$$\sum_{i=1}^{m} \frac{p(s=1)}{p(s=-1)} \exp(-\mathbf{v}^\mathsf{T} \mathbf{x}_i) \ell_{\mathbf{w}}(y_i \mathbf{w}^\mathsf{T} \mathbf{x}_i) + \frac{1}{2\sigma_{\mathbf{w}}^2} \mathbf{w}^\mathsf{T} \mathbf{w}.$$

The criterion of Optimization Problem 3 weights the loss $\ell_{\mathbf{w}}(y_i \mathbf{w}^\mathsf{T} \mathbf{x}_i)$ that each example incurs such that the sample is matched to the test distribution. The last term $\frac{1}{2\sigma_{\mathbf{w}}^2} \mathbf{w}^\mathsf{T} \mathbf{w}$ is the regularizer of the regression. Optimization Problem 3 can easily be adapted to virtually any type of classification mechanism by inserting the appropriate loss function $\ell_{\mathbf{w}}(y_i \mathbf{w}^\mathsf{T} \mathbf{x}_i)$ and regularizer. Operationally, an arbitrary classification procedure is applied to a sample that is either resampled from the training data according to sampling distribution $\frac{p(s=1)}{p(s=-1)} \exp(-\mathbf{v}^\mathsf{T} \mathbf{x}_i)$, or the classifier is applied to the training data with the example-specific loss scaled according to $\frac{p(s=1)}{p(s=-1)} \exp(-\mathbf{v}^\mathsf{T} \mathbf{x}_i)$.

8. Relationship to Kernel Mean Matching

Huang et al. (2007) motivate the kernel mean matching algorithm as a procedure that minimizes the distance between the means of unlabeled and weighted labeled data in feature space. If the kernel is universal this is equivalent to minimizing the difference of the distributions. We derive a new interpretation for kernel mean matching that shows its relation to Optimization Problem 2 and the above two-stage approximation.

Using a hinge loss for $\ell_{\mathbf{v}}(s_i(\mathbf{v}^\mathsf{T} \mathbf{x}_i + b))$ in Optimization Problem 2 and an explicit offset parameter b we obtain a regular support vector machine. The kernel matrix of this SVM is $\begin{bmatrix} \mathbf{K}_{(LL)} & \mathbf{K}_{(LT)} \\ \mathbf{K}_{(LT)}^\mathsf{T} & \mathbf{K}_{(TT)} \end{bmatrix}$ and the target variables are $s_i \in \{-1, 1\}$. An SVM can heuristically be simplified by setting the dual parameters α_i for the unlabeled examples to a fixed value $\frac{m}{n}$. This can be interpreted as a mixture between an SVM and a Rocchio classifier. The α_i corresponding to the labeled examples ($s_i = 1$) are trained with an SVM; setting α_i of all unlabeled examples ($s_i = -1$) to $\frac{m}{n}$ approximates the negative class (the unlabeled examples) by their centroid in feature space in accordance with the Rocchio classifier (Joachims, 1997).

The SVM optimization criterion with fixed $\alpha_i = \frac{m}{n}$ for examples with $s_i = -1$ is

$$\begin{aligned} \min_{\alpha_L} \quad & \tfrac{1}{2} \alpha_L^\mathsf{T} \mathbf{K}_{(LL)} \alpha_L - \tfrac{m}{n} \alpha_L^\mathsf{T} \mathbf{K}_{(LT)} \mathbf{1} + \tfrac{1}{2} \tfrac{m^2}{n^2} \mathbf{1} \mathbf{K}_{(TT)} \mathbf{1} - \alpha_L^\mathsf{T} \mathbf{1} - n \tfrac{m}{n} \\ & \text{subject to } \alpha_i \in \left[0, \sigma_{\mathbf{v}}^2\right] \text{ and } \textstyle\sum_{i=1}^m \alpha_i = \sum_{i=1}^n \frac{m}{n} = m; \end{aligned}$$

vector α_L denotes all elements α_i with $i = 1, \ldots, m$. We can drop the constant terms ($\alpha_L^\mathsf{T} \mathbf{1}$ is constant because of the second constraint) and arrive at Optimization Problem 4.

Optimization Problem 4

$$\min_{\alpha_L} \quad \tfrac{1}{2} \alpha_L^\mathsf{T} \mathbf{K}_{(LL)} \alpha_L - \tfrac{m}{n} \alpha_L^\mathsf{T} \mathbf{K}_{(LT)} \mathbf{1} \quad \text{subject to } \alpha_i \in \left[0, \sigma_{\mathbf{v}}^2\right] \text{ and } \alpha_L^\mathsf{T} \mathbf{1} = m.$$

This is the dual objective of kernel mean matching. The only difference is that Huang et al. (2007) relax the second constraint up to a small constant ε, their constraint is $m(1-\varepsilon) \leq \alpha_L^\mathsf{T} \mathbf{1} \leq m(1+\varepsilon)$. Empirically we find that setting ε to zero has no impact on the performance. The parameter $\sigma_{\mathbf{v}}^2$ corresponds to parameter B in Equation 2.

In order to solve the second stage (Optimization Problem 3), kernel mean matching does not use re-weighting factors $\frac{p(s=1)}{p(s=-1)} \exp(-\mathbf{v}^\mathsf{T} \mathbf{x}_i - b)$ but directly uses the dual α_i parameters as weights.

To sum up, kernel mean matching can be interpreted as a variant of Optimization Problem 2. It discriminates training against test examples using a partially Rocchio-style approximation to the SVM optimization criterion.

9. Parameter Tuning

Optimization Problem 1 relies on hyper-parameters $\sigma_{\mathbf{v}}^2$ and $\sigma_{\mathbf{w}}^2$ that need to be tuned. For the two-stage approximation of Section 7 and reference methods like kernel mean matching two similar parameters need to be specified. In addition to the regularization parameters kernel parameters need to be tuned for non-linear kernels. Parameter tuning for covariate shift models is much more difficult than for regular prediction models because in the covariate shift setting there is no labeled data available drawn from the test distribution. Parameter tuning by regular cross-validation on the labeled training data is inappropriate because the labeled training data is not governed by the test distribution.

In the following paragraphs we describe different tuning procedures; two procedures require prior knowledge and one does not require prior knowledge on the hyper-parameters. The tuning procedures with prior knowledge can be used for all described models. The one without prior knowledge cannot be used for kernel mean matching and the one-stage model of Optimization Problem 1.

A typical setting with prior knowledge on the hyper-parameters is when the difference between training and test data is introduced by a covariate shift over time and the input distribution shifts constantly over time. The most recent data is the unlabeled test data and the older data has been labeled and is the training data. In this setting the parameters can be tuned by splitting the labeled training data into two consecutive parts. The tuning models are learned on the part with earlier timestamps and the hyper-parameters $\sigma_{\mathbf{v}}^2$ and $\sigma_{\mathbf{w}}^2$ and kernel parameters are optimized on the part with later timestamps.

Another setting with prior knowledge is when in addition to the pair of training and test set an additional pair of training and fully labeled test set from a different domain with a similar magnitude of covariate shift is available. This additional set can be used to tune the parameters. Due to the similar magnitude of the covariate shift the optimal parameters for the additional domain are assumed to be a good choice for the parameters of the target domain.

For some two-stage models for covariate shift there is no prior knowledge necessary to tune hyper-parameters. Sugiyama et al. (2008) propose to tune the regularizer of the KLIEP model with cross-validation. In this manner the first stage parameter $\sigma_{\mathbf{v}}^2$ (and kernel parameters) of the two-stage model of Section 7 can be tuned as follows. The training and the test data are both split into training and tuning folds and the hold-out likelihood of the tuning folds is optimized with grid search on $\sigma_{\mathbf{v}}^2$ (and kernel parameters). The hold-out likelihood measures the predictive performance of the model $p(s|\mathbf{x};\mathbf{v})$ with respect to predicting the selector variable s of the hold out examples. Once the regularizer of the first stage is tuned, the second stage parameter $\sigma_{\mathbf{w}}^2$ (and kernel parameters) can be tuned with cross-validation on weighted training data (Sugiyama and Müller, 2005). The data of training folds as well as the data of tuning folds are weighted with the estimated training-to-test ratio.

Kernel mean matching does not provide out-of-sample predictions and it is therefore difficult to tune the regularization parameter B with cross-validation. The one-stage model of Optimization Problem 1 is also difficult to tune with cross-validation because there is a bidirectional influence between the parameters $\sigma_{\mathbf{v}}^2$ and $\sigma_{\mathbf{w}}^2$.

In order to compare the one-stage model and kernel mean matching to the other two-stage models we use tuning procedures based on prior knowledge in the empirical studies in the next section.

10. Empirical Results

We study the benefit of two versions of the integrated classifier for covariate shift and other reference methods on spam filtering, text classification, and landmine detection problems. The first integrated classifier uses a logistic model for $\ell_{\mathbf{w}}$ ("integrated log model"), the second an exponential model for $\ell_{\mathbf{w}}$ ("integrated exp model"); $\ell_{\mathbf{v}}$ is a logistic model in both cases.

The first baseline is a classifier trained under *iid* assumption with logistic $\ell_{\mathbf{w}}$. All other reference methods consist of a two-stage procedure: first, the difference between training and test distribution is estimated, the classifier is trained on weighted data in a second step. The second method is kernel mean matching (Huang et al., 2007); we set $\varepsilon = \sqrt{m-1}/\sqrt{m}$ as proposed by the authors. In the third method, separate density estimates for $p(\mathbf{x}|\lambda)$ and $p(\mathbf{x}|\theta)$ are obtained using kernel density estimation (Shimodaira, 2000), the bandwidth of the kernel is chosen according to the rule-of-thumb of Silverman (1986).

The last two reference methods rely on the two-stage approximation of Optimization Problems 2 and 3 with a logistic regression ("two-stage LR") and an exponential model classifier ("two-stage exp model") as their second stages. The example weights are computed according to Equation 17 using a logistic model in the first stage, $p(s=1|\mathbf{x};\mathbf{v})$ is estimated by training a logistic regression that discriminates training from test examples.

The baselines differ in the first stage, the second stage is based on a logistic regression classifier with weighted examples in all cases but the two-stage exponential model baseline. We use a maximum likelihood estimate of $\frac{m}{n}$ for $\frac{p(s=1)}{p(s=-1)}$. We use tuning procedures that rely on prior knowledge (cf. Section 9). Short descriptions of the respective tuning data can be found below. For all experiments we tune the regularization parameters of all methods (and the variance parameter of the RBF kernels for the landmine experiments) by maximizing AUC on the tuning set.

We use the spam filtering data of Bickel et al. (2007); the collection contains nine different inboxes with test emails (5270 to 10964 emails, depending on inbox) and one set of training emails compiled from various different sources. We use a fixed set of 1000 emails as training data. We randomly select between 32 and 2048 emails from one of the original inboxes. We repeat this process 10 times for 2048 test emails and 20 to 640 times for 1024 to 32 test emails. As tuning data we use the labeled emails from an additional inbox different from the test inboxes.

The performance measure is the rate by which the $1-\text{AUC}$ risk is reduced over the *iid* baseline (Bickel and Scheffer, 2007); it is computed as $1-\frac{1-\text{AUC}}{1-\text{AUC}_{iid}}$. We use linear kernels for all methods. We analyze the rank of the kernel matrix and find that it fulfills the universal kernel requirement of kernel mean matching; this is due to the high-dimensionality of the data.

Figure 1 (top row) shows the results for various numbers of unlabeled examples. The left column of Figure 1 compares the integrated classifiers for covariate shift to the kernel mean matching and kernel density estimation baselines. The right column compares the integrated classifiers (Optimization Problem 1) with the two-stage approximations (Optimization Problems 2 and 3). The results for a specific number of unlabeled examples are averaged over 10 to 640 random test samples and averaged over all nine inboxes. Averaged over all users and inbox sizes the absolute AUC of the *iid* classifier is 0.994. Error bars indicate standard errors of the $1-\text{AUC}$ risk.

The integrated and two-step logistic regression and exponential models and kernel mean matching perform similarly well. The differences to the *iid* baseline are highly significant. For 1048 examples the $1-\text{AUC}$ risk is even reduced by an average of 30% with the integrated exponential model classifier! The kernel density estimation procedure is not able to beat the *iid* baseline. The

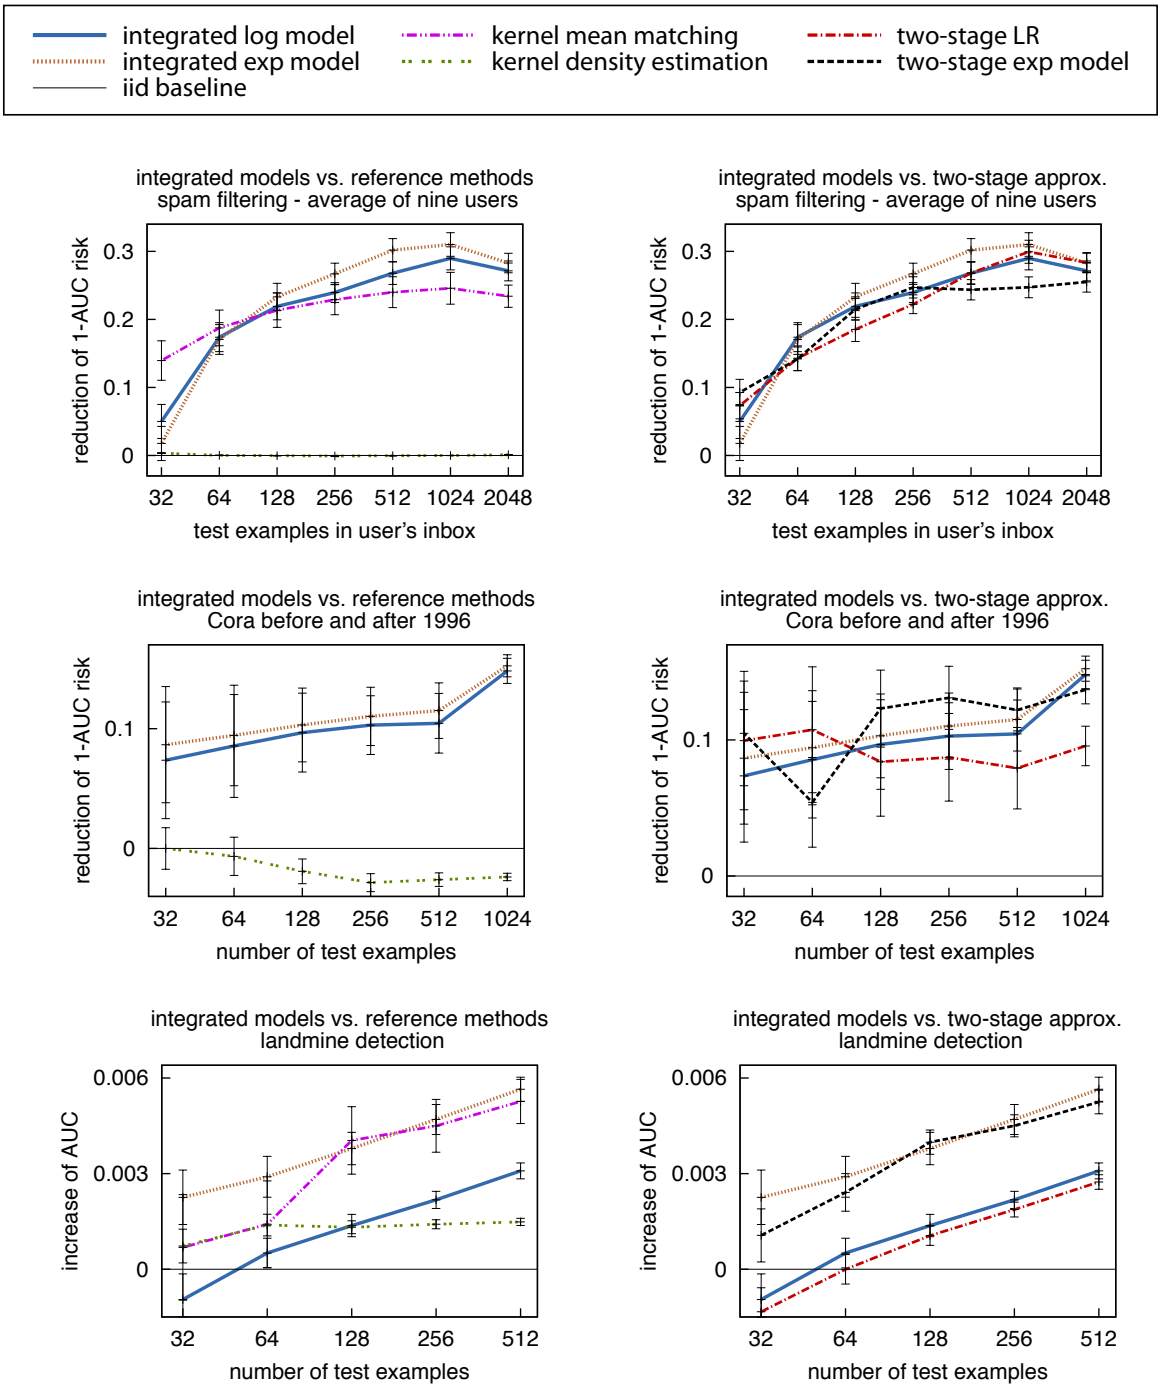

Figure 1: Average reduction of $1 - \text{AUC}$ risk over nine users for spam filtering (top row) and Cora *Machine Learning/Networking* classification before and after 1996 (second row) and average increase of AUC for landmine detection over 812 pairs of mine fields (bottom row) depending on the number of unlabeled test examples.

convex integrated exponential model performs slightly better than its two-stage approximation; for larger number of test examples (512 to 2048) this difference is statistically significant according to a paired t-test with significance level of 5%. For the logistic model, the two-stage optimization performs similarly well as the integrated version.

We now study text classification using computer science papers from the Cora data set. The task is to discriminate Machine Learning from Networking papers. We select 812 papers written before 1996 from both classes as training examples and 1285 papers written after 1996 as test examples. For parameter tuning we apply an additional time split on the training data; we train on the papers written before 1995 and tune on papers written 1995 (cf. Section 9).

Title and abstract are transformed into *tfidf* vectors, the number of distinct words is about 40,000. We again use linear kernels (rank analysis verifies the universal kernel property) and average the results over 20 to 640 random test samples for different sizes (1024 for 20 samples to 32 for 640 samples) of test sets. The resulting $1-\text{AUC}$ risk is shown in Figure 1 (second row). The average absolute AUC of the *iid* classifier is 0.998. The methods based on discriminative density estimates significantly outperform all other methods. Kernel mean matching is not displayed because its average performance lies far below the *iid* baseline. The integrated models reduce the $1-\text{AUC}$ risk by 15% for 1024 test examples.

In a third set of experiments we study the problem of detecting landmines using the data set of Xue et al. (2007). The collection contains data of 29 mine fields in different regions. Binary labels (landmine or safe ground) and nine dimensional feature vectors extracted from radar images are provided. There are about 500 examples for each mine field. Each of the fields has a distinct distribution of input patterns, varying from highly foliated to desert areas.

We enumerate all 29×28 pairs of mine fields, using one field as training and the other as test data. For tuning we hold out 4 of the 812 pairs. Results are increases over the *iid* baseline, averaged over all $29 \times 28 - 4$ combinations. We use RBF kernels with kernel width 0.3 for all methods. The results are displayed in Figure 1 (bottom row). The average absolute AUC of the *iid* baseline is 0.64 with a standard deviation of 0.07; note, that the error bars are much smaller than the absolute standard deviation because they indicate the standard error of the *differences* to the *iid* baseline.

For this problem, the exponential model classifiers and kernel mean matching significantly outperform all other methods on average. Considering only methods with logistic target model, kernel mean matching is better than all other methods. Integrated logistic regression and two-stage logistic regression are still significantly better than the *iid* baseline except for 32 and 64 test examples. The integrated classifiers are slightly better than the two-stage variants.

11. Conclusion

We derived a discriminative model for learning under differing training and test distributions. The contribution of each training instance to the optimization problem ideally needs to be weighted with its test-to-training density ratio. We show that this ratio can be expressed—without modeling either training or test density—by a discriminative model that characterizes how much more likely an instance is to occur in the test sample than it is to occur in the training sample.

We described a generative model whose parameters can be estimated with a joint MAP hypothesis of both the parameters of the test-to-training model and the final classifier. Optimizing these dependent parameters sequentially incurs an additional approximation compared to solving the joint optimization problem. We derived a primal and a kernelized Newton gradient descent procedure for

the joint optimization problem. Theorem 4 specifies the condition for the convexity of Optimization Problem 1. Checking the condition using popular loss functions as models of the negative log-likelihoods reveals that Optimization Problem 1 is convex with exponential loss.

We gave a new interpretation for kernel mean matching and show that it is also based on a discriminative model similar to Optimization Problem 2.

Empirically, we found that the integrated and the two-stage models as well as kernel mean matching outperform the *iid* baseline and the kernel density estimation model in almost all cases. In some cases, the integrated models perform slightly better than their two-stage counterparts. The performance of kernel mean matching depends on the problem; for one out of three problems it did not beat the *iid* baseline, for the others it yielded comparable results to the integrated models.

The two-stage model is conceptually simpler than the integrated model, and may in some cases have the greatest practical utility. The main advantage compared to the integrated model is that regularization parameters can be tuned without prior knowledge by cross-validation. Another advantage of the two-stage model is that in the second stage, after the example-specific weights have been derived, virtually any learning mechanism can be employed to produce the final classifier from the weighted training sample. This comes at the cost of only a marginal loss of performance compared to the integrated model.

Appendix A. Newton Gradient Descent—Proof of Theorem 3

In this Appendix, we derive Newton gradient descent updates for Optimization Problem 1 and thereby prove Theorem 3. We abbreviate

$$\ell_{\mathbf{v},i} = \ell_{\mathbf{v}}(s_i \mathbf{v}^\mathsf{T} \mathbf{x}_i); \;\; \ell'_{\mathbf{v},i} s_i x_{ij} = \frac{\partial \ell_{\mathbf{v}}(s_i \mathbf{v}^\mathsf{T} \mathbf{x}_i)}{\partial v_j}; \;\; \ell''_{\mathbf{v},i} x_{ij} x_{ik} = \frac{\partial^2 \ell_{\mathbf{v}}(s_i \mathbf{v}^\mathsf{T} \mathbf{x}_i)}{\partial v_j v_k}; \tag{31}$$

$$\ell_{\mathbf{w},i} = \ell_{\mathbf{w}}(y_i \mathbf{w}^\mathsf{T} \mathbf{x}_i); \;\; \ell'_{\mathbf{w},i} y_i x_{ij} = \frac{\partial \ell_{\mathbf{w}}(y_i \mathbf{w}^\mathsf{T} \mathbf{x}_i)}{\partial w_j}; \;\; \ell''_{\mathbf{w},i} x_{ij} x_{ik} = \frac{\partial^2 \ell_{\mathbf{w}}(y_i \mathbf{w}^\mathsf{T} \mathbf{x}_i)}{\partial w_j w_k}; \tag{32}$$

$$\omega_i = \frac{p(s=1)}{p(s=-1)} \exp(-\mathbf{v}^\mathsf{T} \mathbf{x}_i)$$

and denote the objective function of Optimization Problem 1 by

$$F(\mathbf{v}, \mathbf{w}) \;\; = \;\; \sum_{i=1}^{m} \omega_i \ell_{\mathbf{w},i} + \sum_{i=1}^{m+n} \ell_{\mathbf{v},i} + \frac{1}{2\sigma_{\mathbf{w}}^2} \mathbf{w}^\mathsf{T} \mathbf{w} + \frac{1}{2\sigma_{\mathbf{v}}^2} \mathbf{v}^\mathsf{T} \mathbf{v}.$$

We compute the gradient with respect to $\mathbf{v}$ and $\mathbf{w}$.

$$\begin{aligned}\frac{\partial F(\mathbf{v},\mathbf{w})}{\partial v_j} &= -\sum_{i=1}^{m}\omega_i\ell_{\mathbf{w},i}x_{ij}+\sum_{i=1}^{m+n}\ell'_{\mathbf{v},i}s_ix_{ij}+\frac{1}{\sigma_{\mathbf{v}}^2}v_j\\ \frac{\partial F(\mathbf{v},\mathbf{w})}{\partial w_j} &= \sum_{i=1}^{m}\omega_i\ell'_{\mathbf{w},i}y_ix_{ij}+\frac{1}{\sigma_{\mathbf{w}}^2}w_j.\end{aligned}$$

The Hessian is the matrix of second derivatives.

$$\begin{aligned}\frac{\partial^2 F(\mathbf{v},\mathbf{w})}{\partial v_j\partial v_k} &= \sum_{i=1}^{m}\omega_i\ell_{\mathbf{w},i}x_{ij}x_{ik}+\sum_{i=1}^{m+n}\ell''_{\mathbf{v},i}x_{ij}x_{ik}+\frac{1}{\sigma_{\mathbf{v}}^2}\delta_{jk}\\ \frac{\partial^2 F(\mathbf{v},\mathbf{w})}{\partial v_j\partial w_k} &= -\sum_{i=1}^{m}\omega_i\ell'_{\mathbf{w},i}y_ix_{ij}x_{ik}\\ \frac{\partial^2 F(\mathbf{v},\mathbf{w})}{\partial w_j\partial w_k} &= \sum_{i=1}^{m}\omega_i\ell''_{\mathbf{w},i}x_{ij}x_{ik}+\frac{1}{\sigma_{\mathbf{w}}^2}\delta_{jk}.\end{aligned}$$

We can rewrite the gradient as $\mathbf{X}\mathbf{g}+\mathbf{S}\begin{bmatrix}\mathbf{v}\\ \mathbf{w}\end{bmatrix}$ and the Hessian as $\mathbf{X}\mathbf{\Lambda}\mathbf{X}^\mathsf{T}+\mathbf{S}$ using the following definitions, where d is the dimensionality of $\mathbf{X}_T$ and $\mathbf{X}_L$.

$$\begin{aligned}g_i &= -\omega_i\ell_{\mathbf{w},i}+\ell'_{\mathbf{v},i} && \text{for} \quad i=1,\ldots,m;\\ g_{m+i} &= -\ell'_{\mathbf{v},m+i} && \text{for} \quad i=1,\ldots,n;\\ g_{m+n+i} &= \omega_i\ell'_{\mathbf{w},i}y_i && \text{for} \quad i=1,\ldots,m;\\ S_{i,i} &= \sigma_{\mathbf{v}}^{-2} && \text{for} \quad i=1,\ldots,d;\\ S_{d+i,d+i} &= \sigma_{\mathbf{w}}^{-2} && \text{for} \quad i=1,\ldots,d;\end{aligned}$$

$$\mathbf{\Lambda}=\begin{bmatrix}\operatorname*{diag}_{i=1,\ldots,m}\left(\omega_i\ell_{\mathbf{w},i}+\ell''_{\mathbf{v},i}\right) & \mathbf{0} & -\operatorname*{diag}_{i=1,\ldots,m}\left(\omega_i\ell'_{\mathbf{w},i}y_i\right)\\ \mathbf{0} & \operatorname*{diag}_{i=1,\ldots,n}\left(\ell''_{\mathbf{v},m+i}\right) & \mathbf{0}\\ -\operatorname*{diag}_{i=1,\ldots,m}\left(\omega_i\ell'_{\mathbf{w},i}y_i\right) & \mathbf{0} & \operatorname*{diag}_{i=1,\ldots,m}\left(\omega_i\ell''_{\mathbf{w},i}\right)\end{bmatrix}.$$

The update step for the Newton gradient descent minimization of Optimization Problem 1 is $[\mathbf{v}',\mathbf{w}']^\mathsf{T}\leftarrow[\mathbf{v},\mathbf{w}]^\mathsf{T}+[\Delta_\mathbf{v},\Delta_\mathbf{w}]^\mathsf{T}$ with

$$(\mathbf{X}\mathbf{\Lambda}\mathbf{X}^\mathsf{T}+\mathbf{S})\begin{bmatrix}\Delta_\mathbf{v}\\ \Delta_\mathbf{w}\end{bmatrix}=-\mathbf{X}\mathbf{g}-\mathbf{S}\begin{bmatrix}\mathbf{v}\\ \mathbf{w}\end{bmatrix}.$$

Abstract

We have developed an optimized cutting plane algorithm (OCA) for solving large-scale risk minimization problems. We prove that the number of iterations OCA requires to converge to a ε precise solution is approximately linear in the sample size. We also derive OCAS, an OCA-based linear binary Support Vector Machine (SVM) solver, and OCAM, a linear multi-class SVM solver. In an extensive empirical evaluation we show that OCAS outperforms current state-of-the-art SVM solvers like $\text{SVM}^{\text{light}}$, SVM^{perf} and BMRM, achieving speedup factor more than 1,200 over $\text{SVM}^{\text{light}}$ on some data sets and speedup factor of 29 over SVM^{perf} , while obtaining the same precise support vector solution. OCAS, even in the early optimization steps, often shows faster convergence than the currently prevailing approximative methods in this domain, SGD and Pegasos. In addition, our proposed linear multi-class SVM solver, OCAM, achieves speedups of factor of up to 10 compared to $\text{SVM}^{\text{multi-class}}$. Finally, we use OCAS and OCAM in two real-world applications, the problem of human acceptor splice site detection and malware detection. Effectively parallelizing OCAS, we achieve state-of-the-art results on an acceptor splice site recognition problem only by being able to learn from all the available 50 million examples in a 12-million-dimensional feature space. Source code, data sets and scripts to reproduce the experiments are available at `http://cmp.felk.cvut.cz/~xfrancv/ocas/html/`.

Keywords: risk minimization, linear support vector machine, multi-class classification, binary classification, large-scale learning, parallelization

1. Introduction

Many applications in, for example, bioinformatics, IT-security and text classification come with *huge* numbers (e.g., millions) of data points, which are indeed *necessary* to obtain state-of-the-

*. A large part of the work was done while VF and SS were at the Fraunhofer Institute FIRST, Kekulestr. 7, 12489 Berlin, Germany.

art results. They, therefore, require extremely efficient computational methods capable of dealing with ever growing data sizes. A wide range of machine learning methods can be described as the unconstrained regularized risk minimization problem

$$\mathbf{w}^* = \operatorname*{argmin}_{\mathbf{w}\in\Re^n} F(\mathbf{w}) := \frac{1}{2}\|\mathbf{w}\|^2 + CR(\mathbf{w}), \tag{1}$$

where $\mathbf{w} \in \Re^n$ denotes the parameter vector to be learned, $\frac{1}{2}\|\mathbf{w}\|^2$ is a quadratic regularization term, $C > 0$ is a fixed regularization constant and $R\colon \Re^n \to \Re$ is a non-negative convex risk function approximating the empirical risk (e.g., training error).

Special cases of problem (1) are, for example, support vector classification and regression (e.g., Cortes and Vapnik, 1995; Cristianini and Shawe-Taylor, 2000), logistic regression (Collins et al., 2000), maximal margin structured output classification (Tsochantaridis et al., 2005), SVM for multivariate performance measures (Joachims, 2005), novelty detection (Schölkopf et al., 1999), learning Gaussian processes (Williams, 1998) and many others.

Problem (1) has usually been solved in its dual formulation, which typically only uses the computation of dot products between examples. This enables the use of kernels that implicitly compute the dot product between examples in a Reproducing Kernel Hilbert Space (RKHS) (Schölkopf and Smola, 2002). On the one hand, solving the dual formulation is efficient when dealing with high-dimensional data. On the other hand, efficient and accurate solvers for optimizing the kernelized dual formulation for large sample sizes do not exist.

Recently, focus has shifted towards methods optimizing problem (1) directly in the primal. Using the primal formulation is efficient when the number of examples is very large and the dimensionality of the input data is moderate or the inputs are sparse. This is typical in applications like text document analysis and bioinformatics, where the inputs are strings embedded into a sparse high-dimensional feature space, for example, by using the bag-of-words representation. A way to exploit the primal formulation for learning in the RKHS is based on decomposing the kernel matrix and thus effectively linearizing the problem (Schölkopf and Smola, 2002).

Due to its importance, the literature contains a plethora of specialized solvers dedicated to particular risk functions $R(\mathbf{w})$ of problem (1). Binary SVM solvers employing the hinge risk $R(\mathbf{w}) = \frac{1}{m}\sum_{i=1}^{m} \max\{0, 1 - y_i\langle \mathbf{w}, \mathbf{x}_i\rangle\}$ especially have been studied extensively (e.g., Joachims, 1999; Zanni et al., 2006; Chang and Lin, 2001; Sindhwani and Keerthi, 2007; Chapelle, 2007; Lin et al., 2007). Recently, Teo et al. (2007) proposed the Bundle Method for Risk Minimization (BMRM), which is a general approach for solving problem (1). BMRM is not only a general but also a highly modular solver that only requires two specialized procedures, one to evaluate the risk $R(\mathbf{w})$ and one to compute its subgradient. BMRM is based on iterative approximation of the risk term by cutting planes. It solves a reduced problem obtained by substituting the cutting plane approximation of the risk into the original problem (1). Teo et al. (2007) compared BMRM with specialized solvers for SVM classification, SV regression and ranking, and reported promising results. However, we will show that the implementation of the cutting plane algorithm (CPA) used in BMRM can be drastically sped up making it efficient even for large-scale SVM binary and multi-class classification problems.

In this paper, we develop an *efficient and general* algorithm to solve the regularized risk minimization problem (1). Building on the work of Teo et al. (2007), we propose an *optimized cutting plane algorithm* (OCA) that extends the standard CPA in two ways. First, unlike CPA, we use the solution of the reduced problem as a direction in the line-search to directly minimize the original

(master) problem (1). Second, we introduce a new cutting plane selection strategy that reduces the number of cutting planes required to achieve the prescribed precision and thus significantly speeds up convergence. An *efficient* line-search procedure for the optimization of (1) is the *only additional requirement* of OCA compared to the standard CPA (or BMRM).

While our proposed method (OCA) is applicable to a wide range of risk terms R, we will—due to their importance—discuss in more detail two special cases: learning of the binary (two-class) and multi-class SVM classifiers. We show that the line-search procedure required by OCA can be solved exactly for both the binary and multi-class SVM problems in $O(m \log m)$ and $O(m \cdot Y^2 + m \cdot Y \log(m \cdot Y))$ time, respectively, where m is the number of examples and Y is the number of classes. We abbreviate OCA for binary SVM classifiers with OCAS and the multi-class version with OCAM.

We perform an extensive experimental evaluation of the proposed methods, OCAS and OCAM, on several problems comparing them with the current state of the art. In particular, we would like to highlight the following experiments and results:

- We compare OCAS with the state-of-the-art solvers for binary SVM classification on previously published data sets. We show that OCAS significantly outperforms the competing approaches achieving speedups factors of more than 1,200.
- We evaluate OCAS using the large-scale learning challenge data sets and evaluation protocols described in Sonnenburg et al. (2009). Although OCAS is an implementation of a general method for risk minimization (1), it is shown to be competitive with dedicated binary SVM solvers, which ultimately won the large-scale learning challenge.
- We demonstrate that OCAS can be sped up by efficiently parallelizing its core subproblems.
- We compare OCAM with the state-of-the-art implementation of the CPA-based solver for training multi-class SVM classifiers. We show that OCAM achieves speedups of an order of magnitude.
- We show that OCAS and OCAM achieve state-of-the-art recognition performance for two real-world applications. In the first application, we attack a splice site detection problem from bioinformatics. In the second, we address the problem of learning a malware behavioral classifier used in computer security systems.

The OCAS solver for training the binary SVM classification was published in our previous paper (Franc and Sonnenburg, 2008a). This paper extends the previous work in several ways. First, we formulate OCA for optimization of the general risk minimization problem (1). Second, we give an improved convergence proof for the general OCA (in Franc and Sonnenburg 2008a the upper bound on the number of iterations as a function of precision ε scales with $O(\frac{1}{\varepsilon^2})$, while in this paper the bound is improved to $O(\frac{1}{\varepsilon})$). Third, we derive a new instance of OCA for training the multi-class SVM classifiers. Fourth, the experiments are extended by (i) including the comparison on the challenge data sets and using the challenge protocol, (ii) performing experiments on multi-class classification problems and (iii) solving two real-world applications from bioinformatics and computer security.

The remainder of this paper is organized as follows. The standard cutting plane algorithm (CPA) to solve (1) is reviewed in Section 2. In Section 3, we point out a source of inefficiency

of CPA and propose a new optimized cutting plane algorithm (OCA) to drastically reduce training times. We then develop OCA for two special cases linear binary SVMs (OCAS, see Section 3.1) and linear multiclass SVMs (OCAM, see Section 3.2). In Section 4, we empirically show that using OCA, training times can be drastically reduced on a wide range of large-scale data sets including the challenge data sets. Finally, we attack two real-world applications. First, in Section 5.1, we apply OCAS to a human acceptor splice site recognition problem achieving state-of-the art results by training on all available sequences—a data set of 50 million examples (itself about 7GB in size) using a 12 million dimensional feature space. Second, in Section 5.2, we apply OCAM to learn a behavioral malware classifier and achieve a speedup of factor of 20 compared to the previous approach and a speedup of factor of 10 compared to the state-of-the-art implementation of the CPA. Section 6 concludes the paper.

2. Cutting Plane Algorithm

In CPA terminology, the original problem (1) is called the master problem. Using the approach of Teo et al. (2007), one may define a reduced problem of (1) which reads

$$\mathbf{w}_t = \operatorname*{argmin}_{\mathbf{w}} F_t(\mathbf{w}) := \left[\frac{1}{2}\|\mathbf{w}\|^2 + CR_t(\mathbf{w})\right]. \tag{2}$$

(2) is obtained from master problem (1) by substituting a piece-wise linear approximation R_t for the risk R. Note that only the risk term R is approximated while the regularization term $\frac{1}{2}\|\mathbf{w}\|^2$ remains unchanged. The idea is that in practise one usually needs only a small number of linear terms in the piece-wise linear approximation R_t to adequately approximate the risk R around the optimum $\mathbf{w}^*$. Moreover, it was shown in Teo et al. (2007) that the number of linear terms needed to achieve arbitrary precise approximation does not depend on the number of examples.

We now derive the approximation to R. Since the risk term R is a convex function, it can be approximated at any point $\mathbf{w}'$ by a linear under estimator

$$R(\mathbf{w}) \geq R(\mathbf{w}') + \langle \mathbf{a}', \mathbf{w} - \mathbf{w}' \rangle, \qquad \forall \mathbf{w} \in \Re^n, \tag{3}$$

where $\mathbf{a}' \in \partial R(\mathbf{w}')$ is any subgradient of R at the point $\mathbf{w}'$. We will use a shortcut $b' = R(\mathbf{w}') - \langle \mathbf{a}', \mathbf{w}' \rangle$ to abbreviate (3) as $R(\mathbf{w}) \geq \langle \mathbf{a}', \mathbf{w} \rangle + b'$. In CPA terminology, $\langle \mathbf{a}', \mathbf{w} \rangle + b' = 0$ is called a cutting plane.

To approximate the risk R better than by using a single cutting plane, we can compute a collection of cutting planes $\{\langle \mathbf{a}_i, \mathbf{w} \rangle + b_i = 0 \mid i = 1, \ldots, t\}$ at t distinct points $\{\mathbf{w}_1, \ldots, \mathbf{w}_t\}$ and take their point-wise maximum

$$R_t(\mathbf{w}) = \max\left\{0, \max_{i=1,\ldots,t} \left(\langle \mathbf{a}_i, \mathbf{w} \rangle + b_i\right)\right\}. \tag{4}$$

The zero cutting plane is added to the maximization as the risk R is assumed to be non-negative. The subscript $_t$ denotes the number of cutting planes used in the approximation R_t. It follows directly from (3) that the approximation R_t is exact at the points $\{\mathbf{w}_1, \ldots, \mathbf{w}_t\}$ and that R_t lower bounds R, that is, that $R(\mathbf{w}) \geq R_t(\mathbf{w}), \forall \mathbf{w} \in \Re^n$ holds. In turn, the objective function F_t of the reduced problem lower bounds the objective F of the master problem.

Having readily computed R_t, we may now use it in the reduced problem (2). Substituting (4) with (2), the reduced problem can be expressed as a linearly constrained quadratic problem

$$(\mathbf{w}_t, \xi_t) := \operatorname*{argmin}_{\mathbf{w} \in \Re^n, \xi \in \Re} \left[\frac{1}{2}\|\mathbf{w}\|^2 + C\xi\right], \tag{5}$$

subject to

$$\xi \geq 0\,, \quad \xi \geq \langle \mathbf{a}_i, \mathbf{w} \rangle + b_i\,, \quad i = 1, \ldots, t\,.$$

The number of constraints in (5) equals the number of cutting planes t which can be drastically lower than the number of constraints in the master problem (1) when expressed as a constrained QP task. As the number of cutting planes is typically much smaller than the data dimensionality n, it is convenient to solve the reduced problem (5) by optimizing its dual formulation, which reads

$$\alpha_t := \operatorname*{argmax}_{\alpha \in \mathcal{A}_t} D_t(\alpha) := \Big[\sum_{i=1}^{t} \alpha_i b_i - \frac{1}{2} \Big\| \sum_{i=1}^{t} \mathbf{a}_i \alpha_i \Big\|^2 \Big]\,, \tag{6}$$

where $\mathcal{A}_t$ is a convex feasible set containing all vectors $\alpha \in \Re^t$ satisfying

$$\sum_{i=1}^{t} \alpha_i \leq C\,, \qquad \alpha_i \geq 0\,, i = 1, \ldots, t\,.$$

The dual formulation contains only t variables bound by $t+1$ constraints of simple form. Thus task (6) can be efficiently optimized by standard QP solvers. Having (6) solved, the primal solution can be computed as

$$\mathbf{w}_t = -\sum_{i=1}^{t} \mathbf{a}_i [\alpha_t]_i\,, \quad \text{and} \quad \xi_t = \max_{i=1,\ldots,t} \left(\langle \mathbf{w}_t, \mathbf{a}_i \rangle + b_i \right).$$

Solving the reduced problem is beneficial if we can effectively select a small number of cutting planes such that the solution of the reduced problem is sufficiently close to the master problem. CPA selects the cutting planes using a simple strategy described by Algorithm 1.

Algorithm 1 Cutting Plane Algorithm (CPA)

1: $t := 0$.
2: **repeat**
3: Compute $\mathbf{w}_t$ by solving the reduced problem (5).
4: Add a new cutting plane to approximate the risk R at the current solution $\mathbf{w}_t$, that is, compute $\mathbf{a}_{t+1} \in \partial R(\mathbf{w}_t)$ and $b_{t+1} := R(\mathbf{w}_t) - \langle \mathbf{a}_{t+1}, \mathbf{w}_t \rangle$.
5: $t := t + 1$
6: **until** a stopping condition is satisfied.

The algorithm is very general. To use it for a particular problem one only needs to supply a formula to compute the cutting plane as required in Step 4, that is, formulas for computing the subgradient $\mathbf{a} \in \partial R(\mathbf{w})$ and the objective value $R(\mathbf{w})$ at given point $\mathbf{w}$.

It is natural to stop the algorithm when

$$F(\mathbf{w}_t) - F_t(\mathbf{w}_t) \leq \varepsilon \tag{7}$$

holds. Because $F_t(\mathbf{w}_t)$ is the lower bound of the optimal value, $F(\mathbf{w}^*)$, it follows that a solution $\mathbf{w}_t$ satisfying (7) also guarantees $F(\mathbf{w}_t) - F(\mathbf{w}^*) \leq \varepsilon$, that is, the objective value differs from the optimal one by ε at most. An alternative stopping condition advocated in Joachims (2006) stops the algorithm when $R(\mathbf{w}_t) - R_t(\mathbf{w}_t) \leq \hat{\varepsilon}$. It can be seen that the two stopping conditions become equivalent if we set $\varepsilon = C\hat{\varepsilon}$. Hence we will consider only the former stopping condition (7).

Theorem 1 by Teo et al. (2007) guarantees convergence of the CPA algorithm in $O(\frac{1}{\varepsilon})$ time for a broad class of risk functions:

Theorem 1 *(Teo et al., 2007) Assume that $\|\partial R(\mathbf{w})\| \leq G$ for all $\mathbf{w} \in \mathcal{W}$, where $\mathcal{W}$ is some domain of interest containing all $\mathbf{w}_{t'}$ for $t' \leq t$. In this case, for any $\varepsilon > 0$ and $C > 0$, Algorithm 1 satisfies the stopping condition (7) after at most*

$$\log_2 \frac{F(\mathbf{0})}{4C^2G^2} + \frac{8C^2G^2}{\varepsilon} - 2$$

iterations.

3. Optimized Cutting Plane Algorithm (OCA)

We first point out a source of inefficiency in CPA and then propose a new method to alleviate the problem.

CPA selects a new cutting plane such that the reduced problem objective function $F_t(\mathbf{w}_t)$ monotonically increases w.r.t. the number of iterations t. However, there is no such guarantee for the master problem objective $F(\mathbf{w}_t)$. Even though it will ultimately converge arbitrarily close to the minimum $F(\mathbf{w}^*)$, its value can heavily fluctuate between iterations (Figure 1). The reason for these

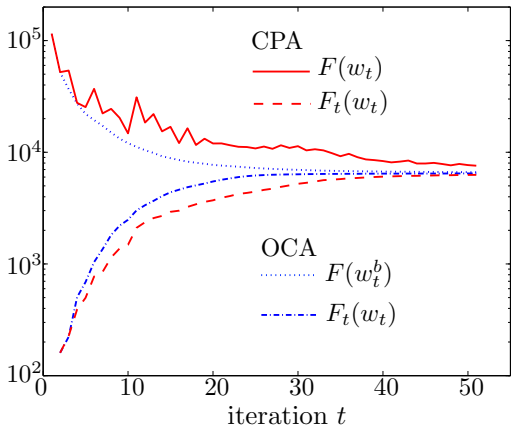

Figure 1: Convergence behavior of the standard CPA vs. the proposed OCA.

fluctuations is that at each iteration t, CPA selects the cutting plane that perfectly approximates the master objective F *at the current solution* $\mathbf{w}_t$. However, there is no guarantee that such a cutting plane will be an active constraint in the vicinity of the optimum $\mathbf{w}^*$, nor must the new solution $\mathbf{w}_{t+1}$ of the reduced problem improve the master objective. In fact, it often occurs that $F(\mathbf{w}_{t+1}) > F(\mathbf{w}_t)$. As a result, a lot of the selected cutting planes do not contribute to the approximation of the master objective around the optimum which, in turn, increases the number of iterations.

To speed up the convergence of CPA, we propose a new method which we call the *optimized cutting plane algorithm* (OCA). Unlike standard CPA, OCA aims at simultaneously optimizing the master and reduced problems' F and F_t objective functions, respectively. In addition, OCA tries to select cutting planes that have a higher chance of actively contributing to the approximation of the master objective function F around the optimum $\mathbf{w}^*$. In particular, we propose the following three changes to CPA.

Change 1 We maintain the best-so-far best solution $\mathbf{w}_t^{\mathrm{b}}$ obtained during the first t iterations, that is, $F(\mathbf{w}_1^{\mathrm{b}}),\ldots,F(\mathbf{w}_t^{\mathrm{b}})$ forms a monotonically decreasing sequence.

Change 2 The new best-so-far solution $\mathbf{w}_t^{\mathrm{b}}$ is found by searching along a line starting at the previous solution $\mathbf{w}_{t-1}^{\mathrm{b}}$ and crossing the reduced problem's solution $\mathbf{w}_t$, that is,

$$\mathbf{w}_t^{\mathrm{b}} = \min_{k\geq 0} F(\mathbf{w}_{t-1}^{\mathrm{b}}(1-k)+\mathbf{w}_t k)\,. \tag{8}$$

Change 3 The new cutting plane is computed to approximate the master objective F at a point $\mathbf{w}_t^{\mathrm{c}}$ which lies in a vicinity of the best-so-far solution $\mathbf{w}_t^{\mathrm{b}}$. In particular, the point $\mathbf{w}_t^c$ is computed as

$$\mathbf{w}_t^c = \mathbf{w}_t^{\mathrm{b}}(1-\mu)+\mathbf{w}_t\mu\,, \tag{9}$$

where $\mu\in(0,1]$ is a prescribed parameter. Having the point $\mathbf{w}_t^c$, the new cutting plane is given by $\mathbf{a}_{t+1}\in\partial R(\mathbf{w}_t^c)$ and $b_{t+1}=R(\mathbf{w}_t^c)-\langle\mathbf{a}_{t+1},\mathbf{w}_t^c\rangle$.

Algorithm 2 describes the proposed OCA. Figure 1 shows the impact of the proposed changes to the convergence. OCA generates a monotonically decreasing sequence of master objective values and a monotonically and strictly increasing sequence of reduced objective values, that is,

$$F(\mathbf{w}_1^{\mathrm{b}})\geq\ldots\geq F(\mathbf{w}_t^{\mathrm{b}})\,,\quad\text{and}\quad F_1(\mathbf{w}_1)<\ldots<F_t(\mathbf{w}_t)\,.$$

Note that for CPA only the latter is satisfied. Similar to CPA, a natural stopping condition for OCA reads

$$F(\mathbf{w}_t^{\mathrm{b}})-F_t(\mathbf{w}_t)\leq\varepsilon\,, \tag{10}$$

where $\varepsilon>0$ is a prescribed precision parameter. Satisfying the condition (10) guarantees that $F(\mathbf{w}_t^{\mathrm{b}})-F(\mathbf{w}^*)\leq\varepsilon$ holds.

Algorithm 2 Optimized Cutting Plane Algorithm (OCA)

1: Set $t:=0$ and $\mathbf{w}_0^{\mathrm{b}}:=\mathbf{0}$.
2: **repeat**
3: Compute $\mathbf{w}_t$ by solving the reduced problem (5).
4: Compute a new best-so-far solution $\mathbf{w}_t^{\mathrm{b}}$ using the line-search (8).
5: Add a new cutting plane: compute $\mathbf{a}_{t+1}\in\partial R(\mathbf{w}_t^c)$ and $b_{t+1}:=R(\mathbf{w}_t^c)-\langle\mathbf{a}_{t+1},\mathbf{w}_t^c\rangle$ where $\mathbf{w}_t^{\mathrm{c}}$ is given by (9).
6: $t:=t+1$
7: **until** a stopping condition is satisfied

Theorem 2 *Assume that $\|\partial R(\mathbf{w})\|\leq G$ for all $\mathbf{w}\in\mathcal{W}$, where $\mathcal{W}$ is some domain of interest containing all $\mathbf{w}_{t'}$ for $t'\leq t$. In this case, for any $\varepsilon>0$, $C>0$ and $\mu\in(0,1]$, Algorithm 2 satisfies the stopping condition (10) after at most*

$$\log_2\frac{F(\mathbf{0})}{4C^2G^2}+\frac{8C^2G^2}{\varepsilon}-2$$

iterations.

Theorem 2 is proven in Appendix A. Finally, there are two relevant remarks regarding Theorem 2:

Remark 1 Although Theorem 2 holds for any μ from the interval $(0,1]$ its particular value has impact on the convergence speed in practice. We found experimentally (see Section 4.1) that $\mu = 0.1$ works consistently well throughout experiments.

Remark 2 Note that the bound on the maximal number of iterations of OCA given in Theorem 2 coincides with the bound for CPA in Theorem 1. Despite the same theoretical bounds, in practice OCA converges significantly faster compared to CPA, achieving speedups of more than one order of magnitude as will be demonstrated in the experiments (Section 4). In the convergence analysis (see Appendix A) we give an intuitive explanation of why OCA converges faster than CPA.

In the following subsections we will use the OCA Algorithm 2 to develop efficient binary linear and multi-class SVM solvers. To this end, we develop fast methods to solve the problem-dependent subtasks, the line-search step (step 4 in Algorithm 2) and the addition of a new cutting plane (step 5 in Algorithm 2).

3.1 Training Linear Binary SVM Classifiers

Given an example set $\{(\mathbf{x}_1, y_1), \ldots, (\mathbf{x}_m, y_m)\} \in (\Re^n \times \{-1,+1\})^m$, the goal is to find a parameter vector $\mathbf{w} \in \Re^n$ of the liner classification rule $h(\mathbf{x}) = \mathrm{sgn}\langle \mathbf{w}, \mathbf{x} \rangle$. The parameter vector $\mathbf{w}$ is obtained by minimizing

$$F(\mathbf{w}) := \frac{1}{2}\|\mathbf{w}\|^2 + \frac{C}{m}\sum_{i=1}^{m} \max\{0, 1 - y_i \langle \mathbf{w}, \mathbf{x}_i \rangle\}\,, \tag{11}$$

which is a special instance of the regularized risk minimization problem (1) with the risk

$$R(\mathbf{w}) := \frac{1}{m}\sum_{i=1}^{m} \max\{0, 1 - y_i \langle \mathbf{w}, \mathbf{x}_i \rangle\}\,. \tag{12}$$

It can be seen that (12) is a convex piece-wise linear approximation of the training error $\frac{1}{m}\sum_{i=1}^{m} [\![h(\mathbf{x}_i) \neq y_i]\!]$.

To use the OCA Algorithm 2 for solving (12), we need the problem-dependent steps 4 and 5. First, we need to supply a procedure performing the line-search (8) as required in Step 4. Section 3.1.1 describes an efficient algorithm solving the line-search exactly in $O(m \log m)$ time. Second, Step 5 requires a formula for computing a subgradient $\mathbf{a} \in \partial R(\mathbf{w})$ of the risk (12) which reads

$$\mathbf{a} = -\frac{1}{m}\sum_{i=1}^{m} \pi_i y_i \mathbf{x}_i\,, \qquad \pi_i = \begin{cases} 1 & \text{if} \quad y_i \langle \mathbf{w}, \mathbf{x}_i \rangle \leq 1\,, \\ 0 & \text{if} \quad y_i \langle \mathbf{w}, \mathbf{x}_i \rangle > 1\,. \end{cases}$$

Both the line-search and computation of the subgradient can be sped up via the parallelization described in Section 3.1.2. We call the resulting algorithm the *optimized cutting plane algorithm for SVM* (OCAS).

3.1.1 LINE-SEARCH FOR LINEAR BINARY SVM CLASSIFIERS

The line-search (8) requires minimization of a univariate convex function

$$F(\mathbf{w}_{t-1}^{\mathrm{b}}(1-k)+\mathbf{w}_t k) = \frac{1}{2}\|\mathbf{w}_{t-1}^{\mathrm{b}}(1-k)+\mathbf{w}_t k\|^2 + CR(\mathbf{w}_{t-1}^{\mathrm{b}}(1-k)+\mathbf{w}_t k)\,, \tag{13}$$

with R defined by (12). Note that the line-search very much resembles the master problem (1) with one-dimensional data. We show that the line-search can be solved exactly in $O(m\log m)$ time.

We abbreviate $F(\mathbf{w}_{t-1}^{\mathrm{b}}(1-k)+\mathbf{w}_t k)$ by $f(k)$ which is defined as

$$f(k) := f_0(k) + \sum_{i=1}^{m} f_i(k) = \frac{1}{2}k^2 A_0 + kB_0 + C_0 + \sum_{i=1}^{m} \max\{0, kB_i + C_i\}\,,$$

where

$$\begin{array}{rclcrcl} A_0 &=& \|\mathbf{w}_{t-1}^{\mathrm{b}} - \mathbf{w}_t\|^2 & & & & \\ B_0 &=& \langle \mathbf{w}_{t-1}^{\mathrm{b}}, \mathbf{w}_t - \mathbf{w}_{t-1}^{\mathrm{b}}\rangle\,, & B_i &=& \frac{C}{m} y_i \langle \mathbf{x}_i, \mathbf{w}_{t-1}^{\mathrm{b}} - \mathbf{w}_t\rangle\,, & i=1,\ldots,m\,, \\ C_0 &=& \frac{1}{2}\|\mathbf{w}_{t-1}^{\mathrm{b}}\|^2\,, & C_i &=& \frac{C}{m}(1 - y_i\langle \mathbf{x}_i, \mathbf{w}_{t-1}^{\mathrm{b}}\rangle)\,, & i=1,\ldots,m\,. \end{array} \tag{14}$$

Hence the line-search (8) involves solving $k^* = \operatorname{argmin}_{k\geq 0} f(k)$ and computing $\mathbf{w}_t^{\mathrm{b}} = \mathbf{w}_{t-1}^{\mathrm{b}}(1-k^*) + \mathbf{w}_t k^*$. Since $f(k)$ is a convex function, its unconstrained minimum is attained at the point k^*, at which the sub-differential $\partial f(k)$ contains zero, that is, $0 \in \partial f(k^*)$ holds. The subdifferential of f reads

$$\partial f(k) = kA_0 + B_0 + \sum_{i=1}^{m} \partial f_i(k)\,, \quad \text{where} \quad \partial f_i(k) = \begin{cases} 0 & \text{if} \quad kB_i + C_i < 0\,, \\ B_i & \text{if} \quad kB_i + C_i > 0\,, \\ [0, B_i] & \text{if} \quad kB_i + C_i = 0\,. \end{cases}$$

Note that the subdifferential is not a function because there exist k's for which $\partial f(k)$ is an interval. The first term of the subdifferential $\partial f(k)$ is an ascending linear function $kA_0 + B_0$ since A_0 must be greater than zero. Note that $A_0 = \|\mathbf{w}_{t-1}^{\mathrm{b}} - \mathbf{w}_t\|^2$ equals 0 only if the algorithm has converged to the optimum $\mathbf{w}^*$, but in this case the line-search is not invoked. The term $\partial f_i(k)$ appearing in the sum is

	$k < k_i$	$k = k_i$	$k > k_i$
$B_i = 0$	0	0	0
$B_i < 0$	B_i	$[B_i, 0]$	0
$B_i > 0$	0	$[0, B_i]$	B_i

Table 1: The value of $\partial f_i(k)$ with respect to k.

either constantly zero, if $B_i = 0$, or it is a step-like jump whose value changes at the point $k_i = -\frac{C_i}{B_i}$. In particular, the value of $\partial f_i(k)$ w.r.t. k is summarized in Table 1. Hence the subdifferential $\partial f(k)$ is a monotonically increasing function as is illustrated in Figure 2. To solve $k^* = \operatorname{argmin}_{k\geq 0} f(k)$ we proceed as follows:

1. We compute the maximal value of the subdifferential $\partial f(k)$ at point 0:

$$\max(\partial f(0)) = B_0 + \sum_{i=1}^{m} [\![(B_i < 0 \wedge k_i > 0) \vee (B_i > 0 \wedge k_i \leq 0)]\!] B_i\,.$$

2. If $\max(\partial f(0))$ is strictly greater than zero, we know that the unconstrained minimum $\operatorname{argmin}_k f(k)$ is attained at a point less than or equal to 0. Thus, the constrained minimum $k^* = \operatorname{argmin}_{k\geq 0} f(k)$, that is, the result of the line-search, is attained at the point $k^* = 0$.

3. If $\max(\partial f(0))$ is less than zero, then the optimum $k^* = \operatorname{argmin}_{k\geq 0} f(k)$ corresponds to the unconstrained optimum $\operatorname{argmin}_k f(k)$. To get k^* we need to find an intersection between the graph of $\partial f(k)$ and the x-axis. This can be done efficiently by sorting points $K = \{k_i \mid k_i > 0, i = 1,\ldots,m\}$ and checking the condition $0 \in \partial f(k)$ for $k \in K$ and for k in the intervals which split the domain $(0,\infty)$ in the points K. These computations are dominated by sorting the numbers K, which takes $O(|K|\log|K|)$ time.

Computing the parameters (14) of the function $f(k)$ requires $O(mn)$ time, where m is the number of examples and n is the number of features. Having the parameters computed, the worst-case time complexities of the steps 1, 2 and 3 are $O(m)$, $O(1)$ and $O(m\log m)$, respectively.

3.1.2 PARALLELIZATION

Apart from solving the reduced problem (2), all subtasks of OCAS can be efficiently parallelized:

Output computation. This involves computation of the dot products $\langle \mathbf{w}_t, \mathbf{x}_i \rangle$ for all $i = 1,\ldots,m$, which requires $O(s)$ time, where s equals the number of all non-zero elements in the training examples. Distributing the computation equally to p processors reduces the effort to $O(\frac{s}{p})$. Note that the remaining products with data required by OCAS, that is, $\langle \mathbf{w}_t^{\mathrm{b}}, \mathbf{x}_i \rangle$ and $\langle \mathbf{w}_t^{\mathrm{c}}, \mathbf{x}_i \rangle$, can be computed from $\langle \mathbf{w}_t, \mathbf{x}_i \rangle$ in time $O(m)$.

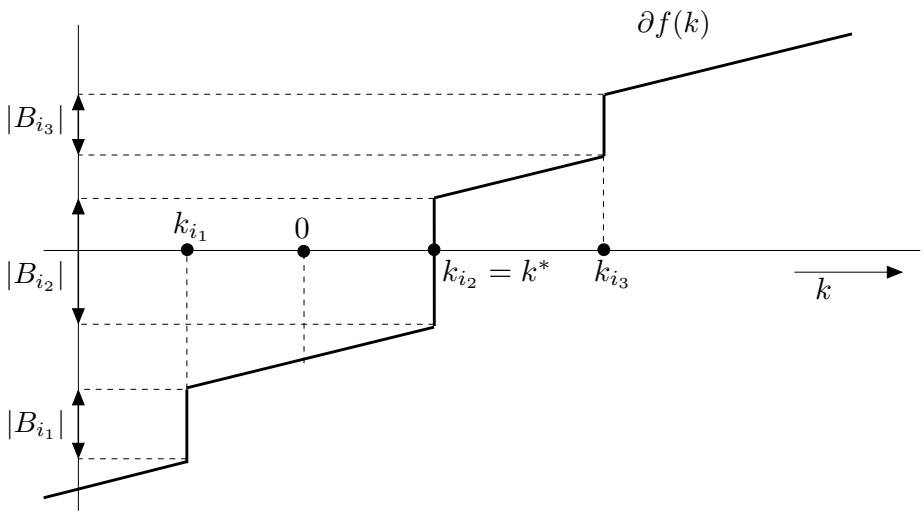

Figure 2: Graph depicting the subdifferential $\partial f(k)$ of the objective function $f(k)$. The line-search requires computing $k^* = \min_{k\geq 0} f(k)$ which is equivalent to finding the intersection k^* between the graph of $\partial f(k)$ and the positive part of the x-axis.

Line-search. The dominant part is sorting $|K|$ numbers which can be done in $O(|K|\log|K|)$ time. A speedup can be achieved by parallelizing the sorting function by using p processors, reducing time complexity to $O\big(\frac{|K|\log|K|}{p}\big)$. Note that our implementation of OCAS uses quicksort, whose worst-case time complexity is $O(|K|^2)$, although its *expected* run-time is $O(|K|\log|K|)$.

Cutting plane computation. The dominant part requires the sum $-\frac{1}{m}\sum_{i=1}^{m}\pi_i y_i \mathbf{x}_i$, which can be done in $O(s_\pi)$ time, where $s_\pi = |\{i|\pi_i \neq 0,\ \forall i = 1,\ldots,m\}|$ is the number of non-zero π_i. Using p processors results in a time complexity of $O(\frac{s_\pi}{p})$.

It is worth mentioning that OCAS usually requires a small number of iterations (usually less than 100 and almost always less than 1000). Hence, solving the reduced problem, which cannot be parallelized, is not the bottleneck, especially when the number of examples m is large.

3.2 Training General Linear Multi-Class SVM Classifiers

So far we have assumed that (i) the ultimate goal is to minimize the probability of misclassification, (ii) the input observations $\mathbf{x}$ are vectors from $\Re^n$ and (iii) the label y can attain only two values $\{-1,+1\}$. In this section, we will consider the regularized risk minimization framework applied to the learning of a general linear classifier (Tsochantaridis et al., 2005).

We assume that the input observation x is from an arbitrary set $\mathcal{X}$ and the label y can have values from $\mathcal{Y} = \{1,\ldots,Y\}$. In addition, let $\delta\colon \mathcal{Y}\times\mathcal{Y}\to\Re$ be an arbitrary loss function which satisfies $\delta(y,y) = 0, \forall y\in\mathcal{Y}$, and $\delta(y,y') > 0, \forall (y,y')\in\mathcal{Y}\times\mathcal{Y}, y\neq y'$. We consider the multi-class classification rule $h\colon \mathcal{X}\to\mathcal{Y}$ defined as

$$h(x;\mathbf{w}) = \operatorname*{argmax}_{y\in\mathcal{Y}} \langle \mathbf{w}, \Psi(x,y)\rangle\,,$$

where $\mathbf{w}\in\Re^d$ is a parameter vector and $\Psi\colon \mathcal{X}\times\mathcal{Y}\to\Re^d$ is an arbitrary map from the input-output space to the parameter space. Given example set $\{(x_1,y_1),\ldots,(x_m,y_m)\}\in(\mathcal{X}\times\mathcal{Y})^m$, learning the parameter vector $\mathbf{w}$ using the regularized risk minimization framework requires solving problem (1) with the empirical risk $R_{\text{emp}}(h(\cdot;\mathbf{w})) = \frac{1}{m}\sum_{i=1}^{m}\delta(h(x_i),y_i)$. Tsochantaridis et al. (2005) propose two convex piece-wise linear upper bounds on risk $R_{\text{emp}}(h(\cdot;\mathbf{w}))$. The first one, called the *margin re-scaling* approach, defines the proxy risk as

$$R(\mathbf{w}) := \frac{1}{m}\sum_{i=1}^{m}\max_{y\in\mathcal{Y}}\big(\delta(y,y_i) + \langle\Psi(x_i,y) - \Psi(x_i,y_i),\mathbf{w}\rangle\big)\,. \tag{15}$$

The second one, called the *slack re-scaling* approach, defines the proxy risk as

$$R(\mathbf{w}) := \frac{1}{m}\sum_{i=1}^{m}\max_{y\in\mathcal{Y}}\delta(y,y_i)\big(1 + \langle\Psi(x_i,y) - \Psi(x_i,y_i),\mathbf{w}\rangle\big)\,. \tag{16}$$

In the rest of this section we will derive the OCA solver for minimization of the margin re-scaling risk (15). Note that modification of the solver to optimize the slack re-scaling risk (16) is straightforward and that both variants have exactly the same computational complexity. Note also that for the special case when $\delta(y,y')$ is the 0/1-loss, both (15) and (16) become equivalent.

To use the OCA Algorithm 2 for the regularized minimization of (15), we need, first, to derive a procedure performing the line-search (8) required in Step 4 and, second, to derive a formula for the computation of the subgradient of the risk R as required in Step 5. Section 3.2.1 describes an efficient algorithm solving the line-search exactly in $O(m \cdot Y^2 + m \cdot Y \log(m \cdot Y))$ time. The formula for computing the subgradient $\mathbf{a} \in \partial R(\mathbf{w})$ of the risk (15) reads

$$\mathbf{a} = \frac{1}{m} \sum_{i=1}^{m} \left(\Psi(x_i, \hat{y}_i) - \Psi(x_i, y_i) \right),$$

where

$$\hat{y}_i = \operatorname*{argmax}_{y \in \mathcal{Y}} \left(\delta(y_i, y) + \langle \Psi(x_i, y) - \Psi(x_i, y_i), \mathbf{w} \rangle \right).$$

We call the resulting method the *optimized cutting plane algorithm for multi-class SVM* (OCAM). Finally, note that the subtasks of OCAM can be parallelized in a fashion similar to the binary case (see Section 3.1.2).

3.2.1 LINE-SEARCH FOR GENERAL MULTI-CLASS LINEAR SVM CLASSIFIERS

In this section, we derive an efficient algorithm to solve the line-search (8) for the margin re-scaling risk (15). The algorithm is a generalization of the line-search for the binary SVM described in Section 3.1.1. Since the core idea remains the same we only briefly describe the main differences.

The goal of the line-search is to minimize a univariate function $F(\mathbf{w}_{t-1}^b(1-k) + \mathbf{w}_t k)$ defined by (13) with the risk R given by (15). We can abbreviate $F(\mathbf{w}_{t-1}^b(1-k) + \mathbf{w}_t k)$ by $f(k)$ which reads

$$f(k) := f_0(k) + \sum_{i=1}^{m} f_i(k) = \frac{1}{2} k^2 A_0 + k B_0 + C_0 + \sum_{i=1}^{m} \max_{y \in \mathcal{Y}} \left(k B_i^y + C_i^y \right),$$

where the constants $A_0, B_0, C_0, (B_i^y, C_i^y), i = 1, \ldots, m, y \in \mathcal{Y}$ are computed accordingly. Similar to the binary case, the core idea is to find an explicit formula for the subdifferential $\partial f(k)$, which, consequently, allows solving the optimality condition $0 \in \partial f(k)$. For a given $f_i(k)$, let $\hat{\mathcal{Y}}_i(k) = \{ y \in \mathcal{Y} \mid k B_i^y + C_i^y = \max_{y' \in \mathcal{Y}} \left(k B_i^{y'} + C_i^{y'} \right) \}$ be a set of indices of the linear terms which are active at the point k. Then the subdifferential of $f(k)$ reads

$$\partial f(k) = k A_0 + B_0 + \sum_{i=1}^{m} \partial f_i(k) \quad \text{where} \quad \partial f_i(k) = \operatorname{co}\{ B_i^y \mid y \in \hat{\mathcal{Y}}_i(k) \}. \tag{17}$$

The subdifferential (17) is composed of a linear term $kA_0 + B_0$ and a sum of maps $\partial f_i \colon \Re \to I$, $i = 1, \ldots, m$, where I is a set of all closed intervals on a real line. From the definition (17) it follows that ∂f_i is a step-function (or staircase function), that is, ∂f_i is composed of piece-wise linear horizontal and vertical segments. An explicit description of these linear segments is crucial for solving the optimality condition $0 \in \partial f(k)$ efficiently. Unlike the binary case, the segments cannot be computed directly from the parameters $(B_i^y, C_i^y), y \in \mathcal{Y}$, however, they can be found by the simple algorithm described below.

First, we introduce an equivalent representation of ∂f_i. Unlike (17), the new representation explicitly defines intervals where $\partial f_i(k)$ is a constant and the points for which the constant value of

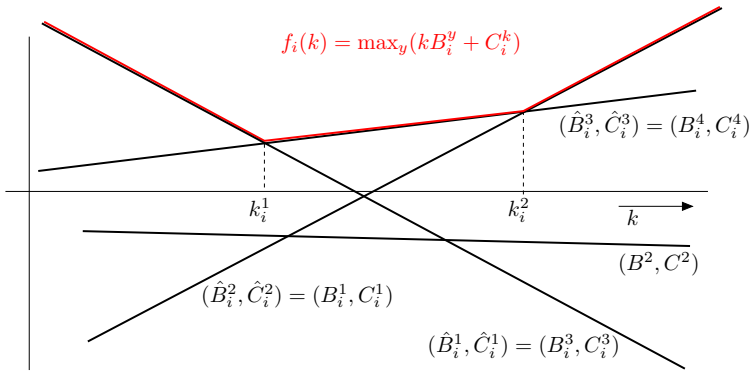

Figure 3: Figure shows an example of the function $f_i(k)$ which is defined as the point-wise maximum over linear terms $kB_i^y + C_i^y$, $y = 1,\ldots,4$. The parameters $(\hat{B}_i^z, \hat{C}_i^z)$, $z = 1,\ldots,3$, and points k_i^z, $z = 1,2$ found by Algorithm 3 are also visualized.

$\partial f_i(k)$ changes. Let $Z \in \{1,\ldots,Y-1\}$ be a given integer and $k_i^1,\ldots,k_i^{Z-1}$ be a strictly increasing sequence of real numbers. Then we define a system of Z open intervals $\{I_i^1,\ldots,I_i^Z\}$ such that

$$I_i^1 = (-\infty, k_i^1), \quad I_i^Z = (k_i^{Z-1}, \infty), \quad \text{and} \quad I_i^z = (k_i^{z-1}, k_i^z), \forall 1 < z < Z.$$

It can be seen that there exist an integer Z and a sequence $k_i^1,\ldots,k_i^{Z-1}$ such that the map ∂f_i can be equivalently written as

$$\partial f_i(k) = \begin{cases} \hat{B}_i^z & \text{if} \quad k \in I_i^z, \\ [\hat{B}_i^z, \hat{B}_i^{z+1}] & \text{if} \quad k \in k_i^z, \end{cases} \tag{18}$$

where $\{\hat{B}_i^1,\ldots,\hat{B}_i^Z\}$ is a subset of $\{B_i^1,\ldots,B_i^Y\}$. Provided the representation (18) is known for all ∂f_i, $i = 1,\ldots,m$, the line-search $k^* = \operatorname{argmin}_{k>0} f(k)$ can be solved exactly by finding the intersection of $\partial f(k)$ and the x-axis, that is, solving the optimality condition $0 \in \partial f(k)$. To this end, we can use the same algorithm as in the binary case (see Section 3.1.1). The only difference is that the number of points k_i^z in which the subdifferential $\partial f(k)$ changes its value is higher; $m \cdot (Y-1)$ in the worst case. As the computations of the algorithm for solving $0 \in \partial f(k)$ are dominated by sorting the points k_i^z, the worst-case computational complexity is approximately $O(m \cdot Y \log(m \cdot Y))$.

Finally, we introduce Algorithm 3, which finds the required representation (18) for a given ∂f_i. In the description of Algorithm 3, we do not use the subscript $_i$ to simplify the notation. Figure 3 shows an example of input linear terms (B_i^y, C_i^y), $y \in \mathcal{Y}$ defining the function $f_i(k)$ and the sorted sequence of active terms $(\hat{B}_i^z, \hat{C}_i^z)$, $z = 1,\ldots,Z$, and points k_i^z, $z = 1,\ldots,Z$, in which the activity of the linear terms changes. At the beginning, the algorithm finds a linear term which is active in the leftmost interval $(-\infty, k^1)$, that is, the line with the maximal slope. Then the algorithm computes intersections with the leftmost active linear term that was found and the remaining lines with lower slopes. The leftmost intersection identifies the next active term. This process is repeated until the rightmost active term is found. The worst-case computational complexity of Algorithm 3 is $O(Y^2)$. In turn, the total complexity of the line-search procedure is $O(m \cdot Y^2 + m \cdot Y \log(m \cdot Y))$, that is, $O(m \cdot Y^2)$ time is required for running Algorithm 3 m times and $O(m \cdot Y \log(m \cdot Y))$ time for solving the optimality condition $0 \in \partial f_i(k)$ as described above.

Algorithm 3 Finding explicit piece-wise linear representation (18) of ∂f_i

Require: $(B^y, C^y), y \in \mathcal{Y}$
Ensure: $Z, \{\hat{B}^1, \ldots, \hat{B}^Z\}$, and $\{k^1, \ldots, k^{Z-1}\}$
1: $\hat{y} := \text{argmax}_{y \in \hat{\mathcal{Y}}} C^y$ where $\hat{\mathcal{Y}} := \{y \mid B^y = \min_{y' \in \mathcal{Y}} B^{y'}\}$.
2: $Z := 1, k := -\infty$ and $\hat{B}^1 := B^{\hat{y}}$
3: **while** $k < \infty$ **do**
4: $\quad \hat{\mathcal{Y}} := \{y \mid B^y > B^{\hat{y}}\}$
5: $\quad$ **if** $\hat{\mathcal{Y}}$ is empty **then**
6: $\quad\quad k := \infty$
7: $\quad$ **else**
8: $\quad\quad \ddot{y} := \text{argmin}_{y \in \hat{\mathcal{Y}}} \frac{C^y - C^{\hat{y}}}{B^y - B^{\hat{y}}}$
9: $\quad\quad k^Z := \frac{C^{\ddot{y}} - C^{\hat{y}}}{B^{\ddot{y}} - B^{\hat{y}}}$
10: $\quad\quad Z := Z + 1$
11: $\quad\quad \hat{B}^Z := B^{\ddot{y}}$
12: $\quad\quad \hat{y} := \ddot{y}$
13: $\quad$ **end if**
14: **end while**

Note that the described algorithm is practical only if the output space $\mathcal{Y}$ is of moderate size since the complexity of the line-search grows quadratically with $Y = |\mathcal{Y}|$. For that reason, this algorithm is ineffective for structured output learning where the cardinality of $\mathcal{Y}$ grows exponentially with the number of hidden states.

4. Experiments

In this section we perform an extensive empirical evaluation of the proposed optimized cutting plane algorithm (OCA) applied to linear binary SVM classification (OCAS) and multi-class SVM classification (OCAM) .

In particular, we compare OCAS to various state-of-the-art SVM solvers. Since several of these solvers did not take part in the large-scale learning challenge, we perform an evaluation of SVM$^{\text{light}}$, Pegasos, GPDT, SGD, BMRM, SVM$^{\text{perf}}$ version 2.0 and version 2.1 on previously published medium-scale data sets (see Section 4.1.1). We show that OCAS outcompetes previous solvers gaining speedups of several orders of magnitude over some of the methods and we also analyze the speedups gained by parallelizing the various core components of OCAS.

In addition, we use the challenge data sets and follow the challenge protocol to compare OCAS with the best performing methods, which were LaRank and LibLinear (see Section 4.1.2). Finally, in section 4.2, we compare the multi-class SVM solver OCAM to the standard CPA implemented for multi-class SVM on four real-world problems using the challenge evaluation protocol.

4.1 Comparison of Linear Binary SVM

We first compare OCAS with several binary linear SVM solvers on previously published data sets followed by an analysis using the challenge criteria on the challenge data sets.

4.1.1 EVALUATION ON PREVIOUSLY USED DATA SETS

We now compare current state-of-the-art SVM solvers (SGD, Pegasos, SVM^{light} , SVM^{perf} , BMRM, GPDT[1]), on a variety of data sets with the proposed method (OCAS), using 6 experiments measuring:

1. Influence of the hyper-parameter μ on the speed of convergence
2. Training time and objective for optimal C
3. Speed of convergence (time vs. objective)
4. Time to perform a full model selection
5. Effects of parallelization
6. Scalability w.r.t. data set size

To this end, we implemented OCAS and the standard CPA[2] in C. We use the very general compressed sparse column (CSC) representation to store the data. Here, each element is represented by an index and a value (each 64bit). To solve the reduced problem (2), we use our implementation of improved SMO (Fan et al., 2005). The source code of OCAS is freely available for download as part of LIBOCAS (Franc and Sonnenburg, 2008b) and as a part of the SHOGUN toolbox (Sonnenburg and Rätsch, 2007).

All competing methods train SVM classifiers by solving the convex problem (1) either in its primal or dual formulation. Since in practice only limited precision solutions can be obtained, solvers must define an appropriate stopping condition. Based on the stopping condition, solvers can be categorized into *approximative* and *accurate*.

Approximative Solvers make use of heuristics (e.g., learning rate, number of iterations) to obtain (often crude) approximations of the optimal solution. They have a very low per-iteration cost and low total training time. Especially for large-scale problems, they are claimed to be sufficiently precise while delivering the best performance vs. training time trade-off (Bottou and Bousquet, 2007), which may be attributed to the robust nature of *large-margin* SVM solutions. However, while they are fast in the beginning they often fail to achieve a precise solution. Among the most efficient solvers to-date are Pegasos (Shwartz et al., 2007) and SGD (Bottou and Bousquet, 2007), both of which are based on stochastic (sub-)gradient descent.

Accurate Solvers In contrast to approximative solvers, accurate methods solve the optimization problem up to a given precision ε, where ε commonly denotes the violation of the relaxed KKT conditions (Joachims, 1999) or the (relative) duality gap. Accurate methods often have good asymptotic convergence properties, and thus for small ε converge to very precise solutions being limited only by numerical precision. Among the state-of-the-art accurate solvers are SVM^{light} , SVM^{perf} , BMRM and GPDT.

Because there is no widely accepted consensus on which approach is "better", we used both types of methods in our comparison.

1. Solvers include: SGD version 1.1 (svmsgd2) `http://leon.bottou.org/projects/sgd`, SVM^{light} 6.01 and SVM^{perf} 2.1 `http://svmlight.joachims.org`, pegasos `http://ttic.uchicago.edu/~shai/code/`, BMRM version 0.01 `http://users.rsise.anu.edu.au/~chteo/BMRM.html` and GPDT `http://dm.unife.it/gpdt`.
2. To not measure implementation specific effects (solver, dot-product computation etc.).

Experimental Setup We trained all methods on the data sets summarized in Table 2. We augmented the Cov1, CCAT, Astro data sets from Joachims (2006) by the MNIST, an artificial dense data set and two larger bioinformatics splice site recognition data sets for worm and human.[3]

Data Set	MNIST	Astro	Artificial	Cov1	CCAT	Worm	Human
Examples	70,000	99,757	150,000	581,012	804,414	1,026,036	15,028,326
Dim	784	62,369	500	54	47,236	804	564
Sparsity	19	0.08	100	22	0.16	25	25
Split	77/09/14	43/05/52	33/33/33	81/09/10	87/10/03	80/05/15	-

Table 2: Summary of the data sets used in the experimental evaluation. Sparsity denotes the average number of non-zero elements of a data set in percent. Split describes the size of the train/validation/test sets in percent.

These data sets have been used and are described in detail in Joachims (2006), Shwartz et al. (2007) and Franc and Sonnenburg (2008a). The Covertype, Astrophysics and CCAT data sets were provided to us by Shai Shalev-Shwartz and should match the ones used in Joachims (2006). The Worm splice data set was provided by Gunnar Rätsch. We did not apply any extra preprocessing to these data sets.[4]

The artificial data set was generated from two Gaussian distributions with different diagonal covariance matrices of multiple scale. Unless otherwise stated, experiments were performed on a 2.4GHz AMD Opteron Linux machine. We disabled the bias term in the comparison. As stopping conditions we use the defaults: $\varepsilon_{light} = \varepsilon_{gpdt} = 0.001$, $\varepsilon_{perf} = 0.1$ and $\varepsilon_{bmrm} = 0.001$. For OCAS we used the same stopping condition that is implemented in SVM$^{\text{perf}}$, that is, $\frac{F(\mathbf{w})-F_t(\mathbf{w})}{C} \leq \frac{\varepsilon_{perf}}{100} = 10^{-3}$. Note that these ε have very different meanings denoting the maximum KKT violation for SVM$^{\text{light}}$, the maximum tolerated violation of constraints for SVM$^{\text{perf}}$ and for BMRM the relative duality gap. For SGD we fix the number of iterations to 10 and for Pegasos we use $100/\lambda$, as suggested in Shwartz et al. (2007). For the regularization parameter C and λ we use the following relations: $\lambda = 1/C$, $C_{perf} = C/100$, $C_{bmrm} = C$ and $C_{light} = Cm$. Throughout the experiments we use C as a shortcut for C_{light}.[5]

Influence of the Hyper-parameter μ on the Speed of Convergence In contrast to the standard CPA, OCAS has a single hyper-parameter μ (see Section 3). The value of μ determines the point $\mathbf{w}_t^c = \mathbf{w}_t^b(1-\mu) + \mathbf{w}_t\mu$ at which the new cutting plane is selected. The convergence proof (see Theorem 2) requires μ to be from the interval $(0,1]$, however, the theorem does not indicate which value is the optimal one. For this reason, we empirically determined the value of μ.

For varying $\mu \in \{0.01, 0.05, 0.1, \ldots, 1\}$ we measured the time required by OCAS to train the classifier on the Astro, CCAT and Cov1 data sets. The regularization constant C was set to the

3. Data sets found at: Worm and Human `http://www.fml.tuebingen.mpg.de/raetsch/projects/lsmkl`, Cov1 `http://kdd.ics.uci.edu/databases/covertype/covertype.html`, CCAT `http://www.daviddlewis.com/resources/testcollections/rcv1/`, MNIST `http://yann.lecun.com/exdb/mnist/`.
4. However, we noted that the Covertype, Astro-ph and CCAT data set already underwent preprocessing because the latter two have $\|x_i\|_2 = 1$.
5. The exact cmdlines are: `svm_perf_learn -l 2 -m 0 -t 0 --b 0 -e 0.1 -c` C_{perf}, `pegasos -lambda` λ `-iter` $100/\lambda$ `-k 1`, `svm_learn -m 0 -t 0 -b 0 -e 1e-3 -c` C_{light}, `bmrm-train -r 1 -m 10000 -i 999999 -e 1e-3 -c` C_{bmrm}, `svmsgd2 -lambda` λ `-epochs 10`.

optimal value for the given data set. Figure 4 shows the results. For Astro and CCAT the optimal value is $\mu = 0.1$ while for Cov1 it is $\mu = 0.01$. For all three data sets the training time does not change significantly within the interval $(0, 0.2)$. Thus we selected $\mu = 0.1$ to be the best value and we used this setting in all remaining experiments.

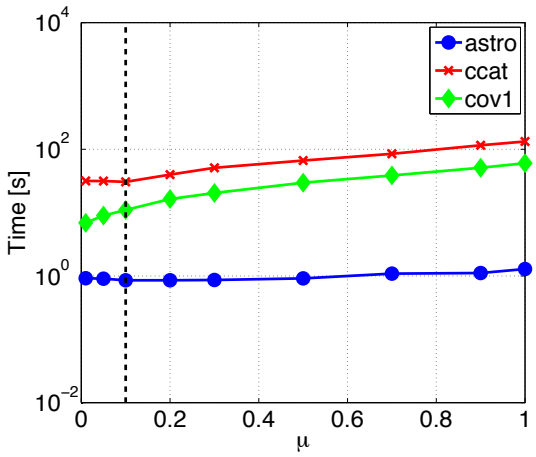

Figure 4: Training time vs. value of the hyper-parameter μ of the OCAS solver measured on the Astro, CCAT and Cov1 data sets. The value $\mu = 0.1$ (dash line) is used in all remaining experiments.

Training Time and Objective For Optimal C We trained all methods on all except the human splice data set using the training data and measured training time (in seconds) and computed the unconstrained objective value $F(\mathbf{w})$ (cf. Equation 11).

The results are displayed in Table 3. The proposed method—OCAS—consistently outperforms all its competitors in the *accurate solver* category on all benchmark data sets in terms of training time while obtaining a comparable (often the best) objective value. BMRM and SVM$^{\text{perf}}$ implement the same CPA algorithm but due to implementation-specific details, results can be different. Our implementation of CPA gives very similar results (not shown).[6] Note that for SGD, Pegasos (and SVM$^{perf2.0}$—not shown), the objective value sometimes deviates significantly from the true objective. As a result, the learned classifier may differ substantially from the optimal parameter $\mathbf{w}^*$. However, as training times for SGD are significantly below all others, it is unclear whether SGD achieves the same precision using less time with further iterations. An answer to this question is given in the next paragraph.

Speed of Convergence (Time vs. Objective) To address this problem we re-ran the best methods, CPA, OCAS and SGD, recording *intermediate* progress, that is, in the course of optimization record time and objective for several time points. The results are shown in Figure 5. OCAS was stopped when reaching the maximum time or a precision of $1 - F(\mathbf{w}^*)/F(\mathbf{w}) \leq 10^{-6}$ and in all cases achieved the minimum objective. In three of the six data sets, OCAS not only, achieves the

6. In contrast to SVM$^{\text{perf}}$, BMRM and our implementation of CPA did not converge for large C on Worm even after 5000 iterations. Most likely, the core solver of SVM$^{\text{perf}}$ is more robust.

Table 3: Training time for optimal C comparing OCAS with other SVM solvers. "-" means not converged, blank not attempted. Shown in bold is the unconstrained SVM objective value Eq. (11). The two numbers below the objective value denote the number of iterations (left) and the training time in seconds (right). Lower time and objective values are better. All methods solve the unbiased problem. As convergence criteria, the standard settings described in Section 4.1.1 are used. On MNIST Pegasos ran into numerical problems. OCAS clearly outperforms all of its competitors in the *accurate solver* category by a large margin achieving similar and often the lowest objective value. The objective value obtained by SGD and Pegasos is often far away from the optimal solution; see text for a further discussion.

best objective as expected at a later time point, but already from the very beginning. Further analysis made clear that OCAS wins over SGD in cases where *large C*s were used and thus the optimization problem is more difficult. Still, plain SGD outcompetes even CPA. One may argue that, practically, the true objective is not the unconstrained SVM-primal value (11) but the performance on a validation set, that is, optimization is stopped when the validation error does not change. This has been discussed for leave-one-out in Franc et al. (2008) and we—to some extent—agree with this. One should, however, note that in this case one does not obtain an SVM but *some classifier* instead. A comparison should not then be limited to SVM solvers but should also be open to any other large scale approach, like online algorithms (e.g., perceptrons). We argue that to compare *SVM solvers* in a fair way one needs to compare objective values. We therefore ran Pegasos using a larger number of iterations on the Astro and splice data sets. On the Astro data set, Pegasos surpassed the SVM$^{\text{light}}$ objective after 10^8 iterations, requiring 228 seconds. SVM$^{\text{light}}$, in comparison, needed only 22 seconds. Also, on the splice data set we ran Pegasos for 10^{10} iterations, which took 13,000 seconds and achieved a similar objective as that of SVM$^{perf2.0}$, requiring only 1224 seconds. Finally, note that, although BMRM, SVM$^{\text{perf}}$ and our implementation of CPA solve the same equivalent problem using the CPA, differences in implementations lead to varying results.[7] Since it

7. Potentially due to a programming error in this pre-release of BMRM, it did not show convergence on the splice data set even after > 6500 iterations.

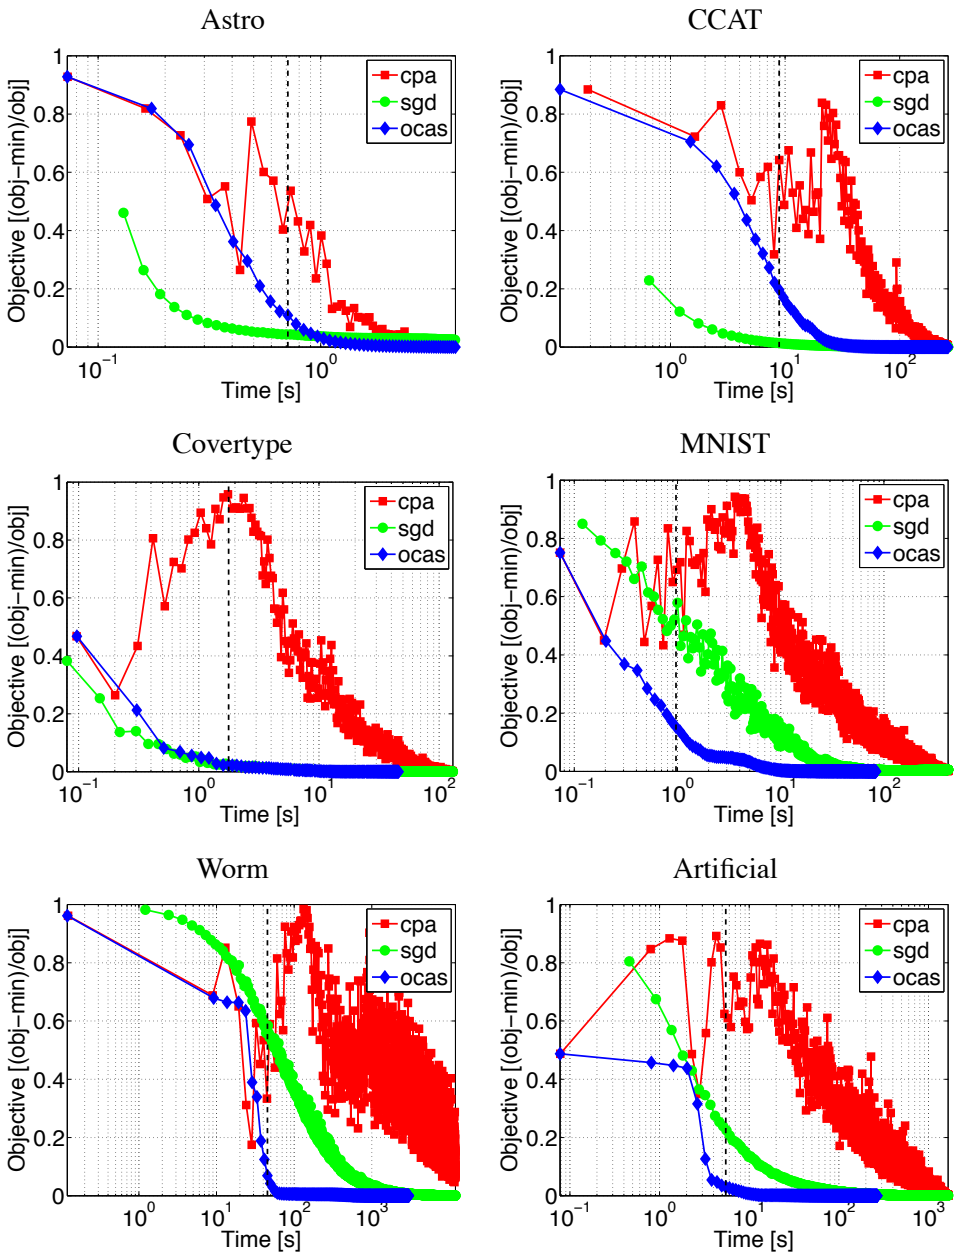

Figure 5: Objective value vs. training time of CPA (red), SGD (green) and OCAS (blue) measured for different numbers of training examples.The dashed line shows the time required to run SGD for 10 iterations. OCAS was stopped when the precision fell below 10^{-6} or the training time for CPA was achieved. In all cases, OCAS achieves the minimal objective value and, even from the beginning, outperforms all other methods, including SGD, on half of the data sets.

is still interesting to see how the methods perform w.r.t. classification performance, we describe the analysis under this criterion in the next paragraph.

Time to Perform a Full Model Selection When using SVMs in practice, their C parameter needs to be tuned during model selection. We therefore train all methods using different settings[8] for C on the training part of all data sets, evaluate them on the validation set and choose the best model to do predictions on the test set. As the performance measure, we use the area under the receiver operator characteristic curve (auROC) (Fawcett, 2003). Results are displayed in Table 4.

	Astro		CCAT		Cov1		MNIST		Worm		Artificial

Table 4: Model selection experiment comparing OCAS with other SVM solvers. "-" means not converged, blank not attempted. Shown in bold is the area under the receiver operator characteristic curve (auROC) obtained for the best model chosen based on model selection over a wide range of regularization constants C. In each cell, numbers on the left denote the optimal C, numbers on the right the training time in seconds to perform the whole model selection. Because there is little variance, for accurate SVM solvers only the mean and standard deviation of the auROC are shown. SGD is clearly fastest achieving similar performance for all except the artificial data set. However, often a C smaller than the ones chosen by accurate SVMs is selected—an indication that the learned decision function is only remotely SVM-like. Among the accurate solvers, OCAS clearly outperforms its competitors. It should be noted that training times for all accurate methods are dominated by training for large C (see Table 3 for training times for the optimal C). For further discussion see the text.

Again, among the *accurate methods* OCAS outperforms its competitors by a large margin, followed by SVM$^{\text{perf}}$. Note that for all *accurate methods* the performance is very similar and has little variance. Except for the artificial data set, plain SGD is clearly fastest while achieving a similar accuracy. However, the optimal parameter settings for accurate SVMs and SGD are different. Accurate SVM solvers use a larger C constant than SGD. For a lower C, the objective function is dominated by the regularization term $\|w\|$. A potential explanation is that SGD's update rule puts more emphasis on the regularization term, and SGD, when not run for a large number of iterations, does imply early stopping.

Our suggestion for practitioners is to use OCAS whenever a reliable and efficient large-scale solver with proven convergence guarantees is required. This is typically the case when the solver is

8. For Worm and Artificial we used $C \in \{0.001, 0.005, 0.01, 0.05, 0.1, 0.5, 1, 5\}$, for CCAT, Astro, Cov1 $C \in \{0.1, 0.5, 1, 5, 10\}$ and for MNIST $C \in \{1, 5, 10, 50, 100\}$.

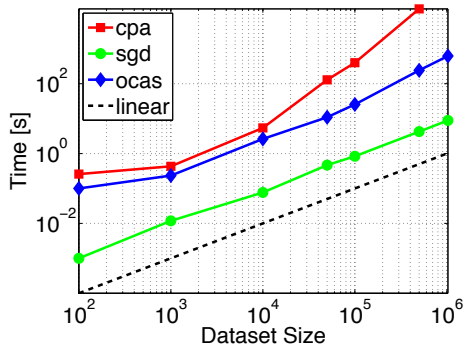

Figure 6: This figure displays how the methods scale with data set size on the Worm splice data set. The slope of the "lines" in this figure denotes the exponent e in $O(m^e)$, where the black line denotes linear effort $O(m)$.

to be operated by non-expert users who know little (or nothing) about tuning the hyper-parameters of the optimization algorithm. Therefore, as long as the full data set fits into memory, we recommend OCAS. Otherwise, if sub-sampling is not an option, online approximative solvers like SGD are the only viable way to proceed.

Effects of Parallelization As OCAS training times are very low on the above data sets, we also apply OCAS to the 15 million human splice data set. Using a 2.4GHz 16-core AMD Opteron Linux machine, we run OCAS using $C = 0.0001$ on 1 to 16 CPUs and show the accumulated times for each of the subtasks, the total training time and the speedup w.r.t. the single CPU algorithm in Table 5. Also shown is the accumulated time for each of the threads. As can be seen—except for the line-

CPUs	1	2	4	8	16
speedup	1	1.77	3.09	4.5	4.6
line search (s)	238	184	178	139	117
$\mathbf{a}_t$ (s)	270	155	80	49	45
output (s)	2476	1300	640	397	410
total (s)	3087	1742	998	684	671

Table 5: Speedups due to parallelizing OCAS on the 15 million human splice data set.

search—computations distribute nicely. Using 8 CPU cores the speedup saturates at a factor of 4.5, most likely as memory access becomes the bottleneck (for 8 CPUs output computation creates a load of 28GB/s just on memory reads).

Scalability w.r.t. Data Set Size In this section, we investigate how computational times of OCAS, CPA and SGD scale with the number of examples on the Worm splice data set for sizes 100 to 1,026,036. Results are shown in Figure 6. We again use our implementation of CPA which shares essential sub-routines with OCAS. Both OCAS and SGD scale roughly linearly. Note that SGD is much faster (because it runs for a fixed number of iterations and thus stops early).

4.1.2 EVALUATION ON CHALLENGE DATA

In this section, we use the challenge data sets and follow the challenge protocol to compare OCAS to the best-performing methods, which were LaRank (Bordes et al., 2007) and LibLinear (Fan et al., 2008). To this end, we apply OCAS to the challenge data sets Alpha, Gamma and Zeta following the challenge protocol for the SVM track.

The data sets are artificially generated based on a mixture of Gaussians and have certain properties (see Table 6): The Alpha data set is separable with a large margin using quadratic features.

Data Set	Optimal Model	Number of examples training	testing	validation	Dim.	Description
Alpha	quadratic	500,000	300,000	100,000	500	well separable
Gamma	semi-quadratic	500,000	300,000	100,000	500	Multiscale low var.
Zeta	linear	500,000	300,000	100,000	2000	Intrinsic dim. 400

Table 6: Summary of the three challenge data sets used: Alpha, Gamma, Zeta.

The Gamma data set is well separable too, but contains features living on different scales. Finally, the optimal model for Zeta is a linear classifier—of its 2,000 features 1,600 are nuisance dimensions. The challenge protocol requires training on the unmodified data sets with $C = 0.01$ and precision $\varepsilon = 0.01$. To measure convergence speed, objective values are measured *while training*. The second challenge experiment simulates model selection by training for different $C \in \{0.0001, 0.001, 0.01, 0.1, 1, 10\}$.

The left column in Figure 7 displays the course of convergence of the three methods. While OCAS is quite competitive on Gamma and Zeta in this experiment, it is slower on Alpha. It should also be noted that OCAS, in contrast to the online-style algorithms LaRank and LibLinear, has to do a full pass through the data in each iteration. However, it usually requires very few iterations to obtain precise solutions.

In the simulated model selection experiment (right column of Figure 7), OCAS performs well for low values of C on all data sets. However, at first glance it is competitive for large values of C only on Zeta. Investigating objective values on Gamma for LibLinear, we noticed that they significantly deviate (objective values much larger, deviation by 50% for $C = 10$) from LaRank/OCAS for $C \in \{1, 10\}$. Still, on Alpha OCAS is slower.

4.2 Comparison of Linear Multi-Class SVMs

In this section, we compare the proposed multi-class SVM solver OCAM described in Section 3.2 with multi-class CPA (CPAM). We consider the Crammer and Singer (2001) formulation of multi-class SVMs which corresponds to the minimization of the following convex objective,

$$F(\mathbf{w}) := \frac{1}{2}\|\mathbf{w}\|^2 + \frac{C}{m}\sum_{i=1}^{m} \max_{y \in \mathcal{Y}} \left([\![y_i \neq y]\!] + \langle \mathbf{w}_y - \mathbf{w}_{y_i}, \mathbf{x}_i \rangle \right), \tag{19}$$

where $\mathbf{w} = [\mathbf{w}_1, \ldots, \mathbf{w}_Y]$ is a matrix of parameter vectors and $\{(\mathbf{x}_1, y_i), \ldots, (\mathbf{x}_m, y_m)\} \in (\Re^n \times \mathcal{Y})^m$ is a set of training examples. The multi-class classification rule then reads $h(\mathbf{x}) = \operatorname{argmax}_{y \in \mathcal{Y}} \langle \mathbf{x}, \mathbf{w}_y \rangle$.

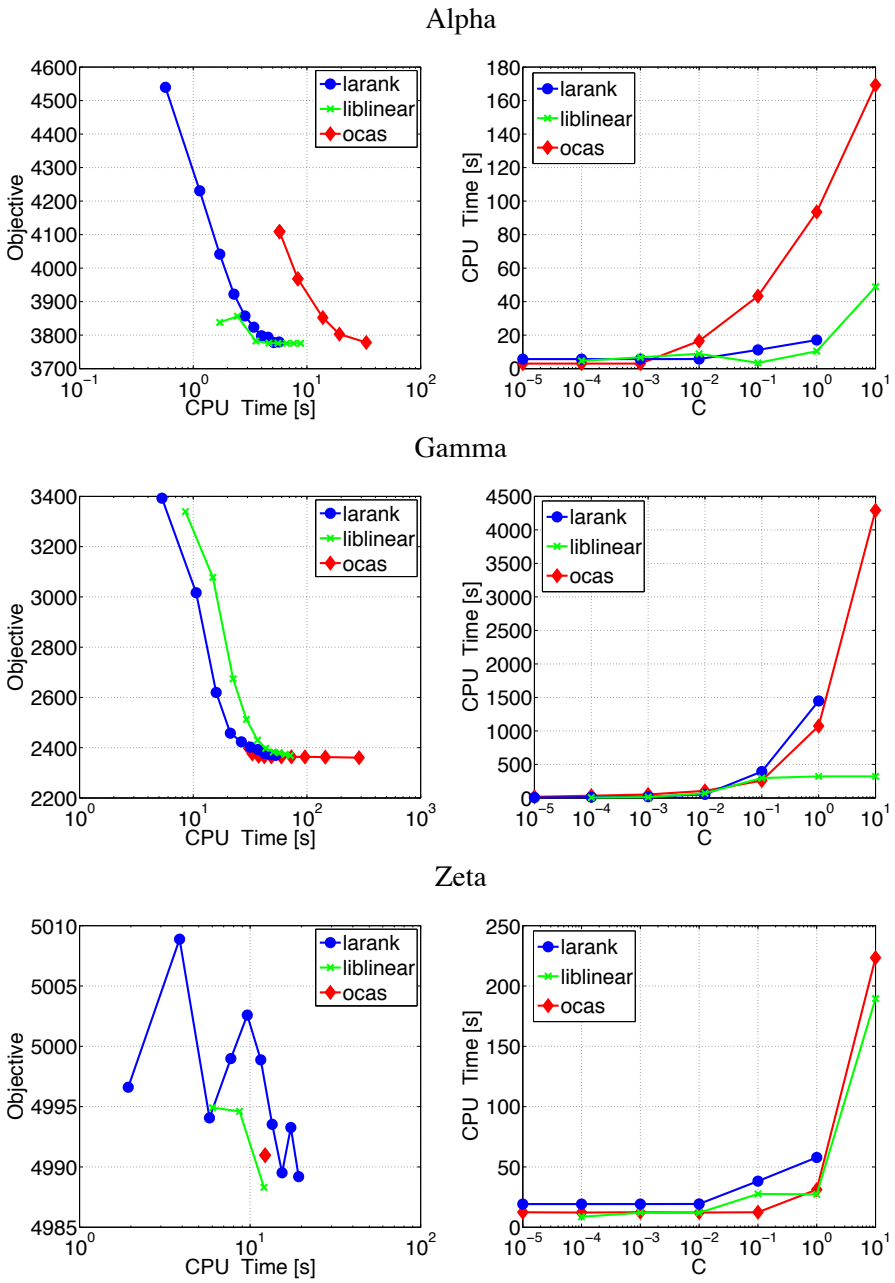

Figure 7: Results of LaRank, LibLinear and OCAS on the Alpha, Gamma and Zeta challenge data sets. The left column of the figures displays the unconstrained SVM primal objective (11) (C is not scaled with m) w.r.t. SVM training time for fixed $C = 0.01$. The right column displays the SVM training time for different C. We omitted the data set size vs. CPU time figure since all three methods show a similar curve (a line with slope ≈ 1 in log-log representation, corresponding to the expected $O(m)$ effort) . Note that for the Zeta data set OCAS converges after a single pass through the data, which results in collapsing the performance curve into a single point. For low C, OCAS achieves very competitive results. For further explanation see text.

We implemented OCAM and CPAM in C, exactly according to the description in Section 3.2. Both implementations use the Improved Mitchel-Demyanov-Malozemov algorithm (Franc, 2005) as the core QP solver and they use exactly the same functions for the computation of cutting planes and classifier outputs. The implementation of both methods is freely available for download as part of LIBOCAS (Franc and Sonnenburg, 2008b). The experiments are performed on an AMD Opteron-based 2.2GHz machine running Linux.

In the evaluation we compare OCAM with CPAM to minimize programming bias. In addition, we perform a comparison with SVM$^{\text{multi-class}}$ v2.20 later in Section 5.2.

We use four data sets with inherently different properties that are summarized in Table 7. The Malware data set is described in Section 5.2. The remaining data sets, MNIST, News20 and Sector, are downloaded from `http://www.csie.ntu.edu.tw/~cjlin/libsvmtools/datasets/multiclass.html`. We used the versions with the input features scaled to the interval $[0,1]$. Each data set is randomly split into a training and a testing part.

	features		number of	num. of examples	
	number of	type	classes	training	testing
Malware	3,413	dense	14	3,413	3,414
MNIST	780	dense	10	60,000	10,000
News20	62,060	sparse	20	15,935	3,993
Sector	55,197	sparse	105	6,412	3,207

Table 7: Multi-class data sets used in the comparison of OCAM and CPAM.

	Malware		MNIST		News20		Sector	
	error	time	error	time	error	time	error	time
Standard CPAM	10.25	12685	7.07	15898	14.45	7276	5.58	12840
Proposed OCAM	10.16	1705	7.08	5387	14.45	1499	5.61	3970
speedup		7.4		3.0		4.9		3.2

Table 8: Comparison of OCAM and CPA on a simulated model selection problem. The reported time corresponds to training over the whole range of regularization constants Cs. The error is the minimal test classification over the classifiers trained with different Cs.

In the first experiment, we train the multi-class classifiers on training data with a range of regularization constants $C = \{10^0, 10^1, \ldots, 10^7\}$ (for Malware $C = \{10^0, \ldots, 10^8\}$ since the optimal $C = 10^7$ is the boundary value). Both solvers use the same stopping condition (10) with $\varepsilon = 0.01F(\mathbf{w})$. We measure the total time required for training over the whole range of Cs and the best classification error measured on the testing data. Table 8 summarizes the results. While the classification accuracy of OCAM and CPAM are comparable, OCAM consistently outperforms the standard CPAM in terms of runtime, achieving speedup of factor from 3 to 7.4.

In the second experiment, we measure the three performance figures defined in the large-scale challenge: (i) the objective value as a function of the runtime, (ii) the runtime as a function of C and (iii) the runtime as a function of the data set size. For figures (i) and (ii) we use the optimal C obtained in the first experiments. Results for the first three data sets are shown in Figure 8.

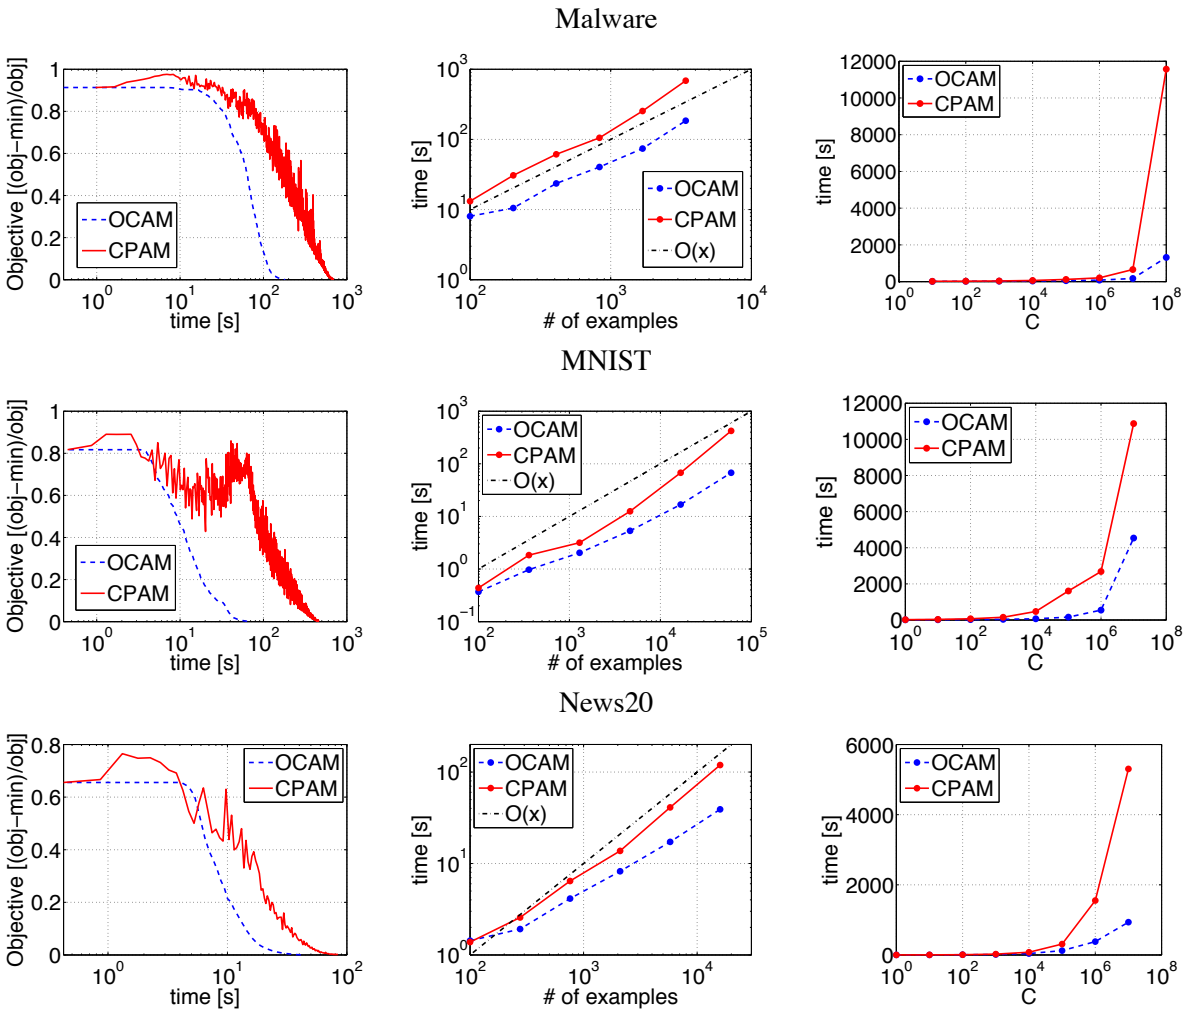

Figure 8: Results of the standard CPAM and the proposed OCAM on the Malware, MNIST and News20 data sets. The left column of figures displays the unconstrained SVM objective (19) w.r.t. SVM training time. The middle column displays the training time as a function of the number of examples. In both experiments C was fixed to its optimal value as determined in model selection. The right column shows the training time for different Cs. See text for a discussion of the results.

The objective vs. time figure is consistent with the results obtained in Section 4.1 for the two-class variant, that is, the objective value of the standard CPAM significantly fluctuates while OCAM decreases the objective monotonically and converges faster in all cases. The data size vs. time figure shows that in both cases the runtime is approximately linear w.r.t. the number of examples, though the curve of CPAM grows slightly faster compared to OCAM. The main difference shows the figure depicting the runtime as a function of C. It is seen that OCAM is considerably faster for large values of C, which is crucial for efficient model selection (see the experiment in Section 5.2) .

5. Applications

In this section we attack two real-world applications. First, in Section 5.1, we apply OCAS to a human acceptor splice site recognition problem. Second, in Section 5.2, we use OCAM for learning a behavioral malware classifier.

5.1 Human Acceptor Splice Site Recognition

To demonstrate the effectiveness of our proposed method, OCAS, we apply it to the problem of human acceptor splice site detection. Splice sites mark the boundaries between potentially protein-coding exons and (non-coding) introns. In the process of translating DNA to protein, introns are excised from pre-mRNA after transcription (Figure 9). Most splice sites are so-called *canonical splice sites* that are characterized by the presence of the dimers `GT` and `AG` at the donor and acceptor sites, respectively.

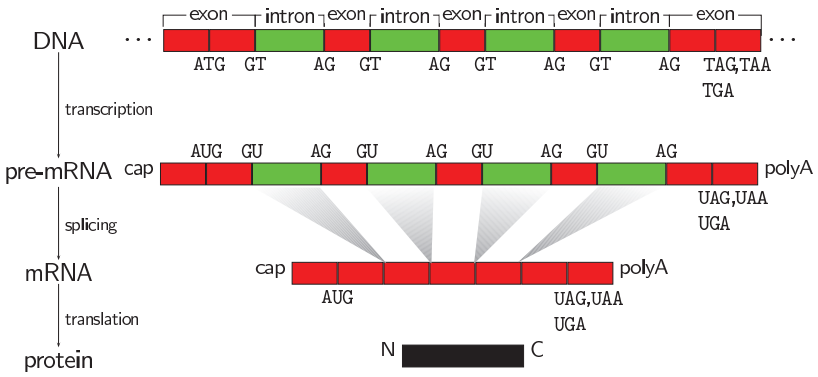

Figure 9: The major steps in protein synthesis. In the process of converting DNA to messenger RNA, the introns (green) are spliced out. Here we focus on detecting the so-called acceptor splice sites that employ the `AG` consensus and are found at the "left-hand side" boundary of exons. Figure taken from (Sonnenburg, 2002).

However, the occurrence of the dimer alone is not sufficient to detect a splice site. The classification task for splice site sensors, therefore, consists in discriminating true splice sites from decoy sites that also exhibit the consensus dimers. Assuming a uniform distribution of the four bases, adenine (`A`), cytosine (`C`), guanine (`G`) and thymine (`T`), one would expect 1/16th of the dimers to contain the `AG` acceptor splice site consensus. Considering the size of the human genome, which consists of about 3 billion base pairs, this constitutes a large-scale learning problem (the expected number of `AG`s is 180 million).

Many different methods to detect splice sites have been proposed. They all predict splice sites based on the local context, that is, a short window around the `AG` dimer. Currently, support vector machines are the most accurate splice site detectors (Degroeve et al., 2005; Sonnenburg et al., 2007b). Sonnenburg et al. (2007b) showed that prediction accuracy steadily increases with training sample size. However, even though they already used the `linadd` algorithm (Sonnenburg et al., 2007a) to speed up string kernel-based SVMs on a quad-core system, they could not use all available 50 million training points (but "only" 8 million). The string kernel that performed best was the

weighted degree (WD) string kernel *with shifts* (Rätsch et al., 2005). It basically counts matching k-mers for various k in a position-dependent way. Employing a giant string kernel feature space, Sonnenburg et al. (2007b) achieved $45.58\% \pm 0.38$ aoPRC in a genome-wide study on human acceptor splice sites—also available as the DNA data set used in the large-scale learning challenge.

On the other hand, Degroeve et al. (2005) trained a linear SVM based on a number of preselected and explicitly computed string kernel feature spaces that are subsets from the spectrum (Leslie et al., 2002) and WD kernel (Rätsch et al., 2005) feature spaces: Left and right of the splice site spectrum kernels of order 3 up to order 6 were used (Leslie et al., 2002). Over the whole window, a WD kernel of order 3 with weights equal to 1 was used (Rätsch and Sonnenburg, 2004). Even though this approach scales well, they used $< 100,000$ data points (potentially, since they relied on the unmodified SVM$^{\text{light}}$ binary).

Here, we propose to train OCAS on all available 50 million strings of length 141 from Sonnenburg et al. (2007b) using the features corresponding to two weighted spectrum kernels (one left and one right of the splice site, that is, positions 1-59 and 62-141) and a WD kernel (applied to the whole string). For the spectrum kernels of order 1 up to 8 and for the WD kernel of order 8 is used. Thus, the spanned string kernel feature space has 12,495,340 dimensions.

As the raw string-based data set already has a size of $7.1 \cdot 10^9$ bytes and even a sparse representation of each string would increase the data set by a factor of more than 3,000 ($(141+59+80) \cdot 12$ bytes per feature vector, assuming a 4 byte integer and an 8 byte float), we will *implicitly* compute features from the raw input strings on demand. The only required operations in OCAS for which we will have to expand the features are the addition to a dense vector $\mathbf{w} \leftarrow \mathbf{w} + \alpha\Phi(x)$ and the output computation $\mathbf{w} \cdot \Phi(x)$.

We implemented a rather general framework that allows stacking of arbitrary features that support such operations (dense and sparse real-valued, weighted spectrum and WD kernel features for specified k-mer length). As we know from Section 4.1.1, most time is spent in computing outputs, hence we parallelized this part of the code (based on shared memory parallelization, that is, posix threads).

Before training on the 50 million examples, we perform model selection on only 1 million examples to determine the optimal k-mer length for the two spectrum kernels, the WD kernel and its weighting and the SVM regularization constant C. The optimal parameter setting was found to be $C = 1$, $k_{wspec} = 8$, $k_{wd} = 8$, where the WD kernel weights are taken from the first 8 weights of the weights of a wd kernel of order 40.[9] Parameters were selected from $C \in \{0.5, 1, 3, 5, 10\}$, $k_{wspec} \in \{3, 6, 8\}$, $k_{wd} = \{3, 6, 8\}$ with the WD kernel-weighting from order 8, 25 or 40.

We then trained on 50 million examples on an 8-core AMD Opteron Linux-based machine, obtaining a record area over the precision recall curve (aoPRC) of 42.23%. For comparison, the previous best method achieved aoPRC of 45.58% (variance 0.38%). Note that this is the DNA data set used in the large-scale learning challenge, for which the best participant obtained an aoPRC of 80.89% (lower is better). OCAS converged in just 138 iterations, however, the total training time was about 40 hours, of which almost 34 hours were spent on computing outputs (already in a parallelized way; see Table 9 for the detailed timing statistics). Even though we observed that this parallelization was quite effective, it suggests that we are measuring random memory access speed. Due to the size of the normal vector (about 100MB since we are using double precision floats) we see only cache misses. This suggests that even using just single precision floats would reduce the

9. In Sonnenburg (2008) it was suggested that the WD kernel-weighting influences the effect of mismatches of the WD kernel score.

training time by 17 hours. Even though modern DDR-SDRAM is capable of speeds of up to 8 GB/s (Wikipedia, 2009) when being accessed in a linear way, we observed a memory speed of only 1.4GB/s on this system. It turns out that only DDR-333 memory is installed with a peak transfer rate of 2.7GB/s. Thus, additional speedups can be achieved by distributed memory parallelization and by grouping the access of features in $\mathbf{w}$ to minimize cache misses. Alternatively, switching to a many-core architecture like the NVIDIA Tesla s1070 computing system[10] that employs 960 CPU cores and a peak memory rate of 400GB/s could drastically reduce training times, potentially to even under 1 minute. Finally, it should be noted that storing the 138 cutting planes required almost 13 GB of memory.

Iterations	Output	Line Search	Add $\mathbf{a}_t$	Solver	Total
138	34 hours	222s	7 hours	5min	41 hours

Table 9: Timing statistics for the human acceptor splice site experiment.

5.2 Malware Classification

Malware is malicious software that occurs in the form of Internet worms, computer viruses and Trojan horses. Due to an enormous increase of new variants of malware, methods for its automatic detection and categorization are becoming crucial in modern anti-malware products. Rieck et al. (2008) propose a malware behavioral classifier trained from labeled examples. Malware binaries are collected via honeypots and spam-traps, and malware family labels are generated by running an anti-virus tool. This results in a corpus of more than 10,000 unique malware instances. The behavior of each binary is monitored in a sand box environment and behavior-based analysis reports summarizing operations, such as opening an outgoing IRC connection or stopping a network service, are generated. The reports have a form of text files which are then embedded into a high-dimensional vector space using the bag-of-words model. Finally, a discriminative multi-class SVM classifier is trained.

Rieck et al. (2008) use the multi-class classifier based on one-against-all decomposition, where each binary classifier is trained by a kernel SVM. To increase classification performance, the scale of the independently trained binary discriminant functions, forming the multi-class classifier, is normalized by fitting a logistic function. Rieck et al. (2008) report promising results achieving 88% classification accuracy, which is competitive with commercial anti-virus software tools handcrafted manually by computer security experts. Apart from the classification accuracy, the ability to retrain swiftly on new examples is a crucial feature for practical application of the system. While the classification accuracy was the main focus in Rieck et al. (2008), the issue of fast training was not addressed. The SVM$^{\text{light}}$ that they used required approximately 13-14 hours to perform the whole model selection on a high-end single CPU computer.[11]

To resolve the problem of fast training, we apply our proposed OCAM solver and compare its performance with SVM$^{\text{multi-class}}$ (Joachims et al., 2009). SVM$^{\text{multi-class}}$ version 2.20[12] is a highly optimized implementation of CPAM which uses numerous heuristic speedups like adaptive accu-

10. Found at `http://www.nvidia.com/object/product_tesla_s1070_us.html`.
11. Personal communication with authors of Rieck et al. (2008).
12. Found at `http://www.cs.cornell.edu/People/tj/svm_light/svm_multiclass.html`.

racy management, caching or 1-slack reformulation (for more details see Joachims et al. 2009). Note that OCAM is the plain implementation of the proposed Algorithm 2, hence there is still the possibility to improve its performance by implementing the same heuristics. SVM$^{\text{multi-class}}$ optimizes a slightly modified risk $R'(\mathbf{w}) = \frac{1}{m}\sum_{i=1}^{m} \max_{y\in\mathcal{Y}} \left(100[\![y_i \neq y]\!] + \langle \mathbf{w}_y - \mathbf{w}_{y_i}, \mathbf{x}_i\rangle\right)$. To make objectives of SVM$^{\text{multi-class}}$ and OCAM equivalent we use the transform: $\mathbf{x}_i = \mathbf{x}'_i/100$ and $C = 100C'$ where $\mathbf{x}'_i$ and C' denote inputs and the regularization constant used by SVM$^{\text{multi-class}}$. SVM$^{\text{multi-class}}$ stops optimization when $F(\mathbf{w}_t) - F_t(\mathbf{w}_t) \leq C\varepsilon'$, hence we apply $\varepsilon = C\varepsilon'$ in OCAM to use equivalent stopping conditions. In addition, we use $\varepsilon' = 0.1$, which is the default setting in SVM$^{\text{multi-class}}$.

solver	error [%]	training time	
SVM$^{\text{multi-class}}$ v2.20	11.45 ± 0.72	25,330 sec	$\approx$ 7 hours
OCAM	11.49 ± 0.91	2,451 sec	$\approx$ 40 minutes
Rieck et al. (2008)	12		$\approx$ 13-14 hours

Table 10: Comparison of SVM$^{\text{multi-class}}$ v2.20 with the proposed OCAM on the malware classification problem. The reported error is a 5-fold cross-validation estimate of the per-class average classification error. The training time refers to the total time required by model selection. We also compare with the previous results reported in Rieck et al. (2008). OCAS achieves a speedup of factor 10 over SVM$^{\text{multi-class}}$ and of factor 20 compared to the one-against-all based classifier trained by kernel SVM$^{\text{light}}$ used in Rieck et al. (2008).

We adopted the evaluation protocol from Rieck et al. (2008). The classification accuracy is measured in terms of average per-class classification error, that is, $E = \frac{1}{Y}\sum_{y\in\mathcal{Y}} \frac{1}{m_i}\sum_{i|y_i=y}[\![y_i \neq h(\mathbf{x}_i)]\!]$, where m_i is the number of examples in the i-th class. The malware corpus of 10,072 examples is randomly split 5 times into training, validation and testing partitions of approximately equal size. The training partition is used to train the multi-class SVM using a range of different regularization constants $C \in \{10^0, 10^1, \ldots, 10^{10}\}$. The best C is selected based on classification accuracy measured on the validation part. Finally, we report average and standard deviations of the per-class average classification error computed on testing data over the 5 random splits.

Due to the very high-dimensional feature space, the explicit representation of the input vectors is inefficient. To apply the linear SVM solvers, we use the standard trick of representing the kernel matrix by the whitened empirical kernel map (Schölkopf and Smola, 2002). This representation reduces the number of features to the number of training examples. The runtime required by the singular value decomposition (SVD) to compute the whitened matrix is approximately 5 minutes, which is negligible w.r.t. the runtime of the SVM solvers. Note that training linear SVMs on the whitened kernel map is equivalent to training the kernel SVM classifier.

The experiments are performed on a laptop computer with an Intel CPU @ 1.8 GHz. Table 10 summarizes the results. The classification performance of SVM$^{\text{multi-class}}$ and OCAM is almost identical. The performance of both methods is slightly better than the results reported by Rieck et al. (2008), who used a heuristic one-against-all decomposition combined with the logistic regression. Comparison of the runtimes shows that the proposed OCAM is more than 10 times faster than the competing SVM$^{\text{multi-class}}$ and more than 20 times faster than the SVM$^{\text{light}}$ solver used in Rieck et al. (2008).

6. Conclusions

We have developed a novel method for solving large-scale risk minimization problems. Our proposed optimized cutting plane algorithm (OCA) extends the standard CPA algorithm of Teo et al. (2007) by, first, optimizing directly the primal problem via a line-search and, second, developing a new cutting plane selection strategy which significantly reduces the number of cutting planes needed to achieve an accurate solution. We have shown that the number of iterations OCA requires to converge to a ε-precise solution is approximately linear in the sample size. Applying OCA to two important learning problems, we obtained very fast specialized solvers for linear binary SVM classification (OCAS), and linear multi-class SVM classification (OCAM). In an extensive empirical evaluation on a large variety of problems comparing the proposed OCA with previous state-of-the-art SVM solvers, we achieved (depending on the task) speedups of up to three orders of magnitude obtaining the same precise SV solution. By parallelizing the subtasks of the algorithm, OCAS gained additional speedups of factors of up to 4.6 on a multi-core multiprocessor machine. Applying OCAS to a real-world splice site detection problem, we were able to train on a 12-million dimensional data set containing 50 million examples, achieving a new record performance for that task. Finally, we could reduce the training time on a malware classification problem by a factor of 20 over the previous approach. It remains as future work to derive OCAS for general structured output learning problems. Furthermore, we plan to extend OCAS to incorporate a bias term. Finally, it will be future work to investigate how the kernel framework can be incorporated into OCAS.

Acknowledgments

This work was supported in part by the FP7-ICT Programme of the European Union under the PASCAL2 Network of Excellence (ICT-216886) and by the Learning and Interference Platform of the Max Planck and Fraunhofer Societies. The main part of this work was done while VF was with the Fraunhofer IDA.FIRST when he was supported by a Marie Curie Intra-European Fellowship Grant SCOLES (MEIF-CT-2006-042107). VF was also supported by Czech Ministry of Education project 1M0567 during his current fellowship in the Center for Machine Perception. We thank Alexander Zien, Gunnar Rätsch, Konrad Rieck and Gilles Blanchard for great discussions. We also thank Konrad Rieck for providing us with the malware corpus.

Appendix A. Convergence Analysis

In this section we prove the convergence of OCA (Theorem 2). The core of the proof is adopted from Teo et al. (2007) who proved the Convergence Theorem 1 of the standard CPA. The main idea of the convergence theorem is based on deriving a lower bound on the improvement of the duality gap $F(\mathbf{w}_t^b) - F_t(\mathbf{w}_t) = \varepsilon_t$ and expressing this lower bound as a difference inequality (20), defined in Theorem 3. Having the difference inequality, (20) the proof of the convergence Theorem 2 follows easily.

The most laborious part is thus proving the auxiliary Theorem 3. The lower bound on the improvement $\varepsilon_t - \varepsilon_{t+1}$, which is the core inequality (20) in Theorem 3, is proven by showing that the objective value of the reduced problem solved at iteration $t+1$ must increase, provided the new added cutting plane violates the constraints of the reduced problem at iteration t. In the standard CPA, it is trivial to show that the new added cutting plane violates these constraints by at least ε_t.

Due to the sophisticated cutting plane selection strategy used in OCA, the violation of constraints is not obvious. Nevertheless, it can be proven, as we show in Lemma 1. Lemma 1 constitutes the main difference in the proofs of the standard CPA and the proposed OCA. The same lemma also explains why OCA converges faster than CPA. It will be shown that the minimal improvement of the reduced problem objective is a function of the constraint violation. While in the standard CPA the violation is guaranteed to be ε_t, the inequality (21) shows that the new cutting plane added in OCA violates the constraints by $\varepsilon_t + \frac{C}{2}\|\mathbf{w}_t^c - \mathbf{w}_t\|^2$. Unfortunately, we do not know how to bound the second term and thus the resulting lower bounds are the same for both algorithms.

The rest of this section is organized as follows. We first derive Lemmas 1, 2 and then we prove the auxiliary Theorem 3. Finally, we give the proof of the Convergence Theorem 2, which uses all previous results.

Theorem 3 *Assume that $\|\partial R(\mathbf{w})\| \leq G$ for all $\mathbf{w} \in \mathcal{W}$, where $\mathcal{W}$ is some domain of interest containing all $\mathbf{w}_{t'}$ for $t' \leq t$, and that $F(\mathbf{w}_t^b) - F_t(\mathbf{w}_t) = \varepsilon_t > 0$. In this case*

$$\varepsilon_t - \varepsilon_{t+1} \geq \frac{\varepsilon_t}{2} \min\left\{1, \frac{\varepsilon_t}{4C^2G^2}\right\}. \tag{20}$$

Lemma 1 *Let $F(\mathbf{w}_t^b) - F_t(\mathbf{w}_t) = \varepsilon_t > 0$. Then Algorithm 2 computes a new cutting plane $\langle \mathbf{w}, \mathbf{a}_{t+1}\rangle + b_{t+1} = 0$ which violates the constraints of the reduced problem (5) solved in the t-th iteration by at least $\frac{\varepsilon_t}{C}$, that is, it holds that*

$$C\big(b_{t+1} + \langle \mathbf{w}_t, \mathbf{a}_{t+1}\rangle - \xi_t\big) \geq \varepsilon_t + \frac{C}{2}\|\mathbf{w}_t^c - \mathbf{w}_t\|^2 \geq \varepsilon_t\,. \tag{21}$$

PROOF : We use the subgradient $\mathbf{w}_t^c + C\mathbf{a}_{t+1} \in \partial F(\mathbf{w}_t^c)$ to put a lower bound on the master objective F by means of a linear function at the point $\mathbf{w}_t^c$, that is,

$$f(\mathbf{w}) = F(\mathbf{w}_t^c) + \langle \mathbf{w}_t^c + C\mathbf{a}_{t+1}, \mathbf{w} - \mathbf{w}_t^c\rangle \leq F(\mathbf{w})\,, \qquad \forall \mathbf{w} \in \Re^n\,. \tag{22}$$

In Step 4 of Algorithm 2, the new best-so-far solution, $\mathbf{w}_t^b$, is computed as the minimizer of F over the line connecting the old best-so-far solution, $\mathbf{w}_{t-1}^b$, and the solution of reduced problem $\mathbf{w}_t$. In step 5, the new cutting plane $\langle \mathbf{w}, \mathbf{a}_{t+1}\rangle + b_{t+1} = 0$ is taken at the point $\mathbf{w}_t^c = \mathbf{w}_t^b(1-\mu) + \mathbf{w}_t\mu$, $\mu \in (0,1]$. Hence we conclude that $F(\mathbf{w}_t^b) \leq F(\mathbf{w}_t^c)$. Using the latter inequality and the lower bound (22), we obtain

$$f(\mathbf{w}_t^b) \leq F(\mathbf{w}_t^b) \leq F(\mathbf{w}_t^c) = f(\mathbf{w}_t^c)\,.$$

Since $\mathbf{w}_t^c$ lies on the line segment connecting $\mathbf{w}_t^b$ with $\mathbf{w}_t$ and because $f(\mathbf{w}_t^b) \leq f(\mathbf{w}_t^c)$ we conclude that

$$f(\mathbf{w}_t^c) \leq f(\mathbf{w}_t)\,. \tag{23}$$

Note that the inequality (23) holds only for $\mu \in (0,1]$. Using (22) we can rewrite (23) as

$$F(\mathbf{w}_t^c) \leq F(\mathbf{w}_t^c) + \langle \mathbf{w}_t^c + C\mathbf{a}_{t+1}, \mathbf{w}_t - \mathbf{w}_t^c\rangle\,. \tag{24}$$

Combining $F(\mathbf{w}_t^b) \leq F(\mathbf{w}_t^c)$ and $F(\mathbf{w}_t^b) - F_t(\mathbf{w}_t) = \varepsilon_t$ we get $F(\mathbf{w}_t^c) - F_t(\mathbf{w}_t) \geq \varepsilon_t$. Finally, substituting (24) to the latter inequality yields

$$F(\mathbf{w}_t^c) + \langle \mathbf{w}_t^c + C\mathbf{a}_{t+1}, \mathbf{w}_t - \mathbf{w}_t^c\rangle - F_t(\mathbf{w}_t) \geq \varepsilon_t\,,$$

which can be further rearranged into (21). ■

Lemma 2 *(Teo et al., 2007) Let $\Delta(\tau) = l\tau - \frac{h}{2}\tau^2$ be a concave quadratic function such that $\Delta'(0) \geq L > 0$ and $|\Delta''(\tau)| = h \leq H$, $\forall \tau \in [0,1]$. Then the maximal value of Δ attained for the interval $[0,1]$ has a lower bound defined by*

$$\max_{\tau \in [0,1]} \Delta(\tau) \geq \frac{L}{2} \min\left(1, \frac{L}{H}\right).$$

PROOF : Using $l \geq L$ and $h \leq H$ we obtain a lower bound $\Delta(\tau)$ by $L\tau - \frac{H}{2}\tau^2$. The unconstrained maximum of the lower bound is attained at point $\frac{L}{H}$, which leads to the value of $\frac{L^2}{2H}$. If $\frac{L}{H} > 1$ then the constrained maximum of the lower bound is attained at 1, which yields the maximal value of $L - \frac{H}{2}$. Using $\frac{L}{H} > 1$, the value of $L - \frac{H}{2}$ has a lower bound of $\frac{L}{2}$. Taking the minimum over both maxima proves the claim. ■

PROOF OF THEOREM 3: We can put a lower bound on the difference $\varepsilon_t - \varepsilon_{t+1}$ using the improvement of the dual objective function $D_{t+1}(\alpha_{t+1}) - D_t(\alpha_t)$ because

$$\begin{aligned} \varepsilon_t - \varepsilon_{t+1} &= F(\mathbf{w}_t^b) - F_t(\mathbf{w}_t) - F(\mathbf{w}_{t+1}^b) + F_{t+1}(\mathbf{w}_{t+1}) \\ &\geq F_{t+1}(\mathbf{w}_{t+1}) - F_t(\mathbf{w}_t) \\ &= D_{t+1}(\alpha_{t+1}) - D_t(\alpha_t). \end{aligned}$$

The inequality follows after excluding the term $F(\mathbf{w}_t^b) - F(\mathbf{w}_{t+1}^b) \geq 0$ and the last equality is the result of the fact that the primal and dual optimal values are equal.

The value of $D_{t+1}(\alpha_{t+1})$ is defined as the maximum of D_{t+1} w.r.t. the convex feasible set $\mathcal{A}_{t+1}$. Hence, by maximizing D_{t+1} w.r.t. a line segment lying entirely inside $\mathcal{A}_{t+1}$ we get a lower bound on $D_{t+1}(\alpha_{t+1})$, that is,

$$D_{t+1}(\alpha_{t+1}) - D_t(\alpha_t) \geq \max_{\tau \in [0,1]} \Delta(\tau) := D_{t+1}\big(\beta(1-\tau) + \gamma\tau\big) - D_t(\alpha_t),$$

where β and γ are arbitrary vectors from $\mathcal{A}_{t+1}$. Specifically, we define the vectors as

$$\beta = (\alpha_t; 0) \in \Re^{t+1} \quad \text{and} \quad \gamma = (\mathbf{0}; C) \in \Re^{t+1}. \tag{25}$$

Now we show that $\Delta(\tau)$ is a function compliant with the assumptions of Lemma 2, which will allow us to lower bound its value for the interval $[0,1]$. To this end, we need to derive the explicit form of $\Delta(\tau)$ and then compute $\Delta'(0)$ and an upper bound on $\Delta''(\tau)$, $\forall \tau \in [0,1]$. Defining a vector $\mathbf{b} = (b_1; \ldots; b_{t+1}) \in \Re^{t+1}$ and a matrix $\mathbf{A} = (\mathbf{a}_1, \ldots, \mathbf{a}_{t+1}) \in \Re^{n \times (t+1)}$ we can write the objective of the dual of the reduced problem as $D_{t+1}(\alpha) = \langle \alpha, \mathbf{b} \rangle - \frac{1}{2}\|\mathbf{A}\alpha\|^2$. Using the latter definition of D_{t+1} and (25), we can rewrite $\Delta(\tau)$ as

$$\Delta(\tau) = \tau\big\langle \gamma - \beta, \mathbf{b} - \mathbf{A}^T\mathbf{A}\beta \big\rangle - \frac{1}{2}\tau^2 \big\|\mathbf{A}\beta - \mathbf{A}\gamma\big\|^2.$$

The value of the derivative $\Delta'(0)$ can be written as

$$\Delta'(0) = \big\langle \gamma - \beta, \mathbf{b} - \mathbf{A}^T\mathbf{A}\beta \big\rangle = C\big(b_{t+1} + \langle \mathbf{w}_t, \mathbf{a}_{t+1} \rangle - \xi_t\big). \tag{26}$$

The second equality of (26) was derived by using (25), $\mathbf{w}_t = -\sum_{i=1}^t \mathbf{a}_i[\alpha_t]_i$ and $F_t(\mathbf{w}_t) = D_t(\alpha_t)$. Using Lemma 1, we get a lower bound of the right-hand side of (26), that is

$$\Delta'(0) \geq \varepsilon_t. \tag{27}$$

The absolute value of the second derivative $|\Delta''(\tau)|$ can be upper bound by

$$|\Delta''(\tau)| = \|\mathbf{A}\beta - \mathbf{A}\gamma\|^2 \leq \|\mathbf{A}\beta\|^2 + \|\mathbf{A}\gamma\|^2 \leq 4C^2 \max_{i=1,\ldots,t+1} \|\mathbf{a}_i\|^2 \leq 4C^2G^2\,, \tag{28}$$

where we use the assumption $\mathbf{a}_i = \|\partial F(\mathbf{w})\| \leq G$ and the fact that the vector $\frac{1}{C}\mathbf{A}\alpha$ equals the convex combination of the columns of $\mathbf{A}$ for any $\alpha \in \mathcal{A}_{t+1}$, hence, its norm cannot be greater than $\max_i \|\mathbf{a}_i\|$. Finally, using (27) and (28) in Lemma 2 yields the claim of Theorem 3. ■

PROOF OF THEOREM 2: The proof is adopted from Teo et al. (2007). For any $\varepsilon_t > 4C^2G^2$ it follows from (20) that $\varepsilon_{t+1} \leq \frac{\varepsilon_t}{2}$. Moreover, $\varepsilon_0 \leq F(\mathbf{0})$, since F is nonnegative. Hence, we need at most $\log_2 \frac{F(\mathbf{0})}{4C^2G^2}$ iterations to achieve a level of precision better than $4C^2G^2$. Subsequently, we need to solve the following difference equation:

$$\varepsilon_{t+1} - \varepsilon_t = -\frac{\varepsilon_t^2}{8C^2G^2}\,.$$

Since this is monotonically decreasing, we can upper bound this by solving the differential equation $\varepsilon'(t) = -\frac{\varepsilon^2(t)}{8C^2G^2}$, with the boundary condition $\varepsilon(0) = 4C^2G^2$. This in turn yields $\varepsilon(t) = \frac{8C^2G^2}{t+2}$, and hence $t \leq \frac{8C^2G^2}{\varepsilon} - 2$ to achieve $\varepsilon(t) \leq \varepsilon$. For a given ε we will need $\frac{8C^2G^2}{\varepsilon} - 2$ more iterations to converge. This proves the claim.

Abstract

We study boosting algorithms for learning to rank. We give a general margin-based bound for ranking based on covering numbers for the hypothesis space. Our bound suggests that algorithms that maximize the ranking margin will generalize well. We then describe a new algorithm, smooth margin ranking, that precisely converges to a maximum ranking-margin solution. The algorithm is a modification of RankBoost, analogous to "approximate coordinate ascent boosting." Finally, we prove that AdaBoost and RankBoost are equally good for the problems of bipartite ranking and classification in terms of their asymptotic behavior on the training set. Under natural conditions, AdaBoost achieves an area under the ROC curve that is equally as good as RankBoost's; furthermore, RankBoost, when given a specific intercept, achieves a misclassification error that is as good as AdaBoost's. This may help to explain the empirical observations made by Cortes and Mohri, and Caruana and Niculescu-Mizil, about the excellent performance of AdaBoost as a bipartite ranking algorithm, as measured by the area under the ROC curve.

Keywords: ranking, RankBoost, generalization bounds, AdaBoost, area under the ROC curve

1. Introduction

Consider the following supervised learning problem: Sylvia would like to get some recommendations for good movies before she goes to the theater. She would like a ranked list that agrees with her tastes as closely as possible, since she will probably go to see the movie closest to the top of the list that is playing at the local theater. She does not want to waste her time and money on a movie she probably will not like.

The information she provides is as follows: for many different pairs of movies she has seen, she will tell the learning algorithm whether or not she likes the first movie better than the second one.[1] This allows her to rank whichever pairs of movies she wishes, allowing for the possibility of ties

*. Also at Center for Computational Learning Systems, Columbia University, 475 Riverside Drive MC 7717, New York, NY 10115.

1. In practice, she could simply rate the movies, but this gives pairwise information also. The pairwise setting is strictly more general in this sense.

between movies, and the possibility that certain movies cannot necessarily be compared by her (for instance, she may not wish to directly compare cartoons with action movies). Sylvia does not need to be consistent, in the sense that she may rank $\mathbf{a} > \mathbf{b} > \mathbf{c} > \mathbf{a}$. (The loss function and algorithm will accommodate this. See Martin Gardner's amusing article (Gardner, 2001) on how nontransitivity can arise naturally in many situations.) Each pair of movies such that Sylvia ranks the first above the second is called a "crucial pair."

The learning algorithm has access to a set of n individuals, called "weak rankers" or "ranking features," who have also ranked pairs of movies. The learning algorithm must try to combine the views of the weak rankers in order to match Sylvia's preferences, and generate a recommendation list that will generalize her views. In this paper, our goal is to design and study learning algorithms for ranking problems such as this collaborative filtering task.

The ranking problem was studied in depth by Freund et al. (2003), where the RankBoost algorithm was introduced. In this setting, the ranked list is constructed using a linear combination of the weak rankers. Ideally, this combination should minimize the probability that a crucial pair is misranked, that is, the probability that the second movie in the crucial pair is ranked above the first. RankBoost aims to minimize an exponentiated version of this misranking probability.

A special case of the general ranking problem is the "bipartite" ranking problem, where there are only two classes: a positive class (good movies) and a negative class (bad movies). In this case, the misranking probability is the probability that a good movie will be ranked below a bad movie. This quantity is an affine transformation of the (negative of the) area under the Receiver-Operator-Characteristic curve (AUC).

Bipartite ranking is different from the problem of classification; if, for a given data set, the misclassification error is zero, then the misranking error must also be zero, but the converse is not necessarily true. For the ranking problem, the examples are viewed relative to each other and the decision boundary is irrelevant.

Having described the learning setting, we can now briefly summarize our three main results.

- *Generalization bound:* In Section 3, we provide a margin-based bound for ranking in the general setting described above. Our ranking margin is defined in analogy with the classification margin, and the complexity measure for the hypothesis space is a "sloppy covering number," which yields, as a corollary, a bound in terms of the L_∞ covering number. Our bound indicates that algorithms that maximize the margin will generalize well.

- *Smooth margin ranking algorithm:* We present a ranking algorithm in Section 4 designed to maximize the margin. Our algorithm is based on a "smooth margin," and we present an analysis of its convergence.

- *An equivalence between AdaBoost and RankBoost:* A remarkable property of AdaBoost is that it not only solves the classification problem, but simultaneously solves the same problem of bipartite ranking as its counterpart, RankBoost. This is proved in Section 5. One does not need to alter AdaBoost in any way for this property to hold. Conversely, the solution of RankBoost can be slightly altered to achieve a misclassification loss that is equally as good as AdaBoost's.

We now provide some background and related results.

Generalization bounds are useful for showing that an algorithm can generalize beyond its training set, in other words, that prediction is possible. More specifically, bounds indicate that a small

probability of error will most likely be achieved through a proper balance of the empirical error and the complexity of the hypothesis space. This complexity can by measured by many informative quantities; for instance, the VC dimension, which is linked in a fundamental way to classification, and the Rademacher and Gaussian complexities (Bartlett and Mendelson, 2002). The use of these quantities is tied to a kind of natural symmetry that typically exists in such problems, for instance, in the way that positive and negative examples are treated symmetrically in a classification setting. The limited bipartite case has this symmetry, but not the more general ranking problem that we have described. Prior bounds on ranking have either made approximations in order to use the VC Dimension for the general problem (as discussed by Clemençon et al., 2005, 2007, who work on statistical aspects of ranking) or focused on the bipartite case (Freund et al., 2003; Agarwal et al., 2005; Usunier et al., 2005). For our bound, we choose a covering number in the spirit of Bartlett (1998). The covering number is a general measure of the capacity of the hypothesis space; it does not lend itself naturally to classification like the VC dimension, is not limited to bipartite ranking, nor does it require symmetry in the problem. Thus, we are able to work around the lack of symmetry in this setting. In fact, a preliminary version of our work (Rudin et al., 2005) has been extended to a highly nonsymmetric setting, namely the case where the top part of the list is considered more important (Rudin, 2009). Several other recent works also consider this type of highly nonsymmetric setting for ranking (Dekel et al., 2004; Cossock and Zhang, 2008; Clemençon and Vayatis, 2007; Shalev-Shwartz and Singer, 2006; Le and Smola, 2007).

When deriving generalization bounds, it is important to consider the "separable" case, where all training instances are correctly handled by the learning algorithm so that the empirical error is zero. In the case of bipartite ranking, the separable case means that all positive instances are ranked above all negative instances, and the area under the ROC curve is exactly 1. In the separable case for classification, one important indicator of a classifier's generalization ability is the "margin." The margin has proven to be an important quantity in practice for determining an algorithm's generalization ability, for example, in the case of AdaBoost (Freund and Schapire, 1997) and support vector machines (SVMs) (Cortes and Vapnik, 1995). Although there has been some work devoted to generalization bounds for ranking as we have mentioned (Clemençon et al., 2005, 2007; Freund et al., 2003; Agarwal et al., 2005; Usunier et al., 2005), the bounds that we are aware of are not margin-based, and thus do not provide this useful type of discrimination between ranking algorithms in the separable case.

Since we are providing a general margin-based bound for ranking in Section 3, we derive algorithms which create large margins. For the classification problem, it was proved that AdaBoost does not always fully maximize the (classification) margin (Rudin et al., 2004). In fact, AdaBoost does not even necessarily make progress towards increasing the margin at every iteration. Since AdaBoost (for the classification setting) and RankBoost (for the ranking setting) were derived analogously for the two settings, RankBoost does not directly maximize the ranking margin, and it does not necessarily increase the margin at every iteration. In Section 4.1 we introduce a "smooth margin" ranking algorithm, and prove that it makes progress towards increasing the smooth margin for ranking at every iteration; this is the main step needed in proving convergence and convergence rates. This algorithm is analogous to the smooth margin classification algorithm "approximate coordinate ascent boosting" (Rudin et al., 2007) in its derivation, but the analogous proof that progress occurs at each iteration is much trickier; hence we present this proof here, along with a theorem stating that this algorithm converges to a maximum margin solution.

Although AdaBoost and RankBoost were derived analogously for the two settings, the parallels between AdaBoost and RankBoost are deeper than their derivations. A number of papers, including those of Cortes and Mohri (2004) and Caruana and Niculescu-Mizil (2006) have noted that in fact, AdaBoost experimentally seems to be very good at the bipartite ranking problem, even though it was RankBoost that was explicitly designed to solve this problem, not AdaBoost. Or, stated another way, AdaBoost often achieves a large area under the ROC curve. In Section 5, we present a possible explanation for these experimental observations. Namely, we show that if the weak learning algorithm is capable of producing the constant classifier (the classifier whose value is always one), then remarkably, AdaBoost and RankBoost produce equally good solutions to the ranking problem in terms of loss minimization and area under the ROC curve on the training set. More generally, we define a quantity called "F-skew," an exponentiated version of the "skew" used in the expressions of Cortes and Mohri (2004, 2005) and Agarwal et al. (2005). If the F-skew vanishes, AdaBoost minimizes the exponentiated ranking loss, which is the same loss that RankBoost explicitly minimizes; thus, the two algorithms will produce equally good solutions to the exponentiated problem. Moreover, if AdaBoost's set of weak classifiers includes the constant classifier, the F-skew always vanishes. From there, it is only a small calculation to show that AdaBoost and RankBoost achieve the same asymptotic AUC value whenever it can be defined. An analogous result does not seem to hold true for support vector machines; SVMs designed to maximize the AUC only seem to yield the same AUC as the "vanilla" classification SVM in the separable case, when the AUC is exactly one (Rakotomamonjy, 2004; Brefeld and Scheffer, 2005). The main result may be useful for practitioners: if the cost of using RankBoost is prohibitive, it may be useful to consider AdaBoost to solve the ranking problem.

The converse result also holds, namely that a solution of RankBoost can be slightly modified so that the F-skew vanishes, and the asymptotic misclassification loss is equal to AdaBoost's whenever it can be defined.

We proceed from the most general to the most specific. First, in Section 3 we provide a margin-based bound for general ranking. In Sections 4.1 and 4.2 we fix the form of the hypothesis space to match that of RankBoost, that is, the space of binary functions. Here, we discuss RankBoost, AdaBoost and other coordinate-based ranking algorithms, and introduce the smooth margin ranking algorithm. In Section 5, we focus on the bipartite ranking problem, and discuss conditions for AdaBoost to act as a bipartite ranking algorithm by minimizing the exponentiated loss associated with the AUC. Sections 3 and 4.2 focus on the separable case where the training error vanishes, and Sections 4.1 and 5 focus on the nonseparable case. Sections 6, 7, and 8 contain the major proofs.

A preliminary version of this work appeared in a conference paper with Cortes and Mohri (Rudin et al., 2005). Many of the results from that work have been made more general here.

2. Notation

We use notation similar to Freund et al. (2003). The training data for the supervised ranking problem consists of *instances* and their *truth function* values. The *instances*, denoted by S, are $\{\mathbf{x}_i\}_{i=1,\ldots,m}$, where $\mathbf{x}_i \in \mathcal{X}$ for all i. The set $\mathcal{X}$ is arbitrary and may be finite or infinite, usually $\mathcal{X} \subset \mathbb{R}^N$. In the case of the movie ranking problem, the $\mathbf{x}_i$'s are the movies and $\mathcal{X}$ is the set of all possible movies. We assume $\mathbf{x}_i \in \mathcal{X}$ are chosen independently and at random (iid) from a fixed but unknown probability distribution $\mathcal{D}$ on $\mathcal{X}$ (assuming implicitly that anything that needs to be measurable is measurable). The notation $\mathbf{x} \sim \mathcal{D}$ means $\mathbf{x}$ is chosen randomly according to distribution $\mathcal{D}$. The notation $S \sim \mathcal{D}^m$

means each of the m elements of the training set S are chosen independently at random according to $\mathcal{D}$.

The values of the *truth function* $\pi : \mathcal{X} \times \mathcal{X} \to \{0,1\}$, which is defined over pairs of instances, are analogous to the "labels" in classification. If $\pi(\mathbf{x}^{(1)}, \mathbf{x}^{(2)}) = 1$, this means that the pair $\mathbf{x}^{(1)}, \mathbf{x}^{(2)}$ is a *crucial pair*: $\mathbf{x}^{(1)}$ should be ranked more highly than $\mathbf{x}^{(2)}$. We will consider a non-noisy case where π is deterministic, which means $\pi(\mathbf{x}^{(1)}, \mathbf{x}^{(1)}) = 0$, meaning that $\mathbf{x}^{(1)}$ should not be ranked higher than itself, and also that $\pi(\mathbf{x}^{(1)}, \mathbf{x}^{(2)}) = 1$ implies $\pi(\mathbf{x}^{(2)}, \mathbf{x}^{(1)}) = 0$, meaning that if $\mathbf{x}^{(1)}$ is ranked more highly than $\mathbf{x}^{(2)}$, then $\mathbf{x}^{(2)}$ should not be ranked more highly than $\mathbf{x}^{(1)}$. It is possible to have $\pi(\mathbf{a}, \mathbf{b}) = 1$, $\pi(\mathbf{b}, \mathbf{c}) = 1$, and $\pi(\mathbf{c}, \mathbf{a}) = 1$, in which case the algorithm will always suffer some loss; we will be in the nonseparable case when this occurs. The total number of crucial training pairs can be no larger than $m(m-1)/2$ based on the rules of π, and should intuitively be of the order m^2 in order for us to perform ranking with sufficient accuracy. We assume that for each pair of training instances $\mathbf{x}_i, \mathbf{x}_k$ we receive, we also receive the value of $\pi(\mathbf{x}_i, \mathbf{x}_k)$. In a more general model, we allow the value $\pi(\mathbf{x}_i, \mathbf{x}_k)$ to be generated probabilisitically conditional on each training pair $\mathbf{x}_i, \mathbf{x}_k$. For the generalization bounds in this paper, for simplicity of presentation, we do not consider this more general model, although all of our results can be shown to hold in the more general case as well. The quantity $E := \mathbb{E}_{\mathbf{x}^{(1)}, \mathbf{x}^{(2)} \sim \mathcal{D}}[\pi(\mathbf{x}^{(1)}, \mathbf{x}^{(2)})]$ is the expected proportion of pairs in the database that are crucial pairs, $0 \leq E \leq 1/2$.

Back to the collaborative filtering example, to obtain the training set, Sylvia is given a random sample of movies, chosen randomly from the distribution of movies being shown in the theater. Sylvia must see these training movies and tell us all pairs of these movies such that she would rank the first above the second to determine values of the truth function π.

Our goal is to construct a ranking function $f : \mathcal{X} \to \mathbb{R}$, which gives a real valued score to each instance in $\mathcal{X}$. We do not care about the actual values of each instance, only the relative values; for instance, we do not care if $f(\mathbf{x}^{(1)}) = .4$ and $f(\mathbf{x}^{(2)}) = .1$, only that $f(\mathbf{x}^{(1)}) > f(\mathbf{x}^{(2)})$, which we interpret to mean that $\mathbf{x}^{(1)}$ is predicted by f to be ranked higher (better) than $\mathbf{x}^{(2)}$. Also, the function f should be bounded, $f \in L_\infty(\mathcal{X})$ (or in the case where $|\mathcal{X}|$ is finite, $f \in \ell_\infty(\mathcal{X})$).

In the usual setting of boosting for classification, $|f(\mathbf{x})| \leq 1$ for all $\mathbf{x}$ and the *margin of training instance i* (with respect to classifier f) is defined by Schapire et al. (1998) to be $y_i f(\mathbf{x}_i)$, where y_i is the classification label, $y_i \in \{-1, 1\}$. The *margin of classifier f* is defined to be the minimum margin over all training instances, $\min_i y_i f(\mathbf{x}_i)$. Intuitively, the margin tells us how much the classifier f can change before one of the training instances is misclassified; it gives us a notion of how stable the classifier is.

For the ranking setting, we define an analogous notion of margin. Here, we normalize our bounded function f so that $0 \leq f \leq 1$. The *margin of crucial pair* $\mathbf{x}_i$,$\mathbf{x}_k$ (with respect to ranking function f) will be defined as $f(\mathbf{x}_i) - f(\mathbf{x}_k)$. The *margin of ranking function f*, is defined to be the minimum margin over all crucial pairs,

$$\text{margin}_f := \mu_f := \min_{\{i,k|\pi(\mathbf{x}_i,\mathbf{x}_k)=1\}} f(\mathbf{x}_i) - f(\mathbf{x}_k).$$

Intuitively, the margin tells us how much the ranking function can change before one of the crucial pairs is misranked. As with classification, we are in the separable case whenever the margin of f is positive.

In Section 5 we will discuss the problem of bipartite ranking. Bipartite ranking is a subset of the general ranking framework we have introduced. In the bipartite ranking problem, every training

instance falls into one of two categories, the positive class Y_+ and the negative class Y_-. To transform this into the general framework, take $\pi(\mathbf{x}_i, \mathbf{x}_k) = 1$ for each pair $i \in Y_+$ and $k \in Y_-$. That is, a crucial pair exists between an element of the positive class and an element of the negative class. The class of each instance is assumed deterministic, consistent with the setup described earlier. Again, the results can be shown to hold in the case of nondeterministic class labels.

It may be tempting to think of the ranking framework as if it were just classification over the space $\mathcal{X} \times \mathcal{X}$. However, this is not the case; the examples are assumed to be drawn randomly from $\mathcal{X}$, rather than pairs of examples drawn from $\mathcal{X} \times \mathcal{X}$. Furthermore, the scoring function f has domain $\mathcal{X}$, that is, in order to produce a single ranked list, we should have $f : \mathcal{X} \to \mathbb{R}$ rather than $f : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$. In the latter case, one would need an additional mechanism to reconcile the scores to produce a single ranked list. Furthermore, the bipartite ranking problem does not have the same goal as classification even though the labels are $\{-1, +1\}$. In classification, the important quantity is the misclassification error involving the sign of f, whereas for bipartite ranking, the important quantity is perhaps the area under the ROC curve, relying on differences between f values. A change in the position of one example can change the bipartite ranking loss without changing the misclassification error and vice versa.

3. A Margin-Based Bound for Ranking

Bounds in learning theory are useful for telling us which quantities (such as the margin) are involved in the learning process (see Bousquet, 2003, for discussion on this matter). In this section, we provide a margin-based bound for ranking, which gives us an intuition for separable-case ranking and yields theoretical encouragement for margin-based ranking algorithms. The quantity we hope to minimize here is the misranking probability; for two randomly chosen instances, if they are a crucial pair, we want to minimize the probability that these instances will be misranked. Formally, this misranking probability is:

$$\begin{aligned}\mathbb{P}_{\mathcal{D}}\{\text{misrank}_f\} &:= \mathbb{P}_{\mathcal{D}}\{f(\bar{\mathbf{x}}) \le f(\tilde{\mathbf{x}}) \mid \pi(\bar{\mathbf{x}}, \tilde{\mathbf{x}}) = 1\} = \mathbb{E}_{\bar{\mathbf{x}}, \tilde{\mathbf{x}} \sim \mathcal{D}}[\mathbf{1}_{[f(\bar{\mathbf{x}}) \le f(\tilde{\mathbf{x}})]} \mid \pi(\bar{\mathbf{x}}, \tilde{\mathbf{x}}) = 1] \\ &= \frac{\mathbb{E}_{\bar{\mathbf{x}}, \tilde{\mathbf{x}} \sim \mathcal{D}}[\mathbf{1}_{[f(\bar{\mathbf{x}}) \le f(\tilde{\mathbf{x}})]} \pi(\bar{\mathbf{x}}, \tilde{\mathbf{x}})]}{\mathbb{E}_{\bar{\mathbf{x}}, \tilde{\mathbf{x}} \sim \mathcal{D}}[\pi(\bar{\mathbf{x}}, \tilde{\mathbf{x}})]} = \frac{\mathbb{E}_{\bar{\mathbf{x}}, \tilde{\mathbf{x}} \sim \mathcal{D}}[\mathbf{1}_{[f(\bar{\mathbf{x}}) \le f(\tilde{\mathbf{x}})]} \pi(\bar{\mathbf{x}}, \tilde{\mathbf{x}})]}{E}. \end{aligned} \tag{1}$$

The numerator of (1) is the fraction of pairs that are both crucial and incorrectly ranked by f, and the denominator, $E := \mathbb{E}_{\bar{\mathbf{x}}, \tilde{\mathbf{x}} \sim \mathcal{D}}[\pi(\bar{\mathbf{x}}, \tilde{\mathbf{x}})]$ is the fraction of pairs that are crucial pairs. Thus, $\mathbb{P}_{\mathcal{D}}\{\text{misrank}_f\}$ is the fraction of crucial pairs that are incorrectly ranked by f.

Since we do not know $\mathcal{D}$, we may calculate only empirical quantities that rely only on our training sample. An empirical quantity that is analogous to $\mathbb{P}_{\mathcal{D}}\{\text{misrank}_f\}$ is the following:

$$\begin{aligned}\mathbb{P}_S\{\text{misrank}_f\} &:= \mathbb{P}_S\{\text{margin}_f \le 0\} := \mathbb{P}_S\{f(\mathbf{x}_i) \le f(\mathbf{x}_k) \mid \pi(\mathbf{x}_i, \mathbf{x}_k) = 1\} \\ &= \frac{\sum_{i=1}^m \sum_{k=1}^m \mathbf{1}_{[f(\mathbf{x}_i) \le f(\mathbf{x}_k)]} \pi(\mathbf{x}_i, \mathbf{x}_k)}{\sum_{i=1}^m \sum_{k=1}^m \pi(\mathbf{x}_i, \mathbf{x}_k)}. \end{aligned}$$

We make this terminology more general, by allowing it to include a margin of θ. For the bound we take $\theta > 0$:

$$\begin{aligned}\mathbb{P}_S\{\text{margin}_f \le \theta\} &:= \mathbb{P}_S\{f(\mathbf{x}_i) - f(\mathbf{x}_k) \le \theta \mid \pi(\mathbf{x}_i, \mathbf{x}_k) = 1\} \\ &= \frac{\sum_{i=1}^m \sum_{k=1}^m \mathbf{1}_{[f(\mathbf{x}_i) - f(\mathbf{x}_k) \le \theta]} \pi(\mathbf{x}_i, \mathbf{x}_k)}{\sum_{i=1}^m \sum_{k=1}^m \pi(\mathbf{x}_i, \mathbf{x}_k)}, \end{aligned}$$

that is, $\mathbb{P}_S\{\text{margin}_f \leq \theta\}$ is the fraction of crucial pairs in $S \times S$ with margin not larger than θ.

We want to bound $\mathbb{P}_{\mathcal{D}}\{\text{misrank}_f\}$ in terms of an empirical, margin-based term and a complexity term. The type of complexity we choose is a "sloppy covering number" of the sort used by Schapire et al. (1998). Since such a covering number can be bounded by an L_∞ covering number, we will immediately obtain L_∞ covering number bounds as well, including a strict improvement on the one derived in the preliminary version of our work (Rudin et al., 2005). Here, we implicitly assume that $\mathcal{F} \subset L_\infty(\mathcal{X})$, $f \in \mathcal{F}$ are everywhere defined.

We next define sloppy covers and sloppy covering numbers.

Definition 1 *For $\varepsilon, \theta \geq 0$, a set $\mathcal{G}$ is a* θ-sloppy ε-cover *for $\mathcal{F}$ if for all $f \in \mathcal{F}$ and for all probability distributions $\mathcal{D}$ on $\mathcal{X}$, there exists $g \in \mathcal{G}$ such that*

$$\mathbb{P}_{\mathbf{x}\sim D}[|f(\mathbf{x}) - g(\mathbf{x})| \geq \theta] \leq \varepsilon.$$

The corresponding sloppy covering number *is the size of the smallest θ-sloppy ε-cover $\mathcal{G}$, and is written $\mathcal{N}(\mathcal{F}, \theta, \varepsilon)$.*

The *L_∞ covering number* $\mathcal{N}_\infty(\mathcal{F}, \varepsilon)$ is defined as the minimum number of (open) balls of radius ε needed to cover $\mathcal{F}$, using the L_∞ metric. Since $\|f - g\|_\infty < \theta$ implies that $\mathbb{P}_{\mathbf{x}\sim D}[|f(\mathbf{x}) - g(\mathbf{x})| \geq \theta] = 0$, we have that the sloppy covering number $\mathcal{N}(\mathcal{F}, \theta, \varepsilon)$ is never more than $\mathcal{N}_\infty(\mathcal{F}, \theta)$, and in some cases it can be exponentially smaller, such as for convex combinations of binary functions as discussed below.

Here is our main theorem, which is proved in Section 6:

Theorem 2 *(Margin-based generalization bound for ranking) For $\varepsilon > 0$, $\theta > 0$ with probability at least*

$$1 - 2\mathcal{N}\left(\mathcal{F}, \frac{\theta}{4}, \frac{\varepsilon}{8}\right) \exp\left[-\frac{m(\varepsilon E)^2}{8}\right]$$

over the random choice of the training set S, every $f \in \mathcal{F}$ satisfies:

$$\mathbb{P}_{\mathcal{D}}\{\text{misrank}_f\} \leq \mathbb{P}_S\{\text{margin}_f \leq \theta\} + \varepsilon.$$

In other words, the misranking probability is upper bounded by the fraction of instances with margin below θ, plus ε; this statement is true with probability depending on $m, E, \theta, \varepsilon$, and $\mathcal{F}$.

We have chosen to write our bound in terms of E, but we could equally well have used an analogous empirical quantity, namely

$$\mathbb{E}_{\mathbf{x}_i, \mathbf{x}_k \sim S}[\pi(\mathbf{x}_i, \mathbf{x}_k)] = \frac{1}{m(m-1)} \sum_{i=1}^{m} \sum_{k=1}^{m} \pi(\mathbf{x}_i, \mathbf{x}_k).$$

This is an arbitrary decision; we can in no way influence $\mathbb{E}_{\mathbf{x}_i, \mathbf{x}_k \sim S}[\pi(\mathbf{x}_i, \mathbf{x}_k)]$ in our setting, since we are choosing training instances randomly. E can be viewed as a constant, where recall $0 < E \leq 1/2$. If $E = 0$, it means that there is no information about the relative ranks of examples, and accordingly the bound becomes trivial. Note that in the special bipartite case, E is the proportion of positive examples multiplied by the proportion of negative examples.

In order to see that this bound encourages the margin to be made large, consider the simplified case where the empirical error term is 0, that is, $\mathbb{P}_S\{\text{margin}_f \leq \theta\} = 0$. Now, the only place where

θ appears is in the covering number. In order to make the probability of success larger, the covering number should be made as small as possible, which implies that θ should be made as large as possible.

As a special case of the theorem, we consider the standard setting where f is a (normalized) linear combination of a dictionary of step functions (or "weak rankers"). In this case, we can show the following, proved in Section 6:

Lemma 3 *(Upper bound on covering numbers for convex combinations of binary weak classifiers) For the following hypothesis space:*

$$\mathcal{F} = \left\{ f : f = \sum_j \lambda_j h_j,\ \sum_j \lambda_j = 1,\ \forall j\, \lambda_j \geq 0,\ h_j : \mathcal{X} \to \{0,1\}, h_j \in \mathcal{H} \right\},$$

we have

$$\ln \mathcal{N}(\mathcal{F}, \theta, \varepsilon) \leq \frac{\ln |\mathcal{H}|\ \ln(2/\varepsilon)}{2\theta^2}.$$

Thus, Theorem 2 implies the following corollary.

Corollary 4 *(Margin-based generalization bound for ranking, convex combination of binary weak rankers) For $\varepsilon > 0$, $\theta > 0$ with probability at least*

$$1 - 2\exp\left(\frac{\ln |\mathcal{H}|\ \ln(16/\varepsilon)}{\theta^2/8} - \frac{m(\varepsilon E)^2}{8} \right)$$

over the random choice of the training set S, every $f \in \mathcal{F}$ satisfies:

$$\mathbb{P}_{\mathcal{D}}\{\text{misrank}_f\} \leq \mathbb{P}_S\{\text{margin}_f \leq \theta\} + \varepsilon.$$

In this case, we can lower bound the right hand side by $1 - \delta$ for an appropriate choice of ε. In particular, Corollary 4 implies that

$$\mathbb{P}_{\mathcal{D}}\{\text{misrank}_f\} \leq \mathbb{P}_S\{\text{margin}_f \leq \theta\} + \varepsilon$$

with probability at least $1 - \delta$ if

$$\varepsilon = \sqrt{\frac{4}{mE^2}\left[\frac{8\ln|\mathcal{H}|}{\theta^2} \ln\left(\frac{4mE^2\theta^2}{\ln|\mathcal{H}|} \right) + 2\ln\left(\frac{2}{\delta} \right) \right]}. \tag{2}$$

This bound holds provided that θ is not too small relative to m, specifically, if

$$m\theta^2 \geq \frac{64\ln|\mathcal{H}|}{E^2}.$$

Note that the bound in (2) is only polylogarithmic in $|\mathcal{H}|$.

As we have discussed above, Theorem 2 can be trivially upper bounded using the L_∞ covering number.

Corollary 5 *(Margin-based generalization bound for ranking, L_∞ covering numbers) For $\varepsilon > 0$, $\theta > 0$ with probability at least*

$$1 - 2\mathcal{N}_\infty\left(\mathcal{F}, \frac{\theta}{4}\right)\exp\left[-\frac{m(\varepsilon E)^2}{8}\right]$$

over the random choice of the training set S, every $f \in \mathcal{F}$ satisfies:

$$\mathbb{P}_{\mathcal{D}}\{\text{misrank}_f\} \leq \mathbb{P}_S\{\text{margin}_f \leq \theta\} + \varepsilon.$$

Consider the case of a finite hypothesis space $\mathcal{F}$ where every function is far apart (in L_∞) from every other function. In this case, the covering number is equal to the number of functions. This is the worst possible case, where $\mathcal{N}\left(\mathcal{F}, \frac{\theta}{4}\right) = |\mathcal{F}|$ for any value of θ. In this case, we can solve for ε directly:

$$\delta := 2|\mathcal{F}|\exp\left[-\frac{m(\varepsilon E)^2}{8}\right] \Longrightarrow \varepsilon = \frac{1}{\sqrt{m}}\sqrt{\frac{8}{E^2}(\ln 2|\mathcal{F}| + \ln(1/\delta))}.$$

This indicates that the error may scale as $1/\sqrt{m}$. For the ranking problem, since we are dealing with pairwise relationships, we might expect worse dependence, but this does not appear to be the case. In fact, the dependence on m is quite reasonable in comparison to bounds for the problem of classification, which does not deal with examples pairwise. This is true not only for finite hypothesis spaces (scaling as $1/\sqrt{m}$) but also when the hypotheses are convex combinations of weak rankers (scaling as $\sqrt{\ln(m)/m}$).

4. Coordinate-Based Ranking Algorithms

In the previous section we presented a uniform bound that holds for all $f \in \mathcal{F}$. In this section, we discuss how a learning algorithm might pick one of those functions in order to make $\mathbb{P}_{\mathcal{D}}\{\text{misrank}_f\}$ as small as possible, based on intuition gained from the bound of Theorem 2. Our bound suggests that given a fixed hypothesis space $\mathcal{F}$ and a fixed number of instances m we try to maximize the margin. We will do this using coordinate ascent. Coordinate ascent/descent is similar to gradient ascent/descent except that the optimization moves along single coordinate axes rather than along the gradient. (See Burges et al., 2005, for a gradient-based ranking algorithm based on a probabilistic model.) We first derive the plain coordinate descent version of RankBoost, and show that it is different from RankBoost itself. In Section 4.2 we define the smooth ranking margin $\tilde{G}$. Then we present the "smooth margin ranking" algorithm, and prove that it makes significant progress towards increasing this smooth ranking margin at each iteration, and converges to a maximum margin solution.

4.1 Coordinate Descent and Its Variation on RankBoost's Objective

We take the hypothesis space $\mathcal{F}$ to be the class of convex combinations of weak rankers $\{h_j\}_{j=1,\ldots,n}$, where $h_j : X \to \{0,1\}$. The function f is constructed as a normalized linear combination of the h_j's:

$$f = \frac{\sum_j \lambda_j h_j}{||\boldsymbol{\lambda}||_1},$$

where $||\boldsymbol{\lambda}||_1 = \sum_j \lambda_j, \lambda_j \geq 0$.

We will derive and mention many different algorithms based on different objective functions; here is a summary of them:

$F(\boldsymbol{\lambda})$: For the *classification* problem, AdaBoost minimizes its objective, denoted $F(\boldsymbol{\lambda})$, by coordinate descent.

$G(\boldsymbol{\lambda})$: For *classification limited to the separable case*, the algorithms "coordinate ascent boosting" and "approximate coordinate ascent boosting" are known to maximize the margin (Rudin et al., 2007). These algorithms are based on the smooth classification margin $G(\boldsymbol{\lambda})$.

$\tilde{F}(\boldsymbol{\lambda})$: For *ranking*, "coordinate descent RankBoost" minimizes its objective, denoted $\tilde{F}(\boldsymbol{\lambda})$, by coordinate descent. RankBoost itself minimizes $\tilde{F}(\boldsymbol{\lambda})$ by a variation of coordinate descent that chooses the coordinate with knowledge of the step size.

$\tilde{G}(\boldsymbol{\lambda})$: For *ranking limited to the separable case*, "smooth margin ranking" is an approximate coordinate ascent algorithm that maximizes the ranking margin. It is based on the smooth ranking margin $\tilde{G}(\boldsymbol{\lambda})$.

The objective function for RankBoost is a sum of exponentiated margins:

$$\tilde{F}(\boldsymbol{\lambda}) := \sum_{\{i,k:[\pi(\mathbf{x}_i,\mathbf{x}_k)=1]\}} e^{-\left(\sum_j \lambda_j h_j(\mathbf{x}_i) - \sum_j \lambda_j h_j(\mathbf{x}_k)\right)} = \sum_{ik \in \mathcal{C}_p} e^{-(\mathbf{M}\boldsymbol{\lambda})_{ik}},$$

where we have rewritten in terms of a structure $\mathbf{M}$, which describes how each individual weak ranker j ranks each crucial pair $\mathbf{x}_i, \mathbf{x}_k$; this will make notation significantly easier. Define an index set that enumerates all crucial pairs $\mathcal{C}_p = \{i,k : \pi(\mathbf{x}_i,\mathbf{x}_k) = 1\}$. Formally, the elements of the two-dimensional matrix $\mathbf{M}$ are defined as follows, for index ik corresponding to crucial pair $\mathbf{x}_i, \mathbf{x}_k$:

$$M_{ik,j} := h_j(\mathbf{x}_i) - h_j(\mathbf{x}_k).$$

The first index of $\mathbf{M}$ is ik, which runs over crucial pairs, that is, elements of $\mathcal{C}_p$, and the second index j runs over weak rankers. The size of $\mathbf{M}$ is $|\mathcal{C}_p| \times n$. Since the weak rankers are binary, the entries of $\mathbf{M}$ are within $\{-1, 0, 1\}$. The notation $(\cdot)_j$ means the j^{th} index of the vector, so that the following notation is defined:

$$(\mathbf{M}\boldsymbol{\lambda})_{ik} := \sum_{j=1}^{n} M_{ik,j}\lambda_j = \sum_{j=1}^{n} \lambda_j h_j(\mathbf{x}_i) - \lambda_j h_j(\mathbf{x}_k), \text{ and } (\mathbf{d}^T\mathbf{M})_j := \sum_{ik \in \mathcal{C}_p} d_{ik} M_{ik,j},$$

for $\boldsymbol{\lambda} \in \mathbb{R}^n$ and $\mathbf{d} \in \mathbb{R}^{|\mathcal{C}_p|}$.

4.1.1 COORDINATE DESCENT RANKBOOST

Let us perform standard coordinate descent on this objective function, and we will call the algorithm "coordinate descent RankBoost." We will not get the RankBoost algorithm this way; we will show how to do this in Section 4.1.2. For coordinate descent on $\tilde{F}$, at iteration t, we first choose a direction j_t in which $\tilde{F}$ is decreasing very rapidly. The direction chosen at iteration t (corresponding to the choice of weak ranker j_t) in the "optimal" case (where the best weak ranker is chosen at each iteration) is given as follows. The notation $\mathbf{e}_j$ indicates a vector of zeros with a 1 in the j^{th} entry:

$$\begin{aligned} j_t \in \operatorname*{argmax}_j \left[-\frac{\partial \tilde{F}(\boldsymbol{\lambda}_t + \alpha \mathbf{e}_j)}{\partial \alpha}\Big|_{\alpha=0} \right] &= \operatorname*{argmax}_j \sum_{ik \in \mathcal{C}_p} e^{-(\mathbf{M}\boldsymbol{\lambda}_t)_{ik}} M_{ik,j} \\ &= \operatorname*{argmax}_j \sum_{ik \in \mathcal{C}_p} d_{t,ik} M_{ik,j} = \operatorname*{argmax}_j (\mathbf{d}_t^T \mathbf{M})_j, \end{aligned} \quad (3)$$

where the "weights" $d_{t,ik}$ are defined by:

$$d_{t,ik} := \frac{e^{-(\mathbf{M}\boldsymbol{\lambda}_t)_{ik}}}{\tilde{F}(\boldsymbol{\lambda}_t)} = \frac{e^{-(\mathbf{M}\boldsymbol{\lambda}_t)_{ik}}}{\sum_{\tilde{ik}\in C_p} e^{-(\mathbf{M}\boldsymbol{\lambda}_t)_{\tilde{ik}}}}.$$

From this calculation, one can see that the chosen weak ranker is a natural choice, namely, j_t is the most accurate weak ranker with respect to the weighted crucial training pairs; maximizing $(\mathbf{d}_t^T\mathbf{M})_j$ encourages the algorithm to choose the most accurate weak ranker with respect to the weights.

The step size our coordinate descent algorithm chooses at iteration t is α_t, where α_t satisfies the following equation for the line search along direction j_t. Define $I_{t+} := \{ik : M_{ik,j_t} = 1\}$, and similarly, $I_{t-} := \{ik : M_{ik,j_t} = -1\}$. Also define $d_{t+} := \sum_{ik\in I_+} d_{t,ik}$ and $d_{t-} := \sum_{ik\in I_-} d_{t,ik}$. The line search is:

$$\begin{aligned}
0 &= -\frac{\partial \tilde{F}(\boldsymbol{\lambda}_t + \alpha \mathbf{e}_{j_t})}{\partial \alpha}\Big|_{\alpha=\alpha_t} = \sum_{ik\in C_p} e^{-(\mathbf{M}(\boldsymbol{\lambda}_t+\alpha_t \mathbf{e}_{j_t}))_{ik}} M_{ik,j_t} \\
&= \sum_{ik\in I_{t+}} e^{-(\mathbf{M}\boldsymbol{\lambda}_t)_{ik}} e^{-\alpha_t} - \sum_{ik\in I_{t-}} e^{-(\mathbf{M}\boldsymbol{\lambda}_t)_{ik}} e^{\alpha_t} \\
0 &= d_{t+} e^{-\alpha_t} - d_{t-} e^{\alpha_t} \\
\alpha_t &= \frac{1}{2}\ln\left(\frac{d_{t+}}{d_{t-}}\right). \qquad (4)
\end{aligned}$$

Thus, we have derived the first algorithm, coordinate descent RankBoost. Pseudocode can be found in Figure 1. In order to make the calculation for $\mathbf{d}_t$ numerically stable, we write $\mathbf{d}_t$ in terms of its update from the previous iteration.

4.1.2 RANKBOOST

Let us contrast coordinate descent RankBoost with RankBoost. They both minimize the same objective $\tilde{F}$, but they differ by the ordering of steps: for coordinate descent RankBoost, j_t is calculated first, then α_t. In contrast, RankBoost uses the formula (4) for α_t in order to calculate j_t. In other words, at each step RankBoost selects the weak ranker that yields the largest decrease in the loss function, whereas coordinate descent RankBoost selects the weak ranker of steepest slope. Let us derive RankBoost. Define the following for iteration t (eliminating the t subscript):

$$\begin{aligned}
I_{+j} &:= \{ik : M_{ik,j} = 1\}, \quad I_{-j} := \{ik : M_{ik,j} = -1\}, \quad I_{0j} := \{ik : M_{ik,j} = 0\}, \\
d_{+j} &:= \sum_{ik\in I_{+j}} d_{t,ik}, \quad d_{-j} := \sum_{ik\in I_{-j}} d_{t,ik}, \quad d_{0j} := \sum_{ik\in I_{0j}} d_{t,ik}.
\end{aligned}$$

For each j, we take a step according to (4) of size $\frac{1}{2}\ln\frac{d_{+j}}{d_{-j}}$, and choose the j_t which makes the objective function $\tilde{F}$ decrease the most. That is:

$$\begin{aligned}
j_t : &= \operatorname*{argmin}_j \tilde{F}\left(\boldsymbol{\lambda}_t + \left(\frac{1}{2}\ln\frac{d_{+j}}{d_{-j}}\right)\mathbf{e}_{j_t}\right) = \operatorname*{argmin}_j \sum_{ik\in C_p} e^{-(\mathbf{M}\boldsymbol{\lambda}_t)_{ik}} e^{-M_{ik,j}\frac{1}{2}\ln\frac{d_{+j}}{d_{-j}}} \\
&= \operatorname*{argmin}_j \sum_{ik} d_{t,ik}\left(\frac{d_{+j}}{d_{-j}}\right)^{-\frac{1}{2}M_{ik,j}} \\
&= \operatorname*{argmin}_j \left[2(d_{+j}d_{-j})^{1/2} + d_{0j}\right]. \qquad (5)
\end{aligned}$$

1. **Input:** Matrix $\mathbf{M}$, No. of iterations t_{max}

2. **Initialize:** $\lambda_{1,j} = 0$ for $j = 1,...,n$, $d_{1,ik} = 1/m$ for all ik

3. **Loop for** $t = 1,...,t_{max}$

   (a) $j_t \in \operatorname{argmax}_j (\mathbf{d}_t^T \mathbf{M})_j$ "optimal" case choice of weak classifier

   (b) $d_{t+} = \sum_{\{ik:M_{ik,j_t}=1\}} d_{t,ik}$, $d_{t-} = \sum_{\{ik:M_{ik,j_t}=-1\}} d_{t,ik}$

   (c) $\alpha_t = \frac{1}{2} \ln \left(\frac{d_{t+}}{d_{t-}} \right)$

   (d) $d_{t+1,ik} = d_{t,ik} e^{-M_{ik,j_t} \alpha_t} /$normaliz. for each crucial pair ik in C_p

   (e) $\boldsymbol{\lambda}_{t+1} = \boldsymbol{\lambda}_t + \alpha_t \mathbf{e}_{j_t}$, where $\mathbf{e}_{j_t}$ is 1 in position j_t and 0 elsewhere.

4. **Output:** $\boldsymbol{\lambda}_{t_{max}} / ||\boldsymbol{\lambda}_{t_{max}}||_1$

Figure 1: Pseudocode for coordinate descent RankBoost.

After we make the choice of j_t, then we can plug back into the formula for α_t, yielding $\alpha_t = \frac{1}{2} \ln \frac{d_{+j_t}}{d_{-j_t}}$. We have finished re-deriving RankBoost. As we mentioned before, the plain coordinate descent algorithm has more natural weak learning associated with it, since the weak ranker chosen tries to find the most accurate weak ranker with respect to the weighted crucial pairs; in other words, we argue (3) is a more natural weak learner than (5).

Note that for AdaBoost's objective function, choosing the weak classifier with the steepest slope (plain coordinate descent) yields the same as choosing the weak classifier with the largest decrease in the loss function: both yield AdaBoost.[2]

2. For AdaBoost, entries of the matrix $\mathbf{M}$ are $M_{ij}^{Ada} := y_i h_j(\mathbf{x}_i) \in \{-1,1\}$ since hypotheses are assumed to be $\{-1,1\}$ valued for AdaBoost. Thus $d_{0j} = 0$, and from plain coordinate descent: $j_t = \operatorname{argmax}_j d_{+j} - d_{-j} = \operatorname{argmax}_j 2d_{+j} - 1$, that is, $j_t = \operatorname{argmax}_j d_{+j}$. On the other hand, for the choice of weak classifier with the greatest decreases in the loss (same calculation as above):

$$\begin{aligned} j_t &= \operatorname{argmin}_j 2(d_{+j} d_{-j})^{1/2}, \text{ that is,} \\ j_t &= \operatorname{argmin}_j d_{+j}(1 - d_{+j}) = \operatorname{argmax}_j d_{+j}^2 - d_{+j}, \end{aligned}$$

and since $d_{+j} > 1/2$, the function $d_{+j}^2 - d_{+j}$ is monotonically increasing in d_{+j}, so $j_t = \operatorname{argmax}_j d_{+j}$. Thus, whether or not AdaBoost chooses its weak classifier with knowledge of the step size, it would choose the same weak classifier anyway.

4.2 Smooth Margin Ranking

The value of $\tilde{F}$ does not directly tell us anything about the margin, only whether the margin is positive. In fact, it is possible to minimize $\tilde{F}$ with a positive margin that is arbitrarily small, relative to the optimal.[3] Exactly the same problem occurs for AdaBoost. It has been proven (Rudin et al., 2004) that it is possible for AdaBoost not to converge to a maximum margin solution, nor even to make progress towards increasing the margin at every iteration. Thus, since the calculations are identical for RankBoost, there are certain cases in which we can expect RankBoost not to converge to a maximum margin solution.

Theorem 6 *(RankBoost does not always converge to a maximum margin solution) There exist matrices $\boldsymbol{M}$ for which RankBoost converges to a margin that is strictly less than the maximum margin.*

Proof Since RankBoost and AdaBoost differ only in their definitions of the matrix $\mathbf{M}$, they possess exactly the same convergence properties for the same choice of $\mathbf{M}$. There is an 8×8 matrix $\mathbf{M}$ in Rudin et al. (2004) for which AdaBoost converges to a margin value of $1/3$, when the maximum margin is $3/8$. Thus, the same convergence property applies for RankBoost. It is rare in the separable case to be able to solve for the asymptotic margin that AdaBoost or RankBoost converges to; for this 8×8 example, AdaBoost's weight vectors exhibit cyclic behavior, which allowed convergence of the margin to be completely determined. ■

A more complete characterization of AdaBoost's convergence with respect to the margin (and thus RankBoost's convergence) can be found in Rudin et al. (2007).

In earlier work, we have introduced a smooth margin function, which one can maximize in order to achieve a maximum margin solution for the classification problem (Rudin et al., 2007). A coordinate ascent algorithm on this function makes progress towards increasing the smooth margin at every iteration. Here, we present the analogous smooth ranking function and the smooth margin ranking algorithm. The extension of the convergence proofs for this algorithm is nontrivial; our main contribution in this section is a condition under which the algorithm makes progress.

The smooth ranking function $\tilde{G}$ is defined as follows:

$$\tilde{G}(\boldsymbol{\lambda}) := \frac{-\ln \tilde{F}(\boldsymbol{\lambda})}{||\boldsymbol{\lambda}||_1}.$$

It is not hard to show (see Rudin et al., 2007) that:

$$\tilde{G}(\boldsymbol{\lambda}) < \mu(\boldsymbol{\lambda}) \leq \rho, \tag{6}$$

where the margin can be written in this notation as:

$$\mu(\boldsymbol{\lambda}) = \min_i \frac{(\mathbf{M}\boldsymbol{\lambda})_i}{\|\boldsymbol{\lambda}\|_1}$$

3. One can see this by considering any vector $\boldsymbol{\lambda}$ such that $(\mathbf{M}\boldsymbol{\lambda})_{ik}$ is positive for all crucial pairs ik. That is, we choose any $\boldsymbol{\lambda}$ that yields a positive margin. We can make the value of $\tilde{F}$ arbitrarily small by multiplying $\boldsymbol{\lambda}$ by a large positive constant; this will not affect the value of the margin because the margin is $\min_{ik \in \mathcal{C}_p} (\mathbf{M}\boldsymbol{\lambda})_{ik} / ||\boldsymbol{\lambda}||_1$, and the large constant will cancel. In this way, the objective can be arbitrarily small, while the margin is certainly not maximized. Thus, coordinate descent on $\tilde{F}$ does not necessarily have anything to do with maximizing the margin.

and the best possible margin is:

$$\rho = \min_{\{\mathbf{d}:\sum_{ik} d_{ik}=1, d_{ik}\geq 0\}} \max_j (\mathbf{d}^T \mathbf{M})_j = \max_{\{\bar{\boldsymbol{\lambda}}:\sum_j \bar{\lambda}_j=1, \bar{\lambda}_j\geq 0\}} \min_i (\mathbf{M}\bar{\boldsymbol{\lambda}})_i.$$

In other words, the smooth ranking margin is always less than the true margin, although the two quantities become closer as $||\boldsymbol{\lambda}||_1$ increases. The true margin is no greater than ρ, the min-max value of the game defined by $\mathbf{M}$ (see Freund and Schapire, 1999).

We now define the smooth margin ranking algorithm, which is approximately coordinate ascent on $\tilde{G}$. As usual, the input to the algorithm is matrix $\mathbf{M}$, determined from the training data. Also, we will only define this algorithm when $\tilde{G}(\boldsymbol{\lambda})$ is positive, so that we only use it once the data has become separable; we can use RankBoost or coordinate descent RankBoost to get us to this point.

We will define iteration $t+1$ in terms of the quantities known at iteration t. At iteration t, we have calculated $\boldsymbol{\lambda}_t$, at which point the following quantities can be calculated:

$$\begin{aligned} g_t &:= \tilde{G}(\boldsymbol{\lambda}_t) \\ \text{weights on crucial pairs } d_{t,ik} &:= e^{-(\mathbf{M}\boldsymbol{\lambda}_t)_{ik}}/\tilde{F}(\boldsymbol{\lambda}_t) \\ \text{direction } j_t &= \operatorname*{argmax}_j (\mathbf{d}_t^T \mathbf{M})_j \\ \text{edge } r_t &:= (\mathbf{d}_t^T \mathbf{M})_{j_t}. \end{aligned}$$

The choice of j_t is the same as for coordinate descent RankBoost (also see Rudin et al., 2007). The step size α_t is chosen to obey Equation (12) below, but we need a few more definitions before we state its value, so we do not define it yet; we will first define recursive equations for $\tilde{F}$ and $\tilde{G}$. We also have $s_t = ||\boldsymbol{\lambda}_t||_1$ and $s_{t+1} = s_t + \alpha_t$, and $g_{t+1} = \tilde{G}(\boldsymbol{\lambda}_t + \alpha_t \mathbf{e}_{j_t})$, where α_t has not yet been defined.

As before, $I_{t+} := \{i,k | M_{ikj_t} = 1, \pi(\mathbf{x}_i, \mathbf{x}_k) = 1\}$, $I_{t-} := \{i,k | M_{ikj_t} = -1, \pi(\mathbf{x}_i, \mathbf{x}_k) = 1\}$, and now, $I_{t0} := \{i,k | M_{ikj_t} = 0, \pi(\mathbf{x}_i, \mathbf{x}_k) = 1\}$. Also $d_{t+} := \sum_{I_{t+}} d_{t,ik}$, $d_{t-} := \sum_{I_{t-}} d_{t,ik}$, and $d_{t0} := \sum_{I_{t0}} d_{t,ik}$. Thus, by definition, we have $d_{t+} + d_{t-} + d_{t0} = 1$. Now, r_t can be written $r_t = d_{t+} - d_{t-}$. Define the factor

$$\tau_t := d_{t+} e^{-\alpha_t} + d_{t-} e^{\alpha_t} + d_{t0}, \tag{7}$$

and define its "derivative":

$$\tau_t' := \frac{\partial \tau_t (d_{t+} e^{-\alpha} + d_{t-} e^{\alpha} + d_{t0})}{\partial \alpha}\Big|_{\alpha=\alpha_t} = -d_{t+} e^{-\alpha_t} + d_{t-} e^{\alpha_t}. \tag{8}$$

We now derive a recursive equation for $\tilde{F}$, true for any α.

$$\begin{aligned} \tilde{F}(\boldsymbol{\lambda}_t + \alpha \mathbf{e}_{j_t}) &= \sum_{\{i,k|\pi(\mathbf{x}_i,\mathbf{x}_k)=1\}} e^{(-\mathbf{M}\boldsymbol{\lambda}_t)_{ik}} e^{-M_{ikj_t}\alpha} \\ &= \tilde{F}(\boldsymbol{\lambda}_t)(d_{t+} e^{-\alpha} + d_{t-} e^{\alpha} + d_{t0}). \end{aligned}$$

Thus, we have defined τ_t so that

$$\tilde{F}(\boldsymbol{\lambda}_{t+1}) = \tilde{F}(\boldsymbol{\lambda}_t + \alpha_t \mathbf{e}_{j_t}) = \tilde{F}(\boldsymbol{\lambda}_t)\tau_t.$$

We use this to write a recursive equation for $\tilde{G}$.

$$\begin{aligned}\tilde{G}(\boldsymbol{\lambda}_t + \alpha \mathbf{e}_{j_t}) &= \frac{-\ln(\tilde{F}(\boldsymbol{\lambda}_t + \alpha \mathbf{e}_{j_t}))}{s_t + \alpha} = \frac{-\ln(\tilde{F}(\boldsymbol{\lambda}_t)) - \ln\left(d_{t+}e^{-\alpha} + d_{t-}e^{\alpha} + d_{t0}\right)}{s_t + \alpha} \\ &= g_t \frac{s_t}{s_t + \alpha} - \frac{\ln\left(d_{t+}e^{-\alpha} + d_{t-}e^{\alpha} + d_{t0}\right)}{s_t + \alpha}.\end{aligned}$$

For our algorithm, we set $\alpha = \alpha_t$ in the above expression and use the notation defined earlier:

$$\begin{aligned}g_{t+1} &= g_t \frac{s_t}{s_t + \alpha_t} - \frac{\ln \tau_t}{s_t + \alpha_t} \\ g_{t+1} - g_t &= \frac{g_t s_t - g_t s_t - g_t \alpha_t}{s_t + \alpha_t} - \frac{\ln \tau_t}{s_t + \alpha_t} = -\frac{1}{s_{t+1}} \left[g_t \alpha_t + \ln \tau_t\right]. \end{aligned} \tag{9}$$

Now we have gathered enough notation to write the equation for α_t for smooth margin ranking. For plain coordinate ascent, the update α^* solves:

$$\begin{aligned}0 &= \frac{\partial \tilde{G}(\boldsymbol{\lambda}_t + \alpha \mathbf{e}_{j_t})}{\partial \alpha}\Big|_{\alpha=\alpha^*} = \frac{\partial}{\partial \alpha}\left[\frac{-\ln \tilde{F}(\boldsymbol{\lambda}_t + \alpha \mathbf{e}_{j_t})}{s_t + \alpha}\right]\Big|_{\alpha=\alpha^*} \\ &= \frac{1}{s_t + \alpha^*}\left[-\left[\frac{-\ln \tilde{F}(\boldsymbol{\lambda}_t + \alpha^* \mathbf{e}_{j_t})}{s_t + \alpha^*}\right] + \left[\frac{-\partial \tilde{F}(\boldsymbol{\lambda}_t + \alpha \mathbf{e}_{j_t})/\partial \alpha\Big|_{\alpha=\alpha^*}}{\tilde{F}(\boldsymbol{\lambda}_t + \alpha^* \mathbf{e}_{j_t})}\right]\right] \\ &= \frac{1}{s_t + \alpha^*}\left[-\tilde{G}(\boldsymbol{\lambda}_t + \alpha^* \mathbf{e}_{j_t}) + \left[\frac{-\partial \tilde{F}(\boldsymbol{\lambda}_t + \alpha \mathbf{e}_{j_t})/\partial \alpha\Big|_{\alpha=\alpha^*}}{\tilde{F}(\boldsymbol{\lambda}_t + \alpha^* \mathbf{e}_{j_t})}\right]\right].\end{aligned} \tag{10}$$

We could solve this equation numerically for α^* to get a smooth margin coordinate ascent algorithm; however, we avoid this line search for α^* in smooth margin ranking. We will do an approximation that allows us to solve for α^* directly so that the algorithm is just as easy to implement as RankBoost. To get the update rule for smooth margin ranking, we set α_t to solve:

$$\begin{aligned}0 &= \frac{1}{s_t + \alpha_t}\left[-\tilde{G}(\boldsymbol{\lambda}_t) + \left[\frac{-\partial \tilde{F}(\boldsymbol{\lambda}_t + \alpha \mathbf{e}_{j_t})/\partial \alpha\Big|_{\alpha=\alpha_t}}{\tilde{F}(\boldsymbol{\lambda}_t + \alpha_t \mathbf{e}_{j_t})}\right]\right] \\ &= \frac{1}{s_t + \alpha_t}\left(-g_t + \frac{-\tau_t' \tilde{F}(\boldsymbol{\lambda}_t)}{\tau_t \tilde{F}(\boldsymbol{\lambda}_t)}\right) \\ g_t \tau_t &= -\tau_t'.\end{aligned} \tag{11}$$

This expression can be solved analytically for α_t, but we avoid using the exact expression in our calculations whenever possible, since the solution is not that easy to work with in our analysis:

$$\alpha_t = \ln\left[\frac{-g_t d_{t0} + \sqrt{g_t^2 d_{t0}^2 + (1+g_t)(1-g_t)4 d_{t+} d_{t-}}}{(1+g_t)2 d_{t-}}\right]. \tag{12}$$

We are done defining the algorithm and in the process we have derived some useful recursive relationships. In summary:

Smooth margin ranking is the same as described in Figure 1, except that (3c) is replaced by (12), where $d_{t0} = 1 - d_{t+} - d_{t-}$ *and* $g_t = G(\boldsymbol{\lambda}_t)$.

Binary weak rankers were required to obtain an analytical solution for α_t, but if one is willing to perform a 1-dimensional linesearch (10) at each iteration, real-valued features can just as easily be used.

Now we move onto the convergence proofs, which were loosely inspired by the analysis of Zhang and Yu (2005). The following theorem gives conditions when the algorithm makes significant progress towards increasing the value of $\tilde{G}$ at iteration t. An analogous statement was an essential tool for proving convergence properties of approximate coordinate ascent boosting (Rudin et al., 2007), although the proof of the following theorem is significantly more difficult since we could not use the hyperbolic trigonometric tricks from prior work. As usual, the weak learning algorithm must always achieve an edge r_t of at least ρ for the calculation to hold, where recall $r_t = (\mathbf{d}_t^T \mathbf{M})_{j_t} = d_{t+} - d_{t-}$. At every iteration, there is always a weak ranker which achieves edge at least ρ, so this requirement is always met in the "optimal case," where we choose the best possible weak ranker at every iteration (i.e., the argmax over j). There is one more condition in order for the algorithm to make progress, namely that most of the weight should indicate the strength of the weak ranker, which implies that d_{t0} cannot take too much of the weight. Specifically, $d_{t0} < \frac{2}{3}(1-r_t)(1-r_t^2)$, which is derived from a bound on the second derivative of the step size.

Theorem 7 *(Progress according to the smooth margin) For* $0 \leq g_t < r_t < 1$ *and* $0 \leq d_{t0} < \frac{2}{3}(1 - r_t)(1-r_t^2)$ *the algorithm makes progress at iteration t:*

$$g_{t+1} - g_t \geq \frac{1}{2} \frac{\alpha_t (r_t - g_t)}{s_{t+1}}.$$

The proof of this theorem is in Section 7. This theorem tells us that the value of the smooth ranking margin increases significantly when the condition on d_0 holds. This theorem is the main step in proving convergence theorems, for example:

Theorem 8 *(Convergence for smooth margin ranking) If* $d_{t0} < \frac{2}{3}(1-r_t)(1-r_t^2)$ *for all t, the smooth margin ranking algorithm converges to a maximum margin solution, that is,* $\lim_{t\to\infty} g_t = \rho$. *Thus the limiting margin is* ρ, *that is,* $\lim_{t\to\infty} \mu(\boldsymbol{\lambda}_t) = \rho$.

Besides Theorem 7, the only other key step in the proof of Theorem 8 is the following lemma, proved in Section 7:

Lemma 9 *(Step-size does not increase too quickly for smooth margin ranking)*

$$\lim_{t\to\infty} \frac{\alpha_t}{s_{t+1}} = 0.$$

From here, the proof of the convergence theorem is not difficult. The two conditions found in Theorem 7 and Lemma 9 are identical to those of Lemma 5.1 and Lemma 5.2 of Rudin et al. (2007). These are the only two ingredients necessary to prove asymptotic convergence using the proof outline of Theorem 5.1 of Rudin et al. (2007); an adaptation of this proof suffices to show Theorem 8, which we now outline.

Proof *(of Theorem 8)* The values of g_t constitute a nondecreasing sequence which is uniformly bounded by 1. Thus, a limit g_∞ must exist, $g_\infty := \lim_{t\to\infty} g_t$. By (6), we know that $g_t \leq \rho$ for all

t. Thus, $g_\infty \leq \rho$. Let us suppose that $g_\infty < \rho$, so that $\rho - g_\infty \neq 0$. This assumption, together with Theorem 7 and Lemma 9 can be used in the same way as in Rudin et al. (2007) to show that $\sum_t \alpha_t$ is finite, implying that:

$$\lim_{t\to\infty} \alpha_t = 0.$$

Using this fact along with (11), we find:

$$\begin{aligned} g_\infty &= \lim_{t\to\infty} g_t = \liminf_{t\to\infty} g_t = \liminf_{t\to\infty} \frac{-\tau_t'}{\tau_t} = \liminf_{t\to\infty} \frac{-(-d_{t+}e^{-\alpha_t} + d_{t-}e^{\alpha_t})}{d_{t+}e^{-\alpha_t} + d_{t-}e^{\alpha_t} + d_{t0}} \\ &= \liminf_{t\to\infty} r_t \geq \rho. \end{aligned}$$

This is a contradiction with the original assumption that $g_\infty < \rho$. It follows that $g_\infty = \rho$, or $\lim_{t\to\infty}(\rho - g_t) = 0$. Thus, the smooth ranking algorithm converges to a maximum margin solution. ■

5. AdaBoost and RankBoost in the Bipartite Ranking Problem

In this section, we present an equivalence between AdaBoost and RankBoost in terms of their behavior on the training set. Namely, we show that under very natural conditions, AdaBoost asymptotically produces an area under the ROC curve value that is equally as good as RankBoost's. Conversely, RankBoost (but with a change in the intercept), produces a classification that is equally as good as AdaBoost's. Note that this result is designed for the non-separable case; it holds in the separable case, but the result is trivial since the area under the curve is exactly one. Also, let us be clear that the result is a theoretical proof based on the optimization of the training set only. It is not an experimental result, nor is it a probabilistic guarantee about performance on a test set (such as Theorem 2).

In the bipartite ranking problem, the focus of this section, recall that every training instance falls into one of two categories, the positive class Y_+ and the negative class Y_-. We will take $\pi(\mathbf{x}_i, \mathbf{x}_k) = 1$ for each pair $i \in Y_+$ and $k \in Y_-$ so that crucial pairs exist between elements of the positive class and elements of the negative class. Define $y_i = +1$ when $i \in Y_+$, and $y_i = -1$ otherwise. The AUC (area under the Receiver Operator Characteristic curve) is equivalent to the Mann-Whitney U statistic, and it is closely related to the fraction of misranks. Specifically,

$$1 - \text{AUC}(\boldsymbol{\lambda}) = \frac{\sum_{i\in Y_+}\sum_{k\in Y_-} \mathbf{1}_{[(\mathbf{M}\boldsymbol{\lambda})_{ik}\leq 0]}}{|Y_+||Y_-|} = \text{fraction of misranks.}$$

In the bipartite ranking problem, the function $\tilde{F}$ becomes an exponentiated version of the AUC, that is, since $\mathbf{1}_{[x\leq 0]} \leq e^{-x}$, we have:

$$|Y_+||Y_-|(1 - \text{AUC}(\boldsymbol{\lambda})) = \sum_{i\in Y_+}\sum_{k\in Y_-} \mathbf{1}_{[(\mathbf{M}\boldsymbol{\lambda})_{ik}\leq 0]} \leq \sum_{i\in Y_+}\sum_{k\in Y_-} e^{-(\mathbf{M}\boldsymbol{\lambda})_{ik}} = \tilde{F}(\boldsymbol{\lambda}). \tag{13}$$

We define the matrix $\mathbf{M}^{Ada}$, which is helpful for describing AdaBoost. $\mathbf{M}^{Ada}$ is defined elementwise by $M^{Ada}_{ij} = y_i h_j(\mathbf{x}_i)$ for $i = 1,...,m$ and $j = 1,...,n$. Thus, $M_{ikj} = h_j(\mathbf{x}_i) - h_j(\mathbf{x}_k) = y_i h_j(\mathbf{x}_i) + y_k h_j(\mathbf{x}_k) = M^{Ada}_{ij} + M^{Ada}_{kj}$. (To change from AdaBoost's usual $\{-1,1\}$ hypotheses to RankBoost's usual $\{0,1\}$ hypotheses, divide entries of $\mathbf{M}$ by 2.) Define the following functions:

$$F_+(\boldsymbol{\lambda}) := \sum_{i\in Y_+} e^{-(\mathbf{M}^{Ada}\boldsymbol{\lambda})_i} \text{ and } F_-(\boldsymbol{\lambda}) := \sum_{k\in Y_-} e^{-(\mathbf{M}^{Ada}\boldsymbol{\lambda})_k}.$$

The objective function for AdaBoost is $F(\boldsymbol{\lambda}) := F_+(\boldsymbol{\lambda}) + F_-(\boldsymbol{\lambda})$. The objective function for RankBoost is:

$$\begin{aligned}\tilde{F}(\boldsymbol{\lambda}) &= \sum_{i\in Y_+}\sum_{k\in Y_-}\exp\left[-\sum_j \lambda_j h_j(\mathbf{x}_i)\right]\exp\left[+\sum_j \lambda_j h_j(\mathbf{x}_k)\right] \\ &= \sum_{i\in Y_+}\sum_{k\in Y_-}\exp\left[-\sum_j \lambda_j y_i h_j(\mathbf{x}_i)\right]\exp\left[-\sum_j \lambda_j y_k h_j(\mathbf{x}_k)\right] = F_+(\boldsymbol{\lambda})F_-(\boldsymbol{\lambda}). \qquad (14)\end{aligned}$$

Thus, both objective functions involve exponents of the margins of the training instances, but with a different balance between the positive and negative instances. In both cases, the objective function favors instances to be farther away from the decision boundary—even when the instances are correctly classified and not close to the decision boundary. (This is in contrast to support vector machines which do not suffer any loss for non-support vectors. This is the main reason why an analogous result does not hold for SVMs.)

We now define a quantity called *F-skew*:

$$\text{F-skew}(\boldsymbol{\lambda}) := F_+(\boldsymbol{\lambda}) - F_-(\boldsymbol{\lambda}). \qquad (15)$$

F-skew is the exponentiated version of the "skew," which measures the imbalance between positive and negative instances. The "skew" plays an important role in the expressions of Cortes and Mohri (2004, 2005) and Agarwal et al. (2005). The F-skew measures how much greater the positive instances contribute to AdaBoost's objective than the negative instances. If the F-skew is 0, it means that the positive and negative classes are contributing equally.

The following theorem shows that whenever the F-skew vanishes, any sequence $\boldsymbol{\lambda}_t$ that optimizes AdaBoost's objective F also optimizes RankBoost's objective $\tilde{F}$, and vice versa.

Theorem 10 *(Equivalence between AdaBoost and RankBoost's objectives) Let $\{\boldsymbol{\lambda}_t\}_{t=1}^{\infty}$ be any sequence for which AdaBoost's objective is minimized,*

$$\lim_{t\to\infty} F(\boldsymbol{\lambda}_t) = \inf_{\boldsymbol{\lambda}} F(\boldsymbol{\lambda}), \qquad (16)$$

and $\lim_{t\to\infty} \text{F-skew}(\boldsymbol{\lambda}_t) = 0$. *Then RankBoost's objective is minimized,*

$$\lim_{t\to\infty} \tilde{F}(\boldsymbol{\lambda}_t) = \inf_{\boldsymbol{\lambda}} \tilde{F}(\boldsymbol{\lambda}). \qquad (17)$$

Conversely, for any sequence for which RankBoost's objective is minimized, and for which the F-skew vanishes, AdaBoost's objective is minimized as well.

The proof of the converse follows directly from

$$(F_+(\boldsymbol{\lambda}) + F_-(\boldsymbol{\lambda}))^2 - (F_+(\boldsymbol{\lambda}) - F_-(\boldsymbol{\lambda}))^2 = 4F_+(\boldsymbol{\lambda})F_-(\boldsymbol{\lambda}),$$

Equations (14) and (15), and continuity of the functions involved. The proof of the forward direction in Section 8 uses a theory of convex duality for Bregman divergences developed by Della Pietra et al. (2002) and used by Collins et al. (2002). This theory allows characterization for functions that may have minima at infinity like F and $\tilde{F}$.

Theorem 10 has very practical implications due to the following, proved in Section 8:

Corollary 11 *(AdaBoost minimizes RankBoost's objective) If the constant weak hypothesis $h_0(\mathbf{x}) = 1$ is included in the set of AdaBoost's weak classifiers, or equivalently, if $\mathbf{M}^{Ada}$ has a column j_0 such that $M^{Ada}_{i,j_0} = y_i$ for all i, and if the $\{\boldsymbol{\lambda}_t\}_{t=1}^{\infty}$ sequence obeys (16), then* $\lim_{t\to\infty} \text{F-skew}(\boldsymbol{\lambda}_t) = 0$.

This result and the previous together imply that if the constant weak hypothesis is included in the set of AdaBoost's weak classifiers, then the F-skew vanishes, and RankBoost's objective $\tilde{F}$ is minimized.

Not only does AdaBoost minimize RankBoost's exponential objective function in this case, it also achieves an equally good misranking loss. Before we state this formally as a theorem, we need to avoid a very particular nonuniqueness problem. Namely, there is some ambiguity in the definition of the ranking loss for RankBoost and AdaBoost due to the arbitrariness in the algorithms, and the discontinuity of the function $\mathbf{1}_{[z\leq 0]}$, which is used for the misranking loss $\sum_i \mathbf{1}_{[(\mathbf{M}\boldsymbol{\lambda})_i \leq 0]}$. The arbitrariness in the algorithms arises from the argmax step; since argmax is a set that may contain more than one element, and since the algorithm does not specify which element in that set to choose, solutions might be different for different implementations. There are many examples where the argmax set does contain more than one element (for instance, the examples in Rudin et al., 2004). The vector $\lim_{t\to\infty} \mathbf{1}_{[\mathbf{M}\boldsymbol{\lambda}_t \leq 0]}$ may not be uniquely defined; for some i,k pair we may have $\lim_{t\to\infty} (\mathbf{M}\boldsymbol{\lambda}_t)_{ik} = 0$, and in that case, values of $\lim_{t\to\infty} \mathbf{1}_{[(\mathbf{M}\boldsymbol{\lambda}_t)_{ik} \leq 0]}$ may take on the values 0, 1, or the limit may not exist, depending on the algorithm. Thus, in order to write a sensible theorem, we must eliminate this pathological case. No matter which implementation we choose, this only becomes a problem if $\lim_{t\to\infty} (\mathbf{M}\boldsymbol{\lambda}_t)_{ik} = 0$, that is, there is a tie in the rankings. If there is no tie, the result is deterministic. In other words, when the pathological case is eliminated, the limiting AUC can be defined and AdaBoost asymptotically achieves the same AUC as RankBoost:

Theorem 12 *(AdaBoost and RankBoost achieve the same area under the ROC curve) Consider any two sequences $\{\boldsymbol{\lambda}_t\}_t$ and $\{\boldsymbol{\lambda}'_t\}_t$ that minimize RankBoost's objective $\tilde{F}$, that is,*

$$\lim_{t\to\infty} \tilde{F}(\boldsymbol{\lambda}_t) = \lim_{t\to\infty} \tilde{F}(\boldsymbol{\lambda}'_t) = \inf_{\boldsymbol{\lambda}} \tilde{F}(\boldsymbol{\lambda}).$$

Then, if each positive example has a final score distinct from each negative example, that is, $\forall ik$, $\lim_{t\to\infty} (\boldsymbol{M}\boldsymbol{\lambda}_t)_{ik} \neq 0$, $\lim_{t\to\infty} (\boldsymbol{M}\boldsymbol{\lambda}'_t)_{ik} \neq 0$, then both sequences will asymptotically achieve the same AUC value. That is:

$$\lim_{t\to\infty} \left[\sum_{i\in Y_+} \sum_{k\in Y_-} \mathbf{1}_{[(\mathbf{M}\boldsymbol{\lambda}_t)_{ik} \leq 0]} \right] = \lim_{t\to\infty} \left[\sum_{i\in Y_+} \sum_{k\in Y_-} \mathbf{1}_{[(\mathbf{M}\boldsymbol{\lambda}'_t)_{ik} \leq 0]} \right].$$

The proof is in Section 8. This theorem shows that, in the case where the F-skew vanishes and there are no ties, AdaBoost will generate the same area under the curve value that RankBoost does. That is, a sequence of $\boldsymbol{\lambda}'_t$'s generated by AdaBoost and a sequence of $\boldsymbol{\lambda}_t$'s generated by RankBoost will asymptotically produce the same value of the AUC.

Combining Theorem 10, Corollary 11 and Theorem 12, we can conclude the following, assuming distinct final scores: *if the constant hypothesis is included in the set of AdaBoost's weak classifiers, then AdaBoost will converge to exactly the same area under the ROC curve value as RankBoost*. Given these results, it is now understandable (but perhaps still surprising) that AdaBoost performs so well as a ranking algorithm.

This logic can be made to work in reverse, so that adding a constant hypothesis to RankBoost's output will also produce a minimizer of AdaBoost's objective. In order for this to work, we need to assign the coefficient for the constant classifier (the intercept) to force the F-skew to vanish. Changing the coefficient of the constant hypothesis does not affect RankBoost's objective, but it does affect AdaBoost's. We choose the coefficient to obey the following:

Corollary 13 *(RankBoost minimizes AdaBoost's objective) Define j_0 as the entry corresponding to the constant weak classifier. Take $\boldsymbol{\lambda}_t$ to be a minimizing sequence for RankBoost's objective, that is, $\boldsymbol{\lambda}_t$ obeys (17). Consider $\boldsymbol{\lambda}_t^{corrected}$ where:*

$$\boldsymbol{\lambda}_t^{corrected} := \boldsymbol{\lambda}_t + b_t \mathbf{e}_{j_0},$$

where $\mathbf{e}_{j_0}$ is 1 in the j_0^{th} entry corresponding to the constant weak classifier, and 0 otherwise, and where:

$$b_t = \frac{1}{2} \ln \frac{F_+(\boldsymbol{\lambda}_t)}{F_-(\boldsymbol{\lambda}_t)}.$$

Then, $\boldsymbol{\lambda}_t^{corrected}$ converges to a minimum of AdaBoost's objective, that is, $\boldsymbol{\lambda}_t^{corrected}$ obeys (16).

The proof is in Section 8. Now, we can extend to the misclassification error. The proof of the following is also in Section 8:

Theorem 14 *(AdaBoost and RankBoost achieve the same misclassification error) Consider any two sequences $\{\boldsymbol{\lambda}_t^{corrected}\}_t$ and $\{\boldsymbol{\lambda}_t^{\prime corrected}\}_t$, corrected as in Corollary 13, that minimize RankBoost's objective $\tilde{F}$, that is,*

$$\lim_{t\to\infty} \tilde{F}(\boldsymbol{\lambda}_t^{corrected}) = \lim_{t\to\infty} \tilde{F}(\boldsymbol{\lambda}_t^{\prime corrected}) = \inf_{\boldsymbol{\lambda}} \tilde{F}(\boldsymbol{\lambda}).$$

Then, if no example is on the decision boundary, that is, $\forall i, \lim_{t\to\infty} (\boldsymbol{M}^{Ada}\boldsymbol{\lambda}_t^{corrected})_i \neq 0$, $\forall k \lim_{t\to\infty} (\boldsymbol{M}^{Ada}\boldsymbol{\lambda}_t^{corrected})_k \neq 0$, and $\forall i, \lim_{t\to\infty} (\boldsymbol{M}^{Ada}\boldsymbol{\lambda}_t^{\prime corrected})_i \neq 0, \forall k \lim_{t\to\infty} (\boldsymbol{M}^{Ada}\boldsymbol{\lambda}_t^{\prime corrected})_k \neq 0$, then both sequences will asymptotically achieve the same misclassification loss. That is:

$$\lim_{t\to\infty} \left[\sum_{i\in Y_+} \mathbf{1}_{[(\mathbf{M}^{\mathrm{Ada}}\boldsymbol{\lambda}_t^{corrected})_i \leq 0]} + \sum_{k\in Y_-} \mathbf{1}_{[(\mathbf{M}^{\mathrm{Ada}}\boldsymbol{\lambda}_t^{corrected})_k \leq 0]} \right]$$
$$= \lim_{t\to\infty} \left[\sum_{i\in Y_+} \mathbf{1}_{[(\mathbf{M}^{\mathrm{Ada}}\boldsymbol{\lambda}_t^{\prime corrected})_i \leq 0]} + \sum_{k\in Y_-} \mathbf{1}_{[(\mathbf{M}^{\mathrm{Ada}}\boldsymbol{\lambda}_t^{\prime corrected})_k \leq 0]} \right].$$

Thus, we have shown quite a strong equivalence relationship between RankBoost and AdaBoost. Under natural conditions, AdaBoost achieves the same area under the ROC curve as RankBoost, and RankBoost can be easily made to achieve the same misclassification error as AdaBoost on the training set.

The success of an algorithm is often judged using both misclassification error and the area under the ROC curve. A practical implication of this result is that AdaBoost and RankBoost both solve the classification and ranking problems at the same time. This is true under the conditions specified, namely using a set of binary weak classifiers that includes the constant classifier, and using the

correction for RankBoost's intercept. In terms of which should be used, we have found that AdaBoost tends to converge faster for classification (and uses less memory), whereas RankBoost tends to converge faster for ranking. If the algorithm is stopped early, we suggest that if misclassification error is more important, to choose AdaBoost, and conversely, if area under the ROC curve is more important, to choose RankBoost. Asymptotically, as we have shown, they produce equally good solutions for both classification and ranking on the training set.

5.1 Connection to Multiclass/Multilabel Algorithms

The results above imply convergence properties of two algorithms for solving multiclass/ multilabel problems. Specifically, the algorithms AdaBoost.MH and AdaBoost.MR of Schapire and Singer (1999) have the same relationship to each other as AdaBoost and RankBoost.

In the multilabel setting, each training instance $\mathbf{x} \in \mathcal{X}$ may belong to multiple labels in $\mathcal{Y}$, where $\mathcal{Y}$ is a finite set of labels or classes. The total number of classes is denoted by c. Examples are ordered pairs $(\mathbf{x}, Y), Y \subset \mathcal{Y}$. We use the reduction of Schapire and Singer (1999) where training example i is replaced by a set of single-labeled training examples $\{(\mathbf{x}_i, y_{i\ell})\}_{\ell=1,\ldots,c}$, where $y_{i\ell} = 1$ if $y_{i\ell} \in Y_i$ and -1 otherwise. Thus, the set of training examples are indexed by pairs i, ℓ. Within this reduction, the weak classifiers become $h_j : \mathcal{X} \times \mathcal{Y} \to \mathbb{R}$.

Let us now re-index the training pairs. The training pairs i, ℓ will now be assigned a single index. Define the entries of matrix $\breve{\mathbf{M}}$ by $\breve{M}_{\breve{\imath}j} = y_{\breve{\imath}} h_j(\mathbf{x}_{\breve{\imath}}, y_{\breve{\imath}})$ for all pairs i, ℓ indexed by $\breve{\imath}$. With this notation, the objective function of AdaBoost.MH becomes:

$$F_{MH}(\boldsymbol{\lambda}) := \sum_{\breve{\imath}} \exp(-\breve{\mathbf{M}}\boldsymbol{\lambda})_{\breve{\imath}}.$$

Using similar notation, the objective function of AdaBoost.MR becomes:

$$F_{MR}(\boldsymbol{\lambda}) := \sum_{\breve{\imath} \in \{\{i,\ell\}: y_{i\ell}=1\}} \exp(-\breve{\mathbf{M}}\boldsymbol{\lambda})_{\breve{\imath}} \sum_{\breve{k} \in \{\{i,\ell\}: y_{i\ell}=-1\}} \exp(-\breve{\mathbf{M}}\boldsymbol{\lambda})_{\breve{k}}.$$

The forms of functions F_{MH} and F_{MR} are the same as those of AdaBoost and RankBoost, respectively, allowing us to directly apply all of the above results. In other words, the same equivalence relationship that we have shown for AdaBoost and RankBoost applies to AdaBoost.MH and AdaBoost.MR.

Now, we move onto the proofs.

6. Proofs from Section 3

This proof in large part follows the approach of Bartlett (1998) and Schapire et al. (1998).

For $f \in \mathcal{F}$, we will be interested in the expectation

$$\mathrm{P}_{\theta,f} := \mathbb{P}_{\bar{\mathbf{x}},\tilde{\mathbf{x}} \sim \mathcal{D}}\left[f(\bar{\mathbf{x}}) - f(\tilde{\mathbf{x}}) \leq \theta \mid \pi(\bar{\mathbf{x}},\tilde{\mathbf{x}}) = 1\right] = \mathbb{E}_{\bar{\mathbf{x}},\tilde{\mathbf{x}} \sim \mathcal{D}}\left[\mathbf{1}_{[f(\bar{\mathbf{x}}) - f(\tilde{\mathbf{x}}) \leq \theta]} \mid \pi(\bar{\mathbf{x}},\tilde{\mathbf{x}}) = 1\right]$$

as well as its empirical analog

$$\begin{aligned} \hat{\mathrm{P}}_{\theta,f} := \mathbb{P}_S\{\mathrm{margin}_f \leq \theta\} &= \mathbb{P}_{\bar{\mathbf{x}},\tilde{\mathbf{x}} \sim S}\left[f(\bar{\mathbf{x}}) - f(\tilde{\mathbf{x}}) \leq \theta \mid \pi(\bar{\mathbf{x}},\tilde{\mathbf{x}}) = 1\right] \\ &= \mathbb{E}_{\bar{\mathbf{x}},\tilde{\mathbf{x}} \sim S}\left[\mathbf{1}_{[f(\bar{\mathbf{x}}) - f(\tilde{\mathbf{x}}) \leq \theta]} \mid \pi(\bar{\mathbf{x}},\tilde{\mathbf{x}}) = 1\right]. \end{aligned}$$

Note that in this notation,

$$\mathbb{P}_{\mathcal{D}}\{\text{misrank}_f\} = \mathrm{P}_{0,f}.$$

Our goal is to show that $\mathrm{P}_{0,f} \leq \hat{\mathrm{P}}_{\theta,f} + \varepsilon$ for all $f \in \mathcal{F}$ with high probability. To do so, we will first show that for every $f \in \mathcal{F}$,

$$\mathrm{P}_{0,f} - \hat{\mathrm{P}}_{\theta,f} \leq \mathrm{P}_{\theta/2,g} - \hat{\mathrm{P}}_{\theta/2,g} + \frac{\varepsilon}{2}$$

for some g in the cover $\mathcal{G}$, and then show that the difference $\mathrm{P}_{\theta/2,g} - \hat{\mathrm{P}}_{\theta/2,g}$ on the right must be small for all $g \in \mathcal{G}$, with high probability.

Lemma 15 *Let f and g be any functions in $\mathcal{F}$, and let D be any joint distribution on pairs $\bar{\mathbf{x}}, \tilde{\mathbf{x}}$. Let $0 \leq \theta_1 < \theta_2$. Then*

$$\begin{aligned}
&\mathbb{E}_{\bar{\mathbf{x}},\tilde{\mathbf{x}}\sim D}\left[\mathbf{1}_{[f(\bar{\mathbf{x}})-f(\tilde{\mathbf{x}})\leq\theta_1]} - \mathbf{1}_{[g(\bar{\mathbf{x}})-g(\tilde{\mathbf{x}})\leq\theta_2]}\right] \\
&\quad\leq\quad \mathbb{P}_{\bar{\mathbf{x}},\tilde{\mathbf{x}}\sim D}\left\{|f(\bar{\mathbf{x}}) - g(\bar{\mathbf{x}})| \geq \frac{\theta_2-\theta_1}{2}\right\} + \mathbb{P}_{\bar{\mathbf{x}},\tilde{\mathbf{x}}\sim D}\left\{|f(\tilde{\mathbf{x}}) - g(\tilde{\mathbf{x}})| \geq \frac{\theta_2-\theta_1}{2}\right\}.
\end{aligned}$$

Proof First, note that

$$\mathbf{1}_{[y\leq\theta_1]} - \mathbf{1}_{[z\leq\theta_2]} = \begin{cases} 1 & \text{if } y \leq \theta_1 < \theta_2 < z \\ 0 & \text{otherwise} \end{cases}$$

which means that this difference can be equal to 1 only if $z - y$ is at least $\theta_2 - \theta_1$. Thus,

$$\begin{aligned}
&\mathbb{E}_{\bar{\mathbf{x}},\tilde{\mathbf{x}}\sim D}\left[\mathbf{1}_{[f(\bar{\mathbf{x}})-f(\tilde{\mathbf{x}})\leq\theta_1]} - \mathbf{1}_{[g(\bar{\mathbf{x}})-g(\tilde{\mathbf{x}})\leq\theta_2]}\right] \\
&\quad=\quad \mathbb{P}_{\bar{\mathbf{x}},\tilde{\mathbf{x}}\sim D}\{f(\bar{\mathbf{x}}) - f(\tilde{\mathbf{x}}) \leq \theta_1 < \theta_2 < g(\bar{\mathbf{x}}) - g(\tilde{\mathbf{x}})\} \\
&\quad\leq\quad \mathbb{P}_{\bar{\mathbf{x}},\tilde{\mathbf{x}}\sim D}\{|(f(\bar{\mathbf{x}}) - f(\tilde{\mathbf{x}})) - (g(\bar{\mathbf{x}}) - g(\tilde{\mathbf{x}}))| \geq \theta_2 - \theta_1\} \\
&\quad\leq\quad \mathbb{P}_{\bar{\mathbf{x}},\tilde{\mathbf{x}}\sim D}\{|f(\bar{\mathbf{x}}) - g(\bar{\mathbf{x}})| + |f(\tilde{\mathbf{x}}) - g(\tilde{\mathbf{x}})| \geq \theta_2 - \theta_1\} \\
&\quad\leq\quad \mathbb{P}_{\bar{\mathbf{x}},\tilde{\mathbf{x}}\sim D}\left\{|f(\bar{\mathbf{x}}) - g(\bar{\mathbf{x}})| \geq \frac{\theta_2-\theta_1}{2} \vee |f(\tilde{\mathbf{x}}) - g(\tilde{\mathbf{x}})| \geq \frac{\theta_2-\theta_1}{2}\right\} \\
&\quad\leq\quad \mathbb{P}_{\bar{\mathbf{x}},\tilde{\mathbf{x}}\sim D}\left\{|f(\bar{\mathbf{x}}) - g(\bar{\mathbf{x}})| \geq \frac{\theta_2-\theta_1}{2}\right\} + \mathbb{P}_{\bar{\mathbf{x}},\tilde{\mathbf{x}}\sim D}\left\{|f(\tilde{\mathbf{x}}) - g(\tilde{\mathbf{x}})| \geq \frac{\theta_2-\theta_1}{2}\right\}
\end{aligned}$$

by the union bound. ■

The following lemma is true for every training set S:

Lemma 16 *Let $\mathcal{G}$ be a $\theta/4$-sloppy $\varepsilon/8$-cover for $\mathcal{F}$. Then for all $f \in \mathcal{F}$, there exists $g \in \mathcal{G}$ such that*

$$P_{0,f} - \hat{P}_{\theta,f} \leq P_{\theta/2,g} - \hat{P}_{\theta/2,g} + \frac{\varepsilon}{2}.$$

Proof Let $g \in \mathcal{G}$. Lemma 15, applied to the distribution $\mathcal{D}$, conditioned on $\pi(\bar{\mathbf{x}}, \tilde{\mathbf{x}}) = 1$, implies

$$\mathrm{P}_{0,f} - \mathrm{P}_{\theta/2,g} \leq \mathbb{P}_{\mathbf{x}\sim D_1}\left\{|f(\mathbf{x}) - g(\mathbf{x})| \geq \frac{\theta}{4}\right\} + \mathbb{P}_{\mathbf{x}\sim D_2}\left\{|f(\mathbf{x}) - g(\mathbf{x})| \geq \frac{\theta}{4}\right\}$$

where D_1 and D_2 denote the marginal distributions on $\bar{\mathbf{x}}$ and $\tilde{\mathbf{x}}$, respectively, under distribution $\bar{\mathbf{x}}, \tilde{\mathbf{x}} \sim \mathcal{D}$, conditioned on $\pi(\bar{\mathbf{x}}, \tilde{\mathbf{x}}) = 1$. In other words, for any event $\omega(\mathbf{x})$, $\mathbb{P}_{\mathbf{x}\sim D_1}\{\omega(\mathbf{x})\}$ is the same as $\mathbb{P}_{\bar{\mathbf{x}},\tilde{\mathbf{x}}\sim\mathcal{D}}\{\omega(\bar{\mathbf{x}}) \mid \pi(\bar{\mathbf{x}}, \tilde{\mathbf{x}}) = 1\}$, and similarly $\mathbb{P}_{\mathbf{x}\sim D_2}\{\omega(\mathbf{x})\}$ is the same as $\mathbb{P}_{\bar{\mathbf{x}},\tilde{\mathbf{x}}\sim\mathcal{D}}\{\omega(\tilde{\mathbf{x}}) \mid \pi(\bar{\mathbf{x}}, \tilde{\mathbf{x}}) = 1\}$.

Likewise,

$$\hat{\mathrm{P}}_{\theta/2,g} - \hat{\mathrm{P}}_{\theta,f} \leq \mathbb{P}_{\mathbf{x}\sim S_1}\left\{|f(\mathbf{x}) - g(\mathbf{x})| \geq \frac{\theta}{4}\right\} + \mathbb{P}_{\mathbf{x}\sim S_2}\left\{|f(\mathbf{x}) - g(\mathbf{x})| \geq \frac{\theta}{4}\right\}$$

where S_1 and S_2 are distributions defined analogously for the empirical distribution on S. Thus,

$$\begin{aligned}
\mathrm{P}_{0,f} - \mathrm{P}_{\theta/2,g} + \hat{\mathrm{P}}_{\theta/2,g} - \hat{\mathrm{P}}_{\theta,f} &\leq \mathbb{P}_{\mathbf{x}\sim D_1}\left\{|f(\mathbf{x}) - g(\mathbf{x})| \geq \frac{\theta}{4}\right\} + \mathbb{P}_{\mathbf{x}\sim D_2}\left\{|f(\mathbf{x}) - g(\mathbf{x})| \geq \frac{\theta}{4}\right\} \\
&\quad + \mathbb{P}_{\mathbf{x}\sim S_1}\left\{|f(\mathbf{x}) - g(\mathbf{x})| \geq \frac{\theta}{4}\right\} + \mathbb{P}_{\mathbf{x}\sim S_2}\left\{|f(\mathbf{x}) - g(\mathbf{x})| \geq \frac{\theta}{4}\right\} \\
&= 4\,\mathbb{P}_{\mathbf{x}\sim D^*}\left\{|f(\mathbf{x}) - g(\mathbf{x})| \geq \frac{\theta}{4}\right\} \qquad (18)
\end{aligned}$$

where D^* is the (uniform) mixture of the four distributions D_1, D_2, S_1 and S_2. Constructing D^* in this way allows us to find a g that is close to f for all four terms simultaneously, which is needed for the next step. Since $\mathcal{G}$ is a $\theta/4$-sloppy $\varepsilon/8$-cover, we can now choose g to be a function in the cover $\mathcal{G}$ such that

$$\mathbb{P}_{\mathbf{x}\sim D^*}\left\{|f(\mathbf{x}) - g(\mathbf{x})| \geq \frac{\theta}{4}\right\} \leq \frac{\varepsilon}{8}$$

which, plugging in to equation (18), proves the lemma. ■

In the proof of the theorem, we will use the g's to act as representatives (for slightly different events), so we must show that we do not lose too much by doing this.

