cdot a| \leq 1/\sqrt{4(d-1)}$ is at most $1/2$, so with probability at least $1/4$ (since the distribution is symmetric), the signed quantity $\hat{u}' \cdot \hat{x}' < -1/\sqrt{4(d-1)} < -1/\sqrt{4d(1-1/(4d))}$. ■

We are now ready to prove Lemma 8.

Proof [of Lemma 8] Suppose that condition (6) fails to hold for some t's. Let t be the smallest number such that (6) fails. By our choice of s_1, clearly $t > 1$. Moreover, since t is the smallest such number, and $u \cdot v_t$ is increasing, it must be the case that $s_t = s_{t-1}/2$, that is we just saw a run of R labeled examples (x_i, y_i), for $i = t-R, \ldots, t-1$, with no mistakes, $v_i = v_t$, and

$$s_i = 2s_t < \sqrt{\frac{1-(u \cdot v_t)^2}{4d}} = \sqrt{\frac{1-(u \cdot v_i)^2}{4d}}. \tag{8}$$

Such an event is highly unlikely, however, for any t. In particular, from Lemma 9, we know that the probability of (8) holding for any particular i and the algorithm not erring is at most $3/4$. Thus the chance of having any such run of length R is at most $L(3/4)^R$. ■

Lemma 9 also tells us something interesting about the fraction of errors that we are missing because we do not ask for labels. In particular,

Lemma 10 *Given that $s_t \geq \sqrt{(1-(u \cdot v_t)^2)/(16d)}$, upon the tth update, each erroneous example is queried with probability at least 1/32, that is,*

$$P_{x \in S}\left[|x \cdot v_t| \leq s_t \;\middle|\; x \in \xi_t\right] \geq \frac{1}{32}.$$

Proof Using Lemmas 9 and 4, we have

$$\begin{aligned}
P_{x\in S}\left[x\in\xi_t \wedge |x\cdot v_t|\le s_t\right] &\ge P_{x\in S}\left[x\in\xi_t\wedge|x\cdot v_t|\le\sqrt{\frac{1-(u\cdot v_t)^2}{16d}}\right]\\
&\ge \frac{1}{4}P_{x\in S}\left[|x\cdot v_t|\le\sqrt{\frac{1-(u\cdot v_t)^2}{16d}}\right]\\
&\ge \frac{1}{64}\sqrt{1-(u\cdot v_t)^2}=\frac{1}{64}\sin\theta_t\\
&\ge \frac{\theta_t}{32\pi}.
\end{aligned}$$

For the last inequality, we have used (2). However, $P_{x\in S}[x\in\xi_t]=\theta_t/\pi$, so we are querying an error $x\in\xi_t$ with probability at least $1/32$, that is, the above inequality implies,

$$P_{x\in S}\left[|x\cdot v_t|\le s_t \;\middle|\; x\in\xi_t\right]=\frac{P_{x\in S}[x\in\xi_t\wedge|x\cdot v_t|\le s_t]}{P_{x\in S}[x\in\xi_t]}\ge\frac{\theta_t/(32\pi)}{\theta_t/\pi}=\frac{1}{32}.$$

■

Next, we show that the updates are likely to make progress.

Lemma 11 *Assuming that* $s_t\ge\sqrt{(1-(u\cdot v_t)^2)/(16d)}$*, a random update is good with probability at least* $1/2$*, that is,*

$$P_{x_t\in S}\left[(1-v_{t+1}\cdot u)\le(1-v_t\cdot u)\left(1-\frac{c}{d}\right)\;\middle|\;|x\cdot v_t|\le s_t\wedge x_t\in\xi_t\right]\ge\frac{1}{2}.$$

Proof By Lemma 10, each error is queried with probability 1/32. On the other hand, by Lemma 6 of the previous section, 63/64 of all errors are good. Since we are querying at least 2/64 fraction of all errors, at least half of our queried errors must be good. ■

We now have the pieces to guarantee the convergence rate of the active algorithm, thereby proving Theorem 3. This involves bounding both the number of labels that we query as well as the number of total errors, which includes updates as well as errors that were never detected.

Theorem 3 *With probability* $1-\delta$ *with respect to the uniform distribution on the unit sphere, in the realizable setting, using* $L=O\big(d\log\big(\frac{1}{\epsilon\delta}\big)(\log\frac{d}{\delta}+\log\log\frac{1}{\epsilon})\big)$ *labels and making a total number of errors of* $O\big(d\log\big(\frac{1}{\epsilon\delta}\big)(\log\frac{d}{\delta}+\log\log\frac{1}{\epsilon})\big)$*, the final error of the active modified Perceptron algorithm will be* ϵ*, when run with the above* L *and* $R=O(\log\frac{d}{\delta}+\log\log\frac{1}{\epsilon})$*.*

Proof Let U be the number of updates performed. We know, by Lemma 8 that with probability $1-L(\frac{3}{4})^R$,

$$s_t\ge\frac{\sin\theta_t}{4\sqrt{d}}\ge\frac{\theta_t}{2\pi\sqrt{d}} \tag{9}$$

for all t. Again, we have used (2). By Lemma 11, we know that for each t which is an update, either (9) fails or

$$E[1-u\cdot v_{t+1}|v_t]\le(1-u\cdot v_t)\left(1-\frac{c}{2d}\right).$$

Hence, after U updates, using Markov's inequality,

$$P\left[1 - u \cdot v_L \geq \frac{4}{\delta}\left(1 - \frac{c}{2d}\right)^U\right] \leq \frac{\delta}{4} + L\left(\frac{3}{4}\right)^R.$$

In other words, with probability $1 - \frac{\delta}{4} - L(\frac{3}{4})^R$, we also have

$$U \leq \frac{2d}{c}\log\frac{4}{\delta(1 - u \cdot v_L)} \leq \frac{2d}{c}\log\frac{\pi^2}{\delta\theta_L^2} = O\left(d\log\frac{1}{\delta\varepsilon}\right),$$

where for the last inequality we used (1). In total, $L \leq R\left(U + \log_2\frac{1}{s_L}\right)$. This is because once every R labels we either have at least one update or we decrease s_L by a factor of 2. Equivalently, $s_L \leq 2^{U - L/R}$. Hence, with probability $1 - \frac{\delta}{4} - L(\frac{3}{4})^R$,

$$\frac{\theta_L}{2\pi\sqrt{d}} \leq s_L \leq 2^{O(d\log\frac{1}{\delta\varepsilon}) - L/R}.$$

Working backwards, we choose $L/R = \Theta(d\log\frac{1}{\varepsilon\delta})$ so that the above expression implies $\frac{\theta_L}{\pi} \leq \varepsilon$, as required. We choose

$$R = 10\log\frac{2L}{\delta R} = \Theta\left(\log\frac{d\log\frac{1}{\varepsilon\delta}}{\delta}\right) = O\left(\log\frac{d}{\delta} + \log\log\frac{1}{\varepsilon}\right).$$

The first equality ensures that $L(\frac{3}{4})^R \leq \frac{\delta}{4}$. Hence, for the L and R chosen in the theorem, with probability $1 - \frac{3}{4}\delta$, we have error $\frac{\theta_L}{\pi} < \varepsilon$. Finally, either condition (9) fails or each error is queried with probability at least $\frac{1}{32}$. By the multiplicative Chernoff bound, if there were a total of $E > 64U$ errors, with probability $\geq 1 - \frac{\delta}{4}$, at least $E/64 > U$ would have been caught and used as updates. Hence, with probability at most $1 - \delta$, we have achieved the target error using the specified number of labels and observing the specified number of errors. ■

7. Discussion and Conclusions

In the evolving theory of active learning, the most concrete, nontrivial scenario in which active learning has been shown to give an exponential improvement in sample complexity is that of learning a linear separator for data distributed uniformly over the unit sphere. In this paper, we have demonstrated that this particular case can be solved by a much simpler algorithm than was previously known. Table 1 summarizes our contributions in context. We report bounds for all the algorithms with respect to our setting: learning homogeneous half-spaces when the data distribution is uniform on the unit sphere and separable through the origin, although a few of the algorithms were designed for more general distributions. This paper gives the lower bounds stated for Perceptron, and provides an algorithm that attains the upper bounds in the bottom row. While we list a host of results for comparison, it is important to note that the algorithm of Dasgupta (2005) has not shown to be efficiently implementable, and that we state bounds for this realizable problem, even though the algorithm of Balcan et al. (2007) can handle certain types of noise, and A^2 (Balcan et al., 2006) and the algorithm of Dasgupta et al. (2007) were designed to handle the agnostic setting.

	Samples	Mistakes	Labels	Noise tolerance
PAC bounds	$\tilde{O}(\frac{d}{\varepsilon}), \Omega(\frac{d}{\varepsilon})$			
Perceptron	$\tilde{O}(\frac{d}{\varepsilon^3}), \Omega(\frac{1}{\varepsilon^2})$	$\tilde{O}(\frac{d}{\varepsilon^2}), \Omega(\frac{1}{\varepsilon^2})$	$\Omega(\frac{1}{\varepsilon^2})$	Unknown
D'05	$\tilde{O}(\frac{d}{\varepsilon}\log^2\frac{1}{\varepsilon})$	$\tilde{O}(d\log^2\frac{1}{\varepsilon})$	$\tilde{O}(d\log^2\frac{1}{\varepsilon})$	No
A^2	$\tilde{O}(\frac{d^{1.5}}{\varepsilon}\log\frac{1}{\varepsilon})$	$\tilde{O}(d^{1.5}\log\frac{1}{\varepsilon})$	$\tilde{O}(d^{1.5}\log\frac{1}{\varepsilon})$	Yes
DHM'07	$\tilde{O}(\frac{d^{1.5}}{\varepsilon}\log\frac{1}{\varepsilon})$	$\tilde{O}(d^{1.5}\log\frac{1}{\varepsilon})$	$\tilde{O}(d^{1.5}\log\frac{1}{\varepsilon})$	Yes
QBC	$\tilde{O}(\frac{d}{\varepsilon}\log\frac{1}{\varepsilon})$	$\tilde{O}(d\log\frac{1}{\varepsilon})$	$\tilde{O}(d\log\frac{1}{\varepsilon})$	No
BBZ'07	$\tilde{O}(\frac{d}{\varepsilon}\log\frac{1}{\varepsilon})$	$\tilde{O}(d\log\frac{1}{\varepsilon})$	$\tilde{O}(d\log\frac{1}{\varepsilon})$	Yes
Our algorithm	$\tilde{O}(\frac{d}{\varepsilon}\log\frac{1}{\varepsilon})$	$\tilde{O}(d\log\frac{1}{\varepsilon})$	$\tilde{O}(d\log\frac{1}{\varepsilon})$	Unknown

Table 1: Results in context, for learning half-spaces through the origin. The last column indicates whether each algorithm has been proved to exhibit some noise tolerance when used for active learning.

In all these papers, the uniform distribution of data has consistently proved amenable to analysis. This is an impressive distribution to learn against because it is difficult in some ways—most of the data is close to the decision boundary, for instance—but a more common assumption would be to make the two classes Gaussian, or to merely stipulate that they are separated by a margin. As a modest step towards relaxing this distributional assumption, we can show an (at most) polynomial dependence of the label complexity on λ (Monteleoni, 2006), when the input distribution is λ-similar to uniform, a setting studied in Freund et al. (1997).

Our algorithm is in some ways fine-tuned for linearly-separable data that are distributed uniformly; for instance, in the choice of the parameters R and s_1. An immediate open problem is therefore the following:

1. Design a version of the algorithm that is sensible for general data distributions which may not be linearly separable.

2. What types of noise can be tolerated by this scheme?

3. For what distributions can its label complexity be analyzed?

A step towards the practical realization of our algorithm is the work of Monteleoni and Kääriäinen (2007), which applies a version of it to an optical character recognition problem.

Appendix A. Proof of Lemma 4

Proof [Lemma 4] Let $r = \gamma/\sqrt{d}$ and let A_d be the area of a d-dimensional unit sphere, that is, the surface of a $(d+1)$-dimensional unit ball. Then

$$P_x[|a \cdot x| \le r] = \frac{\int_{-r}^{r} A_{d-2}(1-z^2)^{\frac{d-2}{2}}(1-z^2)^{-1/2}dz}{A_{d-1}} = \frac{2A_{d-2}}{A_{d-1}} \int_0^r (1-z^2)^{(d-3)/2}dz.$$

First observe,

$$r(1-r^2)^{(d-3)/2} \le \int_0^r (1-z^2)^{(d-3)/2}dz \le r. \tag{10}$$

For $x \in [0,0.5]$, $1-x \ge 4^{-x}$. Hence, for $0 \le r \le 2^{-1/2}$,

$$(1-r^2)^{(d-3)/2} \ge 4^{-r^2((d-3)/2)} \ge 2^{-r^2 d}.$$

So we can conclude that the integral of (10) is in $[r/2, r]$ for $r \in [0, 1/\sqrt{d}]$. The ratio $2A_{d-2}/A_{d-1}$ can be shown to be in the range $[\sqrt{d/3}, \sqrt{d}]$ by straightforward induction on d, using the definition of the Γ function, and the fact that $A_{d-1} = 2\pi^{d/2}/\Gamma(d/2)$. ■

Abstract

We address the problem of improving the reliability of independence-based causal discovery algorithms that results from the execution of statistical independence tests on small data sets, which typically have low reliability. We model the problem as a knowledge base containing a set of independence facts that are related through Pearl's well-known axioms. Statistical tests on finite data sets may result in errors in these tests and inconsistencies in the knowledge base. We resolve these inconsistencies through the use of an instance of the class of defeasible logics called argumentation, augmented with a preference function, that is used to reason about and possibly correct errors in these tests. This results in a more robust conditional independence test, called an *argumentative independence test*. Our experimental evaluation shows clear positive improvements in the accuracy of argumentative over purely statistical tests. We also demonstrate significant improvements on the accuracy of causal structure discovery from the outcomes of independence tests both on sampled data from randomly generated causal models and on real-world data sets.

Keywords: independence-based causal discovery, causal Bayesian networks, structure learning, argumentation, reliability improvement

1. Introduction and Motivation

Directed graphical models, also called *Bayesian networks*, can be used to represent the probability distribution of a domain. This makes them a useful and important tool for machine learning where a common task is inference, that is, predicting the probability distribution of a variable of interest given some other knowledge, usually in the form of values of other variables in the domain. An additional use of Bayesian networks comes by augmenting them with causal semantics that represent cause and effect relationships in the domain. The resulting networks are called *causal*. An important problem is inferring the structure of these networks, a process that is sometimes called *causal discovery*, which can provide insights into the underlying data generation process.

Two major classes of algorithms exist for learning the structure of Bayesian networks. One class contains so-called *score-based* methods, which learn the structure by conducting a search in the space of all structures in an attempt to find the structure of maximum score. This score is usually penalized log-likelihood, for example, the Bayesian Information Criterion (BIC) or the (equivalent) Minimum Description Length (MDL). A second class of algorithms works by exploiting the fact that a causal Bayesian network implies the existence of a set of conditional independence statements between sets of domain variables. Algorithms in this class use the outcomes of a number of conditional independences to constrain the set of possible structures consistent with these to a singleton (if possible) and infer that structure as the only possible one. As such they are called *constraint-based* or *independence-based* algorithms. In this paper we address open problems related to the latter class of algorithms.

It is well-known that independence-based algorithms have several shortcomings. A major one has to do with the effect that unreliable independence information has on the their output. In general such independence information comes from two sources: (a) a domain expert that can provide his or her opinion on the validity of certain conditional independences among some of the variables, sometimes with a degree of confidence attached to them, and/or (b) statistical tests of independence, conducted on data gathered from the domain. As expert information is often costly and difficult to obtain, (b) is the most commonly used option in practice. A problem that occurs frequently however is that the data set available may be small. This may happen for various reasons: lack of subjects to observe (e.g., in medical domains), an expensive data-gathering process, privacy concerns and others. Unfortunately, the reliability of statistical tests significantly diminishes on small data sets. For example, Cochran (1954) recommends that Pearson's χ^2 independence test be deemed unreliable if more than 20% of the cells of the test's contingency table have an expected count of less than 5 data points. Unreliable tests, besides producing errors in the resulting causal model structure, may also produce cascading errors due to the way that independence-based algorithms work: their operation, including which test to evaluate next, typically depends on the outcomes of previous ones. Thus a single error in a statistical test can be propagated by the subsequent choices of tests to be performed by the algorithm, and finally when the edges are oriented. Therefore, an error in a previous test may have large (negative) consequences in the resulting structure, a property that is called *instability* in Spirtes et al. (2000). One possible method for addressing the effect of multiple errors in the construction of a causal model through multiple independence tests is the Bonferroni correction (Hochberg, 1988; Abdi, 2007), which works by dividing the type I error probability α of each test by the number of such tests evaluated during the entire execution of the causal learning algorithm. As a result, the collective type I error probability (of all tests evaluated) is α, that is, 0.05 typically. However, this may make the detection of true dependences harder, as now larger data sets would be required to reach the adjusted confidence threshold of each test. The types of adjustments that may be appropriate for each case to tests that may be dependent is an open problem and the subject of current research in statistics (Benjamini and Hochberg, 1995; Benjamini and Yekutieli, 2001; Storey, 2002).

In this paper we present and evaluate a number of methods for increasing the reliability of independence tests for small data sets. A result of this is the improvement in reliability of independence-based causal discovery algorithms that use these data sets, as we demonstrate in our experiments. We model this setting as a knowledge base whose contents are propositions representing conditional independences that may contain errors. Our main insight is to recognize that the outcomes of independence tests are not themselves independent but are constrained by the outcomes of other tests through Pearl's well-known properties of the conditional independence relation (Pearl, 1988; Dawid, 1979). These can therefore be seen as *integrity constraints* that can correct certain inconsistent test outcomes, choosing instead the outcome that can be inferred by tests that do not result in contradictions. We illustrate this by an example.

Example 1. *Consider an independence-based knowledge base that contains the following propositions, obtained through statistical tests on data.*

$$(\{0\} \perp\!\!\!\perp \{1\} \mid \{2\}) \tag{1}$$
$$(\{0\} \not\perp\!\!\!\perp \{3\} \mid \{2\}) \tag{2}$$
$$(\{0\} \perp\!\!\!\perp \{3\} \mid \{1,2\}) \tag{3}$$

where $(\mathbf{X} \perp\!\!\!\perp \mathbf{Y} \mid \mathbf{Z})$ *denotes conditional independence of the set of variables* $\mathbf{X}$ *with* $\mathbf{Y}$ *conditional on set* $\mathbf{Z}$*, and* $(\mathbf{X} \not\perp\!\!\!\perp \mathbf{Y} \mid \mathbf{Z})$ *denotes conditional dependence. Suppose that (3) is in fact wrong. Such an error can be avoided if there exists a constraint involving these independence propositions. For example, suppose that we also know that the following rule holds in the domain (this is an instance of an application of the Contraction and Decomposition axioms, described later in Section 2):*

$$(\{0\} \perp\!\!\!\perp \{1\} \mid \{2\}) \wedge (\{0\} \not\perp\!\!\!\perp \{3\} \mid \{2\}) \implies (\{0\} \not\perp\!\!\!\perp \{3\} \mid \{1,2\}). \tag{4}$$

Rule (4), together with independence proposition (1) and dependence proposition (2), contradict independence proposition (3), resulting in an inconsistent knowledge base. If Rule (4) and propositions (1) and (2) are accepted, then proposition (3) must be rejected (and its value reversed), correcting the error in this case. The framework presented in the rest of the paper provides a principled approach for resolving such inconsistencies.

The situation described in the previous example, while simple, illustrates the general idea that we will use in the rest of the paper: the set of independences and dependences used in a causal discovery algorithm form a potentially inconsistent knowledge base, and making use of general rules, derived from axioms and theorems that we know hold in the domain, helps us correct certain outcomes of statistical tests. In this way we will be able to improve the reliability of causal discovery algorithms that use them to derive causal models. To accomplish this we use the framework of *argumentation*, which provides a sound and elegant way of resolving inconsistencies in such knowledge bases, including ones that contain independences.

The rest of the paper is organized as follows. The next section introduces our notation and definitions. Section 3 presents the argumentation framework and its extension with preferences, and describes our approach for applying it to represent and reason in knowledge bases containing independence facts that may be inconsistent. Section 4 introduces the argumentative independence test, implemented by the top-down algorithm introduced in Section 5. We then present an approximation for the top-down algorithm in Section 6 that reduces its time complexity to polynomial. We experimentally evaluate our approach in Section 7, and conclude with a summary and possible directions of future research in Section 8. Most of the proofs are presented in detail in Appendices A and B, which contain proofs for the computability (termination) and the validity (no AIT test can return a dependence and an independence result at the same time) of AIT, respectively. Note that, as our main goal in this paper is to address the problem of robust causal learning and not necessarily to advance the theory of argumentation itself, our exposition in the rest of the paper is geared toward causality theorists and practitioners. As this community may be unfamiliar with the theory and methods of the argumentation framework, we have included a self-contained discussion that covers the basic definitions and theorems of argumentation theory in some detail.

2. Notation and Preliminaries

In this work we denote random variables with capitals (e.g., X, Y, Z) and sets of variables with bold capitals (e.g., $\mathbf{X}, \mathbf{Y}, \mathbf{Z}$). In particular, we denote by $\mathbf{V} = \{1, \ldots, n\}$ the set of all n variables in the domain, naming the variables by their indices in $\mathbf{V}$; for instance, we refer to the third variable in $\mathbf{V}$ simply by 3. We assume that all variables in the domain are discrete following a multinomial distribution or are continuous following a Gaussian distribution. We denote the data set by D and its size (number of data points) by N. We use the notation $(\mathbf{X} \perp\!\!\!\perp \mathbf{Y} \mid \mathbf{Z})$ to denote that the variables in set $\mathbf{X}$ are (jointly) independent of those in $\mathbf{Y}$ conditional on the values of the variables in $\mathbf{Z}$, for disjoint sets of variables $\mathbf{X}$, $\mathbf{Y}$, and $\mathbf{Z}$, while $(\mathbf{X} \not\!\perp\!\!\!\perp \mathbf{Y} \mid \mathbf{Z})$ denotes conditional dependence. For the sake of readability, we slightly abuse this notation and use $(X \perp\!\!\!\perp Y \mid Z)$ as shorthand for $(\{X\} \perp\!\!\!\perp \{Y\} \mid \{Z\})$.

A Bayesian network (**BN**) is a directed graphical model which represents the joint probability distribution over $\mathbf{V}$. Each node in the graph represents one of the random variables in the domain. The structure of the network implicitly represents a set of conditional independences on the domain variables. Given the structure of a BN, the set of independences implied by it can be identified by a process called *d-separation* (Pearl, 1988); the latter follows from the *local Markov property* that states that each node in the network is conditionally independent of all its non-descendants in the graph given its parents. All independences identified by d-separation are implied by the model structure. If, in addition, all remaining triplets $(\mathbf{X}, \mathbf{Y}, \mathbf{Z})$ correspond to dependencies, we say that the BN is *directed graph-isomorph* (abbreviated *DAG-isomorph*) or simply *causal* (as defined by Pearl, 1988). The concept of DAG-isomorphism is equivalent to a property called Faithfulness in Spirtes et al. (2000). A graph G is said to be *faithful* to some distribution if exactly those independences that exist in the distribution and no others are returned by the process of d-separation on G. In this paper we assume Faithfulness. For learning the structure of the Bayesian network of a domain we make use of the PC algorithm (Spirtes et al., 2000), which is only able to correctly identify the structure under the assumption of *causal sufficiency*. We therefore also assume causal sufficiency. A domain is causally sufficient if it does not contain any *hidden* or *latent* variables.

As mentioned above, independence-based algorithms operate by conducting a series of conditional independence queries. For these we assume that an *independence-query oracle* exists that is able to provide such information. This approach can be viewed as an instance of the statistical query oracle theory of Kearns and Vazirani (1994). In practice such an oracle does not exist, but can be implemented approximately by a statistical test evaluated on the data set (for example, this can be Pearson's conditional independence χ^2 (chi-square) test (Agresti, 2002), Wilk's G^2 test, a mutual information test etc.). In this work we used Wilk's G^2 test (Agresti, 2002). To determine conditional independence between two variables X and Y given a set $\mathbf{Z}$ from data, the statistical test G^2 (and many other independence tests based on hypothesis testing, for example, the χ^2 test) uses the values in the contingency table (a table containing the data point counts for each possible combination of the variables that participate in the test) to compute a *test statistic*. For a given value of the test statistic, the test then computes the likelihood of obtaining that or a more extreme value by chance under the *null hypothesis*, which in our case is that the two variables are conditionally independent. This likelihood, called the *p-value* of the test, is then returned. The p-value of a test equals the probability of falsely rejecting the null hypothesis (independence). Assuming that the p-value of a test is $p(X, Y \mid \mathbf{Z})$, the statistical test concludes independence if and only if $p(X, Y \mid \mathbf{Z})$ is greater than a threshold α, that is,

$$(X \perp\!\!\!\perp Y \mid \mathbf{Z}) \iff p(X, Y \mid \mathbf{Z}) > \alpha.$$

$$\boxed{\begin{array}{rl}
\textbf{(Symmetry)} & (\mathbf{X} \perp\!\!\!\perp \mathbf{Y} \mid \mathbf{Z}) \iff (\mathbf{Y} \perp\!\!\!\perp \mathbf{X} \mid \mathbf{Z}) \\
\textbf{(Decomposition)} & (\mathbf{X} \perp\!\!\!\perp \mathbf{Y} \cup \mathbf{W} \mid \mathbf{Z}) \implies (\mathbf{X} \perp\!\!\!\perp \mathbf{Y} \mid \mathbf{Z}) \wedge (\mathbf{X} \perp\!\!\!\perp \mathbf{W} \mid \mathbf{Z}) \\
\textbf{(Weak Union)} & (\mathbf{X} \perp\!\!\!\perp \mathbf{Y} \cup \mathbf{W} \mid \mathbf{Z}) \implies (\mathbf{X} \perp\!\!\!\perp \mathbf{Y} \mid \mathbf{Z} \cup \mathbf{W}) \\
\textbf{(Contraction)} & (\mathbf{X} \perp\!\!\!\perp \mathbf{Y} \mid \mathbf{Z}) \wedge (\mathbf{X} \perp\!\!\!\perp \mathbf{W} \mid \mathbf{Z} \cup \mathbf{Y}) \implies (\mathbf{X} \perp\!\!\!\perp \mathbf{Y} \cup \mathbf{W} \mid \mathbf{Z}) \\
\textbf{(Intersection)} & (\mathbf{X} \perp\!\!\!\perp \mathbf{Y} \mid \mathbf{Z} \cup \mathbf{W}) \wedge (\mathbf{X} \perp\!\!\!\perp \mathbf{W} \mid \mathbf{Z} \cup \mathbf{Y}) \implies (\mathbf{X} \perp\!\!\!\perp \mathbf{Y} \cup \mathbf{W} \mid \mathbf{Z})
\end{array}} \tag{5}$$

$$\boxed{\begin{array}{rl}
\textbf{(Symmetry)} & (\mathbf{X} \perp\!\!\!\perp \mathbf{Y} \mid \mathbf{Z}) \iff (\mathbf{Y} \perp\!\!\!\perp \mathbf{X} \mid \mathbf{Z}) \\
\textbf{(Composition)} & (\mathbf{X} \perp\!\!\!\perp \mathbf{Y} \mid \mathbf{Z}) \wedge (\mathbf{X} \perp\!\!\!\perp \mathbf{W} \mid \mathbf{Z}) \implies (\mathbf{X} \perp\!\!\!\perp \mathbf{Y} \cup \mathbf{W} \mid \mathbf{Z}) \\
\textbf{(Decomposition)} & (\mathbf{X} \perp\!\!\!\perp \mathbf{Y} \cup \mathbf{W} \mid \mathbf{Z}) \implies (\mathbf{X} \perp\!\!\!\perp \mathbf{Y} \mid \mathbf{Z}) \wedge (\mathbf{X} \perp\!\!\!\perp \mathbf{W} \mid \mathbf{Z}) \\
\textbf{(Intersection)} & (\mathbf{X} \perp\!\!\!\perp \mathbf{Y} \mid \mathbf{Z} \cup \mathbf{W}) \wedge (\mathbf{X} \perp\!\!\!\perp \mathbf{W} \mid \mathbf{Z} \cup \mathbf{Y}) \implies (\mathbf{X} \perp\!\!\!\perp \mathbf{Y} \cup \mathbf{W} \mid \mathbf{Z}) \\
\textbf{(Weak Union)} & (\mathbf{X} \perp\!\!\!\perp \mathbf{Y} \cup \mathbf{W} \mid \mathbf{Z}) \implies (\mathbf{X} \perp\!\!\!\perp \mathbf{Y} \mid \mathbf{Z} \cup \mathbf{W}) \\
\textbf{(Contraction)} & (\mathbf{X} \perp\!\!\!\perp \mathbf{Y} \mid \mathbf{Z}) \wedge (\mathbf{X} \perp\!\!\!\perp \mathbf{W} \mid \mathbf{Z} \cup \mathbf{Y}) \implies (\mathbf{X} \perp\!\!\!\perp \mathbf{Y} \cup \mathbf{W} \mid \mathbf{Z}) \\
\textbf{(Weak Transitivity)} & (\mathbf{X} \perp\!\!\!\perp \mathbf{Y} \mid \mathbf{Z}) \wedge (\mathbf{X} \perp\!\!\!\perp \mathbf{Y} \mid \mathbf{Z} \cup \gamma) \implies (\mathbf{X} \perp\!\!\!\perp \gamma \mid \mathbf{Z}) \vee (\gamma \perp\!\!\!\perp \mathbf{Y} \mid \mathbf{Z}) \\
\textbf{(Chordality)} & (\alpha \perp\!\!\!\perp \beta \mid \gamma \cup \delta) \wedge (\gamma \perp\!\!\!\perp \delta \mid \alpha \cup \beta) \implies (\alpha \perp\!\!\!\perp \beta \mid \gamma) \vee (\alpha \perp\!\!\!\perp \beta \mid \delta)
\end{array}} \tag{6}$$

Common values in statistics for α are 0.05 and 0.01, corresponding to *confidence thresholds* $(1-\alpha)$ of 0.95 and 0.99 respectively. The value 0.10 for α is also sometimes used, depending on the application, while values as low as 0.005 and 0.001 are sometimes used for structure learning.

The conditional independences and dependences of a domain are connected through a set of general rules, introduced in Pearl (1988) and shown boxed in Eq. (5). These can be seen as constraints in a meta-space representing all possible independences in the domain. More specifically, let us imagine a meta-space of binary variables, each corresponding to the truth value of the independence of a triplet $(\mathbf{X}, \mathbf{Y} \mid \mathbf{Z})$ (e.g., `true` for independence and `false` for dependence). Each point in this space corresponds to a conditional independence assignment to all possible triplets in the domain. In this conceptual space not all points are tenable; in particular the set of rules of Eq. (5) constrain the truth values of independences corresponding to triplets. For domains for which there exists a faithful Bayesian network a more relaxed set of properties hold, shown boxed in Eq. (6) where α, β, γ and δ correspond to single variables. In both sets of axioms, the property of Intersection holds if the probability distribution of the domain is positive, meaning that every assignment to all variables in the domain has a non-zero probability. Eq. (6) were first introduced by Dawid (1979) in a slightly different form and independently re-discovered by Pearl and Paz (1985).

Note that the axioms of Eq. (5) are necessarily incomplete; Studený (1991) showed that there is no finite axiomatization of the conditional independence relation in general. The implication of this is that there may be some inconsistencies involving some set of independences and dependences that no method can detect and resolve.

In the next section we describe the argumentation framework, which allows one to make beneficial use of these constraints. This is followed by its application to our problem of answering independence queries from knowledge bases that contain sets of potentially inconsistent independence propositions.

3. The Argumentation Framework

There exist two major approaches for reasoning with information contained in inconsistent knowledge bases such as those containing independence statements that were described in the previous section. These two distinct approaches correspond to two different attitudes: One is to resolve the inconsistencies by removing a subset of propositions such that the resulting KB becomes consistent; this is called *belief revision* in the literature (Gärdenfors, 1992; Gärdenfors and Rott, 1995; Shapiro, 1998; Martins, 1992). A potential shortcoming (Shapiro, 1998) of belief revision stems from the fact that it removes propositions, which discards potentially valuable information. In addition, an erroneous modification of the KB (such as the removal of a proposition) may have unintended negative consequences if later more propositions are inserted in the KB. A second approach to inconsistent KBs is to allow inconsistencies but to use rules that may be possibly contained in it to deduce which truth value of a proposition query is "preferred" in some way. One instance of this approach is *argumentation* (Dung, 1995; Loui, 1987; Prakken, 1997; Prakken and Vreeswijk, 2002), which is a sound approach that allows inconsistencies but uses a proof procedure that is able to deduce (if possible) that one of the truth values of certain propositions is preferred over its negation. Argumentation is a reasoning model that belongs to the broader class of defeasible logics (Pollock, 1992; Prakken, 1997). Our approach uses the argumentation framework of Amgoud and Cayrol (2002) that considers preferences over arguments, extending Dung's more fundamental framework (Dung, 1995). Preference relations give an extra level of specificity for comparing arguments, allowing a more refined form of selection between conflicting propositions. Preference-based argumentation is presented in more detail in Section 3.2.

We proceed now to describe the argumentation framework.

Definition 1. *An* argumentation framework *is a pair $\langle \mathcal{A}, \mathcal{R} \rangle$, where $\mathcal{A}$ is a set of arguments and $\mathcal{R}$ is a binary relation representing a defeasibility relationship between arguments, that is, $\mathcal{R} \subseteq \mathcal{A} \times \mathcal{A}$. $(a,b) \in \mathcal{R}$ or equivalently "a $\mathcal{R}$ b" reads that argument a defeats argument b. We also say that a and b are in conflict.*

An example of the defeat relation $\mathcal{R}$ is *logical defeat*, which occurs when an argument contradicts another logically.

The elements of the argumentation framework are not propositions but *arguments*. Given a potentially inconsistent knowledge base $\mathcal{K} = \langle \Sigma, \Psi \rangle$ with a set of propositions Σ and a set of inference rules Ψ, arguments are defined formally as follows.

Definition 2. *An* argument *over knowledge base $\langle \Sigma, \Psi \rangle$ is a pair (H,h) where $H \subseteq \Sigma$ such that:*

- *H is consistent,*
- *$H \vdash_\Psi h$,*
- *H is minimal (with respect to set inclusion).*

H is called the support *and h the* conclusion *or* head *of the argument.*

In the above definition $\vdash_\Psi$ stands for classical logical inference over the set of inference rules Ψ. Intuitively an argument (H,h) can be thought as an "if-then" rule, that is, "if H then h." In inconsistent knowledge bases two arguments may contradict or *defeat* each other. The defeat relation is defined through the *rebut* and *undercut* relations, defined as follows.

Definition 3. *Let (H_1,h_1), (H_2,h_2) be two arguments.*

- *(H_1,h_1)* rebuts *(H_2,h_2) iff $h_1 \equiv \neg h_2$.*

Algorithm 1 Recursive computation of acceptable arguments: $Acc_{\mathcal{R}} = \mathcal{F}(\mathcal{A}, \mathcal{R}, S)$

```
1: $S' \longleftarrow S \cup \{a \in \mathcal{A} \mid a \text{ is defended by } S\}$
2: **if** $S = S'$ **then**
3:     **return** $S'$
4: **else**
5:     **return** $\mathcal{F}(\mathcal{A}, \mathcal{R}, S')$
```

- (H_1, h_1) undercuts (H_2, h_2) *iff* $\exists h \in H_2$ *such that* $h \equiv \neg h_1$.

If (H_1, h_1) *rebuts or undercuts* (H_2, h_2) *we say that* (H_1, h_1) defeats (H_2, h_2).

(The symbol "$\equiv$" stands for logical equivalence.) In other words, $(H_1, h_1)\ \mathcal{R}\ (H_2, h_2)$ if and only if (H_1, h_1) *rebuts* or *undercuts* (H_2, h_2).

The objective of argumentation is to decide on the acceptability of a given argument. There are three possibilities: an argument can be accepted, rejected, or neither. This partitions the space of arguments $\mathcal{A}$ in three classes:

- The class $Acc_{\mathcal{R}}$ of *acceptable arguments*. Intuitively, these are the "good" arguments. In the case of an inconsistent knowledge base, these will be inferred from the knowledge base.

- The class $Rej_{\mathcal{R}}$ of *rejected arguments*. These are the arguments defeated by acceptable arguments. When applied to an inconsistent knowledge base, these will not be inferred from it.

- The class $Ab_{\mathcal{R}}$ of arguments *in abeyance*. These arguments are neither accepted nor rejected.

The semantics of acceptability proposed by Dung (1995) dictates that an argument should be accepted if it is not defeated, or if it is defended by acceptable arguments, that is, each of its defeaters is itself defeated by an acceptable argument. This is formalized in the following definitions.

Definition 4. *Let* $\langle \mathcal{A}, \mathcal{R} \rangle$ *be an argumentation framework, and* $S \subseteq \mathcal{A}$. *An argument* a *is* defended *by* S *if and only if* $\forall b$, *if* $(b\ \mathcal{R}\ a)$ *then* $\exists c \in S$ *such that* $(c\ \mathcal{R}\ b)$.

Dung characterizes the set of acceptable arguments by a monotonic function $\mathcal{F}$, that is, $\mathcal{F}(S) \subseteq \mathcal{F}(S \cup T)$ for some S and T. Given a set of arguments $S \subseteq \mathcal{A}$ as input, $\mathcal{F}$ returns the set of all arguments defended by S:

Definition 5. *Let* $S \subseteq \mathcal{A}$. *Then* $\mathcal{F}(S) = \{a \in \mathcal{A} \mid a \text{ is defended by } S\}$.

Slightly overloading our notation, we define $\mathcal{F}(\varnothing)$ to contain the set of arguments that are not defeated by any argument in the framework.

Definition 6. $\mathcal{F}(\varnothing) = \{a \in \mathcal{A} \mid a \text{ is not defeated by any argument in } \mathcal{A}\}$.

Dung proved that the set of acceptable arguments is the least fix-point of $\mathcal{F}$, that is, the smallest set S such that $\mathcal{F}(S) = S$.

Theorem 7 (Dung 1995)**.** *Let* $\langle \mathcal{A}, \mathcal{R} \rangle$ *be an argumentation framework. The set of acceptable arguments* $Acc_{\mathcal{R}}$ *is the least fix-point of the function* $\mathcal{F}$.

Dung also showed that if the argumentation framework $\langle \mathcal{A}, \mathcal{R} \rangle$ is finitary, that is, for each argument A there are finitely many arguments that defeat A, the least fix-point of function $\mathcal{F}$ can be obtained by iterative application of $\mathcal{F}$ to the empty set. We can understand this intuitively: From our semantics of acceptability it follows that all arguments in $\mathcal{F}(\varnothing)$ are accepted. Also, every argument in $\mathcal{F}(\mathcal{F}(\varnothing))$ must be acceptable as well since each of its arguments is defended by acceptable arguments. This reasoning can be applied recursively until a fix-point is reached. This happens when the arguments in S cannot be used to defend any other argument not in S, that is, no additional argument is accepted. This suggests a simple algorithm for computing the set of acceptable arguments. Algorithm 1 shows a recursive procedure for this, based on the above definition. The algorithm takes as input an argumentation framework $\langle \mathcal{A}, \mathcal{R} \rangle$ and the set S of arguments found acceptable so far, that is, $S = \varnothing$ initially.

Let us illustrate these ideas with an example.

Example 2. *Let $\langle \mathcal{A}, \mathcal{R} \rangle$ be an argumentation framework defined by $\mathcal{A} = \{a,b,c\}$ and $\mathcal{R} = \{(a,b), (b,c)\}$. The only argument that is not defeated is a, and therefore $\mathcal{F}(\varnothing) = \{a\}$. Argument b is defeated by the acceptable argument a, so b cannot be defended and is therefore rejected, that is, $b \in Rej_{\mathcal{R}}$. Argument c, though defeated by b, is defended by (acceptable argument) a which defeats b, so c is acceptable. The set of acceptable arguments is therefore $Acc_{\mathcal{R}} = \{a,c\}$ and the set of rejected arguments is $Rej_{\mathcal{R}} = \{b\}$.*

The **bottom-up** approach of Algorithm 1 has the disadvantage that it requires the computation of all acceptable arguments to answer the acceptability status of a single one. In practice, and in particular in the application of argumentation to independence tests, the entire set of acceptable arguments is rarely needed. An alternative is to take a top-down approach (Amgoud and Cayrol, 2002; Dung, 1995; Toni and Kakas, 1995; Kakas and Toni, 1999) that evaluate the acceptability of some input argument by evaluating (recursively) the acceptability of its attackers. Below we present an alternative algorithm, called the **top-down algorithm**, for deciding the acceptability of an input argument. This algorithm is a version of the *dialog tree* algorithm of Amgoud and Cayrol (2002), where details unnecessary for the current exposition are not shown. This algorithm is provably equivalent to Algorithm 1 (whenever it is given the same input it is guaranteed to produce the same output), but it is considerably more efficient (as shown later in Section 5.2). We sketch the algorithm here and show a concrete version using the preference-based argumentation framework in Section 3.2.

Given an input argument a, the top-down algorithm employs a goal-driven approach for answering whether a is accepted or not. Its operation is guided by the same acceptability semantics as those used for Algorithm 1. Let us denote the predicates $A(a) \equiv (a \in Acc_{\mathcal{R}})$, $R(a) \equiv (a \in Rej_{\mathcal{R}})$, and $Ab(a) \equiv (a \in Ab_{\mathcal{R}})$. Then, the acceptability semantics are as follows.

Algorithm 2 Top-down computation of acceptable arguments: *top-down*$(\mathcal{A}, \mathcal{R}, a)$

```
1: $defeaters \leftarrow$ set of arguments in $\mathcal{A}$ that defeat $a$ according to $\mathcal{R}$.
2: for $d \in defeaters$ do
3:     if $top\text{-}down(\mathcal{A}, \mathcal{R}, d)$ = accepted then
4:         return rejected
5: return accepted
```

(Acceptance) A node is accepted iff it has no defeaters or all its defeaters are rejected:

$$A(a) \iff \forall b \in \mathit{defeaters}(a), R(b).$$

(Rejection) A node is rejected iff at least one of its defeaters is accepted:

$$R(a) \iff \exists b \in \mathit{defeaters}(a), A(b). \tag{7}$$

(Abeyance) A node is in abeyance iff its not accepted nor rejected:

$$Ab(a) \iff \neg A(a) \wedge \neg R(a).$$

The logic of these equations can be easily implemented with a recursive algorithm, shown in Algorithm 2. The algorithm, given some input argument a, loops over all defeaters of a and responds `rejected` if any of its defeaters is accepted (line 4). If execution reaches the end of the loop at line 5 then that means that none of its defeaters was accepted, and thus the algorithm accepts the input argument a. We can represent the execution of the top-down algorithm graphically by a tree that contains a at the root node, and all the defeaters of a node as its children. A leaf is reached when a node has no defeaters. In that case the loop contains no iterations and line 5 is reached trivially.

Unfortunately, the top-down algorithm, as shown in Algorithm 2, will fail to terminate when a node is in abeyance. This is clear from the following lemma (proved formally in Appendix A but reproduced here to aid our intuition).

Lemma 8. *For every argument a,*

$$Ab(a) \implies \exists b \in \mathit{attackers}(a), Ab(b).$$

(An attacker is a type of defeater; it is explained in detail in the next section. For the following discussion the reader can substitute "attacker" with "defeater" in the lemma above.) From this lemma we can see that, if an argument is in abeyance, its set of defeaters must contain an argument in abeyance and thus the recursive call of the top-down algorithm will never terminate, as there will always be another defeater in abeyance during each call. While there are ways to overcome this difficulty in the general case, we can prove that using the preference-based argumentation framework (presented later in the paper) and for the particular preference relation introduced for deciding on independence tests (c.f. Section 3.3), no argument can be in abeyance and thus the top-down algorithm always terminates. A formal proof of this is presented later in Section 5.

We conclude the section by proving that the top-down algorithm is equivalent to the bottom-up algorithm of Algorithm 1 that is, given the same input as Algorithm 1 it is guaranteed to produce the same output. The proof assumes no argument is in abeyance. This assumption is satisfied for argumentation in independence knowledge bases (c.f. Theorem 20, Section 5).

Theorem 9. *Let a be an argument in the argumentation framework $\langle \mathcal{A}, \mathcal{R} \rangle$, and let $\mathcal{F}$ be the set of acceptable arguments output by Algorithm 1. Assuming a is not in abeyance,*

$$\mathit{top\text{-}down}(\mathcal{A}, \mathcal{R}, a) = \texttt{accepted} \iff a \in \mathcal{F} \tag{8}$$

$$\mathit{top\text{-}down}(\mathcal{A}, \mathcal{R}, a) = \texttt{rejected} \iff a \notin \mathcal{F}. \tag{9}$$

Proof According to Theorem 7, the fix point of function $\mathcal{F}$ returned by Algorithm 1 contains the set of arguments considered acceptable by the acceptability semantics of Dung. As the top-down algorithm is a straightforward implementation of Dung's acceptability semantics expressed by Eq. (7), the double implication of Eq. (8) must follow. To prove Eq. (9) we can prove the equivalent expression with both sides negated, that is,

$$\textit{top-down}(\mathcal{A},\mathcal{R},a) \neq \texttt{rejected} \iff a \in \mathcal{F}.$$

Since a is not in abeyance, if the top-down algorithm does not return `rejected` it must return `accepted`. The double implication is thus equivalent to Eq. (8), which was proved true. ■

3.1 Argumentation in Independence Knowledge Bases

We can now apply the argumentation framework to our problem of answering queries from knowledge bases that contain a number of potentially inconsistent independences and dependencies and a set of rules that express relations among them.

Definition 10. *An* independence knowledge base *(**IKB**) is a knowledge base $\langle \Sigma, \Psi \rangle$ such that its set of propositions Σ contains independence propositions of the form $(\mathbf{X} \perp\!\!\!\perp \mathbf{Y} \mid \mathbf{Z})$ or $(\mathbf{X} \not\perp\!\!\!\perp \mathbf{Y} \mid \mathbf{Z})$ for $\mathbf{X}$, $\mathbf{Y}$ and $\mathbf{Z}$ disjoint subsets of $\mathbf{V}$, and its set of inference rules Ψ is either the general set of axioms shown in Eq. (5) or the specific set of axioms shown in Eq. (6).*

For IKBs, the set of arguments $\mathcal{A}$ is obtained in two steps. First, for each proposition $\sigma \in \Sigma$ (independence or dependence) we add to $\mathcal{A}$ the argument $(\{\sigma\},\sigma)$. This is a valid argument according to Definition 2 since its support $\{\sigma\}$ is (trivially) consistent, it (trivially) implies the head σ, and it is minimal (the pair $(\varnothing,\sigma)$ is not a valid argument since $\varnothing$ is equivalent to the proposition `true` which does not entail σ in general). We call arguments of the form $(\{\sigma\},\sigma)$ *propositional arguments* since they correspond to single propositions. The second step in the construction of the set of arguments $\mathcal{A}$ concerns rules. Based on the chosen set of axioms (general or directed) we construct an alternative, logically equivalent set of rules Ψ', each member of which is *single-headed*, that is, contains a single proposition as the consequent, and *decomposed*, that is, each of its propositions is an independence statement over single variables (the last step is justified by the fact that typical algorithms for causal learning never produce nor require the evaluation of independence between sets).

To construct the set of single-headed rules we consider, for each axiom, all possible contrapositive versions of it that have a single head. To illustrate, consider the Weak Transitivity axiom

$$(\mathbf{X} \perp\!\!\!\perp \mathbf{Y} \mid \mathbf{Z}) \wedge (\mathbf{X} \perp\!\!\!\perp \mathbf{Y} \mid \mathbf{Z} \cup \gamma) \implies (\mathbf{X} \perp\!\!\!\perp \gamma \mid \mathbf{Z}) \vee (\gamma \perp\!\!\!\perp \mathbf{Y} \mid \mathbf{Z})$$

from which we obtain the following set of single-headed rules:

$$\begin{aligned}
(\mathbf{X} \perp\!\!\!\perp \mathbf{Y} \mid \mathbf{Z}) \wedge (\mathbf{X} \perp\!\!\!\perp \mathbf{Y} \mid \mathbf{Z} \cup \gamma) \wedge (\mathbf{X} \not\perp\!\!\!\perp \gamma \mid \mathbf{Z}) &\implies (\gamma \perp\!\!\!\perp \mathbf{Y} \mid \mathbf{Z})\\
(\mathbf{X} \perp\!\!\!\perp \mathbf{Y} \mid \mathbf{Z}) \wedge (\mathbf{X} \perp\!\!\!\perp \mathbf{Y} \mid \mathbf{Z} \cup \gamma) \wedge (\gamma \not\perp\!\!\!\perp \mathbf{Y} \mid \mathbf{Z}) &\implies (\mathbf{X} \perp\!\!\!\perp \gamma \mid \mathbf{Z})\\
(\mathbf{X} \perp\!\!\!\perp \mathbf{Y} \mid \mathbf{Z} \cup \gamma) \wedge (\gamma \not\perp\!\!\!\perp \mathbf{Y} \mid \mathbf{Z}) \wedge (\mathbf{X} \not\perp\!\!\!\perp \gamma \mid \mathbf{Z}) &\implies (\mathbf{X} \not\perp\!\!\!\perp \mathbf{Y} \mid \mathbf{Z})\\
(\mathbf{X} \perp\!\!\!\perp \mathbf{Y} \mid \mathbf{Z}) \wedge (\gamma \not\perp\!\!\!\perp \mathbf{Y} \mid \mathbf{Z}) \wedge (\mathbf{X} \not\perp\!\!\!\perp \gamma \mid \mathbf{Z}) &\implies (\mathbf{X} \not\perp\!\!\!\perp \mathbf{Y} \mid \mathbf{Z} \cup \gamma).
\end{aligned}$$

To obtain decomposed rules we apply the Decomposition axiom to every single-headed rule to produce only propositions over singletons. To illustrate, consider the Intersection axiom:

$$(\mathbf{X} \perp\!\!\!\perp \mathbf{Y} \mid \mathbf{Z} \cup \mathbf{W}) \wedge (\mathbf{X} \perp\!\!\!\perp \mathbf{W} \mid \mathbf{Z} \cup \mathbf{Y}) \implies (\mathbf{X} \perp\!\!\!\perp \mathbf{Y} \cup \mathbf{W} \mid \mathbf{Z}).$$

In the above the consequent coincides with the antecedent of the Decomposition axiom, and we thus replace the Intersection axiom with a decomposed version:

$$(\mathbf{X} \perp\!\!\!\perp \mathbf{Y} \mid \mathbf{Z} \cup \mathbf{W}) \wedge (\mathbf{X} \perp\!\!\!\perp \mathbf{W} \mid \mathbf{Z} \cup \mathbf{Y}) \implies (\mathbf{X} \perp\!\!\!\perp \mathbf{Y} \mid \mathbf{Z}) \wedge (\mathbf{X} \perp\!\!\!\perp \mathbf{W} \mid \mathbf{Z}).$$

Finally, note that it is easy to show that this rule is equivalent to two single-headed rules, one implying $(\mathbf{X} \perp\!\!\!\perp \mathbf{Y} \mid \mathbf{Z})$ and the other implying $(\mathbf{X} \perp\!\!\!\perp \mathbf{W} \mid \mathbf{Z})$.

The result of the application of the above procedures is a set of single-headed, decomposed rules Ψ'. We construct, for each such rule $(\Phi_1 \wedge \Phi_2 \ldots \wedge \Phi_n \implies \varphi) \in \Psi'$ and for each subset of Σ that matches exactly the set of antecedents, that is, each subset $\{\varphi_1, \varphi_2 \ldots, \varphi_n\}$ of Σ such that $\Phi_1 \equiv \varphi_1, \Phi_2 \equiv \varphi_2 \ldots \Phi_n \equiv \varphi_n$, the argument $(\{\varphi_1 \wedge \varphi_2 \wedge \ldots \wedge \varphi_n\}, \varphi)$, and add it to $\mathcal{A}$.[1]

IKBs can be augmented with a set of preferences that allow one to take into account the reliability of each test when deciding on the truth value of independence queries. This is described in the next section.

3.2 Preference-based Argumentation Framework

Following Amgoud and Cayrol (2002), we now refine the argumentation framework of Dung (1995) for cases where it is possible to define a preference order Π over arguments.

Definition 11. *A* preference-based argumentation framework *(**PAF**) is a triplet $\langle \mathcal{A}, \mathcal{R}, \Pi \rangle$ where $\mathcal{A}$ is a set of arguments, $\mathcal{R} \subseteq \mathcal{A} \times \mathcal{A}$ is a binary relation representing a defeat relationship between pairs of arguments, and Π is a (partial or total) order over $\mathcal{A}$.*

For the case of inconsistent knowledge bases, preference Π over arguments follows the preference π over their support, that is, stronger support implies a stronger argument, which is given as a partial or total order over sets of propositions. Formally:

Definition 12. *Let $\mathcal{K} = \langle \Sigma, \Psi \rangle$ be a knowledge base, π be a (partial or total) order on subsets of Σ and (H, h), (H', h') two arguments over $\mathcal{K}$. Argument (H, h) is* π-preferred *to (H', h') (denoted $(H, h) \gg_\pi (H', h')$) if and only if H is preferred to H' with respect to π.*

In what follows we overload our notation by using π to denote either the ordering over arguments or over their supports.

An important sub-class of preference relations is the *strict* and *transitive* preference relation, defined as follows.

Definition 13. *We say that preference relation π over arguments is* strict *if the order of arguments induced by it is strict and total, that is, for every pair of arguments a and b,*

$$\left(a \gg_\pi b\right) \iff \neg\left(b \gg_\pi a\right).$$

1. This is equivalent to propositionalizing the set of rules, which are first-order (the rules of Eqs. (5) and (6) are universally quantified over all sets of variables, and thus are the rules in Ψ'). As this may be expensive (exponential in the number of propositions), in practice it is not implemented in this way; instead, appropriate rules are matched on the fly during the argumentation inference process.

Definition 14. *We say that preference relation* π *over arguments is* transitive *if, for every three arguments a, b and c,*

$$\big(a \gg_\pi b\big) \wedge \big(b \gg_\pi c\big) \implies \big(a \gg_\pi c\big).$$

The importance of the properties of strictness and transitivity will become clear later when we talk about the correctness of the argumentative independence test (defined later in Section 4).

We now introduce the concept of *attack* relation, a combination of the concepts of defeat and preference relation.

Definition 15. *Let* $\langle \mathcal{A}, \mathcal{R}, \pi \rangle$ *be a PAF, and* $a, b \in \mathcal{A}$ *be two arguments. We say* b attacks a *if and only if* $b \ \mathcal{R}\ a$ *and* $\neg(a \gg_\pi b)$.

We can see that the attack relation is a special case of the defeat relation and therefore the same conclusions apply; in particular Theorem 7, which allows us to compute the set of acceptable arguments of a PAF using Algorithm 1 or Algorithm 2.

In Sections 3.3 and 4 below, we apply these ideas to construct an approximation to the independence-query oracle that is more reliable than a statistical independence test.

3.3 Preference-based Argumentation in Independence Knowledge Bases

We now describe how to apply the preference-based argumentation framework of Section 3.2 to improve the reliability of conditional independence tests conducted on a (possibly small) data set. A preference-based argumentation framework has three components. The first two, namely $\mathcal{A}$ and $\mathcal{R}$, are identical to the general argumentation framework. We now describe how to construct the third component, namely the preference order π over subsets H of Σ, in IKBs. We define it using a belief estimate $\nu(H)$ that all propositions in H are correct,

$$H \gg_\pi H' \iff \nu(H) > \nu(H') \vee \big[\nu(H) = \nu(H') \wedge f(H, H')\big]. \tag{10}$$

That is, H is preferred over H' if and only if its belief of correctness is higher than that of H' or, in the case that these beliefs are equal, we break the tie using predicate f. For that we require that

$$\forall H, H' \subseteq \mathcal{A}, \text{ such that } H \neq H', \ f(H, H') = \neg f(H', H). \tag{11}$$

In addition, we require that f be transitive, that is, $f(H,H') \wedge f(H',H'') \Longrightarrow f(H,H'')$. This implies that the preference relation π is transitive, which is a necessary condition for proving a number of important theorems in Appendix A. In our implementation we resolved ties by assuming an arbitrary order of the variables in the domain, determined at the beginning of the algorithm and maintained fixed during its entire execution. Based on this ordering, $f(H,H')$ resolved ties by the lexicographic order of the variables in H and H'. By this definition, our f is both non-commutative and transitive.

Before we define $\nu(H)$ we first show that π, as defined by Eqs. (10) and (11) and for any definition of $\nu(H)$, satisfies two important properties, namely strictness (Definition 13) and transitivity (Definition 14). We do this in the following two lemmas.

Lemma 16. *The preference relation for independence knowledge bases defined by Equations (10) and (11) is strict.*

Proof

$$\begin{aligned}
& H \gg_\pi H' \\
\iff\; & \nu(H) > \nu(H') \vee \big[\nu(H) = \nu(H') \wedge f(H,H')\big] && \textbf{[By Eq. (10)]} \\
\iff\; & \nu(H) \geq \nu(H') \wedge \big[\nu(H) > \nu(H') \vee f(H,H')\big] && \textbf{[Distributivity of } \vee \textbf{ over } \wedge\textbf{]} \\
\iff\; & \neg\big\{\nu(H') > \nu(H) \vee \big[\nu(H') \geq \nu(H) \wedge f(H',H)\big]\big\} && \textbf{[Double negation and Eq. (11)]} \\
\iff\; & \neg\big\{\big[\nu(H') > \nu(H) \vee \nu(H') \geq \nu(H)\big] \wedge \big[\nu(H') > \nu(H) \vee f(H',H)\big]\big\} \\
\iff\; & \neg\big\{\nu(H') \geq \nu(H) \wedge \big[\nu(H') > \nu(H) \vee f(H',H)\big]\big\} \\
\iff\; & \neg\big\{\big[\nu(H') > \nu(H) \vee \nu(H') = \nu(H)\big] \wedge \big[\nu(H') > \nu(H) \vee f(H',H)\big]\big\} \\
\iff\; & \neg\big\{\nu(H') > \nu(H) \vee \big[\nu(H') = \nu(H) \wedge f(H',H)\big]\big\} && \textbf{[Common factor } \nu(H') > \nu(H)\textbf{]} \\
\iff\; & \neg(H' \gg_\pi H) && \textbf{[Again by Eq. (10)]}
\end{aligned}$$

■

Lemma 17. *The preference relation defined by Equations (10) and (11) is transitive.*

Proof

$$\begin{aligned}
& H \gg_\pi J \;\wedge\; J \gg_\pi K \\
\iff\; & \Big\{\nu(H) > \nu(J) \;\vee\; \big[\nu(H) = \nu(J) \;\wedge\; f(H,J)\big]\Big\} \\
& \wedge \Big\{\nu(J) > \nu(K) \;\vee\; \big[\nu(J) = \nu(K) \;\wedge\; f(J,K)\big]\Big\} && \textbf{[By Eq. (10)]} \\
\iff\; & \big[\nu(H) > \nu(J) \;\wedge\; \nu(J) > \nu(K)\big] && \textbf{[Case A]} \\
& \vee \big[\nu(H) > \nu(J) \;\wedge\; \nu(J) = \nu(K) \;\wedge\; f(J,K)\big] && \textbf{[Case B]} \\
& \vee \big[\nu(H) = \nu(J) \;\wedge\; f(H,J) \;\wedge\; \nu(J) > \nu(K)\big] && \textbf{[Case C]} \\
& \vee \big[\nu(H) = \nu(J) \;\wedge\; f(H,J) \;\wedge\; \nu(J) = \nu(K) \;\wedge\; f(J,K)\big] && \textbf{[Case D]}
\end{aligned}$$

To complete the proof we show that each of the cases A, B, C and D implies $H \gg_\pi K$.

(Case A) $\nu(H) > \nu(J) \;\wedge\; \nu(J) > \nu(K) \Longrightarrow \nu(H) > \nu(K) \Longrightarrow H \gg_\pi K$.

(Case B) $\nu(H) > \nu(J) \;\wedge\; \nu(J) = \nu(K) \;\wedge\; f(J,K) \Longrightarrow \nu(H) > \nu(K) \Longrightarrow H \gg_\pi K$.

(Case C) $\nu(H) = \nu(J) \;\wedge\; f(H,J) \;\wedge\; \nu(J) > \nu(K) \Longrightarrow \nu(H) > \nu(K) \Longrightarrow H \gg_\pi K$.

(Case D)

$$\begin{aligned}
\nu(H) = \nu(J) \;\wedge\; f(H,J) \;\wedge\; \nu(J) = \nu(K) \;\wedge\; f(J,K) \quad &\Longrightarrow \quad \nu(H) = \nu(K) \;\wedge\; f(H,K) \\
&\Longrightarrow \quad H \gg_\pi K,
\end{aligned}$$

due to the transitivity of predicate f.

■

We now return to the computation of $\nu(H)$. We estimate the belief $\nu(H)$ that a set of propositions H is correct by assuming independence among these propositions.[2] Overloading notation and denoting by $\nu(h)$ the probability of an individual proposition h being correct, the probability of all elements in H being correct under this assumption of independence is

$$\nu(H) = \prod_{h \in H} \nu(h). \tag{12}$$

The belief that a proposition stating independence is correct can be computed in different ways, depending on the particular choice of independence oracle chosen. In this paper we use Wilk's G^2 test, but the resulting belief can be easily adapted to any other independence oracle that produces p-values. We hope that the following discussion serves as a starting point for others to adapt it to other types of independence oracles.

As discussed in Section 2, the p-value $p(X,Y \mid \mathbf{Z})$ computed by this test is the probability of error in rejecting the null hypothesis (conditional independence in our case) and assuming that X and Y are dependent. Therefore, the probability of a test returning dependence of being correct is

$$\nu_D(X \not\perp\!\!\!\perp Y \mid \mathbf{Z}) = 1 - p(X,Y \mid \mathbf{Z})$$

where the subscript D indicates that this expression is valid only for dependencies. Formally, the error of falsely rejecting the null hypothesis is called a *type I error*. To determine the preference of a test returning independence we can, in principle, use this procedure symmetrically: use the probability of error in falsely accepting the null hypothesis (again, this is conditional independence), called a *type II error*, which we denote by $\beta(X,Y \mid \mathbf{Z})$. In this case we can define the preference of independence $(X \perp\!\!\!\perp Y \mid \mathbf{Z})$ as the probability of correctly assuming independence by

$$\nu_I(X \perp\!\!\!\perp Y \mid \mathbf{Z}) = 1 - \beta(X,Y \mid \mathbf{Z})$$

where again the subscript I indicates that it is valid only for independences. Unfortunately value of β cannot be obtained without assumptions, because it requires the computation of the probability of the test statistic under the hypothesis of dependence, and there are typically an infinite number of dependent models. In statistical applications, the β value is commonly approximated by assuming one particular dependence model if prior knowledge about that is available. In the absence of such information however in this paper we estimate it using a heuristic function of the p-value, assuming the following heuristic constraints on β:

$$\beta(X,Y \mid \mathbf{Z}) = \begin{cases} 1 & \text{if } p(X,Y \mid \mathbf{Z}) = 0 \\ \alpha - \frac{\alpha}{2+|\mathbf{Z}|} & \text{if } p(X,Y \mid \mathbf{Z}) = 1 \\ \alpha & \text{if } p(X,Y \mid \mathbf{Z}) = \alpha. \end{cases}$$

The first constraint (for $p(X,Y \mid \mathbf{Z}) = 0$) corresponds to the intuition that when the p-value of the test is close to 0, the test statistic is very far from its value under the model that assumes independence, and thus we would give more preference to the "dependence" decision. The intuition for

2. The assumption of independence is a heuristic, and is made mainly due to the difficulty of determining the dependence between two or more statistical tests evaluated on the same data set. Other possible ways of defining the preference of a set of propositions are possible. The problem of dealing with multiple tests is an open problem and an area of active research in statistics; see Section 1 for a discussion.

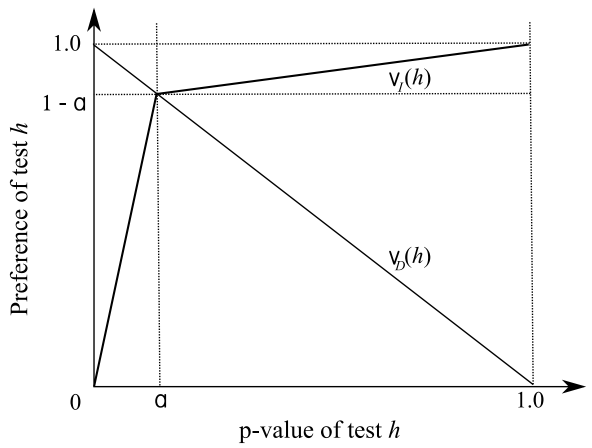

Figure 1: Preference functions $\nu_I(h)$ and $\nu_D(h)$ for statements of independence and dependence respectively, as functions of the p-value of test h.

the second case ($p(X,Y \mid \mathbf{Z}) = 1$) is reversed—when the value of the statistic is very close to the expected one under independence then independence is preferred. The value of the second case is tempered by the number of variables in the conditioning set. This reflects the practical consideration that, as the number $2+|\mathbf{Z}|$ of variables involved in the test increases, given a fixed data set, the discriminatory power of the test diminishes as $|\mathbf{Z}| \to \infty$. The third case causes the two functions ν_I and ν_D to intersect at p-value α. This is due to fairness: in the absence of non-propositional arguments (i.e., in the absence of inference rules in our knowledge base), the independence decisions of the argumentation framework should match those of the purely statistical tests, that is, "dependence" if and only if (p-value $\leq \alpha$). If instead we chose a different intersection point, then the resulting change in the outcome of tests may have been simply due to bias in the independence decision that favors dependence or independence, that is, equivalent to an arbitrary change of the threshold of the statistical test, and the comparison of the statistical and the new test based on argumentation would not be a fair one. The remaining values of β are approximated by linear interpolation among the above points. The result is summarized in Fig. 1, which depicts preference functions ν_D and ν_I with respect to the p-value of the corresponding statistical test.

Let us illustrate how the preference-based argumentation can be used to resolve the inconsistencies of Example 1.

Example 3. *In example 1 we considered an IKB with the following propositions*

$$(0 \perp\!\!\!\perp 1 \mid 2) \tag{13}$$
$$(0 \not\perp\!\!\!\perp 3 \mid 2) \tag{14}$$
$$(0 \perp\!\!\!\perp 3 \mid \{1,2\}) \tag{15}$$
$$(0 \perp\!\!\!\perp 1 \mid 2) \wedge (0 \not\perp\!\!\!\perp 3 \mid 2) \implies (0 \not\perp\!\!\!\perp 3 \mid \{1,2\}). \tag{16}$$

Following the IKB construction procedure described in the previous section, propositions (13), (14) and (15) correspond to the following arguments, respectively:

$$\begin{gathered}\left(\left\{(0 \perp\!\!\!\perp 1 \mid 2)\right\}, (0 \perp\!\!\!\perp 1 \mid 2)\right)\\ \left(\left\{(0 \not\perp\!\!\!\perp 3 \mid 2)\right\}, (0 \not\perp\!\!\!\perp 3 \mid 2)\right)\\ \left(\left\{(0 \perp\!\!\!\perp 3 \mid \{1,2\})\right\}, (0 \perp\!\!\!\perp 3 \mid \{1,2\})\right) \qquad (17)\end{gathered}$$

while rule (16) corresponds to the argument

$$\left(\left\{(0 \perp\!\!\!\perp 1 \mid 2), (0 \not\perp\!\!\!\perp 3 \mid 2)\right\}, (0 \not\perp\!\!\!\perp 3 \mid \{1,2\})\right). \qquad (18)$$

Let us extend this IKB with the following preference values for its propositions and rule.

$$\begin{aligned} Pref[(0 \perp\!\!\!\perp 1 \mid 2)] &= 0.8\\ Pref[(0 \not\perp\!\!\!\perp 3 \mid 2)] &= 0.7\\ Pref[(0 \perp\!\!\!\perp 3 \mid \{1,2\})] &= 0.5.\end{aligned}$$

According to Definition (12), the preference of each argument $(\{\sigma\}, \sigma)$ *is equal to the preference value of* $\{\sigma\}$ *which is equal to the preference of* σ*, as it contains only a single proposition. Thus,*

$$\begin{aligned} Pref\left[\left(\left\{(0 \perp\!\!\!\perp 1 \mid 2)\right\}, (0 \perp\!\!\!\perp 1 \mid 2)\right)\right] &= 0.8\\ Pref\left[\left(\left\{(0 \not\perp\!\!\!\perp 3 \mid 2)\right\}, (0 \not\perp\!\!\!\perp 3 \mid 2)\right)\right] &= 0.7\\ Pref\left[\left(\left\{(0 \perp\!\!\!\perp 3 \mid \{1,2\})\right\}, (0 \perp\!\!\!\perp 3 \mid \{1,2\})\right)\right] &= 0.5.\end{aligned}$$

The preference of argument (18) equals the preference of the set of its antecedents, which, according to Eq. (12), is equal to the product of their individual preferences, that is,

$$Pref\left[\left(\left\{(0 \perp\!\!\!\perp 1 \mid 2), (0 \not\perp\!\!\!\perp 3 \mid 2)\right\}, (0 \not\perp\!\!\!\perp 3 \mid \{1,2\})\right)\right] = 0.8 \times 0.7 = 0.56.$$

Proposition (15) and rule (16) contradict each other logically, that is, their corresponding arguments (17) and (18) defeat each other. However, argument (18) is not attacked as its preference is 0.56 *which is larger than* 0.5*, the preference of its defeater argument (17). Since no other argument defeats (18), it is acceptable, and (17), being attacked by an acceptable argument, must be rejected. We therefore see that using preferences the inconsistency of Example 1 has been resolved in favor of rule (16).*

Let us now illustrate the defend relation, that is, how an argument can be defended by some other argument. The example also illustrates an alternative resolution for the inconsistency of Example 1, this time in favor of the independence proposition (15).

Example 4. *Let us extend the IKB of Example 3 with two additional independence propositions and an additional rule. The new propositions and their preference are:*

$$\begin{aligned} Pref[(0 \perp\!\!\!\perp 4 \mid \{2,3\})] &= 0.9\\ Pref[(0 \perp\!\!\!\perp 3 \mid \{2,4\})] &= 0.8\end{aligned}$$

and the new rule is:

$$(0 \perp\!\!\!\perp 4 \mid \{2,3\}) \wedge (0 \perp\!\!\!\perp 3 \mid \{2,4\}) \quad \Longrightarrow \quad (0 \perp\!\!\!\perp 3 \mid 2).$$

This rule is an instance of the Intersection axiom followed by Decomposition.

The corresponding arguments and preferences are:

$$\begin{aligned} Pref\Big[\Big(\Big\{(0 \perp\!\!\!\perp 4 \mid \{2,3\})\Big\}, (0 \perp\!\!\!\perp 4 \mid \{2,3\})\Big)\Big] &= 0.9 \\ Pref\Big[\Big(\Big\{(0 \perp\!\!\!\perp 3 \mid \{2,4\})\Big\}, (0 \perp\!\!\!\perp 3 \mid \{2,4\})\Big)\Big] &= 0.8 \end{aligned}$$

corresponding to the two propositions, and

$$Pref\Big[\Big(\Big\{(0 \perp\!\!\!\perp 4 \mid \{2,3\}), (0 \perp\!\!\!\perp 3 \mid \{2,4\})\Big\}, (0 \perp\!\!\!\perp 3 \mid 2)\Big)\Big] = 0.9 \times 0.8 = 0.72 \tag{19}$$

corresponding to the rule.

As in Example 3, argument (17) is attacked by argument (18). Let us represent this graphically using an arrow from argument a to argument b to denote that a attacks b, that is,

$$Argument\ (18) \longrightarrow Argument\ (17).$$

If the IKB was as in Example 3, (18) would had been accepted and (17) would have been rejected. However, the additional argument (19) now defeats (undercuts) (18) by logically contradicting its antecedent $(0 \not\perp\!\!\!\perp 3 \mid 2)$. *Since the preference of (19), namely* 0.72, *is larger than that of (18), namely* 0.56, *(19) attacks (18). Therefore, (19) defends all arguments that are attacked by argument (18), and in particular (17). Graphically,*

$$Argument\ (19) \longrightarrow Argument\ (18) \longrightarrow Argument\ (17).$$

Note this is not sufficient for accepting (17) as it has not been proved that its defender (19) is itself acceptable. We leave the proof of this as an exercise for the reader.

4. The Argumentative Independence Test (AIT)

The independence-based preference argumentation framework described in the previous section provides a semantics for the acceptance of arguments consisting of independence propositions. However, what we need is a procedure for a test of independence that, given as input a triplet $\sigma = (X, Y \mid \mathbf{Z})$ responds whether X is independent or dependent of Y given $\mathbf{Z}$. In other words, we need a semantics for the acceptance of propositions, not arguments. Let us consider the two propositions related to the input triplet $\sigma = (X, Y \mid \mathbf{Z})$, proposition $(\sigma = \texttt{true})$, abbreviated $\sigma_{\texttt{t}}$, and proposition $(\sigma = \texttt{false})$, abbreviated $\sigma_{\texttt{f}}$, that correspond to independence $(X \perp\!\!\!\perp Y \mid \mathbf{Z})$ and dependence $(X \not\perp\!\!\!\perp Y \mid \mathbf{Z})$ of σ, respectively. The basic idea for deciding on the independence or dependence of input triplet σ is to define a semantics for the acceptance or rejection of propositions $\sigma_{\texttt{t}}$ and $\sigma_{\texttt{f}}$ based on the acceptance or rejection of their respective propositional arguments $(\{\sigma_{\texttt{t}}\}, \sigma_{\texttt{t}})$ and $(\{\sigma_{\texttt{f}}\}, \sigma_{\texttt{f}})$. Formally,

$$\begin{aligned} (X \not\perp\!\!\!\perp Y \mid \mathbf{Z}) \text{ is accepted} \quad &\text{iff} \quad (\{(X \not\perp\!\!\!\perp Y \mid \mathbf{Z})\}, (X \not\perp\!\!\!\perp Y \mid \mathbf{Z})) \text{ is accepted, and} \\ (X \perp\!\!\!\perp Y \mid \mathbf{Z}) \text{ is accepted} \quad &\text{iff} \quad (\{(X \perp\!\!\!\perp Y \mid \mathbf{Z})\}, (X \perp\!\!\!\perp Y \mid \mathbf{Z})) \text{ is accepted.} \end{aligned} \tag{20}$$

Based on this semantics over propositions, we decide on the dependence or independence of triplet σ as follows:

$$\begin{aligned} \sigma_{\mathtt{t}} = (X \perp\!\!\!\perp Y \mid \mathbf{Z}) \text{ is accepted} &\implies (X \perp\!\!\!\perp Y \mid \mathbf{Z}) \\ \sigma_{\mathtt{f}} = (X \not\perp\!\!\!\perp Y \mid \mathbf{Z}) \text{ is accepted} &\implies (X \not\perp\!\!\!\perp Y \mid \mathbf{Z}). \end{aligned} \tag{21}$$

We call the test that determines independence in this manner the **Argumentative Independence Test** or **AIT**. For the above semantics to be well-defined, a triplet σ must be either independent or dependent, that is, not both or neither. For that, exactly one of the antecedents of the above implications of Eq. (21) must be true. Formally,

Theorem 18. *For any input triplet $\sigma = (X, Y \mid \mathbf{Z})$, the argumentative independence test (**AIT**) defined by Eqs. (20) and (21) produces a non-ambiguous decision, that is, it decides σ evaluates to either independence or dependence, but nor both or neither.*

For that to happen, one and only one of its corresponding propositions $\sigma_{\mathtt{t}}$ or $\sigma_{\mathtt{f}}$ must be accepted. A necessary condition for this is given by the following theorem.

Theorem 19. *Given a PAF $\langle \mathcal{A}, \mathcal{R}, \pi \rangle$ with a strict and transitive preference relation π, every propositional argument $(\{\sigma_{\mathtt{t}}\}, \sigma_{\mathtt{t}}) \in \mathcal{A}$ and its negation $(\{\sigma_{\mathtt{f}}\}, \sigma_{\mathtt{f}})$ satisfy*

$$(\{\sigma_{\mathtt{t}}\}, \sigma_{\mathtt{t}}) \textit{ is accepted iff } (\{\sigma_{\mathtt{f}}\}, \sigma_{\mathtt{f}}) \textit{ is rejected}.$$

The above theorem is not sufficient because the propositions may still be in abeyance, but this possibility is ruled out for strict preference relations by Theorem 20, presented in the next section.

The formal proofs of Theorems 18, 19 and 20 are presented in Appendix B. We now illustrate the use of AIT with an example.

Example 5. *We consider an extension of Example 3 to illustrate the use of the AIT to decide on the independence or dependence of input triplet $(0, 3 \mid \{1, 2\})$. According to Eq. (20) the decision depends on the status of the two propositional arguments:*

$$(\{(0 \not\perp\!\!\!\perp 3 \mid \{1,2\})\}, (0 \not\perp\!\!\!\perp 3 \mid \{1,2\})), \textit{ and} \tag{22}$$

$$(\{(0 \perp\!\!\!\perp 3 \mid \{1,2\})\}, (0 \perp\!\!\!\perp 3 \mid \{1,2\})). \tag{23}$$

Argument (23) is equal to argument (17) of Example 3 that was proved to be rejected in that example. Therefore, according to Theorem 19, its negated propositional argument Eq. (22) must be accepted, and we can conclude that triplet $(0, 3 \mid \{1, 2\})$ corresponds to a dependence, that is, we conclude that $(0 \not\perp\!\!\!\perp 3 \mid \{1, 2\})$.

5. The Top-down AIT Algorithm

We now discuss in more detail the top-down algorithm which is used to implement the argumentative independence test, introduced in Section 3. We start by simplifying the recursion of Eq. (7) that determines the state (accepted, rejected, or in abeyance) of an argument a. We then explain the algorithm and analyze its computability (i.e., prove that its recursive execution is always finite) and its time complexity.

To simplify the recursion Eq. (7) we use the following theorem (proved in Appendix B).

Theorem 20. *Let $\langle \mathcal{A}, \mathcal{R}, \pi \rangle$ be a PAF with a strict preference relation π. Then no argument $a \in \mathcal{A}$ is in abeyance.*

This theorem reduces the number of states of each argument to two, that is, an argument can be either accepted or not accepted (rejected). We will use the name of the argument a to denote the predicate "a is accepted" and its negation $\neg a$ to denote the predicate "a is rejected." With this notation, the above theorem, and the fact that we have extended the semantics of acceptability from the defeat to the attack relation (using preferences), the recursion of Eq. (7) can be expressed as follows

$$\begin{aligned} a &\iff \forall b \in attackers(a),\ \neg b \\ \neg a &\iff \exists b \in attackers(a),\ b \end{aligned}$$

or, equivalently,

$$\begin{aligned} a &\iff \bigwedge_{b \in attackers(a)} \neg b \\ \neg a &\iff \bigvee_{b \in attackers(a)} b. \end{aligned}$$

Finally, we notice that the second formula is logically equivalent to the first (simply negating both sides of the double implication recovers the first). Therefore, the Boolean value of the dialog tree for a can be computed by the simple expression

$$a \iff \bigwedge_{b \in attackers(a)} \neg b. \tag{24}$$

To illustrate, consider an attacker b of a. If b is rejected, that is, $\neg b$, the conjunction on the right cannot be determined without examining the other attackers of a. Only when all attackers of a are known to be rejected can the value of a be determined, that is, accepted. Instead, if b is accepted, that is, b, the state of $\neg b$ is `false` and the conjunction can be immediately evaluated to `false`, that is, a is rejected regardless of the acceptability of any other attackers.

An iterative version of the top-down algorithm is shown in Algorithm 3. We assume that the algorithm can access a global PAF $\langle \mathcal{A}, \mathcal{R}, \pi \rangle$, with arguments in $\mathcal{A}$ defined over a knowledge base $\mathcal{K} = \langle \Sigma, \Psi \rangle$. Given as input a triplet $t = (X, Y \mid \mathbf{Z})$, if the algorithm returns `true` (`false`) then we conclude that t is independent (dependent). It starts by creating a root node u for the propositional argument U of proposition $t = \texttt{true}$ (lines 1–6). According to Eqs. (20) and (21), the algorithm then decides `true` if U is accepted (line 22). Otherwise, the algorithm returns `false` (line 23). This is because in this case, according to Theorem 19, the negation of propositional argument U must be accepted.

Algorithm 3 is an iterative version of a tree traversal algorithm. It maintains a queue of the nodes that have not been expanded yet. A node is expanded when its children are added to the tree. In the algorithm, this is done in the loop of lines 17 to 21, which uses subroutine *getAttackers* of Algorithm 5 to obtain all attackers of an argument. This subroutine finds all attackers of the input argument a in a backward-chaining fashion, that is, given an argument $a = (H, h)$, it searches for all rules in the knowledge base $\mathcal{K}$ whose consequent matches the negation of some proposition in the

Algorithm 3 *independent*$(triplet\ t)$.

```
1: $f_{\texttt{true}} \leftarrow$ proposition $(t = \texttt{true})$    /* Creates independence proposition $(t = \texttt{true})$. */
2: $U_{\texttt{true}} \leftarrow (\{f_{\texttt{true}}\}, f_{\texttt{true}})$
3: $u_{\texttt{true}} \leftarrow$ node for argument $U_{\texttt{true}}$
4: $u_{\texttt{true}}.parent \leftarrow \texttt{nil}$
5: $u.STATE \leftarrow \texttt{nil}$
6: $fringe \leftarrow [u]$        /* Initialize with u (root). */
7: /* Create global rejected node, denoted by $\rho$. */
8: $\rho \leftarrow$ node with no argument and state rejected
9: while $fringe \neq \varnothing$ do
10:    $u \leftarrow dequeue(fringe)$
11:    $attackers \leftarrow getAttackers(u.argument)$
12:    if $(attackers = \varnothing)$ then
13:        $u.STATE \leftarrow \texttt{accepted}$
14:        if $sendMsg(\rho, u) = terminate$ then break
15:    $attackers \leftarrow$ sort attackers in decreasing order of preference.
16:    /* Enqueue attackers after decomposing them. */
17:    for each $A \in attackers$ do
18:        $a \leftarrow$ node for argument $A$
19:        $a.parent \leftarrow u$
20:        $a.STATE \leftarrow \texttt{nil}$
21:        enqueue $a$ in $fringe$        /* See details in text. */
22: if $(u.STATE = \texttt{accepted})$ then return true
23: if $(u.STATE = \texttt{rejected})$ then return false
```

Algorithm 4 *sendMsg*$(Node\ c, Node\ p)$.

```
1: /* Try to evaluate node p given new information in c.STATE */
2: if $p \neq \texttt{nil}$ then
3:    if $c.STATE = \texttt{accepted}$ then $p.STATE \leftarrow \texttt{rejected}$
4:    else if ($\forall$ children $q$ of $p$, $q.STATE \neq \texttt{rejected}$) then $p.STATE \leftarrow \texttt{accepted}$
5:    /* If p was successfully evaluated, try to evaluate its parent by sending message upward. */
6:    if $p.STATE \neq \texttt{nil}$ then
7:        return $sendMsg(p, p.parent)$
8:    else
9:        return $continue$
10: else
11:    return $terminate$ /* The root node has been evaluated. */
```

support H (undercutters), or the negation of its head h (rebutters). Every node maintains a three-valued state variable $STATE \in \{\texttt{nil}, \texttt{accepted}, \texttt{rejected}\}$. The nil state denotes that the value of the node is not yet known, and a node is initialized to this state when it is added to the tree.

The algorithm recurses down the dialog tree until a node is found that has no attackers (line 12). Such a node is accepted in line 13, that is, the conjunction of Eq. (24) is trivially true, and its *STATE* is propagated upwards toward the root to the parent using subroutine *sendMsg* (Algorithm 4). Every

Algorithm 5 Finds all attackers of input argument a in knowledge base $\mathcal{K} = \langle \Sigma, \Psi \rangle$: *getAttackers*$(a = (H, h))$

```
1:  $attackers \leftarrow \varnothing$
2:  /* Get all undercutters or rebutters of $a$. */
3:  for all propositions $\varphi \in H \cup \{h\}$ do
4:      /* Get all defeaters of proposition $\varphi$. */
5:      for all rules $(\Phi_1 \wedge \Phi_2 \ldots \wedge \Phi_n \implies \neg\varphi) \in \Psi$ do
6:          /* Find all propositionalizations of the rule whose consequent matches $\neg\varphi$. */
7:          for all subsets $\{\varphi_1, \varphi_2 \ldots, \varphi_n\}$ of $\Sigma$ s.t. $\Phi_1 \equiv \varphi_1, \Phi_2 \equiv \varphi_2 \ldots \Phi_n \equiv \varphi_n$ do
8:              $d \leftarrow (\{\varphi_1 \wedge \varphi_2 \ldots \varphi_n\}, \neg\varphi)$ /* Create defeater. */
9:              /* Is the defeater an attacker? */
10:             if $\neg(a \gg_\pi d)$ then
11:                 $attackers \leftarrow attackers \cup \{d\}$
12: return $attackers$
```

time a node receives a message from a child, if the message is `accepted`, the node is rejected (line 3 of Algorithm 4), otherwise the node is accepted if all its children has been evaluated to `rejected` (line 4 of Algorithm 4). The subroutine *sendMsg* then proceeds recursively by forwarding a message to the parent whenever a node has been evaluated (line 7). If the root is reached and evaluated, the message is sent to its parent, which is `nil`. In this case, the subroutine returns the special keyword *terminate* back to the caller, indicating that the root has been evaluated and thus the main algorithm (Algorithm 3) can terminate. The caller can be either the subroutine *sendMsg*, in which case it pushes the returned message up the method-calling stack, or the top-down algorithm in line 14, in which case its "while" loop is terminated.

An important part of the algorithm is yet underspecified, namely the order in which the attackers of a node are explored in the tree (i.e., the priority with which nodes are enqueued in line 21). This affects the order of expansion of the nodes in the dialog tree. Possible orderings are depth-first, breadth-first, iterative deepening, as well as informed searches such as best-first when a heuristic is available. In our experiments we used iterative deepening because it combines the benefits of depth-first and breadth-first search, that is, small memory requirements on the same order as depth-first search (i.e., on the order of the maximum number of children a node can have) but also the advantage of finding the shallowest solution like breadth-first search. We also used a heuristic for enqueuing the children of a node. According to iterative deepening, the position in the queue of the children of a node is specified relative to other nodes, but not relative to each other. We therefore specified the relative order of the children according to the value of the preference function: children with higher preference are enqueued first (line 15 of the top-down algorithm), and thus, according to iterative deepening, would be dequeued first.

5.1 Computability of the Top-Down Algorithm

An open question is whether the top-down algorithm is computable, that is, whether it always terminates. In this section we prove that it is. To prove this we need to show that under certain general conditions the acceptability of an argument a can always be determined, that is, that the algorithm always terminates. This is proved by the following theorem.

Theorem 21. *Given an arbitrary triplet $t = (X, Y \mid \mathbf{Z})$, and a PAF $\langle \mathcal{A}, \mathcal{R}, \pi \rangle$ with a strict preference relation π, Algorithm 3 with input t over $\langle \mathcal{A}, \mathcal{R}, \pi \rangle$ terminates.*

The proof consists on showing that the path from the root a to any leaf is always finite. For that, the concept of an attack sequence is needed.

Definition 22. *An* attack sequence *is a sequence $\langle a_1, a_2, \dots, a_n \rangle$ of n arguments such that for every $2 \leq i \leq n$, a_i attacks a_{i-1}.*

By the manner in which the top-down algorithm constructs the dialog tree it is clear that any path from the root to a leaf is an attack sequence. It therefore suffices to show that any such sequence is finite. This is done by the following theorem.

Theorem 23. *Every attack sequence $\langle a_1, a_2, \dots, a_n \rangle$ in a PAF $\langle \mathcal{A}, \mathcal{R}, \pi \rangle$ with strict π and finite $\mathcal{A}$ is finite.*

Intuitively, if the preference relation is strict then an element can attack its predecessor in the sequence but not vice versa. Since the set of arguments $\mathcal{A}$ is finite, the only way for an attack sequence to be infinite is to contain a cycle. In that case, an argument would be attacking at least one of its predecessors, which cannot happen in a PAF with a strict preference relation. We present formal proofs of Theorems 21 and 23 in Appendix A.

We thus arrived at the important conclusion that, under a strict preference function and a finite argument set, the state of any argument is computable. As we showed in Section 3.3, the preference function for independence knowledge bases is strict, and thus the computability of the top-down algorithm is guaranteed.

5.2 Computational Complexity of the Top-Down Algorithm

Since Algorithm 3 is a tree traversal algorithm, its time complexity can be obtained by techniques contained in standard algorithmic texts, for example, Cormen et al. (2001). The actual performance depends on the tree exploration procedure. In our case we used iterative deepening due to its linear memory requirements in d, where d is the smallest depth at which the algorithm terminates. Iterative deepening has a worst-time time complexity of $O(b^d)$, where b is an upper bound on the *dialog tree branching factor*. Therefore, for a constant $b > 1$ the execution time is exponential in d in the worst case. Furthermore, for the case of independence tests, b itself may also be exponential in n (the number of variables in the domain). This is because the inference rules of Eqs. (5) and (6) are universally quantified, and therefore their propositionalization (lines 7–11 of Algorithm 5), may result in an exponential number of rules with the same consequent (attackers). A tighter bound may be possible but, lacking such a bound, we introduce in the next section an approximate top-down algorithm, which reduces the running time to polynomial. As we show in our experiments, the use of this approximation does not appreciably affect the accuracy improvement due to argumentation.

6. The Approximate Top-Down AIT Algorithm

As the top-down algorithm has a theoretically exponential running time in the worst case, we hereby present a practical polynomial-time approximation of the top-down algorithm. We make use of two approximations: (a) To address the exponential behavior due to the depth of the dialog tree we apply a *cutoff depth d* for the process of iterative deepening. (b) To address the potentially exponential size of the branching factor b (which equals the maximum number of defeaters of any argument appearing in the dialog tree) we limit the number of defeaters of each node—thus bounding the number of its attackers/children—to a polynomial function of n (the domain size) during the propositionalization process of Algorithm 5 (lines 7–11). Let (H,h) be an argument and let $\varphi \in H \cup \{h\}$ be one of its propositions, as in line 3 of Algorithm 5. The set of attackers Σ_φ of (H,h) consists of all rules $\{\varphi_1 \wedge \varphi_2 \ldots \wedge \varphi_k \implies \neg\varphi\}$ of Σ, for some constant upper bound k on the size of their support. If $\varphi = (\mathbf{X},\mathbf{Y} \mid \mathbf{Z})$ and $\varphi_i = (\mathbf{X}_i,\mathbf{Y}_i \mid \mathbf{Z}_i)$ for all $1 \le i \le k$, then our approximation generates and uses a subset of Σ_φ in the dialog tree such that

$$\begin{array}{rcccl} |\mathbf{X}|-c & \le & |\mathbf{X}_i| & \le & |\mathbf{X}|+c \\ |\mathbf{Y}|-c & \le & |\mathbf{Y}_i| & \le & |\mathbf{Y}|+c \\ |\mathbf{Z}|-c & \le & |\mathbf{Z}_i| & \le & |\mathbf{Z}|+c \end{array} \tag{25}$$

where $|\cdot|$ denotes set cardinality, and c is a user-specified integer parameter that defines the approximation. We call this the **approximate top-down algorithm**. The computational complexity of the approximate top-down algorithm is polynomial in n, as shown in the next section.

6.1 Test Complexity of the Approximate Top-Down Algorithm

In this section we prove that the number of statistical tests required by the Approximate Top-Down algorithm is polynomial in n. As described in the previous section, the approximate algorithm generates a bounded number of attackers for each proposition in the argument corresponding to some node in the dialog tree. A bound on the number of the possible attackers can be defined by the approximation of Eq. (25). These equations dictate that the size of each possible set $\mathbf{X}_i$ in some proposition $(\mathbf{X}_i,\mathbf{Y}_i \mid \mathbf{Z}_i)$ of some attacker of proposition $(\mathbf{X},\mathbf{Y} \mid \mathbf{Z})$ is between $|\mathbf{X}|+c$ and $|\mathbf{X}|-c$ (inclusively). As the number of elements that can be members of $\mathbf{X}_i$ is bounded by n (the domain size), this produces at most n^{2c+1} possible instantiations for set $\mathbf{X}_i$. Similarly, the number of possible instantiations for $\mathbf{Y}_i$ and $\mathbf{Z}_i$ is also n^{2c+1}. Therefore, an upper bound for the number of matches to some proposition in the antecedent of an attacking rule is $O(n^{6c+3})$ for some constant c. As there are r rules in the rule set and up to k propositions in each rule for some constants r and k (for example, $r = 5$ and $k = 3$ for Eq. (5) and $r = 8$ and $k = 4$ for Eq. (6)), an upper bound on the number of children of a node in the dialog tree is $O(rkn^{6c+3})$, and thus an upper bound on the number of nodes in the dialog tree of depth d is $O((rk)^d n^{d(6c+3)})$. As we demonstrate in our experiments, this is a rather loose upper bound and the performance of the approximate top-down algorithm is reasonable in practice, but it does serve to show that the theoretical worst-case performance is polynomial in n. In the experiments shown in the next section we used $c = 1$ and $d = 3$.

7. Experimental Results

We conducted experiments on sampled and real-world data sets for the purpose of (a) evaluating the accuracy improvement of the argumentative test (both the exact and approximate versions) over its statistical counterpart; (b) demonstrating the performance improvements that can be achieved by the approximate version compared to the exact counterpart, without significant reduction in accuracy improvement; and (c) evaluating the improvements that result by the use of the argumentative framework for causal discovery. We address these issues below.

7.1 Comparative Evaluation of Bottom-Up, Exact Top-Down, and Approximate Top-Down Argumentative Tests

In this section we demonstrate that the argumentation approach, implemented either by the (exact) bottom-up or the exact top-down algorithm (Algorithm 3), improves the accuracy of independence tests on small data sets. We also show that the approximate top-down algorithm (see Section 6) has accuracy performance improvements similar to its exact counterpart but significantly better execution times (orders of magnitude), that make it more practical and usable for larger domains. As the output of the bottom-up algorithm is guaranteed to be equal to the exact top-down algorithm as Theorem 9 of Section 3, we omit accuracy results for the bottom-up algorithm here.

As the exact algorithm is impractical for large domains, for the present comparison we sampled data sets from two randomly generated Bayesian networks with $n = 8$ nodes. The networks were generated using *BNGenerator* (Ide et al., 2002), a publicly available Java package, with maximum degree per node τ equal to 3 and 7 to evaluate the performance in sparsely as well as densely connected domains. A large data set D was sampled from each network and our experiments were conducted on subsets of it containing an increasing number of data points N. This was done in order to assess the accuracy on varying conditions of reliability, as the reliability of a test varies (typically increases) with the amount of data available. To reduce variance, each experiment was repeated for ten data subsets of equal size, obtained by permuting the data points of D randomly and using the first N of them as input to our algorithms.

We first compare the accuracy of argumentative tests versus their purely statistical counterparts (i.e., the G^2 test) on several data sets sampled from randomly generated Bayesian networks. Sampled data experiments have the advantage of a more precise estimation of the accuracy since the underlying model is known. We present experiments for two versions of the exact top-down argumentative test, one using Pearl's general axioms of of Eq. (5), denoted $\mathbf{AIT_t\text{-}G}$, and another that uses Pearl's "directed" axioms of Eq. (6), denoted $\mathbf{AIT_t\text{-}D}$, as well as two versions of the approximate top-down argumentative test, denoted $\widehat{\mathbf{AIT}}_\mathbf{t}\mathbf{\text{-}G}$ and $\widehat{\mathbf{AIT}}_\mathbf{t}\mathbf{\text{-}D}$ respectively. We abbreviate purely statistical independence tests as **SIT**.

We report the estimated accuracy, which, for each data set, is calculated by comparing the result of a number of conditional independence tests (SITs or AITs) on data with the true value of independence, computed by querying the underlying model for the conditional independence of the same test using d-separation. Since the number of possible tests is exponential, we estimated the independence accuracy by randomly sampling a set $\mathcal{T}$ of 1,000 triplets $(X,Y,\mathbf{Z})$, evenly distributed among all possible conditioning set sizes $m \in \{0,\ldots,n-2\}$, that is, $1000/(n-1)$ tests for each m. The independence or dependence value of the triplets (in the true, underlying model) were not controlled, but left to be decided randomly. This resulted in a non-uniform distribution of dependencies and independences. For instance, in the experiments shown next ($n = 8, \tau = 3, 7$), the average proportion of independences vs. dependencies was 36.6% to 63.4% respectively for $\tau = 3$, and 11.4% to 88.6% respectively for $\tau = 7$. Denoting a triplet in $\mathcal{T}$ by t, by $I_{\text{true}}(t)$ the result of a test on t performed on the underlying model, and by $I_{\text{data-}\mathcal{Y}}(t)$ the results of performing a test on t of type $\mathcal{Y}$ on data, for $\mathcal{Y}$ equal to SIT, AIT_t-G, AIT_t-D, $\widehat{\text{AIT}}_\text{t}$-G, or $\widehat{\text{AIT}}_\text{t}$-D, the estimated accuracy of test type $\mathcal{Y}$ is defined as

$$\widehat{acc}_{\mathcal{Y}}^{\text{data}} = \frac{1}{|\mathcal{T}|}\left|\left\{t \in \mathcal{T} \mid I_{\text{data-}\mathcal{Y}}(t) = I_{\text{true}}(t)\right\}\right|.$$

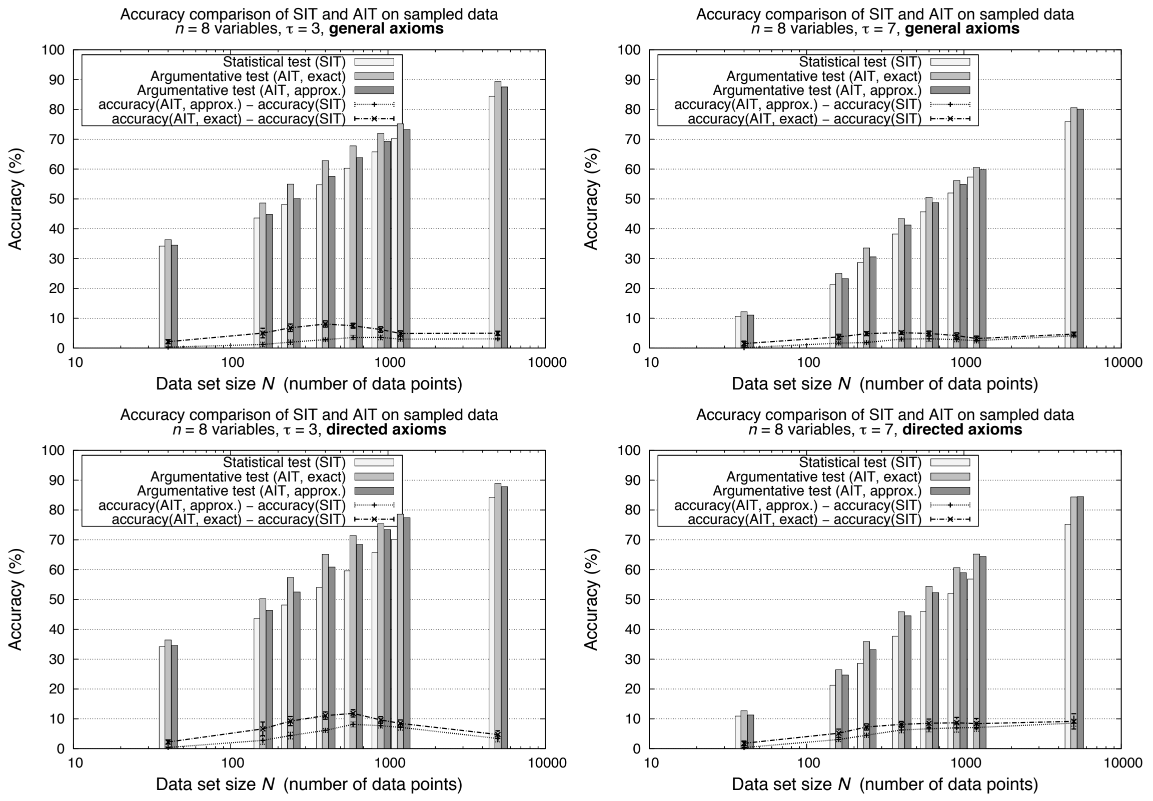

Figure 2: Accuracy comparison of statistical tests (SIT) vs. exact and approximate argumentative tests for domain size $n = 8$ and maximum degree per node $\tau = 3, 7$. The histograms show the absolute value of the accuracy while the line curves show the difference between SIT and the argumentative tests. 95% confidence intervals are also shown for the line graphs. **Top row:** General axioms. **Bottom row:** Directed axioms.

Figure 2 (top row) shows a comparison of the SIT with the exact and approximate top-down argumentative test over the general axioms for data set with increasing number of data points. The figure shows two plots for $\tau = 3, 7$ of the mean values (over runs for ten different data sets) of $\widehat{acc}^{\text{data}}_{\text{SIT}}$, $\widehat{acc}^{\text{data}}_{\text{AIT}_t\text{-G}}$, and $\widehat{acc}^{\text{data}}_{\widehat{\text{AIT}_t}\text{-G}}$ (histograms) and the difference between the accuracies of the AIT tests and the statistical one (line graphs) for various data set sizes N. A positive value of the difference corresponds to an improvement of the argumentative test over SIT. The plots also show the statistical significance of this difference with 95% confidence intervals (error bars), that is, the interval around the mean value that has a 0.95 probability of containing the true difference. The figure demonstrates that there exist modest but consistent and statistically significant improvements in the accuracy of both the exact and approximate argumentative tests over the statistical test. We can observe improvements over the entire range of data set sizes in both cases with maximum improvements of up to 9% and 6% for the exact and approximate cases respectively (at $\tau = 3$ and $N = 600$).

In certain situations where the experimenter knows that the underlying distribution belongs to the class of Bayesian networks, it is appropriate to use the specific axioms of Eq. (6) instead of the general axioms of Eq. (5). The bottom row of Figure 2 presents the same comparison as the top row but for the exact and approximate argumentative tests AIT_t-D and $\widehat{\mathrm{AIT}}_t$-D that use the directed axioms instead of the general ones. As in the case for AIT using the general axioms, we can observe statistically significant improvements over the entire range of data set sizes in both cases. In this case however, the improvements are larger, with maximum increases in the accuracy of the exact and approximate test of up to 13% and 9% respectively (again for $\tau = 3$ and $N = 600$).

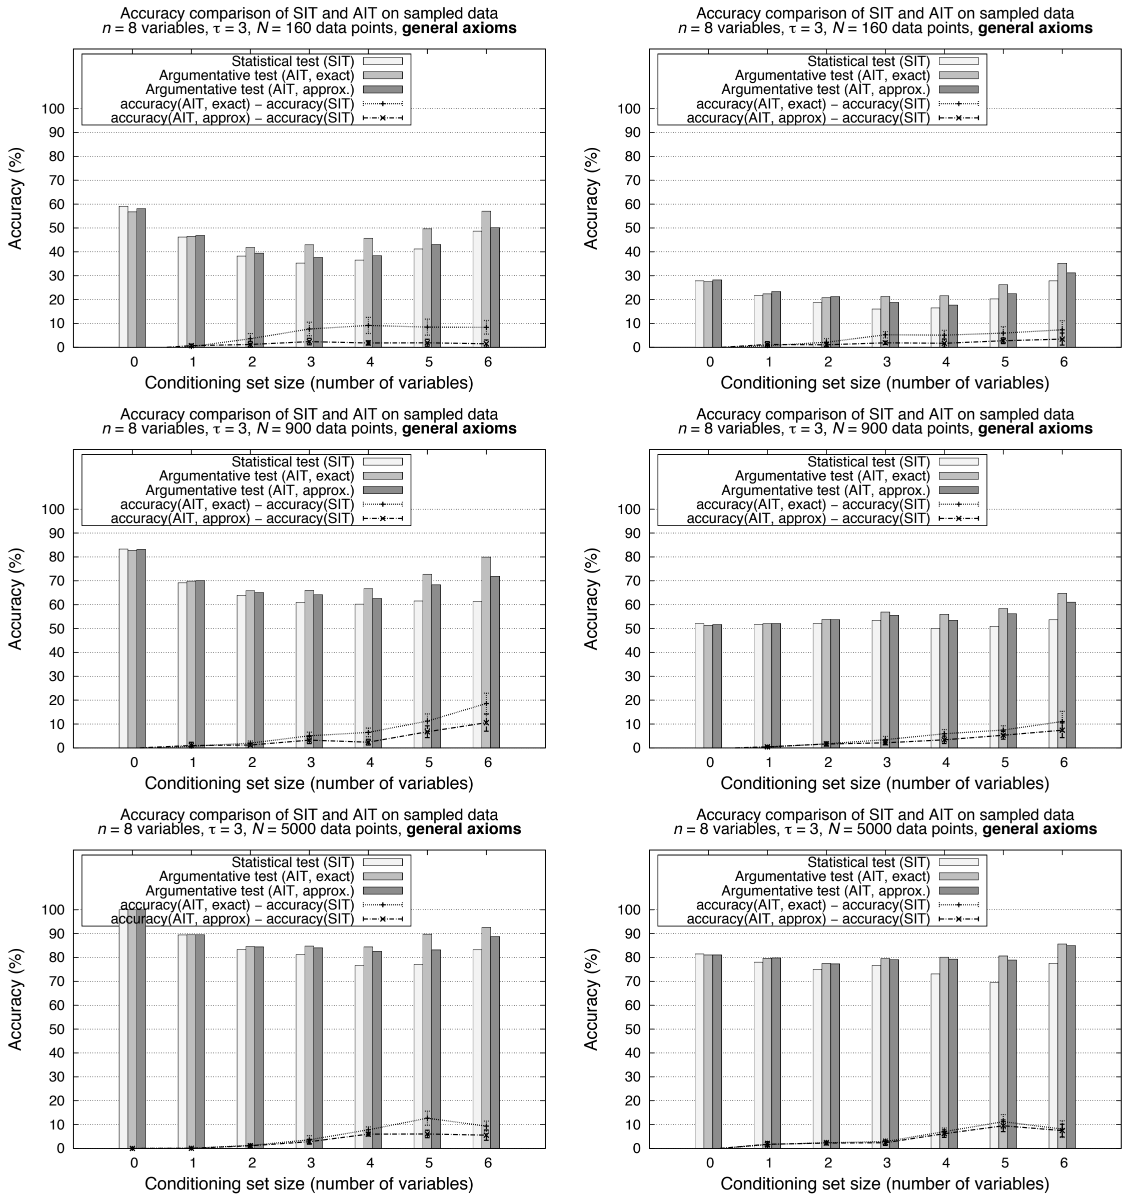

Figure 3: Accuracy comparison of SIT vs. exact (AIT_t-G) and approximate ($\widehat{\mathrm{AIT}}_t$-G) argumentative tests over the general axioms for increasing conditioning set sizes. The six plots correspond to maximum degrees per node $\tau = 3, 7$, and data set sizes $N = 160, 900$ and 5000.

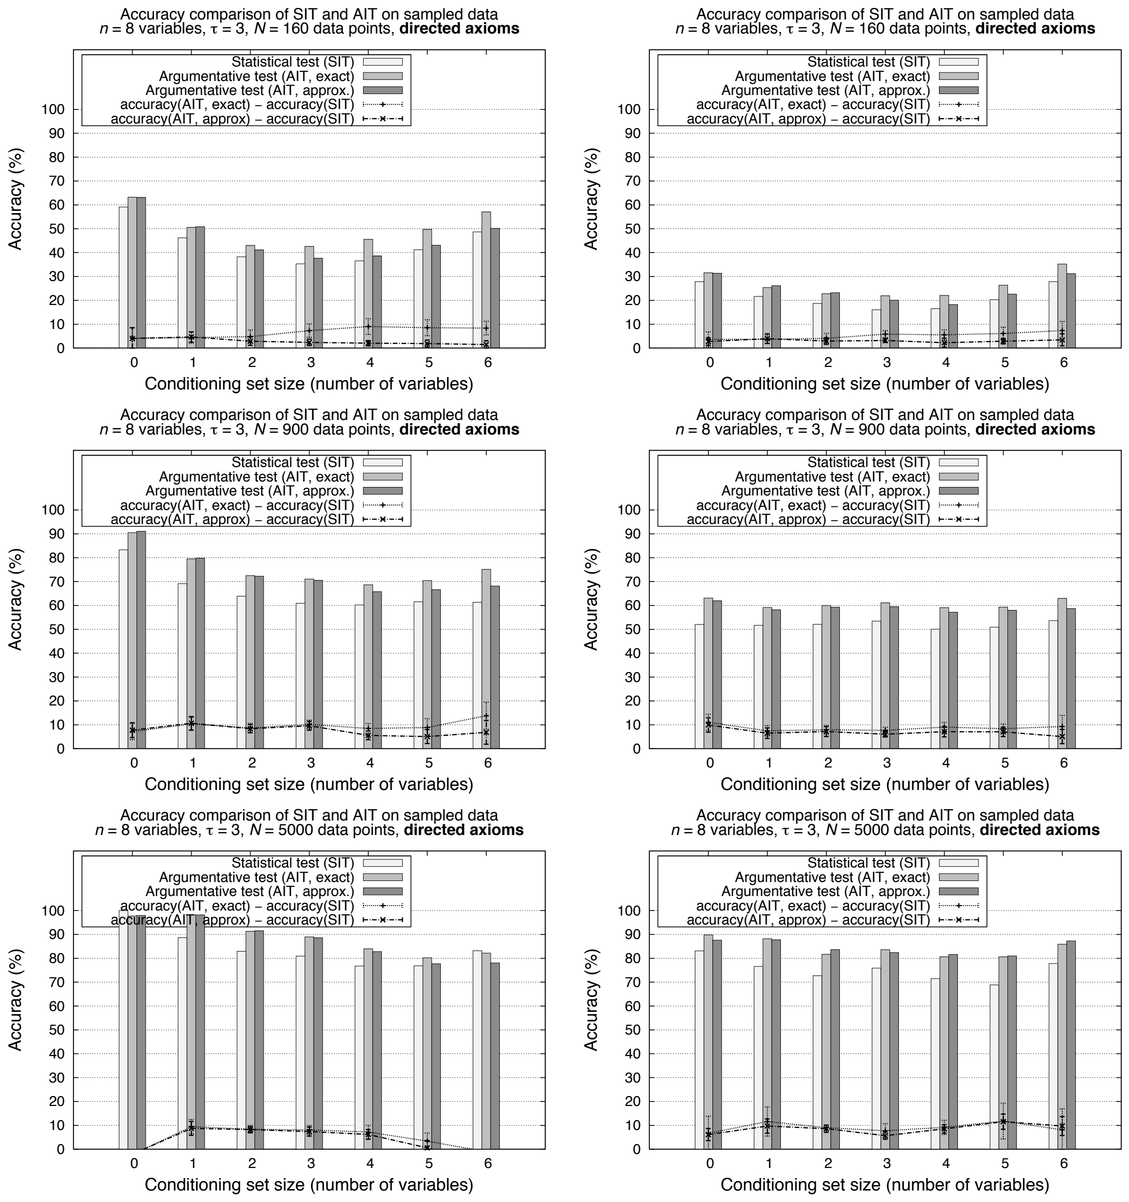

Figure 4: Same as Figure 3 but for AIT using the directed axioms instead of the general ones.

We also evaluated the accuracy of these tests for increasing conditioning set sizes. Figures 3 and 4 show a comparison of the SIT with the exact and approximate top-down argumentative test using the general and directed axioms respectively, for accuracies over increasing conditioning set size for data sizes $N = 160, 900$, and 5000 (different rows). We can observe statistically significant improvements over the entire range of conditioning set sizes in all twelve graphs. Except in one case (directed axioms, $N = 5000, \tau = 3$), all graphs show an upward trend in accuracy for increasing conditioning set size, representing a positive impact of the argumentative approach that increases with a decrease in test reliability, that is, increasing conditioning set size.

We also compared the execution times of the bottom-up, exact top-down and approximate top-down algorithms on the same data sets. To run the bottom-up algorithm we generated the set of all propositional arguments possible, that is, arguments of the form $(\{\sigma\},\sigma)$, by iterating over all possible triplets $(\mathbf{X},\mathbf{Y} \mid \mathbf{Z})$, and inserted them in the knowledge base together with their preference, as described in Section 3.1. Similarly, for the set of axioms that we used in each case, that is, either the general (Eq. (5)) or the specific ones (Eq. (6)), we iterated over all possible matches of each rule, inserting the corresponding (single-headed and decomposed) instantiated rule in the knowledge base again together with its preference. The reason for including all propositional and rule-based arguments in our IKB is to allow the argumentation framework to consider all possible arguments in favor of or against an independence query. We compared the bottom-up algorithm AIT_b, the exact top-down algorithms AIT_t, and the approximate top-down algorithm $\widehat{\mathrm{AIT}}_\mathrm{t}$. For this, we measured the time it takes to discover the structure of a Bayesian networks using three versions of the PC algorithm (Spirtes et al., 2000), each using one of the three argumentative tests AIT_b, AIT_t, or $\widehat{\mathrm{AIT}}_\mathrm{t}$ to conduct the independence tests. As usual, we consider two versions of each test AIT_b, AIT_t, and $\widehat{\mathrm{AIT}}_\mathrm{t}$, one that uses the general axioms of Eq. (5), that is, AIT_b-G, AIT_t-G, and $\widehat{\mathrm{AIT}}_\mathrm{t}$-G, respectively, and one that uses the specific axioms of Eq. (6) (applicable to Bayesian networks), that is, AIT_b-D, AIT_t-D, and $\widehat{\mathrm{AIT}}_\mathrm{t}$-D, respectively. The data sets used are the same as the ones used in the accuracy comparisons above.

Figure 5 plots the execution time of argumentative tests AIT_b-G vs. AIT_t-G vs. $\widehat{\mathrm{AIT}}_\mathrm{t}$-G (top row) and AIT_b-D vs. AIT_t-D vs. $\widehat{\mathrm{AIT}}_\mathrm{t}$-D (bottom row) for tests that were conducted by the PC algorithm while learning the structure. Note that both the x and y-axes are plotted in log-scale. We can observe improvements in the execution time of the exact top-down algorithm over that of the bottom-up algorithm of an order of magnitude over the entire range of data set sizes in all four plots. We can also see improvement of a similar order between the exact and approximate top-down argumentative algorithms. For instance, for the general axioms and $\tau = 3$ (top-left plot), the execution time for $N = 5000$ is 2749 seconds for the bottom-up against 107 seconds for the exact top-down and 15 seconds for the approximate top-down algorithm. We see even more pronounced execution time improvements when using the directed axioms (bottom row of Fig. 5).

The execution-time results demonstrate that the exact top-down algorithm performs significantly better than the bottom-up algorithm, while producing the exact same output (according to Theorem 9 of Section 3). This implies a clear advantage of using the top-down over the bottom-up algorithm. Furthermore, we also saw that the approximate top-down algorithm performs similarly in terms of accuracy improvement while having polynomial worst-case execution time and in practice being several orders of magnitude faster than the exact top-down algorithm, which is exponential in the worst-case. As in the next two sections we continue our evaluation on domains significantly larger than the $n = 8$ variables that we examined here, it would be difficult or impractical for the exact algorithms to be employed. For these reasons in the following experiments we use the more practical approximate algorithm, which can be applied to larger domains.

7.2 Causal Discovery in Larger Domains

We also conducted experiments that demonstrate the performance of the approximate top-down algorithm by (a) showing its applicability to large domains, and (b) demonstrating positive improvements in accuracy of argumentative tests on the learning of the structure of Bayesian networks, the main problem faced by causal discovery algorithms. In the following experiments we used the PC

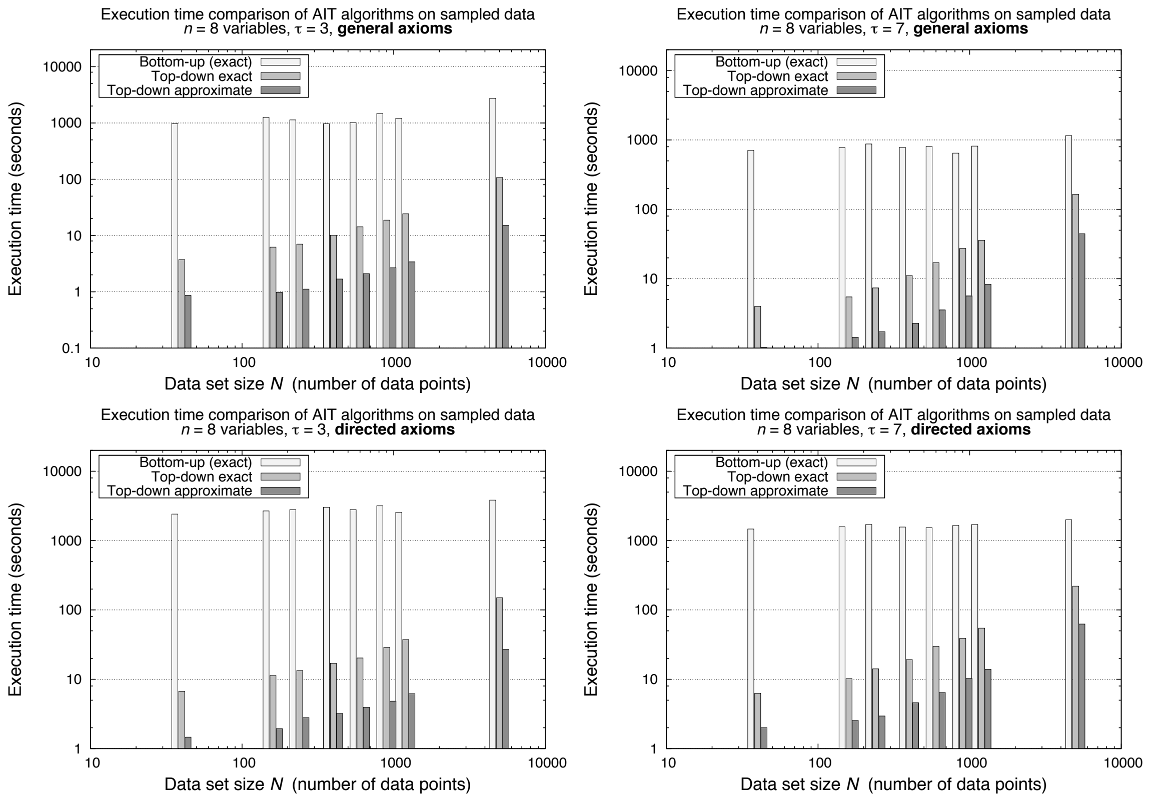

Figure 5: Execution time comparison for the PC algorithm when it uses the bottom-up and exact top-down and approximate top-down argumentative tests to learn the structure of a Bayesian network from data sampled from Bayesian models with domain size $n = 8$, maximum degrees $\tau = 3, 7$. The bars show the absolute value of the running time using a logarithmic scale. **Top row:** general axioms. **Bottom row:** directed axioms.

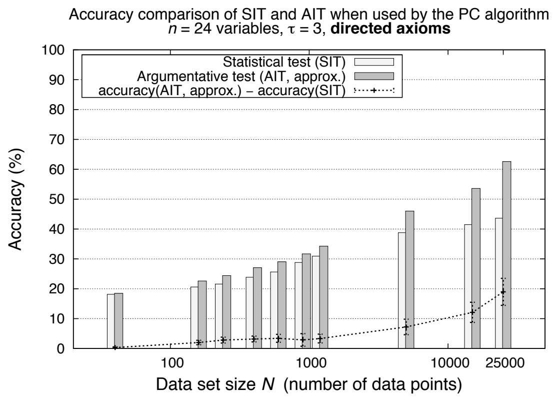
algorithm. We compared the true structure of the underlying model to the resulting structure of the PC algorithm when it uses SITs as independence tests, denoted PC-SIT, and its output when it uses argumentative independence tests, denoted PC-$\widehat{\mathrm{AIT}}_{\mathrm{t}}$-D, when using the directed axioms.

We evaluated the resulting networks by their ability to accurately represent the true independences in the domain, calculated by comparing the results (`true` or `false`) of a number of conditional tests conducted using d-separation on the output networks (PC-SIT or PC-$\widehat{\mathrm{AIT}}_{\mathrm{t}}$-D). Denoting by $\mathcal{T}$ this set of 2,000 triplets, by $t \in \mathcal{T}$ a triplet, by $I_{\mathrm{true}}(t)$ the result of a test performed on the underlying model, and by $I_{\text{PC-}\mathcal{Y}}(t)$ the result of performing a d-separation test on the network output by the PC algorithm using the $\mathcal{Y}$ test, $\mathcal{Y}$ equal to SIT or $\widehat{\mathrm{AIT}}_{\mathrm{t}}$-D, the estimated accuracy is defined as

$$\widehat{acc}^{\mathrm{PC}}_{\mathcal{Y}} = \frac{1}{|\mathcal{T}|}\left|\left\{t \in \mathcal{T} \mid I_{\text{PC-}\mathcal{Y}}(t) = I_{\mathrm{true}}(t)\right\}\right|. \tag{26}$$

We considered data sampled from randomly generated Bayesian networks of sizes $n = 24$, and maximum degrees $\tau = 3, 7$. For each network we sampled ten data sets, and, for each data set, we



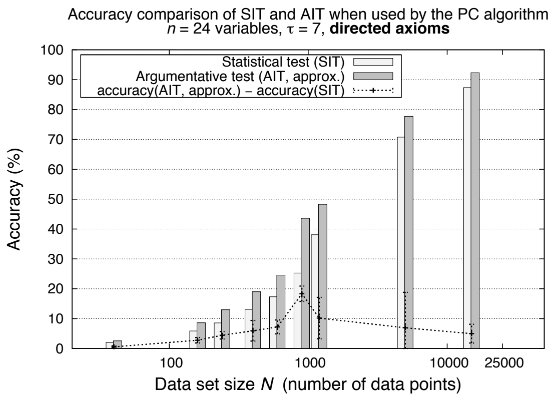


Figure 6: Comparison of statistical tests (SIT) vs. approximate argumentative tests on the directed axioms ($\widehat{\text{AIT}_t}$-D) for data sets sampled from Bayesian models for domain size $n = 24$ and maximum degrees $\tau = 3,7$.

conducted experiments on subsets of D containing an increasing number of data points. We report the average over the ten data sets of the estimated accuracy calculated using Eq. (26), for $\mathcal{Y}$ = SIT or $\widehat{\text{AIT}_t}$-D, as well as the difference between the average accuracies including the 95% confidence interval for the difference.

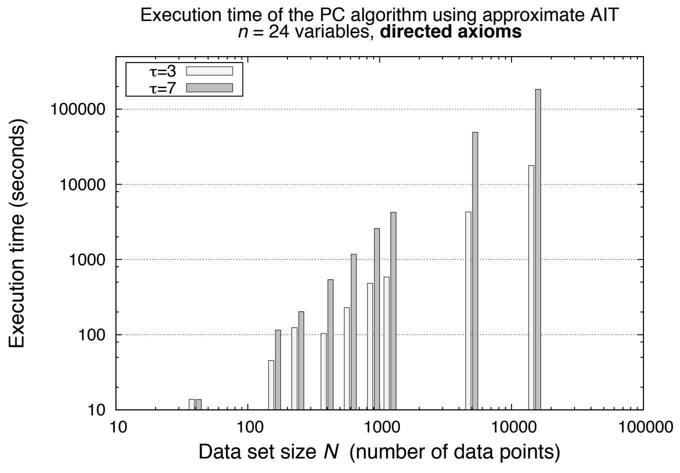

Figure 7: Execution times for the PC algorithm using the approximate argumentative test on the directed axioms ($\widehat{\text{AIT}_t}$-D) on data sets sampled from Bayesian models for domain size $n = 24$ and maximum degrees $\tau = 3,7$. For the approximate AIT test we limited the depth of the dialog tree to 3 and its the branching factor as described in Section 6.

Figure 6 shows a comparison of the argumentative tests $\widehat{\text{AIT}_t}$-D using the directed axioms with the corresponding SIT. The figure shows two plots for different values of τ of the mean values (over runs for ten different data sets) of $\widehat{acc}^{\text{PC}}_{\text{SIT}}$ and $\widehat{acc}^{\text{PC}}_{\widehat{\text{AIT}_t}\text{-D}}$ (histograms), the difference between these averages (line graph), and the 95% confidence intervals for the difference (error bars), for different data set sizes N. As usual, a positive value of the difference corresponds to an improvement of $\widehat{\text{AIT}}_\text{t}$-D over SIT. As in practically all experiments so far, we have statistically significant improvements over the entire range of data set sizes, with maximum improvements of up to 20% for $\tau = 3$, $N = 25000$, and $\tau = 7, N = 900$. The corresponding execution times for the entire PC algorithm are shown in Fig. 7. We can make two observations from this graph. One, the cost is significantly lower for sparse domains, which benefits real-world application domains that are sparse. The second observation is that the execution time scales linearly with the number of data points; this exhibits the same behavior as the use of a SIT test in PC, as each test needs to scan the data set once to compute the contingency table and relevant test statistics.

In summary, these results demonstrate that the approximate argumentative test is practical for larger domains and can result in positive, statistically significant accuracy improvements when used for causal discovery. However, the cost of AIT for large data sets, although not prohibitive, can be non-negligible. Therefore the accuracy benefits of AIT vs. a SIT must be carefully weighed off the ability of the user to expend the extra computation. Note that the practicality of the approximate algorithm also depends on the parameters used (the cutoff depth of iterative deepening and the branching factor limit—see Section 6); different parameter values or alternative ways of limiting the size of the dialog tree may be needed for even larger domains.

7.3 Real-world and Benchmark Data Experiments

While the sampled data set studies of the previous section have the advantage of a more controlled and systematic study of the performance of the algorithms, experiments on real-world data are necessary for a more realistic assessment. In this section we present experiments on a number of real-world and benchmark data sets obtained from the UCI machine learning repository (D. J. Newman and Merz, 1998) and the Knowledge Discovery Data repository (Hettich and Bay, 1999). As in the sampled data case of the previous section, for each data set D, we conducted experiments on subsets of D containing an increasing number of data points N to assess the performance of the independence tests on varying conditions of reliability. Again, to reduce variance we repeated each experiment ten times, each time choosing a different randomly selected data subset of equal size.

Because for real-world data sets the underlying model is unknown, we could only be sure the general axioms of Eq. (5) apply. We therefore only used these axioms in this section. Also, as mentioned in the previous section, because some of the data sets have much larger domains (e.g., the alarm data set contains 37 variables), and given the exponential nature of the exact algorithms we could only perform experiments for the approximate version of the argumentative test. For these reasons, in the following experiments we only report the accuracy of $\widehat{\text{AIT}}_\text{t}$-G, the approximate argumentative independence test defined over the general axioms. Unfortunately, for real-world data the underlying model is typically unknown and therefore it is impossible to know the true value of any independence. We therefore approximate it by a statistical test on the entire data set, and limit the size of the data set subsets that we use up to a third of the size of the entire data set. This corresponds to the hypothetical scenario that a much smaller data set is available to the researcher, allowing us to evaluate the improvement of argumentation under these more challenging situations. Again, as in the previous two sections, for comparison we sampled 2,000 triplets and calculated the accuracy as a fraction of tests correct, where for the true value of independences and dependences we used the method just described.

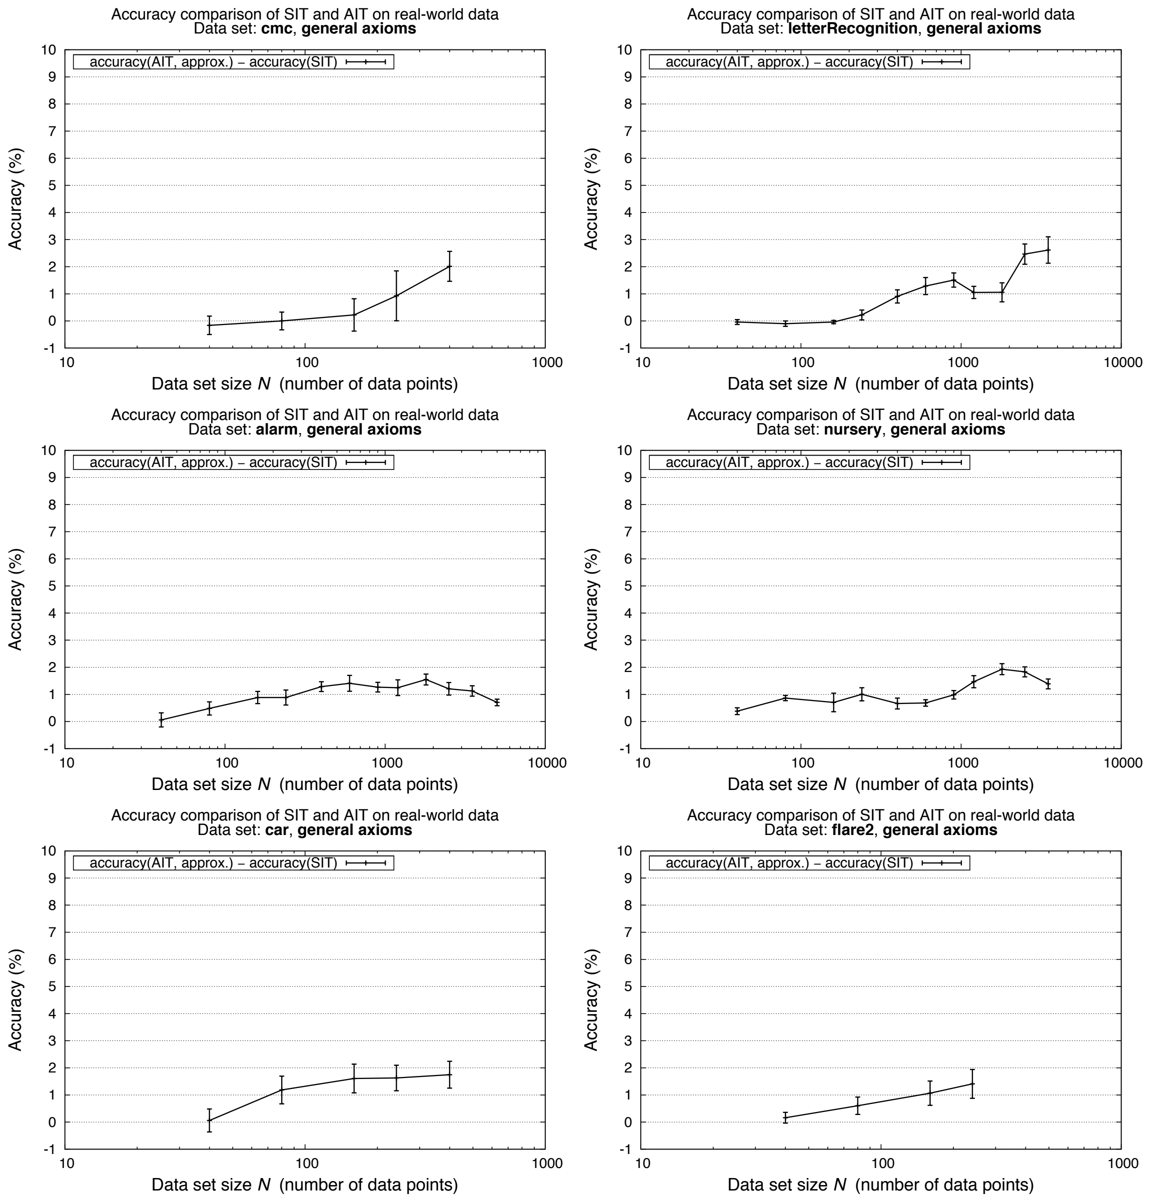

Figure 8: Difference in the mean value of the accuracy $\widehat{\mathrm{AIT}}_{\mathrm{t}}$-G with the mean value of the accuracy of SIT for a number of real-world data sets. The error bars denote the 95% confidence interval of the difference.

Figure 8 and Table 1 show the result of our comparison between the argumentative test $\widehat{\mathrm{AIT}}_{\mathrm{t}}$-G and statistical test SIT for real-world data sets. In the table, the best-performing method is shown in bold. The figure contains 6 plots, one for each data set, depicting the difference between the mean value of the accuracy of $\widehat{\mathrm{AIT}}_{\mathrm{t}}$-G and that of SIT, where as usual a positive value denotes an improvement of $\widehat{\mathrm{AIT}}_{\mathrm{t}}$-G over SIT. While in a few cases the average difference is negative (e.g., data set `cmc`, $N = 40$), in each case the negative value is not statistically significant as the confidence in-

	$\widehat{\text{AIT}}_{\text{t}}$-G − SIT				2.6 ± 0.7	1.3 ± 0.3	1.1 ± 0.3
	Runtime of $\widehat{\text{AIT}}_{\text{t}}$-G (ms)				24540.51	76.48	3895.2

Table 1: Average accuracies (in percentage) of SIT and $\widehat{\text{AIT}}_{\text{t}}$-G, their differences (denoted $\widehat{\text{AIT}}_{\text{t}}$-G − SIT in the table), the 95% confidence interval for the difference, and the average runtime per test (in ms) for $\widehat{\text{AIT}}_{\text{t}}$-G for several real-world and benchmark data sets. For each data set the table shows these quantities for number of data points $N = 40, 240, 600, 1200, 3500$. The best performing algorithm ($\widehat{\text{AIT}}_{\text{t}}$-G or SIT, with respect to accuracy) is indicated in bold. Empty cells correspond to cases where one third of the data set was smaller than the value of N in that column.

terval contains a portion of the positive half-plane. The figure demonstrates a clear advantage of the argumentative approach, with all data sets reaching statistically significant positive improvements in accuracy of up to 3% and all confidence intervals covering positive values either partially or completely. The table also shows the average execution time (in ms) for the $\widehat{\text{AIT}}_{\text{t}}$-G tests evaluated.

8. Conclusion

We presented a framework for addressing one of the most important problems of independence-based structure discovery algorithms, namely the problem of unreliability of statistical independence tests. Our main idea was to recognize the existence of interdependences among the outcomes of conditional independence tests—in the form of Pearl's axiomatic characterization of the conditional independence relation—that can be seen as integrity constraints and exploited to correct unreliable statistical tests. We modeled this setting as a knowledge base containing conditional independences that are potentially inconsistent, and used the preference-based argumentation framework to reason with and resolve these inconsistencies. We presented in detail how to apply the argumentation framework to independence knowledge bases and how to compute the preference among the independence propositions. We also presented a number of algorithms, both exact and approximate, for implementing statistical testing using this framework. We analyzed the approximate algorithm and proved that is has polynomial worst-case execution time. We also experimentally verified that its accuracy improvement is close to the exact one while providing orders of magnitude faster execution, making possible its use for causal discovery in large domains. Overall, our experimental evaluation demonstrated statistically significant improvements in the accuracy of causal discovery for the overwhelming majority of sampled, benchmark and real-world data sets.

Appendix A. Computability of the Argumentative Independence Test

In this appendix we prove that the argumentative test terminates, a property that we call its *computability*. Some of the theorems and lemmas presented are not original work but adaptations of well known properties of relations. We include them to allow a complete exposition of the proof of computability, given by Theorem 21. We first introduce some notation. We denote independence propositions (e.g., $(X \perp\!\!\!\perp Y \mid \mathbf{Z})$) by σ and their negation (e.g., $(X \not\!\perp\!\!\!\perp Y \mid \mathbf{Z})$) by $\neg\sigma$. We abbreviate their corresponding propositional arguments $(\{\sigma\}, \sigma)$ and $(\{\neg\sigma\}, \neg\sigma)$ by a_σ and $a_{\neg\sigma}$, respectively, and we will refer to $a_{\neg\sigma}$ as the *negation* of a_σ (and vice versa). Also, we use the predicates $A(a)$, $R(a)$, $Ab(a)$ to denote the fact the argument a is accepted, rejected, or in abeyance, respectively.

For completeness we repeat here the definition of strict and transitive preference relation.

Definition 13. *We say preference relation π over arguments is* strict *if the ordering of arguments induced by it is strict and total, that is, for every pair of arguments a and b,*

$$a \gg_\pi b \iff \neg\big(b \gg_\pi a\big). \tag{27}$$

Definition 14. *We say that preference relation π over arguments is* transitive *if, for every three arguments a, b and c,*

$$\big(a \gg_\pi b\big) \wedge \big(b \gg_\pi c\big) \implies \big(a \gg_\pi c\big).$$

Lemma 24. *A strict preference relation π satisfies the condition that for every pair of arguments such that a defeats b and b defeats a, it is the case that a attacks b or b attacks a, that is, at least one of a and b attacks the other.*

Proof We prove by contradiction: Let us assume that a defeats b and b defeats a but neither a attacks b nor b attacks a. By definition of the attack relation (Definition 15),

$$\neg\big(a \textit{ attacks } b\big) \implies \neg\big(\neg(b \gg_\pi a)\big) \implies b \gg_\pi a$$

and

$$\neg\big(b \textit{ attacks } a\big) \implies \neg\big(\neg(a \gg_\pi b)\big) \implies a \gg_\pi b.$$

However, this is a contradiction since, by assumption, the preference ordering is strict, and therefore it cannot be true that both $a \gg_\pi b$ and $b \gg_\pi a$ are true at the same time. ■

Lemma 25. *A strict preference π satisfies the condition that for every pair a and b of arguments, it is not the case that both a attacks b and b attacks a, that is, there can be no mutual attack.*

Proof We prove by contradiction. Let us consider two mutually attacking arguments a and b. By the definition of the attack relation, and because π is a total order, we have that

$$a \textit{ attacks } b \implies \neg(b \gg_\pi a) \implies \big(a \gg_\pi b \vee a \equiv_\pi b\big)$$

and

$$b \text{ attacks } b \implies \neg(a \gg_\pi b) \implies \big(b \gg_\pi a \vee b \equiv_\pi a\big)$$

where $a \equiv_\pi b$ means a is equally preferable to b. However, equality of preference is not possible in a strict preference relation. Therefore it must be the case that $a \gg_\pi b$ and $b \gg_\pi a$, which is a contradiction of Eq. (27), again due to strictness. ■

We next prove that no argument is in abeyance if the preference relation over arguments is strict. For that, we first prove that an argument in abeyance is always attacked by at least another argument in abeyance.

Lemma 8. *For every argument a,*

$$Ab(a) \implies \exists b \in attackers(a), Ab(b).$$

Proof By definition, an argument a is in abeyance if it is neither accepted nor rejected. Applying the definitions of acceptance and rejection and manipulating the Boolean formulae we obtain,

$$\begin{aligned}
Ab(a) &\iff \neg A(a) \wedge \neg R(a) \\
&\iff \neg\big(\forall b \in attackers(a), R(b)\big) \wedge \neg\big(\exists b \in attackers(a), A(b))\big) \\
&\iff \big(\exists b \in attackers(a), \neg R(b)\big) \wedge \big(\forall b \in attackers(a), \neg A(b))\big) \\
&\iff \big(\exists b \in attackers(a), (A(b) \vee Ab(b))\big) \wedge \big(\forall b \in attackers(a), \neg A(b))\big) \\
&\iff \big(\exists b \in attackers(a), Ab(b)\big) \wedge \big(\forall b \in attackers(a), \neg A(b))\big) \\
&\implies \exists b \in attackers(a), Ab(b).
\end{aligned}$$

■

Definition 22. *An* attack sequence *is a sequence $\langle a_1, a_2, \ldots, a_n\rangle$ of n arguments such that for every $2 \le i \le n$, a_i attacks a_{i-1}.*

Lemma 26. *Let $\langle \mathcal{A}, \mathcal{R}, \pi\rangle$ be a PAF with a strict and transitive preference relation π. Then, no argument can appear more than once in any attack sequence, that is, for every attack sequence $\langle a_1, a_2, \ldots, a_n\rangle$ and every pair of integers $i, j \in [1, n]$ such that $i \neq j$, $a_i \neq a_j$.*

Proof

We first note that by definition of the attack relation, it must be the case that for any two consecutive arguments a_i, a_{i+1}, it is true that $\neg(a_i \gg_\pi a_{i+1})$. Since π is strict, this is equivalent to $a_{i+1} \gg_\pi a_i$ (c.f. Eq. (27)). That is,

$$a_n \gg_\pi a_{n-1} \gg_\pi \ldots \gg_\pi a_2 \gg_\pi a_1 \tag{28}$$

We now assume, for contradiction, there exists an argument $a^\star$ that appears twice in the attack sequence at indexes $i^\star$ and $j^\star$, that is,

$$\exists\ i^\star, j^\star \in [1, n], i^\star \neq j^\star, \text{ such that } a_{i^\star} = a_{j^\star} = a^\star.$$

Since no argument defeats itself, it cannot attack itself, and thus the smallest possible attack sequence with a repeated argument must have at least length 3. From this fact, Eq. (28), and transitivity, there must exist an argument $b \neq a^\star$ such that $a^\star \gg_\pi b \gg_\pi a^\star$. This last fact implies that $a^\star \gg_\pi b$ and $b \gg_\pi a^\star$ must hold, which contradicts strictness (Eq. (27)). ■

A corollary of this lemma is the following theorem.

Theorem 23. *Every attack sequence $\langle a_1, a_2, \ldots, a_n \rangle$ in a PAF $\langle \mathcal{A}, \mathcal{R}, \pi \rangle$ with strict and transitive π, and finite $\mathcal{A}$ is finite.*

Proof Follows directly from Lemma 26 and the fact that $\mathcal{A}$ is finite. ■

We can now prove the main result of this section in the following theorem.

Theorem 21. *Given an arbitrary triplet $t = (X, Y \mid \mathbf{Z})$, and a PAF $\langle \mathcal{A}, \mathcal{R}, \pi \rangle$ with a strict and transitive preference relation π, and finite arguments set $\mathcal{A}$, the top-down algorithm of Algorithm 3 run for input t over $\langle \mathcal{A}, \mathcal{R}, \pi \rangle$ terminates.*

Proof In the tree traversed by the top-down algorithm, any path from the root to a leaf is an attack sequence. Since for strict and transitive π, and finite $\mathcal{A}$ each such sequence is finite, the algorithm always terminates. ■

Appendix B. Validity of the Argumentative Independence Test

In this section we prove the property of the argumentative independence test of deciding that an input triplet $(X, Y \mid \mathbf{Z})$ evaluates to either independence or dependence, but not both or neither. We call this property the *validity* of the test.

We start we proving that under the assumption of a strict and transitive preference relation, no argument is in abeyance.

Theorem 20. *Let $\langle \mathcal{A}, \mathcal{R}, \pi \rangle$ be a PAF with a strict and transitive preference relation π. Then no argument $a \in \mathcal{A}$ is in abeyance.*

Proof Let us assume, for contradiction, that there is an argument a in abeyance. From Lemma 8, not only a has an attacker in abeyance, say argument b, but b also has an attacker in abeyance, and so on. That is, we can construct an attack sequence starting at a that contains only arguments in abeyance. Moreover, this sequence must be infinite, since the lemma assures as we always have at least one attacker in abeyance. This is in direct contradiction with Theorem 23. ■

Corollary 27. *For every argument a in a PAF $\langle \mathcal{A}, \mathcal{R}, \pi \rangle$ with strict and transitive π,*

$$A(a) \iff \neg R(a).$$

We now prove a number of lemmas that hold only for the sub-class of propositional arguments (arguments whose support contains only one proposition, equal to the head of that argument). We start with a lemma that demonstrates that it cannot be the case that an attacker of a propositional argument a_σ and an attacker of its negation $a_{\neg\sigma}$ do not attack each other. The former must attack the latter or vice versa.

Lemma 28. *Let $\langle \mathcal{A}, \mathcal{R}, \pi \rangle$ be a PAF with a strict preference relation π, $a_\sigma \in \mathcal{A}$ be a propositional argument, and $a_{\neg\sigma}$ its negation. For every pair of arguments b and c that attacks a_σ and $a_{\neg\sigma}$ respectively,*

$$(b \textit{ attacks } c) \vee (c \textit{ attacks } b).$$

Proof Since a_σ and $a_{\neg\sigma}$ are propositional arguments, their support contains the head and only the head, and thus any defeater (i.e., rebutter or undercutter) must have as head $\neg\sigma$ and σ, respectively, that is, the head of b must be $\neg\sigma$ and the head of c must be σ. Thus, b rebuts (and thus defeats) c and vice versa. The lemma then follows directly from Lemma 24. ■

Lemma 29. *Let $\langle \mathcal{A}, \mathcal{R}, \pi \rangle$ be a PAF with a strict preference relation π, and a_σ and $a_{\neg\sigma}$ be a propositional argument and its negation. Then,*

$$R(a_\sigma) \implies \neg R(a_{\neg\sigma}).$$

Proof By assumption, $R(a_\sigma)$. We assume, for contradiction, that $R(a_{\neg\sigma})$. Therefore, by the definition of rejection, $\exists b \in attackers(a_\sigma)$ such that $A(b)$, and $\exists c \in attackers(a_{\neg\sigma})$ such that $A(c)$. By Lemma 28 b *attacks* c or c *attacks* b. In either case, an accepted argument is attacking an accepted argument, which contradicts the definition of acceptance. ■

Lemma 30. *Given a PAF $\langle \mathcal{A}, \mathcal{R}, \pi \rangle$ with a strict preference relation π, every propositional argument $a_\sigma \in \mathcal{A}$ satisfies*

$$A(a_\sigma) \implies \neg A(a_{\neg\sigma})$$

Proof We prove by contradiction. Let us assume that both a_σ and $a_{\neg\sigma}$ are accepted. Since a_σ and $a_{\neg\sigma}$ are propositional arguments, they defeat each other. Then, by Lemma 24 a_σ attacks $a_{\neg\sigma}$ or vice versa. In either case an accepted argument has an accepted attacker, which is a contradiction. ■

We now prove Theorem 19 that was introduced in Section 4, reproduced here for convenience.

Theorem 19. *Given a PAF $\langle \mathcal{A}, \mathcal{R}, \pi \rangle$ with a strict and transitive preference relation π, every propositional argument $a_\sigma \in \mathcal{A}$ and its negation $a_{\neg\sigma}$ satisfy*

$$A(a_\sigma) \iff R(a_{\neg\sigma}).$$

Proof The ($\implies$) direction follows from Lemma 30 and Theorem 20. The ($\impliedby$) direction follows from Lemma 29 and Theorem 20. ■

In Section 4 we defined the following semantics for deciding on the dependence or independence of an input triplet $(X, Y \mid \mathbf{Z})$:

$$\begin{aligned} (\{(X \not\perp\!\!\!\perp Y \mid \mathbf{Z})\}, (X \not\perp\!\!\!\perp Y \mid \mathbf{Z})) \text{ is accepted} &\iff (X \not\perp\!\!\!\perp Y \mid \mathbf{Z}) \text{ is accepted} \implies (X \not\perp\!\!\!\perp Y \mid \mathbf{Z}) \\ (\{(X \perp\!\!\!\perp Y \mid \mathbf{Z})\}, (X \perp\!\!\!\perp Y \mid \mathbf{Z})) \text{ is accepted} &\iff (X \perp\!\!\!\perp Y \mid \mathbf{Z}) \text{ is accepted} \implies (X \perp\!\!\!\perp Y \mid \mathbf{Z}) \end{aligned} \quad (29)$$

where acceptance is defined over an independence-based PAF as defined in Section 3.3. For this argumentative test of independence to be valid, its decision must be non-ambiguous, that is, it must decide either independence or dependence, but not both or neither. For that, exactly one of the antecedents of the above implications must be true. Formally:

Theorem 18. *For any input triplet $\sigma = (X, Y \mid \mathbf{Z})$, the argumentative independence test defined by Eq. (29) produces a non-ambiguous decision, that is, it decides that σ evaluates to either independence or dependence, but not both or neither.*

Proof Let us denote $(X \perp\!\!\!\perp Y \mid \mathbf{Z})$ by $\sigma_{\mathtt{t}}$ and $(X \not\perp\!\!\!\perp Y \mid \mathbf{Z})$ by $\sigma_{\mathtt{f}}$. Since strictness and transitivity of the independence preference relation hold (proved in Section 3.3, lemmas 16 and 17 respectively), Theorems 19 and 20 hold as well. From Theorem 20 we know that neither of the propositional arguments is in abeyance. Thus, since $a_{\sigma_{\mathtt{t}}}$ corresponds to the negation of $a_{\sigma_{\mathtt{f}}}$ it follows from Theorem 19 that exactly one of them is accepted. ■

Abstract

In this paper, we study low-rank matrix nearness problems, with a focus on learning low-rank positive semidefinite (kernel) matrices for machine learning applications. We propose efficient algorithms that scale linearly in the number of data points and quadratically in the rank of the input matrix. Existing algorithms for learning kernel matrices often scale poorly, with running times that are cubic in the number of data points. We employ Bregman matrix divergences as the measures of nearness—these divergences are natural for learning low-rank kernels since they preserve rank as well as positive semidefiniteness. Special cases of our framework yield faster algorithms for various existing learning problems, and experimental results demonstrate that our algorithms can effectively learn both low-rank and full-rank kernel matrices.

Keywords: kernel methods, Bregman divergences, convex optimization, kernel learning, matrix nearness

1. Introduction

Underlying many machine learning algorithms is a measure of distance, or divergence, between data objects. A number of factors affect the choice of the particular divergence measure used: the data may be intrinsically suited for a specific divergence measure, an algorithm may be faster or easier to implement for some measure, or analysis may be simpler for a particular measure. For example, the KL-divergence is popular when the data is represented as discrete probability vectors (i.e., non-negative vectors whose sum is 1), and the ℓ_1-norm distance is often used when sparsity is desired.

When measuring the divergence between matrices, similar issues must be considered. Typically, matrix norms such as the Frobenius norm are used, but these measures are not appropriate for all problems. Analogous to the KL-divergence for vectors, when the matrices under consideration are positive semidefinite (i.e., they have non-negative eigenvalues), then one may want to choose a divergence measure that is well-suited to such matrices; positive semidefinite (PSD) matrices arise frequently in machine learning, in particular with kernel methods. Existing learning techniques involving PSD matrices often employ matrix norms, but their use requires an additional constraint that the matrix stay positive semidefinite, which ultimately leads to algorithms involving expensive eigenvector computation. Kernel alignment, a measure of similarity between PSD matrices used in some kernel learning algorithms (Cristianini et al., 2002), also requires explicit enforcement of positive definiteness. On the other hand, the two main divergences used in this paper are defined only over the cone of positive semidefinite matrices, and our algorithms lead to automatic enforcement of positive semidefiniteness.

This paper focuses on kernel learning using two divergence measures between PSD matrices—the LogDet divergence and the von Neumann divergence. Our kernel learning goal is to find a PSD matrix which is as close as possible (under the LogDet or von Neumann divergence) to some input PSD matrix, but which additionally satisfies linear equality or inequality constraints. We argue that these two divergences are natural for problems involving positive definite matrices. First, they have several properties which make optimization computationally efficient and useful for a variety of learning tasks. For example, the LogDet divergence has a scale-invariance property which makes it particularly well-suited to machine learning applications. Second, these divergences arise naturally in several problems; for example, the LogDet divergence arises in problems involving the differential relative entropy between Gaussian distributions while the von Neumann divergence arises in quantum computing and problems such as online PCA.

One of the key properties that we demonstrate and exploit is that, for low-rank matrices, the divergences enjoy a *range-space preserving* property. That is, the LogDet divergence between two matrices is finite if and only if their range spaces are identical, and a similar property holds for the von Neumann divergence. This property leads to simple projection-based algorithms for learning PSD (or kernel) matrices that preserve the rank of the input matrix—if the input matrix is low-rank then the resulting learned matrix will also be low-rank. These algorithms are efficient; they scale linearly with the number of data points n and quadratically with the rank of the input matrix. The efficiency of the algorithms arises from new results developed in this paper which demonstrate that Bregman projections for these matrix divergences can be computed in time that scales quadratically with the rank of the input matrix. Our algorithms stand in contrast to previous work on learning kernel matrices, which scale as $O(n^3)$ or worse, relying on semidefinite programming or repeated eigenvector computation. We emphasize that our methods *preserve* rank, so they can learn low-rank kernel matrices when the input kernel matrix has low rank; however our methods do not decrease rank so they are not applicable to the non-convex problem of finding a low-rank solution given a full (or higher) rank input kernel matrix.

One special case of our method is the DefiniteBoost optimization problem from Tsuda et al. (2005); our analysis shows how to improve the running time of their algorithm by a factor of n, from $O(n^3)$ time per projection to $O(n^2)$. This projection is also used in online-PCA (Warmuth and Kuzmin, 2006), and we obtain a factor of n speedup for that problem as well. In terms of experimental results, a direct application of our techniques is in learning low-rank kernel matrices in the setting where we have background information for a subset of the data; we discuss and experiment with learning low-rank kernel matrices for classification and clustering in this setting, demonstrating that we can scale to large data sets. We also discuss the use of our divergences for learning Mahalanobis distance functions, which allows us to move beyond the transductive setting and generalize to new points. In this vein, we empirically compare our methods to existing metric learning algorithms; we are particularly interested in large-scale applications, and discuss some recent applications of the algorithms developed in this paper to computer vision tasks.

2. Background and Related Work

In this section, we briefly review relevant background material and related work.

2.1 Kernel Methods

Given a set of training points $\boldsymbol{a}_1, ..., \boldsymbol{a}_n$, a common step in kernel algorithms is to transform the data using a nonlinear function ψ. This mapping, typically, represents a transformation of the data to a higher-dimensional feature space. A kernel function κ gives the inner product between two vectors in the feature space:

$$\kappa(\boldsymbol{a}_i, \boldsymbol{a}_j) = \psi(\boldsymbol{a}_i) \cdot \psi(\boldsymbol{a}_j).$$

It is often possible to compute this inner product without explicitly computing the expensive mapping of the input points to the higher-dimensional feature space. Generally, given n points $\boldsymbol{a}_i$, we form an $n \times n$ matrix K, called the kernel matrix, whose (i, j) entry corresponds to $\kappa(\boldsymbol{a}_i, \boldsymbol{a}_j)$. In kernel-based algorithms, the only information needed about the input data points is the inner products; hence, the kernel matrix provides all relevant information for learning in the feature space. A kernel matrix formed from any set of input data points is always positive semidefinite. See Shawe-Taylor and Cristianini (2004) for more details.

2.2 Low-Rank Kernel Representations and Kernel Learning

Despite the popularity of kernel methods in machine learning, many kernel-based algorithms scale poorly; low-rank kernel representations address this issue. Given an $n \times n$ kernel matrix K, if the matrix is of low rank, say $r < n$, we can represent the kernel matrix in terms of a factorization $K = GG^T$, with G an $n \times r$ matrix.

In addition to easing the burden of memory overhead from $O(n^2)$ storage to $O(nr)$, this low-rank decomposition can lead to improved efficiency. For example, Fine and Scheinberg (2001) show that SVM training reduces from $O(n^3)$ to $O(nr^2)$ when using a low-rank decomposition. Empirically, the algorithm in Fine and Scheinberg (2001) outperforms other SVM training algorithms in terms of training time by several factors. In clustering, the kernel k-means algorithm (Dhillon et al., 2004) has a running time of $O(n^2)$ per iteration, which can be improved to $O(nrc)$ time per iteration with a low-rank kernel representation, where c is the number of desired clusters. Low-rank kernel representations are often obtained using incomplete Cholesky decompositions (Fine and Scheinberg, 2001). Recently, work has been done on using labeled data to improve the quality of low-rank decompositions (Bach and Jordan, 2005).

Low-rank decompositions have also been employed for solving a number of other machine learning problems. For example, in Kulis et al. (2007b), low-rank decompositions were employed for clustering and embedding problems. In contrast to work in this paper, their focus was on using low-rank decompositions to develop algorithms for such problems as k-means and maximum variance unfolding. Other examples of using low-rank decompositions to speed up machine learning algorithms include Weinberger et al. (2006) and Torresani and Lee (2006).

In this paper, our focus is on using distance and similarity constraints to learn a low-rank kernel matrix. In related work, Lanckriet et al. (2004) have studied transductive learning of the kernel matrix and multiple kernel learning using semidefinite programming. In Kwok and Tsang (2003), a formulation based on idealized kernels is presented to learn a kernel matrix when some labels are given. Another recent paper (Weinberger et al., 2004) considers learning a kernel matrix for nonlinear dimensionality reduction; like much of the research on learning a kernel matrix, they use semidefinite programming and the running time is at least cubic in the number of data points. Our work is closest to that of Tsuda et al. (2005), who learn a (full-rank) kernel matrix using von Neumann divergence under linear constraints. However, our framework is more general and our emphasis is on low-rank kernel learning. Our algorithms are more efficient than those of Tsuda et al.; we use exact instead of approximate projections to speed up convergence, and we consider algorithms for the LogDet divergence in addition to the von Neumann divergence. For the case of the von Neumann divergence, our algorithm also corrects a mistake in Tsuda et al. (2005); see Appendix B for details.

An earlier version of our work appeared in Kulis et al. (2006). In this paper, we substantially expand on the analysis of Bregman matrix divergences, giving a formal treatment of low-rank Bregman matrix divergences and proving several new properties. We also present further algorithmic analysis for the LogDet and von Neumann algorithms, provide connections to semidefinite programming and metric learning, and present additional experiments, including ones on much larger data sets.

3. Optimization Framework

We begin with an overview of the optimization framework applied to the problem studied in this paper. We introduce Bregman matrix divergences—the matrix divergence measures considered in this paper—and discuss their properties. Then we overview Bregman's method, the optimization algorithm that is used to learn low-rank kernel matrices.

3.1 Bregman Matrix Divergences

To measure the nearness between two matrices, we will use Bregman matrix divergences, which are generalizations of Bregman vector divergences. Let φ be a real-valued strictly convex function defined over a convex set $S = \text{dom}(\varphi) \subseteq \mathbb{R}^m$ such that φ is differentiable on the relative interior of S. The *Bregman vector divergence* (Bregman, 1967) with respect to φ is defined as

$$D_\varphi(\boldsymbol{x}, \boldsymbol{y}) = \varphi(\boldsymbol{x}) - \varphi(\boldsymbol{y}) - (\boldsymbol{x} - \boldsymbol{y})^T \nabla\varphi(\boldsymbol{y}).$$

For example, if $\varphi(\boldsymbol{x}) = \boldsymbol{x}^T\boldsymbol{x}$, then the resulting Bregman divergence is $D_\varphi(\boldsymbol{x}, \boldsymbol{y}) = \|\boldsymbol{x} - \boldsymbol{y}\|_2^2$. Another example is $\varphi(\boldsymbol{x}) = \sum_i (x_i \log x_i - x_i)$, where the resulting Bregman divergence is the (unnormalized) relative entropy $D_\varphi(\boldsymbol{x}, \boldsymbol{y}) = KL(\boldsymbol{x}, \boldsymbol{y}) = \sum_i (x_i \log \frac{x_i}{y_i} - x_i + y_i)$. Bregman divergences generalize many properties of squared loss and relative entropy. See Censor and Zenios (1997) for more details.

We can naturally extend this definition to real, symmetric $n \times n$ matrices, denoted by S^n. Given a strictly convex, differentiable function $\phi : S^n \to \mathbb{R}$, the Bregman matrix divergence is defined to be

$$D_\phi(X,Y) = \phi(X) - \phi(Y) - \text{tr}((\nabla\phi(Y))^T (X - Y)),$$

where $\text{tr}(A)$ denotes the trace of matrix A. Examples include $\phi(X) = \|X\|_F^2$, which leads to the well-known squared Frobenius norm $\|X - Y\|_F^2$. In this paper, we will extensively study two less well-known divergences. Let ϕ be the entropy of the eigenvalues of a positive definite matrix. Specifically, if X has eigenvalues $\lambda_1, ..., \lambda_n$, let $\phi(X) = \sum_i (\lambda_i \log \lambda_i - \lambda_i)$, which may be expressed as $\phi(X) = \text{tr}(X \log X - X)$, where $\log X$ is the matrix logarithm.[1] The resulting Bregman divergence is

$$D_{vN}(X,Y) = \text{tr}(X \log X - X \log Y - X + Y), \tag{1}$$

1. If $X = V\Lambda V^T$ is the eigendecomposition of the positive definite matrix X, the matrix logarithm can be written as $V \log\Lambda V^T$, where $\log\Lambda$ is the diagonal matrix whose entries contain the logarithm of the eigenvalues. The matrix exponential can be defined analogously.

and we call it the von Neumann divergence. This divergence is also called quantum relative entropy, and is used in quantum information theory (Nielsen and Chuang, 2000). Another important matrix divergence arises by taking the Burg entropy of the eigenvalues, that is, $\phi(X) = -\sum_i \log \lambda_i$, or equivalently as $\phi(X) = -\log \det X$. The resulting Bregman divergence over positive definite matrices is

$$D_{\ell d}(X,Y) = \mathrm{tr}(XY^{-1}) - \log\det(XY^{-1}) - n, \tag{2}$$

and is commonly called the LogDet divergence (we called it the Burg matrix divergence in Kulis et al. (2006)). For now, we assume that X is positive definite for both divergences; later we will discuss extensions when X is positive semidefinite, that is, low-rank.

3.2 Properties

It is important to justify the use of the divergences introduced above for kernel learning, so we now discuss some important properties of the divergences.

The most obvious computational benefit of using the divergences for kernel learning arises from the fact that they are defined only over positive definite matrices. Because of this, our algorithms will not need to explicitly constrain our learned matrices to be positive definite, which in turn leads to efficient algorithms. Beyond automatic enforcement of positive definiteness, we will see later that the divergences have a range-space preserving property, which leads to further computational benefits.

Appendix A covers some important properties of the divergences. Examples include the scale-invariance of the LogDet divergence ($D_{\ell d}(X,Y) = D_{\ell d}(\alpha X, \alpha Y)$) and, more generally, transformation-invariance ($D_{\ell d}(X,Y) = D_{\ell d}(M^T X M, M^T Y M)$ for any square, non-singular M), which are useful properties for learning algorithms. For instance, if we have applied a linear kernel over a set of data vectors, scale-invariance implies that we can scale all the features of our data vectors, and our learned kernel will simply be scaled by the same factor. Similarly, if we scale each of the features in our data vectors differently (for example, if some features are measured in feet and others in meters as opposed to all features measured in feet), then the learned kernel will be scaled by an appropriate diagonal transformation. Note that this natural property does not hold for loss functions such as the Frobenius norm distance.

Another critical property concerns generalization to new points. Typically kernel learning algorithms work in the transductive setting, meaning that all of the data is given up-front, with some of it labeled and some unlabeled, and one learns a kernel matrix over all the data points. If some new data point is given, there is no way to compare it to existing data points, so a new kernel matrix must be learned. However, as has recently been shown in Davis et al. (2007), we can move beyond the transductive setting when using the LogDet divergence, and can evaluate the kernel function over new data points. A similar result can be shown for the von Neumann divergence. We overview this recent work in Section 6.1, though the main focus in this paper remains in the transductive setting.

Furthermore, both the LogDet divergence and the von Neumann divergence have precedence in a number of areas. The von Neumann divergence is used in quantum information theory (Nielsen and Chuang, 2000), and has been employed in machine learning for online principal component analysis (Warmuth and Kuzmin, 2006). The LogDet divergence is called Stein's loss in the statistics literature, where it has been used as a measure of distance between covariance matrices (James and Stein, 1961). It has also been employed in the optimization community; the updates for the BFGS and DFP algorithms (Fletcher, 1991), both quasi-Newton algorithms, can be viewed as LogDet optimization programs. In particular, the update to the approximation of the Hessian given in these algorithms is the result of a LogDet minimization problem with linear constraints (given by the secant equation).

For all three divergences introduced above, the generating convex function of the Bregman matrix divergence can be viewed as a composition $\phi(X) = (\varphi \circ \lambda)(X)$, where $\lambda(X)$ is the function that lists the eigenvalues in algebraically decreasing order, and φ is a strictly convex function defined over vectors (Dhillon and Tropp, 2007). In general, every such φ defines a Bregman matrix divergence over real, symmetric matrices via the eigenvalue mapping. For example, if $\varphi(\boldsymbol{x}) = \boldsymbol{x}^T\boldsymbol{x}$, then the resulting composition $(\varphi \circ \lambda)(X)$ is the squared Frobenius norm. We call such divergences *spectral Bregman matrix divergences*.

Consider a spectral Bregman matrix divergence $D_\phi(X,Y)$, where $\phi = \varphi \circ \lambda$. We now show an alternate expression for $D_\phi(X,Y)$ based on the eigenvalues and eigenvectors of X and Y, which will prove to be useful when motivating extensions to the low-rank case.

Lemma 1 *Let the eigendecompositions of X and Y be $V\Lambda V^T$ and $U\Theta U^T$ respectively, and assume that φ is* separable*, that is, $\phi(X) = (\varphi \circ \lambda)(X) = \sum_i \varphi_i(\lambda_i)$. Then*

$$D_\phi(X,Y) = \sum_{i,j} (\boldsymbol{v}_i^T \boldsymbol{u}_j)^2 (\varphi_i(\lambda_i) - \varphi_j(\theta_j) - (\lambda_i - \theta_j)\nabla\varphi_j(\theta_j)).$$

Proof We have

$$\begin{aligned} D_\phi(X,Y) &= \phi(X) - \phi(Y) - \mathrm{tr}((X-Y)^T(\nabla\phi(Y))) \\ &= \sum_i \varphi_i(\lambda_i) - \sum_j \varphi_j(\theta_j) - \mathrm{tr}((V\Lambda V^T - U\Theta U^T)^T(\nabla\phi(Y))) \\ &= \sum_{i,j} (\boldsymbol{v}_i^T \boldsymbol{u}_j)^2 \varphi_i(\lambda_i) - \sum_{i,j} (\boldsymbol{v}_i^T \boldsymbol{u}_j)^2 \varphi_j(\theta_j) - \mathrm{tr}((V\Lambda V^T - U\Theta U^T)^T(\nabla\phi(Y))). \end{aligned}$$

The second line above uses the separability of φ, while the third line uses the fact that $\sum_i (\boldsymbol{v}_i^T \boldsymbol{u}_j)^2 = \sum_j (\boldsymbol{v}_i^T \boldsymbol{u}_j)^2 = 1$. We can express $\nabla\phi(Y)$ as:

$$\nabla\phi(Y) = U \begin{pmatrix} \nabla\varphi_1(\theta_1) & 0 & \dots \\ 0 & \nabla\varphi_2(\theta_2) & \dots \\ \vdots & \vdots & \ddots \end{pmatrix} U^T,$$

and so we have $\mathrm{tr}(U\Theta U^T \nabla\phi(Y)) = \sum_j \theta_j \nabla\varphi_j(\theta_j) = \sum_{i,j} (\boldsymbol{v}_i^T \boldsymbol{u}_j)^2 \theta_j \nabla\varphi_j(\theta_j)$. Finally, the term $\mathrm{tr}(V\Lambda V^T \nabla\phi(Y))$ can be expanded as $\sum_{i,j} (\boldsymbol{v}_i^T \boldsymbol{u}_j)^2 \lambda_i \nabla\varphi_j(\theta_j)$. Putting this all together, we have:

$$D_\phi(X,Y) = \sum_{i,j} (\boldsymbol{v}_i^T \boldsymbol{u}_j)^2 (\varphi_i(\lambda_i) - \varphi_j(\theta_j) - \nabla\varphi_j(\theta_j) \cdot (\lambda_i - \theta_j)).$$

■

Note that each of the divergences discussed earlier—the squared Frobenius divergence, the LogDet divergence, and the von Neumann divergence—arise from separable convex functions. Furthermore, in these three cases, the functions φ_i do not depend on i (so we denote $\varphi = \varphi_1 = \ldots = \varphi_n$) and the corollary below follows:

Corollary 2 *Given $X = V\Lambda V^T$ and $Y = U\Theta U^T$, the squared Frobenius, von Neumann and LogDet divergences satisfy:*

$$D_\phi(X,Y) = \sum_{i,j} (\boldsymbol{v}_i^T \boldsymbol{u}_j)^2 D_\varphi(\lambda_i, \theta_j). \tag{3}$$

This formula highlights the connection between a separable spectral matrix divergence and the corresponding vector divergence. It also illustrates how the divergence relates to the geometrical properties of the argument matrices as represented by the eigenvectors.

3.3 Problem Description

We now give a formal statement of the problem that we study in this paper. Given an input kernel matrix X_0, we attempt to solve the following for X:

$$\begin{aligned} \text{minimize} \quad & D_\phi(X, X_0) \\ \text{subject to} \quad & \operatorname{tr}(XA_i) \le b_i,\ 1 \le i \le c, \\ & \operatorname{rank}(X) \le r, \\ & X \succeq 0. \end{aligned} \tag{4}$$

Any of the linear inequality constraints $\operatorname{tr}(XA_i) \le b_i$ may be replaced with equalities. The above problem is clearly non-convex in general, due to the rank constraint. However, when the rank of X_0 does not exceed r, then this problem turns out to be convex when we use the von Neumann and LogDet matrix divergences. This is because these divergences restrict the search for the optimal X to the linear subspace of matrices that have the same range space as X_0. The details will emerge in Section 4. Another advantage of using the von Neumann and LogDet divergences is that the algorithms used to solve the minimization problem implicitly maintain the positive semidefiniteness constraint, so no extra work needs to be done to enforce positive semidefiniteness. This is in contrast to the squared Frobenius divergence, where the positive semidefiniteness constraint has to be explicitly enforced.

Though it is possible to handle general linear constraints of the form $\operatorname{tr}(XA_i) \le b_i$, we will focus on two specific types of constraints, which will be useful for our kernel learning applications. The first is a distance constraint. The squared Euclidean distance in feature space between the jth and the kth data points is given by $X_{jj} + X_{kk} - 2X_{jk}$. The constraint $X_{jj} + X_{kk} - 2X_{jk} \le b_i$ can be represented as $\operatorname{tr}(XA) \le b_i$, where $A_i = \boldsymbol{z}_i \boldsymbol{z}_i^T$, and $\boldsymbol{z}_i(j) = 1$, $\boldsymbol{z}_i(k) = -1$, and all other entries 0 (equivalently, $\boldsymbol{z}_i = \boldsymbol{e}_j - \boldsymbol{e}_k$). The second type of constraint has the form $X_{jk} \le b_i$, which can be written as $\operatorname{tr}(XA_i) \le b_i$ using $A_i = \frac{1}{2}(\boldsymbol{e}_j \boldsymbol{e}_k^T + \boldsymbol{e}_k \boldsymbol{e}_j^T)$ (we maintain symmetry of A_i).

For the algorithms developed in Section 5, we will assume that the matrices A_i in (4) are rank one (so $A_i = \boldsymbol{z}_i \boldsymbol{z}_i^T$) and that $r = \operatorname{rank}(X_0)$ (we briefly discuss extensions to higher-rank constraints in Section 6.2.2). In this case, we can write the optimization problem as:

$$\begin{aligned} \text{minimize} \quad & D_\phi(X, X_0) \\ \text{subject to} \quad & \boldsymbol{z}_i^T X \boldsymbol{z}_i \le b_i,\ 1 \le i \le c, \\ & \operatorname{rank}(X) \le r, \\ & X \succeq 0. \end{aligned} \tag{5}$$

Furthermore, we assume that there exists a feasible solution to the above problem; we discuss an extension to the infeasible case involving slack variables in Section 6.2.1. Note that in this case, we assume $b_i \geq 0$, as otherwise there cannot be a feasible solution.

The key application of the above optimization problem is in learning a kernel matrix in the setting where we have side information about some of the data points (e.g., labels or constraints), and we want to learn a kernel matrix over all the data points in order to perform classification, regression, or semi-supervised clustering. We will also discuss other applications throughout the paper.

3.4 Bregman Projections

Consider the convex optimization problem (4) presented above, but without the rank constraint (we will see how to handle the rank constraint later). To solve this problem, we use the method of Bregman projections (Bregman, 1967; Censor and Zenios, 1997). Suppose we wish to minimize $D_\phi(X,X_0)$ subject to linear equality and inequality constraints. The idea behind Bregman projections is to choose one constraint per iteration, and perform a projection so that the current solution satisfies the chosen constraint. Note that the projection is not an orthogonal projection, but rather a *Bregman projection*, which is tailored to the particular function that is being minimized. In the case of inequality constraints, an appropriate correction is also enforced. This process is then repeated by cycling through the constraints (or employing a more sophisticated control mechanism). This method may also be viewed as a dual coordinate ascent procedure that optimizes the dual with respect to a single dual variable per iteration (with all other dual variables remaining fixed). Under mild conditions, it can be shown that the method of cyclic Bregman projections (or a control mechanism that visits each constraint infinitely often) converges to the globally optimal solution; see Censor and Zenios (1997) and Dhillon and Tropp (2007) for more details.

Now for the details of each iteration. For an equality constraint of the form $\mathrm{tr}(XA_i) = b_i$, the Bregman projection of the current iterate X_t may be computed by solving:

$$\begin{aligned} \text{minimize}_X \quad & D_\phi(X,X_t) \\ \text{subject to} \quad & \mathrm{tr}(XA_i) = b_i. \end{aligned} \tag{6}$$

Introduce the dual variable α_i, and form the Lagrangian $\mathcal{L}(X,\alpha_i) = D_\phi(X,X_t) + \alpha_i(b_i - \mathrm{tr}(XA_i))$. By setting the gradient of the Lagrangian (with respect to X and α_i) to zero, we can obtain the Bregman projection by solving the resulting system of equations simultaneously for α_i and X_{t+1}:

$$\begin{aligned} \nabla\phi(X_{t+1}) &= \nabla\phi(X_t) + \alpha_i A_i \qquad (7) \\ \mathrm{tr}(X_{t+1}A_i) &= b_i. \end{aligned}$$

For an inequality constraint of the form $\mathrm{tr}(XA_i) \leq b_i$, let $\nu_i \geq 0$ be the corresponding dual variable. To maintain non-negativity of the dual variable (which is necessary for satisfying the KKT conditions), we can solve (7) for α_i and perform the following update:

$$\alpha_i' = \min(\nu_i, \alpha_i), \;\; \nu_i \leftarrow \nu_i - \alpha_i'. \tag{8}$$

See Appendix B for a discussion on why the dual variable corrections are needed. Clearly the update guarantees that $\nu_i \geq 0$. Finally, update X_{t+1} via

$$\nabla\phi(X_{t+1}) = \nabla\phi(X_t) + \alpha_i' A_i. \tag{9}$$

Note that (8) may be viewed as a correction step that follows the projection given by (7). Both of our algorithms in Section 5 are based on this method, which iteratively chooses a constraint and performs a Bregman projection until convergence. The main difficulty lies in efficiently solving the nonlinear system of equations given in (7).

In the case where $A_i = \boldsymbol{z}_i\boldsymbol{z}_i^T$, by calculating the gradient for the LogDet and von Neumann matrix divergences, respectively, (7) simplifies to:

$$\begin{aligned} X_{t+1} &= \left(X_t^{-1} - \alpha_i \boldsymbol{z}_i\boldsymbol{z}_i^T\right)^{-1} \\ X_{t+1} &= \exp(\log(X_t) + \alpha_i \boldsymbol{z}_i\boldsymbol{z}_i^T), \end{aligned} \tag{10}$$

subject to $\boldsymbol{z}_i^T X_{t+1}\boldsymbol{z}_i = b_i$. In (10), exp and log denote the matrix exponential and matrix logarithm, respectively. As we will see, for the von Neumann and LogDet divergences, these projections can be computed very efficiently (and are thus more desirable than other methods that involve multiple constraints at a time).

4. Bregman Divergences for Rank-Deficient Matrices

As given in (1) and (2), the von Neumann and LogDet divergences are undefined for low-rank matrices. For the LogDet divergence, the convex generating function $\phi(X) = -\log\det X$ is infinite when X is singular, that is, its effective domain is the set of positive definite matrices. For the von Neumann divergence the situation is somewhat better, since one can define $\phi(X) = \mathrm{tr}(X\log X - X)$ via continuity for rank-deficient matrices.

The key to using these divergences in the low-rank setting comes from restricting the convex function ϕ to the range spaces of the matrices. We motivate our approach using Corollary 2, before formalizing it in Section 4.2. Subsequently, we discuss the computation of Bregman projections for low-rank matrices in Section 4.3.

4.1 Motivation

If X and Y have eigendecompositions $X = V\Lambda V^T$ and $Y = U\Theta U^T$, respectively, then whenever X or Y is of low-rank, some eigenvalues λ_i of X or θ_j of Y are equal to zero. Consequently, if we could apply Corollary 2, the $D_\varphi(\lambda_i, \theta_j)$ terms that involve zero eigenvalues need careful treatment. More specifically, for the von Neumann divergence we have:

$$D_\varphi(\lambda_i, \theta_j) = \lambda_i \log\lambda_i - \lambda_i \log\theta_j - \lambda_i + \theta_j. \tag{11}$$

Using the convention that $0\log 0 = 0$, $D_\varphi(\lambda_i, \theta_j)$ equals 0 when both λ_i and θ_j are 0, but is infinite when θ_j is 0 but λ_i is non-zero. Similarly, with the LogDet divergence, we have

$$D_\varphi(\lambda_i, \theta_j) = \frac{\lambda_i}{\theta_j} - \log\frac{\lambda_i}{\theta_j} - 1. \tag{12}$$

In cases where $\lambda_i = 0$ and $\theta_j \neq 0$, or $\lambda_i \neq 0$ and $\theta_j = 0$, $D_\varphi(\lambda_i, \theta_j)$ is infinite.

For finiteness of the corresponding matrix divergence we require that $\boldsymbol{v}_i^T\boldsymbol{u}_j = 0$ whenever $D_\varphi(\lambda_i, \theta_j)$ is infinite so a cancellation will occur (via appropriate continuity arguments) and the divergence will be finite. This leads to properties of rank-deficient X and Y that are required for the matrix divergence to be finite. The following observations are discussed more formally in Section 4.2.

Observation 1 *The von Neumann divergence $D_{vN}(X,Y)$ is finite iff* $\text{range}(X) \subseteq \text{range}(Y)$.

The term $\lambda_i \log \theta_j$ from (11) is $-\infty$ if $\theta_j = 0$ but $\lambda_i \neq 0$. By using Corollary 2 and distributing the $(\boldsymbol{v}_i^T \boldsymbol{u}_j)^2$ term into the scalar divergence, we obtain: $\lambda_i(\boldsymbol{v}_i^T \boldsymbol{u}_j)^2 \log \theta_j$. Thus, if $\boldsymbol{v}_i^T \boldsymbol{u}_j = 0$ when $\theta_j = 0$, then $\lambda_i(\boldsymbol{v}_i^T \boldsymbol{u}_j)^2 \log \theta_j = 0$ (using $0 \log 0 = 0$), and the divergence is finite. When $\theta_j = 0$, the corresponding eigenvector $\boldsymbol{u}_j$ is in the null space of Y; therefore, for finiteness of the divergence, every vector $\boldsymbol{u}_j$ in the null space of Y is orthogonal to any vector $\boldsymbol{v}_i$ in the range space of X. This implies that the null space of Y contains the null space of X or, equivalently, $\text{range}(X) \subseteq \text{range}(Y)$.

Observation 2 *The LogDet divergence $D_{\ell d}(X,Y)$ is finite iff* $\text{range}(X) = \text{range}(Y)$.

To show the observation, we adopt the conventions that $\log \frac{0}{0} = 0$ and $\frac{0}{0} = 1$ in (12), which follow by continuity assuming that the rate at which the numerator and denominator approach zero is the same. Then, distributing the $(\boldsymbol{v}_i^T \boldsymbol{u}_j)^2$ term into D_φ, we have that $\boldsymbol{v}_i$ and $\boldsymbol{u}_j$ must be orthogonal whenever $\lambda_i = 0, \theta_j \neq 0$ or $\lambda_i \neq 0, \theta_j = 0$. This in turn says that: a) every vector $\boldsymbol{u}_j$ in the null space of Y must be orthogonal to every vector $\boldsymbol{v}_i$ in the range space of X and, b) every vector $\boldsymbol{v}_i$ in the null space of X must be orthogonal to every vector $\boldsymbol{u}_j$ in the range space of Y. It follows that the range spaces of X and Y are equal.

Assuming the eigenvalues of X and Y are listed in non-increasing order, we can write the low-rank equivalent of (3) simply as:

$$D_\phi(X,Y) = \sum_{i,j \leq r} (\boldsymbol{v}_i^T \boldsymbol{u}_j)^2 D_\varphi(\lambda_i, \theta_j),$$

where $r = \text{rank}(X)$.

If we now revisit our optimization problem formulated in (4), where we aim to minimize $D_\phi(X, X_0)$, we see that the LogDet and von Neumann divergences naturally maintain rank constraints if the problem is feasible. For the LogDet divergence, the equality of the range spaces of X and X_0 implies that when minimizing $D_\phi(X, X_0)$, we maintain $\text{rank}(X) = \text{rank}(X_0)$, assuming that there is a feasible X with a finite $D_\phi(X, X_0)$. Similarly, for the von Neumann divergence, the property that $\text{range}(X) \subseteq \text{range}(X_0)$ implies $\text{rank}(X) \leq \text{rank}(X_0)$.

4.2 Formalization Via Restrictions on the Range Space

The above section demonstrated informally that for $D_\phi(X,Y)$ to be finite the range spaces of X and Y must be equal for the LogDet divergence, and the range space of X must be contained in the range space of Y for the von Neumann divergence.

We now formalize the generalization to low-rank matrices. Let W be an orthogonal $n \times r$ matrix, such that its columns span the range space of Y. We will use the following simple and well known lemma later on:

Lemma 3 *Let Y be a symmetric $n \times n$ matrix with* $\text{rank}(Y) \leq r$, *and let W be an $n \times r$ column orthogonal matrix ($W^T W = I$) with* $\text{range}(Y) \subseteq \text{range}(W)$. *Then $Y = WW^T YWW^T$.*

Proof Extend W to a full $n \times n$ orthogonal matrix and denote it by W_f. Notice that the last $(n-r)$ rows of $W_f^T Y$ and the last $(n-r)$ columns of YW_f consist of only zeros. It follows that the matrix $Y_1 = W_f^T Y W_f$ contains only zeros except for the $r \times r$ sub-matrix in the top left corner, which coincides with $\hat{Y} = W^T Y W$. Observe that $Y = W_f Y_1 W_f^T = W \hat{Y} W^T = WW^T YWW^T$ to finish the proof. ■

We are now ready to extend the domain of the von Neumann and LogDet divergences to low-rank matrices.

Definition 4 *Consider the positive semidefinite $n \times n$ matrices X and Y that satisfy* $\mathrm{range}(X) \subseteq \mathrm{range}(Y)$ *when considering the von Neumann divergence, and* $\mathrm{range}(X) = \mathrm{range}(Y)$ *when considering the LogDet divergence. Let W be an $n \times r$ column orthogonal matrix such that range$(Y) \subseteq$ range(W) and define:*

$$D_\phi(X,Y) = D_{\phi,W}(X,Y) = D_\phi(W^T XW, W^T YW), \tag{13}$$

where D_ϕ is either the von Neumann or the LogDet divergence.

The first equality in (13) implicitly assumes that the right hand side is not dependent on the choice of W.

Lemma 5 *In Definition 4, $D_{\phi,W}(X,Y)$ is independent of the choice of W.*

Proof All the $n \times r$ orthogonal matrices with the same range space as W can be expressed as a product WQ, where Q is an $r \times r$ orthogonal matrix. Introduce $\hat{X} = W^T XW$ and $\hat{Y} = W^T YW$ and substitute WQ in place of W in (13):

$$\begin{aligned} D_{\phi,WQ}(X,Y) &= D_\phi((WQ)^T X(WQ), (WQ)^T Y(WQ)) \\ &= D_\phi(Q^T \hat{X} Q, Q^T \hat{Y} Q) \\ &= D_\phi(\hat{X}, \hat{Y}) = D_{\phi,W}(X,Y). \end{aligned}$$

The first equality is by Definition 4, and the third follows from the fact that the von Neumann and the LogDet divergences are invariant under any orthogonal similarity transformation[2] (see Proposition 11 in Appendix A). ■

We now show that Definition 4 is consistent with Corollary 2, demonstrating that our low-rank formulation agrees with the informal discussion given earlier.

Theorem 6 *Let the positive semidefinite matrices X and Y have eigendecompositions $X = V\Lambda V^T$, $Y = U\Theta U^T$ and let* $\mathrm{range}(X) \subseteq \mathrm{range}(Y)$. *Let the rank of Y equal r. Assuming that the eigenvalues of X and Y are sorted in non-increasing order, that is, $\lambda_1 \geq \lambda_2 \geq \ldots \geq \lambda_r$ and $\theta_1 \geq \theta_2 \geq \ldots \geq \theta_r$, then*

$$D_{vN}(X,Y) = \sum_{i,j \leq r} (\boldsymbol{v}_i^T \boldsymbol{u}_j)^2 (\lambda_i \log \lambda_i - \lambda_i \log \theta_j - \lambda_i + \theta_j).$$

Proof Denote the upper left $r \times r$ submatrices of Λ and Θ by Λ_r and Θ_r respectively, and the corresponding reduced eigenvector matrices for X and Y by V_r and U_r. Picking W in (13) to equal U_r, we get:

$$D_{vN}(X,Y) = D_{vN}(U_r^T XU_r, U_r^T YU_r) = D_{vN}((U_r^T V_r)\Lambda_r(V_r^T U_r), \Theta_r).$$

The arguments on the right hand side are $r \times r$ matrices and Θ_r is not rank-deficient. We can now apply Corollary 2 to get the result. ■

2. In fact, in the case of the LogDet divergence we have invariance under any invertible congruence transformation, see Proposition 12 in Appendix A.

Theorem 7 *Let the positive semidefinite matrices X and Y have eigendecompositions $X = V\Lambda V^T$, $Y = U\Theta U^T$, and let* range$(X) =$ range(Y) *and assume that the eigenvalues of X and Y are sorted in decreasing order. Then:*

$$D_{\ell d}(X,Y) = \sum_{i,j \le r} (\boldsymbol{v}_i^T \boldsymbol{u}_j)^2 \left(\frac{\lambda_i}{\theta_j} - \log \frac{\lambda_i}{\theta_j} - 1 \right).$$

Proof Similar to the proof of Theorem 6. Note that the range spaces must coincide in this case, because the determinant of XY^{-1} should not vanish for the restricted transformations, which agrees with the range$(X) =$ range(Y) restriction. ■

We next show that the optimization problem and Bregman's projection algorithm for low-rank matrices can be cast as a full rank problem in a lower dimensional space, namely the range space. This equivalence implies that we do not have to rederive the convergence proofs and other properties of Bregman's algorithm in the low-rank setting.

Consider the optimization problem (4) for low-rank X_0, and denote a suitable orthogonal matrix as required in Definition 4 by W. The matrix of the eigenvectors of the reduced eigendecomposition of X_0 is a suitable choice. Consider the following matrix mapping:

$$M \longrightarrow \hat{M} = W^T M W.$$

By Lemma 3, the mapping is one-to-one on the set of symmetric matrices with range space contained in range(W). We now apply the mapping to all matrices in the optimization problem (4) to obtain:

$$\begin{array}{ll} \text{minimize} & D_\phi(\hat{X}, \hat{X}_0) \\ \text{subject to} & \operatorname{tr}(\hat{X}\hat{A}_i) \le b_i, \; 1 \le i \le c \\ & \operatorname{rank}(\hat{X}) \le r \\ & \hat{X} \succeq 0. \end{array} \tag{14}$$

The rank constraint is automatically satisfied when rank$(X_0) = r$ and the problem is feasible. Clearly, $\hat{X} \succeq 0$ if and only if $X \succeq 0$. By Definition 4, $D_\phi(\hat{X}, \hat{X}_0) = D_\phi(X, X_0)$. Finally, the next lemma verifies that the constraints are equivalent as well.

Lemma 8 *Given a column orthogonal $n \times r$ matrix W satisfying* range$(X) \subseteq$ range(W), *it follows that* tr$(\hat{X}\hat{A}_i) =$ tr(XA_i), *where $\hat{X} = W^T X W$, $\hat{A}_i = W^T A_i W$.*

Proof Choose a reduced rank-r eigendecomposition of X to be $V\Lambda V^T$ such that the columns of V form an orthogonal basis of range(W). Note that Λ will be singular when rank(X) is less than r. There exists an $r \times r$ orthogonal Q that satisfies $W = VQ$, and so:

$$\begin{aligned} \operatorname{tr}(\hat{X}\hat{A}_i) &= \operatorname{tr}((W^T X W)(W^T A_i W)) = \operatorname{tr}(Q^T V^T V \Lambda V^T V Q Q^T V^T A_i V Q) \\ &= \operatorname{tr}(V Q Q^T \Lambda Q Q^T V^T A_i) = \operatorname{tr}(V \Lambda V^T A_i) = \operatorname{tr}(X A_i). \end{aligned}$$

■

If we assume that the optimization problem (4) has a (rank-deficient) solution with finite divergence measure, then the corresponding full-rank optimization problem (14) also has a solution. Conversely, by Lemma 3, for a solution $\hat{X}$ of (14), there is a unique solution of (4), namely $X = W\hat{X}W^T$ (with finite $D_\phi(X, X_0)$) that satisfies the range space restriction.

4.3 Bregman Projections for Rank-deficient Matrices

Lastly, we derive the explicit updates for Bregman's algorithm in the low-rank setting. From now on we omit the constraint index for simplicity. Recall (7), which we used to calculate the projection update for Bregman's algorithm and apply it to the mapped problem (14):

$$\begin{aligned}\nabla\phi(\hat{X}_{t+1}) &= \nabla\phi(\hat{X}_t)+\alpha\hat{A}\\ \mathrm{tr}(\hat{X}_{t+1}\hat{A}) &= b.\end{aligned}$$

In case of the von Neumann divergence this leads to the update $\hat{X}_{t+1}=\exp(\log(\hat{X}_t)+\alpha\hat{A})$. The discussion in Section 4.2 and induction on t implies that $X_{t+1}=W\hat{X}_{t+1}W^T$ (with W as in Definition 4), or explicitly:

$$X_{t+1}=W\exp(\log(W^TX_tW)+\alpha(W^TAW))W^T.$$

If we choose $W=V_t$ from the reduced eigendecomposition $X_t=V_t\Lambda_tV_t^T$, then the update is written as:

$$X_{t+1}=V_t\exp(\log(\Lambda_t)+\alpha V_t^TAV_t)V_t^T, \tag{15}$$

which we will use in the von Neumann kernel learning algorithm. Note that the limit of $\exp(\log(X_t+\varepsilon I)+\alpha A)$ as ε approaches zero yields the same formula, which becomes clear if we apply a basis transformation that puts X_t in diagonal form.

The same argument applies to the Bregman projection for the LogDet divergence. In this case we arrive at the update:

$$X_{t+1}=V_t((V_t^TX_tV_t)^{-1}-\alpha(V_t^TAV_t))^{-1}V_t^T, \tag{16}$$

using Lemma 3 and the fact that $\mathrm{range}(X_{t+1})=\mathrm{range}(X_t)$. The right hand side of (16) can be calculated without any eigendecomposition as we will show in Section 5.1.1.

5. Algorithms

In this section, we derive efficient algorithms for solving the optimization problem (5) for low-rank matrices using the LogDet and von Neumann divergences.

5.1 LogDet Divergence

We first develop a cyclic projection algorithm to solve (5) when the matrix divergence is the LogDet divergence.

5.1.1 MATRIX UPDATES

Consider minimizing $D_{\ell d}(X,X_0)$, the LogDet divergence between X and X_0. As given in (16), the projection update rule for low-rank X_0 and a rank-one constraint matrix $A=\boldsymbol{z}\boldsymbol{z}^T$ is:

$$X_{t+1}=V_t((V_t^TX_tV_t)^{-1}-\alpha(V_t^T\boldsymbol{z}\boldsymbol{z}^TV_t))^{-1}V_t^T,$$

where the eigendecomposition of X_t is $V_t\Lambda_tV_t^T$. Recall the Sherman-Morrison inverse formula (Sherman and Morrison, 1949; Golub and Van Loan, 1996):

$$(A+\boldsymbol{u}\boldsymbol{v}^T)^{-1}=A^{-1}-\frac{A^{-1}\boldsymbol{u}\boldsymbol{v}^TA^{-1}}{1+\boldsymbol{v}^TA^{-1}\boldsymbol{u}}.$$

Applying this formula to the middle term of the projection update, we arrive at a simplified expression for X_{t+1}:

$$\begin{aligned} X_{t+1} &= V_t\left(V_t^T X_t V_t + \frac{\alpha V_t^T X_t V_t V_t^T \boldsymbol{z}\boldsymbol{z}^T V_t V_t^T X_t V_t}{1-\alpha \boldsymbol{z}^T V_t V_t^T X_t V_t V_t^T \boldsymbol{z}}\right)V_t^T \\ &= V_t\left(\Lambda_t + \frac{\alpha \Lambda_t V_t^T \boldsymbol{z}\boldsymbol{z}^T V_t \Lambda_t}{1-\alpha \boldsymbol{z}^T V_t \Lambda_t V_t^T \boldsymbol{z}}\right)V_t^T \\ &= V_t \Lambda_t V_t^T + \frac{\alpha V_t \Lambda_t V_t^T \boldsymbol{z}\boldsymbol{z}^T V_t \Lambda_t V_t^T}{1-\alpha \boldsymbol{z}^T X_t \boldsymbol{z}} \\ &= X_t + \frac{\alpha X_t \boldsymbol{z}\boldsymbol{z}^T X_t}{1-\alpha \boldsymbol{z}^T X_t \boldsymbol{z}}. \end{aligned} \tag{17}$$

Since X_{t+1} must satisfy the constraint, i. e., $\mathrm{tr}(X_{t+1}\boldsymbol{z}\boldsymbol{z}^T) = \boldsymbol{z}^T X_{t+1}\boldsymbol{z} = b$, we can solve the following equation for α:

$$\boldsymbol{z}^T\left(X_t + \frac{\alpha X_t \boldsymbol{z}\boldsymbol{z}^T X_t}{1-\alpha \boldsymbol{z}^T X_t \boldsymbol{z}}\right)\boldsymbol{z} = b. \tag{18}$$

Let $p = \boldsymbol{z}^T X_t \boldsymbol{z}$. Note that in the case of distance constraints, p is the distance between the two data points. When $p \neq 0$, elementary arguments reveal that there is exactly one solution for α provided that $b \neq 0$. The unique solution, in this case, can be expressed as:

$$\alpha = \frac{1}{p} - \frac{1}{b}. \tag{19}$$

If we let

$$\beta = \alpha/(1-\alpha p), \tag{20}$$

then our matrix update is given by

$$X_{t+1} = X_t + \beta X_t \boldsymbol{z}\boldsymbol{z}^T X_t. \tag{21}$$

This update is pleasant and surprising; usually the projection parameter for Bregman's algorithm does not admit a closed form solution (see Section 5.2.2 for the case of the von Neumann divergence). In the case where $p = 0$, (18) rewrites to $b = p/(1-\alpha p)$, which has a solution if and only if $b = 0$ (while α is arbitrary). It follows that $\boldsymbol{z}$ is in the null space of X_t, and by (17), $X_{t+1} = X_t$.

The following lemma confirms the expectation that we remain in the positive semidefinite cone and that the range space is unchanged.

Lemma 9 *Given a positive semidefinite matrix X_t, the matrix X_{t+1} from the update in (21) is positive semidefinite with* $\mathrm{range}(X_{t+1}) = \mathrm{range}(X_t)$, *assuming that (6) is feasible.*

Proof Factor the positive semidefinite matrix X_t as GG^T, where G is an $n \times r$ matrix and $r = \mathrm{rank}(X_t)$. The LogDet update produces:

$$X_{t+1} = GG^T + \beta GG^T \boldsymbol{z}\boldsymbol{z}^T GG^T = G(I + \beta G^T \boldsymbol{z}\boldsymbol{z}^T G)G^T.$$

We deduce immediately that $\mathrm{range}(X_{t+1}) \subseteq \mathrm{range}(G) = \mathrm{range}(X_t)$.

In order to prove that X_{t+1} is positive semidefinite and that the range space does not shrink, it suffices to show that all eigenvalues of $\beta G^T \boldsymbol{z}\boldsymbol{z}^T G$ are strictly larger than -1, implying that $I + \beta G^T \boldsymbol{z}\boldsymbol{z}^T G$ remains positive definite. The only non-zero eigenvalue of the rank-one $\beta G^T \boldsymbol{z}\boldsymbol{z}^T G$ equals $\mathrm{tr}(\beta G^T \boldsymbol{z}\boldsymbol{z}^T G) = \beta \boldsymbol{z}^T G G^T \boldsymbol{z} = \beta p$. According to (19) and (20) we calculate $\beta p = \frac{b}{p} - 1$, and noting that $b, p > 0$ completes the proof. ■

The update for X_{t+1} can alternatively be written using the pseudoinverse (Golub and Van Loan, 1996):

$$X_{t+1} = (X_t^\dagger - \alpha \tilde{A}_i)^\dagger,$$

where $\tilde{A}_i = WW^T A_i WW^T$ for an orthogonal matrix W satisfying $\mathrm{range}(W) = \mathrm{range}(X_t)$.[3]

Lemma 10 *Let $\tilde{A}_i = WW^T A_i WW^T$ and W be an orthogonal $n \times r$ matrix such that* $\mathrm{range}(W) = \mathrm{range}(X_t)$. *Then the following updates are equivalent:*

$$\begin{aligned} a)\ X_{t+1} &= W((W^T X_t W)^{-1} - \alpha(W^T A_i W))^{-1} W^T \\ b)\ X_{t+1} &= (X_t^\dagger - \alpha \tilde{A}_i)^\dagger \end{aligned}$$

Proof Since $\mathrm{range}(W) = \mathrm{range}(X_t)$, by Lemma 3 we have $\hat{X}_t = W^T X_t W$ and $X_t = W\hat{X}_t W^T$, where $\hat{X}_t$ is an invertible $r \times r$ matrix. Note that $W\hat{X}_t^{-1}W^T$ satisfies the properties required for the Moore-Penrose pseudoinverse, for example:

$$X_t(W\hat{X}_t^{-1}W^T)X_t = W\hat{X}_t W^T W \hat{X}_t^{-1} W^T W \hat{X}_t W^T = W\hat{X}_t W^T = X_t.$$

Thus $X_t^\dagger = W\hat{X}_t^{-1}W^T$ and we finish the proof by rewriting:

$$\begin{aligned} (X_t^\dagger - \alpha \tilde{A}_i)^\dagger &= (W\hat{X}_t^{-1}W^T - \alpha WW^T A_i WW^T)^\dagger = \left(W(\hat{X}_t^{-1} - \alpha W^T A_i W)W^T\right)^\dagger \\ &= W((W^T X_t W)^{-1} - \alpha(W^T A_i W))^{-1} W^T. \end{aligned}$$

■

5.1.2 UPDATE FOR THE FACTORED MATRIX

A naive implementation of the update given in (21) costs $O(n^2)$ operations per iteration. However, we can achieve a more efficient update for low-rank matrices by working on a suitable factored form of the matrix X_t resulting in an $O(r^2)$ algorithm. Both the reduced eigendecomposition and the Cholesky factorization are possible candidates for the factorization; we prefer the latter because the resulting algorithm does not have to rely on iterative methods.

The positive semidefinite rank-r matrix X_t can be factored as GG^T, where G is an $n \times r$ matrix, and thus the update can be written as:

$$X_{t+1} = G(I + \beta G^T \boldsymbol{z}\boldsymbol{z}^T G)G^T.$$

The matrix $I + \beta \tilde{\boldsymbol{z}}_i \tilde{\boldsymbol{z}}_i^T$, where $\tilde{\boldsymbol{z}}_i = G^T \boldsymbol{z}$, is an $r \times r$ matrix. To update G for the next iteration, we factor this matrix as LL^T; then our new G is updated to GL. Since $I + \beta \tilde{\boldsymbol{z}}_i \tilde{\boldsymbol{z}}_i^T$ is a rank-one

3. In Kulis et al. (2006), we had inadvertently used A_i instead of $\tilde{A}_i$.

Algorithm 1 CHOLUPDATEMULT(α, x, B). Right multiplication of a lower triangular $r \times r$ matrix B with the Cholesky factor of $I + \alpha \boldsymbol{x}\boldsymbol{x}^T$ in $O(r^2)$ time.

```
Input: $\alpha, \boldsymbol{x}, B$, with $I + \alpha \boldsymbol{x}\boldsymbol{x}^T \succeq 0$, $B$ is lower triangular
Output: $B \leftarrow BL$, with $LL^T = I + \alpha \boldsymbol{x}\boldsymbol{x}^T$
 1: $\alpha_1 = \alpha$
 2: for $i = 1$ to $r$ do
 3:     $t = 1 + \alpha_i x_i^2$
 4:     $h_i = \sqrt{t}$
 5:     $\alpha_{i+1} = \alpha_i / t$
 6:     $t = B_{ii}$
 7:     $s = 0$
 8:     $B_{ii} = B_{ii} h_i$
 9:     for $j = i - 1$ downto $1$ do
10:         $s = s + t x_{j+1}$
11:         $t = B_{ij}$
12:         $B_{ij} = (B_{ij} + \alpha_{j+1} x_j s) h_j$
13:     end for
14: end for
```

perturbation of the identity, this update can be done in $O(r^2)$ time using a standard Cholesky rank-one update routine.

To increase computational efficiency, we note that $G = G_0 B$, where B is the product of all the L matrices from every iteration and $X_0 = G_0 G_0^T$. Instead of updating G explicitly at each iteration, we simply update B to BL. The matrix $I + \beta G^T \boldsymbol{z}\boldsymbol{z}^T G$ is then $I + \beta B^T G_0^T \boldsymbol{z}\boldsymbol{z}^T G_0 B$. In the case of distance constraints, we can compute $G_0^T \boldsymbol{z}$ in $O(r)$ time as the difference of two rows of G_0. The multiplication update BL appears to have $O(r^3)$ complexity, dominating the run time. In the next section we derive an algorithm that combines the Cholesky rank-one update with the matrix multiplication into a single $O(r^2)$ routine.

5.1.3 FAST MULTIPLICATION WITH A CHOLESKY UPDATE FACTOR

We efficiently combine the Cholesky rank-one update with the matrix multiplication in CHOLUPDATEMULT given by Algorithm 1. A simple analysis of this algorithm reveals that it requires $3r^2 + 2r$ floating point operations (flops). This is opposed to the usual $O(r^3)$ time needed by matrix multiplication. We devote this section to the development of this fast multiplication algorithm.

Recall the algorithm used for the Cholesky factorization of an $r \times r$ matrix A (see Demmel, 1997, page 78):

```
for $j = 1$ to $r$ do
    $l_{jj} = (a_{jj} - \sum_{k=1}^{j-1} l_{jk}^2)^{1/2}$
    for $i = j + 1$ to $r$ do
        $l_{ij} = (a_{ij} - \sum_{k=1}^{j-1} l_{ik} l_{jk}) / l_{jj}$
    end for
end for
```

We will derive a corresponding algorithm in a manner similar to Demmel (1997), while exploiting the special structure present in our problem. Let us denote $I_r + \alpha_1 \boldsymbol{x}\boldsymbol{x}^T$ by A ($\alpha_1 = \alpha$) and write it as a product of three block matrices:

$$A = \begin{bmatrix} \sqrt{1+\alpha_1 x_1^2} & 0 \\ \frac{\alpha_1 x_1}{\sqrt{1+\alpha_1 x_1^2}}\boldsymbol{x}_{2:r} & I_{r-1} \end{bmatrix} \begin{bmatrix} 1 & 0 \\ 0 & \tilde{A}_{22} \end{bmatrix} \begin{bmatrix} \sqrt{1+\alpha_1 x_1^2} & \frac{\alpha_1 x_1}{\sqrt{1+\alpha_1 x_1^2}}\boldsymbol{x}_{2:r}^T \\ 0 & I_{r-1} \end{bmatrix}.$$

It follows that $\tilde{A}_{22} + \frac{\alpha_1^2 x_1^2}{1+\alpha_1 x_1^2}\boldsymbol{x}_{2:r}\boldsymbol{x}_{2:r}^T = A_{22} = I_{r-1} + \alpha_1 \boldsymbol{x}_{2:r}\boldsymbol{x}_{2:r}^T$, leading to:

$$\tilde{A}_{22} = I_{r-1} + \frac{\alpha_1}{1+\alpha_1 x_1^2}\boldsymbol{x}_{2:r}\boldsymbol{x}_{2:r}^T.$$

Introduce $\alpha_2 = \frac{\alpha_1}{1+\alpha_1 x_1^2}$ and proceed by induction. We extract the following algorithm which calculates L satisfying $LL^T = A$:

```
for $j = 1$ to $r$ do
    $t = 1 + \alpha_j x_j^2$
    $l_{jj} = \sqrt{t}$
    $\alpha_{j+1} = \alpha_j / t$
    $t = \alpha_j x_j / l_{jj}$
    for $i = j+1$ to $r$ do
        $l_{ij} = t x_i$
    end for
end for
```

The above algorithm uses $\frac{1}{2}r^2 + \frac{13}{2}r$ flops to calculate L, while $\frac{1}{2}r^3 + O(r^2)$ are needed for the general algorithm. However, we do not necessarily have to calculate L explicitly, since the parameters α_i together with $\boldsymbol{x}$ implicitly determine L. Notice that the cost of calculating $\alpha_1, \alpha_2, \ldots, \alpha_r$ is linear in r.

Next we show how to calculate $\boldsymbol{u}^T L$ for a given vector $\boldsymbol{u}$ without explicitly calculating L and arrive at an $O(r)$ algorithm for this vector-matrix multiplication. The elements of $\boldsymbol{v}^T = \boldsymbol{u}^T L$ are equal to:

$$\begin{aligned} v_1 &= u_1\sqrt{1+\alpha_1 x_1^2} + \frac{\alpha_2}{\sqrt{1+\alpha_1 x_1^2}} x_1(u_2x_2 + u_3x_3 + \ldots u_r x_r) \\ v_2 &= u_2\sqrt{1+\alpha_2 x_2^2} + \frac{\alpha_3}{\sqrt{1+\alpha_2 x_2^2}} x_2(u_3x_3 + \ldots u_r x_r) \\ &\vdots \\ v_{r-1} &= u_{r-1}\sqrt{1+\alpha_{r-1} x_{r-1}^2} + \frac{\alpha_r}{\sqrt{1+\alpha_{r-1} x_{r-1}^2}} x_{r-1} u_r x_r \\ v_r &= u_r\sqrt{1+\alpha_r x_r^2}. \end{aligned}$$

We can avoid the recalculation of some intermediate results if we evaluate v_r first, followed by v_{r-1} up to v_1. This strategy leads to the following algorithm:

Algorithm 2 Learning a low-rank kernel matrix in LogDet divergence under distance constraints.

```
Input: $G_0$: input kernel factor matrix, that is, $X_0 = G_0G_0^T$, $r$: desired rank, $\{A_i\}_{i=1}^c$: distance
    constraints, where $A_i = (e_{i_1} - e_{i_2})(e_{i_1} - e_{i_2})^T$
Output: $G$: output low-rank kernel factor matrix, that is, $X = GG^T$
 1: Set $B = I_r$, $i = 1$, and $\nu_j = 0$ $\forall$ constraints $j$.
 2: repeat
 3:     $\boldsymbol{v}^T = G_0(i_1,:) - G_0(i_2,:)$
 4:     $\boldsymbol{w} = B^T\boldsymbol{v}$
 5:     $\alpha = \min\left(\nu_i, \frac{1}{\|\boldsymbol{w}\|_2^2} - \frac{1}{b_i}\right)$
 6:     $\nu_i \leftarrow \nu_i - \alpha$
 7:     $\beta = \alpha/(1 - \alpha\|\boldsymbol{w}\|_2^2)$
 8:     Call CHOLUPDATEMULT$(\beta, \boldsymbol{w}, B)$ to factor $I + \beta\boldsymbol{w}\boldsymbol{w}^T = LL^T$ and update $B \leftarrow BL$.
 9:     Set $i \leftarrow \mathrm{mod}(i+1, c)$.
10: until convergence of $\nu$
11: return $G = G_0B$
```

```
$v_r = u_r\sqrt{1 + \alpha_r x_r^2}$
s = 0;
for $j = r - 1$ downto 1 do
    $s = s + u_{j+1}x_{j+1}$
    $t = \sqrt{1 + \alpha_j x_j^2}$
    $v_j = u_j t + \alpha_{j+1}x_j s/t$
end for
```

Exactly $11r - 6$ flops are required by the above algorithm, and therefore we can readily multiply an $r \times r$ matrix by L using $11r^2 - 6r$ flops. Even fewer flops are sufficient to implement the matrix multiplication if we observe that the square root expression above is repeatedly calculated for each row, since it depends only on x_j and α_j. Additionally, when multiplying with a lower triangular matrix, the presence of zeros allows further simplifications. Taking these considerations into account we arrive at the previously presented Algorithm 1, which uses exactly $3r^2 + 2r$ flops.

5.1.4 KERNEL LEARNING ALGORITHM

We are now ready to present the overall algorithm for distance inequality constraints using the LogDet divergence, see Algorithm 2. As discussed in the previous section, every projection can be done in $O(r^2)$ time. Thus, cycling through all c constraints requires $O(cr^2)$ time, but the total number of Bregman iterations may be large. The only dependence on the number of data points n occurs in steps 3 and 11. The last step, multiplying $G = G_0B$, takes $O(nr^2)$ time.

As discussed earlier, convergence is guaranteed since we have mapped the original low-rank problem into a full-rank problem in a lower-dimensional space. Convergence can be checked by using the dual variables ν. The cyclic projection algorithm can be viewed as a dual coordinate ascent algorithm, thus convergence can be measured as follows: after cycling through all constraints, we check to see how much ν has changed after a full cycle. At convergence, this change (as measured with a vector norm) should be small.

5.2 Von Neumann Divergence

In this section we develop a cyclic projection algorithm to solve (5) when the matrix divergence is the von Neumann divergence.

5.2.1 MATRIX UPDATES

Consider minimizing $D_{vN}(X,X_0)$, the von Neumann divergence between X and X_0. Recall the projection update (15) for constraint i:

$$X_{t+1} = V_t \exp(\log(\Lambda_t) + \alpha V_t^T \boldsymbol{z}\boldsymbol{z}^T V_t) V_t^T.$$

If the eigendecomposition of the exponent $\log(\Lambda_t) + \alpha V_t^T \boldsymbol{z}\boldsymbol{z}^T V_t$ is $U_t \Theta_{t+1} U_t^T$, then the eigendecomposition of X_{t+1} is given by $V_{t+1} = V_t U_t$ and $\Lambda_{t+1} = \exp(\Theta_{t+1})$. This special eigenvalue problem (diagonal plus rank one update) can be solved in $O(r^2)$ time; see Golub (1973), Gu and Eisenstat (1994) and Demmel (1997). This means that the matrix multiplication $V_{t+1} = V_t U_t$ becomes the most expensive step in the computation, yielding $O(nr^2)$ complexity.

We reduce this cost by modifying the decomposition slightly. Let $X_t = V_t W_t \Lambda_t W_t^T V_t^T$ be the factorization of X_t, where W_t is an $r \times r$ orthogonal matrix, initially $W_0 = I_r$, while V_t and Λ_t are defined as before. The matrix update becomes

$$X_{t+1} = V_t W_t \exp(\log \Lambda_t + \alpha W_t^T V_t^T \boldsymbol{z}\boldsymbol{z}^T V_t W_t) W_t^T V_t^T,$$

yielding the following formulae:

$$V_{t+1} = V_t,\ W_{t+1} = W_t U_t,\ \Lambda_{t+1} = \exp(\Theta_{t+1}),$$

where $\log \Lambda_t + \alpha W_t^T V_t^T \boldsymbol{z}\boldsymbol{z}^T V_t W_t = U_t \Theta_{t+1} U_t^T$. For a general rank-one constraint the product $V_t^T \boldsymbol{z}$ is calculated in $O(nr)$ time, but for distance constraints $O(r)$ operations are sufficient. The calculation of $W_t^T V_t^T \boldsymbol{z}$ and computing the eigendecomposition $U_t \Theta_{t+1} U_t^T$ will both take $O(r^2)$ time. The matrix product $W_t U_t$ appears to cost $O(r^3)$ time, but in fact a right multiplication by U_t^T can be approximated very accurately in $O(r^2 \log r)$ and even in $O(r^2)$ time using the fast multipole method—see Barnes and Hut (1986) and Greengard and Rokhlin (1987).

Since we repeat the above update calculations until convergence, we can avoid calculating the logarithm of Λ_t at every step by maintaining $\Theta_t = \log \Lambda_t$ throughout the algorithm.

5.2.2 COMPUTING THE PROJECTION PARAMETER

In the previous section, we assumed that the projection parameter α has already been calculated. In contrast to the LogDet divergence, this parameter does not have a closed form solution. Instead, we must compute α by solving the nonlinear system of equations given by (7).

In the von Neumann case and in the presence of distance constraints, the problem amounts to finding the unique root of the function

$$f(\alpha) = \boldsymbol{z}^T V_t W_t \exp(\Theta_t + \alpha W_t^T V_t^T \boldsymbol{z}\boldsymbol{z}^T V_t W_t) W_t^T V_t^T \boldsymbol{z} - b.$$

It can be shown that $f(\alpha)$ is monotone in α, see Sustik and Dhillon (2008).

Using the approach from the previous section, $f(\alpha)$ can be computed in $O(r^2)$ time. One natural choice to find the root of $f(\alpha)$ is to apply Brent's general root finding method (Brent, 1973),

Algorithm 3 Learning a low-rank kernel matrix in von Neumann matrix divergence under distance constraints.

```
Input: $V_0, \Lambda_0$: input kernel factors, i. e., $X_0 = V_0\Lambda_0V_0^T$, $r$: rank of desired kernel matrix, $\{A_i\}_{i=1}^c$:
    distance constraints, where $A_i = (e_{i_1} - e_{i_2})(e_{i_1} - e_{i_2})^T$
Output: $V, \Lambda$: output low-rank kernel factors, i. e., $X = V\Lambda V^T$
1: Set $W = I_r$, $\Theta = \log\Lambda_0$, $i = 1$, and $\nu_j = 0$ $\forall$ constraints $j$.
2: repeat
3:     $\boldsymbol{v}^T = V_0(i_1,:) - V_0(i_2,:)$
4:     $\boldsymbol{w} = W^T\boldsymbol{v}$
5:     Call ZEROFINDER$(\Theta, \boldsymbol{w}, b_i)$ to determine $\alpha$.
6:     $\beta = \min(\nu_i, \alpha)$
7:     $\nu_i \leftarrow \nu_i - \beta$.
8:     Compute eigendecomposition of $\Theta + \beta\boldsymbol{w}\boldsymbol{w}^T = U\tilde{\Theta}U^T$, $\Theta \leftarrow \tilde{\Theta}$.
9:     Update $W \leftarrow WU$.
10:    $i = \mod(i+1, c)$
11: until convergence of $\nu$
12: return $V = V_0W$, $\Lambda = \exp(\Theta)$
```

which does not need the calculation of the derivative of $f(\alpha)$. We have built an even more efficient custom root finder that is optimized for this problem. We rarely need more than six evaluations per projection to accurately compute α. A more detailed description of our root finder is beyond the scope of this paper, see Sustik and Dhillon (2008) for details.

5.2.3 KERNEL LEARNING ALGORITHM

The algorithm for distance inequality constraints using the von Neumann divergence is given as Algorithm 3. By using the fast multipole method every projection can be done in $O(r^2)$ time. Note that the asymptotic running time of this algorithm is the same as the LogDet divergence algorithm, although the root finding step makes Algorithm 3 slightly slower than Algorithm 2.

5.3 Limitations of our Approach

We conclude this section by briefly mentioning some limitations of our approach. First, though we are able to learn low-rank kernel matrices in our framework, the initial kernel matrix must be low-rank. As a result, we cannot use our methods to reduce the dimensionality of our data. Secondly, the method of Bregman projections may require iterating many cycles through all constraints to reach convergence. Although we have heavily optimized each iteration in this paper, it may be beneficial to search for an algorithm with faster convergence.

6. Discussion

We now further develop several aspects of the algorithms presented in the previous section. In particular, we discuss ways to move beyond the transductive setting in our framework for learning kernels, we briefly overview some generalizations of the problem formulation, we highlight how special cases of our method are related to existing techniques, and we briefly analyze connections between our approach and semidefinite programming.

6.1 Handling New Data Points

The kernel learning algorithms of Section 5 are restricted to learning in the transductive setting; that is, we assume that we have all the data points up front, but labels or other forms of supervision are only available for some of the data points. This approach suffers when new, unseen data points are added, since this would require re-learning the entire kernel matrix.

Though we do not consider this situation in depth in the current paper, we can circumvent it. When learning a kernel matrix minimizing either the LogDet divergence or the von Neumann divergence, the range space restriction implies that the learned kernel K has the form $K = G_0 B B^T G_0^T$, where B is $r \times r$ and the input kernel is $K_0 = G_0 G_0^T$. We can view the matrix B as a linear transformation applied to our input data vectors G_0 and therefore we can apply this linear transformation to new points. In particular, recent work (Davis et al., 2007) has shown that the learning algorithms considered in this paper can equivalently be viewed as learning a *Mahalanobis distance function* given constraints on the data, which is simply the Euclidean distance after applying a linear transformation over the input data.

Since our algorithms can be viewed as Mahalanobis distance learning techniques, it is natural to compare against other existing metric learning algorithms. Such methods include metric learning by collapsing classes (MCML) (Globerson and Roweis, 2005), large-margin nearest neighbor metric learning (LMNN) (Weinberger et al., 2005), and many others. In the experimental results section, we provide some results comparing our algorithms with these existing methods.

6.2 Generalizations

There are several simple ways to extend the algorithms developed in Section 5. In this section, we introduce slack variables and discuss more general constraints than the distance constraints discussed earlier.

6.2.1 SLACK VARIABLES

In many cases, especially if the number of constraints is large, no feasible solution will exist to the Bregman divergence optimization problem given in (4). When no feasible solution exists, a common approach is to incorporate *slack variables*, which allows constraints to be violated but penalizes such violations.

There are many ways to introduce slack variables into the optimization problem (4). We add a new vector variable $\boldsymbol{b}$ with coordinates representing perturbed right hand sides of the linear constraints, and use the corresponding vector divergence to measure the deviation from the original constraints described by the input vector $\boldsymbol{b}_0$. The resulting optimization problem is as follows:

$$\begin{aligned} \text{minimize}_{X,\boldsymbol{b}} \quad & D_\phi(X, X_0) + \gamma D_\varphi(\boldsymbol{b}, \boldsymbol{b}_0) \\ \text{subject to} \quad & \operatorname{tr}(XA_i) \leq \boldsymbol{e}_i^T \boldsymbol{b},\ 1 \leq i \leq c \\ & X \succeq 0. \end{aligned} \tag{22}$$

Note that we use $D_\varphi(\boldsymbol{b}, \boldsymbol{b}_0)$ as the penalty for constraints as it is computationally simple; other choices of constraint penalty are possible, as long as the resulting objective function is convex.

The $\gamma > 0$ parameter governs the tradeoff between satisfying the constraints and minimizing the divergence between X and X_0. Note that we have also removed the implicit rank constraint for simplicity.

We form the Lagrangian to solve the above problem; recall the similar system of equations (7) in Section 3.4. Define $\mathcal{L}(X_{t+1}, \boldsymbol{b}_{t+1}, \alpha_i) = D_\phi(X_{t+1}, X_t) + \gamma D_\varphi(\boldsymbol{b}_{t+1}, \boldsymbol{b}_t) + \alpha_i(\boldsymbol{e}_i^T \boldsymbol{b}_{t+1} - \operatorname{tr}(X_{t+1}A_i))$, and set the gradients to zero with respect to X_{t+1}, $\boldsymbol{b}_{t+1}$ and α_i to get the following update equations:

$$\begin{aligned} \nabla\phi(X_{t+1}) &= \nabla\phi(X_t) + \alpha_i A_i, \\ \nabla\varphi(\boldsymbol{b}_{t+1}) &= \nabla\varphi(\boldsymbol{b}_t) - \frac{\alpha_i}{\gamma}\boldsymbol{e}_i, \\ \operatorname{tr}(X_{t+1}A_i) &= \boldsymbol{e}_i^T \boldsymbol{b}_{t+1}. \end{aligned} \tag{23}$$

In particular, for the LogDet divergence we arrive at the following updates:

$$X_{t+1}^{-1} = X_t^{-1} - \alpha_i A_i, \quad \boldsymbol{e}_i^T \boldsymbol{b}_{t+1} = \frac{\gamma \boldsymbol{e}_i^T \boldsymbol{b}_t}{\gamma + \alpha_i \boldsymbol{e}_i^T \boldsymbol{b}_t}, \quad \operatorname{tr}(X_{t+1}A_i) - \boldsymbol{e}_i^T \boldsymbol{b}_{t+1} = 0.$$

Assuming $A_i = \boldsymbol{z}_i \boldsymbol{z}_i^T$, we can still compute α_i in closed form as

$$\alpha_i = \frac{\gamma}{\gamma+1}\left(\frac{1}{p} - \frac{1}{b_i}\right), \text{ where } p = \boldsymbol{z}_i^T X_t \boldsymbol{z}_i, b_i = \boldsymbol{e}_i^T \boldsymbol{b}_t.$$

The ith element of $\boldsymbol{b}_t$ is updated to $\gamma b_i/(\gamma + \alpha_i b_i)$ and the matrix update is calculated as in the non-slack case.

In case of the von Neumann divergence the update rules turn out to be:

$$\log X_{t+1} = \log X_t + \alpha_i A_i, \quad \boldsymbol{e}_i^T \boldsymbol{b}_{t+1} = \boldsymbol{e}_i^T \boldsymbol{b}_t e^{-\frac{\alpha_i}{\gamma}}, \quad \operatorname{tr}(X_{t+1}A_i) - \boldsymbol{e}_i^T \boldsymbol{b}_{t+1} = 0.$$

The projection parameter α_i is not available in closed form, instead we calculate it as the root of the non-linear equation:

$$\log \operatorname{tr}(\exp(\log X_t + \alpha_i A_i)A_i) + \frac{\alpha_i}{\gamma} - \log \boldsymbol{e}_i^T \boldsymbol{b}_t = 0.$$

The scale invariance of the LogDet divergence implies that $D_{\ell d}(\boldsymbol{b}, \boldsymbol{b_0}) = D_{\ell d}(\boldsymbol{b}/\boldsymbol{b_0}, \mathbf{1})$ where the division is elementwise and therefore we implicitly measure "relative" error, that is the magnitude of the coordinates of vector $\boldsymbol{b}_0$ are naturally taken into account. For the von Neumann divergence scale invariance does not hold, but one may alternatively use $D_{vN}(\boldsymbol{b}/\boldsymbol{b_0}, \mathbf{1})$ as the penalty function.

6.2.2 OTHER CONSTRAINTS

In earlier sections, we focused on the case of distance constraints. We now briefly discuss generalizing to other constraints.

When the constraints are similarity constraints (i.e., $K_{jl} \leq b_i$), the updates can be easily modified. As discussed earlier, we must retain symmetry of the A_i constraint matrices, so for similarity constraints, we require $A_i = \frac{1}{2}(\boldsymbol{e}_j \boldsymbol{e}_l^T + \boldsymbol{e}_l \boldsymbol{e}_j^T)$. Notice that the constraint matrix now has rank two. This complicates the algorithms slightly; for example, with the LogDet divergence, the Sherman-Morrison formula must be applied twice, leading to a more complicated update rule (albeit one that still has a closed-form solution and can be computed in $O(r^2)$ time).

Other constraints are possible as well; for example, one could incorporate distance constraints such as $\|\boldsymbol{a}_j - \boldsymbol{a}_k\|_2^2 \leq \|\boldsymbol{a}_l - \boldsymbol{a}_m\|_2^2$, or further similarity constraints such as $K_{jk} \leq K_{lm}$. These are sometimes referred to as relative comparison constraints, and are useful in ranking algorithms (Schultz and Joachims, 2003); for these also, the cost per projection remains $O(r^2)$. Finally, arbitrary linear constraints can also be applied, the cost per projection update will then be $O(nr)$.

6.3 Special Cases

If we use the von Neumann divergence, let $r = n$, and set $b_i = 0$ for all constraints, we exactly obtain the DefiniteBoost optimization problem from Tsuda et al. (2005). In this case, our algorithm computes the projection update in $O(n^2)$ time. In contrast, the algorithm from Tsuda et al. (2005) computes the projection in a more expensive manner in $O(n^3)$ time. Another difference with our approach is that we compute the exact projection, whereas Tsuda et al. (2005) compute an approximate projection. Though computing an approximate projection may lead to a faster per-iteration cost, it takes many more iterations to converge to the optimal solution. We illustrate this further in the experimental results section.

The online-PCA problem discussed in Warmuth and Kuzmin (2006) employs a similar update based on the von Neumann divergence. As with the DefiniteBoost algorithm, the projection is not an exact Bregman projection; however, the projection can be computed in the same way as in our von Neumann kernel learning projection. As a result, the cost of an iteration of online-PCA can be improved from $O(n^3)$ to $O(n^2)$ with our approach.

Another special case is the *nearest correlation matrix* problem (Higham, 2002) that arises in financial applications. A correlation matrix is a positive semidefinite matrix with unit diagonal. For this case, we set the constraints to be $K_{ii} = 1$ for all i. Our algorithms from this paper give new divergence measures and methods for finding low-rank correlation matrices. Previous algorithms scale cubically in n, whereas our method scales linearly with n and quadratically with r for low-rank correlation matrices.

Our formulation can also be employed to solve a problem similar to that of Weinberger et al. (2004). The enforced constraints on the kernel matrix (centering and isometry) are linear, and thus can be encoded into our framework. The only difference is that Weinberger et al. maximize the trace of K, whereas we minimize a matrix divergence. Comparisons between these approaches is a potential area of future research.

6.4 Connections to Semidefinite Programming

In this section, we present a connection between minimizing the LogDet divergence and the solution to a semidefinite programming problem (SDP). As an example, we consider the min-balanced-cut problem.

Suppose we are given an n-vertex graph, whose adjacency matrix is A. Let $L = \text{diag}(A\boldsymbol{e}) - A$ be the Laplacian of A, where $\boldsymbol{e}$ is the vector of all ones. The semidefinite relaxation to the minimum balanced cut problem (Lang, 2005) results in the following SDP:

$$\begin{array}{rl}\min_X & \mathrm{tr}(LX) \\ \text{subject to} & \mathrm{diag}(X) = \boldsymbol{e} \\ & \mathrm{tr}(X\boldsymbol{e}\boldsymbol{e}^T) = 0 \\ & X \succeq 0.\end{array}$$

Let $L^\dagger$ denote the pseudoinverse of the Laplacian, and let V be an orthonormal basis for the range space of L. Let r denote the rank of L; it is well known that $n-r$ equals the number of connected components of the graph. Consider the LogDet divergence between X and $\varepsilon L^\dagger$:

$$\begin{aligned}D_{\ell d}(X, \varepsilon L^\dagger) &= D_{\ell d}(V^TXV, V^T(\varepsilon L^\dagger)V) \\ &= \mathrm{tr}(V^TXV(V^T(\varepsilon L^\dagger)V)^{-1}) - \log\det(V^TXV(V^T(\varepsilon L^\dagger)V)^{-1}) - r \\ &= \mathrm{tr}\left(V^TXV\left(\frac{1}{\varepsilon}V^TLV\right)\right) - \log\det\left(V^TXV\left(\frac{1}{\varepsilon}V^TLV\right)\right) - r \\ &= \frac{1}{\varepsilon}\mathrm{tr}(LX) - \log\det\left(\frac{1}{\varepsilon}V^TXVV^TLV\right) - r \\ &= \frac{1}{\varepsilon}\mathrm{tr}(LX) - \log\det(V^TXVV^TLV) - r - \log(\varepsilon^{-r}).\end{aligned}$$

The fourth line uses Lemma 8 to replace $\mathrm{tr}(V^TXV(\frac{1}{\varepsilon}V^TLV))$ with $\frac{1}{\varepsilon}\mathrm{tr}(LX)$. If we aim to minimize this divergence, we can drop the last two terms, as they are constants. In this case, we have:

$$\begin{aligned}\mathrm{argmin}_X D_{\ell d}(X, \varepsilon L^\dagger) &= \mathrm{argmin}_X \frac{1}{\varepsilon}\mathrm{tr}(LX) - \log\det(V^TXVV^TLV) \\ &= \mathrm{argmin}_X\, \mathrm{tr}(LX) - \varepsilon\log\det(V^TXVV^TLV).\end{aligned}$$

As ε becomes small, the $\mathrm{tr}(LX)$ term dominates the objective function.

Now consider the constraints from the min balanced cut SDP. The $\mathrm{diag}(X) = \boldsymbol{e}$ constraint is exactly the constraint from the nearest correlation matrix problem (that is, $X_{ii} = 1$ for all i). The $X \succeq 0$ constraint is implicitly satisfied when LogDet is used, leaving the balancing constraint $\boldsymbol{e}^TX\boldsymbol{e} = 0$. Recall that $\mathrm{null}(X) = \mathrm{null}(L^\dagger)$, and from standard spectral graph theory, that $L\boldsymbol{e} = 0$. Therefore $L^\dagger\boldsymbol{e} = 0$, which further implies

$$\boldsymbol{e}^TL^\dagger\boldsymbol{e} = 0 \Rightarrow \boldsymbol{e}^TX\boldsymbol{e} = 0$$

by the fact that the LogDet divergence preserves the range space of $L^\dagger$. Thus, the null space restriction in LogDet divergence naturally yields the constraint $\boldsymbol{e}^TX\boldsymbol{e} = 0$ and so the min balanced cut SDP problem on A is equivalent (for sufficiently small ε) to finding the nearest correlation matrix to $\varepsilon L^\dagger$ under the LogDet divergence.

Many other semidefinite programming problems can be solved in a similar manner to the one given above for the min balanced cut problem. It is beyond the scope of this paper to determine the practicality of such an optimization method; our aim here is simply to demonstrate an intriguing relationship between semidefinite programming and minimizing the LogDet divergence. For further information on this relationship, see Kulis et al. (2007a).

6.5 Changing the Range Space

The key property of the LogDet and von Neumann divergences which allow the algorithms to learn low-rank kernel matrices is their range space preservation property, discussed in Section 4. While this property leads to efficient algorithms for learning low-rank kernel matrices, it also forces the learned matrices to maintain the range space of the input matrix, which is a limitation of our method.

Allowing the range space to change is potentially a very useful tool, but is still an open research question. One possibility worth exploring is to augment the input matrix X_0 with a matrix capturing the complementary space, that is, the input would be $X_0 + \varepsilon N$, where N captures the null space of X_0. Even if there does not exist a solution to the optimization problem of minimizing $D_\phi(X, X_0)$, there is always a solution to minimizing $D_\phi(X, X_0 + \varepsilon N)$. Details of this approach are to be pursued as future work.

A related approach to circumvent this problem is to apply an appropriate kernel function over the input data, the result of which is that the algorithm learns a non-linear transformation of the data over the input space. Recently, Davis et al. (2007) discussed how one can generalize to new data points with the LogDet divergence even after applying such a kernel function, making this approach practical in many situations.

7. Experiments

In this section, we present a number of results using our algorithms, and provide references to recent work which has applied our algorithms to large-scale learning tasks. We first begin with the basic algorithm, and present results on transductive learning—the scenario where all data is provided upfront but labels are available for only a subset of the data—and clustering. We then discuss some results comparing our methods to existing metric learning algorithms.

We run the kernel learning algorithms in MATLAB, with some routines written in C and compiled with the MEX compiler. An efficient implementation of the special matrix multiplication appearing in step 9 of Algorithm 3 could achieve further run-time improvements. Unfortunately, an efficient and accurate implementation—based on the fast multipole method—is not readily available.

7.1 Transductive Learning and Clustering Results

To show the effectiveness of our algorithms, we present results from clustering as well as classification. We consider several data sets from real-life applications:

1. `Digits:` a subset of the *Pendigits* data from the UCI repository that contains handwritten samples of the digits 3, 8, and 9. The raw data for each digit is 16-dimensional; this subset contains 317 digits and is a standard data set for semi-supervised clustering (e.g., see, Bilenko et al., 2004).

2. `GyrB:` a protein data set: a 52×52 kernel matrix among bacteria proteins, containing three bacteria species. This matrix is identical to the one used to test the DefiniteBoost algorithm in Tsuda et al. (2005).

3. `Spambase:` a data set from the UCI repository containing 4601 email messages, classified as spam or not spam—1813 of the emails are spam (39.4 percent). This data has 57 attributes.

4. `Nursery:` data set developed to rank applications for nursery schools. This set contains 12960 instances with 8 attributes, and 5 class labels.

For classification, we compute accuracy using a k-nearest neighbor classifier ($k = 5$) that computes distance in the feature space, with a 50/50 training/test split and two-fold cross validation. Our results are averaged over 20 runs. For clustering, we use the kernel k-means algorithm and compute accuracy using the Normalized Mutual Information (NMI) measure, a standard technique for determining quality of clusters, which measures the amount of statistical information shared by the random variables representing the cluster and class distributions (Strehl et al., 2000). If C is the random variable denoting the cluster assignments of the points, and K is the random variable denoting the underlying class labels on the points then the NMI measure is defined as:

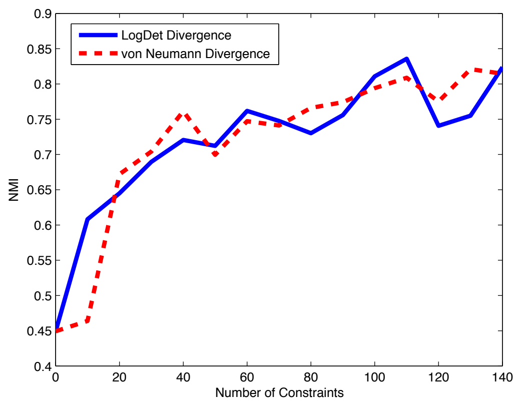
$$NMI = \frac{I(C;K)}{(H(C)+H(K))/2}$$

where $I(X;Y) = H(X) - H(X|Y)$ is the mutual information between the random variables X and Y, $H(X)$ is the Shannon entropy of X, and $H(X|Y)$ is the conditional entropy of X given Y (Cover and Thomas, 1991). The normalization by the average entropy of C and K makes the value of NMI stay between 0 and 1.

We consider two different experiments, each with their own constraint selection procedure. One experiment is to learn a kernel matrix *only using constraints*. In this case, we generate constraints from some target kernel matrix, and judge performance on the learned kernel matrix as we provide an increasing number of constraints. This setup was employed for the `GyrB` data set allowing us to compare to the methods and results of Tsuda et al. (2005). Constraints were generated randomly as follows: two data points are chosen at random and a distance constraint is constructed as follows. If the data points are in the same class, the constraint is of the form $d(i, j) \leq b$, where b is the corresponding distance between points i and j from the original kernel matrix, and if the data points are from different classes, then the constraint is of the form $d(i, j) \geq b$.

For the remaining data sets, we were interested in adding supervised class information to *improve* an existing low-rank kernel matrix. In this case, we took our initial low-rank kernel to be a linear kernel over the original data matrix and we added constraints of the form $d(i, j) \leq (1-\varepsilon)b$ for same class pairs and $d(i, j) \geq (1+\varepsilon)b$ for different class pairs (b is the original distance and $\varepsilon = .25$). This is very similar to "idealizing" the kernel, as in Kwok and Tsang (2003). Our convergence tolerance was set to 10^{-3}, and we incorporated slack variables for the larger data sets `Spambase` and `Nursery` (the smaller data sets did not require slack variables to converge). Note that there are other methods for choosing constraints; for example, instead of using $(1-\varepsilon)b$ for the right-hand side for same class pairs, one could instead choose a global value u for all same class constraints (and analogously for different class pairs).

We first show that the low-rank kernels learned by our algorithms attain good clustering and classification accuracies. We ran our algorithms on the `Digits` data set to learn a rank-16 kernel matrix using randomly generated constraints. The Gram matrix of the original `Digits` data was used as our initial (rank-16) kernel matrix. The left plot of Figure 1 shows clustering NMI values with increasing constraints. Adding just a few constraints improves the results significantly, and both of the kernel learning algorithms perform comparably. Classification accuracy using the k-nearest neighbor method was also computed for this data set: marginal classification accuracy gains were observed with the addition of constraints (an increase from 94 to 97 percent accuracy for



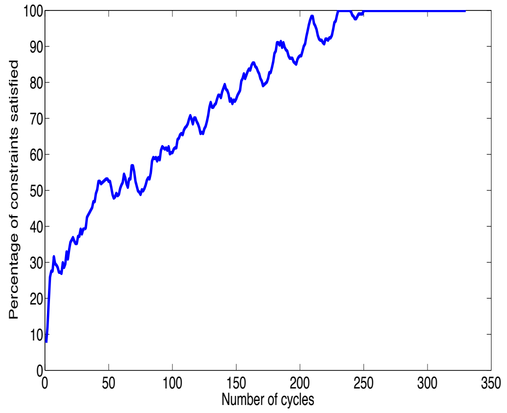


Figure 1: (Left) Normalized Mutual Information results of clustering the `Digits` data set—both algorithms improve with a small number of constraints (Right) Percentage of constraints satisfied (to a tolerance of 10^{-3}) in Bregman's algorithm as a function of the number of cycles, using the LogDet divergence

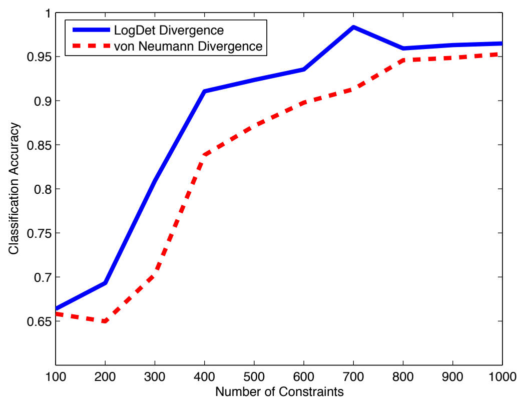

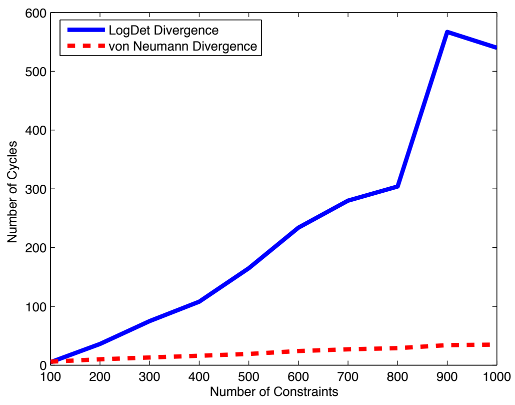

Figure 2: Classification accuracy (left) and convergence (right) on the `GyrB` data set

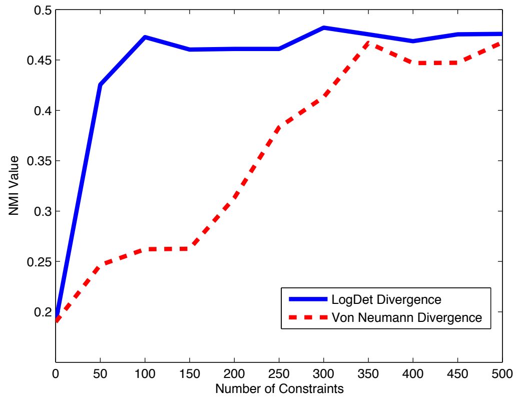
both divergences). We also recorded convergence data on `Digits` in terms of the number of cycles through all constraints; for the von Neumann divergence, convergence was attained in 11 cycles for 30 constraints and in 105 cycles for 420 constraints, while for the LogDet divergence, between 17 and 354 cycles were needed for convergence. This experiment highlights how our algorithm can use constraints to learn a low-rank kernel matrix. It is noteworthy that the learned kernel performs better than the original kernel for clustering as well as classification. Furthermore, in the right plot of Figure 1, we plot the number of constraints satisfied within a tolerance of 10^{-3} (300 total constraints) as a function of the number of cycles through all constraints, when using the LogDet divergence. Similar results are obtained with the von Neumann divergence. The number of cycles required for convergence to high accuracy can potentially be large, but for typical machine learning tasks, high accuracy solutions are not necessary and low to medium accuracy solutions can be achieved much faster.



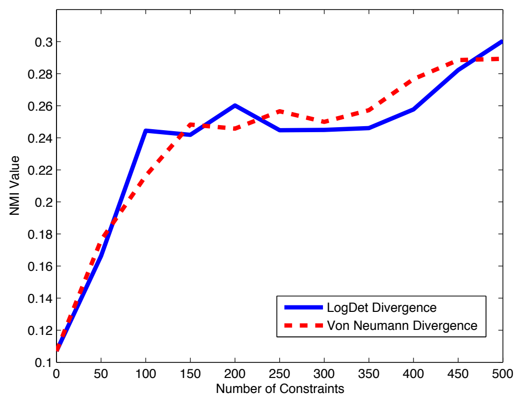


Figure 3: Clustering accuracy on `Spambase` (left) and `Nursery` (right)

As a second experiment, we performed experiments on `GyrB` and comparisons to the DefiniteBoost algorithm of Tsuda et al. (2005) (modified to correctly handle inequality constraints). Using only constraints, we attempt to learn a kernel matrix that achieves high classification accuracy. In order to compare to DefiniteBoost, we learned a full-rank kernel matrix starting from the scaled identity matrix as in Tsuda et al. (2005). In our experiments, we observed that using approximate projections—as done in DefiniteBoost—considerably increases the number of cycles needed for convergence. For example, starting with the scaled identity as the initial kernel matrix and 100 constraints, it took our von Neumann algorithm only 11 cycles to converge, whereas it took 3220 cycles for the DefiniteBoost algorithm to converge. Since the optimal solutions are the same for approximate versus exact projections, we converge to the same kernel matrix as DefiniteBoost but in far fewer iterations. Furthermore, our algorithm has the ability to learn low-rank kernels (as in the case of the `Digits` example). Figure 2 depicts the classification accuracy and convergence of our LogDet and von Neumann algorithms on this data set. The slow convergence of the DefiniteBoost algorithm did not allow us to run it with a larger set of constraints. For the LogDet and the von Neumann exact projection algorithms, the number of cycles required for convergence never exceeded 600 on runs of up to 1000 constraints on `GyrB`. The classification accuracy on the original matrix is .948, and so our learned kernels achieve even higher accuracy than the target kernel with a sufficient number of constraints. These results highlight that excellent classification accuracy can be obtained using a kernel that is learned using only distance constraints. Note that the starting kernel was the identity matrix, and so did not encode any domain information.

On the larger data sets `Spambase` and `Nursery`, we found similar improvements in clustering accuracy while learning rank-57 and rank-8 kernel matrices, respectively, using the same setup as in the `Digits` experiment. Figures 3 and 4 show the clustering accuracy and convergence on these data sets. Note that both data sets are too large for DefiniteBoost to handle, and furthermore, storing the full kernel matrix would require significant memory overhead (for example, MATLAB runs out of memory while attempting to store the full kernel matrix for `Nursery`); this scenario highlights the memory overhead advantage of using low-rank kernels. We see that on the `Spambase` data set, the LogDet divergence algorithm produces clustering accuracy improvements with very little supervision, but the number of cycles to converge is much larger than the von Neumann algorithm (for 500 constraints, the von Neumann algorithm requires only 29 cycles to converge). The slower

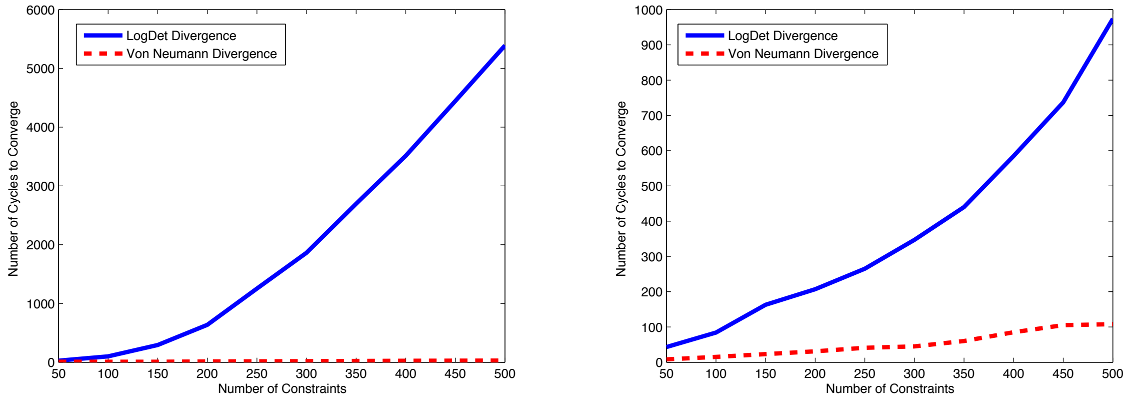

Figure 4: Convergence on `Spambase` (left) and `Nursery` (right)

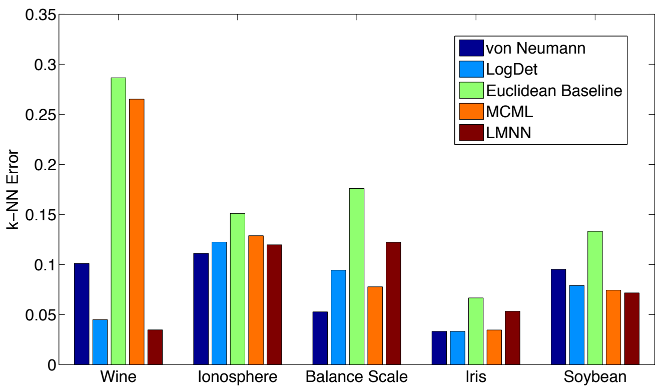

Figure 5: Classification error rates for *k*-nearest neighbor classification via different learned metrics over UCI data sets. The von Neumann and LogDet algorithms are competitive with existing state of the art metric learning methods, and significantly outperform the baseline.

convergence of the LogDet divergence algorithm is a topic of future work—note, however, that even though the number of cycles for LogDet to converge is higher than for von Neumann, the overall running time is often lower due to the efficiency of each LogDet iteration and the lack of a suitable implementation of the fast multiple method. On the `Nursery` data set, both algorithms perform similarly in terms of clustering accuracy, and the discrepancy in terms of cycles to converge between the algorithms is less drastic. We stress that other methods for learning kernel matrices, such as using the squared Frobenius norm in place of the LogDet or von Neumann divergences, would lead to learning full-rank matrices and would require significantly more memory and computational resources.

7.2 Metric Learning and Large-Scale Experiments

We now move beyond the transductive setting in order to compare with existing metric learning algorithms. As briefly discussed in Section 6.1, learning a low-rank kernel with the same range space as the input kernel is equivalent to learning a linear transformation of the input data, so we now compare against some existing methods for learning linear transformations. In particular, we compare against two popular Mahalanobis metric learning algorithms: metric learning by collapsing classes (MCML) (Globerson and Roweis, 2005) and large-margin nearest neighbor metric learning (LMNN) (Weinberger et al., 2005). As a baseline, we consider the squared Euclidean distance.

For each data set, we use two-fold cross validation to learn a linear transformation of our training data. This transformation is used in a k-nearest neighbor classifier on our test data, and the resulting error is reported. For the LogDet and von Neumann algorithms, we cross-validate the γ parameter and use the constraint selection procedure described in Davis et al. (2007). In particular, we generate constraints of the form $d(i,j) \leq u$ for same-class pairs and $d(i,j) \geq \ell$ for different-class pairs, where u and ℓ are chosen based on the 5th and 95th percentile of all distances in the training data. We randomly choose $40c^2$ constraints, where c is the number of classes in the data.

We ran on a number of standard UCI data sets to compare with existing methods. In Figure 5, we display k-NN accuracy ($k = 4$) over five data sets. Overall, we see that both the LogDet and von Neumann algorithms compare favorably with existing methods.

In terms of large-scale experiments, we also ran on the MNIST data set, a handwritten digits data set. This data has 60,000 training points and 10,000 test points. After deskewing the images and performing dimensionality reduction to the first 100 principal components of MNIST, we ran our methods successfully with 10,000 and 100,000 constraints, chosen as in the metric learning experiments above. The baseline error for a 1-nearest neighbor search over the top 100 principal components after deskewing is 2.35%. For 10,000 constraints, the LogDet algorithm ran in 4.8 minutes and achieved a test error of 2.29%, while the von Neumann algorithm ran in 7.7 minutes and achieved 2.30% error. For 100,000 constraints, LogDet ran in 11.3 minutes and achieved an error of 2.18% while von Neumann ran in 71.4 minutes and achieved an error of 2.17%.

Finally, we note that our methods have recently been applied to very large problems in the computer vision domain. We refer the reader to Jain et al. (2008), which adapts the algorithms discussed in this paper to three large-scale vision experiments: human body pose estimation, feature indexing for 3-d reconstruction, and object classification. For pose estimation, the size of the data was 500,000 images and for feature indexing, there were 300,000 image patches. These experiments validate the use of our methods on large-scale data, and also demonstrate that they can be used to outperform state of the art methods in computer vision.

8. Conclusions

In this paper, we have developed algorithms for using Bregman matrix divergences for low-rank matrix nearness problems. In particular, we have developed a framework for using the LogDet divergence and the von Neumann divergence when the initial matrices are low-rank; this is achieved via a restriction of the range space of the matrices. Unlike previous kernel learning algorithms, which have running times that are cubic in the number of data points, our resulting algorithms are efficient—both algorithms have running times linear in the number of data points and quadratic in the rank of the kernel. Furthermore, our algorithms can be used in conjunction with a number of kernel-based learning algorithms that are optimized for low-rank kernel representations. The experimental results demonstrate that our algorithms are effective in learning low-rank and full-rank kernels for classification and clustering problems on large-scale data sets that arise in diverse applications.

There is still much to be gained from studying these divergences. Algorithmically, we have considered only projections onto a single constraint, but it is worth pursuing other approaches to solve the optimization problems such as methods that optimize with respect to multiple constraints simultaneously. We discussed how the LogDet divergence exhibits connections to Mahalanobis metric learning and semidefinite programming, and there is significant ongoing work in these areas. Finally, we hope that our framework will lead to new insights and algorithms for other machine learning problems where matrix nearness problems need to be solved.

Appendix A. Properties of Bregman Matrix Divergences

In this section, we highlight some important properties of Bregman matrix divergences.

Proposition 11 *Let Q be a square, orthogonal matrix, that is, $Q^TQ = QQ^T = I$. Then for all spectral Bregman matrix divergences, $D_\phi(Q^TXQ, Q^TYQ) = D_\phi(X,Y)$.*

Proof This follows from Lemma 1 by observing that if $X = V\Lambda V^T$ and $Y = U\Theta U^T$, the ith eigenvector of Q^TXQ is $Q^T\boldsymbol{v}_i$ and the jth eigenvector of Q^TYQ is $Q^T\boldsymbol{u}_j$. The eigenvalues remain unchanged by the orthogonal similarity transformation. Thus, the term $((Q^T\boldsymbol{v}_i)^T(Q^T\boldsymbol{u}_j))^2$ in Lemma 1 simplifies to $(\boldsymbol{v}_i^T\boldsymbol{u}_j)^2$ using the fact that $QQ^T = I$. ■

Proposition 12 *Let M be a square, non-singular matrix, and let X and Y be $n\times n$ positive definite matrices. Then $D_{\ell d}(M^TXM, M^TYM) = D_{\ell d}(X,Y)$.*

Proof First observe that if X is positive definite, then M^TXM is positive definite. Then:

$$\begin{aligned}
D_{\ell d}(M^TXM, M^TYM) &= \operatorname{tr}(M^TXM(M^TYM)^{-1}) - \log\det(M^TXM(M^TYM)^{-1}) - n \\
&= \operatorname{tr}(M^TXMM^{-1}Y^{-1}M^{-T}) - \log\det(M^TXMM^{-1}Y^{-1}M^{-T}) - n \\
&= \operatorname{tr}(XY^{-1}) - \log\det(XY^{-1}) - n \\
&= D_{\ell d}(X,Y)
\end{aligned}$$

■

Note that, as a corollary, we have that the LogDet divergence is *scale-invariant*, that is, $D_{\ell d}(X,Y) = D_{\ell d}(cX, cY)$, for any positive scalar c. Furthermore, this proposition may be extended to the case when X and Y are positive semidefinite, using the definition of the LogDet divergence for rank-deficient matrices.

Proposition 13 *Let Y be a positive definite matrix, and let X be any positive semidefinite matrix. Then $D_{\ell d}(X,Y) = D_{vN}(I, Y^{-\frac{1}{2}}XY^{-\frac{1}{2}}) = D_{\ell d}(Y^{-\frac{1}{2}}XY^{-\frac{1}{2}}, I)$*

Proof The first equality by expanding the definition of the von Neumann divergence:

$$\begin{aligned} D_{vN}(I, Y^{-\frac{1}{2}}XY^{-\frac{1}{2}}) &= \mathrm{tr}(I \log I - I \log(Y^{-\frac{1}{2}}XY^{-\frac{1}{2}}) - I + Y^{-\frac{1}{2}}XY^{-\frac{1}{2}}) \\ &= \mathrm{tr}(Y^{-\frac{1}{2}}XY^{-\frac{1}{2}}) - \mathrm{tr}(\log(Y^{-\frac{1}{2}}XY^{-\frac{1}{2}})) - \mathrm{tr}(I) \\ &= \mathrm{tr}(XY^{-1}) - \log\det(Y^{-\frac{1}{2}}XY^{-\frac{1}{2}}) - n \\ &= \mathrm{tr}(XY^{-1}) - \log\det(XY^{-1}) - n \\ &= D_{\ell d}(X,Y), \end{aligned}$$

where we have used the fact that $\mathrm{tr}(\log A) = \log\det(A)$. The second equality follows by applying Proposition 12 to $D_{\ell d}(X,Y)$ with $M = Y^{-\frac{1}{2}}$. ∎

Appendix B. Necessity of Dual Variable Corrections

In Section 3.4, we presented the method of Bregman projections and showed that, in the presence of inequality constraints, a dual variable correction is needed to guarantee convergence to the globally optimal solution. In some recent machine learning papers such as Tsuda et al. (2005), this correction has been omitted from the algorithm. We now briefly demonstrate why such corrections are needed.

A very simple example illustrating the failure of Bregman projections without corrections is in finding of the nearest 2×2 (positive definite) matrix X to the identity matrix that satisfies a single linear constraint:

$$\begin{aligned} \text{minimize}_X \quad & D_\phi(X, I) \\ \text{subject to} \quad & X_{11} + X_{22} - 2X_{12} \geq 1 \\ & X \succeq 0. \end{aligned}$$

The starting (identity) matrix satisfies the linear constraint, but a single projection step (to the corresponding equality constraint) without corrections will produce a suboptimal matrix, regardless of the divergence used. On the other hand, employing corrections leads to $\alpha_i' = 0$, and the input matrix remains unchanged.

It is also not sufficient to repeatedly perform Bregman projections only on violated constraints (without any corrections) until all constraints are satisfied—this approach is used by Tsuda et al. (2005). To demonstrate this more involved case, we consider an example over vectors, where the goal is to minimize the relative entropy to a given vector $\boldsymbol{x}_0$ under linear constraints. Note that the argument carries over to the matrix case, but is more difficult to visualize.

$$\begin{aligned} \text{minimize}_{\boldsymbol{x}} \quad & KL(\boldsymbol{x}, \boldsymbol{x}_0) \\ \text{subject to} \quad & \boldsymbol{x}^T \begin{bmatrix} 0.0912 & 0.9385 & -0.4377 \end{bmatrix} \geq 0.0238 \\ & \boldsymbol{x}^T \begin{bmatrix} 0.6020 & 0.6020 & -0.4377 \end{bmatrix} \geq 0.2554 \\ & \boldsymbol{x}^T \begin{bmatrix} 1 & 1 & 1 \end{bmatrix} = 1. \end{aligned} \tag{24}$$

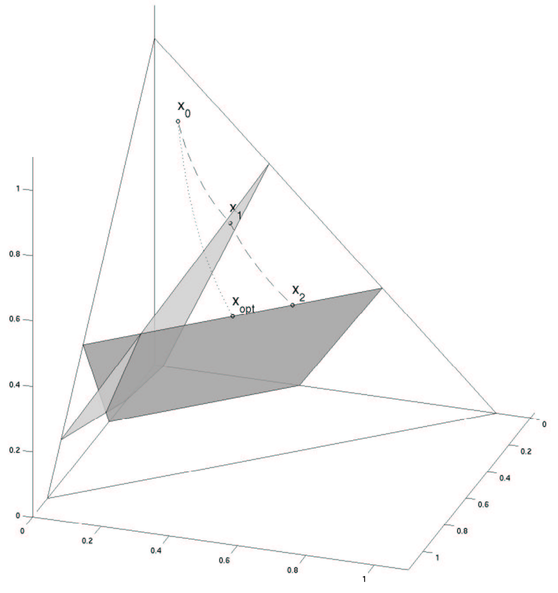

Figure 6: Termination points for the relative entropy example described by (24). The shaded regions illustrate the hyperplanes associated with the two inequality constraints of the optimization problem. The optimal solution is the maximum entropy vector $x_{opt} = \left[\frac{1}{3}\ \frac{1}{3}\ \frac{1}{3}\right]$, but without corrections we arrive at $x_2 = \left[\frac{1}{5}\ \frac{7}{15}\ \frac{1}{3}\right]$ after two projection steps starting from $x_0 = [0.1\ 0.1\ 0.8]$.

In the above problem, $KL(\boldsymbol{x}, \boldsymbol{x}_0)$ refers to the relative entropy, defined earlier. The first two constraints are linear inequality constraints while the third constraint forces $\boldsymbol{x}$ to remain on the unit simplex so that it is a probability vector. Let $\boldsymbol{x}_0$ equal $[0.1\ 0.1\ 0.8]$. If we process the constraints in the above order without corrections, after two projection steps (one projection onto each of the first two constraints), we arrive at the vector

$$\begin{bmatrix} \frac{1}{5} & \frac{7}{15} & \frac{1}{3} \end{bmatrix},$$

which satisfies all three constraints. Therefore this vector is returned as the optimal solution if no corrections are applied. In comparison, a proper execution of Bregman's algorithm employing corrections arrives at

$$\begin{bmatrix} \frac{1}{3} & \frac{1}{3} & \frac{1}{3} \end{bmatrix},$$

which is the maximum entropy vector. It is also worth noting that if we project to the second constraint first, then we arrive at the optimal solution immediately. By appropriately modifying the constraints and the starting point in this example, the incorrect algorithm can be made to converge arbitrarily close to $[0\ 0\ 1]$, a minimum entropy vector, thus drastically demonstrating the necessity of dual variable corrections.

Abstract

This paper gives a survey of contrast set mining (CSM), emerging pattern mining (EPM), and subgroup discovery (SD) in a unifying framework named *supervised descriptive rule discovery*. While all these research areas aim at discovering patterns in the form of rules induced from labeled data, they use different terminology and task definitions, claim to have different goals, claim to use different rule learning heuristics, and use different means for selecting subsets of induced patterns. This paper contributes a novel understanding of these subareas of data mining by presenting a unified terminology, by explaining the apparent differences between the learning tasks as variants of a unique supervised descriptive rule discovery task and by exploring the apparent differences between the approaches. It also shows that various rule learning heuristics used in CSM, EPM and SD algorithms all aim at optimizing a trade off between rule coverage and precision. The commonalities (and differences) between the approaches are showcased on a selection of best known variants of CSM, EPM and SD algorithms. The paper also provides a critical survey of existing supervised descriptive rule discovery visualization methods.

Keywords: descriptive rules, rule learning, contrast set mining, emerging patterns, subgroup discovery

1. Introduction

Symbolic data analysis techniques aim at discovering comprehensible patterns or models in data. They can be divided into techniques for *predictive induction*, where models, typically induced from class labeled data, are used to predict the class value of previously unseen examples, and *descriptive induction*, where the aim is to find comprehensible patterns, typically induced from unlabeled data. Until recently, these techniques have been investigated by two different research communities: predictive induction mainly by the machine learning community, and descriptive induction mainly by the data mining community.

*. Also at University of Nova Gorica, Vipavska 13, 5000 Nova Gorica, Slovenia.

Data mining tasks where the goal is to find humanly interpretable differences between groups have been addressed by both communities independently. The groups can be interpreted as class labels, so the data mining community, using the association rule learning perspective, adapted association rule learners like Apriori by Agrawal et al. (1996) to perform a task named *contrast set mining* (Bay and Pazzani, 2001) and *emerging pattern mining* (Dong and Li, 1999). On the other hand, the machine learning community, which usually deals with class labeled data, was challenged by, instead of building sets of classification/prediction rules (e.g., Clark and Niblett, 1989; Cohen, 1995), to build individual rules for exploratory data analysis and interpretation, which is the goal of the task named *subgroup discovery* (Wrobel, 1997).

This paper gives a survey of contrast set mining (CSM), emerging pattern mining (EPM), and subgroup discovery (SD) in a unifying framework, named *supervised descriptive rule discovery*. Typical applications of supervised descriptive rule discovery include patient risk group detection in medicine, bioinformatics applications like finding sets of overexpressed genes for specific treatments in microarray data analysis, and identifying distinguishing features of different customer segments in customer relationship management. The main aim of these applications is to understand the underlying phenomena and not to classify new instances. Take another illustrative example, where a manufacturer wants to know in what circumstances his machines may break down; his intention is not to predict breakdowns, but to understand the factors that lead to them and how to avoid them.

The main contributions of this paper are as follows. It provides a survey of supervised descriptive rule discovery approaches addressed in different communities, and proposes a unifying supervised descriptive rule discovery framework, including a critical survey of visualization methods. The paper is organized as follows: Section 2 gives a survey of past research done in the main supervised descriptive rule discovery areas: contrast set mining, emerging pattern mining, subgroup discovery and other related approaches. Section 3 is dedicated to unifying the terminology, definitions and the heuristics. Section 4 addresses visualization as an important open issue in supervised descriptive rule discovery. Section 5 provides a short summary.

2. A Survey of Supervised Descriptive Rule Discovery Approaches

Research on finding interesting rules from class labeled data evolved independently in three distinct areas—contrast set mining, mining of emerging patterns and subgroup discovery—each area using different frameworks and terminology. In this section, we provide a survey of these three research areas. We also discuss other related approaches.

2.1 An Illustrative Example

Let us illustrate contrast set mining, emerging pattern mining and subgroup discovery using data from Table 1, a very small, artificial sample data set,[1] adapted from Quinlan (1986). The data set contains the results of a survey on 14 individuals, concerning the approval or disapproval of an issue analyzed in the survey. Each individual is characterized by four attributes—`Education` (with values `primary` school, `secondary` school, or `university`), `MaritalStatus` (`single`, `married`, or `divorced`), `Sex` (`male` or `female`), and `HasChildren` (`yes` or `no`)—that encode rudimentary information about the sociodemographic background. The last column `Approved` is the designated

1. Thanks to Johannes Fürnkranz for providing this data set.

Education	Marital Status	Sex	Has Children	Approved
primary	single	male	no	no
primary	single	male	yes	no
primary	married	male	no	yes
university	divorced	female	no	yes
university	married	female	yes	yes
secondary	single	male	no	no
university	single	female	no	yes
secondary	divorced	female	no	yes
secondary	single	female	yes	yes
secondary	married	male	yes	yes
primary	married	female	no	yes
secondary	divorced	male	yes	no
university	divorced	female	yes	no
secondary	divorced	male	no	yes

Table 1: A sample database.

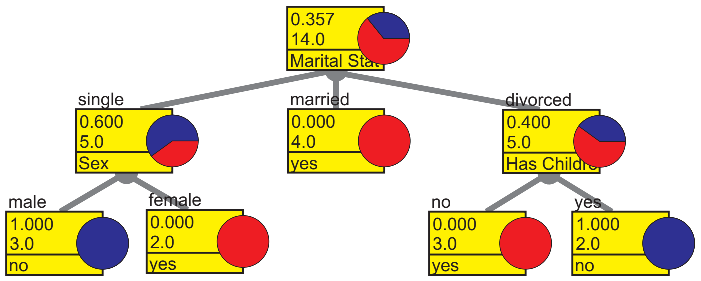

Figure 1: A decision tree, modeling the data set shown in Table 1.

class attribute, encoding whether the individual approved or disapproved the issue. Since there is no need for expert knowledge to interpret the results, this data set is appropriate for illustrating the results of supervised descriptive rule discovery algorithms, whose task is to find interesting patterns describing individuals that are likely to approve or disapprove the issue, based on the four demographic characteristics.

The task of *predictive induction* is to induce, from a given set of *training examples*, a domain model aimed at predictive or classification purposes, such as the *decision tree* shown in Figure 1, or a *rule set* shown in Figure 2, as learned by C4.5 and C4.5rules (Quinlan, 1993), respectively, from the sample data in Table 1.

```
Sex = female  →  Approved = yes
MaritalStatus = single  AND  Sex = male  →  Approved = no
MaritalStatus = married  →  Approved = yes
MaritalStatus = divorced  AND  HasChildren = yes  →  Approved = no
MaritalStatus = divorced  AND  HasChildren = no  →  Approved = yes
```

Figure 2: A set of predictive rules, modeling the data set shown in Table 1.

```
MaritalStatus = single AND Sex = male  →  Approved = no
Sex = male  →  Approved = no
Sex = female  →  Approved = yes
MaritalStatus = married  →  Approved = yes
MaritalStatus = divorced AND HasChildren = yes  →  Approved = no
MaritalStatus = single  →  Approved = no
```

Figure 3: Selected descriptive rules, describing individual patterns in the data of Table 1.

In contrast to predictive induction algorithms, *descriptive induction* algorithms typically result in rules induced from unlabeled examples. E.g., given the examples listed in Table 1, these algorithms would typically treat the class Approved no differently from any other attribute. Note, however, that in the learning framework discussed in this paper, that is, in the framework of *supervised descriptive rule discovery*, the discovered rules of the form $X \rightarrow Y$ are induced from class labeled data: the class labels are taken into account in learning of patterns of interest, constraining Y at the right hand side of the rule to assign a value to the class attribute.

Figure 3 shows six descriptive rules, found for the sample data using the Magnum Opus (Webb, 1995) software. Note that these rules were found using the default settings except that the critical value for the statistical test was relaxed to 0.25. These descriptive rules differ from the predictive rules in several ways. The first rule is redundant with respect to the second. The first is included as a strong pattern (*all* 3 single males do not approve) whereas the second is weaker but more general (4 out of 7 males do not approve, which is not highly predictive, but accounts for 4 out of all 5 respondents who do not approve). Most predictive systems will include only one of these rules, but either may be of interest to someone trying to understand the data, depending upon the specific application. This particular approach to descriptive pattern discovery does not attempt to second guess which of the more specific or more general patterns will be the more useful.

Another difference between the predictive and the descriptive rule sets is that the descriptive rule set does not include the pattern that divorcees without children approve. This is because, while the pattern is highly predictive in the sample data, there are insufficient examples to pass the statistical test which assesses the probability that, given the frequency of respondents approving, the apparent correlation occurs by chance. The predictive approach often includes such rules for the sake of completeness, while some descriptive approaches make no attempt at such completeness, assessing each pattern on its individual merits.

Exactly which rules will be induced by a supervised descriptive rule discovery algorithm depends on the task definition, the selected algorithm, as well as the user-defined constraints concerning minimal rule support, precision, etc. In the following section, the example set of Table 1 is used to illustrate the outputs of emerging pattern and subgroup discovery algorithms (see Figures 4 and 5, respectively), while a sample output for contrast set mining is shown in Figure 3 above.

2.2 Contrast Set Mining

The problem of mining contrast sets was first defined by Bay and Pazzani (2001) as finding contrast sets as "conjunctions of attributes and values that differ meaningfully in their distributions across groups." The example rules in Figure 3 illustrate this approach, including all conjunctions of attributes and values that pass a statistical test for productivity (explained below) with respect to attribute Approved that defines the 'groups.'

2.2.1 CONTRAST SET MINING ALGORITHMS

The STUCCO algorithm (Search and Testing for Understandable Consistent Contrasts) by Bay and Pazzani (2001) is based on the Max-Miner rule discovery algorithm (Bayardo, 1998). STUCCO discovers a set of contrast sets along with their supports[2] on groups. STUCCO employs a number of pruning mechanisms. A potential contrast set X is discarded if it fails a statistical test for independence with respect to the group variable Y. It is also subjected to what Webb (2007) calls a test for *productivity*. Rule $X \rightarrow Y$ is productive iff

$$\forall Z \subset X : \textit{confidence}(Z \rightarrow Y) < \textit{confidence}(X \rightarrow Y)$$

where $\textit{confidence}(X \rightarrow Y)$ is a maximum likelihood estimate of conditional probability $P(Y|X)$, estimated by the ratio $\frac{\textit{count}(X,Y)}{\textit{count}(X)}$, where $\textit{count}(X,Y)$ represents the number of examples for which both X and Y are true, and $\textit{count}(X)$ represents the number of examples for which X is true. Therefore a more specific contrast set must have higher confidence than any of its generalizations. Further tests for minimum counts and effect sizes may also be imposed.

STUCCO introduced a novel variant of the Bonferroni correction for multiple tests which applies ever more stringent critical values to the statistical tests employed as the number of conditions in a contrast set is increased. In comparison, the other techniques discussed below do not, by default, employ any form of correction for multiple comparisons, as result of which they have high risk of making *false discoveries* (Webb, 2007).

It was shown by Webb et al. (2003) that contrast set mining is a special case of the more general rule learning task. A contrast set can be interpreted as the antecedent of rule $X \rightarrow Y$, and group G_i for which it is characteristic—in contrast with group G_j—as the rule consequent, leading to rules of the form $\textit{ContrastSet} \rightarrow G_i$. A standard descriptive rule discovery algorithm, such as an association-rule discovery system (Agrawal et al., 1996), can be used for the task if the consequent is restricted to a variable whose values denote group membership.

In particular, Webb et al. (2003) showed that when STUCCO and the general-purpose descriptive rule learning system Magnum Opus were each run with their default settings, but the consequent restricted to the contrast variable in the case of Magnum Opus, the contrasts found differed mainly as a consequence only of differences in the statistical tests employed to screen the rules.

Hilderman and Peckham (2005) proposed a different approach to contrast set mining called CIGAR (ContrastIng Grouped Association Rules). CIGAR uses different statistical tests to STUCCO or Magnum Opus for both independence and productivity and introduces a test for *minimum support*.

Wong and Tseng (2005) have developed techniques for discovering contrasts that can include negations of terms in the contrast set.

In general, contrast set mining approaches require discrete data, which is in real world applications frequently not the case. A data discretization method developed specifically for set mining purposes is described by Bay (2000). This approach does not appear to have been further used by the contrast set mining community, except for Lin and Keogh (2006), who extended contrast set mining to time series and multimedia data analysis. They introduced a formal notion of a time series contrast set along with a fast algorithm to find time series contrast sets. An approach to quantitative contrast set mining without discretization in the preprocessing phase is proposed by Simeon

2. The support of a contrast set *ContrastSet* with respect to a group G_i, $\textit{support}(\textit{ContrastSet}, G_i)$, is the percentage of examples in G_i for which the contrast set is true.

and Hilderman (2007) with the algorithm Gen_QCSets. In this approach, a slightly modified equal width binning interval method is used.

Common to most contrast set mining approaches is that they generate all candidate contrast sets from discrete (or discretized) data and later use statistical tests to identify the interesting ones. Open questions identified by Webb et al. (2003) are yet unsolved: selection of appropriate heuristics for identifying interesting contrast sets, appropriate measures of quality for sets of contrast sets, and appropriate methods for presenting contrast sets to the end users.

2.2.2 SELECTED APPLICATIONS OF CONTRAST SET MINING

The contrast mining paradigm does not appear to have been pursued in many published applications. Webb et al. (2003) investigated its use with retail sales data. Wong and Tseng (2005) applied contrast set mining for designing customized insurance programs. Siu et al. (2005) have used contrast set mining to identify patterns in synchrotron x-ray data that distinguish tissue samples of different forms of cancerous tumor. Kralj et al. (2007b) have addressed a contrast set mining problem of distinguishing between two groups of brain ischaemia patients by transforming the contrast set mining task to a subgroup discovery task.

2.3 Emerging Pattern Mining

Emerging patterns were defined by Dong and Li (1999) as itemsets whose support increases significantly from one data set to another. Emerging patterns are said to capture emerging trends in time-stamped databases, or to capture differentiating characteristics between classes of data.

2.3.1 EMERGING PATTERN MINING ALGORITHMS

Efficient algorithms for mining emerging patterns were proposed by Dong and Li (1999) and Fan and Ramamohanarao (2003). When first defined by Dong and Li (1999), the purpose of emerging patterns was "to capture emerging trends in time-stamped data, or useful contrasts between data classes". Subsequent emerging pattern research has largely focused on the use of the discovered patterns for classification purposes, for example, classification by emerging patterns (Dong et al., 1999; Li et al., 2000) and classification by jumping emerging patterns[3] (Li et al., 2001). An advanced Bayesian approach (Fan and Ramamohanara, 2003) and bagging (Fan et al., 2006) were also proposed.

From a semantic point of view, emerging patterns are association rules with an itemset in rule antecedent, and a fixed consequent: $ItemSet \rightarrow D_1$, for given data set D_1 being compared to another data set D_2.

The measure of quality of emerging patterns is the *growth rate* (the ratio of the two supports). It determines, for example, that a pattern with a 10% support in one data set and 1% in the other is better than a pattern with support 70% in one data set and 10% in the other (as $\frac{10}{1} > \frac{70}{10}$). From the association rule perspective, $GrowthRate(ItemSet, D_1, D_2) = \frac{confidence(ItemSet \rightarrow D_1)}{1 - confidence(ItemSet \rightarrow D_1)}$. Thus it can be seen that growth rate provides an identical ordering to confidence, except that growth rate is undefined when confidence = 1.0.

3. Jumping emerging patterns are emerging patterns with support zero in one data set and greater then zero in the other data set.

```
MaritalStatus = single AND Sex = male  →  Approved = no
MaritalStatus = married  →  Approved = yes
MaritalStatus = divorced AND HasChildren = yes  →  Approved = no
```

Figure 4: Jumping emerging patterns in the data of Table 1.

Some researchers have argued that finding all the emerging patterns above a minimum growth rate constraint generates too many patterns to be analyzed by a domain expert. Fan and Ramamohanarao (2003) have worked on selecting the interesting emerging patterns, while Soulet et al. (2004) have proposed condensed representations of emerging patterns.