Lemma 17 *Let $\mathcal{G}$ be a $\theta/4$-sloppy $\varepsilon/8$-cover for $\mathcal{F}$. Then*

$$\mathbb{P}_{S\sim\mathcal{D}^m}\left\{\exists f \in \mathcal{F} : P_{0,f} - \hat{P}_{\theta,f} \geq \varepsilon\right\} \leq \mathbb{P}_{S\sim\mathcal{D}^m}\left\{\exists g \in \mathcal{G} : P_{\theta/2,g} - \hat{P}_{\theta/2,g} \geq \frac{\varepsilon}{2}\right\}.$$

Proof By Lemma 16, for every training set S, for any $f \in \mathcal{F}$, there exists some $g \in \mathcal{G}$ such that

$$\mathrm{P}_{0,f} - \hat{\mathrm{P}}_{\theta,f} \leq \hat{\mathrm{P}}_{\theta/2,g} - \mathrm{P}_{\theta/2,g} + \frac{\varepsilon}{2}.$$

Thus, if there exists an $f \in \mathcal{F}$ such that $\mathrm{P}_{0,f} - \hat{\mathrm{P}}_{\theta,f} \geq \varepsilon$, then there exists a $g \in \mathcal{G}$ such that $\mathrm{P}_{\theta/2,g} - \hat{\mathrm{P}}_{\theta/2,g} \geq \frac{\varepsilon}{2}$. The statement of the lemma follows directly. ■

Now we incorporate the fact that the training set is chosen randomly. We will use a generalization of Hoeffding's inequality due to McDiarmid, as follows:

Theorem 18 ***(McDiarmid's Inequality McDiarmid 1989)*** *Let $X_1, X_2, \ldots X_m$ be independent random variables under distribution D. Let $f(\mathbf{x}_1, \ldots, \mathbf{x}_m)$ be any real-valued function such that for all $\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_m; \mathbf{x}_i'$,*

$$|f(\mathbf{x}_1, \ldots, \mathbf{x}_i, \ldots, \mathbf{x}_m) - f(\mathbf{x}_1, \ldots, \mathbf{x}_i', \ldots \mathbf{x}_m)| \leq c_i.$$

Then for any $\varepsilon > 0$,

$$\begin{aligned}
\mathbb{P}_{X_1,X_2,\ldots,X_m\sim D}\left\{f(X_1, X_2, \ldots, X_m) - \mathbb{E}[f(X_1, X_2, \ldots, X_m)] \geq \varepsilon\right\} &\leq \exp\left(-\frac{2\varepsilon^2}{\sum_{i=1}^m c_i^2}\right), \\
\mathbb{P}_{X_1,X_2,\ldots,X_m\sim D}\left\{\mathbb{E}[f(X_1, X_2, \ldots, X_m)] - f(X_1, X_2, \ldots, X_m) \geq \varepsilon\right\} &\leq \exp\left(-\frac{2\varepsilon^2}{\sum_{i=1}^m c_i^2}\right).
\end{aligned}$$

Lemma 19 *For any $f \in \mathcal{F}$,*

$$\mathbb{P}_{S\sim\mathcal{D}^m}\{P_{\theta,f} - \hat{P}_{\theta,f} \geq \varepsilon/2\} \leq 2\exp\left[-\frac{m(\varepsilon E)^2}{8}\right].$$

Proof To make notation easier for this lemma, we introduce some shorthand notation:

$$\begin{aligned}
\mathrm{top}_{\mathcal{D}} &:= \mathbb{E}_{\tilde{\mathbf{x}},\tilde{\mathbf{x}}\sim\mathcal{D}}[\mathbf{1}_{[f(\tilde{\mathbf{x}})-f(\tilde{\mathbf{x}})\leq\theta]}\pi(\tilde{\mathbf{x}},\tilde{\mathbf{x}})] \\
\mathrm{top}_S &:= \frac{1}{m(m-1)}\sum_{i=1}^{m}\sum_{k=1}^{m}\mathbf{1}_{[f(\mathbf{x}_i)-f(\mathbf{x}_k)\leq\theta]}\pi(\mathbf{x}_i,\mathbf{x}_k) \\
\mathrm{bot}_{\mathcal{D}} := E &:= \mathbb{E}_{\tilde{\mathbf{x}},\tilde{\mathbf{x}}\sim\mathcal{D}}[\pi(\tilde{\mathbf{x}},\tilde{\mathbf{x}})] \\
\mathrm{bot}_S &:= \frac{1}{m(m-1)}\sum_{i=1}^{m}\sum_{k=1}^{m}\pi(\mathbf{x}_i,\mathbf{x}_k).
\end{aligned}$$

Since diagonal terms have $\pi(\mathbf{x}_i,\mathbf{x}_i)$ which is always 0, $\mathrm{top}_{\mathcal{D}} = \mathbb{E}_{S\sim\mathcal{D}^m}[\mathrm{top}_S]$ and similarly, $\mathrm{bot}_{\mathcal{D}} = \mathbb{E}_{S\sim\mathcal{D}^m}[\mathrm{bot}_S]$. Thus, we can bound the difference between top_S and $\mathrm{top}_{\mathcal{D}}$ using large deviation bounds, and similarly for the difference between bot_S and $\mathrm{bot}_{\mathcal{D}}$. We choose McDiarmid's Inequality to perform this task. It is not difficult to show using the rules of π that the largest possible change in top_S due to the replacement of one example is $1/m$. Similarly the largest possible change in bot_S is $1/m$. Thus, McDiarmid's inequality applied to top_S and bot_S implies that for every $\varepsilon_1 > 0$:

$$\begin{aligned}
\mathbb{P}_{S\sim\mathcal{D}^m}\{\mathrm{top}_{\mathcal{D}} - \mathrm{top}_S \geq \varepsilon_1\} &\leq \exp[-2\varepsilon_1^2 m] \\
\mathbb{P}_{S\sim\mathcal{D}^m}\{\mathrm{bot}_S - \mathrm{bot}_{\mathcal{D}} \geq \varepsilon_1\} &\leq \exp[-2\varepsilon_1^2 m].
\end{aligned}$$

Here, we use ε_1 to avoid confusion with the ε in the statement of the lemma; we will specify ε_1 in terms of ε later, but since the equations are true for any $\varepsilon_1 > 0$, we work with general ε_1 for now. Consider the following event:

$$\mathrm{top}_{\mathcal{D}} - \mathrm{top}_S < \varepsilon_1 \quad \text{and} \quad \mathrm{bot}_S - \mathrm{bot}_{\mathcal{D}} < \varepsilon_1.$$

By the union bound, this event is true with probability at least $1 - 2\exp[-2\varepsilon_1^2 m]$. When the event is true, we can rearrange the equations to be a bound on

$$\frac{\mathrm{top}_{\mathcal{D}}}{\mathrm{bot}_{\mathcal{D}}} - \frac{\mathrm{top}_S}{\mathrm{bot}_S}.$$

We do this as follows:

$$\frac{\mathrm{top}_{\mathcal{D}}}{\mathrm{bot}_{\mathcal{D}}} - \frac{\mathrm{top}_S}{\mathrm{bot}_S} < \frac{\mathrm{top}_{\mathcal{D}}}{\mathrm{bot}_{\mathcal{D}}} - \frac{\mathrm{top}_{\mathcal{D}} - \varepsilon_1}{\mathrm{bot}_{\mathcal{D}} + \varepsilon_1}. \tag{19}$$

If we now choose:

$$\varepsilon_1 = \frac{\varepsilon \mathrm{bot}_{\mathcal{D}}}{2 - \varepsilon + 2\frac{\mathrm{top}_{\mathcal{D}}}{\mathrm{bot}_{\mathcal{D}}}} \geq \frac{\varepsilon \mathrm{bot}_{\mathcal{D}}}{4} =: \frac{\varepsilon E}{4}$$

then the right hand side of (19) is equal to $\varepsilon/2$. Here, we have used $E := \mathrm{bot}_{\mathcal{D}}$, and by the definition of $\mathrm{top}_{\mathcal{D}}$ and $\mathrm{bot}_{\mathcal{D}}$, we always have $\mathrm{top}_{\mathcal{D}} \leq \mathrm{bot}_{\mathcal{D}}$. We directly have:

$$1 - 2\exp[-2\varepsilon_1^2 m] \geq 1 - 2\exp\left(-2m\left[\frac{\varepsilon E}{4}\right]^2\right).$$

Therefore, from our earlier application of McDiarmid, we find that with probability at least

$$1 - 2\exp\left[-\frac{m(\varepsilon E)^2}{8}\right]$$

the following holds:

$$\mathrm{P}_{\theta,f} - \hat{\mathrm{P}}_{\theta,f} = \frac{\mathrm{top}_{\mathcal{D}}}{\mathrm{bot}_{\mathcal{D}}} - \frac{\mathrm{top}_S}{\mathrm{bot}_S} < \varepsilon/2.$$

■

As mentioned earlier, we could have equally well have written the lemma in terms of the empirical quantity $\mathrm{bot}_{\mathcal{D}}$ rather than in terms of E. We have made this decision because the bound is useful for allowing us to determine which quantities are important to maximize in our algorithms; we cannot maximize $\mathrm{bot}_{\mathcal{D}}$ in practice because we are choosing m random instances from $\mathcal{D}$, thus we have no influence at all over the value of $\mathrm{bot}_{\mathcal{D}}$ in practice. Either way, the bound tells us that the margin should be an important quantity to consider in the design of algorithms.

Also, note that this proof implicitly used our simplifying assumption that the truth function π is deterministic. In the more general case, where the value $\pi(\mathbf{x}_i, \mathbf{x}_k)$ of each training pair $\mathbf{x}_i, \mathbf{x}_k$ is determined probabilistically, an alternative proof giving the same result can be given using Azuma's lemma.

Proof *(of Theorem 2)* Let $\mathcal{G}$ be a $\theta/4$-sloppy $\varepsilon/8$-cover of $\mathcal{F}$ of minimum size. Applying Lemma 17, the union bound, and then Lemma 19 for $\theta/2$, we find:

$$\begin{aligned}
\mathbb{P}_{S\sim\mathcal{D}^m}\left\{\exists f \in \mathcal{F} : \mathrm{P}_{0,f} - \hat{\mathrm{P}}_{\theta,f} \geq \varepsilon\right\} &\leq \mathbb{P}_{S\sim\mathcal{D}^m}\left\{\exists g \in \mathcal{G} : \mathrm{P}_{\theta/2,g} - \hat{\mathrm{P}}_{\theta/2,g} \geq \frac{\varepsilon}{2}\right\}. \\
&\leq \sum_{g\in\mathcal{G}} \mathbb{P}_{S\sim\mathcal{D}^m}\left\{\mathrm{P}_{\theta/2,g} - \hat{\mathrm{P}}_{\theta/2,g} \geq \frac{\varepsilon}{2}\right\} \\
&\leq \sum_{g\in\mathcal{G}} 2\exp\left(-\frac{m(\varepsilon E)^2}{8}\right) \\
&= \mathcal{N}\left(\mathcal{F}, \frac{\theta}{4}, \frac{\varepsilon}{8}\right) 2\exp\left[-\frac{m(\varepsilon E)^2}{8}\right].
\end{aligned}$$

Now we put everything together. With probability at least

$$1 - \mathcal{N}\left(\mathcal{F}, \frac{\theta}{4}, \frac{\varepsilon}{8}\right) 2\exp\left[-\frac{m(\varepsilon E)^2}{8}\right],$$

we have

$$\mathbb{P}_D\{\mathrm{misrank}_f\} = \mathrm{P}_{0,f} \leq \hat{\mathrm{P}}_{\theta,f} + \varepsilon = \mathbb{P}_S\{\mathrm{margin}_f \leq \theta\} + \varepsilon.$$

Thus, the theorem has been proved. ■

We now provide a proof for Lemma 3, which gives an estimate of the covering number for convex combinations of dictionary elements.

Proof *(of Lemma 3)* We are trying to estimate the covering number for $\mathcal{F}$, where

$$\mathcal{F} = \left\{ f : f = \sum_j \lambda_j h_j, \sum_j \lambda_j = 1, \forall j\, \lambda_j \geq 0, h_j : \mathcal{X} \to \{0,1\}, h_j \in \mathcal{H} \right\}.$$

Consider the following set $\mathcal{G}_N$ of all g that can be written as a simple average of N elements of $\mathcal{H}$:

$$\mathcal{G}_N = \left\{ \frac{1}{N}(g_1 + \cdots + g_N) : g_1, \ldots, g_N \in \mathcal{H} \right\}.$$

We claim that $\mathcal{G}_N$ is a θ-sloppy ε-cover when

$$N \geq \frac{\ln(2/\varepsilon)}{2\theta^2}. \tag{20}$$

To show this, let f be any function $\mathcal{F}$, and let D be any distribution. We know that $f = \sum_j \lambda_j h_j$ for some λ_j's as above, where the number of terms in the sum can be much more than N. Let us pick N dictionary elements $g_1, \ldots, g_N$ from $\mathcal{H}$ by choosing them randomly and independently with replacement according to the distribution imposed by the coefficients $\boldsymbol{\lambda}$. That is, each g_i is selected to be h_j with probability equal to λ_j. Thus, if λ_j is large, it is more likely that h_j will be chosen as one of the N chosen elements $g_1, \ldots, g_N$. Construct g as the average of those N elements.

Let $\mathbf{x} \in \mathcal{X}$ be any fixed element. Then $g(\mathbf{x})$ is an average of N Bernoulli random variables, namely, $g_1(\mathbf{x}), \ldots, g_N(\mathbf{x})$; by the manner in which each g_j was chosen, each of these Bernoulli random variables is 1 with probability exactly $f(\mathbf{x})$. Therefore, by Hoeffding's inequality,

$$\mathbb{P}_g \left\{ |g(\mathbf{x}) - f(\mathbf{x})| \geq \theta \right\} \leq 2e^{-2\theta^2 N}$$

where $\mathbb{P}_g\{\cdot\}$ denotes probability with respect to the random choice of g.

This holds for every $\mathbf{x}$. Now let $\mathbf{x}$ be random according to D. Then

$$\begin{aligned} \mathbb{E}_g \left[\mathbb{P}_{\mathbf{x}\sim D} \left\{ |f(\mathbf{x}) - g(\mathbf{x})| \geq \theta \right\} \right] &= \mathbb{E}_{\mathbf{x}\sim D} \left[\mathbb{P}_g \left\{ |f(\mathbf{x}) - g(\mathbf{x})| \geq \theta \right\} \right] \\ &\leq \mathbb{E}_{\mathbf{x}\sim D} \left[2e^{-2\theta^2 N} \right] = 2e^{-2\theta^2 N}. \end{aligned}$$

Thus, there exists $g \in \mathcal{G}_N$ such that

$$\mathbb{P}_{\mathbf{x}\sim D} \left\{ |f(\mathbf{x}) - g(\mathbf{x})| \geq \theta \right\} \leq 2e^{-2\theta^2 N}.$$

Hence, selecting N as in equation (20) ensures that $\mathcal{G}_N$ is a θ-sloppy ε-cover. The covering number $\mathcal{N}(\mathcal{F}, \theta, \varepsilon)$ is thus at most

$$|\mathcal{G}_N| \leq |\mathcal{H}|^N,$$

which is the bound given in the statement of the lemma. ■

7. Proofs from Section 4.2

Proof *(of Lemma 9)* There are two possibilities; either $\lim_{t\to\infty} s_t = \infty$ or $\lim_{t\to\infty} s_t < \infty$. We handle these cases separately, starting with the case $\lim_{t\to\infty} s_t = \infty$. From (9),

$$\begin{aligned} s_{t+1}(g_{t+1} - g_t) &= -g_t\alpha_t - \ln\tau_t \\ s_t(g_{t+1} - g_t) &= -g_t\alpha_t - \alpha_t(g_{t+1} - g_t) - \ln\tau_t \\ s_t(g_{t+1} - g_t) &= -\alpha_t g_{t+1} - \ln\tau_t \\ s_t(g_{t+1} - g_t) + \ln\tau_t + \alpha_t &= \alpha_t(1 - g_{t+1}) \geq \alpha_t(1-\rho) \\ \frac{g_{t+1} - g_t}{1-\rho} + \frac{\ln\tau_t + \alpha_t}{s_t(1-\rho)} &\geq \frac{\alpha_t}{s_t} \geq \frac{\alpha_t}{s_{t+1}}. \end{aligned}$$

Since the g_t's constitute a nondecreasing sequence bounded by 1, $(g_{t+1} - g_t) \to 0$ as $t \to \infty$, so the first term on the left vanishes. The second term will vanish as long as we can bound $\ln \tau_t + \alpha_t$ by a constant, since by assumption, $s_t \to \infty$.

We define $g_{\tilde{1}}$ as the first positive value of $\tilde{G}(\boldsymbol{\lambda}_t)$; the value of $\tilde{G}$ only increases from this value. In order to bound $\ln \tau_t + \alpha_t$, we use Equation (11):

$$\begin{aligned} \ln \tau_t + \alpha_t &= \ln(-\tau_t') - \ln g_t + \alpha_t = \ln[d_{t+} e^{-\alpha_t} - d_{t-} e^{\alpha_t}] - \ln g_t + \alpha_t \\ &= \ln[d_{t+} - d_{t-} e^{2\alpha_t}] + \ln e^{-\alpha_t} - \ln g_t + \alpha_t \\ &\leq \ln d_{t+} - \ln g_t \leq \ln 1 - \ln g_{\tilde{1}} = -\ln g_{\tilde{1}} < \infty. \end{aligned}$$

Thus, the second term will vanish, and we now have the sequence α_t / s_{t+1} upper bounded by a vanishing sequence; thus, it too will vanish.

Now for the case where $\lim_{t\to\infty} s_t < \infty$. Consider

$$\begin{aligned} \sum_{t=\tilde{1}}^{T} \frac{\alpha_t}{s_{t+1}} &= \sum_{t=\tilde{1}}^{T} \frac{s_{t+1} - s_t}{s_{t+1}} = \sum_{t=\tilde{1}}^{T} \int_{s_t}^{s_{t+1}} \frac{1}{s_{t+1}} du \\ &\leq \sum_{t=\tilde{1}}^{T} \int_{s_t}^{s_{t+1}} \frac{1}{u} du = \int_{s_{\tilde{1}}}^{s_{T+1}} \frac{1}{u} du = \ln \frac{s_{T+1}}{s_{\tilde{1}}}. \end{aligned}$$

By our assumption that $\lim_{t\to\infty} s_t < \infty$, the above sequence is a bounded increasing sequence. Thus, $\sum_{t=\tilde{1}}^{\infty} \frac{\alpha_t}{s_{t+1}}$ converges. In particular,

$$\lim_{t\to\infty} \frac{\alpha_t}{s_{t+1}} = 0.$$

■

Proof *(of Theorem 7)* The proof relies completely on an important calculus lemma, Lemma 20 below. Before we state the lemma, we make some definitions and derive some tools for later use.

We will be speaking only of iterations t and $t+1$, so when the iteration subscript has been eliminated, it refers to iteration t rather than iteration $t+1$. From now on, the basic independent variables will be r, g and d_0. Here, the ranges are $0 < r < 1$, $0 \leq g < r$, $0 \leq d_0 < \frac{2}{3}(1-r)(1-r^2)$. We change our notation to reinforce this: d_+ and d_- can be considered functions of the basic variables r and d_0 since $d_+ = (1 + r - d_0)/2$ and $d_- = (1 - r - d_0)/2$. Also define $\tau(r, g, d_0) := \tau_t$, $\tau'(r, g, d_0) = \tau_t'$, and $\alpha(r, g, d_0) := \alpha_t$, which are specified by (7), (8) and (11).

Define the following:

$$\begin{aligned} \Gamma(r, g, d_0) &:= \frac{-\ln \tau(r, g, d_0)}{\alpha(r, g, d_0)}. \\ \mathcal{B}(r, g, d_0) &:= \frac{\Gamma(r, g, d_0) - g}{r - g}. \end{aligned}$$

Now we state the important lemma we need for proving the theorem.

Lemma 20 *For* $0 < r < 1$, $0 \leq g < r$, $0 \leq d_0 < \frac{2}{3}(1-r)(1-r^2)$,

$$\mathcal{B}(r, g, d_0) > 1/2.$$

The proof is technical and has been placed in the Appendix. Using only this lemma, we can prove the theorem directly. Let us unravel the notation a bit. From the definition of $\Gamma(r,g,d_0)$ and Lemma 20:

$$\begin{aligned}\frac{-\ln\tau(r,g,d_0)}{\alpha(r,g,d_0)} = \Gamma(r,g,d_0) = g+(r-g)\mathcal{B}(r,g,d_0) &> \frac{r+g}{2}\\ -\ln\tau(r,g,d_0) &> \frac{(r+g)\alpha(r,g,d_0)}{2}.\end{aligned}$$

Using this relation at time t and incorporating the recursive equation, Equation (9),

$$g_{t+1}-g_t = \frac{1}{s_{t+1}}\left[-g_t\alpha_t-\ln\tau_t\right] > \frac{\alpha_t}{s_{t+1}}\left[-g_t+\frac{(r_t+g_t)}{2}\right] = \frac{1}{2}\frac{\alpha_t(r_t-g_t)}{s_{t+1}}.$$

■

We have proved the theorem, minus the proof of Lemma 20 which was the key step. Lemma 20 is a challenging calculus problem in three variables. For the sake of intuition, we plot $\mathcal{B}$ as a function of r and g for fixed $d_0 = 0.01$ in Figure 2. The result of Lemma 20 is apparent, namely that $\mathcal{B}$ is lower bounded by $1/2$.

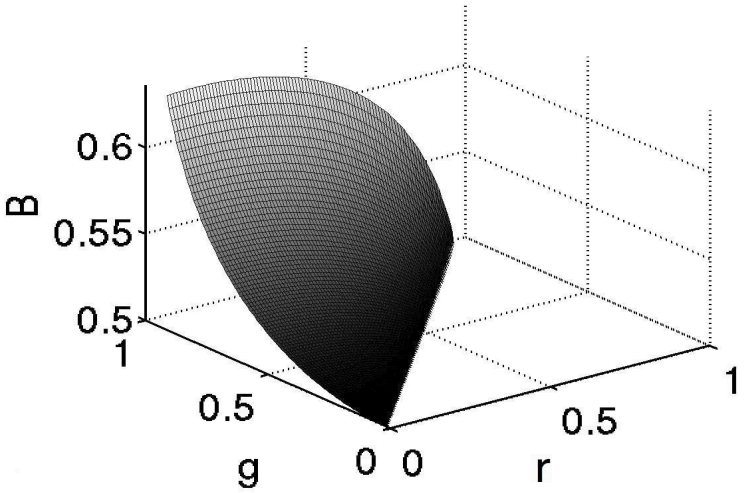

Figure 2: Surface plot of $\mathcal{B}$ as a function of r and g with $d_0 = 0.01$.

8. Proofs from Section 5

Proof *(of Theorem 10)* A proof is only necessary to handle the nonseparable case, since the statement of the theorem is trivial in the separable case. To see this, assume first that we are in the separable case, that is,

$$\lim_{t\to\infty} F_+(\boldsymbol{\lambda}_t) = \lim_{t\to\infty} F_-(\boldsymbol{\lambda}_t) = 0,$$

thus

$$\lim_{t\to\infty} \tilde{F}(\boldsymbol{\lambda}_t) = \lim_{t\to\infty} F(\boldsymbol{\lambda}_t) = 0$$

and we are done. For the rest of the proof, we handle the nonseparable case.

It is possible that the infimum of F or $\tilde{F}$ occurs at infinity, that is, F or $\tilde{F}$ may have no minimizers. Thus, it is not possible to characterize the minimizers by setting the first derivatives to zero. So, in order to more precisely describe the conditions (16) and (17), we now use a technique used by Della Pietra et al. (2002) and later used by Collins et al. (2002), in which we consider F and $\tilde{F}$ as functions of another variable, where the infimum can be achieved. Define, for a particular matrix $\bar{\mathbf{M}}$, the function

$$F_{\bar{\mathbf{M}}}(\boldsymbol{\lambda}) := \sum_{i=1}^{\bar{m}} e^{-(\bar{\mathbf{M}}\boldsymbol{\lambda})_i}.$$

Define

$$\bar{\mathcal{P}} := \{\mathbf{p} | p_i \geq 0 \; \forall i, \; (\mathbf{p}^T \bar{\mathbf{M}})_j = 0 \; \forall \; j\}$$

$$\bar{\mathcal{Q}} := \{\mathbf{q} | q_i = \exp(-(\bar{\mathbf{M}}\boldsymbol{\lambda})_i) \text{ for some } \boldsymbol{\lambda}\}.$$

We may thus consider $\bar{F}_{\bar{\mathbf{M}}}$ as a function of $\bar{\mathbf{q}}$, that is, $\bar{F}_{\bar{\mathbf{M}}}(\bar{\mathbf{q}}) = \sum_{i=1}^{\bar{m}} \bar{q}_i$, where $\bar{\mathbf{q}} \in \bar{\mathcal{Q}}$. We know that since all $\bar{q}_i$'s are positive, the infimum of $\bar{F}$ occurs in a bounded region of $\bar{\mathbf{q}}$ space, which is just what we need.

Theorem 1 of Collins et al. (2002), which is taken directly from Della Pietra et al. (2002), implies that the following are equivalent:

1. $\bar{\mathbf{q}}^* \in \bar{\mathcal{P}} \cap$ closure $(\bar{\mathcal{Q}})$.
2. $\bar{\mathbf{q}}^* \in \text{argmin}_{\bar{\mathbf{q}} \in \text{ closure}(\bar{\mathcal{Q}})} \bar{F}_{\bar{\mathbf{M}}}(\bar{\mathbf{q}})$.

Moreover, either condition is satisfied by exactly one vector $\bar{\mathbf{q}}^*$.

The objective function for AdaBoost is $F = \bar{F}_{\mathbf{M}^{Ada}}$ and the objective for RankBoost is $\tilde{F} = \bar{F}_{\mathbf{M}}$, so the theorem holds for both objectives separately. For the function F, denote $\bar{\mathbf{q}}^*$ as $\mathbf{q}^*$, also $\bar{\mathcal{P}}$ as $\mathcal{P}^{Ada}$ and $\bar{\mathcal{Q}}$ as $\mathcal{Q}^{Ada}$. For the function $\tilde{F}$, denote $\bar{\mathbf{q}}^*$ as $\tilde{\mathbf{q}}^*$, also $\bar{\mathcal{P}}$ as $\tilde{\mathcal{P}}$ and $\bar{\mathcal{Q}}$ as $\tilde{\mathcal{Q}}$. The condition $\mathbf{q}^* \in \mathcal{P}^{Ada}$ can be rewritten as:

$$\sum_{i \in Y_+} q_i^* M_{ij}^{Ada} + \sum_{k \in Y_-} q_k^* M_{kj}^{Ada} = 0 \; \forall \; j. \tag{21}$$

Define $\mathbf{q}_t$ element-wise by: $q_{t,i} := e^{-(\mathbf{M}^{Ada}\boldsymbol{\lambda}_t)_i}$, where the $\boldsymbol{\lambda}_t$'s are a sequence that obey (16), for example, a sequence produced by AdaBoost. Thus, $\mathbf{q}_t \in \mathcal{Q}^{Ada}$ automatically. By assumption, $F(\mathbf{q}_t)$ converges to the minimum of F. Thus, since F is continuous, any limit point of the $\mathbf{q}_t$'s must minimize F as well. But because $\mathbf{q}^*$ is the unique minimizer of F, this implies that $\mathbf{q}^*$ is the one and only ℓ_p-limit point of the $\mathbf{q}_t$'s, and therefore, that the entire sequence of $\mathbf{q}_t$'s converges to $\mathbf{q}^*$ in ℓ_p.

Now define vectors $\tilde{\mathbf{q}}_t$ element-wise by

$$\tilde{q}_{t,ik} := q_{t,i} q_{t,k} = \exp[-(\mathbf{M}^{Ada}\boldsymbol{\lambda}_t)_i - (\mathbf{M}^{Ada}\boldsymbol{\lambda}_t)_k] = \exp[-(\mathbf{M}\boldsymbol{\lambda}_t)_{ik}].$$

Automatically, $\tilde{\mathbf{q}}_t \in \tilde{\mathcal{Q}}$. For any pair i,k the limit of the sequence $\tilde{q}_{t,ik}$ is $\tilde{q}_{ik}^{\infty} := q_i^* q_k^*$.

What we need to show is that $\tilde{\mathbf{q}}^{\infty} = \tilde{\mathbf{q}}^*$. If we can prove this, we will have shown that $\{\boldsymbol{\lambda}_t\}_t$ converges to the minimum of RankBoost's objective function, $\tilde{F}$. We will do this by showing

that $\tilde{\mathbf{q}}^{\infty} \in \tilde{\mathcal{P}}$; once we accomplish this, due to the uniqueness of $\tilde{\mathbf{q}}^*$ as the intersection of $\tilde{\mathcal{P}}$ and closure$(\tilde{Q})$, we will have proved that $\tilde{\mathbf{q}}^{\infty} = \tilde{\mathbf{q}}^*$. So, now we proceed to show $\tilde{\mathbf{q}}^{\infty} \in \tilde{\mathcal{P}}$, using our assumption that the F-skew vanishes. Our assumption that the F-skew vanishes can be rewritten as:

$$\lim_{t\to\infty} \left[\sum_{i\in Y_+} q_{t,i} - \sum_{k\in Y_-} q_{t,k} \right] = 0,$$

that is, since all terms are bounded,

$$\sum_{i\in Y_+} q_i^* = \sum_{k\in Y_-} q_k^*. \tag{22}$$

Consider the quantities $(\tilde{\mathbf{q}}^{\infty T}\mathbf{M})_j$. Remember, if these quantities are zero for every j, then $\tilde{\mathbf{q}}^{\infty} \in \tilde{\mathcal{P}}$ and we have proved the theorem.

$$\begin{aligned}(\tilde{\mathbf{q}}^{\infty T}\mathbf{M})_j &= \sum_{i\in Y_+}\sum_{k\in Y_-} q_i^* q_k^* (M_{ij}^{Ada} + M_{kj}^{Ada}) \\ &= \left(\sum_{k\in Y_-} q_k^*\right)\left(\sum_{i\in Y_+} q_i^* M_{ij}^{Ada}\right) + \left(\sum_{i\in Y_+} q_i^*\right)\left(\sum_{k\in Y_-} q_k^* M_{kj}^{Ada}\right). \end{aligned} \tag{23}$$

Incorporating (22), which is the condition that F-skew$(\mathbf{q}^*) = 0$, (23) becomes:

$$(\tilde{\mathbf{q}}^{\infty T}\mathbf{M})_j = \left(\sum_{i\in Y_+} q_i^*\right)\left[\sum_{i\in Y_+} q_i^* M_{ij}^{Ada} + \sum_{k\in Y_-} q_k^* M_{kj}^{Ada}\right].$$

In fact, according to (21), the bracket in this expression is zero for all j. Thus, $\tilde{\mathbf{q}}_{\infty} \in \tilde{\mathcal{P}}$. We have proved the forward direction of the theorem. The backwards direction, as noted earlier, follows from $(F_+ + F_-)^2 - (F_+ - F_-)^2 = 4F_+F_-$. ■

Proof *(of Corollary 11)* Recall that $\mathbf{q}^* \in \mathcal{P}^{Ada}$. Specifically writing this condition just for the constant weak classifier yields:

$$\begin{aligned} 0 &= \sum_{i\in Y_+} q_i^* M_{i0}^{Ada} + \sum_{k\in Y_-} q_k^* M_{k0}^{Ada} = \sum_{i\in Y_+} q_i^* y_i + \sum_{k\in Y_-} q_k^* y_k \\ &= \sum_{i\in Y_+} q_i^* - \sum_{k\in Y_-} q_k^* = \lim_{t\to\infty} \text{F-skew}(\boldsymbol{\lambda}_t). \end{aligned}$$

■

Proof *(of Theorem 12)* We know from the proof of Theorem 10 that since $\{\boldsymbol{\lambda}_t\}_t$ and $\{\boldsymbol{\lambda}'_t\}_t$ minimize $\tilde{F}$, we automatically have $\tilde{q}_t \to \tilde{q}^*$ and $q'_t \to \tilde{q}^*$ in ℓ_p where

$$q'_{t,ik} := e^{-(\mathbf{M}\boldsymbol{\lambda}'_t)_{ik}}.$$

Thus, we have that for all crucial pairs i,k such that $i \in Y_+$ and $k \in Y_-$:

$$\lim_{t\to\infty} e^{-(\mathbf{M}\boldsymbol{\lambda}_t)_{ik}} = \lim_{t\to\infty} e^{-(\mathbf{M}\boldsymbol{\lambda}'_t)_{ik}} = \tilde{q}^*_{ik}.$$

For each crucial pair i,k, if $\tilde{q}^*_{ik} > 1$ then $\lim_{t\to\infty} (\mathbf{M}\boldsymbol{\lambda}_t)_{ik} < 0$, that is,

$$\lim_{t\to\infty} \mathbf{1}_{[(\mathbf{M}\boldsymbol{\lambda}_t)_{ik}\leq 0]} = 1,$$

and conversely, if $\tilde{q}^*_{ik} < 1$ then

$$\lim_{t\to\infty} \mathbf{1}_{[(\mathbf{M}\boldsymbol{\lambda}_t)_{ik}\leq 0]} = 0.$$

This is provided by the continuity of the function $\mathbf{1}_{[z\leq 0]}$ away from $z = 0$, and since there are no asymptotic ties in score as we have assumed, $\tilde{q}^*_{ik} \neq 1$. The same statement holds for $\boldsymbol{\lambda}'_t$. Summing over i,k pairs yields:

$$\lim_{t\to\infty} \left[\sum_{i\in Y_+} \sum_{k\in Y_-} \mathbf{1}_{[(\mathbf{M}\boldsymbol{\lambda}_t)_{ik}\leq 0]} \right] = \lim_{t\to\infty} \left[\sum_{i\in Y_+} \sum_{k\in Y_-} \mathbf{1}_{[(\mathbf{M}\boldsymbol{\lambda}'_t)_{ik}\leq 0]} \right].$$

The theorem has been proved. Note that the AUC value is obtained from this sum by the formula (13). ■

Proof *(of Corollary 13)* By Theorem 10, it is sufficient to show that the correction does not influence the value of $\tilde{F}(\boldsymbol{\lambda}_t)$ and that it makes the F-skew vanish. Consider the vector $\boldsymbol{\lambda}_t + c\mathbf{e}_{j_0}$.

$$\begin{aligned}
\tilde{F}(\boldsymbol{\lambda} + c\mathbf{e}_{j_0}) &= \sum_{i\in Y_+} \sum_{k\in Y_-} \exp\left[-\sum_j \lambda_j h_j(\mathbf{x}_i) - c \right] \exp\left[+\sum_j \lambda_j h_j(\mathbf{x}_k) + c \right] \\
&= \sum_{i\in Y_+} \sum_{k\in Y_-} \exp\left[-\sum_j \lambda_j h_j(\mathbf{x}_i) \right] \exp\left[+\sum_j \lambda_j h_j(\mathbf{x}_k) \right] = \tilde{F}(\boldsymbol{\lambda}).
\end{aligned}$$

So, changing the coefficient of the constant weak classifier will not affect the values of $\tilde{F}(\boldsymbol{\lambda})$. Now, let's compute the F-skew of the corrected sequence:

$$\begin{aligned}
\text{F-skew}(\boldsymbol{\lambda}_t^{\text{corrected}}) &= F_+(\boldsymbol{\lambda}_t + b_t\mathbf{e}_{j_0}) - F_-(\boldsymbol{\lambda}_t + b_t\mathbf{e}_{j_0}) \\
&= \sum_{i\in Y_+} e^{-(\mathbf{M}^{Ada}\boldsymbol{\lambda}_t)_i - b_t} - \sum_{k\in Y_-} e^{-(\mathbf{M}^{Ada}\boldsymbol{\lambda}_t)_k + b_t} \\
&= e^{-b_t} F_+(\boldsymbol{\lambda}_t) - e^{b_t} F_-(\boldsymbol{\lambda}_t) = 0
\end{aligned}$$

where this latter expression is equal to zero by our choice of b_t. Since the F-skew of the corrected sequence is always 0, the corrected sequence will minimize not only RankBoost's objective, but also AdaBoost's. ■

Proof *(of Theorem 14)* We will use a similar argument as in Theorem 12 for misclassification error rather than for ranking error. By assumption, $\boldsymbol{\lambda}_t$ is a sequence that minimizes RankBoost's objective $\tilde{F}$ and the correction forces the F-skew to be zero. Thus $\boldsymbol{\lambda}_t^{\text{corrected}}$ minimizes RankBoost's objective, and Theorem 10 implies that $\boldsymbol{\lambda}_t^{\text{corrected}}$ is also a minimizing sequence for AdaBoost's objective F. Using the same argument as in Theorem 12 substituting AdaBoost for RankBoost, we have that

$$\lim_{t\to\infty} e^{-(\mathbf{M}^{Ada}\boldsymbol{\lambda}_t^{\text{corrected}})_i} =: q_i^*$$

exists for all i and

$$\lim_{t\to\infty} e^{-(\mathbf{M}^{Ada}\boldsymbol{\lambda}_t^{\text{corrected}})_k} =: q_k^*$$

exists for all k. Now, we have that for each example i, if $q_i^* > 1$ then $\lim_{t\to\infty}(\mathbf{M}^{Ada}\boldsymbol{\lambda}_t)_i < 0$, that is,

$$\lim_{t\to\infty} \mathbf{1}_{[(\mathbf{M}^{Ada}\boldsymbol{\lambda}_t^{\text{corrected}})_i \le 0]} = 1,$$

and conversely, if $\tilde{q}_i^* < 1$ then

$$\lim_{t\to\infty} \mathbf{1}_{[(\mathbf{M}^{Ada}\boldsymbol{\lambda}_t^{\text{corrected}})_i \le 0]} = 0.$$

The same holds for all k and for $\boldsymbol{\lambda}_t'^{\text{corrected}}$. Again, there is no asymptotic convergence to the decision boundary as we have assumed, $\tilde{q}_i^* \neq 1$, $\tilde{q}_k^* \neq 1$. The same statement holds for $\boldsymbol{\lambda}_t'^{\text{corrected}}$. Summing over i and k yields:

$$\begin{aligned}
&\lim_{t\to\infty}\left[\sum_{i\in Y_+} \mathbf{1}_{[(\mathbf{M}^{Ada}\boldsymbol{\lambda}_t^{\text{corrected}})_i \le 0]} + \sum_{k\in Y_-} \mathbf{1}_{[(\mathbf{M}^{Ada}\boldsymbol{\lambda}_t^{\text{corrected}})_k \le 0]}\right] \\
&= \lim_{t\to\infty}\left[\sum_{i\in Y_+} \mathbf{1}_{[(\mathbf{M}^{Ada}\boldsymbol{\lambda}_t'^{\text{corrected}})_i \le 0]} + \sum_{k\in Y_-} \mathbf{1}_{[(\mathbf{M}^{Ada}\boldsymbol{\lambda}_t'^{\text{corrected}})_k \le 0]}\right].
\end{aligned}$$

■

9. Conclusions

We have presented three main results. First, in Section 3, we presented a generalization bound for ranking. This bound incorporates a margin, allowing it to be useful in the separable case. The second main result is an algorithm, smooth margin ranking, that maximizes the ranking margin. Our third result is that under very general conditions, AdaBoost solves classification and ranking problems simultaneously, performing just as well for the ranking problem as RankBoost. Conversely, RankBoost with a change in intercept performs just as well for the classification problem as AdaBoost.

10. Open Problems and Future Work

The three main results presented in this paper yield many new directions for future research. We gave a margin-based bound for general ranking. It is worth investigating the design of more specialized margin-based bounds for ranking. We have developed one such bound in Rudin (2009); In that work, we develop a specialized bound based on Theorem 2, designed to emphasize the top portion of the list.

We described a new ranking algorithm, smooth margin ranking, that maximizes the margin. It would be natural to compare the empirical performance of the smooth margin ranking algorithm and RankBoost. In fact, it is also worth considering the empirical performance of AdaBoost to RankBoost, now that we know AdaBoost can be used for ranking.

Acknowledgments

We would like to thank the anonymous reviewers and the editor for their helpful comments; some of these comments were especially helpful in formulating Corollary 13. Thanks to Adrian Banner and Richard Sharp for their patience and assistance with earlier versions of the proof of Lemma 20. Thanks also to Corinna Cortes and Mehryar Mohri, who co-authored a preliminary conference version of this work.

Appendix A. Proof of Lemma 20

We will first prove some properties of α, τ, Γ, and $\mathcal{B}$ in the following lemmas. First, we show $\alpha(r,g,d_0)$ is a nonnegative, deceasing function of g, and that $\tau(r,g,d_0)$ is an increasing function of g. We also provide a bound on the second derivative of α, which is the key step in the proof of Lemma 20.

Lemma 21 *(Properties of $\alpha(r,g,d_0)$ and $\tau(r,g,d_0)$) For fixed values of r and d_0, considering g as a variable, within the range $0 \le g < r$:*

$$\text{(i)} \quad \lim_{g \to r} \alpha(r,g,d_0) = 0,$$

$$\text{(ii)} \quad \frac{\partial \alpha(r,g,d_0)}{\partial g} = \frac{-\tau(r,g,d_0)}{g\tau'(r,g,d_0) + \tau''(r,g,d_0)} = \frac{-\tau(r,g,d_0)}{(1-g^2)\tau(r,g,d_0) - d_0} < 0,$$

$$\text{(iii)} \quad \lim_{g \to r} \frac{\partial \alpha(r,g,d_0)}{\partial g} = \frac{-1}{1-r^2-d_0} < 0,$$

$$\text{(iv)} \quad \frac{\partial \tau(r,g,d_0)}{\partial g} \ge 0,$$

$$\text{(v)} \quad \tau(r,0,1-r) = 1 - r \le d_0 + \sqrt{(1-d_0)^2 - r^2} = \tau(r,0,d_0),$$

$$\text{(vi)} \quad \frac{\partial^2 \alpha(r,g,d_0)}{\partial g^2} < 0 \text{ whenever } d_0 \le \frac{2}{3}(1-r)(1-r^2) \text{ and } g > 0.$$

Proof By definition

$$\tau(r,g,d_0) = \frac{(1+r-d_0)}{2} e^{-\alpha(r,g,d_0)} + \frac{(1-r-d_0)}{2} e^{\alpha(r,g,d_0)} + d_0,$$

$$\tau'(r,g,d_0) = -\frac{(1+r-d_0)}{2} e^{-\alpha(r,g,d_0)} + \frac{(1-r-d_0)}{2} e^{\alpha(r,g,d_0)},$$

and similarly define $\tau''(r,g,d_0) = \tau(r,g,d_0) - d_0$. Part (i) can be seen from (11), that is, $-\tau'(r,g,d_0) = g\tau(r,g,d_0)$, which simplifies to

$$\frac{(1+r-d_0)}{2} e^{-\alpha(r,g,d_0)} - \frac{(1-r-d_0)}{2} e^{\alpha(r,g,d_0)}$$

$$= g\frac{(1+r-d_0)}{2}e^{-\alpha(r,g,d_0)} + g\frac{(1-r-d_0)}{2}e^{\alpha(r,g,d_0)} + gd_0,$$

so one sets $g = r$ and verifies that $\alpha = 0$ satisfies the equation. Part (ii) is shown by taking implicit derivatives of (11) as follows:

$$\frac{\partial\alpha(r,g,d_0)}{\partial g}(g\tau'(r,g,d_0)+\tau''(r,g,d_0))+\tau(r,g,d_0) = 0,$$

that is,

$$\frac{\partial\alpha(r,g,d_0)}{\partial g} = \frac{-\tau(r,g,d_0)}{g\tau'(r,g,d_0)+\tau''(r,g,d_0)}, \tag{24}$$

and then simplifying using (11) and the definition of $\tau''(r,g,d_0)$. For the inequality, the numerator is negative, and the denominator is (using d_+, d_- notation) $g(-d_+e^{-\alpha}+d_-e^{\alpha})+d_+e^{-\alpha}+d_-e^{\alpha} = (1-g)d_+e^{-\alpha}+(1+g)d_-e^{\alpha} > 0$ since $g < 1$. Part (iii) is shown from (i) and (ii); for $g \to r$, we have $\alpha(r,g,d_0) \to 0$, and thus $\tau(r,g,d_0) \to 1$. The inequality comes from $1-r^2-d_0 > 1-r-d_0 = 2d_- \geq 0$. To show (iv), by the chain rule,

$$\frac{\partial\tau(r,g,d_0)}{\partial g} = \tau'(r,g,d_0)\frac{\partial\alpha(r,g,d_0)}{\partial g}.$$

Since $\tau(r,g,d_0) > 0$ and $\tau'(r,g,d_0) = -g\tau(r,g,d_0)$, we know $\tau'(r,g,d_0) \leq 0$. Additionally, from (ii), $\frac{\partial\alpha}{\partial g} < 0$. Thus (iv) is proved. For (v), we know that when $g = 0$, $\tau'(r,g,d_0) = -g\tau(r,g,d_0)$ means $\tau'(r,0,d_0) = 0$. Using the definition for $\tau'(r,g,d_0)$, we find that $e^{\alpha(r,0,d_0)} = \left(\frac{1+r-d_0}{1-r-d_0}\right)^{1/2}$. Substituting this into the definition of τ yields the equality conditions in (v). The inequality comes from the fact that the right hand side, $d_0+\sqrt{(1-d_0)^2-r^2}$, is monotonically decreasing in d_0. For (vi), a derivative of (24) yields:

$$(g\tau'(r,g,d_0)+\tau''(r,g,d_0))\frac{\partial^2\alpha(r,g,d_0)}{\partial g^2}$$

$$= -\left(\frac{\partial\alpha(r,g,d_0)}{\partial g}\right)\left[\left(\frac{\partial\alpha(r,g,d_0)}{\partial g}\right)(g\tau''(r,g,d_0)+\tau'''(r,g,d_0))+2\tau'(r,g,d_0)\right],$$

where $\tau'''(r,g,d_0) = \tau'(r,g,d_0)$. The left expression (using d_+, d_- notation) is $g\tau'(r,g,d_0)+\tau''(r,g,d_0) = d_+(1-g)e^{-\alpha}+d_-(1+g)e^{\alpha} > 0$ since $g < 1$. Since (ii) shows that $\partial\alpha/\partial g < 0$, we are left to show that the bracketed expression on the right is negative in order for the second derivative of α to be negative. Consider that quantity:

$$\left(\frac{\partial\alpha(r,g,d_0)}{\partial g}\right)(g\tau''(r,g,d_0)+\tau'''(r,g,d_0))+2\tau'(r,g,d_0)$$

$$= \tau'(r,g,d_0)\left[\frac{\partial\alpha(r,g,d_0)}{\partial g}\left(\frac{g\tau''(r,g,d_0)+\tau'(r,g,d_0)}{\tau'(r,g,d_0)}\right)+2\right]$$

and substituting $\tau'(r,g,d_0) = -g\tau(r,g,d_0)$ and $\tau''(r,g,d_0) = \tau(r,g,d_0) - d_0$,

$$\begin{aligned}
&= \tau'(r,g,d_0)\left[\frac{\partial\alpha(r,g,d_0)}{\partial g}\left(\frac{g\tau(r,g,d_0) - gd_0 - g\tau(r,g,d_0)}{-g\tau(r,g,d_0)}\right) + 2\right] \\
&= \tau'(r,g,d_0)\left[\frac{\partial\alpha(r,g,d_0)}{\partial g}\left(\frac{d_0}{\tau(r,g,d_0)}\right) + 2\right] \text{ and from (ii),} \\
&= \tau'(r,g,d_0)\left[\frac{-d_0}{(1-g^2)\tau(r,g,d_0) - d_0} + 2\right]. \qquad (25)
\end{aligned}$$

Since $-\tau'(r,g,d_0) = g\tau(r,g,d_0)$, we know $\tau'(r,g,d_0) < 0$ when $g > 0$. Let us show that the bracketed expression of (25) is positive. Using our assumption on d_0, also $1 - r^2 < 1 - g^2$, (v), and (iv),

$$\begin{aligned}
d_0 &< (1-r^2)(1-r)\frac{2}{3} < (1-g^2)(1-r)\frac{2}{3} = (1-g^2)\tau(r,0,1-r)\frac{2}{3} \\
&\leq (1-g^2)\tau(r,0,d_0)\frac{2}{3} \leq (1-g^2)\tau(r,g,d_0)\frac{2}{3}.
\end{aligned}$$

Rearranging this yields

$$\frac{d_0}{[(1-g^2)\tau(r,g,d_0) - d_0]} < 2.$$

The proof is finished. ■

In order to build up to Lemma 20, we need some properties of $\Gamma(r,g,d_0)$ and B.

Lemma 22 *(Properties of $\Gamma(r,g,d_0)$) For every fixed value of r and d_0, considering g as a variable, within the range $0 \leq g < r$:*

$$\begin{aligned}
&\text{(i)} && \lim_{g\to r}\Gamma(r,g,d_0) = r \\
&\text{(ii)} && \Gamma(r,g,d_0) > g \\
&\text{(iii)} && \frac{\partial\Gamma(r,g,d_0)}{\partial g} > 0 \\
&\text{(iv)} && \Gamma(r,g,d_0) < r.
\end{aligned}$$

Proof The proof of (i) uses L'Hôpital's rule, which we have permission to use from Lemma 21 (i) since $\lim_{g\to r}\alpha(r,g,d_0) = 0$.

$$\lim_{g\to r}\Gamma(r,g,d_0) = \lim_{g\to r}\frac{-\ln\tau(r,g,d_0)}{\alpha(r,g,d_0)} = \lim_{g\to r}\frac{-\frac{\tau'(r,g,d_0)}{\tau(r,g,d_0)}\frac{\partial\alpha(r,g,d_0)}{\partial g}}{\frac{\partial\alpha(r,g,d_0)}{\partial g}} = \lim_{g\to r} g = r.$$

Here we have used that $\lim_{g\to r}\frac{\partial\alpha(r,g,d_0)}{\partial g}$ is finite from Lemma 21 (ii), and applied (11), that is, $-\tau'(r,g,d_0) = g\tau(r,g,d_0)$.

For the proofs of (ii) and (iii) we consider the derivative of $\Gamma(r,g,d_0)$ with respect to g. Recall that $\tau'(r,g,d_0)$ is given by the formula (8).

$$\begin{aligned}
\frac{\partial\Gamma(r,g,d_0)}{\partial g} &= \left[\frac{-\tau'(r,g,d_0)}{\tau(r,g,d_0)} + \frac{\ln\tau(r,g,d_0)}{\alpha(r,g,d_0)}\right]\frac{1}{\alpha(r,g,d_0)}\frac{\partial\alpha(r,g,d_0)}{\partial g} \\
&= (\Gamma(r,g,d_0) - g)\left(-\frac{\partial\alpha(r,g,d_0)}{\partial g}\right)\frac{1}{\alpha(r,g,d_0)}. \qquad (26)
\end{aligned}$$

For the last line above we used (11) and the definition of $\Gamma(r,g,d_0)$. Since $\alpha(r,g,d_0)$ is a positive, decreasing function of g from Lemma 21 (ii), we know $-\partial\alpha(r,g,d_0)/\partial g$ and $1/\alpha(r,g,d_0)$ are positive. Thus,

$$\text{sign}\left(\frac{\partial\Gamma(r,g,d_0)}{\partial g}\right) = \text{sign}(\Gamma(r,g,d_0)-g). \tag{27}$$

We show next that $\Gamma(r,0,d_0) > 0$. From (11), we know $0 = -\tau'(r,0,d_0)$, which by definition of $\tau'(r,g,d_0)$ in (8) gives $\alpha(r,0,d_0) = \frac{1}{2}\ln(d_+/d_-) > 0$. Now,

$$\Gamma(r,0,d_0) = \frac{-\ln\tau(r,0,d_0)}{\alpha(r,0,d_0)} = \frac{1}{\alpha(r,0,d_0)}\left(-\ln\left(2(d_-d_+)^{1/2}+d_0\right)\right).$$

We also have $2(d_-d_+)^{1/2}+d_0 < d_-+d_++d_0 = 1$, so we are done showing that $\Gamma(r,0,d_0) > 0$.

Now we proceed by contradiction. Assume that there is some value of $\bar{g}$, where $0 \le \bar{g} < r$, for which $\Gamma(r,\bar{g},d_0) \le \bar{g}$. That is, assume the functions $\Gamma(r,g,d_0)$ and $f(g) = g$ cross. In that case, the derivative $\partial\Gamma(r,g,d_0)/\partial g$ would have a nonpositive sign at $g = \bar{g}$ by (27), and the function $\Gamma(r,g,d_0)$ would be a nonincreasing function for $\bar{g} < g < r$. That is, since $\Gamma(r,g,d_0)$ would have a nonpositive slope at $\bar{g}$, it cannot increase to cross the line $f(g) = g$ in order to reverse the sign of the slope. However, this is a contradiction, since the function must indeed increase; it must reach the limiting value r as $g \to r$, as we showed in (i). Hence, $\Gamma(r,g,d_0) > g$ for all g such that $0 \le g < r$, proving (ii), and thus by (27), $\partial\Gamma(r,g,d_0)/\partial g > 0$ for all g such that $0 \le g < r$, proving (iii).

The proof of (iv) is again by contradiction. Fix arbitrary values of r and d_0. Assume $\Gamma(r,\bar{g},d_0) \ge r$ for some $\bar{g} < r$. Since the function $\Gamma(r,g,d_0)$ is an increasing function of g, $\Gamma(r,g,d_0)$ must be larger than r and strictly increasing for $g > \bar{g}$. Yet by (i), $\Gamma(r,g,d_0) \to r$ as $g \to r$ for each fixed pair of r and d_0. This is a contradiction, since $\Gamma(r,g,d_0)$ cannot decrease to meet this limit. ■

Lemma 23

(i) $\quad 0 < \mathcal{B}(r,g,d_0) < 1$

(ii) $\quad \lim_{g\to r}\mathcal{B}(r,g,d_0) = \frac{1}{2}$ *for fixed* r *and* d_0.

Proof From Lemma 22 (ii), $\Gamma(r,g,d_0)-g$ is positive, and by assumption $g < r$. Thus, $\mathcal{B}(r,g,d_0) > 0$. Also, from Lemma 22 (iv), $\Gamma(r,g,d_0) < r$. Thus, $\mathcal{B}(r,g,d_0) < 1$. Thus (i) is proved. The proof of (ii) uses L'Hôpital's rule twice (which we may use by Lemma 21 (i)) also (11), and the fact that derivatives of $\alpha(r,g,d_0)$ with respect to g are finite.

$$\begin{aligned}
\lim_{g\to r}\mathcal{B}(r,g,d_0) &= \lim_{g\to r}\frac{\frac{-\ln\tau(r,g,d_0)}{\alpha(r,g,d_0)}-g}{r-g} = \lim_{g\to r}\frac{-\ln\tau(r,g,d_0)-g\alpha(r,g,d_0)}{\alpha(r,g,d_0)(r-g)} \\
&= \lim_{g\to r}\frac{-\frac{\tau'(r,g,d_0)}{\tau(r,g,d_0)}\frac{\partial\alpha(r,g,d_0)}{\partial g}-g\frac{\partial\alpha(r,g,d_0)}{\partial g}-\alpha(r,g,d_0)}{-\alpha(r,g,d_0)+(r-g)\frac{\partial\alpha(r,g,d_0)}{\partial g}} \\
&= \lim_{g\to r}\frac{-\alpha(r,g,d_0)}{-\alpha(r,g,d_0)+(r-g)\frac{\partial\alpha(r,g,d_0)}{\partial g}} \\
&= \lim_{g\to r}\frac{-\frac{\partial\alpha(r,g,d_0)}{\partial g}}{-2\frac{\partial\alpha(r,g,d_0)}{\partial g}+(r-g)\frac{\partial^2\alpha(r,g,d_0)}{\partial g^2}} = \frac{1}{2}.
\end{aligned}$$

■

There is one thing left in order to prove Lemma 20. This is where the key step appears, that is, our bound on the second derivative of α.

Lemma 24

$$\frac{(r-g)}{\alpha(r,g,d_0)}\left(-\frac{\partial\alpha(r,g,d_0)}{\partial g}\right) < 1.$$

Proof Define

$$\phi(r,g,d_0) := (r-g)\left(-\frac{\partial\alpha(r,g,d_0)}{\partial g}\right) - \alpha(r,g,d_0).$$

In order to prove the lemma, we need only to show that $\phi(r,g,d_0)$ is always negative. We will show that $\partial\phi(r,g,d_0)/\partial g$ is positive. Thus, the largest possible value of $\phi(r,g,d_0)$ occurs when g is at its maximum, namely, when $g = r$. If $g = r$, then $\phi(r,g,d_0) = 0$. Thus, $\phi(r,g,d_0)$ is everywhere negative and the lemma is proved. Now we have only to prove $\partial\phi(r,g,d_0)/\partial g$ is positive. Again, we take derivatives:

$$\frac{\partial\phi(r,g,d_0)}{\partial g} = (r-g)\left(-\frac{\partial^2\alpha(r,g,d_0)}{\partial g^2}\right),$$

and since $r-g$ is always positive, and since we have taken efforts to ensure α's second derivative is negative (except at the irrelevant endpoint $g = 0$) in Lemma 21 (vi), we are done. ■

We finally prove Lemma 20.

Proof *(of Lemma 20)* We consider $\partial\mathcal{B}(r,g,d_0)/\partial g$ for each fixed pair of r and d_0 values and derive a differential equation for $\mathcal{B}$. We will prove that the derivative is always nonnegative. Then we will use Lemma 23 to show that $\mathcal{B}(r,g,d_0)$ is nonnegative. Here is the differential equation:

$$\begin{aligned}
\frac{\partial\mathcal{B}(r,g,d_0)}{\partial g} &= \frac{1}{r-g}\left[\frac{\partial\Gamma(r,g,d_0)}{\partial g} - 1 + \frac{\Gamma(r,g,d_0)-g}{r-g}\right] \\
&= \frac{1}{r-g}\left[\frac{\partial\Gamma(r,g,d_0)}{\partial g} - 1 + \mathcal{B}(r,g,d_0)\right] \\
&= \frac{1}{r-g}\left[(\Gamma(r,g,d_0)-g)\left(-\frac{\partial\alpha(r,g,d_0)}{\partial g}\frac{1}{\alpha(r,g,d_0)}\right) - 1 + \mathcal{B}(r,g,d_0)\right] \\
&= \frac{1}{r-g}\left[\mathcal{B}(r,g,d_0)(r-g)\left(-\frac{\partial\alpha(r,g,d_0)}{\partial g}\frac{1}{\alpha(r,g,d_0)}\right) - 1 + \mathcal{B}(r,g,d_0)\right] \\
&= \frac{\mathcal{B}(r,g,d_0)}{r-g}\left[(r-g)\left(-\frac{\partial\alpha(r,g,d_0)}{\partial g}\frac{1}{\alpha(r,g,d_0)}\right) - \left(\frac{1}{\mathcal{B}(r,g,d_0)} - 1\right)\right]. \qquad (28)
\end{aligned}$$

Here we have incorporated the differential equation for $\Gamma(r,g,d_0)$ from (26). Again, we will prove by contradiction. Assume that for some values of r and g, where $g < r$, we have $\mathcal{B}(r,g,d_0) \leq 1/2$. That is, assume $\left(\frac{1}{\mathcal{B}(r,g,d_0)} - 1\right) \geq 1$. In that case, the bracket in Equation (28) is negative, by Lemma 24. Since $0 < \mathcal{B}(r,g,d_0) < 1$ from Lemma 23, and $g < r$ by assumption, the factor $\mathcal{B}(r,g,d_0)/(r-g)$ of Equation (28) is positive and the bracket is negative, thus $\frac{\partial\mathcal{B}(r,g,d_0)}{\partial g} < 0$, so $\mathcal{B}(r,g,d_0)$ is a decreasing function. Hence, for each fixed r and d_0, $\mathcal{B}(r,g,d_0)$ decreases from a value

which is less than or equal to $1/2$. Recall from Lemma 23 that $\lim_{g \to r} \mathcal{B}(r,g,d_0) = 1/2$, and thus this limit can never be attained. Contradiction. Thus, for all values of r, d_0 and g within $0 < r < 1$, $0 \leq g < r, 0 \leq d_0 < \frac{2}{3}(1-r)(1-r^2)$, we must have $\mathcal{B}(r,g,d_0) > 1/2$. We have proved the lemma. ■

The P-Norm Push: A Simple Convex Ranking Algorithm that Concentrates at the Top of the List

Editor: Michael Collins

Abstract

We are interested in supervised ranking algorithms that perform especially well near the top of the ranked list, and are only required to perform sufficiently well on the rest of the list. In this work, we provide a general form of convex objective that gives high-scoring examples more importance. This "push" near the top of the list can be chosen arbitrarily large or small, based on the preference of the user. We choose ℓ_p-norms to provide a specific type of push; if the user sets p larger, the objective concentrates harder on the top of the list. We derive a generalization bound based on the p-norm objective, working around the natural asymmetry of the problem. We then derive a boosting-style algorithm for the problem of ranking with a push at the top. The usefulness of the algorithm is illustrated through experiments on repository data. We prove that the minimizer of the algorithm's objective is unique in a specific sense. Furthermore, we illustrate how our objective is related to quality measurements for information retrieval.

Keywords: ranking, RankBoost, generalization bounds, ROC, information retrieval

1. Introduction

The problem of supervised ranking is useful in many application domains, for instance, maintenance operations to be performed in a specific order, natural language processing, information retrieval, and drug discovery. Many of these domains require the construction of a ranked list, yet often, only the top portion of the list is used in practice. For instance, in the setting of supervised movie ranking, the learning algorithm provides the user (an avid movie-goer) with a ranked list of movies based on preference data. We expect the user to examine the top portion of the list as a recommendation. It is possible that she never looks at the rest of the list, or examines it only briefly. Thus, we wish to make sure that the top portion of the list is correctly constructed. This is the problem on which we concentrate.

We present a fairly general and flexible technique for solving these types of problems. Specifically, we derive a convex objective function that places more emphasis at the top of the list. The algorithm we develop using this technique ("The P-Norm Push") is based on minimization of a specific version of this objective. The user chooses a parameter "p" in the objective, corresponding to the p of an ℓ_p norm. By varying p, one changes the degree of concentration ("push") at the top of the list. One can concentrate at the very top of the list (a big push, large p), or one can have a moderate emphasis at the top (a little push, low p), or somewhere in between. The case with no

emphasis at the top (no push, $p = 1$) corresponds to a standard objective for supervised bipartite ranking, namely the exponentiated pairwise misranking error.

The P-Norm Push is motivated in the setting of supervised bipartite ranking. In the supervised bipartite ranking problem, each training instance has a label of +1 or -1; each movie is either a good movie or a bad movie. In this case, we want to push the bad movies away from the top of the list where the good movies are desired. The quality of a ranking can be determined by examining the Receiver Operator Characteristic (ROC) curve. The AUC (Area Under the ROC Curve) is precisely a constant times one minus the total standard pairwise misranking error. The accuracy measure for our problem is different; we care mostly about the leftmost portion of the ROC curve, corresponding to the top of the ranked list. We wish to make the leftmost portion of the curve higher. Thus, we choose to make a tradeoff: in order make the leftmost portion of the curve higher, we sacrifice on the total area underneath the curve. The parameter p in the P-Norm Push allows the user to directly control this tradeoff.

This problem is highly asymmetric with respect to the positive and negative classes, and is not represented by a sum of independent random variables. It is interesting to consider generalization bounds for such a problem; it is not clear how to use standard techniques that require natural symmetry with respect to the positive and negative examples, for instance, many VC bounds rely on this kind of symmetry. In this work, we present a generalization bound that uses covering numbers as a measure of complexity. This bound is designed specifically to handle these asymmetric conditions. The bound underscores an important property of algorithms that concentrate on a small portion of the domain, such as algorithms that concentrate on the top of a ranked list: these algorithms require more examples for generalization.

Recently, there has been a large amount of interest in the supervised ranking problem, and especially in the bipartite problem. Freund et al. (2003) have developed the RankBoost algorithm for the general setting. We inherit the setup of RankBoost, and our algorithm will also be a boosting-style algorithm. Oddly, Freund and Schapire's classification algorithm AdaBoost (Freund and Schapire, 1997) performs just as well for bipartite ranking as RankBoost; both algorithms achieve equally good values of the AUC (Rudin and Schapire, 2009). This is in contrast with support vector machine classifiers (Cortes and Vapnik, 1995), which do not tend to perform well for the bipartite ranking problem (Rakotomamonjy, 2004; Brefeld and Scheffer, 2005). Mozer et al. (2002) aim to manipulate specific points of the ROC curve in order to study "churn" in the telecommunications industry. Perhaps the closest algorithm to ours is the one proposed by Dekel et al. (2004), who have used a similar form of objective with different specifics to achieve a different goal, namely to rank labels in a multilabel setting. Other related works on label ranking include those of Crammer and Singer (2001) and Shalev-Shwartz and Singer (2006). The work of Yan et al. (2003) contains a brief mention of a method to optimize the lower left corner of the ROC curve, though their multi-layer perception approach is highly non-convex. There is a lot of recent work on generalization bounds (and large deviation bounds) for supervised ranking, namely, the bounds of Freund et al. (2003), Clemençon et al. (2008), Agarwal et al. (2005), Usunier et al. (2005), Hill et al. (2002), Rudin et al. (2005) and Rudin and Schapire (2009), though we were only able to adapt techniques from the latter two bounds to our particular setting, since the covering number approach can handle the natural asymmetry of our problem. There is also a body of work on ROC curves in general, for example, the estimation of confidence bands for ROC curves (Macskassy et al., 2005), and more recent works by Clemençon and Vayatis addressing statistical aspects of ranking problems (e.g., Clemençon and Vayatis, 2007, 2008).

There is a large body of literature on information retrieval (IR) that considers other quality measurements for a ranked list, including "discounted cumulative gain," "average precision" and "winner take all." In essence, the P-Norm Push algorithm can be considered as a way to interpolate between AUC maximization (no push, $p = 1$) and a quantity similar to "winner take all" (largest possible push, $p = \infty$). A simple variation of the P-Norm Push derivation can be used to derive convex objectives that are somewhat similar to the "discounted cumulative gain" as we illustrate in Section 7. Our approach yields simple smooth convex objectives that can be minimized using simple coordinate techniques. In that sense, our work complements those of Tsochantaridis et al. (2005) and Le and Smola (2007) who also minimize a convex upper bound of IR ranking measurements, but with a structured learning approach that requires optimization with exponentially many constraints; those works have suggested useful ways to combat this problem. Additionally, there are recent works (Cossock and Zhang, 2006; Zheng et al., 2007) that suggest regression approaches to optimize ranking criteria for information retrieval.

Here is the outline of the work: in Section 2, we present a general form of objective function, allowing us to incorporate a push near the top of the ranked list. In order to construct a specific case of this objective, one chooses both a loss function ℓ and a convex "price" function g. We will choose g to be a power law, $g(r) = r^p$, so that a higher power p corresponds to a larger push near the top. In Section 3 we give some examples to illustrate how the objective works. In Section 4, we provide a generalization bound for our objective with ℓ as the 0-1 loss, based on L_∞ covering numbers. The generalization bound has been improved from the conference version of this work (Rudin, 2006). In Section 5 we derive the "P-Norm Push" coordinate descent algorithm based on the objective with ℓ chosen as the exponential loss used for AdaBoost and RankBoost. Section 6 discusses uniqueness of the minimizer of the P-Norm Push algorithm's objective. We prove that the minimizer is unique in a specific sense. This result is based on conjugate duality and the theory of Bregman distances (Della Pietra et al., 2002), and is analogous to the result of Collins et al. (2002) for AdaBoost. The "primal" problem for AdaBoost can be written as relative entropy minimization. For the objective of the P-Norm Push algorithm, the problem is more difficult and the primal is not a common function. Section 7 illustrates the similarity between quality measurements used for information retrieval and our objective, and gives other variations of the objective. In Section 8, we demonstrate the P-Norm Push on repository data. Section 9 discusses open problems and future work. Sections 10 and 11 contain the major proofs from Sections 4 and 6. The P-Norm Push was recently applied to the problem of prioritizing manholes in New York City for maintenance and repair (Rudin et al., 2009).

The main contributions of this work are: a generalization bound for a learning problem that is asymmetric by design, a simple user-adjustable, easy-to-implement algorithm for supervised ranking with a "push," and a proof that the minimizer of the algorithm's objective is unique in a specific sense.

2. An Objective for Ranking with a Push

The set of instances with positive labels is $\{\mathbf{x}_i\}_{i=1,\ldots,I}$, where $\mathbf{x}_i \in \mathcal{X}$. The negative instances are $\{\tilde{\mathbf{x}}_k\}_{k=1,\ldots,K}$, where $\tilde{\mathbf{x}}_k \in \mathcal{X}$. We always use i for the index over positive instances and k for the index over negative instances. In the case of the movie ranking problem, the $\mathbf{x}_i$'s are the good movies used for training, the $\tilde{\mathbf{x}}_k$'s are the bad movies, and $\mathcal{X}$ is a database of movies. Our goal is to construct a ranking function f that gives a real valued score to each instance in $\mathcal{X}$, that is, $f : \mathcal{X} \to \mathcal{R}$. We do

not care about the actual values of each instance, only the relative values; for positive-negative pair $\mathbf{x}_i, \tilde{\mathbf{x}}_k$, we care that $f(\mathbf{x}_i) > f(\tilde{\mathbf{x}}_k)$ but it is not important to know, for example, that $f(\mathbf{x}_i) = 0.4$ and $f(\tilde{\mathbf{x}}_k) = 0.1$.

Let us now derive the general form of our objective. For a particular negative example, we wish to reduce its *Height*, which is the number of positive examples ranked beneath it. That is, for each k, we wish to make Height(k) small, where:

$$\text{Height}(k) := \sum_{i=1}^{I} \mathbf{1}_{[f(\mathbf{x}_i) \leq f(\tilde{\mathbf{x}}_k)]}.$$

Let us now add the push. We want to concentrate harder on negative examples that have high scores; we want to push these examples down from the top. Since the highest scoring negative examples also achieve the largest Heights, these are the examples for which we impose a larger price. Namely, for convex, non-negative, monotonically increasing function $g : \mathcal{R}_+ \to \mathcal{R}_+$, we place the price $g(\text{Height}(k))$ on negative example k:

$$g\left(\sum_{i=1}^{I} \mathbf{1}_{[f(\mathbf{x}_i) \leq f(\tilde{\mathbf{x}}_k)]}\right).$$

If g is very steep, we pay an extremely large price for a high scoring negative example. Examples of steep functions include $g(r) = e^r$ and $g(r) = r^p$ for p large. Thus we have derived an objective to minimize, namely the sum of the prices for the negative examples:

$$R_{g,\mathbf{1}}(f) := \sum_{k=1}^{K} g\left(\sum_{i=1}^{I} \mathbf{1}_{[f(\mathbf{x}_i) \leq f(\tilde{\mathbf{x}}_k)]}\right).$$

The effect of g is to force the value of $R_{g,\mathbf{1}}$ to come mostly from the highest scoring negative examples. These high scoring negative examples are precisely the examples represented by the leftmost portion of the ROC Curve. Minimizing $R_{g,\mathbf{1}}$ should thus boost performance around high scoring negative examples and increase the leftmost portion of the ROC Curve.

It is hard to minimize $R_{g,\mathbf{1}}$ directly due to the 0-1 loss in the inner sum. Instead, we will minimize an upper bound, $R_{g,\ell}$, which incorporates $\ell : \mathcal{R} \to \mathcal{R}_+$, a convex, non-negative, monotonically decreasing upper bound on the 0-1 loss. Popular loss functions include the exponential, logistic, and hinge losses. We can now define the general form of our objective:

$$R_{g,\ell}(f) := \sum_{k=1}^{K} g\left(\sum_{i=1}^{I} \ell\Big(f(\mathbf{x}_i) - f(\tilde{\mathbf{x}}_k)\Big)\right).$$

To construct a specific version of this objective, one chooses the loss ℓ, the price function g, and an appropriate hypothesis space $\mathcal{F}$ over which to minimize $R_{g,\ell}$. In order to derive RankBoost's specific objective from $R_{g,\ell}$, we would choose ℓ as the exponential loss and g to be the identity.

For the moment, let us assume we care only about the very top of the list, that is, we wish to push the most offending negative example as far down the list as possible. Equivalently, we wish to minimize $R_{\max}$, the number of positives below the highest scoring negative example:

$$R_{\max}(f) := \max_k \sum_{i=1}^{I} \mathbf{1}_{[f(\mathbf{x}_i) \leq f(\tilde{\mathbf{x}}_k)]}.$$

Minimizing this misranking error at the very top is similar to optimizing a "winner take all" loss such as $\mathbf{1}_{[\max_i f(\mathbf{x}_i) \leq \max_k f(\tilde{\mathbf{x}}_k)]}$ in that both would choose a ranked list where a negative example is not at the top of the list.

Although it is hard to minimize $R_{\max}(f)$ directly, $R_{g,\ell}$ can give us some control over $R_{\max}$. Namely, the following relationships exist between $R_{g,\ell}$, $R_{g,\mathbf{1}}$ and $R_{\max}$.

Theorem 1 *For all convex, non-negative, monotonic g and for all ℓ that are upper bounds for the 0-1 loss, we have that:*

$$Kg\left(\frac{1}{K}R_{\max}(f)\right) \leq R_{g,\mathbf{1}}(f) \leq Kg\Big(R_{\max}(f)\Big) \quad \text{and} \quad R_{g,\mathbf{1}}(f) \leq R_{g,\ell}(f).$$

Proof The proof of the first inequality follows from the monotonicity of g and Jensen's inequality for convex function g.

$$\begin{aligned} Kg\left(\frac{1}{K}R_{\max}(f)\right) &= Kg\left(\frac{1}{K}\max_k \sum_{i=1}^{I} \mathbf{1}_{[f(\mathbf{x}_i)\leq f(\tilde{\mathbf{x}}_k)]}\right) \leq Kg\left(\frac{1}{K}\sum_{k=1}^{K}\sum_{i=1}^{I} \mathbf{1}_{[f(\mathbf{x}_i)\leq f(\tilde{\mathbf{x}}_k)]}\right) \\ &\leq \sum_{k=1}^{K} g\left(\sum_{i=1}^{I} \mathbf{1}_{[f(\mathbf{x}_i)\leq f(\tilde{\mathbf{x}}_k)]}\right) = R_{g,\mathbf{1}}(f). \end{aligned}$$

For the second inequality, we use the fact that g is monotonic:

$$\begin{aligned} R_{g,\mathbf{1}}(f) &= \sum_{k=1}^{K} g\left(\sum_{i=1}^{I} \mathbf{1}_{[f(\mathbf{x}_i)\leq f(\tilde{\mathbf{x}}_k)]}\right) \leq K\max_k g\left(\sum_{i=1}^{I} \mathbf{1}_{[f(\mathbf{x}_i)\leq f(\tilde{\mathbf{x}}_k)]}\right) \\ &= Kg\left(\max_k \sum_{i=1}^{I} \mathbf{1}_{[f(\mathbf{x}_i)\leq f(\tilde{\mathbf{x}}_k)]}\right) = Kg\Big(R_{\max}(f)\Big). \end{aligned}$$

Using that ℓ is an upper bound on the 0-1 loss, we have the last inequality:

$$R_{g,\mathbf{1}}(f) = \sum_{k=1}^{K} g\left(\sum_{i=1}^{I} \mathbf{1}_{[f(\mathbf{x}_i)\leq f(\tilde{\mathbf{x}}_k)]}\right) \leq \sum_{k=1}^{K} g\left(\sum_{i=1}^{I} \ell\Big(f(\mathbf{x}_i) - f(\tilde{\mathbf{x}}_k)\Big)\right) = R_{g,\ell}(f).$$

■

The fact that the function $Kg(\frac{1}{K}r)$ is monotonic in r adds credibility to our choice of objective $R_{g,\ell}$; if $R_{g,\ell}(f)$ is minimized, causing a reduction in $Kg(\frac{1}{K}R_{\max}(f))$, then $R_{\max}(f)$ will also be reduced. Thus, Theorem 1 suggests that $R_{g,\ell}$ is a reasonable quantity to minimize in order to incorporate a push at the top, for instance, in order to diminish $R_{\max}$. Also recall that if g is especially steep, for instance $g(r) = e^r$ or $g(r) = r^p$ for p large, then $g^{-1}(\sum_{k=1}^{K} g(r_k)) \approx \max_k r_k$. That is, the quantity $g^{-1}(R_{g,\mathbf{1}})$, for steep functions g, will approximate $R_{\max}$.

For most of the paper, we are considering the power law (or "p-norm") price functions $g(r) = r^p$. By allowing the user to choose p, we allow the amount of push to be specified to match the application. At the heart of this derivation, we are using ℓ_p-norms to interpolate between the ℓ_1-norm (the AUC), and the ℓ_∞-norm (the values of $R_{\max}$). In what follows, we overload notation by defining $R_{p,\ell}$ to denote $R_{g,\ell}$ where $g(r) = r^p$:

$$R_{p,\ell}(f) := \sum_{k=1}^{K} \left(\sum_{i=1}^{I} \ell\Big(f(\mathbf{x}_i) - f(\tilde{\mathbf{x}}_k)\Big)\right)^p.$$

Thus, $R_{p,\ell}^{1/p}(f) \to R_{\max,\ell}(f)$ as $p \to \infty$, where $R_{\max,\ell}(f) := \max_k \sum_{i=1}^{I} \ell\big(f(\mathbf{x}_i) - f(\tilde{\mathbf{x}}_k)\big)$.

As we will discuss, the choice of p should depend on the number of examples. More examples are needed for generalization if a larger value of p is chosen.

3. Illustrating That It Works

In this section, we will give some examples to illustrate how the objective concentrates on the top of the list when p is large, or more generally, when g is steep.

3.1 First Illustration: Swap on the Bottom vs. Swap on the Top

For our first illustration, we aim simply to show that the objective function we have derived really does care more about the top of the list than the rest. Consider the set of examples $\mathbf{x}_1, \mathbf{x}_2, \mathbf{x}_3, \ldots, \mathbf{x}_8$ with vector of labels:

$$(-1, +1, -1, +1, -1, -1, +1, +1).$$

Consider scoring function f_{orig} which gives the scores: $f_{\text{orig}}(\mathbf{x}_i) = i$ for all i. Placing the labels in rank order of f_{orig} yields:

$$\text{labels in original rank order: } (-1 \quad +1 \quad -1 \quad +1 \quad -1 \quad -1 \quad +1 \quad +1) \ .$$

Using the power law $g(r) = r^4$ for the price function, we can compute the value of $R_{4,\mathbf{1}}(f_{\text{orig}})$ for this ranked list: $0^4 + 1^4 + 2^4 + 2^4 = 33$.

Now consider $f_{\text{swapOnBot}}$ which swaps the scores of a pair of examples at the bottom of the ranked list, $f_{\text{swapOnBot}}(\mathbf{x}_1) = 2, f_{\text{swapOnBot}}(\mathbf{x}_2) = 1$, and $f_{\text{swapOnBot}}(\mathbf{x}_i) = i$ for all other i. The new rank ordering of labels is:

$$\text{swap on the bottom: } (+1 \quad -1 \quad -1 \quad +1 \quad -1 \quad -1 \quad +1 \quad +1) \ .$$

Here a negative example is ranked above one more positive example than before. Computing the value of $R_{4,\mathbf{1}}(f_{\text{swapOnBot}})$ yields $1^4 + 1^4 + 2^4 + 2^4 = 34 > 33$; the value of $R_{4,\mathbf{1}}$ changes slightly when a swap is made at the bottom of the list, only from 33 to 34. Let us now instead consider a swap near the top of the list, so that the new set of labels is again only one swap away from the original, $f_{\text{swapOnTop}}(\mathbf{x}_6) = 7, f_{\text{swapOnTop}}(\mathbf{x}_7) = 6$, and $f_{\text{swapOnTop}}(\mathbf{x}_i) = i$ for all other i. The new ordering of labels is:

$$\text{swap on the top: } (-1 \quad +1 \quad -1 \quad +1 \quad -1 \quad +1 \quad -1 \quad +1) \ .$$

Here, the value of $R_{4,\mathbf{1}}(f_{\text{swapOnTop}})$ is $0^4 + 1^4 + 2^4 + 3^4 = 98 \gg 33$. So, in both cases only one swap was made between neighboring examples; however, the swap at the top of the list changed the objective dramatically (from 33 to 98) while the swap at the bottom hardly changed the objective at all (from 33 to 34). So, we have now illustrated that the objective function $R_{p,\mathbf{1}}(f)$ concentrates at the top of the list.

The same behavior occurs using different loss functions ℓ. This is summarized in Table 1 for three loss functions: the 0-1 loss which we have just explained, the exponential loss $\ell(r) = e^{-r}$, and the logistic loss $\ell(r) = \log(1 + e^{-r})$. (Note that using natural log for the logistic loss does not give an upper bound on the 0-1 loss, it is off by a multiplicative factor that is irrelevant in experiments.)

$\mathbf{x}_1, \mathbf{x}_2, \mathbf{x}_3, \mathbf{x}_4, \mathbf{x}_5, \mathbf{x}_6, \mathbf{x}_7, \mathbf{x}_8$ y: $(-1,+1,-1,+1,-1,-1,+1,+1)$	$R_{4,\mathbf{1}}(f)$	$R_{4,\exp}(f)$	$R_{4,\text{logistic}}(f)$
labels ordered by f_{orig} : $(-1,+1,-1,+1,-1,-1,+1,+1)$	33	17,160.17	430.79
labels ordered by $f_{\text{swapOnBot}}$: $(+1,-1,-1,+1,-1,-1,+1,+1)$	34	72,289.39	670.20
labels ordered by $f_{\text{swapOnTop}}$: $(-1,+1,-1,+1,-1,+1,-1,+1)$	98	130,515.09	1,212.23

Table 1: Values of the objective function $R_{4,\ell}$ for the three slightly different labelings, using the 0-1 loss (column $R_{4,\mathbf{1}}$), exponential loss (column $R_{4,\exp}$), and logistic loss (column $R_{4,\text{logistic}}$). The objective functions change much more in reaction to the swap at the top of the list: the values in the third row (swap on the top) are significantly higher than those in the second row (swap on the bottom).

3.2 A Second Illustration: Reversal of Polarity

Let us assume we want to choose a scoring function f by minimizing our objective $R_{p,\ell}(f)$ over $f \in \mathcal{F}$ where $\mathcal{F}$ has only two functions, $\mathcal{F} = \{f_1, f_2\}$. This is an interesting experiment in which there are only 2 choices available for the function f: the first concentrates on the top of the ranked list, but performs poorly on the rest, whereas the second performs badly on the top of the ranked list, but performs well over all. In fact, the second scoring function f_2 is exactly a negation of the first scoring function f_1. Here are the labels and hypotheses:

labels	$+1$	$+1$	-1	-1	-1	-1	-1	$+1$	$+1$	$+1$	$+1$	$+1$	-1	-1	
f_1 :	(14	13	12	11	10	9	8	7	6	5	4	3	2	1	)/14
f_2 :	$(-14$	-13	-12	-11	-10	-9	-8	-7	-6	-5	-4	-3	-2	-1	)/14

Here, f_1 performs well at the top of the list (the two top-scoring examples are positive), but the whole middle of the list is reversed; there are 5 negative examples in a row, and below that 5 positives. On the other hand, f_2 misses the top two examples which have scores -1/14 and -2/14, however, the 10 middle examples are correctly ranked. f_2 has a larger AUC than f_1, but f_1 is better at the top of the list. Now, which of f_1 and f_2 would the misranking objectives from Section 2 prefer? Let us answer this for various $R_{p,\ell}$, for different p and ℓ. Specifically, we will demonstrate that as p becomes larger, $R_{p,\ell}$ prefers the first hypothesis which performs better at the top. Table 2 shows values of $R_{p,\ell}$ for three different loss functions and for various values of p. This table shows that for smaller p, f_2 is preferred. At some value of p, the "polarity" reverses and then f_1 is preferred. So, using steeper price functions means that we are more likely to prefer scoring functions that perform well at the top of the list.

p	$R_{p,\mathbf{1}}(f_1)$	$R_{p,\mathbf{1}}(f_2)$	$\operatorname{argmin}_{f\in\{f_1,f_2\}} R_{p,\mathbf{1}}(f)$	$R_{p,\exp}(f_1)$	$R_{p,\exp}(f_2)$	$\operatorname{argmin}_{f\in\{f_1,f_2\}} R_{p,\exp}(f)$
1	25	24	f_2	50.25	49.80	f_2
2	125	118	f_2	367.39	362.35	f_2
3	625	726	f_1	$2.73*10^3$	$2.70*10^3$	f_2

10	$7.98*10^7$	$8.74*10^7$	f_1

Table 2: This table shows that as the price function gets steeper (as p increases), the scoring function f_1 that performs better on the top of the list is preferred. We show the values for each of the objectives $R_{p,\mathbf{1}}, R_{p,\exp}$ and $R_{p,\text{logistic}}$ for $p = 1,\ldots,10$ applied to f_1 (first column) and f_2 (second column). The third column shows which of the two scoring functions f_1 or f_2 achieve a lower value of the objective.

3.3 Third Illustration: Contribution of Each Positive-Negative Pair

Consider the following list of labels and function values :

$$\begin{array}{rl} y: & (1\ \ 1\ -1\ \ 1\ \ 1\ -1\ \ 1\ \ 1\ -1\ \ 1\ \ 1\ -1\ \ 1\ \ 1\ -1\ -1\ -1) \\ f: & (20\ 19\ 18\ 17\ 16\ 15\ 14\ 13\ 12\ 11\ 10\ \ 9\ \ 8\ \ 7\ \ 6\ \ 5\ \ 4\ \ 3\ \ 2\ \ 1)/20 \end{array}$$

Figure 1 illustrates the amount that each positive-negative pair contributes to $R_{p,\exp}$ for various values of p. We aim to show that $R_{p,\exp}$ becomes more influenced by the highest scoring negative examples as p is increased. On the vertical axis are the positive examples $i = 1,\ldots,12$ ordered by score, with the highest scoring examples at the bottom. On the horizontal axis are the negative examples $k = 1,\ldots,8$ ordered by score, with the highest scoring examples on the

left. The value of the $(i,k)^{th}$ entry is the contribution of the k^{th} highest scoring negative example, $\left(\sum_{\bar{i}} e^{-(f(\mathbf{x}_{\bar{i}})-f(\tilde{\mathbf{x}}_k))}\right)^p$, multiplied by the proportion attributed to the i^{th} highest scoring positive example, $e^{-(f(\mathbf{x}_i)-f(\tilde{\mathbf{x}}_k))} / \sum_{\bar{i}} e^{-(f(\mathbf{x}_{\bar{i}})-f(\tilde{\mathbf{x}}_k))}$. As we adjust the value of p, one can see that most of the contribution shifts towards the left, or equivalently, towards the highest scoring negative examples.

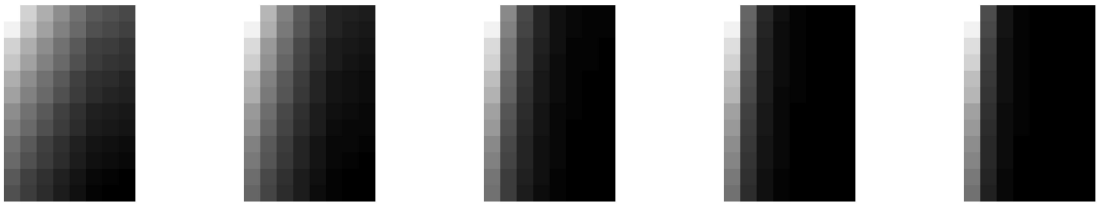

Figure 1: Contribution of each positive-negative pair to the objective $R_{p,\exp}$. Each square represents an i,k pair, where i is an index along the vertical axis, and k is along the horizontal axis. Lighter colors indicate larger contributions to $R_{p,\exp}$. The upper left corner represents the highest (worst) ranked negative and the lowest (worst) ranked positive.

4. A Generalization Bound for $R_{p,\mathbf{1}}$

We present two bounds, where the second has better dependence on p than the first. A preliminary version of the first bound appears in the conference version of this paper (Rudin, 2006). This work is inspired by the works of Koltchinskii and Panchenko (2002), Cucker and Smale (2002), and Bousquet (2003).

Assume that the positive instances $\mathbf{x}_i \in \mathcal{X}$, $i = 1,...,I$ are chosen independently and at random (iid) from a fixed but unknown probability distribution $\mathcal{D}_+$ on $\mathcal{X}$. Assume the negative instances $\tilde{\mathbf{x}}_k \in \mathcal{X}$, $k = 1,...,K$ are chosen iid from $\mathcal{D}_-$. The notation $\mathbf{x} \sim \mathcal{D}$ means $\mathbf{x}$ is chosen randomly according to distribution $\mathcal{D}$. The notation $S_+ \sim \mathcal{D}_+^I$ means each of the I elements of the training set S_+ are chosen independently at random according to $\mathcal{D}_+$. Similarly for $S_- \sim \mathcal{D}_-^K$.

We now define the "true" objective function for the underlying distribution:

$$\begin{aligned} R^{\text{true}}_{p,\mathbf{1}}(f) &:= \left(\mathbb{E}_{\mathbf{x}_-\sim\mathcal{D}_-}\left(\mathbb{E}_{\mathbf{x}_+\sim\mathcal{D}_+}\mathbf{1}_{[f(\mathbf{x}_+)-f(\mathbf{x}_-)\le 0]}\right)^p\right)^{1/p} \\ &= \left\|\mathbb{P}_{\mathbf{x}_+\sim\mathcal{D}_+}\left(f(\mathbf{x}_+)-f(\mathbf{x}_-)\le 0|\mathbf{x}_-\right)\right\|_{L_p(\mathcal{X}_-,\mathcal{D}_-)}. \end{aligned}$$

The empirical loss associated with $R^{\text{true}}_{p,\mathbf{1}}(f)$ is the following:

$$R^{\text{empirical}}_{p,\mathbf{1}}(f) := \left(\frac{1}{K}\sum_{k=1}^{K}\left(\frac{1}{I}\sum_{i=1}^{I}\mathbf{1}_{[f(\mathbf{x}_i)-f(\tilde{\mathbf{x}}_k)\le 0]}\right)^p\right)^{1/p}.$$

Here, for a particular $\tilde{\mathbf{x}}_k$, $R^{\text{empirical}}_{p,\mathbf{1}}(f)$ takes into account the average number of positive examples that have scores below $\tilde{\mathbf{x}}_k$. It is a monotonic function of $R_{p,\mathbf{1}}$. To make this notion more general, let

us consider the average number of positive examples that have scores that are *close to* or below $\tilde{\mathbf{x}}_k$. A more general version of $R^{\text{empirical}}_{p,\mathbf{1}}(f)$ is thus defined as:

$$R^{\text{empirical}}_{p,\mathbf{1},\theta}(f) := \left(\frac{1}{K} \sum_{k=1}^{K} \left(\frac{1}{I} \sum_{i=1}^{I} \mathbf{1}_{[f(\mathbf{x}_i) - f(\tilde{\mathbf{x}}_k) \leq \theta]} \right)^p \right)^{1/p}.$$

This terminology incorporates the "margin" value θ. As before, we suffer some loss whenever positive example $\mathbf{x}_i$ is ranked below negative example $\tilde{\mathbf{x}}_k$, but now we also suffer loss whenever $\mathbf{x}_i$ and $\tilde{\mathbf{x}}_k$ have scores within θ of each other. Note that $R^{\text{empirical}}_{p,\mathbf{1},\theta}$ is an empirical quantity, so it can be measured for any θ. We will state two bounds, proved in Section 10, where the second is tighter than the first. The first bound is easier to understand and is a direct corollary of the second bound.

Theorem 2 *(First Generalization Bound) For all $\varepsilon > 0, p \geq 1, \theta > 0$, the probability over random choice of training set, $S_+ \sim \mathcal{D}_+^I, S_- \sim \mathcal{D}_-^K$ that there exists an $f \in \mathcal{F}$ such that*

$$R^{\text{true}}_{p,\mathbf{1}}(f) \geq R^{\textit{empirical}}_{p,\mathbf{1},\theta}(f) + \varepsilon$$

is at most:

$$2\mathcal{N}\left(\mathcal{F}, \frac{\varepsilon\theta}{8}\right) \left(\exp\left[-2 \left(\frac{\varepsilon}{4}\right)^{2p} K \right] + \exp\left[-\frac{\varepsilon^2}{8} I + \ln K \right] \right).$$

Here the covering number $\mathcal{N}(\mathcal{F}, \varepsilon)$ is defined as the number of ε-sized balls needed to cover $\mathcal{F}$ in L_∞, and it is used here as a complexity measure for $\mathcal{F}$. This expression states that, provided I and K are large, then with high probability, the true error $R^{\text{true}}_{p,\mathbf{1}}(f)$ is not too much more than the empirical error $R^{\text{empirical}}_{p,\mathbf{1},\theta}(f)$.

It is important to note the implications of this bound for scalability. More examples are required for larger p. This is because we are concentrating on a small portion of input space corresponding to the top of the ranked list. If most of the value of $R^{\text{true}}_{p,\mathbf{1}}$ comes from a small portion of input space, it is necessary to have more examples in that part of the space in order to estimate its value with high confidence. The fact that more examples are required for large p can affect performance in practice. A 1-dimensional demonstration of this fact is given at the end of Section 10.

Theorem 2 shows that the dependence on p is important for generalization. The following theorem shows that in most circumstances, we have much better dependence on p. Specifically, the dependence can be shifted from $-\varepsilon^{2p}$ in the exponential to a factor related to $-\varepsilon^2 \left(\inf_f R^{\text{true}}_{p,\mathbf{1}}(f) \right)^{2(p-1)}$. The bound becomes much tighter than Theorem 2 when all hypotheses have a large enough true risk, that is, when $\inf_f R^{\text{true}}_{p,\mathbf{1}}(f)$ is large compared to ε.

Theorem 3 *(Second Generalization Bound) For all $\varepsilon > 0, p \geq 1, \theta > 0$, the probability over random choice of training set, $S_+ \sim \mathcal{D}_+^I, S_- \sim \mathcal{D}_-^K$ that there exists an $f \in \mathcal{F}$ such that*

$$R^{\text{true}}_{p,\mathbf{1}}(f) \geq R^{\textit{empirical}}_{p,\mathbf{1},\theta}(f) + \varepsilon$$

is at most:

$$2\mathcal{N}\left(\mathcal{F}, \frac{\varepsilon\theta}{8}\right) \left(\exp\left[-2K \max\left\{ \frac{\varepsilon^2}{16} \left(R_{p,\min}\right)^{2(p-1)}, \left(\frac{\varepsilon}{4}\right)^{2p} \right\} \right] + \exp\left[-\frac{\varepsilon^2}{8} I + \ln K \right] \right).$$

where $R_{p,\min} := \inf_{f \in \mathcal{F}} R^{\text{true}}_{p,\mathbf{1}}(f)$.

The proof is in Section 10. The dependence on p is now much better than in Theorem 2. It is possible that the bound can be tightened in other ways, for instance, to use a different type of covering number. For instance, one might use the "sloppy covering number" in Rudin and Schapire (2009)'s ranking bound, which is adapted from the classification bound of Schapire et al. (1998).

The purpose of Theorems 2 and 3 is to provide the theoretical justification required for our choice of objective, provided a sufficient number of training examples. Having completed this, let us now write an algorithm for minimizing that objective.

5. A Boosting-Style Algorithm

We now choose a specific form for our objective $R_{g,\ell}$ by choosing ℓ. We have already chosen g to be a power law, $g(r) = r^p$. From now on, ℓ will be the exponential loss $\ell(r) = e^{-r}$. One could just as easily choose another loss; we choose the exponential loss in order to compare with RankBoost. The objective when $p = 1$ is exactly that of RankBoost, whose global objective is $R_{1,\exp}$. Here is the objective function, $R_{p,\exp}$ for $p \geq 1$:

$$R_{p,\exp}(f) := \sum_{k=1}^{K} \left(\sum_{i=1}^{I} e^{-(f(\mathbf{x}_i) - f(\tilde{\mathbf{x}}_k))} \right)^p .$$

The function f is constructed as a linear combination of "weak rankers" or "ranking features," $\{h_j\}_{j=1,\ldots,n}$, with $h_j : \mathcal{X} \to [0,1]$ so that $f = \sum_j \lambda_j h_j$, where $\boldsymbol{\lambda} \in \mathcal{R}^n$. Thus, the hypothesis space $\mathcal{F}$ is the class of convex combinations of weak rankers. Our objective is now $R_{p,\exp}(\boldsymbol{\lambda})$:

$$R_{p,\exp}(\boldsymbol{\lambda}) := \sum_{k=1}^{K} \left(\sum_{i=1}^{I} e^{-\left(\sum_j \lambda_j h_j(\mathbf{x}_i) - \sum_j \lambda_j h_j(\tilde{\mathbf{x}}_k)\right)} \right)^p = \sum_{k=1}^{K} \left(\sum_{i=1}^{I} e^{-(\mathbf{M}\boldsymbol{\lambda})_{ik}} \right)^p ,$$

where we have rewritten in terms of a matrix $\mathbf{M}$, which describes how each individual weak ranker j ranks each positive-negative pair $\mathbf{x}_i, \tilde{\mathbf{x}}_k$; this will make notation significantly easier. Define an index set that enumerates all positive-negative pairs $\mathcal{C}_p = \{ik : i \in 1,\ldots,I, k \in 1,\ldots,K\}$ where index ik corresponds to the i^{th} positive example and the k^{th} negative example. Formally,

$$M_{ik,j} := h_j(\mathbf{x}_i) - h_j(\tilde{\mathbf{x}}_k).$$

The size of $\mathbf{M}$ is $|\mathcal{C}_p| \times n$. The notation $(\cdot)_a$ means the a^{th} index of the vector, that is,

$$(\mathbf{M}\boldsymbol{\lambda})_{ik} := \sum_{j=1}^{n} M_{ik,j}\lambda_j = \sum_{j=1}^{n} \lambda_j h_j(\mathbf{x}_i) - \lambda_j h_j(\tilde{\mathbf{x}}_k).$$

The function $R_{p,\exp}(\boldsymbol{\lambda})$ is convex in $\boldsymbol{\lambda}$. This is because $e^{-(\mathbf{M}\boldsymbol{\lambda})_{ik}}$ is a convex function of $\boldsymbol{\lambda}$, any sum of convex functions is convex, and a composition of an increasing convex function with a convex function is convex. (Note that $R_{p,\exp}(\boldsymbol{\lambda})$ is convex but not necessarily strictly convex.)

We now derive a boosting-style coordinate descent algorithm for minimizing $R_{p,\exp}$ as a function of $\boldsymbol{\lambda}$. At each iteration of the algorithm, the coefficient vector $\boldsymbol{\lambda}$ is updated. At iteration t, we denote the coefficient vector by $\boldsymbol{\lambda}_t$. There is much background material available on the convergence of similar coordinate descent algorithms (for instance, see Zhang and Yu, 2005). We start with the objective at iteration t:

$$R_{p,\exp}(\boldsymbol{\lambda}_t) := \sum_{k=1}^{K} \left(\sum_{i=1}^{I} e^{(-\mathbf{M}\boldsymbol{\lambda}_t)_{ik}} \right)^p .$$

We then compute the variational derivative along each "direction" and choose weak ranker j_t to have largest absolute variational derivative. The notation $\mathbf{e}_j$ means a vector of 0's with a 1 in the j^{th} entry.

$$j_t \in \operatorname*{argmax}_j \left[-\frac{dR_{p,\exp}(\boldsymbol{\lambda}_t + \alpha \mathbf{e}_j)}{d\alpha}\Big|_{\alpha=0} \right], \text{ where}$$

$$\frac{dR_{p,\exp}(\boldsymbol{\lambda}_t + \alpha \mathbf{e}_j)}{d\alpha}\Big|_{\alpha=0} = p \sum_{k=1}^{K} \left[\left(\sum_{i=1}^{I} e^{(-\mathbf{M}\boldsymbol{\lambda}_t)_{ik}} \right)^{p-1} \left(\sum_{i=1}^{I} -M_{ik,j} e^{-(\mathbf{M}\boldsymbol{\lambda}_t)_{ik}} \right) \right].$$

Define the vector $\mathbf{q}_t$ on pairs i,k as $q_{t,ik} := e^{(-\mathbf{M}\boldsymbol{\lambda}_t)_{ik}}$, and the weight vector $\mathbf{d}_t$ as $d_{t,ik} := q_{t,ik} / \sum_{ik} q_{t,ik}$. Our choice of j_t becomes (ignoring constant factors that do not affect the argmax):

$$\begin{aligned} j_t \quad &\in \quad \operatorname*{argmax}_j \sum_{k=1}^{K} \left[\left(\sum_{i=1}^{I} d_{t,ik} \right)^{p-1} \sum_{i=1}^{I} d_{t,ik} M_{ik,j} \right] \\ &= \quad \operatorname*{argmax}_j \sum_{ik} \tilde{d}_{t,ik} M_{ik,j}, \text{ where } \tilde{d}_{t,ik} = d_{t,ik} \left(\sum_{i'} d_{t,i'k} \right)^{p-1}. \end{aligned}$$

To update the coefficient of weak ranker j_t, we now perform a linesearch for the minimum of $R_{p,\exp}$ along the j_t^{th} direction. The distance to travel in the j_t^{th} direction, denoted α_t, solves $0 = \frac{dR_{p,\exp}(\boldsymbol{\lambda}_t + \alpha \mathbf{e}_{j_t})}{d\alpha}\Big|_{\alpha_t}$. Ignoring division by constants, this equation becomes:

$$0 = \sum_{k=1}^{K} \left[\left(\sum_{i=1}^{I} d_{t,ik} e^{-\alpha_t M_{ik,j_t}} \right)^{p-1} \left(\sum_{i=1}^{I} M_{ik,j_t} d_{t,ik} e^{-\alpha_t M_{ik,j_t}} \right) \right]. \tag{1}$$

The value of α_t can be computed analytically in some cases, for instance, when the weak rankers are binary-valued and $p = 1$ (this is RankBoost). Otherwise, we simply use a linesearch to solve this equation for α_t. To complete the algorithm, we set $\boldsymbol{\lambda}_{t+1} = \boldsymbol{\lambda}_t + \alpha_t \mathbf{e}_{j_t}$. To avoid having to compute $\mathbf{d}_{t+1}$ directly from $\boldsymbol{\lambda}_t$, we can perform the update by:

$$d_{t+1,ik} = \frac{d_{t,ik} e^{-\alpha_t M_{ik,j_t}}}{z_t} \quad \text{where} \quad z_t := \sum_{ik} d_{t,ik} e^{-\alpha_t M_{ik,j_t}}.$$

The full algorithm is shown in Figure 2. This implementation is not optimized for very large data sets since the size of $\mathbf{M}$ is $|C_p| \times n$. Note that the weak learning part of this algorithm in Step 3(a), when written in this form, is the same as for AdaBoost and RankBoost. Thus, any current implementation of a weak learning algorithm for AdaBoost or RankBoost can be directly used for the P-Norm Push.

6. Uniqueness of the Minimizer

We now show that a function $f = \sum_j \lambda_j h_j$ (or limit of functions) minimizing our objective is unique in some sense. Since $\mathbf{M}$ is not required to be invertible (and often is not), we cannot expect to find a unique vector $\boldsymbol{\lambda}$; one may achieve the identical values of $(\mathbf{M}\boldsymbol{\lambda})_{ik}$ with different choices of $\boldsymbol{\lambda}$. It is also true that elements of $\boldsymbol{\lambda}_t$ may approach $\pm\infty$, and furthermore, elements of $\mathbf{M}\boldsymbol{\lambda}_t$ often approach

1. **Input:** $\{\mathbf{x}_i\}_{i=1,...,I}$ positive examples, $\{\tilde{\mathbf{x}}_k\}_{k=1,...,K}$ negative examples, $\{h_j\}_{j=1,...,n}$ weak classifiers, $t_{\max}$ number of iterations, p power.

2. **Initialize:** $\lambda_{1,j} = 0$ for $j = 1,...,n$, $d_{1,ik} = 1/IK$ for $i = 1,...,I, k = 1,...,K$ $M_{ik,j} = h_j(\mathbf{x}_i) - h_j(\tilde{\mathbf{x}}_k)$ for all i,k,j

3. **Loop for** $t = 1,...,t_{\max}$

   (a) $j_t \in \text{argmax}_j \sum_{ik} \tilde{d}_{t,ik} M_{ik,j}$ where $\tilde{d}_{t,ik} = d_{t,ik} \left(\sum_{i'} d_{t,i'k}\right)^{p-1}$

   (b) Perform a linesearch for α_t. That is, find a value α_t that solves (1).

   (c) $\boldsymbol{\lambda}_{t+1} = \boldsymbol{\lambda}_t + \alpha_t \mathbf{e}_{j_t}$, where $\mathbf{e}_{j_t}$ is 1 in position j_t and 0 elsewhere.

   (d) $z_t = \sum_{ik} d_{t,ik} e^{-\alpha_t M_{ik,j_t}}$

   (e) $d_{t+1,ik} = d_{t,ik} e^{-\alpha_t M_{ik,j_t}} / z_t$ for $i = 1,...,I, k = 1,...,K$

4. **Output:** $\boldsymbol{\lambda}_{t_{\max}}$

Figure 2: Pseudocode for the "P-Norm Push" algorithm.

$+\infty$, so it would seem difficult to prove (or even define) uniqueness. A trick that comes in handy for such situations is to use the closure of the space $Q' := \{\mathbf{q}' \in \mathcal{R}_+^{IK} | q'_{ik} = e^{-(\mathbf{M}\boldsymbol{\lambda})_{ik}} \text{ for some } \boldsymbol{\lambda} \in \mathcal{R}^n\}$. The closure of Q' includes the limits where $\mathbf{M}\boldsymbol{\lambda}_t$ becomes infinite, and considers the linear combination of hypotheses $\mathbf{M}\boldsymbol{\lambda}$ rather than $\boldsymbol{\lambda}$ itself, so it does not matter whether $\mathbf{M}$ is invertible. With the help of convex analysis, we will be able to show that our objective function yields a unique minimizer in the closure of Q'. Here is our uniqueness theorem:

Theorem 4 *Define* $Q' := \{\mathbf{q}' \in \mathcal{R}_+^{IK} | q'_{ik} = e^{-(\mathbf{M}\boldsymbol{\lambda})_{ik}} \text{ for some } \boldsymbol{\lambda} \in \mathcal{R}^n\}$ *and define* $\bar{Q}'$ *as the closure of* Q' *in* $\mathcal{R}^{IK}$. *Then for* $p \geq 1$, *there is a unique* $\mathbf{q}'^* \in \bar{Q}'$ *where:*

$$\mathbf{q}'^* = \text{argmin}_{\mathbf{q}' \in \bar{Q}'} \sum_k \left(\sum_i q'_{ik} \right)^p .$$

Our uniqueness proof depends mainly on the theory of convex duality for a class of Bregman distances, as defined by Della Pietra et al. (2002). This proof is inspired by Collins et al. (2002) who have proved uniqueness of this type for AdaBoost. In the case of AdaBoost, the primal optimization problem corresponds to a minimization over relative entropy. Our case is more unusual and the primal is not a common function. The proof of Theorem 4 is located in Section 11.

7. Variations of the Objective and Relationship to Information Retrieval Measures

It is possible to use variations of our basic derivation in Section 2 to derive other specialized objectives. Some of these objectives are similar to current popular quality measurements from information retrieval (IR), such as the "discounted cumulative gain" (DCG) (Järvelin and Kekäläinen, 2000). A basic property of this quality measurement, and additionally the average precision (the mean of precision values), is that it is proportional to a sum over relevant documents (which are the

positive examples in this setting), and uses a discounting factor that decreases according to the rank of a relevant document. The discounting factor here is analogous to the price function. Let us use the framework we have developed to derive new quality measurements with these properties.

Our derivation in Section 2 is designed to push the highly ranked negative examples down. Rearranging this argument, we can also pull the positive examples up, using the "reverse height." The reverse height of positive example i is the number of negative examples ranked above it.

$$\text{Reverse Height}(i) := \sum_k \mathbf{1}_{[f(\mathbf{x}_i) \leq f(\tilde{\mathbf{x}}_k)]}.$$

The reverse height is very similar to the rank used in the IR quality measurements. The reverse height only considers the relationship of the positives to the negatives, and disregards the relationship of positives to each other. Precisely, define:

$$\text{Rank}(i) := \sum_k \mathbf{1}_{[f(\mathbf{x}_i) \leq f(\tilde{\mathbf{x}}_k)]} + \sum_{\tilde{i}} \mathbf{1}_{[f(\mathbf{x}_i) \leq f(\mathbf{x}_{\tilde{i}})]} = \text{Reverse Height}(i) + \sum_{\tilde{i}} \mathbf{1}_{[f(\mathbf{x}_i) \leq f(\mathbf{x}_{\tilde{i}})]}.$$

The rank can often be substituted for the reverse height. For discounting factor $g : \mathcal{R}_+ \to \mathcal{R}_+$, consider the variations of our objective:

$$R_{g,\mathbf{1}}^{\text{Reverse Height}}(f) = \sum_i g\left(\text{Reverse Height}(i)\right) = \sum_i g\left(\sum_k \mathbf{1}_{[f(\mathbf{x}_i) \leq f(\tilde{\mathbf{x}}_k)]}\right).$$

$$R_{g,\mathbf{1}}^{\text{Rank}}(f) = \sum_i g\left(\text{Rank}(i)\right) = \sum_i g\left(\sum_k \mathbf{1}_{[f(\mathbf{x}_i) \leq f(\tilde{\mathbf{x}}_k)]} + \sum_{\tilde{i}} \mathbf{1}_{[f(\mathbf{x}_i) \leq f(\mathbf{x}_{\tilde{i}})]}\right).$$

Then, one might maximize $R_{g,\mathbf{1}}^{\text{Rank}}$ for various g. The function g should achieve the largest values for the positive examples i that possess the smallest reverse heights or ranks, since those are at the top of the list. It should thus be a decreasing function with steep negative slope near the y-axis. Choosing $g(z) = 1/z$ gives the average value of $1/\text{rank}$. Choosing $g(z) = 1/\ln(1+z)$ gives the discounted cumulative gain:

$$\text{AveR}(f) = \sum_i \frac{1}{\text{Rank}(i)} = \sum_i \frac{1}{\sum_k \mathbf{1}_{[f(\mathbf{x}_i) \leq f(\tilde{\mathbf{x}}_k)]} + \sum_{\tilde{i}} \mathbf{1}_{[f(\mathbf{x}_i) \leq f(\mathbf{x}_{\tilde{i}})]}},$$

$$\text{DCG}(f) = \sum_i \frac{1}{\ln\left(1 + \text{Rank}(i)\right)} = \sum_i \frac{1}{\ln\left(1 + \sum_k \mathbf{1}_{[f(\mathbf{x}_i) \leq f(\tilde{\mathbf{x}}_k)]} + \sum_{\tilde{i}} \mathbf{1}_{[f(\mathbf{x}_i) \leq f(\mathbf{x}_{\tilde{i}})]}\right)}.$$

Let us consider the practical implications of minimizing the negation of the DCG. The discounting function $1/\ln(1+z)$ is decreasing, but its negation is not convex so there is no optimization guarantee. This is true even if we incorporate the exponential loss since $-1/\ln(1+e^z)$ is not convex. The same observation holds for the AveR.

It is possible, however, to choose a different discounting factor that allows us to create a convex objective to minimize. Let us choose a discounting factor of $-\ln(1+z)$, which is similar to the discounting factors for the AveR and DCG in that it is decreasing and convex. Figure 3 illustrates these discounting factors. Using this new discounting factor, and using the reverse height rather than the rank (which is an arbitrary choice), we arrive at the following objective:

$$R_{g_{\text{IR}},\mathbf{1}}(f) := \sum_i \ln\left(1 + \sum_k \mathbf{1}_{[f(\mathbf{x}_i) \leq f(\tilde{\mathbf{x}}_k)]}\right),$$

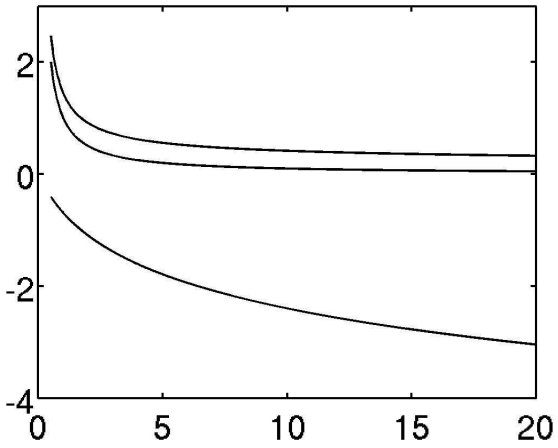

Figure 3: Discounting factor for discounted cumulative gain $1/\ln(1+z)$ (upper curve), discounting factor for the average of the reciprocal of the ranks $1/z$ (middle curve), and new discounting factor $-\ln(1+z)$ (lower curve) versus z.

and bounding the 0-1 loss from above,

$$R_{g_{\mathrm{IR}},\exp}(f) := \sum_i \ln\left(1+\sum_k e^{-(f(\mathbf{x}_i)-f(\tilde{\mathbf{x}}_k))}\right). \qquad \text{“IR Push”} \tag{2}$$

Equation (2) is our version of IR-ranking measures, which we refer to by “IR Push” in Section 8. It is also very similar in essence to the objective for the multilabel problem defined by Dekel et al. (2004). The objective (2) is globally convex. In general, one must be careful when defining discounting factors in order to avoid non-convexity. Figure 4 illustrates the contribution of each positive-negative pair to $R_{g_{\mathrm{IR}},\exp}(f)$ for the set of labels and examples defined in Section 3.3. The slant towards the lower left indicates that this objective is biased towards the top of the list.

Concentrating on the Bottom: Since our objective concentrates at the top of the ranked list, it can just as easily be made to concentrate on the bottom of the ranked list by reversing the positive and negative examples, or equivalently, by using the reverse height with a discounting factor of $-z^p$. In this case, our p-norm objective becomes:

$$R^{\mathrm{Bottom}}_{p,\exp}(f) := \sum_{i=1}^{I}\left(\sum_{k=1}^{K} e^{-(f(\mathbf{x}_i)-f(\tilde{\mathbf{x}}_k))}\right)^p.$$

Here, positive examples that score very badly are heavily penalized. $R^{\mathrm{Bottom}}_{p,\exp}(f)$ is also convex, so it can be easily minimized. Also, one can now write an objective that concentrates on the top and bottom simultaneously such as $R_{p,\exp}(f) + \text{const}\, R^{\mathrm{Bottom}}_{p,\exp}(f)$.

Crucial Pairs Formulation: The bipartite ranking problem is a specific case of the pairwise ranking problem. For the more general problem, the labels are replaced by a “truth function” $\pi : \mathcal{X} \times \mathcal{X} \rightarrow$

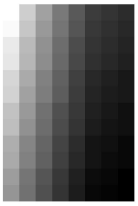

Figure 4: Contribution of each positive-negative pair to the objective $R_{g_{IR},\exp}$. Each square represents an i,k pair, where i is an index along the vertical axis, and k is along the horizontal axis, as described in Section 3.3. Lighter colors indicate larger contribution. The value of the i,k^{th} entry is the contribution of the i^{th} positive example, $\ln\left(1+\sum_k e^{-(f(\mathbf{x}_i)-f(\bar{\mathbf{x}}_k))}\right)$, multiplied by the proportion of the loss attributed to the k^{th} negative example, $e^{-(f(\mathbf{x}_i)-f(\bar{\mathbf{x}}_k))}/\sum_{\bar{k}} e^{-(f(\mathbf{x}_i)-f(\bar{\mathbf{x}}_{\bar{k}}))}$.

$\{0,1\}$, indicating whether the first element of the pair should be ranked above the second. In this case, one can replace the objective by:

$$R_{g,\ell}^{\text{Crucial Pairs}}(f) := \sum_{k=1}^{m} g\left(\sum_{i=1}^{m} \ell\Big(f(\mathbf{x}_i)-f(\mathbf{x}_k)\Big)\pi(\mathbf{x}_i,\mathbf{x}_k)\right),$$

where the indices i and k now run over all training examples. A slightly more general version of the above formula for $g(z)=z^p$ and the exponential loss was used by Ji et al. (2006) for the natural language processing problem of named entity recognition in Chinese. This algorithm performed quite well, in fact, within the margin of error of the best algorithm, but with a much faster training time. Its performance was substantially better than the support vector machine algorithm tested for this experiment. In Ji et al. (2006)'s setup, the P-Norm Push was used twice; the first time, a low value of p was chosen and a cutoff was made. The algorithm was used again for re-ranking (after some additional processing) with a higher value of p.

8. Experiments

The experiments of Ji et al. (2006) indicate the usefulness of our approach for larger, real-world problems. In this section, we will discuss the performance of the P-Norm Push on some smaller problems, since smaller problems are challenging when it comes to generalization. The choices we have made in Section 5 allow us to compare with RankBoost, which also uses the exponential loss. Furthermore, the choice of g as an adjustable power law allows us to illustrate the effect of the price g on the quality of the solution. Experiments have been performed using the P-Norm Push for $p=1$ (RankBoost), $2,4,8,16$ and 64, and using the IR Push information retrieval objective (2). For the P-Norm Push, the linesearch for α_t was performed using matlab's "fminunc" subroutine. The total number of iterations, $t_{\max}$, was fixed at 100 for all experiments. For the information retrieval objective, "fminunc" was used for the full optimization, which can be done for small experiments. Data were obtained from the UCI machine learning repository (Asuncion and Newman, 2007) and

all features were normalized to $[0,1]$. The three data sets chosen were MAGIC, ionosphere, and housing.

The first experiment uses the UCI MAGIC data set, which contains data from the Major Atmospheric Gamma Imaging Cherenkov Telescope project. The goal is to discriminate the statistical signatures of Monte Carlo simulated "gamma" particles from simulated "hadron" particles. In this problem, there are several relevant points on the ROC curve that determine the quality of the result. These points correspond to different acceptable false positive rates for different experiments, and all are close to the top of the list. There are 19020 examples (12332 gamma and 6688 hadron) and 11 features. Positive examples represent gamma particles and negative examples represent hadron particles. As a sample run, we chose 1000 examples randomly for training and tested on the rest.

Table 3 shows how different algorithms (the columns) performed with respect to different quality measures (the rows) on the MAGIC data. Each column of Table 3 represents a P-Norm Push or IR Push trial. The quality of the results is measured using the AUC (top row, larger values are better), $R_{p,\mathbf{1}}$ for various p (middle rows, smaller values are better), and the DCG and AveR (bottom rows, larger values are better). The best algorithms for each measure are summarized in bold and in the rightmost column. ROC curves and zoomed-in versions of the ROC curves for this sample run are shown in Figure 5. We expect the P-Norm Push for small p to yield the best results for

MAGIC data set

measure	p=1	p=2	p=4	p=8	p=16	p=64	IR	best
AUC	0.8370	**0.8402**	**0.8397**	0.8363	0.8329	0.8288	0.8284	small p
$R_{2,\mathbf{1}}$	6.5515	5.9731	5.5896	**5.4806**	**5.4990**	5.5819	5.5886	medium p

$R_{8,\mathbf{1}}$	3.8830	2.9138	2.1091	1.6266	1.3923	**1.2396**	**1.2257**	IR / large p
$R_{16,\mathbf{1}}$	6.8153	4.7208	3.0545	1.9698	1.4494	**1.1096**	**1.0823**	IR / large p
DCG	1.4022	1.4048	1.4066	1.4084	**1.4087**	**1.4087**	**1.4087**	IR / large p
AveR	8.1039	8.5172	8.6860	9.6701	**9.7520**	**9.7679**	**9.7688**	IR / large p

Table 3: Test performance of minimizers of $R_{p,\text{exp}}$ and $R_{g_{IR},\text{exp}}$ on a sample run with the MAGIC data set. Only significant digits are kept (factors of 10 have been removed). The best scores in each row are in bold and the right column summarizes the result by listing which algorithms performed the best with respect to each quality measure.

optimizing AUC, and we expect the large p and IR columns to yield the best results for $R_{p,\mathbf{1}}$ when p is large, and for the DCG and AveR. In other words, the rightmost column ought to say "small p" towards the top, followed by "medium p," and then "IR / large p." This general trend is observed. In this particular trial run, the IR Push and P-Norm Push for $p = 64$ yielded almost identical results, and their ROC curves are almost on top of each other in Figure 5.

The next experiment uses a much smaller data set, namely the UCI ionosphere data set, which has 351 examples (225 positive and 126 negative). These are data collected from a phased array of antennas. The goal is to distinguish "good" radar returns from "bad" radar returns. The good returns represent signals that reflect back towards the antenna, indicating structure in the ionosphere. The features are based on characteristics of the received signal. Out of the 34 features, we choose 5 of them (the last 5 features), which helps to alleviate overfitting, though there is still significant variation in results due to the small size of the data set. We used 3-fold cross-validation, where all

algorithms were run once on each split, and the mean performance is reported in Table 4. ROC curves from one of the trials is presented in Figure 6. The trend from small to large p is able to be observed, despite variation due to train/test splits.

Table 4: Mean test performance of minimizers of $R_{p,\text{exp}}$ and $R_{g_{IR},\text{exp}}$ over 3-fold cross-validation on the ionosphere data set.

We last consider the Boston Housing data set, which has 506 examples (35 positive, 471 negative), 13 features. This data set is skewed; there are significantly fewer positive examples than negative examples. In order to use the housing data set for a bipartite ranking problem, we used the fourth feature (which is binary) as the label y. The fourth feature describes whether a tract bounds the Charles River. Since there is some correlation between this feature and the other features

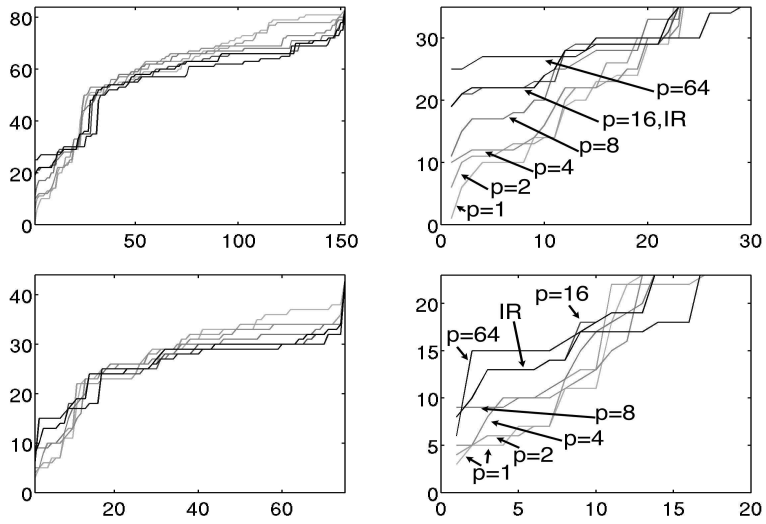

Figure 6: ROC Curves for the P-Norm Push and IR Push on ionosphere data set. All plots are number of true positives vs. number of false positives. *Upper Left:* Full ROC Curves for training. *Upper Right:* Zoomed-in version of training ROC Curves. *Lower Left:* Full ROC Curves for testing. *Lower Right:* Zoomed-in version of testing ROC Curves.

(such as distance to employment centers and tax-rate), it is reasonable for our learning algorithm to predict whether the tract bounds the Charles River based on the other features. We used 3-fold cross-validation (≈ 12 positives in each test set), where all algorithms were run once on each split, and the mean performance is reported in Table 5. ROC curves from one of the trials is presented in Figure 7. The trend from small to large p is again generally observed, despite variation due to data set size.

For all of these experiments, in agreement with our algorithm's derivation, a larger push (p large) causes the algorithm to perform better near the top of the ranked list on the training set. As discussed, this ability to correct the top of the list is not without sacrifice; we do sacrifice the ranks of items farther down on the list and we do reduce the value of the AUC, but we have made this choice on purpose in order to perform better near the top of the list.

9. Discussion and Open Problems

Here we describe interesting directions for future work.

9.1 Producing Dramatic Changes in the ROC curve

An open question is to quantify what properties of a hypothesis space and data set would allow an increase in p to cause a dramatic change in the ROC curve. In Section 8, we have shown cases where the benefits of increasing p are substantial, and in Section 3.2 we have shown that a dramatic

housing data set

measure	p=1	p=2	p=4	p=8	p=16	p=64	IR	best
AUC	**0.7739**	0.7633	0.7532	0.7500	0.7420	0.7330	0.7373	small p
$R_{2,\mathbf{1}}$	**3222**	3406	3665	3799	3818	3759	3847	small p
$R_{4,\mathbf{1}}$	**294078**	**292870**	304457	307135	305498	298611	304915	small/med p
$R_{8,\mathbf{1}}$	3.9056	3.5246	3.3908	3.2953	**3.2479**	3.3173	**3.2346**	IR / large p

Table 5: Mean test performance of minimizers of $R_{p,\exp}$ and $R_{g_{IR},\exp}$ over 3-fold cross validation with the housing data set. Only significant digits are kept (factors of 10 have been removed). The best scores in each row are in bold and the right column summarizes the result by listing which algorithms performed the best with respect to each quality measure.

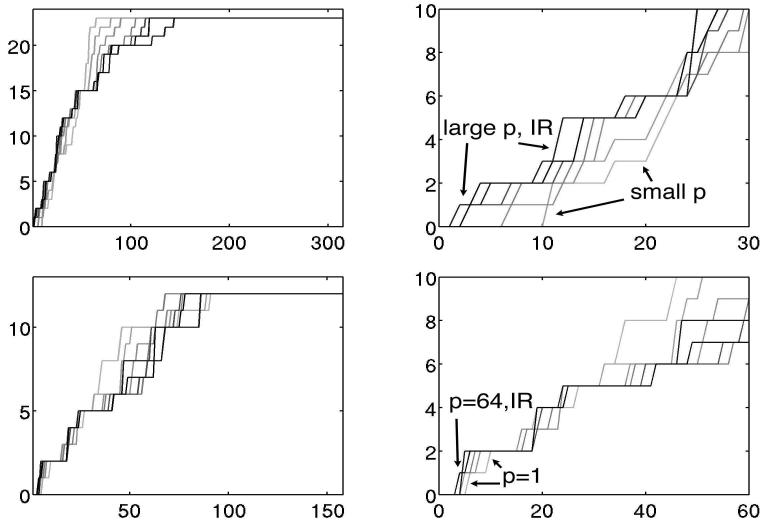

Figure 7: ROC Curves for the P-Norm Push and IR Push on the housing data set. All plots are number of true positives vs. number of false positives. *Upper Left:* Full ROC Curves for training. *Upper Right:* Zoomed-in version of training ROC Curves. *Lower Left:* Full ROC Curves for testing. *Lower Right:* Zoomed-in version of testing ROC Curves.

change is possible, even using an extremely small hypothesis space. However, it is sometimes the case that changes in p do not greatly affect the ROC curve.

A factor involved in this open question involves the flexibility of the hypothesis space with respect to the training set. Given a low capacity hypothesis space in which there is not too much flexibility in the set of solutions that yield good rankings, increasing p will not have much of an

effect. On the other hand, if a learning machine is high capacity, it probably has the flexibility to change the shape of the ROC curve dramatically. However, a high capacity learning machine generally is able to produce a consistent (or nearly consistent) ranking, and again, the choice of p probably does not have much effect. With respect to optimization on the training set, we have found the effect of increasing p to be the most dramatic when the hypothesis space is: limited (so as not to produce an almost consistent ranking), not too limited (features themselves are better than random guesses) and flexible (for instance, allowing some hypotheses to negate in order to produce a better solution as in Section 3.2). If such hypotheses are not available, we believe it is unlikely that any algorithm, whether the P-Norm Push, or any optimization algorithm for information retrieval measures, would be able to achieve a dramatic change in the ROC curve.

9.2 Optimizing $R_{\max}$ Directly

Given that there is no generalization guarantee for the ∞-norm, that is, $R_{\max}$, is it useful to directly minimize $R_{\max}$? This is still a convex optimization problem, and variations of this are done in other contexts, for instance, in the context of label ranking by Shalev-Shwartz and Singer (2006) and Crammer and Singer (2001). One might consider, for instance, optimizing $R_{\max}$ and measuring success on the test set using $R_{p,\mathbf{1}}$ for $p < \infty$.

One answer is provided by the equivalence of norms in finite dimensions. For instance, the value of $R_{\max}$ scales with $R_{p,\mathbf{1}}$, as demonstrated in Theorem 1. So optimizing $R_{\max}$ would still possibly be useful with respect to measuring success on smaller p (though in this case, one could optimize $R_{p,\ell}$).

9.3 Choices for ℓ and g

An important direction for future research is the choice of loss function ℓ and price function g. This framework is flexible in that different choices for ℓ and g can be chosen based on the particular goal, whether it is to optimize the AUC, $R_{p,\mathbf{1}}$ for some p, one of the IR measures suggested, or something totally different. The objective for the IR measures needed a concave price function $\ln(1+z)$, in which case the objective convex was made convex by using the exponential loss, in other words., $\ln(1+e^x)$ is convex. It may be possible to leverage the loss function in other cases, allowing us to consider more varied price functions while still working with an objective that is convex. One appealing possibility is to choose a non-monotonic function for g, which might allow us to concentrate on a specific portion of the ROC Curve; however, it may be difficult to maintain the convexity of the objective through the choice of the loss function.

Now we move on to the proofs.

10. Proof of Theorem 2 and Theorem 3

We define a Lipschitz function $\phi : \mathcal{R} \to \mathcal{R}$ (with Lipschitz constant $\mathrm{Lip}(\phi)$) which will act as our loss function, and gives us the margin. We will eventually use the same piecewise linear definition of ϕ as Koltchinskii and Panchenko (2002), but for now, we require only that ϕ obey $0 \le \phi(z) \le 1 \; \forall z$ and $\phi(z) = 1$ for $z < 0$. Since $\phi(z) \ge \mathbf{1}_{[z \le 0]}$, we can define an upper bound for $R^{\text{true}}_{p,\mathbf{1}}(f)$:

$$R^{\text{true}}_{p,\phi}(f) := \left(\mathbb{E}_{\mathbf{x}_- \sim \mathcal{D}_-} \left(\mathbb{E}_{\mathbf{x}_+ \sim \mathcal{D}_+} \phi\big(f(\mathbf{x}_+) - f(\mathbf{x}_-)\big) \right)^p \right)^{1/p}.$$

We have $R^{\text{true}}_{p,\mathbf{1}}(f) \leq R^{\text{true}}_{p,\phi}(f)$. The empirical error associated with $R^{\text{true}}_{p,\phi}$ is:

$$R^{\text{empirical}}_{p,\phi}(f) := \left(\frac{1}{K} \sum_{k=1}^{K} \left(\frac{1}{I} \sum_{i=1}^{I} \phi\big(f(\mathbf{x}_i) - f(\tilde{\mathbf{x}}_k)\big) \right)^p \right)^{1/p}.$$

First, we bound from above the quantity $R^{\text{true}}_{p,\phi}$ by two terms: the empirical error term $R^{\text{empirical}}_{p,\phi}$, and a term characterizing the deviation of $R^{\text{empirical}}_{p,\phi}$ from $R^{\text{true}}_{p,\phi}$ uniformly:

$$\begin{aligned} R^{\text{true}}_{p,\mathbf{1}}(f) &\leq R^{\text{true}}_{p,\phi}(f) = R^{\text{true}}_{p,\phi}(f) - R^{\text{empirical}}_{p,\phi}(f) + R^{\text{empirical}}_{p,\phi}(f) \\ &\leq \sup_{\bar{f} \in \mathcal{F}} \left(R^{\text{true}}_{p,\phi}(\bar{f}) - R^{\text{empirical}}_{p,\phi}(\bar{f}) \right) + R^{\text{empirical}}_{p,\phi}(f). \end{aligned}$$

The proof of Theorem 3 mainly involves an upper bound on the first term. The second term will be upper bounded by $R^{\text{empirical}}_{p,\mathbf{1},\theta}(f)$ by our choice of ϕ. Define $L(f)$ as follows:

$$L(f) := R^{\text{true}}_{p,\phi}(f) - R^{\text{empirical}}_{p,\phi}(f).$$

Let us outline the proof that follows. The goal is to bound $L(f)$ uniformly over $f \in \mathcal{F}$. To do this, we use a covering number argument similar to that of Cucker and Smale (2002). First, we will cover $\mathcal{F}$ by L_∞ disks. We show in Lemma 5 (below) that the value of $L(f)$ within each disk does not change very much provided that the disks are small. We then derive a probabilistic bound on $L(f)$ for any f in Lemma 9, and use this bound on representatives f_r from each disk. A union bound over disks yields the result. The most effort of this proof is devoted to the bound on $L(f)$ in Lemma 9 below, which uses McDiarmid's Inequality. Let us now proceed with the proof.

The following lemma is true for every training set S. It will be used later to show that the value of $L(f)$ does not change much within each L_∞ ball.

Lemma 5 *For any two functions $f_1, f_2 \in L_\infty(\mathcal{X})$,*

$$L(f_1) - L(f_2) \leq 4\text{Lip}(\phi)||f_1 - f_2||_\infty.$$

Proof First, we rearrange the terms:

$$\begin{aligned} L(f_1) - L(f_2) &= R^{\text{true}}_{p,\phi}(f_1) - R^{\text{empirical}}_{p,\phi}(f_1) - R^{\text{true}}_{p,\phi}(f_2) + R^{\text{empirical}}_{p,\phi}(f_2) \\ &= [R^{\text{true}}_{p,\phi}(f_1) - R^{\text{true}}_{p,\phi}(f_2)] - [R^{\text{empirical}}_{p,\phi}(f_1) - R^{\text{empirical}}_{p,\phi}(f_2)]. \end{aligned} \quad (3)$$

We bound from above the second bracketed term of (3),

$$\begin{aligned}
&R^{\text{empirical}}_{p,\phi}(f_1) - R^{\text{empirical}}_{p,\phi}(f_2) \\
&= \left[\frac{1}{K}\sum_{k=1}^{K}\left[\frac{1}{I}\sum_{i=1}^{I}\phi\Big(f_1(\mathbf{x}_i) - f_1(\tilde{\mathbf{x}}_k)\Big)\right]^p\right]^{1/p} - \left[\frac{1}{K}\sum_{k=1}^{K}\left[\frac{1}{I}\sum_{i=1}^{I}\phi\Big(f_2(\mathbf{x}_i) - f_2(\tilde{\mathbf{x}}_k)\Big)\right]^p\right]^{1/p} \\
&\leq \left[\frac{1}{K}\sum_{k=1}^{K}\left|\frac{1}{I}\sum_{i=1}^{I}\phi\Big(f_1(\mathbf{x}_i) - f_1(\tilde{\mathbf{x}}_k)\Big) - \frac{1}{I}\sum_{i=1}^{I}\phi\Big(f_2(\mathbf{x}_i) - f_2(\tilde{\mathbf{x}}_k)\Big)\right|^p\right]^{1/p} \\
&\leq \left[\frac{1}{K}\sum_{k=1}^{K}\left[\frac{1}{I}\sum_{i=1}^{I}\left|\phi\Big(f_1(\mathbf{x}_i) - f_1(\tilde{\mathbf{x}}_k)\Big) - \phi\Big(f_2(\mathbf{x}_i) - f_2(\tilde{\mathbf{x}}_k)\Big)\right|\right]^p\right]^{1/p} \\
&\leq \left[\frac{1}{K}\sum_{k=1}^{K}\left[\frac{1}{I}\sum_{i=1}^{I}\text{Lip}(\phi)\Big|f_1(\mathbf{x}_i) - f_1(\tilde{\mathbf{x}}_k) - f_2(\mathbf{x}_i) + f_2(\tilde{\mathbf{x}}_k)\Big|\right]^p\right]^{1/p} \\
&\leq \left[\frac{1}{K}\sum_{k=1}^{K}\left[\frac{1}{I}\sum_{i=1}^{I}\text{Lip}(\phi)2\sup_{\mathbf{x}}\Big|f_1(\mathbf{x}) - f_2(\mathbf{x})\Big|\right]^p\right]^{1/p} = 2\text{Lip}(\phi)\|f_1 - f_2\|_\infty.
\end{aligned}$$

Here, we have used Minkowski's inequality for $\ell_p(\mathcal{R}^K)$, which is the triangle inequality $\|f-g\|_p \geq \|f\|_p - \|g\|_p$, and the definition of the Lipschitz constant for ϕ. An identical calculation for the first bracketed term of (3), again using Minkowski's inequality yields:

$$R^{\text{true}}_{p,\phi}(f_1) - R^{\text{true}}_{p,\phi}(f_2) \leq 2\text{Lip}(\phi)||f_1 - f_2||_\infty.$$

Combining the two terms yields the statement of the lemma. ■

The following step appears in Cucker and Smale (2002). Let $\ell_\varepsilon := \mathcal{N}\left(\mathcal{F}, \frac{\varepsilon}{8\text{Lip}(\phi)}\right)$, the covering number of $\mathcal{F}$ by L_∞ disks of radius $\frac{\varepsilon}{8\text{Lip}(\phi)}$. Define $f_1, f_2, ..., f_{\ell_\varepsilon}$ to be the centers of such a cover. In other words, the collection of L_∞ disks B_r centered at f_r and with radius $\frac{\varepsilon}{8\text{Lip}(\phi)}$ is a cover for $\mathcal{F}$. In the proof of the theorem, we will use the center of each disk to act as a representative for the whole disk. So, we must show that we do not lose too much by using f_r as a representative for disk B_r.

Lemma 6 *For all* $\varepsilon > 0$,

$$\mathbb{P}_{S_+\sim\mathcal{D}_+^I, S_-\sim\mathcal{D}_-^K}\left\{\sup_{f\in B_r} L(f) \geq \varepsilon\right\} \leq \mathbb{P}_{S_+\sim\mathcal{D}_+^I, S_-\sim\mathcal{D}_-^K}\left\{L(f_r) \geq \frac{\varepsilon}{2}\right\}.$$

Proof By Lemma 5, for every training set S and for all $f \in B_r$,

$$\sup_{f\in B_r} L(f) - L(f_r) \leq 4\text{Lip}(\phi)\sup_{f\in B_r}||f - f_r||_\infty \leq 4\text{Lip}(\phi)\frac{\varepsilon}{8\text{Lip}(\phi)} = \frac{\varepsilon}{2}$$

Thus,

$$\sup_{f\in B_r} L(f) \geq \varepsilon \implies L(f_r) \geq \frac{\varepsilon}{2}.$$

The statement of the lemma follows directly. ■

Here is an inequality that will be useful in the next proof as the mechanism for incorporating p into the bound.

Lemma 7 *For $0 \leq a, b \leq 1$,*

$$|a^{1/p} - b^{1/p}| \leq \min\left\{ |a-b|a^{(1/p)-1}, |a-b|^{1/p} \right\}.$$

Proof For $p = 1$ there is nothing to prove, so take $p > 1$. We need to show both

$$|a^{1/p} - b^{1/p}| \leq |a-b|a^{(1/p)-1} \tag{4}$$

and

$$|a^{1/p} - b^{1/p}| \leq |a-b|^{1/p}. \tag{5}$$

Let us show (5) first. For $z_1, z_2 \geq 0$, it is true that $z_1^p + z_2^p \leq (z_1 + z_2)^p$ as an immediate consequence of the binomial theorem. When $a \geq b$, substitute $z_1 = (a-b)^{1/p}$, $z_2 = b^{1/p}$. The result follows after simplification. The case $a \leq b$ is completely symmetric so no additional work is needed. To show (4), consider first the case $a \geq b$, so that

$$b^{1/p-1} \geq a^{1/p-1}.$$

Multiplying by b yields $b^{1/p} \geq a^{1/p-1}b$, negating and adding $a^{1/p}$ yields

$$a^{1/p} - b^{1/p} \leq a^{1/p} - a^{1/p-1}b, \text{ so } a^{1/p} - b^{1/p} \leq (a-b)a^{1/p-1}.$$

Exactly the same steps (with reversed inequalities) can be used to show the $b \geq a$ case. ■

The benefit of using the minimum in Lemma 7 is that the first term most often gives a tighter bound. In the case where it does not do so, the second term applies. An illustration of this inequality is provided in Figure 8.

We now incorporate the fact that the training set is chosen randomly. We will use a generalization of Hoeffding's inequality due to McDiarmid, as follows:

Theorem 8 ***(McDiarmid, 1989)*** *Let $X_1, X_2, ...X_m$ be independent random variables under distribution D on $\mathcal{X}$. Let $f : \mathcal{X}^m \to \mathcal{R}$ be any function such that:*

$$\sup_{\mathbf{x}_1, \mathbf{x}_2, \cdots, \mathbf{x}_m, \mathbf{x}_i'} \left| f(\mathbf{x}_1, \ldots, \mathbf{x}_i, \ldots, \mathbf{x}_m) - f(\mathbf{x}_1, \ldots, \mathbf{x}_i', \ldots \mathbf{x}_m) \right| \leq c_i \quad \textit{for} \quad 1 \leq i \leq m.$$

Then for any $\varepsilon > 0$,

$$\begin{aligned}
\mathbb{P}_{X_1, X_2, \ldots, X_m \sim D}\left\{ f(X_1, X_2, ..., X_m) - \mathbb{E}\left[f(X_1, X_2, ..., X_m) \right] \geq \varepsilon \right\} &\leq \exp\left(-\frac{2\varepsilon^2}{\sum_{i=1}^m c_i^2} \right), \\
\mathbb{P}_{X_1, X_2, \ldots, X_m \sim D}\left\{ \mathbb{E}\left[f(X_1, X_2, ..., X_m) \right] - f(X_1, X_2, ..., X_m) \geq \varepsilon \right\} &\leq \exp\left(-\frac{2\varepsilon^2}{\sum_{i=1}^m c_i^2} \right),
\end{aligned}$$

and thus by the union bound,

$$\mathbb{P}_{X_1, X_2, \ldots, X_m \sim D}\left\{ \left| f(X_1, X_2, ..., X_m) - \mathbb{E}\left[f(X_1, X_2, ..., X_m) \right] \right| \geq \varepsilon \right\} \leq 2\exp\left(-\frac{2\varepsilon^2}{\sum_{i=1}^m c_i^2} \right).$$

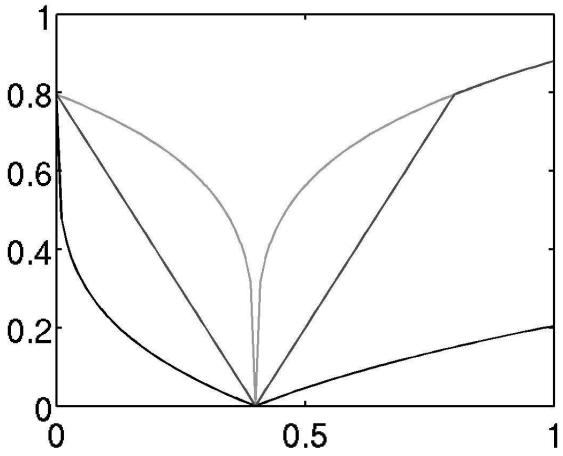

Figure 8: Functions $|a^{1/p} - b^{1/p}|$ (lower curve), $|a-b|^{1/p}$ (upper curve), and $\min(|a-b|a^{(1/p)-1}, |a-b|^{1/p})$ (middle curve) versus b. For this figure $p = 4$ and $a = 0.4$. One can see that in most cases, $|a-b|a^{(1/p)-1}$ is a better approximation to $|a^{1/p} - b^{1/p}|$ than $|a-b|^{1/p}$).

Here is our main probabilistic bound on $L(f)$ for an individual f. It uses McDiarmid's Inequality (Theorem 8) and Lemma 7.

Lemma 9 *For all $\varepsilon_1 > 0$, for all $f \in \mathcal{F}$:*

$$\begin{aligned}
&\mathbb{P}_{S_+ \sim \mathcal{D}_+^I, S_- \sim \mathcal{D}_-^K} \left(L(f) \geq \varepsilon_1 \right) \\
&\quad \leq \quad 2\exp\left[-2K \max\left\{ \frac{\varepsilon_1^2}{4} \left(R_{p,\phi}^{\text{true}}(f) \right)^{2(p-1)}, \left(\frac{\varepsilon_1}{2} \right)^{2p} \right\} \right] + 2\exp\left[-\frac{\varepsilon_1^2}{2} I + \ln K \right]. \qquad (6)
\end{aligned}$$

Proof Define

$$R_{p,\phi}^{\mathcal{DS}}(f) := \left(\frac{1}{K} \sum_{k=1}^{K} \left(\mathbb{E}_{\mathbf{x}_+ \sim \mathcal{D}_+} \phi\Big(f(\mathbf{x}_+) - f(\tilde{\mathbf{x}}_k) \Big) \right)^p \right)^{1/p}.$$

Now,

$$\begin{aligned}
&\mathbb{P}_{S_+ \sim \mathcal{D}_+^I, S_- \sim \mathcal{D}_-^K} \Big(L(f) \geq \varepsilon_1 \Big) \\
&\quad = \quad \mathbb{P}_{S_+ \sim \mathcal{D}_+^I, S_- \sim \mathcal{D}_-^K} \Big(R_{p,\phi}^{\text{true}}(f) - R_{p,\phi}^{\mathcal{DS}}(f) + R_{p,\phi}^{\mathcal{DS}}(f) - R_{p,\phi}^{\text{empirical}}(f) \geq \varepsilon_1 \Big) \\
&\quad \leq \quad \mathbb{P}_{S_- \sim \mathcal{D}_-^K} \left(R_{p,\phi}^{\text{true}}(f) - R_{p,\phi}^{\mathcal{DS}}(f) \geq \frac{\varepsilon_1}{2} \right) + \mathbb{P}_{S_+ \sim \mathcal{D}_+^I, S_- \sim \mathcal{D}_-^K} \left(R_{p,\phi}^{\mathcal{DS}}(f) - R_{p,\phi}^{\text{empirical}}(f) \geq \frac{\varepsilon_1}{2} \right) \\
&\quad =: \quad \text{term}_1 + \text{term}_2. \qquad (7)
\end{aligned}$$

We bound term_1 and term_2 of (7) separately.

Bound on term$_1$*:* The following uses Lemma 7 above (translating into notation of the lemma):

$$\begin{aligned}
&R^{\text{true}}_{p,\phi}(f) - R^{\mathcal{D}S}_{p,\phi}(f) \\
&= \left(\mathbb{E}_{\mathbf{x}_-\sim\mathcal{D}_-}\left(\mathbb{E}_{\mathbf{x}_+\sim\mathcal{D}_+}\phi\Big(f(\mathbf{x}_+) - f(\mathbf{x}_-)\Big)\right)^p\right)^{1/p} \\
&\quad - \left(\frac{1}{K}\sum_{k=1}^{K}\left(\mathbb{E}_{\mathbf{x}_+\sim\mathcal{D}_+}\phi\Big(f(\mathbf{x}_i) - f(\tilde{\mathbf{x}}_k)\Big)\right)^p\right)^{1/p} \\
&= a^{1/p} - b^{1/p} \leq |a^{1/p} - b^{1/p}| \leq \min\left\{|a-b|a^{(1/p)-1}, |a-b|^{1/p}\right\}.
\end{aligned}$$

Thus for all $\varepsilon_1 > 0$,

$$\begin{aligned}
&\mathbb{P}_{S_-\sim\mathcal{D}_-^K}\left(R^{\text{true}}_{p,\phi}(f) - R^{\mathcal{D}S}_{p,\phi}(f) \geq \frac{\varepsilon_1}{2}\right) \\
&\leq \mathbb{P}_{S_-\sim\mathcal{D}_-^K}\left(\min\left\{|a-b|a^{(1/p)-1}, |a-b|^{1/p}\right\} \geq \frac{\varepsilon_1}{2}\right) \\
&= \mathbb{P}_{S_-\sim\mathcal{D}_-^K}\left(|a-b|a^{1/p-1} \geq \frac{\varepsilon_1}{2} \bigcap |a-b|^{\frac{1}{p}} \geq \frac{\varepsilon_1}{2}\right) \\
&= \mathbb{P}_{S_-\sim\mathcal{D}_-^K}\left(|a-b| \geq \frac{\varepsilon_1}{2}a^{1-1/p} \bigcap |a-b| \geq \left(\frac{\varepsilon_1}{2}\right)^p\right) \\
&= \mathbb{P}_{S_-\sim\mathcal{D}_-^K}\left(|a-b| \geq \frac{\varepsilon_1}{2}\left(R^{\text{true}}_{p,\phi}(f)\right)^{p-1} \bigcap |a-b| \geq \left(\frac{\varepsilon_1}{2}\right)^p\right) \\
&= \mathbb{P}_{S_-\sim\mathcal{D}_-^K}\left(|a-b| \geq \max\left\{\frac{\varepsilon_1}{2}\left(R^{\text{true}}_{p,\phi}(f)\right)^{p-1}, \left(\frac{\varepsilon_1}{2}\right)^p\right\}\right).
\end{aligned}$$

Let

$$\varepsilon_2 := \max\left\{\frac{\varepsilon_1}{2}\left(R^{\text{true}}_{p,\phi}(f)\right)^{p-1}, \left(\frac{\varepsilon_1}{2}\right)^p\right\}.$$

Then,

$$\begin{aligned}
&\mathbb{P}_{S_-\sim\mathcal{D}_-^K}\left(R^{\text{true}}_{p,\phi}(f) - R^{\mathcal{D}S}_{p,\phi}(f) \geq \frac{\varepsilon_1}{2}\right) \\
&\leq \mathbb{P}_{S_-\sim\mathcal{D}_-^K}\left(\left|\mathbb{E}_{\mathbf{x}_-\sim\mathcal{D}_-}\left(\mathbb{E}_{\mathbf{x}_+\sim\mathcal{D}_+}\phi\Big(f(\mathbf{x}_+) - f(\mathbf{x}_-)\Big)\right)^p - \right.\right. \\
&\qquad \left.\left.\frac{1}{K}\sum_{k=1}^{K}\left(\mathbb{E}_{\mathbf{x}_+\sim\mathcal{D}_+}\phi\Big(f(\mathbf{x}_+) - f(\tilde{\mathbf{x}}_k)\Big)\right)^p\right| \geq \varepsilon_2\right).
\end{aligned}$$

The largest possible change in $\frac{1}{K}\sum_{k=1}^{K}\left(\mathbb{E}_{\mathbf{x}_+\sim\mathcal{D}_+}\phi\Big(f(\mathbf{x}_+) - f(\tilde{\mathbf{x}}_k)\Big)\right)^p$ due to the replacement of one negative example is $1/K$. By McDiarmid's inequality,

$$\begin{aligned}
&\mathbb{P}_{S_-\sim\mathcal{D}_-^K}\left(R^{\text{true}}_{p,\phi}(f) - R^{\mathcal{D}S}_{p,\phi}(f) \geq \frac{\varepsilon_1}{2}\right) \\
&\leq \exp\left(-\frac{2\varepsilon_2^2}{K\frac{1}{K^2}}\right) = 2\exp(-2K\varepsilon_2^2) \\
&= 2\exp\left(-2K\max\left\{\frac{\varepsilon_1^2}{4}\left(R^{\text{true}}_{p,\phi}(f)\right)^{2(p-1)}, \left(\frac{\varepsilon_1}{2}\right)^{2p}\right\}\right). \qquad (8)
\end{aligned}$$

Bound on term$_2$:

$$\begin{aligned} & R^{\mathcal{D}S}_{p,\phi}(f) - R^{\text{empirical}}_{p,\phi}(f) \\ = & \left(\frac{1}{K}\sum_{k=1}^{K}\left(\mathbb{E}_{\mathbf{x}_+\sim\mathcal{D}_+}\phi\Big(f(\mathbf{x}_+) - f(\mathbf{x}_-)\Big)\right)^p\right)^{1/p} \\ & - \left(\frac{1}{K}\sum_{k=1}^{K}\left(\frac{1}{I}\sum_{i=1}^{I}\phi\Big(f(\mathbf{x}_i) - f(\tilde{\mathbf{x}}_k)\Big)\right)^p\right)^{1/p}. \end{aligned}$$

Thus for all $\varepsilon_1 > 0$,

$$\begin{aligned} & \mathbb{P}_{S_+\sim\mathcal{D}_+^I, S_-\sim\mathcal{D}_-^K}\left(R^{\mathcal{D}S}_{p,\phi}(f) - R^{\text{empirical}}_{p,\phi}(f) \geq \frac{\varepsilon_1}{2}\right) \\ = & \mathbb{P}_{S_+\sim\mathcal{D}_+^I, S_-\sim\mathcal{D}_-^K}\left(\frac{1}{K^{1/p}}\left\|\mathbb{E}_{\mathbf{x}_+\sim\mathcal{D}_+}\phi\Big(f(\mathbf{x}_+) - f(\cdot)\Big)\right\|_{\ell_p(R^K)}\right. \\ & \qquad \left. - \frac{1}{K^{1/p}}\left\|\frac{1}{I}\sum_{i=1}^{I}\phi\Big(f(\mathbf{x}_i) - f(\cdot)\Big)\right\|_{\ell_p(R^K)} \geq \frac{\varepsilon_1}{2}\right) \\ \leq & \mathbb{P}_{S_+\sim\mathcal{D}_+^I, S_-\sim\mathcal{D}_-^K}\left(\frac{1}{K^{1/p}}\left\|\mathbb{E}_{\mathbf{x}_+\sim\mathcal{D}_+}\phi\Big(f(\mathbf{x}_+) - f(\cdot)\Big) - \frac{1}{I}\sum_{i=1}^{I}\phi\Big(f(\mathbf{x}_i) - f(\cdot)\Big)\right\|_{\ell_p(R^K)} \geq \frac{\varepsilon_1}{2}\right) \\ \leq & \mathbb{P}_{S_+\sim\mathcal{D}_+^I, S_-\sim\mathcal{D}_-^K}\left(\left\|\mathbb{E}_{\mathbf{x}_+\sim\mathcal{D}_+}\phi\Big(f(\mathbf{x}_+) - f(\cdot)\Big) - \frac{1}{I}\sum_{i=1}^{I}\phi\Big(f(\mathbf{x}_i) - f(\cdot)\Big)\right\|_{\ell_\infty(R^K)} \geq \frac{\varepsilon_1}{2}\right) \\ = & \mathbb{P}_{S_+\sim\mathcal{D}_+^I, S_-\sim\mathcal{D}_-^K}\left(\exists k : \left|\mathbb{E}_{\mathbf{x}_+\sim\mathcal{D}_+}\phi\Big(f(\mathbf{x}_+) - f(\tilde{\mathbf{x}}_k)\Big) - \frac{1}{I}\sum_{i=1}^{I}\phi\Big(f(\mathbf{x}_i) - f(\tilde{\mathbf{x}}_k)\Big)\right| \geq \frac{\varepsilon_1}{2}\right). \end{aligned}$$

We now use McDiarmid's Inequality. The largest possible change in $\frac{1}{I}\sum_{i=1}^{I}\phi\Big(f(\mathbf{x}_i) - f(\tilde{\mathbf{x}}_k)\Big)$ due to the replacement of one positive example is $1/I$. Thus, for all $\tilde{\mathbf{x}}_k$,

$$\begin{aligned} & \mathbb{P}_{S_+\sim\mathcal{D}_+^I, S_-\sim\mathcal{D}_-^K}\left(\left|\mathbb{E}_{\mathbf{x}_+\sim\mathcal{D}_+}\phi\Big(f(\mathbf{x}_+) - f(\tilde{\mathbf{x}}_k)\Big) - \frac{1}{I}\sum_{i=1}^{I}\phi\Big(f(\mathbf{x}_i) - f(\tilde{\mathbf{x}}_k)\Big)\right| \geq \frac{\varepsilon_1}{2}\right) \\ \leq & 2\exp\left[-\frac{2\left(\frac{\varepsilon_1}{2}\right)^2}{I\frac{1}{I^2}}\right] = 2\exp\left[-\frac{\varepsilon_1^2}{2}I\right]. \end{aligned}$$

By the union bound over the K negative examples:

$$\begin{aligned} & \mathbb{P}_{S_+\sim\mathcal{D}_+^I, S_-\sim\mathcal{D}_-^K}\left(\exists k : \left|\mathbb{E}_{\mathbf{x}_+\sim\mathcal{D}_+}\phi\Big(f(\mathbf{x}_+) - f(\tilde{\mathbf{x}}_k)\Big) - \frac{1}{I}\sum_{i=1}^{I}\phi\Big(f(\mathbf{x}_i) - f(\tilde{\mathbf{x}}_k)\Big)\right| \geq \frac{\varepsilon_1}{2}\right) \\ \leq & 2K\exp\left[-\frac{\varepsilon_1^2}{2}I\right] = 2\exp\left[-\frac{\varepsilon_1^2}{2}I + \ln(K)\right], \end{aligned}$$

and thus,

$$\mathbb{P}_{S_+\sim\mathcal{D}_+^I, S_-\sim\mathcal{D}_-^K}\left(R^{\text{true}}_{p,\phi}(f) - R^{\mathcal{D}S}_{p,\phi}(f) \geq \frac{\varepsilon_1}{2}\right) \leq 2\exp\left[-\frac{\varepsilon_1^2}{2}I + \ln K\right].$$

Combining this with (8) and (7) yields the statement of the lemma. ■

Proof *(Of Theorem 2 and Theorem 3)* Since the B_r are a cover for $\mathcal{F}$, it is true that

$$\sup_{f\in\mathcal{F}} L(f) \geq \varepsilon \iff \exists r \leq \ell_\varepsilon \text{ such that } \sup_{f\in B_r} L(f) \geq \varepsilon.$$

First applying the union bound over balls, then applying Lemma 6 we find:

$$\begin{aligned}
&\mathbb{P}_{S_+\sim\mathcal{D}^I, S_-\sim\mathcal{D}^K}\left\{\sup_{f\in\mathcal{F}} L(f) \geq \varepsilon\right\} \\
&\leq \sum_{r=1}^{\ell_\varepsilon} \mathbb{P}_{S_+\sim\mathcal{D}^I, S_-\sim\mathcal{D}^K}\left\{\sup_{f\in B_r} L(f) \geq \varepsilon\right\} \\
&\leq \sum_{r=1}^{\ell_\varepsilon} \mathbb{P}_{S_+\sim\mathcal{D}^I, S_-\sim\mathcal{D}^K}\left\{L(f_r) \geq \varepsilon/2\right\}.
\end{aligned}$$

We bound from above using (6) in order to prove Theorem 3 using $\varepsilon_1 = \varepsilon/2$, also $R^{\text{true}}_{p,\phi}(f_r) \geq R^{\text{true}}_{p,\mathbf{1}}(f_r)$ and additionally $R^{\text{true}}_{p,\mathbf{1}}(f_r) \geq \inf_{f\in\mathcal{F}} R^{\text{true}}_{p,\mathbf{1}}(f)$ for every f_r:

$$\begin{aligned}
&\mathbb{P}_{S_+\sim\mathcal{D}^I, S_-\sim\mathcal{D}^K}\left\{\sup_{f\in\mathcal{F}} L(f) \geq \varepsilon\right\} \\
&\leq \sum_{r=1}^{\ell_\varepsilon} 2\exp\left[-2K\max\left\{\frac{\varepsilon^2}{16}\left(R^{\text{true}}_{p,\phi}(f_r)\right)^{2(p-1)}, \left(\frac{\varepsilon}{4}\right)^{2p}\right\}\right] + 2\exp\left[-\frac{\varepsilon^2}{8}I + \ln K\right] \\
&\leq \mathcal{N}\left(\mathcal{F}, \frac{\varepsilon}{8\text{Lip}(\phi)}\right)\left[2\exp\left[-2K\max\left\{\frac{\varepsilon^2}{16}\left(\min_r R^{\text{true}}_{p,\phi}(f_r)\right)^{2(p-1)}, \left(\frac{\varepsilon}{4}\right)^{2p}\right\}\right]\right. \\
&\qquad \left. +2\exp\left[-\frac{\varepsilon^2}{8}I + \ln K\right]\right] \qquad (9) \\
&\leq \mathcal{N}\left(\mathcal{F}, \frac{\varepsilon}{8\text{Lip}(\phi)}\right)\left[2\exp\left[-2K\max\left\{\frac{\varepsilon^2}{16}\left(\inf_{\tilde{f}\in\mathcal{F}} R^{\text{true}}_{p,\mathbf{1}}(\tilde{f})\right)^{2(p-1)}, \left(\frac{\varepsilon}{4}\right)^{2p}\right\}\right]\right. \\
&\qquad \left. +2\exp\left[-\frac{\varepsilon^2}{8}I + \ln K\right]\right].
\end{aligned}$$

Now we put everything together. The probability that there exists an $f \in \mathcal{F}$ where

$$R^{\text{true}}_{p,\phi}(f) \geq R^{\text{empirical}}_{p,\phi}(f) + \varepsilon$$

is at most

$$\mathcal{N}\left(\mathcal{F}, \frac{\varepsilon}{8\text{Lip}(\phi)}\right)\left[2\exp\left[-2K\max\left\{\frac{\varepsilon^2}{16}\left(R_{p,\min}\right)^{2(p-1)}, \left(\frac{\varepsilon}{4}\right)^{2p}\right\}\right] + 2\exp\left[-\frac{\varepsilon^2}{8}I + \ln K\right]\right],$$

where $R_{p,\min} = \inf_f R^{\text{true}}_{p,\mathbf{1}}(f)$. Let us choose $\phi(z) = 1$ for $z \leq 0$, $\phi(z) = 0$ for $z \geq \theta$, and linear in between, with slope $-1/\theta$. Thus, $\text{Lip}(\phi) = 1/\theta$. Since $\phi(z) \leq 1$ for $z \leq \theta$, we have:

$$\begin{aligned} R^{\text{empirical}}_{p,\phi}(f) &= \left(\frac{1}{K}\sum_{k=1}^{K}\left(\frac{1}{I}\sum_{i=1}^{I}\phi\Big(f(\mathbf{x}_i) - f(\tilde{\mathbf{x}}_k)\Big)\right)^p\right)^{1/p} \\ &\leq \left(\frac{1}{K}\sum_{k=1}^{K}\left(\frac{1}{I}\sum_{i=1}^{I}\mathbf{1}_{[f(\mathbf{x}_i)-f(\tilde{\mathbf{x}}_k)\leq\theta]}\right)^p\right)^{1/p} = R^{\text{empirical}}_{p,\mathbf{1},\theta}(f). \end{aligned}$$

Thus, the probability that there exists an $f \in \mathcal{F}$ where

$$R^{\text{true}}_{p,\mathbf{1}}(f) \geq R^{\text{empirical}}_{p,\mathbf{1},\theta}(f) + \varepsilon$$

is at most

$$\mathcal{N}\left(\mathcal{F}, \frac{\varepsilon\theta}{8}\right)\left[2\exp\left[-2K\max\left\{\frac{\varepsilon^2}{16}\left(R_{p,\min}\right)^{2(p-1)}, \left(\frac{\varepsilon}{4}\right)^{2p}\right\}\right] + 2\exp\left[-\frac{\varepsilon^2}{8}I + \ln K\right]\right].$$

Thus, the theorem has been proved. A tighter bound is obtained if we bound differently at (9): instead of using $R^{\text{true}}_{p,\mathbf{1}}(f_r) \geq \inf_{f\in\mathcal{F}} R^{\text{true}}_{p,\mathbf{1}}(f)$, we could stop at $R^{\text{true}}_{p,\mathbf{1}}(f_r) \geq \min_r R^{\text{true}}_{p,\mathbf{1}}(f_r)$ and then choose the $\{f_r\}_r$ to maximize $\min_r R^{\text{true}}_{p,\mathbf{1}}(f_r)$.

Theorem 2 follows directly from the statement of Theorem 3. ■

10.1 1-Dimensional Illustration

As discussed earlier, since most of the value of $R^{\text{true}}_{p,\mathbf{1}}$ comes from a small portion of the domain, more examples are needed to compensate. Let us give a 1-dimensional illustration where this is the case. Almost half the distribution (proportion $\frac{1}{2} - \frac{\varepsilon}{2}$) consists of negative examples uniformly distributed on $[-1,0]$. Almost half the distribution (proportion $\frac{1}{2} - \frac{\varepsilon}{2}$) are positive examples uniformly distributed on $[0,1]$. An $\varepsilon/2$ proportion of the distribution are positive examples distributed on $[-2,-1]$, and the remaining $\varepsilon/2$ are negative examples on $[1,2]$. Drawing a training set of size m from that distribution, with probability $(1-\varepsilon)^m$, all examples will be drawn from $[-1,1]$, missing the essential part of the distribution. Let the hypothesis space $\mathcal{F}$ consist of one monotonically increasing function, and one monotonically decreasing function. Assuming the test set is large and represents the full distribution, the correct function to minimize $R_{\max}$ on the test set is the decreasing function. However, with high probability $(1-\varepsilon)^m$, the increasing function will be (wrongly) chosen, achieving on the training set, $R_{\max} = 0$, but on the test set, the worst possible value $R_{\max} = I$. Thus, $R_{\max}$ relies heavily on an ε-sized portion of the input space. Contrast this with behavior of the AUC, which is hardly affected by this portion of the input space, and is close to 1 with high probability for both training and testing.

11. Proof of Theorem 4

We will use a theorem of Della Pietra et al. (2002), and we will follow their definitions leading to this theorem. Consider a function $\phi : S \subset \mathcal{R}^{IK} \to [-\infty, \infty]$ (unrelated to the ϕ of the proof of Theorem 3). We will use this function to define a Bregman distance and consider an optimization

problem related to this Bregman distance. The dual of this optimization problem will be almost exactly the same as minimization of $R_{p,\exp}$ due to our choice of ϕ. The theorem of Della Pietra et al. (2002) will then provide a kind of uniqueness of the minimizer. The most difficult part of this theorem is finding the function ϕ and showing that the conditions of the framework are satisfied.

Let us first give the definition of a Bregman distance with respect to function ϕ, and then define the primal and dual optimization problems. The *effective domain* of ϕ, denoted Δ_ϕ, is the set of points where ϕ is finite. The function ϕ is *proper* if there is no $\mathbf{p}$ such that $\phi(\mathbf{p}) = -\infty$ and at least some $\mathbf{p}$ with $\phi(\mathbf{p}) \neq \infty$. (Do not confuse the vector $\mathbf{p} \in \mathcal{R}^{IK}$ with the scalar power p. Entries of $\mathbf{p}$ will always be indexed by p_{ik} to avoid confusion.) A proper function ϕ is *essentially smooth* if it is differentiable on the interior of the domain $\text{int}(\Delta_\phi)$ and if $\lim_\ell |\nabla\phi(\mathbf{p}_\ell)| = +\infty$ (element-wise) whenever $\mathbf{p}_\ell$ is a sequence in $\text{int}(\Delta_\phi)$, converging to a point on the boundary. Assume that the function ϕ is *Legendre*, meaning that it is closed (lower semi-continuous), convex and proper, and additionally that $\text{int}(\Delta_\phi)$ is convex, and ϕ is essentially smooth and strictly convex on $\text{int}(\Delta_\phi)$. The *Bregman Distance* associated with ϕ is $B_\phi : \Delta_\phi \times \text{int}(\Delta_\phi) \to [0,\infty]$ defined as:

$$B_\phi(\mathbf{p},\mathbf{q}) := \phi(\mathbf{p}) - \phi(\mathbf{q}) - \langle \nabla\phi(\mathbf{q}), \mathbf{p}-\mathbf{q}\rangle.$$

Fix a vector $\mathbf{p}_0 \in \Delta_\phi$. The *feasible set* for $\mathbf{p}_0$ with respect to matrix $\mathbf{M} \in \mathcal{R}^{IK\times n}$ is: $\mathcal{P} = \{\mathbf{p} \in \mathcal{R}^{IK} | \mathbf{p}^T\mathbf{M} = \mathbf{p}_0^T\mathbf{M}\}$. This will be the domain of the primal problem. The primal problem is to find, for fixed $\mathbf{q}_0 \in \Delta_\phi$:

$$\text{argmin}_{\mathbf{p}\in\mathcal{P}} B_\phi(\mathbf{p},\mathbf{q}_0). \qquad \textit{(primal problem)}$$

Now we lead up to the definition of the dual problem. The *Legendre-Bregman Conjugate* associated with ϕ is $\ell_\phi : \text{int}(\Delta_\phi) \times \mathcal{R}^{IK} \to \mathcal{R} \cup \{\infty\}$ defined as:

$$\ell_\phi(\mathbf{q},\mathbf{v}) := \sup_{\mathbf{p}\in\Delta_\phi} \Big(\langle \mathbf{v},\mathbf{p}\rangle - B_\phi(\mathbf{p},\mathbf{q}) \Big).$$

Note that for fixed $\mathbf{q}$, the Legendre-Bregman conjugate is exactly the convex conjugate of $B_\phi(\cdot,\mathbf{q})$. The *Legendre-Bregman Projection* is the argument of the sup whenever it is well-defined, namely, $\mathcal{L}_\phi : \text{int}(\Delta_\phi) \times \mathcal{R}^{IK} \to \Delta_\phi$ is defined by:

$$\mathcal{L}_\phi(\mathbf{q},\mathbf{v}) := \text{argmax}_{\mathbf{p}\in\Delta_\phi} \Big(\langle \mathbf{v},\mathbf{p}\rangle - B_\phi(\mathbf{p},\mathbf{q}) \Big),$$

whenever this is well-defined. Della Pietra et al. (2002) have shown that:

$$\mathcal{L}_\phi(\mathbf{q},\mathbf{v}) = (\nabla\phi)^{-1}(\nabla\phi(\mathbf{q}) + \mathbf{v}). \tag{10}$$

The dual problem can also be viewed as a minimization of a Bregman distance. Namely, it can be shown (cf. Proposition 2.7 of Della Pietra et al., 2002) that the dual objective can be written in terms of $\mathcal{L}_\phi(\mathbf{q}_0,\mathbf{v})$:

$$\langle \mathbf{v},\mathbf{p}_0\rangle - \ell_\phi(\mathbf{q}_0,\mathbf{v}) = B_\phi(\mathbf{p}_0,\mathbf{q}_0) - B_\phi\Big(\mathbf{p}_0, \mathcal{L}_\phi(\mathbf{q}_0,\mathbf{v})\Big).$$

Thus, since the first term on the right is not a function of $\mathbf{v}$, the dual problem can be written:

$$\begin{aligned} &\text{argmax}_{\mathbf{v}\in\mathcal{R}^{IK}} B_\phi(\mathbf{p}_0,\mathbf{q}_0) - B_\phi\Big(\mathbf{p}_0, \mathcal{L}_\phi(\mathbf{q}_0,\mathbf{v})\Big) \\ = \quad &\text{argmin}_{\mathbf{v}\in\mathcal{R}^{IK}} B_\phi\Big(\mathbf{p}_0, \mathcal{L}_\phi(\mathbf{q}_0,\mathbf{v})\Big), \qquad \textit{(dual problem)} \end{aligned}$$

where we have assumed in the domain of $\mathbf{v}$ that $\Delta_{\phi^*} = \mathcal{R}^{IK}$ and where ϕ^* is the convex conjugate of ϕ. We will rewrite the domain of the dual problem as the class $\mathcal{Q}$, defined as follows. For the $\mathbf{q}_0 \in \Delta_\phi$ and $\mathbf{M} \in \mathcal{R}^{IK \times n}$ fixed in the primal problem, the *Legendre-Bregman projection family for* $\mathbf{q}_0$ *and* $\mathbf{M}$ is defined by:

$$\mathcal{Q}(\mathbf{q}_0, \mathbf{M}) = \{\mathbf{q} \in \Delta_\phi | \mathbf{q} = \mathcal{L}_\phi(\mathbf{q}_0, -\mathbf{M}\boldsymbol{\lambda}) \text{ for some } \boldsymbol{\lambda} \in \mathcal{R}^n\}.$$

So instead of considering the minimizer with respect to $\mathbf{v}$, we will instead consider the minimizer with respect to $\mathbf{q} \in \mathcal{Q}$. In order to proceed, a few more technical conditions are required, namely:

- A1. ϕ is Legendre.
- A2. $\Delta_{\phi^*} = \mathcal{R}^{IK}$ where ϕ^* is the convex conjugate of ϕ.
- A3. B_ϕ extends to a function $B_\phi : \Delta_\phi \times \Delta_\phi \to [0, \infty]$ such that $B_\phi(\mathbf{p}, \mathbf{q})$ is continuous in $\mathbf{p}$ and $\mathbf{q}$, and satisfies $B_\phi(\mathbf{p}, \mathbf{q}) = 0$ iff $\mathbf{p} = \mathbf{q}$.
- A4. $\mathcal{L}_\phi$ extends to a function $\mathcal{L}_\phi : \Delta_\phi \times \mathcal{R}^{IK} \to \Delta_\phi$ satisfying $\mathcal{L}_\phi : (\mathbf{q}, \mathbf{0}) = \mathbf{q}$, such that $\mathcal{L}_\phi(\mathbf{q}, \mathbf{v})$ and $B_\phi(\mathcal{L}_\phi(\mathbf{q}, \mathbf{v}), \mathbf{q})$ are jointly continuous in $\mathbf{q}$ and $\mathbf{v}$.
- A5. $B_\phi(\mathbf{p}, \cdot)$ is *coercive* for every $\mathbf{p} \in \Delta_\phi \backslash \text{int}(\Delta_\phi)$, where a function $f : S \to [-\infty, \infty]$ is coercive if the level sets $\{\mathbf{q} \in S | f(\mathbf{q}) \leq c\}$ are bounded for every $c \in \mathcal{R}$.

We now state Proposition 3.2 of Della Pietra et al. (2002) which will give us uniqueness within the closure of the set $\mathcal{Q}$. Define $\bar{\mathcal{Q}}$ as the closure of $\mathcal{Q}$ in $\mathcal{R}^{IK}$.

Theorem 10 *(Della Pietra et al., 2002) Let* ϕ *satisfy A1.-A5. and suppose that* $\mathbf{p}_0, \mathbf{q}_0 \in \Delta_\phi$ *with* $B_\phi(\mathbf{p}_0, \mathbf{q}_0) < \infty$. *Then there exists a unique* $\mathbf{q}^* \in \Delta_\phi$ *satisfying the following four properties:*

1. $\mathbf{q}^* \in \mathcal{P} \bigcap \bar{\mathcal{Q}}$
2. $B_\phi(\mathbf{p}, \mathbf{q}) = B_\phi(\mathbf{p}, \mathbf{q}^*) + B_\phi(\mathbf{q}^*, \mathbf{q})$ *for any* $\mathbf{p} \in \mathcal{P}$ *and* $\mathbf{q} \in \bar{\mathcal{Q}}$
3. $\mathbf{q}^* = \text{argmin}_{\mathbf{p} \in \mathcal{P}} B_\phi(\mathbf{p}, \mathbf{q}_0)$ *(primal problem)*
4. $\mathbf{q}^* = \text{argmin}_{\mathbf{q} \in \bar{\mathcal{Q}}} B_\phi(\mathbf{p}_0, \mathbf{q})$ *(dual problem)*

Moreover, any one of these four properties determines $\mathbf{q}^*$ *uniquely.*

If we can prove that our objective function fits into this framework, we can use part (4) of this theorem to provide uniqueness in the closure of the set $\mathcal{Q}$, which will be related to our set $\mathcal{Q}'$. Let us now do exactly this.

Consider the following function $\phi : \mathcal{R}^{IK}_{\geq 0} \to [-\infty, \infty]$:

$$\phi(\mathbf{q}) := \sum_{ik} q_{ik} \gamma(q_{ik}, \mathbf{q}), \text{ where } \gamma(q_{ik}, \mathbf{q}) := \ln \left(\frac{q_{ik}}{p^{1/p} (\sum_{i'} q_{i'k})^{(p-1)/p}} \right).$$

We extend the definition to $\mathcal{R}^{IK}_+$ by the conventions $0 \ln 0 = 0$ and $q_{ik}\gamma(q_{ik}, \mathbf{q}) = 0$ whenever $q_{ik} = 0$ for all i. Thus, Δ_ϕ is now $\mathcal{R}^{IK}_+$. The boundary in our case is where q_{ik} equals 0 for one or more ik pairs. We must now show that ϕ is Legendre.

Lemma 11 *ϕ is strictly convex in* $\mathrm{int}(\Delta_\phi)$*, where Δ_ϕ are vectors in $\mathcal{R}_+^{IK}$ with strictly positive entries.*

The proof is in the Appendix.

Lemma 12 *ϕ is Legendre.*

Proof ϕ is proper since there is no $\mathbf{q}$ such that $\phi(\mathbf{q}) = -\infty$. In order to achieve this, the term inside the logarithm must be exactly zero. When that happens, $q_{ik} = 0$, and by our convention, $q_{ik}\gamma(q_{ik}, \mathbf{q}) = 0$, thus the entire ik term is zero rather than $-\infty$. It can be verified that ϕ is lower semi-continuous. Also, $\mathrm{int}(\Delta_\phi) = \mathcal{R}_{\gg 0}^{IK}$ which is convex. We have already shown that ϕ is strictly convex on $\mathrm{int}(\Delta_\phi)$ in Lemma 11, and by our definition of ϕ on the boundary, it is convex on Δ_ϕ. We now show that ϕ is essentially smooth with respect to the boundary. Consider the following calculation for the gradient of ϕ in $\mathrm{int}(\Delta_\phi)$:

$$(\nabla\phi(\mathbf{q}))_{ik} = \frac{\partial\phi(\mathbf{q})}{\partial q_{ik}} = \frac{1}{p} + \ln\left(\frac{q_{ik}}{p^{1/p}\left(\sum_{i'} q_{i'k}\right)^{(p-1)/p}}\right) = \frac{1}{p} + \gamma(q_{ik}, \mathbf{q}), \tag{11}$$

since $\gamma(q_{ik}, \mathbf{q}) \to -\infty$ as $q_{ik} \to 0$, ϕ is essentially smooth. All the conditions have now been checked. ■

Also, we require the following:

Lemma 13 *Conditions A1.-A5. are obeyed.*

The proof of this lemma is in the Appendix.

Proof *(Of Theorem 4)* Let us compute the quantities above for our function ϕ, namely we would like to find the space Q and the dual objective $B_\phi(\mathbf{p}_0, \mathbf{q})$. Using (11) it can be shown that:

$$\left((\nabla\phi)^{-1}(\mathbf{z})\right)_{ik} = pe^{(z_{ik}-1/p)}\left(\sum_{i'} e^{(z_{i'k}-1/p)}\right)^{p-1}.$$

We now wish to compute $\mathcal{L}_\phi$. First, let us compute a term that appears often:

$e^{z_{ik}-1/p}$ where $z_{ik} = (\nabla\phi(\mathbf{q}) + \mathbf{v})_{ik} = \dfrac{1}{p} + \gamma(q_{ik}, \mathbf{q}) + v_{ik}$ can be rewritten:

$$e^{z_{ik}-1/p} \quad = \quad \exp\left[\frac{1}{p} - \frac{1}{p} + \gamma(q_{ik}, \mathbf{q}) + v_{ik}\right] = e^{v_{ik}}e^{\gamma(q_{ik}, \mathbf{q})}.$$

Thus from (10),

$$\begin{aligned}
\mathcal{L}_\phi(\mathbf{q}, \mathbf{v})_{ik} &= pe^{v_{ik}}e^{\gamma(q_{ik}, \mathbf{q})}\left(\sum_{i'} e^{v_{i'k}}e^{\gamma(q_{i'k}, \mathbf{q})}\right)^{p-1} \\
&= pe^{v_{ik}}\frac{q_{ik}}{p^{1/p}(\sum_{i'} q_{i'k})^{(p-1)/p}}\left(\frac{\sum_{i'} e^{v_{i'k}}q_{i'k}}{p^{1/p}(\sum_{i'} q_{i'k})^{(p-1)/p}}\right)^{p-1} \\
&= e^{v_{ik}}q_{ik}\left(\sum_{i'} e^{v_{i'k}}q_{i'k}\right)^{(p-1)}\frac{1}{(\sum_{i'} q_{i'k})^{(p-1)}}.
\end{aligned} \tag{12}$$

In our case, we choose $\mathbf{q}_0$ to be constant, $q_{0ik} = q_0$ for all i,k. We can now obtain $\mathcal{Q}$:

$$\mathcal{Q}(\mathbf{q}_0, \mathbf{M}) = \left\{ \mathbf{q} \Big| \mathbf{q} = e^{-(\mathbf{M}\boldsymbol{\lambda})_{ik}} \left(\sum_{i'} e^{-(\mathbf{M}\boldsymbol{\lambda})_{i'k}} \right)^{(p-1)} \frac{q_0}{I^{(p-1)}} \text{ for some } \boldsymbol{\lambda} \in \mathcal{R}^n \right\}.$$

In order to make the last fraction become 1, we choose $q_0 = I^{(p-1)}$. We now need only to define $\mathbf{p}_0$ in order to define the dual problem. In our case, we choose $\mathbf{p}_0 = \mathbf{0}$ so that the dual objective function is $B_\phi(\mathbf{0}, \mathbf{q})$. Let us choose $\mathbf{q} \in \mathcal{Q}$, that is, $\mathbf{q}_{ik} = e^{-(\mathbf{M}\boldsymbol{\lambda})_{ik}} \left(\sum_{i'} e^{-(\mathbf{M}\boldsymbol{\lambda})_{i'k}} \right)^{(p-1)}$ and substitute using (11) and the definitions of ϕ and B_ϕ:

$$\begin{aligned}
B_\phi(\mathbf{0}, \mathbf{q}) &= \phi(\mathbf{0}) - \phi(\mathbf{q}) - \langle \nabla\phi(\mathbf{q}), \mathbf{0} - \mathbf{q} \rangle \\
&= -\phi(\mathbf{q}) + \mathbf{q} \cdot \nabla\phi(\mathbf{q}) \\
&= -\phi(\mathbf{q}) + \frac{1}{p} \sum_{ik} q_{ik} + \phi(\mathbf{q}) \\
&= \frac{1}{p} \sum_k \left(\sum_i e^{-(\mathbf{M}\boldsymbol{\lambda})_{ik}} \right) \left(\sum_{i'} e^{-(\mathbf{M}\boldsymbol{\lambda})_{i'k}} \right)^{(p-1)} \\
&= \frac{1}{p} \sum_k \left(\sum_i e^{-(\mathbf{M}\boldsymbol{\lambda})_{ik}} \right)^p = \frac{1}{p} R_{p,\exp}(\boldsymbol{\lambda}).
\end{aligned}$$

Thus, we have arrived at exactly the objective function for our algorithm. In other words, the function ϕ was carefully chosen so that the dual objective would be exactly as we wished, modulo the constant factor $1/p$ which does not affect minimization.

Part 4 of Theorem 10 tells us that the objective function of our algorithm has a unique minimizer in $\bar{\mathcal{Q}}$ as long as A1.-A5. are obeyed, which holds from Lemma 13. It remains only to show that a vector in $\bar{\mathcal{Q}}$ yields a unique vector in $\bar{\mathcal{Q}}'$. Consider a sequence of vectors in $\mathcal{Q}$ defined element-wise by $q_{\ell,ik} = e^{-(\mathbf{M}\boldsymbol{\lambda})_{\ell,ik}} \left(\sum_{i'} e^{-(\mathbf{M}\boldsymbol{\lambda})_{\ell,i'k}} \right)^{p-1}$ such that $q_\ell \to \bar{q}$ as $\ell \to \infty$. Then consider the sequence defined by:

$$\frac{q_{\ell,ik}}{\left(\sum_{i'} q_{\ell,i'k}\right)^{(p-1)/p}} = e^{-(\mathbf{M}\boldsymbol{\lambda})_{\ell,ik}}.$$

By definition of $\mathcal{Q}'$, each vector in this sequence is in $\mathcal{Q}'$. This sequence converges pointwise to $\frac{\bar{q}_{ik}}{\left(\sum_{i'} \bar{q}_{i'k}\right)^{(p-1)/p}} \in \bar{\mathcal{Q}}'$, or if $\bar{q}_{ik} = 0$, then the ik^{th} component of the sequence converges to 0. Since we are in a finite dimensional space, namely $\mathcal{R}^{IK}$, pointwise convergence is sufficient. ■

It was unnecessary to state the primary objective $B_\phi(\mathbf{p}, \mathbf{q}_0)$ explicitly to prove the theorem, however, we state it in order to compare with the relative entropy case where $p = 1$. Recall that $\mathbf{q}_0$ is the constant vector with entries I^{p-1}. Thus, $(\nabla\phi(\mathbf{q}_0))_{ik} = \frac{1}{p} + \gamma(q_0, \mathbf{q}_0) = \frac{1}{p} + \ln(q_0 / [p^{1/p} (I q_0)^{(p-1)/p}]) = \frac{1}{p}(1 - \ln p)$ for all ik.

$$\begin{aligned}
B_\phi(\mathbf{p}, \mathbf{q}_0) &= \phi(\mathbf{p}) - \phi(\mathbf{q}_0) - \langle \nabla\phi(\mathbf{q}_0), \mathbf{p} - \mathbf{q}_0 \rangle \\
&= \phi(\mathbf{p}) - \langle \nabla\phi(\mathbf{q}_0), \mathbf{p} \rangle + \frac{1}{p} I^p K = \phi(\mathbf{p}) - (\nabla\phi(\mathbf{q}_0))_{ik} \sum_{ik} p_{ik} + \frac{1}{p} I^p K \\
&= \sum_{ik} p_{ik} \ln \left[\frac{p_{ik}}{p^{1/p} \left(\sum_{i'} p_{i'k}\right)^{(p-1)/p}} \right] - \frac{1}{p}(1 - \ln p) \sum_{ik} p_{ik} + \frac{1}{p} I^p K.
\end{aligned}$$

For $p = 1$ this reduces exactly to the relative entropy case.

One interesting note is how to find a function ϕ to suit such a problem; when we introduced it, we gave no indication of the techniques required to find such a function. In this case, we discovered the function ϕ again via convex duality. We knew the desired dual problem was precisely our objective $R_{p,\exp}$, thus, we were able to recover the primal problem by convex conjugation. The double dual in this case is the objective itself. From there, the function ϕ was obtained by analogy with the relative entropy case.

12. Conclusions

We have provided a method for constructing a ranked list where correctness at the top of the list is most important. Our main contribution is a general set of convex objective functions determined by a loss ℓ and price function g. A boosting-style algorithm based on a specific family of these objectives is derived. We have demonstrated the effect of a number of different price functions, and it is clear, both theoretically and empirically, that a steeper price function concentrates harder at the top of the list.

Acknowledgments

Thanks to the anonymous reviewers regarding Theorem 3, the experiments, and parts of the discussion, and especially for finding the numerous errors that come about from single authorship. Thanks to Rob Schapire for his advice, particularly with Lemma 11, thanks to Adrian Banner for careful proofreading, and thanks to Sinan Güntürk, particularly regarding Lemma 7. Also thanks to Eero Simoncelli and Dave Waltz. This work was supported by an NSF postdoctoral research fellowship under grant DBI-0434636 at New York University.

Appendix A.

We provide proofs of Lemma 11 and Lemma 13.

Proof (Of Lemma 11) First, rewrite ϕ:

$$\phi(\mathbf{q}) = \sum_k \left[\left(\sum_i q_{ik} \ln q_{ik} \right) - (\ln p^{1/p}) \left(\sum_i q_{ik} \right) - \frac{p-1}{p} \left(\sum_i q_{ik} \right) \ln \left(\sum_i q_{ik} \right) \right].$$

The middle term is linear so it does not affect convexity of the sum. It is sufficient to prove convexity of the following function, since ϕ would then be a sum (over k) of convex functions. Define $f : \mathcal{R}^I_{\geqslant 0} \to \mathcal{R}$ as follows, for $\mathbf{q} \in \mathcal{R}^I_+$:

$$f(\mathbf{q}) := \left(\sum_i q_i \ln q_i \right) + \frac{1-p}{p} \left(\sum_i q_i \right) \ln \left(\sum_i q_i \right).$$

Thus, the Hessian is:

$$\frac{\partial f(\mathbf{q})}{\partial q_\ell \partial q_i} = \frac{1}{q_i} \delta_{i=\ell} + \frac{1-p}{p} \frac{1}{\sum_{i'} q_{i'}}.$$

To show that the Hessian is positive definite, we show that $\mathbf{w}^{\mathbf{T}}\mathbf{H}\mathbf{w} > 0$ whenever $\mathbf{w} \neq \mathbf{0}$.

$$\begin{aligned}\sum_{i\ell} w_i w_\ell \frac{\partial f}{\partial q_\ell \partial q_i} &= \sum_i w_i^2 \frac{1}{q_i} + \frac{1-p}{p}\left(\sum_i w_i\right)^2 \frac{1}{\sum_i q_i} \\ &= \left(\frac{1}{\sum_i q_i}\right)\left[\left(\sum_i w_i^2 \frac{1}{q_i}\right)\left(\sum_i q_i\right) + \left(\frac{1}{p}-1\right)\left(\sum_i w_i\right)^2\right].\end{aligned}$$

Now, consider the Cauchy-Schwarz inequality, used in the following way:

$$\left(\sum_i w_i\right)^2 = \left\langle \frac{\mathbf{w}}{\sqrt{\mathbf{q}}}, \sqrt{\mathbf{q}}\right\rangle^2 \leq \left\|\frac{\mathbf{w}}{\sqrt{\mathbf{q}}}\right\|_2^2 \|\sqrt{\mathbf{q}}\|_2^2 = \left(\sum_i \frac{w_i^2}{q_i}\right)\left(\sum_i q_i\right).$$

Substituting back,

$$\begin{aligned}\sum_{i\ell} w_i w_\ell \frac{\partial f}{\partial q_\ell \partial q_i} &\geq \left(\frac{1}{\sum_i q_i}\right)\left[\left(\sum_i w_i^2 \frac{1}{q_i}\right)\left(\sum_i q_i\right) + \frac{1}{p}\left(\sum_i w_i\right)^2 - \left(\sum_i w_i^2 \frac{1}{q_i}\right)\left(\sum_i q_i\right)\right] \\ &= \left(\frac{1}{\sum_i q_i}\right)\frac{1}{p}\left(\sum_i w_i\right)^2.\end{aligned}$$

Recall that equality in Cauchy-Schwarz is only achieved when vectors are dependent, that is, for some $\alpha \in \mathcal{R}$, $w_i = \alpha q_i$ for all i. Since the elements of $\mathbf{q}$ are all strictly positive, if $w_i = \alpha q_i$, then at the same time we cannot have $\sum_i w_i = 0$. Thus, when equality holds in Cauchy-Schwarz, then $(\sum_i w_i)^2 > 0$ unless $\mathbf{w} = \mathbf{0}$. Thus, whether the Cauchy-Schwarz inequality is strict or not, we have:

$$\sum_{i\ell} w_i w_\ell \frac{\partial f}{\partial q_\ell \partial q_i} > 0 \text{ whenever } \mathbf{w} \neq \mathbf{0}.$$

Thus, ϕ is strictly convex. ■

Proof *(Of Lemma 13)* Condition A1. was proven in Lemma 12. To show A2., note that:

$$(\phi^*(\mathbf{v}))_{ik} = p e^{(v_{ik}-1/p)}\left(\sum_{i'} e^{(v_{i'k}-1/p)}\right)^{p-1}.$$

Thus, $\Delta_{\phi^*} = \mathcal{R}^{IK}$.

For A3., let us simplify using (11), where this calculation is valid for $\mathbf{p}, \mathbf{q} \in \Delta_\phi \times \text{int}(\Delta_\phi)$:

$$\begin{aligned}B_\phi(\mathbf{p},\mathbf{q}) &= \phi(\mathbf{p}) - \phi(\mathbf{q}) - \nabla\phi(\mathbf{q})\cdot(\mathbf{p}-\mathbf{q}) \\ &= \sum_{ik} p_{ik}\gamma(p_{ik},\mathbf{p}) - \phi(\mathbf{q}) - \frac{1}{p}\sum_{ki}(p_{ik}-q_{ik}) - \sum_{ik} p_{ik}\gamma(q_{ik},\mathbf{q}) + \phi(\mathbf{q}) \\ &= \sum_{ik} p_{ik}\Big(\gamma(p_{ik},\mathbf{p}) - \gamma(q_{ik},\mathbf{q})\Big) - \frac{1}{p}\sum_{ik}(p_{ik}-q_{ik}). \qquad (13)\end{aligned}$$

Now we consider the boundary. If for some ik pair, $p_{ik}=0$ then let $p_{ik}(\gamma(p_{ik},\mathbf{p})-\gamma(q_{ik},\mathbf{q}))=0$ for all $\mathbf{q}$. If for some ik pair, $p_{ik}\neq 0$ and additionally $q_{ik}=0$ we define $B_\phi(\mathbf{p},\mathbf{q})=\infty$. This completes our definition of B_ϕ on the boundary of $\mathcal{R}_+^{IK}$. Let us prove that $B_\phi(\mathbf{p},\mathbf{q})=0$ implies $\mathbf{p}=\mathbf{q}$. Considering the interior, B_ϕ can only be 0 at a minimum since it is non-negative. A necessary condition for B_ϕ to be at a minimum is for $\partial B_\phi(\mathbf{p},\mathbf{q})/\partial p_{ik}=0$ for all ik:

$$\forall ik \quad 0=\frac{\partial B_\phi(\mathbf{p},\mathbf{q})}{\partial p_{ik}}=1-\frac{p-1}{p}+\gamma(p_{ik},\mathbf{p})-\gamma(q_{ik},\mathbf{q})-\frac{1}{p}\Rightarrow \forall ik \quad \gamma(p_{ik},\mathbf{p})-\gamma(q_{ik},\mathbf{q})=0.$$

It is true that $\gamma(p_{ik},\mathbf{p})-\gamma(q_{ik},\mathbf{q})=0$ for pair ik implies that $p_{ik}=q_{ik}$. To see this, note that one can determine p_{ik} directly from the $\gamma(p_{ik},\mathbf{p})$ values as follows. Set $z_{ik}:=p^{1/p}\exp(\gamma(p_{ik},\mathbf{p}))$. Now,

$$z_{ik}\left(\sum_{i'} z_{i'k}\right)^{p-1}=p_{ik}.$$

Hence, $\forall ik, \gamma(p_{ik},\mathbf{p})-\gamma(q_{ik},\mathbf{q})=0$ implies that $\mathbf{p}=\mathbf{q}$. Consider now the boundary. If for any ik, $p_{ik}\neq 0$ and $q_{ik}=0$ then $B_\phi(\mathbf{p},\mathbf{q})=\infty\neq 0$. So, if $B_\phi(\mathbf{p},\mathbf{q})=0$, then whenever $q_{ik}=0$ we must have $p_{ik}=0$. On the other hand, if $p_{ik}=0$, there will be a contribution to $B_\phi(\mathbf{p},\mathbf{q})$ of $\frac{1}{p}q_{ik}$, implying that q_{ik} must be 0 in order for $B_\phi(\mathbf{p},\mathbf{q})=0$. Thus, A3. holds.

We now show A4. Let us define the boundary values for $\mathcal{L}_\phi$. If for some k we have $\sum_{i'} q_{i'k}=0$, then let $(\mathcal{L}_\phi(\mathbf{q},\mathbf{v}))_{ik}=0$ for all i. Otherwise, (12) can be used as written. Thus, we always have $\mathcal{L}_\phi(\mathbf{q},\mathbf{0})=\mathbf{q}$, and $\mathcal{L}_\phi(\mathbf{q},\mathbf{v})$ is jointly continuous in $\mathbf{q}$ and $\mathbf{v}$. Now consider $B_\phi(\mathcal{L}_\phi(\mathbf{q},\mathbf{v}),\mathbf{q})$. Let us simplify this expression in the interior, starting from (12) and (13) and using the notation $\{\mathcal{L}\}_{ik}$ for the vector $\{\mathcal{L}_\phi(\mathbf{q},\mathbf{v})\}_{ik}$.

$$\begin{aligned}
B_\phi(\mathcal{L},\mathbf{q}) &= \sum_{ik}\mathcal{L}_{ik}\Big(\gamma(\mathcal{L}_{ik},\mathcal{L})-\gamma(q_{ik},\mathbf{q})\Big)-\frac{1}{p}\sum_{ik}(\mathcal{L}_{ik}-q_{ik})\\
&= \sum_{ik}\mathcal{L}_{ik}\ln\left(\frac{\mathcal{L}_{ik}}{p^{1/p}(\sum_{i'}\mathcal{L}_{i'k})^{(p-1)/p}}\frac{p^{1/p}(\sum_{i'}q_{i'k})^{(p-1)/p}}{q_{ik}}\right)-\frac{1}{p}\sum_{ik}(\mathcal{L}_{ik}-q_{ik})\\
&= \sum_{ik}\mathcal{L}_{ik}\ln\left[\frac{e^{v_{ik}}q_{ik}(\sum_{i'}e^{v_{i'k}}q_{i'k})^{p-1}\left(\frac{1}{\sum_{i'}q_{i'k}}\right)^{p-1}}{\left[(\sum_{i'}e^{v_{i'k}}q_{i'k})^p\left(\frac{1}{\sum_i q_{i'k}}\right)^{p-1}\right]^{(p-1)/p}}\frac{(\sum_{i'}q_{i'k})^{(p-1)/p}}{q_{ik}}\right]\\
&\qquad -\frac{1}{p}\sum_{ik}(\mathcal{L}_{ik}-q_{ik})\\
&= \sum_{ik}\mathcal{L}_{ik}v_{ik}-\frac{1}{p}\sum_{ik}(\mathcal{L}_{ik}-q_{ik}).
\end{aligned}$$

Thus, since $\mathcal{L}_\phi$ is jointly continuous in $\mathbf{q}$ and $\mathbf{v}$, B_ϕ is jointly continuous in $\mathbf{q}$ and $\mathbf{v}$.

For A5., we need to show that $B_\phi(\mathbf{p},\cdot)$ is coercive, meaning that the level set $\{\mathbf{q}\in\Delta_\phi : B_\phi(\mathbf{p},\mathbf{q})\leq c\}$ is bounded, with $\mathbf{p}\in\Delta_\phi\backslash\text{int}(\Delta_\phi)$ which are vectors in $\mathcal{R}_+^{IK}$ with at least one entry that is 0. Recall that we use the convention $0\ln 0=0$. Consider from (13), using the fact that for any ik pair,

$\ln q_{ik}^{(p-1)/p} \leq \ln \left(\sum_i q_{ik}\right)^{(p-1)/p}$:

$$\begin{aligned} B_\phi(\mathbf{p},\mathbf{q}) &= \sum_{ik} p_{ik}\Big(\gamma(p_{ik},\mathbf{p}) - \gamma(q_{ik},\mathbf{q})\Big) - \frac{1}{p}\sum_{ik}(p_{ik}-q_{ik}) \\ &= \sum_{ik} -p_{ik}\gamma(q_{ik},\mathbf{q}) + \frac{1}{p}q_{ik} + \text{function}(\mathbf{p}) \\ &\geq \sum_{ik} -p_{ik}\ln q_{ik} + p_{ik}\ln\left(q_{ik}^{(p-1)/p}\right) + \frac{1}{p}q_{ik} + \text{function}(\mathbf{p}) \\ &= \frac{1}{p}\sum_{ik} -p_{ik}\ln q_{ik} + q_{ik} + \text{function}(\mathbf{p}). \end{aligned}$$

Since logarithms grow slowly, one can choose a q_{ik} large enough so that this sum exceeds any fixed constant c, regardless of the values of the other q_{ik}'s. Thus, the set $\{\mathbf{q} \in \Delta_\phi : B_\phi(\mathbf{p},\mathbf{q}) \leq c\}$ is bounded. We are done checking the conditions. ■

Abstract

Nondeterministic classifiers are defined as those allowed to predict more than one class for some entries from an input space. Given that the true class should be included in predictions and the number of classes predicted should be as small as possible, these kind of classifiers can be considered as Information Retrieval (IR) procedures. In this paper, we propose a family of IR loss functions to measure the performance of nondeterministic learners. After discussing such measures, we derive an algorithm for learning optimal nondeterministic hypotheses. Given an entry from the input space, the algorithm requires the posterior probabilities to compute the subset of classes with the lowest expected loss. From a general point of view, nondeterministic classifiers provide an improvement in the proportion of predictions that include the true class compared to their deterministic counterparts; the price to be paid for this increase is usually a tiny proportion of predictions with more than one class. The paper includes an extensive experimental study using three deterministic learners to estimate posterior probabilities: a multiclass Support Vector Machine (SVM), a Logistic Regression, and a Naïve Bayes. The data sets considered comprise both UCI multi-class learning tasks and microarray expressions of different kinds of cancer. We successfully compare nondeterministic classifiers with other alternative approaches. Additionally, we shall see how the quality of posterior probabilities (measured by the Brier score) determines the goodness of nondeterministic predictions.

Keywords: nondeterministic, multiclassification, reject option, multi-label classification, posterior probabilities

1. Introduction

There are several learners that successfully solve classification tasks in which the number of classes is higher than two; see for instance Wu et al. (2004) and Lin et al. (2008). However, for each class C most classification errors frequently occur between small subsets of classes that are somehow similar to C, regardless of the approach used. This fact suggests that multiclass classifiers would increase in reliability if they were allowed to express their doubts whenever they were asked to classify some entries.

In this paper we explore how to learn classifiers with multiple outcomes, like nondeterministic automata; we shall call them *nondeterministic classifiers*. Since they return a set of values, these classifiers could be called *set-valued* classifiers. To fix ideas, let us consider a screening for a set of medical diseases (or other diagnostic situations); for some inputs, a nondeterministic classifier

would be able to predict not just one single disease, but a set of options. These multiple predictions will be provided to domain experts when the classifier is not sure enough to give a unique class. Thus nondeterministic predictions may discard some options and allow domain experts to make practical decisions. Even when the nondeterministic classifier returns most of the available classes for the representation of an entry, we can read that the learned hypothesis is acknowledging its ignorance about how to deal with that entry.

It is evident that nondeterministic classifiers will include *true* classes in their predictions more frequently than deterministic hypotheses: they only have one possibility to be right. In this sense, nondeterministic predictions are backed by greater reliability. To be useful, however, nondeterministic classifiers should not only predict a set of classes containing the correct or true one, but their prediction sets should also be as small as possible. Notice that these requirements are common in algorithms designed for *Information Retrieval*. In this case, the queries are the entries to be classified and the *Recall* and *Precision* are then applied to each prediction. Hence, the loss functions for nondeterministic classifiers can be built as combinations of IR measures, as F_β functions are.

Starting from the distribution of posterior probabilities of classes, given one entry, we present an algorithm that computes the subset of classes with the lowest expected loss. In the experiments reported at the end of the paper, we employed three deterministic learners that provide posterior probabilities: Support Vector Machines *(SVM)*, Logistic Regression *(LR)*, and Naïve Bayes *(NB)*. We successfully compared the achievements of our nondeterministic classifiers with those obtained by other alternative approaches.

The paper is organized as follows. In the next section, we present an overview of related work on classifiers that return subsets of classes instead of a single class. The formal settings both for nondeterministic classifiers and their loss functions are presented in the third section. After that, in Section 4, we derive an algorithm to learn nondeterministic hypotheses. Then, we conclude the paper with a section in which we report an experimental study of their performance. In addition to the comparison mentioned above, we discuss the role played by the deterministic learner that provides posterior probabilities. We see that the quality of posterior probabilities determines the goodness of nondeterministic predictions. The data sets used are publicly available and, in addition to a group of data sets from the UCI Repository (Asuncion and Newman, 2007), they include a group of classification tasks of cancer patients from gene expressions captured by microarrays.

2. Related Work

Nondeterministic classifiers are somehow related to classifiers with *reject option* (Chow, 1970). In this approach, the entries that are likely to be misclassified are rejected, they are not classified and can be handled by more sophisticated procedures: a manual classification, for instance. The core assumption is that the cost of making a wrong decision is 1, while the cost of using the reject option is given by some $d, 0 < d < 1$. In this context, provided that posterior probabilities are exactly known, an optimal rejection rule can be devised (Chow, 1970; Bartlett and Wegkamp, 2008): an entry is rejected if the maximum posterior probability is less than a threshold. Notice that classifiers with reject option are a relaxed version of nondeterministic classifiers. Rejection is a nondeterministic classification that includes the complete set of classes. On the other hand, instead of avoiding difficult classifications, for each entry, nondeterministic classifers adventure a set of possible classes, not necessarily the complete set.

However, predictors of more than one class are not completely new. Given an $\varepsilon \in [0,1]$, the so-called confidence machines make *conformal predictions* (Shafer and Vovk, 2008): they produce a set of labels containing the true class with a probability greater than $1-\varepsilon$.

To the best of our knowledge, the most directly related work to the approach presented in this paper is that of Zaffalon (2002) and Corani and Zaffalon (2008a,b). In these papers, the authors describe the *Naïve Credal Classifier*, a set-valued classifier which is an extension of the Naïve Bayes classifier to imprecise probabilities. The Naïve Credal Classifier models prior ignorance about the distribution of classes by means of a set of prior densities (also called the prior *credal set*), which is turned into a set of posterior probabilities by element-wise application of Bayes' rule. The classifier returns all the classes that are *non-dominated* by any other class according to the posterior credal set.

Another learning task that is related to this paper is multi-label classification. However, training instances in multi-label tasks can belong to more than one class, while nondeterministic training sets are the same as those of standard classification. In Tsoumakas and Katakis (2007), the authors provide an in-depth description of multi-label classification, enumerate several methods and compare their performance using Information Retrieval measures. Some applications have likewise arisen within the context of hierarchical organization of biological objects: predicting gene functions (Clare and King, 2003), or mapping biological entities into ontologies (Kriegel et al., 2004).

The formal setting presented in this paper was previously introduced in Alonso et al. (2008). There, we dealt with an interesting application of nondeterministic classifiers, in which classes (or *ranks*, in that context) are linearly ordered. The aim was to predict the rank (in an ordered scale) of carcasses of beef cattle. This value determines, on the one hand, the prices to be obtained by carcasses and, on the other, the genetic value of animals in order to select studs for the next generation. In this application, nondeterministic classifiers return an interval of ranks. Interval predictions are useful even when the intervals comprise more than one rank. For instance, it is possible to reject an animal as a stud for the next generation when a prediction interval is included in the lowest part of the scale. However, if we need a unique rank, we may decide to appeal to an *actual* expert to resolve the ambiguity, an expensive classification procedure not always available in practice.

The novelty of this paper is that now we deal with a standard classification setting; that is, the sets of classes are not ordered. This fact is very important as the search for the optimal prediction leads to a dramatic difference in complexity. Thus, if k is the number of classes, the search in the ordinal case is just of order k^2, while in the unordered case, at a first glance, the search is of order 2^k. However, the Theorem of Correctness of Algorithm 1 proves that this search can be accomplished in polynomial time.

Additionally, this paper reports an extensive experimental study. First, we test whether nondeterministic classifiers outperform *Naïve Credal Classifiers* and other alternative approaches. We then investigate the role played by the ingredients of nondeterministic classifiers.

3. Formal Presentation and Notation

Let $\mathcal{X}$ be an input space and $\mathcal{Y} = \{C_1, ..., C_k\}$ a finite set of classes. We consider a multiclassification task given by a training set $S = \{(x_1, y_1), \ldots, (x_n, y_n)\}$ drawn from an unknown distribution $Pr(X,Y)$ from the product $\mathcal{X} \times \mathcal{Y}$. Within this context, we define

Definition 1 *A* nondeterministic hypothesis *is a function h from the input space to the set of non-empty subsets of $\mathcal{Y}$; in symbols, if $\mathscr{P}(\mathcal{Y})$ is the set of all subsets of $\mathcal{Y}$,*

$$h : \mathcal{X} \longrightarrow \mathscr{P}(\mathcal{Y}) \setminus \{\varnothing\}.$$

The aim of such a learning task is to find a nondeterministic hypothesis h from a space $\mathcal{H}$ that optimizes the *expected prediction performance (or risk)* on samples S' independently and identically distributed (i.i.d.) according to the distribution $Pr(X,Y)$

$$R^{\Delta}(h) = \int \Delta(h(x),y)\, d(Pr(x,y)),$$

where $\Delta(h(x),y)$ is a loss function that measures the penalty due to the prediction $h(x)$ when the true value is y.

In nondeterministic classification, we would like to favor those decisions of h that contain the true classes, and a smaller rather than a larger number of classes. In other words, we interpret the output $h(x)$ as an imprecise answer to a query about the right class of an entry $x \in \mathcal{X}$. Thus, nondeterministic classification can be seen as a kind of Information Retrieval task for each entry.

Performance in Information Retrieval is compared using different measures in order to consider different perspectives. The most frequently used measures are *Recall* (proportion of all relevant documents that are found by a search) and *Precision* (proportion of retrieved documents that are relevant). The harmonic average of the two amounts is used to capture the goodness of a hypothesis in a single measure. In the weighted case, the measure is called F_β. The idea is to measure a tradeoff between *Recall* and *Precision*.

For further reference, let us recall the formal definitions of these Information Retrieval measures. Thus, for a prediction of a nondeterministic hypothesis $h(x)$ with $x \in \mathcal{X}$, and a class $y \in \mathcal{Y}$, we can compute the following contingency matrix, where $z \in \mathcal{Y}$,

	$y = z$	$y \neq z$
$z \in h(x)$	a	b
$z \notin h(x)$	c	d

(1)

in which each entry (a,b,c,d) is the number of times that the corresponding combination of memberships occurs. Notice that a can only be 1 or 0, depending on whether the class y is included in the prediction $h(x)$ or not; b is the number of classes different from y included in $h(x)$; $c = 1 - a$; and d is the number of classes different from y that are not included in $h(x)$.

According to the matrix, Equation (1), if h is a nondeterministic hypothesis and $(x,y) \in \mathcal{X} \times \mathcal{Y}$, we thus have the following definitions.

Definition 2 *The* Recall *in a* query *(i.e., an entry x) is defined as the proportion of relevant classes (y) included in $h(x)$:*

$$R(h(x),y) = \frac{a}{a+c} = a = 1_{y \in h(x)}.$$

Definition 3 *The* Precision *is defined as the proportion of retrieved classes in $h(x)$ that are relevant (y):*

$$P(h(x),y) = \frac{a}{a+b} = \frac{1_{y \in h(x)}}{|h(x)|}.$$

$h(x)$	*Precision*	*Recall*	F_1	F_2
$[1,2,3]$	0.33	1	0.50	0.71
$[1,2]$	0.50	1	0.67	0.83
$[1]$	1	1	1	1
$[2,3,4]$	0	0	0	0

Table 1: The *Precision*, *Recall*, F_1, and F_2 for different predictions of a nondeterministic classifier h for an entry x with class 1, $(y = 1)$

In other words, given a hypothesis h, the *Precision* for an entry x, that is, $P(h(x), y)$, is the probability of finding the true class (y) of the entry (x) by randomly choosing one of the classes of $h(x)$.

Finally, the tradeoff is formalized by

Definition 4 *The F_β is defined, in general, by*

$$F_\beta(h(x), y) = \frac{(1+\beta^2)PR}{\beta^2 P + R} = \frac{(1+\beta^2)a}{(1+\beta^2)a + b + \beta^2 c}. \tag{2}$$

Thus, for a nondeterministic classifier h and a pair (x, y),

$$F_\beta(h(x), y) = \begin{cases} \frac{1+\beta^2}{\beta^2+|h(x)|} & \text{if} \quad y \in h(x) \\ 0 & \text{otherwise.} \end{cases} \tag{3}$$

The most frequently used F-measure is F_1. For ease of reference, let us state that

$$F_1(h(x), y) = \frac{2_{y \in h(x)}}{1 + |h(x)|}.$$

Notice that for deterministic classifiers, the accuracy is equal to *Recall*, *Precision*, and F_β given that $|h(x)| = 1$.

To illustrate the use of the F-measures of an entry, let us consider an example. If we assume that the true class of an entry x is 1, $(y = 1)$, then, depending on the value of $h(x)$, Table 1 reports the *Recall*, *Precision*, F_1, and F_2. We observe that the reward attached to a prediction containing the true class with another extra class ranges from 0.667 for F_1 to 0.833 for F_2; whereas the amounts are lower when the prediction includes 2 extra classes.

Once we have the definition of F_β for individual entries, it is straightforward to extend it to a test set. Hence, when S' is a test set of size n, the average loss on it will be computed by

$$\begin{aligned} R^{\Delta^{ND}}(h, S') &= \frac{1}{n}\sum_{j=1}^{n} \Delta^{ND}(h(x'_j), y'_j) = \frac{1}{n}\sum_{j=1}^{n} \left(1 - F_\beta(h(x'_j), y'_j)\right) \\ &= \frac{1}{n}\sum_{j=1}^{n} \left(1 - \frac{1+\beta^2}{\beta^2 + |h(x'_j)|} 1_{y'_j \in h(x'_j)}\right). \end{aligned} \tag{4}$$

The average *Recall* and *Precision* can be similarly defined. For ease of reference, let us remark that the *Recall* is the proportion of times that $h(x')$ includes y' and is thus a generalization of the *deterministic accuracy*.

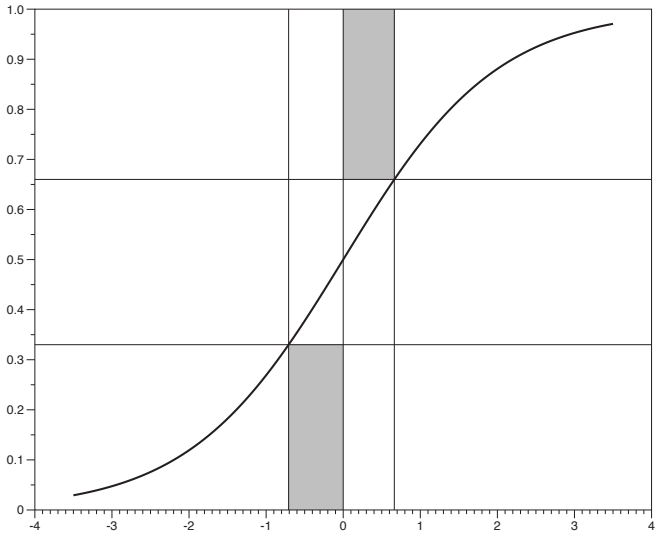

Figure 1: Conditional probabilities of class $+1$ given the discriminant value (horizontal axis) of entries $x \in \mathcal{X}$. Vertical bars separate the region where both classes $\{-1,+1\}$ have a probability of over $1/3$

3.1 Nondeterministic Classification in a Binary Task

To complete this section, let us show what nondeterministic classifiers look like in the simplest case, which will be further developed in the following sections. Let us assume that in a binary classification task (the classes are codified by -1 and $+1$) we have a loss 1 for each false classification. On the other hand, we are allowed to predict both classes, in which case the loss will be $1/3$: the F_1 for a classification of 2 classes containing the true one; see Table 1. The extension for dealing with F_β, with $\beta \neq 1$, is straightforward.

The optimum classifier will return only one class when it is sufficiently sure. In doubtful situations, however, the nondeterministic classifier should opt for predicting the 2 classes. This will be the case whenever the probability of error for both classes is higher than $1/3$, since this is the loss for predictions of two classes; see Figure 1. Therefore, if we have the conditional probabilities of classes given the entries, the optimum classifier will be given by

$$h_{ND}(x) = \begin{cases} \{-1\} & if \quad \eta(x) < 1/3 \\ \{-1,+1\} & if \quad 1/3 \leq \eta(x) < 2/3 \\ \{+1\} & if \quad 2/3 \leq \eta(x), \end{cases} \tag{5}$$

where we are representing by $\eta(x)$ the posterior probability:

$$\eta(x) = Pr(class = +1|x).$$

Notice that Equation (5) is equivalent to the generalized Bayes discriminant function described in Bartlett and Wegkamp (2008) when the cost of using the reject option is calculated using the F_1 loss function.

Algorithm 1 The nondeterministic classifier $nd^{\bullet}$, an algorithm for computing the prediction with one or more classes for an entry x provided that the posterior probabilities of classes are given

Input: $\{C_j : j = 1,..,k \, sorted \, by \, Pr(C_j|x)\}$
Input: β: trade-off between *Recall* and *Precision*
Initialize $i = 0, \Delta_0 = 1$
repeat
  $i = i + 1$
  $\Delta_i = 1 - \frac{1+\beta^2}{\beta^2+i} \sum_{j=1}^{i} Pr(C_j|x)$
until $((i == k)$ or $(\Delta_{i-1} \leq \Delta_i)$
if $(\Delta_{i-1} \leq \Delta_i)$ **then**
  return $\{C_j : j = 1,..,i-1\}$
else
  return $\{C_j : j = 1,..,k\}$
end if

4. Nondeterministic Classification Using Multiclass Posterior Probabilities

In the general multiclass setting presented at the beginning of Section 3, let x be an entry of the input space $\mathcal{X}$ and let us now assume that we know the conditional probabilities of classes given the entry, $Pr(C_j|x)$. Additionally, we shall assume that the classes are ordered according to these probabilities. In this context, we wish to define the

$$h(x) = Z \subset \mathcal{Y} = \{C_1, \ldots, C_k\}$$

that minimizes the risk defined in Equation (1) when we use the nondeterministic loss given by F_β, (Equations 2, 3, and 4). We shall prove that such an $h(x)$ can be computed by Algorithm 1, which does not need to search through all non-empty subsets of $\mathcal{Y}$.

Theorem 1 *(Correctness). If the conditional probabilities $Pr(C_j|x)$ are known, Algorithm 1 returns the nondeterministic prediction for $h(x)$ that minimizes the risk given by the loss $1 - F_\beta$.*

Proof To minimize the risk, Equation (1), it suffices to compute

$$\Delta_x(Z) = \sum_{y \in \mathcal{Y}} \Delta^{ND}(Z, y) Pr(y|x), \tag{6}$$

with $Z \subset \{C_1, \ldots, C_k\}$. Then, we only have to define

$$h(x) = argmin\{\Delta_x(Z) : Z \subset \{C_1, \ldots, C_k\}\}.$$

The proof has two parts. First, we shall see that if $h(x)$ has r classes, then those are the r classes with the highest probabilities; bearing in mind that classes are ordered, $h(x) = Z_r = \{C_j : j = 1,..,r\}$. For this purpose, we need to see that any other subset of r classes will increase the loss due to Z_r. This is a consequence of the following.

The value of Equation (6) for Z_r is Δ_r in Algorithm 1. In fact, with the complementary probability of $\sum_{j=1}^{r} Pr(C_j|x)$, we expect a loss of 1: the *true* class will not be one of the r first classes. On

the other hand, with this sum of probabilities, the *true* class will be in $h(x)$, and therefore the loss will be 1 minus the F_β of the prediction $h(x) = \{C_j : j = 1,..,r\}$:

$$\begin{aligned}\Delta_x(C_j : j = 1,..,r) &= \left(1 - \sum_{j=1}^{r} Pr(C_j|x)\right) + \left(\sum_{j=1}^{r} Pr(C_j|x)\right)\left(1 - \frac{1+\beta^2}{\beta^2+r}\right) \\ &= 1 - \frac{1+\beta^2}{\beta^2+r}\sum_{j=1}^{r} Pr(C_j|x) \\ &= \Delta_r.\end{aligned}$$

Notice that for any other subset of r classes, we could achieve a similar expression simply by modifying the set of posterior probabilities of the last sum. Therefore, to minimize the value of Equation (6) with r classes, we need those with the highest probability.

In the second step, we only have to show that the index r returned by the Algorithm is the right one. We shall see that the search for the best r can be accomplished in linear time, as in the Algorithm. In fact, we shall establish that when the Algorithm reaches the number of classes with which the loss increases, adding further classes will only increase the loss. In symbols, we shall prove that

$$\Delta_r \leq \Delta_{r+1} \Rightarrow \Delta_{r+1} \leq \Delta_{r+2}.$$

To do so, we shall next express the exit condition of the loop $\Delta_r \leq \Delta_{r+1}$ when $(r+1) \leq k$ in a different way. The following expressions are equivalent:

$$\Delta_r \leq \Delta_{r+1} \tag{7}$$

$$\frac{1+\beta^2}{\beta^2+r}\sum_{j=1}^{r} Pr(C_j|x) \geq \frac{1+\beta^2}{\beta^2+r+1}\sum_{j=1}^{r+1} Pr(C_j|x)$$

$$(\beta^2+r+1)\sum_{j=1}^{r} Pr(C_j|x) \geq (\beta^2+r)\sum_{j=1}^{r+1} Pr(C_j|x)$$

$$\sum_{j=1}^{r} Pr(C_j|x) \geq (\beta^2+r)Pr(C_{r+1}|x).$$

Therefore, if $\Delta_r \leq \Delta_{r+1}$ and $(r+1) \leq k$, then

$$Pr(C_{r+1}|x) + \sum_{j=1}^{r} Pr(C_j|x) \geq (\beta^2+r)Pr(C_{r+1}|x) + Pr(C_{r+1}|x).$$

However, bearing in mind that the classes are ordered, we have that $Pr(C_{r+1}|x) \geq Pr(C_{r+2}|x)$, and using Equation (7), we conclude that

$$\sum_{j=1}^{r+1} Pr(C_j|x) \geq (\beta^2+r+1)Pr(C_{r+2}|x) \Leftrightarrow \Delta_{r+1} \leq \Delta_{r+2}.$$

■

4.1 Corollaries

In order to draw some practical consequences, let us reword the previous Theorem. It states that the optimum classification for an input x is the set of r classes with the highest posterior probabilities, where r is the lowest integer that fulfills

$$\sum_{j=1}^{r} Pr(C_j|x) \geq (\beta^2 + r) Pr(C_{r+1}|x), \tag{8}$$

or the set of all classes when this condition is not fulfilled by any r. Expressed in this way, it is straightforward to see that for two classes, with $\beta = 1$, Algorithm 1 coincides with the rule defined in Equation (5).

Additionally, we would like to underscore that Equation (8) hinders the use of naïve *thresholds* to compute nondeterministic predictions. Thus, a nondeterministic classifier that always predicts the top r classes for a constant value r is not a correct option. Equation (8) shows that r, at least, depends on the input x.

Moreover, we should not search for a threshold λ to return, for all inputs, the first r classes whose sum of probabilities is above λ:

$$\sum_{j=1}^{r} Pr(C_j|x) \geq \lambda. \tag{9}$$

Note that given a λ value in $[0,1]$, Equation (9) straightforwardly gives rise to a nondeterministic classifier as follows. For each input x, if the set of classes is ordered according to their posterior probabilities, we define

$$h_\lambda(x) = \left\{ C_1, \ldots, C_r : \sum_{j=1}^{r} Pr(C_j|x) \geq \lambda \quad \& \quad \sum_{j=1}^{r-1} Pr(C_j|x) < \lambda \right\}. \tag{10}$$

Again, the right-hand side of Equation (8) shows that the threshold (λ) would depend on the number of classes predicted, the probability of the first class excluded from the prediction, and the parameter β: the trade-off between *Precision* and *Recall*. The idea behind Equation (8) is that, once we have decided to include the top r classes, to add the $(r+1)^{th}$ class we should guarantee that $Pr(C_{r+1}|x)$ is not much smaller than the sum of probabilities of the top r classes.

However, it may be argued that the inaccuracy of posterior probabilities would partially invalidate the preceding theoretical discussion. In fact, posterior probabilities are not known in practice: they are estimated by algorithms that frequently try to optimize the classification accuracy of a hypothesis that returns the class with the highest probability. In other words, probabilities are discriminant values instead of thorough descriptions of the distribution of classes in a learning task. Therefore, in the experiments reported at the end of the paper, we shall consider the classifiers defined by Equation (10) as a possible alternative method to the nondeterministic classifier of Algorithm 1.

5. Experimental Results

In this section we report the results of a set of experiments conducted to evaluate the proposals of this paper. The next subsection describes the settings used in the experiments: deterministic learners, data sets, procedures to set parameters, and methods to estimate the scores.

Table 2: Description of the data sets downloaded from the UCI repository. The classes are not linearly separable

We have two goals here. On the one hand, we compare our approach with two alternative methods. The comparison will first be established with a state-of-the-art set-valued algorithm, the Naïve Credal Classifier *(NCC)* (Zaffalon, 2002; Corani and Zaffalon, 2008a,b). This algorithm is an extension of the traditional Naïve Bayes classifier towards imprecise probabilities and is designed to return robust set-valued (nondeterministic) classifications. We show that our method can improve the performance of *NCC*. We then contrast our method with an implementation of Equation (10); once again our proposals outperform this alternative way to learn nondeterministic classifiers.

On the other hand, we analyze the influence of a number of factors related to nondeterministic learners. We accordingly discuss how the scores of a nondeterministic learner are affected by the quality of posterior probabilities. We see that the performance of a nondeterministic classifier is highly correlated with the accuracy of its deterministic counterpart. The section ends with a study of the meaning of the parameter β.

5.1 Experimental Settings

We used three different methods for learning posterior probabilities in order to build nondeterministic classifiers. First, we employed the Naïve Bayes *(NB)* used by *NCC* as its deterministic counterpart (Corani and Zaffalon, 2008b). The second deterministic learner was a multiclass *SVM*; the implementation used was *libsvm* (Wu et al., 2004) with the linear kernel. Last, we employed the *logistic regression (LR)* of Lin et al. (2008). It should be noted that we are not only using the multiclass classifiers learned by *SVM* or *LR*. Primarily, we apply the mechanisms that provide posterior probabilities from their outputs.

For each of these learners, we built nd^d, where d stands for the name of the deterministic counterpart, *nb*, *svm* or *lr*. Recall that nd^d is the implementation of Algorithm 1 that aims to optimize F_1; that is, $\beta = 1$.

Table 3: Description of cancer microarray data sets used in the experiments including the original sources and papers from which they are taken. For the sake of brevity, we have denoted the papers as follows: [1] Tibshirani and Hastie (2007), [2] Tan et al. (2005), [3] Staunton et al. (2001), [4] Yeung and Bumgarner (2003)

In the experiments that follow, we used two kinds of data sets. First, we considered data sets downloaded from the UCI repository (Asuncion and Newman, 2007), all of which have more examples than attributes. We included all the data sets that fulfill the following rules: continuous or ordinal attribute values, no more than 40 attributes and no more than 20000 examples. The intention was to consider small data sets that are not linearly separable. Additionally, we excluded those learning tasks with missing values or in which every deterministic learner considered *(NB, SVM, LR)* achieves a proportion of successful classifications of over 95%; otherwise nondeterministic learners would be too similar to their deterministic counterpart. A description of the group of data sets considered can be found in Table 2.

We then evaluated the performance on learning tasks in which the aim was to classify cancer patients from gene expressions captured by microarrays. Unlike the first package of data sets, all the classes are now linearly separable given the dimensions of the input space and the number of entries. Table 3 shows the details of these data sets.

Every table of scores (Tables 4, 5, 6, 7, 8) is devoted to reporting the experimental results achieved in one of the kinds of data sets by one of the deterministic learners and by two nondeterministic algorithms that are to be compared. All the tables have a similar layout. First, they contain the scores of the deterministic learner d: the F_1 (or accuracy or *Recall*), and the Brier score, a measure for the quality of posterior probabilities (Brier, 1950; Yeung et al., 2005), computed by means of

$$BS = \frac{1}{2n} \sum_{i=1}^{n} \sum_{j=1}^{k} \left([y_i = C_j] - Pr(C_j|x_i) \right)^2 .$$

Then we report, for each nondeterministic learner, the F_1, *Precision*, *Recall*, and the average number of classes predicted ($|h(x)|$). All the scores were estimated by means of a 5-fold cross validation repeated 2 times. We did not use the 10-fold procedure, since in certain data sets there are too few examples in some of the classes.

Following Demšar (2006), we used the Wilcoxon signed ranks test to compare the performance of two classifiers when the measurements are F_1, *Precision*, *Recall*, or the average $|h(x)|$. Unless

Table 4: Scores obtained by Naïve Bayes, the Naïve Credal Classifier and nondeterministic classifiers on UCI data sets using a 5-fold cross validation repeated 2 times. For ease of reading, F_1, Precision (*P*), and Recall (*R*) are expressed as percentages. The best nondeterministic F_1 for each data set is boldfaced

explicitly stated, we use the expression statistically *significant differences* to mean that $p < 0.01$. Additionally, in order to provide a quick view of the order of magnitude of the scores, we have boldfaced the best nondeterministic F_1 score for each data set.

To select the regularization parameter, C, for *SVM* and *LR*, we used a 2-fold cross validation repeated 5 times performed on training sets. We searched within $C \in [10^{-2}, \ldots, 10^{2}]$.

5.2 Nondeterministic Classifiers vs. Naïve Credal Classifiers

In this subsection, we compare our nondeterministic learner with *NCC* (Corani and Zaffalon, 2008b), a state-of-the-art set-valued (nondeterministic) algorithm. In order to ensure a fair comparison, our approach uses the Naïve Bayes *(NB)* employed by *NCC* as its deterministic counterpart. Table 4 reports the scores of *NB*, *NCC* and our algorithm nd^{nb}.

The nondeterministic nd^{nb} is significantly (remember that we are using Wilcoxon tests) better than *NCC* both in *Recall* and F_1. Moreover, nd^{nb} wins in 12 out of 14 data sets in F_1, and in 11 out of 14 in *Recall*. However, the scores in *Precision* and size of predictions are more balanced; the differences are not significant. In *Precision*, *NCC* wins in 5 cases, loses in 8, and there is 1 tie situation. The size scores are favorable to *NCC* in 8 out of 14 data sets.

To complete the comparison, we should discuss the results achieved on high dimensional data sets (Table 3). Nevertheless, we do not show the scores on each data set. The characteristics of these tasks are not appropriate for Naïve Bayes (a large number of attributes with a small number of examples); therefore, the posterior probabilities of *NB* are poor (they are significantly worse than those achieved by *SVM* and *LR*) and this affects the performance of our nondeterministic algorithm and *NCC*. Our method tends to be almost deterministic, the average value for the size of predictions is $|h(x)| = 1.008$. This is not optimal, as we shall see later, but it is acceptable behavior. However,

Table 6: Scores obtained by *LR* learners on UCI data sets using a 5-fold cross validation repeated 2 times. For ease of reading, F_1, Precision (P), and Recall (R) are expressed as percentages. The best nondeterministic F_1 for each data set is boldfaced

the scores of *NCC* on these data sets are inadmissible; their classifiers predict almost all classes for every example, their average values are: $F_1 = 25.73, P = 15.39, R = 100$, and $|h(x)| = 8.58$.

In fact, the behavior of *NCC* is difficult to predict, sometimes it is almost a deterministic classifier, whereas in other tasks the number of classes predicted by *NCC* is very high. Moreover, its degree of nondeterminism is not related to the difficulty of the learning task. When the accuracy of the deterministic classifiers decreases, the average number of classes predicted would be expected

to increase. However the correlation between the accuracy of *NB* and $|h(x)|$ of *NCC* is 0.24. In the case of nd^{nb}, this correlation is -0.75: negative and quite high.

5.3 Comparing nd with Another Alternative Method

In accordance with the discussion in Section 4.1, we shall now compare the nondeterministic classifiers learned by Algorithm 1 with the alternative classifier defined in Equation (10) that uses a threshold λ for the sum of posterior probabilities. The comparison will be established with posterior probabilities provided by *SVM* and *LR* given that both outperform the accuracy achieved by Naïve Bayes classifiers in the data sets used in these experiments. The λ nondeterministic classifiers will be denoted by nd_{λ}^{d}, where *d* stands for the deterministic counterpart.

To select the parameter λ, we use a grid search employing a 2-fold cross validation repeated 5 times, aiming to optimize F_1. The searching space depends on the learning task *S*. If the proportion of successful classifications for deterministic classifiers, the accuracy, is *a*, then we search within

$\lambda \in [a_0, a_1, \ldots, a_5]$; six options distribute from a to 0.99. In symbols, $a_0 = a, a_5 = 0.99$, and $a_{i+1} - a_i = \frac{0.99-a}{5}$.

In UCI data sets, Tables 5 and 6, nd^{svm} and nd^{lr} win the corresponding nd_λ in 13 out of 14 data sets in F_1 and *Precision*. In *Recall* we have the opposite situation; λ classifiers win in 13 out of 14 cases. Moreover, λ classifiers always predict more classes than nd^{svm} and nd^{lr}. In other words, λ classifiers predict more classes than necessary. All differences are significant. Thus, our *nd* classifiers are better than those computed with the λ parameter.

In cancer microarray data, Tables 7 and 8, nd^{svm} always wins in F_1, *Precision*, and average $|h(x)|$; while nd^{svm} always loses in *Recall*. All differences are again significant. However, when posterior probabilities are provided by *LR*, the differences are not significant in F_1, although nd^{lr} has 5 wins, 1 tie and 4 losses; in *Precision* and average size of predictions the differences are significant in favor of nd^{lr}. Furthermore, as usual, the *Recall* is significantly higher for λ classifiers.

The conclusion is that λ classifiers seem to need more classes in their predictions than *nd* classifiers. In fact, Equation (9) only considers the *Recall*. In practice, this means more *Recall*, but less *Precision* and F_1. Therefore, to optimize the F_1 measure, in an experimental environment, Equation (8) is more adequate than Equation (9), as we have conjectured theoretically in Section 4.1.

5.4 The Importance of Posterior Probabilities

The objective of this subsection is to experimentally investigate the degree of dependency between nondeterministic scores and the accuracy of posterior probabilities. In this study we again employ *SVM* and *LR* with the collection of data sets detailed in Tables 2 and 3.

Let us first consider the set of UCI data sets. Comparing the results in Tables 5 and 6, it can be seen that the scores of nd^{lr} are significantly worse than those of nd^{svm} in F_1, *Precision*, *Recall* ($p < 0.03$), and in average size of predictions. The general message is that nd^{lr} include unnecessary classes in their predictions. The base posterior probabilities seem to be the cause of this behavior: the Brier score of *LR* is significantly worse than that of *SVM*.

On the other hand, the scores obtained with cancer microarray data sets are shown in Tables 7 and 8. The characteristics of UCI and microarray data sets are quite different, and this affects the performance of classifiers. The main difference is that *LR* now has a significantly better Brier score than *SVM*. Moreover, the nd^{lr} algorithm achieves better results than nd^{svm}. The differences are significant in F_1, *Precision*, *Recall* ($p < 0.02$), and average $|h(x)|$. Yet again, inferior posterior probabilities seem to be responsible for the inclusion of unnecessary classes in nondeterministic predictions.

In the preceding discussion of the scores achieved by nondeterministic learners, we found significant differences when the Brier scores of the deterministic counterparts presented significant differences. In fact, the scores of a learner built with Algorithm 1 depend on the quality of the posterior probabilities supplied by the corresponding deterministic learner. It seems plausible to draw the conclusion that the better the posterior probabilities, the better the nondeterministic scores. In order to quantify this statement, we compared deterministic Brier scores with nondeterministic F_1, *Recall*, and *Precision* values; see Figure 2. We separated the scores achieved by UCI and cancer data sets and included the scores of nd^{nb} in UCI data sets. Similar results would be achieved if we compared nondeterministic scores with deterministic accuracy.

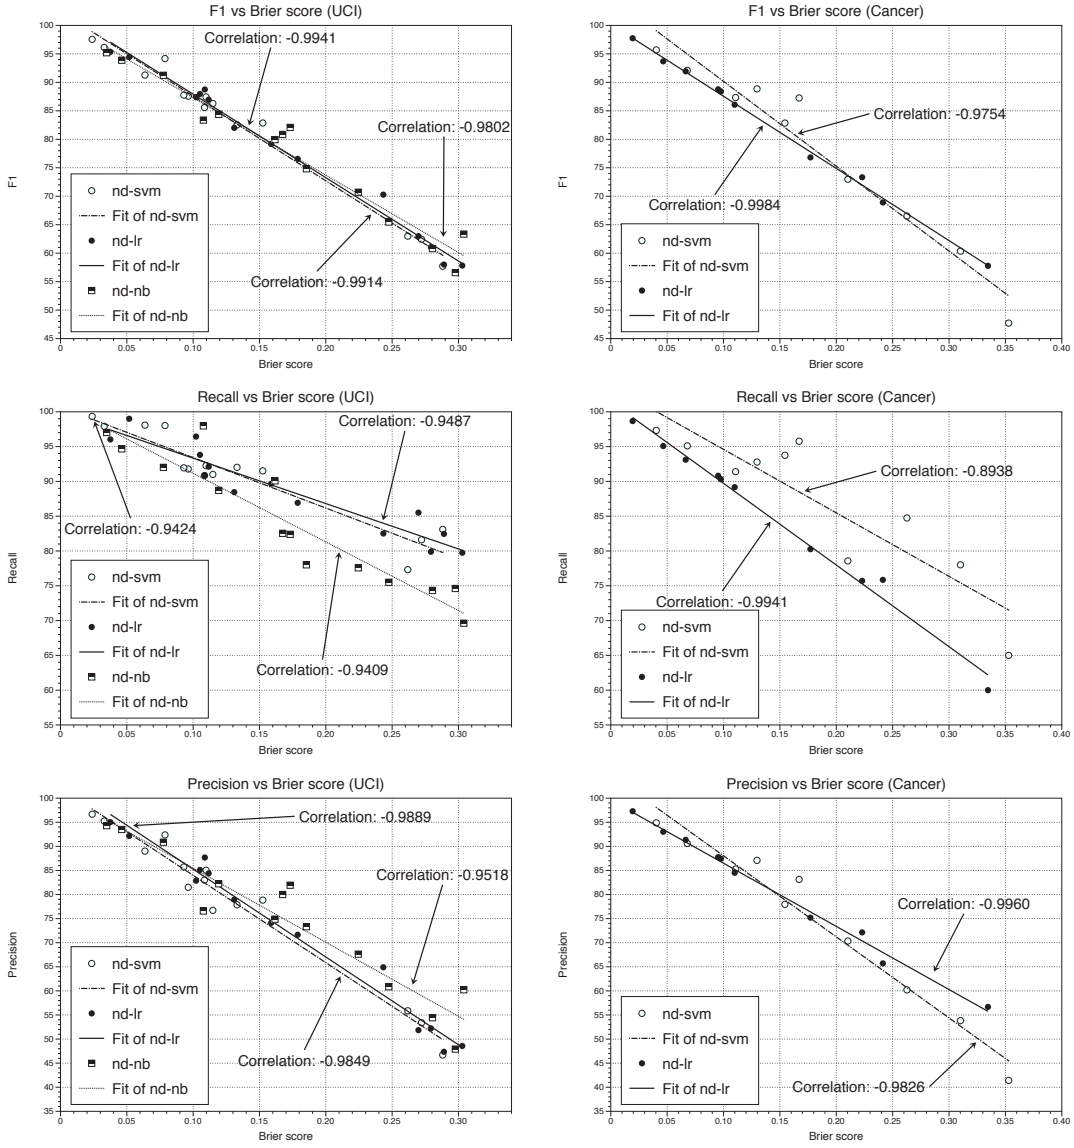

Figure 2: Correlation between Brier scores and F_1, *Recall*, and *Precision*. The left column shows the results with UCI data sets, while the right column uses cancer data sets. Similar results would be achieved if we compared nondeterministic scores with deterministic accuracy

We observed that the correlations between the Brier scores of deterministic learners and nondeterministic scores (F_1, *Recall*, and *Precision*) are very high: their absolute values are in all cases greater than 0.89. Therefore, in order to choose a nondeterministic approach in a practical application, given a data set, it would be recommendable to first analyze the Brier score of different deterministic learners.