Boulesteix et al. (2003) introduced a CART-based approach to discover emerging patterns in microarray data. The method is based on growing decision trees from which the emerging patterns are extracted. It combines pattern search with a statistical procedure based on Fisher's exact test to assess the significance of each emerging pattern. Subsequently, sample classification based on the inferred emerging patterns is performed using maximum-likelihood linear discriminant analysis.

Figure 4 shows all jumping emerging patterns found for the data in Table 1 when using a minimum support of 15%. These were discovered using the Magnum Opus software, limiting the consequent to the variable *approved*, setting minimum confidence to 1.0 and setting minimum support to 2.

2.3.2 SELECTED APPLICATIONS OF EMERGING PATTERNS

Emerging patterns have been mainly applied to the field of bioinformatics, more specifically to microarray data analysis. Li et al. (2003) present an interpretable classifier based on simple rules that is competitive to the state of the art black-box classifiers on the acute lymphoblastic leukemia (ALL) microarray data set. Li and Wong (2002) have focused on finding groups of genes by emerging patterns and applied it to the ALL/AML data set and the colon tumor data set. Song et al. (2001) used emerging patterns together with unexpected change and the added/perished rule to mine customer behavior.

2.4 Subgroup Discovery

The task of subgroup discovery was defined by Klösgen (1996) and Wrobel (1997) as follows: "Given a population of individuals and a property of those individuals that we are interested in, find population subgroups that are statistically 'most interesting', for example, are as large as possible and have the most unusual statistical (distributional) characteristics with respect to the property of interest".

2.4.1 SUBGROUP DISCOVERY ALGORITHMS

Subgroup descriptions are conjunctions of features that are characteristic for a selected class of individuals (property of interest). A subgroup description can be seen as the condition part of a rule *SubgroupDescription* → *Class*. Therefore, subgroup discovery can be seen as a special case of a more general rule learning task.

Subgroup discovery research has evolved in several directions. On the one hand, exhaustive approaches guarantee the optimal solution given the optimization criterion. One system that can use both exhaustive and heuristic discovery algorithms is Explora by Klösgen (1996). Other algo-

```
Sex = female  →  Approved = yes
MaritalStatus = married  →  Approved = yes
MaritalStatus = divorced AND HasChildren = no  →  Approved = yes
Education = university  →  Approved = yes
MaritalStatus = single AND Sex = male  →  Approved = no
```

Figure 5: Subgroup descriptions induced by Apriori-SD from the data of Table 1.

rithms for exhaustive subgroup discovery are the SD-Map method by Atzmüller and Puppe (2006) and Apriori-SD by Kavšek and Lavrač (2006). On the other hand, adaptations of classification rule learners to perform subgroup discovery, including algorithm SD by Gamberger and Lavrač (2002) and algorithm CN2-SD by Lavrač et al. (2004b), use heuristic search techniques drawn from classification rule learning coupled with constraints appropriate for descriptive rules.

Relational subgroup discovery approaches have been proposed by Wrobel (1997, 2001) with algorithm Midos, by Klösgen and May (2002) with algorithm SubgroupMiner, which is designed for spatial data mining in relational space databases, and by Železný and Lavrač (2006) with the algorithm RSD (Relational Subgroup Discovery). RSD uses a propositionalization approach to relational subgroup discovery, achieved through appropriately adapting rule learning and first-order feature construction. Other non-relational subgroup discovery algorithms were developed, including an algorithm for exploiting background knowledge in subgroup discovery (Atzmüller et al., 2005a), and an iterative genetic algorithm SDIGA by del Jesus et al. (2007) implementing a fuzzy system for solving subgroup discovery tasks.

Different heuristics have been used for subgroup discovery. By definition, the interestingness of a subgroup depends on its unusualness and size, therefore the rule quality evaluation heuristics needs to combine both factors. Weighted relative accuracy (*WRAcc*, see Equation 2 in Section 3.3) is used by algorithms CN2-SD, Apriori-SD and RSD and, in a different formulation and in different variants, also by MIDOS and EXPLORA. Generalization quotient (q_g, see Equation 3 in Section 3.3) is used by the SD algorithm. SubgroupMiner uses the classical binominal test to verify if the target share is significantly different in a subgroup.

Different approaches have been used for eliminating redundant subgroups. Algorithms CN2-SD, Apriori-SD, SD and RSD use weighted covering (Lavrač et al., 2004b) to achieve rule diversity. Algorithms Explora and SubgroupMiner use an approach called subgroup suppression (Klösgen, 1996). A sample set of subgroup describing rules, induced by Apriori-SD with parameters *support* set to 15% (requiring at least 2 covered training examples per rule) and *confidence* set to 65%, is shown in Figure 5.

2.4.2 SELECTED APPLICATIONS OF SUBGROUP DISCOVERY

Subgroup discovery was used in numerous real-life applications. The applications in medical domains include the analysis of coronary heart disease (Gamberger and Lavrač, 2002) and brain ischaemia data analysis (Kralj et al., 2007b,a; Lavrač et al., 2007), as well as profiling examiners for sonographic examinations (Atzmüller et al., 2005b). Spatial subgroup mining applications include mining of census data (Klösgen et al., 2003) and mining of vegetation data (May and Ragia, 2002). There are also applications in other areas like marketing (del Jesus et al., 2007; Lavrač et al., 2004a) and analysis of manufacturing shop floor data (Jenkole et al., 2007).

2.5 Related Approaches

Research in some closely related areas of rule learning, performed independently from the above described approaches, is outlined below.

2.5.1 CHANGE MINING

The paper by Liu et al. (2001) on *fundamental rule changes* proposes a technique to identify the set of fundamental changes in two given data sets collected from two time periods. The proposed approach first generates rules and in the second phase it identifies changes (rules) that can not be explained by the presence of other changes (rules). This is achieved by applying statistical χ^2 test for homogeneity of support and confidence. This differs from contrast set discovery through its consideration of rules for each group, rather than itemsets. A change in the frequency of just one itemset between groups may affect many association rules, potentially all rules that have the itemset as either an antecedent or consequent.

Liu et al. (2000) and Wang et al. (2003) present techniques that identify differences in the decision trees and classification rules, respectively, found on two different data sets.

2.5.2 MINING CLOSED SETS FROM LABELED DATA

Closed sets have been proven successful in the context of compacted data representation for association rule learning. However, their use is mainly descriptive, dealing only with unlabeled data. It was recently shown that when considering labeled data, closed sets can be adapted for classification and discrimination purposes by conveniently contrasting covering properties on positive and negative examples (Garriga et al., 2006). The approach was successfully applied in potato microarray data analysis to a real-life problem of distinguishing between virus sensitive and resistant transgenic potato lines (Kralj et al., 2006).

2.5.3 EXCEPTION RULE MINING

Exception rule mining considers a problem of finding a set of rule pairs, each of which consists of an exception rule (which describes a regularity for fewer objects) associated with a strong rule (description of a regularity for numerous objects with few counterexamples). An example of such a rule pair is “using a seat belt is safe” (strong rule) and “using a seat belt is risky for a child” (exception rule). While the goal of exception rule mining is also to find descriptive rules from labeled data, in contrast with other rule discovery approaches described in this paper, the goal of exception rule mining is to find “weak” rules—surprising rules that are an exception to the general belief of background knowledge.

Suzuki (2006) and Daly and Taniar (2005), summarizing the research in exception rule mining, reveal that the key concerns addressed by this body of research include interestingness measures, reliability evaluation, practical application, parameter reduction and knowledge representation, as well as providing fast algorithms for solving the problem.

2.5.4 IMPACT RULES, BUMP HUNTING, QUANTITATIVE ASSOCIATION RULES

Supervised descriptive rule discovery seeks to discover sets of conditions that are related to deviations in the class distribution, where the class is a qualitative variable. A related body of research seeks to discover sets of conditions that are related to deviations in a target quantitative variable.

Contrast Set Mining	Emerging Pattern Mining	Subgroup Discovery	Rule Learning
contrast set	itemset	subgroup description	rule condition
groups $G_1, \ldots G_n$	data sets D_1 and D_2	class/property C	class/concept C_i
attribute-value pair	item	logical (binary) feature	condition
examples in groups $G_1, \ldots G_n$	transactions in data sets D_1 and D_2	examples of C and $\overline{C}$	examples of $C_1 \ldots C_n$
examples for which the contrast set is true	transactions containing the itemset	subgroup of instances	covered examples
support of contrast set on G_i support of contrast set on G_j	support of EP in data set D_1 support of EP in data set D_2	true positive rate false positive rate	true positive rate false positive rate

Table 2: Table of synonyms from different communities, showing the compatibility of terms.

Such techniques include Bump Hunting (Friedman and Fisher, 1999), Quantitative Association Rules (Aumann and Lindell, 1999) and Impact Rules (Webb, 2001).

3. A Unifying Framework for Supervised Descriptive Rule Induction

This section presents a unifying framework for contrast set mining, emerging pattern mining and subgroup discovery, as the main representatives of supervised descriptive rule discovery approaches. This is achieved by unifying the terminology, the task definitions and the rule learning heuristics.

3.1 Unifying the Terminology

Contrast set mining (CSM), emerging pattern mining (EPM) and subgroup discovery (SD) were developed in different communities, each developing their own terminology that needs to be clarified before proceeding. Below we show that terms used in different communities are compatible, according to the following definition of compatibility.

Definition 1: Compatibility of terms. *Terms used in different communities are compatible if they can be translated into equivalent logical expressions and if they bare the same meaning, that is, if terms from one community can replace terms used in another community.*

Lemma 1: *Terms used in CSM, EPM and SD are compatible.*
Proof The compatibility of terms is proven through a term dictionary, whose aim is to translate all the terms used in CSM, EPM and SD into the terms used in the rule learning community. The term dictionary is proposed in Table 2. More specifically, this table provides a dictionary of equivalent terms from contrast set mining, emerging pattern mining and subgroup discovery, in a unifying terminology of classification rule learning, and in particular of concept learning (considering class C_i as the concept to be learned from the positive examples of this concept, and the negative examples formed of examples of all other classes). ■

3.2 Unifying the Task Definitions

Having established a unifying view on the terminology, the next step is to provide a unifying view on the different task definitions.

CSM A contrast set mining task is defined as follows (Bay and Pazzani, 2001). Let A_1, A_2, ..., A_k be a set of k variables called attributes. Each A_i can take values from the set $\{v_{i1}, v_{i2}, \ldots, v_{im}\}$. Given a set of user defined groups G_1, G_2, ..., G_n of data instances, a contrast set is a conjunction of attribute-value pairs, defining a pattern that best discriminates the instances of different user-defined groups. A special case of contrast set mining considers only two contrasting groups (G_1 and G_2). In such cases, we wish to find characteristics of one group discriminating it from the other and vice versa.

EPM An emerging patterns mining task is defined as follows (Dong and Li, 1999). Let $I = \{i_1, i_2, \ldots, i_N\}$ be a set of items (note that an item is equivalent to a binary feature in SD, and an individual attribute-value pair in CSM). A transaction is a subset T of I. A *dataset* is a set D of transactions. A subset X of I is called an *itemset*. Transaction T contains an itemset X in a data set D, if $X \subseteq T$. For two data sets D_1 and D_2, emerging pattern mining aims at discovering itemsets whose support increases significantly from one data set to another.

SD In subgroup discovery, subgroups are described as conjunctions of features, where features are of the form $A_i = v_{ij}$ for nominal attributes, and $A_i > value$ or $A_i \leq value$ for continuous attributes. Given the property of interest C, and the population of examples of C and $\overline{C}$, the subgroup discovery task aims at finding population subgroups that are as large as possible and have the most unusual statistical (distributional) characteristics with respect to the property of interest C (Wrobel, 1997).

The definitions of contrast set mining, emerging pattern mining and subgroup discovery appear different: contrast set mining searches for discriminating characteristics of groups called contrast sets, emerging pattern mining aims at discovering itemsets whose support increases significantly from one data set to another, while subgroup discovery searches for subgroup descriptions. By using the dictionary from Table 2 we can see that the goals of these three mining tasks are very similar, it is primarily the terminology that differs.

Definition 2: Compatibility of task definitions. *Definitions of different learning tasks are compatible if one learning task can be translated into another learning task without substantially changing the learning goal.*

Lemma 2: *Definitions of CSM, EPM and SD tasks are compatible.*

Proof To show the compatibility of task definitions, we propose a unifying table (Table 3) of task definitions, allowing us to see that emerging pattern mining task $EPM(D_1,D_2)$ is equivalent to $CSM(G_i,G_j)$. It is also easy to show that a two-group contrast set mining task $CSM(G_i,G_j)$ can be directly translated into the following two subgroup discovery tasks: $SD(G_i)$ for $C = G_i$ and $\overline{C} = G_j$, and $SD(G_j)$ for $C = G_j$ and $\overline{C} = G_i$.

Contrast Set Mining	Emerging Pattern Mining	Subgroup Discovery	Rule Learning
Given	**Given**	**Given**	**Given**
examples in G_1 vs. G_j	transactions in D_1 and D_2	in examples C	examples in C_i
from $G_1, \dots G_i$	from D_1 and D_2	from C and $\overline{C}$	from $C_1 \dots C_n$
Find	**Find**	**Find**	**Find**
$ContrastSet_{i_k} \rightarrow G_i$	$ItemSet_{1_k} \rightarrow D_1$	$SubgrDescr_k \rightarrow C$	$\{RuleCond_{i_k} \rightarrow C_i\}$
$ContrastSet_{j_l} \rightarrow G_j$	$ItemSet_{2_l} \rightarrow D_2$		

Table 3: Table of task definitions from different communities, showing the compatibility of task definitions in terms of output rules.

Having proved that the subgroup discovery task is compatible with a two-group contrast set mining task, it is by induction compatible with a general contrast set mining task, as shown below.

```
$CSM(G_1, \dots G_n)$
  for i=2 to n do
    for j=1, j≠ i to n-1 do
      $SD(C = G_i \ vs. \ \overline{C} = G_j)$
```

Note that in Table 3 of task definitions column 'Rule Learning' again corresponds to a concept learning task instead of the general classification rule learning task. In the concept learning setting, which is better suited for the comparisons with supervised descriptive rule discovery approaches, a distinguished class C_i is learned from examples of this class, and examples of all other classes $C_1, \dots, C_{i-1}, C_{i+1}, C_N$ are merged to form the set of examples of class $\overline{C_i}$. In this case, induced rule set $\{RuleCond_{i_k} \rightarrow C_i\}$ consists only of rules for distinguished class C_i. On the other hand, in a general classification rule learning setting, from examples of N different classes a set of rules would be learned $\{\dots, RuleCond_{i_k} \rightarrow C_i, RuleCond_{i_{k+1}} \rightarrow C_i, \dots, RuleCond_{j_l} \rightarrow C_j, \dots, Default\}$, consisting of sets of rules of the form $RuleCond_{i_k} \rightarrow C_i$ for each individual class C_i, supplemented by the default rule. ■

While the primary tasks are very closely related, each of the three communities has concentrated on different sets of issues around this task. The contrast set discovery community has paid greatest attention to the statistical issues of multiple comparisons that, if not addressed, can result in high risks of false discoveries. The emerging patterns community has investigated how supervised descriptive rules can be used for classification. The contrast set and emerging pattern communities have primarily addressed only categorical data whereas the subgroup discovery community has also considered numeric and relational data. The subgroup discovery community has also explored techniques for discovering small numbers of supervised descriptive rules with high coverage of the data.

3.3 Unifying the Rule Learning Heuristics

The aim of this section is to provide a unifying view on rule learning heuristics used in different communities. To this end, we first investigate the rule quality measures.

Most rule quality measures are derived by analyzing the covering properties of the rule and the class in the rule consequent considered as positive. This relationship can be depicted by a confusion

	predicted		
actual	# of positives	# of negatives	
# of positives	$p = \lvert TP(X,Y)\rvert$	$\overline{p} = \lvert FN(X,Y)\rvert$	P
# of negatives	$n = \lvert FP(X,Y)\rvert$	$\overline{n} = \lvert TN(X,Y)\rvert$	N
	$p+n$	$\overline{p}+\overline{n}$	$P+N$

Table 4: Confusion matrix: $TP(X,Y)$ stands for true positives, $FP(X,Y)$ for false positives, $FN(X,Y)$ for false negatives and $TN(X,Y)$ for true negatives, as predicted by rule $X \rightarrow Y$.

matrix (Table 4, see, e.g., Kohavi and Provost, 1998), which considers that rule $R = X \rightarrow Y$ is represented as (X,Y), and defines p as the number of true positives (positive examples correctly classified as positive by rule (X,Y)), n as the number of false positives, etc., from which other covering characteristics of a rule can be derived: true positive rate $TPr(X,Y) = \frac{p}{P}$ and false positive rate $FPr(X,Y) = \frac{n}{N}$.

CSM Contrast set mining aims at discovering contrast sets that best discriminate the instances of different user-defined groups. The support of contrast set X with respect to group G_i, $support(X,G_i)$, is the percentage of examples in G_i for which the contrast set is true. Note that *support of a contrast set with respect to group G* is the same as *true positive rate* in the classification rule and subgroup discovery terminology, that is, $support(X,G_i) = \frac{count(X,G_i)}{|G_i|} = TPr(X,G_i)$. A derived goal of contrast set mining, proposed by Bay and Pazzani (2001), is to find contrast sets whose support differs meaningfully across groups, for δ being a user-defined parameter.

$$SuppDiff(X,G_i,G_j) = |support(X,G_i) - support(X,G_j)| \geq \delta.$$

EPM Emerging pattern mining aims at discovering itemsets whose support increases significantly from one data set to another Dong and Li (1999), where *support* of itemset X in data set D is computed as $support(X,D) = \frac{count(X,D)}{|D|}$, for $count(X,D)$ being the number of transactions in D containing X. Suppose we are given an ordered pair of data sets D_1 and D_2. The *GrowthRate* of an itemset X from D_1 to D_2, denoted as $GrowthRate(X,D_1,D_2)$, is defined as follows:

$$GrowthRate(X,D_1,D_2) = \frac{support(X,D_1)}{support(X,D_2)}. \quad (1)$$

Definitions of special cases of $GrowthRate(X,D_1,D_2)$ are as follows, if $support(X,D_1) = 0$ then $GrowthRate(X,D_1,D_2) = 0$, if $support(X,D_2) = 0$ then $GrowthRate(X,D_1,D_2) = \infty$.

SD Subgroup discovery aims at finding population subgroups that are as large as possible and have the most unusual statistical (distributional) characteristics with respect to the property of interest (Wrobel, 1997). There were several heuristics developed and used in the subgroup discovery community. Since they follow from the task definition, they try to maximize subgroup size and the distribution difference at the same time. Examples of such heuristics are the *weighted relative accuracy* (Equation 2, see Lavrač et al., 2004b) and the *generalization*

Contrast Set Mining	Emerging Pattern Mining	Subgroup Discovery	Rule Learning
$SuppDiff(X,G_i,G_j)$		$WRAcc(X,C)$	Piatetski-Shapiro heuristic leverage
	$GrowthRate(X,D_1,D_2)$	$q_g(X,C)$	odds ratio for $g=0$ accuracy/precision, for $g=p$

Table 5: Table of relationships between the pairs of heuristics, and their equivalents in classification rule learning.

quotient (Equation 3, see Gamberger and Lavrač, 2002) , for g being a user-defined parameter.

$$WRAcc(X,C) = \frac{p+n}{P+N} \cdot \left(\frac{p}{p+n} - \frac{P}{P+N} \right), \tag{2}$$

$$q_g(X,C) = \frac{p}{n+g}. \tag{3}$$

Let us now investigate whether the heuristics used in CSM, EPM and SD are compatible, using the following definition of compatibility.

Definition 3: Compatibility of heuristics.
Heuristic function h_1 is compatible *with h_2 if h_2 can be derived from h_1 and if for any two rules R and R', $h_1(R) > h_1(R') \Leftrightarrow h_2(R) > h_2(R')$.*

Lemma 3: *Definitions of CSM, EPM and SD heuristics are pairwise compatible.*
Proof The proof of Lemma 3 is established by proving two sub-lemmas, Lemma 3a and Lemma 3b, which prove the compatibility of two pairs of heuristics, whereas the relationships between these pairs is established through Table 5, and illustrated in Figures 6 and 7. ■

Lemma 3a: *The support difference heuristic used in CSM and the weighted relative accuracy heuristic used in SD are compatible.*
Proof Note that, as shown below, weighted relative accuracy (Equation 2) can be interpreted in terms of probabilities of rule antecedent X and consequent Y (class C representing the property of interest), and the conditional probability of class Y given X, estimated by relative frequencies.

$$WRAcc(X,Y) = P(X) \cdot (P(Y|X) - P(Y)).$$

From this equation we see that, indeed, when optimizing weighted relative accuracy of rule $X \rightarrow Y$, we optimize two contrasting factors: rule coverage $P(X)$ (proportional to the size of the subgroup), and distributional unusualness $P(Y|X) - P(Y)$ (proportional to the difference of the number of positive examples correctly covered by the rule and the number of positives in the original training set). It is straightforward to show that this measure is equivalent to the Piatetski-Shapiro measure, which evaluates the conditional (in)dependence of rule consequent and rule antecedent as follows:

$$PS(X,Y) = P(X \cdot Y) - P(X) \cdot P(Y).$$

Weighted relative accuracy, known from subgroup discovery, and support difference between groups, used in contrast set mining, are related as follows:[4]

$$\begin{aligned}
&WRAcc(X,Y) = \\
&\quad = P(X)\cdot[P(Y|X)-P(Y)] = P(Y\cdot X)-P(Y)\cdot P(X)\\
&\quad = P(Y\cdot X)-P(Y)\cdot[P(Y\cdot X)+P(\overline{Y}\cdot X)]\\
&\quad = (1-P(Y))\cdot P(Y\cdot X)-P(Y)\cdot P(\overline{Y}\cdot X)\\
&\quad = P(\overline{Y})\cdot P(Y)\cdot P(X|Y)-P(Y)\cdot P(\overline{Y})\cdot P(X|\overline{Y})\\
&\quad = P(\overline{Y})\cdot P(Y)\cdot[P(X|Y)-P(X|\overline{Y})]\\
&\quad = P(Y)\cdot P(\overline{Y})\cdot[TPr(X,Y)-FPr(X,Y)].
\end{aligned}$$

Since the distribution of examples among classes is constant for any data set, the first two factors $P(Y)$ *and* $P(\overline{Y})$ are constant within a data set. Therefore, when maximizing the weighted relative accuracy, one is maximizing the second factor $TPr(X,Y)-FPr(X,Y)$, which actually is support difference when we have a two group contrast set mining problem. Consequently, for $C=G_1$, and $\overline{C}=G_2$ the following holds:

$$WRAcc(X,C) = WRAcc(X,G_1) = P(G_1)\cdot P(G_2)\cdot[support(X,G_1)-support(X,G_2)].$$

■

Lemma 3b: *The growth rate heuristic used in EPM and the generalization quotient heuristic used in SD are compatible.*
Proof Equation 1 can be rewritten as follows:

$$GrowthRate(X,D_1,D_2) = \frac{support(X,D_1)}{support(C,D_2)} =$$
$$= \frac{count(X,D_1)}{count(X,D_2)}\cdot\frac{|D_2|}{|D_1|} = \frac{p}{n}\cdot\frac{N}{P}.$$

Since the distribution of examples among classes is constant for any data set, the quotient $\frac{N}{P}$ is constant. Consequently, the growth rate is the generalization quotient with $g=0$, multiplied by a constant. Therefore, the growth rate is compatible with the generalization quotient.

$$GrowthRate(X,C,\overline{C}) = q_0(X,C)\cdot\frac{N}{P}.$$

■

The lemmas prove that heuristics used in CSM and EPM can be translated into heuristics used in SD and vice versa. In this way, we have shown the compatibility of CSM and SD heuristics, as well as the compatibility of EPM and SD heuristics. While the lemmas do not prove direct compatibility of CSM and EPM heuristics, they prove that heuristics used in CSM and EPM can be translated into two heuristics used in SD, both aiming at trading-off between coverage and distributional difference.

4. Peter A. Flach is acknowledged for having derived these equations.

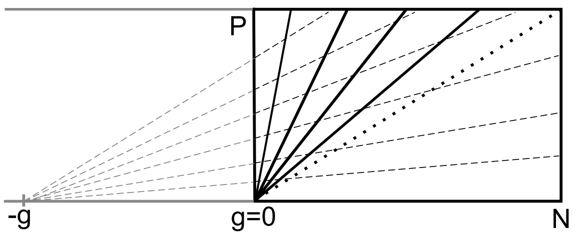

Figure 6: Isometrics for q_g. The dotted lines show the isometrics for a selected $g > 0$, while the full lines show the special case when $g = 0$, compatible to the EPM *growth rate* heuristic.

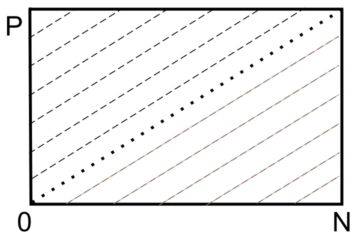

Figure 7: Isometrics for *WRAcc*, compatible to the CSM *support difference* heuristic.

Table 5 provides also the equivalents of these heuristics in terms of heuristics known from the classification rule learning community, details of which are beyond the scope of this paper (an interested reader can find more details on selected heuristics and their ROC representations in Fürnkranz and Flach, 2003).

Note that the growth rate heuristic from EPM, as a special case of the generalization quotient heuristic with $g = 0$, does not consider rule coverage. On the other hand, its compatible counterpart, the generalization quotient q_g heuristic used in SD, can be tailored to favor more general rules by setting the g parameter value, as for a general g value, the q_g heuristic provides a trade-off between rule accuracy and coverage. Figure 6[5] illustrates the q_g isometrics, for a general g value, as well as for value $g = 0$.

Note also that standard rule learners (such as CN2 by Clark and Niblett, 1989) tend to generate very specific rules, due to using accuracy heuristic $Acc(X,Y) = \frac{p+\bar{n}}{P+N}$ or its variants: the Laplace and the *m*-estimate. On the other hand, the CSM support difference heuristic and its SD counterpart *WRAcc* both optimize a trade-off between rule accuracy and coverage. The *WRAcc* isometrics are plotted in Figure 7.[6]

3.4 Comparison of Rule Selection Mechanisms

Having established a unifying view on the terminology, definitions and rule learning heuristics, the last step is to analyze rule selection mechanisms used by different algorithms. The motivation for rule selection can be either to find only significant rules or to avoid overlapping rules (too many too similar rules), or to avoid showing redundant rules to the end users. Note that rule selection is not always necessary and that depending on the goal, redundant rules can be valuable (e.g., clas-

5. This figure is due to Gamberger and Lavrač (2002).
6. This figure is due to Fürnkranz and Flach (2003).

sification by aggregating emerging patterns by Dong et al., 1999). Two approaches are commonly used: statistic tests and the (weighted) covering approach. In this section, we compare these two approaches.

Webb et al. (2003) show that contrast set mining is a special case of the more general rule discovery task. However, an experimental comparison of STUCCO, OPUS_AR and C4.5 has shown that standard rule learners return a larger set of rules compared to STUCCO, and that some of them are also not interesting to end users. STUCCO (see Bay and Pazzani 2001 for more details) uses several mechanisms for rule pruning. Statistical significance pruning removes contrast sets that, while significant and large, derive these properties only due to being specializations of more general contrast sets: any specialization is pruned that has a similar support to its parent or that fails a χ^2 test of independence with respect to its parent.

In the context of OPUS_AR, the emphasis has been on developing statistical tests that are robust in the context of the large search spaces explored in many rule discovery applications Webb (2007). These include tests for independence between the antecedent and consequent, and tests to assess whether specializations have significantly higher confidence than their generalizations.

In subgroup discovery, the *weighted covering approach* (Lavrač et al., 2004b) is used with the aim of ensuring the diversity of rules induced in different iterations of the algorithm. In each iteration, after selecting the best rule, the weights of positive examples are decreased according to the number of rules covering each positive example $rule\_count(e)$; they are set to $w(e) = \frac{1}{rule\_count(e)}$. For selecting the best rule in consequent iterations, the SD algorithm (Gamberger and Lavrač, 2002) uses—instead of the unweighted q_g measure (Equation 3)—the weighted variant of q_g defined in Equation 4, while the CN2-SD (Lavrač et al., 2004b) and APRIORI-SD (Kavšek and Lavrač, 2006) algorithms use the weighted relative accuracy (Equation 2) modified with example weights, as defined in Equation 5, where $p' = \sum_{TP(X,Y)} w(e)$ is the sum of the weights of all covered positive examples, and P' is the sum of the weights of all positive examples.

$$q'_g(X,Y) = \frac{p'}{n+g}, \tag{4}$$

$$WRAcc'(X,Y) = \frac{p'+n}{P'+N} \cdot \left(\frac{p'}{p'+n} - \frac{P}{P+N} \right). \tag{5}$$

Unlike in the sections on the terminology, task definitions and rule learning heuristics, the comparison of rule pruning mechanisms described in this section does not result in a unified view; although the goals of rule pruning may be the same, the pruning mechanisms used in different subareas of supervised descriptive rule discovery are—as shown above—very different.

4. Visualization

Webb et al. (2003) identify a need to develop appropriate methods for presenting contrast sets to end users, possibly through contrast set visualization. This open issue, concerning the visualization of contrast sets and emerging patterns, can be resolved by importing some of the solutions proposed in the subgroup discovery community. Several methods for subgroup visualization were developed by Wettschereck (2002), Wrobel (2001), Gamberger et al. (2002), Kralj et al. (2005) and Atzmüller and Puppe (2005). They are here illustrated using the coronary heart disease data set, originally analyzed by Gamberger and Lavrač (2002). The visualizations are evaluated by considering their

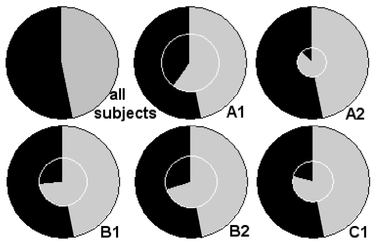

Figure 8: Subgroup visualization by pie charts.

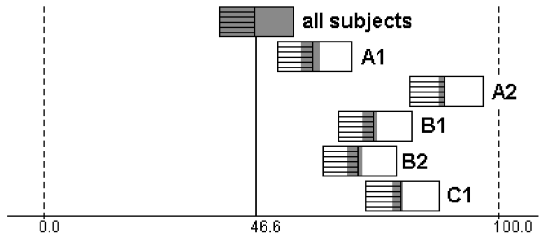

Figure 9: Subgroup visualization by box plots.

intuitiveness, correctness of displayed data, usefulness, ability to display contents besides the numerical properties of subgroups, (e.g., plot subgroup probability densities against the values of an attribute), and their extensibility to multi-class problems.

4.1 Visualization by Pie Charts

Slices of pie charts are the most common way of visualizing parts of a whole. They are widely used and understood. Subgroup visualization by pie chart, proposed by Wettschereck (2002), consists of a two-level pie for each subgroup. The base pie represents the distribution of individuals in terms of the property of interest of the entire example set. The inner pie represents the size and the distribution of individuals in terms of the property of interest in a specific subgroup. An example of five subgroups (subgroups A1, A2, B1, B2, C1), as well as the base pie "all subjects" are visualized by pie charts in Figure 8.

The main weakness of this visualization is the misleading representation of the relative size of subgroups. The size of a subgroup is represented by the radius of the circle. The faultiness arises from the surface of the circle which increases with the square of its radius. For example, a subgroup that covers 20% of examples is represented by a circle that covers only 4% of the whole surface, while a subgroup that covers 50% of examples is represented by a circle that covers 25% of the whole surface. In terms of usefulness, this visualization is not very handy since—in order to compare subgroups—one would need to compare sizes of circles, which is difficult. The comparison of distributions in subgroups is also not straightforward. This visualization also does not show the contents of subgroups. It would be possible to extend this visualization to multi-class problems.

4.2 Visualization by Box Plots

In subgroup visualization by box plots, introduced by Wrobel (2001), each subgroup is represented by one box plot (all examples are also considered as one subgroup and are displayed in the top box). Each box shows the entire population; the horizontally stripped area on the left represents the positive examples and the white area on the right-hand side of the box represents the negative examples. The grey area within each box indicates the respective subgroup. The overlap of the grey area with the hatched area shows the overlap of the group with the positive examples. Hence, the more to the left the grey area extends the better. The less the grey area extends to the right of the hatched area, the more specific a subgroup is (less overlap with the subjects of the negative class). Finally, the location of the box along the X-axis indicates the relative share of the target class within each subgroup: the more to the right a box is placed, the higher is the share of the target value within this subgroup. The vertical line (in Figure 9 at value 46.6%) indicates the default accuracy, that is, the number of positive examples in the entire population. An example box plot visualization of five subgroups is presented in Figure 9.

On the negative side, the intuitiveness of this visualization is relatively poor since an extensive explanation is necessary for understanding it. It is also somewhat illogical since the boxes that are placed more to the right and have more grey color on the left-hand side represent the best subgroups. This visualization is not very attractive since most of the image is white; the grey area (the part of the image that really represents the subgroups) is a relatively tiny part of the entire image. On the positive side, all the visualized data are correct and the visualization is useful since the subgroups are arranged by their confidence. It is also easier to contrast the sizes of subgroups compared to their pie chart visualization. However, this visualization does not display the contents of the data. It would also be difficult to extend this visualization to multi-class problems.

4.3 Visualizing Subgroup Distribution w.r.t. a Continuous Attribute

The distribution of examples w.r.t. a continuous attribute, introduced by Gamberger and Lavrač (2002) and Gamberger et al. (2002), was used in the analysis of several medical domains. It is the only subgroup visualization method that offers an insight of the visualized subgroups. The approach assumes the existence of at least one numeric (or ordered discrete) attribute of expert's interest for subgroup analysis. The selected attribute is plotted on the X-axis of the diagram. The Y-axis represents the target variable, or more precisely, the number of instances belonging to target property C (shown on the $Y+$ axis) or not belonging to C (shown on the $Y-$ axis) for the values of the attribute on the X-axis. It must be noted that both directions of the Y-axis are used to indicate the number of instances. The entire data set and two subgroups A1 and B2 are visualized by their distribution over a continuous attribute in Figure 10.

This visualization method is not completely automatic, since the automatic approach does not provide consistent results. The automatic approach calculates the number of examples for each value of the attribute on the X-axis by moving a sliding window and counting the number of examples in that window. The outcome is a smooth line. The difficulty arises when the attribute from the X-axis appears in the subgroup description. In such a case, a manual correction is needed for this method to be realistic.

This visualization method is very intuitive since it practically does not need much explanation. It is attractive and very useful to the end user since it offers an insight in the contents of displayed

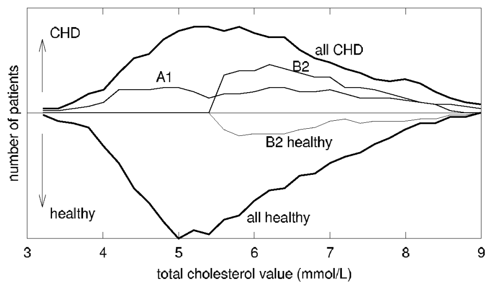

Figure 10: Subgroup visualization w.r.t. a continuous attribute. For clarity of the picture, only the positive (Y+) side of subgroup A1 is depicted.

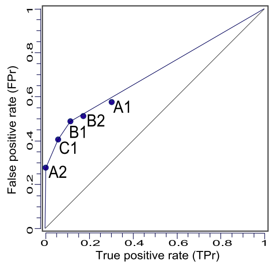

Figure 11: Representation of subgroups in the ROC space.

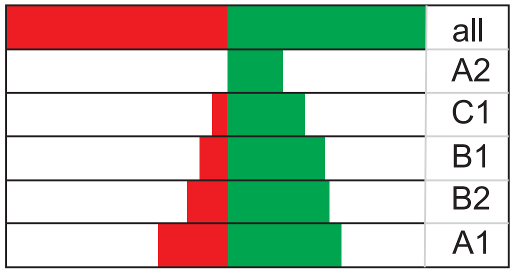

Figure 12: Subgroup visualization by bar charts.

examples. However, the correctness of displayed data is questionable. It is impossible to generalize this visualization to multi-class problems.

4.4 Representation in the ROC Space

The ROC (Receiver Operating Characteristics) (Provost and Fawcett, 2001) space is a 2-dimensional space that shows classifier (rule/rule set) performance in terms of its false positive rate (*FPr*) plotted on the X-axis, and true positive rate (*TPr*) plotted on the Y-axis. The ROC space is appropriate for measuring the success of subgroup discovery, since subgroups whose $\frac{TPr}{FPr}$ tradeoffs are close to the main diagonal (line connecting the points (0, 0) and (1, 1) in the ROC space) can be discarded as insignificant (Kavšek and Lavrač, 2006); the reason is that the rules with the $\frac{TPr}{FPr}$ ration on the main diagonal have the same distribution of covered positives and negatives (*TPr*= *FPr*) as the distribution in the entire data set. An example of five subgroups represented in the ROC space is shown in Figure 11.

Even though the ROC space is an appropriate rule visualization, it is usually used just for the evaluation of discovered rules. The ROC convex hull is the line connecting the potentially optimal subgroups. The area under the ROC convex hull (AUC, area under curve) is a measure of quality of the resulting ruleset.[7]

This visualization method is not intuitive to the end user, but is absolutely clear to every machine learning expert. The displayed data is correct, but there is no content displayed. An advantage of this method compared to the other visualization methods is that it allows the comparison of outcomes of different algorithms at the same time. The ROC space is designed for two-class problems and is therefore inappropriate for multi-class problems.

4.5 Bar Charts Visualization

The visualization by bar charts was introduced by Kralj et al. (2005). In this visualization, the purpose of the first line is to visualize the distribution of the entire example set. The area on the right represents the positive examples and the area on the left represents the negative examples of the target class. Each following line represents one subgroup. The positive and the negative examples of each subgroup are drawn below the positive and the negative examples of the entire example set. Subgroups are sorted by the relative share of positive examples (precision).

7. Note that in terms of $\frac{TPr}{FPr}$ ratio optimality, two subgroups (A1 and B2) are suboptimal, lying below the ROC convex hull.

An example of five subgroups visualized by bar charts is shown in Figure 12. It is simple, understandable and shows all the data correctly. This visualization method allows simple comparison between subgroups and is therefore useful. It is relatively straight-forward to understand and can be extended to multi-class problems. It does not display the contents of data, though.

4.6 Summary of Subgroup Visualization Methods

In this section, we (subjectively) compare the five different subgroup visualization methods by considering their intuitiveness, correctness of displayed data, usefulness, ability to ability to display contents besides the numerical properties of subgroups, (e.g., plot subgroup probability densities against the values of an attribute), and their extensibility to multi-class problems. The summary of the evaluation is presented in Table 6.

	Pie chart	Box plot	Continuous attribute	ROC	Bar chart
Intuitiveness	+	-	+	+/-	+
Correctness	-	+	-	+	+
Usefulness	-	+	+	+	+
Contents	-	-	+	-	-
Multi-class	+	-	-	-	+

Table 6: Our evaluation of subgroup visualization methods.

Two visualizations score best in Table 6 of our evaluation of subgroup visualization methods: the visualization of subgroups w.r.t. a continuous attribute and the bar chart visualization. The visualization of subgroups w.r.t. a continuous attribute is the only visualization that directly shows the contents of the data; its main shortcomings are the doubtful correctness of the displayed data and its difficulty to be extended to multi-class problems. It also requires a continuous or ordered discrete attribute in the data. The bar chart visualization combines the good properties of the pie chart and the box plot visualization. In Table 6, it only fails in displaying the contents of the data. By using the two best visualizations, one gets a very good understanding of the mining results.

To show the applicability of subgroup discovery visualizations for supervised descriptive rule discovery, the bar visualizations of results of contrast set mining, jumping emerging patterns and subgroup discovery on the survey data analysis problem of Section 2 are shown in Figures 13, 14 and 15, respectively.

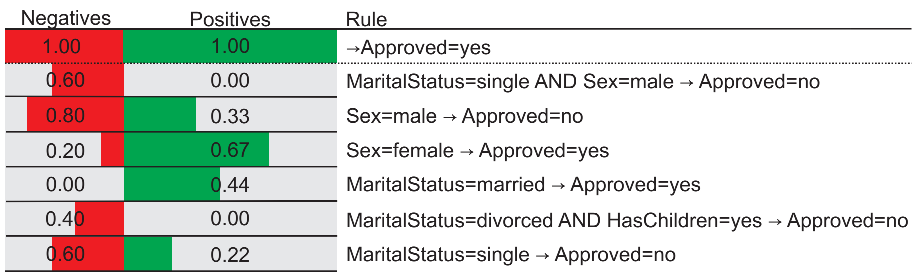

Figure 13: Bar visualization of contrast sets of Figure 3.

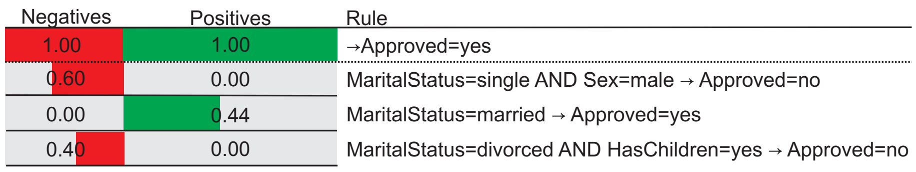

Figure 14: Bar visualization of jumping emerging patterns of Figure 4.

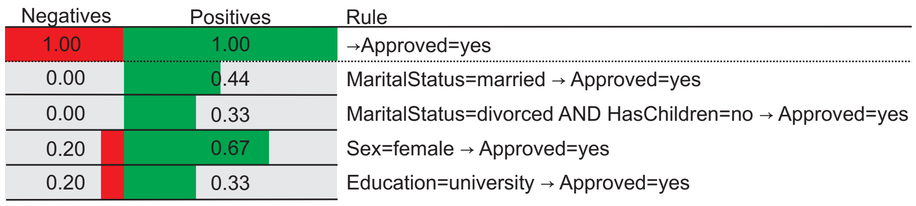

Figure 15: Bar visualization of subgroups of Figure 5 of individuals who have approved the issue.

5. Conclusions

Patterns in the form of rules are intuitive, simple and easy for end users to understand. Therefore, it is not surprising that members of different communities have independently addressed supervised descriptive rule induction, each of them solving similar problems in similar ways and developing vocabularies according to the conventions of their respective research communities.

This paper sheds a new light on previous work in this area by providing a systematic comparison of the terminology, definitions, goals, algorithms and heuristics of contrast set mining (CSM), emerging pattern mining (EPM) and subgroup discovery (SD) in a unifying framework called supervised descriptive rule discovery. We have also shown that the heuristics used in CSM and EPM can be translated into two well-known heuristics used in SD, both aiming at trading-off between coverage and distributional difference. In addition, the paper presents a critical survey of existing visualization methods, and shows that some methods used in subgroup discovery can be easily adapted for use in CSM and EPM.

Abstract

This paper proposes the application of particle swarm optimization (*PSO*) to the problem of *full model selection, FMS,* for classification tasks. *FMS* is defined as follows: given a pool of preprocessing methods, feature selection and learning algorithms, to select the combination of these that obtains the lowest classification error for a given data set; the task also includes the selection of hyperparameters for the considered methods. This problem generates a vast search space to be explored, well suited for stochastic optimization techniques. *FMS* can be applied to any classification domain as it does not require domain knowledge. Different model types and a variety of algorithms can be considered under this formulation. Furthermore, competitive yet simple models can be obtained with *FMS*. We adopt *PSO* for the search because of its proven performance in different problems and because of its simplicity, since neither expensive computations nor complicated operations are needed. Interestingly, the way the search is guided allows *PSO* to avoid overfitting to some extend. Experimental results on benchmark data sets give evidence that the proposed approach is very effective, despite its simplicity. Furthermore, results obtained in the framework of a model selection challenge show the competitiveness of the models selected with *PSO*, compared to models selected with other techniques that focus on a single algorithm and that use domain knowledge.

Keywords: full model selection, machine learning challenge, particle swarm optimization, experimentation, cross validation

1. Introduction

Model selection is the task of picking the model that best describes a data set (Hastie et al., 2001). Since the phrase *describing a data set* can be interpreted in several different ways, the model selection task can denote diverse related problems, including: variable and feature selection (Bengio and Chapados, 2003; Guyon et al., 2006a; Guyon and Elisseeff, 2003), system identification (Voss and Feng, 2002; Nelles, 2001), parameter-hyperparameter optimization (Guyon et al., 2006b; Kim et al., 2002; Hastie et al., 2001; Cawley and Talbot, 2007b; Escalante et al., 2007), and discretization (Boullé, 2007; Hue and Boullé, 2007). In this paper we give a broader interpretation to this task and call it *full model selection* (*FMS*). The *FMS* problem consists on the following: given a pool of preprocessing methods, feature selection and learning algorithms, select the combination of these that obtains the lowest classification error for a given data set. This task also includes the selection of hyperparameters for the considered methods, resulting in a vast search space that is well suited for stochastic optimization techniques.

Adopting a broader interpretation to the model selection problem allows us to consider different model types and a variety of methods, in contrast to techniques that consider a single model type (i.e., either learning algorithm or feature selection method, but not both) and a single method (e.g., neural networks). Also, since neither prior domain knowledge nor machine learning knowledge is required, *FMS* can be applied to any classification problem without modification. This is a clear advantage over ad-hoc model selection methods that perform well on a single domain or that work for a fixed algorithm. This will help users with limited machine learning knowledge, since *FMS* can be seen as a black-box tool for model selection. Machine learning experts can also benefit from this approach. For example, several authors make use of search strategies for the selection of *candidate models* (Lutz, 2006; Boullé, 2007; Reunanen, 2007; Wichard, 2007), the *FMS* approach can be adopted for obtaining such candidate models.

One could expect a considerable loss of accuracy by gaining generality. However, this is not the case of the proposed approach since in international competitions it showed comparable performance to other techniques that were designed for a single algorithm (i.e., doing hyperparameter optimization) and to methods that took into account domain knowledge (Guyon et al., 2008). The main drawback is the computational cost to explore the vast search space, particularly for large data sets. But, we can gain efficiency without a significant loss in accuracy, by adopting a random subsampling strategy, see Section 4.3. The difficult interpretability of the selected models is another limitation of the proposed approach. However, naive users may accept to trade interpretably for ease-of-use, while expert users may gain insight in the problem at hand by analyzing the structure of the selected model (type of preprocessing chosen, number of features selected, linearity or non-linearity of the predictor).

In this paper, we propose to use particle swarm optimization (*PSO*) for exploring the full-models search space. *PSO* is a bio-inspired search technique that has shown comparable performance to that of evolutionary algorithms (Angeline, 1998; Reyes and Coello, 2006). Like evolutionary algorithms, *PSO* is useful when other techniques such as gradient descend or direct analytical discovery are not applicable. Combinatoric and real-valued optimization problems in which the optimization surface possesses many locally optimal solutions, are well suited for swarm optimization. In *FMS* it must be found the best combination of methods (for preprocessing, feature selection and learning) and simultaneously optimizing real valued functions (finding pseudo-optimal parameters for the considered methods), in consequence, the application of *PSO* is straightforward.

The methodological differences between swarm optimization and evolutionary algorithms have been highlighted by several authors (Angeline, 1998; Kennedy and Eberhart, 1995, 2001). However a difference in performance has not been demonstrated in favor of either method. Such demonstration would be a difficult task because no black-box stochastic optimization algorithm can outperform another over all optimization problems, not even over random search (Wolpert and Macready, 1997; van den Bergh, 2001). We selected *PSO* instead of evolutionary algorithms because of its simplicity and generality as no important modification was made for applying it to *FMS*. *PSO* is easier to implement than evolutionary algorithms because it only involves a single operator for updating solutions. In contrast, evolutionary algorithms require a particular representation and specific methods for cross-over, mutation, speciation and selection. Furthermore, *PSO* has been found to be very effective in a wide variety of applications, being able to produce good solutions at a very low computational cost (Gudise and Venayagamoorthy, 2003; Hernández et al., 2004; Xiaohui et al., 2003; Yoshida et al., 2001; Robinson, 2004; Kennedy and Eberhart, 2001; Reyes and Coello, 2006).

PSO is compared to pattern search (*PS*) in order to evaluate the added value of using the swarm strategy instead of another intensive search method. We consider *PS* among other search techniques because of its simplicity and proved performance in model selection (Momma and Bennett, 2002; Bi et al., 2003; Dennis and Torczon, 1994). Cross validation (*CV*) is used in both techniques for assessing the *goodness* of models. Experimental results in benchmark data give evidence that both *PSO* and *PS* are effective strategies for *FMS*. However, it was found that *PSO* outperforms *PS*, showing better convergence behavior and being less prone to overfitting. Furthermore, the proposed method was evaluated in the context of a model selection competition in which several specialized and prior-knowledge based methods for model selection were used. Models selected with *PSO* were always among the top ranking models through the different stages of the challenge (Guyon et al., 2006c, 2007, 2008; Escalante et al., 2007). During the challenge, our best entry was ranked 8th over all ranked participants, 5th among the methods that did not use domain knowledge and 2nd among the methods that used the software provided by the organizers (Guyon et al., 2006c, 2007, 2008). In this paper we outperform the latter entry while reducing the computational burden by using a subsampling strategy; our best entry is currently the top-ranked one among models that do not use prior domain knowledge and 2nd over all entries, see Section 4.3.

PSO has been widely used for parameter selection in supervised learning (Kennedy and Eberhart, 1995, 2001; Salerno, 1997; Gudise and Venayagamoorthy, 2003). However, parameter selection is related with the first level of inference in which, given a learning algorithm, the task is to find parameters for such algorithm in order to describe the data. For example, in neural networks the adjustment of weights between units according to some training data is a parameter selection problem. Hyperparameter optimization, on the other hand, is related with the second level of inference, that is, finding parameters for the methods that in turn should determine parameters for describing the data. In the neural network example, selecting the optimal number of units, the learning rate, and the number of epochs for training the network is a hyperparameter optimization problem. *FMS* is capable of operating across several levels of inference by simultaneously performing feature selection, preprocessing and classifier selection, and hyperparameter optimization for the selected methods. *PSO* has been used for hyperparameter optimization by Voss and Feng (2002), however they restricted the problem to linear systems for univariate data sets, considering one hundred data observations. In this paper we are going several steps further: we applied *PSO* for *FMS* considering non-linear models in multivariate data sets with a large number of observations.

Parallel to this work, Gorissen et al. used genetic algorithms for meta-model selection in regression tasks (Gorissen, 2007; Gorissen et al., 2008), a similar approach that emerged totally independently to our proposal. One should note, however, that this method has been used for a different task in low dimensional data sets; most results are reported for 2D data. Even with this dimensionality the method has been run for only a few iterations with a small population size. Their use of a genetic algorithm required the definition of specific operators *for each of the considered models*. Gorissen et al. considered seven different models (including neural networks and kernel methods) that required of 18 different genetic operators for creation, mutation and cross-over (Gorissen, 2007; Gorissen et al., 2008). Additionally, general operators for speciation and selection were also defined. In the present work a single operator was used for updating solutions, regardless of the considered models. This clearly illustrates the main advantage of *PSO* over genetic algorithms, namely generality and simplicity.

The main contribution of this work is experimental: we provide empirical evidence indicating that by using *PSO* we were able to perform intensive search over a huge space and succeeded in selecting competitive models without significantly overfitting. This is due to the way the search is guided in *PSO*: performing a broad search around promising solutions but not overdoing in terms of really fine optimization. This sort of search is known to help avoiding overfitting by *undercomputing* (Dietterich, 1995). Experimental results supported by some a posteriori analysis give evidence of the validity of our approach. The way we approached the model selection problem and the use of a stochastic-search strategy are also contributions. To the best of our knowledge there are no similar works that consider the *FMS* problem for classification tasks.

The rest of this paper is organized as follows. In the next section we describe the general *PSO* algorithm. In Section 3, we describe the application of *PSO* to *FMS*. Section 4 presents experimental results in benchmark data; comparing the performance of *PSO* to that of *PS* in *FMS* and analyzing the performance of *PSO* under different parameter settings; also, are described the results obtained in the framework of a model selection competition. In Section 5, we analyze mechanisms in *PSMS* that allow to select competitive models without overfitting the data. Finally, in Section 6, we present the conclusions and outline future research directions.

2. Particle Swarm Optimization (*PSO*)

PSO is a population-based search algorithm inspired by the behavior of biological communities that exhibit both individual and social behavior; examples of these communities are flocks of birds, schools of fishes and swarms of bees. Members of such societies share common goals (e.g., finding food) that are realized by exploring its environment while interacting among them. Proposed by Kennedy and Eberhart (1995), *PSO* has become an established optimization algorithm with applications ranging from neural network training (Kennedy and Eberhart, 1995; Salerno, 1997; Kennedy and Eberhart, 2001; Gudise and Venayagamoorthy, 2003; Engelbrecht, 2006) to control and engineering design (Hernández et al., 2004; Xiaohui et al., 2003; Yoshida et al., 2001; Robinson, 2004). The popularity of *PSO* is due in part to the simplicity of the algorithm (Kennedy and Eberhart, 1995; Reyes and Coello, 2006; Engelbrecht, 2006), but mainly to its effectiveness for producing good results at a very low computational cost (Gudise and Venayagamoorthy, 2003; Kennedy and Eberhart, 2001; Reyes and Coello, 2006). Like evolutionary algorithms, *PSO* is appropriate for problems with immense search spaces that present many local minima.

In *PSO* each solution to the problem at hand is called a particle. At each time t, each particle, i, has a position $\mathbf{x}_i^t =< x_{i,1}^t, x_{i,2}^t, \ldots, x_{i,d}^t >$ in the search space; where d is the dimensionality of the solutions. A set of particles $\mathbf{S} = \{\mathbf{x}_1^t, \mathbf{x}_2^t, \ldots, \mathbf{x}_m^t\}$ is called a swarm. Particles have an associated velocity value that they use for *flying* (exploring) through the search space. The velocity of particle i at time t is given by $\mathbf{v}_i^t =< v_{i,1}^t, v_{i,2}^t, \ldots, v_{i,d}^t >$, where $v_{i,k}^t$ is the velocity for dimension k of particle i at time t. Particles adjust their flight trajectories by using the following updating equations:

$$v_{i,j}^{t+1} = W \times v_{i,j}^t + c_1 \times r_1 \times (p_{i,j} - x_{i,j}^t) + c_2 \times r_2 \times (p_{g,j} - x_{i,j}^t), \quad (1)$$

$$x_{i,j}^{t+1} = x_{i,j}^t + v_{i,j}^{t+1} \quad (2)$$

where $p_{i,j}$ is the value in dimension j of the best solution found so far by particle i; $\mathbf{p}_i =< p_{i,1}, \ldots, p_{i,d} >$ is called personal best. $p_{g,j}$ is the value in dimension j of the best particle found so far in the swarm ($\mathbf{S}$); $\mathbf{p}_g =< p_{g,1}, \ldots, p_{g,d} >$ is considered the leader particle. Note that through

$\mathbf{p}_i$ and $\mathbf{p}_g$ each particle i takes into account individual (local) and social (global) information for updating its velocity and position. In that respect, $c_1, c_2 \in \mathbb{R}$ are constants weighting the influence of local and global best solutions, respectively. $r_1, r_2 \sim U[0,1]$ are values that introduce randomness into the search process. W is the so called inertia weight, whose goal is to control the impact of the past velocity of a particle over the current one, influencing the local and global exploration abilities of the algorithm. This is one of the most used improvements of *PSO* for enhancing the rate of convergence of the algorithm (Shi and Eberhart, 1998, 1999; van den Bergh, 2001). For this work we considered an adaptive inertia weight specified by a triplet $\mathbf{W} = (w_{start}, w_f, w_{end})$; where w_{start} and w_{end} are the initial and final values for W, respectively, and w_f indicates the fraction of iterations in which W is decreased. Under this setting W is decreased by $W = W - wdec$ from iteration $t = 1$ (where $W = w_{start}$) up to iteration $t = I \times w_f$ (after which $W = w_{end}$); where $w_{dec} = \frac{w_{start} - w_{end}}{I \times w_f}$ and I is the maximum number of iterations. This setting allows us to explore a large area at the start of the optimization, when W is large, and to slightly refine the search later by using a smaller inertia weight (Shi and Eberhart, 1998, 1999; van den Bergh, 2001).

An adaptive W can be likened to the temperature parameter in simulated annealing (Kirkpatrick et al., 1983); this is because, in essence, both parameters influence the global and local exploration abilities of their respective algorithms, although in different ways. A constant W is analogous to the momentum parameter p in gradient descend with momentum term (Qian, 1999), where weights are updated by considering both the current gradient and the weight change of the previous step (weighed by p). Interestingly, the inertia weight is also similar to the weight-decay constant (γ) used in machine learning to prevent overfitting. In neural networks the weights are decreased by $(1-\gamma)$ in each learning step, which is equivalent to add a penalty term into the error function that encourages the magnitude of the weights to decay towards zero (Bishop, 2006; Hastie et al., 2001); the latter penalizes complex models and can be used to obtain sparse solutions (Bishop, 2006).

The pseudo code of the *PSO* algorithm considered in this work is shown in Algorithm 1; default recommended values for the *FMS* problem are shown as well (these values are based on the analysis of Section 2.1 and experimental results from Section 4.2). The swarm is randomly initialized, considering restrictions on the values that each dimension can take. Next, the *goodness* of each particle is evaluated and $\mathbf{p}_g$, $\mathbf{p}_{1,\ldots,m}$ are initialized. Then, the iterative *PSO* process starts, in each iteration: *i*) the velocities and positions of each particle in every dimension are updated according to Equations (1) and (2); *ii*) the *goodness* of each particle is evaluated; *iii*) $\mathbf{p}_g$ and $\mathbf{p}_{1,\ldots,m}$ are updated, if needed; and *iv*) the inertia weight is decreased. This process is repeated until either a maximum number of iterations is reached or a minimum fitness value is obtained by a particle in the swarm (we used the first criterion for *FMS*); eventually, an (locally) optimal solution is found.

A fitness function is used to evaluate the aptitude (*goodness*) of candidate solutions. The definition of a specific fitness function depends on the problem at hand; in general it must reflect the proximity of the solutions to the optima. A fitness function $F : \Psi \rightarrow \mathbb{R}$, where Ψ is the space of particles positions, should return a scalar $f_{\mathbf{x}_i}$ for each particle position $\mathbf{x}_i$, indicating how far particle i is from the optimal solution to the problem at hand. For *FMS* the goal is to improve classification accuracy of full models. Therefore, any function F, which takes as input a model and returns an estimate of classification performance, is suitable (see Section 3.3).

Note that in Equation (1) every particle in the swarm knows the best position found so far by any other particle within the swarm, that is $\mathbf{p}_g$. Under this formulation a fully-connected swarm-topology is considered in which every member knows the leader particle. This topology has shown to converge faster than any other topology (Kennedy and Mendes, 2002; Reyes and Coello, 2006;

Algorithm 1 Particle swarm optimization.

  end for
  Update $\mathbf{p}_g$ (if necessary)
  if $t < \lfloor I \times w_f \rfloor$ then
    $W = W - w_{dec}$
  end if
  $t^{++}$
end while
return $\mathbf{p}_g$
```

Kennedy and Eberhart, 2001; Engelbrecht, 2006). With this topology, however, the swarm is prone to converge to local minima. We tried to overcome this limitation by using the adaptive inertia weight, W.

2.1 PSO Parameters

Selecting the best parameters (W, c_1, c_2, m, I) for *PSO* is another model selection task. In the application of *PSO* for *FMS* we are dealing with a very complex problem lying in the third level of inference. Fortunately, several empirical and theoretical studies have been performed about the parameters of *PSO* from which useful information can be obtained (Shi and Eberhart, 1998, 1999; Kennedy and Mendes, 2002; Reyes and Coello, 2006; Ozcan and Mohan, 1998; Clerc and Kennedy, 2002; van den Bergh, 2001). In the rest of this section the *PSO* parameters are analyzed in order to select appropriate values for *FMS*. Later on, in Section 4.2, results of experiments with *PSO* for *FMS* under different parameter settings are presented.

We will start analyzing $c_1, c_2 \in \mathbb{R}$, the weighting factors for individual and social behavior. It has been shown that convergence is guaranteed[1] for *PSO* under certain values of c_1, c_2 (van den Bergh, 2001; Reyes and Coello, 2006; Ozcan and Mohan, 1998; Clerc and Kennedy, 2002). Most convergence studies have simplified the problem to a single one-dimensional particle, setting $\phi = c_1 \times r_1 + c_2 \times r_2$, and $\mathbf{p}_g$ and $\mathbf{p}_i$ constant (van den Bergh, 2001; Reyes and Coello, 2006; Ozcan and Mohan, 1998; Clerc and Kennedy, 2002). A complete study including the inertia weight is carried out by van den Bergh (2001). In agreement with this study the value $\phi < 3.8$ guarantees eventual convergence of the algorithm when the inertia weight W is close to 1.0. For the experiments in this work it was fixed $c_1 = c_2 = 2$, with these values we have $\phi < 3.8$ with high probability $P(\phi < 3.8) \approx 0.9$, given the uniformly distributed numbers r_1, r_2 (van den Bergh, 2001). The configuration $c_1 = c_2 = 2$ also has been proven, empirically, to be an effective choice for these parameters (Kennedy and Eberhart, 1995; Shi and Eberhart, 1998, 1999; Kennedy and Mendes, 2002).

Note, however, the restriction that W remains close to 1.0. In our experiments we considered a value of $W = 1.2$ at the beginning of the search, decreasing it during 50% (i.e., $w_f = 0.5$) of the *PSO* iterations up to the value $W = 0.4$. In consequence, it is possible that at the end of the search process the swarm may show divergent behavior. In practice, however, the latter configuration for W resulted very useful for *FMS*, see Section 4. This selection of W should not be surprising since even the configuration $\mathbf{W} = (1, 1, 0)$ has obtained better results than using a fixed W in empirical studies (Shi and Eberhart, 1998). Experimental results with different configurations of $\mathbf{W}$ for *FMS* give evidence that the configuration we selected can provide better models than using constant $\mathbf{W}$, see Section 4.2; although further experiments need to be performed in order to select the best $\mathbf{W}$ configuration for *FMS*.

With respect to m, the size of the swarm, experimental results suggest that the size of the population does not damage the performance of *PSO* (Shi and Eberhart, 1999), although slightly better results have been obtained with a large value of m, (Shi and Eberhart, 1999). Our experimental results in Section 4.2 confirm that the selection of m is not crucial, although (contrary to previous results) slightly better models are obtained by using a small swarm size. The latter is an important result for *FMS* because using a small number of particles reduces the number of fitness function evaluations, and in consequence the computational cost of the search.

Regarding the number of iterations, to the best of our knowledge, there is no work on the subject. This is mainly due to the fact that this issue depends mostly on the complexity of the problem at hand and therefore a general rule cannot be derived. For *FMS* the number of iterations should not be large to avoid oversearching (Dietterich, 1995). For most experiments in this paper we fixed $I = 100$. However, experimental results in Section 4.2 show that by running *PSO* for a smaller number of iterations is enough to obtain models of the same, and even better, generalization performance. This gives evidence that early stopping can be an useful mechanism to avoid overfitting, see Section 5.

3. Particle Swarm Model Selection

Since one of the strong advantages of *PSO* is its simplicity, its application to *FMS* is almost direct. Particle swarm full model selection (hereafter *PSMS*, that is the application of *PSO* to *FMS*) is

1. Note that in *PSO* we say that the swarm converges iff $\lim_{t \to \inf} \mathbf{p}_{gt} = \mathbf{p}$, where $\mathbf{p}$ is an arbitrary position in the search space and t indexes iterations of *PSO*. Since $\mathbf{p}$ refers to an arbitrary position, this definition does not mean either convergence to local or global optimum, but convergence to the global best position in the swarm (van den Bergh, 2001; Reyes and Coello, 2006; Engelbrecht, 2006).

ID	Object name	F	Hyperparameters	Description
1	*Ftest*	*FS*	$f_{max}, w_{min}, p_{val}, fdr_{max}$	Feature ranking according the F-statistic

Table 1: Feature selection (*FS*), preprocessing (*Pre*) and postprocessing (*Pos*) objects available in *CLOP*. A brief description of the methods and their hyperparameters is presented.

described by the pseudocode in Algorithm 1, in this section are presented additional details about *PSMS*: first we describe the pool of methods considered in this work; then, we describe the representation of particles and the fitness function used; finally, we briefly discuss complexity issues. The code of *PSMS* is publicly available from the following website `http://ccc.inaoep.mx/~hugojair/code/psms/`.

3.1 The Challenge Learning Object Package

In order to implement *PSMS* we need to define the models search space. For this purpose we consider the set of methods in a machine learning toolbox from which full models can be generated. Currently, there are several machine learning toolboxes, some of them publicly available (Franc and Hlavac, 2004; van der Heijden et al., 2004; Wichard and Merkwirth, 2007; Witten and Frank, 2005; Saffari and Guyon, 2006; Weston et al., 2005); even there is a track of this journal (*JMLR*) dedicated to machine learning software. This is due to the increasing interest from the machine learning community in the dissemination and popularization of this research field (Sonnenburg, 2006). The *Challenge Learning Object Package*[2] (*CLOP*) is one of such development kits distributed under the GNU license (Saffari and Guyon, 2006; Guyon et al., 2006c, 2007, 2008). *CLOP* is a *Matlab*^{R} toolbox with implementations of feature-variable selection methods and machine learning algorithms (*CLOP* also includes the *PSMS* implementation used in this work). The list of available preprocessing, feature selection and postprocessing methods in the *CLOP* toolbox is shown in Table 1; a description of the learning algorithms available in *CLOP* is presented in Table 2. One should note that this version of *CLOP* includes the methods that best performed in a model selection competition (Guyon et al., 2008; Cawley and Talbot, 2007a; Lutz, 2006).

6	*neural*	units number, shrinkage, maxiter, balance	Neural network (Netlab)
7	*svc*	shrinkage, kernel parameters (coef0, degree, gamma)	SVM classifier
8	*kridge*	shrinkage, kernel parameters (coef0, degree, gamma)	Kernel ridge regression
9	*rf*	units number, balance, mtry	Random forest (R)
10	*lssvm*	shrinkage, kernel parameters (coef0, degree, gamma), balance	Kernel ridge regression

Table 2: Available learning objects with their respective hyperparameters in the CLOP package.

In consequence, for *PSMS* the pool[3] of methods to select from are those methods described in Tables 1 and 2. In *CLOP* a typical model consists of the *chain*, which is a grouping object that allows us to perform serial concatenation of different methods. A chain may include combinations of (several/none) feature selection algorithm(s) followed by (several/none) preprocessing method(s), in turn followed by a learning algorithm and finally (several/none) postprocessing algorithm(s). For example, the model given by:
chain$\{$*gs(*$fmax = 8$*),standardize(center=1),neural(units=10,s=0.5,balance=1,iter=10)*$\}$
uses *gs* for feature selection, *standardization* of data and a balanced *neural network* classifier with 10 hidden units, learning rate of 0.5, and trained for 10 iterations. In this work chain objects that include methods for preprocessing, feature selection and classification are considered full-models. Specifically, we consider models with at most one feature selection method, but allowing to perform preprocessing before feature selection and viceversa, see Section 3.2. The bias method was used as postprocessing in every model tested to set an optimal threshold in the output of the models in order to minimize their error. The search space in *FMS* is given by all the possible combinations of methods and hyperparameters; an infinite search space due to the real valued parameters.

3.2 Representation

In *PSO* each potential solution to the problem at hand is considered a particle. Particles are represented by their position, which is nothing but a $d-$dimensional numerical vector (d being the dimensionality of the solution). In *FMS* potential solutions are full-models, in consequence, for *PSMS* we need a way to codify a full-model by using a vector of numbers. For this purpose we propose the representation described in Equation (3), the dependence on time (t) is omitted for clarity.

$$\mathbf{x}_i = < x_{i,pre}, y_{i,1\dots N_{pre}}, x_{i,fs}, y_{i,1,\dots N_{fs}}, x_{i,sel}, x_{i,class}, y_{i,1,\dots N_{class}} > \tag{3}$$

where $x_{i,pre} \in \{1,\dots,8\}$ represents a combination of preprocessing methods. Each combination is represented by a binary vector of size 3 (i.e., the number of preprocessing methods considered), there are $2^3 = 8$ possible combinations. Each element of the binary vector represents a single preprocessing method; if the value of the k^{th} element is set to 1 then the preprocessing method with *ID* = k is used (see Table 1). For example, the first combination $< 0,0,0 >$ means *no preprocessing*; while the seventh $< 1,1,0 >$ means that this model ($\mathbf{x}_i$) uses *normalization* and *standardization* as

3. Notice that the *CLOP* package includes also the spider package (Weston et al., 2005) which in turn includes other implementations of learning algorithms and preprocessing methods. However, in this work we only used *CLOP* objects.

preprocessing. $y_{i,1\dots N_{pre}}$ codify the hyperparameters for the selected combination of preprocessing methods, $N_{pre} = 3$ because each preprocessing method has a single hyperparameter; note that the order of the preprocessing methods is fixed (i.e., *standardization* can never be performed before *normalization*), in the future we will relax this constraint. $x_{i,fs} \in \{0, \dots, 12\}$ represents the *ID* of the feature selection method used by the model (see Table 1), and $y_{i,1\dots N_{fs}}$ its respective hyperparameters; N_{fs} is set to the maximum number of hyperparameters that any feature selection method can take. $x_{i,sel}$ is a binary variable that indicates whether preprocessing should be performed before feature selection or viceversa. $x_{i,class} \in \{1, \dots, 10\}$ represents the classifier selected and $y_{i,1,\dots N_{class}}$ its respective hyperparameters; N_{class} is the maximum number of hyperparameters that a classifier can take. This numerical codification must be decoded and used with the *chain* grouping object for obtaining a full-model from a particle position $\mathbf{x}_i$. Note that the dimensionality of each particle is $d = 1 + N_{pre} + 1 + N_{fs} + 1 + 1 + N_{class} = 16$.

3.3 Fitness Function

In *FMS* it is of interest to select models that minimize classification errors on unseen data (i.e., maximizing generalization performance). Therefore, the fitness function (F) should relate a model with an estimate of its classification performance in unseen data. The simplicity of *PSMS* allows us to use any classification performance measure as F, because the method does not require derivatives. Thus, valid options for F include mean absolute error, balanced error rate, squared root error, recall, precision, area under the *ROC* curve, etcetera. For this work it was used the balanced error rate (*BER*) as F. *BER* takes into account misclassification rates in both classes, which prevents *PSMS* of selecting biased models (favoring the majority class) in imbalanced data sets. Furthermore, *BER* has been used in machine learning challenges as leading error measure for ranking participants (Guyon et al., 2007, 2008). The *BER* of model ψ is the average of the misclassifications obtained by ψ over the classes in a data set, as described in Equation (4):

$$BER(\psi) = \frac{E_+ + E_-}{2} \tag{4}$$

where E_+ and E_- are the misclassifications rates for the positive and negative classes, respectively.

The selection of the fitness function is a crucial aspect in *PSO*. However, for *PSMS*, the critical part lies in the way an estimate of generalization performance of a model (given F and training data) is obtained, and not in the fitness function itself. This is the main challenge of model selection, since error estimates using training data are very optimistic about the behavior of models on unseen data, this phenomenon is known as overfitting (Bishop, 2006; Hastie et al., 2001; Nelles, 2001). In order to overcome overfitting the *BER* was calculated using a $k-$fold cross validation *(k-fold CV)* approach (Note that the *BER* is still obtained from training data). This is the only explicit mechanism of *PSMS* to avoid overfitting. *k-fold CV* is the most used hold-out approach for model selection (Nelles, 2001; Hastie et al., 2001; Cawley and Talbot, 2007b). Using a high value for k, say $k = N$ where N is the training set size (i.e., *leave one out - CV*), the error estimate is almost unbiased, but can have high variance because the N training sets are very similar to each other (Nelles, 2001; Cawley and Talbot, 2007b); furthermore, computation time could be a serious problem (Hastie et al., 2001; Nelles, 2001). With a low value for k, the estimate can have low variance but the bias could be a problem. The selection of an optimal k is still an open problem in the model selection field. For this work were performed experiments with $k \in \{2, 5, 10\}$, but no statistically-significant difference, among these values, was found, see Section 4.2.

3.4 Computational Complexity

As we have seen, the search space in the *FMS* problem is composed by all the possible models that can be built given the considered methods and their hyperparameters. This is an infinite search space even with the restriction imposed to the values that models can take; this is the main drawback of *FMS*. However, the use of particle swarm optimization (PSO) allows us to harness the complexity of this problem. Most algorithms used for *FMS* cannot handle very big search spaces. But PSO is well suited to large search spaces: it converges fast and has a manageable computational complexity (Kennedy and Eberhart, 2001; Reyes and Coello, 2006). As we can see from Algorithm 1, *PSO* is very simple and does not involve expensive operations.

The computational expensiveness of *PSMS* is due to the fitness function we used. For each selected model the fitness function should train and evaluate such model $k-$times. Depending on the model complexity this process can be performed on linear, quadratic or higher order times. Clearly, computing the fitness function using the entire training set, as opposed to *k-fold CV*, could reduce *PSMS* complexity, although we could easily overfit the data. For a single run of *PSMS* the fitness function should be evaluated $\rho = m \times (I+1)$ times, with m being the swarm size and I the number of iterations. Suppose the computational complexity of model λ is bounded by λ_O then the computational complexity of *PSMS* will be bounded by $\rho \times k \times \lambda_O$. Because λ_O is related to the computational complexity of model λ (which depends on the size and dimensionality of the data set) this value may vary dramatically. For instance, computing the fitness function for a naïve Bayes model in a high dimensional data set takes around two seconds[4], whereas computing the same fitness function for the same data set could take several minutes if a support vector classifier is used.

In order to reduce the computational cost of *PSMS* we could introduce a complexity penalty-term into the fitness function (this is current work). A simpler alternative solution is calculating the fitness function for each model using only a small subset of the available data; randomly selected and different each time. This approach can also be useful for avoiding local minima. The subsampling heuristic was used for high-dimensional data sets and for data sets with a large number of examples. Experimental results show an important reduction of processing time, without a significant loss of accuracy, see Section 4.3. We emphasize that complexity is due to the nature of the *FMS* problem. With this approach, however, users will be able to obtain models for their data without requiring knowledge on the data or on machine learning techniques.

4. Experimental Results

In this section results of experiments with *PSMS* using benchmark data from two different sources are presented. First, we present results on a suite of benchmark machine learning data sets[5] used by several authors (Mika et al., 2000; Rätsch et al., 2001; Cawley and Talbot, 2007b); such data sets are described in Table 3, ten replications (i.e., random splits of training and testing data) of each data set were considered. These data sets were used to compare *PSO* to *PS* in the *FMS* problem (Section 4.1) and to study the performance of *PSMS* under different settings (Section 4.2). Next we applied *PSMS* to the data sets used in a model selection competition (Section 4.3). The goal of the latter experiments is to compare the performance of *PSMS* against other model selection strategies.

4. Most of the experiments were carried out on a workstation with *Pentium*^{TM} 4 processor at 2.5 GHz, and 1 gigabyte in RAM.
5. These data sets are available from `http://ida.first.fraunhofer.de/projects/bench/benchmarks.htm`.

4.1 A Comparison of *PSO* and *PS*

In the first set of experiments we compared the performance of *PSO* to that of another search strategy in the *FMS* problem. The goal was to evaluate the advantages of using the swarm strategy over another intensive search method. Among the available search techniques we selected *PS* because of its simplicity and proved performance in model selection (Dennis and Torczon, 1994; Momma and Bennett, 2002; Bi et al., 2003). *PS* is a direct search method that samples points in the search space in a fixed pattern about the best solution found so far (the center of the pattern). Fitness values are calculated for the sampled points trying to find a minimizer; if a new minimum is find then the center of the pattern is changed, otherwise the search step is reduced by half; this process is iterated until a stop criteria is met. The considered *PS* algorithm described in Algorithm 2 is an adaptation of that proposed by Momma et al. for hyperparameter optimization of support vector regression (Momma and Bennett, 2002; Bi et al., 2003).

The input to *PS* is the pattern P and the search step Δ. Intuitively, P specifies the direction of the neighboring solutions that will be explored; while Δ specifies the distance to such neighboring solutions. There are several ways to generate P; for this work we used the nearest neighbor sampling pattern (Momma and Bennett, 2002). Such pattern is given numerically by $P = [\mathbf{I}_d \; -\mathbf{I}_d \; \mathbf{0}_{1\times d}^T]$, where $\mathbf{I}_d$ is the identity matrix of size d; $\mathbf{0}_{1\times d}$ is a vector of size $1_\times d$ with all zero entries; d is the dimensionality of the problem. Δ, a vector of size $1 \times d$, is the search step by which the space of solutions is explored. We defined $\Delta = \frac{\mathbf{q}_{maxvals} - \mathbf{q}_{minvals}}{2}$, where $\mathbf{q}_{maxvals}$ and $\mathbf{q}_{minvals}$ are the maximum and minimum values that the solutions can take, respectively. Each iteration of *PS* involves the evaluation of $N_c - 1$ solutions (where N_c is the number of columns of P). Solutions are updated by adding s_j ($j \in 1,\ldots,N_c - 1$) to the current-best solution $\mathbf{q}_g$; where each s_j is obtained by multiplying (element-by-element) the search step vector Δ and the j^{th} column of P. $\mathbf{q}_g$ is replaced by a new solution $\mathbf{q}_j$ only if $f_{\mathbf{q}_j} < f_{min} = f_{\mathbf{q}_g}$. The output of *PS* is $\mathbf{q}_g$, the solution with the lowest fitness value; we encourage the reader to follow the references for further details (Momma and Bennett, 2002; Dennis and Torczon, 1994).

For applying *PS* to the *FMS* problem (hereafter *PATSMS*) the solution $\mathbf{q}_g$ was initialized in the same way that each particle in the swarm was initialized for *PSMS* (i.e., randomly). The same

Algorithm 2 Pattern search. p_i is the i^{th} column of P, N_c the number of columns in P.

```
**Require:**
– $I_{ps}$: number of iterations
– $\mathbf{F}(\Psi \rightarrow \mathbb{R})$: fitness function
– $\mathbf{P}$: pattern
– $\Delta$: search step
Initialize solution $\mathbf{q}_i$ $(i = 1)$
Compute $f_{\mathbf{q}_i} = F(\mathbf{q}_i)$ (Section 3.3)
Set $\mathbf{q}_g = \mathbf{q}_i$; $f_{min} = f_{\mathbf{q}_i}$
while $i < I_{ps}$ do
  for all $p_j \in P_{1,\dots,N_c-1}$ do
    $s_j = \Delta . p_j$
    $\mathbf{q}_j = \mathbf{q}_g + s_j$
    Compute $f_{\mathbf{q}_j} = F(\mathbf{q}_j)$
    if $f_{\mathbf{q}_j} < f_{min}$ then
      Update $\mathbf{q}_g$ $(\mathbf{q}_g = \mathbf{q}_j, f_{min} = f_{\mathbf{q}_j})$
    end if
    $i^{++}$
  end for
  $\Delta = \Delta/2$
end while
return $\mathbf{q}_g$
```

representation, fitness function and restrictions on the values that each dimension can take were considered for both methods, see Section 3. Under these settings *PS* is a very competitive baseline for *PSO*.

In each experiment described below, we let *PS* and *PSO* perform the same number of fitness function evaluations, using exactly the same settings and data sets, guaranteeing a fair comparison. Since both methods use the same fitness function and perform the same number of fitness function evaluations, the difference in performance indicates the gain we have by guiding the search according to Equations (1) and (2). As recommended by Demsar, we used the Wilcoxon signed-rank test for the comparison of the resultant models (Demsar, 2006). In the following we will refer to this statistical test with 95% of confidence when mentioning statistical significance.

We compared the *FMS* ability of *PSMS* and *PATSMS* by evaluating the accuracy of the selected models at the end of the search process; that is, we compared the performance of models $\mathbf{p}_g$ and $\mathbf{q}_g$ in Algorithms 1 and 2, respectively. We also compared the performance of the solutions tried through the search. For each trial we fixed the number of iterations for *PSMS* to $I = 100$ with a swarm size of $m = 10$. In consequence, both search strategies performed $m \times (I+1) = 1010$ evaluations of the fitness function in each run. Because more than $180,000$ models were tested we used $2-$fold *CV* for computing the fitness function. In each trial the training set was used for *FMS* and the resultant model was evaluated in the test set. This process was repeated for each replica of each data set described in Table 3. Averaged results of this experiment are shown in Table 4. We show the average *CV* error obtained through the search process (*CV-BER*) and the error obtained by the selected model, at the end of the search, in the test set (*test-BER*).

ID	Data set	PATSMS test-BER	PSMS test-BER	PATSMS CV-BER	PSMS CV-BER

Table 4: Average and variance of *test-BER* and *CV-BER* obtained by models selected with *PSMS* and *PATSMS*, the best results are shown in **bold**. *test-BER* is the *BER* obtained by the selected model using the test set (averaged over 10 replications of each data set). *CV-BER* is the average of *CV BER* obtained by each of the candidate solutions through the search process (averaging performed over all particles and iterations and over 10 replications of each data set) .

The performance of both search strategies is similar. *PSMS* outperformed *PATSMS* through all of the data sets at the end of the search process (Columns 3 and 4 in Table 4). The *test-BER* differences are statistically significant for all but the *flare-solar* and *german* data sets. In the latter data sets the hypothesis that models selected with *PATSMS* and *PSMS* perform equally cannot be rejected. However, note that for these data sets the models selected with *PSMS* outperformed those selected with *PATSMS* in 6 out of 10 replications. Globally, we noticed that from the 90 trials ($9-$data sets, $\times$ $10-$replications for each, see Table 3), 68.9% of the models selected with *PSMS* outperformed those obtained with *PATSMS*. While only in 22.2% of the runs *PATSMS* outperformed *PSMS*, in the rest both methods tied in performance. A statistical test over these 90 results was performed and a statistically-significant difference, favoring *PSMS*, was found. Despite *PATSMS* being a strong baseline, these results give evidence that *PSMS* outperforms *PATSMS* at the end of the search process.

Columns five and six in Table 4 show the average *BER* obtained with each strategy through the 1010 evaluations for each data set (averaged over replications). *CV-BER* reflects the behavior of the search strategies through the search process. *PATSMS* slightly outperformed *PSMS* in this aspect, though the difference is statistically significant only for the *Heart*, *image* and *thyroid* data sets. The slight superior performance of *PATSMS* in *CV-BER* is due to the pattern we used and the search procedure itself. *PATSMS* performs a finer grained search over a restricted search area around the initial solution $\mathbf{q}_g$. The latter results in a lower *CV-BER* because *PATSMS* always moves the pattern towards the local minimum nearest to the initial solution, $\mathbf{q}_g$. *PSMS,* on the other hand, explores a much larger search space because the search is not only guided by the best solution found so far ($\mathbf{p}_g$), but also by the individual best solutions of each particle ($\mathbf{p}_{1,\dots,m}$). The latter produces a higher *CV-BER* in average because, even when the *CV-BER* of the final models is low, many models of varied *CV-BER* performance are tried through the search.

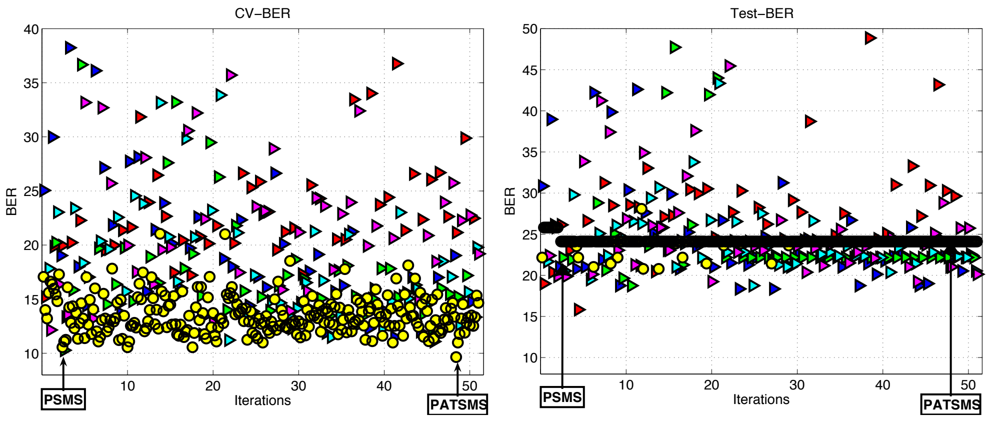

Figure 1: Performance of *PATSMS* (circles) and *PSMS* (triangles) as a function of number of iterations for an experiment with one replication of the *Heart* data set. For *PSMS* we show the performance of each particle with a different color. Left: Cross-validation Balanced Error Rate (*BER*). Right: Test set *BER*. In both plots we indicate with an arrow the model selected by each search strategy.

In Figure 1 we show the performance of the solutions tried through the search by each method for a single replication of the *Heart* data set (for clarity in the plots we used $m = 5$ and $I = 50$ for this experiment). We show the *CV* and test *BER* for every model tried through the search. It can be seen that the *CV-BER* of *PATSMS* is lower than that of *PSMS*, showing an apparent better convergence behavior (left plot in Figure 1). However, by looking the test *BER* of the models tried, it becomes evident that *PATSMS* is trapped into a local minimum since the very first iterations (right plot in Figure 1). *PSMS*, on the other hand, obtains a higher *CV-BER* through the search, though it is less prone to follow a local minimum. This is because with *PSMS* the search is guided by one global and m local solutions, which prevents *PSMS* from performing a pure local search; the latter in turn prevents *PSMS* of overfitting the data. This result gives evidence of the better convergence behavior of *PSMS*.

The model selected with *PSMS* obtained a lower *test-BER* than that selected with *PATSMS* (see right plot in Figure 1). In fact all of the solutions in the final swarm outperformed the solution obtained with *PATSMS* in *test-BER*. With *PSMS* the model of lowest test *BER* was obtained after 3 iterations of *PSMS*, giving evidence of the fast convergence of *PSO*. One should note that the *test-BER* of the worst *PSMS* solutions is higher than that of the best *PATSMS* solution. However, near the end of the search, the possibilities that *PSMS* can select a worse solution than *PATSMS* are small.

We have seen that *PATSMS* is prone to get trapped into a local minimum because it performs a fine grained search over a small area. This causes that only a few methods are considered through the search with this method. *PSMS*, on the other hand, tries a wide variety of classifiers and feature selection methods, exploring a larger search space and being able to escape from local minima. In order to analyze the diversity of the methods considered by *PSMS*, in Figure 2 we show the

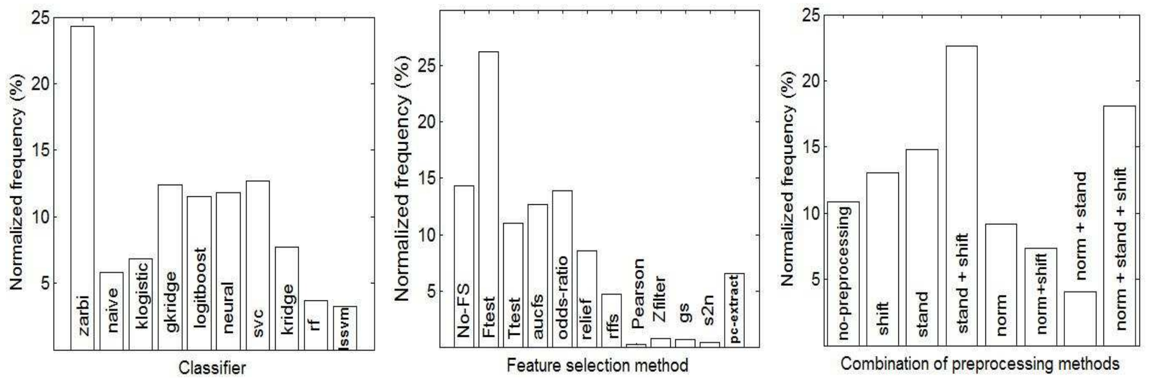

Figure 2: Normalized frequency of classifiers (left), feature selection method (middle) and combination of preprocessing methods (right) preferred by *PSMS* through the search process. In the right plot, the abbreviations *shift*, *stand* and *norm* stand for *shift-scale*, *standardization* and *normalization*, respectively. Results are normalized over the 90,900 models tried for obtaining the results from Table 4.

normalized frequency of methods preferred by *PSMS*[6] through the search. The results shown in this figure are normalized over the 90,900 models tried for obtaining the results from Table 4. From this figure, we can see that most of the classifiers and feature selection methods were considered for creating solutions. No classifier, feature selection method or combination of preprocessing methods was used for more than 27% of the models. This reflects the fact that different methods are required for different data sets and that some are equivalent. There were, however, some methods that were slightly more used than others.

The preferred classifier was the *zarbi CLOP*-object, that was used for about 23% of the models. This is a surprising result because *zarbi* is a very simple linear classifier that separates the classes by using information from the mean and variance of training examples (Golub et al., 1999). However, in 97.35% of the times that *zarbi* was used it was combined with a feature selection method. *Gkridge, svc, neural* and *logitboost* were all equally selected after *zarbi*. *Ftest* was the most used feature selection method, though most of the feature selection strategies were used. Note that *Pearson, Zfilter, gs* and *s2n* were considered only for a small number of models. The combination *standardize* + *shift-scale* was mostly used for preprocessing, although the combination *normalize* + *standardize* + *shift-scale* was also highly used. Interestingly, in 70.1% of the time preprocessing was performed before feature selection. These plots illustrate the diversity of classifiers considered by *PSMS* through the search process, showing that *PSMS* is not biased towards models that tend to perform very well individually (e.g., *logitboost, rf* or *gkridge*). Instead, *PSMS* attempts to find the best full model for each data set.

6. We do not show those preferred by *PATSMS* because the methods selected with this strategy are, most of the times, those considered in the initial solution. In our experiments we found that for each replication *PATSMS* used the same classifier and feature selection method for about 95% of the search iterations. The selection of these methods depended on the initial solution instead of the way the search space is explored or the individual performance of the methods. Therefore, no useful information can be obtained about why some methods are preferred over others, even when in average (over the 90,900 solutions tried) the histograms may look similar to those shown in Figure 2.

k	CV-BER	test-BER	test-BER*	Time
2	25.36$\pm$0.56	22.99$\pm$1.18	25.79$\pm$0.59	4166.85
5	25.18$\pm$0.59	20.50$\pm$1.53	26.30$\pm$0.46	6062.56
10	24.54$\pm$0.63	20.82$\pm$1.74	26.03$\pm$0.51	7737.11

Table 5: Average *CV-BER* (average CV result over all particles and iterations), *test-BER* (test result corresponding to the best CV result), *test-BER** (average test result over all particles and iterations) and processing time (in seconds) for different values of k in the $k-$fold *CV*. Results are averaged over a single replication of each data set described in Table 3.

4.2 Parameter Selection for *PSMS*

In this section we analyze the performance of *PSMS* under different settings. The goal is to identify mechanisms in *PSMS* that allow us obtaining competitive models and, to some extent, avoiding overfitting. For the experiments described in this section we consider a single replication for each data set. As before, we show the average *CV* error of the solutions considered during the search as well as the error of the selected model in the test set. We also show the average test set error of all solutions tried through the search *test-BER** (averaging performed over all particles and all iterations), providing information about the generalization performance of the models considered throughout the search.

4.2.1 VALUE OF K IN K-FOLD CV

First we analyze the behavior of *PSMS* for different values of k in the *CV* for computing the fitness function. We consider the values $k = [2,5,10]$. Average results of this experiment are shown in Table 5.

From this table, we can see that the performance is similar for the different values of k considered. The best results at the end of the search are obtained with $k = 5$ (column 3 in Table 5), while the best generalization performance is obtained with $k = 2$ (column 4 in Table 5). However, these differences are not statistically significant. Therefore, the null hypothesis that models selected with $k = [2,5,10]$ perform equally in *test-BER* and *test-BER** cannot be rejected. The latter is an important result because by using $k = 2$ the processing time of *PSMS* is considerably reduced. Note that for models of quadratic (or higher order) complexity, computing the fitness function with $2-$fold *CV* is even more efficient than computing the fitness function using the full training set. It is not surprising that processing time increases as we increase k (column 5 in Table 5). Although it is worth mentioning that the variance in processing time was very large (e.g., for $k = 2$ it took 7 minutes applying *PSMS* to the *titanic* data set and about five hours for the *image* data set).

4.2.2 NUMBER I OF ITERATIONS

Next we performed experiments varying the number of iterations (I), using $2-fold$ *CV* for computing the fitness function and a swarm size of $m = 10$. We considered the values $I = [10,25,50,100]$. Averaged results for this experiment are shown in Table 6 (rows 2 - 5). As we can see the best results were obtained by running *PSMS* for 50 iterations. Interestingly, models selected by running *PSMS* for 10 iterations outperformed those selected after 100 iterations in *test-BER*, though the difference

Setting	CV-BER	test-BER	test-BER*
I=10	25.33$\pm$0.33	22.17$\pm$1.81	27.64$\pm$0.52
I=25	25.29$\pm$0.33	21.88$\pm$1.68	27.59$\pm$0.49
I=50	**24.02$\pm$0.38**	**21.12$\pm$1.74**	**26.72$\pm$0.65**
I=100	24.57$\pm$0.37	22.81$\pm$1.44	27.27$\pm$0.48
m=5	**24.27$\pm$0.49**	**20.81$\pm$1.50**	**25.01$\pm$0.85**
m=10	25.07$\pm$0.34	21.64$\pm$2.04	25.99$\pm$0.74
m=20	25.09$\pm$0.34	21.76$\pm$1.84	26.00$\pm$0.64
m=40	24.82$\pm$0.43	21.45$\pm$2.13	25.96$\pm$0.78
m=50	25.32$\pm$0.44	22.54$\pm$1.65	26.11$\pm$0.77
W=(0,0,0)	**23.86$\pm$0.71**	20.40$\pm$1.71	**22.46$\pm$1.32**
W=(1.2,0.5,0.5)	24.22$\pm$0.76	**19.41$\pm$1.37**	23.38$\pm$1.34
W=(1,1,1)	27.62$\pm$0.30	21.88$\pm$1.68	27.13$\pm$0.53

Table 6: Average *CV-BER*, *test-BER* and *test-BER** for different settings of m, I and $\mathbf{W}$. The best results are shown in **bold**. Results are averaged over a single replication of each data set described in Table 3.

was not statistically significant. The difference in performance between models selected after 50 and 100 iterations was statistically significant. This result shows the fast convergence property of *PSMS* and that early stopping could be an useful mechanism to avoid overfitting, see Section 5.

4.2.3 SWARM SIZE M

In the next experiment we fixed the number of iterations to $I = 50$ and varied the swarm size as follows, $m = [5, 10, 20, 40, 50]$. Results of this experiment are shown in rows 6-10 in Table 6. This time the best result was obtained by using a swarm size of 5, however there is a statistically-significant difference only between $m = 5$ and $m = 50$. Therefore, models of comparable performance can be obtained by using $m = [5, 10, 20, 40]$. This is another interesting result because using a small swarm size reduces the number of fitness function evaluations for *PSMS* and therefore makes it more practical. An interesting result is that by using 50 iterations with any swarm size the *test-BER* is very close to the *CV-BER* estimate. Again, this provides evidence that early stopping can improve the average generalization performance of the models.

4.2.4 INERTIA WEIGHT W

We also performed experiments with different configurations for $\mathbf{W}$, the adaptive inertia weight. Each configuration is defined by a triplet $\mathbf{W} = (w_{start}, w_f, w_{end})$, whose elements indicate the starting value for W, the proportion of iterations to vary it and its final value, respectively, see Section 2. Three configurations were tried with the goal of evaluating the advantages of using an adaptive inertia weight instead of constant values. Results of this experiment are shown in rows 11-13 in Table 6. It can be seen that the best results in *CV-BER* and *Test-BER** were obtained with $\mathbf{W} = (0, 0, 0)$; the differences with the other results are statistically-significant. Under this configuration *PSMS* is not taking into account information from past velocities for updating solutions; which causes *PSMS* to converge quickly into a local minimum and refining the search around this point.

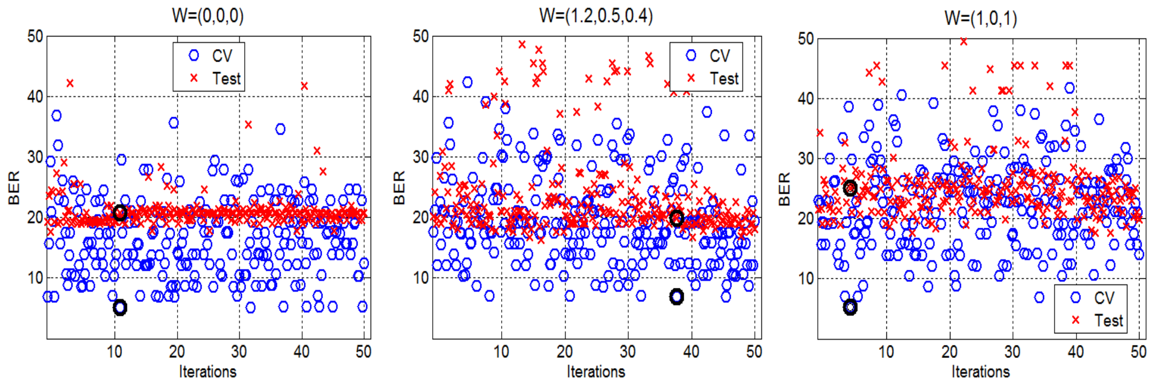

Figure 3: Algorithm performance as a function of number of iterations for different configurations of $\mathbf{W}$. *CV-BER* (circles) and *test-BER** (crosses) for the *Heart* data set. We are displaying the test and CV BER values for each particle at every time step. Since each time step involves m=5 particles, then for each iteration are displayed m=5 crosses and m=5 circles. We consider the following configurations: $\mathbf{W} = (0,0,0)$ (left), $\mathbf{W} = (1.2,0.5,0.4)$ (middle) and $\mathbf{W} = (1,0,1)$ (right). The *CV-BER* and *test-BER* of the best solution found by *PSMS* are enclosed within a bold circle.

The best result at the end of the search (column 3 in Table 6) was obtained with $\mathbf{W} = (1.2,0.5,0.4)$, the difference with the other results is statistically-significant. Under this configuration both global and local search is performed during the *PSMS* iterations; which caused higher *CV-BER* and *test-BER** than that of the first configuration, however, the generalization performance of the final model was better. The configuration $\mathbf{W} = (1,0,1)$ obtained the worst results in all of the measures; this is because under this configuration the search is never refined, since *PSMS* always takes into account the past velocity for updating solutions. The latter configuration could be a better choice for *FMS* because this way *PSMS* does not over-search around any solution; however, local search is also an important component of any search algorithm. In Figure 3 we show the *CV* and test *BER* of solutions tried during the search for the *Heart* data set under the different configurations tried. From this figure we can appreciate the fact that using constant values for W results in more local (when $\mathbf{W} = (0,0,0)$) or global search (when $\mathbf{W} = (1,0,1)$). An adaptive inertia weight, on the other hand, aims to control the tradeoff between global and local search, which results in a model with lower variance for this example. Therefore, an adaptive inertia weight seems to be a better option for *FMS*; this is because it prevents, to some extend, *PSMS* to overfit the data. However, further experiments need to be performed in order to select the best configuration for $\mathbf{W}$.

4.2.5 INDIVIDUAL (c_1) AND GLOBAL (c_2) WEIGHTS

We now analyze the performance of *PSMS* under different settings of the individual (c_1) and global (c_2) weights. We considered three configurations for c_1 and c_2; in the first one both weights have the same influence in the search (i.e., $c_1 = 2; c_2 = 2$), this was the setting used for all of the experiments reported in Section 4. In the second setting the local weight has no influence in the search (i.e., $c_1 = 0; c_2 = 2$), while in the third configuration the global weight is not considered in the search (i.e., $c_1 = 2; c_2 = 0$). We ran *PSMS* for $I = 50$ iterations with a swarm size of $m = 5$, using a single

ID	Setting	CV-BER	test-BER	test-BER*
1	$c_1 = 2; c_2 = 2$	**23.69$^+_-$0.68**	**19.72$^+_-$1.45**	**23.92$^+_-$1.16**
2	$c_1 = 0; c_2 = 2$	26.87$^+_-$0.43	22.42$^+_-$1.32	27.13$^+_-$0.55
3	$c_1 = 2; c_2 = 0$	24.99$^+_-$0.41	21.73$^+_-$1.42	25.59$^+_-$0.66

Table 7: Average *CV-BER*, *test-BER* and *test-BER** for different settings of c_1 and c_2 in Equation (1). The best results are shown in **bold**. Results are averaged over a single replication of each data set described in Table 3.

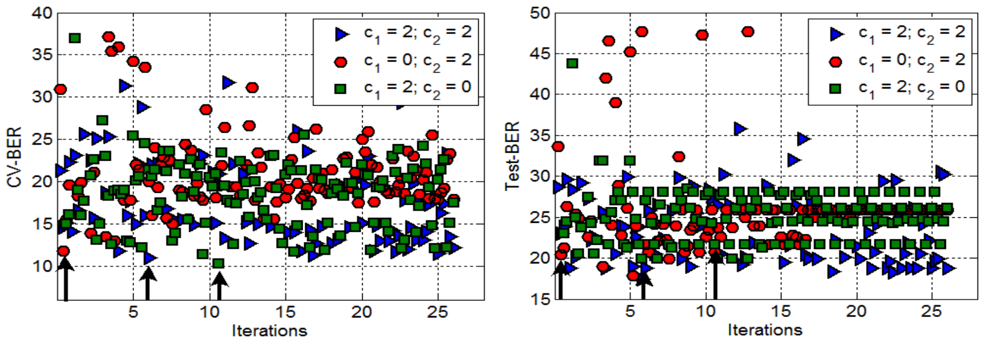

Figure 4: Performance of *PSMS* as a function of number of iterations using different settings for c_1 and c_2, see Table 7. We show the *CV-BER* (left) and *Test-BER* (right) for a single replication of the *Heart* data set. *PSMS* was ran for $I = 25$ iterations in this experiment. The models selected with each configuration are indicated with arrows.

replication for each data set described in Table 3; for the three configurations considered it was used the same adaptive inertia weight $\mathbf{W} = (1.2, 0.5, 0.4)$; averaged results of this experiment are shown in Table 7.

From this table we can see that the best performance is obtained by assigning equal weights to both factors. The difference in performance is statistically-significant over all measures with respect to the other two configurations. Therefore, by using the first configuration we can obtain solutions of better performance through and at the end of the search. More importantly, solutions of better generalization performance can be obtained with this configuration as well. The difference in performance is higher with the second configuration, where the individual-best solutions have no influence in the search; therefore, *PSMS* is searching locally around the global best solution. In the third configuration the global-best solution has no influence in the search; in consequence, the search is guided according the $m-$individual-best solutions. For illustration in Figures 4 and 5 we show the performance of *PSMS* as a function of the number of iterations for a single replication of the *Heart* data set. In Figure 4 we show the performance of *PSMS* for $I = 25$ iterations and in Figure 5 for $I = 100$ iterations.

From these figures we can see that the *CV* estimate is very similar for the different settings we considered (left plots in Figures 4 and 5). However, by looking at the performance of the solutions in the test set (right plots in Figures 4 and 5), we can appreciate that configurations 2 and 3 overfit

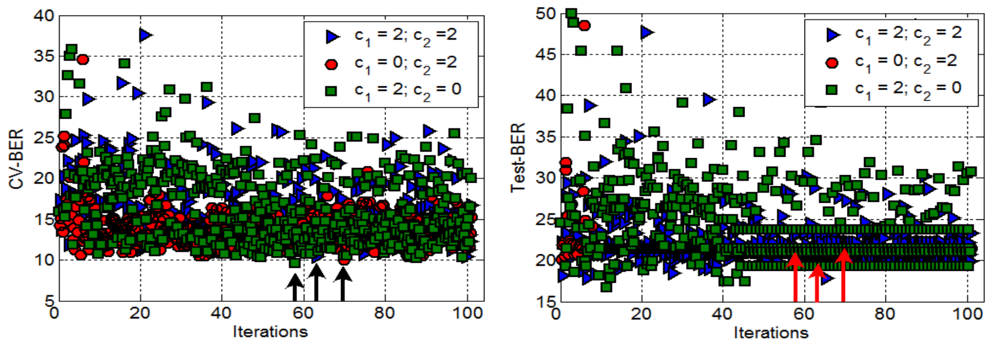

Figure 5: Performance of *PSMS* as a function of number of iterations using different settings for c_1 and c_2, see Table 7. We show the *CV-BER* (left) and *Test-BER* (right) for a single replication of the *Heart* data set. *PSMS* was ran for $I = 100$ iterations in this experiment. The models selected with each configuration are indicated with arrows.

the data (red circles and green squares). With $c_1 = 0$ we have that the $m = 5$ particles converge to single local minima, performing a fine grained search over this solution (red circles). With $c_2 = 0$ each of the $m-$particles converge to different local minima, overdoing the search over each of the m solutions (green squares). On the other hand, with the configuration $c_1 = 2, c_2 = 2$ *PSMS* is not trapped into a local minimum (blue triangles); searching around promising solutions, but without doing a fine grained search over any of them.

Better models (indicated by arrows) are selected by *PSMS* with the first configuration, even when their *CV* is higher than that of the models selected with the other configurations. This result confirms that *PSMS* is overfitting the data with the configurations 2 and 3. Note that with $I = 25$ iterations (Figure 4) the first configuration is not converging to a local minimum yet; while with $I = 100$ iterations (Figure 5) it looks like *PSMS* starts searching locally at the last iterations. This result illustrates why early stopping can be useful for obtaining better models with *PSMS*.

In order to better appreciate the generalization performance for the different configurations, in Figure 6 we plot the *CV-BER* as a function of *test-BER* for the run of *PSMS* with $I = 25$, we plot each particle with a different color.

From this figure we can see that the best model is obtained with the first configuration; for the configurations 2 and 3 the particles obtain the same *test-BER* for different solutions (middle and right plots in Figure 6). Despite the *CV* estimate is being minimized for these configurations, the *test-BER* performance of models does not improve. It is clear from the right plot in Figure 6 that with $c_2 = 0$ each particle is trapped in different local minima, doing a fine grained search over them that causes *PSMS* to overfit the data. It also can be seen from the middle plot that with $c_1 = 0$ the search is biased towards a single global-best solution (magenta circle), again, causing *PSMS* to overfit the data. On the other hand, results with the first configuration (left plot in Figure 6) show that particles do not oversearch at any solution.

4.3 Results on the Model Selection Challenge

In this section we describe experimental results of *PSMS* in the framework of a model selection competition called *agnostic learning vs. prior knowledge challenge* (*ALvsPK*) (Guyon et al., 2007,

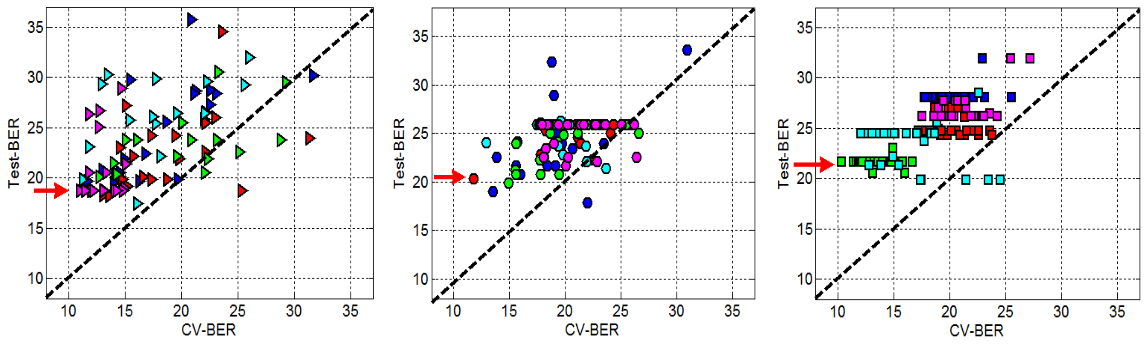

Figure 6: *Test-BER* as a function of *CV-BER* for a run of *PSMS* for $I = 25$ iterations in the *Heart* data set. Results with different configurations for c_1 and c_2 are shown. Left: $c_1 = 2$, $c_2 = 2$. Middle: $c_1 = 0, c_2 = 2$. Right: $c_1 = 2, c_2 = 0$. In each plot each particle is shown with a different color. The selected model with each configuration is indicated with an arrow.

2008). The goal of these experiments is to compare the performance of *PSMS* against other model selection strategies that work for a single algorithm or that use domain knowledge for this task. Through its different stages, the *ALvsPK* competition evaluated novel strategies for model selection as well as the added value of using prior knowledge for improving classification accuracy (Guyon et al., 2008). This sort of competitions are very useful because through them the real effectiveness of methods can be evaluated; motivating further research in the field and collaborations among participants.

4.3.1 CHALLENGE PROTOCOL AND CLOP

The rules of the challenge were quite simple, the organizers provided five data sets for binary classification together with the *CLOP* toolbox (Saffari and Guyon, 2006). The task was to obtain the model with the lowest *BER* over the five data sets on unseen data. Participants were free to elect using *CLOP* or their own learning machine implementations. The challenge is over now, although the challenge website[7] still remains open, allowing the evaluation of learning techniques and model selection methods. A complete description of the challenge and a comprehensive analysis of the results are described by Guyon et al. (2006c, 2007, 2008).

The competition was divided into two stages. The first stage, called *the model selection game* (Guyon et al., 2006c), was focused on the evaluation of pure model selection strategies. In the second stage, the goal was to evaluate the gain we can have by introducing prior knowledge into the model selection process (Guyon et al., 2007, 2008). In the latter stage participants could introduce knowledge of the data domain into the model selection process (*prior knowledge track*). Also, participants could use agnostic methods in which no domain knowledge is considered in the selection process (*agnostic track*).

The data sets used in the agnostic track of the *ALvsPK* challenge are described in Table 8, these data sets come from real domains. Data sets used for the agnostic and prior knowledge tracks were

7. See `http://www.agnostic.inf.ethz.ch/`.

different. For the agnostic track the data were preprocessed and dummy features were introduced, while for the prior knowledge track raw data were used, together with a description of the domain. We should emphasize that, although all of the approaches evaluated in the *ALvsPK* competition faced the same problem (that of choosing a model that obtains the lowest classification error for the data), such methods did not adopt the *FMS* interpretation. Most of the proposed approaches focused on a fixed machine learning technique like tree-based classifiers (Lutz, 2006), or kernel-based methods (Cawley, 2006; Pranckeviciene et al., 2007; Guyon et al., 2008), and did not take into account feature selection methods. Participants in the prior knowledge track could introduce domain knowledge. Furthermore, most of participants used their own implementations, instead of the *CLOP* toolbox.

After the challenge, the CLOP toolkit was augmented with methods, which performed well in the challenge (Cawley, 2006; Cawley and Talbot, 2007a; Lutz, 2006). These include Logitboost (Friedman et al., 2000), LSSVM (Suykens and Vandewalle, 1999), and kernel ridge regression (Saunders et al., 1998; Hastie et al., 2001).

4.3.2 COMPETITIVENESS OF PSMS

In both stages of the competition we evaluated models obtained with *PSMS* under different settings. Models obtained by *PSMS* were ranked high in the participants list, showing the competitiveness of *PSMS* for model selection (Guyon et al., 2006c, 2007, 2008; Escalante et al., 2007). Furthermore, the difference with methods that used prior knowledge was relatively small, showing that *FMS* can be a viable solution for the model selection problem without the need of investing time in introducing domain knowledge, and by considering a wide variety of methods.

The results of *PSMS* in the *ALvsPK* challenge have been partially analyzed and discussed elsewhere (Escalante et al., 2007; Guyon et al., 2007, 2008). During the challenge, our best entry (called *Corrida-final*) was ranked[8] 8^{th} over all ranked participants, 5^{th} among the methods that did not use domain knowledge and 2^{nd} among the methods that used the software provided by the organizers (Guyon et al., 2006c, 2007, 2008). For *Corrida-final* we used $k = 5$ and the full training set for computing the fitness function; we ran *PSMS* for 500 iterations for the *Ada* data set and 100 iterations for *Hiva*, *Gina* and *Sylva*. We did not applied *PSMS* to the *Nova* data set in that entry, instead we selected a model for *Nova* by trial and error. For such entry we used a version of *CLOP* where only there were available the following classifiers *zarbi, naive, neural* and *svc* (Escalante et al., 2007); also, only four feature selection methods were considered.

4.3.3 POST-CHALLENGE EXPERIMENTS

In the rest of this section we present results of *PSMS* using the augmented toolkit, including all methods described in Tables 1 and 2. In these tables we consider implementations of *logitboost, lssvm and gkridge,* which are the classifiers that won the *ALvsPK* challenge (Cawley, 2006; Cawley and Talbot, 2007a; Lutz, 2006) and were added to CLOP after the end of the challenge.

In order to efficiently apply *PSMS* to the challenge data sets we adopted a subsample strategy in which, instead of using the full training set, small subsamples of the training data were used to compute the fitness function. Each time the fitness function is computed we obtain a different random sample of size $S_{sub} = \frac{N}{SF}$, where N is the number of instances and SF is a constant that specifies the proportion of samples to be used. Subsamples are only used for the search process. At

8. See `http://www.clopinet.com/isabelle/Projects/agnostic/Results.html`.

Data set	Domain	Type	Features	Training	Validation	Testing
Ada	Marketing	Dense	48	4174	415	41471
Gina	Digits	Dense	970	3153	315	31532
Hiva	Drug discovery	Dense	1617	3845	384	38449
Nova	Text classification	Sparse binary	16969	1754	175	17537
Sylva	Ecology	Dense	216	13086	1309	130857

Table 8: Benchmark data sets used for the model selection challenges (Guyon et al., 2006c, 2007, 2008).

Data	SF	Model	Time (m)	Test-BER
Ada	1	chain({logitboost(units=469,shrinkage=0.4,depth=1),bias}	368.12	16.86
Gina	2	chain({sns(1),relief(fmax=487),gkridge,bias}	482.23	2.41
Hiva	3	chain({norm(1),rffs(fmax=1001),lssvm(gamma=0.096),bias}	124.54	28.01
Nova	1	chain({rffs(fmax=338),norm(1),std(1),sns(1),gkridge,bias}	82.12	5.27
Sylva	10	chain({sns(1),odds-ratio(fmax=60),gkridge,bias}	787.58	0.62

Table 9: Models selected with *PSMS* for the data sets of the *ALvsPK* challenge. For each data set we show the subsampling factor used (**SF**), the selected model (**Model**, some hyperparameters are omitted for clarity), the processing **Time** in minutes and the **test-BER** obtained. *sns* is for *shit-scale*, *std* is for *standardize* and *norm* is for *normalize*. See Tables 1 and 2 for a description of methods and their hyperparameters.

the end of the search the selected model is trained using the full training set (for the experiments reported in this paper we considered as training set the union of the training and validation data sets, see Table 8). Due to the dimensionality of the *Nova* data set we applied principal component analysis to this data set. Then we used the first 400 components for applying *PSMS*. We fixed $k = 2$, $I = 50$ and $m = 5$ for our experiments based on the results from previous sections. Then we ran *PSMS* for all of the data sets under the above described settings using different values for *SF*. The predictions of the resultant models were uploaded to the challenge website in order to evaluate them. Our best ranked entry in the *ALvsPK* challenge website (called *psmsx_jmlr_run_I*) is described in Table 9, and a comparison of it with the currently best-ranked entries is shown in Table 10.

We can see from Table 9 that very different models were selected by *PSMS* for each data set. This is the main advantage the *FMS* because it allows us selecting an ad-hoc model for each data set by considering different model types and a wide diversity of methods. With exception of *Ada*, the selected models included a feature selection method; this result shows the importance of feature selection methods and that some of them are more compatible than others with some classifiers; note that different numbers of features were selected for each data set. In all but the *Nova* data set preprocessing was performed before feature selection. This can be due to the fact that for *Nova* we used principal components instead of the original features. For *Ada* it was selected a *logitboost* classifier, while for *Hiva* it was selected a *lssvm* classifier with gaussian kernel. For *Gina, Nova* and *Sylva* it was selected the *gkridge* classifier; this classifier performs virtual leave-one out model selection each time it is trained (Cawley et al., 2007). Note that both *gkridge* and *logitboost* were the classifiers that best performed during the challenge (Guyon et al., 2007, 2008); this result gives evidence that *PSMS* can obtain similar and even better models, without spending time on ad-hoc modifications for each data set and without using domain knowledge.

The use of the subsampling strategy allowed to efficiently apply *PSMS* to all of the data sets. About six hours were required to obtain a competitive model for *Ada*, while about only two for the *Hiva* data set. Note that applying *PSMS* for *Hiva* using the entire training set (*Corrida-final*) took about 80 hours in the same machine (Escalante et al., 2007). During our experiments we found that the larger the subsamples the better the performance of the selected model. However, the selection of *SF* also depends on the available computer resources and time restrictions. One should note that we can increase speed of *PSMS* by caching intermediate results that can be reused (e.g., preprocessing the data sets off-line).

Despite the use of the subsampling technique the models selected with *PSMS* resulted very competitive as shown in Table 10. Currently, the *PSMS* run is the top-ranked agnostic entry in the challenge website; furthermore, the performance of this entry is superior than all but one prior-knowledge entry: *Interim-all-prior*; which is the best ranked entry overall, using "prior knowledge" or "domain knowledge". Note that the latter entry is formed of models that were designed ad-hoc for each data set, requiring much more time, effort and knowledge than *PSMS*. In average *PSMS* outperforms the best results presented in the *ALvsPK* challenge: *IJCNN07AL*, row 4 in Table 10 (Guyon et al., 2007); and the best-ranked agnostic entry (after *PSMS*): *Logitboost-with-trees*, row 5 in Table 10 (Lutz, 2006).

The performance of *PSMS* is very close to that of *IJCNN07AL*, tieing in *Sylva* and outperforming one to the other in two data sets. *PSMS* outperforms *Logitboost-with-trees* in three out of the five data sets and achieves very close performance for the other two data sets. The latter entry is ranked 10^{th} in the challenge website. It is very interesting that for the *Ada* data set the best model so far is a *logitboost* classifier with about 1000 trees (Lutz, 2006); while with *PSMS* we were able to achieve almost the same performance by using a half that number of trees, see row 2 in Table 9. This is important because simpler models of similar performance can be obtained with *PSMS*.

PSMS clearly outperformed our best-ranked entry during the challenge (row 6 in Table 10); this result gives evidence that we obtained better results by using more and better classifiers; also, the use of subsamples instead of the entire training set (when computing the fitness function), does not damage the performance of *PSMS*, although the reduction in processing time is very important. Note that for *Nova* the *PSMS* entry obtained a slightly worse result than that of *Corrida-final*; however, the model for *Nova* in *Corrida-final* was selected by trial and error which required of much more effort and time.

Results reported in this section show the efficacy of *PSMS* for model selection. Despite its simplicity it has shown comparable and even superior performance to those obtained by other model selection strategies that focused on a single learning algorithm and to methods that used prior domain knowledge for guiding the model selection process (Lutz, 2006; Reunanen, 2007; Boullé, 2007; Pranckeviciene et al., 2007; Wichard, 2007). Models selected with *PSMS* are simple and yet very competitive; furthermore, with *PSMS* no knowledge is needed on the methods to choose from, nor on the domain. In consequence, it is very easy to obtain classifiers that can achieve state-of-the-art performance without spending time on designing, developing and optimizing an ad-hoc model. Even though *PSMS* can be applied to any binary classification problem, we are not claiming it will obtain satisfactory results in every domain; however, it can be considered as a first option when dealing with binary classification tasks. It is expected that this will further improve the performance of models selected with *PSMS* if domain knowledge is used.

Entry	Description	Ada	Gina	Hiva	Nova	Sylva	Overall	Rank
Interim-all-prior	Best-PK	17.0	2.33	27.1	4.71	0.59	10.35	1th
psmsx_jmlr_run_I	PSMS	16.86	**2.41**	**28.01**	5.27	**0.62**	10.63	2nd
IJCNN07AL	Best-AL	**16.60**	3.39	28.27	**4.56**	**0.62**	10.68	4th
Logitboost-with-trees	Best-AL	**16.60**	3.53	30.18	4.69	0.78	11.15	10th
Corrida-final	Best-PSMS-ALvsPK	18.27	6.14	28.54	5.11	1.22	11.86	42th

Table 10: Comparison of models selected with *PSMS* and the best entries in the *ALvsPK* challenge data sets. We show, for reference, the best prior-knowledge entry (*Interim-all-prior*); the entry formed by the models described in Table 9 (*psmx_jmlr_run_I*); the best individual entries for each data set in the *ALvsPK* challenge(*IJCNN07AL*) (Guyon et al., 2007, 2008); the second-best entry of the agnostic track (*Logitboost-with-trees*) and our best ranked entry evaluated during the challenge *Corrida-final*. The best results in the agnostic track are shown in **bold**.

5. Discussion

In this section, we discuss the advantages and disadvantages of *PSMS* and perform a synthesis of our experiments aiming at better understanding how *PSMS* performs intensive search in hyperparameter space without overfitting the data.

5.1 Robust and Computationally Tractable Intensive Search

In Section 4 we reported experimental results that give evidence of the validity of the *PSMS* approach, demonstrating in particular that *PSMS* can outperform *PATSMS* through and at the end of the search, showing better convergence behavior and generalization performance. This is obtained at the expense of moderate additional computational complexity. This claim is supported by the theoretical analysis of the computational complexity (Section 3.4), indicating that computations are dominated by the number of learning machine trainings, and by the experiments (Section 4.2), indicating as few as 5 particles (learning machines) and 10 iterations (i.e., 50 trainings) are needed to attain the best performance. The efficiency of *PSMS* can be improved, for instance by preferably exploring learning machines, which have a lower computational cost of training. We explored successfully other heuristics, including subsampling training data, which reduced computations, at the expense of no performance degradation.

An analysis of the diversity of models tried by *PSMS* shows that this method is not biased towards models that tend to perform well individually. Investigating the operation of *PSMS* under different settings we found that the performance of *PSMS* is not significantly affected by modifying its hyperparameters. However, experimental results indicate that the use of an adaptive inertia weight may be helpful to explore the search space better.We also observed that certain parameter configurations allow the selection of competitive models, while reducing processing time. Section 5.4 provides a final set of practical recommendations.

Results of international competitions suggest that *PSMS* is competitive with model selection strategies specific to single algorithms and to strategies using prior domain knowledge. The latter is an important result because it shows that we can obtain competitive models without the need of an expert on the domain, a careful analysis to the data, or even machine learning knowledge.

5.2 Intensive Search without Overfitting

The findings summarized above provide empirical evidence suggesting *PSMS* is a reliable strategy for agnostic model selection. However, it is not obvious why *PSMS* succeeds in selecting competitive models without significantly overfitting data. Our hypothesis is that *PSMS* is able to avoid overfitting because of the way the search is guided: *PSMS* performs a broad search around promising solutions without focusing on reaching local minima. Solutions in *PSMS* are updated by taking into account information from both: the global-best solution ($\mathbf{p}_g$, weighted by c_2) and the individual-best solutions of each particle ($\mathbf{p}_{1,\dots,m}$, weighted by c_1), see Equations (1) and (2). The latter combined with an adaptive inertia weight and early stopping cause do not exaggerate the search at any local minima. Methods like *PATSMS*, on the contrary, update solutions by moving the pattern towards the local minimum nearest the initial solution, see Algorithm 2. Reaching exactly a local minimum causes *PATSMS* to learn peculiarities in the data set and does not necessarily result in obtaining a better predictive model.

The experiments we performed in Section 4.2.5 support the above conjecture. The results from Table 7 and Figures 4, 5 and 6 indicate that *PSMS* is able to avoid overfitting (to some extend) because of the way the search is guided. *PSMS* searches around good solutions without overdoing in terms of really fine-grained optimization. This sort of search can be considered as suboptimal in Dietterich's sense: *"In machine learning it is optimal to be suboptimal!"* (Dietterich, 1995). The latter statement makes reference to the well known fact that oversearching (i.e., trying to be optimal) in model selection can lead to select models that fit very well the peculiarities of the considered data set without deriving a general predictive rule (Dietterich, 1995; Jensen and Cohen, 2000; Quinlan and Cameron-Jones, 1995; Hastie et al., 2001; Loughrey and Cunningham, 2005). On the contrary, *PSMS* is able to *undercompute* because for updating solutions it considers local and global knowledge, information from past solutions (weighted by the inertia term) and randomness; note that the latter holds when a reasonable small number of iterations is performed. Furthermore, our experimental results provide empirical evidence that agrees with recent, yet traditional, explanations about why and how *PSO* works (Kennedy, 2008; Kennedy and Eberhart, 2001). Kennedy has argued the success of *PSO* is due to the fact that it performs a *"collaborative trial and error"* search (Kennedy, 2008). That is, *PSO* obtains good results mainly because the search is directed according both individual and social knowledge; the same conclusion derived from experimental results in this section. It is not surprising that distributed and collaborative computing can improve results of centralized (individualized) methods. For *FMS*, however, it is very interesting that updating solutions in a heterogeneous way allows us to avoid oversearching and, in consequence, overfitting; even when the *FMS* search space is infinite and has many local minima solutions.

5.3 Comparison with Related Work

A variety of approaches have been proposed to select parameters of specific methods for regression, classification, feature selection, discretization etcetera (Hastie et al., 2001; Bishop, 2006; Voss and Feng, 2002; Nelles, 2001; Guyon et al., 2006b; Kim et al., 2002; Hastie et al., 2001; Cawley and Talbot, 2007b; Boullé, 2007; Hue and Boullé, 2007). However, despite the potential advantages of *FMS* (namely generality, simplicity and competitiveness), this problem has been little studied because of the huge search space involved and because intensive search methods are prone to overfit the data (Gorissen et al., 2008; Escalante et al., 2007). Nevertheless, in the rest of this section we outline techniques used to avoid oversearching/overfitting in search that are applicable/related to

FMS. One should note that traditional model selection techniques just like Akaike and Bayesian information criteria, the minimum description length principle and the *VC*-dimension are not directly applicable to *FMS* and therefore they are excluded of analysis.

Grid search (with *CV*) is the widely used search-approach to model selection in practical applications (Momma and Bennett, 2002; Hsu et al., 2003). This method consists of defining a uniform grid over the search space where each point in the grid defines a solution; every point in the grid is evaluated and the point of lowest error is selected. The granularity of the grid determines both the performance of the selected solution and the efficiency of the search. A fine-grained grid may be inefficient and can lead to oversearching; while a sparse grid will result in low performance models. Note that the heterogeneousness of models and the variety of ranges for the models parameters make very difficult the application of grid search to the *FMS* problem; furthermore, the choice of an adequate granularity can be a serious problem. Other methods already used for parameter optimization that can be applied to *FMS* include: greedy search (Dietterich, 1995), random search (e.g., the bumping technique) (Hastie et al., 2001), *PS* (Bi et al., 2003; Momma and Bennett, 2002), evolutionary computation approaches (Engelbrecht, 2006; Gorissen et al., 2008; Angeline, 1998), and other swarm-optimization techniques (Kennedy and Eberhart, 2001; Engelbrecht, 2006). Note that despite one may think that exhaustive search is the best search option in model selection, this approach is impractical for most real world problems and when applicable it suffers from the oversearching phenomenon (Dietterich, 1995).

Early stopping has been widely used to prevent overfitting in search methods (Hastie et al., 2001; Engelbrecht, 2006; Loughrey and Cunningham, 2005). The goal of this heuristic is to stop searching/learning when the model starts overfitting the data. There are several variants to stop the search: after a small number of iterations, when no improvement is found after a number of iterations, when a solution of acceptable performance has been found, etcetera. A problem with early stopping is that premature stopping the algorithm would lead to selecting a solution that has not converged yet, while a late stopping of the search will cause severely overfitting the data because of oversearching. For *PSMS* we found that a small number of iterations can be enough to obtain satisfactory results in benchmark data, although the number of iterations is problem dependent; therefore, we can adopt other stopping criteria for *FMS* in the future.

Randomness has bring into play in machine learning in order avoid overfitting and to escape from local minima in search (Hastie et al., 2001; Bishop, 2006; Kirkpatrick et al., 1983; Kennedy and Eberhart, 2001). In learning algorithms, it has been successfully used to prevent overfitting and to obtain better predictors; learning methods that use randomness include bagging classifiers (Hastie et al., 2001), neural and deep belief networks (Hastie et al., 2001; Hinton et al., 2006) and randomized decision-tree algorithms (Breiman, 2001; Geurts et al., 2006). Bootstrapping is a technique (used in bagging and random forest classifiers) based on random sampling that has been widely used to estimate the generalization performance of methods as an alternative to *CV* (Hastie et al., 2001). In *PSMS* randomness played an important role because it introduces diversity into the search process and allows *PSMS* to avoid local minima. Furthermore, the subsampling strategy we used to increase the speed of *PSMS* is related to bootstrapping; in future work on *PSMS* we will explicitly consider different subsampling estimations for the selection of the final model.

As the adaptive inertia weight in *PSO*, see Section 2, there are parameters in other algorithms that aim to avoid overfitting by exploring the search space both globally and locally; examples are the temperature parameter in simulated annealing (Kirkpatrick et al., 1983) and the momentum term in on-line gradient descend and backpropagation (Qian, 1999). The ridge in ridge-regression and weight decay in neural networks training are also related to the inertia weight. Model averaging and the use of ensembles have proved to be helpful to improve predictions and avoid overfitting; this is because different models have different biases that in average result in improved performance (Hastie et al., 2001; Bishop, 2006). Future work includes in *PSMS* consists of combining particles in order to improve the performance of the swarm strategy. Finally, adding noise to the training data is another overfitting avoidance mechanism in model selection that also can be used with *PSMS*.

5.4 A Practical Guide to PSMS

In this section we describe the way *PSMS* can be put in practice in any binary classification problem. Due to the simplicity and generality of the approach below we describe a practical guide to use the *Matlab*^{R} implementation of *PSMS* (included in the *CLOP* toolbox). It is assumed that the user has available a data set (in Matlab^R format) with N samples for binary classification: a matrix $\mathbf{X}_{N\times d}$ contains the N training samples of dimensionality d and a vector $\mathbf{Y}_{N\times 1}$ their respective labels ($y_i \in [-1,1]$). After downloading and installing *CLOP* (Saffari and Guyon, 2006), *PSMS* can be applied to any data set by typing the following *Matlab*^{R} code:

```
%% load your data into the MatlabR workspace
1: >> load train_data.mat;
%%  Create A Clop Data-Object
2: >> D = data(X,Y);
%% Create A CLOP PSMS-Object with default parameters
3: >> P = psmsx;
%% Perform PSMS
4: >> [Dat, Res] = train(P, D);
%% Train the selected model with the full training set
5: >> [Odat, TrM] = train(Res.Best_Model,D);
%% Create a test data set, note that Yt can be empty
6: >> load test_data; Dt = data(Xt,Yt);
%% Test the selected and trained model on unseen data Dt
7: >> [Pred] = test(TrM, Dt);
%% Estimate the model's performance on unseen data Dt, if Yt is available
8: >> [BER] = balanced_errate(Pred.X, Pred.Y);
%% Analyze the ROC performance of the selected model
9: >> roc(Pred);
```

Note that steps 1–2 and 5–9 are associated with loading the data and the evaluation of the selected model, respectively; which are operations not attained to *PSMS*. Steps 3 and 4 will create the *PSMS* object and will start the search, respectively. Besides the selected model, the output of the search (**Res**, line 4), is a structure with useful information about the search process, see the *PSMS* documentation (Escalante, In preparation, 2009).

In Section 4.2 were presented experimental results that suggest that there is not significant difference in performance by modifying most of the *PSMS* hyperparameters. Therefore, one can choose parameter settings for *PSMS* that make practical its application without a significant decrement of performance. Below are shown recommended values for the *PSMS* hyperparameters. These parameters and other options of the current implementation can be modified very simply (Escalante, In preparation, 2009).

Recommended PSMS parameters:

Weight for individual best solution	$c_1 = 2$
Weight for global best solution	$c_2 = 2$
Adaptive inertia weight	$\mathbf{W} = (1.2, 0.5, 0.4)$
Number of iterations	$I = 50$
Swarm size	$m = 5$
Folds in *CV*	$k = 2$
Subsampling factor	$SF = 1$ (as small as possible in large data sets)

6. Conclusions

In this paper we proposed Particle Swarm Model Selection (*PSMS*), that is, the application of Particle Swarm Optimization (*PSO*) to the problem of Full Model Selection (*FMS*). Given a data set, the *FMS* problem consists of selecting the combination of preprocessing, feature selection and learning methods that obtains the lowest classification error. *FMS* also includes hyperparameter optimization for the selected methods. This approach to the model selection problem has the following advantages. First, the generality of the approach allows us to consider different model types (for preprocessing, feature selection and learning) and a variety of methods. Second, *PSMS* can be applied to any data set, since neither domain knowledge nor machine learning knowledge is required, therefore it can be considered a black-box model selection method. Third, and most importantly, competitive and yet simple models can be obtained with *PSMS*. We provide empirical evidence that shows that *PSMS* can be applied efficiently, without a significant loss of accuracy, by using a subsampling heuristic and parameter settings that reduce the computational cost.

The simplicity of *PSO* and its proven performance, comparable to that of evolutionary algorithms, make this search algorithm well suited for *FMS*. However, the application of any other stochastic optimization strategy is also possible. The main advantage of *PSO* is that a single equation for updating solutions is needed, as opposed to evolutionary algorithms where methods for representation, mutation, cross-over, speciation and selection have to be considered. Interestingly, the way the search is guided in *PSMS* allows it obtaining competitive models without significantly overfitting. Experimental results in benchmark data show superior performance of *PSMS* when compared to Pattern Search Model Selection (*PATSMS*), a direct search method that constitutes a competitive baseline.

Results obtained by models selected with *PSMS* in the framework of a model selection challenge show that it is a very competitive model selection method, despite its simplicity and generality. In such competitions, models selected with *PSMS* were always among the top ranking models, together with methods performing solely hyperparameter selection in a given model family and methods relying on prior knowledge. This demonstrates that, via the use of *PSO*, *FMS* is a viable strategy for model selection. This is remarkable because we noted in previous competitions (Guyon et al., 2005; Guyon et al., 2006b) that each data set had a different best performing method, yet researchers performing *FMS* (in an effort to find the model family best suited to a given problem) were not successful. The participants, which obtained the best results on average over all data sets restricted themselves to hyperparameter selection in one given model family. In contrast, in this paper we demonstrated the viability of *FMS* using the *PSO* search strategy. Our work paves the way to the use of intensive search techniques to perform *FMS* in the entire model space of machine learning toolkits. With the increasing availability of diverse and sophisticated machine learning toolkits and the improvements in computing power, we foresee that *FMS* will become an effective methodology.

Current work includes the use of *PSMS* for the selection of model-members for ensembles and the hierarchical application of *PSO* for *FMS* and hyperparameter optimization. *PSMS* is currently being applied to different tasks, including galaxy classification, automatic image annotation, object recognition and text classification. Future work includes the introduction of a penalty-term into the fitness function; such that (computationally) inexpensive models be favored by PSMS. The extension of *PSMS* to the multi-class classification and regression problems is another future work direction.

Acknowledgments

We would like to thank the organizers and participants of the NIPS multi-level inference workshop and model selection game, and of the *IJCNN ALvsPK* challenge. The first author thanks the UNIPEN foundation and the US National Science Foundation for travel support. We also thank editors and anonymous reviewers for their useful comments that have help us to improve this paper. We thank Dr. Eduardo Morales for his useful suggestions about the content of the paper. Last, but not least, we thank Dr. Aurelio López and INAOE for the provided support.

Abstract

The problem of ranking, in which the goal is to learn a real-valued ranking function that induces a ranking or ordering over an instance space, has recently gained much attention in machine learning. We study generalization properties of ranking algorithms using the notion of algorithmic stability; in particular, we derive generalization bounds for ranking algorithms that have good stability properties. We show that kernel-based ranking algorithms that perform regularization in a reproducing kernel Hilbert space have such stability properties, and therefore our bounds can be applied to these algorithms; this is in contrast with generalization bounds based on uniform convergence, which in many cases cannot be applied to these algorithms. Our results generalize earlier results that were derived in the special setting of bipartite ranking (Agarwal and Niyogi, 2005) to a more general setting of the ranking problem that arises frequently in applications.

Keywords: ranking, generalization bounds, algorithmic stability

1. Introduction

A central focus in learning theory research has been the study of generalization properties of learning algorithms. Perhaps the first work in this direction was that of Vapnik and Chervonenkis (1971), who derived generalization bounds for classification algorithms based on uniform convergence. Since then, a large number of different tools have been developed for studying generalization, and have been applied successfully to analyze algorithms for both classification (learning of binary-valued functions) and regression (learning of real-valued functions), two of the most well-studied problems in machine learning.

In recent years, a new learning problem, namely that of *ranking*, has gained attention in machine learning (Cohen et al., 1999; Herbrich et al., 2000; Crammer and Singer, 2002; Joachims, 2002; Freund et al., 2003; Agarwal et al., 2005; Rudin et al., 2005; Burges et al., 2005; Cossock and Zhang, 2006; Cortes et al., 2007; Clemencon et al., 2008). In ranking, one learns a real-valued function that assigns scores to instances, but the scores themselves do not matter; instead, what is

[*]. A preliminary version of this paper (which focused on the special setting of bipartite ranking) appeared in the Proceedings of the 18th Annual Conference on Learning Theory (COLT) in 2005.

important is the relative ranking of instances induced by those scores. This problem is distinct from both classification and regression, and it is natural to ask what kinds of generalization properties hold for algorithms for this problem.

Although there have been several recent advances in developing algorithms for various settings of the ranking problem, the study of generalization properties of ranking algorithms has been largely limited to the special setting of bipartite ranking (Freund et al., 2003; Agarwal et al., 2005). In this paper, we study generalization properties of ranking algorithms in a more general setting of the ranking problem that arises frequently in applications. Our generalization bounds are derived using the notion of algorithmic stability; we show that a number of practical ranking algorithms satisfy the required stability conditions, and therefore can be analyzed using our bounds.

1.1 Previous Results

While ranking has been studied extensively in some form or another in fields as diverse as social choice theory (Arrow, 1970), statistics (Lehmann, 1975), and mathematical economics (Chiang and Wainwright, 2005), the study of ranking in machine learning is relatively new: the first paper on the subject appeared less than a decade ago (Cohen et al., 1999). Since then, however, the number of domains in which ranking has found applications has grown quickly, and as a result, ranking has gained considerable attention in machine learning and learning theory in recent years.

Some of the earlier work, by Herbrich et al. (2000) and by Crammer and Singer (2002), focused on the closely related but distinct problem of ordinal regression. Freund et al. (2003) gave one of the first learning algorithms for ranking, termed RankBoost, which was based on the principles of boosting. Since then there have been many other algorithmic developments: for example, Radlinski and Joachims (2005) have developed an algorithmic framework for ranking in information retrieval applications; Burges et al. (2005) have developed a neural network based algorithm for ranking; and Agarwal (2006) has developed an algorithmic framework for ranking in a graph-based transductive setting. More recently, there has been some interest in learning ranking functions that emphasize accuracy at the top of the ranked list; work by Rudin (2006), Cossock and Zhang (2006) and Clemencon and Vayatis (2007) falls in this category. There has also been interest in statistical analysis of ranking; in recent work, Clemencon et al. (2008) have studied statistical convergence properties of ranking algorithms—specifically, ranking algorithms based on empirical and convex risk minimization—using the theory of U-statistics.

In the paper that developed the RankBoost algorithm, Freund et al. (2003) also gave a basic generalization bound for the algorithm in the bipartite setting. Their bound was derived from uniform convergence results for the binary classification error, and was expressed in terms of the VC-dimension of a class of binary classification functions derived from the class of ranking functions searched by the algorithm. Agarwal et al. (2005) also gave a generalization bound for bipartite ranking algorithms based on uniform convergence; in this case, the uniform convergence result was derived directly for the bipartite ranking error, and the resulting generalization bound was expressed in terms of a new set of combinatorial parameters that measure directly the complexity of the class of ranking functions searched by a bipartite ranking algorithm. Agarwal and Niyogi (2005) used a different tool, namely that of algorithmic stability (Rogers and Wagner, 1978; Bousquet and Elisseeff, 2002), to obtain generalization bounds for bipartite ranking algorithms that have good stability properties. Unlike bounds based on uniform convergence, the stability-based bounds depend on properties of the algorithm rather than the function class being searched, and can be applied also to algorithms that search function classes of unbounded complexity.

As can be noted from the above discussion, the question of generalization properties of ranking algorithms has so far been investigated mainly in the special setting of bipartite ranking. There have been limited studies of generalization properties in more general settings. For example, Rudin et al. (2005) derived a margin-based bound which is expressed in terms of covering numbers and relies ultimately on a uniform convergence result; this bound is derived for a non-bipartite setting of the ranking problem, but under the restrictive distributional assumption of a "truth" function. Cortes et al. (2007) consider a different setting of the ranking problem and derive stability-based generalization bounds for algorithms in this setting. However, they also implicitly assume a "truth" function. In addition, as we discuss later in the paper, the results of Cortes et al. as stated involve some strong assumptions about the function class searched by an algorithm. These assumptions rarely hold for practical ranking algorithms, which prevents the direct application of their results. We shall discuss in Section 6 how this can be remedied.

1.2 Our Results

We use the notion of algorithmic stability to study generalization properties of ranking algorithms in a more general setting of the ranking problem than has been considered previously, and that arises frequently in applications. The notion of algorithmic stability, first studied for learning algorithms by Rogers and Wagner (1978), has been used to obtain generalization bounds for classification and regression algorithms that satisfy certain stability conditions (Bousquet and Elisseeff, 2002; Kutin and Niyogi, 2002). Here we show that algorithmic stability can be useful also in analyzing generalization properties of ranking algorithms in the setting we consider; in particular, we derive generalization bounds for ranking algorithms that have good stability properties. We show that kernel-based ranking algorithms that perform regularization in a reproducing kernel Hilbert space (RKHS) have such stability properties, and therefore our bounds can be applied to these algorithms. Our techniques are based on those of Bousquet and Elisseeff (2002); indeed, we show that the ranking error in our setting satisfies the same conditions that were used to establish the classification and regression bounds of Bousquet and Elisseeff (2002), and therefore essentially the same proof techniques can be used to analyze the ranking problem we consider. Our results generalize those of Agarwal and Niyogi (2005), which focused on bipartite ranking.

We describe the general ranking problem and the setting we consider in detail in Section 2, and define notions of stability for ranking algorithms in this setting in Section 3. Using these notions, we derive generalization bounds for stable ranking algorithms in Section 4. In Section 5 we show stability of kernel-based ranking algorithms that perform regularization in an RKHS, and apply the results of Section 4 to obtain generalization bounds for these algorithms. Section 6 provides comparisons with related work; we conclude with a discussion in Section 7.

2. The Ranking Problem

In the problem of ranking, one is given a finite number of examples of order relationships among instances in some instance space $\mathcal{X}$, and the goal is to learn from these examples a ranking or ordering over $\mathcal{X}$ that ranks accurately future instances. Examples of ranking problems arise in a variety of domains: in information retrieval, one wants to rank documents according to relevance to some query or topic; in user-preference modeling, one wants to rank books or movies according to a user's likes and dislikes; in computational biology, one wants to rank genes according to their relevance to some disease.

In the most general setting of the ranking problem, the learner is given training examples in the form of ordered pairs of instances $(x,x') \in \mathcal{X} \times \mathcal{X}$ labeled with a ranking preference $r \in \mathbb{R}$, with the interpretation that x is to be ranked higher than (preferred over) x' if $r > 0$, and lower than x' if $r < 0$ ($r = 0$ indicates no ranking preference between the two instances); the penalty for mis-ordering such a pair is proportional to $|r|$. Given a finite number of such examples $((x_1,x'_1,r_1),\ldots,(x_m,x'_m,r_m))$, the goal is to learn a real-valued ranking function $f : \mathcal{X} \to \mathbb{R}$ that ranks accurately future instances; f is considered to rank an instance $x \in \mathcal{X}$ higher than an instance $x' \in \mathcal{X}$ if $f(x) > f(x')$, and lower than x' if $f(x) < f(x')$. Thus, assuming that ties are broken uniformly at random, the expected penalty (or loss) incurred by a ranking function f on a pair of instances (x,x') labeled by r can be written as

$$|r| \left(\mathbf{I}_{\{r(f(x)-f(x'))<0\}} + \frac{1}{2}\mathbf{I}_{\{f(x)=f(x')\}} \right) ,$$

where $\mathbf{I}_{\{\phi\}}$ is 1 if ϕ is true and 0 otherwise.

A particular setting of the ranking problem that has been investigated in some detail in recent years is the *bipartite* setting (Freund et al., 2003; Agarwal et al., 2005). In the bipartite ranking problem, instances come from two categories, positive and negative; the learner is given examples of instances labeled as positive or negative, and the goal is to learn a ranking in which positive instances are ranked higher than negative ones. Formally, the learner is given a training sample (S^+,S^-) consisting of a sequence of 'positive' examples $S^+ = (x_1^+,\ldots,x_m^+)$ and a sequence of 'negative' examples $S^- = (x_1^-,\ldots,x_n^-)$, the x_i^+ and x_j^- being instances in some instance space $\mathcal{X}$, and the goal is to learn a real-valued ranking function $f : \mathcal{X} \to \mathbb{R}$ that ranks future positive instances higher than negative ones. The bipartite ranking problem is easily seen to be a special case of the general ranking problem described above, since a training sample $(S^+,S^-) \in \mathcal{X}^m \times \mathcal{X}^n$ in the bipartite setting can be viewed as consisting of mn examples of the form $(x_i^+,x_j^-,1)$, for $1 \le i \le m$, $1 \le j \le n$; in other words, mis-ranking any positive-negative pair of instances incurs a constant penalty of 1. Thus, assuming again that ties are broken uniformly at random, the expected penalty incurred by f on a positive-negative pair (x^+,x^-) is simply

$$\mathbf{I}_{\{f(x^+)-f(x^-)<0\}} + \frac{1}{2}\mathbf{I}_{\{f(x^+)=f(x^-)\}} ;$$

the penalty incurred on a pair of positive instances or a pair of negative instances is zero.

In this paper, we consider a more general setting: the learner is given examples of instances labeled by real numbers, and the goal is to learn a ranking in which instances labeled by larger numbers are ranked higher than instances labeled by smaller numbers. Such ranking problems arise frequently in practice: for example, in information retrieval, one is often given examples of documents with real-valued relevance scores for a particular topic or query; similarly, in computational biology, one often receives examples of molecular structures with real-valued biological activity scores with respect to a particular target.

Formally, the setting we consider can be described as follows. The learner is given a finite sequence of labeled training examples $S = ((x_1,y_1),\ldots,(x_m,y_m))$, where the x_i are instances in some instance space $\mathcal{X}$ and the y_i are real-valued labels in some bounded set $\mathcal{Y} \subseteq \mathbb{R}$ which we take without loss of generality to be $\mathcal{Y} = [0,M]$ for some $M > 0$, and the goal is to learn a real-valued function $f : \mathcal{X} \to \mathbb{R}$ that ranks future instances with larger labels higher than those with smaller labels. The penalty for mis-ranking a pair of instances could again be taken to be constant for all pairs; here we consider the more general case where the penalty is larger for mis-ranking a pair of instances with a greater difference between their real-valued labels. In particular, in our setting, the penalty for mis-ranking a pair of instances is proportional to the absolute difference between their real-valued labels. Thus, assuming again that ties are broken uniformly at random, the expected penalty incurred by f on a pair of instances (x,x') with corresponding real-valued labels y and y' can be written as

$$|y-y'|\left(\mathbf{I}_{\{(y-y')(f(x)-f(x'))<0\}}+\frac{1}{2}\mathbf{I}_{\{f(x)=f(x')\}}\right).$$

This problem can also be seen to be a special case of the general ranking problem described above; a training sample $S=((x_1,y_1),\ldots,(x_m,y_m))\in(\mathcal{X}\times\mathcal{Y})^m$ in this setting can be viewed as consisting of $\binom{m}{2}$ examples of the form (x_i,x_j,y_i-y_j), for $1\leq i<j\leq m$.

In studying generalization properties of learning algorithms, one usually assumes that both training examples and future, unseen examples are generated according to some underlying random process. We shall assume in our setting that all examples (x,y) (both training examples and future, unseen examples) are drawn randomly and independently according to some (unknown) distribution $\mathcal{D}$ on $\mathcal{X}\times\mathcal{Y}$.[1] The quality of a ranking function $f:\mathcal{X}\rightarrow\mathbb{R}$ can then be measured by its *expected ranking error*, which we denote by $R(f)$ and define as follows:

$$R(f) \;=\; \mathbf{E}_{((X,Y),(X',Y'))\sim\mathcal{D}\times\mathcal{D}}\left[|Y-Y'|\left(\mathbf{I}_{\{(Y-Y')(f(X)-f(X'))<0\}}+\frac{1}{2}\mathbf{I}_{\{f(X)=f(X')\}}\right)\right]. \qquad (1)$$

Note that the expected error $R(f)$ is simply the expected mis-ranking penalty of f on a pair of examples drawn randomly and independently according to $\mathcal{D}$, assuming that ties are broken uniformly at random. In practice, since the distribution $\mathcal{D}$ is unknown, the expected error of a ranking function f must be estimated from an empirically observable quantity, such as its *empirical ranking error* with respect to a sample $S=((x_1,y_1),\ldots,(x_m,y_m))\in(\mathcal{X}\times\mathcal{Y})^m$, which we denote by $\widehat{R}(f;S)$ and define as follows:

$$\widehat{R}(f;S) \;=\; \frac{1}{\binom{m}{2}}\sum_{i=1}^{m-1}\sum_{j=i+1}^{m}|y_i-y_j|\left(\mathbf{I}_{\{(y_i-y_j)(f(x_i)-f(x_j))<0\}}+\frac{1}{2}\mathbf{I}_{\{f(x_i)=f(x_j)\}}\right). \qquad (2)$$

This is simply the average mis-ranking penalty incurred by f on the $\binom{m}{2}$ pairs (x_i,x_j), where $1\leq i<j\leq m$, assuming that ties are broken uniformly at random.

A learning algorithm for the ranking problem described above takes as input a training sample $S\in\bigcup_{m=1}^{\infty}(\mathcal{X}\times\mathcal{Y})^m$ and returns as output a ranking function $f_S:\mathcal{X}\rightarrow\mathbb{R}$. For simplicity we consider only deterministic algorithms. We are concerned in this paper with generalization properties of such algorithms; in particular, we are interested in bounding the expected error of a learned ranking function in terms of an empirically observable quantity such as its empirical error on the training sample from which it is learned. The following definitions will be useful in our study.

Definition 1 (Ranking loss function) *Define a* ranking loss function *to be a function* $\ell:\mathbb{R}^{\mathcal{X}}\times(\mathcal{X}\times\mathcal{Y})\times(\mathcal{X}\times\mathcal{Y})\rightarrow\mathbb{R}^+\cup\{0\}$ *that assigns to each* $f:\mathcal{X}\rightarrow\mathbb{R}$ *and* $(x,y),(x',y')\in(\mathcal{X}\times\mathcal{Y})$ *a non-negative real number* $\ell(f,(x,y),(x',y'))$*, interpreted as the penalty or loss of* f *in its relative*

1. Cortes et al. (2007) consider a similar setting as ours; however, they assume that only instances $x\in\mathcal{X}$ are drawn randomly, and that labels $y\in\mathcal{Y}$ are then determined according to a "truth" function $f^*:\mathcal{X}\rightarrow\mathcal{Y}$.

ranking of x and x' given corresponding labels y and y'. We shall require that ℓ be symmetric with respect to (x,y) and (x',y'), that is, that $\ell(f,(x,y),(x',y')) = \ell(f,(x',y'),(x,y))$ for all $f,(x,y),(x',y')$.

Definition 2 (Expected ℓ-error) *Let $f : \mathcal{X} \to \mathbb{R}$ be a ranking function on $\mathcal{X}$. Let $\ell : \mathbb{R}^{\mathcal{X}} \times (\mathcal{X} \times \mathcal{Y}) \times (\mathcal{X} \times \mathcal{Y}) \to \mathbb{R}^+ \cup \{0\}$ be a ranking loss function. Define the* expected ℓ-error *of f, denoted by $R_\ell(f)$, as*

$$R_\ell(f) \quad = \quad \mathbf{E}_{((X,Y),(X',Y')) \sim \mathcal{D} \times \mathcal{D}} \left[\ell(f,(X,Y),(X',Y')) \right] .$$

Definition 3 (Empirical ℓ-error) *Let $f : \mathcal{X} \to \mathbb{R}$ be a ranking function on $\mathcal{X}$, and let $S = ((x_1,y_1),\ldots,(x_m,y_m)) \in (\mathcal{X} \times \mathcal{Y})^m$. Let $\ell : \mathbb{R}^{\mathcal{X}} \times (\mathcal{X} \times \mathcal{Y}) \times (\mathcal{X} \times \mathcal{Y}) \to \mathbb{R}^+ \cup \{0\}$ be a ranking loss function. Define the* empirical ℓ-error *of f with respect to S, denoted by $\widehat{R}_\ell(f;S)$, as*

$$\widehat{R}_\ell(f;S) \quad = \quad \frac{1}{\binom{m}{2}} \sum_{i=1}^{m-1} \sum_{j=i+1}^{m} \ell(f,(x_i,y_i),(x_j,y_j)) .$$

As mentioned above, one choice for a ranking loss function could be a 0-1 loss that simply assigns a constant penalty of 1 to any mis-ranked pair:

$$\ell_{0\text{-}1}(f,(x,y),(x',y')) \quad = \quad \mathbf{I}_{\{(y-y')(f(x)-f(x'))<0\}} + \frac{1}{2}\mathbf{I}_{\{f(x)=f(x')\}} .$$

The (empirical) $\ell_{0\text{-}1}$-error then simply counts the fraction of mis-ranked pairs, which corresponds to the well-known Kendall τ measure. However, the 0-1 loss effectively uses only the sign of the difference $y - y'$ between labels, and ignores the magnitude of this difference; the loss function we use, which we term the *discrete ranking loss* and denote as

$$\ell_{\text{disc}}(f,(x,y),(x',y')) \quad = \quad |y-y'| \left(\mathbf{I}_{\{(y-y')(f(x)-f(x'))<0\}} + \frac{1}{2}\mathbf{I}_{\{f(x)=f(x')\}} \right) , \tag{3}$$

takes the magnitude of this difference into account. Comparing with Eqs. (1-2) above, we see that the expected and empirical ranking errors we have defined are simply the corresponding ℓ_{disc}-errors:

$$R(f) \equiv R_{\ell_{\text{disc}}}(f) ; \;\; \widehat{R}(f;S) \equiv \widehat{R}_{\ell_{\text{disc}}}(f;S) .$$

While our focus will be on bounding the expected (ℓ_{disc}-)ranking error of a learned ranking function, our results can be used also to bound the expected $\ell_{0\text{-}1}$-error.

Several other ranking loss functions will be useful in our study; these will be introduced in the following sections as needed.

3. Stability of Ranking Algorithms

A stable algorithm is one whose output does not change significantly with small changes in the input. The input to a ranking algorithm in our setting is a training sample of the form $S = ((x_1,y_1),\ldots,(x_m,y_m)) \in (\mathcal{X} \times \mathcal{Y})^m$ for some $m \in \mathbb{N}$; we consider changes to such a sample that consist of replacing a single example in the sequence with a new example. For $1 \le i \le m$ and $(x_i',y_i') \in (\mathcal{X} \times \mathcal{Y})$, we use S^i to denote the sequence obtained from S by replacing (x_i,y_i) with (x_i',y_i').

Several different notions of stability have been used in the study of classification and regression algorithms (Rogers and Wagner, 1978; Devroye and Wagner, 1979; Kearns and Ron, 1999; Bousquet and Elisseeff, 2002; Kutin and Niyogi, 2002; Poggio et al., 2004). The notions of stability that we define below for ranking algorithms in our setting are based on those defined earlier for bipartite ranking algorithms (Agarwal and Niyogi, 2005) and are most closely related to the notions of stability used by Bousquet and Elisseeff (2002).

Definition 4 (Uniform loss stability) *Let $\mathcal{A}$ be a ranking algorithm whose output on a training sample S we denote by f_S, and let ℓ be a ranking loss function. Let $\beta : \mathbb{N} \rightarrow \mathbb{R}$. We say that $\mathcal{A}$ has* uniform loss stability β *with respect to ℓ if for all $m \in \mathbb{N}$, $S \in (\mathcal{X} \times \mathcal{Y})^m$, $1 \leq i \leq m$ and $(x_i', y_i') \in (\mathcal{X} \times \mathcal{Y})$, we have for all $(x,y), (x',y') \in (\mathcal{X} \times \mathcal{Y})$,*

$$\left| \ell(f_S, (x,y), (x',y')) - \ell(f_{S^i}, (x,y), (x',y')) \right| \quad \leq \quad \beta(m) .$$

Definition 5 (Uniform score stability) *Let $\mathcal{A}$ be a ranking algorithm whose output on a training sample S we denote by f_S. Let $\nu : \mathbb{N} \rightarrow \mathbb{R}$. We say that $\mathcal{A}$ has* uniform score stability ν *if for all $m \in \mathbb{N}$, $S \in (\mathcal{X} \times \mathcal{Y})^m$, $1 \leq i \leq m$ and $(x_i', y_i') \in (\mathcal{X} \times \mathcal{Y})$, we have for all $x \in \mathcal{X}$,*

$$|f_S(x) - f_{S^i}(x)| \quad \leq \quad \nu(m) .$$

If a ranking algorithm has uniform loss stability β with respect to ℓ, then changing an input training sample of size m by a single example leads to a difference of at most $\beta(m)$ in the ℓ-loss incurred by the output ranking function on any pair of examples $(x,y), (x',y')$. Therefore, a smaller value of $\beta(m)$ corresponds to greater loss stability. Similarly, if a ranking algorithm has uniform score stability ν, then changing an input training sample of size m by a single example leads to a difference of at most $\nu(m)$ in the score assigned by the output ranking function to any instance x. A smaller value of $\nu(m)$ therefore corresponds to greater score stability.

The term 'uniform' in the above definitions refers to the fact that the bounds on the difference in loss or score are required to hold uniformly for all training samples S (and all single-example changes to them) and for all examples $(x,y), (x',y')$ or instances x. This is arguably a strong requirement; one can define weaker notions of stability, analogous to the hypothesis stability considered by Devroye and Wagner (1979), Kearns and Ron (1999), and Bousquet and Elisseeff (2002), or the almost-everywhere stability considered by Kutin and Niyogi (2002), which would require the bounds to hold only in expectation or with high probability (and would therefore depend on the distribution $\mathcal{D}$ governing the data). However, we do not consider such weaker notions of stability in this paper; we shall show later (Section 5) that several practical ranking algorithms in fact exhibit good uniform stability properties.

4. Generalization Bounds for Stable Ranking Algorithms

In this section we give generalization bounds for ranking algorithms that exhibit good (uniform) stability properties. The methods we use are based on those of Bousquet and Elisseeff (2002), who derived such bounds for classification and regression algorithms. Our main result is the following, which bounds the expected ℓ-error of a ranking function learned by an algorithm with good uniform loss stability in terms of its empirical ℓ-error on the training sample.

Theorem 6 *Let $\mathcal{A}$ be a symmetric ranking algorithm*[2] *whose output on a training sample $S \in (\mathcal{X} \times \mathcal{Y})^m$ we denote by f_S, and let ℓ be a bounded ranking loss function such that $0 \leq \ell(f,(x,y),(x',y')) \leq B$ for all $f : \mathcal{X} \to \mathbb{R}$ and $(x,y),(x',y') \in (\mathcal{X} \times \mathcal{Y})$. Let $\beta : \mathbb{N} \to \mathbb{R}$ be such that $\mathcal{A}$ has uniform loss stability β with respect to ℓ. Then for any $0 < \delta < 1$, with probability at least $1 - \delta$ over the draw of S (according to $\mathcal{D}^m$),*

$$R_\ell(f_S) \quad < \quad \widehat{R}_\ell(f_S;S) + 2\beta(m) + (m\beta(m) + B)\sqrt{\frac{2\ln(1/\delta)}{m}}\,.$$

The proof follows the proof of a similar result for classification and regression algorithms by Bousquet and Elisseeff (2002). In particular, the random variable $R_\ell(f_S) - \widehat{R}_\ell(f_S;S)$, representing the difference between the expected and empirical ℓ-errors of the ranking function f_S learned from the random sample S, is shown to satisfy the conditions of McDiarmid's inequality (McDiarmid, 1989), as a result of which the deviation of this difference from its expected value $\mathbf{E}_{S \sim \mathcal{D}^m}[R_\ell(f_S) - \widehat{R}_\ell(f_S;S)]$ can be bounded with high probability; a bound on this expected value then allows the above result to be established. Details of the proof are provided in Appendix A.

A few remarks on the significance of the above result are in order, especially in relation to the results of Bousquet and Elisseeff (2002). As can be seen from the definitions given in the preceding two sections, the main difference in the formulation of the ranking problem as compared to the problems of classification and regression is that the performance or loss in ranking is measured on *pairs* of examples, rather than on individual examples. This means in particular that, unlike the empirical error in classification or regression, the empirical error in ranking cannot be expressed as a sum of independent random variables. Indeed, this is the reason that in deriving uniform convergence bounds for the ranking error, the standard Hoeffding inequality used to obtain such bounds in classification and regression can no longer be applied (Agarwal et al., 2005). It may initially come as a bit of a surprise, therefore, that the proof methods of Bousquet and Elisseeff (2002) carry through for ranking without siginificant change. The reason for this is that they rely on the more general inequality of McDiarmid which, in Bousquet and Elisseeff's work, is used to capture the effect of stability, but which is also powerful enough to capture the structure of the ranking error; indeed, the uniform convergence bound for the (bipartite) ranking error derived by Agarwal et al. (2005) also made use of McDiarmid's inequality. Thus, in general, any learning problem in which the empirical performance measure fits the conditions of McDiarmid's inequality should be amenable to a stability analysis similar to Bousquet and Elisseeff's, provided of course that appropriate notions of stability are defined.

Theorem 6 gives meaningful bounds when $\beta(m) = o(1/\sqrt{m})$. This means the theorem cannot be applied directly to obtain bounds on the expected ranking error, since it is not possible to have non-trivial uniform loss stability with respect to the discrete ranking loss ℓ_{disc} defined in Eq. (3). (To see this, note that unless an algorithm picks essentially the same ranking function that orders all instances the same way for all training samples of a given size m, in which case the algorithm trivially has uniform loss stability $\beta(m) = 0$ with respect to ℓ_{disc}, there must be some $S \in (\mathcal{X} \times \mathcal{Y})^m$, $1 \leq i \leq m$, $(x_i', y_i') \in (\mathcal{X} \times \mathcal{Y})$ and some $x, x' \in \mathcal{X}$ such that f_S and f_{S^i} order x, x' differently. In this case, for $y = 0$ and $y' = M$, we get $|\ell_{\text{disc}}(f_S,(x,y),(x',y')) - \ell_{\text{disc}}(f_{S^i},(x,y),(x',y'))| = M$, giving loss stability $\beta(m) = M$ with respect to ℓ_{disc}.) However, for any ranking loss ℓ that satisfies $\ell_{\text{disc}} \leq \ell$,

2. A symmetric ranking algorithm is one whose output is independent of the order of elements in the training sequence S.

Theorem 6 can be applied to ranking algorithms that have good uniform loss stability with respect to ℓ to obtain bounds on the expected ℓ-error; since in this case $R \le R_\ell$, these bounds apply also to the expected ranking error. We consider below a specific ranking loss that satisfies this condition, and with respect to which we will be able to show good loss stability of certain ranking algorithms; other ranking losses which can also be used in this manner will be discussed in later sections.

For $\gamma > 0$, let the γ *ranking loss*, denoted by ℓ_γ, be defined as follows:

$$\ell_\gamma(f,(x,y),(x',y'))$$

$$= \begin{cases} |y-y'| & \text{if } \frac{(f(x)-f(x'))\cdot\mathrm{sgn}(y-y')}{\gamma} \le 0 \\ |y-y'| - \frac{(f(x)-f(x'))\cdot\mathrm{sgn}(y-y')}{\gamma} & \text{if } 0 < \frac{(f(x)-f(x'))\cdot\mathrm{sgn}(y-y')}{\gamma} < |y-y'| \\ 0 & \text{if } \frac{(f(x)-f(x'))\cdot\mathrm{sgn}(y-y')}{\gamma} \ge |y-y'|, \end{cases}$$

where for $u \in \mathbb{R}$,

$$\mathrm{sgn}(u) = \begin{cases} 1 & \text{if } u > 0 \\ 0 & \text{if } u = 0 \\ -1 & \text{if } u < 0. \end{cases}$$

Clearly, for all $\gamma > 0$, we have $\ell_{\text{disc}} \le \ell_\gamma$. Therefore, for any ranking algorithm that has good uniform loss stability with respect to ℓ_γ for some $\gamma > 0$, Theorem 6 can be applied to bound the expected ranking error of a learned ranking function in terms of its empirical ℓ_γ-error on the training sample. The following lemma shows that, for every $\gamma > 0$, a ranking algorithm that has good uniform score stability also has good uniform loss stability with respect to ℓ_γ.

Lemma 7 *Let $\mathcal{A}$ be a ranking algorithm whose output on a training sample $S \in (\mathcal{X} \times \mathcal{Y})^m$ we denote by f_S. Let $\nu : \mathbb{N} \to \mathbb{R}$ be such that $\mathcal{A}$ has uniform score stability ν. Then for every $\gamma > 0$, $\mathcal{A}$ has uniform loss stability β_γ with respect to the γ ranking loss ℓ_γ, where for all $m \in \mathbb{N}$,*

$$\beta_\gamma(m) = \frac{2\nu(m)}{\gamma}.$$

Proof Let $m \in \mathbb{N}$, $S \in (\mathcal{X} \times \mathcal{Y})^m$, $1 \le i \le m$ and $(x'_i, y'_i) \in (\mathcal{X} \times \mathcal{Y})$. Let $(x,y),(x',y') \in (\mathcal{X} \times \mathcal{Y})$. We want to show

$$\left|\ell_\gamma(f_S,(x,y),(x',y')) - \ell_\gamma(f_{S^i},(x,y),(x',y'))\right| \le \frac{2\nu(m)}{\gamma}.$$

Now, if $\ell_\gamma(f_S,(x,y),(x',y')) = \ell_\gamma(f_{S^i},(x,y),(x',y'))$, then trivially

$$\left|\ell_\gamma(f_S,(x,y),(x',y')) - \ell_\gamma(f_{S^i},(x,y),(x',y'))\right| = 0 \le \frac{2\nu(m)}{\gamma},$$

and there is nothing to prove. Therefore assume $\ell_\gamma(f_S,(x,y),(x',y')) \ne \ell_\gamma(f_{S^i},(x,y),(x',y'))$. Without loss of generality, let $\ell_\gamma(f_S,(x,y),(x',y')) > \ell_\gamma(f_{S^i},(x,y),(x',y'))$. There are four possibilities:

(i) $\frac{(f_S(x)-f_S(x'))\cdot\mathrm{sgn}(y-y')}{\gamma} \le 0$ and $0 < \frac{(f_{S^i}(x)-f_{S^i}(x'))\cdot\mathrm{sgn}(y-y')}{\gamma} < |y-y'|$.

In this case, we have

$$\begin{aligned}
&\left|\ell_\gamma(f_S,(x,y),(x',y')) - \ell_\gamma(f_{S^i},(x,y),(x',y'))\right| \\
&\quad = \; |y-y'| - \left(|y-y'| - \tfrac{(f_{S^i}(x)-f_{S^i}(x'))\cdot\mathrm{sgn}(y-y')}{\gamma}\right) \\
&\quad \leq \; \left(|y-y'| - \tfrac{(f_S(x)-f_S(x'))\cdot\mathrm{sgn}(y-y')}{\gamma}\right) - \left(|y-y'| - \tfrac{(f_{S^i}(x)-f_{S^i}(x'))\cdot\mathrm{sgn}(y-y')}{\gamma}\right) \\
&\quad \leq \; \frac{1}{\gamma}\left(|f_S(x)-f_{S^i}(x)| + \left|f_S(x')-f_{S^i}(x')\right|\right) \\
&\quad \leq \; \frac{2\nu(m)}{\gamma}.
\end{aligned}$$

(ii) $0 < \frac{(f_S(x)-f_S(x'))\cdot\mathrm{sgn}(y-y')}{\gamma} < |y-y'|$ and $\frac{(f_{S^i}(x)-f_{S^i}(x'))\cdot\mathrm{sgn}(y-y')}{\gamma} \geq |y-y'|$.

In this case, we have

$$\begin{aligned}
&\left|\ell_\gamma(f_S,(x,y),(x',y')) - \ell_\gamma(f_{S^i},(x,y),(x',y'))\right| \\
&\quad = \; \left(|y-y'| - \tfrac{(f_{S^i}(x)-f_{S^i}(x'))\cdot\mathrm{sgn}(y-y')}{\gamma}\right) - 0 \\
&\quad \leq \; \left(|y-y'| - \tfrac{(f_S(x)-f_S(x'))\cdot\mathrm{sgn}(y-y')}{\gamma}\right) - \left(|y-y'| - \tfrac{(f_{S^i}(x)-f_{S^i}(x'))\cdot\mathrm{sgn}(y-y')}{\gamma}\right) \\
&\quad \leq \; \frac{1}{\gamma}\left(|f_S(x)-f_{S^i}(x)| + \left|f_S(x')-f_{S^i}(x')\right|\right) \\
&\quad \leq \; \frac{2\nu(m)}{\gamma}.
\end{aligned}$$

(iii) $\frac{(f_S(x)-f_S(x'))\cdot\mathrm{sgn}(y-y')}{\gamma} \leq 0$ and $\frac{(f_{S^i}(x)-f_{S^i}(x'))\cdot\mathrm{sgn}(y-y')}{\gamma} \geq |y-y'|$.

In this case, we have

$$\begin{aligned}
&\left|\ell_\gamma(f_S,(x,y),(x',y')) - \ell_\gamma(f_{S^i},(x,y),(x',y'))\right| \\
&\quad = \; |y-y'| - 0 \\
&\quad \leq \; \left(|y-y'| - \tfrac{(f_S(x)-f_S(x'))\cdot\mathrm{sgn}(y-y')}{\gamma}\right) - \left(|y-y'| - \tfrac{(f_{S^i}(x)-f_{S^i}(x'))\cdot\mathrm{sgn}(y-y')}{\gamma}\right) \\
&\quad \leq \; \frac{1}{\gamma}\left(|f_S(x)-f_{S^i}(x)| + \left|f_S(x')-f_{S^i}(x')\right|\right) \\
&\quad \leq \; \frac{2\nu(m)}{\gamma}.
\end{aligned}$$

(iv) $0 < \frac{(f_S(x)-f_S(x'))\cdot\mathrm{sgn}(y-y')}{\gamma} < |y-y'|$ and $0 < \frac{(f_{S^i}(x)-f_{S^i}(x'))\cdot\mathrm{sgn}(y-y')}{\gamma} < |y-y'|$.

In this case, we have

$$\left|\ell_\gamma(f_S,(x,y),(x',y')) - \ell_\gamma(f_{S^i},(x,y),(x',y'))\right|$$

$$\begin{aligned}
&= \left(|y-y'| - \tfrac{(f_S(x)-f_S(x'))\cdot \text{sgn}(y-y')}{\gamma}\right) - \left(|y-y'| - \tfrac{(f_{S^i}(x)-f_{S^i}(x'))\cdot \text{sgn}(y-y')}{\gamma}\right) \\
&\leq \frac{1}{\gamma}\left(|f_S(x)-f_{S^i}(x)| + \left|f_S(x')-f_{S^i}(x')\right|\right) \\
&\leq \frac{2\nu(m)}{\gamma}\,.
\end{aligned}$$

Thus in all cases, $\left|\ell_\gamma(f_S,(x,y),(x',y')) - \ell_\gamma(f_{S^i},(x,y),(x',y'))\right| \leq \frac{2\nu(m)}{\gamma}$. ■

Putting everything together, we thus get the following result which bounds the expected ranking error of a learned ranking function in terms of its empirical ℓ_γ-error for any ranking algorithm that has good uniform score stability.

Theorem 8 *Let $\mathcal{A}$ be a symmetric ranking algorithm whose output on a training sample $S \in (\mathcal{X} \times \mathcal{Y})^m$ we denote by f_S. Let $\nu : \mathbb{N} \to \mathbb{R}$ be such that $\mathcal{A}$ has uniform score stability ν, and let $\gamma > 0$. Then for any $0 < \delta < 1$, with probability at least $1-\delta$ over the draw of S (according to $\mathcal{D}^m$),*

$$R(f_S) \quad < \quad \widehat{R}_{\ell_\gamma}(f_S;S) + \frac{4\nu(m)}{\gamma} + \left(\frac{2m\nu(m)}{\gamma} + M\right)\sqrt{\frac{2\ln(1/\delta)}{m}}\,.$$

Proof The result follows by applying Theorem 6 to $\mathcal{A}$ with the ranking loss ℓ_γ (using Lemma 7), which satisfies $0 \leq \ell_\gamma \leq M$, and from the fact that $R \leq R_{\ell_\gamma}$. ■

5. Stable Ranking Algorithms

In this section we show (uniform) stability of certain ranking algorithms that select a ranking function by minimizing a regularized objective function. We start by deriving a general result for regularization-based ranking algorithms in Section 5.1. In Section 5.2 we use this result to show stability of kernel-based ranking algorithms that perform regularization in a reproducing kernel Hilbert space (RKHS). We show, in particular, stability of two such ranking algorithms, and apply the results of Section 4 to obtain generalization bounds for these algorithms. Again, the methods we use to show stability of these algorithms are based on those of Bousquet and Elisseeff (2002), who showed similar results for classification and regression algorithms. We also use these stability results to give a consistency theorem for kernel-based ranking algorithms (Section 5.2.3).

5.1 General Regularizers

Given a ranking loss function ℓ, a class $\mathcal{F}$ of real-valued functions on $\mathcal{X}$, and a regularization functional $N : \mathcal{F} \to \mathbb{R}^+ \cup \{0\}$, consider the following regularized empirical ℓ-error of a ranking function $f \in \mathcal{F}$ (with respect to a sample $S \in (\mathcal{X} \times \mathcal{Y})^m$), with regularization parameter $\lambda > 0$:

$$\widehat{R}^\lambda_\ell(f;S) \quad = \quad \widehat{R}_\ell(f;S) + \lambda N(f)\,.$$

We consider ranking algorithms that minimize such a regularized objective function, that is, ranking algorithms that, given a training sample S, output a ranking function $f_S \in \mathcal{F}$ that satisfies

$$f_S = \arg\min_{f\in\mathcal{F}} \widehat{R}_\ell^\lambda(f;S), \tag{4}$$

for some fixed choice of ranking loss ℓ, function class $\mathcal{F}$, regularizer N, and regularization parameter λ. It is worth noting that the parameter λ often depends on the sample size m; we use λ here rather than λ_m for notational simplicity. We give below a general result that will be useful for showing stability of such regularization-based algorithms.

Definition 9 (σ-admissibility) *Let $\mathcal{F}$ be a class of real-valued functions on $\mathcal{X}$. Let ℓ be a ranking loss and let $\sigma > 0$. We say that ℓ is* σ-admissible *with respect to $\mathcal{F}$ if for all $f_1, f_2 \in \mathcal{F}$ and all $(x,y),(x',y') \in (\mathcal{X}\times\mathcal{Y})$, we have*

$$\left|\ell(f_1,(x,y),(x',y')) - \ell(f_2,(x,y),(x',y'))\right| \le \sigma\Big(\left|f_1(x)-f_2(x)\right| + \left|f_1(x')-f_2(x')\right|\Big).$$

Lemma 10 *Let $\mathcal{F}$ be a convex class of real-valued functions on $\mathcal{X}$. Let ℓ be a ranking loss such that $\ell(f,(x,y),(x',y'))$ is convex in f, and let $\sigma > 0$ be such that ℓ is σ-admissible with respect to $\mathcal{F}$. Let $\lambda > 0$, and let $N : \mathcal{F}\to\mathbb{R}^+\cup\{0\}$ be a functional defined on $\mathcal{F}$ such that for all samples $S \in (\mathcal{X}\times\mathcal{Y})^m$, the regularized empirical ℓ-error $\widehat{R}_\ell^\lambda(f;S)$ has a minimum (not necessarily unique) in $\mathcal{F}$. Let $\mathcal{A}$ be a ranking algorithm defined by Eq. (4), and let $S = ((x_1,y_1),\ldots,(x_m,y_m)) \in (\mathcal{X}\times\mathcal{Y})^m$, $1 \le i \le m$, and $(x_i',y_i') \in (\mathcal{X}\times\mathcal{Y})$. For brevity, denote $f \equiv f_S$, $f^i \equiv f_{S^i}$, and let $\Delta f = f^i - f$. Then we have that for any $t \in [0,1]$,*

$$\begin{aligned} N(f) - N(f+t\Delta f) + N(f^i) - N(f^i - t\Delta f) \\ \le \frac{t\sigma}{\lambda\binom{m}{2}} \sum_{j\ne i}\Big(|\Delta f(x_i)| + 2|\Delta f(x_j)| + |\Delta f(x_i')|\Big). \end{aligned}$$

The proof follows that of a similar result for regularization-based algorithms for classification and regression (Bousquet and Elisseeff, 2002); it is based crucially on the convexity of the ranking loss ℓ. Details are provided in Appendix B.

As we shall see below, the above result can be used to establish stability of certain regularization-based ranking algorithms.

5.2 Regularization in Hilbert Spaces

Let $\mathcal{F}$ be a reproducing kernel Hilbert space (RKHS) of real-valued functions on $\mathcal{X}$, with kernel $K : \mathcal{X}\times\mathcal{X}\to\mathbb{R}$. Then the reproducing property of $\mathcal{F}$ gives that for all $f \in \mathcal{F}$ and all $x \in \mathcal{X}$,

$$|f(x)| = |\langle f, K_x\rangle_K|, \tag{5}$$

where $K_x : \mathcal{X}\to\mathbb{R}$ is defined as

$$K_x(x') = K(x,x'),$$

and $\langle\cdot,\cdot\rangle_K$ denotes the RKHS inner product in $\mathcal{F}$. In particular, applying the Cauchy-Schwartz inequality to Eq. (5) then gives that for all $f \in \mathcal{F}$ and all $x \in X$,

$$\begin{aligned} |f(x)| &\le \|f\|_K\,\|K_x\|_K \\ &= \|f\|_K\sqrt{K(x,x)}, \end{aligned} \tag{6}$$

where $\|\cdot\|_K$ denotes the RKHS norm in $\mathcal{F}$.

Further details about RKHSs can be found, for example, in expositions by Haussler (1999) and Evgeniou et al. (2000). We shall consider ranking algorithms that perform regularization in the RKHS $\mathcal{F}$ using the squared norm in $\mathcal{F}$ as a regularizer. Specifically, let $N : \mathcal{F} \rightarrow \mathbb{R}^+ \cup \{0\}$ be the regularizer defined by

$$N(f) \quad = \quad \|f\|_K^2 .$$

We show below that, if the kernel K is such that $K(x,x)$ is bounded for all $x \in \mathcal{X}$, then a ranking algorithm that minimizes an appropriate regularized error over $\mathcal{F}$, with regularizer N as defined above, has good uniform score stability.

Theorem 11 *Let $\mathcal{F}$ be an RKHS with kernel K such that for all $x \in \mathcal{X}$, $K(x,x) \leq \kappa^2 < \infty$. Let ℓ be a ranking loss such that $\ell(f,(x,y),(x',y'))$ is convex in f and ℓ is σ-admissible with respect to $\mathcal{F}$. Let $\lambda > 0$, and let $\mathcal{A}$ be a ranking algorithm that, given a training sample S, outputs a ranking function $f_S \in \mathcal{F}$ that satisfies $f_S = \arg\min_{f \in \mathcal{F}} \left\{ \widehat{R}_\ell(f;S) + \lambda \|f\|_K^2 \right\}$. Then $\mathcal{A}$ has uniform score stability ν, where for all $m \in \mathbb{N}$,*

$$\nu(m) = \frac{8\sigma\kappa^2}{\lambda m} .$$

Proof Let $m \in \mathbb{N}$, $S = ((x_1,y_1),\ldots,(x_m,y_m)) \in (\mathcal{X} \times \mathcal{Y})^m$, $1 \leq i \leq m$, and $(x_i',y_i') \in (\mathcal{X} \times \mathcal{Y})$. Applying Lemma 10 with $t = 1/2$, we get (using the notation of Lemma 10) that

$$\begin{aligned} &\|f\|_K^2 - \|f + \tfrac{1}{2}\Delta f\|_K^2 + \|f^i\|_K^2 - \|f^i - \tfrac{1}{2}\Delta f\|_K^2 \\ &\qquad \leq \frac{\sigma}{\lambda m(m-1)} \sum_{j \neq i} \Big(|\Delta f(x_i)| + 2|\Delta f(x_j)| + |\Delta f(x_i')| \Big) . \end{aligned} \tag{7}$$

Note that since $\mathcal{F}$ is a vector space, $\Delta f \in \mathcal{F}$, $(f + \frac{1}{2}\Delta f) \in \mathcal{F}$, and $(f^i - \frac{1}{2}\Delta f) \in \mathcal{F}$, so that $\|f + \frac{1}{2}\Delta f\|_K$ and $\|f^i - \frac{1}{2}\Delta f\|_K$ are well-defined. Now, we have

$$\begin{aligned} &\|f\|_K^2 - \|f + \tfrac{1}{2}\Delta f\|_K^2 + \|f^i\|_K^2 - \|f^i - \tfrac{1}{2}\Delta f\|_K^2 \\ &\qquad = \|f\|_K^2 + \|f^i\|_K^2 - \frac{1}{2}\|f + f^i\|_K^2 \\ &\qquad = \frac{1}{2}\|f\|_K^2 + \frac{1}{2}\|f^i\|_K^2 - \langle f, f^i \rangle_K \\ &\qquad = \frac{1}{2}\|\Delta f\|_K^2 . \end{aligned}$$

Combined with Eq. (7), this gives

$$\frac{1}{2}\|\Delta f\|_K^2 \quad \leq \quad \frac{\sigma}{\lambda m(m-1)} \sum_{j \neq i} \Big(|\Delta f(x_i)| + 2|\Delta f(x_j)| + |\Delta f(x_i')| \Big) .$$

Since (as noted above) $\Delta f \in \mathcal{F}$, by Eq. (6), we thus get that

$$\begin{aligned} \frac{1}{2}\|\Delta f\|_K^2 \quad &\leq \quad \frac{\sigma}{\lambda m(m-1)} \|\Delta f\|_K \sum_{j \neq i} \left(\sqrt{K(x_i,x_i)} + 2\sqrt{K(x_j,x_j)} + \sqrt{K(x_i',x_i')} \right) \\ &\leq \quad \frac{4\sigma\kappa}{\lambda m} \|\Delta f\|_K , \end{aligned}$$

which gives

$$\|\Delta f\|_K \;\leq\; \frac{8\sigma\kappa}{\lambda m}\,. \tag{8}$$

Thus, by Eqs. (6) and (8), we have for all $x \in \mathcal{X}$,

$$|f_S(x) - f_{S^i}(x)| = |\Delta f(x)| \;\leq\; \frac{8\sigma\kappa^2}{\lambda m}\,.$$

The result follows. ■

This gives the following generalization bound for kernel-based ranking algorithms:

Corollary 12 *Under the conditions of Theorem 11, we have that for any* $0 < \delta < 1$*, with probability at least* $1 - \delta$ *over the draw of* S *(according to* $\mathcal{D}^m$*), the expected ranking error of the ranking function* f_S *learned by* $\mathcal{A}$ *is bounded by*

$$R(f_S) \;<\; \widehat{R}_{\ell_1}(f_S;S) + \frac{32\sigma\kappa^2}{\lambda m} + \left(\frac{16\sigma\kappa^2}{\lambda} + M\right)\sqrt{\frac{2\ln(1/\delta)}{m}}\,.$$

Proof The result follows from Theorem 11, by applying Theorem 8 with $\gamma = 1$. ■

Under the conditions of the above results, a kernel-based ranking algorithm minimizing a regularized empirical ℓ-error also has good uniform loss stability with respect to ℓ; this follows from the following simple lemma:[3]

Lemma 13 *Let* $\mathcal{F}$ *be a class of real-valued functions on* $\mathcal{X}$*, and let* $\mathcal{A}$ *be a ranking algorithm that, given a training sample* S*, outputs a ranking function* $f_S \in \mathcal{F}$*. If* $\mathcal{A}$ *has uniform score stability* ν *and* ℓ *is a ranking loss that is* σ*-admissible with respect to* $\mathcal{F}$*, then* $\mathcal{A}$ *has uniform loss stability* β *with respect to* ℓ*, where for all* $m \in \mathbb{N}$*,*

$$\beta(m) \;=\; 2\sigma\nu(m)\,.$$

Proof Let $m \in \mathbb{N}$, $S \in (\mathcal{X} \times \mathcal{Y})^m$, $1 \leq i \leq m$ and $(x_i', y_i') \in (\mathcal{X} \times \mathcal{Y})$. Let $(x,y), (x',y') \in (\mathcal{X} \times \mathcal{Y})$. Then we have

$$\begin{aligned}
\left|\ell(f_S,(x,y),(x',y')) - \ell(f_{S^i},(x,y),(x',y'))\right| \;&\leq\; \sigma\Big(|f_S(x) - f_{S^i}(x)| + |f_S(x') - f_{S^i}(x')|\Big) \\
&\leq\; 2\sigma\nu(m)\,,
\end{aligned}$$

where the first inequality follows from σ-admissibility and the second from uniform score stability. ■

3. We note that the proof of Lemma 7 in Section 4 really amounts to showing that ℓ_γ is $\frac{1}{\gamma}$-admissible with respect to the set of all ranking functions on $\mathcal{X}$; the result then follows by the observation in Lemma 13.

Corollary 14 *Under the conditions of Theorem 11, $\mathcal{A}$ has uniform loss stability* β *with respect to ℓ, where for all $m \in \mathbb{N}$,*

$$\beta(m) = \frac{16\sigma^2\kappa^2}{\lambda m}.$$

Proof Immediate from Theorem 11 and Lemma 13. ■

This leads to the following additional bound for kernel-based ranking algorithms that minimize a regularized empirical ℓ-error where ℓ is bounded and satisfies $\ell_{\text{disc}} \leq \ell$:

Corollary 15 *Under the conditions of Theorem 11, if in addition the ranking loss ℓ satisfies $\ell_{\text{disc}}(f,(x,y),(x',y')) \leq \ell(f,(x,y),(x',y')) \leq B$ for all $f : \mathcal{X} \to \mathbb{R}$ and $(x,y),(x',y') \in (\mathcal{X} \times \mathcal{Y})$, then we have that for any $0 < \delta < 1$, with probability at least $1-\delta$ over the draw of S (according to $\mathcal{D}^m$), the expected ranking error of the ranking function f_S learned by $\mathcal{A}$ is bounded by*

$$R(f_S) \quad < \quad \widehat{R}_\ell(f_S;S) + \frac{32\sigma^2\kappa^2}{\lambda m} + \left(\frac{16\sigma^2\kappa^2}{\lambda} + B\right)\sqrt{\frac{2\ln(1/\delta)}{m}}.$$

Proof The result follows from Corollary 14, by applying Theorem 6 and the fact that $R \leq R_\ell$. ■

The results of both Corollary 12 and Corollary 15 show that a larger regularization parameter λ leads to better stability and, therefore, a tighter confidence interval in the resulting generalization bound. In particular, when σ is independent of λ, one must have $\lambda \gg \frac{1}{\sqrt{m}}$ in order for either of these bounds to be meaningful. In practice, the ranking losses ℓ minimized by kernel-based ranking algorithms tend to be larger than the loss ℓ_1, and therefore Corollary 12 tends to provide tighter bounds on the expected ranking error than Corollary 15. Below we look at two specific algorithms that minimize two different (regularized) ranking losses.

5.2.1 HINGE RANKING LOSS

Consider the following ranking loss function, which we refer to as the *hinge ranking loss* due to its similarity to the hinge loss in classification:

$$\ell_{\text{h}}(f,(x,y),(x',y')) \quad = \quad \Big(|y-y'| - (f(x)-f(x'))\cdot \text{sgn}(y-y')\Big)_+,$$

where for $a \in \mathbb{R}$,

$$a_+ \quad = \quad \begin{cases} a & \text{if } a > 0 \\ 0 & \text{otherwise.} \end{cases}$$

We consider a ranking algorithm $\mathcal{A}_{\text{h}}$ that minimizes the regularized ℓ_h-error in an RKHS $\mathcal{F}$. Specifically, let $\mathcal{A}_{\text{h}}$ be a ranking algorithm which, given a training sample $S \in (\mathcal{X} \times \mathcal{Y})^m$, outputs a ranking function $f_S \in \mathcal{F}$ that satisfies (for some fixed $\lambda > 0$)

$$f_S \quad = \quad \arg\min_{f\in\mathcal{F}} \left\{ \widehat{R}_{\ell_{\text{h}}}(f;S) + \lambda\|f\|_K^2 \right\}.$$

We note that this algorithm has an equivalent quadratic programming formulation similar to SVMs in the case of classification. In particular, the problem of minimizing $\widehat{R}^{\lambda}_{\ell_h}(f;S)$ is equivalent to that of minimizing

$$\frac{1}{2}\|f\|_K^2 + C\sum_{i=1}^{m-1}\sum_{j=i+1}^{m}\xi_{ij}$$

subject to

$$\begin{aligned}\xi_{ij} &\geq |y_i - y_j| - (f(x_i) - f(x_j)\cdot \mathrm{sgn}(y_i - y_j))\\ \xi_{ij} &\geq 0\end{aligned}$$

for all $1 \leq i < j \leq m$, where $C = 1/(\lambda m(m-1))$. The dual formulation of this problem obtained by introducing Lagrange multipliers leads to a quadratic program similar to that obtained for SVMs; for example, see the related algorithms described by Herbrich et al. (1998, 2000), Joachims (2002), Rakotomamonjy (2004), and Agarwal (2006).

It can be verified that $\ell_h(f,(x,y),(x',y'))$ is convex in f, and that ℓ_h is 1-admissible with respect to $\mathcal{F}$ (the proof of 1-admissibility is similar to the proof of Lemma 7 which, as noted earlier in Footnote 3, effectively shows $\frac{1}{\gamma}$-admissibility of the γ ranking loss ℓ_γ). Thus, if $K(x,x) \leq \kappa^2$ for all $x \in \mathcal{X}$, then from Corollary 12 we get that for any $0 < \delta < 1$, with probability at least $1-\delta$ over the draw of S (according to $\mathcal{D}^m$), the expected ranking error of the ranking function f_S learned by the above algorithm $\mathcal{A}_h$ is bounded by

$$R(f_S) \quad < \quad \widehat{R}_{\ell_1}(f_S;S) + \frac{32\kappa^2}{\lambda m} + \left(\frac{16\kappa^2}{\lambda} + M\right)\sqrt{\frac{2\ln(1/\delta)}{m}}\,.$$

5.2.2 LEAST SQUARES RANKING LOSS

Consider now the following *least squares ranking loss*:

$$\ell_{sq}(f,(x,y),(x',y')) \quad = \quad \Big(|y-y'| - \mathrm{sgn}(y-y')\cdot(f(x)-f(x'))\Big)^2\,. \tag{9}$$

Let $\mathcal{A}_{sq}$ be a ranking algorithm that minimizes the regularized ℓ_{sq}-error in an RKHS $\mathcal{F}$, that is, given a training sample $S \in (\mathcal{X}\times\mathcal{Y})^m$, the algorithm $\mathcal{A}_{sq}$ outputs a ranking function $f_S \in \mathcal{F}$ that satisfies (for some fixed $\lambda > 0$)

$$f_S \quad = \quad \arg\min_{f\in\mathcal{F}}\left\{\widehat{R}_{\ell_{sq}}(f;S) + \lambda\|f\|_K^2\right\}.$$

It can be verified that $\ell_{sq}(f,(x,y),(x',y'))$ is convex in f. Now, we claim that the effective search space of $\mathcal{A}_{sq}$ on training samples of size m is actually $\mathcal{F}_\lambda = \left\{f \in \mathcal{F} \,\middle|\, \|f\|_K^2 \leq \frac{M^2}{\lambda}\right\}$, that is, that for any training sample $S = ((x_1,y_1),\ldots,(x_m,y_m)) \in (\mathcal{X}\times\mathcal{Y})^m$, the ranking function f_S returned by $\mathcal{A}_{sq}$ satisfies $\|f_S\|_K^2 \leq \frac{M^2}{\lambda}$. To see this, note that for the zero function $f_0 \in \mathcal{F}$ which assigns $f_0(x) = 0$ for all $x \in \mathcal{X}$, we have

$$\begin{aligned}\widehat{R}_{\ell_{sq}}(f_0;S) + \lambda\|f_0\|_K^2 &= \frac{1}{\binom{m}{2}}\sum_{i=1}^{m-1}\sum_{j=i+1}^{m}(|y_i-y_j|-0)^2 + \lambda\cdot 0\\ &\leq M^2\,.\end{aligned}$$

Therefore, by definition of f_S,

$$\widehat{R}_{\ell_{\text{sq}}}(f_S;S) + \lambda \|f_S\|_K^2 \;\; \leq \;\; M^2 .$$

Since $\widehat{R}_{\ell_{\text{sq}}}(f_S;S) \geq 0$, this implies

$$\|f_S\|_K^2 \;\; \leq \;\; \frac{M^2}{\lambda} .$$

It is easily verified that the effective search space $\mathcal{F}_\lambda$ is a convex set. The following lemma shows that if $K(x,x) \leq \kappa^2$ for all $x \in \mathcal{X}$, then ℓ_{sq} is $(2M + \frac{4\kappa M}{\sqrt{\lambda}})$-admissible with respect to $\mathcal{F}_\lambda$.

Lemma 16 *Let $\mathcal{F}$ be an RKHS with kernel K such that for all $x \in \mathcal{X}$, $K(x,x) \leq \kappa^2 < \infty$. Let $\lambda > 0$, and let $\mathcal{F}_\lambda = \left\{ f \in \mathcal{F} \;\middle|\; \|f\|_K^2 \leq \frac{M^2}{\lambda} \right\}$. Then the least squares ranking loss ℓ_{sq}, defined in Eq. (9) above, is $(2M + \frac{4\kappa M}{\sqrt{\lambda}})$-admissible with respect to $\mathcal{F}_\lambda$.*

Proof First, note that for any $f \in \mathcal{F}_\lambda$ and any $x \in \mathcal{X}$, we have from Eq. (6) that

$$|f(x)| \;\leq\; \kappa \|f\|_K \;\leq\; \frac{\kappa M}{\sqrt{\lambda}} .$$

Now, let $f_1, f_2 \in \mathcal{F}_\lambda$, and let $(x,y),(x',y') \in (\mathcal{X} \times \mathcal{Y})$. Then we have,

$$\begin{aligned}
&\Big| \ell_{\text{sq}}(f_1,(x,y),(x',y')) - \ell_{\text{sq}}(f_1,(x,y),(x',y')) \Big| \\
&\quad = \;\; \Big| \Big((y-y') - (f_1(x) - f_1(x')) \Big)^2 - \Big((y-y') - (f_2(x) - f_2(x')) \Big)^2 \Big| \\
&\quad = \;\; \Big| 2(y-y') - (f_1(x) - f_1(x')) - (f_2(x) - f_2(x')) \Big| \cdot \Big| (f_2(x) - f_2(x')) - (f_1(x) - f_1(x')) \Big| \\
&\quad \leq \;\; \Big(2|y-y'| + |f_1(x)| + |f_1(x')| + |f_2(x)| + |f_2(x')| \Big) \cdot \Big(|f_1(x) - f_2(x)| + |f_1(x') - f_2(x')| \Big) \\
&\quad \leq \;\; \Big(2M + \frac{4\kappa M}{\sqrt{\lambda}} \Big) \cdot \Big(|f_1(x) - f_2(x)| + |f_1(x') - f_2(x')| \Big) ,
\end{aligned}$$

where the second equality follows from the identity $|a^2 - b^2| = |a+b| \cdot |a-b|$. ■

An analysis of the proof of Lemma 10 shows that if a regularization-based ranking algorithm minimizing a regularized ℓ-error in some convex function class $\mathcal{F}$ is such that the ranking function returned by it for training samples of a given size m always lies in some effective search space $\mathcal{F}_m \subseteq \mathcal{F}$ that is also convex, then the result of the lemma holds even when for each m, the loss function ℓ is σ_m-admissible, for some $\sigma_m > 0$, only with respect to the smaller function class $\mathcal{F}_m$. This in turn implies more general versions of Theorem 11 and Corollary 12, in which the same results hold even if a ranking algorithm minimizing a regularized ℓ-error in an RKHS $\mathcal{F}$ is such that for each m, ℓ is σ_m-admissible with respect to a convex subset $\mathcal{F}_m \subseteq \mathcal{F}$ that serves as an effective search space for training samples of size m. Thus, from Lemma 16 and the discussion preceding it, it follows that if $K(x,x) \leq \kappa^2$ for all $x \in \mathcal{X}$, then we can apply (the more general version of) Corollary 12 with $\sigma_m = (2M + \frac{4\kappa M}{\sqrt{\lambda}})$ (recall that $\lambda \equiv \lambda_m$ may depend on the sample size m) to get that for any $0 < \delta < 1$, with probability at least $1-\delta$ over the draw of S (according to $\mathcal{D}^m$), the expected ranking error of the ranking function f_S learned by the algorithm $\mathcal{A}_{\text{sq}}$ is bounded by

$$R(f_S) \quad < \quad \widehat{R}_{\ell_1}(f_S;S) + \frac{64\kappa^2 M}{\lambda m}\Big(1+\frac{2\kappa}{\sqrt{\lambda}}\Big) + \left(\frac{32\kappa^2 M}{\lambda}\Big(1+\frac{2\kappa}{\sqrt{\lambda}}\Big)+M\right)\sqrt{\frac{2\ln(1/\delta)}{m}}\,.$$

5.2.3 CONSISTENCY

We can also use the above results to show consistency of kernel-based ranking algorithms. In particular, let $R^*_\ell(\mathcal{F})$ denote the optimal expected ℓ-error in an RKHS $\mathcal{F}$ (for a given distribution $\mathcal{D}$):

$$R^*_\ell(\mathcal{F}) \quad = \quad \inf_{f\in\mathcal{F}} R_\ell(f)\,.$$

Then for bounded loss functions ℓ, we can show that with an appropriate choice of the regularization parameter λ, the expected ℓ-error $R_\ell(f_S)$ of the ranking function f_S learned by a kernel-based ranking algorithm that minimizes a regularized empirical ℓ-error in $\mathcal{F}$ converges (in probability) to this optimal value. To show this, we shall need the following simple lemma:

Lemma 17 *Let $f : \mathcal{X}\to\mathbb{R}$ be a fixed ranking function, and let ℓ be a bounded ranking loss function such that $0 \le \ell(f,(x,y),(x',y')) \le B$ for all $f : \mathcal{X}\to\mathbb{R}$ and $(x,y),(x',y') \in (\mathcal{X}\times\mathcal{Y})$. Then for any $0<\delta<1$, with probability at least $1-\delta$ over the draw of $S \in (\mathcal{X}\times\mathcal{Y})^m$ (according to $\mathcal{D}^m$),*

$$\widehat{R}_\ell(f;S) \quad < \quad R_\ell(f) + B\sqrt{\frac{2\ln(1/\delta)}{m}}\,.$$

The proof involves a simple application of McDiarmid's inequality to the random variable $\widehat{R}_\ell(f;S)$; details are provided in Appendix C. We then have the following consistency result:

Theorem 18 *Let $\mathcal{F}$ be an RKHS with kernel K such that for all $x\in\mathcal{X}$, $K(x,x)\le\kappa^2<\infty$. Let ℓ be a ranking loss such that $\ell(f,(x,y),(x',y'))$ is convex in f and ℓ is σ-admissible with respect to $\mathcal{F}$. Furthermore, let ℓ be bounded such that $0 \le \ell(f,(x,y),(x',y')) \le B$ for all $f : \mathcal{X}\to\mathbb{R}$ and $(x,y),(x',y') \in (\mathcal{X}\times\mathcal{Y})$, and let f^*_ℓ be any fixed function in $\mathcal{F}$ that satisfies*

$$R_\ell(f^*_\ell) \quad \le \quad R^*_\ell(\mathcal{F}) + \frac{1}{m}\,. \tag{10}$$

(Note that such a function f^*_ℓ exists by definition of $R^*_\ell(\mathcal{F})$.) Let $\lambda>0$, and let $\mathcal{A}$ be a ranking algorithm that, given a training sample S, outputs a ranking function $f_S\in\mathcal{F}$ that satisfies $f_S = \arg\min_{f\in\mathcal{F}}\left\{\widehat{R}_\ell(f;S)+\lambda\|f\|_K^2\right\}$. Then we have that for any $0<\delta<1$, with probability at least $1-\delta$ over the draw of S (according to $\mathcal{D}^m$),

$$R_\ell(f_S) \quad < \quad R^*_\ell(\mathcal{F}) + \lambda\|f^*_\ell\|_K^2 + \frac{1}{m} + \frac{32\sigma^2\kappa^2}{\lambda m} + \left(\frac{16\sigma^2\kappa^2}{\lambda}+2B\right)\sqrt{\frac{2\ln(2/\delta)}{m}}\,.$$

Thus, if $\lambda = o(1)$ and $\lambda = \omega(\frac{1}{\sqrt{m}})$ (for example, if $\lambda = m^{-1/4}$), then $R_\ell(f_S)$ converges in probability to the optimal value $R^*_\ell(\mathcal{F})$ (as $m\to\infty$).

Proof As in Corollary 15, we can use Corollary 14 and apply Theorem 6 with $\frac{\delta}{2}$ to get that with probability at least $1-\frac{\delta}{2}$,

$$R_\ell(f_S) \quad < \quad \widehat{R}_\ell(f_S;S) + \frac{32\sigma^2\kappa^2}{\lambda m} + \left(\frac{16\sigma^2\kappa^2}{\lambda} + B\right)\sqrt{\frac{2\ln(2/\delta)}{m}}\,. \tag{11}$$

Now,

$$\begin{aligned}\widehat{R}_\ell(f_S;S) \quad &\leq \quad \widehat{R}_\ell(f_S;S) + \lambda\|f_S\|_K^2 \\ &\leq \quad \widehat{R}_\ell(f_\ell^*;S) + \lambda\|f_\ell^*\|_K^2\,,\end{aligned}$$

where the first inequality is due to non-negativity of $\|f_S\|_K^2$ and the second inequality follows from the definition of f_S. Applying Lemma 17 to f_ℓ^* with $\frac{\delta}{2}$, we thus get that with probability at least $1-\frac{\delta}{2}$,

$$\widehat{R}_\ell(f_S;S) \quad < \quad \left(R_\ell(f_\ell^*) + B\sqrt{\frac{2\ln(2/\delta)}{m}}\right) + \lambda\|f_\ell^*\|_K^2\,. \tag{12}$$

Combining the inequalities in Eqs. (11-12), each of which holds with probability at least $1-\frac{\delta}{2}$, together with the condition in Eq. (10), gives the desired result. ■

6. Comparisons With Related Work

In the above sections we have derived stability-based generalization bounds for ranking algorithms in a setting that is more general than what has been considered previously, and have shown that kernel-based ranking algorithms that perform regularization in an RKHS in this setting satisfy the required stability conditions. In this section we discuss how our results relate to other recent studies.

6.1 Comparison with Stability Bounds for Classification/Regression

As pointed out earlier, our stability analysis of ranking algorithms is based on a similar analysis for classification and regression algorithms by Bousquet and Elisseeff (2002); therefore it is instructive to compare the generalization bounds we obtain here with those obtained in that work. Such a comparison shows that the bounds we obtain here for ranking are very similar to those obtained for classification and regression, differing only in constants (and, of course, in the precise definition of stability, which is problem-dependent). The difference in constants in the two bounds is due in part to the difference in loss functions in ranking and classification/regression, and in part to a slight difference in definitions of stability (in particular, our definitions are in terms of changes to a training sample that consist of replacing one element in the sample with a new one, while the definitions of Bousquet and Elisseeff are in terms of changes that consist of removing one element from the sample). As discussed in Section 4, the reason that we are able to obtain bounds for ranking algorithms using the same methods as those of Bousquet and Elisseeff lies in the power of McDiarmid's inequality, which was used by Bousquet and Elisseeff to capture the effect of stability but is also general enough to capture the structure of the ranking problem.

It is also instructive to compare our bounds with those obtained for bipartite ranking algorithms (Agarwal and Niyogi, 2005). In particular, the bounds for kernel-based ranking algorithms in the bipartite setting differ from our bounds in that the sample size m in our case is replaced with the term $mn/(m+n)$, where m,n denote the numbers of positive and negative examples, respectively, in the bipartite setting. This suggests that in general, the effective sample size in ranking is the ratio between the number of pairs in the training sample (mn in the bipartite setting) and the total number of examples ($m+n$); indeed, in our setting, this ratio is $\binom{m}{2}/m = m/2$, which fits our bounds.

6.2 Comparison with Uniform Convergence Bounds

While uniform convergence bounds for ranking have not been derived explicitly in the setting we consider, it is not hard to see that the techniques used to derive such bounds in the settings of Agarwal et al. (2005) and Clemencon et al. (2008) can be extended to obtain similar bounds in our setting. The crucial difference between such bounds and those derived in this paper is that uniform convergence bounds depend on the complexity of the function class searched by an algorithm. As discussed in the context of bipartite ranking (Agarwal and Niyogi, 2005), this means that such bounds can quickly become uninformative in high dimensions; in the case of function classes whose complexity cannot be bounded (such as the RKHS corresponding to a Gaussian kernel), uniform convergence bounds cannot be applied at all. In both these cases, the stability analysis provides a more useful viewpoint.

6.3 Comparison with Cortes et al. (2007)

The work that is perhaps most closely related to ours is that of Cortes et al. (2007), who study "magnitude-preserving" ranking algorithms—most of which perform regularization in an RKHS—and also use algorithmic stability to derive generalization bounds for such algorithms. The setting considered by Cortes et al. is similar to ours: the learner is given a finite sequence of labeled training examples $((x_1,y_1),\ldots,(x_m,y_m)) \in (\mathcal{X}\times\mathbb{R})^m$, and the goal is to learn a real-valued function $f:\mathcal{X}\to\mathbb{R}$ that ranks future instances with larger labels higher than those with smaller labels. The term "magnitude-preserving" comes from their view of the magnitude of the difference $(y-y')$ in the labels of two examples $(x,y),(x',y')$ as not just a penalty for mis-ranking the pair (x,x'), but as a quantity to be explicitly preserved by f, in the sense that $(f(x)-f(x'))$ be close to $(y-y')$.

There are three important differences between our work and that of Cortes et al. (2007). First, Cortes et al. implicitly assume the existence of a "truth" function: their results are derived under that assumption that only instances $x\in\mathcal{X}$ are drawn randomly, and that labels $y\in\mathcal{Y}$ are then determined according to a "truth" function $f^*:\mathcal{X}\to\mathcal{Y}$. In our work, we make the more general distributional assumption that all examples (x,y) are drawn randomly according to a joint distribution on $\mathcal{X}\times\mathcal{Y}$.

Second, Cortes et al. consider only the notion of uniform loss stability; they do not consider uniform score stability. As a consequence, the bounds they obtain for ranking algorithms performing regularization in an RKHS are similar to our bound in Corollary 15, which bounds the expected ranking error $R(f_S)$ of a learned ranking function f_S in terms of the empirical ℓ-error $\widehat{R}_\ell(f_S;S)$, where ℓ is the loss minimized by the algorithm.[4] In contrast, our bound in Corollary 12, which

4. Cortes et al. do not actually bound the expected ranking error $R(f_S)$ (which in our view is the primary performance measure of a ranking function in our setting); their results simply give bounds on the expected ℓ-error $R_\ell(f_S)$, where ℓ again is the loss minimized by the algorithm. However, for $\ell_{\text{disc}} \le \ell$, one can easily deduce bounds on $R(f_S)$ from these results.

makes use of the notion of score stability, bounds the expected error $R(f_S)$ in terms of the empirical ℓ_1-error $\widehat{R}_{\ell_1}(f_S;S)$. As mentioned in Section 5.2, the ℓ_1 loss tends to be smaller than many of the loss functions minimized by kernel-based ranking algorithms in practice (indeed, it is never greater than the hinge ranking loss ℓ_{h}), thus leading to tighter bounds for the same algorithms.

The third and most important difference between our work and that of Cortes et al. is that the results of Cortes et al. involve certain strong assumptions on the function class searched by an algorithm. In particular, they assume that the function class $\mathcal{F}$ searched by a ranking algorithm is bounded in the sense that $\exists\, M' > 0$ such that for all $f \in \mathcal{F}$ and all $x \in \mathcal{X}$, $|f(x) - f^*(x)| \leq M'$ (where, as mentioned above, $f^* : \mathcal{X} \rightarrow \mathbb{R}$ is the truth function in their setting). No RKHS $\mathcal{F}$ satisfies this condition, and so their results as stated do not apply to the kernel-based ranking algorithms they consider. On closer inspection, one notices that for the loss functions they show to be 1-admissible, they do not actually need this assumption. For the loss functions they show to be $4M'$-admissible, however, a non-trivial fix is required. We expect that an approach similar to that of separating out the effective search space, as we have done in the case of the least squares ranking loss in Section 5.2.2, should work; indeed, in the case of the least squares ranking loss, assuming a bounded label space Y, it is easy to see from the observations in Section 5.2.2 that $|f(x) - y|$ is bounded for all f in the *effective* search space (and all $(x,y) \in (\mathcal{X} \times \mathcal{Y})$).

6.4 Comparison with Rudin et al. (2005)

Rudin et al. (2005) studied a different setting of the ranking problem, in which one assumes the existence of a pair-wise "truth" function $\pi : \mathcal{X} \times \mathcal{X} \rightarrow \{0,1\}$ that assigns a binary ranking preference $\pi(x,x')$ to each pair of instances (x,x'), such that $\pi(x,x') = 1 \Rightarrow \pi(x',x) = 0$: if $\pi(x,x') = 1$, then x is to be ranked higher than x'; if $\pi(x',x) = 1$, then x' is to be ranked higher than x; and if $\pi(x,x') = \pi(x',x) = 0$, then there is no ranking preference between x and x'. The training sample given to a learner in this setting consists of a finite number of instances $x_1, \ldots, x_m$, each drawn randomly and independently according to some (unknown) distribution on $\mathcal{X}$, together with the corresponding ranking preferences $\pi(x_i,x_j)$ for $i,j \in \{1,\ldots,m\}, i \neq j$. Rudin et al. derived a generalization bound for this setting using techniques inspired by the works of Cucker and Smale (2002), Koltchinskii and Panchenko (2002), and Bousquet (2003). Their bound, expressed in terms of covering numbers, is a margin-based bound, which is of interest when the learned ranking function has zero empirical error on the training sample.

Noting that the labels y_i, y_j corresponding to a pair of instances x_i, x_j in our setting are used in our results only in the form of ranking preferences $(y_i - y_j)$, we can clearly view the setting of Rudin et al. as a special case of ours: the ranking preferences $(y_i - y_j)$, which are random variables in our setting, get replaced by the deterministic preferences $\pi(x_i,x_j)$. All quantities can be adapted accordingly; for example, the expected ranking error of a ranking function $f : \mathcal{X} \rightarrow \mathbb{R}$ in this setting (with respect to a distribution $\mathcal{D}$ on $\mathcal{X}$) becomes

$$R(f) \quad = \quad \mathbf{E}_{(X,X') \sim \mathcal{D} \times \mathcal{D}} \left[|\pi(X,X')| \left(\mathbf{I}_{\{\pi(X,X')(f(X) - f(X')) < 0\}} + \frac{1}{2} \mathbf{I}_{\{f(X) = f(X')\}} \right) \right].$$

In fact, rather than restrict ourselves to binary preferences, we can extend the setting of Rudin et al. to allow real-valued preferences, requiring that $\pi(x,x') = -\pi(x',x)$ for all $x,x' \in \mathcal{X}$; if π takes values in $[-M,M]$, we get the same results as we have derived in our setting (with the probabilities now being over the random draw of instances only).

We can also consider another extension of interest in the pair-wise truth function setting, where we may not have access to the preferences for all pairs of instances in the training sample, but rather are given preferences for only a limited number of pairs; in this case, the learner receives a sequence of instances $S = (x_1, \ldots, x_m)$, and preferences $\pi(x_i, x_j)$ for only a subset of pairs $E \subseteq \{(i,j) \mid 1 \le i < j \le m\}$. It is interesting then to consider a model in which not only the instances in S but also the pairs in E for which the ranking preferences are provided may be chosen randomly. If the instances in S are drawn randomly and independently according to some distribution $\mathcal{D}$ on $\mathcal{X}$, and the set E is drawn randomly (independently of S) from some distribution $\mathcal{E}_m$ on the set of possible (undirected) edge sets for a graph on m vertices $\{1, \ldots, m\}$ (for example, E could be obtained by including each edge with some fixed probability $0 < p_m < 1$, or by selecting at random a subset of α_m edges for some $\alpha_m \le \binom{m}{2}$), then under some natural conditions on $\mathcal{E}_m$, we can extend our techniques to obtain generalization bounds in this setting too. In the remainder of this section we discuss some details of this extension.

In particular, the empirical ranking error of a ranking function $f : \mathcal{X} \to \mathbb{R}$ in the above setting, with respect to a training sample $T = (S, E, \pi|_{(S,E)})$ where S and E are as above and $\pi|_{(S,E)}$ is the restriction of π to $\{(x_i, x_j) \mid (i,j) \in E\}$, is given by

$$\widehat{R}(f;T) \quad = \quad \frac{1}{|E|} \sum_{(i,j) \in E} |\pi(x_i, x_j)| \left(\mathbf{I}_{\{\pi(x_i,x_j)(f(x_i) - f(x_j)) < 0\}} + \frac{1}{2} \mathbf{I}_{\{f(x_i) = f(x_j)\}} \right) .$$

Given a loss function ℓ that assigns for any ranking function f, any pair of instances (x, x') and any $r \in [-M, M]$ a non-negative loss $\ell(f, x, x', r)$, the expected and empirical ℓ-errors can be defined similarly:

$$\begin{aligned} R_\ell(f) \quad &= \quad \mathbf{E}_{(X,X') \sim \mathcal{D} \times \mathcal{D}} \left[\ell(f, X, X', \pi(X, X')) \right] ; \\ \widehat{R}_\ell(f;T) \quad &= \quad \frac{1}{|E|} \sum_{(i,j) \in E} \ell(f, x_i, x_j, \pi(x_i, x_j)) . \end{aligned}$$

A ranking algorithm $\mathcal{A}$ in this setting, which given a training sample T outputs a ranking function f_T, has uniform loss stability β with respect to ℓ if for all $m \in \mathbb{N}$, $S \in \mathcal{X}^m$, $E \subseteq \{(i,j) \mid 1 \le i < j \le m\}$, $\pi : \mathcal{X} \times \mathcal{X} \to [-M, M]$, $1 \le i \le m$ and $x_i' \in \mathcal{X}$, we have for all $x, x' \in \mathcal{X}$ and all $r \in [-M, M]$,

$$\left| \ell(f_T, x, x', r) - \ell(f_{T^i}, x, x', r) \right| \quad \le \quad \beta(m) ,$$

where $T = (S, E, \pi|_{(S,E)})$ as above and $T^i = (S^i, E, \pi|_{(S^i,E)})$, with S^i being the sequence obtained from S by replacing x_i with x_i'. Then we can show the following bound for ranking algorithms with good loss stability in this setting:

Theorem 19 *Let $\pi : \mathcal{X} \times \mathcal{X} \to [-M, M]$ be a pair-wise truth function such that $\pi(x, x') = -\pi(x', x)$ for all $x, x' \in \mathcal{X}$. Let $\mathcal{A}$ be a symmetric ranking algorithm in the pair-wise truth function setting whose output on a training sample $T = (S, E, \pi|_{(S,E)})$ we denote by f_T, and let ℓ be a bounded ranking loss function such that $0 \le \ell(f, x, x', r) \le B$ for all $f : \mathcal{X} \to \mathbb{R}$, $x, x' \in \mathcal{X}$ and $r \in [-M, M]$. Let $\beta : \mathbb{N} \to \mathbb{R}$ be such that $\mathcal{A}$ has uniform loss stability β with respect to ℓ as defined above. Let $\mathcal{D}$ be any distribution on $\mathcal{X}$, and let $\{\mathcal{E}_m\}$ be any family of distributions on the sets of possible (undirected) edge sets for a graph on m vertices $\{1, \ldots, m\}$ that satisfies the following condition: $\exists\, s > 1$ and a sequence (δ_m) satisfying $\delta_m \ge 0$, $\lim_{m \to \infty} \delta_m = 0$, such that for all m, $\mathbf{P}_{E \sim \mathcal{E}_m}(|E| < m^s) \le \delta_m$. Then* *for any* $0 < \delta < 1$, *for all m large enough such that* $\delta_m \leq \frac{\delta}{2}$, *we have with probability at least* $1-\delta$ *over the draw of* (S,E) *according to* $\mathcal{D}^m \times \mathcal{E}_m$,

$$R_\ell(f_T) \quad < \quad \widehat{R}_\ell(f_T;T) + 2\beta(m) + \sqrt{\frac{1}{2}\left(4m(\beta(m))^2 + 8B\beta(m) + \frac{2B^2}{m-1} + \frac{B^2}{m^{s-1}}\right)\ln(2/\delta)}\,.$$

The proof makes use of McDiarmid's inequality and is similar to that of Theorem 6, with two main differences. First, McDiarmid's inequality is first applied to obtain a bound conditioned on an edge set E with $|E| \geq m^s$; the bound on the probability that $|E| < m^s$ then allows us to obtain the unconditional bound. Second, the constants c_k in the application of McDiarmid's inequality are different for each k, and depend on the degrees of the corresponding vertices in the graph with edge set E; the sum $\sum_k c_k^2$ is then bounded using a bound on the sum of squares of degrees in a graph due to de Caen (1998). Details of the proof are provided in Appendix D.

The condition on $\mathcal{E}_m$ in the above theorem states that with high probability (probability at least $1-\delta_m$), an edge set E drawn according to $\mathcal{E}_m$ has at least m^s edges for some $s > 1$, that is, $|E|$ is super-linear in m.[5] Thus, in the pair-wise truth function setting, we need not have access to the ranking preferences $\pi(x_i, x_j)$ for all $\binom{m}{2}$ pairs of instances in S; having the preferences for any super-linear number of pairs (where the pairs are selected independently of the instances S themselves) suffices to give a generalization bound (albeit with a correspondingly slower convergence rate, as quantified by the $\frac{1}{m^{s-1}}$ term in the bound above). Below we give examples of two families of distributions $\{\mathcal{E}_m\}$ that satisfy the above condition.

Example 1 *Fix any* $1 < s < 2$, *and let* $\mathcal{E}_m$ *be the distribution that corresponds to selecting a random subset of* α_m *edges, with* $\alpha_m = \min\left(\binom{m}{2}, \lceil m^s \rceil\right)$. *Then for large enough m,* $\alpha_m = \lceil m^s \rceil$, *and* $\mathbf{P}_{E\sim\mathcal{E}_m}(|E| < m^s) = 0$.

Example 2 *Fix any* $1 < s < 2$, *and let* $\mathcal{E}_m$ *be the distribution that corresponds to including each edge with a fixed probability* p_m, *with* $p_m = \min\left(1, \frac{8}{m^{2-s}}\right)$. *Then for large enough m,* $p_m = \frac{8}{m^{2-s}}$, *and assuming without loss of generality that* $m \geq 2$, *it is easy to show using a Chernoff bound that in this case,* $\mathbf{P}_{E\sim\mathcal{E}_m}(|E| < m^s) \leq e^{-m^s/4}$. *Indeed, for any such m, let* Z_m *be the random variable equal to the number of edges* $|E|$. *Then* Z_m *is a binomial random variable with parameters* $\binom{m}{2}$ *and* $p_m = \frac{8}{m^{2-s}}$, *and*

$$\begin{aligned}
\mathbf{E}[Z_m] &= \tbinom{m}{2} p_m \\
&= 4(m-1)m^{s-1} \\
&= 2(m^s + (m-2)m^{s-1}) \\
&\geq 2m^s\,,
\end{aligned}$$

where the inequality follows from our assumption that $m \geq 2$. *The Chernoff bound for deviations below the mean of a binomial random variable tells us that for any* $0 < \delta < 1$, $\mathbf{P}(Z_m < (1-\delta)\mathbf{E}[Z_m]) \leq e^{-\mathbf{E}[Z_m]\delta^2/2}$. *Thus we have*

$$\mathbf{P}(Z_m < m^s) \quad = \quad \mathbf{P}\Big(Z_m < \Big(1 - \frac{1}{2}\Big)2m^s\Big)$$

5. Note that in the statement of Theorem 19 we require $|E|$ to be super-linear in m by a polynomial factor; a smaller super-linear growth also leads to a generalization bound, but with a slower convergence rate.

$$
\begin{aligned}
&\leq \mathbf{P}\Big(Z_m < \Big(1 - \frac{1}{2}\Big)\mathbf{E}[Z_m]\Big) \\
&\leq e^{-\mathbf{E}[Z_m](\frac{1}{2})^2/2} \\
&\leq e^{-m^s/4}.
\end{aligned}
$$

Comparing the bound in Theorem 19 with that of Theorem 6, it is worth noting that the effective sample size in the above setting becomes m^{s-1}. This is consistent with the discussion in Section 6.1, in that the ratio between the number of pairs in the training sample and the total number of examples in this case is (with high probability) at least $m^s/m = m^{s-1}$.

7. Discussion

Our goal in this paper has been to study generalization properties of ranking algorithms in a setting where ranking preferences among instances are indicated by real-valued labels on the instances. This setting of the ranking problem arises frequently in practice and is more general than those considered previously. We have derived generalization bounds for ranking algorithms in this setting using the notion of algorithmic stability; in particular, we have shown that ranking algorithms that exhibit good stability properties also have good generalization properties, and have applied our results to obtain generalization bounds for kernel-based ranking algorithms that perform regularization in a reproducing kernel Hilbert space. Such algorithms often cannot be analyzed using uniform convergence results.

The main difference in the mathematical formulation of ranking problems as compared to classification or regression problems is that the loss function in ranking is 'pair-wise' rather than 'point-wise'. Indeed, ranking often resembles weighted 'classification on pairs', with the weights being given by the corresponding ranking preferences (although learning a real-valued function that induces a total ordering on the instance space is not quite the same as learning a binary-valued function on instance pairs that simply decides which of two instances should be ranked higher, Cohen et al. 1999; Balcan et al. 2007; Ailon and Mohri 2008). However, generalization bounds from classification cannot be applied directly to ranking, due to dependences among the instance pairs. As discussed earlier, the reason that we are able to obtain bounds for ranking algorithms using the same methods as those used by Bousquet and Elisseeff (2002) for classification and regression algorithms lies in the power of McDiarmid's inequality, which was used by Bousquet and Elisseeff to capture the effect of stability but is also general enough to capture the structure of the ranking problems we consider. A comparison of our results with those of Bousquet and Elisseeff (2002) and Agarwal and Niyogi (2005) suggests that the effective sample size in ranking is proportional to the ratio between the number of pairs in the training sample and the total number of examples; this can be smaller than the number of examples m if ranking preferences are provided for less than m^2 pairs.

The notions of uniform stability studied in this paper correspond most closely to those studied by Bousquet and Elisseeff (2002). These notions are strict in that they require changes in a sample to have bounded effect uniformly over all samples and replacements. One can define weaker notions of stability, analogous to the hypothesis stability considered by Devroye and Wagner (1979), Kearns and Ron (1999), and Bousquet and Elisseeff (2002), or the almost-everywhere stability considered by Kutin and Niyogi (2002), which would require the bounds to hold only in expectation or with high probability. Such notions would lead to a distribution-dependent treatment as opposed to the distribution-free treatment obtained with uniform stability, and it would be particularly interesting to see if making distributional assumptions in ranking can mitigate the reduced sample size effect discussed above.

For the sake of simplicity and to keep the focus on the main ideas involved in applying stability techniques to ranking, we have focused in this paper on bounding the expected ranking error in terms of the empirical ranking error. In classification and regression, stability analysis has also been used to provide generalization bounds in terms of the leave-one-out error (Bousquet and Elisseeff, 2002; Kearns and Ron, 1999), and with a slight change in definitions of stability, similar results can be obtained in the case of ranking as well. In particular, in this case we need to define (for a ranking algorithm which given a training sample S returns a ranking function f_S) a 'leave-two-out' ranking error as follows:

$$\widetilde{R}_\ell(f_S;S) \quad = \quad \frac{1}{\binom{m}{2}} \sum_{1 \le i < j \le m} \ell(f_{S^{\setminus ij}}, (x_i,y_i), (x_j,y_j)) \,,$$

where $S^{\setminus ij}$ denotes the sequence obtained by removing the ith and jth examples from a sample $S = ((x_1,y_1), \ldots, (x_m,y_m)) \in (\mathcal{X} \times \mathcal{Y})^m$. Then, defining notions of stability in terms of changes to a sample that consist of removing two examples rather than replacing one example, one can obtain very similar generalization bounds for ranking algorithms in terms of the above leave-two-out error as those we have derived in terms of the empirical error.

An open question concerns the analysis of other ranking algorithms using the algorithmic stability framework. For example, it has been shown that the AdaBoost algorithm for classification is stability-preserving, in the sense that stability of base classifiers implies stability of the final learned classifier (Kutin and Niyogi, 2001). It would be interesting if a similar result could be shown for the RankBoost ranking algorithm (Freund et al., 2003), which is based on the same principles of boosting as AdaBoost.

Finally, it is also an open question to analyze generalization properties of ranking algorithms in even more general settings of the ranking problem. For example, a more general setting would be one in which a finite number of instances $x_1, \ldots, x_m \in \mathcal{X}$ are drawn randomly and independently according to some distribution $\mathcal{D}$ on $\mathcal{X}$, and then pair-wise ranking preferences $r_{ij} \in [-M,M]$ for $i < j$ are drawn from a conditional distribution, conditioned on the corresponding pair of instances (x_i,x_j). We are not aware of any generalization bounds for such a setting.

Appendix A. Proof of Theorem 6

Our main tool will be the following powerful concentration inequality of McDiarmid (1989), which bounds the deviation of any function of a sample for which a single change in the sample has limited effect.

Theorem 20 (McDiarmid 1989) *Let $X_1,\ldots,X_m$ be independent random variables, each taking values in a set A. Let $\phi : A^m \to \mathbb{R}$ be such that for each $1 \leq k \leq m$, there exists $c_k > 0$ such that*

$$\sup_{x_1,\ldots,x_m\in A, x'_k\in A} \Big|\phi(x_1,\ldots,x_m) - \phi(x_1,\ldots,x_{k-1},x'_k,x_{k+1},\ldots,x_m)\Big| \quad\leq\quad c_k\,.$$

Then for any $\varepsilon > 0$,

$$\mathbf{P}\Big(\phi(X_1,\ldots,X_m) - \mathbf{E}\left[\phi(X_1,\ldots,X_m)\right] \geq \varepsilon\Big) \quad\leq\quad e^{-2\varepsilon^2/\sum_{k=1}^m c_k^2}\,.$$

Before we apply McDiarmid's inequality to prove Theorem 6, we shall need the following technical lemma. In the following, we shall drop explicit references to distributions where clear from context, replacing, for example, $\mathbf{E}_{(X,Y)\sim\mathcal{D}}[\ldots]$ with simply $\mathbf{E}_{(X,Y)}[\ldots]$.

Lemma 21 *Let $\mathcal{A}$ be a symmetric ranking algorithm whose output on a training sample $S \in (\mathcal{X}\times\mathcal{Y})^m$ we denote by f_S, and let ℓ be a ranking loss function. Then for all $1 \leq i < j \leq m$, we have*

$$\begin{aligned}&\mathbf{E}_{S\sim\mathcal{D}^m}\Big[R_\ell(f_S) - \widehat{R}_\ell(f_S;S)\Big]\\ &\quad= \quad \mathbf{E}_{S\sim\mathcal{D}^m,((X'_i,Y'_i),(X'_j,Y'_j))\sim\mathcal{D}\times\mathcal{D}}\Big[\ell(f_S,(X'_i,Y'_i),(X'_j,Y'_j)) - \ell(f_{S^{i,j}},(X'_i,Y'_i),(X'_j,Y'_j))\Big]\,.\end{aligned}$$

Proof Denoting $S = ((X_1,Y_1),\ldots,(X_m,Y_m))$, we have by linearity of expectation,

$$\mathbf{E}_S\Big[\widehat{R}_\ell(f_S;S)\Big] \quad=\quad \frac{1}{\binom{m}{2}}\sum_{i=1}^{m-1}\sum_{j=i+1}^{m}\mathbf{E}_S\Big[\ell(f_S,(X_i,Y_i),(X_j,Y_j))\Big]\,.$$

By symmetry, the term in the summation is the same for all i,j. Therefore, for all $1 \leq i < j \leq m$, we get

$$\begin{aligned}\mathbf{E}_S\Big[\widehat{R}_\ell(f_S;S)\Big] \quad&=\quad \mathbf{E}_S\Big[\ell(f_S,(X_i,Y_i),(X_j,Y_j))\Big]\\ &=\quad \mathbf{E}_{S,((X'_i,Y'_i),(X'_j,Y'_j))}\Big[\ell(f_S,(X_i,Y_i),(X_j,Y_j))\Big]\,.\end{aligned}$$

Interchanging the roles of (X_i,Y_i) with (X'_i,Y'_i) and (X_j,Y_j) with (X'_j,Y'_j), we get

$$\mathbf{E}_S\Big[\widehat{R}_\ell(f_S;S)\Big] \quad=\quad \mathbf{E}_{S,((X'_i,Y'_i),(X'_j,Y'_j))}\Big[\ell(f_{S^{i,j}},(X'_i,Y'_i),(X'_j,Y'_j))\Big]\,.$$

Since by definition

$$\mathbf{E}_S\Big[R_\ell(f_S)\Big] \quad=\quad \mathbf{E}_{S,((X'_i,Y'_i),(X'_j,Y'_j))}\Big[\ell(f_S,(X'_i,Y'_i),(X'_j,Y'_j))\Big]\,,$$

the result follows. ■

Proof *(of Theorem 6)*
Let $\phi : (\mathcal{X}\times\mathcal{Y})^m \to \mathbb{R}$ be defined as follows:

$$\phi(S) \quad=\quad R_\ell(f_S) - \widehat{R}_\ell(f_S;S)\,.$$

We shall show that ϕ satisfies the conditions of McDiarmid's inequality (Theorem 20). Let $S = ((x_1,y_1),\dots,(x_m,y_m)) \in (\mathcal{X}\times\mathcal{Y})^m$. Then for each $1 \le k \le m$, we have for any $(x'_k,y'_k) \in (\mathcal{X}\times\mathcal{Y})$:

$$\begin{aligned}\left|\phi(S)-\phi(S^k)\right| &= \left|\left(R_\ell(f_S)-\widehat{R}_\ell(f_S;S)\right)-\left(R_\ell(f_{S^k})-\widehat{R}_\ell(f_{S^k};S^k)\right)\right| \\ &\le \left|R_\ell(f_S)-R_\ell(f_{S^k})\right|+\left|\widehat{R}_\ell(f_S;S)-\widehat{R}_\ell(f_{S^k};S^k)\right|.\end{aligned}$$

Now,

$$\begin{aligned}\left|R_\ell(f_S)-R_\ell(f_{S^k})\right| &= \left|\mathbf{E}_{((X,Y),(X',Y'))}\left[\ell(f_S,(X,Y),(X',Y'))-\ell(f_{S^k},(X,Y),(X',Y'))\right]\right| \\ &\le \mathbf{E}_{((X,Y),(X',Y'))}\left[\left|\ell(f_S,(X,Y),(X',Y'))-\ell(f_{S_k},(X,Y),(X',Y'))\right|\right] \\ &\le \beta(m),\end{aligned}$$

and

$$\begin{aligned}&\left|\widehat{R}_\ell(f_S;S)-\widehat{R}_\ell(f_{S^k};S^k)\right| \\ &\le \frac{1}{\binom{m}{2}}\sum_{1\le i<j\le m, i\ne k, j\ne k}\left|\ell(f_S,(x_i,y_i),(x_j,y_j))-\ell(f_{S^k},(x_i,y_i),(x_j,y_j))\right| \\ &\quad+\frac{1}{\binom{m}{2}}\sum_{i\ne k}\left|\ell(f_S,(x_i,y_i),(x_k,y_k))-\ell(f_{S^k},(x_i,y_i),(x'_k,y'_k))\right| \\ &\le \frac{1}{\binom{m}{2}}\sum_{1\le i<j\le m, i\ne k, j\ne k}\beta(m) \;+\; \frac{1}{\binom{m}{2}}\sum_{i\ne k}B \\ &= \frac{1}{\binom{m}{2}}\left(\left(\binom{m}{2}-(m-1)\right)\beta(m)+(m-1)B\right) \\ &< \beta(m)+\frac{2B}{m}.\end{aligned}$$

Thus we have

$$\left|\phi(S)-\phi(S^k)\right| \;\le\; 2\left(\beta(m)+\frac{B}{m}\right).$$

Therefore, applying McDiarmid's inequality to ϕ, we get for any $\varepsilon>0$,

$$\begin{aligned}\mathbf{P}_S\left(\left(R_\ell(f_S)-\widehat{R}_\ell(f_S;S)\right)-\mathbf{E}_S\left[R_\ell(f_S)-\widehat{R}_\ell(f_S;S)\right]\ge\varepsilon\right)& \\ &\le e^{-2\varepsilon^2/m(2(\beta(m)+\frac{B}{m}))^2} \\ &= e^{-m\varepsilon^2/2(m\beta(m)+B)^2}.\end{aligned}$$

Now, by Lemma 21, we have (for any $1\le i<j\le m$),

$$\begin{aligned}&\mathbf{E}_S\left[R_\ell(f_S)-\widehat{R}_\ell(f_S;S)\right] \\ &= \mathbf{E}_{S,((X'_i,Y'_i),(X'_j,Y'_j))}\left[\ell(f_S,(X'_i,Y'_i),(X'_j,Y'_j))-\ell(f_{S^{i,j}},(X'_i,Y'_i),(X'_j,Y'_j))\right] \\ &\le \mathbf{E}_{S,((X'_i,Y'_i),(X'_j,Y'_j))}\left[\left|\ell(f_S,(X'_i,Y'_i),(X'_j,Y'_j))-\ell(f_{S^i},(X'_i,Y'_i),(X'_j,Y'_j))\right|\right] \\ &\quad+\mathbf{E}_{S,((X'_i,Y'_i),(X'_j,Y'_j))}\left[\left|\ell(f_{S^i},(X'_i,Y'_i),(X'_j,Y'_j))-\ell(f_{S^{i,j}},(X'_i,Y'_i),(X'_j,Y'_j))\right|\right] \\ &\le 2\beta(m).\end{aligned}$$

Thus we get for any $\varepsilon > 0$,

$$\mathbf{P}_S \left(R_\ell(f_S) - \widehat{R}_\ell(f_S;S) - 2\beta(m) \geq \varepsilon \right) \quad \leq \quad e^{-m\varepsilon^2/2(m\beta(m)+B)^2} .$$

The result follows by setting the right hand side equal to δ and solving for ε. ■

Appendix B. Proof of Lemma 10

Proof *(of Lemma 10)*
Recall that a convex function $\phi : \mathcal{U} \to \mathbb{R}$ satisfies for all $u, v \in \mathcal{U}$ and for all $t \in [0,1]$,

$$\phi(u + t(v-u)) - \phi(u) \ \leq \ t(\phi(v) - \phi(u)) .$$

Since $\ell(f,(x,y),(x',y'))$ is convex in f, we have that $\widehat{R}_\ell(f;S)$ is convex in f. Therefore for any $t \in [0,1]$, we have

$$\widehat{R}_\ell(f + t\Delta f;S) - \widehat{R}_\ell(f;S) \quad \leq \quad t\left(\widehat{R}_\ell(f^i;S) - \widehat{R}_\ell(f;S) \right), \tag{13}$$

and also (interchanging the roles of f and f^i),

$$\widehat{R}_\ell(f^i - t\Delta f;S) - \widehat{R}_\ell(f^i;S) \quad \leq \quad t\left(\widehat{R}_\ell(f;S) - \widehat{R}_\ell(f^i;S) \right). \tag{14}$$

Adding Eqs. (13) and (14), we get

$$\widehat{R}_\ell(f + t\Delta f;S) - \widehat{R}_\ell(f;S) + \widehat{R}_\ell(f^i - t\Delta f;S) - \widehat{R}_\ell(f^i;S) \quad \leq \quad 0 . \tag{15}$$

Now, since $\mathcal{F}$ is convex, we have that $(f + t\Delta f) \in \mathcal{F}$ and $(f^i - t\Delta f) \in \mathcal{F}$. Since f minimizes $\widehat{R}^\lambda_\ell(f;S)$ in $\mathcal{F}$ and f^i minimizes $\widehat{R}^\lambda_\ell(f;S^i)$ in $\mathcal{F}$, we thus have

$$\widehat{R}^\lambda_\ell(f;S) - \widehat{R}^\lambda_\ell(f + t\Delta f;S) \quad \leq \quad 0 , \tag{16}$$

$$\widehat{R}^\lambda_\ell(f^i;S^i) - \widehat{R}^\lambda_\ell(f^i - t\Delta f;S^i) \quad \leq \quad 0 . \tag{17}$$

Adding Eqs. (15), (16) and (17), we get

$$\begin{aligned}
&\lambda\Big(N(f) - N(f + t\Delta f) + N(f^i) - N(f^i - t\Delta f) \Big) \\
&\leq \quad \widehat{R}_\ell(f^i;S) - \widehat{R}_\ell(f^i;S^i) + \widehat{R}_\ell(f^i - t\Delta f;S^i) - \widehat{R}_\ell(f^i - t\Delta f;S) \\
&= \quad \frac{1}{\binom{m}{2}} \sum_{j \neq i} \Big(\ell(f^i,(x_i,y_i),(x_j,y_j)) - \ell(f^i,(x'_i,y'_i),(x_j,y_j)) \\
&\qquad\qquad + \ell(f^i - t\Delta f,(x'_i,y'_i),(x_j,y_j)) - \ell(f^i - t\Delta f,(x_i,y_i),(x_j,y_j)) \Big) \\
&= \quad \frac{1}{\binom{m}{2}} \sum_{j \neq i} \Big(\Big(\ell(f^i,(x_i,y_i),(x_j,y_j)) - \ell(f^i - t\Delta f,(x_i,y_i),(x_j,y_j)) \Big) \\
&\qquad\qquad + \Big(\ell(f^i - t\Delta f,(x'_i,y'_i),(x_j,y_j)) - \ell(f^i,(x'_i,y'_i),(x_j,y_j)) \Big) \Big) \\
&\leq \quad \frac{t\sigma}{\binom{m}{2}} \sum_{j \neq i} \Big(|\Delta f(x_i)| + 2|\Delta f(x_j)| + |\Delta f(x'_i)| \Big),
\end{aligned}$$

where the last inequality follows by σ-admissibility. The result follows. ■

Appendix C. Proof of Lemma 17

The proof is a simple application of McDiarmid's inequality.
Proof *(of Lemma 17)*
Let $\phi : (\mathcal{X} \times \mathcal{Y})^m \to \mathbb{R}$ be defined as follows:

$$\phi(S) \;=\; \widehat{R}_\ell(f;S)\,.$$

Then by linearity of expectation,

$$\begin{aligned}\mathbf{E}_{S\sim\mathcal{D}^m}\Big[\phi(S)\Big] &= \frac{1}{\binom{m}{2}}\sum_{i=1}^{m-1}\sum_{j=i+1}^{m}\mathbf{E}_{((X_i,Y_i),(X_j,Y_j))\sim\mathcal{D}\times\mathcal{D}}\Big[\ell(f,(X_i,Y_i),(X_j,Y_j))\Big] \\ &= R_\ell(f)\,.\end{aligned}$$

We shall show that ϕ satisfies the conditions of McDiarmid's inequality (Theorem 20). Let $S = ((x_1,y_1),\ldots,(x_m,y_m)) \in (\mathcal{X}\times\mathcal{Y})^m$. Then for each $1 \le k \le m$, we have for any $(x'_k,y'_k) \in (\mathcal{X}\times\mathcal{Y})$:

$$\begin{aligned}\big|\phi(S)-\phi(S^k)\big| &= \Big|\widehat{R}_\ell(f;S)-\widehat{R}_\ell(f;S^k)\Big| \\ &\le \frac{1}{\binom{m}{2}}\sum_{i\neq k}\Big|\ell(f,(x_i,y_i),(x_k,y_k))-\ell(f,(x_i,y_i),(x'_k,y'_k))\Big| \\ &\le \frac{1}{\binom{m}{2}}(m-1)B \\ &= \frac{2B}{m}\,.\end{aligned}$$

Therefore, applying McDiarmid's inequality to ϕ, we get for any $\varepsilon > 0$,

$$\begin{aligned}\mathbf{P}_{S\sim\mathcal{D}^m}\Big(\widehat{R}_\ell(f;S)-R_\ell(f)\ge\varepsilon\Big) &\le e^{-2\varepsilon^2/m(\frac{2B}{m})^2} \\ &= e^{-m\varepsilon^2/2B^2}\,.\end{aligned}$$

The result follows by setting the right hand side equal to δ and solving for ε. ■

Appendix D. Proof of Theorem 19

The proof of this result also makes use of McDiarmid's inequality and is similar to the proof of Theorem 6 in Appendix A, with two main differences. First, McDiarmid's inequality is first applied to obtain a bound conditioned on an edge set E with $|E| \ge m^s$; the bound on the probability that $|E| < m^s$ then allows us to obtain the unconditional bound. Second, the constants c_k in the application of McDiarmid's inequality are different for each k, and depend on the degrees of the corresponding vertices in the graph with edge set E; the sum $\sum_k c_k^2$ is then bounded using a bound on the sum of squares of degrees in a graph due to de Caen (1998).
Proof *(of Theorem 19)*
Let $m \in \mathbb{N}$, and fix any edge set $E_0 \subseteq \{(i,j) \mid 1 \le i < j \le m\}$ with $|E_0| \ge m^s$. Let $\phi_{E_0} : \mathcal{X}^m \to \mathbb{R}$ be defined as follows:

$$\phi_{E_0}(S) \;=\; R_\ell(f_T)-\widehat{R}_\ell(f_T;T)\,,$$

where $T = (S, E_0, \pi|_{(S,E_0)})$. We shall show that ϕ_{E_0} satisfies the conditions of McDiarmid's inequality (Theorem 20). Let $S = (x_1, \ldots, x_m) \in \mathcal{X}^m$. Then for each $1 \leq k \leq m$, we have for any $x'_k \in \mathcal{X}$:

$$\begin{aligned}\left|\phi_{E_0}(S) - \phi_{E_0}(S^k)\right| &= \left|\Big(R_\ell(f_T) - \widehat{R}_\ell(f_T;T)\Big) - \Big(R_\ell(f_{T^k}) - \widehat{R}_\ell(f_{T^k};T^k)\Big)\right| \\ &\leq \Big|R_\ell(f_T) - R_\ell(f_{T^k})\Big| + \Big|\widehat{R}_\ell(f_T;T) - \widehat{R}_\ell(f_{T^k};T^k)\Big|.\end{aligned}$$

Now,

$$\begin{aligned}\Big|R_\ell(f_T) - R_\ell(f_{T^k})\Big| &= \Big|\mathbf{E}_{(X,X')}\Big[\ell(f_T, X, X', \pi(X,X')) - \ell(f_{T^k}, X, X', \pi(X,X'))\Big]\Big| \\ &\leq \mathbf{E}_{(X,X')}\Big[\Big|\ell(f_T, X, X', \pi(X,X')) - \ell(f_{T^k}, X, X', \pi(X,X'))\Big|\Big] \\ &\leq \beta(m),\end{aligned}$$

and

$$\begin{aligned}&\Big|\widehat{R}_\ell(f_T;T) - \widehat{R}_\ell(f_{T^k};T^k)\Big| \\ &\leq \frac{1}{|E_0|}\sum_{(i,j)\in E_0, i\neq k, j\neq k}\Big|\ell(f_T, x_i, x_j, \pi(x_i,x_j)) - \ell(f_{T^k}, x_i, x_j, \pi(x_i,x_j))\Big| \\ &\quad + \frac{1}{|E_0|}\sum_{(i,k)\in E_0}\Big|\ell(f_T, x_i, x_k, \pi(x_i,x_k)) - \ell(f_{T^k}, x_i, x'_k, \pi(x_i,x'_k))\Big| \\ &\quad + \frac{1}{|E_0|}\sum_{(k,j)\in E_0}\Big|\ell(f_T, x_k, x_j, \pi(x_k,x_j)) - \ell(f_{T^k}, x'_k, x_j, \pi(x'_k,x_j))\Big| \\ &\leq \frac{1}{|E_0|}\sum_{(i,j)\in E_0, i\neq k, j\neq k}\beta(m) + \frac{1}{|E_0|}\sum_{(i,k)\in E_0} B + \frac{1}{|E_0|}\sum_{(k,j)\in E_0} B \\ &\leq \beta(m) + \frac{d_k}{|E_0|}B,\end{aligned}$$

where d_k is the degree of vertex k in the graph with edge set E_0. Thus we have

$$\Big|\phi_{E_0}(S) - \phi_{E_0}(S^k)\Big| \leq c_k,$$

where

$$c_k = 2\beta(m) + \frac{d_k}{|E_0|}B.$$

Now,

$$\sum_{k=1}^m d_k = 2|E_0|,$$

and using a bound on the sum of squares of degrees in a graph due to de Caen (1998), we have

$$\sum_{k=1}^m d_k^2 \leq |E_0|\left(\frac{2|E_0|}{m-1} + m - 2\right).$$

Therefore,

$$\begin{aligned}
\sum_{k=1}^{m} c_k^2 &= \sum_{k=1}^{m} \left(2\beta(m) + \frac{d_k}{|E_0|} B \right)^2 \\
&= 4m(\beta(m))^2 + \frac{4B\beta(m)}{|E_0|} \sum_{k=1}^{m} d_k + \frac{B^2}{|E_0|^2} \sum_{k=1}^{m} d_k^2 \\
&\leq 4m(\beta(m))^2 + 8B\beta(m) + \frac{2B^2}{m-1} + \frac{B^2(m-2)}{|E_0|} \\
&\leq \underbrace{4m(\beta(m))^2 + 8B\beta(m) + \frac{2B^2}{m-1} + \frac{B^2}{m^{s-1}}}_{\gamma(m)},
\end{aligned}$$

where the last inequality follows since $|E_0| \geq m^s$. Thus, applying McDiarmid's inequality to ϕ_{E_0}, we get for any $\varepsilon > 0$,

$$\mathbf{P}_S \left(\left(R_\ell(f_T) - \widehat{R}_\ell(f_T;T) \right) - \mathbf{E}_S \left[R_\ell(f_T) - \widehat{R}_\ell(f_T;T) \;\middle|\; E = E_0 \right] \geq \varepsilon \;\middle|\; E = E_0 \right) \leq e^{-2\varepsilon^2/\gamma(m)}.$$

Now, as in Theorem 6, we can show that

$$\mathbf{E}_S \left[R_\ell(f_T) - \widehat{R}_\ell(f_T;T) \;\middle|\; E = E_0 \right] \leq 2\beta(m).$$

Thus we get for any $\varepsilon > 0$,

$$\mathbf{P}_S \left(R_\ell(f_T) - \widehat{R}_\ell(f_T;T) - 2\beta(m) \geq \varepsilon \;\middle|\; E = E_0 \right) \leq e^{-2\varepsilon^2/\gamma(m)}.$$

Since the above bound holds for all E_0 with $|E_0| \geq m^s$, we have

$$\begin{aligned}
\mathbf{P}_{(S,E)} \left(R_\ell(f_T) - \widehat{R}_\ell(f_T;T) - 2\beta(m) \geq \varepsilon \right) &\leq \mathbf{P}_E(|E| < m^s) + e^{-2\varepsilon^2/\gamma(m)} \\
&\leq \delta_m + e^{-2\varepsilon^2/\gamma(m)}.
\end{aligned}$$

Thus for m large enough such that $\delta_m \leq \frac{\delta}{2}$, we get

$$\mathbf{P}_{(S,E)} \left(R_\ell(f_T) - \widehat{R}_\ell(f_T;T) - 2\beta(m) \geq \varepsilon \right) \leq \frac{\delta}{2} + e^{-2\varepsilon^2/\gamma(m)}.$$

Setting the second term on the right hand side equal to $\frac{\delta}{2}$ and solving for ε gives the desired result. ■

Abstract

In real world applications, graphical statistical models are not only a tool for operations such as classification or prediction, but usually the network structures of the models themselves are also of great interest (e.g., in modeling brain connectivity). The false discovery rate (FDR), the expected ratio of falsely claimed connections to all those claimed, is often a reasonable error-rate criterion in these applications. However, current learning algorithms for graphical models have not been adequately adapted to the concerns of the FDR. The traditional practice of controlling the type I error rate and the type II error rate under a conventional level does not necessarily keep the FDR low, especially in the case of sparse networks. In this paper, we propose embedding an FDR-control procedure into the PC algorithm to curb the FDR of the skeleton of the learned graph. We prove that the proposed method can control the FDR under a user-specified level at the limit of large sample sizes. In the cases of moderate sample size (about several hundred), empirical experiments show that the method is still able to control the FDR under the user-specified level, and a heuristic modification of the method is able to control the FDR more accurately around the user-specified level. The proposed method is applicable to any models for which statistical tests of conditional independence are available, such as discrete models and Gaussian models.

Keywords: Bayesian networks, false discovery rate, PC algorithm, directed acyclic graph, skeleton

1. Introduction

Graphical models have attracted increasing attention in the fields of data mining and machine learning in the last decade. These models, such as Bayesian networks (also called belief networks) and Markov random fields, generally represent events or random variables as vertices (also referred to as nodes), and encode conditional-independence relationships among the events or variables as directed or undirected edges (also referred to as arcs) according to the Markov properties (see Lauritzen, 1996, Chapt. 3). Of particular interest here are Bayesian networks (see Pearl, 1988, Chapt. 3.3) that encode conditional-independence relationships according to the directed Markov property (see Lauritzen, 1996, pages 46–53) with directed acyclic graphs (DAGs) (i.e., graphs with only directed edges and with no directed cycles). The directed acyclic feature facilitates the computation of Bayesian networks because the joint probability can be factorized recursively into many local conditional probabilities.

As a fundamental and intuitive tool to analyze and visualize the association and/or causality relationships among multiple events, graphical models have become more and more explored in biomedical researches, such as discovering gene regulatory networks and modelling functional connectivity between brain regions. In these real world applications, graphical models are not only a tool for operations such as classification or prediction, but often the network structures of the models themselves are also output of great interest: a set of association and/or causality relationships discovered from experimental observations. For these applications, a desirable structure-learning method needs to account for the error rate of the graphical features of the discovered network. Thus, it is important for structure-learning algorithms to control the error rate of the association/causality relationships discovered from a limited number of observations closely below a user-specified level, in addition to finding a model that fits the data well. As edges are fundamental elements of a graph, error rates related to them are of natural concerns.

In a statistical decision process, there are basically two sources of errors: the type I errors, that is, falsely rejecting negative hypotheses when they are actually true; and the type II errors, that is, falsely accepting negative hypotheses when their alternatives, the positive hypotheses are actually true. In the context of learning graph structures, a negative hypothesis could be that an edge does not exist in the graph while the positive hypothesis could be that the edge does exist. Because of the stochastic nature of random sampling, data of a limited sample size may appear to support a positive hypothesis more than a negative hypothesis even when actually the negative hypothesis is true, or vice versa. Thus it is generally impossible to absolutely prevent the two types of errors simultaneously, but has to set a threshold on a certain type of errors, or keep a balance between the them, for instance by minimizing a certain lost function associated with the errors according to the Bayesian decision theory. For example, when diagnosing cancer, to catch the potential chance of saving a patient's life, doctors probably hope that the type II error rate, that is, the probability of falsely diagnosing a cancer patient as healthy, to be low, such as less than 5%. Meanwhile, when diagnosing a disease whose treatment is so risky that may cause the loss of eyesight, to avoid the unnecessary but great risk for healthy people, doctors probably hope that the type I error rate, that is, the probability of falsely diagnosing a healthy people as affected by the disease, to be extremely low, such as less than 0.1%. Learning network structures may face scenarios similar to the two cases above of diagnosing diseases. Given data of a limited sample size, there is not an algorithm guaranteeing a perfect recovery of the structure of the underlying graphical model, and any algorithm has to compromise on the two types of errors.

For problems involving simultaneously testing multiple hypotheses, such as verifying the existence of edges in a graph, there are several different criteria for their error-rate control (see Table 2), depending on researchers' concerns or the scenario of the study. Generally there are not mathematically or technically superior relationships among different error-rate criteria if the research scenario is not specified. One error-rate criterion may be favoured in one scenario while another criterion may be right of interest in a different scenario, just as the aforementioned examples of diagnosing diseases. In real world applications, selecting the error rate of interest is largely not an abstract question "which error rate is superior over others?", but a practical question "which error rate is the researchers' concern?" For extended discussions on why there are not general superior relationships among different error-rate criteria, please refer to Appendix C, where examples of typical research scenarios, accompanied by theoretical discussions, illustrate that each of the four error-rate criteria in Table 2 may be favoured in a certain study.

The false discovery rate (FDR) (see Benjamini and Yekutieli, 2001; Storey, 2002), defined as the expected ratio of falsely discovered positive hypotheses to all those discovered, has become an important and widely used criterion in many research fields, such as bioinformatics and neuroimaging. In many real world applications that involve multiple hypothesis testing, the FDR is more reasonable than the traditional type I error rate and type II error rate. Suppose that in a pilot study researchers are selecting candidate genes for a genetic research on schizophrenia. Due to the limited funding, only a limited number of genes can be studied thoroughly in the afterward genetic research. To use the funding efficiently, researchers would hope that 95% of the candidate genes selected in the pilot study are truly associated with the disease. In this case, the FDR is chosen as the error rate of interest and should be controlled under 5%. Simply controlling the type I error rate and the type II error rate under certain levels does not necessarily keep the FDR sufficiently low, especially in the case of sparse networks. For example, suppose a gene regulatory network involves 100 genes, where each gene interacts in average with 3 others, that is, there are 150 edges in the network. Then an algorithm with the *realized* type I error rate = 5% and the *realized* power = 90% (i.e., the *realized* type II error rate = 10%) will recover a network with $150\times 90\%=135$ correct connections and $[100\times(100-1)/2-150]\times 5\% = 240$ false connections. This means that $240/(240+135) = 64\%$ of the claimed connections actually do not exist in the true network. Due to the popularity of the FDR in research practices, it is highly desirable to develop structure-learning algorithms that allow the control over the FDR on network structures.

However, current structure-learning algorithms for Bayesian networks have not been adequately adapted to explicitly controlling the FDR of the claimed "discovered" networks. Score-based search methods (see Heckerman et al., 1995) look for a suitable structure by optimizing a certain criterion of goodness-of-fit, such as the Akaike information criterion (AIC), the Bayesian information criterion (BIC), or the Bayesian Dirichlet likelihood equivalent metric (BDE), with a random walk (e.g., simulated annealing) or a greedy walk (e.g., hill-climbing), in the space of DAGs or their equivalence classes.[1] It is worth noting that the restricted case of tree-structured Bayesian networks has been optimally solved, in the sense of Kullback-Leibler divergence, with Chow and Liu (1968)'s method, and that Chickering (2002) has proved that the greedy equivalence search can identify the true equivalence class in the limit of large sample sizes. Nevertheless, scores do not directly reflect the error rate of edges, and the sample sizes in real world applications are usually not large enough to guarantee the perfect asymptotic identification.

The Bayesian approach first assumes a certain prior probability distribution over the network structures, and then estimates the posterior probability distribution of the structures after data are observed. Theoretically, the posterior probability of any structure features, such as the existence of an edge, the existence of a path, or even the existence of a sub-graph, can be estimated with the Bayesian approach. This consequently allows the control of the posterior error rate of these structure features, that is, the posterior probability of the non-existence of these features. It should be pointed out that the posterior error rate is conceptually different from those error rates such as the type I error rate, the type II error rate, and the FDR, basically because they are from different statistical perspectives. The posterior error rate is defined from the perspective of Bayesian statistics. From the Bayesian perspective, network structures are assumed to be random, according to a probability distribution, and the posterior error rate is the probability of the non-existence of certain features according to the posterior probability distribution over the network structures. Given the same data,

1. An equivalence class of DAGs is a set of DAGs that encode the same set of conditional-independence relationships according to the directed Markov property.

different posterior distributions will be derived from different prior distributions. The type I error rate, the type II error rate, and the FDR are defined from the perspective of classical statistics. From the classical perspective, there is a true, yet unknown, model behind the data, and the error rates are defined by comparing with the true model. Nevertheless, a variant of the FDR, the positive false discovery rate (pFDR) proposed by Storey (2002), can be interpreted from the Bayesian perspective (Storey, 2003).

The Bayesian approach for structure learning is usually conducted with the maximum-*a posteriori*-probability (MAP) method or the posterior-expectation method. The MAP method selects the network structure with the largest posterior probability. The optimal structure is usually searched for in a score-based manner, with the posterior probability or more often approximations to the relative posterior probability (for instance the BIC score) being the score to optimize. Cooper and Herskovits (1992) developed a heuristic greedy search algorithm called K2[2] that can finish the search in a polynomial time with respect to the number of vertices, given the order of vertices. The MAP method provides us with a single network structure, the posteriorly most probable one, but does not address error rates in the Bayesian approach.

To control errors in the Bayesian approach, the network structure should be learned with the posterior-expectation method, that is, calculating the posterior probabilities of network structures, and then deriving the posterior expectation of the existence of certain structure features. Though theoretically the posterior-expectation method can control the error rate of any structure features, in practice its capacity is largely limited for computational reasons. The number of DAGs increases super-exponentially as the number of vertices increases (Robinson, 1973). For 10 vertices, there are already about 4.2×10^{18} DAGs. Though the number of equivalence classes of DAGs is much smaller than the number of DAGs, it is still forbiddingly large, empirically asymptotically decreasing to 1/13.652 of the number of DAGs, as the number of vertices increases (Steinsky, 2003). Therefore, exact inferences of posterior probabilities are only feasible for small scale problems, or under certain additional constraints. For certain prior distributions, and given the order of vertices, Friedman and Koller (2003) have derived a formula that can be used to calculate the exact posterior probability of a structure feature with the computational complexity bounded by $O(N^{D_{in}+1})$, where N is the number of vertices and D_{in} is the upper bound of the in-degree for each vertex. Considering similar prior distributions, but without the restriction on the order of vertices, Koivisto and Sood (2004) have developed a fast exact Bayesian inference algorithm based on dynamic programming that is able to compute the exact posterior probability of a sub-network with the computational complexity bounded by $O(N2^N + N^{D_{in}+1}L(m))$, where $L(m)$ is the complexity of computing a marginal conditional likelihood from m samples. In practice, this algorithm runs fairly fast when the number of vertices is less than 25. For networks with more than 30 vertices, the authors suggested setting more restrictions or combining with inexact techniques. These two breakthroughs made exact Bayesian inferences practical for certain prior distributions. However, as Friedman and Koller (2003) pointed out, the prior distributions which facilitate the exact inference are not hypothesis equivalent (see Heckerman et al., 1995), that is, different network structures that are in the same equivalence class often have different priors. The simulation performed by Eaton and Murphy (2007) confirmed that these prior distributions deviate far from the uniform distributions. This implies that the methods cannot be applied to the widely accepted uninformative prior, that is, the uniform prior distribution over DAGs. For general problems, the posterior probability of a structure feature can be approx-

2. The algorithm is named K2 because it evolved from a system named Kutato (Herskovits and Cooper, 1990).

imated with Markov chain Monte Carlo (MCMC) methods (Madigan et al., 1995). As a versatile implementation of Bayesian inferences, the MCMC method can estimate the posterior probability given any prior probability distribution. However, MCMC usually requires intensive computation and results may depend on the initial state of the randomization.

Constraint-based approaches, such as the SGS[3] algorithm (see Spirtes et al., 2001, pages 82–83), inductive causation (IC)[4] (see Pearl, 2000, pages 49–51), and the PC[5] algorithm (see Spirtes et al., 2001, pages 84–89), are rooted in the directed Markov property, the rule by which Bayesian networks encode conditional independence. These methods first test hypotheses of conditional independence among random variables, and then combine those accepted hypotheses of conditional independence to construct a partially directed acyclic graph (PDAG) according to the directed Markov property. The computational complexity of these algorithms is difficult to analyze exactly, though for the worst case, which rarely occurs in real world applications, is surely bounded by $O(N^2 2^N)$ where N is the number of vertices. In practice, the PC algorithm and the fast-causal-inference (FCI) algorithm (see Spirtes et al., 2001, pages 142–146) can achieve polynomial time if the maximum degree of a graph is fixed. It has been proved that if the true model satisfies the faithfulness constraints (see Spirtes et al., 2001, pages 13 and 81) and all the conditional-independence/dependence relationships are correctly identified, then the PC algorithm and the IC algorithm can exactly recover the true equivalence class, and so do the FCI algorithm and the IC* algorithm[6] (see Pearl, 2000, pages 51–54) for problems with latent variables. Kalisch and Bühlmann (2007) have proved that for Gaussian Bayesian networks, the PC algorithm can consistently estimate the equivalence class of an underlying sparse DAG as the sample size m approaches infinity, even if the number of vertices N grows as fast as $O(m^\lambda)$ for any $0 < \lambda < \infty$. Yet, as in practice hypotheses of conditional independence are tested with statistical inference from limited data, false decisions cannot be entirely avoided and thus the ideal recovery cannot be achieved. In current implementations of the constraint-based approaches, the error rate of testing conditional independence is usually controlled individually for each test, under a conventional level such as 5% or 1%, without correcting the effect of multiple hypothesis testing. Therefore these implementations may fail to curb the FDR, especially for sparse graphs.

In this paper, we propose embedding an FDR-control procedure into the PC algorithm to curb the error rate of the skeleton of the learned PDAGs. Instead of individually controlling the type I error rate of each hypothesis test, the FDR-control procedure considers the hypothesis tests together to correct the effect of simultaneously testing the existence of multiple edges. We prove that the proposed method, named as the PC_{fdr}-skeleton algorithm, can control the FDR under a user-specified level at the limit of large sample sizes. In the case of moderate sample sizes (about several hundred), empirical experiments show that the method is able to control the FDR under the user-specified level, and a heuristic modification of the method is able to control the FDR more accurately around the user-specified level. Schäfer and Strimmer (2005) have applied an FDR procedure to graphical Gaussian models to control the FDR of the non-zero entries of the partial correlation matrix. Different from Schäfer and Strimmer (2005)'s work, our method, built within the frame-

6. See footnote 4.

work of the PC algorithm, is not only applicable to the special case of Gaussian models, but also generally applicable to any models for which conditional-independence tests are available, such as discrete models.

We are particularly interested in the PC algorithm because it roots in conditional-independence relationships, the backbone of Bayesian networks, and p-values of hypothesis testing represent one type of error rates. We consider the skeleton of graphs because constraint-based algorithms usually first construct an undirected graph, and then annotate it into different types of graphs while keeping the skeleton as the same as that of the undirected one.

The PC$_{\text{fdr}}$-skeleton algorithm is not designed to replace or claimed to be superior over the standard PC algorithm, but provide the PC algorithm with the ability to control the FDR over the skeleton of the recovered network. The PC$_{\text{fdr}}$-skeleton algorithm controls the FDR while the standard PC algorithm controls the type I error rate, as illustrated in Section 3.1. Since there are no general superior relationships between different error-rate criteria, as explained in Appendix C, neither be there between the PC$_{\text{fdr}}$-skeleton algorithm and the standard PC algorithm. In research practices, researchers first decide which error rate is of interest, and then choose appropriate algorithms to control the error rate of interest. Generally they will not select an algorithm that sounds "superior" but controls the wrong error rate. Since the purpose of the paper is to provide the PC algorithm with the control over the FDR, we assume in this paper that the FDR has been selected as the error rate of interest, and selecting the error rate of interest is out of the scope of the paper.

The remainder of the paper is organized as follows. In Section 2, we review the PC algorithm, present the FDR-embedded PC algorithm, prove its asymptotic performance, and analyze its computational complexity. In Section 3, we evaluate the proposed method with simulated data, and demonstrate its real world applications to learning functional connectivity networks between brain regions using functional-magnetic-resonance-imaging (fMRI). Finally, we discuss the advantages and limitations of the proposed method in Section 4.

2. Controlling FDR with PC Algorithm

In this section, we first briefly introduce Bayesian networks and review the PC algorithm. Then, we expatiate on the FDR-embedded PC algorithm and its heuristic modification, prove their asymptotic performances, and analyze their computational complexity. At the end, we discuss other possible ideas of embedding FDR control into the PC algorithm.

2.1 Notations and Preliminaries

To assist the reading, notations frequently used in the paper are listed as follows:

$a, b, \cdots$	: vertices
$X_a, X_b, \cdots$	: variables respectively represented by vertices $a, b, \cdots$
$A, B, \cdots$	: vertex sets
$X_A, X_B, \cdots$	: variable sets respectively represented by vertex sets $A, B, \cdots$
V	: the vertex set of a graph
$N = \|V\|$	: the number of vertices of a graph
$a \rightarrow b$	: a directed edge or an ordered pair of vertices
$a \sim b$	: an undirected edge, or an unordered pair of vertices

E	: a set of directed edges
$E^{\sim}$	: the undirected edges derived from E, that is, $\{a \sim b \mid a \to b \text{ or } b \to a \in E\}$
$G = (V, E)$	: a directed graph composed of vertices in V and edges in E
$G^{\sim} = (V, E^{\sim})$	: the skeleton of a directed graph $G = (V, E)$
$\text{adj}(a, G)$	: vertices adjacent to a in graph G, that is, $\{b \mid a \to b \text{ or } b \to a \in E\}$
$\text{adj}(a, G^{\sim})$	: vertices adjacent to a in graph $G^{\sim}$, that is, $\{b \mid a \sim b \in E^{\sim}\}$
$a \perp b \mid C$	: vertices a and b are d-separated by vertex set C
$X_a \perp X_b \mid X_C$	: X_a and X_b are conditional independent given X_C
$p_{a \perp b \mid C}$	: the p-value of testing $X_a \perp X_b \mid X_C$

A Bayesian network encodes a set of conditional-independence relationships with a DAG $G = (V, E)$ according to the directed Markov property defined as follows.

Definition 1 ***the Directed Markov Property:*** *if A and B are d-separated by C where A, B and C are three disjoint sets of vertices, then X_A and X_B are conditionally independent given X_C, that is, $P(X_A, X_B|X_C) = P(X_A|X_C)P(X_B|X_C)$. (see Lauritzen, 1996, pages 46–53)*

The concept of *d-separation* (see Lauritzen, 1996, page 48) is defined as follows. A chain between two vertices a and b is a sequence $a = a_0, a_1, \ldots, a_n = b$ of distinct vertices such that $a_{i-1} \sim a_i \in E^{\sim}$ for all i=1, ... , n. Vertex b is a descendant of vertex a if and only if there is a sequence $a = a_0, a_1, \ldots, a_n = b$ of distinct vertices such that $a_{i-1} \to a_i \in E$ for all i=1, ..., n. For three disjoint subsets A, B and $C \subseteq V$, C d-separates A and B if and only if any chain π between $\forall a \in A$ and $\forall b \in B$ contains a vertex $\gamma \in \pi$ such that either

- arrows of π do not meet head-to-head at γ and $\gamma \in C$, or
- arrows of π meet head-to-head at γ and γ is neither in C nor has any descendants in C.

Moreover, a probability distribution P is *faithful* to a DAG G (see Spirtes et al., 2001, pages 13 and 81) if all and only the conditional-independence relationships derived from P are encoded by G. In general, a probability distribution may possess other independence relationships besides those encoded by a DAG.

It should be pointed out that there are often several different DAGs encoding the same set of conditional-independence relationships and they are called an *equivalence class* of DAGs. An equivalence class can be uniquely represented by a completed acyclic partially directed graph (CPDAG) (also called the essential graph in the literature) that has the same skeleton as a DAG does except that some edges are not directed (see Andersson et al., 1997).

2.2 PC Algorithm

If a probability distribution P is faithful to a DAG G, then the PC algorithm (see Spirtes et al., 2001, pages 84–89) is able to recover the equivalence class of the DAG G, given the set of the conditional-independence relationships. In general, a probability distribution may include other independence relationships besides those encoded by a DAG. The faithfulness assumption assures that the independence relationships can be perfectly encoded by a DAG. In practice, the information on conditional independence is usually unknown but extracted from data with statistical hypothesis testing. If the p-value of testing a hypothesis $X_a \perp X_b \mid X_C$ is lower than a user-specified level α

(conventionally 5% or 1%), then the hypothesis of conditional independence is rejected while the hypothesis of conditional dependence $X_a \not\perp X_b | X_C$ is accepted.

The first step of the PC algorithm is to construct an undirected graph $G^{\sim}$ whose edge directions will later be further determined with other steps, while the skeleton is kept the same as that of $G^{\sim}$. Since we restrict ourselves to the error rate of the skeleton, here we only present in Algorithm 1 the first step of the PC algorithm, as implemented in software Tetrad version 4.3.8 (see http://www.phil.cmu.edu/projects/tetrad), and refer to it as the PC-skeleton algorithm.

Algorithm 1 PC-skeleton

Input: the data X_V generated from a probability distribution faithful to a DAG G_{true},
and the significance level α for every statistical test of conditional independence
Output: the recovered skeleton $G^{\sim}$

```
1:  Form the complete undirected graph $G^{\sim}$ on the vertex set $V$.
2:  Let depth $d = 0$.
3:  repeat
4:    for each ordered pair of adjacent vertices $a$ and $b$ in $G^{\sim}$, that is, $a \sim b \in E^{\sim}$ do
5:      if $|\text{adj}(a, G^{\sim}) \setminus \{b\}| \geq d$, then
6:        for each subset $C \subseteq \text{adj}(a, G^{\sim}) \setminus \{b\}$ and $|C| = d$ do
7:          Test hypothesis $X_a \perp X_b | X_C$ and calculate the $p$-value $p_{a \perp b|C}$.
8:          if $p_{a \perp b|C} \geq \alpha$, then
9:            Remove edge $a \sim b$ from $G^{\sim}$.
10:           Update $G^{\sim}$ and $E^{\sim}$.
11:           break the for loop at line 6
12:         end if
13:       end for
14:     end if
15:   end for
16:   Let $d = d + 1$.
17: until $|\text{adj}(a, G^{\sim}) \setminus \{b\}| < d$ for every ordered pair of adjacent vertices $a$ and $b$ in $G^{\sim}$.
```

The theoretical foundation of the PC-skeleton algorithm is **Proposition 1**: if two vertices a and b are not adjacent in a DAG G, then there is a set of other vertices C that either all are neighbors of a or all are neighbors of b such that C d-separates a and b, or equivalently, $X_a \perp X_b | X_C$, according to the directed Markov property. Since two adjacent vertices are not d-separated by any set of other vertices (according to the directed Markov property), **Proposition 1** implies that a and b are not adjacent if and only if there is a d-separating C in either neighbors of a or neighbors of b. Readers should notice that the proposition does not imply that a and b are d-separated only by such a C, but just guarantees that a d-separating C can be found in either neighbors of a or neighbors b.

Proposition 1 *If vertices a and b are not adjacent in a DAG G, then there is a set of vertices C which is either a subset of* $\text{adj}(a, G) \setminus \{b\}$ *or a subset of* $\text{adj}(b, G) \setminus \{a\}$ *such that C d-separates a and b in G.* This proposition is a corollary of Lemma 5.1.1 on page 411 of book *Causation, Prediction, and Search* (Spirtes et al., 2001).

The logic of the PC-skeleton algorithm is as follows, under the assumption of perfect judgment on conditional independence. The most straightforward application of **Proposition 1** to structure learning is to exhaustively search all the possible neighbors of a and b to verify whether there is such a d-separating C to disconnect a and b. Since the possible neighbors of a and b are unknown, to guarantee the detection of such a d-separating C, all the vertices other than a and b should be searched as possible neighbors of a and b. However, such a straightforward application is very inefficient because it probably searches many unnecessary combinations of vertices by considering all the vertices other than a and b as their possible neighbors, especially when the true DAG is sparse. The PC-skeleton algorithm searches more efficiently, by keeping updating the possible neighbors of a vertex once some previously-considered possible neighbors have been found actually not connected with the vertex. Starting with a fully connected undirected graph $G^{\sim}$ (step 1), the algorithm searches for the d-separating C progressively by increasing the size of C, that is, the number of conditional variables, from zero (step 2) with the step size of one (step 16). Given the size of C, the search is performed for every vertex pair a and b (step 4). Once a C d-separating a and b is found (step 8), a and b are disconnected (step 9), and the neighbors of a and b are updated (step 10). In the algorithm, $G^{\sim}$ is continually updated, so $\text{adj}(a, G^{\sim})$ is also constantly updated as the algorithm progresses. The algorithm stops when all the subsets of the current neighbors of each vertex have been examined (step 17). The Tetrad implementation of the PC-skeleton algorithm examines an edge $a \sim b$ as two ordered pairs (a, b) and (b, a) (step 4), each time searching for the d-separating C in the neighbors of the first element of the pair (step 6). In this way, both the neighbors of a and the neighbors of b are explored.

The accuracy of the PC-skeleton algorithm depends on the discriminability of the statistical test of conditional independence. If the test can perfectly distinguish dependence from independence, then the algorithm can correctly recover the true underlying skeleton, as proved by Spirtes et al. (2001, pages 410–412). The outline of the proof is as follows. First, all the true edges will be recovered because an adjacent vertex pair $a \sim b$ is not d-separated by any vertex set C that excludes a and b. Second, if the edge between a non-adjacent vertex pair a and b has not been removed, subsets of either $\text{adj}(a, G) \setminus \{b\}$ or $\text{adj}(b, G) \setminus \{a\}$ will be searched until the C that d-separates a and b according to **Proposition 1** is found, and consequently the edge between a and b will be removed. If the judgments on conditional independence and conditional dependence are imperfect, the PC-skeleton algorithm is unstable. If an edge is mistakenly removed from the graph in the early stage of the algorithm, then other edges which are not in the true graph may be included in the graph (see Spirtes et al., 2001, page 87).

2.3 False Discovery Rate

In a statistical decision process, there are basically two sources of errors: the type I errors, that is, falsely rejecting negative hypotheses when they are actually true; and the type II errors, that is, falsely accepting negative hypotheses when their alternative, the positive hypotheses are actually true. The FDR (see Benjamini and Yekutieli, 2001) is a criterion to assess the errors when multiple hypotheses are simultaneously tested. It is the expected ratio of the number of falsely claimed positive results to that of all those claimed to be positive, as defined in Table 2. A variant of the FDR, the positive false discovery rate (pFDR), defined as in Table 2, was proposed by Storey (2002). Clearly, pFDR = FDR / $P(R_2 > 0)$, so the two measures will be similar if $P(R_2 > 0)$ is close to 1, and quite different otherwise.

Test Results	Truth		
	Negative	Positive	Total
Negative	TN (true negative)	FN (false negative)	R_1
Positive	FP (false positive)	TP (true positive)	R_2
Total	T_1	T_2	

Table 1: Results of multiple hypothesis testing, categorized according to the claimed results and the truth.

Full Name	Abbreviation	Definition
False Discovery Rate	FDR	$E(\mathrm{FP}/R_2)$ (See note *)
Positive False Discovery Rate	pFDR	$E(\mathrm{FP}/R_2 \mid R_2 > 0)$
Family-Wise Error Rate	FWER	$P(\mathrm{FP} \geq 1)$
Type I Error Rate (False Positive Rate)	α	$E(\mathrm{FP}/T_1)$
Specificity (True Negative Rate)	$1-\alpha$	$E(\mathrm{TN}/T_1)$
Type II Error Rate (False Negative Rate)	β	$E(\mathrm{FN}/T_2)$
Power (Sensitivity, True Positive Rate)	$1-\beta$	$E(\mathrm{TP}/T_2)$

Table 2: Criteria for multiple hypothesis testing. Here $E(x)$ means the expected value of x, and $P(\mathcal{A})$ means the probability of event $\mathcal{A}$. Please refer to Table 1 for related notations. * If $R_2 = 0$, FP/R_2 is defined to be 0.

The FDR is a reasonable criterion when researchers expect the "discovered" results are trustful and dependable in afterward studies. For example, in a pilot study, we are selecting candidate genes for a genetic research on Parkinson's disease. Because of the limited funding, we can only study a limited number of genes in the afterward genetic research. Thus, when selecting candidate genes in the pilot study, we hope that 95% of the selected candidate genes are truly associated with the disease. In this case, the FDR is chosen as the error rate of interest and should be controlled under 5%. Since similar situations are quite common in research practices, the FDR has been widely adopted in many research fields such as bioinformatics and neuroimaging.

In the context of learning the skeleton of a DAG, a negative hypothesis could be that a connection does not exist in the DAG, and a positive hypothesis could be that the connection exists. The FDR is the expected proportion of the falsely discovered connections to all those discovered. Learning network structures may face scenarios similar to the aforementioned pilot study, but the FDR control has not yet received adequate attention in structure learning.

Benjamini and Yekutieli (2001) have proved that, when the test statistics have positive regression dependency on each of the test statistics corresponding to the true negative hypotheses, the FDR can be controlled under a user-specified level q by Algorithm 2. In other cases of dependency, the FDR can be controlled with a simple conservative modification of the procedure by replacing H^* in Eq. (1) with $H(1+1/2,\ldots,+1/H)$. Storey (2002) has provided algorithms to control the pFDR for independent test statistics. For a review and comparison of more FDR methods, please refer to Qian and Huang (2005)'s work. It should be noted that the FDR procedures do not control the *realized* FDR of a trial under q, but control the *expected value* of the error rate when the procedures are repetitively applied to randomly sampled data.

Algorithm 2 FDR-stepup

Input: a set of p-values $\{p_i | i = 1, \ldots, H\}$, and the threshold of the FDR q
Output: the set of rejected null hypotheses