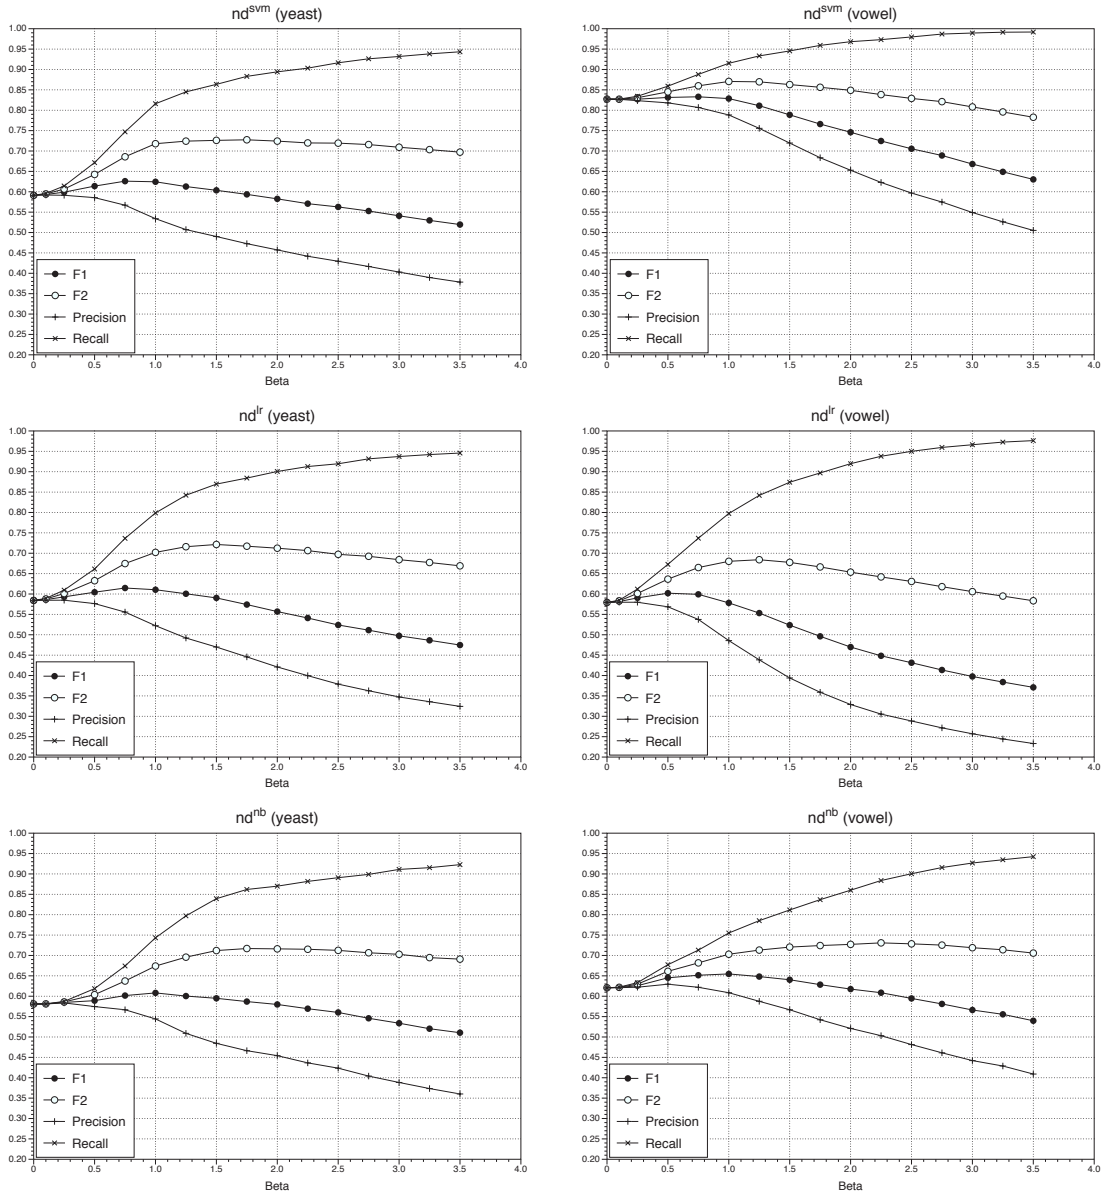

Figure 3: Evolution of F_1, F_2, *Precision* and *Recall* on two UCI data sets (*yeast* and *vowel*) for different β values and for the nondeterministic learners generated by *SVM*, *LR*, and *NB*

5.5 The Meaning of β

In this subsection, we analyze from the point of view of the user the role played by the parameter β in Algorithm 1. Its theoretical aim is to control the size of predictions: as the β value increases, the size of predictions will become bigger and therefore the *Recall* scores will be higher; see Equation (8). The problem is that it is not always of interest to increase *Recall* values, since that would worsen F_1 scores: adding more classes in predictions increases incorrect answers.

In Figure 3 we show the evolution of F_1, F_2, *Precision* and *Recall* on two UCI data sets (*yeast* and *vowel*) for different β values and for the nondeterministic learners generated by *SVM*, *LR*, and

NB. Quite similar graphs could have been generated for the other data sets used in the experiments reported in this section.

Initially, $\beta = 0$ makes the nondeterministic classifiers deterministic. Therefore, the scores represented in the left-hand side of all the graphs in Figure 3 are all the same: the accuracy of the deterministic classifier. As β values become higher, the *Recall* increases and the *Precision* decreases. The main goal of the learning method proposed here is to look for a tradeoff of these measures that is determined by β, a user-modifiable parameter.

In practice, the value of β that the classifier must aim to optimize should be fixed by an expert in the field of application in which the classifier is going to be employed. The kind of decisions that one would like to take from nondeterministic classifications must be considered.

It can be observed in the graphs in Figure 3 that the best scores in F_1 are not always achieved for $\beta = 1$. With small values of β, F_1 increases. However, when some point near 1 is exceeded, the F_1 score of the nondeterministic learner typically falls below the accuracy of the corresponding deterministic learner. Nonetheless, optimal values are frequently reached around the *nominal* value: $\beta = 1$ (or 2 respectively). Slight improvements can be achieved in F_1 (in general F_β) if we use a grid search for β values to be used in Algorithm 1.

6. Conclusions

We have studied classifiers that are allowed to predict more than one class for entries from an input space: nondeterministic or set-valued classifiers. Using a clear analogy with Information Retrieval, we have proposed a family of loss functions based on F_β measures. After discussing such measures, we derived an algorithm to learn optimal nondeterministic hypothesis. Given an entry from the input space, the algorithm requires the posterior probabilities to compute the subset of classes with the lowest expected loss.

The paper includes a set of experiments carried out on two collections of data sets. The first one was downloaded from the UCI repository, the classes of which are not linearly separable. The second group is formed by data sets whose input spaces represent microarray expressions of different kinds of cancer, the classes of which are separable.

Using these benchmarks, we first compared nondeterministic learners obtained from a Naïve Bayes with those learned by a state-of-the-art set-valued (nondeterministic) algorithm, the Naïve Credal Classifier *(NCC)* (Zaffalon, 2002; Corani and Zaffalon, 2008a,b), an extension of the traditional Naïve Bayes classifier designed to return robust set-valued classifications. We showed that, using the loss measures defined in this paper, our method can improve the performance of *NCC*. Additionally, an important advantage of our nondeterministic classifiers over *NCC* is that we can control the degree of nondeterministic behavior. We can regulate the number of classes predicted by fixing the F_β to be optimized: as β is higher (the weight of *Recall* is increased in the harmonic average F_β), the size of our predictions grows (see Section 5.5). However the nondeterministic behavior of *NCC* is quite difficult to predict.

In addition to Naïve Bayes, we used a multiclass *SVM* and a Logistic Regression. With the posterior probabilities provided by these deterministic learners, we built another alternative method to predict more than one class: the set of classes which the highest posterior probabilities summing more than a threshold λ. We also found that the classifiers built with our algorithm outperform this option based on a threshold.

On the other hand, in the experiments reported in this paper, we studied the role of the deterministic learners that explicitly provide posterior probabilities. We found that the better the posterior probabilities, the better the nondeterministic classifiers. In fact we obtained very high correlations between the Brier scores of deterministic probabilities and the F_1, *Precision* and *Recall* values of their nondeterministic counterparts.

Abstract

Recent methods for estimating sparse undirected graphs for real-valued data in high dimensional problems rely heavily on the assumption of normality. We show how to use a semiparametric Gaussian copula—or "nonparanormal"—for high dimensional inference. Just as additive models extend linear models by replacing linear functions with a set of one-dimensional smooth functions, the nonparanormal extends the normal by transforming the variables by smooth functions. We derive a method for estimating the nonparanormal, study the method's theoretical properties, and show that it works well in many examples.

Keywords: graphical models, Gaussian copula, high dimensional inference, sparsity, ℓ_1 regularization, graphical lasso, paranormal, occult

1. Introduction

The linear model is a mainstay of statistical inference that has been extended in several important ways. An extension to high dimensions was achieved by adding a sparsity constraint, leading to the lasso (Tibshirani, 1996). An extension to nonparametric models was achieved by replacing linear functions with smooth functions, leading to additive models (Hastie and Tibshirani, 1999). These two ideas were recently combined, leading to an extension called sparse additive models (SpAM) (Ravikumar et al., 2008, 2009a). In this paper we consider a similar nonparametric extension of undirected graphical models based on multivariate Gaussian distributions in the high dimensional setting. Specifically, we use a high dimensional Gaussian copula with nonparametric marginals, which we refer to as a nonparanormal distribution.

If X is a p-dimensional random vector distributed according to a multivariate Gaussian distribution with covariance matrix Σ, the conditional independence relations between the random variables $X_1, X_2, \ldots, X_p$ are encoded in a graph formed from the precision matrix $\Omega = \Sigma^{-1}$. Specifically, missing edges in the graph correspond to zeroes of Ω. To estimate the graph from a sample of size n, it is only necessary to estimate Σ, which is easy if n is much larger than p. However, when p is larger than n, the problem is more challenging. Recent work has focused on the problem of estimating the graph in this high dimensional setting, which becomes feasible if G is sparse. Yuan and Lin (2007)

Assumptions	Dimension	Regression	Graphical Models
parametric	low	linear model	multivariate normal
	high	lasso	graphical lasso
nonparametric	low	additive model	nonparanormal
	high	sparse additive model	ℓ_1-regularized nonparanormal

Figure 1: Comparison of regression and graphical models. The nonparanormal extends additive models to the graphical model setting. Regularizing the inverse covariance leads to an extension to high dimensions, which parallels sparse additive models for regression.

and Banerjee et al. (2008) propose an estimator based on regularized maximum likelihood using an ℓ_1 constraint on the entries of Ω, and Friedman et al. (2007) develop an efficient algorithm for computing the estimator using a graphical version of the lasso. The resulting estimation procedure has excellent theoretical properties, as shown recently by Rothman et al. (2008) and Ravikumar et al. (2009b).

While Gaussian graphical models can be useful, a reliance on exact normality is limiting. Our goal in this paper is to weaken this assumption. Our approach parallels the ideas behind sparse additive models for regression (Ravikumar et al., 2008, 2009a). Specifically, we replace the Gaussian with a semiparametric Gaussian copula. This means that we replace the random variable $X = (X_1, \ldots, X_p)$ by the transformed random variable $f(X) = (f_1(X_1), \ldots, f_p(X_p))$, and assume that $f(X)$ is multivariate Gaussian. This semiparametric copula results in a nonparametric extension of the normal that we call the *nonparanormal* distribution. The nonparanormal depends on the functions $\{f_j\}$, and a mean μ and covariance matrix Σ, all of which are to be estimated from data. While the resulting family of distributions is much richer than the standard parametric normal (the paranormal), the independence relations among the variables are still encoded in the precision matrix $\Omega = \Sigma^{-1}$. We propose a nonparametric estimator for the functions $\{f_j\}$, and show how the graphical lasso can be used to estimate the graph in the high dimensional setting. The relationship between linear regression models, Gaussian graphical models, and their extensions to nonparametric and high dimensional models is summarized in Figure 1.

Most theoretical results on semiparametric copulas focus on low or at least finite dimensional models (Klaassen and Wellner, 1997; Tsukahara, 2005). Models with increasing dimension require a more delicate analysis; in particular, simply plugging in the usual empirical distribution of the marginals does not lead to accurate inference. Instead we use a truncated empirical distribution. We give a theoretical analysis of this estimator, proving consistency results with respect to risk, model selection, and estimation of Ω in the Frobenius norm.

In the following section we review the basic notion of the graph corresponding to a multivariate Gaussian, and formulate different criteria for evaluating estimators of the covariance or inverse covariance. In Section 3 we present the nonparanormal, and in Section 4 we discuss estimation of the model. We present a theoretical analysis of the estimation method in Section 5, with the detailed proofs collected in an appendix. In Section 6 we present experiments with both simulated data and gene microarray data, where the problem is to construct the isoprenoid biosynthetic pathway.

2. Estimating Undirected Graphs

Let $X = (X_1, \ldots, X_p)$ denote a random vector with distribution $P = N(\mu, \Sigma)$. The undirected graph $G = (V, E)$ corresponding to P consists of a vertex set V and an edge set E. The set V has p elements, one for each component of X. The edge set E consists of ordered pairs (i, j) where $(i, j) \in E$ if there is an edge between X_i and X_j. The edge between (i, j) is excluded from E if and only if X_i is independent of X_j given the other variables $X_{\setminus\{i,j\}} \equiv (X_s : \ 1 \leq s \leq p, \ \ s \neq i, j)$, written

$$X_i \perp\!\!\!\perp X_j \ \Big| \ X_{\setminus\{i,j\}}. \tag{1}$$

It is well known that, for multivariate Gaussian distributions, (1) holds if and only if $\Omega_{ij} = 0$ where $\Omega = \Sigma^{-1}$.

Let $X^{(1)}, X^{(2)}, \ldots, X^{(n)}$ be a random sample from P, where $X^{(i)} \in \mathbb{R}^p$. If n is much larger than p, then we can estimate Σ using maximum likelihood, leading to the estimate $\widehat{\Omega} = S^{-1}$, where

$$S = \frac{1}{n} \sum_{i=1}^{n} \left(X^{(i)} - \overline{X} \right) \left(X^{(i)} - \overline{X} \right)^T$$

is the sample covariance, with $\overline{X}$ the sample mean. The zeroes of Ω can then be estimated by applying hypothesis testing to $\widehat{\Omega}$ (Drton and Perlman, 2007, 2008).

When $p > n$, maximum likelihood is no longer useful; in particular, the estimate $\widehat{\Sigma}$ is not positive definite, having rank no greater than n. Inspired by the success of the lasso for linear models, several authors have suggested estimating Σ by minimizing

$$-\ell(\Omega) + \lambda \sum_{j \neq k} |\Omega_{jk}|$$

where

$$\ell(\Omega) = \frac{1}{2} \left(\log |\Omega| - \mathrm{tr}(\Omega S) - p \log(2\pi) \right)$$

is the log-likelihood with S the sample covariance matrix. The estimator $\widehat{\Omega}$ can be computed efficiently using the glasso algorithm (Friedman et al., 2007), which is a block coordinate descent algorithm that uses the standard lasso to estimate a single row and column of Ω in each iteration. Under appropriate sparsity conditions, the resulting estimator $\widehat{\Omega}$ has been shown to have good theoretical properties (Rothman et al., 2008; Ravikumar et al., 2009b).

There are several different ways to judge the quality of an estimator $\widehat{\Sigma}$ of the covariance or $\widehat{\Omega}$ of the inverse covariance. We discuss three in this paper, persistency, norm consistency, and sparsistency. Persistency means consistency in risk, when the model is not necessarily assumed to be correct. Suppose the true distribution P has mean μ_0, and that we use a multivariate normal $p(x; \mu_0, \Sigma)$ for prediction; we do not assume that P is normal. We observe a new vector $X \sim P$ and define the prediction risk to be

$$R(\Sigma) = -\mathbb{E} \log p(X; \mu_0, \Sigma) = -\int \log p(x; \mu_0, \Sigma) \, dP(x).$$

It follows that

$$R(\Sigma) = \frac{1}{2} \left(\mathrm{tr}(\Sigma^{-1} \Sigma_0) + \log |\Sigma| - p \log(2\pi) \right)$$

where Σ_0 is the covariance of X under P. If $\mathcal{S}$ is a set of covariance matrices, the oracle is defined to be the covariance matrix Σ_* that minimizes $R(\Sigma)$ over $\mathcal{S}$:

$$\Sigma_* = \arg\min_{\Sigma \in \mathcal{S}} R(\Sigma).$$

Thus $p(x;\mu_0,\Sigma_*)$ is the best predictor of a new observation among all distributions in $\{p(x;\mu_0,\Sigma) : \Sigma \in \mathcal{S}\}$. In particular, if $\mathcal{S}$ consists of covariance matrices with sparse graphs, then $p(x;\mu_0,\Sigma_*)$ is, in some sense, the best sparse predictor. An estimator $\widehat{\Sigma}_n$ is *persistent* if

$$R(\widehat{\Sigma}_n) - R(\Sigma_*) \xrightarrow{P} 0$$

as the sample size n increases to infinity. Thus, a persistent estimator approximates the best estimator over the class $\mathcal{S}$, but we do not assume that the true distribution has a covariance matrix in $\mathcal{S}$, or even that it is Gaussian. Moreover, we allow the dimension $p = p_n$ to increase with n. On the other hand, norm consistency and sparsistency require that the true distribution is Gaussian. In this case, let Σ_0 denote the true covariance matrix. An estimator is *norm consistent* if

$$\|\widehat{\Sigma}_n - \Sigma\| \xrightarrow{P} 0$$

where $\|\cdot\|$ is a norm. If $E(\Omega)$ denotes the edge set corresponding to Ω, an estimator is *sparsistent* if

$$\mathbb{P}\Big(E(\Omega) \neq E(\widehat{\Omega}_n)\Big) \to 0.$$

Thus, a sparsistent estimator identifies the correct graph consistently. We present our theoretical analysis on these properties of the nonparanormal in Section 5.

3. The Nonparanormal

We say that a random vector $X = (X_1,\ldots,X_p)^T$ has a *nonparanormal* distribution if there exist functions $\{f_j\}_{j=1}^p$ such that $Z \equiv f(X) \sim N(\mu,\Sigma)$, where $f(X) = (f_1(X_1),\ldots,f_p(X_p))$. We then write

$$X \sim NPN(\mu,\Sigma,f).$$

When the f_j's are monotone and differentiable, the joint probability density function of X is given by

$$p_X(x) = \frac{1}{(2\pi)^{p/2}|\Sigma|^{1/2}} \exp\left\{-\frac{1}{2}(f(x)-\mu)^T \Sigma^{-1}(f(x)-\mu)\right\} \prod_{j=1}^p |f_j'(x_j)|. \tag{2}$$

Lemma 1 *The nonparanormal distribution $NPN(\mu,\Sigma,f)$ is a Gaussian copula when the f_j's are monotone and differentiable.*

Proof By Sklar's theorem (Sklar, 1959), any joint distribution can be written as

$$F(x_1,\ldots,x_p) = C\{F_1(x_1),\ldots,F_p(x_p)\}$$

where the function C is called a copula. For the nonparanormal we have

$$F(x_1,\ldots,x_p) = \Phi_{\mu,\Sigma}(\Phi^{-1}(F_1(x_1)),\ldots,\Phi^{-1}(F_p(x_p)))$$

where $\Phi_{\mu,\Sigma}$ is the multivariate Gaussian cdf and Φ is the univariate standard Gaussian cdf. Thus, the corresponding copula is

$$C(u_1,\ldots,u_p) = \Phi_{\mu,\Sigma}(\Phi^{-1}(u_1),\ldots,\Phi^{-1}(u_p)).$$

This is exactly a Gaussian copula with parameters μ and Σ. If each f_j is differentiable then the density of X has the same form as (2). ■

Note that the density in (2) is not identifiable; to make the family identifiable we demand that f_j preserve means and variances:

$$\mu_j = \mathbb{E}(Z_j) = \mathbb{E}(X_j) \text{ and } \sigma_j^2 \equiv \Sigma_{jj} = \mathrm{Var}(Z_j) = \mathrm{Var}(X_j). \tag{3}$$

Note that these conditions only depend on $\mathrm{diag}(\Sigma)$ but not the full covariance matrix.

Let $F_j(x)$ denote the marginal distribution function of X_j. Then

$$F_j(x) = \mathbb{P}(X_j \le x) = \mathbb{P}(Z_j \le f_j(x)) = \Phi\left(\frac{f_j(x)-\mu_j}{\sigma_j}\right)$$

which implies that

$$f_j(x) = \mu_j + \sigma_j \Phi^{-1}(F_j(x)). \tag{4}$$

The following basic fact says that the independence graph of the nonparanormal is encoded in $\Omega = \Sigma^{-1}$, as for the parametric normal.

Lemma 2 *If $X \sim NPN(\mu,\Sigma,f)$ is nonparanormal and each f_j is differentiable, then $X_i \perp\!\!\!\perp X_j \,|\, X_{\setminus\{i,j\}}$ if and only if $\Omega_{ij} = 0$, where $\Omega = \Sigma^{-1}$.*

Proof From the form of the density (2), it follows that the density factors with respect to the graph of Ω, and therefore obeys the global Markov property of the graph. ■

Next we show that the above is true for any choice of identification restrictions.

Lemma 3 *Define*

$$h_j(x) = \Phi^{-1}(F_j(x)) \tag{5}$$

and let Λ be the covariance matrix of $h(X)$. Then $X_j \perp\!\!\!\perp X_k \,|\, X_{\setminus\{j,k\}}$ if and only if $\Lambda^{-1}_{jk} = 0$.

Proof We can rewrite the covariance matrix as

$$\Sigma_{jk} = \mathrm{Cov}(Z_j,Z_k) = \sigma_j\sigma_k \mathrm{Cov}(h_j(X_j),h_k(X_k)).$$

Hence $\Sigma = D\Lambda D$ and

$$\Sigma^{-1} = D^{-1}\Lambda^{-1}D^{-1},$$

where D is the diagonal matrix with $\mathrm{diag}(D) = \sigma$. The zero pattern of Λ^{-1} is therefore identical to the zero pattern of Σ^{-1}. ■

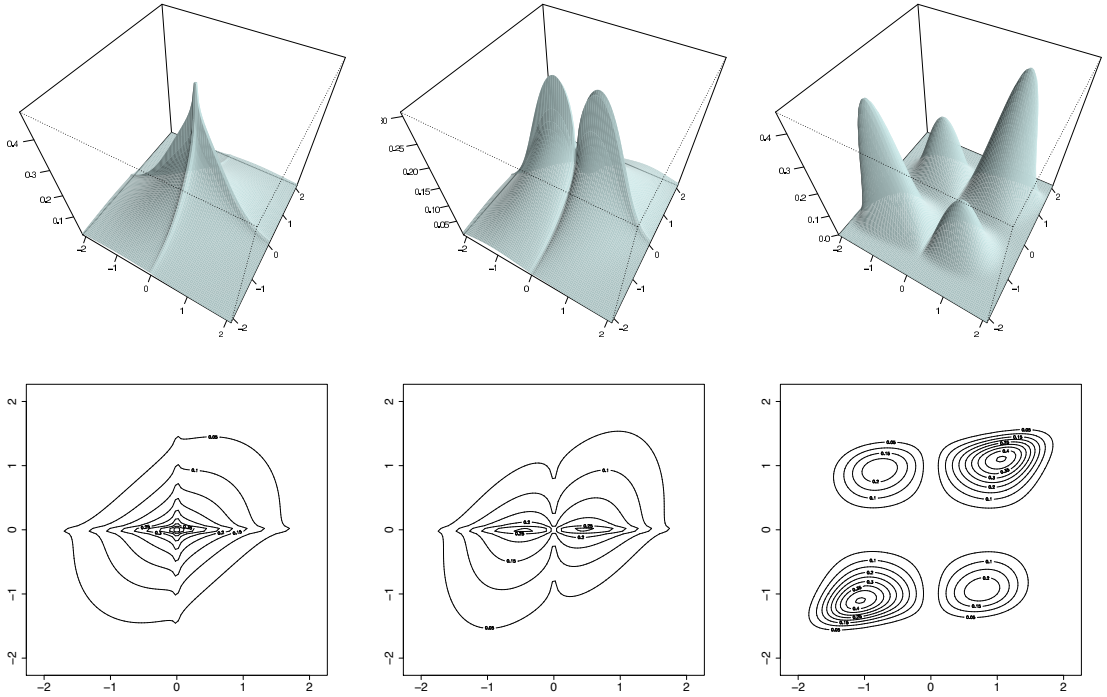

Figure 2: Densities of three 2-dimensional nonparanormals. The component functions have the form $f_j(x) = \text{sign}(x)|x|^{\alpha_j}$. Left: $\alpha_1 = 0.9$, $\alpha_2 = 0.8$; center: $\alpha_1 = 1.2$, $\alpha_2 = 0.8$; right $\alpha_1 = 2, \alpha_2 = 3$. In each case $\mu = (0,0)$ and $\Sigma = \binom{1\ .5}{.5\ 1}$.

Thus, it is not necessary to estimate μ or σ to estimate the graph.

Figure 2 shows three examples of 2-dimensional nonparanormal densities. In each case, the component functions $f_j(x)$ take the form

$$f_j(x) = a_j \text{sign}(x)|x|^{\alpha_j} + b_j$$

where the constants a_j and b_j are set to enforce the identifiability constraints (3). The covariance in each case is $\Sigma = \binom{1\ .5}{.5\ 1}$ and the mean is $\mu = (0,0)$. The exponent α_j determines the nonlinearity. It can be seen how the concavity of the density changes with the exponent α, and that $\alpha > 1$ can result in multiple modes.

The assumption that $f(X) = (f_1(X_1), \ldots, f_p(X_p)$ is normal leads to a semiparametric model where only one dimensional functions need to be estimated. But the monotonicity of the functions f_j, which map onto $\mathbb{R}$, enables computational tractability of the nonparanormal. For more general functions f, the normalizing constant for the density

$$p_X(x) \propto \exp\left\{-\frac{1}{2}(f(x)-\mu)^T \Sigma^{-1}(f(x)-\mu)\right\}$$

cannot be computed in closed form.

4. Estimation Method

Let $X^{(1)},\ldots,X^{(n)}$ be a sample of size n where $X^{(i)} = (X_1^{(i)},\ldots,X_p^{(i)})^T \in \mathbb{R}^p$. In light of (5) we define

$$\widehat{h}_j(x) = \Phi^{-1}(\widetilde{F}_j(x))$$

where $\widetilde{F}_j$ is an estimator of F_j. A natural candidate for $\widetilde{F}_j$ is the marginal empirical distribution function

$$\widehat{F}_j(t) \equiv \frac{1}{n}\sum_{i=1}^{n} \mathbf{1}_{\left\{X_j^{(i)} \le t\right\}}.$$

Now, let θ denote the parameters of the copula. Tsukahara (2005) suggests taking $\widehat{\theta}$ to be the solution of

$$\sum_{i=1}^{n} \phi\left(\widetilde{F}_1(X_1^{(i)}),\ldots,\widetilde{F}_p(X_p^{(i)}),\theta\right) = 0$$

where ϕ is an estimating equation and $\widetilde{F}_j(t) = n\widehat{F}_j(t)/(n+1)$. In our case, θ corresponds to the covariance matrix. The resulting estimator $\widehat{\theta}$, called a rank approximate Z-estimator, has excellent theoretical properties. However, we are interested in the high dimensional scenario where the dimension p is allowed to increase with n; the variance of $\widehat{F}_j(t)$ is too large in this case. Instead, we use the following truncated or *Winsorized*[1] estimator:

$$\widetilde{F}_j(x) = \begin{cases} \delta_n & \text{if } \widehat{F}_j(x) < \delta_n \\ \widehat{F}_j(x) & \text{if } \delta_n \le \widehat{F}_j(x) \le 1-\delta_n \\ (1-\delta_n) & \text{if } \widehat{F}_j(x) > 1-\delta_n, \end{cases} \tag{6}$$

where δ_n is a truncation parameter. Clearly, there is a bias-variance tradeoff in choosing δ_n. Essentially the same estimator with $\delta_n = 1/n$ is studied by Klaassen and Wellner (1997) in the case of bivariate Gaussian copula. In what follows we use

$$\delta_n \equiv \frac{1}{4n^{1/4}\sqrt{\pi \log n}}.$$

This provides the right balance so that we can achieve the desired rate of convergence in our estimate of Ω and the associated undirected graph G in the high dimensional setting.

Given this estimate of the distribution of variable X_j, we then estimate the transformation function f_j by

$$\widetilde{f}_j(x) \equiv \widehat{\mu}_j + \widehat{\sigma}_j \widetilde{h}_j(x) \tag{7}$$

where

$$\widetilde{h}_j(x) = \Phi^{-1}\left(\widetilde{F}_j(x)\right)$$

and $\widehat{\mu}_j$ and $\widehat{\sigma}_j$ are the sample mean and the standard deviation:

$$\widehat{\mu}_j \equiv \frac{1}{n}\sum_{i=1}^{n} X_j^{(i)} \text{ and } \widehat{\sigma}_j = \sqrt{\frac{1}{n}\sum_{i=1}^{n}\left(X_j^{(i)} - \widehat{\mu}_j\right)^2}.$$

1. After Charles P. Winsor, whom John Tukey credited with converting him from topology to statistics Mallows 1990.

Now, let $S_n(\widetilde{f})$ be the sample covariance matrix of $\widetilde{f}(X^{(1)}),\ldots,\widetilde{f}(X^{(n)})$; that is,

$$\begin{aligned} S_n(\widetilde{f}) &\equiv \frac{1}{n}\sum_{i=1}^{n}\left(\widetilde{f}(X^{(i)})-\mu_n(\widetilde{f})\right)\left(\widetilde{f}(X^{(i)})-\mu_n(\widetilde{f})\right)^T \qquad (8)\\ \mu_n(\widetilde{f}) &\equiv \frac{1}{n}\sum_{i=1}^{n}\widetilde{f}(X^{(i)}). \end{aligned}$$

We then estimate Ω using $S_n(\widetilde{f})$. For instance, the maximum likelihood estimator is $\widehat{\Omega}_n^{\mathrm{MLE}} = S_n(\widetilde{f})^{-1}$. The ℓ_1-regularized estimator is

$$\widehat{\Omega}_n = \arg\min_{\Omega}\left\{\mathrm{tr}\left(\Omega S_n(\widetilde{f})\right)-\log|\Omega|+\lambda\|\Omega\|_1\right\} \qquad (9)$$

where λ is a regularization parameter, and $\|\Omega\|_1=\sum_{j\neq k}|\Omega_{jk}|$. The estimated graph is then $\widehat{E}_n = \{(j,k):\ \widehat{\Omega}_{jk}\neq 0\}$.

The nonparanormal is analogous to a sparse additive regression model (Ravikumar et al., 2009a), in the sense that both methods transform the variables by univariate functions. However, while sparse additive models use a regularized risk criterion to fit univariate transformations, our nonparanormal estimator uses a two-step procedure:

1. Replace the observations, for each variable, by their respective normal scores, subject to a Winsorized truncation.

2. Apply the graphical lasso to the transformed data to estimate the undirected graph.

The first step is non-iterative and computationally efficient, with no tuning parameters; it also makes the nonparanormal amenable to theoretical analysis.

Starting with the model in (2), another possibility would be to parametrize each f_j according to some parametric class of monotone functions such as the Box-Cox family, and then find the maximum likelihood estimates of $(\Omega, f_1, \ldots f_p)$ in that class. This might lead to estimates of f_j that depend on Ω, and vice versa, and the estimation problem would not in general be convex. Alternatively, due to (4), the marginal information could be used to estimate the parameters. Our nonparametric approach to estimating the transformations has the advantages of making few assumptions and being easy to compute. In the following section we analyze the theoretical properties of this estimator.

5. Theoretical Results

In this section we present our theoretical results on risk consistency, model selection consistency, and norm consistency of the covariance Σ and inverse covariance Ω. From Lemma 3, the estimate of the graph does not depend on $\sigma_j,\ j\in\{1,\ldots,p\}$ and μ, so we assume that $\sigma_j=1$ and $\mu=0$. Our key technical result is an analysis of the covariance of the Winsorized estimator defined in (6), (7), and (8). In particular, we show that under appropriate conditions,

$$\max_{j,k}\left|S_n(\widetilde{f})_{jk}-S_n(f)_{jk}\right| = o_P(1)$$

where $S_n(\widetilde{f})_{jk}$ denotes the (j,k) entry of the matrix. This result allows us to leverage the recent analysis of Rothman et al. (2008) and Ravikumar et al. (2009b) in the Gaussian case to obtain consistency results for the nonparanormal. More precisely, our main theorem is the following.

Theorem 4 *Suppose that $p = n^{\xi}$ and let $\widetilde{f}$ be the Winsorized estimator defined in* (7) *with* $\delta_n = \frac{1}{4n^{1/4}\sqrt{\pi \log n}}$. *Define*

$$C_M \equiv \frac{48}{\sqrt{\pi}}\left(\sqrt{2M}-1\right)(M+2). \tag{10}$$

For some $M \geq 2(\xi+1)$.

Then for any $\varepsilon \geq C_M \sqrt{\frac{\log p \log^2 n}{n^{1/2}}}$ *and sufficiently large n, we have*

$$\begin{aligned}
&\mathbb{P}\left(\max_{jk}\left|S_n(\widetilde{f})_{jk} - S_n(f)_{jk}\right| > 2\varepsilon\right) \\
&\quad\leq \quad \frac{1}{2\sqrt{\pi \log(np)}} + 2\exp\left(2\log p - \frac{n^{1/2}\varepsilon^2}{1232\pi^2 \log^2 n}\right) + 2\exp\left(2\log p - \frac{n^{1/2}}{8\pi \log n}\right) + o(1).
\end{aligned}$$

The proof of the above theorem is given in Section 7. The following corollary is immediate, and specifies the scaling of the dimension in terms of sample size.

Corollary 5 *Let* $M \geq \max\{15\pi, 2\xi+1\}$. *Then*

$$\mathbb{P}\left(\max_{jk}\left|S_n(\widetilde{f})_{jk} - S_n(f)_{jk}\right| > 2C_M\sqrt{\frac{\log p \log^2 n}{n^{1/2}}}\right) = o(1).$$

Hence,

$$\max_{j,k}\left|S_n(\widetilde{f})_{jk} - S_n(f)_{jk}\right| = O_P\left(\sqrt{\frac{\log p \log^2 n}{n^{1/2}}}\right).$$

The following corollary yields estimation consistency in both the Frobenius norm and the ℓ_2-operator norm. The proof follows the same arguments as the proof of Theorem 1 and Theorem 2 from Rothman et al. (2008), replacing their Lemma 1 with our Theorem 4.

For a matrix $A = (a_{ij})$, the Frobenius norm $\|\cdot\|_F$ is defined as $\|A\|_{\mathrm{F}} \equiv \sqrt{\sum_{i,j} a_{ij}^2}$. The ℓ_2-operator norm $\|\cdot\|_2$ is defined as the magnitude of the largest eigenvalue of the matrix, $\|A\|_2 \equiv \max_{\|x\|_2=1}\|Ax\|_2$. In the following, we write $a_n \asymp b_n$ if there are positive constants c and C independent of n such that $c \leq a_n/b_n \leq C$.

Corollary 6 *Suppose that the data are generated as* $X^{(i)} \sim NPN(\mu_0, \Sigma_0, f_0)$, *and let* $\Omega_0 = \Sigma_0^{-1}$. *If the regularization parameter* λ_n *is chosen as*

$$\lambda_n \asymp 2C_M\sqrt{\frac{\log p \log^2 n}{n^{1/2}}}$$

where C_M *is defined in Theorem 4. Then the nonparanormal estimator* $\widehat{\Omega}_n$ *of* (9) *satisfies*

$$\|\widehat{\Omega}_n - \Omega_0\|_{\mathrm{F}} = O_P\left(\sqrt{\frac{(s+p)(\log p \log^2 n)}{n^{1/2}}}\right)$$

and

$$\|\widehat{\Omega}_n - \Omega_0\|_2 = O_P\left(\sqrt{\frac{s(\log p \log^2 n)}{n^{1/2}}}\right),$$

where

$$s \equiv \mathrm{Card}\left(\{(i,j) \in \{1,\ldots,p\} \times \{1,\ldots,p\} \,|\, \Omega_0(i,j) \neq 0,\ i \neq j\}\right)$$

is the number of nonzero off-diagonal elements of the true precision matrix.

To prove the model selection consistency result, we need further assumptions. We follow Ravikumar (2009) and let the $p^2 \times p^2$ Fisher information matrix of Σ_0 be $\Gamma \equiv \Sigma_0 \otimes \Sigma_0$ where $\otimes$ is the Kronecker matrix product, and define the support set S of $\Omega_0 = \Sigma_0^{-1}$ as

$$S \equiv \{(i,j) \in \{1,\ldots,p\} \times \{1,\ldots,p\} \,|\, \Omega_0(i,j) \neq 0\}.$$

We use S^c to denote the complement of S in the set $\{1,\ldots,p\} \times \{1,\ldots,p\}$, and for any two subsets T and T' of $\{1,\ldots,p\} \times \{1,\ldots,p\}$, we use $\Gamma_{TT'}$ to denote the sub-matrix with rows and columns of Γ indexed by T and T' respectively.

Assumption 1 *There exists some $\alpha \in (0,1]$, such that $\left\|\Gamma_{S^cS}(\Gamma_{SS})^{-1}\right\|_\infty \leq 1-\alpha$.*

As in Ravikumar et al. (2009b), we define two quantities $K_{\Sigma_0} \equiv \|\Sigma_0\|_\infty$ and $K_\Gamma \equiv \|(\Gamma_{SS})^{-1}\|_\infty$. Further, we define the maximum row degree as

$$d \equiv \max_{i=1,\ldots,p} \mathrm{Card}\left(\{j \in 1,\ldots,p \,|\, \Omega_0(i,j) \neq 0\}\right).$$

Assumption 2 *The quantities K_{Σ^0} and K_Γ are bounded, and there are positive constants C such that*

$$\min_{(j,k)\in S} |\Omega_0(j,k)| \geq C\sqrt{\frac{\log^3 n}{n^{1/2}}}$$

for large enough n.

The proof of the following corollary uses our Theorem 4 in place of Equation (12) in the analysis of Ravikumar et al. (2009b).

Corollary 7 *Suppose the regularization parameter is chosen as*

$$\lambda_n \asymp 2C_M\sqrt{\frac{\log p \log^2 n}{n^{1/2}}}$$

where $C(M,n,p)$ is defined in Theorem 4. Then the nonparanormal estimator $\widehat{\Omega}_n$ satisfies

$$\mathbb{P}\left(\mathcal{G}\left(\widehat{\Omega}_n, \Omega_0\right)\right) \geq 1 - o(1)$$

where $\mathcal{G}(\widehat{\Omega}_n, \Omega_0)$ is the event

$$\left\{\mathrm{sign}\left(\widehat{\Omega}_n(j,k)\right) = \mathrm{sign}\left(\Omega_0(j,k)\right), \quad \forall j,k \in S\right\}.$$

Our persistency (risk consistency) result parallels the persistency result for additive models given in Ravikumar et al. (2009a), and allows model dimension that grows exponentially with sample size. The definition in this theorem uses the fact (from Lemma 11) that $\sup_x \Phi^{-1}\left(\widetilde{F}_j(x)\right) \leq \sqrt{2\log n}$ when $\delta_n = 1/(4n^{1/4}\sqrt{\pi \log n})$.

In the next theorem, we do not assume the true model is nonparanormal and define the population and sample risks as

$$\begin{aligned} R(f,\Omega) &= \frac{1}{2}\left\{\mathrm{tr}\left[\Omega \mathbb{E}(f(X)f(X)^T\right] - \log|\Omega| - p\log(2\pi)\right\} \\ \widehat{R}(f,\Omega) &= \frac{1}{2}\left\{\mathrm{tr}\left[\Omega S_n(f)\right] - \log|\Omega| - p\log(2\pi)\right\}. \end{aligned}$$

Theorem 8 *Suppose that $p \leq e^{n^\xi}$ for some $\xi < 1$, and define the classes*

$$\begin{aligned} \mathcal{M}_n &= \left\{f : \mathbb{R} \to \mathbb{R} : f \text{ is monotone with } \|f\|_\infty \leq C\sqrt{\log n}\right\} \\ \mathcal{C}_n &= \left\{\Omega : \|\Omega^{-1}\|_1 \leq L_n\right\}. \end{aligned}$$

Let $\widehat{\Omega}_n$ be given by

$$\widehat{\Omega}_n = \underset{\Omega \in \mathcal{C}_n}{\arg\min}\left\{tr\left(\Omega S_n(\widetilde{f})\right) - \log|\Omega|\right\}.$$

Then

$$R(\widetilde{f}_n, \widehat{\Omega}_n) - \inf_{(f,\Omega)\in \mathcal{M}_n^p \oplus \mathcal{C}_n} R(f,\Omega) = O_P\left(L_n\sqrt{\frac{\log n}{n^{1-\xi}}}\right).$$

Hence the Winsorized estimator of (f,Ω) with $\delta_n = 1/(4n^{1/4}\sqrt{\pi\log n})$ is persistent over $\mathcal{C}_n$ when $L_n = o\left(n^{(1-\xi)/2}/\sqrt{\log n}\right)$.

The proofs of Theorems 4 and 8 are given in Section 7.

6. Experimental Results

In this section, we report experimental results on synthetic and real data sets. We mainly compare the ℓ_1-regularized nonparanormal and Gaussian (paranormal) models, computed using the graphical lasso algorithm (glasso) of Friedman et al. (2007). The primary conclusions are: (i) When the data are multivariate Gaussian, the performance of the two methods is comparable; (ii) when the model is correct, the nonparanormal performs much better than the graphical lasso in many cases; (iii) for a particular gene microarray data set, our method behaves differently from the graphical lasso, and may support different biological conclusions.

Note that we can reuse the glasso implementation to fit a sparse nonparanormal. In particular, after computing the Winsorized sample covariance $S_n(\widetilde{f})$, we pass this matrix to the glasso routine to carry out the optimization

$$\widehat{\Omega}_n = \underset{\Omega}{\arg\min}\left\{\mathrm{tr}\left(\Omega S_n(\widetilde{f})\right) - \log|\Omega| + \lambda_n\|\Omega\|_1\right\}.$$

6.1 Neighborhood Graphs

We begin by describing a procedure to generate graphs as in (Meinshausen and Bühlmann, 2006), with respect to which several distributions can then be defined. We generate a p-dimensional sparse graph $G \equiv (V,E)$ as follows: Let $V = \{1,\ldots,p\}$ correspond to variables $X = (X_1,\ldots,X_p)$. We associate each index j with a point $(Y_j^{(1)}, Y_j^{(2)}) \in [0,1]^2$ where

$$Y_1^{(k)},\ldots,Y_n^{(k)} \sim \text{Uniform}[0,1]$$

for $k = 1,2$. Each pair of nodes (i,j) is included in the edge set E with probability

$$\mathbb{P}\left((i,j) \in E\right) = \frac{1}{\sqrt{2\pi}} \exp\left(-\frac{\|y_i - y_j\|_n^2}{2s}\right)$$

where $y_i \equiv (y_i^{(1)}, y_i^{(2)})$ is the observation of $(Y_i^{(1)}, Y_i^{(2)})$ and $\|\cdot\|_n$ represents the Euclidean distance. Here, $s = 0.125$ is a parameter that controls the sparsity level of the generated graph. We restrict the maximum degree of the graph to be four and build the inverse covariance matrix Ω_0 according to

$$\Omega_0(i,j) = \begin{cases} 1 & \text{if } i = j \\ 0.245 & \text{if } (i,j) \in E \\ 0 & \text{otherwise,} \end{cases}$$

where the value 0.245 guarantees positive definiteness of the inverse covariance matrix.

Given Ω_0, n data points are sampled from

$$X^{(1)},\ldots,X^{(n)} \sim NPN(\mu_0, \Sigma_0, f_0)$$

where $\mu_0 = (1.5,\ldots,1.5)$, $\Sigma_0 = \Omega_0^{-1}$. For simplicity, the transformation functions for all dimensions are the same, $f_1 = \ldots = f_p = f$. To sample data from the nonparanormal distribution, we also require $g \equiv f^{-1}$; two different transformations g are employed.

Definition 9 (Gaussian CDF Transformation) *Let g_0 be a one-dimensional Gaussian cumulative distribution function with mean μ_{g_0} and the standard deviation σ_{g_0}, that is,*

$$g_0(t) \equiv \Phi\left(\frac{t - \mu_{g_0}}{\sigma_{g_0}}\right).$$

We define the transformation function $g_j = f_j^{-1}$ for the j-th dimension as

$$g_j(z_j) \equiv \sigma_j \left(\frac{g_0(z_j) - \int g_0(t)\phi\left(\frac{t-\mu_j}{\sigma_j}\right) dt}{\sqrt{\int \left(g_0(y) - \int g_0(t)\phi\left(\frac{t-\mu_j}{\sigma_j}\right) dt\right)^2 \phi\left(\frac{y-\mu_j}{\sigma_j}\right) dy}} \right) + \mu_j$$

where $\sigma_j = \Sigma_0(j,j)$.

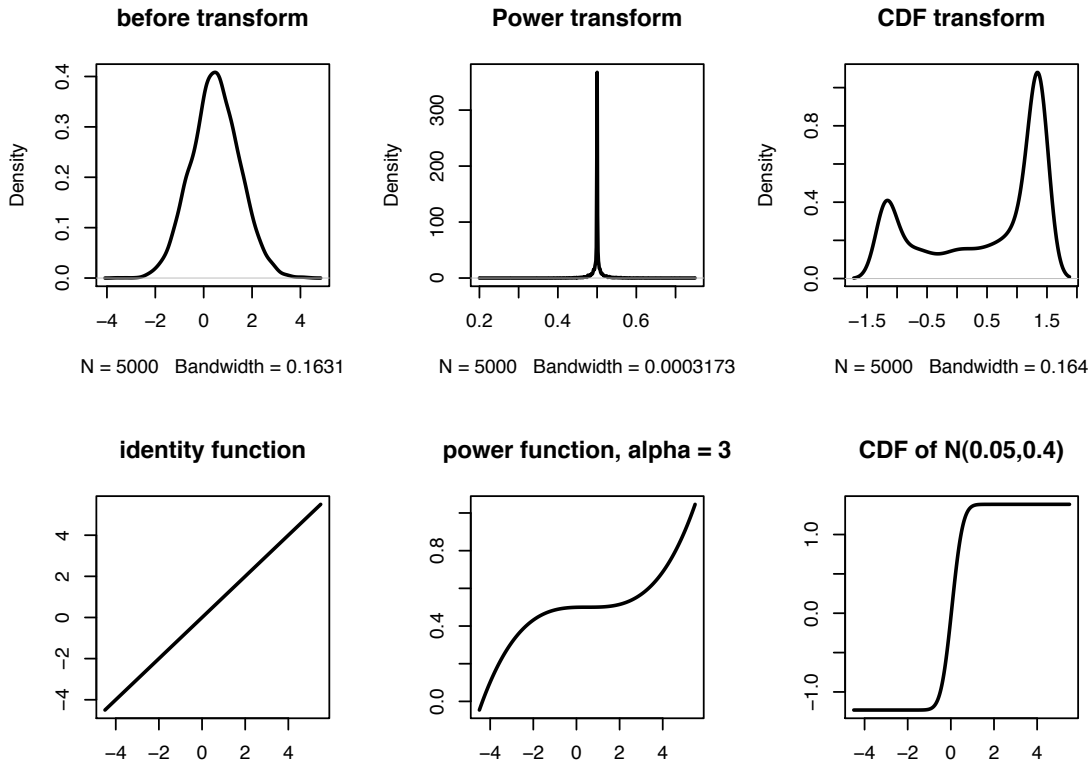

Figure 3: The power and cdf transformations. The densities are estimated using a kernel density estimator with bandwidths selected by cross-validation.

Definition 10 (Symmetric Power Transformation) *Let g_0 be the symmetric and odd transformation given by*

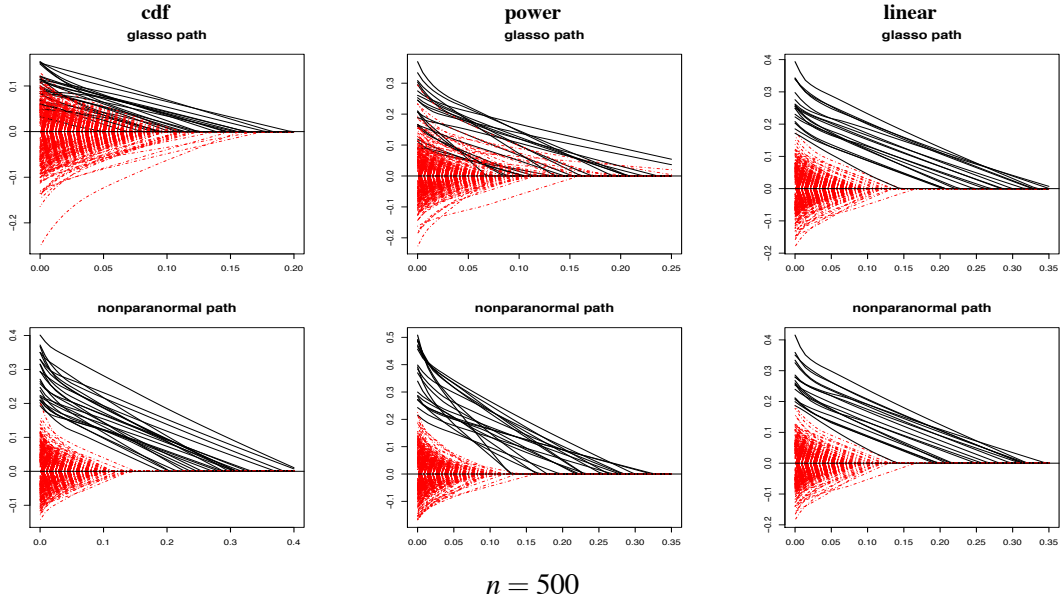
$$g_0(t) = \text{sign}(t)|t|^\alpha$$

where $\alpha > 0$ is a parameter. We define the power transformation for the j-th dimension as

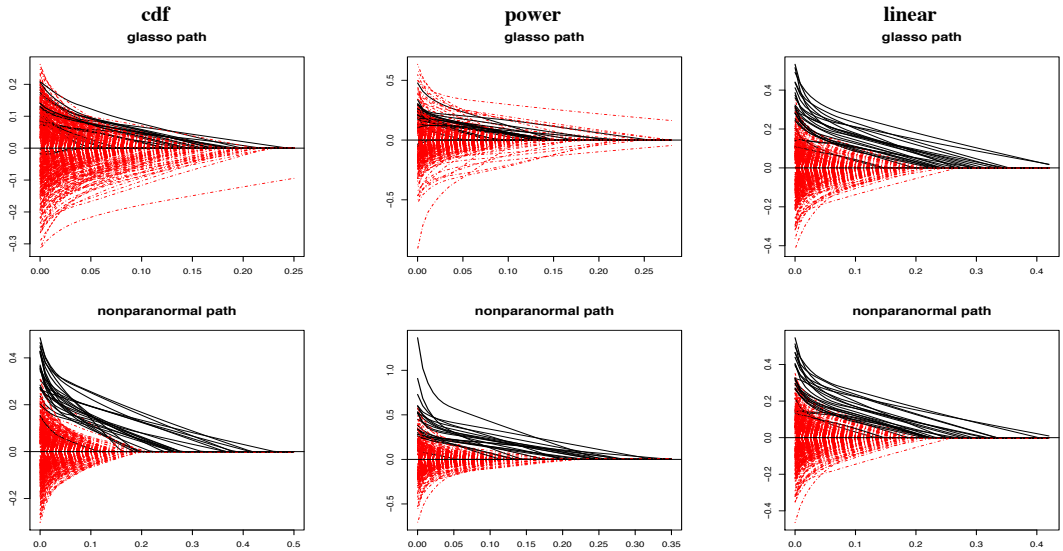
$$g_j(z_j) \equiv \sigma_j \left(\frac{g_0(z_j - \mu_j)}{\sqrt{\int g_0^2(t-\mu_j)\phi\left(\frac{t-\mu_j}{\sigma_j}\right) dt}} \right) + \mu_j.$$

These transformation are constructed to preserve the marginal mean and standard deviation. In the following experiments, we refer to them as the cdf transformation and the power transformation, respectively. For the cdf transformation, we set $\mu_{g_0} = 0.05$ and $\sigma_{g_0} = 0.4$. For the power transformation, we set $\alpha = 3$.

To visualize these two transformations, we sample 5000 data points from a one-dimensional normal distribution $N(0.5, 1.0)$ and then apply the above two transformations; the results are shown in Figure 3. It can be seen how the cdf and power transformations map a univariate normal distribution into a highly skewed and a bi-modal distribution, respectively.



$n = 500$



$n = 200$

Figure 4: Regularization paths for the glasso and nonparanormal with $n = 500$ (top) and $n = 200$ (bottom). The paths for the relevant variables (nonzero inverse covariance entries) are plotted as solid (black) lines; the paths for the irrelevant variables are plotted as dashed (red) lines. For non-Gaussian distributions, the nonparanormal better separates the relevant and irrelevant dimensions.

To generate synthetic data, we set $p = 40$, resulting in $\binom{40}{2} + 40 = 820$ parameters to be estimated, and vary the sample sizes from $n = 200$ to $n = 1000$. Three conditions are considered, corresponding to using the cdf transform, the power transform, or no transformation. In each case, both the glasso and the nonparanormal are applied to estimate the graph.

6.1.1 COMPARISON OF REGULARIZATION PATHS

We choose a set of regularization parameters Λ; for each $\lambda \in \Lambda$, we obtain an estimate $\widehat{\Omega}_n$ which is a 40×40 matrix. The upper triangular matrix has 780 parameters; we vectorize it to get a 780-dimensional parameter vector. A regularization path is the trace of these parameters over all the regularization parameters within Λ. The regularization paths for both methods are plotted in Figure 4. For the cdf transformation and the power transformation, the nonparanormal separates the relevant and the irrelevant dimensions very well. For the glasso, relevant variables are mixed with irrelevant variables. If no transformation is applied, the paths for both methods are almost the same.

6.1.2 ESTIMATED TRANSFORMATIONS

For sample size $n = 1000$, we plot the estimated transformations for three of the variables in Figure 5. It is clear that Winsorization plays a significant role for the power transformation. This is intuitive due to the high skewness of the nonparanormal distribution in this case.

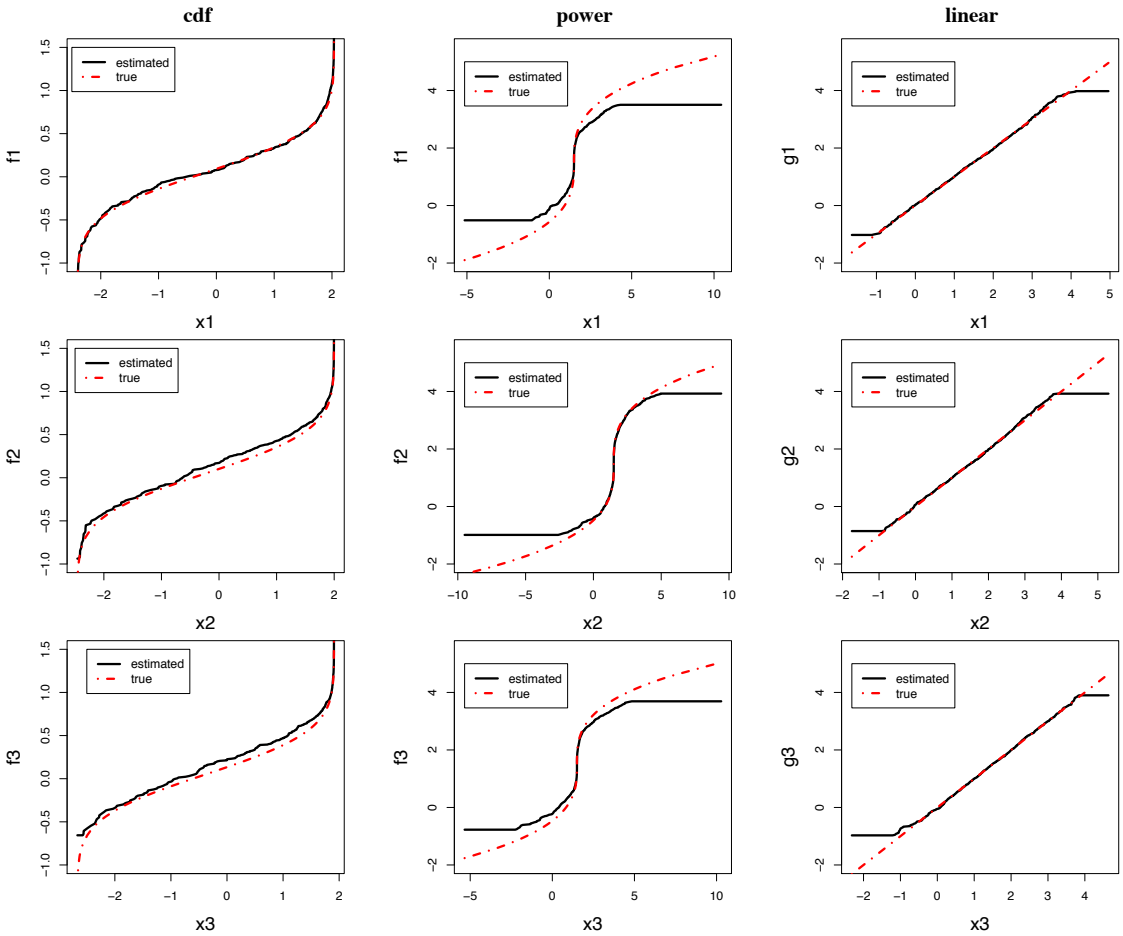


Figure 5: Estimated transformations for the first three variables. Winsorization plays a significant role for the power transformation due to its high skewness.

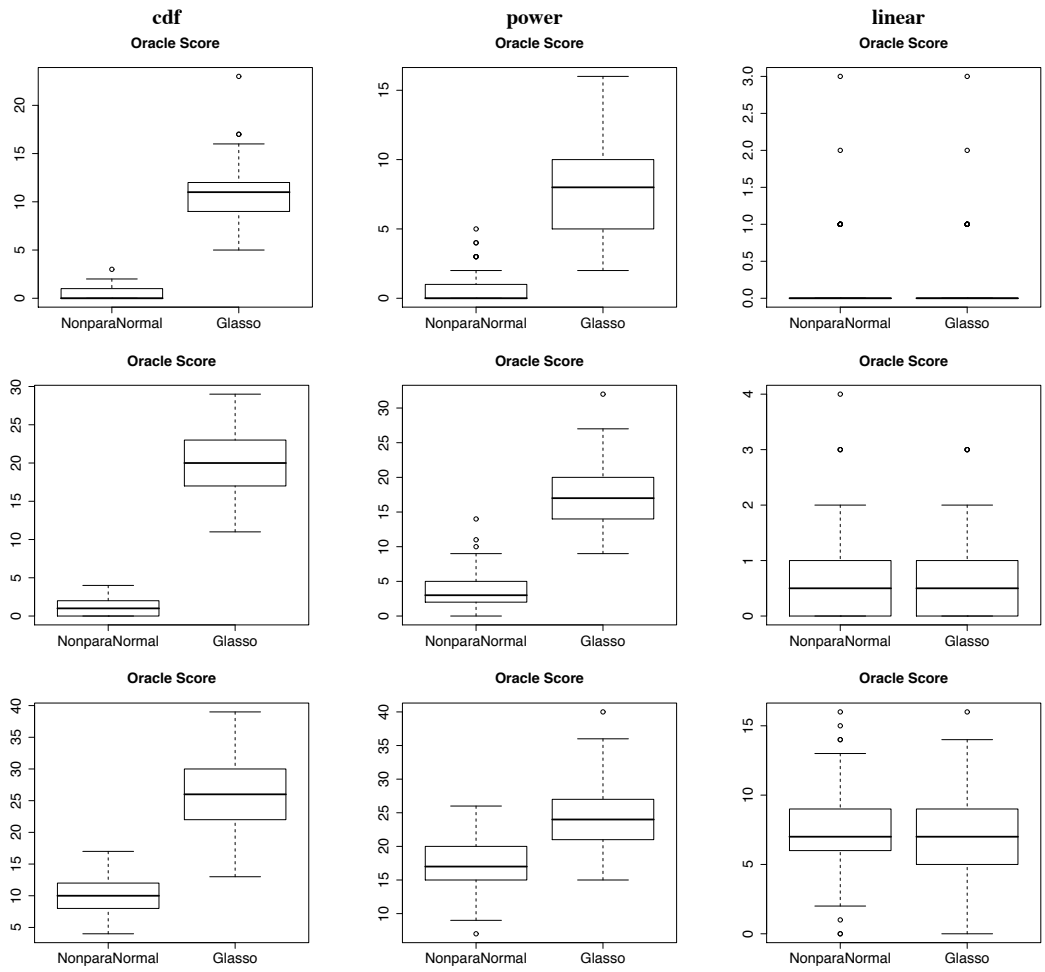

Figure 6: Boxplots of the oracle scores for $n = 1000, 500, 200$ (top, center, bottom).

6.1.3 QUANTITATIVE COMPARISON

To evaluate the performance for structure estimation quantitatively, we use false positive and false negative rates. Let $G = (V, E)$ be a p-dimensional graph (which has at most $\binom{p}{2}$ edges) in which there are $|E| = r$ edges, and let $\widehat{G}^{\lambda} = (V, \widehat{E}^{\lambda})$ be an estimated graph using the regularization parameter λ. The number of false positives at λ is

$$\mathrm{FP}(\lambda) \equiv \text{number of edges in } \widehat{E}^{\lambda} \text{ not in } E$$

The number of false negatives at λ is defined as

$$\mathrm{FN}(\lambda) \equiv \text{number of edges in } E \text{ not in } \widehat{E}^{\lambda}.$$

The oracle regularization level λ^* is then

$$\lambda^* = \arg\min_{\lambda \in \Lambda} \{\mathrm{FP}(\lambda) + \mathrm{FN}(\lambda)\}.$$

The oracle score is $\mathrm{FP}(\lambda^*) + \mathrm{FN}(\lambda^*)$. Figure 6 shows boxplots of the oracle scores for the two methods, calculated using 100 simulations.

To illustrate the overall performance of these two methods over the full paths, ROC curves are shown in Figure 7, using

$$\left(1 - \frac{\mathrm{FN}(\lambda)}{r}, 1 - \frac{\mathrm{FP}(\lambda)}{\binom{p}{2} - r}\right).$$

The curves clearly show how the performance of both methods improves with sample size, and that the nonparanormal is superior to the Gaussian model in most cases.

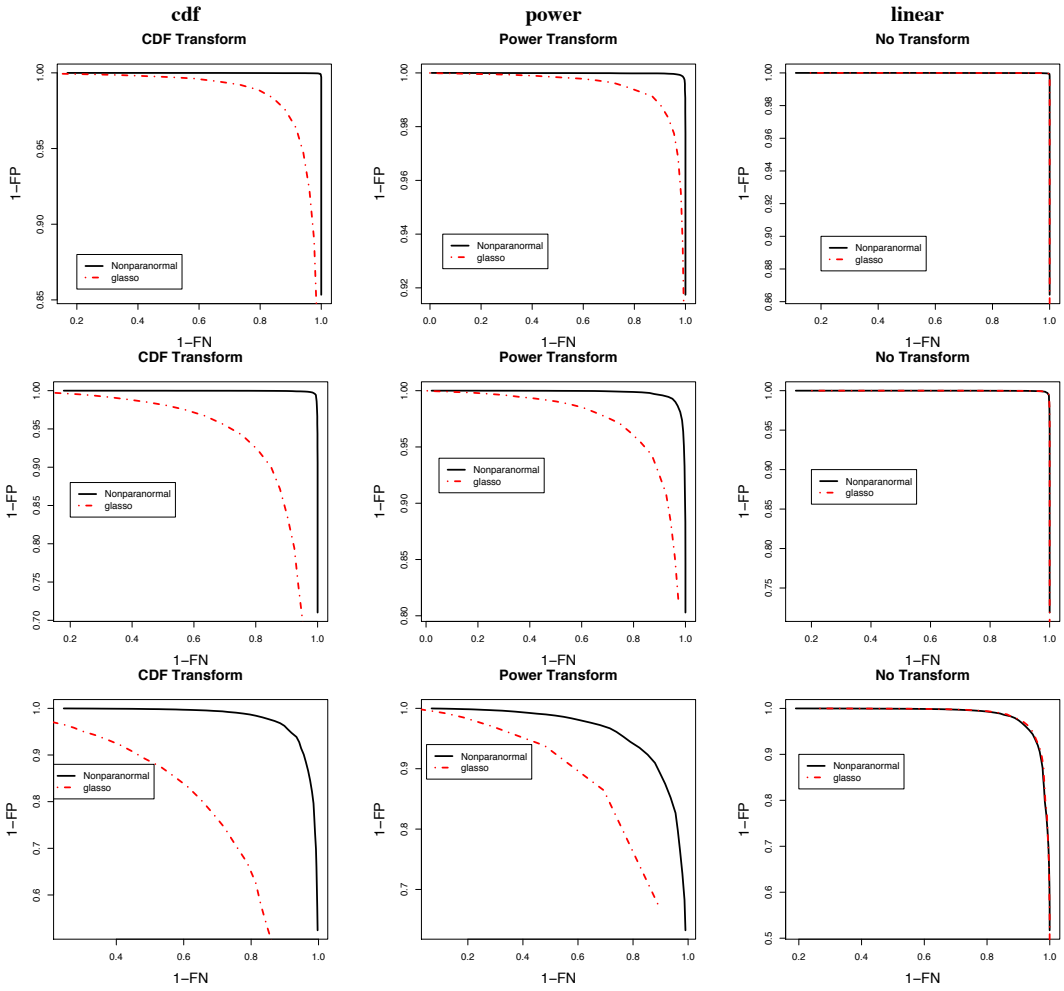

Figure 7: ROC curves for sample sizes $n = 1000, 500, 200$ (top, middle, bottom).

Let $\mathrm{FPE} \equiv \mathrm{FP}(\lambda^*)$ and $\mathrm{FNE} \equiv \mathrm{FN}(\lambda^*)$, Tables 1, 2, and 3 provide numerical comparisons of both methods on data sets with different transformations, where we repeat the experiments 100 times and report the average FPE and FNE values with the corresponding standard deviations. It's clear from the tables that the nonparanormal achieves significantly smaller errors than the glasso if the true distribution of the data is not multivariate Gaussian and achieves performance comparable to the glasso when the true distribution is exactly multivariate Gaussian.

Figure 8 shows typical runs for the cdf and power transformations. It's clear that when the glasso estimates the graph incorrectly, the mistakes include both false positives and negatives.

6.1.4 COMPARISON IN THE GAUSSIAN CASE

The previous experiments indicate that the nonparanormal works almost as well as the glasso in the Gaussian case. This initially appears surprising, since a parametric method is expected to be more efficient than a nonparametric method if the parametric assumption is correct. To manifest this efficiency loss, we conducted some experiments with very small n and relatively large p. For multivariate Gaussian models, Figure 9 shows results with $(n, p, s) = (50, 40, 1/8), (50, 100, 1/15)$

	Nonparanormal				glasso			
n	FPE	(sd(FPE))	FNE	(sd(FNE))	FPE	(sd(FPE))	FNE	(sd(FNE))
1000	0.10	(0.3333)	0.05	(0.2190)	0.09	(0.3208)	0.06	(0.2386)
900	0.24	(0.7537)	0.14	(0.4025)	0.22	(0.6447)	0.15	(0.4113)
800	0.17	(0.4277)	0.16	(0.3949)	0.16	(0.4431)	0.19	(0.4191)
700	0.25	(0.6871)	0.33	(0.8534)	0.29	(0.8201)	0.27	(0.7501)

200	1.62	(1.7219)	5.89	(2.7373)	1.55	(1.6779)	5.62	(2.6620)

Table 3: Quantitative comparison on the data set without any transformation. The two methods behave similarly, the glasso is slightly better.

and $(30, 100, 1/15)$. From the mean ROC curves, we see that nonparanormal does indeed behave worse than the glasso, suggesting some efficiency loss. However, from the corresponding boxplots, the efficiency reduction is relatively insignificant.

6.1.5 THE CASE WHEN $p \gg n$

Figure 10 shows results from a simulation of the nonparanormal using cdf transformations with $n = 200, p = 500$ and sparsity level $s = 1/40$. The boxplot shows that the nonparanormal outperforms the glasso. A typical run of the regularization paths confirms this conclusion, showing that the nonparanormal path separates the relevant and irrelevant dimensions very well. In contrast, with the glasso the relevant variables are "buried" among the irrelevant variables.

6.2 Gene Microarray Data

In this study, we consider a data set based on Affymetrix GeneChip microarrays for the plant *Arabidopsis thaliana*, (Wille et al., 2004). The sample size is $n = 118$. The expression levels for each chip are pre-processed by log-transformation and standardization. A subset of 40 genes from the isoprenoid pathway are chosen, and we study the associations among them using both the paranormal and nonparanormal models. Even though these data are generally treated as multivariate Gaussian in the previous analysis (Wille et al., 2004), our study shows that the results of the nonparanormal and the glasso are very different over a wide range of regularization parameters. This suggests the nonparanormal could support different scientific conclusions.

6.2.1 COMPARISON OF THE REGULARIZATION PATHS

We first compare the regularization paths of the two methods, in Figure 11. To generate the paths, we select 50 regularization parameters on an evenly spaced grid in the interval $[0.16, 1.2]$. Although

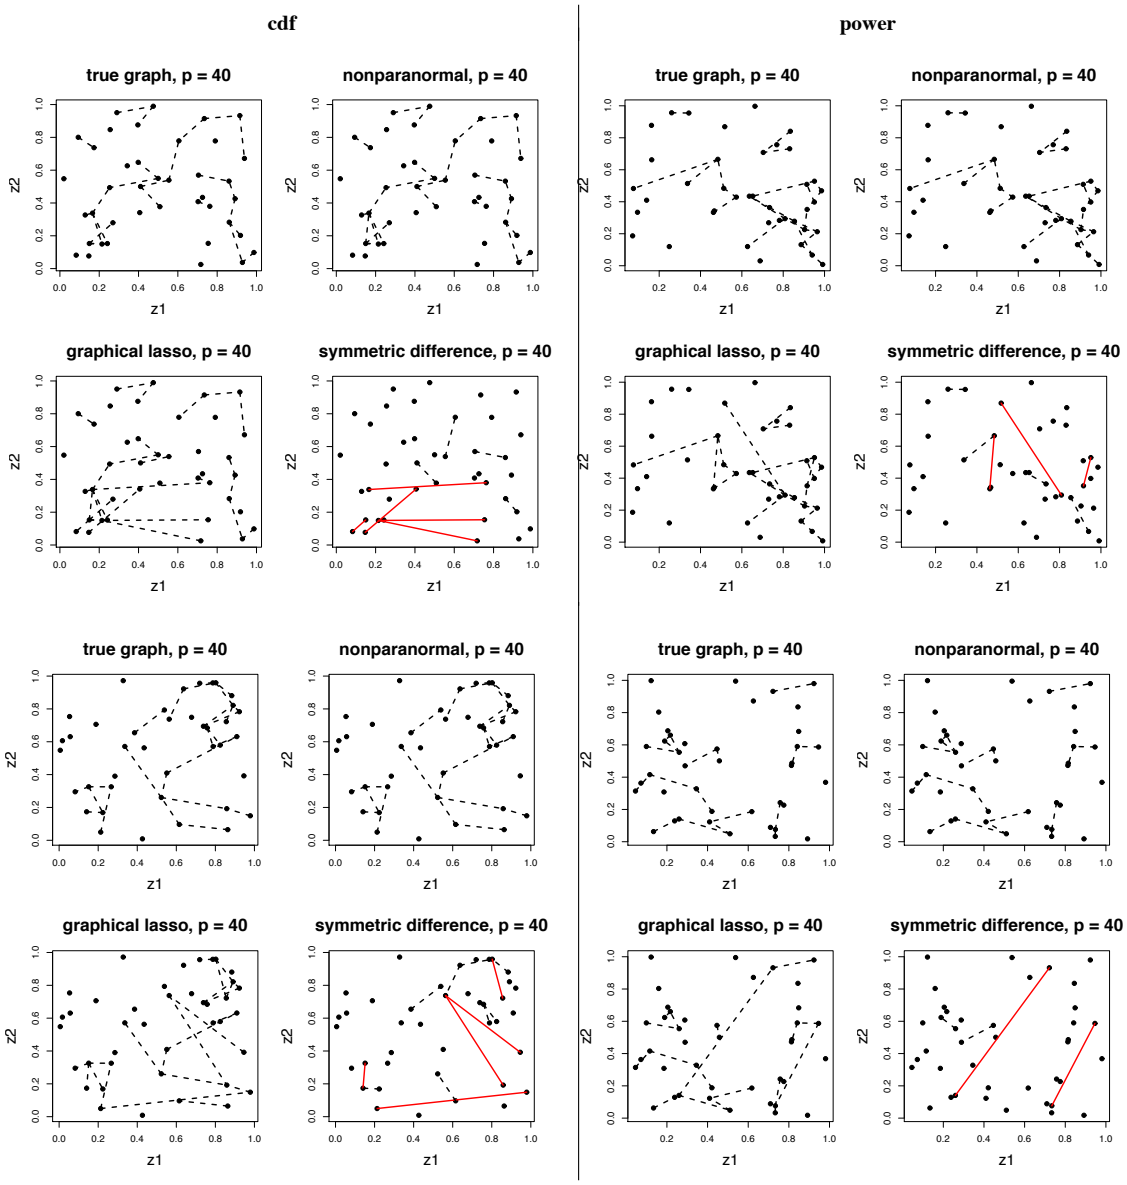

Figure 8: Typical runs for the two methods for $n = 1000$ using the cdf and power transformations. The dashed (black) lines in the symmetric difference plots indicate edges found by the glasso but not the nonparanormal, and vice-versa for the solid (red) lines.

the paths for the two methods look similar, there are some subtle differences. In particular, variables become nonzero in a different order, especially when the regularization parameter is in the range $\lambda \in [0.2, 0.3]$. As shown below, these subtle differences in the paths lead to different model selection behaviors.

6.2.2 COMPARISON OF THE ESTIMATED GRAPHS

Figure 12 compares the estimated graphs for the two methods at several values of the regularization parameter λ in the range $[0.16, 0.37]$. For each λ, we show the estimated graph from the nonparanormal in the first column. In the second column we show the graph obtained by scanning the full

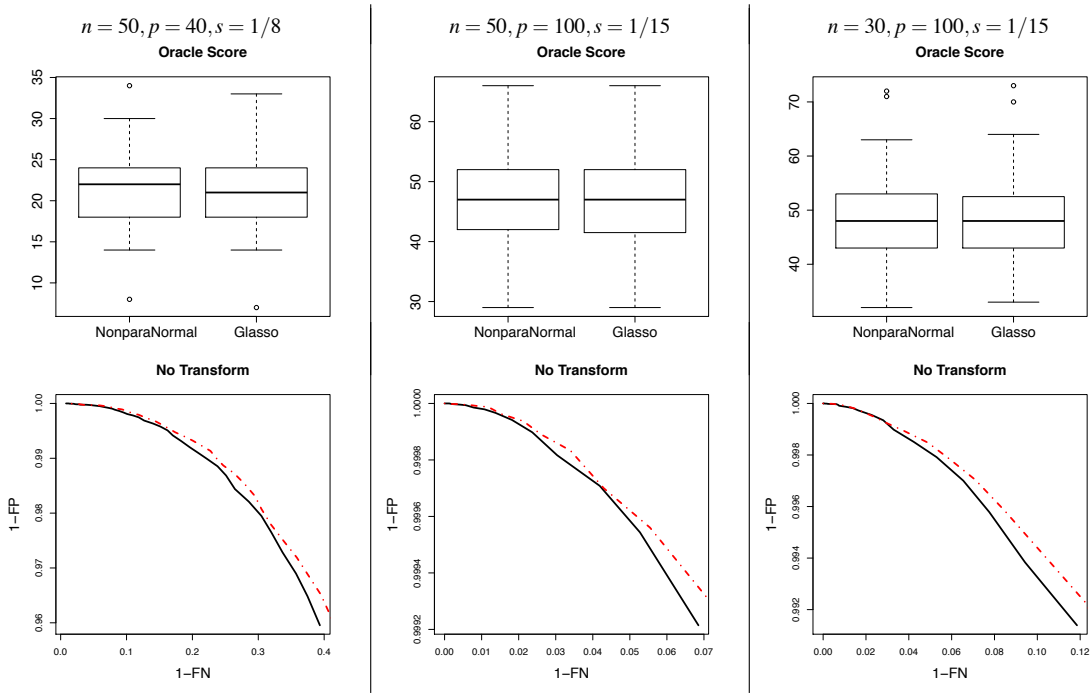

Figure 9: For Gaussian models, comparison of boxplots of the oracle scores and ROC curves for small n and relatively large p. The ROC curves suggest some efficiency loss of the nonparanormal; however, the corresponding boxplots indicate this loss is insignificant.

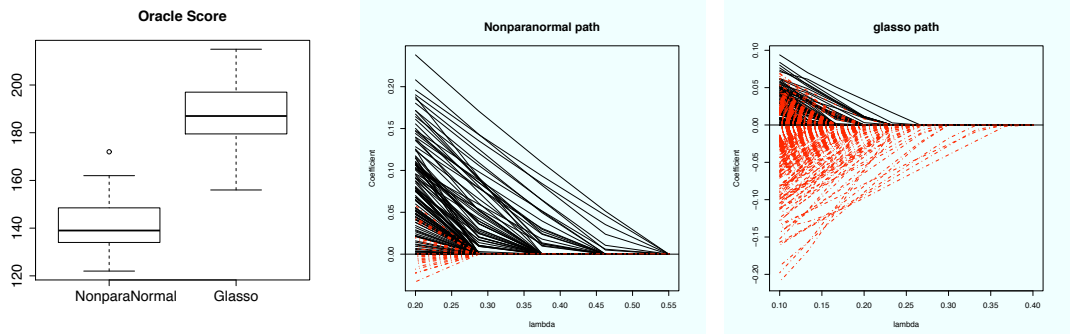

Figure 10: For the cdf transformation with $n = 200, p = 500, s = 1/40$, comparison of the boxplots and a typical run of the regularization paths. The nonparanormal paths separate the relevant from the irrelevant dimensions well. For the glasso, the relevant variables are "buried" in irrelevant variables.

regularization path of the glasso fit and finding the graph having the smallest symmetric difference with the nonparanormal graph. The symmetric difference graph is shown in in the third column. The closest glasso fit is different, with edges selected by the glasso not selected by the nonparanormal, and vice-versa. Several estimated transformations are plotted in Figure 13, which are are nonlinear. Interestingly, several of the differences between the fitted graphs are related to these variables.

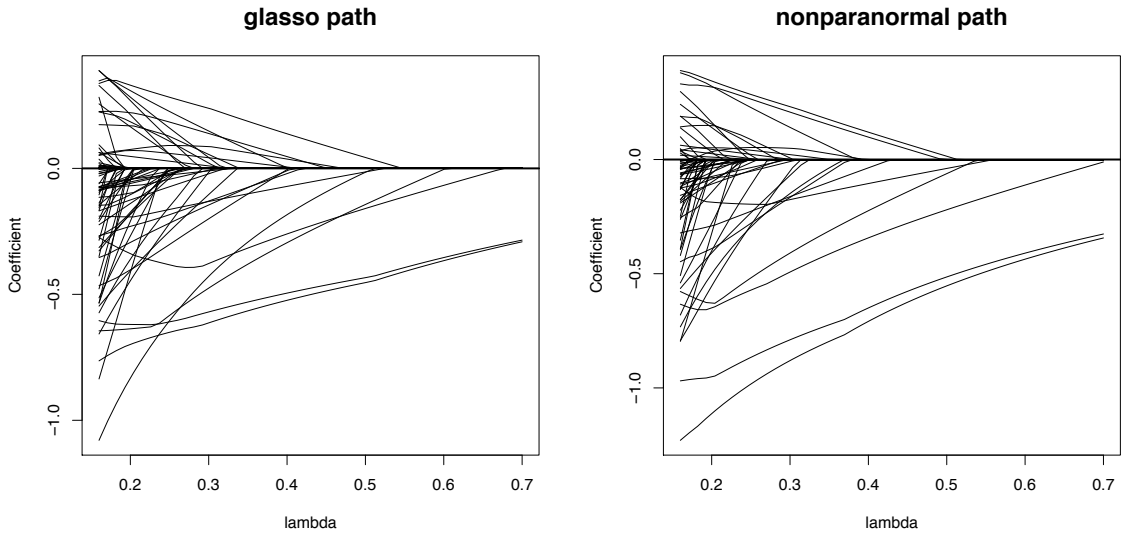

Figure 11: The regularization paths of both methods on the microarray data set. Although the paths for the two methods look similar, there are some subtle differences.

7. Proofs

We assume, without loss of generality from Lemma 3, that $\mu_j = 0$ and $\sigma_j = 1$ for all $j = 1, \ldots, p$. Thus, define $\widetilde{f}_j(x) \equiv \Phi^{-1}(\widetilde{F}_j(x))$ and $f_j(x) \equiv \Phi^{-1}(F_j(x))$, and let $g_j \equiv f_j^{-1}$.

7.1 Proof of Theorem 4

We start with some useful lemmas; the first is from Abramovich et al. (2006).

Lemma 11 *(Gaussian Distribution function vs. Quantile function) Let Φ and ϕ denote the distribution and density functions of a standard Gaussian random variable. Then*

$$\frac{\phi(t)}{2t} \leq 1 - \Phi(t) \leq \frac{\phi(t)}{t} \quad \text{if } t \geq 1$$

and

$$(\Phi^{-1})'(\eta) = \frac{1}{\phi(\Phi^{-1}(\eta))}.$$

Also, for $\eta \geq 0.99$, we have

$$\Phi^{-1}(\eta) = \sqrt{2\log\left(\frac{1}{1-\eta}\right)} - r(\eta) \tag{11}$$

where $r(\eta) \in [0, 1.5]$.

Lemma 12 *(Distribution function of the transformed random variable) For any $\alpha \in (-\infty, \infty)$*

$$\Phi^{-1}\left(F_j\left(g_j(\alpha\sqrt{\log n})\right)\right) = \alpha\sqrt{\log n}.$$

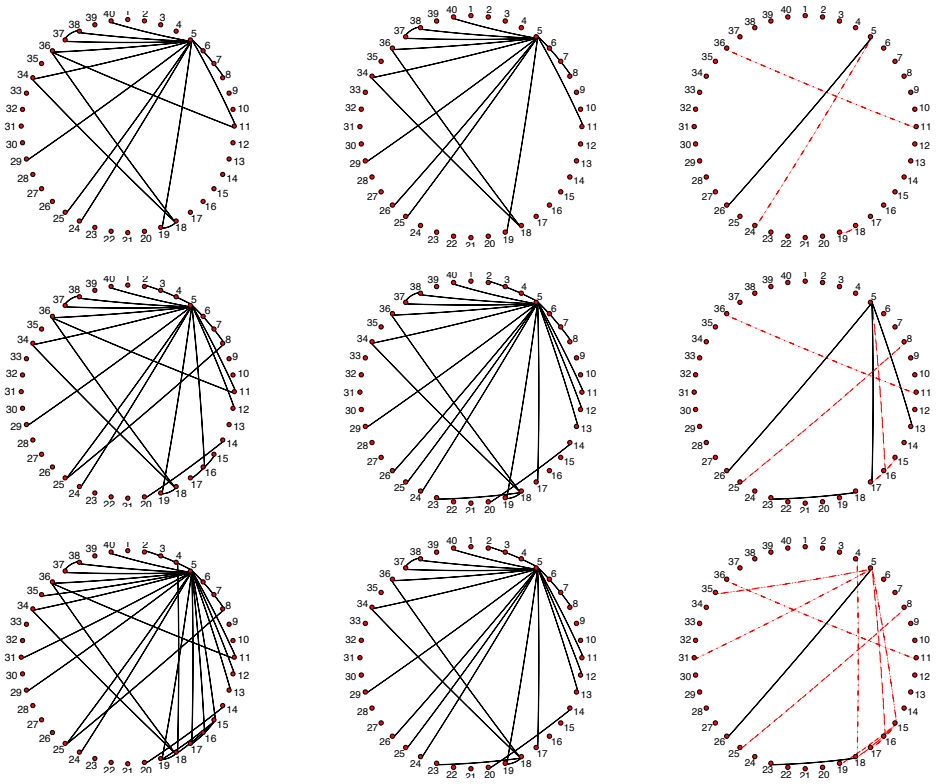

Figure 12: The nonparanormal estimated graph for three values of $\lambda = 0.2448, 0.2661, 0.30857$ (left column), the closest glasso estimated graph from the full path (middle) and the symmetric difference graph (right).

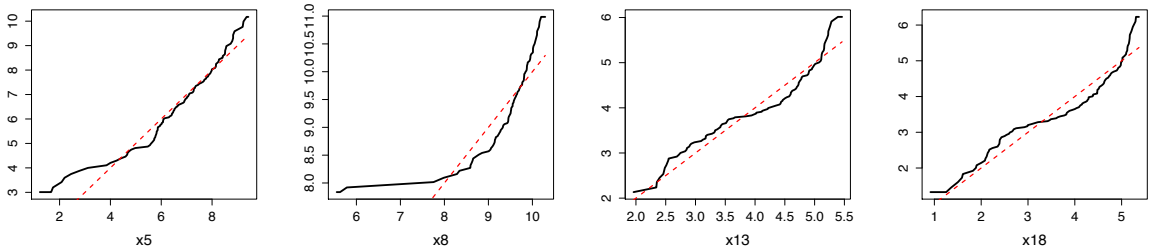

Figure 13: Estimated transformations for the microarray data set, indicating non-Gaussian marginals. The corresponding genes are among the nodes appearing in the symmetric difference graphs above.

Proof The statement follows from

$$F_j(t) = \mathbb{P}(X_j \leq t) = \mathbb{P}(g_j(Z_j) \leq t) = \mathbb{P}(Z_j \leq g_j^{-1}(t)) = \Phi\left(g_j^{-1}(t)\right). \tag{12}$$

which holds for any t. ■

Lemma 13 *(Gaussian maximal inequality) Let $W_1, \ldots, W_n$ be identically distributed standard Gaussian random variables (do not have to be independent). Then for any $\alpha > 0$*

$$\mathbb{P}\left(\max_{1\le i\le n} W_i > \sqrt{\alpha \log n}\right) \le \frac{1}{n^{\alpha/2-1}\sqrt{2\pi\alpha\log n}}.$$

Proof Using Mill's inequality, we have

$$\mathbb{P}\left(\max_{1\le i\le n} W_i > \sqrt{\alpha\log n}\right) \le \sum_{i=1}^{n} \mathbb{P}\left(W_i > \sqrt{\alpha\log n}\right) \le n\frac{\phi(\sqrt{\alpha\log n})}{\sqrt{\alpha\log n}} = \frac{1}{n^{\alpha/2-1}\sqrt{2\pi\alpha\log n}},$$

from which the result follows. ■

Lemma 14 *For any $\alpha > 0$ that satisfies $1-\delta_n - \Phi\left(\sqrt{\alpha\log n}\right) > 0$ for all n, we have*

$$\mathbb{P}\left[\widehat{F}_j\left(g_j\left(\sqrt{\alpha\log n}\right)\right) > 1-\delta_n\right] \le \exp\left\{-2n\left(1-\delta_n-\Phi\left(\sqrt{\alpha\log n}\right)\right)^2\right\}. \tag{13}$$

and

$$\mathbb{P}\left[\widehat{F}_j\left(g_j\left(-\sqrt{\alpha\log n}\right)\right) < \delta_n\right] \le \exp\left\{-2n\left(1-\delta_n-\Phi\left(\sqrt{\alpha\log n}\right)\right)^2\right\}. \tag{14}$$

Proof Using Hoeffding's inequality,

$$\begin{aligned}
&\mathbb{P}\left[\widehat{F}_j\left(g_j\left(\sqrt{\alpha\log n}\right)\right) > 1-\delta_n\right] \\
&= \mathbb{P}\left[\widehat{F}_j\left(g_j\left(\sqrt{\alpha\log n}\right)\right) - F_j\left(g_j\left(\sqrt{\alpha\log n}\right)\right) > 1-\delta_n - F_j\left(g_j\left(\sqrt{\alpha\log n}\right)\right)\right] \\
&\le \exp\left\{-2n\left(1-\delta_n-F_j\left(g_j\left(\sqrt{\alpha\log n}\right)\right)\right)^2\right\}.
\end{aligned}$$

Equation (13) then follows from equation (12). The proof of equation (14) uses the same argument. ■

Now let $M > 2$ and set $\beta = \frac{1}{2}$. We split the interval

$$\left[g_j(-\sqrt{M\log n}), g_j(\sqrt{M\log n})\right]$$

into two parts, the middle

$$\mathcal{M}_n \equiv \left(g_j\left(-\sqrt{\beta\log n}\right), g_j\left(\sqrt{\beta\log n}\right)\right)$$

and ends

$$\mathcal{E}_n \equiv \left[g_j\left(-\sqrt{M\log n}\right), g_j\left(-\sqrt{\beta\log n}\right)\right] \cup \left[g_j\left(\sqrt{\beta\log n}\right), g_j\left(\sqrt{M\log n}\right)\right].$$

The behaviors of the function estimates in these two regions are different, so we first establish bounds on the probability that a sample can fall in the end region $\mathcal{E}_n$.

Lemma 15 *Let* $A \equiv \sqrt{\frac{2}{\pi}}(\sqrt{M} - \sqrt{\beta})$. *Then*

$$\mathbb{P}(X_{1j} \in \mathcal{E}_n) \leq A\sqrt{\frac{\log n}{n^\beta}}, \ \ \forall j \in \{1,\ldots,p\}.$$

Proof Using Equation (12) and the mean value theorem, we have

$$\begin{aligned}
&\mathbb{P}(X_{1j} \in \mathcal{E}_n) \\
&= \mathbb{P}\left(X_{1j} \in \left[g_j(\sqrt{\beta\log n}), g_j(\sqrt{M\log n})\right]\right) + \mathbb{P}\left(X_{1j} \in \left[g_j(-\sqrt{M\log n}), g_j(-\sqrt{\beta\log n})\right]\right) \\
&= F_j\left(g_j(\sqrt{M\log n})\right) - F_j\left(g_j(\sqrt{\beta\log n})\right) + F_j\left(g_j(-\sqrt{\beta\log n})\right) - F_j\left(g_j(-\sqrt{M\log n})\right) \\
&= 2\left(\Phi(\sqrt{M\log n}) - \Phi(\sqrt{\beta\log n})\right) \\
&\leq 2\phi\left(\sqrt{\beta\log n}\right)\left(\sqrt{M\log n} - \sqrt{\beta\log n}\right).
\end{aligned}$$

The result of the lemma follows directly. ■

We next bound the error of the Winsorized estimate of a component function over the end region.

Lemma 16 *For all n, we have*

$$\sup_{t\in\mathcal{E}_n}\left|\Phi^{-1}(\widetilde{F}_j(t)) - \Phi^{-1}(F_j(t))\right| < \sqrt{2(M+2)\log n}, \ \ \forall j \in \{1,\ldots,p\}.$$

Proof From Lemma 12 and the definition of $\mathcal{E}_n$, we have

$$\sup_{t\in\mathcal{E}_n}\left|\Phi^{-1}(F_j(t))\right| \in \left[0, \sqrt{M\log n}\right].$$

Given the fact that $\delta_n = \dfrac{1}{4n^{1/4}\sqrt{\pi\log n}}$, we have $\widetilde{F}_j(t) \in \left(\dfrac{1}{n}, 1-\dfrac{1}{n}\right)$. Therefore, from Equation (11),

$$\sup_{t\in\mathcal{E}_n}\left|\Phi^{-1}\left(\widetilde{F}_j(t)\right)\right| \in \left[0, \sqrt{2\log n}\right).$$

The result follows from the triangle inequality and $\sqrt{M} + \sqrt{2} \leq \sqrt{2(M+2)}$. ■

Now for any $\varepsilon > 0$, we have

$$\begin{aligned}
&\mathbb{P}\left(\max_{j,k}\left|S_n(\widetilde{f})_{jk} - S_n(f)_{jk}\right| > 2\varepsilon\right) \\
&= \mathbb{P}\left(\max_{j,k}\left|\frac{1}{n}\sum_{i=1}^n\left\{\widetilde{f}_j(X_{ij})\widetilde{f}_k(X_{ik}) - f_j(X_{ij})f_k(X_{ik}) - \mu_n(\widetilde{f}_j)\mu_n(\widetilde{f}_k) + \mu_n(f_j)\mu_n(f_k)\right\}\right| > 2\varepsilon\right) \\
&\leq \mathbb{P}\left(\max_{j,k}\left|\frac{1}{n}\sum_{i=1}^n\left(\widetilde{f}_j(X_{ij})\widetilde{f}_k(X_{ik}) - f_j(X_{ij})f_k(X_{ik})\right)\right| > \varepsilon\right) \\
&\quad + \mathbb{P}\left(\max_{j,k}\left|\mu_n(\widetilde{f}_j)\mu_n(\widetilde{f}_k) - \mu_n(f_j)\mu_n(f_k)\right| > \varepsilon\right).
\end{aligned}$$

We only need to analyze the rate for the first term above, since the second one is of higher order (Cai et al., 2008). Let

$$\Delta_i(j,k) \equiv \widetilde{f}_j(X_{ij})\widetilde{f}_k(X_{ik}) - f_j(X_{ij})f_k(X_{ik})$$

and

$$\Theta_{t,s}(j,k) \equiv \widetilde{f}_j(t)\widetilde{f}_k(s) - f_j(t)f_k(s).$$

We define the event $\mathcal{A}_n$ as

$$\mathcal{A}_n \equiv \left\{ g_j\left(-\sqrt{M\log n}\right) \le X_{1j},\ldots,X_{nj} \le g_j\left(\sqrt{M\log n}\right), j=1,\ldots,p \right\}.$$

Then, by Lemma 13, when $M \ge 2(\xi+1)$, we have

$$\mathbb{P}(\mathcal{A}_n^c) \le \mathbb{P}\left(\max_{i,j\in\{1,\ldots,n\}\times\{1,\ldots,p\}} |f_j(X_{ij})| > \sqrt{2\log(np)} \right) \le \frac{1}{2\sqrt{\pi\log(np)}}.$$

Therefore

$$\begin{aligned}
\mathbb{P}\left(\max_{j,k} \left| \frac{1}{n}\sum_{i=1}^n \Delta_i(j,k) \right| > \varepsilon \right) &\le \mathbb{P}\left(\max_{j,k} \left| \frac{1}{n}\sum_{i=1}^n \Delta_i(j,k) \right| > \varepsilon, \mathcal{A}_n \right) \quad + \quad \mathbb{P}(\mathcal{A}_n^c) \\
&\le \mathbb{P}\left(\max_{j,k} \left| \frac{1}{n}\sum_{i=1}^n \Delta_i(j,k) \right| > \varepsilon, \mathcal{A}_n \right) \quad + \quad \frac{1}{2\sqrt{\pi\log(np)}}.
\end{aligned}$$

Thus, we only need to carry out our analysis on the event $\mathcal{A}_n$. On this event, we have the following decomposition:

$$\begin{aligned}
&\mathbb{P}\left(\max_{j,k} \left| \frac{1}{n}\sum_{i=1}^n \Delta_i(j,k) \right| > \varepsilon,\ \mathcal{A}_n \right) \\
&\le \quad \mathbb{P}\left(\max_{j,k} \frac{1}{n} \sum_{X_{ij}\in\mathcal{M}_n, X_{ik}\in\mathcal{M}_n} |\Delta_i(j,k)| > \frac{\varepsilon}{4} \right) + \mathbb{P}\left(\max_{j,k} \frac{1}{n} \sum_{X_{ij}\in\mathcal{L}_n, X_{ik}\in\mathcal{L}_n} |\Delta_i(j,k)| > \frac{\varepsilon}{4} \right) \\
&\quad + 2\mathbb{P}\left(\max_{j,k} \frac{1}{n} \sum_{X_{ij}\in\mathcal{M}_n, X_{ik}\in\mathcal{L}_n} |\Delta_i(j,k)| > \frac{\varepsilon}{4} \right).
\end{aligned}$$

We now analyze each of these terms separately.

Lemma 17 *On the event $\mathcal{A}_n$, let $\beta = 1/2$ and $\varepsilon \ge C_M \sqrt{\dfrac{\log p \log^2 n}{n^{1/2}}}$, then*

$$\mathbb{P}\left(\max_{j,k} \frac{1}{n} \sum_{X_{ij}\in\mathcal{L}_n, X_{ik}\in\mathcal{L}_n} |\Delta_i(j,k)| > \frac{\varepsilon}{4} \right) = o(1).$$

Proof We define

$$\theta_1 \equiv \frac{n^{\beta/2}\varepsilon}{8A\sqrt{\log n}}$$

with the same parameter A as in Lemma 15. Such a θ_1 guarantees that

$$\frac{n\varepsilon}{4\theta_1} - nA\sqrt{\frac{\log n}{n^\beta}} = nA\sqrt{\frac{\log n}{n^\beta}} > 0.$$

By Lemma 15, we have

$$\begin{aligned}
\mathbb{P}\left(\frac{1}{n}\sum_{i=1}^n \mathbf{1}_{\{X_{ij}\in\mathcal{E}_n, X_{ik}\in\mathcal{E}_n\}} > \frac{\varepsilon}{4\theta_1}\right) &\le \mathbb{P}\left(\sum_{i=1}^n \mathbf{1}_{\{X_{ij}\in\mathcal{E}_n\}} > \frac{n\varepsilon}{4\theta_1}\right) \\
&= \mathbb{P}\left(\sum_{i=1}^n \left(\mathbf{1}_{\{X_{ij}\in\mathcal{E}_n\}} - \mathbb{P}(X_{1j}\in\mathcal{E}_n)\right) > \frac{n\varepsilon}{4\theta_1} - n\mathbb{P}(X_{1j}\in\mathcal{E}_n)\right) \\
&\le \mathbb{P}\left(\sum_{i=1}^n \left(\mathbf{1}_{\{X_{ij}\in\mathcal{E}_n\}} - \mathbb{P}(X_{1j}\in\mathcal{E}_n)\right) > \frac{n\varepsilon}{4\theta_1} - nA\sqrt{\frac{\log n}{n^\beta}}\right).
\end{aligned}$$

Using the Bernstein's inequality, for $\beta = \frac{1}{2}$,

$$\begin{aligned}
\mathbb{P}\left(\frac{1}{n}\sum_{i=1}^n \mathbf{1}_{\{X_{ij}\in\mathcal{E}_n, X_{ik}\in\mathcal{E}_n\}} > \frac{\varepsilon}{4\theta_1}\right) &\le \mathbb{P}\left(\sum_{i=1}^n \left(\mathbf{1}_{\{X_{ij}\in\mathcal{E}_n\}} - \mathbb{P}(X_{1j}\in\mathcal{E}_n)\right) > nA\sqrt{\frac{\log n}{n^\beta}}\right) \\
&\le \exp\left(-\frac{c_1 n^{2-\beta}\log n}{c_2 n^{1-\beta/2}\sqrt{\log n} + c_3 n^{1-\beta/2}\sqrt{\log n}}\right) = o(1),
\end{aligned}$$

where $c_1, c_2, c_3 > 0$ are generic constants.

Therefore,

$$\begin{aligned}
&\mathbb{P}\left(\max_{j,k}\frac{1}{n}\sum_{X_{ij}\in\mathcal{E}_n, X_{ik}\in\mathcal{E}_n}|\Delta_i(j,k)| > \frac{\varepsilon}{4}\right) \\
&= \mathbb{P}\left(\max_{j,k}\frac{1}{n}\sum_{X_{ij}\in\mathcal{E}_n, X_{ik}\in\mathcal{E}_n}|\Delta_i(j,k)| > \frac{\varepsilon}{4}, \max_{j,k}\sup_{t\in\mathcal{E}_n, s\in\mathcal{E}_n}|\Theta_{t,s}(j,k)| > \theta_1\right) \\
&\quad + \mathbb{P}\left(\max_{j,k}\frac{1}{n}\sum_{X_{ij}\in\mathcal{E}_n, X_{ik}\in\mathcal{E}_n}|\Delta_i(j,k)| > \frac{\varepsilon}{4}, \max_{j,k}\sup_{t\in\mathcal{E}_n, s\in\mathcal{E}_n}|\Theta_{t,s}(j,k)| \le \theta_1\right) \\
&\le \mathbb{P}\left(\max_{j,k}\sup_{t\in\mathcal{E}_n, s\in\mathcal{E}_n}|\Theta_{t,s}(j,k)| > \theta_1\right) + \mathbb{P}\left(\frac{1}{n}\sum_{i=1}^n \mathbf{1}_{\{X_{ij}\in\mathcal{E}_n, X_{ik}\in\mathcal{E}_n\}} > \frac{\varepsilon}{4\theta_1}\right) \\
&= \mathbb{P}\left(\max_{j,k}\sup_{t\in\mathcal{E}_n, s\in\mathcal{E}_n}|\Theta_{t,s}(j,k)| > \theta_1\right) + o(1).
\end{aligned}$$

Now, we analyze the first term

$$\begin{aligned}\mathbb{P}\left(\max_{j,k}\sup_{t\in\mathcal{E}_n,s\in\mathcal{E}_n}|\Theta_{t,s}(j,k)|>\theta_1\right) &\leq p^2\mathbb{P}\left(\sup_{t\in\mathcal{E}_n,s\in\mathcal{E}_n}|\Theta_{t,s}(j,k)|>\theta_1\right)\\ &= p^2\mathbb{P}\left(\sup_{t\in\mathcal{E}_n,s\in\mathcal{E}_n}|\widetilde{f}_j(t)\widetilde{f}_k(s)-f_j(t)f_k(s)|>\theta_1\right).\end{aligned}$$

By adding and subtracting terms $f_j(t)$ and $f_s(t)$, we have

$$\begin{aligned}&\mathbb{P}\left(\sup_{t\in\mathcal{E}_n,s\in\mathcal{E}_n}|\widetilde{f}_j(t)\widetilde{f}_k(s)-f_j(t)f_k(s)|>\theta_1\right)\\ &\qquad\leq \mathbb{P}\left(\sup_{t\in\mathcal{E}_n,s\in\mathcal{E}_n}|(\widetilde{f}_j(t)-f_j(t))(\widetilde{f}_k(s)-f_k(s))|>\frac{\theta_1}{3}\right)\\ &\qquad\quad+\mathbb{P}\left(\sup_{t\in\mathcal{E}_n,s\in\mathcal{E}_n}|(\widetilde{f}_j(t)-f_j(t))|\cdot|f_k(s)|>\frac{\theta_1}{3}\right)\\ &\qquad\quad+\mathbb{P}\left(\sup_{t\in\mathcal{E}_n,s\in\mathcal{E}_n}|(\widetilde{f}_k(s)-f_k(s))|\cdot|f_j(t)|>\frac{\theta_1}{3}\right).\end{aligned}$$

The first term can further be decomposed to be

$$\begin{aligned}&\mathbb{P}\left(\sup_{t\in\mathcal{E}_n,s\in\mathcal{E}_n}|(\widetilde{f}_j(t)-f_j(t))(\widetilde{f}_k(s)-f_k(s))|>\frac{\theta_1}{3}\right)\\ &\quad\leq \mathbb{P}\left(\sup_{t\in\mathcal{E}_n}|(\widetilde{f}_j(t)-f_j(t))|>\sqrt{\frac{\theta_1}{3}}\right)+\mathbb{P}\left(\sup_{s\in\mathcal{E}_n}|(\widetilde{f}_k(s)-f_k(s))|>\sqrt{\frac{\theta_1}{3}}\right).\end{aligned}$$

Also, from the definition of $\mathcal{E}_n$, we have

$$\sup_{t\in\mathcal{E}_n}|f_j(t)|=\sup_{t\in\mathcal{E}_n}\left|g_j^{-1}(t)\right|\leq\sqrt{M\log n}.$$

Since $\varepsilon\geq C_M\sqrt{\frac{\log p\log^2 n}{n^{1/2}}}$, we have

$$\frac{\theta_1}{3}=\frac{n^{\beta/2}\varepsilon}{24A\sqrt{\log n}}\geq\frac{C_M\sqrt{\log p\log^2 n}}{24A\sqrt{\log n}}=2(M+2)\log n.$$

This implies that

$$\sqrt{\frac{\theta_1}{3}}\geq\sqrt{2(M+2)\log n}\ \text{ and }\ \frac{\theta_1}{3\sqrt{M\log n}}\geq\sqrt{2(M+2)\log n}.$$

Then, from Lemma 16, we get

$$\mathbb{P}\left(\sup_{t\in\mathcal{E}_n}|(\widetilde{f}_j(t)-f_j(t))|>\sqrt{\frac{\theta_1}{3}}\right)=0$$

and

$$\mathbb{P}\left(\sup_{t\in\mathcal{E}_n,s\in\mathcal{E}_n}|(\widetilde{f}_j(t)-f_j(t))|\cdot|f_k(s)|>\frac{\theta_1}{3}\right)=0.$$

The claim of the lemma then follows directly. ■

Remark 18 *From the above analysis, we see that the data in the tails doesn't affect the rate. Using exactly the same argument, we can also show that*

$$\mathbb{P}\left(\max_{j,k}\frac{1}{n}\sum_{X_{ij}\in\mathcal{M}_n,X_{ik}\in\mathcal{E}_n}|\Delta_i(j,k)|>\frac{\varepsilon}{4}\right)=o(1).$$

Lemma 19 *On the event $\mathcal{A}_n$, let $\beta=1/2$ and $\varepsilon\geq C_M\sqrt{\frac{\log p\log^2 n}{n^{1/2}}}$. We have*

$$\mathbb{P}\left(\max_{j,k}\frac{1}{n}\sum_{X_{ij}\in\mathcal{M}_n,X_{ik}\in\mathcal{M}_n}|\Delta_i(j,k)|>\frac{\varepsilon}{4}\right)\leq 2\exp\left(2\log p-\frac{n^{1/2}\varepsilon^2}{1232\pi^2\log^2 n}\right)+2\exp\left(2\log p-\frac{n^{1/2}}{8\pi\log n}\right).$$

Proof We have

$$\begin{aligned}\mathbb{P}\left(\max_{j,k}\frac{1}{n}\sum_{X_{ij}\in\mathcal{M}_n,X_{ik}\in\mathcal{M}_n}|\Delta_i(j,k)|>\frac{\varepsilon}{4}\right)&\leq p^2\mathbb{P}\left(\sup_{t\in\mathcal{M}_n,s\in\mathcal{M}_n}|\widetilde{f}_j(t)\widetilde{f}_k(s)-f_j(t)f_k(s)|>\frac{\varepsilon}{4}\right)\\&\leq p^2\mathbb{P}\left(\sup_{t\in\mathcal{M}_n,s\in\mathcal{M}_n}|(\widetilde{f}_j(t)-f_j(t))(\widetilde{f}_k(s)-f_k(s))|>\frac{\varepsilon}{12}\right)\\&\quad+2p^2\mathbb{P}\left(\sup_{t\in\mathcal{M}_n,s\in\mathcal{M}_n}|(\widetilde{f}_j(t)-f_j(t))|\cdot|f_k(s)|>\frac{\varepsilon}{12}\right).\end{aligned}$$

Further, since

$$\sup_{t\in\mathcal{M}_n}|f_j(t)|=\sup_{t\in\mathcal{M}_n}\left|g_j^{-1}(t)\right|=\sqrt{\beta\log n}$$

and $\sup_{t\in\mathcal{M}_n,s\in\mathcal{M}_n}|(\widetilde{f}_j(t)-f_j(t))(\widetilde{f}_k(s)-f_k(s))|$ is of higher order than $\sup_{t\in\mathcal{M}_n,s\in\mathcal{M}_n}|(\widetilde{f}_j(t)-f_j(t))|\cdot|f_k(s)|$, we only need to analyze the term $\mathbb{P}\left(\sup_{t\in\mathcal{M}_n}|(\widetilde{f}_j(t)-f_j(t))|>\frac{\varepsilon}{12\sqrt{\beta\log n}}\right)$.

Since $\delta_n=\frac{1}{4n^{\beta/2}\sqrt{2\pi\beta\log n}}$, using Mill's inequality we have

$$2\delta_n=\frac{\phi(\sqrt{\beta\log n})}{2\sqrt{\beta\log n}}\leq 1-\Phi(\sqrt{\beta\log n}).$$

This implies that

$$1-\delta_n-\Phi(\sqrt{\beta\log n})\geq\delta_n>0.$$

Using Lemma 14, we have

$$p^2\mathbb{P}\left(\widehat{F}_j\left(g_j\left(\sqrt{\beta\log n}\right)\right)>1-\delta_n\right)\leq p^2\exp\left(-2n\delta_n^2\right)=\exp\left(2\log p-\frac{n^{1-\beta}}{(16\pi\beta\log n)}\right) \tag{15}$$

and

$$p^2\mathbb{P}\left(\widehat{F}_j\left(g_j\left(-\sqrt{\beta\log n}\right)\right)<\delta_n\right)\leq\exp\left(2\log p-\frac{n^{1-\beta}}{(16\pi\beta\log n)}\right). \tag{16}$$

Define an event $\mathcal{B}_n$ as

$$\mathcal{B}_n\equiv\left\{\delta_n\leq\widehat{F}_j\left(g_j\left(\sqrt{\beta\log n}\right)\right)\leq 1-\delta_n, j=1,\ldots,p\right\}.$$

From (15) and (16), it is easy to see that

$$\mathbb{P}\left(\mathcal{B}_n^c\right)\leq 2\exp\left(2\log p-\frac{n^{1/2}}{8\pi\log n}\right).$$

From the definition of $\widetilde{F}_j$, we have

$$\begin{aligned}
&p^2\mathbb{P}\left(\sup_{t\in\mathcal{M}_n}|\widetilde{f}_j(t)-f_j(t)|>\frac{\varepsilon}{12\sqrt{\beta\log n}}\right)\\
&\leq\quad p^2\mathbb{P}\left(\sup_{t\in\mathcal{M}_n}\left|\Phi^{-1}\left(\widetilde{F}_j(t)\right)-\Phi^{-1}\left(F_j(t)\right)\right|>\frac{\varepsilon}{12\sqrt{\beta\log n}},\mathcal{B}_n\right)+\mathbb{P}\left(\mathcal{B}_n^c\right).\\
&\leq\quad p^2\mathbb{P}\left(\sup_{t\in\mathcal{M}_n}\left|\Phi^{-1}\left(\widehat{F}_j(t)\right)-\Phi^{-1}\left(F_j(t)\right)\right|>\frac{\varepsilon}{12\sqrt{\beta\log n}}\right)+2\exp\left(2\log p-\frac{n^{1/2}}{8\pi\log n}\right).
\end{aligned}$$

Define

$$T_{1n}\equiv\max\left\{F_j\left(g_j\left(\sqrt{\beta\log n}\right)\right),1-\delta_n\right\}\ \text{ and }\ T_{2n}\equiv 1-\min\left\{F_j\left(g_j\left(-\sqrt{\beta\log n}\right)\right),\delta_n\right\}.$$

From Equation (12) and the fact that $1-\delta_n\geq\Phi\left(\sqrt{\beta\log n}\right)$, we have that

$$T_{1n}=T_{2n}=1-\delta_n.$$

Thus, by the mean value theorem,

$$\begin{aligned}
&\mathbb{P}\left(\sup_{t\in\mathcal{M}_n}\left|\Phi^{-1}\left(\widehat{F}_j(t)\right)-\Phi^{-1}\left(F_j(t)\right)\right|>\frac{\varepsilon}{12\sqrt{\beta\log n}}\right)\\
&\leq\quad\mathbb{P}\left((\Phi^{-1})'\left(\max\left\{T_{1n},T_{2n}\right\}\right)\sup_{t\in\mathcal{M}_n}\left|\widehat{F}_j(t)-F_j(t)\right|>\frac{\varepsilon}{12\sqrt{\beta\log n}}\right)\\
&=\quad\mathbb{P}\left((\Phi^{-1})'\left(1-\delta_n\right)\sup_{t\in\mathcal{M}_n}\left|\widehat{F}_j(t)-F_j(t)\right|>\frac{\varepsilon}{12\sqrt{\beta\log n}}\right).
\end{aligned}$$

Finally, using the Dvoretzky-Kiefer-Wolfowitz inequality,

$$\begin{aligned}
&\mathbb{P}\left(\sup_{t\in\mathcal{M}_n}\left|\Phi^{-1}\left(\widehat{F}_j(t)\right)-\Phi^{-1}\left(F_j(t)\right)\right|>\frac{\varepsilon}{12\sqrt{\beta\log n}}\right)\\
&\qquad\leq\ \mathbb{P}\left(\sup_{t\in\mathcal{M}_n}\left|\widehat{F}_j(t)-F_j(t)\right|>\frac{\varepsilon}{(\Phi^{-1})'(1-\delta_n)\,12\sqrt{\beta\log n}}\right)\\
&\qquad\leq\ 2\exp\left(-2\frac{n\varepsilon^2}{144\beta\log n\left[(\Phi^{-1})'(1-\delta_n)\right]^2}\right).
\end{aligned}$$

Furthermore, by Lemma 11,

$$(\Phi^{-1})'(1-\delta_n)=\frac{1}{\phi(\Phi^{-1}(1-\delta_n))}\leq\frac{1}{\phi\left(\sqrt{2\log\frac{1}{\delta_n}}\right)}=\sqrt{2\pi}\left(\frac{1}{\delta_n}\right)=8\pi n^{\beta/2}\sqrt{\beta\log n}.$$

This implies that

$$p^2\mathbb{P}\left(\sup_{t\in\mathcal{M}_n}\left|\Phi^{-1}\left(\widehat{F}_j(t)\right)-\Phi^{-1}\left(F_j(t)\right)\right|>\frac{\varepsilon}{12\sqrt{\beta\log n}}\right)\leq 2\exp\left(2\log p-\frac{n^{1/2}\varepsilon^2}{1232\pi^2\log^2 n}\right).$$

In summary, we have

$$\mathbb{P}\left(\max_{j,k}\frac{1}{n}\sum_{X_{ij}\in\mathcal{M}_n,X_{ik}\in\mathcal{E}_n}|\Delta_i(j,k)|>\frac{\varepsilon}{4}\right)\leq 2\exp\left(2\log p-\frac{n^{1/2}\varepsilon^2}{1232\pi^2\log^2 n}\right)+2\exp\left(2\log p-\frac{n^{1/2}}{8\pi\log n}\right)$$

This finish the proof. ■

The conclusion of Theorem 4 follows from Lemma 17 and Lemma 19.

7.2 Proof of Theorem 8

Proof First note that the population and sample risks are

$$\begin{aligned}
R(f,\Omega) &= \frac{1}{2}\left\{\mathrm{tr}\left[\Omega\mathbb{E}(f(X)f(X)^T\right]-\log|\Omega|-p\log(2\pi)\right\}\\
\widehat{R}(f,\Omega) &= \frac{1}{2}\left\{\mathrm{tr}\left[\Omega S_n(f)\right]-\log|\Omega|-p\log(2\pi)\right\}.
\end{aligned}$$

Therefore, for all $(f,\Omega)\in\mathcal{M}_n^p\oplus\mathcal{C}_n$, we have

$$\begin{aligned}
|\widehat{R}(f,\Omega)-R(f,\Omega)| &= \frac{1}{2}\left|\mathrm{tr}\left[\Omega\left(\mathbb{E}[ff^T]-S_n(f)\right)\right]\right|\\
&\leq \frac{1}{2}\|\Omega\|_1\max_{jk}\sup_{f_j,f_k\in\mathcal{M}_n}|\mathbb{E}(f_j(X_j)f_k(X_k)-S_n(f)_{jk}|\\
&\leq \frac{L_n}{2}\max_{jk}\sup_{f_j,f_k\in\mathcal{M}_n}|\mathbb{E}(f_j(X_j)f_k(X_k)-S_n(f)_{jk}|.
\end{aligned}$$

Now, if $\mathcal{F}$ is a class of functions, we have

$$\mathbb{E}\left(\sup_{g\in\mathcal{F}}|\widehat{\mu}(g)-\mu(g)|\right)\leq\frac{CJ_{[]}(\|F\|_\infty,\mathcal{F})}{\sqrt{n}} \tag{17}$$

for some $C>0$, where $F(x)=\sup_{g\in cF}|g(x)|, \mu(g)=\mathbb{E}(g(X))$ and $\widehat{\mu}(g)=n^{-1}\sum_{i=1}^n g(X_i)$ (see Corollary 19.35 of van der Vaart 1998). Here the bracketing integral is defined to be

$$J_{[]}(\delta,\mathcal{F})=\int_0^\delta\sqrt{\log N_{[]}(u,\mathcal{F})}\,du$$

where $\log N_{[]}(\varepsilon,\mathcal{F})$ is the bracketing entropy. For the class of one dimensional, bounded and monotone functions, the bracketing entropy satisfies

$$\log N_{[]}(\varepsilon,\mathcal{M})\leq K\left(\frac{1}{\varepsilon}\right)$$

for some $K>0$ (van der Vaart and Wellner, 1996).

Now, let $\mathcal{P}_{n,p}$ be the class of all functions of the form $m(x)=f_j(x_j)f_k(x_k)$ for $j,k\in\{1,\ldots,p\}$, where $f_j\in\mathcal{M}_n$ for each j. Then the bracketing entropy satisfies

$$\log N_{[]}(C\sqrt{\log n},\mathcal{P}_{n,p})\leq 2\log p+K\left(\frac{1}{\varepsilon}\right)$$

and the bracketing integral satisfies $J_{[]}(C\sqrt{\log n},\mathcal{P}_{n,p})=O(\sqrt{\log n\log p})$. It follows from (17) and Markov's inequality that

$$\max_{jk}\sup_{f_j,f_k\in\mathcal{M}_n}|S_n(f)_{jk}-\mathbb{E}(f_j(X_j)f_k(X_k)|=O_P\left(\sqrt{\frac{\log n\log p}{n}}\right)=O_P\left(\sqrt{\frac{\log n}{n^{1-\xi}}}\right).$$

Therefore,

$$\sup_{(f,\Omega)\in\mathcal{M}_n^p\oplus\mathcal{C}_n}|\widehat{R}(f,\Omega)-R(f,\Omega)|=O_P\left(\frac{L_n\sqrt{\log n}}{n^{(1-\xi)/2}}\right).$$

As a consequence, we have

$$\begin{aligned}
R(f^*,\Omega^*) &\leq R(\widetilde{f}_n,\widehat{\Omega}_n)\\
&\leq \widehat{R}(\widetilde{f}_n,\widehat{\Omega}_n)+O_P\left(\frac{L_n\sqrt{\log n}}{n^{(1-\xi)/2}}\right)\\
&\leq \widehat{R}(f^*,\Omega^*)+O_P\left(\frac{L_n\sqrt{\log n}}{n^{(1-\xi)/2}}\right)\\
&\leq R(f^*,\Omega^*)+O_P\left(\frac{L_n\sqrt{\log n}}{n^{(1-\xi)/2}}\right)
\end{aligned}$$

and the conclusion follows. ■

8. Concluding Remarks

In this paper we have introduced the nonparanormal, a type of Gaussian copula with nonparametric marginals that is suitable for estimating high dimensional undirected graphs. The nonparanormal can be viewed as an extension of sparse additive models to the setting of graphical models. We proposed an estimator for the component functions that is based on thresholding the tails of the empirical distribution function at appropriate levels. A theoretical analysis was given to bound the difference between the sample covariance with respect to these estimated functions and the true sample covariance. This analysis was leveraged with the recent work of Ravikumar et al. (2009b) and Rothman et al. (2008) to obtain consistency results for the nonparanormal. Computationally, fitting a high dimensional nonparanormal is no more difficult than estimating a multivariate Gaussian, and indeed one can exploit existing software for the graphical lasso. Our experimental results indicate that the sparse nonparanormal can give very different results than a sparse Gaussian graphical model. This suggests that it may be a useful tool for relaxing the normality assumption, which is often made only for convenience.

Abstract

In recursive linear models, the multivariate normal joint distribution of all variables exhibits a dependence structure induced by a recursive (or acyclic) system of linear structural equations. These linear models have a long tradition and appear in seemingly unrelated regressions, structural equation modelling, and approaches to causal inference. They are also related to Gaussian graphical models via a classical representation known as a path diagram. Despite the models' long history, a number of problems remain open. In this paper, we address the problem of computing maximum likelihood estimates in the subclass of 'bow-free' recursive linear models. The term 'bow-free' refers to the condition that the errors for variables i and j be uncorrelated if variable i occurs in the structural equation for variable j. We introduce a new algorithm, termed Residual Iterative Conditional Fitting (RICF), that can be implemented using only least squares computations. In contrast to existing algorithms, RICF has clear convergence properties and yields exact maximum likelihood estimates after the first iteration whenever the MLE is available in closed form.

Keywords: linear regression, maximum likelihood estimation, path diagram, structural equation model, recursive semi-Markov model, residual iterative conditional fitting

1. Introduction

A system of linear structural equations determines a linear model for a set of variables by dictating that, up to a random error term, each variable is equal to a linear combination of some of the remaining variables. Traditionally the errors are assumed to have a centered joint multivariate normal distribution. Presenting a formalism for simultaneously representing causal and statistical hypothe-

ses (Pearl, 2000; Spirtes et al., 2000), these normal linear models, which are also called *structural equation models*, are widely used in the social sciences (Bollen, 1989) and many other contexts.

In seminal work, Wright (1921, 1934) introduced *path diagrams*, which are useful graphical representations of structural equations. A path diagram is a graph with one vertex for each variable and directed and/or bi-directed edges. A directed edge $i \to j$ indicates that variable i appears as covariate in the equation for variable j. The directed edges are thus in correspondence with the *path coefficients*, that is, the coefficients appearing in the linear structural equations. A bi-directed edge $i \leftrightarrow j$ indicates correlation between the errors in the equations for variables i and j. Graphs of this kind are also considered by Shpitser and Pearl (2006), who refer to them as recursive semi-Markovian causal models.

1.1 A Motivating Example

We motivate the normal linear models analyzed here with the following example, which is adapted from a more complex longitudinal study considered in Robins (2008).

Consider a two-phase sequential intervention study examining the effect of exercise and diet on diabetes. In the first phase patients are randomly assigned to a number of hours of exercise per week (Ex) drawn from a log-normal distribution. At the end of this phase blood pressure (BP) levels are measured. In the second phase patients are randomly assigned to a strict calorie controlled diet that produces a change in body-mass index (ΔBMI). The assigned change in BMI, though still randomized, is drawn, by design, from a normal distribution with mean depending linearly on $X = \log(\text{Ex})$ and BP. The dependence here is due to practical and ethical considerations. Finally at the end of the second phase, triglyceride levels (Y) indicating diabetic status are measured.

A question of interest is whether or not there is an effect of X on the outcome Y that is not mediated through the dependence of ΔBMI on X and BP. In other words, if there had been no ethical or practical restrictions, and the assignment (ΔBMI) in the second phase was completely randomized and thus independent of BP and X, would there still be any dependence between X and Y? Note that due to underlying confounding factors such as life history and genetic background, we would expect to observe dependence between BP and Y even if the null hypothesis of no effect of X on Y was true and the second treatment (ΔBMI) was completely randomized.

Our model consists of two pieces. First, the design of the study dictates that

$$X = \alpha_0 + \varepsilon_X, \tag{1}$$

$$\Delta\text{BMI} = \gamma_0 + \gamma_1 X + \gamma_2 \,\text{BP} + \varepsilon_{\Delta\text{BMI}}, \tag{2}$$

where $\varepsilon_X \sim \mathcal{N}(0, \sigma_X^2)$ and $\varepsilon_{\Delta\text{BMI}} \sim \mathcal{N}(0, \sigma_{\Delta\text{BMI}}^2)$ are independent. This assignment model is complemented by a model describing how BP and Y respond to the prior treatments:

$$\text{BP} = \beta_0 + \beta_1 X + \varepsilon_{\text{BP}}, \tag{3}$$

$$Y = \delta_0 + \delta_1 X + \delta_2 \,\Delta\text{BMI} + \varepsilon_Y, \tag{4}$$

where $(\varepsilon_{\text{BP}}, \varepsilon_Y)^t$ are centered bivariate normal and independent of ε_X and $\varepsilon_{\Delta\text{BMI}}$. We denote the variances of ε_{BP} and ε_Y by σ_{BP}^2 and σ_Y^2, respectively, and write $\sigma_{\text{BP},Y}$ for the possibly non-zero covariance of ε_{BP} and ε_Y. Figure 1 shows the path diagram for this structural equation model.

Equations (1), (2) and (3) simply specify conditional expectations that can be estimated in regressions. However, this is not the case in general with (4). Instead,

$$\text{E}\,[Y \mid X, \Delta\text{BMI}] = \bar{\delta}_0 + \bar{\delta}_1 X + \bar{\delta}_2 \,\Delta\text{BMI}$$

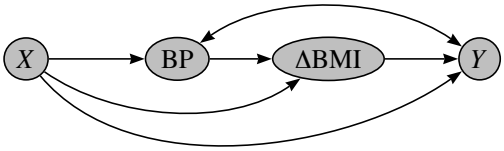

Figure 1: Path diagram illustrating a two-phase trial with two treatments (X and ΔBMI) and two responses (BP and Y). The treatment X is randomly assigned, and ΔBMI is randomized conditional on BP and X. The bi-directed edge indicates possible dependence due to unmeasured factors (genetic or environmental).

with

$$\bar{\delta}_1 = \delta_1 - \frac{\gamma_2 \sigma_{\mathrm{BP},Y}(\beta_1\gamma_2 + \gamma_1)}{\gamma_2^2\sigma_{\mathrm{BP}}^2 + \sigma_{\Delta\mathrm{BMI}}^2},$$

$$\bar{\delta}_2 = \delta_2 + \frac{\gamma_2 \sigma_{\mathrm{BP},Y}}{\gamma_2^2\sigma_{\mathrm{BP}}^2 + \sigma_{\Delta\mathrm{BMI}}^2},$$

and $\bar{\delta}_0 = \delta_0 + (\delta_1 - \bar{\delta}_1)\,\mathrm{E}[X] + (\delta_2 - \bar{\delta}_2)\,\mathrm{E}[\Delta\mathrm{BMI}]$. We see that δ_1 and δ_2 would have an interpretation as regression coefficients if: (i) the assignment of ΔBMI did not depend on BP (i.e., $\gamma_2 = 0$) and thus both treatments were completely randomized, or (ii) there were no dependence between ε_Y and $\varepsilon_{\mathrm{BP}}$ (i.e., $\sigma_{\mathrm{BP},Y} = 0$). Similarly, in $\mathrm{E}[Y \mid X, \mathrm{BP}, \Delta\mathrm{BMI}]$, the coefficient of ΔBMI is equal to δ_2 but the coefficient for X is $\delta_1 - \beta_1\sigma_{\mathrm{BP},Y}/\sigma_{\mathrm{BP}}^2$.

In this paper we consider likelihood-based methods for fitting a large class of structural equation models that includes the one given by (1)-(4) and can be used for consistent estimation of parameters such as δ_1. For alternative semi-parametric methods, see Robins (1999) and Gill and Robins (2001).

1.2 Challenges in Structural Equation Modelling

A number of mathematical and statistical problems arise in the normal linear models associated with systems of structural equations:

1. Different path diagrams may induce the same statistical model, that is, family of multivariate normal distributions. Such *model equivalence* occurs, for example, for the two path diagrams $1 \to 2$ and $1 \leftarrow 2$, which differ substantively by the direction of the cause-effect relationship. The two associated statistical models, however, are identical, both allowing for correlation between the two variables.

2. In many important special cases the path coefficient associated with a directed edge $i \to j$ has a population interpretation as a regression coefficient in a regression of j on a set of variables including i. However, as seen already in §1.1, this interpretation is not valid in general.

3. The parameters of the model may not be identifiable, so two different sets of parameter values may lead to the same population distribution; for an early review of this problem see Fisher (1966).

4. The set of parameterized covariance matrices may contain 'singularities' at which it cannot be approximated locally by a linear space. At 'singular' points, χ^2 and normal approximation to the distribution of likelihood ratio tests and maximum likelihood estimators (MLE) may not be valid; see, for instance, Drton (2009).

5. Iterative procedures are typically required for maximization of the likelihood function, which for some models can be multimodal (Drton and Richardson, 2004). Such multimodality typically occurs in small samples or under model misspecification.

The problems listed may arise in models without unobserved variables and become only more acute in latent variable models. They are challenging in full generality, but significant progress has been made in special cases such as recursive linear models with uncorrelated errors, which are also known as directed acyclic graph (DAG) models or 'Bayesian' networks (Lauritzen, 1996; Pearl, 1988). A normal DAG model is equivalent to a series of linear regressions, is always identified and has standard asymptotics. Under simple sample size conditions, the MLE exists almost surely and is a rational function of the data. Graphical modelling theory also solves problem 1 by characterizing all DAGs that induce the same statistical model (Andersson et al., 1997). For more recent progress on the general equivalence problem see Ali et al. (2009, 2005) and Zhang and Spirtes (2005).

1.3 Contribution of This Work

The requirement of uncorrelated errors may be overly restrictive in many settings. While arbitrary correlation patterns over the errors may yield rather ill-behaved statistical models, there are subclasses of models with correlated errors in which some of the nice properties of DAG models are preserved; compare McDonald (2002). In this paper we consider path diagrams in which there are no directed cycles and no 'double' edges of the form $i \leftrightarrows j$ (compare Def. 2 and 3). Since such double edges have been called 'bows', we call this class *bow-free acyclic path diagrams* (BAPs). An example of a BAP arose in our motivating example in §1.1; see Figure 1. While instrumental variable models, which are much studied in economics, contain bows, most models in other social sciences are based on BAPs. For instance, all path diagrams in Bollen (1989) are BAPs.

Bow-free acyclic path diagrams were also considered by Brito and Pearl (2002) who showed that the associated normal linear models are almost everywhere identifiable; see §2.2 for the definition. This result and other identification properties of BAP models are reviewed in Section 2. In Section 3 we give details on likelihood equations and Fisher-information of normal structural equation models. This sets the scene for our main contribution: the *Residual Iterative Conditional Fitting* (RICF) algorithm for maximization of the likelihood function of BAP models, which is presented in Section 4. Standard software for structural equation modelling currently employs general-purpose optimization routines for this task (Bollen, 1989, Appendix 4C). Many of these algorithms, however, neglect constraints of positive definiteness on the covariance matrix and suffer from convergence problems. According to Steiger (2001), failure to converge is 'not uncommon' and presents significant challenges to novice users of existing software. In contrast, our RICF algorithm produces positive definite covariance matrix estimates during all its iterations and has good convergence properties, as illustrated in the simulations in Section 5. Further discussion of RICF is provided in Section 6.

2. Normal Linear Models and Path Diagrams

Let $Y = (Y_i \mid i \in V) \in \mathbb{R}^V$ be a random vector, indexed by the finite set V, that follows a multivariate normal distribution $\mathcal{N}(0,\Sigma)$ with positive definite covariance matrix Σ. A zero mean vector is assumed merely to avoid notational overhead. The models we consider subsequently are induced by linear structural equations as follows.

2.1 Systems of Structural Equations and Path Diagrams

Let $\{\mathrm{pa}(i) \mid i \in V\}$ and $\{\mathrm{sp}(i) \mid i \in V\}$ be two families of index sets. For reasons explained below, we refer to these index sets as sets of parents and spouses, respectively. We require that $i \notin \mathrm{pa}(i) \cup \mathrm{sp}(i)$ for all $i \in V$; moreover, let the second family satisfy the symmetry condition that $j \in \mathrm{sp}(i)$ if and only if $i \in \mathrm{sp}(j)$. These two families determine a system of structural equations

$$Y_i = \textstyle\sum_{j \in \mathrm{pa}(i)} \beta_{ij} Y_j + \varepsilon_i, \quad i \in V, \tag{5}$$

whose zero-mean errors ε_i and ε_j are uncorrelated if $i \notin \mathrm{sp}(j)$, or equivalently, $j \notin \mathrm{sp}(i)$. The equations in (5) correspond to a *path diagram*, that is, a mixed graph G featuring both *directed* ($\rightarrow$) and *bi-directed* ($\leftrightarrow$) edges but no edges from a vertex i to itself (see Figures 1 and 2). The vertex set of G is the index set V, and G contains the edge $j \rightarrow i$ if and only if $j \in \mathrm{pa}(i)$, and the edge $j \leftrightarrow i$ if and only if $j \in \mathrm{sp}(i)$ (or equivalently, $i \in \mathrm{sp}(j)$). Subsequently, we exploit the path diagram representation of (5). If $i \rightarrow j$ is an edge in G, then we call i a *parent* of j, and if $i \leftrightarrow j$ is in G then i is referred to as a *spouse* of j. Thus, as remarked above, $\mathrm{pa}(i)$, $\mathrm{sp}(i)$ are, respectively, the sets of parents and spouses of i.

Let G be a path diagram and define $\mathbf{B}(G)$ to be the collection of all $V \times V$ matrices $B = (\beta_{ij})$ that satisfy

$$\beta_{ij} = 0 \quad \text{whenever } j \rightarrow i \text{ is not an edge in } G, \tag{6}$$

and are such that $I - B$ is invertible. Let $\mathbf{P}(V)$ be the cone of positive definite $V \times V$ matrices and $\mathbf{O}(G) \subseteq \mathbf{P}(V)$ the set of matrices $\Omega = (\omega_{ij}) \in \mathbf{P}(V)$ that satisfy

$$\omega_{ij} = 0 \quad \text{whenever } i \neq j \text{ and } j \leftrightarrow i \text{ is not in } G. \tag{7}$$

(Here and in the sequel, a symbol such as V denotes both a finite set and its cardinality.) The system (5) associated with the path diagram G can be written compactly as $Y = BY + \varepsilon$. If we assume that $B \in \mathbf{B}(G)$ and that the error covariance matrix $\mathrm{Var}(\varepsilon) = \Omega$ is in $\mathbf{O}(G)$, then (5) has a unique solution Y that is a multivariate normal random vector with covariance matrix $\Sigma = (I-B)^{-1}\Omega(I-B)^{-t}$. Here, I is the identity matrix and the superscript '$-t$' stands for transposition and inversion.

The above considerations lead to the following definition of a linear model associated with a path diagram (or equivalently, a system of structural equations).

Definition 1 *The normal linear model $\mathbf{N}(G)$ associated with a path diagram G is the family of multivariate normal distributions $\mathcal{N}(0,\Sigma)$ with covariance matrix in the set $\mathbf{P}(G) = \left\{(I-B)^{-1}\Omega(I-B)^{-t} \mid B \in \mathbf{B}(G), \Omega \in \mathbf{O}(G)\right\}$. We call the map $\Phi_G : \mathbf{B}(G) \times \mathbf{O}(G) \rightarrow \mathbf{P}(G)$ given by*

$$\Phi_G(B,\Omega) = (I-B)^{-1}\Omega(I-B)^{-t}$$

the parameterization map of $\mathbf{N}(G)$.

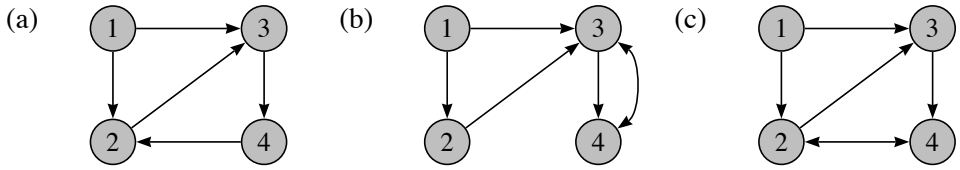

Figure 2: Path diagrams that are (a) cyclic, (b) acyclic but not bow-free, (c) acyclic and bow-free. Only path diagram (c) yields a curved exponential family.

Example 1 The path diagram G in Figure 2(a) depicts the equation system

$$\begin{aligned} Y_1 &= \varepsilon_1, & Y_2 &= \beta_{21}Y_1 + \beta_{24}Y_4 + \varepsilon_2, \\ Y_3 &= \beta_{31}Y_1 + \beta_{32}Y_2 + \varepsilon_3, & Y_4 &= \beta_{43}Y_3 + \varepsilon_4, \end{aligned}$$

where $\varepsilon_1, \varepsilon_2, \varepsilon_3, \varepsilon_4$ are pairwise uncorrelated, that is, the matrices $\Omega \in \mathbf{O}(G)$ are diagonal. This system exhibits a circular covariate-response structure as the path diagram contains the directed cycle $2 \to 3 \to 4 \to 2$. This feedback loop is reflected in the fact that $\det(I-B) = 1 - \beta_{24}\beta_{43}\beta_{32}$ for $B \in \mathbf{B}(G)$. Therefore, the path coefficients need to satisfy $\beta_{24}\beta_{43}\beta_{32} \neq 1$ in order to lead to a positive definite covariance matrix in $\mathbf{P}(G)$. This example is considered in more detail in Drton (2009), where it is shown that the parameter space $\mathbf{P}(G)$ has singularities that lead to non-standard behavior of likelihood ratio tests.

The models considered in the remainder of this paper do not have any feedback loops, that is, they have the following structure.

Definition 2 *A path diagram G and its associated normal linear model $\mathbf{N}(G)$ are* recursive *or* acyclic *if G does not contain directed cycles, that is, there do not exist $i, i_1, \ldots, i_k \in V$ such that G features the edges $i \to i_1 \to i_2 \to \cdots \to i_k \to i$.*

We use the term *acyclic* rather than *recursive*, as some authors have used the term 'recursive' for path diagrams that are acyclic *and* contain no bi-directed edges. If G is acyclic, then the vertices in V can be ordered such that a matrix B that satisfies (6) is lower-triangular. It follows that

$$\det(I-B) = 1. \tag{8}$$

In particular, $I-B$ is invertible for any choice of the path coefficients β_{ij}, $j \to i$ in G, and the parameterization map Φ_G is a polynomial map.

2.2 Bow-free Acyclic Path Diagrams (BAPs)

The normal linear model $\mathbf{N}(G)$ associated with a path diagram G is *everywhere identifiable* if the parameterization map Φ_G is one-to-one, that is, for all $B_0 \in \mathbf{B}(G)$ and $\Omega_0 \in \mathbf{O}(G)$ it holds that

$$\Phi_G(B,\Omega) = \Phi_G(B_0,\Omega_0) \quad \Longrightarrow \quad B = B_0 \text{ and } \Omega = \Omega_0. \tag{9}$$

If there exists a Lebesgue null set $N_G \subseteq \mathbf{B}(G) \times \mathbf{O}(G)$ such that (9) holds for all $(B_0,\Omega_0) \notin N_G$, then we say that $\mathbf{N}(G)$ is *almost everywhere identifiable*.

Acyclic path diagrams may contain *bows*, that is, double edges $i \leftrightarrows j$. It is easy to see that normal linear models associated with path diagrams with bows are never everywhere identifiable. However, they may sometimes be almost everywhere identifiable as is the case for the next example. This example illustrates that almost everywhere identifiability is not enough to ensure regular behavior of statistical procedures.

Example 2 The path diagram G in Figure 2(b) features the bow $3 \leftrightarrows 4$. The associated normal linear model $\mathbf{N}(G)$ is also known as an instrumental variable model. The 9-dimensional parameter space $\mathbf{P}(G)$ is part of the hypersurface defined by the vanishing of the so-called *tetrad* $\sigma_{13}\sigma_{24} - \sigma_{14}\sigma_{23}$. It follows that the model $\mathbf{N}(G)$ lacks regularity because the tetrad hypersurface has singularities at points $\Sigma \in \mathbf{P}(G)$ with $\sigma_{13} = \sigma_{14} = \sigma_{23} = \sigma_{24} = 0$. These singularities occur if and only if $\beta_{31} = \beta_{32} = 0$, and correspond to points at which the identifiability property in (9) fails to hold. This lack of smoothness expresses itself statistically, for example, when testing the hypothesis $\beta_{31} = \beta_{32} = 0$ in model $\mathbf{N}(G)$. Using the techniques in Drton (2009), the likelihood ratio statistic for this problem can be shown to have non-standard behavior with a large-sample limiting distribution that is given by the larger of the two eigenvalues of a 2×2-Wishart matrix with 2 degrees of freedom and the identity matrix as scale parameter.

Definition 3 *A path diagram G and its associated normal linear model $\mathbf{N}(G)$ are* bow-free *if G contains at most one edge between any pair of vertices. If G is bow-free and acyclic, we call it a bow-free acyclic path diagram (BAP).*

As stressed in the introduction, BAPs are widespread in applications. Examples are shown in Figures 1, 2(c) and 6. Contrary to some path diagrams with bows, the normal linear models associated with BAPs are always at least almost everywhere identifiable.

Theorem 4 (Brito and Pearl, 2002) *If G is a BAP, then the normal linear model $\mathbf{N}(G)$ is almost everywhere identifiable.*

Many BAP models are in fact everywhere identifiable.

Theorem 5 (Richardson and Spirtes, 2002) *Suppose G is an ancestral BAP, that is, G does not contain an edge $i \leftrightarrow j$ such that there is a directed path $j \to i_1 \to \cdots \to i_k \to i$ that leads from vertex j to vertex i. Then the normal linear model $\mathbf{N}(G)$ is everywhere identifiable.*

The next example shows that the condition in Theorem 5 is sufficient but not necessary for identification. The characterization of the class of BAPs whose associated normal linear models are everywhere identifiable remains an open problem.

Example 3 The BAP G in Figure 2(c) is not ancestral because it contains the edges $4 \leftrightarrow 2 \to 3 \to 4$. Nevertheless, the associated normal linear model $\mathbf{N}(G)$ is everywhere identifiable, which can be shown by identifying the parameters in B and Ω row-by-row following the order $1 < 2 < 3 < 4$. It is noteworthy that the model $\mathbf{N}(G)$ in this example is not a Markov model, that is, a generic multivariate normal distribution in $\mathbf{N}(G)$ exhibits no conditional independence relations. Instead, the entries of covariance matrices $\Sigma = (\sigma_{ij}) \in \mathbf{P}(G)$ satisfy

$$(\sigma_{11}\sigma_{22} - \sigma_{12}^2)(\sigma_{14}\sigma_{33} - \sigma_{13}\sigma_{34}) = (\sigma_{13}\sigma_{24} - \sigma_{14}\sigma_{23})(\sigma_{12}\sigma_{13} - \sigma_{11}\sigma_{23}). \tag{10}$$

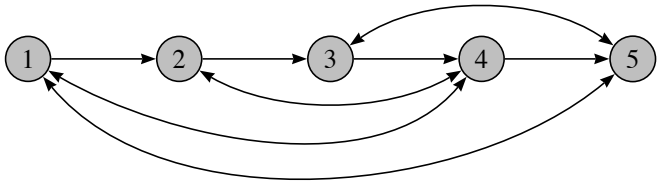

Figure 3: Bow-free acyclic path diagram whose associated normal linear model is almost, but not everywhere, identifiable. The model is not a curved exponential family.

The constraint in (10) has a nice interpretation. Let $(Y_1, \ldots, Y_4)$ have (positive definite) covariance matrix $\Sigma = (\sigma_{ij})$, and define $e_2 = Y_2 - \sigma_{21}/\sigma_{11} Y_1$ to be the residual in the regression of Y_2 on Y_1. Then (10) holds for Σ if and only if Y_1 and Y_4 are conditionally independent given e_2 and Y_3.

The above-stated Theorem 4 was proved in Brito and Pearl (2002), and an inspection of their proof reveals the following fact.

Lemma 6 *If the normal linear model $\mathbf{N}(G)$ associated with a BAP G is everywhere identifiable, then the (bijective) parameterization map Φ_G has an inverse that is a rational map with no pole on $\mathbf{P}(G)$.*

By (8), the parameterization map Φ_G for a BAP G is polynomial and thus smooth. If Φ_G^{-1} is rational and without pole, then the image of Φ_G, that is, $\mathbf{P}(G)$ is a smooth manifold (see, e.g., Edwards, 1994, II.4). This has an important consequence.

Corollary 7 *If the normal linear model $\mathbf{N}(G)$ associated with a BAP G is everywhere identifiable, then $\mathbf{N}(G)$ is a curved exponential family.*

The theory of curved exponential families is discussed by Kass and Vos (1997). It implies in particular that maximum likelihood estimators in curved exponential families are asymptotically normal, and that likelihood ratio statistics comparing two such families are asymptotically chi-square regardless of where in the null hypothesis a true parameter is located. Unfortunately, however, Lemma 6 and Corollary 7 do not hold for every BAP.

Example 4 The normal linear model associated with the BAP G in Figure 3 is not a curved exponential family. In this model the identifiability property in (9) breaks down if and only if (B, Ω) satisfy

$$\beta_{21}\omega_{14}\omega_{24} - \omega_2\omega_4 + \omega_{24}^2 = 0, \quad \beta_{32}\beta_{43}\omega_2 + \omega_{24} = 0.$$

It can be shown that the covariance matrices $\Phi_G(B, \Omega)$ associated with this set of parameters yield points at which the 13-dimensional set $\mathbf{P}(G)$ has more than 13 linearly independent tangent directions. Hence, $\mathbf{P}(G)$ is singular at these covariance matrices.

3. Likelihood Inference

Suppose a sample of size N is drawn from a multivariate normal distribution $\mathcal{N}(0,\Sigma)$ in the linear model $\mathbf{N}(G)$ associated with a BAP $G=(V,E)$. We group the observed random vectors as columns in the $V\times N$ matrix Y such that Y_{in} represents the observation of variable i on subject n. Having assumed a zero mean vector, we define the empirical covariance matrix as

$$S=(s_{ij})=\frac{1}{N}YY^t\in\mathbb{R}^{V\times V}.$$

Assuming $N\geq V$, the matrix S is positive definite with probability one. (As before, V here also denotes the cardinality of the set.) Models with unknown mean vector $\mu\in\mathbb{R}^V$ can be treated by estimating μ by the empirical mean vector and adjusting the empirical covariance matrix accordingly; $N\geq V+1$ then ensures almost sure positive definiteness of the empirical covariance matrix.

3.1 Likelihood Function and Likelihood Equations

Given observations Y with empirical covariance matrix S, the log-likelihood function $\ell:\mathbf{B}(G)\times\mathbf{O}(G)\to\mathbb{R}$ of the model $\mathbf{N}(G)$ takes the form

$$\ell(B,\Omega)=-\frac{N}{2}\log\det(\Omega)-\frac{N}{2}\mathrm{tr}\big[(I-B)^t\Omega^{-1}(I-B)S\big]. \tag{11}$$

Here we ignored an additive constant and used that $\det(I-B)=1$ if $B\in\mathbf{B}(G)$; compare (8). Let $\beta=(\beta_{ij}\mid i\in V,\ j\in\mathrm{pa}(i))$ and $\omega=(\omega_{ij}\mid i\leq j,\ j\in\mathrm{sp}(i)\text{ or }i=j)$ be the vectors of unconstrained elements in B and Ω. Let P and Q be the matrices with entries in $\{0,1\}$ that satisfy $\mathrm{vec}(B)=P\beta$ and $\mathrm{vec}(\Omega)=Q\omega$, respectively, where $\mathrm{vec}(A)$ refers to stacking of the columns of the matrix A. Taking the first derivatives of $\ell(B,\Omega)$ with respect to β and ω we obtain the likelihood equations.

Proposition 8 *The likelihood equations of the normal linear model $\mathbf{N}(G)$ associated with a BAP G can be written as*

$$P^t\,\mathrm{vec}\left(\Omega^{-1}(I-B)S\right)=P^t\,\mathrm{vec}\left(\Omega^{-1}S\right)-P^t\left(S\otimes\Omega^{-1}\right)P\beta=0, \tag{12}$$

$$Q^t\,\mathrm{vec}\left(\Omega^{-1}-\Omega^{-1}(I-B)S(I-B)^t\Omega^{-1}\right)=0, \tag{13}$$

where $\otimes$ denotes the Kronecker product.

In general, the likelihood equations need to be solved iteratively. One possible approach proceeds by alternately solving (12) and (13) for β and ω, respectively. For fixed ω, (12) is a linear equation in β and easily solved. For fixed β, (13) constitutes the likelihood equations of a multivariate normal covariance model for $\varepsilon=(I-B)Y$, which is specified by requiring that $\Omega_{ij}=0$ whenever the edge $i\leftrightarrow j$ is not in G. The solution of (13), with β fixed, requires, in general, another iterative method. As an alternative to this nesting of two iterative methods, we propose in Section 4 a method that solves (12) and (13) in joint updates of β and ω.

Remark 9 When proving their identifiability result for BAP models, Brito and Pearl (2002) gave an algorithm for recovering the parameters β and ω from a population covariance matrix. Applied to the empirical covariance matrix S, this algorithm produces consistent estimates $\tilde{\beta}$ and $\tilde{\omega}$. However, these are generally not the maximum likelihood estimators (MLE) and the error covariance matrix corresponding to $\tilde{\omega}$ may fail to be positive definite.

3.2 Fisher-Information

Large-sample confidence intervals for (β, ω) can be obtained by approximating the distribution of the MLE $(\hat{\beta}, \hat{\omega})$ by the normal distribution with mean vector (β, ω) and covariance matrix $\frac{1}{N} I(\beta, \omega)^{-1}$. Here, $I(\beta, \omega)$ denotes the Fisher-information, which, as shown in Appendix A, is of the following form.

Proposition 10 *The (expected) Fisher-information of the normal linear model* $\mathbf{N}(G)$ *associated with a BAP G is*

$$I(\beta, \omega) = \begin{pmatrix} P^t \left(\Sigma \otimes \Omega^{-1}\right) P & P^t \left[(I-B)^{-1} \otimes \Omega^{-1}\right] Q \\ Q^t \left[(I-B)^{-t} \otimes \Omega^{-1}\right] P & \frac{1}{2} Q^t \left(\Omega^{-1} \otimes \Omega^{-1}\right) Q \end{pmatrix}.$$

The Fisher-information in Proposition 10 need not be block-diagonal, in which case the estimation of the covariances ω affects the asymptotic variance of the MLE $\hat{\beta}$. However, this does not happen for *bi-directed chain graphs*, which form one of the model classes discussed by Wermuth and Cox (2004). A path diagram G is a bi-directed chain graph if its vertex set V can be partitioned into disjoint subsets $\tau_1, \ldots, \tau_T$, known as *chain components*, such that all edges in each subgraph G_{τ_t} are bi-directed and edges between two subsets $\tau_s \neq \tau_t$ are directed, pointing from τ_s to τ_t, if $s < t$. Since bi-directed chain graphs are ancestral graphs the associated normal linear models are everywhere identifiable.

Proposition 11 *For a BAP G, the following two statements are equivalent:*

(i) For all underlying covariance matrices $\Sigma \in \mathbf{P}(G)$*, the MLEs of the parameter vectors* β *and* ω *of the normal linear model* $\mathbf{N}(G)$ *are asymptotically independent.*

(ii) The path diagram G is a bi-directed chain graph.

A proof of Proposition 11 is given in Appendix A. This result is an instance of the asymptotic independence of mean and natural parameters in mixed parameterizations of exponential families (Barndorff-Nielsen, 1978).

4. Residual Iterative Conditional Fitting

We now present an algorithm for computing the MLE in the normal linear model $\mathbf{N}(G)$ associated with a BAP. The algorithm extends the *iterative conditional fitting* (ICF) procedure of Chaudhuri et al. (2007), which is for path diagrams with exclusively bi-directed edges.

Let $Y_i \in \mathbb{R}^N$ denote the i-th row of the observation matrix Y and $Y_{-i} = Y_{V \setminus \{i\}}$ the $(V \setminus \{i\}) \times N$ submatrix of Y. The ICF algorithm proceeds by repeatedly iterating through all vertices $i \in V$ and carrying out three steps: (i) fix the marginal distribution of Y_{-i}, (ii) fit the conditional distribution of Y_i given Y_{-i} under the constraints implied by the model $\mathbf{N}(G)$, and (iii) obtain a new estimate of Σ by combining the estimated conditional distribution $(Y_i \mid Y_{-i})$ with the fixed marginal distribution of Y_{-i}. The crucial point is then that for path diagrams containing only bi-directed edges, the problem of fitting the conditional distribution for $(Y_i \mid Y_{-i})$ under the constraints of the model can be rephrased as a least squares regression problem. Unfortunately, the consideration of the conditional distribution of $(Y_i \mid Y_{-i})$ is complicated for path diagrams that contain also directed edges. However, as we show below, the directed edges can be 'removed' by consideration of *residuals*, which here refers to estimates of the error terms $\varepsilon = (I - B)Y$. Since it is based on this idea, we give our new extended algorithm the name *Residual Iterative Conditional Fitting* (RICF).

4.1 The RICF Algorithm

The main building block of the new algorithm is the following decomposition of the log-likelihood function. We adopt the shorthand notation X_C for the $C \times N$ submatrix of a $D \times N$ matrix X, where $C \subseteq D$.

Theorem 12 *Let G be a BAP and $i \in V$. Let $\|x\|^2 = x^t x$ and define*

$$\omega_{ii.-i} = \omega_{ii} - \Omega_{i,-i}\Omega^{-1}_{-i,-i}\Omega_{-i,i} \tag{14}$$

to be the conditional variance of ε_i given ε_{-i}; recall that $\Omega^{-1}_{-i,-i} = (\Omega_{-i,-i})^{-1}$. Then the log-likelihood function $\ell(B,\Omega)$ of the model $\mathbf{N}(G)$ can be decomposed as

$$\begin{aligned}\ell(B,\Omega) = &-\frac{N}{2}\log\omega_{ii.-i} - \frac{1}{2\omega_{ii.-i}}\left\|Y_i - B_{i,\mathrm{pa}(i)}Y_{\mathrm{pa}(i)} - \Omega_{i,\mathrm{sp}(i)}(\Omega^{-1}_{-i,-i}\varepsilon_{-i})_{\mathrm{sp}(i)}\right\|^2 \\ &-\frac{N}{2}\log\det(\Omega_{-i,-i}) - \frac{1}{2}\mathrm{tr}\big(\Omega^{-1}_{-i,-i}\varepsilon_{-i}\varepsilon^t_{-i}\big).\end{aligned} \tag{15}$$

Proof Forming $\varepsilon = (I-B)Y$, we rewrite (11) as

$$\ell(B,\Omega) = -\frac{N}{2}\log\det(\Omega) - \frac{1}{2}\mathrm{tr}\big(\Omega^{-1}\varepsilon\varepsilon^t\big) =: \ell(\Omega \mid \varepsilon). \tag{16}$$

Using the inverse variance lemma (Whittaker, 1990, Prop. 5.7.3), we partition Ω^{-1} as

$$\begin{pmatrix}\omega_{ii} & \Omega_{i,-i}\\ \Omega_{-i,i} & \Omega_{-i,-i}\end{pmatrix}^{-1} = \begin{pmatrix}\omega^{-1}_{ii.-i} & -\omega^{-1}_{ii.-i}\Omega_{i,-i}\Omega^{-1}_{-i,-i}\\ -\Omega^{-1}_{-i,-i}\Omega_{-i,i}\omega^{-1}_{ii.-i} & \Omega^{-1}_{-i,-i} + \Omega^{-1}_{-i,-i}\Omega_{-i,i}\omega^{-1}_{ii.-i}\Omega_{i,-i}\Omega^{-1}_{-i,-i}\end{pmatrix}.$$

We obtain that the log-likelihood function in (16) equals

$$\begin{aligned}\ell(\Omega \mid \varepsilon) = &-\frac{N}{2}\log\omega_{ii.-i} - \frac{1}{2\omega_{ii.-i}}\left\|\varepsilon_i - \Omega_{i,-i}\Omega^{-1}_{-i,-i}\varepsilon_{-i}\right\|^2 \\ &-\frac{N}{2}\log\det(\Omega_{-i,-i}) - \frac{1}{2}\mathrm{tr}\big(\Omega^{-1}_{-i,-i}\varepsilon_{-i}\varepsilon^t_{-i}\big).\end{aligned}$$

By definition, $\varepsilon_i = Y_i - B_{i,\mathrm{pa}(i)}Y_{\mathrm{pa}(i)}$. Moreover, under the restrictions (7),

$$\Omega_{i,-i}\Omega^{-1}_{-i,-i}\varepsilon_{-i} = \Omega_{i,\mathrm{sp}(i)}(\Omega^{-1}_{-i,-i}\varepsilon_{-i})_{\mathrm{sp}(i)},$$

which yields the claimed decomposition. ■

The log-likelihood decomposition (15) is essentially based on the decomposition of the joint distribution of ε into the marginal distribution of ε_{-i} and the conditional distribution $(\varepsilon_i \mid \varepsilon_{-i})$. This leads to the idea of building an iterative algorithm whose steps are based on fixing the marginal distribution of ε_{-i} and estimating a conditional distribution. In order to fix the marginal distribution ε_{-i} we need to fix the submatrix $\Omega_{-i,-i}$ comprising all but the i-th row and column of Ω as well as the submatrix $B_{-i,V}$, which comprises all but the i-th row of B. With $\Omega_{-i,-i}$ and $B_{-i,V}$ fixed we can compute ε_{-i} as well as the *pseudo-variables*, defined by

$$Z_{-i} = \Omega^{-1}_{-i,-i}\varepsilon_{-i}. \tag{17}$$

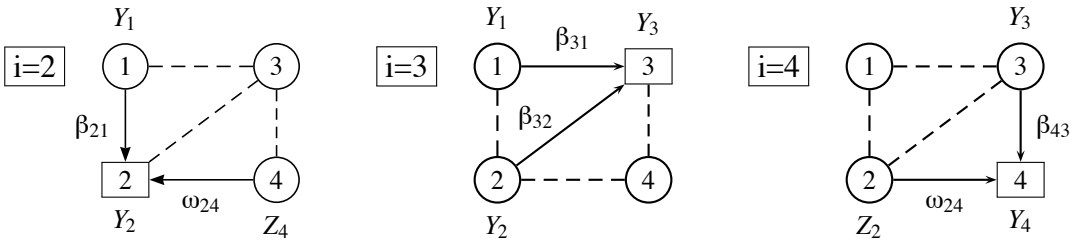

Figure 4: Illustration of the RICF update steps in Example 5. The structure of each least squares regression is indicated by directed edges pointing from the predictor variables to the response variable depicted by a square node. (See text for details.)

From (15), it now becomes apparent that, for fixed $\Omega_{-i,-i}$ and $B_{-i,V}$, the maximization of the log-likelihood function $\ell(B,\Omega)$ can be solved by maximizing the function

$$\big((\beta_{ij})_{j\in\mathrm{pa}(i)},(\omega_{ik})_{k\in\mathrm{sp}(i)},\omega_{ii.-i}\big)\mapsto -\frac{N}{2}\log\omega_{ii.-i}-\frac{1}{2\omega_{ii.-i}}\Big\|Y_i-\sum_{j\in\mathrm{pa}(i)}\beta_{ij}Y_j-\sum_{k\in\mathrm{sp}(i)}\omega_{ik}Z_k\Big\|^2 \quad (18)$$

over $\mathbb{R}^{\mathrm{pa}(i)}\times\mathbb{R}^{\mathrm{sp}(i)}\times(0,\infty)$. The maximizers of (18), however, are the least squares estimates in the regression of Y_i on both $(Y_j \mid j\in\mathrm{pa}(i))$ and $(Z_k \mid k\in\mathrm{sp}(i))$.

Employing the above observations, the *RICF algorithm* for computing the MLE $(\hat{B},\hat{\Omega})$ repeats the following steps for each $i\in V$:

1. Fix $\Omega_{-i,-i}$ and $B_{-i,V}$, and compute residuals ε_{-i} and pseudo-variables $Z_{\mathrm{sp}(i)}$;
2. Obtain least squares estimates of β_{ij}, $j\in\mathrm{pa}(i)$, ω_{ik}, $k\in\mathrm{sp}(i)$, and $\omega_{ii.-i}$ by regressing response variable Y_i on the covariates Y_j, $j\in\mathrm{pa}(i)$ and Z_k, $k\in\mathrm{sp}(i)$;
3. Compute an estimate of $\omega_{ii}=\omega_{ii.-i}+\Omega_{i,-i}\Omega^{-1}_{-i,-i}\Omega_{-i,i}$ using the new estimates and the fixed parameters; compare (14).

After steps 1 to 3, we move on to the next vertex in V. After the last vertex in V we return to consider the first vertex. The procedure is continued until convergence.

Example 5 For illustration of the regressions performed in RICF, we consider the normal linear model associated with the BAP G in Figure 2(c). The parameters to be estimated in this model are $\beta_{21},\beta_{31},\beta_{32},\beta_{43}$ and $\omega_{11},\omega_{22},\omega_{33},\omega_{44},\omega_{24}$.

Vertex 1 in Figure 2(c) has no parents or spouses, and its RICF update step consists of a trivial regression. In other words, the variance ω_{11} is the unconditional variance of Y_1 with MLE $\hat{\omega}_{11}=s_{11}$. For the remaining vertices, the corresponding RICF update steps are illustrated in Figure 4, where the response variable Y_i in the i-th update step is shown as a square node while the remaining variables are depicted as circles. Directed edges indicate variables acting as covariates in the least squares regression. These covariates are labelled according to whether the random variable Y_j, or the pseudo-variable Z_j defined in (17), is used in the regression. Note that since $\mathrm{sp}(3)=\emptyset$, repetition of steps 1-3 in §4.1 is required only for $i\in\{2,4\}$.

In RICF, the log-likelihood function $\ell(B,\Omega)$ from (11) is repeatedly maximized over sections in the parameter space defined by fixing the parameters $\Omega_{-i,-i}$, and $B_{-i,V}$. RICF thus is an iterative partial maximization algorithm and has the following convergence properties.

Theorem 13 *If G is a BAP and the empirical covariance matrix S is positive definite, then the following holds:*

(i) For any starting value $(\hat{B}^0,\hat{\Omega}^0) \in \mathbf{B}(G) \times \mathbf{O}(G)$, RICF constructs a sequence of estimates $(\hat{B}^s,\hat{\Omega}^s)_s$ in $\mathbf{B}(G) \times \mathbf{O}(G)$ whose accumulation points are local maxima or saddle points of the log-likelihood function $\ell(B,\Omega)$. Moreover, evaluating the log-likelihood function at different accumulation points yields the same value.

(ii) If the normal linear model $\mathbf{N}(G)$ is everywhere identifiable and the likelihood equations have only finitely many solutions then the sequence $(\hat{B}^s,\hat{\Omega}^s)_s$ converges to one of these solutions.

Proof Let $\ell(\Sigma)$ be the log-likelihood function for the model of all centered multivariate normal distributions on $\mathbb{R}^V$. If S is positive definite then the set C that comprises all positive definite matrices $\Sigma \in \mathbb{R}^{V\times V}$ at which $\ell(\Sigma) \geq \ell(\hat{B}^0,\hat{\Omega}^0)$ is compact. In particular, the log-likelihood function in (11) is bounded, and claim (i) can be derived from general results about iterative partial maximization algorithms; see for example, Drton and Eichler (2006). For claim (ii) note that if $\mathbf{N}(G)$ is everywhere identifiable, then the compact set C has compact preimage $\phi_G^{-1}(C)$ under the model parameterization map; recall Lemma 6. ■

Remark 14 If the normal linear model $\mathbf{N}(G)$ associated with a BAP G is not everywhere identifiable, then it is possible that a sequence of estimates $(\hat{B}^s,\hat{\Omega}^s)_s$ produced by RICF diverges and does not have any accumulation points. In these cases, however, the corresponding sequence of covariance matrices $\Phi_G(\hat{B}^s,\hat{\Omega}^s)_s$ still has at least one accumulation point because it ranges in the compact set C exhibited in the proof of Theorem 13. Divergence of $(\hat{B}^s,\hat{\Omega}^s)_s$ occurs in two instances in the simulations in §5; compare Table 1. In both cases, the sequence $\Phi_G(\hat{B}^s,\hat{\Omega}^s)_s$ converges to a positive definite covariance matrix.

4.2 Computational Savings in RICF

If G is a DAG, that is, an acyclic path diagram without bi-directed edges, then the MLE $(\hat{B},\hat{\Omega})$ in $\mathbf{N}(G)$ can be found in a finite number of regressions (e.g., Wermuth, 1980). However, we can also run RICF. Since in a DAG, $\mathrm{sp}(i) = \emptyset$ for all $i \in V$, step 2 of RICF regresses variable Y_i solely on its parents Y_j, $j \in \mathrm{pa}(i)$. Not involving pseudo-variables that could change from one iteration to the other, this regression remains the same throughout different iterations, and RICF converges in one step.

Similarly, for a general BAP G, if vertex $i \in V$ has no spouses, $\mathrm{sp}(i) = \emptyset$, then the MLE of $B_{i,\mathrm{pa}(i)}$ and ω_{ii} can be determined by a single iteration of the algorithm. In other words, RICF reveals these parameters as being estimable in closed form, namely as rational functions of the data. (This occurred for vertex $i = 3$ in Example 5.) It follows that, to estimate the remaining parameters, the iterations need only be continued over vertices j with $\mathrm{sp}(j) \neq \emptyset$.

For further computational savings note that $\Omega_{\mathrm{dis}(i),V\setminus(\mathrm{dis}(i)\cup\{i\})} = 0$, where $\mathrm{dis}(i) = \{j \mid j \leftrightarrow \cdots \leftrightarrow i, j \neq i\}$ is the district of $i \in V$. Hence, since $\mathrm{sp}(i) \subseteq \mathrm{dis}(i)$,

$$(\Omega^{-1}_{-i,-i}\varepsilon_{-i})_{\mathrm{sp}(i)} = (\Omega^{-1}_{\mathrm{dis}(i),\mathrm{dis}(i)}\varepsilon_{\mathrm{dis}(i)})_{\mathrm{sp}(i)};$$

see Koster (1999, Lemma 3.1.6) and Richardson and Spirtes (2002, Lemma 8.10). Since $\varepsilon_{\mathrm{dis}(i)} = Y_{\mathrm{dis}(i)} - B_{\mathrm{dis}(i),\mathrm{pa}(\mathrm{dis}(i))}Y_{\mathrm{pa}(\mathrm{dis}(i))}$, it follows that in the RICF update step for vertex i attention can be restricted to the variables in $\{i\} \cup \mathrm{pa}(i) \cup \mathrm{dis}(i) \cup \mathrm{pa}(\mathrm{dis}(i))$.

Finally, note that while the RICF algorithm is described in terms of the entire data matrix Y, the least squares estimates computed in its iterations are clearly functions of the empirical covariance matrix, which is a sufficient statistic.

5. Simulation Studies

In order to evaluate the performance of the RICF algorithm we consider two scenarios. First, we fit linear models based on randomly generated BAPs to gene expression data. This scenario is relevant for model selection tasks, and we compare RICF's performance in this problem to that of algorithms implemented in software for structural equation modelling. Second, we study how RICF behaves when it is used to fit larger models to data simulated from the respective model. In contrast to the first scenario, the second scenario involves models that generally fit the considered data well.

5.1 Gene Expression Data

We consider data on gene expression in *Arabidopsis thaliana* from Wille et al. (2004). We restrict attention to 13 genes that belong to one pathway: DXPS1-3, DXR, MCT, CMK, MECPS, HDS, HDR, IPPI1, GPPS, PPDS1-2. Data from $n = 118$ microarray experiments are available. We fit randomly generated BAP models to these data using RICF and two alternative methods.

The BAP models are generated as follows. For each of the 78 possible pairs of vertices $i < j$ in $V = \{1,\ldots,13\}$ we draw from a multinomial distribution to generate a possible edge. The probability for drawing the edge $i \to j$ is d, and the probability for drawing $i \leftrightarrow j$ is b so that with probability $1-d-b$ there is no edge between i and j. We then apply a random permutation to the vertices to obtain the final BAP. For each of twelve combinations (d,b) with $d = 0.05, 0.1, 0.2, 0.3$ and $b = 0.05, 0.1, 0.2$, we simulate 1000 BAPs. The expected number of edges thus varies between 7.8 and 39.

For fitting the simulated BAPs to the gene expression data, we implemented RICF in the statistical programming environment R (R Development Core Team, 2007). As alternatives, we consider the R package 'sem' (Fox, 2006) and the widely used software LISREL (Jöreskog and Sörbom, 1997) in its student version 8.7 for Linux (student versions are free but limited to 15 variables). Both these programs employ general purpose optimizers, for example, 'sem' makes a call to the R function 'nlm'.

Our simulation results are summarized in Table 1. Each row in the table corresponds to a choice of the edge probabilities d and b. The first three columns count how often, in 1000 simulations, the three considered fitting routines failed to converge. The starting values of LISREL and 'sem' were set according to program defaults, and RICF was started by setting $\hat{B}^{(0)}$ and $\hat{\Omega}^{(0)}$ equal to the MLE in the DAG model associated with the DAG obtained by removing all bi-directed edges from the considered BAP.

		No convergence			All	All	Running time		
d	b	RICF	LIS	SEM	converge	agree	RICF	LIS	SEM
0.05	0.05	0	36	47	941	940	0.03	0.02	1.15

Table 1: Fitting simulated BAPs to gene expression data using RICF, LISREL and 'sem'. Each row is based on 1000 simulations. Running time is average CPU time (in sec.) for the cases in which all three algorithms converged. (See text for details.)

LISREL and 'sem' failed to converge for a rather large number of models. The LISREL output explained why convergence failed, and virtually all failures were due to the optimizer converging to matrices that were not positive definite. The remedy would be to try new starting values but doing this successfully in an automated fashion is a challenging problem in itself. For RICF convergence failure arose in only two cases. In both cases the RICF estimates $(\hat{B}, \hat{\Omega})$ had some diverging entries. Despite the divergence in (B, Ω)-space, the sequence of associated covariance matrices $\Phi_G(\hat{B}, \hat{\Omega})$ computed by RICF converged, albeit very slowly. Recall that this phenomenon is possible in models that are almost, but not everywhere, identifiable (Remark 14). In these examples LISREL produced similarly divergent sequences with approximately the same likelihood, and 'sem' reported convergence in one case but gave an estimate whose likelihood was nearly 40 points smaller than the intermediate estimates computed by LISREL and RICF.

The columns labelled 'All converge' and 'All agree' in Table 1 show how often all methods converged, and when this occurred, how often the three computed maxima of the log-likelihood function were the same up to one decimal place. Since all methods are for local maximization, substantial disagreements in the computed maxima can occur if the likelihood function is multimodal.

Finally, the last three columns give average CPU time use for the cases in which all three algorithms converge. These are quoted to show that RICF is competitive in terms of computational efficiency, but for the following reasons the precise times should not be used for a formal comparison. On the one hand, LISREL is fast because it is compiled code. This is not the case for the R-based 'sem' and RICF. On the other hand, the fitting routines in LISREL and 'sem' not only compute the MLE but also produce various other derived quantities of interest. This is in contrast to our RICF routine, which only computes the MLE.

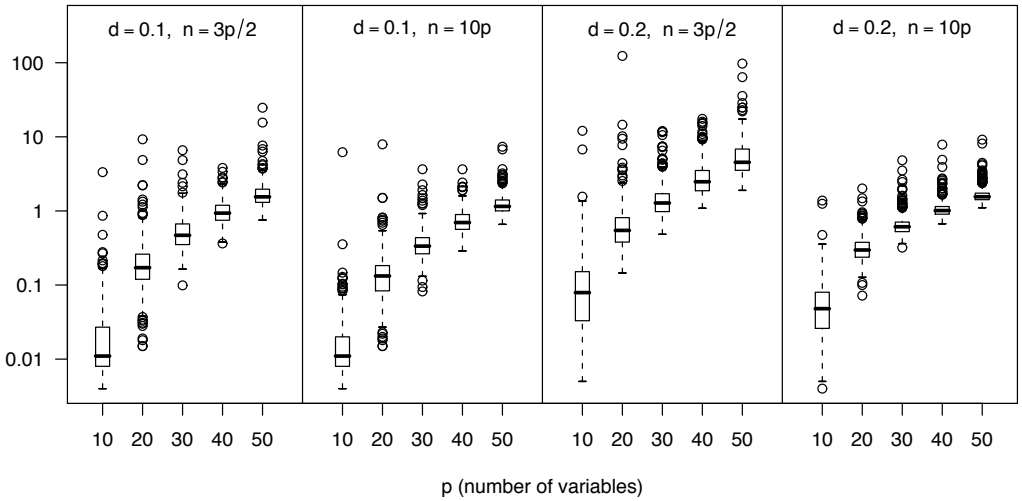

Figure 5: Boxplots of CPU times (in sec. on $\log_{10}$-scale) used by RICF when fitting BAP models to simulated data. Each boxplot summarizes 500 simulations. The number of variables is denoted by p, the sample size is n, and the parameter d determines the expected number of edges of the simulated BAPs (see text for details).

5.2 Simulated Data

In order to demonstrate how RICF behaves when fitting larger models we use the algorithm on simulated data. We consider different choices for the number of variables p and generate random BAPs according to the procedure used in §5.1. We limit ourselves to two different settings for the expected number of edges, choosing $d = 0.1$ or $d = 0.2$ and setting $b = d/2$ in each case. For each BAP G, we simulate a covariance matrix $\Sigma = (I-B)^{-1}\Omega(I-B)^{-t} \in \mathbf{P}(G)$ as follows. The free entries in $B \in \mathbf{B}(G)$ and the free off-diagonal entries in $\Omega \in \mathbf{O}(G)$ are drawn from a $\mathcal{N}(0,1)$ distribution. The diagonal entries ω_{ii} are obtained by adding a draw from a χ^2_1-distribution to the sum of the absolute values of the off-diagonal entries in the i-th row of Ω. This makes Ω diagonally dominant and thus positive definite. Finally, we draw a sample of size n from the resulting multivariate normal distribution $\mathbf{N}(G)$. For each distribution two cases, namely $n = 3p/2$ and $n = 10p$, are considered to illustrate sample size effects. For each combination of p, d and n, we simulate 500 BAPs and associated data sets.

Figure 5 summarizes the results of our simulations in boxplots. As could be expected, the running time for RICF increases with the number of variables p and the expected number of edges in the BAP (determined by d). Moreover, the running time decreases for increased sample size n, which is plausible because the empirical covariance matrix of a larger sample tends to be closer to the underlying parameter space $\mathbf{P}(G)$. The boxplots show that even with $p = 50$ variables the majority of the RICF computations terminate within a few seconds. However, there are also a number of computations in which the running time is considerably longer, though still under two

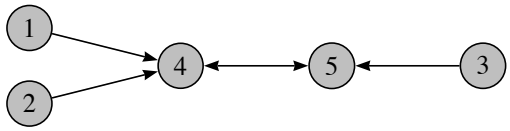

Figure 6: Path diagram for seemingly unrelated regressions.

minutes. This occurs in particular for the denser case with smaller sample size ($d = 0.2$ and $n = 3p/2$).

6. Discussion

As mentioned in the introduction, normal linear models associated with path diagrams are employed in many applied disciplines. The models, also known as structural equation models, have a long tradition but remain of current interest in particular due to the more recent developments in causal inference; compare, for example, Pearl (2000) and Spirtes et al. (2000). Despite their long tradition, however, many mathematical, statistical and computational problems about these models remain open.

The new contribution of this paper is the Residual Iterative Conditional Fitting (RICF) algorithm for maximum likelihood estimation in BAP models. Software for computation of MLEs in structural equation models often employs optimization methods that are not designed to deal with positive definiteness constraints on covariance matrices. This can be seen in particular in Table 1 which shows that two available programs, LISREL (Jöreskog and Sörbom, 1997) and the R package 'sem' (Fox, 2006), fail to converge in a rather large number of problems. This is in line with previous experience by other authors; see, for example, Steiger (2001). Our new RICF algorithm, on the other hand, does not suffer from these problems. It has clear convergence properties (Theorem 13) and can handle problems with several tens of variables (see Figure 5). In addition, RICF has the desirable feature that it estimates parameters in closed form (in a single cycle of its iterations) if this is possible. If applied to a model based on a directed acyclic graph (DAG), the algorithm converges in a single cycle and performs exactly the regressions commonly used for fitting multivariate normal DAG models. This feature and the fact that RICF can be implemented using nothing but least squares computations make it an attractive alternative to less specialized optimization methods.

In another special case, namely seemingly unrelated regressions, RICF reduces to the algorithm of Telser (1964). A path diagram representing seemingly unrelated regressions is shown in Figure 6. The variables Y_1, Y_2 and Y_3 are then commonly thought of as covariates. Since they have no spouses, the MLEs of the variances ω_{11}, ω_{22} and ω_{33} are equal to the empirical variances s_{11}, s_{22} and s_{33}. For the remaining variables Y_i, $i = 4, 5$, RICF performs regressions on both the "covariates" $Y_{\mathrm{pa}(i)}$ and the residual ε_j, $j \in \{4,5\} \setminus \{i\}$. These are precisely the steps performed by Telser.

Existing structural equation modelling software also fits models with latent variables, whereas the RICF algorithm applies only to BAP models without latent variables. However, RICF could be used to implement the M-step in the EM algorithm (Kiiveri, 1987) in order to fit latent variable models. This EM-RICF approach would yield an algorithm with theoretical convergence properties.

Finally, we emphasize that the RICF algorithm is determined by the path diagram. However, different path diagrams may induce the same statistical model; recall point (1) in §1.2 in the intro-

duction. This model equivalence of path diagrams may be exploited to find a diagram for which the running time of RICF is short. For example, for every BAP that is equivalent to a DAG model, parameter estimates could be computed in closed form and hence in finitely many steps. Relevant graphical constructions for this problem are described in Drton and Richardson (2008) and Ali et al. (2005).

Appendix A. Proofs

Proof [Proof of Proposition 10] Let β and ω be the vectors of unconstrained elements in B and Ω, respectively. The second derivatives of the log-likelihood function with respect to β and ω are:

$$\frac{\partial^2 \ell(B,\Omega)}{\partial\beta\,\partial\beta^t} = -N \cdot P^t \big(S \otimes \Omega^{-1}\big) P, \tag{19}$$

$$\frac{\partial^2 \ell(B,\Omega)}{\partial\beta\,\partial\omega^t} = -N \cdot P^t \big[S(I-B)^t\Omega^{-1} \otimes \Omega^{-1}\big] Q, \tag{20}$$

$$\begin{aligned}\frac{\partial^2 \ell(B,\Omega)}{\partial\omega\,\partial\omega^t} = -\frac{N}{2} Q^t \big\{ &\big[\Omega^{-1} \otimes \Omega^{-1}(I-B)S(I-B)^t\Omega^{-1}\big] \\ &+ \big[\Omega^{-1}(I-B)S(I-B)^t\Omega^{-1} \otimes \Omega^{-1}\big]\big\} Q.\end{aligned} \tag{21}$$

Replacing S by $\mathrm{E}[S] = (I-B)^{-1}\Omega(I-B)^{-t}$ in (19)-(21) yields the claim. ■

Proof [Proof of Proposition 11] If G is a bi-directed chain graph, then the submatrix $B_{\tau_t,\tau_t} = 0$ for all t, while for $s \neq t$ we have $\Omega_{\tau_s,\tau_t} = 0$. In this case the second derivative of the log-likelihood function with respect to β_{ij} and ω_{kl} is equal to $\partial^2\ell(B,\Omega)/\partial\beta_{ij}\,\partial\omega_{kl} = [(I-B)^{-1}]_{jl}\,(\Omega^{-1})_{ik}$. Now $[(I-B)^{-1}]_{jl}$ may only be non-zero if $j = l$ or l is an ancestor of j, that is, if there exists a directed path $l \to j_1 \to \cdots \to j_m \to j$ in G. On the other hand, $(\Omega^{-1})_{ik} = 0$ whenever i and k are not in the same chain component. Therefore, the second derivative in (20) is equal to zero.

Conversely, it follows that the second derivative in (20) vanishes for all parameters only if the graph belongs to the class of bi-directed chain graphs. ■

Abstract

Consider the following problem: given sets of unlabeled observations, each set with known label proportions, predict the labels of another set of observations, possibly with known label proportions. This problem occurs in areas like e-commerce, politics, spam filtering and improper content detection. We present consistent estimators which can reconstruct the correct labels with high probability in a uniform convergence sense. Experiments show that our method works well in practice.

Keywords: unsupervised learning, Gaussian processes, classification and prediction, probabilistic models, missing variables

1. Introduction

Different types of learning problems assume different problem settings. In *supervised* learning, we are given sets of labeled instances. Another learning type called *unsupervised* learning focuses on the setting where unlabeled instances are given. Recently, it has been realized that unlabeled instances when used in conjunction with a small amount of labeled instances can deliver considerable learning performance improvement in comparison to using labeled instances alone. This leads to a *semi-supervised* learning setting.

∗. A short version of this paper appeared in Quadrianto et al. (2008).

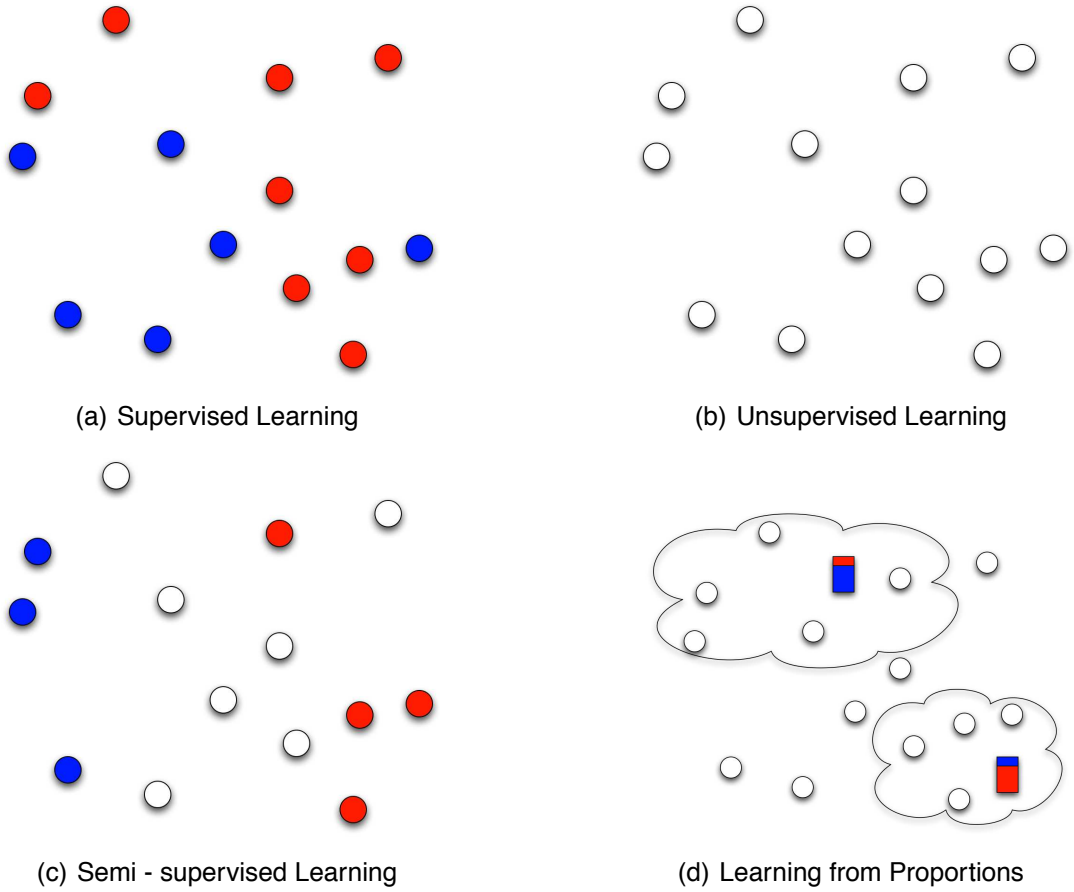

Figure 1: Different types of learning problems (colors encode class labels). 1(a) - `supervised learning`: only labeled instances are given; 1(b) - `unsupervised learning`: only unlabeled instances are given; 1(c) - `semi-supervised learning`: both labeled and unlabeled instances are given; 1(d): `learning from proportions`: at least as many data aggregates (groups of data with their associated class label proportions) as there are number of classes are given.

We are interested in a learning setting where groups of unlabeled instances are given. The number of group is at least as many as number of classes. Each group is equipped with information on class label *proportions*. We called this informative group as aggregate (see Figure 1 for an illustration). This type of learning problem appears in areas like e-commerce, politics, spam filtering and improper content detection, as we illustrate below.

Assume that an internet services company wants to increase its profit in sales. Obviously sending out discount coupons will increase sales, but sending coupons to customers who would have purchased the goods anyway decreases the margins. Alternatively, failing to send coupons to customers who would only buy in case of a discount reduces overall sales. We would like to identify the class of would-be customers who are most likely to change their purchase decision when receiving a coupon. The problem is that there is no direct access to a sample of would-be customers.

Typically only a sample of people who buy regardless of coupons (those who bought when there was no discount) and a mixed sample (those who bought when there was discount) are available. The mixing *proportions* can be reliably estimated using random assignment to control and treatment groups. How can we use this information to determine the would-be customers?

Politicians face the same problem. They can rely on a set of always-favorable voters who will favor them regardless, plus a set of swing voters who will make their decision dependent on what the candidates offer. Since the candidate's resources (finance, ability to make election promises, campaign time) are limited, it is desirable for them to focus their attention on that part of the demographic where they can achieve the largest gains. Previous elections can directly reveal the profile of those who favor regardless, that is those who voted in favor where low campaign resources were committed. Those who voted in favor where substantial resources were committed can be either swing voters or always-favorable. So in a typical scenario there is no separate sample of swing voters.

Likewise, consider the problem of spam filtering. Data sets of spam are likely to contain almost pure spam (this is achieved e.g. by listing e-mails as spam bait), while user's inboxes typically contain a mix of spam and non-spam. We would like to use the inbox data to improve estimation of spam. In many cases it is possible to estimate the *proportions* of spam and non-spam in a user's inbox much more cheaply than the actual labels. We would like to use this information to categorize e-mails into spam and non-spam.

Similarly, consider the problem of filtering images with "improper content". Data sets of such images are readily accessible thanks to user feedback, and it is reasonable to assume that this labeling is highly reliable. However the rest of images on the web (those not labeled) is a far larger data set, albeit without labels (after all, this is what we would like to estimate the labels for). That said, it is considerably cheaper to obtain a good estimate of the *proportions* of proper and improper content in addition to having one data set of images being of likely improper content. We would like to obtain a classifier based on this information.

2. Problem Definition

In this paper, we present a method that makes use of the knowledge of label proportions *directly*. As motivated by the above examples, our method would be practically useful in many domains such as identifying potential customers, potential voters, spam e-mails and improper images. We also prove bounds indicating that the estimates obtained are close to those from a fully labeled scenario.

Before defining the problem, we emphasize that the formal setting is more general than the above examples might suggest. More specifically, we may not require *any* label to be known, only their proportions within each of the involved data sets. Also the general problem is not restricted to the binary case but instead can deal with large numbers of classes. Finally, it is possible to apply our method to problems where the *test label proportions* are unknown, too. This simple modification allows us to use this technique whenever covariate shift via label bias is present.

Formally, in a learning from proportions setting, we are given n sets of observations $X_i = \{x_1^i, \ldots, x_{m_i}^i\}$ of respective sample sizes m_i (calibration set) $i = 1, \ldots, n$ as well as a set $X = \{x_1, \ldots, x_m\}$ (test set). Moreover, we are given the fractions π_{iy} of labels $y \in \mathcal{Y}$ ($|\mathcal{Y}| \leq n$) contained in each set X_i. These fractions form a full (column) rank mixing matrix, $\pi \in \mathbb{R}^{n \times |\mathcal{Y}|}$ with the constraint that each row sums up to 1 and all entries are nonnegative. The marginal probability $p(y)$ of the test set X may or may not be known. Note that the label dictionaries $\mathcal{Y}_i$ do not need to be the same

across all sets i (define $\mathcal{Y} := \cup_i \mathcal{Y}_i$) and we also allow for $\pi_{iy} = 0$ if needed. It is our goal to design algorithms which are able to obtain conditional class probability estimates $p(y|x)$ solely based on this information.

As an illustration, take the spam filtering example. We have $X_1 =$ "mail in spam box" (only spam) and $X_2 =$ "mail in inbox" (spam mixed with non-spam). Also suppose that we may know the proportion of spam vs non-spam in our inbox is $1:9$. That means, we know: $\pi_{1,\text{spam}} = 1.0, \pi_{1,\text{non-spam}} = 0, \pi_{2,\text{spam}} = 0.1$ and $\pi_{2,\text{non-spam}} = 0.9$. The test set X then may be X_2 itself, for example. Thus, the marginal probability of the test set will simply be: $p(y = \text{spam}) = 0.1, p(y = \text{non}-\text{spam}) = 0.9$. The goal is to find $p(\text{spam}|\text{mail})$ in X. Note that, in general, our setting is different and more difficult than that of transduction. The latter requires at least some labeled instances of *all classes* are given. In the spam filtering example, we have no pure non-spam instances.

Key to our proposed solution is a conditional independence assumption, $x \perp\!\!\!\perp i \,|\, y$. In other words, we assume that the *conditional* distribution of x is independent of the index i, as long as we know the label y. This is a crucial assumption: after all, we want the distributions within each class to be independent of which aggregate they can be found in. If this were not the case it would be impossible to infer about the distribution on the test set from the (biased) distributions over the aggregates.

3. Mean Operators

Our idea relies on uniform convergence properties of the expectation operator and of corresponding risk functionals (Altun and Smola, 2006; Dudík and Schapire, 2006). In doing so, we are able to design estimators with the same performance guarantees in terms of uniform convergence as those with full access to the label information.

At the heart of our reasoning lies the fact that many estimators rely on data by solving a convex optimization problem. We begin our exposition by discussing how this strategy can be employed in the context of exponential families. Subsequently we state convergence guarantees and we discuss how our method can be extended to other estimates such as Csiszar and Bregman divergences and other function spaces.

3.1 Exponential Families

Denote by $\mathcal{X}$ the space of observations and let $\mathcal{Y}$ be the space of labels. Moreover, let $\phi(x,y) : \mathcal{X} \times \mathcal{Y} \to \mathcal{H}$ be a feature map into a Reproducing Kernel Hilbert Space (RKHS) $\mathcal{H}$ with kernel $k((x,y),(x',y'))$. In this case we may state conditional exponential models via

$$p(y|x,\theta) = \exp\left(\langle \phi(x,y),\theta\rangle - g(\theta|x)\right) \text{ with } g(\theta|x) = \log \sum_{y\in\mathcal{Y}} \exp\langle \phi(x,y),\theta\rangle,$$

where the normalization g is called the log-partition function, often referred to as the cumulant generating function. Note that while in general there is no need for $\mathcal{Y}$ to be discrete, we make this simplifying assumption in order to be able to reconstruct the class probabilities efficiently. For $\{(x_i,y_i)\}$ drawn iid from a distribution $p(x,y)$ on $\mathcal{X}\times\mathcal{Y}$ the conditional log-likelihood is given by

$$\log p(Y|X,\theta) = \sum_{i=1}^{m} \left[\langle \phi(x_i,y_i),\theta\rangle - g(\theta|x_i)\right] = m\,\langle \mu_{XY},\theta\rangle - \sum_{i=1}^{m} g(\theta|x_i),$$

where the empirical mean in feature space μ_{XY} is defined as in Table 2. In order to avoid overfitting one commonly maximizes the log-likelihood penalized by a prior $p(\theta)$. This means that we need to solve the following optimization problem

$$\theta^* := \operatorname*{argmin}_\theta \left[-\log\{p(Y|X,\theta)p(\theta)\}\right]. \tag{1}$$

For instance, for a Gaussian prior on θ, i.e. for

$$-\log p(\theta) = \lambda \|\theta\|^2 + \text{const.},$$

we have

$$\theta^* = \operatorname*{argmin}_\theta \left[\sum_{i=1}^m g(\theta|x_i) - m\langle \mu_{XY}, \theta\rangle + \lambda\|\theta\|^2\right]. \tag{2}$$

The problem is that in our setting we do not know the labels y_i, so the sufficient statistics μ_{XY} cannot be computed exactly. Note, though that the only place where the labels enter the estimation process is via the mean μ_{XY}. Our strategy is to exploit the fact that this quantity, however, is statistically well behaved and converges under relatively mild technical conditions at rate $O(m^{-\frac{1}{2}})$ to its expected value

$$\mu_{xy} := \mathbf{E}_{(x,y)\sim p(x,y)}[\phi(x,y)],$$

as will be shown in Theorem 3. Our goal therefore will be to estimate μ_{xy} and use it as a proxy for μ_{XY}, and only then solve (2) with the estimated $\hat{\mu}_{XY}$ instead of μ_{XY}. We will discuss explicit convergence guarantees in Section 5 after describing how to compute the mean operator in detail.

3.2 Estimating the Mean Operator

In order to obtain θ^* we would need μ_{XY}, which is impossible to compute exactly, since we do not have Y. However, we know that μ_{XY} converges to μ_{xy}. Hence, if we are able to approximate μ_{xy} then this, in turn, will be a good estimate for μ_{XY}.

Our quest is therefore as follows: express μ_{xy} as a linear combination over expectations with respect to the distributions on the data sets $X_1,\ldots,X_n$ (where $n \geq |\mathcal{Y}|$). Secondly, show that the expectations of the distributions having generated the sets X_i ($\mu_x^{\text{set}}[i,y']$, see Table 2), can be approximated by empirical means ($\mu_X^{\text{set}}[i,y']$, see Table 2). Finally, we need to combine both steps to provide guarantees for μ_{XY}.

It will turn out that in certain cases some of the algebra can be sidestepped, in particular whenever we may be able to identify several sets with each other (e.g. the test set X is one of the calibration data sets X_i) or whenever $\phi(x,y)$ factorizes into $\psi(x)\otimes\varphi(y)$. We will discuss these simplifications in Section 4.

3.2.1 MEAN OPERATOR

Since μ_{xy} is a linear operator mapping $p(x,y)$ into a Hilbert Space we may expand μ_{xy} via

$$\mu_{xy} = \mathbf{E}_{(x,y)\sim p(x,y)}[\phi(x,y)] = \sum_{y\in\mathcal{Y}} p(y)\mathbf{E}_{x\sim p(x|y)}[\phi(x,y)] = \sum_{y\in\mathcal{Y}} p(y)\mu_x^{\text{class}}[y,y],$$

X_i	i^{th} set of observations: $X_i = \{x_1^i, \ldots, x_{m_i}^i\}$
m_i	number of observations in X_i
X	test set of observations: $X = \{x_1, \ldots, x_m\}$
Y	test set of labels: $Y = \{y_1, \ldots, y_m\}$
m	number of observations in the test set X
π_{iy}	proportion of label y in set i
$\phi(x,y)$	map from (x,y) to a Hilbert Space

Table 1: Notations used in the paper.

Expectations with respect to the model:

$$\begin{aligned}
\mu_{xy} &:= \mathbf{E}_{(x,y)\sim p(x,y)}[\phi(x,y)] \\
\mu_x^{\text{class}}[y,y'] &:= \mathbf{E}_{(x)\sim p(x|y)}[\phi(x,y')] \\
\mu_x^{\text{set}}[i,y'] &:= \mathbf{E}_{(x)\sim p(x|i)}[\phi(x,y')] \\
\mu_x^{\text{class}}[y] &:= \mathbf{E}_{(x)\sim p(x|y)}[\psi(x)] \\
\mu_x^{\text{set}}[i] &:= \mathbf{E}_{(x)\sim p(x|i)}[\psi(x)]
\end{aligned}$$

Expectations with respect to data:

$$\begin{aligned}
\mu_{XY} &:= \tfrac{1}{m}\textstyle\sum_{i=1}^m \phi(x_i,y_i) \\
\text{(1a)}\quad \mu_X^{\text{set}}[i,y'] &:= \tfrac{1}{m_i}\textstyle\sum_{x\in X_i} \phi(x,y') \ \textbf{(known)} \\
\text{(1b)}\quad \mu_X^{\text{set}}[i] &:= \tfrac{1}{m_i}\textstyle\sum_{x\in X_i} \psi(x) \ \textbf{(known)}
\end{aligned}$$

Estimates:

$$\begin{aligned}
\text{(2)}\quad \hat{\mu}_x^{\text{class}} &= (\pi^\top\pi)^{-1}\pi^\top\mu_X^{\text{set}} \\
\text{(3a)}\quad \hat{\mu}_{XY} &= \textstyle\sum_{y\in\mathcal{Y}} p(y)\hat{\mu}_x^{\text{class}}[y,y] \\
\text{(3b)}\quad \hat{\mu}_{XY} &= \textstyle\sum_{y\in\mathcal{Y}} p(y)\varphi(y)\otimes\hat{\mu}_x^{\text{class}}[y] \\
\text{(4)}\quad \hat{\theta}^* &\text{ solution of (2) for } \mu_{XY} = \hat{\mu}_{XY}.
\end{aligned}$$

Table 2: Major quantities of interest in the paper. Numbers on the left represent the order in which the corresponding quantity is computed in the algorithm (letters denote the variant of the algorithm: 'a' for general feature map $\phi(x,y)$ and 'b' for factorizing feature map $\phi(x,y) = \psi(x)\otimes\varphi(y)$). Lowercase subscripts refer to model expectations, uppercase subscripts are sample averages.

where the shorthand $\mu_x^{\text{class}}[y,y]$ is defined in Table 2. This means that if we were able to compute $\mu_x^{\text{class}}[y,y]$ we would be able to "reassemble" μ_{xy} from its individual components. We now show that $\mu_x^{\text{class}}[y,y]$ can be estimated directly.

Our conditional independence assumption, $p(x|y,i) = p(x|y)$, yields the following:

$$p(x|i) = \sum_y p(x|y,i)p(y|i) = \sum_y p(x|y)\pi_{iy}. \tag{3}$$

In the above equation, we form a mixing matrix π with the element $\pi_{iy} = p(y|i)$. This allows us to define the following means

$$\mu_x^{\text{set}}[i,y'] := \mathbf{E}_{x\sim p(x|i)}[\phi(x,y')] \overset{(3)}{=} \sum_y \pi_{iy}\mu_x^{\text{class}}[y,y'].$$

Algorithm 1

Input data sets $X, \{X_i\}$, probabilities π_{iy} and $p(y)$
for $i = 1$ **to** n **and** $y' \in \mathcal{Y}$ **do**
  Compute empirical means $\mu_X^{\text{set}}[i, y']$
end for
Compute $\hat{\mu}_x^{\text{class}} = (\pi^\top \pi)^{-1} \pi^\top \mu_X^{\text{set}}$
Compute $\hat{\mu}_{XY} = \sum_{y \in \mathcal{Y}} p(y) \hat{\mu}_x^{\text{class}}[y, y]$
Solve the minimization problem

$$\hat{\theta}^* = \operatorname*{argmin}_{\theta} \left[\sum_{i=1}^{m} g(\theta | x_i) - m \langle \hat{\mu}_{XY}, \theta \rangle + \lambda \|\theta\|^2 \right]$$

Return $\hat{\theta}^*$.

Note that in order to compute $\mu_x^{\text{set}}[i, y']$ we do *not* need any label information with respect to $p(x|i)$. It is simply the expectation of $\phi(\cdot, y')$ on the distribution of bag i. However, since we have at least $|\mathcal{Y}|$ of those equations and we assumed that π has full column rank, they allow us to solve a linear system of equations and compute $\mu_x^{\text{class}}[y, y]$ from $\mu_x^{\text{set}}[i, y']$ for all i. In shorthand we may use

$$\mu_x^{\text{set}} = \pi \mu_x^{\text{class}} \text{ and hence } \mu_x^{\text{class}} = (\pi^\top \pi)^{-1} \pi^\top \mu_x^{\text{set}} \tag{4}$$

to compute $\mu_x^{\text{class}}[y, y]$ for all $y \in \mathcal{Y}$. With some slight abuse of notation we have μ_x^{class} and μ_x^{set} represent the *matrices* of terms $\mu_x^{\text{class}}[y, y']$ and $\mu_x^{\text{set}}[i, y']$ respectively. There will be as many matrices as the dimensions of $\phi(x, y)$, thus (4) has to be solved separately for each dimension of $\phi(x, y)$.

Obviously we cannot compute $\mu_x^{\text{set}}[i, y']$ explicitly, since we only have *samples* from $p(x|i)$. However the same convergence results governing the convergence of μ_{XY} to μ_{xy} also hold for the convergence of $\mu_X^{\text{set}}[i, y']$ to $\mu_x^{\text{set}}[i, y']$. Hence we may use the empirical average $\mu_X^{\text{set}}[i, y']$ as the estimate for $\mu_x^{\text{set}}[i, y']$ and from that find an estimate for μ_{XY}.

3.2.2 BIG PICTURE

Overall, our strategy is as follows: use empirical means on the bags X_i to approximate expectations with respect to the bag distribution. Use the latter to compute expectations with respect to a given label, and finally, use the means conditional on the label distribution to obtain μ_{xy} which is a good proxy for μ_{XY} (see Algorithm 1), i.e.

$$\mu_X^{\text{set}}[i, y'] \longrightarrow \mu_x^{\text{set}}[i, y'] \longrightarrow \mu_x^{\text{class}}[y, y'] \longrightarrow \mu_{xy} \longrightarrow \mu_{XY}.$$

For the first and last step in the chain we can invoke uniform convergence results. The remaining two steps in the chain follow from linear algebra. As we shall see, whenever there are considerably more bags than classes we can exploit the overdetermined system to our advantage to reduce the overall estimation error and use a rescaled version of (4).

4. Special Cases

In some cases the calculations described in Algorithm 1 can be carried out more efficiently. They arise whenever the matrix π has special structure or whenever the test set and one of the training

sets coincide. Moreover, we may encounter situations where the fractions of observations in the test set are unknown and we would like, nonetheless, to find a good proxy for μ_{XY}.

4.1 Minimal Number of Sets

Assuming that $|\mathcal{Y}| = n$ and that π has full rank it follows that $(\pi^\top\pi)^{-1}\pi^\top = \pi^{-1}$. Hence we can obtain the proxy for μ_{XY} more directly via $\mu_x^{\text{class}} = \pi^{-1}\mu_x^{\text{set}}$.

4.2 Testing on One of the Calibration Sets

Note that there is no need for requiring that the test set X be different from one of the calibration sets (vide example in Problem Definition). In particular, when $X = X_i$ the uncertainty in the estimate of μ_{XY} can be greatly reduced provided that the estimate of μ_{XY} as given in (4) contains a large fraction of the mean of at least one of the classes. We will discuss this situation in more detail when it comes to binary classification since there the advantages will be most obvious.

4.3 Special Feature Map

Whenever the feature map $\phi(x,y)$ factorizes into $\psi(x) \otimes \varphi(y)$ we can simplify calculation of the means considerably. More specifically, instead of estimating $O(|\mathcal{Y}| \cdot n)$ parameters we only require calculation of $O(n)$ terms. The reason for this is that we may pull the dependency on y out of the expectations. Defining $\mu_x^{\text{class}}[y], \mu_x^{\text{set}}[i]$, and $\mu_X^{\text{set}}[i]$ as in Table 2 allows us to simplify

$$\hat{\mu}_{XY} = \sum_{y \in \mathcal{Y}} p(y)\varphi(y) \otimes \hat{\mu}_x^{\text{class}}[y] \text{ where } \hat{\mu}_x^{\text{class}} = (\pi^\top\pi)^{-1}\pi^\top\mu_X^{\text{set}}. \tag{5}$$

Here the last equation is understood to apply to the vector of means $\mu_x := (\mu[1], \ldots, \mu[n])$ and μ_X accordingly. A significant advantage of (5) is that we only need to perform $O(n)$ averaging operations rather than $O(n \cdot |\mathcal{Y}|)$. Obviously the cost of computing $(\pi^\top\pi)^{-1}\pi^\top$ remains unchanged but the latter is negligible compared to the operations in Hilbert Space. Note that $\psi(x) \in \mathbb{R}^D$ denotes an arbitrary feature representation of the inputs, which in many cases can be defined implicitly via a kernel function. As the joint feature map $\phi(x,y)$ factorizes into $\psi(x) \otimes \varphi(y)$, we can write the inner product in the joint representation as $\langle \phi(x,y), \phi(x',y') \rangle = \langle \psi(x), \psi(x') \rangle \langle \varphi(y), \varphi(y') \rangle = k(x,x')k(y,y')$. In general, the kernel function on inputs and labels can be different. Specifically, for a label diagonal kernel $k(y,y') = \delta(y,y')$, the standard winner-takes-all multiclass classification is recovered (Tsochantaridis et al., 2005). With this setting, the input feature $\psi(x)$ can be defined implicitly via a kernel function by invoking the Representer Theorem (Schölkopf and Smola, 2002).

4.4 Binary Classification

One may show (Hofmann et al., 2006) that the feature map $\phi(x,y)$ takes on a particularly appealing form of $\phi(x,y) = y\psi(x)$ where $y \in \{\pm 1\}$. This follows since we can always re-calibrate $\langle \phi(x,y), \theta \rangle$ by an offset independent of y such that $\phi(x,1) + \phi(x,-1) = 0$.

If we moreover assume that X_1 only contains class 1 and $X_2 = X$ contains a mixture of classes with labels 1 and -1 with proportions $p(1) =: \rho$ and $p(-1) = 1 - \rho$ respectively, we obtain the mixing matrix

$$\pi = \begin{bmatrix} 1 & 0 \\ \rho & 1-\rho \end{bmatrix} \Rightarrow \pi^{-1} = \begin{bmatrix} 1 & 0 \\ \frac{-\rho}{1-\rho} & \frac{1}{1-\rho} \end{bmatrix}.$$

Plugging this into (5) yields

$$\begin{aligned}\hat{\mu}_{XY} &= \rho\mu_X^{\text{set}}[1] - (1-\rho)\left[\tfrac{-\rho}{1-\rho}\mu_X^{\text{set}}[1] + \tfrac{1}{1-\rho}\mu_X^{\text{set}}[2]\right] \\ &= 2\rho\mu_X^{\text{set}}[1] - \mu_X^{\text{set}}[2]. \end{aligned} \tag{6}$$

Consequently, taking a simple weighted difference between the averages on two sets, e.g. one set containing spam whereas the other one containing an unlabeled mix of spam and non-spam, allows one to obtain the sufficient statistics needed for estimation.

4.5 Overdetermined Systems

Assume that we have significantly more bags n than class labels $|\mathcal{Y}|$, possibly with varying numbers of observations m_i per bag. In this case it would make sense to find a weighting of the bags such that those which are largest and most relevant for the test set are given the highest degree of importance. Instead of stating the problem as one of solving a linear system we now restate it as one of solving an approximation problem. To simplify notation we assume that the feature map factorizes, i.e. that $\phi(x,y) = \psi(x) \otimes \varphi(y)$. A weighted linear combination of the squared discrepancy between the class means and the set means is given by

$$\underset{\mu_x^{\text{class}}}{\text{minimize}} \sum_{i=1}^{n} w_i \left\| \mu_X^{\text{set}}[i] - \sum_{y\in\mathcal{Y}} \pi_{iy}\mu_x^{\text{class}}[y] \right\|^2, \tag{7}$$

where w_i are some previously chosen weights which reflect the importance of each bag. Typically we might choose $w_i = O(m_i^{-\frac{1}{2}})$ to reflect the fact that convergence between empirical means and expectations scales with $O(m^{-\frac{1}{2}})$. Before we discuss specific methods for choosing a weighting, let us review the statistical properties of the estimator.

Remark 1 (Underdetermined Systems) *Similarly, when we have less bags n than class labels $|\mathcal{Y}|$, we can state the problem as one of solving a regularized least squares problem as follows*

$$\underset{\mu_x^{\text{class}}}{\text{minimize}} \sum_{i=1}^{n} \left\| \mu_X^{\text{set}}[i] - \sum_{y\in\mathcal{Y}} \pi_{iy}\mu_x^{\text{class}}[y] \right\|^2 + \lambda\Omega(\mu_x^{\text{class}}[y]\,\forall y \in \mathcal{Y}).$$

For example, we can let $\Omega(\mu_x^{\text{class}}[y]\,\forall y \in \mathcal{Y}) = \sum_{y\in\mathcal{Y}} \left\|\mu_x^{\text{class}}[y] - \mu_x^{\text{class}}[y+1]\right\|^2$. This makes sense whenever different labels have related means $\mu_x^{\text{class}}[y]$.

5. Convergence Bounds

The obvious question is how well $\hat{\mu}_{XY}$ manages to approximate μ_{XY} and secondly, how badly any error in estimating μ_{XY} would affect the overall quality of the solution. We approach this problem as follows: first we state the uniform convergence properties of μ_{XY} and similar empirical operators relative to μ_{xy}. Secondly, we apply those bounds to the cases discussed above, and thirdly, we show that the approximate minimizer of the log-posterior has a bounded deviation from what we would have obtained by knowing μ_{XY} exactly. Much of the reasoning follows the ideas of Altun and Smola (2006).

5.1 Uniform Convergence for Mean Operators

An important tool in studying uniform convergence properties of random variables are Rademacher averages (Ledoux and Talagrand, 1991; Mendelson, 2002). They are needed to state the key results in our context.

Definition 2 (Rademacher Averages) *Let $\mathcal{X}$ be a domain and p a distribution on $\mathcal{X}$ and assume that $X := \{x_1, \ldots, x_m\}$ is drawn iid from p. Moreover, let $\mathcal{F}$ be a class of functions $\mathcal{X} \to \mathbb{R}$. Furthermore denote by σ_i Rademacher random variables, i.e. $\{\pm 1\}$ valued with zero mean. The Rademacher average is*

$$R_m(\mathcal{F}, p) := \mathbf{E}_X \mathbf{E}_\sigma \left[\sup_{f \in \mathcal{F}} \left| \frac{1}{m} \sum_{i=1}^{m} \sigma_i f(x_i) \right| \right].$$

This quantity measures the flexibility of the function class $\mathcal{F}$ —in our case linear functions in $\phi(x,y)$. Altun and Smola (2006) state the following result:

Theorem 3 (Convergence of Empirical Means) *Denote by $\phi : \mathcal{X} \to \mathcal{B}$ a map into a Banach space $\mathcal{B}$, denote by $\mathcal{B}^*$ its dual space and let $\mathcal{F}$ the class of linear functions on $\mathcal{B}$ with bounded $\mathcal{B}^*$ norm by 1. Let $R > 0$ such that for all $f \in \mathcal{F}$ we have $|f(x)| \leq R$. Moreover, assume that X is an m-sample drawn from p on $\mathcal{X}$. For $\bar{\varepsilon} > 0$ we have that with probability at least $1 - \exp(-\bar{\varepsilon}^2 m / 2R^2)$ the following holds:*

$$\|\mu_X - \mu_x\|_{\mathcal{B}} \leq 2R_m(\mathcal{F}, p) + \bar{\varepsilon}.$$

For $k \geq 0$ we only have a failure probability of $1 - \exp(-\bar{\varepsilon}^2 m / R^2)$.

Theorem 4 (Bartlett and Mendelson 2002) *Whenever $\mathcal{B}$ is a Reproducing Kernel Hilbert Space with kernel $k(x,x')$ the Rademacher average can be bounded from above by $R_m(\mathcal{F}) \leq m^{-\frac{1}{2}} \left[\mathbf{E}_x[k(x,x)] \right]^{\frac{1}{2}}$.*

Our approximation error can be bounded as follows. From the triangle inequality we have:

$$\|\hat{\mu}_{XY} - \mu_{XY}\| \leq \|\hat{\mu}_{XY} - \mu_{xy}\| + \|\mu_{xy} - \mu_{XY}\|.$$

For the second term we may employ Theorem 3 directly. To bound the first term note that by linearity

$$\varepsilon := \hat{\mu}_{XY} - \mu_{xy} = \sum_y p(y) \left[(\pi^\top \pi)^{-1} \pi^\top \hat{\varepsilon} \right]_{y,y}, \tag{8}$$

where we define the "matrix" of coefficients

$$\hat{\varepsilon}\left[i, y'\right] := \mu_x^{\text{set}}[i, y'] - \mu_X^{\text{set}}[i, y']. \tag{9}$$

In the more general case of overdetermined systems we have

$$\varepsilon = \sum_y p(y) \left[(\pi^\top W \pi)^{-1} \pi^\top W \hat{\varepsilon} \right]_{y,y}.$$

Now note that all $\hat{\mathfrak{e}}[i,y']$ also satisfy the conditions of Theorem 3 since the sets X_i are drawn iid from the distributions $p(x|i)$ respectively. We may bound each term individually in this fashion and subsequently apply the union bound to ensure that all $n \cdot |\mathcal{Y}|$ components satisfy the constraints. Hence each of the terms needs to satisfy the constraint with probability $1-\delta/(n|\mathcal{Y}|)$ to obtain an overall bound with probability $1-\delta$. To obtain bounds we would need to bound the linear operator mapping $\hat{\mathfrak{e}}$ into $\mathfrak{e}$.

Note that this statement can be improved since all errors $\hat{\mathfrak{e}}[i,y']$ and $\hat{\mathfrak{e}}[j,y']$ for $i \neq j$ are independent of each other simply by the fact that each bag X_i was sampled independently from the other. We will discuss this in the context of choosing a practically useful value of W below.

5.2 Special Cases

A closed form solution in the general case is not particularly useful since it depends heavily on the kernel k, the mixing proportions π and the class probabilities on the test set. However, for a number of special cases it is possible to provide more detailed explicit analysis: firstly the situation where $\phi(x,y) = \psi(x) \otimes \varphi(y)$ and secondly, the binary classification setting where $\phi(x,y) = y\psi(x)$ and $X_2 = X$, where much tighter bounds are available.

5.3 Special Feature Map with Full Rank

Here we only need to deal with n rather than with $n \times |\mathcal{Y}|$ empirical estimates, i.e. $\mu_X^{\text{set}}[i]$ vs. $\mu_X^{\text{set}}[i,y']$. Hence (8) and (9) specialize to

$$\begin{aligned}\mathfrak{e} &= \sum_y p(y) \sum_{i=1}^{n} \varphi(y) \otimes \left[(\pi^\top \pi)^{-1}\pi^\top\right]_{yi} \hat{\mathfrak{e}}[i] \\ \hat{\mathfrak{e}}[i] &:= \mu_x^{\text{set}}[i] - \mu_X^{\text{set}}[i].\end{aligned}$$

Assume that with high probability each $\hat{\mathfrak{e}}[i]$ satisfies $\|\hat{\mathfrak{e}}[i]\| \leq c_i$ (we will deal with the explicit constants c_i later). Moreover, assume for simplicity that $|\mathcal{Y}| = n$ and that π has full rank (otherwise we need to follow through on our expansion using $(\pi^\top\pi)^{-1}\pi^\top$ instead of π^{-1}). This implies that

$$\begin{aligned}\|\mathfrak{e}\|^2 &= \sum_{i,j} \langle \hat{\mathfrak{e}}[i], \hat{\mathfrak{e}}[j] \rangle \times \sum_{y,y'} p(y)p(y')k(y,y') \left[\pi^{-1}\right]_{yi} \left[\pi^{-1}\right]_{y'j} \\ &\leq \sum_{i,j} c_i c_j \left| \left[\pi^{-1}\right]^\top K^{y,p} \pi^{-1} \right|_{ij}, \end{aligned} \tag{10}$$

where $K^{y,p}_{y,y'} = k(y,y')p(y)p(y')$. Combining several bounds we have the following theorem:

Theorem 5 *Assume that we have n sets of observations X_i of size m_i, each of which drawn from distributions with probabilities π_{iy} of observing data with label y. Moreover, assume that $k((x,y),(x',y')) = k(x,x')k(y,y') \geq 0$ where $k(x,x) \leq 1$ and $k(y,y) \leq 1$. Finally, assume that $m = |X|$. In this case the mean operator μ_{XY} can be estimated by $\hat{\mu}_{XY}$ with probability at least $1-\delta$ with precision*

$$\|\mu_{XY} - \hat{\mu}_{XY}\| \leq \left[2 + \sqrt{\log((n+1)/\delta)}\right] \times \left[m^{-\frac{1}{2}} + \left[\sum_{i,j} m_i^{-\frac{1}{2}} m_j^{-\frac{1}{2}} \left| \left[\pi^{-1}\right]^\top K^{y,p} \pi^{-1} \right|_{ij}\right]^{\frac{1}{2}}\right].$$

Proof We begin our argument by noting that both for $\phi(x,y)$ and for $\psi(x)$ the corresponding Rademacher averages R_m for functions of RKHS norm bounded by 1 is bounded by $m^{-\frac{1}{2}}$. This is a consequence of all kernels being bounded by 1 in Theorem 4 and $k \geq 0$.

Next note that in Theorem 3 we may set $R = 1$, since for $\|f\| \leq 1$ and $k((x,y),(x,y)) \leq 1$ and $k(x,x) \leq 1$ it follows from the Cauchy Schwartz inequality that $|f(x)| \leq 1$. Solving $\delta \leq \exp -m\varepsilon^2$ for ε yields $\varepsilon \leq m^{-\frac{1}{2}} \left[2 + \sqrt{\log(1/\delta)}\right]$.

Finally, note that we have $n+1$ deviations which we need to bound: one between μ_{XY} and μ_{xy}, and n for each of the $\varepsilon[i]$ respectively. Dividing the failure probability δ into $n+1$ cases yields bounds of the form $m^{-\frac{1}{2}} \left[2 + \sqrt{\log((n+1)/\delta)}\right]$ and $m_i^{-\frac{1}{2}} \left[2 + \sqrt{\log((n+1)/\delta)}\right]$ respectively. Plugging all error terms into (10) and summing over terms yields the claim and substituting this back into the triangle inequality proves the claim. ■

5.4 Binary Classification

Next we consider the special case of binary classification where $X_2 = X$. Using (6) we see that the corresponding estimator is given by

$$\hat{\mu}_{XY} = 2\rho\mu_X^{\text{set}}[1] - \mu_X^{\text{set}}[2].$$

Since $\hat{\mu}_{XY}$ shares a significant fraction of terms with μ_{XY} we are able to obtain tighter bounds as follows:

Theorem 6 *With probability* $1-\delta$ *(for* $1 > \delta > 0$*) the following bound holds:*

$$\|\hat{\mu}_{XY} - \mu_{XY}\| \leq 2\rho \left[2 + \sqrt{\log(2/\delta)}\right] \left[m_1^{-\frac{1}{2}} + m_+^{-\frac{1}{2}}\right],$$

where m_+ *is the number of observations with* $y = 1$ *in* X_2.

Proof Denote by $\mu[X_+]$ and $\mu[X_-]$ the averages over the subsets of X_2 with positive and negative labels respectively. By construction we have that

$$\begin{aligned}\mu_{XY} &= \rho\mu[X_+] - (1-\rho)\mu[X_-] \\ \hat{\mu}_{XY} &= 2\rho\mu_X^{\text{set}}[1] - \rho\mu[X_+] - (1-\rho)\mu[X_-].\end{aligned}$$

Taking the difference yields $2\rho\left[\mu_X^{\text{set}}[1] - \mu[X_+]\right]$. To prove the claim note that we may use Theorem 3 both for $\left\|\mu_X^{\text{set}}[1] - \mathbf{E}_{x\sim p(x|y=1)}[\psi(x)]\right\|$ and for $\left\|\mu[X_+] - \mathbf{E}_{x\sim p(x|y=1)}[\psi(x)]\right\|$. Taking the union bound and summing over terms proves the claim. ■

The bounds we provided show that $\hat{\mu}_{XY}$ converges at the same rate to μ_{xy} as μ_{XY} does, assuming that the sizes of the sets X_i increase at the same rate as X.

5.5 Overdetermined Systems

Given the optimal value of weighting W, the class mean can be reconstructed as a solution of a weighted least square problem in (7) and this minimizer is given by

$$\hat{\mu}_x^{\text{class}} = (\pi^\top W \pi)^{-1} \pi^\top W \mu_X^{\text{set}} \text{ where } W = \text{diag}(w_1, \ldots, w_n) \text{ and } w_i > 0.$$

It is easy to see that whenever $n = |\mathcal{Y}|$ and π has full rank there is only one possible solution regardless of the choice of W. For overdetermined systems the choice of W may greatly affect the

quality of the solution and it is therefore desirable to choose a weighting which minimizes the error in estimating μ_{XY}.

In choosing a weighting, we may take advantage of the fact that the errors $\hat{\varepsilon}[i]$ are independent for all i. This follows from the fact that all bags are drawn independently of each other. Moreover, we know that $\mathbf{E}[\hat{\varepsilon}[i]] = 0$ for all i. Finally we make the assumption that $k(y,y') = \delta(y,y')$, that is, that the kernel in the labels is diagonal. In this situation our analysis is greatly simplified and we have:

$$\varepsilon = \sum_y \varphi(y) \otimes p(y)(\pi^\top W \pi)^{-1} \pi W \hat{\varepsilon}$$

$$\text{and hence } \mathbf{E}\left[\|\varepsilon\|^2\right] = \sum_{i=1}^n \sum_y \mathbf{E}\left[\|\hat{\varepsilon}[i]\|^2\right] W_{ii}^2 \left[\pi_i^\top (\pi^\top W \pi)^{-1}\right]_y^2 p^2(y).$$

Using the assumption that $\mathbf{E}\left[\|\hat{\varepsilon}[i]\|^2\right] = O(m_i^{-1})$ we may find a suitable scale of the weight vectors by minimizing

$$\sum_{i=1}^n \sum_y \frac{W_{ii}^2}{m_i} \left[\pi_i^\top (\pi^\top W \pi)^{-1}\right]_y^2 p^2(y) \tag{11}$$

with respect to the diagonal matrix W. Note that the optimal value of W depends *both* on the mixtures of the bags π_i *and* on the propensity of each class $p(y)$. That is, being able to well estimate a class which hardly occurs at all is of limited value.

5.6 Stability Bounds

To complete our reasoning we need to show that our bounds translate into guarantees in terms of the minimizer of the log-posterior. In other words, estimates using the correct mean μ_{XY} vs. its estimate $\hat{\mu}_{XY}$ do not differ by a significant amount. For this purpose we make use of Altun and Smola (2006, Lemma 17).

Lemma 7 *Denote by f a convex function on $\mathcal{H}$ and let $\mu, \hat{\mu} \in \mathcal{H}$. Moreover let $\lambda > 0$. Finally denote by $\theta^*, \in \mathcal{H}$ the minimizer of*

$$L(\theta, \mu) := f(\theta) - \langle \mu, \theta \rangle + \lambda \|\theta\|^2$$

with respect to θ and $\hat{\theta}^*$ the minimizer of $L(\hat{\theta}, \hat{\mu})$ respectively. In this case the following inequality holds:

$$\left\|\theta^* - \hat{\theta}^*\right\| \leq \lambda^{-1} \left\|\mu - \hat{\mu}\right\|. \tag{12}$$

This means that a good estimate for μ immediately translates into a good estimate for the minimizer of the approximate log-posterior. This leads to the following bound on the risk minimizer.

Corollary 8 *The deviation between θ^*, as defined in (1) and $\hat{\theta}^*$, the minimizer of the approximate log-posterior using $\hat{\mu}_{XY}$ rather than μ_{XY}, is bounded by $O(m^{-\frac{1}{2}} + \sum_i m_i^{-\frac{1}{2}})$.*

Finally, we may use Altun and Smola (2006, Theorem 16) to obtain bounds on the quality of $\hat{\theta}^*$ when considering how well it minimizes the *true* negative log-posterior. Using the bound

$$L(\hat{\theta}^*, \mu) - L(\theta^*, \mu) \leq \left\|\hat{\theta}^* - \theta^*\right\| \left\|\hat{\mu} - \mu\right\|$$

yields the following bound for the log-posterior:

Corollary 9 *The minimizer $\hat{\theta}^*$ of the approximate log-posterior using $\hat{\mu}_{XY}$ rather than μ_{XY} incurs a penalty of at most $\lambda^{-1}\|\hat{\mu}_{XY}-\mu_{XY}\|^2$.*

5.7 Stability Bounds under Perturbation

Denote $1 \in \{1\}^{|\mathcal{Y}|}$ as the vector of all ones and $0 \in \{0\}^{|\mathcal{Y}|}$ as the vector of all zeros. Let Δ be the perturbation matrix such that the perturbed mixing matrix $\tilde{\pi}$ is related to the original mixing matrix π by $\tilde{\pi} = \pi + \Delta$. Note that the perturbed mixing matrix $\tilde{\pi}$ still needs to have non-negative entries and each row sums up to $1, \tilde{\pi}1 = 1$. The stochasticity constraint on the perturbed mixing matrix imposes special structure on the perturbation matrix, i.e. each row of perturbation matrix must sum up to 0, $\Delta 1 = 0$. Let $\hat{\theta}^*$ be the minimizer of (2) with mean $\hat{\mu}_{XY}$ approximated via mixing matrix π. Similarly, define $\tilde{\theta}^*$ for $\tilde{\mu}_{XY}$ with mixing matrix $\tilde{\pi}$. We would like to bound the distance $\left\|\hat{\theta}^* - \tilde{\theta}^*\right\|$ between the minimizers. Our perturbation bound relies on Lemma 7 and on the fact that we can bound the errors made in computing an (pseudo-) inverse of a matrix:

Lemma 10 (Stability of Inverses) *For any matrix norm $\|.\|$ and full rank matrices π and $\pi+\Delta$, the error between the inverses of π and $\pi+\Delta$ is bounded by*

$$\left\|\pi^{-1} - (\pi+\Delta)^{-1}\right\| \leq \left\|\pi^{-1}\right\| \left\|(\pi+\Delta)^{-1}\right\| \|\Delta\|.$$

Proof We use the following identity $\pi^{-1} - (\pi+\Delta)^{-1} = (\pi+\Delta)^{-1}\Delta\pi^{-1}$. The identity can be shown by left multiplying both sides of equation with $(\pi+\Delta)$. Finally, by submultiplicative property of a matrix norm, the inequality $\left\|\pi^{-1}\Delta(\pi+\Delta)^{-1}\right\| \leq \left\|\pi^{-1}\right\| \|\Delta\| \left\|(\pi+\Delta)^{-1}\right\|$ follows. ■

Theorem 11 (Stability of Pseudo-Inverses: Wedin 1973) *For any unitarily invariant matrix norm $\|.\|$ and full column rank matrices π and $\pi+\Delta$, the error between the pseudo-inverses of π and $\pi+\Delta$ is bounded by*

$$\left\|\pi^{\dagger} - (\pi+\Delta)^{\dagger}\right\| \leq \mu \left\|\pi^{\dagger}\right\|_{\sigma\infty} \left\|(\pi+\Delta)^{\dagger}\right\|_{\sigma\infty} \|\Delta\|,$$

where μ denotes a scalar constant depending on the matrix norm, $\|.\|_{\sigma\infty}$ denotes the spectral norm of a matrix, and the pseudo-inverse $\pi^{\dagger}$ defined as $\pi^{\dagger} := (\pi^{\top}\pi)^{-1}\pi^{\top}$.

Proof See Wedin (1973, Theorem 4.1) for a proof. ■

Remark 12 *For full rank matrices, the constant term μ in Theorem 11 is equal to unity regardless of the matrix norm considered (Wedin, 1973).*

First, we would like to bound the difference between $\hat{\mu}_{XY}$ and $\tilde{\mu}_{XY}$, i.e. $\varepsilon_p := \hat{\mu}_{XY} - \tilde{\mu}_{XY}$. For the special feature map with full rank, this translates to

$$\varepsilon_p = \sum_y p(y) \sum_{i=1}^{n} \varphi(y) \otimes \left[\pi^{-1} - \tilde{\pi}^{-1}\right]_{yi} \mu_X^{\text{set}}[i]$$

$$\|\varepsilon_p\|^2 = \sum_{i,j} \left\langle \mu_X^{\text{set}}[i], \mu_X^{\text{set}}[j] \right\rangle \times \left[(\pi^{-1} - \tilde{\pi}^{-1})^{\top} K^{y,p} (\pi^{-1} - \tilde{\pi}^{-1})\right]_{ij}.$$

Lemma 13 *Define $K^{y,p} := V_{y,p}^\top V_{y,p}$. With the spectral norm $\|.\|_{\sigma\infty}$ and a full rank mixing matrix π, the following bound holds:*

$$\|\hat{\mu}_{XY} - \tilde{\mu}_{XY}\|_{\sigma\infty} \leq \|V_{y,p}\|_{\sigma\infty} \left\|\pi^{-1}\right\|_{\sigma\infty} \|\Delta\|_{\sigma\infty} \left\|(\pi+\Delta)^{-1}\right\|_{\sigma\infty} \left[\sum_{i,j} \left\langle \mu_X^{set}[i], \mu_X^{set}[j] \right\rangle\right]^{\frac{1}{2}}. \quad (13)$$

Proof We first upper bound $\left[(\pi^{-1} - \tilde{\pi}^{-1})^\top K^{y,p} (\pi^{-1} - \tilde{\pi}^{-1})\right]_{ij}$ by $\left\|(\pi^{-1} - \tilde{\pi}^{-1})^\top K^{y,p} (\pi^{-1} - \tilde{\pi}^{-1})\right\|_{\sigma\infty}$. We factorize $K^{y,p}$ as $V_{y,p}^\top V_{y,p}$ since $K^{y,p}$ is a positive (semi-) definite matrix. The element $K^{y,p}_{y,y'} = k(y,y')p(y)p(y')$ is obtained by multiplying a kernel $k(y,y')$ with a rank-one kernel $k'(y,y') = p(y)p(y')$ where p is a positive function. This conformal transformation preserves the positive (semi-) definiteness of $K^{y,p}$ (Schölkopf and Smola, 2002). Thus, $\left\|(\pi^{-1} - \tilde{\pi}^{-1})^\top K^{y,p} (\pi^{-1} - \tilde{\pi}^{-1})\right\|_{\sigma\infty} \leq \left\|V_{y,p}(\pi^{-1} - \tilde{\pi}^{-1})\right\|_{\sigma\infty}^2 \leq$ $\left[\|V_{y,p}\|_{\sigma\infty} \left\|(\pi^{-1} - \tilde{\pi}^{-1})\right\|_{\sigma\infty}\right]^2 \leq \left[\|V_{y,p}\|_{\sigma\infty} \left\|\pi^{-1}\right\|_{\sigma\infty} \|\Delta\|_{\sigma\infty} \left\|(\pi+\Delta)^{-1}\right\|_{\sigma\infty}\right]^2$. The last inequality follows directly from Lemma 10. ■

Corollary 14 *Define $K^{y,p} := V_{y,p}^\top V_{y,p}$. With the spectral norm $\|.\|_{\sigma\infty}$ and a full column rank mixing matrix π, the following bound holds:*

$$\|\hat{\mu}_{XY} - \tilde{\mu}_{XY}\|_{\sigma\infty} \leq \sqrt{2}\,\|V_{y,p}\|_{\sigma\infty} \left\|\pi^{\dagger}\right\|_{\sigma\infty} \|\Delta\|_{\sigma\infty} \left\|(\pi+\Delta)^{\dagger}\right\|_{\sigma\infty} \left[\sum_{i,j} \left\langle \mu_X^{set}[i], \mu_X^{set}[j] \right\rangle\right]^{\frac{1}{2}}. \quad (14)$$

Proof Similar to Lemma 13 with the constant factor μ in Theorem 11 equals to $\sqrt{2}$ for a spectral norm. ■

Combining Lemma 13 for the full rank mixing matrix case (or Corollary 14 for the full column rank mixing matrix case) with Lemma 7, we are ready to state the stability bound under perturbation:

Lemma 15 (Stability Bound under Perturbation) *The distance ε_s between the two minimizers, $\hat{\theta}^*$ and $\tilde{\theta}^*$, is bounded by*

$$\varepsilon_s \leq \lambda^{-1} \|\hat{\mu}_{XY} - \tilde{\mu}_{XY}\|.$$

It is clear from (13) and (14) that the stability of our algorithm under perturbation will depend on the size of the perturbation and on the behavior of the (pseudo-) inverse of the perturbed mixing matrix. Note that by the triangle inequality, the distance in (12) can be decomposed as $\left\|\theta^* - \hat{\theta}^*\right\| \leq \left\|\theta^* - \tilde{\theta}^*\right\| + \left\|\tilde{\theta}^* - \hat{\theta}^*\right\|$ and the second term in RHS vanishes whenever the size of perturbation Δ is zero.

6. Extensions

We describe two types of extensions on our proposed estimator: function spaces and unknown label proportions on the test sets. We will discuss both of them in turn.

6.1 Function Spaces

Note that our analysis so far focused on a specific setting, namely maximum-a-posteriori analysis in exponential families. While this is a common and popular setting, the derivations are by no means restricted to this. We have the entire class of (conditional) models described by Altun and Smola (2006) and Dudík and Schapire (2006) at our disposition. They are characterized via

$$\underset{p}{\text{minimize}} -H(p) \text{ subject to } \|\mathbf{E}_{z\sim p}[\phi(z)] - \mu\| \leq \varepsilon.$$

Here p is a distribution, H is an entropy-like quantity defined on the space of distributions, and $\phi(z)$ is some evaluation map into a Banach space. This means that the optimization problem can be viewed as an approximate maximum entropy estimation problem, where we do not enforce exact moment matching of μ but rather allow ε slack. In both Altun and Smola (2006) and Dudík and Schapire (2006) the emphasis lay on *unconditional* density models: the dual of the above optimization problem. In particular, it follows that for H being the Shannon-Boltzmann entropy, the dual optimization problem is the maximum a posteriori estimation problem, which is what we are solving here.