```
1: Sort the $p$-values of $H$ hypothesis tests in the ascendant order as $p_{(1)} \leq \ldots \leq p_{(H)}$.
2: Let $i = H$, and $H^* = H$ (or $H^* = H(1 + 1/2, \ldots, +1/H)$, depending on the assumption of the
   dependency among the test statistics).
3: while
       $$\frac{H^*}{i} p_{(i)} > q \quad \text{and} \quad i > 0, \qquad (1)$$
   do
4:     Let $i = i - 1$.
5: end while
6: Reject the null hypotheses associated with $p_{(1)}, \ldots, p_{(i)}$, and accept the null hypotheses associ-
   ated with $p_{(i+1)}, \ldots, p_{(H)}$.
```

Besides the FDR and the pFDR, other criteria, as listed in Table 2, can also be applied to assess the uncertainty of multiple hypothesis testing. The type I error rate is the expected ratio of the type I errors to all the negative hypotheses that are actually true. The type II error rate is the expected ratio of the type II errors to all the positive hypotheses that are actually true. The family-wise error rate is the probability that at least one of the accepted positive hypotheses are actually wrong. Generally, there are not mathematically or technically superior relationships among these error-rate criteria. Please refer to Appendix C for examples of typical research scenarios where each particular error rate is favoured.

Controlling both the type I and the type II error rates under a conventional level (such as $\alpha <$ 5% or 1% and $\beta <$ 10% or 5%) does not necessarily curb the FDR at a desired level. As shown in Eq. (2), if FP/T_1 and FN/T_2 are fixed and positive, FP/R_2 approaches 1 when T_2/T_1 is small enough. This is the case of sparse networks where the number of existing connections T_2 is much smaller than the number of non-existing connections T_1.

$$\frac{\mathrm{FP}}{R_2} = \frac{\frac{\mathrm{FP}}{T_1}}{\frac{\mathrm{FP}}{T_1} + (1 - \frac{\mathrm{FN}}{T_2})\frac{T_2}{T1}}. \qquad (2)$$

2.4 PC Algorithm with FDR

Steps 8–12 of the PC-skeleton algorithm control the type I error rate of each statistical test of conditional independence individually below a pre-defined level α, so the algorithm can not explicitly control the FDR. We propose embedding an FDR-control procedure into the algorithm to curb the error rate of the learned skeleton. The FDR-control procedure collectively considers the hypothesis tests related to the existence of multiple edges, correcting the effect of multiple hypothesis testing. The proposed method is described in Algorithm 3, and we name it as the $\mathrm{PC}_{\mathrm{fdr}}$-skeleton algorithm. Similar to the PC-skeleton algorithm, $G^{\sim}$, $\mathrm{adj}(a,G^{\sim})$ and $E^{\sim}$ are constantly updated as the algorithm progresses.

The PC$_{\mathrm{fdr}}$-skeleton and the PC-skeleton algorithms share the same search strategy, but differ on the judgment of conditional independence. The same as the PC-skeleton algorithm, the PC$_{\mathrm{fdr}}$-skeleton algorithm increases d, the number of conditional variables, from zero (step 3) with the step size of one (step 25), and also keeps updating the neighbors of vertices (steps 14 and 15) when some previously-considered possible neighbors have been considered not connected (step 13). The PC$_{\mathrm{fdr}}$-skeleton algorithm differs from the PC-skeleton algorithm on the inference of d-separation, with its steps 11–20 replacing steps 8–12 of the PC-skeleton algorithm. In the PC-skeleton algorithm, two vertices are regarded as d-separated once the conditional-independence test between them yields a p-value larger than the pre-defined significant level α. In this way, the type I error of each statistical test is controlled separately, without consideration of the effect of multiple hypothesis testing. The PC$_{\mathrm{fdr}}$-skeleton algorithm records in $p^{max}_{a\sim b}$ the up-to-date maximum p-value associated with an edge $a \sim b$ (steps 9 and 10), and progressively removes those edges whose non-existence is accepted by the FDR procedure (step 12), with $P^{max} = \{p^{max}_{a\sim b}\}_{a\neq b}$ and the pre-defined FDR level q being the input. The FDR procedure, **Algorithm 2**, is invoked at step 12, either immediately after every element of P^{max} has been assigned a valid p-value for the first time, or later once any element of P^{max} is updated.

The $p^{max}_{a\sim b}$ is the upper bound of the p-value of testing the hypothesis that a and b are d-separated by at least one of the vertex sets C searched in step 7. According to the directed Markov property, a and b are not adjacent if and only if there is a set of vertices $C \subseteq V \setminus \{a,b\}$ d-separating a and b. As the algorithm progresses, the d-separations between a and b by vertex sets $C_1,\ldots,C_K \subseteq V \setminus \{a,b\}$ are tested respectively, and consequently a sequence of p-values $p_1,\ldots,p_K$ are calculated. If we use $p^{max}_{a\sim b} = \max_{i=1}^{K} p_i$ as the statistic to test the negative hypothesis that there is, though unknown, a C_j among $C_1,\ldots,C_K$ d-separating a and b, then due to

$$P(p^{max}_{a\sim b} \leq p) = P(p_i \leq p \text{ for all } i=1,\ldots,K) \leq P(p_j \leq p) = p, \tag{3}$$

$p^{max}_{a\sim b}$ is the upper bound of the p-value of testing the negative hypothesis. Eq. (3) also clearly shows that the PC-skeleton algorithm controls the type I error rate of the negative hypothesis, since its step 8 is equivalent to "if $p^{max}_{a\sim b} < \alpha$, then … " if $p^{max}_{a\sim b}$ is recorded in the PC-skeleton algorithm.

The statistical tests performed at step 8 of the PC$_{\mathrm{fdr}}$-skeleton algorithm generally are not independent with each other, since the variables involved in two hypotheses of conditional independence may overlap. For example, conditional-independence relationships $a\perp b_1|C$ and $a\perp b_2|C$ both involve a and C. It is very difficult to prove whether elements of P^{max} have positive regression dependency or not, so rigorously the conservative modification of Algorithm 2, should be applied at step 12. However, since $p^{max}_{a\sim b}$ is probably a loose upper bound of the p-value of testing $a \nsim b$, in practice we simply apply the FDR procedure that is correct for positive regression dependency.

It should be noted that different from step 9 of the PC-skeleton algorithm, step 14 of the PC$_{\mathrm{fdr}}$-skeleton algorithm may remove edges other than just $a \sim b$, because the decisions on other edges can be affected by the updating of $p^{max}_{a\sim b}$.

A heuristic modification of the PC$_{\mathrm{fdr}}$-skeleton algorithm is to remove $p^{max}_{a\sim b}$ from P^{max} once edge $a \sim b$ has been deleted from $G^{\sim}$ at step 14. We name this modified version as the PC$_{\mathrm{fdr*}}$-skeleton algorithm. In the PC$_{\mathrm{fdr}}$-skeleton algorithm, $p^{max}_{a\sim b}$ is still recorded in P^{max} and input to the FDR procedure after the edge $a \sim b$ has been removed. This guarantees that the algorithm can asymptotically keep the FDR under the user-specified level q (see Section 2.5). The motivation of

Algorithm 3 PC$_{\text{fdr}}$-skeleton

Input: the data X_V generated from a probability distribution faithful to a DAG G_{true},
and the FDR level q for the discovered skeleton
Output: the recovered skeleton $G^{\sim}$

```
1:  Form the complete undirected graph $G^{\sim}$ on the vertex set $V$
2:  Initialize the maximum $p$-values associated with edges as
    $P^{max} = \{p^{max}_{a\sim b} = -1\}_{a \neq b}$.
3:  Let depth $d = 0$.
4:  repeat
5:    for each ordered pair of adjacent vertices $a$ and $b$ in $G^{\sim}$, that is, $a \sim b \in E^{\sim}$ do
6:      if $|\mathrm{adj}(a, G^{\sim}) \setminus \{b\}| \geq d$, then
7:        for each subset $C \subseteq \mathrm{adj}(a, G^{\sim}) \setminus \{b\}$ and $|C| = d$ do
8:          Test hypothesis $X_a \perp X_b | X_C$ and calculate the $p$-value $p_{a\perp b|C}$.
9:          if $p_{a\perp b|C} > p^{max}_{a\sim b}$, then
10:           Let $p^{max}_{a\sim b} = p_{a\perp b|C}$.
11:           if every element of $P^{max}$ has been assigned a valid $p$-value by step 10, then
12:             Run the FDR procedure, Algorithm 2, with $P^{max}$ and $q$ as the input.
13:             if the non-existence of certain edges are accepted, then
14:               Remove these edges from $G^{\sim}$.
15:               Update $G^{\sim}$ and $E^{\sim}$.
16:               if $a \sim b$ is removed, then
17:                 break the for loop at line 7.
18:               end if
19:             end if
20:           end if
21:         end if
22:       end for
23:     end if
24:   end for
25:   Let $d = d + 1$.
26: until $|\mathrm{adj}(a, G^{\sim}) \setminus \{b\}| < d$ for every ordered pair of adjacent vertices $a$ and $b$ in $G^{\sim}$.
```

* A heuristic modification at step 15 of the algorithm is to remove from P^{max} the $p^{max}_{a\sim b}$s whose associated edges have been deleted from $G^{\sim}$ at step 14, that is, to update P^{max} as $P^{max} = \{p^{max}_{a\sim b}\}_{a\sim b \in E^{\sim}}$ right after updating $E^{\sim}$ at step 15. This heuristic modification is named as the **PC$_{\text{fdr*}}$-skeleton algorithm**.

the heuristic modification is that if an edge has been eliminated, then it should not be considered in the FDR procedure any longer. Though we cannot theoretically prove the asymptotic performance of the heuristic modification in the sense of controlling the FDR, it is shown to control the FDR closely around the user-specified level in our empirical experiments and gain more detection power than that of the PC$_{\text{fdr}}$-skeleton algorithm (see Section 3).

2.5 Asymptotic Performance

Here we prove that the PC$_{\text{fdr}}$-skeleton algorithm is able to control the FDR under a user-specified level q ($q > 0$) at the limit of large sample sizes if the following assumptions are satisfied:

(A1) The probability distribution P is faithful to a DAG G_{true}.

(A2) The number of vertices is fixed.

(A3) Given a fixed significant level of testing conditional-independence relationships, the power of detecting conditional-dependence relationships with statistical tests approaches 1 at the limit of large sample sizes. (For the definition of power in hypothesis testing, please refer to Table 2.)

Assumption (A1) is generally assumed when graphical models are applied, although it restricts the probability distribution P to a certain class. Assumption (A2) is usually implicitly stated, but here we explicitly emphasize it because it simplifies the proof. Assumption (A3) may seem demanding, but actually it can be easily satisfied by standard statistical tests, such as the likelihood-ratio test introduced by Neyman and Pearson (1928), if the data are identically and independently sampled. Two statistical tests that satisfy Assumption (A3) are listed in Appendix B.

The detection power and the FDR of the PC$_{\text{fdr}}$-skeleton algorithm and its heuristic modification at the limit of large sample sizes are elucidated in Theorems 1 and 2. The detailed proofs are provided in Appendix A.

Theorem 1 *Assuming (A1), (A2) and (A3), both the PC$_{\text{fdr}}$-skeleton algorithm and its heuristic modification, the PC$_{\text{fdr*}}$-skeleton algorithm, are able to recover all the true connections with probability one as the sample size approaches infinity:*

$$\lim_{m\to\infty} P(E^{\sim}_{true} \subseteq E^{\sim}) = 1,$$

where $E^{\sim}_{true}$ denotes the set of the undirected edges derived from the true DAG G_{true}, $E^{\sim}$ denotes the set of the undirected edges recovered with the algorithms, and m denotes the sample size.

Theorem 2 *Assuming (A1), (A2) and (A3), the FDR of the undirected edges recovered with the PC$_{\text{fdr}}$-skeleton algorithm approaches a value not larger than the user-specified level q as the sample size m approaches infinity:*

$$\limsup_{m\to\infty} \mathrm{FDR}(E^{\sim}, E^{\sim}_{true}) \le q,$$

where $\mathrm{FDR}(E^{\sim}, E^{\sim}_{true})$ *is defined as*

$$\begin{cases} \mathrm{FDR}(E^{\sim}, E^{\sim}_{true}) & = & E\left[\frac{|E^{\sim}\backslash E^{\sim}_{true}|}{|E^{\sim}|}\right], \\ \text{Define } \frac{|E^{\sim}\backslash E^{\sim}_{true}|}{|E^{\sim}|} & = & 0, \quad \text{if } |E^{\sim}| = 0. \end{cases}$$

2.6 Computational Complexity

The PC$_{\text{fdr}}$-skeleton algorithm spends most of its computation on performing statistical tests of conditional independence at step 8 and controlling the FDR at step 12. Since steps 13 to 19 of the PC$_{\text{fdr}}$-skeleton algorithm play a role similar to steps 8 to 12 of the PC-skeleton algorithm do, and all the other parts of both algorithms employ the same search strategy, the computation spent by the PC$_{\text{fdr}}$-skeleton algorithm on statistical tests has the same complexity as that by the PC-skeleton algorithm. The only extra computational cost of the PC$_{\text{fdr}}$-skeleton algorithm is at step 12 for controlling the FDR.

The computational complexity of the search strategy employed by the PC algorithm has been studied by Kalisch and Bühlmann (2007) and Spirtes et al. (see 2001, pages 85–87). Here to make the paper self-contained, we briefly summarize the results as follows. It is difficult to analyze the complexity exactly, but if the algorithm stops at the depth $d = d_{max}$, then the number of conditional-independence tests required is bounded by

$$T = 2C_N^2 \sum_{d=0}^{d_{max}} C_{N-2}^d,$$

where N is the number of vertices, C_N^2 is the number of combinations of choosing 2 un-ordered and distinct elements from N elements, and similarly C_{N-2}^2 is the number of combinations of choosing from $N-2$ elements. In the worst case that $d_{max} = N-2$, the complexity is bounded by $2C_N^2 2^{N-2}$. The bound usually is very loose, because it assumes that no edge has been removed until $d = d_{max}$. In real world applications, the algorithm is very fast for sparse networks.

The computational complexity of the FDR procedure, Algorithm 2, generally is $O(\ H\log(H)$ + $H) = O(H\log(H))$ where $H = C_N^2$ is the number of input p-values. The sorting at step 1 costs $H\log(H)$ and the "while" loop from step 3 to step 5 repeats H times at most. However, if the sorted P^{max} is recorded during the computation, each time when an element of P^{max} is updated at step 10 of the PC$_{\text{fdr}}$-skeleton algorithm, the complexity of keeping the updated P^{max} sorted is only $O(H)$. With this optimization, the complexity of the FDR-control procedure is $O(H\log(H))$ at its first operation, and is $O(H)$ later. The FDR procedure is invoked only when $p_{a\perp b|C} > p_{a\sim b}^{max}$. In the worst case that $p_{a\perp b|C}$ is always larger than $p_{a\sim b}^{max}$, the complexity of the computation spent on the FDR control in total is bounded by $O(C_N^2 \log(C_N^2) + TC_N^2)$ = $O(N^2\log(N) + TN^2)$ where T is the number of performed conditional-independence tests. This is a very loose bound because it is rare that $p_{a\perp b|C}$ is always larger than $p_{a\sim b}^{max}$.

The computational complexity of the heuristic modification, the PC$_{\text{fdr*}}$-skeleton algorithm, is the same as that of the PC$_{\text{fdr}}$-skeleton algorithm, since they share the same search strategy and both employ the FDR procedure. In the PC$_{\text{fdr*}}$-skeleton algorithm, the size of P^{max} keeps decreasing as the algorithm progresses, so each operation of the FDR procedure is more efficient. However, since the PC$_{\text{fdr*}}$-skeleton algorithm adjusts the effect of multiple hypothesis testing less conservatively, it may remove less edges than the PC$_{\text{fdr}}$-skeleton algorithm does, and invokes more conditional-independence tests. Nevertheless, their complexity is bounded by the same limit in the worst case.

It is unfair to directly compare the computational time of the PC$_{\text{fdr}}$-skeleton algorithm against that of the PC-skeleton algorithm, because if the q of the former is set at the same value as the α of the latter, the former will remove more edges and perform much less statistical tests, due to its more stringent control over the type I error rate. A reasonable way is to compare the time spent on the FDR control at step 12 against that on conditional-independence tests at step 8 in each run of the PC$_{\text{fdr}}$-skeleton algorithm. If P^{max} is kept sorted during the learning process as aforementioned, then each time (except the first time) the FDR procedure just needs linear computation time (referring to the size of P^{max}) with simple operations such as division and comparing two numerical values. Thus, we suspect that the FDR procedure will not contribute much to the total computation time of the structure learning. In our simulation study in Section 3.1, the extra computation added by the FDR control was only a tiny portion, less than 0.5%, to that spent on testing conditional independence, performed with the Cochran-Mantel-Haenszel (CMH) test (see Agresti, 2002, pages 231–232), as shown in Tables 3 and 4.

2.7 Miscellaneous Discussions Discussions

An intuitive and attracting idea of adapting the PC-skeleton algorithm to the FDR control is to "smartly" determine such an appropriate threshold of the type I error rate α that will let the errors be controlled at the pre-defined FDR level q. Given a particular problem, it is very likely that the FDR of the graphs learned by the PC-skeleton algorithm is an monotonically increasing function of the pre-defined threshold α of the type I error rate. If this hypothesis is true, then there is a one-to-one mapping between α and q for the particular problem. Though we cannot prove this hypothesis rigorously, the following argument may be enlightening. Instead of directly focusing on FDR = $E(\mathrm{FP}/R_2)$ (see Table 2), the expected ratio of the number of false positives (FP) to the number of accepted positive hypotheses (R_2), we first focus on $E(\mathrm{FP})/E(R_2)$, the ratio of the expected number of false positives to the expected number of accepted positive hypotheses, since the latter is easier to link with the type I error rate according to Eq. (2), as shown in Eq. (4),

$$\frac{E(\mathrm{FP})}{E(R_2)} = \frac{E\left(\frac{\mathrm{FP}}{T_1}\right)}{E\left(\frac{\mathrm{FP}}{T_1}+(1-\frac{\mathrm{FN}}{T_2})\frac{T_2}{T1}\right)} = \frac{E\left(\frac{\mathrm{FP}}{T_1}\right)}{E\left(\frac{\mathrm{FP}}{T_1}\right)+\left(1-E\left(\frac{\mathrm{FN}}{T_2}\right)\right)\frac{T_2}{T_1}} = \frac{\alpha}{\alpha+(1-\beta)\frac{T_2}{T_1}}, \tag{4}$$

where α and β are the type I error rate and the type II error rate respectively. A sufficient condition for $E(\mathrm{FP})/E(R_2)$ being a monotonically increasing function of the type I error rate includes (I) $(1-\beta)/\alpha > \partial(1-\beta)/\partial\alpha$, (II) $T_1 > 0$ and (III) $T_2 > 0$, where $\partial(1-\beta)/\partial\alpha$ is the derivative of $(1-\beta)$ over α. If $(1-\beta)$, regarded as a function of α, is a concave curve from $(0,0)$ to $(1,1)$, then condition (I) is satisfied. Recall that $(1-\beta)$ versus α actually is the receiver operating characteristic (ROC) curve, and that with an appropriate statistic the ROC curve of a hypothesis test is usually a concave curve from $(0,0)$ to $(1,1)$, we speculate that condition (I) is not difficult to satisfy. With the other two mild conditions (II) $T_1 > 0$ and (III) $T_2 > 0$, we could expect that $E(\mathrm{FP})/E(R_2)$ is a monotonically increasing function of α. $E(\mathrm{FP})/E(R_2)$ is the ratio of the expected values of two random variables, while $E(\mathrm{FP}/R_2)$ is the expected value of the ratio of two random variables. Generally, there is not a monotonic relationship between $E(\mathrm{FP})/E(R_2)$ and $E(\mathrm{FP}/R_2)$. Nevertheless, if the average number of false positives, $E(\mathrm{FP})$, increases proportionally faster than that of the accepted positives, $E(R_2)$, we speculate that under certain conditions, the FDR = $E(\mathrm{FP}/R_2)$ also increases accordingly. Thus the FDR may be a monotonically increasing function of the threshold α of the type I error rate for the PC-skeleton algorithm.

However, even though the FDR of the PC-skeleton algorithm may decrease as the pre-defined significant level α decreases, the FDR of the PC-skeleton algorithm still cannot be controlled at the user-specified level for general problems by "smartly" choosing an α beforehand, but somehow has to be controlled in a slightly different way, such as the PC$_{\mathrm{fdr}}$-skeleton algorithm does. First, the value of such an α for the FDR control depends on the true graph, but unfortunately the graph is unknown in problems of structure learning. According to Eq. (2), the realized FDR is a function of the realized type I and type II error rates, as well as T_2/T_1, which in the context of structure learning is the ratio of the number of true connections to the number of non-existing connections. Since

T_2/T_1 is unknown, such an α cannot be determined completely in advance without any information about the true graph, but has to be estimated practically from the observed data. Secondly, the FDR method we employ is such a method that estimates the α from the data to control the FDR of multiple hypothesis testing. The output of the FDR algorithm is the rejection of those null hypotheses associated with p-values $p_{(1)}, \ldots, p_{(i)}$ (see Algorithm 2). Given $p_{(1)} \leq \ldots \leq p_{(H)}$, the output is equivalent to the rejection of all those hypotheses whose p-values are smaller than or equal to $p_{(i)}$. In other words, it is equivalent to setting $\alpha = p_{(i)}$ in the particular multiple hypothesis testing. Thirdly, the PC$_{\text{fdr}}$-skeleton algorithm is a valid solution to combining the FDR method with the PC-skeleton algorithm. Because the estimation of the α depends on p-values, and p-values are calculated one by one as the PC-skeleton algorithm progresses with hypothesis tests, the α cannot be estimated separately before the PC-skeleton algorithm starts running, but the estimation has to be embedded within the algorithm, like in the PC$_{\text{fdr}}$-skeleton algorithm.

Another idea on the FDR control in structure learning is a two-stage algorithm. The first stage is to draft a graph that correctly includes all the existing edges and their orientations but may also include non-existing edges as well. The second stage is to select the real parents for each vertex, with the FDR controlled, from the set of potential parents determined in the first stage. The advantage of this algorithm is that the selection of real parent vertices in the second stage is completely decoupled from the determination of edge orientations, because all the parents of each vertex have been correctly connected with the particular vertex in the first stage. However, a few concerns about the algorithm should be noticed before researchers start developing this two-stage algorithm. First, to avoid missing many existing edges in the first stage, a considerable number of non-existing edges may have to be included. To guarantee a perfect protection of the existing edges given any randomly sampled data, the first stage must output a graph whose skeleton is a fully connected graph. The reason for this is that the type I error rate and the type II error rate contradict each other and the latter reaches zero generally when the former approaches one (see Appendix C). Rather than protecting existing edges perfectly, the first stage should trade off between the type I and the type II errors, in favour of keeping the type II error rate low. Second, selecting parent vertices from a set of candidate vertices in the second stage, in certain sense, can be regarded as learning the structure of a sub-graph locally, in which error-rate control remains as a crucial problem. Thus erro-rate control is still involved in both of the two stages. Though this two-stage idea may not essentially reduce the problem of the FDR control to an easier task, it may break the big task of simultaneously learning all edges to many local structure-learning tasks.

3. Empirical Evaluation

The PC$_{\text{fdr}}$-skeleton algorithm and its heuristic modification are evaluated with simulated data sets, in comparison with the PC-skeleton algorithm, in the sense of the FDR, the type I error rate and the power. The PC$_{\text{fdr}}$-skeleton and the PC-skeleton algorithms are also applied to two real functional-magnetic-resonance-imaging (fMRI) data sets, to check whether the two algorithms correctly curb the error rates that they are supposed to control in real world applications.

3.1 Simulation Study

The simulated data sets are generated from eight different DAGs, shown in Figure 1, with the number of vertices N = 15, 20, 25 or 30, and the average degree of vertices D = 2 or 3. The DAGs are generated as follows:

(1) Sample $\frac{N \times D}{2}$ undirected edges from $\{a \sim b | a, b \in V \text{ and } a \neq b\}$ with equal probabilities and without replacement to compose an undirected graph $G^{\sim}_{true}$.

(2) Generate a random order $\succ$ of vertices with permutation.

(3) Orientate the edges of $G^{\sim}$ according to the order $\succ$. If a is before b in the order $\succ$, then orientate the edge $a \sim b$ as $a \rightarrow b$. Denote the orientated graph as a DAG G_{true}.

For each DAG, we associate its vertices with (conditional) binary probability distributions as follows, to extend it to a Bayesian network.

(1) Specify the strength of (conditional) dependence as a parameter $\delta > 0$.

(2) Randomly assign each vertex $a \in V$ with a dependence strength $\delta_a = 0.5\delta$ or -0.5δ, with equal possibilities.

(3) Associate each vertex $a \in V$ with a logistic regression model

$$\begin{aligned} \Delta &= \sum_{b \in \text{pa}[a]} X_b \delta_b, \\ P(X_a = 1 | X_{\text{pa}[a]}) &= \frac{\exp(\Delta)}{1 + \exp(\Delta)}, \\ P(X_a = -1 | X_{\text{pa}[a]}) &= \frac{1}{1 + \exp(\Delta)}, \end{aligned}$$

where pa$[a]$ denotes the parent vertices of a.

The parameter δ reflects the strength of dependence because if the values of all the other parent variables are fixed, the difference between the conditional probabilities of a variable $X_a = 1$ given a parent variable $X_b = 1$ and -1 is

$$\left| \text{logit}[P(X_a = 1 | X_b = 1, X_{\text{pa}[a] \setminus \{b\}})] - \text{logit}[P(X_a = 1 | X_b = -1, X_{\text{pa}[a] \setminus \{b\}})] \right| = |2\delta_b| = \delta,$$

where the logit function is defined as $\text{logit}(x) = \log(\frac{x}{1-x})$.

Since the accuracy of the PC-skeleton algorithm and its FDR versions is related to the discriminability of the statistical tests, we generated data with different values of δ (δ= 0.5, 0.6, 0.7, 0.8, 0.9 and 1.0) to evaluate the algorithms' performances with different power of detecting conditional dependence. The larger the absolute value of δ is, the easier the dependence can be detected with statistical tests. Because statistical tests are abstract queries yielding p-values about conditional independence for the structure-learning algorithms, the accuracy of the algorithms is not determined by the particular procedure of a statistical test, or a particular family of conditional probability distributions but by the discriminability of the statistical tests. Given a fixed sample size, the stronger the conditional-dependence relationships are, the higher discriminability the statistical tests have. By varying the dependence strength δ of the *binary* conditional probability distributions, we have varied the discriminability of the statistical tests, as if by varying the dependence strength of *other* probability distribution families. To let the readers intuitively understand the dependence strength of these δ values, we list as follows examples of probability pairs whose logit contrasts are equal to these δ values:

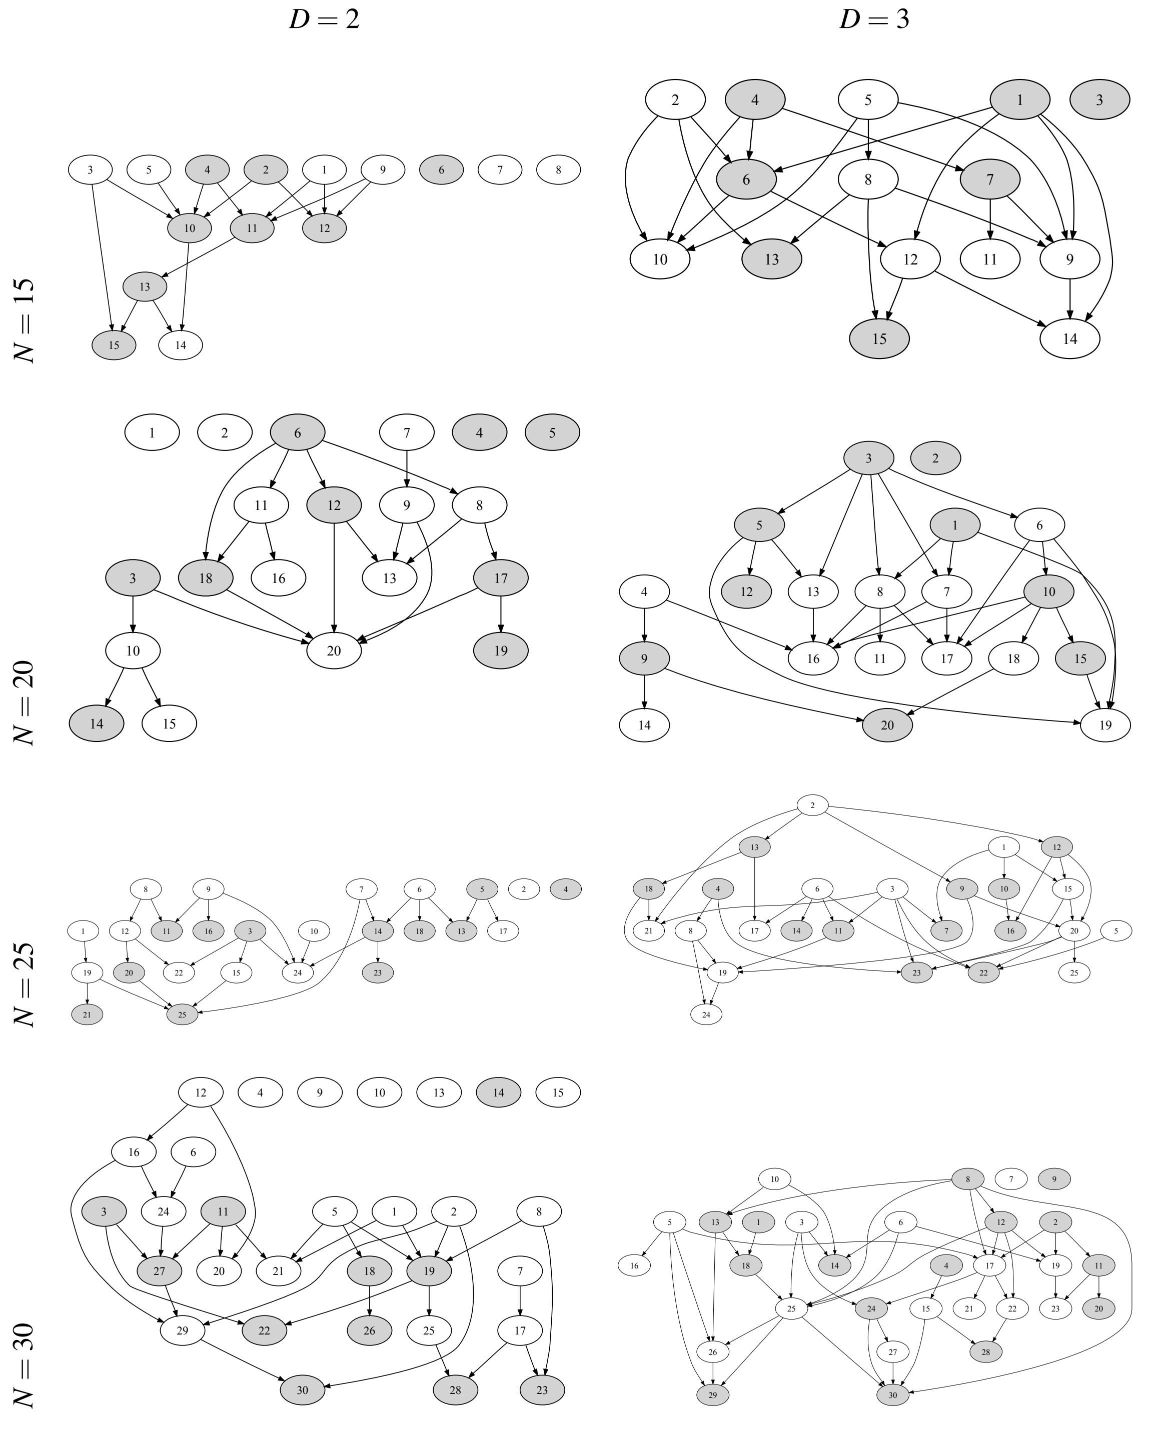

Figure 1: DAGs used in the simulation study. N denotes the number of vertices and D denotes the average degree of the vertices. Unshaded vertices are associated with positive dependence strength 0.5δ, and shaded ones are associated with negative dependence strength -0.5δ.

$$0.5 = \text{logit}(0.5622) - \text{logit}(0.4378), \quad 0.6 = \text{logit}(0.5744) - \text{logit}(0.4256),$$
$$0.7 = \text{logit}(0.5866) - \text{logit}(0.4134), \quad 0.8 = \text{logit}(0.5987) - \text{logit}(0.4013),$$
$$0.9 = \text{logit}(0.6106) - \text{logit}(0.3894), \quad 1.0 = \text{logit}(0.6225) - \text{logit}(0.3775).$$

.

In total, we performed the simulation with 48 Bayesian networks generated with all the combinations of the following parameters:

$$\begin{aligned} N &= 15, 20, 25, 30; \\ D &= 2, 3; \\ \delta &= 0.5, 0.6, 0.7, 0.8, 0.9, 1.0. \end{aligned}$$

From each Bayesian network, we repetitively generated 50 data sets each of 500 samples to estimate the statistical performances of the algorithms. A non-model-based test, the Cochran-Mantel-Haenszel (CMH) test (see Agresti, 2002, pages 231–232), was employed to the test conditional independence among random variables. Both the significant level α of the PC-skeleton algorithm and the FDR level q of the PC$_{\text{fdr}}$-skeleton algorithm and its heuristic modification were set at 5%.

Figures 2, 3 and 4 respectively show the empirical FDR, power and type I error rate of the algorithms, estimated from the 50 data sets repetitively generated from each Bayesian network, with error bars indicating the 95% confidence intervals of these estimations. The PC$_{\text{fdr}}$-skeleton algorithm controls the FDR under the user-specified level 5% for all the 48 Bayesian networks, and the PC$_{\text{fdr*}}$-skeleton algorithm steadily controls the FDR closely around 5%, while the PC-skeleton algorithm yields the FDR ranging from about 5% to about 35%, and above 15% in many cases, especially for those sparser DAGs with the average degree of vertices $D = 2$. The PC$_{\text{fdr}}$-skeleton algorithm is conservative, with the FDR notably lower than the user-specified level, while its heuristic modification controls the FDR more accurately around the user-specified level, although the correctness of the heuristic modification has not been theoretically proved. As the discriminability of the statistical tests increases, the power of all the algorithms approaches 1. When their FDR level q is set at the same value as the α of the PC-skeleton algorithm, the PC$_{\text{fdr}}$-skeleton algorithm and its heuristic modification control the type I error rate more stringently than the PC-skeleton algorithm does, so their power generally is lower than that of the PC-skeleton algorithm. Figure 4 also clearly shows, as Eq. 3 implies, that it is the type I error rate, rather than the FDR, that the PC-skeleton algorithm controls under 5%.

Figure 5 shows the average computational time spent during each run of the PC$_{\text{fdr}}$-skeleton algorithm and its heuristic modification on the statistical tests of (conditional) independence at step 8 and the FDR control at step 12. The computational time was estimated on the platform of an Intel Xeon 1.86GHz CPU and 4G RAM, and with the code implemented in Matlab R14. Tables 3 and 4 show the average ratios of the computational time spent on the FDR control to that spent on the statistical tests. The average ratios are not more than 2.57‰ for all the 48 Bayesian networks. The relatively small standard deviations, as shown in brackets in the tables, indicate that these estimated ratios are trustful. Because the PC$_{\text{fdr}}$-skeleton algorithm and its heuristic modification employ the same search strategy as the PC-skeleton algorithm does, this result evidences that the extra computation cost to achieve the control over the FDR is trivial in comparison with the computation already spent by the PC-skeleton algorithm on statistical tests.

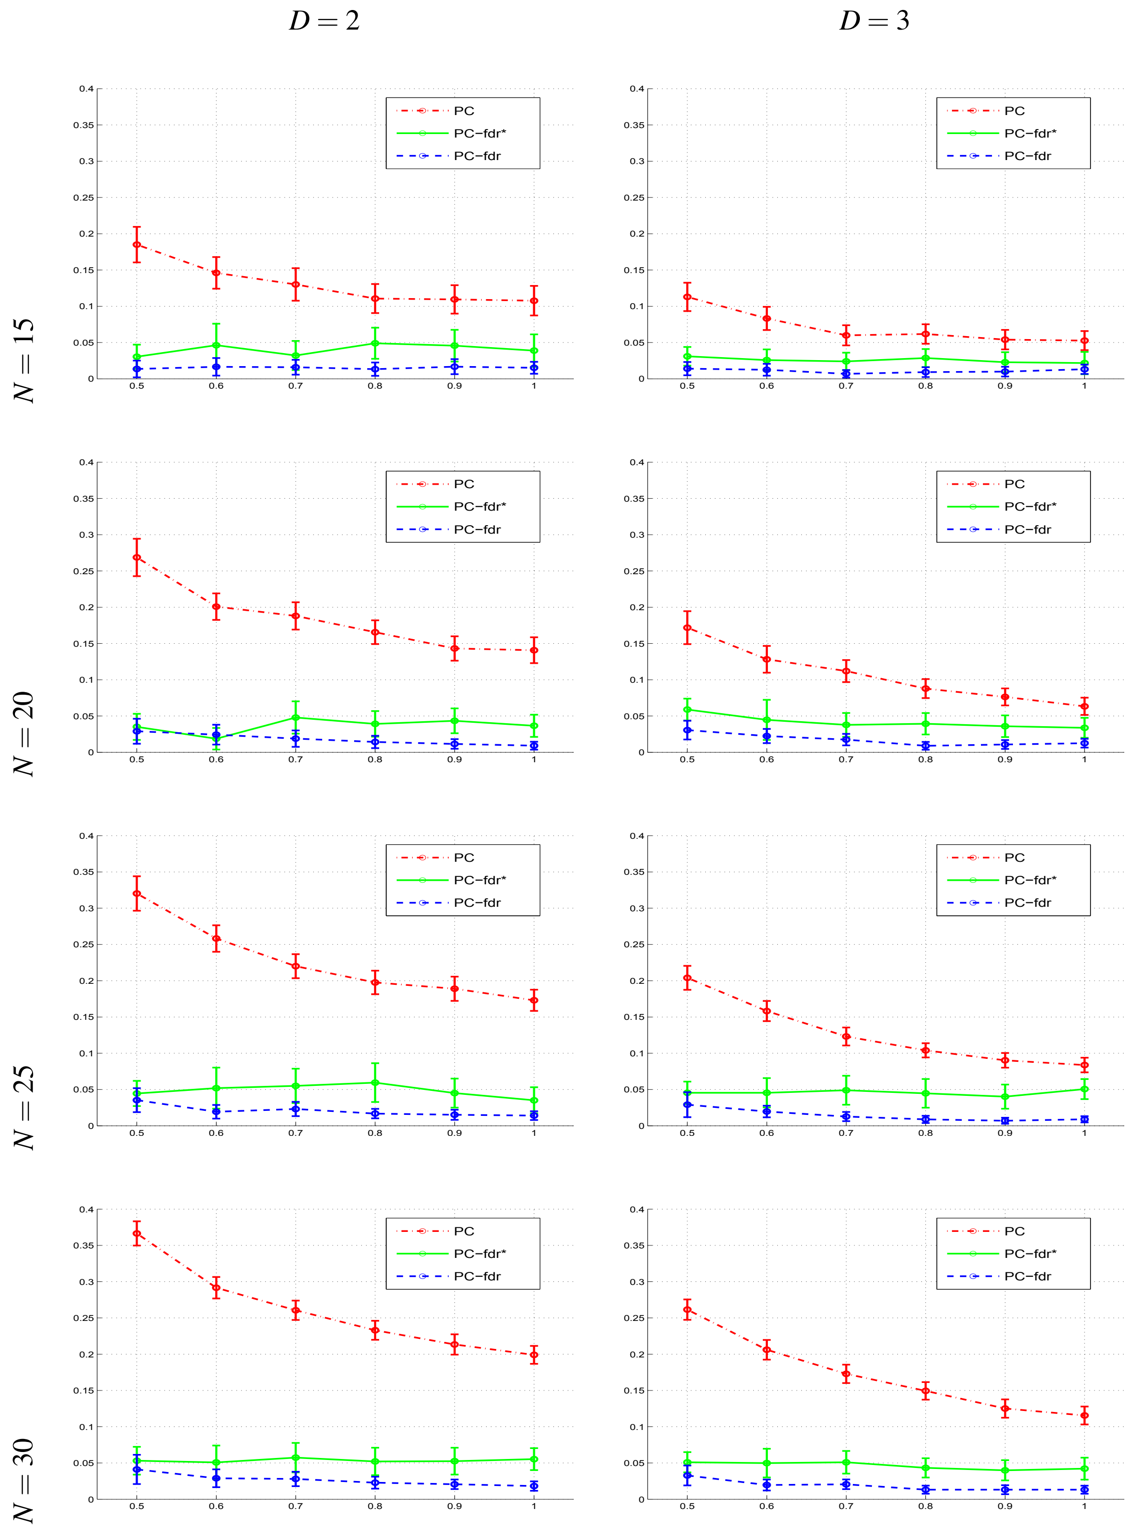

Figure 2: The FDR (with 95% confidence intervals) of the PC-skeleton algorithm, the PC_{fdr}-skeleton algorithm and the $\text{PC}_{\text{fdr}*}$-skeleton algorithm on the DAGs in Figure 1, as the dependence parameter δ shown on the x-axes increases from 0.5 to 1.0.

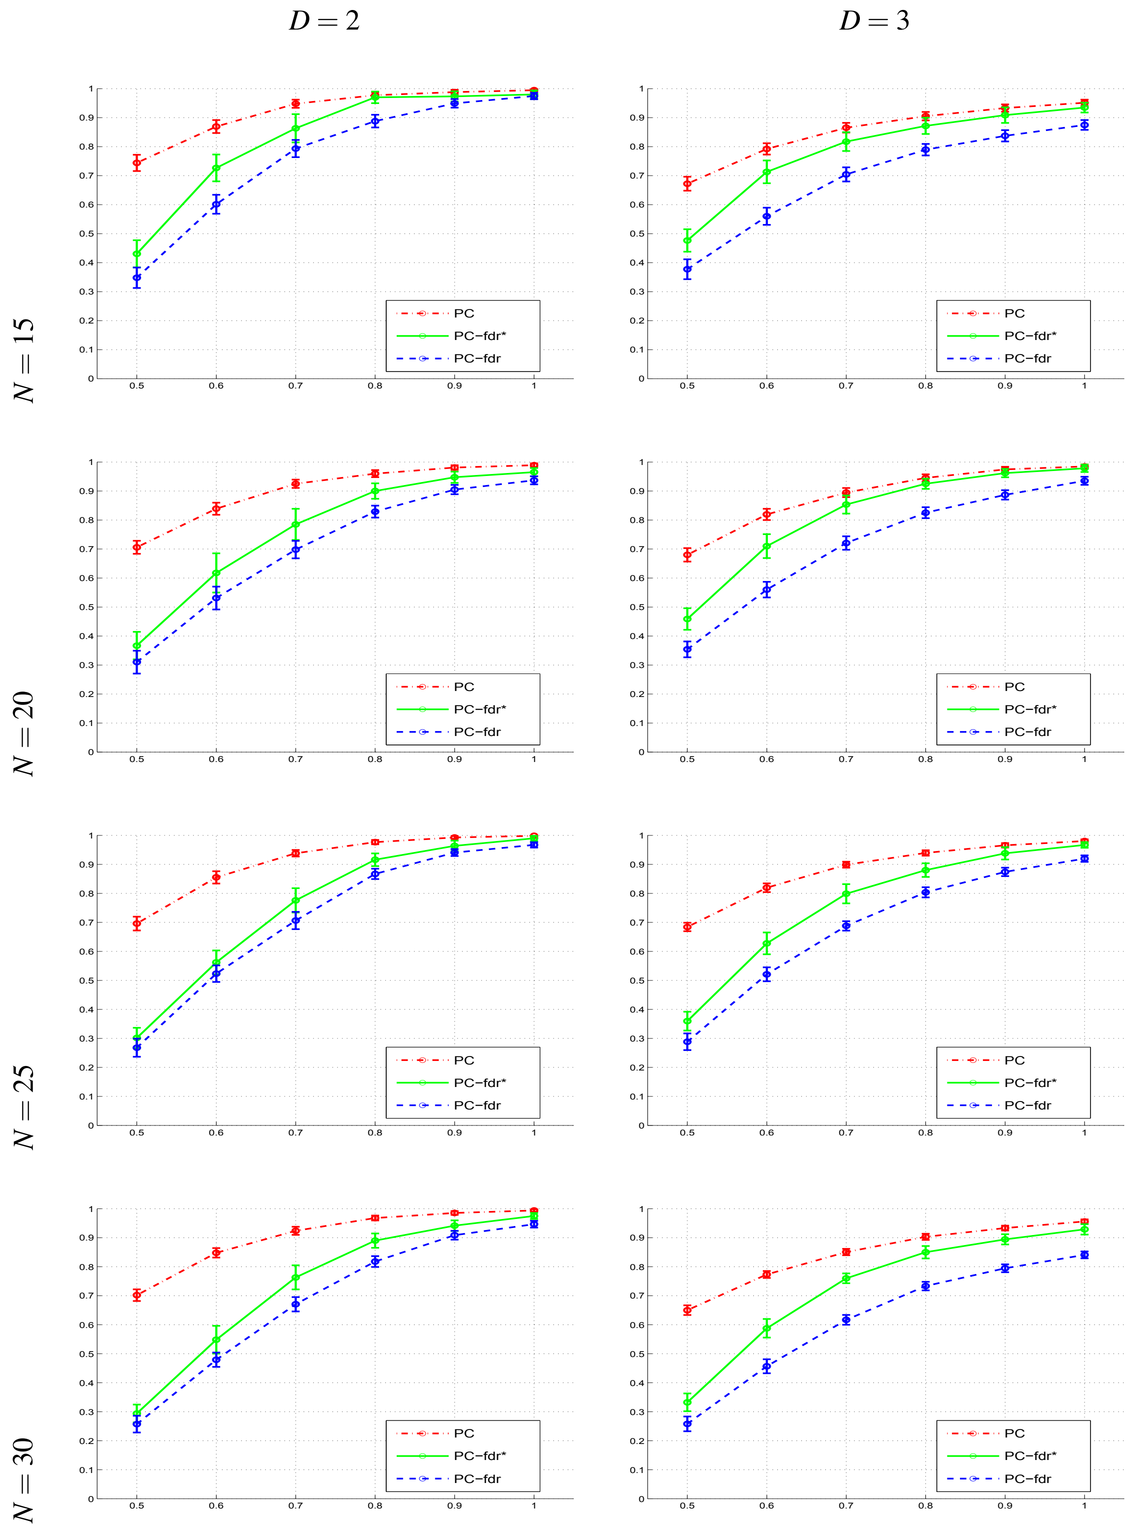

Figure 3: The power (with 95% confidence intervals) of the PC-skeleton algorithm, the $\mathrm{PC_{fdr}}$-skeleton algorithm and the $\mathrm{PC_{fdr*}}$-skeleton algorithm on the DAGs in Figure 1, as the dependence parameter δ shown on the x-axes increases from 0.5 to 1.0.

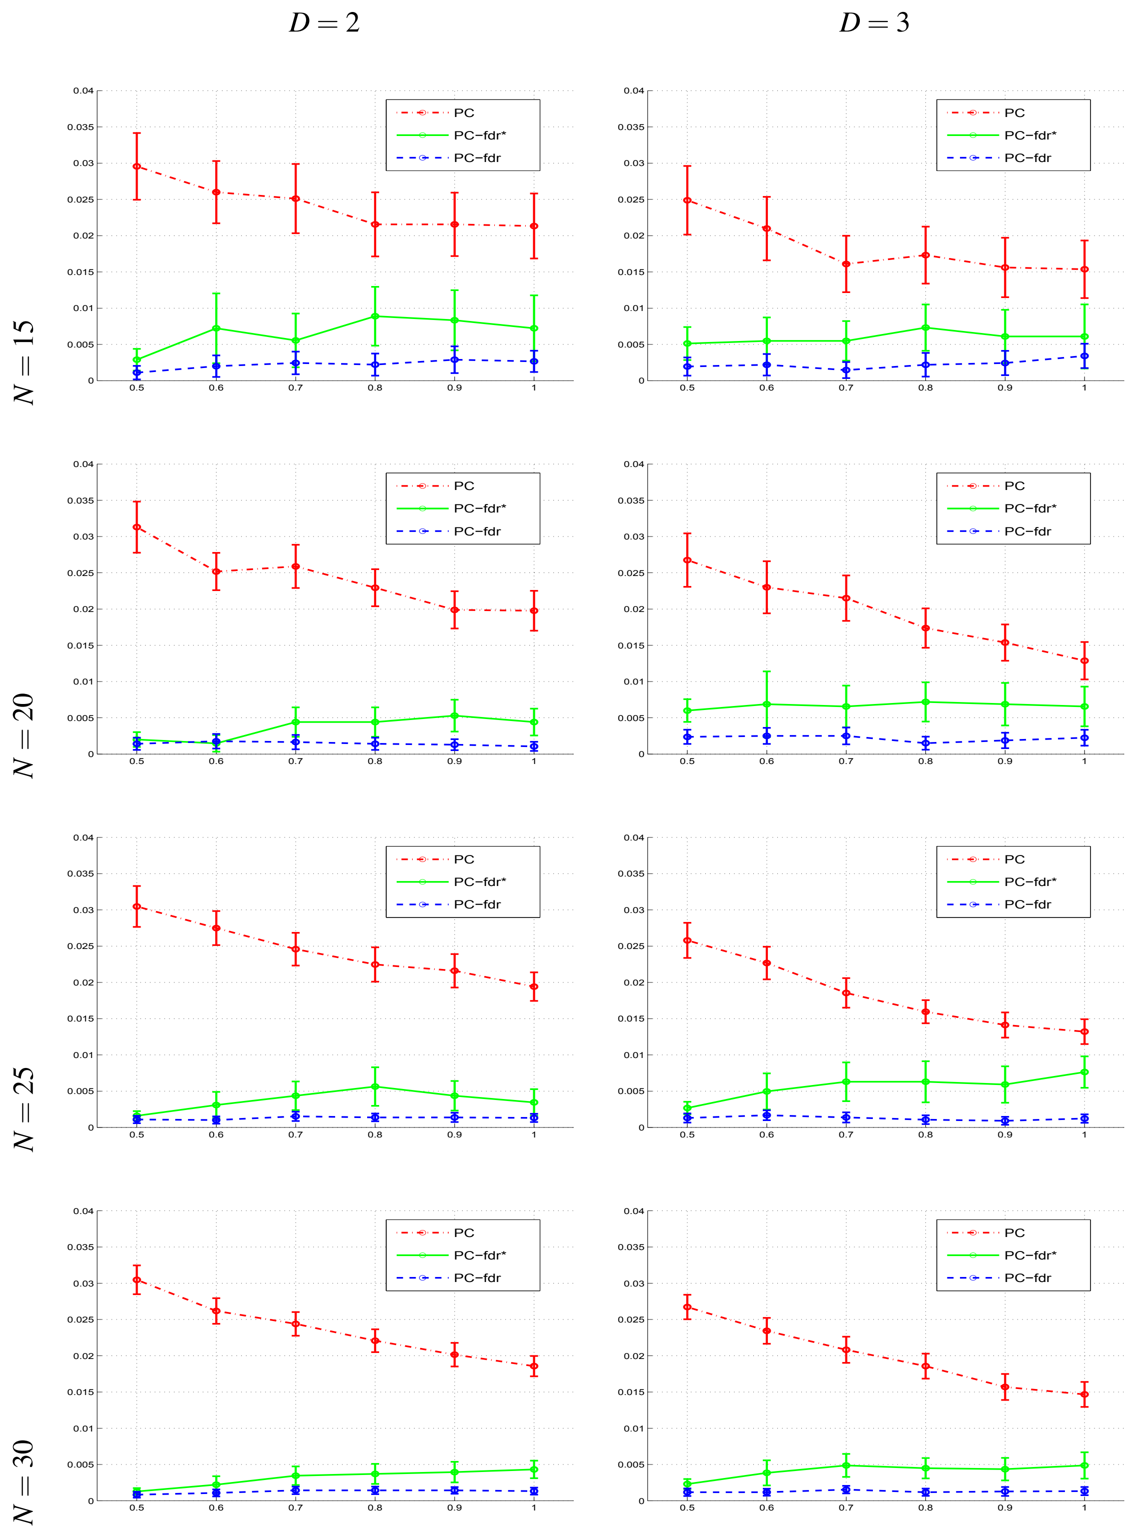

Figure 4: The type I error rates (with 95% confidence intervals) of the PC-skeleton algorithm, the PC_{fdr}-skeleton algorithm and the PC_{fdr*}-skeleton algorithm on the DAGs in Figure 1, as the dependence parameter δ shown on the x-axes increases from 0.5 to 1.0.

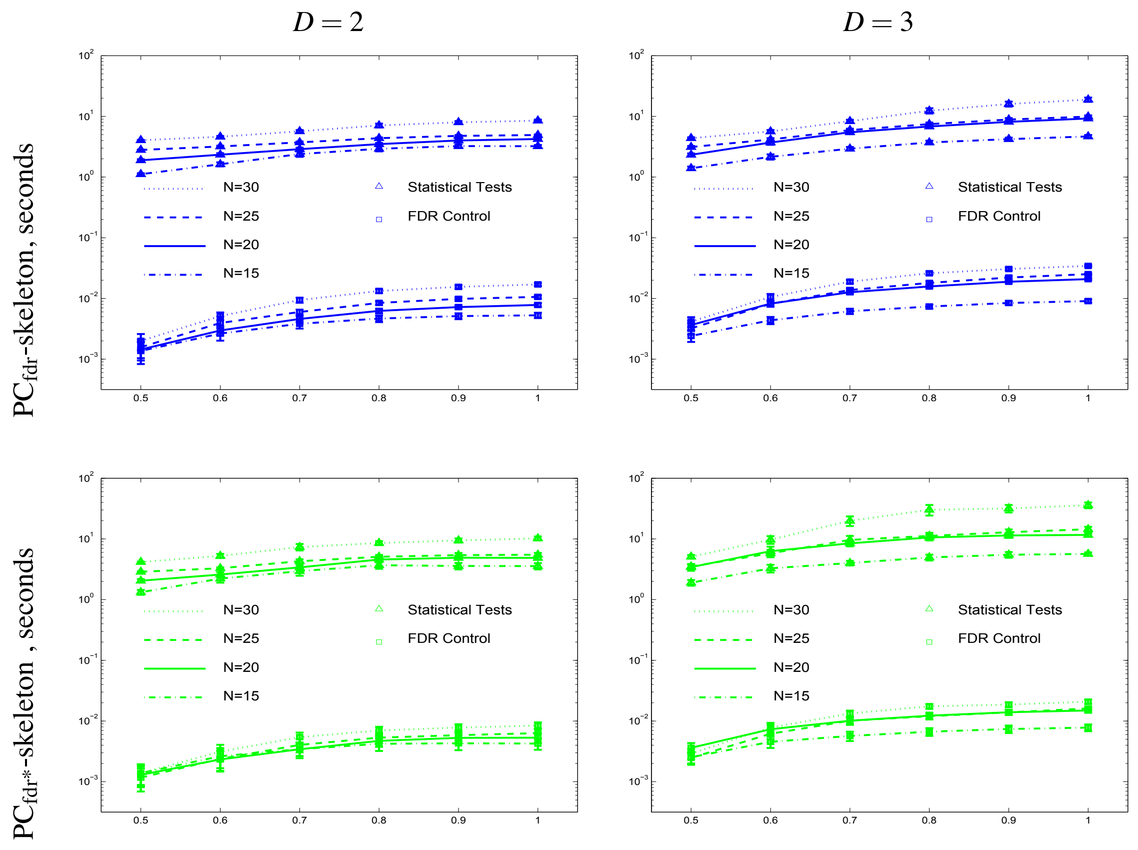

Figure 5: The average computational time (in seconds, with 95% confidence intervals) spent on the FDR control and statistical tests during each run of the PC$_{\text{fdr}}$-skeleton algorithm and its heuristic modification.

3.2 Applications to Real fMRI Data

We applied the PC_{fdr}-skeleton and the PC-skeleton algorithms to real-world research tasks, studying the connectivity network between brain regions using functional magnetic resonance imaging (fMRI). The purpose of the applications is to check whether the two algorithms correctly curb the error rates in real world applications. The purpose of the applications is not, and also should not be, to answer the question "which algorithm, the PC_{fdr}-skeleton or the PC-skeleton, is superior?", for the following reasons. Basically, the two algorithms control different error rates between which there is not a superior relationship (see Appendix C). Secondly, the error rate of interest for a specific application is selected largely not by mathematical superiority, but by researchers' interest and the scenario of research (see Appendix C). Thirdly, the simulation study has clearly revealed the properties of and the differences (not superiority) between the two algorithms. Lastly, the approximating graphical models behind the real fMRI data are unknown, so the comparison on the real fMRI data is rough, rather than rigorous.

The two algorithms were applied to two real fMRI data sets, one including 11 discrete variables and 1300 observations, and the other including 25 continuous variables and 1098 observations. The first data set, denoted by "the bulb-squeezing data set", was collected from 10 healthy subjects each of whom was asked to squeeze a rubber bulb with their left hand at three different speeds or at a constant force, as cued by visual instruction. The data involve eleven variables: the speed of squeezing and the activities of the ten brain regions listed in Table 5. The speed of squeezing is coded as a discrete variable with four possible values: the high speed, the medium speed, the low speed, and the constant force. The activities of the brain regions are coded as discrete variables with three possible values: high activation, medium activation and low activation. The data of each subject include 130 time points. The data of the ten subjects are pooled together, so in total there are 1300 time points. For details of the data set, please refer to Li et al. (2008).

The second data set, denoted by "the sentence-picture data set", was collected from a single subject performing a cognitive task. In each trial of the task, the subject was shown in sequence an affirmative sentence and a simple picture, and then answered whether the sentence correctly

described the picture. In half of the trials, the picture was presented first, followed by the sentence. In the remaining trials, the sentence was presented first, followed by the picture. The data involve the activities of 25 brain regions, as listed in Table 6, encoded as continuous variables, at 1098 time points. For details of the data set, please refer to Keller et al. (2001) and Mitchell et al. (2004).

The PC_{fdr}-skeleton and the PC-skeleton algorithms were applied to both the bulb-squeezing and the sentence-picture data sets. Both the FDR level q of the PC_{fdr}-skeleton algorithm and the type-I-error-rate level α of the PC-skeleton algorithm were set at 5%. For the bulb-squeezing data set, all of whose variables are discrete, conditional independence was tested with Pearson's Chi-square test; for the sentence-picture data set, all of whose variables are continuous, conditional independence was tested with the t-test for partial correlation coefficients (Fisher, 1924).

The networks learned from the bulb-squeezing data set and the networks learned from the sentence-picture data set are shown in Figures 6 and 7 respectively. For ease of comparison, the

PC_{fdr}	39	$\frac{25*(25-1)}{2}-39=261$	39	3	**7.14%**	1.14%
PC			39	12	23.5%	**4.60%**

Table 7: The *realized* error rates of the PC_{fdr}-skeleton and the PC algorithms on the bulb-squeezing and sentence-picture data sets, under the TI assumption that all and only those connections detected by both of the two algorithms truly exist.

networks learned by the two algorithms are overlaid. Thin solid black edges are those connections detected by both the two algorithms; thin dashed blue edges are those detected only by the PC_{fdr}-skeleton algorithm; thick solid red edges are those detected only by the PC-skeleton algorithm. In Figure 6, there are 17 thin solid black edges, 0 thin dashed blue edge and 1 thick solid red edge; in Figure 7, there are 39 thin solid black edges, 3 thin dashed blue edges and 12 thick solid red edges.

The results intuitively, though not rigorously, support our expectation of the performances of the two algorithms in real world applications. First, since the data sets are relatively large, with the sample sizes more than 1000, it is expected that both algorithms will recover many of the existing connections, and consequently the networks recovered by the two algorithms may share many common connections. This is consistent with the fact that in Figures 6 and 7 there are many thin solid black edges, that is, the connections recovered by both algorithms.

Second, since the PC_{fdr}-skeleton algorithm is designed to control the FDR while the PC-skeleton algorithm to control the type I error rate, it is expected that the two algorithms will control the corresponding error rate under or around the pre-defined level, which is 5% in this study. To verify whether the error rates were controlled as expected, we need to know which connections really exist and which do not. Unfortunately, this is very difficult for real data sets, because unlike the simulated data, the true models behind the real data are unknown, and in the literature, researchers usually tend to report evidences supporting the existence of connections rather than supporting the non-existence. However, since the sample sizes of the two data sets are relatively large, more than 1000, we can speculate that both of the two algorithms have recovered most of the existing connections. Extrapolating this speculation a bit, we intuitively assume that those connections detected by both of the two algorithms truly exist while all the others do not. In other words, we assume that all and only the thin black edges in the figures truly exist. We refer to this assumption as the "True Intersection" (TI) assumption. The statistics about Figures 6 and 7, under the TI assumption, are listed in Table 7. The *realized* FDR of the PC_{fdr}-skeleton algorithm on the bulb-squeezing and sentence-picture data sets are 0.00% and 7.14%, respectively; the *realized* type I error rate of the PC-skeleton algorithm on the bulb-squeezing and sentence-picture data sets are 2.63% and 4.60%, respectively. Considering that the *realized* error rate, as a statistic extracted from just a trial, may slightly deviate from its expected value, these results, derived under the TI assumption, support that the two algorithms controlled the corresponding error rate under the pre-defined level 5%.

Third, according to Eq. (2), the sparser and the larger the true network is, the higher the FDR of the PC-skeleton algorithm will be. For the bulb-squeezing data set, there are 11 vertices, and under the TI assumption, 17 existing connections and 38 non-existing connections. In this case, the *realized* FDR of the PC-skeleton algorithm is only 5.56% (Table 7). For the sentence-picture data set, there are 25 vertices, and under the TI assumption, 39 existing connections and 261 non-existing connections. In this case, the *realized* FDR of the PC-skeleton algorithm rises to 23.5% (Table 7). This notable increase of the *realized* FDR is consistent with the prediction based on Eq. (2).

It should be noted that the preceding arguments are rough rather than rigorous, since they are based on the TI assumption rather than the true models behind the data. However, because the true models behind the real data are unknown, the TI assumption is a practical and intuitive approach to assess the performance of the two algorithms in the two real world applications.

4. Conclusions and Discussions

We have proposed a modification of the PC algorithm, the $\mathrm{PC_{fdr}}$-skeleton algorithm, to curb the false discovery rate (FDR) of the skeleton of the learned Bayesian networks. The FDR-control procedure embedded into the PC algorithm collectively considers the hypothesis tests related to the existence of multiple edges, correcting the effect of multiple hypothesis testing. Under mild assumptions, it is proved that the $\mathrm{PC_{fdr}}$-skeleton algorithm can control the FDR under a user-specified level q ($q > 0$) at the limit of large sample sizes (see Theorem 2). In the cases of moderate sample size (about several hundred), empirical experiments have shown that the method is still able to control the FDR under the user-specified level. The $\mathrm{PC_{fdr*}}$-skeleton algorithm, a heuristic modification of the proposed method, has shown better performance in the simulation study, steadily controlling the FDR closely around the user-specified level and gaining more detection power, although its asymptotic performance has not been theoretically proved. Both the $\mathrm{PC_{fdr}}$-skeleton algorithm and its heuristic modification can asymptotically recover all the edges of the true DAG (see Theorem 1). The idea of controlling the FDR can be extended to other constraint-based methods, such as the inductive causation (IC) algorithm (see Pearl, 2000, pages 49–51) and the fast-causal-inference (FCI) algorithm (see Spirtes et al., 2001, pages 142–146).

The simulation study has also shown that the extra computation spent on achieving the FDR control is almost negligible when compared with that already spent by the PC algorithm on statistical tests of conditional independence. The computational complexity of the new algorithm is closely comparable with that of the PC algorithm.

As a modification based on the PC algorithm, the proposed method is modular, consisting of the PC search strategy, statistical tests of conditional independence and an FDR-control procedure. Different statistical tests and FDR-control procedures can be “plugged in”, depending on the data type and the statistical model. Thus, the method is applicable to any models for which statistical tests of conditional independence are available, such as discrete models and Gaussian models.

It should be noted that the $\mathrm{PC_{fdr}}$-skeleton algorithm is not proposed to replace the PC-skeleton algorithm. Instead, it provides an approach to controlling the FDR, a certain error-rate criterion for testing the existence of multiple edges. When multiple edges are involved in structure learning, there are different applicable error-rate criteria, such as those listed in Table 2. The selection of these criteria depends on researchers’ interest and the scenarios of studies, which is beyond the scope of this paper. When the FDR is applied, the PC$_{\text{fdr}}$-skeleton algorithm is preferable; when the type I error rate is applied, the PC-skeleton algorithm is preferable. The technical difference between the two algorithms is that the PC$_{\text{fdr}}$-skeleton algorithm adaptively adjusts the type I error rate according to the sparseness of the network to achieve the FDR control, while the PC-skeleton algorithm fixes the type I error rate.

Currently the FDR control is applied only to the skeleton of the graph, but not to the directions of the edges yet. The final output of the PC algorithm is a partially directed acyclic graph that uniquely represents an equivalence class of DAGs, so a possible improvement for the PC$_{\text{fdr}}$-skeleton algorithm is to extend the FDR control to the directions of the recovered edges. Because both type I and type II errors may lead to wrong directions in the later steps of the PC algorithm, minimizing direction errors may lead to a related, yet different, error-control task.

The asymptotic performance of the PC$_{\text{fdr}}$-skeleton algorithm has only been proved under the assumption that the number of vertices is fixed. Its behavior when both the number of vertices and the sample size approach infinity has not been studied yet. Kalisch and Bühlmann (2007) proved that for Gaussian Bayesian networks, the PC algorithm consistently recovers the equivalence class of the underlying sparse DAG, as the sample size m approaches infinity, even if the number of vertices N grows as quickly as $O(m^{\lambda})$ for any $0 < \lambda < \infty$. Their idea is to adaptively decrease the type I error rate α of the PC-skeleton algorithm as both the number of vertices and the sample size increase. It is desirable to study whether similar behavior can be achieved with the PC$_{\text{fdr}}$-skeleton algorithm if the FDR level q is adjusted appropriately as the sample size increases.

A Matlab® package of the PC$_{\text{fdr}}$-skeleton algorithm and its heuristic modification is downloadable at www.junningli.org/software.

The authors thank Dr. Martin J. McKeown for sharing the functional magnetic resonance imaging (fMRI) data (Li et al., 2008) and helpful discussions.

Appendix A. Proof of Theorems

To assist the reading, we list below notations frequently used in the proof:

$G^{\sim}_{true}$: the skeleton of the true underlying Bayesian network.

$\mathcal{A}_{a\sim b}$: the event that edge $a \sim b$ is in the graph recovered by the PC$_{\text{fdr}}$-skeleton algorithm.

$\mathcal{A}_{E^{\sim}_{true}}$: $\mathcal{A}_{E^{\sim}_{true}} = \bigcap_{a\sim b \in E^{\sim}_{true}} \mathcal{A}_{a\sim b}$, the joint event that all the edges in $G^{\sim}_{true}$, the skeleton of the true DAG, are recovered by the PC$_{\text{fdr}}$-skeleton algorithm.

$E^{\nsim}_{true}$: the set of the undirected edges that are not in $G^{\sim}_{true}$.

$p_{a\sim b}$: the value of $p^{max}_{a\sim b}$ when the PC$_{\text{fdr}}$-skeleton algorithm stops.

$C^{*}_{a\sim b}$: a certain vertex set that d-separates a and b in G_{true} and that is also a subset of either $\text{adj}(a, G^{\sim}_{true}) \setminus \{b\}$ or $\text{adj}(b, G^{\sim}_{true}) \setminus \{a\}$, according to Proposition 1. $C^{*}_{a\sim b}$ is defined only for vertex pairs that are not adjacent in the true DAG G_{true}.

$p^*_{a\sim b}$: the p-value of testing $X_a \perp X_b | X_{C^*_{a\sim b}}$. The conditional-independence relationship may not be really tested during the process of the PC$_{\text{fdr}}$-skeleton algorithm, but $p^*_{a\sim b}$ can still denote the value as if the conditional-independence relationship was tested.

H^*: the value in Eq. (1) that is either H or $H(1+1/2,\ldots,+1/H)$, depending on the assumption of the dependency of the p-values.

Lemma 1 *If as m approaches infinity, the probabilities of K events $\mathcal{A}_i(m),\cdots,\mathcal{A}_K(m)$ approach 1 at speed*

$$P(\mathcal{A}_i(m)) = 1 - o(\beta(m))$$

where $\lim_{m\to\infty} \beta(m) = 0$ and K is a finite integer, then the probability of the joint of all these events approaches 1 at speed

$$P\left(\bigcap_{i=1}^{K} \mathcal{A}_i(m)\right) \geq 1 - Ko(\beta(m))$$

as m approaches infinity.

Proof

$\because \bigcap_{i=1}^{K} \mathcal{A}_i(m) = \overline{\bigcup_{i=1}^{K} \overline{\mathcal{A}}_i(m)}$.

$\therefore P\left(\bigcap_{i=1}^{K} \mathcal{A}_i(m)\right) = 1 - P\left(\bigcup_{i=1}^{K} \overline{\mathcal{A}}_i(m)\right) \geq 1 - \sum_{i=1}^{K} P(\overline{\mathcal{A}}_i(m))$

$= 1 - \sum_{i=1}^{K} [1 - P(\mathcal{A}_i(m))] = 1 - \sum_{i=1}^{K} o(\beta(m)) = 1 - Ko(\beta(m)).$ ■

Corollary 1 *If $\mathcal{A}_i(m),\cdots,\mathcal{A}_K(m)$ are a finite number of events whose probabilities each approach 1 as m approaches infinity:*

$$\lim_{m\to\infty} P(\mathcal{A}_i(m)) = 1,$$

then the probability of the joint of all these events approaches 1 as m approaches infinity:

$$\lim_{m\to\infty} P\left(\bigcap_{i=1}^{K} \mathcal{A}_i(m)\right) = 1.$$

Lemma 2 *If there are F ($F \geq 1$) false hypotheses among H tested hypotheses, and the p-values of the all the false hypotheses are smaller than or equal to $\frac{F}{H^*}q$, where H^* is either H or $H(1+1/2,\ldots,+1/H)$, depending on the assumption of the dependency of the p-values, then all the F false hypotheses will be rejected by the FDR procedure, Algorithm 2.*

Proof

Let p_i ($i = 1,\cdots,H$) denote the p-value of the ith hypothesis, p_f denote the maximum of the p-values of the F false hypotheses, and r_f denote the rank of p_f in the ascending order of $\{p_i\}_{i=1,\cdots,H}$.

$\because p_f$ is the maximum of the p-values of the F false hypotheses.

$\therefore r_f = |\{p_i | p_i \leq p_f\}| \geq F$.

$\therefore \frac{H^*}{r_f} p_f \leq \frac{H^*}{F} p_f$.

$\because p_f \leq \frac{F}{H^*}q$.
$\therefore \frac{H^*}{r_f}p_f \leq \frac{H^*}{F}p_f \leq q$.
$\therefore$ Hypotheses with p-values not greater than p_f will be rejected.
$\because$ The p-values of the F false hypotheses are not greater than p_f.
$\therefore$ All the F false hypotheses will be rejected by the FDR procedure, Algorithm 2. ■

Proof of **Theorem 1**
If there is not any edge in the true DAG G_{true}, then the proof is trivially $E^{\sim}_{true} = \emptyset \subseteq E^{\sim}$. In the following part of the proof, we assume $E^{\sim}_{true} \neq \emptyset$. For the PC$_{\text{fdr}}$-skeleton algorithm and its heuristic modification, whenever the FDR procedure, Algorithm 2, is invoked, $p^{max}_{a\sim b}$ is always less than $\max_{C \in V\setminus\{a,b\}}\{p_{a\perp b|C}\}$, and the number of p-values input to the FDR algorithm is always not more than C^2_N. Thus, according to Lemma 2, if

$$\max_{a\sim b\in E^{\sim}_{true}}\left\{\max_{C\in V\setminus\{a,b\}}\{p_{a\perp b|C}\}\right\} \leq \frac{|E^{\sim}_{true}|}{C^2_N\sum_{i=1}^{C^2_N}\frac{1}{i}}q, \tag{5}$$

then all the true connections will be recovered by the PC$_{\text{fdr}}$-skeleton algorithm and its heuristic modification. Let $\mathcal{A}'_{a\perp b|C}$ denote the event

$$p_{a\perp b|C} \leq \frac{|E^{\sim}_{true}|}{C^2_N\sum_{i=1}^{C^2_N}\frac{1}{i}}q,$$

$\mathcal{A}'_{E^{\sim}_{true}}$ denote the event of Eq. (5), and $\mathcal{A}_{E^{\sim}_{true}}$ denote the event that all the true connections are recovered by the PC$_{\text{fdr}}$-skeleton algorithm and its heuristic modification.
$\because \mathcal{A}'_{E^{\sim}_{true}}$ is a sufficient condition for $\mathcal{A}_{E^{\sim}_{true}}$, according to Lemma 2.
$\therefore \mathcal{A}_{E^{\sim}_{true}} \supseteq \mathcal{A}'_{E^{\sim}_{true}}$.
$\therefore P(\mathcal{A}_{E^{\sim}_{true}}) \geq P(\mathcal{A}'_{E^{\sim}_{true}})$.
$\because \mathcal{A}'_{E^{\sim}_{true}}$ is the joint of a limited number of events as

$$\mathcal{A}'_{E^{\sim}_{true}} = \bigcap_{a\sim b\in E^{\sim}_{true}}\ \bigcap_{C\subseteq V\setminus\{a,b\}} \mathcal{A}'_{a\perp b|C},$$

and $\lim_{m\to\infty} P(\mathcal{A}'_{a\perp b|C}) = 1$ according to Assumption (A3).
$\therefore$ According to Corollary 1, $\lim_{m\to\infty} P(\mathcal{A}'_{E^{\sim}_{true}}) = 1$.
$\therefore 1 \geq \lim_{m\to\infty} P(\mathcal{A}_{E^{\sim}_{true}}) \geq \lim_{m\to\infty} P(\mathcal{A}'_{E^{\sim}_{true}}) = 1$.
$\therefore \lim_{m\to\infty} P(\mathcal{A}_{E^{\sim}_{true}}) = 1$. ■

Lemma 3 *Given any FDR level $q > 0$, if the p-value vector $P = [p_1, \cdots, p_H]$ input to Algorithm 2 is replaced with $P' = [p'_1, \cdots, p'_H]$, such that (1) for the those hypotheses that are rejected when P is the input, p'_i is equal to or less than p_i, and (2) for all the other hypotheses, p'_i can be any value between 0 and 1, then the set of rejected hypotheses when P' is the input is a superset of those rejected when P is the input.*

Proof
Let R and R' denote the sets of the rejected hypotheses when P and P' are respectively input to the FDR procedure.

If $R = \emptyset$, then the proof is trivially $R' \supseteq \emptyset = R$.

If $R \neq \emptyset$, let us define $\alpha = \max_{i \in R} p_i$ and $\alpha' = \max_{i \in R} p'_i$. Let $r = |R|$ denote the rank of α in the ascending order of P and r' denote the rank of α' in the ascending order of P'.
$\because p'_i \leq p_i$ for all $i \in R$.
$\therefore \alpha' \leq \alpha$.
$\because \alpha' = \max_{i \in R} p'_i$.
$\therefore r' \geq |R| = r$.
$\because \frac{H^*}{r}\alpha \leq q$.
$\therefore \frac{H^*}{r'}\alpha' \leq \frac{H^*}{r}\alpha \leq q$.
$\therefore$ When P' is the input, hypotheses with p'_i smaller than or equal to α' will be rejected.
$\because p'_i \leq \alpha', \forall i \in R$.
$\therefore R \subseteq R'$, equivalently $R' \supseteq R$. ■

Corollary 2 *Given any FDR level $q > 0$, if the p-value vector $P = [p_1, \cdots, p_H]$ input to Algorithm 2 is replaced with $P' = [p'_1, \cdots, p'_H]$ such that $p'_i \leq p_i$ for all $i = 1, \cdots, H$, then the set of rejected hypotheses when P' is the input is a superset of those rejected when P is the input.*

Proof of **Theorem 2**
Let $E^{\sim}_{stop}$ and $E^{\nsim}_{stop}$ denote the undirected edges respectively recovered and removed by the PC$_{\text{fdr}}$-skeleton algorithm when the algorithm stops. Let sequence $P^{max}_1, \cdots, P^{max}_K$ denote the values of P^{max} when the FDR procedure is invoked at step 12 as the algorithm progresses, in the order of the update process of P^{max}, and let $E^{\nsim}_k$ denote the set of removable edges indicated by the FDR procedure, with P^{max}_k as the input. $E^{\nsim}_k$ may include edges that have already been removed.
$\because$ The PC$_{\text{fdr}}$-skeleton algorithm accumulatively removes edges in $E^{\nsim}_k$.
$\therefore E^{\nsim}_{stop} = \bigcup_{k=1}^{K} E^{\nsim}_k$.
$\because P^{max}$ is updated increasingly at step 10 of the algorithm.
$\therefore$ According to **Corollary 2**, $E^{\nsim}_1 \subseteq \cdots \subseteq E^{\nsim}_K$.
$\therefore E^{\nsim}_{stop} = \bigcup_{k=1}^{K} E^{\nsim}_k = E^{\nsim}_K$.

Let $P = \{p_{a \sim b}\}$ denote the value of P^{max} when the PC$_{\text{fdr}}$-skeleton algorithm stops.
$\because$ The FDR procedure is invoked whenever P^{max} is updated.
$\therefore$ The value of P^{max} does not change after the FDR procedure is invoked for the last time.
$\therefore P = P^{max}_K$.
$\therefore E^{\sim}_{stop}$ is the same as the edges recovered by directly applying the FDR procedure to P.

The theorem is proved through comparing the result of the PC$_{\text{fdr}}$-skeleton algorithm with that of applying the FDR procedure to a virtual p-value set constructed from P. The virtual p-value set P^* is defined as follows.

For a vertex pair $a \sim b$ that is not adjacent in the true DAG G_{true}, let $C^*_{a \sim b}$ denote a certain vertex set that d-separates a and b in G_{true} and that is also a subset of either $\text{adj}(a, G^{\sim}_{true}) \setminus \{b\}$ or

$\text{adj}(b, G^{\sim}_{true}) \setminus \{a\}$. Let us define $P^* = \{p^*_{a\sim b}\}$ as:

$$p^*_{a\sim b} = \begin{cases} p_{a\perp b|C^*_{a\sim b}} & : \quad a\sim b \in E^{\not\sim}_{true}, \\ p_{a\sim b} & : \quad a\sim b \in E^{\sim}_{true}. \end{cases}$$

Though $p_{a\perp b|C^*_{a\sim b}}$ may not be actually calculated during the process of the algorithm, $p_{a\perp b|C^*_{a\sim b}}$ still can denote the value as if it was calculated. Let us design a virtual algorithm, called $Algorithm^*$, that recovers edges by just applying the FDR procedure to P^*, and let $E^{\sim *}$ denote the edges recovered by this virtual algorithm. This algorithm is virtual and impracticable because the calculation of P^* depends on the unknown $E^{\sim}_{true}$, but this algorithm exists because $E^{\sim}_{true}$ exists. For any vertex pair a and b that is not adjacent in G_{true}:
$\because$ X_a and X_b are conditional independent given $X_{C^*_{a\sim b}}$.
$\therefore$ $p_{a\perp b|C^*_{a\sim b}}$ follows the uniform distribution on [0, 1].
$\therefore$ The FDR of $Algorithm^*$ is under q.

When all the true edges are recovered by the PC$_{\text{fdr}}$-skeleton algorithm, that is, $E^{\sim}_{true} \subseteq E^{\sim}_{stop}$, the conditional independence between X_a and X_b given $X_{C^*_{a\sim b}}$ is tested for all the falsely recovered edges $a\sim b \in E^{\not\sim}_{true} \bigcap E^{\sim}_{stop}$, because for these edges, subsets of $\text{adj}(a, G_{true}) \setminus \{b\}$ and subsets of $\text{adj}(a, G_{true}) \setminus \{b\}$ have been exhaustively searched and $C^*_{a\sim b}$ is one of them. Therefore, $p_{a\sim b} \geq p^*_{a\sim b}$ for all $a\sim b \in E^{\sim}_{stop}$ when event $\mathcal{A}_{E^{\sim}_{true}}$ happens. Consequently, according to Lemma 3, if event $\mathcal{A}_{E^{\sim}_{true}}$ happens, $E^{\sim}_{stop} \subseteq E^{\sim *}$.

Let $q(E^{\sim})$ denote the realized FDR of reporting $E^{\sim}$ as the recovered skeleton of the true DAG:

$$q(E^{\sim}) = \begin{cases} \frac{|E^{\sim} \bigcap E^{\not\sim}_{true}|}{|E^{\sim}|} & : \quad E^{\sim} \neq \emptyset, \\ 0 & : \quad E^{\sim} = \emptyset. \end{cases}$$

The FDRs of the PC$_{\text{fdr}}$-skeleton algorithm and $Algorithm^*$ are $E[q(E^{\sim}_{stop})]$ and $E[q(E^{\sim *})]$ respectively. Here $E[x]$ means the expected value of x.

$\because$ $E[q(E^{\sim}_{stop})] = E[q(E^{\sim}_{stop})|\mathcal{A}_{E^{\sim}_{true}}]P(\mathcal{A}_{E^{\sim}_{true}}) + E[q(E^{\sim}_{stop})|\overline{\mathcal{A}}_{E^{\sim}_{true}}]P(\overline{\mathcal{A}}_{E^{\sim}_{true}})$
$\leq Q + P(\overline{\mathcal{A}}_{E^{\sim}_{true}})$, where $Q = E[q(E^{\sim}_{stop})|\mathcal{A}_{E^{\sim}_{true}}]P(\mathcal{A}_{E^{\sim}_{true}})$.
$\therefore$ $\limsup_{m\to\infty} E[q(E^{\sim}_{stop})] \leq \limsup_{m\to\infty} Q + \limsup_{m\to\infty} P(\overline{\mathcal{A}}_{E^{\sim}_{true}})$.
$\because$ $\lim_{m\to\infty} P(\mathcal{A}_{E^{\sim}_{true}}) = 1$, according to **Theorem 1**.
$\therefore$ $\limsup_{m\to\infty} P(\overline{\mathcal{A}}_{E^{\sim}_{true}}) = \lim_{m\to\infty} P(\overline{\mathcal{A}}_{E^{\sim}_{true}}) = 0$.
$\therefore$ $\limsup_{m\to\infty} E[q(E^{\sim}_{stop})] \leq \limsup_{m\to\infty} Q$.
$\because$ $Q \leq E[q(E^{\sim}_{stop})]$.
$\therefore$ $\limsup_{m\to\infty} Q \leq \limsup_{m\to\infty} E[q(E^{\sim}_{stop})]$.
$\therefore$ $\limsup_{m\to\infty} E[q(E^{\sim}_{stop})] = \limsup_{m\to\infty} Q = \limsup_{m\to\infty} E[q(E^{\sim}_{stop})|\mathcal{A}_{E^{\sim}_{true}}]P(\mathcal{A}_{E^{\sim}_{true}})$.

Similarly, $\limsup_{m\to\infty} E[q(E^{\sim *})] = \limsup_{m\to\infty} E[q(E^{\sim *})|\mathcal{A}_{E^{\sim}_{true}}]P(\mathcal{A}_{E^{\sim}_{true}})$.

$\because$ Given event $\mathcal{A}_{E^{\sim}_{true}}$, $E^{\sim}_{true} \subseteq E^{\sim}_{stop} \subseteq E^{\sim *}$.

$\therefore$ Given event $\mathcal{A}_{E^{\sim}_{true}}$,

$$q(E^{\sim}_{stop}) = \frac{|E^{\sim}_{stop}| - |E^{\sim}_{true}|}{|E^{\sim}_{stop}|} = 1 - \frac{|E^{\sim}_{true}|}{|E^{\sim}_{stop}|} \leq 1 - \frac{|E^{\sim}_{true}|}{|E^{\sim *}|} = \frac{|E^{\sim *}| - |E^{\sim}_{true}|}{|E^{\sim *}|} = q(E^{\sim *}).$$

$\therefore \limsup_{m\to\infty} E[q(E^{\sim}_{stop})|\mathcal{A}_{E^{\sim}_{true}}]P(\mathcal{A}_{E^{\sim}_{true}}) \leq \limsup_{m\to\infty} E[q(E^{\sim *})|\mathcal{A}_{E^{\sim}_{true}}]P(\mathcal{A}_{E^{\sim}_{true}})$.
$\therefore \limsup_{m\to\infty} E[q(E^{\sim}_{stop})] \leq \limsup_{m\to\infty} E[q(E^{\sim *})]$.
$\because$ $Algorithm^*$ controls the FDR under q.
$\therefore E[q(E^{\sim *})] \leq q$.
$\therefore \limsup_{m\to\infty} E[q(E^{\sim *})] \leq q$.
$\therefore \limsup_{m\to\infty} E[q(E^{\sim}_{stop})] \leq q$. ■

Appendix B. Statistical Tests with Asymptotic Power Equal to One

Assumption (A3) on the asymptotic power of detecting conditional dependence appears demanding, but actually the detection power of several standard statistical tests approaches one as the number of identically and independently sampled observations approaches infinity. Listed as follows are two statistical tests satisfying Assumption (A3) for Gaussian models or discrete models.

B.1 Fisher's z Transformation on Sample Partial-correlation-coefficients for Gaussian Models

In multivariate Gaussian models, X_a and X_b are conditional independent given X_C if and only if the partial-correlation-coefficient of X_a and X_b given X_C is zero (see Lauritzen, 1996, pages 129–130). The partial-correlation-coefficient ρ is defined as:

$$\begin{aligned} \rho &= \frac{\text{Cov}\,[Y_a,Y_b]}{\sqrt{\text{Var}[Y_a]\text{Var}[Y_b]}}, \\ Y_a &= X_a - < W_a, X_C >, \\ Y_b &= X_b - < W_b, X_C >, \\ W_a &= \arg\min_w E[(X_a - < w, X_C >)^2], \\ W_b &= \arg\min_w E[(X_b - < w, X_C >)^2]. \end{aligned}$$

The sample partial-correlation-coefficient $\hat{\rho}$ can be calculated from m i.i.d. samples $[x_{ai}, x_{bi}, x_{Ci}]$ $(i = 1, \cdots, m)$ as:

$$\begin{aligned}
\hat{\rho} &= \frac{\frac{1}{m}\sum_{i=1}^{m}[(\hat{y}_{ai}-\bar{y}_a)(\hat{y}_{bi}-\bar{y}_b)]}{\sqrt{\frac{1}{m}\sum_{i=1}^{m}(\hat{y}_{ai}-\bar{y}_a)^2\frac{1}{m}\sum_{i=1}^{m}(\hat{y}_{bi}-\bar{y}_b)^2}},\\
\bar{y}_a &= \frac{1}{m}\sum_{i=1}^{m}\hat{y}_{ai},\\
\bar{y}_b &= \frac{1}{m}\sum_{i=1}^{m}\hat{y}_{bi},\\
\hat{y}_{ai} &= x_{ai}- <\hat{W}_a, x_{Ci}>,\\
\hat{y}_{bi} &= x_{bi}- <\hat{W}_b, x_{Ci}>,\\
\hat{W}_a &= \arg\min_w \sum_{i=1}^{m}(x_{ai}- <w, x_{Ci}>)^2,\\
\hat{W}_b &= \arg\min_w \sum_{i=1}^{m}(x_{bi}- <w, x_{Ci}>)^2.
\end{aligned}$$

The asymptotic distribution of $z(\hat{\rho})$, where $z(x)$, the Fisher's z transformation (see Fisher, 1915), is defined as

$$z(x) = \frac{1}{2}\log\frac{1+x}{1-x},$$

is the normal distribution with mean $z(\rho)$ and variance $1/(m-|C|-3)$ (see Anderson, 1984, pages 120–134). When the type I error rate is kept lower than α, the power of detecting $\rho \neq 0$ with Fisher's z transformation is the probability that $\sqrt{m-|C|-3}\ z(\hat{\rho})$ falls in the range $(-\infty, \Phi^{-1}(\alpha/2)]$ or $[\Phi^{-1}(1-\alpha/2), +\infty)$, where Φ is the cumulative distribution function of the standard normal distribution and Φ^{-1} is its inverse function. Without loss of generality, we assume the true partial-correlation-coefficient ρ is greater than zero, then the asymptotic power is

$$\begin{aligned}
&\lim_{m\to\infty}\text{Power} \geq \lim_{m\to\infty} P\left(\sqrt{m-|C|-3}\ z(\hat{\rho}) \geq \Phi^{-1}(1-\alpha/2)\right)\\
&= \lim_{m\to\infty}\left(1-\Phi[\Phi^{-1}(1-\alpha/2)-\sqrt{m-|C|-3}\ z(\rho)]\right) = (1-\Phi[-\infty]) = 1.
\end{aligned}$$

B.2 The Likelihood-ratio Test Generally Applicable to Nested Models

The likelihood ratio is the ratio of the maximum likelihood of a restricted model to that of a saturated model (see Neyman and Pearson, 1928). Let $f(x, \theta)$ denote the probability density function of a random vector x parametrized with $\theta = [\theta^1, \cdots, \theta^k]$. The null hypothesis restricts θ to a set Ω specified with r $(r \leq k)$ constraints

$$\xi_1(\theta) = \xi_2(\theta) = \cdots = \xi_r(\theta) = 0.$$

Given i.i.d. observations $x_1, \cdots, x_m$, let $L(\theta)$ denote the likelihood function

$$L(\theta) = \prod_{i=1}^{m} f(x_i, \theta).$$

The likelihood ratio Λ given the observations is defined as

$$\Lambda = \frac{\sup L(\theta)}{\sup\limits_{\theta\in\Omega} L(\theta)}.$$

Wald (1943) has proved that under certain assumptions on $f(x,\theta)$ and $\xi_1(\theta),\cdots,\xi_r(\theta)$, the limit distribution of the statistic $-2log\Lambda$ is the χ_r^2 distribution with r degrees of freedom if the null hypothesis true. If the null hypothesis is not true, the distribution of $-2log\Lambda$ approaches the non-central $\chi_r^2(\lambda)$ distribution with r degrees of freedom and the non-central parameter

$$\begin{aligned}\lambda &= mD(\theta) \geq 0,\\ D(\theta) &= \sum_{i=1}^{k}\sum_{j=1}^{k} \frac{\xi_i(\theta)\xi_j(\theta)}{\sum\limits_{p=1}^{k}\sum\limits_{q=1}^{k} \frac{\frac{\partial \xi_i}{\partial \theta^p}\frac{\partial \xi_j}{\partial \theta^p}}{E\left[-\frac{\partial^2 f(x,\theta)}{\partial \theta^p \partial \theta^q}\right]}}.\end{aligned}$$

If $D(\theta) > 0$, then $\lim\limits_{m\to\infty} \lambda = \infty$. Let t ($t < \infty$) denote the threshold of rejecting the null hypothesis with type I error rate under α ($\alpha > 0$). The asymptotic power of detecting a θ that is not in Ω and whose $D(\theta)$ is greater than 0 is $\lim\limits_{\lambda\to\infty} P(\chi_r^2(\lambda) > t)$. The mean and the variance of the $\chi_r^2(\lambda)$ distribution is $u = r+\lambda$ and $\sigma^2 = 2(r+2\lambda)$, respectively. When λ is large enough,

$$P\left(\chi_r^2(\lambda) > t\right) \geq P\left(t < \chi_r^2(\lambda) < u+(u-t)\right) = 1 - P\left(|\chi_r^2(\lambda) - u| \geq u-t\right).$$

According to Chebyshev's inequality,

$$P\left(|\chi_r^2(\lambda) - u| \geq u-t\right) \leq \frac{\sigma^2}{(u-t)^2} = \frac{2(r+2\lambda)}{(r+\lambda-t)^2}.$$

$\therefore$ When λ is large enough, $P(\chi_r^2(\lambda) > t) \geq 1 - \frac{2(r+2\lambda)}{(r+\lambda-t)^2}$.
$\because \lim\limits_{m\to\infty} \lambda = \infty$ and both r and t are fixed.
$\therefore \lim\limits_{m\to\infty} \frac{2(r+2\lambda)}{(r+\lambda-t)^2} = 0$.
$\therefore \lim\limits_{m\to\infty} P(\chi_r^2(\lambda) > t) = 1$.

Appendix C. Error Rates of Interest

Statistical decision processes usually involve choices between negative hypotheses and their alternatives, positive hypotheses. In the decision, there are basically two sources of errors: the type I errors, that is, falsely rejecting negative hypotheses when they are actually true; and the type II errors, that is, falsely accepting negative hypotheses when their alternatives, the positive hypotheses are actually true. In the context of learning graph structures, a negative hypothesis could be that an edge does not exist in the graph, while the positive hypothesis could be that the edge does exist. It is generally impossible to absolutely prevent the two types of errors simultaneously, because observations of a limited sample size may appear to support a positive hypothesis more than a negative hypothesis even when actually the negative hypothesis is true, or vice versa, due to the stochastic nature of random sampling. Moreover, the two types of errors generally contradict each other. Given a fixed sample size and a certain statistic extracted from the data, decreasing the type I errors will increase the type II errors, and vice versa. To guarantee the absolute prevention of the type I errors in any situations, one must accept all negative hypotheses, which will generally lead the type II error rate to be one, and vice versa. The contradiction between the two types of errors is clearly revealed by the monotone increase of receiver operating characteristic (ROC) curves. Thus the errors must be controlled by setting a threshold on a certain type of errors, or trading off between them, for instance, by minimizing a certain lost function associated with the errors according to the Bayesian decision theory.

Rooted in the two types of errors, there are several different error-rate criteria (as listed in Table 2) for problems involving simultaneously testing multiple hypotheses, such as verifying the existence of edges in a graph. The type I error rate is the expected ratio of the type I errors to all the negative hypotheses that are actually true; the type II error rate is the expected ratio of the type II errors to all the positive hypotheses that are actually true; the false discovery rate (FDR) (see Benjamini and Yekutieli, 2001; Storey, 2002), is the expected ratio of falsely accepted positive hypotheses to all those accepted positive hypotheses; the family-wise error rate is the probability that at least one of the accepted positive hypotheses is actually wrong.

Generally, there are no mathematically or technically superior relationships among these error-rate criteria. Each of these error rates may be favoured in certain research scenarios. For example:

- We are diagnosing a dangerous disease whose treatment is so risky that may cause the loss of eyesight. Due to the great risk of the treatment, we hope that less than 0.1% of healthy people will be falsely diagnosed as patients of the disease. In this case, the type I error rate should be controlled under 0.1%.

- We are diagnosing cancer patients. Because failure in detecting the disease will miss the potential chance to save the patient's life, we hope that 95% of the cancer patients will be correctly detected. In this case, the type II error rate should be controlled under 5%.

- In a pilot study, we are selecting candidate genes for a genetic research on Parkinson's disease. Because of the limited funding, we can only study a limited number of genes in the afterward genetic research, so when selecting candidate genes in the pilot study, we hope that 95% of the selected candidate genes are truly associated with the disease. In this case, the FDR will be chosen as the error rate of interest and should be controlled under 5%.

- We are selecting electronic components to make a device. Any error in any component will cause the device to run out of order. To guarantee the device functions well with a probability higher than 99%, the family-wise error rate should be controlled under 1%.

In these examples, the particular error-rate criteria are selected by reasons beyond mathematical or technical superiority, but by the researchers' interest, to minimize a certain lost function associated with the errors according to the Bayesian decision theory. Learning network structures in real world applications may face scenarios similar to the above examples.

The excellent discrimination between negative hypotheses and positive hypotheses cannot be achieved by "smartly" setting a threshold on a "superior" error-rate criterion. Setting a threshold on a certain type of error rate is just choosing a cut-point on the ROC curve. If the ROC curve is not sharp enough, any cut-point on the curve away from the ends (0,0) and (1,1) still leads to considerable errors. To discriminate more accurately between a negative hypothesis and a positive hypothesis, one must design a better statistic or increase the sample size to achieve a sharper ROC curve.

Abstract

We introduce novel online Bayesian methods for the identification of a family of noisy recurrent neural networks (RNNs). We present Bayesian active learning techniques for stimulus selection given past experiences. In particular, we consider the unknown parameters as stochastic variables and use A-optimality and D-optimality principles to choose optimal stimuli. We derive myopic cost functions in order to maximize the information gain concerning network parameters at each time step. We also derive the A-optimal and D-optimal estimations of the additive noise that perturbs the dynamical system of the RNN. Here we investigate myopic as well as non-myopic estimations, and study the problem of simultaneous estimation of both the system parameters and the noise. Employing conjugate priors our derivations remain approximation-free and give rise to simple update rules for the online learning of the parameters. The efficiency of our method is demonstrated for a number of selected cases, including the task of controlled independent component analysis.

Keywords: active learning, system identification, online Bayesian learning, A-optimality, D-optimality, infomax control, optimal design

1. Introduction

When studying systems in *interactive* and *online* fashion, it is of high relevance to facilitate fast information gain during the interaction (Fedorov, 1972; Cohn, 1994). As an example, consider experiments aiming at the description of the receptive field of different neurons. These experiments look for those stimuli that maximize the response of the given neuron (deCharms et al., 1998; Földiák, 2001). Neurons, however, might change due to the investigation, so the minimization of interaction is highly desired. Different techniques have been developed to speed up the identification procedure. One approach searches for stimulus distribution that maximizes mutual information between stimulus and response (Machens et al., 2005). A recent technique assumes that the unknown system belongs to the family of generalized linear models (Lewi et al., 2007) and treats the parameters as probabilistic variables. Then the goal is to find the optimal stimuli by maximizing mutual information between the parameter set and the system's response.

This example motivates our interest in active learning (MacKay, 1992; Cohn et al., 1996; Fukumizu, 1996; Sugiyama, 2006) of noisy recurrent artificial neural networks (RNNs), when we have the freedom to interrogate the network and to measure its responses.

[*]. Present address: Department of Computing Science, University of Alberta, Athabasca Hall, Edmonton, Canada, T6G 2E8

In active learning, the training set may be modified by the learning process itself based on the progress experienced so far. The goal of this modification is to maximize the expected improvement of the precision of the estimation. This idea can for example be used to improve generalization capability in regression and classification tasks or to better estimate hidden parameters. Theoretical concepts have been formulated in the fields of Optimal Experimental Design, or Optimal Bayesian Design (Kiefer, 1959; Fedorov, 1972; Steinberg and Hunter, 1984; Toman and Gastwirth, 1993; Pukelsheim, 1993).

Although active learning is in the focus of current research interest, some relevant theoretical issues are still unresolved. While there are promising studies showing that active learning may outperform uniform sampling under certain conditions (Freund et al., 1997; Seung et al., 1992), in other cases it has been proven that active learning has no advantage over non-adaptive algorithms. For example, this is the case in compressed sensing (Castro et al., 2006a) and also for certain function classes in the area of function approximation (Castro et al., 2006b). Even more problematic is the observation that active learning heuristics may be less efficient than uniform sampling in some situations (Schein, 2005).

There are several forms of active learning. The most relevant difference is in the definition of the value of information. One of the simplest heuristics is the Uncertainty Sampling (US): US suggests that in regression or in classification tasks one should choose those training examples, which have the largest uncertainty in the value of the function or in the label of the class, respectively (Lewis and Catlett, 1994; Lewis and Gale, 1994; Cohn et al., 1996). Although several US versions exist with different measure of the uncertainty itself, they all lack robustness. The Query by Committee method improves upon robustness (Seung et al., 1992; Freund et al., 1997): the committee of a few models are trained on the existing training set and the next query points are selected to reduce the disagreement among these models. The method of Roy and McCallum (2001) minimizes the direct error, that is, it tries to choose training points to minimize the expected classification error directly.

In the literature there are other approaches, including decision theory based methods. The original ideas were worked out in Raiffa and Schlaifer (1961) and Lindley (1971). The objective in this method family is to choose the design such that the predicted value of a given utility function become maximal. Numerous utility functions have been proposed. For example, if we aim to estimate the unknown parameter $\boldsymbol{\theta}$, then one possible direction is the minimization of, for example, the entropy or the standard deviation of the posterior distribution. If we minimize the entropy then we arrive at the D-optimality principle (Bernardo, 1979; Stone, 1959). This principle is equivalent to the information maximization method (also known as infomax principle) of Lewi et al. (2007). If we intend to minimize the standard deviation then the result is the A-optimality principle (Duncan and DeGroot, 1976). A special case is called the c-optimality principle (Chaloner, 1984) when the goal is to estimate a linear projection of parameter $\boldsymbol{\theta}$ ($\mathbf{c}^T\boldsymbol{\theta}$). There exist a number of other methods, called alphabetical optimality and utility functions. For a review see, for example, Chaloner and Verdinelli (1995). Although the original ideas belong to the field of optimal experimental design, they have appeared also in active learning recently (MacKay, 1992; Tong and Koller, 2000; Schein and Ungar, 2007).

Today, active learning is present almost in all fields of machine learning and there are many popular applications on diverse areas, including Gaussian Processes (Krause and Guestrin, 2007), Artificial Neural Networks (Fukumizu, 2000), Support Vector Machines (Tong and Koller, 2001b), Generalized Linear Models (Bach, 2007; Lewi et al., 2007), Logistic Regression (Schein, 2005), learning the parameters and structure of Bayes nets (Tong and Koller, 2000, 2001a) and Hidden Markov Models (Anderson and Moore, 2005).

Our framework is similar to the generalized linear model (GLM) approach used by Lewi et al. (2007): we would like to choose interrogating, or '*control*' inputs in order to (i) identify the parameters of the network and (ii) estimate the additive noise efficiently. From now on, we use the terms *control* and *interrogation* interchangeably; control is the conventional expression, whereas the word interrogation expresses our aims better. We apply online Bayesian learning (Opper and Winther, 1999; Solla and Winther, 1999; Honkela and Valpola, 2003; Ghahramani, 2000). For Bayesian methods, prior updates often lead to intractable posterior distributions such as a mixture of exponentially numerous distributions. Here, we show that, for the model studied in this paper, computations are both tractable and approximation-free. Further, the emerging learning rules are simple. We also show that different stimuli are needed for the same RNN model depending on whether the goal is to estimate the weights of the RNN or the additive perturbation (referred to as 'driving noise').

In this article we investigate the D-optimality, as well as the A-optimality principles. To the best of our knowledge, neither of them has been applied to the typical non-spiking stochastic artificial recurrent neural network model that we treat here.

The contribution of this paper can be summarized as follows: We use A-optimality and D-optimality principles and derive cost functions and algorithms for (i) the learning of parameters of the stochastic RNN and (ii) the estimation of its driving noise. We show that, (iii) using the D-optimality interrogation technique, these two tasks are incoherent in the myopic (i.e., single step look-ahead) control scheme: signals derived from this principle for parameter estimation are sub-optimal (basically the worst possible) for the estimation of the driving noise and vice versa. (iv) We show that for the case of noise estimation task the two principles, that is, A- and D-optimality principles result in the same cost function. (v) For the A-optimality case, we derive equations for the joined estimation of the noise and the parameters. On the contrary, we show also that (vi) D-optimality cannot be applied on the same joined task. For the case of noise estimation, (vii) a non-myopic multiple step look-ahead heuristics is introduced and we demonstrate its applicability through numerical experiments.

The paper is structured as follows: In Section 2 we introduce our model. Section 3 concerns the Bayesian equations of the RNN model. In Section 4 optimal control for parameter identification is derived from the D-optimality principle. Section 5 is about the same task, but using the A-optimality principle instead. Section 6 deals with our second task, when the goal is the estimation of the driving noise of the RNN. Here we treat the D-optimality principle. Section 7 is about the same problem, but for the A-optimality principle. We combine the two tasks for both optimality principles in Section 8 and consider the cost functions for the joined estimation of the parameters and the driving noise. All of these considerations concern myopic algorithms. In Section 9 a non-myopic heuristics is introduced for the noise estimation task. Section 10 contains our numerical experiments for a number of cases, including independent component analysis. The paper ends with a short discussion and some conclusions (Section 11). Technical details of the derivations can be found in the Appendix.

2. The Model

Let $P(\mathbf{e}) = \mathcal{N}_{\mathbf{e}}(\mathbf{m},\mathbf{V})$ denote the probability density of a normally distributed stochastic variable $\mathbf{e}$ with mean $\mathbf{m}$ and covariance matrix $\mathbf{V}$. Let us assume that we have d simple computational units called '*neurons*' in a recurrent neural network:

$$\mathbf{r}_{t+1} \quad = \quad g\left(\sum_{i=0}^{I}\mathbf{F}_i\mathbf{r}_{t-i} + \sum_{j=0}^{J}\mathbf{B}_j\mathbf{u}_{t+1-j} + \mathbf{e}_{t+1}\right), \tag{1}$$

where $\{\mathbf{e}_t\}$, the driving noise of the RNN, denotes temporally independent and identically distributed (i.i.d.) stochastic variables and $P(\mathbf{e}_t) = \mathcal{N}_{\mathbf{e}_t}(\mathbf{0},\mathbf{V})$, $\mathbf{r}_t \in \mathbb{R}^d$ represents the observed activities of the neurons at time t. Let $\mathbf{u}_t \in \mathbb{R}^c$ denote the control signal at time t. The neural network is formed by the weighted delays represented by matrices $\mathbf{F}_i$ $(i = 0,\ldots,I)$ and $\mathbf{B}_j$ $(j = 0,\ldots,J)$, which connect neurons to each other and also the control components to the neurons, respectively. Control can also be seen as the means of interrogation, or the stimulus to the network (Lewi et al., 2007). We assume that function $g : \mathbb{R}^d \to \mathbb{R}^d$ in (1) is known and invertible. The computational units, the neurons, sum up weighted previous neural activities as well as weighted control inputs. These sums are then passed through identical non-linearities according to Eq. (1). Our goal is to estimate the parameters $\mathbf{F}_i \in \mathbb{R}^{d\times d}$ $(i = 0,\ldots,I)$, $\mathbf{B}_j \in \mathbb{R}^{d\times c}$ $(j = 0,\ldots,J)$ and the covariance matrix $\mathbf{V}$, as well as the driving noise $\mathbf{e}_t$ by means of the control signals.

In artificial neural network terms, (1) is in the form of *rate code models*. This is the typical form for RNNs, but there are methods to approximate rate code description with spike codes and vice versa. For the case of RNNs, the best is to compare Liquid State Machine, a spike code model of Maass et al. (2002) with the Echo State Network, the corresponding rate code model of Jaeger (2001). Rate code, very crudely, is the low pass filtered spike code, whereas spike code can be seen as the response of integrate-and-fire neurons. We show that analytic cost functions emerge for the rate code RNN model. Due to the applied conjugate priors, we can calculate the high dimensional integrals involved in our derivations, and hence these derivations remain approximation-free and give rise to simple update rules.

3. Bayesian Approach

Here we embed the estimation task into the Bayesian framework. First, we introduce the following notations: $\mathbf{x}_{t+1} = [\mathbf{r}_{t-I};\ldots;\mathbf{r}_t;\mathbf{u}_{t-J+1};\ldots;\mathbf{u}_{t+1}]$, $\mathbf{y}_{t+1} = g^{-1}(\mathbf{r}_{t+1})$, $\mathbf{A} = [\mathbf{F}_I,\ldots,\mathbf{F}_0,\mathbf{B}_J,\ldots,\mathbf{B}_0] \in \mathbb{R}^{d\times m}$. With these notations, model (1) reduces to a linear equation

$$\mathbf{y}_t \quad = \quad \mathbf{A}\mathbf{x}_t + \mathbf{e}_t. \tag{2}$$

In order to estimate the unknown quantities (parameter matrix $\mathbf{A}$, noise $\mathbf{e}_t$ and its covariance matrix $\mathbf{V}$) in an online fashion, we rely on Bayes' method. We assume that prior knowledge is available and we update our posteriori knowledge on the basis of the observations. Control will be chosen at each instant to provide maximal expected information concerning the quantities we have to estimate. Starting from an arbitrary prior distribution of the parameters the posterior distribution needs to be computed. This latter distribution, however, can be highly complex, so approximations are applied. For example, assumed density filtering, when the computed posterior is projected to simpler distributions, has been suggested (Boyen and Koller, 1998; Minka, 2001; Opper and Winther, 1999). In order to avoid approximations, we apply the method of conjugated priors (Gelman et al., 2003). For matrix **A** we assume a matrix valued normal distribution prior.

For the case of D-optimality principle, we shall use the inverted Wishart (IW) distribution as our prior for covariance matrix **V**. This is the most general known conjugate prior distribution for the covariance matrix of a normal distribution at present. For A-optimality, however, we keep the derivations simple and assume that the covariance matrix has diagonal structure. In turn, we replaced the IW assumption on the prior with the distribution of the Product of Inverted Gammas (PIG).

We define the normally distributed matrix valued stochastic variable $\mathbf{A} \in \mathbb{R}^{d\times m}$ by using the following quantities: $\mathbf{M} \in \mathbb{R}^{d\times m}$ is the expected value of **A**. $\mathbf{V} \in \mathbb{R}^{d\times d}$ is the covariance matrix of the rows, and $\mathbf{K} \in \mathbb{R}^{m\times m}$ is the so-called precision parameter matrix that we shall modify in accordance with the Bayesian update. Matrix **K** contains the estimations of the 'Bayesian trainer' about the precision of parameters in **A**. Informally, matrix **K** behaves as the inverse of a covariance matrix. Upon each observation, matrix **K** is updated. The larger the eigenvalues of this matrix, the smaller the variance ellipsoids of the posteriori estimations are.

Both **K** and **V** are positive semi-definite matrices. The density function of the stochastic variable **A** is defined as:

$$\mathcal{N}_{\mathbf{A}}(\mathbf{M},\mathbf{V},\mathbf{K}) = \frac{|\mathbf{K}|^{d/2}}{|2\pi\mathbf{V}|^{m/2}}\exp(-\frac{1}{2}tr((\mathbf{A}-\mathbf{M})^T\mathbf{V}^{-1}(\mathbf{A}-\mathbf{M})\mathbf{K})),$$

where tr, $|\cdot|$, and superscript T denote the trace operation, the determinant, and transposition, respectively (see, e.g., Gupta and Nagar, 1999; Minka, 2000). We assume that $\mathbf{Q} \in \mathbb{R}^{d\times d}$ is a positive definite matrix and $n > 0$. Using these notations, the density of the Inverted Wishart distribution with parameters **Q** and n is as follows (Gupta and Nagar, 1999):

$$\mathcal{IW}_{\mathbf{V}}(\mathbf{Q},n) = \frac{1}{Z_{n,d}}\frac{1}{|\mathbf{V}|^{(d+1)/2}}\left|\frac{\mathbf{V}^{-1}\mathbf{Q}}{2}\right|^{n/2}\exp(-\frac{1}{2}tr(\mathbf{V}^{-1}\mathbf{Q})),$$

where $Z_{n,d} = \pi^{d(d-1)/4}\prod_{i=1}^{d}\Gamma((n+1-i)/2)$ and $\Gamma(.)$ denotes the gamma function.

Similarly, let $\mathbf{V} = diag(\mathbf{v}) \in \mathbb{R}^{d\times d}$ diagonal covariance matrix with $0 < \mathbf{v} \in \mathbb{R}^d$ diagonal values. With the slight abuse of notation we will use later the $\mathbf{v} = diag(\mathbf{V}) \in \mathbb{R}^d$ term, too. Then the density of PIG is defined as

$$\mathcal{PIG}_{\mathbf{V}}(\boldsymbol{\alpha},\boldsymbol{\beta}) = \prod_{i=1}^{d}\frac{\beta_i^{\alpha_i}}{\Gamma(\alpha_i)}v_i^{-\alpha_i-1}\exp(-\frac{\beta_i}{v_i}),$$

where $\alpha_i > 0$ and $\beta_i > 0$ are the shape and scale parameters respectively.

Now, one can rewrite model (2) as follows:

$$\begin{aligned} P(\mathbf{A}|\mathbf{V}) &= \mathcal{N}_{\mathbf{A}}(\mathbf{M},\mathbf{V},\mathbf{K}), &(3)\\ P(\mathbf{e}_t|\mathbf{V}) &= \mathcal{N}_{\mathbf{e}_t}(\mathbf{0},\mathbf{V}), &(4)\\ P(\mathbf{y}_t|\mathbf{A},\mathbf{x}_t,\mathbf{V}) &= \mathcal{N}_{\mathbf{y}_t}(\mathbf{A}\mathbf{x}_t,\mathbf{V}), &(5)\end{aligned}$$

and $P(\mathbf{V}) = \mathcal{PIG}_{\mathbf{V}}(\boldsymbol{\alpha},\boldsymbol{\beta})$ or $P(\mathbf{V}) = \mathcal{IW}_{\mathbf{V}}(\mathbf{Q},n)$ depending on whether we want to use A- or D-optimality.

4. D-Optimality Approach for Parameter Learning

Let us compute the D-optimal parameter estimation strategy for our RNN given by (1) and rewritten into (3)-(5). Let us introduce two shorthands; $\boldsymbol{\theta} = \{\mathbf{A}, \mathbf{V}\}$, and $\{\mathbf{x}\}_i^j = \{\mathbf{x}_i, \dots, \mathbf{x}_j\}$. We choose the control value in (1) at each instant to provide maximal expected information concerning the unknown parameters. Assuming that $\{\mathbf{x}\}_1^t$, $\{\mathbf{y}\}_1^t$ are given, according to the infomax principle our goal is to compute

$$\arg\max_{\mathbf{u}_{t+1}} I(\boldsymbol{\theta}, \mathbf{y}_{t+1}; \{\mathbf{x}\}_1^{t+1}, \{\mathbf{y}\}_1^t), \tag{6}$$

where $I(a,b;c)$ denotes the mutual information of stochastic variables a and b for fixed parameters c. Let $H(a|b;c)$ denote the conditional entropy of variable a conditioned on variable b and for fixed parameter c. Note that

$$I(\boldsymbol{\theta}, \mathbf{y}_{t+1}; \{\mathbf{x}\}_1^{t+1}, \{\mathbf{y}\}_1^t) = H(\boldsymbol{\theta}; \{\mathbf{x}\}_1^{t+1}, \{\mathbf{y}\}_1^t) - H(\boldsymbol{\theta}|\mathbf{y}_{t+1}; \{\mathbf{x}\}_1^{t+1}, \{\mathbf{y}\}_1^t),$$

holds (Cover and Thomas, 1991) and $H(\boldsymbol{\theta}; \{\mathbf{x}\}_1^{t+1}, \{\mathbf{y}\}_1^t) = H(\boldsymbol{\theta}; \{\mathbf{x}\}_1^t, \{\mathbf{y}\}_1^t)$ is independent from $\mathbf{u}_{t+1}$, hence our task is reduced to the evaluation of the following quantity:

$$\begin{aligned} &\arg\min_{\mathbf{u}_{t+1}} H(\boldsymbol{\theta}|\mathbf{y}_{t+1}; \{\mathbf{x}\}_1^{t+1}, \{\mathbf{y}\}_1^t) = \\ &= \arg\min_{\mathbf{u}_{t+1}} - \int d\mathbf{y}_{t+1} P(\mathbf{y}_{t+1}|\{\mathbf{x}\}_1^{t+1}, \{\mathbf{y}\}_1^t) \int d\boldsymbol{\theta} P(\boldsymbol{\theta}|\{\mathbf{x}\}_1^{t+1}, \{\mathbf{y}\}_1^{t+1}) \log P(\boldsymbol{\theta}|\{\mathbf{x}\}_1^{t+1}, \{\mathbf{y}\}_1^{t+1}). \end{aligned} \tag{7}$$

In order to solve this minimization problem we need to evaluate $P(\mathbf{y}_{t+1}|\{\mathbf{x}\}_1^{t+1}, \{\mathbf{y}\}_1^t)$, the posterior $P(\boldsymbol{\theta}|\{\mathbf{x}\}_1^{t+1}, \{\mathbf{y}\}_1^{t+1})$, and the entropy of the posterior, that is $\int d\boldsymbol{\theta} P(\boldsymbol{\theta}|\{\mathbf{x}\}_1^{t+1}, \{\mathbf{y}\}_1^{t+1}) \log P(\boldsymbol{\theta}|\{\mathbf{x}\}_1^{t+1}, \{\mathbf{y}\}_1^{t+1})$, where $P(a|b)$ denotes the conditional probability of variable a given condition b. The main steps of these computations are presented below.

Assume that the *a priori* distributions $P(\mathbf{A}|\mathbf{V}, \{\mathbf{x}\}_1^t, \{\mathbf{y}\}_1^t) = \mathcal{N}(\mathbf{A}|\mathbf{M}_t, \mathbf{V}, \mathbf{K}_t)$ and $P(\mathbf{V}|\{\mathbf{x}\}_1^t, \{\mathbf{y}\}_1^t) = \mathcal{IW}_{\mathbf{V}}(\mathbf{Q}_t, n_t)$ are known. Then the posterior distribution of $\boldsymbol{\theta}$ is:

$$\begin{aligned} P(\mathbf{A}, \mathbf{V}|\{\mathbf{x}\}_1^{t+1}, \{\mathbf{y}\}_1^{t+1}) &= \frac{P(\mathbf{y}_{t+1}|\mathbf{A}, \mathbf{V}, \mathbf{x}_{t+1}) P(\mathbf{A}|\mathbf{V}, \{\mathbf{x}\}_1^t, \{\mathbf{y}\}_1^t) P(\mathbf{V}|\{\mathbf{x}\}_1^t, \{\mathbf{y}\}_1^t)}{P(\mathbf{y}_{t+1}|\{\mathbf{x}\}_1^{t+1}, \{\mathbf{y}\}_1^t)}, \\ &= \frac{\mathcal{N}_{\mathbf{y}_{t+1}}(\mathbf{A}\mathbf{x}_{t+1}, \mathbf{V}) \mathcal{N}_{\mathbf{A}}(\mathbf{M}_t, \mathbf{V}, \mathbf{K}_t) \mathcal{IW}_{\mathbf{V}}(\mathbf{Q}_t, n_t)}{\int_{\mathbf{A}} \int_{\mathbf{V}} \mathcal{N}_{\mathbf{y}_{t+1}}(\mathbf{A}\mathbf{x}_{t+1}, \mathbf{V}) \mathcal{N}_{\mathbf{A}}(\mathbf{M}_t, \mathbf{V}, \mathbf{K}_t) \mathcal{IW}_{\mathbf{V}}(\mathbf{Q}_t, n_t)}. \end{aligned}$$

This expression can be rewritten in a more useful form: let $\mathbf{K} \in \mathbb{R}^{m \times m}$ and $\mathbf{Q} \in \mathbb{R}^{d \times d}$ be positive definite matrices. Let $\mathbf{A} \in \mathbb{R}^{d \times m}$, and let us introduce the density function of the matrix valued Student-t distribution (Kotz and Nadarajah, 2004; Minka, 2000) as follows:

$$\mathcal{T}_{\mathbf{A}}(\mathbf{Q}, n, \mathbf{M}, \mathbf{K}) = \frac{|\mathbf{K}|^{d/2}}{\pi^{dm/2}} \frac{Z_{n+m,d}}{Z_{n,d}} \frac{|\mathbf{Q}|^{n/2}}{|\mathbf{Q} + (\mathbf{A} - \mathbf{M})\mathbf{K}(\mathbf{A} - \mathbf{M})^T|^{(m+n)/2}}.$$

Now, we need the following lemma:

Lemma 4.1

$$\begin{aligned} \mathcal{N}_{\mathbf{y}}(\mathbf{A}\mathbf{x}, \mathbf{V}) \mathcal{N}_{\mathbf{A}}(\mathbf{M}, \mathbf{V}, \mathbf{K}) \mathcal{IW}_{\mathbf{V}}(\mathbf{Q}, n) = \mathcal{N}_{\mathbf{A}}((\mathbf{M}\mathbf{K} + \mathbf{y}\mathbf{x}^T)(\mathbf{x}\mathbf{x}^T + \mathbf{K})^{-1}, \mathbf{V}, \mathbf{x}\mathbf{x}^T + \mathbf{K}) \times \\ \times \mathcal{IW}_{\mathbf{V}} \left(\mathbf{Q} + (\mathbf{y} - \mathbf{M}\mathbf{x})(1 - \mathbf{x}^T(\mathbf{x}\mathbf{x}^T + \mathbf{K})^{-1}\mathbf{x})(\mathbf{y} - \mathbf{M}\mathbf{x})^T, n+1 \right) \times \\ \times \mathcal{T}_{\mathbf{y}} \left(\mathbf{Q}, n, \mathbf{M}\mathbf{x}, 1 - \mathbf{x}^T(\mathbf{x}\mathbf{x}^T + \mathbf{K})^{-1}\mathbf{x} \right). \end{aligned}$$

The proof can be found in the Appendix.

Using this lemma, we can compute the posterior probabilities. We introduce the following quantities:

$$\begin{aligned}
\gamma_{t+1} &= 1-\mathbf{x}_{t+1}^T(\mathbf{x}_{t+1}\mathbf{x}_{t+1}^T+\mathbf{K}_t)^{-1}\mathbf{x}_{t+1}, && (8)\\
n_{t+1} &= n_t+1, &&\\
\mathbf{M}_{t+1} &= (\mathbf{M}_t\mathbf{K}_t+\mathbf{y}_{t+1}\mathbf{x}_{t+1}^T)(\mathbf{x}_{t+1}\mathbf{x}_{t+1}^T+\mathbf{K}_t)^{-1}, && (9)\\
\mathbf{Q}_{t+1} &= \mathbf{Q}_t+(\mathbf{y}_{t+1}-\mathbf{M}_t\mathbf{x}_{t+1})\,\gamma_{t+1}\,(\mathbf{y}_{t+1}-\mathbf{M}_t\mathbf{x}_{t+1})^T\,. && (10)
\end{aligned}$$

For the posterior probabilities we have determined that

$$\begin{aligned}
P(\mathbf{A}|\mathbf{V},\{\mathbf{x}\}_1^{t+1},\{\mathbf{y}\}_1^{t+1}) &= \mathcal{N}_{\mathbf{A}}(\mathbf{M}_{t+1},\mathbf{V},\mathbf{x}_{t+1}\mathbf{x}_{t+1}^T+\mathbf{K}_t), && (11)\\
P(\mathbf{V}|\{\mathbf{x}\}_1^{t+1},\{\mathbf{y}\}_1^{t+1}) &= \mathcal{IW}_{\mathbf{V}}(\mathbf{Q}_{t+1},n_{t+1}), && (12)\\
P(\mathbf{y}_{t+1}|\{\mathbf{x}\}_1^{t+1},\{\mathbf{y}\}_1^{t}) &= \mathcal{T}_{\mathbf{y}_{t+1}}(\mathbf{Q}_t,n_t,\mathbf{M}_t\mathbf{x}_{t+1},\gamma_{t+1})\,. &&
\end{aligned}$$

Now we are in the position to compute the entropy of the posterior distribution of $\boldsymbol{\theta}=\{\mathbf{A},\mathbf{V}\}$ using the following lemma:

Lemma 4.2 *The entropy of a stochastic variable with density function* $P(\mathbf{A},\mathbf{V}) = \mathcal{N}_{\mathbf{A}}(\mathbf{M},\mathbf{V},\mathbf{K})\,\mathcal{IW}_{\mathbf{V}}(\mathbf{Q},n)$ *assumes the form* $-\frac{d}{2}\ln|\mathbf{K}|+(\frac{m+d+1}{2})\ln|\mathbf{Q}|+f_{1,1}(d,n)$*, where* $f_{1,1}(d,n)$ *depends only on* d *and* n.

The proof can be found in the Appendix.

Lemmas 4.1 and 4.2 lead to the following corollary:

Corollary 4.3 *For the entropy of a stochastic variable with posterior distribution* $P(\mathbf{A},\mathbf{V}|\mathbf{x},\mathbf{y})$ *it holds that*

$$H(\mathbf{A},\mathbf{V};\mathbf{x},\mathbf{y}) = -\frac{d}{2}\ln|\mathbf{x}\mathbf{x}^T+\mathbf{K}|+f_{1,1}(d,n)+(\frac{m+d+1}{2})\ln|\mathbf{Q}+(\mathbf{y}-\mathbf{M}\mathbf{x})\gamma(\mathbf{y}-\mathbf{M}\mathbf{x})^T|.$$

We note that the following lemma also holds:

Lemma 4.4

$$\int \mathcal{T}_{\mathbf{y}}(\mathbf{Q},n,\boldsymbol{\mu},\gamma)\ln|\mathbf{Q}+(\mathbf{y}-\boldsymbol{\mu})\gamma(\mathbf{y}-\boldsymbol{\mu})^T|d\mathbf{y}$$

is independent from both $\boldsymbol{\mu}$ *and* γ*,*

and thus we can compute the conditional entropy expressed in (7):

Lemma 4.5

$$H(\mathbf{A},\mathbf{V}|\mathbf{y};\mathbf{x}) = \int p(\mathbf{y}|\mathbf{x})H(\mathbf{A},\mathbf{V};\mathbf{x},\mathbf{y})d\mathbf{y} = -\frac{d}{2}\ln|\mathbf{x}\mathbf{x}^T+\mathbf{K}|+f_{1,2}(\mathbf{Q},n,m),$$

where $f_{1,2}(\mathbf{Q},n,m)$ *depends only on* $\mathbf{Q}$*,* n *and* m.

Collecting all the terms, we arrive at the following *intriguingly simple* expression

$$\begin{aligned}\mathbf{u}_{t+1}^{opt} &= \arg\min_{\mathbf{u}_{t+1}} \int p\left(\mathbf{y}_{t+1}|\{\mathbf{x}\}_1^{t+1},\{\mathbf{y}\}_1^t\right) H(\mathbf{A},\mathbf{V}|\{\mathbf{x}\}_1^{t+1},\{\mathbf{y}\}_1^t,\mathbf{y}_{t+1})d\mathbf{y}_{t+1},\\ &= \arg\min_{\mathbf{u}_{t+1}} -\frac{d}{2}\ln|\mathbf{x}_{t+1}\mathbf{x}_{t+1}^T+\mathbf{K}_t| = \arg\max_{\mathbf{u}_{t+1}} \mathbf{x}_{t+1}^T\mathbf{K}_t^{-1}\mathbf{x}_{t+1},\end{aligned} \tag{13}$$

where

$$\mathbf{x}_{t+1} \doteq [\mathbf{r}_{t-I};\ldots;\mathbf{r}_t;\mathbf{u}_{t-J+1};\ldots;\mathbf{u}_{t+1}],$$

and we used that $|\mathbf{x}\mathbf{x}^T+\mathbf{K}| = |\mathbf{K}|(1+\mathbf{x}^T\mathbf{K}^{-1}\mathbf{x})$ according to the Matrix Determinant Lemma (Harville, 1997). We assume a bounded domain $\mathcal{U}$ for the control, which is necessary to keep the maximization procedure of (13) finite. This is, however, a reasonable condition for all practical applications. So,

$$\mathbf{u}_{t+1}^{opt} = \arg\max_{\mathbf{u}_{t+1}\in\mathcal{U}} \mathbf{x}_{t+1}^T\mathbf{K}_t^{-1}\mathbf{x}_{t+1}, \tag{14}$$

In what follows D-optimal control will be referred to as *'infomax interrogation scheme'*. The steps of our algorithm are summarized in Table 1.