In the conditional case, p denotes the collection of probabilities $p(y|x_i)$ and the operator $\mathbf{E}_{z\sim p}[\phi(z)] = \frac{1}{m}\sum_{i=1}^{m} \mathbf{E}_{y|p(y|x_i)}[\phi(x_i,y)]$ is the conditional expectation operator on the set of observations. Finally, $\mu = \frac{1}{m}\sum_{i=1}^{m}\phi(x_i,y_i)$, that is, it describes the empirical observations. We have two design parameters:

6.1.1 FUNCTION SPACE

Depending on which Banach Space norm we may choose to measure the deviation between μ and its expectation with respect to p in terms of e.g. the ℓ_2 norm, the ℓ_1 norm or the ℓ_∞ norm. The latter leads to sparse coding and convex combinations. This means that instead of solving an optimization problem of the form of (2) we would minimize expression of the form

$$\sum_{i=1}^{m} g(\theta|x_i) - m\langle \mu_{XY}, \theta\rangle + \lambda \|\theta\|^p_{\mathcal{B}^*},$$

where $p \geq 1$ and $\mathcal{B}^*$ is the Banach space of the natural parameter θ which is dual to the space $\mathcal{B}$ associated with the evaluation functionals $\phi(x,y)$. The most popular choice for $\mathcal{B}^*$ is ℓ_1 which leads to sparse coding (Candes and Tao, 2005; Chen et al., 1995).

6.1.2 ENTROPY AND REGULARITY

Depending on the choice of entropy and divergence functionals we obtain a range of diverse estimators. For instance, if we were to choose the *unnormalized* entropy instead of the entropy, we would obtain algorithms more akin to boosting. We may also use Csiszar and Bregmann divergences. The key point is that our reasoning of estimating μ_{XY} based on an aggregate of samples with unknown labels but known label proportions is still applicable.

6.2 Unknown Test Label Proportions

In many practical applications we may not actually know the label proportions on the test set. For instance, when deploying the algorithm to assess the spam in a user's mailbox we will *not* know

what the fraction would be. Nor is it likely that the user would be willing or able or trustworthy enough to provide a reliable estimate. This means that we need to estimate those proportions in addition to the class means μ_x^{class}.

We may use a fairly straightforward simplification of the covariate shift correction procedure of Huang et al. (2007) in this context. The basic idea is to exploit the fact that there the map $p(x) \to \mu[p(x)] = \mathbf{E}_x[\psi(x)]$ is injective for characteristic kernels (Sriperumbudur et al., 2008). Examples of such a characteristic kernel is Gaussian RBF, Laplacian, and B_{2n+1}-splines. This means that as long as the conditional distributions $p(x|y)$ are different for different choices of y we will be able to recover the test label proportions by the simple procedure of minimizing the distance between $\mu[p]$ and $\sum_y \alpha_y \mu[p(x|y)]$. While we may not have access to the true expectations we are still able to estimate $\mu_x^{\text{class}}[y]$ for all $y \in \mathcal{Y}$. This leads to the optimization problem

$$\begin{aligned} &\underset{\alpha}{\text{minimize}} \quad \left\| \frac{1}{m} \sum_{i=1}^{m} \psi(x_i) - \sum_{y \in \mathcal{Y}} \alpha_y \mu_X^{\text{class}}[y] \right\|^2 \\ &\text{subject to } \alpha_y \geq 0 \text{ and } \sum_{y \in \mathcal{Y}} \alpha_y = 1. \end{aligned} \tag{15}$$

Here the sum is taken over the elements of the test set, that is $x_j \in X$. Very similar bounds to those by Huang et al. (2007) can be obtained and they are omitted for the sake of brevity as the reasoning is essentially identical.

Note that obviously (15) may be used *separately* from the previous discussion, that is, when the training proportions are known but the test proportions are not. However, we believe that the most significant benefit is obtained in using both methods in conjunction since many practical situations exhibit both problems simultaneously.

7. Related Work and Alternatives

While being highly relevant in practice, the problem has not seen as much attention by researchers as one would expect. Some of the few works which cover a related subject are those by Chen et al. (2006) and Musicant et al. (2007), and by Kück and de Freitas (2005). We hope that our work will stimulate research in this area as relevant problems are fairly widespread.

7.1 Transduction

In transduction one attempts to solve a related problem: the patterns x_i on the test set are known, usually also some label proportions on the test set are known but obviously the actual labels on the test set are *not* known. One way of tackling this problem is to perform transduction by enforcing a proportionality constraint on the unlabeled data, e.g. via a Gaussian Process model (Gärtner et al., 2006; Mann and McCallum, 2007).

At first glance these methods might seem applicable for our problem but they do require that we have at least some labeled instances of *all classes* at our disposition which need to be drawn in an unbiased fashion. This is clearly not the case in our setting. That said, it is well possible to use our setting in the context of transduction, that is, to replace the unknown mean μ_{XY}^{test} on the test set by the empirical estimate on the training set. Such strategies lead to satisfactory performance on par with (albeit not exceeding) existing transduction approaches.

7.2 Self Consistent Proportions

Kück and de Freitas (2005) introduced a more informative variant of the binary multiple-instance learning, in which groups of instances are given along with estimates of the fraction of positively-labeled instances per group. The authors build a fully generative model of the process which determines the assignment of observations to individual bags. Such a procedure is likely to perform well when a large number of bags is present.

In order to deal with the estimation of the missing variables a MCMC sampling procedure is used. While Kück and de Freitas (2005) describe the approach only for a binary problem, it could be extended easily to multiclass settings.

In a similar vein, Chen et al. (2006) and Musicant et al. (2007) also use a self-consistent approach where the conditional class estimates need to match the observed ones. Consequently it shares the same similar drawbacks, since we typically only have as many sets as classes.

7.3 Conditional Probabilities

A seemingly valid alternative approach is to try building a classifier for $p(i|x)$ and subsequently recalibrating the probabilities to obtain $p(y|x)$, e.g. via $p(y|i)$. At first sight this may appear promising since this method is easily implemented by most discriminative methods. The idea would be to reconstruct $p(y|x)$ by

$$p(y|x) = \sum_i \pi_{iy} p(i|x).$$

However, this is not a useful estimator in our setting for a simple reason: it assumes the conditional independence $y \perp\!\!\!\perp x \mid i$, which obviously does not hold. Instead, we have the property that $i \perp\!\!\!\perp x| \, y$, that is, the distribution over x for a given class label does not depend on the bag. This mismatch in the probabilistic model can lead to disastrous estimates as the following simple example illustrates:

Example 1 *Assume that $\mathcal{X}, \mathcal{Y} = \{1,2\}$ and that $p(y=1|x=1) = p(y=2|x=2) = 1$. In other words, the estimation problem is solvable since the classes are well separated. Moreover, assume that π is given by*

$$\pi = \begin{bmatrix} 0.5-\varepsilon & 0.5+\varepsilon \\ 0.5 & 0.5 \end{bmatrix} \text{ for } 0 < \varepsilon \ll 1.$$

Here, $p(i|x)$ is useless for estimating $p(y|x)$, since we will only exceed random guessing by at most ε. On the other hand, it is easily possible to obtain a good estimate for μ_{XY} by our proposed procedure.

The reason for this failure can be found in the following expansion

$$p(y|x) = \sum_i p(y|x,i)p(i|x) \neq \sum_i p(y|i)p(i|x) \text{ since } p(y|x,i) \neq p(y|i). \tag{16}$$

The problem with (16) is that the estimator does not really attempt to compute the probability $p(y|x)$, which we are interested in but instead, it attempts to discern which mixture distribution p_i the observation x most likely originated from. For this to work we would need good probability estimates as the *basis* of reweighting. Our approach tackles the problem at the source by recalibrating the sufficient statistics directly.

7.4 Reduction to Binary

For binary classification and real-valued classification scores we may resort to a rather straightforward heuristic: build a classifier which is able to distinguish between the sets X_1 and X_2 and subsequently threshold labels such that the appropriate fraction of observations in X_1 and X_2 matches the proper labels. The intuition is that since the bags X_1 and X_2 do contain some information about how the two classes differ, we should be able to use this information to distinguish between different class labels.

It is likely that one might be able to obtain a proper reduction bound in this context. However, extensions to multi-class are highly nontrivial. It also turns out that even in the binary case this method, while overall fairly competitive, is inferior to our approach.

7.5 Density Estimation

One way of obtaining $p(x|i)$ is to carry out density estimation. While, in principle, this approach is flawed because of the incorrect conditional independence assumptions, it can still lead to acceptable results whenever each of the bags contains one majority class. This allows us to obtain

$$p(x|y) = \sum_i \left[\pi^{-1}\right]_{yi} p(x|i).$$

To re-calibrate the probability estimates Bayes' theorem is invoked to compute posterior probabilities. Since this approach involves density estimation it tends to fail fairly catastrophically for high-dimensional data due to the curse of dimensionality. These problems are also manifest in the experiments.

8. Experiments

Data Sets: We use binary and three-class classification data sets from the UCI repository[1] and the LibSVM site.[2] If separate training and test sets are available, we merge them before performing nested 10-fold cross-validation. Since we need to generate as many splits as classes, we limit ourselves to three classes.

For the binary data sets we use half of the data for X_1 and the rest for X_2. We also remove all instances of class 2 from X_1. That is, the conditional class probabilities in X_2 match those from the repository, whereas in X_1 their counterparts are deleted.

For three-class data sets we investigate two different partitions. In scenario A we use class 1 exclusively in X_1, class 2 exclusively in X_2, and a mix of all three classes weighted by $(0.5 \cdot p(1), 0.6 \cdot p(2), 0.7 \cdot p(3))$ to generate X_3. In scenario B we use the following splits

$$\begin{bmatrix} c_1 \cdot 0.4 \cdot p(1) & c_1 \cdot 0.2 \cdot p(2) & c_1 \cdot 0.2 \cdot p(3) \\ c_2 \cdot 0.1 \cdot p(1) & c_2 \cdot 0.2 \cdot p(2) & c_2 \cdot 0.1 \cdot p(3) \\ c_3 \cdot 0.5 \cdot p(1) & c_3 \cdot 0.6 \cdot p(2) & c_3 \cdot 0.7 \cdot p(3) \end{bmatrix}.$$

Here the constants c_1, c_2 and c_3 are chosen such that the probabilities are properly normalized. As before, X_3 contains half of the data.

1. UCI can be found at `http://archive.ics.uci.edu/ml/`.
2. LibSVM can be found at `http://www.csie.ntu.edu.tw/~cjlin/libsvmtools/`.

Model Selection: As stated, we carry out a *nested* 10-fold cross-validation procedure: 10-fold cross-validation to assess the performance of the estimators; within each fold, 10-fold cross-validation is performed to find a suitable value for the parameters.

For supervised classification, i.e. discriminative sorting, such a procedure is quite straightforward because we can directly optimize for classification error. For kernel density estimation (KDE), we use the log-likelihood as our criterion.

Due to the high number of hyper-parameters (at least 8) in MCMC, it is difficult to perform *nested* 10-fold cross-validation. Instead, we choose the *best* parameters from a simple 10-fold crossvalidation run. In other words, we are giving the MCMC method an unfair advantage over our approach by reporting the best performance during the model selection procedure.

Finally, for the re-calibrated sufficient statistics $\hat{\mu}_{XY}$ we use the estimate of the log-likelihood on the validation set as the criterion for cross-validation, since no other quantity, such as classification errors is readily available for estimation.

Algorithms: For discriminative sorting we use an SVM with a Gaussian RBF kernel whose width is set to the median distance between observations (Schölkopf, 1997); the regularization parameter is chosen by cross-validation. The same strategy applies for our algorithm. For KDE, we use Gaussian kernels. Cross-validation is performed over the kernel width. For MCMC, 10 000 samples are generated after a burn-in period of 10 000 steps (Kück and de Freitas, 2005).

Optimization: Bundle methods (Smola et al., 2007; Teo et al., 2007) are used to solve the optimization problem in Algorithm 1. For our regularized log-likelihood, the solver converges to ε precision in $O(\log(1/\varepsilon))$ steps.

Results: The experimental results are summarized in Table 3. Our method outperforms KDE and discriminative sorting. In terms of computation, our approach is somewhat more efficient, since it only needs to deal with a smaller sample size (only X rather than the union of all X_i). The training time for our method is less than 2 minutes for all cases, whereas MCMC on average takes 15 minutes and maybe even much longer when the number of active kernels and/or observations are high. Note that KDE fails on two data sets due to numerical problems (high dimensional data).

Our method also performs well on multiclass data sets. As described in Section 5.2, the quality of our minimizer of the negative log-posterior depends on the mixing matrix and this is noticeable in the reduction of performance for the dense mixing matrix (scenario B) in comparison to the better conditioned sparse mixing matrix (scenario A). In other words, for ill conditioned π even our method has its limits, simply due to numerical considerations of effective sample size.

Unknown test label proportions: In this experiment, we use binary and three-class classification data sets with the same split procedure as in the previous experiment but we select testing examples by a biased procedure to introduce unknown test label proportions. To describe our biased procedure, consider a random variable ξ_i for each point in the pool of possible testing samples where $\xi_i = 1$ means the i-th sample is being included and $\xi_i = 0$ means the sample is discarded. In our case, the biased procedure only depends on the label y, i.e. $P(\xi = 1|y = 1) = 0.5$ and $P(\xi = 1|y = -1) = 1.0$ for binary problems and $P(\xi = 1|y = 1) = 0.6$, $P(\xi = 1|y = 2) = 0.3$, and $P(\xi = 1|y = 3) = 0.1$ for three-class problems. We then estimate the test proportion by solving the quadratic program in (15) with interior point methods (or any other successive optimization procedure). Since we are interested particularly to assess the effectiveness of our test proportion estimation method, in solving (15) we assume that we can compute $\mu_X^{\text{class}}[y]$ directly, i.e. the instances are labeled. The mean square error rates of test proportions for several binary and three-class data

Table 3: Classification error on UCI/LibSVM data sets. Errors are reported in mean ± standard error. The best result and those not significantly worse than it, are highlighted in boldface. We use a one-sided paired t-test with 95% confidence. `MM`: Mean Map (our method); `KDE`: Kernel Density Estimation; `DS`: Discriminative Sorting (only applicable for binary classification); `MCMC`: the sampling method; `BA`: Baseline, obtained by predicting the major class. †: Program fails (too high dimensional data - only `KDE`). ‡: Program fails (large data sets - only `MCMC`).

sets are presented in Table 4. The results show that our proportion estimation method works reasonably well.

Overdetermined systems: Here we are interested to assess the performance of our estimator with optimized weights when we have more data sets n than class labels $|\mathcal{Y}|$ with varying number of observations m_i per data set. We simulate the problem in binary settings with the following split ($n = 8$)

$$\begin{bmatrix} c_1 \cdot 0.25 \cdot p(1) & c_1 \cdot 0.10 \cdot p(2) \\ c_2 \cdot 0.15 \cdot p(1) & c_2 \cdot 0.10 \cdot p(2) \\ c_3 \cdot 0.05 \cdot p(1) & c_3 \cdot 0.20 \cdot p(2) \\ c_4 \cdot 0.05 \cdot p(1) & c_4 \cdot 0.10 \cdot p(2) \\ c_5 \cdot 0.05 \cdot p(1) & c_5 \cdot 0.00 \cdot p(2) \\ c_6 \cdot 0.05 \cdot p(1) & c_6 \cdot 0.05 \cdot p(2) \\ c_7 \cdot 0.05 \cdot p(1) & c_7 \cdot 0.15 \cdot p(2) \\ c_8 \cdot 0.35 \cdot p(1) & c_8 \cdot 0.30 \cdot p(2) \end{bmatrix}$$

and the split ($n = 6$) in three-class settings is as follows

$$\begin{bmatrix} c_1 \cdot 0.30 \cdot p(1) & c_1 \cdot 0.10 \cdot p(2) & c_1 \cdot 0.00 \cdot p(3) \\ c_2 \cdot 0.10 \cdot p(1) & c_2 \cdot 0.10 \cdot p(2) & c_2 \cdot 0.20 \cdot p(3) \\ c_3 \cdot 0.05 \cdot p(1) & c_3 \cdot 0.00 \cdot p(2) & c_3 \cdot 0.05 \cdot p(3) \\ c_4 \cdot 0.05 \cdot p(1) & c_4 \cdot 0.20 \cdot p(2) & c_4 \cdot 0.05 \cdot p(3) \\ c_5 \cdot 0.00 \cdot p(1) & c_5 \cdot 0.05 \cdot p(2) & c_5 \cdot 0.10 \cdot p(3) \\ c_6 \cdot 0.50 \cdot p(1) & c_6 \cdot 0.55 \cdot p(2) & c_6 \cdot 0.60 \cdot p(3) \end{bmatrix}.$$

We use BFGS to obtain the optimal weights of the minimization problem in (11). We perform 10-fold cross validation with respect to the log-likelihood. The error rates are presented in Table 5. For all cases except one, the estimator with optimized weights improves error rates compared with the unweighted one.

matrix as

$$\tilde{\pi} = \pi + \Delta = \begin{bmatrix} 1 & 0 \\ \rho & 1-\rho \end{bmatrix} + \begin{bmatrix} -\varepsilon_1 & \varepsilon_1 \\ \varepsilon_2 & -\varepsilon_2 \end{bmatrix}.$$

We varied $\varepsilon_1 \in \{0.0, 0.1, 0.2, 0.3, 0.4, 0.5, 0.6, 0.7, 0.8, 0.9, 1.0\}$ and $\varepsilon_2 \in \{0.0, 0.1, 0.3, 0.5\}$ and measured the performance as a function of the size of the perturbation, $\eta = \|\Delta\|^2 = tr(\Delta^\top \Delta)$. Note that unperturbed mixing matrix refer to the case of $\{\varepsilon_1, \varepsilon_2\} = \{0, 0\}$. The experiments are summarized in Figure 2. The results suggest that for a reasonable size of perturbations, our method is stable.

9. Conclusion

In this paper we obtained a rather surprising result, namely that it is possible to consistently reconstruct the labels of a data set if we can only obtain information about the proportions of occurrence of each class (in at least as many data aggregates as there are classes). In particular, we proved that up to constants, our algorithm enjoys the same rates of convergence afforded to methods which have full access to all label information.

This finding has significant implications with regard to the amount of privacy afforded by summary statistics. In particular, it implies that whenever accurate summary statistics exist and whenever the available individual statistics are highly dependent on the summarized random variable we will be able to perform inference on the summarized variable with a high degree of confidence. In other words, some techniques used to anonymize observations, e.g. demographic data, may not be really safe (at least when it is possible to estimate the missing information, provided enough data).

Recently Chiaia et al. (2007) applied a summarization technique to infer drug use based on the concentration of metabolites in the sewage of cities, suburbs or at an even more finely grained resolution. While this only provides aggregate information about the proportions of drug users, such data, in combination with detailed demographic information might be used to perform more detailed inference with regard to the propensity of individuals to use controlled substances. It is in these types of problem where our method could be applied straightforwardly.

Abstract

A Boolean function f is *correlation immune* if each input variable is independent of the output, under the uniform distribution on inputs. For example, the parity function is correlation immune. We consider the problem of identifying relevant variables of a correlation immune function, in the presence of irrelevant variables. We address this problem in two different contexts. First, we analyze *Skewing*, a heuristic method that was developed to improve the ability of greedy decision tree algorithms to identify relevant variables of correlation immune Boolean functions, given examples drawn from the uniform distribution (Page and Ray, 2003). We present theoretical results revealing both the capabilities and limitations of skewing. Second, we explore the problem of identifying relevant variables in the *Product Distribution Choice* (PDC) learning model, a model in which the learner can choose product distributions and obtain examples from them. We prove a lemma establishing a property of Boolean functions that may be of independent interest. Using this lemma, we give two new algorithms for finding relevant variables of correlation immune functions in the PDC model.

Keywords: correlation immune functions, skewing, relevant variables, Boolean functions, product distributions

1. Introduction

A Boolean function $f : \{0,1\}^n \to \{0,1\}$ is *correlation immune* if for every input variable x_i, the values of x_i and $f(x_1,\ldots,x_n)$ are independent, with respect to the uniform distribution on $\{0,1\}^n$ (cf. Roy, 2002). Examples of correlation immune functions include parity of $k \geq 2$ variables, the constant functions $f \equiv 1$ and $f \equiv 0$, and the function $f(x) = 1$ iff all bits of x are equal.

If a function f is not correlation immune, then given access to examples of f drawn from the uniform distribution, one can easily identify (at least one) relevant variable of f by finding an input variable that is correlated with the output of f. This approach clearly fails if f is correlation immune.

We consider the problem of identifying relevant variables of a correlation immune function, in the presence of irrelevant variables. This problem has been addressed by machine learning practitioners through the development of heuristics, and by computational learning theorists, who have analyzed the problem in standard learning models. We were motivated by work from both communities, and present results related to both types of work. First, we present a theoretical analysis of *skewing*, a heuristic method that was developed to improve the ability of greedy decision tree learning algorithms to identify relevant variables of correlation immune functions, given examples drawn from the uniform distribution (Page and Ray, 2003; Ray and Page, 2004). Second, we present algorithms for identifying relevant variables in the *Product Distribution Choice* (PDC) model of learning. The PDC model, which we introduce below, is a variant of the standard PAC learning model (Valiant, 1984) in which the learner can specify product distributions and sample from them.[1]

Greedy decision tree learning algorithms perform poorly on correlation immune functions because they rely on measures such as Information Gain (Quinlan, 1997) and Gini gain (Breiman et al., 1984) to choose which variables to place in the nodes of the decision tree. The correlation immune functions are precisely those in which every attribute has zero gain under all standard gain measures, when the gain is computed on the complete data set (i.e., the truth table) for the function. Thus when examples of a correlation immune function are drawn uniformly at random from the complete data set, the learning algorithms have no basis for distinguishing between relevant and irrelevant attributes.

Experiments have shown skewing to be successful in learning many correlation immune functions (Page and Ray, 2003). One of the original motivations behind skewing was the observation that obtaining examples from non-uniform product distributions can be helpful in learning particular correlation immune functions such as parity. Skewing works by reweighting the given training set to simulate receiving examples from a subclass of product distributions called *skewed* distributions. In a skewed distribution, each input variable x_i is independently set to 1 with probability p_i; further, there is a fixed probability p, such that each p_i is either equal to p or to $1-p$.

However, simulating alternative distributions is not the same as sampling directly from them. The *Product Distribution Choice* (PDC) model allows such direct sampling. This model can be seen as a variant of the PAC model, and has similarities with other learning models studied previously (see Section 5). In the PDC model, the learner has access to an oracle from which it can request examples. Before requesting an example, the learner specifies a product distribution. The oracle then supplies an example drawn from that distribution. In our study of the PDC model, we focus

1. Our PDC model algorithms could be presented independently of any discussion of the skewing heuristic. However, the algorithms rely on technical results that we originally proved to analyze skewing, and we present those technical results as part of our discussion of skewing. Readers who are only interested in understanding the PDC algorithms will need to read some of the material on skewing, but can skip Sections 9.3 and 11.

on a fundamental learning task: the problem of identifying relevant variables in the presence of irrelevant ones.

Note that by setting the parameters of the product distribution to be equal to 0 and 1, one can simulate membership queries in the PDC model. However, we are particularly interested in exploring learning in the PDC model when the parameters of the chosen product distributions are bounded away from 0 and 1.

Our interest in the PDC model is motivated not just by our study of skewing, but by a more general question: In learning, how much does it help to have access to data from different distributions? In practice, it may be possible to obtain data from different distributions by collecting it from different sources or populations. Alternatively, one may be able to alter environmental conditions to change the distribution from which data is obtained. In such settings, it can be expensive to sample from too many distributions, and it may be difficult or impossible to sample from "extreme" distributions. Thus in the PDC model, we are concerned not just with time and sample complexity, but also in the number and type of product distributions specified.

2. Summary of Results

We begin by showing that, given a complete data set, skewing will succeed. That is, given the complete truth table of a target Boolean function as the training set, skewing will find a relevant variable of that function. (More particularly, under any random choice of skewing parameters, a single round of the skewing procedure will find a relevant variable with probability 1.) This result establishes that the approach taken by skewing is fundamentally sound. However, it says nothing about the effectiveness of skewing when, as is typically the case, the training set contains only a small fraction of the examples in the truth table. In particular, this result does not address the question of whether skewing would be effective given only a polynomial-size sample and polynomial time.

We also analyze a variant of skewing called *sequential skewing* (Ray and Page, 2004), in the case that the full truth table is given as input. Experiments indicate that sequential skewing scales better to higher dimensional problems than standard skewing. We show here, however, that even when the entire truth table is available as the training set, sequential skewing is ineffective for a subset of the correlation immune functions known as the *2-correlation immune* functions. A Boolean function $f : \{0,1\}^n \to \{0,1\}$ is 2-correlation immune if, for every pair of distinct input variables x_i and x_j, the variables x_i, x_j, and $f(x_1,\ldots,x_n)$ are mutually independent. Thus, any practical advantage sequential skewing has over standard skewing comes at the cost of not working on this subset of functions.

We present two new algorithms in the PDC model for identifying a relevant variable of an n-variable Boolean function with r relevant variables. The first algorithm uses only r distinct p-biased distributions (i.e., distributions in which each input variable is independently set to 1 with some fixed probability p). It runs in time polynomial in n and its sample size, which is $O((r+1)^{2r} \ln \frac{2nr}{\delta})$. (The algorithm is randomized, but we also give a deterministic version achieving slightly different bounds.) The second algorithm uses $O(e^{3r} \ln \frac{1}{\delta})$ p-biased distributions, and runs in time polynomial in n and the sample size, $O(e^{9r}(r + \ln \frac{n}{\delta}) \ln(\frac{1}{\delta}))$. Both algorithms choose the distributions they use non-adaptively. For $r = O(\log n)$, only the second algorithm runs in time polynomial in n, but the first uses $O(\log n)$ distributions, whereas the second uses a number of distributions that depends polynomially on n.

The second of our two algorithms is based on a new sample complexity result that we prove using martingales.

Previous algorithms for identifying relevant variables in the PDC model, and achieving bounds similar to ours, use distributions that are not p-biased, and choose the distributions they use adaptively. Independently, Arpe and Mossel (to appear) have recently developed an algorithm that is similar to our first algorithm. We discuss these related algorithms further in Sections 5 and 10.

Since p-biased distributions are skewed distributions, our algorithms can be viewed as skewing algorithms for a setting in which it is possible to sample directly from skewed distributions, rather than to just simulate those distributions.

We also examine skewing in the context for which it was originally designed: learning from a random sample drawn from the uniform distribution. We prove a negative result in this context, a sample complexity lower bound for the problem of learning parity functions. Technically, we prove the bound for a variant of skewing, called skewing with independent samples, that is more amenable to analysis than standard skewing. For intuitive reasons, and based on experimental evidence, we think it likely that the bound also holds for standard skewing. The bound implies that skewing with independent samples requires a sample of size at least $n^{\Omega(\log n)}$ to find (with constant probability of failure) a relevant variable of an n-variable Boolean function computing the parity of $\log n$ of its variables.

Correlation immunity is defined in terms of the uniform distribution. We discuss a natural extension of correlation immunity to non-uniform product distributions. We give a simple example of a function that is correlation immune with respect to a non-uniform product distribution. Thus while functions like parity are difficult for greedy learners when examples come from the uniform distribution, other functions can be difficult when examples come from another product distribution.

Our analysis of skewing given a complete data set, and our two new algorithms in the PDC model, are both based on a lemma that we prove which shows that Boolean functions have a certain useful property. Specifically, we show that every non-constant Boolean function f on $\{0,1\}^n$ has a variable x_i such that induced functions $f_{x_i \leftarrow 0}$ and $f_{x_i \leftarrow 1}$ on $\{0,1\}^{n-1}$ (produced by hardwiring x_i to 0 and 1) do not have the same number of positive examples of Hamming weight k, for some k. This lemma may be of independent interest.

3. Organization of the Paper

We first give some background on skewing in Section 4. In Section 5, we discuss related work. Section 6 contains basic definitions and lemmas, including characterizations of correlation immune functions, and simple lemmas on quantities such as Gini gain and the magnitude of the first-order Fourier coefficients. It also contains a simple example of a function that is correlation immune with respect to a non-uniform product distribution. Section 7 discusses sample complexity bounds used later in the paper, and proves an upper bound on the estimation of Gini gain, based on martingales.

In Section 8, we prove the lemma showing the useful property of Boolean functions.

We begin our analysis of skewing in Section 9 with results for the setting in which the entire truth table is given as the training set.

Section 10 contains our two new algorithms for the PDC model. It also contains a discussion of two PDC algorithms that are implicit in the literature.

Finally, Section 11 contains our sample complexity lower bounds on learning parity functions using skewing with independent samples.

4. Background on Skewing

As a motivating example, suppose we have a Boolean function $f(x_1,\ldots,x_n)$ whose value is the parity of r of its variables. Function f is correlation immune. With respect to the uniform distribution on the domain of f, all n variables of f have zero gain. Equivalently, the first-order Fourier coefficients of f are all zero (cf. Section 6.3). But, with respect to other product distributions on the examples, the r relevant variables of f have non-zero gain, while the $n-r$ irrelevant variables still have zero gain (see Page and Ray, 2003; Arpe and Reischuk, 2007). This suggests that learning correlation immune functions might be easier if examples could be obtained from non-uniform product distributions.

In many machine learning applications, however, we have little or no control over the distribution from which we obtain training data. The approach taken by skewing is to reweight the training data, to simulate receiving examples from another distribution. More particularly, the skewing algorithm works by choosing a "preferred setting" (either 0 or 1) for every variable x_i in the examples, and a weighting factor p where $\frac{1}{2} < p < 1$. These choices define a product distribution over examples $x \in \{0,1\}^n$ in which each variable x_i has its preferred setting with probability p, and the negation of that setting with probability $1-p$.

To simulate receiving examples from this product distribution, the skewing algorithm begins by initializing the weight of every example in the training set to 1. Then, for each x_i, and each example, it multiplies the weight of the example by p if the value of x_i in the example matches its preferred setting, and by $1-p$ otherwise. This process is called "skewing" the distribution. The algorithm computes the gain of each variable with respect to the reweighting. The algorithm repeats this procedure a number of times, with different preferred settings chosen each time. Finally, it uses all the calculated gains to determine which variable to output. The exact method used varies in different skewing implementations. In the paper that introduced skewing, the variable chosen was the one whose calculated gains exceeded a certain threshold the maximum number of times (Page and Ray, 2003).

In the context of decision tree learning, skewing is applied at every node of the decision tree, in place of standard gain calculations. After running skewing on the training set at that node, the variable chosen by the skewing procedure is used as the split variable at that node.

In investigating skewing, we are particularly interested in cases in which the number of relevant variables is much less than the total number of variables. Optimally, we would like sample complexity and running time to depend polynomially on n and 2^r (and on $\log\frac{1}{\delta}$), so that we have a polynomial-time algorithm when $r = O(\log n)$.

5. Related Work

Throughout this paper, we focus on the problem of finding a relevant variable of a target Boolean function, given a labeled sample drawn from the uniform distribution. Given a procedure that finds a single relevant variable x_i of a Boolean function f (for any f with at most r relevant variables), it is usually easy to extend the procedure to find all relevant variables of the target by recursively applying it to the induced functions obtained by hardwiring x_i to 1 and 0 respectively.

It is a major open problem whether there is a polynomial-time algorithm for finding relevant variables of a Boolean function of $\log n$ relevant variables (out of n total variables) using examples from the uniform distribution (cf. Blum, 2003). Mossel et al. (2003) gave an algorithm for learning

arbitrary functions on r relevant variables, using examples drawn from the uniform distribution, in time polynomial in n^{cr} and $\ln(1/\delta)$, for some $c < 1$. This improves on the naïve algorithm which requires time polynomial in n^r for small r. The heart of the algorithm is a procedure to find a relevant variable. The algorithm of Mossel et al. uses both Gaussian elimination and estimates of Fourier coefficients, and is based on structural properties of Boolean functions.

Mossel et al. also briefly considered the question of finding a relevant variable, given examples drawn from a single product distribution $[p_1, \ldots, p_n]$.[2] They stated a result that is similar to our Theorem 9.1, namely that if a product distribution is chosen at random, then with probability 1, the Fourier coefficient (for that distribution) associated with any relevant variable will be non-zero. The important difference between that result and Theorem 9.1 is that our theorem applies not to all random product distributions, but just to random skewed distributions. Since skewed distributions have measure zero within the space of all product distributions, the result of Mossel et al. does not imply anything about skewed distributions.

In interesting recent work that was done independently of this paper, Arpe and Mossel (to appear) addressed the problem of finding relevant variables of a Boolean function, using examples from biased distributions. If an input to a Boolean function f is drawn from a p-biased distribution, the output of f on that input is a random variable. Arpe and Mossel observed that the expectation of this random variable is a polynomial in the bias, and expressed the Maclaurin series for this polynomial in terms of the Fourier coefficients of f. They used this expression to develop a family of algorithms for identifying relevant variables. For a function with r relevant variables, the s-th algorithm estimates Fourier coefficients of Hamming weight up to s, using about r/s distributions. They also extended their algorithms to allow estimation of biases by sampling, a problem we do not address here.

Applying the results of Arpe and Mossel for $s = 1$ to the case of uniformly spaced biases yields an algorithm that is almost the same as our first algorithm, with a very different correctness proof. Although Arpe and Mossel did not give the sample size of their algorithm explicitly, some computations show that it is larger than the sample size we give (in Theorem 10.1), by a factor roughly equal to 16^r. Like us, they used a large deviation bound to derive a sample size, but they did not estimate parameters for this bound in the best way known. If that is done, following the approach of Furst et al. (1991), the discrepancy vanishes.

The problem of learning parity functions has been extensively studied in various learning models. It is a well-known open question whether it is possible to PAC-learn parity functions in polynomial time, using examples drawn from the uniform distribution, in the presence of random classification noise. This problem is at least as difficult as other open problems in learning; in fact, a polynomial time algorithm for this problem would imply a polynomial-time algorithm for the problem mentioned above, learning functions of $\log n$ relevant variables using examples from the uniform distribution (Feldman et al., 2006).

Our lower bound result for parity in Section 11 relies on Fourier-based techniques previously used to prove lower bounds for learning parity in statistical query (SQ) learning learning models (Blum et al., 1994; Jackson, 2003). Roughly speaking, statistical query learning algorithms learn a target function by adaptively specifying predicates that are defined over labeled examples of the

2. They also claimed that this result implies an algorithm for learning functions with r relevant variables in time polynomial in 2^r, n, and $\ln(1/\delta)$, given examples drawn from almost any product distribution. However, the justification for their claim was faulty, since it does not take into account the magnitude of the non-zero Fourier coefficient.

function. For each such predicate, the algorithm obtains an estimate (within a certain tolerance) of the probability that a random labeled example of the function satisfies the given predicate.

Jackson (2003) proved that that any "SQ-based" algorithm for learning the class of all parity functions takes time $\Omega(2^{n/2})$. Jackson also showed that a more complex argument could be used to prove a stronger bound of $\Omega(2^n)$. For the problem of learning just the parity functions having r relevant variables, rather than all parity functions, these bounds become $\Omega(\binom{n}{r}^{1/2})$ and $\Omega(\binom{n}{r})$ respectively. Although skewing with independent samples is not an SQ-based algorithm, we prove a bound that is similar to the weaker of these two bounds, using a similar technique. (Our bound is for identifying a single relevant variable of the target parity function, rather than for learning the function.) The proof of Jackson's stronger bound relies on properties of SQ-based algorithms that are not shared by skewing with independent samples, and it is an open question whether a similar bound is achievable for skewing with independent samples.

Subsequent to Jackson's work, Yang gave lower bounds for learning parity using "honest" statistical queries (Yang, 2001, 2005). While the gain estimates performed in skewing seem to correspond to honest statistical queries, the correspondence is not direct. One cannot determine the gain of a variable with respect to a skewed distribution by using only a single honest statistical query. Because lower bounds in statistical query models rely on the fact that only limited information can be obtained from the examples in the sample used to answer a single query, lower bounds for learning with honest statistical queries do not directly imply lower bounds for skewing with independent samples. Further, we were unable to verify relevant lower bounds given by Yang.[3]

At the other extreme from correlation-immune functions are functions for which all first order Fourier coefficients are non-zero (i.e., all relevant variables have non-zero gain). This is true of monotone functions (see Mossel et al., 2003). Arpe and Reischuk, extending previous results, gave a Fourier-based characterization of the class of functions that can be learned using a standard greedy covering algorithm (Arpe and Reischuk, 2007; Akutsu et al., 2003; Fukagawa and Akutsu, 2005). This class is a superset of the set of functions for which all relevant variables have non-zero degree-1 Fourier coefficients.

The PDC model investigated in this paper has some similarity to the extended statistical query model of Bshouty and Feldman (2002). In that model, the learner can specify a product distribution in which each variable is set to 1 with probability $\rho, 1/2$ or $1-\rho$, for some constant $1/2 > \rho > 0$. The learner can then ask a *statistical query* which will be answered with respect to the specified distribution. In the PDC model the user can specify an arbitrary product distribution, and can ask for random examples with respect to that distribution. One could simulate the extended statistical query model in the PDC model by using random examples (drawn with respect to the specified distribution) to answer the statistical queries.

A PDC algorithm for finding relevant variables is implicit in the work of Bshouty and Feldman (2002). We discuss this algorithm in some detail in Section 10. Its running time is polynomial in n and its sample size, which is $O(n2^{16r}\log^2\frac{n}{\delta} + nr2^{16r}\log\frac{n}{\delta})$. It uses n distributions. Like our second new algorithm, when $r = O(\log n)$ it runs in time polynomial in n and $\log\frac{1}{\delta}$. Unlike our new algorithms, it chooses its distributions adaptively, and uses distributions that are not p-biased.

3. Yang (2001) gives an explicit lower bound for learning parity with honest statistical queries, and credits Jackson for proving this implicitly (Jackson, 2003). However, Jackson's proof is for a different statistical query learning model, and his proof does not work for honest statistical queries. Yang (2005) states a general lower bound that can be applied to parity. Its proof, in particular the discussion of "bad queries," seems to us to be incomplete.

Nevertheless, the distributions used by this algorithm are simple. In each, one parameter of the distribution is equal to 1/2, while the others are all equal to 1/4.

As noted in the introduction, it is possible to simulate membership queries in the PDC model by setting the parameters of the chosen product distribution to 0 and 1. The problem of efficiently learning Boolean functions with few relevant variables, using membership queries alone, has been addressed in a number of papers (Blum et al., 1995; Bshouty and Hellerstein, 1998; Damaschke, 2000). The goal in these papers is to have *attribute-efficient* algorithms that use a number of queries that is polynomial in r, the number of relevant variables, but only logarithmic in n, the total number of variables. Guijarro et al. (1999) investigated the problem of identifying relevant variables in the PAC model with membership queries.

In Section 10 we briefly describe a simple adaptive algorithm for identifying relevant variables using membership queries and uniform random examples. The algorithm is not novel; a similar approach is used in a number of algorithms for related problems (see, e.g., Arpe and Reischuk, 2007; Guijarro et al., 1999; Blum et al., 1995; Damaschke, 2000; Bshouty and Hellerstein, 1998). The algorithm runs in time polynomial in n and $\log\frac{1}{\delta}$, and uses $\log n + 1$ distinct product distributions. The time and sample complexity are lower for this algorithm than for the other PDC algorithms discussed in this paper, and for $r = \Omega(\log n)$, the number of product distributions used is lower as well. However, the other algorithms use only distributions whose parameters are bounded away from 0 and 1.

We use Fourier-based techniques in proving some of our results. There is an extensive literature on using Fourier methods in learning, including some of the papers mentioned above. Some of the most important results are described in the excellent survey of Mansour (1994).

Correlation immune functions and k-correlation immune functions have applications to secure communication, and have been widely studied in that field (see Roy, 2002, for a survey). Recent citations stem from the work of Siegenthaler (1984), but research on correlation immune functions predates those citations. Golomb (1999) has pointed out that his work in the 1950's on the classification of Boolean functions (Golomb, 1959) was motivated by the problem, useful for missile guidance, of designing bit sequences that would resist prediction methods based on correlation. During that period, as he states, such military applications "were not explicitly mentioned in the open literature."

Correlation immune functions have also been studied in other fields under different guises. The truth table of a k-correlation immune function corresponds to a certain orthogonal array (Camion et al., 1991). Orthogonal arrays are used in experimental design. The positive examples of a k-correlation immune function form a k-wise independent set. Such sets are used in derandomization (see, e.g., Alon, 1996).

It is natural to ask how many n-variable Boolean functions are correlation immune, since these actually *need* skewing. The question has been addressed in a number of different papers, as described by Roy (2002). Counts of correlation immune functions up to $n = 6$, separated by Hamming weight, were computed by Palmer et al. (1992). For larger n one can use the analytic approximation $2^{2^n} \cdot P_n$, where

$$P_n = \frac{1}{2}\left(\frac{8}{\pi}\right)^{n/2} 2^{-n^2/2}\left(1 - \frac{n^2}{4 \cdot 2^n}\right).$$

Since there are 2^{2^n} Boolean functions in all, P_n approximates the probability that a random Boolean function is correlation immune. Its main term was found by Denisov (1992), and the rest is the

beginning of an asymptotic series investigated by Bach (to appear). Even for small n, the above approximation is fairly accurate. For example, there are 503483766022188 6-variable correlation immune functions, and the above formula gives 4.99×10^{14}.

Skewing was developed as an applied method for learning correlation-immune Boolean functions. Skewing has also been applied to non-Boolean functions, and to Bayes nets (Lantz et al., 2007; Ray and Page, 2005).

The main results in Sections 8 and 9 of this paper appeared in preliminary form in Rosell et al. (2005).

6. Preliminaries

We begin with basic definitions and fundamental lemmas.

6.1 Notation and Terminology

We consider two-class learning problems, where the features, or variables, are Boolean. A *target function* is a Boolean function $f(x_1,\ldots,x_n)$. An *example* is an element of $\{0,1\}^n$. Example $a \in \{0,1\}^n$ is a *positive example* of Boolean function $f(x_1,\ldots,x_n)$ if $f(a)=1$, and a *negative example* of f if $f(a)=0$. A *labeled example* is an element $(a,b) \in \{0,1\}^n \times \{0,1\}$; it is a labeled example of f if $f(a)=b$.

Let $f(x_1,\ldots,x_n)$ be a Boolean function. The function f is a mapping from $\{0,1\}^n$ to $\{0,1\}$. An *assignment* $a=(a_1,\ldots,a_n)$ to the variables $x_1,\ldots,x_n$ is an element of $\{0,1\}^n$. The assignment obtained from a by negating the ith bit of a is denoted by $a_{\neg x_i}$. Given a Boolean function $f(x_1,\ldots,x_n)$, variable x_i is a *relevant variable* of f if there exists $a \in \{0,1\}^n$ such that $f(a) \neq f(a_{\neg x_i})$.

A *parity function* is a Boolean function $f(x_1,\ldots,x_n)$ such that for some $I \subseteq \{1,\ldots,n\}$, $f(x) = (\sum_{i \in I} x_i) \bmod 2$ for all $x \in \{0,1\}^n$.

For $\sigma \in \{0,1\}^n$, let $\sigma^i = (\sigma_1,\ldots,\sigma_{i-1},\sigma_{i+1},\ldots,\sigma_n)$, that is, σ^i denotes σ with its ith bit removed.

A *truth table* for a function f over a set of variables is a list of all assignments over the variables, together with the mapping of f for each assignment. For $i \in [1\ldots n]$ and $b \in \{0,1\}$, $f_{x_i \leftarrow b}$ denotes the function on $n-1$ variables produced by "hardwiring" the ith variable of f to b. More formally, $f_{x_i \leftarrow b} : \{0,1\}^{n-1} \rightarrow \{0,1\}$ such that for all $a \in \{0,1\}^{n-1}$, $f_{x_i \leftarrow b}(a) = f(a_1,a_2,\ldots,a_{i-1},b,a_i,\ldots,a_{n-1})$.

The integers between 1 and n are denoted by $[1\ldots n]$. For real a and b, (a,b) denotes the open interval from a to b.

For any probability distribution D, we use $\Pr_D$ and E_D to denote the probability and expectation with respect to distribution D. When D is defined on a finite set X and $A \subseteq X$, we define $\Pr_D(A)$ to be equal to $\sum_{a \in A} \Pr_D(a)$. We omit the subscript D when it is clear from context.

Given a probability distribution D on $\{0,1\}^n$, and a Boolean function $f : \{0,1\}^n \rightarrow \{0,1\}$, a *random example of f drawn with respect to D* is an example $(x, f(x))$ where x is drawn with respect to D.

A training set T for learning an n-variable Boolean function is a multiset consisting of elements in $\{0,1\}^n \times \{0,1\}$. It defines an associated distribution on $\{0,1\}^n \times \{0,1\}$ sometimes known as the *empirical distribution*. For each $(a,y) \in \{0,1\}^n \times \{0,1\}$, the probability of (a,y) under this distribution is defined to be the fraction of examples in the training set that are equal to (a,y). In the absence of noise, a training set for learning a function $f : \{0,1\}^n \rightarrow \{0,1\}$ is a set of labeled examples $(x, f(x))$. The empirical distribution on such a training set can be viewed as a distribution on $\{0,1\}^n$, rather than on $\{0,1\}^n \times \{0,1\}$.

A product distribution D on $\{0,1\}^n$ is a distribution defined by a parameter vector $[p_1,\ldots,p_n]$ in $[0,1]^n$ where for all $x \in \{0,1\}^n$, $\Pr_D[x] = (\prod_{i:x_i=1} p_i)(\prod_{i:x_i=0}(1-p_i))$. The uniform distribution on $\{0,1\}^n$ is the product distribution defined by $[1/2,1/2,\ldots,1/2]$. For fixed $p \in (0,1)$, we use $D[p]$ to denote the product distribution defined by $[p,\ldots,p]$. Distribution $D[p]$ is the *p-biased distribution*.

A *skew* is a pair (σ,p) where $\sigma \in \{0,1\}^n$ is an assignment, and $p \in (0,1)$. We refer to σ as the *orientation* of the skew, and p as the *weighting factor*.

Each skew (σ,p) induces a probability distribution $D_{(\sigma,p)}$ on the 2^n assignments in $\{0,1\}^n$ as follows. Let $\tau_p : \{0,1\} \times \{0,1\} \to \{p,1-p\}$ be such that for $b,b' \in \{0,1\}$, $\tau_p(b,b') = p$ if $b = b'$ and $\tau_p(b,b') = 1-p$ otherwise. For each $a \in \{0,1\}^n$, distribution $D_{(\sigma,p)}$ assigns probability $\Pi_{i=1}^n \tau_p(\sigma_i,a_i)$ to a. Thus distribution $D_{(\sigma,p)}$ is a product distribution in which every variable is set to 1 either with probability p, or with probability $1-p$. We call distributions $D_{(\sigma,p)}$ *skewed distributions*. When $\sigma = (1,\ldots,1)$, the distribution $D_{(\sigma,p)}$ is the p-biased distribution $D[p]$.

We note that in other papers on skewing, p is required to be in $(1/2,1)$, rather than in $(0,1)$. Here it is more convenient for us to let p be in $(0,1)$. Given any orientation σ, and any $p \in (0,1)$, skew $(\bar{\sigma},1-p)$, where $\bar{\sigma}$ is the bitwise complement of σ, induces the same distribution as (σ,p). Thus allowing p to be in $(0,1)$ does not change the class of skewed distributions, except that we also include the uniform distribution.

Given $a,b \in \{0,1\}^n$, let $\Delta(a,b) = |\{i \in [1,\ldots,n] | a_i \neq b_i\}|$, that is, $\Delta(a,b)$ is the Hamming distance between a and b. For $a,b \in \{0,1\}^n$, let $a+b$ denote the componentwise mod 2 sum of a and b. Given $c \in \{0,1\}^n$, we use $w(c)$ to denote the Hamming weight (number of 1's) of c. Thus $w(a+b) = \Delta(a,b)$.

In the *product distribution choice* (PDC) learning model, the learning algorithm has access to a special type of random example oracle for a target function $f(x_1,\ldots,x_n)$. This random example oracle takes as input the parameters $[p_1,\ldots,p_n]$ of a product distribution D over unlabeled examples $(x_1,\ldots,x_n)$. The oracle responds with a random example $(x_1,\ldots,x_n)$ drawn according to the requested distribution D, together with the value of the target f on that example. The learning algorithm is given as input a confidence parameter δ, where $0 < \delta < 1$. The algorithm is also given n as input.

6.2 Gain

Greedy tree learners partition a data set recursively, choosing a "split variable" at each step. They differ from one another primarily in their measures of "goodness" for split variables. The measure used in the well-known CART system is *Gini gain* (Breiman et al., 1984). Gini gain was also used in the decision tree learners employed in experimental work on skewing (Page and Ray, 2003; Ray and Page, 2004). In this paper, we use the term "gain" to denote Gini gain.

Gini gain is defined in terms of another quantity called the *Gini index*. Let S be a (multi) set of labeled examples. Let $S_1 = \{(x,y) \in S | y = 1\}$ and $S_0 = \{(x,y) \in S | y = 0\}$. The Gini index of S is $2\frac{|S_1||S_0|}{|S|^2}$. Let $\tilde{H}(S)$ denote the Gini index of S.

Let x_i be a potential split variable. Let $T_1 = \{(x,y) \in S | x_i = 1\}$ and $T_0 = \{(x,y) \in S | x_i = 0\}$. The Gini index of S *conditional on* x_i is defined to be $\tilde{H}(S|x_i) := \frac{|T_1|}{|S|}\tilde{H}(T_1) + \frac{|T_0|}{|S|}\tilde{H}(T_0)$. In decision tree terms, this is the weighted sum of the Gini indices of the child nodes resulting from a split on x_i. The *Gini gain* of x_i with respect to S is

$$G(S,x_i) = \tilde{H}(S) - \tilde{H}(S|x_i).$$

The Gini gain is always a value in the interval $[0,1/2]$. Some definitions of Gini gain and Gini index differ from the one above by a factor of 2; our definition follows that of Breiman et al. (1984).

Now suppose that each example in our (multi) set S has an associated *weight*, a real number between 0 and 1. We can define the gain on this weighted set by modifying the above definitions in the natural way: each time the definitions involve the size of a set, we instead use the sum of the weights of the elements in the set.

We can also define Gini index and Gini gain of variable x_i with respect to $f : \{0,1\}^n \to \{0,1\}$ under a distribution D on $\{0,1\}^n$. The Gini index of f with respect to a probability distribution D on $\{0,1\}^n$ is $2\Pr_D[f=1](1-\Pr_D[f=1])$. Let $\tilde{H}_D(f)$ denote the Gini index of f with respect to D. For any potential split variable x_i, the Gini index of f with respect to D, *conditional on* x_i is $\tilde{H}_D(f|x_i) := \Pr_D[x_i=0]\tilde{H}_D(f_{x_i \leftarrow 0}) + \Pr_D[x_i=1]\tilde{H}_D(f_{x_i \leftarrow 1})$. The *Gini gain* of a variable x_i with respect to f, under distribution D, is

$$G_D(f,x_i) = \tilde{H}_D(f) - \tilde{H}_D(f|x_i).$$

The Gini gain of x_i with respect to f, under the uniform distribution on $\{0,1\}^n$, is equal to the Gini gain of x_i with respect to the training set T consisting of all entries in the truth table of f.

Given a skew (σ, p) and a function f, the Gini gain of a variable x_i with respect to f under distribution $D_{(\sigma,p)}$ is equivalent to the gain that is calculated, using the procedure described in Section 4, by applying skew (σ, p) to the training set T consisting of the entire truth table for f.

The following lemma relates the size of the Gini gain with respect to a distribution D to the difference in the conditional probabilities $\Pr_D[f=1|x_i=1] - \Pr_D[f=1|x_i=0]$.

Lemma 1 *Let f be an n-variable Boolean function, and let D be a distribution on $\{0,1\}^n$ such that $\Pr[x_i=1]$ is strictly between 0 and 1. Then $G_D(f,x_i)$, the Gini gain of variable x_i with respect to f, under distribution D, is equal to*

$$2p_i(1-p_i)(Pr_D[f=1|x_i=1] - Pr_D[f=1|x_i=0])^2$$

where $p_i = \Pr_D[x_i=1]$.

Proof. Let $p = p_i$, $\beta = \Pr_D[f=1]$, $\beta_1 = \Pr_D[f=1|x_i=1]$, and $\beta_0 = \Pr_D[f=1|x_i=0]$. Thus $\beta = p\beta_1 + (1-p)\beta_0$.

The Gini gain of x_i with respect to f is

$$\begin{aligned}
&2(\beta(1-\beta) - p(\beta_1(1-\beta_1)) - (1-p)(\beta_0(1-\beta_0))) \\
&\quad = 2(\beta(1-\beta) - (p\beta_1 + (1-p)\beta_0)) + p\beta_1^2 + \beta_0^2(1-p) \\
&\quad = 2(\beta(1-\beta) - \beta + p\beta_1^2 + \beta_0^2(1-p)) \\
&\quad = 2(-\beta^2 + p\beta_1^2 + \beta_0^2(1-p)).
\end{aligned}$$

Substituting $p\beta_1 + (1-p)\beta_0$ for β, we get that the last quantity is

$$\begin{aligned}
&= 2(-p^2\beta_1^2 - 2p(1-p)\beta_0\beta_1 - (1-p)^2\beta_0^2 + p\beta_1^2 + \beta_0^2(1-p)) \\
&= 2((1-p)p(\beta_1^2 - 2\beta_0\beta_1 + \beta_0^2)) \\
&= 2p(1-p)(\beta_1 - \beta_0)^2
\end{aligned}$$

□

Under distribution D on $\{0,1\}^n$, x_i and (the output of) f are independent iff $G_D(f,x_i)=0$.

6.3 Fourier Coefficients

Given a Boolean function $f:\{0,1\}^n\to\{0,1\}$, define an associated function $F=1-2f$. That is, $F:\{0,1\}^n\to\{1,-1\}$ is such that $F(x)=1-2f(x)$ for all $x\in\{0,1\}^n$. The function F can be seen as an alternative representation of Boolean function f, using -1 and 1 respectively to represent true and false outputs, rather than 1 and 0.

For every $z\in\{0,1\}^n$, let $\chi_z:\{0,1\}^n\to\{1,-1\}$ be such that $\chi_z(x)=(-1)^{\sum_{i=1}^n x_i z_i}$. Thus χ_z is the alternative representation of the function computing the parity of the variables set to 1 by z. For $z\in\{0,1\}^n$, n-variable Boolean function f, and associated $F=1-2f$, the *Fourier coefficient* $\hat{f}(z)$ is

$$\hat{f}(z):=E[F(x)\chi_z(x)]$$

where the expectation is with respect to the uniform distribution on $x\in\{0,1\}^n$.

The *degree* of Fourier coefficient $\hat{f}(z)$ is $w(z)$, the Hamming weight of z. The Fourier coefficient *associated with the variable* x_i is $\hat{f}(z)$ where z is the characteristic vector of x_i (i.e., $z_i=1$ and for $j\neq i$, $z_j=0$). In an abuse of notation, we will use $\hat{f}(x_i)$ to denote this Fourier coefficient. Thus $\hat{f}(x_i)=E[F(x)(1-2x_i)]$. The function F can be expressed by its Fourier series, as we have $F(x)=\sum_{z\in\{0,1\}^n}\hat{f}(z)\chi_z(x)$.

Fourier coefficients can be generalized from the uniform distribution to product distributions, as described by Furst et al. (1991). Let D be a product distribution on $\{0,1\}^n$ defined by parameters $[p_1,\ldots,p_n]$, all of which are strictly between 0 and 1. For $z\in\{0,1\}^n$, let $\phi_{D,z}:\{0,1\}^n\to\{0,1\}$ be such that $\phi_{D,z}(x)=\prod_{i:z_i=1}\frac{\mu_i-x_i}{\sigma_i}$ where $\mu_i=p_i$ is $E_D[x_i]$ and $\sigma_i=\sqrt{p_i(1-p_i)}$ is the standard deviation of x_i under D. The Fourier coefficient $\hat{f}_D(z)$, for product distribution D, is

$$\hat{f}_D(z):=E_D[F(x)\phi_{D,z}(x)].$$

When D is the uniform distribution, this is the ordinary Fourier coefficient.

Parseval's identity, applied to the Fourier coefficients of product distributions, states that

$$\sum_{z\in\{0,1\}^n}\hat{f_D}^2(z)=1.$$

The Fourier coefficient associated with the variable x_i, with respect to product distribution D, is $\hat{f}_D(z)$, where z is the characteristic vector of x_i. Abusing notation as before, we will use $\hat{f}_D(x_i)$ to denote this Fourier coefficient. Thus

$$\hat{f}_D(x_i)=\frac{p_iE_D[F(x)]-E_D[x_iF(x)]}{\sqrt{p_i(1-p_i)}}.$$

The next lemma shows that the gain of a variable and its Fourier coefficient are closely related.

Lemma 2 *Let f be an n-variable Boolean function, and let D be a product distribution over $\{0,1\}^n$ defined by $[p_1,\ldots,p_n]$, such that each $p_i\in(0,1)$. Then*

$$\hat{f}_D(x_i)=2\sqrt{p_i(1-p_i)}(\Pr_D[f=1|x_i=1]-\Pr_D[f=1|x_i=0])$$

and

$$G_D(f,x_i)=\hat{f}_D^2(x_i)/2.$$

Proof. By definition,

$$\hat{f}(x_i) = \frac{p_i E_D[F(x)] - E_D[x_i F(x)]}{\sqrt{p_i(1-p_i)}}.$$

Let $\beta = \Pr_D[f = 1]$ (which equals $\Pr_D[F = -1]$), $\beta_1 = \Pr_D[f = 1 | x_i = 1]$, and $\beta_0 = \Pr_D[f = 1 | x_i = 0]$.

Since $p_i E_D[F(x)] = p_i(1-2\beta)$, $E_D[F(x)x_i] = p_i(1-2\beta_1)$, and $\beta = p_i\beta_1 + (1-p_i)\beta_0$, it follows that

$$\begin{aligned} p_i E_D[F(x)] - E_D[x_i F(x)] &= 2p_i(-\beta + \beta_1) \\ &= 2p_i(-p_i\beta_1 - (1-p_i)\beta_0 + \beta_1) \\ &= 2p_i(1-p_i)(\beta_1 - \beta_0). \end{aligned}$$

Dividing by $\sqrt{p_i(1-p_i)}$, we have that

$$\hat{f}_D(x_i) = 2\sqrt{p_i(1-p_i)}(\Pr_D[f = 1 | x_i = 1] - \Pr_D[f = 1 | x_i = 0]).$$

The lemma follows immediately from Lemma 1. □

The following important facts about first-order Fourier coefficients for product distributions are easily shown. For D a product distribution on $\{0,1\}^n$ where each $p_i \in (0,1)$,

1. If x_i is an irrelevant variable of a Boolean function f, then $\hat{f}_D(x_i) = 0$.

2. $G_D(f, x_i) = 0$ iff $\hat{f}_D(x_i) = 0$.

6.4 Correlation Immune Functions

For $k \geq 1$, a Boolean function is defined to be *k-correlation immune* if for all $1 \leq d \leq k$, all degree-d Fourier coefficients of f are equal to 0. An equivalent definition is as follows (Xiao and Massey, 1988; Brynielsson, 1989). Let $x_1, \ldots, x_n$ be random Boolean variables, each chosen uniformly and independently. Let $y = f(x_1, \ldots, x_n)$. Then f is k-correlation immune if and only if, for any distinct variables $x_{i_1}, \ldots, x_{i_k}$ of f, the variables $y, x_{i_1}, x_{i_2}, \ldots, x_{i_k}$ are mutually independent.

A greedy decision tree learner would have difficulty learning k-correlation immune functions using only k-lookahead; to find relevant variables in the presence of irrelevant ones for such functions, it would need to use $k+1$-lookahead.

A Boolean function is *correlation immune* if it is 1-correlation immune. Equivalently, a Boolean function f is correlation immune if all variables of f have zero gain for f, with respect to the uniform distribution on $\{0,1\}^n$. As can be seen from Lemma 1, this is the case iff for every input variable x_i of the function, $\Pr[f = 1 | x_i = 1] = \Pr[f = 1 | x_i = 0]$, where probabilities are with respect to the uniform distribution on $\{0,1\}^n$. The following alternative characterization of correlation-immune functions immediately follows: A Boolean function is correlation-immune iff

$$|\{a \in \{0,1\}^n \mid f(a) = 1 \text{ and } a_i = 1\}| = |\{a \in \{0,1\}^n \mid f(a) = 1 \text{ and } a_i = 0\}|.$$

6.5 Correlation Immune Functions for Product Distributions

Correlation immune functions are defined with respect to the uniform distribution. Here we extend the definition to apply to arbitrary product distributions with parameters strictly between 0 and 1. In particular, for such a product distribution D, we can define a function to be *correlation immune for* D if either (1) The degree-1 Fourier coefficients with respect to D are all 0, or (2) the gain of every variable with respect to D is 0, or (3) $\Pr_D[f = 1|x_i = 1] - \Pr_D[f = 1|x_i = 0] = 0$ for all variables x_i of f. By the results in Section 6, these conditions are equivalent.[4]

A natural question is whether there are (non-constant) correlation immune functions for non-uniform product distributions D. There are, as illustrated by the following example, which can be easily generalized to other similar product distributions.

6.5.1 EXAMPLE

Let n be a multiple of 3, and let D be the product distribution defined by $[2/3, 2/3, \ldots, 2/3]$.

For any n that is a multiple of 3, we will show that the following function f is correlation immune with respect to D.

Let f be the n-variable Boolean function such that $f(x) = 1$ if $x = 110110110110\ldots$ (i.e., $n/3$ repetitions of 110), or when x is equal to one of the two right-shifts of that vector. For all other x, $f(x) = 0$.

To prove correlation immunity, it suffices to show that for each x_i, $\Pr_D[f = 1|x_i = 1] = \Pr_D[f = 1]$.

Each positive example of f has the same probability. It is easy to verify that for each x_i, 2/3 of the positive examples have $x_i = 1$. Thus $\Pr_D[f = 1 \text{ and } x = 1] = 2/3 \Pr_D[f = 1]$. So,

$$\begin{aligned} \Pr_D[f = 1|x = 1] &= \Pr_D[f = 1 \text{ and } x = 1]/\Pr_D[x = 1] \\ &= (2/3\Pr_D[f = 1])/(2/3) \\ &= \Pr_D[f = 1] \end{aligned}$$

□

In Section 9 we will give examples of product distributions D for which there are no correlation-immune functions.

7. Estimating First-order Fourier Coefficients and Gain

Fourier-based learning algorithms work by computing estimates of selected Fourier coefficients using a sample. Given a training set $S = \{(x^{(1)}, y^{(1)}), \ldots, (x^{(m)}, y^{(m)})\}$ for a Boolean function f and $z \in \{0,1\}^n$, the *estimated Fourier coefficient for z, calculated on S, with respect to product distribution D,* is

$$\hat{f}_{S,D}(z) := \frac{1}{m} \sum_{j=1}^{m} (1 - 2y^{(j)}) \phi_{D,z}(x^{(j)}).$$

We will use $\hat{f}_{S,D}(x_i)$ to denote $\hat{f}_{S,D}(z)$, where z is the characteristic vector of x_i.

4. We do not extend the definition of correlation-immunity to non-product distributions. With respect to a non-product distribution, it is possible for both relevant and irrelevant variables to have non-zero gain.

To simplify notation, where D is clear from context, we will often write $\hat{f}_S(z)$ instead of $\hat{f}_{S,D}(z)$. Since $\phi_{D,z}$ depends on D, calculating $\hat{f}_S(z)$ from S requires knowledge of D. Since we will apply this lemma in the context of the PDC model, in which D is known, this is not a problem for us.

If S is a random sample of f drawn with respect to D, then $\hat{f}_D(z) = E_D[(1-2f(x))\phi_{D,z}(x)]$ and $\hat{f}_{S,D}(z)$ is the estimate of the expectation $E_D[(1-2f(x))\phi_{D,z}(x)]$ on sample S.

In Section 10, there are situations in which we will know that, with respect to a known product distribution D, there exists a relevant variable of a function f whose first-order Fourier coefficient has magnitude at least q, for some value q. As mentioned earlier, the first-order Fourier coefficients of irrelevant variables are zero. Thus if one can estimate first-order Fourier coefficients of f so the estimates each have additive error less than $q/2$, then a non-empty subset of the relevant variables of f can be constructed by taking all variables whose Fourier coefficient estimates are at least $q/2$. The following lemma gives an upper bound on the sample size that would be needed to produce the desired estimates with high probability (by setting $\varepsilon = q/2$). The lemma is implicit in the paper of Furst et al. (1991), and follows from a standard bound of Hoeffding.

Lemma 3 *Let f be an n-variable Boolean function and let D be a product distribution over $\{0,1\}^n$ defined by $[p_1,\ldots,p_n]$. Let $\beta = \max_i\{1/p_i, 1/(1-p_i)\}$, $\varepsilon > 0$, and $0 < \delta < 1$. If S is a set of at least*

$$\frac{1}{\varepsilon^2} 2(\beta-1)\ln\frac{2n}{\delta}$$

random examples of f, drawn from distribution D, then with probability at least $1-\delta$, $|\hat{f}_{S,D}(x_i) - \hat{f}_D(x_i)| < \varepsilon$ for all variables x_i of f.

The above lemma is useful only in situations in which the parameters of D are known, so that $\hat{f}_D$ can be computed. A similar bound can be applied when D is an unknown product distribution, and its parameters are estimated from the sample (see Furst et al., 1991).

Skewing works by estimating gain, rather than by estimating first-order Fourier coefficients. More generally, one can use gain estimates rather than Fourier coefficient estimates to try to identify relevant variables of a function (assuming some have non-zero gain). Below in Lemma 6 we give a sample-complexity bound for estimating gain. We prove this bound using martingales. In contrast to the bound given in Lemma 3, this bound can be applied in cases where the distribution is unknown and arbitrary (i.e., it does not have to be a product distribution).

Before presenting the martingale-based bound, however, we first prove a bound that easily follows from the work of Furst et al. (1991) and the relationship between gain and first-order Fourier coefficients given in Lemma 2. The bound itself is the same as the bound for estimating Fourier coefficients given in Lemma 3. Algorithmically, the bound applies to the following procedure for estimating $G(D,x_i)$, when D is a known product distribution. Given a sample S, use it to compute the estimate $\hat{f}_S(x_i)$ of the Fourier coefficient of x_i. If $\hat{f}_S(x_i)$ is in the interval $[-1,1]$, then let $\tilde{f}_S(x_i) = \hat{f}_S(x_i)$, otherwise, let $\tilde{f}_S(x_i) = 1$ if $\hat{f}_S(x_i)$ is positive, and $\tilde{f}_S(x_i) = -1$ otherwise. Thus $\tilde{f}_S(x_i)$ is $\hat{f}_S(x_i)$, restricted to the interval [-1,1]. Output $(\tilde{f}_S(x_i))^2/2$ as the estimate for $G_D(f,x_i)$.

Lemma 4 *Let f be an n-variable Boolean function and let D be a product distribution over $\{0,1\}^n$ defined by $[p_1,\ldots,p_n]$. Let $\beta = \max_i\{1/p_i, 1/(1-p_i)\}$, $\varepsilon > 0$, and $0 < \delta < 1$. If S is a set of*

$$\frac{1}{\varepsilon^2} 2(\beta-1)\ln\frac{2n}{\delta}$$

random examples of f, drawn from distribution D, then with probability at least $1-\delta$, $|(\tilde{f}_S(x_i))^2/2 - G_D(f,x_i)| \leq \varepsilon$.

Proof. By Lemma 2, $G_D(f,x_i) = \frac{\hat{f}_D^2(x_i)}{2}$. Let $Y = \hat{f}_D(x_i)$ and let $\tilde{Y} = \tilde{f}_S(x_i)$. By Lemma 3, with probability at least $1-\delta$, $|\hat{f}_S(x_i) - Y| < \varepsilon$. As noted by Furst et al. (1991), since Y is a Fourier coefficient, $Y \in [-1,1]$, and thus restricting the estimate of Y to $[-1,1]$ can only increase its accuracy. Thus $|\tilde{Y} - Y| < \varepsilon$ as well. It follows that $|\tilde{Y}^2/2 - G_D(f,x_i)| = |\tilde{Y}^2/2 - Y^2/2| = \frac{1}{2}|(\tilde{Y}-Y)(\tilde{Y}+Y)| \leq \varepsilon$, since $|\tilde{Y}+Y| \leq 2$. □

The bound in the above lemma is similar to the martingale-based bound we give below in Lemma 6. The main difference is that it has a factor of $(\beta - 1)$, meaning that it depends on p_i. In Section 10, Theorem 10.2, we apply Lemma 6 to prove a sample complexity result for an algorithm in the PDC model. In this context, p_i is not constant, and applying the bound in Lemma 4 instead would yield a slightly worse sample complexity for the algorithm (by a factor of $O(r)$). We now proceed with the presentation of the martingale-based bound. The bound is based on a standard large deviation estimate, which can be thought of as a "vector" version of the Chernoff bound. It implies that a martingale is unlikely to wander too far from its initial value.

We recall some definitions. Let $Z(0), Z(1), \ldots$ be a discrete-time Markov process in $\mathbb{R}^k$ with differences bounded by c. That is, $Z(0), Z(1), \ldots$ are random variables taking values in $\mathbb{R}^k$, such that the distribution of $Z(t+1)$ given $Z(u)$ for all $u \leq t$ depends only on $Z(t)$, and for each pair $Z(t), Z(t+1)$ the L_2 norm $||Z(t+1) - Z(t)||$ is at most c. We call the process a *martingale* if for all $t \geq 0$, $E[Z(t)]$ exists, and $E[Z(t+1)|Z(t)] = Z(t)$. (More general definitions exist, but this will suffice for our purpose.)

Lemma 5 *Let $Z(t)$ be a martingale in R^k with differences bounded by c. Then for any $\lambda > 0$,*

$$\Pr[\ ||Z(t) - Z(0)|| \geq \lambda\ ] \leq 2\exp(\frac{-\lambda^2}{2tc^2}). \tag{1}$$

Proof See, for example, Pinelis (1992). □

Lemma 6 *Let f be an n-variable Boolean function and let D be a product distribution over $\{0,1\}^n$ whose parameters are in $(0,1)$. Let $\varepsilon > 0$, and $0 < \delta < 1$. If S is a set of at least*

$$256\ln(2n/\delta)/\varepsilon^2$$

random examples of f, drawn from distribution D, then with probability at least $1-\delta$, $|G(S,x_i) - G_D(f,x_i)| \leq \varepsilon$ for all variables x_i of f.

Proof Let x_i be a variable, and consider the 2×2 table

	$f=0$	$f=1$
$x_i = 0$	a_1	a_2
$x_i = 1$	a_3	a_4

In this table, the a_j's are probabilities, so that a_1 denotes the probability (under D) that $x_i = f = 0$, and similarly for the others. Therefore, $0 \leq a_j \leq 1$, and $\sum a_j = 1$.

By drawing a random sample S of f from distribution D, we get counts m_1, m_2, m_3, m_4 corresponding to the a_j's. For example, m_2 is the number of examples in S for which $x_i = 0$ and $f = 1$. We can view the sampling procedure as happening over time, where the tth example is drawn at time t.

At times $t = 0, 1, 2, \ldots$, we can observe

$$Z(t) := (m_1 - a_1 t, m_2 - a_2 t, m_3 - a_3 t, m_4 - a_4 t).$$

By the definition of Z,

$$\begin{aligned} E[Z(t+1) - Z(t) | Z(t)] &= a_1(1-a_1, -a_2, -a_3, -a_4) + a_2(-a_1, 1-a_2, -a_3, -a_4) \\ &\quad + a_3(-a_1, -a_2, 1-a_3, -a_4) + a_4(-a_1, -a_2, -a_3, 1-a_4) \\ &= (0,0,0,0) \end{aligned}$$

where the last equation follows because $\sum a_j = 1$. Thus $Z(0), Z(1), \ldots$ is a martingale in $\mathbf{R}^4$. Also, $Z(t+1) - Z(t)$ equals, up to symmetry, $(1-a_1, -a_2, -a_3, -a_4)$. Since $a_2^2 + a_3^2 + a_4^2 \leq 1$,

$$(1-a_1)^2 + a_2^2 + a_3^2 + a_4^2 \leq 2,$$

and the martingale has differences bounded by $c = \sqrt{2}$.

The gain of x_i in f with respect to distribution D is

$$G_D(f, x_i) = 2\left[\beta(1-\beta) - p\beta_1(1-\beta_1) - (1-p)\beta_0(1-\beta_0)\right]$$

where

$$\beta = \Pr[f = 1] = a_2 + a_4,$$

$$p = \Pr[x_i = 1] = a_3 + a_4,$$

$$\beta_0 = \Pr[f = 1 | x_i = 0] = \frac{a_2}{a_1 + a_2},$$

and

$$\beta_1 = \Pr[f = 1 | x_i = 1] = \frac{a_4}{a_3 + a_4}.$$

Substituting these into the above gain formula and simplifying, we get

$$G_D(f, x_i) = 2\left[(a_1 + a_3)(a_2 + a_4) - \frac{a_3 a_4}{a_3 + a_4} - \frac{a_1 a_2}{a_1 + a_2}\right].$$

Define the function $G(a_1, \ldots, a_4)$ to be equal to the right hand side of the above equation. This is a continuous function of the a_j's, on the simplex $a_j \geq 0, \sum a_j = 1$.

Observe that

$$0 < \frac{\partial}{\partial a_j}\left(\frac{a_j a_k}{a_j + a_k}\right) = \frac{1}{(a_j/a_k + 1)^2} < 1,$$

if $a_j, a_k > 0$, and

$$0 \leq \frac{\partial}{\partial a_j}(a_1 + a_3)(a_2 + a_4) \leq \sum a_i = 1.$$

This implies that $\left|\partial G / \partial a_j\right| \leq 2$ in the interior of the simplex.

Suppose that $b = (b_1, b_2, b_3, b_4)$ and $c = (c_1, c_2, c_3, c_4)$ are two points on the interior of the simplex with $\max_j\{|c_j - b_j|\} = \mu$. Let $a(t) = b + t(c - b)$ be the the parametric equation of the line from b to c, and let $\tilde{G}(t) = G(a(t))$.

Letting $a_i(t)$ be the ith coordinate of $a(t)$, and applying the chain rule, we get that

$$\frac{\partial \tilde{G}}{\partial t} = \sum_i \frac{\partial \tilde{G}}{\partial a_i} \frac{da_i}{dt}. \tag{2}$$

Since $\tilde{G}(0) = G(b)$ and $\tilde{G}(1) = G(c)$, by the mean value theorem, there exists $t^* \in [0,1]$ such that

$$\frac{\partial \tilde{G}}{\partial t}(t^*) = G(c) - G(b). \tag{3}$$

For $(a_1, \ldots, a_4)$ in the interior of the simplex, $\left|\partial \tilde{G}/\partial a_i\right| \leq 2$. By the definition of $a(t)$, $|da_i/dt| = |c_i - b_i| \leq \mu$. Thus (2) and (3) imply that

$$|G(c) - G(b)| \leq 8\mu. \tag{4}$$

Since G is continuous, this holds even for probability vectors b and c on the boundary.

We seek a sample size m large enough that (for all variables x_i)

$$\Pr[\ |G(S, x_i) - G_D(f, x_i)| \geq \varepsilon\ ] \leq \frac{\delta}{n}.$$

Let the empirical frequencies be $\hat{a}_j = m_i/m$, $i = 1, \ldots, 4$. By (4), it will suffice to make m large enough that, with probability at least $1 - \delta/n$, we observe $|\hat{a}_j - a_j| < \varepsilon/8$ for all j. Let's call a sample "bad" if for some j, $|m_j/m - a_j| \geq \varepsilon/8$. Since $Z(0) = \vec{0}$, this implies that $||Z(m) - Z(0)|| \geq \varepsilon m/8$. If we take $\lambda = \varepsilon m/8$, $c = \sqrt{2}$, and $t = m$ in the Chernoff bound (1), we see that

$$\Pr[\text{ bad sample }] \leq 2e^{-\frac{\varepsilon^2 m}{256}}.$$

This will be less than δ/n as soon as

$$m \geq \frac{256 \ln(2n/\delta)}{\varepsilon^2}.$$

□

8. A Property of Non-constant Boolean Functions

In this section we prove a property of Boolean functions that we will use repeatedly in subsequent sections. The property is given in the following lemma.

For $k \in [0, \ldots, n]$, let $W_k(f)$ denote the number of positive assignments of f of Hamming weight k.

Lemma 7 *Let f be a non-constant Boolean function on $\{0,1\}^n$. Then there exists a variable x_i of f and a number $k \in [0, \ldots, n-1]$ such that $W_k(f_{x_i \leftarrow 0}) \neq W_k(f_{x_i \leftarrow 1})$.*

Proof. Assume no such variable x_i exists.

Without loss of generality, assume that $f(0^n) = 1$. We prove that for all $a \in \{0,1\}^n$, $f(a) = 1$. The proof is by induction on the Hamming weight of a, $w(a)$. The base case clearly holds.

Now let $j \in [0,\ldots,n-1]$. Assume inductively that all assignments x of Hamming weight j satisfy $f(x) = 1$. Let $l \in [1,\ldots,n]$. Let $t \in \{0,1\}^n$ be an arbitrary assignment of Hamming weight j such that $t_l = 0$; t exists because $j < n$. By the initial assumption, $W_j(f_{x_l \leftarrow 0}) = W_j(f_{x_l \leftarrow 1})$. Further, by the inductive assumption, for every assignment u such that $w(u) = j$, $f(u) = 1$. There are precisely $\binom{n-1}{j}$ assignments u such that $w(u) = j$ and $u_l = 0$. All these assignments u satisfy $f(u) = 1$, and thus $W_j(f_{x_l \leftarrow 0}) = \binom{n-1}{j}$. Therefore $W_j(f_{x_l \leftarrow 1}) = \binom{n-1}{j}$ also. The quantity $\binom{n-1}{j}$ is equal to the total number of assignments in $\{0,1\}^{n-1}$ of Hamming weight j. It follows that $f_{x_l \leftarrow 1}(b) = 1$ for all $b \in \{0,1\}^{n-1}$ of Hamming weight j, and hence $f(a) = 1$ for all $a \in \{0,1\}^n$ such $a_l = 1$ and $w(a) = j+1$. Since index l is arbitrary, and each assignment of Hamming weight $j+1$ has at least one variable set to 1, it follows that $f(a) = 1$ for all $a \in \{0,1\}^n$ of Hamming weight $j+1$.

We have thus shown by induction that $f(a) = 1$ for all $a \in \{0,1\}^n$. This contradicts the property that f is a non-constant function. □

Lemma 7 can be restated using the terminology of *weight enumerators*. Given a binary code (i.e., a subset C of $\{0,1\}^n$, for some n), the weight enumerator of this code is the polynomial $P(z) = \sum_k W_k z^k$, where W_k is the number of codewords (elements of C) of Hamming weight k. Lemma 7 states that if f is a non-constant Boolean function, then it has a relevant variable x_i such that codes $C_0 := \{x \in \{0,1\}^{n-1} | f_{x_i \leftarrow 0}(x) = 1\}$, and $C_1 := \{x \in \{0,1\}^{n-1} | f_{x_i \leftarrow 1}(x) = 1\}$ have different weight enumerators.

Lemma 7 proves the existence of a variable x_i with a given property. One might conjecture that all relevant variables of f would share this property, but this is not the case, as shown in the following simple example.

8.1 Example

Let $f(x_1,x_2,x_3) = (\neg x_1 \vee \neg x_2 \vee x_3)(x_1 \vee x_2 \vee \neg x_3)$. Let $\sigma = (0,0,0)$. Since $f(1,1,0) \neq f(0,1,0)$, x_1 is a relevant variable of f. It is straightforward to verify that, for $k \in \{0,1,2\}$, $W_k(f_{x_1 \leftarrow 0}) = W_k(f_{x_1 \leftarrow 1})$. The same holds for x_2 by symmetry. Variable x_3 is the only one satisfying the property of Lemma 7.

9. Skewing Given the Entire Truth Table

In this section, we analyze skewing in an idealized setting, where the available data consists of the full truth table of a Boolean function. We then do an analysis of sequential skewing in the same setting.

9.1 A Motivating Example

Recall that a correlation immune function $f(x_1,\ldots,x_n)$ is one such that for every variable x_i, the gain of x_i with respect to f is 0 under the uniform distribution on $\{0,1\}^n$. We are interested in the following question: When skewing is applied to a correlation immune function, will it cause a relevant variable to have non-zero gain under the skewed distribution? (Equivalently, will it cause one of the first-order Fourier coefficients to become non-zero?) We show that, in the idealized

setting, the answer to this question is "yes" for nearly all skews. The answer is somewhat different for sequential skewing.

When we use a skew (σ, p) to reweight a data set that consists of an entire truth table, the weight assigned to each assignment a in the truth table by the skewing procedure is $P_{D(\sigma,p)}(a)$, where $D(\sigma, p)$ is the skewed distribution defined by (σ, p). Moreover, the gain of a variable x_i as measured on the weighted truth table is precisely the gain with respect to $D(\sigma, p)$. By Lemma 1, it follows that a variable x_i will have gain on the skewed (weighted) truth table data set iff $P_D(f = 1|x_i = 1) - P_D(f = 1|x_i = 0) \neq 0$, where $D = D(\sigma, p)$. If x_i is a relevant variable, the difference $P_D(f = 1|x_i = 1) - P_D(f = 1|x_i = 0)$ can be expressed as a polynomial $h(p)$ in p of degree at most $r-1$, where r is the number of relevant variables of f. If x_i is an irrelevant variable, $P_D(f = 1|x_i = 1) - P_D(f = 1|x_i = 0) = 0$. The main work in this section will be to show that for some relevant variable x_i, this polynomial is not identically 0. Having proved that, we will know that for at most $r-1$ values of weight factor p (the roots of h), $h(p) = 0$. For all other values of p, $h(p) \neq 0$, and x_i has gain in f with respect to $D(\sigma, p)$.

We give an example construction of the polynomial $h(p)$ for a particular function and skew. Consider a Boolean function f over 5 variables whose positive examples are $(0,0,0,1,0)$, $(0,0,1,0,0)$, $(1,0,1,1,0)$. Assume a skew (σ, p) where $\sigma = (1,\ldots,1)$ and p is some arbitrary value in $(0,1)$. Let $D = D_{(\sigma,p)}$. There are two positive examples of f setting $x_1 = 0$, namely $(0,0,0,1,0)$ and $(0,0,1,0,0)$. It is easy to verify that $P_D(f = 1|x_1 = 0) = 2p(1-p)^3$. Similarly, $P_D(f = 1|x_1 = 1) = p^2(1-p)^2$. Let $h(p) = P_D(f = 1|x_1 = 1) - P_D(f = 1|x_1 = 0)$. Then $h(p) = p^2(1-p)^2 - 2p(1-p)^3$, which is a degree-4 polynomial in p. This polynomial has at most 4 roots, and it is not identically 0. It follows that for all but at most 4 choices of p, $h(p)$ is not zero. Thus if we choose p uniformly at random from $(0,1)$, with probability 1, x_1 has gain for (f, σ, p).

9.2 Analysis of Skewing Given the Complete Truth Table

For $f : \{0,1\}^n \to \{0,1\}$ a Boolean function, $k \in [1\ldots n]$, and $\sigma \in \{0,1\}^n$, let $W(f, \sigma, k)$ denote the number of assignments $b \in \{0,1\}^n$ such that $f(b) = 1$ and $\Delta(b, \sigma) = k$.

Using the symmetry of the Boolean hypercube, we can generalize Lemma 7 to obtain the following lemma, which we will use in our analysis of skewing.

Lemma 8 *Let f be a non-constant Boolean function on $\{0,1\}^n$, $\sigma \in \{0,1\}^n$ be an orientation, and $i \in [1\ldots n]$. Then there exists a variable x_i of f and $k \in [0,\ldots,n-1]$ such that $W(f_{x_i \leftarrow 1}, \sigma^i, k) \neq W(f_{x_i \leftarrow 0}, \sigma^i, k)$.*

Proof. Recall that given two assignments a and b, we use $a+b$ to denote componentwise addition mod 2. Let $f' : \{0,1\}^n \to \{0,1\}$ be such that $f'(x) = f(x+\sigma)$.

Applying Lemma 7 to function f', let x_i and k be such that $W_k(f'_{x_i \leftarrow 1}) \neq W_k(f'_{x_i \leftarrow 0})$.

For all $a \in \{0,1\}^{n-1}$, $f'_{x_i \leftarrow \sigma_i}(a) = 1$ and $w(a) = k$ iff $f_{x_i \leftarrow 0}(a + \sigma^i) = 1$ and $\Delta(a + \sigma^i, \sigma^i) = w((a + \sigma^i) + \sigma^i) = k$. It follows that $W_k(f'_{x_i \leftarrow \sigma_i}) = W(f_{x_i \leftarrow 0}, \sigma^i, k)$. The analogous statement holds for $W_k(f'_{x_i \leftarrow \neg\sigma_i})$. Thus $W(f_{x_i \leftarrow 1}, \sigma^i, k) \neq W(f_{x_i \leftarrow 0}, \sigma^i, k)$. □

We now show the connection between the above lemma and gain.

Lemma 9 *Let f be a Boolean function on $\{0,1\}^n$, $\sigma \in \{0,1\}^n$ be an orientation, and $i \in [1\ldots n]$. Let r be the number of relevant variables of f. If $W(f_{x_i \leftarrow 1}, \sigma^i, j) = W(f_{x_i \leftarrow 0}, \sigma^i, j)$ for all $j \in [1\ldots n-1]$, then for all weighting factors $p \in (0,1)$, x_i does not have gain for (f, σ, p). Conversely,*

if $W(f_{x_i\leftarrow 1},\sigma^i,j)\neq W(f_{x_i\leftarrow 0},\sigma^i,j)$ *for some* $j\in[1\ldots n-1]$, *then for all but at most* $r-1$ *weighting factors* $p\in(0,1)$, x_i *has gain for* (f,σ,p).

Proof. Let f_0 denote $f_{x_i\leftarrow 0}$ and f_1 denote $f_{x_i\leftarrow 1}$. Let $\sigma\in\{0,1\}^n$ be an orientation.

For real valued variables y and z and for $a\in\{0,1\}^n$, let $T_{\sigma,a}(y,z)$ be the multiplicative term $y^{n-d}z^d$, where $d=\Delta(\sigma,a)$, the Hamming distance between σ and a. So, for example, if $\sigma=(1,1,1)$ and $a=(1,0,0)$, $T_{\sigma,a}(y,z)=yz^2$. Note that for $p\in(0,1)$, $T_{\sigma,a}(p,1-p)$ is the probability assigned to a by distribution $D_{(\sigma,p)}$. For $\sigma\in\{0,1\}^n$ and f a Boolean function on $\{0,1\}^n$, let $g_{f,\sigma}$ be the polynomial in y and z such that

$$g_{f,\sigma}(y,z)=\sum_{a\in\{0,1\}^n:f(a)=1}T_{\sigma,a}(y,z). \tag{5}$$

Thus, for example, if f is the two-variable disjunction $f(x_1,x_2)=x_1\vee x_2$, and $\sigma=(1,1)$, then $g_{f,\sigma}=y^1z^1+y^1z^1+y^2z^0=y^2+2yz$.

Define $g'(y,z)=g_{f_1,\sigma^i}(y,z)-g_{f_0,\sigma^i}(y,z)$, where g is as given in Equation 5. The quantity $W(f,\sigma,k)$ is the value of the coefficient of the term $y^{n-k}z^k$ in $g_{f,\sigma}$. Thus $g'(y,z)=\sum_{j=0}^{n-1}c_jy^{n-1-j}z^j$, where for all $j\in[0\ldots n-1]$, $c_j=W(f_1,\sigma^i,j)-W(f_0,\sigma^i,j)$.

Let $p\in(0,1)$. Under distribution $D_{(\sigma,p)}$, $\Pr(f=1|x_i=0)$ and $\Pr(f=1|x_i=1)$ are equal to $g_{f_0,\sigma^i}(p,1-p)$ and $g_{f_1,\sigma^i}(p,1-p)$ respectively. Thus by Lemma 1, x_i has gain for (f,σ,p) iff $g'(p,1-p)=0$.

Let $h(p)$ be the polynomial in p such that $h(p)=g'(p,1-p)$.

If x_i is irrelevant, then for all fixed $p\in(0,1)$, x_i has no gain for (f,σ,p). Further, $W(f_1,\sigma^i,j)=W(f_0,\sigma^i,j)$ for all $j\in[0\ldots n-1]$. Thus the lemma holds if x_i is irrelevant. In what follows, assume x_i is relevant.

If $W(f_1,\sigma^i,j)=W(f_0,\sigma^i,j)$ for all $j\in[0\ldots n-1]$, then $h(p)$ is identically 0 and for all fixed $p\in(0,1)$, x_i has no gain for (f,σ,p).

Suppose conversely that $W(f_1,\sigma^i,j)\neq W(f_0,\sigma^i,j)$ for some j. Then $g'(y,z)$ is not identically 0. We will show that $h(p)=g'(p,1-p)$ is a polynomial of degree at most $r-1$ that is not identically 0.

We begin by showing that $h(p)$ has degree at most $r-1$. Let $x_l\neq x_i$ be an irrelevant variable of f. Assume without loss of generality that $\sigma_l=1$. Then since $f(a_{x_l\leftarrow 1})=1$ iff $f(a_{x_l\leftarrow 0})=1$,

$$\begin{aligned}
g_{f,\sigma}(p,1-p) &= \sum_{a\in\{0,1\}^n:f(a)=1,a_l=1}pT_{\sigma^l,a^l}(p,1-p)+\sum_{a\in\{0,1\}^n:f(a)=1,a_l=0}(1-p)T_{\sigma^l,a^l}(p,1-p)\\
&= \sum_{a\in\{0,1\}^n:f(a)=1,a_l=0}T_{\sigma^l,a^l}(p,1-p)\\
&= \sum_{b\in\{0,1\}^{n-1}:f_{x_l\leftarrow 0}(b)=1}T_{\sigma^l,b}(p,1-p)\\
&= g_{f_{x_l\leftarrow 0},\sigma^l}(p,1-p).
\end{aligned}$$

That is, $g_{f,\sigma}(p,1-p)$ is equal to the corresponding polynomial for the function $g_{f_{x_l\leftarrow 0},\sigma^l}(p,1-p)$ produced by hardwiring irrelevant variable x_l to 0. By repeating this argument, we get that $g_{f,\sigma}=g_{\tilde{f},\tilde{\sigma}}$ where $\tilde{f}$ is the function obtained from f by hardwiring all of its irrelevant variables to 0, and $\tilde{\sigma}$ is σ restricted to the relevant variables of f. Thus g has degree at most r and $h(p)=g'(p,1-p)$ has degree at most $r-1$.

Let j' be the smallest j such that $W(f_1,\sigma^i,j) \neq W(f_0,\sigma^i,j)$. Then $c_{j'}$ is non-zero, and all (non-zero) terms of $g'(y,z)$ have the form $c_j y^{r-1-j} z^j$ where $j \geq j'$. We can thus factor out $z^{j'}$ from $g'(y,z)$ to get $g'(y,z) = z^{j'} g''(y,z)$, where $g''(y,z) = \sum_{j=j'}^{r-1} c_j y^{r-1-j} z^{j-j'}$. One term of g'' is $c_{j'} y^{r-1-j'}$, while all other terms have a non-zero power of z. Thus for $p=1$, $g''(p,1-p) = c_{j'}$ which is non-zero, proving that $g''(p,1-p)$ is not identically 0. Hence $h(p) = z^{j'} g''(p,1-p)$ is the product of two polynomials that are not identically 0, and so $h(p)$ is not identically 0.

Finally, since $h(p)$ is a polynomial of degree at most $r-1$ that is not identically 0, it has at most $r-1$ roots. It follows that there are at most $r-1$ values of p in $(0,1)$ such that x_i does not have gain for (f,σ,p). □

We now present the main theorem of this section.

Theorem 9.1 *Let f be a non-constant Boolean function on $\{0,1\}^n$. Let $\sigma \in \{0,1\}^n$ be an orientation, and let p be chosen uniformly at random from $(0,1)$. Then with probability 1 there exists at least one variable x_i such that x_i has gain for (f,σ,p).*

Proof. Let $\sigma \in \{0,1\}^n$ be a fixed orientation. Let r be the number of relevant variables of f. Let x_i be the variable of f whose existence is guaranteed by Lemma 8. Thus $W(f_{x_i \leftarrow 1},\sigma^i,j) \neq W(f_{x_i \leftarrow 0},\sigma^i,j)$ for some j. By Lemma 9, for all but at most $r-1$ weighting factors $p \in (0,1)$, x_i has gain for (f,σ,p). With probability 1, a random p chosen uniformly from $(0,1)$ will not be equal to one of those $r-1$ weighting factors. □

Using the techniques above, one can also show that for certain p-biased distributions $D[p]$, there do not exist any non-constant correlation immune functions with respect to $D[p]$. Let f be a non-constant Boolean function defined on $\{0,1\}^n$. By Lemma 8 and the proof of Lemma 9, there is some variable x_i such that associated polynomial $h(p)$ (defined with respect to $\sigma = (1,\ldots,1)$) is not identically 0. It follows that for any p that is not a root of h, x_i has gain for $(f,(1,\ldots,1),p)$, and thus f is not correlation immune with respect to distribution $D[p]$. The polynomial $h(p)$ has degree at most $n-1$ and integer coefficients with magnitude at most 2^n, which restricts its possible roots. For example, every root of h must be algebraic. Thus for any non-algebraic p, there are no Boolean functions that are correlation immune with respect to $D[p]$. Similarly, since h has integral coefficients with magnitude bounded by 2^n, an elementary theorem on polynomials (sometimes called the "Rational Zeroes Theorem") immediately implies that any rational zero of h must have magnitude at least $1/2^n$. Thus for any p such that $0 < p < 1/2^n$, there are no n-variable Boolean functions that are correlation immune with respect to $D[p]$.

With Theorem 9.1 we have shown that for any non-constant function and any orientation σ, there exists at least one variable x_i such that if p is chosen randomly, then, with probability 1, x_i has gain with respect to f under the distribution $D_{(\sigma,p)}$. However, the theorem says nothing about the magnitude of the gain. If the chosen p is close to a root of the polynomial $h(p)$, defined in the proof of Lemma 9, then the gain will be very small. Moreover, the gain can vary depending on the function and on the skew. (We will prove a result later in the paper, in Lemma 11, which shows that with a certain probability, a randomly chosen p will cause x_i to have reasonably large gain.)

The identity of the variable(s) having gain can also depend on the skew. There may be relevant variables other than x_i that don't have gain for any p. In the example given following the proof of Lemma 7, variables x_1 and x_2 will have no gain for $(f,(0,\ldots,0),p)$ no matter the choice of p.

Theorem 9.1 suggests that skewing is an effective method for finding relevant variables of a non-constant Boolean f, because for nearly all skews, there will be at least one variable with non-zero

gain. Equivalently, for nearly all skewed distributions, function f is not correlation immune with respect to that distribution. However, in practice—even in a noiseless situation where examples are all labeled correctly according to a function f—we do not usually have access to the entire truth table, and thus are not able to compute the exact gain of a variable under distribution $D_{(\sigma,p)}$ defined by the skew. We can only estimate that gain. Moreover, in practice we cannot sample from the distribution $D_{(\sigma,p)}$. Instead, we simulate $D_{(\sigma,p)}$ by reweighting our sample.

9.3 Analysis of Sequential Skewing

Sequential skewing is a variant of skewing. In sequential skewing, n iterations of reweighting are performed, where n is the number of input variables of the target function. On the j^{th} iteration, examples are reweighted according to the preferred setting of the j^{th} variable alone; if the setting of the j^{th} variable matches the preferred setting, the example is multiplied by p, otherwise the example is multiplied by $1-p$. The reweighting in the jth iteration is designed to simulate the product distribution in which each variable other than x_j is 1 with probability 1/2, and variable x_j has its preferred setting with probability p. In addition to the n iterations of reweighting, the gain of every variable is also calculated with respect to the original, unweighted, data set. As in standard skewing, the algorithm uses the calculated gains to determine which variable to output.

In the reweighting done by sequential skewing, there is a chosen variable x_i, a preferred setting $c \in \{0,1\}$ of that variable, and a weight factor $p \in (0,1)$. We thus define a (sequential) skew to be a triple (i,c,p), where $i \in [1 \ldots n]$, $c \in \{0,1\}$, and $p \in (0,1)$. Define the probability distribution $D_{(i,c,p)}$ on $\{0,1\}^n$ such that for $a \in \{0,1\}^n$, $D_{(i,c,p)}$ assigns probability $p \cdot (\frac{1}{2})^{n-1}$ to a if $a_i = c$, and $(1-p) \cdot (\frac{1}{2})^{n-1}$ otherwise. Thus $D_{(i,c,p)}$ is the distribution that would be generated by applying sequential skewing, with parameters x_i, c and p, to the entire truth table.

Let f be a Boolean function on $\{0,1\}^n$. We say that variable x_j *has gain for* (f,i,c,p) if under distribution $D_{(i,c,p)}$, $G(f|x_j) > 0$. By Lemma 1, x_j has gain for (i,c,p) iff under distribution $D_{(i,c,p)}$, $\Pr[f=1|x_j=1] \neq \Pr[f=1|x_j=0]$.

We will use the following lemma.

Lemma 10 *A Boolean function f is 2-correlation immune iff it is 1-correlation immune, and for all pairs $i<j$, the inputs x_i and x_j are independent given $f(x_1,\ldots,x_n)$.*

Proof. We first prove the forward direction. If f is 2-correlation immune, then it is certainly 1-correlation immune, and all triples (f,x_i,x_j) are mutually independent.

The reverse direction is a calculation. Let $\alpha,\beta,\gamma \in \{0,1\}$. Using pairwise independence, and then 1-correlation immunity, we get

$$\begin{aligned}\Pr[f=\alpha, x_i=\beta, x_j=\gamma] &= \Pr[f=\alpha]\Pr[x_i=\beta, x_j=\gamma \mid f=\alpha] \\ &= \Pr[f=\alpha]\Pr[x_i=\beta \mid f=\alpha]\Pr[x_j=\gamma \mid f=\alpha] \\ &= \Pr[f=\alpha]\Pr[x_i=\beta]\Pr[x_j=\gamma].\end{aligned}$$

This holds even if $\Pr[f=\alpha]=0$, for then both sides vanish. □

The constant functions $f=0$ and $f=1$ are 2-correlation immune, as is any parity function on 3 or more variables. We have enumerated the 2-correlation immune functions up to $n=5$ and found that when $n \leq 4$, the only such functions are as above, but for $n=5$, others begin to appear. Specifically, there are 1058 2-correlation immune functions of 5 variables, but only 128 parity

functions and complements of these (with no constraint on the relevant variables). (Our enumeration method works as follows. Vanishing of the relevant Fourier coefficients can be expressed as a linear system with 0-1 solutions, which we can count by a "splitting" process reminiscent of the time-space tradeoff for solving subset sum problems, Odlyzko 1980.) Denisov (1992) gave an asymptotic formula for the number of 2-correlation immune functions, and from this work it follows that for large n, only a small fraction of the 2-correlation immune functions will be parity functions.

The following theorem shows that, in our idealized setting, sequential skewing can identify a relevant variable of a function, unless that function is 2-correlation immune. It follows that sequential skewing will be ineffective in finding relevant variables of a parity function, even with unlimited sample sizes. In contrast, standard skewing can identify relevant variables of a parity function if the sample size is large enough.

Theorem 9.2 *Let f be a correlation-immune Boolean function on $\{0,1\}^n$, let $i \in [1\ldots n]$, and let $c \in \{0,1\}$. Let p be chosen uniformly at random from $(0,1)$. If the function f is 2-correlation immune, then for all $j \in [1\ldots n]$, x_j has no gain for (f,i,c,p). Conversely, if f is not 2-correlation immune, then for some $j \in [1\ldots n]$, x_j has gain for (f,i,c,p) with probability 1.*

Proof. Let f be a correlation immune function. Let $i \in [1\ldots n]$ and $c \in \{0,1\}$.

Assume $c = 1$. The proof for $c = 0$ is symmetric and we omit it. Consider skew (i,c,p), where $p \in (0,1)$. Let $f^{-1}(1) = \{x \in \{0,1\}^* | f(x) = 1\}$.

Let $j \in [1\ldots n]$. Let $A_1 = |\{a \in f^{-1}(1) \mid a_i = c \text{ and } a_j = 1\}|$, and $B_1 = |\{a \in f^{-1}(1) \mid a_i \neq c \text{ and } a_j = 1\}|$. Similarly, let $A_0 = |\{a \in f^{-1}(1) \mid a_i = c \text{ and } a_j = 0\}|$, $B_0 = |\{a \in f^{-1}(1) \mid a_i \neq c \text{ and } a_j = 0\}|$.

Under distribution $D_{(i,c,p)}$, if $j \neq i$, $\Pr[f = 1 | x_j = 1] = (A_1 p + B_1(1-p)) \left(\frac{1}{2}\right)^{n-2}$. If $j = i$, then because $c = 1$, $\Pr[f = 1 | x_j = 1] = A_1 \left(\frac{1}{2}\right)^{n-1}$. Similarly, if $j \neq i$, $\Pr[f = 1 | x_j = 0] = (A_0 p + B_0(1-p)) \left(\frac{1}{2}\right)^{n-2}$. If $j = i$, $\Pr[f = 1 | x_j = 0] = B_0 \left(\frac{1}{2}\right)^{n-1}$.

The difference $\Pr[f = 1 | x_j = 1] - \Pr[f = 1 | x_j = 0]$ is a linear function in p. If $i \neq j$, this function is identically zero iff $A_1 = A_0$ and $B_1 = B_0$. If it is not identically 0, then there is at most one value of $p \in (0,1)$ for which it is 0. If $i = j$, this function is identically zero iff $A_1 = B_0$. Also note that for $i = j$, $A_0 = 0$ and $B_1 = 0$ by definition.

In addition, since f is correlation immune, $A_1 + A_0 = B_1 + B_0$. If $i = j$, then $\Pr[f = 1 | x_j = 1] - \Pr[f = 1 | x_j = 0]$ is therefore identically zero and x_i has no gain for (f,i,c,p). If $j \neq i$, then x_j has no gain for (f,i,c,p) iff $A_1 = A_0 = B_1 = B_0$. This latter condition is precisely the condition that $\Pr[x_i = \alpha \wedge x_j = \beta | f = \gamma] = \Pr[x_i = \alpha | f = \gamma] \Pr[x_j = \beta | f = \gamma]$ under the uniform distribution on $\{0,1\}^n$. If this condition holds for all pairs $i \neq j$, no variable x_j has gain for (f,i,c,p), and by Lemma 10, f is 2-correlation immune. Otherwise for some $i \neq j$, x_j has gain for (f,i,c,p) for all but at most 1 value of p. The theorem follows. □

10. Exploiting Product Distributions

Until now we have *simulated* alternative product distributions through skewing. But simulating alternative distributions is not the same as sampling directly from them. In particular, skewing can magnify idiosyncracies in the sample in a way that does not occur when sampling from true alternative distributions. We now consider the PDC model, in which the learning algorithm can specify product distributions and request random examples from those distributions. In practice it might be

possible to obtain examples from such alternative distributions by working with a different population or varying an experimental set-up. Intuitively, one might expect a high degree of overhead in making such changes, in which case it would be desirable to keep the number of alternative distributions small.

10.1 FindRel1: Finding a Relevant Variable Using r Distributions

Let Boolean$_{r,n}$ denote the Boolean functions on n variables that have at most r relevant variables. We first present a simple algorithm that we call FindRel1, based on Theorem 9.1. It identifies a relevant variable of any target function in Boolean$_{r,n}$, with probability $1-\delta$, by estimating the first-order Fourier coefficient of x_i for r distinct product distributions. The algorithm assumes that r is known. If not, standard techniques can be used to compensate. For example, one can repeat the algorithm with increasing values of r (perhaps using doubling), until a variable is identified as being relevant.

The algorithm works as follows. For $j \in \{1,\ldots,r\}$, let D_j denote the product distribution that sets each of the n input variables to 1 with probability $j/(r+1)$. For each D_j, the algorithm requests a sample S_j of size m_0 (we will specify m_0 in the proof below). Then, for each of the n input variables x_i, it estimates the associated first-order Fourier coefficients from sample S_j by computing $\hat{f}_{S,D_j}(x_i)$. At the end, the algorithm outputs the set of all variables x_i whose gain on some S_j exceeded a threshold θ_0 (also specified below).

Theorem 10.1 *For all non-constant $f \in$ Boolean$_{r,n}$, with probability at least $1-\delta$ FindRel1 will output a non-empty subset of the relevant variables of f. FindRel1 uses a total of $O((r+1)^{2r}\ln\frac{2nr}{\delta})$ examples, drawn from r distinct p-biased distributions. The running time of FindRel1 is polynomial in $2^{r\ln r}$, n, and $\ln\frac{1}{\delta}$.*

Proof. Since f is non-constant, it has at least one relevant variable. Recall that for distribution D on $\{0,1\}^n$, $G_D(f,x_i)$ denotes the gain of x_i with respect to f under distribution D. Recall also that $D[p]$ denotes the product distribution that sets each variable x_i to 1 with probability p.

By the arguments in Section 9, for each relevant variable x_i, $\Pr_{D[p]}[f=1|x_i=1]-\Pr_{D[p]}[f=1|x_i=0]$ can be written as a polynomial of degree $r-1$ in p. Call this polynomial $h_i(p)$. For all irrelevant variables x_i of f, $h_i(p)$ is identically 0.

Now let x_i be a relevant variable such that $h_i(p)$ is not identically 0. By Theorem 9.1, f has at least one such relevant variable. The polynomial $h_i(p)$ has degree at most $r-1$ and hence has at most $r-1$ roots. Therefore, for at least one $j \in \{1,\ldots,r\}$, $h_i(j/(r+1)) \neq 0$.

Let $j^* \in \{1,\ldots,r\}$ be such that $h_i(j^*/(r+1)) \neq 0$. Since h_i has integer coefficients and is of degree at most $r-1$, it follows that $h_i(j^*/(r+1)) = b/(r+1)^{r-1}$, for some integer b. Thus the absolute value of $h_i(j^*/(r+1))$ is at least $1/(r+1)^{r-1}$, and by Lemma 2, the first-order Fourier coefficient (for distribution D_{j^*}) associated with x_i has magnitude at least $2\frac{\sqrt{\frac{j^*}{(r+1)}(1-\frac{j^*}{r+1})}}{(r+1)^{(r-1)}}$, which is lower bounded by $q := 2\frac{\sqrt{\frac{1}{(r+1)}(1-\frac{1}{r+1})}}{(r+1)^{(r-1)}}$. Set θ_0 in the description of FindRel1 to be $q/2 = \sqrt{r}/(r+1)^r$.

For any single D_j, it follows from Lemma 3 that if $m_0 = 2(r+1)^{2r}r^{-1}\ln\frac{2nr}{\delta}$, if we use a sample of size m_0 drawn from D_j and estimate all n first-order Fourier coefficients for distribution D_j using that sample, then with probability at least $1-\frac{\delta}{r}$, each of the estimates will have additive error less than $q/2$. Thus with probability at least $1-\delta$, this will hold for all r of the D_j. The total number of examples drawn by FindRel1 is $rm_0 = 2(r+1)^{2r}\ln\frac{2nr}{\delta}$.

Since for some relevant variable, the associated Fourier coefficient is at least q for some D_j, and for all irrelevant variables, the associated Fourier coefficient is 0 for all D_j, the theorem follows. □

Skewing uses gain estimates, rather than estimates of the first-order Fourier coefficients. FindRel1 can be modified to use gain estimates. By a similar argument as above, it follows from Lemma 1 that for distribution D_{j^*}, some relevant variable has gain at least $q' = 2\frac{1}{r+1}(1-\frac{1}{r+1})(\frac{1}{r+1})^{2r-2}$ with respect to that distribution. We could thus modify FindRel1 to output the variables whose gain exceeds $q'/2$. Then Lemma 6 implies that a sample of size $m_0 = O(r^{4r-2}\ln\frac{nr}{\delta})$ would suffice for the modified FindRel1 to output a non-empty subset of relevant variables. This sample complexity bound is higher than the bound for the original FindRel1 based on Fourier coefficients.

10.2 FindRel2: Lowering the Sample Complexity

We now present our second algorithm, FindRel2. As discussed in the introduction, it has an advantage over FindRel1 in terms of running time and sample complexity, but requires examples from a larger number of distinct distributions. FindRel2 is based on the following lemma.

Lemma 11 *Let f have $r \geq 1$ relevant variables. Suppose p is chosen uniformly at random from $(0,1)$. Then there exists a relevant variable x_i of f, and a value $\tau \geq 2e^{-3r}$ such that with probability at least $\tau/2$ (with respect to the choice of p), $G_{D[p]}(f,x_i) \geq \tau/2$.*

Proof By Theorem 9.1 and its proof, there exists a variable x_i of f such that $\Pr_{D[p]}[f=1|x_i=1] - \Pr_{D[p]}[f=1|x_i=0]$ can be expressed as a polynomial $h_i(p)$, which has integer coefficients and is not identically 0. Let $g(p) = G_{D[p]}(f,x_i)$. By Lemma 1,

$$g(p) = 2p(1-p)h_i(p)^2.$$

Then there are integers $\gamma_0,\ldots,\gamma_{2r}$ such that $g(p) = 2\sum_{j=0}^{2r}\gamma_j p^j$. Since $g(p)$ is non-negative but not identically 0, we have

$$\tau := \int_0^1 g(p)dp = 2\sum_{j=0}^{2r}\frac{\gamma_j}{j+1} > 0.$$

This is at least $2/L$, where L is the least common multiple of $\{1,\ldots,2r+1\}$. Observe that for each prime, the number of times it appears in the prime factorization of L equals the number of its powers that are $\leq 2r+1$. By an explicit form of the prime number theorem,

$$\log L = \sum_{\substack{p^k \leq 2r+1 \\ k\geq 1}} \log p \leq 3r.$$

(This can be checked directly for $r=1$, and for $r \geq 2$ we can use Theorem 12 of Rosser and Schoenfeld 1962.) Thus, $\tau \geq 2e^{-3r}$. Now let α be the fraction of $p \in (0,1)$ for which $g(p) \geq \tau/2$. Then,

$$\tau = \int_{g\geq\tau/2} g + \int_{g<\tau/2} g \leq \alpha + (\tau/2)(1-\alpha).$$

This implies $\alpha \geq \tau/(2-\tau) > \tau/2$, and the lemma follows. □

Note that the proof of the above lemma relies crucially on the non-negativity of the gain function, and thus the same proof technique could not be applied to first-order Fourier coefficients, which can be negative.

It is possible that the bounds in the above result could be improved by exploiting how g comes from the Boolean function f. Without such information, however, the bounds are essentially the best possible. Indeed, by properly choosing g, one can use this idea to estimate the density of primes from below, and get within a constant factor of the prime number theorem. See Montgomery (1994) for a discussion of this point.

FindRel2, our second algorithm for finding a relevant variable, follows easily from the above lemma. We describe the algorithm in terms of two size parameters m_1 and m_2, and a classification threshold θ_1.

The algorithm begins by choosing m_1 values for p, uniformly at random from $(0,1)$. Let P be the set of chosen values. For each value $p \in P$, the algorithm requests m_2 random examples drawn with respect to distribution $D[p]$, forming a sample S_p. Then, for each of the n input variables x_i, it computes $G(S_p,x_i)$, the gain of x_i on the sample S_p. At the end, the algorithm outputs all variables x_i such that $G(S_p,x_i) > \theta_1$ for at least one of the generated samples S_p.

Using Lemma 11, we can give values to parameters m_1, m_2, and θ_1 in FindRel2 and prove the following theorem.

Theorem 10.2 *For all non-constant $f \in Boolean_{r,n}$, with probability at least $1-\delta$, FindRel2 will output a non-empty subset of the relevant variables of f. FindRel2 uses $O(e^{9r}(r+\ln(n/\delta))\ln(1/\delta))$ examples, drawn from $O(e^{3r}\log\frac{1}{\delta})$ product distributions. The running time is polynomial in 2^r, n, and $\log\frac{1}{\delta}$.*

Proof. As in the proof of Theorem 10.1, f has at least one relevant variable x_i for which $h_i(p)$ is not identically 0. Let x_{i^*} denote this variable. Let $\delta_1 = \delta_2 = \delta/2$.

If the statement of Lemma 11 holds for any value of τ at all, it holds for the lower bound. We therefore let $\tau = 2e^{-3r}$. By Lemma 11, for at least a $\tau/2$ fraction of the values of $p \in (0,1)$, $G_{D[p]}(f,x_{i^*}) \geq \tau/2$. Let us call these "good" values of p. If a single p is chosen uniformly at random from $(0,1)$, then the probability p is good is at least $\tau/2$.

Let $m_1 = e^{3r}\ln\frac{1}{\delta_1} = \frac{2}{\tau}\ln\frac{1}{\delta_1}$. If the algorithm chooses m_1 independent random values of p to form the set P, the probability that P does not contain any good p's is at most $(1-\tau/2)^{m_1} \leq e^{-m_1\tau/2} = \delta_1$.

Suppose P contains at least one good p. Let p^* be such a p. Let $\gamma = G_{D[p^*]}(f,x_{i^*})$. Then, $\gamma \geq \tau/2 = e^{-3r}$. Set θ_1 in the algorithm to $e^{-3r}/2$, the resulting lower bound for $\gamma/2$.

Set m_2 in the algorithm to be equal to $256\ln(2nm_1/\delta_2)/\theta_1^2$.

Consider any $p \in P$. Then by Lemma 6, with probability at least $1-\delta_2/m_1$, $|G(S_p,x_i) - G_{D[p]}(x_i)| < \gamma/2$ for all variables x_i. Since $|P| = m_1$, it follows that $|G(S_p,x_i) - G_{D[p]}(x_i)| < \gamma/2$ holds for all variables x_i and for all $p \in P$, with probability at least $1-\delta_2$.

Assuming P has at least one good p^*, $G_{D[p^*]}(x_{i^*}) \geq \gamma$, while for all $p \in P$ and all irrelevant x_i, and $G_{D[p]}(x_i) = 0$. Thus if $|G(S_p,x_i) - G_{D[p]}(x_i)| < \gamma/2$ holds for every x_i and $p \in P$, and P contains at least one good p, then FindRel2 outputs a non-empty subset of relevant variables of f.

It follows that the the probability that the algorithm does not output a non-empty subset of the relevant variables is at most $\delta_1 + \delta_2 = \delta$, as claimed.

It remains to estimate the number of examples used, which is $m_1 m_2$. The only problem is with m_2. Since $0 < \delta_1 < 1/2$, we have $0 < \ln(2\ln(1/\delta_1)) < \ln(1/\delta_1)$. Using this, together with the definitions of m_1 and τ, we find that

$$\ln(2nm_1/\delta_2) \quad = \quad \ln(2n) + \ln(2\ln(1/\delta_1)) - \ln(\tau) - \ln(\delta_2)$$

$$\begin{aligned} &\leq \ln(n) + \ln(1/\delta_1) + 3r + \ln(1/\delta_2) \\ &= \ln(n) + 3r + 2\ln(2/\delta). \end{aligned}$$

Combining this with the definitions of m_2 and θ_1 gives us $m_2 = O(e^{6r}(r + \ln(n/\delta)))$, and since $m_1 = e^{3r}\ln(2/\delta)$, we get $m_1 m_2 = O(e^{9r}(r + \ln(n/\delta))\ln(1/\delta))$. □

We do not know the best exponents for which a result like Theorem 10.2 is true. We do note, however, that more careful use of the prime number theorem would allow the exponents 9 and 3 to be lowered to $6 + o(1)$ and $2 + o(1)$, respectively.

Using not too many more examples, the random choices can be eliminated from FindRel2, as follows. Since the g appearing in the proof of Lemma 11 is a polynomial, the set of $p \in [0,1]$ for which $g(p) \geq \tau/2$ is a finite union of closed intervals. Their lengths sum to at least $\tau/2 = e^{-3r}$. In the open interval between any two adjacent closed intervals, there must be a local minimum of g, which is a zero of g', a polynomial of degree $\leq 2r - 1$. It follows that there are at most $2r$ of these closed intervals, making one have length at least $h := e^{-3r}/(2r)$. Our algorithm can therefore try $p = h, 2h, 3h, \ldots$ and be guaranteed that one of these is good. (We don't have to try $p = 0, 1$ because g vanishes there.) With this modification, the number of distributions becomes $O(re^{3r})$ and the number of examples becomes $O(re^{9r}(r + \ln(n/\delta)))$.

10.3 Two Algorithms From The Literature

Another approach to finding a relevant variable is implicit in work of Bshouty and Feldman (2002). We present it briefly here.

Bshouty and Feldman's approach is based on the following facts. Variable x_i is relevant to f iff there is some Fourier coefficient $\hat{f}(z)$ with $z_i = 1$ and $\hat{f}(z) \neq 0$. Further, if f has r relevant variables, the absolute value of every non-zero Fourier coefficient of f is at least $1/2^r$.

For $b \in \{0,1\}^{n-1}$, let $1b$ denote the concatenation of 1 with b. Let $w(b)$ denote the Hamming weight of b. Define $R_1(f) = \sum_{b \in \{0,1\}^{n-1}} \hat{f}^2(1b)(\frac{1}{2^{2w(b)}})$. Thus R_1 is a weighted sum of the Fourier coefficients $\hat{f}(z)$ such that $z_1 = 1$. For any $z \in \{0,1\}^n$, the quantity $\hat{f}^2(z)$ is non-zero only if $\{i | z_i = 1\} \subseteq \{i |$ variable x_i is a relevant variable of $f\}$. Therefore, if $\hat{f}^2(1b) \neq 0$, then $w(b) \leq r$. It follows that if x_1 is relevant, $R_1 > 1/2^{4r}$. If x_1 is irrelevant, $R_1 = 0$. Let D' be the product distribution specified by the parameter vector $[1/2, 1/4, 1/4, \ldots, 1/4]$ and let $w \in \{0,1\}^n$ be such that $w = [1, 0, \ldots, 0]$. As shown by Bshouty and Feldman (2002, proof of Lemma 11), $R_1 = E_{x \sim U}[E_{y \sim D'}[f(y)\chi_w(x \oplus y)]]^2$. Here $x \sim U$ denotes that the first expectation is with respect to an x drawn from the uniform distribution on $\{0,1\}^n$, and $y \sim D'$ denotes that the second expectation is with respect to a y drawn from distribution D'. For any fixed x, $E_{y \sim D'}[f(y)\chi_w(x \oplus y)]]$ can be estimated by drawing random samples $(y, f(y))$ from D'. The quantity R_1 can thus be estimated by uniformly generating values for x, estimating $E_{y \sim D'}[f(y)\chi_w(x \oplus y)]]$ for each x, and then taking the average over all generated values of x. Using arguments of Bshouty and Feldman, which are based on a standard Hoeffding bound, it can be shown that for some constant c_1, a sample of size $O(2^{c_1 r}\log^2(\frac{1}{\delta'}))$ from D' suffices to estimate R_1 to within an additive error of $\frac{1}{2^{4r+1}}$, with probability $1 - \delta'$. If the estimate obtained is within this error, then whether x_i is relevant can be determined by just checking whether the estimate is greater than $\frac{1}{2^{4r+1}}$. We can apply this procedure to all n variables x_i, each time taking a sample of y's from a new distribution. Setting $\delta' = \delta/n$, it follows that a sample of size $O(n2^{c_1 r}\log^2\frac{n}{\delta})$ suffices to determine, with probability $1 - \delta$, which of the n variables are relevant. Thus this algorithm finds all the relevant variables.

The above algorithm uses examples chosen from n product distributions. Each product distribution has exactly one parameter set to $1/2$, and all other parameters set to a fixed value $\rho \neq 1/2$ (here $\rho = 1/4$, although this choice was arbitrary).

If the parameters of the product distribution can be set to 0 and 1, membership queries can be simulated. We now briefly describe an algorithm that uses membership queries and uniform random examples to find a relevant variable of a target function with at most r relevant variables. A similar approach is used in a number of algorithms for related problems (see, e.g., Arpe and Reischuk, 2007; Guijarro et al., 1999; Blum et al., 1995; Damaschke, 2000; Bshouty and Hellerstein, 1998).

The algorithm first finds the value of $f(a)$ for some arbitrary a, either by asking a membership query or choosing a random example. Then, the algorithm draws a random sample S (with respect to the uniform distribution) of size $2^r \ln \frac{1}{\delta}$. Assuming the function contains at least one relevant variable, a random example has probability at least $1/2^r$ of being negative, and probability at least $1/2^r$ of being positive. Thus if the function has at least 1 relevant variable, with probability at least $1-\delta$, S contains an example a' such that $f(a') \neq f(a)$. (If it contains no such example, the algorithm outputs the constant function $f(x) = f(a)$.) The algorithm then takes a and a', and using membership queries, executes a standard binary-search procedure for finding a relevant variable of a Boolean function, given a positive and a negative example of that function (cf. Blum et al., 1995, Lemma 4). This procedure makes $O(\log n)$ membership queries.

If we carry out the membership queries in the PDC model by asking for examples from product distributions with parameters 0 and 1, the result is an algorithm that finds a relevant variable with probability at least $1-\delta$ using $O(\log n)$ product distributions and $O(2^r \log \frac{1}{\delta})$ random examples. The random examples can also be replaced by membership queries on (n,r) universal sets (see, e.g., Bshouty and Hellerstein, 1998).

11. On the Limitations of Skewing

One of the motivating problems for skewing was that of learning the parity of r of n variables. The results of Section 9 imply that skewing is effective for learning parity functions if the entire truth table is available as the training set. (Of course, if the entire truth table is available, there are much more straightforward ways of identifying relevant variables.) Equivalently, we can identify relevant variables if we are able to determine the exact gain of each variable with respect to skewed distributions. In practice, though, we need to estimate gain values based on a random sample. The random sample must be large enough so that we can still identify a relevant variable, even though the gain estimates for the variables will have some error. We now consider the following sample complexity question: how large a random sample is needed so that skewing can be used to identify a relevant variable of the parity function, with "high" probability? We would like to know how quickly this sample complexity grows as r and n grow.

Skewing is not a statistical query learning algorithm, but it is based on the estimation of statistics. In what follows, we use techniques that were previously employed to prove lower bounds for statistical query learning of parity functions.

It is difficult to analyze the behavior of skewing because the same sample is used and re-used for many gain calculations. This introduces dependencies between the resulting gain estimates. Here we consider a modification of the standard skewing procedure, in which we pick a new, independent random sample each time we estimate the gain of a variable with respect to a skew (σ, p). We call this modification "skewing with independent samples." Intuitively, since the motivation behind

skewing is based on estimating statistical quantities, choosing a new sample to make each estimate should not hurt accuracy. In experiments, skewing with independent samples was more effective in finding relevant variables than standard skewing (Ray et al., 2009).

For simplicity, assume that the variable output by the skewing algorithm is one that exceeds a fixed threshold the maximum number of times. However, as we discuss below, our lower bounds would also apply to implementations using other output criteria.

We prove a sample complexity lower bound for skewing with independent samples, when applied to a target function that is the parity of r of n variables. The proof is based on the fact that the skewing algorithm does not use all the information in the examples. Given a skew (σ, p), and an example $(x, f(x))$, the skewing algorithm weights this example according to $d = \Delta(x, \sigma)$, the Hamming distance between x and σ. The calculation of the gain for a variable x_i on the weighted data set then depends only on $f(x)$, whether $x_i = \sigma_i$, and on d. These three pieces of information together constitute a "summary" of the example $(x, f(x))$, for orientation σ. The skewing algorithm uses only these summaries; it does not use any other information about the examples. We will argue that the summaries do not contain enough information to identify relevant variables of a parity function, unless the sample size is "large".

We begin by proving a technical lemma, using techniques of Jackson (2003) and Blum et al. (1994).

Let $\text{Parity}_{r,n}$ be the set of parity functions on n variables which have r relevant variables. So for each $f \in \text{Parity}_{r,n}$, $f(x_1, \ldots, x_n) = x_{i_1} + x_{i_2} + \ldots + x_{i_r}$ where the sum is taken mod 2, and the x_{i_j} are distinct. Let $NEQ(b,c)$ denote the inequality predicate, that is, $NEQ(b,c) = 1$ if $b \neq c$ and $NEQ(b,c) = 0$ if $b = c$.

Let $d \in \{0, \ldots, n\}$ and $b, c \in \{0,1\}$. For $f \in \text{Parity}_{r,n}$ and $\sigma \in \{0,1\}^n$, the quantity $\Pr[NEQ(\sigma_i, x_i) = b, f(x) = c, \text{ and } \Delta(x,\sigma) = d]$ has the same value for all relevant variables x_i of f (where the probability is with respect to the uniform distribution over all $x \in \{0,1\}^n$). The same holds for all irrelevant variables x_i of f. We define $S_1^{f,\sigma}(b,c,d) = \Pr[NEQ(\sigma_i, x_i) = b, f(x) = c, \text{ and } \Delta(x,\sigma) = d]$ when x_i is a relevant variable of f, and $S_2^{f,\sigma}(b,c,d) = \Pr[NEQ(\sigma_i, x_i) = b, f(x) = c, \text{ and } \Delta(x,\sigma) = d]$ when x_i is an irrelevant variable of f.

As an example, suppose $\sigma' \in \{0,1\}^n$ is such that $f(\sigma') = 0$. Then $S_1^{f,\sigma'}(0,1,d) = \frac{1}{2^n} \sum_{t \in T} \binom{r-1}{t} \binom{n-r}{d-t}$ where $T = \{t \in \mathbb{Z} | t \text{ is odd and } 0 \leq t \leq d\}$. Similarly, $S_2^{f,\sigma'}(1,0,d) = \frac{1}{2^n} \sum_{t \in T'} \binom{r}{t} \binom{n-r-1}{d-1-t}$ where $T' = \{t \in \mathbb{Z} | t \text{ is even and } 0 \leq t \leq d-1\}$.

For variable x_i and orientation σ, we call $(NEQ(\sigma_i, x_i), f(x), \Delta(x,\sigma))$ the *summary tuple* corresponding to $(x, f(x))$. Thus for target function $f \in \text{Parity}_{r,n}$ and orientation σ, $S_1^{f,\sigma}(b,c,d)$ is the probability of obtaining a summary tuple (b,c,d) for variable x_i when x_i is relevant, and $S_2^{f,\sigma}(b,c,d)$ is the same probability in the case that x_i is irrelevant.

We prove the following upper bound on $|S_1^{f,\sigma}(b,c,d) - S_2^{f,\sigma}(b,c,d)|$.

Lemma 12 *For all $\sigma \in \{0,1\}^n$, $f \in \text{Parity}_{r,n}$, $b, c \in \{0,1\}$ and $d \in \{0, \ldots, n\}$,*

$$|S_1^{f,\sigma}(b,c,d) - S_2^{f,\sigma}(b,c,d)| \leq \frac{1}{2} \left(\binom{n-1}{r}^{-1/2} + \binom{n-1}{r-1}^{-1/2} \right)$$

.

Proof. Suppose first that $f(\sigma) = 0$. For any $\sigma' \in \{0,1\}^n$ such that $f(\sigma') = 0$, $S_1^{f,\sigma'}(b,c,d) = S_1^{f,\sigma}(b,c,d)$, and the analogous equality holds for S_2. Without loss of generality, we may therefore assume that $\sigma = 0^n$.

Let $S_1 = S_1^{f,\sigma}(b,c,d)$ and $S_2 = S_2^{f,\sigma}(b,c,d)$. Let $\gamma = |S_1 - S_2|$. Define a function $\psi_i(x,y) : \{0,1\}^n \times \{0,1\} \to \{1,-1\}$ such that $\psi_i(x,y) = -1$ if $NEQ(\sigma_i, x_i) = b$, $y = c$, and $\Delta(x,\sigma) = d$, and $\psi_i(x,y) = 1$ otherwise.

For x_i a relevant variable of f, $E[\psi_i(x,f(x))] = 1 - 2S_1$ (where the expectation is with respect to the uniform distribution on $x \in \{0,1\}^n$). Similarly, for x_i an irrelevant variable of f, $E[\psi_i(x,f(x))] = 1 - 2S_2$.

Let x_j be a relevant variable of f, and let x_k be an irrelevant variable of f.

Since $|S_1 - S_2| = \gamma$,

$$|E[\psi_j(x,f(x))] - E[\psi_k(x,f(x))]| = 2|S_1 - S_2| = 2\gamma.$$

As noted by Jackson (2003), it follows from an analysis in Blum et al. (1994) that for any parity function h on n variables, and any function $g : \{0,1\}^{n+1} \to \{1,-1\}$,

$$E[g(x,h(x))] = \hat{g}(0^{n+1}) + \hat{g}(z1)$$

where $z \in \{0,1\}^n$ is the characteristic vector of the relevant variables of h (equivalently, $\chi_z = 1 - 2h$), and $z1$ denotes the assignment $(z_1,\ldots,z_n,1)$.

Thus we have

$$E[\psi_j(x,f(x))] = \hat{\psi}_j(0^{n+1}) + \hat{\psi}_j(z1)$$
$$E[\psi_k(x,f(x))] = \hat{\psi}_k(0^{n+1}) + \hat{\psi}_k(z1)$$

where z is the characteristic vector of the relevant variables of f. It follows from the definition of ψ_i that $\hat{\psi}_j(0^{n+1}) = \hat{\psi}_k(0^{n+1})$. Therefore,

$$|\hat{\psi}_j(z1) - \hat{\psi}_k(z1)| = 2\gamma.$$

Now consider any other parity function $f' \in \text{Parity}_{r,n}$. Since $\sigma = 0^n$, $f'(\sigma) = f(\sigma) = 0$. Therefore, $S_1^{f',\sigma} = S_1$ and $S_2^{f',\sigma} = S_2$. If relevant variable x_j of f is also a relevant variable of f', then $E[\psi_j(x,f'(x))] = \hat{\psi}_j(0^{n+1}) + \hat{\psi}_j(z'1)$, where z' is the characteristic vector of the relevant variables of f'. Thus $\hat{\psi}_j(z'1) = \hat{\psi}_j(z1)$.

There are $\binom{n-1}{r-1}$ functions $f' \in \text{Parity}_{r,n}$ such that x_j is a relevant variable of f'. It follows that there are at least $\binom{n-1}{r-1}$ Fourier coefficients of ψ_j that are equal to $\hat{\psi}_j(z1)$. By Parseval's identity,

$$|\hat{\psi}_j(z1)| \leq \binom{n-1}{r-1}^{-1/2}.$$

Similarly, $E[\psi_k(x,f(x))] = E[\psi_k(x,f'(x))]$ for all $f' \in \text{Parity}_{r,n}$ such that x_k is an irrelevant variable of f'. Since there are $\binom{n-1}{r}$ such f', an analogous argument shows that

$$|\hat{\psi}_k(z1)| \leq \binom{n-1}{r}^{-1/2}.$$

Thus

$$\begin{aligned}\gamma &= \frac{|\hat{\psi}_j(z1) - \hat{\psi}_k(z1)|}{2} \\ &\leq \frac{|\hat{\psi}_j(z1)| + |\hat{\psi}_k(z1)|}{2} \\ &\leq \frac{1}{2}\left(\binom{n-1}{r}^{-1/2} + \binom{n-1}{r-1}^{-1/2}\right).\end{aligned}$$

Thus the lemma holds in the case that $f(\sigma) = 0$.

Now suppose that $f(\sigma) = 1$. Given $a \in \{0,1\}^n$, $f(a) = 1$ iff a differs from σ in an even number of its relevant variables (and in an arbitrary number of its irrelevant variables). Further, $f(a) = 1$ iff a differs from 0^n in an odd number of its relevant variables (and in an arbitrary number of its irrelevant variables). Thus $S_1^{f,\sigma}(b,c,d) = S_1^{f,0^n}(b,1-c,d)$ and $S_2^{f,\sigma}(b,c,d) = S_2^{f,0^n}(b,1-c,d)$.

Since the bound proved above for the case $f(\sigma) = 0$ holds for arbitrary c, it holds for $|S_1^{f,0^n}(b,1-c,d) - S_2^{f,0^n}(b,1-c,d)|$, and the lemma follows. □

The above lemma gives an upper bound on $\gamma = |S_1^{f,\sigma}(b,c,d) - S_2^{f,\sigma}(b,c,d)|$. Another way to prove such an upper bound is to use the fact that a statistical query algorithm could determine whether variable x_i was relevant by asking a query requesting the value of $\Pr[NEQ(\sigma_i,x_i) = b, f(x) = c, \text{ and } \Delta(x,\sigma) = d]$ within tolerance $\gamma/2$ (assuming $\gamma > 0$). Queries of this type could be used to find all the relevant variables of f, which uniquely determines parity function f. If γ were too large, this would contradict known lower bounds on statistical learning of parity. This approach yields a bound that is close to the one given in the lemma above, but the proof is less direct. (See, for example, Blum et al. 1994 for the definition of the statistical query model.)

We now prove a sample complexity lower bound for learning parity functions, using skewing with independent samples.

Theorem 11.1 *Suppose we use skewing with independent samples to identify a relevant variable of f, where $f \in Parity_{r,n}$. Assuming that the samples are drawn from the uniform distribution, to successfully output a relevant variable with probability at least μ requires that the total number of examples used in making the gain estimates be at least $\frac{(\mu - \frac{r}{n})\min\{\binom{n-1}{r-1}^{1/2}, \binom{n-1}{r}^{1/2}\}}{4(n+1)}$.*

Proof. Consider running skewing with independent samples with a target function $f \in \text{Parity}_{r,n}$. To estimate the gain of a variable x_i with respect to a skew (σ, p), the skewing algorithm uses a sample drawn from the uniform distribution. In calculating this estimate, the algorithm does not use the full information in the examples. For each labeled example $(x, f(x))$, it uses only the information in the corresponding summary tuple $(b,c,d) = (NEQ(\sigma_i,x_i), f(x), \Delta(x,\sigma))$. We may therefore assume that the skewing algorithm is, in fact, given only the summary tuples, rather than the raw examples.

The number of distinct possible summary tuples is at most $4(n+1)$, since there are two possible values each for b and c, and $n+1$ possible values for d. The uniform distribution on examples x induces a distribution D on the summary tuples generated for skew (σ, p) and variable x_i. For fixed σ, distribution D is the same for all relevant variables x_i of f. It is also the same for all irrelevant variables x_i of f. Let D_1^σ be the distribution for the relevant variables, and D_2^σ be the distribution for

the irrelevant variables. Let q be the distance between D_1^σ and D_2^σ as measured in the L_1 norm. That is, if K denotes the set of possible summary tuples, then $q = \sum_{z \in K} |\Pr_{D_1^\sigma}[z] - \Pr_{D_2^\sigma}[z]|$.

Since there are at most $4(n+1)$ possible summary tuples. it follows from Lemma 12 that $q \leq 2(n+1)(\binom{n-1}{r-1}^{-1/2} + \binom{n-1}{r}^{-1/2})$.

Let m be the total number of examples used to estimate the gain of all variables x_i under all skews (σ, p) used by the skewing algorithm. Since the L_1 distance between D_1^σ and D_2^σ is at most q for every skew (σ, p) and every variable x_i, it follows that during execution of the algorithm, with probability at least $(1-q)^m$, the summary tuples generated for the relevant variables of f are distributed in the same way as the summary tuples generated for the irrelevant variables of f.

By the symmetry of the parity function, if the target function f is randomly chosen from $\text{Parity}_{r,n}$, then with probability at least $(1-q)^m$, the final variable output by the skewing algorithm when run on this f is equally likely to be any of the n input variables of f. Thus the probability that the skewing algorithm outputs an irrelevant variable is at least $(1-q)^m(\frac{n-r}{n})$, and the probability that it outputs a relevant variable is at most $1-(1-q)^m(\frac{n-r}{n}) < 1-(1-qm)(1-\frac{r}{n}) < \frac{r}{n}+qm(1-\frac{r}{n}) < \frac{r}{n}+qm$. The first inequality in this sequence holds because $(1-q)^m \geq (1-qm)$, since $0 < q < 1$.

Since the above holds for a random target function in $\text{Parity}_{r,n}$, it holds for the worst-case $f \in \text{Parity}_{r,n}$. It follows that if skewing with independent samples outputs a relevant variable of f (for any $f \in \text{Parity}_{r,n}$) with probability at least μ, then the total number of examples used must be at least $\frac{\mu - \frac{r}{n}}{q}$. Since $q \leq 2(n+1)(\binom{n-1}{r-1}^{-1/2} + \binom{n-1}{r}^{-1/2})$, it follows that $1/q \geq \frac{\min\{\binom{n-1}{r-1}^{1/2}, \binom{n-1}{r}^{1/2}\}}{4(n+1)}$. □

To make the theorem concrete, consider the case where $r = \log n$. Note that if we simply choose one of the n variables at random, the probability of choosing a relevant variable in this case is $\frac{\log n}{n}$. It follows from the theorem that for skewing to output a relevant variable with success "noticeably" greater than random guessing, that is, with probability at least $\frac{logn}{n} + \frac{1}{p(n)}$, for some polynomial p, it would need to use more than a superpolynomial number of examples.

The above proof relies crucially on the fact that skewing uses only the information in the summary tuples. The details of how the summary tuples are used is not important to the proof. Thus the lower bound applies not only to the implementation of skewing that we assumed (in which the chosen variable is the one whose gain exceeds the fixed threshold the maximum number of times). Assuming independent samples, the lower bound would also apply to other skewing implementations, including, for example, an implementation in which the variable with highest gain over all skews was chosen as the output variable.

On the other hand, one can also imagine variants of skewing to which the proof would not apply. For example, suppose that we replaced the single parameter p used in skewing by a vector of parameters $[p_1, \ldots, p_n]$, so that in reweighting an example, variable x_i causes the weight to be multiplied by either p_i or $1-p_i$, depending on whether there is a match with x_i's preferred setting. Our proof technique would not apply here, since we would be using information not present in the summary tuples. To put it another way, the proof exploits the fact that the distributions used by skewing are simple ones, defined by a pair (σ, p). Interestingly, it was our focus on such simple distributions that led us to the two new algorithms in Section 10.

The negative result above depends on the fact that for f a parity function with r relevant variables, the distribution of the summary tuples for a relevant variable x_i is very close to the distribution of the summary tuples for an irrelevant variable x_i. For other correlation immune functions, the distributions are further apart, making those functions easier for skewing to handle. For example, consider $\text{Consensus}_{r,n}$, the set of all n-variable Boolean functions with r relevant variables, whose

value is 1 iff the r relevant variables are all equal. The functions in this set are correlation immune. Assume $n+r$ is even. Let $d=(n+r)/2$ and $\sigma=(1,1,\ldots,1)$. Let $S_1=\Pr[x_i=0,\Delta(x,\sigma)=d,$ and $f(x)=1]$ when x_i is a relevant variable of f. Let $S_2=\Pr[x_i=0,\Delta(x,\sigma)=d,$ and $f(x)=1]$ when x_i is an irrelevant variable of f. Then $S_1=\frac{1}{2^n}\binom{n-r}{\frac{n-r}{2}}$ and $S_2=\frac{1}{2^n}(\binom{n-r-1}{\frac{n-r}{2}-1}+\binom{n-r-1}{\frac{n+r}{2}-1})$. Then $S_1-S_2=\Omega(\frac{1}{2^n}\binom{n-r}{\frac{n-r}{2}})$, since the first term of S_2 is equal to $S_1/2$, and the second term of S_2 is much smaller than the first. Since $\binom{m}{m/2}=\theta(\frac{2^m}{\sqrt{m}})$, $S_1-S_2=\Omega(\frac{1}{\sqrt{n-r}2^r})$. Even for r as large as $n/2$, this is $\Omega(\frac{1}{\sqrt{n}2^r})$. Note the difference between this quantity and the analogous bound for parity. The dependence here is on $\frac{1}{2^r}$ rather than on roughly $\binom{n}{r}^{1/2}$.

12. Conclusions and Open Questions

In this paper, we studied methods of finding relevant variables that are based on exploiting product distributions.

We provided a theoretical study of skewing, an approach to learning correlation immune functions (through finding relevant variables) that has been shown empirically to be quite successful. On the positive side, we showed that when the skewing algorithm has access to the complete truth table of a target Boolean function—a case in which standard greedy gain-based learners fail—skewing will succeed in finding a relevant variable of that function. More particularly, under any random choice of skewing parameters, a single round of the skewing procedure will find a relevant variable with probability 1.

In some sense the correlation immune functions are the hardest Boolean functions to learn, and parity functions are among the hardest of these to learn, since a parity function of $k+1$ variables is k-correlation immune. In contrast to the positive result above, we showed (using methods from statistical query learning) that skewing needs a sample size that is superpolynomial in n to learn parity of $\log n$ relevant variables, given examples from the uniform distribution.

We leave as an open question the characterization of the functions of $\log n$ variables that skewing can learn using a sample of size polynomial in n, given examples from the uniform distribution.

Skewing operates on a sample from a single distribution, and can only *simulate* alternative product distributions. We used the PDC model to study how efficiently one can find relevant variables, given the ability to sample directly from alternative product distributions. We presented two new algorithms in the PDC model for identifying a relevant variable of an n-variable Boolean function with r relevant variables.

We leave as an open problem the development of PDC algorithms with improved bounds, and a fuller investigation of the tradeoffs between time and sample complexity, and the number and types of distributions used. As a first step, it would be interesting to show an algorithm whose time complexity is polynomial in n when $r=\log n$, using a number of p-biased distributions that is polynomial in $\log n$. Our lower bound for parity relied on the assumption of independent samples. We suspect that the lower bound also holds if the assumption is removed, but proving it seems to require a different approach. As we mentioned earlier, it is a major open problem whether there is a polynomial-time algorithm for finding relevant variables of a function of $\log n$ variables, using only examples from the uniform distribution.

Abstract

We study the problem of learning near-optimal behavior in finite Markov Decision Processes (MDPs) with a polynomial number of samples. These "PAC-MDP" algorithms include the well-known E^3 and R-MAX algorithms as well as the more recent Delayed Q-learning algorithm. We summarize the current state-of-the-art by presenting bounds for the problem in a unified theoretical framework. A more refined analysis for upper and lower bounds is presented to yield insight into the differences between the model-free Delayed Q-learning and the model-based R-MAX.

Keywords: reinforcement learning, Markov decision processes, PAC-MDP, exploration, sample complexity

1. Introduction

In the reinforcement-learning (RL) problem (Sutton and Barto, 1998), an agent acts in an unknown or incompletely known environment with the goal of maximizing an external reward signal. In the most standard mathematical formulation of the problem, the environment is modeled as a finite Markov Decision Process (MDP) where the goal of the agent is to obtain near-optimal discounted return. Recent research has dealt with probabilistic bounds on the number of samples required for near-optimal learning in finite MDPs (Kearns and Singh, 2002; Kakade, 2003; Brafman and Tennenholtz, 2002; Strehl and Littman, 2005; Strehl et al., 2006a,b). The purpose of this paper is to summarize this field of knowledge by presenting the best-known upper and lower bounds for the problem. For the upper bounds, we present constructive proofs using a unified framework in Section 3.1; these tools may be useful for future analysis. While none of the bounds we present are entirely new, the main contribution of this paper is to streamline as well as consolidate their

∗. Some of this work was completed while A. Strehl was at Rutgers University and also while he was at Yahoo! Research.

†. Some of this work was completed while L. Li was at Rutgers University.

analyses. In addition, the bounds we present are stated in terms of an *admissible* heuristic provided to the algorithm (see Section 1.3) and the (unknown) optimal value function. These bounds are more refined than the ones previously presented in the literature and more accurately reflect the performance of the corresponding algorithms. For the lower bound, we provide an improved result that matches the upper bound in terms of the number of states of the MDP.

An outline of the paper is as follows. This introduction section concludes with a formal specification of the problem and related work. In Section 2, R-MAX and Delayed Q-learning are described. Then, we present their analyses and prove PAC-MDP upper bounds in Section 3. A new lower bound is proved in Section 4.

1.1 Main Results

We present two upper bounds and one lower bound on the achievable *sample complexity* of general reinforcement-learning algorithms (see Section 1.5 for a formal definition). The two upper bounds dominate all previously published bounds, but differ from one another. When logarithmic factors are ignored, the first bound, for the R-MAX algorithm, is

$$\tilde{O}(S^2A/(\varepsilon^3(1-\gamma)^6)),$$

while the corresponding second bound, for the Delayed Q-learning algorithm, is

$$\tilde{O}(SA/(\varepsilon^4(1-\gamma)^8)).$$

Here, S and A are the number of states and the number of actions, respectively, of the MDP, ε and δ are accuracy parameters, and γ is a discount factor. R-MAX works by building an approximate MDP model and the S^2A term in its sample complexity follows from requiring accuracy in each of the S^2A parameters of the model. Delayed Q-learning, on the other hand, does not build an explicit model and can be viewed as an approximate version of value iteration. Thus, accuracy only needs to be guaranteed for each of the SA entries in the value function.

While previous bounds are in terms of an upper bound $1/(1-\gamma)$ on the value function, we find that tighter bounds are possible if a more informative value-function upper bound is given. Specifically, we can rewrite the bounds in terms of the initial admissible heuristic values (see Section 1.3) supplied to the algorithms, $U(\cdot,\cdot)$, and the true (unknown) value function $V^*(\cdot)$. Ignoring logarithmic factors, for R-MAX the bound is

$$\tilde{O}\left(\frac{V_{\max}^3 S\,|\{(s,a)\in\mathcal{S}\times\mathsf{A}|U(s,a)\geq V^*(s)-\varepsilon\}|}{\varepsilon^3(1-\gamma)^3}\right), \tag{1}$$

and for Delayed Q-learning

$$\tilde{O}\left(\frac{V_{\max}^3 \sum_{(s,a)\in\mathcal{S}\times\mathsf{A}}[U(s,a)-V^*(s)]_+}{\varepsilon^4(1-\gamma)^4}\right), \tag{2}$$

where $V_{\max}\geq \max_{s,a}U(s,a)$ is an upper bound on the admissible heuristic (and also on the true value function), and $[x]_+$ is defined as $\max(0,x)$ for $x\in\mathbb{R}$. Thus, we observe that for R-MAX one factor of $SA/(1-\gamma)^3$ gets replaced by $|\{(s,a):U(s,a)\geq V^*(s)-\varepsilon\}|V_{\max}^3$,[1] the number of state-action pairs whose heuristic initial value is larger than $V^*-\varepsilon$, while for Delayed Q-learning the

1. This quantity can be as small as $SV_{\max}^3$ and as large as $SAV_{\max}^3$, where $V_{\max}\in[0,\frac{1}{1-\gamma}]$.

factor $SA/(1-\gamma)^4$ is replaced by $V_{\max}^3 \sum_{(s,a)\in S\times A}(U(s,a)-V^*(s))$,[2] $V_{\max}^3$ times the total sum of differences between the heuristic values and the optimal value function. The latter term is better, because it takes more advantage of accurate heuristics. For instance, if $U(s,a)=V^*(s)+\varepsilon$ and $V^*(s)$ is large for all s, then the bound for R-MAX stays essentially the same but the one for Delayed Q-learning is greatly improved. Please see Russell and Norvig (1994) for discussions and references on admissible heuristics. The method of incorporating admissible heuristics into Q-learning (Ng et al., 1999) and R-MAX (Asmuth et al., 2008) are well known, but the bounds given in Equation 1 and Equation 2 are new.

The upper bounds summarized above may be pessimistic and thus may not reflect the worst-case behavior of these algorithms. Developing lower bounds, especially *matching* lower bounds, tells us what can (or cannot) be achieved. Although matching lower bounds are known for deterministic MDPs (Koenig and Simmons, 1996; Kakade, 2003), it remains an open question for general MDPs. The previous best lower bound is due to Kakade (2003), and was developed for the slightly different notion of H-horizon value functions instead of the γ-discounted ones we focus on here. Adapting his analysis to discounted value functions, we get the following lower bound:

$$\Omega\left(\frac{SA}{\varepsilon(1-\gamma)^2}\ln\frac{1}{\delta}\right).$$

Based on the work of Mannor and Tsitsiklis (2004), we provide an improved lower bound

$$\Omega\left(\frac{SA}{\varepsilon^2}\ln\frac{S}{\delta}\right) \tag{3}$$

which simultaneously increases the dependence on both S and $1/\varepsilon$. While we choose to drop dependence on $1/(1-\gamma)$ in our lower bound to facilitate a cleaner analysis, we believe it is possible to force a quadratic dependence by a more careful analysis. This new lower bound (3) has a few important implications. First, it implies that Delayed Q-learning's worst-case sample complexity has the *optimal* dependence on S. Second, it increases the dependence on $1/\varepsilon$ significantly from linear to quadratic. It would be interesting to know whether a cubic dependence on $1/\varepsilon$ is possible, which would match the upper bound for R-MAX (ignoring logarithmic factors).

Our lower bound is tight for the factors S, $1/\varepsilon$, and $1/\delta$, in the weaker *parallel sampling* model (Kearns and Singh, 1999). This finding suggests that a worse dependence on $1/\varepsilon$ is possible only in MDPs with slow *mixing* rates.[3] In both the parallel sampling model and the MDP used to prove the lower bound given by Equation 3 (see Section 4), the distribution of states being sampled/visited mixes extremely fast (in one and two timesteps, respectively). The slower the mixing rate, the more difficult the *temporal credit assignment* problem (Sutton and Barto, 1998). In other words, a worse dependence on $1/\varepsilon$ may require the construction of an MDP where *deep planning* is necessary.

Before finishing the informal introduction, we should point out that the present paper focuses on *worst-case* upper bounds and so the sample complexity of exploration bounds like Equations 1 and 2 can be too conservative for MDPs encountered in practice. However, the algorithms and their analyses have proved useful for guiding development of more practical exploration schemes as well as improved algorithms. First of all, these algorithms formalize the principle of "optimism under the

2. This quantity can be as small as 0 and as large as $SAV_{\max}^4$, where $V_{\max}\in[0,\frac{1}{1-\gamma}]$.

3. There are many ways to define a mixing rate. Roughly speaking, it measures how fast the distribution of states an agent reaches becomes independent of the initial state and the policy being followed.

face of uncertainty" (Brafman and Tennenholtz, 2002) which has been empirically observed to be effective for encouraging active exploration (Sutton and Barto, 1998). Sample complexity analysis not only shows soundness of this principle in a mathematically precise manner, but also motivates novel RL algorithms with efficient exploration (e.g., Nouri and Littman 2009 and Li et al. 2009). Second, there are several places in the proofs where the analysis can be tightened under various assumptions about the MDP. The use of admissible heuristic functions as discussed above is one example; another example is the case where the number of next states reachable from any state-action pair is bounded by a constant, implying the factor S in Equation 1 may be shaved off (cf., Lemma 14). More opportunities lie in MDPs with various structural assumptions. Examples include factored-state MDPs (Kearns and Koller, 1999; Strehl et al., 2007; Diuk et al., 2009), Relocatable Action Models (Leffler et al., 2007), and Object-Oriented MDPs (Walsh et al., 2009), in all of which an exponential reduction in sample complexity can be achieved, as well as in MDPs where prior information about the model is available (Asmuth et al., 2009). Third, the streamlined analysis we present here is very general and applies not only to finite MDPs. Similar proof techniques have found useful in analyzing model-based algorithms for continuous-state MDPs whose dynamics are linear (Strehl and Littman, 2008a) or multivariate normal (Brunskill et al., 2008); see Li (2009) for a survey.

1.2 Markov Decision Processes

This section introduces the Markov Decision Process (MDP) notation used throughout the paper; see Sutton and Barto (1998) for an introduction. Let $\mathcal{P}_X$ denote the set of probability distributions over the set X. A finite MDP M is a five tuple $\langle \mathcal{S}, \mathsf{A}, T, \mathcal{R}, \gamma \rangle$, where $\mathcal{S}$ is a finite set called the state space, A is a finite set called the action space, $T : \mathcal{S} \times \mathsf{A} \to \mathcal{P}_{\mathcal{S}}$ is the transition distribution, $\mathcal{R} : \mathcal{S} \times \mathsf{A} \to \mathcal{P}_{\mathbb{R}}$ is the reward distribution, and $0 \leq \gamma < 1$ is a discount factor on the summed sequence of rewards. We call the elements of $\mathcal{S}$ and A states and actions, respectively, and use S and A to denote the number of states and the number of actions, respectively. We let $T(s'|s,a)$ denote the transition probability of state s' of the distribution $T(s,a)$. In addition, $R(s,a)$ denotes the expectation of the distribution $\mathcal{R}(s,a)$.

We assume that the learner (also called the *agent*) receives S, A, and γ as input. The learning problem is defined as follows. The agent always occupies a single state s of the MDP M. The agent is told this state and must choose an action a. It then receives an *immediate reward* $r \sim \mathcal{R}(s,a)$ and is transported to a *next state* $s' \sim T(s,a)$. This procedure then repeats forever. The first state occupied by the agent may be chosen arbitrarily. Intuitively, the solution or goal of the problem is to obtain as large as possible reward in as short as possible time. In Section 1.5, we provide one possible formalization of this objective within the PAC-MDP framework. We define a *timestep* to be a single interaction with the environment, as described above. The t^{th} timestep encompasses the process of choosing the t^{th} action. We also define an *experience* of state-action pair (s,a) to refer to the event of taking action a from state s.

A *policy* is any strategy for choosing actions. A stationary policy is one that produces an action based on only the current state, ignoring the rest of the agent's history. We assume (unless noted otherwise) that rewards[4] all lie in the interval $[0,1]$. For any policy π, let $V_M^\pi(s) = \mathbf{E}[\sum_{j=1}^{\infty} \gamma^{j-1} r_j | s]$ ($Q_M^\pi(s,a) = \mathbf{E}[\sum_{j=1}^{\infty} \gamma^{j-1} r_j | s,a]$) denote the discounted, infinite-horizon value (action-value) func-

4. It is easy to generalize, by linear transformations (Ng et al., 1999), to the case where the rewards are bounded above and below by known but arbitrary constants without changing the optimal policy.

tion for π in M (which may be omitted from the notation) from state s. If H is a positive integer, let $V_M^\pi(s,H)$ denote the H-step value of policy π from s. If π is non-stationary, then s is replaced by a *partial path* $c_t = (s_1, a_1, r_1, \ldots, s_t)$, in the previous definitions. Specifically, let s_t and r_t be the t^{th} encountered state and received reward, respectively, resulting from execution of policy π in some MDP M. Then, $V_M^\pi(c_t) = \mathbf{E}[\sum_{j=0}^{\infty} \gamma^j r_{t+j} | c_t]$ and $V_M^\pi(c_t, H) = \mathbf{E}[\sum_{j=0}^{H-1} \gamma^j r_{t+j} | c_t]$. These expectations are taken over all possible infinite paths the agent might follow in the future. The optimal policy is denoted π^* and has value functions $V_M^*(s)$ and $Q_M^*(s,a)$. Note that a policy cannot have a value greater than $1/(1-\gamma)$ by the assumption that the maximum reward is 1.[5]

1.3 Admissible Heuristics

We also assume that the algorithms are given an admissible heuristic for the problem before learning occurs. An **admissible heuristic** is a function $U : \mathcal{S} \times \mathsf{A} \to \mathbb{R}$ that satisfies $U(s,a) \geq Q^*(s,a)$ for all $s \in \mathcal{S}$ and $a \in \mathsf{A}$. We also assume that $U(s,a) \leq V_{\max}$ for all $(s,a) \in \mathcal{S} \times \mathsf{A}$ and some quantity $V_{\max}$. Prior information about the problem at hand can be encoded into the admissible heuristic and its upper bound $V_{\max}$. With no prior information, we can always set $U(s,a) = V_{\max} = 1/(1-\gamma)$ since $V^*(s) = \max_{a \in \mathsf{A}} Q^*(s,a)$ is at most $1/(1-\gamma)$. Therefore, without loss of generality, we assume $0 \leq U(s,a) \leq V_{\max} \leq 1/(1-\gamma)$ for all $(s,a) \in \mathcal{S} \times \mathsf{A}$.

1.4 A Note on the Use of Subscripts

Each algorithm that we consider maintains several variables. For instance, an *action value* or *action-value estimate*, $Q(s,a)$, sometimes called a *Q-value*, where (s,a) is any state-action pair, is maintained. We will often discuss a particular instance or time t during the execution of the algorithm. In this case, when we refer to $Q(s,a)$ we mean the value of that variable at the current moment. To be more explicit, we may write $Q_t(s,a)$, which refers to the value of $Q(s,a)$ immediately preceding the t^{th} action of the agent. Thus, $Q_1(s,a)$ is the initial value of $Q(s,a)$.

1.5 PAC-MDP Model

There are three essential ways to quantify the performance of a reinforcement-learning algorithm. They are *computational complexity*, the amount of per-timestep computation the algorithm uses during learning; *space complexity*, the amount of memory used by the algorithm; and *learning complexity*, a measure of how much experience the algorithm needs to learn in a given task. The last of these is difficult to define and several different ideas have been discussed in the literature. On the one hand, requiring an algorithm to "optimally explore"—meaning to obtain maximum expected discounted reward ($\mathbf{E}[\sum_{t=1}^{\infty} \gamma^{t-1} r_t]$) over a known prior of MDPs—is an extremely difficult task tractable only in highly specialized cases (Gittins, 1989). Thus, we consider the relaxed but still challenging and useful goal of acting near-optimally on all but a polynomial number of steps (Kakade, 2003; Strehl and Littman, 2008b).

To formalize the notion of "efficient learning", we allow the learning algorithm to receive two additional inputs, ε and δ, both positive real numbers. The first parameter, ε, controls the quality of behavior we require of the algorithm (how close to optimality do we want the algorithm to be) and the second parameter, δ, is a measure of confidence (how certain do we want to be of the algorithm's

5. Thus, when comparing our results to the original R-MAX paper Brafman and Tennenholtz (2002), note that 1 takes the place of the quantity *Rmax*.

performance). As these parameters approach zero, greater exploration and learning is necessary, as higher quality is demanded of the algorithms.

In the following definition, we view an algorithm as a non-stationary (in terms of the current state) policy that, on each timestep, takes as input an entire history or trajectory through the MDP (its actual history) and outputs an action (which the agent then executes). Formally, we define the policy of any algorithm $\mathcal{A}$ at a fixed instance in time t to be a function $\mathcal{A}_t : \{\mathcal{S} \times \mathsf{A} \times [0,1]\}^* \times \mathcal{S} \to \mathsf{A}$, that maps future paths to future actions.[6]

Definition 1 *(Kakade 2003) Let $c = (s_1, a_1, r_1, s_2, a_2, r_2, \ldots)$ be a random path generated by executing an algorithm $\mathcal{A}$ in an MDP M. For any fixed $\varepsilon > 0$, the* **sample complexity of exploration** *(**sample complexity**, for short) of $\mathcal{A}$ is the number of timesteps t such that the policy at time t, $\mathcal{A}_t$, satisfies $V^{\mathcal{A}_t}(s_t) < V^*(s_t) - \varepsilon$.*

Note that the sample complexity of an algorithm is dependent on some infinite-length path through the MDP. We believe this definition captures the essence of measuring learning. It directly measures the number of times the agent acts poorly (quantified by ε) and we view "fast" learners as those that act poorly as few times as possible. Based on this intuition, we define what it means to be an "efficient" learning algorithm.

Definition 2 *An algorithm $\mathcal{A}$ is said to be an* **efficient PAC-MDP** *(Probably Approximately Correct in Markov Decision Processes) algorithm if, for any $\varepsilon > 0$ and $0 < \delta < 1$, the per-timestep computational complexity, space complexity, and the sample complexity of $\mathcal{A}$ are less than some polynomial in the relevant quantities $(S, A, 1/\varepsilon, 1/\delta, 1/(1-\gamma))$, with probability at least $1-\delta$. It is simply* **PAC-MDP** *if we relax the definition to have no computational complexity requirement.*

The terminology, PAC, in this definition is borrowed from Angluin (1988) for the distribution-free supervised-learning model of Valiant (1984). One thing to note is that we only require a PAC-MDP algorithm to behave poorly (non-ε-optimally) on no more than a small (polynomially) number of timesteps. We do not place any limitations on when the algorithm acts poorly or how poorly it acts on those timesteps. This definition is in contrast to Valiant's PAC notion, which is more "off-line" in that it requires the algorithm to make all of its mistakes ahead of time (during the learning phase) before identifying a near-optimal policy. The notion of PAC-MDP is also closely related to the Mistake Bound (MB) model of Littlestone (1988) where the goal of a learner that predicts sequentially must make a small (polynomial) number of mistakes during a whole run. Indeed, if we count every timestep in which an algorithm behaves non-ε-optimally as a mistake, then a PAC-MDP algorithm makes only a polynomial number of mistakes during a whole run with high probability, similar to an MB algorithm. However, a mistake in a PAC-MDP algorithm refers to the quality of a policy rather than prediction errors as in MB.

Efficient learnability in the sample-complexity framework from above implies efficient learnability in a more realistic framework called *Average Loss* that measures the actual return (sum of rewards) achieved by the agent against the expected return of the optimal policy (Strehl and Littman, 2008b). The analysis of R-MAX by Kakade (2003) and of MBIE by Strehl and Littman (2005) use the same definition as above. The analysis of R-MAX by Brafman and Tennenholtz (2002) and of

6. The action of an agent on timestep t in state s_t is given by the function evaluated at the empty history, $\mathcal{A}_t(\emptyset, s_t)$.

E^3 by Kearns and Singh (2002) use slightly different definitions of efficient learning.[7] Our analyses are essentially equivalent, but simpler in the sense that mixing-time arguments are avoided. Compared with recently published regret bounds (Auer et al., 2009), our sample complexity bounds are easier to obtain and do not depend on quantities like mixing time or diameter that may be hard to determine *a priori*.

1.6 Related Work

There has been some theoretical work analyzing RL algorithms. In a Bayesian setting, with a known prior over possible MDPs, we could ask for the policy that maximizes expected reward. This problem has been solved (Gittins, 1989) for a specialized class of MDPs, called K-armed bandits. However, a solution to the more general problem seems unlikely to be tractable, although progress has been made (Duff and Barto, 1997; Poupart et al., 2006).

Early results include proving that under certain conditions various algorithms can, in the limit, compute the optimal value function from which the optimal policy can be extracted (Watkins and Dayan, 1992). These convergence results make no performance guarantee after only a finite amount of experience, although more recent work has looked at convergence rates (Szepesvári, 1998; Kearns and Singh, 1999; Even-Dar and Mansour, 2003). These types of analyses make assumptions that simplify the exploration issue.

The work by Fiechter (1994) was the first to prove that efficient (polynomial) approximate learning is achievable, via a model-based algorithm, when the agent has an action that *resets* it to a distinguished start state. Other recent work has shown that various model-based algorithms, including E^3 (Kearns and Singh, 2002), R-MAX (Brafman and Tennenholtz, 2002), and MBIE (Strehl and Littman, 2005) can achieve polynomial learning guarantees without the necessity of resets.

2. Algorithms

The total number of RL algorithms introduced in the literature is huge, so we limit the study to those with the best formal PAC-MDP learning-time guarantees. The two algorithms we study are R-MAX and Delayed Q-learning, because the best sample complexity bounds known for any PAC-MDP algorithm are dominated by the bound for one of these two algorithms. However, the bounds for R-MAX and Delayed Q-learning are incomparable—the bound for R-MAX is better in terms of $1/\varepsilon$ and $1/(1-\gamma)$, while the bound for Delayed Q-learning is better in terms of S. In fact, in Section 4 we will show that the sample complexity of Delayed Q-learning is optimal in terms of S via a matching lower bound.

2.1 R-MAX

Suppose that the agent has acted for some number of timesteps and consider its experience with respect to some fixed state-action pair (s,a). Let $n(s,a)$ denote the number of timesteps in which the agent has taken action a from state s. Suppose the agent has observed the following $n(s,a)$ immediate rewards for taking action a from state s: $r[1],r[2],\ldots,r[n(s,a)]$. Then, the empirical

7. Kearns and Singh (2002) dealt with discounted and undiscounted MDPs differently. In the discounted case the agent is required to halt after a polynomial amount of time and output a near-optimal policy from the current state, with high probability.

mean reward is

$$\hat{R}(s,a) := \frac{1}{n(s,a)} \sum_{i=1}^{n(s,a)} r[i].$$

Let $n(s,a,s')$ denote the number of times the agent has taken action a from state s and immediately transitioned to the state s'. Then, the *empirical transition distribution* is the distribution $\hat{T}(s,a)$ satisfying

$$\hat{T}(s'|s,a) := \frac{n(s,a,s')}{n(s,a)} \text{ for each } s' \in S.$$

In the R-MAX algorithm, the action-selection step is always to choose the action that maximizes the current action value, $Q(s,\cdot)$. The update step is to solve the following set of Bellman equations:

$$\begin{aligned} Q(s,a) &= \hat{R}(s,a) + \gamma \sum_{s'} \hat{T}(s'|s,a) \max_{a'} Q(s',a'), && \text{if } n(s,a) \geq m, \\ Q(s,a) &= U(s,a), && \text{otherwise,} \end{aligned} \tag{4}$$

where $\hat{R}(s,a)$ and $\hat{T}(\cdot|s,a)$ are the empirical (maximum-likelihood) estimates for the reward and transition distribution of state-action pair (s,a) using only data from the first m observations of (s,a). Solving this set of equations is equivalent to computing the optimal action-value function of an MDP, which we call *Model(R-MAX)*. This MDP uses the empirical transition and reward distributions for those state-action pairs that have been experienced by the agent at least m times. Rather than attempt to model the other state-action pairs, we assert their value to be $U(s,a)$, which is guaranteed to be an upper bound on the true value function. An important point is that R-MAX uses *only the first m samples* in the empirical model. To avoid complicated notation, we redefine $n(s,a)$ to be the minimum of m and the number of times state-action pair (s,a) has been experienced. This usage is consistent with the pseudo-code provided in Algorithm 1. That is, the computation of $\hat{R}(s,a)$ and $\hat{T}(s'|s,a)$ in Equation 4, uses only the first $n(s,a) = m$ samples.

Any implementation of R-MAX must choose a technique for solving the set of Equations 4 such as dynamic programming and linear programming approaches (Puterman, 1994), and this choice will affect the computational complexity of the algorithm. However, for concreteness we choose *value iteration* (Puterman, 1994), a relatively simple and fast MDP solving routine that is widely used in practice. Rather than require exact solution of Equations 4, a more practical approach is to only guarantee a near-optimal greedy policy. The following two classic results are useful in quantifying the number of iterations needed.

Proposition 3 *(Corollary 2 from Singh and Yee 1994) Let $Q'(\cdot,\cdot)$ and $Q^*(\cdot,\cdot)$ be two action-value functions over the same state and action spaces. Suppose that Q^* is the optimal value function of some MDP M. Let π be the greedy policy with respect to Q' and π^* be the greedy policy with respect to Q^*, which is the optimal policy for M. For any $\alpha > 0$ and discount factor $\gamma < 1$, if $\max_{s,a} \{|Q'(s,a) - Q^*(s,a)|\} \leq \alpha(1-\gamma)/2$, then $\max_s \{V^{\pi^*}(s) - V^{\pi}(s)\} \leq \alpha$.*

Proposition 4 *Let $\beta > 0$ be any real number satisfying $\beta < 1/(1-\gamma)$ where $\gamma < 1$ is the discount factor. Suppose that value iteration is run for $\left\lceil \frac{\ln(1/(\beta(1-\gamma)))}{1-\gamma} \right\rceil$ iterations where each initial action-value estimate, $Q(\cdot,\cdot)$, is initialized to some value between 0 and $1/(1-\gamma)$. Let $Q'(\cdot,\cdot)$ be the resulting action-value estimates. Then, we have that $\max_{s,a} \{|Q'(s,a) - Q^*(s,a)|\} \leq \beta$.*

Proof Let $Q_i(s,a)$ denote the action-value estimates after the i^{th} iteration of value iteration.[8] Let $\Delta_i := \max_{(s,a)} |Q^*(s,a) - Q_i(s,a)|$. Now, we have that

$$\begin{aligned}
\Delta_i &= \max_{(s,a)} |(R(s,a) + \gamma \sum_{s'} T(s,a,s')V^*(s')) - (R(s,a) + \gamma \sum_{s'} T(s,a,s')V_{i-1}(s'))| \\
&= \max_{(s,a)} |\gamma \sum_{s'} T(s,a,s')(V^*(s') - V_{i-1}(s'))| \\
&\leq \gamma \Delta_{i-1}.
\end{aligned}$$

Using this bound along with the fact that $\Delta_0 \leq 1/(1-\gamma)$ shows that $\Delta_i \leq \gamma^i/(1-\gamma)$. Setting this value to be at most β and solving for i yields $i \geq \frac{\ln(\beta(1-\gamma))}{\ln\gamma}$. We claim that

$$\frac{\ln \frac{1}{\beta(1-\gamma)}}{1-\gamma} \geq \frac{\ln(\beta(1-\gamma))}{\ln(\gamma)}. \tag{5}$$

Note that Equation 5 is equivalent to the statement $1-\gamma \leq -\ln\gamma$, which follows from the identity $e^x \geq 1+x$. ■

The previous two propositions imply that if we require value iteration to produce an α-optimal policy it is sufficient to run it for $O\left(\frac{\ln(1/(\alpha(1-\gamma)))}{1-\gamma}\right)$ iterations. The resulting pseudo-code for R-MAX is given in Algorithm 1. We have added a real-valued parameter, ε_1, that specifies the desired closeness to optimality of the policies produced by value iteration. In Section 3.2.2, we show that both m and ε_1 can be set as functions of the other input parameters, ε, δ, S, A, and γ, in order to make theoretical guarantees about the learning efficiency of R-MAX.

2.2 Delayed Q-learning

The *Delayed Q-learning* algorithm was introduced by Strehl et al. (2006b) as the first algorithm that is known to be PAC-MDP and its per-timestep computational demands are minimal (roughly equivalent to those of Q-learning). Due to its low memory requirements, it can also be viewed as a *model-free* algorithm and the first to be provably PAC-MDP. Its analysis is also noteworthy because the polynomial upper bound on its sample complexity is a significant improvement, asymptotically, over the best previously known upper bound for any algorithm, when only the dependence on S and A is considered.

The algorithm is called "delayed" because it waits until a state-action pair has been experienced m times before updating that state-action pair's associated action value, where m is a parameter provided as input. When it does update an action value, the update can be viewed as an average of the target values for the m most recently missed update opportunities. An important observation is that, when m is large enough, a Delayed Q-learning update will be sufficiently close to a true Bellman update (Lemma 22). In this sense, this algorithm is similar to Real-Time Dynamic Programming (Barto et al., 1995), but uses online transitions to dynamically form an approximate Bellman backup.

To encourage exploration, Delayed Q-learning uses the "optimism in the face of uncertainty" principle as in R-MAX. Specifically, its initial action-value function is an over-estimate of the true

8. The initial values are therefore denoted by $Q_0(\cdot,\cdot)$.

Algorithm 1 R-MAX

Inputs: $S, A, \gamma, m, \varepsilon_1$, and $U(\cdot,\cdot)$
for all (s,a) **do**
  $Q(s,a) \leftarrow U(s,a)$ // *action-value estimates*
  $r(s,a) \leftarrow 0$
  $n(s,a) \leftarrow 0$
  for all $s' \in S$ **do**
    $n(s,a,s') \leftarrow 0$
  end for
end for
for $t = 1,2,3,\cdots$ **do**
  Let s denote the state at time t.
  Choose action $a := \text{argmax}_{a' \in A} Q(s,a')$.
  Let r be the immediate reward and s' the next state after executing action a from state s.
  if $n(s,a) < m$ **then**
    $n(s,a) \leftarrow n(s,a) + 1$
    $r(s,a) \leftarrow r(s,a) + r$ // *Record immediate reward*
    $n(s,a,s') \leftarrow n(s,a,s') + 1$ // *Record immediate next-state*
    if $n(s,a) = m$ **then**
      for $i = 1,2,3,\cdots, \left\lceil \frac{\ln(1/(\varepsilon_1(1-\gamma)))}{1-\gamma} \right\rceil$ **do**
        for all $(\bar{s},\bar{a})$ **do**
          if $n(\bar{s},\bar{a}) \geq m$ **then**
            $Q(\bar{s},\bar{a}) \leftarrow \hat{R}(\bar{s},\bar{a}) + \gamma \sum_{s'} \hat{T}(s'|\bar{s},\bar{a}) \max_{a'} Q(s',a')$.
          end if
        end for
      end for
    end if
  end if
end for

function; during execution, the successive value function estimates remain over-estimates with high probability, thanks to the delayed update rule (Lemma 23).

Like R-MAX, Delayed Q-learning performs a finite number of action-value updates. Due to the strict restrictions on the computational demands used by Delayed Q-learning, slightly more sophisticated internal logic is needed to guarantee this property. Pseudo-code[9] for Delayed Q-learning is provided in Algorithm 2. More details are provided in the following subsections.

In addition to the standard inputs, the algorithm also relies on two free parameters,

- $\varepsilon_1 \in (0,1)$: Used to provide a constant "exploration bonus" that is added to each action-value estimate when it is updated.

9. Compared to the implementation provided by Strehl et al. (2006b), we have modified the algorithm to keep track of $b(s,a)$, the "beginning" timestep for the current attempted update for (s,a). The original pseudo-code kept track of $t(s,a)$, the time of the last attempted update for (s,a). The original implementation is less efficient and adds a factor of 2 to the computational bounds. The analysis of Strehl et al. (2006b) also applies to the pseudo-code presented here, however.

Algorithm 2 Delayed Q-learning

Inputs: $S, A, \gamma, m, \varepsilon_1$, and $U(\cdot,\cdot)$
for all (s,a) **do**
  $Q(s,a) \leftarrow U(s,a)$ *// action-value estimates*
  $AU(s,a) \leftarrow 0$ *// used for attempted updates*
  $l(s,a) \leftarrow 0$ *// counters*
  $b(s,a) \leftarrow 0$ *// beginning timestep of attempted update*
  $LEARN(s,a) \leftarrow true$ *// the LEARN flags*
end for
$t^* \leftarrow 0$ *// time of most recent action value change*
for $t = 1,2,3,\cdots$ **do**
  Let s denote the state at time t.
  Choose action $a := \text{argmax}_{a' \in A} Q(s,a')$.
  Let r be the immediate reward and s' the next state after executing action a from state s.
  if $b(s,a) \leq t^*$ **then**
    $LEARN(s,a) \leftarrow true$
  end if
  if $LEARN(s,a) = true$ **then**
    if $l(s,a) = 0$ **then**
      $b(s,a) \leftarrow t$
    end if
    $l(s,a) \leftarrow l(s,a) + 1$
    $AU(s,a) \leftarrow AU(s,a) + r + \gamma \max_{a'} Q(s',a')$
    if $l(s,a) = m$ **then**
      if $Q(s,a) - AU(s,a)/m \geq 2\varepsilon_1$ **then**
        $Q(s,a) \leftarrow AU(s,a)/m + \varepsilon_1$
        $t^* \leftarrow t$
      else if $b(s,a) > t^*$ **then**
        $LEARN(s,a) \leftarrow false$
      end if
      $AU(s,a) \leftarrow 0$
      $l(s,a) \leftarrow 0$
    end if
  end if
end for

- A positive integer m: Represents the number of experiences of a state-action pair before an update is allowed.

In the analysis of Section 3.3, we provide precise values for m and ε_1 in terms of the other inputs (S, A, ε, δ, and γ) that guarantee the resulting algorithm is PAC-MDP. In addition to its action-value estimates, $Q(s,a)$, the algorithm also maintains the following internal variables,

- $l(s,a)$ for each (s,a): The number of samples (or target values) gathered for (s,a).

- $AU(s,a)$ for each (s,a): Stores the running sum of target values used to update $Q(s,a)$ once enough samples have been gathered.
- $b(s,a)$ for each (s,a): The timestep for which the first experience of (s,a) was obtained for the most recent or ongoing attempted update.
- $LEARN(s,a) \in \{true, false\}$ for each (s,a): A Boolean flag that indicates whether or not, samples are being gathered for (s,a).

2.2.1 THE UPDATE RULE

Suppose that, at time $t \geq 1$, action a is performed from state s, resulting in an *attempted update*, according to the rules to be defined in Section 2.2.2. Let $s_{k_1}, s_{k_2}, \ldots, s_{k_m}$ be the m most recent next-states observed from executing (s,a) at times $k_1 < k_2 < \cdots < k_m$, respectively ($k_m = t$). For the remainder of the paper, we also let r_i denote the i^{th} reward received during the execution of Delayed Q-learning.

Thus, at time k_i, action a was taken from state s, resulting in a transition to state s_{k_i} and an immediate reward r_{k_i}. After the t^{th} action, the following update occurs:

$$Q_{t+1}(s,a) = \frac{1}{m} \sum_{i=1}^{m} (r_{k_i} + \gamma V_{k_i}(s_{k_i})) + \varepsilon_1 \tag{6}$$

as long as performing the update would result in a new action-value estimate that is at least ε_1 smaller than the previous estimate. In other words, the following equation must be satisfied for an update to occur:

$$Q_t(s,a) - \left(\frac{1}{m} \sum_{i=1}^{m} (r_{k_i} + \gamma V_{k_i}(s_{k_i})) \right) \geq 2\varepsilon_1. \tag{7}$$

If this condition does not hold, then no update is performed, and so $Q_{t+1}(s,a) = Q_t(s,a)$.

2.2.2 MAINTENANCE OF THE *LEARN* FLAGS

We provide an intuition behind the behavior of the *LEARN* flags. Please see Algorithm 2 for a formal description of the update rules. The main computation of the algorithm is that every time a state-action pair (s,a) is experienced m times, an update of $Q(s,a)$ is attempted as in Section 2.2.1. For our analysis to hold, however, we cannot allow an infinite number of attempted updates. Therefore, attempted updates are only allowed for (s,a) when $LEARN(s,a)$ is *true*. Besides being set to *true* initially, $LEARN(s,a)$ is also set to *true* when any state-action pair is updated (because our estimate $Q(s,a)$ may need to reflect this change). $LEARN(s,a)$ can only change from *true* to *false* when no updates are made during a length of time for which (s,a) is experienced m times and the next attempted update of (s,a) fails. In this case, no more attempted updates of (s,a) are allowed until another action-value estimate is updated.

2.2.3 DELAYED Q-LEARNING'S MODEL

Delayed Q-learning was introduced as a *model-free* algorithm. This terminology was justified by noting that the space complexity of Delayed Q-learning, which is $O(SA)$, is much less than what is needed in the worst case to completely represent an MDP's transition probabilities ($O(S^2A)$).

However, there is a sense in which Delayed Q-learning can be thought of as using a model. This interpretation follows from the fact that Delayed Q-learning's update (Equation 6) is identical to ε_1 plus the result of a full Bellman backup using the empirical (maximum likelihood) model derived from the m most recent experiences of the state-action pair being updated. Since m is much less than what is needed to accurately model the true transition probability (in the $L1$ distance metric), we say that Delayed Q-learning uses a *sparse model* (Kearns and Singh, 1999). In fact, Delayed Q-learning uses this sparse model precisely once, throws it away, and then proceeds to gather experience for another sparse model. When $m = 1$, this process may occur on every timestep and the algorithm behaves very similarly to a version of Q-learning that uses a unit learning rate.

3. PAC-MDP Analysis

First, we present a general framework that allows us to prove the bounds for both algorithms. We then proceed to analyze R-MAX and Delayed Q-learning.

3.1 General Framework

We now develop some theoretical machinery to prove PAC-MDP statements about various algorithms. Our theory will be focused on algorithms that maintain a table of action values, $Q(s,a)$, for each state-action pair (denoted $Q_t(s,a)$ at time t).[10] We also assume an algorithm always chooses actions greedily with respect to the action values. This constraint is not really a restriction, since we could define an algorithm's action values as 1 for the action it chooses and 0 for all other actions. However, the general framework is understood and developed more easily under the above assumptions. For convenience, we also introduce the notation $V(s)$ to denote $\max_a Q(s,a)$ and $V_t(s)$ to denote $V(s)$ at time t.

Definition 5 *Suppose an RL algorithm $\mathcal{A}$ maintains a value, denoted $Q(s,a)$, for each state-action pair $(s,a) \in \mathcal{S} \times \mathsf{A}$. Let $Q_t(s,a)$ denote the estimate for (s,a) immediately before the t^{th} action of the agent. We say that $\mathcal{A}$ is a* **greedy algorithm** *if the t^{th} action of $\mathcal{A}$, a_t, is $a_t := \text{argmax}_{a \in \mathsf{A}} Q_t(s_t,a)$, where s_t is the t^{th} state reached by the agent.*

For all algorithms, the action values $Q(\cdot,\cdot)$ are implicitly maintained in separate max-priority queues (implemented with max-heaps, say) for each state. Specifically, if $\mathsf{A} = \{a_1, \ldots, a_k\}$ is the set of actions, then for each state s, the values $Q(s,a_1), \ldots, Q(s,a_k)$ are stored in a single priority queue. Therefore, the operations $\max_{a' \in \mathsf{A}} Q(s,a)$ and $\text{argmax}_{a' \in \mathsf{A}} Q(s,a)$, which appear in almost every algorithm, takes constant time, but the operation $Q(s,a) \leftarrow V$ for any value V takes $O(\ln(A))$ time (Cormen et al., 1990). It is possible that other data structures may result in faster algorithms.

The following is a definition of a new MDP that will be useful in our analysis.

Definition 6 *Let $M = \langle \mathcal{S}, \mathsf{A}, T, \mathcal{R}, \gamma \rangle$ be an MDP with a given set of action values, $Q(s,a)$, for each state-action pair (s,a), and a set K of state-action pairs, called the* **known state-action pairs**. *We define the* **known state-action MDP** *$M_K = \langle \mathcal{S} \cup \{z_{s,a} | (s,a) \notin K\}, \mathsf{A}, T_K, R_K, \gamma \rangle$ as follows. For each unknown state-action pair, $(s,a) \notin K$, we add a new state $z_{s,a}$ to M_K, which has self-loops for each*

10. However, the main result in this subsection (Theorem 10) does not rely on the algorithm having an explicit representation of each action value. For example, they could be implicitly held inside of a function approximator (e.g., Brunskill et al. 2008).

action ($T_K(z_{s,a}|z_{s,a},\cdot) = 1$). For all $(s,a) \in K$, $R_K(s,a) = R(s,a)$ and $T_K(\cdot|s,a) = T(\cdot|s,a)$. For all $(s,a) \notin K$, $R_K(s,a) = Q(s,a)(1-\gamma)$ and $T_K(z_{s,a}|s,a) = 1$. For the new states, the reward is $R_K(z_{s,a},\cdot) = Q(s,a)(1-\gamma)$.

The known state-action MDP is a generalization of the standard notions of a "known state MDP" of Kearns and Singh (2002) and Kakade (2003). It is an MDP whose dynamics (reward and transition functions) are equal to the true dynamics of M for a subset of the state-action pairs (specifically those in K). For all other state-action pairs, the value of taking those state-action pairs in M_K (and following any policy from that point on) is equal to the current action-value estimates $Q(s,a)$. We intuitively view K as a set of state-action pairs for which the agent has sufficiently accurate estimates of their dynamics.

Definition 7 *For algorithm $\mathcal{A}$, for each timestep t, let K_t (we drop the subscript t if t is clear from context) be a set of state-action pairs defined arbitrarily in a way that depends only on the history of the agent up to timestep t (before the $(t)^{\text{th}}$ action). We define A_K to be the event, called the* **escape event**, *that some state-action pair $(s,a) \notin K_t$ is experienced by the agent at time t.*

The following is a well-known result of the Chernoff-Hoeffding Bound and will be needed later; see Li (2009, Lemma 56) for a slightly improved result.

Lemma 8 *Suppose a weighted coin, when flipped, has probability $p > 0$ of landing with heads up. Then, for any positive integer k and real number $\delta \in (0,1)$, there exists a number $m = O((k/p)\ln(1/\delta))$, such that after m tosses, with probability at least $1-\delta$, we will observe k or more heads.*

One more technical lemma is needed before presenting the main result in this section. Note that even if we assume $V^*_M(s) \le V_{\max}$ and $Q(s,a) \le V_{\max}$ for all $s \in \mathcal{S}$ and $a \in \mathsf{A}$, it may not be true that $V^*_{M_K}(s) \le V_{\max}$. However, the following lemma shows we may instead use $2V_{\max}$ as an upper bound.

Lemma 9 *Let $M = \langle \mathcal{S}, \mathsf{A}, T, \mathcal{R}, \gamma \rangle$ be an MDP whose optimal value function is upper bounded by $V_{\max}$. Furthermore, let M_K be a known state-action MDP for some $K \subseteq \mathcal{S} \times \mathsf{A}$ defined using value function $Q(s,a)$. Then, $V^*_{M_K}(s) \le V_{\max} + \max_{s',a'} Q(s',a')$ for all $s \in \mathcal{S}$.*

Proof For any policy π and any state $s \in \mathcal{S}$, let $(s_1,a_1,r_1,s_2,a_2,r_2,s_3,a_3,r_3,\ldots)$ be a path generated by starting in state $s = s_1$ and following π in the known state-action MDP, M_K, where s_t and r_t are the state and reward at timestep t, and $a_t = \pi(s_t)$ for all t. The value function, $V^\pi_{M_K}(s)$, can be written as (see, e.g., Sutton and Barto 1998)

$$V^\pi_{M_K}(s) = \mathbf{E}_{M_K}\left[r_1 + \gamma r_2 + \gamma^2 r_3 + \cdots \mid s_1 = s, \pi\right],$$

which says the quantity $V^\pi_{M_K}(s)$ is the expected discounted total reward accumulated on this random path. Here, we use $\mathbf{E}_{M_K}$ to denote the expectation with respect to randomness in the MDP M_K.

Denote by τ be the *first* timestep in which $(s_\tau, a_\tau) \notin K$; note $\tau = \infty$ if all visited state-actions are in K. Due to construction of M_K, if τ is finite, then

$$\begin{aligned} s_\tau &= s_{\tau+1} = s_{\tau+2} = \cdots \\ a_\tau &= a_{\tau+1} = a_{\tau+2} = \cdots = \pi(s_\tau) \\ r_\tau &= r_{\tau+1} = r_{\tau+2} = \cdots = (1-\gamma)Q(s_\tau, a_\tau). \end{aligned}$$

Thus, for any fixed $\tau \geq 1$, the discounted total reward

$$\begin{aligned} & r_1 + \gamma r_2 + \gamma^2 r_3 + \cdots \\ &= \; r_1 + \gamma r_2 + \cdots + \gamma^{\tau-2} r_{\tau-1} + \gamma^{\tau-1} Q(s_\tau, a_\tau) \\ &\leq \; r_1 + \gamma r_2 + \cdots + \gamma^{\tau-2} r_{\tau-1} + \max_{s',a'} Q(s',a'), \end{aligned}$$

where the first step is due to the way we define transition/reward functions in M_K for state-actions outside K. The above upper bound holds for all fixed value of τ (finite or infinite), and so

$$\begin{aligned} & \mathbf{E}_{M_K}\left[r_1 + \gamma r_2 + \gamma^2 r_3 + \cdots \mid s_1 = s, \pi\right] \\ &\leq \; \mathbf{E}_{M_K}\left[r_1 + \gamma r_2 + \cdots + \gamma^{\tau-2} r_{\tau-1} \mid s_1 = s, \pi\right] + \max_{s',a'} Q(s',a'). \end{aligned}$$

Finally, since the transition and reward functions of M and M_K are identical for state-actions in K, we have

$$\begin{aligned} & \mathbf{E}_{M_K}\left[r_1 + \gamma r_2 + \cdots + \gamma^{\tau-2} r_{\tau-1} \mid s_1 = s, \pi\right] \\ &= \; \mathbf{E}_{M}\left[r_1 + \gamma r_2 + \cdots + \gamma^{\tau-2} r_{\tau-1} \mid s_1 = s, \pi\right], \end{aligned}$$

which implies

$$\begin{aligned} & \mathbf{E}_{M_K}\left[r_1 + \gamma r_2 + \gamma^2 r_3 + \cdots \mid s_1 = s, \pi\right] \\ &\leq \; \mathbf{E}_{M}\left[r_1 + \gamma r_2 + \cdots + \gamma^{\tau-2} r_{\tau-1}\right] + \max_{s',a'} Q(s',a') \\ &\leq \; V_M^{\pi}(s) + \max_{s',a'} Q(s',a') \\ &\leq \; V_{\max} + \max_{s',a'} Q(s',a'). \end{aligned}$$

■

Note that all learning algorithms we consider take ε and δ as input. We let $\mathcal{A}(\varepsilon,\delta)$ denote the version of algorithm $\mathcal{A}$ parameterized with ε and δ. The proof of Theorem 10 follows the structure of the work of Kakade (2003), but generalizes several key steps. The theorem also generalizes a previous result by Strehl et al. (2006a) by taking the admissible heuristic into account.

Theorem 10 *Let $\mathcal{A}(\varepsilon,\delta)$ be any greedy learning algorithm such that, for every timestep t, there exists a set K_t of state-action pairs that depends only on the agent's history up to timestep t. We assume that $K_t = K_{t+1}$ unless, during timestep t, an update to some state-action value occurs or the escape event A_K happens. Let M_{K_t} be the known state-action MDP and π_t be the current greedy policy, that is, for all states s, $\pi_t(s) = \operatorname{argmax}_a Q_t(s,a)$. Furthermore, assume $Q_t(s,a) \leq V_{\max}$ for all t and (s,a). Suppose that for any inputs ε and δ, with probability at least $1-\delta$, the following conditions hold for all states s, actions a, and timesteps t: (1) $V_t(s) \geq V^*(s) - \varepsilon$ (optimism), (2) $V_t(s) - V_{M_{K_t}}^{\pi_t}(s) \leq \varepsilon$ (accuracy), and (3) the total number of updates of action-value estimates plus the number of times the escape event from K_t, A_K, can occur is bounded by $\zeta(\varepsilon,\delta)$ (learning complexity). Then, when $\mathcal{A}(\varepsilon,\delta)$ is executed on any MDP M, it will follow a 4ε-optimal policy from its current state on all but*

$$O\left(\frac{V_{\max}\zeta(\varepsilon,\delta)}{\varepsilon(1-\gamma)} \ln\frac{1}{\delta} \ln\frac{1}{\varepsilon(1-\gamma)}\right)$$

timesteps, with probability at least $1-2\delta$.

Proof Suppose that the learning algorithm $\mathcal{A}(\varepsilon,\delta)$ is executed on MDP M. Fix the history of the agent up to the t^{th} timestep and let s_t be the t^{th} state reached. Let $\mathcal{A}_t$ denote the current (non-stationary) policy of the agent. Let $H = \frac{1}{1-\gamma}\ln\frac{1}{\varepsilon(1-\gamma)}$. From Lemma 2 of Kearns and Singh (2002), we have that $|V^{\pi}_{M_{K_t}}(s,H) - V^{\pi}_{M_{K_t}}(s)| \leq \varepsilon$, for any state s and policy π. Let W denote the event that, after executing policy $\mathcal{A}_t$ from state s_t in M for H timesteps, one of the two following events occur: (a) the algorithm performs a successful update (a change to any of its action values) of some state-action pair (s,a), or (b) some state-action pair $(s,a) \notin K_t$ is experienced (escape event A_K). Assuming the three conditions in the theorem statement hold, we have the following:

$$\begin{aligned}
&V^{\mathcal{A}_t}_M(s_t,H) \\
&\quad\geq\; V^{\pi_t}_{M_{K_t}}(s_t,H) - 2V_{\max}\Pr(W) \\
&\quad\geq\; V^{\pi_t}_{M_{K_t}}(s_t) - \varepsilon - 2V_{\max}\Pr(W) \\
&\quad\geq\; V(s_t) - 2\varepsilon - 2V_{\max}\Pr(W) \\
&\quad\geq\; V^*(s_t) - 3\varepsilon - 2V_{\max}\Pr(W).
\end{aligned}$$

The first step above follows from the fact that following $\mathcal{A}_t$ in MDP M results in behavior identical to that of following π_t in M_{K_t} unless event W occurs, in which case a loss of at most $2V_{\max}$ can occur (Lemma 9). The second step follows from the definition of H above. The third and final steps follow from Conditions 2 and 1, respectively, of the proposition.

Now, suppose that $\Pr(W) < \frac{\varepsilon}{2V_{\max}}$. Then, we have that the agent's policy on timestep t is 4ε-optimal:

$$V^{\mathcal{A}_t}_M(s_t) \geq V^{\mathcal{A}_t}_M(s_t,H) \geq V^*_M(s_t) - 4\varepsilon.$$

Otherwise, we have that $\Pr(W) \geq \frac{\varepsilon}{2V_{\max}}$, which implies that an agent following $\mathcal{A}_t$ will either perform a successful update in H timesteps, or encounter some $(s,a) \notin K_t$ in H timesteps, with probability at least $\frac{\varepsilon}{2V_{\max}}$. Call such an event a "success". Then, by Lemma 8, after $O(\frac{\zeta(\varepsilon,\delta)HV_{\max}}{\varepsilon}\ln 1/\delta)$ timesteps t where $\Pr(W) \geq \frac{\varepsilon}{2V_{\max}}$, $\zeta(\varepsilon,\delta)$ successes will occur, with probability at least $1-\delta$. Here, we have identified the event that a success occurs after following the agent's policy for H steps with the event that a coin lands with heads facing up. However, by Condition 3 of the proposition, with probability at least $1-\delta$, $\zeta(\varepsilon,\delta)$ is the maximum number of successes that will occur throughout the execution of the algorithm.

To summarize, we have shown that with probability $1-2\delta$, the agent will execute a 4ε-optimal policy on all but $O(\frac{\zeta(\varepsilon,\delta)HV_{\max}}{\varepsilon}\ln\frac{1}{\delta}) = O(\frac{\zeta(\varepsilon,\delta)V_{\max}}{\varepsilon(1-\gamma)}\ln\frac{1}{\delta}\ln\frac{1}{\varepsilon(1-\gamma)})$ timesteps. ■

3.2 Analysis of R-MAX

We will analyze R-MAX using the tools from Section 3.1.

3.2.1 COMPUTATIONAL COMPLEXITY

When the initial value function is $U(s,a) = 1/(1-\gamma)$ for all (s,a), there is a simple way to change the R-MAX algorithm that has a minimal affect on its behavior and saves greatly on computation. The important observation is that for a fixed state s, the maximum action-value estimate, $\max_a Q(s,a)$ will be $1/(1-\gamma)$ until all actions have been tried m times. Thus, there is no need to

run value iteration (lines 17 to 25 in Algorithm 1) until each action has been tried exactly m times. In addition, if there are some actions that have been tried m times and others that have not, the algorithm should choose one of the latter. One method to accomplish this balance is to order each action and try one after another until all are chosen m times. Kearns and Singh (2002) called this behavior "balanced wandering". However, it is not necessary to use balanced wandering; for example, it would be perfectly fine to try the first action m times, the second action m times, and so on. Any deterministic method for breaking ties in line 11 of Algorithm 1 is valid as long as mA experiences of a state-action pair results in all action being chosen m times.

On most timesteps, the R-MAX algorithm performs a constant amount of computation to choose its next action. Only when a state's last action has been tried m times does it solve its internal model. Our version of R-MAX uses value iteration to solve its model. Therefore, the per-timestep computational complexity of R-MAX is

$$\Theta\left(SA(S+\ln(A))\left(\frac{1}{1-\gamma}\right)\ln\frac{1}{\varepsilon_1(1-\gamma)}\right).$$

This expression is derived using the fact that value iteration performs $\left\lceil \frac{1}{1-\gamma}\ln\frac{1}{\varepsilon_1(1-\gamma)}\right\rceil$ iterations, where each iteration involves SA full Bellman backups (one for each state-action pair). A Bellman backup requires examining all possible $O(S)$ successor states and the update to the priority queue takes time $O(\ln(A))$. Note that R-MAX updates its model at most S times. From this observation we see that the total computation time of R-MAX is $O\left(B+\frac{S^2A(S+\ln(A))}{1-\gamma}\ln\frac{1}{\varepsilon_1(1-\gamma)}\right)$, where B is the number of timesteps for which R-MAX is executed.

When a general admissible initial value function U is used, we need to run value iteration whenever some $n(s,a)$ reaches the threshold m. In this case, a similar analysis shows that the total computation time of R-MAX is $O\left(B+\frac{S^2A^2(S+\ln(A))}{1-\gamma}\ln\frac{1}{\varepsilon_1(1-\gamma)}\right)$.

3.2.2 SAMPLE COMPLEXITY

The main result of this section is the following theorem.

Theorem 11 *Suppose that* $0\le\varepsilon<\frac{1}{1-\gamma}$ *and* $0\le\delta<1$ *are two real numbers and* $M=\langle\mathcal{S},\mathsf{A},T,\mathcal{R},\gamma\rangle$ *is any MDP. There exists inputs* $m=m(\frac{1}{\varepsilon},\frac{1}{\delta})$ *and* ε_1*, satisfying* $m(\frac{1}{\varepsilon},\frac{1}{\delta})=O\left(\frac{(S+\ln(SA/\delta))V_{\max}^2}{\varepsilon^2(1-\gamma)^2}\right)$ *and* $\frac{1}{\varepsilon_1}=O(\frac{1}{\varepsilon})$*, such that if R-MAX is executed on* M *with inputs* m *and* ε_1*, then the following holds. Let* $\mathcal{A}_t$ *denote R-MAX's policy at time* t *and* s_t *denote the state at time* t*. With probability at least* $1-\delta$*,* $V_M^{\mathcal{A}_t}(s_t)\ge V_M^*(s_t)-\varepsilon$ *is true for all but*

$$O\left(\frac{|\{(s,a)\in\mathcal{S}\times\mathsf{A}|U(s,a)\ge V^*(s)-\varepsilon\}|}{\varepsilon^3(1-\gamma)^3}\left(S+\ln\frac{SA}{\delta}\right)V_{\max}^3\ln\frac{1}{\delta}\ln\frac{1}{\varepsilon(1-\gamma)}\right)$$

timesteps t*.*

First, we discuss the accuracy of the model maintained by R-MAX. The following lemma shows that two MDPs with similar transition and reward functions have similar value functions. Thus, an agent need only ensure accuracy in the transitions and rewards of its model to guarantee near-optimal behavior.

Lemma 12 *(Strehl and Littman, 2005) Let $M_1 = \langle \mathcal{S}, \mathsf{A}, T_1, R_1, \gamma \rangle$ and $M_2 = \langle \mathcal{S}, \mathsf{A}, T_2, R_2, \gamma \rangle$ be two MDPs with non-negative rewards bounded by 1 and optimal value functions bounded by $V_{\max}$. Suppose that $|R_1(s,a) - R_2(s,a)| \leq \alpha$ and $\|T_1(s,a,\cdot) - T_2(s,a,\cdot)\|_1 \leq 2\beta$ for all states s and actions a. There exists a constant $C > 0$ such that for any $0 \leq \varepsilon \leq 1/(1-\gamma)$ and stationary policy π, if $\alpha = 2\beta = C\varepsilon(1-\gamma)/V_{\max}$, then*

$$|Q_1^\pi(s,a) - Q_2^\pi(s,a)| \leq \varepsilon.$$

Let $n_t(s,a)$ denote the value of $n(s,a)$ at time t during execution of the algorithm. For R-MAX, let the "known" state-action pairs K_t, at time t (See Definition 6), to be

$$K_t := \{(s,a) \in \mathcal{S} \times \mathsf{A} | n_t(s,a) \geq m\},$$

which is dependent on the parameter m that is provided as input to the algorithm. In other words, K_t is the set of state-action pairs that have been experienced by the agent at least m times. We will show that for large enough m, the dynamics, transition and reward, associated with these pairs can be accurately approximated by the agent.

The following event will be used in our proof that R-MAX is PAC-MDP. We will provide a sufficient condition (specifically, L_1-accurate transition and reward functions) to guarantee that the event occurs, with high probability. In words, the condition says that the value of any state s, under any policy, in the empirical known state-action MDP ($\hat{M}_{K_t}$) is ε_1-close to its value in the true known state-action MDP (M_{K_t}).

Event A1 *For all stationary policies π, timesteps t and states s during execution of the R-MAX algorithm on some MDP M, $|V^\pi_{M_{K_t}}(s) - V^\pi_{\hat{M}_{K_t}}(s)| \leq \varepsilon_1$.*

Next, we quantify the number of samples needed from both the transition and reward distributions for a state-action pair to compute accurate approximations.

Lemma 13 *Suppose that $r[1], r[2], \ldots, r[m]$ are m rewards drawn independently from the reward distribution, $\mathcal{R}(s,a)$, for state-action pair (s,a). Let $\hat{R}(s,a)$ be the empirical (maximum-likelihood) estimate of $\mathcal{R}(s,a)$. Let δ_R be any positive real number less than 1. Then, with probability at least $1 - \delta_R$, we have that $|\hat{R}(s,a) - \mathcal{R}(s,a)| \leq \varepsilon^R_{n(s,a)}$, where*

$$\varepsilon^R_m := \sqrt{\frac{\ln(2/\delta_R)}{2m}}.$$

Proof This result follows directly from Hoeffding's bound (Hoeffding, 1963). ■

Lemma 14 *Suppose that $\hat{T}(s,a)$ is the empirical transition distribution for state-action pair (s,a) using m samples of next states drawn independently from the true transition distribution $T(s,a)$. Let δ_T be any positive real number less than 1. Then, with probability at least $1 - \delta_T$, we have that $\|T(s,a) - \hat{T}(s,a)\|_1 \leq \varepsilon^T_{n(s,a)}$ where*

$$\varepsilon^T_m = \sqrt{\frac{2[\ln(2^S - 2) - \ln(\delta_T)]}{m}}.$$

Proof The result follows immediately from an application of Theorem 2.1 of Weissman et al. (2003).[11] ■

Lemma 15 *There exists a constant C such that if R-MAX with parameters m and ε_1 is executed on any MDP $M = \langle \mathcal{S}, \mathsf{A}, T, \mathcal{R}, \gamma \rangle$ and m satisfies*

$$m \geq C V_{\max}^2 \left(\frac{S + \ln(SA/\delta)}{{\varepsilon_1}^2 (1-\gamma)^2} \right) = \tilde{O}\left(\frac{S V_{\max}^2}{{\varepsilon_1}^2 (1-\gamma)^2} \right),$$

then Event A1 will occur with probability at least $1 - \delta$.

Proof Event A1 occurs if R-MAX maintains a close approximation of its known state-action MDP. By Lemmas 9 and 12, it is sufficient to obtain $(C\varepsilon_1(1-\gamma)/V_{\max})$-approximate transition and reward functions (where C is a constant), for those state-action pairs in K_t. The transition and reward functions that R-MAX uses are the maximum-likelihood estimates, using only the first m samples (of immediate reward and next-state pairs) for each $(s,a) \in K$. Intuitively, as long as m is large enough, the empirical estimates for these state-action pairs will be accurate, with high probability.[12] Consider a fixed state-action pair (s,a). From Lemma 13, we can guarantee the empirical reward distribution is accurate enough, with probability at least $1 - \delta'$, as long as $\sqrt{\frac{\ln(2/\delta')}{2m}} \leq C\varepsilon_1(1-\gamma)/V_{\max}$. From Lemma 14, we can guarantee the empirical transition distribution is accurate enough, with probability at least $1 - \delta'$, as long as $\sqrt{\frac{2[\ln(2^S - 2) - \ln(\delta')]}{m}} \leq C\varepsilon_1(1-\gamma)/V_{\max}$. It is possible to choose m, as a function of the parameters of the MDP M, large enough so that both these expressions are satisfied but small enough so that

$$m \propto \frac{S + \ln(1/\delta')}{\varepsilon_1^2 (1-\gamma)^2} V_{\max}^2.$$

With this choice, we guarantee that the empirical reward and empirical distribution for a single state-action pair will be sufficiently accurate, with high probability. However, to apply the simulation bounds of Lemma 12, we require accuracy for all state-action pairs. To ensure a total failure probability of δ, we set $\delta' = \delta/(2SA)$ in the above equations and apply the union bound over all state-action pairs. ■

Proof (of Theorem 11). We apply Theorem 10. Let $\varepsilon_1 = \varepsilon/2$. Assume that Event A1 occurs. Consider some fixed time t. First, we verify Condition 1 of the theorem. We have that $V_t(s) \geq V^*_{\hat{M}_{K_t}}(s) - \varepsilon_1 \geq V^*_{M_{K_t}}(s) - 2\varepsilon_1 \geq V^*(s) - 2\varepsilon_1$. The first inequality follows from the fact that

11. The result of Weissman et al. (2003) is established using an information-theoretic argument. A similar result can be obtained (Kakade, 2003) by the multiplicative form of Chernoff's bounds.

12. There is a minor technicality here. The samples, in the form of immediate rewards and next states, experienced by an online agent in an MDP are not necessarily independent samples. The reason is that the learning environment or the agent could prevent future experiences of state-action pairs based on previously observed outcomes. Nevertheless, all the tail inequality bounds, including the Chernoff and Hoeffding Bounds, that hold for independent samples also hold for online samples in MDPs that can be viewed as martingales, a fact that follows from the Markov property. There is an extended discussion and formal proof of this fact elsewhere (Strehl and Littman, 2008b). An excellent review (with proofs) of the tail inequalities for martingales that we use in the present paper is by McDiarmid (1989).

R-MAX computes its action values by computing an ε_1-approximate solution of its internal model ($\hat{M}_{K_t}$) (using Proposition 4). The second inequality follows from Event A1 and the third from the fact that M_{K_t} can be obtained from M by removing certain states and replacing them with a maximally rewarding state whose actions are self-loops, an operation that only increases the value of any state. Next, we note that Condition 2 of the theorem follows from Event A1. Finally, observe that the learning complexity, $\zeta(\varepsilon,\delta) \leq |\{(s,a)|U(s,a) \geq V^*(s)-\varepsilon\}|m$. To see this fact, first note that state-action pair (s,a) with $U(s,a) < V^*(s)-\varepsilon$ will never be experienced, with high probability, because initially the agent chooses actions greedily with respect to $U(s,a)$ and there always exists another action a' such that $Q_t(s,a') > V^*(s)-\varepsilon$. Next, note that each time an escape occurs, some $(s,a) \notin K$ is experienced. However, once (s,a) is experienced m times, it becomes part of and never leaves the set K. To guarantee that Event A1 occurs with probability at least $1-\delta$, we use Lemma 15 to set m. ■

3.3 Analysis of Delayed Q-learning

In this section, we analyze the computational and sample complexity of Delayed Q-learning.

3.3.1 COMPUTATIONAL COMPLEXITY

On most timesteps, Delayed Q-learning performs only a constant amount of computation. Its worst-case computational complexity per timestep is

$$\Theta(\ln(A)),$$

where the logarithmic term is due to updating the priority queue that holds the action-value estimates for the current state. Since Delayed Q-learning performs at most $SA\left(1+\frac{SA}{(1-\gamma)\varepsilon_1}\right)$ attempted updates (see Lemma 19), each update involves m transitions, and each transition requires computing the greedy action whose computation complexity is $O(\ln(A))$, the total computation time of Delayed Q-learning is

$$O\left(B+\frac{mS^2A^2\ln(A)}{\varepsilon_1(1-\gamma)}\right),$$

where B is the number of timesteps for which Delayed Q-learning is executed. Since the number of attempted updates is bounded by a constant, the amortized computation time per step is $O(1)$ as B approaches ∞.

3.3.2 SAMPLE COMPLEXITY

In this section, we show that Delayed Q-learning is PAC-MDP.

Theorem 16 *(Strehl et al., 2006b) Suppose that* $0 \leq \varepsilon < \frac{1}{1-\gamma}$ *and* $0 \leq \delta < 1$ *are two real numbers and* $M = \langle \mathcal{S}, \mathsf{A}, T, \mathcal{R}, \gamma \rangle$ *is any MDP. There exists inputs* $m = m(\frac{1}{\varepsilon}, \frac{1}{\delta})$ *and* ε_1*, satisfying* $m(\frac{1}{\varepsilon}, \frac{1}{\delta}) = O\left(\frac{(1+\gamma V_{\max})^2}{\varepsilon_1^2}\ln\frac{SA}{\varepsilon_1\delta(1-\gamma)}\right)$ *and* $\frac{1}{\varepsilon_1} = O(\frac{1}{\varepsilon(1-\gamma)})$*, such that if Delayed Q-learning is executed on* M*, then the following holds. Let* $\mathcal{A}_t$ *denote Delayed Q-learning's policy at time* t *and* s_t *denote the state at*

time t. With probability at least $1-\delta$, $V_M^{\mathcal{A}_t}(s_t) \geq V_M^*(s_t) - \varepsilon$ is true for all but

$$O\left(\frac{V_{\max}(1+\gamma V_{\max})^2 \sum_{(s,a)\in\mathcal{S}\times\mathsf{A}}[U(s,a)-V^*(s)]_+}{\varepsilon^4(1-\gamma)^4} \ln\frac{1}{\delta} \ln\frac{1}{\varepsilon(1-\gamma)} \ln\frac{SA}{\delta\varepsilon(1-\gamma)}\right)$$

timesteps t.

Definition 17 *An* **update** *(or* **successful update***) of state-action pair (s,a) is a timestep t for which a change to the action-value estimate $Q(s,a)$ occurs. An* **attempted update** *of state-action pair (s,a) is a timestep t for which (s,a) is experienced, LEARN(s,a) = true and $l(s,a) = m$. An attempted update that is not successful is an* **unsuccessful update**.

To prove the main theorem we need some additional results. The following lemmas are modified slightly from Strehl et al. (2006b). For convenience, define

$$\kappa := \frac{SA}{(1-\gamma)\varepsilon_1}.$$

Lemma 18 *The total number of updates during any execution of Delayed Q-learning is at most κ.*

Proof Consider a fixed state-action pair (s,a). Its associated action-value estimate $Q(s,a)$ is initialized to $U(s,a) \leq 1/(1-\gamma)$ before any updates occur. Each time $Q(s,a)$ is updated it decreases by at least ε_1. Since all rewards encountered are non-negative, the quantities involved in any update (see Equation 6) are non-negative. Thus, $Q(s,a)$ cannot fall below 0. It follows that $Q(s,a)$ cannot be updated more than $1/(\varepsilon(1-\gamma))$ times. Since there are SA state-action pairs, we have that there are at most $SA/(\varepsilon(1-\gamma))$ total updates. ■

Lemma 19 *The total number of attempted updates during any execution of Delayed Q-learning is at most $SA(1+\kappa)$.*

Proof Consider a fixed state-action pair (s,a). Once (s,a) is experienced for the m^{th} time, an attempted update will occur. Suppose that an attempted update of (s,a) occurs during timestep t. Afterwards, for another attempted update to occur during some later timestep t', it must be the case that a successful update of some state-action pair (not necessarily (s,a)) has occurred on or after timestep t and before timestep t'. From Lemma 18, there can be at most κ total successful updates. Therefore, there are at most $1+\kappa$ attempted updates of (s,a). Since there are SA state-action pairs, there can be at most $SA(1+\kappa)$ total attempted updates. ■

Definition 20 *During timestep t of the execution of Delayed Q-learning, we define K_t to be the set*

$$K_t := \left\{(s,a) \in \mathcal{S}\times\mathsf{A} \mid Q_t(s,a) - \left(R(s,a) + \gamma\sum_{s'} T(s'|s,a)V_t(s')\right) \leq 3\varepsilon_1\right\}.$$

The set K_t consists of the state-action pairs with low Bellman residual. The state-action pairs not in K_t are the ones whose action-value estimates are overly optimistic in the sense that they would decrease significantly if subjected to a Bellman backup (as in value iteration). Intuitively, if $(s,a) \notin K_t$, then it is very likely that (s,a) will be updated successfully by Delayed Q-learning if visited m times. This intuition is formalized by the following definition and lemma.

Definition 21 *Suppose we execute Delayed Q-learning in an MDP M. Define* **Event A2** *to be the event that for all timesteps t, if $(s,a) \notin K_{k_1}$ and an attempted update of (s,a) occurs during timestep t, then the update will be successful, where $k_1 < k_2 < \cdots < k_m = t$ are m last timesteps during which (s,a) is experienced consecutively by the agent.*

Lemma 22 *Suppose we execute Delayed Q-learning with parameter m satisfying*

$$m \geq \frac{(1+\gamma V_{\max})^2}{2{\varepsilon_1}^2} \ln\left(\frac{3SA}{\delta}\left(1+\frac{SA}{\varepsilon_1(1-\gamma)}\right)\right) \tag{8}$$

in an MDP M. The probability that Event A2 occurs is greater than or equal to $1-\delta/3$.

Proof Fix any timestep k_1 (and the complete history of the agent up to k_1) satisfying: the agent is in state s and about to take action a, where $(s,a) \notin K_{k_1}$ on timestep k_1, $LEARN(s,a) = true$, and $l(s,a) = 0$ at time k_1. In other words, if (s,a) is experienced $m-1$ more times after timestep k_1, then an attempted update will result. Let $Q = [(s[1],r[1]),\ldots,(s[m],r[m])] \in (S \times \mathbb{R})^m$ be any sequence of m next-state and immediate reward tuples. Due to the Markov assumption, whenever the agent is in state s and chooses action a, the resulting next-state and immediate reward are chosen independently of the history of the agent. Thus, the probability of the joint event

1. (s,a) is experienced $m-1$ more times, and
2. the resulting next-state and immediate reward sequence equals Q

is at most the probability that Q is obtained by m independent draws from the transition and reward distributions (for (s,a)). Therefore, it suffices to prove this lemma by showing that the probability that a random sequence Q could cause an unsuccessful update of (s,a) is at most $\delta/3$. We prove this statement next.

Suppose m rewards, $r[1],\ldots,r[m]$, and m next states, $s[1],\ldots,s[m]$, are drawn independently from the reward and transition distributions, respectively, for (s,a). By a straightforward application of the Hoeffding bound (with random variables $X_i := r[i] + \gamma V_{k_1}(s[i])$ so that $0 \leq X_i \leq (1+\gamma V_{\max})$), it can be shown that our choice of m guarantees that

$$\frac{1}{m}\sum_{i=1}^{m}(r[i]+\gamma V_{k_1}(s[i])) - \mathbf{E}[X_1] < \varepsilon_1$$

holds with probability at least $1-\delta/(3SA(1+\kappa))$. If it does hold and an attempted update is performed for (s,a) using these m samples, then the resulting update will succeed. To see the claim's validity, suppose that (s,a) is experienced at times $k_1 < k_2 < \cdots < k_m = t$ and at time k_i the agent is transitioned to state $s[i]$ and receives reward $r[i]$ (causing an attempted update at time t). Then, we have that

$$Q_t(s,a) - \left(\frac{1}{m}\sum_{i=1}^{m}(r[i]+\gamma V_{k_i}(s[i]))\right) \;>\; Q_t(s,a) - \mathbf{E}[X_1] - \varepsilon_1 \;>\; 2\varepsilon_1.$$

We have used the fact that $V_{k_i}(s') \leq V_{k_1}(s')$ for all s' and $i = 1, \ldots, m$. Therefore, with high probability, Equation 7 will be true and the attempted update of $Q(s,a)$ at time k_m will succeed.

Finally, we extend our argument, using the union bound, to all possible timesteps k_1 satisfying the condition above. The number of such timesteps is bounded by the same bound we showed for the number of attempted updates (that is, $SA(1+\kappa)$). ■

The next lemma states that, with high probability, Delayed Q-learning will maintain optimistic action values.

Lemma 23 *During execution of Delayed Q-learning, if m satisfies Equation 8, then $Q_t(s,a) \geq Q^*(s,a)$ holds for all timesteps t and state-action pairs (s,a), with probability at least $1-\delta/3$.*

Proof It can be shown, by a similar argument as in the proof of Lemma 22, that $(1/m)\sum_{i=1}^{m}(r_{k_i} + \gamma V^*(s_{k_i})) > Q^*(s,a) - \varepsilon_1$ holds, for all attempted updates, with probability at least $1-\delta/3$. Assuming this equation does hold, the proof is by induction on the timestep t. For the base case, note that $Q_1(s,a) = U(s,a) \geq Q^*(s,a)$ for all (s,a). Now, suppose the claim holds for all timesteps less than or equal to t. Thus, we have that $Q_t(s,a) \geq Q^*(s,a)$, and $V_t(s) \geq V^*(s)$ for all (s,a). Suppose s is the t^{th} state reached and a is the action taken at time t. If it does not result in an attempted update or it results in an unsuccessful update, then no action-value estimates change, and we are done. Otherwise, by Equation 6, we have that $Q_{t+1}(s,a) = (1/m)\sum_{i=1}^{m}(r_{k_i} + \gamma V_{k_i}(s_{k_i})) + \varepsilon_1 \geq (1/m)\sum_{i=1}^{m}(r_{k_i} + \gamma V^*(s_{k_i})) + \varepsilon_1 \geq Q^*(s,a)$, by the induction hypothesis and an application of the equation from above. ■

Lemma 24 *(Strehl et al., 2006b) If Event A2 occurs, then the following statement holds: If an unsuccessful update occurs at time t and $LEARN_{t+1}(s,a) = false$, then $(s,a) \in K_{t+1}$.*

Proof (By contradiction) Suppose an unsuccessful update occurs at timestep t, $LEARN_{t+1}(s,a) = false$, and $(s,a) \notin K_{t+1}$. Let $k_1 < k_2 < \cdots < k_m$ be the most recent m timesteps in which a is taken in state s. Clearly, $k_m = t$. Because of Event A2, we have $(s,a) \in K_{k_1}$. Since no update occurred on timestep t, we have that $K_t = K_{t+1}$. It follows from $K_t = K_{t+1}$ that $(s,a) \notin K_t$, implying that there must exist some timestep $t' > k_1$ in which a successful update occurs. Thus, by the rules of Section 2.2.2, $LEARN_{t+1}(s,a)$ remains $true$, which contradicts our assumption. ■

The following lemma bounds the number of timesteps t in which a state-action pair $(s,a) \notin K_t$ is experienced.

Lemma 25 *If Event A2 occurs and $Q_t(s,a) \geq Q^*(s,a)$ holds for all timesteps t and state-action pairs (s,a), then the number of changes to the Q-function is at most $\sum_{(s,a)\in S\times A} \frac{[U(s,a)-V^*(s)]_+}{\varepsilon_1}$, and the number of timesteps t such that a state-action pair $(s_t,a_t) \notin K_t$ is at most $2m\sum_{(s,a)\in S\times A} \frac{[U(s,a)-V^*(s)]_+}{\varepsilon_1}$.*

Proof We claim that $Q(s,a)$ cannot be changed more than $\frac{[U(s,a)-V^*(s)]_+}{\varepsilon_1}$ times. First, note that $Q(s,a)$ is initialized to $U(s,a)$ and each successful update decreases its value by at least ε_1. Now, let $a^* = \text{argmax}_a Q^*(s,a)$. By assumption $Q(s,a^*) \geq Q^*(s,a^*) = V^*(s)$. Thus, we conclude that once

$Q(s,a)$ falls below $V^*(s)$, action a will never again be chosen in state s, since actions are chosen greedily with respect to $Q(\cdot,\cdot)$. Updates to (s,a) only occur after (s,a) has been experienced. Thus, at most $\frac{[U(s,a)-V^*(s)]_+}{\varepsilon_1}$ changes to $Q(s,a)$ can occur, and the total number of changes to the Q-function is at most $\sum_{(s,a)\in\mathcal{S}\times\mathsf{A}} \frac{[U(s,a)-V^*(s)]_+}{\varepsilon_1}$.

Suppose $(s,a)\notin K_t$ is experienced at time t and $LEARN_t(s,a) = \mathit{false}$ (implying the last attempted update was unsuccessful). By Lemma 24, we have that $(s,a)\in K_{t'+1}$ where t' was the time of the last attempted update of (s,a). Thus, some successful update has occurred since time $t'+1$. By the rules of Section 2.2.2, we have that $LEARN(s,a)$ will be set to *true* and by Event A2, the next attempted update will succeed.

Now, suppose that $(s,a)\notin K_t$ is experienced at time t and $LEARN_t(s,a) = \mathit{true}$. Within at most m more experiences of (s,a), an attempted update of (s,a) will occur. Suppose this attempted update takes place at time q and that the m most recent experiences of (s,a) happened at times $k_1 < k_2 < \cdots < k_m = q$. By Event A2, if $(s,a)\notin K_{k_1}$, the update will be successful. Otherwise, since $(s,a)\in K_{k_1}$, some successful update must have occurred between times k_1 and t (since $K_{k_1}\neq K_t$). Hence, even if the update is unsuccessful, $LEARN(s,a)$ will remain *true*, $(s,a)\notin K_{q+1}$ will hold, and the next attempted update of (s,a) will be successful.

In either case, if $(s,a)\notin K_t$, then within at most $2m$ more experiences of (s,a), a successful update of $Q(s,a)$ will occur. Thus, reaching a state-action pair not in K_t at time t will happen at most $2m\sum_{(s,a)\in\mathcal{S}\times\mathsf{A}} \frac{[U(s,a)-V^*(s)]_+}{\varepsilon_1}$ times. ■

Using these Lemmas we can prove the main result.

Proof (of Theorem 16) We apply Theorem 10. Set m as in Lemma 22 and let $\varepsilon_1 = \varepsilon(1-\gamma)/3$. First, note that K_t is defined with respect to the agent's action-value estimates $Q(\cdot,\cdot)$ and other quantities that don't change during learning. Thus, we have that $K_t = K_{t+1}$ unless an update to some action-value estimate takes place. We now assume that Event A2 occurs, an assumption that holds with probability at least $1-\delta/3$, by Lemma 22. By Lemma 23, we have that Condition 1 of Theorem 10 holds, namely that $V_t(s)\geq V^*(s)-\varepsilon$ for all timesteps t. Next, we claim that Condition 2, $V_t(s)-V^{\pi_t}_{M_{K_t}}(s)\leq \frac{3\varepsilon_1}{1-\gamma}=\varepsilon$ also holds. For convenience let M' denote M_{K_t}. Recall that for all (s,a), either $Q_t(s,a)=Q^{\pi_t}_{M'}(s,a)$ when $(s,a)\notin K_t$, or $Q_t(s,a)-(R(s,a)+\gamma\sum_{s'}T(s'|s,a)V_t(s'))\leq 3\varepsilon_1$ when $(s,a)\in K_t$ (by definition of K_t). Note that $V^{\pi_t}_{M'}$ is the solution to the following set of Bellman equations:

$$\begin{aligned} V^{\pi_t}_{M'}(s) &= R(s,\pi_t(s))+\gamma\sum_{s'\in S} T(s'|s,\pi_t(s))V^{\pi_t}_{M'}(s') && \text{if } (s,\pi_t(s))\in K_t,\\ V^{\pi_t}_{M'}(s) &= Q_t(s,\pi_t(s)), && \text{if } (s,\pi_t(s))\notin K_t. \end{aligned}$$

The vector V_t is the solution to a similar set of equations except with some additional positive reward terms on the right-hand side for the case $(s,\pi_t(s))\in K_t$, each bounded by $3\varepsilon_1$, due to our definition of the set K_t. This fact implies that $V_t(s)-V^{\pi_t}_{M_{K_t}}(s)\leq\frac{3\varepsilon_1}{1-\gamma}$, as desired; see, e.g., Munos and Moore (2000) for a proof. Finally, for Condition 3 of Theorem 10, we note that by Lemma 25, $\zeta(\varepsilon,\delta) = O\left(2m\sum_{(s,a)\in\mathcal{S}\times\mathsf{A}}\frac{[U(s,a)-V^*(s)]_+}{\varepsilon_1}\right) = O\left(\frac{(1+\gamma V_{\max})^2\sum_{(s,a)\in\mathcal{S}\times\mathsf{A}}[U(s,a)-V^*(s)]_+}{\varepsilon^3(1-\gamma)^3}\ln\frac{SA}{\varepsilon\delta(1-\gamma)}\right)$, where $\zeta(\varepsilon,\delta)$ is the number of updates and escape events that occur during execution of Delayed Q-learning with inputs ε and δ (equivalently, with inputs ε_1 and m, which are derived from ε and δ). ■

We've proven upper bounds on the learning complexity of Delayed Q-learning and R-MAX. The analysis techniques are general and have proven useful in analyzing other related algorithms (Asmuth et al., 2008; Brunskill et al., 2008; Leffler et al., 2007; Strehl et al., 2007; Strehl and Littman, 2008a).

4. A New Lower Bound

The main result of this section (Theorem 26) is an improvement on published lower bounds for learning in MDPs. Existing results (Kakade, 2003) show a linear dependence on S and ε, but we find that a linearithmic on S and a quadratic dependence on ε are necessary for any reinforcement-learning algorithm $\mathcal{A}$ that satisfies the following assumptions:

- $\mathcal{A}_t$ is a deterministic policy at all timesteps t, and
- $\mathcal{A}_t$ and $\mathcal{A}_{t+1}$ can differ only in s_t; namely, the action-selection policy of the algorithm may change only in the most recently visited state.

Both assumptions are introduced to simplify our analysis. We anticipate the same lower bound to hold without these assumptions as they do not appear to restrict the power of an algorithm in the family of difficult-to-learn MDPs that we will describe soon. Also, while we choose to drop dependence on $1/(1-\gamma)$ in our new lower bound to facilitate a cleaner analysis, we believe it is possible to force a quadratic dependence by a more careful analysis. Finally, we note that the analysis bears some similarity to the lower bound analysis of Leffler et al. (2005) although their result is different and is for a different learning model.

Theorem 26 *For any reinforcement-learning algorithm $\mathcal{A}$ that satisfies the two assumptions above, there exists an MDP M such that the sample complexity of $\mathcal{A}$ in M is*

$$\Omega\left(\frac{SA}{\varepsilon^2}\ln\frac{S}{\delta}\right).$$

To prove this theorem, consider the family of MDPs depicted in Figure 1. The MDPs have $S = N+2$ states: $\mathcal{S} = \{1,2,\ldots,N,+,-\}$, and A actions. For convenience, denote by $[N]$ the set $\{1,2,\ldots,N\}$. Transitions from each state $i \in [N]$ are the same, so only the transitions from state 1 are depicted. One of the actions (the solid one) deterministically transports the agent to state $+$ with reward $0.5+\varepsilon$. Let a be any of the other $A-1$ actions (the dashed ones). From any state $i \in [N]$, taking a will transition to $+$ with reward 1 and probability p_{ia}, and to $-$ with reward 0 otherwise, where $p_{ia} \in \{0.5, 0.5+2\varepsilon\}$ are numbers very close to $0.5+\varepsilon$. Furthermore, for each i, there is at most one a such that $p_{ia} = 0.5+2\varepsilon$. Transitions from states $+$ and $-$ are identical: they simply reset the agent to one of the states in $[N]$ uniformly at random.

In fact, the MDP defined above can be viewed as N copies of a multi-armed bandit problem where the states $+$ and $-$ are dummy states for randomly resetting the agent to the next "real" state. Therefore, the optimal action in a state i is independent of the optimal action in any other state: it is the solid action if $p_{ia} = 0.5$ for all dashed actions a; otherwise, it is the dashed action a for which $p_{ia} = 0.5+2\varepsilon$. Intuitively, this MDP is hard to learn for exactly the same reason that a biased coin is hard to learn if the bias (that is, the probability of head after a coin toss) is close to 0.5.

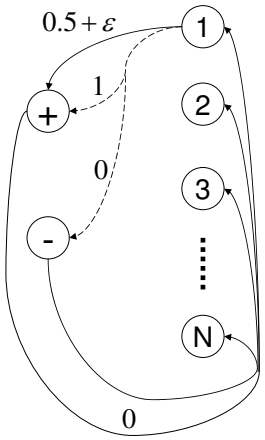

Figure 1: The difficult-to-learn MDPs for an improved sample complexity lower bound.

Lemma 27 *There exist constants $c_1, c_2 \in (0,1)$ such that during a whole run of the algorithm $\mathcal{A}$, for any state $i \in [N]$, the probability that $\mathcal{A}$ takes sub-optimal actions in i more than m_i times is at least $p(m_i)$, where*

$$p(m_i) := c_2 \exp\left(-\frac{m_i \varepsilon^2}{c_1 A}\right).$$

The following result is useful for proving Lemma 27.

Lemma 28 *(Mannor and Tsitsiklis, 2004, Theorem 1) Consider the K-armed bandit problem and let $\varepsilon, \delta \in (0,1)$. We call an algorithm $\mathcal{A}_B$ (ε,δ)-correct if it always terminates after a finite number T of trials and outputs an ε-optimal arm with probability at least $1-\delta$. Here, the sample complexity T is a random variable, and we let $\mathbf{E}$ be the expectation with respect to randomness in the bandit's rewards and $\mathcal{A}_B$ (if the algorithm is stochastic). Then there exist constants $c_1, c_2, \varepsilon_0, \delta_0 \in (0,1)$, such that for every $K \geq 2$, $\varepsilon \in (0, \varepsilon_0)$, and $\delta \in (0, \delta_0)$, and for every (ε,δ)-correct algorithm $\mathcal{A}_B$, there is a K-armed bandit problem such that*

$$\mathbf{E}[T] \geq \frac{c_1 K}{\varepsilon^2} \ln \frac{c_2}{\delta}.$$

Proof (of Lemma 27) If we treat decision making in each state as an A-arm bandit problem, finding the optimal action for that state becomes one of finding an ε-optimal arm (action) in the bandit problem. This bandit problem is the one used by Mannor and Tsitsiklis (2004) to establish the sample complexity lower bound in Lemma 28.[13]

By construction of the MDP in Figure 1, there is at most one optimal action in each state $i \in [N]$. Thus, if any RL algorithm $\mathcal{A}$ can guarantee, with probability at least $1-\delta_i$, that at most m_i sub-optimal actions are taken in state i during a whole run, then we can turn it into a bandit algorithm $\mathcal{A}_B$ with a sample complexity of $2m_i + 1$ in the following way: we simply run $\mathcal{A}$ for $2m_i + 1$ steps and the majority action must be ε-optimal with probability at least $1-\delta_i$. In other words, Lemma 28

13. The lower bound of Mannor and Tsitsiklis (2004) is for *expected* sample complexity. But, this result automatically applies to *worst-case* sample complexity, which is what we consider in the present paper.

for sample complexity in K-armed bandits results immediately in a lower bound for the total number of sub-optimal actions taken by $\mathcal{A}$, yielding

$$m_i \geq \frac{c_1 A}{\varepsilon^2} \ln \frac{c_2}{\delta_i}$$

for appropriately chosen constants c_1 and c_2. Reorganizing terms gives the desired result. ■

We will need two technical lemma to prove the lower bound. Their proofs are given after the proof of the main theorem.

Lemma 29 *Let c and Δ be constants in $(0,1)$. Under the constraints $\sum_i m_i \leq \zeta$ and $m_i > 0$ for all i, the function*

$$f(m_1, m_2, \ldots, m_N) = 1 - \prod_{i=1}^{N} (1 - c\Delta^{m_i})$$

is minimized when $m_1 = m_2 = \cdots = m_N = \frac{\zeta}{N}$. Therefore,

$$f(m_1, m_2, \ldots, m_N) \geq 1 - \left(1 - c\Delta^{\frac{\zeta}{N}}\right)^N.$$

Lemma 30 *If there exist some constants $c_1, c_2 > 0$ such that*

$$\delta \geq 1 - \left(1 - c_2 \exp\left(-\frac{\zeta\eta}{c_1\Psi}\right)\right)^{\Psi},$$

for some positive quantities η, ζ, Ψ, and δ, then

$$\zeta = \Omega\left(\frac{\Psi}{\eta} \ln \frac{\Psi}{\delta}\right).$$

Proof (of Theorem 26) Let $\zeta(\varepsilon, \delta)$ be an upper bound of the sample complexity of any PAC-MDP algorithm $\mathcal{A}$ with probability at least $1 - \delta$. Let sub-optimal actions be taken m_i times in state $i \in [N]$ during a whole run of $\mathcal{A}$. Consequently,

$$\delta \geq \Pr\left(\sum_{i=1}^{N} m_i > \zeta(\varepsilon, \delta)\right) = 1 - \Pr\left(\sum_{i=1}^{N} m_i \leq \zeta(\varepsilon, \delta)\right),$$

where the first step is because the actual sample complexity of $\mathcal{A}$ is at least $\sum_i m_i$.

We wish to find a lower bound for the last expression above by optimizing the values of m_i's subject to the constraint, $\sum_i m_i \leq \zeta(\varepsilon, \delta)$. Due to the statistical independence of what states $i \in [N]$ are visited by the algorithm,[14] we can factor the probability above to obtain

$$\delta \geq 1 - \max_{m_1, \ldots, m_N; \sum_i m_i \leq \zeta(\varepsilon, \delta)} \prod_{i=1}^{N} (1 - p(m_i)).$$

14. It does not help for the algorithm to base its policy in one state on samples collected in other states, due to the independence of states in this MDP. If an algorithm attempts to do so, an adversary can make use of this fact to assign p_{ia} to even *increase* the failure probability of the algorithm.

where Lemma 27 is applied.

We now use Lemma 29 to obtain a lower bound of the last expression above, which in turn lower-bounds δ. Applying this lemma with $c = c_2$ and $\Delta = \exp(-\frac{\varepsilon^2}{c_1 A})$ gives

$$\delta \geq 1 - \left(1 - c_2 \exp\left(-\frac{\zeta(\varepsilon,\delta)\varepsilon^2}{c_1 NA}\right)\right)^N. \tag{9}$$

The theorem then follows immediately from Lemma 30 using $\Psi = N$ and $\eta = \varepsilon^2/A$. ■

Proof (of Lemma 29) Since $f(m_1,\ldots,m_N) \in (0,1)$, finding the *minimum* of f is equivalent to finding the *maximum* of the following function:

$$g(m_1,m_2,\ldots,m_N) = \ln\left(1 - f(m_1,m_2,\ldots,m_N)\right) = \sum_{i=1}^{N} \ln\left(1 - c\Delta^{m_i}\right),$$

under the same constraints. Due to the concavity of $\ln(\cdot)$, we have

$$g(m_1,m_2,\ldots,m_N) \leq N \ln\left(\frac{1}{N}\sum_{i=1}^{N}\left(1 - c\Delta^{m_i}\right)\right) = N \ln\left(1 - \frac{c}{N}\sum_{i=1}^{N}\Delta^{m_i}\right).$$

Finally, we use the fact that the arithmetic mean is no less than the geometric mean to further simplify the upper bound of g:

$$g(m_1,m_2,\ldots,m_N) \leq N \ln\left(1 - c\Delta^{\frac{1}{N}\sum_{i=1}^{N} m_i}\right) \leq N \ln\left(1 - c\Delta^{\frac{\zeta}{N}}\right).$$

Equality holds in all inequalities above when $m_1 = m_2 = \cdots = m_N = \frac{\zeta}{N}$. ■

Proof (of Lemma 30) Reorganizing terms in Equation (9) gives

$$1 - c_2 \exp\left(-\frac{\zeta\eta}{c_1\Psi}\right) \geq (1-\delta)^{\frac{1}{\Psi}}.$$

The function $(1-\delta)^{1/\delta}$ is a decreasing function of δ for $0 < \delta < 1$, and $\lim_{\delta\to 0^+}(1-\delta)^{1/\delta} = 1/e$. Therefore, as long as δ is less than some constant $c_3 \in (0,1)$, we will have

$$(1-\delta)^{\frac{1}{\Psi}} = \left((1-\delta)^{\frac{1}{\delta}}\right)^{\frac{\delta}{\Psi}} \geq (c_4)^{\frac{\delta}{\Psi}} = \exp\left(-\frac{c_5\delta}{\Psi}\right),$$

where $c_4 = (1-c_3)^{1/c_3} \in \left(0,\frac{1}{e}\right)$ and $c_5 = \ln\frac{1}{c_4} \in (1,\infty)$ are two constants. It is important to note that c_3 (and thus c_4 and c_5) does not depend on η or Ψ. Now, apply the inequality $e^x \geq 1 + x$ for $x = -c_5\delta/\Psi$ to get $\exp(-c_5\delta/\Psi) \geq 1 - c_5\delta/\Psi$. The above chain of inequalities results in:

$$1 - c_2 \exp\left(-\frac{\zeta\eta}{c_1\Psi}\right) \geq 1 - \frac{c_5\delta}{\Psi}.$$

Solving this inequality for ζ gives the desired lower bound for ζ. ■

We have shown a new sample complexity lower bound that has a linearithmic dependence on S in the worst case. Thus, Delayed Q-learning is optimal in the sense of minimizing the dependence (of sample complexity of exploration) on the number of states.

5. Conclusion

We have presented and improved PAC-MDP upper and lower bounds reported in the literature. We studied two algorithms, R-MAX (which is model *based*) and Delayed Q-learning (which is model *free*) that are able to make use of non-trivial admissible heuristic functions. Comparing the relative strengths of model-based and model-free algorithms has been an important problem in the reinforcement-learning community (see, e.g., Atkeson and Gordon 1997 and Kearns and Singh 1999). Our analysis indicates that both can learn efficiently in finite MDPs in the PAC-MDP framework. The bounds suggest that a model-free method can be less sensitive on the size of the state space (linearithmic vs. quadratic dependence in the bound, matching the lower bound) whereas a model-based method can be less sensitive to the effective horizon, $1/(1-\gamma)$. Future work should focus on tightening bounds further and expanding analyses to state spaces in which generalization is necessary.

Acknowledgments

The authors appreciate supports from the National Science Foundation (IIS-0325281) and Rutgers University (Bevier fellowship). We thank John Langford, Eric Wiewiora, Sham Kakade, and Csaba Szepesvári for helpful discussions, especially on the analysis of Delayed Q-learning. We also thank the anonymous reviewers for their insightful comments that have significantly improved the quality of the paper.

Abstract

We show that the Brier game of prediction is mixable and find the optimal learning rate and substitution function for it. The resulting prediction algorithm is applied to predict results of football and tennis matches, with well-known bookmakers playing the role of experts. The theoretical performance guarantee is not excessively loose on the football data set and is rather tight on the tennis data set.

Keywords: Brier game, classification, on-line prediction, strong aggregating algorithm, weighted average algorithm

1. Introduction

The paradigm of prediction with expert advice was introduced in the late 1980s (see, e.g., DeSantis et al., 1988, Littlestone and Warmuth, 1994, Cesa-Bianchi et al., 1997) and has been applied to various loss functions; see Cesa-Bianchi and Lugosi (2006) for a recent book-length review. An especially important class of loss functions is that of "mixable" ones, for which the learner's loss can be made as small as the best expert's loss plus a constant (depending on the number of experts). It is known (Haussler et al., 1998; Vovk, 1998) that the optimal additive constant is attained by the "strong aggregating algorithm" proposed in Vovk (1990) (we use the adjective "strong" to distinguish it from the "weak aggregating algorithm" of Kalnishkan and Vyugin, 2008).

There are several important loss functions that have been shown to be mixable and for which the optimal additive constant has been found. The prime examples in the case of binary observations are the log loss function and the square loss function. The log loss function, whose mixability is obvious, has been explored extensively, along with its important generalizations, the Kullback-Leibler divergence and Cover's loss function (see, e.g., the review by Vovk, 2001, Section 2.5).

In this paper we concentrate on the square loss function. In the binary case, its mixability was demonstrated in Vovk (1990). There are two natural directions in which this result could be generalized:

Regression: observations are real numbers (square-loss regression is a standard problem in statistics).

Classification: observations take values in a finite set (this leads to the "Brier game", to be defined shortly, a standard way of measuring the quality of predictions in meteorology and other applied fields: see, e.g., Dawid, 1986).

The mixability of the square loss function in the case of observations belonging to a bounded interval of real numbers was demonstrated in Haussler et al. (1998); Haussler et al.'s algorithm was simplified in Vovk (2001). Surprisingly, the case of square-loss non-binary classification has never been analysed in the framework of prediction with expert advice. The purpose of this paper is to fill this gap. Its short conference version (Vovk and Zhdanov, 2008a) appeared in the ICML 2008 proceedings.

2. Prediction Algorithm and Loss Bound

A game of prediction consists of three components: the observation space Ω, the decision space Γ, and the loss function $\lambda : \Omega \times \Gamma \to \mathbb{R}$. In this paper we are interested in the following *Brier game* (Brier, 1950): Ω is a finite and non-empty set, $\Gamma := \mathcal{P}(\Omega)$ is the set of all probability measures on Ω, and

$$\lambda(\omega, \gamma) = \sum_{o \in \Omega} (\gamma\{o\} - \delta_\omega\{o\})^2 ,$$

where $\delta_\omega \in \mathcal{P}(\Omega)$ is the probability measure concentrated at ω: $\delta_\omega\{\omega\} = 1$ and $\delta_\omega\{o\} = 0$ for $o \neq \omega$. (For example, if $\Omega = \{1,2,3\}$, $\omega = 1$, $\gamma\{1\} = 1/2$, $\gamma\{2\} = 1/4$, and $\gamma\{3\} = 1/4$, $\lambda(\omega,\gamma) = (1/2-1)^2 + (1/4-0)^2 + (1/4-0)^2 = 3/8$.)

The game of prediction is being played repeatedly by a learner having access to decisions made by a pool of experts, which leads to the following prediction protocol:

Protocol 1 Prediction with expert advice

$L_0 := 0$.
$L_0^k := 0, k = 1, \dots, K$.
for $N = 1, 2, \dots$ **do**
  Expert k announces $\gamma_N^k \in \Gamma, k = 1, \dots, K$.
  Learner announces $\gamma_N \in \Gamma$.
  Reality announces $\omega_N \in \Omega$.
  $L_N := L_{N-1} + \lambda(\omega_N, \gamma_N)$.
  $L_N^k := L_{N-1}^k + \lambda(\omega_N, \gamma_N^k), k = 1, \dots, K$.
end for

At each step of Protocol 1 Learner is given K experts' advice and is required to come up with his own decision; L_N is his cumulative loss over the first N steps, and L_N^k is the kth expert's cumulative loss over the first N steps. In the case of the Brier game, the decisions are probability forecasts for the next observation.

An optimal (in the sense of Theorem 1 below) strategy for Learner in prediction with expert advice for the Brier game is given by the strong aggregating algorithm (see Algorithm 1). For each expert k, the algorithm maintains its weight w^k, constantly slashing the weights of less successful experts. Its description uses the notation $t^+ := \max(t, 0)$.

The algorithm will be derived in Section 5. The following result (to be proved in Section 4) gives a performance guarantee for it that cannot be improved by any other prediction algorithm.

Algorithm 1 Strong aggregating algorithm for the Brier game

$w_0^k := 1, k = 1, \dots, K$.
for $N = 1, 2, \dots$ **do**
  Read the Experts' predictions $\gamma_N^k, k = 1, \dots, K$.
  Set $G_N(\omega) := -\ln \sum_{k=1}^K w_{N-1}^k e^{-\lambda(\omega, \gamma_N^k)}$, $\omega \in \Omega$.
  Solve $\sum_{\omega \in \Omega} (s - G_N(\omega))^+ = 2$ in $s \in \mathbb{R}$.
  Set $\gamma_N\{\omega\} := (s - G_N(\omega))^+ / 2$, $\omega \in \Omega$.
  Output prediction $\gamma_N \in \mathcal{P}(\Omega)$.
  Read observation ω_N.
  $w_N^k := w_{N-1}^k e^{-\lambda(\omega_N, \gamma_N^k)}$.
end for

Theorem 1 *Using Algorithm 1 as Learner's strategy in Protocol 1 for the Brier game guarantees that*

$$L_N \le \min_{k=1,\dots,K} L_N^k + \ln K \tag{1}$$

for all $N = 1, 2, \dots$. *If* $A < \ln K$, *Learner does not have a strategy guaranteeing*

$$L_N \le \min_{k=1,\dots,K} L_N^k + A \tag{2}$$

for all $N = 1, 2, \dots$.

3. Experimental Results

In our first empirical study of Algorithm 1 we use historical data about 8999 matches in various English football league competitions, namely: the Premier League (the pinnacle of the English football system), the Football League Championship, Football League One, Football League Two, the Football Conference. Our data, provided by Football-Data, cover four seasons, 2005/2006, 2006/2007, 2007/2008, and 2008/2009. The matches are sorted first by date, then by league, and then by the name of the home team. In the terminology of our prediction protocol, the outcome of each match is the observation, taking one of three possible values, "home win", "draw", or "away win"; we will encode the possible values as 1, 2, and 3.

For each match we have forecasts made by a range of bookmakers. We chose eight bookmakers for which we have enough data over a long period of time, namely Bet365, Bet&Win, Gamebookers, Interwetten, Ladbrokes, Sportingbet, Stan James, and VC Bet. (And the seasons mentioned above were chosen because the forecasts of these bookmakers are available for them.)

A probability forecast for the next observation is essentially a vector (p_1, p_2, p_3) consisting of positive numbers summing to 1. The bookmakers do not announce these numbers directly; instead, they quote three betting odds, a_1, a_2, and a_3. Each number $a_i > 1$ is the total amount which the bookmaker undertakes to pay out to a client betting on outcome i per unit stake in the event that i happens (if the bookmaker wishes to return the stake to the bettor, it should be included in a_i; i.e., the odds are announced according to the "continental" rather than "traditional" system). The inverse value $1/a_i$, $i \in \{1, 2, 3\}$, can be interpreted as the bookmaker's quoted probability for the observation i. The bookmaker's quoted probabilities are usually slightly (because of the competition with other bookmakers) in his favour: the sum $1/a_1 + 1/a_2 + 1/a_3$ exceeds 1 by the amount called

the *overround* (at most 0.15 in the vast majority of cases). We use Victor Khutsishvili's (2009) formula

$$p_i := a_i^{-\gamma}, \quad i = 1,2,3, \tag{3}$$

for computing the bookmaker's probability forecasts, where $\gamma > 0$ is chosen such that $a_1^{-\gamma} + a_2^{-\gamma} + a_3^{-\gamma} = 1$. Such a value of γ exists and is unique since the function $a_1^{-\gamma} + a_2^{-\gamma} + a_3^{-\gamma}$ continuously and strictly decreases from 3 to 0 as γ changes from 0 to ∞. In practice, we usually have $\gamma > 1$ as $a_1^{-1} + a_2^{-1} + a_3^{-1} > 1$ (i.e., the overround is positive). The method of bisection was more than sufficient for us to solve $a_1^{-\gamma} + a_2^{-\gamma} + a_3^{-\gamma} = 1$ with satisfactory accuracy. Khutsishvili's argument for (3) is outlined in Appendix B.

Typical values of γ in (3) are close to 1, and the difference $\gamma - 1$ reflects the bookmaker's target profit margin. In this respect $\gamma - 1$ is similar to the overround; indeed, the approximate value of the overround is $(\gamma - 1)\sum_{i=1}^{3} a_i^{-1} \ln a_i$ assuming that the overround is small and none of a_i is too close to 0. The coefficient of proportionality $\sum_{i=1}^{3} a_i^{-1} \ln a_i$ can be interpreted as the entropy of the quoted betting odds.

The results of applying Algorithm 1 to the football data, with 8 experts and 3 possible observations, are shown in Figure 1. Let L_N^k be the cumulative loss of Expert k, $k = 1, \dots, 8$, over the first N matches and L_N be the corresponding number for Algorithm 1 (i.e., we essentially continue to use the notation of Theorem 1). The dashed line corresponding to Expert k shows the excess loss $N \mapsto L_N^k - L_N$ of Expert k over Algorithm 1. The excess loss can be negative, but from the first part of Theorem 1 (Equation (1)) we know that it cannot be less than $-\ln 8$; this lower bound is also shown in Figure 1. Finally, the thick line (the positive part of the x axis) is drawn for comparison: this is the excess loss of Algorithm 1 over itself. We can see that at each moment in time the algorithm's cumulative loss is fairly close to the cumulative loss of the best expert (at that time; the best expert keeps changing over time).

Figure 2 shows the distribution of the bookmakers' overrounds. We can see that in most cases overrounds are between 0.05 and 0.15, but there are also occasional extreme values, near zero or in excess of 0.3.

Figure 3 shows the results of another empirical study, involving data about a large number of tennis tournaments in 2004, 2005, 2006, and 2007, with the total number of matches 10,087. The tournaments include, for example, Australian Open, French Open, US Open, and Wimbledon; the data is provided by Tennis-Data. The matches are sorted by date, then by tournament, and then by the winner's name. The data contain information about the winner of each match and the betting odds of 4 bookmakers for his/her win and for the opponent's win. Therefore, now there are two possible observations (player 1's win and player 2's win). There are four bookmakers: Bet365, Centrebet, Expekt, and Pinnacle Sports. The results in Figure 3 are presented in the same way as in Figure 1.

Typical values of the overround are below 0.1, as shown in Figure 4 (analogous to Figure 2).

In both Figure 1 and Figure 3 the cumulative loss of Algorithm 1 is close to the cumulative loss of the best expert. The theoretical bound is not hopelessly loose for the football data and is rather tight for the tennis data. The pictures look almost the same when Algorithm 1 is applied in the more realistic manner where the experts' weights w^k are not updated over the matches that are played simultaneously.

Our second empirical study (Figure 3) is about binary prediction, and so the algorithm of Vovk (1990) could have also been used (and would have given similar results). We included it since we are not aware of any empirical studies even for the binary case.

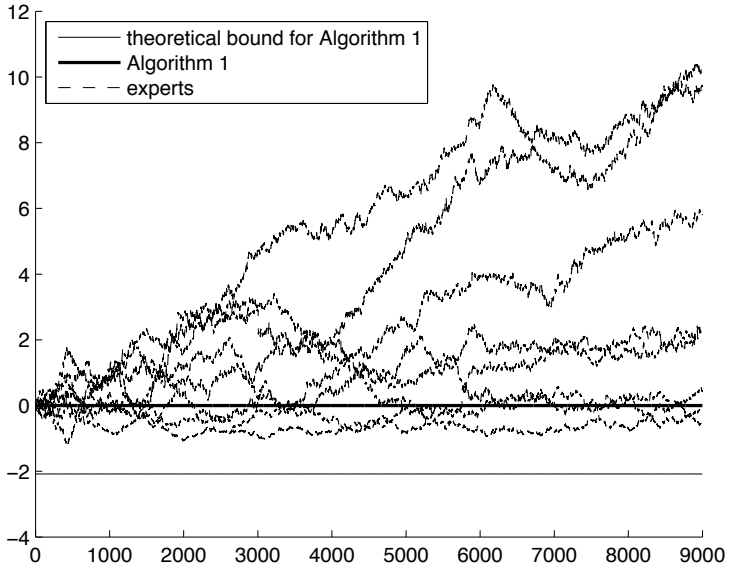

Figure 1: The difference between the cumulative loss of each of the 8 bookmakers (experts) and of Algorithm 1 on the football data. The theoretical lower bound $-\ln 8$ from Theorem 1 is also shown.

For comparison with several other popular prediction algorithms, see Appendix C. The data used for producing all the figures and tables in this section and in Appendix C can be downloaded from `http://vovk.net/ICML2008`.

4. Proof of Theorem 1

This proof will use some basic notions of elementary differential geometry, especially those connected with the Gauss-Kronecker curvature of surfaces. (The use of curvature in this kind of results is standard: see, e.g., Vovk, 1990, and Haussler et al., 1998.) All definitions that we will need can be found in, for example, Thorpe (1979).

A vector $f \in \mathbb{R}^\Omega$ (understood to be a function $f : \Omega \to \mathbb{R}$) is a *superprediction* if there is $\gamma \in \Gamma$ such that, for all $\omega \in \Omega$, $\lambda(\omega,\gamma) \le f(\omega)$; the set Σ of all superpredictions is the *superprediction set*. For each *learning rate* $\eta > 0$, let $\Phi_\eta : \mathbb{R}^\Omega \to (0,\infty)^\Omega$ be the homeomorphism defined by

$$\Phi_\eta(f) : \omega \in \Omega \mapsto e^{-\eta f(\omega)}, \quad f \in \mathbb{R}^\Omega. \tag{4}$$

The image $\Phi_\eta(\Sigma)$ of the superprediction set will be called the η-*exponential superprediction set*. It is known that

$$L_N \le \min_{k=1,\dots,K} L_N^k + \frac{\ln K}{\eta}, \quad N = 1,2,\dots,$$

can be guaranteed if and only if the η-exponential superprediction set is convex (part "if" for all K and part "only if" for $K \to \infty$ are proved in Vovk, 1998; part "only if" for all K is proved by Chris Watkins, and the details can be found in Appendix A). Comparing this with (1) and (2) we can see that we are required to prove that

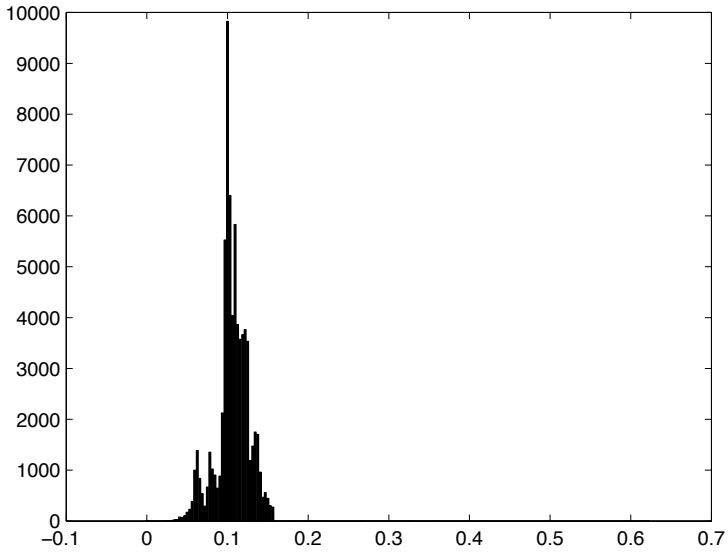

Figure 2: The overround distribution histogram for the football data, with 200 bins of equal size between the minimum and maximum values of the overround.

- $\Phi_\eta(\Sigma)$ is convex when $\eta \le 1$;
- $\Phi_\eta(\Sigma)$ is not convex when $\eta > 1$.

Define the η-*exponential superprediction surface* to be the part of the boundary of the η-exponential superprediction set $\Phi_\eta(\Sigma)$ lying inside $(0,\infty)^\Omega$. The idea of the proof is to check that, for all $\eta < 1$, the Gauss-Kronecker curvature of this surface is nowhere vanishing. Even when this is done, however, there is still uncertainty as to in which direction the surface is bulging (towards the origin or away from it). The standard argument (as in Thorpe, 1979, Chapter 12, Theorem 6) based on the continuity of the smallest principal curvature shows that the η-exponential superprediction set is bulging away from the origin for small enough η: indeed, since it is true at some point, it is true everywhere on the surface. By the continuity in η this is also true for all $\eta < 1$. Now, since the η-exponential superprediction set is convex for all $\eta < 1$, it is also convex for $\eta = 1$.

Let us now check that the Gauss-Kronecker curvature of the η-exponential superprediction surface is always positive when $\eta < 1$ and is sometimes negative when $\eta > 1$ (the rest of the proof, an elaboration of the above argument, will be easy). Set $n := |\Omega|$; without loss of generality we assume $\Omega = \{1,\dots,n\}$.

A convenient parametric representation of the η-exponential superprediction surface is

$$\begin{pmatrix} x_1 \\ x_2 \\ \vdots \\ x_{n-1} \\ x_n \end{pmatrix} = \begin{pmatrix} e^{-\eta((u_1-1)^2+u_2^2+\cdots+u_n^2)} \\ e^{-\eta(u_1^2+(u_2-1)^2+\cdots+u_n^2)} \\ \vdots \\ e^{-\eta(u_1^2+\cdots+(u_{n-1}-1)^2+u_n^2)} \\ e^{-\eta(u_1^2+\cdots+u_{n-1}^2+(u_n-1)^2)} \end{pmatrix}, \tag{5}$$

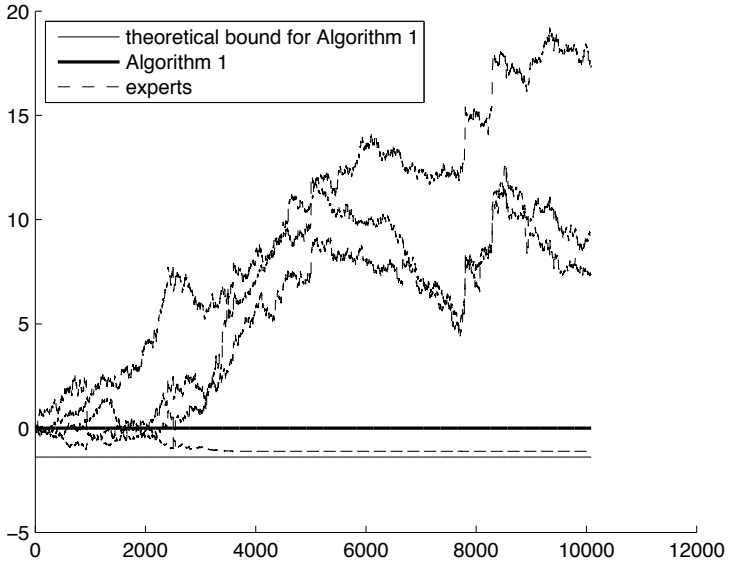

Figure 3: The difference between the cumulative loss of each of the 4 bookmakers and of Algorithm 1 on the tennis data. Now the theoretical bound is $-\ln 4$.

where $u_1,\dots,u_{n-1}$ are the coordinates on the surface, $u_1,\dots,u_{n-1}\in(0,1)$ subject to $u_1+\cdots u_{n-1}<1$, and u_n is a shorthand for $1-u_1-\cdots-u_{n-1}$. The derivative of (5) in u_1 is

$$\frac{\partial}{\partial u_1}\begin{pmatrix}x_1\\x_2\\\vdots\\x_{n-1}\\x_n\end{pmatrix}=2\eta\begin{pmatrix}(u_n-u_1+1)e^{-\eta((u_1-1)^2+u_2^2+\cdots+u_{n-1}^2+u_n^2)}\\(u_n-u_1)e^{-\eta(u_1^2+(u_2-1)^2+\cdots+u_{n-1}^2+u_n^2)}\\\vdots\\(u_n-u_1)e^{-\eta(u_1^2+u_2^2+\cdots+(u_{n-1}-1)^2+u_n^2)}\\(u_n-u_1-1)e^{-\eta(u_1^2+u_2^2+\cdots+u_{n-1}^2+(u_n-1)^2)}\end{pmatrix}\propto\begin{pmatrix}(u_n-u_1+1)e^{2\eta u_1}\\(u_n-u_1)e^{2\eta u_2}\\\vdots\\(u_n-u_1)e^{2\eta u_{n-1}}\\(u_n-u_1-1)e^{2\eta u_n}\end{pmatrix},$$

the derivative in u_2 is

$$\frac{\partial}{\partial u_2}\begin{pmatrix}x_1\\x_2\\\vdots\\x_{n-1}\\x_n\end{pmatrix}\propto\begin{pmatrix}(u_n-u_2)e^{2\eta u_1}\\(u_n-u_2+1)e^{2\eta u_2}\\\vdots\\(u_n-u_2)e^{2\eta u_{n-1}}\\(u_n-u_2-1)e^{2\eta u_n}\end{pmatrix},$$

and so on, up to

$$\frac{\partial}{\partial u_{n-1}}\begin{pmatrix}x_1\\x_2\\\vdots\\x_{n-1}\\x_n\end{pmatrix}\propto\begin{pmatrix}(u_n-u_{n-1})e^{2\eta u_1}\\(u_n-u_{n-1})e^{2\eta u_2}\\\vdots\\(u_n-u_{n-1}+1)e^{2\eta u_{n-1}}\\(u_n-u_{n-1}-1)e^{2\eta u_n}\end{pmatrix},$$

all coefficients of proportionality being equal and positive.

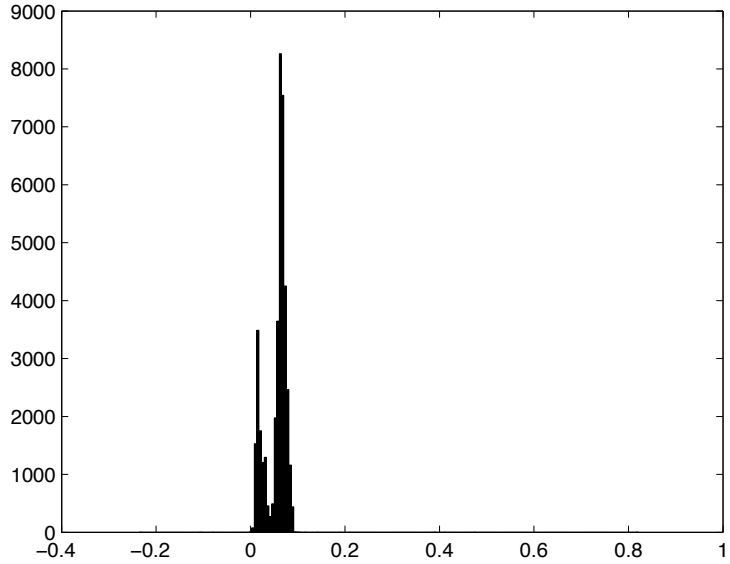

Figure 4: The overround distribution histogram for the tennis data.

A normal vector to the surface can be found as

$$Z := \begin{vmatrix} e_1 & \cdots & e_{n-1} & e_n \\ (u_n - u_1 + 1)e^{2\eta u_1} & \cdots & (u_n - u_1)e^{2\eta u_{n-1}} & (u_n - u_1 - 1)e^{2\eta u_n} \\ \vdots & \ddots & \vdots & \vdots \\ (u_n - u_{n-1})e^{2\eta u_1} & \cdots & (u_n - u_{n-1} + 1)e^{2\eta u_{n-1}} & (u_n - u_{n-1} - 1)e^{2\eta u_n} \end{vmatrix},$$

where e_i is the ith vector in the standard basis of $\mathbb{R}^n$ and $|\cdot|$ stands for the determinant (the matrix contains both scalars and vectors, but its determinant can still be computed using the standard rules). The coefficient in front of e_1 is the $(n-1)\times(n-1)$ determinant

$$\begin{vmatrix} (u_n - u_1)e^{2\eta u_2} & \cdots & (u_n - u_1)e^{2\eta u_{n-1}} & (u_n - u_1 - 1)e^{2\eta u_n} \\ (u_n - u_2 + 1)e^{2\eta u_2} & \cdots & (u_n - u_2)e^{2\eta u_{n-1}} & (u_n - u_2 - 1)e^{2\eta u_n} \\ \vdots & \ddots & \vdots & \vdots \\ (u_n - u_{n-1})e^{2\eta u_2} & \cdots & (u_n - u_{n-1} + 1)e^{2\eta u_{n-1}} & (u_n - u_{n-1} - 1)e^{2\eta u_n} \end{vmatrix}$$

$$\propto e^{-2\eta u_1} \begin{vmatrix} u_n - u_1 & \cdots & u_n - u_1 & u_n - u_1 - 1 \\ u_n - u_2 + 1 & \cdots & u_n - u_2 & u_n - u_2 - 1 \\ \vdots & \ddots & \vdots & \vdots \\ u_n - u_{n-1} & \cdots & u_n - u_{n-1} + 1 & u_n - u_{n-1} - 1 \end{vmatrix}$$

$$= e^{-2\eta u_1} \begin{vmatrix} 1 & 1 & \cdots & 1 & u_n - u_1 - 1 \\ 2 & 1 & \cdots & 1 & u_n - u_2 - 1 \\ 1 & 2 & \cdots & 1 & u_n - u_3 - 1 \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ 1 & 1 & \cdots & 2 & u_n - u_{n-1} - 1 \end{vmatrix} = e^{-2\eta u_1} \begin{vmatrix} 1 & 1 & \cdots & 1 & u_n - u_1 - 1 \\ 1 & 0 & \cdots & 0 & u_1 - u_2 \\ 0 & 1 & \cdots & 0 & u_1 - u_3 \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & \cdots & 1 & u_1 - u_{n-1} \end{vmatrix}$$

$$
\begin{aligned}
&= e^{-2\eta u_1}\big((-1)^n(u_n-u_1-1)+(-1)^{n+1}(u_1-u_2)\\
&+(-1)^{n+1}(u_1-u_3)+\cdots+(-1)^{n+1}(u_1-u_{n-1})\big)\\
&= e^{-2\eta u_1}(-1)^n\big((u_2+u_3+\cdots+u_n)-(n-1)u_1-1\big)\\
&= -e^{-2\eta u_1}(-1)^n n u_1 \propto u_1 e^{-2\eta u_1} \qquad (6)
\end{aligned}
$$

(with a positive coefficient of proportionality, $e^{2\eta}$, in the first $\propto$; the third equality follows from the expansion of the determinant along the last column and then along the first row).

Similarly, the coefficient in front of e_i is proportional (with the same coefficient of proportionality) to $u_i e^{-2\eta u_i}$ for $i = 2,\dots,n-1$; indeed, the $(n-1)\times(n-1)$ determinant representing the coefficient in front of e_i can be reduced to the form analogous to (6) by moving the ith row to the top.

The coefficient in front of e_n is proportional to

$$
\begin{aligned}
&e^{-2\eta u_n}\begin{vmatrix}
u_n-u_1+1 & u_n-u_1 & \cdots & u_n-u_1 & u_n-u_1\\
u_n-u_2 & u_n-u_2+1 & \cdots & u_n-u_2 & u_n-u_2\\
\vdots & \vdots & \ddots & \vdots & \vdots\\
u_n-u_{n-2} & u_n-u_{n-2} & \cdots & u_n-u_{n-2}+1 & u_n-u_{n-2}\\
u_n-u_{n-1} & u_n-u_{n-1} & \cdots & u_n-u_{n-1} & u_n-u_{n-1}+1
\end{vmatrix}\\
&= e^{-2\eta u_n}\begin{vmatrix}
1 & 0 & \cdots & 0 & u_n-u_1\\
0 & 1 & \cdots & 0 & u_n-u_2\\
\vdots & \vdots & \ddots & \vdots & \vdots\\
0 & 0 & \cdots & 1 & u_n-u_{n-2}\\
-1 & -1 & \cdots & -1 & u_n-u_{n-1}+1
\end{vmatrix} = e^{-2\eta u_n}\begin{vmatrix}
1 & 0 & \cdots & 0 & u_n-u_1\\
0 & 1 & \cdots & 0 & u_n-u_2\\
\vdots & \vdots & \ddots & \vdots & \vdots\\
0 & 0 & \cdots & 1 & u_n-u_{n-2}\\
0 & 0 & \cdots & 0 & nu_n
\end{vmatrix}\\
&= nu_n e^{-2\eta u_n}
\end{aligned}
$$

(with the coefficient of proportionality $e^{2\eta}(-1)^{n-1}$).

The Gauss-Kronecker curvature at the point with coordinates $(u_1,\dots,u_{n-1})$ is proportional (with a positive coefficient of proportionality, possibly depending on the point) to

$$
\begin{vmatrix}
\frac{\partial Z^{\mathrm{T}}}{\partial u_1}\\
\vdots\\
\frac{\partial Z^{\mathrm{T}}}{\partial u_{n-1}}\\
Z^{\mathrm{T}}
\end{vmatrix} \qquad (7)
$$

(Thorpe, 1979, Chapter 12, Theorem 5, with $^{\mathrm{T}}$ standing for transposition).

A straightforward calculation allows us to rewrite determinant (7) (ignoring the positive coefficient $((-1)^{n-1}ne^{2\eta})^n$) as

$$
\begin{vmatrix}
(1-2\eta u_1)e^{-2\eta u_1} & 0 & \cdots & 0 & (2\eta u_n-1)e^{-2\eta u_n}\\
0 & (1-2\eta u_2)e^{-2\eta u_2} & \cdots & 0 & (2\eta u_n-1)e^{-2\eta u_n}\\
\vdots & \vdots & \ddots & \vdots & \vdots\\
0 & 0 & \cdots & (1-2\eta u_{n-1})e^{-2\eta u_{n-1}} & (2\eta u_n-1)e^{-2\eta u_n}\\
u_1 e^{-2\eta u_1} & u_2 e^{-2\eta u_2} & \cdots & u_{n-1}e^{-2\eta u_{n-1}} & u_n e^{-2\eta u_n}
\end{vmatrix}
$$

$$\propto \begin{vmatrix} 1-2\eta u_1 & 0 & \cdots & 0 & 2\eta u_n - 1 \\ 0 & 1-2\eta u_2 & \cdots & 0 & 2\eta u_n - 1 \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & \cdots & 1-2\eta u_{n-1} & 2\eta u_n - 1 \\ u_1 & u_2 & \cdots & u_{n-1} & u_n \end{vmatrix}$$

$$= u_1(1-2\eta u_2)(1-2\eta u_3)\cdots(1-2\eta u_n) + u_2(1-2\eta u_1)(1-2\eta u_3)\cdots(1-2\eta u_n) + \cdots + u_n(1-2\eta u_1)(1-2\eta u_2)\cdots(1-2\eta u_{n-1}) \quad (8)$$

(with a positive coefficient of proportionality; to avoid calculation of the parities of various permutations, the reader might prefer to prove the last equality by induction in n, expanding the last determinant along the first column). Our next goal is to show that the last expression in (8) is positive when $\eta < 1$ but can be negative when $\eta > 1$.

If $\eta > 1$, set $u_1 = u_2 := 1/2$ and $u_3 = \cdots = u_n := 0$. The last expression in (8) becomes negative. It will remain negative if u_1 and u_2 are sufficiently close to $1/2$ and $u_3, \ldots, u_n$ are sufficiently close to 0.

It remains to consider the case $\eta < 1$. Set $t_i := 1 - 2\eta u_i$, $i = 1, \ldots, n$; the constraints on the t_i are

$$\begin{gathered} -1 < 1 - 2\eta < t_i < 1, \quad i = 1, \ldots, n, \\ t_1 + \cdots + t_n = n - 2\eta > n - 2. \end{gathered} \quad (9)$$

Our goal is to prove

$$(1-t_1)t_2t_3\cdots t_n + \cdots + (1-t_n)t_1t_2\cdots t_{n-1} > 0,$$

that is,

$$t_2t_3\cdots t_n + \cdots + t_1t_2\cdots t_{n-1} > nt_1\cdots t_n. \quad (10)$$

This reduces to

$$\frac{1}{t_1} + \cdots + \frac{1}{t_n} > n \quad (11)$$

if $t_1 \cdots t_n > 0$, and to

$$\frac{1}{t_1} + \cdots + \frac{1}{t_n} < n \quad (12)$$

if $t_1 \cdots t_n < 0$. The remaining case is where some of the t_i are zero; for concreteness, let $t_n = 0$. By (9) we have $t_1 + \cdots + t_{n-1} > n-2$, and so all of $t_1, \ldots, t_{n-1}$ are positive; this shows that (10) is indeed true.

Let us prove (11). Since $t_1 \cdots t_n > 0$, all of $t_1, \ldots, t_n$ are positive (if two of them were negative, the sum $t_1 + \cdots + t_n$ would be less than $n-2$; cf. (9)). Therefore,

$$\frac{1}{t_1} + \cdots + \frac{1}{t_n} > \underbrace{1 + \cdots + 1}_{n \text{ times}} = n.$$

To establish (10) it remains to prove (12). Suppose, without loss of generality, that $t_1 > 0$, $t_2 > 0, \ldots, t_{n-1} > 0$, and $t_n < 0$. We will prove a slightly stronger statement allowing $t_1, \ldots, t_{n-2}$ to take value 1 and removing the lower bound on t_n. Since the function $t \in (0,1] \mapsto 1/t$ is convex, we can also assume, without loss of generality, $t_1 = \cdots = t_{n-2} = 1$. Then $t_{n-1} + t_n > 0$, and so

$$\frac{1}{t_{n-1}} + \frac{1}{t_n} < 0;$$

therefore,

$$\frac{1}{t_1}+\cdots+\frac{1}{t_{n-2}}+\frac{1}{t_{n-1}}+\frac{1}{t_n}<n-2<n.$$

Finally, let us check that the positivity of the Gauss-Kronecker curvature implies the convexity of the η-exponential superprediction set in the case $\eta\le 1$, and the lack of positivity of the Gauss-Kronecker curvature implies the lack of convexity of the η-exponential superprediction set in the case $\eta>1$. The η-exponential superprediction surface will be oriented by choosing the normal vector field directed towards the origin. This can be done since

$$\begin{pmatrix}x_1\\ \vdots\\ x_n\end{pmatrix}\propto\begin{pmatrix}e^{2\eta u_1}\\ \vdots\\ e^{2\eta u_n}\end{pmatrix},\quad Z\propto(-1)^{n-1}\begin{pmatrix}u_1e^{-2\eta u_1}\\ \vdots\\ u_ne^{-2\eta u_n}\end{pmatrix},\tag{13}$$

with both coefficients of proportionality positive (cf. (5) and the bottom row of the first determinant in (8)), and the sign of the scalar product of the two vectors on the right-hand sides in (13) does not depend on the point $(u_1,\dots,u_{n-1})$. Namely, we take $(-1)^nZ$ as the normal vector field directed towards the origin. The Gauss-Kronecker curvature will not change sign after the re-orientation: if n is even, the new orientation coincides with the old, and for odd n the Gauss-Kronecker curvature does not depend on the orientation.

In the case $\eta>1$, the Gauss-Kronecker curvature is negative at some point, and so the η-exponential superprediction set is not convex (Thorpe, 1979, Chapter 13, Theorem 1 and its proof).

It remains to consider the case $\eta\le 1$. Because of the continuity of the η-exponential superprediction surface in η we can and will assume, without loss of generality, that $\eta<1$.

Let us first check that the smallest principal curvature $k_1=k_1(u_1,\dots,u_{n-1},\eta)$ of the η-exponential superprediction surface is always positive (among the arguments of k_1 we list not only the coordinates $u_1,\dots,u_{n-1}$ of a point on the surface (5) but also the learning rate $\eta\in(0,1)$). At least at some $(u_1,\dots,u_{n-1},\eta)$ the value of $k_1(u_1,\dots,u_{n-1},\eta)$ is positive: take a sufficiently small η and the point on the surface (5) with coordinates $u_1=\dots=u_{n-1}=1/n$; a simple calculation shows that this point will be a point of local maximum for $x_1+\dots+x_n$. Therefore, for all $(u_1,\dots,u_{n-1},\eta)$ the value of $k_1(u_1,\dots,u_{n-1},\eta)$ is positive: if k_1 had different signs at two points in the set

$$\left\{(u_1,\dots,u_{n-1},\eta)\,|\,u_1\in(0,1),\dots,u_{n-1}\in(0,1),u_1+\dots+u_{n-1}<1,\eta\in(0,1)\right\},\tag{14}$$

we could connect these points by a continuous curve lying completely inside (14); at some point on the curve, k_1 would be zero, in contradiction to the positivity of the Gauss-Kronecker curvature $k_1\cdots k_{n-1}$.

Now it is easy to show that the η-exponential superprediction set is convex. Suppose there are two points A and B on the η-exponential superprediction surface such that the interval $[A,B]$ contains points outside the η-exponential superprediction set. The intersection of the plane OAB, where O is the origin, with the η-exponential superprediction surface is a planar curve; the curvature of this curve at some point between A and B will be negative (remember that the curve is oriented by directing the normal vector field towards the origin), contradicting the positivity of k_1 at that point.

5. Derivation of the Prediction Algorithm

To achieve the loss bound (1) in Theorem 1 Learner can use, as discussed earlier, the strong aggregating algorithm (see, e.g., Vovk, 2001, Section 2.1, (15)) with $\eta=1$. In this section we will find

a substitution function for the strong aggregating algorithm for the Brier game with $\eta \le 1$, which is the only component of the algorithm not described explicitly in Vovk (2001). Our substitution function will not require that its input, the generalized prediction, should be computed from the normalized distribution $(w^k)_{k=1}^K$ on the experts; this is a valuable feature for generalizations to an infinite number of experts (as demonstrated in, e.g., Vovk, 2001, Appendix A.1).

Suppose that we are given a generalized prediction $(l_1,\dots,l_n)^{\mathrm{T}}$ computed by the aggregating pseudo-algorithm from a normalized distribution on the experts. Since $(l_1,\dots,l_n)^{\mathrm{T}}$ is a superprediction (remember that we are assuming $\eta \le 1$), we are only required to find a permitted prediction

$$\begin{pmatrix} \lambda_1 \\ \lambda_2 \\ \vdots \\ \lambda_n \end{pmatrix} = \begin{pmatrix} (u_1-1)^2+u_2^2+\dots+u_n^2 \\ u_1^2+(u_2-1)^2+\dots+u_n^2 \\ \vdots \\ u_1^2+u_2^2+\dots+(u_n-1)^2 \end{pmatrix} \tag{15}$$

(cf. (5)) satisfying

$$\lambda_1 \le l_1,\dots,\lambda_n \le l_n. \tag{16}$$

Now suppose we are given a generalized prediction $(L_1,\dots,L_n)^{\mathrm{T}}$ computed by the aggregating pseudo-algorithm from an unnormalized distribution on the experts; in other words, we are given

$$\begin{pmatrix} L_1 \\ \vdots \\ L_n \end{pmatrix} = \begin{pmatrix} l_1+c \\ \vdots \\ l_n+c \end{pmatrix}$$

for some $c \in \mathbb{R}$. To find (15) satisfying (16) we can first find the largest $t \in \mathbb{R}$ such that $(L_1 - t,\dots,L_n-t)^{\mathrm{T}}$ is still a superprediction and then find (15) satisfying

$$\lambda_1 \le L_1 - t,\dots,\lambda_n \le L_n - t. \tag{17}$$

Since $t \ge c$, it is clear that $(\lambda_1,\dots,\lambda_n)^{\mathrm{T}}$ will also satisfy the required (16).

Proposition 2 *Define $s \in \mathbb{R}$ by the requirement*

$$\sum_{i=1}^n (s-L_i)^+ = 2. \tag{18}$$

The unique solution to the optimization problem $t \to \max$ under the constraints (17) with $\lambda_1,\dots,\lambda_n$ as in (15) will be

$$u_i = \frac{(s-L_i)^+}{2}, \quad i=1,\dots,n, \tag{19}$$

$$t = s - 1 - u_1^2 - \dots - u_n^2. \tag{20}$$

There exists a unique s satisfying (18) since the left-hand side of (18) is a continuous, increasing (strictly increasing when positive) and unbounded above function of s. The substitution function is given by (19).

Proof of Proposition 2 Let us denote the u_i and t defined by (19) and (20) as $\overline{u}_i$ and $\overline{t}$, respectively. To see that they satisfy the constraints (17), notice that the ith constraint can be spelt out as

$$\overline{u}_1^2 + \cdots + \overline{u}_n^2 - 2\overline{u}_i + 1 \le L_i - \overline{t},$$

which immediately follows from (19) and (20). As a by-product, we can see that the inequality becomes an equality, that is,

$$\overline{t} = L_i - 1 + 2\overline{u}_i - \overline{u}_1^2 - \cdots - \overline{u}_n^2, \tag{21}$$

for all i with $\overline{u}_i > 0$.

We can rewrite (17) as

$$\begin{cases} t \le L_1 - 1 + 2u_1 - u_1^2 - \cdots - u_n^2, \\ \vdots \\ t \le L_n - 1 + 2u_n - u_1^2 - \cdots - u_n^2, \end{cases} \tag{22}$$

and our goal is to prove that these inequalities imply $t < \overline{t}$ (unless $u_1 = \overline{u}_1, \ldots, u_n = \overline{u}_n$). Choose $\overline{u}_i$ (necessarily $\overline{u}_i > 0$ unless $u_1 = \overline{u}_1, \ldots, u_n = \overline{u}_n$; in the latter case, however, we can, and will, also choose $\overline{u}_i > 0$) for which $\varepsilon_i := \overline{u}_i - u_i$ is maximal. Then every value of t satisfying (22) will also satisfy

$$\begin{aligned} t &\le L_i - 1 + 2u_i - \sum_{j=1}^n u_j^2 \\ &= L_i - 1 + 2\overline{u}_i - 2\varepsilon_i - \sum_{j=1}^n \overline{u}_j^2 + 2\sum_{j=1}^n \varepsilon_j \overline{u}_j - \sum_{j=1}^n \varepsilon_j^2 \\ &\le L_i - 1 + 2\overline{u}_i - \sum_{j=1}^n \overline{u}_j^2 - \sum_{j=1}^n \varepsilon_j^2 \le \overline{t}. \end{aligned} \tag{23}$$

The penultimate $\le$ in (23) follows from

$$-\varepsilon_i + \sum_{j=1}^n \varepsilon_j \overline{u}_j = \sum_{j=1}^n (\varepsilon_j - \varepsilon_i)\overline{u}_j \le 0.$$

The last $\le$ in (23) follows from (21) and becomes $<$ when not all u_j coincide with $\overline{u}_j$. ■

The detailed description of the resulting prediction algorithm was given as Algorithm 1 in Section 2. As discussed, that algorithm uses the generalized prediction $G_N(\omega)$ computed from unnormalized weights.

6. Conclusion

In this paper we only considered the simplest prediction problem for the Brier game: competing with a finite pool of experts. In the case of square-loss regression, it is possible to find efficient closed-form prediction algorithms competitive with linear functions (see, e.g., Cesa-Bianchi and Lugosi, 2006, Chapter 11). Such algorithms can often be "kernelized" to obtain prediction algorithms competitive with reproducing kernel Hilbert spaces of prediction rules. This would be an appealing research programme in the case of the Brier game as well.

Acknowledgments

Victor Khutsishvili has been extremely generous in sharing his ideas with us. Comments by Alexey Chernov, Yuri Kalnishkan, Alex Gammerman, Bob Vickers, and the anonymous referees for the conference and journal versions have helped us improve the presentation. The referees for the conference version also suggested comparing our results with the Weighted Average Algorithm and the Hedge algorithm. We are grateful to Football-Data and Tennis-Data for providing access to the data used in this paper. This work was supported in part by EPSRC (grant EP/F002998/1).

Appendix A. Watkins's Theorem

Watkins's theorem is stated in Vovk (1999, Theorem 8) not in sufficient generality: it presupposes that the loss function is mixable. The proof, however, shows that this assumption is irrelevant (it can be made part of the conclusion), and the goal of this appendix is to give a self-contained statement of a suitable version of the theorem. (The reader will notice that the generality of the new version is essential only for our discussion in Section 4, not for Theorem 1 itself.)

In this appendix we will use a slightly more general notion of a game of prediction $(\Omega, \Gamma, \lambda)$: namely, the loss function $\lambda : \Omega \times \Gamma \to \overline{\mathbb{R}}$ is now allowed to take values in the extended real line $\overline{\mathbb{R}} := \mathbb{R} \cup \{-\infty, \infty\}$ (although the value $-\infty$ will be later disallowed).

Partly following Vovk (1998), for each $K = 1, 2, \ldots$ and each $a > 0$ we consider the following perfect-information game $\mathcal{G}_K(a)$ (the "global game") between two players, Learner and Environment. Environment is a team of $K+1$ players called Expert 1 to Expert K and Reality, who play with Learner according to Protocol 1. Learner wins if, for all $N = 1, 2, \ldots$ and all $k \in \{1, \ldots, K\}$,

$$L_N \le L_N^k + a; \tag{24}$$

otherwise, Environment wins. It is possible that $L_N = \infty$ or $L_N^k = \infty$ in (24); the interpretation of inequalities involving infinities is natural.

For each K we will be interested in the set of those $a > 0$ for which Learner has a winning strategy in the game $\mathcal{G}_K(a)$ (we will denote this by $\mathrm{L} \smile \mathcal{G}_K(a)$). It is obvious that

$$\mathrm{L} \smile \mathcal{G}_K(a) \,\&\, a' > a \Longrightarrow \mathrm{L} \smile \mathcal{G}_K(a');$$

therefore, for each K there exists a unique *borderline value* a_K such that $\mathrm{L} \smile \mathcal{G}_K(a)$ holds when $a > a_K$ and fails when $a < a_K$. It is possible that $a_K = \infty$ (but remember that we are only interested in finite values of a).

These are our assumptions about the game of prediction (similar to those in Vovk, 1998):

- Γ is a compact topological space;
- for each $\omega \in \Omega$, the function $\gamma \in \Gamma \mapsto \lambda(\omega, \gamma)$ is continuous ($\overline{\mathbb{R}}$ is equipped with the standard topology);
- there exists $\gamma \in \Gamma$ such that, for all $\omega \in \Omega$, $\lambda(\omega, \gamma) < \infty$;
- the function λ is bounded below.

We say that the game of prediction $(\Omega, \Gamma, \lambda)$ is η-*mixable*, where $\eta > 0$, if

$$\forall \gamma_1 \in \Gamma, \gamma_2 \in \Gamma, \alpha \in [0,1]\ \exists \delta \in \Gamma\ \forall \omega \in \Omega\colon\ e^{-\eta\lambda(\omega,\delta)} \geq \alpha e^{-\eta\lambda(\omega,\gamma_1)} + (1-\alpha)e^{-\eta\lambda(\omega,\gamma_2)}. \tag{25}$$

In the case of finite Ω, this condition says that the image of the superprediction set under the mapping Φ_η (see (4)) is convex. The game of prediction is *mixable* if it is η-mixable for some $\eta > 0$.

It follows from Hardy et al. (1952, Theorem 92, applied to the means $\mathfrak{M}_\phi$ with $\phi(x) = e^{-\eta x}$) that if the prediction game is η-mixable it will remain η'-mixable for any positive $\eta' < \eta$. (For another proof, see the end of the proof of Lemma 9 in Vovk, 1998.) Let η^* be the supremum of the η for which the prediction game is η-mixable (with $\eta^* := 0$ when the game is not mixable). The compactness of Γ implies that the prediction game is η^*-mixable.

Theorem 3 (Chris Watkins) *For any $K \in \{2,3,\ldots\}$,*

$$a_K = \frac{\ln K}{\eta^*}.$$

In particular, $a_K < \infty$ if and only if the game is mixable.

The theorem does not say explicitly, but it is easy to check, that $\mathrm{L} \smile \mathcal{G}_K(a_K)$: this follows both from general considerations (cf. Lemma 3 in Vovk, 1998) and from the fact that the strong aggregating algorithm wins $\mathcal{G}_K(a_K) = \mathcal{G}_K(\ln K/\eta^*)$.

Proof of Theorem 3 The proof will use some notions and notation used in the statement and proof of Theorem 1 of Vovk (1998). Without loss of generality we can, and will, assume that the loss function satisfies $\lambda > 1$ (add a suitable constant to λ if needed). Therefore, Assumption 4 of Vovk (1998) (the only assumption in that paper not directly made here) is satisfied. In view of the fact that $\mathrm{L} \smile \mathcal{G}_K(\ln K/\eta^*)$, we only need to show that $\mathrm{L} \smile \mathcal{G}_K(a)$ does not hold for $a < \ln K/\eta^*$. Fix $a < \ln K/\eta^*$.

The separation curve consists of the points $(c(\beta), c(\beta)/\eta) \in [0,\infty)^2$, where $\beta := e^{-\eta}$ and η ranges over $[0,\infty]$ (see Vovk, 1998, Theorem 1). Since the two-fold convex mixture in (25) can be replaced by any finite convex mixture (apply two-fold mixtures repeatedly), setting $\eta := \eta^*$ shows that the point $(1, 1/\eta^*)$ is Northeast of (actually belongs to) the separation curve. On the other hand, the point $(1, a/\ln K)$ is Southwest and outside of the separation curve (use Lemmas 8–12 of Vovk, 1998). Therefore, E (i.e., Environment) has a winning strategy in the game $\mathcal{G}(1, a/\ln K)$. It is easy to see from the proof of Theorem 1 in Vovk (1998) that the definition of the game $\mathcal{G}$ can be modified, without changing the conclusion about $\mathcal{G}(1, a/\ln K)$, by replacing the line

E chooses $n \geq 1$ {size of the pool}

in the protocol on p. 153 of Vovk (1998) by

E chooses $n^* \geq 1$ {lower bound on the size of the pool}

L chooses $n \geq n^*$ {size of the pool}

(indeed, the proof in Section 6 of Vovk, 1998, only requires that there should be sufficiently many experts). Let n^* be the first move by Environment according to her winning strategy.

Now suppose $\mathrm{L} \smile \mathcal{G}_K(a)$. From the fact that there exists Learner's strategy $\mathcal{L}_1$ winning $\mathcal{G}_K(a)$ we can deduce: there exists Learner's strategy $\mathcal{L}_2$ winning $\mathcal{G}_{K^2}(2a)$ (we can split the K^2 experts into K groups of K, merge the experts' decisions in each group with $\mathcal{L}_1$, and finally merge the groups' decisions with $\mathcal{L}_1$); there exists Learner's strategy $\mathcal{L}_3$ winning $\mathcal{G}_{K^3}(3a)$ (we can split the K^3 experts

into K groups of K^2, merge the experts' decisions in each group with $\mathcal{L}_2$, and finally merge the groups' decisions with $\mathcal{L}_1$); and so on. When the number K^m of experts exceeds n^*, we obtain a contradiction: Learner can guarantee

$$L_N \le L_N^k + ma$$

for all N and all K^m experts k, and Environment can guarantee that

$$L_N > L_N^k + \frac{a}{\ln K}\ln(K^m) = L_N^k + ma$$

for some N and k. ■

Appendix B. Khutsishvili's Theory

In the conference version of this paper (Vovk and Zhdanov, 2008a) we used

$$p_i := \frac{1/a_i}{1/a_1 + 1/a_2 + 1/a_3}, \quad i = 1,2,3, \tag{26}$$

in place of (3). A natural way to compare formulas (3) and (26) is to compare the losses of the probability forecasts found from the bookmakers' betting odds using those formulas. Using Khutsishvili's formula (3) consistently leads to smaller losses as measured by the Brier loss function: see Tables 1 and 2. The improvement of each bookmaker's total loss over the football data set is in the range 0.72–5.84; over the tennis data set the difference is in the range 1.27–11.64. These differences are of the order of the differences in cumulative loss between different bookmakers, and so the improvement is significant.

The goal of this appendix is to present, in a rudimentary form, Khutsishvili's theory behind (3). The theory is based on a very idealized model of a bookmaker, who is assumed to compute the betting odds a for an event of probability p using a function f,

$$a := f(p).$$

Loss resulting from (3)	Loss resulting from (26)	Difference
3935.32	3944.02	8.69
3943.83	3945.10	1.27
3945.70	3957.33	11.64
3953.83	3957.75	3.92

Table 2: The bookmakers' cumulative Brier losses over the tennis data set when their probability forecasts are computed using formula (3) and formula (26).

Different bookmakers (and the same bookmaker at different times) can use different functions f. Therefore, different bookmakers may quote different odds because they may use different f and because they may assign different probabilities to the same event.

The following simple corollary of Darboux's theorem describes the set of possible functions f; its interpretation will be discussed straight after the proof.

Theorem 4 (Victor Khutsishvili) *Suppose a function $f : (0,1) \to (1,\infty)$ satisfies the condition*

$$f(pq) = f(p)f(q) \tag{27}$$

for all $p,q \in (0,1)$. There exists $c > 0$ such that $f(p) = p^{-c}$ for all $p \in (0,1)$.

Proof Equation (27) is one of the four fundamental Cauchy equations, which can be easily reduced to each other. For example, introducing a new function $g : (0,\infty) \to (0,\infty)$ by $g(u) := \ln f(e^{-u})$ and new variables $x,y \in (0,\infty)$ by $x := -\ln p$ and $y := -\ln q$, we transform (27) to the most standard Cauchy equation $g(x+y) = g(x)+g(y)$. By Darboux's theorem (see, e.g., Aczél, 1966, Section 2.1, Theorem 1(b)), $g(x) = cx$ for all $x > 0$, that is, $f(p) = p^{-c}$ for all $p \in (0,1)$. ■

The function f is defined on $(0,1)$ since we assume that in real life no bookmaker will assign a subjective probability of exactly 0 or 1 to an event on which he accepts bets. It would be irrational for the bookmaker to have $f(p) \le 1$ for some p, so $f : (0,1) \to (1,\infty)$. To justify the requirement (27), we assume that the bookmaker offers not only "single" but also "double" bets (Wikipedia, 2009). If there are two events with quoted odds a and b that the bookmaker considers independent, his quoted odds on the conjunction of the two events will be ab. If the probabilities of the two events are p and q, respectively, the probability of their conjunction will be pq. Therefore, we have (27).

Theorem 4 provides a justification of Khutsishvili's formula (3): we just assume that the bookmaker applies the same function f to all three probabilities p_1, p_2, and p_3. If $f(p) = p^{-c}$, we have $p_i = a_i^{-\gamma}$, where $\gamma = 1/c$ and $i = 1,2,3$, and γ can be found from the requirement $p_1 + p_2 + p_3 = 1$.

An important advantage of (3) over (26) is that (3) does not impose any upper limits on the overround that the bookmaker may charge (Khutsishvili, 2009). If the game has n possible outcomes ($n = 3$ for football and $n = 2$ for tennis) and the bookmaker uses $f(p) = p^{-c}$, the overround is

$$\sum_{i=1}^{n} a_i^{-1} - 1 = \sum_{i=1}^{n} p_i^c - 1$$

and so continuously changes between -1 and $n-1$ as c ranges over $(0,\infty)$ (in practice, the overround is usually positive, and so $c \in (0,1)$). Even for $n=2$, the upper bound of 1 is too large to be considered a limitation. The situation with (26) is very different: upper bounding the numerator of (26) by 1 and replacing the denominator by $1+o$, where o is the overround, we obtain $p_i < \frac{1}{1+o}$ for all i, and so $o < \min_i p_i^{-1} - 1$; this limitation on o is restrictive when one of the p_i is close to 1.

An interesting phenomenon in racetrack betting, known since Griffith (1949), is that favourites are usually underbet while longshots are overbet (see, e.g., Snowberg and Wolfers, 2007, for a recent survey and analysis). Khutsishvili's formula (3) can be regarded as a way of correcting this "favourite-longshot bias": when a_i is large (the outcome i is a longshot), (3) slashes $1/a_i$ when computing p_i more than (26) does.

Appendix C. Comparison with Other Prediction Algorithms

Other popular algorithms for prediction with expert advice that could be used instead of Algorithm 1 in our empirical studies reported in Section 3 are, among others, the Weighted Average Algorithm (WdAA, proposed by Kivinen and Warmuth, 1999), the weak aggregating algorithm (WkAA, proposed independently by Kalnishkan and Vyugin, 2008, and Cesa-Bianchi and Lugosi, 2006, Theorem 2.3; we are using Kalnishkan and Vyugin's name), and the Hedge algorithm (HA, proposed by Freund and Schapire, 1997). In this appendix we pay most attention to the WdAA since neither WkAA nor HA satisfy bounds of the form (2). (The reader can consult Vovk and Zhdanov, 2008b, for details of experiments with the latter two algorithms and formula (26) used for extracting probabilities from the quoted betting odds.) We also briefly discuss three more naive algorithms.

The Weighted Average Algorithm is very similar to the strong aggregating algorithm (SAA) used in this paper: the WdAA maintains the same weights for the experts as the SAA, and the only difference is that the WdAA merges the experts' predictions by averaging them according to their weights, whereas the SAA uses a more complicated "minimax optimal" merging scheme (given by (19) for the Brier game). The performance guarantee for the WdAA applied to the Brier game is weaker than the optimal (1), but of course this does not mean that its empirical performance is necessarily worse than that of the SAA (i.e., Algorithm 1). Figures 5 and 6 show the performance of this algorithm, in the same format as before (see Figures 1 and 3). We can see that for the football data the maximal difference between the cumulative loss of the WdAA and the cumulative loss of the best expert is slightly larger than that for Algorithm 1 but still well within the optimal bound $\ln K$ given by (1). For the tennis data the maximal difference is almost twice as large as for Algorithm 1, violating the optimal bound $\ln K$.

In its most basic form (Kivinen and Warmuth, 1999, the beginning of Section 6), the WdAA works in the following protocol. At each step each expert, Learner, and Reality choose an element of the unit ball in $\mathbb{R}^n$, and the loss function is the squared distance between the decision (Learner's or an expert's move) and the observation (Reality's move). This covers the Brier game with $\Omega = \{1,\dots,n\}$, each observation $\omega \in \Omega$ represented as the vector $(\delta_\omega\{1\},\dots,\delta_\omega\{n\})$, and each decision $\gamma \in \mathcal{P}(\Omega)$ represented as the vector $(\gamma\{1\},\dots,\gamma\{n\})$. However, in the Brier game the decision makers' moves are known to belong to the simplex $\{(u_1,\dots,u_n) \in [0,\infty)^n \mid \sum_{i=1}^n u_i = 1\}$, and Reality's move is known to be one of the vertices of this simplex. Therefore, we can optimize the ball radius by considering the smallest ball containing the simplex rather than the unit ball. This is what we did for the results reported here (although the results reported in the conference version of this paper, Vovk and Zhdanov, 2008a, are for the WdAA applied to the unit ball in $\mathbb{R}^n$). The

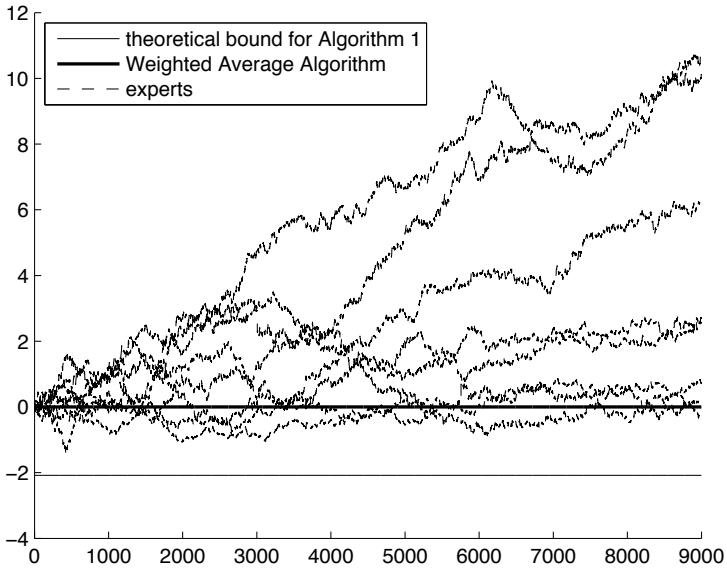

Figure 5: The difference between the cumulative loss of each of the 8 bookmakers and of the Weighted Average Algorithm (WdAA) on the football data. The chosen value of the parameter $c = 1/\eta$ for the WdAA, $c := 16/3$, minimizes its theoretical loss bound. The theoretical lower bound $-\ln 8 \approx -2.0794$ for Algorithm 1 is also shown (the theoretical lower bound for the WdAA, -11.0904, can be extracted from Table 3 below).

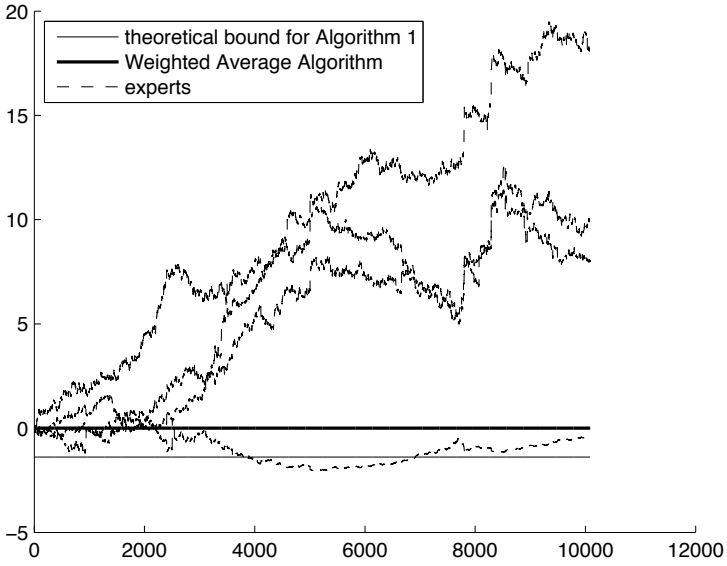

Figure 6: The difference between the cumulative loss of each of the 4 bookmakers and of the WdAA for $c := 4$ on the tennis data.

Algorithm	Maximal difference	Theoretical bound
Algorithm 1	1.2318	2.0794
WdAA ($c = 16/3$)	1.4076	11.0904
WdAA ($c = 1$)	1.2255	none

Table 3: The maximal difference between the loss of each algorithm in the selected set and the loss of the best expert for the football data (second column); the theoretical upper bound on this difference (third column).

radius of the smallest ball is

$$R := \sqrt{1 - \frac{1}{n}} \approx \begin{cases} 0.8165 & \text{if } n = 3 \\ 0.7071 & \text{if } n = 2 \\ 1 & \text{if } n \text{ is large.} \end{cases}$$

As described in Kivinen and Warmuth (1999), the WdAA is parameterized by $c := 1/\eta$ instead of η, and the optimal value of c is $c = 8R^2$, leading to the guaranteed loss bound

$$L_N \le \min_{k=1,\dots,K} L_N^k + 8R^2 \ln K$$

for all $N = 1, 2, \dots$ (see Kivinen and Warmuth, 1999, Section 6). This is significantly looser than the bound (1) for Algorithm 1.

The values $c = 16/3$ and $c = 4$ used in Figures 5 and 6, respectively, are obtained by minimizing the WdAA's performance guarantee, but minimizing a loose bound might not be such a good idea. Figure 7 shows the maximal difference

$$\max_{N=1,\dots,8999} \left(L_N(c) - \min_{k=1,\dots,8} L_N^k \right), \tag{28}$$

where $L_N(c)$ is the loss of the WdAA with parameter c on the football data over the first N steps and L_N^k is the analogous loss of the kth expert, as a function of c. Similarly, Figure 8 shows the maximal difference

$$\max_{N=1,\dots,10087} \left(L_N(c) - \min_{k=1,\dots,4} L_N^k \right) \tag{29}$$

for the tennis data. And indeed, in both cases the value of c minimizing the empirical loss is far from the value minimizing the bound; as could be expected, the empirical optimal value for the WdAA is not so different from the optimal value for Algorithm 1. The following two figures, 9 and 10, demonstrate that there is no such anomaly for Algorithm 1.

Figures 11 and 12 show the behaviour of the WdAA for the value of parameter $c = 1$, that is, $\eta = 1$, that is optimal for Algorithm 1. They look remarkably similar to Figures 1 and 3, respectively.

Precise numbers associated with the figures referred to above are given in Tables 3 and 4: the second column gives the maximal differences (28) and (29), respectively. The third column gives the theoretical upper bound on the maximal difference (i.e., the optimal value of A in (2), if available).

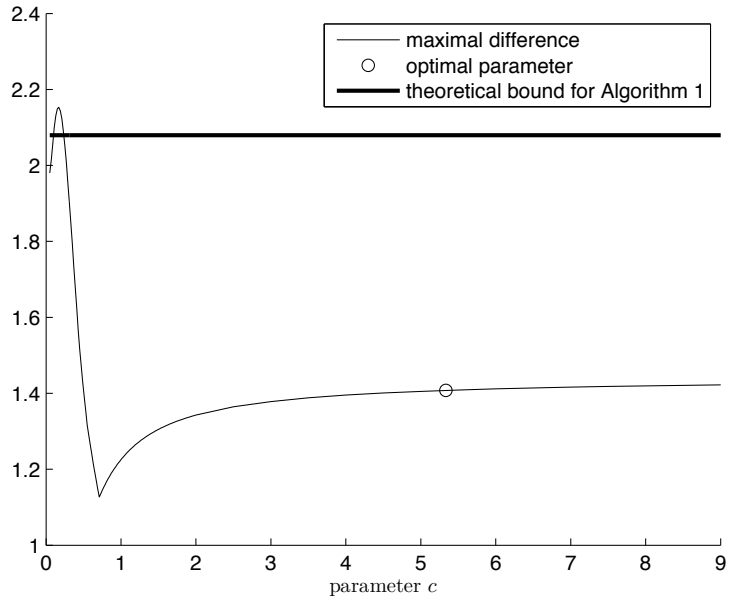

Figure 7: The maximal difference (28) for the WdAA as function of the parameter c on the football data. The theoretical guarantee $\ln 8$ for the maximal difference for Algorithm 1 is also shown (the theoretical guarantee for the WdAA, 11.0904, is given in Table 3).

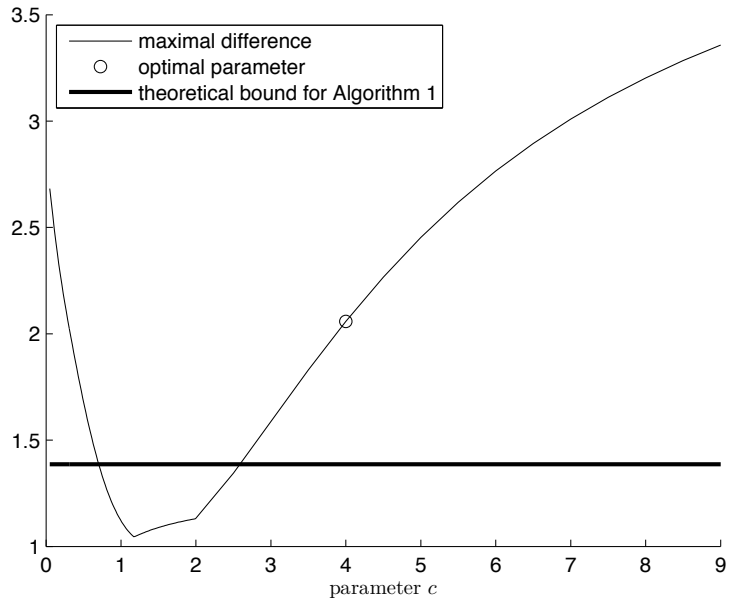

Figure 8: The maximal difference (29) for the WdAA as function of the parameter c on the tennis data. The theoretical bound for the WdAA is 5.5452 (see Table 4).

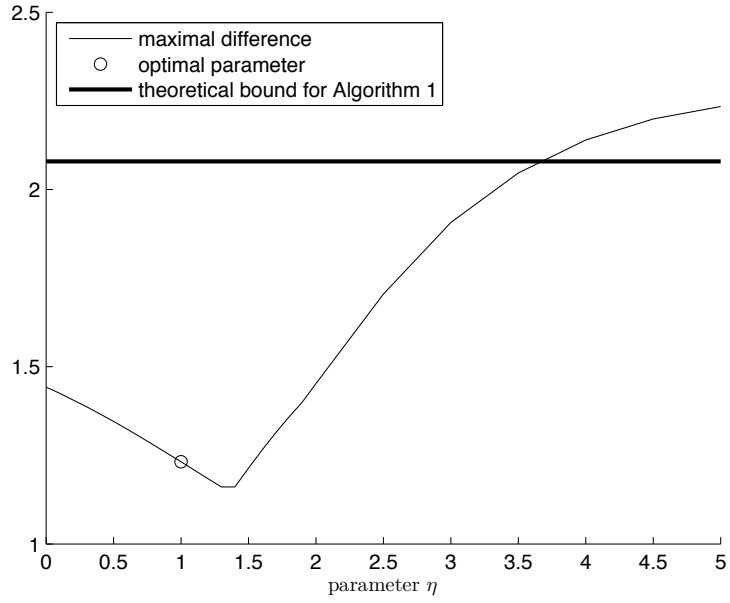

Figure 9: The maximal difference ((28) with η in place of c) for Algorithm 1 as function of the parameter η on the football data.

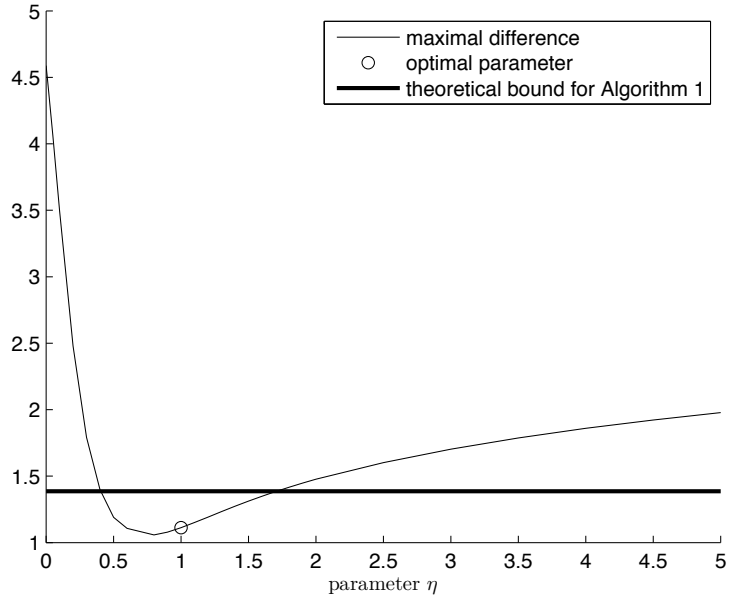

Figure 10: The maximal difference ((29) with η in place of c) for Algorithm 1 as function of the parameter η on the tennis data.

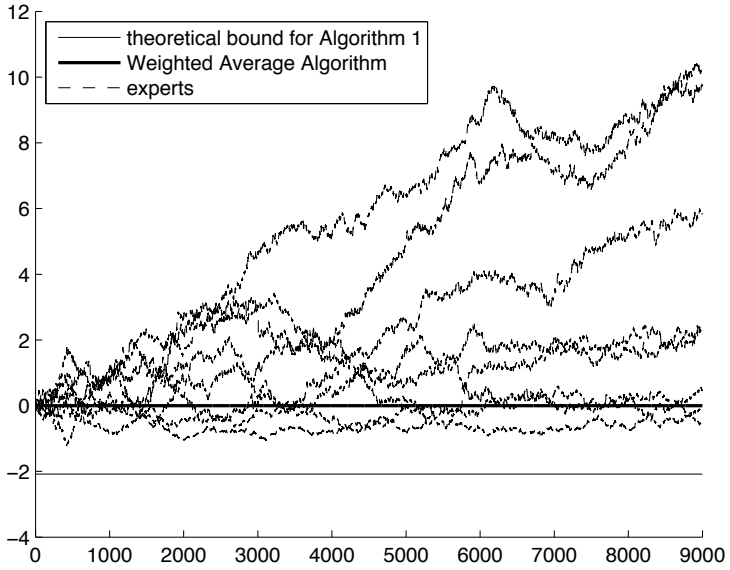

Figure 11: The difference between the cumulative loss of each of the 8 bookmakers and of the WdAA on the football data for $c = 1$ (the value of parameter minimizing the theoretical performance guarantee for Algorithm 1).

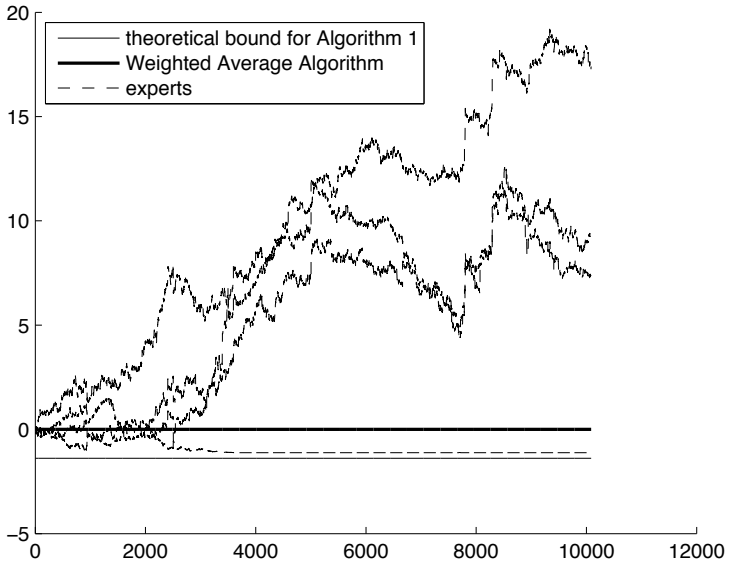

Figure 12: The difference between the cumulative loss of each of the 4 bookmakers and of the WdAA for $c = 1$ on the tennis data.

Algorithm	Maximal difference	Theoretical bound
Algorithm 1	1.1119	1.3863
WdAA ($c = 4$)	2.0583	5.5452
WdAA ($c = 1$)	1.1207	none

Table 4: The maximal difference between the loss of each algorithm in the selected set and the loss of the best expert for the tennis data (second column); the theoretical upper bound on this difference (third column).

The following two algorithms, the weak aggregating algorithm (WkAA) and the Hedge algorithm (HA), make increasingly weaker assumptions about the prediction game being played. Algorithm 1 computes the experts' weights taking full account of the degree of convexity of the loss function and uses a minimax optimal substitution function. Not surprisingly, it leads to the optimal loss bound of the form (2). The WdAA computes the experts' weights in the same way, but uses a suboptimal substitution function; this naturally leads to a suboptimal loss bound. The WkAA "does not know" that the loss function is strictly convex; it computes the experts' weights in a way that leads to decent results for all convex functions. The WkAA uses the same substitution function as the WdAA, but this appears less important than the way it computes the weights. The HA "knows" even less: it does not even know that its and the experts' performance is measured using a loss function. At each step the HA decides which expert it is going to follow, and at the end of the step it is only told the losses suffered by all experts. Both WkAA and HA depend on a parameter, which is denoted c in the case of WkAA and β in the case of HA; the ranges of the parameters are $c \in (0,\infty)$ and $\beta \in [0,1)$. The loss bounds that we give below assume that the loss function takes values in the interval $[0,L]$, in the case of the WkAA, and that the losses are chosen from $[0,L]$, in the case of HA, where L is a known constant. In the case of the Brier loss function, $L = 2$.

In the notation of (1), a simple loss bound for the WkAA is

$$L_N \le \min_{k=1,\dots,K} L_N^k + 2L\sqrt{N \ln K} \tag{30}$$

(Kalnishkan and Vyugin, 2008, Corollary 14); this is quite different from (1) as the "regret term" $2L\sqrt{N \ln K}$ in (30) depends on N. This bound is guaranteed for $c = \sqrt{\ln K}/L$. For $c = \sqrt{8 \ln K}/L$, Cesa-Bianchi and Lugosi (2006, Theorem 2.3) prove the stronger bound

$$L_N \le \min_{k=1,\dots,K} L_N^k + L\sqrt{2N \ln K} + L\sqrt{\frac{\ln K}{8}}.$$

The performance of the WkAA on our data sets is significantly worse than that of the WdAA with $c = 1$: the maximal difference (28)–(29) does not exceed $\ln K$ for all reasonable values of c in the case of football but only for a very narrow range of c (which is far from both Kalnishkan and Vyugin's $\sqrt{\ln K}/2$ and Cesa-Bianchi and Lugosi's $\sqrt{8 \ln K}/2$) in the case of tennis. Moreover, the WkAA violates the bound for Algorithm 1 for all reasonable values of c on some natural subsets of the football data set: for example, when prediction starts from the second (2006/2007) season. Nothing similar happens for the WdAA with $c = 1$ on our data sets.

The loss bound for the HA is

$$\mathbb{E}L_N \le \frac{L_N^* \ln \frac{1}{\beta} + L \ln K}{1-\beta} \tag{31}$$

(Freund and Schapire, 1997, Theorem 2), where $\mathbb{E}L_N$ stands for Learner's expected loss (the HA is a randomized algorithm) and L_N^* stands for $\min_{k=1,\dots,K} L_N^k$. In the same framework, the strong aggregating algorithm attains the stronger bound

$$\mathbb{E}L_N \le \frac{L_N^* \ln \frac{1}{\beta} + L \ln K}{K \ln \frac{K}{K+\beta-1}} \tag{32}$$

(Vovk, 1998, Example 7). Of course, the SAA applied to the HA framework (as described above, with no loss function) is very different from Algorithm 1, which is the SAA applied to the Brier game; we refer to the former algorithm as SAA-HA. Figure 13 shows the ratio of the right-hand side of (32) to the right-hand side of (31) as function of β.

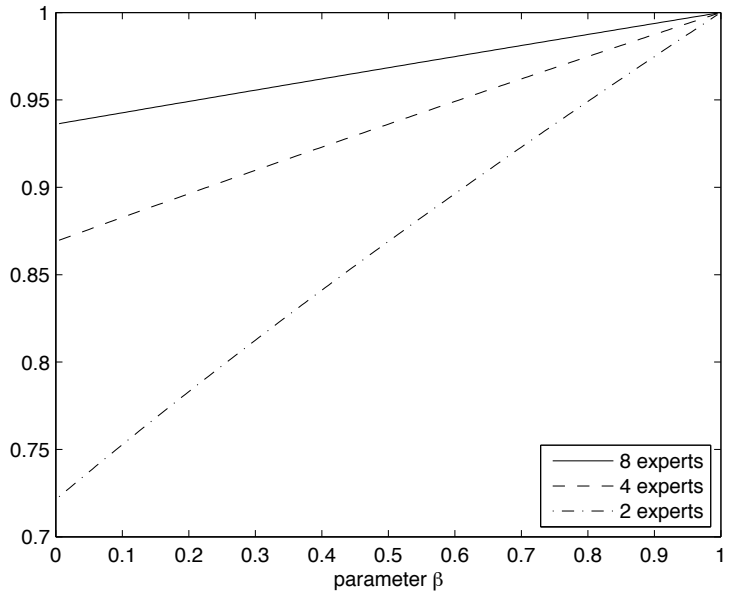

Figure 13: The relative performance of the HA and SAA-HA for various numbers of experts as function of parameter β.

The losses suffered by the HA and the SAA-HA on our data sets are very close and violate Algorithm 1's regret term $\ln K$ for all values of β. It is interesting that, for both football and tennis data, the loss of the HA is almost minimized by setting its parameter β to 0 (the qualification "almost" is necessary only in the case of the tennis data). The HA with $\beta = 0$ coincides with the Follow the Leader Algorithm (FLA), which chooses the same decision as the best (with the smallest loss up to now) expert; if there are several best experts (which almost never happens after the first step), their predictions are averaged with equal weights. Standard examples (see, e.g., Cesa-Bianchi

and Lugosi, 2006, Section 4.3) show that this algorithm (unlike its version Follow the Perturbed Leader) can fail badly on some data sequences. Its empirical performance on the football data set is not so bad: it violates the loss bound for Algorithm 1 only slightly; however, on the tennis data set the bound is violated badly.

The decent performance of the Follow the Leader Algorithm on the football data set suggests checking the empirical performance of other similarly naive algorithms, such as the following two. The *Simple Average Algorithm*'s decision is defined as the arithmetic mean of the experts' decisions (with equal weights). The *Bayes Mixture Algorithm* (BMA) is the strong aggregating algorithm applied to the log loss function; this algorithm is in fact optimal, but not for the Brier loss function. The BMA has a very simple description (Cesa-Bianchi and Lugosi, 2006, Section 9.2), and was studied from the point of view of prediction with expert advice already in DeSantis et al. (1988).

We have found that none of the three naive algorithms perform consistently poorly, but they always fail badly on some natural part of our data sets. The advantage of the more sophisticated algorithms having strong performance guarantees is that there is no danger of catastrophic performance on any data set.

Bi-Level Path Following for Cross Validated Solution of Kernel Quantile Regression

Editor: Ingo Steinwart

Abstract

We show how to follow the path of *cross validated* solutions to families of regularized optimization problems, defined by a combination of a parameterized loss function and a regularization term. A primary example is kernel quantile regression, where the parameter of the loss function is the quantile being estimated. Even though the bi-level optimization problem we encounter for every quantile is non-convex, the manner in which the optimal cross-validated solution evolves with the parameter of the loss function allows tracking of this solution. We prove this property, construct the resulting algorithm, and demonstrate it on real and artificial data. This algorithm allows us to efficiently solve the whole family of bi-level problems. We show how it can be extended to cover other modeling problems, like support vector regression, and alternative in-sample model selection approaches.[1]

1. Introduction

In the standard predictive modeling setting, we are given a *training sample* of n examples $\{\mathbf{x}_1, y_1\}, ..., \{\mathbf{x}_n, y_n\}$ drawn i.i.d from a joint distribution $P(X,Y)$, with $\mathbf{x}_i \in \mathbb{R}^p$ and $y_i \in \mathbb{R}$ for regression, $y_i \in \{0,1\}$ for two-class classification. We aim to employ these data to build a model $\hat{Y} = \hat{f}(X)$ to describe the relationship between X and Y, and later use it to predict the value of Y given new X values. This is often done by defining a family of models $\mathcal{F}$ and finding (exactly or approximately) the model $f \in \mathcal{F}$ which minimizes an *empirical loss function*: $\sum_{i=1}^{n} L(y_i, f(\mathbf{x}_i))$. Examples of such algorithms include linear and logistic regression, empirical risk minimization in classification and others.

If $\mathcal{F}$ is complex, it is often desirable to add *regularization* to control model complexity and overfitting. The generic regularized optimization problem can be written as:

$$\hat{f} = \arg\min_{f \in \mathcal{F}} \sum_{i=1}^{n} L(y_i, f(\mathbf{x}_i)) + \lambda J(f) \ ,$$

where $J(f)$ is an appropriate model complexity penalty and λ is the regularization parameter. Given a loss and a penalty, selection of a good value of λ is a *model selection* problem. Popular approaches that can be formulated as regularized optimization problems include all versions of support vector

1. A short version of this paper appeared at ICML 2008 (Rosset, 2008).

machines, ridge regression, the Lasso and many others. For an overview of predictive modeling, regularized optimization and the algorithms mentioned above, see for example Hastie et al. (2001).

In this paper we are interested in a specific setup where we have a family of regularized optimization problems, defined by a parameterized loss function and a regularization term. A major motivating example for this setting is regularized quantile regression (Koenker, 2005). In regularized linear quantile regression we take the family $\mathcal{F}$ to be all linear combinations characterized by a coefficient vector $\beta \in \mathbb{R}^p$ and the modeling problem is

$$\hat{\beta}(\tau,\lambda) = \arg\min_{\beta} \sum_{i=1}^{n} L_\tau(y_i - \beta^T \mathbf{x}_i) + \lambda \|\beta\|_q^q \ , \ 0 < \tau < 1, \ 0 \leq \lambda < \infty \ , \tag{1}$$

where L_τ, the parameterized quantile loss function, has the form:

$$L_\tau(r) = \begin{cases} r\tau & r \geq 0 \\ -r(1-\tau) & r < 0 \end{cases} \ ,$$

and is termed τ-*quantile loss* because its population optimizer is the appropriate quantile (Koenker, 2005):

$$\arg\min_{c} E(L_\tau(Y-c)|X=\mathbf{x}) = \text{quantile } \tau \text{ of } P(Y|X=\mathbf{x}) \ . \tag{2}$$

Because quantile loss has this optimizer, the solution of the quantile regression problems for the whole range $0 < \tau < 1$ has often been advocated as an approach to estimating the full conditional probability of $P(Y|X)$ (Koenker, 2005; Perlich et al., 2007). Much of the interesting information about the behavior of $Y|X$ may lie in the details of this conditional distribution, and if it is not *nicely behaved* (i.i.d Gaussian noise being the most commonly used concept of nice behavior), just estimating a conditional mean or median is often not sufficient to properly understand and model the mechanisms generating Y. The importance of estimating a complete conditional distribution, and not just a central quantity like the conditional mean, has long been noted and addressed in various communities, like econometrics, education and finance (Koenker, 2005; Buchinsky, 1994; Eide and Showalter, 1998). There has been a surge of interest in the machine learning community in conditional quantile estimation in recent years, including theoretical analyses of consistency in quantile estimation and connections with support vector machines (Steinwart and Christmann, 2008; Christmann and Steinwart, 2008); methodological work on algorithms for quantile regression and their performance (Meinshausen, 2006; Takeuchi et al., 2006; Mease et al., 2007); and work on practical uses of extreme quantile estimation for data mining applications Perlich et al. (2007). Figure 1 shows a graphical representation of L_τ for several values of τ, and a demonstration of the conditional quantile curves in a univariate regression setting, where the linear model is correct for the median, but the noise has a non-homoscedastic distribution.

On the penalty side, we typically use the ℓ_q norm of the parameters with $q \in \{1,2\}$. Adding a penalty can be thought of as shrinkage, complexity control or putting a prior to express our expectation that the β's should be small.

As has been noted in the literature (Rosset and Zhu, 2007; Hastie et al., 2004; Li et al., 2007; Takeuchi et al., 2009) if $q \in \{1,2\}$ and if we fix $\tau = \tau_0$, we can devise *path following* (AKA parametric programming) algorithms to efficiently generate the 1-dimensional curve of solutions $\{\hat{\beta}(\tau_0,\lambda) \ : \ 0 \leq \lambda < \infty\}$. Although it has not been explicitly noted by most of these authors (a notable exception being Takeuchi et al. 2009), it naturally follows that similar algorithms exist for the case that we fix $\lambda = \lambda_0$ and are interested in generating the curve $\{\hat{\beta}(\tau,\lambda_0) \ : \ 0 < \tau < 1\}$.

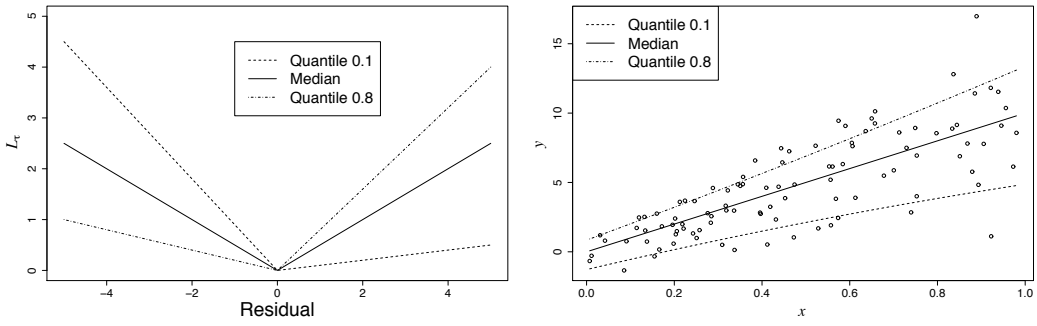

Figure 1: Quantile loss function for some values of τ (left) and an example where the median of Y is linear in X but the quantiles of $P(Y|X)$ are not because the noise is not identically distributed (right).

In addition to parameterized quantile regression, there are other modeling problems in the literature which combine a parameterized loss function problem with the existence of efficient path following algorithms. These include :

1. Support vector regression (SVR, Smola and Schölkopf 2004, see Gunther and Zhu 2005 for path following algorithm) with ℓ_1 or ℓ_2 regularization, where the parameter ε determines the width of the *don't care* region around 0.

2. Weighted support vector machines, where the parameter of the loss function corresponds to reweighting the hinge loss differentially for the two classes, for example as a means for deriving accurate probability estimates (as recently suggested by Wang et al. 2008).

3. Huberized Lasso (Rosset and Zhu, 2007) with ℓ_1 regularization, where *huberizing* adds robustness to the traditional squared error loss, with a tunable parameter.

An important extension of the ℓ_2-regularized optimization problem is to *non-linear* fitting through kernel embedding (Schölkopf and Smola, 2002). The kernelized version of Problem (1) is

$$\hat{f}(\tau,\lambda) = \arg\min_f \sum_i L_\tau(y_i - f(\mathbf{x}_i)) + \frac{\lambda}{2}\|f\|^2_{\mathcal{H}_K}\,, \tag{3}$$

where $\|\cdot\|_{\mathcal{H}_K}$ is the norm induced by the positive-definite kernel K in the Reproducing Kernel Hilbert Space (RKHS) it generates. The well known *representer theorem* (Kimeldorf and Wahba, 1971) implies that the solution of Problem (3) lies in a low dimensional subspace spanned by the representer functions $\{K(\cdot,\mathbf{x}_i), i \in 1,...,n\}$. Following the ideas of Hastie et al. (2004) for the support vector machine, Li et al. (2007) have shown that the λ-path of solutions to Problem (3) when τ is fixed can also be efficiently generated. A similar approach was independently developed by Takeuchi et al. (2009).

It is important to note the difference in the roles of the two parameters τ, λ. The former defines a family of loss functions, in our case leading to estimation of different quantiles. Thus we would typically want to build and use a model for every value of τ. The latter is a regularization parameter, controlling model complexity with the aim of generating a better model and avoiding overfitting,

and is not part of the prediction objective (at least as long as we avoid the Bayesian view). We would therefore typically want to generate a set of models $\beta^*(\tau)$ (or $f^*(\tau)$ in the kernel case), by selecting a good regularization parameter $\lambda^*(\tau)$ for every value of τ, thus obtaining a family of good models for estimating the range of conditional quantiles, and consequently the whole conditional distribution.

This problem, of model selection to find a good regularization parameter, is often handled through *cross-validation*. In its simplest form, cross-validation entails having a second, independent set of data $\{\tilde{\mathbf{x}}_i, \tilde{y}_i\}_{i=1}^N$ (often referred to as a *validation set*), which is used to evaluate the performance of the models and select a good regularization parameter. For a fixed τ, we can write our model selection problem as a *Bi-level programming* extension of Problems (1) and (3), where $f^*(\tau) = \hat{f}(\tau, \lambda^*)$ and λ^* solves

$$\min_{\lambda} \quad \sum_{i=1}^{N} L_{\text{cv}}(\tilde{y}_i, \hat{f}(\tau,\lambda)^T \tilde{\mathbf{x}}_i) \qquad (4)$$
$$\text{s.t. } \hat{f}(\tau,\lambda) \text{ solves Problem (3)} ,$$

where L_{CV} is the cross validation loss function (the bi-level formulation for Problem (1) would be identical, with $\hat{\beta}$ replacing $\hat{f}$). We will assume for now that $L_{\text{CV}} = L_\tau$, in order to evaluate the performance in estimating the τth quantile. The objective of this minimization problem is not convex as a function of λ. A similar non-convex optimization problem has been tackled by Kunapuli et al. (2008) for the support vector machine, which is very similar to quantile regression from an optimization perspective (piecewise linear objective with quadratic penalty). The fundamental difference between their setting and ours is that they had a single bi-level optimization problem, while we have a family of such problems, parameterized by τ. This allows us to take advantage of internal structure to solve the bi-level problem for all values of τ *simultaneously* (or more accurately, in one run of our algorithm).

The concept of a parameterized family of bi-level regularized quantile regression problems is demonstrated in Figure 2, where we see the cross-validation curves of the objective of (4) as a function of λ for several values of τ on the same data set. As we can see, the optimal level of regularization varies with the quantile, and correct choice of the regularization parameter can have a significant effect on the success of our quantile prediction model.

The main goal of this paper is to devise algorithms for following the bi-level optimal solution path $f^*(\tau)$ as a function of τ, and demonstrate their practicality. Our algorithms are based on extensions and generalizations of some of the ideas underlying the path following algorithms for 1-dimensional paths on convex problems (Hastie et al., 2004; Li et al., 2007; Rosset and Zhu, 2007). We concentrate our attention on the quantile regression case (both kernelized and linear), as one where the parameterized-loss problem is well motivated and historically useful, but we also discuss the similarities and differences in algorithms for the other examples we mentioned above. We show that this non-convex family of bi-level programs can be solved exactly, as the optimum among the solutions of $O(n+N)$ standard (convex) path-following problems, with some additional twists. This result is based on a characterization of the evolution of the solution path $\hat{f}(\tau,\cdot)$ as τ varies, and on an understanding of the properties of optimal solutions of the bi-level problem, which can only occur at a limited set of points. We combine these insights to formulate an actual algorithm for solving this family of bi-level programs via path-following. However, this algorithm carries a heavy computational burden. The question of whether it is practical from a computational perspective depends on

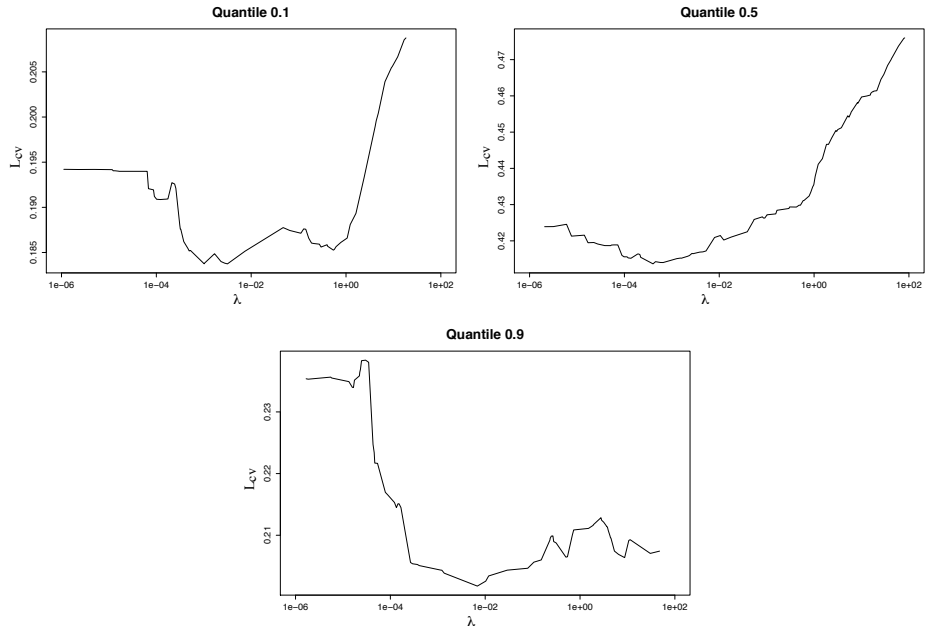

Figure 2: Estimated prediction error curves of Kernel Quantile Regression for some quantiles on one data set. The errors are shown as a function of the regularization parameter λ.

the properties of the modeling problems at hand, and may also benefit greatly from computational tricks and optimization shortcuts which are not the focus of this paper. We demonstrate its ability to successfully generate the complete set of cross-validated solutions on some illuminating simulation problems and on two medium-size real-life data-sets.

The rest of this paper is organized as follows. In Section 2 we discuss the properties of the quantile regression solution paths $\hat{f}(\tau,\lambda)$ and their evolution as τ changes. We then discuss in Section 3 the properties of the bi-level optimization Problem (4) and demonstrate that the solutions change predictably with τ. This is because the optimal solution always corresponds to a situation where either one of the validation points is crossing the non-differentiability *elbow* in the cross validation loss L_{CV}, or the regularization path is going thorough a *knot* in its piecewise linear change. However, due to the non-convexity of the problem, the solutions occasionally "jump" from one such point to another. It turns out that to follow this jumpy behavior we need to follow, not one path of solutions, but about $N+n$ of them, corresponding to all possible candidates for L_{CV} optimizers. Bringing together all our insights leads us to formulate an algorithm in Section 4, which allows us to follow the path of solutions $\{f^*(\tau)\ ,\ 0<\tau<1\}$ and only requires following a large but manageable number of solution paths of problem (3) simultaneously. In Section 5 we discuss the extension of our methodology to other scenarios, including application of our methodology to SVR. We demonstrate our methods with a simulated and real data study in Section 6, where we show that our approach leads to model-selection that is more efficient than previous approaches, and illustrate the interesting behavior of KQR in practice.

2. Quantile Regression Solution Paths

We concentrate our discussion on the kernel quantile regression (KQR) formulation in (3), with the understanding that it subsumes the linear formulation (1) with ℓ_2 regularization by using the *linear* kernel $K(\mathbf{x},\tilde{\mathbf{x}}) = \mathbf{x}^\intercal\tilde{\mathbf{x}}$.

We briefly survey the results of Li et al. (2007) regarding the properties of $\hat{f}(\tau,\cdot)$, the optimal solution path of (3), with τ fixed. Similar results were independently generated by Takeuchi et al. (2009), who concentrate on the properties of $\hat{f}(\tau,\cdot)$ with λ fixed (as we elaborate below, these problems are in fact very similar). The representer theorem (Kimeldorf and Wahba, 1971) implies that the solution can be written as

$$\hat{f}(\tau,\lambda)(\mathbf{x}) = \frac{1}{\lambda}\left[\hat{\beta}_0 + \sum_{i=1}^{n}\hat{\theta}_i K(\mathbf{x},\mathbf{x}_i)\right] \quad . \tag{5}$$

For a proposed solution $f(\mathbf{x})$ define:

- $\mathcal{E} = \{i : y_i - f(\mathbf{x}_i) = 0\}$ (points on *elbow* of L_τ)
- $\mathcal{L} = \{i : y_i - f(\mathbf{x}_i) < 0\}$ (left of elbow)
- $\mathcal{R} = \{i : y_i - f(\mathbf{x}_i) > 0\}$ (right of elbow).

Then Li et al. (2007) show that the Karush-Kuhn-Tucker (KKT) conditions for optimality of a solution $\hat{f}(\tau,\lambda)$ of problem (3) can be phrased as

- $i \in \mathcal{E} \;\Rightarrow\; -(1-\tau) \le \hat{\theta}_i \le \tau$
- $i \in \mathcal{L} \;\Rightarrow\; \hat{\theta}_i = -(1-\tau)$
- $i \in \mathcal{R} \;\Rightarrow\; \hat{\theta}_i = \tau$
- $\sum_i \hat{\theta}_i = 0$.

With some additional algebra, they show that for a fixed τ, there is a series of *knots*, $0 = \lambda_0 < \lambda_1 < \ldots < \lambda_m < \infty$ such that for $\lambda \ge \lambda_m$ we have $\hat{f}(\tau,\lambda) = \textit{constant}$ and for $\lambda_{k-1} < \lambda \le \lambda_k$ we have

$$\hat{f}(\tau,\lambda)(\mathbf{x}) = \frac{1}{\lambda}\left(\lambda_k \hat{f}(\tau,\lambda_k)(\mathbf{x}) + (\lambda - \lambda_k)h_k(\mathbf{x})\right) \ , \tag{6}$$

where $h_k(\mathbf{x}) = b_0^k + \sum_{i\in\mathcal{E}_k} b_i^k K(\mathbf{x},\mathbf{x}_i)$ can be thought of as the *direction* in which the solution is moving for the region $\lambda_{k-1} < \lambda \le \lambda_k$. The knots λ_k are points on the path where an observation passes between $\mathcal{E}$ and either $\mathcal{L}$ or $\mathcal{R}$, that is $\exists i \in \mathcal{E}$ such that exactly $\theta_i = \tau$ or $\theta_i = -(1-\tau)$. This observation may be either *entering* the elbow (if it was previously in $\mathcal{L}$ or $\mathcal{R}$), or *exiting* it (if it previously had $\theta_i \in (-(1-\tau),\tau)$).[2] These insights lead Li et al. (2007) to an algorithm for incrementally generating $\hat{f}(\tau,\lambda)$ as a function of λ for fixed τ, starting from $\lambda = \infty$ (where the solution only contains the intercept β_0).

2. It is clear that the definition of an observation as *entering* or *exiting* the elbow is arbitrary, since an observation which enters at λ_k when we are decreasing λ actually exits at λ_k if we choose to traverse the path while increasing λ. There is also a possibility of more than one observation making this transition at once. With general τ and points in general location, this event has probability zero. As we will see, in the course of our investigation of the paths we are bound to encounter such cases, and we will address this issue when it comes up.

Although Li et al. (2007) suggest it is a topic for further study, it is in fact a reasonably straight forward extension of their results to show that a similar scenario holds when we fix λ and allow τ only to change. As previously mentioned, this has been recognized and used by other authors, including Takeuchi et al. (2009) for quantile regression, and Wang et al. (2008) for weighted hinge loss. More interestingly, the same is also true when both τ, λ are changing together *along a straight line*, that is, a 1-dimensional subspace of the (τ,λ) space (this has been observed by Wang et al. (2006) for SVR, which is very similar from an optimization perspective). The following lemma makes this more general result concrete. The proof relies on a study of the KKT conditions in the spirit of Li et al. (2007) and the other references above, and we omit it.

Lemma 1 *Let $\tau(\lambda) = u\lambda + v$, and denote $\hat{f}(\lambda) = \hat{f}(\tau(\lambda),\lambda)$. Then in the range $\Gamma = \{\lambda \geq 0 :\ 0 < \tau(\lambda) < 1\}$ there exist* knots $\lambda_0 < ... < \lambda_m$ *such that for $\lambda_{k-1} < \lambda \leq \lambda_k$ we have:*

$$\hat{f}(\lambda)(\mathbf{x}) = \frac{1}{\lambda}\left(\lambda_k \hat{f}(\lambda_k)(\mathbf{x}) + (\lambda - \lambda_k) h_k(\mathbf{x})\right) ,$$

where $h_k(\mathbf{x}) = b_0^k + \sum_{i\in\mathcal{E}_k} b_i^k K(\mathbf{x},\mathbf{x}_i)$, and the direction $\mathbf{b}^k = \begin{pmatrix} b_0^k \\ \vdots \\ b_{|\mathcal{E}_k|}^k \end{pmatrix}$ is the solution of a set of linear equations with $|\mathcal{E}_k|+1$ unknowns:

$$\mathbf{A}^k \mathbf{b}^k = \begin{pmatrix} 0 \\ \mathbf{r}_{\mathcal{E}_k} \end{pmatrix}$$

with

$$\mathbf{A}^k = \begin{pmatrix} 0 & \mathbf{1}^\intercal \\ \mathbf{1} & \mathbf{K}_{\mathcal{E}_k} \end{pmatrix} ,$$

as defined in Li et al. (2007); and $r_j = y_j + u \cdot \left(\sum_{i\in\mathcal{R}_k} K(\mathbf{x}_j,\mathbf{x}_i) - \sum_{i\in\mathcal{L}_k} K(\mathbf{x}_j,\mathbf{x}_i)\right)$ for $j \in \mathcal{E}_k$.

Armed with this result, we next show the main result of this section: that the knots themselves move in a (piecewise) straight line as τ changes, and can therefore be *tracked* as τ and the regularization path change. Fix a quantile τ_0 and assume that λ_k is a knot in the λ-solution path for quantile τ_0. Further, let i_k be the observation that is passing in or out of the elbow at knot λ_k. Assume WLOG that $\hat{\theta}_{i_k}(\tau_0,\lambda_k) = \tau_0$, that is, it is on the boundary between $\mathcal{R}_k$ and $\mathcal{E}_k$. Let $\tilde{\mathbf{K}}_{\mathcal{E}_k}$ be the matrix $\mathbf{K}_{\mathcal{E}_k}$ with the i_k column removed, and $\tilde{\mathbf{b}}^k = \mathbf{b}^k$ with index i_k removed. Let $s_i = \sum_{j\in\mathcal{R}\cup\mathcal{L}\cup\{i_k\}} K(\mathbf{x}_i,\mathbf{x}_j)$ for $i \in \mathcal{E}_k$. Let $\mathbf{s}_{\mathcal{E}_k}$ be the vector of all these values.

Theorem 2 *Any knot λ_k moves linearly as τ changes. That is, there exists a constant c_k such that for quantile $\tau_0 + \delta$ there is a knot in the λ-solution path at $\lambda_k + c_k\delta$, for $\delta \in [-\varepsilon_k, \nu_k]$, a non-empty neighborhood of 0. c_k is determined through the solution of another set of $|\mathcal{E}_k|+1$ linear equations with $|\mathcal{E}_k|+1$ unknowns*

$$\mathbf{B}^k \begin{pmatrix} \tilde{\mathbf{b}}^k \\ c_k \end{pmatrix} = \begin{pmatrix} -(|\mathcal{R}| + |\mathcal{L}| + 1) \\ -\mathbf{s}_{\mathcal{E}_k} \end{pmatrix} ,$$

with

$$\mathbf{B}^k = \begin{pmatrix} 0 & \mathbf{1}^\intercal & 0 \\ \mathbf{1} & \tilde{\mathbf{K}}_{\mathcal{E}_k} & -\mathbf{y}_{\mathcal{E}_k} \end{pmatrix} .$$

And the fit at this knot progresses as

$$\hat{f}(\tau_0+\delta,\lambda_k+c_k\delta) = \frac{1}{\lambda_k+c_k\delta}\left(\lambda_k\hat{f}(\lambda_k,\tau_0)(\mathbf{x})+\delta h_k(\mathbf{x})\right) \tag{7}$$

$$h_k(\mathbf{x}) = \tilde{b}_0^k + \sum_{i\in\mathcal{E}_k-i_k}\tilde{b}_i^k K(\mathbf{x},\mathbf{x}_i) + \sum_{i\in\mathcal{L}\cup\mathcal{R}\cup\{i_k\}} K(\mathbf{x},\mathbf{x}_i)\ . \tag{8}$$

Proof For small δ, the *modified* knot should be characterized by $\theta_{i_k} = \tau_0+\delta$, and $\mathcal{L},\mathcal{R},\mathcal{E}$ remaining the same. If we can find a c_k such that this holds for quantile $\tau_0+\delta$ and $\lambda = \lambda_k + c_k\delta$, and also the KKT conditions are maintained, we have our knot for quantile $\tau_0+\delta$. Assume this can be accomplished by moving in a direction h_k as in Equations (7) and (8). For the KKT conditions to hold we need to maintain:

C1. $\hat{f}(\tau_0+\delta,\lambda_k+c_k\delta)(\mathbf{x}_i) = y_i\ ,\ \ \forall i\in\mathcal{E}$

C2. $\hat{\theta}_i(\tau_0+\delta,\lambda_k+c_k\delta) = \hat{\theta}_i(\tau_0,\lambda_k)+\delta\ ,\ \ \forall i\in\mathcal{L}\cup\mathcal{R}\cup\{i_k\}$

C3. $\sum_{i\in\mathcal{E}_k-\{i_k\}}\tilde{b}_i^k = -|\mathcal{L}\cup\mathcal{R}\cup\{i_k\}|$

where C1 maintains the observations in $\mathcal{E}$ at the elbow, C2 maintains the equality requirements on $\hat{\theta}$ for the observations in $\mathcal{L}\cup\mathcal{R}$ (and the one on the boundary), and C3 maintains the constraint that the $\hat{\theta}$'s sum to 0.

We can express C1 in terms of Equations (7) and (8) and condition C2:

$$\begin{aligned} & \hat{f}(\tau_0+\delta,\lambda_k+c_k\delta)(\mathbf{x}_i) = y_i\ ,\ \ \forall i\in\mathcal{E} \\ \Leftrightarrow \quad & h_k(\mathbf{x}_i) = \tilde{b}_0^k + \sum_{j\in\mathcal{E}_k-i_k}\tilde{b}_j^k K(\mathbf{x}_j,\mathbf{x}_i) + \sum_{j\in\mathcal{L}\cup\mathcal{R}\cup\{i_k\}} K(\mathbf{x}_j,\mathbf{x}_i) = c_k y_i\ ,\ \ \forall i\in\mathcal{E}\ , \end{aligned} \tag{9}$$

where the last term on the RHS of (9) accounts for the changes in the $\hat{\theta}_j$ which C2 implies for $j\in\mathcal{L}\cup\mathcal{R}\cup\{i_k\}$.

Now, by combining C3 and (9) into one set of equations in matrix notation, we get the result of the theorem:

$$\begin{pmatrix}\tilde{\mathbf{b}}^k \\ c_k\end{pmatrix} = \left(\mathbf{B}^k\right)^{-1}\begin{pmatrix}-(|\mathcal{R}|+|\mathcal{L}|+1) \\ -\mathbf{s}_{\mathcal{E}_k}\end{pmatrix}$$

and moving in the direction of the solution of this matrix equation as in (7,8) maintains the KKT conditions and the observation at the elbow, hence is a knot on the λ-solution path for quantile $\tau+\delta$ for every (small enough) δ.

■

This theorem tells us that we can in fact track the knots in the solution efficiently as τ changes. We still have to account for various types of *events* that can change the direction the knot is moving in. The value θ_i for a point in $\mathcal{E}_k-\{i_k\}$ can reach τ or $-(1-\tau)$, or a point in $\mathcal{L}\cup\mathcal{R}$ may reach the elbow $\mathcal{E}$. These events correspond to *knots crossings*, that is, the knot λ_k is encountering another knot (which is tracking the other event). There are also *knot birth* events, and *knots merge* events, which are possible but rare, and somewhat counter-intuitive. We defer the details of how these are identified and handled to the detailed algorithm description (Appendix A). When any of these events occurs, the set of knots has to be updated and their directions have to be re-calculated using Lemma 1, Theorem 2 and the new identity of the sets $\mathcal{E},\mathcal{L},\mathcal{R}$ and the observation i_k. This in essence allows us to map the whole 2-dimensional solution surface $\hat{f}(\tau,\lambda)$.

3. The Bi-level Optimization Problem

Our next task is to show how our ability to track the knots as τ changes allows us to track the solution of the bi-level optimization Problem (4) as τ changes. The key to this step is the following result.

Theorem 3 *When the cross validation loss is the quantile loss (i.e., $L_{CV} = L_\tau$), then any minimizer*[3] *of (4) is always either at a knot in the λ-path for this τ or a point where a validation observation crosses the elbow. In other words, one of the two following statements must hold:*

- λ^* *is a knot:* $\exists i \in \{1...n\}$ *s.t.* $\hat{f}(\tau, \lambda^*(\tau))(\mathbf{x}_i) = y_i$ *and* $\theta_i \in \{\tau, -(1-\tau)\}$, *or*
- λ^* *is a* validation crossing*:* $\exists i \in \{1...N\}$ *s.t.* $\hat{f}(\tau, \lambda^*(\tau))(\tilde{\mathbf{x}}_i) = \tilde{y}_i$

Proof Define $\tilde{\mathcal{L}}, \tilde{\mathcal{R}}$ in the obvious way, as the sets of validation observations with negative and positive residuals, respectively, for a given model. Fix τ, and consider the cross validation loss for a given value of λ:

$$\begin{aligned} L_{\text{cv}}(\lambda) &:= \sum_{i=1}^{N} L_{\text{CV}}(\tilde{y}_i, \hat{f}(\lambda)(\tilde{\mathbf{x}}_i)) = \sum_{i \in \tilde{\mathcal{L}}} (1-\tau)(\hat{f}(\lambda)(\tilde{\mathbf{x}}_i) - \tilde{y}_i) + \sum_{i \in \tilde{\mathcal{R}}} \tau \cdot (\tilde{y}_i - \hat{f}(\lambda)(\tilde{\mathbf{x}}_i)) = \\ &= \tau \sum_{i \in \tilde{\mathcal{R}}} y_i - (1-\tau) \sum_{i \in \tilde{\mathcal{L}}} y_i - \tau \sum_{i \in \tilde{\mathcal{R}}} \hat{f}(\lambda_k)(\tilde{\mathbf{x}}_i) + (1-\tau) \sum_{i \in \tilde{\mathcal{L}}} \hat{f}(\lambda_k)(\tilde{\mathbf{x}}_i) + \\ &\quad + \frac{(\lambda - \lambda_k)}{\lambda} \left[-\tau \sum_{i \in \tilde{\mathcal{R}}} (h_k(\tilde{\mathbf{x}}_i) - \hat{f}(\lambda_k)(\tilde{\mathbf{x}}_i)) + (1-\tau) \sum_{i \in \tilde{\mathcal{L}}} (h_k(\tilde{\mathbf{x}}_i) - \hat{f}(\lambda_k)(\tilde{\mathbf{x}}_i)) \right] \end{aligned}$$

where k is such that $\lambda_{k-1} \leq \lambda \leq \lambda_k$ (where the list of $\lambda_\cdot$'s now combines both knots and validation crossings), and we take advantage of the representation in (6). From the last two rows we can see that L_{cv} is monotone in λ as long as $\tilde{\mathcal{L}}, \tilde{\mathcal{R}}$ are fixed (i.e., no validation crossing occurs) and h_k is fixed (i.e., no knot is encountered). Therefore any local (or global) extremum must be at a knot or a validation crossing. ■

Corollary 4 *Given the complete solution path for $\tau = \tau_0$, the solutions of the bi-level Problem (4) for a range of quantiles around τ_0 can be obtained by following the paths of the knots and the validation crossings only, as τ changes.*

To implement this corollary in practice, we have two main issues to resolve:

1. How do we follow the paths of the validation crossings?
2. How do we determine which one of the knots and validation crossings is going to be optimal for every value of τ?

The first question is easy to answer when we consider the similarity between the knot following problem we solve in Theorem 2 and the validation crossing following problem. In each case we

3. In pathological cases there may be a "segment" of minimizers. In this case it can be shown that such a segment will always be flanked by points described in the theorem.

have a set of *elbow* observations whose fit must remain fixed as τ changes, but whose $\hat{\theta}$ values may vary; sets $\mathcal{L}, \mathcal{R}$ whose $\hat{\theta}$ are changing in a pre-determined manner with τ, but whose fit may vary freely; and one special observation which *characterizes* the knot or validation crossing. The only difference is that in a knot this is a *border* observation from the training set, so both its fit and its $\hat{\theta}$ are pre-determined, while in the case of validation crossing it is a *validation* observation, whose fit must remain fixed (at the *elbow*), but which does not even have a $\hat{\theta}$ value. Taking all of this into account, it is easy to show the following result, closely related to Theorem 2. Assume there is a validation crossing at λ_v for quantile τ_0, and that validation set observation j_v is the one crossing the elbow, that is,

$$\hat{f}(\tau_0, \lambda_v)(\tilde{\mathbf{x}}_{j_v}) = 0 \, .$$

Let $\mathbf{s}_{\mathcal{E}_v}, K_{\mathcal{E}_v}, \mathbf{b}_{\mathcal{E}_v}$ be defined as in Theorem 2 (with $\{i_v\} = \Phi$ for definition of $\mathbf{s}$). Let $\mathbf{k}_v = (K(X_{\mathcal{E}_v}, \tilde{\mathbf{x}}_{j_v}))$ be a $1 \times |\mathcal{E}_v|$ vector of the kernel evaluations at $\tilde{\mathbf{x}}_{j_v}$ for the elbow observation functionals.

Proposition 5 *λ_v moves linearly as τ changes. That is, there exists a constant d_v such that for quantile $\tau_0 + \delta$ there is a validation crossing in the λ-solution path at $\lambda_v + d_v\delta$, for $\delta \in [-\varepsilon_v, \nu_v]$, a non-empty neighborhood of 0. d_v is determined through the solution of a set of $|\mathcal{E}_v| + 2$ linear equations with $|\mathcal{E}_v| + 2$ unknowns:*

$$\mathbf{B}^v \begin{pmatrix} \tilde{\mathbf{b}}^v \\ d_v \end{pmatrix} = \begin{pmatrix} -(|\mathcal{R}| + |\mathcal{L}|) \\ -\mathbf{s}_{\mathcal{E}_v} \\ -\tilde{s}_{j_v} \end{pmatrix}$$

with

$$\mathbf{B}^v = \begin{pmatrix} 0 & \mathbf{1}^\intercal & 0 \\ \mathbf{1} & \mathbf{K}_{\mathcal{E}_v} & -\mathbf{y}_{\mathcal{E}_v} \\ 1 & \mathbf{k}_v & -\tilde{y}_{j_v} \end{pmatrix} \, .$$

Furthermore, the solution $\hat{f}(\tau_0 + \delta, \lambda_v + c_v\delta)$ is given by:

$$\hat{f}(\tau_0 + \delta, \lambda_v + c_v\delta) = \frac{1}{\lambda_v + c_v\delta} \left(\lambda_v \hat{f}(\lambda_v, \tau_0)(\mathbf{x}) + \delta h_v(\mathbf{x}) \right)$$
$$h_v(\mathbf{x}) = \tilde{b}_0^v + \sum_{i \in \mathcal{E}_v} b_i^v K(\mathbf{x}, \mathbf{x}_i) + \sum_{i \in \mathcal{L} \cup \mathcal{R}} K(\mathbf{x}, \mathbf{x}_i) \, .$$

The proof relies on following the same steps as the proof of Theorem 2 and is omitted for brevity.

The second question we have posed requires us to explicitly express the validation loss (i.e., L_τ on the validation set) at every knot and validation crossing in terms of δ, so we can compare them and identify the optimum at every value of δ. Using the representation in (7) we can write the *validation loss* for a knot k (denote $f^k(\delta) = \hat{f}(\tau_0 + \delta, \lambda_k + c_k\delta)$):

$$\begin{aligned} \textstyle\sum_{i=1}^N \quad & L_{\text{cv}}(\tilde{y}_i, f^k(\delta)(\tilde{\mathbf{x}}_i)) = \\ & = -(1 - \tau_0 - \delta) \sum_{i \in \mathcal{L}} (\tilde{y}_i - f^k(\delta)(\tilde{\mathbf{x}}_i)) + (\tau_0 + \delta) \sum_{i \in \mathcal{R}} (\tilde{y}_i - f^k(\delta)(\tilde{\mathbf{x}}_i)) = \\ & = \sum_{i=1}^N L_{\text{cv}}(\tilde{y}_i, f^k(0)(\tilde{\mathbf{x}}_i)) + \delta \sum_i |\tilde{y}_i - f^k(0)(\tilde{\mathbf{x}}_i)| + \frac{\delta}{\lambda_k + c_k\delta} \cdot \qquad (10) \\ & \cdot \left[-(1 - \tau_0 - \delta) \sum_{i \in \mathcal{L}} (c_k f^k(0)(\tilde{\mathbf{x}}_i) - h_k(\tilde{\mathbf{x}}_i)) + (\tau_0 + \delta) \sum_{i \in \mathcal{R}} (c_k f^k(0)(\tilde{\mathbf{x}}_i) - h_k(\tilde{\mathbf{x}}_i)) \right] \, . \end{aligned}$$

A similar expression can be derived for validation crossings (with f^k, c_k, h_k replaced by f^v, d_v, h_v in the obvious way). These are rational functions of δ with quadratic expressions in the numerator and linear expressions in the denominator. Our cross-validation task can be re-formulated as the identification of the minimum of these rational functions among all knots and validation crossings, for every value of τ in the current *segment*, where the directions h_k, h_v of all knots and validation crossings are fixed (and therefore so are the coefficients in the rational functions). This is a *lower-envelope* tracking problem, which has been extensively studied in the literature (Sharir and Agarwal 1995 and references therein). The algorithms developed mostly conform to the common-sense approach of maintaining the order of the validation loss scores from smallest to largest; identifying the τ values where elements with neighboring scores *meet* (i.e., obtain identical score); and whenever a meeting occurs, re-calculating only the relevant crossing points, that is, those of the elements that changed order and their immediate neighbors. We also have to re-calculate some of the validation loss scores whenever an *event* happens on the training solution path (like a *knot crossing*).

To calculate the meeting point of two elements with neighboring scores (assume WLOG that they are two knots k, l) we find the zeros of the cubic equation obtained by requiring equality for the two rational functions of the form (10) corresponding to the two elements. Writing the expression in (10) for both k and l, and requiring equality gives us the cubic equation:

$$\begin{aligned} 0 = \quad & \lambda_k\lambda_l(lo_k - lo_l) + \\ & +\delta[(\lambda_k c_l + \lambda_l c_k)(lo_k - lo_l) + \lambda_k\lambda_l(la_k - la_l) + \lambda_l(\tau_0 LR_k - Le_k) - \lambda_k(\tau_0 LR_l - Le_l)] \\ & +\delta^2[c_k c_l(lo_k - lo_l) + (c_k\lambda_l + c_l\lambda_k)(la_k - la_l) + \\ & \quad +c_l(\tau_0 LR_k - Le_k) + \lambda_l LR_k - c_k(\tau_0 LR_l - Le_l) - \lambda_k LR_l] \\ & +\delta^3[c_k c_l(la_k - la_l) + c_l LR_k - c_k LR_l] \,, \end{aligned} \tag{11}$$

where:

$$\begin{aligned} lo_k &= \sum_{i=1}^{N} L_{\mathrm{cv}}(\tilde{y}_i, f^k(0)(\tilde{\mathbf{x}}_i)) \\ la_k &= \sum_{i} |\tilde{y}_i - f^k(0)(\tilde{\mathbf{x}}_i)| \\ LR_k &= \sum_{i\in\mathcal{L}} (c_k f^k(0)(\tilde{\mathbf{x}}_i) - h_k(\tilde{\mathbf{x}}_i)) + \sum_{i\in\mathcal{R}} (c_k f^k(0)(\tilde{\mathbf{x}}_i) - h_k(\tilde{\mathbf{x}}_i)) \\ Le_k &= \sum_{i\in\mathcal{L}} (c_k f^k(0)(\tilde{\mathbf{x}}_i) - h_k(\tilde{\mathbf{x}}_i)) \,, \end{aligned}$$

with similar expressions for the elements with subscript l derived in the obvious way. The smallest non-negative solution for δ is the one we are interested in.

Figure 3 gives a simple illustration of the process of following the validation loss scores, and identifying their optimum, while updating the directions of the knots and validation crossings as events occur. It shows the set of training and validation loss scores for two knots and the validation loss only for one validation crossing. The training loss is shown in solid lines, and the validation loss in dashed lines. Assuming these are the only three candidates in Theorem 3, the figure shows in bold the lower envelope which defines the optimal cross validation solution at every value of τ. As we can see, in this example the first (left) switch is between two knots as a result of a knot crossing, while the second (right) is a result of a validation crossing becoming optimal. It should be noted,

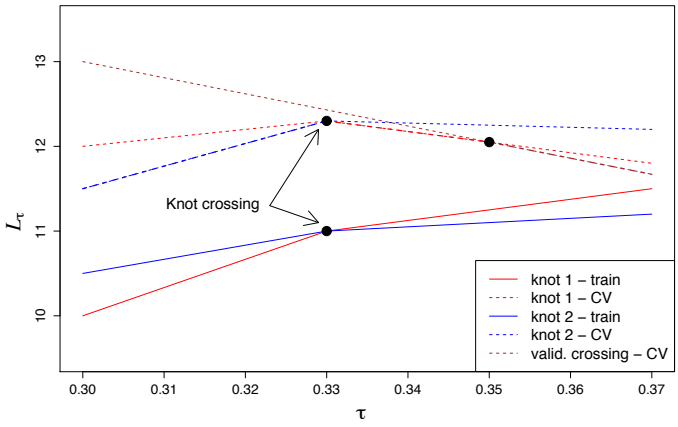

Figure 3: Illustration of the process of lower envelope tracking, in the presence of two knots and one validation crossing being tracked. See text for details.

that the linearity of the solid and dashed lines in Figure 3 is for illustration simplicity, and is not a realistic depiction of the non-linear evolution of the loss as τ varies, as discussed above.

4. Algorithm Overview

Bringing together all the elements from the previous sections, we now give a succinct overview of the resulting algorithm (Algorithm 1). Since there is a multitude of details, we defer a detailed pseudo-code description of our algorithm to Appendix A.

The algorithm follows the knots of the λ-solution path as τ changes using the results of Section 2, and keeps track of the cross-validated solution using the results of Section 3. Every time an *event* happens (like a knot crossing), the direction in which two of the knots are moving has to be changed, or knots have to be added or deleted. Between these events, the evolution of the cross-validation objective at all knots and validation crossings has to be sorted and followed. Their order is maintained and updated whenever crossings occur between them.

4.1 Approximate Computational Complexity

Looking at Algorithm 1, we should consider the number of steps of the two loops and the complexity of the operations inside the loops. Even for a "standard" λ-path following problem for fixed τ, it is in fact impossible to rigorously bound the number of steps in the general case, but it has been argued and empirically demonstrated by several authors that the number of knots in the path behaves as $O(n)$, the number of samples (Rosset and Zhu, 2007; Hastie et al., 2004; Li et al., 2007). In our case the outer loop of Algorithm 1 implements a 2-dimensional path following problem, that can be thought of as following $O(n)$ 1-dimensional paths traversed by the knots of the path. It therefore stands to reason (and we confirm it empirically below) that the outer loop typically has $O(n^2)$ steps where *events* happen. The events in the inner loop, in turn, have to do with the N validation observations meeting the $O(n)$ knots. So a similar logic would lead us to assume that the number of meeting events (counted by the inner loop) should be at most $O(nN)$ total for the whole running

Algorithm 1: Main steps of our algorithm

Input: The entire λ-solution path for quantile τ_0; the bi-level optimizer $\lambda^*(\tau_0)$
Output: Cross-validated solutions $f^*(\tau)$ for $\tau \in [\tau_0, \tau_{\text{end}}]$

Initialization: Identify all knots and validation crossings in the solution path for τ_0; Find direction of each knot according to Theorem 2 ;
Find direction of each validation crossing according to Proposition 5;
Create a list M of knots and validation crossings sorted by their validation loss ;
Let $\lambda^*(\tau_0)$ be the one at the bottom of the list M, and $f^*(\tau_0)$ accordingly ;
Calculate future meeting of each pair of neighbors in M by solving the cubic equation implied by (10);
Set $\tau_{\text{now}} = \tau_0$;
while $\tau_{\text{now}} < \tau_{\text{end}}$ **do**
    Find value $\tau_1 > \tau_{\text{now}}$ where first knot crossing occurs;
    Find value $\tau_2 > \tau_{\text{now}}$ where first knot merge occurs;
    Find value $\tau_3 > \tau_{\text{now}}$ where first knot birth occurs;
    Set $\tau_{\text{new}} = \min(\tau_1, \tau_2, \tau_3)$;
    while $\tau_{\text{now}} < \tau_{\text{new}}$ **do**
        Find value $\tau_4 > \tau_{\text{now}}$ where first future meeting (order change) in M occurs;
        Find value $\tau_5 > \tau_{\text{now}}$ where first validation crossing birth occurs;
        Find value $\tau_6 > \tau_{\text{now}}$ where first validation crossing cancelation occurs;
        Set $\tau_{\text{next}} = \min(\tau_4, \tau_5, \tau_6, \tau_{\text{new}})$;
        Update $\lambda^*(\tau), f^*(\tau)$ for $\tau \in (\tau_{\text{now}}, \tau_{\text{next}})$ as the evolution of the knot or validation crossing attaining the minimal L_{cv} in M (i.e., the one at $\lambda^*(\tau_{\text{now}})$) ;
        Update M according to the first event (order change, birth, cancelation);
        Update the future meetings of the affected elements using (10);
        Set $\tau_{\text{now}} = \tau_{\text{next}}$;
    end
    Update the list of knots according to the first event (knot crossing, birth, merge) ;
    Update the directions of affected knots using Theorem 2 ;
end

of the algorithm (i.e., many iterations of the outer loop may have no events happening in the inner loop). Each iteration of either loop requires a re-calculation of up to three directions (of knots or validation crossings), using Theorem 2 or Proposition 5. These calculations involve updating and inverting matrices that are roughly $|\mathcal{E}| \times |\mathcal{E}|$ in size (where $|\mathcal{E}|$ is the number of observations in the elbow). However note that only one row and column are involved in the updating, leading to a complexity of $O(n + |\mathcal{E}|^2)$ for the whole direction calculation operation, using the Sherman-Morrison formula (Sherman and Morrison, 1949) for updating the inverse. In principle, $|\mathcal{E}|$ can be equal to n, although it is typically much smaller for most of the steps of the algorithm, on the order of $\sqrt{n}$ or less. So we assume here that the loop cost is between $O(n)$ and $O(n^2)$.

Putting all of these facts and assumptions together, we can estimate the algorithm's computational complexity's *typical* dependence on the number of observations in the training and validation set as ranging between $O(n^2 \cdot \max(n, N))$ and $O(n^3 \cdot \max(n, N))$. Clearly, this estimation procedure

falls well short of a formal "worst case" complexity calculation, but we offer it as an intuitive guide to support our experiments below and get an idea of the dependence of running time on the amount of data used.

We have not considered the complexity of the lower envelope tracking problem in our analysis, because it is expected to have a much lower complexity (number of order changes $O(\max(n,N)\log(\max(n,N)))$ and each order change involves $O(1)$ work).

5. Extensions

In this section we discuss some of the possible extensions of our algorithm. First we discuss the design of algorithms that are similar in spirit for other parameterized loss function problems, in particular for support vector regression (ε-SVR) and *Huberized* least squares regression. We then move on to the use of in-sample model selection criteria instead of cross validation. Finally, we address the issue of possible non-monotonicity in τ, noted by previous authors (Koenker, 2005; Takeuchi et al., 2006). We demonstrate how our algorithm can be naturally extended to amend this situation.

5.1 Support Vector Regression and Weighted Support Vector Machines

One possible view of regularized ε-SVR (Smola and Schölkopf, 2004) is similar to the quantile regression problem for $\tau = 0.5$:

$$\hat{f}(\varepsilon,\lambda) = \arg\min_f \sum_i L_\varepsilon(y_i - f(\mathbf{x}_i)) + \frac{\lambda}{2}\|f\|^2_{\mathcal{H}_K} \tag{12}$$

where the parameterized loss function L_ε is piecewise linear and symmetric around zero, with a *don't care* region of size 2ε:

$$L_\varepsilon(r) = \begin{cases} r-\varepsilon & r \geq \varepsilon \\ 0 & -\varepsilon < r < \varepsilon \\ -r-\varepsilon & r \leq -\varepsilon \end{cases} .$$

The loss is parameterized by ε. From an optimization perspective, this problem is very similar to KQR, with a piecewise linear loss and an RKHS norm penalty. The solution can be represented as in (5), and the KKT conditions for optimality of solutions of (12) in terms of coefficients of representer functions have been formalized and used to design λ-path following algorithms by Gunther and Zhu (2005). For example, if we define for a proposed solution $f(\mathbf{x})$ of ε-SVR:

- $\mathcal{L} = \{i : y_i - f(\mathbf{x}_i) < -\varepsilon\}$ (points on left of *left elbow* of L_ε)
- $\mathcal{E}_\mathcal{L} = \{i : y_i - f(\mathbf{x}_i) = -\varepsilon\}$ (*left elbow*)
- $\mathcal{C} = \{i : |y_i - f(\mathbf{x}_i)| < \varepsilon\}$ (don't care region)
- $\mathcal{E}_\mathcal{R} = \{i : y_i - f(\mathbf{x}_i) = \varepsilon\}$ (*right elbow*)
- $\mathcal{R} = \{i : y_i - f(\mathbf{x}_i) > 0\}$ (right of *right elbow*),

Then the Karush-Kuhn-Tucker (KKT) conditions for optimality of a solution $\hat{f}(\varepsilon,\lambda)$ of Problem (12) can be phrased as:

- $i \in \mathcal{C} \;\Rightarrow\; \hat{\theta}_i = 0$
- $i \in \mathcal{L} \;\Rightarrow\; \hat{\theta}_i = -1$
- $i \in \mathcal{R} \;\Rightarrow\; \hat{\theta}_i = 1$
- $i \in \mathcal{E}_{\mathcal{L}} \;\Rightarrow\; -1 \leq \hat{\theta}_i \leq 0$
- $i \in \mathcal{E}_{\mathcal{R}} \;\Rightarrow\; 0 \leq \hat{\theta}_i \leq 1$
- $\sum_i \hat{\theta}_i = 0$.

Wang et al. (2006) have noted that ε-paths (with fixed λ) can similarly be followed. Because of the fundamental similarity in the optimization setting, all our results regarding behavior of λ-paths and knots as τ changes in quantile regression (e.g., Theorem 2) can be adapted in a reasonably straight forward manner to follow paths and knots of λ-solution paths in ε-SVR, as ε varies.

There is, however, a fundamental difference in the statistical setting between parameterized quantile loss and parameterized ε-SVR loss. While every quantile loss function defines an interesting modeling problem of estimation of a given conditional quantile, there is no such clear motivation for varying ε. Furthermore, there is no obvious way in which the cross validation loss should change with ε, if at all. In most cases, it seems ε is viewed more as another tuning parameter for a single modeling problem (like λ), than a parameter defining a range of loss functions, each of its own independent interest. In this situation, the only motivation for solving the range of bi-level problems parameterized by ε may be as a way to efficiently traverse the entire (ε, λ) solution space in search of a single "best" prediction model. It may therefore be appropriate to use a single cross validation objective L_{cv} independent of ε. If we choose $L_{\text{cv}} = L_{\tau=0.5}$ (the symmetric quantile loss, sometimes called absolute loss), then our observations on the bi-level path following problem (e.g., Theorem 3) would require slight modifications, but the ideas would carry through to the ε-SVR case in a straight forward manner.

An interesting recent development is the proposal of weighted support vector machines for probability estimation by Wang et al. (2008). Their proposed approach calls for fitting weighted versions of the support vector machine, with a range of relative weights applied to the two classes, as a provably valuable approach for estimating probabilities. We omit the details for brevity, but note that like the SVR case above, extending our bi-level approach to this problem is straight forward.

5.2 ℓ_1-regularized Huberized Squared Loss

Rosset and Zhu (2007) suggested the use of robust versions of squared error loss with ℓ_1 regularization, as an approach for combining computational efficiency and robustness to long-tailed error distribution. Huber's loss function is quadratic for small absolute residuals, then continues linearly as the residuals move away from zero, while maintaining differentiability. It is parameterized with a *huberizing point* t:

$$L_t(r) = \begin{cases} r^2 & |r| < t \\ 2t|r| - r^2 & \text{otherwise} \end{cases}.$$

The algorithm proposed in Rosset and Zhu (2007) for λ-path following can be thought of as an extension of the LARS-Lasso algorithm proposed for the Lasso (squared error loss with ℓ_1 penalty) by Efron et al. (2004). The loss function is differentiable, there is no concept of *elbow* (although

there are still knots), the KKT conditions are quite different, and if we also use a differentiable L_{cv}, the cross validation procedure would be affect as well. However, the general reasoning of this paper can still be applied to build bi-level path following algorithms for the Huberized lasso problem, and to choose good t, λ combinations.

5.3 Use of In-sample Model Selection Criteria

Li et al. (2007) follow the literature in proposing two model selection criteria for selecting λ^* for a fixed value of τ, when there is no validation sample. These are Schwartz information criterion (SIC, Schwarz, 1978) and generalized approximate cross validation (GACV, Yuan, 2006). Both of these use the model's effective degrees of freedom (DF) as a complexity measure which penalizes the empirical error. Following Zou et al. (2007), Li et al. (2007) show that an unbiased estimate of DF is the size of the elbow $|\mathcal{E}|$. Thus, they arrive at following SIC and GACV approximations:

$$\text{SIC}(\lambda) = \log\left(\frac{1}{n}\sum_{i=1}^{n} L_\tau(y_i - \hat{f}(\tau,\lambda)(\mathbf{x}_i))\right) + \frac{\log n}{2n}|\mathcal{E}| \quad (13)$$

$$\text{GACV}(\lambda) = \frac{\sum_{i=1}^{n} L_\tau(y_i - \hat{f}(\tau,\lambda)(\mathbf{x}_i))}{n - |\mathcal{E}|}\,. \quad (14)$$

If we were to adopt these measures (or similar ones) for model selection instead of the cross validation approach using an independent validation set, tracking the optimal solution $\lambda^*(\tau)$ requires no extra work besides following the knots of the solution (as described in Sections 2, 4). This is guaranteed by the following simple result:

Proposition 6 *For any fixed τ, the minimizer $\lambda^*(\tau)$ of SIC, GACV and any similar model selection criterion which is monotone in both $\sum_{i=1}^{n} L_\tau(y_i - \hat{f}(\tau,\lambda)(\mathbf{x}_i))$ and $|\mathcal{E}|$, is always at one of the knots of the solution path.*

Proof The loss is monotone between knots (e.g., from looking at Equation 6), while $|\mathcal{E}|$ is fixed. ■

Thus, if we wish to use SIC or similar measures for selecting $\lambda^*(\tau)$, the inner loop of Algorithm 1 (lines 12-21) can be omitted and replaced with a simple tracking of the value of SIC at the knots that are being followed. Since the algorithmic complexity of applying SIC/GACV is reduced compared to cross validation, and given the ongoing debates in the literature on the merits of in-sample versus out-of-sample model selection, it may often be beneficial to apply these in-sample methods in addition, or even instead of, cross validation. We demonstrate and compare performance of the two approaches in Section 6 below.

5.4 Addressing *Quantile Crossings*

The problem of quantile crossing, as formulated by Koenker (2005), is that for any fixed λ (in particular $\lambda = 0$ in the linear quantile regression case, which is the one that Koenker (2005) concentrates on), the prediction $\hat{f}(\tau,\lambda)(\mathbf{x})$ may not be non-decreasing in τ for a fixed $\mathbf{x}$. That is, we may have $\tau_0 < \tau_1$ and $\hat{f}(\tau_0,\lambda)(\mathbf{x}) > \hat{f}(\tau_1,\lambda)(\mathbf{x})$, which can never be true of the corresponding population conditional quantiles, of course.

Takeuchi et al. (2006) address this problem by constraining the solution to comply with the monotonicity requirement over a *finite* set of "interesting" quantiles. Their approach cannot work

in our case, since our algorithm is local in nature and generates the solutions for the complete space of (τ,λ) values. However, we can offer a partial remedy to the quantile crossing problem through observation of the guaranteed sub-optimality of the resulting solutions, and a consequent *envelope tracking* modification. The main motivation is the following:

Proposition 7 *Assume* $\tau_0 < \tau_1$ *and* $\hat{f}(\tau_0,\lambda)(\mathbf{x}) > \hat{f}(\tau_1,\lambda)(\mathbf{x})$ *for some* $\lambda,\mathbf{x}$. *Then either*

$$\mathbb{E}_{Y|X=\mathbf{x}} L_{\tau_0}(Y,\hat{f}(\tau_0,\lambda)(\mathbf{x})) \geq \mathbb{E}_{Y|X=\mathbf{x}} L_{\tau_0}(Y,\hat{f}(\tau_1,\lambda)(\mathbf{x}))\,. \tag{15}$$

or

$$\mathbb{E}_{Y|X=\mathbf{x}} L_{\tau_1}(Y,\hat{f}(\tau_0,\lambda)(\mathbf{x})) \leq \mathbb{E}_{Y|X=\mathbf{x}} L_{\tau_1}(Y,\hat{f}(\tau_1,\lambda)(\mathbf{x})) \tag{16}$$

Thus, we can always improve the predictive quality of either $\hat{f}(\tau_0,\lambda)$ *or* $\hat{f}(\tau_1,\lambda)$ *by eliminating the non-monotonicity.*

Proof In what follows we eliminate the explicit conditioning in the expectations. All expectations are with regard to the distribution $P(Y|X=\mathbf{x})$. Denote by c_0 and c_1 the τ_0 and τ_1 quantiles respectively of $P(Y|X=\mathbf{x})$. By definition, $c_0 \leq c_1$. We also assume $\hat{f}(\tau_0,\lambda)(\mathbf{x}) > \hat{f}(\tau_1,\lambda)(\mathbf{x})$. We hereafter denote these two fitted value by $\hat{f}_0,\hat{f}_1$ respectively for brevity. This gives us three possible scenarios:

1. $\hat{f}_1 \geq c_0$. In this case (15) holds, since:

$$\begin{aligned}
\mathbb{E}L_{\tau_0}(Y,\hat{f}_0) &= \tau_0 \int_{y\geq\hat{f}_0} y-\hat{f}_0 dP(y|\mathbf{x}) + (1-\tau_0)\int_{y<\hat{f}_0} -y+\hat{f}_0 dP(y|\mathbf{x}) \\
&= \tau_0 \int_{y\geq\hat{f}_0} P(Y\geq y|\mathbf{x})dy + (1-\tau_0)\int_{y<\hat{f}_0} P(Y\leq y|\mathbf{x})dy \\
&= \mathbb{E}L_{\tau_0}(Y,\hat{f}_1) + \int_{\hat{f}_1}^{\hat{f}_0} \left[(1-\tau_0)P(Y\leq y|\mathbf{x}) - \tau_0 P(Y\geq y|\mathbf{x})\right] dy \\
&\geq \mathbb{E}L_{\tau_0}(Y,\hat{f}_1)\,,
\end{aligned}$$

   where the inequality on the last line is because $P(Y\leq y|X=\mathbf{x}) \geq \tau_0$ in the range $\hat{f}_1 \leq y \leq \hat{f}_0$ (by our assumption that $c_0 \leq \hat{f}_1 < \hat{f}_0$).

2. $\hat{f}_0 \leq c1$. By the same line of argument in this case (16) holds.

3. If neither of the previous two holds, we must have $\hat{f}_1 < c_0 \leq c_1 < \hat{f}_0$. Following the same steps as in case 1 we write:

$$\mathbb{E}L_{\tau_0}(Y,\hat{f}_0) = \mathbb{E}L_{\tau_0}(Y,\hat{f}_1) + \int_{\hat{f}_1}^{\hat{f}_0} \left[(1-\tau_0)P(Y\leq y|\mathbf{x}) - \tau_0 P(Y\geq y|\mathbf{x})\right] dy \tag{17}$$

$$\mathbb{E}L_{\tau_1}(Y,\hat{f}_0) = \mathbb{E}L_{\tau_1}(Y,\hat{f}_1) + \int_{\hat{f}_1}^{\hat{f}_0} \left[(1-\tau_1)P(Y\leq y|\mathbf{x}) - \tau_1 P(Y\geq y|\mathbf{x})\right] dy\,. \tag{18}$$

   Assume $\mathbb{E}L_{\tau_0}(Y,\hat{f}_0) < \mathbb{E}L_{\tau_0}(Y,\hat{f}_1)$. It implies the integral in (17) is negative which in turn implies that the integral in (18) is also negative, since trivially

$$\frac{\partial}{\partial\tau}\int_{\hat{f}_1}^{\hat{f}_0} \left[(1-\tau)P(Y\leq y|\mathbf{x}) - \tau P(Y\geq y|\mathbf{x})\right] dy < 0\,.$$

   This negativity implies $\mathbb{E}L_{\tau_1}(Y,\hat{f}_0) < EL_{\tau_1}(Y,\hat{f}_1)$.

■

The following is an immediate consequence of Proposition 7 if we take $P(Y|\tilde{\mathbf{x}}_i)$ to be a point mass at $Y = \tilde{y}_i$.

Corollary 8 *If non-monotonicity holds at a validation point, that is,* $\tau_0 < \tau_1$ *and* $\hat{f}(\tau_0,\lambda)(\tilde{\mathbf{x}}_i) > \hat{f}(\tau_1,\lambda)(\tilde{\mathbf{x}}_i)$*, then either*

$$L_{\tau_0}(\tilde{y}_i, \hat{f}(\tau_0,\lambda)(\tilde{\mathbf{x}}_i)) \geq L_{\tau_0}(\tilde{y}_i, \hat{f}(\tau_1,\lambda)(\tilde{\mathbf{x}}_i))$$

or

$$L_{\tau_1}(\tilde{y}_i, \hat{f}(\tau_0,\lambda)(\tilde{\mathbf{x}}_i)) \leq L_{\tau_1}(\tilde{y}_i, \hat{f}(\tau_1,\lambda)(\tilde{\mathbf{x}}_i)) \ .$$

Thus, we can improve our holdout performance at either quantile τ_0 *or* τ_1 *by appropriately enforcing monotonicity.*

We conclude that eliminating non-monotonicity can improve both predictive performance and cross validation performance. In terms of practical implications, it is easy to see (though not trivial to implement) how our algorithm can be extended to identify quantile crossings. When these occur, at least one knot will be moving in the 'wrong direction', that is, the expression in (7) will be decreasing in δ. The algorithm will then have to keep careful tabs on the upper and lower limits of the fit at every λ as τ changes (the quantile-crossing gap). Discussion of the details and the appropriate way to resolve the non-monotonicity given this envelope is left for future work.

6. Experiments

Our methodology offers a new approach for generating the full set of cross-validated kernel quantile regression models. There are several interesting aspects of the modeling problem in general and our algorithm in particular that should be studied through a data-based study.

First, to evaluate the new algorithm, the efficiency of the algorithm should be compared to alternative approaches that allow generation of complete set of solutions and cross-validation. This includes the naive *grid-based* search whereby the KQR problem is solved using standard approaches (Takeuchi et al., 2006) for a grid of values in the (τ,λ) space, and a good regularization parameter is chosen for each value of τ by cross-validation; and the method of Li et al. (2007), which can be used to generate the complete λ-path at a grid of τ-values and cross validate each path separately. As Li et al. (2007) demonstrated clearly, their λ-path method is far superior to the grid-based approach in terms of computation, and so we concentrate on comparison to the λ-path approach only, and show that our algorithm compares favorably to it in generating the full set of bi-level solutions.

Second, we may also be interested in studying properties of the modeling problem, not necessarily tied to the new algorithm. Cross-validation based selection of regularization should be compared to *in-sample* approaches such as SIC (Schwarz, 1978) and GACV (Yuan, 2006). As noted above, all of these can be implemented in our framework. It is obvious that given the same amount of data for model fitting, it is better to use holdout data for model selection. However, the fair comparison should be between integrating the validation set into the training set and implementing an in-sample model selection approach, and using a smaller training set in a cross-validation framework.

Another interesting question about the modeling approach regards the ability of KQR to deal with skewed and non-homogeneous error distributions, and still generate reasonable estimates of the underlying quantiles.

We address all of these aspects in this section.

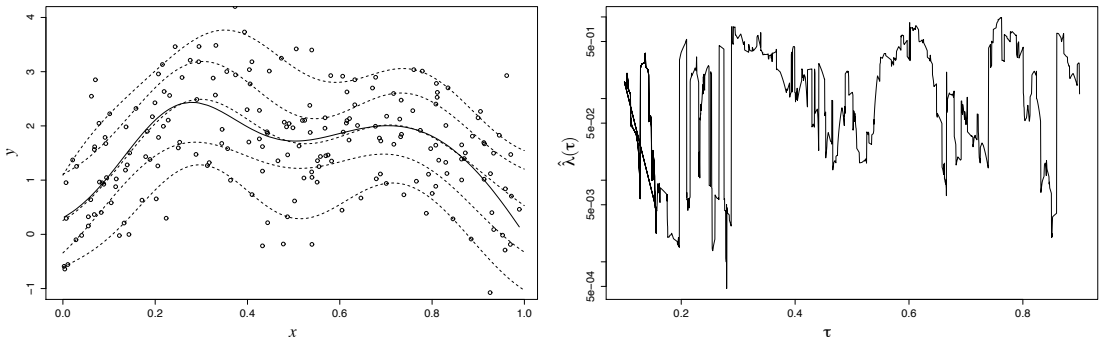

Figure 4: Left: The function $f(x)$ (solid), data points drawn from it with i.i.d normal error, and our cross-validated estimates of quantiles $0.1, 0.25, 0.5, 0.75, 0.9$ (dashed lines, from bottom to top). Right: Evolution of optimal regularization parameter $\hat{\lambda}(\tau)$, as τ varies.

6.1 Simulations

Our simulation setup starts with univariate data $x \in [0,1]$ and a "generating" function $f(x) = 2 \cdot \left(\exp(-30 \cdot (x-0.25)^2) + \sin(\pi \cdot x^2)\right)$ (see Figure 4). We then let $Y = f(x) + \varepsilon$, where the errors ε are independent, with a distribution that can be either:

1. $\varepsilon \sim N(0,1)$, that is, i.i.d standard normal errors
2. $\varepsilon + (x+1)^2 \sim \exp(1/(x+1)^2)$, which gives us errors that are still independent and have mean 0, but are asymmetric and have non-constant variance, with small signal-to-noise ratio on the higher values of x (see Figure 5).

Figure 4 demonstrates the results of the algorithm with i.i.d normal errors, 200 training samples and 200 validation samples and a Gaussian kernel with parameter $\sigma = 0.2$. In the left panel, we see that the quantile estimates all capture the general shape of the true curve, with some "smoothing" due to regularization. In the right panel we see the evolution of the optimal regularization parameter $\hat{\lambda}(\tau)$ as τ varies. We see the expected "jumpy" behavior of the optimal parameter, but we do not see a clear tendency to be smaller for quantiles closer to $1/2$. This is somewhat surprising when we think in terms of bias and variance (or approximation error and estimation error) in learning. Values of τ closer to $1/2$ typically create learning problems that are "easier", that is, variance is smaller (Koenker, 2005), and this should in principle allow us to build more complex models (reduce regularization), and decrease bias. A confounding factor in this analysis is the fact that the scale of quantile error need not be comparable for different quantiles. In particular, we may expect that loss magnitude would be larger for quantiles close to 0.5, where both types of errors get penalized equally. If that is the case, then having the similar regularization parameter may in fact imply *less* regularization for τ close to 0.5 compared to extreme quantiles. Another interesting observation is that while $\lambda^*(\tau)$ may be jumpy, both the empirical and the validation loss may vary smoothly. This smoothness is in fact guaranteed for the validation loss L_{cv}, since it is easily seen that the "jumps" are points where validation loss is equal at two knots or validation crossings.

Next we consider the computational complexity of the algorithm, and its dependence on the number of training samples (with 200 validation samples). We compare it to the KQR algorithm

NTRAIN	NSTEPS	TIME(BI-LEVEL)	TIME(LI ET AL.)	BREAK-EVEN RESOLUTION
200	29238	931 SEC.	2500 SEC.	3000
100	12269	99 SEC.	900 SEC.	900
50	2249	23 SEC.	480 SEC.	400

Table 1: Number of steps and run times of our algorithm and of Li et al. (2007), for the whole path from $\tau = 0.1$ to $\tau = 0.9$, as a function of the number of training observations NTRAIN. These results are based on applying Li et al. (2007) at 8000 different values of τ. The last column shows what resolution would give similar running times to both approaches (see text for details).

of Li et al. (2007), who have already demonstrated that their algorithm is significantly more efficient than grid-based approaches for generating 1-dimensional paths for fixed τ. Table 1 shows the number of steps of the main (outer) loop of Algorithm 1 and the total run time of our algorithm for generating the complete set of cross-validated solutions for $\tau \in [0.1, 0.9]$ as a function of the number of training samples (with validation sample fixed at 200). Also shown is the run time for the algorithm of Li et al. (2007), when we use it on a grid of 8000 evenly spaced τ values in $[0.1, 0.9]$ and find the best cross validated solution by enumerating the candidates as identified in Section 3. Our conjecture that the number of knots in the 2-dimensional path behaves like $O(n^2)$ seems to be consistent with these results, as is the hypothesized overall time complexity dependence of $O(n^3)$. Since 8000 is typically an unnecessarily fine grid for practical applications, we offer in the last column an evaluation of the comparative efficiency of the two methods in terms of the number of distinct τ values that can be fitted with the Li et al. (2007) approach in roughly the same running time as our approach. It is clear from these results that if just a small number of τ values (say, 10) are sufficient to address the complete problem, our approach does not carry a computational benefit.

Next, we demonstrate the ability of KQR to capture the quantiles with "strange" errors from model 2. Figure 5 shows a data sample generated from this model and the $(0.25, 0.5, 0.75)$ quantiles of the conditional distribution $P(Y|X)$ (solid), compared to their cross-validated KQR estimates (dashed), using 500 samples for learning and 200 for validation (more data is needed for learning because of the very large variance at values of x close to 1). As expected, we can see that estimation of the lower quantiles, and at smaller values of x is easier, because the distribution $P(Y|X = x)$ has long right tails everywhere and has much larger variance when x is big.

6.2 Baseball Data and California Housing

As discussed in Perlich et al. (2007), estimating conditional quantiles is often a modeling task that is well grounded in practical applications. In the context of house prices, we can think of estimating a high (but not extreme[4]) conditional quantile as the seller's search for a favorable bargaining position in negotiations. Similarly for salaries, estimating a high conditional quantile can serve as a measure of what an employee can expect to receive optimistically (but still realistically), given his characteristics and performance.We therefore demonstrate KQR on two well studied data sets that correspond to such modeling problems: baseball salaries as a function of a player's home runs and years of experience (He et al., 1998) and the California housing data set (Pace and Barry, 1997),

4. Extreme quantile estimation is also of interest in some contexts, but we do not demonstrate it here due to the inherent statistical difficulty and questionable results, see some discussion in Conclusion section.

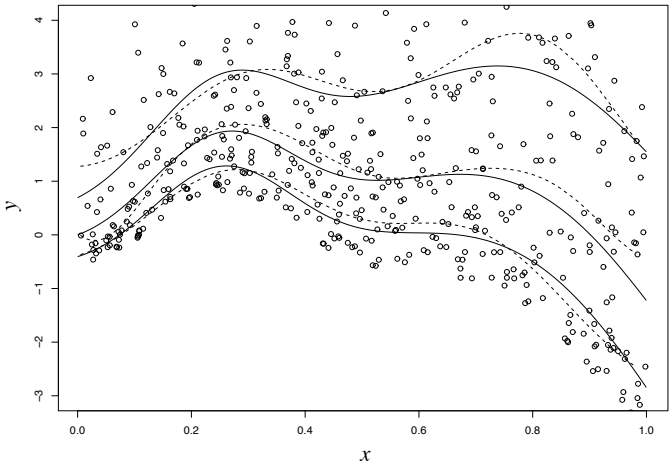

Figure 5: Quantiles of $P(Y|X)$ (solid), and their estimates (dashed) for quantiles $(0.25, 0.5, 0.75)$ with the exponential error model.

which describes the median prices of houses in neighborhoods of California along with nine explanatory demographic variables. We seek to demonstrate predictive performance, fitted models and the relative performance of different model selection approaches.

For our experiments, we use a Gaussian kernel, with the parameter $\gamma = 1$ chosen based on experimentation, to give flexible but not overly jumpy fits. We demonstrate the fit and accuracy of model selection using CV compared to using SIC. For CV, we used 50 of the 263 players in the data set for validation (selection of $\hat{\lambda}(\tau)$) and 50 more for testing the accuracy of the resulting model. Thus, 163 examples were used for training. For SIC, we used 213 (training+validation) as the training set, and applied Equation (13) for selecting $\hat{\lambda}(\tau)$. Both approaches were evaluated using the 50 test observations. In Figure 6 we show the resulting fit in both approaches, for three different quantiles. As expected, compensation seems to be monotone in performance (home runs) but not in experience (salary tends to increase as players gain experience, but then decreases as they get older and performance deteriorates). As we can see, the model-selected surfaces are quite similar between CV and SIC, though this need not be the case, as we should keep in mind that SIC is choosing between models trained on more data. In terms of accuracy on the test set (shown above each plot), The results are also very comparable. When comparing the two approaches we should also keep in mind the reduced complexity of applying SIC, and the existing literature on instability of CV-based model selection, though this is not evident in our results.

For the California housing data set, we use only longitude and latitude as the two explanatory variables in fitting KQR, to facilitate meaningful visualization of results. We model the log of the median price, since the actual median fluctuates widely over the data. We use 500 observations for training and 50 as validation for CV, 550 as training for SIC, and 500 additional observations for testing. Figure 7 shows the results. It is clear that visualization is hampered by the fact that California is far from being rectangular, so one corner of the plots (latitude 34N, longitude 122W) is well inside the ocean, while the other (latitude 40N, longitude 115W) is well inland from the California border. The wild extrapolation of the fit in that direction is therefore not informative.

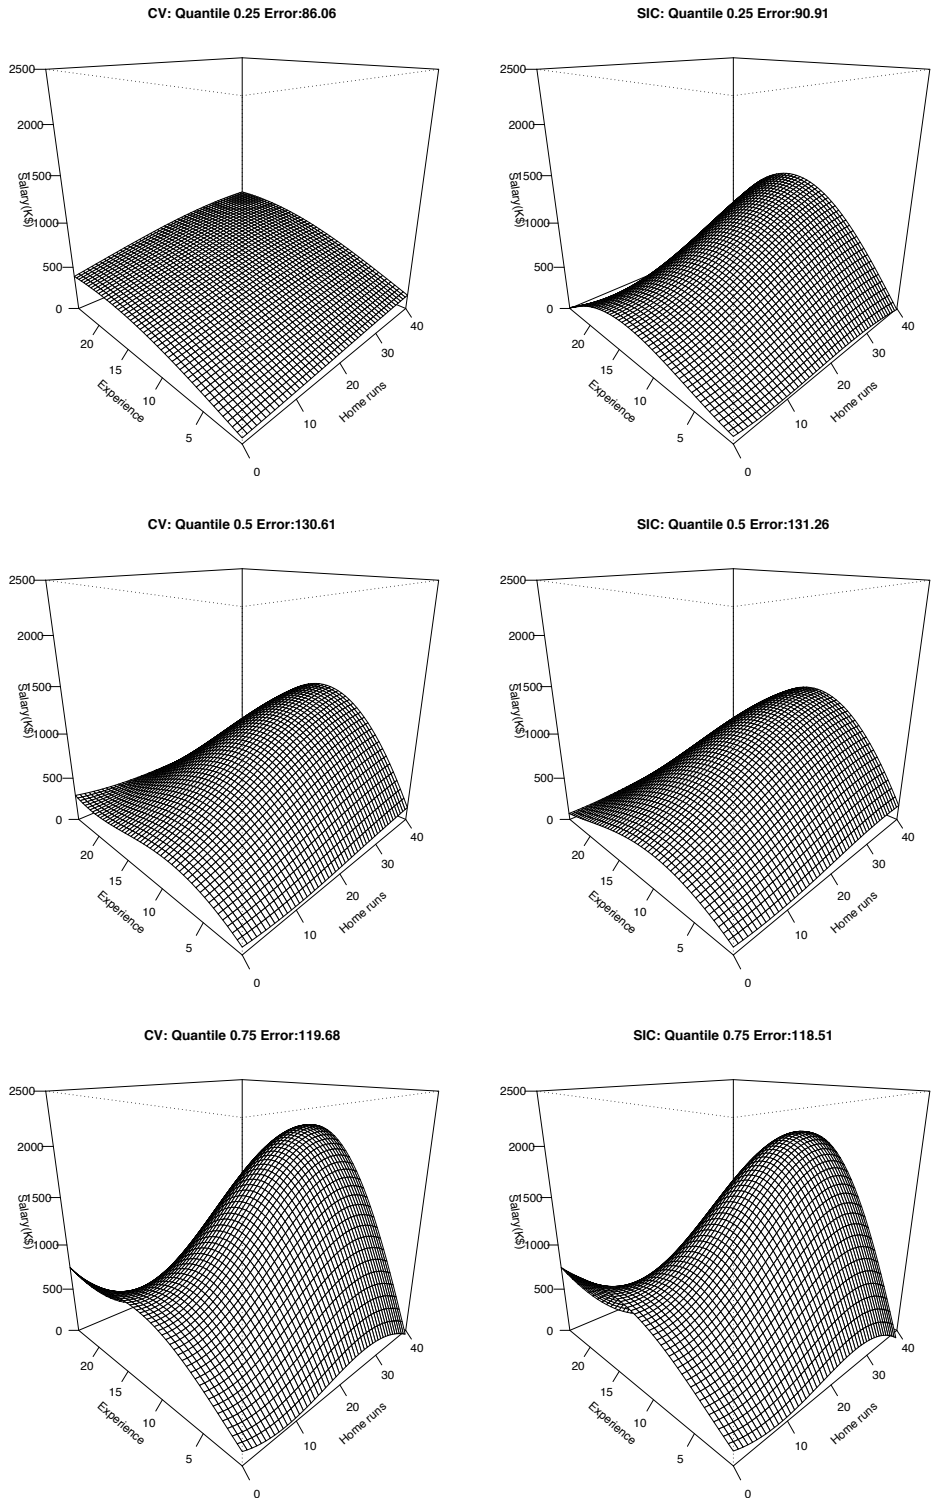

Figure 6: Models selected using CV (left) and SIC (right) on the Baseball data, for three different quantiles.

On each plot the fit at San Francisco (red circle), Los Angeles (blue square) and Sacramento (green triangle) are marked. We can see that the selected fits using CV and SIC are quite similar, with possible exception to the more jumpy fit selected by SIC for quantile 0.5. The valid insights that seem to arise out of these plots relate to the lower house values in the central valley of California compared to the coastal area, and the reduced house values in the Sacramento area compared to near by the Bay Area.

7. Conclusions and Future Work

In this paper we have demonstrated that the family of bi-level optimization Problems (4) defined by the family of loss functions L_τ can be solved via a *path following* approach which essentially maps the whole surface of solutions $\hat{f}(\tau,\lambda)$ as a function of both τ and λ and uses insights about the possible locations of the bi-level optima to efficiently find them. This leads to a closed-form algorithm for finding $f^*(\tau)$ for all quantiles. We see two main contributions in this work: a. Characterization of a family of non-convex optimization problems of great practical interest which can be solved using solely convex optimization techniques and b. Formulation of a practical algorithm for generating the full set of cross-validated solutions for the family of kernel quantile regression problems.

We have shown how our approach can be extended to other modeling problems with a parameterized loss function, such as SVR, and to other versions of KQR, including using in-sample model selection criteria and enforcing monotonicity on the resulting quantiles.

There are many other interesting aspects of our work, which we have not touched on here, including: development of further optimization shortcuts to improve algorithmic efficiency, investigation of the range of applicability of our algorithmic approach beyond KQR and SVR, analysis of the use of various kernels for KQR and how the kernel parameters and kernel properties interact with the solutions, and more extensive empirical studies.

It is of particular interest to us to investigate the bias-variance tradeoff in loss function selection. As we have mentioned, modeling with the quantile loss function L_τ leads to estimation of the τth quantile of $P(Y|x)$ in the *decision theoretic* sense that the population optimizer of the loss function is this quantile (see Equation 2). However, this by no means guarantees that a model learned from finite data using L_τ (with or without regularization) will do well in predicting the τth quantile. In particular, there is no guarantee that a model built using a different loss function (say, L_η, $\eta \neq \tau$) will not do better in predicting this quantile. This can be thought of in terms of bias and variance, where the model generating quantile η is similar enough to the one for quantile τ (i.e., bias is small), but it is "easier" to learn with L_η, that is, variance is smaller, which would typically be the case if η is closer to $1/2$ than τ (Koenker, 2005). A detailed investigation of this question is outside the scope of the current work, but will be a natural extension.

A particularly important and difficult type of quantile estimation problems pertains to estimation of *extreme* quantiles (e.g., $\tau = 0.01$ or $\tau = 0.99$) which can serve as approximations for expected extreme values of the function being estimated. These problems are typically very difficult *statistically*, that is, hard because of the scarcity of information implicit in trying to estimate events we rarely observe. However they are not expected to be particularly difficult algorithmically. That is, our (and others') KQR approaches can estimate these models, but it is not clear how useful the results are. These observations are verified by our limited experiments (results not shown), which yield very "jumpy" and unstable models for extreme quantiles.

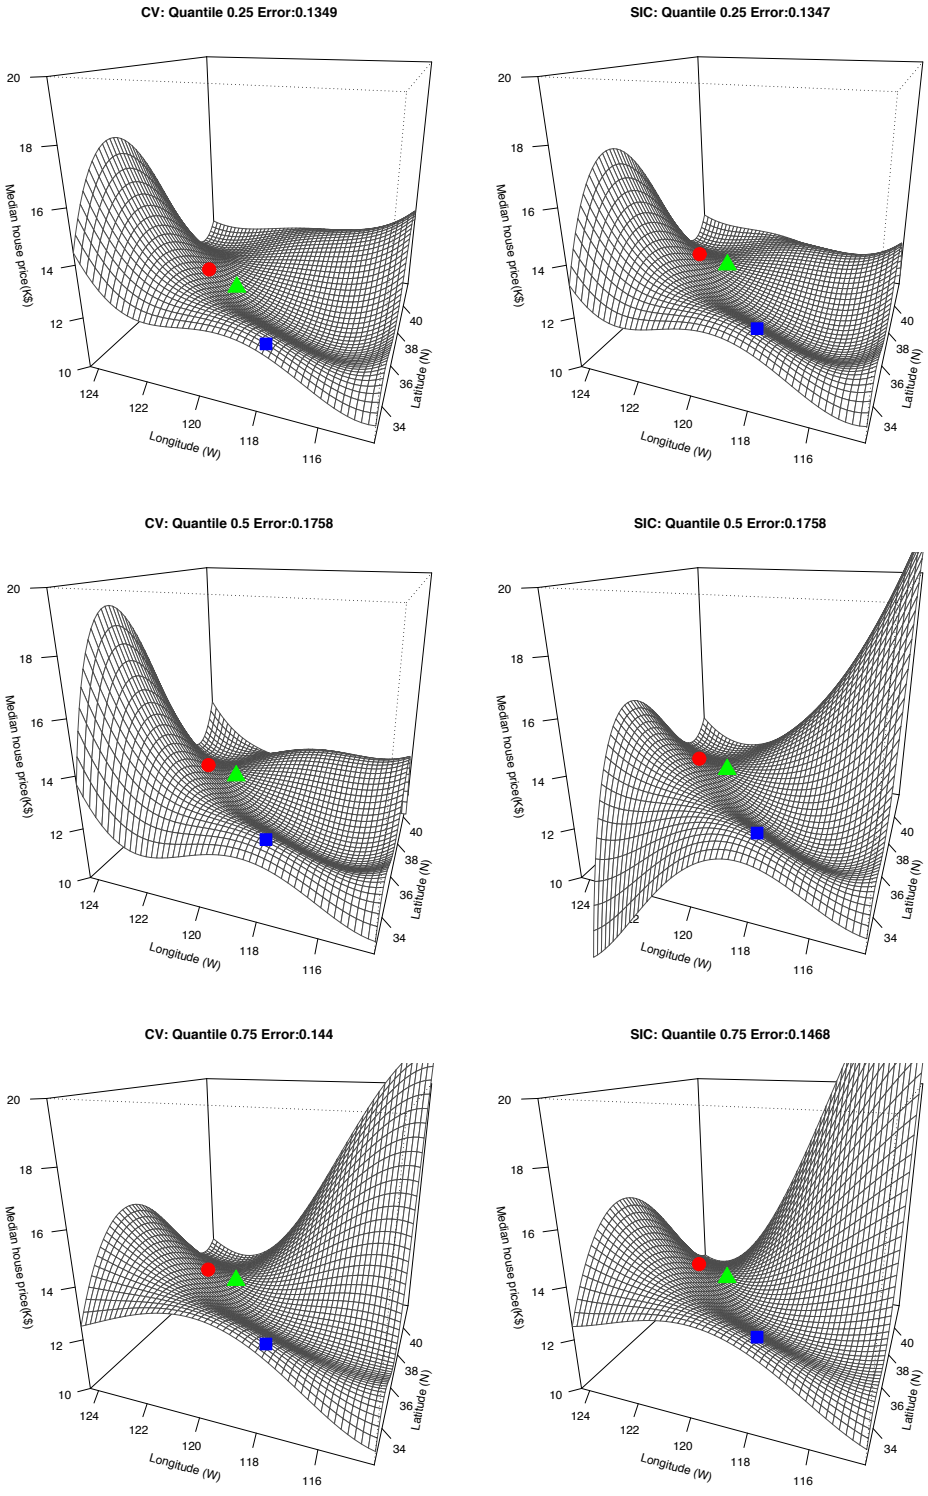

Figure 7: Synthetic maps of the models selected using CV (left) and SIC (right) on the CA housing data, for three different quantiles. The fits at San Francisco (red circle), Los Angeles (blue square) and Sacramento (green triangle) are marked on each map.

Acknowledgments

The author thanks Ramesh Natarajan for useful early discussions, Ji Zhu for help with the KQR code of Li et al. (2007), and the action editor, two anonymous referees and Ronny Luss for their useful comments.

Appendix A. Pseudo-code of Algorithm

Algorithm 2 and its accompanying procedures describe our implementation in some detail. This pseudo code is meant to complete the implementation details given in the paper. We use mathematical notation rather than programming commands as much as possible, to make understanding easier. Given the complexities and intricacies involved in the complete implementation, it seems unrealistic and probably non-useful to give an exhaustive description. Rather, we concentrate on clarifying the general flow of the algorithm and the mathematical problems it solves at each step. We also emphasize the aspects of the algorithm not covered in technical detail in the main text, such as the differentiation of different types of events (knot crossing, knot merging, knot splitting). Where the text offers the technical content, we simply refer to that point. For example, Theorem 2 describes the direction calculation and also implicitly the accounting orf the identities of the sets $\mathcal{E}, \mathcal{L}, \mathcal{R}$ required for it. We thus simply refer back to it where relevant in the algorithm.

Some further comments on the pseudo code:

- We assume the training and validation data are "global variables" known to all procedures.
- We use $\hat{f}$ and $\hat{\theta}$ interchangeably, given formula (5).
- Some of the elements are not described in the most efficient implementation, which would require a lot more accounting and data management. For example, the search for the minima in the function UpdateValidList does not have to be done from scratch on every call, but a list can be maintained, and only the necessary items updated.
- The pseudo-code glosses over numerical issues which plague the actual implementation. In particular, all equalities must have "tolerance" in the practical implementation due to machine rounding errors. This obviously creates a problem when events on the path are bunched together close enough that two distinct events fall within this tolerance.
- We avoid repetition of similar procedures. Thus the call to function *KnotSplit* at end of Algorithm 2 is replaced with a brief explanation of its near-identity to the function *KnotCross* which is already given.

Algorithm 2: Algorithm description

Input: The entire λ-solution path for quantile τ_0 characterized by its m knots $\boldsymbol{\lambda} = \lambda_1, ..., \lambda_m$; the solution directions $\mathbf{g} = g_1, ..., g_m$ as defined in (6); and $\mathbf{i} = i_1, ..., i_m$ the observations which "hit the elbow" at every knot

Output: Cross-validated solutions $f^*(\tau)$ for $\tau \in [\tau_0, \tau_{\text{end}}]$ described as set of intervals in the variable OPT

`/* Initialization: find validation crossings, calculate cross validation loss at knots and validation crossings, sort by it, find future meetings of neighbors on the list, where the order changes */`

Set M = InitializeValidList($\tau_0, \boldsymbol{\lambda}, \mathbf{g}$);

Set $OPT = (\tau_0, f^*(\tau_0), h^*)$ where $f^*(\tau_0) = \hat{f}(\tau_0, M.\lambda_1)$, $h^* = M.h_1$ are from the first (smallest loss) entry in M;

Set $\tau_{\text{now}} = \tau_0$;

Let T be the list of the fits $\mathbf{f} = (\hat{f}(\tau_0, \lambda_1), ..., \hat{f}(\tau_0, \lambda_m))$, regularization values $\boldsymbol{\lambda} = (\lambda_1, ..., \lambda_m)$, rates $\mathbf{c} = (c_1, ..., c_m)$, and directions $\mathbf{h} = (h_1, ..., h_m)$ as defined in Theorem 2; `/* Main loop */`

while $\tau_{\text{now}} < \tau_{\text{end}}$ **do**

  Update $\{\tau_{\text{new}}, k_{\text{new}}, i_{\text{new}}, \text{type}\}$ = FindEvent(T);

  Update $T.\lambda_k = T.\lambda_k + (\tau_{\text{new}} - \tau_{\text{now}})T.c_k$ for $k = 1, ..., m$;

  Update $T.f_k$ according to (6);

  while $\tau_{\text{now}} < \tau_{\text{new}}$ **do**

    Set $\tau_{\text{keep}} = \tau_{\text{now}}$;

    (M, change, τ_{now}) = UpdateValidList($M, \tau_{\text{keep}}, \tau_{\text{new}}$);

    if *change=TRUE* **then**

      $OPT = concatenate(OPT, (\tau_{\text{now}}, f^*(\tau_{\text{now}}), h^*))$ where $f^*(\tau_{\text{now}}) = f(\tau_{\text{now}}, M.\lambda_1)$, $h^* = M.h_1$ are from the first (smallest loss) entry in M;

    end

  end

  if *type = cross* **then** `/* Knot crossing of knots` k_{new}, $k_{\text{new}}+1$ `*/`

    Set T = KnotCross($T, k_{\text{new}}, \tau_{\text{now}}$);

  else if *type = merge* **then** `/* Knot merge of` k_{new}, $k_{\text{new}}+1$, $k_{\text{new}}+2$ `*/`

    Remove knots $k_{\text{new}}, k_{\text{new}+2}$ from T;

    Update sets $\mathcal{E}, \mathcal{R}, \mathcal{L}$ for the remaining knot (Move the observation which defined the two removed knots from $\mathcal{E}$ to $\mathcal{L}$ or $\mathcal{R}$);

    else `/* Knot split of knot` k_{new} `with observation` i_{new} `*/`

      `/* Function` ***KnotSplit*** `would be identical to` ***KnotCross***`---identify two observations at border and find legal directions---except that a split situation yields three such directions, hence three knots, while a cross situation yields two */`

end

Procedure "IntializeValidList": Initialization of bi-level candidate list

Input: Initial value τ_0, vector of knot values $\boldsymbol{\lambda}$, corresponding directions $\mathbf{g}$

Output: A list $M = \{(r_k, \lambda_k, l_k, h_k, \tau_k) : k = 1, ..., m+v\}$ sorted by $l_1 \leq l_2 \leq .... \leq l_{m+v}$, where:

r_k is an indicator in $\{knot, valx\}$ whether this is a knot or a validation crossing

λ_k is its "location" on the path

l_k is its cross validation loss

h_k is its direction

τ_k is knot meeting point

Find knot directions $h_1, ..., h_m$ according to Theorem 2;

/* Identify all validation crossings in the solution path for τ_0 */

Set $V = \Phi$ the empty set;

for $k = 1, ..., m$ *knots and* $i = 1, ..., N$ *validation observations* **do**

  if $\hat{f}(\tau_0, \lambda_{k-1})(\tilde{\mathbf{x}}_i) > \tilde{y}_i$ *and* $\hat{f}(\tau_0, \lambda_k)(\tilde{\mathbf{x}}_i) < \tilde{y}_i$ *or vice versa* **then**

    Set $\tilde{\lambda} = \lambda_k \frac{\hat{f}(\tau_0, \lambda_k)(\tilde{\mathbf{x}}_i) - g_k(\tilde{\mathbf{x}}_i)}{\tilde{y}_i - g_k(\tilde{\mathbf{x}}_i)}$;

    Find the validation crossing direction $\tilde{h}(\mathbf{x})$ according to Proposition 5;

    Add the entry $(\tilde{\lambda}, \tilde{h})$ characterizing the validation crossing to the set V;

  end

end

/* Sort knots and validation crossings by their loss */

Denote the number of validation crossings by $v = |V|$;

for $k = 1, ..., m$ **do**

  Calculate knot validation loss: $l_k = \sum_{i=1}^{N} L_{\tau_0}(\hat{f}(\tau_0, \lambda_k)(\tilde{\mathbf{x}}_i), \tilde{y}_i)$;

end

for $k = 1, ..., v$ **do**

  Calculate validation crossing loss: $l_{m+k} = \sum_{i=1}^{N} L_{\tau_0}(\hat{f}(\tau_0, \tilde{\lambda}_k)(\tilde{\mathbf{x}}_i), \tilde{y}_i)$;

end

Create list $M = \{(r_k, \lambda_k, l_k, h_k, \tau_k) : k = 1, ..., m+v\}$ sorted by $l_1 \leq l_2 \leq .... \leq l_{m+v}$, where:

r_k is an indicator whether this is a knot or a validation crossing with possible values *knot* and *valx* respetively

λ_k is its "location" on the path

l_k is its cross validation loss

h_k is its direction

τ_k is knot meeting point, defined below;

/* Identify mtg pts of neighboring knots or valid. crossings */

for $k = 1, ..., m+v-1$ **do**

  Let $\tau_k = \tau_0 + \delta_k$ where δ_k is the minimal positive solution of the Problem (11) with $l = k+1$;

end

Procedure "`FindEvent`": Find the next event on the path as τ changes

Input: The list T of knots and their directions

Output: Event type in $\{cross, merge, birth\}$, τ_{new} where next event happens, k_{new} the knot where this event happens, i_{new} the observation involved in the event (if a birth)

`/* Next knot crossing or knot merging */`

Set $\tilde{\tau}_k = \frac{T.\lambda_k - T.\lambda_{k+1}}{T.c_{k+1} - T.c_k}$, $k = 1, ..., m-1$;

Set $k_{\text{new}} = \arg\min_{k=1,...,m-1}\{\tilde{\tau}_k : \tilde{\tau}_k > 0\}$;

Set $\tau_{\text{new}} = \tilde{\tau}_{k_{\text{new}}}$ **if** $\tilde{\tau}_{k_{\text{new}}} = \tilde{\tau}_{k_{\text{new}}+1}$ **then**

    type=*merge* ; `/* Knots merging` $3 \Rightarrow 1$ `*/`

else

    type=*cross*; `/* Two knots crossing */`

end

`/* Next observation-knot crossing = knot birth */`

for $k = 1, ..., m$ **do**

    Set $i'_k = \arg\min_{i=1,...,n}\{\frac{T.\lambda_k(\hat{f}(T.\lambda_k)(\mathbf{x}_i) - y_i)}{T.c_k(y_i - h_k(\mathbf{x}_i))} : \frac{T.\lambda_k(\hat{f}(T.\lambda_k)(\mathbf{x}_i) - y_i)}{T.c_k(y_i - h_k(\mathbf{x}_i))} > 0\}$;

    Set τ'_k to be the minimum attained;

end

Set $k' = \arg\min_k \tau'_k$;

if $\tau'_{k'} < \tau_{\text{new}}$ **then**

    Set $\tau_{\text{new}} = \tau'_{k'}$, $k_{\text{new}} = k'$, type=*birth* ;

end

Procedure "UpdateValidList": Find the next validation event on the path as τ changes, and update the list if necessary

Input: Validation candidate list M, current value τ_{keep}, next event on main path τ_{new}

Output: Logical indicator *change* whether optimum changed, Updated list M, and τ_{now} where next validation event happens

Set change = FALSE ;

/* Pair of validation crossings can disappear, or a new a validation crossing can appear, or a regular order change in the elements in M can occur. We first identify the next order change in the list M */

Set $\tau_{\text{now}} = \min_{k=1,\ldots,m+v-1} M.\tau_k$;

Set $k_{\text{now}} = \arg\min_{k=1,\ldots,m+v-1} M.\tau_k$;

/* Now find the next time a validation observation hits a knot $\Rightarrow$ new validation crossing */

For $i = 1,\ldots N$ and $k = 1\ldots,m$ set $\Delta\tau(i,k) = M.\lambda_k \frac{\hat{f}(\tau_{\text{keep}}, M.\lambda_k)(\tilde{\mathbf{x}}_i) - \tilde{y}_i}{\tilde{y}_i M.c_k - M.h_k(\tilde{\mathbf{x}}_i)}$;

Set $\tilde{\tau} = \tau_{\text{keep}} + \min_{i=1,\ldots,N,k=1,\ldots,m}\{\Delta\tau(i,k) : \Delta\tau(i,k) > 0\}$;

Set $(\tilde{i},\tilde{k}) = \arg\min_{i=1,\ldots,N,k=1,\ldots,m}\{\Delta\tau(i,k) : \Delta\tau(i,k) > 0\}$;

if $\tau_{\text{now}} > \tau_{\text{new}}$ *and* $\tilde{\tau} > \tau_{\text{new}}$ **then** /* No validation event before τ_{new} */

  $\tau_{\text{now}} = \tau$new;

  return;

else if $\tau_{\text{now}} > \tilde{\tau}$ **then** /* New validation xing appears---add it to list */

  Set $\tilde{\lambda} = (\tilde{\tau} - \tau_{\text{keep}}) M.c_{\tilde{k}} + M.\lambda_{\tilde{k}}$;

  Set $\tilde{l} = \sum_{i=1}^{N} L_{\tilde{\tau}}(\hat{f}(\tilde{\tau},\tilde{\lambda})(\tilde{\mathbf{x}}_i), \tilde{y}_i)$;

  Set the validation xing direction $\tilde{h}(\mathbf{x})$ according to Proposition 5;

  Find the location k' in the sorted list of the cross validation loss $\tilde{l}$ and insert the element $(r = valx, \tilde{\lambda}, \tilde{l}, \tilde{h})$ into M at location k' ;

  Recalculate $\tau_{k'-1}, \tau_{k'}$ in M according to (11);

  Set $\tau_{\text{now}} = \tilde{\tau}$;

else

  /* If two validation crossings meet knot---the two disappear */

  Set $(merged, M)$ = CheckMerge(M, k_{now});

  if *merged=FALSE* **then** /* Usual situation: swap elements, update meetings */

    Swap elements k_{now} and $k_{\text{now}} + 1$ in M;

    Recalculate $\tau_{k_{\text{now}}-1}, \tau_{k_{\text{now}}}, \tau_{k_{\text{now}}+1}$ in M according to (11);

    if $k_{\text{now}} = 1$ **then** /* First element changed $\Rightarrow$ change of optimum */

      changed = TRUE;

    end

  end

end

Procedure `"CheckMerge"`: Find out if the validation event is in fact two validation crossings of same observation meeting a knot and merging

Input: Validation candidate list M, index of event point k

Output: Logical indicator *merge* whether a merge occurred, updated list M

merge = FALSE;
`/* With observations in general location,` $\tau_k = \tau_{k+1}$ `in` M `implies immediately that we have a merge. Two of` $k, k+1, k+2$ `are validation crossings of the same observation, the knot is the third involved in the crossing. If we do not assume that, more checks are required! */`
if $M.\tau_k = M.\tau_{k+1}$ **then**
    merge = TRUE ;
    `/* Find out which one of the entries` $k, k+1, k+2$ `in` M `is a knot, delete the other two */`
    if $M.r_k =$ knot **then**
        remove entries $k+1, k+2$ from M;
    else if $M.r_{k+1} =$ knot **then**
        remove entries $k, k+2$ from M ;
    else `/*` $M.r_{k+2} =$ knot `*/`
        remove entries $k, k+1$ from M ;
    Update $M.\tau_{k-1}, M.\tau_k$ according to (11);
end

Procedure "KnotCross": Update directions when knots cross

Input: Knot list T, index of first of crossing knots k, current quantile τ

Output: Updated list T

/* Identify i_1, i_2, the ''knot'' observations at the two knots */

Find i_1, i_2 s.t. $\theta_{i_j} \in \{\tau, -(1-\tau)\}$ and $y_{i_j} = \hat{f}(\tau, T.\lambda_{k+j-1})(\mathbf{x}_{i_j})$ for $j \in \{1,2\}$;

Calculate the sets $\mathcal{E}, \mathcal{R}, \mathcal{L}$ as defined in the text for the meeting knots (leaving out the "border observations" i_1, i_2);

Set $u = k$ **for** rel $= 1,2$ **do** /* try releasing each border observation to $\mathcal{E}$ or $\mathcal{L}$ or $\mathcal{R}$ as appropriate */

  Add observation i_{rel} to $\mathcal{E}$ and calculate direction h, c according to Theorem 2;

  /* Check sign and magnitude of $b_{i_{\text{rel}}}$ for consistency (to maintain $\theta_{i_{\text{rel}}} \in [-(1-\tau), \tau]$ as τ increases) */

  if $b_{i_{\text{rel}}} \leq 1$ *and* $\hat{\theta}_{i_{\text{rel}}} = \tau$ **then**

    Update entry u in T with this direction h, c, set $u = u + 1$;

  else if $b_{i_{\text{rel}}} \geq -1$ *and* $\hat{\theta}_{i_{\text{rel}}} = -(1-\tau)$ **then**

    Update entry u in T with this direction h, c, set $u = u + 1$;

  end

  if $\hat{\theta}(i_{\text{rel}}) = \tau$ **then**

    Add i_{rel} to $\mathcal{R}$;

  else /* $\hat{\theta}(i_{\text{rel}}) = -1 - \tau$ */

    Add i_{rel} to $\mathcal{L}$;

  Calculate direction h and c according to Theorem 2;

  /* Check sign and magnitude of $h(\mathbf{x}_{i_{\text{rel}}})$ for sign consistency */

  if $h(\mathbf{x}_{i_{\text{rel}}}) < 0$ *and* $\hat{\theta}_{i_{\text{rel}}} = \tau$ **then**

    Update entry u in T with this direction h, c, set $u = u + 1$;

  else if $h(\mathbf{x}_{i_{\text{rel}}}) > 0$ *and* $\hat{\theta}_{i_{\text{rel}}} = -(1-\tau)$ **then**

    Update entry u in T with this direction h, c, set $u = u + 1$;

  end

end

Abstract

We consider a general class of regularization methods which learn a vector of parameters on the basis of linear measurements. It is well known that if the regularizer is a nondecreasing function of the L_2 norm, then the learned vector is a linear combination of the input data. This result, known as the *representer theorem*, lies at the basis of kernel-based methods in machine learning. In this paper, we prove the necessity of the above condition, in the case of differentiable regularizers. We further extend our analysis to regularization methods which learn a matrix, a problem which is motivated by the application to multi-task learning. In this context, we study a more general representer theorem, which holds for a larger class of regularizers. We provide a necessary and sufficient condition characterizing this class of matrix regularizers and we highlight some concrete examples of practical importance. Our analysis uses basic principles from matrix theory, especially the useful notion of matrix nondecreasing functions.

Keywords: kernel methods, matrix learning, minimal norm interpolation, multi-task learning, regularization

1. Introduction

Regularization in Hilbert spaces is an important methodology for learning from examples and has a long history in a variety of fields. It has been studied, from different perspectives, in statistics (see Wahba, 1990, and references therein), in optimal estimation (Micchelli and Rivlin, 1985) and recently has been a focus of attention in machine learning theory, see, for example (Cucker and Smale, 2001; De Vito et al., 2004; Micchelli and Pontil, 2005a; Shawe-Taylor and Cristianini, 2004; Vapnik, 2000) and references therein. Regularization is formulated as an *optimization problem* involving an *error term* and a *regularizer*. The regularizer plays an important role, in that it favors solutions with certain desirable properties. It has long been observed that certain regularizers exhibit an appealing

property, called the *representer theorem*, which states that there exists a solution of the regularization problem that is a linear combination of the data. This property has important computational implications in the context of regularization with positive semidefinite *kernels*, because it transforms high or infinite-dimensional problems of this type into finite dimensional problems of the size of the number of available data (Schölkopf and Smola, 2002; Shawe-Taylor and Cristianini, 2004).

The topic of interest in this paper will be to determine the conditions under which representer theorems hold. In the first half of the paper, we describe a property which a regularizer should satisfy in order to give rise to a representer theorem. It turns out that this property has a simple geometric interpretation and that the regularizer can be equivalently expressed as a *nondecreasing* function of the Hilbert space norm. Thus, we show that this condition, which has already been known to be sufficient for representer theorems, is also *necessary*. In the second half of the paper, we depart from the context of Hilbert spaces and focus on a class of problems in which *matrix structure* plays an important role. For such problems, which have recently appeared in several machine learning applications, we show a modified version of the representer theorem that holds for a class of regularizers significantly larger than in the former context. As we shall see, these matrix regularizers are important in the context of multi-task learning: the matrix columns are the parameters of different regression tasks and the regularizer encourages certain dependences across the tasks.

In general, we consider problems in the framework of *Tikhonov regularization* (Tikhonov and Arsenin, 1977). This approach finds, on the basis of a set of input/output data $(x_1, y_1), \ldots, (x_m, y_m) \in \mathcal{H} \times \mathcal{Y}$, a vector in $\mathcal{H}$ as the solution of an optimization problem. Here, $\mathcal{H}$ is a prescribed Hilbert space equipped with the inner product $\langle \cdot, \cdot \rangle$ and $\mathcal{Y} \subseteq \mathbb{R}$ a set of possible output values. The optimization problems encountered in regularization are of the type

$$\min \left\{ \mathcal{E}\big((\langle w, x_1 \rangle, \ldots, \langle w, x_m \rangle), (y_1, \ldots, y_m) \big) + \gamma\, \Omega(w) : w \in \mathcal{H} \right\}, \tag{1}$$

where $\gamma > 0$ is a regularization parameter. The function $\mathcal{E} : \mathbb{R}^m \times \mathcal{Y}^m \to \mathbb{R}$ is called an *error function* and $\Omega : \mathcal{H} \to \mathbb{R}$ is called a *regularizer*. The error function measures the error on the data. Typically, it decomposes as a sum of univariate functions. For example, in regression, a common choice would be the sum of square errors, $\sum_{i=1}^m (\langle w, x_i \rangle - y_i)^2$. The function Ω, called the regularizer, favors certain regularity properties of the vector w (such as a small norm) and can be chosen based on available prior information about the target vector. In some Hilbert spaces such as Sobolev spaces the regularizer is a measure of smoothness: the smaller the norm the smoother the function.

This framework includes several well-studied learning algorithms, such as ridge regression (Hoerl and Kennard, 1970), support vector machines (Boser et al., 1992), and many more—see Schölkopf and Smola (2002) and Shawe-Taylor and Cristianini (2004) and references therein.

An important aspect of the practical success of this approach is the observation that, for certain choices of the regularizer, solving (1) reduces to identifying m parameters and not $\dim(\mathcal{H})$. Specifically, when the regularizer is the square of the Hilbert space norm, the representer theorem holds: there exists a solution $\hat{w}$ of (1) which is a linear combination of the input vectors,

$$\hat{w} = \sum_{i=1}^m c_i x_i, \tag{2}$$

where c_i are some real coefficients. This result is simple to prove and dates at least from the 1970's, see, for example, Kimeldorf and Wahba (1970). It is also known that it extends to any regularizer that is a *nondecreasing* function of the norm (Schölkopf et al., 2001). Several other variants

and results about the representation form (2) have also appeared in recent years (De Vito et al., 2004; Dinuzzo et al., 2007; Evgeniou et al., 2000; Girosi et al., 1995; Micchelli and Pontil, 2005b; Steinwart, 2003; Wahba, 1992). Moreover, the representer theorem has been important in machine learning, particularly within the context of learning in reproducing kernel Hilbert spaces (Aronszajn, 1950)—see Schölkopf and Smola (2002) and Shawe-Taylor and Cristianini (2004) and references therein.

Our first objective in this paper is to derive necessary and sufficient conditions for representer theorems to hold. Even though one is mainly interested in regularization problems, it is more convenient to study *interpolation* problems, that is, problems of the form

$$\min\left\{\Omega(w) : w \in \mathcal{H}, \langle w, x_i\rangle = y_i,\ \forall i = 1,\ldots,m\right\}. \tag{3}$$

Thus, we begin this paper (Section 2) by showing how representer theorems for interpolation and regularization relate. On one side, a representer theorem for interpolation easily implies such a theorem for regularization with the same regularizer and any error function. Therefore, *all representer theorems obtained in this paper apply equally to interpolation and regularization*. On the other side, though, the converse implication is true under certain weak qualifications on the error function.

Having addressed this issue, we concentrate in Section 3 on proving that an interpolation problem (3) admits solutions representable in the form (2) *if and only if* the regularizer is *a nondecreasing function of the Hilbert space norm*. That is, we provide a complete characterization of regularizers that give rise to representer theorems, which had been an open question. Furthermore, we discuss how our proof is motivated by a geometric understanding of the representer theorem, which is equivalently expressed as a monotonicity property of the regularizer. We note that for simplicity throughout the paper we shall assume that Ω is differentiable. However our results are constructive and it should be possible to extend them to the non-differentiable case.

Our second objective is to formulate and study the novel question of representer theorems for *matrix problems*. To make our discussion concrete, let us consider the problem of learning n linear regression vectors, represented by the parameters $w_1,\ldots,w_n \in \mathbb{R}^d$, respectively. Each vector can be thought of as a "task" and the goal is to *jointly* learn these n tasks. In such problems, there is usually prior knowledge that *relates* these tasks and it is often the case that learning can improve if this knowledge is appropriately taken into account. Consequently, a good regularizer should favor such task relations and involve *all tasks jointly*.

In the case of interpolation, this learning framework can be formulated concisely as

$$\min\left\{\Omega(W) : W \in \mathbf{M}_{d,n},\ w_t^\top x_{ti} = y_{ti},\ \ \forall i = 1,\ldots,m_t,\ t = 1,\ldots,n\right\}, \tag{4}$$

where $\mathbf{M}_{d,n}$ denotes the set of $d \times n$ real matrices and the column vectors $w_1,\ldots,w_n \in \mathbb{R}^d$ form the matrix W. Each task t has its own input data $x_{t1},\ldots,x_{tm_t} \in \mathbb{R}^d$ and corresponding output values $y_{t1},\ldots,y_{tm_t} \in \mathcal{Y}$.

An important feature of such problems that distinguishes them from the type (3) is the appearance of *matrix products* in the constraints, unlike the inner products in (3). In fact, as we will discuss in Section 4.1, problems of the type (4) can be written in the form (3). Consequently, the representer theorem applies if the matrix regularizer is a nondecreasing function of the Frobenius norm.[1] However, the optimal vector $\hat{w}_t$ for each task can be represented as a linear combination of

1. Defined as $\|W\|_2 = \sqrt{\mathrm{tr}(W^\top W)}$.

only those input vectors corresponding to this particular task. Moreover, with such regularizers it is easy to see that each task in (4) can be optimized independently. Hence, these regularizers are of no practical interest if the tasks are expected to be related.

This observation leads us to formulate a *modified representer theorem*, which is appropriate for matrix problems, namely,

$$\hat{w}_t = \sum_{s=1}^{n} \sum_{i=1}^{m_s} c_{si}^{(t)} x_{si} \qquad \forall t = 1, \ldots, n, \tag{5}$$

where $c_{si}^{(t)}$ are scalar coefficients, for $t, s = 1, \ldots, n,\ i = 1, \ldots, m_s$. In other words, we now allow for *all input vectors* to be present in the linear combination representing each column of the optimal matrix. As a result, this definition greatly expands the class of regularizers that give rise to representer theorems.

Moreover, this framework can be used in many applications where matrix optimization problems are involved. Our immediate motivation, however, has been more specific than that, namely *multi-task learning*. Learning multiple tasks jointly has been a growing area of interest in machine learning and other fields, especially during the past few years (Abernethy et al., 2009; Argyriou et al., 2006, 2008a, 2007; Candès and Recht, 2009; Cavallanti et al., 2008; Izenman, 1975; Maurer, 2006a,b; Srebro et al., 2005; Wolf et al., 2007; Xiang and Bennett, 2005; Xiong et al., 2006; Yuan et al., 2007). For instance, some of these approaches use regularizers which involve the *trace norm*[2] of matrix W. There have been several motivations for the trace norm, derived from kernel learning, maximum likelihood, matrix factorization or graphical models. Another motivation is that under conditions a small trace norm favors low-rank matrices. This means that the tasks (the columns of W) are related in that they all lie in a low-dimensional subspace of $\mathbb{R}^d$. In the case of the trace norm, the representer theorem (5) is known to hold—see Abernethy et al. (2009), Argyriou et al. (2008a) and Amit et al. (2007); see also the discussion in Section 4.1.

It is natural, therefore, to ask a question similar to that in the standard Hilbert space (or single-task) setting. That is, under which conditions on the regularizer a representer theorem holds. In Section 4.2, we provide an answer by *proving a necessary and sufficient condition for representer theorems* (5) *to hold for problem* (4)*, expressed as a simple monotonicity property*. This property is analogous to the one in the Hilbert space setting, but its geometric interpretation is now algebraic in nature. We also give a functional description equivalent to this property, that is, *we show that the regularizers of interest are the matrix nondecreasing functions of the quantity* $W^\top W$.

Our results cover matrix problems of the type (4) which have already been studied in the literature. But they also point towards some new learning methods that may perform well in practice and can now be made computationally efficient. Thus, we close the paper with a discussion of possible regularizers that satisfy our conditions and have been used or can be used in the future in machine learning problems.

1.1 Notation

Before proceeding, we introduce the notation used in this paper. We use $\mathbb{N}_d$ as a shorthand for the set of integers $\{1, \ldots, d\}$. We use $\mathbb{R}^d$ to denote the linear space of vectors with d real components. The standard inner product in this space is denoted by $\langle \cdot, \cdot \rangle$, that is, $\langle w, v \rangle = \sum_{i \in \mathbb{N}_d} w_i v_i,\ \forall w, v \in \mathbb{R}^d$,

2. Equal to the sum of the singular values of W.

where w_i, v_i are the i-th components of w, v respectively. More generally, we will consider Hilbert spaces which we will denote by $\mathcal{H}$, equipped with an inner product $\langle \cdot, \cdot \rangle$.

We also let $\mathbf{M}_{d,n}$ be the linear space of $d \times n$ real matrices. If $W, Z \in \mathbf{M}_{d,n}$ we define their Frobenius inner product as $\langle W, Z \rangle = \mathrm{tr}(W^\top Z)$, where tr denotes the trace of a matrix. With $\mathbf{S}^d$ we denote the set of $d \times d$ real symmetric matrices and with $\mathbf{S}^d_+$ ($\mathbf{S}^d_{++}$) its subset of positive semidefinite (definite) ones. We use $\succ$ and $\succeq$ for the positive definite and positive semidefinite partial orderings, respectively. Finally, we let $\mathbf{O}^d$ be the set of $d \times d$ orthogonal matrices.

2. Regularization Versus Interpolation

The line of attack which we shall follow in this paper will go through *interpolation*. That is, our main concern will be to obtain necessary and sufficient conditions for representer theorems that hold for interpolation problems. However, in practical applications one encounters *regularization* problems more frequently than interpolation problems.

First of all, the family of the former problems is more general than that of the latter ones. Indeed, an interpolation problem can be simply obtained in the limit as the *regularization parameter* goes to zero (Micchelli and Pinkus, 1994). More importantly, regularization enables one to trade off interpolation of the data against smoothness or simplicity of the model, whereas interpolation frequently suffers from *overfitting*.

Thus, frequently one considers problems of the form

$$\min \left\{ \mathcal{E}\big((\langle w, x_1 \rangle, \ldots, \langle w, x_m \rangle), (y_1, \ldots, y_m) \big) + \gamma\, \Omega(w) : w \in \mathcal{H} \right\}, \tag{6}$$

where $\gamma > 0$ is called the regularization parameter. This parameter is not known in advance but can be tuned with techniques like *cross validation*, see, for example, Wahba (1990). Here, the function $\Omega : \mathcal{H} \to \mathbb{R}$ is a *regularizer*, $\mathcal{E} : \mathbb{R}^m \times \mathcal{Y}^m \to \mathbb{R}$ is an error function and $x_i \in \mathcal{H}, y_i \in \mathcal{Y}, \forall i \in \mathbb{N}_m$, are given input and output data. The set $\mathcal{Y}$ is a subset of $\mathbb{R}$ and varies depending on the context, so that it is typically assumed equal to $\mathbb{R}$ in the case of regression or equal to $\{-1, 1\}$ in binary classification problems. One may also consider the associated interpolation problem, which is

$$\min \left\{ \Omega(w) : w \in \mathcal{H}, \langle w, x_i \rangle = y_i,\ \forall i \in \mathbb{N}_m \right\}. \tag{7}$$

Under certain assumptions, the minima in problems (6) and (7) are attained (the latter whenever the constraints in (7) are satisfiable). Such assumptions could involve, for example, lower semicontinuity and boundedness of sublevel sets for Ω and boundedness from below for $\mathcal{E}$. These issues will not concern us here, as we shall assume the following about the error function $\mathcal{E}$ and the regularizer Ω, from now on.

Assumption 1 *The minimum* (6) *is attained for any* $\gamma > 0$, *any input and output data* $\{x_i, y_i : i \in \mathbb{N}_m\}$ *and any* $m \in \mathbb{N}$. *The minimum* (7) *is attained for any input and output data* $\{x_i, y_i : i \in \mathbb{N}_m\}$ *and any* $m \in \mathbb{N}$, *whenever the constraints in* (7) *are satisfiable*.

The main objective of this paper is to obtain *necessary and sufficient* conditions on Ω so that the solution of problem (6) satisfies a *linear representer theorem*.

Definition 2 *We say that a class of optimization problems such as* (6) *or* (7) *satisfies the* linear representer theorem *if, for any choice of data* $\{x_i, y_i : i \in \mathbb{N}_m\}$ *such that the problem has a solution,* there exists *a solution that belongs to* $\mathrm{span}\{x_i : i \in \mathbb{N}_m\}$.

In this section, we show that the existence of representer theorems for regularization problems is equivalent to the existence of representer theorems for interpolation problems, under a quite general condition that has a simple geometric interpretation.

We first recall a lemma from (Micchelli and Pontil, 2004, Sec. 2) which states that (linear or not) representer theorems for interpolation lead to representer theorems for regularization, under no conditions on the error function.

Lemma 3 *Let $E : \mathbb{R}^m \times Y^m \to \mathbb{R}$, $\Omega : \mathcal{H} \to \mathbb{R}$ satisfying Assumption 1. Then if the class of interpolation problems* (7) *satisfies the linear representer theorem, so does the class of regularization problems* (6).

Proof Consider a problem of the form (6) and let $\hat{w}$ be a solution. We construct an associated interpolation problem

$$\min\left\{\Omega(w) : w \in \mathcal{H}, \langle w, x_1\rangle = \langle \hat{w}, x_1\rangle, \ldots, \langle w, x_m\rangle = \langle \hat{w}, x_m\rangle\right\}. \tag{8}$$

By hypothesis, there exists a solution $\tilde{w}$ of (8) that lies in $\operatorname{span}\{x_i : i \in \mathbb{N}_m\}$. But then $\Omega(\tilde{w}) \leq \Omega(\hat{w})$ and hence $\tilde{w}$ is a solution of (6). The result follows. ■

This lemma requires no special properties of the functions involved. Its converse, in contrast, requires assumptions about the analytical properties of the error function. We provide one such natural condition in the theorem below, but other conditions could conceivably work too. The main idea in the proof is, based on a single input, to construct a sequence of appropriate regularization problems for different values of the regularization parameter γ. Then, it suffices to show that letting $\gamma \to 0^+$ yields a limit of the minimizers that satisfies an interpolation constraint.

Theorem 4 *Let $E : \mathbb{R}^m \times Y^m \to \mathbb{R}$ and $\Omega : \mathcal{H} \to \mathbb{R}$. Assume that E, Ω are lower semicontinuous, that Ω has bounded sublevel sets and that E is bounded from below. Assume also that, for some $v \in \mathbb{R}^m \setminus \{0\}, y \in Y^m$, there exists a* unique *minimizer of* $\min\{E(av, y) : a \in \mathbb{R}\}$ *and that this minimizer does not equal zero. Then if the class of regularization problems* (6) *satisfies the linear representer theorem, so does the class of interpolation problems* (7).

Proof Fix an arbitrary $x \neq 0$ and let a_0 be the minimizer of $\min\{E(av, y) : a \in \mathbb{R}\}$. Consider the problems

$$\min\left\{E\left(\frac{a_0}{\|x\|^2}\langle w, x\rangle v, y\right) + \gamma\,\Omega(w) : w \in \mathcal{H}\right\},$$

for every $\gamma > 0$, and let w_γ be a solution in the span of x (known to exist by hypothesis). We then obtain that

$$E(a_0 v, y) + \gamma\Omega(w_\gamma) \leq E\left(\frac{a_0}{\|x\|^2}\langle w_\gamma, x\rangle v, y\right) + \gamma\,\Omega(w_\gamma) \leq E(a_0 v, y) + \gamma\,\Omega(x). \tag{9}$$

Thus, $\Omega(w_\gamma) \leq \Omega(x)$ and so, by the hypothesis on Ω, the set $\{w_\gamma : \gamma > 0\}$ is bounded. Therefore, there exists a convergent subsequence $\{w_{\gamma_\ell} : \ell \in \mathbb{N}\}$, with $\gamma_\ell \to 0^+$, whose limit we call $\bar{w}$. By taking the limit inferior as $\ell \to \infty$ on the inequality on the right in (9), we obtain

$$E\left(\frac{a_0}{\|x\|^2}\langle \bar{w}, x\rangle v, y\right) \leq E(a_0 v, y).$$

Consequently,

$$\frac{a_0}{\|x\|^2}\langle \bar{w}, x\rangle \;= a_0$$

or, using the hypothesis that $a_0 \neq 0$,

$$\langle \bar{w}, x\rangle \;= \|x\|^2.$$

In addition, since w_γ belongs to the span of x for every $\gamma > 0$, so does $\bar{w}$. Thus, we obtain that $\bar{w} = x$. Moreover, from the definition of w_γ we have that

$$\mathcal{E}\left(\frac{a_0}{\|x\|^2}\langle w_\gamma, x\rangle\, v, y\right) + \gamma\,\Omega(w_\gamma) \leq \mathcal{E}\,(a_0\, v, y) + \gamma\,\Omega(w) \qquad \forall w \in \mathcal{H} \text{ such that } \langle w, x\rangle = \|x\|^2$$

and, combining with the definition of a_0, we obtain that

$$\Omega(w_\gamma) \leq \Omega(w) \qquad \forall w \in \mathcal{H} \text{ such that } \langle w, x\rangle = \|x\|^2.$$

Taking the limits inferior as $\ell \to \infty$, we conclude that $\bar{w} = x$ is a solution of the problem

$$\min\{\Omega(w) : w \in \mathcal{H}, \langle w, x\rangle = \|x\|^2\}\,.$$

Moreover, this assertion holds even when $x = 0$, since the hypothesis implies that 0 is a global minimizer of Ω. Indeed, any regularization problem of the type (6) with zero inputs, $x_i = 0, \forall i \in \mathbb{N}_m$, admits a solution in their span. Thus, we have shown that Ω satisfies property (13) in the next section and the result follows immediately from Lemma 9 below. ■

We now comment on some commonly used error functions. The first is the *square loss*,

$$\mathcal{E}(z, y) = \sum_{i \in \mathbb{N}_m} (z_i - y_i)^2\,,$$

for $z, y \in \mathbb{R}^m$. It is immediately apparent that Theorem 4 applies in this case.

The second function is the *hinge loss*,

$$\mathcal{E}(z, y) = \sum_{i \in \mathbb{N}_m} \max(1 - z_i y_i, 0)\,,$$

where the outputs y_i are assumed to belong to $\{-1, 1\}$ for the purpose of classification. In this case, we may select $y_i = 1, \forall i \in \mathbb{N}_m$, and $v = (1, -2, 0, \ldots, 0)^\top$ for $m \geq 2$. Then the function $\mathcal{E}(\cdot\, v, y)$ is the one shown in Figure 1.

Finally, the *logistic loss*,

$$\mathcal{E}(z, y) = \sum_{i \in \mathbb{N}_m} \log\left(1 + e^{-z_i y_i}\right)\,,$$

is also used in classification problems. In this case, we may select $y_i = 1, \forall i \in \mathbb{N}_m$, and $v = (2, -1)^\top$ for $m = 2$ or $v = (m-2, -1, \ldots, -1)^\top$ for $m > 2$. In the latter case, for example, setting to zero the derivative of $\mathcal{E}(\cdot\, v, y)$ yields the equation $(m-1)e^{a(m-1)} + e^a - m + 2 = 0$, which can easily be seen to have a unique solution.

Summarizing, we obtain the following corollary.

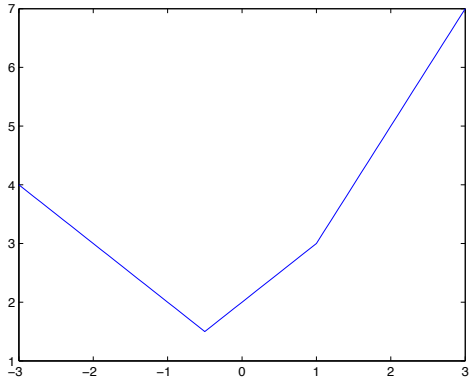

Figure 1: Hinge loss along the direction $(1,-2,0,\ldots,0)$.

Corollary 5 *If $\mathcal{E}:\mathbb{R}^m\times\mathcal{Y}^m\to\mathbb{R}$ is the square loss, the hinge loss (for $m\geq 2$) or the logistic loss (for $m\geq 2$) and $\Omega:\mathcal{H}\to\mathbb{R}$ is lower semicontinuous with bounded sublevel sets, then the class of problems* (6) *satisfies the linear representer theorem if and only if the class of problems* (7) *does.*

Note also that the condition on $\mathcal{E}$ in Theorem 4 is rather weak in that an error function $\mathcal{E}$ may satisfy it without being convex. At the same time, an error function that is "too flat", such as a constant loss, will not do.

We conclude with a remark about the situation in which the inputs x_i are *linearly independent*.[3] It has a brief and straightforward proof, which we do not present here.

Remark 6 *Let $\mathcal{E}$ be the hinge loss or the logistic loss and $\Omega:\mathcal{H}\to\mathbb{R}$ be of the form $\Omega(w)=h(\|w\|)$, where $h:\mathbb{R}_+\to\mathbb{R}$ is a lower semicontinuous function with bounded sublevel sets. Then the class of regularization problems* (6) *in which the inputs $x_i, i\in\mathbb{N}_m$, are linearly independent, satisfies the linear representer theorem.*

3. Representer Theorems for Interpolation Problems

The results of the previous section allow us to focus on linear representer theorems for interpolation problems of the type (7). We are going to consider the case of a Hilbert space $\mathcal{H}$ as the domain of an interpolation problem. Interpolation constraints will be formed as inner products of the variable with the input data.

In this section, we consider the interpolation problem

$$\min\{\Omega(w): w\in\mathcal{H}, \langle w,x_i\rangle = y_i, i\in\mathbb{N}_m\}. \tag{10}$$

We coin the term *admissible* to denote the class of regularizers we are interested in.

Definition 7 *We say that the function $\Omega:\mathcal{H}\to\mathbb{R}$ is* admissible *if, for every $m\in\mathbb{N}$ and any data set $\{(x_i,y_i): i\in\mathbb{N}_m\}\subseteq\mathcal{H}\times\mathcal{Y}$ such that the interpolation constraints are satisfiable, problem* (10)

3. This occurs frequently in practice, especially when the dimensionality d is high.

admits a solution $\hat{w}$ of the form

$$\hat{w} = \sum_{i \in \mathbb{N}_m} c_i x_i, \tag{11}$$

where c_i are some real parameters.

We say that $\Omega : \mathcal{H} \to \mathbb{R}$ is differentiable if, for every $w \in \mathcal{H}$, there is a unique vector denoted by $\nabla\Omega(w) \in \mathcal{H}$, such that for all $p \in \mathcal{H}$,

$$\lim_{t \to 0} \frac{\Omega(w + tp) - \Omega(w)}{t} = \langle \nabla\Omega(w), p \rangle.$$

This notion corresponds to the usual notion of directional derivative on $\mathbb{R}^d$ and in that case $\nabla\Omega(w)$ is the gradient of Ω at w.

In the remainder of the section, we always assume that Assumption 1 holds for Ω. The following theorem provides a necessary and sufficient condition for a regularizer to be admissible.

Theorem 8 *Let $\Omega : \mathcal{H} \to \mathbb{R}$ be a differentiable function and $\dim(\mathcal{H}) \geq 2$. Then Ω is admissible if and only if*

$$\Omega(w) = h(\langle w, w \rangle) \qquad \forall\, w \in \mathcal{H}, \tag{12}$$

for some nondecreasing function $h : \mathbb{R}_+ \to \mathbb{R}$.

It is well known that the above functional form is sufficient for a representer theorem to hold, see, for example, Schölkopf et al. (2001). Here we show that it is also necessary.

The route we follow to prove the above theorem is based on a geometric interpretation of representer theorems. This intuition can be formally expressed as condition (13) in the lemma below. Both condition (13) and functional form (12) express the property that the contours of Ω are *spheres* (or regions between spheres), which is apparent from Figure 2.

Lemma 9 *A function $\Omega : \mathcal{H} \to \mathbb{R}$ is admissible if and only if it satisfies the property that*

$$\Omega(w + p) \geq \Omega(w) \qquad \forall\, w, p \in \mathcal{H} \text{ such that } \langle w, p \rangle = 0. \tag{13}$$

Proof Suppose that Ω satisfies property (13), consider arbitrary data $x_i, y_i, i \in \mathbb{N}_m$, and let $\hat{w}$ be a solution to problem (10). We can uniquely decompose $\hat{w}$ as $\hat{w} = \bar{w} + p$ where $\bar{w} \in \mathcal{L} := \text{span}\{x_i : i \in \mathbb{N}_m\}$ and $p \in \mathcal{L}^\perp$. From (13) we obtain that $\Omega(\hat{w}) \geq \Omega(\bar{w})$. Also $\bar{w}$ satisfies the interpolation constraints and hence we conclude that $\bar{w}$ is a solution to problem (10).

Conversely, if Ω is admissible choose any $w \in \mathcal{H}$ and consider the problem $\min\{\Omega(z) : z \in \mathcal{H}, \langle z, w \rangle = \langle w, w \rangle\}$. By hypothesis, there exists a solution belonging in $\text{span}\{w\}$ and hence w is a solution to this problem. Thus, we have that $\Omega(w + p) \geq \Omega(w)$ for every p such that $\langle w, p \rangle = 0$. ■

It remains to establish the equivalence of the geometric property (13) to condition (12), which says that Ω is a nondecreasing function of the L_2 norm.

Proof of Theorem 8 Assume first that (13) holds and $\dim(\mathcal{H}) < \infty$. In this case, we only need to consider the case that $\mathcal{H} = \mathbb{R}^d$ since (13) can always be rewritten as an equivalent condition on $\mathbb{R}^d$, using an orthonormal basis of $\mathcal{H}$.

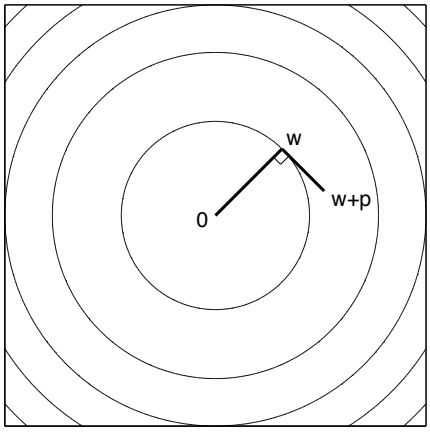

Figure 2: Geometric interpretation of Theorem 8. The function Ω should not decrease when moving to orthogonal directions. The contours of such a function should be spherical.

First we observe that, since Ω is differentiable, this property implies the condition that

$$\langle \nabla \Omega(w), p \rangle = 0\,, \tag{14}$$

for all $w, p \in \mathbb{R}^d$ such that $\langle w, p \rangle = 0$.

Now, fix any $w_0 \in \mathbb{R}^d$ such that $\|w_0\| = 1$. Consider an arbitrary $w \in \mathbb{R}^d \setminus \{0\}$. Then there exists an orthogonal matrix $U \in \mathbf{O}^d$ such that $w = \|w\| U w_0$ and $\det(U) = 1$ (see Lemma 20 in the appendix). Moreover, we can write $U = e^D$ for some skew-symmetric matrix $D \in \mathbf{M}_{d,d}$ (see Example 6.2.15 in Horn and Johnson, 1991). Consider now the path $z : [0,1] \to \mathbb{R}^d$ with

$$z(\lambda) = \|w\| e^{\lambda D} w_0 \qquad\qquad \forall\, \lambda \in [0,1].$$

We have that $z(0) = \|w\| w_0$ and $z(1) = w$. Moreover, since $\langle z(\lambda), z(\lambda) \rangle = \langle w, w \rangle$, we obtain that

$$\langle z'(\lambda), z(\lambda) \rangle = 0 \qquad\qquad \forall\, \lambda \in (0,1).$$

Applying (14) with $w = z(\lambda), p = z'(\lambda)$, it follows that

$$\frac{d\Omega(z(\lambda))}{d\lambda} = \langle \nabla \Omega(z(\lambda)), z'(\lambda) \rangle = 0.$$

Consequently, $\Omega(z(\lambda))$ is constant and hence $\Omega(w) = \Omega(\|w\| w_0)$. Setting $h(\xi) = \Omega(\sqrt{\xi} w_0),\ \forall \xi \in \mathbb{R}_+$, yields (12). In addition, h must be nondecreasing in order for Ω to satisfy property (13).

For the case $\dim(\mathcal{H}) = \infty$ we can argue similarly using instead the path

$$z(\lambda) = \frac{(1-\lambda) w_0 + \lambda w}{\|(1-\lambda) w_0 + \lambda w\|} \|w\|$$

which is differentiable on $(0,1)$ when $w \notin \text{span}\{w_0\}$. We confirm equation (12) for vectors in $\text{span}\{w_0\}$ by a limiting argument on vectors not in $\text{span}\{w_0\}$ since Ω is continuous.

Conversely, if $\Omega(w) = h(\langle w, w\rangle)$ and h is nondecreasing, property (13) follows immediately. ■

The assumption of differentiability is crucial for the above proof and we postpone the issue of removing it to future work. Nevertheless, property (13) follows immediately from functional form (12) without any assumptions.

Remark 10 *Let $\Omega : \mathcal{H} \to \mathbb{R}$ be a function of the form*

$$\Omega(w) = h(\langle w, w\rangle) \qquad \forall\, w \in \mathcal{H},$$

for some nondecreasing function $h : \mathbb{R}_+ \to \mathbb{R}$. Then Ω is admissible.

We also note that we could modify Definition 7 by requiring that *any* solution of problem (10) be in the linear span of the input data. We call such regularizers *strictly admissible*. Then with minor modifications to Lemma 9 (namely, requiring that equality in (13) holds only if $p = 0$) and to the proof of Theorem 8 (namely, requiring h to be strictly increasing) we have the following corollary.

Corollary 11 *Let $\Omega : \mathcal{H} \to \mathbb{R}$ be a differentiable function and $dim(\mathcal{H}) \geq 2$. Then Ω is* strictly *admissible if and only if $\Omega(w) = h(\langle w, w\rangle)$, $\forall w \in \mathcal{H}$, where $h : \mathbb{R}_+ \to \mathbb{R}$ is* strictly *increasing.*

Theorem 8 can be used to verify whether the linear representer theorem can be obtained when using a regularizer Ω. For example, the function $\|w\|_p^p = \sum_{i \in \mathbb{N}_d} |w_i|^p$ is not admissible for any $p > 1, p \neq 2$, because it cannot be expressed as a function of the Hilbert space norm. Indeed, if we choose any $a \in \mathbb{R}$ and let $w = (a\delta_{i1} : i \in \mathbb{N}_d)$, the requirement that $\|w\|_p^p = h(\langle w, w\rangle)$ would imply that $h(a^2) = |a|^p, \forall a \in \mathbb{R}$, and hence that $\|w\|_p = \|w\|$.

4. Matrix Learning Problems

In this section, we investigate how representer theorems and results like Theorem 8 can be extended in the context of optimization problems which involve matrices.

4.1 Exploiting Matrix Structure

As we have already seen, our discussion in Section 3 applies to any Hilbert space. Thus, we may consider the finite Hilbert space of $d \times n$ matrices $\mathbf{M}_{d,n}$ equipped with the Frobenius inner product $\langle \cdot, \cdot \rangle$. As in Section 3, we could consider interpolation problems of the form

$$\min \{\Omega(W) : W \in \mathbf{M}_{d,n}, \langle W, X_i\rangle = y_i, \forall i \in \mathbb{N}_m\} \tag{15}$$

where $X_i \in \mathbf{M}_{d,n}$ are prescribed input matrices and $y_i \in \mathcal{Y}$ are scalar outputs, for $i \in \mathbb{N}_m$. Then Theorem 8 states that such a problem admits a solution of the form

$$\hat{W} = \sum_{i \in \mathbb{N}_m} c_i X_i, \tag{16}$$

where c_i are some real parameters, if and only if Ω can be written in the form

$$\Omega(W) = h(\langle W, W\rangle) \qquad \forall\, W \in \mathbf{M}_{d,n}, \tag{17}$$

where $h : \mathbb{R}_+ \to \mathbb{R}$ is nondecreasing.

However, in machine learning practice, optimization problems of the form (15) occur most frequently in a more special form. That is, usually the constraints of (15) use the structure inherent in matrices—and hence the matrix variable cannot be regarded as a vector variable. Thus, in many recent applications, some of which we shall briefly discuss below, it is natural to consider problems like

$$\min\{\Omega(W) : W \in \mathbf{M}_{d,n},\ w_t^\top x_{ti} = y_{ti},\ \ \forall i \in \mathbb{N}_{m_t}, t \in \mathbb{N}_n\}\,. \tag{18}$$

Here, $w_t \in \mathbb{R}^d$ denote the columns of matrix W, for $t \in \mathbb{N}_n$, and $x_{ti} \in \mathbb{R}^d, y_{ti} \in \mathcal{Y}$ are prescribed inputs and outputs, for $i \in \mathbb{N}_{m_t}, t \in \mathbb{N}_n$. In addition, the desired representation form for solutions of such matrix problems is different from (16). In this case, one may encounter representer theorems of the form

$$\hat{w}_t = \sum_{s \in \mathbb{N}_n} \sum_{i \in \mathbb{N}_{m_s}} c_{si}^{(t)} x_{si} \qquad\qquad \forall t \in \mathbb{N}_n, \tag{19}$$

where $c_{si}^{(t)}$ are scalar coefficients for $s, t \in \mathbb{N}_n, i \in \mathbb{N}_{m_s}$.

To illustrate the above, consider the problem of multi-task learning and problems closely related to it (Abernethy et al., 2009; Ando and Zhang, 2005; Argyriou et al., 2006, 2008a, 2007; Candès and Recht, 2009; Cavallanti et al., 2008; Izenman, 1975; Maurer, 2006a,b; Raina et al., 2006; Srebro et al., 2005; Xiong et al., 2006; Yuan et al., 2007, etc.). In learning multiple tasks jointly, each task may be represented by a vector of regression parameters that corresponds to the column w_t in our notation. There are n tasks and m_t data examples $\{(x_{ti}, y_{ti}) : i \in \mathbb{N}_{m_t}\}$ for the t-th task. The learning algorithm used is

$$\min\left\{\mathcal{E}\left(w_t^\top x_{ti}, y_{ti} : i \in \mathbb{N}_{m_t}, t \in \mathbb{N}_n\right) + \gamma\,\Omega(W) : W \in \mathbf{M}_{d,n}\right\}, \tag{20}$$

where $\mathcal{E} : \mathbb{R}^M \times \mathcal{Y}^M \to \mathbb{R}, M = \sum_{t \in \mathbb{N}_n} m_t$. The error term expresses the objective that the regression vector for each task should fit well the data for this particular task. Note, however, that this term need not separate as the sum of functions of the individual task vectors. The choice of the regularizer Ω is important in that it captures certain relationships between the tasks. One common choice is the *trace norm*, which is defined to be the sum of the singular values of a matrix or, equivalently,

$$\Omega(W) = \|W\|_1 := \mathrm{tr}(W^\top W)^{\frac{1}{2}}\,.$$

Regularization with the trace norm learns the tasks as one joint optimization problem and can be seen as a convex relaxation of regularization with the rank (Fazel et al., 2001). It has been shown that for certain configurations of the input data the low rank solution can be recovered using the trace norm approach (Candès and Recht, 2009; Recht et al., 2008). More generally, regardless of the rank of the solution, it has been demonstrated that this approach allows for accurate estimation of related tasks even when there are only *few* data points available for each task.

Thus, it is natural to consider optimization problems of the form (18). In fact, these problems can be seen as instances of problems of the form (15), because the quantity $w_t^\top x_{ti}$ can be written as the inner product between W and a matrix having all its columns equal to zero except for the t-th column being equal to x_{ti}. It is also easy to see that (15) is a richer class since the corresponding constraints are less restrictive.

Despite this fact, by focusing on the class (18) we concentrate on problems of more practical interest and we can obtain representer theorems for a richer class of regularizers, which includes

the trace norm and other useful functions. In contrast, regularization with the functional form (17) is not a satisfactory approach since it ignores matrix structure. In particular, regularization with the Frobenius norm (and a separable error function) corresponds to learning each task *independently*, ignoring relationships among the tasks.

A representer theorem of the form (19) for regularization with the trace norm has been shown in Argyriou et al. (2008a). Related results have also appeared in Abernethy et al. (2009) and Amit et al. (2007). We repeat here the statement and the proof of this theorem, in order to better motivate our proof technique of Section 4.2.

Theorem 12 *If Ω is the trace norm then problem* (18) *(or problem* (20)*) admits a solution $\hat{W}$ of the form* (19)*, for some $c_{si}^{(t)} \in \mathbb{R},\ i \in \mathbb{N}_{m_s}, s,t \in \mathbb{N}_n$.*

Proof Let $\hat{W}$ be a solution of (18) and let $\mathcal{L} := \operatorname{span}\{x_{si} : s \in \mathbb{N}_n, i \in \mathbb{N}_{m_s}\}$. We can decompose the columns of $\hat{W}$ as $\hat{w}_t = \bar{w}_t + p_t,\ \forall t \in \mathbb{N}_n$, where $\bar{w}_t \in \mathcal{L}$ and $p_t \in \mathcal{L}^\perp$. Hence $\hat{W} = \bar{W} + P$, where $\bar{W}$ is the matrix with columns $\bar{w}_t$ and P is the matrix with columns p_t. Moreover we have that $P^\top \bar{W} = 0$. From Lemma 21 in the appendix, we obtain that $\|\hat{W}\|_1 \geq \|\bar{W}\|_1$. We also have that $\hat{w}_t^\top x_{ti} = \bar{w}_t^\top x_{ti}$, for every $i \in \mathbb{N}_{m_t}, t \in \mathbb{N}_n$. Thus, $\bar{W}$ preserves the interpolation constraints (or the value of the error term) while not increasing the value of the regularizer. Hence, it is a solution of the optimization problem and the assertion follows. ■

A simple but important observation about this and related results is that each task vector w_t is a linear combination of the data for *all* the tasks. This contrasts to the representation form (16) obtained by using Frobenius inner product constraints. Interpreting (16) in a multi-task context, by appropriately choosing the X_i as described above, would imply that each w_t is a linear combination of only the data for task t.

Finally, in some applications the following variant, similar to the type (18), has appeared,

$$\min\{\Omega(W) : W \in \mathbf{M}_{d,n},\ w_t^\top x_i = y_{ti},\ \ \forall i \in \mathbb{N}_m, t \in \mathbb{N}_n\}\ . \tag{21}$$

Problems of this type correspond to a special case in multi-task learning applications in which the input data are the same for all the tasks. For instance, this is the case with collaborative filtering or applications in marketing where the same products/entities are rated by all users/consumers (see, for example, Aaker et al., 2004; Evgeniou et al., 2005; Lenk et al., 1996; Srebro et al., 2005, for various approaches to this problem).

4.2 Characterization of Matrix Regularizers

Our objective in this section will be to state and prove a general representer theorem for problems of the form (18) or (21) using a functional form analogous to (12). The key insight used in the proof of Argyriou et al. (2008a) has been that the trace norm is defined in terms of a matrix function that preserves the partial ordering of matrices. That is, it satisfies Lemma 21, which is a matrix analogue of the geometric property (13). To prove our main result (Theorem 15), we shall build on this observation in a way similar to the approach followed in Section 3.

We shall focus on the interpolation problems (18) and (21). First of all, observe that, by definition, problems of the type (18) include those of type (21). Conversely, consider a simple problem of type (18) with two constraints, $W_{11} = 1, W_{22} = 1$. If the set of matrices satisfying these constraints

also satisfied constraints of the form $w_t^\top x_1 = y_{t1}$ for some $x_1 \in \mathbb{R}^d, y_{t1} \in \mathcal{Y}$, then x_1 would have to be the zero vector. Therefore, the class of problems (18) is strictly larger than the class (21).

However, it turns out that with regard to representer theorems of the form (19) there is no distinction between these two classes of problems. In other words, the representer theorem holds for the same regularizers Ω, independently of whether each task has its own specific inputs or the inputs are the same across the tasks. More importantly, we can connect the existence of representer theorems to a geometric property of the regularizer, in a way analogous to property (13) in Section 3. These facts are stated in the following proposition.

Proposition 13 *The following statements are equivalent:*

(a) *Problem* (21) *admits a solution of the form* (19)*, for every data set* $\{(x_i, y_{ti}) : i \in \mathbb{N}_m, t \in \mathbb{N}_n\} \subseteq \mathbb{R}^d \times \mathcal{Y}$ *and every* $m \in \mathbb{N}$*, such that the interpolation constraints are satisfiable.*

(b) *Problem* (18) *admits a solution of the form* (19)*, for every data set* $\{(x_{ti}, y_{ti}) : i \in \mathbb{N}_{m_t}, t \in \mathbb{N}_n\} \subseteq \mathbb{R}^d \times \mathcal{Y}$ *and every* $\{m_t : t \in \mathbb{N}_n\} \subseteq \mathbb{N}$*, such that the interpolation constraints are satisfiable.*

(c) *The function* Ω *satisfies the property*

$$\Omega(W+P) \geq \Omega(W) \qquad \forall\, W, P \in \mathbf{M}_{d,n} \text{ such that } W^\top P = 0\,. \tag{22}$$

Proof We will show that (a) $\Longrightarrow$ (c), (c) $\Longrightarrow$ (b) and (b) $\Longrightarrow$ (a).

[(a) $\Longrightarrow$ (c)] Consider any $W \in \mathbf{M}_{d,n}$. Choose $m = n$ and the input data to be the columns of W. In other words, consider the problem

$$\min\{\Omega(Z) : Z \in \mathbf{M}_{d,n}, Z^\top W = W^\top W\}\,.$$

By hypothesis, there exists a solution $\hat{Z} = WC$ for some $C \in \mathbf{M}_{n,n}$. Since $(\hat{Z} - W)^\top W = 0$, all columns of $\hat{Z} - W$ have to belong to the null space of $W^\top$. But, at the same time, they have to lie in the range of W and hence we obtain that $\hat{Z} = W$. Therefore, we obtain property (22) after the variable change $P = Z - W$.

[(c) $\Longrightarrow$ (b)] Consider arbitrary $x_{ti} \in \mathbb{R}^d, y_{ti} \in \mathcal{Y}, \forall i \in \mathbb{N}_{m_t}, t \in \mathbb{N}_n$, and let $\hat{W}$ be a solution to problem (18). We can decompose the columns of $\hat{W}$ as $\hat{w}_t = \bar{w}_t + p_t$, where $\bar{w}_t \in \mathcal{L} := \text{span}\{x_{si}, i \in \mathbb{N}_{m_s}, s \in \mathbb{N}_n\}$ and $p_t \in \mathcal{L}^\perp$, $\forall t \in \mathbb{N}_n$. By hypothesis $\Omega(\hat{W}) \geq \Omega(\bar{W})$. Since $\hat{W}$ interpolates the data, so does $\bar{W}$ and therefore $\bar{W}$ is a solution to (18).

[(b) $\Longrightarrow$ (a)] Trivial, since any problem of type (21) is also of type (18). ■

We remark in passing that, by a similar proof, property (22) is also equivalent to representer theorems (19) for the class of problems (15).

The above proposition provides us with a criterion for characterizing all regularizers satisfying representer theorems of the form (19), in the context of problems (15), (18) or (21). Our objective will be to obtain a functional form analogous to (12) that describes functions satisfying property (22). This property does not have a simple geometric interpretation, unlike (13) which describes functions with spherical contours. The reason is that matrix products are more difficult to tackle than inner products.

Similar to the Hilbert space setting (12), where we required h to be a nondecreasing real function, the functional description of the regularizer now involves the notion of a *matrix nondecreasing* function.

Definition 14 *We say that the function $h : \mathbf{S}_+^n \to \mathbb{R}$ is nondecreasing in the order of matrices if $h(A) \leq h(B)$ for all $A, B \in \mathbf{S}_+^n$ such that $A \preceq B$.*

Theorem 15 *Let $d, n \in \mathbb{N}$ with $d \geq 2n$. The differentiable function $\Omega : \mathbf{M}_{d,n} \to \mathbb{R}$ satisfies property* (22) *if and only if there exists a matrix nondecreasing function $h : \mathbf{S}_+^n \to \mathbb{R}$ such that*

$$\Omega(W) = h(W^\top W) \qquad \forall\, W \in \mathbf{M}_{d,n}. \tag{23}$$

Proof We first assume that Ω satisfies property (22). From this property it follows that, for all $W, P \in \mathbf{M}_{d,n}$ with $W^\top P = 0$,

$$\langle \nabla\Omega(W), P \rangle = 0. \tag{24}$$

To see this, observe that if the matrix $W^\top P$ is zero then, for all $\varepsilon > 0$, we have that

$$\frac{\Omega(W + \varepsilon P) - \Omega(W)}{\varepsilon} \geq 0.$$

Taking the limit as $\varepsilon \to 0^+$ we obtain that $\langle \nabla\Omega(W), P \rangle \geq 0$. Similarly, choosing $\varepsilon < 0$ we obtain that $\langle \nabla\Omega(W), P \rangle \leq 0$ and equation (24) follows.