```
Control Calculation
    $\mathbf{u}_{t+1} = \arg\max_{\mathbf{u}\in\mathcal{U}} \hat{\mathbf{x}}_{t+1}^T\mathbf{K}_t^{-1}\hat{\mathbf{x}}_{t+1}$
    where $\hat{\mathbf{x}}_{t+1} = [\mathbf{r}_{t-I};\ldots;\mathbf{r}_t;\mathbf{u}_{t-J+1};\ldots;\mathbf{u}_t;\mathbf{u}]$
    set $\mathbf{x}_{t+1} = [\mathbf{r}_{t-I};\ldots;\mathbf{r}_t;\mathbf{u}_{t-J+1};\ldots;\mathbf{u}_t;\mathbf{u_{t+1}}]$
Observation
    observe $\mathbf{r}_{t+1}$, and let $\mathbf{y}_{t+1} = g^{-1}(\mathbf{r}_{t+1})$
Bayesian update
    $\mathbf{M}_{t+1} = (\mathbf{M}_t\mathbf{K}_t + \mathbf{y}_{t+1}\mathbf{x}_{t+1}^T)(\mathbf{x}_{t+1}\mathbf{x}_{t+1}^T+\mathbf{K}_t)^{-1}$
    $\mathbf{K}_{t+1} = \mathbf{x}_{t+1}\mathbf{x}_{t+1}^T + \mathbf{K}_t$
    $n_{t+1} = n_t + 1$
    $\gamma_{t+1} = 1 - \mathbf{x}_{t+1}^T(\mathbf{x}_{t+1}\mathbf{x}_{t+1}^T+\mathbf{K}_t)^{-1}\mathbf{x}_{t+1}$
    $\mathbf{Q}_{t+1} = Q_t + (\mathbf{y}_{t+1}-\mathbf{M}_t\mathbf{x}_{t+1})\gamma_{t+1}(\mathbf{y}_{t+1}-\mathbf{M}_t\mathbf{x}_{t+1})^T$
```

Table 1: Pseudocode of the algorithm

Computation of the inverse $(\mathbf{x}_{t+1}\mathbf{x}_{t+1}^T+\mathbf{K}_t)^{-1}$ in Table 1 can be simplified considerably by the following recursion: let $\mathbf{P}_t = \mathbf{K}_t^{-1}$, then according to the Sherman-Morrison formula (Golub and Van Loan, 1996)

$$\mathbf{P}_{t+1} = (\mathbf{x}_{t+1}\mathbf{x}_{t+1}^T+\mathbf{K}_t)^{-1} = \mathbf{P}_t - \frac{\mathbf{P}_t\mathbf{x}_{t+1}\mathbf{x}_{t+1}^T\mathbf{P}_t}{1+\mathbf{x}_{t+1}^T\mathbf{P}_t\mathbf{x}_{t+1}}. \tag{15}$$

In this expression matrix inversion disappears and only a real number is inverted instead.

5. A-Optimality Approach for Parameter Learning

The D-optimality principle aims to minimize the expected posteriori entropy of the parameters. A-optimality principle differs; it measures the uncertainty by means of the variance and not the entropy. Thus, instead of (7), the A-optimal objective function is as follows:

$$\mathbf{u}_{t+1}^{opt} = \arg\min_{\mathbf{u}_{t+1}} \int d\mathbf{y}_{t+1} P(\mathbf{y}_{t+1}|\{\mathbf{x}\}_1^{t+1},\{\mathbf{y}\}_1^{t}) tr Var[\boldsymbol{\theta}|\{\mathbf{x}\}_1^{t+1},\{\mathbf{y}\}_1^{t+1}]. \tag{16}$$

where $Var[\boldsymbol{\theta}|\mathcal{F}]$ denotes the conditional covariance matrix of $\boldsymbol{\theta}$ given the condition $\mathcal{F}$.

To keep the calculations simple, in this case we use $\mathcal{PIG}_{\mathbf{V}}(\boldsymbol{\alpha}_t,\boldsymbol{\beta}_t)$ prior distribution for the covariance matrix instead of $\mathcal{IW}_{\mathbf{V}}(\mathbf{Q}_t,n_t)$. Using the notations of (8)-(10), the posterior distributions assume the following forms:

Lemma 5.1

$$\begin{aligned}
P(\mathbf{A}|\mathbf{V},\{\mathbf{x}\}_1^{t+1},\{\mathbf{y}\}_1^{t+1}) &= \mathcal{N}_{\mathbf{A}}(\mathbf{M}_{t+1},\mathbf{V},\mathbf{x}_{t+1}\mathbf{x}_{t+1}^T+\mathbf{K}_t), && (17)\\
P(\mathbf{V}|\{\mathbf{x}\}_1^{t+1},\{\mathbf{y}\}_1^{t+1}) &= \mathcal{PIG}_{\mathbf{V}}(\boldsymbol{\alpha}_{t+1},\boldsymbol{\beta}_{t+1}),\\
P(\mathbf{y}_{t+1}|\{\mathbf{x}\}_1^{t+1},\{\mathbf{y}\}_1^{t}) &= \prod_{i=1}^{d} \mathcal{T}_{(\mathbf{y}_{t+1})_i}\left((\boldsymbol{\beta}_t)_i, 2(\boldsymbol{\alpha}_t)_i, (\mathbf{M}_t\mathbf{x}_{t+1})_i, \frac{\gamma_{t+1}}{2}\right), && (18)
\end{aligned}$$

where we used the shorthands

$$\begin{aligned}
(\boldsymbol{\alpha}_{t+1})_i &= (\boldsymbol{\alpha}_t)_i + 1/2,\\
(\boldsymbol{\beta}_{t+1})_i &= (\boldsymbol{\beta}_t)_i + ((\mathbf{y}_{t+1})_i - (\mathbf{M}_t\mathbf{x}_{t+1})_i)^2\frac{\gamma_{t+1}}{2}. && (19)
\end{aligned}$$

The proof can be found in the Appendix.

Given that $P(\mathbf{V}|\{\mathbf{x}\}_1^{t+1},\{\mathbf{y}\}_1^{t+1})$ belongs to the $\mathcal{PIG}$ family we can calculate the quantity $Var(\mathbf{V}|\{\mathbf{x}\}_1^{t+1},\{\mathbf{y}\}_1^{t+1})$ (Gelman et al., 2003):

$$tr\left(Var[\mathbf{V}|\{\mathbf{x}\}_1^{t+1},\{\mathbf{y}\}_1^{t+1}]\right) = \sum_{i=1}^{d} \frac{(\boldsymbol{\beta}_{t+1})_i}{((\boldsymbol{\alpha}_{t+1})_i-1)^2((\boldsymbol{\alpha}_{t+1})_i-2)}.$$

We will need the following lemma:

Lemma 5.2

$$\begin{aligned}
tr\left(Var[\mathbf{A}|\{\mathbf{x}\}_1^{t+1},\{\mathbf{y}\}_1^{t+1}]\right) &= tr\left(\left(\mathbf{K}_t+\mathbf{x}_{t+1}\mathbf{x}_{t+1}^T\right)^{-1}\right) E[tr\mathbf{V}|\{\mathbf{x}\}_1^{t+1},\{\mathbf{y}\}_1^{t+1}],\\
&= tr\left(\left(\mathbf{K}_t+\mathbf{x}_{t+1}\mathbf{x}_{t+1}^T\right)^{-1}\right)\sum_{i=1}^{d}\frac{(\boldsymbol{\beta}_{t+1})_i}{(\boldsymbol{\alpha}_{t+1})_i-1}.
\end{aligned}$$

The proof can be found in the Appendix.

Now we can elaborate on the A-optimal cost function for parameter estimation (16):

$$\begin{aligned}
&\int d\mathbf{y}_{t+1} P(\mathbf{y}_{t+1}|\{\mathbf{x}\}_1^{t+1},\{\mathbf{y}\}_1^{t}) trVar[\boldsymbol{\theta}|\{\mathbf{x}\}_1^{t+1},\{\mathbf{y}\}_1^{t+1}] = && (20)\\
=\ & \int d\mathbf{y}_{t+1}\prod_{i=1}^{d}\mathcal{T}_{(\mathbf{y}_{t+1})_i}\left((\boldsymbol{\beta}_t)_i, 2(\boldsymbol{\alpha}_t)_i, (\mathbf{M}_t\mathbf{x}_{t+1})_i, \frac{\gamma_{t+1}}{2}\right)\times\\
&\times\left(tr\left(\left(\mathbf{K}_t+\mathbf{x}_{t+1}\mathbf{x}_{t+1}^T\right)^{-1}\right)\sum_{i=1}^{d}\frac{(\boldsymbol{\beta}_{t+1})_i}{(\boldsymbol{\alpha}_{t+1})_i-1}+\sum_{i=1}^{d}\frac{(\boldsymbol{\beta}_{t+1})_i}{((\boldsymbol{\alpha}_{t+1})_i-1)^2((\boldsymbol{\alpha}_{t+1})_i-2)}\right),\\
=\ & tr\left(\left(\mathbf{K}_t+\mathbf{x}_{t+1}\mathbf{x}_{t+1}^T\right)^{-1}\right) f_{2,1}(\boldsymbol{\alpha}_{t+1},\boldsymbol{\beta}_t)+f_{2,2}(\boldsymbol{\alpha}_{t+1},\boldsymbol{\beta}_t),
\end{aligned}$$

where $f_{2,1}$ and $f_{2,2}$ depend only on $\boldsymbol{\alpha}_{t+1}$, and $\boldsymbol{\beta}_t$. Here we used (18), (19) and Lemma 4.4.

Applying again the Sherman-Morrison formula (15) and the fact that $tr[\mathbf{K}_t^{-1}\mathbf{x}_{t+1}\mathbf{x}_{t+1}^T\mathbf{K}_t^{-1}] = tr[\mathbf{x}_{t+1}^T\mathbf{K}_t^{-1}\mathbf{K}_t^{-1}\mathbf{x}_{t+1}]$, we arrive at the following expression for A-optimal parameter estimation:

$$\mathbf{u}_{t+1}^{opt} = \arg\max_{\mathbf{u}_{t+1}\in\mathcal{U}} \frac{\mathbf{x}_{t+1}^T\mathbf{K}_t^{-1}\mathbf{K}_t^{-1}\mathbf{x}_{t+1}}{1+\mathbf{x}_{t+1}^T\mathbf{K}_t^{-1}\mathbf{x}_{t+1}}, \tag{21}$$

which is a hyperbolic programming task.

We can conclude that while in the D-optimality case the task is to minimize expression $|(\mathbf{K}_t + \mathbf{x}_{t+1}\mathbf{x}_{t+1}^T)^{-1}|$, the A-optimality principle is concerned with the minimization of $tr[(\mathbf{K}_t+\mathbf{x}_{t+1}\mathbf{x}_{t+1}^T)^{-1}]$.

6. D-Optimality Approach for Noise Estimation

One might wish to compute the optimal control for estimating noise $\mathbf{e}_t$ in (1), instead of the identification problem above. Based on (1) and because

$$\mathbf{e}_{t+1} = \mathbf{y}_{t+1} - \sum_{i=0}^{I}\mathbf{F}_i\mathbf{r}_{t-i} - \sum_{j=0}^{J}\mathbf{B}_j\mathbf{u}_{t+1-j}, \tag{22}$$

one might think that the best strategy is to use the optimal infomax control of Table 1, since it provides good estimations for parameters $\mathbf{A} = [\mathbf{F}_I,\ldots,\mathbf{F}_0,\mathbf{B}_J,\ldots,\mathbf{B}_0]$ and so for noise $\mathbf{e}_t$.

Another—and different—thought is the following. At time $t+1$, let the estimation of the noise be $\hat{\mathbf{e}}_{t+1} = \mathbf{y}_{t+1} - \sum_{i=0}^{I}\hat{\mathbf{F}}_i^t\mathbf{r}_{t-i} - \sum_{j=0}^{J}\hat{\mathbf{B}}_j^t\mathbf{u}_{t+1-j}$, where $\hat{\mathbf{F}}_i^t$ (i=0,...,I), and $\hat{\mathbf{B}}_j^t$ (j=0,...,J) denote the estimations of $\mathbf{F}$ and $\mathbf{B}$ respectively.

Using (22), we have that

$$\mathbf{e}_{t+1} - \hat{\mathbf{e}}_{t+1} = \sum_{i=0}^{I}(\mathbf{F}_i - \hat{\mathbf{F}}_i^t)\mathbf{r}_{t-i} + \sum_{j=0}^{J}(\mathbf{B}_j - \hat{\mathbf{B}}_j^t)\mathbf{u}_{t+1-j}. \tag{23}$$

This hints that the control should be $\mathbf{u}_t = \mathbf{0}$ for all times in order to get rid of the error contribution of matrix $\mathbf{B}_j$ in (23).

Straightforward D-optimality considerations oppose the utilization of objective (6) for the present task. One can optimize, instead, the following quantity:

$$\arg\max_{\mathbf{u}_{t+1}} I(\mathbf{e}_{t+1},\mathbf{y}_{t+1};\{\mathbf{x}\}_1^{t+1},\{\mathbf{y}\}_1^t).$$

In other words, for the estimation of the noise we want to design a control signal $\mathbf{u}_{t+1}$ such that the next output is the best from the point of view of greedy optimization of mutual information between the next output $\mathbf{y}_{t+1}$ and the noise $\mathbf{e}_{t+1}$. It is easy to show that this task is equivalent to the following optimization problem:

$$\arg\min_{\mathbf{u}_{t+1}} \int d\mathbf{y}_{t+1} P(\mathbf{y}_{t+1}|\{\mathbf{x}\}_1^{t+1},\{\mathbf{y}\}_1^t) H(\mathbf{e}_{t+1};\{\mathbf{x}\}_1^{t+1},\{\mathbf{y}\}_1^{t+1}), \tag{24}$$

where $H(\mathbf{e}_{t+1};\{\mathbf{x}\}_1^{t+1},\{\mathbf{y}\}_1^{t+1}) = H(\mathbf{A}\mathbf{x}_{t+1};\{\mathbf{x}\}_1^{t+1},\{\mathbf{y}\}_1^{t+1})$, because $\mathbf{e}_{t+1} = \mathbf{y}_{t+1} - \mathbf{A}\mathbf{x}_{t+1}$.

In practice, we perform this optimization in an appropriate domain $\mathcal{U}$. After some mathematical calculation we can prove that the D-optimal interrogation scheme for noise estimation gives rise to the following control:

Lemma 6.1

$$\mathbf{u}_{t+1}^{opt} = \arg\min_{\mathbf{u}_{t+1}\in\mathcal{U}} \mathbf{x}_{t+1}^T \mathbf{K}_t^{-1} \mathbf{x}_{t+1}. \tag{25}$$

The proof of this lemma can be found in the Appendix.

It is worth noting that this D-optimal cost function for noise estimation and the D-optimal cost function derived for parameter estimation in (13) are not compatible with each other. Estimating one of them quickly will necessarily delay the estimation of the other.

We shall show later (Section 9) that for large t values, expression (25) gives rise to control values close to $\mathbf{u}_t = \mathbf{0}$.

7. A-Optimality Approach for Noise Estimation

Instead of (24), our task is to compute the following quantity:

$$\arg\min_{\mathbf{u}_{t+1}} \int d\mathbf{y}_{t+1} P(\mathbf{y}_{t+1}|\{\mathbf{x}\}_1^{t+1},\{\mathbf{y}\}_1^{t})\, tr\left(Var[\mathbf{e}_{t+1}|\{\mathbf{x}\}_1^{t+1},\{\mathbf{y}\}_1^{t+1}]\right). \tag{26}$$

We will apply the identity

$$\begin{aligned}\mathcal{N}_{\mathbf{A}\mathbf{x}_{t+1}}&\left(\mathbf{M}_{t+1}\mathbf{x}_{t+1},\mathbf{V},\left(\mathbf{x}_{t+1}^T\mathbf{K}_{t+1}^{-1}\mathbf{x}_{t+1}\right)^{-1}\right)\mathcal{PIG}_{\mathbf{V}}(\boldsymbol{\alpha}_{t+1},\boldsymbol{\beta}_{t+1}) = \\ =\prod_{i=1}^{d}\mathcal{T}_{(\mathbf{A}\mathbf{x}_{t+1})_i}&\left((\boldsymbol{\beta}_{t+1})_i,2(\boldsymbol{\alpha}_{t+1})_i,(\mathbf{M}_{t+1}\mathbf{x}_{t+1})_i,\left(\mathbf{x}_{t+1}^T\frac{\mathbf{K}_{t+1}^{-1}}{2}\mathbf{x}_{t+1}\right)^{-1}\right)\times \\ \times\mathcal{PIG}_{\mathbf{V}}&\left(\boldsymbol{\alpha}_{t+1}+1,\boldsymbol{\beta}_{t+1}+diag[(\mathbf{y}_{t+1}-\mathbf{M}_t\mathbf{x}_{t+1})\frac{\gamma_{t+1}}{2}(\mathbf{y}_{t+1}-\mathbf{M}_t\mathbf{x}_{t+1})^T]\right),\end{aligned}$$

which can be proven by using Lemma A.1. We can simplify (26) by noting that

$$tr\left(Var[\mathbf{e}_{t+1}|\{\mathbf{x}\}_1^{t+1},\{\mathbf{y}\}_1^{t+1}]\right) = tr\left(Var[\mathbf{A}\mathbf{x}_{t+1}|\{\mathbf{x}\}_1^{t+1},\{\mathbf{y}\}_1^{t+1}]\right).$$

We also take advantage of the fact that

$$Var_{\mathbf{V}}[E[\mathbf{A}\mathbf{x}_{t+1}|\mathbf{V},\{\mathbf{x}\}_1^{t+1},\{\mathbf{y}\}_1^{t+1}]] = Var_{\mathbf{V}}[\mathbf{M}_{t+1}\mathbf{x}_{t+1}] = 0,$$

and proceed as

$$\begin{aligned}E_{\mathbf{V}}[trVar(\mathbf{A}\mathbf{x}_{t+1}|\mathbf{V},\{\mathbf{x}\}_1^{t+1},\{\mathbf{y}\}_1^{t+1})] &= E_{\mathbf{V}}[tr(\mathbf{V}\otimes\mathbf{x}_{t+1}^T\mathbf{K}_{t+1}^{-1}\mathbf{x}_{t+1}|\{\mathbf{x}\}_1^{t+1},\{\mathbf{y}\}_1^{t+1}],\\ &= tr(E[\mathbf{V}|\{\mathbf{x}\}_1^{t+1},\{\mathbf{y}\}_1^{t+1}])\mathbf{x}_{t+1}^T\mathbf{K}_{t+1}^{-1}\mathbf{x}_{t+1},\\ &= \mathbf{x}_{t+1}^T\mathbf{K}_{t+1}^{-1}\mathbf{x}_{t+1}\sum_{i=1}^{d}\frac{(\boldsymbol{\beta}_{t+1})_i}{(\boldsymbol{\alpha}_{t+1})_i-1},\end{aligned}$$

where $\otimes$ denotes the Kronecker product. The law of total variance says that

$$Var[\mathbf{A}\mathbf{x}] = Var[E[\mathbf{A}\mathbf{x}|\mathbf{V}]] + E[Var[\mathbf{A}\mathbf{x}|\mathbf{V}]],$$

and hence

$$tr\,Var[\mathbf{A}\mathbf{x}_{t+1}|\{\mathbf{x}\}_1^{t+1},\{\mathbf{y}\}_1^{t+1}] = \mathbf{x}_{t+1}^T\mathbf{K}_{t+1}^{-1}\mathbf{x}_{t+1}\sum_{i=1}^{d}\frac{(\boldsymbol{\beta}_{t+1})_i}{(\boldsymbol{\alpha}_{t+1})_i-1}.$$

There is another way to arrive at the same result. One can apply (37) with Lemma A.1 and use the fact that the covariance matrix of a $\mathcal{T}_{\mathbf{x}}(\beta,\alpha,\boldsymbol{\mu},\mathbf{K})$ distributed variable is $\frac{\beta\mathbf{K}^{-1}}{\alpha-2}$ (Gelman et al., 2003). That is, we have

$$trVar[\mathbf{A}\mathbf{x}_{t+1}|\{\mathbf{x}\}_1^{t+1},\{\mathbf{y}\}_1^{t+1}] = \sum_{i=1}^{d}\left(\frac{(\boldsymbol{\beta}_{t+1})_i\left(\mathbf{x}_{t+1}^T\frac{\mathbf{K}_{t+1}^{-1}}{2}\mathbf{x}_{t+1}\right)}{2(\boldsymbol{\alpha}_{t+1})_i-2}\right).$$

Now, we can proceed as

$$\begin{aligned}
\int d\mathbf{y}_{t+1}P(\mathbf{y}_{t+1}|\{\mathbf{x}\}_1^{t+1},\{\mathbf{y}\}_1^{t})tr\left(Var[\mathbf{e}_{t+1}|\{\mathbf{x}\}_1^{t+1},\{\mathbf{y}\}_1^{t+1}]\right) &= \\
\int d\mathbf{y}_{t+1}P(\mathbf{y}_{t+1}|\{\mathbf{x}\}_1^{t+1},\{\mathbf{y}\}_1^{t})tr(E[\mathbf{V}|\{\mathbf{x}\}_1^{t+1},\{\mathbf{y}\}_1^{t+1}])\mathbf{x}_{t+1}^T\mathbf{K}_{t+1}^{-1}\mathbf{x}_{t+1} &= \\
\mathbf{x}_{t+1}^T\mathbf{K}_{t+1}^{-1}\mathbf{x}_{t+1}\int d\mathbf{y}_{t+1}P(\mathbf{y}_{t+1}|\{\mathbf{x}\}_1^{t+1},\{\mathbf{y}\}_1^{t})\sum_{i=1}^{d}\frac{(\boldsymbol{\beta}_{t+1})_i}{(\boldsymbol{\alpha}_{t+1})_i-1} &= \\
\mathbf{x}_{t+1}^T\mathbf{K}_{t+1}^{-1}\mathbf{x}_{t+1}\sum_{i=1}^{d}f_4((\boldsymbol{\alpha}_{t+1})_i,(\boldsymbol{\beta}_t)_i), &
\end{aligned} \tag{27}$$

where we used (18), (19) and Lemma 4.4 again. Applying the Sherman-Morrison formula one can see that the task is the same as in (25).

8. Joint Parameter and Noise Estimation

So far we wanted to optimize the control in order to speed-up learning of either the parameters of the dynamics or the noise. In this section we investigate the A- and D-optimality principles for the joint parameter and noise estimation task.

8.1 A-optimality

According to the A-optimality principle, the joined objective for parameter and noise estimation is given as:

$$\int d\mathbf{y}_{t+1}P(\mathbf{y}_{t+1}|\{\mathbf{x}\}_1^{t+1},\{\mathbf{y}\}_1^{t})\,trVar[vec(\mathbf{A}),diag(\mathbf{V}),\mathbf{e}_{t+1}|\{\mathbf{x}\}_1^{t+1},\{\mathbf{y}\}_1^{t+1}].$$

By means of (20), (27) and Lemma 5.2, it is equivalent to:

$$\int d\mathbf{y}_{t+1}P(\mathbf{y}_{t+1}|\{\mathbf{x}\}_1^{t+1},\{\mathbf{y}\}_1^{t})E[tr\mathbf{V}|\mathbf{x}_1^{t+1},\mathbf{y}_1^{t+1}]\,tr\left(\left(\mathbf{K}_t+\mathbf{x}_{t+1}\mathbf{x}_{t+1}^T\right)^{-1}+\mathbf{x}_{t+1}^T\mathbf{K}_{t+1}^{-1}\mathbf{x}_{t+1}\right).$$

From here, one can prove the following lemma in a few steps:

Lemma 8.1 *The A-optimality principle in the joined parameter and noise estimation task gives rise to the following choice for control:*

$$\mathbf{u}_{t+1}^{opt} = \arg\max_{\mathbf{u}_{t+1}\in\mathcal{U}}\frac{1+\mathbf{x}_{t+1}^T\mathbf{K}_t^{-1}\mathbf{K}_t^{-1}\mathbf{x}_{t+1}}{1+\mathbf{x}_{t+1}^T\mathbf{K}_t^{-1}\mathbf{x}_{t+1}}. \tag{28}$$

The proof can be found in the Appendix.

Thus, the task is a hyperbolic programming task, similar to (21).

8.2 D-optimality

One of the most salient differences between A-optimality and D-optimality is that for D-optimality we have

$$H(X,Y) = H(X|Y) + H(Y),$$

however, for A-optimality the corresponding equation does not hold in general, because:

$$trVar(X,Y) \neq E_Y[trVar(X|Y)] + trVar(Y).$$

An implication—as we shall see below—is that we cannot use the D-optimality principle for the joint parameter and noise estimation task. For D-optimality our cost function would be

$$\arg\min_{\mathbf{u}_{t+1}} \int d\mathbf{y}_{t+1} P(\mathbf{y}_{t+1}|\{\mathbf{x}\}_1^{t+1}, \{\mathbf{y}\}_1^{t}) H(\mathbf{A}, \mathbf{V}, \mathbf{e}_{t+1}|\{\mathbf{x}\}_1^{t+1}, \{\mathbf{y}\}_1^{t+1}),$$

but the following equality holds:

$$H(\mathbf{A}, \mathbf{V}, \mathbf{e}_{t+1}|\{\mathbf{x}\}_1^{t+1}, \{\mathbf{y}\}_1^{t+1}) = H(\mathbf{A}, \mathbf{V}|\{\mathbf{x}\}_1^{t+1}, \{\mathbf{y}\}_1^{t+1}) + H(\mathbf{e}_{t+1}|\mathbf{A}, \mathbf{V}\{\mathbf{x}\}_1^{t+1}, \{\mathbf{y}\}_1^{t+1}),$$

and since $\mathbf{e}_{t+1} = \mathbf{y}_{t+1} - \mathbf{A}\mathbf{x}_{t+1}$, therefore the last term $H(\mathbf{e}_{t+1}|\mathbf{A}, \mathbf{V}\{\mathbf{x}\}_1^{t+1}, \{\mathbf{y}\}_1^{t+1}) = -\infty$. The first term is a finite real number, thus we can conclude that the D-optimality cost function is constant $-\infty$, and therefore the D-optimality principle does not suit the joint parameter and noise estimation task.

9. Non-myopic Optimization

Until now, we considered myopic methods for the optimization of control, that is, we aimed to determine the optimum of the objective only for the next step. In this section, we show a non-myopic heuristics for the noise estimation task (25).

The optimization of the derived objective function, $\mathbf{x}_{t+1}^T \mathbf{K}_t^{-1} \mathbf{x}_{t+1}$, is simple, provided that $\mathbf{K}_t$ is fixed during the optimization of $\mathbf{u}_{t+1}$. If so, then the optimization task is quadratic. To see this, let us partition matrix $\mathbf{K}_t$ as follows:

$$\mathbf{K}_t = \begin{pmatrix} \mathbf{K}_t^{11} & \mathbf{K}_t^{12} \\ \mathbf{K}_t^{21} & \mathbf{K}_t^{22} \end{pmatrix},$$

where $\mathbf{K}_t^{11} \in \mathbb{R}^{d\times d}$,$\mathbf{K}_t^{21} \in \mathbb{R}^{m-d\times d}$, $\mathbf{K}_t^{22} \in \mathbb{R}^{m-d\times m-d}$. It is easy to see that if domain $\mathcal{U}$ in (25) is large enough then

$$\mathbf{u}_{t+1}^{opt} = (\mathbf{K}_t^{22})^{-1} \mathbf{K}_t^{21} \mathbf{r}_t. \tag{29}$$

It occurs, however, that the objective $\mathbf{x}_{t+1}^T \mathbf{K}_t^{-1} \mathbf{x}_{t+1}$ may be improved by considering multiple-step lookaheads. In this case matrix $\mathbf{K}_t$ can be subject to changes in $\mathbf{x}_{t+1}^T \mathbf{K}_t^{-1} \mathbf{x}_{t+1}$, because it depends on previous control inputs $\mathbf{u}_1, \ldots, \mathbf{u}_t$ derived from previous optimization steps.

We propose a two-step heuristics for the long-term minimization of expression $\mathbf{x}_{t+1}^T \mathbf{K}_t^{-1} \mathbf{x}_{t+1}$. During the first τ-step long stage, we focus only on the minimization of the quantity $|\mathbf{K}_t^{-1}|$. Then, if this quantity $|\mathbf{K}_t^{-1}|$ becomes small, we start the second stage: we consider $\mathbf{K}_t^{-1}$ as given and search for control that minimizes quantity $\mathbf{x}_{t+1}^T \mathbf{K}_t^{-1} \mathbf{x}_{t+1}$, so we now apply the rule of (29). Thus, this method 'sacrifices' the first τ steps in order to achieve smaller costs later; this heuristic optimization is non-myopic. More formally, we use the strategy of Table 1 in the first τ steps in order to decrease quantity $|\mathbf{K}_t^{-1}|$ fast. Then after this τ-steps, we switch to the control method of (29). This will decrease the cost function (25) further. We will call this non-greedy interrogation heuristics introduced for noise estimation *'τ-infomax noise interrogation'*. This non-myopic heuristics admits that parameter estimation of the dynamics is the prerequisite of noise estimation, because improper parameter estimation makes apparent noise, and thus the heuristics sacrifices τ steps for parameter estimation.

In Section 10 we will empirically show that using this non-myopic strategy, after τ steps we can achieve smaller cost values in (25)—as well as better performance in parameter estimation—than using the greedy competitors. The compromise is that in the first τ steps the performance of the non-myopic control can be worse than that of the other control methods.

We note that in the τ-infomax noise interrogation, for large switching time τ and for large t values, $|\mathbf{K}_t^{22}|$ will be large, and hence—according to (29)—the optimal $\mathbf{u}_t$ for interrogation will be close to $\mathbf{0}$. (In Section 10 we will show this empirically.) A reasonable approximation of the 'τ-infomax noise interrogation' is to use the control given in Table 1 for τ steps and to switch to *zero-interrogation* onwards. This scheme will be called the *'τ-zero interrogation'* scheme.

10. Numerical Illustrations

We illustrate by numerical simulations the power of A- and D-optimizations.

10.1 Generated Data

This section provides numerical experiments for parameter and noise estimations on artificially generated toy problems.

10.1.1 PARAMETER ESTIMATION

We investigated the parameter estimation capability of the D- and A-optimal interrogation. Matrix $\mathbf{F} \in \mathbb{R}^{d \times d}$ has been generated as a random orthogonal matrix multiplied by 0.9 so that the magnitudes of its eigenvalues remained below 1. Random matrix $\mathbf{B} \in \mathbb{R}^{d \times c}$ was generated from standard normal distribution. Elements of the diagonal covariance matrix $\mathbf{V}$ of noise $\mathbf{e}_t$ were generated from the uniform distribution over $[0,1]$. The process is stable under these conditions.

To study whether or not the D- and A-optimal interrogations are able to estimate the true parameters we measured the averages of the squared deviations of the true matrices $\mathbf{F}$ and $\mathbf{B}$ and the means of their posterior estimations, respectively. The square roots of these estimations are the mean squared errors (MSE). One might use other options to measure performance. For example, L_2 norm could be replaced by the L_1 norm and the variance of the posterior estimations could also be added as the complementary information for the bias.

We examined the following strategies: (i) D-optimal control of Table 1 with $\mathcal{U} = [-\delta, \delta]^c$, which defines a c-dimensional hypercube. The value of δ was set to 50. (ii) A-optimal control of (21) with the same $\mathcal{U}$, (iii) zero control: $\mathbf{u}_t = \mathbf{0} \in \mathbb{R}^c \ \forall t$, (iv) random control: $u_t \in [-\delta, \delta]^c$ generated randomly from the uniform distribution in the c-dimensional hypercube, (v) control defined by (25) for noise estimation, called 'noise control', (vi) 25-zero control and (vii) 75-zero control defined in Section 9.

For solving the quadratic problem of (14) and (25) we used a subspace trust-region procedure, which is based on the interior-reflective Newton method described by Coleman and Li (1996). Its implementation is available in the Matlab Optimization toolbox. However, the optimization task in (21) is more involved: Generally, the optimization of a constrained hyperbolic programming task is quite difficult. We tried the gradient ascent method, but its convergence appeared to be very slow and we got poor results. In this case, it was more efficient to apply a simplex method as follows: we know that the optimal solution of (21) lies at the boundary of $\mathcal{U}$. Thus, we chose one corner of hypercube $\mathcal{U}$ randomly with uniform distribution and moved greedily to the neighboring corners with the best improvement in the objective. This procedure was iterated until convergence. The method was efficient for our special simple optimization domain.

We investigated two distinct cases. In the first case we set $d = 10 < c = 40$; the dimension of the observations is smaller than the dimension of the control. By contrast, in the other case we set $d = 40 > c = 10$. Results are shown in Fig. 1 (a-b) and in Fig. 2 (a-b). We separated the MSE values of matrices $\mathbf{B}$ and $\mathbf{F}$. According to the figure, zero control may give rise to early and sudden drops in the MSE values of matrix $\mathbf{F}$. Not surprisingly, however, zero control is unable to estimate matrix $\mathbf{B}$. For both types of matrices as well as for $d < c$ and for $d > c$, the D-optimal procedure produced the smallest MSE after about 50 online estimations, but the A-optimal method reached very similar levels only a few iterations later. As can be expected, τ-zero control, which is identical to D-optimal control in the first τ steps fell behind D-optimal control after τ since it changes the objective and estimates the noise and not the parameters afterwards.

For statistical significance studies, we introduced the concept of average correlation curves. We use Fig. 1 to explain this concept. There are 7 curves in Fig. 1 each representing the averages of 25 computer runs. Error bars make the curves incomprehensible and they hide the correlations that may be present between the errors. We note that the relative order of the curves is of interest for us. However, it is possible that in each run the relative order of the curves was the same and the overlap of the error bars—which originates from the large differences between the individual runs—hides this important piece of information. We treat this problem as follows. In each time instant $1 \leq t \leq 250$ and for all $1 \leq i < j \leq 25$ we compute the empirical (linear, or rank) correlation of the 7 curves of the i^{th} and j^{th} experiment and take the average of the $25 \times 24/2 = 300$ values. The most significant case gives rise to 1 for each of the 300 correlations, that is, the 25 experiments agree in the height of the curves at that time instant, or in their relative orderings for the case of rank correlation. If there is any single experiment out of 25 that produces different heights or orders then the average correlation becomes smaller than 1. For randomly chosen curves the average correlation is 0. Results can be seen in Fig. 1 (c-d) and Fig. 2 (c-d) for linear Pearson and for Kendal rank correlations, respectively. The curves demonstrate that after about 50 steps, the correlations, in particular the linear correlation is almost 1. This means that the curves behaved similarly in a considerable portion of the experiments. The slightly different picture shown by the linear correlation and the rank correlation could be due to the fact that the performance of the A and D-optimal control is very similar after some time, and their ordering may change often, thus giving rise to changes in the ranks in different experiments.

10.1.2 NOISE ESTIMATIONS

In Section 7 we showed that A- and D-optimality principles result in the same cost function.

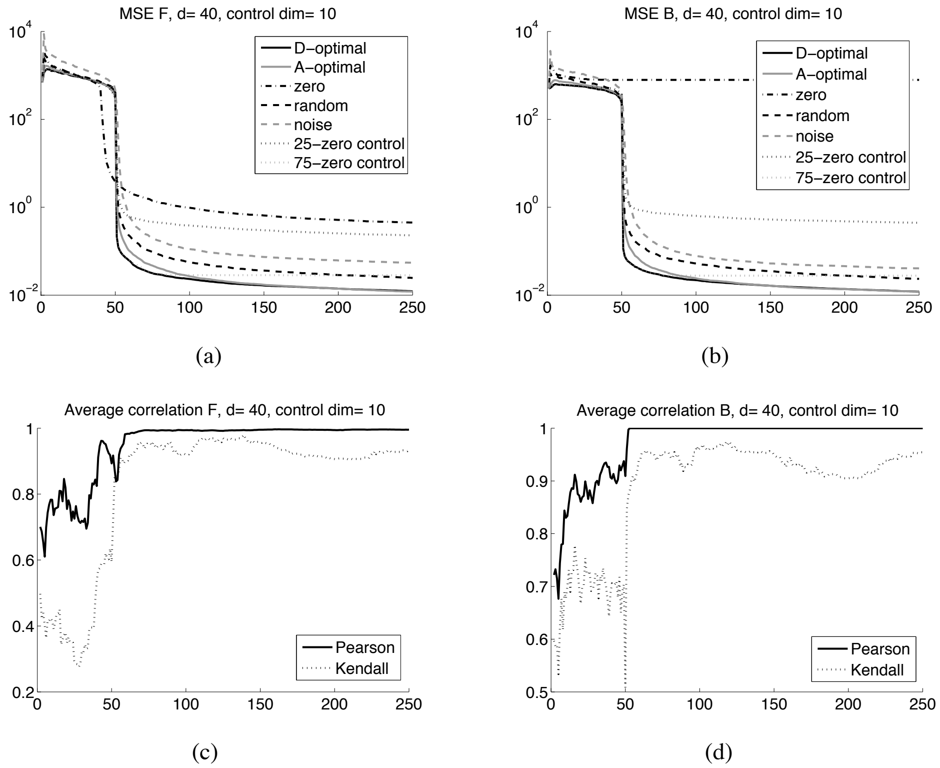

Figure 1: Mean Square Error of the estimated parameters for different control strategies and the significance of the curves. Magnitude of MSE as a function of time is averaged for 25 runs. Dimension of the control is 10. $\mathbf{F} \in \mathbb{R}^{40\times 40}$, $\mathbf{B} \in \mathbb{R}^{40\times 10}$. (a): MSE of the estimated matrix $\hat{\mathbf{F}}$. (b): MSE of the estimated matrix $\hat{\mathbf{B}}$. (c): The average correlation curves for the estimation of $\mathbf{F}$. (d): The average correlation curves for the estimation of $\mathbf{B}$. For details see the text.

We investigated the noise estimation capability of the interrogation in (25) for four cases. The first set of experiments illustrates that the estimation of driving noise $\mathbf{e}_t$ for large τ values barely differs if we replace the τ-*infomax noise interrogation* with the τ-*zero interrogation* scheme. Parameters were the same as above and the MSE of the noise estimation was computed. Results are shown in Fig. 3: for the case of $\tau = 21$, cost function (25) of the τ-zero interrogation is higher than that of τ-infomax interrogation. However, for values $\tau = 51$ and 81 the performances of the two schemes are approximately identical. Given that τ-zero and τ-infomax noise interrogation behave similarly for large τ values, we compare the τ-zero interrogation scheme with other schemes in our numerical experiments.

In the second experiment we investigated the problem of noise estimation on a toy problem. Parameters were set as in Section 10.1.1, and the following strategies were compared: zero control, infomax control, random control and τ-zero control for different τ values. Results are shown in Fig. 4. It is clear from the figure that neither the zero control, nor the infomax (D-optimal) control of Table 1 work for this case. If we want to have minimal MSE in approximately τ steps then the best strategy is to apply the τ-zero strategy, that is, the strategy of Table 1 up to τ steps and then to switch to zero control. Note, however, that parameter estimation requires to keep control values non-negligible forever (Table 1).

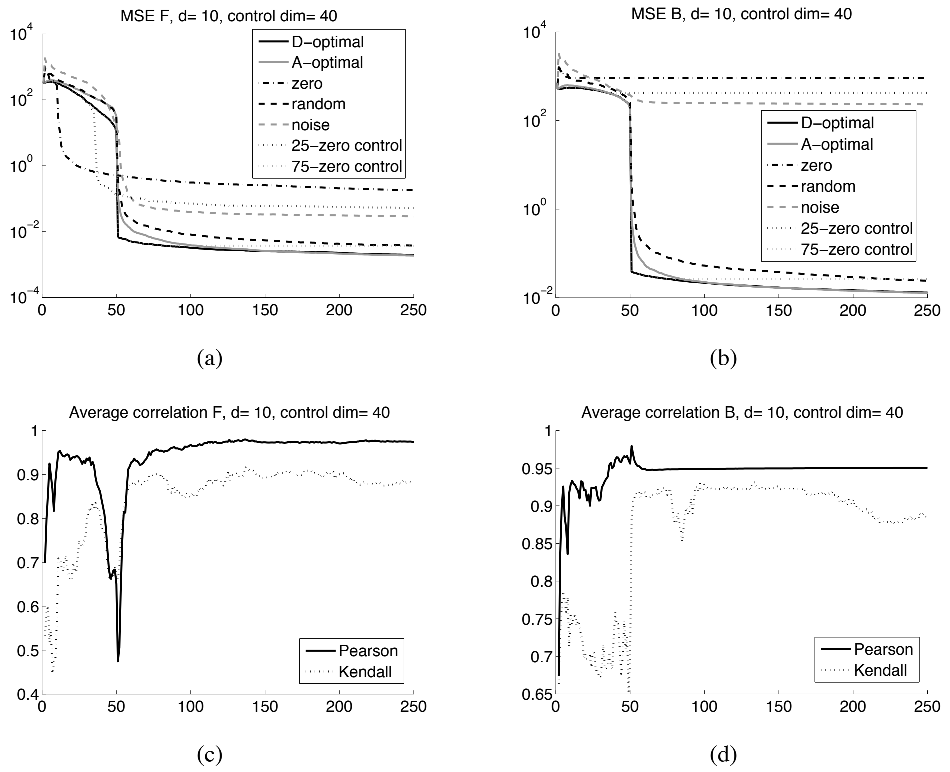

Figure 2: Mean Square Error of the estimated parameters for different control strategies and the significance of the curves. Magnitude of MSE as a function of time is averaged for 25 runs. Dimension of the control is 40. $\mathbf{F} \in \mathbb{R}^{10\times 10}$, $\mathbf{B} \in \mathbb{R}^{10\times 40}$. (a): MSE of the estimated matrix $\hat{\mathbf{F}}$. (b): MSE of the estimated matrix $\hat{\mathbf{B}}$. (c): The average correlation curves for the estimation of $\mathbf{F}$. (d): The average correlation curves for the estimation of $\mathbf{B}$. For details see the text.

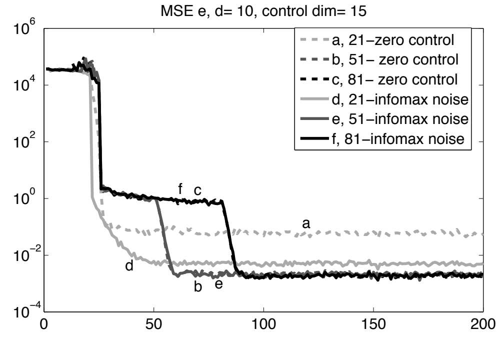
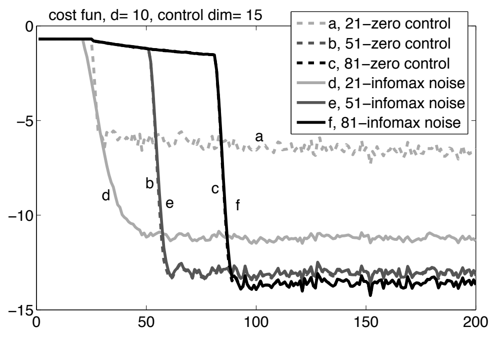
In the third experiment we used numerical tools to support our the arguments we made in Section 9. We investigate the D-optimal, the zero, the random, and the greedy noise control of (25), as well as the 71-zero and 101-zero controls. Results show that if we may sacrifice the first τ steps, then the non-myopic $\tau - zero$ control gives rise to the smallest MSE for the estimated noise and the smallest values for the cost function (25) *after* τ steps considering all studied control methods. Figure 5a shows the MSE of the estimated driving noise, whereas Fig. 5b depicts the cost $\mathbf{x}_{t+1}^T \mathbf{K}_t^{-1} \mathbf{x}_{t+1}$. Figure 5c is about the time dependence of $\log|\mathbf{K}_t|$ that supports our argument in Section 9, namely, it may be worth to sacrifice steps at the beginning to quickly decrease $|\mathbf{K}_t^{-1}|$ (i.e., to decrease $\log|\mathbf{K}_t|$) in order to estimate (25) efficiently later. The problem we studied was the same as before, except that $d = 25$ and $c = 25$ were applied.

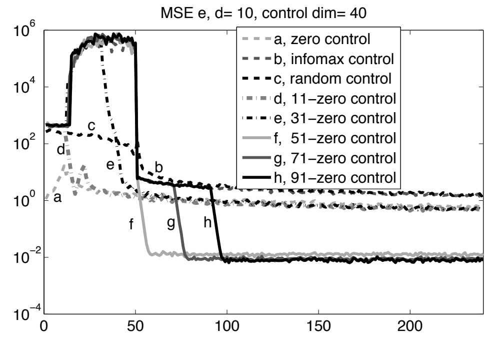
The fourth experiment illustrates the efficiency of the approximation of the noise for the case when our assumptions on $\mathbf{e}_t$ are not fulfilled. Here noise $\mathbf{e}_t$ was neither Gaussian nor i.i.d. 'Noise' $\mathbf{e}_t$ was chosen as equidistant points smoothly 'walking' along a 3 dimensional spiral curve as a function of time (Fig. 6a). Dimensions of observation and control were 3 and 15, respectively. Results are shown in Fig. 6. Neither random control, nor infomax interrogation of Table 1 (Fig. 6c), nor zero control (Fig. 6d) could produce reasonable estimation. However, the τ-zero interrogation scheme

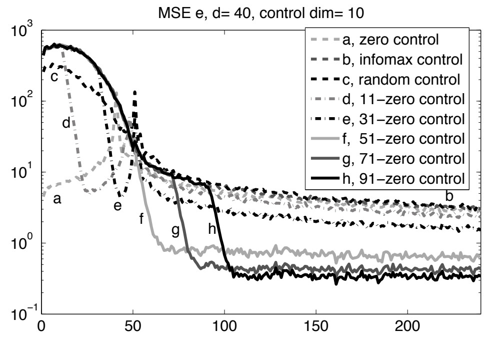




(a) (b)

Figure 3: Comparing τ-infomax noise and τ-zero interrogations. The curves are averaged for 50 runs. Dimension of the control is 15 and the dimension of the observation is 10. (a): MSE of the estimated noise (b): Cost function as given in (25). 'τ-infomax noise' (τ-zero) means that up to step number τ strategy of Table 1 applies and then the control of Eq. (29) is followed.





(a) (b)

Figure 4: Mean Square Error of the estimated noise for different control strategies. Magnitude of MSE as a function of time is averaged for 20 runs. (a): Dimension of the control is 40. $\mathbf{F} \in \mathbb{R}^{40\times 40}$, $\mathbf{B} \in \mathbb{R}^{40\times 10}$. (b): Dimension of the control is 10. $\mathbf{F} \in \mathbb{R}^{10\times 10}$, $\mathbf{B} \in \mathbb{R}^{10\times 40}$. 'τ-zero' means that up to step number τ the strategy illustrated in Table 1 was applied and then zero control followed.

produced a good approximation for large enough τ values (Fig. 6e). Details of this illustration are shown in Fig. 6f.

10.1.3 Joint Parameter and Noise Estimations

In Section 8 we showed that the objective of the D-optimality principle is constant for the joined parameter and noise estimation task. However, A-optimality principle provides sensible cost function (Eq. (28)). Unfortunately, it leads to a hyperbolic programming task. This optimization is hard in most cases. One can estimate the complexity of the objective by inspecting lower dimensional cases. We show the negative logarithm of (28) for the 2 dimensional case for different $\mathbf{K}$ matrices (Fig. 7). In one of the cases the null vector corresponds to the minimum, whereas in the other case the minimum is at a boundary point of the optimization domain. Also, the cost functions appear to be flat in a large part of their domains, rendering gradient based methods ineffective.

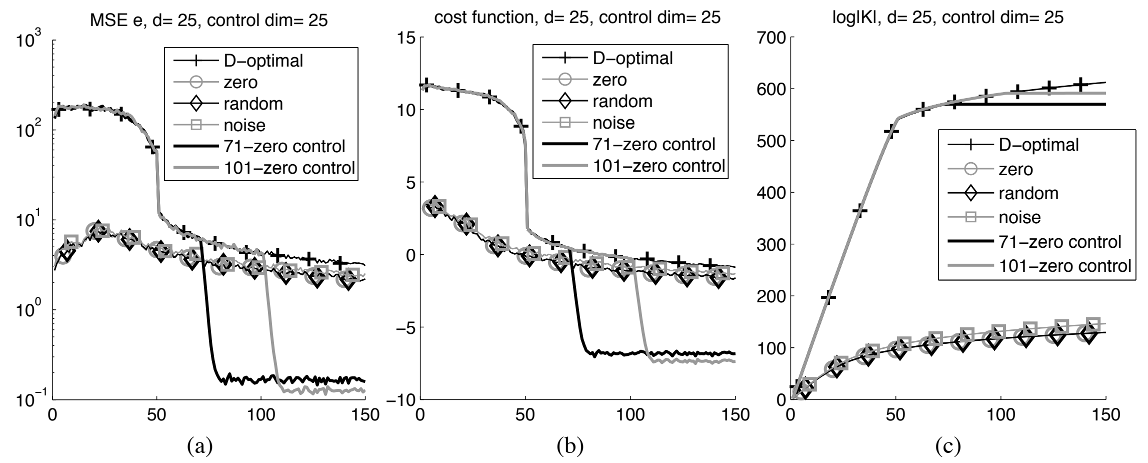


Figure 5: Empirical study on non-myopic controls for noise estimation. We sacrifice the first τ steps to achieve better MSE and smaller cost function. The curves are averaged over 25 runs. The dimension of the control and the dimension of the observation is 25. (a): MSE of noise estimation for different control strategies. (b): $\mathbf{x}_{t+1}^T \mathbf{K}_t^{-1} \mathbf{x}_{t+1}$ cost function for different control strategies. (c): $\log|\mathbf{K}_t|$ function for different control strategies.

Studies were conducted on the problem family of 10.1.1 for observation dimension $d = 15$ and control dimension $c = 30$. For the optimization, we modified the simplex method that we used for the hyperbolic task before. The single difference is that upon convergence, the best value was compared with the value of the objective at the 0 point and we chose the better one for control. We have compared this strategy with the parameter estimation strategy of the D-optimality principle, with zero control strategy, with random control strategy, and with $\tau - \textit{zero}$ control for several τ values. Results are shown in Fig. 8. The figure indicates that control derived from the A-optimality principle (28) provides superior MSE results at approximately 45 iterations and then onwards compared to the other *myopic* techniques, however its performance was slightly worse than the *non-myopic* τ-zero control for τ values larger than an appropriate threshold.

Inspecting the optimal control series of the winner, we found that the algorithm chooses control values from the boundaries of the hypercube in the first 45 or so iterations. Then up to about 130 iterations it is switching between zero control and controls on the boundaries, but eventually it uses zero controls only. That is, the A-optimality principle is able to detect the need for the switch from high control values (to determine the parameters of the dynamics) to zero control values for noise estimation. This automated switching behavior is a special advantage of the A-optimality principle.

10.2 Controlled Independent Component Analysis

In this section we study the usefulness of our methods for auto-regressive (AR) hidden processes with independent driving sources and we would like to find the independent causes that drive the processes. This task belongs to independent component analysis (ICA) (Jutten and Hérault, 1991; Comon, 1994; Hyvärinen et al., 2001). Informally, we assume that our sources are doubly covered: they are the driving noise processes of AR processes which can not be directly observed due to the mixing with an unknown matrix. We will study our methods for this particular example and we

.

assume that the processes can be exogenously controlled. Such processes are called ARX processes where X stands for letter x of the word eXogenous.

The 'classical' ICA task is as follows: we are given temporally i.i.d. signals $\mathbf{e}_t \in \mathbb{R}^d$ $(t = 1, 2, \ldots, T)$ with statistically independent coordinates. We are unable to measure them directly, but their mixture $\mathbf{r}_t = \mathbf{C}\mathbf{e}_t$ is available for observation, where $\mathbf{C} \in \mathbb{R}^{d \times d}$ is an unknown invertible matrix. The task is to measure the observable signals and to estimate both mixing matrix $\mathbf{C}$ and sources $\mathbf{e}_t$.

There are several generalizations of this problem. Hyvärinen (1998) has introduced an algorithm to solve the ICA task even if the hidden sources are AR processes, whereas Szabó and Lőrincz (2008) generalized this problem for ARX processes in the following way: Processes $\tilde{\mathbf{e}}_t \in \mathbb{R}^d$ are given and they are statistically independent for the different coordinates and are temporally i.i.d signals. They generate ARX process $\mathbf{s}_t$ by means of parameters $\tilde{\mathbf{F}} \in \mathbb{R}^{d\times d}, \tilde{\mathbf{B}} \in \mathbb{R}^{d\times c}$:

$$\mathbf{s}_{t+1} = \sum_{i=0}^{I} \tilde{\mathbf{F}}_i \mathbf{s}_{t-i} + \sum_{j=0}^{J} \tilde{\mathbf{B}}_j \mathbf{u}_{t+1-j} + \tilde{\mathbf{e}}_{t+1}. \tag{30}$$

We assume that ARX process $\mathbf{s}_t$ can not be observed directly, but its mixture

$$\mathbf{r}_t = \mathbf{C}\mathbf{s}_t \tag{31}$$

is observable, where mixing matrix $\mathbf{C} \in \mathbb{R}^{d\times d}$ is invertible, *but unknown*. Our task is to estimate the original independent processes also called sources, noises or 'causes', that is, $\tilde{\mathbf{e}}_t$, the hidden process $\mathbf{s}_t$ and mixing matrix $\mathbf{C}$ from observations $\mathbf{r}_t$. It is easy to see that (30) and (31) can be rewritten into the following form

$$\mathbf{r}_{t+1} = \sum_{i=0}^{I} \mathbf{C}\tilde{\mathbf{F}}_i \mathbf{C}^{-1} \mathbf{r}_{t-i} + \sum_{j=0}^{J} \mathbf{C}\tilde{\mathbf{B}} \mathbf{u}_{t+1-j} + \mathbf{C}\tilde{\mathbf{e}}_{t+1}. \tag{32}$$

Using notations $\mathbf{F}_i = \mathbf{C}\tilde{\mathbf{F}}_i\mathbf{C}^{-1}, \mathbf{B}_j = \mathbf{C}\tilde{\mathbf{B}}_j, \mathbf{e}_{t+1} = \mathbf{C}\tilde{\mathbf{e}}_{t+1}$, (32) takes the form of the model (1) that we are studying with function g being the identity matrix. The only difference is that in ICA tasks $\mathbf{e}_t$ is assumed to be non-Gaussian, whereas in our derivations we always used the Gaussian assumption. In our studies, however, we found that the different control methods can be useful for non-Gaussian noise, too. Furthermore, the Central Limit Theorem says that the mixture of the variables $\tilde{\mathbf{e}}_t$, that is, $\mathbf{C}\tilde{\mathbf{e}}_t$ approximates Gaussian distributions, provided that the number of mixed variables is large enough.

In our numerical experiments we studied the following special case:

$$\mathbf{r}_{t+1} \quad = \quad \mathbf{F}\mathbf{r}_t + \mathbf{B}\mathbf{u}_{t+1} + \mathbf{C}\mathbf{e}_{t+1},$$

where the dimension of the noise was 3, the dimension of the control was 15. Matrices $\mathbf{F}$ and $\mathbf{B}$ were generated the same way as before, matrix $\mathbf{C}$ was a randomly chosen orthogonal mixing, noise sources $\mathbf{e}_{t+1}$ were chosen from the benchmark tasks of the fastICA toolbox[1] (Hyvärinen, 1999). We compared 5 different control methods (zero control, D-optimal control developed for parameter estimation, random control, A-optimal control developed for joint estimation of parameters and noise, as well as the τ-zero control with τ=81 that we developed for noise estimation). Comparisons are executed by first estimating the noise ($\mathbf{C}\mathbf{e}_{t+1}$) for times $T = 1,\ldots,1000$ and then applying the JADE ICA algorithm (Cardoso, 1999) for the estimation of the noise components ($\mathbf{e}_{t+1}$). Estimation was executed in each fiftieth steps, but only for the preceding 300 elements of the time series.

The quality of separation is evaluated by means of the Amari-error (Amari et al., 1996) as follows. Let $\mathbf{W} \in \mathbb{R}^{d\times d}$ be the estimated demixing matrix, and let $\mathbf{G} := \mathbf{W}\mathbf{C} \in \mathbb{R}^{d\times d}$. In case

1. Found at `http://www.cis.hut.fi/projects/ica/fastica/`.

of perfect separation the matrix **G** is a scaled permutation matrix. The Amari-error evaluates the quality of the separation by measuring the 'distance' of matrix **G** from permutation matrices:

$$r(\mathbf{G}) = \frac{1}{2d(d-1)}\sum_{i=1}^{d}\left(\frac{\sum_{j=1}^{d}|G_{ij}|}{\max_j |G_{ij}|}-1\right)+\frac{1}{2d(d-1)}\sum_{j=1}^{d}\left(\frac{\sum_{i=1}^{d}|G_{ij}|}{\max_i |G_{ij}|}-1\right).$$

The Amari-error $r(G)$ has the property that $0 \leq r(\mathbf{G}) \leq 1$, and $r(\mathbf{G}) = 0$ if and only if **G** is a permutation matrix.

Results are shown in Fig. 9. In short, τ-zero control performs slightly better than the joint parameter and noise estimation using the A-optimality principle. We note that for A-optimality design one does not have to worry about the duration of the parameter estimation. The performance of the other methods were considerably worse, especially for early times.

Most importantly, we found that if we use Bayesian methods for noise separation in ARX problems then it is worth to interrogate the system actively to improve the efficiency of the estimation.

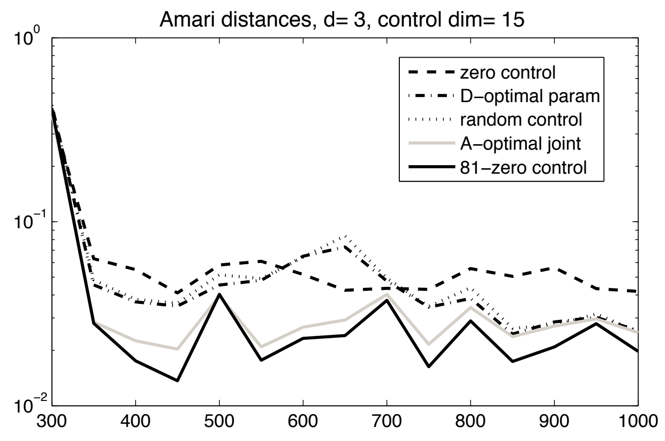

Figure 9: ARX-ICA experiment. Amari-error as a function of time for different control methods. Curves show the means of 100 experiments.

10.3 Model of the Furuta Pendulum

This section is concerned with more realistic simulations and investigate the robustness of our approach. We use a model of the Furuta pendulum (e.g., Yamakita et al., 1995) as our example, In this case, conditions of the theorems are not fulfilled and the task—in our formulation—can not be represented with a few matrices. In this simulation, we studied the D-optimality principle and compared it with the random control method. We were interested in the parameter estimation task in this example.

The two-segment Furuta pendulum problem (e.g., Yamakita et al., 1995; Gäfvert, 1998) was used. The pendulum has two links. Configuration of the pendulum is determined by the length of the links and by two angles. Dynamics of the pendulum are also determined by the different masses, that is, the masses of the links and the mass of the end effector as well as by the two motors, which are able to rotate the horizontal link and the swinging link in both directions. The angles of the horizontal and the swinging links are denoted by φ and θ, respectively (Fig. 10). Parameters

Name of parameter	Value	Unit	Notation
Angle of swinging link		rad	θ
Angle of horizontal link		rad	ϕ
Mass of horizontal link	0.072	kg	m_a
Mass of vertical link	0.00775	kg	m_p
Mass of the weight	0.02025	kg	M
Length of horizontal link	0.25	m	l_a
Length of vertical link	0.4125	m	l_p

of computer illustrations are provided in Table 2 for the sake of reproducibility. The state of the pendulum is given by ϕ, θ, $\dot{\phi}$ and $\dot{\theta}$. The magnitude of angular speeds $\dot{\phi}$ and $\dot{\theta}$ was restricted to 2 rotations/s, that is, to the interval $[-2\frac{\text{rot}}{\text{s}}, 2\frac{\text{rot}}{\text{s}}]$. For the equations of the dynamics and the details of the parameters, see, for example, the related technical report (Gäfvert, 1998).

.

The pendulum is a continuous dynamical system that we observe in discrete time steps. Furthermore, we assume that our observations are limited; we have only 144 low resolution and overlapping sensors for observing angles ϕ and θ. In each time step these sensors form our $\mathbf{r}(t) \in \mathbb{R}^{144}$ observations, which were simulated as follows: Space of angles ϕ and θ is $[0,2\pi) \times [0,2\pi)$, which we divided into $12 \times 12 = 144$ squared domains of equal sizes. There is a Gaussian sensor at the center of each domain. Each sensor gives maximal response 1 when angles θ and ϕ of the pendulum are in the center of the respective sensor, whereas the response decreased according to the Gaussian function. For example, for the i^{th} $(1 \leq i \leq 144)$ sensor characterized by angles θ_i, ϕ_i response y_i scaled as $y_i = \frac{1}{\sqrt{2\pi}\sigma}\exp(-\frac{(\theta-\theta_i)^2+(\phi-\phi_i)^2}{2\sigma^2})$ and the value of σ was set to 1.58 in radians. Sensors were crude but noise-free; no noise was added to the sensory outputs. The inset at label 4 of Fig. 11 shows the outputs of the sensors in a typical case. Sensors satisfied periodic boundary conditions; if sensor S was centered around zero degree in any of the directions, then it sensed both small (around 0 radian) and large (around 2π radian) angles. We note that the outputs of the 144 domains are arranged for purposes of visualization; the underlying geometry of the sensors is hidden for the learning algorithm.

We observed these $\mathbf{r}_t \in \mathbb{R}^{144}$ quantities and then calculated the $\mathbf{u}_{t+1} \in \mathbb{R}^2$ D-optimal control using the algorithm of Table 1, where we approximated the pendulum with the model $\tilde{\mathbf{r}}_{t+1} = \mathbf{F}\mathbf{r}_t + \mathbf{B}\mathbf{u}_{t+1}$, $\mathbf{F} \in \mathbb{R}^{144\times 144}$, $\mathbf{B} \in \mathbb{R}^{144\times 2}$. Components of vector $\mathbf{u}_{t+1}$ controlled the 2 actuators of the angles separately. Maximal magnitude of each control signal was set to 0.05 Nm. Clearly we do not know the best parameters for $\mathbf{F}$ and $\mathbf{B}$ in this case, so we studied the prediction error and the number of visited domains instead. This procedure is detailed below.

First, we note that the angle of the swinging link and the angular speeds are important from the point of view of the prediction of the dynamics, whereas the angle of the horizontal link can be neglected. Thus, for the investigation of the learning process, we used the 3D space determined by $\dot{\phi}, \theta$ and $\dot{\theta}$. As was mentioned above, angular speeds were restricted to the $[-2\frac{\text{rot}}{\text{s}}, 2\frac{\text{rot}}{\text{s}}]$ domain. We divided each angular speed domain into 12 equal regions. We also used the 12-fold division of angle θ. Counting the domains, we had $12 \times 12 \times 12 = 1,728$ rectangular block shaped domains. Our algorithm provides estimations for $\hat{\mathbf{F}}_t$ and $\hat{\mathbf{B}}_t$ in each instant. We can use them to compute the predicted observation vector $\hat{\mathbf{r}}_{t+1} = \hat{\mathbf{F}}_t\mathbf{r}_t + \hat{\mathbf{B}}_t\mathbf{u}_{t+1}$. An example is shown in inset at label 4 of Fig. 11. We investigated the $\|\mathbf{r}_{t+1} - \hat{\mathbf{r}}_{t+1}\|$ prediction error (see Fig. 11) *cumulated over these domains* as follows. For each of the 1,728 domain, we set the initial error value at 30, a value somewhat larger than the maximal error we found in the computer runs. Therefore the cumulated error at start was $1,728 \times 30 = 51,840$.

The D-optimal algorithm does two things simultaneously: (i) it explores new domains, and (ii) it decreases the errors in the domains already visited. Thus, we measured the cumulated prediction errors during learning and corrected the estimation at each step. So, if our cumulated error estimation at time t was $e(t) = \sum_{k=1}^{1,728} e_k(t)$ and the pendulum entered the i^{th} domain at time $t+1$, then we set $e_k(t+1) = e_k(t)$ for all $k \neq i$ and $e_i(t+1)$ at $e_i(t+1) = \|\mathbf{r}_{t+1} - \hat{\mathbf{r}}_{t+1}\|$. Then we computed the new cumulated prediction error, that is, $e(t+1) = \sum_{k=1}^{1,728} e_k(t+1)$.

We compared the random and the D-optimality interrogation schemes. We show two sets of figures, Figs. 12a and 12b, as well as Figs. 12c and 12d. The upper set depicts the results for the full set of the 1,728 domains. It is hard for the random control to guide the pendulum to the upper domain, so we also investigated how the D-optimal control performs here. We computed the performance for cases when the swinging link was above vertical, that is for 864 domains (Figs. 12c and 12d).

For the full domain the number of visited domains is 456 (26%) and 818 (47%) for the random control and the D-optimal control, respectively after 5,000 control steps (Fig. 12a). The error drops by 13,390 (26%) and by 24,040 (46%), respectively (Fig. 12b). While the D-optimal controlled pendulum visited more domains and achieved smaller errors, the domain-wise estimation error is about the same for the domains visited; both methods gained about 29.4% per domains.

We can compute the same quantities for the upper domains as well. The number of visited upper domains is 9 and 114 for the random control and for the D-optimal control, respectively (Fig. 12c). The decrease of error is 265 and 3,342, respectively (Fig. 12d). In other words, D-optimal control gained 29.3% in each domain on average, whereas random control, on average, gained 29.4 %,

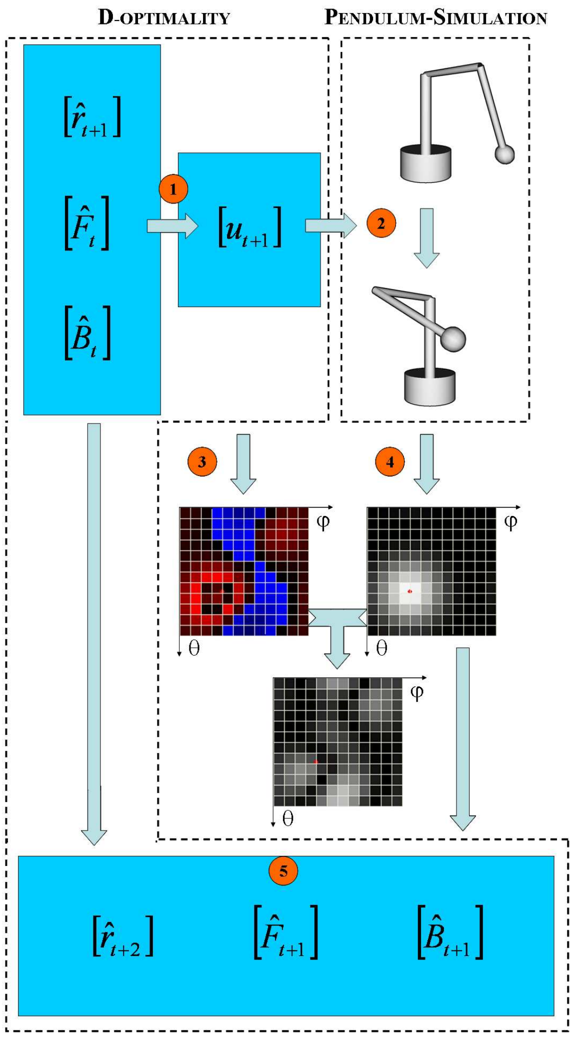

Figure 11: Scheme of D-optimal interrogation. (1) Control $\mathbf{u}_{t+1}$ is computed from D-optimal principle, (2) control acts upon the pendulum, (3) signals predicted before control step, (4) sensory information after control step. Difference between (3) and (4) is used for the computation of the cumulated prediction error. (5) Parameters were updated according to the pseudocode of Table 1. For more details, see text.

which are very close to the previous values in both cases. In this experiment D-optimal control gains more information concerning the system to be identified by visiting new domains.

This observation is further emphasized by the following data: The D-optimal algorithm discovered 37 new domains in the last 500 steps of the 5,000 step experiment. Out of these 37 domains, 20 (17) were discovered in the lower (upper) domain. By contrast, the random algorithm discovered 9 domains, out of which 5 (4) was in the lower (upper) domain. That is, D-optimality principle has a similar (roughly fourfold) lead in both the upper and lower domains, although the complexity of the task is different and the relative number of available volumes is also different in these two domains.

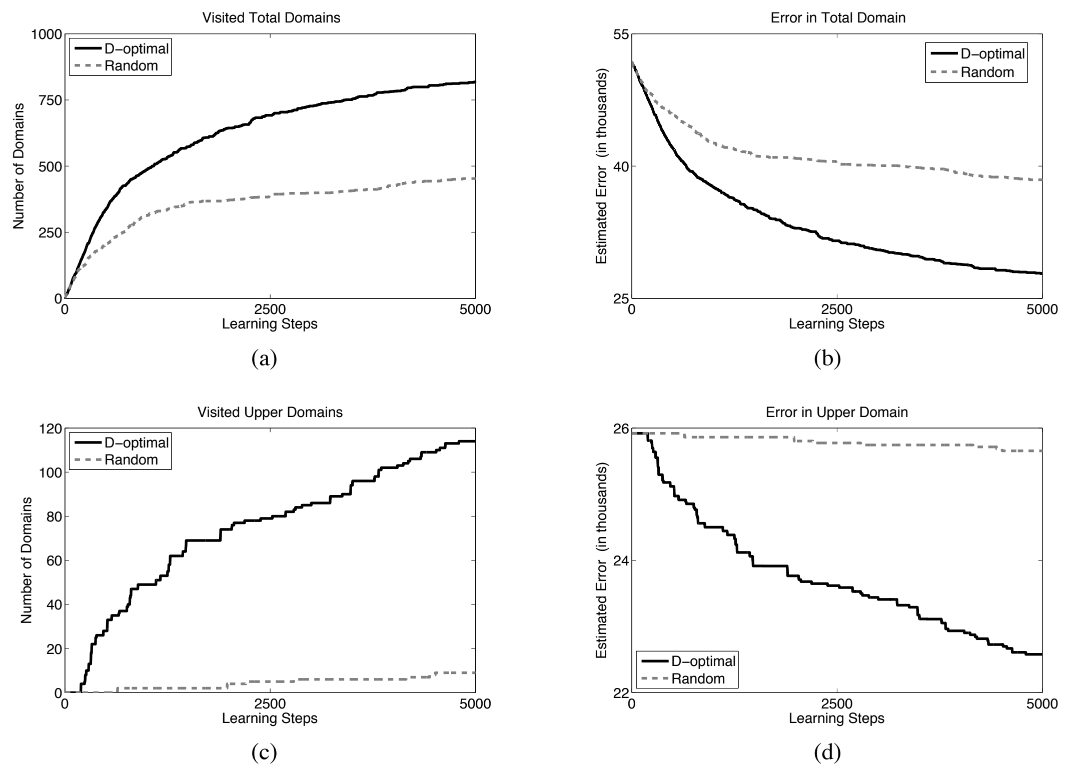

Figure 12: Furuta experiments driven by random and D-optimality controls. Solid (dotted) line: D-optimal (random) case. (a-b): Number of domains is 1728. (a): Visited domains, (b): upper bound for cumulated estimation error in all domains, (c-d): Number of domains is 864. (c): visited domains for swing angle above horizontal, (d): upper bound for cumulated estimation error for domains with swing angle above vertical. For more details, see text.

11. Discussion and Conclusions

We have treated the identification problem of recurrent neural networks as defined by the model detailed in (1). We applied active learning to solve this task. In particular, we studied the learning properties of the online A-optimality and D-optimality principles for parameter and noise estimations. We note that the D-optimal interrogation scheme is also called InfoMax control in the literature by Lewi et al. (2007). This name originates from the cost function that optimizes the mutual information.

In the generalized linear model (GLM) used by Lewi et al. (2007) $\mathbf{r}_{t+1}$ is drawn from an exponential family distribution with link function g and

$$E[\mathbf{r}_{t+1}] = g\left(\sum_{i=0}^{I} \mathbf{F}_i \mathbf{r}_{t-i} + \sum_{j=0}^{J} \mathbf{B}_j \mathbf{u}_{t+1-j}\right)$$

expected value. This model can be rewritten as

$$\mathbf{r}_{t+1} = g\left(\sum_{i=0}^{I} \mathbf{F}_i \mathbf{r}_{t-i} + \sum_{j=0}^{J} \mathbf{B}_j \mathbf{u}_{t+1-j}\right) + \mathbf{e}_{t+1}, \tag{33}$$

where $\{\mathbf{e}_t\}$ is a special noise process with $\mathbf{0} \in \mathbb{R}^d$ mean. The elements of this error series are independent of each other, but usually they are *not* identically distributed. The authors modeled spiking neurons and assumed that the main source of the noise is this spiking, which appears at the output of the neurons and adds linearly to the neural activity. They investigated the case in which the observed quantity $\mathbf{r}_t$ had a Poisson distribution. Unfortunately, in this model Bayesian equations become intractable and the estimation of the posterior may be corrupted, because the distribution is projected to the family of normal distributions at each instant. A serious problem with this approach is that the extent of the information loss caused by this approximation is not known. Our stochastic RNN model

$$\mathbf{r}_{t+1} = g\left(\sum_{i=0}^{I} \mathbf{F}_i \mathbf{r}_{t-i} + \sum_{j=0}^{J} \mathbf{B}_j \mathbf{u}_{t+1-j} + \mathbf{e}_{t+1}\right),$$

differs only slightly from the GLM model of (33), but it has considerable advantages, as we discuss it later. Note that the two models assume the same form if function g is the identity matrix and if the noise distribution is normal.

Our model is very similar to the well-studied non-linear Wiener (Celka et al., 2001) and Hammerstein (Pearson and Pottmann, 2000; Abonyi et al., 2000) systems. The Hammerstein model develops according to the following dynamics

$$\mathbf{r}_{t+1} = \sum_{i=0}^{I} \mathbf{F}_i \mathbf{r}_{t-i} + \sum_{j=0}^{J} \mathbf{B}_j g(\mathbf{u}_{t+1-j}) + \mathbf{e}_{t+1}.$$

The dynamics of the Wiener system is

$$\mathbf{r}_{t+1} = g\left(\sum_{i=0}^{I} \mathbf{F}_i g^{-1}(\mathbf{r}_{t-i}) + \sum_{j=0}^{J} \mathbf{B}_j \mathbf{u}_{t+1-j} + \mathbf{e}_{t+1}\right),$$

where we assumed that function g is invertible.

The Wiener and the Hammerstein systems have found applications in a broad range of areas, including financial predictions to the modeling of chemical processes. These models are special cases of non-linear ARX (NARX) models (Billings and Leontaritis, 1981). They are popular, because they belong to the simplest non-linear systems. Using block representation, they are simply the compositions of a static non-linear function and a dynamic ARX system. As a result, their properties can be investigated in a relatively simple manner and they are still able to model a large class of sophisticated non-linear phenomena.

Interesting comparisons between Wiener and Hammerstein systems can be found in Bai (2002), Aguirre et al. (2005), and Haber and Unbehauen (1990). We note that our Bayesian interrogation methods can be easily transferred to both the Wiener and to the Hammerstein systems.

Bayesian designs of different kinds were derived for the linear regression problem by Verdinelli (2000):

$$\mathbf{y} = \mathbf{X}\boldsymbol{\theta} + \mathbf{e}, \tag{34}$$
$$P(\mathbf{e}) = \mathcal{N}_{\mathbf{e}}(0, \sigma^2 \mathbf{I}).$$

This problem is similar to ours ((3)-(5)), but while the goal of Verdinelli (2000) was to find an optimal design for the explanatory variables $\boldsymbol{\theta}$, we were concerned with the parameter ($\mathbf{X}$ in 34) and

	Parameter	Noise	Joint
D-optimal	$\max_{\mathbf{u}_{t+1}\in\mathcal{U}} \mathbf{x}_{t+1}^T\mathbf{K}_t^{-1}\mathbf{x}_{t+1}$	$\min_{\mathbf{u}_{t+1}\in\mathcal{U}} \mathbf{x}_{t+1}^T\mathbf{K}_t^{-1}\mathbf{x}_{t+1}$	N/A
A-optimal	$\max_{\mathbf{u}_{t+1}\in\mathcal{U}} \frac{\mathbf{x}_{t+1}^T\mathbf{K}_t^{-1}\mathbf{K}_t^{-1}\mathbf{x}_{t+1}}{1+\mathbf{x}_{t+1}^T\mathbf{K}_t^{-1}\mathbf{x}_{t+1}}$	$\min_{\mathbf{u}_{t+1}\in\mathcal{U}} \mathbf{x}_{t+1}^T\mathbf{K}_t^{-1}\mathbf{x}_{t+1}$	$\max_{\mathbf{u}_{t+1}\in\mathcal{U}} \frac{1+\mathbf{x}_{t+1}^T\mathbf{K}_t^{-1}\mathbf{K}_t^{-1}\mathbf{x}_{t+1}}{1+\mathbf{x}_{t+1}^T\mathbf{K}_t^{-1}\mathbf{x}_{t+1}}$

Table 3: Cost functions in the parameter, noise, and in the joined parameter noise estimation task.

the noise (**e**) estimation tasks. In Verdinelli's paper inverted gamma prior and vector-valued normal distribution were assumed on the isotropic noise and on the explanatory variables, respectively. By contrast, we were interested in the matrix-valued coefficients and in general, non-isotropic noises. We used matrix-valued normal distribution for the coefficients, and in the D-optimal case we applied inverted Wishart distribution for the covariance matrix of the noise. Due to the properties of the inverted Wishart distribution, the noise covariance matrix is not restricted to the isotropic form. However, in the A-optimal case, we kept the derivations simple and we applied product of inverted gamma distributions for the covariance matrix as the conjugate prior.

The Bayesian online learning framework allowed us to derive analytic results for the myopic optimization of the parameters as well as the driving noise. In the *D-optimal* case the optimal interrogation strategies for parameter (14) and noise estimation (25) appeared in attractive, intriguingly simple quadratic forms. We have shown that these two tasks are incompatible with each other. Parameter and noise estimations require the maximization and the minimization of expression $\mathbf{x}_{t+1}^T\mathbf{K}_t^{-1}\mathbf{x}_{t+1}$, respectively. We have shown also that D-optimality can not be applied to the joined estimation of parameters and noise, because the corresponding cost function is constant.

For the *A-optimality* principle, we found that the objective of the noise estimation task is identical to that of the D-optimality principle. In this case, we were able to derive sensible results for the joined estimation of parameters and noise, and received hyperbolic optimization task. We also received a similar hyperbolic optimization task for the parameter estimation problem. The optimization of this task is non-trivial. For a simple hyper-cube domain we put forth a heuristics based on the simplex method. The different cost functions are summarized in Table 3.

We found empirically in the *parameter learning* task that the different objectives—that is, the minimization of $|(\mathbf{K}_t+\mathbf{x}_{t+1}\mathbf{x}_{t+1}^T)^{-1}|$ and $tr[(\mathbf{K}_t+\mathbf{x}_{t+1}\mathbf{x}_{t+1}^T)^{-1}]$, the results of the D-optimality and A-optimality principles, respectively—exhibit similar performances (Fig. 1, Fig. 2). However, D-optimality has slightly better performance and it is easier to compute, since we need to solve a quadratic problem only as opposed to a hyperbolic one. One of the reasons for the similar performance could be that the corresponding matrices are positive definite and thus they are diagonally dominant. In this case both the trace and the determinant are dominated by diagonal elements of the matrices.

In the *noise estimation* task, however, cost functions of the A- and D-optimality principles are the same. The main difficulty here is the non-myopic optimization of this cost function (Fig. 3, Fig. 4, Fig. 5, Fig. 6). The problem of non-greedy optimization of the full task has been left open for both the A-optimality and the D-optimality principles. For the noise estimation task, we suggested a heuristic solution that we called τ-infomax noise interrogation. Numerical experiments served to show that τ-infomax noise interrogation overcomes several other estimation strategies. The novel τ-infomax noise interrogation uses the D-optimal interrogation of Table 1 up to τ-steps, and applies the noise estimation control detailed in (25) afterwards. This heuristics decreases the estimation error of the coefficients of matrices $\mathbf{F}$ and $\mathbf{B}$ up to time τ and thus—upon turning off the explorative D-optimization—tries to minimize the estimation error of the value of the noise at time $\tau+1$. We introduced the τ-zero interrogation scheme and showed that it is a good approximation of the τ-infomax noise scheme for large τ values.

In the *joint noise parameter estimation* task the D-optimal principle leads to a meaningless constant valued cost function. The A-optimal objective is a hyperbolic programming task, which is difficult to optimize. Still, its myopic optimization gave us better results than the myopic D-optimal objective derived for parameter estimation only. Interestingly, myopic A-optimal interrogations behaved similarly to the non-myopic τ-zero control (D-optimal parameter estimation up to τ steps, then zero control) with emergent automatic τ selection. However, these myopic results were somewhat worse than the non-myopic results from the τ-zero interrogation, when τ was larger than an appropriate threshold (Fig. 8).

In the field of active-learning, non myopic optimization is one of the most challenging tasks so most studies are concerned with greedy optimization only. Still, greedy optimization has produced valuable results in many cases. A few studies are concerned with non-greedy optimization of active learning, but only for certain special cases (Krause and Guestrin, 2007; Rangarajan et al., 2007). This field is in a rather early stage at the moment.

We illustrated the working of the algorithm on artificial databases both for the parameter estimation problem and for the noise estimation task. In the first set of experiments the database satisfied the conditions of our theorems. We studied the robustness of the algorithm and studied the noise estimation problem for a situation in which the conditions of our theorems were not satisfied, namely when the noise was neither Gaussian nor i.i.d. In particular, we studied the ARX problem family, when the hidden driving sources are non-Gaussian and statistically independent i.i.d. processes. We found that active control can speed-up the learning process. Function g was the identity function in these experiments.

We have also started to characterize the algorithm for a problem closer to reality. We chose the two-link Furuta pendulum task in these studies. We used a crude discretization for the pendulum, where the underlying dynamics and the low-dimensional nature of the problem are both hidden. Clearly we could express neither the ideal parameters for this case nor the noise that arose as a result of the disctretization. Thus we have studied the volume explored by the D-optimality method as well as the magnitude of the prediction errors.

The pendulum problem demonstrated that D-optimality maximizes mutual information by exploring new areas without significant compromise in the precision of estimation in the visited domains. The discovery rate is in favor of the D-optimality algorithm, which has a significant lead in both the frequently visited and the rarely visited domains, although the task is different and the relative number of available volumes is also different in these domains.

Our method treats the identification problem of non-linear ARX systems. We plan to generalize the method to NARMAX systems in the future. Such systems have several application fields, including financial modeling and the modeling of gas turbines (Chiras et al., 2001). One may try to apply these principles in a broad variety of fields, including selective laser chemistry Rabitz (2003), or the analysis of brain signals ‘controlled’ by visual inputs, for example, in brain-computer interfaces Vaughan et al. (2003).

Finally, it seems desirable to determine the conditions under which the algorithms derived from the optimality principles are both consistent and efficient. The tractable form of our approximation-free results is promising in this respect.

Acknowledgments

We thank the anonymous reviewers for their valuable comments. We are grateful to György Flórea and László A. Jeni for running the pendulum simulations, and to Gábor Szirtes for his valuable comments. This research has been supported by the EC NEST 'Perceptual Consciousness: Explication and Testing' grant under contract 043261. Opinions and errors in this manuscript are the author's responsibility, they do not necessarily reflect the opinions of the EC or other project members.

Appendix A.

In this section we provide the technical details of our derivations.

A.1 Proof of Lemma 4.1

It is easy to show that the following equations hold:

$$\begin{aligned}\mathcal{N}_{\mathbf{y}}(\mathbf{Ax},\mathbf{V})\mathcal{N}_{\mathbf{A}}(\mathbf{M},\mathbf{V},\mathbf{K}) &= \mathcal{N}_{\mathbf{A}}(\mathbf{M}^+,\mathbf{V},\mathbf{xx}^T+\mathbf{K})\mathcal{N}_{\mathbf{y}}(\mathbf{Mx},\mathbf{V},\gamma),\\ \mathcal{N}_{\mathbf{A}}(\mathbf{M},\mathbf{V},\mathbf{K})\mathcal{IW}_{\mathbf{V}}(\mathbf{Q},n) &= \mathcal{IW}_{\mathbf{V}}(\mathbf{Q}+\mathbf{H},n+m)\,\mathcal{T}_{\mathbf{A}}(\mathbf{Q},n,\mathbf{M},\mathbf{K}),\end{aligned}$$

where $\mathbf{M}^+ = (\mathbf{MK}+\mathbf{yx}^T)(\mathbf{xx}^T+\mathbf{K})^{-1}$, $\gamma = 1-\mathbf{x}^T(\mathbf{xx}^T+\mathbf{K})^{-1}\mathbf{x}$, $\mathbf{H} = (\mathbf{A}-\mathbf{M})\mathbf{K}(\mathbf{A}-\mathbf{M})^T$ for the sake of brevity. Then we have

$$\mathcal{N}_{\mathbf{y}}(\mathbf{Mx},\mathbf{V},\gamma)\mathcal{IW}_{\mathbf{V}}(\mathbf{Q},n) = \mathcal{IW}_{\mathbf{V}}(\mathbf{Q}+(\mathbf{y}-\mathbf{Mx})\gamma(\mathbf{y}-\mathbf{Mx})^T,n+1)\mathcal{T}_{\mathbf{y}}(\mathbf{Q},n,\mathbf{Mx},\gamma),$$

and the statement of the lemma follows.

A.2 Proof of Lemma 4.2

Let $vec(\mathbf{A})$ denote a vector of dm dimensions where the $(d(i-1)+1)^{th},\ldots,(id)^{th}$ $(1\le i\le m)$ elements of this vector are equal to the elements of the i^{th} column of matrix $\mathbf{A}\in\mathbb{R}^{d\times m}$ in the appropriate order. Let $\otimes$ denote the Kronecker-product. It is known that for $P(\mathbf{A}) = \mathcal{N}_{\mathbf{A}}(\mathbf{M},\mathbf{V},\mathbf{K})$, $P(vec(\mathbf{A})) = \mathcal{N}_{vec(\mathbf{A})}(vec(\mathbf{M}),\mathbf{V}\otimes\mathbf{K}^{-1})$ holds (Minka, 2000). Using the well-known formula for the entropy of a multivariate and normally distributed variable (Cover and Thomas, 1991) and applying the relation $|\mathbf{V}\otimes\mathbf{K}^{-1}| = |\mathbf{V}|^m/|\mathbf{K}|^d$, we have that

$$H(\mathbf{A};\mathbf{V}) = \frac{1}{2}\ln|\mathbf{V}\otimes\mathbf{K}^{-1}| + \frac{dm}{2}\ln(2\pi e) = \frac{m}{2}\ln|\mathbf{V}| - \frac{d}{2}\ln|\mathbf{K}| + \frac{dm}{2}\ln(2\pi e).$$

By exploiting certain properties of the Wishart distribution, we can compute the entropy of distribution $\mathcal{IW}_{\mathbf{V}}(\mathbf{Q},n)$. The density of the Wishart distribution is defined by

$$\mathcal{W}_{\mathbf{V}}(\mathbf{Q},n) = \frac{1}{Z_{n,d}}|\mathbf{V}|^{(n-d-1)/2}\left|\frac{\mathbf{Q}^{-1}}{2}\right|^{n/2}\exp\left(-\frac{1}{2}tr(\mathbf{VQ}^{-1})\right).$$

Let Ψ denote the digamma function, and let $f_{1,3}(d,n) = -\sum_{i=1}^{d}\Psi(\frac{n+1-i}{2})) - d\ln 2$. Replacing $\mathbf{V}^{-1}$ with $\mathbf{S}$, we have for the Jacobian that $|\frac{d\mathbf{V}}{d\mathbf{S}}| = |\frac{d\mathbf{S}^{-1}}{d\mathbf{S}}| = |\mathbf{S}|^{-(d+1)}$ (Gupta and Nagar, 1999). To proceed we use that $E_{\mathcal{W}_{\mathbf{S}}(\mathbf{Q},n)}\mathbf{S} = n\mathbf{Q}$, and $E_{\mathcal{W}_{\mathbf{S}}(\mathbf{Q},n)} \ln|\mathbf{S}| = \ln|\mathbf{Q}| - f_{1,3}(d,n)$, (Beal, 2003) and substitute them into $E_{\mathcal{IW}_{\mathbf{V}}(\mathbf{Q},n)} \ln|\mathbf{V}|$, and $E_{\mathcal{IW}_{\mathbf{V}}(\mathbf{Q},n)} tr(\mathbf{Q}\mathbf{V}^{-1})$:

$$\begin{aligned}
E_{\mathcal{IW}_{\mathbf{V}}(\mathbf{Q},n)} \ln|\mathbf{V}| &= \int \frac{1}{Z_{n,d}} \frac{1}{|\mathbf{V}|^{(d+1)/2}} \left|\frac{\mathbf{V}^{-1}\mathbf{Q}}{2}\right|^{n/2} \exp\left(-\frac{1}{2}tr(\mathbf{V}^{-1}\mathbf{Q})\right) \ln|\mathbf{V}| d\mathbf{V}, \\
&= -\int \frac{1}{Z_{n,d}} |\mathbf{S}|^{(d+1)/2} \left|\frac{\mathbf{S}\mathbf{Q}}{2}\right|^{n/2} \exp\left(-\frac{1}{2}tr(\mathbf{S}\mathbf{Q})\right) \ln|\mathbf{S}||\mathbf{S}|^{-d-1} d\mathbf{S}, \\
&= -\int \frac{1}{Z_{n,d}} |\mathbf{S}|^{(n-d-1)/2} \left|\frac{\mathbf{Q}}{2}\right|^{n/2} \exp\left(-\frac{1}{2}tr(\mathbf{S}\mathbf{Q})\right) \ln|\mathbf{S}| d\mathbf{S}, \\
&= -E_{\mathcal{W}_{\mathbf{S}}(\mathbf{Q}^{-1},n)} \ln|\mathbf{S}|, \\
&= \ln|\mathbf{Q}| + f_{1,3}(d,n). \qquad (35)
\end{aligned}$$

One can also show that

$$\begin{aligned}
E_{\mathcal{IW}_{\mathbf{V}}(\mathbf{Q},n)} tr(\mathbf{Q}\mathbf{V}^{-1}) &= \int \frac{1}{Z_{n,d}} \frac{1}{|\mathbf{V}|^{(d+1)/2}} \left|\frac{\mathbf{V}^{-1}\mathbf{Q}}{2}\right|^{n/2} \exp\left(-\frac{1}{2}tr(\mathbf{V}^{-1}\mathbf{Q})\right) tr(\mathbf{Q}\mathbf{V}^{-1}) d\mathbf{V}, \\
&= \int \frac{1}{Z_{n,d}} |\mathbf{S}|^{(d+1)/2} \left|\frac{\mathbf{S}\mathbf{Q}}{2}\right|^{n/2} \exp\left(-\frac{1}{2}tr(\mathbf{S}\mathbf{Q})\right) tr(\mathbf{Q}\mathbf{S})|\mathbf{S}|^{-d-1} d\mathbf{S}, \\
&= \int \frac{1}{Z_{n,d}} |\mathbf{S}|^{(n-d-1)/2} \left|\frac{\mathbf{Q}}{2}\right|^{n/2} \exp\left(-\frac{1}{2}tr(\mathbf{S}\mathbf{Q})\right) tr(\mathbf{Q}\mathbf{S}) d\mathbf{S}, \\
&= E_{\mathcal{W}_{\mathbf{S}}(\mathbf{Q}^{-1},n)} tr(\mathbf{Q}\mathbf{S}), \\
&= tr(\mathbf{Q}\mathbf{Q}^{-1}n) = nd. \qquad (36)
\end{aligned}$$

We calculate the entropy of stochastic variable $\mathbf{V}$ with distribution $\mathcal{IW}_{\mathbf{V}}(\mathbf{Q},n)$. It follows from Eq. (35) and Eq. (36) that

$$\begin{aligned}
H(\mathbf{V}) &= -E_{\mathcal{IW}_{\mathbf{V}}(\mathbf{Q},n)} \left[-\ln(Z_{n,d}) + \frac{n}{2}\ln\left|\frac{\mathbf{Q}}{2}\right| - \frac{n+d+1}{2}\ln|\mathbf{V}| - \frac{1}{2}tr(\mathbf{V}^{-1}\mathbf{Q})\right], \\
&= \ln(Z_{n,d}) - \frac{n}{2}\ln\left|\frac{\mathbf{Q}}{2}\right| + \frac{n+d+1}{2}\left[\ln|\mathbf{Q}| - \sum_{i=1}^{d}\Psi(\frac{n+1-i}{2})) - d\ln 2\right] + \frac{nd}{2}, \\
&= \frac{d+1}{2}\ln|\mathbf{Q}| + f_{1,4}(d,n),
\end{aligned}$$

where $f_{1,4}(d,n)$ depends only on d and n.

Given the results above, we complete the computation of entropy $H(\mathbf{A},\mathbf{V})$ as follows:

$$\begin{aligned}
H(\mathbf{A},\mathbf{V}) &= H(\mathbf{A}|\mathbf{V}) + H(\mathbf{V}) = H(\mathbf{V}) + \int d\mathbf{V}\, \mathcal{IW}_{\mathbf{V}}(\mathbf{Q},n) H(\mathbf{A};\mathbf{V}), \\
&= \int d\mathbf{V}\, \mathcal{IW}_{\mathbf{V}}(\mathbf{Q},n) \left(\frac{m}{2}\ln|\mathbf{V}| - \frac{d}{2}\ln|\mathbf{K}| + \frac{dm}{2}\ln(2\pi e)\right) + H(\mathbf{V}), \\
&= -\frac{d}{2}\ln|\mathbf{K}| + \frac{dm}{2}\ln(2\pi e) + \frac{m}{2}[\ln|\mathbf{Q}| + f_{1,3}(d,n)] + \frac{d+1}{2}\ln|\mathbf{Q}| + f_{1,4}(d,n), \\
&= -\frac{d}{2}\ln|\mathbf{K}| + (\frac{m+d+1}{2})\ln|\mathbf{Q}| + f_{1,1}(d,n).
\end{aligned}$$

This is exactly what was claimed in Lemma 4.2.

A.3 Proof of Lemma 5.1

The proof is analogous to the D-optimality case. We need the following lemma:

Lemma A.1 *Let* $\mathbf{V}$ *diagonal positive definite matrix. Let* $\mathbf{X}_{(i,:)}$ *denote the* i^{th} *row of matrix* $\mathbf{X}$. *Let* $\eta_i = (\mathbf{A}_{(i,:)} - \mathbf{M}_{(i,:)})\mathbf{K}(\mathbf{A}_{(i,:)} - \mathbf{M}_{(i,:)})^T$, $\forall i = 1,\dots,d$. $\boldsymbol{\eta} \in \mathbb{R}^d$. *Then the following statement holds:*

$$\mathcal{N}_{\mathbf{A}}(\mathbf{M},\mathbf{V},\mathbf{K})\mathcal{PIG}_{\mathbf{V}}(\boldsymbol{\alpha},\boldsymbol{\beta}) = \mathcal{PIG}_{\mathbf{V}}(\boldsymbol{\alpha}+m/2,\boldsymbol{\beta}+\boldsymbol{\eta}/2)\prod_{i=1}^{d}\mathcal{T}_{\mathbf{A}_{(i,:)}}(\beta_i, 2\alpha_i, \mathbf{M}_{(i,:)}, \frac{\mathbf{K}}{2}).$$

Proof:

$$\begin{aligned}
&\mathcal{N}_{\mathbf{A}}(\mathbf{M},\mathbf{V},\mathbf{K})\mathcal{PIG}_{\mathbf{V}}(\boldsymbol{\alpha},\boldsymbol{\beta}) = \\
&= \frac{|\mathbf{K}|^{d/2}}{|2\pi\mathbf{V}|^{m/2}}\exp(-\frac{1}{2}tr(\mathbf{V}^{-1}(\mathbf{A}-\mathbf{M})\mathbf{K}(\mathbf{A}-\mathbf{M})^T))\prod_{i=1}^{d}\frac{\beta_i^{\alpha_i}}{\Gamma(\alpha_i)}v_i^{-\alpha_i-1}\exp(-\frac{\beta_i}{v_i}),\\
&= \frac{|\mathbf{K}|^{d/2}}{\prod_{i=1}^{d}(2\pi)^{m/2}v_i^{m/2}}\exp(-\frac{1}{2}\sum_{i=1}^{d}\frac{1}{v_i}\eta_i)\prod_{i=1}^{d}\frac{\beta_i^{\alpha_i}}{\Gamma(\alpha_i)}v_i^{-\alpha_i-1}\exp(-\frac{\beta_i}{v_i}),\\
&= \frac{|\mathbf{K}|^{d/2}}{\prod_{i=1}^{d}(2\pi)^{m/2}}\prod_{i=1}^{d}\frac{\beta_i^{\alpha_i}}{\Gamma(\alpha_i)}v_i^{-\alpha_i-m/2-1}\exp(-\frac{\beta_i+\eta_i/2}{v_i}),\\
&= \frac{|\mathbf{K}|^{d/2}}{\prod_{i=1}^{d}(2\pi)^{m/2}}\prod_{i=1}^{d}\frac{\beta_i^{\alpha_i}}{\Gamma(\alpha_i)}\frac{(\beta_i+\eta_i/2)^{\alpha_i+m/2}}{(\beta_i+\eta_i/2)^{\alpha_i+m/2}}\frac{\Gamma(\alpha_i+m/2)}{\Gamma(\alpha_i+m/2)},v_i^{-\alpha_i-m/2-1}\exp(-\frac{\beta_i+\eta_i/2}{v_i}),\\
&= \frac{|\mathbf{K}|^{d/2}}{\prod_{i=1}^{d}(2\pi)^{m/2}}\prod_{i=1}^{d}\frac{\beta_i^{\alpha_i}\Gamma(\alpha_i+m/2)/\Gamma(\alpha_i)}{(\beta_i+\eta_i/2)^{\alpha_i+m/2}}\prod_{i=1}^{d}\frac{(\beta_i+\eta_i/2)^{\alpha_i+m/2}}{\Gamma(\alpha_i+m/2)}v_i^{-\alpha_i-m/2-1}\exp(-\frac{\beta_i+\eta_i/2}{v_i}),\\
&= \prod_{i=1}^{d}\frac{|\mathbf{K}|^{1/2}}{(2\pi)^{m/2}}\frac{\Gamma(\alpha_i+m/2)}{\Gamma(\alpha_i)}\frac{\beta_i^{\alpha_i}}{(\beta_i+\eta_i/2)^{\alpha_i+m/2}}\mathcal{PIG}_{\mathbf{v}}(\boldsymbol{\alpha}+m/2,\boldsymbol{\beta}+\boldsymbol{\eta}/2),\\
&= \prod_{i=1}^{d}\frac{|\frac{\mathbf{K}}{2}|^{1/2}}{\pi^{m/2}}\frac{\Gamma(\alpha_i+m/2)\beta_i^{\alpha_i}}{\Gamma(\alpha_i)(\beta_i+(\mathbf{A}_{(i,:)}-\mathbf{M}_{(i,:)})\frac{\mathbf{K}}{2}(\mathbf{A}_{(i,:)}-\mathbf{M}_{(i,:)})^T)^{\alpha_i+m/2}}\mathcal{PIG}_{\mathbf{v}}(\boldsymbol{\alpha}+m/2,\boldsymbol{\beta}+\boldsymbol{\eta}/2),\\
&= \mathcal{PIG}_{\mathbf{v}}(\boldsymbol{\alpha}+m/2,\boldsymbol{\beta}+\boldsymbol{\eta}/2)\prod_{i=1}^{d}\mathcal{T}_{\mathbf{A}_{(i,:)}}(\beta_i,2\alpha_i,\mathbf{M}_{(i,:)},\frac{\mathbf{K}}{2}).
\end{aligned}$$

Lemma A.2

$$\begin{aligned}
\mathcal{N}_{\mathbf{y}}(\mathbf{Ax},\mathbf{V})\mathcal{N}_{\mathbf{A}}(\mathbf{M},\mathbf{V},\mathbf{K})\mathcal{PIG}_{\mathbf{V}}(\boldsymbol{\alpha},\boldsymbol{\beta}) &= \mathcal{N}_{\mathbf{A}}((\mathbf{MK}+\mathbf{yx}^T)(\mathbf{xx}^T+\mathbf{K})^{-1},\mathbf{V},\mathbf{xx}^T+\mathbf{K})\times\\
&\times\mathcal{PIG}_{\mathbf{V}}\left(\boldsymbol{\alpha}+1/2,\boldsymbol{\beta}+diag\,(\mathbf{y}-\mathbf{Mx})\frac{(1-\mathbf{x}^T(\mathbf{xx}^T+\mathbf{K})^{-1}\mathbf{x})}{2}(\mathbf{y}-\mathbf{Mx})^T\right)\times\\
&\times\prod_{i=1}^{d}T_{y_i}\left(\beta_i,2\alpha_i,(\mathbf{Mx})_i,\frac{1-\mathbf{x}^T(\mathbf{xx}^T+\mathbf{K})^{-1}\mathbf{x}}{2}\right).
\end{aligned}$$

Proof:

$$\begin{aligned}
\mathcal{N}_{\mathbf{y}}(\mathbf{Ax},\mathbf{V})\mathcal{N}_{\mathbf{A}}(\mathbf{M},\mathbf{V},\mathbf{K})\mathcal{PIG}_{\mathbf{V}}(\boldsymbol{\alpha},\boldsymbol{\beta}) &= \mathcal{N}_{\mathbf{A}}((\mathbf{MK}+\mathbf{yx}^T)(\mathbf{xx}^T+\mathbf{K})^{-1},\mathbf{V},\mathbf{xx}^T+\mathbf{K})\times\\
&\mathcal{N}_{\mathbf{y}}((\mathbf{Mx},\mathbf{V},1-\mathbf{x}^T(\mathbf{xx}^T+\mathbf{K})^{-1}\mathbf{x})\times\\
&\mathcal{PIG}_{\mathbf{V}}(\boldsymbol{\alpha},\boldsymbol{\beta}).
\end{aligned}$$

A.4 Proof of Lemma 5.2

We can see that $Var_{\mathbf{V}}[E[\mathbf{A}|\mathbf{V},\{\mathbf{x}\}_1^{t+1},\{\mathbf{y}\}_1^{t+1}]] = Var_{\mathbf{V}}[\mathbf{M}_{t+1}] = 0$, and

$$\begin{aligned} E_{\mathbf{V}}[trVar(\mathbf{A}|\mathbf{V},\{\mathbf{x}\}_1^{t+1},\{\mathbf{y}\}_1^{t+1})] &= E_{\mathbf{V}}[tr(\mathbf{V}\otimes(\mathbf{K}_t+\mathbf{x}_{t+1}\mathbf{x}_{t+1}^T)^{-1})|\{\mathbf{x}\}_1^{t+1},\{\mathbf{y}\}_1^{t+1}], \\ &= tr(E[\mathbf{V}|\{\mathbf{x}\}_1^{t+1},\{\mathbf{y}\}_1^{t+1}])tr[(\mathbf{K}_t+\mathbf{x}_{t+1}\mathbf{x}_{t+1}^T)^{-1}], \\ &= tr[(\mathbf{K}_t+\mathbf{x}_{t+1}\mathbf{x}_{t+1}^T)^{-1}]\sum_{i=1}^d \frac{(\boldsymbol{\beta}_{t+1})_i}{(\boldsymbol{\alpha}_{t+1})_i-1}, \end{aligned}$$

where we used that $P(\mathbf{V}|\{\mathbf{x}\}_1^{t+1},\{\mathbf{y}\}_1^{t+1}) = \mathcal{PIG}_{\mathbf{V}}(\boldsymbol{\alpha}_{t+1},\boldsymbol{\beta}_{t+1})$.

The law of total variance says that $Var[\mathbf{A}] = Var[E[\mathbf{A}|\mathbf{V}]] + E[Var[\mathbf{A}|\mathbf{V}]]$, hence

$$trVar[\mathbf{A}|\{\mathbf{x}\}_1^{t+1},\{\mathbf{y}\}_1^{t+1}] = tr(\mathbf{K}_t+\mathbf{x}_{t+1}\mathbf{x}_{t+1}^T)^{-1}\sum_{i=1}^d \frac{(\boldsymbol{\beta}_{t+1})_i}{(\boldsymbol{\alpha}_{t+1})_i-1}.$$

A.5 Proof of Lemma 6.1

To compute (24) we need the following lemma (Minka, 2000):

Lemma A.3 *If* $P(\mathbf{A}) = \mathcal{N}_{\mathbf{A}}(\mathbf{M},\mathbf{V},\mathbf{K})$*, then* $P(\mathbf{A}\mathbf{x}) = \mathcal{N}_{\mathbf{A}\mathbf{x}}\left(\mathbf{M}\mathbf{x},\mathbf{V},\left(\mathbf{x}^T\mathbf{K}^{-1}\mathbf{x}\right)^{-1}\right)$.

Applying this lemma and using (11) we have that

$$P(\mathbf{A}\mathbf{x}_{t+1}|\mathbf{V},\{\mathbf{x}\}_1^{t+1},\{\mathbf{y}\}_1^{t+1}) = \mathcal{N}_{\mathbf{A}\mathbf{x}_{t+1}}\left(\mathbf{M}_{t+1}\mathbf{x}_{t+1},\mathbf{V},\left(\mathbf{x}_{t+1}^T\mathbf{K}_{t+1}^{-1}\mathbf{x}_{t+1}\right)^{-1}\right). \tag{37}$$

We introduce the notations

$$\begin{aligned} \tilde{K}_{t+1} &= \left(\mathbf{x}_{t+1}^T\mathbf{K}_{t+1}^{-1}\mathbf{x}_{t+1}\right)^{-1}\in\mathbb{R}, \\ \lambda_{t+1} &= 1+(\mathbf{A}\mathbf{x}_{t+1}-\mathbf{M}_{t+1}\mathbf{x}_{t+1})^T(\tilde{K}_{t+1}\mathbf{Q}_{t+1}^{-1})(\mathbf{A}\mathbf{x}_{t+1}-\mathbf{M}_{t+1}\mathbf{x}_{t+1})\in\mathbb{R}. \end{aligned} \tag{38}$$

Exploit the fact that

$$\mathcal{N}_{\mathbf{A}}(\mathbf{M},\mathbf{V},\mathbf{K})\,\mathcal{IW}_{\mathbf{V}}(\mathbf{Q},n) = \mathcal{IW}_{\mathbf{V}}(\mathbf{Q}+\mathbf{H},n+m)\,\mathcal{T}_{\mathbf{A}}(\mathbf{Q},n,\mathbf{M},\mathbf{K}),$$

and use (12) for the posterior distribution (37) and get

$$\begin{aligned} P(\mathbf{A}\mathbf{x}_{t+1}|\{\mathbf{x}\}_1^{t+1},\{\mathbf{y}\}_1^{t+1}) &= \mathcal{T}_{\mathbf{A}\mathbf{x}_{t+1}}\left(\mathbf{Q}_{t+1},n_{t+1},\mathbf{M}_{t+1}\mathbf{x}_{t+1},\tilde{K}_{t+1}\right), \\ &= \pi^{-d/2}|\tilde{K}_{t+1}^{-1}\mathbf{Q}_{t+1}|^{-1/2}\frac{\Gamma(\frac{n_{t+1}+1}{2})}{\Gamma(\frac{n_{t+1}+1-d}{2})}\lambda_{t+1}^{\frac{n_{t+1}+1}{2}}. \end{aligned}$$

The Shannon-entropy of this distribution according to Zografos and Nadarajah (2005) can be written as:

$$H(\mathbf{A}\mathbf{x}_{t+1};\{\mathbf{x}\}_1^{t+1},\{\mathbf{y}\}_1^{t+1}) = f_{3,1}(d,n_{t+1})+\frac{d}{2}\log|\tilde{K}_{t+1}^{-1}|+\log|\mathbf{Q}_{t+1}|,$$

where

$$f_{3,1}(d,n_{t+1}) = -\log\frac{\Gamma(\frac{n_{t+1}+1}{2})}{\pi^{d/2}\Gamma(\frac{n_{t+1}+1-d}{2})}+\frac{n_{t+1}+1}{2}\left(\Psi\left(\frac{n_{t+1}+1}{2}\right)-\Psi\left(\frac{n_{t+1}+1-d}{2}\right)\right).$$

Using the notations introduced in (10) and in (38), the above expressions can be transcribed as follows:

$$
\begin{aligned}
H(\mathbf{A}\mathbf{x}_{t+1};\{\mathbf{x}\}_1^{t+1},\{\mathbf{y}\}_1^{t+1}) &= f_{3,1}(d,n_{t+1}) - \frac{d}{2}\log|\tilde{K}_{t+1}| + \log|\mathbf{Q}_{t+1}|,\\
&= f_{3,1}(d,n_{t+1}) + \frac{d}{2}\log|\mathbf{x}_{t+1}^T(\mathbf{K}_t+\mathbf{x}_{t+1}\mathbf{x}_{t+1}^T)^{-1}\mathbf{x}_{t+1}| + \log|\mathbf{Q}_{t+1}|,\\
&= f_{3,1}(d,n_{t+1}) + \frac{d}{2}\log|\mathbf{x}_{t+1}^T(\mathbf{K}_t+\mathbf{x}_{t+1}\mathbf{x}_{t+1}^T)^{-1}\mathbf{x}_{t+1}| +\\
&\quad + \log|\mathbf{Q}_t + (\mathbf{y}_{t+1}-\mathbf{M}_t\mathbf{x}_{t+1})\gamma_{t+1}(\mathbf{y}_{t+1}-\mathbf{M}_t\mathbf{x}_{t+1})^T|.
\end{aligned}
$$

Now, we are in a position to calculate (24) by applying Lemma 4.4 as before. We get that

$$
\begin{aligned}
&\int d\mathbf{y}_{t+1}P(\mathbf{y}_{t+1}|\{\mathbf{x}\}_1^{t+1},\{\mathbf{y}\}_1^t)H(\mathbf{e}_{t+1};\{\mathbf{x}\}_1^{t+1},\{\mathbf{y}\}_1^{t+1}) =\\
&= f_{3,2}(\mathbf{Q}_t,n_{t+1}) + \frac{d}{2}\log|\mathbf{x}_{t+1}^T(\mathbf{K}_t+\mathbf{x}_{t+1}\mathbf{x}_{t+1}^T)^{-1}\mathbf{x}_{t+1}|,
\end{aligned}
$$

where $f_{3,2}(\mathbf{Q}_t,n_{t+1})$ depends only on $\mathbf{Q}_t$, and n_{t+1}. We can proceed as follows

$$
\begin{aligned}
\arg\max_{\mathbf{u}_{t+1}} I(\mathbf{e}_{t+1},\mathbf{y}_{t+1};\{\mathbf{x}\}_1^{t+1},\{\mathbf{y}\}_1^t) &= \arg\min_{\mathbf{u}_{t+1}}\log|\mathbf{x}_{t+1}^T(\mathbf{K}_t+\mathbf{x}_{t+1}\mathbf{x}_{t+1}^T)^{-1}\mathbf{x}_{t+1}|,\\
&= \arg\min_{\mathbf{u}_{t+1}}\log\left|\mathbf{x}_{t+1}^T\left(\mathbf{K}_t^{-1} - \frac{\mathbf{K}_t^{-1}\mathbf{x}_{t+1}\mathbf{x}_{t+1}^T\mathbf{K}_t^{-1}}{1+\mathbf{x}_{t+1}^T\mathbf{K}_t^{-1}\mathbf{x}_{t+1}}\right)\mathbf{x}_{t+1}\right|,\\
&= \arg\min_{\mathbf{u}_{t+1}}\log\left|\frac{\mathbf{x}_{t+1}^T\mathbf{K}_t^{-1}\mathbf{x}_{t+1}}{1+\mathbf{x}_{t+1}^T\mathbf{K}_t^{-1}\mathbf{x}_{t+1}}\right|,\\
&= \arg\min_{\mathbf{u}_{t+1}}\mathbf{x}_{t+1}^T\mathbf{K}_t^{-1}\mathbf{x}_{t+1}.
\end{aligned}
$$

This is exactly what we were to prove.

A.6 Proof of Lemma 8.1

One needs to compute the value of the integral

$$
\int d\mathbf{y}_{t+1}P(\mathbf{y}_{t+1}|\{\mathbf{x}\}_1^{t+1},\{\mathbf{y}\}_1^t)E[tr\mathbf{V}|\mathbf{x}_1^{t+1},\mathbf{y}_1^{t+1}]tr\left(\left(\mathbf{K}_t+\mathbf{x}_{t+1}\mathbf{x}_{t+1}^T\right)^{-1}+\mathbf{x}_{t+1}^T\mathbf{K}_{t+1}^{-1}\mathbf{x}_{t+1}\right).
$$

However,

$$
\begin{aligned}
&\int d\mathbf{y}_{t+1}P(\mathbf{y}_{t+1}|\{\mathbf{x}\}_1^{t+1},\{\mathbf{y}\}_1^t)E[tr\mathbf{V}|\mathbf{x}_1^{t+1},\mathbf{y}_1^{t+1}]\\
&= \int d\mathbf{y}_{t+1}\prod_{i=1}^d \mathcal{T}_{(\mathbf{y}_{t+1})_i}\left((\boldsymbol{\beta}_t)_i, 2(\boldsymbol{\alpha}_t)_i, (\mathbf{M}_t\mathbf{x}_{t+1})_i, \frac{\gamma_{t+1}}{2}\right)\sum_{i=1}^d\frac{(\boldsymbol{\beta}_{t+1})_i}{(\boldsymbol{\alpha}_{t+1})_i-1},
\end{aligned}
$$

and depends only on the values of α_{t+1} and β_t as a result of (19) and Lemma 4.4, and is independent of the value of $\mathbf{x}_{t+1}$. Thus, we arrive at the minimization of the following expression:

$$
\begin{aligned}
tr\left[\left(\mathbf{K}_t^{-1}-\frac{\mathbf{K}_t^{-1}\mathbf{x}_{t+1}\mathbf{x}_{t+1}^T\mathbf{K}_t^{-1}}{1+\mathbf{x}_{t+1}^T\mathbf{K}_t^{-1}\mathbf{x}_{t+1}}\right)+\mathbf{x}_{t+1}^T\left(\mathbf{K}_t^{-1}-\frac{\mathbf{K}_t^{-1}\mathbf{x}_{t+1}\mathbf{x}_{t+1}^T\mathbf{K}_t^{-1}}{1+\mathbf{x}_{t+1}^T\mathbf{K}_t^{-1}\mathbf{x}_{t+1}}\right)\mathbf{x}_{t+1}\right]& \\
=\left[tr(\mathbf{K}_t^{-1})-tr\frac{\mathbf{K}_t^{-1}\mathbf{x}_{t+1}\mathbf{x}_{t+1}^T\mathbf{K}_t^{-1}}{1+\mathbf{x}_{t+1}^T\mathbf{K}_t^{-1}\mathbf{x}_{t+1}}+\frac{\mathbf{x}_{t+1}^T\mathbf{K}_t^{-1}\mathbf{x}_{t+1}}{1+\mathbf{x}_{t+1}^T\mathbf{K}_t^{-1}\mathbf{x}_{t+1}}\right]&, \\
=\left[tr(\mathbf{K}_t^{-1})-\frac{\mathbf{x}_{t+1}^T\mathbf{K}_t^{-1}\mathbf{K}_t^{-1}\mathbf{x}_{t+1}}{1+\mathbf{x}_{t+1}^T\mathbf{K}_t^{-1}\mathbf{x}_{t+1}}+\frac{\mathbf{x}_{t+1}^T\mathbf{K}_t^{-1}\mathbf{x}_{t+1}}{1+\mathbf{x}_{t+1}^T\mathbf{K}_t^{-1}\mathbf{x}_{t+1}}\right]&, \\
=\frac{1+\mathbf{x}_{t+1}^T\mathbf{K}_t^{-1}\mathbf{K}_t^{-1}\mathbf{x}_{t+1}}{1+\mathbf{x}_{t+1}^T\mathbf{K}_t^{-1}\mathbf{x}_{t+1}}&\ .
\end{aligned}
$$

Abstract

This paper studies the feature selection problem using a greedy least squares regression algorithm. We show that under a certain irrepresentable condition on the design matrix (but independent of the sparse target), the greedy algorithm can select features consistently when the sample size approaches infinity. The condition is identical to a corresponding condition for Lasso.

Moreover, under a sparse eigenvalue condition, the greedy algorithm can reliably identify features as long as each nonzero coefficient is larger than a constant times the noise level. In comparison, Lasso may require the coefficients to be larger than $O(\sqrt{s})$ times the noise level in the worst case, where s is the number of nonzero coefficients.

Keywords: greedy algorithm, feature selection, sparsity

1. Introduction

We are interested in the statistical feature selection problem for least squares regression. Let $X = [\mathbf{x}_1, \ldots, \mathbf{x}_d] \in \mathbb{R}^{n \times d}$ be an $n \times d$ data matrix with $\mathbf{x}_j \in \mathbb{R}^n$ $(j = 1, \ldots, d)$ as its columns. Assume that the response vector $\mathbf{y} = [y_1, \ldots, y_n] \in \mathbb{R}^n$ is generated from a sparse linear combination of the basis vectors $\{\mathbf{x}_j\}$ plus a zero-mean stochastic noise vector $\mathbf{z} \in \mathbb{R}^n$:

$$\mathbf{y} = X\bar{\beta} + \mathbf{z} = \sum_{j=1}^{d} \bar{\beta}_j \mathbf{x}_j + \mathbf{z}, \tag{1}$$

where most coefficients $\bar{\beta}_j$ equal zero. The goal of feature selection is to identify the set of nonzeros $\{j : \bar{\beta}_j \neq 0\}$, where $\bar{\beta} = [\bar{\beta}_1, \ldots, \bar{\beta}_d]$. The purpose of this paper is study the performance of greedy least squares regression for feature selection.

The following notations are used throughout the paper. Given $\beta \in \mathbb{R}^d$, define

$$\mathrm{supp}(\beta) = \{j : \beta_j \neq 0\}.$$

Given $\mathbf{x} \in \mathbb{R}^n$ and $\bar{F} \subset \{1, \ldots, d\}$, let

$$\hat{\beta}_X(\bar{F}, \mathbf{x}) = \min_{\beta \in \mathbb{R}^d} \frac{1}{n} \|X\beta - \mathbf{x}\|_2^2 \quad \text{subject to} \quad \mathrm{supp}(\beta) \subset \bar{F}.$$

*. Supported by NSF grant DMS-0706805.

That is, $\hat{\beta}_X(\bar{F},\mathbf{x})$ is the least squares solution with coefficients restricted to $\bar{F}$.

Given $\bar{F} \in \{1,\ldots,d\}$, we let $X_{\bar{F}}$ be the $n \times |\bar{F}|$ matrix that is the restriction of columns of X to $\bar{F}$. That is, $X_{\bar{F}}$'s columns are the basis functions $\mathbf{x}_j$ with $j \in \bar{F}$ arranged in the ascending order. The following quantity, appeared in Tropp (2004), is important in our analysis (also see Wainwright, 2006):

$$\mu_X(\bar{F}) = \max_{j \notin \bar{F}} \|(X_{\bar{F}}^T X_{\bar{F}})^{-1} X_{\bar{F}}^T \mathbf{x}_j\|_1.$$

We also define for all $\bar{F} \subset \{1,\ldots,d\}$

$$\rho_X(\bar{F}) = \inf\left\{\frac{1}{n}\|X\beta\|_2^2/\|\beta\|_2^2 : \mathrm{supp}(\beta) \subset \bar{F}\right\}.$$

This quantity is the smallest eigenvalue of the restricted design matrix $\frac{1}{n}X_{\bar{F}}^T X_{\bar{F}}$, which has also appeared in previous work such as Wainwright (2006) and Zhao and Yu (2006). The requirement that $\rho_X(F)$ is bounded away from zero for small $|F|$ is often referred to as the sparse eigenvalue condition (or the restricted isometry condition).

2. Related Work

The feature selection problem of estimating $\mathrm{supp}(\bar{\beta})$ from observation $\mathbf{y}$ defined in (1) has attracted significant attention in recent years. One of the frequently used method for feature selection is Lasso, which solves the following L_1 regularization problem:

$$\hat{\beta} = \arg\min_{\beta}\left[\frac{1}{n}\left\|\sum_{j=1}^{d}\beta_j\mathbf{x}_j - \mathbf{y}\right\|_2^2 + \lambda\|\beta\|_1\right], \tag{2}$$

where $\lambda > 0$ is an appropriately chosen regularization parameter.

The effectiveness of feature selection using Lasso was established in Zhao and Yu (2006) (also see Meinshausen and Buhlmann, 2006) under irrepresentable conditions that depend on the signs of the true target $\mathrm{sgn}(\bar{\beta})$. Results established in this paper have cruder forms that depend only on the design matrix but not the sparse target $\bar{\beta}$. Such conditions have also been studied by Zhao and Yu (2006) (also see Wainwright, 2006).

In addition to Lasso, greedy algorithms have also been widely used for feature selection. Greedy algorithms for least squares regression are called matching pursuit in the signal processing community (Mallat and Zhang, 1993). The particular algorithm analyzed in this paper (some time referred to as orthogonal matching pursuit or OMP) is presented in Figure 1. The algorithm is often called forward greedy selection in the machine learning literature.

This paper investigates the behavior of greedy least squares algorithm in Figure 1 for feature selection under the stochastic noise model (1). Our result extends that of Tropp (2004), which only considered the situation without stochastic noise. It was shown by Tropp (2004) that $\mu_X(\bar{F}) < 1$ is sufficient for the greedy algorithm to identify the correct feature set $\mathrm{supp}(\bar{\beta})$ when the noise vector $\mathbf{z} = 0$. The main contribution of this paper is to generalize Tropp's analysis to handle non-zero sub-Gaussian stochastic noise vectors. In particular, we will establish conditions on $\min_{j\in\mathrm{supp}(\bar{\beta})}|\bar{\beta}_j|$ and the stopping criterion ϵ in Figure 1, so that the algorithm finds the correct feature set $\mathrm{supp}(\bar{\beta})$. The selection of stopping criterion ϵ in the greedy algorithm is equivalent to selecting an appropriate

Figure 1: Greedy Least Squares Regression (OMP)

regularization condition λ in the Lasso formulation (2), which is necessary both in theory and in practice. The condition on $\min_{j \in \text{supp}(\bar{\beta})} |\bar{\beta}_j|$ also naturally appears in the analysis of Lasso (Zhao and Yu, 2006). In fact, our result shows that the condition of $\min_{j \in \text{supp}(\bar{\beta})} |\bar{\beta}_j|$ required for greedy algorithm is weaker than the corresponding condition for Lasso.

The greedy algorithm analysis employed in this paper is a combination of an observation by Tropp (2004, see Lemma 11) and some technical lemmas for the behavior of greedy least squares regression by Zhang (2008), which are included in Appendix A for completeness. Note that Zhang (2008) only studied a forward-backward procedure, but not the more standard forward greedy algorithm considered here. In this paper, both the employment of the condition $\mu_X(\bar{F}) < 1$ and the proof in Appendix B are new.

As we shall see in this paper, the condition $\mu_X(\bar{F}) \leq 1$ is necessary for the success of the forward greedy procedure. It is worth mentioning that Lasso is consistent in parameter estimation under a weaker sparse eigenvalue condition, even if the condition $\mu_X(\bar{F}) \leq 1$ fails (which means Lasso may not estimate the true feature set correctly): for example, see Meinshausen and Yu (2008) and Zhang (2009). Although similar results may be obtained for greedy least squares regression, when the condition $\mu_X(\bar{F}) \leq 1$ fails, it was shown by Zhang (2008) that the performance of greedy algorithm can be improved by incorporating backward steps. In contrast, results in this paper show that if the design matrix satisfies the additional condition $\mu_X(\bar{F}) < 1$, then the standard forward greedy algorithm will be successful without complicated backward steps.

3. Feature Selection using Greedy Least Squares Regression

We would like to establish conditions under which the forward greedy algorithm in Figure 1 never makes any mistake (with large probability), and thus suitable for feature selection. For convenience, we state an assumption before stating the theoretical result.

Assumption 1 *Assume that*

- *The basis functions are normalized such that* $\frac{1}{n}\|\mathbf{x}_j\|_2^2 = 1$ *for all* $j = 1, \ldots, d$.
- *The target function is truly sparse: there exists* $\bar{\beta} \in \mathbb{R}^d$ *with* $\bar{F} = \text{supp}(\bar{\beta})$ *such that* $\mathbf{E}\mathbf{y} = X\bar{\beta}$.
- $\mu_X(\bar{F}) < 1$ *and* $\rho_X(\bar{F}) > 0$.

- $\mathbf{y} = [y_i]_{i=1,\ldots,n}$ *are independent (but not necessarily identically distributed) sub-Gaussians: there exists* $\sigma \geq 0$ *such that* $\forall i \in \{1,\ldots,n\}$ *and* $\forall t \in \mathbb{R}$, $\mathbf{E}_{y_i} e^{t(y_i - \mathbf{E}y_i)} \leq e^{\sigma^2 t^2/2}$.

Both Gaussian and bounded random variables are sub-Gaussian using the above definition. For example, if a random variable $\xi \in [a,b]$, then $\mathbf{E}_\xi e^{t(\xi - \mathbf{E}\xi)} \leq e^{(b-a)^2 t^2/8}$. If a random variable is Gaussian: $\xi \sim N(0,\sigma^2)$, then $\mathbf{E}_\xi e^{t\xi} \leq e^{\sigma^2 t^2/2}$.

The following theorem gives conditions under which the forward greedy algorithm can identify the correct set of features.

Theorem 1 *Consider the greedy least squares algorithm in Figure 1, where Assumption 1 holds. Given any* $\eta \in (0,0.5)$*, with probability larger than* $1-2\eta$*, if the stopping criterion satisfies*

$$\epsilon > \frac{1}{1-\mu_X(\bar{F})}\sigma\sqrt{2\ln(2d/\eta)}, \qquad \min_{j\in\bar{F}} |\bar{\beta}_j| \geq 3\epsilon\rho_X(\bar{F})^{-1}/\sqrt{n},$$

then when the procedure stops, we have $F^{(k-1)} = \bar{F}$ *and*

$$\|\beta^{(k-1)} - \bar{\beta}\|_\infty \leq \sigma\sqrt{(2\ln(2|\bar{F}|/\eta))/(n\rho_X(\bar{F}))}.$$

The result is a simple consequence of the following slightly more general theorem (its proof is left to Appendix B).

Theorem 2 *Consider the greedy least squares algorithm in Figure 1, where Assumption 1 holds. Given any* $\eta \in (0,0.5)$*, with probability larger than* $1-2\eta$*, if the stopping criterion satisfies*

$$\epsilon > \frac{1}{1-\mu_X(\bar{F})}\sigma\sqrt{2\ln(2d/\eta)},$$

then when the procedure stops, the following claims are true:

- $F^{(k-1)} \subset \bar{F}$.
- $|\bar{F} - F^{(k-1)}| \leq 2|\{j \in \bar{F} : |\bar{\beta}_j| < 3\epsilon\rho_X(\bar{F})^{-1}/\sqrt{n}\}|$
- $\|\beta^{(k-1)} - \hat{\beta}_X(\bar{F},\mathbf{y})\|_2 \leq \epsilon\rho(\bar{F})^{-1}\sqrt{|\bar{F} - F^{(k-1)}|/n}$.
- $\|\hat{\beta}_X(\bar{F},\mathbf{y}) - \bar{\beta}\|_\infty \leq \sigma\sqrt{(2\ln(2|\bar{F}|/\eta))/(n\rho_X(\bar{F}))}$.

In the following, we discuss some consequences of Theorem 1 and Theorem 2, and compare them with those of Lasso. Let $k(\epsilon)$ be the number of $j \in \bar{F}$ such that $|\bar{\beta}_j| < 3\epsilon\rho_X(\bar{F})^{-1}/\sqrt{n}$. Theorem 2 implies that $|\bar{F} - F^{(k-1)}| \leq 2k(\epsilon)$; that is, $|\bar{F} - F^{(k-1)}|$ is small when $k(\epsilon)$ is small. In such case, the feature set $F^{(k-1)}$ selected by the greedy least squares algorithm is approximately correct. Moreover, we have $\beta^{(k-1)} \approx \bar{\beta}$. In fact, one can show (e.g., see Zhang, 2008) that with probability larger than $1-\eta$:

$$\|\hat{\beta}_X(\bar{F},\mathbf{y}) - \bar{\beta}\|_2 \leq \sigma\sqrt{|\bar{F}|/(\rho(\bar{F})n)}[1 + \sqrt{20\ln(1/\eta)}].$$

By combining this estimate with Theorem 2, we have

$$\|\beta^{(k-1)} - \bar{\beta}\|_2 \leq \sigma\sqrt{|\bar{F}|/(\rho(\bar{F})n)}[1 + \sqrt{20\ln(1/\eta)}] + \epsilon\rho(\bar{F})^{-1}\sqrt{2k(\epsilon)/n}.$$

That is, $\|\beta^{(k-1)}-\bar{\beta}\|_2 = O(\sqrt{|\bar{F}|/n}+\epsilon\sqrt{k(\epsilon)/n})$. This implies that when $\mu_X(\bar{F})<1$, greedy least squares regression leads to a good estimation of the true parameter $\bar{\beta}$. By choosing $\epsilon = O(\sigma\sqrt{\ln(2d/\eta)})$, we obtain $\|\beta^{(k-1)}-\bar{\beta}\|_2 = O(\sqrt{|\bar{F}|/n}+\sqrt{k(\epsilon)\ln d/n})$. The corresponding result for the Lasso estimator $\hat{\beta}$ in (2) is $\|\hat{\beta}-\bar{\beta}\|_2 = O(\lambda\sqrt{|\bar{F}|/n})$, where we require λ to be of the order $\sigma\sqrt{\ln(d/\eta)/n}$ or larger. Therefore, if $k(\epsilon)$ is small, then Lasso is inferior due to the extra $\ln d$ factor. This factor is inherent to the L_1 regularization in Lasso, which introduces a bias that cannot be removed.

In this paper, we are mainly interested in the situation $k(\epsilon)=0$, which implies that with the stopping criterion ϵ, greedy least squares regression can correctly identify all features with large probability. Note that in order to correctly identify all features ($F^{(k-1)}=\bar{F}$), the requirement $\min_{j\in\bar{F}}|\bar{\beta}_j| \geq 3\epsilon\rho_X(\bar{F})^{-1}/\sqrt{n}$ in Theorem 1 is natural. Observe that we may take $\epsilon = \sigma\sqrt{3\ln(d/\eta)}/(1-\mu_X(\bar{F}))$. This means that under the assumption of Theorem 1, it is possible to identify all features correctly using the greedy least squares algorithm as long as the target coefficients $\bar{\beta}_j$ ($j\in\bar{F}$) are larger than the order $\sigma\sqrt{\ln(d/\eta)/n}$.

In fact, since $\sigma\sqrt{\ln(d/\eta)/n}$ is the noise level, if there exists a target coefficient $\bar{\beta}_j$ that is smaller than $O(\sigma\sqrt{\ln(d/\eta)/n})$ in absolute value, then we cannot distinguish such a small coefficient from zero (or noise) with large probability. Therefore when the condition $\mu_X(\bar{F})<1$ holds, it is not possible to do much better than greedy least squares regression except for the constant hidden in $O(\cdot)$ and its dependency on $\rho(\bar{F})$ and $\mu_X(\bar{F})$.

In comparison, for Lasso, the condition required of $\min_{j\in\bar{F}}|\bar{\beta}_j|$ depends not only on $\rho(\bar{F})^{-1}$ and $(1-\mu_X(\bar{F}))^{-1}$, but also on the quantity $\|(X_{\bar{F}}^T X_{\bar{F}})^{-1}\|_{\infty,\infty}$ (see Wainwright, 2006), where

$$\|(X_{\bar{F}}^T X_{\bar{F}})^{-1}\|_{\infty,\infty} = \sup_{\mathbf{u}\in\mathbb{R}^{|\bar{F}|}} \frac{\|(X_{\bar{F}}^T X_{\bar{F}})^{-1}\mathbf{u}\|_\infty}{\|\mathbf{u}\|_\infty}.$$

Consider the matrix $(X_{\bar{F}}^T X_{\bar{F}})^{-1} = I + 0.5B/\sqrt{|\bar{F}|}$, where $B_{i,j}=1$ when either $i=1$ or $j=1$ or $i=j$, and $B_{i,j}=0$ otherwise. Then it is not hard to verify that $\rho(\bar{F})^{-1}<2$ and $\|(X_{\bar{F}}^T X_{\bar{F}})^{-1}\|_{\infty,\infty} > 0.5\sqrt{|\bar{F}|}$ (by taking $\mathbf{u}=[1,\ldots,1]$). This means that in the worst case, we can find matrix $X_{\bar{F}}^T X_{\bar{F}}$ such that

$$\|(X_{\bar{F}}^T X_{\bar{F}})^{-1}\|_{\infty,\infty} > 0.25\sqrt{|\bar{F}|}\rho(\bar{F})^{-1}.$$

Therefore, if we only assume that $\rho(\bar{F})$ is bounded away from zero without using the quantity $\|(X_{\bar{F}}^T X_{\bar{F}})^{-1}\|_{\infty,\infty}$, the feature consistency result in Zhao and Yu (2006) and Wainwright (2006) for Lasso requires the condition

$$\min_{j\in\mathrm{supp}(\bar{\beta})} |\bar{\beta}_j| \geq c\sigma\sqrt{|\bar{F}|\ln(d/\eta)/n}$$

for some constant c that is proportional to $\rho(\bar{F})^{-1}(1-\mu_X(\bar{F}))^{-1}$. This is a more restrictive condition than that of greedy least squares regression. Unfortunately, the factor $\sqrt{|\bar{F}|}$ cannot be removed for Lasso, unless we make the additional and stronger assumption that $\|(X_{\bar{F}}^T X_{\bar{F}})^{-1}\|_{\infty,\infty} = O(\rho(\bar{F})^{-1})$.

As we discussed after Theorem 2, the bias of L_1-regularization also leads to suboptimal estimation for Lasso. For example, for the greedy algorithm, we can show $\|\hat{\beta}_X(\bar{F},\mathbf{y})-\bar{\beta}\|_2 = O(\sigma\sqrt{|\bar{F}|/n})$ and $\|\hat{\beta}_X(\bar{F},\mathbf{y})-\bar{\beta}\|_\infty = O(\sigma\sqrt{\ln|\bar{F}|/n})$. Under the conditions of Theorem 1, we have $\beta^{(k-1)} = \hat{\beta}_X(\bar{F},\mathbf{y})$, and thus $\|\beta^{(k-1)}-\bar{\beta}\|_2 = O(\sigma\sqrt{|\bar{F}|/n})$ and $\|\beta^{(k-1)}-\bar{\beta}\|_\infty = O(\sigma\sqrt{\ln|\bar{F}|/n})$. Under the same conditions, for the Lasso estimator $\hat{\beta}$ of (2), we have $\|\hat{\beta} - \bar{\beta}\|_2 = O(\sigma\sqrt{|\bar{F}| \ln d/n})$ and $\|\hat{\beta} - \bar{\beta}\|_\infty = O(\sigma\sqrt{\ln d/n})$. The $\ln d$ factor (bias) is inherent to Lasso, which can be removed with two-stage procedures (e.g., Zhang, 2009). However, such procedures are less robust and more complicated than the simple greedy algorithm.

4. Feature Selection Consistency

As we have mentioned before, the effectiveness of feature selection using Lasso was established by Zhao and Yu (2006), under more refined irrepresentable conditions that depend on the signs of the true target $\mathrm{sgn}(\bar{\beta})$. In comparison, the condition $\mu_X(\bar{F}) < 1$ in Theorem 2 depends only on the design matrix but not the sparse target $\bar{\beta}$. That is, the condition is with respect to the worst case choice of $\bar{\beta}$ with support $\mathrm{supp}(\bar{\beta}) = \bar{F}$. Due to the complexity of greedy procedure, we cannot establish a simple target dependent condition that ensures feature selection consistency. This means for any specific target, the behavior of forward greedy algorithm and Lasso might be different, and one may be preferred over the other under different scenarios. Experiments in Zhang (2008) illustrated this point.

In the following, we introduce the target independent irrepresentable conditions that are equivalent to the irrepresentable conditions of Zhao and Yu (2006) with the worst case choice of $\mathrm{sgn}(\bar{\beta})$ (also see Wainwright, 2006).

Definition 3 *Consider a sequence of problems indexed by n: at each sample size n, let $X^{(n)}$ be an $n \times d^{(n)}$ dimensional data matrix, and we observe $\mathbf{y}^{(n)} \in \mathbb{R}^n$ that is corrupted with noise. Let $\bar{F}^{(n)}$ be the feature set, where $\mathbf{E}\mathbf{y}^{(n)} = X^{(n)}\bar{\beta}^{(n)}$ and $\mathrm{supp}(\bar{\beta}^{(n)}) = \bar{F}^{(n)}$.*

We say that the sequence satisfies the strong target independent irrepresentable *condition if there exists $\delta > 0$ such that $\overline{\lim}_{n\to\infty}\mu_{X^{(n)}}(\bar{F}^{(n)}) \leq 1 - \delta$.*

We say that the sequence satisfies the weak target independent irrepresentable *condition if $\mu_{X^{(n)}}(\bar{F}^{(n)}) \leq 1$ for all sufficiently large n.*

It was shown by Zhao and Yu (2006) that the strong (target independent) irrepresentable condition is sufficient for Lasso to select features consistently for all possible sign combination of $\bar{\beta}^{(n)}$ when $n \to \infty$ (under appropriate assumptions). In addition, the weak (target independent) irrepresentable condition is necessary for Lasso to select features consistently when $n \to \infty$. The target independent irrepresentable conditions are considered by Zhao and Yu (2006) and Wainwright (2006). Similar conditions were also considered by Tropp (2004) without stochastic noise.

Results parallel to that of Lasso can be obtained for Algorithm 1. Specifically, the following two theorems show that the strong target independent irrepresentable condition is sufficient for Algorithm 1 to select features consistently, while the weak target independent irrepresentable condition is necessary.

Theorem 4 *Consider regression problems indexed by the sample size n, and use notations in Definition 3. Let Assumption 1 hold, with noise σ independent of n. Assume that the strong irrepresentable condition holds. For each problem of sample size n, denote by F_n the feature set from Algorithm 1 when it stops with $\varepsilon = n^{s/2}$ for some $s \in (0,1]$. Then for all sufficiently large n, we have*

$$P(F_n \neq \bar{F}^{(n)}) \leq \exp(-n^s/\ln n)$$

if the following conditions hold:

1. $d_n \leq \exp(n^s/\ln n)$

2. $\min_{j \in \bar{F}^{(n)}} |\bar{\beta}_j^{(n)}| \geq 3n^{(s-1)/2}/\rho(\bar{F}^{(n)})$.

Proof When n is sufficiently large, the two conditions of Theorem 1 hold with $\eta = 0.5\exp(-n^s/\ln n)$. Therefore the theorem is a direct consequence. ■

Theorem 5 *Consider regression problems indexed by the sample size n, and use notations in Definition 3. Let Assumption 1 hold, with noise σ independent of n. Assume that the weak irrepresentable condition is violated at sample sizes $n_1 < n_2 < \cdots$. There exist targets $\bar{\beta}^{(n_j)}$ with arbitrarily large $\min_{i \in \bar{F}^{(n_j)}} |\bar{\beta}_i^{(n_j)}|$, such that at each sample size n_j, Algorithm 1 chooses a basis $i^{(1)} \notin \bar{F}$ in the first step with probability larger than* 0.5.

Proof By definition of $\mu_X(\bar{F})$, there exists $\mathbf{v} = (X_{\bar{F}}^T X_{\bar{F}})\mathbf{u} \in \mathbb{R}^{|\bar{F}|}$ such that

$$\begin{aligned}
\mu_X(\bar{F}) &= \max_{j \notin \bar{F}} \|(X_{\bar{F}}^T X_{\bar{F}})^{-1} X_{\bar{F}}^T \mathbf{x}_j\|_1 \\
&= \max_{j \notin \bar{F}} \frac{|\mathbf{v}^T (X_{\bar{F}}^T X_{\bar{F}})^{-1} X_{\bar{F}}^T \mathbf{x}_j|}{\|\mathbf{v}\|_\infty} \\
&= \max_{j \notin \bar{F}} \frac{|\mathbf{u}^T X_{\bar{F}}^T \mathbf{x}_j|}{\|(X_{\bar{F}}^T X_{\bar{F}})\mathbf{u}\|_\infty} \\
&= \frac{\max_{j \notin F} |\mathbf{x}_j^T X_{\bar{F}} \mathbf{u}|}{\max_{i \in \bar{F}} |(\mathbf{x}_i^T X_{\bar{F}})\mathbf{u}|}.
\end{aligned}$$

Therefore if $\mu_X(\bar{F}) > 1$, we can find $\mathbf{u} \in \mathbb{R}^{|\bar{F}|}$ such that $\max_{j \notin F} |\mathbf{x}_j^T X_{\bar{F}} \mathbf{u}| > \max_{i \in \bar{F}} |(\mathbf{x}_i^T X_{\bar{F}})\mathbf{u}|$.

Consider an arbitrary sequence $\delta_n > 0$ ($n = 1, 2, \ldots$). At any sample size $n = n_j$, since $\mu_{X^{(n)}}(\bar{F}^{(n)}) > 1$, we can find a sufficiently large target vector $\bar{\beta}^{(n)}$ such that

$$\max_{i \in \bar{F}^{(n)}} |\mathbf{x}_i^T X^{(n)} \bar{\beta}^{(n)}| < \max_{j \notin \bar{F}^{(n)}} |\mathbf{x}_j^T X^{(n)} \bar{\beta}^{(n)}| - 2\delta_n. \tag{3}$$

Now we may take $\delta_n = \sigma\sqrt{2n\ln(4d_n)}$; then Lemma 8 implies that with probability larger than 0.5, $\max_{j \in \{1,\ldots,d\}} |\mathbf{x}_j^T (\mathbf{y} - X^{(n)}\bar{\beta}^{(n)})| \leq \delta_n$. Therefore (3) implies that

$$\max_{i \in \bar{F}^{(n)}} [|\mathbf{x}_i^T X^{(n)} \bar{\beta}^{(n)}| + |\mathbf{x}_i^T (\mathbf{y} - X^{(n)}\bar{\beta}^{(n)})|] < \max_{j \notin \bar{F}^{(n)}} [|\mathbf{x}_j^T X^{(n)} \bar{\beta}^{(n)}| - |\mathbf{x}_j^T (\mathbf{y} - X^{(n)}\bar{\beta}^{(n)})|].$$

Therefore

$$\max_{i \in \bar{F}^{(n)}} |\mathbf{x}_i^T \mathbf{y}| < \max_{j \notin \bar{F}^{(n)}} |\mathbf{x}_j^T \mathbf{y}|.$$

This means that we pick $i^{(1)} \notin \bar{F}$ in the first step with probability larger than 0.5. ■

5. Conclusion

We have shown that weak and strong target independent irrepresentable conditions are necessary and sufficient conditions for a greedy least squares regression algorithm to select features consistently. These conditions match the target independent versions of the necessary and sufficient conditions for Lasso by Zhao and Yu (2006).

Moreover, if the eigenvalue $\rho(\bar{F})$ is bounded away from zero, then the greedy algorithm can reliably identify features as long as each nonzero coefficient is larger than a constant times the noise level. In comparison, under the same condition, Lasso may require the coefficients to be larger than $O(\sqrt{s})$ times the noise level, where s is the number of nonzero coefficients. This implies that under some conditions, greedy least squares regression may potentially select features more effectively than Lasso in the presence of stochastic noise.

Although the target independent versions of the irrepresentable conditions for greedy least squares regression match those of Lasso, our result does not show which algorithm is better for any specific target. In fact, the target specific behaviors of the two algorithms are different, and one may be preferred over the other under different scenarios.

Acknowledgments

This paper is the outcome of some private discussion with Joel Tropp, which drew the author's attention to the similarities and differences between orthogonal matching pursuit and Lasso for estimating sparse signals.

Appendix A. Auxiliary Lemmas

The following technical lemmas from Zhang (2008) are needed to analyze the behavior of greedy least squares regression under stochastic noise. For completeness, we include them here with proofs.

The following lemma relates the squared error reduction in one greedy step to correlation coefficients.

Lemma 6 *For all* $\mathbf{x}, \mathbf{x}', \mathbf{y} \in \mathbb{R}^n$, *we have*

$$\inf_{\alpha \in \mathbb{R}} \|\mathbf{x} + \alpha \mathbf{x}' - \mathbf{y}\|_2^2 = \|\mathbf{x} - \mathbf{y}\|_2^2 - ((\mathbf{x} - \mathbf{y})^T \mathbf{x}')^2 / \|\mathbf{x}'\|_2^2.$$

Proof The equality follows from simple algebra with the optimal α achieved at $-(\mathbf{x} - \mathbf{y})^T \mathbf{x}' / \|\mathbf{x}'\|_2^2$. ■

The following lemma provides a bound on the squared error reduction of one forward greedy step. Some ingredients of the proof has appeared in Natarajan (1995).

Lemma 7 *Let Assumption 1 hold. Consider* $F \subset \bar{F} \subset \{1, \ldots, d\}$. *Let* $\beta' = \hat{\beta}_X(\bar{F}, \mathbf{y})$, $\beta = \hat{\beta}_X(F, \mathbf{y})$, $\mathbf{x}' = X\beta'$, *and* $\mathbf{x} = X\beta$. *Then*

$$\inf_{\alpha \in \mathbb{R}, j \in \bar{F} - F} \|\mathbf{x} + \alpha \mathbf{x}_j - \mathbf{y}\|_2^2 \leq \|\mathbf{x} - \mathbf{y}\|_2^2 - \frac{\rho(\bar{F})}{|\bar{F} - F|} \|\mathbf{x} - \mathbf{x}'\|_2^2.$$

Proof For all $j \in F$, we have $\|\mathbf{x} + \alpha \mathbf{x}_j - \mathbf{y}\|_2^2$ achieves the minimum at $\alpha = 0$. This implies that $(\mathbf{x}-\mathbf{y})^T\mathbf{x}_j = 0$ for $j \in F$. Therefore we have

$$\begin{aligned}&(\mathbf{x}-\mathbf{y})^T \sum_{j\in\bar{F}-F} (\beta'_j - \beta_j)\mathbf{x}_j \\ =&(\mathbf{x}-\mathbf{y})^T \sum_{j\in\bar{F}\cup F} (\beta'_j - \beta_j)\mathbf{x}_j = (\mathbf{x}-\mathbf{y})^T(\mathbf{x}'-\mathbf{x}) \\ =&-\|\mathbf{x}-\mathbf{x}'\|_2^2 + (\mathbf{x}'-\mathbf{y})^T(\mathbf{x}'-\mathbf{x}) = -\|\mathbf{x}-\mathbf{x}'\|_2^2.\end{aligned}$$

The last quality follows from the definition of $\beta' = \hat{\beta}_X(\bar{F},\mathbf{y})$ and $F \subset \bar{F}$, which implies that $(\mathbf{x}' - \mathbf{y})^T(\mathbf{x}'-\mathbf{x}) = 0$. Now, let $s' = |\bar{F} - F|$, then the above inequality leads to the following derivation $\forall \eta > 0$:

$$\begin{aligned}&s' \inf_{j\in\bar{F}-F} \|\mathbf{x} + \eta(\beta'_j - \beta_j)\mathbf{x}_j - \mathbf{y}\|_2^2 \\ \leq& \sum_{j\in\bar{F}-F} \|\mathbf{x} + \eta(\beta'_j - \beta_j)\mathbf{x}_j - \mathbf{y}\|_2^2 \\ =&s'\|\mathbf{x}-\mathbf{y}\|_2^2 + \eta^2 \sum_{j\in\bar{F}-F} (\beta'_j - \beta_j)^2\|\mathbf{x}_j\|_2^2 + 2\eta(\mathbf{x}-\mathbf{y})^T \sum_{j\in\bar{F}-F} (\beta'_j - \beta_j)\mathbf{x}_j \\ =&s'\|\mathbf{x}-\mathbf{y}\|_2^2 + n\eta^2 \sum_{j\in\bar{F}-F} (\beta'_j - \beta_j)^2 - 2\eta\|\mathbf{x}'-\mathbf{x}\|_2^2.\end{aligned}$$

Note that in the last equation, we have used $\|\mathbf{x}_j\|_2^2 = n$ in Assumption 1. By optimizing over η, we obtain

$$\begin{aligned}&s' \inf_{j\in\bar{F}-F} \|\mathbf{x} + \eta(\beta'_j - \beta_j)\mathbf{x}_j - \mathbf{y}\|_2^2 \\ \leq& s'\|\mathbf{x}-\mathbf{y}\|_2^2 - \frac{\|\mathbf{x}'-\mathbf{x}\|_2^4}{n\sum_{j\in\bar{F}}(\beta'_j - \beta_j)^2} \leq s'\|\mathbf{x}-\mathbf{y}\|_2^2 - \rho(\bar{F})\|\mathbf{x}'-\mathbf{x}\|_2^2.\end{aligned}$$

This leads to the lemma. ■

The following lemma is a standard empirical processes bound for sub-Gaussian random variables. The bound is used to derive probability estimates in our analysis.

Lemma 8 *Consider n independent random variables* $\xi_1, \ldots, \xi_n$ *such that* $\mathbf{E}e^{t(\xi_i - \mathbf{E}\xi_i)} \leq e^{\sigma_i^2 t^2/2}$ *for all t and i. Consider* $g_{i,j}$ *for* $i = 1, \ldots, n$ *and* $j = 1, \ldots, m$, *we have for all* $\eta \in (0,1)$, *with probability larger than* $1 - \eta$*:*

$$\sup_j \left|\sum_{i=1}^n g_{i,j}(\xi_i - \mathbf{E}\xi_i)\right| \leq a\sqrt{2\ln(2m/\eta)},$$

where $a^2 = \sup_j \sum_{i=1}^n g_{i,j}^2 \sigma_i^2$.

Proof For a fixed j, we let $s_j = \sum_{i=1}^n g_{i,j}(\xi_i - \mathbf{E}\xi_i)$; then by assumption, $\mathbf{E}(e^{ts_j} + e^{-ts_j}) \leq 2e^{a^2t^2/2}$, which implies that for all $\varepsilon > 0$: $P(|s_j| \geq \varepsilon)e^{t\varepsilon} \leq 2e^{a^2t^2/2}$. Now let $t = \varepsilon/a^2$, we obtain:

$$P\left(\left|\sum_{i=1}^n g_{i,j}(\xi_i - \mathbf{E}\xi_i)\right| \geq \varepsilon\right) \leq 2e^{-\varepsilon^2/2a^2}.$$

This implies that

$$P\left[\sup_j \left|\sum_{i=1}^n g_{i,j}(\xi_i - \mathbf{E}\xi_i)\right| \geq \varepsilon\right] \leq m \sup_j P\left[\left|\sum_{i=1}^n g_{i,j}(\xi_i - \mathbf{E}\xi_i)\right| \geq \varepsilon\right] \leq 2me^{-\varepsilon^2/(2a^2)}.$$

This implies the lemma. ■

The following lemma gives a bound on the infinity norm of the difference between the estimated parameter $\hat{\beta}_X(\bar{F},\mathbf{y})$ and the true parameter $\bar{\beta}$ when the set of features $\bar{F}$ are known in advance.

Lemma 9 *Let Assumption 1 hold. Consider any fixed* $\bar{F} \subset \{1,\ldots,d\}$. *For all* $\eta \in (0,1)$, *with probability larger than* $1-\eta$, *we have*

$$\|\hat{\beta}_X(\bar{F},\mathbf{y}) - \hat{\beta}_X(\bar{F},\mathbf{E}\mathbf{y})\|_\infty \leq \sigma\sqrt{(2\ln(2|\bar{F}|/\eta))/(n\rho(\bar{F}))}.$$

Proof For simplicity, let $G = X_{\bar{F}}$ and $\bar{k} = |\bar{F}|$. Let $\hat{\beta}' \in \mathbb{R}^{\bar{k}}$ and $\bar{\beta}' \in \mathbb{R}^{\bar{k}}$ be the restrictions of $\hat{\beta}_X(\bar{F},\mathbf{y}) \in \mathbb{R}^d$ and $\hat{\beta}_X(\bar{F},\mathbf{E}\mathbf{y}) \in \mathbb{R}^d$ to $\bar{F}$ respectively. Algebraically, we have $\hat{\beta}' = (G^TG)^{-1}G^T\mathbf{y}$ and $\bar{\beta}' = (G^TG)^{-1}G^T\mathbf{E}\mathbf{y}$. It follows that

$$\hat{\beta}' - \bar{\beta}' = (G^TG)^{-1}G^T(\mathbf{y} - \mathbf{E}\mathbf{y}).$$

Therefore

$$|\hat{\beta}'_j - \bar{\beta}'_j| = |\mathbf{e}_j^T(G^TG)^{-1}G^T(\mathbf{y} - \mathbf{E}\mathbf{y})|.$$

Lemma 8 implies that with probability larger than $1-\eta$, for all j:

$$|\mathbf{e}_j^T(G^TG)^{-1}G^T(\mathbf{y} - \mathbf{E}\mathbf{y})| \leq \sigma\|\mathbf{e}_j^T(G^TG)^{-1}G^T\|_2\sqrt{2\ln(2\bar{k}/\eta)}.$$

Since by definition, $\rho(\bar{F})n$ is no larger than the smallest eigenvalue of G^TG, the desired inequality follows from the estimate

$$\|\mathbf{e}_j^T(G^TG)^{-1}G^T\|_2^2 = \mathbf{e}_j^T(G^TG)^{-1}\mathbf{e}_j \leq 1/(n\rho(\bar{F})).$$

■

The following lemma estimates the correlation coefficient of $\mathbf{x}_j$ with $j \notin \bar{F}$.

Lemma 10 *Let Assumption 1 hold. Assume also that* $\mathbf{E}\mathbf{y} = X\bar{\beta}$ *with* $\operatorname{supp}(\bar{\beta}) \subset \bar{F} \subset \{1,\ldots,d\}$. *For all* $\eta \in (0,1)$, *with probability larger than* $1-\eta$, *we have*

$$\max_{j\notin\bar{F}} |(X\hat{\beta}_X(\bar{F},\mathbf{y}) - \mathbf{y})^T\mathbf{x}_j| \leq \sigma\sqrt{2n\ln(2d/\eta)}.$$

Proof Let P be the projection operator to the subspace spanned by $\{\mathbf{x}_j : j \in \bar{F}\}$ on $\mathbb{R}^n$. Lemma 8 implies that with probability larger than $1-\eta$:

$$\sup_{j=1,\ldots,d} |(\mathbf{y} - \mathbf{E}\mathbf{y})^T(I-P)\mathbf{x}_j| \leq \sigma\sqrt{2n\ln(2d/\eta)},$$

where we have used $\|\mathbf{x}_j\|_2 = \sqrt{n}$. Let $\hat{\mathbf{x}} = X\hat{\beta}_X(\bar{F},\mathbf{y})$. Since $(\hat{\mathbf{x}} - \mathbf{y})^T\mathbf{x}_j = 0$ for all $j \in \bar{F}$, we have $\hat{\mathbf{x}} = P\mathbf{y}$. Moreover, since $(I-P)\mathbf{E}\mathbf{y} = (I-P)X\bar{\beta} = 0$, we have

$$(\mathbf{y} - \mathbf{E}\mathbf{y})^T(I-P)\mathbf{x}_j = ((I-P)\mathbf{y} - (I-P)\mathbf{E}\mathbf{y})^T\mathbf{x}_j = (\mathbf{y} - \hat{\mathbf{x}})^T\mathbf{x}_j.$$

Combine this equation with the previous inequality, we obtain the desired bound. ■

Appendix B. Proof of Theorem 2

Before the formal proof, we give a brief outline of the main argument. First, Lemma 10 implies that with large probability, $\max_{j\notin\bar{F}} |(X\hat{\beta}_X(\bar{F},\mathbf{y}) - \mathbf{y})^T\mathbf{x}_j|$ is small. Using this fact, and the assumption that $\mu_X(\bar{F}) < 1$, it follows from Lemma 11 below that when $\mathrm{supp}(\beta^{(k-1)}) \subset \bar{F}$, either $\max_i |(X\beta^{(k-1)} - \mathbf{y})^T\mathbf{x}_i|$ is sufficiently small (which implies that the greedy procedure stops and $\beta^{(k-1)} \approx \bar{\beta}$), or $\max_{j\notin\bar{F}} |(X\beta^{(k-1)} - \mathbf{y})^T\mathbf{x}_j| < \max_{i\in\bar{F}} |(X\beta^{(k-1)} - \mathbf{y})^T\mathbf{x}_i|$ (which implies that the greedy procedure chooses a direction $i^{(k)} \in \bar{F}$ in the next iteration). The claims of the theorem then follow by induction.

We start the formal proof by introducing the following critical lemma, which generalizes the essential idea of Tropp (2004). Note that the result there only considered the case $X\hat{\beta}_X(\bar{F},\mathbf{y}) = \mathbf{y}$.

Lemma 11 *Consider* $\beta \in \mathbb{R}^d$ *such that* $\mathrm{supp}(\beta) \subset \bar{F}$. *We have*

$$\max_{j\notin\bar{F}} |(X\beta - \mathbf{y})^T\mathbf{x}_j| \le \max_{j\notin\bar{F}} |(X\hat{\beta}_X(\bar{F},\mathbf{y}) - \mathbf{y})^T\mathbf{x}_j| + \mu_X(\bar{F}) \max_{i\in\bar{F}} |(X\beta - \mathbf{y})^T\mathbf{x}_i|.$$

Proof Let $\beta' = \hat{\beta}_X(\bar{F},\mathbf{y})$. Note that $(X\beta' - \mathbf{y})^T\mathbf{x}_i = 0$ when $i \in \bar{F}$. Therefore

$$\max_{i\in\bar{F}} |(X\beta - \mathbf{y})^T\mathbf{x}_i| = \max_{i\in\bar{F}} |\mathbf{x}_i^T X(\beta - \beta')| = \|X_{\bar{F}}^T X_{\bar{F}}(\beta - \beta')\|_\infty.$$

Let $\mathbf{v} = X_{\bar{F}}^T X_{\bar{F}}(\beta - \beta')$, then the definition of $\mu_X(\bar{F})$ implies that

$$\mu_X(\bar{F}) \ge \max_{j\notin\bar{F}} \frac{|\mathbf{x}_j^T X_{\bar{F}}(X_{\bar{F}}^T X_{\bar{F}})^{-1}\mathbf{v}|}{\|\mathbf{v}\|_\infty} = \frac{\max_{j\notin\bar{F}} |\mathbf{x}_j^T X_{\bar{F}}(\beta - \beta')|}{\|X_{\bar{F}}^T X_{\bar{F}}(\beta - \beta')\|_\infty}.$$

We obtain from the above

$$\max_{j\notin\bar{F}} |\mathbf{x}_j^T X(\beta - \beta')| \le \mu_X(\bar{F})\|X_{\bar{F}}^T X_{\bar{F}}(\beta - \beta')\|_\infty = \mu_X(\bar{F}) \max_{i\in\bar{F}} |(X\beta - \mathbf{y})^T\mathbf{x}_i|.$$

Now, the lemma follows from the simple inequality

$$\max_{j\notin\bar{F}} |(X\beta - \mathbf{y})^T\mathbf{x}_j| \le \max_{j\notin\bar{F}} |\mathbf{x}_j^T X(\beta - \beta')| + \max_{j\notin\bar{F}} |\mathbf{x}_j^T(X\beta' - \mathbf{y})|$$

■

Now we are ready to prove the theorem. From Lemma 9, we obtain with probability larger than $1-\eta$,

$$\|\hat{\beta}_X(\bar{F},\mathbf{y}) - \bar{\beta}\|_\infty \le \sigma\sqrt{(2\ln(2|\bar{F}|/\eta))/(n\rho(\bar{F}))}.$$

From Lemma 10, we obtain with probability larger than $1-\eta$,

$$\max_{j\notin\bar{F}} |(X(\hat{\beta}_X(\bar{F},\mathbf{y}))-\mathbf{y})^T\tilde{\mathbf{x}}_j| \leq \sigma\sqrt{2\ln(2d/\eta)} < (1-\mu_X(\bar{F}))\varepsilon. \qquad (4)$$

With probability larger than $1-2\eta$, both claims hold.

We now proceed by induction on k to show that $F^{(k-1)}\subset\bar{F}$ before the procedure stops. Assume the claim is true after $k-1$ steps for $k\geq 1$. By induction hypothesis, we have $F^{(k-1)}\subset\bar{F}$ at the beginning of step k. Therefore Lemma 7 implies

$$\min_{\alpha,i\in\bar{F}} \|X\beta^{(k-1)}+\alpha\mathbf{x}_i-\mathbf{y}\|_2^2 \leq \|X\beta^{(k-1)}-\mathbf{y}\|_2^2 - \frac{\rho(\bar{F})}{|\bar{F}-F^{(k-1)}|}\|X(\beta^{(k-1)}-\hat{\beta}_X(\bar{F},\mathbf{y}))\|_2^2.$$

Using the above inequality, we obtain from Lemma 6 the following bound on the correlation coefficients:

$$\begin{aligned}\max_{i\in\bar{F}} |(X\beta^{(k-1)}-\mathbf{y})^T\tilde{\mathbf{x}}_i| &= \left(\|X\beta^{(k-1)}-\mathbf{y}\|_2^2 - \min_{\alpha,i\in\bar{F}}\|X\beta^{(k-1)}+\alpha\mathbf{x}_i-\mathbf{y}\|_2^2\right)^{1/2}\\ &\geq \frac{\sqrt{\rho(\bar{F})}}{\sqrt{|\bar{F}-F^{(k-1)}|}}\|X(\beta^{(k-1)}-\hat{\beta}_X(\bar{F},\mathbf{y}))\|_2\\ &\geq \frac{\sqrt{n}\rho(\bar{F})}{\sqrt{|\bar{F}-F^{(k-1)}|}}\|\beta^{(k-1)}-\hat{\beta}_X(\bar{F},\mathbf{y})\|_2.\end{aligned}$$

We only need to consider the following two scenarios:

- $\|\beta^{(k-1)}-\hat{\beta}_X(\bar{F},\mathbf{y})\|_2 > \varepsilon\rho(\bar{F})^{-1}\sqrt{|\bar{F}-F^{(k-1)}|/n}$.

  In this case, we have

  $$\max_{i\in\bar{F}}|(X\beta^{(k-1)}-\mathbf{y})^T\tilde{\mathbf{x}}_i| > \varepsilon > \max_{j\notin\bar{F}}|(X\hat{\beta}_X(\bar{F},\mathbf{y})-\mathbf{y})^T\tilde{\mathbf{x}}_j|/(1-\mu_X(\bar{F})).$$

  The second inequality is due to (4). Now by combining this estimate with Lemma 11, we obtain

  $$\max_{j\notin\bar{F}}|(X\beta^{(k-1)}-\mathbf{y})^T\tilde{\mathbf{x}}_j| < \max_{i\in\bar{F}}|(X\beta^{(k-1)}-\mathbf{y})^T\tilde{\mathbf{x}}_i|.$$

  This implies that $i^{(k)}\in\bar{F}$ and the procedure does not stop.

- $\|\beta^{(k-1)}-\hat{\beta}_X(\bar{F},\mathbf{y})\|_2 \leq \varepsilon\rho(\bar{F})^{-1}\sqrt{|\bar{F}-F^{(k-1)}|/n}$.

  In this case, we have the following scenarios:

  1. $i^{(k)}\notin\bar{F}$: By Lemma 11, we must have:

  $$\begin{aligned}\max_{i\in\bar{F}}|(X\beta-\mathbf{y})^T\tilde{\mathbf{x}}_i| &\leq \max_{j\notin\bar{F}}|(X\beta-\mathbf{y})^T\tilde{\mathbf{x}}_j|\\ &\leq \max_{j\notin\bar{F}}|(X\hat{\beta}_X(\bar{F},\mathbf{y})-\mathbf{y})^T\tilde{\mathbf{x}}_j| + \mu_X(\bar{F})\max_{i\in\bar{F}}|(X\beta-\mathbf{y})^T\tilde{\mathbf{x}}_i|\\ &\leq \max_{j\notin\bar{F}}|(X\hat{\beta}_X(\bar{F},\mathbf{y})-\mathbf{y})^T\tilde{\mathbf{x}}_j| + \mu_X(\bar{F})\max_{j\notin\bar{F}}|(X\beta-\mathbf{y})^T\tilde{\mathbf{x}}_j|.\end{aligned}$$

Therefore

$$\max_{j\notin\bar{F}} |(X\beta-\mathbf{y})^T\tilde{\mathbf{x}}_j| \leq \frac{1}{1-\mu_X(\bar{F})} \max_{j\notin\bar{F}} |(X\hat{\beta}_X(\bar{F},\mathbf{y})-\mathbf{y})^T\tilde{\mathbf{x}}_j| < \varepsilon.$$

The last inequality is due to (4). This implies that the procedure stops.

2. $i^{(k)} \in \bar{F}$ and the procedure does not stop.
3. $i^{(k)} \in \bar{F}$ and the procedure stops.

The above situations imply that if the procedure does not stop, then $i^{(k)} \in \bar{F}$. If the procedure stops, then

$$\|\beta^{(k-1)} - \hat{\beta}_X(\bar{F},\mathbf{y})\|_2 \leq \varepsilon\rho(\bar{F})^{-1}\sqrt{|\bar{F}-F^{(k-1)}|/n}.$$

Therefore by induction, when the procedure stops, the following three claims hold:

- $F^{(k-1)} \subset \bar{F}$.
- $\|\beta^{(k-1)} - \hat{\beta}_X(\bar{F},\mathbf{y})\|_2 \leq \varepsilon\rho_X(\bar{F})^{-1}\sqrt{|\bar{F}-F^{(k-1)}|/n}$.
- $\|\hat{\beta}_X(\bar{F},\mathbf{y}) - \bar{\beta}\|_\infty \leq \sigma\sqrt{(2\ln(2|\bar{F}|/\eta))/(n\rho_X(\bar{F}))} < \varepsilon/\sqrt{n\rho_X(\bar{F})}$.

Now, we can let $\gamma = \sqrt{8}\varepsilon\rho_X(\bar{F})^{-1}/\sqrt{n}$, then the above claims imply that

$$\begin{aligned}
&\gamma\sqrt{|\{j\in\bar{F}-F^{(k-1)}:|\bar{\beta}_j|\geq\gamma\}|}\\
\leq&\left[\sum_{j\in\bar{F}-F^{(k-1)}}|\bar{\beta}_j|^2\right]^{1/2}\\
\leq&\left[\sum_{j\in\bar{F}-F^{(k-1)}}|\bar{\beta}_j-\hat{\beta}_X(\bar{F},\mathbf{y})|^2\right]^{1/2}+\left[\sum_{j\in\bar{F}-F^{(k-1)}}|\hat{\beta}_X(\bar{F},\mathbf{y})|^2\right]^{1/2}\\
\leq&\sqrt{|\bar{F}-F^{(k-1)}|}\|\bar{\beta}-\hat{\beta}_X(\bar{F},\mathbf{y})\|_\infty+\|\beta^{(k-1)}-\hat{\beta}_X(\bar{F},\mathbf{y})\|_2\\
<&\sqrt{|\bar{F}-F^{(k-1)}|/(n\rho_X(\bar{F}))}\varepsilon+\varepsilon\rho_X(\bar{F})^{-1}\sqrt{|\bar{F}-F^{(k-1)}|/n}\\
\leq&2\varepsilon\rho_X(\bar{F})^{-1}\sqrt{|\bar{F}-F^{(k-1)}|/n}=\gamma\sqrt{|\bar{F}-F^{(k-1)}|/2}.
\end{aligned}$$

Therefore

$$2|\{j\in\bar{F}-F^{(k-1)}:|\bar{\beta}_j|\geq\gamma\}| \leq |\bar{F}-F^{(k-1)}|,$$

which implies that

$$\begin{aligned}
|\bar{F}-F^{(k-1)}| =&2|\bar{F}-F^{(k-1)}|-|\bar{F}-F^{(k-1)}|\\
\leq&2|\bar{F}-F^{(k-1)}|-2|\{j\in\bar{F}-F^{(k-1)}:|\bar{\beta}_j|\geq\gamma\}|\\
=&2|\{j\in\bar{F}-F^{(k-1)}:|\bar{\beta}_j|<\gamma\}|\\
\leq&2|\{j\in\bar{F}:|\bar{\beta}_j|<\gamma\}|.
\end{aligned}$$

This proves the theorem.

Abstract

We study online learning where a decision maker interacts with Nature with the objective of maximizing her long-term average reward subject to some sample path average constraints. We define the reward-in-hindsight as the highest reward the decision maker could have achieved, while satisfying the constraints, had she known Nature's choices in advance. We show that in general the reward-in-hindsight is *not* attainable. The convex hull of the reward-in-hindsight function is, however, attainable. For the important case of a single constraint, the convex hull turns out to be the highest attainable function. Using a calibrated forecasting rule, we provide an explicit strategy that attains this convex hull. We also measure the performance of heuristic methods based on non-calibrated forecasters in experiments involving a CPU power management problem.

Keywords: online learning, calibration, regret minimization, approachability

1. Introduction

We consider a repeated game from the viewpoint of a decision maker (player P1) who plays against Nature (player P2). The opponent (Nature) is "arbitrary" in the sense that player P1 has no prediction, statistical or strategic, of the opponent's choice of actions. This setting was considered by Hannan (1957), in the context of repeated matrix games. Hannan introduced the Bayes utility with respect to the current empirical distribution of the opponent's actions, as a performance goal for adaptive play. This quantity, defined as the highest average reward that player P1 could have achieved, in hindsight, by playing some fixed action against the observed action sequence of player P2. Player P1's *regret* is defined as the difference between the highest average reward-in-hindsight that player P1 could have hypothetically achieved, and the actual average reward obtained by player P1. It was established in Hannan (1957) that there exist strategies whose regret converges to zero as

[*]. Also at Department of Electrical Engineering, Technion, Israel, 32000.

the number of stages increases, even in the absence of any prior knowledge on the strategy of player P2. For recent advances on online learning, see Cesa-Bianchi and Lugosi (2006).

In this paper we consider regret minimization under sample-path constraints. That is, in addition to maximizing the average reward, or more precisely, minimizing the regret, the decision maker has some side constraints that need to be satisfied on the average. In particular, for every joint action of the players, there is an additional penalty vector that is accumulated by the decision maker. The decision maker has a predefined set in the space of penalty vectors, which represents the acceptable tradeoffs between the different components of the penalty vector. An important special case arises when the decision maker wishes to keep some constrained resource below a certain threshold. Consider, for example, a wireless communication system where the decision maker can adjust the transmission power to improve the probability that a message is received successfully. Of course, the decision maker does not know a priori how much power will be needed (this depends on the behavior of other users, the channel conditions, etc.). Still, a decision maker is usually interested in both the rate of successful transmissions, and in the average power consumption. In an often considered variation of this problem, the decision maker wishes to maximize the transmission rate, while keeping the average power consumption below some predefined threshold. We refer the reader to Mannor and Shimkin (2004) and references therein for a discussion of constrained average cost stochastic games and to Altman (1999) for constrained Markov decision problems. We note that the reward and the penalty are not treated the same; otherwise they could have been combined into a single scalar value, resulting in a much simpler problem.

The paper is organized as follows. In Section 2, we present formally the basic model, and provide a result that relates attainability with the value of the game. In Section 3, we provide an example where the reward-in-hindsight cannot be attained. In light of this negative result, in Section 4 we define the closed convex hull of the reward-in-hindsight, and show that it is attainable. Furthermore, in Section 5, we show that when there is a single constraint, this is the maximal attainable objective. In Section 6, we provide a simple strategy, based on calibrated forecasting, that attains the closed convex hull. Section 7 presents heuristic algorithms derived from an online forecaster, while incorporating strictly enforced constraints. The application of the algorithms of Section 7 to a power management domain is presented in Section 8. We finally conclude in Section 9 with some open questions and directions for future research.

2. Problem Definition

We consider a repeated game against Nature, in which a decision maker tries to maximize her reward, while satisfying some constraints on certain time-averages. The underlying stage game is a game with two players: P1 (the decision maker of interest) and P2 (who represents Nature and is assumed arbitrary). For our purposes, we only need to define rewards and constraints for P1.

A constrained game with respect to a set T is defined by a tuple (A,B,R,C,T) where:

1. A is the set of actions of P1; we will assume $A = \{1,2,\ldots,|A|\}$.

2. B is the set of actions of P2; we will assume $B = \{1,2,\ldots,|B|\}$.

3. R is an $|A| \times |B|$ matrix where the entry $R(a,b)$ denotes the expected reward obtained by P1, when P1 plays action $a \in A$ and P2 action $b \in B$. The actual rewards obtained at each play of actions a and b are assumed to be IID random variables, with finite second moments,

distributed according to a probability law $\Pr_R(\cdot\,|\,a,b)$. Furthermore, the reward streams for different pairs (a,b) are statistically independent.

4. C is an $|A| \times |B|$ matrix, where the entry $C(a,b)$ denotes the expected d-dimensional penalty vector incurred by P1, when P1 plays action $a \in A$ and P2 action $b \in B$. The actual penalty vectors obtained at each play of actions a and b are assumed to be IID random variables, with finite second moments, distributed according to a probability law $\Pr_C(\cdot\,|\,a,b)$. Furthermore, the penalty vector streams for different pairs (a,b) are statistically independent.

5. T is a set in $\mathbb{R}^d$ within which we wish the average of the penalty vectors to lie. We assume that T is convex and closed. Since the entries of C are bounded, we will also assume, without loss of generality, that T is bounded.

The game is played in stages. At each stage t, P1 and P2 simultaneously choose actions $a_t \in A$ and $b_t \in B$, respectively. Player P1 obtains a reward r_t, distributed according to $\Pr_R(\cdot\,|\,a_t,b_t)$, and a penalty c_t, distributed according to $\Pr_C(\cdot\,|\,a_t,b_t)$. We define P1's average reward by time t to be

$$\hat{r}_t = \frac{1}{t}\sum_{\tau=1}^{t} r_\tau, \tag{1}$$

and P1's average penalty vector by time t to be

$$\hat{c}_t = \frac{1}{t}\sum_{\tau=1}^{t} c_\tau. \tag{2}$$

A *strategy* for P1 (resp. P2) is a mapping from the set of all possible past histories to the set of mixed actions on A (resp. B), which prescribes the (mixed) action of that player at each time t, as a function of the history in the first $t-1$ stages. Loosely, P1's goal is to maximize the average reward while having the average penalty vector converge to T, pathwise:

$$\limsup_{t\to\infty} \operatorname{dist}(\hat{c}_t, T) \to 0, \qquad \text{a.s.}, \tag{3}$$

where $\operatorname{dist}(\cdot)$ is the point-to-set Euclidean distance, that is, $\operatorname{dist}(x,T) = \inf_{y\in T}\|y-x\|_2$, and the probability measure is the one induced by the policy of P1, the policy of P2, and the randomness in the rewards and penalties.

We will often consider the important special case where $T = \{c \in \mathbb{R}^d : c \le c_0\}$, for some given $c_0 \in \mathbb{R}^d$, with the inequality interpreted component-wise. We simply call such a game a constrained game with respect to (a vector) c_0. For that special case, the requirement (3) is equivalent to:

$$\limsup_{t\to\infty} \hat{c}_t \le c_0, \quad \text{a.s.}.$$

For a set D, we will use the notation $\Delta(D)$ to denote the set of all probability measures on D. If D is finite, we will identify $\Delta(D)$ with the set of probability vectors of the same size as D. If D is a subset of Euclidean space, we will assume that it is endowed with the Borel σ-field.

2.1 Reward-in-hindsight

We define $\hat{q}_t \in \Delta(B)$ as the empirical distribution of P2's actions by time t, that is,

$$\hat{q}_t(b) = \frac{1}{t}\sum_{\tau=1}^{t} 1_{\{b_t = b\}}, \quad b \in B. \tag{4}$$

If P1 knew in advance that $\hat{q}_t$ will equal q, and if P1 were restricted to using a fixed action, then P1 would pick an optimal response (generally a mixed action) to the mixed action q, subject to the constraints specified by T. In particular, P1 would solve the convex program[1]

$$\begin{aligned} \max_{p \in \Delta(A)} \quad & \sum_{a,b} p(a)q(b)R(a,b), \\ \text{s.t.} \quad & \sum_{a,b} p(a)q(b)C(a,b) \in T. \end{aligned} \tag{5}$$

By playing a p that solves this convex program, P1 would meet the constraints (up to small fluctuations that are a result of the randomness and the finiteness of t), and would obtain the maximal average reward. We are thus led to define P1's reward-in-hindsight, which we denote by $r^* : \Delta(B) \mapsto \mathbb{R}$, as the optimal objective value in the program (5), as a function of q. The function r^* is often referred to as the *Bayes envelope*.

For the special case of a constrained game with respect to a vector c_0, the convex constraint $\sum_{a,b} p(a)q(b)C(a,b) \in T$ is replaced by $\sum_{a,b} p(a)q(b)C(a,b) \leq c_0$ (the inequality is to be interpreted component-wise).

The following examples show some of the properties of the Bayes envelope. Consider a 2×2 constrained game with respect to a scalar c_0 specified by:

$$\begin{pmatrix} (1,0) & (0,1) \\ (0,1) & (1,0) \end{pmatrix},$$

where each entry (pair) corresponds to $(R(a,b), C(a,b))$ for a pair of actions a and b. (Here a and b correspond to a choice of row and column, respectively.) Suppose first that $c_0 = 1$. In that case the constraint does not play a part in the problem, and we are dealing with a version of the matching pennies game. So, if we identify q with the frequency of the first action, we have that $r^*(q) = \max(q, 1-q)$. Suppose now that $c_0 = 1/2$. In this case, it is not difficult to show that $r^*(q) = 1/2$, since P1 cannot take advantage of any deviation from $q = 1/2$ while satisfying the constraint.

The next example involves a game where P2's action does not affect the constraints; such games are further discussed in Section 4.1. Consider a 2×2 constrained game with respect to a scalar c_0, specified by:

$$\begin{pmatrix} (1,1) & (0,1) \\ (0,0) & (1,0) \end{pmatrix},$$

1. If T is a polyhedron (specified by finitely many linear inequalities), then the optimization problem is a linear program.

where each entry (pair) corresponds to $(R(a,b),C(a,b))$ for a pair of actions a and b. We identify q with the frequency of the second action of P2 as before. Suppose first that $c_0 = 1$. As before, the constraint has no effect and $r^*(q) = \max(q, 1-q)$. Suppose now that $c_0 = 1/2$. It is not hard to show that in this case $r^*(q) = \max(q, 1/2)$. Finally, if $c_0 = 0$, P1 is forced to choose the second action; in this case, $r^*(q) = q$. The monotonicity of $r^*(q)$ in c_0 is to be expected since the lower c_0 is, the more stringent the constraint in Eq. (5).

2.2 The Objective

Formally, our goal is to attain a function r in the sense of the following definition. Naturally, the higher the function r, the better.

Definition 1 *A function $r : \Delta(B) \mapsto \mathbb{R}$ is* attainable *by P1 in a constrained game with respect to a set T if there exists a strategy σ of P1 such that for every strategy ρ of P2:*

(i) $\liminf_{t\to\infty}(\hat{r}_t - r(\hat{q}_t)) \geq 0$, *a.s., and*

(ii) $\limsup_{t\to\infty} \operatorname{dist}(\hat{c}_t, T) \to 0$, *a.s.,*

where the almost sure convergence is with respect to the probability measure induced by σ and ρ.

In constrained games with respect to a vector c_0 we can replace (ii) in the definition with

$$\limsup_{t\to\infty} \hat{c}_t \leq c_0, \quad \text{a.s.}$$

2.3 The Value of the Game

In this section, we consider the attainability of a constant function $r : \Delta(B) \mapsto \mathbb{R}$, that is, $r(q) = \alpha$, for all q. We will establish that attainability is equivalent to having $\alpha \leq \mathrm{v}$, where v is a naturally defined "value of the constrained game."

We first introduce the assumption that P1 is always able to satisfy the constraint.

Assumption 1 *For every mixed action $q \in \Delta(B)$ of P2, there exists a mixed action $p \in \Delta(A)$ of P1, such that:*

$$\sum_{a,b} p(a)q(b)C(a,b) \in T. \tag{6}$$

For constrained games with respect to a vector c_0, the condition (6) reduces to the inequality $\sum_{a,b} p(a)q(b)C(a,b) \leq c_0$.

If Assumption 1 is not satisfied, then P2 can choose a q such that for every (mixed) action of P1, the constraint is violated in expectation. By repeatedly playing this q, P1's average penalty vector will be outside T, and the objectives of P1 will be impossible to meet.

The following result deals with the attainability of the value, v, of an average reward repeated constrained game, defined by

$$\mathrm{v} = \inf_{q\in\Delta(B)} \sup_{p\in\Delta(A):\sum_{a,b} p(a)q(b)C(a,b)\in T} \sum_{a,b} p(a)q(b)R(a,b). \tag{7}$$

The existence of a strategy for P1 that attains the value was proven in Shimkin (1994) in the broader context of stochastic games.

Proposition 2 *Suppose that Assumption 1 holds. Then,*

(i) P1 has a strategy that guarantees that the constant function $r(q) \equiv \mathrm{v}$ is attained with respect to T.

(ii) For every number $\mathrm{v}' > \mathrm{v}$ there exists $\delta > 0$ such that P2 has a strategy that guarantees that either $\liminf_{t\to\infty} \hat{r}_t < \mathrm{v}' - \delta$ or $\limsup_{t\to\infty} \mathrm{dist}(\hat{c}_t, T) > \delta$, almost surely. (In particular, the constant function v' is not attainable.)

Proof The proof relies on Blackwell's approachability theory (Blackwell, 1956a). We construct a nested family of convex sets in $\mathbb{R}^{d+1}$ defined by $S_\alpha = \{(r,c) \in \mathbb{R} \times \mathbb{R}^d : r \geq \alpha, c \in T\}$. Obviously, $S_\alpha \subset S_\beta$ for $\alpha > \beta$. Consider the vector-valued game in $\mathbb{R}^{d+1}$ associated with the constrained game. In this game, P1's vector-valued payoff at time t is the $d+1$ dimensional vector $m_t = (r_t, c_t)$ and P1's average vector-valued payoff is $\hat{m}_t = (\hat{r}_t, \hat{c}_t)$. Since S_α is convex, it follows from approachability theory for convex sets (Blackwell, 1956a) that each S_α is either approachable[2] or excludable.[3] If S_α is approachable, then S_β is approachable for every $\beta < \alpha$. We define $\mathrm{v}_0 = \sup\{\beta \mid S_\beta \text{ is approachable}\}$. It follows that S_{v_0} is approachable (as the limit of approachable sets; see Spinat, 2002). By Blackwell's theorem, for every $q \in \Delta(B)$, an approachable convex set must intersect the set of feasible payoff vectors when P2 plays q. Using this fact, it is easily shown that v_0 equals v, as defined by Eq. (7), and part (i) follows. Part (ii) follows because a convex set which is not approachable is excludable. ■

Note that part (ii) of the proposition implies that, essentially, v is the highest average reward P1 can attain while satisfying the constraints, if P2 plays an adversarial strategy. By comparing Eq. (7) with Eq. (5), we see that $\mathrm{v} = \inf_q r^*(q)$. On the other hand, if P2 does not play adversarially, P1 may be able to do better, perhaps attaining $r^*(q)$. Our subsequent results address the question whether this is indeed the case.

Remark 3 *In general, the infimum and supremum in (7)* cannot *be interchanged. This is because the set of feasible p in the inner maximization depends on the value of q. Moreover, it can be shown that the set of (p,q) pairs that satisfy the constraint $\sum_{a,b} p(a)q(b)C(a,b) \in T$ is not necessarily convex.*

2. A set X is approachable if there exists a strategy for the agent such that for every $\varepsilon > 0$, there exists an integer N such that, for every opponent strategy:

$$\Pr\left(\mathrm{dist}\left(\frac{1}{n}\sum_{t=1}^{n} m_t, X\right) \geq \varepsilon \text{ for some } n \geq N\right) < \varepsilon.$$

3. A set X is excludable if there exists a strategy for the opponent such that there exists $\delta > 0$ such that for every $\varepsilon > 0$, there exists an integer N such that, for every agent strategy:

$$\Pr\left(\mathrm{dist}\left(\frac{1}{n}\sum_{t=1}^{n} m_t, X\right) \geq \delta \text{ for all } n \geq N\right) > 1 - \varepsilon.$$

2.4 Related Works

Notwithstanding the apparent similarity, the problem that we consider is not an instance of online convex optimization (Zinkevich, 2003; Hazan and Megiddo, 2007). In the latter setting, there is a convex feasible domain $\mathcal{F} \subset \mathbb{R}^n$, and an arbitrary sequence of convex functions $f_t : \mathcal{F} \to \mathbb{R}$. At every step t, the decision maker picks $x_t \in \mathcal{F}$ based on the past history, without knowledge of the future functions f_t, and with the objective of minimizing the regret

$$\sum_{t=1}^{T} f_t(x_t) - \min_{y\in\mathcal{F}} \sum_{t=1}^{T} f_t(y).$$

An analogy with our setting might be possible, by identifying x_t and f_t with a_t and b_t, respectively, and by somehow relating the feasibility constraints described by $\mathcal{F}$ to our constraints. However, this attempt seems to run into some fundamental obstacles. In particular, in our setting, feasibility is affected by the opponent's actions, whereas in online convex optimization, the feasible domain $\mathcal{F}$ is fixed for all time steps. For this reason, we do not see a way to reduce the problem of online learning with constraints to an online convex optimization problem, and given the results below, it is unlikely that such a reduction is possible.

3. Reward-in-Hindsight Is Not Attainable

As it turns out, the reward-in-hindsight cannot be attained in general. This is demonstrated by the following simple 2×2 matrix game, with just a single constraint.

Consider a 2×2 constrained game specified by:

$$\begin{pmatrix} (1,-1) & (1,1) \\ (0,-1) & (-1,-1) \end{pmatrix},$$

where each entry (pair) corresponds to $(R(a,b),C(a,b))$ for a pair of actions a and b. At a typical stage, P1 chooses a row, and P2 chooses a column. We set $c_0 = 0$. Let q denote the frequency with which P2 chooses the second column. The reward of the first row dominates the reward of the second one, so if the constraint can be satisfied, P1 would prefer to choose the first row. This can be done as long as $0 \le q \le 1/2$, in which case $r^*(q) = 1$. For $1/2 \le q \le 1$, player P1 needs to optimize the reward subject to the constraint. Given a specific q, P1 will try to choose a mixed action that satisfies the constraint (on the average) while maximizing the reward. If we let α denote the frequency of choosing the first row, we see that the reward and penalty are:

$$r(\alpha,q) = \alpha - (1-\alpha)q, \quad c(\alpha,q) = 2\alpha q - 1,$$

respectively. We observe that for every q, $r(\alpha)$ and $c(\alpha)$ are monotonically increasing functions of α. As a result, P1 will choose the maximal α that satisfies $c(\alpha) \le 0$, which is $\alpha(q) = 1/2q$, and the optimal reward is $1/2 + 1/2q - q$. We conclude that the reward-in-hindsight is:

$$r^*(q) = \begin{cases} 1, & \text{if } 0 \le q \le 1/2, \\ \dfrac{1}{2} + \dfrac{1}{2q} - q, & \text{if } 1/2 \le q \le 1. \end{cases}$$

The graph of $r^*(q)$ is the solid line in Figure 1.

We now claim that P2 can make sure that P1 does not attain r^*.

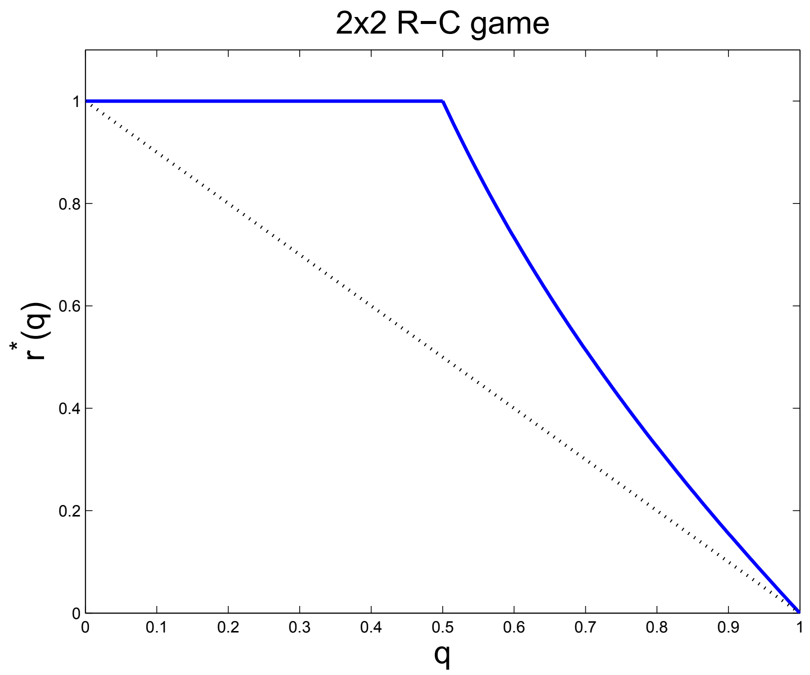

Figure 1: The reward-in-hindsight of the constrained game. Here, $r^*(q)$ is the solid line, and the dotted line connects the two extreme values, for $q = 0$ and $q = 1$.

Proposition 4 *If $c_0 = 0$, then there exists a strategy for P2 such that r^* cannot be attained.*

Proof Suppose that the opponent, P2, plays according to the following strategy. Initialize a counter $k = 1$. Let $\hat{\alpha}_t$ be the empirical frequency with which P1 chooses the *first* row during the first t time steps. Similarly, let $\hat{q}_t$ be the empirical frequency with which P2 chooses the *second* column during the first t time steps.

1. While $k = 1$ or $\hat{\alpha}_{t-1} > 3/4$, P2 chooses the second column, and k is incremented by 1.
2. For the next k times, P2 chooses the first column. Then, reset the counter k to , and go back to Step 1.

We now show that if

$$\limsup_{t\to\infty} \hat{c}_t \leq 0, \quad \text{a.s.},$$

then a strict inequality holds for the regret:

$$\liminf_{t\to\infty} (\hat{r}_t - r^*(\hat{q}_t)) < 0, \quad \text{a.s.}$$

Suppose that Step 2 is entered only a finite number of times. Then, after some finite time, P2 keeps choosing the second column, and $\hat{q}_t$ converges to 1. For P1 to satisfy the constraint $\limsup_{t\to\infty} \hat{c}_t \leq$

0, we must have $\lim \hat{\alpha}_t \leq 1/2$. But then, the condition $\hat{\alpha}_{t-1} > 3/4$ will be eventually violated. This shows that Step 2 is entered an infinite number of times. In particular, there exist infinite sequences t_i and t'_i such that $t_i < t'_i < t_{i+1}$ and (i) if $t_i < t \leq t'_i$, P2 chooses the second column (Step 1); (ii) if $t'_i < t \leq t_{i+1}$, P2 chooses the first column (Step 2).

Note that Steps 1 and 2 last for an equal number of time steps. Thus, we have $\hat{q}_{t_i} = 1/2$, and $r^*(\hat{q}_{t_i}) = 1$, for all i. Furthermore, $t_{i+1} - t'_i \leq t'_i$, or $t'_i \geq t_{i+1}/2$. Note that $\hat{\alpha}_{t'_i} \leq 3/4$, because otherwise P2 would still be in Step 1 at time $t'_i + 1$. Thus, during the first t_{i+1} time steps, P1 has played the first row at most

$$3t'_i/4 + (t_{i+1} - t'_i) = t_{i+1} - t'_i/4 \leq 7t_{i+1}/8$$

times. Due to the values of the reward matrix, we have $\limsup_{t\to\infty} \hat{r}_t < \limsup_{i\to\infty} \hat{r}_{t_i}$. In particular, we have $\hat{r}_{t_{i+1}} \leq 7/8$, and $\liminf_{t\to\infty}(\hat{r}_t - r^*(\hat{q}_t)) \leq 7/8 - 1 < 0$. ■

Intuitively, the strategy that was described above allows P2 to force P1 to move, back and forth, between the extreme points ($q = 0$ and $q = 1$) that are linked by the dotted line in Figure 1. Since $r^*(q)$ is not convex, and since the dotted line is strictly below $r^*(q)$ for $q = 1/2$, this strategy precludes P1 from attaining $r^*(q)$. We note that the choice of c_0 is critical in this example. With other choices of c_0 (for example, $c_0 = -1$), the reward-in-hindsight may be attainable.

4. Attainability of the Convex Hull

Since the reward-in-hindsight is not attainable in general, we have to settle for a more modest objective. More specifically, we are interested in functions $f : \Delta(B) \to \mathbb{R}$ that are attainable with respect to a given constraint set T. As a target we suggest the closed convex hull of the reward-in-hindsight, r^*. After defining it, we prove that it is indeed attainable. In the next section, we will also show that it is the highest possible attainable function, when there is a single constraint.

Given a function $f : X \mapsto \mathbb{R}$, over a convex domain X, its *closed convex hull* is the function whose epigraph is

$$\overline{\text{conv}}(\{(x,r) : r \geq f(x)\}),$$

where $\text{conv}(D)$ is the convex hull, and $\overline{D}$ is the closure of a set D. We denote the closed convex hull of r^* by r^c.

We will make use of the following facts. Forming the convex hull and then the closure results in a larger epigraph, hence a smaller function. In particular, $r^c(q) \leq r^*(q)$, for all q. Furthermore, the closed convex hull is guaranteed to be continuous on $\Delta(B)$. (This would not be true if we had considered the convex hull, without forming its closure.) Finally, for every q in the interior of $\Delta(B)$, we have:

$$\begin{aligned} r^c(q) \quad = \quad & \inf_{q_1,q_2,\ldots,q_k\in\Delta(B),\alpha_1,\ldots,\alpha_k} \sum_{i=1}^{k} \alpha_i r^*(q_i) \\ & \text{s.t.} \quad \sum_{i=1}^{k} \alpha_i q_i(b) = q(b), \quad \forall b \in B, \\ & \qquad \alpha_i \geq 0, \quad i = 1,2,\ldots,k, \\ & \qquad \sum_{i=1}^{k} \alpha_i = 1, \end{aligned} \tag{8}$$

where k can be taken equal to $|B|+2$ by Caratheodory's Theorem.

The following result is proved using Blackwell's approachability theory. The technique is similar to that used in other no-regret proofs (e.g., Blackwell, 1956b; Mannor and Shimkin, 2003), and is based on the convexity of a target set in an appropriately defined space.

Theorem 5 *Let Assumption 1 hold for a given convex set $T \subset \mathbb{R}^d$. Then r^c is attainable with respect to T.*

Proof Define the following game with vector-valued payoffs, where the payoffs belong to $\mathbb{R} \times \mathbb{R}^d \times \Delta(B)$ (a $|B|+d+1$ dimensional space, which we denote by $\mathcal{M}$). Suppose that P1 plays a_t, P2 plays b_t, P1 obtains an immediate reward of r_t and an immediate penalty vector of c_t. Then, the vector-valued payoff obtained by P1 is

$$m_t = (r_t, c_t, e(b_t)),$$

where $e(b)$ is a vector of zeroes, except for a 1 in its bth component. It follows that the average vector-valued reward at time t, which we define as $\hat{m}_t = \frac{1}{t}\sum_{\tau=1}^{t} m_\tau$, satisfies: $\hat{m}_t = (\hat{r}_t, \hat{c}_t, \hat{q}_t)$, where $\hat{r}_t$, $\hat{c}_t$, and $\hat{q}_t$ were defined in Eqs. (1), (2), and (4), respectively. Consider the sets:

$$\mathcal{B}_1 = \{(r,c,q) \in \mathcal{M} : r \geq r^c(q)\}, \qquad \mathcal{B}_2 = \{(r,c,q) \in \mathcal{M} : c \in T\},$$

and let $\mathcal{B} = \mathcal{B}_1 \cap \mathcal{B}_2$. Note that $\mathcal{B}$ is a convex set. We claim that $\mathcal{B}$ is approachable. Let $m : \Delta(A) \times \Delta(B) \to \mathcal{M}$ describe the expected payoff in a single stage game, when P1 and P2 choose actions p and q, respectively. That is,

$$m(p,q) = \Big(\sum_{a,b} p(a)q(b)R(a,b),\ \sum_{a,b} p(a)q(b)C(a,b),\ q \Big).$$

Using the sufficient condition for approachability of convex sets (Blackwell, 1956a), it suffices to show that for every q there exists a p such that $m(p,q) \in \mathcal{B}$. Fix $q \in \Delta(B)$. By Assumption 1, the constraint $\sum_{a,b} p(a)q(b)C(a,b) \in T$ is feasible, which implies that the program (5) has an optimal solution p^*. It follows that $m(p^*,q) \in \mathcal{B}$. We now claim that a strategy that approaches $\mathcal{B}$ also attains r^c in the sense of Definition 1. Indeed, since $\mathcal{B} \subseteq \mathcal{B}_2$ we have that $\Pr(d(c_t,T) > \varepsilon \text{ infinitely often}) = 0$ for every $\varepsilon > 0$. Since $\mathcal{B} \subseteq \mathcal{B}_1$ and using the continuity of r^c, we obtain $\liminf(\hat{r}_t - r^c(\hat{q}_t)) \geq 0$. ■

We note that Theorem 5 is not constructive. Indeed, a strategy that approaches $\mathcal{B}$, based on a naive implementation Blackwell's approachability theory, requires an efficient procedure for computing the closest point in $\mathcal{B}$,and therefore a computationally efficient description of $\mathcal{B}$, which may not be available (we do not know whether $\mathcal{B}$ can be described efficiently). This motivates the development of the calibration based scheme in Section 6.

Remark 6 *Convergence rate results also follow from general approachability theory, and are generally of the order of $t^{-1/3}$; see Mertens et al. (1994). It may be possible, perhaps, to improve upon this rate and obtain $t^{-1/2}$, which is the best possible convergence rate for the unconstrained case.*

Remark 7 *For every $q \in \Delta(B)$, we have $r^*(q) \geq \mathrm{v}$, which implies that $r^c(q) \geq \mathrm{v}$. Thus, attaining r^c guarantees an average reward at least as high as the value of the game.*

4.1 Degenerate Cases

In this section, we consider the degenerate cases where the penalty vector is affected by only one of the players. We start with the case where P1 alone affects the penalty vector, and then discuss the case where P2 alone affects the penalty vector.

If P1 alone affects the penalty vector, that is, if $C(a,b) = C(a,b')$ for all $a \in A$ and $b,b' \in B$, then $r^*(q)$ is convex. Indeed, in this case, Eq. (5) becomes (writing $C(a)$ for $C(a,b)$)

$$r^*(q) = \max_{p\in\Delta(A):\sum_a p(a)C(a)\in T} \sum_{a,b} p(a)q(b)R(a,b),$$

which is the maximum of a collection of linear functions of q (one function for each feasible p), and is therefore convex.

If P2 alone affects the penalty vector, that is, if $c(a,b) = c(a',b)$ for all $b \in B$ and $a,a' \in A$, then Assumption 1 implies that the constraint is always satisfied. Therefore,

$$r^*(q) = \max_{p\in\Delta(A)} \sum_{a,b} p(a)q(b)R(a,b),$$

which is again a maximum of linear functions, hence convex.

We conclude that in both degenerate cases, if Assumption 1 holds, then the reward-in-hindsight is attainable.

5. Tightness of the Convex Hull

We now show that r^c is the maximal attainable function, for the case of a single constraint.

Theorem 8 *Suppose that $d = 1$, T is of the form $T = \{c \mid c \le c_0\}$, where c_0 is a given scalar, and that Assumption 1 is satisfied. Let $\tilde{r} : \Delta(B) \mapsto \mathbb{R}$ be a continuous attainable function with respect to the scalar c_0. Then, $r^c(q) \ge \tilde{r}(q)$ for all $q \in \Delta(B)$.*

Proof The proof is constructive, as it provides a concrete strategy for P2 that prevents P1 from attaining $\tilde{r}$, unless $r^c(q) \ge \tilde{r}(q)$ for every q. Assume, in order to derive a contradiction, that there exists some $\tilde{r}$ that violates the theorem. Since $\tilde{r}$ and r^c are continuous, there exists some $q^0 \in \Delta(B)$ and some $\varepsilon > 0$ such that $\tilde{r}(q) > r^c(q) + \varepsilon$ for all q in an open neighborhood of q^0. In particular, q^0 can be taken to lie in the interior of $\Delta(B)$. Using Eq. (8), it follows that there exist $q^1,\ldots,q^k \in \Delta(B)$ and $\alpha_1,\ldots,\alpha_k$ (with $k \le |B|+2$, due to Caratheodory's Theorem) such that

$$\sum_{i=1}^{k} \alpha_i r^*(q^i) \le r^c(q^0) + \frac{\varepsilon}{2} < \tilde{r}(q^0) - \frac{\varepsilon}{2};$$

$$\sum_{i=1}^{k} \alpha_i q^i(b) = q^0(b), \quad \forall\, b \in B; \qquad \sum_{i=1}^{k} \alpha_i = 1; \qquad \alpha_i \ge 0,\ \forall\, i.$$

Let τ be a large positive integer (τ is to be chosen large enough to ensure that the events of interest occur with high probability, etc.). We will show that if P2 plays each q^i for $\lceil \alpha_i \tau \rceil$ time steps, in an appropriate order, then either P1 does not satisfy the constraint along the way or $\hat{r}_\tau \le \tilde{r}(\hat{q}_\tau) - \varepsilon/2$.

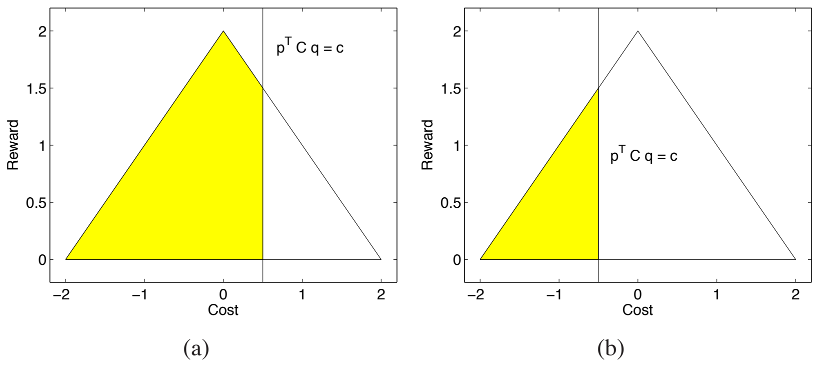

Figure 2: In either part (a) or (b) of the figure, we fix some $q \in \Delta(B)$. The triangle is the set of possible reward-cost pairs, as we vary p over the set $\Delta(A)$. Then, for a given value c in the upper bound on the cost (cf. 10), the shaded region is the set of reward-cost pairs that also satisfy the cost constraint.

We let q^i, $i = 1,\ldots,k$, be fixed, as above, and define a function $f_i : \mathbb{R}^d \to \mathbb{R} \cup \{-\infty\}$ as:

$$f_i(c) = \max_{p \in \Delta(A)} \sum_{a,b} p(a) q^i(b) R(a,b), \tag{9}$$

$$\text{subject to} \qquad \sum_{a,b} p(a) q^i(b) C(a,b) \le c, \tag{10}$$

where the maximum over an empty set is defined to equal $-\infty$. Observe that the feasible set (and hence, optimal value) of the above linear program depends on c. Figure 2 illustrates how the feasible sets to (10) may depend on the value of c. By viewing Eqs. (9)-(10) as a parametric linear program, with a varying right-hand side parameter c, we see that $f_i(c)$ is piecewise linear, concave, and nondecreasing in c (Bertsimas and Tsitsiklis, 1997). Furthermore, $f_i(c_0) = r^*(q^i)$. Let ∂f_i^+ be the right directional derivative of f_i at $c = c_0$, and note that $\partial f_i^+ \ge 0$. From now on, we assume that the q^i have been ordered so that the sequence ∂f_i^+ is nonincreasing (e.g., as in Figure 3). To visualize the ordering that we have introduced, consider the set of possible pairs (r,c), given a fixed q. That is, consider the set $M(q^i) = \{(r,c) : \exists p \in \Delta(A) \text{ s.t. } r = \sum_{a,b} p(a)q^i(b)R(a,b),\ c = \sum_{a,b} p(a)q^i(b)C(a,b)\}$. The set $M(q^i)$ is the image of the simplex under a linear transformation, and is therefore a polytope, as illustrated by the triangular areas in Figure 2. The strategy of P2 is to first play q^i such that the p that maximizes the reward (Eq. 9) satisfies Eq. (10) with equality. (Such a q^i results in a set $M(q^i)$ like the one shown in Figure 2(b).) After all these q^i are played, P2 plays those q^i for which the p that maximizes the reward (Eq. 9) satisfies Eq. (10) with strict inequality, and $\partial f_i^+ = 0$. (Such a q^i results in a set $M(q^i)$ like the one shown in Figure 2(a).)

Suppose that P1 knows the sequence $q^1,\ldots,q^k$ (ordered as above) in advance, and that P2 follows the strategy described earlier. We assume that τ is large enough so that we can ignore the effects of dealing with a finite sample. Let p^i be the average of the mixed actions chosen by P1 while player P2 plays q^i. We introduce the constraints

$$\sum_{i=1}^{\ell} \alpha_i \sum_{a,b} p^i(a) q^i(b) C(a,b) \le c_0 \sum_{i=1}^{\ell} \alpha_i, \quad \ell = 1,2,\ldots,k.$$

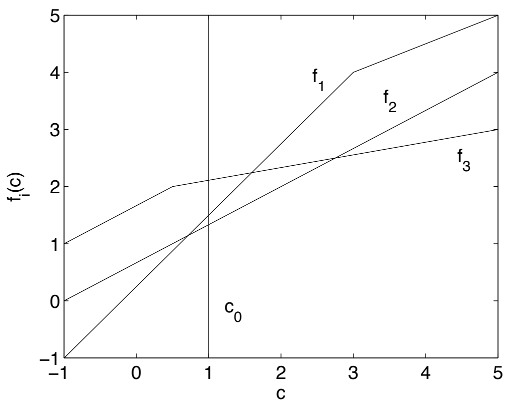

Figure 3: An example of functions f_i ordered according to ∂f_i^+.

These constraints must be satisfied in order to guarantee that $\hat{c}_t$ has negligible probability of substantially exceeding c_0, at the "switching" times from one mixed action to another. If P1 exploits the knowledge of P2's strategy to maximize her average reward at time τ, the resulting expected average reward at time τ will be the optimal value of the objective function in the following linear programming problem:

$$\begin{aligned}&\max_{p^1,p^2,\ldots,p^k} \sum_{i=1}^{k} \alpha_i \sum_{a,b} p^i(a)q^i(b)R(a,b)\\ &\quad \text{s.t.} \sum_{i=1}^{\ell} \alpha_i \sum_{a,b} p^i(a)q^i(b)C(a,b) \le c_0 \sum_{i=1}^{\ell} \alpha_i, \quad \ell = 1,2,\ldots,k,\\ &\quad p^\ell \in \Delta(A), \quad \ell = 1,2,\ldots,k.\end{aligned} \tag{11}$$

Of course, given the value of $\sum_{a,b} p^i(a)q^i(b)C(a,b)$, to be denoted by c_i, player P1 should choose a p^i that maximizes rewards, resulting in $\sum_{a,b} p^i(a)q^i(b)R(a,b) = f_i(c_i)$. Thus, the above problem can be rewritten as

$$\begin{aligned}&\max_{c_1,\ldots,c_k} \sum \alpha_i f_i(c_i)\\ &\quad \text{s.t.} \sum_{i=1}^{\ell} \alpha_i c_i \le c_0 \sum_{i=1}^{\ell} \alpha_i, \quad \ell = 1,2,\ldots,k.\end{aligned} \tag{12}$$

We claim that letting $c_i = c_0$, for all i, is an optimal solution to the problem (12). This will then imply that the optimal value of the objective function for the problem (11) is $\sum_{i=1}^{k} \alpha_i f_i(c_0)$, which equals $\sum_{i=1}^{k} \alpha_i r^*(q^i)$, which in turn, is bounded above by $\tilde{r}(q^0) - \varepsilon/2$. Thus, $\hat{r}_\tau < \tilde{r}(q^0) - \varepsilon/2 + \delta(\tau)$, where the term $\delta(\tau)$ incorporates the effects due to the randomness in the process. By repeating this argument with ever increasing values of τ (so that the stochastic term $\delta(\tau)$ is averaged out and becomes negligible), we obtain that the event $\hat{r}_t < \tilde{r}(q^0) - \varepsilon/2$ will occur infinitely often, and therefore $\tilde{r}$ is not attainable.

It remains to establish the claimed optimality of $(c_0,\ldots,c_0)$. Suppose that $(\bar{c}_1,\ldots,\bar{c}_k) \neq (c_0,\ldots,c_0)$ is an optimal solution of the problem (12). If $\bar{c}_i \le c_0$ for all i, the monotonicity of the f_i implies that $(c_0,\ldots,c_0)$ is also an optimal solution. Otherwise, let j be the smallest index for which $\bar{c}_j > c_0$. If $\partial f_j^+ = 0$ (as in the case shown in Figure 2(b)) we have that $f_i(c)$ is maximized at c_0 for all $i \geq j$ and $(c_0,\ldots,c_0)$ is optimal. Suppose that $\partial f_j^+ > 0$. In order for the constraint (12) to be satisfied, there must exist some index $s < j$ such that $\bar{c}_s < c_0$. Let us perturb this solution by setting $\delta = \min\{\alpha_s(c_0 - \bar{c}_s), \alpha_j(\bar{c}_j - c_0)\}$, increasing $\bar{c}_s$ to $\tilde{c}_s = \bar{c}_s + \delta/\alpha_s$, and decreasing $\bar{c}_j$ to $\tilde{c}_j = \bar{c}_j - \delta/\alpha_j$. This new solution is clearly feasible. Let $\partial f_s^- = \lim_{\varepsilon\downarrow 0}(f_s(c_0) - f_s(c_0 - \varepsilon))/\varepsilon$, which is the left derivative of f_s at c_0. Using the concavity of f_s, and the earlier introduced ordering, we have $\partial f_s^- \geq \partial f_s^+ \geq \partial f_j^+$. Observe that

$$f_s(\tilde{c}_s) = f_s(\bar{c}_s) + \partial f_s^- \delta/\alpha_s,$$
$$f_j(\tilde{c}_j) = f_j(\bar{c}_j) - \partial f_j^+ \delta/\alpha_j,$$

so that $\alpha_s f_s(\tilde{c}_s) + \alpha_j f_j(\tilde{c}_j) \geq \alpha_s f_s(\bar{c}_s) + \alpha_j f_j(\bar{c}_j)$. Therefore, the new solution must also be optimal, but has fewer components that differ from c_0. By repeating this process, we eventually conclude that $(c_0,\ldots,c_0)$ is an optimal solution of (12). ■

To the best of our knowledge, this is the first tightness result for a performance envelope (the reward-in-hindsight) different than the Bayes envelope, for repeated games. On the other hand, we note that our proof relies crucially on the assumption of a single constraint ($d = 1$), which allows us to order the ∂f_i^+.

6. Attaining the Convex Hull Using Calibrated Forecasts

In this section, we consider a specific strategy that attains the convex hull, thus providing a constructive proof for Theorem 5. The strategy is based on forecasting P2's action, and playing a best response (in the sense of Eq. 5) against the forecast. The quality of the resulting strategy depends, of course, on the quality of the forecasts; it is well known that *calibrated* forecasts lead to no-regret strategies in standard repeated matrix games. See Foster and Vohra (1997) and Cesa-Bianchi and Lugosi (2006) for a discussion of calibration and its implications in learning in games. In this section we consider the consequences of calibrated play for repeated games with constraints.

We start with a formal definition of calibrated forecasts and calibrated play, and then show that calibrated play attains r^c in the sense of Definition 1.

A forecasting scheme specifies at each stage k a probabilistic forecast $q_k \in \Delta(B)$ of P2's action b_k. More precisely a (randomized) forecasting scheme is a sequence of maps that associate with each possible history h_{k-1} during the first $k-1$ stages a probability measure μ_k over $\Delta(B)$. The forecast $q_k \in \Delta(B)$ is then selected at random according to the distribution μ_k. Let us clarify that for the purposes of this section, the history is defined to include the realized past forecasts.

We shall use the following definition of calibrated forecasts.

Definition 9 (Calibrated forecasts) *A forecasting scheme is* calibrated *if for every (Borel measurable) set $Q \subset \Delta(B)$ and every strategy of P1 and P2*

$$\lim_{t\to\infty} \frac{1}{t} \sum_{\tau=1}^{t} 1\{q_\tau \in Q\}(e(b_\tau) - q_\tau) = 0, \quad a.s., \tag{13}$$

where $e(b)$ is a vector of zeroes, except for a 1 in its bth component.

Calibrated forecasts, as defined above, have been introduced into game theory in Foster and Vohra (1997), and several algorithms have been devised to achieve them (see Cesa-Bianchi and Lugosi, 2006, and references therein). These algorithms typically start with predictions that are restricted to a finite grid, and gradually increase the number of grid points.

The proposed strategy is to let P1 play a best response against P2's forecasted play while still satisfying the constraints (in expectation, for the single stage game). Formally, we let:

$$\begin{aligned} p^*(q) &= \operatorname*{argmax}_{p\in\Delta(A)} \sum_{a,b} p(a)q(b)R(a,b) \\ &\quad\ \text{s.t.} \sum_{a,b} p(a)q(b)C(a,b) \in T, \end{aligned}$$

where in the case of a non-unique maximum we assume that $p^*(q)$ is uniquely determined by some tie-breaking rule; this is easily done, while keeping $p^*(\cdot)$ a measurable function. The strategy is to play $p_t = p^*(q_t)$, where q_t is a calibrated forecast of P2's actions.[4] We call such a strategy a *calibrated strategy*.

The following theorem states that a calibrated strategy attains the convex hull.

Theorem 10 *Let Assumption 1 hold, and suppose that P1 uses a calibrated strategy. Then, r^c is attained with respect to T.*

Proof Fix $\varepsilon > 0$. We need to show that by playing the calibrated strategy, P1 obtains $\liminf_{t\to\infty}(\hat{r}_t - r^c(\hat{q}_t)) \geq 0$ and $\limsup_{t\to\infty} \operatorname{dist}(\hat{c}_t, T) \leq 0$, almost surely.

Fix some $\varepsilon > 0$. Consider a partition of the simplex $\Delta(B)$ to finitely many measurable sets $Q_1, Q_2, \ldots, Q_\ell$ such that $q, q' \in Q_i$ implies that $\|q - q'\| \leq \varepsilon$ and $\|p^*(q) - p^*(q')\| \leq \varepsilon$. (Such a partition exists by the compactness of $\Delta(B)$ and $\Delta(A)$. The measurability of the sets Q_i can be guaranteed because the mapping $p^*(\cdot)$ is measurable.) For each i, let us fix a representative element $q^i \in Q_i$, and let $p^i = p^*(q^i)$.

Since we have a calibrated forecast, Eq. (13) holds for every Q_i, $1 \leq i \leq \ell$. Define $\Gamma_t(i) = \sum_{\tau=1}^t 1\{q_\tau \in Q_i\}$ and assume without loss of generality that $\Gamma_t(i) > 0$ for large t (otherwise, eliminate those i for which $\Gamma_t(i) = 0$ for all t, and renumber the Q_i). To simplify the presentation, we assume that for every i, and for large enough t, we have $\Gamma_t(i) \geq \varepsilon t$. (If for some i, and t this condition is violated, the contribution of such an i in the expressions that follow will be $O(\varepsilon)$.)

By a law of large numbers for martingales, we have

$$\lim_{t\to\infty}\left(\hat{c}_t - \frac{1}{t}\sum_{\tau=1}^t C(a_\tau, b_\tau)\right) = 0, \qquad \text{a.s.}$$

By definition, we have

$$\frac{1}{t}\sum_{\tau=1}^t C(a_\tau, b_\tau) = \sum_i \frac{\Gamma_t(i)}{t} \sum_{a,b} C(a,b) \frac{1}{\Gamma_t(i)} \sum_{\tau=1}^t 1\{q_\tau \in Q_i\} 1\{a_\tau = a\} 1\{b_\tau = b\}.$$

Observe that whenever $q_\tau \in Q_i$, we have $\left\|p_\tau - p^i\right\| \leq \varepsilon$, where $p_\tau = p^*(q_\tau)$ and $p^i = p^*(q^i)$ because of the way the sets Q_i were constructed. By martingale convergence, the frequency with which a

4. When the forecast μ_t is mixed, q_t is the realization of the mixed rule.

will be selected whenever $q_\tau \in Q_i$ and $b_\tau = b$, will be approximately $p^i(a)$. Hence, for all b,

$$\limsup_{t\to\infty} \left| \frac{1}{\Gamma_t(i)} \sum_{\tau=1}^{t} 1\{q_\tau \in Q_i\} 1\{a_\tau = a\} 1\{b_\tau = b\} - p^i(a) \frac{1}{\Gamma_t(i)} \sum_{\tau=1}^{t} 1\{q_\tau \in Q_i\} 1\{b_\tau = b\} \right| \le \varepsilon,$$

almost surely. By the calibration property (13) for $Q = Q_i$, and the fact that whenever $q, q' \in Q_i$, we have $\|q - q'\| \le \varepsilon$, we obtain

$$\limsup_{t\to\infty} \left| \frac{1}{\Gamma_t(i)} \sum_{\tau=1}^{t} 1\{q_\tau \in Q_i\} 1\{b_\tau = b\} - q^i(b) \right| \le \varepsilon, \qquad \text{a.s.}$$

By combining the above bounds, we obtain

$$\lim_{t\to\infty} \left| \hat{c}_t - \sum_i \frac{\Gamma_t(i)}{t} \sum_{a,b} C(a,b) p^i(a) q^i(b) \right| \le 2\varepsilon, \qquad \text{a.s.} \tag{14}$$

Note that the sum over index i in Eq. (14) is a convex combination (because the coefficients $\Gamma_t(i)/t$ sum to 1) of elements of T (because of the definition of p^i), and is therefore an element of T (because T is convex). This establishes that the constraint is asymptotically satisfied within $O(\varepsilon)$. Note that in this argument, whenever $\Gamma_t(i)/t < \varepsilon$, the summand corresponding to i is indeed of order $O(\varepsilon)$ and can be safely ignored, as stated earlier.

Regarding the average reward, an argument similar to the above yields

$$\liminf_{t\to\infty} \hat{r}_t \ge \liminf_{t\to\infty} \sum_i \frac{\Gamma_t(i)}{t} \sum_{a,b} R(a,b) p^i(a) q^i(b) - 2\varepsilon, \qquad \text{a.s.}$$

Next, observe that

$$\sum_i \frac{\Gamma_t(i)}{t} \sum_{a,b} R(a,b) p^i(a) q^i(b) = \sum_i \frac{\Gamma_t(i)}{t} r^*(q^i) \ge r^c\Big(\sum_i \frac{\Gamma_t(i)}{t} q^i \Big),$$

where the equality is a consequence of the definition of p^i, and the inequality follows by the definition of r^c as the closed convex hull of r^*. Observe also that the calibration property (13), with $Q = \Delta(B)$, implies that

$$\lim_{t\to\infty} \left\| \hat{q}_t - \frac{1}{t} \sum_{\tau=1}^{t} q_\tau \right\| = 0, \qquad \text{a.s.}$$

In turn, since $\|q_\tau - q^i\| \le \varepsilon$ for a fraction $\Gamma_t(i)/t$ of the time,

$$\limsup_{t\to\infty} \left\| \hat{q}_t - \sum_i \frac{\Gamma_t(i)}{t} q^i \right\| = \limsup_{t\to\infty} \left\| \frac{1}{t} \sum_{\tau=1}^{t} q_\tau - \sum_i \frac{\Gamma_t(i)}{t} q^i \right\| \le \varepsilon, \qquad \text{a.s.}$$

Recall that the function r^c is continuous, hence uniformly continuous. Thus, there exists some function g, with $\lim_{\varepsilon\downarrow 0} g(\varepsilon) = 0$, such that when the argument of r^c changes by at most ε, the value of r^c changes by at most $g(\varepsilon)$. By combining the preceding results, we obtain

$$\liminf_{t\to\infty} \hat{r}_t \ge r^c(\hat{q}_t) - 2\varepsilon - g(\varepsilon), \qquad \text{a.s.}$$

The above argument involves a fixed ε, and a fixed number ℓ of sets Q_i, and lets t increase to infinity. As such, it establishes that for any $\varepsilon > 0$ the function $r^c - 2\varepsilon - g(\varepsilon)$ is attainable with respect to the set T^ε defined by $T^\varepsilon = \{x \mid \mathrm{dist}(x,T) \leq 2\varepsilon\}$. Since this is true for every $\varepsilon > 0$, we conclude that the calibrated strategy attains r^c as claimed. ■

7. Algorithms

The results in the previous section motivate us to develop algorithms for online learning with constraints, perhaps based on calibrated forecasts. For practical reasons, we are interested in computationally efficient methods, but there are no known computationally efficient calibrated forecasting algorithms. For this reason, we will consider related heuristics that are similar in spirit, even if they do not have all the desired guarantees.

We first consider a method based on the weighted average predictor. The algorithm in Table 1 keeps track of the performance of the different actions in the set A, updating a corresponding set of weights accordingly at each step. The main idea is to quantify "performance" by a linear combination of the total reward and the magnitude of the constraint violation. The parameter $\lambda > 0$ of the algorithm, which acts similar to a Lagrange multiplier, determines the tradeoff between these two objectives. When the average penalty is higher than c_0 (i.e., there is a violation), the weight of the cost term increases. When the average penalty is lower than c_0, the weight of the cost term decreases. The parameters $\overline{M}$ and $\underline{M}$ are used to bound the magnitude of the weight of the cost term; in the experiments reported in Section 8, they were set to 1000 and 0.001, respectively.