Now, consider any matrix $W \in \mathbf{M}_{d,n}$. Let $r = \operatorname{rank}(W)$ and let us write W in a singular value decomposition as follows

$$W = \sum_{i \in \mathbb{N}_r} \sigma_i u_i v_i^\top,$$

where $\sigma_1 \geq \sigma_2 \geq \cdots \geq \sigma_r > 0$ are the singular values and $u_i \in \mathbb{R}^d$, $v_i \in \mathbb{R}^n$, $\forall i \in \mathbb{N}_r$, are sets of singular vectors, so that $u_i^\top u_j = v_i^\top v_j = \delta_{ij}$, $\forall i, j \in \mathbb{N}_r$. Also, let $u_{r+1}, \ldots, u_d \in \mathbb{R}^d$ be vectors that together with $u_1, \ldots, u_r$ form an orthonormal basis of $\mathbb{R}^d$. Without loss of generality, let us pick u_1 and consider any *unit* vector z *orthogonal* to the vectors $u_2, \ldots, u_r$. Let $k = d - r + 1$ and $q \in \mathbb{R}^k$ be the unit vector such that

$$z = Rq,$$

where $R = (u_1, u_{r+1}, \ldots, u_d)$. We can complete q by adding $d - r$ columns to its right in order to form an orthogonal matrix $Q \in \mathbf{O}^k$ and, since $d > n$, we may select these columns so that $\det(Q) = 1$. Furthermore, we can write this matrix as $Q = e^D$ with $D \in \mathbf{M}_{k,k}$ a skew-symmetric matrix (see Horn and Johnson, 1991, Example 6.2.15).

We also define the path $Z : [0,1] \to \mathbf{M}_{d,n}$ as

$$Z(\lambda) = \sigma_1 R e^{\lambda D} e_1 v_1^\top + \sum_{i=2}^{r} \sigma_i u_i v_i^\top \qquad \forall \lambda \in [0,1],$$

where e_1 denotes the vector $(1\,0 \ldots 0)^\top \in \mathbb{R}^k$. In other words, we fix the singular values, the right singular vectors and the $r-1$ left singular vectors $u_2, \ldots, u_r$ and only allow the first left singular vector to vary. This path has the properties that $Z(0) = W$ and $Z(1) = \sigma_1 z v_1^\top + \sum_{i=2}^r \sigma_i u_i v_i^\top$.

By construction of the path, it holds that

$$Z'(\lambda) = \sigma_1 R e^{\lambda D} D e_1 v_1^\top$$

and hence

$$Z(\lambda)^\top Z'(\lambda) = \left(\sigma_1 R e^{\lambda D} e_1 v_1^\top\right)^\top \sigma_1 R e^{\lambda D} D e_1 v_1^\top = \sigma_1^2 v_1 e_1^\top D e_1 v_1^\top = 0\,,$$

for every $\lambda \in (0,1)$, because $D_{11} = 0$. Hence, using equation (24), we have that

$$\langle \nabla\Omega(Z(\lambda)), Z'(\lambda)\rangle = 0$$

and, since $\dfrac{d\Omega(Z(\lambda))}{d\lambda} = \langle \nabla\Omega(Z(\lambda)), Z'(\lambda)\rangle$, we conclude that $\Omega(Z(\lambda))$ equals a constant independent of λ. In particular, $\Omega(Z(0)) = \Omega(Z(1))$, that is,

$$\Omega(W) = \Omega\left(\sigma_1 z v_1^\top + \sum_{i=2}^{r} \sigma_i u_i v_i^\top\right).$$

In other words, if we fix the singular values of W, the right singular vectors and all the left singular vectors but one, Ω does not depend on the remaining left singular vector (because the choice of z is independent of u_1).

In fact, this readily implies that Ω does not depend on the left singular vectors at all. Indeed, fix an arbitrary $Y \in \mathbf{M}_{d,n}$ such that $Y^\top Y = I$. Consider the matrix $Y(W^\top W)^{\frac{1}{2}}$, which can be written using the same singular values and right singular vectors as W. That is,

$$Y(W^\top W)^{\frac{1}{2}} = \sum_{i \in \mathbb{N}_r} \sigma_i \tau_i v_i^\top\,,$$

where $\tau_i = Y v_i,\ \forall i \in \mathbb{N}_r$. Now, we select unit vectors $z_1, \ldots, z_r \in \mathbb{R}^d$ as follows:

$$\begin{aligned}
&z_1 = u_1\\
&z_2 \perp z_1, u_3, \ldots, u_r, \tau_1\\
&\quad\vdots\quad\vdots\\
&z_r \perp z_1, \ldots, z_{r-1}, \tau_1, \ldots, \tau_{r-1}\,.
\end{aligned}$$

This construction is possible since $d \geq 2n$. Replacing successively u_i with z_i and then z_i with τ_i, $\forall i \in \mathbb{N}_r$, and applying the invariance property, we obtain that

$$\begin{aligned}
\Omega(W) &= \Omega\left(\sum_{i\in\mathbb{N}_r} \sigma_i u_i v_i^\top\right) \\
&= \Omega\left(\sigma_1 z_1 v_1^\top + \sigma_2 z_2 v_2^\top + \sum_{i=3}^{r} \sigma_i u_i v_i^\top\right) \\
&\quad \vdots \quad \vdots \\
&= \Omega\left(\sum_{i\in\mathbb{N}_r} \sigma_i z_i v_i^\top\right) \\
&= \Omega\left(\sigma_1 \tau_1 v_1^\top + \sum_{i=2}^{r} \sigma_i z_i v_i^\top\right) \\
&\quad \vdots \quad \vdots \\
&= \Omega\left(\sum_{i\in\mathbb{N}_r} \sigma_i \tau_i v_i^\top\right) = \Omega\left(Y(W^\top W)^{\frac{1}{2}}\right).
\end{aligned}$$

Therefore, defining the function $h : \mathbf{S}_+^n \to \mathbb{R}$ as $h(A) = \Omega(YA^{\frac{1}{2}})$, we deduce that $\Omega(W) = h(W^\top W)$.

Finally, we show that h is matrix nondecreasing, that is, $h(A) \leq h(B)$ if $0 \preceq A \preceq B$. For any such A, B and since $d \geq 2n$, we may define $W = \begin{pmatrix} A^{\frac{1}{2}} \\ 0 \\ 0 \end{pmatrix}$, $P = \begin{pmatrix} 0 \\ (B-A)^{\frac{1}{2}} \\ 0 \end{pmatrix} \in \mathbf{M}_{d,n}$. Then $W^\top P = 0$, $A = W^\top W$, $B = (W+P)^\top (W+P)$ and thus, by hypothesis,

$$h(B) = \Omega(W+P) \geq \Omega(W) = h(A).$$

This completes the proof in one direction of the theorem.

To show the converse, assume that $\Omega(W) = h(W^\top W)$, where the function h is matrix nondecreasing. Then for any $W, P \in \mathbf{M}_{d,n}$ with $W^\top P = 0$, we have that $(W+P)^\top (W+P) = W^\top W + P^\top P \succeq W^\top W$ and, so, $\Omega(W+P) \geq \Omega(W)$, as required. ■

As in Section 3, differentiability is not required for sufficiency, which follows from the last lines of the above proof. Moreover, the assumption on d and n is not required either.

Remark 16 *Let the function $\Omega : \mathbf{M}_{d,n} \to \mathbb{R}$ be of the form*

$$\Omega(W) = h(W^\top W) \qquad \forall\, W \in \mathbf{M}_{d,n},$$

for some matrix nondecreasing function $h : \mathbf{S}_+^n \to \mathbb{R}$. Then Ω satisfies property (22).

We conclude this section by providing a necessary and sufficient first-order condition for the function h to be matrix nondecreasing.

Proposition 17 *Let $h : \mathbf{S}_+^n \to \mathbb{R}$ be a differentiable function. The following properties are equivalent:*

(a) h is matrix nondecreasing

(b) the matrix $\nabla h(A) := \left(\frac{\partial h}{\partial a_{ij}} : i, j \in \mathbb{N}_n\right)$ *is positive semidefinite, for every* $A \in \mathbf{S}_+^n$.

Proof If (a) holds, we choose any $x \in \mathbb{R}^n, t > 0, A \in \mathbf{S}_+^n$ and note that

$$\frac{h(A + txx^\top) - h(A)}{t} \geq 0.$$

Letting t go to zero gives that $x^\top \nabla h(A) x \geq 0$.

Conversely, if (b) is true, we have, for every $x \in \mathbb{R}^n, M \in \mathbf{S}_+^n$, that $x^\top \nabla h(M) x = \langle \nabla h(M), xx^\top \rangle \geq 0$ and, so, $\langle \nabla h(M), C \rangle \geq 0$ for all $C \in \mathbf{S}_+^n$. For any $A, B \in \mathbf{S}_+^n$ such that $A \preceq B$, consider the univariate function $g : [0,1] \to \mathbb{R}$, $g(t) = h(A + t(B - A))$. By the chain rule it is easy to verify that g is nondecreasing. Therefore we conclude that $h(A) = g(0) \leq g(1) = h(B)$. ■

4.3 Examples

Using Proposition 13, Theorem 15 and Remark 16, one may easily verify that the representer theorem holds for a variety of regularizers. In particular, functional description (23) subsumes the special case of *monotone spectral functions*.

Definition 18 *Let* $r = \min\{d, n\}$. *A function* $\Omega : \mathbf{M}_{d,n} \to \mathbb{R}$ *is called* monotone spectral *if there exists a function* $h : \mathbb{R}_+^r \to \mathbb{R}$ *such that*

$$\Omega(W) = h(\sigma_1(W), \ldots, \sigma_r(W)) \qquad \forall\, W \in \mathbf{M}_{d,n},$$

where $\sigma_1(W) \geq \cdots \geq \sigma_r(W) \geq 0$ *denote the singular values of matrix* W *and*

$$h(\sigma_1, \ldots, \sigma_r) \leq h(\tau_1, \ldots, \tau_r) \quad \textit{whenever} \;\; \sigma_i \leq \tau_i \textit{ for all } i \in \mathbb{N}_r.$$

Corollary 19 *Assume that the function* $\Omega : \mathbf{M}_{d,n} \to \mathbb{R}$ *is monotone spectral. Then* Ω *satisfies property* (22).

Proof Clearly, $\Omega(W) = h\left(\lambda\left((W^\top W)^{\frac{1}{2}}\right)\right)$, where $\lambda : \mathbf{S}_+^n \to \mathbb{R}_+^r$ maps a matrix to the ordered vector of its r highest eigenvalues. Let $A, B \in \mathbf{S}_+^n$ such that $A \preceq B$. Weyl's monotonicity theorem (Horn and Johnson, 1985, Cor. 4.3.3) states that if $A \preceq B$ then the spectra of A and B are ordered. Thus, $\lambda(A^{\frac{1}{2}}) \leq \lambda(B^{\frac{1}{2}})$ and hence $h(\lambda(A^{\frac{1}{2}})) \leq h(\lambda(B^{\frac{1}{2}}))$. Applying Remark 16, the assertion follows. ■

We note that related results to the above corollary have appeared in Abernethy et al. (2009). They apply to the setting of (15) when the X_i are rank one matrices.

Interesting examples of monotone spectral functions are the *Schatten L_p norms* and *prenorms*,

$$\Omega(W) = \|W\|_p := \|\sigma(W)\|_p,$$

where $p \in [0, +\infty)$ and $\sigma(W)$ denotes the $\min\{d, n\}$-dimensional vector of the singular values of W. For instance, we have already mentioned in Section 4.1 that the representer theorem holds when the regularizer is the trace norm (the L_1 norm of the spectrum). But it also holds for the *rank* of a matrix.

Rank minimization is an NP-hard optimization problem (Vandenberghe and Boyd, 1996), but the representer theorem has some interesting implications. First, that the problem can be reformulated in terms of reproducing kernels and second, that an equivalent problem in as few variables as the total sample size can be obtained.

If we exclude spectral functions, the functions that remain are invariant under *left* multiplication with an orthogonal matrix. Examples of such functions are Schatten norms and prenorms composed with *right* matrix scaling,

$$\Omega(W) = \|WM\|_p, \tag{25}$$

where $M \in \mathbf{M}_{n,n}$. In this case, the corresponding h is the function $S \mapsto \|\sqrt{\lambda(M^\top SM)}\|_p$. To see that this function is matrix nondecreasing, observe that if $A, B \in \mathbf{S}_+^n$ and $A \preceq B$ then $0 \preceq M^\top AM \preceq M^\top BM$ and hence $\lambda(M^\top AM) \leq \lambda(M^\top BM)$ by Weyl's monotonicity theorem (Horn and Johnson, 1985, Cor. 4.3.3). Therefore, $\|\sqrt{\lambda(M^\top AM)}\|_p \leq \|\sqrt{\lambda(M^\top BM)}\|_p$.

For instance, the matrix M above can be used to select a subset of the columns of W. In addition, more complicated structures can be obtained by summation of matrix nondecreasing functions and by taking minima or maxima over sets. For example, we can obtain a regularizer such as

$$\Omega(W) = \min\left\{\sum_{k\in\mathbb{N}_K} \|W(I_k)\|_1 : \{I_1,\ldots,I_K\} \in \mathcal{P}\right\},$$

where $\mathcal{P}$ is the set of partitions of $\mathbb{N}_n$ in K subsets and $W(I_k)$ denotes the submatrix of W formed by just the columns indexed by I_k. This regularizer is an extension of the trace norm ($K = 1$) and can be used for multi-task learning via dimensionality reduction on multiple subspaces (Argyriou et al., 2008b).

Yet another example of a valid regularizer is the one considered in (Evgeniou et al., 2005, Sec. 3.1), which encourages the tasks to be close to each other, namely

$$\Omega(W) = \sum_{t\in\mathbb{N}_n} \left\| w_t - \frac{1}{n}\sum_{s\in\mathbb{N}_n} w_s \right\|^2.$$

This regularizer immediately verifies property (22), and so by Theorem 15 it is a matrix nondecreasing function of $W^\top W$. One can also verify that this regularizer is the square of the form (25) with $p = 2$ and $M = I_n - \frac{1}{n}\mathbf{1}\mathbf{1}^\top$, where $\mathbf{1}$ denotes the n-dimensional vector all of whose components are equal to one.

Finally, it is worth noting that the representer theorem does *not* apply to a family of "mixed" matrix norms of the form

$$\Omega(W) = \sum_{i\in\mathbb{N}_d} \|w^i\|_2^p,$$

where w^i denotes the i-th row of W and $p > 1,\ p \neq 2$.

5. Conclusion

We have characterized the classes of vector and matrix regularizers which lead to certain forms of the solution of the associated interpolation problems. In the vector case, we have proved the necessity of a well-known sufficient condition for the "standard representer theorem", which is encountered in many learning and statistical estimation problems. In the matrix case, we have described

a novel class of regularizers which lead to a modified representer theorem. This class, which relies upon the notion of matrix nondecreasing function, includes and extends significantly the vector class. To motivate the need for our study, we have discussed some examples of regularizers which have been recently used in the context of multi-task learning and collaborative filtering.

In the future, it would be valuable to study in more detail special cases of the matrix regularizers which we have encountered, such as those based on orthogonally invariant functions. It would also be interesting to investigate how the presence of additional constraints affects the representer theorem. In particular, we have in mind the possibility that the matrix may be constrained to be in a convex cone, such as the set of positive semidefinite matrices. Finally, we leave to future studies the extension of the ideas presented here to the case in which matrices are replaced by operators between two Hilbert spaces.

Appendix A.

Here we collect some auxiliary results which are used in the above analysis.

The first lemma states a basic property of connectedness through rotations.

Lemma 20 *Let $w, v \in \mathbb{R}^d$ and $d \geq 2$. Then there exists $U \in \mathbf{O}^d$ with determinant 1 such that $v = Uw$ if and only if $\|w\| = \|v\|$.*

Proof If $v = Uw$ we have that $v^\top v = w^\top w$. Conversely, if $\|w\| = \|v\| \neq 0$, we may choose orthonormal vectors $\{x_\ell : \ell \in \mathbb{N}_{d-1}\} \perp w$ and $\{z_\ell : \ell \in \mathbb{N}_{d-1}\} \perp v$ and form the matrices $R = \begin{pmatrix} w & x_1 & \ldots & x_{d-1} \end{pmatrix}$ and $S = \begin{pmatrix} v & z_1 & \ldots & z_{d-1} \end{pmatrix}$. We have that $R^\top R = S^\top S$. We wish to solve the equation $UR = S$. For this purpose we choose $U = SR^{-1}$ and note that $U \in \mathbf{O}^d$ because $U^\top U = (R^{-1})^\top S^T S R^{-1} = (R^{-1})^\top R^\top R R^{-1} = I$. Since $d \geq 2$, in the case that $\det(U) = -1$ we can simply change the sign of one of the x_ℓ or z_ℓ to get $\det(U) = 1$ as required. ■

The second lemma concerns the monotonicity of the trace norm.

Lemma 21 *Let $W, P \in \mathbf{M}_{d,n}$ such that $W^\top P = 0$. Then $\|W + P\|_1 \geq \|W\|_1$.*

Proof Weyl's monotonicity theorem (Horn and Johnson, 1985, Cor. 4.3.3) implies that if $A, B \in \mathbf{S}_+^n$ and $A \succeq B$ then $\lambda(A) \geq \lambda(B)$ and hence $\operatorname{tr} A^{\frac{1}{2}} \geq \operatorname{tr} B^{\frac{1}{2}}$. We apply this fact to the matrices $W^\top W + P^\top P$ and $P^\top P$ to obtain that

$$\|W + P\|_1 = \operatorname{tr}((W+P)^\top (W+P))^{\frac{1}{2}} = \operatorname{tr}(W^\top W + P^\top P)^{\frac{1}{2}} \geq \operatorname{tr}(W^\top W)^{\frac{1}{2}} = \|W\|_1 .$$

Abstract

The standard maximum margin approach for structured prediction lacks a straightforward probabilistic interpretation of the learning scheme and the prediction rule. Therefore its unique advantages such as dual sparseness and kernel tricks cannot be easily conjoined with the merits of a probabilistic model such as Bayesian regularization, model averaging, and ability to model hidden variables. In this paper, we present a new general framework called *maximum entropy discrimination Markov networks* (MaxEnDNet, or simply, MEDN), which integrates these two approaches and combines and extends their merits. Major innovations of this approach include: 1) It extends the conventional max-entropy discrimination learning of classification rules to a new *structural* max-entropy discrimination paradigm of learning a distribution of Markov networks. 2) It generalizes the extant Markov network structured-prediction rule based on a point estimator of model coefficients to an averaging model akin to a Bayesian predictor that integrates over a learned posterior distribution of model coefficients. 3) It admits flexible entropic regularization of the model during learning. By plugging in different prior distributions of the model coefficients, it subsumes the well-known maximum margin Markov networks (M^3N) as a special case, and leads to a model similar to an L_1-regularized M^3N that is simultaneously primal and dual sparse, or other new types of Markov networks. 4) It applies a modular learning algorithm that combines existing variational inference techniques and convex-optimization based M^3N solvers as subroutines. Essentially, MEDN can be understood as a jointly maximum likelihood and maximum margin estimate of Markov network. It represents the first successful attempt to combine maximum entropy learning (a dual form of maximum likelihood learning) with maximum margin learning of Markov network for structured input/output problems; and the basic principle can be generalized to learning arbitrary graphical models, such as the generative Bayesian networks or models with structured hidden variables. We discuss a number of theoretical properties of this approach, and show that empirically it outperforms a wide array of competing methods for structured input/output learning on both synthetic and real OCR and web data extraction data sets.

Keywords: maximum entropy discrimination, structured input/output model, maximum margin Markov network, graphical models, entropic regularization, L_1 regularization

1. Introduction

Inferring structured predictions based on high-dimensional, often multi-modal and hybrid covariates remains a central problem in data mining (e.g., web-info extraction), machine intelligence (e.g., machine translation), and scientific discovery (e.g., genome annotation). Several recent approaches to this problem are based on learning discriminative graphical models defined on composite features

that explicitly exploit the structured dependencies among input elements and structured interpretational outputs. Major instances of such models include the conditional random fields (CRFs) (Lafferty et al., 2001), Markov networks (MNs) (Taskar et al., 2003), and other specialized graphical models (Altun et al., 2003). Various paradigms for training such models based on different loss functions have been explored, including the maximum conditional likelihood learning (Lafferty et al., 2001) and the maximum margin learning (Altun et al., 2003; Taskar et al., 2003; Tsochantaridis et al., 2004), with remarkable success.

The likelihood-based models for structured predictions are usually based on a joint distribution of both input and output variables (Rabiner, 1989) or a conditional distribution of the output given the input (Lafferty et al., 2001). Therefore this paradigm offers a flexible probabilistic framework that can naturally facilitate: hidden variables that capture latent semantics such as a generative hierarchy (Quattoni et al., 2004; Zhu et al., 2008a); Bayesian regularization that imposes desirable biases such as sparseness (Lee et al., 2006; Wainwright et al., 2006; Andrew and Gao, 2007); and Bayesian prediction based on combining predictions across all values of model parameters (i.e., model averaging), which can reduce the risk of overfitting. On the other hand, the margin-based structured prediction models leverage the maximum margin principle and convex optimization formulation underlying the support vector machines, and concentrate directly on the input-output mapping (Taskar et al., 2003; Altun et al., 2003; Tsochantaridis et al., 2004). In principle, this approach can lead to a robust decision boundary due to the dual sparseness (i.e., depending on only a few support vectors) and global optimality of the learned model. However, although arguably a more desirable paradigm for training highly discriminative structured prediction models in a number of application contexts, the lack of a straightforward probabilistic interpretation of the maximum-margin models makes them unable to offer the same flexibilities of likelihood-based models discussed above.

For example, for domains with complex feature space, it is often desirable to pursue a "sparse" representation of the model that leaves out irrelevant features. In likelihood-based estimation, sparse model fitting has been extensively studied. A commonly used strategy is to add an L_1-penalty to the likelihood function, which can also be viewed as a MAP estimation under a Laplace prior. However, little progress has been made so far on learning sparse MNs or log-linear models in general based on the maximum margin principle. While sparsity has been pursued in maximum margin learning of certain discriminative models such as SVM that are "unstructured" (i.e., with a univariate output), by using L_1-regularization (Bennett and Mangasarian, 1992) or by adding a cardinality constraint (Chan et al., 2007), generalization of these techniques to structured output space turns out to be non-trivial, as we discuss later in this paper. There is also very little theoretical analysis on the performance guarantee of margin-based models under direct L_1-regularization. Our empirical results as shown in this paper suggest that an L_1-regularized maximum margin Markov network, even when estimable, can be sensitive to the magnitude of the regularization coefficient. Discarding the features that are not completely irrelevant can potentially hurt generalization ability. Another example, it is well known that presence of hidden variables in MNs can cause significant difficulty for maximum margin learning. Indeed, semi-supervised or unsupervised learning of structured maximum margin model remains an open problem of which progress was only made in a few special cases, with usually computationally very expensive algorithms (Xu et al., 2006; Altun et al., 2006; Brefeld and Scheffer, 2006).

In this paper, we propose a general theory of maximum entropy discrimination Markov networks (MaxEnDNet, or simply MEDN) for structured input/output learning and prediction. This formalism offers a formal paradigm for integrating both generative and discriminative principles and

the Bayesian regularization techniques for learning structured prediction models. It integrates the spirit of maximum margin learning from SVM, the design of discriminative structured prediction model in maximum margin Markov networks (M^3N), and the ideas of entropic regularization and model averaging in maximum entropy discrimination methods (Jaakkola et al., 1999). Essentially, MaxEnDNet can be understood as a jointly maximum likelihood and maximum margin estimate of Markov networks. It allows one to learn a *distribution* of structured prediction models that offers a wide range of important advantages over conventional models such as M^3N, including more robust prediction due to an averaging prediction-function based on the learned distribution of models, Bayesian-style regularization that can lead to a model that is simultaneous primal and dual sparse, and allowance of hidden variables and semi-supervised learning based on partially labeled data.

While the formalism of MaxEnDNet is extremely general, our main focus and contributions of this paper will be concentrated on the following results. We will formally define the MaxEnDNet as solving a generalized entropy optimization problem subject to expected margin constraints on the structured predictions, and under an arbitrary prior of feature coefficients; and we derive a general form of the solution to this problem. An interesting insight immediately following this general form is that, a trivial assumption on the prior distribution of the coefficients, that is, a standard normal, reduces the linear MaxEnDNet to the standard M^3N, as shown in Theorem 3. This understanding opens the way to use different priors for MaxEnDNet to achieve more interesting regularization effects. We show that, by using a Laplace prior for the feature coefficients, the resulting Laplace MaxEnDNet (LapMEDN) is effectively an M^3N that is not only dual sparse (i.e., defined by a few support vectors), but also primal sparse (i.e., shrinkage on coefficients corresponding to irrelevant features). We develop a novel variational learning method for the LapMEDN, which leverages on the hierarchical/scale-mixture representation of the Laplace prior (Andrews and Mallows, 1974; Figueiredo, 2003) and the reducibility of MaxEnDNet to M^3N, and combines the variational Bayesian technique with existing convex optimization algorithms developed for M^3N (Taskar et al., 2003; Bartlett et al., 2004; Ratliff et al., 2007). We also provide a formal analysis of the generalization error of the MaxEnDNet, and prove a PAC-Bayes bound on the prediction error by MaxEnDNet. We performed a thorough comparison of the Laplace MaxEnDNet with competing methods, including M^3N (i.e., the Gaussian MaxEnDNet), L_1-regularized M^3N (Zhu et al., 2009b), CRFs, L_1-regularized CRFs, and L_2-regularized CRFs, on both synthetic and real structured input/output data. The Laplace MaxEnDNet exhibits mostly superior, and sometimes comparable performance in all scenarios been tested.

As demonstrated in our recent work (Zhu et al., 2008c, 2009a), MaxEnDNet is not limited to fully observable MNs, but can readily facilitate jointly maximum entropy and maximum margin learning of partially observed structured I/O models, and directed graphical models such as the supervised latent Dirichlet allocation (LDA). Due to space limit, we leave these instantiations and generalizations to future papers.

The rest of the paper is structured as follows. In the next section, we review the basic structured prediction formalism and set the stage for our model. Section 3 presents the general theory of maximum entropy discrimination Markov networks and some basic theoretical results, followed by two instantiations of the general MaxEnDNet, the Gaussian MaxEnDNet and the Laplace MaxEnDNet. Section 4 offers a detailed discussion of the primal and dual sparsity property of Laplace MaxEnDNet. Section 5 presents a novel iterative learning algorithm based on variational approximation and convex optimization. In Section 6, we briefly discuss the generalization bound of MaxEnDNet.

Then, we show empirical results on both synthetic and real OCR and web data extraction data sets in Section 7. Section 8 discusses some related work and Section 9 concludes this paper.

2. Preliminaries

In structured prediction problems such as natural language parsing, image annotation, or DNA decoding, one aims to learn a function $h : \mathcal{X} \to \mathcal{Y}$ that maps a structured input $\mathbf{x} \in \mathcal{X}$, e.g., a sentence or an image, to a structured output $\mathbf{y} \in \mathcal{Y}$, e.g., a sentence parsing or a scene annotation, where, unlike a standard classification problem, $\mathbf{y}$ is a multivariate prediction consisting of multiple labeling elements. Let L denote the cardinality of the output, and m_l where $l = 1, \ldots, L$ denote the arity of each element, then $\mathcal{Y} = \mathcal{Y}_1 \times \cdots \times \mathcal{Y}_L$ with $\mathcal{Y}_l = \{a_1, \ldots, a_{m_l}\}$ represents a combinatorial space of structured interpretations of the multi-facet objects in the inputs. For example, $\mathcal{Y}$ could correspond to the space of all possible instantiations of the parse trees of a sentence, or the space of all possible ways of labeling entities over some segmentation of an image. The prediction $\mathbf{y} \equiv (y_1, \ldots, y_L)$ is *structured* because each individual label $y_l \in \mathcal{Y}_l$ within $\mathbf{y}$ must be determined in the context of other labels $y_{l' \neq l}$, rather than independently as in classification, in order to arrive at a globally satisfactory and consistent prediction.

Let $F : \mathcal{X} \times \mathcal{Y} \to \mathbb{R}$ represent a discriminant function over the input-output pairs from which one can define the predictive function, and let $\mathcal{H}$ denote the space of all possible F. A common choice of F is a linear model, $F(\mathbf{x}, \mathbf{y}; \mathbf{w}) = g(\mathbf{w}^\top \mathbf{f}(\mathbf{x}, \mathbf{y}))$, where $\mathbf{f} = [f_1 \ldots f_K]^\top$ is a K-dimensional column vector of the feature functions $f_k : \mathcal{X} \times \mathcal{Y} \to \mathbb{R}$, and $\mathbf{w} = [w_1 \ldots w_K]^\top$ is the corresponding vector of the weights of the feature functions. Typically, a structured prediction model chooses an optimal estimate $\mathbf{w}^\star$ by minimizing some loss function $J(\mathbf{w})$, and defines a predictive function in terms of an optimization problem that maximizes $F(\,\cdot\,; \mathbf{w}^\star)$ over the response variable $\mathbf{y}$ given an input $\mathbf{x}$:

$$h_0(\mathbf{x}; \mathbf{w}^\star) = \arg \max_{\mathbf{y} \in \mathcal{Y}(\mathbf{x})} F(\mathbf{x}, \mathbf{y}; \mathbf{w}^\star), \tag{1}$$

where $\mathcal{Y}(\mathbf{x}) \subseteq \mathcal{Y}$ is the feasible subset of structured labels for the input $\mathbf{x}$. Here, we assume that $\mathcal{Y}(\mathbf{x})$ is finite for any $\mathbf{x}$.

Depending on the specific choice of $g(\cdot)$ (e.g., linear, or log linear), and the loss function $J(\mathbf{w})$ (e.g., likelihood, or margin-based loss) for estimating the parameter $\mathbf{w}^\star$, incarnations of the general structured prediction formalism described above can be seen in classical generative models such as the HMM (Rabiner, 1989) where $g(\cdot)$ can be an exponential family distribution function and $J(\mathbf{w})$ is the (negative) joint likelihood of the input and its labeling; and in recent discriminative models such as CRFs (Lafferty et al., 2001), where $g(\cdot)$ is a Boltzmann machine and $J(\mathbf{w})$ is the (negative) conditional likelihood of the structured labeling given input; and the M^{3}N (Taskar et al., 2003), where $g(\cdot)$ is an identity function and $J(\mathbf{w})$ is a loss defined on the margin between the true labeling and any other feasible labeling in $\mathcal{Y}(\mathbf{x})$. Our approach toward a more general discriminative training is based on a maximum entropy principle that allows an elegant combination of the discriminative maximum margin learning with the generative Bayesian regularization and hierarchical modeling, and we consider the more general problem of finding a distribution of $F(\,\cdot\,; \mathbf{w})$ over $\mathcal{H}$ that enables a convex combination of discriminant functions for robust structured prediction.

Before delving into the exposition of the proposed approach, we end this section with a brief recapitulation of the basic M^{3}N, upon which the proposed approach is built. Under a max-margin

framework, given a set of fully observed training data $\mathcal{D} = \{\langle \mathbf{x}^i, \mathbf{y}^i \rangle\}_{i=1}^N$, we obtain a point estimate of the weight vector $\mathbf{w}$ by solving the following max-margin problem P0 (Taskar et al., 2003):

$$\begin{aligned} \text{P0 (M}^3\text{N)}: \quad & \min_{\mathbf{w},\boldsymbol{\xi}} \ \frac{1}{2}\|\mathbf{w}\|^2 + C\sum_{i=1}^{N} \xi_i \\ \text{s.t. } \forall i, \forall \mathbf{y} \neq \mathbf{y}^i: \quad & \mathbf{w}^\top \Delta\mathbf{f}_i(\mathbf{y}) \geq \Delta\ell_i(\mathbf{y}) - \xi_i,\ \xi_i \geq 0\ , \end{aligned}$$

where $\Delta\mathbf{f}_i(\mathbf{y}) = \mathbf{f}(\mathbf{x}^i, \mathbf{y}^i) - \mathbf{f}(\mathbf{x}^i, \mathbf{y})$ and $\Delta F_i(\mathbf{y}; \mathbf{w}) = \mathbf{w}^\top \Delta\mathbf{f}_i(\mathbf{y})$ is the "margin" between the true label $\mathbf{y}^i$ and a prediction $\mathbf{y}$, $\Delta\ell_i(\mathbf{y})$ is a labeling loss with respect to $\mathbf{y}^i$, and ξ_i represents a slack variable that absorbs errors in the training data. Various forms of the labeling loss have been proposed in the literature (Tsochantaridis et al., 2004). In this paper, we adopt the *hamming loss* used by Taskar et al. (2003): $\Delta\ell_i(\mathbf{y}) = \sum_{j=1}^{L} \mathbb{I}(y_j \neq y_j^i)$, where $\mathbb{I}(\cdot)$ is an indicator function that equals to one if the argument is true and zero otherwise. The problem P0 is not directly solvable by using a standard constrained optimization toolbox because the feasible space for $\mathbf{w}$,

$$\mathcal{F}_0 = \left\{ \mathbf{w} : \mathbf{w}^\top \Delta\mathbf{f}_i(\mathbf{y}) \geq \Delta\ell_i(\mathbf{y}) - \xi_i;\ \forall i, \forall \mathbf{y} \neq \mathbf{y}^i \right\},$$

is defined by $O(N|\mathcal{Y}|)$ number of constraints, and $\mathcal{Y}$ is exponential to the size of the input $\mathbf{x}$. Exploring sparse dependencies among individual labels y_l in $\mathbf{y}$, as reflected in the specific design of the feature functions (e.g., based on pair-wise labeling potentials in a pair-wise Markov network), and the convex duality of the objective, efficient optimization algorithms based on cutting-plane (Tsochantaridis et al., 2004) or message-passing (Taskar et al., 2003) have been proposed to obtain an approximate optimum solution to P0. As described shortly, these algorithms can be directly employed as subroutines in solving our proposed model.

3. Maximum Entropy Discrimination Markov Networks

Instead of learning a point estimator of $\mathbf{w}$ as in M^{3}N, in this paper, we take a Bayesian-style approach and learn a distribution $p(\mathbf{w})$, in a max-margin manner. For prediction, we employ a convex combination of all possible models $F(\,\cdot\,; \mathbf{w}) \in \mathcal{H}$ based on $p(\mathbf{w})$, that is:

$$h_1(\mathbf{x}) = \arg\max_{\mathbf{y} \in \mathcal{Y}(\mathbf{x})} \int p(\mathbf{w}) F(\mathbf{x}, \mathbf{y}; \mathbf{w})\, \mathrm{d}\mathbf{w}\,. \tag{2}$$

Now, the open question underlying this averaging prediction rule is how we can devise an appropriate loss function and constraints over $p(\mathbf{w})$, in a similar spirit as the margin-based scheme over $\mathbf{w}$ in P0, that lead to an optimum estimate of $p(\mathbf{w})$. In the sequel, we present *Maximum Entropy Discrimination Markov Networks*, a novel framework that facilitates the estimation of a Bayesian-style regularized *distribution* of M^{3}Ns defined by $p(\mathbf{w})$. As we show below, this new Bayesian-style max-margin learning formalism offers several advantages such as simultaneous primal and dual sparsity, PAC-Bayesian generalization guarantee, and estimation robustness. Note that the MaxEnDNet is different from the traditional Bayesian methods for discriminative structured prediction such as the Bayesian CRFs (Qi et al., 2005), where the likelihood function is well defined. Here, our approach is of a "Bayesian-style" because it learns and uses a "posterior" distribution of all predictive models instead of choosing one model according to some criterion, but the learning algorithm is not

based on the Bayes theorem, but a maximum entropy principle that biases towards a distribution that makes less additional assumptions over a given prior over the predictive models. We emphasize that this "posterior" is different from, and should not be confused with, the conventional Bayesian posterior defined according to the Bayes rule.

It is well-known that exponential family distributions can be expressed variationally as the solution to a maximum entropy estimation subject to moment constraints, and the maximum entropy estimation of parameters can be understood as a dual to the maximum likelihood estimation of the parameters of exponential family distributions. Thus our combination of the maximum entropy principle with the maximum margin principle to be presented in the sequel offers an elegant way of achieving jointly maximum margin and maximum likelihood effects on learning structured input/output Markov networks, and in fact, general exponential family graphical models.

3.1 Structured Maximum Entropy Discrimination

Given a training set $\mathcal{D}$ of structured input-output pairs, analogous to the feasible space $\mathcal{F}_0$ for the weight vector $\mathbf{w}$ in a standard M^{3}N (c.f., problem P0), we define the feasible subspace $\mathcal{F}_1$ for the weight distribution $p(\mathbf{w})$ by a set of *expected* margin constraints:

$$\mathcal{F}_1 = \Big\{ p(\mathbf{w}) : \int p(\mathbf{w})[\Delta F_i(\mathbf{y};\mathbf{w}) - \Delta\ell_i(\mathbf{y})]\,\mathrm{d}\mathbf{w} \geq -\xi_i,\ \forall i, \forall \mathbf{y} \neq \mathbf{y}^i \Big\}.$$

We learn the optimum $p(\mathbf{w})$ from $\mathcal{F}_1$ based on a *structured maximum entropy discrimination principle* generalized from the maximum entropy discrimination (Jaakkola et al., 1999). Under this principle, the optimum $p(\mathbf{w})$ corresponds to the distribution that minimizes its relative entropy with respect to some chosen prior p_0, as measured by the Kullback-Leibler divergence between p and p_0: $KL(p||p_0) = \langle \log(p/p_0) \rangle_p$, where $\langle\cdot\rangle_p$ denotes the expectations with respect to p. If p_0 is uniform, then minimizing this KL-divergence is equivalent to maximizing the entropy $H(p) = -\langle \log p \rangle_p$. A natural information theoretic interpretation of this formulation is that we favor a distribution over the discriminant function class $\mathcal{H}$ that bears minimum assumptions among all feasible distributions in $\mathcal{F}_1$. The p_0 is a regularizer that introduces an appropriate bias, if necessary.

To accommodate non-separable cases in the discriminative prediction problem, instead of minimizing the usual KL, we optimize the *generalized entropy* (Dudík et al., 2007; Lebanon and Lafferty, 2001), or a regularized KL-divergence, $KL(p(\mathbf{w})||p_0(\mathbf{w})) + U(\xi)$, where $U(\xi)$ is a closed proper convex function over the slack variables. This term can be understood as an additional "potential" in the maximum entropy principle. Putting everything together, we can now state a general formalism based on the following maximum entropy discrimination Markov network framework:

Definition 1 (Maximum Entropy Discrimination Markov Networks) *Given training data $\mathcal{D} = \{\langle \mathbf{x}^i, \mathbf{y}^i \rangle\}_{i=1}^N$, a chosen form of discriminant function $F(\mathbf{x},\mathbf{y};\mathbf{w})$, a loss function $\Delta\ell(\mathbf{y})$, and an ensuing feasible subspace $\mathcal{F}_1$ (defined above) for parameter distribution $p(\mathbf{w})$, the MaxEnDNet model that leads to a prediction function of the form of Equation (2) is defined by the following generalized relative entropy minimization with respect to a parameter prior $p_0(\mathbf{w})$:*

$$\text{P1 (MaxEnDNet)}: \quad \min_{p(\mathbf{w}),\xi} KL(p(\mathbf{w})||p_0(\mathbf{w})) + U(\xi) \quad \text{s.t. } p(\mathbf{w}) \in \mathcal{F}_1,\ \xi_i \geq 0, \forall i.$$

The P1 defined above is a variational optimization problem over $p(\mathbf{w})$ in a subspace of valid parameter distributions. Since both the KL and the function U in P1 are convex, and the constraints in $\mathcal{F}_1$ are linear, P1 is a convex program. In addition, the expectations $\langle F(\mathbf{x},\mathbf{y};\mathbf{w})\rangle_{p(\mathbf{w})}$ are required to be bounded in order for F to be a meaningful model. Thus, the problem P1 satisfies the *Slater's condition*[1] (Boyd and Vandenberghe, 2004, chap. 5), which together with the convexity make P1 enjoy nice properties, such as strong duality and the existence of solutions. The problem P1 can be solved via applying the calculus of variations to the Lagrangian to obtain a variational extremum, followed by a dual transformation of P1. We state the main results below as a theorem, followed by a brief proof that lends many insights into the solution to P1 which we will explore in subsequent analysis.

Theorem 2 (Solution to MaxEnDNet) *The variational optimization problem P1 underlying the MaxEnDNet gives rise to the following optimum distribution of Markov network parameters* $\mathbf{w}$*:*

$$p(\mathbf{w}) = \frac{1}{Z(\alpha)} p_0(\mathbf{w}) \exp\Big\{ \sum_{i,\mathbf{y}\neq\mathbf{y}^i} \alpha_i(\mathbf{y})[\Delta F_i(\mathbf{y};\mathbf{w}) - \Delta\ell_i(\mathbf{y})] \Big\}, \tag{3}$$

where $Z(\alpha)$ *is a normalization factor and the Lagrange multipliers* $\alpha_i(\mathbf{y})$ *(corresponding to the constraints in* $\mathcal{F}_1$*) can be obtained by solving the dual problem of P1:*

$$\begin{aligned} \text{D1}: \quad & \max_{\alpha} \; -\log Z(\alpha) - U^\star(\alpha) \\ & \text{s.t. } \alpha_i(\mathbf{y}) \geq 0, \; \forall i, \; \forall \mathbf{y} \neq \mathbf{y}^i \end{aligned}$$

where $U^\star(\cdot)$ *is the conjugate of the slack function* $U(\cdot)$*, that is,* $U^\star(\alpha) = \sup_\xi \big(\sum_{i,\mathbf{y}\neq\mathbf{y}^i} \alpha_i(\mathbf{y})\xi_i - U(\xi)\big)$.

Proof (*sketch*) Since the problem P1 is a convex program and satisfies the Slater's condition, we can form a Lagrangian function, whose saddle point gives the optimal solution of P1 and D1, by introducing a non-negative dual variable $\alpha_i(\mathbf{y})$ for each constraint in $\mathcal{F}_1$ and another non-negative dual variable c for the normalization constraint $\int p(\mathbf{w})\,\mathrm{d}\mathbf{w} = 1$. Details are deferred to Appendix B.1. ■

Since the problem P1 is a convex program and satisfies the Slater's condition, the saddle point of the Lagrangian function is the KKT point of P1. From the KKT conditions (Boyd and Vandenberghe, 2004, Chap. 5), it can be shown that the above solution enjoys *dual sparsity*, that is, only a few Lagrange multipliers will be non-zero, which correspond to the active constraints whose equality holds, analogous to the support vectors in SVM. Thus MaxEnDNet enjoys a similar generalization property as the M^{3}N and SVM due to the the small "effective size" of the margin constraints. But it is important to realize that this does not mean that the learned model is "primal-sparse", that is, only a few elements in the weight vector $\mathbf{w}$ are non-zero. We will return to this point in Section 4.

For a closed proper convex function $\phi(\mu)$, its conjugate is defined as $\phi^\star(\nu) = \sup_\mu[\nu^\top\mu - \phi(\mu)]$. In the problem D1, by convex duality (Boyd and Vandenberghe, 2004), the log normalizer $\log Z(\alpha)$ can be shown to be the conjugate of the KL-divergence. If the slack function is $U(\xi) = C\|\xi\| =$

1. Since $\langle F(\mathbf{x},\mathbf{y};\mathbf{w})\rangle_{p(\mathbf{w})}$ are bounded and $\xi_i \geq 0$, there always exists a ξ, which is large enough to make the pair $(p(\mathbf{w}),\xi)$ satisfy the Slater's condition.

$C\sum_i \xi_i$, it is easy to show that $U^\star(\alpha) = \mathbb{I}_\infty(\sum_{\mathbf{y}} \alpha_i(\mathbf{y}) \leq C,\ \forall i)$, where $\mathbb{I}_\infty(\cdot)$ is a function that equals to zero when its argument holds true and infinity otherwise. Here, the inequality corresponds to the trivial solution $\xi = 0$, that is, the training data are perfectly separable. Ignoring this inequality does not affect the solution since the special case $\xi = 0$ is still included. Thus, the Lagrange multipliers $\alpha_i(\mathbf{y})$ in the dual problem D1 comply with the set of constraints that $\sum_{\mathbf{y}} \alpha_i(\mathbf{y}) = C,\ \forall i$. Another example is $U(\xi) = KL(p(\xi)||p_0(\xi))$ by introducing uncertainty on the slack variables (Jaakkola et al., 1999). In this case, expectations with respect to $p(\xi)$ are taken on both sides of all the constraints in $\mathcal{F}_1$. Take the duality, and the dual function of U is another log normalizer. More details were provided by Jaakkola et al. (1999). Some other U functions and their dual functions are studied by Lebanon and Lafferty (2001) and Dudík et al. (2007).

Unlike most extant structured discriminative models including the highly successful M^{3}N, which rely on a point estimator of the parameters, the MaxEnDNet model derived above gives an optimum parameter distribution, which is used to make prediction via the rule (2). Indeed, as we will show shortly, the MaxEnDNet is strictly more general than the M^{3}N and subsumes the later as a special case. But more importantly, the MaxEnDNet in its full generality offers a number of important advantages while retaining all the merits of the M^{3}N. **First**, MaxEnDNet admits a prior that can be designed to introduce useful regularization effects, such as a primal sparsity bias. **Second**, the MaxEnDNet prediction is based on model averaging and therefore enjoys a desirable smoothing effect, with a uniform convergence bound on generalization error. **Third**, MaxEnDNet offers a principled way to incorporate *hidden* generative models underlying the structured predictions, but allows the predictive model to be discriminatively trained based on partially labeled data. In the sequel, we analyze the first two points in detail; exploration of the third point is beyond the scope of this paper, and can be found in Zhu et al. (2008c), where a *partially observed* MaxEnDNet (PoMEN) is developed, which combines (possibly latent) generative model and discriminative training for structured prediction.

3.2 Gaussian MaxEnDNet

As Equation (3) suggests, different choices of the parameter prior can lead to different MaxEnDNet models for predictive parameter distribution. In this subsection and the following one, we explore a few common choices, e.g., Gaussian and Laplace priors.

We first show that, when the parameter prior is set to be a standard normal, MaxEnDNet leads to a predictor that is identical to that of the M^{3}N. This somewhat surprising reduction offers an important insight for understanding the property of MaxEnDNet. Indeed this result should not be totally unexpected given the striking isomorphisms of the opt-problem P1, the feasible space $\mathcal{F}_1$, and the predictive function h_1 underlying a MaxEnDNet, to their counterparts P0, $\mathcal{F}_0$, and h_0, respectively, underlying an M^{3}N. The following theorem makes our claim explicit.

Theorem 3 (Gaussian MaxEnDNet: Reduction of MEDN to M^{3}N) *Assuming* $F(\mathbf{x},\mathbf{y};\mathbf{w}) = \mathbf{w}^\top \mathbf{f}(\mathbf{x},\mathbf{y})$, $U(\xi) = C\sum_i \xi_i$, *and* $p_0(\mathbf{w}) = \mathcal{N}(\mathbf{w}|0,I)$, *where I denotes an identity matrix, then the posterior distribution is* $p(\mathbf{w}) = \mathcal{N}(\mathbf{w}|\mu,I)$, *where* $\mu = \sum_{i,\mathbf{y}\neq\mathbf{y}^i} \alpha_i(\mathbf{y})\Delta\mathbf{f}_i(\mathbf{y})$, *and the Lagrange multipliers* $\alpha_i(\mathbf{y})$ *in* $p(\mathbf{w})$ *are obtained by solving the following dual problem, which is isomorphic to the dual form of the M^{3}N:*

$$\max_{\alpha} \sum_{i,\mathbf{y}\neq\mathbf{y}^i} \alpha_i(\mathbf{y})\Delta\ell_i(\mathbf{y}) - \frac{1}{2}\|\sum_{i,\mathbf{y}\neq\mathbf{y}^i} \alpha_i(\mathbf{y})\Delta\mathbf{f}_i(\mathbf{y})\|^2$$

$$\text{s.t.} \quad \sum_{\mathbf{y} \neq \mathbf{y}^i} \alpha_i(\mathbf{y}) = C;\ \alpha_i(\mathbf{y}) \geq 0,\ \forall i,\ \forall \mathbf{y} \neq \mathbf{y}^i,$$

where $\Delta \mathbf{f}_i(\mathbf{y}) = \mathbf{f}(\mathbf{x}^i, \mathbf{y}^i) - \mathbf{f}(\mathbf{x}^i, \mathbf{y})$ *as in P0. When applied to* h_1*,* $p(\mathbf{w})$ *leads to a predictive function that is identical to* $h_0(\mathbf{x}; \mathbf{w})$ *given by Equation (1).*

Proof See Appendix B.2 for details. ■

The above theorem is stated in the duality form. We can also show the following equivalence in the primal form.

Corollary 4 *Under the same assumptions as in Theorem 3, the mean* μ *of the posterior distribution* $p(\mathbf{w})$ *under a Gaussian MaxEnDNet is obtained by solving the following primal problem:*

$$\begin{aligned} &\min_{\mu, \xi} \ \frac{1}{2}\mu^\top \mu + C \sum_{i=1}^{N} \xi_i \\ &\text{s.t.} \ \ \mu^\top \Delta \mathbf{f}_i(\mathbf{y}) \geq \Delta \ell_i(\mathbf{y}) - \xi_i;\ \xi_i \geq 0, \ \ \forall i,\ \forall \mathbf{y} \neq \mathbf{y}^i. \end{aligned}$$

Proof See Appendix B.3 for details. ■

Theorem 3 and Corollary 4 both show that in the supervised learning setting, the M^{3}N is a special case of MaxEnDNet when the slack function is linear and the parameter prior is a standard normal. As we shall see later, this connection renders many existing techniques for solving the M^{3}N directly applicable for solving the MaxEnDNet.

3.3 Laplace MaxEnDNet

Recent trends in pursuing "sparse" graphical models has led to the emergence of regularized version of CRFs (Andrew and Gao, 2007) and Markov networks (Lee et al., 2006; Wainwright et al., 2006). Interestingly, while such extensions have been successfully implemented by several authors in maximum likelihood learning of various sparse graphical models, they have not yet been fully explored or evaluated in the context of maximum margin learning, although some existing methods can be extended to achieve sparse max-margin estimators, as explained below.

One possible way to learn a sparse M^{3}N is to adopt the strategy of L_1-SVM (Bennett and Mangasarian, 1992; Zhu et al., 2004) and directly use an L_1 instead of the L_2-norm of $\mathbf{w}$ in the loss function (see appendix A for a detailed description of this formulation and the duality derivation). However, the primal problem of an L_1-regularized M^{3}N is not directly solvable using a standard optimization toolbox by re-formulating it as an LP problem due to the exponential number of constraints; solving the dual problem, which now has only a polynomial number of constraints as in the dual of M^{3}N, is also non-trivial due to the complicated form of the constraints. The constraint generation methods (Tsochantaridis et al., 2004) are possible. However, although such methods have been shown to be efficient for solving the QP problem in the standard M^{3}N, our preliminary empirical results show that such a scheme with an LP solver for the L_1-regularized M^{3}N can be extremely expensive for a non-trivial real data set. Another type of possible solvers are based on a projection to L_1-ball (Duchi et al., 2008), such as the gradient descent (Ratliff et al., 2007) and the dual extragradient (Taskar et al., 2006) methods.

The MaxEnDNet interpretation of the M^{3}N offers an alternative strategy that resembles Bayesian regularization (Tipping, 2001; Kaban, 2007) in maximum likelihood estimation, where shrinkage effects can be introduced by appropriate priors over the model parameters. As Theorem 3 reveals, an M^{3}N corresponds to a Gaussian MaxEnDNet that admits a standard normal prior for the weight vector $\mathbf{w}$. According to the standard Bayesian regularization theory, to achieve a sparse estimate of a model, in the posterior distribution of the feature weights, the weights of irrelevant features should peak around zero with very small variances. However, the isotropy of the variances in all dimensions of the feature space under a standard normal prior makes it infeasible for the resulting M^{3}N to adjust the variances in different dimensions to fit a sparse model. Alternatively, now we employ a Laplace prior for $\mathbf{w}$ to learn a Laplace MaxEnDNet. We show in the sequel that, the parameter posterior $p(\mathbf{w})$ under a Laplace MaxEnDNet has a shrinkage effect on small weights, which is similar to directly applying an L_1-regularizer on an M^{3}N. Although exact learning of a Laplace MaxEnDNet is also intractable, we show that this model can be efficiently approximated by a variational inference procedure based on existing methods.

The Laplace prior of $\mathbf{w}$ is expressed as $p_0(\mathbf{w}) = \prod_{k=1}^{K} \frac{\sqrt{\lambda}}{2} e^{-\sqrt{\lambda}|w_k|} = (\frac{\sqrt{\lambda}}{2})^K e^{-\sqrt{\lambda}\|\mathbf{w}\|}$. This density function is heavy tailed and peaked at zero; thus, it encodes a prior belief that the distribution of $\mathbf{w}$ is strongly peaked around zero. Another nice property of the Laplace density is that it is log-concave, or the negative logarithm is convex, which can be exploited to obtain a convex estimation problem analogous to LASSO (Tibshirani, 1996).

Theorem 5 (Laplace MaxEnDNet: a sparse M^{3}N) *Assuming* $F(\mathbf{x},\mathbf{y};\mathbf{w}) = \mathbf{w}^\top \mathbf{f}(\mathbf{x},\mathbf{y})$, $U(\xi) = C\sum_i \xi_i$, *and* $p_0(\mathbf{w}) = \prod_{k=1}^{K} \frac{\sqrt{\lambda}}{2} e^{-\sqrt{\lambda}|w_k|} = (\frac{\sqrt{\lambda}}{2})^K e^{-\sqrt{\lambda}\|\mathbf{w}\|}$, *then the Lagrange multipliers* $\alpha_i(\mathbf{y})$ *in* $p(\mathbf{w})$ *(as defined in Theorem 2) are obtained by solving the following dual problem:*

$$\max_{\alpha} \sum_{i,\mathbf{y}\neq\mathbf{y}^i} \alpha_i(\mathbf{y})\Delta\ell_i(\mathbf{y}) - \sum_{k=1}^{K} \log\frac{\lambda}{\lambda-\eta_k^2}$$
$$\text{s.t.} \sum_{\mathbf{y}\neq\mathbf{y}^i} \alpha_i(\mathbf{y}) = C;\ \alpha_i(\mathbf{y}) \geq 0,\ \forall i,\ \forall \mathbf{y} \neq \mathbf{y}^i.$$

where $\eta_k = \sum_{i,\mathbf{y}\neq\mathbf{y}^i} \alpha_i(\mathbf{y})\Delta\mathbf{f}_i^k(\mathbf{y})$, *and* $\Delta\mathbf{f}_i^k(\mathbf{y}) = f_k(\mathbf{x}^i,\mathbf{y}^i) - f_k(\mathbf{x}^i,\mathbf{y})$ *represents the kth component of* $\Delta\mathbf{f}_i(\mathbf{y})$. *Furthermore, constraints* $\eta_k^2 < \lambda,\ \forall k$, *must be satisfied*.

Since several intermediate results from the proof of this Theorem will be used in subsequent presentations, we provide the complete proof below. Our proof is based on a hierarchical representation of the Laplace prior. As noted by Andrews and Mallows (1974), the Laplace distribution $p(w) = \frac{\sqrt{\lambda}}{2} e^{-\sqrt{\lambda}|w|}$ is equivalent to a two-layer hierarchical Gaussian-exponential model, where w follows a zero-mean Gaussian distribution $p(w|\tau) = \mathcal{N}(w|0,\tau)$ and the variance τ admits an exponential hyper-prior density,

$$p(\tau|\lambda) = \frac{\lambda}{2}\exp\{-\frac{\lambda}{2}\tau\},\ \text{ for } \tau \geq 0.$$

This alternative form straightforwardly leads to the following new representation of our multivariate Laplace prior for the parameter vector $\mathbf{w}$ in MaxEnDNet:

$$p_0(\mathbf{w}) = \prod_{k=1}^{K} p_0(w_k) = \prod_{k=1}^{K} \int p(w_k|\tau_k)p(\tau_k|\lambda)\,d\tau_k = \int p(\mathbf{w}|\tau)p(\tau|\lambda)\,d\tau, \tag{4}$$

where $p(\mathbf{w}|\tau) = \prod_{k=1}^{K} p(w_k|\tau_k)$ and $p(\tau|\lambda) = \prod_{k=1}^{K} p(\tau_k|\lambda)$ represent multivariate Gaussian and exponential, respectively, and $d\tau \triangleq d\tau_1 \cdots d\tau_K$.

Proof (*of Theorem 5*) Substitute the hierarchical representation of the Laplace prior (Equation 4) into $p(\mathbf{w})$ in Theorem 2, and we get the normalization factor $Z(\alpha)$ as follows,

$$\begin{aligned}
Z(\alpha) &= \int\int p(\mathbf{w}|\tau)p(\tau|\lambda)\,d\tau \cdot \exp\{\mathbf{w}^\top\eta - \sum_{i,\mathbf{y}\neq\mathbf{y}^i} \alpha_i(\mathbf{y})\Delta\ell_i(\mathbf{y})\}\,d\mathbf{w} \\
&= \int p(\tau|\lambda)\int p(\mathbf{w}|\tau)\cdot\exp\{\mathbf{w}^\top\eta - \sum_{i,\mathbf{y}\neq\mathbf{y}^i} \alpha_i(\mathbf{y})\Delta\ell_i(\mathbf{y})\}\,d\mathbf{w}\,d\tau \\
&= \int p(\tau|\lambda)\int \mathcal{N}(\mathbf{w}|0,A)\exp\{\mathbf{w}^\top\eta - \sum_{i,\mathbf{y}\neq\mathbf{y}^i} \alpha_i(\mathbf{y})\Delta\ell_i(\mathbf{y})\}\,d\mathbf{w}\,d\tau \\
&= \int p(\tau|\lambda)\exp\{\frac{1}{2}\eta^\top A\eta - \sum_{i,\mathbf{y}\neq\mathbf{y}^i} \alpha_i(\mathbf{y})\Delta\ell_i(\mathbf{y})\}d\tau \\
&= \exp\{-\sum_{i,\mathbf{y}\neq\mathbf{y}^i} \alpha_i(\mathbf{y})\Delta\ell_i(\mathbf{y})\}\prod_{k=1}^{K}\int\frac{\lambda}{2}\exp(-\frac{\lambda}{2}\tau_k)\exp(\frac{1}{2}\eta_k^2\tau_k)d\tau_k \\
&= \exp\{-\sum_{i,\mathbf{y}\neq\mathbf{y}^i} \alpha_i(\mathbf{y})\Delta\ell_i(\mathbf{y})\}\prod_{k=1}^{K}\frac{\lambda}{\lambda-\eta_k^2}, \qquad (5)
\end{aligned}$$

where $A = \mathrm{diag}(\tau_k)$ is a diagonal matrix and η is a column vector with η_k defined as in Theorem 5. The last equality is due to the moment generating function of an exponential distribution. The constraint $\eta_k^2 < \lambda,\ \forall k$ is needed in this derivation to avoid the integration going infinity. Substituting the normalization factor derived above into the general dual problem D1 in Theorem 2, and using the same argument of the convex conjugate of $U(\xi) = C\sum_i \xi_i$ as in Theorem 3, we arrive at the dual problem in Theorem 5. ■

It can be shown that the dual objective function of Laplace MaxEnDNet in Theorem 5 is concave.[2] But since each η_k depends on all the dual variables α and η_k^2 appears within a logarithm, the optimization problem underlying Laplace MaxEnDNet would be very difficult to solve. The SMO (Taskar et al., 2003) and the exponentiated gradient methods (Bartlett et al., 2004) developed for the QP dual problem of M^{3}N cannot be easily applied here. Thus, we will turn to a variational approximation method, as shown in Section 5. For completeness, we end this section with a corollary similar to the Corollary 4, which states the primal optimization problem underlying the MaxEnDNet with a Laplace prior. As we shall see, the primal optimization problem in this case is complicated and provides another perspective of the hardness of solving the Laplace MaxEnDNet.

Corollary 6 *Under the same assumptions as in Theorem 5, the mean μ of the posterior distribution $p(\mathbf{w})$ under a Laplace MaxEnDNet is obtained by solving the following primal problem:*

$$\begin{aligned}
&\min_{\mu,\xi}\ \sqrt{\lambda}\sum_{k=1}^{K}\Big(\sqrt{\mu_k^2+\frac{1}{\lambda}} - \frac{1}{\sqrt{\lambda}}\log\frac{\sqrt{\lambda\mu_k^2+1}+1}{2}\Big) + C\sum_{i=1}^{N}\xi_i \\
&\text{s.t.}\ \ \mu^\top\Delta\mathbf{f}_i(\mathbf{y}) \geq \Delta\ell_i(\mathbf{y}) - \xi_i;\ \xi_i \geq 0,\ \ \forall i,\ \forall\mathbf{y}\neq\mathbf{y}^i.
\end{aligned}$$

2. η_k^2 is convex over α because it is the composition of $f(x) = x^2$ with an affine mapping. So, $\lambda - \eta_k^2$ is concave and $\log(\lambda - \eta_k^2)$ is also concave due to the composition rule (Boyd and Vandenberghe, 2004).

Proof The proof requires the result of Corollary 7. We defer it to Appendix B.4. ■

Since the "norm"[3]

$$\sum_{k=1}^{K}\Big(\sqrt{\mu_k^2+\frac{1}{\lambda}}-\frac{1}{\sqrt{\lambda}}\log\frac{\sqrt{\lambda\mu_k^2+1}+1}{2}\Big)\triangleq\|\mu\|_{KL}$$

corresponds to the KL-divergence between $p(\mathbf{w})$ and $p_0(\mathbf{w})$ under a Laplace MaxEnDNet, we will refer to it as a *KL-norm* and denote it by $\|\cdot\|_{KL}$ in the sequel. This KL-norm is different from the L_2-norm as used in M^{3}N, but is closely related to the L_1-norm, which encourages a sparse estimator. In the following section, we provide a detailed analysis of the sparsity of Laplace MaxEnDNet resulted from the regularization effect from this norm.

4. Entropic Regularization and Sparse M^{3}N

Comparing to the structured prediction law h_0 due to an M^{3}N, which enjoys dual sparsity (i.e., few support vectors), the h_1 defined by a Laplace MaxEnDNet is not only dual-sparse, but also primal sparse; that is, features that are insignificant will experience strong shrinkage on their corresponding weight w_k.

The primal sparsity of h_1 achieved by the Laplace MaxEnDNet is due to a shrinkage effect resulting from the *Laplacian entropic regularization*. In this section, we take a close look at this regularization effect, in comparison with other common regularizers, such as the L_2-norm in M^{3}N (which is equivalent to the Gaussian MaxEnDNet), and the L_1-norm that at least in principle could be directly applied to M^{3}N. Since our main interest here is the sparsity of the structured prediction law h_1, we examine the posterior mean under $p(\mathbf{w})$ via exact integration. It can be shown that under a Laplace MaxEnDNet, $p(\mathbf{w})$ exhibits the following posterior shrinkage effect.

Corollary 7 (Entropic Shrinkage) *The posterior mean of the Laplace MaxEnDNet has the following form:*

$$\langle w_k\rangle_p=\frac{2\eta_k}{\lambda-\eta_k^2},\ \forall 1\le k\le K, \tag{6}$$

where $\eta_k=\sum_{i,\mathbf{y}\neq\mathbf{y}^i}\alpha_i(\mathbf{y})(f_k(\mathbf{x}^i,\mathbf{y}^i)-f_k(\mathbf{x}^i,\mathbf{y}))$ *and* $\eta_k^2<\lambda,\ \forall k$.

Proof Using the integration result in Equation (5), we can get:

$$\frac{\partial\log Z}{\partial\alpha_i(\mathbf{y})}=v^\top\Delta\mathbf{f}_i(\mathbf{y})-\Delta\ell_i(\mathbf{y}), \tag{7}$$

where v is a column vector and $v_k=\frac{2\eta_k}{\lambda-\eta_k^2},\ \forall 1\le k\le K$. An alternative way to compute the derivatives is using the definition of Z: $Z=\int p_0(\mathbf{w})\cdot\exp\{\mathbf{w}^\top\eta-\sum_{i,\mathbf{y}\neq\mathbf{y}^i}\alpha_i(\mathbf{y})\Delta\ell_i(\mathbf{y})\}\,\mathrm{d}\mathbf{w}$. We can get:

$$\frac{\partial\log Z}{\partial\alpha_i(\mathbf{y})}=\langle\mathbf{w}\rangle_p^\top\Delta\mathbf{f}_i(\mathbf{y})-\Delta\ell_i(\mathbf{y}). \tag{8}$$

3. This is not exactly a norm because the positive scalability does not hold. But the KL-norm is non-negative due to the non-negativity of KL-divergence. In fact, by using the inequality $e^x\ge 1+x$, we can show that each component $(\sqrt{\mu_k^2+\frac{1}{\lambda}}-\frac{1}{\sqrt{\lambda}}\log\frac{\sqrt{\lambda\mu_k^2+1}+1}{2})$ is monotonically increasing with respect to μ_k^2 and $\|\mu\|_{KL}\ge K/\sqrt{\lambda}$, where the equality holds only when $\mu=0$. Thus, $\|\mu\|_{KL}$ penalizes large weights. For convenient comparison with the popular L_2 and L_1 norms, we call it a KL-norm.

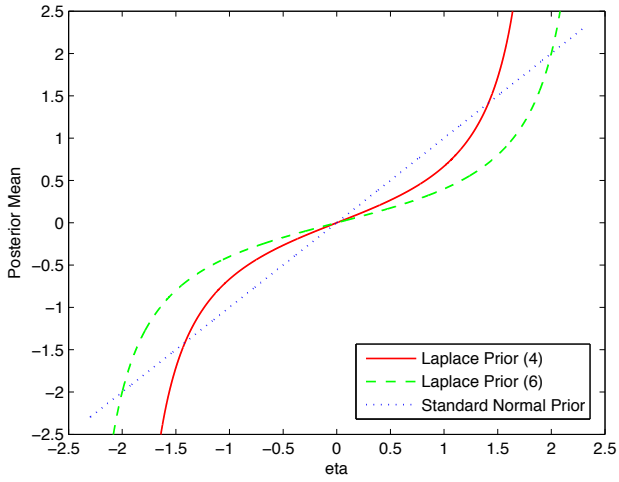

Figure 1: Posterior means with different priors against their corresponding $\eta = \sum_{i,\mathbf{y}\neq\mathbf{y}^i} \alpha_i(\mathbf{y})\Delta\mathbf{f}_i(\mathbf{y})$. Note that the η for different priors are generally different because of the different dual parameters.

Comparing Equations (7) and (8), we get $\langle \mathbf{w} \rangle_p = v$, that is, $\langle w_k \rangle_p = \frac{2\eta_k}{\lambda - \eta_k^2}$, $\forall 1 \leq k \leq K$. The constraints $\eta_k^2 < \lambda$, $\forall k$ are required to get a finite normalization factor as shown in Equation (5). ■

Here η is isomorphic to an unregularized estimate of the feature weight vector which directly comes from a linear combination of support vectors (and therefore not sparsified). A plot of the relationship between $\langle w_k \rangle_p$ under a Laplace MaxEnDNet and the corresponding η_k revealed by Corollary 7 is shown in Figure 1 (for example, the red curve), from which we can see that, the smaller the η_k is, the more shrinkage toward zero is imposed on $\langle w_k \rangle_p$.

This entropic shrinkage effect on $\mathbf{w}$ is not present in the standard M^{3}N, and the Gaussian MaxEnDNet. Recall that by definition, the vector $\eta \triangleq \sum_{i,\mathbf{y}} \alpha_i(\mathbf{y})\Delta\mathbf{f}_i(\mathbf{y})$ is determined by the dual parameters $\alpha_i(\mathbf{y})$ obtained by solving a model-specific dual problem. When the $\alpha_i(\mathbf{y})$'s are obtained by solving the dual of the standard M^{3}N, it can be shown that the optimum point solution of the parameters $\mathbf{w}^\star = \eta$. When the $\alpha_i(\mathbf{y})$'s are obtained from the dual of the Gaussian MaxEnDNet, Theorem 3 shows that the posterior mean of the parameters $\langle \mathbf{w} \rangle_{p_{\text{Gaussian}}} = \eta$. (As we have already pointed out, since these two dual problems are isomorphic, the $\alpha_i(\mathbf{y})$'s for M^{3}N and Gaussian MaxEnDNet are identical, hence the resulting η's are the same.) In both cases, there is no shrinkage along any particular dimension of the parameter vector $\mathbf{w}$ or of the mean vector of $p(\mathbf{w})$. Therefore, although both M^{3}N and Gaussian MaxEnDNet enjoy the dual sparsity, because the KKT conditions imply that most of the dual parameters $\alpha_i(\mathbf{y})$'s are zero, $\mathbf{w}^\star$ and $\langle \mathbf{w} \rangle_{p_{\text{Gaussian}}}$ are not primal sparse. From Equation (6), we can conclude that the Laplace MaxEnDNet is also dual sparse, because its mean $\langle \mathbf{w} \rangle_{p_{\text{Laplace}}}$ can be uniquely determined by η. But the shrinkage effect on different components of the $\langle \mathbf{w} \rangle_{p_{\text{Laplace}}}$ vector causes $\langle \mathbf{w} \rangle_{p_{\text{Laplace}}}$ to be also primal sparse.

A comparison of the posterior mean estimates of $\mathbf{w}$ under MaxEnDNet with three different priors versus their associated η is shown in Figure 1. The three priors in question are, a standard normal, a Laplace with $\lambda = 4$, and a Laplace with $\lambda = 6$. It can be seen that, under the entropic

regularization with a Laplace prior, the $\langle \mathbf{w} \rangle_p$ gets shrunk toward zero when η is small. The larger the λ value is, the greater the shrinkage effect. For a fixed λ, the shape of the shrinkage curve (i.e., the $\langle \mathbf{w} \rangle_p - \eta$ curve) is smoothly nonlinear, but no component is explicitly discarded, that is, no weight is set explicitly to zero. In contrast, for the Gaussian MaxEnDNet, which is equivalent to the standard M^{3}N, there is no such a shrinkage effect.

Corollary 6 offers another perspective of how the Laplace MaxEnDNet relates to the L_1-norm M^{3}N, which yields a sparse estimator. Note that as λ goes to infinity, the KL-norm $\|\mu\|_{KL}$ approaches $\|\mu\|_1$, that is, the L_1-norm.[4] This means that the MaxEnDNet with a Laplace prior will be (nearly) the same as the L_1-M^{3}N if the regularization constant λ is large enough.

A more explicit illustration of the entropic regularization under a Laplace MaxEnDNet, comparing to the conventional L_1 and L_2 regularization over an M^{3}N, can be seen in Figure 2, where the feasible regions due to the three different norms used in the regularizer are plotted in a two dimensional space. Specifically, it shows (1) L_2-norm: $w_1^2 + w_2^2 \leq 1$; (2) L_1-norm: $|w_1| + |w_2| \leq 1$; and (3) KL-norm:[5] $\sqrt{w_1^2 + 1/\lambda} + \sqrt{w_2^2 + 1/\lambda} - (1/\sqrt{\lambda}) \log(\sqrt{\lambda w_1^2 + 1}/2 + 1/2) - (1/\sqrt{\lambda}) \log(\sqrt{\lambda w_1^2 + 1}/2 + 1/2) \leq b$, where b is a parameter to make the boundary pass the $(0,1)$ point for easy comparison with the L_2 and L_1 curves. It is easy to show that b equals to $\sqrt{1/\lambda} + \sqrt{1 + 1/\lambda} - (1/\sqrt{\lambda}) \log(\sqrt{\lambda + 1}/2 + 1/2)$. It can be seen that the L_1-norm boundary has sharp turning points when it passes the axises, whereas the L_2 and KL-norm boundaries turn smoothly at those points. This is the intuitive explanation of why the L_1-norm directly gives sparse estimators, whereas the L_2-norm and KL-norm due to a Laplace prior do not. But as shown in Figure 2(b), when the λ gets larger and larger, the KL-norm boundary moves closer and closer to the L_1-norm boundary. When $\lambda \to \infty$, $\sqrt{w_1^2 + 1/\lambda} + \sqrt{w_2^2 + 1/\lambda} - (1/\sqrt{\lambda}) \log(\sqrt{\lambda w_1^2 + 1}/2 + 1/2) - (1/\sqrt{\lambda}) \log(\sqrt{\lambda w_1^2 + 1}/2 + 1/2) \to |w_1| + |w_2|$ and $b \to 1$, which yields exactly the L_1-norm in the two dimensional space. Thus, under the linear model assumption of the discriminant functions $F(\,\cdot\,; \mathbf{w})$, our framework can be seen as a smooth relaxation of the L_1-M^{3}N.

5. Variational Learning of Laplace MaxEnDNet

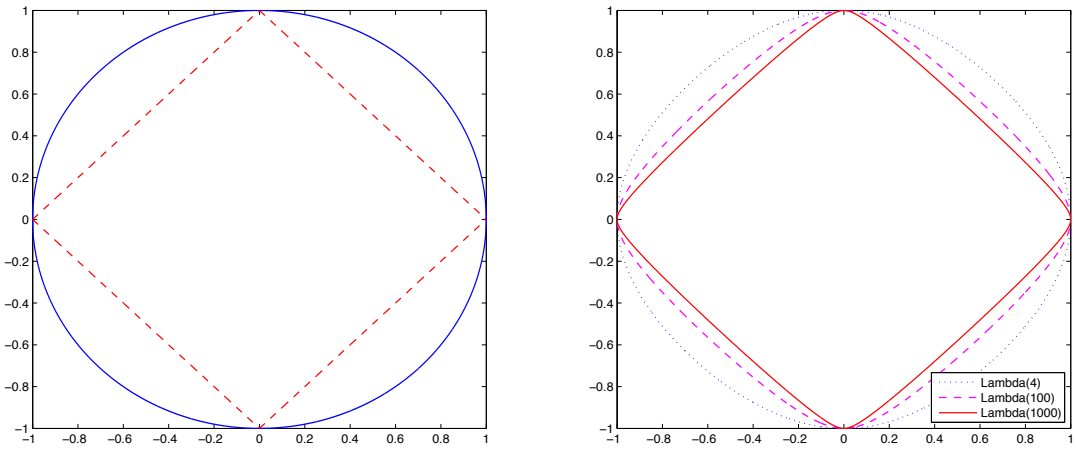
Although Theorem 2 seems to offer a general closed-form solution to $p(\mathbf{w})$ under an arbitrary prior $p_0(\mathbf{w})$, in practice the Lagrange multipliers $\alpha_i(\mathbf{y})$ in $p(\mathbf{w})$ can be very hard to estimate from the dual problem D1 except for a few special choices of $p_0(\mathbf{w})$, such as a normal as shown in Theorem 3, which can be easily generalized to any normal prior. When $p_0(\mathbf{w})$ is a Laplace prior, as we have shown in Theorem 5 and Corollary 6, the corresponding dual problem or primal problem involves a complex objective function that is difficult to optimize. Here, we present a variational method for an approximate learning of the Laplace MaxEnDNet.

Our approach is built on the hierarchical interpretation of the Laplace prior as shown in Equation (4). Replacing the $p_0(\mathbf{w})$ in Problem P1 with Equation (4), and applying the Jensen's inequality, we get an upper bound of the KL-divergence:

$$KL(p||p_0) \qquad = -H(p) - \langle \log \int p(\mathbf{w}|\tau) p(\tau|\lambda)\, \mathrm{d}\tau \rangle_p$$

4. As $\lambda \to \infty$, the logarithm terms in $\|\mu\|_{KL}$ disappear because of the fact that $\frac{\log x}{x} \to 0$ when $x \to \infty$.

5. The curves are drawn with a symbolic computational package to solve an equation of the form: $2x - \log x = a$, where x is the variable to be solved and a is a constant.



(a) (b)

Figure 2: (a) L_2-norm (solid line) and L_1-norm (dashed line); (b) KL-norm with different Laplace priors.

$$\begin{aligned} &\leq -H(p) - \langle \int q(\tau) \log \frac{p(\mathbf{w}|\tau)p(\tau|\lambda)}{q(\tau)} \, \mathrm{d}\tau \rangle_p \\ &\triangleq \mathcal{L}(p(\mathbf{w}), q(\tau)), \end{aligned}$$

where $q(\tau)$ is a variational distribution used to approximate $p(\tau|\lambda)$. The upper bound is in fact a KL-divergence: $\mathcal{L}(p(\mathbf{w}), q(\tau)) = KL(p(\mathbf{w})q(\tau)||p(\mathbf{w}|\tau)p(\tau|\lambda))$. Thus, $\mathcal{L}$ is convex over $p(\mathbf{w})$, and $q(\tau)$, respectively, but not necessarily joint convex over $(p(\mathbf{w}), q(\tau))$.

Substituting this upper bound for the KL-divergence in P1, we now solve the following Variational MaxEnDNet problem,

$$\text{P1}' \text{ (vMEDN)}: \qquad \min_{p(\mathbf{w}) \in \mathcal{F}_1; q(\tau); \xi} \mathcal{L}(p(\mathbf{w}), q(\tau)) + U(\xi).$$

P1$'$ can be solved with an iterative minimization algorithm alternating between optimizing over $(p(\mathbf{w}), \xi)$ and $q(\tau)$, as outlined in Algorithm 1, and detailed below.

Step 1: Keep $q(\tau)$ fixed, optimize P1$'$ with respect to $(p(\mathbf{w}), \xi)$. Using the same procedure as in solving P1, we get the posterior distribution $p(\mathbf{w})$ as follows,

$$\begin{aligned} p(\mathbf{w}) \quad &\propto \exp\{\int q(\tau) \log p(\mathbf{w}|\tau) \, \mathrm{d}\tau - b\} \cdot \exp\{\mathbf{w}^\top \eta - \sum_{i, \mathbf{y} \neq \mathbf{y}^i} \alpha_i(\mathbf{y}) \Delta \ell_i(\mathbf{y})\} \\ &\propto \exp\{-\frac{1}{2} \mathbf{w}^\top \langle A^{-1} \rangle_q \mathbf{w} - b + \mathbf{w}^\top \eta - \sum_{i, \mathbf{y} \neq \mathbf{y}^i} \alpha_i(\mathbf{y}) \Delta \ell_i(\mathbf{y})\} \\ &= \mathcal{N}(\mathbf{w}|\mu, \Sigma), \end{aligned}$$

Algorithm 1 Variational MaxEnDNet

Input: data $\mathcal{D} = \{\langle \mathbf{x}^i, \mathbf{y}^i \rangle\}_{i=1}^N$, constants C and λ, iteration number T
Output: posterior mean $\langle \mathbf{w} \rangle_p^T$
Initialize $\langle \mathbf{w} \rangle_p^1 \leftarrow 0, \Sigma^1 \leftarrow I$
for $t = 1$ **to** $T-1$ **do**
  Step 1: solve (9) or (10) for $\langle \mathbf{w} \rangle_p^{t+1} = \Sigma^t \eta$; update $\langle \mathbf{w}\mathbf{w}^\top \rangle_p^{t+1} \leftarrow \Sigma^t + \langle \mathbf{w} \rangle_p^{t+1} (\langle \mathbf{w} \rangle_p^{t+1})^\top$.
  Step 2: use (11) to update $\Sigma^{t+1} \leftarrow \text{diag}(\sqrt{\frac{\langle w_k^2 \rangle_p^{t+1}}{\lambda}})$.
end for

where $\eta = \sum_{i,\mathbf{y} \neq \mathbf{y}^i} \alpha_i(\mathbf{y}) \Delta \mathbf{f}_i(\mathbf{y})$, $A = \text{diag}(\tau_k)$, and $b = KL(q(\tau)||p(\tau|\lambda))$ is a constant. The posterior mean and variance are $\langle \mathbf{w} \rangle_p = \mu = \Sigma\eta$ and $\Sigma = (\langle A^{-1} \rangle_q)^{-1} = \langle \mathbf{w}\mathbf{w}^\top \rangle_p - \langle \mathbf{w} \rangle_p \langle \mathbf{w} \rangle_p^\top$, respectively. Note that this posterior distribution is also a normal distribution. Analogous to the proof of Theorem 3, we can derive that the dual parameters α are estimated by solving the following dual problem:

$$\begin{aligned} \max_{\alpha} \quad & \sum_{i,\mathbf{y} \neq \mathbf{y}^i} \alpha_i(\mathbf{y}) \Delta \ell_i(\mathbf{y}) - \frac{1}{2} \eta^\top \Sigma \eta \\ \text{s.t.} \quad & \sum_{\mathbf{y} \neq \mathbf{y}^i} \alpha_i(\mathbf{y}) = C;\ \alpha_i(\mathbf{y}) \geq 0,\ \forall i,\ \forall \mathbf{y} \neq \mathbf{y}^i. \end{aligned} \tag{9}$$

This dual problem is now a standard quadratic program symbolically identical to the dual of an M^3N, and can be directly solved using existing algorithms developed for M^3N, such as the SMO (Taskar et al., 2003) and the exponentiated gradient (Bartlett et al., 2004) methods. Alternatively, we can solve the following primal problem:

$$\begin{aligned} \min_{\mathbf{w},\xi} \quad & \frac{1}{2} \mathbf{w}^\top \Sigma^{-1} \mathbf{w} + C \sum_{i=1}^N \xi_i \\ \text{s.t.} \quad & \mathbf{w}^\top \Delta \mathbf{f}_i(\mathbf{y}) \geq \Delta \ell_i(\mathbf{y}) - \xi_i;\ \xi_i \geq 0,\ \ \forall i,\ \forall \mathbf{y} \neq \mathbf{y}^i. \end{aligned} \tag{10}$$

Based on the proof of Corollary 4, it is easy to show that the solution of the problem (10) leads to the posterior mean of $\mathbf{w}$ under $p(\mathbf{w})$, which will be used to do prediction by h_1. The primal problem can be solved with the subgradient (Ratliff et al., 2007), cutting-plane (Tsochantaridis et al., 2004), or extragradient (Taskar et al., 2006) method.

Step 2: Keep $p(\mathbf{w})$ fixed, optimize P1′ with respect to $q(\tau)$. Taking the derivative of $\mathcal{L}$ with respect to $q(\tau)$ and set it to zero, we get:

$$q(\tau) \quad \propto p(\tau|\lambda) \exp\{\langle \log p(\mathbf{w}|\tau) \rangle_p\}.$$

Since both $p(\mathbf{w}|\tau)$ and $p(\tau|\lambda)$ can be written as a product of univariate Gaussian and univariate exponential distributions, respectively, over each dimension, $q(\tau)$ also factorizes over each dimension: $q(\tau) = \prod_{k=1}^K q(\tau_k)$, where each $q(\tau_k)$ can be expressed as:

$$\begin{aligned} \forall k: \quad q(\tau_k) \quad & \propto p(\tau_k|\lambda) \exp\{\langle \log p(w_k|\tau_k) \rangle_p\} \\ & \propto \mathcal{N}(\sqrt{\langle w_k^2 \rangle_p}|0,\tau_k) \exp(-\frac{1}{2}\lambda\tau_k). \end{aligned}$$

The same distribution has been derived by Kaban (2007), and similar to the hierarchical representation of a Laplace distribution we can get the normalization factor: $\int \mathcal{N}(\sqrt{\langle w_k^2\rangle_p}|0,\tau_k)\cdot \frac{\lambda}{2}\exp(-\frac{1}{2}\lambda\tau_k)\,d\tau_k = \frac{\sqrt{\lambda}}{2}\exp(-\sqrt{\lambda\langle w_k^2\rangle_p})$. Also, we can calculate the expectations $\langle\tau_k^{-1}\rangle_q$ which are required in calculating $\langle A^{-1}\rangle_q$ as follows,

$$\langle\frac{1}{\tau_k}\rangle_q = \int \frac{1}{\tau_k} q(\tau_k)\,d\tau_k = \sqrt{\frac{\lambda}{\langle w_k^2\rangle_p}}. \tag{11}$$

We iterate between the above two steps until convergence. Due to the convexity (not joint convexity) of the upper bound, the algorithm is guaranteed to converge to a local optimum. Then, we apply the posterior distribution $p(\mathbf{w})$, which is in the form of a normal distribution, to make prediction using the averaging prediction law in Equation (2). Due to the shrinkage effect of the Laplacian entropic regularization discussed in Section 4, for irrelevant features, the variances should converge to zeros and thus lead to a sparse estimation of $\mathbf{w}$. To summarize, the intuition behind this iterative minimization algorithm is as follows. First, we use a Gaussian distribution to approximate the Laplace distribution and thus get a QP problem that is analogous to that of the standard M^{3}N; then, in the second step we update the covariance matrix in the QP problem with an exponential hyper-prior on the variance.

6. Generalization Bound

The PAC-Bayes theory for averaging classifiers (McAllester, 1999; Langford et al., 2001) provides a theoretical motivation to learn an averaging model for classification. In this section, we extend the classic PAC-Bayes theory on binary classifiers to MaxEnDNet, and analyze the generalization performance of the structured prediction rule h_1 in Equation (2). In order to prove an error bound for h_1, the following mild assumption on the boundedness of discriminant function $F(\,\cdot\,;\mathbf{w})$ is necessary, that is, there exists a positive constant c, such that,

$$\forall \mathbf{w}, \quad F(\,\cdot\,;\mathbf{w}) \in \mathcal{H}: \quad \mathcal{X}\times\mathcal{Y} \to [-c,c].$$

Recall that the averaging structured prediction function under the MaxEnDNet is defined as $h(\mathbf{x},\mathbf{y}) = \langle F(\mathbf{x},\mathbf{y};\mathbf{w})\rangle_{p(\mathbf{w})}$. Let's define the predictive margin of an instance $(\mathbf{x},\mathbf{y})$ under a function h as $M(h,\mathbf{x},\mathbf{y}) = h(\mathbf{x},\mathbf{y}) - \max_{\mathbf{y}'\neq\mathbf{y}} h(\mathbf{x},\mathbf{y}')$. Clearly, h makes a wrong prediction on $(\mathbf{x},\mathbf{y})$ only if $M(h,\mathbf{x},\mathbf{y}) \leq 0$. Let Q denote a distribution over $\mathcal{X}\times\mathcal{Y}$, and let $\mathcal{D}$ represent a sample of N instances randomly drawn from Q. With these definitions, we have the following structured version of PAC-Bayes theorem.

Theorem 8 (PAC-Bayes Bound of MaxEnDNet) *Let p_0 be any continuous probability distribution over $\mathcal{H}$ and let $\delta\in(0,1)$. If $F(\,\cdot\,;\mathbf{w})\in\mathcal{H}$ is bounded by $\pm c$ as above, then with probability at least $1-\delta$, for a random sample $\mathcal{D}$ of N instances from Q, for every distribution p over $\mathcal{H}$, and for all margin thresholds $\gamma>0$:*

$$\Pr_Q(M(h,\mathbf{x},\mathbf{y})\leq 0) \leq \Pr_{\mathcal{D}}(M(h,\mathbf{x},\mathbf{y})\leq\gamma) + O\Big(\sqrt{\frac{\gamma^{-2}KL(p||p_0)\ln(N|\mathcal{Y}|)+\ln N+\ln\delta^{-1}}{N}}\Big),$$

where $\Pr_Q(.)$ *and* $\Pr_{\mathcal{D}}(.)$ *represent the probabilities of events over the true distribution* Q*, and over the empirical distribution of* $\mathcal{D}$*, respectively.*

The proof of Theorem 8 follows the same spirit of the proof of the original PAC-Bayes bound, but with a number of technical extensions dealing with structured outputs and margins. See appendix B.5 for the details.

Recently, McAllester (2007) presents a *stochastic* max-margin structured prediction model, which is different from the averaging predictor under the MaxEnDNet model, by defining/designing a "posterior" distribution from which a model is sampled to make prediction, and achieves a PAC-Bayes bound which holds for arbitrary models sampled from the particular posterior distribution. Langford and Shawe-Taylor (2003) show an interesting connection between the PAC-Bayes bounds for averaging classifiers and stochastic classifiers, again by designing a posterior distribution. But our posterior distribution is solved with MaxEnDNet and is generally different from those designed by McAllester (2007) and Langford and Shawe-Taylor (2003).

7. Experiments

In this section, we present empirical evaluations of the proposed Laplace MaxEnDNet (LapMEDN) on both synthetic and real data sets. We compare LapMEDN with M^3N (i.e., the Gaussian MaxEnDNet), L_1-regularized M^3N (L_1-M^3N), CRFs, L_1-regularized CRFs (L_1-CRFs), and L_2-regularized CRFs (L_2-CRFs). We use the quasi-Newton method (Liu and Nocedal, 1989) and its variant (Andrew and Gao, 2007) to solve the optimization problem of CRFs, L_1-CRFs, and L_2-CRFs. For M^3N and LapMEDN, we use the exponentiated gradient method (Bartlett et al., 2004) to solve the dual QP problem; and we also use the sub-gradient method (Ratliff et al., 2007) to solve the corresponding primal problem. To the best of our knowledge, no formal description, implementation, and evaluation of the L_1-M^3N exist in the literature, therefore for comparison purpose we had to develop this model and algorithm anew. Details of our work along this line was reported in Zhu et al. (2009b), which is beyond the scope of this paper. But briefly, for our experiments on synthetic data, we implemented the constraint generating method (Tsochantaridis et al., 2004) which uses MOSEK to solve an equivalent LP re-formulation of L_1-M^3N. However, this approach is extremely slow on larger problems; therefore on real data we instead applied the sub-gradient method (Ratliff et al., 2007) with a projection to an L_1-ball (Duchi et al., 2008) to solve the larger L_1-M^3N based on the equivalent re-formulation with an L_1-norm constraint (i.e., the second formulation in Appendix A).

7.1 Evaluation on Synthetic Data

We first evaluate all the competing models on synthetic data where the true structured predictions are known. Here, we consider sequence data, that is, each input $\mathbf{x}$ is a sequence $(x_1, \ldots, x_L)$, and each component x_l is a d-dimensional vector of input features. The synthetic data are generated from pre-specified conditional random field models with either i.i.d. instantiations of the input features (i.e., elements in the d-dimensional feature vectors) or correlated (i.e., structured) instantiations of the input features, from which samples of the structured output $\mathbf{y}$, that is, a sequence $(y_1, \ldots, y_L)$, can be drawn from the conditional distribution $p(\mathbf{y}|\mathbf{x})$ defined by the CRF based on a Gibbs sampler.

7.1.1 I.I.D. INPUT FEATURES

The first experiment is conducted on synthetic sequence data with 100 i.i.d. input features (i.e., $d = 100$). We generate three types of data sets with 10, 30, and 50 relevant input features, respectively. For each type, we randomly generate 10 linear-chain CRFs with 8 binary labeling states (i.e., $L = 8$ and $\mathcal{Y}_l = \{0,1\}$). The feature functions include: a real valued state-feature function over a one dimensional input feature and a class label; and 4 (2×2) binary transition feature functions capturing pairwise label dependencies. For each model we generate a data set of 1000 samples. For each sample, we first *independently* draw the 100 input features from a standard normal distribution, and then apply a Gibbs sampler (based on the conditional distribution of the generated CRFs) to assign a labeling sequence with 5000 iterations.

For each data set, we randomly draw a subset as training data and use the rest for testing. The sizes of training set are 30, 50, 80, 100, and 150. The QP problem in M^{3}N and the first step of LapMEDN is solved with the exponentiated gradient method (Bartlett et al., 2004). In all the following experiments, the regularization constants of L_1-CRFs and L_2-CRFs are chosen from $\{0.01, 0.1, 1, 4, 9, 16\}$ by a 5-fold cross-validation during the training. For the LapMEDN, we use the same method to choose λ from 20 roughly evenly spaced values between 1 and 268. For each setting, a performance score is computed from the average over 10 random samples of data sets.

The results are shown in Figure 3. All the results of the LapMEDN are achieved with 3 iterations of the variational learning algorithm. From the results, we can see that under different settings LapMEDN consistently outperforms M^{3}N and performs comparably with L_1-CRFs and L_1-M^{3}N, both of which encourage a sparse estimate; and both the L_1-CRFs and L_2-CRFs outperform the un-regularized CRFs, especially in the cases where the number of training data is small. One interesting result is that the M^{3}N and L_2-CRFs perform comparably. This is reasonable because as derived by Lebanon and Lafferty (2001) and noted by Globerson et al. (2007) that the L_2-regularized maximum likelihood estimation of CRFs has a similar convex dual as that of the M^{3}N, and the only difference is the loss they try to optimize, that is, CRFs optimize the log-loss while M^{3}N optimizes the hinge-loss. Another interesting observation is that when there are very few relevant features, L_1-M^{3}N performs the best (slightly better than LapMEDN); but as the number of relevant features increases LapMEDN performs slightly better than the L_1-M^{3}N. Finally, as the number of training data increases, all the algorithms consistently achieve better performance.

7.1.2 CORRELATED INPUT FEATURES

In reality, most data sets contain redundancies and the input features are usually correlated. So, we evaluate our models on synthetic data sets with correlated input features. We take the similar procedure as in generating the data sets with i.i.d. features to first generate 10 linear-chain CRF models. Then, each CRF is used to generate a data set that contain 1000 instances, each with 100 input features of which 30 are relevant to the output. The 30 relevant input features are partitioned into 10 groups. For the features in each group, we first draw a real-value from a standard normal distribution and then corrupt the feature with a random Gaussian noise to get 3 correlated features. The noise Gaussian has a zero mean and standard variance 0.05. Here and in all the remaining experiments, we use the sub-gradient method (Ratliff et al., 2007) to solve the QP problem in both M^{3}N and the variational learning algorithm of LapMEDN. We use the learning rate and complexity constant that are suggested by the authors, that is, $\alpha_t = \frac{1}{2\beta\sqrt{t}}$ and $C = 200\beta$, where β is a parameter we introduced to adjust α_t and C. We do K-fold CV on each data set and take the average over the

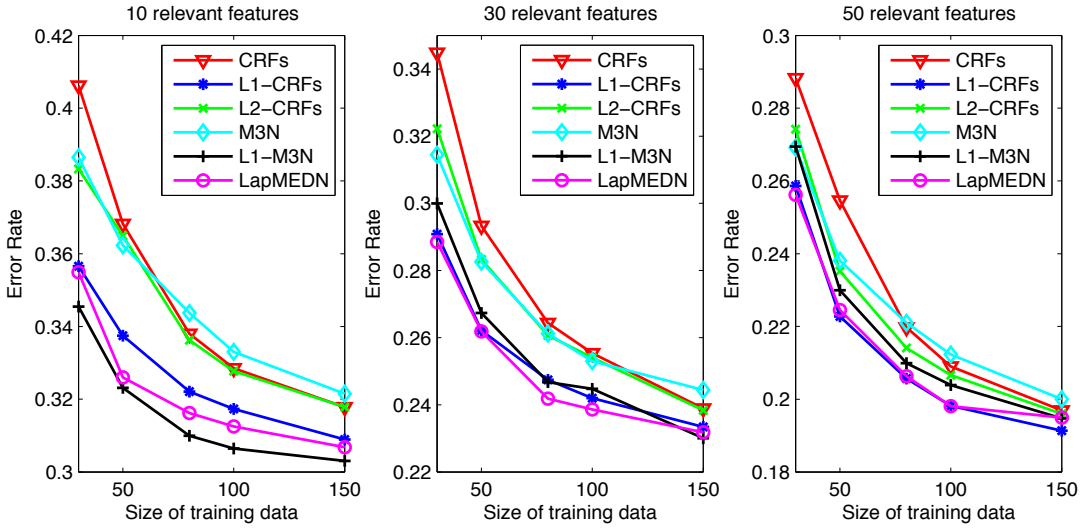


Figure 3: Evaluation results on data sets with i.i.d features.

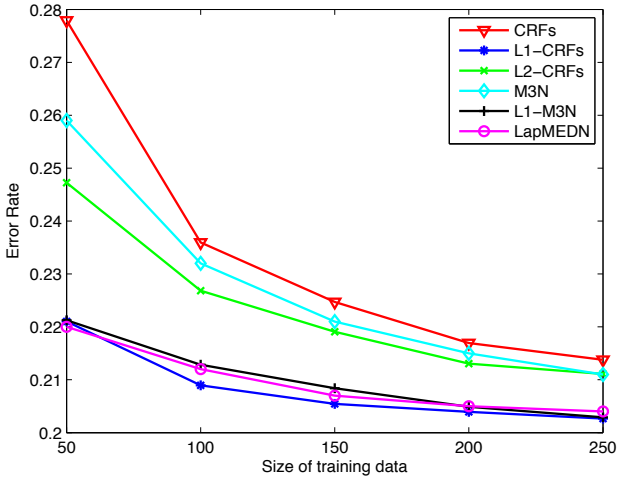

Figure 4: Results on data sets with 30 relevant features.

10 data sets as the final results. Like the method of Taskar et al. (2003), in each run we choose one part to do training and test on the rest K-1 parts. We vary K from 20, 10, 7, 5, to 4. In other words, we use 50, 100, about 150, 200, and 250 samples during the training. We use the same grid search to choose λ and β from $\{9, 16, 25, 36, 49, 64\}$ and $\{1, 10, 20, 30, 40, 50, 60\}$ respectively. Results are shown in Figure 4. We can get the same conclusions as in the previous results.

Figure 5 shows the true weights of the corresponding 200 state feature functions in the model that generates the first data set, and the average of estimated weights of these features under all competing models fitted from the first data set. All the averages are taken over 10 fold cross-validation. From the plots (2 to 7) of the average model weights, we can see that: for the last 140 state feature functions, which correspond to the last 70 irrelevant features, their average weights under LapMEDN (averaged posterior means $\mathbf{w}$ in this case), L_1-M^{3}N and L_1-CRFs are extremely small, while CRFs and L_2-CRFs can have larger values; for the first 60 state feature functions, which correspond to the 30 relevant features, the overall weight estimation under LapMEDN is similar to

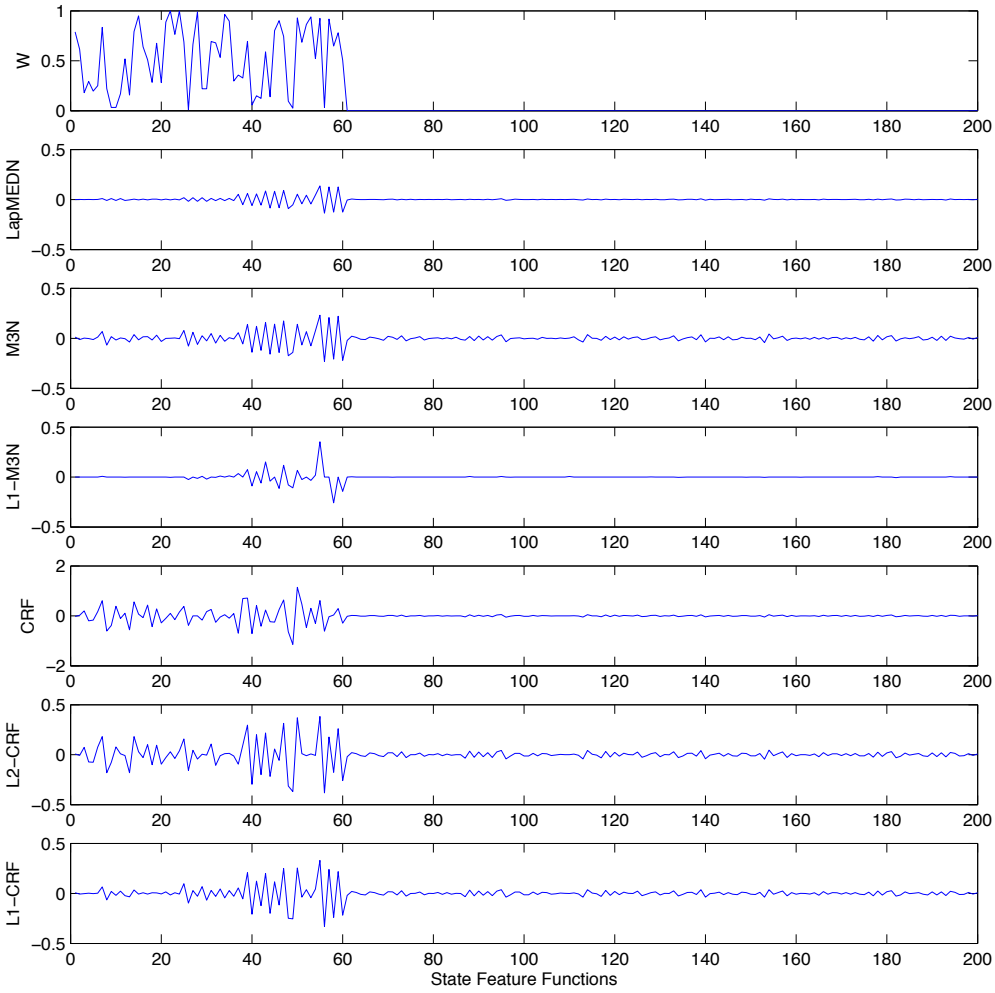

Figure 5: From top to bottom, plot 1 shows the weights of the state feature functions in the linear-chain CRF model from which the data are generated; plot 2 to plot 7 show the average weights of the learned LapMEDN, M^{3}N, L_1-M^{3}N, CRFs, L_2-CRFs, and L_1-CRFs over 10 fold CV, respectively.

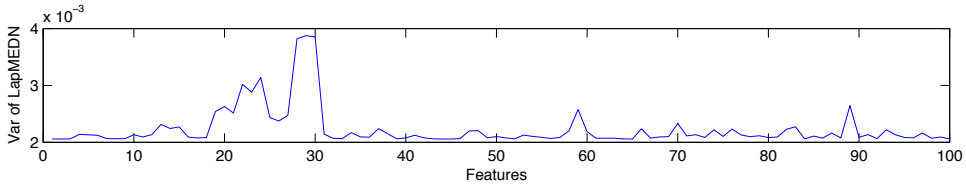

Figure 6: The average variances of the features on the first data set by LapMEDN.

that of the sparse L_1-CRFs and L_1-M^{3}N, but appear to exhibit more shrinkage. Noticeably, CRFs and L_2-CRFs both have more feature functions with large average weights. Note that all the models have quite different average weights from the model (see the first plot) that generates the data. This is because we use a stochastic procedure (i.e., Gibbs sampler) to assign labels to the generated data samples instead of using the labels that are predicted by the model that generates the data. In fact, if we use the model that generates the data to do prediction on its generated data, the error rate is about 0.5. Thus, the learned models, which get lower error rates, are different from the model that generates the data. Figure 6 shows the variances of the 100-dimensional input features (since the variances of the two feature functions that correspond to the same input feature are the same, we collapse each pair into one point) learned by LapMEDN. Again, the variances are the averages over 10 fold cross-validation. From the plot, we can see that the LapMEDN can recover the correlation among the features to some extend, e.g., for the first 30 correlated features, which are the relevant to the output, the features in the same group tend to have similar (average) variances in LapMEDN, whereas there is no such correlation among all the other features. From these observations in both Figure 5 and 6, we can conclude that LapMEDN can reasonably recover the sparse structures in the input data.

7.2 Real-World OCR Data Set

The OCR data set is partitioned into 10 subsets for 10-fold CV as in Taskar et al. (2003) and Ratliff et al. (2007). We randomly select N samples from each fold and put them together to do 10-fold CV. We vary N from 100, 150, 200, to 250, and denote the selected data sets by OCR100, OCR150, OCR200, and OCR250, respectively. On these data sets and the web data as in Section 7.4, our implementation of the cutting plane method for L_1-M^{3}N is extremely slow. The warm-start simplex method of MOSEK does not help either. For example, if we stop the algorithm with 600 iterations on OCR100, then it will take about 20 hours to finish the 10 fold CV. Even with more than 5 thousands of constraints in each training, the performance is still very bad (the error rate is about 0.45). Thus, we turn to an approximate projected sub-gradient method to solve the L_1-M^{3}N by combining the on-line subgradient method (Ratliff et al., 2007) and the efficient L_1-ball projection algorithm (Duchi et al., 2008). The projected sub-gradient method does not work so well as the cutting plane method on the synthetic data sets. That's why we use two different methods.

For $\beta = 4$ on OCR100 and OCR150, $\beta = 2$ on OCR200 and OCR250, and $\lambda = 36$, the results are shown in Figure 7. We can see that as the number of training instances increases, all the algorithms get lower error rates and smaller variances. Generally, the LapMEDN consistently outperforms all the other models. M^{3}N outperforms the standard, non-regularized, CRFs and the L_1-CRFs. Again, L_2-CRFs perform comparably with M^{3}N. This is a bit surprising but still reasonable due to the understanding of their only difference on the loss functions (Globerson et al., 2007) as we have stated. By examining the prediction accuracy during the learning, we can see an obvious over-fitting in CRFs and L_1-CRFs as shown in Figure 8. In contrast, L_2-CRFs are very robust. This is because unlike the synthetic data sets, features in real-world data are usually not completely irrelevant. In this case, putting small weights to zero as in L_1-CRFs will hurt generalization ability and also lead to instability to regularization constants as shown later. Instead, L_2-CRFs do not put small weights to zero but shrink them towards zero as in the LapMEDN. The non-regularized maximum likelihood estimation can easily lead to over-fitting too. For the two sparse models, the results suggest the

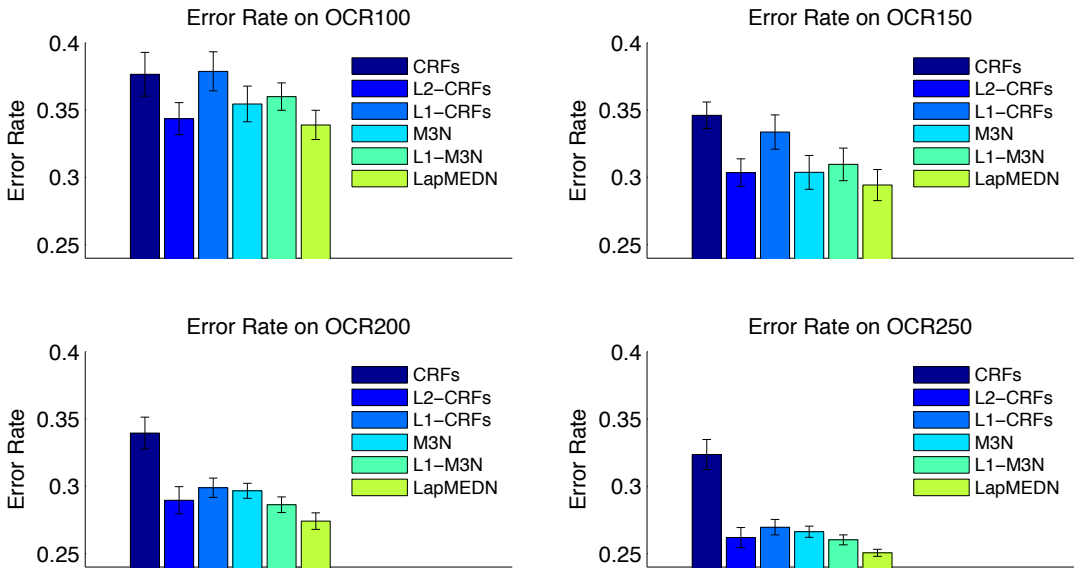

Figure 7: Evaluation results on OCR data set with different numbers of selected data.

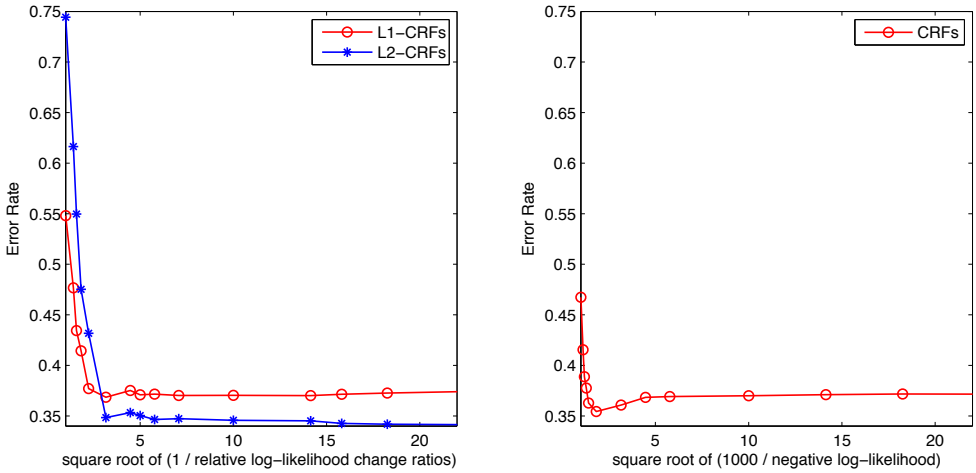

Figure 8: The error rates of CRF models on test data during the learning. For the left plot, the horizontal axis is $\sqrt{1/ratioLL}$, where *ratioLL* is the relative change ratios of the log-likelihood and from left to right, the change ratios are 1, 0.5, 0.4, 0.3, 0.2, 0.1, 0.05, 0.04, 0.03, 0.02, 0.01, 0.005, 0.004, 0.003, 0.002, 0.001, 0.0005, 0.0004, 0.0003, 0.0002, 0.0001, and 0.00005; for the right plot, the horizontal axis is $\sqrt{1000/negLL}$, where *negLL* is the negative log-likelihood, and from left to right *negLL* are 1000, 800, 700, 600, 500, 300, 100, 50, 30, 10, 5, 3, 1, 0.5, 0.3, 0.1, 0.05, 0.03, 0.01, 0.005, 0.003, and 0.002.

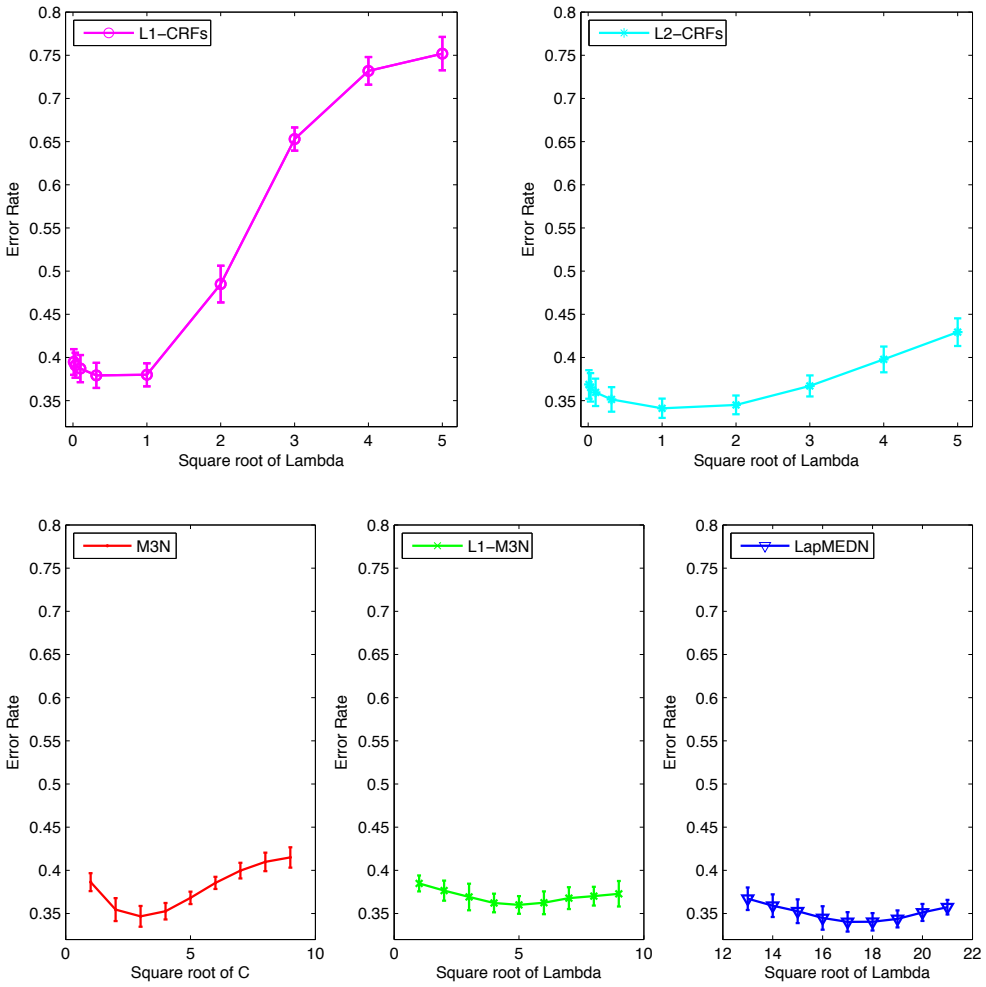

Figure 9: Error rates of different models on OCR100 with different regularization constants. The regularization constant is the parameter C for M^{3}N, and for all the other models, it is the parameter λ. From left to right, the regularization constants for the two regularized CRFs (above plot) are $0.0001, 0.001, 0.01, 0.1, 1, 4, 9, 16$, and 25; for M^3N and LapMEDN, the regularization constants are $k^2,\ 1 \leq k \leq 9$; and for L_1-M^{3}N, the constants are $k^2,\ 13 \leq k \leq 21$.

potential advantages of L_1-norm regularized M^{3}N, which are consistently better than the L_1-CRFs. Furthermore, as we shall see later, L_1-M^{3}N is more stable than the L_1-CRFs.

7.3 Sensitivity to Regularization Constants

Figure 9 shows the error rates of the models in question on the data set OCR100 over different magnitudes of the regularization constants. For M^{3}N, the regularization constant is the parameter

C, and for all the other models, the regularization constant is the parameter λ. When the λ changes, the parameter C in LapMEDN and L_1-M^{3}N is fixed at the unit 1.

From the results, we can see that the L_1-CRFs are quite sensitive to the regularization constants. However, L_2-CRFs, M^{3}N, L_1-M^{3}N and LapMEDN are much less sensitive. LapMEDN and L_1-M^{3}N are the most stable models. The stability of LapMEDN is due to the posterior weighting instead of hard-thresholding to set small weights to zero as in the L_1-CRFs. One interesting observation is that the max-margin based L_1-M^{3}N is much more stable compared to the L_1-norm regularized CRFs. One possible reason is that like LapMEDN, L_1-M^{3}N enjoys both the primal and dual sparsity, which makes it less sensitive to outliers; whereas the L_1-CRF is only primal sparse.

7.4 Real-World Web Data Extraction

The last experiments are conducted on the real world web data extraction as extensively studied by Zhu et al. (2008a). Web data extraction is a task to identify interested information from web pages. Each sample is a data record or an entire web page which is represented as a set of HTML elements. One striking characteristic of web data extraction is that various types of structural dependencies between HTML elements exist, e.g. the HTML tag tree or the Document Object Model (DOM) structure is itself hierarchical. In the work of Zhu et al. (2008a), hierarchical CRFs are shown to have great promise and achieve better performance than flat models like linear-chain CRFs (Lafferty et al., 2001). One method to construct a hierarchical model is to first use a parser to construct a so called vision tree. Then, based on the vision tree, a hierarchical model can be constructed accordingly to extract the interested attributes, e.g. a product's name, image, price, description, etc. See the paper (Zhu et al., 2008a) for an example of the vision tree and the corresponding hierarchical model. In such a hierarchical extraction model, inner nodes are useful to incorporate long distance dependencies, and the variables at one level are refinements of the variables at upper levels.

In these experiments,[6] we identify product items for sale on the Web. For each product item, four attributes—*Name*, *Image*, *Price*, and *Description* are extracted. We use the data set that is built with web pages generated by 37 different templates (Zhu et al., 2008a). For each template, there are 5 pages for training and 10 for testing. We evaluate all the methods on the *record level*, that is, we assume that data records are given, and we compare different models on the accuracy of extracting attributes in the given records. In the 185 training pages, there are 1585 data records in total; in the 370 testing pages, 3391 data records are collected. As for the evaluation criteria, we use the two comprehensive measures, that is, average F1 and block instance accuracy. As defined by Zhu et al. (2008a), average F1 is the average value of the F1 scores of the four attributes, and block instance accuracy is the percent of data records whose *Name*, *Image*, and *Price* are all correctly identified.

We randomly select $m = 5, 10, 15, 20, 30, 40, \text{or}, 50$ percent of the training records as training data, and test on all the testing records. For each m, 10 independent experiments were conducted and the average performance is summarized in Figure 10. From the results, we can see that all: first, the models (especially the max-margin models, that is, M^{3}N, L_1-M^{3}N, and LapMEDN) with regularization (i.e., L_1-norm, L_2-norm, or the entropic regularization of LapMEDN) can significantly outperform the un-regularized CRFs. Second, the max-margin models generally outperform the conditional likelihood-based models (i.e., CRFs, L_2-CRFs, and L_1-CRFs). Third, the LapMEDN perform comparably with the L_1-M^{3}N, which enjoys both dual and primal sparsity as the LapMEDN, and

6. These experiments are slightly different from those by Zhu et al. (2008a). Here, we introduce more general feature functions based on the content and visual features as used by Zhu et al. (2008a).

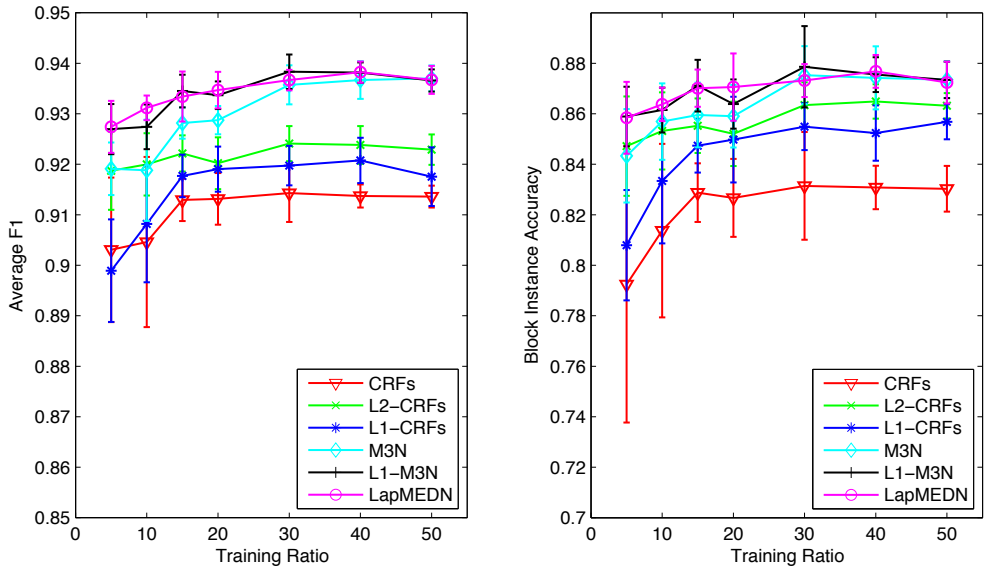

Figure 10: The average F1 values and block instance accuracy on web data extraction with different number of training data.

outperforms all other models, especially when the number of training data is small. Finally, as in the previous experiments on OCR data, the L_1-M^{3}N generally outperforms the L_1-CRFs, which suggests the potential promise of the max-margin based L_1-M^{3}N.

8. Related Work

Our work is motivated by the maximum entropy discrimination (MED) method proposed by Jaakkola et al. (1999), which integrates SVM and entropic regularization to obtain an averaging maximum margin model for classification. The MaxEnDNet model presented is essentially a structured version of MED built on M^{3}N—the so called "structured SVM". As we presented in this paper, this extension leads to a substantially more flexible and powerful new paradigm for structured discriminative learning and prediction, which enjoys a number of advantages such as model averaging, primal and dual sparsity, accommodation of latent generative structures, but at the same time raises new algorithmic challenges in inference and learning.

Related to our approach, a sparse Bayesian learning framework has been proposed to find sparse and robust solutions to regression and classification. One example along this line is the relevance vector machine (RVM) (Tipping, 2001). The RVM was proposed based on SVM. But unlike SVM which directly optimizes on the margins, RVM defines a likelihood function from the margins with a Gaussian distribution for regression and a logistic sigmoid link function for classification and then does *type-II maximum likelihood* estimation, that is, RVM maximizes the *marginal likelihood*. Although called *sparse Bayesian learning* (Figueiredo, 2001; Eyheramendy et al., 2003), as shown by Kaban (2007) the sparsity is actually due to the MAP estimation. The similar ambiguity of RVM is justified by Wipf et al. (2003). Unlike these approaches, we adhere to a full Bayesian-style principle and learn a distribution of predictive models by optimizing a generalized maximum entropy under a set of the *expected* margin constraints. By defining likelihood functions with margins, similar

Bayesian interpretations of both binary and multi-class SVM were studied by Sollich (2002) and Zhang and Jordan (2006).

The hierarchical interpretation of the Laplace prior has been explored in a number of contexts in the literature. Based on this interpretation, a Jeffrey's non-informative second-level hyper-prior was proposed by Figueiredo (2001), with an EM algorithm developed to find the MAP estimate. The advantage of the Jeffrey's prior is that it is parameter-free. But as shown by Eyheramendy et al. (2003) and Kaban (2007), usually no advantage is achieved by using the Jeffrey's hyper-prior over the Laplace prior. A gamma hyper-prior was used by Tipping (2001) in place of the second-level exponential as in the hierarchical interpretation of the Laplace prior.

To encourage sparsity in SVM, two strategies have been used. The first one is to replace the L_2-norm by an L_1-norm of the weights (Bennett and Mangasarian, 1992; Zhu et al., 2004). The second strategy is to explicitly add a cardinality constraint on the weights. This will lead to a hard non-convex optimization problem; thus relaxations must be applied (Chan et al., 2007). Under the maximum entropy discrimination models, feature selection was studied by Jebara and Jaakkola (2000) by introducing a set of structural variables. Recently, a smooth posterior shrinkage effect was shown by Jebara (2009), which is similar to our entropic regularization effect. However, an analysis of their connections and differences is still not obvious.

Although the parameter distribution $p(\mathbf{w})$ in Theorem 2 has a similar form as that of the Bayesian Conditional Random Fields (BCRFs) (Qi et al., 2005), MaxEnDNet is fundamentally different from BCRFs as we have stated. Dredze et al. (2008) present an interesting confidence-weighted linear classification method, which automatically estimates the mean and variance of model parameters in online learning. The procedure is similar to (but indeed different from) our variational Bayesian method of Laplace MaxEnDNet.

Finally, some of the results shown in this paper can be also found in our recent conference papers (Zhu et al., 2008b; Zhu and Xing, 2009).

9. Conclusions and Future Work

To summarize, we have presented a general theory of maximum entropy discrimination Markov networks for structured input/output learning and prediction. This formalism offers a formal paradigm for integrating both generative and discriminative principles and the Bayesian regularization techniques for learning structured prediction models. It subsumes popular methods such as support vector machines, maximum entropy discrimination models (Jaakkola et al., 1999), and maximum margin Markov networks as special cases, and therefore inherits all the merits of these techniques.

The MaxEnDNet model offers a number of important advantages over conventional structured prediction methods, including: 1) model averaging, which leads to a PAC-Bayesian bound on generalization error; 2) entropic regularization over max-margin learning, which can be leveraged to learn structured prediction models that are simultaneously primal and dual sparse; and 3) latent structures underlying the structured input/output variables, which enables better incorporation of domain knowledge in model design and semi-supervised learning based on partially labeled data. In this paper, we have discussed in detail the first two aspects, and the third aspect was explored in (Zhu et al., 2008c). We have also shown that certain instantiations of the MaxEnDNet model, such as the LapMEDN that achieves primal and dual sparsity, can be efficiently trained based on an iterative optimization scheme that employs existing techniques such as the variational Bayes approximation and the convex optimization procedures that solve the standard M^3N. We demonstrated that on syn-

thetic data the LapMEDN can recover the sparse model as well as the sparse L_1-regularized MAP estimation, and on real data sets LapMEDN can achieve superior performance.

Overall, we believe that the MaxEnDNet model can be extremely general and adaptive, and it offers a promising new framework for building more flexible, generalizable, and large scale structured prediction models that enjoy the benefits from both generative and discriminative modeling principles. While exploring novel instantiations of this model will be an interesting direction to pursue, development of more efficient learning algorithms, formulation of tighter but easy to solve convex relaxations, and adapting this model to challenging applications such as statistical machine translation, and structured associations of genome markers to complex disease traits could also lead to fruitful results. Finally, the basic principle of MaxEnDNet can be generalized to directed graphical models. The MedLDA model (Zhu et al., 2009a) for discriminative topic modeling represents our first successful attempt along this direction.

Appendix A. L_1-M^{3}N and its Lagrange-Dual

Based on the L_1-norm regularized SVM (Zhu et al., 2004; Bennett and Mangasarian, 1992), a straightforward formulation of L_1-M^{3}N is as follows,

$$\begin{aligned}&\min_{\mathbf{w},\xi} \ \frac{1}{2}\|\mathbf{w}\| + C\sum_{i=1}^{N}\xi_i \\ &\text{s.t.} \ \ \mathbf{w}^\top \Delta\mathbf{f}_i(\mathbf{y}) \geq \Delta\ell_i(\mathbf{y}) - \xi_i;\ \xi_i \geq 0,\ \forall i,\ \forall \mathbf{y} \neq \mathbf{y}^i\end{aligned}$$

where $\|.\|$ is the L_1-norm. $\Delta\mathbf{f}_i(\mathbf{y}) = \mathbf{f}(\mathbf{x}^i,\mathbf{y}^i) - \mathbf{f}(\mathbf{x}^i,\mathbf{y})$, and $\Delta\ell_i(\mathbf{y})$ is a loss function. Another equivalent formulation[7] is as follows:

$$\begin{aligned}&\min_{\mathbf{w},\xi} \ C\sum_{i=1}^{N}\xi_i \\ &\text{s.t.} \ \ \begin{cases} \|\mathbf{w}\| \leq \lambda \\ \mathbf{w}^\top \Delta\mathbf{f}_i(\mathbf{y}) \geq \Delta\ell_i(\mathbf{y}) - \xi_i;\ \xi_i \geq 0,\ \forall i,\ \forall \mathbf{y} \neq \mathbf{y}^i. \end{cases}\end{aligned}$$

7. See Taskar et al. (2006) for the transformation technique.

To derive the convex dual problem, we introduce a dual variable $\alpha_i(\mathbf{y})$ for each constraint in the former formulation and form the Lagrangian as follows,

$$L(\alpha, \mathbf{w}, \xi) = \frac{1}{2}\|\mathbf{w}\| + C\sum_{i=1}^{N}\xi_i - \sum_{i,\mathbf{y}\neq\mathbf{y}^i}\alpha_i(\mathbf{y})(\mathbf{w}^\top\Delta\mathbf{f}_i(\mathbf{y}) - \Delta\ell_i(\mathbf{y}) + \xi_i).$$

By definition, the Lagrangian dual is,

$$\begin{aligned} L^\star(\alpha) &= \inf_{\mathbf{w},\xi} L(\alpha, \mathbf{w}, \xi) \\ &= \inf_{\mathbf{w}}\Big[\frac{1}{2}\|\mathbf{w}\| - \sum_{i,\mathbf{y}\neq\mathbf{y}^i}\alpha_i(\mathbf{y})\mathbf{w}^\top\Delta\mathbf{f}_i(\mathbf{y})\Big] + \inf_{\xi}\Big[C\sum_{i=1}^{N}\xi_i - \sum_{i,\mathbf{y}\neq\mathbf{y}^i}\alpha_i(\mathbf{y})\xi_i\Big] + \ell \\ &= -\sup_{\mathbf{w}}\Big[\mathbf{w}^\top(\sum_{i,\mathbf{y}\neq\mathbf{y}^i}\alpha_i(\mathbf{y})\Delta\mathbf{f}_i(\mathbf{y})) - \frac{1}{2}\|\mathbf{w}\|\Big] - \sup_{\xi}\Big[\sum_{i,\mathbf{y}\neq\mathbf{y}^i}\alpha_i(\mathbf{y})\xi_i - C\sum_{i=1}^{N}\xi_i\Big] + \ell, \end{aligned}$$

where $\ell = \sum_{i,\mathbf{y}\neq\mathbf{y}^i}\alpha_i(\mathbf{y})\Delta\ell_i(\mathbf{y})$.

Again, by definition, the first term on the right-hand side is the convex conjugate of $\phi(\mathbf{w}) = \frac{1}{2}\|\mathbf{w}\|$ and the second term is the conjugate of $U(\xi) = C\sum_{i=1}^{N}\xi_i$. It is easy to show that,

$$\phi^\star(\alpha) = \mathbb{I}_\infty(|\sum_{i,\mathbf{y}\neq\mathbf{y}^i}\alpha_i(\mathbf{y})\Delta\mathbf{f}_i^k(\mathbf{y})| \leq \frac{1}{2},\ \forall 1 \leq k \leq K),$$

and

$$U^\star(\alpha) = \mathbb{I}_\infty(\sum_{\mathbf{y}\neq\mathbf{y}^i}\alpha_i(\mathbf{y}) \leq C,\ \forall i),$$

where as defined before $\mathbb{I}_\infty(\cdot)$ is an indicator function that equals zero when its argument is true and infinity otherwise. $\Delta\mathbf{f}_i^k(\mathbf{y}) = f_k(\mathbf{x}^i, \mathbf{y}^i) - f_k(\mathbf{x}^i, \mathbf{y})$.

Therefore, we get the dual problem as follows,

$$\begin{aligned} \max_{\alpha}\ & \sum_{i,\mathbf{y}\neq\mathbf{y}^i}\alpha_i(\mathbf{y})\Delta\ell_i(\mathbf{y}) \\ \text{s.t. }\ & |\sum_{i,\mathbf{y}\neq\mathbf{y}^i}\alpha_i(\mathbf{y})\Delta\mathbf{f}_i^k(\mathbf{y})| \leq \frac{1}{2},\ \forall k \\ & \sum_{\mathbf{y}\neq\mathbf{y}^i}\alpha_i(\mathbf{y}) \leq C,\ \forall i. \end{aligned}$$

Appendix B. Proofs of Theorems and Corollaries

In this section, we prove the theorems and corollaries.

B.1 Proof of Theorem 2

Proof As we have stated, P1 is a convex program and satisfies the Slater's condition. To compute its convex dual, we introduce a non-negative dual variable $\alpha_i(\mathbf{y})$ for each constraint in $\mathcal{F}_1$ and another

non-negative dual variable c for the normalization constraint $\int p(\mathbf{w})\,\mathrm{d}\mathbf{w} = 1$. This gives rise to the following Lagrangian:

$$\begin{aligned} L(p(\mathbf{w}),\xi,\alpha,c) \quad &= KL(p(\mathbf{w})||p_0(\mathbf{w})) + U(\xi) + c(\int p(\mathbf{w})\,\mathrm{d}\mathbf{w} - 1) \\ &- \sum_{i,\mathbf{y}\neq\mathbf{y}^i} \alpha_i(\mathbf{y})(\int p(\mathbf{w})[\Delta F_i(\mathbf{y};\mathbf{w}) - \Delta\ell_i(\mathbf{y})]\,\mathrm{d}\mathbf{w} + \xi_i). \end{aligned}$$

The Lagrangian dual function is defined as $L^\star(\alpha,c) \triangleq \inf_{p(\mathbf{w});\xi} L(p(\mathbf{w}),\xi,\alpha,c)$. Taking the derivative of L w.r.t $p(\mathbf{w})$, we get,

$$\frac{\partial L}{\partial p(\mathbf{w})} = 1 + c + \log\frac{p(\mathbf{w})}{p_0(\mathbf{w})} - \sum_{i,\mathbf{y}\neq\mathbf{y}^i} \alpha_i(\mathbf{y})[\Delta F_i(\mathbf{y};\mathbf{w}) - \Delta\ell_i(\mathbf{y})].$$

Setting the derivative to zero, we get the following expression of distribution $p(\mathbf{w})$,

$$p(\mathbf{w}) = \frac{1}{Z(\alpha)} p_0(\mathbf{w}) \exp\{\sum_{i,\mathbf{y}\neq\mathbf{y}^i} \alpha_i(\mathbf{y})[\Delta F_i(\mathbf{y};\mathbf{w}) - \Delta\ell_i(\mathbf{y})]\},$$

where $Z(\alpha) \triangleq \int p_0(\mathbf{w}) \exp\{\sum_{i,\mathbf{y}\neq\mathbf{y}^i} \alpha_i(\mathbf{y})[\Delta F_i(\mathbf{y};\mathbf{w}) - \Delta\ell_i(\mathbf{y})]\}\,\mathrm{d}\mathbf{w}$ is a normalization constant and $c = -1 + \log Z(\alpha)$.

Substituting $p(\mathbf{w})$ into $L^\star$, we obtain,

$$\begin{aligned} L^\star(\alpha,c) &= \inf_{p(\mathbf{w});\xi} (-\log Z(\alpha) + U(\xi) - \sum_{i,\mathbf{y}\neq\mathbf{y}^i} \alpha_i(\mathbf{y})\xi_i) \\ &= -\log Z(\alpha) + \inf_{\xi} (U(\xi) - \sum_{i,\mathbf{y}\neq\mathbf{y}^i} \alpha_i(\mathbf{y})\xi_i) \\ &= -\log Z(\alpha) - \sup_{\xi} (\sum_{i,\mathbf{y}\neq\mathbf{y}^i} \alpha_i(\mathbf{y})\xi_i - U(\xi)) \\ &= -\log Z(\alpha) - U^\star(\alpha), \end{aligned}$$

which is the objective in the dual problem D1. The $\{\alpha_i(\mathbf{y})\}$ derived from D1 lead to the optimum $p(\mathbf{w})$ according to Equation (3). ■

B.2 Proof of Theorem 3

Proof Replacing $p_0(\mathbf{w})$ and $\Delta F_i(\mathbf{y};\mathbf{w})$ in Equation (3) with $\mathcal{N}(\mathbf{w}|0,I)$ and $\mathbf{w}^\top \Delta\mathbf{f}_i(\mathbf{y})$ respectively, we can obtain the following closed-form expression of the $Z(\alpha)$ in $p(\mathbf{w})$:

$$\begin{aligned} Z(\alpha) \quad &\triangleq \int \mathcal{N}(\mathbf{w}|0,I) \exp\Big\{\sum_{i,\mathbf{y}\neq\mathbf{y}^i} \alpha_i(\mathbf{y})[\mathbf{w}^\top \Delta\mathbf{f}_i(\mathbf{y}) - \Delta\ell_i(\mathbf{y})]\Big\}\,\mathrm{d}\mathbf{w} \\ &= \int (2\pi)^{-\frac{K}{2}} \exp\Big\{-\frac{1}{2}\mathbf{w}^\top\mathbf{w} + \sum_{i,\mathbf{y}\neq\mathbf{y}^i} \alpha_i(\mathbf{y})[\mathbf{w}^\top \Delta\mathbf{f}_i(\mathbf{y}) - \Delta\ell_i(\mathbf{y})]\Big\}\,\mathrm{d}\mathbf{w} \\ &= \exp\Big(-\sum_{i,\mathbf{y}\neq\mathbf{y}^i} \alpha_i(\mathbf{y})\Delta\ell_i(\mathbf{y}) + \frac{1}{2}\|\sum_{i,\mathbf{y}\neq\mathbf{y}^i} \alpha_i(\mathbf{y})\Delta\mathbf{f}_i(\mathbf{y})\|^2\Big). \end{aligned}$$

Substituting the normalization factor into the general dual problem D1, we get the dual problem of Gaussian MaxEnDNet. As we have stated, the constraints $\sum_{\mathbf{y}\neq\mathbf{y}^i}\alpha_i(\mathbf{y}) = C$ are due to the conjugate of $U(\xi) = C\sum_i \xi_i$.

For prediction, again replacing $p_0(\mathbf{w})$ and $\Delta F_i(\mathbf{y};\mathbf{w})$ in Equation (3) with $\mathcal{N}(\mathbf{w}|0,I)$ and $\mathbf{w}^\top\Delta\mathbf{f}_i(\mathbf{y})$ respectively, we can get $p(\mathbf{w}) = \mathcal{N}(\mathbf{w}|\mu,I)$, where $\mu = \sum_{i,\mathbf{y}\neq\mathbf{y}^i}\alpha_i(\mathbf{y})\Delta\mathbf{f}_i(\mathbf{y})$. Substituting $p(\mathbf{w})$ into the predictive function h_1, we can get $h_1(\mathbf{x}) = \arg\max_{\mathbf{y}\in\mathcal{Y}(\mathbf{x})}\mu^\top\mathbf{f}(\mathbf{x},\mathbf{y}) = (\sum_{i,\mathbf{y}\neq\mathbf{y}^i}\alpha_i(\mathbf{y})\Delta\mathbf{f}_i(\mathbf{y}))^\top\mathbf{f}(\mathbf{x},\mathbf{y})$, which is identical to the prediction rule of the standard M^{3}N (Taskar et al., 2003) because the dual parameters are achieved by solving the same dual problem. ■

B.3 Proof of Corollary 4

Proof Suppose $(p^\star(\mathbf{w}),\xi^\star)$ is the optimal solution of P1, then we have: for any $(p(\mathbf{w}),\xi),\ p(\mathbf{w}) \in \mathcal{F}_1$ and $\xi \geq 0$,

$$KL(p^\star(\mathbf{w})||p_0(\mathbf{w})) + U(\xi^\star) \leq KL(p(\mathbf{w})||p_0(\mathbf{w})) + U(\xi).$$

From Theorem 3, we conclude that the optimum predictive parameter distribution is $p^\star(\mathbf{w}) = \mathcal{N}(\mathbf{w}|\mu^\star,I)$. Since $p_0(\mathbf{w})$ is also normal, for any distribution $p(\mathbf{w}) = \mathcal{N}(\mathbf{w}|\mu,I)$[8] with several steps of algebra it is easy to show that $KL(p(\mathbf{w})|p_0(\mathbf{w})) = \frac{1}{2}\mu^\top\mu$. Thus, we can get: for any $(\mu,\xi),\ \mu \in \{\mu:\ \mu^\top\Delta\mathbf{f}_i(\mathbf{y}) \geq \Delta\ell_i(\mathbf{y}) - \xi_i,\ \forall i,\ \forall\mathbf{y}\neq\mathbf{y}^i\}$ and $\xi \geq 0$,

$$\frac{1}{2}(\mu^\star)^\top(\mu^\star) + U(\xi^\star) \leq \frac{1}{2}\mu^\top\mu + U(\xi^\star),$$

which means the mean of the optimum posterior distribution under a Gaussian MaxEnDNet is achieved by solving a primal problem as stated in the Corollary. ■

B.4 Proof of Corollary 6

Proof The proof follows the same structure as the above proof of Corollary 4. Here, we only present the derivation of the KL-divergence under the Laplace MaxEnDNet.

Theorem 2 shows that the general posterior distribution is $p(\mathbf{w}) = \frac{1}{Z(\alpha)}p_0(\mathbf{w})\exp(\mathbf{w}^\top\eta - \sum_{i,\mathbf{y}\neq\mathbf{y}^i}\alpha_i(\mathbf{y})\Delta\ell_i(\mathbf{y}))$ and $Z(\alpha) = \exp(-\sum_{i,\mathbf{y}\neq\mathbf{y}^i}\alpha_i(\mathbf{y})\Delta\ell_i(\mathbf{y}))\prod_{k=1}^K\frac{\lambda}{\lambda-\eta_k^2}$ for the Laplace MaxEnDNet as shown in Equation (5). Use the definition of KL-divergence and we can get:

$$KL(p(\mathbf{w})|p_0(\mathbf{w})) = \langle\mathbf{w}\rangle_p^\top\eta - \sum_{k=1}^K\log\frac{\lambda}{\lambda-\eta_k^2} = \sum_{k=1}^K\mu_k\eta_k - \sum_{k=1}^K\log\frac{\lambda}{\lambda-\eta_k^2},$$

Corollary 7 shows that $\mu_k = \frac{2\eta_k}{\lambda-\eta_k^2},\ \forall 1\leq k\leq K$. Thus, we get $\frac{\lambda}{\lambda-\eta_k^2} = \frac{\lambda\mu_k}{2\eta_k}$ and a set of equations: $\mu_k\eta_k^2 + 2\eta_k - \lambda\mu_k = 0,\ \forall 1\leq k\leq K$. To solve these equations, we consider two cases. First, if $\mu_k = 0$, then $\eta_k = 0$. Second, if $\mu_k \neq 0$, then we can solve the quadratic equation to get

8. Although $\mathcal{F}_1$ is much richer than the set of normal distributions with an identity covariance matrix, Theorem 3 shows that the solution is a restricted normal distribution. Thus, it suffices to consider only these normal distributions in order to learn the mean of the optimum distribution. The similar argument applies to the proof of Corollary 6.

η_k: $\eta_k = \frac{-1\pm\sqrt{1+\lambda\mu_k^2}}{\mu_k}$. The second solution includes the first one since we can show that when $\mu_k \to 0$, $\frac{-1\pm\sqrt{1+\lambda\mu_k^2}}{\mu_k} \to 0$ by using the *L'Hospital's Rule*. Thus, we get:

$$\mu_k\eta_k = -1 \pm \sqrt{\lambda\mu_k^2+1}.$$

Since $\eta_k^2 < \lambda$ (otherwise the problem is not bounded), $\mu_k\eta_k$ is always positive. Thus, only the solution $\mu_k\eta_k = -1+\sqrt{1+\lambda\mu_k^2}$ is feasible. So, we get:

$$\frac{\lambda}{\lambda-\eta_k^2} = \frac{\lambda\mu_k^2}{2(\sqrt{\lambda\mu_k^2+1}-1)} = \frac{\sqrt{\lambda\mu_k^2+1}+1}{2},$$

and

$$\begin{aligned} KL(p(\mathbf{w})|p_0(\mathbf{w})) &= \sum_{k=1}^{K}\Big(\sqrt{\lambda\mu_k^2+1} - \log\frac{\sqrt{\lambda\mu_k^2+1}+1}{2}\Big) - K \\ &= \sqrt{\lambda}\sum_{k=1}^{K}\Big(\sqrt{\mu_k^2+\frac{1}{\lambda}} - \frac{1}{\sqrt{\lambda}}\log\frac{\sqrt{\lambda\mu_k^2+1}+1}{2}\Big) - K. \end{aligned}$$

Applying the same arguments as in the above proof of Corollary 4 and using the above result of the KL-divergence, we get the problem in Corollary 6, where the constant $-K$ is ignored. The margin constraints defined with the mean μ are due to the linearity assumption of the discriminant functions. ■

B.5 Proof of Theorem 8

We follow the same structure as the proof of PAC-Bayes bound for binary classifier (Langford et al., 2001) and employ the similar technique to generalize to multi-class problems (Schapire et al., 1998). Recall that the output space is $\mathcal{Y}$, and the base discriminant function is $F(\,\cdot\,;\mathbf{w}) \in \mathcal{H} : \mathcal{X}\times\mathcal{Y} \to [-c,c]$, where $c>0$ is a constant. Our averaging model is specified by $h(\mathbf{x},\mathbf{y}) = \langle F(\mathbf{x},\mathbf{y};\mathbf{w})\rangle_{p(\mathbf{w})}$. We define the margin of an example $(\mathbf{x},\mathbf{y})$ for such a function h as,

$$M(h,\mathbf{x},\mathbf{y}) = h(\mathbf{x},\mathbf{y}) - \max_{\mathbf{y}'\neq\mathbf{y}} h(\mathbf{x},\mathbf{y}'). \tag{12}$$

Thus, the model h makes a wrong prediction on $(\mathbf{x},\mathbf{y})$ only if $M(h,\mathbf{x},\mathbf{y}) \le 0$. Let Q be a distribution over $\mathcal{X}\times\mathcal{Y}$, and let $\mathcal{D}$ be a sample of N examples independently and randomly drawn from Q. With these definitions, we have the PAC-Bayes theorem. For easy reading, we copy the theorem in the following:

Theorem 8 (PAC-Bayes Bound of MaxEnDNet) *Let p_0 be any continuous probability distribution over $\mathcal{H}$ and let $\delta\in(0,1)$. If $F(\,\cdot\,;\mathbf{w}) \in \mathcal{H}$ is bounded by $\pm c$ as above, then with probability*

at least $1-\delta$*, for a random sample* $\mathcal{D}$ *of* N *instances from* Q*, for every distribution* p *over* $\mathcal{H}$*, and for all margin thresholds* $\gamma > 0$*:*

$$\Pr_Q(M(h,\mathbf{x},\mathbf{y}) \leq 0) \leq \Pr_{\mathcal{D}}(M(h,\mathbf{x},\mathbf{y}) \leq \gamma) + O\Big(\sqrt{\frac{\gamma^{-2}KL(p||p_0)\ln(N|\mathcal{Y}|) + \ln N + \ln \delta^{-1}}{N}}\Big),$$

where $\Pr_Q(.)$ *and* $\Pr_{\mathcal{D}}(.)$ *represent the probabilities of events over the true distribution* Q*, and over the empirical distribution of* $\mathcal{D}$*, respectively.*

Proof Let m be any natural number. For every distribution p, we independently draw m base models (i.e., discriminant functions) $F_i \sim p$ at random. We also independently draw m variables $\mu_i \sim U([-c,c])$, where U denote the uniform distribution. We define the binary functions $g_i : \mathcal{X} \times \mathcal{Y} \to \{-c,+c\}$ by:

$$g_i(\mathbf{x},\mathbf{y};F_i,\mu_i) = 2cI(\mu_i < F_i(\mathbf{x},\mathbf{y})) - c.$$

With the F_i, μ_i, and g_i, we define $\mathcal{H}_m$ as,

$$\mathcal{H}_m = \{f : (\mathbf{x},\mathbf{y}) \mapsto \frac{1}{m}\sum_{i=1}^{m} g_i(\mathbf{x},\mathbf{y};F_i,\mu_i) | F_i \in \mathcal{H}, \mu_i \in [-c,c]\}.$$

We denote the distribution of f over the set $\mathcal{H}_m$ by p^m. For a fixed pair $(\mathbf{x},\mathbf{y})$, the quantities $g_i(\mathbf{x},\mathbf{y};F_i,\mu_i)$ are i.i.d bounded random variables with the mean:

$$\begin{aligned}
\langle g_i(\mathbf{x},\mathbf{y};F_i,\mu_i)\rangle_{F_i\sim p,\mu_i\sim U[-c,c]} &= \langle (+c)p[\mu_i \leq F_i(\mathbf{x},\mathbf{y})|F_i] + (-c)p[\mu_i > F_i(\mathbf{x},\mathbf{y})|F_i]\rangle_{F_i\sim p} \\
&= \langle \frac{1}{2c}c(c+F_i(\mathbf{x},\mathbf{y})) - \frac{1}{2c}c(c-F_i(\mathbf{x},\mathbf{y}))\rangle_{F_i\sim p} \\
&= h(\mathbf{x},\mathbf{y}).
\end{aligned}$$

Therefore, $\langle f(\mathbf{x},\mathbf{y})\rangle_{f\sim p^m} = h(\mathbf{x},\mathbf{y})$. Since $f(\mathbf{x},\mathbf{y})$ is the average over m i.i.d bounded variables, Hoeffding's inequality applies. Thus, for every $(\mathbf{x},\mathbf{y})$,

$$\Pr_{f\sim p^m}[f(\mathbf{x},\mathbf{y}) - h(\mathbf{x},\mathbf{y}) > \xi] \leq e^{-\frac{m}{2c^2}\xi^2}.$$

For any two events A and B, we have the inequality,

$$\Pr(A) = \Pr(A,B) + \Pr(A,\bar{B}) \leq \Pr(B) + \Pr(\bar{B}|A).$$

Thus, for any $\gamma > 0$ we have

$$\Pr_Q[M(h,\mathbf{x},\mathbf{y}) \leq 0] \leq \Pr_Q[M(f,\mathbf{x},\mathbf{y}) \leq \frac{\gamma}{2}] + \Pr_Q[M(f,\mathbf{x},\mathbf{y}) > \frac{\gamma}{2} | M(h,\mathbf{x},\mathbf{y}) \leq 0], \tag{13}$$

where the left hand side does not depend on f. We take the expectation w.r.t $f \sim p^m$ on both sides and can get

$$\Pr_Q[M(h,\mathbf{x},\mathbf{y}) \leq 0] \leq \quad \langle \Pr_Q[M(f,\mathbf{x},\mathbf{y}) \leq \frac{\gamma}{2}] \rangle_{f\sim p^m} + \langle \Pr_Q[M(f,\mathbf{x},\mathbf{y}) > \frac{\gamma}{2} | M(h,\mathbf{x},\mathbf{y}) \leq 0] \rangle_{f\sim p^m}. \tag{14}$$

Fix $h, \mathbf{x}$, and $\mathbf{y}$, and let $\mathbf{y}'$ achieve the margin in (12). Then, we get

$$M(h,\mathbf{x},\mathbf{y}) = h(\mathbf{x},\mathbf{y}) - h(\mathbf{x},\mathbf{y}'), \text{ and } M(f,\mathbf{x},\mathbf{y}) \leq f(\mathbf{x},\mathbf{y}) - f(\mathbf{x},\mathbf{y}').$$

With these two results, since $\langle f(\mathbf{x},\mathbf{y}) - f(\mathbf{x},\mathbf{y}') \rangle_{f\sim p^m} = h(\mathbf{x},\mathbf{y}) - h(\mathbf{x},\mathbf{y}')$, we can get

$$\begin{aligned}
\langle \Pr_Q[M(f,\mathbf{x},\mathbf{y}) > \frac{\gamma}{2} | M(h,\mathbf{x},\mathbf{y}) \leq 0] \rangle_{f\sim p^m} &= \langle \Pr_{f\sim p^m}[M(f,\mathbf{x},\mathbf{y}) > \frac{\gamma}{2} | M(h,\mathbf{x},\mathbf{y}) \leq 0] \rangle_Q \\
&\leq \langle \Pr_{f\sim p^m}[f(\mathbf{x},\mathbf{y}) - f(\mathbf{x},\mathbf{y}') > \frac{\gamma}{2} | M(h,\mathbf{x},\mathbf{y}) \leq 0] \rangle_Q \\
&\leq \langle \Pr_{f\sim p^m}[f(\mathbf{x},\mathbf{y}) - f(\mathbf{x},\mathbf{y}') - M(h,\mathbf{x},\mathbf{y}) > \frac{\gamma}{2}] \rangle_Q \\
&\leq e^{-\frac{m\gamma^2}{32c^2}},
\end{aligned} \tag{15}$$

where the first two inequalities are due to the fact that if two events $A \subseteq B$, then $p(A) \leq p(B)$, and the last inequality is due to the Hoeffding's inequality.

Substitute (15) into (14), and we get,

$$\Pr_Q[M(h,\mathbf{x},\mathbf{y}) \leq 0] \leq \langle \Pr_Q[M(f,\mathbf{x},\mathbf{y}) \leq \frac{\gamma}{2}] \rangle_{f\sim p^m} + e^{-\frac{m\gamma^2}{32c^2}}. \tag{16}$$

Let p_0^m be a prior distribution on $\mathcal{H}_m$. p_0^m is constructed from p_0 over $\mathcal{H}$ exactly as p^m is constructed from p. Then, $KL(p^m||p_0^m) = mKL(p||p_0)$. By the PAC-Bayes theorem (McAllester, 1999), with probability at least $1-\delta$ over sample $\mathcal{D}$, the following bound holds for any distribution p,

$$\langle \Pr_Q[M(f,\mathbf{x},\mathbf{y}) \leq \frac{\gamma}{2}] \rangle_{f\sim p^m} \leq \langle \Pr_{\mathcal{D}}[M(f,\mathbf{x},\mathbf{y}) \leq \frac{\gamma}{2}] \rangle_{f\sim p^m} + \sqrt{\frac{mKL(p||p_0) + \ln N + \ln \delta^{-1} + 2}{2N-1}}. \tag{17}$$

By the similar statement as in (13), for every $f \in \mathcal{H}_m$ we have,

$$\Pr_{\mathcal{D}}[M(f,\mathbf{x},\mathbf{y}) \leq \frac{\gamma}{2}] \leq \Pr_{\mathcal{D}}[M(h,\mathbf{x},\mathbf{y}) \leq \gamma] + \Pr_{\mathcal{D}}[M(f,\mathbf{x},\mathbf{y}) \leq \frac{\gamma}{2} | M(h,\mathbf{x},\mathbf{y}) > \gamma].$$

Taking the expectation at both sides w.r.t $f \sim p^m$, we can get

$$\begin{aligned}\langle \Pr_{\mathcal{D}}[M(f,\mathbf{x},\mathbf{y}) \leq \frac{\gamma}{2}] \rangle_{f\sim p^m} \quad &\leq \Pr_{\mathcal{D}}[M(h,\mathbf{x},\mathbf{y}) \leq \gamma] \\ &+ \langle \Pr_{\mathcal{D}}[M(f,\mathbf{x},\mathbf{y}) \leq \frac{\gamma}{2} | M(h,\mathbf{x},\mathbf{y}) > \gamma] \rangle_{f\sim p^m}, \end{aligned} \tag{18}$$

where the second term at the right hand side equals to $\langle \Pr_{f\sim p^m}[M(f,\mathbf{x},\mathbf{y}) \leq \frac{\gamma}{2} | M(h,\mathbf{x},\mathbf{y}) > \gamma] \rangle_{(\mathbf{x},\mathbf{y})\sim\mathcal{D}}$ by exchanging the orders of expectations, and we can get

$$\begin{aligned}\Pr_{f\sim p^m}\left[M(f,\mathbf{x},\mathbf{y}) \leq \frac{\gamma}{2} | M(h,\mathbf{x},\mathbf{y}) > \gamma\right] \quad &= \Pr_{f\sim p^m}\left[\exists \mathbf{y}' \neq \mathbf{y} : \Delta f(\mathbf{x},\mathbf{y}') \leq \frac{\gamma}{2} | \forall \mathbf{y}' \neq \mathrm{y} : \Delta h(\mathbf{x},\mathbf{y}') > \gamma\right] \\ &\leq \Pr_{f\sim p^m}\left[\exists \mathbf{y}' \neq \mathbf{y} : \Delta f(\mathbf{x},\mathbf{y}') \leq \frac{\gamma}{2} | \Delta h(\mathbf{x},\mathbf{y}') > \gamma\right] \\ &\leq \sum_{\mathbf{y}'\neq\mathbf{y}} \Pr_{f\sim p^m}\left[\Delta f(\mathbf{x},\mathbf{y}') \leq \frac{\gamma}{2} | \Delta h(\mathbf{x},\mathbf{y}') > \gamma\right] \\ &\leq (|\mathcal{Y}|-1) e^{-\frac{m\gamma^2}{32c^2}}, \end{aligned} \tag{19}$$

where we use $\Delta f(\mathbf{x},\mathbf{y}')$ to denote $f(\mathbf{x},\mathbf{y}) - f(\mathbf{x},\mathbf{y}')$, and use $\Delta h(\mathbf{x},\mathbf{y}')$ to denote $h(\mathbf{x},\mathbf{y}) - h(\mathbf{x},\mathbf{y}')$.

Put (16), (17), (18), and (19) together, then we get following bound holding for any fixed m and $\gamma > 0$,

$$\Pr_Q[M(h,\mathbf{x},\mathbf{y}) \leq 0] \quad \leq \Pr_{\mathcal{D}}[M(h,\mathbf{x},\mathbf{y}) \leq \gamma] + |\mathcal{Y}| e^{-\frac{m\gamma^2}{32c^2}} + \sqrt{\frac{mKL(p||p_0) + \ln N + \ln \delta^{-1} + 2}{2N-1}}.$$

To finish the proof, we need to remove the dependence on m and γ. This can be done by applying the union bound. By the definition of f, it is obvious that if $f \in \mathcal{H}_m$ then $f(\mathbf{x},\mathbf{y}) \in \{(2k-m)c/m : k = 0,1,\ldots,m\}$. Thus, even though γ can be any positive value, there are no more than $m+1$ events of the form $\{M(f,\mathbf{x},\mathbf{y}) \leq \gamma/2\}$. Since only the application of PAC-Bayes theorem in (17) depends on (m,γ) and all the other steps are true with probability one, we just need to consider the union of countably many events. Let $\delta_{m,k} = \delta/(m(m+1)^2)$, then the union of all the possible events has a probability at most $\sum_{m,k}\delta_{m,k} = \sum_m (m+1)\delta/(m(m+1)^2) = \delta$. Therefore, with probability at least $1-\delta$ over random samples of $\mathcal{D}$, the following bound holds for all m and all $\gamma > 0$,

$$\begin{aligned}\Pr_Q[M(h,\mathbf{x},\mathbf{y}) \leq 0] - \Pr_{\mathcal{D}}[M(h,\mathbf{x},\mathbf{y}) \leq \gamma] \quad &\leq |\mathcal{Y}| e^{-\frac{m\gamma^2}{32c^2}} + \sqrt{\frac{mKL(p||p_0) + \ln N + \ln \delta_{m,k}^{-1} + 2}{2N-1}} \\ &\leq |\mathcal{Y}| e^{-\frac{m\gamma^2}{32c^2}} + \sqrt{\frac{mKL(p||p_0) + \ln N + 3\ln\frac{m+1}{\delta} + 2}{2N-1}}. \end{aligned}$$

Setting $m = \lceil 16c^2\gamma^{-2} \ln \frac{N|\mathcal{Y}|^2}{KL(p||p_0)+1} \rceil$ gives the results in the theorem. ■

Abstract

Many learning tasks, such as large-scale text categorization and word prediction, can benefit from efficient training and classification when the number of classes, in addition to instances and features, is large, that is, in the thousands and beyond. We investigate the learning of sparse class *indices* to address this challenge. An index is a mapping from features to classes. We compare the index-learning methods against other techniques, including one-versus-rest and top-down classification using perceptrons and support vector machines. We find that index learning is highly advantageous for space and time efficiency, at both training and classification times. Moreover, this approach yields similar and at times better accuracies. On problems with hundreds of thousands of instances and thousands of classes, the index is learned in minutes, while other methods can take hours or days. As we explain, the design of the learning update enables conveniently constraining each feature to connect to a small subset of the classes in the index. This constraint is crucial for scalability. Given an instance with l active (positive-valued) features, each feature on average connecting to d classes in the index (in the order of 10s in our experiments), update and classification take $O(dl \log(dl))$.

Keywords: index learning, many-class learning, multiclass learning, online learning, text categorization

1. Introduction

A fundamental activity of intelligence is to repeatedly and rapidly categorize. Categorization (classification or prediction) has a number of uses; in particular, categorization enables inferences and the taking of appropriate actions in different situations. Advanced intelligence, whether of animals or artificial systems, may require effectively working with myriad classes (concepts or categories). How can a system quickly classify when the number of classes is huge (Figure 1), that is, in the thousands and beyond? In nature, this problem of rapid classification in the presence of many classes may have been addressed (for evidence of fast classification in the visual domain, see Thorpe et al. 1996 and Grill-Spector and Kanwisher 2005). Furthermore, ideally, we seek systems that *efficiently*

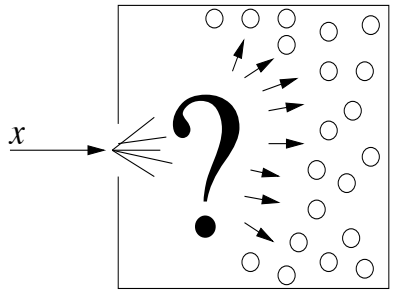

Figure 1: The problem of quick classification in the presence of myriad classes: How can a system quickly classify a given instance, specified by a feature vector $x \in R^n$, into a small subset of classes from among possibly millions of candidate classes (shown by small circles)? How can a system *efficiently learn* to quickly classify?

learn to efficiently classify in the presence of myriad classes. Many tasks can be viewed as instantiations of this *large-scale many-class* learning problem, including: (1) classifying text fragments (such as queries, advertisements, news articles, or web pages) into a large collection of categories, such as the ones in the Yahoo! topic hierarchy (`http://dir.yahoo.com`) or the Open Directory Project (`http://dmoz.org`) (e.g., Dumais and Chen, 2000; Liu et al., 2005; Madani et al., 2007; Xue et al., 2008), (2) statistical language modeling and similar prediction problems (e.g., Goodman, 2001; Even-Zohar and Roth, 2000; Madani et al., 2009), and (3) determining the visual categories for image tagging, object recognition, and multimedia retrieval (e.g., Wang et al., 2001; Forsyth and Ponce, 2003; Fidler and Leonardis, 2007; Chua et al., 2009; Aradhye et al., 2009). The following realization is important: in many prediction tasks, such as predicting words in text (statistical language modeling), training data is abundant because the class labels are not costly, that is, *the source of class feedback (the labels) need not be explicit assignment by humans* (see also Section 3.1).

To classify an instance, applying binary classifiers, one by one, to determine the correct class(es) is quickly rendered impractical with increasing number of classes. Moreover, learning binary classifiers can be too costly with large numbers of classes and instances (millions and beyond). Other techniques, such as nearest neighbors, can suffer similar drawbacks, such as prohibitive space requirements, possibly slow classification speeds, or poor generalization. Ideally, we desire scalable discriminative learning methods that learn compact classification systems that attain adequate accuracy.

One idea for achieving quick classification is to use the features of the given instance as cues to dramatically reduce the space of possibilities, that is, to build and update a mapping, or an *index*, from features to the classes. We explore this idea in this work. An index here is a weighted bipartite graph that connects each feature to zero or more classes. During classification, given an instance containing certain features, the index is used ("looked up") much like a typical inverted index for document retrieval would be. Here, classes are retrieved and ranked by the scores that they obtain during retrieval, as we describe. The ranking or the scores can then be used for class assignment. In this work, we explore the learning of such cues and connections, which we refer to as *index learning*. For this approach to be effective overall, roughly, two properties need to hold: To achieve adequate accuracy and efficiency and in many problems arising in practice, (1) each feature need only connect

to a relatively small number of classes, and (2) these connections can be discovered efficiently. We provide empirical evidence for these conjectures by presenting efficient and competitive indexing algorithms.

We design our algorithms to efficiently learn sparse indices that yield accurate class rankings. As we explain, the computations may best be viewed as being carried out from the side of features. During learning, each feature determines to which relatively few classes it should lend its weights (votes) to, subject to (space) efficiency constraints. This parsimony in connections is achieved by a kind of *sparsity-preserving* updates. Given an instance with l active (i.e., positive-valued) features, each feature on average connecting to d classes in the index, update and classification take $O(dl\log(dl))$ operations. d is in the order of 10s in our experiments. The approach we develop uses ideas from online learning and multiclass learning, including mistake driven and margin-based updates, and expert aggregation (e.g., (e.g., Rosenblatt, 1958; Genest and Zidek, 1986; Littlestone, 1988; Crammer and Singer, 2003a), as well as the idea of the inverted index, a core data structure in information retrieval (e.g., Witten et al., 1994; Turtle and Flood, 1995; Baeza-Yates and Ribeiro-Neto, 1999).

We empirically compare our algorithms to one-versus-rest and top-down classifier based methods (e.g., Rifkin and Klautau, 2004; Liu et al., 2005; Dumais and Chen, 2000), and to the first proposal for index learning by Madani et al. (2007). We use linear classifiers—perceptrons and support vector machines—in the one-versus-rest and top-down methods. One-versus-rest is a simple strategy that has been shown to be quite competitive in accuracy in multiclass settings, when properly regularized binary classifiers are used (Rifkin and Klautau, 2004), and linear support vector machines achieve the state of the art in accuracy in many text classification problems (e.g., Sebastiani, 2002; Lewis et al., 2004). Hierarchical training and classification is a fairly scalable and conceptually simple method that has commonly been used for large-scale text categorization (e.g., Koller and Sahami, 1997; Dumais and Chen, 2000; Dekel et al., 2003; Liu et al., 2005).

In our experiments on six text categorization data sets and one word prediction problem, we find that the index is learned in seconds or minutes, while the other methods can take hours or days. The index learned is more efficient in its use of space than those of the other classification systems, and yields quicker classification time. Very importantly, we find that budgeting the connections of the features is a major factor in rendering the approach scalable. We explain how the design of the update makes this budget enforcement convenient. We have observed that the accuracies are as good as and at times better than the best of the other methods that we tested. As we explain, methods based on binary classifiers, such as one-versus-rest and top-down, are at a disadvantage in our many-class tasks, not just in terms of efficiency but also in accuracy. The indexing approach is simple: it requires neither taxonomies, nor extra feature reduction preprocessing. Thus, we believe that index learning offers a viable option for various many-class settings.

The contribution of this paper include:

- Raising the problem of large-scale many-class learning, with the goal of achieving both efficient classification and efficient training
- Proposing and exploring index learning, and developing a novel weight-update method in the process
- Empirically comparing index learning to several commonly used techniques, on a range of small and large problems and under several evaluation measures of accuracy and space and

time efficiency, and providing evidence that very scalable systems are possible without sacrificing accuracy

This paper is organized as follows. In Section 2, we discuss related work. In Section 3, we describe and motivate the learning problem, independent of the solution strategy. We explain the index, and describe our implementation and measures of index quality, in terms of both accuracy and efficiency. We then report on the NP-hardness of a formalization of the index learning problem. In Section 4, we present our index learning approach. Throughout this section, we discuss and motivate the choices in the design of the algorithms. In particular, the consideration of what each feature should do in isolation turns out to be very useful. In Section 5, we briefly describe the other methods we compare against, including the one-versus-rest and top-down methods. In Section 6, we present a variety of experiments. We report on comparisons among the techniques and our observations on the effects of parameter choices and tradeoffs. In Section 7, we summarize and provide concluding thoughts. In the appendices, we present a proof of NP-hardness and additional experiments.

2. Related Work

Related work includes multiclass learning and online learning, expert methods, indexing, streaming algorithms, and concepts in cognitive psychology.

There exists much work on multiclass learning, including nearest neighbors approaches, naive Bayes, support vector machine variants, one-versus-rest and output-codes (see, for example, Hastie et al., 2001; Rennie et al., 2003; Dietterich and Bakiri, 1995); however, the focus has not been scalability to very large numbers of classes.

Multiclass online algorithms with the goal of obtaining good rankings include the multiclass and multilabel perceptron (MMP) algorithm (Crammer and Singer, 2003a) and subsequent work (e.g., Crammer and Singer, 2003b; Crammer et al., 2006). These algorithms are very flexible and include both additive and multiplicative variants, and may optimize an objective in each update; some variants can incorporate non-linear kernel techniques. We may refer to them as prototype methods because the operations (such as weight adjustments and imposing various constraints) can be viewed as being performed on the (prototype) weight vector for each class. In our indexing algorithms it is the features that update and normalize their connections to the classes. This difference is motivated by efficiency (for further details, see Sections 4.1 and 4.4, and the experiments). Similar to the perceptron algorithm (Rosenblatt, 1958), we use a variant of mistake driven updating. The variant is based on trying to achieve and preserve a margin during online updating. Learning to improve or optimize some measure of margin has been shown to improve generalization (Vapnik, 2000). On use of margin for online methods, see for instance Krauth and Mezard (1987), Anlauf and Biehl (1989), Freund and Schapire (1999), Gentile (2001), Li and Long (2002), Li et al. (2002), Crammer et al. (2006) and Carvalho and Cohen (2006). In our setting, a simple example shows that keeping a margin can be beneficial over pure mistake-driven updating even when considering a single feature in isolation (Section 4.3.1).

The indexing approach in its focus on features (predictors) has similarities with additive models and tree-induction algorithms (Hastie et al., 2001), and may be viewed as a variant of so-called expert (opinion or forecast) aggregation and weight learning (e.g., Mesterharm, 2000; Freund et al., 1997; Cesa-Bianchi et al., 1997; Vovk, 1990; Genest and Zidek, 1986). In the standard experts problems, all or most experts provide their output, and the output is usually binary or a probability

(the outcome to predict is binary). In our setting, a relatively small set of features are active in each instance, and only those features are used for voting and ranking. In this respect, the problem is in the setting of the "sleeping" or "specialist" experts scenarios (Freund et al., 1997; Cohen and Singer, 1999). Differences or special properties of our setting include the fact that here each expert provides a partial class-ranking with its votes, the votes can change over time (not fixed), and the pattern of change is dependent on the algorithm used (the experts are not "autonomous"). In a multiclass calendar scheduling task (Blum, 1997), Blum investigates an algorithm in which each feature votes for (connects to) the majority class in the past 5 classes seen for that feature (the classes of the most recent 5 instances in which the feature was active). This design choice was due to the temporal (drifting) nature of the learning task. Feature weights for the goodness of the features are learned (in a multiplicative or Winnow style manner). Mesterharm refers to such features (or experts) as subexperts (Mesterharm, 2000, 2001), as the performance can be significantly enhanced by learning a good weighting for mixing (aggregating) the experts' votes,[1] and it is shown how different linear threshold algorithms can be extended to the multiclass weight learning setting. The classifier is referred to as a *linear-max* classifier, since the maximum scoring class is assigned to the instance (as opposed to a linear-threshold classifier). Mesterharm's work includes the case where the experts may cast probabilities for each class, but the focus is not on how the features may compute such probabilities (it is assumed the experts are given). Learning different weights for the features can complement indexing techniques. Section 4.3.2 gives a limited form of differential expert weighting (see also Madani, 2007a).

The one-versus-rest technique (e.g., Rifkin and Klautau, 2004) and use of a class hierarchy (taxonomy) (e.g., Liu et al., 2005; Dumais and Chen, 2000; Koller and Sahami, 1997) for top-down training are simple intuitive techniques commonly used for text categorization. The use of the structure of a taxonomy for training and classification offers a number of efficiency and/or accuracy advantages (Koller and Sahami, 1997; Liu et al., 2005; Dumais and Chen, 2000; Dekel et al., 2003; Xue et al., 2008), but also can present several drawbacks. Issues such as multiple taxonomies, evolving taxonomies, unnecessary intermediate categories on the path from the root to deeper categories, or unavailability of a taxonomy are all difficulties for the tree-based approaches. In our experiments, we find that index learning offers both several efficiency advantages and ease of use (Section 6). No taxonomy or separate feature-reduction pre-processing is required. Indeed, our method can be viewed as a feature selection or reduction method. On the other hand, researchers have shown some accuracy advantages from the use of the taxonomy structure (e.g., top-down) compared to "flat" one-versus-rest training (in addition to efficiency) (e.g., Dumais and Chen, 2000; Liu et al., 2005; Dekel et al., 2003) (this depends somewhat on the particular method and the loss used). Our current indexing approach is flat (but see Huang et al. 2008, for a two-stage nonlinear method using fast index learning for the first stage). One advantage that classifier-based methods such as one-versus-rest and top-down may offer is that the training can be highly parallelized: learning of each binary classifier can be carried out independent of the others.

The inverted index, for instance from terms to documents, is a fundamental data structure in information retrieval (Witten et al., 1994; Baeza-Yates and Ribeiro-Neto, 1999). Akin to the TFIDF weight representation and variants, the index learned is also weighted. However, in our case, the classes (to be indexed), unlike the documents, are implicit, indirectly specified by the training instances (the instances are not the "documents" to be indexed), and the index construction becomes

1. Theoretical work often focuses the analysis on learning the best expert, and the use of term "subexpert" is introduced by Mesterharm to differentiate.

a learning problem. As one simple consequence, the presence of a feature in a training instance that belongs to class c does not imply that the feature will point to class c in the index learned. We give a baseline algorithm, similar to TFIDF index construction in its independent computation of weights, in Section 4.2. Indexing has also been used to speed up nearest neighbor methods, classification, and retrieval and matching schemes (e.g., Grobelnik and Mladenic, 1998; Bayardo et al., 2007; Fidler and Leonardis, 2007). Indexing could be used to index already trained (say linear) classifiers, but the issues of space and time efficient learning remain, and accuracy can suffer when using binary classifiers for class ranking (see Section 6.1). Learning of an unweighted index was introduced by Madani et al. (2007), in which the problem of efficient classification under myriad classes was motivated. This two-stage approach is explained in Section 6.4.1, and we see in Section 6.4.1 that learning a weighted index to improve ranking appears to be a better strategy than the original approach in terms of accuracy, as well as simplicity and efficiency. Subsequent work on indexing by Madani and Huang (2008) explores further variations and advances to feature updating (e.g., supporting nonstationarity and hinge-loss minimization), taking as a starting point the findings of this work on the benefits of efficient feature updating. It also includes comparisons with additional multiclass approaches. This paper is an extension of the work by Madani and Connor (2008).

The field of data-streaming algorithms studies methods for efficiently computing statistics of interest over data streams, for example, reporting the items with proportions exceeding a threshold, or the highest k proportion items (sometimes called "hot-list" or "iceberg" queries). This is to be achieved under certain efficiency constraints, for example, with at most two passes over the data and poly logarithmic space (e.g., see Fang et al., 1998; Gibbons and Matias, 1999). Note that in the case of a single feature, if we only value good rankings, computing weights may not be necessary, but in the general case of multiple features, the weights become the votes given to each class, and are essential in significantly improving the final rankings. An algorithm similar to our single-feature update for the Boolean case is used as a subroutine by Karp et al. (2003), for efficiently computing most frequent items. In some scenarios, drifts in proportions can exist, and then online and possibly competitive measures of performance may become important (Borodin and El Yaniv, 1998; Albers and Westbrook, 1998). In this ranking and drifting respect, the feature-update task has similarities with online list-serving and caching (Borodin and El Yaniv, 1998), although we may assume that the sequence is randomly ordered (at minimum, not ordered by an adversary). Some connections and differences between goals in machine learning research and space-efficient streaming and online computations are discussed by Guha and McGregor (2007).

Statistical language modeling and similar prediction tasks are often accomplished by n-gram (Markov) models (Goodman, 2001), but the supervised (or discriminative) approach may provide superior performance due to its potential for effectively aggregating richer feature sets (Even-Zohar and Roth, 2000; Madani et al., 2009). Prior work has focused on discriminating within a small (confusion) set of possibilities. In the related task of *prediction games* (Madani, 2007a,b), Madani proposes and explores an integrated learning activity in which a system builds its own classes to be predicted and to help predict. That approach involves large-scale long-term online learning, where the number of concepts grows over time, and can exceed millions.

Concepts and various phenomena associated with them have been studied extensively in cognitive psychology (e.g., Murphy, 2002). A general question that motivated our work, and that appears heretofore uninvestigated, is the question of computational processes required for a system to effectively deal with a huge number of concepts. Three prominent theories on the nature of the representation of concepts are the classical theory (logical representations), the exemplar theory (akin

to nearest neighbors), and the prototype theory (akin to linear feature-based representations). Prototype theory is perhaps the most successful in explaining various observed phenomena regarding human concepts (Murphy, 2002). Interestingly, our work suggests a predictor-based representation for efficient recall/recognition purposes, that is, the representation of a concept, at a minimum for recall/retrieval purposes, is distributed among the features (predictors or cues). However, the predictor-based representation remains closest to the prototype theory.

3. Many-Class Learning and Indexing

In this section, we first present the learning setting and introduce some notation in the process. Next, we motivate many-class learning and the indexing approach. In Section 3.2, we define the index and how it is implemented and used in this work. We then present our accuracy and efficiency evaluation measures in Section 3.3. Before moving to index learning (Section 4), we analyze the computational complexity of a formulation of index learning in Section 3.4.

A learning problem consists of a collection S of instances, where S can denote a finite set, or, in the online setting, a sequence of instances. Each training instance is specified by a vector of feature values, $\mathbf{v_x}$, as well as a class (or assigned label) that the instance belongs to,[2] c_x. Thus each instance x is a pair $\langle \mathbf{v_x}, c_x \rangle$. $\mathcal{F}$ and $\mathcal{C}$ denote respectively the set of all features and classes. Our proposed algorithms ignore features with nonpositive value,[3] and in our experiments feature values range in $[0,1]$. $\mathbf{v_x}[f]$ denotes the value of feature f in the vector of features of instance x, where $\mathbf{v_x}[f] \geq 0$. If $\mathbf{v_x}[f] > 0$, we say feature f is *active* (in instance x), and denote this aspect by $f \in x$. Thus, an instance may be viewed as a set of active features, and the input problem may be seen as a tripartite graph (Figure 2). The number of active features is denoted by $|x|$. We also use the expression $x \in c$ to denote that instance x belongs to class c (c is a class of x).

As an example, in text categorization, a "document" (e.g., an email, an advertisement, a news article, etc.) is typically translated to a vector by a "bag of words" method as follows. Each term (e.g., "ball", "cat", "the", "victory", ...) is assigned an exclusive unique integer id. The finite set of words (more generally phrases or ngrams), those appearing in at least one document in the data set, comprise the set of features $\mathcal{F}$. Thus the vector $\mathbf{v_x}$ corresponding to a document lives in an $|\mathcal{F}|$ dimensional space, where $\mathbf{v_x}[i] = k$ iff the word with id i (corresponding to dimension i) appears k times in the document, where $k \geq 0$ (other possibilities for feature values include Boolean and TFIDF weighting). Therefore, in typical text categorization tasks, the number of active features in an instance is the number of unique words that appear in the corresponding document. The documents in the training set are assigned zero or more true class ids as well. Section 6 describes further the feature representation and other aspects of our experimental data. For background on machine learning in particular when applied to text classification, please refer to Sebastiani (2002) or Lewis et al. (2004).

2. In this paper, to keep the treatment focused, and for simplicity of evaluation and algorithm description, we treat the multiclass but single class (label) per instance setting. However, two of our seven data sets include multilabel instances. Whenever necessary, we briefly note the changes needed, for example, to the algorithm, to handle multiple labels. However, the multilabel setting may require additional treatment for better accuracy.
3. A partial remedy is to replace each feature that can also have negative values by two features, one having value $\max(v,0)$, the other $\max(0,-v)$.

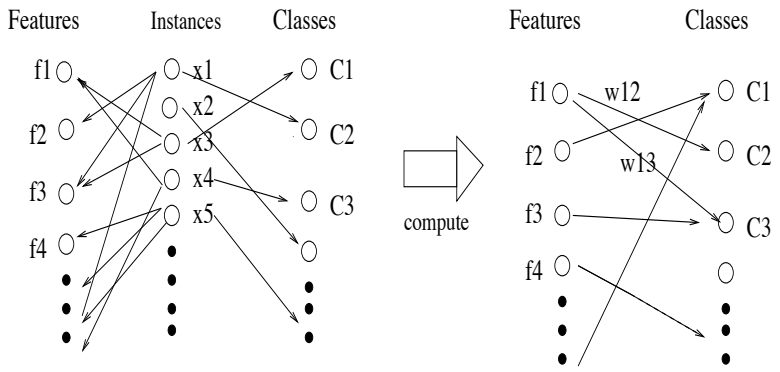

Figure 2: A depiction of the problem: the input can be viewed as a tripartite graph, possibly weighted, and perhaps only seen one instance at a time in an online manner. Our goal is to learn an accurate efficient index, that is, a sparse weighted bipartite graph that connects each feature to zero or more classes, such that an adequate level of accuracy is achieved when the index is used for classification. The instances are ephemeral: they serve only as intermediaries in affecting the connections from features to classes. The index to learn is also equivalent to a sparse weight matrix (in which the entries are nonnegative in our current work) (see Sections 3.2 and 3.2.1).

3.1 The Level of Human Involvement in Teaching and Many-Class Learning

Learning under myriad-classes is not confined to a few text-classification problems. There are a number of tasks that could be viewed as problems with many classes and, if effective many-class methods are developed, such an interpretation can be quite useful. In terms of the sources of the classes, we may roughly distinguish supervised learning problems along the following dimensions (the roles of the teacher):

1. The source that defines the classes of interest, that is, the space of the target classes to predict.

2. The source of supervisory feedback, that is, the source or the process that assigns to each instance one or more class labels, using the defined set of classes. This is necessary for the procurement of training data, for supervised learning.

In many familiar cases, the classes are both human-defined and human-assigned. These include typical text classification problems (e.g., see Lewis et al. 2004 and Open Directory Project or Yahoo! directories/topics). In many others, class assignment is achieved by some "natural" or indirect activity, that is, the "labeling" process is not as explicit or controlled. The labeling is a by-product of an activity carried out for other purposes. One example of this case is data sets obtained from news groups postings (e.g., Lang, 1995). In this case, users post or reply to messages, without necessarily verifying whether their message is topically relevant to the group. Another example problem is predicting words using the context that the word appears (the words are the classes). In these problems, the set of the classes of interest may be viewed as human-defined, but the labeling is implicit (collections of written or spoken texts in the word prediction task). The extreme case

where both the set of classes and the labeling is achieved with little or no human involvement is also possible, and we believe very important. For instance, Madani (2007b,a) explores tasks in which it is (primarily) the machine that builds its own many concepts, through experience, and learns prediction connections among them. This is a kind of *autonomous* learning. As human involvement and control diminishes over the learning process, the amount of noise tends to increase. However, training data as well as the number of classes can increase significantly. We have used the term "many-class" (in contrast to multiclass) to emphasize this aspect of the large number of classes in these problems.

Thus, in large-scale many-class learning problems, all the three sets S, $\mathcal{C}$, and $\mathcal{F}$ can be huge. For instance, in experiments reported here, $\mathcal{C}$ and $\mathcal{F}$ can be in the tens of thousands, and S can be in the millions. S can be an infinite stream of instances and $\mathcal{C}$ and $\mathcal{F}$ can grow indefinitely in some tasks (e.g., Madani, 2007a). While $\mathcal{F}$ can be large (e.g., hundreds of thousands), in many applications such as text classification, instances tend to be relatively sparse: relatively a few of the features (tens or hundreds) are active in each instance.

The number of classes is so large that indexing them, not unlike the inverted index used for retrieval of documents and other object types, is a plausible approach. An important difference from traditional indexing is that classes, unlike documents, are implicit, specified only by the instances that belong to them. An index is a common technique for fast retrieval and classification, for instance to speed up nearest neighbor or nearest centroid computations (e.g., Grobelnik and Mladenic, 1998; Bayardo et al., 2007; Gabrilovich and Markovitch, 2007; Fidler and Leonardis, 2007). Also, for fast classification when there is a large number of classes, after one-versus-rest training of linear binary classifiers (see Section 5 on one-versus-rest training), a natural and perhaps necessary technique is to index the weights, that is, to build an index mapping each feature to those classifiers in which the feature has nonzero weight. This approach is indirect and does not adequately address efficient classification and space efficiency,[4] and the problem of slow training time for one-versus-rest training remains. Here, we propose to learn the index edges as well as their weights directly. For good classification performance as well as efficiency, we need to be very selective in the choice of the index entries, that is, which connections to create and with what weights. Figure 3 presents the basic cycle of categorization via index look up and learning via index updating (adjustments to connection weights). We have termed the system that is learned a *Recall System* (Madani et al., 2007): a system that, when presented with an instance, quickly "recalls" the appropriate classes from a potentially huge number of possibilities.

3.2 Index Definition, Implementation, and Use

The use of the index for retrieval, scoring, and ranking (classification) is similar to the use of inverted indexes for document retrieval. Here, features "index" classes instead of documents. In our implementation, for each feature there corresponds exactly one list that contains information about the feature's connections (similar to inverted or posting lists Witten et al. 1994 and Baeza-Yates and Ribeiro-Neto 1999). The list may be empty. Each entry in the list corresponds to a class that the feature is *connected* to. An entry in the list for feature f contains the id of a class c, as well as the *connection or edge weight* $w_{f,c}$, $w_{f,c} > 0$. Each class has at most one entry in a feature's list. If a class c doesn't have an entry in the list for feature f, then $w_{f,c}$ is taken to be 0. The connection

4. Our experiments show that if we do not drop some of the connections during learning, training and classification time and space consumption suffer significantly.

Basic Mode of Operation:
Repeat
1. Get next instance x
2. Retrieve, score, and rank classes via active features of x
3. If update condition is met:
3.1 Update index.
4. Zero (reset) the scores of the retrieved classes.
(a)

Algorithm RankedRetrieval(x**,** d_{max}**)**
/* initially, for each class c**, its score** s_c **is zero */**
1. For each active feature f **(i.e.,** $\mathbf{v_x}[f] > 0$**):**
For the first d_{max} **classes with highest connection weight to** f**:**
1.1. $s_c \leftarrow s_c + (r_f \times w_{f,c} \times \mathbf{v_x}[f])$
2. Return those classes with nonzero score, ranked by score.
(b)

Figure 3: (a) The cycle of classification and learning (updating). During pure classification (e.g., when testing), step 3 is skipped. See part (b) and Section 3.2 for how to use the index, and Section 4 for when and how to update the index. (b) The algorithm that uses a weighted index for retrieving and scoring classes. See Section 3.2.

weights are updated during learning. Our index learning algorithms keep the lists small for space and time efficiency (as we explain in Section 4.1). For ease of updating and efficiency, the lists are doubly linked circular dynamic lists in our implementation, and are kept sorted by weight.

Figure 3(b) shows how the index is used, via a procedure that we name RankedRetrieval. On presentation of an instance, the active features score the classes that they are connected to. The score that a class c receives, s_c, can be written as

$$s_c = \sum_{f \in x} r_f \times w_{f,c} \times \mathbf{v_x}[f], \tag{1}$$

where r_f is a measure of the predictiveness power or the *rating* of feature f, and we describe a method for computing it in Section 4.3.2. Currently, for simplicity, we may assume the rating is 1 for all features.[5] Note that the sum need only go over the entries in the list for each active feature (other weights are zero). We use a hash map to efficiently update the class scores during scoring. In a sense, each active feature casts votes for a subset of the classes, and those classes receive and tally their incoming votes (scores). In this work, the scores of the retrieved classes are positive. The positive scoring classes can then be ranked by their score, or, if it suffices, only the maximum scoring class can be kept track of and reported. Note that if negative scores (or edge weights) were allowed, then, when some true class obtains a negative score, the system would potentially have to process (i.e., retrieve or update) all zero scoring classes as well, hurting efficiency (this depends on how update and classification are defined). The scores of the retrieved classes are reset to 0 before the next call to RankedRetrieval.

On instance x, and with d connections per feature in the index, there can be at most $|\mathbf{v_x}|d$ unique classes scored. The average computation time of RankedRetrieval is thus $O(d|\mathbf{v_x}|\log(d|\mathbf{v_x}|))$, where d denotes the average number of connections of a randomly picked feature (from a randomly picked instance). In our implementation, for each active feature, only at most the d_{max} classes (25 in our experiments) with highest connection weights to the feature participate in scoring.

5. After index learning, r_f can be incorporated into the connection weights $w_{f,c}$.

3.2.1 GRAPH AND LINEAR-ALGEBRAIC VIEWS OF THE INDEX

A useful way of viewing the index is as a directed weighted bipartite graph (Figure 2): on one side there are features (one node per feature) and on the other side there are the classes. The index maps (connects) each feature to a subset of zero or more classes. An edge connecting feature f to class c has a positive weight denoted by $w_{f,c}$, or $w_{i,j}$ for feature i and class j, and corresponds to a list entry in the list for feature f. Absent edges have zero weight. The *outdegree* of a feature is the number of (outgoing) edges of the feature. Small feature outdegrees translates to efficiency in retrieval (and updating as we will see).

In addition to the graph-theoretic view, the index can also be seen as a sparse non-negative (weight) matrix $\mathbf{W}$. Let the rows correspond to the features and let the columns correspond to the classes. Retrieval or classification involves efficiently computing[6] the vector of class scores $\mathbf{v_x^T W}$, and post-processing the resulting (sparse) score vector (e.g., sorting the positive scoring classes). Efficiency constraints translate to limiting the number of nonzero entries in each row. In the indexing algorithms of this paper, the sum of the entries in each row does not exceed 1. Lemma 1 below states that this restriction does not lose power, among the set of nonnegative matrices, for achieving good rankings.

3.3 Evaluating the Index

We evaluate index learning based on efficiency as well as the quality of classification (accuracy). In large-scale learning, both memory and time efficiency are important, and both at training as well as classification times.[7] Our other goal is to maintain satisfactory accuracy. In our experiments in Section 6.2 (on finite samples), we report on three measures of efficiency: training time T_{tr}, the size of the index learned, denoted by $|\mathbf{W}|$, meaning the number of edges or nonzero weights in the index, and the average number of edges d touched (processed) per feature during classification (a measure of work/speed during classification time). We next describe our classification accuracy measures.

We use the standard accuracy (i.e., one minus zero-one error), here denoted R_1, as well as other measures of ranking quality. R_1 allows us to compare to other published results. A method for ranking classes, given an instance x, outputs a sorted list of zero or more classes. In addition to weighted indices, we describe other methods for ranking the classes in Section 5. An instance may belong to multiple classes in some tasks (two of our data sets in Figure 8). To simplify evaluation and presentation, in this paper we only consider the highest ranked true class. Let k_x be the rank of the highest ranked true class after presenting instance x to the system. Thus $k_x \in \{1,2,3,\cdots\}$. If the true class does not appear in the ranked list, then $k_x = \infty$. We use R_k to denote *recall at (rank) k*, which measures the proportion of (test) instances for which one of the true classes ended in the top k classes:

$$R_k = \text{ recall at } k = E_x[k_x \leq k],$$

where E_x denotes expectation over the instance distribution and $[k_x \leq k] = 1$ iff $k_x \leq k$, and 0 otherwise (Iverson bracket). So we get a reward of 1 if the true class is within top k for a given instance, 0 otherwise, and R_k is the expectation. In our experiments, we will report on (average) recall at rank 1, R_1, and recall at rank 5, R_5, on held-out sets. R_1 is simply the standard accuracy, that is,

6. Feature ratings, can be incorporated in a diagonal matrix $\mathbf{R}$, where $\mathbf{R}[\mathbf{i},\mathbf{i}] = \mathbf{r_i}$ (the rating of feature i) and $\mathbf{R}[\mathbf{i},\mathbf{j}] = \mathbf{0}$, when $i \neq j$. Obtaining the scores would then be $\mathbf{v_x^T RW}$.

7. Note that in online learning, there isn't a sharp separation between the training and testing phases.

the highest ranked class is assigned to the instance, and R_1 measures the proportions of instances to which the true class was assigned.

We also report on the harmonic (mean) rank (HR) (reciprocal of mean reciprocal rank or MRR), defined as:

$$MRR = E_x \frac{1}{k_x}, \text{ and } HR = MRR^{-1}.$$

MRR gives a reward of 1 if a correct class is ranked highest, the reward drops to 1/2 at rank 2, and slowly goes down the higher the k (the lower the rank). If the right class is not retrieved, the reward is 0. MRR is the expectation or the empirical average of such reward over (test) instances, and we simply invert it to get a measure of ranking performance, the harmonic rank HR. The lower the HR, the better, and it has a minimum of 1 (rank 1 is best). MRR is a commonly used measure in information retrieval, such as in question answering tasks (e.g., Radev et al., 2002). In our experiments, we report the HR values so that the reader can quickly get an impression of the average class-ranking performance of the various methods.

Both R_k and MRR are appropriate for settings in which we value better ranks *significantly* more than worse ranks. Thus, if an index is perfect half the time, that is, ranks the correct class of the given instance at top (rank 1) half the time, but fully fails the rest of the time, that is, does not retrieve the correct class at all, then its HR value is 2. However, for an index that always retrieves the correct class, but ranks it third, the HR value is worse, at 3. Note that one could raise the fraction $\frac{1}{k_x}$ to a different exponent (instead of 1) to shift the emphasis in one direction or another. R_k does not reflect the quality of ranking within top k, and it simply cuts the reward off if the right class is outside top k. HR is a smoother measure. Our evaluation measure are from the point of view of an instance to be classified. This is appropriate with large numbers of classes and in many applications, such as personalization or text prediction, in which a given instance (a query, a page, etc.) should be classified into one or a few classes that the system is confident about. In a number of information retrieval tasks such as question answering and document retrieval, the extra emphasis on higher ranks is well motivated. We expect that the situation would be similar for typical many-class problems, such as text categorization. The common precision and recall measures used in machine learning are often computed from the point of view of a class: for each class, the instances are ranked according to the classifier's scores for the class. This is especially appropriate when we are interested in performance on a single class at a time. For instance, when we seek to rank or filter instances based on their degree of membership in a given class of interest (e.g., a news topic). Our indexing techniques are more appropriate for the problem of obtaining good rankings per instance, similar to some other multiclass ranking algorithms (e.g., Crammer and Singer, 2003a). However, existing techniques for improving precision/recall for imbalanced classes may be applicable (e.g., Li et al., 2002). We conclude this section with a simplifying property of non-negative matrices, for the purposes of ranking.

Lemma 1 *Let* $\mathbf{W}$ *be the non-negative matrix corresponding to an index (features correspond to the rows and classes are the columns). The ranking that* $\mathbf{W}$ *produces on nonzero scoring classes is not changed under positive scaling, that is,* $\alpha\mathbf{W}$*, for* $\alpha > 0$*, produces the same ranking.*

Proof The score for each class is obtained in the vector $\mathbf{v_x^T W}$. Therefore, the ranking obtained from $\mathbf{v_x^T} \alpha\mathbf{W} = \alpha \mathbf{v_x^T W}$, is the same as the ranking in the vector $\mathbf{v_x^T W}$, when $\alpha > 0$ and all entries in $\mathbf{v_x^T W}$ are non-negative. ■

The lemma implies that optimal matrices, for the objective of say maximizing R_1 on the training set, among non-negative matrices in which the entries in each row sum to at most 1.0, exist. The indexing algorithms presented in this paper learn non-negative weight matrices.

3.4 Computational Complexity of Index Learning

Can we efficiently compute an index achieving maximum training accuracy given any finite set S of instances? If we constrain the outdegree of each feature to be below a given constant (motivated by space and time efficiency), then the corresponding decision problem is NP-hard under plausible objectives such as optimizing accuracy (R_1):

Theorem 2 *The index learning problem with the objective of either maximizing accuracy (R_1) or minimizing HR on a given set of instances, and with the constraint of a constant upper bound (e.g., 1) on the outdegree of each feature is NP-Hard.*

The proof is by a reduction from the minimum cover problem (see Appendix A). A problem involving only two classes is shown NP-hard. We do not know whether the indexing problem is approximable in polynomial time however, or whether removing the constraint on the outdegree alters the complexity. Linear programming formulations exist with continuous objectives and no explicit outdegree constraint (Madani and Connor, 2007; Madani and Huang, 2008).

The next section describes very efficient online algorithms that perform well in our experiments. We motivate our choices in the algorithm design, but leave theoretical guarantees to future work.

4. Feature Focus Algorithms for Index Learning

Figure 4 present our main index learning technique. After first giving a quick overview of the approach, we motivate the choices in the design of the algorithm in the rest of this section.

On a given instance, after the use of the index for scoring and ranking (an invocation of RankedRetrieval), if a measure of *margin* (to be described shortly) is not large enough, an update to the index is made. The margin is the score obtained by the true class, minus the highest scoring incorrect (negative) class (either of the two scores can be zero). Our index learning algorithms may be best described as performing their updates from the features' side or features' "point of view" (rather than the classes' side or class prototypes), and hence we name the whole family *feature-focus* algorithms. As we will explain, this design was motivated by considerations of efficiency (Sections 4.1 and 4.4). The basic question for each feature is to which subset of classes it should connect (possibly none), and with what weights. Figure 4(d) gives a generic feature updating scheme and Figure 4(c) gives the instantiation we use in our experiments. Initially, all weights are zero. Note that when a weight is zeroed, the connection is removed. This means that, in our index implementation, the list entry corresponding to the edge is removed from the list of the edges of the feature.

We next motivate the design choices in FF. The problem of what each feature in isolation should do during learning turns out to be helpful and we first explore and discuss this single feature case. We then present the IND(ependent) method, a baseline in which effectively on every instance every feature updates. We then motivate mistake-driven updating, and in particular the use of margin.[8]

8. All the examples given to illustrate various aspects make the assumption of Boolean feature values, but the feature-focus algorithm as presented works with the more general nonnegative values.

/* The FF Algorithm */
Algorithm FeatureFocus(x, w_{min}, d_{max}, δ_m)
1. RankedRetrieval(x, d_{max})**. /* retrieve/score */**
2. Compute the margin δ**:**
$\delta = s_{c_x} - s'_x$**, where** $s'_x = \max_{c \neq c_x} s_c$**.**
3. If $\delta > \delta_m$**, return. /* update not necessary */**
4. Otherwise, for each active $f \in x$**:**
/* update active features' connections */
4.1 FSU(x, f, w_{min})**.**
(a)

Algorithm RankedRetrieval(x, d_{max})
/* initially, for each class c**, its score** s_c **is zero */**
1. For each active feature f **(i.e.,** $\mathbf{v_x}[f] > 0$**):**
For the first d_{max} **classes with highest connection weight to** f**:**
1.1. $s_c \leftarrow s_c + (r_f \times w_{f,c} \times \mathbf{v_x}[f])$
2. Return those classes with nonzero score, ranked by score.
(b)

/* Feature Streaming Update (allowing "leaks") */
Algorithm FSU(x, f, w_{min}) **/* Single feature updating */**
1. $w'_{f,c_x} \leftarrow w'_{f,c_x} + \mathbf{v_x}[f]$ **/* increase weight to** c_x**. */**
2. $w'_f \leftarrow w'_f + \mathbf{v_x}[f]$ **/* increase total out-weight */**
3. $\forall c,\ w_{f,c} \leftarrow \frac{w'_{f,c}}{w'_f}$ **/* (re)compute proportions */**
4. If $w_{f,c} < w_{min}$**, then /* drop tiny weights */**
$w_{f,c} \leftarrow 0, w'_{f,c} \leftarrow 0$
(c)

Algorithm GenericWeightUpdate
Each active feature:
1. Strengthens weight to true class
2. Weakens other class connections
3. Drops weak edges (tiny weights)
(d)

Figure 4: (a) Pseudo-code for the Feature-Focus (FF) learning algorithm. The FF algorithm is invoked on every training instance. This corresponds to steps 2 and 3 in Figure 3(a). (b) The RankedRetrieval procedure for scoring and ranking (copied from Figure 3(b)). (c) Feature streaming update, or FSU: The connection weight of f to the true class c_x is strengthened. Others connections are weakened due to the division. All the weights are zero at the beginning of index learning. (e) Generic weight updating: on each training instance, each active feature strengthens its weight to the true class, weakens its other connections, and drops those that are too weak.

We conclude with a comparison of FF to existing online algorithms, in particular the perceptron algorithm and Winnow. The reader may wish to skip some of these sections at this point and go to the experiments (Section 6) on a first reading.

4.1 Updating for a Single Feature

Assume (training) instances arrive in a streaming fashion (from some infinite source), and assume the single label (per instance) setting. Fix one feature and imagine the substream of instances that have that feature active. Let us consider Boolean feature values only ($\mathbf{v_x}[f] \in \{0,1\}$) here for simplicity. Thus, we basically obtain a stream of observed classes, $<c^{(1)}, c^{(2)}, c^{(3)}, \cdots>$, for the given feature. Ignoring other features for now, and considering efficiency constraints, to which classes should this feature connect to, and with what weights? We next argue that our objective of a good ranking, subject to efficiency, reduces to computing the proportion in the sequence for those classes (if any) that exceed a desired proportion threshold.

In this single feature case, classes are ranked by the weight assigned to them by the feature. The constraint (of space efficiency) is that the feature may connect to only a subset of all possible classes, say d_{max} at most. The question is how the feature should connect so that an objective such as R_k or HR (harmonic rank) is maximized. We will focus on the scenario where the stream of classes is generated by an iid drawing from a fixed probability distribution.

It is not hard to verify that the best classes are the d_{max} classes with the highest proportions in the stream, or the highest $P(c)$ if the distribution is fixed and known (more precisely, $P(c|f)$, but f is fixed here) and the ranking should also be by $P(c)$. For a finite sequence on which we are allowed to compute proportions before having to connect the feature, this can easily be established.

Lemma 3 *A finite sequence of classes is given (class observations). To maximize HR, when the feature can connect to at most k different classes, a k highest frequency set of classes should be picked, that is, choose S, such that* $|S| = k$ *and* $S = \{c|n_c \geq n_{c'}, \forall c' \notin S\}$*), where* n_c *denotes the number of times c occurs in the sequence. The classes in S should be ordered by their occurrence counts to maximize HR. The same set maximizes* R_k*.*

Proof This can be established by a simple "swapping" or "exchange" argument. We look at the sum of rewards over the sequence rather than averages, as the sequence length is fixed. Consider maximizing R_k first. Let n_c denote the number of times class c appears in the sequence. For any chosen set S of size k, a pair of classes (c, c') is out of order if $n_c < n_{c'}$, but $c \in S$, and $c' \notin S$. Then R_k for S is improved if c is replaced by c', the improvement is $n_{c'} - n_c$. Similarly HR is improved for an ordered set S if a pair like above exists (improvement of $(n_{c'} - n_c)\frac{1}{j}$, where j denotes the rank of c in S), or a pair within the chosen set is out of order (improvement of $(n_{c'} - n_c)(1/j - 1/j')$, where $j', j' > j$, denotes the old rank of c'.). ■

For unbounded streams generated by iid drawing of classes from a fixed distribution over a finite number of classes, the empirical proportions of classes, over the sequence seen so far (of length at least k), take the place of the counts, in order to maximize expected HR or expected R_k on the unseen portion of the sequence.

We will use FSU (*Feature Streaming Update*, Figure 4(c)) in our main feature-focus algorithm. An FSU update takes at most two list traversals (involving finding or inserting the connection). With d connections per feature, a full update on an instance takes $\tilde{O}(d|x|)$. Note that when features are Boolean, FSU simply computes edge weights that approximate the conditional probabilities $P(c|f)$ (the probability that instance $x \in c$ given that $f \in x$ and FSU is invoked). Since the weights are between 0 and 1 and approximate probabilities, it eases the decision of assessing importance of a connection: weights below w_{min} are dropped at the expense of some potential loss in accuracy. FSU keeps total counts (w'_f and w'_{f,c_x}, which we will describe and motivate later). Note that w_{min} effectively bounds the maximum outdegree during learning to be $\frac{1}{w_{min}}$. We note that this space efficiency of FSU is central to making feature-focus algorithms space and time efficient (see Section 6.3.1). Given that FSU zeros some weights during its computation, it is instructive to look at how well it does in approximating proportions for the (sub)stream of classes that it processes for a single feature. This gives us an idea of how to set the w_{min} parameter and what to expect. Appendix A presents synthetic experiments and a discussion. To summarize, when the true probability (weight) w of interest is several multiples of w_{min}, with sufficient sample size, the chance of dropping it is very low (the probability quickly goes down to 0 with increasing $\frac{w}{w_{min}}$), and moreover, the computed weight is also close to the true conditional. See Section 6.3.3 on the effect of choice of $w_{min} \in \{0.001, 0.01, 0.1\}$ on accuracy on several data sets.

4.1.1 UNINFORMATIVE FEATURES, ADAPTABILITY, AND DRIFTING ISSUES

In FSU, we keep and update two sets of weights, the edge weights $w_{f,c}$ (not greater than 1), $w'_{f,c}$, as well as total weight w'_f. In case of binary features ($\mathbf{v_x}[f] = 1$), we can simply think of w'_f as total count of times FSU has been invoked for the feature, and $w'_{f,c}$ as an under-estimate of the co-occurrence count in that stream ($w'_{f,c}$ can be less than the co-occurrence count, as it is reset to 0 if the edge is dropped). Note that if c_x is not already connected (for example in the beginning), $w_{f,c}$ and $w'_{f,c}$ are 0. An important point is that total weight w'_f is never reduced. This is useful as a way of down-weighing uninformative features (such as "the"). Thus, due to edge dropping, we may have the sum of proportions remain less than 1, $\sum_c w_{f,c} < 1$, even when $w'_f > 0$. We have found this alternative slightly better in our experiments than the case in which $w'_f = \sum_c w'_{f,c}$ (i.e., when w'_f is kept as the exact sum of the weights). See Section 6.3.5.

In case of non-Boolean feature values, similar to perceptron and Winnow updates (Rosenblatt, 1958; Littlestone, 1988), the degree of activity of the feature, $\mathbf{v_x}[f]$, affects how much the connection between the feature and the true class is strengthened. We could use a *learning rate*, a multiplier for $\mathbf{v_x}[f]$, to further control the aggressiveness of the updates. We have not experimented with that option.

Note also that as w_f grows, the feature may become less adaptive, as a new class will have to occur more frequently to obtain a strong weight ratio with respect to w_f. In particular, after $w_f > \frac{1}{w_{min}}$, a new class will be immediately dropped.[9] For long-term online learning, where distributions can drift (nonstationarity), this can slow or stop adaptation, and updates that effectively keep a finite memory or history are more appropriate. Note also that, if the same training instances can be seen multiple times (e.g., in multiple passes on finite data sets), with w_f growing, the fitting capability of the algorithms is curbed. This may be desired as a means of overfitting prevention. Other indexing updates have been developed, offering various trade-offs (see our discussion in Section 4.4, and Madani and Huang 2008, and Madani et al. 2009, in particular for a simple update appropriate for nonstationarity).

Before describing the main feature-focus algorithm, we describe a baseline algorithm we refer to as IND(ependent). This algorithm can be implemented in an offline (batch) manner. It is based on computing the conditionals $P(c|f)$.

4.2 Always Updating (the IND Algorithm)

One method of index construction is to simply assign each edge the class conditional probabilities, $P(c|f)$ (the conditional probability that instance $x \in c$ given that $f \in x$). This can be computed for each feature independent of other features. We refer to this variant as the IND ("INDependent") algorithm (Figure 5). Features are treated as Boolean here ($\mathbf{v_x}[f] \in \{0,1\}$). After processing the training set (computing counts and then conditional probabilities), only weights exceeding a threshold p_{ind} are kept. The use of p_{ind} not only leads to space savings, but also can improve accuracy significantly. The best threshold p_{ind} (for improving accuracy) is often significantly greater than 0 (see Section 6.3.7). In our experiments with IND, we choose the best threshold by observing performance on a random 20% subset of the training set. We thus implemented the IND algorithm

9. At this point, updates can only affect classes already connected, and updates may improve the accuracy of their assigned weights, though there is a small chance that even classes with significant weights may be eventually dropped (this has probability 1 over an infinite sequence!). In any case, at this point or soon after, it is possible to stop updating. In our experiments, with finite data and small number of passes over the data sets, this was not an issue.

Algorithm IND(S, p_{ind}) /* IND algorithm */
1. For each instance x in training sample S:
1.1 For each $f \in x$: /* increment counts for f */
1.1.1 $n_f \leftarrow n_f + 1$
1.1.2 $n_{f,c_x} \leftarrow n_{f,c_x} + 1$
2. Build the index: for each feature f and class c:
2.1 $w \leftarrow \frac{n_{f,c}}{n_f}$**.**
2.2 If $w \geq p_{ind}$**,** $w_{f,c} \leftarrow w$**. (otherwise** $w_{f,c} \leftarrow 0$**.)**

Figure 5: Pseudo-code for the IND(ependent) algorithm, implemented for the case of Boolean features only. The choice of p_{ind} affects accuracy significantly, and is picked using a held out set (see Section 4.2).

as a batch algorithm, that is, we computed the weights $P(c|f)$ exactly, not in an online streaming manner described[10] for FSU. The exact computation can be done on the relatively smaller data sets. IND is in fact the fastest algorithm on the smaller data sets, since the count updates are simple and there is no call to index retrieval during training. This counting phase for index construction can also be distributed. On larger data sets, IND runs into memory problems and becomes very slow during training, due to many features keeping connections to too many classes.[11] This aspect points to the importance of space efficiency for large-scale learning.

The IND algorithm, in its independent computations of weights for each feature, has similarities with the multiclass Naive Bayes algorithm (e.g., Rennie et al. 2003). Major differences include the computation of $P(f|c)$ (the reverse) in plain multiclass Naive Bayes, and that for classification, we are summing the weights (instead of multiplying under the independence assumption), similar to some techniques for expert opinion aggregation (Genest and Zidek, 1986; Cesa-Bianchi et al., 1997). We have found that summing improves accuracy. See Madani and Connor (2007) for a more detailed comparison to multiclass Naive Bayes. In its independent computation of weights, IND is also similar to inverted index construction using, for instance, TFIDF.

IND offers a nice baseline, but we can potentially do significantly better than computing proportions for each feature independently. Often features are inter-dependent. For instance, features can be near duplicates or redundant. In particular, with increasing feature vector sizes, the accuracy of methods that in effect assume feature independence can degrade significantly.

4.3 Mistake-Driven Updating Using a Margin (the FF Algorithm)

FF adds and drops edges and modifies edge weights during learning by processing one instance at a time,[12] and by invoking a feature updating algorithm, such as FSU. Unlike IND, FF addresses feature dependencies by not updating the index on every training instance. Equivalently, a feature updates its connection on only a fraction of the training instances in which it is active. This is motivated and explained next.

10. In case the instance belongs to multiple classes, step 1.1.2 is executed for each true class.
11. However, note that the FSU algorithm can be instead employed here to keep memory consumption in check.
12. The feature and class sets can also grow incrementally.

4.3.1 WHEN TO UPDATE?

FSU should not be invoked on every training instance. In particular, *"lazy"* or mistake-driven updating (not updating all the time) can, to some extent, address issues with feature dependencies. It can, for example, avoid over counting the influence of features that are basically duplicates by learning relatively low connection weights for each such feature (similar to a rational for mistake driven updates in other learning algorithms such as the perceptron). We next give a simple scenario, *case 1*, to demonstrate accuracy improvements that can be obtained by lazy updating.

Case 1. Imagine the simple case of two classes, c_1 and c_2, and two Boolean features, f_1 and f_2. Assume f_1 is perfect for c_1, $P(c_1|f_1) = P(f_1|c_1) = 1$, but that f_2 appears in instances of both classes, and $P(f_2|c_1) = 1$ (i.e., f_2 appears in all instances of c_1), but also $P(f_2|c_2) = 1$. Then, given only f_2, that is, an instance $x = \{f_2\}$ (x contains f_2 only), we want to rank c_2 higher. Now, if say $P(c_1) > P(c_2)$ (c_1 is more frequent than c_2), and we always invoked FSU, f_2 would also give a higher weight to c_1, ranking c_1 higher than c_2 on $x \in c_2$. An optimal solution, for accuracy R_1 or for HR, has the property that f_2 has a higher connection weight to c_2 than to c_1 (with $w_{f_1,c_2} = 0$, an optimal solution satisfies: $w_{f_1,c_1} > w_{f_2,c_2} > w_{f_2,c_1}$.). Now, if FF invoked FSU only when the correct class was not ranked highest, the connection weights in this example would converge to an optimal configuration. To see this, note that as soon as $x \in c_1$ is seen f_1 obtains a weight of 1 to c_1. Next, only updates on $x \in c_2$ will be performed, since c_1 is ranked correctly due to f_1 having a weight of 1 and f_2 keeping some nonzero weight to it. f_2 makes a stronger connection to c_2 than c_1 after at most 2 FSU invocations. R_1 in the optimal case would be 1.0 here, while it can approach 0.5 if we always update. Note that as fewer updates in general mean fewer connections (sparser indices), we may also save in space in this lazy update regime (see Section 6).

On the other hand, if we don't update at all when the right class is at rank 1, we may also suffer from suboptimal performance. This happens even in the case of a single feature. Thus *"proactive"* updating is useful too. The next case elaborates.

Case 2. Consider the single feature case and three classes c_1, c_2, c_3, where $P(c_1) = 0.5$, while $P(c_2) = P(c_3) = 0.25$. Thus c_1 should be ranked highest, for say maximizing R_1. This yields optimal $R_1 = 0.5$, and if we always invoke FSU, this will be the case after a few updates (we will soon get $w_{1,1} \approx 0.5$, and $w_{1,2} \approx w_{1,3} \approx 0.25$). If we don't update when true class is at rank 1, c_2 or c_3 can easily take the place of c_1 when an instance $x \in c_2$ or $x \in c_3$ is presented, but we need to reverse the situation subsequently when $x' \in c_1$ is presented, and instances belonging to c_1 are more frequent. In general, the connection weights from the feature to c_1, c_2, and c_3 will be similar in the purely mistake-driven updating regime, and on sequences that look like the worst case alternating sequence: $c_1, c_2, c_1, c_3, c_1, c_2, \cdots$, the running value of R_1 can approach 0. While random sequences are not as bad, we should still expect significant inferior performance. On randomly generated sample of size 2000 according to above class distribution, averaging over 100 80-20 splits, always (proactive) updating gave an average R_1 performance of 0.479 ± 0.02 (standard deviation of 0.02), while the lazy update gave 0.428 ± 0.09.

Therefore, not updating when the rank of the right class is adequate may cause unnecessary instability in behavior and inferior performance as well. Of course, we desire an algorithm that can perform well in the single feature case. Continued updating even when the true class is ranked highest is akin to keeping a kind of extended memory (in the connection weights).

We strike a balance between the two desirables by using the notion of *margin*. The margin on the current instance is the score of the positive class minus the score of the highest scoring negative

class:

$$\delta = s_{c_x} - s'_x, \text{ where } s_{c_x} \geq 0, s'_x \geq 0, s'_x = \max_{c \neq c_x} s_c.$$

If the margin δ does not exceed a desired margin threshold δ_m, we update[13] (invoke FSU). Note that both s_{c_x} and s'_x can be 0. If we set the margin threshold to 0, we may fit more instances in the training set, and handle situations like case 1, but underperform for case 2 situations. With a sufficiently high margin, updates are always made and case 2 is covered, but fitting power (case 1) can suffer. There is a tradeoff, and a good question is what the best choice of threshold may be? The best choice depends on the problem and the feature vector representation. Individual edge weights are in the $[0,1]$ range, and when the instances are l_2 normalized, we have observed that on average top classes obtain scores in the $[0,1]$ range as well, irrespective of data sets or choice of margin threshold (Madani and Connor, 2007).

Our use of margin is somewhat similar to the use of margin for online algorithms such as perceptron and Winnow (e.g., Carvalho and Cohen, 2006; Crammer and Singer, 2003a), although our particular motivation from considering case 2, "stability" or keeping some "extended memory" for each feature, appears to be different.

4.3.2 RATING THE FEATURES: DOWN-WEIGH INFREQUENT FEATURES

It may be a good idea to down-weigh or eliminate those features' votes that are only seen a few times during learning, as their proportion estimates (connection weights) can be inaccurate and in particular higher than what they should be. Consider the first time FSU is invoked on a feature. After that update, such a feature gives a weight of 1 (the maximum possible) to the class it gets connected to. This is undesired. Of course, how much to down-weigh can depend on the problem, and how feature values are distributed. In our experiments, during scoring of the class, we multiply a feature's score for class c, $w_{f,c}$, by a rating r_f (see Equation 1 in Section 3.2), $r_f = \min(1, \frac{\#_f}{10})$, where $\#_f \geq 1$ denotes the number of times feature f has been seen so far. $\#_f$ is computed only during the first pass over training data. We show that on some problems, this option improves accuracy.

4.4 Summary and Relations to other Methods

The FF algorithm aggregates the votes of each features for ranking and classification. During learning, FF may be viewed as directing a stream of classes to each feature, so that each feature can compute weights for a subset of the classes that it may connect to. The stream, for example with the use of margin, may be hard to characterize and may show drifts during learning: it may initially be those instances in which the feature is active, but later it may correspond to a subsequence of those instances which are somewhat hard to classify. Features may be space constrained: they need to be space efficient in the number of connections they make as well as in computing their connection weights. This efficiency aspect is especially important in large-scale many-class learning.

The FF algorithm has similarities with online algorithms such as Winnow (Littlestone, 1988), as it normalizes (in general weakens some of) the weights, and the perceptron algorithm (Rosenblatt, 1958), as for example the updates are in part additive (ignoring the normalization or weakening). The important difference that changes the nature of the algorithm is that changes to weights are

13. For instances with multiple true classes, the margin is computed for each positive true class. Every active feature is updated for each true class for which its margin is below the margin threshold.

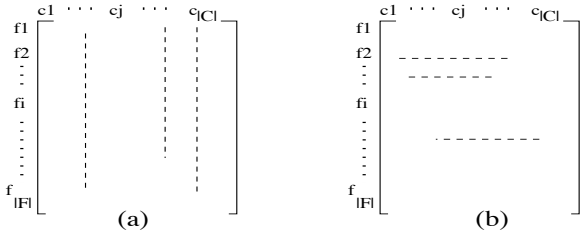

Figure 6: In learning a weight matrix for multiclass learning (here the features corresponding to the rows), prototype methods operate on the columns (part a), for instance in normalizing the (column) weight vectors, while feature-focus methods operate on the rows (part b), for example in ensuring that the number of nonzeros in each row remain within a budget.

done from the side of features, unlike Winnow or perceptron. The Winnow algorithm does the normalization from the side of the classes: each class is represented by a classifier (a class prototype), and each classifier has its feature weights normalized after each update. If normalization is done for all features, many features, whether or not active, get weakened. In a sense, the classifier ranks the features in order of importance for its own concept. A number of learning algorithms in the family of linear classifier learning algorithms, focus on the class side, for example, learning a prototype classifier for each class (e.g., Crammer and Singer, 2003a) (see Figure 6). This is a natural approach for binary classification. In our case, it is the classes whose connections to a feature may be weakened due to one or more classes being strengthened. In the FSU update given in this paper, this weakening happens irrespective of whether a class was ranked high (this aspect is similar to Winnow, but again, for class weights instead of feature weights). Alternative feature-focus updates are possible (e.g., Madani and Huang, 2008). It is best to view each feature as a voter or "expert", and the goal is to obtain good class rankings for each instance by adjusting the votes. A prototype for a class is more appropriate for ranking instances for that class.

To keep memory consumption in check, it seems most direct to constrain features not to connect to more than say 10s of classes, rather than somehow constraining the classes (class prototypes). It appeared harder to us to bound the number of features a class needs, and different classes may require widely varying number of features for adequate performance. See Raghavan et al. (2007) for an exploration of the number of useful features that different (binary) learning problems need for achieving (nearly) maximum accuracy. We also note that in many problems of interest, the number of classes, while large, is significantly smaller than the number of features. In many domains, as the number of classes grows, the number of features tends to grow too (possibly in a proportional manner). In the best of worlds, each feature could be predictive for at most one class. While reality is far from this idealized picture, and we anticipate many interactions, expecting that features may not require high outdegrees for good accuracy, can be a good first assumption. A fruitful future avenue may be exploring this assumption via modeling and developing theoretical arguments.

A second related reason is that constraining the feature outdegrees to remain relatively small (e.g., 10s) appears easier to implement and more time efficient in an online processing regime. Again, a class may require 100s of features and beyond for good performance. Therefore processing the needed classes, to examine importance of features, can take more time, per instance. Finally, we seek rapid categorization per instance, and constraining indegree of classes may not guarantee that

the outdegree of commonly occurring features would be small. Constraining the degrees of classes is not directly related to the average time required for processing an instance. Given that an index is required for efficient classification, that is, efficient access from features to the relevant classes, one would need additional data structures (additional memory) for efficient prototype processing.

For the perceptron update, continued updating can increase weight magnitudes with no bound. This makes designing an effective weight management criterion difficult. False positive classes may obtain negative connections to features they weren't connected to (when ranked higher than the true positive). These extra connections hurt sparsity. Moreover negative connections may not be as useful in the task of ranking multiple classes, to the extent that they are useful in the binary-class case and when learning a single prototype, for ranking instances: in the many-class case, the true class could simply have higher positive weights to the appropriate features. Of course, our discussion does not preclude efficient algorithms that, nevertheless, perform their operations from the class side.

5. Techniques Based on Binary Classifier Training

We compare against hierarchical or top-down training and classification, a commonly used method when a taxonomy of classes, a tree from general classes at the top to specific classes, is available (Dumais and Chen, 2000; Liu et al., 2005). The hierarchical method reduces to one-versus-rest classification when the classes are flat (when there is just one level), which is another common method for multiclass classification (e.g., Rifkin and Klautau, 2004). We compare against one-versus-rest on relatively small sets, to see how indexing performs in more traditional classification settings. Note that the FF algorithm, while motivated by many-class learning, is a linear method applicable to few classes and in particular binary classification as well.

The one-versus-rest method simply trains a binary classifier for each class using all the data. During classification, all the classifiers are applied and their scores rather than classification outcomes are used for ranking.[14] We observed no advantage in obtaining probabilities here compared to using raw scores. The one-versus-rest method becomes quickly inefficient, at both training and classification times, as the number of classes increases (as all the classifiers need to be applied to a given instance).

Linear classifiers such as support vector machines (SVMs) often perform the best in very high dimensional problems such as text classification (Lewis et al., 2004; Sebastiani, 2002). We tested perceptrons and SVMs in one-versus-rest and top-down methods. We use single pass and multiple pass perceptrons (Rosenblatt, 1958) as well as committees of them. Here, each perceptron in the committee is represented as a sparse vector and random weight initialization, in $[-1, 1]$, is used when a new feature is added to the prototype. Unless specified, we run the perceptron learning algorithm until the 0/1 error on training is not improved (computed at the end of each pass), for 5 consecutive passes. Perceptron committees often obtain performance close to SVMs (e.g., Carvalho and Cohen, 2006), although their training time can be less.

14. Note that the use of index for classification is one-versus-rest (or "flat" classification), but the index was not obtained by training binary classifiers.

Algorithm TopDownProbabilities(x, c, p, $\tilde{C}_x$)
1. For each class c_i **that is a child of** c**:**
1.1 $p_{c_i} \leftarrow p \times P_{c_i}(x)$**. /* obtain probability */**
1.2 If $p_{c_i} \geq p_{min}$
1.2.1 $\tilde{C}_x \leftarrow \tilde{C}_x \cup \{(c_i, p_{c_i})\}$
1.2.2 TopDownProbabilities(x, c_i, p_{c_i}, $\tilde{C}_x$)

Figure 7: Pseudo-code for top-down classification. $P_{c_i}(x)$ denotes the probability assigned to x by the classifier trained for c_i in the tree. For each instance x, the first call is TopDownProbabilities(x, root, 1.0, {}).

5.1 Hierarchical Training and Classification

Briefly, hierarchical training works by first training classifiers for the first level classes in a one-vs-rest manner (e.g., Dumais and Chen, 2000). Then the same procedure can be repeated for the children of each class residing in the 2nd level (in general, the level below), training each classifier only on the instances that belong to one of the siblings. Only the classifiers for the top level classes will be trained on all the instances. For ranking and categorization using the hierarchical approach, we use classifier probabilities. We obtain probabilities from classifier scores by the method of sigmoid fitting (Platt, 1999). This may require additional training time for improved accuracy. In the experiments, we report on the effect of increasing the number of sigmoid-fitting trials on one of the data sets (Reuters RCV1).

During classification, whenever a classifier is applied, we use the probability it assigns. The probabilities are multiplied along a path top-down (Figure 7). A path of candidate classes is terminated if the probability falls under some threshold p_{min}. All the classifier at the first level (corresponding to the classes at the top level) are applied to a given instance. During test time, we tried several thresholds: $p_{min} = 0.05 + 0.05k, k = 1, 2, \cdots$, and report results on the threshold giving highest accuracy R_1. All our ranking methods are evaluated on the deepest classes an instance is assigned to. For the evaluation of the top-down method, from the list of candidates obtained for a given test instance, any class whose child is also in the list is removed, and the remaining classes are sorted by their assigned probabilities. For the list of the true classes of the test instance, again only those true classes with no child in the list are kept. Then R_1, R_5 and HR are computed (for the highest ranked true positive class).

We note that if we don't use the probabilities and ranking, that is, use class assignments to follow a path, the classification performance greatly suffers. This is since classifiers (when having to assign a class) in the higher levels can make "premature" false positive and false negative mistakes (and false negative mistakes are very costly). This inferior performance has been noted before too (e.g., Dekel et al., 2003).

6. Experiments

In this section, after describing the data sets we use and the experimental set up, we report on comparisons with other approaches. We then report on several ablation experiments as well as comparisons to the simpler IND algorithm and a previous (unweighted) indexing method. We conclude the section with experiments on some properties of our index learning method and the indices

Data Sets	$\lvert S\rvert$	$\lvert\mathcal{F}\rvert$	$\lvert\mathcal{C}\rvert$	$E_x\lvert\mathbf{v_x}\rvert$	$E_x\lvert C_x\rvert$

Ads	369k	301k	12.6k	27.2	1.4
Web	70k	685k	14k	210	1
Jane Austen	749k	299k	17.4k	15.1	1

Figure 8: Data sets: $|S|$ is number of instances, $|\mathcal{F}|$ is the number of features, $|\mathcal{C}|$ is the total number of classes, $E_x|\mathbf{v_x}|$ is the average (expected) number of unique active features per instance (avg. vector size), and $E_x|C_x|$ is the average number of class labels per instance.

learned (average class indegrees, performance on the training data, ...), and we give a few examples of the learned connections.

Figure 8 presents the data sets that we use, shown in order of class size $|\mathcal{C}|$. The first 6 are text categorization, and the last is a word prediction task. Ads refers to a text classification problem provided by Yahoo! Web refers to a web page classification into Yahoo! directory of topics. Jane Austen is 6 online novels of Jane Austen, concatenated (obtained from project Gutenberg (`http://www.gutenberg.org/`). The others are commonly used text categorization data sets (Lang, 1995; Rose et al., 2002.; Lewis et al., 2004).

On the first three small sets, we compare against one-versus-rest, and our purpose is mainly to compare accuracy. On the next 3, Reuters RCV1, Ads, and Web, we compare against the top-down method. In both the one-versus-rest and top-down methods, we deploy either single perceptron training, committee of 10 perceptrons, or a fast algorithm for learning linear SVMs (Keerthi and DeCoste, 2005). We could not run the SVM on the Web data as it took longer than a day, and had to limit our SVM experiments on Ads.[15] For the final word prediction data, the task is to predict each word given features derived from the surrounding words in the sentence. For this problem, since the classes (the words) do not form a hierarchy and one-versus-rest is too inefficient, we only show performance of the indexing method.

All instance vectors are l_2 (cosine) normalized. For text categorization data, the features are standard unigram or bigram words and phrases. The feature vectors were obtained from publicly available sources in the cases of Reuters RCV1 (Lewis et al., 2004), and the newsgroups (from Rennie[16]). For RCV1, we used the training split only (23k documents) to be able to experiment with the slower algorithms. We obtained the Ads and Web data sets from Yahoo! For the web data set, to obtain a sufficient number of instances per class, we cut the taxonomy at depth 4, that is, we only considered the true classes up to depth 4. To simplify evaluation, we used the lowest true class(es) in the hierarchy the instance was classified under at test time. Thus an instance in Reuters RCV1 corpus on average is assigned two true classes. We note that in many practical text

15. There has been further advances on speeding up linear SVM training algorithms since the submission of this paper (e.g., Shalev-Schwartz et al., 2007; Hsieh et al., 2008). The perceptron training timings in our tables may be a better indicator of the training times for the more recent algorithms.

16. Obtained from people.csail.mit.edu/jrennie/20Newsgroups.

categorization applications such as personalization, classes at the top level are too generic to be informative/useful. For top-down training, we trained the classifier on the internal classes as well. Web and Ads had just over 20 classes in the first level (after root), while Reuters RCV1 has two (we used both the Industry and Topic trees). The Jane Austen (word prediction) data set was obtained by processing Jane Austen's six online novels: the surrounding neighborhood of each word, 3 words on one side, 3 on the other, and their conjunctions, provided the features (about 15 many).

We report on the average performance over ten trials. In each trial a random 10% of the data is held out. The exception is the newsgroup data set where we use the 10 train-test splits by Rennie et al. (2003), each 80-20, and we used their vector representations, to be able to compare directly with their results. We used a 2.4GHz AMD Opteron processor with 64 GB of RAM, with light load.

Figures 9 and 10 present the algorithms' performance under both accuracy and efficiency criteria. As a simple baseline, we report the performance of FrequencyBaseline (FB) as well, which ranks classes simply based on the frequency of the classes in the training data set.

For the FF algorithm, we used w_{min} =0.01 for the minimum weight threshold during learning, and d_{max} =25 (max-outdegree during look up). Note that d_{max} of 25 means a class is retrieved as along as it is within the first 25 highest weight connections of some active feature, even if its weight is not much higher than w_{min}. During training, the FF algorithm looks for a true (positive) class within the first 50 top scoring classes. If it is not found, the score of the positive class is assumed 0. We report on performance after pass 1 with 0 margin threshold ($\delta_m = 0$), as well as best performance in R_1 within the first 10 passes, with $\delta_m \in \{0, 0.1, 0.5\}$. We did not optimize on the choice of these parameters, for example, we may do better for lower d_{max} values (see Section 6.3.2). Note that a δ_m value above 0.5 basically means to update on most instances as index edge weights are less than 1, and thus class score differences tend not to be much higher than 1.0, when instances are l_2 normalized. For the SVM, we report the best performance in R_1 over the regularization parameter $C \in \{1, 5, 10, 100\}$ for the first three small data sets and $C \in \{1, 10\}$ for the large ones. Often $C = 1$ and 10 suffices (accuracies are close). There are 10 perceptrons in the committee (often, 5 to 20 suffices for attaining much of the accuracy).

6.1 Accuracy Comparisons

We first observe that the FF algorithm is competitive with the best of others. In particular it achieves the highest R_5 in 5 of the 6 categorization domains, and the highest average R_1 in 4 of 6 cases. We have observed that comparison based on the HR results often yields similar rankings of the algorithms tested as does R_1. We limit the discussions to R_1 and R_5. In particular R_1 (plain accuracy or one minus zero-one error) is a simple commonly used performance measure. For the classifier based methods, observe that there is a good separation from perceptron to SVMs, suggesting that the classification tasks are challenging. The performance of FF on newsgroup ties the best performance achieved by Rennie et al. (2003), and they used special feature vector representations, for the linear SVM as well as their methods, to reach that performance.[17] In the case of RCVI, for top-down training, we experimented with using a fixed sigmoid, that is, no sigmoid fitting, as well as sigmoid fitting using one or more trials of obtaining scores (score-class pairs). When not fitting, we used fixed values of 0 bias and -2 slope: $\frac{1}{1+e^{-2s}}$, where s denotes the score of classifier on the instance.

17. On the industry data set, we found that the classes have similar proportions, close to 0.01. As we keep only 10% for test, and there are only just under 10k instances in the whole set, we see that the performance of Frequency Baseline is very low. The classes with the highest proportion in training are not the classes with the highest proportion on the test set.

Figure 9: Comparisons on the smaller data sets. T_{tr} is training time (s=seconds, m=minutes, h=hours), d is the number of "connections" touched on average per feature of a test instance, and $|\mathbf{W}|$ denotes the number of (nonzero) weights in the system (see Section 6.2). The first two rows for each set report on FF, the first row being FF with 0 margin threshold, after one pass (p=4 means trained for four passes). Some example standard deviations for R_1 are also shown.

Thus, at score of 0, the (probability) value obtained is 0.5, and score of 1, the probability is $\frac{1}{1+e^{-1}} \approx 0.73$. When sigmoid fitting, we used one or more 80-20 splits of the training data, trained on 80, obtained the scores on the remaining 20, pooled the scores from different trials and fitted a sigmoid on the points. We then trained the classifier on the whole set. With more trials, we got better results on RCV1, but with diminishing returns, and this takes more time. For Ads, we could run the SVM with no fitting. Committee and perceptron used 3 trials. We performed the binomial sign test to compare the performance of FF (the second row for each data set) against the best of others (this is the SVM result, when available) as follows. We paired the R_k values on the same splits of data, 10 many for each data set, and counted the number of wins and losses of FF. The bold-faced R_1 and R_5 values indicate significance with confidence level $p \leq 0.05$ (i.e., either 9 or 10 wins). We observe that FF is superior with statistical significance in many cases, and only in one case, R_1 on the smallest data set, does it have statistically significant inferior performance.

The competitive and even superior accuracy of the FF algorithm provides evidence that improving class ranking on each instance, in the context of other classes that may be relevant (other retrieved classes), and at the same time, keeping the index sparse, is a good strategy or learning bias for our high performance categorization task. Methods based on binary classifiers can be at

Figure 10: Comparisons on the larger data sets. T_{tr} is training time (s=seconds, m=minutes, h=hours), d is the number of "connections" touched on average per feature of a test instance, and $|\mathbf{W}|$ denotes the number of (nonzero) weights in the system (see Section 6.2). The first two rows for each set report on FF, the first row being FF with 0 margin threshold, after one pass (p=4 means trained for four passes). Some example standard deviations for R_1 are also shown.

a disadvantage because the task of choosing whether a single class should be assigned or not, in isolation, can be error-prone, especially with large numbers of classes. Classifier scores can be used for ranking classes, but the classifiers were not obtained with the objective of a good ranking of the classes for each instance (and their scores may not be calibrated):[18] a typical binary classifier such as an SVM is trained to yield a separation among instances (a good class prototype). The scores of such a classifier are more suitable for ranking the instances for the corresponding class than ranking classes for each instance. Top-down classification can help accuracy in that the top classifiers may effectively discover features useful for making general distinctions, and lower-level classifiers can similarly use features for making fine distinctions among a smaller set of sibling classes. On the

18. However, for the one-versus-rest experiments, we also evaluated rankings using the probabilities obtained via sigmoid fitting, instead of using the raw classifier scores, but saw no change or inferior accuracies (not shown).

other hand, top-down classification inherits the problems of one-versus-rest (for the children of every parent node, the problem is akin to one-versus-rest). Furthermore, the errors of the intermediate classifiers along a classification path can add up. Indexing achieves a kind of direct "flat" classification (akin to one-versus-rest, but not via binary classifiers). Features that are directly predictive of classes can be discovered, skipping error-prone intermediary classifiers. On the other hand, distinguishing thousands of classes via a single linear classifier (the index) can be error-prone.[19] It is ultimately an empirical question which of these fairly different learning techniques may outperform others.

6.2 Efficiency and Ease of Use

We see that the training times of the FF algorithm is dramatically lower than others, and the ratio grows with data set size, reaching or exceeding two orders of magnitude.

Our measure of work, d, is the expected number of "connections" touched per feature of a randomly drawn instance during categorization. For example, for the ads data set, on average just under 8 connections (classes) are touched during index look up per feature, or 8×27 total are touched per instance (the average number of features of a vector is 27, see Figure 8), while for top-down ranking, 80 classifiers are applied on average (over 22 at the top level) during the course of top-down ranking/classification. We are assuming the classifiers have a memory-time efficient hashed representation. Again, we see that the indexing approach can have a significant advantage here.

In the case of the index, the space consumption $|\mathbf{W}|$ is simply the number of edges (positive weights) in the bipartite graph. In the case of classifiers, we assumed a sparse representation (only nonzero weights are explicitly represented), and in most cases used a perceptron classifier, trained in a mistake driven fashion as a lower estimate for other classifiers.[20] On the smaller data sets, the difference is not important. However, we see that on the large categorization data sets the classifier based methods can consume significantly more space. We also note that for the FF algorithm, with higher δ_m, the index size increases. This is caused by more updates being performed with higher δ_m, and more updates tends to increase edge additions. This does not appear to increase the work d though.

The FF algorithm is very flexible. We could run it on our workstations for all the data sets (with 2 to 4 GB RAM), each pass taking no more than a few minutes at most. This was not possible for the classifier based methods on the large data sets (inadequate memory). In general, the top-down method required significant engineering effort (encoding the taxonomy structure, writing the classifiers to file for largest data sets, etc). Liu et al. (2005) also report on the considerable engineering effort required and the need for distributing the computation.

6.3 Effects of Various Options and Parameters

In this section, we investigate the effects of various parameters and options on accuracy and efficiency. For each option, we show performance on a subset of data sets to show the difference that using that option can make. In each case, unless otherwise specified, the remaining parameters (such as choice of margin) are as in Figures 9 and 10 for best performance, and as before we report

19. Huang et al. (2008) explore a multi-stage data-driven classification approach, using fast indexing for the first stage.
20. We have observed that the committee of perceptrons can be converted into a single linear classifier by weight averaging after training without degrading accuracy.