```
1. Set $\lambda, w_0, \overline{M}$, and $\underline{M}$.
2. For $t = 1,2,\ldots$:
    (a) Sample an independent random variable $a_t$ distributed so that
            $a_t = a, \quad \text{with probability } \frac{w_t(a)}{\sum_{a\in A} w_t(a)} \text{ for } a \in A.$
    (b) Compute:
            $w_t(a) = w_{t-1}(a)\, \exp\left(\eta\left(R(a,b_t) - \lambda C(a,b_t)\right)\right), \quad a \in A.$
    (c) For $t = 1,2,\ldots$, update $\lambda$:
            $\lambda := \begin{cases} \min(2\lambda, \overline{M}), & \text{if } \hat{c}_t > c_0, \\ \max(\lambda/2, \underline{M}), & \text{otherwise.} \end{cases}$
```

Table 1: Exponentially weighted average predictor.

The second algorithm uses the tracking forecaster (Mannor et al., 2007) as the forecasting method. This forecaster predicts that the distribution of the next action as a weighted average of previous actions, weighing recent actions more than less recent ones others. For the special case of only two actions, it is calibrated, but *not* calibrated in general. There are, however, some special cases where it is calibrated, in particular if the sequence it tries to calibrate comes from a source with some specific properties; see Mannor et al. (2007) for details. The algorithm is presented in Table 2. If there is a current violation, it selects an action that minimizes the immediate forecasted cost. If the current average penalty does not violate the constraint, it selects a best response to the forecasted action of P2, while satisfying the constraints.

1. Set $\rho \in (0,1)$, c_0, and $f_0 = (1/|B|)\vec{1}$.
2. For $t = 1, 2, \ldots$:
   (a) If $t = 1$ or $\hat{c}_t > c_0$, choose an action that minimizes the worst-case cost:
   $$a_t \in \operatorname*{argmin}_{a \in A} \left(C(a,b) f_{t-1}(b) \right),$$
   (b) Otherwise (if $\hat{c}_t \le c_0$ and $t > 1$), solve
   $$\begin{array}{ll} \displaystyle\max_{p \in \Delta(A)} & \displaystyle\sum_{a,b} p(a) R(a,b) f_{t-1}(b), \\ \text{subject to} & \displaystyle\sum_{a,b} p(a) C(a,b) f_{t-1}(b) \le c_0. \end{array}$$
   and choose a random action distributed according to the solution to the above linear program.
   (c) After observing b_t, update the forecast f_t on the probability distribution of the next opponent action b_{t+1}:
   $$f_t = f_{t-1} + (1/t)^{\rho} \left(e_{b_t} - f_{t-1} \right),$$
   where e_b is a unit vector in $\mathbb{R}^{|B|}$ with the element 1 in the component corresponding to $b \in B$.

Table 2: Tracking forecaster.

8. Experimental Setup

Our experiment addresses the problem of minimizing power consumption in a computer with a human user. The agent is a low-level software controller that decides when to put the central processor (CPU) into a low-power state, thereby reducing power expenditures during periods when the user is idle. The system is driven by a human user, as well as different hardware processes, and can be realistically assumed to be non-stationary. The actions of the system correspond to hardware interrupts (most interrupts are generated by hardware controllers on the motherboard such as direct memory access, hard disk interrupts and networking interrupts) and the ongoing running processes. In the particular application at hand, there is a software interrupt (generated by the Windows operating system) every 16 milliseconds. The times of these interrupts are the decision epochs, at which the software controller can decide if and when to put the CPU to sleep before the next scheduled periodic interrupt.

However, saving energy by putting the processor in the low-power state comes at a cost. In the low-power state, a delay is incurred each time that the processor moves back into the high-power state in response to user-generated interrupts. We wish to limit the delay perceived by the human user. For this purpose, we assign a cost to the event that an interrupt arrives while the processor is in the low-power state, and impose a constraint on the time average of these costs. A similar model was used in Kveton et al. (2008), and we refer the reader to that work for further details.

We formulate the problem as follows. We divide a typical 16 millisecond interval into ten intervals. We let P1's action set be $A = \{0, 0.1, 0.2, \ldots, 1\}$, where action a corresponds to turning off the CPU after $16a$ milliseconds (the action $a = 1$ means the CPU is not turned off during the interval while the action $a = 0$ means it is turned off for the whole interval). Similarly, the action set of P2 is $B = \{0, 0.1, 0.2, \ldots, 0.9\}$, where action b corresponds to an interrupt after $16b$ milliseconds. (Note that the action $b = 0$ means there is no interrupt and that there is no point in including an action $b = 1$ in B since it would coincide with the known periodic interrupt.) The assumption is that an interrupt is handled instantaneously so if the CPU chooses a slightly larger than b it maximizes the power savings while incurring no penalty for observed delay (it is assumed for the sake of discussion that only a single interrupt is possible in each 16 millisecond interval). We define the reward at each stage as follows:

$$R(a,b) = \begin{cases} 1-a, & \text{if } b = 0 \text{ or } a > b, \quad \text{that is, if no interrupt occurs or an interrupt occurs} \\ & \text{before the CPU turns off,} \\ b-a, & \text{if } b > 0 \text{ and } a \leq b, \quad \text{that is, if there is an interrupt} \\ & \text{after the CPU is turned off.} \end{cases}$$

The cost is:

$$C(a,b) = \begin{cases} 1, & \text{if } a \leq b \text{ and } b > 0, \\ 0, & \text{otherwise.} \end{cases}$$

In "normal" operation where the CPU is powered throughout, the action is $a = 1$ and in that case there is no reward (no power saving) and no cost (no perceived delay). When $a = 0$ the CPU is turned off immediately and in this case the reward will be proportional to the amount of time until an interrupt (or until the next decision). The cost in the case $a = 0$ is 0 only is there is no interrupt ($b = 0$).

We used the real data trace obtained from what is known as MobileMark 2005 (MM05), a performance benchmark that simulates the activity of an average Microsoft Windows user. This CPU activity trace is 90 minutes long and contains more than 500,000 interrupts, including the periodic scheduled interrupts mentioned earlier. The exponentially weighted algorithm (Table 1) and the tracking forecaster (Table 2) were run on this data set. Figure 4 shows the performance of the two algorithms. The straight line shows the tradeoff between constraint violation and average reward by picking a fixed action over the entire time horizon. The different points for the exponential weighted predictor (Table 1) or the tracking forecaster (Table 2) correspond to different values of c_0. We observe that for the same average cost, the tracking forecast performs better (i.e., gets higher reward).

We selected $c_0 = 0.3$ and used both algorithms for the MM05 trace. Figures 5(a) and 5(b) show the instantaneous cost incurred by the tracking forecaster and the weighted average forecaster over the same short period. It should be observed that the cost of the algorithms is different, reflecting the fact that different policies are employed. Figures 6(a) and 6(b) show the time evolution of the

average reward and average cost for the same experiment. In spite of not being calibrated, the tracking forecast based algorithm outperforms the exponentially weighted based algorithm.

9. Conclusions

There are several open problems and directions for future research that are worth mentioning. First, the issue of convergence rate is yet to be settled. We noted that there exists an algorithm based on approachability that converges at the rate of $t^{-1/3}$, and that the usual lower bound of $t^{-1/2}$ holds. The other algorithm based on calibration suffers from potentially even worse convergence rate, as

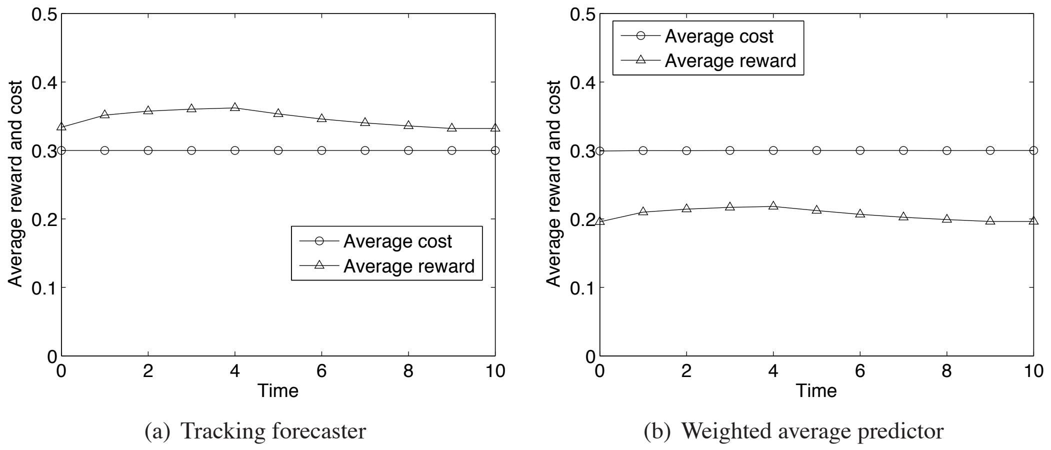

Figure 6: Time evolution of average reward and average cost for the tracking forecaster and weighted average forecaster with $c_0 = 0.3$ for the MM05 data.

we are not aware of any approximate calibration algorithm with comparable convergence rates. Second, the complexity of these two online learning algorithms leaves much to be desired. The complexity of a policy based on approachability theory is left undetermined because we do not have a specific procedure for computing P1's action at each stage. The per stage complexity is unknown for calibrated forecasts, but is exponential for approximately calibrated schemes (Cesa-Bianchi and Lugosi, 2006). Moreover, it is not clear whether online learning with constraints is as hard computationally as finding a calibrated forecast. Third, we only established the tightness of the lower convex hull of the Bayes envelope for the case of a one-dimensional penalty function. This is a remarkable result because it establishes the tightness of an envelope other than the Bayes envelope, and we are not aware of any such results for similar settings. However, it is not clear whether such a result also holds for two-dimensional penalties. In particular, the proof technique of the tightness result does not seem to extend to higher dimensions.

Our formulation of the learning problem (learning with pathwise constraints) is only a first step in considering multi-objective problems in online learning. In particular, other formulations, for example, that consider the number of time-windows where the constraints are violated, are of interest; see Kveton et al. (2008).

Acknowledgments

Abstract

In this paper we propose a new multilayer classifier architecture. The proposed hybrid architecture has two cascaded modules: feature extraction module and classification module. In the feature extraction module we use the multilayered perceptron (MLP) neural networks, although other tools such as radial basis function (RBF) networks can be used. In the classification module we use support vector machines (SVMs)—here also other tool such as MLP or RBF can be used. The feature extraction module has several sub-modules each of which is expected to extract features capturing the discriminating characteristics of different areas of the input space. The classification module classifies the data based on the extracted features. The resultant architecture with MLP in feature extraction module and SVM in classification module is called NEUROSVM. The NEUROSVM is tested on twelve benchmark data sets and the performance of the NEUROSVM is found to be better than both MLP and SVM. We also compare the performance of proposed architecture with that of two ensemble methods: majority voting and averaging. Here also the NEUROSVM is found to perform better than these two ensemble methods. Further we explore the use of MLP and RBF in the classification module of the proposed architecture. The most attractive feature of NEUROSVM is that it practically eliminates the severe dependency of SVM on the choice of kernel. This has been verified with respect to both linear and non-linear kernels. We have also demonstrated that for the feature extraction module, the full training of MLPs is not needed.

Keywords: feature extraction, neural networks (NNs), support vector machines (SVMs), hybrid system, majority voting, averaging

1. Introduction

A classifier designed from a data set $X = \{\mathbf{x}_i | i = 1, 2, \ldots, N, \mathbf{x}_i \in \Re^p\}$, where $\Re^p$ is the p dimensional real space, can be defined as a function $G : \Re^p \rightarrow N_c$. Here $N_c = \{\mathbf{y} \in \Re^c : y_k \in \{0,1\} \forall k, \sum_{k=1}^{c} y_k = 1\}$ is the set of label vectors and c is the number of classes. For any input vector $\mathbf{x} \in \Re^p$, $G(\mathbf{x})$ is a vector in c dimension with only one component as 1 and all others 0. In this paper our primary objective is to find a good G combining neural networks (NNs) and support vector machines (SVMs).

In machine learning literature NN and SVM are two widely used classifiers. NNs have been developed for many years and been used in various applications (Haykin, 1999; Pal et al., 2006). The SVM (Vapnik, 1995) is a classification and regression tool. It is comparatively a new family of learning tools including training algorithms for optimal margin classifiers (Boser et al., 1992) and support vector networks (Cortes and Vapnik, 1995). In SVM the input data are often transformed into a high dimensional space using some kernel functions. A linear separating hyper plane with the maximal margin between the closest positive and closest negative samples in the mapped space is found. The SVM works by solving a quadratic optimization problem that minimizes a sum of two terms. The first term is related with the reciprocal of norm of weight vector associated with the hyper plane and the second term is related to the sum of classification error. The SVM is a very active topic of research (von Luxburg et al., 2004; Adankon and Cheriet, 2007) and it has been successfully applied to many areas including handwritten digit recognition (Vapnik, 1995), object recognition (Pontil and Verri, 1998), protein structure prediction (Nguyen and Rajapakse, 2003) and texture classification (Kim et al., 2002). But there are some computational difficulties associated with using SVM. One of them is the required memory, which grows very quickly with the size of the training data since the SVM algorithm involves solving a large quadratic programming problem where every training data point forms a constraint. This is a constraint on the application of SVM to very large data sets. More importantly, the performance of SVM is significantly dependent on the choice of kernel. Needless to say that for non-linearly separable data, the performance of linear and nonlinear SVM also differs significantly.

Use of an ensemble of classifiers is a popular approach to improve the classification performance. Many ensemble methods are used by researchers to report the improvement in performance over single classifier (Hansen, 1999; Maqsood et al., 2004; Chawla et al., 2004). An ensemble of classifiers can be constructed using both homogeneous and heterogeneous classifiers (Hansen, 1999; Prevost et al., 2003; Garcia-Pedrajas et al., 2005). An ensemble of neural networks is often used for pattern classification problems (Garcia-Pedrajas et al., 2005; Islam et al., 2003) including face recognition (Melin et al., 2005), weather forecasting (Maqsood et al., 2004), protein secondary structure prediction (Guimaraes et al., 2003). Different approaches for constructing ensemble of neural networks have been suggested in the literatures (Wu et al., 2001; Zhou et al., 2002; Windeatt, 2006). In this paper for the purpose of comparison we have considered two ensemble methods for neural networks, one uses the average output of the ensemble of networks while the other one makes the ensemble vote on a classification task.

In this context, the ensemble method of Garcia-Pedrajas et al. (2007) needs a special attention as this method also uses a multilayer perceptron network for feature extraction and hence one may get a false impression that this method and our proposed method are quite similar.

This is an ensemble method where a large number of classifiers are trained and then their outcomes are aggregated using the majority voting rule. This is an interesting method but quite different from our proposed scheme.

Like AdaBoost the first baseline classifier is trained using the original training data while each of the subsequent classifiers is trained using a projected data set created using the hidden output of a trained MLP. The second baseline classifier uses data projected through the hidden layer of a projection network (MLP here). The projection network is an MLP network with number of hidden nodes equal to the number of inputs in the original training data and it is trained using only that *subset* of the training data which are not classified correctly by the first baseline classifier. The projection network (again an MLP with number of hidden nodes equal to the number of inputs in the original data) for the third baseline classifier is trained using the original data points whose projected versions are wrongly classified by the second baseline classifier. The process is repeated to generate a large number of baseline classifiers.

Note that, our proposed method falls in the category of hybrid system. There have been several attempts to combine different machine learning tools to develop efficient hybrid systems for pattern classification problems (Huang and LeCun, 2006; Happel and Murre, 1994; Vincent and Bengio, 2000; Mitra et al., 2006, 2005). To design a hybrid system different combination of classifiers is used including neural network-SVM (Mitra et al., 2005, 2006; Vincent and Bengio, 2000), convolution network-SVM (Huang and LeCun, 2006). Neural networks and support vector machines are used to design a hybrid system for text classification in Mitra et al. (2005) and Lidar detection of underwater objects in Mitra et al. (2006). Mitra et al. (2005) proposed a hybrid system called neuro-SVM which takes the component wise product of the outputs of a cascaded-SVM classifier and a recurrent neural network, and applies a set of heuristic rules to decide on the class. In the work of Mitra et al. (2006), after preprocessing Lidar signal is modeled using a polynomial as well as a linear predictor. The optimal coefficients of the polynomial are used as inputs to train a RBF, while coefficients of the linear predictor are used to train an MLP. The products of the corresponding components of the output vectors from the two networks are used as input to a cascaded-SVM classifier. Huang and LeCun (2006) presented a hybrid system for object recognition that uses the outputs of the last hidden layer of a convolution network to train a SVM with Gaussian kernel. The convolution network is generally used for computer vision problems. A convolution network has several hidden layers alternately consisting of convolution layer and sub-sampling layer. In a convolution network, the successive layers are designed to learn progressively higher-level features until the last layer, which produces categories.

There have been a number of attempts to develop modular networks to solve complex problems efficiently (Ronco and Gawthrop, 1995; Bottou and Gallinari, 1991). The basic philosophy of developing a modular network is to divide the task into a number of, preferably, meaningful subtasks, and then design one module for each subtask. Finally one needs to devise a mechanism to integrate these modules—this will dictate how different modules interact and lead to the final output. Sometimes the knowledge of the problem domain can be used to find the subtasks, but often clustering is used for this purpose. For example in Pal et al. (2003) a self organized map (SOM) is used to find natural clusters (subtasks) in the data and then for each cluster a separate network is trained. A given input is routed to the appropriate MLP module using the SOM. Jenkins and Yuhas (1993) have presented a simple solution to the truck backer-upper problem by decomposing it into subtasks. Then all subtasks are realized in parallel (that is, off line) to obtain the final two-layer feed-forward network, which is used to control the truck. Although our proposed architecture uses several modules, this is not designed following the usual principle of modular network.

In this paper we propose a new classifier architecture called NEUROSVM. The proposed classifier has two modules. In the first module we have used an MLP. We view the first module as a feature extraction module (FM), because outputs of this module can be used as inputs to any other classifier. This new set of features is used in the next module, termed as the classification module (CM). In the classification module we have used SVM with different kernel functions. Instead of SVM, one can use any other classifier also. We also consider the MLP and RBF neural networks in the CM of our proposed architecture. To further demonstrate the effectiveness of NEUROSVM we compare it with two other ensemble methods: majority voting and averaging. We demonstrate the effect of the kernel on SVM and NEUROSVM.

Our proposed method is neither an ensemble method nor has any relation to boosting. There is only one classifier. The classifier uses features extracted from the hidden nodes of several trained networks where typically the number of hidden nodes in a network is smaller than input dimension. Each network used for feature extraction is trained using the same data and each network sees the entire input space as represented through the training data. Thus typically to get improved performance we need fewer feature extraction networks than that would be needed by the ensemble type methods.

2. Methods

The section is arranged as follows. First, we provide a brief description of neural networks for the sake of completeness. Next, we give a brief description of the support vector machine (SVM) classifier and how several binary SVMs can be combined to solve a multiclass problem. Then we explain two popular existing ensemble methods that will be used for comparison. This is followed by a detailed discussion of the proposed method.

2.1 MLP and RBF Neural Networks

The two most widely used neural networks for pattern recognition are multilayer perceptron (MLP) and radial basis function (RBF) networks (Haykin, 1999). We have used the back-propagation algorithm for training MLP networks with single hidden layer.

The RBF network consists of exactly three layers: input layer, basis function layer and output layer. Unlike MLP, the activation functions of the hidden nodes are not of sigmoidal type, rather each hidden node represents a radial basis function. The transformation from the input space to the hidden space is nonlinear but each node in the output layer computes just the weighted sum of the outputs of the previous layer, that is, each output layer node makes a linear transformation. The learning of RBF network is usually performed in two phases. An unsupervised learning method is applied to estimate the basis function parameters. Then a supervised learning method, such as gradient descent or least square error estimate, is applied to tune the network weights between the hidden layer and the output layer. However, the parameters of the basis functions can also be tuned using gradient descent technique. Here we have used the MATLAB implementation of RBF network.

2.2 Support Vector Machines (SVMs)

The basic SVM (Haykin, 1999; Vapnik, 1995) formulation is for two class problems. If the training data are linearly separable, then SVM finds an optimum hyperplane that maximizes the margin of separation between the two classes.

Given a training set (X,Y), $\mathbf{x}_i \in X$, $\mathbf{x}_i \in \Re^p$ and $y_i \in Y$, the class label associated with $\mathbf{x}_i$; $y_i \in \{-1,+1\}$, the learning problem for SVMs is to find the weight vector $\mathbf{w}$ and bias b such that they satisfy the constraints:

$$\mathbf{x}_i.\mathbf{w}+b \geqslant +1 \qquad \text{for } y_i = +1 \tag{1}$$

$$\mathbf{x}_i.\mathbf{w}+b \leqslant -1 \qquad \text{for } y_i = -1 \tag{2}$$

and the weight vector $\mathbf{w}$ minimizes the cost function

$$\Phi(\mathbf{w}) = \frac{1}{2}\mathbf{w}^T\mathbf{w}.$$

The constraints written in Equations (1)-(2) can be combined as

$$y_i(\mathbf{x}_i.\mathbf{w}+b) \geqslant +1\ \forall i.$$

If the training points are not linearly separable, then there is no hyperplane that separates them into positive and negative classes. In this case, the problem is reformulated considering the slack variables $\xi_i \geqslant 0; i = 1,2,\ldots,N$. For most $\mathbf{x}_i$, $\xi_i = 0$. The constraints are now modified as follows:

$$\mathbf{x}_i.\mathbf{w}+b \geqslant +1-\xi_i \qquad \text{for } y_i = +1 \tag{3}$$

$$\mathbf{x}_i.\mathbf{w}+b \leqslant -1+\xi_i \qquad \text{for } y_i = -1 \tag{4}$$

$$\xi_i \geqslant 0,\ \forall i. \tag{5}$$

The SVM then finds $\mathbf{w}$, minimizing

$$\Phi(\mathbf{w},\xi) = \frac{1}{2}\mathbf{w}^T\mathbf{w} + C\sum_{i=1}^{N}\xi_i$$

subject to constraints as in Equations (3)-(5). The constant C is termed as a regularization parameter as it controls the trade off between the complexity of the machine and the number of misclassifications.

Typically, when the training points are not linearly separable, a nonlinear mapping φ is used to map the training data from $\Re^p$ to some higher dimensional feature space H, with a hope that the data may be linearly separable in H. The mapping is implicitly realized using a kernel function.

Two kernels that are popular for non-linear SVMs are:

1. Polynomial of degree d: $K(\mathbf{x},\mathbf{x}_i) = (s\mathbf{x}.\mathbf{x}_i+1)^d$, where s is the scaling coefficient of the dot product.

2. Radial Basis Function (RBF): $K(\mathbf{x},\mathbf{x}_i) = e^{-\gamma\|\mathbf{x}-\mathbf{x}_i\|^2}, \gamma > 0$.

In this study, we shall extensively use the RBF kernel with a wide range of γ. We shall also demonstrate the utility of the proposed method with polynomial kernel.

We have used SVM^{light} (Joachims, 2002) software for learning the SVM classifier. Note that, NEUROSVM uses SVM^{light} in the classification module. We also use SVMs on the original data to compare its performance with that of NEUROSVM.

2.3 SVM for Multiclass Problems

The preceding SVM formulation is for two class problems. Multiclass SVMs are generally realized using several two class SVMs. We use the One versus One (OVO) method (Nguyen and Rajapakse, 2003; Weston and Watkins, 1999). Let us assume that we have a c class problem. In this method we construct one binary classifier for every pair of distinct classes. So we get $c \times (c-1)/2$ binary classifiers for a c class problem. In the training data, suppose k_i samples are from class $i, N = \sum_{i=1}^{c} k_i$. For the class pair (i, j), a binary classifier C_{ij} is trained using k_i and k_j data points from class i and j. An unknown sample $\mathbf{x}$ is then classified by each of the $c \times (c-1)/2$ different classifiers. If classifier C_{ij} classifies $\mathbf{x}$ as class i then the vote for class i for sample $\mathbf{x}$ is increased by one. Otherwise, vote for class j for sample $\mathbf{x}$ is increased by one. In this way for sample $\mathbf{x}$, the votes for all c classes are calculated using the output of all $c \times (c-1)/2$ classifiers. After that we assign $\mathbf{x}$ to class l, if class l has the largest number of votes for $\mathbf{x}$. Ties are randomly resolved.

2.4 Ensemble Methods: Majority Voting and Averaging

Different methods of classifier fusion are available in the literature (Maqsood et al., 2004; Ko et al., 2007; Brown et al., 2005; Tang et al., 2006; Kuncheva and Whitaker, 2003; Windeatt, 2006; Islam et al., 2003), of which the majority voting scheme is probably the most popular method (Stepenosky et al., 2006). In this method, the final class is determined by the maximum number of votes counted among all the classifiers fused. Let us consider a c class problem and let m be the number of classifiers to be fused. For an unknown sample $\mathbf{x}$, vote for class j, $v_j, (j = 1, 2, \ldots, c)$ is computed from the ensemble of classifiers $C_i, (i = 1, 2, ..., m)$. If $C_i, (i = 1, 2, ..., m)$ assigns sample $\mathbf{x}$ to class j then v_j is incremented by 1. Note that, initially vote for every class is initialized to 0; that is, $v_j = 0, (j = 1, 2, ..., c)$. The final class determination by the ensemble for sample $\mathbf{x}$ is k, if $v_k = \max_{j=1}^{c}\{v_j\}$.

Averaging also is a simple but effective method and is used in many classification problems (Guimaraes et al., 2003; Naftaly et al., 1997). In this method, the final class is determined by the average of continuous outputs of all classifiers (here MLPs) fused. For an unknown sample $\mathbf{x}$, let the output for class j $(j = 1, 2, ..., c)$ from classifier $C_i, (i = 1, 2, ..., m)$ be o_{ij}. Then the output from the ensemble classifier is obtained as $O_j = \frac{1}{m} \sum_{i=1}^{m} o_{ij}, \; j = 1, 2, \ldots, c$. The final class assignment by the ensemble to $\mathbf{x}$ is k, if $O_k = \max_{j=1}^{c}\{O_j\}$.

2.5 Proposed NEUROSVM Classifier

The proposed multilayer architecture can be thought of as a combination of two types of modules: feature extraction module (FM) and classification module (CM). The FM consists of a number of sub-modules SFM$_i$, $i = 1, 2, \ldots, m$. Each sub-module SFM$_i$ takes the same p dimensional data $\mathbf{x} = (x_1, x_2, \ldots, x_p)^T$ as input and produces n_i dimensional output vectors $\mathbf{v}_i = (v_{i1}, v_{i2}, \ldots, v_{in_i})^T$. Thus $n = \sum_{i=1}^{m} n_i$ output values together as shown in Equations (6) and (7) constitute an n dimensional input to the classification module.

$$\mathbf{z} = \begin{pmatrix} \mathbf{v}_1 \\ \mathbf{v}_2 \\ \vdots \\ \mathbf{v}_m \end{pmatrix} \in \Re^{n_1+n_2+\ldots+n_m} \tag{6}$$

and

$$\begin{aligned} \mathbf{v}_1 &= (v_{11}, v_{12}, \ldots, v_{1n_1})^T, \\ \mathbf{v}_2 &= (v_{21}, v_{22}, \ldots, v_{2n_2})^T, \\ &\vdots \\ \mathbf{v}_m &= (v_{m1}, v_{m2}, \ldots, v_{mn_m})^T. \end{aligned} \tag{7}$$

In general, different SFM$_i$ can use different methods of feature extractions or they can use the same principle for feature extraction. Similarly, the classification module can use any principle like neurocomputing, support vector machines and so on.

In this investigation, the sub-modules SFM$_i$s are derived from multilayer perceptron networks, while the classification module consists of support vector machines. And, hence, we call the resulting architecture NEUROSVM.

In order to constitute the i^{th} sub-module SFM$_i$, we consider an MLP with just one hidden layer, with architecture (p, n_i, c), where p is the input dimension, n_i is the number of nodes in the hidden layer and c is the number of classes. Note that, although the number of input and output nodes in each MLP remains the same, the number of nodes in the hidden layer could be different for different MLPs. Each MLP is then trained using the training data $X = \{\mathbf{x}_i; i = 1, 2, \ldots, N\} \subset \Re^p$, $Y = \{\mathbf{y}_i; i = 1, 2, \ldots, N\} \subset \Re^c$ where $\mathbf{y}_i$ is the target output corresponding to $\mathbf{x}_i$.

Once each network is trained, the output of the hidden layer can be taken as the extracted features. These features capture characteristics of the data that can discriminate between classes; hence using these features we can do the classification job using just a single layer network.

Note that, instead of MLP, we can use RBF also in the feature extraction module. In Figure 1, the top panel has m different trained MLPs labeled as $\text{MLP}_1, \text{MLP}_2, \ldots, \text{MLP}_m$. After the training, we remove the output layer and its associated connections from each of the MLPs and then the truncated two-layer sub-networks are taken as feature extraction sub-modules. The subnets $\text{SFM}_1, \text{SFM}_2, \ldots, \text{SFM}_m$ in the lower panel of the NEUROSVM are constructed from the trained MLPs in the upper panel. The first two layers of MLP$_i$ constitute $\text{SFM}_i, i = 1, 2, \ldots, m$.

As depicted in the lower panel of Figure 1, the output from the m sub-modules, taken together constitutes the input to the classification module. Here we consider SVMs for classification, but other classifiers such as neural networks (MLP or RBF network) can also be used. Note that, each sub-module receives the same input $\mathbf{x} = (x_1, x_2, \ldots, x_p)^T$.

Given the training data X and Y, in order to train the CM we use the following data set. For each $\mathbf{x}_i \in X$, the FM produces an output $\mathbf{z}_i \in \Re^n$ as in Equation (6). Like an MLP, every node in the second layer of NEUROSVM computes the weighted sum of its input and applies a sigmoidal activation function to produce its output. Thus $Z = \{\mathbf{z}_i; i = 1, 2, \ldots, N\}, \mathbf{z}_i \in \Re^n$, as in Equation (6), is used as the input data and corresponding to each $\mathbf{z}_i \in Z$, the associated $\mathbf{y}_i \in \Re^c$, $\mathbf{y}_i \in Y$ is taken as the target output. The CM is trained using (Z, Y).

In the present case the CM has two layers. The first layer, as shown in Figure 1, is the SVM kernel layer where each node is associated to a mapped training sample $\mathbf{z}_i$ (it is the output from an FM that represents a support vector) and it computes the kernel output $K(\mathbf{z}, \mathbf{z}_i)$ on a mapped input $\mathbf{z}$, while the other layer is the output layer.

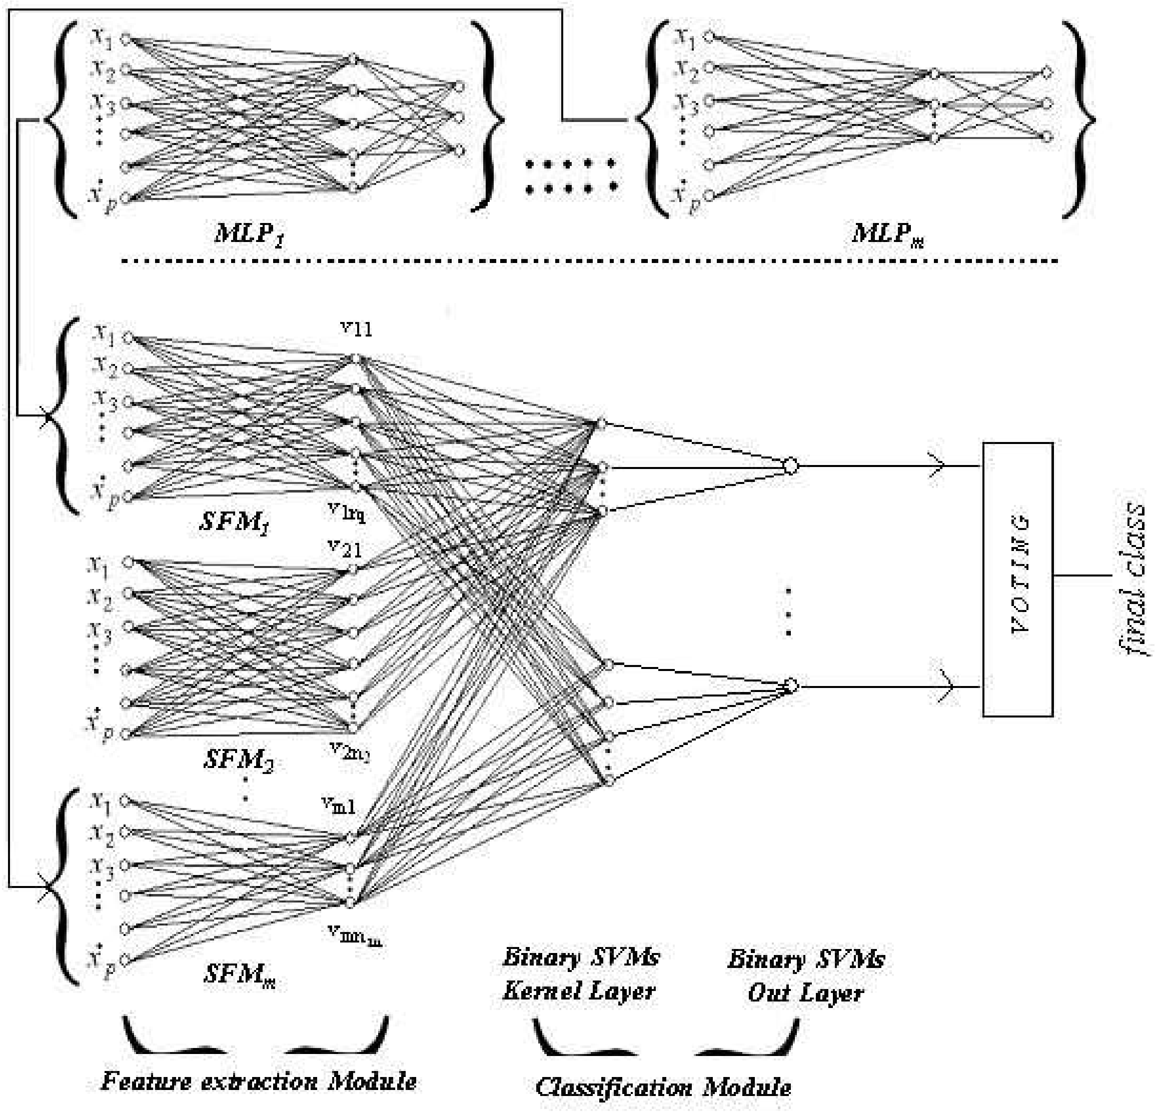

Figure 1: The proposed NEUROSVM classifier

2.6 Advantages of the Proposed Method

A natural question comes, why such an architecture (NEUROSVM) will be better or more useful than the usual SVM or MLP? There are number of reasons behind this. Note that, we are not considering very simple data sets where most classifiers will lead to zero training-test errors.

1. Typically, due to the local minima problem of MLP training and its dependence on initialization, different MLPs may learn different areas of the input space better. Hence when we combine the output of the hidden layer of different networks to generate new features, the learning task becomes simpler to the CM. This is true irrespective of whether the CM is a neural network or SVM.

2. The extracted features result in simpler classification boundaries because a single layer network can classify the new data (consider a two layer network consisting of the hidden and output layers of an MLP). This also makes the learning task of the CM simpler.

3. For high dimensional data, typically the number of nodes in the hidden layer is much smaller than the number of the input nodes and one does not need many feature extraction submodules (SFMs). Hence, the dimensionality of the input for the CM can be reduced compared to the original dimension of the input. This makes simpler error surface, faster learning and allows us to do more experiments, if CM is a neural network.

4. This is not an ensemble method but it makes fusion of salient characteristics of the input space as extracted/learnt by different feature extraction networks. It can at least be viewed as an implicit fusion of multiple classifiers, and hence improvement in performance is expected.

5. For large data sets, it may not be necessary to make full training of the MLPs for constructing the SFM$_i$s, because the objective of the MLPs here is to capture the inherent attributes of the data by the FM.

For low dimensional data sets or simpler data sets this method may not have much advantage because then n (dimension of input to the CM) can be more than p (original dimension of the input) and different SFMs may capture the same attributes of the data resulting in not much of benefits. Note that, the advantages mentioned in 2 and 3 are also applicable to MLPs.

3. Experiments

The section is arranged as follows. First we have listed the selected data sets to validate our proposed method. Then experimental setup is described. Next, the experimental results are presented. Finally, a control experiment to justify one of the advantages of the proposed method is demonstrated.

3.1 Data Sets

To demonstrate the effectiveness of the proposed method, we consider twelve data sets from the UCI Machine Learning Repository (Blake and Merz, 1998). We divide the data sets into two Groups: A and B. The Group A consists of eight data sets: Iris, Vehicle, Breast Cancer (WDBC), Glass, Sonar, Ionosphere, Lymphography Domain (Lymph) and Pima Indians Diabetes (Pima) data. The Group B contains Pendigits, Image-Segmentation (Img. Seg.), Landsat satellite image (Sat. Img.) and Optdigits data. For Group A data sets some results are available in the literature but the details of the experimental protocols (such as training/test divisions) used are not available. Hence, we report the performance with ten-fold cross-validation experiments. Each data set is divided into ten subsets of almost equal size. One of the subsets is used for testing and the remaining nine subsets are used for training. The procedure is repeated ten times and the average performance is reported. We report the results in terms of mean test error and its standard error for Group A data sets. For the four data sets in Group B, benchmark results with different classifiers are available along with the training-test partition. Hence we have used the same training-test partition here and report the error on the fixed test set. Table 1 and Table 2 summarize the Group A and Group B data sets respectively.

Data set	No. of classes	No. of features	Size of the data set and class wise distribution
Iris	3	4	150 (= 50 + 50 +50)
Vehicle	4	18	846 (=212+217+218+199)
WDBC	2	30	569 (=212 + 357)
Glass	6	9	214 (=70+76+17+13+9+29)
Sonar	2	60	208 (=97+111)
Ionosphere	2	34	351 (=225+126)
Lymph	4	18	148 (=2+81+61+4)
Pima	2	8	768 (=500+268)

Table 2: Group B data sets

3.2 Experimental Setup

In this subsection we describe the selection method for hyper parameters of MLP and SVM classifiers. To select the optimal architecture for an MLP, Andersen and Martinezr (1999) used ten-fold cross-validation experiments. Adankon and Cheriet (2007) discussed another scheme for SVM model selection. Here we have used ten-fold cross-validation experiments for MLP architecture selection as well as for selection of SVM kernel parameters. For Group B data sets training-test partitions are fixed and hence we have used ten-fold cross-validation on the training set to select the hyper parameters of classifiers. For Group A data sets, as mentioned earlier, the performances are reported based on ten-fold cross-validation. So, we perform double blind ten-fold cross-validation experiments to select hyper parameters of classifiers for Group A data sets.

Note that, for the FM of NEUROSVM, we need to select $m \geqslant 1$ MLPs. A natural choice would be to select the best m architectures corresponding to the smallest m values of validation errors.

Based on validation error we choose m architectures for each of the ten folds for Group A data sets and m architectures for each of the Group B data sets for NEUROSVM.

In a similar manner the regularization parameter C and spread γ of RBF kernels of SVMs are chosen based on ten-fold cross-validation experiments. We have experimented with n_c choices of C and n_g choices of γ. So, we have used $n_c \times n_g$ sets of choice of parameters. For each choice, the ten-fold cross-validation experiments are conducted. Here we also select the (C,γ) pair that leads to the minimum average validation error. In this investigation $n_c = 12$ and $n_g = 15$ are used resulting in a total of 180 pairs of parameters.

We have also used ten-fold cross-validation to find the sub-modules for NEUROSVM. The hyper parameters of SVMs in the classification module of NEUROSVM are also estimated through ten-fold cross-validation experiments. Note, for Group A data sets we have used double blind ten-fold cross-validation. We have selected m (=5) SFMs. Hence using the m SFMs we can generate $2^m - 1$ different feature subsets combinations. In our case it is $2^5 - 1 = 31$. Then for each of the 31 combinations with all 180 pairs of (C,γ) we have conducted the ten-fold cross-validation experiments on training set(s). We have obtained the best (C,γ) for each of the 31 combinations. Then the best combination is chosen based on the minimum average validation error over all 31 combinations. Finally using the best combination and corresponding (C,γ) pair the performance of NEUROSVM is reported.

We have performed statistical tests (Dietterich, 1998) to compare the proposed algorithms with that of standard algorithms. For Group A data sets where cross-validation is performed, we have applied the ten-fold cross-validation paired t-test with 9 degrees of freedom and 95% significance level. For the four data sets of Group B where a single test set is employed, we have constructed McNemar test with 1 degree of freedom and 95% significance level. The formulations of these tests are as follows.

3.2.1 K-FOLD CROSS-VALIDATION PAIRED T-TEST (DIETTERICH, 1998)

Consider two classifier models, D_1 and D_2, and a data set X. The data set is split into K parts of approximately equal sizes, and each part is used in turn for testing of a classifier built on the pooled remaining $K-1$ parts. Classifiers D_1 and D_2 are trained on the training set and tested on the test set. Denote the observed test accuracies as P_1 and P_2, respectively. This process is repeated K times and test accuracies are tagged with superscript $(i), i = 1,2,\ldots,K$. Thus a set of K differences is obtained, $P^{(1)} = P_1^{(1)} - P_2^{(1)}$ to $P^{(K)} = P_1^{(K)} - P_2^{(K)}$. Under the null hypothesis (H_0: equal accuracies), the following statistic has a t-distribution with $K-1$ degrees of freedom

$$t = \frac{\overline{P}\sqrt{K}}{\sqrt{\sum_{i=1}^{K}(P^{(i)} - \overline{P})^2/(K-1)}},$$

where $\overline{P} = (1/K)\sum_{i=1}^{K} P^{(i)}$. If the calculated t is greater than the tabulated value for chosen level of significance (here 0.05) and $K-1$ (here 9) degrees of freedom, we reject null hypothesis H_0 and accept that there are significant differences in the two compared classifier models.

3.2.2 McNemar Test (Dietterich, 1998)

As done before consider two classifiers D_1 and D_2. Let us define the following: N_{00} = number of samples which both D_1 and D_2 classify incorrectly, N_{01} = number of samples which D_1 classifies incorrectly but D_2 classifies correctly, N_{10} = number of samples which D_1 classifies correctly but D_2 classifies incorrectly and N_{11}= number of samples which both D_1 and D_2 classify correctly. Let, $N = N_{00} + N_{01} + N_{10} + N_{11}$ be the total number of samples in the test set. The null hypothesis, H_0, is that there is no difference between the accuracies of the two classifiers. If the null hypothesis is correct, then the expected counts for N_{01} and N_{10} are $\frac{1}{2}(N_{01} + N_{10})$. The discrepancy between the expected and the observed counts is measured by the following statistic

$$\chi^2 = \frac{(|N_{01} - N_{10}| - 1)}{N_{01} + N_{10}},$$

which is approximately distributed as χ^2 with 1 degree of freedom. To carry out the test we simply calculate χ^2 and compare it with the tabulated χ^2 value for a given level of significance, say, 0.05 (in our case).

We have performed all experiments using two Sun Blade 2500 with dual processors. The svm_learn and svm_classify modules for binary SVMs training and classification are used from SVM^{light} (Joachims, 2002) software. For the RBF neural network MATLAB toolbox is used. All other programs are written in c.

3.3 Experimental Results

In this subsection first we list the selected hyper parameters of MLP and SVM by cross-validation experiments. Next selection of sub-modules and hyper parameters of NEUROSVM is discussed. The performance comparison of NEUROSVM with the baseline classifiers and standard ensemble methods is presented. Finally, we present the performance of other variants of NEUROSVM and compare it with the baseline classifiers as well as ensemble methods.

3.3.1 Selection of Hyper Parameters for MLPs to Construct the FM

For Group A data set we use double blind ten-fold cross-validation. The partitioning of data for Group A data sets is explained in Appendix A. For each of the outer level cross validation loop, finding the optimal number of hidden nodes and computation of the test error are explained in the procedure RunMLP in Appendix B. The initial weights of the MLPs are chosen randomly in [-0.5, +0.5] and the learning rate used to train the MLPs is 0.60. The number of iterations used to train the networks for different data sets are chosen based on a few trial experiments. For each data set, a set of choices on the number of hidden nodes is used to train the MLPs. In Table 3, number of iterations and number of hidden nodes that are used to train the MLPs for the twelve data sets are listed. We have decided to use $m = 5$ neural networks for feature extraction modules and hence for each fold, we have to select a set of five hidden nodes to train five MLPs.

First we display the variation of the average validation error of cross-validation experiments as a function of the number of hidden nodes for both Group A and Group B data sets. Since for each data set in Group A 10 panels are required for the 10 folds, we include the figure for only one data set, Vehicle, in Figure 2. In Figure 3, four panels are included, one for each of the four data sets in Group B. In both Figures 2 and 3 we also include the average training errors. As mentioned earlier, for the FM of NEUROSVM, we want to use $m = 5$ networks (SFMs). Consider a data set in Group

A. Suppose, we have trained MLPs with M different architectures, that is, with M different choices of hidden nodes. Then for each of the outer level fold, we shall have M different hidden nodes each associated with an average validation error. Now we order these M hidden nodes in ascending order of the associated validation error. Then select the top five hidden nodes from this ordered list. These five different choices of hidden nodes will be used to train five MLPs for feature extraction for that particular fold. For each data set, in Table 4, we depict the list of selected hidden nodes for each fold (outer level). As an example, for the IRIS data for the first fold (outer level), the selected hidden nodes are (7, 2, 5, 6, 8). This means that for the first fold (outer level) we got the least validation error with 7 hidden nodes; the next smaller validation error is obtained with 2 hidden nodes and so on.

Since the first element of this set of five resulted in the smallest validation error, we use this choice of hidden nodes to train MLPs when we report the performance of the MLP networks as classifiers. For each data set in Group B, since the training and test partitions are fixed, we have only one outer loop and hence only one set with five choices of hidden nodes as shown in Table 4. We follow the same protocol as that of Group A data sets to choose the number of hidden nodes for computing the performance of MLP networks.

Data set	Training iterations	Hidden nodes explore
Iris	1500	2-10
Vehicle	2000	3-16

Table 3: List of explore hidden nodes and number of iterations for MLP for the twelve data sets

3.3.2 SELECTION OF HYPER PARAMETERS FOR SVMS

In this section we consider the problem of selecting hyper parameters for a regular SVM that we shall use as benchmark in experiments for the purpose of comparison with NEUROSVM. To select the regularization parameter C and spread γ for RBF kernel of SVM classifiers we have tried a wide range of C and γ. In this experiment we have used 12 different values of C and 15 different values of γ resulting in a total of 180 pairs of (C,γ). The 12 different values of C are 0.001, 0.01, 0.10, 0.20, 0.50, 1.00, 2.00, 5.00, 10.00, 20.00, 100.00 and 1000.00. The 15 different values of γ that we have used are 0.0001, 0.001, 0.01, 0.10, 0.20, 0.40, 0.80, 1.00, 2.00, 5.00, 10.00, 20.00, 100.00, 1000.00 and 10000.00. In a manner similar to the way the optimal number of hidden node is chosen for each fold (outer level), the optimal (C,γ) is chosen using ten-fold cross-validation experiments. This is further explained by Procedure RunSVM included in Appendix C. For each of the twelve data sets,

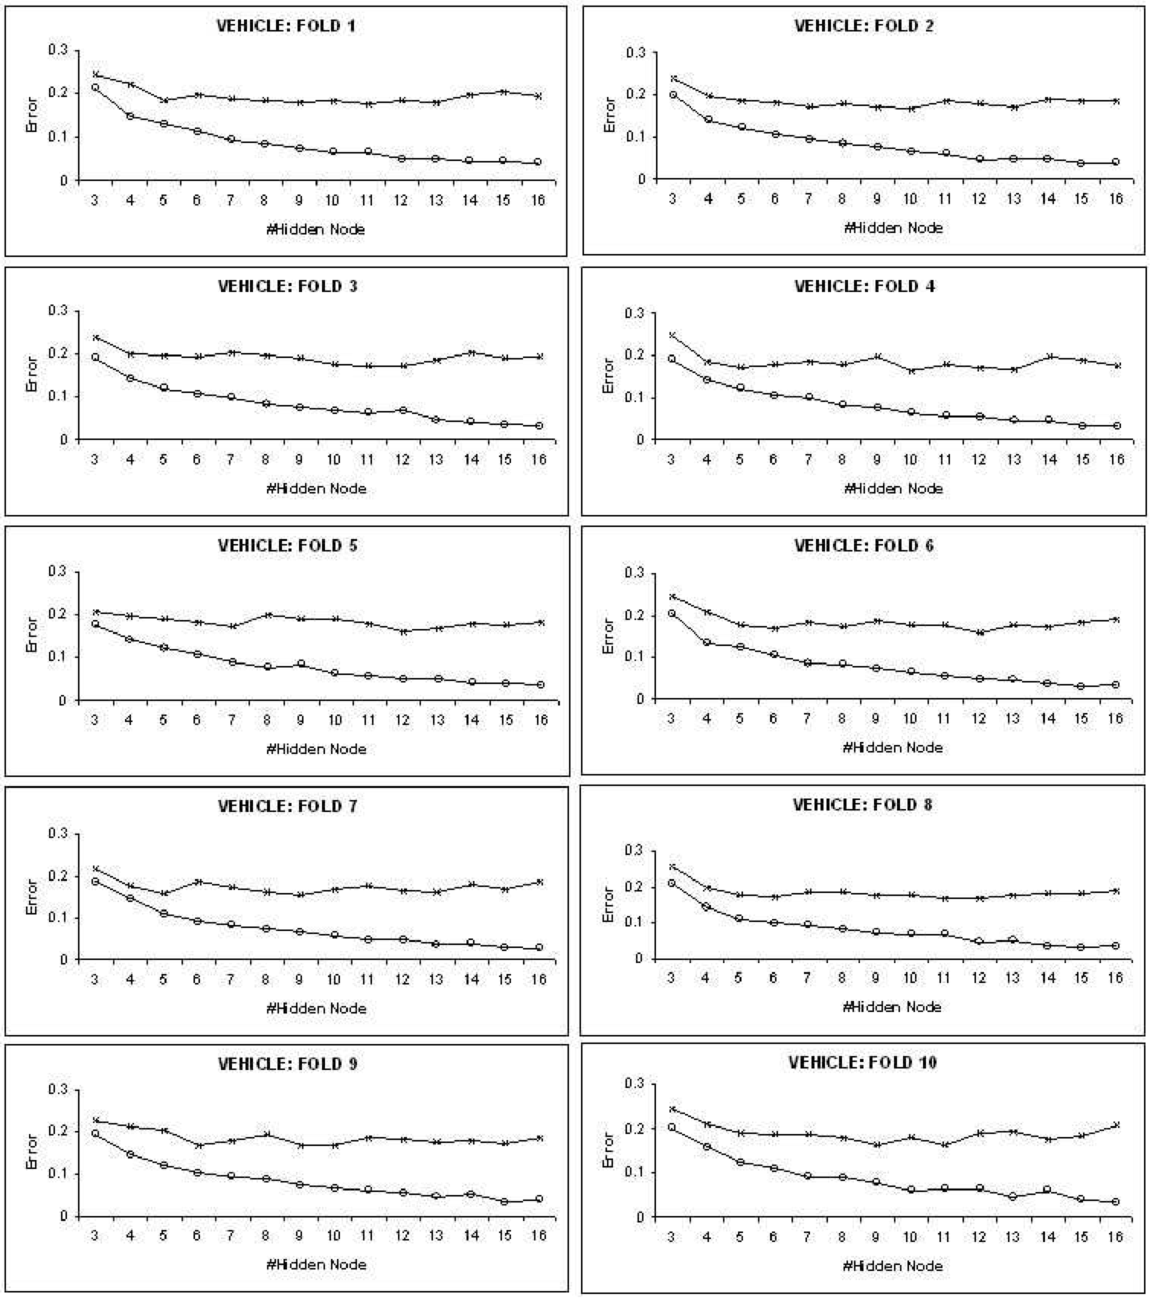

Figure 2: For each of the ten-folds the variation of cross-validation error with different choices of number of hidden nodes for MLPs on the Vehicle data set. The lines with cross-mark denote the validation error while the lines with circles denote the training error.

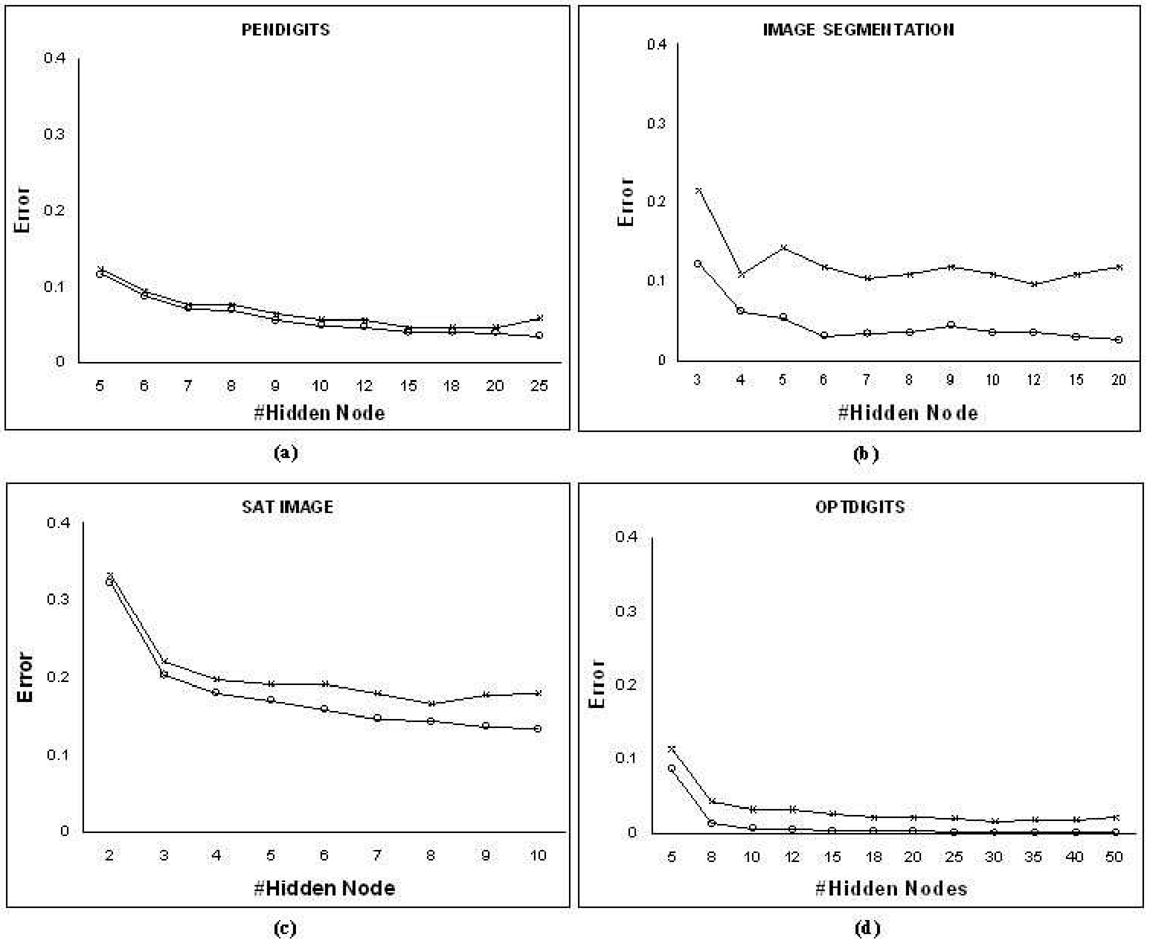

Figure 3: Variation of cross-validation error with different choices of number of hidden nodes for MLPs on four data sets in Group B: (a) Pendigits (b) Img. Seg. (c) Sat. Img. and (d) Optdigits. The lines with cross-mark denote the validation error while the lines with circles denote the training error.

the obtained optimal set of parameters is in Table 5. The results reported for SVMs correspond to these choices.

Table 4: List of selected hidden nodes for SFMs of the NEUROSVM for the twelve data sets selected by cross-validation experiments

3.3.3 SELECTION OF SFMS AND HYPER PARAMETERS FOR NEUROSVM

We have already explained, for each fold how to choose the number of hidden nodes for the five MLPs that will be required in the feature extraction module of NEUROSVM. These choices for different data sets are listed in Table 4. In order to use these data extraction MLPs, two issues need to be addressed. First do we need all five feature extraction MLPs, or for different folds, different subsets of the five would be more appropriate. In other words, for each fold, using five feature extraction MLPs we can have 31 possible combinations of feature sets. And we have to use the

Table 5: List of regularization parameter and spread of the RBF kernel for SVMs selected by cross-validation experiments

most appropriate combination for each fold. The second issue is to find the optimal hyper parameter for each combination of feature sets. Thus for each fold, to obtain the best choice of combination of feature subsets and the associated optimal hyper parameter, for each of the 31 combinations, as we did for SVM (in Procedure RunSVM) we use ten-fold cross-validation. This is summarized in Appendix D by Procedure RunNEUROSVM. The selected combinations of SFMs along with the hyper parameters for the twelve data sets are listed in Table 6. The set within braces in the second column of Table 6 shows the best combination of feature extraction MLPs selected by cross-validation experiments. As an illustration, for fold 1 of Iris, a set of 7 features is used in the classification module, which is generated by two selected SFMs each with 2 and 5 hidden nodes. The (C,γ) pair within parenthesis followed by the combination shows the regularization parameter

(C) and spread (γ) of the RBF kernel for SVM classifiers in the classification module that are selected by the cross-validation. From Table 6 we see that NEUROSVM with single SFM is not selected for any data sets. Hence using just one SFM we shall not gain anything. The selected combination of SFMs and corresponding (C,γ) are used to report the results of NEUROSVM. From Table 5 and Table 6 we observe that the values of γ chosen for SVM are usually smaller than those for NEUROSVM. It is probably because the hidden layers of neural networks are more suited for linear classification than the original inputs, so a higher γ (less non-linearity) is more appropriate.

Four of the twelve data sets have dimensionality 30 or more. For these four data sets dimensionality is reduced in the classification module of NEUROSVM. The dimensions of the four data sets, WDBC, Sonar, Ionosphere and Optdigits, in the classification module of NEUROSVM are reduced by 16.67-56.67% (average 41.33%), 16.67-80.00% (average 48.33%), 47.06-67.65% (average 54.41%) and 14.06% respectively. Hence for high dimensional data the dimensionality of input for the CM can be reduced compared to original dimension of the input.

3.3.4 PERFORMANCE COMPARISON OF NEUROSVM WITH THE BASELINE CLASSIFIERS AND STANDARD ENSEMBLE METHODS

We compare the performance of NEUROSVM with MLP, SVM as well as two existing neural ensemble methods. The majority voting and averaging are simple yet effective ensemble methods. In Table 7, test error results of NEUROSVM, MLP, SVM, majority voting and averaging are shown. In Table 7, majority voting ensemble method is denoted by MVOTING while the average ensemble method is denoted by AVERAGING. The results in Table 7 show that based on the paired t-test for Group A data sets and McNemar test for Group B data sets NEUROSVM is significantly better than the baseline classifiers for 11 data sets when compared with MLP and for 6 data sets when compared with SVM.

Note that the results of MVOTING and AVERAGING in Table 7 are obtained using the same combinations of networks (SFMs) that are used in the FM of NEUROSVM. From Table 7 we see that NEUROSVM performs significantly better than the standard ensemble methods for 11 data sets when compared with majority voting and for 10 data sets when compared with averaging.

As a summary, NEUROSVM is superior to MLP, SVM as well as two ensemble methods for 6 data sets. These data sets are Vehicle, WDBC, Ionosphere, Lymph, Pima and Img. Seg. For four out of remaining six data sets NEUROSVM performs significantly better than MLP, MVOTING and AVERAGING. The performance of NEUROSVM and SVM for these four data sets, Iris, Sonar, Pendigits and Sat. Img, is not significantly different. For the Glass data, the performance of NEUROSVM is significantly better than MLP and MVOTING but is not significantly different from that of SVM and AVERAGING. For the Optdigits data set all algorithms perform equally well. No data set is found where two baseline classifiers (MLP and SVM) or two ensemble methods perform better than NEUROSVM.

For the results in Table 7, for each data set, the combination of SFMs used is selected by cross-validation for NEUROSVM. So, a natural question arises, will other combinations perform better with majority voting or averaging than NEUROSVM? To investigate this we have compared the performance of NEUROSVM using the combinations selected by cross-validation separately for each of MVOTING and AVERAGING. Following the same protocol as used for NEUROSVM, the SFMs for MVOTING and AVERAGING are selected using the double ten-fold cross-validation for Group A data sets and ten-fold cross-validation for Group B data sets. The selected combinations of

Table 7: Performance comparison of NEUROSVM with baseline classifiers and standard ensemble methods

the standard ensemble methods for 8 data sets when compared with majority voting and for 7 data sets when compared with averaging. Here also no data set is found where two ensemble methods perform better than NEUROSVM. Hence we can conclude that NEUROSVM performs consistently better than majority voting and averaging.

3.3.5 PERFORMANCE COMPARISON OF OTHER VARIANTS OF NEUROSVM WITH BASELINE CLASSIFIERS AND STANDARD ENSEMBLE METHODS

As stated earlier, for the proposed architecture, in the classification module we can use other tools also. Here we demonstrate the effect of using MLP and RBF neural networks in the classification module instead of SVM. We termed these two architectures as NMLP and NRBF respectively. The combination of SFMs and the number of hidden nodes for MLP and RBF networks in the classification module are selected using double ten-fold cross-validation for Group A data sets and using ten-fold cross-validation for Group B data sets. The performance comparison of these variants of NEUROSVM with the original NEUROSVM is shown in Table 10. From Table 10, we see that original NEUROSVM is significantly better than other variants for 4 data sets when compared with NMLP and better than 2 data sets when compared with NRBF. The performance of NEUROSVM and NMLP is equally well for 8 data sets. There is no significant difference in performance between NEUROSVM and NRBF for 10 data sets. For six out of twelve data sets, all three variants of the proposed architecture perform equally well. So, proposed architecture can be considered a general one.

Now we compare the performance of baseline classifiers and two ensemble methods with the two new variants of NEUROSVM, that is, NMLP and NRBF, by statistical test. These results are summarized in Table 11 for NMLP and in Table 12 for NRBF. The results of MVOTING and AVERAGING are obtained in Table 11 and Table 12 using the same combinations of SFMs that are

Data set		Selected combinations

Table 8: The combination of SFMs for MVOTING and AVERAGING selected by cross-validation for each of the twelve data sets

used in the FM of NMLP and NRBF respectively. From Table 11 we can see that NMLP performs significantly better than baseline classifiers for 8 data sets when compared with MLP and better than 5 data sets when compared with SVM. The NMLP performs significantly better than MVOTING on 8 data sets. It also performs significantly better than AVERAGING for 7 data sets. From Table 12, it is observed that NRBF performs significantly better than MLP on 8 data sets and it is better than SVM for 4 data sets. The SVM performs significantly better than NRBF *only* with one data set. When compared with the standard ensemble methods the NRBF is found to perform significantly better for majority of the data sets. For example, NRBF performs significantly better than majority voting for 8 data sets and better than averaging for 7 data sets.

Now we compare the results of NMLP and NRBF with the results of MVOTING and AVERAGING in Table 9 by statistical test. We find that the NMLP is significantly better than the standard ensemble methods for 3 data sets (Pima, Pendigits and Sat. Img.) when compared with majority voting and for 2 data sets (Pima and Pendigits) when compared with averaging. The NRBF performs

bold/*Italic* significantly worse/better than NRBF using ten-fold cross-validation paired t-test for Group A data sets and McNemar test for Group B data sets.

Table 12: Performance comparison of NRBF with baseline classifiers and standard ensemble methods

3.4 Controlled Experiments - Avoiding Full Training of Networks for Feature Extraction

We have mentioned in Section 2.6 that for large data sets it may not be necessary to make full training of the MLPs for constructing the SFMs. Now we are going to prove it by experiments. We consider two data sets, one from each group for this experiment. More specifically, we use the Sonar data (in 60 dimension) from Group A and Optdigits (in 64 dimension) from Group B.

We have conducted the experiments as before for NEUROSVM except we stop the training of MLPs to construct SFMs only after 100 iterations. In this case, we have obtained the test error of 0.135 ± 0.087 for Sonar and 0.023 for Optdigits data sets. By statistical test we observe that these errors are not significantly different from the previous NEUROSVM errors when the MLPs were fully trained.

4. The Kernel Independence of NEUROSVM

In this section we shall illustrate an attractive feature of NEUROSVM, its kernel independence. In order to perform such study we choose three kernels for SVM: linear, RBF and polynomial. We choose these kernels also for SVMs in the classification module of NEUROSVM. The different kernels are tried with a set of parameters. We perform ten-fold (double ten-fold for Group A data sets) cross-validation to select the best parameter set for each kernel of SVM. We also conducted cross-validation experiments to select the best combination of SFMs and hyper parameters of NEUROSVM for each of three choices of kernel. For the RBF kernel we choose 12 different C and 15 different γ resulting 180 pairs. Similarly, for the polynomial kernel we choose 12 different C, 5 different degrees d and 7 different scaling coefficients of dot products s resulting 420 triplets and 12 different C are used in linear kernel. The values of C and γ are presented in Section 3.3.2. The five values of d for the polynomial kernel are $2, 3, 4, 5$ and 6. The seven different choices of s are 0.001, 0.01, 0.10, 1.00, 10.00, 100.00 and 1000.00.

In Figure 4, the test errors of SVM and NEUROSVM with three choices of kernel for the twelve data sets are shown. It is clear from Figures 4(b)-4(h) that the performance of SVM significantly depends on the choice of kernels for Vehicle, WDBC, Glass, Sonar, Ionosphere, Lymph and Pima data sets respectively. Also the kernel dependency of SVM is noticeable for the data sets Iris, Pendigits, Img. Seg. and Optdigits (Figure 4(a), 4(i), 4(j) and 4(l)). Only for the Sat. Img. the SVM produces almost the same test errors for all three choices of kernel. On the other hand, from Figures 4(a)-4(l) we see that the performance of NEUROSVM for eight (out of the twelve) data sets practically does not depend on the choice of kernels. To observe it more closely for each data set we find out the difference of percentage errors between the maximum and minimum errors produce by the three kernels for SVM and NEUROSVM (Table 13). To explain the entries in Table 13, consider the WDBC data set. The test errors produced by SVM on WDBC data set with the three kernels are 0.049, 0.070 and 0.095 respectively. Hence the minimum and maximum errors are 0.049 and 0.095 respectively. So, the difference in error rates and hence the percentage are 0.046 and 4.60% respectively. Whereas the test error rates for NEUROSVM on WDBC data set with the three kernels are $0.023, 0.019$ and 0.023 respectively. Here the minimum, maximum and percentage of difference of these two errors are $0.019, 0.023$ and 0.40% respectively. From Table 13, it is clear that for eight data sets the performance of NEUROSVM using the three kernels remains almost the same (with error less than 1%). On the other hand, with SVM only for Sat. Img. the difference is less than 1%. Thus NEUROSVM is found to perform equally well with different choices of kernels of the SVM in the classification module.

5. Conclusions

We have proposed a multilayer classifier architecture consisting of two modules. The first module is the feature extraction module (FM), while the second module is the classification module (CM). In

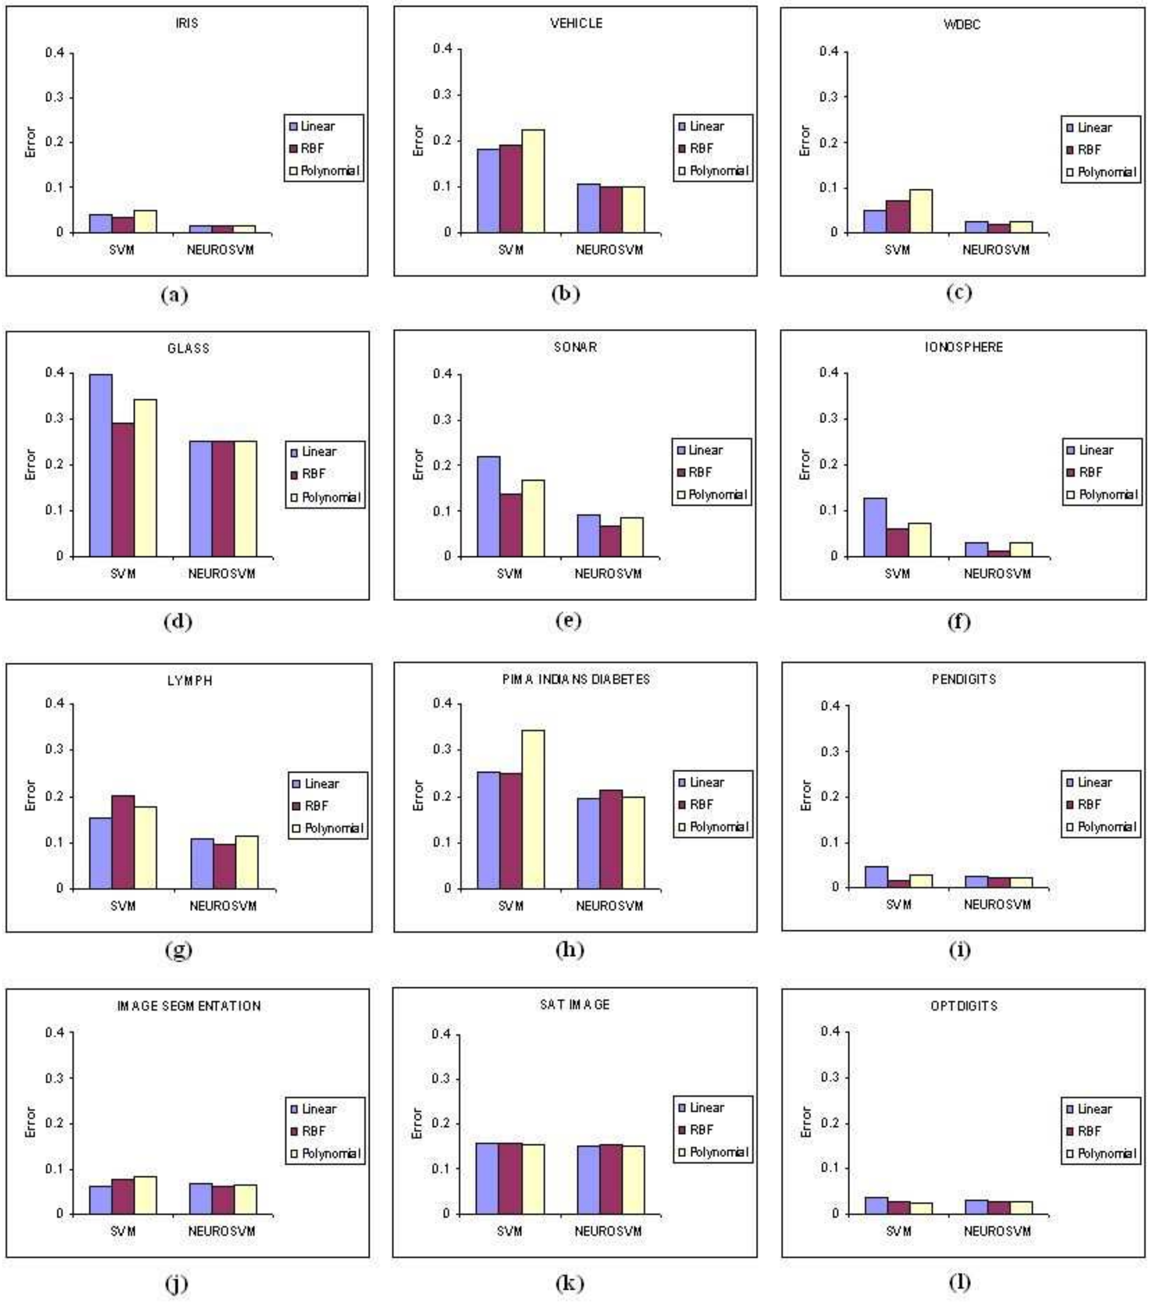

Figure 4: Comparison of the test errors of SVM and NEUROSVM for twelve data sets using Linear, RBF, and Polynomial kernels.

	Differences of the percentage error	
Data set	SVM	NEUROSVM
Iris	1.40%	0.00%
Vehicle	4.10%	0.60%
WDBC	4.60%	0.40%
Glass	10.80%	0.00%
Sonar	8.40%	2.30%
Ionosphere	6.50%	2.10%
Lymph	4.80%	2.00%
Pima	9.30%	1.40%
Pendigits	2.70%	0.10%
Img. Seg.	1.90%	0.90%
Sat. Img.	0.20%	0.20%
Optdigits	1.40%	0.10%

Table 13: Differences of the percentage errors between the maximum and minimum errors produced by linear, RBF and polynomial kernels for SVM and NEUROSVM

the FM, we have used MLP, while for the CM we have used SVM resulting in the classifier, called NEUROSVM. The architecture is general in nature and both for FM and CM other tools can be used. We have experimented using RBF and MLP in the CM. We have tested the performance of the proposed system on twelve benchmark data sets and NEUROSVM is found to perform consistently better than MLP and SVM. The performance of NEUROSVM is also better than the ensemble methods based on majority voting and averaging. A noticeable feature of NEUROSVM is that nonlinear NEUROSVM and linear NEUROSVM perform equally well on all data sets tried.

Other advantages of NEUROSVM are as follows:

- For large data sets, it may not be necessary to make a full training of the MLPs in the FM because in an MLP, the extraction of the salient feature of the data is done at the beginning of the training.

- Typically the number of nodes in the hidden layer of MLPs is much smaller than the number of the input nodes, and one does not need many feature extraction sub-modules. Hence, the dimensionality of the input for the SVMs (or MLP/RBF) in the classification module can be reduced compared to the original dimension of the input. So, for solving bioinformatics problems such as protein secondary structure prediction or protein fold recognition such an architecture may be very useful.

- It may be viewed as an implicit fusion of multiple classifiers and hence the improvement in performance is expected.

We have demonstrated the advantages of the proposed architecture by good experimental results. In our experimental results we have noticed that most of the time out of the 5 SFMs, 2 or 3 are selected for NEUROSVM by the cross-validation method. This limited use of the architectures could be due to the fact that all networks are trained using the same data and some of the networks may be extracting similar information from the data. We are currently working on developing a more theoretical view of our proposed method that may help further explain the results reported here.

Appendix A. Procedure DataPreparation