	No Constraints	Default Constraints	T_{tr} (single pass)
Small Reuters	0.884 $\pm$0.008	0.884 $\pm$0.008	0s vs 0s
News Group	0.866 $\pm$0.006	0.865 $\pm$0.005	3s vs 2s
Industry	0.889 $\pm$0.009	0.886 $\pm$0.008	9s vs 4s
RCV1	0.787 $\pm$0.007	0.787 $\pm$0.008	$[40s-50s]$ vs 6s
Ads	0.716	0.711	45m vs 27s
Web	0.327	0.347	2h vs 64s
Jane Austen	0.276	0.274	1h vs 41s

Figure 11: No constraints on d_{max} (maximum outdegree) nor w_{min} (w_{min} set to 0), compared to the default settings. Accuracies (R_1 values) are not affected much, but efficiency suffers greatly. The rough training times for a single pass are compared.

averages and standard deviations for 10 random trials of 90-10 splits (except for news groups, for which the 80-20 split is given).

6.3.1 REMOVING EFFICIENCY CONSTRAINTS

We designed the FF algorithm with efficiency in mind. It is instructive to see how the algorithm performs when we remove the efficiency constraints (w_{min} and d_{max}). Note however that such constraints may actually help accuracy somewhat by removing unreliable weights and preventing overfitting.

In these experiments, we set w_{min} to 0 and d_{max} to a large number (1000). We show the best R_1 result for choice of margin threshold $\delta_m \in \{0, 0.1, 0.5\}$, over the first 5 passes, and compare to default values for the efficiency constraints. We observe that the accuracies are not affected. However FF now takes much space and time to learn, and classification time is hurt too. On the web data, for instance, the number of edges in the index grows to 6.5meg after first pass (it was about 1.5meg before). The average number of edges touched per feature grows to 1633, versus 8 for the default, thus 200 times larger, which explains the slow-down in training time.

For the ads, web, and Jane Austen, due to the very long running times, we ran FF for only a few trials, sufficient to convince ourselves that the accuracy does not change (see also next section). We report the result (with or without constraints) from the first pass of a single trial, on the same split of data.

6.3.2 OUTDEGREE CONSTRAINT

Figure 12 shows accuracy against the degree constraint, d_{max}, on the 3 large categorization data sets. We see that accuracy may in fact improve with lower degrees (RCV1 and Web). At outdegree constraint of 3 for RCV1, the number of edges in the learned index is around 80k instead of 180k (for the default $d_{max} = 25$), and the number of classes (connections) touched per feature is under 3, instead of 15 (Figure 10).

In general, it may be a better policy to use a weight threshold, greater than w_{min}, instead of a max outdegree constraint, for more efficient retrieval, as well as more reduction in index size, without loss in ranking accuracy.

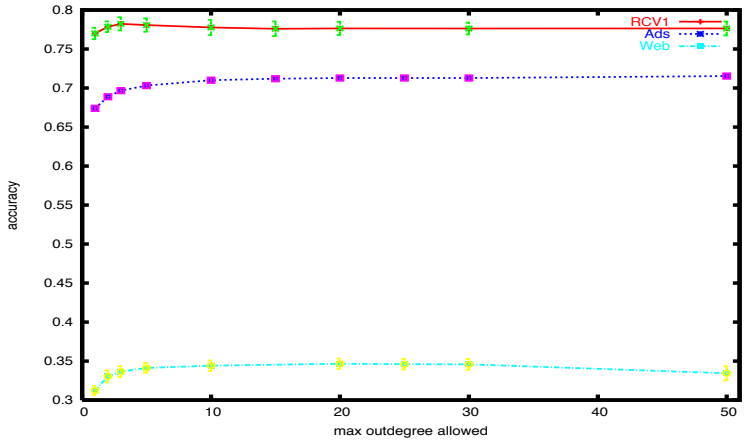

Figure 12: Accuracy (R_1) after one pass against the outdegree constraint.

	0.001	0.01	0.1
RCV1	0.786 $\pm$0.009	0.787 $\pm$0.008	0.761 $\pm$0.008
Ads	0.728 $\pm$0.002	0.725 $\pm$0.003	0.701 $\pm$0.003
Web	0.332 $\pm$0.005	0.352 $\pm$0.003	0.30 $\pm$0.006

Figure 13: The effect of w_{min} on accuracy. We took the best R_1 within the first 5 passes. The standard deviations are also shown. The value $w_{min} = 0.1$ is significantly inferior, while setting w_{min} to 0.001 does not lead to significant improvements.

6.3.3 THE MINIMUM WEIGHT CONSTRAINT

We noted in Section 4.1 that a w_{min} value of 0.01 can be adequate if we expect most useful edge weights to be in say $[0.05, 1]$ range, while a w_{min} value of 0.1 is probably inadequate for best performance. Figure 13 shows the R_1 values for $w_{min} \in \{0.001, 0.01, 0.1\}$ on the three bigger text categorization data sets. Other options were set as in Figure 10, and the best R_1 value within first 5 passes is reported.

Note that while w_{min} =0.1 is inferior, the bulk of accuracy is achieved by weights above 0.1, and $w_{min} \leq 0.01$ does not make a difference on these data sets.

6.3.4 MULTIPLE PASSES AND CHOICE OF MARGIN

Figure 14 shows accuracy (with standard deviations over 10 runs for two plots) as a function of the number of passes and different margin values, in the case of Reuters RCV1. As can be seen, different margin values can result in different accuracies. In some data sets, accuracy degrades somewhat right after pass 1, exhibiting possible overfitting as training performance increases.

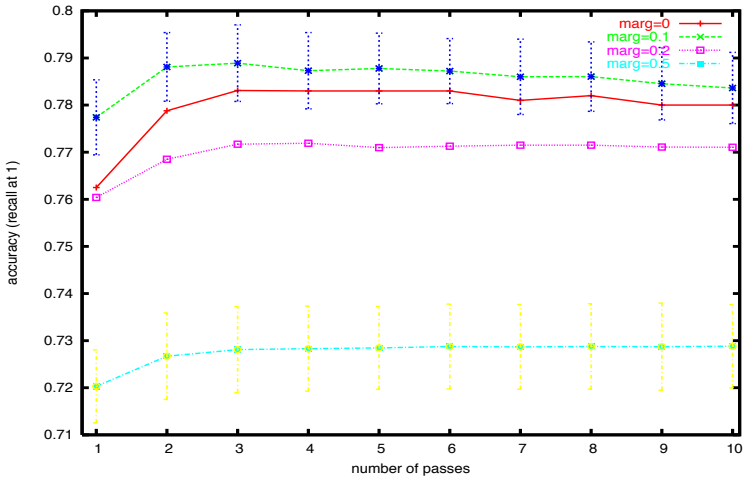

Figure 14: Reuters RCV1: Accuracy (R_1) for margin threshold $\delta_m \in \{0, 0.1, 0.2, 0.5\}$ against the number of passes.

	No Leakage	Allow Leakage
News Group	0.866 $\pm$0.005	0.865 $\pm$0.005
RCV1	0.780 $\pm$0.008	0.787 $\pm$0.008
Ads	0.696 $\pm$ 0.002	0.725 $\pm$ 0.003

Figure 15: On some data sets, allowing weight leakage when dropping edges can significantly improve accuracy.

6.3.5 DISALLOWING WEIGHT "LEAKS"

An uninformative feature such as "the" should give low votes to all classes. However, since the outdegree is constrained for memory reasons, if we imposed a constraint that the connection weights of a feature should sum to 1, then "the" may give significant but inaccurate weights to the classes that it happens to get connected with. Allowing for weight leaks is one way of addressing this issue. Figure 15 compares results. For the NO case in the figure (not allowing), whenever an edge from f to c is dropped, its weight, $w'_{f,c}$, is subtracted from w'_f. Thus $w'_f = \sum w'_{f,c}$ when we don't allow leaks, and $w'_f \geq \sum w'_{f,c}$ when we allow them.

6.3.6 DOWN WEIGHING LITTLE SEEN FEATURES

Figure 16 shows the effect of down weighing infrequent features (the default option, see Section 4.3.2), against treating all features as equal (not using the option). Down-weighing infrequent features can significantly help.

	No Down-Weigh	With Down-Weigh
Newsgroup	0.860 ±0.005	0.865 ±0.005
RCV1	0.758 ±0.007	0.787 ±0.008
Web	0.327 ±0.006	0.352 ± 0.007

Figure 16: Down-weighing infrequent features can significantly improve accuracy.

	IND	Bool FF p=1	best Bool FF	best FF
News Group	0.846 ±0.006	0.860 ±0.006	0.860 ±0.005	0.865 ±0.005
Industry	0.799 ±0.01	0.839 ±0.011	0.867 ±0.008	0.886 ±0.009
RCV1	0.686 ±0.009	0.76 ±0.01	0.780 ±0.008	0.789 ±0.008

Figure 17: Comparisons with IND and the effect of using feature values or treating them as Boolean and no l_2 normalization. The last column (best FF) contains results when default FF (with the use of feature values, l_2 normalization) is used (from Figure 9). Boolean FF with the right margin can significantly beat IND in accuracy, and use of feature values in FF appears to help over Boolean representation.

6.3.7 IND AND BOOLEAN FEATURES

IND treats features independently and as Boolean, but computes the conditionals exactly. Thus IND is similar to Boolean FF with high margin and $w_{min} = 0$, but IND also has a post-improvement step of adjusting p_{ind} (using the training set), which we have observed can improve the test accuracy of IND significantly (in addition to reducing index size). In these experiments p_{ind} was chosen from,

$$\{0.01, 0.02, \cdots, 0.09, 0.1, 0.15, 0.2, 0.25, \cdots, 0.6\}.$$

Here we compare IND against FF with Boolean values (and feature vectors are not l_2 normalized). This allows us to see how much using features values helps, as well as a comparison to a simpler heuristic of computing the conditional probabilities exactly and dropping the small values afterward. Figure 17 shows the results. For Newsgroup, Industry and RCV1, the best value of p_{ind} was respectively $0.01, 0.1$, and 0.3. To see the effect of edge removal on the accuracy of IND, if we chose $p_{ind} = 0$ (did no edge removal), we would get R_1 averaging below 0.58 on RCV1 (instead of current 0.69).

To achieve the best performance with Boolean features for FF on newsgroup, we had to raise the margin threshold to 7.0. Margin threshold of 1 or below gave significantly inferior results of 0.82 or below. Note that the scores that the classes receive during retrieval can increase significantly with Boolean features (compared to using the feature values in l_2 normalized vector representation).

We conclude that IND can be significantly outperformed by FF with an appropriate margin.

6.4 Other Experiments

Here, we first compare to an older indexing method (Madani et al., 2007) and then report and discuss some properties of the FF learning algorithm, such as the training performance, average scores of the top class, and a few example connections learned.

	No Classifiers	With Classifiers	FF
News Group	0.681 ±0.007	0.768 ±0.006	0.86
Industry	0.658 ±0.009	0.795 ± 0.01	0.88± 0.008

Figure 18: The performance of the non-ranking indexer algorithm, learning an unweighted index, with and without classifiers (first two columns) (Madani et al., 2007). The goal of improving class rankings, via learning a weighted index, simplifies indexing and improves classification accuracy.

6.4.1 COMPARISON TO OLDER INDEX LEARNING

The first idea for use of an index was to drastically lower the number of candidate classes to a manageable set when classifying a given instance, say 10s, and then use classifiers, possibly trained using the index as well (for efficient training), to precisely categorize the instances (Madani et al., 2007). Here, we briefly compare using that method, which we will refer to as *unweighted* indexing, against our current FF method. We have already noted that (binary) classifiers appear inferior for class ranking, especially as we increase the number of classes, in our comparisons in one-versus-rest experiments. Here, we present results showing that adding an intermediate index trained as described by Madani et al. (2007) does not improve accuracy. Furthermore, FF is significantly faster and easier to use.

The unweighted indexing algorithm of Madani et al. (2007) uses a threshold t_{tol} during training and updates the index only when more than t_{tol} many false positive classes are retrieved on a training instance or when a false negative occurs. In that work, class-feature weights are computed only to decide whether a connection or an edge should go into the index. We report accuracy under two regimes when we test unweighted indexing: (1) as a baseline, when only using the class-feature weights (without training classifiers), (2) when classifiers are also trained, here committee of perceptrons, trained in an online manner in tandem with the learning of the index, and the classes are ranked using the scores of the retrieved classifiers on the instance. For further details on that algorithm, please refer to Madani et al. (2007). Note that if we use the classifiers for direct classification (and not ranking) we obtain significantly inferior accuracy.

Figure 18 shows the results on the newsgroup and Industry data sets. When using no classifiers, we obtained the best R_1 performance with $t_{tol} = 5$ (out of $t_{tol} \in \{2, 5, 20\}$) on the newsgroup and Industry data sets. The accuracy improves with more passes, but reaches a ceiling in under 20 passes, and we have reported the best performance over the passes. With the addition of classifiers, the best R_1 is obtained when we don't use the indexer (see Figure 9), but the results from using the indexer can be close as the number of classes grows and with tolerance set in 10s. We have shown the result for t_{tol} =5 for newsgroup, and t_{tol} =20 for Industry. We observe that we require classifiers for the unweighted index learning method, to significantly improve accuracy, and the combination still lags behind FF in accuracy.

We note that while unweighted indexing without classifier training is fast, classifier training adds significant space and time overhead. Training was an order of magnitude slower than FF on the two data sets we reported on, and the classifiers also require 10 or more training passes to reach best performance.

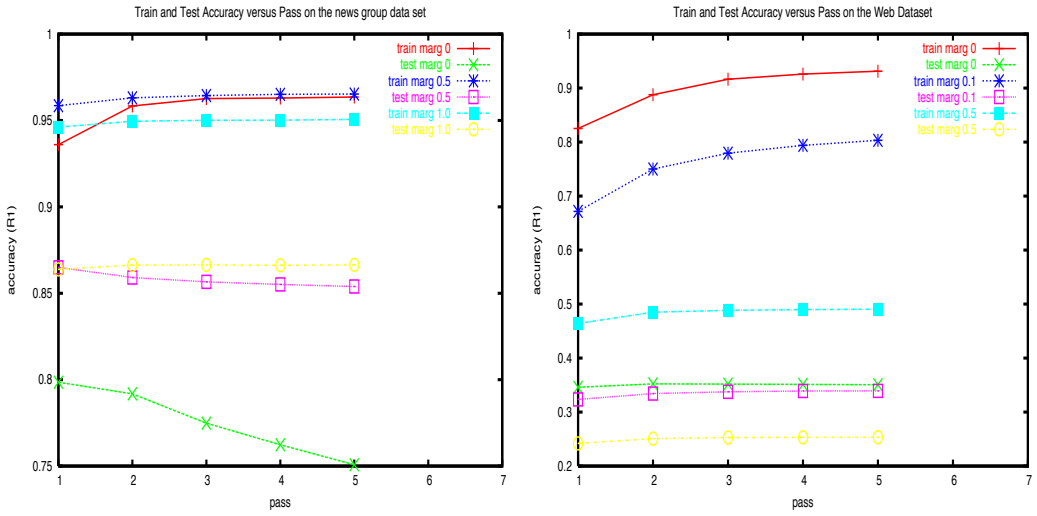

Figure 19: Train and test accuracy versus the number of passes, on the newsgroup (left) and web (right) data sets. Increasing the margin threshold can help control overfitting, but may not result in best test performance.

6.4.2 TRAINING VERSUS TEST PERFORMANCE OF FF

Figure 19 shows the train and test R_1 values as a function of pass. For the training performance, at end of each pass, the R_1 performance is computed on the same training instances rather than on the held-put sets. The higher the margin threshold, the less the capacity for fitting and therefor the less the possibility of overfitting. In the case of the newsgroup, we see that we reach the best performance with a relatively high margin threshold of $\delta_m \approx 1$, and the test and training performance remain roughly steady with more passes, unlike the case for $\delta_m = 0$. For the web data set, we see that the difference between train and test performance also decreases as we increase the margin threshold, but the best test performance is obtained with margin threshold of 0.

6.4.3 LEARNING CLASS PROTOTYPES

FF does not necessarily learn good (binary) classifiers or class prototypes, that is, the incoming weights into a class c_i (the vector $(w_{1,i}, \cdots, w_{f_{|F|},i})$), may make a poor class prototype vector. For example, we used such "prototypes" for ranking instances for each class in Reuters-21578 and newsgroup. The ranking quality (max F1) was significantly lower than that obtained from a single perceptron or a linear SVM trained for the class (5 to 10% reduction in absolute value of Max-F1 compared to perceptron on Reuters-21578 classes). On the newsgroup data set, the Max-F1 performances were comparable to single perceptrons but lagged the performance of SVMs.

6.4.4 CLASS INDEGREES

In Section 4.4 it was mentioned that prototypes may require more (nonzero) weights and processing time than features, and thus feature-based methods could have an efficiency advantage over

prototype-based methods (even when adjusted for the average vector length times average feature outdegree). Of course, this all depends on the details of what processing needs to be performed for a given algorithm and what the average numbers come out to. It may be useful to look at the average indegree of a class during the FF algorithm on our data sets.

Let the indegree of a class, that is, the length of the prototype vector, be the number of features that have a significant edge to the class (within the highest d_{max} edges for each feature). After one pass of training, the indegree for the top ranking class (averaged over test instances), for the Newsgroup, Industry, RCV1, Ads, and Web was respectively: 6k, 2k, 4k, 530, and 14k. The true class had a lower but somewhat similar average indegree, except for the web, where the true class had an average indegree of 6700. Furthermore, in general, the average indegree of classes at given rank goes down with increasing rank. This is plausible: concepts with relatively higher indegree (i.e., more connections) tend to beat others in the score received: they tend to be ranked closer to the top.

Observe that the uniform averages (indegree of a class picked uniformly at random) is significantly lower for the big data sets, due to the skew in class frequencies. The uniform averages can be computed from Figures 9 and 10, for example, for the Web data it is: $\frac{1.5meg}{14k} \approx 100$.

6.4.5 EXAMPLE FEATURES AND CONNECTIONS

On RCV1, there were about 300 feature-class connections with weight greater than 0.9 (strong connections). Examples included: "figurehead" to the class "EQUITY MARKETS", "gunfir" to the class "WAR, CIVIL WAR", and "manuf" (manufacturing) to "LEADING INDICATORS". Examples of features with relatively large "leaks", that is, with $w_f = \sum_c w_{f,c} < 0.25$, and thus likely uninformative, included "ago", "base", "year", and "intern".[21]

7. Conclusions

We raised the challenge of large-scale many-class learning and explored the approach of index learning. In this index-learning context, we began with the informal conjecture that (1) each feature need only connect to a relatively small number of classes, and (2) these connections can be discovered efficiently. We provided evidence that there exist very efficient online learning algorithms that nevertheless enjoy competitive and at times better accuracy performance than other commonly used methods. The algorithms may best be viewed as performing the computations from the side of features (the predictors) rather than the classes (the predicted). Each feature computes that choice of classes it may connect to and the connection weights. In particular, for very large-scale problems, each feature is space constrained in performing its computations and in the number of classes to which it can connect.

Much work remains in terms of advancing the algorithms and developing an understanding of their successes and limitations, including developing insights into the possible regularities in naturally occurring data that could explain the observed successes. We intend to further investigate index-learning algorithms, including different update methods and objectives, to develop theoretical properties, and to explore applications to various domains.

21. The feature "the" was probably dropped (a "stop" word) during the tokenization of this data set (Lewis et al., 2004).

Acknowledgments

Thanks to the anonymous reviewers of the paper for their valuable feedback and suggestions, which improved the presentation. Research for suggestions, pointers, and discussions, and Pradhuman Jahala, Xiaofei He, and Cliff Brunk for providing us the web data.

Appendix A. NP-Hardness

For the purpose of establishing hardness, the problem is specified by a finite set of instances, wherein each instance is assigned a class and specified by the set of its active features. The features need only be Boolean. Of course, more general problems are at least as hard. We show NP-hardness when a fixed upper constraint is imposed on the outdegree on each feature in the index. The problem is NP-hard under either objective of maximizing accuracy or maximizing the MRR reward on the given set. For MRR, for each instance, the reward is the reciprocal rank $\frac{1}{k_x}$, that is, the rank of the correct class in the ranking returned by the index. On a single instance, the reward could be 0, if the class is not retrieved, and maxes at 1, if the correct class has rank 1. Note that MRR in Section 3.3 is simply the average reward per instance. For accuracy (R_1), the reward is either 1, if the correct class is ranked highest, or otherwise 0. The decision problem is then to determine whether a weighted index (a weighted bipartite graph) satisfying the outdegree constraint exists that yields a total reward, $\sum_{x \in X} r(c_x)$, exceeding a desired threshold.

Theorem 4 *The index learning problem with the objective of either maximizing accuracy (R_1) or minimizing HR on a given set of instances, with the constraint of a constant upper bound, such as 1, on the outdegree of each feature is NP-Hard.*

Proof The reduction is from the SET COVER problem (Garey and Johnson., 1979). We reduce the SET COVER problem to problem of computing an index wherein each feature can connect to at most 1 class.

An instance I of SET COVER consist of a set $U = \{e_1, \ldots, e_n\}$ of elements and a set $\mathcal{S} = \{S_1, \ldots, S_m\}$ of subsets of U. The goal is to find a smallest subset $\mathcal{S}' \subseteq S$ such that $\bigcup_{S_i \in \mathcal{S}'} = U$. Given a SET COVER instance I, we construct an instance of the indexing problem with only two classes c_1 and c_2 such that there is a SET COVER solution of size C for I iff there is an index (with the maximum outdegree of 1 constraint), such that the maximum total reward, the number of instances for which the right class is ranked highest, is $|U| + |\mathcal{S}| - C$.

In the constructed indexing problem, there is one feature f_i corresponding to each set $S_i \in \mathcal{S}$, for a total of m features. There is also one instance x_j for each element $e_j \in U$ ($1 \leq j \leq n$), and x_j contains feature f_i (x_j is connected to f_i) iff the element e_j belongs to the set S_i. These instances, called the "original instances", belong to class c_1. In addition, there are m "extra" instances, one for each set (or each feature). Each of these extra instances contains only the feature it corresponds to, and belongs only to class c_2 (see Figure 20).

Here, in constructing an index, we need to decide for each feature whether to connect the feature to c_1 or to c_2 (we can only connect to one of the two), and with what weights. Now, if a cover of size C exists, then we can easily obtain an index yielding reward of $|U| + |\mathcal{S}|$ - C: we connect the

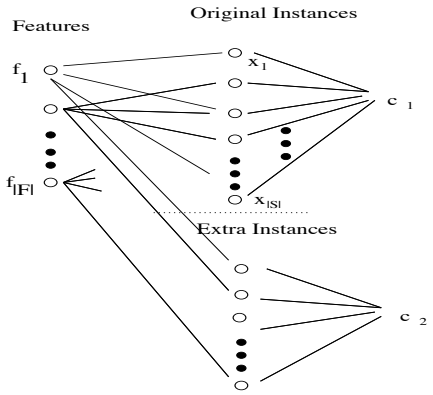

Figure 20: Reduction of the minimum set cover problem to index learning.

features in the cover (i.e., those features whose corresponding sets are in the cover) to c_1, each with weight of $|\mathcal{S}|$, and we connect all the other features to c_2 with a relatively small weight of say 1. In this way, for any original instance ($|U|$ many), c_1 is ranked highest, as at least one of its feature (the one(s) in the cover) connects to c_1 with high weight. For only $|\mathcal{S}|-C$ many of the extra instances, the correct class is missed, thus the total reward is $|U|+|\mathcal{S}|-C$.

For the reverse direction, we want to show that if an index with reward R exists, then there is a cover size $C \leq |U|+|\mathcal{S}|-R$. Assume an index is given with reward R. Note that lowering the connection weights to c_2 does not degrade the reward. So assume all such weights are at fixed minimum value v_{min}. Next, we note that any index can be converted to one in which all the original instances are "covered", that is, the index ranks the right class highest: take any original instance for which this is not the case, and take one of its features that is connected to c_2 (there must be at least one), drop that edge, and connect it to c_1 with high enough weight so that c_1 is ranked highest. The weight can simply be $v_{min}|\mathcal{S}|$. This operation does not degrade total reward as we lose on exactly one extra instance, but gain on at least one original instance. We may repeat this operation until all original instances are covered, and the reward is now $R' \geq R$. Now, we see that $R' = |U|+|\mathcal{S}|-n$, where n is the number of those extra instances for which c_2 is not retrieved, equal to the number of features covering the original instances (connecting to c_1), or the cover size in the original problem is $C = n = |U|+|\mathcal{S}|-R' \leq |U|+|\mathcal{S}|-R$. ■

Observe that the NP-hardness remains and is easier to show if we use the maximum incoming score rule for class retrieval (each class gets the maximum of its incoming edge weights) instead of the sum. This reduction does not establish NP-hardness of constant-ratio approximability of class ranking (due to the subtraction), which remains an interesting open problem. For instance, either a constant-ratio approximation to loss (for problems with high accuracy) or accuracy (for problems with high loss) would be interesting. A similar reduction for the problem of computing an *unweighted* index shows that problem is NP-hard even to approximate (Madani et al., 2007).

Appendix B. Approximation Consequences of Edge Dropping

Consider the setting of Section 4.1 wherein a feature wants to compute the proportions of the (sufficiently frequent) classes in the stream it observes. There are two causes for inaccuracies in computing proportions:

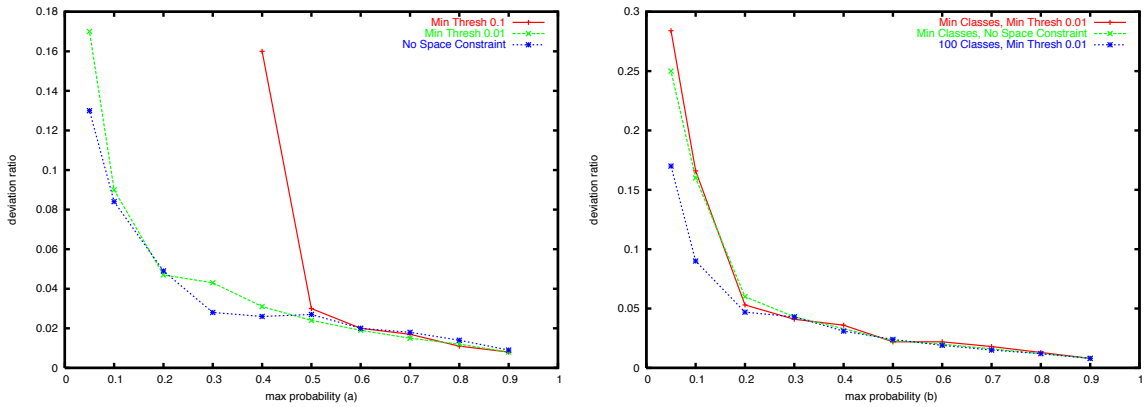

Figure 21: The performance of FSU under different allowances w_{min}. FSU computes the class proportions from processing a stream of 1000 class observations. For a choice of highest true probability p^*, the remaining probability mass $(1-p^*)$ is spread evenly over remaining classes. This is done under two regimes of generating classes. In (a) the number of unique classes is fixed at $|\mathcal{C}| = 100$, and in (b) it is $|\mathcal{C}| = \lceil \frac{1}{p^*} \rceil$ (i.e., modeling the situation in which other classes tie or have close probabilities to the maximum). The experiment, consisting of picking a class distribution and generating a 1000 draws, is repeated for 200 trials. In each trial, the deviation ratio of the highest proportion value computed by FSU, $\tilde{p}_{c_1}$, from the true maximum probability, p^*, is computed. This deviation (ratio) is $\frac{|\tilde{p}_{c_1} - p^*|}{p^*}$. The average deviation over the 200 trials is plotted against p^*. In the plot of part (b), the deviation is also compared to the case of 100 classes and $w_{min} = 0.01$. We note that $w_{min} \approx 0.01$ appears satisfactory for $p^* \geq 0.05$, while $w_{min} \approx 0.1$ performs well for a much smaller range.

- Finite samples (at any given time only a finite sample has been observed).
- Setting small weights (below w_{min}) to 0 (dropping edges) to save memory.

As FSU may drop and reinsert edges repeatedly, its approximation of actual proportions suffers from more than the issue of finite samples alone. We want to get an idea of this extra loss that we incur compared to the case when memory is not an issue (when no edges are dropped). Intuitively, FSU should work well as long as the proportions we are interested in sufficiently exceed the w_{min} threshold. The probability that a class with say probability p is not seen in some $\frac{1}{w_{min}}$ trials is $(1-p)^{1/w_{min}}$, and as long the ratio $\frac{p}{w_{min}}$ is high (several multiples), for example, $p > 4w_{min}$, this probability is relatively small. For example, for $w_{min} = 0.01$, and $p = 0.05$, the probability of not seeing such a class for a stretch of 100 consecutive trials is 0.006. More generally, the chance of being set to 0 (dropped) for a class with occurrence probability p quickly diminishes as we increase the ratio $\frac{p}{w_{min}}$, and therefore the cause of inaccuracies due to finite memory (the outdegree constraint on features) is mitigated.

We conducted experiments to see how much the proportion estimation by FSU deviates from true proportions and in particular compared that deviation to the deviations when FSU is not memory constrained (when w_{min} is set to 0). Figures 21 and 22 show the results. The experiments differ on how we generated the classes and computed the deviations. In the first of these experiments, to generate the true-class distribution, for some fixed number of classes $|\mathcal{C}|$, one class is given a

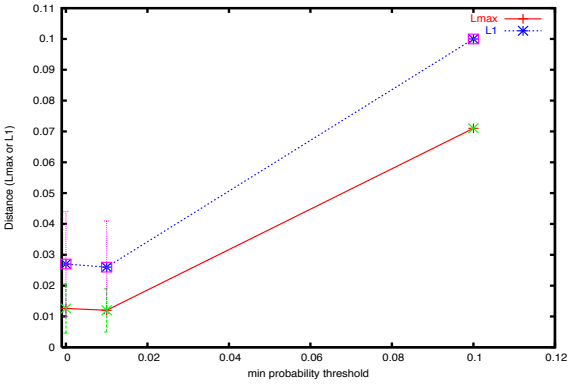

Figure 22: The performance of FSU, under different allowances w_{min}. The vector of true class probabilities is generated by uniformly and sequentially picking from $[0,1]$, and keeping track of total mass p (which should not exceed 1). If for latest generated class the probability drawn is greater than remaining mass $1-p$, the remaining mass is assigned instead, and class generation is stopped. FSU is evaluated after seeing a stream of 1000 classes iid drawn from such a source. The l_1 and l_∞ (or l_{max}) distances between the vector of empirical proportions that FSU computes and the true probabilities vector, averaged over 200 trials, is reported. FSU with w_{min} =0.01 yields distances comparable to FSU with $w_{min} = 0$, but w_{min} =0.1 yields significantly inferior estimates.

highest probability p^*, and the remaining classes obtain the remaining probability mass divided uniformly: $\frac{1-p^*}{|\mathcal{C}|-1}$. We then generated a stream of 1000 class observations (1000 iid draws) from such a distribution, and gave it to FSU with different values of w_{min}. We computed the deviation ratio: $\frac{|\tilde{p}_{c_1}-p^*|}{p^*}$, where c_1 denotes the class ranked highest by FSU, and $\tilde{p}_{c_1}$ is its assigned probability (highest computed probability). We averaged this deviation (ratio) over 200 trials of repeating the experiments. Figure 21(a) shows the averages when $|\mathcal{C}| = 100$ (so all classes except for one, obtain $\frac{1-p^*}{99}$). Figure 21(b) shows the results for $|\mathcal{C}| = \lceil \frac{1}{p^*} \rceil$ (e.g., for when $p^* \geq 0.5$, $|\mathcal{C}| = 2$, and when $p^* = 0.05, |\mathcal{C}| = 20$). Thus Figure 21(b) shows how FSU with limited w_{min} compares when the classes have similar proportions.

In the second set of experiments, we generated the probability for each class uniformly from the $[0,1]$ interval, keeping track of the total probability p used up during the course of generation. If the newest class gets a probability greater than $1-p$, $1-p$ is assigned to it and class generation, for selecting a distribution, is stopped. We then sampled iid to get a sequence of 1000 class observations. We compared the vector of class proportions that FSU computed using l_1 or l_∞ distance against the vector of true probabilities. We averaged the distances over 200 trials. We plot the results for FSU under different w_{min} constraints. We see that a threshold of $w_{min} \geq 0.1$ is not appropriate if the proportions we are interested in may be below 0.5, but a threshold of $w_{min} \approx 0.01$ does well, if we are interested in true proportions that are greater than 0.05 say. We compared a number of other statistics, such as the maximum deviation from true probability, and the probability that the deviation is larger than a threshold, and FSU with $w_{min} = 0.01$ performed similarly to $w_{min} = 0$ on the distributions tested. The reason as alluded to earlier is that those classes with proportions

significantly greater than w_{min} have a high chance of being seen early and frequently enough in the stream and not being dropped.

Thus, as long as we expect that the useful proportions are a few multiples away from the w_{min} we choose, FSU is expected to compute proportions that are close to ones computed by the FSU with w_{min} set to 0 (no space constraints). Further, we expected that most often the important feature connection weights that determine the true classes during ranking have fairly high weight. Note also that the constraint of finite samples also points to the limited utility of trying to keep track of relatively low proportions: for most useful features, we may see them below say a 1000 times (in common data sets), and commonly occurring features tend not to be discriminative. Finally, vector length is a factor: if there tend to exist strong features-class connections, the influence of the weaker connections on changing the ranking will be limited, in particular when the number of active features is adequately small. Thus, in many practical learning problems, expecting that most useful proportions (weights) are in a relatively small interval, say $[0.05, 1]$ (or that the features do not require high outdegree) may be reasonable (see Section 6.3.3). In general however, some experimentation may be required to set the w_{min} parameter.

Abstract

We propose hashing to facilitate efficient kernels. This generalizes previous work using sampling and we show a principled way to compute the kernel matrix for data streams and sparse feature spaces. Moreover, we give deviation bounds from the exact kernel matrix. This has applications to estimation on strings and graphs.

Keywords: hashing, stream, string kernel, graphlet kernel, multiclass classification

1. Introduction

In recent years, a number of methods have been proposed to deal with the fact that kernel methods have slow runtime performance if the number of kernel functions used in the expansion is large. We denote by $\mathcal{X}$ the domain of observations and we assume that $\mathcal{H}$ is a Reproducing Kernel Hilbert Space $\mathcal{H}$ with kernel $k : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$.

1.1 Keeping the Kernel Expansion Small

One line of research (Burges and Schölkopf, 1997) aims to reduce the number of basis functions needed in the overall function expansion. This led to a number of reduced set Support Vector algorithms which work as follows: a) solve the full estimation problem resulting in a kernel expansion,

b) use a subset of basis functions to approximate the exact solution, c) use the latter for estimation. While the approximation of the full function expansion is typically not very accurate, very good generalization performance is reported. The big problem in this approach is that the optimization of the reduced set of vectors is rather nontrivial.

Work on estimation on a budget (Dekel et al., 2006) tries to ensure that this problem does not arise in the first place by ensuring that the number of kernel functions used in the expansion never exceeds a given budget or by using an ℓ_1 penalty (Mangasarian, 1998). For some algorithms, for example, binary classification, guarantees are available in the online setting.

1.2 Keeping the Kernel Simple

A second line of research uses variants of sampling to achieve a similar goal. That is, one uses the feature map representation

$$k(x,x') = \left\langle \phi(x), \phi(x') \right\rangle.$$

Here ϕ maps $\mathcal{X}$ into some feature space $\mathcal{F}$. This expansion is approximated by a mapping $\overline{\phi} : \mathcal{X} \to \overline{\mathcal{F}}$

$$\overline{k}(x,x') = \left\langle \overline{\phi}(x), \overline{\phi}(x') \right\rangle \text{ often } \overline{\phi}(x) = M\phi(x).$$

Here $\overline{\phi}$ has more desirable computational properties than ϕ. For instance, $\overline{\phi}$ is finite dimensional (Fine and Scheinberg, 2001; Kontorovich, 2007; Rahimi and Recht, 2008), or $\overline{\phi}$ is particularly sparse (Li et al., 2007).

1.3 Our Contribution

Firstly, we show that the sampling schemes of Kontorovich (2007) and Rahimi and Recht (2008) can be applied to a considerably larger class of kernels than originally suggested—the authors only consider languages and radial basis functions respectively. Secondly, we propose a biased approximation $\overline{\phi}$ of ϕ which allows efficient computations even on data streams. Our work is inspired by the count-min sketch of Cormode and Muthukrishnan (2004), which uses hash functions as a computationally efficient means of randomization. This affords storage efficiency (we need not store random vectors) and at the same time they give performance guarantees comparable to those obtained by means of random projections.

As an application, we demonstrate computational benefits over suffix array string kernels in the case of document analysis and we discuss a kernel between graphs which only becomes computationally feasible by means of compressed representation.

1.4 Outline

We begin with a description of previous work in Section 2 and propose the hash kernels in Section 3 which is suitable for data with simple structure such as strings. An analysis follows in Section 4. And we propose a graphlet kernel which generalizes hash kernels to data with general structure—graphs and discuss a MCMC sampler in Section 5. Finally we conclude with experiments in Section 6.

2. Previous Work and Applications

Recently much attention has been paid to efficient algorithms with randomization or hashing in the machine learning community.

2.1 Generic Randomization

Kontorovich (2007) and Rahimi and Recht (2008) independently propose the following: denote by $c \in \mathcal{C}$ a random variable with measure P. Moreover, let $\phi_c : \mathcal{X} \to \mathbb{R}$ be functions indexed by $c \in \mathcal{C}$. For kernels of type

$$k(x,x') = \mathbf{E}_{c\sim \mathrm{P}(c)} \left[\phi_c(x)\phi_c(x')\right] \tag{1}$$

an approximation can be obtained by sampling $C = \{c_1,\ldots,c_n\} \sim \mathrm{P}$ and expanding

$$\overline{k}(x,x') = \frac{1}{n}\sum_{i=1}^{n} \phi_{c_i}(x)\phi_{c_i}(x').$$

In other words, we approximate the feature map $\phi(x)$ by $\overline{\phi}(x) = n^{-\frac{1}{2}}\left(\phi_{c_1}(x),\ldots,\phi_{c_n}(x)\right)$ in the sense that their resulting kernel is similar. Assuming that $\phi_c(x)\phi_c(x')$ has bounded range, that is, $\phi_c(x)\phi_c(x') \in [a,a+R]$ for all c, x and x' one may use Chernoff bounds to give guarantees for large deviations between $k(x,x')$ and $\overline{k}(x,x')$. For matrices of size $m \times m$ one obtains bounds of type $O(R^2\varepsilon^{-2}\log m)$ by combining Hoeffding's theorem with a union bound argument over the $O(m^2)$ different elements of the kernel matrix. The strategy has widespread applications beyond those of Kontorovich (2007) and Rahimi and Recht (2008):

- Kontorovich (2007) uses it to design kernels on regular languages by sampling from the class of languages.
- The marginalized kernels of Tsuda et al. (2002) use a setting identical to (1) as the basis for comparisons between strings and graphs by defining a random walk as the feature extractor. Instead of exact computation we could do sampling.
- The Binet-Cauchy kernels of Vishwanathan et al. (2007b) use this approach to compare trajectories of dynamical systems. Here c is the (discrete or continuous) time and $\mathrm{P}(c)$ discounts over future events.
- The empirical kernel map of Schölkopf (1997) uses $\mathcal{C} = \mathcal{X}$ and employs some kernel function κ to define $\phi_c(x) = \kappa(c,x)$. Moreover, $\mathrm{P}(c) = \mathrm{P}(x)$, that is, placing our sampling points c_i on training data.
- For RBF kernels, Rahimi and Recht (2008) use the fact that k may be expressed in the system of eigenfunctions which commute with the translation operator, that is the Fourier basis

  $$k(x,x') = \mathbf{E}_{w\sim \mathrm{P}(w)}[e^{-i\langle w,x\rangle} e^{i\langle w,x'\rangle}]. \tag{2}$$

  Here $\mathrm{P}(w)$ is a nonnegative measure which exists for any RBF kernel by virtue of Bochner's theorem, hence (2) can be recast as a special case of (1). What sets it apart is the fact that the variance of the features $\phi_w(x) = e^{i\langle w,x\rangle}$ is relatively evenly spread. (2) extends immediately to Fourier transformations on other symmetry groups (Berg et al., 1984).
- The conditional independence kernel of Watkins (2000) is one of the first instances of (1). Here $\mathcal{X},\mathcal{C}$ are domains of biological sequences, $\phi_c(x) = \mathrm{P}(x|c)$ denotes the probability of observing x given the ancestor c, and $\mathrm{P}(c)$ denotes a distribution over ancestors.

While in many cases straightforward sampling may suffice, it can prove disastrous whenever $\phi_c(x)$ has only a small number of significant terms. For instance, for the pair-HMM kernel most strings c are *unlikely* ancestors of x and x', hence $P(x|c)$ and $P(x'|c)$ will be negligible for most c. As a consequence the number of strings required to obtain a good estimate is prohibitively large—we need to reduce $\overline{\phi}$ further.

2.2 Locally Sensitive Hashing

The basic idea of randomized projections (Indyk and Motawani, 1998) is that due to concentration of measures the inner product $\langle \phi(x), \phi(x') \rangle$ can be approximated by $\sum_{i=1}^{n} \langle v_i, \phi(x) \rangle \langle v_i, \phi(x') \rangle$ efficiently, provided that the distribution generating the vectors v_i satisfies basic regularity conditions. For example, $v_i \sim \mathcal{N}(0, I)$ is sufficient, where I is an identity matrix. This allows one to obtain Chernoff bounds and $O(\varepsilon^{-2} \log m)$ rates of approximation, where m is the number of instances. The main cost is to store v_i and perform the $O(nm)$ multiply-adds, thus rendering this approach too expensive as a preprocessing step in many applications.

Achlioptas (2003) proposes a random projection approach that uses symmetric random variables to project the original feature onto a lower dimension feature space. This operation is simple and faster and the author shows it does not sacrifice the quality of the embedding. Moreover, it can be directly applied to online learning tasks. Unfortunately, the projection remains dense resulting in relatively poor computational and space performance in our experiments.

2.3 Sparsification

Li et al. (2007) propose to sparsify $\phi(x)$ by randomization while retaining the inner products. One problem with this approach is that when performing optimization for linear function classes, the weight vector w which is a linear combination of $\phi(x_i)$ remains large and dense, thus obliterating a significant part of the computational savings gained in sparsifying ϕ.

2.4 Count-Min Sketch

Cormode and Muthukrishnan (2004) propose an ingenious method for representing data streams. Denote by $\mathcal{I}$ an index set. Moreover, let $h : \mathcal{I} \to \{1, \ldots, n\}$ be a hash function and assume that there exists a distribution over h such that they are pairwise independent.

Assume that we draw d hash functions h_i at random and let $S \in \mathbb{R}^{n \times d}$ be a sketch matrix. For a stream of symbols s update $S_{h_i(s),i} \leftarrow S_{h_i(s),i} + 1$ for all $1 \leq i \leq d$. To retrieve the (approximate) counts for symbol s' compute $\min_i S_{h_i(s'),i}$. Hence the name count-min sketch. The idea is that by storing counts of s according to several hash functions we can reduce the probability of collision with another particularly large symbol. Cormode and Muthukrishnan (2004) show that only $O(\varepsilon^{-1} \log 1/\delta)$ storage is required for an ε-good approximation, where $1 - \delta$ is the confidence.

Cormode and Muthukrishnan (2004) discuss approximating inner products and the extension to signed rather than nonnegative counts. However, the bounds degrade for real-valued entries. Even worse, for the hashing to work, one needs to take the minimum over a set of inner product candidates.

2.5 Random Feature Mixing

Ganchev and Dredze (2008) provide empirical evidence that using hashing can eliminate alphabet storage and reduce the number of parameters without severely impacting model performance. In addition, Langford et al. (2007) released the Vowpal Wabbit fast online learning software which uses a hash representation similar to the one discussed here.

2.6 Hash Kernel on Strings

Shi et al. (2009) propose a hash kernel to deal with the issue of computational efficiency by a very simple algorithm: high-dimensional vectors are compressed by adding up all coordinates which have the same hash value—one only needs to perform as many calculations as there are nonzero terms in the vector. The hash kernel can jointly hash both label and features, thus the memory footprint is essentially independent of the number of classes used.

3. Hash Kernels

Our goal is to design a possibly biased approximation which a) approximately preserves the inner product, b) which is generally applicable, c) which can work on data streams, and d) which increases the density of the feature matrices (the latter matters for fast linear algebra on CPUs and graphics cards).

3.1 Kernel Approximation

As before denote by $\mathcal{I}$ an index set and let $h : \mathcal{I} \to \{1,\dots,n\}$ be a hash function drawn from a distribution of pairwise independent hash functions. Finally, assume that $\phi(x)$ is indexed by $\mathcal{I}$ and that we may compute $\phi_i(x)$ for all nonzero terms efficiently. In this case we define the hash kernel as follows:

$$\overline{k}(x,x') = \left\langle \overline{\phi}(x), \overline{\phi}(x') \right\rangle \text{ with } \overline{\phi}_j(x) = \sum_{i \in \mathcal{I}; h(i)=j} \phi_i(x) \tag{3}$$

We are accumulating all coordinates i of $\phi(x)$ for which $h(i)$ generates the same value j into coordinate $\overline{\phi}_j(x)$. Our claim is that hashing preserves information as well as randomized projections with significantly less computation. Before providing an analysis let us discuss two key applications: efficient hashing of kernels on strings and cases where the number of classes is very high, such as categorization in an ontology.

3.2 Strings

Denote by $\mathcal{X} = \mathcal{I}$ the domain of strings on some alphabet. Moreover, assume that $\phi_i(x) := \lambda_i \#_i(x)$ denotes the number of times the substring i occurs in x, weighted by some coefficient $\lambda_i \geq 0$. This allows us to compute a large family of kernels via

$$k(x,x') = \sum_{i \in \mathcal{I}} \lambda_i^2 \#_i(x) \#_i(x'). \tag{4}$$

Teo and Vishwanathan (2006) propose a storage efficient $O(|x| + |x'|)$ time algorithm for computing k for a *given* pair of strings x, x'. Here $|x|$ denotes the length of the string. Moreover, a weighted combination $\sum_i \alpha_i k(x_i, x)$ can be computed in $O(|x|)$ time after $O(\sum_i |x_i|)$ preprocessing.

The big drawback with string kernels using suffix arrays/trees is that they require large amounts of working memory. Approximately a factor of 50 additional storage is required for processing and analysis. Moreover, updates to a weighted combination are costly. This makes it virtually impossible to apply (4) to millions of documents. Even for modest document lengths this would require Terabytes of RAM.

Hashing allows us to reduce the dimensionality. Since for every document x only a relatively small number of terms $\#_i(x)$ will have nonzero values—at most $O(|x|^2)$ but in practice we will restrict ourselves to substrings of a bounded length l leading to a cost of $O(|x| \cdot l)$—this can be done efficiently in a single pass over x. Moreover, we can compute $\overline{\phi}(x)$ as a pre-processing step and discard x altogether.

Note that this process spreads out the features available in a document *evenly* over the coordinates of $\overline{\phi}(x)$. Moreover, note that a similar procedure can be used to obtain good estimates for a TF/IDF reweighting of the counts obtained, thus rendering preprocessing as memory efficient as the actual computation of the kernel.

3.3 Multiclass

Classification can sometimes lead to a very high dimensional feature vector even if the underlying feature map $x \to \phi(x)$ may be acceptable. For instance, for a bag-of-words representation of documents with 10^4 unique words and 10^3 classes this involves up to 10^7 coefficients to store the parameter vector directly when the $\phi(x,y) = e_y \otimes \phi(x)$, where $\otimes$ is the tensor product and e_y is a vector whose y-th entry is 1 and the rest are zero. The dimensionality of e_y is the number of classes.

Note that in the above case $\phi(x,y)$ corresponds to a sparse vector which has nonzero terms only in the part corresponding to e_y. That is, by using the joint index (i,y) with $\phi(x,y)_{(i,y')} = \phi_i(x)\delta_{y,y'}$ we may simply apply (3) to an extended index to obtain hashed versions of multiclass vectors. We have

$$\overline{\phi}_j(x,y) = \sum_{i \in \mathbb{J}; h(i,y)=j} \phi_i(x).$$

In some cases it may be desirable to compute a compressed version of $\phi(x)$, that is, $\overline{\phi}(x)$ first and subsequently expand terms with y. In particular for strings this can be useful since it means that we need not parse x for every potential value of y. While this deteriorates the approximation in an additive fashion it can offer significant computational savings since all we need to do is permute a given feature vector as opposed to performing any summations.

3.4 Streams

Some features of observations arrive as a stream. For instance, when performing estimation on graphs, we may obtain properties of the graph by using an MCMC sampler. The advantage is that we need not store the entire data stream but rather just use summary statistics obtained by hashing.

4. Analysis

We show that the penalty we incur from using hashing to compress the number of coordinates only grows *logarithmically* with the number of objects and with the number of classes. While we are

unable to obtain the excellent $O(\varepsilon^{-1})$ rates offered by the count-min sketch, our approach retains the inner product property thus making hashing accessible to linear estimation.

4.1 Bias and Variance

A first step in our analysis is to compute bias and variance of the approximation $\overline{\phi}(x)$ of $\phi(x)$. Whenever needed we will write $\overline{\phi}^h(x)$ and $\overline{k}^h(x,x')$ to make the dependence on the hash function h explicit. Using (3) we have

$$\begin{aligned}\overline{k}^h(x,x') &= \sum_j \sum_{i:h(i)=j} \phi_i(x) \sum_{i':h(i')=j} \phi'_i(x') \\ &= k(x,x') + \sum_{i,i':i\neq i'} \phi_i(x)\phi_{i'}(x')\delta_{h(i),h(i')} \end{aligned} \tag{5}$$

where δ is the Kronecker delta function. Taking the expectation with respect to the random choice of hash functions h we obtain the expected bias

$$\mathbf{E}_h[\overline{k}^h(x,x')] = \left(1-\tfrac{1}{n}\right)k(x,x') + \tfrac{1}{n}\sum_i \phi_i(x)\sum_{i'}\phi_{i'}(x')$$

Here we exploited the fact that for a random choice of hash functions the collision probability is $\frac{1}{n}$ uniformly over all pairs (i,j). Consequently $\overline{k}(x,x')$ is a biased estimator of the kernel matrix, with the bias decreasing inversely proportional to the number of hash bins.

The main change is a *rank-1* modification in the kernel matrix. Given the inherent high dimensionality of the estimation problem, a one dimensional change does not in general have a significant effect on generalization.

Straightforward (and tedious) calculation which is completely analogous to the above derivation leads to the following expression for the variance $\mathrm{Var}_h[\overline{k}^h(x,x')]$ of the hash kernel:

$$\mathrm{Var}_h[\overline{k}^h(x,x')] = \tfrac{n-1}{n^2}\left(k(x,x)k(x',x') + k^2(x,x') - 2\sum_i \phi_i^2(x)\phi_i^2(x')\right)$$

Key in the derivation is our assumption that the family of hash functions we are dealing with is pairwise independent.

As can be seen, the variance decreases $O(n^{-1})$ in the size of the values of the hash function. This means that we have an $O(n^{-\frac{1}{2}})$ convergence asymptotically to the expected value of the kernel.

4.2 Information Loss

One of the key fears of using hashing in machine learning is that hash collisions harm performance. For example, the well-known birthday paradox shows that if the hash function maps into a space of size n then with $O(n^{\frac{1}{2}})$ features a collision is likely. When a collision occurs, information is lost, which may reduce the achievable performance for a predictor.

Definition 1 *(Information Loss) A hash function h causes information loss on a distribution D with a loss function L if the expected minimum loss before hashing is less than the expected minimum loss after hashing:*

$$\min_f \underset{(x,y)\sim D}{E}[L(f(x),y))] < \min_g \underset{(x,y)\sim D}{E}[L(g(h(x)),y))]$$

Redundancy in features is very helpful in avoiding information loss. The redundancy can be explicit or systemic such as might be expected with a bag-of-words or substring representation. In the following we analyze explicit redundancy where a feature is mapped to two or more values in the space of size n. This can be implemented with a hash function by (for example) appending the string $i \in \{1,\ldots,c\}$ to feature f and then computing the hash of $f \circ i$ for the i-th duplicate.

The essential observation is that the information in a feature is only lost if all duplicates of the feature collide with other features. Given this observation, it's unsurprising that increasing the size of n by a constant multiple c and duplicating features c times makes collisions with all features unlikely. It's perhaps more surprising that when keeping the size of n *constant* and duplicating features, the probability of information loss can go *down*.

Theorem 2 *For a random function mapping l features duplicated c times into a space of size n, for all loss functions L and and distributions D on n features, the probability (over the random function) of no information loss is at least:*

$$1 - l[1 - (1 - c/n)^c + (lc/n)^c].$$

To see the implications consider $l = 10^5$ and $n = 10^8$. Without duplication, a birthday paradox collision is virtually certain. However, if $c = 2$, the probability of information loss is bounded by about 0.404, and for $c = 3$ it drops to about 0.0117.

Proof The proof is essentially a counting argument with consideration of the fact that we are dealing with a hash *function* rather than a random variable. It is structurally similar to the proof for a Bloom filter (Bloom, 1970), because the essential question we address is: "What is a lower bound on the probability that all features have one duplicate not colliding with any other feature?"

Fix a feature f. We'll argue about the probability that all c duplicates of f collide with other features.

For feature duplicate i, let $h_i = h(f \circ i)$. The probability that $h_i = h(f' \circ i')$ for some other feature $f' \circ i'$ is bounded by $(l-1)c/n$ because the probability for each other mapping of a collision is $1/n$ by the assumption that h is a random function, and the union bound applied to the $(l-1)c$ mappings of other features yields $(l-1)c/n$. Note that we do not care about a collision of two duplicates of the same feature, because the feature value is preserved.

The probability that all duplicates $1 \le i \le c$ collide with another feature is bounded by $(lc/n)^c + 1 - (1 - c/n)^c$. To see this, let $c' \le c$ be the number of distinct duplicates of f after collisions. The probability of a collision with the first of these is bounded by $\frac{(l-1)c}{n}$. Conditioned on this collision, the probability of the next collision is at most $\frac{(l-1)c-1}{n-1}$, where 1 is subtracted because the first location is fixed. Similarly, for the ith duplicate, the probability is $\frac{(l-1)c-(i-1)}{n-(i-1)}$. We can upper bound each term as $\frac{lc}{n}$, implying the probability of all c' duplicates colliding with other features is at most $(lc/n)^{c'}$. The probability that $c' = c$ is the probability that none of the duplicates of f collide, which is $\frac{(n-1)!}{n^c(n-c-1)!} \ge ((n-c)/n)^c$. If we pessimistically assume that $c' < c$ implies that every duplicate collides with another feature, then

$$\begin{aligned} \mathrm{P}(\mathrm{coll}) &\le \mathrm{P}(\mathrm{coll}|c' = c)\,\mathrm{P}(c' = c) + \mathrm{P}(c' \ne c) \\ &\le (lc/n)^c + 1 - ((l-c)/l)^c. \end{aligned}$$

Simplification gives $(lc/n)^c + 1 - (1 - c/n)^c$ as claimed. Taking a union bound over all l features, we get that the probability any feature has all duplicates collide is bounded by $l[1 - (1 - c/n)^c +$

$(lc/n)^c]$. ■

4.3 Rate of Convergence

As a first step note that any convergence bound only depends *logarithmically* on the size of the kernel matrix.

Theorem 3 *Assume that the probability of deviation between the hash kernel and its expected value is bounded by an exponential inequality via*

$$\mathrm{P}\left[\left|\overline{k}^h(x,x') - \mathbf{E}_h\left[\overline{k}^h(x,x')\right]\right| > \varepsilon\right] \leq c\exp(-c'\varepsilon^2 n)$$

for some constants c, c' depending on the size of the hash and the kernel used. In this case the error ε arising from ensuring the above inequality, with probability at least $1-\delta$, for m observations and M classes (for a joint feature map $\phi(x,y)$, is bounded by

$$\varepsilon \leq \sqrt{(2\log(m+1) + 2\log(M+1) - \log\delta + \log c - 2\log 2)/nc'}.$$

Proof Apply the union bound to the kernel matrix of size $(mM)^2$, that is, to all $T := m(m+1)M(M+1)/4$ unique elements. Solving

$$Tc\exp(-c'\varepsilon^2 n) = \delta,$$

we get the bound on ε is

$$\sqrt{\frac{\log(Tc) - \log\delta}{c'n}}. \tag{6}$$

Bounding $\log(Tc)$ from above

$$\log(Tc) = \log T + \log c \leq 2\log(m+1) + 2\log(M+1) + \log c - 2\log 2,$$

and plugging it into (6) yields the result. ■

4.4 Generalization Bound

The hash kernel approximates the original kernel by big storage and computation saving. An interesting question is whether the generalization bound on the hash kernel will be **much worse** than the bound obtained on the original kernel.

Theorem 4 (Generalization Bound) *For binary class SVM, let $\overline{K} = \left\langle \overline{\phi}(x), \overline{\phi}(x') \right\rangle, K = \langle \phi(x), \phi(x') \rangle$ be the hash kernel matrix and original kernel matrix. Assume there exists $b \geq 0$ such that $b \geq tr(\overline{K}) - tr(K)$. Let $\mathcal{F}$ be the class of functions mapping from $\mathcal{X} \times \mathcal{Y}$ to $\mathbb{R}$ given by $f(x,y) = -yg(x)$, where g is a linear function in a kernel-defined feature space with norm at most 1. For any size m sample $\{(x_1,y_1),\ldots,(x_m,y_m)\}$ drawn i.i.d. from data distribution D over $\mathcal{X} \times \mathcal{Y}$ and for any*

$\delta \in (0,1)$ *and any* $\gamma > 0$*, with probability at least* $1-\delta$*, we have*

$$P(y \neq sgn(g(x))) \leq \frac{1}{m\gamma}\sum_{i=1}^{m}\xi_i + \frac{4}{m\gamma}\sqrt{tr(\overline{K})} + 3\sqrt{\frac{ln(\frac{2}{\delta})}{2m}} \tag{7}$$

$$\leq \frac{1}{m\gamma}\sum_{i=1}^{m}\xi_i + \frac{4}{m\gamma}\sqrt{tr(K)} + \frac{4}{m\gamma}\sqrt{b} + 3\sqrt{\frac{ln(\frac{2}{\delta})}{2m}}, \tag{8}$$

where $\xi_i = \max\{0, \gamma - y_i g(x_i)\}$*, and* $g(x_i) = \left\langle w, \overline{\phi}(x_i, y_i)\right\rangle$.

Proof The standard Rademacher bound states that for any size m sample drawn i.i.d from D, for any $\delta \in (0,1)$ and any $\gamma > 0$, with probability at least $1-\delta$, the true error of the binary SVM ,whose kernel matrix is denoted as K', can be bounded as follows:

$$P(y \neq sgn(g(x))) \leq \frac{1}{m\gamma}\sum_{i=1}^{m}\xi_i + \frac{4}{m\gamma}\sqrt{tr(K')} + 3\sqrt{\frac{ln(\frac{2}{\delta})}{2m}}. \tag{9}$$

We refer the reader to Theorem 4.17 in Shawe-Taylor and Cristianini (2004) for a detailed proof. The inequality (7) follows by letting $K' = \overline{K}$. Because $tr(\overline{K}) \leq b + tr(K) \leq (\sqrt{b} + \sqrt{tr(K)})^2$, we have $\frac{4}{m\gamma}\sqrt{tr(\overline{K})} \leq \frac{4}{m\gamma}\sqrt{tr(K)} + \frac{4}{m\gamma}\sqrt{b}$. Plugging above inequality into inequality (7) gives inequality (8). So the theorem holds. ■

The approximation quality depends on the both the feature and the hash collision. From the definition of hash kernel (see (3)), the feature entries with the same hash value will add up and map to a new feature entry indexed by the hash value. The higher collision of the hash has, the more entries will be added up. If the feature is sparse, the added up entries are mostly zeros. So the difference of the maximum and the sum of the entries is reasonably small. In this case, the hash kernel gives a good approximation of the original kernel, so b is reasonably small. Thus the generalization error does not increase much as the collision increases. This is verified in the experiment section in Table 4—increasing the collision rate from 0.82% to 94.31% only slightly worsens the test error (from 5.586% to 6.096%).

Moreover, Theorem 4 shows us the generalization bounds on the hash kernel and the original kernel only differ by $O((m\gamma)^{-1})$. This means that when our data set is large, the difference can be ignored. A surprising result as we shall see immediately is that in fact, the difference on the generalization bound is always nearly zero regardless of m, γ.

4.5 The Scaling Factor Effect

An interesting observation on Theorem 4 is that, if we use a new feature mapping $\phi' = a\phi$, where $a \in [0,1)$, it will make the bias term in (5) small. As we decrease a enough, the bias term can be arbitrarily small. Indeed, it vanishes when $a = 0$. It seems that thus we can get a much tighter bound according to Theorem 4—the term with b vanishes when $a = 0$. So is there an optimal scaling factor a that maximizes the performance? It turns out that any nonzero a doesn't effect the performance at all, although it does tighten the bound.

Let's take a closer look at the hash kernel binary SVM, which can be formalized as

$$\min_{w} \quad \frac{\lambda||w||^2}{2} + \sum_{i=1}^{m}\max\{0, 1 - y_i\left\langle w, \overline{\phi}(x_i, y_i)\right\rangle\}. \tag{10}$$

Applying a new feature mapping $\hat{\phi} = a\bar{\phi}$ gives

$$\min_{\hat{w}} \quad \frac{\hat{\lambda}||\hat{w}||^2}{2} + \sum_{i=1}^{m} \max\{0, 1 - y_i \left\langle \hat{w}, \bar{\phi}(x_i, y_i) \right\rangle\}, \tag{11}$$

where $\hat{\lambda} = \frac{\lambda}{a^2}$ and $\hat{w} = aw$. $\hat{\lambda}$ is usually determined by model selection. As we can see, given a training data set, the solutions to (10) and (11) are exactly identical for $a \neq 0$. When $a = 0$, $g(x) \equiv 0$ for all x, w, and the prediction degenerates to random guessing. Moreover, the generalization bound can be tighten by applying a small a nearly zero. This shows that hashing kernel SVM has nearly the same generalization bound as the original SVM in theory.

5. Graphlet Kernels

Denote by G a graph with vertices $V(G)$ and edges $E(G)$. Several methods have been proposed to perform classification on such graphs. Most recently, Przulj (2007) proposed to use the distribution over graphlets, that is, subgraphs, as a characteristic property of the graph. Unfortunately, brute force evaluation does not allow calculation of the statistics for graphlets of size more than 5, since the cost for exact computation scales exponentially in the graphlet size.

In the following we show that sampling and hashing can be used to make the analysis of larger subgraphs tractable in practice. For this denote by $S \subseteq G$ an induced subgraph of G, obtained by restricting ourselves to only $V(S) \subseteq V(G)$ vertices of G and let $\#_S(G)$ be the number of times S occurs in G. This suggests that the feature map $G \to \phi(G)$, where $\phi_S(G) = \#_S(G)$ will induce a useful kernel: adding or removing an edge (i, j) only changes the properties of the subgraphs using the pair (i, j) as part of their vertices.

5.1 Counting and Sampling

Depending on the application, the distribution over the counts of subgraphs may be significantly skewed. For instance, in sparse graphs we expect the fully disconnected subgraphs to be considerably overrepresented. Likewise, whenever we are dealing with almost complete graphs, the distribution may be skewed towards the other end (i.e., most subgraphs will be complete). To deal with this, we impose weights $\beta(k)$ on subgraphs containing k edges $|E(S)|$.

To deal with the computational complexity issue simultaneously with the issue of reweighting the graphs S we simply replace explicit counting with sampling from the distribution

$$\mathrm{P}(S|G) = c(G)\beta(|E(S)|) \tag{12}$$

where $c(G)$ is a normalization constant. Samples from $\mathrm{P}(S|G)$ can be obtained by a Markov-Chain Monte Carlo approach.

Lemma 5 *The following MCMC sampling procedure has the stationary distribution (12).*

1. *Choose a random vertex, say i, of S uniformly.*
2. *Add a vertex j from $G \backslash S_i$ to S_i with probability $c(S_i, G)\beta(|E(S_{ij})|)$.*

Here S_i denotes the subgraph obtained by removing vertex i from S, and S_{ij} is the result of adding vertex j to S_i.

Note that sampling over j is easy: all vertices of G which do not share an edge with $S\backslash i$ occur with the same probability. All others depend only on the number of joining edges. This allows for easy computation of the normalization $c(S_i, G)$.

Proof We may encode the sampling rule via

$$T(S_{ij}|S,G) = \frac{1}{k} c(S_i, G)\beta(|E(S_{ij})|)$$

where $c(S_i, G)$ is a suitable normalization constant. Next we show that T satisfies the balance equations and therefore can be used as a proposal distribution with acceptance probability 1.

$$\begin{aligned}&\frac{T(S_{ij}|S,G)\,\mathrm{P}(S)}{T(S|S_{ij},G)\,\mathrm{P}(S_{ij})}\\ =&\frac{k^{-1}c(S_i,G)\beta(|E(S_{ij})|)c(G)\beta(|E(S)|)}{k^{-1}c(S_{ij,j},G)\beta(|E(S_{ij,ji})|)c(G)\beta(|E(S_{ij})|)} = 1.\end{aligned}$$

This follows since $S_{ij,j} = S_i$ and likewise $S_{ij,ji} = S$. That is, adding and removing the same vertex leaves a graph unchanged. ■

In summary, we obtain an algorithm which will readily draw samples S from $\mathrm{P}(S|G)$ to characterize G.

5.2 Dependent Random Variables

The problem with sampling from a MCMC procedure is that the random variables are *dependent* on each other. This means that we cannot simply appeal to Chernoff bounds when it comes to averaging. Before discussing hashing we briefly discuss averages of dependent random variables:

Definition 6 (Bernoulli Mixing) *Denote by Z a stochastic process indexed by $t \in \mathbb{Z}$ with probability measure* P *and let Σ_n be the σ-algebra on Z_t with $t \in \mathbb{Z}\backslash 1, \ldots, n-1$. Moreover, denote by* P_- *and* P_+ *the probability measures on the negative and positive indices t respectively. The mixing coefficient β is*

$$\beta(n, \mathrm{P}_X) := \sup_{A \in \Sigma_n} \left| \mathrm{P}(A) - \mathrm{P}_- \times \mathrm{P}_+(A) \right|.$$

If $\lim_{n\to\infty} \beta(n, \mathrm{P}_z) = 0$ we call Z to be β-mixing.

That is, $\beta(n, \mathrm{P}_X)$ measures how much dependence a sequence has when cutting out a segment of length n. Nobel and Dembo (1993) show how such mixing processes can be related to iid observations.

Theorem 7 *Assume that* P *is β-mixing. Denote by* P^* *the product measure obtained from $\ldots \mathrm{P}_t \times \mathrm{P}_{t+1} \ldots$ Moreover, denote by $\Sigma_{l,n}$ the σ-algebra on $Z_n, Z_{2n}, \ldots, Z_{ln}$. Then the following holds:*

$$\sup_{A \in \Sigma_{l,n}} |\mathrm{P}(A) - \mathrm{P}^*(A)| \leq l\beta(n, \mathrm{P}).$$

This allows us to obtain bounds for expectations of variables drawn from P rather than P^*.

Theorem 8 *Let* P *be a distribution over a domain* $\mathcal{X}$ *and denote by* $\phi : \mathcal{X} \to \mathcal{H}$ *a feature map into a Hilbert Space with* $\langle \phi(x), \phi(x') \rangle \in [0,1]$. *Moreover, assume that there is a* β*-mixing MCMC sampler of* P *with distribution* P^{MC} *from which we draw* l *observations* x_{in} *with an interleave of* n *rather than sampling from* P *directly. Averages with respect to* P^{MC} *satisfy the following with probability at least* $1-\delta$*:*

$$\left\| \mathop{\mathbf{E}}_{x \sim \mathrm{P}(x)}[\phi(x)] - \frac{1}{l}\sum_{i=1}^{l} \phi(x_{in}) \right\| \leq l\beta(n, \mathrm{P}^{\mathrm{MC}}) + \frac{2+\sqrt{\log \frac{2}{\delta}}}{\sqrt{l}}.$$

Proof Theorem 7, the bound on $\|\phi(x)\|$, and the triangle inequality imply that the expectations with respect to P^{MC} and P^* only differ by $l\beta$. This establishes the first term of the bound. The second term is given by a uniform convergence result in Hilbert Spaces from Altun and Smola (2006). ■

Hence, sampling from a MCMC sampler for the purpose of approximating inner products is sound, provided that we only take sufficiently independent samples (i.e., a large enough n) into account. The translation of Theorem 8 into bounds on inner products is straightforward, since

$$\begin{aligned} &|\langle x, y \rangle - \langle x', y' \rangle| \\ \leq &\left\|x - x'\right\| \|y\| + \left\|y - y'\right\| \|x\| + \left\|x - x'\right\| \left\|y - y'\right\|. \end{aligned}$$

5.3 Hashing and Subgraph Isomorphism

Sampling from the distribution over subgraphs $S \in G$ has two serious problems in practice which we will address in the following: firstly, there are several graphs which are isomorphic to each other. This needs to be addressed with a graph isomorphism tester, such as Nauty (McKay, 1984). For graphs up to size 12 this is a very effective method. Nauty works by constructing a lookup table to match isomorphic objects.

However, even after the graph isomorphism mapping we are still left with a sizable number of distinct objects. This is where a hash map on data streams comes in handy. It obviates the need to store any intermediate results, such as the graphs S or their unique representations obtained from Nauty. Finally, we combine the convergence bounds from Theorem 8 with the guarantees available for hash kernels to obtain the approximate graph kernel.

Note that the two randomizations have very different purposes: the sampling over graphlets is done as a way to approximate the *extraction* of features whereas the compression via hashing is carried out to ensure that the representation is computationally efficient.

6. Experiments

To test the efficacy of our approach we applied hashing to the following problems: first we used it for classification on the Reuters RCV1 data set as it has a relatively large feature dimensionality. Secondly, we applied it to the DMOZ ontology of topics of webpages[1] where the number of topics is high. The third experiment—Biochemistry and Bioinformatics Graph Classification uses our hashing scheme, which makes comparing all possible subgraph pairs tractable, to compare graphs (Vishwanathan et al., 2007a). On publicly available data sets like MUTAG and PTC as well as on

1. Dmoz L2 denotes non-parent topic data in the top 2 levels of the topic tree and Dmoz L3 denotes non-parent topic data in the top 3 levels of the topic tree.

Data Sets	#Train	#Test	#Labels
RCV1	781,265	23,149	2
Dmoz L2	4,466,703	138,146	575
Dmoz L3	4,460,273	137,924	7,100

Table 1: Text data sets. #X denotes the number of observations in X.

Algorithm	Pre	TrainTest	Error %
BSGD	303.60s	10.38s	6.02
VW	303.60s	87.63s	5.39
VWC	303.60s	5.15s	5.39
HK	0s	25.16s	5.60

Table 2: Runtime and Error on RCV1. BSGD: Bottou's SGD. VW: Vowpal Wabbit without cache. VWC: Vowpal Wabbit using cache file. HK: hash kernel with feature dimension 2^{20}. Pre: preprocessing time. TrainTest: time to load data, train and test the model. Error: misclassification rate. Apart from the efficacy of hashing operation itself, the gain of speed is also due to a multi-core implementation—hash kernel uses 4-cores to access the disc for online hash feature generation. For learning and testing evaluation, all algorithms use single-core.

the biologically inspired data set DD used by Vishwanathan et al. (2007a), our method achieves the best known accuracy.

In both RCV1 and Dmoz, we use linear kernel SVM with stochastic gradient descent (SGD) as the workhorse. We apply our hash kernels and random projection (Achlioptas, 2003) to the SGD linear SVM. We don't apply the approach in Rahimi and Recht (2008) since it requires a shift-invariant kernel $k(x,y) = k(x-y)$, such as RBF kernel, which is not applicable in this case. In the third experiment, existing randomization approaches are not applicable since enumerating all possible subgraphs is intractable. Instead we compare hash kernel with existing graph kernels: random walk kernel, shortest path kernel and graphlet kernel (see Borgwardt et al. 2007).

6.1 Reuters Articles Categorization

We use the Reuters RCV1 binary classification data set (Lewis et al., 2004). 781,265 articles are used for training by stochastic gradient descent (SGD) and 23,149 articles are used for testing. Conventionally one would build a bag of words representation first and calculate exact term frequency / inverse document frequency (TF-IDF) counts from the contents of each article as features. The problem is that the TF calculation needs to maintain a very large dictionary throughout the whole process. Moreover, it is impossible to extract features online since the entire vocabulary dictionary is usually unobserved during training. Another disadvantage is that calculating exact IDF requires us to preprocess all articles in a first pass. This is not possible as articles such as news may vary daily.

However, it suffices to compute TF and IDF approximately as follows: using hash features, we no longer require building the bag of words. Every word produces a hash key which is the dimension index of the word. The frequency is recorded in the dimension index of its hash key. Therefore,

Algorithm	Dim	Pre	TrainTest	orgTrainSize	newTrainSize	Error %
RP	2^8	748.30s	210.23s	423.29Mb	1393.65Mb	29.35%
	2^9	1079.30s	393.46s	423.29Mb	2862.90Mb	25.08%
	2^{10}	1717.30s	860.95s	423.29Mb	5858.48Mb	19.86%
HK	2^8	0s	22.82s	NA	NA	17.00%
	2^9	0s	24.19s	NA	NA	12.32%
	2^{10}	0s	24.41s	NA	NA	9.93%

Table 3: Hash kernel vs. random projections with various feature dimensionalities on RCV1. RP: random projections in Achlioptas (2003). HK: hash kernel. Dim: dimension of the new features. Pre: preprocessing time. TrainTest: time to load data, train and test the model. orgTrainSize: compressed original training feature file size. newTrainSize: compressed new training feature file size. Error: misclassification rate. NA: not applicable. In hash kernel there is no preprocess step, so there is no original/new feature files. Features for hash kernel are built up online via accessing the string on disc. The disc access time is taken into account in **TrainTest**. Note that the TrainTest for random projection time increases as the new feature dimension increases, whereas for hash kernel the TrainTest is almost independent of the feature dimensionality.

Dim	#Unique	Collision %	Error %
2^{24}	285614	0.82	5.586
2^{22}	278238	3.38	5.655
2^{20}	251910	12.52	5.594
2^{18}	174776	39.31	5.655
2^{16}	64758	77.51	5.763
2^{14}	16383	94.31	6.096

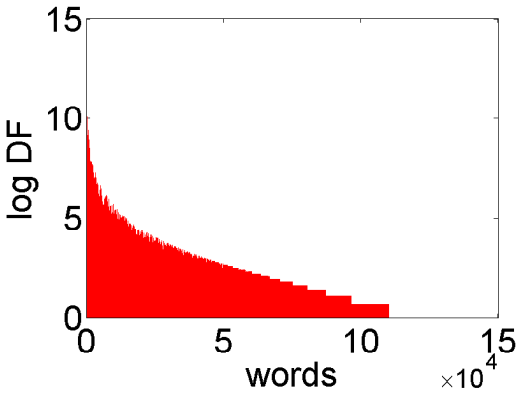
Table 4: Influence of new dimension on Reuters (RCV1) on collision rates (reported for both training and test set combined) and error rates. Note that there is no noticeable performance degradation even for a 40% collision rate.

every article has a frequency count vector as TF. This TF is a much denser vector which requires no knowledge of the vocabulary. IDF can be approximated by scanning a smaller *part* of the training set.

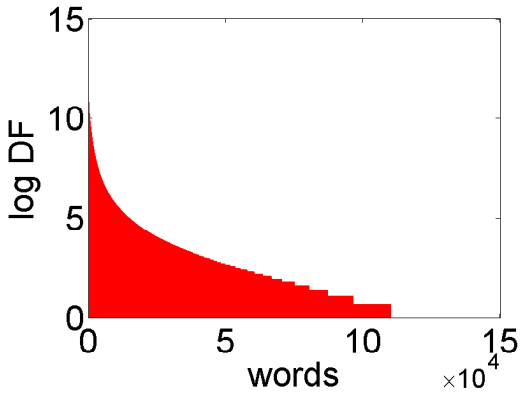
A quantile-quantile plot in Figure 1 shows that this approximation is justified—the dependency between the statistics on the subset (200k articles) and the full training set (800k articles) is perfectly linear.

We compare the hash kernel with Leon Bottou's Stochastic Gradient Descent SVM[2] (BSGD), Vowpal Wabbit (Langford et al., 2007) (VW) and Random Projections (RP) (Achlioptas, 2003). Our hash scheme is generating features online. BSGD is generating features offline and learning them online. VW uses BSGD's preprocessed features and creates further features online. Caching speeds up VW considerably. However, it requires one run of the original VW code for this purpose. RP uses BSGD's preprocessed features and then creates the new projected lower dimension features. Then it uses BSGD for learning and testing. We compare these algorithms on RCV1 in Table 2.

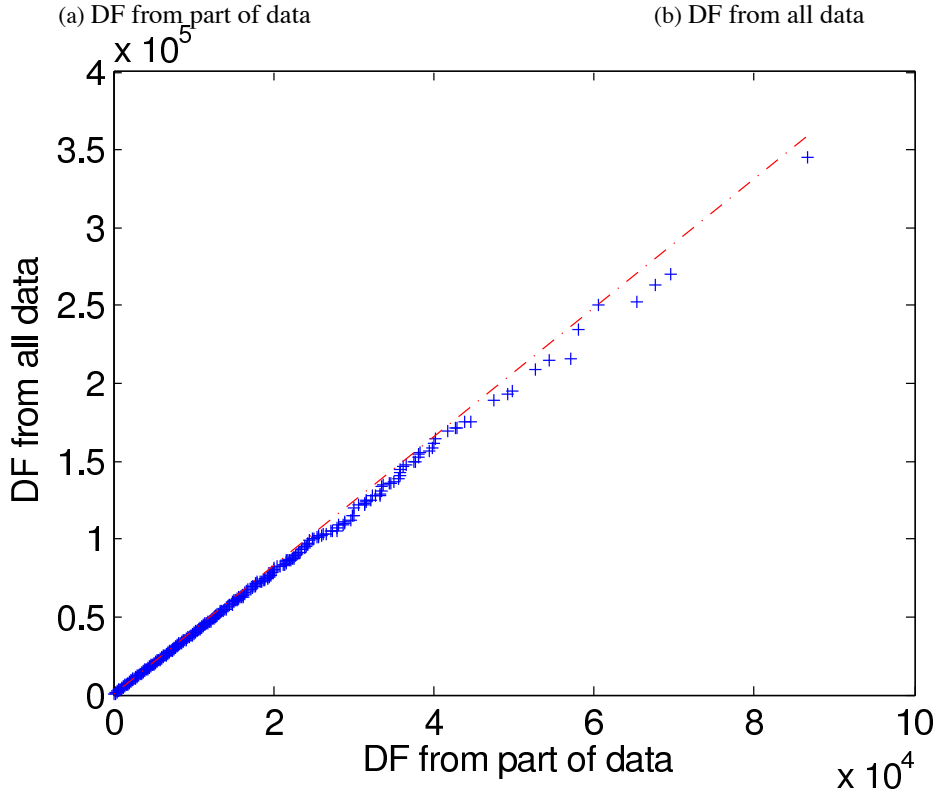
2. Code can be found at `http://leon.bottou.org/projects/sgd`.



(a) DF from part of data



(b) DF from all data



(c) Quantile-Quantile plot

Figure 1: Quantile-quantile plot of the DF counts computed on a subset (200k documents) and the full data set (800k documents). DF(t) is the number of documents in a collection containing word t.

Table 2. RP is not included in this table because it would be intractable to run it with the same feature dimensionality as HK for a fair comparison. As can be seen, the preprocessing time of BSGD and VW is considerably longer compared to the time for training and testing, due to the TF-IDF calculation which is carried out offline. For a fair comparison, we measure the time for feature loading, training and testing together. It can also be seen that the speed of online feature generation

	HLF (2^{28})		**HLF** (2^{24})		**HF**		**no hash**	**U base**	**P base**
	error	mem	error	mem	error	mem	mem	error	error
L2	30.12	2G	30.71	0.125G	31.28	2.25G (2^{19})	7.85G	99.83	85.05
L3	52.10	2G	53.36	0.125G	51.47	1.73G (2^{15})	96.95G	99.99	86.83

Table 5: Misclassification and memory footprint of hashing and baseline methods on DMOZ. HLF: joint hashing of labels and features. HF: hash features only. no hash: direct model (not implemented as too large, hence only memory estimates—we have 1,832,704 unique words). U base: baseline of uniform classifier. P base: baseline of majority vote. mem: memory used for the model. Note: the memory footprint in HLF is essentially independent of the number of classes used.

	HLF		**KNN**			**Kmeans**		
	2^{28}	2^{24}	S= 3%	6%	9%	S= 3%	6%	9%
L2	69.88	69.29	50.23	52.59	53.81	42.29	42.96	42.76
L3	47.90	46.64	30.93	32.67	33.71	31.63	31.56	31.53

Table 6: Accuracy comparison of hashing, KNN and Kmeans. HLF: joint hashing of labels and features. KNN: apply K Nearest Neighbor on sampled training set as search set. Kmeans: apply Kmeans on sampled training set to do clustering and then take its majority class as predicted class. S is the sample size which is the percentage of the entire training set.

is considerable compared to disk access. Table 2 shows that the test errors for hash kernel, BSGD and VW are competitive.

In table 3 we compare hash kernel to RP with different feature dimensions. As we can see, the error reduces as the new feature dimension increases. However, the error of hash kernel is always much smaller (by about 10%) than RP given the same new dimension. An interesting thing is that the new feature file created after applying RP is much bigger than the original one. This is because the projection maps the original sparse feature to a dense feature. For example, when the feature dimension is 2^{10}, the compressed new feature file size is already 5.8G. Hash kernel is much more efficient than RP in terms of speed, since to compute a hash feature one requires only $O(d_{nz})$ hashing operations, where d_{nz} is the number of non-zero entries. To compute a RP feature one requires $O(dn)$ operations, where d is the original feature dimension and and n is the new feature dimension. And with RP the new feature is always dense even when n is big, which further increases the learning and testing runtime. When $d_{nz} \ll d$ such as in text process, the difference is significant. This is verified in our experiment (see in Table 3). For example, hash kernel (including **Pre** and **TrainTest**) with 2^{10} feature size is over 100 times faster than RP.

Furthermore, we investigate the influence of the new feature dimension on the misclassification rate. As can be seen in Table 4, when the feature dimension decreases, the collision and the error rate increase. In particular, a 2^{24} dimension causes almost no collisions. Nonetheless, a 2^{18} dimension which has almost 40% collisions performs equally well on the problem. This leads to rather memory-efficient implementations.

Data	Algorithm	Dim	Pre	TrainTest	Error %
L2	RP	2^7	779.98s	1258.12s	82.06%
	RP	2^8	1496.22s	3121.66s	72.66%
	RP	2^9	2914.85s	8734.25s	62.75%
	HK	2^7	0s	165.13s	62.28%
	HK	2^8	0s	165.63s	55.96%
	HK	2^9	0s	174.83s	50.98%
L3	RP	2^7	794.23s	18054.93s	89.46%
	RP	2^8	1483.71s	38613.51s	84.06%
	RP	2^9	2887.55s	163734.13s	77.25%
	HK	2^7	0s	1573.46s	76.31%
	HK	2^8	0s	1726.67s	71.93%
	HK	2^9	0s	1812.98s	67.18%

Table 7: Hash kernel vs. random projections with various feature dimensionalities on Dmoz. RP: random projections in Achlioptas (2003). HK: hash kernel. Dim: dimension of the new features. Pre: preprocessing time—generation of the random projected features. TrainTest: time to load data, train and test the model. Error: misclassification rate. Note that the TrainTest time for random projections increases as the new feature dimension increases, whereas for hash kernel the TrainTest is almost independent of the feature dimensionality. Moving the dimension from 2^8 to 2^9 the increasing in processing time of RP is not linear—we suspect this is because with 2^8 the RP model has $256 \times 7100 \times 8 \approx 14$MB, which is small enough to fit in the CPU cache (we are using a 4-cores cpu with a total cache size of 16MB), while with 2^9 the model has nearly 28MB, no longer fitting in the cache.

6.2 Dmoz Websites Multiclass Classification

In a second experiment we perform topic categorization using the DMOZ topic ontology. The task is to recognize the topic of websites given the short descriptions provided on the webpages. To simplify things we categorize only the leaf nodes (Top two levels: L2 or Top three levels: L3) as a flat classifier (the hierarchy could be easily taken into account by adding hashed features for each part of the path in the tree). This leaves us with 575 leaf topics on L2 and with 7100 leaf topics on L3.

Conventionally, assuming M classes and l features, training M different parameter vectors w requires $O(Ml)$ storage. This is infeasible for massively multiclass applications. However, by hashing data and labels jointly we are able to obtain an efficient joint representation which makes the implementation computationally possible.

As can be seen in Table 5 joint hashing of features and labels is very attractive in items of memory usage and in many cases is necessary to make large multiclass categorization computationally feasible at all (naive online SVM ran out of memory). In particular, hashing features only produces worse results than joint hashing of labels and features. This is likely due to the increased collision rate: we need to use a smaller feature dimension to store the class dependent weight vectors explicitly.

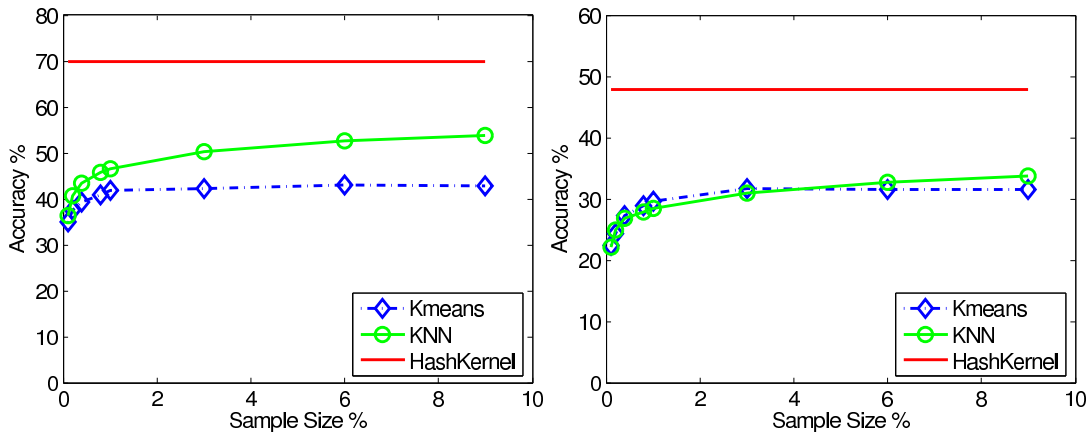


Figure 2: Test accuracy comparison of KNN and Kmeans on Dmoz with various sample sizes. Left: results on L2. Right: results on L3. Hash kernel (2^{28}) result is used as an upper bound.

Next we compare hash kernel with K Nearest Neighbor (KNN) and Kmeans. Running the naive KNN on the entire training set is very slow.[3] Hence we introduce sampling to KNN. We first sample a subset from the entire training set as search set and then do KNN classification. To match the scheme of KNN, we use sampling in Kmeans too. Again we sample from the entire training set to do clustering. The number of clusters is the minimal number of classes which have at least 90% of the documents. Each test example is assigned to one of the clusters, and we take the majority class of the cluster as the predicted label of the test example. The accuracy plot in Figure 2 shows that in both Dmoz L2 and L3, KNN and Kmeans with various sample sizes get test accuracies of 30% to 20% off than the upper bound accuracy achieved by hash kernel. The trend of the KNN and Kmeans accuracy curve suggests that the bigger the sample size is, the less accuracy increment can be achieved by increasing it. A numerical result with selected sample sizes is reported in Table 6.

We also compare hash kernel with RP with various feature dimensionality on Dmoz. Here RP generates the random projected feature first and then does online learning and testing. It uses the same 4-cores implementation as hash kernel does. The numerical result with selected dimensionalities is in Table 7. It can be seen that hash kernel is not only much faster but also has much smaller error than RP given the same feature dimension. Note that both hash kernel and RP reduce the error as they increase the feature dimension. However, RP can't achieve competitive error to what hash kernel has in Table 5, simply because with large feature dimension RP is too slow—the estimated run time for RP with dimension 2^{19} on dmoz L3 is 2000 days.

Furthermore we investigate whether such a good misclassification rate is obtained by predicting well only on a few dominant topics. We reorder the topic histogram in accordance to ascending error rate. Figure 3 shows that hash kernel does very well on the first one hundred topics. They correspond to easy categories such as language related sets "World/Italiano","World/Japanese","World/Deutsch".

3. In fact the complexity of KNN is $O(N \times T)$, where N, T are the size of the training set and the testing set. We estimate the running time for the original KNN, in a batch processing manner ignoring the data loading time, is roughly 44 days on a PC with a 3.2GHz cpu.

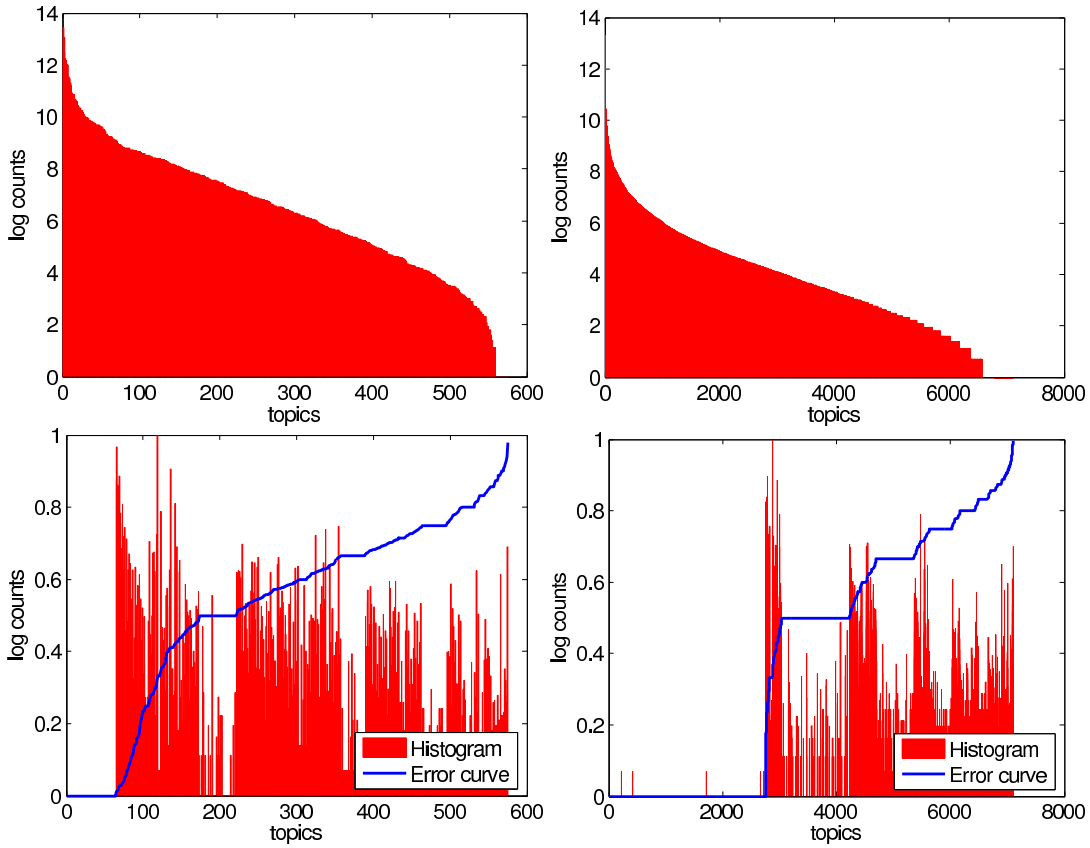

Figure 3: Left: results on L2. Right: results on L3. Top: frequency counts for topics as reported on the training set (the test set distribution is virtually identical). We see an exponential decay in counts. Bottom: log-counts and error probabilities on the test set. Note that the error is reasonably evenly distributed among the size of the classes (besides a number of near empty classes which are learned perfectly).

6.3 Biochemistry and Bioinformatics Graph Classification

For the final experiment we work with graphs. The benchmark data sets we used here contain three real-world data sets: two molecular compounds data sets, Debnath et al. (1991) and PTC (Toivonen et al., 2003), and a data set for protein function prediction task (DD) from Dobson and Doig (2003). In this work we used the unlabeled version of these graphs, see, for example, Borgwardt et al. (2007).

All these data sets are made of sparse graphs. To capture the structure of the graphs, we sampled connected subgraphs with varying number of nodes, from $n = 4$ to $n = 9$. We used graph isomorphism techniques, implemented in Nauty (McKay, 1984) for getting a canonically-labeled isomorph of each sampled subgraph. The feature vector of each example (graph) is composed of the number of times each canonical isomorph was sampled. Each graph was sampled 10000 times for each of $n = 4, 5 \ldots 9$. Note that the number of connected unlabeled graphs grows exponentially fast with the number of nodes, so the sampling is extremely sparse for large values of n. For this reason we normalized the counts so that for each data set each feature of $\phi(x)$ satisfies $1 \geq \phi(x) \geq 0$.

Data Sets	RW	SP	GKS	GK	HK	HKF
MUTAG	0.719	0.813	0.819	0.822	0.855	0.865
PTC	0.554	0.554	0.594	0.597	0.606	0.635
DD	>24h	>24h	0.745	>24h	0.799	0.841

Table 8: Classification accuracy on graph benchmark data sets. RW: random walk kernel, SP: shortest path kernel, GKS = graphlet kernel sampling 8497 graphlets, GK: graphlet kernel enumerating all graphlets exhaustively, HK: hash kernel, HKF: hash kernel with feature selection. '>24h' means computation did not finish within 24 hours.

Feature	All		Selection	
STATS	ACC	AUC	ACC	AUC
MUTAG	0.855	0.93	0.865	0.912
PTC	0.606	0.627	0.635	0.670
DD	0.799	0.81	0.841	0.918

Table 9: Non feature selection vs feature selection for hash kernel. All: all features. Selection: feature selection; ACC: accuracy; AUC: Area under ROC.

We compare the proposed hash kernel (with/without feature selection) with random walk kernel, shortest path kernel and graphlet kernel on the benchmark data sets. From Table 8 we can see that the hash Kernel even without feature selection still significantly outperforms the other three kernels in terms of classification accuracy over all three benchmark data sets.

The dimensionality of the canonical isomorph representation is quite high and many features are extremely sparse, a feature selection step was taken that removed features suspected as non-informative. To this end, each feature was scored by the absolute vale of its correlation with the target. Only features with scores above median were retained. As can be seen in Table 9 feature selection on hash kernel can furthermore improve the test accuracy and area under ROC.

7. Discussion

In this paper we showed that hashing is a computationally attractive technique which allows one to approximate kernels for very high dimensional settings efficiently by means of a sparse projection into a lower dimensional space. In particular for multiclass categorization this makes all the difference in terms of being able to implement problems with thousands of classes in practice on large amounts of data and features.

DL-Learner: Learning Concepts in Description Logics

Jens Lehmann LEHMANN@INFORMATIK.UNI-LEIPZIG.DE

Editor: Soeren Sonnenburg

Abstract

In this paper, we introduce DL-Learner, a framework for learning in description logics and OWL. OWL is the official W3C standard ontology language for the Semantic Web. Concepts in this language can be learned for constructing and maintaining OWL ontologies or for solving problems similar to those in Inductive Logic Programming. DL-Learner includes several learning algorithms, support for different OWL formats, reasoner interfaces, and learning problems. It is a cross-platform framework implemented in Java. The framework allows easy programmatic access and provides a command line interface, a graphical interface as well as a WSDL-based web service.

Keywords: concept learning, description logics, OWL, classification, open-source

1. Introduction

The *Semantic Web* grows steadily[1] and contains knowledge from diverse areas such as science, music, literature, geography, social networks, as well as from upper and cross domain *ontologies*[2]. The underlying semantic technologies currently start to create substantial industrial impact in application scenarios on and off the web, including knowledge management, expert systems, web services, e-commerce, e-collaboration, etc. Since 2004, the *Web Ontology Language OWL*, which is based on *description logics* (Baader et al., 2007), has been the W3C-recommended standard for Semantic Web ontologies and is a key to the growth of the Semantic Web.

Within this field, there is a need for well-structured ontologies with large amounts of instance data, since engineering such ontologies constitutes a considerable investment of resources. Nowadays, knowledge bases often provide large amounts of instance data without sophisticated schemata. Methods for automated schema acquisition and maintenance are therefore sought (see, e.g., Buitelaar et al. 2007). In particular, concept learning methods have attracted much interest, see, for example, Esposito et al. (2004), Lehmann (2007), Lehmann and Hitzler (2008) and Lisi and Esposito (2008). DL-Learner provides an open source framework for such methods as we will briefly describe in the sequel. Several learning algorithms have been implemented within this framework. Outside of DL-Learner, there exist only non open source implementations of algorithms (YinYang, DL-FOIL) to the best of our knowledge.

1. To give a rough estimate, the semantic index Sindice (`http://sindice.com/`) lists more than 10 billion entities from more than 100 million web pages.
2. See, for example, `http://tomgruber.org/writing/ontology-definition-2007.htm` for a definition of ontology in computer science.

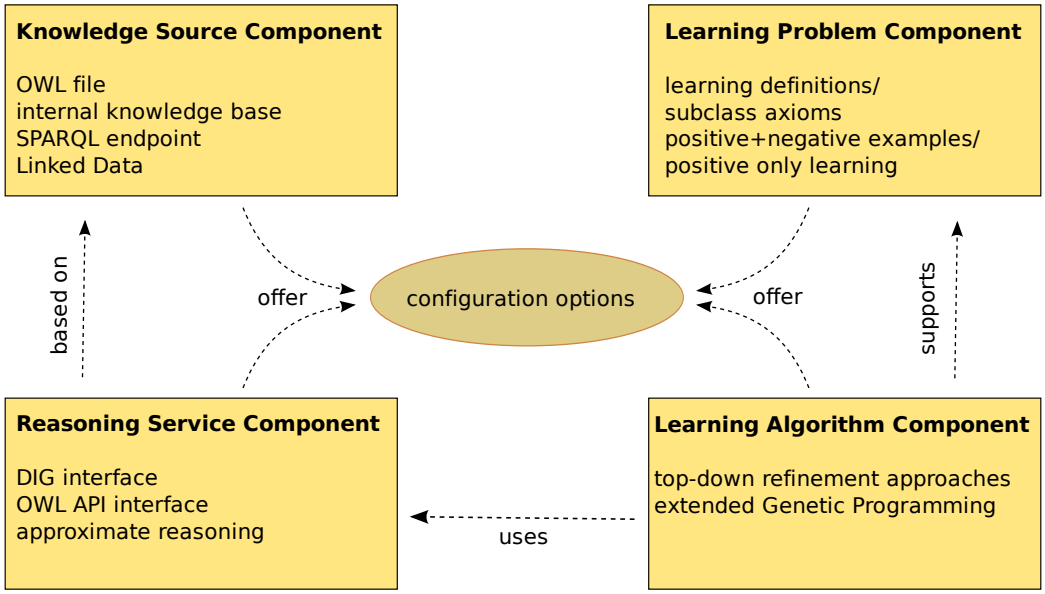

Figure 1: The architecture of DL-Learner is based on four component types each of which can have their own configuration options. A component manager can be used to create, combine, and configure components.

2. Framework

DL-Learner consists of core functionality, which provides Machine Learning algorithms for solving learning problems in OWL, support for different knowledge base formats, an OWL library, and reasoner interfaces. There are several interfaces for accessing this functionality, a couple of tools which use the DL-Learner algorithms, and a set of convenience scripts.

To be flexible and easily extensible, DL-Learner uses a component-based model. There are four types of components: knowledge source, reasoning service, learning problem, and learning algorithm. For each type, there are several implemented components and each component can have its own configuration options as illustrated in Figure 1. Configuration options can be used to change parameters/settings of a component.

Knowledge Sources integrate background knowledge. Almost all standard OWL formats are supported through the OWL API,[3] for example, RDF/XML, Manchester OWL Syntax, or Turtle. DL-Learner supports the inclusion of several knowledge sources, since knowledge can be widespread in the Semantic Web. In addition, DL-Learner facilitates the extraction of knowledge fragments from SPARQL[4] endpoints. This feature allows DL-Learner to scale up to very large knowledge bases containing millions of axioms (cf. Hellmann et al., 2009).

Reasoner Components provide connections to existing or own reasoners. Two components are the DIG 1.1[5] and OWL API reasoner interfaces, which allow to connect to all standard OWL reasoners via an HTTP and XML-based mechanism or a Java interface, respectively. Furthermore,

3. Information about the OWL API can be found at `http://owlapi.sourceforge.net`.
4. The W3C SPARQL recommendation is available at `http://www.w3.org/TR/rdf-sparql-query/`.
5. Information about DIG can be found at `http://dl.kr.org/dig/`.

DL-Learner offers its own approximate reasoner, which uses Pellet[6] for bootstrapping and loading the inferred model in memory. Afterwards, instance checks are performed very efficiently by using a local closed world assumption (see Badea and Nienhuys-Cheng 2000 on why this assumption is useful in description logics).

Learning Problems specify the problem type, which is to be solved by an algorithm. Currently, three problem components are implemented: 1.) learning from positive and negative examples 2.) positive-only learning and 3.) class axiom learning. The latter type is split into learning definitions and super class axioms. Amongst other methods, the components provide efficient coverage checks which can be used in the learning algorithms, for example, stochastic approaches for computing coverage up to a desired accuracy with respect to a 95% confidence interval are available.

Learning Algorithm components provide methods to solve one or more specified learning problem types. Apart from simple algorithms involving brute force or random guessing techniques, DL-Learner comprises a number of sophisticated algorithms based on genetic programming with a novel genetic operator (Lehmann, 2007), refinement operators for the description logic $\mathcal{ALC}$ (Lehmann and Hitzler, 2008), an extended operator supporting many features of OWL including datatype support, and an algorithm tailored for ontology engineering with a strong bias on short and readable concepts. Some of those algorithms have shown to be superior to other description logic learning systems and also superior to state-of-the-art ILP systems, for example, on the carcinogenesis problem.[7]

3. Implementation

The homepage of DL-Learner is `http://dl-learner.org` and contains up-to-date information about documentation and development of the software. A manual,[8] which complements the homepage and describes how to run DL-Learner, is included in its release. For developers, the Javadoc of DL-Learner is available online.[9]

The code base of DL-Learner consists of approximately 50,000 lines of code (excluding comments) with its core, that is, the component framework itself, accounting for roughly 1,500 lines. It is licensed under GPL 3. About 20 learning examples are included in the latest release (to be precise: 132 if smaller variations of existing problems/configurations are counted). 27 unit tests based on the JUnit framework are used to detect errors.

There are several interfaces available to access DL-Learner: To use components programmatically, the core package, in particular the component manager, can be of service. Similar methods are also available at the web service interface, which is based on WSDL. DL-Learner starts a web service included in Java 6, that is, no further tools are necessary. For end users, a command line interface is available. Settings are stored in *conf files*, which can then be executed in a similar fashion to other ILP tools. A prototypical graphical user interface is equally available, which can create, load, and save conf files. It provides widgets for modifying components and configuration options. An advantage of the component-based architecture is that all the interfaces mentioned need not to be changed, when new components are added or existing ones modified. This makes DL-Learner easily extensible. Another means to access DL-Learner, in particular for ontology engineering, is

6. The Pellet homepage is `http://clarkparsia.com/pellet/`.

Bounded Kernel-Based Online Learning*

Francesco Orabona FORABONA@IDIAP.CH

CH-1920 Martigny, Switzerland

Editor: Yoav Freund

Abstract

A common problem of kernel-based online algorithms, such as the kernel-based Perceptron algorithm, is the amount of memory required to store the online hypothesis, which may increase without bound as the algorithm progresses. Furthermore, the computational load of such algorithms grows linearly with the amount of memory used to store the hypothesis. To attack these problems, most previous work has focused on discarding some of the instances, in order to keep the memory bounded. In this paper we present a new algorithm, in which the instances are not discarded, but are instead projected onto the space spanned by the previous online hypothesis. We call this algorithm Projectron. While the memory size of the Projectron solution cannot be predicted before training, we prove that its solution is guaranteed to be bounded. We derive a relative mistake bound for the proposed algorithm, and deduce from it a slightly different algorithm which outperforms the Perceptron. We call this second algorithm Projectron++. We show that this algorithm can be extended to handle the multiclass and the structured output settings, resulting, as far as we know, in the first online bounded algorithm that can learn complex classification tasks. The method of bounding the hypothesis representation can be applied to any conservative online algorithm and to other online algorithms, as it is demonstrated for ALMA_2. Experimental results on various data sets show the empirical advantage of our technique compared to various bounded online algorithms, both in terms of memory and accuracy.

Keywords: online learning, kernel methods, support vector machines, bounded support set

1. Introduction

Kernel-based discriminative online algorithms have been shown to perform very well on binary and multiclass classification problems (see, for example, Freund and Schapire, 1999; Crammer and Singer, 2003; Kivinen et al., 2004; Crammer et al., 2006). Each of these algorithms works in rounds, where at each round a new instance is provided. On rounds where the online algorithm makes a prediction mistake or when the confidence in the prediction is not sufficient, the algorithm adds the instance to a set of stored instances, called the *support set*. The online classification function is defined as a weighted sum of kernel combination of the instances in the support set. It is clear that if the problem is not linearly separable or the target hypothesis is changing over time, the classification function will never stop being updated, and consequently, the support set will grow unboundedly.

*. A preliminary version of this paper appeared in the Proceedings of the 25th International Conference on Machine Learning under the title "The Projectron: a Bounded Kernel-Based Perceptron".

†. Current affiliation: Toyota Technological Institute at Chicago, 6045 S Kenwood Ave., Chicago, IL 60637.

This leads, eventually, to a memory explosion, which limits the applicability of these algorithms for those tasks, such as autonomous agents, for example, where data must be acquired continuously over time.

Several authors have tried to address this problem, mainly by bounding a priori the size of the support set with a fixed value, called a *budget*. The first algorithm to overcome the unlimited growth of the support set was proposed by Crammer et al. (2003), and refined by Weston et al. (2005). In these algorithms, once the size of the support set reaches the budget, an instance from the support set that meets some criterion is removed, and replaced by the new instance. The strategy is purely heuristic and no mistake bound is given. A similar strategy is also used in NORMA (Kivinen et al., 2004) and SILK (Cheng et al., 2007). The very first online algorithm to have a fixed memory budget and a relative mistake bound is the Forgetron algorithm (Dekel et al., 2007). A stochastic algorithm that on average achieves similar performance to Forgetron, and with a similar mistake bound was proposed by Cesa-Bianchi et al. (2006). Unlike all previous work, the analysis presented in the last paper is within a probabilistic context, and all the bounds derived there are in expectation. A different approach to address this problem for online Gaussian processes is proposed in Csató and Opper (2002), where, in common with our approach, the instances are not discarded, but rather projected onto the space spanned by the instances in the support set. However, in that paper no mistake bound is derived and there is no use of the hinge loss, which often produces sparser solutions. Recent work by Langford et al. (2008) proposed a parameter that trades accuracy for sparseness in the weights of online learning algorithms. Nevertheless, this approach cannot induce sparsity in online algorithms with kernels.

In this paper we take a different route. While previous work focused on discarding some of the instances in order to keep the support set bounded, in this work the instances are not discarded. Either they are projected onto the space spanned by the support set, or they are added to the support set. By using this method, we show that the support set and, hence, the online hypothesis, is guaranteed to be bounded, although we cannot predict its size before training. Instead of using a budget parameter, representing the maximum size of the support set, we introduce a parameter trading accuracy for sparseness, depending on the needs of the task at hand. The main advantage of this setup is that by using all training samples, we are able to provide an online hypothesis with high online accuracy. Empirically, as suggested by the experiments, the output hypotheses are represented with relatively small number of instances, and have high accuracy.

We start with the most simple and intuitive kernel-based algorithm, namely the kernel-based Perceptron. We modify the Perceptron algorithm so that the number of stored samples needed to represent the online hypothesis is always bounded. We call this new algorithm *Projectron*. The empirical performance of the Projectron algorithm is on a par with the original Perceptron algorithm. We present a relative mistake bound for the Projectron algorithm, and deduce from it a new online bounded algorithm which outperforms the Perceptron algorithm, but still retains all of its advantages. We call this second algorithm *Projectron++*. We then extend Projectron++ to the more general cases of multiclass and structured output. As far as we know, this is the first bounded multiclass and structured output online algorithm, with a relative mistake bound.[1] Our technique for bounding the size of the support set can be applied to any conservative kernel-based online algorithm and to other online algorithms, as we demonstrate for ALMA_2 (Gentile, 2001). Finally, we present some experiments with common data sets, which suggest that Projectron is comparable to

1. Note that converting the budget algorithms presented by other authors, such as the Forgetron, to the multiclass or the structured output setting is not trivial, since these algorithms are inherently binary in nature.

Perceptron in performance, but it uses a much smaller support set. Moreover, experiments with Projectron++ shows that it outperforms all other bounded algorithms, while using the smallest support set. We also present experiments on the task of phoneme classification, which is considered to be difficult and naturally with a relatively very high number of support vectors. When comparing the Projectron++ algorithm to the Passive-Aggressive multiclass algorithm (Crammer et al., 2006), it turns out that the cumulative online error and the test error, after online-to-batch conversion, of both algorithms are comparable, although Projectron++ uses a smaller support set.

In summary, the contributions of this paper are (1) a new algorithm, called Projectron, which is derived from the kernel-based Perceptron algorithm, which empirically performs equally well, but has a bounded support set; (2) a relative mistake bound for this algorithm; (3) another algorithm, called Projectron++, based on the notion of large margin, which outperforms the Perceptron algorithm and the proposed Projectron algorithm; (4) the multiclass and structured output Projectron++ online algorithm with a bounded support set; and (5) an extension of our technique to other online algorithms, exemplified in this paper for ALMA_2.

The rest of the paper is organized as follows: in Section 2 we state the problem definition and the kernel-based Perceptron algorithm. Section 3 introduces Projectron, along with its theoretical analysis. Next, in Section 4 we derive Projectron++. Section 5 presents the multiclass and structured learning variant of Projectron++. In Section 6 we apply our technique for another kernel-based online algorithm, ALMA_2. Section 7 describes experimental results of the algorithms presented, on different data sets. Section 8 concludes the paper with a short discussion.

2. Problem Setting and the Kernel-Based Perceptron Algorithm

The basis of our study is the well known *Perceptron* algorithm (Rosenblatt, 1958; Freund and Schapire, 1999). The Perceptron algorithm learns the mapping $f : \mathcal{X} \to \mathbb{R}$ based on a set of examples $\mathcal{T} = \{(\mathbf{x}_1, y_1), (\mathbf{x}_2, y_2), \ldots\}$, where $\mathbf{x}_t \in \mathcal{X}$ is called an *instance* and $y_t \in \{-1, +1\}$ is called a *label*. We denote the prediction of the Perceptron algorithm as $\text{sign}(f(\mathbf{x}))$ and we interpret $|f(\mathbf{x})|$ as the confidence in the prediction. We call the output f of the Perceptron algorithm a *hypothesis*, and we denote the set of all attainable hypotheses by $\mathcal{H}$. In this paper we assume that $\mathcal{H}$ is a Reproducing Kernel Hilbert Space (RKHS) with a positive definite kernel function $k : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$ implementing the inner product $\langle \cdot, \cdot \rangle$. The inner product is defined so that it satisfies the reproducing property, $\langle k(\mathbf{x}, \cdot), f(\cdot) \rangle = f(\mathbf{x})$.

The Perceptron algorithm is an online algorithm, where learning takes place in rounds. At each round a new hypothesis function is estimated, based on the previous one. We denote the hypothesis estimated after the t-th round by f_t. The algorithm starts with the zero hypothesis, $f_0 = \mathbf{0}$. At each round t, an instance $\mathbf{x}_t \in \mathcal{X}$ is presented to the algorithm, which predicts a label $\hat{y}_t \in \{-1, +1\}$ using the current function, $\hat{y}_t = \text{sign}(f_t(\mathbf{x}_t))$. Then, the correct label y_t is revealed. If the prediction $\hat{y}_t$ differs from the correct label y_t, the hypothesis is updated as $f_t = f_{t-1} + y_t k(\mathbf{x}_t, \cdot)$, otherwise the hypothesis is left intact, $f_t = f_{t-1}$. The hypothesis f_t can be written as a kernel expansion according to the representer theorem (Schölkopf et al., 2001),

$$f_t(\mathbf{x}) = \sum_{\mathbf{x}_i \in \mathcal{S}_t} \alpha_i k(\mathbf{x}_i, \mathbf{x}), \tag{1}$$

where $\alpha_i = y_i$ and $\mathcal{S}_t$ is defined to be the set of instances for which an update of the hypothesis occurred, that is, $\mathcal{S}_t = \{\mathbf{x}_i, 0 \le i \le t \,|\, \hat{y}_i \ne y_i\}$. The set $\mathcal{S}_t$ is called the *support set*. The Perceptron algorithm is summarized in Figure 1.

Initialize: $\mathcal{S}_0 = \emptyset$, $f_0 = \mathbf{0}$
For $t = 1, 2, \ldots$
  Receive new instance $\mathbf{x}_t$
  Predict $\hat{y}_t = \text{sign}(f_{t-1}(\mathbf{x}_t))$
  Receive label y_t
  If $y_t \neq \hat{y}_t$
    $f_t = f_{t-1} + y_t k(\mathbf{x}_t, \cdot)$ *(update the hypothesis)*
    $\mathcal{S}_t = \mathcal{S}_{t-1} \cup \mathbf{x}_t$ *(add instance $\mathbf{x}_t$ to the support set)*
  Else
    $f_t = f_{t-1}$
    $\mathcal{S}_t = \mathcal{S}_{t-1}$

Figure 1: The kernel-based Perceptron Algorithm.

Although the Perceptron algorithm is very simple, it produces an online hypothesis with good performance. Our goal is to derive and analyze a new algorithm, which outputs a hypothesis that attains almost the same performance as the Perceptron hypothesis, but can be represented using many fewer instances, that is, an online hypothesis that is "close" to the Perceptron hypothesis but represented by a smaller support set. Recall that the hypothesis f_t is represented as a weighted sum over all the instances in the support set. The size of this representation is the cardinality of the support set, $|\mathcal{S}_t|$.

3. The Projectron Algorithm

This section starts by deriving the Projectron algorithm, motivated by an example of a finite dimensional kernel space. It continues with a description of how to calculate the projected hypothesis and describes some other computational aspects of the algorithm. The section concludes with a theoretical analysis of the algorithm.

3.1 Definition and Derivation

Let us first consider a finite dimensional RKHS $\mathcal{H}$ induced by a kernel such as the polynomial kernel. Since $\mathcal{H}$ is finite dimensional, there are a finite number of linearly independent hypotheses in this space. Hence, any hypothesis in this space can be expressed using a finite number of examples. We can modify the Perceptron algorithm to use only one set of independent instances as follows. On each round the algorithm receives an instance and predicts its label. On a prediction mistake, we check if the instance $\mathbf{x}_t$ can be spanned by the support set, namely, for scalars $d_i \in \mathbb{R}, 1 \leq i \leq |\mathcal{S}_{t-1}|$, not all zeros, such that

$$k(\mathbf{x}_t, \cdot) = \sum_{\mathbf{x}_i \in \mathcal{S}_{t-1}} d_i k(\mathbf{x}_i, \cdot) \ .$$

If we can find such scalars, the instance is not added to the support set, but instead, the coefficients $\{\alpha_i\}$ in the expansion Equation (1) are changed to reflect the addition of this instance to the support

set. Namely, for every i

$$\alpha_i = y_i + y_t d_i \ .$$

On the other hand, if the instance and the support set are linearly independent, the instance is added to the set with $\alpha_t = y_t$ as before. This technique reduces the size of the support set without changing the hypothesis. A similar approach was used by Downs et al. (2001) to simplify SVM solutions.

Let us consider now the more elaborate case of an infinite dimensional RKHS $\mathcal{H}$ induced by a kernel such as the Gaussian kernel. In this case, it is not possible to find a finite number of linearly independent vectors which span the whole space, and hence there is no guarantee that the hypothesis can be expressed by a finite number of instances. However, we can approximate the concept of linear independence with a finite number of vectors (Csató and Opper, 2002; Engel et al., 2004; Orabona et al., 2007).

In particular, let us assume that at round t of the algorithm there is a prediction mistake, and that the mistaken instance $\mathbf{x}_t$ should be added to the support set, $\mathcal{S}_{t-1}$. Let $\mathcal{H}_{t-1}$ be an RKHS which is the span of the kernel images of the instances in the set $\mathcal{S}_{t-1}$. Formally,

$$\mathcal{H}_{t-1} = \text{span}\left(\{k(\mathbf{x},\cdot)|\mathbf{x} \in \mathcal{S}_{t-1}\}\right) \ . \tag{2}$$

Before adding the instance to the support set, we construct two hypotheses: a *temporary hypothesis*, f'_t, using the function $k(\mathbf{x}_t,\cdot)$, that is, $f'_t = f_{t-1} + y_t k(\mathbf{x}_t,\cdot)$, and a *projected hypothesis*, f''_t, that is the projection of f'_t onto the space $\mathcal{H}_{t-1}$. That is, the projected hypothesis is that hypothesis from the space $\mathcal{H}_{t-1}$ which is the *closest* to the temporary hypothesis. In a later section we will describe an efficient way to calculate the projected hypothesis. Denote by δ_t the distance between the hypotheses, $\delta_t = f''_t - f'_t$. If the norm of distance $\|\delta_t\|$ is below some threshold η, we use the projected hypothesis as our next hypothesis, that is, $f_t = f''_t$, otherwise we use the temporary hypothesis as our next hypothesis, that is, $f_t = f'_t$. As we show in the following theorem, this strategy assures that the maximum size of the support set is always finite, regardless of the dimension of the RKHS $\mathcal{H}$. Guided by these considerations we can design a new Perceptron-like algorithm that projects the solution onto the space spanned by the previous support vectors whenever possible. We call this algorithm *Projectron*. The algorithm is given in Figure 2.

The parameter η plays an important role in our algorithm. If η is equal to zero, we obtain exactly the same solution as the Perceptron algorithm. In this case, however, the Projectron solution can still be sparser when some of the instances are linearly dependent or when the kernel induces a finite dimensional RKHS $\mathcal{H}$. If η is greater than zero we trade precision for sparseness. Moreover, as shown in the next section, this implies a bounded algorithmic complexity, namely, the memory and time requirements for each step are bounded. We analyze the effect of η on the classification accuracy in Subsection 3.3.

3.2 Practical Considerations

We now consider the problem of deriving the projected hypothesis f''_t in a Hilbert space $\mathcal{H}$, induced by a kernel function $k(\cdot,\cdot)$. Recall that f'_t is defined as $f'_t = f_t + y_t k(\mathbf{x}_t,\cdot)$. Denote by $P_{t-1} f'_t$ the projection of $f'_t \in \mathcal{H}$ onto the subspace $\mathcal{H}_{t-1} \subseteq \mathcal{H}$. The projected hypothesis f''_t is defined as $f''_t = P_{t-1} f'_t$. Schematically, this is depicted in Figure 3.

Expanding f'_t we have

$$f''_t = P_{t-1} f'_t = P_{t-1}\left(f_{t-1} + y_t k(\mathbf{x}_t,\cdot)\right) \ .$$

Initialize: $\mathcal{S}_0 = \emptyset$, $f_0 = \mathbf{0}$
For $t = 1, 2, \ldots$
  Receive new instance $\mathbf{x}_t$
  Predict $\hat{y}_t = \text{sign}(f_{t-1}(\mathbf{x}_t))$
  Receive label y_t
  If $y_t \neq \hat{y}_t$
    Set $f'_t = f_{t-1} + y_t k(\mathbf{x}_t, \cdot)$ (*temporary hypothesis*)
    Set $f''_t = f'_t$ projected onto the space $\mathcal{H}_{t-1}$ (*projected hypothesis*)
    Set $\delta_t = f''_t - f'_t$
    If $\|\delta_t\| \leq \eta$
      $f_t = f''_t$
      $\mathcal{S}_t = \mathcal{S}_{t-1}$
    Else
      $f_t = f'_t$
      $\mathcal{S}_t = \mathcal{S}_{t-1} \cup \mathbf{x}_t$ (*add* $\mathbf{x}_t$ *to the support set)*
  Else
    $f_t = f_{t-1}$
    $\mathcal{S}_t = \mathcal{S}_{t-1}$

Figure 2: The Projectron Algorithm.

The projection is a linear operator, hence

$$f''_t = f_{t-1} + y_t P_{t-1} k(\mathbf{x}_t, \cdot) \; . \tag{3}$$

Recall that $\delta_t = f''_t - f'_t$. By substituting f''_t from Equation (3) and f'_t we have

$$\delta_t = f''_t - f'_t = y_t P_{t-1} k(\mathbf{x}_t, \cdot) - y_t k(\mathbf{x}_t, \cdot) \; . \tag{4}$$

The projection of $f'_t \in \mathcal{H}$ onto a subspace $\mathcal{H}_{t-1} \subset \mathcal{H}$ is defined as the hypothesis in $\mathcal{H}_{t-1}$ closest to f'_t. Hence, let $\sum_{\mathbf{x}_j \in \mathcal{S}_{t-1}} d_j k(\mathbf{x}_j, \cdot)$ be an hypothesis in $\mathcal{H}_{t-1}$, where $\mathbf{d} = (d_1, \ldots, d_{|\mathcal{S}_{t-1}|})$ is a set of coefficients, with $d_i \in \mathbb{R}$. The closest hypothesis is the one for which it holds that

$$\|\delta_t\|^2 = \min_{\mathbf{d}} \left\| \sum_{\mathbf{x}_j \in \mathcal{S}_{t-1}} d_j k(\mathbf{x}_j, \cdot) - k(\mathbf{x}_t, \cdot) \right\|^2 \; . \tag{5}$$

Expanding Equation (5) we get

$$\|\delta_t\|^2 = \min_{\mathbf{d}} \left(\sum_{\mathbf{x}_i, \mathbf{x}_j \in \mathcal{S}_{t-1}} d_j d_i k(\mathbf{x}_j, \mathbf{x}_i) - 2 \sum_{\mathbf{x}_j \in \mathcal{S}_{t-1}} d_j k(\mathbf{x}_j, \mathbf{x}_t) + k(\mathbf{x}_t, \mathbf{x}_t) \right) \; .$$

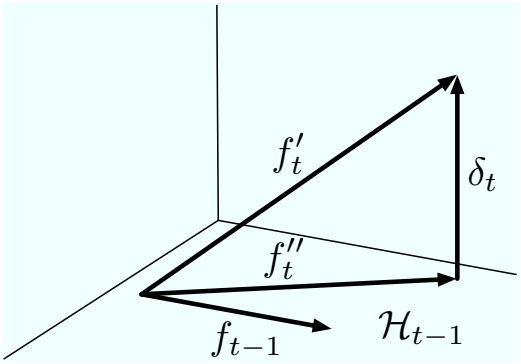

Figure 3: Geometrical interpretation of the projection of the hypothesis f''_t onto the subspace $\mathcal{H}_{t-1}$.

Let us define $\mathbf{K}_{t-1} \in \mathbb{R}^{t-1 \times t-1}$ to be the matrix generated by the instances in the support set $\mathcal{S}_{t-1}$, that is, $\{\mathbf{K}_{t-1}\}_{i,j} = k(\mathbf{x}_i, \mathbf{x}_j)$ for every $\mathbf{x}_i, \mathbf{x}_j \in \mathcal{S}_{t-1}$. Let us also define $\mathbf{k}_t \in \mathbb{R}^{t-1}$ to be the vector whose i-th element is $k_{t_i} = k(\mathbf{x}_i, \mathbf{x}_t)$. We have

$$\|\delta_t\|^2 = \min_{\mathbf{d}} \left(\mathbf{d}^T \mathbf{K}_{t-1} \mathbf{d} - 2\mathbf{d}^T \mathbf{k}_t + k(\mathbf{x}_t, \mathbf{x}_t) \right) . \tag{6}$$

Solving Equation (6), that is, applying the extremum conditions with respect to $\mathbf{d}$, we obtain

$$\mathbf{d}^\star = \mathbf{K}_{t-1}^{-1} \mathbf{k}_t \tag{7}$$

and, by substituting Equation (7) into Equation (6),

$$\|\delta_t\|^2 = k(\mathbf{x}_t, \mathbf{x}_t) - \mathbf{k}_t^T \mathbf{d}^\star . \tag{8}$$

Furthermore, by substituting Equation (7) back into Equation (3) we get

$$f''_t = f_{t-1} + y_t \sum_{\mathbf{x}_j \in \mathcal{S}_{t-1}} \mathbf{d}^\star_j k(\mathbf{x}_j, \cdot) . \tag{9}$$

We have shown how to calculate both the distance δ_t and the projected hypothesis f''_t. In summary, one needs to compute $\mathbf{d}^\star$ according to Equation (7), and plug the result either into Equation (8) to obtain δ_t, or into Equation (9) to obtain the projected hypothesis.

In order to make the computation more tractable, we need an efficient method to calculate the matrix inversion $\mathbf{K}_t^{-1}$ iteratively. The first method, used by Cauwenberghs and Poggio (2000) for incremental training of SVMs, directly updates the inverse matrix. An efficient way to do this, exploiting the incremental nature of the approach, is to recursively update the inverse matrix. Using the matrix inversion lemma it is possible to show (see, e.g., Csató and Opper, 2002) that after the addition of a new sample, $\mathbf{K}_t^{-1}$ becomes

$$\mathbf{K}_t^{-1} = \begin{bmatrix} & & & 0 \\ & \mathbf{K}_{t-1}^{-1} & & \vdots \\ & & & 0 \\ 0 & \cdots & 0 & 0 \end{bmatrix} + \frac{1}{\|\delta_t\|^2} \begin{bmatrix} \mathbf{d}^\star \\ -1 \end{bmatrix} \begin{bmatrix} \mathbf{d}^{\star T} & -1 \end{bmatrix}$$

Input: new instance $\mathbf{x}_t$, $\mathbf{K}_{t-1}^{-1}$, and the support set $\mathcal{S}_{t-1}$

- Set $\mathbf{k}_t = \big(k(\mathbf{x}_1,\mathbf{x}_t), k(\mathbf{x}_2,\mathbf{x}_t), \ldots, k(\mathbf{x}_{|\mathcal{S}_{t-1}|},\mathbf{x}_t)\big)$
- Solve $\mathbf{d}^\star = \mathbf{K}_{t-1}^{-1}\mathbf{k}_t$
- Set $\|\delta_t\|^2 = k(\mathbf{x}_t,\mathbf{x}_t) - \mathbf{k}_t^T\mathbf{d}^\star$
- The projected hypothesis is $f_t'' = f_{t-1} + y_t \sum_{\mathbf{x}_j \in \mathcal{S}_{t-1}} \mathbf{d}_j^\star k(\mathbf{x}_j,\cdot)$
- Kernel inverse matrix for the next round

$$\mathbf{K}_t^{-1} = \begin{bmatrix} & & & 0 \\ & \mathbf{K}_{t-1}^{-1} & & \vdots \\ & & & 0 \\ 0 & \cdots & 0 & 0 \end{bmatrix} + \frac{1}{\|\delta_t\|^2} \begin{bmatrix} \mathbf{d}^\star \\ -1 \end{bmatrix} \begin{bmatrix} \mathbf{d}^{\star T} & -1 \end{bmatrix}$$

Output: the projected hypothesis f_t'', the measure δ_t and the kernel inverse matrix $\mathbf{K}_t^{-1}$.

Figure 4: Calculation of the projected hypothesis f_t''.

where $\mathbf{d}^\star$ and $\|\delta_t\|^2$ are already evaluated during the previous steps of the algorithm, as given by Equation (7) and Equation (8). Thanks to this incremental evaluation, the time complexity of the linear independence check is $O(|\mathcal{S}_{t-1}|^2)$, as one can easily see from Equation (7). Note that the matrix $\mathbf{K}_{t-1}$ can be safely inverted since, by incremental construction, it is always full-rank.

An alternative way to derive the inverse matrix is to use the Cholesky decomposition of $\mathbf{K}_{t-1}$ and to update it recursively. This is known to be numerically more stable than directly updating the inverse. In our experiments, however, we found out that the method presented here is as stable as the Cholesky decomposition.

Overall, the time complexity of the algorithm is $O(|\mathcal{S}_t|^2)$, as described above, and the space complexity is $O(|\mathcal{S}_t|^2)$, due to the storage of the matrix $\mathbf{K}_t^{-1}$, similar to the second-order Perceptron algorithm (Cesa-Bianchi et al., 2005). A summary of the derivation of f_t'', the projection of f_t' onto the space spanned by $\mathcal{S}_{t-1}$, is described in Figure 4.

3.3 Analysis

We now analyze the theoretical aspects of the proposed algorithm. First, we present a theorem which states that the size of the support set of the Projectron algorithm is bounded.

Theorem 1 *Let $k : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$ be a continuous Mercer kernel, with $\mathcal{X}$ a compact subset of a Banach space. Then, for any training sequence $\mathcal{T} = \{(\mathbf{x}_i, y_i)\}, i = 1, 2, \cdots$ and for any $\eta > 0$, the size of the support set of the Projectron algorithm is finite.*

Proof The proof of this theorem follows the same lines as the proof of Theorem 3.1 in Engel et al. (2004). From the Mercer theorem it follows that there exists a mapping $\phi : \mathcal{X} \to \mathcal{H}'$, where $\mathcal{H}'$ is

an Hilbert space, $k(\mathbf{x},\mathbf{x}') = \langle \phi(\mathbf{x}), \phi(\mathbf{x}') \rangle$ and ϕ is continuous. Given that ϕ is continuous and that $\mathcal{X}$ is compact, we obtain that $\phi(\mathcal{X})$ is compact. From the definition of δ_t in Equation (5) we get that every time a new basis vector is added we have

$$\begin{aligned}\eta^2 \leq \|\delta_t\|^2 &= \min_{\mathbf{d}} \left\| \sum_{\mathbf{x}_j \in \mathcal{S}_{t-1}} d_j k(\mathbf{x}_j, \cdot) - k(\mathbf{x}_t, \cdot) \right\|^2 \leq \min_{d_j} \left\| d_j k(\mathbf{x}_j, \cdot) - k(\mathbf{x}_t, \cdot) \right\|^2 \\ &= \min_{d_j} \left\| d_j \phi(\mathbf{x}_j) - \phi(\mathbf{x}_t) \right\|^2 \leq \left\| \phi(\mathbf{x}_j) - \phi(\mathbf{x}_t) \right\|^2\end{aligned}$$

for any $1 \leq j \leq |\mathcal{S}_{t-1}|$. Hence from the definition of packing numbers (Cucker and Zhou, 2007, Definition 5.17), we get that the maximum size of the support set in the Projectron algorithm is bounded by the packing number at scale η of $\phi(\mathcal{X})$. This number, in turn, is bounded by the covering number at scale $\eta/2$, and it is finite because the set is compact (Cucker and Zhou, 2007, Proposition 5.18). ■

Note that this theorem guarantees that the size of the support set is bounded, however it does not state that the size of the support set is fixed or that it can be estimated before training.

The next theorem provides a mistake bound. The main idea is to bound the maximum number of mistakes of the algorithm, relative to any hypothesis $g \in \mathcal{H}$, even chosen in hindsight. First, we define the loss with a margin $\gamma \in \mathbb{R}$ of the hypothesis g on the example $(\mathbf{x}_t, y_t)$ as

$$\ell_\gamma(g(\mathbf{x}_t), y_t) = \max\{0, \gamma - y_t g(\mathbf{x}_t)\}, \tag{10}$$

and we define the cumulative loss, D_γ, of g on the first T examples as

$$D_\gamma = \sum_{t=1}^{T} \ell_\gamma(g(\mathbf{x}_t), y_t) \ .$$

Before stating the bound, we present a lemma that will be used in the rest of our proofs. We will use its first statement to bound the scalar product between a projected sample and the competitor, and its second statement to derive the scalar product between the current hypothesis and the projected sample.

Lemma 2 *Let $(\hat{\mathbf{x}}, \hat{y})$ be an example, with $\hat{\mathbf{x}} \in \mathcal{X}$ and $\hat{y} \in \{+1, -1\}$. If we denote by $f(\cdot)$ an hypothesis in $\mathcal{H}$, and denote by $q(\cdot)$ any function in $\mathcal{H}$, then the following holds*

$$\hat{y}\langle f, q \rangle \geq \gamma - \ell_\gamma(f(\hat{\mathbf{x}}), \hat{y}) - \|f\| \cdot \|q - k(\hat{\mathbf{x}}, \cdot)\| \ .$$

Moreover, if $f(\cdot)$ can be written as $\sum_{i=1}^{m} \alpha_i k(\mathbf{x}_i, \cdot)$ with $\alpha_i \in \mathbb{R}$ and $\mathbf{x}_i \in \mathcal{X}, i = 1, \cdots, m$, and $q(\cdot)$ is the projection of $k(\hat{\mathbf{x}}, \cdot)$ onto the space spanned by $k(\mathbf{x}_i, \cdot), i = 1, \cdots, m$, then

$$\hat{y}\langle f, q \rangle = \hat{y} f(\hat{\mathbf{x}}) \ .$$

Proof The first inequality comes from an application of the Cauchy-Schwarz inequality and the definition of the hinge loss in Equation (10). The second equality follows from the fact that $\langle f, q - k(\hat{\mathbf{x}}, \cdot) \rangle = 0$, because $f(\cdot)$ is orthogonal to the difference between $k(\hat{\mathbf{x}}, \cdot)$ and its projection onto the space in which $f(\cdot)$ lives. ■

With these definitions at hand, we can state the following bound for Projectron.

Theorem 3 *Let $(\mathbf{x}_1, y_1), \cdots, (\mathbf{x}_T, y_T)$ be a sequence of instance-label pairs where $\mathbf{x}_t \in \mathcal{X}$, $y_t \in \{-1, +1\}$, and $k(\mathbf{x}_t, \mathbf{x}_t) \leq 1$ for all t. Assume that the Projectron algorithm is run with $\eta \geq 0$. Then the number of prediction mistakes it makes on the sequence is bounded by*

$$\frac{\|g\|^2}{(1-\eta\|g\|)^2} + \frac{D_1}{1-\eta\|g\|} + \frac{\|g\|}{1-\eta\|g\|}\sqrt{\frac{D_1}{1-\eta\|g\|}}$$

where g is an arbitrary function in $\mathcal{H}$, such that $\|g\| < \frac{1}{\eta}$.

Proof Define the relative progress in each round as $\Delta_t = \|f_{t-1} - \lambda g\|^2 - \|f_t - \lambda g\|^2$, where λ is a positive scalar to be optimized. We bound the progress from above and below, as in Gentile (2003). On rounds where there is no mistake, Δ_t equals 0. On rounds where there is a mistake there are two possible updates: either $f_t = f_{t-1} + y_t P_{t-1} k(\mathbf{x}_t, \cdot)$ or $f_t = f_{t-1} + y_t k(\mathbf{x}_t, \cdot)$. In the following we start bounding the progress from below, when the update is of the former type. In particular we set $q(\cdot) = P_{t-1} k(\mathbf{x}_t, \cdot)$ in Lemma 2 and use $\delta_t = y_t P_{t-1} k(\mathbf{x}_t, \cdot) - y_t k(\mathbf{x}_t, \cdot)$ from Equation (4). Let τ_t be an indicator function for a mistake on the t-th round, that is, τ_t is 1 if there is a mistake on round t and 0 otherwise. We have

$$\begin{aligned}\Delta_t &= \|f_{t-1} - \lambda g\|^2 - \|f_t - \lambda g\|^2 = 2\tau_t y_t \langle \lambda g - f_{t-1}, P_{t-1} k(\mathbf{x}_t, \cdot)\rangle - \tau_t^2 \|P_{t-1} k(\mathbf{x}_t, \cdot)\|^2 \\ &\geq \tau_t \Big(2\lambda - 2\lambda \ell_1(g(\mathbf{x}_t), y_t) - \tau_t \|P_{t-1} k(\mathbf{x}_t, \cdot)\|^2 - 2\lambda \|g\| \cdot \|\delta_t\| - 2 y_t f_{t-1}(\mathbf{x}_t)\Big) \,. \end{aligned} \tag{11}$$

Moreover, on every projection update $\|\delta_t\| \leq \eta$, and $\|P_{t-1} k(\mathbf{x}_t, \cdot)\| \leq 1$ by the theorem's assumption, so we have

$$\Delta_t \geq \tau_t \Big(2\lambda - 2\lambda \ell_1(g(\mathbf{x}_t), y_t) - \tau_t - 2\eta\lambda \|g\| - 2 y_t f_{t-1}(\mathbf{x}_t)\Big) \,.$$

We can further bound Δ_t by noting that on every prediction mistake $y_t f_{t-1}(\mathbf{x}_t) \leq 0$. Overall we have

$$\|f_{t-1} - \lambda g\|^2 - \|f_t - \lambda g\|^2 \geq \tau_t \Big(2\lambda - 2\lambda \ell_1(g(\mathbf{x}_t), y_t) - \tau_t - 2\eta\lambda \|g\|\Big) \,. \tag{12}$$

When there is an update without projection, similar reasoning yields that

$$\|f_{t-1} - \lambda g\|^2 - \|f_t - \lambda g\|^2 \geq \tau_t \Big(2\lambda - 2\lambda \ell_1(g(\mathbf{x}_t), y_t) - \tau_t\Big),$$

hence the bound in Equation (12) holds in both cases.

We sum over t on both sides, remembering that τ_t can be upper bounded by 1. The left hand side of the equation is a telescoping sum, hence it collapses to $\|f_0 - \lambda g\|^2 - \|f_T - \lambda g\|^2$, which can be upper bounded by $\lambda^2 \|g\|^2$, using the fact that $f_0 = \mathbf{0}$ and that $\|f_T - \lambda g\|^2$ is non-negative. Finally, we have

$$\lambda^2 \|g\|^2 + 2\lambda D_1 \geq M\left(2\lambda - 2\eta\lambda \|g\| - 1\right), \tag{13}$$

where M is the number of mistakes. The last equation implies a bound on M for any choice of $\lambda > 0$, hence we can take the minimum of these bounds. From now on we can suppose that $M > \frac{D_1}{1-\eta\|g\|}$. In fact, if $M \leq \frac{D_1}{1-\eta\|g\|}$ then the theorem trivially holds. The minimum of Equation (13) as a function of λ occurs at

$$\lambda^* = \frac{M(1-\eta\|g\|) - D_1}{\|g\|^2} \,.$$

By our hypothesis that $M > \frac{D_1}{1-\eta\|g\|}$ we have that λ^* is positive. Substituting λ^* into Equation (13) we obtain

$$\frac{(D_1 - M(1-\eta\|g\|))^2}{\|g\|^2} - M \leq 0 \ .$$

Solving for M and overapproximating concludes the proof. ■

This theorem suggests that the performance of the Projectron algorithm is slightly worse than that of the Perceptron algorithm. Specifically, if we set $\eta = 0$, we recover the best known bound for the Perceptron algorithm (see for example Gentile, 2003). Hence the degradation in the performance of Projectron compared to Perceptron is related to $\frac{1}{1-\eta\|g\|}$. Empirically, the Projectron algorithm and the Perceptron algorithm perform similarly, for a wide range of settings of η.

4. The Projectron++ Algorithm

The proof of Theorem 3 suggests how to improve the Projectron algorithm to improve upon the performance of the Perceptron algorithm, while maintaining a bounded support set. We can change the Projectron algorithm so that an update takes place not only if there is a prediction mistake, but also when the confidence of the prediction is low. We refer to this latter case as a *margin error*, that is, $0 < y_t f_{t-1}(\mathbf{x}_t) < 1$. This strategy is known to improve the classification rate but also increases the size of the support set (Crammer et al., 2006). A possible solution to this obstacle is not to update on every round in which a margin error occurs, but only when there is a margin error and the new instance *can be projected* onto the support set. Hence, the update on round in which there is a margin error would in general be of the form

$$f_t = f_{t-1} + y_t \tau_t P_{t-1} k(\mathbf{x}_t, \cdot) \ ,$$

with $0 < \tau_t \leq 1$. The last constraint comes from the proof of Theorem 3, where we upper bound τ_t by 1. Note that setting τ_t to 0 is equivalent to leaving the hypothesis unchanged.

In particular, disregarding the loss term in Equation (11), the progress Δ_t can be made positive with an appropriate choice of τ_t. Whenever this progress is non-negative the worst-case number of mistakes decreases, hopefully along with the classification error rate of the algorithm. With this modification we expect better performance, that is, fewer mistakes, but without any increase of the support set size. We can even expect solutions with a smaller support set, since new instances can be added to the support set only if misclassified, hence having fewer mistakes should result in a smaller support set. We name this algorithm *Projectron++*. The following theorem states a mistake bound for Projectron++, and guides us in how to choose τ_t.

Theorem 4 *Let $(\mathbf{x}_1, y_1), \cdots, (\mathbf{x}_T, y_T)$ be a sequence of instance-label pairs where $\mathbf{x}_t \in \mathcal{X}$, $y_t \in \{-1, +1\}$, and $k(\mathbf{x}_t, \mathbf{x}_t) \leq 1$ for all t. Assume that Projectron++ is run with $\eta > 0$. Then the number of prediction mistakes it makes on the sequence is bounded by*

$$\frac{\|g\|^2}{(1-\eta\|g\|)^2} + \frac{D_1}{1-\eta\|g\|} + \frac{\|g\|}{1-\eta\|g\|}\sqrt{max\left(0, \frac{D_1}{1-\eta\|g\|} - B\right)}$$

where g is an arbitrary function in $\mathcal{H}$, such that $\|g\| < \frac{1}{\eta}$,

$$0 < \tau_t < \min \left\{ 2\frac{\ell_1(f_{t-1}(\mathbf{x}_t), y_t) - \frac{\|\delta_t\|}{\eta}}{\|P_{t-1}k(\mathbf{x}_t, \cdot)\|^2}, 1 \right\}$$

and

$$B = \sum_{\{t:0<y_t f_{t-1}(\mathbf{x}_t)<1\}} \tau_t \left(2\ell_1(f_{t-1}(\mathbf{x}_t), y_t) - \tau_t \|P_{t-1}k(\mathbf{x}_t, \cdot)\|^2 - 2\frac{\|\delta_t\|}{\eta} \right) > 0 \, .$$

Proof The proof is similar to the proof of Theorem 3, where the difference is that during rounds in which there is a margin error we update the solution whenever it is possible to project ensuring an improvement of the mistake bound. Assume that $\lambda \geq 1$. On rounds when a margin error occurs, as in Equation (11), we can write

$$\begin{aligned}
\Delta_t + 2\tau_t\lambda\ell_1(g(\mathbf{x}_t), y_t) \geq & \quad \tau_t \left(2\lambda - \tau_t \|P_{t-1}k(\mathbf{x}_t, \cdot)\|^2 - 2\lambda\|\delta_t\| \cdot \|g\| - 2y_t f_{t-1}(\mathbf{x}_t) \right) \\
> & \quad \tau_t \left(2\left(1 - \frac{\|\delta_t\|}{\eta}\right) - \tau_t \|P_{t-1}k(\mathbf{x}_t, \cdot)\|^2 - 2y_t f_{t-1}(\mathbf{x}_t) \right) \\
= & \quad \tau_t \left(2\ell_1(f_{t-1}(\mathbf{x}_t), y_t) - \tau_t \|P_{t-1}k(\mathbf{x}_t, \cdot)\|^2 - 2\frac{\|\delta_t\|}{\eta} \right), \qquad (14)
\end{aligned}$$

where we used the bounds on $\|g\|$ and λ. Let β_t be the right hand-side of Equation (14). A sufficient condition to have β_t positive is

$$\tau_t < 2\frac{\ell_1(f_{t-1}(\mathbf{x}_t), y_t) - \frac{\|\delta_t\|}{\eta}}{\|P_{t-1}k(\mathbf{x}_t, \cdot)\|^2} \, .$$

Constraining τ_t to be less than or equal to 1 yields the update rule in the theorem.

Let $B = \sum_{\{t:0<y_t f_{t-1}(\mathbf{x}_t)<1\}} \beta_t$. Similarly to the proof of Theorem 3, we have

$$\lambda^2\|g\|^2 + 2\lambda D_1 \geq M(2\lambda - 2\eta\lambda\|g\| - 1) + B \, . \qquad (15)$$

Again, the optimal value of λ is

$$\lambda^* = \frac{M(1 - \eta\|g\|) - D_1}{\|g\|^2} \, .$$

We can assume that $M(1-\eta\|g\|) - D_1 \geq \|g\|^2$. In fact, if $M < \frac{\|g\|^2 + D_1}{1-\eta\|g\|}$, then the theorem trivially holds. With this assumption, λ^* is positive and greater than or equal to 1, satisfying our initial constraint on λ. Substituting this optimal value of λ into Equation (15), we have

$$\frac{(D_1 - M(1-\eta\|g\|))^2}{\|g\|^2} - M + B \leq 0 \, .$$

Solving for M concludes the proof. ■

The proof technique presented here is very general, in particular it can be applied to the Passive-Aggressive algorithm PA-I (Crammer et al., 2006). In fact, removing the projection step and updating on rounds in which there is a margin error, with $f_t = f_{t-1} + y_t \tau_t k(\mathbf{x}_t, \cdot)$, we end up with the condition $0 < \tau_t < \min\left\{2\frac{\ell_1(f_{t-1}(\mathbf{x}_t), y_t)}{\|k(\mathbf{x}_t,\cdot)\|^2}, 1\right\}$. This rule generalizes the PA-I bound whenever $R = 1$ and $C = 1$, however the obtained bound substantially improves upon the original bound in Crammer et al. (2006).

The theorem gives us some freedom for the choice of τ_t. Experimentally we have observed that we obtain the best performance if the update is done with the following rule

$$\tau_t = \min\left\{\frac{\ell_1(f_{t-1}(\mathbf{x}_t), y_t)}{\|P_{t-1}k(\mathbf{x}_t,\cdot)\|^2}, 2\frac{\ell_1(f_{t-1}(\mathbf{x}_t), y_t) - \frac{\|\delta_t\|}{\eta}}{\|P_{t-1}k(\mathbf{x}_t,\cdot)\|^2}, 1\right\}.$$

The added term in the minimum comes from ignoring the term $-2\frac{\|\delta_t\|}{\eta}$ and in finding the maximum of the quadratic equation. Notice that the term $\|P_{t-1}k(\mathbf{x}_t,\cdot)\|^2$ in the last equation can be practically computed as $\mathbf{k}_t^T \mathbf{d}^\star$, as can be derived using the same techniques presented in Subsection 3.2.

We note in passing that the condition on whether $\mathbf{x}_t$ can be projected onto $\mathcal{H}_{t-1}$ on margin error may stated as $\ell_1(f_{t-1}(\mathbf{x}_t), y_t) \geq \frac{\|\delta_t\|}{\eta}$. This means that if the loss is relatively large, the progress is also large and the algorithm can afford "wasting" a bit of it for the sake of projecting.

The algorithm is summarized in Figure 2. The performance of the Projectron++ algorithm, the Projectron algorithm and several other bounded online algorithms are compared and reported in Section 7.

5. Extension to Multiclass and Structured Output

In this section we extend Projectron++ to the multiclass and the structured output settings (note that Projectron can be generalized in a similar way). We start by presenting the more complex decision problem, namely the structured output, and then we derive the multiclass decision problem as a special case.

In structured output decision problems the set of possible labels has a unique and defined structure, such as a tree, a graph or a sequence (Collins, 2000; Taskar et al., 2003; Tsochantaridis et al., 2004). Denote the set of all labels as $\mathcal{Y} = \{1, \ldots, k\}$. Each instance is associated with a label from $\mathcal{Y}$. Generally, in structured output problems there may be dependencies between the instance and the label, as well as between labels. Hence, to capture these dependencies, the input and the output pairs are represented in a common feature representation. The learning task is therefore defined as finding a function $f : \mathcal{X} \times \mathcal{Y} \to \mathbb{R}$ such that

$$y_t = \arg\max_{y \in Y} f(\mathbf{x}_t, y)\ . \tag{16}$$

Let us generalize the definition of the RKHS $\mathcal{H}$ introduced in Section 2 to the case of structured learning. A kernel function in this setting should reflect the dependencies between the instances and the labels, hence we define the structured kernel function as a function on the domain of the instances and the labels, namely, $k^S : (\mathcal{X} \times \mathcal{Y})^2 \to \mathbb{R}$. This kernel function induces the RKHS $\mathcal{H}^S$, where the inner product in this space is defined such that it satisfies the reproducing property, $\langle k^S((\mathbf{x}, y), \cdot), f\rangle = f(\mathbf{x}, y)$.

Initialize: $\mathcal{S}_0 = \emptyset$, $f_0 = \mathbf{0}$

For $t = 1, 2, \ldots$

Receive new instance $\mathbf{x}_t$

Predict $\hat{y}_t = \text{sign}(f_{t-1}(\mathbf{x}_t))$

Receive label y_t

If $y_t \neq \hat{y}_t$ (*prediction error*)

Set $f'_t = f_{t-1} + y_t k(\mathbf{x}_t, \cdot)$

Set $f''_t = P_{t-1} f'_t$

Set $\delta_t = f''_t - f'_t$

If $\|\delta_t\| \leq \eta$

$f_t = f''_t$

$\mathcal{S}_t = \mathcal{S}_{t-1}$

Else

$f_t = f'_t$

$\mathcal{S}_t = \mathcal{S}_{t-1} \cup \mathbf{x}_t$

Else If $y_t = \hat{y}_t$ and $y_t f_{t-1}(\mathbf{x}_t) \leq 1$ (*margin error*)

Set $\delta_t = P_{t-1} k(\mathbf{x}_t, \cdot) - k(\mathbf{x}_t, \cdot)$

If $\ell_1(f_{t-1}(\mathbf{x}_t), y_t) \geq \frac{\|\delta_t\|}{\eta}$ (*check if the* $\mathbf{x}_t$ *can be projected onto* $\mathcal{H}_{t-1}$)

Set $\tau_t = \min \left\{ \frac{\ell_1(f_{t-1}(\mathbf{x}_t), y_t)}{\|P_{t-1} k(\mathbf{x}_t, \cdot)\|^2}, 2\frac{\ell_1(f_{t-1}(\mathbf{x}_t), y_t) - \frac{\|\delta_t\|}{\eta}}{\|P_{t-1} k(\mathbf{x}_t, \cdot)\|^2}, 1 \right\}$

Set $f_t = f_{t-1} + y_t \tau_t P_{t-1} k(\mathbf{x}_t, \cdot)$

$\mathcal{S}_t = \mathcal{S}_{t-1}$

Else

$f_t = f_{t-1}$

$\mathcal{S}_t = \mathcal{S}_{t-1}$

Else

$f_t = f_{t-1}$

$\mathcal{S}_t = \mathcal{S}_{t-1}$

Figure 5: The Projectron++ Algorithm.

As in the binary classification algorithm presented earlier, the structured output online algorithm receives instances in a sequential order. Upon receiving an instance, $\mathbf{x}_t \in \mathcal{X}$, the algorithm predicts a label, y'_t, according to Equation (16). After making its prediction, the algorithm receives the correct label, y_t. We define the loss suffered by the algorithm on round t for the example $(\mathbf{x}_t, y_t)$ as

$$\ell^S_\gamma(f, \mathbf{x}_t, y_t) = \max\{0, \gamma - f(\mathbf{x}_t, y_t) + \max_{y'_t \neq y_t} f(\mathbf{x}_t, y'_t)\},$$

and the cumulative loss D_γ^S as

$$D_\gamma^S = \sum_{t=1}^{T} \ell_\gamma^S(f, \mathbf{x}_t, y_t) \ .$$

Note that sometimes it is useful to define γ as a function $\gamma : \mathcal{Y} \times \mathcal{Y} \to \mathbb{R}$ describing the discrepancy between the predicted label and the true label. Our algorithm can handle such a label cost function, but we will not discuss this issue here (see Crammer et al., 2006, for further details).

As in the binary case, on rounds in which there is a prediction mistake, $y_t' \neq y_t$, the algorithm updates the hypothesis f_{t-1} by adding $k((\mathbf{x}_t, y_t), \cdot) - k((\mathbf{x}_t, y_t'), \cdot)$ or its projection. When there is a margin mistake, $0 < \ell_\gamma^S(f_{t-1}, \mathbf{x}_t, y_t) < \gamma$, the algorithm updates the hypothesis f_{t-1} by adding $\tau_t P_{t-1}\left(k((\mathbf{x}_t, y_t), \cdot) - k((\mathbf{x}_t, y_t'), \cdot)\right)$, where $0 < \tau_t < 1$ and will be defined shortly. Now, for the structured output case, δ_t is defined as

$$\delta_t = k((\mathbf{x}_t, y_t), \cdot) - k((\mathbf{x}_t, y_t'), \cdot) - P_{t-1}\left(k((\mathbf{x}_t, y_t), \cdot) - k((\mathbf{x}_t, y_t'), \cdot)\right) \ .$$

The analysis of the structured output Projectron++ algorithm is similar to that provided for the binary case. We can easily obtain the generalization of Lemma 2 and Theorem 4 as follows

Lemma 5 *Let $(\hat{\mathbf{x}}, \hat{y})$ be an example, with $\hat{\mathbf{x}} \in \mathcal{X}$ and $\hat{y} \in \mathcal{Y}$. Denote by $f(\cdot)$ an hypothesis in $\mathcal{H}^S$. Let $q(\cdot) \in \mathcal{H}^S$. Then the following holds for any $y' \in \mathcal{Y}$:*

$$\langle f, q \rangle \geq \gamma - \ell_\gamma^S(f, \hat{\mathbf{x}}, \hat{y}) - \|f\| \cdot \left\| q - \left(k((\hat{\mathbf{x}}, \hat{y}), \cdot) - k((\hat{\mathbf{x}}, y'), \cdot)\right) \right\| \ .$$

Moreover if $f(\cdot)$ can be written as $\sum_{i=1}^m \alpha_i k((\mathbf{x}_i, y_i), \cdot)$ with $\alpha_i \in \mathbb{R}$ and $\mathbf{x}_i \in \mathcal{X}, i = 1, \cdots, m$, and q is the projection of $k((\hat{\mathbf{x}}, \hat{y}), \cdot) - k((\hat{\mathbf{x}}, y'), \cdot)$ in the space spanned by $k((\mathbf{x}_i, y_i), \cdot), i = 1, \cdots, m$, we have that

$$\langle f, q \rangle = f(\hat{\mathbf{x}}, \hat{y}) - f(\hat{\mathbf{x}}, y') \ .$$

Theorem 6 *Let $(\mathbf{x}_1, y_1), \cdots, (\mathbf{x}_T, y_T)$ be a sequence of instance-label pairs where $\mathbf{x}_t \in \mathcal{X}$, $y_t \in \mathcal{Y}$, and $\|k((\mathbf{x}_t, y), \cdot)\| \leq 1/2$ for all t and $y \in \mathcal{Y}$. Assuming that Projectron++ is run with $\eta > 0$, the number of prediction mistakes it makes on the sequence is bounded by*

$$\frac{\|g\|^2}{(1 - \eta\|g\|)^2} + \frac{D_1^S}{1 - \eta\|g\|} + \frac{\|g\|}{1 - \eta\|g\|} \sqrt{max\left(0, \frac{D_1^S}{1 - \eta\|g\|} - B\right)}$$

where g is an arbitrary function in $\mathcal{H}^S$, such that $\|g\| < \frac{1}{\eta}$,

$$\begin{aligned}
a &= P_{t-1}\left(k((\mathbf{x}_t, y_t), \cdot) - k((\mathbf{x}_t, y_t'), \cdot)\right) \\
0 < \tau_t &< \min\left\{ 2\frac{\ell_1^S(f_{t-1}, \mathbf{x}_t, y_t) - \frac{\|\delta_t\|}{\eta}}{\|a\|^2}, 1 \right\} \\
B &= \sum_{\{t : 0 < \ell_1^S(f_{t-1}, \mathbf{x}_t, y_t) < 1\}} \tau_t \left(2\ell_1^S(f_{t-1}, \mathbf{x}_t, y_t) - \tau_t \|a\|^2 - 2\frac{\|\delta_t\|}{\eta} \right) > 0 \ .
\end{aligned}$$

As in Theorem 4 there is some freedom in the choice of τ_t, and again we set it to

$$\tau_t = \min \left\{ \frac{\ell_1^S(f_{t-1}, \mathbf{x}_t, y_t)}{\|a\|^2}, 2\frac{\ell_1^S(f_{t-1}, \mathbf{x}_t, y_t) - \frac{\|\delta_t\|}{\eta}}{\|a\|^2}, 1 \right\}.$$

In the multiclass decision problem case, the kernel $k((\mathbf{x}_1, y_1), (\mathbf{x}_2, y_2))$ is simplified to $\delta_{y_1 y_2} k(\mathbf{x}_1, \mathbf{x}_2)$, where $\delta_{y_1 y_2}$ is the Kronecker delta. This corresponds to the use of a different prototype for each class. This simplifies the projection step, in fact $k((\mathbf{x}_t, y_t), \cdot)$ can be projected only onto the functions in S_{t-1} belonging to y_t, the scalar product with the other functions being zero. So instead of storing a single matrix $\mathbf{K}_{t-1}^{-1}$, we need to store m matrices, where m is the number of classes, each one being the inverse matrix of the Gram matrix of the functions of one class. This results in improvements in both memory usage and computational cost of the algorithm. To see this suppose that we have m classes, each with n vectors in the support set. Storing a single matrix means having a space and time complexity of $O(m^2 n^2)$ (cf. Section 3), while in the second case the complexity is $O(mn^2)$. We use this method in the multiclass experiments presented in Section 7.

6. Bounding Other Online Algorithms

It is possible to apply the technique in the basis of the Projectron algorithm to any conservative online algorithm. A conservative online algorithm is an algorithm that updates its hypothesis only on rounds on which it makes a prediction error. By applying Lemma 2 to a conservative algorithm, we can construct a bounded version of it with worst case mistake bounds. As in the previous proofs, the idea is to use Lemma 2 to bound the scalar product of the competitor and the projected function. This yields an additional term which is subtracted from the margin γ of the competitor.

The technique presented here can be applied to other online kernel-based algorithms. As an example, we apply our technique to ALMA$_2$ (Gentile, 2001). Again we define two hypotheses: a temporary hypothesis f_t', which is the hypothesis of ALMA$_2$ after its update rule, and a projected hypothesis, which is the hypothesis f_t' projected on the set $\mathcal{H}_{t-1}$ as defined in Equation (2). Define the projection error δ_t as $\delta_t = f_t' - f_t''$. The modified ALMA$_2$ algorithm uses the projected hypothesis f_t'' whenever the projection error is smaller than a parameter η, otherwise it uses the temporary hypothesis f_t'. We can state the following bound

Theorem 7 *Let $(\mathbf{x}_1, y_1), \cdots, (\mathbf{x}_T, y_T)$ be a sequence of instance-label pairs where $\mathbf{x}_t \in \mathcal{X}$, $y_t \in \{-1, +1\}$, and $k(\mathbf{x}_t, \mathbf{x}_t) \leq 1$ for all t. Let α, B and $C \in \mathbb{R}^+$ satisfy the equation*

$$C^2 + 2(1-\alpha)BC = 1 \ .$$

Assume ALMA$_2$(α;B,C) projects every time the projection error $\|\delta_t\|$ is less than $\eta \geq 0$, then the number of prediction mistakes it makes on the sequence is bounded by

$$\frac{D_\gamma}{\gamma - \eta} + \frac{\rho^2}{2} + \sqrt{\frac{\rho^4}{4} + \frac{\rho^2}{\gamma - \eta} D_\gamma + \rho^2}$$

where $\gamma > \eta$, $\rho = \frac{1}{C^2(\gamma-\eta)^2}$, and g is an arbitrary function in $\mathcal{H}$, such that $\|g\| \leq 1$.

Proof The proof follows the original proof presented in Gentile (2001). Specifically, according to Lemma 2, one can replace the relation $y_t \langle g, k(\mathbf{x}_t, \cdot) \rangle \geq \gamma - \ell_\gamma(g(\mathbf{x}_t), y_t)$ with $y_t \langle g, P_{t-1} k(\mathbf{x}_t, \cdot) \rangle \geq$

7. Experimental Results

In this section we present experimental results that demonstrate the effectiveness of the Projectron and the Projectron++ algorithms. We compare both algorithms to the Perceptron algorithm, the Forgetron algorithm (Dekel et al., 2007) and the Randomized Budget Perceptron (RBP) algorithm (Cesa-Bianchi et al., 2006). For Forgetron, we choose the state-of-the-art "self-tuned" variant, which outperforms all of its other variants. We used the PA-I variant of the Passive-Aggressive algorithm (Crammer et al., 2006) as a baseline algorithm, as it gives an upper bound on the classification performance of the Projectron++ algorithm. All the algorithms were implemented in MATLAB using the DOGMA library (Orabona, 2009).

We tested the algorithms on several standard machine learning data sets:[2] *a9a*, *ijcnn1*, *news20.binary*, *vehicle (combined)*, *usps*, *mnist*. We also used a synthetic dataset and the acoustic-phonetic dataset *timit*. The synthetic dataset was built in the same way as in Dekel et al. (2007). It is composed of 10000 samples taken from two separate bi-dimensional Gaussian distributions. The means of the positive and negative samples are $(1,1)$ and $(-1,-1)$, respectively, while the covariance matrices for both are diagonal matrices with $(0.2,2)$ as their diagonal. The labels are flipped with a probability of 0.1 to introduce noise. The list of the data sets, their characteristics and the kernels used, are given in Table 1. The parameters of the kernels were selected to have the best performance with the Perceptron and were used for all the other algorithms to result in a fair comparison. The C parameter of PA-I was set to 1, to give an update similar to Perceptron and Projectron. All the experiments were performed over five different permutations of the training set.

Experiments with one setting of η. In the first set of experiments we compared the online average number of mistakes and the support set size of all algorithms. Both Forgetron and RBP work by discarding vectors from the support set, if the size of the support set reaches the budget size, B. Hence for a fair comparison, we set η to some value and selected the budget sizes of Forgetron and RBP to be equal to the final size of the support set of Projectron. In particular, in Figure 6, we set $\eta = 0.1$ in Projectron and ended up with a support set of size 793, hence $B = 793$. In Figure 6(a) the average online error rate for all algorithms on the *a9a* data set is plotted. Note that Projectron closely tracks Perceptron. On the other hand Forgetron and RBP stop improving

2. Downloaded from `http://www.sie.ntu.edu.tw/~cjlin/libsvmtools/datasets/`.

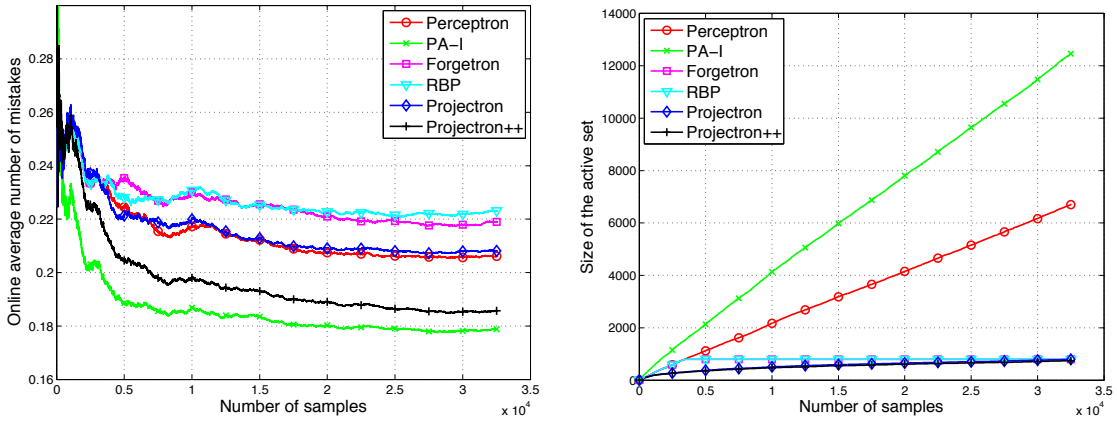

Figure 6: Average online error (left) and size of the support set (right) for the different algorithms on *a9a* data set as a function of the number of training samples (better viewed in color). B is set to 793, $\eta = 0.1$.

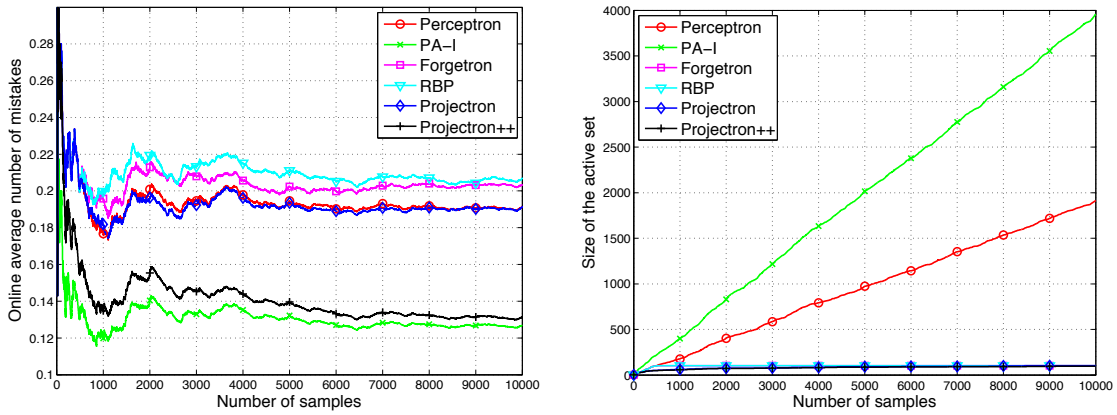
after reaching the support set size B, around 3400 samples. Moreover, as predicted by its theoretical analysis, Projectron++ achieves better results than Perceptron, even with fewer number of supports.

Figure 6(b) shows the growth of the support set as a function of the number of samples. While for the PA-I and the Perceptron the growth is clearly linear, it is sub-linear for Projectron and Projectron++: they will reach a maximum size and then they will stop growing, as stated in Theorem 1. Another important consideration is that Projectron++ outperforms Projectron *both* with respect to the size of the support set and number of mistakes. Using our MATLAB implementation, the running times for this experiment are $\sim$ 35s for RBP and Forgetron, $\sim$ 40s for Projectron and Projectron++, $\sim$ 130s for Perceptron, and $\sim$ 375s for PA-I. Hence Projectron and Projectron++ have a running time smaller than Perceptron and PA-I, due to their smaller support sets.

The same behavior can be seen in Figure 7, for the *synthetic* data set. Here the gain in performance of Projectron++ over Perceptron, Forgetron and RBP is even greater.

Experiments with a range of values for η - Binary. To analyze in more detail the behavior of our algorithms we decided to run other tests using a range of values of η. For each value we obtain a different size of the support set and a different number of mistakes. We used the data to plot a curve corresponding to the percentage of mistakes as a function of the support set size. The same curve was plotted for Forgetron and RBP, where the budget size was selected as described before. In this way we compared the algorithms along the continuous range of budget sizes, displaying the trade-off between sparseness and accuracy. For the remaining experiments we chose not to show the performance of Projectron, as it was always outperformed by Projectron++.

In Figure 8 we show the performance of the algorithms on different binary data sets: (a) *ijcnn1*, (b) *a9a*, (c) *news20.binary*, and (d) *vehicle (combined)*. Because Projectron++ used a different support set size for each permutation of the training samples, we plotted five curves, one for each of the five permutations. RBP and Forgetron have fixed budget sizes set in advance, hence for these algorithms we just plotted standard deviation bars, that are very small so they can be hardly seen in the figures. In all of the experiments Projectron++ outperforms Forgetron and RBP. One may



(a) (b)

Figure 7: Average online error (left) and size of the support set (right) for the different algorithms on the *synthetic* data set as a function of the number of training samples (better viewed in color). B is set to 103, $\eta = 0.04$.

note that there is a point in all the graphs where the performance of Projectron++ is better than Perceptron, and has a smaller support set. Projectron++ gets closer to the classification rate of the PA-I, without paying the price of a larger support set. Note that the performance of Projectron++ is consistently better than RBP and Forgetron, regardless of the kernel used, particularly, on the database *news20.binary*, which is a text classification task with linear kernel. In this task the samples are almost mutually orthogonal, so finding a suitable subspace on which to project is difficult. Nevertheless Projectron++ succeeded in obtaining better performance. The reason is probably due to the margin updates, which are performed without increasing the size of the solution. Note that a similar modification would not be trivial in Forgetron and in RBP, because the proofs of their mistake bounds strongly depend on the rate of growth of the norm of the solution.

Experiments with a range of values for η - Multiclass. We have also considered multiclass data sets, using the multiclass version of Projectron++. Due to the fact that there are no other bounded online algorithms with a mistake bound for multiclass, we have extended RBP in the natural manner to multiclass. In particular we used the *max-score* update in Crammer and Singer (2003), for which a mistake bound exists, discarding a vector at random from the solution each time a new instance is added and the number of support vectors is equal to the budget size. We name it Multiclass Random Budget Perceptron (MRBP). It should be possible to prove a mistake bound for this algorithm, extending the proof in Cesa-Bianchi et al. (2006). In Figure 9 we show the results for Perceptron, Passive-Aggressive, Projectron++ and MRBP trained on (a) *usps*, and (b) *mnist* data sets. The results confirm the findings found for the binary case.

The last data set used in our experiments is a corpus of continuous natural speech for the task of phoneme classification. The data we used is a subset of the TIMIT acoustic-phonetic data set, which is a phonetically transcribed corpus of high quality continuous speech spoken by North American speakers (Lemel et al., 1986). The features were generated from nine adjacent vectors of Mel-Frequency Cepstrum Coefficients (MFCC) along with their first and second derivatives. The TIMIT corpus is divided into a training set and a test set in such a way that no speakers from the training set

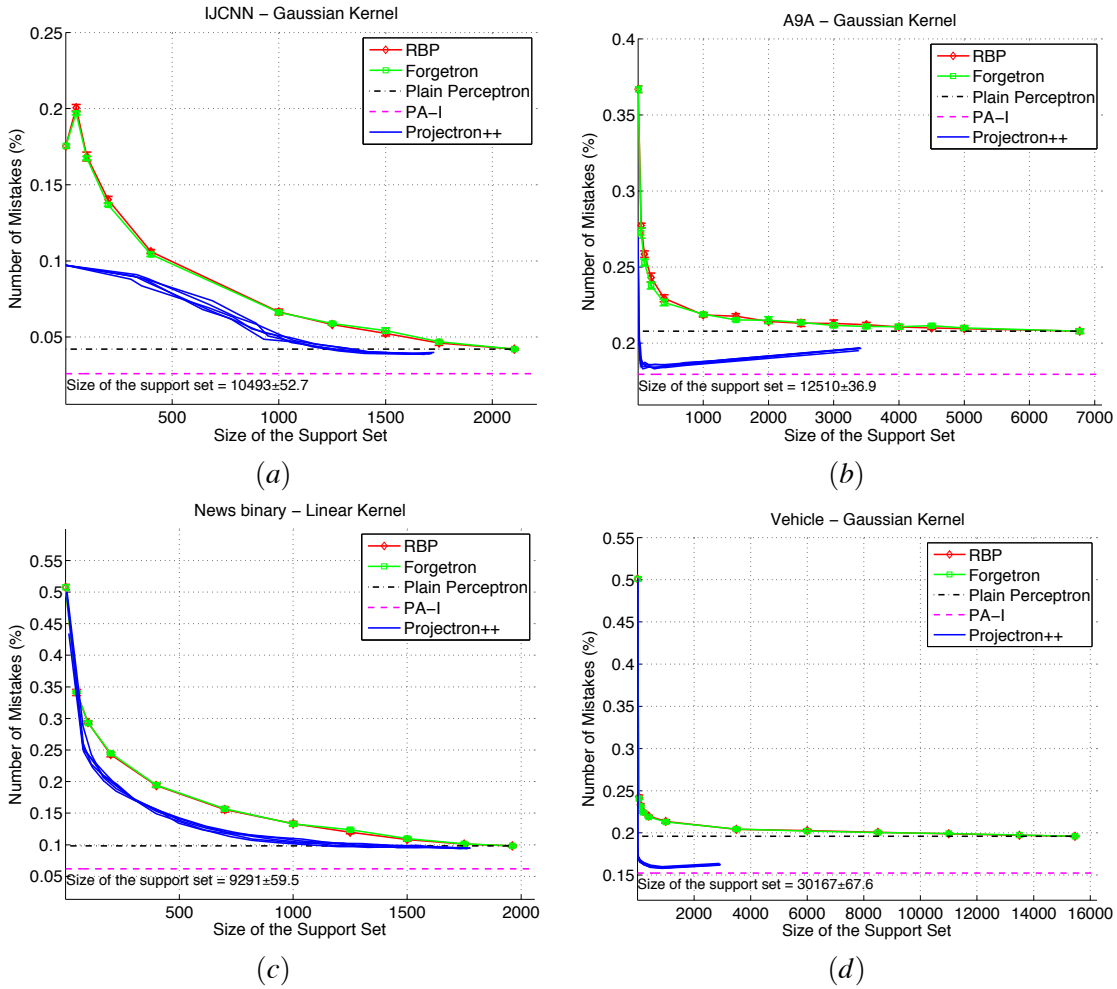


Figure 8: Average online error for the different algorithms as a function of the size of the support set on different binary data sets.

appear in the test set (speaker independent). We randomly selected 500 training utterances from the training set. The average online errors are shown in Figure 10 (a). We also tested the performance of the algorithm on the proposed TIMIT core test set composed of 192 utterances, the results of which are in Figure 10 (b). We used online-to-batch conversion (Cesa-Bianchi et al., 2004) to give a bounded batch solution. We did not test the performance of MRBP on the test set because for this algorithm the online-to-batch conversion does not produce a bounded solution. We compare the batch solution to the online-to-batch conversion of the PA-I solution. The results of Projectron++ are comparable to those of PA-I, while the former uses a smaller support set. These results also suggest that the batch solution is stable when varying the value of η, as the difference in performance on test set is less than 3%.

Figure 10: Average online error (a) and test error (b) for the different algorithms as a function of the size of the support set on a subset of the *timit* data set.

8. Discussion

This paper presented two different versions of a bounded online learning algorithm. The algorithms depend on a parameter that allows one to trade accuracy for sparseness of the solution. The size of the solution is always guaranteed to be bounded, although the size of this bound is unknown before the training begins. Therefore, these algorithms solve the memory explosion problem of the Perceptron and similar algorithms. Although the size of the support set cannot be determined

before training, practically, for a given target accuracy, the size of the support sets of Projectron or Projectron++ are much smaller than those of other budget algorithms such as Forgetron and RBP.

The first algorithm, Projectron, is based on the Perceptron algorithm. The empirical performance of Projectron is comparable to that of Perceptron, but with the advantage of a bounded solution. The second algorithm, Projectron++, introduces the notion of large margin and, for some values of η, outperforms the Perceptron algorithm, while assuring a bounded solution. The experimental results suggest that Projectron++ outperforms other online bounded algorithms such as Forgetron and RBP, with a similar hypothesis size.

There are two unique advantages of Projectron and Projectron++. First, these algorithms can be extended to the multiclass and the structured output settings. Second, a standard online-to-batch conversion can be applied to the online bounded solution of these algorithms, resulting in a bounded batch solution. The major drawback of these algorithms is their time and space complexity, which is quadratic in the size of the support set. Trying to overcome this acute problem is left for future work.

Abstract

Finite structures such as point patterns, strings, trees, and graphs occur as "natural" representations of structured data in different application areas of machine learning. We develop the theory of *structure spaces* and derive geometrical and analytical concepts such as the angle between structures and the derivative of functions on structures. In particular, we show that the gradient of a differentiable structural function is a well-defined structure pointing in the direction of steepest ascent. Exploiting the properties of structure spaces, it will turn out that a number of problems in structural pattern recognition such as central clustering or learning in structured output spaces can be formulated as optimization problems with cost functions that are locally Lipschitz. Hence, methods from nonsmooth analysis are applicable to optimize those cost functions.

Keywords: graphs, graph matching, learning in structured domains, nonsmooth optimization

1. Introduction

In pattern recognition and machine learning, it is common practice to represent data by feature vectors living in a Banach space, because this space provides powerful analytical techniques for data analysis, which are usually not available for other representations. A standard technique to solve a learning problem in a Banach space is to set up a smooth error function, which is then minimized by using local gradient information.

But often, the data we want to learn about have no natural representation as feature vectors and are more naturally represented in terms of finite combinatorial structures such as, for example, point patterns, strings, trees, lattices or graphs. Such learning problems arise in a variety of applications, which range from predicting the biological activity of a given chemical structure over finding frequent substructures of a data set of chemical compounds, and predicting the 3D-fold of a protein given its amino sequence, to natural language parsing, to name just a few.

In many applications, the set $\mathcal{X}$ of finite combinatorial structures is equipped with a distance function $d : \mathcal{X} \times \mathcal{X} \to \mathbb{R}_+$, which is often provided by external knowledge. An example of such a distance function is the edit distance on string, trees, or graphs (Levenshtein, 1966; Sanfeliu and Fu, 1983; Shapiro and Haralick, 1985; Shasha and Zhang, 1989; Zhang, 1996). The edit distance is applied to sequence alignment in bioinformatics (Gusfield, 1997), in chemoinformatics (Raymond and Willett, 2002) by means of the maximum common subgraph isomorphism, and in computer vision (Eshera and Fu, 1986; Myers, Wilson, and Hancock, 2000; Robles-Kelly and Hancock, 2005). Since

distance spaces $(\mathcal{X},d)$ of structures often have less mathematical structure than Banach spaces, several standard statistical pattern recognition techniques cannot be easily applied to $(\mathcal{X},d)$.

There are two main approaches that apply standard statistical pattern recognition techniques to a given distance space $(\mathcal{X},d)$. The first approach directly operates on the space $(\mathcal{X},d)$. Examples are the k-nearest neighbor classifier, the linear programming machine (Graepel, Herbrich, Bollmann-Sdorra, and Obermayer, 1999), and pairwise clustering (Hofmann and Buhmann, 1997; Graepel and Obermayer, 1999). These methods can cope with sets $\mathcal{X}$ that possess an arbitrary distance function d as the sole mathematical structure on $\mathcal{X}$. The problem is that many pattern recognition methods require a space $\mathcal{X}$ with a richer mathematical structure. For example, large margin classifiers require as mathematical structure a complete vector space in which distances and angles can be measured. From an algorithmic point of view, many pattern recognition methods use local gradient information to minimize some cost function. For these methods, Banach spaces are endowed with enough structure to define derivatives and gradients.

The aim of the second approach is to overcome the lack of mathematical structure by embedding a given distance space $(\mathcal{X},d)$ into a mathematically richer space $(\mathcal{X}',d')$. Several methods have been proposed, which mainly differ in the choice of the target space $\mathcal{X}'$ and to which extent the original distance function d is preserved. Typical examples are embeddings into Euclidean spaces (Cox and Cox, 2000; Luo, Wilson, and Hancock, 2003; Minh and Hofmann, 2004), Hilbert spaces (Gärtner, 2003; Hochreiter and Obermayer, 2004, 2006; Kashima, Tsuda, and Inokuchi, 2003; Lodhi, Saunders, Shawe-Taylor, Cristianini, and Watkins, 2002), Banach spaces (Hein, Bousquet, and Schölkopf, 2005; von Luxburg and Bousquet, 2004), and Pseudo-Euclidean spaces (Herbrich, Graepel, Bollmann-Sdorra, and Obermayer, 1998; Goldfarb, 1985; Pekalska, Paclik, and Duin, 2001).

During this transformation, one has to ensure that the relevant information of the original problem is preserved. Under the assumption that d is a reasonable distance function on $\mathcal{X}$ provided by some external knowledge, we can preserve the relevant information by isometrically embedding the original space $(\mathcal{X},d)$ into some target space $(\mathcal{X}',d')$. Depending on the choice of the target space this is only possible if the distance function d satisfies certain properties. Suppose that $\mathcal{S}=\{x_1,\ldots,x_k\}\subseteq\mathcal{X}$ is a finite set and $D=(d_{ij})$ is a distance matrix with elements $d_{ij}=d(x_i,x_j)$. If d is symmetric and homogeneous, we can isometrically embed $\mathcal{D}$ into a Pseudo-Euclidean space (Goldfarb, 1985). In the case that d is a metric, the elements of $\mathcal{D}$ can be isometrically embedded into a Banach space. An isometric embedding of $\mathcal{S}$ into a Hilbert or Euclidean space is possible only if the matrix D^2 is of negative type (Schoenberg, 1937).[1]

Most standard learning methods have been developed in a Hilbert space or in a Euclidean space equipped with a Euclidean distance. But distance matrices of a finite set of combinatorial structures are often not of negative type and therefore an isometric embedding into a Hilbert space or Euclidean space is not possible. Another common problem of most isometric embeddings is that they only preserve distance relations and disregard knowledge about the inherent nature of the elements from the original space. For example the inherent nature of graphs is that they consist of a finite set of vertices together with a binary relation on that set. These information is lost, once we have settled in the target space for solving a pattern recognition problem. But for some methods in pattern recognition it is necessary to either directly access the original data or to recover the effects of the operations performed in the target space. One example is the sample mean of a set of combinatorial

1. A symmetric matrix M is of negative type if $x^TMx <= 0$ for all x with $x^T1=0$.

structures (Jain and Obermayer, 2008; Jiang, Münger, and Bunke, 2001), which is a fundamental concept for several methods in pattern recognition such as principal component analysis and central clustering (Gold, Rangarajan, and Mjolsness, 1996; Günter and Bunke, 2002; Lozano and Escolano, 2003; Jain and Wysotzki, 2004; Bonev, Escolano, Lozano, Suau, Cazorla, and Aguilar, 2007; Jain and Obermayer, 2008). The sample mean of a set of vectors is the vector of sample means of each component of those vectors. Similarly, a sample mean of a set of combinatorial structures is a combinatorial structure composed of the sample means of the constituents parts the structure is composed of. Another example is finding frequent substructures in a given set of combinatorial structures (Dehaspe, Toivonen, and King, 1998; Yan and Han, 2002). For such problems a principled framework is missing.

In this contribution, we present a theoretical framework that isometrically and isostructurally embeds certain metric spaces $(\mathcal{X},d)$ of combinatorial structures into a quotient space $(\mathcal{X}',d')$ of a Euclidean vector space. Instead of discarding information about the inherent nature of the original data, we can weaken the requirement that the embedding of $(\mathcal{X},d)$ into $(\mathcal{X}',d')$ should be isometric for all metrics. Here, we focus on metrics d that are related to the pointwise maximum of a set of Euclidean distances. This restriction is acceptable from an application point of view, because we can show that such metrics on combinatorial structures and their related similarity functions are a common choice of proximity measure in a number of different applications (Gold, Rangarajan, and Mjolsness, 1996; Holm and Sander, 1993; Caprara, Carr, Istrail, Lancia, and Walenz, 2004).

The quotient space $(\mathcal{X}',d')$ preserves the distance relations and the nature of the original data. The related Euclidean space provides the mathematical structure that gives rise to a rich arsenal of learning methods. The goal of the proposed approach is to adopt standard learning methods based on local gradient information to learning on structures in the quotient space $\mathcal{X}'$. In order to do so, we need an approach that allows us to formally adopt geometrical and analytical concepts for finite combinatorial structures. The proposed approach maps combinatorial structures to equivalence classes of vectors, where the elements of the same equivalence class are different vector representations of the same structure. Mapping a combinatorial structure to an equivalence class of vectors rather than to a single vector provides a link to the geometry of Euclidean spaces and at the same time preserves the nature of the original data. The resulting quotient set (the set of equivalence classes) leads to the more abstract notion of $\mathcal{T}$-space. Formally, a $\mathcal{T}$-space $\mathcal{X}_{\mathcal{T}}$ over a vector space $\mathcal{X}$ is a quotient set of $\mathcal{X}$, where the equivalence classes are the orbits of the group action of a transformation group $\mathcal{T}$ on $\mathcal{X}$. We show that $\mathcal{T}$-spaces encompass a variety of different classes of combinatorial structures, which also includes vectors. Thus, the theory of $\mathcal{T}$-spaces generalizes the vector space concept to cope with combinatorial structures and aims at retaining the geometrical and algebraic properties of a vector space to a certain extent.

We present case studies to illustrate that the theoretical framework can be applied to machine learning applications.

This paper is organized as follows: Section 2 provides an overview about the basic idea of the proposed approach. In Section 3, we study $\mathcal{T}$-spaces $\mathcal{X}_{\mathcal{T}}$ over metric, normed, and inner product vector spaces $\mathcal{X}$. We show that the gradient of a smooth function on structures satisfies the necessary condition of optimality and is a well-defined structure pointing in direction of steepest ascent. In Section 4, we use the theory of $\mathcal{T}$-spaces to formulate selected problems in structural pattern recognition as continuous optimization problems. We show that the proposed cost functions are locally Lipschitz and therefore nonsmooth on a set of Lebesgue measure zero. For this class of functions, we can apply methods from nonsmooth optimization. As a case study, we discuss in Section 5 the

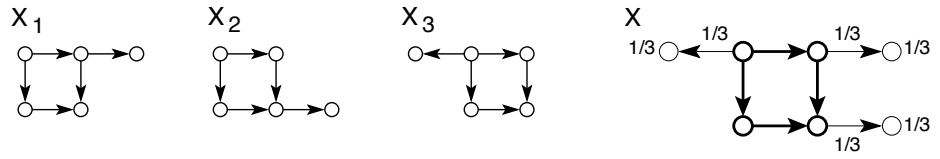

Figure 1: Illustration of a sample mean $\overline{X}$ of the three graphs $\mathcal{D} = \{X_1, X_2, X_3\}$. Vertices and edges of $\overline{X}$ that occur in all of the three example graphs from $\mathcal{D}$ are highlighted with bold lines. All other vertices and edges of $\overline{X}$ are annotated with the relative frequency of their occurrence in $\mathcal{D}$. By annotating the highlighted vertices and edges of $\overline{X}$ with 1, we obtain a weighted graph.

problem of determining a sample mean of a set of structures including its application to central clustering. As structures we consider point patterns and attributed graphs. Section 6 concludes. Technical parts and proofs have been delegated to the appendix.

2. An Example

The purpose of this section is to provide an overview about the basic idea of the proposed approach. To this end, we consider the (open) problem of determining the sample mean of graphs as a simple introductory example. The concept of a sample mean is the theoretical foundation for central clustering algorithms (see Section 4.3 and references therein).

A *directed graph* is a pair $X = (V, E)$ consisting of a finite set V of *vertices* and a set $E = \{(i, j) \in V \times V : i \neq j\}$ of *edges*.

By $\mathcal{G}$ we denote the set of all directed graphs. Suppose that

$$\mathcal{D} = (X_1, \ldots, X_k)$$

is a collection of k not necessarily distinct graphs from $\mathcal{G}$. Our goal is to determine a sample mean of $\mathcal{X}$. Intuitively, a sample mean averages the occurrences of vertices and edges within their structural context as illustrated in Figure 1.

As the sample mean of integers is not necessarily an integer, the sample mean of $\mathcal{D}$ is not necessarily a directed graph from $\mathcal{G}$ (see Figure 1). Therefore, we extend the set $\mathcal{G}$ of directed graphs to the set $\mathcal{G}[\mathbb{R}]$ of weighted directed graphs. A *weighted directed graph* is a triple $X = (V, E, \alpha)$ consisting of a directed graph (V, E) and a *weight function* $\alpha : V \cup V \to \mathbb{R}$ such that each edge has nonzero weight. A weighted directed graph X of order $|V| = n$ is completely specified by its *weight matrix* $X = (x_{ij})$ with elements $x_{ij} = \alpha(i, j)$ for all $i, j \in \{1, \ldots, n\}$.

The standard method

$$\overline{X} = \frac{1}{k} \sum_{i=1}^{k} X_i$$

to determine the sample mean $\overline{X}$ of $\mathcal{D}$ fails, because a well-defined addition of directed graphs is unknown as indicated by Figure 2. Therefore, we consider an equivalent characterization of the standard notion of sample mean. Following Jiang, Münger, and Bunke (2001), we adopt the optimization formulation of the standard sample mean. For vectors, the sample mean minimizes the

sum of squared Euclidean distances from the data points. In line with this formulation, we define a sample mean of $\mathcal{D}$ as a global minimum of the cost function

$$F(X) = \sum_{i=1}^{k} D(X, X_i)^2, \tag{1}$$

where D is some appropriate distance function on $\mathcal{G}[\mathbb{R}]$ that measures structural consistent and inconsistent parts of the graphs under consideration.

In principle, we could use any "well-behaved" distance function.[2] Here, we first consider distance functions on structures that generalize the Euclidean metric, because Euclidean spaces have a rich repository of analytical tools. To adapt at least parts of these tools for structure spaces, it seems to be reasonable to relate the distance function D in Equation (1) to the Euclidean metric. From an application point of view, this restriction is acceptable for the following reasons: (i) Geometric distance functions on graphs and their related similarity functions are a common choice of proximity measure in a number of different applications (Gold, Rangarajan, and Mjolsness, 1996; Holm and Sander, 1993); and (ii) it can be shown that a number of structure-based proximity measures like, for example, the maximum common subgraph (Raymond and Willett, 2002) or maximum contact map overlap problem for protein structure comparison (Goldman, Istrail, and Papadimitriou, 1999) can be related to an inner product and therefore to the Euclidean distance.

The geometric distance functions D we consider here are usually defined as the maximum of a set of Euclidean distances. This definition implies that (i) the cost function F is neither differentiable nor convex; (ii) the sample mean of graphs is not unique as shown in Figure 2; and (iii) determining a sample mean of graphs is NP-complete, because evaluation of D is NP-complete. Thus, we are faced with an intractable combinatorial optimization problem, where, at a first glance, a solution has to be found from an uncountable infinite set. In addition, multiple local minima of the cost function F complicates a characterization of a structural mean.

To deal with these difficulties, we embed graphs into a $\mathcal{T}$-space as we will show shortly. The basic idea is to view graphs as equivalence classes of vectors via their weight matrices, where the elements of the same equivalence class are different vector representations of the same structure. The resulting quotient set (the set of equivalence classes) leads to the more abstract notion of $\mathcal{T}$-space. Formally, a $\mathcal{T}$-space $\mathcal{X}_{\mathcal{T}}$ over a vector space $\mathcal{X}$ is a quotient set of $\mathcal{X}$, where the equivalence classes are the orbits of the group action of a transformation group $\mathcal{T}$ on $\mathcal{X}$. The theory of $\mathcal{T}$-spaces generalizes the vector space concept to cope with combinatorial structures and aims at retaining the geometrical and algebraic properties of a vector space to a certain extent. In doing so, the $\mathcal{T}$-space concept not only clears the way to approach the structural version of the sample mean in a principled way, but also generalizes standard techniques of learning in structured domains.

2.1 The Basic Approach

To construct $\mathcal{T}$-spaces, we demand that all graphs are of bounded order n, where the bound n can be chosen arbitrarily large. For a pattern recognition application this is not a serious restriction, because we can assume that the data graphs of interest are of bounded order. In the second step, we align each weighted directed graph X of order $m < n$ to a graph X' of order n by adding $p = n - m$

2. As we will see later, a distance function is well-behaved if it is locally Lipschitz.

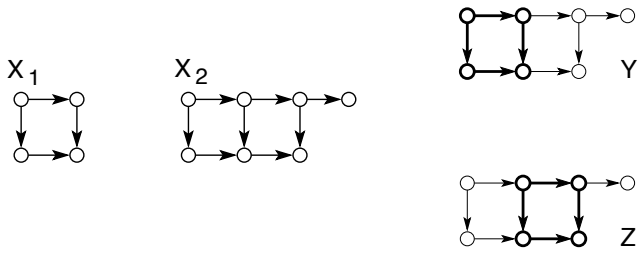

Figure 2: Illustration of one key problem in the domain of graphs: the lack of a well-defined addition. The graph X_1 can be added to X_2 with respect to $D(X_1, X_2)$ in two different ways as indicated by the highlighted subgraphs of Y and Z. As a consequence, Y and Z can be regarded as two distinct sample means of X_1 and X_2.

isolated vertices. The weighted adjacency matrix of the aligned graph X' is then of the form

$$X' = \begin{pmatrix} X & 0_{m,p} \\ 0_{p,m} & 0_{p,p} \end{pmatrix},$$

where X is the weighted adjacency matrix of X, and $0_{m,p}, 0_{p,m}, 0_{p,p}$ are padding zero matrices. By $\mathcal{G}[\mathbb{R}, n]$ we denote the set of weighted directed graphs of bounded order n.

For practical issues, it is important to note that restricting to structures of bounded order n and alignment of structures are purely technical assumptions to simplify mathematics. For machine learning problems, these limitations should have no practical impact, because neither the bound n needs to be specified nor an alignment of all graphs to an identical order needs to be performed. In a practical setting, we cancel out both technical assumptions by considering structure preserving mappings between the vertices of X and Y. Thus, when applying the theory, all we actually require is that the graphs are finite. We will return to this issue later, when we have provided the necessary technicalities.

The positions of the diagonal elements of X determine an ordering of the vertices. Conversely, different orderings of the vertices may result in different matrices. Since we are interested in the structure of a graph, the ordering of its vertices does not really matter. Therefore, we consider two matrices X and X' as being equivalent, denoted by $X \sim X'$, if they can be obtained from one another by reordering the vertices. Mathematically, the equivalence relation can be written as

$$X \sim X' \Leftrightarrow \exists P \in \mathcal{T} : P^{\mathsf{T}} X P = X',$$

where $\mathcal{T}$ denotes the set of all $(n \times n)$-permutation matrices.[3] The set $\mathcal{T}$ together with the function composition $T \circ T'$ for all $T, T' \in \mathcal{T}$ forms an algebraic group. By $[X]$ we denote the equivalence class of all matrices equivalent to X. Occasionally, we also refer to $[X]$ as the equivalence class of the graph X.

There are $n!$ different orderings of the vertices for an arbitrary graph X with n vertices. Each of the $n!$ orderings determines a weighted adjacency matrix. The equivalence class of X consist of all its different matrix representation. Note that different orderings of the vertices may result in the same matrix representation of the graph.

3. The letter $\mathcal{T}$ stands for transformation.

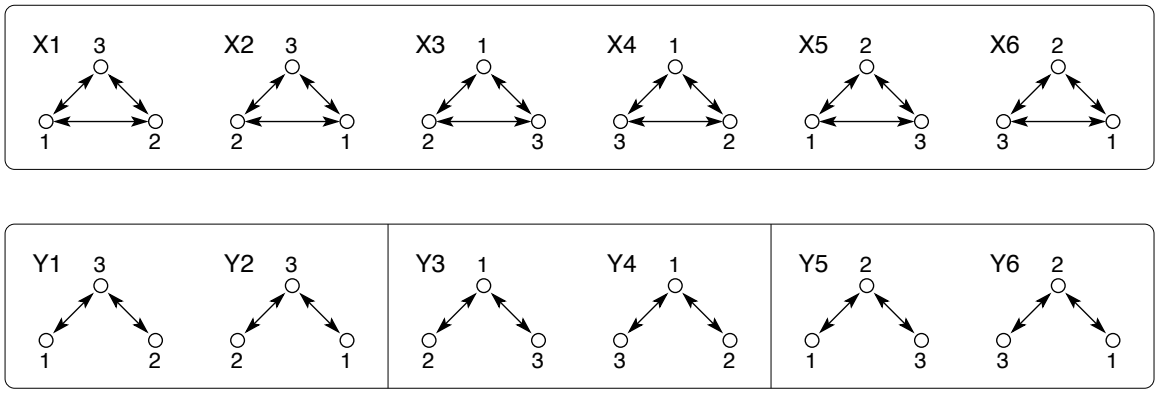

Figure 3: Illustration of two graphs with all possible orderings of their vertices. The number attached to the vertices represents their order (and are *not* attributes). The ordered graphs are grouped together according to their matrix representations. All ordered graphs $X1$-$X6$ yield the same weighted adjacency matrix. In the second row, the pairs $(Y1, Y2)$, $(Y3, Y4)$, and $(Y5, Y6)$ result in identical matrices.

Example 1 *Consider the graphs $X = X1$ and $Y = Y1$ depicted in the first column of Figure 3. The numbers annotated to the vertices represent an arbitrarily chosen ordering. Suppose that all vertices and edges have attribute* 1*. Then the weighted adjacency matrices of X and Y given the chosen ordering of their vertices are of the form*

$$X = \begin{pmatrix} 1 & 1 & 1 \\ 1 & 1 & 1 \\ 1 & 1 & 1 \end{pmatrix} \qquad \text{and} \qquad Y = \begin{pmatrix} 1 & 0 & 1 \\ 0 & 1 & 1 \\ 1 & 1 & 1 \end{pmatrix}$$

The first and second row of Figure 3 show the $3! = 6$ different orderings of X and Y, respectively.

The matrix representation of X is independent of its ordering, that is, each reordering of the vertices of X results in the same matrix representation. Hence, the equivalence class of X consists of the singleton X.

The 6 *different orderings of graph Y result in three different matrix representations. The equivalence class of Y is of the form*

$$[Y] = \left\{ \begin{pmatrix} 1 & 0 & 1 \\ 0 & 1 & 1 \\ 1 & 1 & 1 \end{pmatrix}, \begin{pmatrix} 1 & 1 & 1 \\ 1 & 1 & 0 \\ 1 & 0 & 1 \end{pmatrix}, \begin{pmatrix} 1 & 1 & 0 \\ 1 & 1 & 1 \\ 0 & 1 & 1 \end{pmatrix} \right\},$$

where the first matrix refers to the ordering of $Y = Y1$ and $Y2$, the second to $Y3$ and $Y4$, and the third to $Y5$ and $Y6$.

Since we may regard matrices as vectors, we can embed X into the vector space $\mathcal{X} = \mathbb{R}^{n \times n}$ as the set $[X]$ of all vector representations of X. We call the quotient set

$$\mathcal{X}_{\mathcal{T}} = \mathcal{X} / \sim = \bigcup_{X \in \mathcal{X}} [X]$$

consisting of all equivalence classes *$\mathcal{T}$-space* over the *representation space* $\mathcal{X}$. Figure 4 depicts an embedding of a graph into a vector space.

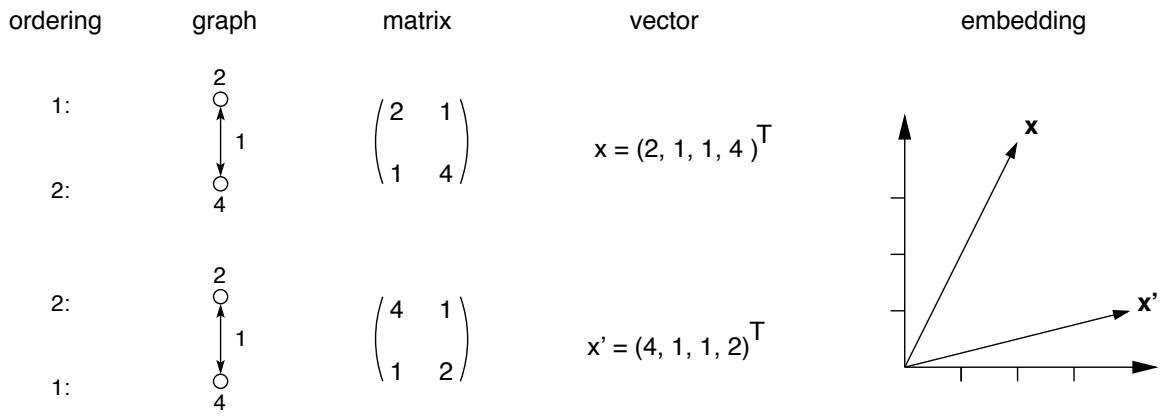

Figure 4: Illustration of an embedding of a graph of order 2. The attributes of the vertices are 2 and 4, and the attribute of the bidirectional edge is 1. Depending on the ordering of the vertices, we obtain two different matrix representations. Stacking the columns of the matrix to a 4-dimensional vector yields the vector representations x and x'. The plot in the last column depicts both representation vectors by considering their first and fourth dimension. Thus a graph is represented as a set of vectors in some vector space.

3. $\mathcal{T}$-spaces

In this section, we formalize the ideas on $\mathcal{T}$-spaces of the previous section. We consider a more general setting in the sense that we include classes of finite structures other than directed graphs with attributes from arbitrary vector spaces rather than weights from $\mathbb{R}$. The chosen approach that allows to formally adopt geometrical and analytical concepts makes use of the notion of *r-structures*. We introduce r-structures in Section 3.1. Based on the notion of r-structures, we develop the theory of $\mathcal{T}$-spaces in Sections 3.2 and 3.3. For a detailed technical treatment of $\mathcal{T}$-spaces we refer to Appendix A and B. Finally, Section 3.4 considers optimization of locally Lipschitz functions on $\mathcal{T}$spaces.

3.1 Attributed r-Structures

A *r-structure* is a pair $X = (\mathcal{P}, \mathcal{R})$ consisting of a finite set $\mathcal{P} \neq \emptyset$, and a subset $\mathcal{R} \subseteq \mathcal{P}^r$. The elements of $\mathcal{P}$ are the *points* of the r-structure X, the elements of $\mathcal{R}$ are its r-ary *relations*. A r-structure with points $\mathcal{P}$ is said to be a r-structure *on* $\mathcal{P}$. For convenience, we occasionally identify the structure X on $\mathcal{P}$ with its relation $\mathcal{R}$.

The following examples serve to indicate that several types of combinatorial structures can be regarded as r-structures. We first show that graphs are 2-structures. For this, we use the following notation: Given a finite set $\mathcal{P}$ of points, let

$$\mathcal{P}^{[2]} = \{(p,q) : p,q \in \mathcal{P}, p \neq q\}$$

be the set of tuples from $\mathcal{P}^2$ without diagonal elements (p,p).

Example 2 (Graphs) *Let $\mathcal{P}$ be a finite set of points, and let $X = (\mathcal{P}, \mathcal{R})$ be a 2-structure with $\mathcal{R} \subseteq \mathcal{P}^2$.*

1. *X is a* directed graph *if* $\mathcal{R} \subseteq \mathcal{P}^{[2]}$.

2. *X is a* simple graph *if* $\mathcal{R} \subseteq \mathcal{P}^{[2]}$ *such that* $(p,q) \in \mathcal{R}$ *implies* $(q,p) \in \mathcal{R}$.

3. *X is a* simple graph with loops *if* $\mathcal{R} \subseteq \mathcal{P}^2$ *such that* $(p,q) \in \mathcal{R}$ *implies* $(q,p) \in \mathcal{R}$. *Loops are edges* (p,p) *with the same endpoints*.

In a similar way, we can define further types of graphs such as, for example, trees, directed acyclic graphs, complete graphs, and regular graphs as 2-structures by specifying the corresponding properties on $\mathcal{R}$.

The next example shows that elements of a set are 1-structures.

Example 3 (Set of Elements) *Let $\mathcal{P}$ be a finite set of points. The* elements $E(\mathcal{P}) = (\mathcal{P}, \mathcal{R})$ *is a* 1*-structure with $\mathcal{R} = \mathcal{P}$, that is its relations are the elements of $\mathcal{P}$.*

To introduce analytical concepts to functions on r-structures, we shift from discrete to continuous spaces by introducing attributes. Let $\mathcal{A} = \mathcal{R}^d$ denote the set of attributes. An *$\mathcal{A}$-attributed r-structure* is a triple $X_\alpha = (\mathcal{P}, \mathcal{R}, \alpha)$ consisting of a r-structure $X = (\mathcal{P}, \mathcal{R})$ and an *attribution* $\alpha : \mathcal{P}^r \to \mathcal{A}$ with $\alpha(p) \neq 0$ if, and only if, $p \in \mathcal{R}$. Besides the technical argument, attributions also have a practical relevance, because they are often used to enhance descriptions of structured objects. The next example collects some attributed structures.

Example 4 *Let $\mathcal{P}$ be a finite set of order n.*

- Attributed graphs*: Let $\mathcal{A} = \mathbb{R}^d$. An* attributed graph *is an $\mathcal{A}$-attributed* 2*-structure $G_\alpha = (\mathcal{P}, \mathcal{R}, \alpha)$, where $G = (\mathcal{P}, \mathcal{R})$ is a simple graph with loops and $\alpha : \mathcal{R} \to \mathcal{A}$ is an attribution that assigns each vertex (loop) and each edge a non-zero feature vector.*

- Point patterns*: Let $\mathcal{A} = \mathbb{R}^2$. A* point pattern *is an $\mathcal{A}$-attributed* 1*-structure $P_\alpha = (\mathcal{P}, \mathcal{R}, \alpha)$, where $E(\mathcal{P}) = (\mathcal{P}, \mathcal{R})$ are the elements of $\mathcal{P}$ and $\alpha : \mathcal{R} \to \mathcal{A}$ is an attribution that assigns each element $p \in \mathcal{P}$ its coordinates $\alpha(p)$.*

The next example shows that vectors are attributed 1-structures. Hence, all results on r-structures are also valid in vector spaces.

Example 5 *Let $\mathcal{A}$ be a vector space. Suppose that $\mathcal{P}$ is of order $n = 1$. A* vector *is an $\mathcal{A}$-attributed* 1*-structure $x_\alpha = (\mathcal{P}, \mathcal{R}, \alpha)$, where $E(\mathcal{P}) = (\mathcal{P}, \mathcal{R})$ is the single element of $\mathcal{P}$ and $\alpha : \mathcal{R} \to \mathcal{A}$ is an attribution that maps a singleton to a vector. Hence, the set of all possible structures x_α on $\mathcal{P}$ reproduces the vector space $\mathcal{A}$.*

Note that we may assume without loss of generality that the attributes of r-relations from $\mathcal{R}$ are nonzero, that is $\alpha(\mathcal{R}) \subseteq \mathcal{A} \setminus \{0\}$. If the zero vector 0 is required as a valid attribute of a r-relation, we can always change, for example, to the vector space $\mathcal{A}' = \mathcal{A} \times \mathbb{R}$ and redefine α as

$$\alpha' : \mathcal{P}^r \to \mathcal{A} \times \mathbb{R}, \quad p \mapsto \begin{cases} (0,0) & : \quad p \in \mathcal{P}^r \setminus \mathcal{R} \\ (\alpha(p), 1) & : \quad p \in \mathcal{R} \end{cases}.$$

An $\mathcal{A}$-attributed r-structure $X = (\mathcal{P}, \mathcal{R}, \alpha)$ is completely specified by its *matrix representation* $X = (x_{p_1 \ldots p_r})$ with elements

$$x_{p_1 \ldots p_r} = \alpha(p_1, \ldots, p_r)$$

for all $p = (p_1, \ldots, p_r) \in \mathcal{P}^r$. For example, the matrix representation of a simple graph is its ordinary adjacency matrix.

Neither the "nature" of the points $\mathcal{P}$ nor the particular form of the r-relations $\mathcal{R}$ of a given r-structure $X = (\mathcal{P}, \mathcal{R}, \alpha)$ do really matter. What matters is the structure described by $\mathcal{R}$. Suppose that X is of order $|\mathcal{P}| = n$. To abstract from the "nature" of points, we choose $\mathbb{Z}_n = \{1, \ldots, n\}$ as our standard set of points. The particular form of $\mathcal{R}$ depends on the numbering of the points from $\mathbb{Z}_n$. To abstract from the particular form of $\mathcal{R}$, we identify sets of r-relations that can be obtained from one another by renumbering the points. Mathematically, we can express these sets by means of *isomorphism classes*. Two $\mathcal{A}$-attributed r-structures $X = (\mathcal{P}, \mathcal{R}, \alpha)$ and $X' = (\mathcal{P}', \mathcal{R}', \alpha')$ are *isomorphic*, written as $X \simeq X'$ if there is a bijective mapping $\phi : \mathcal{P} \to \mathcal{P}'$ satisfying

1. $p = (p_1, \ldots, p_r) \in \mathcal{R} \Leftrightarrow \phi(p) = (\phi(p_1), \ldots, \phi(p_r)) \in \mathcal{R}'$
2. $\alpha(p) = \alpha'(\phi(p))$ for all $p \in \mathcal{R}$.

The *isomorphism* class $[X]$ of X consists of all $\mathcal{A}$-attributed r-structures on $\mathcal{P} = \mathbb{Z}_n$ that are isomorphic to X. By $\mathcal{S}_{\mathcal{A}}^{n,r}$ we denote the set of all $\mathcal{A}$-attributed r-structures on $\mathcal{P} = \mathbb{Z}_n$ and by $\left[\mathcal{S}_{\mathcal{A}}^{n,r}\right]$ the set of all isomorphism classes of structures from $\mathcal{S}_{\mathcal{A}}^{n,r}$.

We can identify any r-structure $X = (\mathbb{Z}_m, \mathcal{R}, \alpha)$ of order $m < n$ with a structure of order n by adding $q = n - m$ isolated points. The aligned structure is then of the form $X' = (\mathbb{Z}_n, \mathcal{R}, \alpha')$, where

$$\alpha'(p) = \begin{cases} \alpha(p) & : \quad p \in \mathcal{R} \\ 0 & : \quad \textit{otherwise} \end{cases} .$$

Using alignment, we can regard $\mathcal{S}_{\mathcal{A}}^{n,r}$ as the set of $\mathcal{A}$-attributed r-structures of bounded order n. Similarly, we may think of $\left[\mathcal{S}_{\mathcal{A}}^{n,r}\right]$ as the set of abstract $\mathcal{A}$-attributed r-structures of bounded order n. Again recall that specifying a bound n and aligning smaller structures to structures of order n are purely technical assumptions to simplify mathematics.

3.2 $\mathcal{T}$-Spaces

Let $\mathcal{X} = \mathbb{R}^n$ be the n-dimensional Euclidean vector space, and let $\mathcal{T}$ be a subgroup of the group of all $n \times n$ permutation matrices. Then the binary operation

$$\cdot : \mathcal{T} \times \mathcal{X} \to \mathcal{X}, \quad (T, x) \mapsto Tx$$

is a group action of $\mathcal{T}$ on $\mathcal{X}$. For $x \in \mathcal{X}$, the *orbit* of x is denoted by

$$[x]_{\mathcal{T}} = \{Tx : T \in \mathcal{T}\}.$$

If no misunderstanding can occur, we write $[x]$ instead of $[x]_{\mathcal{T}}$.

A *$\mathcal{T}$-space* over $\mathcal{X}$ is the orbit space $\mathcal{X}_{\mathcal{T}} = \mathcal{X}/\mathcal{T}$ of all orbits of $x \in \mathcal{X}$ under the action of $\mathcal{T}$. We call $\mathcal{X}$ the *representation space* of $\mathcal{X}_{\mathcal{T}}$. By

$$\mu : \mathcal{X} \to \mathcal{X}_{\mathcal{T}}$$

we denote the *membership function* that sends vector representations to the structure they describe.

$\mathcal{T}$-spaces are a convenient abstraction of r-structures in order to adopt geometrical and analytical concepts. To see this, let $\mathcal{A} = \mathbb{R}^d$ and let $\mathcal{X} = \mathcal{A}^N$, where $N = n^r$. Via the matrix representations,

we can identify r-structures from $\mathcal{S}_{\mathcal{A}}^{n,r}$ as vectors from $\mathcal{X}$. Obviously, we have a relaxation in the sense that $\mathcal{S}_{\mathcal{A}}^{n,r} \subseteq \mathcal{X}$ and $\left[\mathcal{S}_{\mathcal{A}}^{n,r}\right] \subseteq \mathcal{X}_{\mathcal{T}}$ such that μ restricted on $\mathcal{S}_{\mathcal{A}}^{n,r}$ sends vector representations to the structures they represent. Note that there are structures in $\mathcal{X}_{\mathcal{T}}$ that are not well-defined r-structures from $\left[\mathcal{S}_{\mathcal{A}}^{n,r}\right]$. Hence, care must be taken when applying $\mathcal{T}$-spaces.

The following notations, definitions, and results are useful to simplify technicalities. We use capital letters $X, Y, Z, \ldots$ to denote the elements of $\mathcal{X}_{\mathcal{T}}$. Suppose that $X = \mu(x)$ for some $x \in \mathcal{X}$. Then we identify X with $[x]$ and make use of sloppy notations like, for example, $x \in X$ to denote $x \in [x]$.[4]

Let $f : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$ be a symmetric function satisfying $f(x,y) = f(y,x)$ for all $x, y \in \mathcal{X}$. Then f induces symmetric functions

$$F^* : \mathcal{X}_{\mathcal{T}} \times \mathcal{X}_{\mathcal{T}} \to \mathbb{R}, \quad (X,Y) \mapsto \max\{f(x,y) : x \in X, y \in Y\},$$
$$F_* : \mathcal{X}_{\mathcal{T}} \times \mathcal{X}_{\mathcal{T}} \to \mathbb{R}, \quad (X,Y) \mapsto \min\{f(x,y) : x \in X, y \in Y\}.$$

Since $\mathcal{T}$ is finite, the orbits $[x]$ of x are finite. Hence, F^* and F_* assume an extremal value. We call F^* *maximizer* and F_* *minimizer* of f on $\mathcal{X}_{\mathcal{T}} \times \mathcal{X}_{\mathcal{T}}$.

An inner product $\langle \cdot, \cdot \rangle$ on $\mathcal{X}$ gives rise to a maximizer of the form

$$\langle \cdot, \cdot \rangle^* : \mathcal{X}_{\mathcal{T}} \times \mathcal{X}_{\mathcal{T}} \to \mathbb{R}, \quad (X,Y) \mapsto \max\{\langle x,y \rangle : x \in X, y \in Y\}.$$

We call $\langle \cdot, \cdot \rangle^*$ *inner $\mathcal{T}$-product* induced by $\langle \cdot, \cdot \rangle$. The inner $\mathcal{T}$-product is *not* an inner product, because the maximum-operator in the definition of $\langle \cdot, \cdot \rangle^*$ does not preserve the bilinearity property of an inner product. But we can show that an inner $\mathcal{T}$-product satisfies some weaker properties.

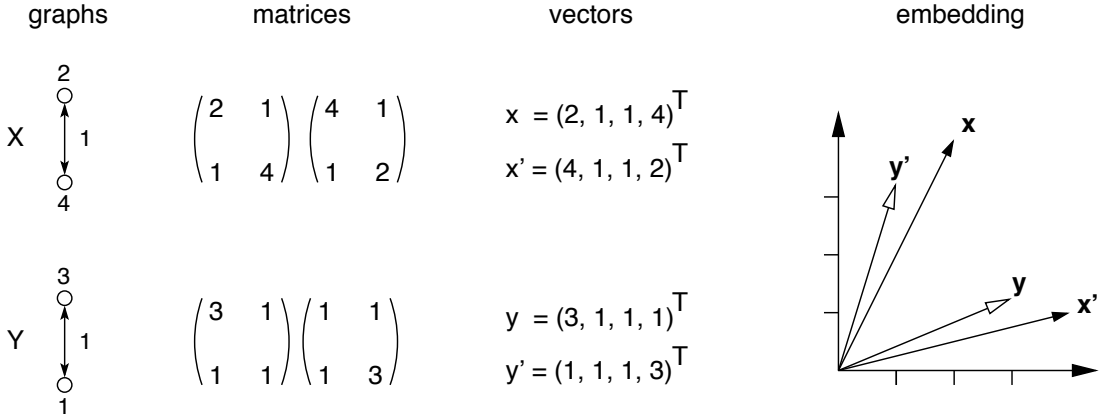

Figure 5: Illustration of two example graphs and their embeddings in a vector space (see Figure 4 for a detailed description).

Example 6 *Consider the graphs X and Y from Figure 5. We have*

$$\langle X,Y \rangle^* = \langle x,y' \rangle = \langle x',y \rangle = 16.$$

4. The notation is sloppy, because X is an element in $\mathcal{X}_{\mathcal{T}}$ and not a set, whereas $[x]$ is a set of equivalent elements from $\mathcal{X}$.

Thus, to determine $\langle X,Y\rangle^*$, we select vector representations $\tilde{x}$ of X and $\tilde{y}$ of Y that have closest angle and then evaluate $\langle \tilde{x},\tilde{y}\rangle$.

Any inner product space $\mathcal{X}$ is a normed space with norm $\|x\| = \sqrt{\langle x,x\rangle}$ and a metric space with metric $d(x,y) = \|x-y\|$. The norm $\|\cdot\|$ and the metric d on $\mathcal{X}$ give rise to minimizers $\|\cdot\|_*$ of $\|\cdot\|$ and D_* of d on $\mathcal{X}_\mathcal{T}$.

Since elements from $\mathcal{T}$ preserve lengths and angles, we have

$$\|Tx\| = \|Tx-0\| = \|Tx-T0\| = \|x-0\| = \|x\|$$

for all $T \in \mathcal{T}$. Hence, $\|X\|_*$ is independent from the choice of vector representation. We call the minimizer $\|\cdot\|_*$ the *$\mathcal{T}$-norm* induced by the norm $\|\cdot\|$. A $\mathcal{T}$-norm is related to an inner $\mathcal{T}$-product in the same way as a norm to an inner product. We have

1. $\langle X,X\rangle^* = \langle x,x\rangle$ for all $x \in X$.
2. $\|X\|_* = \sqrt{\langle X,X\rangle^*}$.

Note that a $\mathcal{T}$-norm is *not* a norm, because a $\mathcal{T}$-space has no well defined addition. But we can show that a $\mathcal{T}$-norm has norm-like properties.

Example 7 *Consider the graphs X and Y from Figure 5. To determine their $\mathcal{T}$-norm, it is sufficient to compute the standard norm of an arbitrarily chosen vector representation. Hence, we have*

$$\|X\|_* = \|x\| = \|x'\| = \sqrt{22},$$
$$\|Y\|_* = \|y\| = \|y'\| = \sqrt{12}.$$

The minimizer D_* of the Euclidean metric $d(x,y) = \|x-y\|$ is also a metric. To distinguish from ordinary metrics, we call the minimizer D_* of a Euclidean metric d on $\mathcal{X}$ the $\mathcal{T}$-metric induced by d. We can express the metric D_* in terms of $\langle\cdot,\cdot\rangle^*$ as follows:

$$D_*(X,Y)^2 = \|X\|_*^2 - 2\langle X,Y\rangle^* + \|Y\|_*^2.$$

Example 8 *Consider the graphs X and Y depicted in Figure 5. To determine $D_*(X,Y)$, we select vector representations $\tilde{x}$ of X and $\tilde{y}$ of Y that have minimal distance $d(\tilde{x},\tilde{y})$. Then we find that*

$$D_*(X,Y) = d(x,y') = d(x',y) = \sqrt{2}.$$

3.3 Functions on $\mathcal{T}$-Spaces

A *$\mathcal{T}$-function* is a function of the form

$$F : \mathcal{X}_\mathcal{T} \to \mathbb{R},$$

where $\mathcal{X}_\mathcal{T}$ is a T-space over $\mathcal{X}$. Instead of considering the $\mathcal{T}$-function F, it is often more convenient to consider its *representation function*

$$f : \mathcal{X} \to \mathbb{R}, \quad x \mapsto F \circ \mu(x),$$

which is invariant under transformations from elements of $\mathcal{T}$.

Here, the focus is on $\mathcal{T}$-functions that are locally Lipschitz. A $\mathcal{T}$-function is *locally Lipschitz* if, and only if, its representation function is locally Lipschitz. We refer to Appendix C for basic definitions and properties from nonsmooth analysis of locally Lipschitz functions.

Suppose that F is a locally Lipschitz function with representation function f. By Rademacher's Theorem 23, f is differentiable almost everywhere. In addition, at non-differentiable points, f admits the concept of generalized gradient. The concepts differentiability and gradient can be transfered to $\mathcal{T}$-spaces in a well-defined way. Assume that f is differentiable at some point $x \in \mathcal{X}$ with gradient $\nabla f(x)$. Then f is differentiable at all points $Tx \in X$ with $T \in \mathcal{T}$ and the gradient of f at Tx is of the form

$$\nabla f(Tx) = T\nabla f(x).$$

We say F is $\mathcal{T}$-differentiable at X, if its representation function f is differentiable at an arbitrary vector representation $x \in X$. The well-defined structure

$$\nabla F(X) = \mu(f(x))$$

is the *$\mathcal{T}$-gradient* of F at X pointing in direction of steepest ascent.

3.4 Optimization of Locally Lipschitz $\mathcal{T}$-Functions

A standard technique in machine learning and pattern recognition is to pose a learning problem as an optimization problem. Here, we consider the problem of solving optimization problems of the form

$$(P1) \qquad \begin{array}{ll} \text{minimize} & F : \mathcal{X}_{\mathcal{T}} \to \mathbb{R}, \qquad X \mapsto \sum_{i=1}^{k} F_i(X) \\ \text{subject to} & X \in \mathcal{U}_{\mathcal{T}} \end{array}$$

where the component functions F_i are locally Lipschitz $\mathcal{T}$-functions and $\mathcal{U}_{\mathcal{T}} \subset \mathcal{X}_{\mathcal{T}}$ is the feasible set of admissible solutions. Then according to Prop. 21, the cost function F is also locally Lipschitz, and we can rewrite (P1) to an equivalent optimization problem

$$(P2) \qquad \begin{array}{ll} \text{minimize} & f : \mathcal{X} \to \mathbb{R}, \qquad x \mapsto \sum_{i=1}^{k} f_i(x) \\ \text{subject to} & x \in \mathcal{U} \end{array}$$

where the component functions f_i are the representation functions of F_i and $\mathcal{U} \subseteq \mathcal{X}$ is the feasible set with $\mu(\mathcal{U}) = \mathcal{U}_{\mathcal{T}}$. Hence, f is the representation function of the locally Lipschitz $\mathcal{T}$-function F and therefore also locally Lipschitz.

To minimize locally Lipschitz functions, the field of nonsmooth optimization offers a number of techniques. A survey of classical methods can be found in Mäkelä and Neittaanmäki (1992); Shor (1985). As an example, we describe subgradient methods, which are easy to implement and well-suited to identify the difficulties arising in nonsmooth optimization. Algorithm 1 outlines the basic procedure:

Algorithm 1 (Basic Incremental Algorithm)

choose starting point $x_1 \in \mathcal{U}$ and set $t := 0$
repeat
  set $\tilde{x}_{t,1} := x_1$
  for $i = 1, \ldots, k$ **do**
    `direction finding`:
      determine $d_{t,i} \in \mathcal{X}$ and $\eta > 0$ s.t. $\tilde{x}_{t,i} + \eta d_{t,i} \in \mathcal{U}$ and

$$f_i(\tilde{x}_{t,i} + \eta d_{t,i}) < f_i(\tilde{x}_{t,i})$$

    `line search`:
      find step size $\eta_{t,i} > 0$ such that $\tilde{x}_{t,i} + \eta_{t,i} d_{t,i} \in \mathcal{U}$ and

$$\eta_{t,i} \approx \arg\min_{\eta > 0} f_i(\tilde{x}_{t,i} + \eta d_{t,i})$$

    `updating`:
      set $\tilde{x}_{t,i+1} := \tilde{x}_{t,i} + \eta_{t,i} d_{t,i}$

  Set $x_{t+1} := \tilde{x}_{t,k+1}$
  Set $t := t + 1$
until some termination criterion is satisfied

To explain the algorithm, we first consider the case that f is smooth and $\mathcal{U} = \mathcal{X}$. In the step *direction finding*, we generate a descent direction by exploiting the fact that the direction opposite to the gradient is locally the steepest descent direction. Line search usually employs some efficient univariate smooth optimization method or polynomial interpolation. The necessary condition for a local minimum yields a termination criterion. Now suppose that f is locally Lipschitz. Then f admits a generalized gradient at each point. The generalized gradient coincides with the gradient at differentiable points and is a convex set of subgradients at non-differentiable points. For more details, we refer to Appendix C.

Subgradients, the elements of a generalized gradient, play a very important role in algorithms for non-differentiable optimization. The basic idea of subgradient methods is to generalize the methods for smooth problems by replacing the gradient by an arbitrary subgradient. In the direction finding step, Algorithm 1 computes an arbitrary subgradient $d \in \partial f(x)$ at the current point x. If f is differentiable at x, then the subgradient d coincides with the gradient $\nabla f(x)$. If in addition $d \neq 0$, then the opposite direction $-d$ is the direction of steepest descent. On the other hand, if f is not differentiable at x, then $-d$ is not necessarily a direction of descent of f at x. But since f is differentiable almost everywhere by Rademacher's Theorem 23, the set of non-differentiable points is a set of Lebesgue measure zero.

Line search uses predetermined step sizes $\eta_{t,i}$, instead of an exact or approximate line search as in the gradient method. One reason for this is that the direction $-d$ computed in the direction finding step is not necessarily a direction of descent. Thus, the viability of subgradient methods depend critically on the sequence of step sizes. One common choice are step sizes that satisfy

$$\sum_{t=0}^{\infty} \eta_t = \infty \quad \text{and} \quad \sum_{t=0}^{\infty} \eta_t^2 < \infty,$$

where $\eta_t = \eta_{t,1}$.

To formulate a termination criterion, we could—in principle—make use of the following necessary condition of optimality.

Theorem 1 *Let $f : \mathcal{X} \to \mathbb{R}$ be locally Lipschitz at its minimum (maximum) $x \in \mathcal{R}$. Then*

$$0 \in \partial f(x).$$

At non-differentiable points, however, an arbitrary subgradient provides no information about the existence of the zero in the generalized gradient $\partial f(x)$. Therefore, when assuming an instantly decreasing step size, one reliable termination criterion stops the algorithm as soon as the step size falls below a predefined threshold.

Since the subgradient method is not a descent method, it is common to keep track of the best point found so far, which is the one with smallest function value. For further advanced and more sophisticated techniques to minimize locally Lipschitz functions, we refer to Mäkelä and Neittaanmäki (1992); Shor (1985).

We conclude this section with a remark on determining intractable subgradients in a practical setting.

3.4.1 APPROXIMATING SUBGRADIENTS

Nonsmooth optimization as discussed in Mäkelä and Neittaanmäki (1992); Shor (1985) assumes that at each point x we can evaluate at least one subgradient $y \in \partial f(x)$ and the function value $f(x)$. In principle, this should be no obstacle for the class of problems we are interested in. In a practical setting, however, evaluating a subgradient as descent direction can be computationally intractable. For example, the pattern recognition problems described later in Section 4.2-4.5 are all computationally efficient for structures like point patterns, but NP-hard for structures like graphs. A solution to this problem is to approximate a subgradient by using polynomial time algorithms. An approximated subgradient corresponds to a direction that is no longer a subgradient of the cost function. In particular, at smooth points, an approximated (sub)gradient (hopefully) corresponds to a descent direction close to the direction of steepest descent. We call Algorithm 1 an *approximate incremental subgradient methods* if the direction finding step produces directions that are not necessarily subgradients of the corresponding component function f_i.

We replace the subgradient by a computationally cheaper approximation as a direction of descent. In a computer simulation, we show that determining a sample mean of weighted graph is indeed possible when using approximate subgradient methods.

Suppose that $\mathcal{X}_\mathcal{T}$ is the $\mathcal{T}$-space of simple weighted graphs over $\mathcal{X} = \mathbb{R}^{n\times n}$, and let $\mathcal{U}_\mathcal{T} \subseteq \mathcal{X}_\mathcal{T}$ be the subset of weighted graphs with attributes from the interval $[0,1]$. Our goal is to determine a sample mean of a collection of simple weighted graphs $\mathcal{D} = \{\mathcal{X}_1, \ldots, \mathcal{X}_k\} \subseteq \mathcal{U}_\mathcal{T}$.

Given a representation x of X, the computationally intractable task is to find a representation x_i of X_i such that $(x, x_i) \in \operatorname{supp}\left(d^2_{X_i}|x\right)$. This problem is closely related to the problem of computing the distance $D_*(X, X_i)$, which is known to be an NP-complete *graph matching problem*. Hence, in a practical setting, exact algorithms that guarantee to find a subgradient as descent direction are useless for all but the smallest graphs. A solution to this problem is to approximate a subgradient by using polynomial time algorithms. An approximated subgradient corresponds to a direction that is no longer a subgradient of the cost function. In particular, at smooth points, an approximated (sub)gradient (hopefully) corresponds to a descent direction close to the direction of steepest

descent. We call Algorithm 1 an *approximate incremental subgradient methods* if the direction finding step produces directions that are not necessarily subgradients of the corresponding component function f_i.

4. Pattern Recognition in $\mathcal{T}$-Spaces

This section shows how the framework of $\mathcal{T}$-spaces can be applied to solve problems in structural pattern recognition. We first propose a generic scheme for learning in distance spaces. Based on this generic scheme, we derive cost functions for determining a sample mean, central clustering, learning large margin classifiers, supervised learning in structured input and/or output spaces, and finding frequent substructures. Apart from the last problem, all other cost functions presented in this section extend standard cost functions from the vector space formalism to $\mathcal{T}$-spaces in the sense that we recover the standard formulations when regarding vectors as r-structures.

4.1 A Generic Approach: Learning in Distance Spaces

Without loss of generality, we may assume that $(\mathcal{X}_\mathcal{T}, D)$ is a distance space, where D is either the metric D_* induced by the Euclidean metric on $\mathcal{X}$ or another (not necessarily metric) distance function that is more appropriate for the problem to hand. A generic approach to solve a learning problem (P) in $\mathcal{X}_\mathcal{T}$ is as follows:

1. Transform (P) to an optimization problem, where the cost function F is a function defined on $\mathcal{X}_\mathcal{T}$.
2. Show that F is locally Lipschitz.
3. Optimize F using methods from nonsmooth optimization.

Since $\mathcal{X}_\mathcal{T}$ is a metric space over an Euclidean vector space, we can apply subgradient methods or other techniques from nonsmooth optimization to minimize locally Lipschitz $\mathcal{T}$-functions on $\mathcal{X}_\mathcal{T}$. If the cost function F depends on a distance measure D, we demand that D is locally Lipschitz to ensure the locally Lipschitz property for F.

4.2 The Sample Mean of k-Structures

The sample mean of structures is a basic concept for a number of methods in statistical pattern recognition. Examples include visualizing or comparing two populations of chemical graphs, and central clustering of structures (Section 4.3).

We define a sample mean of the k elements $X_1, \ldots, X_k \in \mathcal{X}_\mathcal{T}$ as a minimizer of

$$\begin{array}{ll} \text{minimize} & F(X) = \sum_{i=1}^{k} D(X, X_i)^2 \\ \text{subject to} & X \in \mathcal{X}_\mathcal{T} \end{array},$$

where D is a distance function on $\mathcal{X}_\mathcal{T}$. If D is locally Lipschitz, then F is also locally Lipschitz by Prop. 21.

First approaches to study averages of graphs have been pursued by Jiang, Münger, and Bunke (2001). They considered the set median and generalized median of a sample of graphs as a discrete optimization problem with a similar cost function as for the sample mean. To minimize the cost

function, they applied a genetic algorithm to graphs with a small number of discrete attributes. In this contribution, we shift the problem of determining a sample mean from discrete to continuous optimization.

4.3 Central Clustering of k-Structures

Suppose that we are given a training sample $\mathcal{X} = \{X_1, \ldots, X_m\}$ consisting of m structures X_i drawn from the structure space $\mathcal{X}_\mathcal{T}$. The aim of central clustering is to find k cluster centers $\mathcal{Y} = \{Y_1, \ldots, Y_k\} \subseteq \mathcal{X}_\mathcal{T}$ such that the following cost function

$$F(M, \mathcal{Y}, \mathcal{X}) = \frac{1}{m} \sum_{j=1}^{k} \sum_{i=1}^{m} m_{ij} D(X_i, Y_j),$$

is minimized with respect to a given distortion measure D. The matrix $M = (m_{ij})$ is a $(m \times k)$-membership matrix with elements $m_{ij} \in [0,1]$ such that $\sum_j m_{ij} = 1$ for all $i = 1, \ldots, m$.

If the distortion measure is locally Lipschitz, then F as a function of the cluster centers Y_j is locally Lipschitz by Prop. 21.

A number of central clustering algorithms for graphs have been devised recently (Gold, Rangarajan, and Mjolsness, 1996; Günter and Bunke, 2002; Lozano and Escolano, 2003; Jain and Wysotzki, 2004; Bonev, Escolano, Lozano, Suau, Cazorla, and Aguilar, 2007). In experiments it has been shown that the proposed methods converge to satisfactory solutions, although neither the notion of cluster center nor the update rule of the cluster centers is well-defined. Because of these issues one might expect that central clustering algorithm could be prone to oscillations halfway between different cluster centers of the same cluster. An explanation why this rarely occurs can now be given. As long as the cost function is locally Lipschitz, almost all points are differentiable. For these points the update rule is well-defined. Hence, it is very unlikely that the aforementioned oscillations occur over a longer period of time, when using an optimization algorithm that successively decreases the step size.

4.4 Large Margin Classifiers

Consider the function

$$h_{W,b} : \mathcal{X}_\mathcal{T} \to \mathbb{R}, \quad X \mapsto \langle W, X \rangle^* + b,$$

where $W \in \mathcal{X}_\mathcal{T}$ is the *weight structure* and $b \in \mathbb{R}$ the *bias*. The discriminant $h_{W,b}$ implements a two-category classifier in the obvious way: Assign an input structure X to the class labeled $+1$ if $h_{W,b}(X) \geq 0$ and to -1 if $h_{W,b}(X) < 0$.

Suppose that $\mathcal{Z} = \{(X_1, y_1), \ldots, (X_k, y_k)\}$ is a training sample consisting of k training structures $X_i \in \mathcal{X}_\mathcal{T}$ together with corresponding labels $y_i \in \{\pm 1\}$. We say, $\mathcal{Z}$ is *$\mathcal{T}$-separable* if there exists a $W_0 \in \mathcal{X}_\mathcal{T}$ and $b_0 \in \mathbb{R}$ with

$$h_*(X) = \langle W_0, X \rangle^* + b_0 = y$$

for all $(X, y) \in \mathcal{Z}$.

To find an "optimal" discriminant that correctly classifies the training examples, we construct the cost function

$$F(W, b, \alpha) = \frac{1}{2} \|W\|_*^2 - \sum_{i=1}^{k} \alpha_i \left(y_i \left(\langle W, X_i \rangle^* + b \right) - 1 \right),$$

where the $\alpha_i \geq 0$ are the Lagrangian multipliers. The representation function of F is of the form

$$f(w,b,\alpha) = \frac{1}{2}\|w\|^2 - \sum_{i=1}^{k} \alpha_i y_i (s_i(w,b) - 1),$$

where $s_i(w,b) = \max_{T \in \mathcal{T}} \langle w, Tx_i \rangle + b$. The elements $w \in W$ and $x_i \in X_i$ are arbitrary. The first term of f is smooth and convex (and therefore locally Lipschitz). The locally Lipschitz property and convexity of the second term follows from the rules of calculus for locally Lipschitz functions (see Section C) and Prop. 20. Hence, f is locally Lipschitz and convex.