```
Input:   A data set $X$
Output: Training and test data sets
Algorithm:
        1.  if $X$ belongs to Group A then
        2.    Set $no\_of\_fold = 10$.
        3.    $X$ is randomly partitioned into 10 subsets $X_i; i = 1, 2, \ldots, 10$
              such that, $X = \bigcup_{i=1}^{10} X_i, X_i \cap X_j = \phi, i \neq j$.
        4.    Get the training set for fold $i$ of $X$ as $XT_i = \bigcup_{j \neq i} X_j$ and the test data set is
              $XTe_i = X_i$. So we get 10 training-test set $(XT_i, XTe_i), i = 1, 2, , 10$.
        5.  else /* for Group B data sets */
        6.    Set $no\_of\_fold = 1$.
        7.    Let the training set be $XT_1$ and the test set be $XTe_1$ .
        8.  end if
End DataPreparation
```

NB: For a given data set (in Group A), the Procedure DataPreparation returns the same outer level ten-folds to RunMLP, RunSVM and RunNEUROSVM.

Appendix B. Procedure RunMLP

```
Input:   A data set X.
           A set of hidden nodes $H = \{h_1, h_2, \ldots, h_m\}$.
Output: Test error of MLP on X
Algorithm:
        1.  Perform DataPreparation
        2.  for $i = 1$ to $no\_of\_fold$
          /* To choose the optimal network size for $XT_i$, we use ten-fold cross-validation
          experiment on $XT_i$ */
        3.    $XT_i$ is divided into 10 equal (or almost equal) parts $Z_j; j = 1, 2, \ldots, 10$
              such that, $XT_i = \bigcup_{j=1}^{10} Z_j, Z_j \cap Z_k = \phi, j \neq k$ .
        4.    Get the training set for fold $j$ of $XT_i$ as $ZT_j = \bigcup_{k \neq j} Z_k$ and the validation
              set as $ZV_j = Z_j$. So we get 10 training-validation set $(ZT_j, ZV_j)$,
              $j = 1, 2, \ldots, 10$ for fold $i$ of $X$.
        5.    for each $a$ in $\{h_1, h_2, \ldots, h_m\}$
        6.      for $j = 1$ to 10
        7.          Train a network (MLP) for architecture $a$ with training data set $ZT_j$
                    and find validation error on $ZV_j$. Let the validation error with fold
                    $(ZT_j, ZV_j)$ be $e_j^a$.
```

```
 8.        end for /* end for $j$ */
 9.        The average validation error for an architecture $a$ related to $XT_i$ of the
           original fold $(XT_i, XTe_i)$ is $\bar{e}_i^a = \frac{1}{10}\sum_{j=1}^{10} e_j^a$.
10.      end for /* end of for $a$ */
11.      Let $\bar{e}_i^k = \min_a\{\bar{e}_i^a\}$, then we choose $k$ as the optimal architecture for fold $XT_i$.
12.      Train a network (MLP) for architecture $k$ with training data $XT_i$ and find
         test error on $XTe_i$. Let the test error with fold $(XT_i, XTe_i)$ be $E_i$.
13.    end for /* end of for $i$ */
14.    Find average test error $\bar{E} = \frac{1}{no\_of\_fold}\sum_{i=1}^{no\_of\_fold} E_i$.
```

End RunMLP

Appendix C. Procedure RunSVM

Input: A data set X.
A set of 12 choices of C and 15 choices of γ for RBF kernel resulting in a total of 180 pairs of (C,γ).
Output: Test error of SVM on X
Algorithm:

```
  1.   **Perform DataPreparation**
  2.   for $i = 1$ to $no\_of\_fold$
         /* To choose the best $(C,\gamma)$ pair for $XT_i$, we use ten-fold cross-validation
          experiment on $XT_i$ */
3-4.     Same as steps 3-4 of RunMLP
  5.     for each $(C_k,\gamma_k)$ pair on 180 pairs
  6.       for $j = 1$ to $10$
  7.         Train SVM with parameters $(C_k,\gamma_k)$ of RBF kernel for training
             data $ZT_j$ and find validation error on $ZV_j$.
             Let the validation error with fold $(ZT_j, ZV_j)$ be $e_j^k$.
  8.       end for /* end of for $j$ */
  9.       The average validation error for $(C_k,\gamma_k)$ pair related to $XT_i$ of the
           original fold $(XT_i, XTe_i)$ is $\bar{e}_i^k = \sum_{j=1}^{10} e_j^k$.
 10.     end for /* end of for $(C_k,\gamma_k)$ */
 11.     Let $\bar{e}_i^m = \min_k\{\bar{e}_i^k\}$, then we choose $(C_m,\gamma_m)$ pair as the best hyper
         parameters for fold $XT_i$.
 12.     Train SVM with RBF kernel and $(C_m,\gamma_m)$ pair with training data $XT_i$ and
         find test error on $XTe_i$. Let the test error with fold $(XT_i, XTe_i)$ be $E_i$.
 13.   end for /* end of for $i$ */
 14.   Find average test error $\bar{E} = \frac{1}{no\_of\_fold}\sum_{i=1}^{no\_of\_fold} E_i$.
```

End RunSVM

Appendix D. Procedure RunNEUROSVM

```
Input:  A data set $X$.
          A set of hidden nodes $H = \{h_1, h_2, \ldots, h_m\}$.
          A set of 12 choices of $C$ and 15 choices of $\gamma$ for RBF kernel resulting in a total
          of 180 pairs of $(C,\gamma)$.
Output: Test error of NEUROSVM on $X$
Algorithm:
        1.  **Perform DataPreparation**
        2.  for $i = 1$ to $no\_of\_fold$
              /* To choose 5 MLPs for 5 SFMs for $XT_i$, we use ten-fold cross-validation
              experiment on $XT_i$ */
     3-10.      Same as steps 3-10 of RunMLP
       11.      We need to select 5 MLP architectures for 5 SFMs to construct NEUROSVM.
                The best 5 architectures corresponding to the smallest 5 values of $\bar{e}_i^a$.
                In other word, we select 5 architecture $(a_{i1}, a_{i2}, \ldots, a_{i5})$ where
                $\bar{e}_i^{a_{i1}}, \bar{e}_i^{a_{i2}}, \ldots, \bar{e}_i^{a_{i5}}, \ldots$ is the sequence of $\bar{e}_i^a$'s sorted in ascending order.
       12.      Train 5 networks with above 5 selected architectures for training data $XT_i$.
       13.      Find projected data of $(XT_i, XTe_i)$ from hidden layer of above 5 MLPs
                and hence we get 5 SFMs.
       14.      Construct $2^5 - 1 = 31$ combinations of projected data using 5 SFMs, that is,
                31 sets of training-test data using 5 SFMs. So, we get 31 sets of training-test
                data $(\tilde{Z}T_p^i, \tilde{Z}Te_p^i), p = 1, 2, \ldots, 31$ for NEUROSVM.
                /* To select the best combination among 31 combinations and $(C,\gamma)$ pair
                of RBF kernel of SVM in the classification module we perform ten-fold
                cross-validation experiment */
       15.      for $p = 1$ to $31$
       16.          Perform ten-fold cross-validation as steps 3-10 of RunSVM on $\tilde{Z}T_p^i$.
       17.          Choose $(C,\gamma)$ for combination $p$ with minimum average validation error
                    say $\bar{e}_i^p$.
       18.      end for /* end of for $p$ */
       19.      Finally choose $k^{th}$ combination and corresponding $(C,\gamma)$ pair (say $(C_k,\gamma_k)$)
                where $\bar{e}_i^k = \min_p \{\bar{e}_i^p\}$ .
       20.      Train SVM with training data $\tilde{Z}T_k^i$ and $(C_k,\gamma_k)$ pair of RBF kernel.
                Find test error on $\tilde{Z}Te_k^i$ , say test error is $E_i$.
       21.  end for /* end of for $i$ */
       22.  Find average test error $\bar{E} = \frac{1}{no\_of\_fold} \sum_{i=1}^{no\_of\_fold} E_i$.
**End RunNEUROSVM**
```

Abstract

The collaborative filtering (CF) using known user ratings of items has proved to be effective for predicting user preferences in item selection. This thriving subfield of machine learning became popular in the late 1990s with the spread of online services that use recommender systems, such as Amazon, Yahoo! Music, and Netflix. CF approaches are usually designed to work on very large data sets. Therefore the scalability of the methods is crucial. In this work, we propose various scalable solutions that are validated against the Netflix Prize data set, currently the largest publicly available collection. First, we propose various matrix factorization (MF) based techniques. Second, a neighbor correction method for MF is outlined, which alloys the global perspective of MF and the localized property of neighbor based approaches efficiently. In the experimentation section, we first report on some implementation issues, and we suggest on how parameter optimization can be performed efficiently for MFs. We then show that the proposed scalable approaches compare favorably with existing ones in terms of prediction accuracy and/or required training time. Finally, we report on some experiments performed on MovieLens and Jester data sets.

Keywords: collaborative filtering, recommender systems, matrix factorization, neighbor based correction, Netflix prize

1. Introduction

Recommender systems attempt to profile user preferences over items, and model the relation between users and items. The task of recommender systems is to recommend items that fit a user's tastes, in order to help the user in selecting/purchasing items from an overwhelming set of choices. Such systems have great importance in applications such as e-commerce, subscription based services, information filtering, etc. Recommender systems providing personalized suggestions greatly increase the likelihood of a customer making a purchase compared to unpersonalized ones. Personalized recommendations are especially important in markets where the variety of choices is large, the taste of the customer is important, and last but not least the price of the items is modest. Typical areas of such services are mostly related to art (esp. books, movies, music), fashion, food and restaurants, gaming and humor.

With the burgeoning of web based businesses, an increasing number of web based merchant or rental services use recommender systems. Some of the major participants of e-commerce web, like Amazon and Netflix, successfully apply recommender systems to deliver automatically generated personalized recommendation to their customers. The importance of a good recommender system was recognized by Netflix, which led to the announcement of the Netflix Prize (NP) competition to motivate researchers to improve the accuracy of the recommender system of Netflix (see details in Section 5.1.1).

There are two basic strategies that can be applied when generating recommendations. *Content-based approaches* profile users and items by identifying their characteristic features, such us demographic data for user profiling, and product information/descriptions for item profiling. The profiles are used by algorithms to connect user interests and item descriptions when generating recommendations. However, it is usually laborious to collect the necessary information about items, and similarly it is often difficult to motivate users to share their personal data to help create the database for the basis of profiling.

Therefore, the alternative approach, termed *collaborative filtering* (CF), which makes use of only past user activities (for example, transaction history or user satisfaction expressed in ratings), is usually more feasible. CF approaches can be applied to recommender systems independently of the domain. CF algorithms identify relationships between users and items, and make associations using this information to predict user preferences.

In this paper, we focus on the case when users express their opinion of items by means of ratings. In this framework, the user first provides ratings of some items, titles or artifacts, usually on a discrete numerical scale, and the system then recommends other items based on ratings the *virtual community* has already provided. The virtual community was defined by Hill et al. (1995) as "a group of people who share characteristics and interact in essence or effect only." The underlying assumption is that people who had similar tastes in the past may also agree on their tastes in the future.

1.1 Related Work

The first works on the field of CF were published in the early 1990s. Goldberg et al. (1992) presented the Tapestry system that used collaborative filtering to filter mails simultaneously from several mailing lists, based on the opinion of other users on the readings. Resnick et al. (1994) described the GroupLens system that was one of the pioneer applications of the field where users could rate articles on a 1–5 scale after having read them and were then offered suggestions. Breese et al. (1998)

divided the underlying techniques of predicting user preferences into two main groups. *Memory-based* approaches operate on the entire database of ratings collected by the vendor or service supplier. On the other hand, *model-based* approaches use the database to estimate or learn a model and then apply this model for prediction.

Over the last broad decade many CF algorithms have been proposed that approach the problem by different techniques, including similarity/neighborhood based approaches (Resnick et al., 1994; Sarwar et al., 2001), personality diagnosis (Pennock et al., 2000), Bayesian networks (Breese et al., 1998), restricted Boltzmann machines (RBM) (Salakhutdinov et al., 2007), and various matrix factorization techniques (Canny, 2002; Hofmann, 2004; Sarwar et al., 2000; Srebro et al., 2005). Vozalis and Margaritis (2007) presented an MF approach that incorporates demographic information and ratings to enhance plain CF algorithms. Breese et al. (1998) surveyed in detail the major CF approaches of the early years, Rashid et al. (2006) gave a short description of most recent methods, and Adomavicius and Tuzhilin (2005) also investigated in their survey the possible extensions.

The NP competition boosted the interest in CF, and yielded the publication of a number of new methods. We should also mention here the NP related KDD Cup and Workshop (Bennett et al., 2007), which indicated the possible directions of scalable and accurate CF methods. We feature among them the matrix factorization, neighbor based approaches, and their combinations.

Several matrix factorization techniques have been successfully applied to CF, including singular value decomposition (Sarwar et al., 2000), probabilistic latent semantic analysis (Hofmann, 2004), probabilistic matrix factorization (Salakhutdinov and Mnih, 2008), maximum margin matrix factorization (Srebro et al., 2005), expectation maximization for MF (Kurucz et al., 2007), and alternating least squares (Bell and Koren, 2007a).

Simon Funk (Brandyn Webb) published a detailed implementation of a regularized MF with separate feature update.[1] Paterek (2007) introduced a bunch of novel techniques, including MF with biases, applying kernel ridge regression on the residual of MF, linear model for each item, and asymmetric factor models (NSVD1, NSVD2). Kurucz et al. (2007) showed the application of expectation maximization based MF methods for the NP. Bell and Koren (2007a) presented an improved neighborhood based approach, which removes the global effect from the data, and calculates optimal similarity values by solving regression problems. Salakhutdinov et al. (2007) mention without details a momentum based MF method that uses batch learning.

Our methods are different from the above ones in various aspects. Bell and Koren (2007a) use alternate least squares, but we use incremental gradient descent (also known as stochastic gradient descent) method for weight updates. Their method does not use the chronological order of ratings, while we exploit this information in our approaches. They use only positive and ordinary MFs, while we propose the semi-positive version of the MF algorithm. Paterek (2007) applies a different learning scheme following Simon Funk's path (see the detailed comparison in Section 3.1). We point out that this difference makes our training process somewhat faster and does not deteriorate the accuracy. Other differences are that Paterek uses fewer meta-parameters for his MF methods. Salakhutdinov et al. (2007) apply a momentum based MF with batch learning, but we point out that incremental gradient descent is more appropriate for large scale problems.

1.2 Main Results and Organization

The aim of this work is to propose accurate and scalable solutions for a class of collaborative filtering problems. Scalability is crucial since CF systems often have to manage millions of users or items. As it was shown by many researchers (see for example Bell et al., 2007b) combination (also termed blending) of various algorithms typically outperforms single methods in terms of accuracy. Therefore, we would like to emphasize here that a particular method can have beneficial impact on the overall accuracy if (1) it yields a very accurate model on its own or (2) it "blends well", that is it improves the accuracy of the combination of several models. The methods proposed in this paper satisfy one or both of these criteria. We classify the methods presented in this paper into 4 categories:

- crucial in improving accuracy or run-time;
- may negligibly improve accuracy, in a way that is more important for competitions than for real life data;
- does not improve accuracy, but is useful for blending with other techniques;
- important for real life data.

This paper is organized as follows. Section 2 defines the CF setting we focus on in this work. Section 3 describes our proposed MF algorithms. In particular, we present

- a regularized MF and its biased version that use an incremental gradient descent weight updating scheme, termed as RISMF and BRISMF, (biased) regularized incremental simultaneous MF;
- a fast (semi-)positive MF version that approximates the features by using nonnegative values for either users or items or both;
- an accurate momentum based MF approach;
- an incremental variant of MF that efficiently handles new users/ratings (this is crucial in a real-life recommender systems);
- a transductive version of MF that makes use of information from test instances (namely the ratings users have given for certain items) to improve prediction accuracy.

We also introduce a special MF version that supports the visualization of user/item features, which can be used to generate explanation for recommendations. Finally, we illustrate that the learning scheme of some MF algorithms can be directly described in the neural network framework.

Section 4 presents a neighbor based correction approach for MF, which alloys the global perspective of MF and the localized property of neighbor based approaches efficiently. We propose here two similarity functions for items.

Section 5 contains the experiments. First, we introduce the Netflix Prize data set against which our proposed algorithms are validated. In addition, we also describe the MovieLens and the Jester data sets, on which we also run some experiments. Next, we mention some important implementation issues: we comment on the efficient storage of very large rating databases, we consider the proper ordering of training examples, and we outline our parameter optimization heuristic. We then report on our comprehensive experiments run on the NP data set. In order to illustrate the applicability of MF methods to other data sets, we also report on tests executed with a selected MF method, BRISMF, on the MovieLens and Jester data sets and compare the results with baseline predictors. For the NP data set, we report on the results of each proposed method and the most accurate combinations of methods. We briefly analyze the accuracy-time complexity trade-off of MF methods. We finally compare our results to other published ones to show that the proposed methods are comparable to the existing one in terms of root mean squared error (RMSE). We also discuss the time complexity of some selected methods, and we point out that it compares favorably to similar type methods published so far. We further mention here that all the presented methods are part of the blended solution of our team Gravity in the NP contest.

2. Problem Definition

We define the problem of *collaborative filtering* (CF) in the following setting. The problem can be modeled by the random triplet (U,I,R), where

- U taking values from $\{1,\dots,N\}$ is the *user identifier* (N is the number of users),
- I taking values from $\{1,\dots,M\}$ is the *item identifier* (M is the number of items), and
- R taking values from $\mathcal{X} \subset \mathbb{R}$ is the rating value. Typical rating values can be binary ($\mathcal{X} = \{0,1\}$), integers from a given range (for example, $\mathcal{X} = \{1,2,3,4,5\}$), or real numbers of a closed interval (for example, $\mathcal{X} = [-10,10]$).

A realization of (U,I,R) denoted by (u,i,r) means that user u rated item i with value r.

The goal is to estimate R from (U,I) such that the root mean squared error of the estimate,

$$\mathrm{RMSE} = \sqrt{\mathbf{E}\{(\hat{R}-R)^2\}}, \tag{1}$$

is minimal, where $\hat{R}$ is the estimate[2] of R. We briefly discuss other possible evaluation metrics in CF in Section 5.

In practice, the distribution of (U,I,R) is not known: we are only given a finite sample, $\mathcal{T}' = \{(u_1,i_1,r_1),(u_2,i_2,r_2),\dots,(u_t,i_t,r_t)\}$, generated by it. The sample $\mathcal{T}'$ can be used for training predictors. We assume *sampling without replacement* in the sense that (user ID, item ID) pairs are unique in the sample, which means that users do not rate items more than once. Let us introduce the notation $\mathcal{T} = \{(u,i) : \exists r : (u,i,r) \in \mathcal{T}'\}$ for the set of (user ID, item ID) pairs. Note that $|\mathcal{T}'| = |\mathcal{T}|$, and typically $|\mathcal{T}| \ll N \cdot M$, because most of the users rate only a small subset of the entire set of items. The sample can be represented as a partially specified matrix denoted by $\mathbf{R} \in \mathbb{R}^{N\times M}$, where the matrix elements are known in positions $(u,i) \in \mathcal{T}$, and unknown in positions $(u,i) \notin \mathcal{T}$. The value of the matrix $\mathbf{R}$ at position $(u,i) \in \mathcal{T}$, denoted by r_{ui}, stores the rating of user u for item i. For clarity, we use the term (u,i)-th rating in general for r_{ui}, and (u,i)-th training example if $r_{ui} : (u,i) \in \mathcal{T}$.

2. In general, superscript "hat" denotes the prediction of the given quantity, so $\hat{x}$ is the prediction of x.

The goal of this CF setup is to create such predictors that aim at minimizing the error (1). In practice, we cannot measure the error because the distribution of (U,I,R) is unknown, but we can estimate the error on a validation set. Let us denote the validation set by $\mathcal{V}' \subset [1,\dots,N] \times [1,\dots,M] \times \mathcal{X}$, assuming sampling without replacement as defined above, and we further assume the uniqueness of (user ID, item ID) pairs across $\mathcal{T}'$ and $\mathcal{V}'$. We define $\mathcal{V} = \{(u,i) : \exists r : (u,i,r) \in \mathcal{V}'\}$. The assumptions ensure that $\mathcal{T} \cap \mathcal{V} = \emptyset$. If both the training set $\mathcal{T}'$ and validation set $\mathcal{V}'$ are generated from the same distribution the estimate of RMSE can be calculated as

$$\widehat{\text{RMSE}} = \sqrt{\frac{1}{|\mathcal{V}|} \sum_{(u,i)\in\mathcal{V}} (\hat{r}_{ui} - r_{ui})^2}.$$

For better readability, from now on we omit the "hat" from the RMSE, recalling that we always calculate the estimate of the error.

When we predict a given rating r_{ui} by $\hat{r}_{ui}$ we refer to the user u as *active user* and to the item i as *active item*. The (u,i) pair of active user and active item is termed *query*.

3. Matrix Factorization

Matrix factorization is one of the most often applied techniques for CF problems. Numerous different MF variants have been already published and were validated against the NP data set as well. We should credit here again Simon Funk, who published the first detailed implementation notes on this problem. He applied a regularized MF with gradient descent learning scheme. His model trained factors one after another, which can be considered as a series of 1 factor MF training processes performed on the residual of the previous one. Other efficient MF variants were published by Bell and Koren (2007a), where they used alternating least squares for weight updates. Biased MF was applied by Paterek (2007), whose technique was also proposed at the same time in our previous work (Takács et al., 2007) as "constant values in matrices".

In this section we give an overview of our MF variants that proved to be effective in tackling the large scale practical problem of NP, and hence may be considered as a useful collection of tools for practitioners. Here we also propose several modifications for already known MF variants, which are effective in improving the accuracy of the generated models. We also give details concerning the time requirement of certain methods and propose efficient implementation solutions.

The idea behind MF techniques is very simple. Suppose we want to approximate the matrix $\mathbf{R}$ as the product of two matrices:

$$\mathbf{R} \approx \mathbf{PQ},$$

where $\mathbf{P}$ is an $N \times K$ and $\mathbf{Q}$ is a $K \times M$ matrix. We call $\mathbf{P}$ the user feature matrix and $\mathbf{Q}$ the item feature matrix, and K is the number of features in the given factorization. If we consider the matrices as linear transformations, the approximation can be interpreted as follows: matrix $\mathbf{Q}$ is a transform from $\mathcal{S}_1 = \mathbb{R}^M$ into $\mathcal{S}_2 = \mathbb{R}^K$, and matrix $\mathbf{P}$ is a transform from $\mathcal{S}_2$ into $\mathcal{S}_3 = \mathbb{R}^N$. Typically, $K \ll N$ and $K \ll M$, therefore the vector space $\mathcal{S}_2$ acts as a bottleneck when predicting $\mathbf{v}_3 \in \mathcal{S}_3$ from $\mathbf{v}_1 \in \mathcal{S}_1$. In other words, the number of parameters to describe $\mathbf{R}$ can be reduced from $|\mathcal{T}|$ to $NK + KM$. Note that $\mathbf{Q}$ and $\mathbf{P}$ typically contain real numbers, even when $\mathbf{R}$ contains only integers.

In the case of the given problem, the unknown ratings of $\mathbf{R}$ cannot be represented by zero. For this case, the approximation task can be defined as follows. Let p_{uk} denote the elements of

$\mathbf{P} \in \mathbb{R}^{N\times K}$, and q_{ki} the elements of $\mathbf{Q} \in \mathbb{R}^{K\times M}$. Further, let $\mathbf{p}_u$ denote a row (vector) of $\mathbf{P}$, and $\mathbf{q}_i$ a column (vector) of $\mathbf{Q}$. Then:

$$\hat{r}_{ui} = \sum_{k=1}^{K} p_{uk} q_{ki} = \mathbf{p}_u \mathbf{q}_i, \tag{2}$$

$$e_{ui} = r_{ui} - \hat{r}_{ui} \quad \text{for } (u,i) \in \mathcal{T},$$

$$e'_{ui} = \frac{1}{2} e_{ui}^2, \tag{3}$$

$$\mathrm{SSE} = \sum_{(u,i)\in\mathcal{T}} e_{ui}^2 = \sum_{(u,i)\in\mathcal{T}} \left(r_{ui} - \sum_{k=1}^{K} p_{uk} q_{ki} \right)^2,$$

$$\mathrm{SSE}' = \frac{1}{2}\mathrm{SSE} = \sum_{(u,i)\in\mathcal{T}} e'_{ui},$$

$$\mathrm{RMSE} = \sqrt{\mathrm{SSE}/|\mathcal{T}|},$$

$$(\mathbf{P}^*, \mathbf{Q}^*) = \arg\min_{(\mathbf{P},\mathbf{Q})} \mathrm{SSE}' = \arg\min_{(\mathbf{P},\mathbf{Q})} \mathrm{SSE} = \arg\min_{(\mathbf{P},\mathbf{Q})} \mathrm{RMSE}. \tag{4}$$

Here $\hat{r}_{ui}$ denotes how the u-th user would rate the i-th item, according to the model, e_{ui} denotes the training error measured at the (u,i)-th rating, and SSE denotes the sum of squared training errors. Eq. (4) states that the optimal $\mathbf{P}$ and $\mathbf{Q}$ minimize the sum of squared errors only on the known elements of $\mathbf{R}$.

In order to minimize RMSE, which is in this case equivalent to minimizing SSE$'$, we apply a simple incremental gradient descent method to find a local minimum of SSE$'$, where one gradient step intends to decrease the square of prediction error of only one rating, or equivalently, either e'_{ui} or e_{ui}^2.

Minimizing RMSE can be seen as a weighted low-rank approximation of $\mathbf{R}$. Weighted low-rank approximations try to minimize the objective function $\mathrm{SSE_W} = \sum_{u=1}^{N}\sum_{i=1}^{M} w_{ui} \cdot e_{ui}^2$, where w_{ui}-s are predefined non-negative weights. For collaborative filtering problems, w_{ui} is 1 for known ratings, and 0 for unknown ratings. Srebro and Jaakkola (2003) showed that when the rank of $((w_{ui}))$ is 1, all local minima are global minima. However, when it is greater than 1—as in the case of collaborative filtering—this statement does not hold any more, which was shown by the authors via counterexamples.

For the incremental gradient descent method, suppose we are at the (u,i)-th training example, r_{ui}, and its approximation $\hat{r}_{ui}$ is given.

We compute the gradient of e'_{ui}:

$$\frac{\partial}{\partial p_{uk}} e'_{ui} = -e_{ui} \cdot q_{ki}, \qquad \frac{\partial}{\partial q_{ki}} e'_{ui} = -e_{ui} \cdot p_{uk}.$$

We update the weights in the direction opposite to the gradient:

$$p'_{uk} = p_{uk} + \eta \cdot e_{ui} \cdot q_{ki},$$
$$q'_{ki} = q_{ki} + \eta \cdot e_{ui} \cdot p_{uk}.$$

That is, we change the weights in $\mathbf{P}$ and $\mathbf{Q}$ to decrease the square of actual error, thus better approximating r_{ui}. Here η is the learning rate. This basic MF method is referred to as ISMF, that is incremental simultaneous MF, due to its distinctive incremental and simultaneous weight updating method to other MF methods.

When the training has been finished, each value of $\mathbf{R}$ can be computed easily using Eq. (2), even at unknown positions. In other words, the model ($\mathbf{P}^*$ and $\mathbf{Q}^*$) provides a description of how an arbitrary user would rate any item.

3.1 RISMF

The matrix factorization presented in the previous section can overfit for users with few (no more than K) ratings: assuming that the feature vectors of the items rated by the user are linearly independent and $\mathbf{Q}$ does not change, there exists a user feature vector with zero training error. Thus, there is a potential for overfitting, if η and the extent of the change in $\mathbf{Q}$ are both small. A common way to avoid overfitting is to apply regularization by penalizing the square of the Euclidean norm of weights. This is often used in machine learning methods, for example Support Vector Machines and ridge regression apply that. It is common also in neural networks, where it is termed as weight decay (Duda et al.). Penalizing the weights results in a new optimization problem:

$$\begin{aligned} e'_{ui} &= (e_{ui}^2 + \lambda \cdot \mathbf{p}_u \cdot \mathbf{p}_u^T + \lambda \cdot \mathbf{q}_i^T \cdot \mathbf{q}_i)/2, \\ \mathrm{SSE}' &= \sum_{(u,i)\in\mathcal{T}} e'_{ui}, \\ (\mathbf{P}^*, \mathbf{Q}^*) &= \operatorname*{arg\,min}_{(\mathbf{P},\mathbf{Q})} \mathrm{SSE}'. \end{aligned} \tag{5}$$

Here $\lambda \geq 0$ is the regularization factor. Note that minimizing SSE' is no longer equivalent to minimizing SSE, unless $\lambda = 0$, in which case we get back the ISMF. We call this MF variant RISMF that stands for regularized incremental simultaneous MF.

Similar to the ISMF approach, we compute the gradient of e'_{ui}:

$$\frac{\partial}{\partial p_{uk}} e'_{ui} = -e_{ui} \cdot q_{ki} + \lambda \cdot p_{uk}, \qquad \frac{\partial}{\partial q_{ki}} e'_{ui} = -e_{ui} \cdot p_{uk} + \lambda \cdot q_{ki}. \tag{6}$$

We update the weights in the direction opposite to the gradient:

$$\begin{aligned} p'_{uk} &= p_{uk} + \eta \cdot (e_{ui} \cdot q_{ki} - \lambda \cdot p_{uk}), \\ q'_{ki} &= q_{ki} + \eta \cdot (e_{ui} \cdot p_{uk} - \lambda \cdot q_{ki}). \end{aligned} \tag{7}$$

For the training algorithm used in RISMF, see Algorithm 1. Note that we use early stopping in Algorithm 1, thus $\mathbf{P}^*$ and $\mathbf{Q}^*$ differs from Eq. (5), because we optimize for the validation set. Note that the matrices are initialized randomly. If both $\mathbf{P}$ and $\mathbf{Q}$ are initialized with a constant value, that is, both are rank 1, the weight update will not increase the rank, which is equivalent to the $K = 1$ case. Random initialization is a simple way to avoid this. Typically, we uniformly choose random values from $[-0.01, 0.01]$ or $[-0.02, 0.02]$.

We point out that RISMF differs from Funk's MF in a few important aspects. We update each feature simultaneously and initialize the matrix randomly. Simon Funk's approach learns each feature separately during a certain number of epochs, but there are no specification as to when the learning procedure has to step to the next feature. His approach converges slower than ours, because it iterates over $\mathbf{R}$ more times. Both methods use regularization and early stopping to prevent overfitting.

```
   Input: $\mathcal{T}'$: training set, $\eta$: learning rate, $\lambda$: regularization factor
   Output: $\mathbf{P}^*$,$\mathbf{Q}^*$: the user and item feature matrices
1  Partition $\mathcal{T}'$ into two sets: $\mathcal{T}'_{\mathrm{I}}$, $\mathcal{T}'_{\mathrm{II}}$ (validation set)
2  Initialize $\mathbf{P}$ and $\mathbf{Q}$ with small random numbers.
3  loop until the terminal condition is met. One epoch:
4      iterate over each $(u,i,r_{ui})$ element of $\mathcal{T}'_{\mathrm{I}}$:
5          compute $e'_{ui}$;
6          compute the gradient of $e'_{ui}$, according to Eq. (6);
7          for each $k$
8              update $\mathbf{p}_u$, the $u$-th row of $\mathbf{P}$,
9              and $\mathbf{q}_i$, the $i$-th column of $\mathbf{Q}$ according to Eq. (7);
10     calculate the RMSE on $\mathcal{T}'_{\mathrm{II}}$;
11     if the RMSE on $\mathcal{T}'_{\mathrm{II}}$ was better than in any previous epoch:
12         Let $\mathbf{P}^* = \mathbf{P}$ and $\mathbf{Q}^* = \mathbf{Q}$.
13     terminal condition: RMSE on $\mathcal{T}'_{\mathrm{II}}$ does not decrease during two epochs.
14 end
```

Algorithm 1: Training algorithm for RISMF

We observed (Takács et al., 2007), that the learning curve of epochs (RMSE on the validation set as a function of the number of epochs) is always convex, regardless of the value of λ, that is why we use not only regularization but also early stopping.

3.2 BRISMF: Constant Values in Matrices

One may argue that some users tend to rate all items higher or lower than the average. The same may hold for items: some items can be very popular. Although MF can reconstruct the original matrix exactly when K is large enough and $\lambda = 0$, this is not the case when overfitting is to be avoided. There is a straightforward way to extend RISMF to be able to directly model this phenomenon, by extending MF with biases for users and items.

The bias feature idea was mentioned by Paterek (2007). He termed his version RSVD2, which appeared at the same time in our work in a generalized form by incorporating constant values in the MF (Takács et al., 2007). Paterek's and our variants share some common features, but he used Simon Funk's approach to update feature weights.

We incorporate bias features into RISMF by fixing the first column of **P** and the second row of **Q** to the constant value of 1. By "fixing to a constant value" we mean initialize $\mathbf{p}_{\bullet 1}$ and $\mathbf{q}_{2\bullet}$ with a fixed constant value instead of random values and drop the application of (7) when updating $\mathbf{p}_{\bullet 1}$ and $\mathbf{q}_{2\bullet}$. In this way, we get back exactly Paterek's RSVD2, except that we update features simultanously. The pair of these features ($\mathbf{q}_{1\bullet}$ and $\mathbf{p}_{\bullet 2}$) can serve as bias features. Our $\mathbf{p}_{u2}$ and $\mathbf{q}_{1i}$ corresponds to Paterek's c_i and d_j resp.

We refer to this method as BRISMF that stands for biased regularized incremental simultaneous MF. This simple extension speeds up the training phase and yields a more accurate model with better generalization performance. Since BRISMF is always superior to RISMF in terms of both the accuracy and the running time, it is our recommended basic MF method.

3.3 Semipositive and Positive MF

The RISMF algorithm can generate not only positive but also negative feature values. Nonnegative matrix factorization (Lee and Seung, 1999) generates models with only nonnegative features, which enables additive part-based representation of the data. Positive (Bell and Koren, 2007a) and semipositive (Hofmann, 2004) matrix factorization techniques have been successfully applied in the field of CF. We present a simple modification of RISMF that can give positive and semipositive factorizations. Although, these modifications do not yield more accurate models, they are important, because the models are still accurate (Section 5.4.6), they blend well with other methods (Section 5.4.8), and the running time (Section 5.4.10), simplicity and accuracy compares favorably with Bell and Koren's positive MF method.

We talk about semipositive MF when exactly one of **P** and **Q** contains both nonnegative and negative values, and positive MF, when both contains only nonnegative values.

We apply a simple thresholding method to ensure the nonnegativeness of features: for the (u,i)-th training example in a given epoch, if p_{uk} or q_{ki} would become negative when applying (7), we reset their value to 0. We describe the modified equations for the case when both user and item features are required to be nonnegative:

$$\begin{aligned} p'_{uk} &= \max\{0, p_{uk} + \eta \cdot e_{ui} \cdot q_{ki} - \lambda \cdot p_{uk}\}, \\ q'_{ki} &= \max\{0, q_{ki} + \eta \cdot e_{ui} \cdot p_{uk} - \lambda \cdot q_{ki}\}. \end{aligned} \tag{8}$$

If we allow, for instance, user features to be negative, we can simply use Eq. (7) instead of Eq. (8) for p'_{uk}. Allowing only nonnegative item features can be treated similarly.

3.4 Applying Momentum Method

This method modifies the learning rule of RISMF slightly. In each learning step the weight updates are calculated from the actual gradient and from the last weight changes. With the modification of (7) we get the following equations:

$$\begin{aligned} p_{uk}(t+1) &= p_{uk}(t) + \Delta p_{uk}(t+1), \\ \Delta p_{uk}(t+1) &= \eta \cdot (e_{ui} \cdot q_{ki}(t) - \lambda \cdot p_{uk}(t)) + \sigma \cdot \Delta p_{uk}(t), \\ q_{ki}(t+1) &= q_{ki}(t) + \Delta q_{ki}(t+1), \\ \Delta q_{ki}(t+1) &= \eta \cdot (e_{ui} \cdot p_{uk}(t) - \lambda \cdot q_{ki}(t)) + \sigma \cdot \Delta q_{ki}(t). \end{aligned}$$

Here σ is the momentum factor and $p_{uk}(t+1)$ and $p_{uk}(t)$ stands for the new and old k-th feature values of user u, respectively. Analogously, $\Delta p_{uk}(t+1)$ and $\Delta p_{uk}(t)$ denote the current and last change of the given feature value. The notations are similar for the item features.

Without a detailed description, the momentum method was mentioned by Salakhutdinov et al. (2007), but they used batch learning, which makes the training slower. In our experiments, momentum MF does not yield more accurate models; however, it blends well with other methods (Section 5.4.8).

3.5 Retraining User Features

The incremental gradient descent weight update of RISMF has a serious drawback: item features change while we iterate through users. If the change is significant, user features updated in the beginning of an epoch may be inappropriate at the end of the epoch. We found two ways to solve this.

1. We can evaluate the test ratings of a user immediately after iterating through its ratings in the training set, and before starting to iterate through the next user's ratings.
2. We can completely recompute the user features after the learning procedure. This method can serve as an efficient incremental training method for recommender systems. Algorithm 2 summarizes the method.

```
  Input: $\mathcal{T}'$: training set, $\eta$: learning rate, $\lambda$: regularization factor
  Output: $\mathbf{P}^*$,$\mathbf{Q}^*$: the user and item feature matrices
1 Partition $\mathcal{T}'$ into two sets: $\mathcal{T}'_{\mathrm{I}}$, $\mathcal{T}'_{\mathrm{II}}$ (tuning set)
2 First training step: call Algorithm 1, store the result in $(\mathbf{P}_1, \mathbf{Q}_1)$
3 Let $\mathbf{Q} = \mathbf{Q}_1$, initialize $\mathbf{P}$ randomly.
4 Second training step: call Algorithm 1, with the following restrictions:
5     skip the weight initialization step, use $\mathbf{P}$ and $\mathbf{Q}$ from here.
6     do not change weights in $\mathbf{Q}$, that is, do not apply (7) or its variants for $q_{ki}$.
7     store the optimal number of epochs, denote it $n^*$.
8 Return the result of Algorithm 1 called in line 4
9 end
```

Algorithm 2: Algorithm for retraining user features

Note that this method can efficiently incorporate into the model new users or new ratings of existing users without the necessity of retraining the entire model, which is very important for recommender systems. Then we do not apply the whole training procedure, just reset the user feature weights of the active user u and apply the second training procedure for n^* epochs for u. The second training procedure needs to iterate through the entire database—which requires slow (but sequential) disk access operation—only once (not n^* times), as the ratings of user u can be kept in memory and can be immediately re-used in the next epoch.

We remark that the presented algorithm cannot handle the addition of new items, and after the addition of many new ratings to the database, $\mathbf{Q}$ will be obsolete, thus the first training step should be re-run. Retraining user features mostly yields a slightly more accurate model (Section 5.4.7), which means that it is useful for real life recommender systems to handle the addition of new users or ratings.

3.6 Transductive MF

Transductive learning involves the use of validation examples but not their labels. In the case of CF, this means that the algorithm "knows" what validation examples the model will be applied for, the $(u,i) \in \mathcal{V}$ pairs, but not the corresponding r_{ui} values. The first transductive model for CF was the conditional restricted Boltzmann machine (Salakhutdinov et al., 2007). In this RBM variant, the distribution over the visible and hidden units is defined conditional on which items the user has rated. The authors noted that the model performance is significantly improved by using conditional distribution instead of unconditional one.

We give a possible practical example when transductive learning model is useful. Let us suppose that, when buying items, users can optionally rate them. Via the proposed technique, the information that a user purchased but did not rate an item can be incorporated in such cases into the prediction model.

We propose a transductive MF that can exploit this information after the learning process. The idea behind the method is the following: suppose that user u (with feature vector $\mathbf{p}_u$) has the following v queries in the validation set: $r_{u1}, \dots, r_{uv}$. When we are at the i-th validation example of user u, we can predict another feature vector based only on what other items $(1 \leq i' \leq v, i' \neq i)$ are to be predicted. A proper linear combination—not depending on u or i—of the original user feature vector and this new feature vector can yield a third feature vector for the prediction of r_{ui} that produces a better predictor than the original one (see Table 7 for the performance gain obtained by transductive MF). Formally:

$$\mathbf{p}'_u(j) = \frac{1}{\sqrt{|i' : (u,i') \in \mathcal{V}| + 1}} \sum_{\substack{i''=1 \\ i'' \neq i}}^{v} \mathbf{q}_{i''}^T. \tag{9}$$

$$\hat{r}'_{ui} = \hat{r}_{ui} + \nu \cdot \mathbf{p}'_u(j) \cdot \mathbf{q}_i = \mathbf{p}_u \cdot \mathbf{q}_i + \nu \cdot \mathbf{p}'_u(j) \cdot \mathbf{q}_i.$$

The attenuation factor in Eq. (9) ensures that the more ratings a user has in the training set, the less the prediction relies on the information the validation set provides, thus $\hat{r}'_{ui}$ will differ less from $\hat{r}_{ui}$.

In practice, ν need not be determined: we can use $\hat{r}'_{ui}$ and $\mathbf{p}'_u(j) \cdot \mathbf{q}_i$ as two predictions for r_{ui}, and apply linear regression to get an improved RMSE. Transductive MF is a post-processing method for MF, which can exploit the information provided by the existence of ratings even if the values of the ratings are unknown. This can be the case in some real life problems, for example, when a user buys many items but rates only a few of them.

3.7 2D Variant of the Matrix Factorization Algorithm

We propose here an MF variant that provides visual information about MF features, which can be used to generate an explanation for recommendations. The idea is that we store user and item features in a two dimensional (2D) grid instead of a one dimensional row vector. Accordingly, we replace the p_{uk} and q_{ki} notation of feature values with p_{ukl} and q_{imn}. Furthermore we define a simple neighborhood relation between the features based on their distance in the grid. If the difference of the horizontal and vertical positions of two features is small, then the "meaning" of those features should also be close. To achieve this, we modify our error function in (3) to penalize the difference between neighbor features:

$$e_{ui}'' = e'_{ui} + \sum_{k,l} \sum_{m \neq k, n \neq l} s(k,l,m,n)(p_{ukl} - p_{umn})^2 + \sum_{k,l} \sum_{m \neq k, n \neq l} s(k,l,m,n)(q_{ikl} - q_{imn})^2.$$

Here (k,l), (m,n) are the indices in the 2D grid, and $s(k,l,m,n)$ is the similarity between the (k,l)-th and (m,n)-th positions of the grid. For example we can use the inverse of the squared Euclidean distance as similarity:

$$s(k,l,m,n) = \frac{\rho}{(k-m)^2 + (l-n)^2}.$$

With this function the gradient used for learning p_{ukl} and q_{ikl} will be:

$$\frac{\partial}{\partial p_{ukl}} e_{ui}'' = \frac{\partial}{\partial p_{ukl}} e'_{ui} + 2 \sum_{m \neq k, n \neq l} s(k,l,m,n)(p_{ukl} - p_{umn}),$$

$$\frac{\partial}{\partial q_{ikl}} e_{ui}'' = \frac{\partial}{\partial q_{ikl}} e'_{ui} + 2 \sum_{m \neq k, n \neq l} s(k,l,m,n)(q_{ikl} - q_{imn}).$$

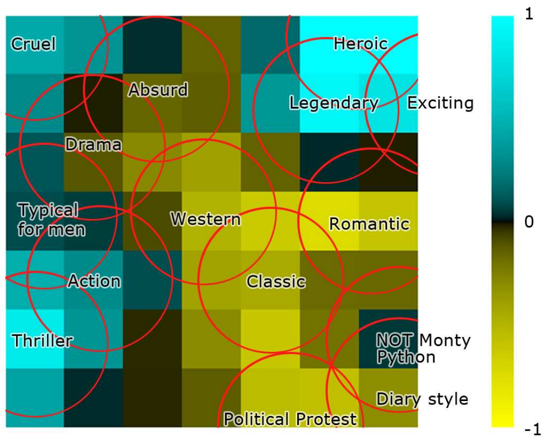

Figure 1: Features of movie *Constantine*

The 2D features of items (or users) can be visualized on a so-called *feature map*. In our next examples, items are movies from the Netflix Prize data set. Meanings can be associated to the regions of the feature map. Note that the labels on Figure 1 are assigned to *groups of features* and not to single features. The labels have been manually determined based on such movies that have extreme values at the given feature group.

The labeling process is performed as follows: we select a cell of the feature map. Then we list the movies with the highest and the lowest feature values in the selected cell; we term them *representative movies*. Finally, we select an expression which describes the best the common properties of the movies with high feature values in contrast to the movies with low feature values. In the case when neighboring features have similar representative movies, we assign a common label to the corresponding cells. As a result of the label unification, we can obtain larger areas of the feature map with the same label; see for instance labels *Classic*, *Western* or *Action* on Figure 1. Since the described labeling process is subjective, it requires human interaction. The size of the areas the labels are assigned to depends on multiple factors like the neighborhood strength ρ, the size of the feature map, and how general the label term assigned is. In the example (Figure 1), the labels principally characterize the features directly under themselves and immediate neighbors. The further a feature is from the label, the less the label reflects its meaning.

Such feature maps are useful for detecting main differences between movies or episodes of the same movie. Figure 2 represents the three episodes of The Matrix movie. One can observe that the main characteristic of the feature maps are the same, but there are noticeable changes between the first and the other episodes. In the first episode the feature values are higher in the area of *Political protest* and *Absurd* and lower around *Legendary*. This may indicate that the first episode presents a unique view of the world, but the other two are rather based on the success of the first episode. Visual feature maps can also be used to demonstrate to the users why they are provided the current recommendations: showing similar feature map of items formerly ranked high by the user can justify the recommendations. This kind visual of explanation may be a preferred by people who can capture the meaning of visual information faster than textual one. We, therefore, recommend this technique for real life recommender systems, although it does not improve the blending of the methods.

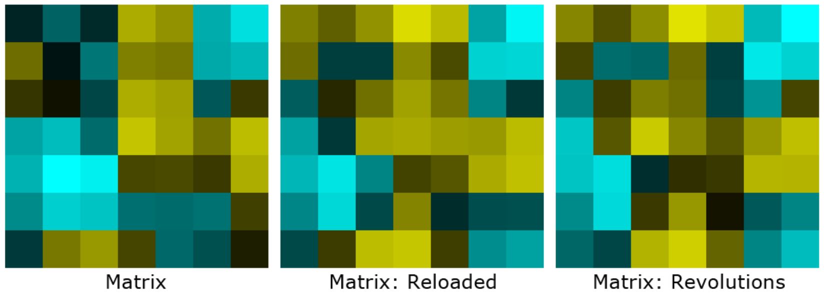

Figure 2: Features of *The Matrix* episodes

3.8 Connections with Neural Networks

In this section we point out that the learning scheme of some MF variants can be directly represented in the framework of neural networks (NN). We show that this correspondence can be exploited by applying the methodology of NN learning for CF problems.

The learning of the ISMF and RISMF models can be paired with the multi-layer perceptron depicted on Figure 3. The network has N inputs, M outputs and K hidden neurons and an identity activation function in each neuron. The weight between the u-th input and the k-th hidden neuron corresponds to p_{uk}, and the weight between the k-th hidden neuron and the i-th output neuron corresponds to q_{ki}.

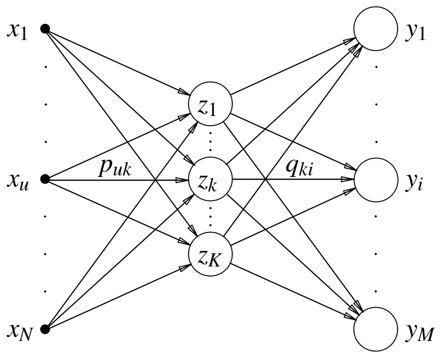

Figure 3: The multilayer perceptron equivalent for the general MF scheme

In the learning phase, an incremental learning method is used. For the (u,i)-th rating, we set the input $\mathbf{x}$ so that x_u is 1 and $x_{u'\neq u} = 0$, thus $z_k = p_{uk}$ holds. Let $\hat{r}_{ui} = y_j$ denote the i-th output of the network. We compute the error: $e_{ui} = r_{ui} - \hat{r}_{ui}$. This error is back-propagated from the i-th output neuron towards the input layer. This neural network (NN) with this special learning is equivalent to the ISMF.

If we apply regularization (weight decay), we get the RISMF approach.

We can extend this NN to be equivalent to the BRISMF: item biases can be handled by adding a bias (constant 1) input to the output neurons; user biases can be handled by setting $\mathbf{q}_{2\bullet}$ weights to 1 and keeping them constant. In the evaluation phase, we set the input as in the learning phase, and y_i $(i = 1, \ldots, M)$ predicts the active user's rating on the i-th item.

It was shown that feed-forward neural networks with linear activation function can find the principal components of a data set (Baldi and Hornik, 1989), since all local minima are global minima there. However, our problem setting differs in two minor and one major issues: First, our goal is to factorize a non-squared matrix (the number of inputs of the neural network is different from the number of outputs), second, we penalize the weights of the neural network, and principally, not all output are defined, since users rate only a small subset of the items. This latter point infers that we cannot expect local minima to be global minima, as it has been reflected on page 629.

4. Neighbor Based Correction of MF

Neighbor based (NB) approaches exploit the observation that similar users rate similar items similarly. In the NB scheme a set of similar users is selected for each query from among those who rated the active item. Or analogously, a set of similar items is selected from among those that have been rated by the active user. The answer of the predictor is then obtained by combining the ratings of similar users (items) for the active item (user). The first variant is termed the user neighbor based, and the second is termed the item neighbor based approach.

MF and NB approaches complement each other well:

- The MF approach views the data from a high level perspective. MF can identify the major structural patterns in the ratings matrix. An appealing property of MF is that it is able to detect the similarity between 2 items, even if no user rated both of them.

- The NB approach is more localized. It is typically good at modeling pairs of users/items and not so good at modeling interdependency within larger sets of users/items. NB methods are memory based, therefore they do not require any training.[3]

It is known that the combination of MF and NB can lead to very accurate predictions (Bell and Koren, 2007a; Bell et al., 2007b). However, the price of additional accuracy is paid by the decreased scalability. Here we propose a scalable solution for unifying the MF and NB approaches. We will point out that it is computationally less expensive than Bell et al's approaches.

The idea is that we try to improve an existing MF model ($\mathbf{P}$,$\mathbf{Q}$) by adding a neighbor based correction term to its answer in the prediction phase. Assuming the item neighbor based scheme, the corrected answer for query (u,i) is the following:

$$\hat{r}_{ui} = \mathbf{p}_u^T \mathbf{q}_i + \gamma \frac{\sum_{j \in \mathcal{T}_u \setminus \{i\}} s_{ij} \left(\mathbf{p}_u^T \mathbf{q}_j - r_{uj} \right)}{\sum_{j \in \mathcal{T}_u \setminus \{i\}} s_{ij}},$$

where s_{ij} is the similarity between $\mathbf{q}_i$ and $\mathbf{q}_j$, and $\mathcal{T}_u$ is set of the items rated by user u. The weight of the correction term γ can be optimized via cross-validation. This model can be seen as a unification of the MF and NB approaches.

3. However, it can be useful to precompute the similarity values to speed up the prediction phase.

The similarity s_{ij} can be defined in many different ways. Here we propose two variants.

- (S1): Normalized scalar product based similarity.

$$s_{ij} = \left(\frac{\max\{0, \sum_{k=1}^{K} q_{ki} q_{kj}\}}{\sqrt{\sum_{k=1}^{K} q_{ki}^2} \cdot \sqrt{\sum_{k=1}^{K} q_{kj}^2}} \right)^{\alpha},$$

  where α is an amplification parameter.

- (S2): Normalized Euclidean distance based similarity.

$$s_{ij} = \left(\frac{\sum_{k=1}^{K} (q_{ki} - q_{kj})^2}{\sqrt{\sum_{k=1}^{K} q_{ki}^2} \cdot \sqrt{\sum_{k=1}^{K} q_{kj}^2}} \right)^{-\alpha}.$$

In both cases, the value s_{jk} can be calculated in $\mathrm{O}(K)$ time, thus $\hat{r}_{ui}$ can be calculated in $\mathrm{O}(K \cdot |\mathcal{T}_u|)$. We remark that one can restrict to use only the top S neighbors of the queried item (Bell and Koren, 2007a), however, it does not affect the time requirement, if we use the same function for s_{ij} and neighbor selection.

Now let us comment in more details on the time and memory requirements of our NB corrected MF in comparison with the improved neighborhood based approach of Bell and Koren (2007a), which can also be applied to further improve the results of an MF. For a given query, the running time of our method is $\mathrm{O}(K \cdot S)$, while their method requires to solve a separate linear least squares problem with S variables, thus it is $\mathrm{O}(S^3)$. Memory requirements: for the u-th user, our method requires the storing $\mathbf{q}_u$ and $\mathbf{Q}$ in the memory, that is $\mathrm{O}(KN)$, while their approach must store the item-by-item matrix and the ratings of the user, which is $\mathrm{O}(M^2 + |\mathcal{T}_u|)$. For all users, our method requires $\mathrm{O}(NK + KM)$ while their approach requires $\mathrm{O}(M^2 + |\mathcal{T}|)$ memory.

Despite the simplicity of our method its effectiveness is comparable with that of Bell and Koren's method, see Section 5.4.9. We highly recommend this method as it improves accuracy significantly, as we show above and in Section 5.4.8.

This model can be seen as simple, scalable, and accurate unification of the MF and NB approaches. The training is identical to the regular MF training. The prediction consists of an MF and a NB term. The similarities used in the NB term need not to be precomputed and stored, because they can be calculated very efficiently from the MF model.

5. Experiments

Currently, the largest publicly available ratings data set is provided by Netflix, a popular online DVD rental company. Netflix initiated the Netflix Prize contest in order to improve their recommender system—called Cinematch—that provides movie recommendations to customers. The data set released for the competition was substantially larger than former benchmark data sets and contained about 100 million ratings from over 480k users on nearly 18k movies (see details in Subsection 5.1.1). For comparison, the well-known EachMovie data set[4] only consists of 2,811,983 ratings of

4. It used to be available upon request from Compaq, but in 2004 the proprietary retired the data set, and since then it has no longer been available for download.

72,916 users and 1,628 movies. Rashid et al. (2006) used a 3 millions ratings subset of the GroupLens project, which entirely contains about 13 million ratings from 105k users on 9k movies. We evaluated all of our algorithms against the Netflix data set, since currently this is the most challenging problem for the collaborative filtering community, and our work was greatly motivated by it. In addition, to illustrate the applicability of the presented methods on other data sets, we also performed experiments with a selected MF, BRISMF, on the 1M MovieLens and the Jester data set (see details in Subsection 5.1.2–5.1.3).

The evaluation metrics of recommender systems can greatly vary depending on the characteristics of the data set (size, rating density, rating scale), the goal of recommendation, the purpose of evaluation (Herlocker et al., 2004). In the current CF setting the goal is to evaluate the predictive accuracy, namely, how closely the recommender system can predict the true ratings of the users, measured in terms of root mean squared error.

In case of MovieLens and Jester data sets, we also provide the mean absolute error (MAE) since this is the most common performance measure for these sets:

$$\mathrm{MAE} = \frac{1}{|\mathcal{V}|} \sum_{(u,i)\in\mathcal{V}} |\hat{r}_{ui} - r_{ui}|.$$

5.1 Data Sets

In this section we describe in details the above mentioned three data sets.

5.1.1 THE NETFLIX PRIZE DATA SET

The data set provided generously by Netflix for the NP competition contains (u, i, r_{ui}, d_{ui}) rating quadruples, representing that user u rated item i as r_{ui} on date d_{ui}, where $d_{ui} \in \mathcal{D}$ the ordered set of possible dates. The ratings r_{ui} are integers from 1 to 5, where 1 is the worst, and 5 is the best. The data were collected between October, 1998 and December, 2005 and reflect the distribution of all ratings received by Netflix during this period (Bennett and Lanning, 2007). The collected data was released in a train-test setting in the following manner (see also Figure 4).

Netflix selected a random subset of users from their entire customer base with at least 20 ratings in the given period. A *Hold-out set* was created from the 9 most recent ratings of the users, consisting of about 4.2 million ratings. The remaining data formed the Training set. The ratings of the Hold-out set were split randomly with equal probability into three subsets of equal size: Quiz, Test and Probe. The *Probe set* was added to the Training set and was released with ratings. The ratings of the *Quiz and Test sets* were withheld as a *Qualifying set* to evaluate competitors. The Quiz/Test split of the Qualifying set is unknown to the public. We remark that the date based partition of the entire NP data set into train-test sets reflects the original aim of recommender systems, which is the prediction of future interest of users from their past ratings/activities.

As the aim of the competition is to improve the prediction accuracy of user ratings, Netflix adopted RMSE as evaluation measure. The goal of the competition is to reduce by at least 10 percent the RMSE on the Test set, relative to the RMSE achieved by Cinematch.[5] The contestants have to submit predictions for the Qualifying set. The organizers return the RMSE of the submissions on

5. The first team achieving the 10 percent improvement is promised to be awarded by a grand prize of $1 million by Netflix. Not surprisingly, this prospective award drawn much interest towards the competition. So far, more than 3 000 teams submitted entries for the competition.

the Quiz set, which is also reported on a public leaderboard.[6] Note that the RMSE on the Test set is withheld by Netflix.

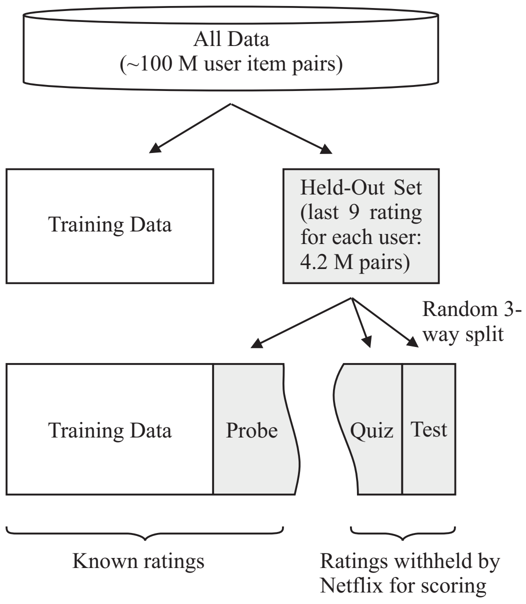

Figure 4: The train-test split and the naming convention of Netflix Prize data set, after Bell et al. (2007a)

There are some interesting characteristics of the data and the set-up of the competition that pose a difficult challenge for prediction:

- The distribution over the time of the ratings of the Hold-out set is quite different from the Training set. As a consequence of the selection method, the Hold-out set does not reflect the skewness of the movie-per-user, observed in the much larger Training set. Therefore the Qualifying set contains approximately equal number of queries for often and rarely rating users.

- The designated aim of the release of the Probe set is to facilitate unbiased estimation of RMSE for the Quiz/Test sets despite of the different distributions of the Training and the Hold-out sets. In addition, it permits off-line comparison of predictors before submission.

- We already mentioned that users' activity at rating is skewed. To put this into numbers, ten percent of users rated 16 or fewer movies and one quarter rated 36 or fewer. The median is 93. Some very active users rated more than 10,000 movies. A similar biased property can be observed for movies: The most-rated movie, *Miss Congeniality* was rated by almost every second user, but a quarter of titles were rated fewer than 190 times, and a handful were rated fewer than 10 times (Bell et al., 2007a).

6. Found at `http://www.netflixprize.com/leaderboard`.

- The variance of movie ratings is also very different. Some movies are rated approximately equally by the user base (typically well), and some partition the users. The latter ones may be more informative in predicting the taste of individual users.

In this experimentation section we evaluate the presented methods on a randomly selected 10% subset of the Probe set, which we term as Probe10.[7] Unless we explicitly mention, from now on the RMSE values refer to the Probe10 RMSE. We have decided to report on RMSE values measured on the Probe10 set, since in our experiments the Probe10 RMSE are significantly closer to the Quiz RMSE than Probe RMSE, and Quiz RMSE tell us more about the accuracy of the predictor, since it excludes the impact of overtraining. On the other hand the rules of NP competition allows only 1 submission daily, which limits the number of the Quiz RMSE calculation drastically. We remark that we measured typically 0.0003 difference between the Probe10 and the Quiz RMSE values (sometimes 0.0010), while this was of an order of magnitude larger for the Probe set. This advantageous property nominates the Probe10 set for being a standard and Netflix-independent evaluation set for predictors trained on the NP data set.

We performed a thorough analysis to check how reliable the Probe10 results are. For this, we will show that if a given method has better RMSE compared to another method for a particular subset of the Probe set, then it has the same performance gain on other subsets of the Probe set. To do this, we partitioned the Probe set into 10 subsets, and we ran 10 different methods using them. Therefore, in total we had 100 runs. We denote the test RMSE of the x-th method on the y-th test set by m_{xy}. To summarize the results, we calculated the average test RMSE for each method, denoted by $(\overline{m}_{1\bullet}, \dots, \overline{m}_{10\bullet})$, and a *difficulty offset* for each test set, denoted by $(o_1, \dots, o_{10})$, defined as

$$o_y = \frac{1}{10} \sum_{x=1}^{10} m_{xy} - \overline{m}_{x\bullet}.$$

The test RMSE of the 100 runs are approximated as $m_{xy} = \overline{m}_{x\bullet} + o_y$. The standard deviation of this approximation is 0.000224 RMSE score, and the maximal deviation is less than 0.0007 RMSE score, which means that m_{xy} is well approximated, thus we can assign a difficulty offset to each test set. Consequently, our initial hypothesis is verified.

When Quiz RMSE values are reported we also mention the percentage of improvement over Cinematch (IoC). We performed all tests on an average single processor laptop (a 2 GHz Intel Pentium M (Dothan) with 1 GB RAM), on which reported training times were measured.

5.1.2 MOVIELENS DATA SET

The 1M MovieLens data set[8] contains cca. 1 million ratings from 6,040 users on 3,900 movies. As in the case of NP, ratings are made on a 5 star scale, and the rating records are also quadruples containing the timestamp of the rating. Demographic data provided with the ratings are not used in our setting. Since there is no standard train-test split of the data set, we applied a simple random split to generate a 90%–10% train-test setting.[9]

7. A Perl script can be downloaded from our homepage, `http://gravityrd.com`, which selects the Probe10 from the original Netflix Probe set to ensure repeatability and comparability.
8. Available at: `http://www.grouplens.org/node/73`.
9. This split can be downloaded from our website: `http://gravityrd.com`.

5.1.3 JESTER DATA SET

The Jester data set[10] (Goldberg et al., 2001) contains 4,136,360 ratings from 73,421 users on 100 jokes. Users rated jokes on the continuous $[-10, +10]$ range. Ten percent of the jokes (called the gauge set, which users were asked to rate) are densely rated, others, more sparsely. Two thirds of the users have rated at least 36 jokes, and the remaining ones have rated between 15 and 35 jokes. The average number of ratings per user is 46, so it is a particularly dense data set compared to NP and MovieLens. Goldberg et al. (2001) created their train-test split by a random division of a subset of 18,000 users into two disjoint sets. For our experiments this split is obviously inappropriate since it does not enable us to integrate user preferences into the model. Therefore, here we also applied a random split to generate a 90%–10% train-test setting.[11]

5.2 Implementation Issues

Because the data set is huge, its storage is an important issue. This was thoroughly investigated in our previous work (see Takács et al., 2007). We have shown there that the entire data set can be stored in 300 MB without storing the dates but keeping the chronological order of the ratings, and in 200 MB without even keeping the order. This enables to perform the algorithms on an average PC (our platform details are given at the end of Section 5.1.1). As we will point out here, MF methods are sensitive to the order of training examples and the selection of their proper order exploits date information. On the other hand, pure NB approaches are not sensitive to the order of training examples.

The users' tastes change in time, and when providing them recommendations, only their current taste matters. This phenomenon is modeled in the NP data set as the value of d_{ui} is greater for test examples than for training examples. We can condition MF methods to exploit the date information by properly ordering training examples. We found the following order to be very effective: iterate over users in an arbitrary order, and for each user, take the ratings in an increasing chronological order, that is, starting from the oldest and ending with the newest. Unless explicitly mentioned otherwise, in our experiments we use this training example order for MF methods. The impact of the order on the accuracy of MFs is investigated in Subsection 5.4.4.

5.3 Parameter Optimization

All of the presented methods have many pre-defined parameters that greatly influence the accuracy. Sometimes a few experiments are enough to set them well, sometimes we need to apply parameter optimization to find the best settings.

We recall that a parameter setting can be advantageous because (1) it produces a very accurate model (low validation RMSE) or (2) it "blends well", that is it improves the accuracy of the blended model. The more parameters a method has, the harder to set them well, but the more chance to get a better RMSE.

We used random search and Algorithm 3 to optimize parameters. The typical value of n is 2. In case of MF, we have experimented with many parameters, namely:

- the number of features: K;
- different learning rate and regularization factor

10. Available at: `http://goldberg.berkeley.edu/jester-data/`.
11. This split can be downloaded from our website: `http://gravityrd.com`.

```
   Input: $L, p_1, \dots, p_L, n$
   Output: $v_1, \dots, v_l$
 1 Randomly initialize parameters $p_1, \dots, p_L$
 2 Iterate forever (iteration is stopped manually).
 3    Randomly choose one parameter: $p_l$;
 4    Randomly generate $n$ different values
 5       to that parameter: $u_1, \dots, u_n$;
 6    Let $u_0$ be the current value of the $p_l$.
 7    For each of the $u_0, \dots, u_n$ values, run a training
 8       algorithm, temporarily setting $p_l$ to that value, and
 9       evaluating the model on the validation set.
10    Assign the best value to $p_l$.
11 end
```

Algorithm 3: Simple parameter optimization algorithm

  - for users and movies ($\eta^{(p)}, \eta^{(q)}, \lambda^{(p)}, \lambda^{(q)}$);
  - for the corresponding variables of bias features ($\eta^{(pb)}, \eta^{(qb)}, \lambda^{(pb)}, \lambda^{(qb)}$);
- minimum and maximum weights in the uniform random initialization of **P** and **Q**: $w_{\underline{p}}, w_{\overline{p}}, w_{\underline{q}}, w_{\overline{q}}$;
- G: the offset to subtract from **R** before learning (can be, for example, set to the global average of ratings);

We subsampled the matrix **R** for faster evaluation of parameter settings. We have experienced that movie-subsampling substantially increased the error, in contrast to user-subsampling, thus we do not perform the former. The reason for this is that in the evaluation data set movies have much more ratings than users. Consequently, if we do user-subsampling for example with 100 instead of the original 200 ratings we lose more information than at movie-subsampling when we have for example 10000 ratings instead of 20000. Interestingly, the larger the subsample is, the fewer iterations are required to achieve the optimal model. This can be explained by the existing redundancy in the data set. This implies also that the time-complexity of MF is sublinear in the number of ratings.

5.4 Results of Matrix Factorization

We recall that we applied linear combinations of methods for blending,[12] and we ordered the training examples user-wise and then by date, as specified in Section 5.2.

5.4.1 COMPARING REGULARIZED AND BIASED MF VARIANTS

We compare:

- an instance of the regularized RISMF, termed as RISMF#0, with the following parameter settings: $K = 40, \eta = 0.01, \lambda = 0.01, w_{\underline{p}} = -w_{\overline{p}} = w_{\underline{q}} = -w_{\overline{q}} = -0.01$
- an instance of the biased BRISMF, named briefly as BRISMF#0, with the following parameter settings: $K = 40, \eta = 0.01, \lambda = 0.01, w_{\underline{p}} = -w_{\overline{p}} = w_{\underline{q}} = -w_{\overline{q}} = -0.01$

12. The source code of our combination algorithm can be downloaded from our web site: `http://gravityrd.com`.

RISMF#0 reaches its optimal RMSE in the 13th epoch: 0.9214, while these numbers for BRISMF#0 are: 10th and 0.9113, which is a 0.0101 improvement.

5.4.2 CHANGING THE PARAMETERS OF THE BRISMF

Table 1 presents the influence of η and λ on the Probe10 RMSE and the optimal number of epochs. Other parameters are the same as in BRISMF#0. The best result is RMSE $= 0.9056$ when $\eta = 0.007, \lambda = 0.005$, which is a 0.0057 improvement. We refer to this MF in the following as BRISMF#1. The running time for this MF is only 14 minutes! Note that running time depends only on K, and on the optimal number of epochs.

Note that decreasing η or increasing λ increases the optimal number of epochs, (except for $\eta = \lambda = 0.020$).

η \ λ	0.005	0.007	0.010	0.015	0.020
0.005	0.9061 / 13	0.9079 / 15	0.9117 / 19	0.9168 / 28	0.9168 / 44
0.007	**0.9056 / 10**	0.9074 / 11	0.9112 / 13	0.9168 / 19	0.9169 / 31
0.010	0.9064 / 7	0.9077 / 8	0.9113 / 10	0.9174 / 13	0.9186 / 21
0.015	0.9099 / 5	0.9111 / 6	0.9152 / 6	0.9257 / 7	0.9390 / 7
0.020	0.9166 / 4	0.9175 / 4	0.9217 / 4	0.9314 / 4	0.9431 / 3

Table 1: Probe10 RMSE/optimal number of epochs of the BRISMF for various η and λ values ($K = 40$)

Now we show that the usage and proper setting of new parameters can boost the performance: we introduce the parameters $\eta^{(p)}, \eta^{(q)}, \lambda^{(p)}, \lambda^{(q)}$ and $\eta^{(pb)}, \eta^{(qb)}, \lambda^{(pb)}, \lambda^{(qb)}$ (see Section 5.3 for explanation).

Initially $\eta^{(p)} = \eta^{(q)} = \eta^{(qb)} = \lambda^{(pb)} = 0.007$, and $\lambda^{(p)} = \lambda^{(q)} = \lambda^{(pb)} = \lambda^{(qb)} = 0.005$, to yield the RMSE $= 0.9056$ given above. Finding the best setting of these 8 variables is practically impossible and can cause overlearning on Probe10. To demonstrate how the parameter optimization algorithm mentioned in Section 5.3 works, we apply its simplified version: we do not use random numbers, just fix the order of these variables and define the possible values for them. Let the order be: $\eta^{(p)}, \eta^{(q)}, \eta^{(pb)}, \lambda^{(qb)}, \lambda^{(p)}, \lambda^{(q)}, \lambda^{(pb)}, \lambda^{(qb)}$. Let the set of values for η variants be $\{0.005, 0.007, 0.010\}$, and for the λ variants: $\{0.003, 0.005, 0.007\}$. Table 2 shows step-by-step how parameters are optimized one-by-one in 8 iterations. The parameter optimization procedure decreased the RMSE score from 0.9056 to 0.9036.

5.4.3 BRISMF RESULTS ON MOVIELENS AND JESTER DATA SETS

We performed several tests on MovieLens and Jester data sets with the BRISMF method. As mentioned earlier there are no standard train-test split for these data sets; therefore it is difficult to compare our obtained results with already published ones. Consequently, we used three baseline methods for comparison. The *constant* method always predicts the average of the ratings in the training set, the *item average* outputs the average of the training ratings of the active item at querying, while the *item neighbor* (Takács et al., 2008b) is an item neighbor based method with Pearson

	0.003	0.005	0.007	0.010	Decision
$\eta^{(p)}$		0.9057	**0.9056**	0.9058	$\eta^{(p)} := 0.007$ (no change)
$\eta^{(q)}$		0.9057	**0.9056**	0.9061	$\eta^{(q)} := 0.007$ (no change)
$\eta^{(pb)}$		0.9059	0.9056	**0.9052**	$\eta^{(pb)} := 0.010$
$\eta^{(qb)}$		0.9053	**0.9052**	0.9056	$\eta^{(qb)} := 0.007$ (no change)
$\lambda^{(p)}$	0.9053	0.9052	**0.9051**		$\lambda^{(p)} := 0.007$
$\lambda^{(q)}$	0.9057	0.9051	**0.9050**		$\lambda^{(q)} := 0.007$
$\lambda^{(pb)}$	0.9053	0.9050	**0.9047**		$\lambda^{(pb)} := 0.007$
$\lambda^{(qb)}$	**0.9036**	0.9047	0.9066		$\lambda^{(qb)} := 0.003$

Table 2: Effect of parameter optimization on BRISMF#1

correlation based similarity. The MAE results for BRISMFs were obtained by using the same **P** and **Q** that were used to get the RMSE values.

For MovieLens, the main training parameters were set to $\eta^{(p)} = \eta^{(q)} = 0.01, \lambda^{(p)} = \lambda^{(q)} = 0.02$, and the number of features (K) was varied as tabulated in Table 3. The obtained results show that the increase of the number of features K yields better accuracy at a decreasing number of epochs.

Model	Epochs	RMSE w/o S2	RMSE with S2	MAE w/o S2	MAE with S2
constant	–	1.1179	–	0.9348	–
item average	–	0.9793	–	0.7829	–
item neighbor	–	0.8521	–	0.6641	–
BRISMF#5	35	0.8555	0.8537	0.6684	0.6667
BRISMF#10	27	0.8471	0.8426	0.6608	0.6563
BRISMF#20	24	0.8435	0.8363	0.6582	0.6507
BRISMF#50	23	0.8396	0.8319	0.6544	0.6461
BRISMF#100	24	0.8378	0.8299	0.6531	0.6444
BRISMF#200	21	0.8365	0.8285	0.6519	0.6430
BRISMF#500	20	0.8353	0.8275	0.6508	0.6424

Table 3: Test RMSE of various methods on the MovieLens data set

In terms of RMSE, the simplest BRISMF#5 achieves 12.64% improvement over the item average, while this is 14.70% for the largest BRISMF#500.[13] We also included in the table the test RMSE value achieved with neighbor correction using similarity function S2 ($\alpha = 5$). The improvement over the item average is 12.82% and 15.5% for the neighbor corrected BRISMF#5 and BRISMF#500, respectively. The S2 correction improves RMSE value from 0.0018 to 0.0080, which can be as large as almost 1% improvement over the RMSE of the non-corrected version. One can observe that the percentage of improvement increases with the number of features. The improvement of BRISMF#500 with S2 correction over item neighbor is 2.89%, which is similar to the results published in Takács et al. (2008b) and Takács et al. (2008a) for the Netflix data set.

13. We recall that Cinematch produces 9.6% improvement over item average (Quiz RMSE= 1.0540) on the NP data set (Bennett and Lanning, 2007).

In terms of MAE, the tendency of the improvements is almost identical. The simplest and the largest BRISMF achieves 14.63% and 16.87% improvements, which become 14.84% and 17.95% with NB correction. Here the magnitude of improvement is somewhat larger.

The reported results on RMSE and MAE value on the MovieLens data set are not directly comparable with ours because of the use of different train-test splits. The best known results are given by Delannay and Verleysen (2007): RMSE 0.875 and MAE 0.648 that are obtained with an interlaced generalized linear model. Similar MAE $= 0.652$ was reported by DeCoste (2006) achieved with ensembles of maximum margin matrix factorizations.

For Jester, the main training parameters were set to $\eta^{(p)} = \eta^{(q)} = 0.002$, $\lambda^{(p)} = \lambda^{(q)} = 0.02$, and K was varied as tabulated in Table 4. The obtained results show that the increase of K yields better accuracy, while the number of epochs is almost the same. Due the different characteristics of the Jester data set, the magnitude of RMSE scores are larger. It is interesting that on the Jester data set the item neighbor method gives better results than BRISMF. We think that this phenomenon is due to the different characteristics of Jester data set when compared to NP and MovieLens data sets: the rating matrix is almost dense and there are only 100 items.

Model	Epochs	RMSE w/o S2	RMSE with S2	MAE w/o S2	MAE with S2
constant	–	5.2976	–	4.4372	–
item average	–	5.0527	–	4.1827	–
item neighbor	–	4.1123	–	3.1616	–
BRISMF#5	7	4.2080	4.1902	3.2608	3.2352
BRISMF#10	8	4.1707	4.1575	3.2201	3.1967
BRISMF#20	7	4.1565	4.1405	3.2095	3.1820
BRISMF#50	8	4.1399	4.1265	3.1876	3.1616
BRISMF#100	7	4.1395	4.1229	3.1909	3.1606

Table 4: RMSE of various methods on the Jester data set

In terms of RMSE, the simplest BRISMF#5 achieves 16.72% improvement over the item average, while this is 18.07% for the largest BRISMF#100. We also included in the table the test RMSE value achieved with neighbor correction using similarity function S2 ($\alpha = 5$). The improvement over the item average is 17.07% and 18.40% for the neighbor corrected BRISMF#5 and BRISMF#100, respectively. The S2 correction improves the RMSE value from 0.0132 to 0.0178, which can be an over 0.4% improvement over the RMSE of the non-corrected version. In terms of MAE, the improvements are somewhat larger; they reach 23.72% without and 24.43% with S2 correction.

Here we also indicate some of the best published RMSE and MAE scores, keeping in mind that those are not directly comparable due to different test settings. Delannay and Verleysen (2007) achieved RMSE 4.17 and MAE 3.26 with an interlaced generalized linear model; the same MAE score was obtained by Canny (2002) with a sparse factor analysis model.

We can conclude from the experiments performed on the MovieLens and Jester data sets that the applicability of MF based methods and neighbor based correction technique is not restricted to the NP data set. Rather, they are useful CF techniques for different problems as well.

5.4.4 ORDER OF EXAMPLES

We examined how the order of examples influences the result by comparing the RMSE of BRISMF#1 on two different orders: For the proposed order the RMSE is 0.9056, and for a random order—obtained by a random shuffle of the ratings of each user—the RMSE is 0.9104.

5.4.5 SUBSAMPLING USERS

On Figure 5 we demonstrate how the number of users (thus, the number of ratings) influences RMSE and the optimal number of training epochs in case of BRISMF#1. RMSE varies between 0.9056 and 0.9677, and the number of epochs between 10 and 26. The smaller the subset of users used for training and testing, the larger the RMSE and the number of epochs. This means that the time-complexity of MF is sublinear in the number of ratings (see Section 5.3). We remark that the number of ratings is proportional to the number of users; the ratio of them—which is equal to the average number of ratings per user—is 209 in the training set.

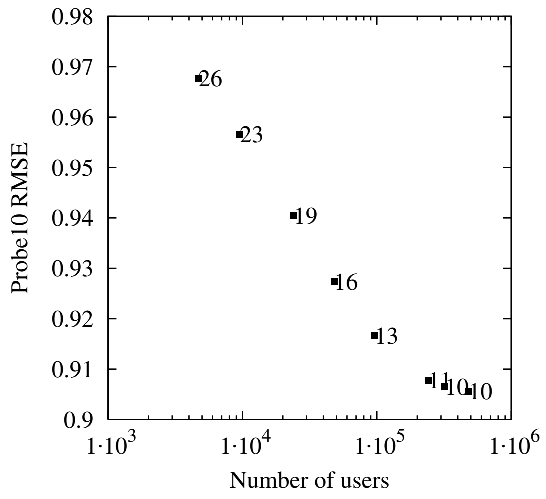

Figure 5: Effect of the number of users on Probe10 RMSE and on the optimal number of training epochs.

5.4.6 SEMIPOSITIVE AND POSITIVE MF

We investigated the accuracy of semipositive and positive variants using the following MFs:

- SemPosMF#800: this is a semipositive MF, where user features are nonnegative and item features are arbitrary. Parameters are set to: $K = 800, w_{\underline{p}} = 0, w_{\overline{p}} = -w_{\underline{q}} = w_{\overline{q}} = 0.005, \eta^{(p)} = \eta^{(pb)} = 0.016, \eta^{(q)} = \eta^{(qb)} = 0.005, \lambda^{(p)} = \lambda^{(q)} = 0.010, \lambda^{(pb)} = \lambda^{(qb)} = 0, G = 3.6043$. After 12 epochs, learning rates are multiplied by 0.01, and the model is trained for another 2 epochs.
- PosMF#400: this is a positive MF. Parameters are the same as in SemPosMF#800, except that $K = 400, w_{\underline{q}} = 0$.
- PosMF#100: like PosMF#400, but $K = 100$.

The results are summarized on Table 5.

Model	Epochs	RMSE
SemPosMF#800	12+2	0.8950
PosMF#400	14	0.9036
PosMF#100	14	0.9078

Table 5: Probe10 RMSE of positive and semipositive MFs

5.4.7 RETRAINING USER FEATURES

We investigated the effectiveness of retraining user features. We tested both solutions proposed in Section 3.5. The experiments were run with three parameter settings: BRISMF#1, and the following two MFs:

- BRISMF#250: $K = 250, w_{\underline{p}} = -0.01, w_{\overline{p}} = -0.006, w_{\underline{q}} = -0.010, w_{\overline{q}} = 0.020, \eta^{(p)} = 0.008, \eta^{(pb)} = 0.016, \eta^{(q)} = 0.015, \eta^{(qb)} = 0.007, \lambda^{(p)} = 0.048, \lambda^{(q)} = 0.008, \lambda^{(pb)} = 0.019, \lambda^{(qb)} = 0, G = 0$.
- BRISMF#1000: the same as BRISMF#250, but $K = 1000$.

First, we investigated the first solution (intra-training user-wise test). For BRISMF#250 the obtained Probe10 RMSE is 0.8959, which is only a slight 0.0002 improvement.

Second, we tested the second solution (see Table 6). Both the simpler case (after the first learning step, reset **P** and retrain only **P**), and the advanced case (after the first learning step, reset **P** and retrain both **P** and **Q**) are analyzed. We append letter "U" to the method name in the simpler case (BRISMF#1 becomes BRISMF#1U, etc.) and letters "UM" in the advanced case (BRISMF#1UM, etc.). We indicated the required number of epochs both in the first and the second training procedure (if available). Note, that in case of BRISMF#250 and BRISMF#1000, the retraining of user features greatly improves their performance. BRISMF#1000UM is currently our best MF: Probe10 RMSE is 0.8921, Quiz RMSE is 0.8918.

Model	Epochs	Probe10	Quiz	IoC
BRISMF#1	10	0.9056		
BRISMF#1U	10+8	0.9072		
BRISMF#1UM	10+6	0.9053		
BRISMF#250	14	0.8961	0.8962	5.80%
BRISMF#250U	14+8	0.8953	0.8954	5.89%
BRISMF#250UM	14+7	0.8937		
BRISMF#1000	14	0.8938	0.8939	6.04%
BRISMF#1000U	14+8	0.8936		
BRISMF#1000UM	14+8	0.8921	0.8918	6.26%

Table 6: Examining the effect of retraining user features

We investigated the effect of retraining only **P**, when BRISMF#250 was learnt on a subset of the database. The question in this case is: how reliable is a **Q** learnt only on a subset of the database.

First, we kept only the 40%, 60% or 80% of users and ran an MF algorithm and fixed the resulting **Q**. Then we reset and learnt **P**, first on the same subset of the database, and then on the entire database. In all 3 cases, the difference between the two Probe10 RMSE results was less than 0.0013. Each Probe10 RMSE was less than 0.8970. Thus, we can conclude that the proposed retraining method can handle the addition of new users.

Second, we discarded the last N_1 ratings of each user and ran the same retraining procedure. In our experiments, N_1 was set to 0, 10, 20, 40. Obviously, the removal of ratings increased Probe10 RMSE significantly; the highest score was 1.0038, whereas Probe10 RMSE on the entire training database went up to only 0.8980, which means that the **Q** calculated on the subset of the data differs slightly from the **Q** calculated on the entire data set. Thus, the proposed retraining method can handle the addition of new ratings as well. These experiments verify the usability of user feature retraining method for handling new users or ratings.

5.4.8 THE EFFECT OF CORRECTION TECHNIQUES

In order to investigate the effect of various correction techniques, we first generated a number of accurate MF models. We will show that correction techniques improve accuracy significantly for all of these models. We applied the parameter optimization method mentioned in section 5.3 to get accurate MFs. Also, we applied the "trial and error" method to get manually parameterized accurate MFs. Here we describe some results of both:

- BRISMF#800: manually parameterized MF, with 800 features. Parameters are set to: $K = 800$, $w_{\underline{p}} = -w_{\overline{p}} = w_{\underline{q}} = -w_{\overline{q}} = -0.005, \eta^{(p)} = \eta^{(pb)} = 0.016, \eta^{(q)} = \eta^{(qb)} = 0.005, \lambda^{(p)} = \lambda^{(q)} = 0.010, \lambda^{(pb)} = \lambda^{(qb)} = 0, G = 3.6043$. After 9 epochs, learning rates are multiplied by 0.01, and the model is trained for another 2 epochs.

- SemPosMF#800: defined in Section 5.4.6.

- MlMF#200: a BRISMF with 200 features. Parameters are found by the parameter optimization algorithm.

- MlMF#80: a BRISMF with 80 features. Parameters are found by the parameter optimization algorithm.

- MomentumMF: a BRISMF with momentum method, manually optimized: $K = 50, \eta = 0.01$, $\sigma = 0.3$ and $\lambda = 0.00005$. Model learnt in 5 epochs.

We refer to a variant of the transductive MF algorithm as Q-correction: in Eq. (9) to improve predictions we use only the ratings in the Qualify set, not in the Probe10 + Qualify set. See Table 7 for the RMSE values of the each method and its blended versions. We applied two NB corrections to the MF models, with similarities S1 and S2.

The results indicated in the Q, S1, S2 and Q + S1 + S2 columns are obtained by using one or more correction techniques; thus those figures refer to linear regression of predictors (columns) on Probe10 data. Each correction technique adds one more column to the combination of the basic method; that is Q, S1, S2 add 1 extra column, Q + S1 + S2 adds 3 extra columns.

One can observe in Table 7 that NB correction significantly improves the result of MF based methods. Starting from an average MF (MlMF#80) the reduction of RMSE can be 0.0179, it reduces the RMSE of the good MomentumMF by 0.0075, and it even improves slightly (0.0026) the very accurate BRISMF#800. We recall that we measured similar accuracy improvement using NB correction (with S2 similarity) in the case of the MovieLens and the Jester data sets (see Sections 5.1.2

#	Model	basic	Q	S1	S2	Q + S1 + S2
1	BRISMF#800	0.8940	0.8930	$0.8916_{(\alpha=8)}$	$0.8914_{(\alpha=7)}$	0.8902
2	SemPosMF#800	0.8950	0.8941	$0.8916_{(\alpha=8)}$	$0.8913_{(\alpha=5)}$	0.8900
3	MlMF#200	0.9112	0.9106	$0.9087_{(\alpha=8)}$	$0.9085_{(\alpha=6)}$	0.9076
4	MlMF#80	0.9251	0.9240	$0.9104_{(\alpha=9)}$	$0.9072_{(\alpha=2)}$	0.9058
5	BRISMF#1000UM	0.8921	0.8918	$0.8905_{(\alpha=7)}$	$0.8907_{(\alpha=5)}$	0.8901
6	MomentumMF	0.9031	0.9020	$0.8979_{(\alpha=6)}$	$0.8956_{(\alpha=3)}$	0.8949
7	$1+2$	0.8923				0.8880
8	$1+2+3$	0.8913				0.8872
9	$1+2+3+4$	0.8909				0.8863
10	$1+2+3+4+5$	0.8895				0.8851
11	$1+2+3+4+5+6$	0.8889				0.8838

Table 7: Probe10 RMSE of accurate MFs without and with applying Q-correction and NB correction (S1 and S2). At columns S1 and S2 we also indicated the optimal value of parameter α.

and 5.1.3). In comparison, BellKor's approach (Bell and Koren, 2007a, Table 2) results in 0.0096 RMSE reduction, starting from MF with 0.9167 RMSE. Here the reduced RMSE score is almost identical with our NB corrected MlMF#80 that has originally only RMSE 0.9251.

If we put in all MFs and all correction techniques, which is a linear combination of 24 methods, then the combination yields RMSE = 0.8838, Quiz RMSE = 0.8839. Using only the first 4 methods with all corrections (combination of 16 methods), it yields RMSE = 0.8863, Quiz RMSE = 0.8862.

It brings only insignificant improvements if one applies Q-correction technique for all MFs. We get RMSE = 0.8839 if we exclude the Q-corrections of all MFs but the first from the combination. Moreover, if we apply neighbor and Q-correction only on BRISMF#800, then the RMSE increases only by 0.0011 to 0.8850. In general, we can state that one "correction technique" brings a major decrease in the RMSE when applied only to a single method in the linear combination. If we apply it multiple times, the improvement becomes less. In other words, Q-correction and NB corrections captures the same aspects of the data, regardless of the MF behind them.

These experiments demonstrate that the Probe10 set containing 140,840 ratings is big enough to evalute not only single methods, but also combinations of many methods.

5.4.9 COMPARISON WITH BELLKOR'S POSTPROCESSING

The neighbor based correction of MF can also be done by running a neighbor based method on the residuals of MF. A very effective known algorithm for postprocessing the residuals of MF is BellKor's neighbor based method (Bell and Koren, 2007b) (BKNB). The comparison of our neighbor correction scheme and BKNB can be seen in Table 8.

In the experiments we applied the techniques on the residuals of 3 models: a BRISMF#100, a SemPosMF#100, and a so called *global effects model* (Bell and Koren, 2007b) with 12 effects. For running S1 and S2 correction on global effects we used the item features of SemPosMF#100.

Model	basic	S1	S2	S1 + S2	BKNB
BRISMF#100	0.8979	0.8940	0.8937	0.8933	0.8948
SemPosMF#100	0.9001	0.8954	0.8951	0.8946	0.8957
GlobalEffects#12	0.9600	0.9196	0.9237	0.9174	0.9145

Table 8: Comparison of NB correction and BKNB in terms of Probe10 RMSE.

For MF models the most accurate postprocessing technique is S2 correction. In the case of global effects BKNB gives the lowest Probe10 RMSE. It is also important to mention that our approach is significantly faster than BKNB (see Section 5.4.10).

5.4.10 SPEED VS. ACCURACY

From the scalability point of view, it is interesting and important to investigate the relationship of speed and accuracy. We ran numerous randomly parameterized MFs with $K = 40$, and collected the best accuracies in each epoch, and then optimized the parameters. Table 9 summarizes the results. One epoch takes 80 seconds ($K = 40$), and the initialization takes an additional 40 seconds (loading the full database into the memory).

An RMSE of 0.9071 can be achieved within 200 seconds (including the time to train with the 100 million available ratings and evaluate on the Probe10)! For a comparison: Netflix's Cinematch algorithm can achieve Quiz RMSE 0.9514, so this fast solution achieves more than 5.6% improvement on Cinematch.

In Table 9, 1.1 epoch means that the model was trained for one epoch and then the ratings of the first 1/10 of users was used for another epoch. The reason is the same as for feature retraining (see Section 3.5): when we train only for 1 epoch, the features of the first trained users will be obsolete at the end of the epoch, since items have nonsense values at the beginning of the training procedure, and item features change significantly by the end of the epoch.

Epoch	Training Time (sec)	RMSE
1	120	0.9179
1.1	128	0.9147
2	200	0.9071
3	280	0.9057
4	360	0.9028
5	440	0.9008
6	520	0.9002

Table 9: Probe10 RMSE and running time of fast and accurate MFs.

To our best knowledge, the running times and accuracies here and in the previous sections are favorable compared to any other method published in the field of Collaborative Filtering. Though this statement might seem somewhat speculative since authors do not tend to publish running times, we can support it with the following arguments:

- we train each feature simultaneously;
- the number of epochs is small;

- we use a gradient descent algorithm, which is the fastest if we can keep the number of required gradient steps low, which is exactly the case.

Note that given n^*, the number of epochs, there are $n^* \cdot |\mathcal{T}| \cdot K$ variable updates in **P** and **Q** during the training. The presented methods can achieve the favorable RMSEs while keeping the number of features (K) and the number of epochs (n^*) low; consequently they are also favorable in terms of time requirement.

Let us compare the time requirement of our MF methods (all major variants) to one of the best published ones. Bell and Koren (2007a) provide a detailed description of their alternating least squares approach proposed to matrix factorization. Briefly, their idea is to initialize **P** and **Q** randomly, recompute one of them using a nonnegative or a regular least squares solver while the other is constant, then recompute the other, and iterate these two alternating steps for a certain number of epochs (n^*). In the case of the **P**-step, one needs to run the solver for each user to determine how the features of the items rated by the user should be combined to best predict the ratings. One run of the solver requires $\Omega(K^3)$ time, which should be run for each user; thus the **P**-step requires $\Omega(|N| \cdot K^3)$ time.[14] Analogously, the **Q**-step requires $\Omega(|M| \cdot K^3)$ time. The K^2 elements of the covariance matrix need to be updated for each rating, thus, in both alternating steps we update K^2 elements $|\mathcal{T}|$ times. Let n^* denote the optimal number of epochs, which is a few dozen according to their paper. In total, their method requires $\Omega((|N| + |M|) \cdot K^3 + |\mathcal{T}| \cdot K^2) \cdot n^*$ time.

Our presented approaches have $O(|\mathcal{T}| \cdot K) \cdot n^*$ computational complexity, where n^* is typically less than 20. We remark that $O(\cdot)$ is an upper bound, while $\Omega(\cdot)$ is a lower bound for the computational complexity.

Here we neglected the cost of parameter optimization. Our MF has 13 parameters. We perform the parameter optimization process (Sec. 5.3) with a subset of users (1/6), and with a small K value (typically K is 20 or 40). The optimization process requires 100–200 MF runs. In case of SemPosMF#800, which is manually parameterized, we performed ~50 runs. One may argue that parameter optimization for alternating least squares type MF is faster, since there are no learning rates, thus it has just 9 parameters. We observed that the more parameters the MF have, the easier it was to tune the parameters to get the same Probe10 RMSE. Consequently, we introduced some additional parameters, for example $\eta^{(p)}, \eta^{(q)}, \eta^{(pb)}, \eta^{(qb)}$ instead of a single η.

5.5 RMSE Values Reported by Other Authors

Finally, let us compare the accuracy of our method (in terms of Probe10 RMSE values that differ from Quiz RMSE values at most by 0.0003) with other RMSE values reported for the Netflix Prize data set. This comparison is difficult since authors often report on RMSE values measured on various custom test sets, different from the Probe and Quiz set. Of the latter two options, Probe RMSE values, which are calculated by leaving out the Probe set from the Train set, can be also misleading, and, consequently, Probe RMSE is often much lower than Quiz RMSE. We remark that Quiz RMSE is often computed by incorporating the Probe data into the training of the predictor. The comparison presented in Table 10 therefore focuses on methods where Quiz RMSE values are available. The table shows that our presented MF method and correction techniques compare favorably with other published ones.

14. There exists somewhat better least squares solvers, but this does not significantly change this comparison.

Source	Method's name	Quiz	IoC	Probe10
Paterek (2007)	Basic + RSVD + RSVD2	0.9070	4.67%	
Salakhutdinov and Mnih (2008)	PMF + PMF with a learnable prior + constrained PMF	0.8970	5.72%	
Bell et al. (2007b)	best stand-alone positive MF	0.9039	4.99%	
	best NB corrected positive MF	0.8953	5.90%	
this paper	stand-alone MF, BRISMF#1000	0.8939	6.04%	0.8938
	stand-alone MF with retrained features, BRISMF#1000UM	0.8918	6.26%	0.8921
	NB corrected MF, BRISMF#1000UM + S1	0.8904	6.41%	0.8905
	stand-alone positive MF, PosMF#400	0.9046	4.92%	0.9036

6. Conclusions

This paper surveyed our approaches for collaborative filtering. We presented several MF methods and a neighbor based correction to the MF. Our methods apply a number of small modifications compared to already published MF variants, but these modifications are together important from the aspects of implementation (time and memory requirements) and accuracy. We performed a comprehensive evaluation of our methods on the Netflix Prize data set, and we showed that the methods can be efficiently applied for other data set (we tested on MovieLens and Jester data sets). We also presented different "correction techniques" to improve prediction accuracy: Q-correction use information from unlabeled examples, while neighbor based correction exploits localized information at prediction. We showed that linear combination of various methods can significantly improve the accuracy of the blended solution. We pointed out that various correction techniques can bring major improvement in accuracy when applied to only one method of the linear combination. We showed that they compare favorably with existing methods in terms of prediction accuracy measured by RMSE and time complexity. The experiments prove that the proposed methods are scalable to large recommender systems having hundreds of millions of ratings.

Abstract

Clustering is often formulated as a discrete optimization problem. The objective is to find, among all partitions of the data set, the best one according to some quality measure. However, in the statistical setting where we assume that the finite data set has been sampled from some underlying space, the goal is not to find the best partition of the given sample, but to approximate the true partition of the underlying space. We argue that the discrete optimization approach usually does not achieve this goal, and instead can lead to inconsistency. We construct examples which provably have this behavior. As in the case of supervised learning, the cure is to restrict the size of the function classes under consideration. For appropriate "small" function classes we can prove very general consistency theorems for clustering optimization schemes. As one particular algorithm for clustering with a restricted function space we introduce "nearest neighbor clustering". Similar to the k-nearest neighbor classifier in supervised learning, this algorithm can be seen as a general baseline algorithm to minimize arbitrary clustering objective functions. We prove that it is statistically consistent for all commonly used clustering objective functions.

Keywords: clustering, minimizing objective functions, consistency

1. Introduction

Clustering is the problem of discovering "meaningful" groups in given data. In practice, the most common approach to clustering is to define a clustering quality function Q_n, and then construct an algorithm which is able to minimize (or maximize) Q_n. There exists a huge variety of clustering quality functions: the K-means objective function based on the distance of the data points to the cluster centers, graph cut based objective functions such as ratio cut or normalized cut, or various criteria based on some function of the within- and between-cluster similarities. Once a particular clustering quality function Q_n has been selected, the objective of clustering is stated as a discrete optimization problem. Given a data set $\mathcal{X}_n = \{X_1, \dots, X_n\}$ and a clustering quality function Q_n, the ideal clustering algorithm should take into account all possible partitions of the data set and output the one that minimizes Q_n. The implicit understanding is that the "best" clustering can be any partition out of the set of all possible partitions of the data set. The practical challenge is then to construct an algorithm which is able to explicitly compute this "best" clustering by solving an optimization problem. We will call this approach the "discrete optimization approach to clustering".

Now let us look at clustering from the perspective of statistical learning theory. Here we assume that the finite data set has been sampled from an underlying data space $\mathcal{X}$ according to some probability measure $\mathbb{P}$. The ultimate goal in this setting is not to discover the best possible partition of the data set $\mathcal{X}_n$, but to learn the "true clustering" of the underlying space $\mathcal{X}$. While it is not obvious how this "true clustering" should be defined in a general setting (cf. von Luxburg and Ben-David, 2005), in an approach based on quality functions this is straightforward. We choose a clustering quality function Q on the set of partitions of the entire data space $\mathcal{X}$, and define the true clustering f^* to be the partition of $\mathcal{X}$ which minimizes Q. In a finite sample setting, the goal is now to approximate this true clustering as well as possible. To this end, we define an empirical quality function Q_n which can be evaluated based on the finite sample only, and construct the empirical clustering f_n as the minimizer of Q_n. In this setting, a very important property of a clustering algorithm is consistency: we require that $Q(f_n)$ converges to $Q(f^*)$ when $n \to \infty$. This strongly reminds of the standard approach in supervised classification, the empirical risk minimization approach. For this approach, the most important insight of statistical learning theory is that in order to be consistent, learning algorithms have to choose their functions from some "small" function space only. There are many ways how the size of a function space can be quantified. One of the easiest ways is to use shattering coefficients $s(\mathcal{F}, n)$ (see Section 2 for details). A typical result in statistical learning theory is that a necessary condition for consistency is $\mathbb{E} \log s(\mathcal{F}, n)/n \to 0$ (cf. Theorem 2.3 in Vapnik, 1995, Section 12.4 of Devroye et al., 1996). That is, the "number of functions" $s(\mathcal{F}, n)$ in $\mathcal{F}$ must not grow exponentially in n, otherwise one cannot guarantee for consistency.

Stated like this, it becomes apparent that the two viewpoints described above are not compatible with each other. While the discrete optimization approach on any given sample attempts to find the best of all (exponentially many) partitions, statistical learning theory suggests to restrict the set of candidate partitions to have sub-exponential size. So from the statistical learning theory perspective, an algorithm which is considered ideal in the discrete optimization setting will not produce partitions which converge to the true clustering of the data space.

In practice, for most clustering objective functions and many data sets the discrete optimization approach cannot be performed perfectly as the corresponding optimization problem is NP hard. Instead, people resort to heuristics and accept suboptimal solutions. One approach is to use local optimization procedures potentially ending in local minima only. This is what happens in the K-means algorithm: even though the K-means problem for fixed K and fixed dimension is not NP hard, it is still too hard for being solved globally in practice. Another approach is to construct a relaxation of the original problem which can be solved efficiently (spectral clustering is an example for this). For such heuristics, in general one cannot guarantee how close the heuristic solution is to the finite sample optimum. This situation is clearly unsatisfactory: in general, we neither have guarantees on the finite sample behavior of the algorithm, nor on its statistical consistency in the limit.

The following alternative approach looks much more promising. Instead of attempting to solve the discrete optimization problem over the set of all partitions, and then resorting to relaxations due to the hardness of this problem, we turn the tables. Directly from the outset, we only consider candidate partitions in some restricted class $\mathcal{F}_n$ containing only polynomially many functions. Then the discrete optimization problem of minimizing Q_n over $\mathcal{F}_n$ is not NP hard—formally it can be solved in polynomially many steps by trying all candidates in $\mathcal{F}_n$. From a theoretical point of view this approach has the advantage that the resulting clustering algorithm has the potential of being consistent. In addition, this approach also has advantages in practice: rather than dealing with uncontrolled relaxations of the original problem, we restrict the function class to some small subset $\mathcal{F}_n$ of "reasonable" partitions. Within this subset, we then have complete control over the solution of the optimization problem and can find the global optimum. Put another way, one can also interpret this approach as some controlled way to approximate a solution of the NP hard optimization problem on the finite sample, with the positive side effect of obeying the rules of statistical learning theory.

This is the approach we want to describe in this paper. In Section 2 we will first construct an example which demonstrates the inconsistency in the discrete optimization approach. Then we will state a general theorem which gives sufficient conditions for clustering optimization schemes to be consistent. We will see that the key point is to control the size of the function classes the clustering are selected from. In Section 3 we will then introduce an algorithm which is able to work with such a restricted function class. This algorithm is called nearest neighbor clustering, and in some sense it can be seen as a clustering-analogue to the well-known nearest neighbor classifier for classification. We prove that nearest neighbor clustering is consistent under minimal assumptions on the clustering quality functions Q_n and Q. Then we will apply nearest neighbor clustering to a large variety of clustering objective functions, such as the K-means objective function, normalized cut and ratio cut, the modularity objective function, or functions based on within-between cluster similarity ratios. For all these functions we will verify the consistency of nearest neighbor clustering in Section 4. Discussion of our results, also in the context of the related literature, can be found in Sections 5 and 6. The proofs of all our results are deferred to the appendix, as some of them are rather technical.

2. General (In)Consistency Results

In the rest of this paper, we consider a space $\mathcal{X}$ which is endowed with a probability measure $\mathbb{P}$. The task is to construct a clustering $f : \mathcal{X} \to \{1, \dots, K\}$ on this space, where K denotes the number of clusters to construct. We denote the space of all $\mathbb{P}$-measurable functions from $\mathcal{X}$ to $\{1,...,K\}$ by $\mathcal{H}$. Let $Q : \mathcal{H} \to \mathbb{R}^+$ denote a clustering quality function: for each clustering, it tells us "how good" a given clustering is. This quality function will usually depend on the probability measure $\mathbb{P}$. An optimal clustering, according to this objective function, is a clustering f^* which satisfies

$$f^* \in \underset{f \in \mathcal{F}}{\operatorname{argmin}}\, Q(f).$$

where $\mathcal{F} \subseteq \mathcal{H}$ is a fixed set of candidate clusterings. Now assume that $\mathbb{P}$ is unknown, but that we are given a finite sample $X_1, ..., X_n \in \mathcal{X}$ which has been drawn i.i.d according to $\mathbb{P}$. Our goal is to use this sample to construct a clustering f_n which "approximates" an optimal clustering f^*. To this end, assume that $Q_n : \mathcal{H} \to \mathbb{R}^+$ is an estimator of Q which can be computed based on the finite sample only (that is, it does not involve any function evaluations $f(x)$ for $x \notin \{X_1, ..., X_n\}$). We then consider the clustering

$$f_n \in \underset{f \in \mathcal{F}_n}{\operatorname{argmin}}\, Q_n(f).$$

Here, $\mathcal{F}_n$ is a subset of $\mathcal{H}$, which might or might not be different from $\mathcal{F}$. The general question we are concerned with in this paper is the question of consistency: under which conditions do we know that $Q(f_n) \to Q(f^*)$?

Note that to avoid technical overload we will assume throughout this paper that all the minima (as in the definitions of f^* and f_n) exist and can be attained. If this is not the case, one can always go over to statements about functions which are ε-close to the corresponding infimum. We also will not discuss issues of measurability in this paper (readers interested in measurability issues for empirical processes are referred to Section 1 of van der Vaart and Wellner, 1996).

2.1 Inconsistency example

In the introduction we suggested that as in the supervised case, the size of the function class $\mathcal{F}_n$ might be the key to consistency of clustering. In particular, we argued that optimizing over the space of all measurable functions might lead to inconsistency. First of all, we would like to prove this statement by providing a example. This example will show that if we optimize a clustering objective function over a too large class of functions, the resulting clusterings are not consistent.

Example 1 (Inconsistency in general) *As data space we choose $\mathcal{X} = [0,1] \cup [2,3]$, and as probability measure $\mathbb{P}$ we simply use the normalized Lebesgue measure λ on $\mathcal{X}$. We define the following similarity function between points in $\mathcal{X}$:*

$$s(x,y) = \begin{cases} 1 & \text{if } x \in [0,1], y \in [0,1] \\ 1 & \text{if } x \in [2,3],\ y \in [2,3] \\ 0 & \text{otherwise.} \end{cases}$$

For simplicity, we consider the case where we want to construct $K = 2$ clusters called C_1 and C_2. Given a clustering function $f : \mathcal{X} \to \{0,1\}$ we call the clusters $C_1 := \{x \in \mathcal{X} \mid f(x) = 0\}$ and $C_2 := \{x \in \mathcal{X} \mid f(x) = 1\}$. As clustering quality function Q we use the between-cluster similarity (equivalent to cut*, see Section* 4.2 *for details):*

$$Q(f) = \int_{x \in C_1} \int_{y \in C_2} s(X,Y)\, d\mathbb{P}(X)\, d\mathbb{P}(Y).$$

As an estimator of Q we will use the function Q_n where the integrals are replaced by sums over the data points:

$$Q_n(f) = \frac{1}{n(n-1)} \sum_{i \in C_1} \sum_{j \in C_2} s(X_i, X_j).$$

As set $\mathcal{F}$ we choose the set of all measurable partitions on $\mathcal{X}$ (note that the same example also holds true when we only look at the set $\mathcal{F}$ of measurable partitions such that both clusters have a minimal mass ε for some $\varepsilon > 0$). For all $n \in \mathbb{N}$ we set $\mathcal{F}_n = \mathcal{F}$. Let $X_1, ..., X_n \in \mathcal{X}$ be our training data. Now define the functions

$$f^*(x) = \begin{cases} 0 & \text{if } x \in [0,1] \\ 1 & \text{if } x \in [2,3] \end{cases} \qquad \text{and} \qquad f_n(x) = \begin{cases} 0 & \text{if } x \in \{X_1, ..., X_n\} \cap [0,1] \\ 1 & \text{if } x \in [2,3] \\ 0 & \text{if } x \in [0, 0.5] \setminus \{X_1, ..., X_n\} \\ 1 & \text{if } x \in [0.5, 1] \setminus \{X_1, ..., X_n\} \end{cases}.$$

It is obvious that $Q(f^*) = 0$ and $Q_n(f_n) = 0$. As both Q and Q_n are non-negative, we can conclude $f^* \in \operatorname{argmin}_{f \in \mathcal{F}} Q(f)$ and $f_n \in \operatorname{argmin}_{f \in \mathcal{F}} Q_n(f)$. It is also straightforward to compute $Q(f_n) = 1/16$ (independently of n). Hence, we have inconsistency: $1/16 = Q(f_n) \not\to Q(f^*) = 0$.

Note that the example is set up in a rather natural way. The data space contains two perfect clusters ($[0,1]$ and $[2,3]$) which are separated by a large margin. The similarity function is the ideal similarity function for this case, giving similarity 1 to points which are in the same cluster, and similarity 0 to points in different clusters. The function f^* is the correct clustering. The empirical clustering f_n, if restricted to the data points, reflects the correct clustering. It is just the "extension" of the empirical clustering to non-training points which leads to the inconsistency of f_n. Intuitively, the reason why this can happen is clear: the function space $\mathcal{F}$ does not exclude the unsuitable extension chosen in the example, the function overfits. This can happen because the function class is too large.

2.2 Main Result

Now we would like to present our first main theorem. It shows that if f_n is only picked out of a "small" function class $\mathcal{F}_n$, then we can guarantee consistency of clustering. Before stating the theorem we would like to recall the definition of the shattering coefficient in a K-class setting. For a function class $\mathcal{F} : \mathcal{X} \to \{1,\ldots,K\}$ the shattering coefficient of size n is defined as

$$s(\mathcal{F},n) = \max_{x_1,\ldots,x_n \in \mathcal{X}} |\{(f(x_1),\ldots,f(x_n)) \mid f \in \mathcal{F}\}|.$$

To state our theorem, we will also require a pseudo-distance d between functions. A pseudo-distance is a dissimilarity function $d : \mathcal{X} \times \mathcal{X} \to \mathbb{R}^+$ which is symmetric, satisfies the triangle inequality and the condition $f = g \implies d(f,g) = 0$, but not necessarily the condition $d(f,g) = 0 \implies f = g$. For distances between sets of functions we use the standard convention $d(\mathcal{F},\mathcal{G}) = \inf_{f\in\mathcal{F},g\in\mathcal{G}} d(f,g)$. Our theorem is as follows:

Theorem 1 (Consistency of a clustering optimizing scheme) *Let $(X_n)_{n\in\mathbb{N}}$ be a sequence of random variables which have been drawn i.i.d. according to some probability measure $\mathbb{P}$ on some set $\mathcal{X}$. Let $\mathcal{F}_n := \mathcal{F}_n(X_1,\ldots,X_n) \subset \mathcal{H}$ be a sequence of function spaces, and $\mathcal{F} \subset \mathcal{H}$. Let $d : \mathcal{H} \times \mathcal{H} \to \mathbb{R}$ be a pseudo-distance defined on $\mathcal{H}$. Let $Q : \mathcal{H} \to \mathbb{R}^+$ be a clustering quality function, and $Q_n : \mathcal{H} \to \mathbb{R}^+$ an estimator of this function which can be computed based on the finite sample only. Finally let*

$$\widetilde{\mathcal{F}_n} := \bigcup_{X_1,\ldots,X_n \in \mathbb{R}^d} \mathcal{F}_n.$$

Define the true and the empirical clusterings as

$$f^* \in \operatorname*{argmin}_{f\in\mathcal{F}} Q(f),$$
$$f_n \in \operatorname*{argmin}_{f\in\mathcal{F}_n} Q_n(f).$$

Assume that the following conditions are satisfied:

1. *$Q_n(f)$ is a consistent estimator of $Q(f)$ which converges sufficiently fast for all $f \in \widetilde{\mathcal{F}_n}$:*

$$\forall \varepsilon > 0,\ \ s(\widetilde{\mathcal{F}_n},2n) \sup_{f\in\widetilde{\mathcal{F}_n}} \mathbb{P}(|Q_n(f) - Q(f)| > \varepsilon) \to 0,$$

2. *$\mathcal{F}_n$ approximates $\mathcal{F}$ in the following sense:*

$$\begin{aligned}(i)&\quad \forall f \in \mathcal{F}, d(f,\mathcal{F}_n) \to 0 \textit{ in probability,}\\ (ii)&\quad \mathbb{P}(f_n \notin \mathcal{F}) \to 0.\end{aligned}$$

3. *Q is uniformly continuous with respect to the pseudo-distance d between $\mathcal{F}$ and $\widetilde{\mathcal{F}_n}$:*

$$\forall \varepsilon > 0\ \exists \delta(\varepsilon) > 0 \textit{ such that } \forall f \in \mathcal{F}\ \forall g \in \widetilde{\mathcal{F}_n}:\ d(f,g) \le \delta(\varepsilon) \Rightarrow |Q(f) - Q(g)| \le \varepsilon.$$

Then the optimization scheme is weakly consistent, that is $Q(f_n) \to Q(f^*)$ in probability.

This theorem states sufficient conditions for consistent clustering schemes. In the context of the standard statistical learning theory, the three conditions in the theorem are rather natural. The first condition mainly takes care of the estimation error. Implicitly, it restricts the size of the function class $\mathcal{F}_n$ by incorporating the shattering coefficient. We decided to state condition 1 in this rather abstract way to make the theorem as general as possible. We will see later how it can be used in concrete applications. Of course, there are many more ways to specify the size of function classes, and many of them might lead to better bounds in the end. However, in this paper we are not so much concerned with obtaining the sharpest bounds, but we want to demonstrate the general concept (as the reader can see in appendix, the proofs are already long enough using simple shattering numbers). The second condition in the theorem takes care of the approximation error. Intuitively it is clear that if we want to approximate solutions in $\mathcal{F}$, eventually $\mathcal{F}_n$ needs to be "close" to $\mathcal{F}$. The third condition establishes a relation between the quality function Q and the distance function d: if two clusterings f and g are close with respect to d, then their quality values $Q(f)$ and $Q(g)$ are close, too. We need this property to be able to conclude from "closeness" as in Condition 2 to "closeness" of the clustering quality values.

Finally, we would like to point out a few technical treats. First of all, note that the function class $\mathcal{F}_n$ is allowed to be data dependent. Secondly, as opposed to most results in empirical risk minimization we do not assume that Q_n is an unbiased estimator of Q (that is, we allow $\mathbb{E}Q_n \neq Q$), nor does Q need to be "an expectation" (that is, of the form $Q(f) = \mathbb{E}(\Omega(f,X))$ for some Ω). Both facts make the proof more technical, as many of the standard tools (symmetrization, concentration inequalities) become harder to apply. However, this is necessary since in the context of clustering biased estimators pop up all over the place. We will see that many of the popular clustering objective functions lead to biased estimators.

3. Nearest Neighbor Clustering—General Theory

The theorem presented in the last section shows sufficient conditions under which clustering can be performed consistently. Now we want to present a generic algorithm which can be used to minimize arbitrary clustering objective functions. With help of Theorem 1 we can then prove the consistency of its results for a large variety of clustering objective functions.

We have seen that the key to obtain consistent clustering schemes is to work with an appropriate function class. But of course, given quality functions Q and Q_n, the question is how such a function space can be constructed in practice. Essentially, three requirements have to be satisfied:

- The function space $\mathcal{F}_n$ has to be "small". Ideally, it should only contain polynomially many functions.

- The function space $\mathcal{F}_n$ should be "rich enough". In the limit $n \to \infty$, we would like to be able to approximate any (reasonable) measurable function.
- We need to be able to solve the optimization problem $\text{argmin}_{f \in \mathcal{F}_n} Q_n(f)$. This sounds trivial at first glance, but in practice is far from easy.

One rather straightforward way to achieve all requirements is to use a function space of piecewise constant functions. Given a partitioning of the data space in small cells, we only look at clusterings which are constant on each cell (that is, the clustering never splits a cell). If we make sure that the number of cells is only of the order $\log(n)$, then we know that the number of clusterings is at most $K^{\log(n)} = n^{\log(K)}$, which is polynomial in n. In the following we will introduce a data-dependent random partition of the space which turns out to be very convenient.

3.1 Nearest Neighbor Clustering—The Algorithm

We will construct a function class $\mathcal{F}_n$ as follows. Given a finite sample $X_1, \ldots, X_n \in \mathbb{R}^d$, the number K of clusters to construct, and a number $m \in \mathbb{N}$ with $K \leq m \ll n$, randomly pick a subset of m "seed points" $X_{s_1}, \ldots, X_{s_m}$. Assign all other data points to their closest seed points, that is for all $j = 1, \ldots, m$ define the set Z_j as the subset of data points whose nearest seed point is X_{s_j}. In other words, the sets $Z_1, \ldots, Z_m$ are the Voronoi cells induced by the seeds $X_{s_1}, \ldots, X_{s_m}$. Then consider all partitions of $\mathcal{X}_n$ which are constant on all the sets $Z_1, ..., Z_m$. More formally, for given seeds we define the set $\mathcal{F}_n$ as the set of all functions

$$\mathcal{F}_n := \{f : \mathcal{X} \to \{1, \ldots, K\} \mid \forall\, j = 1, \ldots, m : \forall z, z' \in Z_j : f(z) = f(z')\}.$$

Obviously, the function class $\mathcal{F}_n$ contains K^m functions, which is polynomial in n if the number m of seeds satisfies $m \in O(\log n)$. Given $\mathcal{F}_n$, the most simple polynomial-time optimization algorithm is then to evaluate $Q_n(f)$ for all $f \in \mathcal{F}_n$ and choose the solution $f_n = \text{argmin}_{f \in \mathcal{F}_n} Q_n(f)$. We call the resulting clustering the *nearest neighbor clustering* and denote it by $\text{NNC}(Q_n)$. The entire algorithm is summarized in Figure 1. We have already published results on the empirical performance

```
**Nearest Neighbor Clustering NNC($Q_n$), naive implementation**

**Parameters:** number $K$ of clusters to construct, number $m \in \mathbb{N}$ of seed points
to use (with $K \leq m \ll n$), clustering quality function $Q_n$

**Input:** data set $\mathcal{X}_n = \{X_1, \ldots, X_n\}$, distances $d_{ij} = d(X_i, X_j)$

    • Subsample $m$ seed points from the data points, without replacement.
    • Build the Voronoi decomposition $Z_1, \ldots, Z_m$ of $\mathcal{X}_n$ based on the distances
      $d_{ij}$ using the seed points as centers
    • Define $\mathcal{F}_n := \{f : \mathcal{X}_n \to \{1, \ldots, K\} \mid f$ constant on all cells $Z_j\}$
    • For all $f \in \mathcal{F}_n$ evaluate $Q_n(f)$.

**Output:** $f_n := \text{argmin}_{f \in \mathcal{F}_n} Q_n(f)$
```

Figure 1: Nearest neighbor clustering for a general clustering objective function Q_n.

of the algorithm in von Luxburg et al. (2008), and more results can be found in Section 3 of Jegelka (2007). We have found that on finite samples, the algorithm performs surprisingly well in terms of quality function: using $m = \log n$ seed points, the objective function values obtained at the solutions are comparable to these of K-means or spectral clustering, respectively. Moreover, there exist efficient ways to compute f_n using branch and bound methods. Using these methods, the running time of nearest neighbor clustering using $m = \log n$ seeds is roughly comparable to the one of the other clustering algorithms. See von Luxburg et al. (2008) and Jegelka (2007) for details on the experimental results.

3.2 Consistency of Nearest Neighbor Clustering (General Statement)

Now we want to prove that nearest neighbor clustering is consistent. We will see that even though we can rely on Theorem 1, the consistency proof for nearest neighbor clustering does not come for free. Let $f : \mathcal{X} \to \{1,\dots,K\}$ be a clustering function. In the following, we will often use the notation f_k for the indicator function of the k-th cluster:

$$f_k(x) := \mathbb{1}_{f(x)=k}.$$

This is a slight abuse of notation, as we already reserved the notation f_n for the minimizer of the empirical quality function. However, from the context it will always be clear whether we will refer to f_n or f_k, respectively, as we will not mix up the letters n (for the sample size) and k (a cluster index).

As distance function between two clusterings we use the 0-1-loss

$$d(f,g) := \mathbb{P}(f(X) \neq g(X) | X_1,\dots,X_n).$$

Here the conditioning is needed for the cases where the functions f or g are data dependent. Note that in clustering, people often consider a variant of this distance which is independent with respect to the choice of labels, that is they choose $\tilde{d}(f,g) := \min_\pi P(f(X) \neq \pi(g(X)) | X_1,\dots,X_n)$, where π runs over all permutations of the set $\{1,\dots,K\}$. However, we will see that for our purposes it does not hurt to use the overly sensitive 0-1 distance instead. The main reason is that at the end of the day, we only want to compare functions based on their quality values, which do not change under label permutations. In general, the theorems and proofs could also be written in terms of $\tilde{d}$. For better readability, we decided to stick to the standard 0-1 distance, though.

We will see below that in many cases, even in the limit case one would like to use a function space $\mathcal{F}$ which is a proper subset of $\mathcal{H}$. For example, one could only be interested in clusterings where all clusters have a certain minimal size, or where the functions satisfy certain regularity constraints. In order to be able to deal with such general function spaces, we will introduce a tool to restrict function classes to functions satisfying certain conditions. To this end, let

$$\Phi : \mathcal{H} \to \mathbb{R}^+$$

be a functional which quantifies certain aspects of a clustering. In most cases, we will use functionals Φ which operate on the individual cluster indicator functions f_k. For example, $\Phi(f_k)$ could measure the size of cluster k, or the smoothness of the cluster boundary. The function class $\mathcal{F}$ will then be defined as

$$\mathcal{F} = \{f \in \mathcal{H} \mid \Phi(f_k) > a \text{ for all } k = 1,\dots,K\},$$