The structurally linear discriminants sets the stage to (i) explore large margin classifiers in structure spaces and (ii) construct neural learning machines for adaptive processing of finite structures. Subgradient methods for maximum margin learning has been applied in Ratliff, Bagnell, and Zinkevich (2006) for predicting structures rather than classes. Finally note that the inner $\mathcal{T}$-product as a maximizer of a set of similarities is not a kernel (Gärtner, 2005).

4.5 Supervised Learning

The next application example generalizes the problem of learning large margin classifiers for k-structures by allowing $\mathcal{T}$-spaces as input and as output space. Note that the in- and output spaces may consist of different classes of k-structures, for example, the input patterns can be feature vectors and the output space can be the domain of graphs.

Assume that we are given a a training sample $\mathcal{Z} = \{(X_1, Y_1), \ldots, (X_k, Y_k)\}$ consisting of k training structures X_i drawn from some $\mathcal{T}$-space $\mathcal{X}_\mathcal{T}$ over $\mathcal{X}$ together with corresponding output structures Y_i from a $\mathcal{T}'$-space $\mathcal{Y}_{\mathcal{T}'}$ over $\mathcal{Y}$. Given the training data $\mathcal{Z}$, our goal is to find an unknown functional relationship (hypothesis)

$$H : \mathcal{X}_\mathcal{T} \to \mathcal{Y}_\mathcal{T}$$

from a hypothesis space $\mathcal{H}$ that best predicts the output structures of unseen examples $(X,Y) \in \mathcal{X}_\mathcal{T} \times \mathcal{Y}_\mathcal{T}$ according to some cost function

$$F(H,\mathcal{Z}) = \frac{1}{k}\sum_{i=1}^{k} L(H(X_i), Y_i),$$

where $L : \mathcal{Y}_\mathcal{T} \times \mathcal{Y}_\mathcal{T} \to \mathbb{R}$ denotes the loss function.

The representation function of F is of the form

$$f(h,\mathcal{Z}) = \frac{1}{k}\sum_{i=1}^{k} \ell(h(x_i), y_i),$$

where $\ell : \mathcal{Y} \times \mathcal{Y} \to \mathbb{R}$ is the representation function of L, $h : \mathcal{X} \to \mathcal{Y}$ the representation function of H, and $x_i \in X_i$, $y_i \in Y_i$. We assume that the functions h have a parametric form and are therefore uniquely determined by the value of their parameter vector θ_h. We make this dependence of h on θ_h explicit by writing $f(\theta_h, \mathcal{Z})$ instead of $f(h,\mathcal{Z})$.

The function f is locally Lipschitz if ℓ and h (as a function of θ_h) are locally Lipschitz. As an example for a locally Lipschitz function f, we extend supervised neural learning machines to k-structures:

- *Loss function*: The loss
$$\ell(x,y) = D_*(\mu(x),\mu(y))^2$$
is locally Lipschitz as a function of x.

- *Hypothesis space*: Consider the set $\mathcal{H}_{NN}$ of all functions $g : \mathcal{X} \to \mathcal{Y}$ that can be implemented by a neural network. Suppose that all functions from $\mathcal{H}_{NN}$ are smooth. If $\dim(\mathcal{V}_\mathcal{Y}) = M$, then g is of the form $g = (g_1,\ldots,g_M)$, where the g_i are the component functions of g. For each component g_i, the pointwise maximizer
$$h_i(x) = \max_{T\in\mathcal{T}} g_i(Tx)$$
is locally Lipschitz. Hence, $h = (h_1,\ldots,h_M)$ is locally Lipschitz.

Compared to common models in predicting structures as applied by Taskar (2004); Tsochantaridis, Hofmann, Joachims, and Altun (2004), the proposed approach differs in two ways: First, the proposed cost function requires no indirection via a score function $f : \mathcal{X}\times\mathcal{Y} \to \mathbb{R}$ to select the prediction from $\mathcal{Y}$ by maximizing f for a given input from $\mathcal{X}$. Second, the proposed approach suggests a formulation that can be exploited to approximately solve discrete and continuous prediction problems.

4.6 Frequent Substructures

Our aim is to find the most frequent substructure occurring in a finite data set $\mathcal{D}$ of k-structures. To show how to apply the theory of $\mathcal{T}$-spaces to this problem, we consider a simplified setting.

First we define what we mean by a substructure. A k-structure $X' = (\mathbb{Z}_m,\mathcal{R}',\alpha')$ is said to be a *substructure* of a k-structure $X = (\mathbb{Z}_n,\mathcal{R},\alpha)$, if there is an isomorphic embedding $\phi : \mathbb{Z}_m \to \mathbb{Z}_n$.

Next, we restrict ourselves to k-structures with attributes from $[0,1] \subseteq \mathbb{R}$ for the sake of simplicity. Let
$$\mathcal{B}_\mathcal{T} = \big\{X = (\mathbb{Z}_n,\mathcal{R}_i,\alpha) \in \mathcal{X}_\mathcal{T} : \alpha(X) \subseteq \{0,1\}\big\},$$
$$\mathcal{U}_\mathcal{T} = \big\{X = (\mathbb{Z}_n,\mathcal{R}_i,\alpha) \in \mathcal{X}_\mathcal{T} : \alpha(X) \subseteq [0,1]\big\}$$
be the set of all $\mathcal{A}$-attributed k-structures $X \in \mathcal{X}_\mathcal{T}$ with attributes from $\{0,1\}$ and $[0,1]$, respectively. Suppose that $\mathcal{D} = \{X_1,\ldots,X_k\} \subseteq \mathcal{B}_\mathcal{T}$ is a set of k-structures.

The characteristic function of the i-th structure $X_i \in \mathcal{D}$
$$\chi_i(X) = \begin{cases} 1 & : \quad X \text{ is a substructure of } X_i \\ 0 & : \quad \text{otherwise} \end{cases}.$$
indicates whether the k-structure X is a substructure of X_i. We say X^* is a *maximal frequent substructure* of order m if it solves the following discrete problem
$$\begin{array}{ll} \text{maximize} & F(X) = \sum_{i=1}^k \chi_i(X) \\ \text{subject to} & |X| = m \\ & X \in \mathcal{B}_\mathcal{T}. \end{array}$$
We cast the discrete to a continuous problem. For this, we define
$$F_i(X) = \frac{\langle X, X_i\rangle^*}{\|X\|_*^2}.$$

for all $X \in \mathcal{U}_\mathcal{T}$. We have $F_i(X) \in [0,1]$ with $F_i(X) = 1$ if, and only if, X is a substructure of X_i. Consider for a moment the problem to maximize the criterion function

$$G(X) = \sum_{i=1}^{k} F_i(X).$$

The problem with this criterion function is that a maximizer $X \in \mathcal{U}_\mathcal{T}$ of G could be a k-structure not occurring as a substructure in any of the k-structures from $\mathcal{D}$. To fix this problem, we use the soft-max function $\exp(\beta(F_i(X)-1))$ with control parameter β. In the limit $\beta \to \infty$, the i-th soft-max function reduces to the characteristic function χ_i. Given a fixed $\beta > 0$, the soft-max formulation of the frequent subgraph problem is of the form

$$\begin{array}{ll} \text{maximize} & F_\beta(X) = \sum_{i=1}^{k} \exp\{\beta(F_i(X)-1)\} \\ \text{subject to} & |X| = m \\ & X \in \mathcal{U}_\mathcal{T}. \end{array}$$

The representation function of F_β is of the form

$$f_\beta(x) = \sum_{i=1}^{k} \exp\left\{\beta\left(\frac{s_i(x)}{\|x\|} - 1\right)\right\},$$

where $s_i(x) = \max_{T \in \mathcal{T}} \langle x, Tx_i \rangle$. Applying the rules of calculus yields that f_β is locally Lipschitz.

The common approach casts the frequent subgraph mining problem to a search problem in a state space, which is then solved by a search algorithm (Dehaspe, Toivonen, and King, 1998; Han, Pei, and Yin, 2000; Inokuchi, Washio, and Motoda, 2000; Kuramochi and Karypis, 2001; Yan and Han, 2002). Here, we suggest a continuous cost function for the frequent subgraph mining problem that can be solved using optimization based methods (see Section 3.4).

5. Experimental Results

To demonstrate the effectiveness and versatility of the proposed framework, we applied it to the problem of determining a sample mean of randomly generated point patterns and weighted graphs as well as to central clustering of letters and protein structures represented by graphs.

5.1 Sample Mean

To assess the performance and to investigate the behavior of the subgradient and approximated subgradient method for determining a sample mean, we conducted an experiments on random graphs, letter graphs, and chemical graphs. For computing approximate subgradients we applied the graduated assignment (`GA`) algorithm (see Appendix D). For data sets consisting of small graphs, we also applied a depth first search (`DF`) algorithm that guarantees to return an exact subgradient.

5.1.1 DATA

Random Graphs. The first data set consists of randomly generated graphs. We sampled k graphs by distorting a given initial graph according to the following scheme: First, we randomly generated an initial graph M_0 with 6 vertices and edge density 0.5. Next, we assigned a feature vector to

	depth-first search	graduated assignment	set mean
Random Graphs	29.6 (± 5.3)	34.5 (± 6.6)	43.0 (± 7.5)
Letter Graphs	42.3 (± 10.1)	43.9 (± 11.1)	60.5 (± 16.6)
Molecules		262.2 (± 113.6)	338.0 (± 115.0)

Table 1: Average SSD of sample mean approximated by depth-first search and graduated assignment. As reference value the average SSD of the set mean is shown in the last column. Standard deviations are given in parentheses.

each vertex and edge of M_0 drawn from a uniform distribution over $[0,1]^d$ ($d = 3$). Given M_0, we randomly generated k distorted graphs as follows: Each vertex and edge was deleted with 20% probability. A new vertex was inserted with 10% probability and randomly connected to other vertices with 50% probability. Uniform noise from $[0,1]^d$ with standard deviation $\sigma \in [0,1]$ was imposed to all feature vectors. Finally, the vertices of the distorted graphs were randomly permuted.

We generated 500 samples each consisting of $k = 10$ graphs. For each sample the noise level $\sigma \in [0,1]$ was randomly prespecified.

Letter Graphs. The letter graphs were taken from the IAM Graph Database Repository. [5] The graphs represent distorted letter drawings from the Roman alphabet that consist of straight lines only. Lines of a letter are represented by edges and ending points of lines by vertices. Each vertex is labeled with a two-dimensional vector giving the position of its end point relative to a reference coordinate system. Edges are labeled with weight 1. We considered the 150 letter graphs representing the capital letter *A* at a medium distortion level.

We generated 100 samples each consisting or $k = 10$ letter graphs drawn from a uniform distribution over the data set of 150 graph letters representing letter *A* at a medium distortion level.

Chemical Graphs. The chemical compound database was taken from the gSpan site[6]. The data set contains 340 chemical compounds, 66 atom types, and 4 types of bonds. On average a chemical compound consists of 27 vertices and 28 edges. Atoms are represented by vertices and bonds between atoms by edges. As attributes for atom types and type of bonds, we used a 1-to-k binary encoding, where $k = 66$ for encoding atom types and $k = 4$ for encoding types of bonds.

We generated 100 samples each consisting of $k = 10$ chemical graphs drawn from a uniform distribution over the data set of 340 chemical graphs.

5.1.2 EVALUATION PROCEDURE

As performance measure, we used the average sum-of-squared distances (SSD) of the sample mean described in Section 4.2 averaged over all samples. The average SSD of the set mean graph serves as our reference value. The set mean is an element from the set $\mathcal{D}$ itself that minimizes the SSD over all structures from $\mathcal{D}$.

Algorithm 2 (K-Means for Structures)

initialize number k of clusters
initialize cluster centers $Y_1, \ldots, Y_k$
repeat
    classify structures X_i according to nearest Y_j
    recompute Y_j
until some termination criterion is satisfied

5.1.3 RESULTS

Table 1 shows the average SSD and its standard deviation. The results show that using exact subgradients gives better approximations of the sample mean than using approximated subgradients. Compared with the set median, the results indicate that the subgradient and approximated subgradient method have found reasonable solutions in the sense that the resulting average SSD is lower.

5.2 Central Clustering

Based on the concept of sample mean for structures, we applied the structural versions of k-means and simple competitive learning on four data sets in order to assess and compare the performance of subgradient methods.

5.2.1 CENTRAL CLUSTERING ALGORITHMS FOR GRAPHS

We consider k-means and simple competitive learning in order to minimize the cluster objective (see Section 4.2)[7]

$$F(M, \mathcal{Y}, \mathcal{X}) = \frac{1}{2} \sum_{j=1}^{k} \sum_{i=1}^{m} m_{ij} D(X_i, Y_j).$$

K-means for graphs. The structural version of k-means is outlined in Algorithm 2. This method operates as the EM algorithm of standard k-means, where the chosen distortion measure in the E-step is D to classify the structures X_i according to nearest cluster center Y_j . In the M-step the basic incremental subgradient method described in Algorithm 1 is applied to recompute the means.
Simple competitive learning. The structural version of simple competitive learning corresponds to the basic incremental subgradient method described in Algorithm 1 for minimizing the cluster objective $F(X)$.

5.2.2 DATA

We selected four data sets described in Riesen and Bunke (2008). The data sets are publicly available at the IAM Graph Database Repository. Each data set is divided into a training, validation, and a test set. In all four cases, we considered data from the test set only. The description of the data

5. The repository can be found at `http://www.iam.unibe.ch/fki/databases/iam-graph-database`.
6. gSpan can be found at `http://www.xifengyan.net/software/gSpan.htm`.
7. We replaced the factor $1/m$ by the factor $1/2$ for convenience of presentation of our results.

data set	#graphs)	#(classes)	avg(nodes)	max(nodes)	avg(edges)	max(edges)
letter	750	15	4.7	8	3.1	6
grec	528	22	11.5	24	11.9	29
fingerprint	900	3	8.3	26	14.1	48
molecules	100	2	24.6	40	25.2	44

Table 2: Summary of main characteristics of the data sets used for central clustering.

sets are mainly excerpts from Riesen and Bunke (2008). Table 2 provides a summary of the main characteristics of the data sets.

Letter Graphs. We consider all 750 graphs from the test data set representing distorted letter drawings from the Roman alphabet that consist of straight lines only (A, E, F, H, I, K, L, M, N, T, V, W, X, Y, Z). The graphs are uniformly distributed over the 15 classes (letters). The letter drawings are obtained by distorting prototype letters at low distortion level. Lines of a letter are represented by edges and ending points of lines by vertices. Each vertex is labeled with a two-dimensional vector giving the position of its end point relative to a reference coordinate system. Edges are labeled with weight 1. Figure 6 shows a prototype letter and distorted version at various distortion levels.

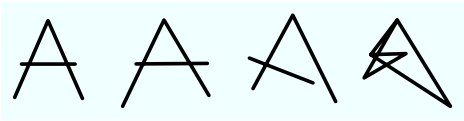

Figure 6: Example of letter drawings: Prototype of letter A and distorted copies generated by imposing low, medium, and high distortion (from left to right) on prototype A.

GREC Graphs. The GREC data set (Dosch and Valveny, 2006) consists of graphs representing symbols from architectural and electronic drawings. We use all 528 graphs from the test data set uniformly distributed over 22 classes. The images occur at five different distortion levels. In Figure 7 for each distortion level one example of a drawing is given. Depending on the distortion level, either erosion, dilation, or other morphological operations are applied. The result is thinned to obtain lines of one pixel width. Finally, graphs are extracted from the resulting denoised images by tracing the lines from end to end and detecting intersections as well as corners. Ending points, corners, intersections and circles are represented by vertices and labeled with a two-dimensional attribute giving their position. The vertices are connected by undirected edges which are labeled as line or arc. An additional attribute specifies the angle with respect to the horizontal direction or the diameter in case of arcs.

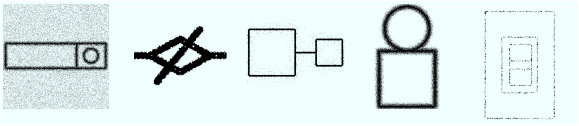

Figure 7: GREC symbols: A sample image of each distortion level

Fingerprint Graphs. We consider a subset of 900 graphs from the test data set representing fingerprint images of the NIST-4 database (Watson and Wilson, 1992). The graphs are uniformly distributed over three classes *left*, *right*, and *whorl*. A fourth class (*arch*) is excluded in order to keep the data set balanced. Fingerprint images are converted into graphs by filtering the images and extracting regions that are relevant (Neuhaus and Bunke, 2005). Relevant regions are binarized and a noise removal and thinning procedure is applied. This results in a skeletonized representation of the extracted regions. Ending points and bifurcation points of the skeletonized regions are represented by vertices. Additional vertices are inserted in regular intervals between ending points and bifurcation points. Finally, undirected edges are inserted to link vertices that are directly connected through a ridge in the skeleton. Each vertex is labeled with a two-dimensional attribute giving its position. Edges are attributed with an angle denoting the orientation of the edge with respect to the horizontal direction. Figure 8 shows fingerprints of each class.

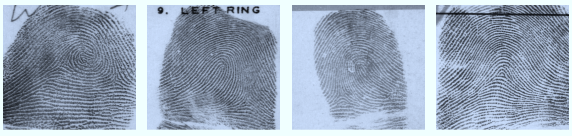

Figure 8: Fingerprints: (a) Left (b) Right (c) Arch (d) Whorl. Fingerprints of class arch are not considered.

Molecules. The mutagenicity data set consists of chemical molecules from two classes (mutagen, non-mutagen). The data set was originally compiled by Kazius, McGuire, and Bursi (2005) and reprocessed by Riesen and Bunke (2008). We consider a subset of 100 molecules from the test data set uniformly distributed over both classes. We describe molecules by graphs in the usual way: atoms are represented by vertices labeled with the atom type of the corresponding atom and bonds between atoms are represented by edges labeled with the valence of the corresponding bonds. We used a 1-to-k binary encoding for representing atom types and valence of bonds, respectively.

5.2.3 GENERAL EXPERIMENTAL SETUP

In all experiments, we applied k-means and simple competitive learning for graphs to the aforementioned data sets. We used the following experimental setup:
Performance measures. We used the following measures to assess the performance of an algorithm on a data set: (1) error value of the cluster objective (see Section 4.2), (2) classification accuracy, and (3) silhouette index. The silhouette index is a cluster validation index taking values from $[-1,1]$. Higher values indicate a more compact and well separated cluster structure. For more details we refer to Theodoridis and Koutroumbas (2009).
Initialization of the clustering algorithms. The number k of centroids as shown in Table 3 was chosen by compromising a satisfactory classification accuracy against the silhouette index. To initialize both clustering algorithms, we used a modified version of the "furthest first" heuristic (Hochbaum and Shmoys, 1985). For each data set $\mathcal{S}$, the first centroid Y_1 is initialized to be a graph closest to the sample mean of $\mathcal{S}$. Subsequent centroids are initialized according to

$$Y_{i+1} = \arg\max_{X \in \mathcal{S}} \min_{Y \in \mathcal{Y}_i} D(X,Y),$$

data set	k	measure	km	cl
letter	30			
		error	11.6	11.1
		accuracy	0.86	0.90
		silhouette	0.38	0.40
grec	33			
		error	32.7	27.6
		accuracy	0.84	0.87
		silhouette	0.40	0.42
fingerprint	60			
		error	1.88	1.30
		accuracy	0.81	0.79
		silhouette	0.32	0.34
molecules	10			
		error	56.0	53.8
		accuracy	0.68	0.70
		silhouette	0.04	0.05

Table 3: Results of k-means (km) and simple competitive learning (cl) on four data sets.

where $\mathcal{Y}_i$ is the set of the first i centroids chosen so far.

Subgradient and graph distance calculations. For subgradient and graph distance calculations, we applied a depth first search algorithm on the letter data set and the graduated assignment algorithm (Gold and Rangarajan, 1996) on the grec, fingerprint, and molecule data set.

5.2.4 RESULTS

Table 3 summarizes the results. The first observation to be made is that simple competitive learning performs slightly better than k-means with respect to all three performance measures. This is in contrast to findings on standard k-means and simple competitive learning in vector spaces. The second observation is that both k-means algorithms yield satisfying classification accuracies on all data sets. This result shows that approximated subgradient methods can be applied to central clustering in the domain of graphs.

5.3 Clustering Protein Structures

In our last experiment, we compared the performance of k-means and simple competitive learning of graphs with hierarchical clustering applied on protein structures.

5.3.1 DATA: PROTEIN CONTACT MAPS

One common way to model the 3D structure of proteins are contact maps. A contact map is a graph $X = (V,E)$ with ordered vertex set. Vertices represent residues. Two vertices are connected by an edge (contact) if the spatial distance of the corresponding residues is below some prespecified threshold.

ID	domain	ID	domain	ID	domain	ID	domain
1	1b00A	11	4tmyB	21	2b3iA	31	1tri
2	1dbwA	12	1rn1A	22	2pcy	32	3ypiA
3	1nat	13	1rn1B	23	2plt	33	8timA
4	1ntr	14	1rn1C	24	1amk	34	1ydvA
5	1qmpA	15	1bawA	25	1aw2A	35	1b71A

Table 4: PDB domain names of the Skolnick test set and their assigned indexes (ID).

No	Style	Residues	Seq. Sim.	Proteins
1	alpha-beta	124	15-30%	1-14
2	beta	99	35-90%	15-23
3	alpha-beta	250	30-90%	24-34
4		170	7-70%	35-40

Table 5: Characteristic properties of the Skolnick test set as taken from Caprara and Lancia (2002). Shown are the fold style, mean number of residues, and the range of similarity obtained by sequence alignment of the protein domains.

We used the Skolnick test set consisting of 40 protein contact maps provided by Xie and Sahinidis (2007). Table 4 shows the PDB domain names of the test set and their assigned indexes.[8] Table 5 describes characteristic properties of the protein domains. The characteristic feature of the Skolnick data is that sequence similarity fails for correct categorization of the proteins as indicated by the fourth column (*Seq. Sim.*) of Table 5. This motivates structural alignment for solving the Skolnick clustering test.

5.3.2 ALGORITHMS

To cluster the contact maps, we minimized the cluster objective described in Section 4.3

$$F(M,\mathcal{Y},\mathcal{X}) = \frac{1}{m}\sum_{j=1}^{k}\sum_{i=1}^{m} m_{ij} D(X_i, Y_j),$$

using the extensions of k-means and simple competitive learning. The chosen distance measure D for both, the letter graphs and the contact maps, is the minimizer of the standard Euclidean metric.

8. The Protein Data Bank (PDB) is a repository for the 3D structures of proteins, nucleic acids, and other large biological molecules.

C	ID	Fold	Superfamily	Family
1	1-11	Flavodin-like	Che Y-like	Che Y-related
2	12-14	Microbial ribonucl.	Microbial ribonucl.	Fungi ribonucl.
3	15-23	Cuperdoxin-like	Cuperdoxins	Plastocyanim-like Plastoazurin-like
4	24-34	TIM-beta alpha-barrel	Triosephosphate isomerase (TIM)	Triosephosphate isomerase (TIM)
5	35-40	Ferritin-like	Ferritin-like	Ferritin

Table 6: Clusters of Skolnick proteins detected by competitive learning and k-means. Shown are the cluster memberships of the proteins via their indexes (ID) as assigned in Table 5. The clusters perfectly agree with the fold, family, and superfamily according to SCOP categories.

For letter graphs the underlying transformation set $\mathcal{T}$ is the set of all possible vertex permutations. In the case of contact maps, the set $\mathcal{T}$ is the subset of all partial vertex permutations that preserve the order of the vertices.

For subgradient and distance calculations, we used a combination of graduated assignment and dynamic programming (Jain and Lappe, 2007).

5.3.3 RESULTS

Competitive learning and k-means both correctly categorized the 40 proteins in 5 clusters according to the SCOP categories as shown in Table 6.[9] This result was also achieved by previous approaches based on hierarchical clustering using pairwise similarity matrices (Xie and Sahinidis, 2007; Caprara and Lancia, 2002; Caprara, Carr, Istrail, Lancia, and Walenz, 2004).

Competitive learning and k-means require less pairwise structural alignments than pairwise clustering. Pairwise clustering of 40 structures requires 780 structural alignments. In contrast, competitive learning required 120 and k-means 440 structural alignments. One problem of central clustering algorithms applied to contact maps is the increasing size of the cluster centers caused by the updating step. A solution to this problem is to restrict the vertices of a cluster center to those vertices that occur in at least one cluster member. In doing so, spurious vertices of former cluster members are removed.

The distinguishing feature of central clustering of structures is that we obtain prototypes for each cluster. According to Jain and Obermayer (2009), the sample mean is equivalent to the multiple alignment of proteins, which is like clustering an essential task in bioinformatics. Hence, central clustering of protein structures can solve two tasks simultaneously, categorizing the proteins and and multiple aligning cluster members, which is useful for protein structure classification, structure-based function prediction, and highlighting structurally conserved regions of functional significance.

9. The *Structural Classification of Proteins* (SCOP) database is a largely manual classification of protein structural domains based on similarities of their amino acid sequences and 3D structures.

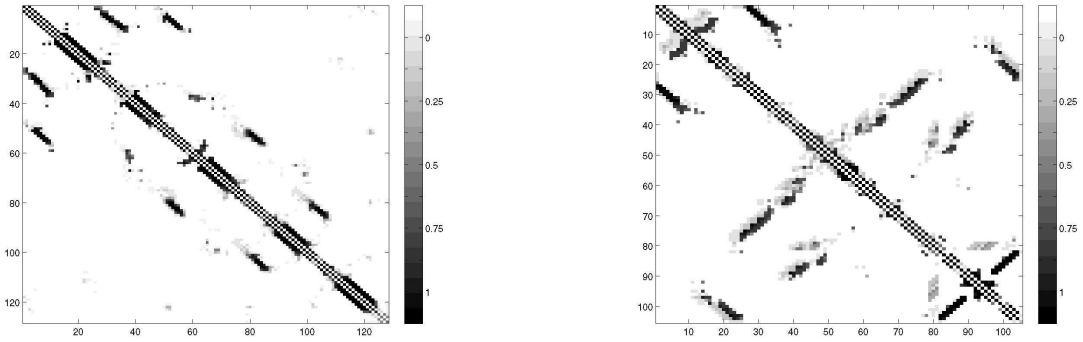

Figure 9: Shown are approximated sample means of the Che Y-like superfamily of cluster C1 (**left**) and the Cuperdoxins superfamily family of cluster C3 (**right**). Diagonal elements show the residues and off-diagonal elements the contacts. Darker shading refers to a higher relative frequency of occurrence of residues/contacts over all cluster members.

Figure 9 shows approximations of sample means of the two largest clusters computed by competitive learning.

6. Summary

In this contribution, we described a generic technique of how to generalize classical learning approaches and other problems from pattern recognition to structured domains. The proposed technique is based on the notion of $\mathcal{T}$-space. A $\mathcal{T}$-space is a quotient set of a metric vector space—the representation space—with all the vectors identified that represent the same structure. The equivalence classes of representation vectors are determined by the subgroup of homogeneous isometrics $\mathcal{T}$. This constructions turns out to be a convenient abstraction of combinatorial structures to formally adopt geometrical and analytical concepts from vector spaces.

The metric of the representation space $\mathcal{X}$ induces a metric on the $\mathcal{T}$-space. A norm on $\mathcal{X}$ induces a $\mathcal{T}$-norm on $\mathcal{X}_\mathcal{T}$. The $\mathcal{T}$-norm corresponds to the same geometric concept of length as the standard norm. Thus, different vector representations of the same structure have the same length. An inner product $\langle\cdot,\cdot\rangle$ on $\mathcal{X}$ induces the inner $\mathcal{T}$-product on $\mathcal{X}_\mathcal{T}$, which is not bilinear but has the same geometrical properties as $\langle\cdot,\cdot\rangle$. In other words, the Cauchy-Schwarz inequality is valid for structures. This result gives rise to a well-defined geometric concept of angle between structures.

The interplay of geometrical intuition, the algebraic group structure of the transformation set $\mathcal{T}$, and the link to the properties of a vector space via the membership function yields the well-defined notions of $\mathcal{T}$-differentiability and $\mathcal{T}$-gradient that generalize the standard definitions of differentiability and gradient of a smooth function at some point from a vector space. In particular, the $\mathcal{T}$-gradient of a $\mathcal{T}$-function at a $\mathcal{T}$-differentiable point is a well-defined structure pointing in direction of steepest ascent and satisfies the necessary condition of optimality. Therefore, we can apply local gradient information to minimize smooth $\mathcal{T}$-functions.

One application of the theory of $\mathcal{T}$-spaces are problems from structural pattern recognition. For selected problems, we presented continuous optimization problems, where the cost functions

defined on $\mathcal{T}$-spaces are locally Lipschitz. Locally Lipschitz functions are nonsmooth on a set of Lebesgue measure zero, but admit a generalized gradient at non-differentiable points. The field of nonsmooth optimization provides techniques like the subgradient method to minimize this class of nonsmooth functions.

As case studies, we considered the problem of computing a sample mean and central clustering in the domain of graphs. The cost functions are locally Lipschitz, but computation of a subgradient is computationally intractable. To cope with the computational complexity, we suggested an approximate subgradient method that chooses the opposite of a direction close to the generalized gradient as descent direction. We illustrated that the proposed method is capable to minimize the cost function of the case study. Even so the high computational complexity of deriving a subgradient demands a reevaluation of existing nonsmooth optimization methods and asks for devising algorithms that use approximations of the generalized gradient.

Appendix A. Introduction to $\mathcal{T}$-spaces

This section formally introduces $\mathcal{T}-spaces$ and presents proofs.

A.1 $\mathcal{T}$-spaces

Let $\mathcal{X} = \mathbb{R}^n$ be the n-dimensional Euclidean vector space, and let $\mathcal{T}$ be a subgroup of the group of all $n \times n$ permutation matrices. Then the binary operation

$$\cdot : \mathcal{T} \times \mathcal{X} \to \mathcal{X}, \quad (T,x) \mapsto Tx$$

is a group action of $\mathcal{T}$ on $\mathcal{X}$. For $x \in \mathcal{X}$, the *orbit* of x is denoted by

$$[x]_{\mathcal{T}} = \{Tx : T \in \mathcal{T}\}.$$

If no misunderstanding can occur, we write $[x]$ instead of $[x]_{\mathcal{T}}$.

A *$\mathcal{T}$-space* over $\mathcal{X}$ is the orbit space $\mathcal{X}_{\mathcal{T}} = \mathcal{X}/\mathcal{T}$ of all orbits of $x \in \mathcal{X}$ under the action of $\mathcal{T}$. We call $\mathcal{X}$ the *representation space* of $\mathcal{X}_{\mathcal{T}}$. By

$$\mu : \mathcal{X} \to \mathcal{X}_{\mathcal{T}}$$

we denote the *membership function* that sends vector representations to the structure they describe.

The following notations, definitions, and results are useful to simplify technicalities. We use capital letters $X, Y, Z, \ldots$ to denote the elements of $\mathcal{X}_{\mathcal{T}}$. Suppose that $X = \mu(x)$ for some $x \in \mathcal{X}$. Then we identify X with $[x]$ and make use of sloppy notations like, for example, $x \in X$ to denote $x \in [x]$.[10]

By $0_{\mathcal{T}}$ we denote the $\mathcal{T}$-zero of $\mathcal{X}_{\mathcal{T}}$. It is easy to show that $0_{\mathcal{T}}$ has only the zero element $0 \in \mathcal{X}$ as its unique representation vector.

Proposition 2 *Let $\mathcal{X}_{\mathcal{T}}$ be a $\mathcal{T}$-space over the metric vector space $\mathcal{X}$. Then $\mu^{-1}(0_{\mathcal{T}}) = [0] = \{0\}$.*

Proof Follows directly from the fact that each $T \in \mathcal{T}$ is homogeneous and injective. ■

A $\mathcal{T}$-space $\mathcal{X}_{\mathcal{T}}$ has, in fact, a $\mathcal{T}$-zero element, but it is unclear how to define an addition $+$ on $\mathcal{X}_{\mathcal{T}}$ such that $\mathcal{X}_{\mathcal{T}}$ together with $+$ forms a group. The absence of an additive group structure is one of the

10. The notation is sloppy, because X is an element in $\mathcal{X}_{\mathcal{T}}$ and not a set, whereas $[x]$ is a set of equivalent elements from $\mathcal{X}$.

major reasons why analytical tools for structured data are extremely rare compared to the plethora of powerful tools developed for feature vectors residing in some Banach space. To mitigate this drawback of $\mathcal{T}$-spaces $\mathcal{X}_\mathcal{T}$, we exploit the vector space axioms of $\mathcal{X}$ via the membership function μ.

We say a membership function $\mu : \mathcal{X} \to \mathcal{X}_\mathcal{T}$ is *$\mathcal{T}$-linear* if

$$\text{(TL1)} \quad [x+y] \subseteq [x] \oplus [y] = \{x' + y' : x' \in [x], y' \in [y]\},$$

$$\text{(TL2)} \quad [\lambda x] = \lambda [x] = \{\lambda x' : x' \in [x]\}$$

for all $x, y \in \mathcal{X}$, and for all $\lambda \in \mathbb{R}$. Note that for (TL1) we have a subset relation and for (TL2) equality. This definition has a sound notation but appears to be independent on μ at first glance. Since we identify the orbits $[x]$ in $\mathcal{X}$ with the elements $\mu(x)$ of $\mathcal{X}_\mathcal{T}$, we can rewrite (TL1) and (TL2) by slight abuse of notation

$$\begin{aligned} \mu(x+y) &\subseteq \mu(x) \oplus \mu(y), \\ \mu(\lambda x) &= \lambda \mu(x). \end{aligned}$$

Membership functions that are $\mathcal{T}$-linear preserve enough structure to transfer some geometrical and analytical concepts from $\mathcal{X}$ to $\mathcal{X}_\mathcal{T}$.

In contrast to the standard definition of linearity, we only require a subset relation in (TL1) rather than equality. The proof of Prop. 3 explains this issue.

Proposition 3 *Let $\mathcal{X}_\mathcal{T}$ be a $\mathcal{T}$-space over the Euclidean space $\mathcal{X}$.Then the membership function $\mu : \mathcal{X} \to \mathcal{X}_\mathcal{T}$ is T-linear.*

Proof Let $z = x + y$, and let $z' \in [x+y]$. Then there is an element $T \in \mathcal{T}$ with $z' = Tz$. Since T is linear by assumption, we obtain

$$z' = Tz = T(x+y) = Tx + Ty \in [x] \oplus [y].$$

This proves (TL1). The proof of (TL2) is similar. ■

For an intuitive understanding it is sometimes more convenient to use the following notation

$$\begin{aligned} \lambda X &= \mu(\lambda x), \\ X_x + Y_y &= \mu(x+y). \end{aligned}$$

It is important to note that the '+' symbol in $X_x + Y_y$ does not refer to some kind of addition in $\mathcal{X}_\mathcal{T}$. The notation $X_x + Y_y$ is simply an alternative and for our purposes more convenient way to refer to the element $\mu(x+y) \in \mathcal{X}_\mathcal{T}$.

We conclude this section with some further useful technical notations and results. Let $\mathcal{X}^n$ be the n-ary cartesian product of a metric vector space $\mathcal{X}$. Any real-valued function $f : \mathcal{X}^n \to \mathbb{R}$ induces functions

$$\begin{aligned} F^* &: \mathcal{X}_\mathcal{T}^n \to \mathbb{R}, \quad (X_1, \ldots, X_n) \mapsto \max\{f(x_1, \ldots, x_n) : x_i \in X_i\}, \\ F_* &: \mathcal{X}_\mathcal{T}^n \to \mathbb{R}, \quad (X_1, \ldots, X_n) \mapsto \min\{f(x_1, \ldots, x_n) : x_i \in X_i\}. \end{aligned}$$

Since $\mathcal{T}$ is finite, the orbits $[x]$ of x are finite. Hence, F^* and F_* assume an extremal value. We call F^* *maximizer* and F_* *minimizer* of f on $\mathcal{X}_\mathcal{T}^n$. Let F be either a maximizer or minimizer of f. The *support*

$$\operatorname{supp}(F | X_1, \ldots, X_n)$$

of F at $(X_1,\ldots,X_n) \in \mathcal{X}_{\mathcal{T}}^n$ is the set of all elements $(x_1,\ldots,x_n) \in \prod_{i=1}^n X_i$ with $f(x_1\ldots,x_n) = F(X_1,\ldots,X_n)$. The next results shows a useful property of the support.

Proposition 4 *Let F be the minimizer or maximizer of a function $f : \mathcal{X}^n \to \mathbb{R}$. Let $X_1,\ldots,X_n \in \mathcal{X}_{\mathcal{T}}$. Then for each $x_i \in X_i$ there are a $x_j \in X_j$ for all $j \in \{1,\ldots,n\} \setminus \{i\}$ such that $(x_1,\ldots,x_n) \in \operatorname{supp}(F|X_1,\ldots,X_n)$.*

Proof Let $x_i \in X_i$. Suppose that $(x_1^*,\ldots,x_n^*) \in \operatorname{supp}(F|X_1,\ldots,X_n)$. Then there is a transformation $T \in \mathcal{T}$ with $Tx_i = x_i^*$. Since $\mathcal{T}$ is a group, the inverse T^{-1} exists. Hence, $x_j = T^{-1}x_j^*$ is an element of X_j for all $j \neq i$. We have

$$F(X_1,\ldots,X_n) = f(x_1^*,\ldots,x_n^*) = f(Tx_1,\ldots,Tx_n) = f(x_1,\ldots,x_n).$$

This shows the assertion. ■

A.2 Metric $\mathcal{T}$-Spaces

Let $\mathcal{X}_{\mathcal{T}}$ be a $\mathcal{T}$-space over the metric vector space $(\mathcal{X},d)$. The minimizer

$$D_* : \mathcal{X}_{\mathcal{T}} \times \mathcal{X}_{\mathcal{T}} \to \mathbb{R}, \quad (X,Y) \mapsto \min\{d(x,y) : x \in X, y \in Y\}.$$

of the metric d is a distance measure on $\mathcal{X}_{\mathcal{T}}$. Theorem 5 shows that D_* is a metric.

Theorem 5 *Let $\mathcal{X}_{\mathcal{T}}$ be a $\mathcal{T}$-space over the metric space $(\mathcal{X},d)$. Then the minimizer D_* of d is a metric on $\mathcal{X}_{\mathcal{T}}$.*

Proof Let $X,Y,Z \in \mathcal{X}_{\mathcal{T}}$.

1. We show $D_*(X,Y) = 0 \Leftrightarrow X = Y$. Let $x \in X$ be a representation vector of X. According to Prop. 4 there is a $y \in Y$ such that $(x,y) \in \operatorname{supp}(D_*|x,y)$. We have

$$\begin{aligned} D_*(X,Y) = 0 &\Leftrightarrow \forall x \in X\, \exists y \in Y\; d(x,y) = 0 \\ &\Leftrightarrow \forall x \in X\, \exists y \in Y\; x = y \\ &\Leftrightarrow X = Y. \end{aligned}$$

2. Symmetry $D_*(X,Y) = D_*(Y,X)$ follows from symmetry of d.

3. We show $D_*(X,Z) \leq D_*(X,Y) + D_*(Y,Z)$. Let $(x,y) \in \operatorname{supp}(D_*|X,Y)$. There is a $z \in Z$ such that $(y,z) \in \operatorname{supp}(D_*|Y,Z)$. Then

$$\begin{aligned} D_*(X,Y) + D_*(Y,Z) &= d(x,y) + d(y,z) \\ &\geq d(x,z) \\ &\geq \min\{d(x,z) : x \in X, z \in Z\} \\ &= D_*(X,Z). \end{aligned}$$

■

Given the assumptions of Theorem 5, we call $(\mathcal{X}_{\mathcal{T}},D_*)$ *metric $\mathcal{T}$-space* over $(\mathcal{X},d)$. A metric space $\mathcal{X}$ is complete if every Cauchy sequence of points in $\mathcal{X}$ converges to a point from $\mathcal{X}$. The next result states that $\mathcal{X}_{\mathcal{T}}$ is complete if $\mathcal{X}$ is complete.

Theorem 6 *Any $\mathcal{T}$-space over a complete metric vector space is a complete metric space.*

Proof Let $\mathcal{X}_\mathcal{T}$ be a $\mathcal{T}$-space over the complete metric space $(\mathcal{X}, d)$. According to Theorem 5, $\mathcal{X}_\mathcal{T}$ is a metric space with metric D_*. To show that $\mathcal{X}_\mathcal{T}$ is complete, consider an arbitrary Cauchy sequence $(X_i)_{i\in\mathbb{N}}$ in $\mathcal{X}_\mathcal{T}$. We construct a Cauchy sequence (x_k) such that $(\mu(x_k))$ is a subsequence of (X_i). For any $k > 0$ there is a n_k such that $D_*(X_i, X_j) < 1/2^k$ for all $i, j > n_k$. For each k, there are $x_k \in X_{n_k}$ and $x_{k+1} \in X_{n_{k+1}}$ with $d(x_k, x_{k+1}) \leq 1/2^k$. By the triangle inequality, we have

$$d(x_i, x_j) \leq \sum_{k=i}^{j-1} d(x_k, x_{k+1}) \leq \frac{1}{2^{i-1}}$$

for any i, j with $i < j$. Hence, (x_k) is a Cauchy sequence in $\mathcal{X}$ and $(\mu(x_k))$ a subsequence of (X_i). Since $\mathcal{X}$ is complete, (x_k) converges to a limit point $x \in \mathcal{X}$. By continuity of μ, we have $\lim_{k\to\infty} \mu(x_k) = \mu(x)$, where $\mu(x) \in \mathcal{X}_\mathcal{T}$. Thus, the whole sequence (X_i) converges to $\mu(x)$. This shows that $\mathcal{X}_\mathcal{T}$ is complete. ■

A.3 $\mathcal{T}$-Spaces over Normed Vector Spaces

Let $\mathcal{X}_\mathcal{T}$ be a $\mathcal{T}$-space over the normed vector space $(\mathcal{X}, \|\cdot\|)$. As a normed vector space, $\mathcal{X}$ is a metric space with metric $d(x, y) = \|x - y\|$ for all $x, y \in \mathcal{X}$. For any $T \in \mathcal{T}$, we have

$$\|Tx\| = \|Tx - 0\| = \|Tx - T0\| = \|x - 0\| = \|x\|.$$

Hence, the minimizer $\|\cdot\|_*$ and maximizer $\|\cdot\|^*$ of $\|\cdot\|$ coincide, that is

$$\|X\|_* = \|X\|^* = \|x\| \tag{2}$$

for all $X \in \mathcal{X}_\mathcal{T}$ and for all $x \in X$.

We call the minimizer $\|\cdot\|_*$ the *$\mathcal{T}$-norm* induced by the norm $\|\cdot\|$. Note that a $\mathcal{T}$-norm is *not* a norm, because a $\mathcal{T}$-space has no well defined addition. But we can show that a $\mathcal{T}$-norm has norm-like properties. We use the notations λX for $\mu(\lambda X)$ and $X_x + Y_y$ for $\mu(x + y)$ as introduced in Section 3.2, p. 2696.

Proposition 7 *Let $(\mathcal{X}_\mathcal{T}, \|\cdot\|_*)$ be a $\mathcal{T}$-space over the normed space $(\mathcal{X}, \|\cdot\|)$. For all $X, Y \in \mathcal{X}_\mathcal{T}$, we have*

1. $\|X\|_* = 0$ *if, and only if,* $X = 0_\mathcal{T}$.
2. $\|\lambda X\|_* = |\lambda| \, \|X\|_*$ *for all* $\lambda \in \mathbb{R}$.
3. $\|X_x + Y_y\|_* \leq \|X\|_* + \|Y\|_*$ *for all* $x \in X$, $y \in Y$.

Proof Follows directly from first applying Equation (2) and then using the properties of the norm $\|\cdot\|$ defined on $\mathcal{X}$. ■

A.4 $\mathcal{T}$-Spaces over Inner Product Spaces

Let $\mathcal{X}_\mathcal{T}$ be a $\mathcal{T}$-space over the inner product space $(\mathcal{X}, \langle\cdot,\cdot\rangle)$, and let

$$\langle\cdot,\cdot\rangle^* : \mathcal{X}_\mathcal{T} \times \mathcal{X}_\mathcal{T} \to \mathbb{R}, \quad (X,Y) \mapsto \max\{\langle x,y\rangle : x \in X, y \in Y\}$$

be the maximizer of the inner product $\langle\cdot,\cdot\rangle$.

We call $\langle\cdot,\cdot\rangle^*$ *inner $\mathcal{T}$-product* induced by the inner product $\langle\cdot,\cdot\rangle$. The inner $\mathcal{T}$-product is *not* an inner product, because the maximum-operator in the definition of $\langle\cdot,\cdot\rangle^*$ does not preserve the bilinearity property of an inner product. But we shall show later that an inner $\mathcal{T}$-product satisfies some weaker properties of an inner product.

Any inner product space $\mathcal{X}$ is a normed space with norm $\|x\| = \sqrt{\langle x,x\rangle}$. The norm $\|\cdot\|$ on $\mathcal{X}$ in turn gives rise to the $\mathcal{T}$-norm $\|\cdot\|_*$ on $\mathcal{X}_\mathcal{T}$. The next result shows that a $\mathcal{T}$-norm is related to an inner $\mathcal{T}$-product in the same way as a norm to an inner product.

Proposition 8 *Let $(\mathcal{X}_\mathcal{T}, \langle\cdot,\cdot\rangle^*)$ be a $\mathcal{T}$-space over the inner product space $(\mathcal{X}, \langle\cdot,\cdot\rangle)$, and let $X \in \mathcal{X}_\mathcal{T}$. Then*

1. $\langle X,X\rangle^* = \langle x,x\rangle$ *for all* $x \in X$.
2. $\|X\|_* = \sqrt{\langle X,X\rangle^*}$.

Proof

1. X is the orbit of x under the group action $\mathcal{T}$. The assertion follows from the fact that each transformation T of $\mathcal{T}$ satisfies

   $$\langle Tx,Tx\rangle = \|Tx\|^2 = \|x\|^2 = \langle x,x\rangle$$

   for all $x \in \mathcal{X}$.

2. Follows from the first part by taking the square root.

■

Using Prop. 8 the following operations to construct $\|\cdot\|_*$ commute

$$\begin{array}{ccc} (\mathcal{X}, \langle\cdot,\cdot\rangle) & \xrightarrow{\langle\cdot,\cdot\rangle^*} & (\mathcal{X}_\mathcal{T}, \langle\cdot,\cdot\rangle^*) \\ {\scriptstyle \|\cdot\|=\sqrt{\langle\cdot,\cdot\rangle}}\downarrow & & \downarrow{\scriptstyle \|\cdot\|_*=\sqrt{\langle\cdot,\cdot\rangle^*}} \\ (\mathcal{X}, \|\cdot\|) & \xrightarrow[\|\cdot\|_*]{} & (\mathcal{X}_\mathcal{T}, \|\cdot\|_*)\,. \end{array}$$

Next we show that an inner $\mathcal{T}$-product satisfies some weaker properties related to an inner product.

Proposition 9 *Let $X,Y,Z \in \mathcal{X}_\mathcal{T}$, and let $x \in X$, $y \in Y$. Then*

1. $\langle X,X\rangle^* \geq 0$ *with* $\langle X,X\rangle^* = 0 \Leftrightarrow X = 0_\mathcal{T}$ (*positive definite*)
2. $\langle X,Y\rangle^* = \langle Y,X\rangle^*$ (*symmetric*)

3. $\langle \lambda X, Y \rangle^* = \lambda \langle X, Y \rangle^*$ *for* $\lambda \geq 0$ (*positive homogeneous*)

4. $\langle X_x + Y_y, Z \rangle^* \leq \langle X, Z \rangle^* + \langle Y, Z \rangle^*$ (*sublinear*)

Proof

1. Follows from Prop. 8 and the positive definiteness of $\langle \cdot, \cdot \rangle$.

2. Follows from the symmetry of $\langle \cdot, \cdot \rangle$.

3. Let $\lambda \geq 0$. Then

$$\begin{aligned} \langle \lambda X, Y \rangle^* &= \max \{ \langle \lambda x, y \rangle : x \in X, y \in Y \} \\ &= \lambda \max \{ \langle x, y \rangle : x \in X, y \in Y \} \\ &= \lambda \langle X, Y \rangle^* . \end{aligned}$$

4. Let $W = X_x + Y_y$, and let $(w,z) \in \operatorname{supp}(\langle \cdot, \cdot \rangle^* | W, Z)$. Since μ is $\mathcal{T}$-linear by Prop. 3, we have $W \subseteq X \oplus Y$. Hence, there are $x \in X$ and $y \in Y$ such that $w = x + y$. Thus,

$$\langle W, Z \rangle = \langle w, z \rangle = \langle x + y, z \rangle = \langle x, z \rangle + \langle y, z \rangle .$$

From $\langle x, z \rangle \leq \langle X, Z \rangle^*$ and $\langle y, z \rangle \leq \langle Y, Z \rangle^*$ follows the assertion.

■

From the proof of Prop. 9 follows that $\mathcal{T}$-linearity of the membership function partially preserves the structure of $\mathcal{X}$ such that the inner $\mathcal{T}$-product is a positive definite, symmetric, and sublinear in both arguments.

Any inner product space $(\mathcal{X}, \langle \cdot, \cdot \rangle)$ is a metric space with metric $d(x,y) = \|x - y\|$. The metric d induces a metric D_* on $\mathcal{X}_\mathcal{T}$. As for the $\mathcal{T}$-norm, we want to express D_* in terms of $\langle \cdot, \cdot \rangle^*$.

Proposition 10 *Let* $(\mathcal{X}_\mathcal{T}, \langle \cdot, \cdot \rangle^*)$ *be a* $\mathcal{T}$*-space over the inner product space* $(\mathcal{X}, \langle \cdot, \cdot \rangle)$. *Then for all* $X, Y \in \mathcal{X}_\mathcal{T}$, *we have*

$$D_*(X,Y)^2 = \|X\|_*^2 - 2 \langle X, Y \rangle^* + \|Y\|_*^2 .$$

Proof We have

$$\begin{aligned} D_*(X,Y)^2 &= \min \left\{ \|x - y\|^2 : x \in X, y \in Y \right\} \\ &= \min \{ \langle x - y, x - y \rangle : x \in X, y \in Y \} \\ &= \min \left\{ \|x\|^2 - 2 \langle x, y \rangle + \|y\|^2 : x \in X, y \in Y \right\} \\ &= \|x\|^2 - 2 \max \{ \langle x, y \rangle : x \in X, y \in Y \} + \|y\|^2 \\ &= \|X\|_*^2 - 2 \langle X, Y \rangle^* + \|Y\|_*^2 . \end{aligned}$$

■

Next, we extend the Cauchy-Schwarz inequality.

Theorem 11 *Let $(\mathcal{X}_\mathcal{T}, \langle\cdot,\cdot\rangle^*)$ be a $\mathcal{T}$-space over the inner product space $(\mathcal{X}, \langle\cdot,\cdot\rangle)$. Then*

$$\left|\langle X,Y\rangle^*\right| \leq \|X\|_* \|Y\|_*.$$

for all $X,Y \in \mathcal{X}_\mathcal{T}$

Proof Let $(x,y) \in \operatorname{supp}(\langle\cdot,\cdot\rangle^* | X,Y)$. Applying the conventional Cauchy-Schwarz inequality for vectors and using Eq. (2) yields

$$\left|\langle X,Y\rangle^*\right| = |\langle x,y\rangle| \leq \|x\| \|y\| = \|X\|_* \|Y\|_*.$$

■

Using Theorem 11, we can show that the angle of structures has a geometrical meaning. For two nonzero structures X and Y, the angle $\theta \in [0,\pi]$ between X and Y is defined (indirectly in terms of its cosine) by

$$\cos\theta = \frac{\langle X,Y\rangle^*}{\|X\|_* \|Y\|_*}.$$

Theorem 11 implies that

$$-1 \leq \frac{\langle X,Y\rangle^*}{\|X\|_* \|Y\|_*} \leq 1$$

and thus assures that this angle is well-defined. It is worthy to mention that $\langle X,Y\rangle^*$ has the same geometrical properties as an inner product, although it does not satisfy the algebraic properties of an inner product. Having the concept of an angle for structures, we can define structural orthogonality in the usual way. Two nonzero structures X and Y, written as $X \perp Y$, are *structurally orthogonal if* $\langle X,Y\rangle^* = 0$. Thus, Theorem 11 constitutes the starting point of a geometry of $\mathcal{T}$-spaces, which we do not further expand.

Appendix B. $\mathcal{T}$-Mappings

This section studies differential and the local Lipschitz property of mappings on $\mathcal{X}_\mathcal{T}$. The key result of this section is that the concept of gradient and its generalizations from nonsmooth analysis can be transferred in a well-defined manner to mappings on $\mathcal{T}$-spaces. Basic definitions and results on nonsmooth analysis of locally Lipschitz mappings are given in Appendix C.

B.1 Properties of $\mathcal{T}$-Mappings

Let $\mathcal{X}_\mathcal{T}$ be a $\mathcal{T}$-space over $\mathcal{X}$ and let $\mathcal{Y}$ be a set. A *$\mathcal{T}$-mapping* is a mapping of the form $F : \mathcal{X}_\mathcal{T} \to \mathcal{Y}$. If $\mathcal{Y}$ is a subset of $\mathbb{R}$, we also call F a *$\mathcal{T}$-function*.

Instead of studying a $\mathcal{T}$-mapping F directly, it is more convenient to consider its *representation mapping* defined by

$$f : \mathcal{X} \to \mathcal{Y}, \quad x \mapsto F \circ \mu(x).$$

Thus, we have to show that analyzing $\mathcal{T}$-mappings is equivalent to analyzing their representation mappings. For this we introduce the notion of $\mathcal{T}$-invariant mapping. A *$\mathcal{T}$-invariant mapping* is a mapping $f : \mathcal{X} \to \mathcal{Y}$ that is constant on the orbits $[x]_\mathcal{T}$ for all $x \in \mathcal{X}$. Obviously, representation mappings are $\mathcal{T}$-invariant. In addition, we have the following universal properties:[11]

11. A universal property can be regarded as some abstract property which requires the existence of a unique mapping under certain conditions.

(UP1) Each mapping $F : \mathcal{X}_\mathcal{T} \to \mathcal{Y}$ has a unique representation $f : \mathcal{X} \to \mathcal{Y}$ with $f = F \circ \mu$.

(UP2) Each $\mathcal{T}$-invariant mapping $f : \mathcal{X} \to \mathcal{Y}$ can be lifted in the obvious way to a unique mapping $F : \mathcal{X}_\mathcal{T} \to \mathcal{Y}$ with $f = F \circ \mu$.

Hence, by (UP1) and (UP2) we may safely identify $\mathcal{T}$-mappings with their representation mappings.

Next, we show that $\mathcal{T}$-spaces over complete metric vector spaces are universal quotients with respect to continuity, the Lipschitz property, and the local Lipschitz property. For this, we need some additional results.

Proposition 12 *Let $(\mathcal{X}_\mathcal{T}, D_*)$ be a metric $\mathcal{T}$-space over the metric space $(\mathcal{X}, d)$. Then the membership function $\mu : \mathcal{X} \to \mathcal{X}_\mathcal{T}$ is a continuous map.*

Proof Let $(x_i)_{i\in\mathbb{N}}$ be a sequence in $\mathcal{X}$ which converges to $x \in \mathcal{X}$. Let (X_i) be the sequence in $\mathcal{X}_\mathcal{T}$ with $X_i = \mu(x_i)$ for all $i \in \mathbb{N}$, and let $X = \mu(x)$. For any $\varepsilon > 0$ there is a number $n = n(\varepsilon)$ with $D_*(X_i, X) \leq d(x_i, x) < \varepsilon$ for all $i > n$. Hence, μ is continuous. ■

A mapping $f : \mathcal{X} \to \mathcal{Y}$ between topological spaces is open if for any open set $\mathcal{U} \in \mathcal{X}$, the image $f(\mathcal{U})$ is open in $\mathcal{Y}$.

Proposition 13 *Let $(\mathcal{X}_\mathcal{T}, D_*)$ be a metric $\mathcal{T}$-space over the metric vector space $(\mathcal{X}, d)$. Then $\mu : \mathcal{X} \to \mathcal{X}_\mathcal{T}$ is an open mapping.*

Proof It is sufficient to show that for any $x \in \mathcal{X}$ and any open neighborhood $\mathcal{U}$ of x there is an open neighborhood $\mathcal{V}_\mathcal{T}$ of $X = \mu(x)$ such that $\mathcal{V}_\mathcal{T} \subseteq \mu(\mathcal{U})$.

Let $x \in \mathcal{X}$, and let $\mathcal{U} \subseteq \mathcal{X}$ be an open set with $x \in \mathcal{U}$. Then there is $\varepsilon > 0$ such that the open neighborhood $\mathcal{N}(x, \varepsilon)$ is contained in $\mathcal{U}$. Let $\mathcal{U}_\mathcal{T} = \mu(U)$ and $\mathcal{V}_\mathcal{T} = \mu(\mathcal{N}(x, \varepsilon))$. Clearly, $X = \mu(x) \in \mathcal{V}_\mathcal{T} \subseteq \mathcal{U}_\mathcal{T}$. We show that $\mathcal{V}_\mathcal{T}$ is open. From $D_*(X, \mu(y)) \leq d(x, y) < \varepsilon$ for all $y \in \mathcal{N}(x, \varepsilon)$ follows $\mathcal{V}_\mathcal{T} \subseteq \mathcal{N}_\mathcal{T}(X, \varepsilon)$. Now let $Y \in \mathcal{N}_\mathcal{T}(X, \varepsilon)$. For x, we can find a a $y \in \mathcal{X}$ with $D_*(X, Y) = d(x, y) < \varepsilon$ by Prop. 4. Hence, $y \in \mathcal{N}(x, \varepsilon)$. This proves that $\mathcal{N}_\mathcal{T}(X, \varepsilon) = \mathcal{V}_\mathcal{T} \subseteq \mathcal{U}_\mathcal{T}$. ■

The next result shows the aforementioned universal property of $\mathcal{X}_\mathcal{T}$ with respect to continuity, the Lipschitz property, and the local Lipschitz property.

Proposition 14 *Let $\mathcal{X}, \mathcal{Y}$ be complete metric vector spaces, and let $\mathcal{X}_\mathcal{T}$ be a metric $\mathcal{T}$-space over X. Suppose that $f : \mathcal{X} \to \mathcal{Y}$ is a $\mathcal{T}$-invariant mapping. If f is continuous (Lipschitz, locally Lipschitz), then f lifts to a unique continuous (Lipschitz, locally Lipschitz) mapping $F : \mathcal{X}_\mathcal{T} \to \mathcal{Y}$ with $f(x) = F(\mu(x))$ for all $x \in \mathcal{X}$.*

Proof By (UP2), the existence of such a $\mathcal{T}$-mapping F implies uniqueness. Thus, it remains to show that F preserves continuity and both Lipschitz properties. In the following let $d_\mathcal{X}$ and $d_\mathcal{Y}$ denote the metric of $\mathcal{X}$ and $\mathcal{Y}$, resp., and let D_* be the metric of $\mathcal{X}_\mathcal{T}$ induced by $d_\mathcal{X}$.

Continuity. Let $\mathcal{U} \subseteq \mathcal{Y}$ open. Then $\mathcal{V} = f^{-1}(\mathcal{U})$ is open in $\mathcal{X}$, because f is continuous. From Prop. 13 follows that $\mathcal{V}_\mathcal{T} = \mu(\mathcal{V})$ is open in $\mathcal{X}_\mathcal{T}$. The assumption follows from the fact $\mathcal{V}_\mathcal{T} = F^{-1}(\mathcal{U})$.

Lipschitz property. Suppose there is a $L \geq 0$ such that

$$d_\mathcal{Y}(f(x), f(y)) \leq L \cdot d_\mathcal{X}(x, y)$$

for all $x,y \in \mathcal{X}$. Let $X,Y \in \mathcal{X}_{\mathcal{T}}$. For $(x,y) \in \operatorname{supp}(D_*|X,Y)$ we have

$$d_{\mathcal{Y}}(F(X),F(Y)) = d_{\mathcal{Y}}(f(x),f(y)) \leq L \cdot d_{\mathcal{X}}(x,y) = L \cdot D_*(X,Y).$$

Since X and Y were chosen arbitrarily, F is Lipschitz.
Local Lipschitz property. Let $X_0 \in \mathcal{X}_{\mathcal{T}}$, and let $x_0 \in X$. Since f is locally Lipschitz at x_0, there is a $L \geq 0$ such that

$$d_{\mathcal{Y}}(f(x),f(y)) \leq L \cdot d_{\mathcal{X}}(x,y)$$

for all x,y from some neighborhood $\mathcal{U} = \mathcal{N}(x_0,\varepsilon)$ in $\mathcal{X}$. Since $\mu : \mathcal{X} \to \mathcal{X}_{\mathcal{T}}$ is an open mapping, there is an open neighborhood $\mathcal{V}_{\mathcal{T}}$ of X_0 with $\mathcal{V}_{\mathcal{T}} \subseteq \mu(\mathcal{U})$. Let $X,Y \in \mathcal{V}_{\mathcal{T}}$ arbitrary. We choose $x,y,y' \in \mu^{-1}(\mathcal{V}_{\mathcal{T}}) \subseteq \mathcal{U}$ with $\mu(x) = X, \mu(y) = \mu(y') = Y$, and $(x,y) \in \operatorname{supp}(D_*|X,Y)$. From $x,y' \in \mathcal{U}$ follows $d_{\mathcal{X}}(x,y') < \varepsilon$ and from $(x,y) \in \operatorname{supp}(D_*|X,Y)$ follows $D_*(X,Y) = d_{\mathcal{X}}(x,y)$. Combining both relations and using that D_* is a minimizer of $d_{\mathcal{X}}$ yields

$$D_*(X,Y) = d_{\mathcal{X}}(x,y) \leq d_{\mathcal{X}}(x,y') < \varepsilon.$$

Hence, we have

$$d_{\mathcal{Y}}(F(X),F(Y)) = d_{\mathcal{Y}}(f(x),f(y)) \leq L \cdot d_{\mathcal{X}}(x,y) = L \cdot D_*(X,Y).$$

Since $X,Y \in \mathcal{V}_{\mathcal{T}}$ were chosen arbitrarily, F is locally Lipschitz at X_0. ■

Now we want to study differential properties of $\mathcal{T}$-mappings via their representation mappings. Let $\mathcal{X}_{\mathcal{T}}$ be a $\mathcal{T}$-space over the Euclidean space $(\mathcal{X},\|\cdot\|)$ and let $\mathcal{Y}$ be another Euclidean space. Suppose that $f : \mathcal{X} \to \mathcal{Y}$ is a $\mathcal{T}$-mapping, which is differentiable at $\bar{x} \in \mathcal{X}$. By

$$Df(\bar{x}) : \mathcal{X} \to \mathcal{Y}, \quad x \mapsto Df(\bar{x})(x)$$

we denote the derivative of f at $\bar{x}$.

Theorem 15 *Let $\mathcal{X}$ and $\mathcal{Y}$ be Euclidean spaces, and let $\mathcal{X}_{\mathcal{T}}$ be a $\mathcal{T}$-space over $\mathcal{X}$. Suppose that $f : \mathcal{X} \to \mathcal{Y}$ is a $\mathcal{T}$-mapping, which is differentiable at $\bar{x} \in \mathcal{X}$. Then f is differentiable at all points $x \in [\bar{x}]$. In addition, we have*

$$Df(T\bar{x}) = Df(\bar{x}) \circ T^{-1}$$

for all $T \in \mathcal{T}$.

Proof By $\|\cdot\|_{\mathcal{X}}$ and $\|\cdot\|_{\mathcal{Y}}$ we denote the norm defined on $\mathcal{X}$ and $\mathcal{Y}$, respectively. Let $x \in [\bar{x}]$. We show that f is differentiable in x. Let $T \in \mathcal{T}$ with $T\bar{x} = x$. For $h \neq 0$, we define the mapping

$$\begin{aligned} r(h) &= \frac{\left\| f(x+h) - f(x) - Df(\bar{x})\left(T^{-1}h\right)\right\|_{\mathcal{Y}}}{\|h\|_{\mathcal{X}}} \\ &= \frac{\left\| f(T\bar{x}+TT^{-1}h) - f(T\bar{x}) - Df(\bar{x})\left(T^{-1}h\right)\right\|_{\mathcal{Y}}}{\|TT^{-1}h\|_{\mathcal{X}}}. \end{aligned}$$

We set $h' = T^{-1}h$ and obtain

$$\begin{aligned} r(h) &= \frac{\|f(T\bar{x}+Th') - f(T\bar{x}) - Df(\bar{x})(h')\|_{\mathcal{Y}}}{\|Th'\|_{\mathcal{X}}} \\ &= \frac{\|f(T(\bar{x}+h')) - f(T\bar{x}) - Df(\bar{x})(h')\|_{\mathcal{Y}}}{\|Th'\|_{\mathcal{X}}}. \end{aligned}$$

Since f is $\mathcal{T}$-invariant, we have $f(T(\bar{x}+h')) = f(\bar{x}+h')$ and $f(T\bar{x}) = f(\bar{x})$. In addition, we have $\|Th'\| = \|h'\|$, because T is an isometry. Thus,

$$r(h) = \frac{\|f(\bar{x}+h') - f(\bar{x}) - Df(\bar{x})(h')\|_{\mathcal{Y}}}{\|h'\|_{\mathcal{X}}}.$$

Since f is differentiable in $\bar{x}$, we have

$$\lim_{h\to 0} r(h) = \lim_{h'\to 0} r(h) = 0.$$

Hence, f is differentiable at x with derivative $Df(x) = Df(T\bar{x}) = Df(\bar{x}) \circ T^{-1}$. ■

A $\mathcal{T}$-mapping $F : \mathcal{X}_{\mathcal{T}} \to \mathcal{Y}$ is said to be *$\mathcal{T}$-differentiable* at $\bar{X} \in \mathcal{X}_{\mathcal{T}}$ if its representation function is differentiable at an arbitrary vector representation of $\bar{X}$. From Theorem 15 follows that differentiability of f at an arbitrary vector representation of $\bar{X}$ implies differentiability at all vector representations of $\bar{X}$. Hence, $\mathcal{T}$-differentiability at $\bar{X} \in \mathcal{X}_{\mathcal{T}}$ is independent from the particular vector representation of $\bar{X}$ and therefore well-defined.

B.2 $\mathcal{T}$-Differentiable Functions

In this section, we study differential properties of $\mathcal{T}$-functions of the form $F : \mathcal{X}_{\mathcal{T}} \to \mathbb{R}$.

Let $f : \mathcal{X} \to \mathbb{R}$ be the representation function of F. Suppose that f is differentiable at $x \in \mathcal{X}$ with gradient $\nabla f(\bar{x})$. Then, by Theorem 15, the $\mathcal{T}$-function F is $\mathcal{T}$-differentiable at $\bar{X} = \mu(\bar{x})$. We call the structure

$$\nabla F(\bar{X}) = \mu(\nabla f(\bar{x})).$$

$\mathcal{T}$-gradient of F at $\bar{X}$. We show that the $\mathcal{T}$-gradient is well-defined, that is independent from the particular choice of vector representation $\bar{x} \in \bar{X}$. To see this let $T \in \mathcal{T}$ be an arbitrary orthogonal transformation from $\mathcal{T}$. By Theorem 15, we have

$$\nabla f(T\bar{x}) = \nabla f(\bar{x})T^{-1} = \nabla f(\bar{x})T',$$

where $T' = T^{-1}$ is the transpose of T. From $\nabla f(\bar{x})T' = T\nabla f(\bar{x})$ follows $\nabla f(T\bar{x}) = T\nabla f(\bar{x})$. Thus, we have

$$\mu(\nabla f(T\bar{x})) = \mu(T\nabla f(\bar{x})) = \mu(\nabla f(\bar{x}))$$

showing that the $\mathcal{T}$-gradient is well-defined.

The $\mathcal{T}$-gradient induces the $\mathcal{T}$-function

$$\nabla F(\bar{X}) : \mathcal{X}_{\mathcal{T}} \to \mathbb{R}, \quad X \mapsto \langle \nabla F(\bar{X}), X \rangle^*.$$

We use this function for showing that the geometrical properties of a gradient also hold for a $\mathcal{T}$-gradient. For this, we define the *directional $\mathcal{T}$-derivative* of F at $\bar{X}$ along the direction V with $\|V\|_* = 1$ by

$$D_V F(\bar{X}) = \langle V, \nabla F(\bar{X}) \rangle^*.$$

The first geometrical result shows that the $\mathcal{T}$-gradient is a structure pointing to the direction of steepest ascent.

Proposition 16 *Let $f : \mathcal{X} \to \mathbb{R}$ be a continuously differentiable representation function of a $\mathcal{T}$-function $F : \mathcal{X}_{\mathcal{T}} \to \mathbb{R}$. Then for all $\bar{X} \in \mathcal{X}_{\mathcal{T}} \setminus \{0_{\mathcal{T}}\}$ and all $V \in \mathcal{U}_{\mathcal{T}} = \{X \in \mathcal{X} : \|X\|_* = 1\}$, we have*

$$\frac{\nabla F(\bar{X})}{\|\nabla F(\bar{X})\|_*} = \arg\max_{V \in \mathcal{U}_{\mathcal{T}}} D_V F(\bar{X}).$$

Proof From the definition of the directional derivative and the implications of Theorem 11 follows

$$D_V F(\bar{X}) = \langle V, \nabla F(\bar{X}) \rangle^* = \|V\|_* \, \|\nabla F(\bar{X})\|_* \cos\alpha,$$

where α is the angle between V and $\nabla F(\bar{X})$. Hence, the directional derivative $D_V F(\bar{X})$ becomes maximal if V points to the same direction as $\nabla F(\bar{X})$. ■

Next, we show that the necessary condition for optimality can be transferred to $\mathcal{T}$-differentiable $\mathcal{T}$-functions.

Proposition 17 *Let $F : \mathcal{X}_{\mathcal{T}} \to \mathbb{R}$ be a $\mathcal{T}$-function with a partial differentiable representation function. If $X \in \mathcal{X}_{\mathcal{T}}$ is a local optimum of F, then we have*

$$\nabla F(X) = 0_{\mathcal{T}}.$$

Proof Let $f : \mathcal{X} \to \mathbb{R}$ be the representation function of F, and let $x \in X$ be a vector representation of X. Since f is partial differentiable, the gradient of f at x exists. By definition of the $\mathcal{T}$-gradient, we have

$$\mu(\nabla f(x)) = \nabla F(X) = 0_{\mathcal{T}}.$$

From Prop. 2 follows that 0 is the unique vector representation of $\nabla F(X)$. Thus, any vector representation x of X is a local optimum of the representation function f. Without loss of generality, we assume that $x \in X$ is a local minimum. Then there is an open neighborhood $\mathcal{U}$ of x with $f(x) \leq f(x')$ for all $x' \in \mathcal{U}$. Since μ is an open mapping by Prop. 13, the set $\mathcal{U}_{\mathcal{T}} = \mu(\mathcal{U})$ is an open neighborhood of X. From the $\mathcal{T}$-invariance of f follows that $F(X) = f(x) \leq f(x') = F(X')$ for all $X' \in \mathcal{U}_{\mathcal{T}}$. This shows that F is a local minimum. ■

An immediate consequence of the proof is that if x is a local minimum (maximum) of the representation function f then all $x' \in [x]$ are local minima (maxima).

B.3 Pointwise Maximizers

This section introduces and studies differential properties of pointwise maximizers and applies the results to structural similarity and distance functions.

B.3.1 POINTWISE MAXIMIZERS

The *pointwise maximizer* of functions $f_1, \ldots, f_m : \mathcal{U} \to \mathbb{R}$ defined on an open subset $\mathcal{U} \subseteq \mathbb{R}^n$ is the function $f : \mathcal{U} \to \mathbb{R}$ with

$$f(x) = \max_{1 \leq i \leq m} f_i(x).$$

We call the set $\operatorname{supp}(f) = \{f_i : 1 \leq i \leq m\}$ the *support* of f, and its elements *support functions*.

Theorem 18 *Let $f : \mathcal{U} \to \mathbb{R}$ be a pointwise maximizer with finite support* $\operatorname{supp}(f)$. *We have:*

- *If all* $f_i \in \text{supp}(f)$ *are locally Lipschitz at* x*, then* f *is locally Lipschitz at* x *and*

$$\partial f(x) \subseteq con\{\partial f_i(x) : f_i \in \text{supp}(f) \wedge f_i(x) = f(x)\}. \tag{3}$$

- *If all* $f_i \in \text{supp}(f)$ *are regular at* x*, then* f *is regular at* x *and equality in (3) holds.*

- *If all* $f_i \in \text{supp}(f)$ *are smooth at* x*, then* f *is regular at* x *and*

$$\partial f(x) = con\{\nabla f_i(x) : f_i \in \text{supp}(f) \wedge f_i(x) = f(x)\}.$$

Proof Mäkelä and Neittaanmäki (1992), Theorem 3.2.12 and Corollary 3.2.14. ■

If all support functions of f^* are locally Lipschitz, then f^* is also locally Lipschitz and admits a generalized gradient at any point from $\mathcal{U}$. In addition, f^* is differentiable almost everywhere on $\mathcal{U}$ by Rademacher's Theorem (see Appendix, Theorem 23).

Similarly, we can define in the obvious way the *pointwise minimizer* of a finite set of functions. According to Theorem 19, all statements made on pointwise maximizers carry over to pointwise minimizers.

Theorem 19 *If* f *be locally Lipschitz at* x*, then*

$$\partial f(\lambda x) = \lambda \partial f(x)$$

for all $\lambda \in \mathbb{R}$.

Proof Mäkelä and Neittaanmäki (1992), Theorem 3.2.4. ■

In the remainder of this section, we consider similarity and distance functions as examples of pointwise maximizers and minimizers, respectively.

B.3.2 SIMILARITY FUNCTIONS: THE GENERAL CASE

We consider similarity functions of the form

$$S^* : \mathcal{X}_\mathcal{T} \times \mathcal{X}_\mathcal{T} \to \mathbb{R}, \quad (X,Y) \mapsto \max_{x \in X, y \in Y} s(x,y)$$

that are maximizers of similarity functions $s : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$. For a given $Y \in \mathcal{X}_\mathcal{T}$, we define the function

$$s_Y : \mathcal{X} \to \mathbb{R}, \quad x \mapsto S^*(\mu(x), Y).$$

The function s_Y represents $S^*(\cdot, Y)$ and is a pointwise maximizer with support

$$\text{supp}(s_Y) = \{s_y : s_y(\cdot) = s(\cdot, y), y \in Y\}.$$

If the support functions of s_Y are locally Lipschitz, regular, or smooth, we can apply Theorem 18 to show that s_Y is locally Lipschitz, admits a generalized gradient at each point of its domain, and is differentiable almost everywhere.

B.3.3 SIMILARITY FUNCTIONS: THE INNER $\mathcal{T}$-PRODUCT

As a specific example of a similarity function as a pointwise maximizer, we consider the inner $\mathcal{T}$-product. Suppose that $S^*(\cdot,\cdot) = \langle\cdot,\cdot\rangle^*$. For a fixed structure $Y \in \mathcal{X}_{\mathcal{T}}$, the support of the pointwise maximizer s_Y is of the form

$$\operatorname{supp}(s_Y) = \{s_y : s_y(\cdot) = \langle\cdot, y\rangle, y \in Y\},$$

As linear functions, these support functions s_y are continuously differentiable. From Theorem 18 follows

- s_Y is locally Lipschitz and regular,
- the generalized gradient $\partial s_Y(x)$ is the convex set

$$\partial s_Y(x) = \operatorname{con}\{y \in Y : (x,y) \in \operatorname{supp}(s_Y|x)\}.$$

The next statement follows directly from Prop. 9.

Proposition 20 *The function $s_Y : \mathcal{X} \to \mathbb{R}$ is convex.*

Proof From Prop. 9 follows that s_y is positively homogeneous and sublinear. Hence, s_Y is convex. ■

B.3.4 DISTANCE FUNCTIONS: THE GENERAL CASE

Suppose that we are given an arbitrary distance function of the form

$$D_* : \mathcal{X}_{\mathcal{T}} \times \mathcal{X}_{\mathcal{T}} \to \mathbb{R}, \quad (X,Y) \mapsto \min_{x\in X, y\in Y} d(x,y).$$

To apply the theorems on pointwise maximizers, we consider the function

$$\widehat{D}_*(X,Y) = -D_*(X,Y) = \max_{x\in X, y\in Y} -d(x,y).$$

For a given $Y \in \mathcal{X}_{\mathcal{T}}$, we define the function

$$\widehat{d_Y} : \mathcal{X} \to \mathbb{R}, \quad x \mapsto \widehat{D}_*(\mu(x), Y).$$

The function $\widehat{d_Y}$ represents $\widehat{D}_*(\cdot, Y)$ and is a pointwise maximizer with support

$$\operatorname{supp}\left(\widehat{d_Y}\right) = \left\{\widehat{d_y} : \widehat{d_y}(\cdot) = -d(\cdot, y), y \in Y\right\}.$$

B.3.5 DISTANCE FUNCTIONS: THE METRIC D_*

Let D_* be the metric on $\mathcal{X}_{\mathcal{T}}$ induced by a metric d on $\mathcal{X}$ of the form $d(x,y) = \|x-y\|$. For a given $Y \in \mathcal{X}_{\mathcal{T}}$, we define the function

$$\widehat{d_Y} : \mathcal{X} \to \mathbb{R}, \quad x \mapsto \widehat{D}_*(\mu(x), Y).$$

The function $\widehat{d_Y}$ represents $\widehat{D}_*(\cdot, Y)$ and is a pointwise maximizer with support

$$\operatorname{supp}\left(\widehat{d_Y}\right) = \{\widehat{d_y} : y \in Y\},$$

where $\widehat{d_y}(x) = -\|x-y\|$ for all $x \in \mathcal{X}$. The support functions of $\widehat{d_Y}$ are locally Lipschitz and regular on $\mathcal{X}$, and smooth on $\mathcal{X} \setminus \{y\}$. From Theorem 18 follows

- $\widehat{d_Y}$ is locally Lipschitz and regular,
- the generalized gradient $\partial\widehat{d_Y}(x)$ is the convex set

$$\partial\widehat{d_Y}(x) = \begin{cases} \operatorname{con}\left\{-\frac{(x-y)}{\|x-y\|} : y \in Y \wedge (y,x) \in \operatorname{supp}(\widehat{d_Y}|x)\right\} & : \quad x \neq y \\ \{y \in \mathcal{X}_\mathcal{T} : \|y\| \leq 1\} & : \quad x = y. \end{cases}$$

As in the Euclidean space, the squared structural Euclidean metric D_*^2 turns out to be more convenient than D_*. As opposed to $\widehat{d_Y}$, the support functions of the squared function $\widehat{d_Y^2}$ are continuously differentiable at all points from $\mathcal{X}$. In particular, we have

- $\widehat{d_Y^2}$ is locally Lipschitz and regular,
- the generalized gradient $\partial\widehat{d_Y^2}(x)$ is the convex set

$$\partial\widehat{d_Y^2}(x) = \operatorname{con}\left\{-2(x-y) : y \in Y \wedge (y,x) \in \operatorname{supp}\left(\widehat{d_Y^2}|x\right)\right\}.$$

Appendix C. Locally Lipschitz Functions

We review some basic properties of locally Lipschitz functions and their generalized gradients. Unless otherwise stated proofs can be found in Clarke (1990), Section 2.3. For a detailed treatment to the first-order generalized derivative we refer to Clarke (1990); Mäkelä and Neittaanmäki (1992).

Let $(\mathcal{X}, d_X)$ and $(\mathcal{Y}, d_Y)$ be metric spaces, and let $\mathcal{U} \subseteq \mathcal{X}$ be an open set. A map $f : \mathcal{X} \to \mathcal{Y}$ is *Lipschitz* on $\mathcal{U}$ if there is a scalar $L \geq 0$ with

$$d_Y(f(u), f(v)) \leq L \cdot d_X(u, v)$$

for all $u, v \in \mathcal{U}$. We say that f is *locally Lipschitz* at $u \in \mathcal{U}$ if f is Lipschitz on some ε-neighborhood $\mathcal{N}(u, \varepsilon) \subseteq \mathcal{U}$ of u.

Proposition 21 *Let $f, g : \mathcal{U} \subseteq \mathcal{X} \to \mathbb{R}$ be locally Lipschitz at u, and let $\lambda \in \mathbb{R}$ be a scalar. Then λf, $f + g$, and $f \cdot g$ are locally Lipschitz at u. If $g(u) \neq 0$, then f/g is locally Lipschitz at u.*

Proposition 22 *Let $f : \mathcal{X} \to \mathcal{Y}$ be locally Lipschitz at x, and let $g : \mathcal{X} \to \mathcal{Z}$ be locally Lipschitz at $y = f(x)$. Then $h = g \circ f$ is locally Lipschitz at x.*

Proof Let $N(x, \varepsilon_x) \subseteq \mathcal{X}, N(y, \varepsilon_y) \subseteq \mathcal{Y}$ be neighborhoods of x and y satisfying the following properties: (i) $f(N(x, \varepsilon_x)) \subseteq N(y, \varepsilon_y)$, (ii) there are $L_x, L_y \geq 0$ such that $d_Y(f(u), f(v)) \leq L_x \cdot d_X(u, v)$ for all $u, v \in N(x, \varepsilon_x)$ and $d_Z(g(p), g(q)) \leq L_y \cdot d_Y(p, q)$ for all $p, q \in N(y, \varepsilon_y)$. For any $u, v \in \mathcal{X}$, we have

$$d_Z(g \circ f(u), g \circ f(v)) \leq L_y d_Y(f(u), f(v)) \leq L_y L_x d_X(u, v).$$

■

Theorem 23 (Rademacher) *Let $\mathcal{U} \subseteq \mathbb{R}^n$ be a nonempty open set, and let $f : \mathcal{U} \to \mathbb{R}$ be locally Lipschitz. Then the set of points at which f is not differentiable has Lebesgue measure zero.*

The function f is *directionally differentiable* at $x \in \mathcal{U}$ if the limit

$$f'(x,d) = \lim_{t \downarrow 0} \frac{f(x+td) - f(x)}{t}$$

exists for all directions $d \in \mathbb{R}^n$. In this case, the value $f'(x,d)$ is the *directional derivative* of f at x in the direction d. We call the function f *directionally differentiable* if f is directionally differentiable at all points $x \in \mathcal{U}$.

The *generalized directional derivative* of f at $x \in \mathcal{U}$ in the direction $d \in \mathcal{X}$ is defined by

$$f^{\circ}(x,d) = \lim_{t \downarrow 0, y \to x} \sup \frac{f(y+td) - f(y)}{t},$$

where $t \downarrow 0$ and $y \to x$ are sequences such that $y + td$ is always in $\mathcal{U}$.

We say f is *regular* at $x \in \mathcal{U}$ if the following conditions are satisfied

1. f is directionally differentiable at x.
2. $f^{\circ}(\bar{x},d) = f'(x,d)$ for all $d \in \mathbb{R}^n$.

A function f is said to be *smooth* at x if f is continuously differentiable at x. We have the following implications.

Proposition 24 *Let $f : \mathcal{U} \to \mathbb{R}$ be a function. The following implications hold:*

1. *f is smooth at x, then f is locally Lipschitz, regular, continuous, and differentiable at x.*
2. *f is locally Lipschitz or differentiable at x, then f is continuous at x.*

Proof

1. Smoothness implies differentiability and continuity are well-known results from analysis. The locally Lipschitz property follows from Mäkelä and Neittaanmäki (1992), Lemma 3.1.6 and regularity from Mäkelä and Neittaanmäki (1992), Theorem 3.2.2.
2. Both assertions are again well-known results from analysis.

■

The *generalized gradient* $\partial f(x)$ of f at x is the set

$$\partial f(x) = \{y \in \mathcal{X} : f^{\circ}(x,d) \geq \langle y,d \rangle \text{ for all } d \in \mathcal{X}\}.$$

The elements of the set $\partial f(x)$ are called *subgradients* of f at x.

Theorem 25 *Let $f : \mathcal{U} \to \mathbb{R}$ be a function on the open subset $\mathcal{U}$. We have:*

- *If f is locally Lipschitz and differentiable at x, then*

$$\nabla f(x) \in \partial f(x).$$

- *If f is locally Lipschitz, regular, and differentiable at x, then*

$$\partial f(x) = \{\nabla f(x)\}.$$

Proof Mäkelä and Neittaanmäki (1992), Theorem 3.1.5, Theorem 3.1.7, and Theorem 3.2.4. ■

Appendix D. The Graduated Assignment Algorithm

We use the graduated assignment algorithm to approximate the NP-hard squared distance $D_*(X,Y)^2$ between two weighted graphs and to determine a subgradient from the generalized gradient ∂d_Y^2 (see Section B.3.5). According to Prop. 10, the squared distance $D_*(X,Y)^2$ can be expressed by the inner $\mathcal{T}$-product. Here, we determine $D_*(X,Y)^2$ via $\langle X,Y\rangle^*$.

Let X and Y be weighted graphs with weighted adjacency matrices $X=(x_{ij})$ and $Y=(y_{ij})$. Suppose that X and Y are of order n and m, respectively. Without loss of generality, we assume that $n<m$. By $\Pi=\Pi^{n\times m}$ we denote the set of $(n\times m)$-match matrices $M=(m_{ij})$ with elements from $[0,1]$ such that each row sums to 1 and each column sums to n/m. Then we have

$$\langle X,Y\rangle^* = \max_{M\in\Pi} \left\langle M'XM, Y\right\rangle,$$

where M' denotes the transpose of M. To compute the inner $\mathcal{T}$-product, graduated assignment minimizes

$$F(M) = -\frac{1}{2}\left\langle M'XM, Y\right\rangle.$$

subject to $M\in\Pi$. Suppose that M_0 is an optimal solution. Then $2\left(M_0'XM_0-Y\right)$ is a subgradient from the generalized gradient $\partial d_Y^2(X)$.

The core of the algorithm implements a deterministic annealing process with annealing parameter T by the following iteration scheme

$$m_{ij}^{(t+1)} = a_i b_j \exp\left(-\frac{1}{T}\sum_{r=1}^{n}\sum_{s=1}^{m} m_{rs}^{(t)}\left\langle x_{ir}, y_{js}\right\rangle\right),$$

where t denotes the time step. The scaling factors a_i, b_i computed by Sinkhorn's algorithm (Sinkhorn, 1964) enforce the constraints of the match matrix. The algorithm in detail is described in Gold, Rangarajan, and Mjolsness (1996).

Abstract

We give new algorithms for learning halfspaces in the challenging *malicious noise* model, where an adversary may corrupt both the labels and the underlying distribution of examples. Our algorithms can tolerate malicious noise rates exponentially larger than previous work in terms of the dependence on the dimension n, and succeed for the fairly broad class of all isotropic log-concave distributions.

We give $\mathrm{poly}(n, 1/\varepsilon)$-time algorithms for solving the following problems to accuracy ε:

- Learning origin-centered halfspaces in $\mathbf{R}^n$ with respect to the uniform distribution on the unit ball with malicious noise rate $\eta = \Omega(\varepsilon^2/\log(n/\varepsilon))$. (The best previous result was $\Omega(\varepsilon/(n\log(n/\varepsilon))^{1/4})$.)

- Learning origin-centered halfspaces with respect to any isotropic log-concave distribution on $\mathbf{R}^n$ with malicious noise rate $\eta = \Omega(\varepsilon^3/\log^2(n/\varepsilon))$. This is the first efficient algorithm for learning under isotropic log-concave distributions in the presence of malicious noise.

We also give a $\mathrm{poly}(n, 1/\varepsilon)$-time algorithm for learning origin-centered halfspaces under any isotropic log-concave distribution on $\mathbf{R}^n$ in the presence of *adversarial label noise* at rate $\eta = \Omega(\varepsilon^3/\log(1/\varepsilon))$. In the adversarial label noise setting (or agnostic model), labels can be noisy, but not example points themselves. Previous results could handle $\eta = \Omega(\varepsilon)$ but had running time exponential in an unspecified function of $1/\varepsilon$.

Our analysis crucially exploits both concentration and anti-concentration properties of isotropic log-concave distributions. Our algorithms combine an iterative outlier removal procedure using Principal Component Analysis together with "smooth" boosting.

Keywords: PAC learning, noise tolerance, malicious noise, agnostic learning, label noise, halfspace learning, linear classifiers

1. Introduction

A *halfspace* is a Boolean-valued function of the form $f = \mathrm{sign}(\sum_{i=1}^{n} w_i x_i - \theta)$. Learning halfspaces in the presence of noisy data is a fundamental problem in machine learning. In addition to its practical relevance, the problem has connections to many well-studied topics such as kernel methods (Shawe-Taylor and Cristianini, 2000), cryptographic hardness of learning (Klivans and Sherstov, 2006), hardness of approximation (Feldman et al., 2006; Guruswami and Raghavendra, 2006), learning Boolean circuits (Blum et al., 1997), and additive/multiplicative update learning algorithms (Littlestone, 1991; Freund and Schapire, 1999).

Learning an unknown halfspace from correctly labeled (non-noisy) examples is one of the best-understood problems in learning theory, with work dating back to the famous Perceptron algorithm of the 1950s (Rosenblatt, 1958) and a range of efficient algorithms known for different settings (Novikoff, 1962; Littlestone, 1987; Blumer et al., 1989; Maass and Turan, 1994). Much less is known, however, about the more difficult problem of learning halfspaces in the presence of noise.

Important progress was made by Blum et al. (1997) who gave a polynomial-time algorithm for learning a halfspace under *classification noise*. In this model each label is flipped independently with some fixed probability; the noise does not affect the actual example points themselves, which are generated according to an arbitrary probability distribution over $\mathbf{R}^n$.

In the current paper we consider a much more challenging *malicious noise* model. In this model, introduced by Valiant (1985) (see also Kearns and Li 1993), there is an unknown target function f and distribution $\mathcal{D}$ over examples. Each time the learner receives an example, independently with probability $1-\eta$ it is drawn from $\mathcal{D}$ and labeled correctly according to f, but with probability η it is an arbitrary pair (x,y) which may be generated by an omniscient adversary. The parameter η is known as the "noise rate."

Malicious noise is a notoriously difficult model with few positive results. It was already shown by Kearns and Li (1993) that for essentially all concept classes, it is information-theoretically impossible to learn to accuracy $1-\varepsilon$ if the noise rate η is greater than $\varepsilon/(1+\varepsilon)$. Indeed, known algorithms for learning halfspaces (Servedio, 2003; Kalai et al., 2008) or even simpler target functions (Mansour and Parnas, 1998) with malicious noise typically make strong assumptions about the underlying distribution $\mathcal{D}$, and can learn to accuracy $1-\varepsilon$ only for noise rates η much smaller than ε. We describe the most closely related work that we know of in Section 1.2.

In this paper we consider learning under the uniform distribution on the unit ball in $\mathbf{R}^n$, and more generally under any isotropic log-concave distribution. The latter is a fairly broad class of distributions that includes spherical Gaussians and uniform distributions over a wide range of convex sets. Our algorithms can learn from malicious noise rates that are quite high, as we now describe.

1.1 Main Results

Our first result is an algorithm for learning halfspaces in the malicious noise model with respect to the uniform distribution on the n-dimensional unit ball:

Theorem 1 *There is a* $\mathrm{poly}(n, 1/\varepsilon)$*-time algorithm that learns origin-centered halfspaces to accuracy* $1-\varepsilon$ *with respect to the uniform distribution on the unit ball in n dimensions in the presence of malicious noise at rate* $\eta = \Omega(\varepsilon^2/\log(n/\varepsilon))$.

The condition on η is expressed using Ω and not O because we are showing that a weak upper bound on the noise rate suffices to achieve accuracy $1-\varepsilon$.

Via a more sophisticated algorithm, we can learn in the presence of malicious noise under any isotropic log-concave distribution:

Theorem 2 *There is a* $\mathrm{poly}(n, 1/\varepsilon)$*-time algorithm that learns origin-centered halfspaces to accuracy* $1-\varepsilon$ *with respect to any isotropic log-concave distribution over* $\mathbf{R}^n$ *and can tolerate malicious noise at rate* $\eta = \Omega(\varepsilon^3/\log^2(n/\varepsilon))$.

We are not aware of any previous polynomial-time algorithms for learning under isotropic log-concave distributions in the presence of malicious noise.

Finally, we also consider a related noise model known as *adversarial label noise*. In this model there is a fixed probability distribution P over $\mathbf{R}^n \times \{-1, 1\}$ (i.e., over labeled examples) for which a $1-\eta$ fraction of draws are labeled according to an unknown halfspace. The marginal distribution over $\mathbf{R}^n$ is assumed to be isotropic log-concave; so the idea is that an "adversary" chooses an η fraction of examples to mislabel, but unlike the malicious noise model she cannot change the (isotropic log-concave) distribution of the actual example points in $\mathbf{R}^n$. Learning with adversarial label noise is clearly harder than with independent misclassification noise—the ability to choose which labels to corrupt allows the adversary to coordinate their effects to an extent.

For the adversarial label noise model we prove:

Theorem 3 *There is a* $\mathrm{poly}(n, 1/\varepsilon)$*-time algorithm that learns origin-centered halfspaces to accuracy* $1-\varepsilon$ *with respect to any isotropic log-concave distribution over* $\mathbf{R}^n$ *and can tolerate adversarial label noise at rate* $\eta = \Omega(\varepsilon^3/\log(1/\varepsilon))$.

1.2 Previous Work

Our work builds on a number of lines of research.

1.2.1 MALICIOUS NOISE

General-purpose tools developed by Kearns and Li (1993) (see also Kearns et al. 1994) directly imply that halfspaces can be learned for any distribution over the domain in randomized $\mathrm{poly}(n, 1/\varepsilon)$ time with malicious noise at a rate $\Omega(\varepsilon/n)$; the algorithm repeatedly picks a random subsample of the training data, hoping to miss all the noisy examples. Kannan (see Arora et al. 1993) devised a deterministic algorithm with a $\Omega(\varepsilon/n)$ bound that repeatedly exploits Helly's Theorem to find a group of $n+1$ examples that includes a noisy example, then removes the group. Kalai et al. (2008) showed that the $\mathrm{poly}(n, 1/\varepsilon)$-time averaging algorithm (Servedio, 2001) tolerates noise at a rate $\Omega(\varepsilon/\sqrt{n})$ when the distribution is uniform. They also described an improvement to $\tilde{\Omega}(\varepsilon/n^{1/4})$ based on the observation that uniform examples will tend to be well-separated, so that pairs of examples that are too close to one another can be removed.

1.2.2 ADVERSARIAL LABEL NOISE

Kalai, et al. showed that if the distribution over the instances is uniform over the unit ball, the averaging algorithm tolerates adversarial label noise at a rate $\Omega(\varepsilon/\sqrt{\log(1/\varepsilon)})$ in $\mathrm{poly}(n, 1/\varepsilon)$ time. (In that paper, learning in the presence of adversarial label noise was called "agnostic learning".) They also described an algorithm that fits low-degree polynomials that tolerates noise at a rate within an additive ε of the accuracy, but in $\mathrm{poly}\left(n^{1/\varepsilon^4}\right)$ time; for log-concave distributions, their algorithm

took poly$\left(n^{d(1/\varepsilon)}\right)$ time, for an unspecified function d. The latter algorithm does not require that the distribution is isotropic, as ours does.

1.2.3 ROBUST PCA

Independently of this work, Xu et al. (2009) designed and analyzed an algorithm that performs principal component analysis when some of the examples are corrupted arbitrarily, as in the malicious noise model studied here. Also, the thesis of Brubaker (2009) presents a "Robust PCA" algorithm which is a PCA variant aimed at ameliorating the effects of noisy examples.

1.3 Techniques

Here is a high-level description of the main techniques in our analysis.

1.3.1 OUTLIER REMOVAL

Consider first the simplest problem of learning an origin-centered halfspace with respect to the uniform distribution on the n-dimensional ball. A natural idea is to use a simple "averaging" algorithm that takes the vector average of the positive examples it receives and uses this as the normal vector of its hypothesis halfspace. Servedio (2001) analyzed this algorithm for the random classification noise model, and Kalai et al. (2008) extended the analysis to the adversarial label noise model.

Intuitively the "averaging" algorithm can only tolerate low malicious noise rates because the adversary can generate noisy examples which "pull" the average vector far from its true location. Our main insight is that the adversary does this most effectively when the noisy examples are coordinated to pull in roughly the same direction. We use a form of outlier detection based on Principal Component Analysis to detect such coordination. This is done by computing the direction $\mathbf{w}$ of maximal variance of the data set; if the variance in direction $\mathbf{w}$ is suspiciously large, we remove from the sample all points $\mathbf{x}$ for which $(\mathbf{w} \cdot \mathbf{x})^2$ is large. Our analysis shows that this causes many noisy examples, and only a few non-noisy examples, to be removed.

We repeat this process until the variance in every direction is not too large. (This cannot take too many stages since many noisy examples are removed in each stage.) While some noisy examples may remain, we show that their scattered effects cannot hurt the algorithm much.

Thus, in a nutshell, our overall algorithm for the uniform distribution is to first do outlier removal[1] by an iterated PCA-type procedure, and then simply run the averaging algorithm on the remaining "cleaned-up" data set.

1.3.2 EXTENDING TO LOG-CONCAVE DISTRIBUTIONS VIA SMOOTH BOOSTING

We are able to show that the iterative outlier removal procedure described above is useful for isotropic log-concave distributions as well as the uniform distribution: if examples are removed in a given stage, then many of the removed examples are noisy and only a few are non-noisy (the analysis here uses concentration bounds for isotropic log-concave distributions). However, even if there were no noise in the data, the average of the positive examples under an isotropic log-concave

1. We note briefly that the sophisticated outlier removal techniques of Blum et al. (1997) and Dunagan and Vempala (2004) do not seem to be useful in our setting; those works deal with a strong notion of outliers, which is such that no point on the unit ball can be an outlier if a significant fraction of points are uniformly distributed on the unit ball.

distribution need not give a high-accuracy hypothesis. Thus the averaging algorithm alone will not suffice after outlier removal.

To get around this, we show that after outlier removal the average of the positive examples gives a (real-valued) *weak* hypothesis that has some nontrivial predictive accuracy. (Interestingly, the proof of this relies heavily on *anti*-concentration properties of isotropic log-concave distributions!) A natural approach is then to use a boosting algorithm to convert this weak learner into a strong learner. This is not entirely straightforward because boosting "skews" the distribution of examples; this has the undesirable effects of both increasing the effective malicious noise rate, and causing the distribution to no longer be isotropic log-concave. However, by using a "smooth" boosting algorithm (Servedio, 2003) that skews the distribution as little as possible, we are able to control these undesirable effects and make the analysis go through. (The extra factor of ε in the bound of Theorem 2 compared with Theorem 1 comes from the fact that the boosting algorithm constructs "$1/\varepsilon$-skewed" distributions.)

We note that our approach of using smooth boosting is reminiscent of earlier work (Servedio, 2002, 2003), but the current algorithm goes well beyond that. Servedio (2002) did not consider a noisy scenario, and Servedio (2003) only considered the averaging algorithm without any outlier removal as the weak learner (and thus could only handle quite low rates of malicious noise in our isotropic log-concave setting).

1.3.3 TOLERATING ADVERSARIAL LABEL NOISE

Finally, our results for learning under isotropic log-concave distributions with adversarial label noise are obtained using a similar approach. The algorithm here is in fact simpler than the malicious noise algorithm: since the adversarial label noise model does not allow the adversary to alter the distribution of the examples in $\mathbf{R}^n$, we can dispense with the outlier removal and simply use smooth boosting with the averaging algorithm as the weak learner. (This is why we get a slightly better quantitative bound in Theorem 3 than Theorem 2).

1.3.4 ORGANIZATION

For completeness we review the precise definitions of isotropic log-concave distributions and the various learning models in Section 2. We present the simpler and more easily understood uniform distribution analysis in Section 3. We extend the algorithm and analysis to isotropic log-concave distributions in Section 4. Learning with adversarial label noise is treated in Section 5. We conclude in Section 6.

2. Definitions and Preliminaries

In this section, we provide some definitions and lemmas that will be used throughout the paper.

2.1 Learning with Malicious Noise

Given a probability distribution $\mathcal{D}$ over $\mathbf{R}^n$, and a target function $f : \mathbf{R}^n \to \{-1, 1\}$, we define the oracle $\mathrm{EX}_\eta(f, \mathcal{D})$ as follows:

- with probability $1 - \eta$ the oracle draws $\mathbf{x}$ according to $\mathcal{D}$, and outputs $(\mathbf{x}, f(\mathbf{x}))$, and

- with probability η the oracle outputs an arbitrary $(\mathbf{x}, y)$ pair. This "noisy" example can be thought of as being generated adversarially and can depend on the state of the learning algorithm and previous draws from the oracle.

Given a data set drawn from $\mathrm{EX}_\eta(f, \mathcal{D})$, we often refer to the examples $(\mathbf{x}, f(\mathbf{x}))$ (that came from $\mathcal{D}$) as "clean" examples and the remaining examples $(\mathbf{x}, y)$ as "dirty" examples.

For a set $\mathcal{S}$ of probability distributions and a set F of possible target functions, we say that a learning algorithm A learns F to accuracy $1-\varepsilon$ with respect to $\mathcal{S}$ in the presence of malicious noise at a rate η if the following holds: for any $f \in F$, and $\mathcal{D} \in \mathcal{S}$, given access to $\mathrm{EX}_\eta(f, \mathcal{D})$, with probability at least $1/2$, the output hypothesis h generated by A satisfies $\Pr_{\mathbf{x}\sim\mathcal{D}}[h(\mathbf{x}) \neq f(\mathbf{x})] \leq \varepsilon$. (The probability of success may be amplified arbitrarily close to 1 using standard techniques (Haussler et al., 1991).)

Since scaling $\mathbf{x}$ by a positive constant does not affect its classification by a linear classifier, drawing examples uniformly from the unit ball is equivalent to drawing them uniformly from the surface $\mathbb{S}^{n-1}$ of the unit sphere. When this is the distribution, we may also assume w.l.o.g. that even noisy examples $(\mathbf{x}, y)$ have $\mathbf{x} \in \mathbb{S}^{n-1}$—this is simply because a learning algorithm can trivially identify and ignore any noisy example $(\mathbf{x}, y)$ that has $\|\mathbf{x}\| \neq 1$.

2.2 Log-concave Distributions

A probability distribution over $\mathbf{R}^n$ is said to be *log-concave* if its density function is $\exp(-\psi(\mathbf{x}))$ for a convex function ψ.

A probability distribution over $\mathbf{R}^n$ is *isotropic* if the mean of the distribution is 0 and the covariance matrix is the identity, that is, $\mathbf{E}[x_i x_j] = 1$ for $i = j$ and 0 otherwise.

Isotropic log-concave (henceforth abbreviated i.l.c.) distributions are a fairly broad class of distributions. It is well known that any distribution induced by taking a uniform distribution over an arbitrary convex set and applying a suitable linear transformation to make it isotropic is then isotropic and log-concave. For an excellent treatment on basic properties of log-concave distributions, see Lovász and Vempala (2007).

We will use the following facts:

Lemma 4 (Lovász and Vempala 2007) *Let $\mathcal{D}$ be an isotropic log-concave distribution over $\mathbf{R}^n$ and $\mathbf{a} \in \mathbb{S}^{n-1}$ any direction. Then for $\mathbf{x}$ drawn according to $\mathcal{D}$, the distribution of $\mathbf{a}\cdot\mathbf{x}$ is an isotropic log-concave distribution over $\mathbf{R}$.*

Lemma 5 (Lovász and Vempala 2007) *Any isotropic log-concave distribution $\mathcal{D}$ over $\mathbf{R}^n$ has light tails,*

$$\Pr_{\mathbf{x}\sim\mathcal{D}}[||\mathbf{x}|| > \beta\sqrt{n}] \leq e^{-\beta+1}.$$

If $n = 1$, the density of $\mathcal{D}$ is bounded:

$$\Pr_{x\sim\mathcal{D}}[\mathbf{x} \in [a,b]] \leq |b-a|.$$

3. The Uniform Distribution and Malicious Noise

In this section we prove Theorem 1. As described above, our algorithm first does outlier removal using PCA and then applies the "averaging algorithm."

We may assume throughout that the noise rate η is smaller than some absolute constant, and that the dimension n is larger than some absolute constant.

3.1 The Algorithm: Removing Outliers and Averaging

Consider the following Algorithm A_{mu}:

Algorithm A_{mu}:

1. Draw a sample S of $m = \mathrm{poly}(n/\varepsilon)$ many examples from the malicious oracle.
2. Identify the direction $\mathbf{w} \in \mathbb{S}^{n-1}$ that maximizes

$$\sigma_{\mathbf{w}}^2 \stackrel{def}{=} \sum_{(\mathbf{x},y)\in S} (\mathbf{w}\cdot\mathbf{x})^2.$$

   If $\sigma_{\mathbf{w}}^2 < \frac{10m\log m}{n}$ then go to Step 4 otherwise go to Step 3.
3. Remove from S every example that has $(\mathbf{w}\cdot\mathbf{x})^2 \geq \frac{10\log m}{n}$. Go to Step 2.
4. For the examples S that remain let $\mathbf{v} = \frac{1}{|S|}\sum_{(\mathbf{x},y)\in S} y\mathbf{x}$ and output the linear classifier $h_{\mathbf{v}}$ defined by $h_{\mathbf{v}}(\mathbf{x}) = \mathrm{sgn}(\mathbf{v}\cdot\mathbf{x})$.

We first observe that Step 2 can be carried out in polynomial time:

Lemma 6 *There is a polynomial-time algorithm that, given a finite collection S of points in $\mathbf{R}^n$, outputs $\mathbf{w} \in \mathbb{S}^{n-1}$ that maximizes $\sum_{\mathbf{x}\in S}(\mathbf{w}\cdot\mathbf{x})^2$.*

Proof. By applying Lagrange multipliers, we can see that the optimal $\mathbf{w}$ is an eigenvector of $A = \sum_{\mathbf{x}\in S}\mathbf{x}\mathbf{x}^T$. Further, if λ is the eigenvalue of $\mathbf{w}$, then $\sum_{\mathbf{x}\in S}(\mathbf{w}\cdot\mathbf{x})^2 = \mathbf{w}^T A\mathbf{w} = \mathbf{w}^T(\lambda\mathbf{w}) = \lambda$. The eigenvector $\mathbf{w}$ with the largest eigenvalue can be found in polynomial time (see, e.g., Jolliffe 2002). ∎

Before embarking on the analysis we establish a terminological convention. Much of our analysis deals with high-probability statements over the draw of the m-element sample S; it is straightforward but quite cumbersome to explicitly keep track of all of the failure probabilities. Thus we write "with high probability" (or "w.h.p.") in various places below as a shorthand for "with probability at least $1 - 1/\mathrm{poly}(n/\varepsilon)$." The interested reader can easily verify that an appropriate $\mathrm{poly}(n/\varepsilon)$ choice of m makes all the failure probabilities small enough so that the entire algorithm succeeds with probability at least $1/2$ as required.

3.2 Properties of the Clean Examples

In this subsection we establish properties of the clean examples that were sampled in Step 1 of A_{mu}. The first says that no direction has much more variance than the expected variance of $1/n$:

Lemma 7 *W.h.p. over a random draw of ℓ clean examples S_{clean}, we have*

$$\max_{a\in\mathbb{S}^{n-1}}\left\{\frac{1}{\ell}\sum_{(\mathbf{x},y)\in S_{\mathrm{clean}}}(\mathbf{a}\cdot\mathbf{x})^2\right\} \leq \frac{1}{n} + \sqrt{\frac{O(n+\log\ell)}{\ell}}.$$

Proof. The proof uses standard tools from VC theory and is in Appendix A. ∎

The next lemma says that in fact no direction has too many clean examples lying far out in that direction:

Lemma 8 *For any $\beta > 0$ and $\kappa > 1$, if S_{clean} is a random set of $\ell \geq \frac{O(1)\cdot n^2\beta^2 e^{\beta^2 n/2}}{(1+\kappa)\ln(1+\kappa)}$ clean examples then w.h.p. we have*

$$\max_{\mathbf{a}\in\mathbb{S}^{n-1}} \frac{1}{\ell}|\{\mathbf{x} \in S_{\text{clean}} : (\mathbf{a}\cdot\mathbf{x})^2 > \beta^2\}| \;\leq\; (1+\kappa)e^{-\beta^2 n/2}.$$

Proof. In Appendix B. ∎

3.3 What is Removed

In this section, we provide bounds on the number of clean and dirty examples removed in Step 3.

The first bound is a Corollary of Lemma 8.

Corollary 9 *W.h.p. over the random draw of the m-element sample S, the number of clean examples removed during any one execution of Step 3 in A_{mu} is at most $6n\log m$.*

Proof. Since the noise rate η is sufficiently small, w.h.p. the number ℓ of clean examples is at least (say) $m/2$. We would like to apply Lemma 8 with $\kappa = 5\ell^4 n\log\ell$ and $\beta = \sqrt{\frac{10\log m}{n}}$, and indeed we may do this because we have

$$\frac{O(1)\cdot n^2\beta^2 e^{\beta^2 n/2}}{(1+\kappa)\ln(1+\kappa)} \leq \frac{O(1)\cdot n(\log m)m^5}{(1+\kappa)\ln(1+\kappa)} \leq O\left(\frac{m}{\log m}\right) \leq \frac{m}{2} \leq \ell$$

for n sufficiently large. Since clean points are only removed if they have $(\mathbf{a}\cdot\mathbf{x})^2 > \beta^2$, Lemma 8 gives us that the number of clean points removed is at most

$$m(1+\kappa)e^{-\beta^2 n/2} \leq 6m^5 n\log(\ell)/m^5 \leq 6n\log m.$$

∎

The counterpart to Corollary 9 is the following lemma. It tells us that if examples are removed in Step 3, then there must be many *dirty* examples removed. It exploits the fact that Lemma 7 bounds the variance in *all* directions $\mathbf{a}$, so that it can be reused to reason about what happens in different executions of step 3.

Lemma 10 *W.h.p. over the random draw of S, whenever A_{mu} executes step 3, it removes at least $\frac{4m\log m}{n}$ noisy examples from S_{dirty}, the set of dirty examples in S.*

Proof. As stated earlier we may assume that $\eta \leq 1/4$. This implies that w.h.p. the fraction $\widehat{\eta}$ of noisy examples in the initial set S is at most $1/2$. Finally, Lemma 7 implies that $m = \tilde{\Omega}(n^3)$ suffices for it to be the case that w.h.p., for all $\mathbf{a} \in \mathbb{S}^{n-1}$, for the original multiset S_{clean} of clean examples drawn in step 1, we have

$$\sum_{(\mathbf{x},y)\in S_{\text{clean}}} (\mathbf{a}\cdot\mathbf{x})^2 \leq \frac{2m}{n}. \tag{1}$$

We shall say that a random sample S that satisfies all these requirements is "reasonable". We will show that for any reasonable data set, the number of noisy examples removed during the execution of step 3 of A_{mu} is at least $\frac{4m\log m}{n}$.

If we remove examples using direction $\mathbf{w}$ then it means $\sum_{(\mathbf{x},y)\in S}(\mathbf{w}\cdot\mathbf{x})^2 \geq \frac{10m\log m}{n}$. Since S is reasonable, by (1) the contribution to the sum from the clean examples that survived to the current stage is at most $2m/n$ so we must have

$$\sum_{(\mathbf{x},y)\in S_{\text{dirty}}}(\mathbf{w}\cdot\mathbf{x})^2 \geq 10m\log(m)/n - 2m/n > 9m\log(m)/n.$$

Let us decompose S_{dirty} into $N\cup F$ where N ("near") consists of those points x s.t. $(\mathbf{w}\cdot\mathbf{x})^2 \leq 10\log(m)/n$ and F ("far") is the remaining points for which $(\mathbf{w}\cdot\mathbf{x})^2 > 10\log(m)/n$. Since $|N| \leq |S_{\text{dirty}}| \leq \widehat{\eta}m$, (any dirty examples removed in earlier rounds will only reduce the size of S_{dirty}) we have

$$\sum_{(\mathbf{x},y)\in N}(\mathbf{w}\cdot\mathbf{x})^2 \leq (\widehat{\eta}m)10\log(m)/n$$

and so

$$|F| \geq \sum_{(\mathbf{x},y)\in F}(\mathbf{w}\cdot\mathbf{x})^2 \geq 9m\log(m)/n - (\widehat{\eta}m)10\log(m)/n \geq 4m\log(m)/n$$

(the last line used the fact that $\widehat{\eta} < 1/2$). Since the points in F are removed in Step 3, the lemma is proved. ∎

3.4 Exploiting Limited Variance in Any Direction

In this section, we show that if all directional variances are small, then the algorithm's final hypothesis will have high accuracy.

We first recall a simple lemma which shows that a sample of "clean" examples results in a high-accuracy hypothesis for the averaging algorithm:

Lemma 11 (Servedio 2001) *Suppose $\mathbf{x}_1,\ldots,\mathbf{x}_m$ are chosen uniformly at random from $\mathbb{S}^{n-1}$, and a target weight vector $\mathbf{u}\in\mathbb{S}^{n-1}$ produces labels $y_1 = \text{sign}(\mathbf{u}\cdot\mathbf{x}_1),\ldots,y_m = \text{sign}(\mathbf{u}\cdot\mathbf{x}_m)$. Let $\mathbf{v} = \frac{1}{m}\sum_{t=1}^{m} y_t\mathbf{x}_t$. Then w.h.p. $\mathbf{u}\cdot\mathbf{v} = \Omega(\frac{1}{\sqrt{n}})$, while $||\mathbf{v} - (\mathbf{u}\cdot\mathbf{v})\mathbf{u}|| = O(\sqrt{\log(n)/m})$.*

Now we can state Lemma 12.

Lemma 12 *Let $S = S_{\text{clean}}\cup S_{\text{dirty}}$ be the sample of m examples drawn from the noisy oracle $\text{EX}_\eta(f,\mathcal{U})$. Let*

- *S'_{clean} be those clean examples that were never removed during step 3 of A_{mu},*
- *S'_{dirty} be those dirty examples that were never removed during step 3 of A_{mu},*
- *$\eta' = \frac{|S'_{\text{dirty}}|}{|S'_{\text{clean}}\cup S'_{\text{dirty}}|}$, that is, the fraction of dirty examples among the examples that survive step 3, and*
- *$\alpha = \frac{|S_{\text{clean}} - S'_{\text{clean}}|}{|S'_{\text{clean}}\cup S'_{\text{dirty}}|}$, the ratio of the number of clean points that were erroneously removed to the size of the final surviving data set.*

Let $S' \stackrel{def}{=} S'_{\text{clean}} \cup S'_{\text{dirty}}$. Suppose that $|S'| \geq m/2$ (i.e., fewer than half the total points were removed) and that, for every direction $\mathbf{w} \in \mathbb{S}^{n-1}$ we have

$$\sigma^2_{\mathbf{w}} \stackrel{def}{=} \sum_{(\mathbf{x},y)\in S'} (\mathbf{w}\cdot\mathbf{x})^2 \leq \frac{10m\log m}{n}.$$

Then w.h.p. over the draw of S, the halfspace with normal vector $\mathbf{v} \stackrel{def}{=} \frac{1}{|S'|}\sum_{(\mathbf{x},y)\in S'} y\mathbf{x}$ has error rate

$$O\left(\sqrt{\eta' \log m} + \alpha\sqrt{n} + \sqrt{\frac{n\log n}{m}}\right).$$

Proof. The claimed bound is trivial unless $\eta' \leq o(1)/\log m$ and $\alpha \leq o(1)/\sqrt{n}$, so we shall freely use these bounds in what follows.

Let $\mathbf{u}$ be the unit length normal vector for the target halfspace. Let $\mathbf{v}_{\text{clean}}$ be the average of *all* the clean examples, $\mathbf{v}'_{\text{dirty}}$ be the average of the dirty (noisy) examples that were not deleted (i.e., the examples in S'_{dirty}), and $\mathbf{v}_{\text{del}}$ be the average of the clean examples that were deleted. Then

$$\begin{aligned}
\mathbf{v} &= \frac{1}{|S'_{\text{clean}} \cup S'_{\text{dirty}}|} \sum_{(\mathbf{x},y)\in S'_{\text{clean}}\cup S'_{\text{dirty}}} y\mathbf{x} \\
&= \frac{1}{|S'_{\text{clean}} \cup S'_{\text{dirty}}|} \left(\left(\sum_{(\mathbf{x},y)\in S_{\text{clean}}} y\mathbf{x}\right) + \left(\sum_{(\mathbf{x},y)\in S'_{\text{dirty}}} y\mathbf{x}\right) - \left(\sum_{(\mathbf{x},y)\in S_{\text{clean}}-S'_{\text{clean}}} y\mathbf{x}\right)\right) \\
\mathbf{v} &= (1-\eta'+\alpha)\mathbf{v}_{\text{clean}} + \eta'\mathbf{v}'_{\text{dirty}} - \alpha\mathbf{v}_{\text{del}}.
\end{aligned}$$

Let us begin by exploiting the bound on the variance in every direction to bound the length of $\mathbf{v}'_{\text{dirty}}$. For any $\mathbf{w} \in \mathbb{S}^{n-1}$ we know that

$$\sum_{(\mathbf{x},y)\in S'} (\mathbf{w}\cdot\mathbf{x})^2 \leq \frac{10m\log m}{n}, \quad \text{and hence} \quad \sum_{(\mathbf{x},y)\in S'_{\text{dirty}}} (\mathbf{w}\cdot\mathbf{x})^2 \leq \frac{10m\log m}{n}$$

since $S'_{\text{dirty}} \subseteq S'$. Since $|S'_{\text{dirty}}| \leq \eta' m$, the fact that $||\mathbf{r}||_1 \leq \sqrt{k}||\mathbf{r}||_2$ for any vector $\mathbf{r} \in \mathbf{R}^k$ gives

$$\sum_{(\mathbf{x},y)\in S'_{\text{dirty}}} |\mathbf{w}\cdot\mathbf{x}| \leq \sqrt{\frac{10m|S'_{\text{dirty}}|\log m}{n}}.$$

Taking $\mathbf{w}$ to be the unit vector in the direction of $\mathbf{v}'_{\text{dirty}}$, we have $\|\mathbf{v}'_{\text{dirty}}\| =$

$$\mathbf{w}\cdot\mathbf{v}'_{\text{dirty}} = \mathbf{w}\cdot\frac{1}{|S'_{\text{dirty}}|}\sum_{(\mathbf{x},y)\in S'_{\text{dirty}}} y\mathbf{x} \leq \frac{1}{|S'_{\text{dirty}}|}\sum_{(\mathbf{x},y)\in S'_{\text{dirty}}} |\mathbf{w}\cdot\mathbf{x}| \leq \sqrt{\frac{10m\log m}{|S'_{\text{dirty}}|n}}. \tag{2}$$

Because the domain distribution is uniform, the error of $h_{\mathbf{v}}$ is proportional to the angle between $\mathbf{v}$ and $\mathbf{u}$, in particular,

$$\Pr[h_{\mathbf{v}} \neq f] = \frac{1}{\pi}\arctan\left(\frac{||\mathbf{v}-(\mathbf{v}\cdot\mathbf{u})\mathbf{u}||}{\mathbf{u}\cdot\mathbf{v}}\right) \leq (1/\pi)\frac{||\mathbf{v}-(\mathbf{v}\cdot\mathbf{u})\mathbf{u}||}{\mathbf{u}\cdot\mathbf{v}}. \tag{3}$$

We have that $||\mathbf{v}-(\mathbf{v}\cdot\mathbf{u})\mathbf{u}||$ equals

$$||(1-\eta'+\alpha)(\mathbf{v}_{\text{clean}}-(\mathbf{v}_{\text{clean}}\cdot\mathbf{u})\mathbf{u})+\eta'(\mathbf{v}'_{\text{dirty}}-(\mathbf{v}'_{\text{dirty}}\cdot\mathbf{u})\mathbf{u})-\alpha(\mathbf{v}_{\text{del}}-(\mathbf{v}_{\text{del}}\cdot\mathbf{u})\mathbf{u})||$$
$$\leq 2||\mathbf{v}_{\text{clean}}-(\mathbf{v}_{\text{clean}}\cdot\mathbf{u})\mathbf{u}||+\eta'||\mathbf{v}'_{\text{dirty}}||+\alpha||\mathbf{v}_{\text{del}}||$$

where we have used the triangle inequality and the fact that α,η are "small." Lemma 11 lets us bound the first term in the sum by $O(\sqrt{\log(n)/m})$, and the fact that $\mathbf{v}_{\text{del}}$ is an average of vectors of length 1 lets us bound the third by α. For the second term, Equation (2) gives us

$$\eta'\|\mathbf{v}'_{\text{dirty}}\|\leq\sqrt{\frac{10m(\eta')^2\log m}{|S'_{\text{dirty}}|n}}=\sqrt{\frac{10m\eta'\log m}{|S'|n}}\leq\sqrt{\frac{20\eta'\log m}{n}},$$

where for the last equality we used $|S'|\geq m/2$. We thus get

$$||\mathbf{v}-(\mathbf{v}\cdot\mathbf{u})\mathbf{u}||\leq O\left(\sqrt{\log(n)/m}\right)+\sqrt{20\eta'\log(m)/n}+\alpha. \tag{4}$$

Now we consider the denominator of (3). We have

$$\mathbf{u}\cdot\mathbf{v}=(1-\eta'+\alpha)(\mathbf{u}\cdot\mathbf{v}_{\text{clean}})+\eta'\mathbf{u}\cdot\mathbf{v}'_{\text{dirty}}-\alpha\mathbf{u}\cdot\mathbf{v}_{\text{del}}.$$

Similar to the above analysis, we again use Lemma 11 (but now the lower bound $\mathbf{u}\cdot\mathbf{v}\geq\Omega(1/\sqrt{n})$), Equation (2), and the fact that $||\mathbf{v}_{\text{del}}||\leq 1$. Since α and η' are "small," we get that there is an absolute constant c such that $\mathbf{u}\cdot\mathbf{v}\geq c/\sqrt{n}-\sqrt{20\eta'\log(m)/n}-\alpha$. Combining this with (4) and (3), we get

$$\Pr[h_{\mathbf{v}}\neq f] \leq \frac{O\left(\sqrt{\frac{\log n}{m}}\right)+\sqrt{\frac{20\eta'\log m}{n}}+\alpha}{\pi\left(\frac{c}{\sqrt{n}}-\sqrt{\frac{20\eta'\log m}{n}}-\alpha\right)}=O\left(\sqrt{\frac{n\log n}{m}}+\sqrt{\eta'\log m}+\alpha\sqrt{n}\right).$$

■

3.5 Proof of Theorem 1

By Corollary 9, w.h.p. each outlier removal stage removes at most $6n\log m$ clean points.

Since, by Lemma 10, each outlier removal stage removes at least $\frac{4m\log m}{n}$ noisy examples, there must be at most $O(n/(\log m))$ such stages. Consequently the total number of clean examples removed across all stages is $O(n^2)$. Since w.h.p. the initial number of clean examples is at least $3m/4$, this means that the final data set (on which the averaging algorithm is run) contains at least $3m/4-O(n^2)$ clean examples, and hence at least $3m/4-O(n^2)$ examples in total. The condition $m\gg n^2$ means that the number of surviving examples will be at least $m/2$. Consequently the value of α from Lemma 12 after the final outlier removal stage (the ratio of the total number of clean examples deleted, to the total number of surviving examples) is at most $\frac{O(n^2)}{m}$.

The standard Hoeffding bound implies that w.h.p. the actual fraction of noisy examples in the original sample S is at most $\eta+\sqrt{O(\log m)/m}$. It is easy to see that w.h.p. the fraction of dirty examples does not increase (since each stage of outlier removal removes more dirty points than clean points, for a suitably large $\text{poly}(n/\varepsilon)$ value of m), and thus the fraction η' of dirty examples among the remaining examples after the final outlier removal stage is at most $\eta+\sqrt{O(\log m)/m}$.

Applying Lemma 12, for a suitably large value $m=\text{poly}(n/\varepsilon)$, we obtain $\Pr[h_{\mathbf{v}}\neq f]\leq O\left(\sqrt{\eta\log m}\right)$. Rearranging this bound, we can learn to accuracy ε even for $\eta=\Omega(\varepsilon^2/\log(n/\varepsilon))$. This completes the proof of the theorem. ■

4. Isotropic Log-concave Distributions and Malicious Noise

Our algorithm A_{mlc} that works for arbitrary isotropic log-concave distributions uses smooth boosting.

4.1 Smooth Boosting

A boosting algorithm uses a subroutine, called a *weak learner*, that is only guaranteed to output hypotheses with a non-negligible advantage over random guessing.[2] The boosting algorithm that we consider uses a *confidence-rated* weak learner (Schapire and Singer, 1999), which predicts $\{-1,1\}$ labels using continuous values in $[-1,1]$. Formally, the *advantage* of a hypothesis h' with respect to a distribution $\mathcal{D}'$ is defined to be $\mathbf{E}_{x\sim\mathcal{D}'}[h'(x)f(x)]$, where f is the target function.

For the purposes of this paper, a boosting algorithm makes use of the weak learner, an example oracle (possibly corrupted with noise), a desired accuracy ε, and a bound γ on the advantage of the hypothesis output by the weak learner.

A boosting algorithm that is trying to learn an unknown target function f with respect to some distribution $\mathcal{D}$ repeatedly simulates a (possibly noisy) example oracle for f with respect to some other distribution $\mathcal{D}'$ and calls a subroutine A_{weak} with respect to this oracle, receiving a *weak hypothesis*, which maps $\mathbf{R}^n$ to the continuous interval $[-1,1]$.

After repeating this for some number of stages, the boosting algorithm combines the weak hypotheses generated during its various calls to the weak learner into a final aggregate hypothesis which it outputs.

Let $\mathcal{D},\mathcal{D}'$ be two distributions over $\mathbf{R}^n$. We say that $\mathcal{D}'$ is $(1/\varepsilon)$-*smooth with respect to* $\mathcal{D}$ if $\mathcal{D}'(E)\leq(1/\varepsilon)\mathcal{D}(E)$ for all events E.

The following lemma from Servedio (2003) (similar results can be readily found elsewhere, see, e.g., Gavinsky 2003) identifies the properties that we need from a boosting algorithm for our analysis.

Lemma 13 (Servedio 2003) *There is a boosting algorithm B and a polynomial p such that, for any $\varepsilon,\gamma>0$, the following properties hold. When learning a target function f using $\mathrm{EX}_\eta(f,\mathcal{D})$, we have: (a) If each call to A_{weak} takes time t, then B takes time $p(t,1/\gamma,1/\varepsilon)$. (b) The weak learner is always called with an oracle $\mathrm{EX}_{\eta'}(f,\mathcal{D}')$ where $\mathcal{D}'$ is $(1/\varepsilon)$-smooth with respect to $\mathcal{D}$ and $\eta'\leq\eta/\varepsilon$. (c) Suppose that for each distribution $\mathrm{EX}_{\eta'}(f,\mathcal{D}')$ passed to A_{weak} by B, the output of A_{weak} has advantage γ. Then the final output h of B satisfies $\Pr_{x\in\mathcal{D}}[h(x)\neq f(x)]\leq\varepsilon$.*

4.2 The Algorithm

Our algorithm for learning under isotropic log-concave distributions with malicious noise, Algorithm A_{mlc}, applies the smooth booster from Lemma 13 with the following weak learner, which we call Algorithm A_{mlcw}. (The value c_0 is an absolute constant that will emerge from our analysis.)

2. For simplicity of presentation we ignore the confidence parameter of the weak learner in our discussion; this can be handled in an entirely standard way.

Algorithm A_{mlcw}:

1. Draw $m = \mathrm{poly}(n/\varepsilon)$ examples from the oracle $\mathrm{EX}_{\eta'}(f, \mathcal{D}')$.
2. Remove all those examples $(\mathbf{x}, y)$ for which $||\mathbf{x}|| > \sqrt{3n \log m}$.
3. Repeatedly
   - find a direction (unit vector) $\mathbf{w}$ that maximizes $\sum_{(\mathbf{x},y)\in S}(\mathbf{w}\cdot\mathbf{x})^2$ (see Lemma 6)
   - if $\sum_{(\mathbf{x},y)\in S}(\mathbf{w}\cdot\mathbf{x})^2 \leq c_0^2 m \log^2(n/\varepsilon)$ then move on to Step 4, and otherwise
   - remove from S all examples $(\mathbf{x}, y)$ for which $|\mathbf{w}\cdot\mathbf{x}| > c_0 \log(n/\varepsilon)$, and iterate again.
4. Let $\mathbf{v} = \frac{1}{|S|}\sum_{(\mathbf{x},y)\in S} y\mathbf{x}$, and return h defined by $h(\mathbf{x}) = \frac{\mathbf{v}\cdot\mathbf{x}}{3n\log m}$, if $|\mathbf{v}\cdot\mathbf{x}| \leq 3n\log m$, and $h(\mathbf{x}) = \mathrm{sgn}(\mathbf{v}\cdot\mathbf{x})$ otherwise.

4.3 The Key Claim: The Weak Learner is Effective

Our main task is to analyze the weak learner. Given the following Lemma, Theorem 2 will be an immediate consequence of Lemma 13.

Lemma 14 *Suppose Algorithm A_{mlcw} is run using $\mathrm{EX}_{\eta'}(f, \mathcal{D}')$ where f is an origin-centered halfspace, $\mathcal{D}'$ is $(1/\varepsilon)$-smooth w.r.t. an isotropic log-concave distribution $\mathcal{D}$, $\eta' \leq \eta/\varepsilon$, and $\eta \leq \Omega(\varepsilon^3/\log^2(n/\varepsilon))$. Then w.h.p. the hypothesis h returned by A_{mlcw} has advantage $\Omega\left(\frac{\varepsilon^2}{n\log(n/\varepsilon)}\right)$.*

Before proving Lemma 14, we need to prove some uniformity results on non-noisy examples drawn from an isotropic, log-concave distribution. This will enable us to use outlier removal and averaging to find a weak learner.

4.4 Lemmas in Support of Lemma 14

In this section, let us consider a single call to the weak learner with an oracle $EX_{\eta'}(f, \mathcal{D}')$ where $\mathcal{D}'$ is $(1/\varepsilon)$-smooth with respect to an isotropic log-concave distribution $\mathcal{D}$ and $\eta' \leq \eta/\varepsilon$. Our analysis will follow the same basic steps as Section 3.

A preliminary observation is that w.h.p. all clean examples drawn in Step 1 of Algorithm A_{mlcw} have $\|\mathbf{x}\| \leq \sqrt{3n\log m}$; indeed, for any given draw of $\mathbf{x}$ from $\mathcal{D}'$, the probability that $\|\mathbf{x}\| > \sqrt{3n\log m}$ is at most $\frac{e}{\varepsilon m^3}$ by Lemma 5 together with the fact that $\mathcal{D}'$ is $1/\varepsilon$-smooth with respect to an i.l.c. distribution. Therefore, w.h.p., only noisy examples are removed in Step 2 of the algorithm, and we shall assume that the distributions $\mathcal{D}$ and $\mathcal{D}'$ are in fact supported entirely on $\{\mathbf{x} : \|\mathbf{x}\| \leq \sqrt{3n\log m}\}$. This assumption affects us in two ways: first, it costs us an additional $\frac{e}{\varepsilon m^2}$ in the failure probability analysis below (which is not a problem and is in fact swallowed up by our "w.h.p." notation). Second, it means that the overall $1-\varepsilon$ accuracy bound we establish for the entire learning algorithm may be slightly worse than the true value. This is because our final hypothesis may always be wrong on the examples $\mathbf{x}$ that have $\|\mathbf{x}\| > \sqrt{3n\log m}$ and are ignored in our analysis; however such examples have probability mass at most $\frac{e}{m^3}$ under the isotropic log-concave distribution $\mathcal{D}$ (again by Lemma 5), and thus the additional accuracy cost is at most $\frac{e}{m^3}$. Since $\varepsilon \gg \frac{e}{m^3}$, this does not affect the overall correctness of our analysis. Note that a consequence of this assumption is that we can just take $h(\mathbf{x}) = \frac{\mathbf{v}\cdot\mathbf{x}}{3n\log m}$.

The remarks about high-probability statements and failure probabilities from Section 3.1 apply here as well, and as in Section 3 we write "w.h.p." as shorthand for "with probability $1 - 1/\mathrm{poly}(n/\varepsilon)$."

We first show that the variance of $\mathcal{D}'$ in every direction is not too large:

Lemma 15 *For any $\mathbf{a} \in \mathbb{S}^{n-1}$ we have $E_{\mathbf{x}\sim\mathcal{D}'}[(\mathbf{a}\cdot\mathbf{x})^2] = O(\log^2(1/\varepsilon))$.*

Proof. For $\mathbf{x}$ chosen according to $\mathcal{D}$, the distribution of $\mathbf{a}\cdot\mathbf{x}$ is a unit variance log-concave distribution by Lemma 4. Thus, for any positive integer k,

$$\begin{aligned} E_{\mathbf{x}\sim\mathcal{D}'}[(\mathbf{a}\cdot\mathbf{x})^2] &\leq k^2 + \sum_{i=k}^{\infty}(i+1)^2 \Pr_{\mathbf{x}\sim\mathcal{D}'}[|\mathbf{a}\cdot\mathbf{x}| \in (i,i+1]] \\ &\leq k^2 + \sum_{i=k}^{\infty}(i+1)^2(1/\varepsilon) \Pr_{\mathbf{x}\sim\mathcal{D}}[|\mathbf{a}\cdot\mathbf{x}| \in (i,i+1]] \\ &\leq k^2 + (1/\varepsilon)\sum_{i=k}^{\infty}(i+1)^2 \Pr_{\mathbf{x}\sim\mathcal{D}}[|\mathbf{a}\cdot\mathbf{x}| > i] \\ &\leq k^2 + (1/\varepsilon)\sum_{i=k}^{\infty}(i+1)^2 e^{-i+1} \leq k^2 + (1/\varepsilon)\cdot\Theta(k^2e^{-k}) \end{aligned}$$

where the first inequality in the last line uses Lemmas 4 and 5.

Setting $k = \ln(1/\varepsilon)$ completes the proof. ∎

The following anticoncentration bound will be useful for proving that clean examples drawn from $\mathcal{D}'$ tend to be classified correctly with a large margin.

Lemma 16 *Let $\mathbf{u} \in \mathbb{S}^{n-1}$. Then*

$$\mathbf{E}_{\mathbf{x}\sim\mathcal{D}'}[|\mathbf{u}\cdot\mathbf{x}|] \geq \varepsilon/8.$$

Proof. Clearly

$$\mathbf{E}_{\mathbf{x}\sim\mathcal{D}'}[|\mathbf{u}\cdot\mathbf{x}|] \geq (\varepsilon/4)\Pr_{\mathbf{x}\sim\mathcal{D}'}[|\mathbf{u}\cdot\mathbf{x}| > \varepsilon/4].$$

But by Lemma 5,

$$\Pr_{\mathbf{x}\sim\mathcal{D}'}[|\mathbf{u}\cdot\mathbf{x}| \leq \varepsilon/4] \leq \frac{1}{\varepsilon}\Pr_{\mathbf{x}\sim\mathcal{D}}[|\mathbf{u}\cdot\mathbf{x}| \leq \varepsilon/4] \leq \frac{\varepsilon/2}{\varepsilon} = 1/2.$$

∎

The next two lemmas are isotropic log-concave analogues of the uniform distribution Lemmas 7 and 8 respectively. The first one says that w.h.p. no direction $\mathbf{a}$ has much more variance than the expected variance in any direction:

Lemma 17 *W.h.p. over a random draw of ℓ clean examples S_{clean} from $\mathcal{D}'$, we have*

$$\max_{\mathbf{a}\in\mathbb{S}^{n-1}}\left\{\frac{1}{\ell}\sum_{(\mathbf{x},y)\in S_{\text{clean}}}(\mathbf{a}\cdot\mathbf{x})^2\right\} \leq O(1)\left(\log^2\frac{1}{\varepsilon} + \frac{n^{3/2}\log^2\ell}{\sqrt{\ell}}\right).$$

Proof. By Lemma 15, for any $\mathbf{a} \in \mathbb{S}^{n-1}$ we have

$$\mathbf{E}_{\mathbf{x}\sim\mathcal{D}'}[(\mathbf{a}\cdot\mathbf{x})^2] = \Theta(\log^2(1/\varepsilon)).$$

Since as remarked earlier we may assume $\mathcal{D}'$ is supported on $\{\mathbf{x} : \|\mathbf{x}\| \leq \sqrt{3n\log m}\}$, we may apply Lemmas 25 and 27 (see Appendix A) with functions $f_{\mathbf{a}}$ defined by $f_{\mathbf{a}} = \frac{(\mathbf{a}\cdot\mathbf{x})^2}{3n\log m}$. This completes the proof. ∎

The second lemma says that for a sufficiently large clean data set, w.h.p. no direction has too many examples lying too far out in that direction:

Lemma 18 *For any $\beta > 0$ and $\kappa > 1$, if S_{clean} is a set of $\ell \geq \frac{O(1)\varepsilon e^{\beta}\left(n\ln\left(e^{-\beta}/\varepsilon\right)+\log m\right)}{(1+\kappa)\ln(1+\kappa)}$ clean examples drawn from $\mathcal{D}'$, then w.h.p. we have*

$$\max_{\mathbf{a}\in\mathbb{S}^{n-1}} \frac{1}{\ell}|\{\mathbf{x}\in S_{\text{clean}} : |\mathbf{a}\cdot\mathbf{x}| > \beta\}| \;\leq\; (1+\kappa)\left(\frac{1}{\varepsilon}\right)e^{-\beta+1}.$$

Proof. Lemma 5 implies that for the original isotropic log-concave distribution $\mathcal{D}$, we have

$$\Pr_{\mathbf{x}\sim\mathcal{D}}[|\mathbf{a}\cdot\mathbf{x}| > \beta] \leq e^{-\beta+1}.$$

Since $\mathcal{D}'$ is $(1/\varepsilon)$-smooth with respect to $\mathcal{D}$, this implies that

$$\Pr_{\mathbf{x}\sim\mathcal{D}'}[|\mathbf{a}\cdot\mathbf{x}| > \beta] \leq \frac{e^{-\beta+1}}{\varepsilon}. \tag{5}$$

In the proof of Lemma 8, we observed that the VC-dimension of

$$\{\{\mathbf{x} : |\mathbf{a}\cdot\mathbf{x}| > \beta\} \;:\; \mathbf{a}\in\mathbf{R}^n, \beta\in\mathbf{R}\}$$

is $O(n)$, so applying Lemma 28 with (5) completes the proof of this lemma. ∎

The following is an isotropic log-concave analogue of Corollary 9, establishing that not too many clean examples are removed in the outlier removal step:

Corollary 19 *W.h.p. over the random draw of the m-element sample S from $EX_{\eta'}(f,\mathcal{D}')$, the number of clean examples removed during any one execution of the outlier removal step (final substep of Step 2) in Algorithm A_{mlcw} is at most $6m\varepsilon^3/n^4$.*

Proof. Since the true noise rate η is assumed sufficiently small, the value $\eta' \leq \eta/\varepsilon$ is at most $\varepsilon/4$, and thus w.h.p. the number ℓ of clean examples in S is at least (say) $m/2$. We would like to apply Lemma 18 with $\kappa = (n/\varepsilon)^{c_0-4}$ and $\beta = c_0\log(n/\varepsilon)$, and we may do this since we have

$$\frac{O(1)\varepsilon e^{\beta}\left(n\ln\left(\varepsilon e^{\beta}\right)+\log m\right)}{(1+\kappa)\ln(1+\kappa)} \leq \frac{O(1)\varepsilon(n/\varepsilon)^{c_0}n\log m}{(n/\varepsilon)^{c_0-4}\log m} \leq O(1)n^5/\varepsilon^3 \ll \frac{m}{2} \leq \ell$$

for a suitable fixed $\text{poly}(n/\varepsilon)$ choice of m. Since clean points are only removed if they have $|\mathbf{a}\cdot\mathbf{x}| \geq \beta$, Lemma 18 gives us that the number of clean points removed is at most

$$m(1+\kappa)\cdot\frac{1}{\varepsilon}e^{-\beta+1} \leq m\frac{(6/\varepsilon)(n/\varepsilon)^{c_0-4}}{(n/\varepsilon)^{c_0}} \leq 6m\varepsilon^3/n^4.$$

∎

The following lemma is an analogue of Lemma 10; it lower bounds the number of dirty examples that are removed in the outlier removal step.

Lemma 20 *W.h.p. over the random draw of S, any time Algorithm A_{mlcw} executes the outlier removal step it removes at least $\frac{m}{O(n)}$ noisy examples.*

Proof. Since our ultimate goal is only to prove that the algorithm succeeds for some η which is $o(\varepsilon)$, we may assume without loss of generality that the original noise rate η is less than $\varepsilon/4$. This means that $\eta' < 1/4$, and consequently a Chernoff bound gives that w.h.p. the fraction $\widehat{\eta}'$ of noisy examples in S at the beginning of the weak learner's training is at most $1/2$. And Lemma 17 implies that for a sufficiently large polynomial choice of m, we have that w.h.p. for all $\mathbf{a} \in \mathbb{S}^{n-1}$, the following holds for all the clean examples in the data before any examples were removed:

$$\sum_{(\mathbf{x},y)\in S_{\mathrm{clean}}} (\mathbf{a}\cdot\mathbf{x})^2 \leq cm\log^2(1/\varepsilon) \tag{6}$$

where c is an absolute constant. We say that a random sample that meets all these requirements is "reasonable." We now set the constant c_0 that is used in the specification of A_{mlcw} to be $\sqrt{2(c+1)}$. We will now show that, for any reasonable sample S, the number of noisy examples removed during the first execution of the outlier removal step of A_{mlcw} is at least $\frac{m}{O(n)}$.

If we remove examples using direction $\mathbf{w}$ then it means $\sum_{x\in S}(\mathbf{w}\cdot\mathbf{x})^2 \geq c_0^2 m\log^2(n/\varepsilon)$. Since S is reasonable, by (6) the contribution to the sum from the clean examples that have survived until this point is at most $cm\log^2(1/\varepsilon)$ so we must have

$$\sum_{(\mathbf{x},y)\in S_{\mathrm{dirty}}} (\mathbf{w}\cdot\mathbf{x})^2 \geq (c_0^2 - c)m\log^2(n/\varepsilon).$$

Let $S_{\mathrm{dirty}} = N \cup F$ where N is the examples $(\mathbf{x},y)$ for which $\mathbf{x}$ satisfies $(\mathbf{w}\cdot\mathbf{x})^2 \leq c_0^2\log^2(n/\varepsilon)$ and F is the other points. We have

$$\sum_{(\mathbf{x},y)\in N} (\mathbf{w}\cdot\mathbf{x})^2 \leq c_0^2\widehat{\eta}' m\log^2(n/\varepsilon).$$

and so, since $||\mathbf{x}|| \leq \sqrt{3n\log m}$ implies that $(\mathbf{w}\cdot\mathbf{x})^2 \leq 3n\log m$ for all unit length $\mathbf{w}$, we have

$$\begin{aligned}
|F| &\geq \sum_{(\mathbf{x},y)\in F} \frac{(\mathbf{w}\cdot\mathbf{x})^2}{3n\log m} = \sum_{(\mathbf{x},y)\in S_{\mathrm{dirty}}} \frac{(\mathbf{w}\cdot\mathbf{x})^2}{3n\log m} - \sum_{(\mathbf{x},y)\in N} \frac{(\mathbf{w}\cdot\mathbf{x})^2}{3n\log m} \\
&\geq \frac{(c_0^2 - c)m\log^2(n/\varepsilon) - c_0^2\widehat{\eta}' m\log^2(n/\varepsilon)}{3n\log m} \\
&\geq \frac{m\log^2(n/\varepsilon)}{3n\log m} \\
&\geq \frac{m}{O(n)}
\end{aligned}$$

where the next-to-last inequality uses $\eta' \leq 1/2$ and $c_0 = \sqrt{2(c+1)}$, and the final one uses $m = O(\mathrm{poly}(n/\varepsilon))$. The points in F are precisely the ones that are removed, and thus the lemma is proved. ∎

4.5 Proof of Lemma 14

We first note that Lemma 20 implies that w.h.p. the weak learner must terminate after at most $O(n)$ iterations of outlier removal.

Let $\mathbf{u}$ be the unit length normal vector of the separating halfspace for the target function f. Recall that we have assumed without loss of generality that $||\mathbf{x}|| \leq \sqrt{3n\log m}$ for all $\mathbf{x}$ in the training set, so that $||\mathbf{v}|| \leq \sqrt{3n\log m}$, and thus the advantage of h with respect to $\mathcal{D}'$ can be expressed as

$$\mathbf{E}_{\mathbf{x}\sim\mathcal{D}'}[h(\mathbf{x})f(\mathbf{x})] = \frac{\mathbf{E}_{\mathbf{x}\sim\mathcal{D}'}[(\mathbf{v}\cdot\mathbf{x})f(\mathbf{x})]}{3n\log m} \tag{7}$$

and so we shall work on lower bounding $\mathbf{E}_{\mathbf{x}\sim\mathcal{D}'}[(\mathbf{v}\cdot\mathbf{x})f(\mathbf{x})]$.

As in the proof of Lemma 12, let

- S_{clean} be all of the clean examples in the initial sample S, and S'_{clean} be those that are not removed in any stage of outlier removal;
- S_{dirty} be all of the dirty examples in the initial sample S, and S'_{dirty} be those that are not removed in any stage of outlier removal;
- $\eta' = \frac{|S'_{\text{dirty}}|}{|S'_{\text{clean}}\cup S'_{\text{dirty}}|}$, that is, the noise rate among the examples that survive until the end of training of the weak learner, and
- $\alpha = \frac{|S_{\text{clean}} - S'_{\text{clean}}|}{|S'_{\text{clean}}\cup S'_{\text{dirty}}|}$, the ratio of the number of clean points that were erroneously removed to the size of the final surviving data set.

As before we write S' for $S'_{\text{clean}} \cup S'_{\text{dirty}}$. Also as before, let $\mathbf{v}_{\text{clean}}$ be the average of *all* the clean examples, $\mathbf{v}'_{\text{dirty}}$ be the average of the dirty (noisy) examples that were not deleted, and $\mathbf{v}_{\text{del}}$ be the average of the clean examples that were deleted. Then arguing exactly as before, we have

$$\mathbf{v} = (1-\eta'+\alpha)\mathbf{v}_{\text{clean}} + \eta'\mathbf{v}'_{\text{dirty}} - \alpha\mathbf{v}_{\text{del}}.$$

The expectation of $\mathbf{v}_{\text{clean}}$ will play a special role in the analysis:

$$\mathbf{v}^*_{\text{clean}} \stackrel{def}{=} \mathbf{E}_{\mathbf{x}\sim\mathcal{D}'}[f(\mathbf{x})\mathbf{x}].$$

Once again, we will demonstrate the limited effect of $\mathbf{v}'_{\text{dirty}}$ by bounding its length. This time, the outlier removal enforces the fact that, for any $\mathbf{w} \in \mathbb{S}^{n-1}$, we have

$$\sum_{(\mathbf{x},y)\in S} (\mathbf{w}\cdot\mathbf{x})^2 \leq c_0^2 m\log^2(n/\varepsilon).$$

Applying this for the unit vector $\mathbf{w}$ in the direction of $\mathbf{v}'_{\text{dirty}}$ as was done in Lemma 12, this implies

$$\|\mathbf{v}'_{\text{dirty}}\| \leq c_0\log(n/\varepsilon)\sqrt{\frac{m}{|S'_{\text{dirty}}|}}.$$

Next, let us apply this to bound an expression that captures the average harm done by $\mathbf{v}'_{\text{dirty}}$.

$$\begin{aligned} |\mathbf{E}_{\mathbf{x}\sim\mathcal{D}'}[f(\mathbf{x})(\mathbf{v}'_{\text{dirty}}\cdot\mathbf{x})]| &= |\mathbf{v}'_{\text{dirty}}\cdot\mathbf{v}^*_{\text{clean}}| \\ &\leq c_0\log(n/\varepsilon)\sqrt{\frac{m}{|S'_{\text{dirty}}|}}||\mathbf{v}^*_{\text{clean}}||. \end{aligned} \tag{8}$$

To show that $\mathbf{v}_{\text{clean}}$ plays a relatively large role, it is helpful to lower bound the length of $\mathbf{v}^*_{\text{clean}}$. We do this by lower bounding the length of its projection onto the unit normal vector $\mathbf{u}$ of the target as follows:

$$\mathbf{v}^*_{\text{clean}}\cdot\mathbf{u} = \mathbf{E}_{\mathbf{x}\sim\mathcal{D}'}[(f(\mathbf{x})\mathbf{x})\cdot\mathbf{u}] = \mathbf{E}_{\mathbf{x}\sim\mathcal{D}'}[\text{sgn}(\mathbf{u}\cdot\mathbf{x})(\mathbf{x}\cdot\mathbf{u})] = \mathbf{E}_{\mathbf{x}\sim\mathcal{D}'}[|\mathbf{x}\cdot\mathbf{u}|] \geq \varepsilon/8,$$

by Lemma 16. Since $\mathbf{u}$ is unit length, this implies

$$||\mathbf{v}^*_{\text{clean}}|| \geq \varepsilon/8. \tag{9}$$

Armed with this bound, we can now lower bound the benefit imparted by $\mathbf{v}_{\text{clean}}$:

$$\begin{aligned} \mathbf{E}_{\mathbf{z}\sim\mathcal{D}'}[f(\mathbf{z})(\mathbf{v}_{\text{clean}}\cdot\mathbf{z})] &= \frac{1}{S_{\text{clean}}}\sum_{(\mathbf{x},y)\in S_{\text{clean}}}\mathbf{E}_{\mathbf{z}\sim\mathcal{D}'}[yf(\mathbf{z})(\mathbf{x}\cdot\mathbf{z})] \\ &= \frac{1}{S_{\text{clean}}}\sum_{(\mathbf{x},y)\in S_{\text{clean}}}(y\mathbf{x})\cdot\mathbf{v}^*_{\text{clean}}. \end{aligned}$$

Since $\mathbf{E}[(y\mathbf{x})\cdot\mathbf{v}^*_{\text{clean}}] = ||\mathbf{v}^*_{\text{clean}}||^2$, and $(y\mathbf{x})\cdot\mathbf{v}^*_{\text{clean}} \in [-3n\log m, 3n\log m]$, a Hoeffding bound implies that w.h.p.

$$\mathbf{E}_{\mathbf{z}\sim\mathcal{D}'}[f(\mathbf{z})(\mathbf{v}_{\text{clean}}\cdot\mathbf{z})] \geq ||\mathbf{v}^*_{\text{clean}}||^2 - O(n\log^{3/2} m)/\sqrt{|S_{\text{clean}}|}.$$

Since the noise rate η' is at most η/ε and η certainly less than $\varepsilon/4$ as discussed above, another Hoeffding bound gives that w.h.p. $|S_{\text{clean}}|$ is at least $m/2$; thus for a suitably large polynomial choice of m, using (9) we have

$$\mathbf{E}_{\mathbf{z}\sim\mathcal{D}'}[f(\mathbf{z})(\mathbf{v}_{\text{clean}}\cdot\mathbf{z})] \geq ||\mathbf{v}^*_{\text{clean}}||^2 - O(n\log^{3/2} m)/\sqrt{m/2} \geq \frac{||\mathbf{v}^*_{\text{clean}}||^2}{2}. \tag{10}$$

Now we are ready to put our bounds together and lower bound the advantage of $\mathbf{v}$. We have

$$\begin{aligned} \mathbf{E}_{\mathbf{x}\sim\mathcal{D}'}[f(\mathbf{x})(\mathbf{v}\cdot\mathbf{x})] &= (1-\eta'+\alpha)\mathbf{E}[f(\mathbf{x})(\mathbf{v}_{\text{clean}}\cdot\mathbf{x})] \\ &\quad +\eta'\mathbf{E}[f(\mathbf{x})(\mathbf{v}'_{\text{dirty}}\cdot\mathbf{x})] - \alpha\mathbf{E}[f(\mathbf{x})(\mathbf{v}_{\text{del}}\cdot\mathbf{x})]. \end{aligned}$$

We bound each of the three contributions in turn. First, using $1-\eta' \geq 1/2$ and (10), we have $(1-\eta'+\alpha)\mathbf{E}[f(\mathbf{x})(\mathbf{v}_{\text{clean}}\cdot\mathbf{x})] \geq \frac{||\mathbf{v}^*_{\text{clean}}||^2}{4}$.

Next, by (8), we have

$$|\eta'\mathbf{E}_{\mathbf{x}\sim\mathcal{D}'}[f(\mathbf{x})(\mathbf{v}'_{\text{dirty}}\cdot\mathbf{x})]| \leq c_0\log(n/\varepsilon)\sqrt{2\eta'}||\mathbf{v}^*_{\text{clean}}||.$$

Since we may assume that $\eta \leq c'\varepsilon^3/\log^2(n/\varepsilon)$ for as small a fixed constant c' as we like (recall the overall bound of Theorem 2), we get

$$c_0\log(n/\varepsilon)\sqrt{2\eta'}||\mathbf{v}^*_{\text{clean}}|| \leq (\varepsilon/64)||\mathbf{v}^*_{\text{clean}}||$$

(for a suitably small constant choice of c'), and this is less than $\frac{||\mathbf{v}^*_{\text{clean}}||^2}{8}$ since $||\mathbf{v}^*_{\text{clean}}|| \geq \varepsilon/8$.

Finally Corollary 19, together with the fact that there are at most $O(n)$ iterations of outlier removal and the final surviving data set is of size at least $m/4$, gives us that $\alpha \leq \frac{O(n)(6m\varepsilon^3/n^4)}{m/4}$, which (recalling that both $\mathbf{v}_{\text{del}}$ and all $\mathbf{x}$ in the support of $\mathcal{D}'$ have norm at most $\sqrt{3n\log m}$) means that $|\alpha \mathbf{E}[f(\mathbf{x})(\mathbf{v}_{\text{del}} \cdot \mathbf{x})]| = o(\varepsilon^2)$.

Combining all these bounds, we get

$$\mathbf{E}_{\mathbf{x}\sim\mathcal{D}'}[f(\mathbf{x})(\mathbf{v}\cdot\mathbf{x})] \geq \frac{||\mathbf{v}^*_{\text{clean}}||^2}{4} - \frac{||\mathbf{v}^*_{\text{clean}}||^2}{8} - o(\varepsilon^2) \geq \frac{\varepsilon^2}{1024}$$

by (9). Together with (7), the proof of Lemma 14 is completed.

5. Learning Under Isotropic Log-concave Distributions with Adversarial Label Noise

In this section, we consider the model where an adversary can change some class labels, but cannot otherwise modify examples.

5.1 The Model

We now define the model of learning with adversarial label noise under isotropic log-concave distributions. In this model the learning algorithm has access to an oracle that provides independent random examples drawn according to a fixed distribution P on $\mathbf{R}^n \times \{-1,1\}$, where

- the marginal distribution over $\mathbf{R}^n$ is isotropic log-concave, and
- there is a halfspace f such that $\Pr_{(\mathbf{x},y)\sim P}[f(\mathbf{x}) \neq y] = \eta$.

The parameter η is the *noise rate*. As usual, the goal of the learner is to output a hypothesis h such that $\Pr_{(\mathbf{x},y)\sim\mathcal{D}}[h(\mathbf{x}) \neq y] \leq \varepsilon$; if an algorithm achieves this goal, we say it learns to accuracy $1-\varepsilon$ in the presence of adversarial label noise at rate η.

5.2 The Algorithm

Like the algorithm A_{mlc} considered in the last section, the algorithm A_{alc} studied in this section applies the smooth boosting algorithm of Lemma 13 to a weak learner that performs averaging. The weak learner A_{alcw} behaves as follows:

Algorithm A_{alcw}:

1. Draw a set S of m examples according to P' (the oracle for a modified distribution provided by the boosting algorithm).
2. Remove all examples $(\mathbf{x},y)$ such that $||\mathbf{x}|| > \sqrt{3n\log m}$ from S.
3. Let $\mathbf{v} = \frac{1}{|S|}\sum_{(\mathbf{x},y)\in S} y\mathbf{x}$. Return the confidence-rated classifier h defined by $h(\mathbf{x}) = \frac{\mathbf{v}\cdot\mathbf{x}}{3n\log m}$ if $|\mathbf{v}\cdot\mathbf{x}| \leq 3n\log m$, and $h(\mathbf{x}) = \text{sgn}(\mathbf{v}\cdot\mathbf{x})$ otherwise.

5.3 Claim About the Weak Learner

As in the previous section, the heart of our analysis will be to analyze the weak learner. We omit discussing the application of the smooth boosting algorithm here, as it is nearly identical to Section 4.

Lemma 21 *Suppose Algorithm A_{alcw} is run using P' as the source of labeled examples, where P' is a distribution that is $(1/\varepsilon)$-smooth with respect to a joint distribution P on $\mathbf{R}^n \times \{-1,1\}$ whose marginal $\mathcal{D}'$ on $\mathbf{R}^n$ is isotropic and log-concave. Further, assume there exists a linear threshold function f such that $\Pr_{(\mathbf{x},y)\sim P'}[f(\mathbf{x}) \neq y] \leq \eta/\varepsilon$ and $\eta \leq \Omega(\frac{\varepsilon^3}{\log(1/\varepsilon)})$. Then with high probability, A_{alcw} outputs a hypothesis with advantage $\Omega(\frac{\varepsilon^2}{n\log(n/\varepsilon)})$.*

5.4 Lemmas in Support of Lemma 21

During this section, let us focus our attention on a single call to the weak learner. Let P' be a distribution as in Lemma 21 and let $\mathcal{D}'$ be the marginal on $\mathbf{R}^n$. We observe that since P' is $(1/\varepsilon)$-smooth with respect to P, the marginal $\mathcal{D}'$ of P' is $(1/\varepsilon)$-smooth with respect to the marginal $\mathcal{D}$ of P.

As in Section 4, we may assume that the support of $\mathcal{D}'$ lies entirely on $\mathbf{x}$ such that $||\mathbf{x}|| \leq \sqrt{3n\log m}$ (this negligibly affects the final bounds obtained in our analyses).

The following technical lemma will be used to limit the extent to which the distribution P' can concentrate a lot of noise in one direction.

Lemma 22 *Let E be any event with positive probability under $\mathcal{D}'$, and let $\kappa = \mathcal{D}'(E)$. For any unit length $\mathbf{a} \in \mathbf{R}^n$, $\mathbf{E}_{\mathbf{x}\sim\mathcal{D}'}[|\mathbf{a}\cdot\mathbf{x}| \mid E] = O\left(\log \frac{1}{\kappa\varepsilon}\right)$.*

Proof. Let β be such that $\Pr_{\mathbf{x}\sim\mathcal{D}'}[|\mathbf{a}\cdot\mathbf{x}| > \beta] = \kappa$. By Lemmas 4 and 5, together with the fact that $\mathcal{D}'$ is $(1/\varepsilon)$ smooth with respect to $\mathcal{D}$, we have

$$\kappa \leq \frac{1}{\varepsilon} e^{-\beta+1}$$

which implies $\beta \leq 1 + \ln\left(\frac{1}{\varepsilon\kappa}\right)$.

Let F be the event that $|\mathbf{a}\cdot\mathbf{x}| > \beta$. We will show that $\mathbf{E}_{\mathbf{x}\sim\mathcal{D}'}[|\mathbf{a}\cdot\mathbf{x}| \mid E] \leq \mathbf{E}_{\mathbf{x}\sim\mathcal{D}'}[|\mathbf{a}\cdot\mathbf{x}| \mid F]$, and then bound $\mathbf{E}_{\mathbf{x}\sim\mathcal{D}'}[|\mathbf{a}\cdot\mathbf{x}| \mid F]$. If $\Pr[(E-F)\cup(F-E)] = 0$, then, obviously, $\mathbf{E}_{\mathbf{x}\sim\mathcal{D}'}[|\mathbf{a}\cdot\mathbf{x}| \mid E] = \mathbf{E}_{\mathbf{x}\sim\mathcal{D}'}[|\mathbf{a}\cdot\mathbf{x}| \mid F]$. Suppose $\Pr[(E-F)\cup(F-E)] > 0$. Then

$$\begin{aligned}
&\mathbf{E}_{\mathbf{x}\sim\mathcal{D}'}[|\mathbf{a}\cdot\mathbf{x}| \mid E] \\
&= \mathbf{E}_{\mathbf{x}\sim\mathcal{D}'}[|\mathbf{a}\cdot\mathbf{x}| \mid E\cap F]\Pr[E\cap F] + \mathbf{E}_{\mathbf{x}\sim\mathcal{D}'}[|\mathbf{a}\cdot\mathbf{x}| \mid E-F]\Pr[E-F] \\
&= \mathbf{E}_{\mathbf{x}\sim\mathcal{D}'}[|\mathbf{a}\cdot\mathbf{x}| \mid E\cap F]\Pr[E\cap F] + \mathbf{E}_{\mathbf{x}\sim\mathcal{D}'}[|\mathbf{a}\cdot\mathbf{x}| \mid E-F]\Pr[F-E] \\
&\qquad\qquad\qquad\qquad\qquad\qquad \text{(because } \Pr[E] = \Pr[F]\text{)} \\
&< \mathbf{E}_{\mathbf{x}\sim\mathcal{D}'}[|\mathbf{a}\cdot\mathbf{x}| \mid E\cap F]\Pr[E\cap F] + \mathbf{E}_{\mathbf{x}\sim\mathcal{D}'}[|\mathbf{a}\cdot\mathbf{x}| \mid F-E]\Pr[F-E],
\end{aligned}$$

because for every $\mathbf{x} \in E-F$ and every $\mathbf{x}' \in F-E$,

$$|\mathbf{a}\cdot\mathbf{x}| \leq \beta < |\mathbf{a}\cdot\mathbf{x}'|.$$

But

$$\mathbf{E}_{\mathbf{x}\sim\mathcal{D}'}[|\mathbf{a}\cdot\mathbf{x}| \mid E\cap F]\Pr[E\cap F] + \mathbf{E}_{\mathbf{x}\sim\mathcal{D}'}[|\mathbf{a}\cdot\mathbf{x}| \mid F-E]\Pr[F-E] = \mathbf{E}_{\mathbf{x}\sim\mathcal{D}'}[|\mathbf{a}\cdot\mathbf{x}| \mid F],$$

so

$$\mathbf{E}_{\mathbf{x}\sim\mathcal{D}'}[|\mathbf{a}\cdot\mathbf{x}| \mid E] < \mathbf{E}_{\mathbf{x}\sim\mathcal{D}'}[|\mathbf{a}\cdot\mathbf{x}| \mid F]. \tag{11}$$

Now, setting $b = \lfloor \beta \rfloor$, we have

$$\begin{aligned}
\mathbf{E}_{\mathbf{x}\sim\mathcal{D}'}[|\mathbf{a}\cdot\mathbf{x}| \mid F] &\leq \frac{1}{\mathcal{D}'(F)} \sum_{i=b} (i+1) \Pr_{\mathbf{x}\sim\mathcal{D}'}[|\mathbf{a}\cdot\mathbf{x}| \in (i, i+1]] \\
&\leq \frac{1}{\mathcal{D}'(F)} \sum_{i=b} (i+1) e^{-i+1} \\
&= \frac{1}{\mathcal{D}'(F)} \left(O\left(\frac{e^{-b} b}{\varepsilon} \right) \right) \\
&= O(b),
\end{aligned}$$

since $\mathcal{D}'(F) = \Theta(e^{-b}/\varepsilon)$. Combining with (11) completes the proof. ∎

5.5 Proof of Lemma 21

Fix some halfspace f such that $\Pr_{(\mathbf{x},y)\sim P}[f(\mathbf{x}) \neq y] = \eta$, and let $\mathbf{u}$ be the unit normal vector of its separating hyperplane.

Let P' be the joint distribution given to A_{alcw} and let $\mathcal{D}'$ be its marginal on $\mathbf{R}^n$. As noted in the previous subsection, $\mathcal{D}'$ is $(1/\varepsilon)$-smooth with respect to the original marginal distribution $\mathcal{D}$ of P.

First, we bound the advantage of the hypothesis h with respect to P' in terms of the tendency of h to agree with the best linear function f:

$$\mathbf{E}_{(\mathbf{x},y)\sim P'}[h(\mathbf{x})y] \geq \mathbf{E}_{(\mathbf{x},y)\sim P'}[h(\mathbf{x})f(\mathbf{x})] - \eta = \mathbf{E}_{\mathbf{x}\sim\mathcal{D}'}[h(\mathbf{x})f(\mathbf{x})] - \eta. \tag{12}$$

Furthermore, as we have assumed without loss of generality that $||\mathbf{x}|| \leq \sqrt{3n\log m}$ for all examples in the training set, and therefore that $||\mathbf{v}|| \leq \sqrt{3n\log m}$, we have

$$\mathbf{E}_{\mathbf{x}\sim\mathcal{D}'}[h(\mathbf{x})f(\mathbf{x})] = \mathbf{E}_{\mathbf{x}\sim\mathcal{D}'}\left[\frac{f(\mathbf{x})(\mathbf{x}\cdot\mathbf{v})}{3n\log m} \right] \tag{13}$$

so we will work on bounding $\mathbf{E}_{\mathbf{x}\sim\mathcal{D}'}[f(\mathbf{x})(\mathbf{x}\cdot\mathbf{v})]$.

Let P'_{clean} be obtained by conditioning a random draw $(\mathbf{x}, y)$ from P' on the event that $f(\mathbf{x}) = y$. Define P'_{dirty} analogously, and let $\mathcal{D}'_{\text{clean}}$ and $\mathcal{D}'_{\text{dirty}}$ be the corresponding marginals on $\mathbf{R}^n$. Let

$$\begin{aligned}
\mathbf{v}^*_{\text{dirty}} &= \mathbf{E}_{(\mathbf{x},y)\sim P'_{\text{dirty}}}[y\mathbf{x}] \\
\mathbf{v}^*_{\text{correct}} &= \mathbf{E}_{\mathbf{x}\sim\mathcal{D}'}[f(\mathbf{x})\mathbf{x}].
\end{aligned}$$

Note that the linearity of expectation implies that

$$\mathbf{E}_{\mathbf{x}\sim\mathcal{D}'}[f(\mathbf{x})(\mathbf{x}\cdot\mathbf{v})] = (\mathbf{E}_{\mathbf{x}\sim\mathcal{D}'}[f(\mathbf{x})(\mathbf{x})])\cdot\mathbf{v} = \mathbf{v}^*_{\text{correct}}\cdot\mathbf{v} = \frac{1}{m}\sum_{(\mathbf{x},y)\in S} \mathbf{v}^*_{\text{correct}}\cdot(y\mathbf{x}). \tag{14}$$

Equation (14) expresses $\mathbf{E}_{\mathbf{x}\sim\mathcal{D}'}[f(\mathbf{x})(\mathbf{x}\cdot\mathbf{v})]$, which is closely related to the advantage of h through (13) and (12), as a sum of independent random variables, one for each example. We will bound $\mathbf{E}_{\mathbf{x}\sim\mathcal{D}'}[f(\mathbf{x})(\mathbf{x}\cdot\mathbf{v})]$ by bounding the expected effect of a random example on its value, and applying a Hoeffding bound.

Let $\eta' = \Pr_{(\mathbf{x},y)\sim P'}[f(\mathbf{x}) \neq y]$. Since P' is $1/\varepsilon$-smooth with respect to P, we have $\eta' \leq \eta/\varepsilon$. We can rearrange the effect of a random example as follows

$$\begin{aligned}
\mathbf{E}_{(\mathbf{x},y)\sim P'}[\mathbf{v}^*_{\text{correct}} \cdot (y\mathbf{x})] &= (1-\eta')\mathbf{E}_{(\mathbf{x},y)\sim P'}[\mathbf{v}^*_{\text{correct}} \cdot (f(\mathbf{x})\mathbf{x})|y = f(\mathbf{x})] \\
&\quad +\eta'\mathbf{E}_{(\mathbf{x},y)\sim P'}[\mathbf{v}^*_{\text{correct}} \cdot (-f(\mathbf{x})\mathbf{x})|y \neq f(\mathbf{x})] \\
&= (1-\eta')\mathbf{E}_{(\mathbf{x},y)\sim P'}[\mathbf{v}^*_{\text{correct}} \cdot (f(\mathbf{x})\mathbf{x})|y = f(\mathbf{x})] \\
&\quad +\eta'\mathbf{E}_{(\mathbf{x},y)\sim P'}[\mathbf{v}^*_{\text{correct}} \cdot (f(\mathbf{x})\mathbf{x})|y \neq f(\mathbf{x})] \\
&\quad -\eta'\mathbf{E}_{(\mathbf{x},y)\sim P'}[\mathbf{v}^*_{\text{correct}} \cdot (f(\mathbf{x})\mathbf{x})|y \neq f(\mathbf{x})] \\
&\quad +\eta'\mathbf{E}_{(\mathbf{x},y)\sim P'}[\mathbf{v}^*_{\text{correct}} \cdot (-f(\mathbf{x})\mathbf{x})|y \neq f(\mathbf{x})]. \qquad (15)
\end{aligned}$$

Since

$$\begin{aligned}
&\mathbf{E}_{(\mathbf{x},y)\sim P'}[\mathbf{v}^*_{\text{correct}} \cdot (f(\mathbf{x})\mathbf{x})] \\
&= \eta'\mathbf{E}_{(\mathbf{x},y)\sim P'}[\mathbf{v}^*_{\text{correct}} \cdot (f(\mathbf{x})\mathbf{x})|y \neq f(\mathbf{x})] + (1-\eta')\mathbf{E}_{(\mathbf{x},y)\sim P'}[\mathbf{v}^*_{\text{correct}} \cdot (f(\mathbf{x})\mathbf{x})|y = f(\mathbf{x})],
\end{aligned}$$

by replacing the first two terms of (15) with $\mathbf{E}_{(\mathbf{x},y)\sim P'}[\mathbf{v}^*_{\text{correct}} \cdot (f(\mathbf{x})\mathbf{x})]$, we get

$$\begin{aligned}
\mathbf{E}_{(\mathbf{x},y)\sim P'}[\mathbf{v}^*_{\text{correct}} \cdot (y\mathbf{x})] &= \mathbf{E}_{(\mathbf{x},y)\sim P'}[\mathbf{v}^*_{\text{correct}} \cdot (f(\mathbf{x})\mathbf{x})] \\
&\quad -\eta'\mathbf{E}_{(\mathbf{x},y)\sim P'}[\mathbf{v}^*_{\text{correct}} \cdot (f(\mathbf{x})\mathbf{x})|y \neq f(\mathbf{x})] \\
&\quad +\eta'\mathbf{E}_{(\mathbf{x},y)\sim P'}[\mathbf{v}^*_{\text{correct}} \cdot (-f(\mathbf{x})\mathbf{x})|y \neq f(\mathbf{x})] \\
&= \mathbf{E}_{(\mathbf{x},y)\sim P'}[\mathbf{v}^*_{\text{correct}} \cdot (f(\mathbf{x})\mathbf{x})] \\
&\quad -2\eta'\mathbf{E}_{(\mathbf{x},y)\sim P'}[\mathbf{v}^*_{\text{correct}} \cdot (f(\mathbf{x})\mathbf{x})|y \neq f(\mathbf{x})].
\end{aligned}$$

Twice applying the linearity of expectation, we get

$$\begin{aligned}
\mathbf{E}_{(\mathbf{x},y)\sim P'}[\mathbf{v}^*_{\text{correct}} \cdot (y\mathbf{x})] &= ||\mathbf{v}^*_{\text{correct}}||^2 - 2\eta'\mathbf{E}_{(\mathbf{x},y)\sim P'}[\mathbf{v}^*_{\text{correct}} \cdot (f(\mathbf{x})\mathbf{x})|y \neq f(\mathbf{x})] \\
&= ||\mathbf{v}^*_{\text{correct}}||^2 - 2\eta'\mathbf{v}_{\text{correct}} \cdot \mathbf{v}^*_{\text{dirty}} \\
&\geq ||\mathbf{v}^*_{\text{correct}}||^2 - 2\eta'||\mathbf{v}^*_{\text{correct}}|| \cdot ||\mathbf{v}^*_{\text{dirty}}|| \\
&\geq \frac{1}{2}||\mathbf{v}^*_{\text{correct}}||^2 - 4(\eta')^2||\mathbf{v}^*_{\text{dirty}}||^2,
\end{aligned}$$

The last line follows from the fact that $q^2 - qr \geq (q^2 - r^2)/2$ for all real q, r.

So now our goals are a lower bound on $||\mathbf{v}^*_{\text{correct}}||$ and an upper bound on $||\mathbf{v}^*_{\text{dirty}}||$.

We can lower bound $||\mathbf{v}^*_{\text{correct}}||$ essentially the same way we did before, by lower bounding its projection onto the "target" normal vector $\mathbf{u}$:

$$\mathbf{v}^*_{\text{correct}} \cdot \mathbf{u} = \mathbf{E}_{(\mathbf{x},y)\sim P'}[(f(\mathbf{x})\mathbf{x}) \cdot \mathbf{u}] = \mathbf{E}_{(\mathbf{x},y)\sim P'}[\text{sgn}(\mathbf{u} \cdot \mathbf{x})(\mathbf{x} \cdot \mathbf{u})] = \mathbf{E}_{(\mathbf{x},y)\sim P'}[|\mathbf{x} \cdot \mathbf{u}|] \geq \varepsilon/16, \qquad (16)$$

by Lemma 16.

We upper bound $||\mathbf{v}^*_{\text{dirty}}||$ as follows:

$$\begin{aligned}
||\mathbf{v}^*_{\text{dirty}}||^2 &= \mathbf{v}^*_{\text{dirty}} \cdot E_{\mathbf{x}\sim\mathcal{D}'_{\text{dirty}}}[-f(\mathbf{x})\mathbf{x}] \\
&= ||\mathbf{v}^*_{\text{dirty}}|| \cdot E_{\mathbf{x}\sim\mathcal{D}'_{\text{dirty}}}\left[\left(\frac{\mathbf{v}^*_{\text{dirty}}}{||\mathbf{v}^*_{\text{dirty}}||}\right) \cdot (-f(\mathbf{x}))\mathbf{x}\right] \\
&\leq ||\mathbf{v}^*_{\text{dirty}}|| \cdot E_{\mathbf{x}\sim\mathcal{D}'_{\text{dirty}}}\left[\left|\left(\frac{\mathbf{v}^*_{\text{dirty}}}{||\mathbf{v}^*_{\text{dirty}}||}\right) \cdot \mathbf{x}\right|\right] \\
&\leq ||\mathbf{v}^*_{\text{dirty}}||O(\log(1/(\eta'\varepsilon)))
\end{aligned}$$

by Lemma 22. Thus $||\mathbf{v}^*_{\text{dirty}}|| \leq O(\log(1/(\eta'\varepsilon)))$.

Combining this with (16) and (14) we have that if

$$\eta'\sqrt{\log(1/(\eta'\varepsilon)} \leq c\varepsilon^2$$

for a suitably small constant c, then $\mathbf{E}_{\mathbf{x}\sim\mathcal{D}'}[f(\mathbf{x})(\mathbf{x}\cdot\mathbf{v})]$ is a sum of m i.i.d. random variables, each with mean at least $\Omega(\varepsilon^2)$, and coming from an interval of length $O(n\log m)$. Applying the standard Hoeffding bound, polynomially many examples suffice for $\mathbf{E}_{\mathbf{x}\sim\mathcal{D}'}[f(\mathbf{x})(\mathbf{x}\cdot\mathbf{v})] \geq \Omega(\varepsilon^2)$. Combining with (13) and (12) completes the proof.

6. Conclusion

Our algorithms use boosting together with a confidence-rated weak learner that perform a simple averaging of labeled examples. As shown in earlier work (Servedio, 2002, 2003) there are close connections between such an approach and the Perceptron algorithm. It seems likely that the Perceptron could be used as an alternative to boosting and averaging in our algorithms; it would be interesting to see if a Perceptron-based approach has any theoretical or empirical advantages over the algorithms we give in this paper.

More generally, there are relatively few algorithms for learning interesting classes of functions in the presence of malicious noise. We hope that our results will help lead to the development of more efficient algorithms for this challenging noise model.

As a challenge for future work, we pose the following question: do there exist computationally efficient algorithms for learning halfspaces under *arbitrary* distributions in the presence of malicious noise? As of now no better results are known for this problem than the generic conversions of Kearns and Li (1993), which can be applied to any concept class. We feel that even a small improvement in the malicious noise rate that can be handled for halfspaces would be a very interesting result.

Appendix A. Proof of Lemma 7

Let us start with a couple of definitions and a couple of bounds from the literature.

Definition 23 (VC-dimension) *A set F of $\{-1,1\}$-valued functions defined on a common domain X* shatters *$x_1,...,x_d$ if every sequence $y_1,...,y_d \in \{-1,1\}$ of function values has a function f such that $f(x_1) = y_1,...,f(x_d) = y_d$. The VC-dimension of F is the size of the largest set shattered by F.*

Definition 24 (pseudo-dimension) *For a set F of real-valued functions defined on a common domain X, the* pseudo-dimension *of F is the VC-dimension of $\{\text{sign}(f(\cdot)-\theta) : f \in F, \theta \in \mathbf{R}\}$.*

Lemma 25 (Pollard 1984; Talagrand 1994) *Let F be a set of real-valued functions defined on a common domain X taking values in $[0,1]$, and let d be the pseudo-dimension of F. Let $\mathcal{D}$ be a probability distribution over X. Then if $x_1,...,x_m$ are obtained by drawing m times independently*

according to $\mathcal{D}$, for any $\delta > 0$,

$$\Pr\left[\exists f \in F, \frac{1}{m}\sum_{s=1}^{m} f(x_s) > E_{\mathcal{D}}[f] + c\sqrt{\frac{d+\log(1/\delta)}{m}}\right] \leq \delta,$$

where $c > 0$ is an absolute constant.

Lemma 26 (see Blumer et al. 1989) *The VC-dimension of unions of two halfspaces is $O(n)$.*

Now, let us bound the pseudo-dimension of the class of functions that we need.

Lemma 27 *Let F_n consist of the functions f from $\mathbf{R}^n$ to $\mathbf{R}$ which can be defined by $f(\mathbf{x}) = (\mathbf{a}\cdot\mathbf{x})^2$ for some $\mathbf{a} \in \mathbf{R}^n$. The pseudo-dimension of F_n is at most $O(n)$.*

Proof. According to the definition, the pseudo dimension of F_n is the VC-dimension of the set G_n of $\{-1,1\}$-valued functions $g_{\mathbf{a},\theta}$ defined by $g_{\mathbf{a},\theta}(\mathbf{x}) = \mathrm{sign}((\mathbf{a}\cdot\mathbf{x})^2 - \theta)$. Each $g_{\mathbf{a},\theta}$ is equivalent to an OR of two halfspaces:

$$\mathbf{a}\cdot\mathbf{x} \geq \sqrt{\theta} \quad \text{OR} \quad (-\mathbf{a})\cdot\mathbf{x} \geq \sqrt{\theta}.$$

Thus the VC-dimension of G_n is at most the VC-dimension of the class of all ORs of two halfspaces. Applying Lemma 26 completes the proof. ∎

Applying Lemmas 25 and 27, we obtain Lemma 7.

Appendix B. Proof of Lemma 8

We will use the following, which strengthens bounds like Lemma 25 when the expectations being estimated are small. It differs from most bounds of this type by providing an especially strong bound on the probability that the estimates are *much* larger than the true expectations.

Lemma 28 (Bshouty et al. 2009) *Suppose F is a set of $\{0,1\}$-valued functions with a common domain X. Let d be the VC-dimension of F. Let $\mathcal{D}$ be a probability distribution over X. Choose $\alpha > 0$ and $K \geq 4$. Then if*

$$m \geq \frac{c\left(d\log\frac{1}{\alpha} + \log\frac{1}{\delta}\right)}{\alpha K \log K},$$

where c is an absolute constant, then

$$\Pr_{\mathbf{u}\sim\mathcal{D}^m}[\exists f \in F,\ \mathbf{E}_{\mathcal{D}}(f) \leq \alpha \textit{ but } \hat{\mathbf{E}}_{\mathbf{u}}(f) > K\alpha] \leq \delta,$$

where $\hat{\mathbf{E}}_{\mathbf{u}}(f) = \frac{1}{m}\sum_{i=1}^{m} f(u_i)$.

To prove Lemma 8, we first use the fact that, for any fixed $\mathbf{a} \in \mathbb{S}^{n-1}$ and $\beta > 0$, it is known (see Kalai et al. 2008) that

$$\Pr_{x\in\mathbb{S}^{n-1}}[|\mathbf{a}\cdot\mathbf{x}| > \beta] \leq e^{-\beta^2 n/2}.$$

Further, as in the proof of Lemma 7, we have that

$$|\mathbf{a}\cdot\mathbf{x}| > \beta \quad \text{if and only if} \quad \mathbf{a}\cdot\mathbf{x} > \beta \text{ OR } (-\mathbf{a})\cdot\mathbf{x} > \beta,$$

so that the set of events whose probabilities we need to estimate is contained in the set of unions of pairs of halfspaces. Applying Lemma 26 and Lemma 28 completes the proof.

Abstract

We introduce the notion of reproducing kernel Banach spaces (RKBS) and study special semi-inner-product RKBS by making use of semi-inner-products and the duality mapping. Properties of an RKBS and its reproducing kernel are investigated. As applications, we develop in the framework of RKBS standard learning schemes including minimal norm interpolation, regularization network, support vector machines, and kernel principal component analysis. In particular, existence, uniqueness and representer theorems are established.

Keywords: reproducing kernel Banach spaces, reproducing kernels, learning theory, semi-inner-products, representer theorems

1. Introduction

Learning a function from its finite samples is a fundamental science problem. The essence in achieving this is to choose an appropriate measurement of similarities between elements in the domain of the function. A recent trend in machine learning is to use a positive definite kernel (Aronszajn, 1950) to measure the similarity between elements in an input space X (Schölkopf and Smola, 2002; Shawe-Taylor and Cristianini, 2004; Vapnik, 1998; Xu and Zhang, 2007, 2009). Set $\mathbb{N}_n := \{1,2,\ldots,n\}$ for $n \in \mathbb{N}$. A function $K : X \times X \to \mathbb{C}$ is called a *positive definite kernel* if for all finite subsets $\mathbf{x} := \{x_j : j \in \mathbb{N}_n\} \subseteq X$ the matrix

$$K[\mathbf{x}] := [K(x_j, x_k) : j,k \in \mathbb{N}_n] \tag{1}$$

is hermitian and positive semi-definite. The reason of using positive definite kernels to measure similarity lies in the celebrated theoretical fact due to Mercer (1909) that there is a bijective correspondence between them and *reproducing kernel Hilbert spaces* (RKHS). An RKHS $\mathcal{H}$ on X is a Hilbert space of functions on X for which point evaluations are always continuous linear functionals. One direction of the bijective correspondence says that if K is a positive definite kernel on X then there exists a unique RKHS $\mathcal{H}$ on X such that $K(x,\cdot) \in \mathcal{H}$ for each $x \in X$ and for all $f \in \mathcal{H}$ and $y \in X$

$$f(y) = (f, K(y,\cdot))_{\mathcal{H}}, \tag{2}$$

where $(\cdot,\cdot)_{\mathcal{H}}$ denotes the inner product on $\mathcal{H}$. Conversely, if $\mathcal{H}$ is an RKHS on X then there is a unique positive definite kernel K on X such that $\{K(x,\cdot) : x \in X\} \subseteq \mathcal{H}$ and (2) holds. In light of this bijective correspondence, positive definite kernels are usually called *reproducing kernels*.

By taking $f := K(x,\cdot)$ for $x \in X$ in Equation (2), we get that

$$K(x,y) = (K(x,\cdot),K(y,\cdot))_{\mathcal{H}}, \ \ x,y \in X. \tag{3}$$

Thus $K(x,y)$ is represented as an inner product on an RKHS. This explains why $K(x,y)$ is able to measure similarities of x and y. The advantages brought by the use of an RKHS include: (1) the inputs can be handled and explained geometrically; (2) geometric objects such as hyperplanes are provided by the RKHS for learning; (3) the powerful tool of functional analysis applies (Schölkopf and Smola, 2002). Based on the theory of reproducing kernels, many effective schemes have been developed for learning from finite samples (Evgeniou et al., 2000; Micchelli et al., 2009; Schölkopf and Smola, 2002; Shawe-Taylor and Cristianini, 2004; Vapnik, 1998). In particular, the widely used regularized learning algorithm works by generating a predictor function from the training data $\{(x_j,y_j) : j \in \mathbb{N}_n\} \subseteq X \times \mathbb{C}$ as the minimizer of

$$\min_{f \in \mathcal{H}_K} \sum_{j \in \mathbb{N}_n} \mathcal{L}(f(x_j),y_j) + \mu \|f\|^2_{\mathcal{H}_K}, \tag{4}$$

where $\mathcal{H}_K$ denotes the RKHS corresponding to the positive definite kernel K, $\mathcal{L}$ is a prescribed loss function, and μ is a positive regularization parameter.

This paper is motivated from machine learning in Banach spaces. There are advantages of learning in Banach spaces over Hilbert spaces. Firstly, there is essentially only one Hilbert space once the dimension of the space is fixed. This follows from the well-known fact that any two Hilbert spaces over $\mathbb{C}$ of the same dimension are isometrically isomorphic. By contrast, for $p \neq q \in [1,+\infty]$, $L^p[0,1]$ and $L^q[0,1]$ are not isomorphic, namely, there does not exist a bijective bounded linear mapping between them (see, Fabian et al., 2001, page 180). Thus, compared to Hilbert spaces, Banach spaces possess much richer geometric structures, which are potentially useful for developing learning algorithms. Secondly, in some applications, a norm from a Banach space is invoked without being induced from an inner product. For instance, it is known that minimizing about the ℓ^p norm on $\mathbb{R}^d$ leads to sparsity of the minimizer when p is close to 1 (see, for example, Tropp, 2006). In the extreme case that $\varphi : \mathbb{R}^d \to [0,+\infty)$ is strictly concave and $\mu > 0$, one can show that the minimizer for

$$\min\{\varphi(x) + \mu\|x\|_{\ell^1} : x \in \mathbb{R}^d\} \tag{5}$$

has at most one nonzero element. The reason is that the extreme points on a sphere in the ℓ^1 norm must lie on axes of the Euclidean coordinate system. A detailed proof of this result is provided in the appendix. Thirdly, since many training data come with intrinsic structures that make them impossible to be embedded into a Hilbert space, learning algorithms based on RKHS may not work well for them. Hence, there is a need to modify the algorithms by adopting norms in Banach spaces. For example, one might have to replace the norm $\|\cdot\|_{\mathcal{H}_K}$ in (4) with that of a Banach space.

There has been considerable work on learning in Banach spaces in the literature. References Bennett and Bredensteiner (2000); Micchelli and Pontil (2004, 2007); Micchelli et al. (2003); Zhang (2002) considered the problem of minimizing a regularized functional of the form

$$\sum_{j \in \mathbb{N}_n} \mathcal{L}(\lambda_j(f),y_j) + \phi(\|f\|_{\mathcal{B}}), \ \ f \in \mathcal{B},$$

where $\mathcal{B}$ is Banach space, λ_j are in the dual $\mathcal{B}^*$, $y_j \in \mathbb{C}$, $\mathcal{L}$ is a loss function, and ϕ is a strictly increasing nonnegative function. In particular, Micchelli et al. (2003) considered learning in Besov spaces (a special type of Banach spaces). On-line learning in finite dimensional Banach spaces was studied, for example, in Gentile (2001). Learning of an L^p function was considered in Kimber and Long (1995). Classifications in Banach spaces, and more generally in metric spaces were discussed in Bennett and Bredensteiner (2000), Der and Lee (2007), Hein et al. (2005), von Luxburg and Bousquet (2004) and Zhou et al. (2002).

The above discussion indicates that there is a need of introducing the notion of reproducing kernel Banach spaces for the systematic study of learning in Banach spaces. Such a definition is expected to result in consequences similar to those in an RKHS. A generalization of RKHS to non-Hilbert spaces using point evaluation with kernels was proposed in Canu et al. (2003), although the spaces considered there might be too general to have favorable properties of an RKHS. We shall introduce the notion of reproducing kernel Banach spaces in Section 2, and a general construction in Section 3. It will become clear that the lack of an inner product may cause arbitrariness in the properties of the associated reproducing kernel. To overcome this, we shall establish in Section 4 s.i.p. reproducing kernel Banach spaces by making use of semi-inner-products for normed vector spaces first defined by Lumer (1961) and further developed by Giles (1967). Semi-inner-products were first applied to machine learning by Der and Lee (2007) to develop hard margin hyperplane classification in Banach spaces. Here the availability of a semi-inner-product enables us to study basic properties of reproducing kernel Banach spaces and their reproducing kernels. In Section 5, we shall develop in the framework of reproducing kernel Banach spaces standard learning schemes including minimal norm interpolation, regularization network, support vector machines, and kernel principal component analysis. Existence, uniqueness and representer theorems for the learning schemes will be proved. We draw conclusive remarks in Section 6 and include two technical results in Appendix.

2. Reproducing Kernel Banach Spaces

Without specifically mentioned, all vector spaces in this paper are assumed to be complex. Let X be a prescribed input space. A normed vector space $\mathcal{B}$ is called a **Banach space of functions** on X if it is a Banach space whose elements are functions on X, and for each $f \in \mathcal{B}$, its norm $\|f\|_{\mathcal{B}}$ in $\mathcal{B}$ vanishes if and only if f, as a function, vanishes everywhere on X. By this definition, $L^p[0,1]$, $1 \le p \le +\infty$, is not a Banach space of functions as it consists of equivalent classes of functions with respect to the Lebesgue measure.

Influenced by the definition of RKHS, our first intuition is to define a reproducing kernel Banach space (RKBS) as a Banach space of functions on X on which point evaluations are continuous linear functionals. If such a definition was adopted then the first example that comes to our mind would be $C[0,1]$, the Banach space of continuous functions on $[0,1]$ equipped with the maximum norm. It satisfies the definition. However, since for each $f \in C[0,1]$,

$$f(x) = \delta_x(f), \quad x \in [0,1],$$

the reproducing kernel for $C[0,1]$ would have to be the delta distribution, which is not a function that can be evaluated. This example suggests that there should exist a way of identifying the elements in the dual of an RKBS with functions. Recall that two normed vector spaces V_1 and V_2 are said to be *isometric* if there is a bijective linear norm-preserving mapping between them. We call such

V_1 and V_2 an *identification* of each other. We would like the dual space $\mathcal{B}^*$ of an RKBS $\mathcal{B}$ on X to be isometric to a Banach space of functions on X. In addition to this requirement, later on we will find it very convenient to jump freely between a Banach space and its dual. For this reason, we would like an RKBS $\mathcal{B}$ to be *reflexive* in the sense that $(\mathcal{B}^*)^* = \mathcal{B}$. The above discussion leads to the following formal definition.

Definition 1 *A* **reproducing kernel Banach space** *(RKBS) on X is a reflexive Banach space $\mathcal{B}$ of functions on X for which $\mathcal{B}^*$ is isometric to a Banach space $\mathcal{B}^\#$ of functions on X and the point evaluation is continuous on both $\mathcal{B}$ and $\mathcal{B}^\#$.*

Several remarks are in order about this definition. First, whether $\mathcal{B}$ is an RKBS is independent of the choice of the identification $\mathcal{B}^\#$ of $\mathcal{B}^*$. In other words, if the point evaluation is continuous on some identification $\mathcal{B}^\#$ then it is continuous on all the identifications. The reason is that any two identifications of $\mathcal{B}^*$ are isometric. Second, an RKHS $\mathcal{H}$ on X is an RKBS. To see this, we set

$$\mathcal{H}^\# := \{\bar{f} : f \in \mathcal{H}\} \tag{6}$$

with the norm $\|\bar{f}\|_{\mathcal{H}^\#} := \|f\|_{\mathcal{H}}$, where $\bar{f}$ denotes the conjugate of f defined by $\bar{f}(x) := \overline{f(x)}, x \in X$. By the Riesz representation theorem (Conway, 1990), each $u^* \in \mathcal{H}^*$ has the form

$$u^*(f) = (f, f_0)_{\mathcal{H}}, \ \ f \in \mathcal{H}$$

for some unique $f_0 \in \mathcal{H}$ and $\|u^*\|_{\mathcal{H}^*} = \|f_0\|_{\mathcal{H}}$. We introduce a mapping $\iota : \mathcal{H}^* \to \mathcal{H}^\#$ by setting

$$\iota(u^*) := \overline{f_0}.$$

Clearly, ι so defined is isometric from $\mathcal{H}^*$ to $\mathcal{H}^\#$. We conclude that an RKHS is a special RKBS. Third, the identification $\mathcal{B}^\#$ of $\mathcal{B}^*$ of an RKBS is usually not unique. However, since they are isometric to each other, we shall assume that one of them has been chosen for an RKBS $\mathcal{B}$ under discussion. In particular, the identification of $\mathcal{H}^*$ of an RKHS $\mathcal{H}$ will always be chosen as (6). Fourth, for notational simplicity, we shall still denote the fixed identification of $\mathcal{B}^*$ by $\mathcal{B}^*$. Let us keep in mind that originally $\mathcal{B}^*$ consists of continuous linear functionals on $\mathcal{B}$. Thus, when we shall be treating elements in $\mathcal{B}^*$ as functions on X, we actually think $\mathcal{B}^*$ as its chosen identification. With this notational convention, we state our last remark that if $\mathcal{B}$ is an RKBS on X then so is $\mathcal{B}^*$.

We shall show that there indeed exists a *reproducing kernel* for an RKBS. To this end, we introduce for a normed vector space V the following *bilinear form* on $V \times V^*$ by setting

$$(u, v^*)_V := v^*(u), \ \ u \in V, \ v^* \in V^*.$$

It is called bilinear for the reason that for all $\alpha, \beta \in \mathbb{C}$, $u, v \in V$, and $u^*, v^* \in V^*$ there holds

$$(\alpha u + \beta v, u^*)_V = \alpha(u, u^*)_V + \beta(v, u^*)_V$$

and

$$(u, \alpha u^* + \beta v^*)_V = \alpha(u, u^*)_V + \beta(u, v^*)_V.$$

Note that if V is a reflexive Banach space then for any continuous linear functional T on V^* there exists a unique $u \in V$ such that

$$T(v^*) = (u, v^*)_V, \ \ v^* \in V^*.$$

Theorem 2 *Suppose that $\mathcal{B}$ is an RKBS on X. Then there exists a unique function $K : X \times X \to \mathbb{C}$ such that the following statements hold.*
(a) For every $x \in X$, $K(\cdot,x) \in \mathcal{B}^*$ and

$$f(x) = (f, K(\cdot,x))_{\mathcal{B}}, \ \text{for all } f \in \mathcal{B}.$$

(b) For every $x \in X$, $K(x,\cdot) \in \mathcal{B}$ and

$$f^*(x) = (K(x,\cdot), f^*)_{\mathcal{B}}, \ \text{for all } f^* \in \mathcal{B}^*. \tag{7}$$

(c) The linear span of $\{K(x,\cdot) : x \in X\}$ is dense in $\mathcal{B}$, namely,

$$\overline{\text{span}}\{K(x,\cdot) : x \in X\} = \mathcal{B}. \tag{8}$$

(d) The linear span of $\{K(\cdot,x) : x \in X\}$ is dense in $\mathcal{B}^*$, namely,

$$\overline{\text{span}}\{K(\cdot,x) : x \in X\} = \mathcal{B}^*. \tag{9}$$

(e) For all $x, y \in X$

$$K(x,y) = (K(x,\cdot), K(\cdot,y))_{\mathcal{B}}. \tag{10}$$

Proof For every $x \in X$, since δ_x is a continuous linear functional on $\mathcal{B}$, there exists $g_x \in \mathcal{B}^*$ such that

$$f(x) = (f, g_x)_{\mathcal{B}}, \ \ f \in \mathcal{B}.$$

We introduce a function $\tilde{K}$ on $X \times X$ by setting

$$\tilde{K}(x,y) := g_x(y), \ \ x, y \in X.$$

It follows that $\tilde{K}(x,\cdot) \in \mathcal{B}^*$ for each $x \in X$, and

$$f(x) = (f, \tilde{K}(x,\cdot))_{\mathcal{B}}, \ \ f \in \mathcal{B}, \ \ x \in X. \tag{11}$$

There is only one function on $X \times X$ with the above properties. Assume to the contrary that there is another $\tilde{G} : X \times X \to \mathbb{C}$ satisfying $\{\tilde{G}(x,\cdot) : x \in X\} \subseteq \mathcal{B}^*$ and

$$f(x) = (f, \tilde{G}(x,\cdot))_{\mathcal{B}}, \ \ f \in \mathcal{B}, \ \ x \in X.$$

The above equation combined with (11) yields that

$$(f, \tilde{K}(x,\cdot) - \tilde{G}(x,\cdot))_{\mathcal{B}} = 0, \ \ \text{for all } f \in \mathcal{B}, \ x \in X.$$

Thus, $\tilde{K}(x,\cdot) - \tilde{G}(x,\cdot) = 0$ in $\mathcal{B}^*$ for each $x \in X$. Since $\mathcal{B}^*$ is a Banach space of functions on X, we get for every $y \in X$ that

$$\tilde{K}(x,y) - \tilde{G}(x,y) = 0,$$

that is, $\tilde{K} = \tilde{G}$.

Likewise, there exists a unique $K : X \times X \to \mathbb{C}$ such that $K(y,\cdot) \in \mathcal{B}$, $y \in X$ and

$$f^*(y) = (K(y,\cdot), f^*)_{\mathcal{B}}, \ \ f^* \in \mathcal{B}^*, \ \ y \in X. \tag{12}$$

Letting $f := K(y,\cdot)$ in (11) yields that

$$K(y,x) = (K(y,\cdot), \tilde{K}(x,\cdot))_{\mathcal{B}}, \ \ x,y \in X, \tag{13}$$

and setting $f^* := \tilde{K}(x,\cdot)$ in (12) ensures that

$$\tilde{K}(x,y) = (K(y,\cdot), \tilde{K}(x,\cdot))_{\mathcal{B}}, \ \ x,y \in X.$$

Combining the above equation with (13), we get that

$$\tilde{K}(x,y) = K(y,x), \ \ x,y \in X.$$

Therefore, K satisfies (a) and (b) as stated in the theorem. Equation (10) in (e) is proved by letting $f^* = K(\cdot,y)$ in (7). To complete the proof, we shall show (c) only, since (d) can be handled in a similar way. Suppose that (8) does not hold. Then by the Hahn-Banach theorem, there exists a nontrivial functional $f^* \in \mathcal{B}^*$ such that

$$(K(x,\cdot), f^*)_{\mathcal{B}} = 0, \ \ \text{for all } x \in X.$$

We get immediately from (12) that $f^*(x) = 0$ for all $x \in X$. Since $\mathcal{B}^*$ is a Banach space of functions on X, $f^* = 0$ in $\mathcal{B}^*$, a contradiction. ■

We call the function K in Theorem 2 the **reproducing kernel** for the RKBS $\mathcal{B}$. By Theorem 2, an RKBS has exactly one reproducing kernel. However, different RKBS may have the same reproducing kernel. Examples will be given in the next section. This results from a fundamental difference between Banach spaces and Hilbert spaces. To explain this, we let $\mathcal{W}$ be a Banach space and V a subset of $\mathcal{W}$ such that $\operatorname{span} V$ is dense in $\mathcal{W}$. Suppose that a norm on elements of V is prescribed. If $\mathcal{W}$ is a Hilbert space and an inner product is defined among elements in V, then the norm extends in a unique way to $\operatorname{span} V$, and hence to the whole space $\mathcal{W}$. Assume now that $\mathcal{W}$ is only known to be a Banach space and $V^* \subseteq \mathcal{W}^*$ satisfying $\overline{\operatorname{span}} V^* = \mathcal{W}^*$ is given. Then even if a bilinear form is defined between elements in V and those in V^*, the norm may not have a unique extension to the whole space $\mathcal{W}$. Consequently, although we have at hand a reproducing kernel K for an RKBS $\mathcal{B}$, the relationship (13), and denseness conditions (8), (9), we still can not determine the norm on $\mathcal{B}$.

3. Construction of Reproducing Kernels via Feature Maps

In this section, we shall characterize reproducing kernels for RKBS. The characterization will at the same time provide a convenient way of constructing reproducing kernels and their corresponding RKBS. For the corresponding results in the RKHS case, see, for example, Saitoh (1997), Schölkopf and Smola (2002), Shawe-Taylor and Cristianini (2004) and Vapnik (1998).

Theorem 3 *Let $\mathcal{W}$ be a reflexive Banach space with dual space $\mathcal{W}^*$. Suppose that there exists $\Phi : X \to \mathcal{W}$, and $\Phi^* : X \to \mathcal{W}^*$ such that*

$$\overline{\operatorname{span}}\, \Phi(X) = \mathcal{W}, \ \ \overline{\operatorname{span}}\, \Phi^*(X) = \mathcal{W}^*. \tag{14}$$

Then $\mathcal{B} := \{(u, \Phi^*(\cdot))_{\mathcal{W}} : u \in \mathcal{W}\}$ *with norm*

$$\|(u, \Phi^*(\cdot))_{\mathcal{W}}\|_{\mathcal{B}} := \|u\|_{\mathcal{W}} \tag{15}$$

is an RKBS on X *with the dual space* $\mathcal{B}^* := \{(\Phi(\cdot), u^*)_{\mathcal{W}} : u^* \in \mathcal{W}^*\}$ *endowed with the norm*

$$\|(\Phi(\cdot), u^*)_{\mathcal{W}}\|_{\mathcal{B}^*} := \|u^*\|_{\mathcal{W}^*}$$

and the bilinear form

$$((u, \Phi^*(\cdot))_{\mathcal{W}}, (\Phi(\cdot), u^*)_{\mathcal{W}})_{\mathcal{B}} := (u, u^*)_{\mathcal{W}}, \ \ u \in \mathcal{W}, \ u^* \in \mathcal{W}^*. \tag{16}$$

Moreover, the reproducing kernel K *for* $\mathcal{B}$ *is*

$$K(x, y) := (\Phi(x), \Phi^*(y))_{\mathcal{W}}, \ \ x, y \in X. \tag{17}$$

Proof We first show that $\mathcal{B}$ defined above is a Banach space of functions on X. To this end, we set $u \in \mathcal{W}$ and assume that

$$(u, \Phi^*(x))_{\mathcal{W}} = 0, \ \ \text{for all } x \in X. \tag{18}$$

Then by the denseness condition (14), $(u, u^*)_{\mathcal{W}} = 0$ for all $u^* \in \mathcal{W}^*$, implying that $u = 0$. Conversely, if $u = 0$ in $\mathcal{W}$ then it is clear that (18) holds true. These arguments also show that the representer $u \in \mathcal{W}$ for a function $(u, \Phi^*(\cdot))_{\mathcal{W}}$ in $\mathcal{B}$ is unique. It is obvious that (15) defines a norm on $\mathcal{B}$ and $\mathcal{B}$ is complete under this norm. Therefore, $\mathcal{B}$ is a Banach space of functions on X. Similarly, so is $\tilde{\mathcal{B}} := \{(\Phi(\cdot), u^*)_{\mathcal{W}} : u^* \in \mathcal{W}^*\}$ equipped with the norm

$$\|(\Phi(\cdot), u^*)_{\mathcal{W}}\|_{\tilde{\mathcal{B}}} := \|u^*\|_{\mathcal{W}^*}.$$

Define the bilinear form T on $\mathcal{B} \times \tilde{\mathcal{B}}$ by setting

$$T((u, \Phi^*(\cdot))_{\mathcal{W}}, (\Phi(\cdot), u^*)_{\mathcal{W}}) := (u, u^*)_{\mathcal{W}}, \ \ u \in \mathcal{W}, \ u^* \in \mathcal{W}^*.$$

Clearly, we have for all $u \in \mathcal{W}$, $u^* \in \mathcal{W}^*$ that

$$|T((u, \Phi^*(\cdot))_{\mathcal{W}}, (\Phi(\cdot), u^*)_{\mathcal{W}})| \le \|u\|_{\mathcal{W}} \|u^*\|_{\mathcal{W}^*} = \|(u, \Phi^*(\cdot))_{\mathcal{W}}\|_{\mathcal{B}} \, \|(\Phi(\cdot), u^*)_{\mathcal{W}}\|_{\tilde{\mathcal{B}}}.$$

Therefore, each function in $\tilde{\mathcal{B}}$ is a continuous linear functional on $\mathcal{B}$. Note that the linear mapping $u \to (u, \Phi^*(\cdot))_{\mathcal{W}}$ is isometric from $\mathcal{W}$ to $\mathcal{B}$. As a consequence, functions in $\tilde{\mathcal{B}}$ exhaust all the continuous linear functionals on $\mathcal{B}$. We conclude that $\mathcal{B}^* = \tilde{\mathcal{B}}$ with the bilinear form (16). Likewise, one can show that $\mathcal{B}$ is the dual of $\mathcal{B}^*$ by the reflexivity of $\mathcal{W}$. We have hence proved that $\mathcal{B}$ is reflexive with dual $\mathcal{B}^*$.

It remains to show that point evaluations are continuous on $\mathcal{B}$ and $\mathcal{B}^*$. To this end, we get for each $x \in X$ and $f := (u, \Phi^*(\cdot))_{\mathcal{W}}, u \in \mathcal{W}$ that

$$|f(x)| = |(u, \Phi^*(x))_{\mathcal{W}}| \le \|u\|_{\mathcal{W}} \|\Phi^*(x)\|_{\mathcal{W}^*} = \|f\|_{\mathcal{B}} \|\Phi^*(x)\|_{\mathcal{W}^*},$$

which implies that δ_x is continuous on $\mathcal{B}$. By similar arguments, it is continuous on $\mathcal{B}^*$. Combining all the discussion above, we reach the conclusion that $\mathcal{B}$ is an RKBS on X.

For the function K on $X \times X$ defined by (17), we get that $K(x,\cdot) \in \mathcal{B}$ and $K(\cdot,x) \in \mathcal{B}^*$ for all $x \in X$. It is also verified that for $f := (u, \Phi^*(\cdot))_{\mathcal{W}}$, $u \in \mathcal{W}$

$$(f, K(\cdot,x))_{\mathcal{B}} = ((u,\Phi^*(\cdot))_{\mathcal{W}}, (\Phi(\cdot),\Phi^*(x))_{\mathcal{W}})_{\mathcal{B}} = (u,\Phi^*(x))_{\mathcal{W}} = f(x).$$

Similarly, for $f^* := (\Phi(\cdot), u^*)_{\mathcal{W}}$, $u^* \in \mathcal{W}^*$

$$(K(x,\cdot), f^*)_{\mathcal{B}} = ((\Phi(x),\Phi^*(\cdot))_{\mathcal{W}}, (\Phi(\cdot),u^*)_{\mathcal{W}})_{\mathcal{B}} = (\Phi(x),u^*)_{\mathcal{W}} = f^*(x).$$

These facts show that K is the reproducing kernel for $\mathcal{B}$ and complete the proof. ■

We call the mappings Φ, Φ^* in Theorem 3 a pair of **feature maps** for the reproducing kernel K. The spaces $\mathcal{W}$, $\mathcal{W}^*$ are called the pair of **feature spaces** associated with the feature maps for K. As a corollary to Theorem 3, we obtain the following characterization of reproducing kernels for RKBS.

Theorem 4 *A function $K : X \times X \to \mathbb{C}$ is the reproducing kernel of an RKBS on X if and only if it is of the form (17), where $\mathcal{W}$ is a reflexive Banach space, and mappings $\Phi : X \to \mathcal{W}$, $\Phi^* : X \to \mathcal{W}^*$ satisfy (14).*

Proof The sufficiency has been shown by the last theorem. For the necessity, we assume that K is the reproducing kernel of an RKBS $\mathcal{B}$ on X, and set

$$\mathcal{W} := \mathcal{B}, \;\; \mathcal{W}^* := \mathcal{B}^*, \;\; \Phi(x) := K(x,\cdot), \;\; \Phi^*(x) := K(\cdot,x), \;\; x \in X.$$

By Theorem 2, $\mathcal{W}, \mathcal{W}^*, \Phi, \Phi^*$ satisfy all the conditions. ■

To demonstrate how we get RKBS and their reproducing kernels by Theorem 3, we now present a nontrivial example of RKBS. Set $X := \mathbb{R}, \mathbb{I} := [-\frac{1}{2}, \frac{1}{2}]$, and $p \in (1, +\infty)$. We make the convention that q is always the conjugate number of p, that is, $p^{-1} + q^{-1} = 1$. Define $\mathcal{W} := L^p(\mathbb{I})$, $\mathcal{W}^* := L^q(\mathbb{I})$ and $\Phi : X \to \mathcal{W}$, $\Phi^* : X \to \mathcal{W}^*$ as

$$\Phi(x)(t) := e^{-i2\pi xt}, \; \Phi^*(x)(t) := e^{i2\pi xt}, \quad x \in \mathbb{R}, \, t \in \mathbb{I}.$$

For $f \in L^1(\mathbb{R})$, its Fourier transform $\hat{f}$ is defined as

$$\hat{f}(t) := \int_{\mathbb{R}} f(x) e^{-i2\pi xt} dx, \;\; t \in \mathbb{R},$$

and its inverse Fourier transform $\check{f}$ is defined by

$$\check{f}(t) := \int_{\mathbb{R}} f(x) e^{i2\pi xt} dx, \;\; t \in \mathbb{R}.$$

The Fourier transform and the inverse Fourier transform can be defined on tempered distributions. Since the Fourier transform is injective on $L^1(\mathbb{R})$ (see, Rudin, 1987, page 185), the denseness requirement (14) is satisfied.

By the construction described in Theorem 3, we obtain

$$\mathcal{B} := \{f \in C(\mathbb{R}) : \operatorname{supp} \hat{f} \subseteq \mathbb{I},\ \hat{f} \in L^p(\mathbb{I})\} \tag{19}$$

with norm $\|f\|_{\mathcal{B}} := \|\hat{f}\|_{L^p(\mathbb{I})}$, and the dual

$$\mathcal{B}^* := \{g \in C(\mathbb{R}) : \operatorname{supp} \hat{g} \subseteq \mathbb{I},\ \hat{g} \in L^q(\mathbb{I})\}$$

with norm $\|g\|_{\mathcal{B}^*} := \|\check{g}\|_{L^q(\mathbb{I})}$. For each $f \in \mathcal{B}$ and $g \in \mathcal{B}^*$, we have

$$(f,g)_{\mathcal{B}} = \int_{\mathbb{I}} \hat{f}(t)\check{g}(t)dt.$$

The kernel K for $\mathcal{B}$ is given as

$$K(x,y) = (\Phi(x), \Phi^*(y))_{\mathcal{W}} = \int_{\mathbb{I}} e^{-i2\pi xt} e^{i2\pi yt} dt = \frac{\sin \pi(x-y)}{\pi(x-y)} = \operatorname{sinc}(x-y).$$

We check that for each $f \in \mathcal{B}$

$$(f, K(\cdot,x))_{\mathcal{B}} = \int_{\mathbb{I}} \hat{f}(t)(K(\cdot,x))\check{}(t)dt = \int_{\mathbb{I}} \hat{f}(t)e^{i2\pi xt}dt = f(x),\ \ x \in \mathbb{R}$$

and for each $g \in \mathcal{B}^*$

$$(K(x,\cdot), g)_{\mathcal{B}} = \int_{\mathbb{I}} (K(x,\cdot))\hat{}(t)\check{g}(t)dt = \int_{\mathbb{I}} \check{g}(t)e^{-i2\pi xt}dt = g(x),\ \ x \in \mathbb{R}.$$

When $p = q = 2$, $\mathcal{B}$ reduces to the classical space of bandlimited functions.

In the above example, $\mathcal{B}$ is isometrically isomorphic to $L^p(\mathbb{I})$. As mentioned in the introduction, $L^p(\mathbb{I})$ with different p are not isomorphic to each other. As a result, for different indices p the spaces $\mathcal{B}$ defined by (19) are essentially different. However, we see that they all have the sinc function as the reproducing kernel. In fact, if no further conditions are imposed on an RKBS, its reproducing kernel can be rather arbitrary. We make a simple observation below to illustrate this.

Proposition 5 *If the input space X is a finite set, then any nontrivial function K on $X \times X$ is the reproducing kernel of some RKBS on X.*

Proof Let K be an arbitrary nontrivial function on $X \times X$. Assume that $X = \mathbb{N}_m$ for some $m \in \mathbb{N}$. Let $d \in \mathbb{N}$ be the rank of the matrix $K[X]$ as defined by (1). By elementary linear algebra, there exist nonsingular matrices $P, Q \in \mathbb{C}^{m\times m}$ such that the transpose $(K[X])^T$ of $K[X]$ has the form

$$(K[X])^T = P \begin{bmatrix} I_d & 0 \\ 0 & 0 \end{bmatrix} Q = P \begin{bmatrix} I_d \\ 0 \end{bmatrix} \begin{bmatrix} I_d & 0 \end{bmatrix} Q, \tag{20}$$

where I_d is the $d \times d$ identity matrix. For $j \in \mathbb{N}_m$, let P_j be the transpose of the jth row of $P \begin{bmatrix} I_d \\ 0 \end{bmatrix}$ and Q_j the jth column of $\begin{bmatrix} I_d & 0 \end{bmatrix} Q$. Choose an arbitrary $p \in (1, +\infty)$. Equation (20) is rewritten as

$$K(j,k) = (Q_j, P_k)_{l^p(\mathbb{N}_d)},\ \ j,k \in \mathbb{N}_m. \tag{21}$$

We set $\mathcal{W} := l^p(\mathbb{N}_d)$, $\mathcal{W}^* := l^q(\mathbb{N}_d)$ and $\Phi(j) := Q_j$, $\Phi^*(j) := P_j$, $j \in \mathbb{N}_m$. Since P, Q are nonsingular, (14) holds true. Also, we have by (21) that

$$K(j,k) = (\Phi(j), \Phi^*(k))_{\mathcal{W}}, \quad j,k \in \mathbb{N}_m.$$

By Theorem 4, K is a reproducing kernel for some RKBS on X. ■

Proposition 5 reveals that due to the lack of an inner product, the reproducing kernel for a general RKBS can be an arbitrary function on $X \times X$. Particularly, it might be nonsymmetric or non-positive definite. In order for reproducing kernels of RKBS to have desired properties as those of RKHS, we may need to impose certain structures on RKBS, which in some sense are substitutes of the inner product for RKHS. For this purpose, we shall adopt the semi-inner-product introduced by Lumer (1961). A semi-inner-product possesses some but not all properties of an inner product. Hilbert space type arguments and results become available with the presence of a semi-inner-product. We shall introduce the notion of semi-inner-product RKBS.

4. S.i.p. Reproducing Kernel Banach Spaces

The purpose of this section is to establish the notion of semi-inner-product RKBS and study its properties. We start with necessary preliminaries on semi-inner-products (Giles, 1967; Lumer, 1961).

4.1 Semi-Inner-Products

A **semi-inner-product** on a vector space V is a function, denoted by $[\cdot,\cdot]_V$, from $V \times V$ to $\mathbb{C}$ such that for all $x, y, z \in V$ and $\lambda \in \mathbb{C}$

1. $[x+y,z]_V = [x,z]_V + [y,z]_V$,
2. $[\lambda x, y]_V = \lambda [x,y]_V$, $[x, \lambda y]_V = \bar{\lambda}[x,y]_V$,
3. $[x,x]_V > 0$ for $x \neq 0$,
4. (Cauchy-Schwartz) $|[x,y]_V|^2 \leq [x,x]_V [y,y]_V$.

The property that $[x, \lambda y]_V = \bar{\lambda}[x,y]_V$ was not required in the original definition by Lumer (1961). We include it here for the observation by Giles (1967) that this property can always be imposed.

It is necessary to point out the difference between a semi-inner-product and an inner product. In general, a semi-inner-product $[\cdot,\cdot]_V$ does not satisfy the conjugate symmetry $[x,y]_V = \overline{[y,x]_V}$ for all $x, y \in V$. As a consequence, there always exist $x, y, z \in V$ such that

$$[x, y+z]_V \neq [x,y]_V + [x,z]_V.$$

In fact, a semi-inner-product is always additive about the second variable only if it degenerates to an inner product. We show this fact below.

Proposition 6 *A semi-inner-product $[\cdot,\cdot]_V$ on a complex vector space V is an inner product if and only if*

$$[x, y+z]_V = [x,y]_V + [x,z]_V, \text{ for all } x, y, z \in V. \tag{22}$$

Proof Suppose that V has a semi-inner-product $[\cdot,\cdot]_V$ that satisfies (22). It suffices to show that for all $x, y \in V$,

$$[x,y]_V = \overline{[y,x]_V}. \tag{23}$$

Set $\lambda \in \mathbb{C}$. By the linearity on the first and the additivity on the second variable, we get that

$$[x+\lambda y, x+\lambda y]_V = [x,x]_V + [\lambda y, \lambda y]_V + \lambda [y,x]_V + \bar{\lambda}[x,y]_V.$$

Since $[z,z]_V \geq 0$ for all $z \in V$, we must have

$$\lambda [y,x]_V + \bar{\lambda}[x,y]_V \in \mathbb{R}.$$

Choosing $\lambda = 1$ yields that $\operatorname{Im}[y,x]_V = -\operatorname{Im}[x,y]_V$. And the choice $\lambda = i$ results that $\operatorname{Re}[y,x]_V = \operatorname{Re}[x,y]_V$. Therefore, (23) holds, which implies that $[\cdot,\cdot]_V$ is an inner product on V. ■

It was shown in Lumer (1961) that a vector space V with a semi-inner-product is a normed space equipped with

$$\|x\|_V := [x,x]_V^{1/2}, \ \ x \in V. \tag{24}$$

Therefore, if a vector space V has a semi-inner-product, we always assume that its norm is induced by (24) and call V an **s.i.p. space**. Conversely, every normed vector space V has a semi-inner-product that induces its norm by (24) (Giles, 1967; Lumer, 1961). By the Cauchy-Schwartz inequality, if V is an s.i.p. space then for each $x \in V$, $y \to [y,x]_V$ is a continuous linear functional on V. We denote this linear functional by x^*. Following this definition, we have that

$$[x,y]_V = y^*(x) = (x, y^*)_V, \ \ x, y \in V. \tag{25}$$

In general, a semi-inner-product for a normed vector space may not be unique. However, a differentiation property of the norm will ensure the uniqueness. We call a normed vector space V **Gâteaux differentiable** if for all $x, y \in V \setminus \{0\}$

$$\lim_{t \in \mathbb{R}, t \to 0} \frac{\|x+ty\|_V - \|x\|_V}{t}$$

exists. It is called **uniformly Fréchet differentiable** if the limit is approached uniformly on $\mathcal{S}(V) \times \mathcal{S}(V)$. Here, $S(V) := \{u \in V : \|u\|_V = 1\}$ is the unit sphere of V. The following result is due to Giles (1967).

Lemma 7 *If an s.i.p. space V is Gâteaux differentiable then for all $x, y \in V$ with $x \neq 0$*

$$\lim_{t \in \mathbb{R}, t \to 0} \frac{\|x+ty\|_V - \|x\|_V}{t} = \frac{\operatorname{Re}[y,x]}{\|x\|_V}. \tag{26}$$

The above lemma indicates that a Gâteaux differentiable normed vector space has a unique semi-inner-product. In fact, we have by (26) that

$$[x,y]_V = \|y\|_V \left(\lim_{t \in \mathbb{R}, t \to 0} \frac{\|y+tx\|_V - \|y\|_V}{t} + i \lim_{t \in \mathbb{R}, t \to 0} \frac{\|iy+tx\|_V - \|y\|_V}{t} \right), \ \ x, y \in V \setminus \{0\}. \tag{27}$$

For this reason, if V is a Gâteaux differentiable normed vector space we always assume that it is an s.i.p. space with the semi-inner-product defined as above. Interested readers are referred to the appendix for a proof that (27) indeed defines an s.i.p.

We shall impose one more condition on an s.i.p. space that will lead to a Riesz representation theorem. A normed vector space V is **uniformly convex** if for all $\varepsilon > 0$ there exists a $\delta > 0$ such that

$$\|x+y\|_V \leq 2-\delta \text{ for all } x,y \in \mathcal{S}(V) \text{ with } \|x-y\|_V \geq \varepsilon.$$

The space $L^p(\Omega,\mu)$, $1 < p < +\infty$, on a measure space $(\Omega,\mathcal{F},\mu)$ is uniformly convex. In particular, by the parallelogram law, any inner product space is uniformly convex. By a remark in Conway (1990), page 134, a uniformly convex Banach space is reflexive. There is a well-known relationship between uniform Fréchet differentiability and uniform convexity (Cudia, 1963). It states that a normed vector space is uniformly Fréchet differentiable if and only if its dual is uniformly convex. Therefore, if $\mathcal{B}$ is a uniformly convex and uniformly Fréchet differentiable Banach space then so is $\mathcal{B}^*$ since $\mathcal{B}$ is reflexive. The important role of uniform convexity is displayed in the next lemma (Giles, 1967).

Lemma 8 *(Riesz Representation Theorem) Suppose that $\mathcal{B}$ is a uniformly convex, uniformly Fréchet differentiable Banach space. Then for each $f \in \mathcal{B}^*$ there exists a unique $x \in \mathcal{B}$ such that $f = x^*$, that is,*

$$f(y) = [y,x]_{\mathcal{B}}, \ \ y \in \mathcal{B}.$$

Moreover, $\|f\|_{\mathcal{B}^*} = \|x\|_{\mathcal{B}}$.

The above Riesz representation theorem is desirable for RKBS. By Lemma 8 and the discussion right before it, we shall investigate in the next subsection RKBS which are both uniformly convex and uniformly Fréchet differentiable.

Let $\mathcal{B}$ be a uniformly convex and uniformly Fréchet differentiable Banach space. By Lemma 8, $x \to x^*$ defines a bijection from $\mathcal{B}$ to $\mathcal{B}^*$ that preserves the norm. Note that this **duality mapping** is in general nonlinear. We call x^* the **dual element** of x. Since $\mathcal{B}^*$ is uniformly Fréchet differentiable, it has a unique semi-inner-product, which is given by

$$[x^*,y^*]_{\mathcal{B}^*} = [y,x]_{\mathcal{B}}, \ \ x,y \in \mathcal{B}. \tag{28}$$

We close this subsection with a concrete example of uniformly convex and uniformly Fréchet differentiable Banach spaces. Let $(\Omega,\mathcal{F},\mu)$ be a measure space and $\mathcal{B} := L^p(\Omega,\mu)$ for some $p \in (1,+\infty)$. It is uniformly convex and uniformly Fréchet differentiable with dual $\mathcal{B}^* = L^q(\Omega,\mu)$. For each $f \in \mathcal{B}$, its dual element in $\mathcal{B}^*$ is

$$f^* = \frac{\bar{f}|f|^{p-2}}{\|f\|^{p-2}_{L^p(\Omega,\mu)}}. \tag{29}$$

Consequently, the semi-inner-product on $\mathcal{B}$ is

$$[f,g]_{\mathcal{B}} = g^*(f) = \frac{\int_\Omega f\bar{g}|g|^{p-2}d\mu}{\|g\|^{p-2}_{L^p(\Omega,\mu)}}.$$

With the above preparation, we shall study a special kind of RKBS which have desired properties.

4.2 S.i.p. RKBS

Let X be a prescribed input space. We call a uniformly convex and uniformly Fréchet differentiable RKBS on X an **s.i.p. reproducing kernel Banach space** (**s.i.p. RKBS**). Again, we see immediately that an RKHS is an s.i.p. RKBS. Also, the dual of an s.i.p. RKBS remains an s.i.p. RKBS. An s.i.p. RKBS $\mathcal{B}$ is by definition uniformly Fréchet differentiable. Therefore, it has a unique semi-inner-product, which by Lemma 8 represents all the interaction between $\mathcal{B}$ and $\mathcal{B}^*$. This leads to a more specific representation of the reproducing kernel. Precisely, we have the following consequences.

Theorem 9 *Let $\mathcal{B}$ be an s.i.p. RKBS on X and K its reproducing kernel. Then there exists a unique function $G : X \times X \to \mathbb{C}$ such that $\{G(x,\cdot) : x \in X\} \subseteq \mathcal{B}$ and*

$$f(x) = [f, G(x,\cdot)]_{\mathcal{B}}, \quad \text{for all } f \in \mathcal{B},\ x \in X. \tag{30}$$

Moreover, there holds the relationship

$$K(\cdot,x) = (G(x,\cdot))^*, \ \ x \in X \tag{31}$$

and

$$f^*(x) = [K(x,\cdot), f]_{\mathcal{B}}, \quad \text{for all } f \in \mathcal{B},\ x \in X. \tag{32}$$

Proof By Lemma 8, for each $x \in X$ there exists a function $G_x \in \mathcal{B}$ such that $f(x) = [f, G_x]_{\mathcal{B}}$ for all $f \in \mathcal{B}$. We define $G : X \times X \to \mathbb{C}$ by $G(x,y) := G_x(y)$, $x, y \in X$. We see that $G(x,\cdot) = G_x \in \mathcal{B}$, $x \in X$, and there holds (30). By the uniqueness in the Riesz representation theorem, such a function G is unique. To prove the remaining claims, we recall from Theorem 2 that the reproducing kernel K satisfies for each $f \in \mathcal{B}$ that

$$f(x) = (f, K(\cdot,x))_{\mathcal{B}}, \ \ x \in X. \tag{33}$$

and

$$f^*(x) = (K(x,\cdot), f^*)_{\mathcal{B}}, \ \ x \in X. \tag{34}$$

By (25), (30) and (33), we have for each $x \in X$ that

$$(f, (G(x,\cdot))^*)_{\mathcal{B}} = [f, G(x,\cdot)]_{\mathcal{B}} = f(x) = (f, K(\cdot,x))_{\mathcal{B}}, \ \ f \in \mathcal{B}.$$

The above equation implies (31). Equation (25) also implies that

$$(K(x,\cdot), f^*)_{\mathcal{B}} = [K(x,\cdot), f]_{\mathcal{B}}.$$

This together with equation (34) proves (32) and completes the proof. ■

We call the unique function G in Theorem 9 the **s.i.p. kernel** of the s.i.p. RKBS $\mathcal{B}$. It coincides with the reproducing kernel K when $\mathcal{B}$ is an RKHS. In general, when $G = K$ in Theorem 9, we call G an **s.i.p. reproducing kernel**. By (30), an s.i.p. reproducing kernel G satisfies the following generalization of (3)

$$G(x,y) = [G(x,\cdot), G(y,\cdot)]_{\mathcal{B}}, \ \ x, y \in X. \tag{35}$$

We shall give a characterization of an s.i.p. reproducing kernel in terms of its corresponding feature map. To this end, for a mapping Φ from X to a uniformly convex and uniformly Fréchet differentiable Banach space $\mathcal{W}$, we denote by Φ^* the mapping from X to $\mathcal{W}^*$ defined as

$$\Phi^*(x) := (\Phi(x))^*, \ \ x \in X.$$

Theorem 10 *Let $\mathcal{W}$ be a uniformly convex and uniformly Fréchet differentiable Banach space and Φ a mapping from X to $\mathcal{W}$ such that*

$$\overline{\text{span}}\,\Phi(X) = \mathcal{W}, \ \ \overline{\text{span}}\,\Phi^*(X) = \mathcal{W}^*. \tag{36}$$

Then $\mathcal{B} := \{[u, \Phi(\cdot)]_{\mathcal{W}} : u \in \mathcal{W}\}$ equipped with

$$\Big[[u, \Phi(\cdot)]_{\mathcal{W}}, [v, \Phi(\cdot)]_{\mathcal{W}}\Big]_{\mathcal{B}} := [u, v]_{\mathcal{W}} \tag{37}$$

and $\mathcal{B}^* := \{[\Phi(\cdot), u]_{\mathcal{W}} : u \in \mathcal{W}\}$ with

$$\Big[[\Phi(\cdot), u]_{\mathcal{W}}, [\Phi(\cdot), v]_{\mathcal{W}}\Big]_{\mathcal{B}^*} := [v, u]_{\mathcal{W}}$$

are uniformly convex and uniformly Fréchet differentiable Banach spaces. And $\mathcal{B}^*$ is the dual of $\mathcal{B}$ with the bilinear form

$$\Big([u, \Phi(\cdot)]_{\mathcal{W}}, [\Phi(\cdot), v]_{\mathcal{W}}\Big)_{\mathcal{B}} := [u, v]_{\mathcal{W}}, \ \ u, v \in \mathcal{W}. \tag{38}$$

Moreover, the s.i.p. kernel G of $\mathcal{B}$ is given by

$$G(x, y) = [\Phi(x), \Phi(y)]_{\mathcal{W}}, \ \ x, y \in X, \tag{39}$$

which coincides with its reproducing kernel K.

Proof We shall show (39) only. The other results can be proved using arguments similar to those in Theorem 3 and those in the proof of Theorem 7 in Giles (1967). Let $f \in \mathcal{B}$. Then there exists a unique $u \in \mathcal{W}$ such that $f = [u, \Phi(\cdot)]_{\mathcal{W}}$. By (38), for $y \in X$,

$$f(y) = [u, \Phi(y)]_{\mathcal{W}} = ([u, \Phi(\cdot)]_{\mathcal{W}}, [\Phi(\cdot), \Phi(y)]_{\mathcal{W}})_{\mathcal{B}} = (f, [\Phi(\cdot), \Phi(y)]_{\mathcal{W}})_{\mathcal{B}}.$$

Comparing the above equation with (33), we obtain that

$$K(\cdot, y) = [\Phi(\cdot), \Phi(y)]_{\mathcal{W}}. \tag{40}$$

On the other hand, by (37), for $x \in X$

$$f(x) = [u, \Phi(x)]_{\mathcal{W}} = [[u, \Phi(\cdot)]_{\mathcal{W}}, [\Phi(x), \Phi(\cdot)]_{\mathcal{W}}]_{\mathcal{B}},$$

which implies that the s.i.p. kernel of $\mathcal{B}$ is

$$G(x, \cdot) = [\Phi(x), \Phi(\cdot)]_{\mathcal{W}}. \tag{41}$$

By (40) and (41),

$$K(x, y) = G(x, y) = [\Phi(x), \Phi(y)]_{\mathcal{W}},$$

which completes the proof. ■

As a direct consequence of the above theorem, we have the following characterization of s.i.p. reproducing kernels.

Theorem 11 *A function G on $X \times X$ is an s.i.p. reproducing kernel if and only if it is of the form (39), where Φ is a mapping from X to a uniformly convex and uniformly Fréchet differentiable Banach space $\mathcal{W}$ satisfying (36).*

Proof The sufficiency is implied by Theorem 10. For the necessity, suppose that G is an s.i.p. reproducing kernel for some s.i.p. RKBS $\mathcal{B}$ on X. We choose $\mathcal{W} = \mathcal{B}$ and $\Phi(x) := G(x, \cdot)$. Then G has the form (39) by equation (35). Moreover, by (8), $\operatorname{span}\Phi(X)$ is dense in $\mathcal{W}$. Assume that $\operatorname{span}\Phi^*(X)$ is not dense in $\mathcal{W}^*$. Then by the Hahn-Banach theorem and Lemma 8, there exists a nontrivial $f \in \mathcal{B}$ such that $[\Phi^*(x), f^*]_{\mathcal{B}^*} = 0, x \in X$. Thus, by (28) we get that

$$f(x) = [f, G(x, \cdot)]_{\mathcal{B}} = [f, \Phi(x)]_{\mathcal{W}} = [\Phi^*(x), f^*]_{\mathcal{B}^*} = 0, \ \ x \in X.$$

We end up with a zero function f, a contradiction. The proof is complete. ■

The mapping Φ and space $\mathcal{W}$ in the above theorem will be called a **feature map** and **feature space** of the s.i.p. reproducing kernel G, respectively.

By the duality relation (31) and the denseness condition (9), the s.i.p kernel G of an s.i.p. RKBS $\mathcal{B}$ on X satisfies

$$\overline{\operatorname{span}}\{(G(x, \cdot))^* : x \in X\} = \mathcal{B}^*. \tag{42}$$

It is also of the form (35). By Theorem 11, G is identical with the reproducing kernel K for $\mathcal{B}$ if and only if

$$\overline{\operatorname{span}}\{G(x, \cdot) : x \in X\} = \mathcal{B}. \tag{43}$$

If $\mathcal{B}$ is not a Hilbert space then the duality mapping from $\mathcal{B}$ to $\mathcal{B}^*$ is nonlinear. Thus, it may not preserve the denseness of a linear span. As a result, (43) would not follow automatically from (42). Here we remark that for most finite dimensional s.i.p. RKBS, (42) implies (43). This is due to the well-known fact that for all $n \in \mathbb{N}$, the set of $n \times n$ singular matrices has Lebesgue measure zero in $\mathbb{C}^{n \times n}$. Therefore, the s.i.p. kernel for most finite dimensional s.i.p. RKBS is the same as the reproducing kernel. Nevertheless, we shall give an explicit example to illustrate that the two kernels might be different.

For each $p \in (1, +\infty)$ and $n \in \mathbb{N}$, we denote by $\ell^p(\mathbb{N}_n)$ the Banach space of vectors in $\mathbb{C}^n$ with norm

$$\|a\|_{\ell^p(\mathbb{N}_n)} := \left(\sum_{j \in \mathbb{N}_n} |a_j|^p \right)^{1/p}, \ \ a = (a_j : j \in \mathbb{N}_n) \in \mathbb{C}^n.$$

As pointed out at the end of Section 4.1, $\ell^p(\mathbb{N}_n)$ is uniformly convex and uniformly Fréchet differentiable. Its dual space is $\ell^q(\mathbb{N}_n)$. To construct the example, we introduce three vectors in $\ell^3(\mathbb{N}_3)$ by setting

$$e_1 := (2, 9, 1), \ e_2 := (1, 8, 0), \ e_3 := (5, 5, 3).$$

By (29), their dual elements in $\ell^{\frac{3}{2}}(\mathbb{N}_3)$ are

$$e_1^* = \frac{1}{(738)^{1/3}}(4, 81, 1), \ e_2^* = \frac{1}{(513)^{1/3}}(1, 64, 0), \ e_3^* = \frac{1}{(277)^{1/3}}(25, 25, 9).$$

It can be directly verified that $\{e_1, e_2, e_3\}$ is linearly independent but $\{e_1^*, e_2^*, e_3^*\}$ is not. Therefore,

$$\operatorname{span}\{e_1, e_2, e_3\} = \ell^3(\mathbb{N}_3) \tag{44}$$

while

$$\operatorname{span}\{e_1^*, e_2^*, e_3^*\} \subsetneqq \ell^{\frac{3}{2}}(\mathbb{N}_3). \tag{45}$$

With the above preparations, we let $\mathbb{N}_3$ be the input space, Φ the function from $\mathbb{N}_3$ to $\ell^3(\mathbb{N}_3)$ defined by $\Phi(j) = e_j$, $j \in \mathbb{N}_3$, and $\mathcal{B}$ the space of all the functions $\Phi_u := [\Phi(\cdot), u]_{\ell^3(\mathbb{N}_3)}$, $u \in \ell^3(\mathbb{N}_3)$, on $\mathbb{N}_3$. By equation (44),

$$\|\Phi_u\| := \|u\|_{\ell^3(\mathbb{N}_3)}, \ \ u \in \ell^3(\mathbb{N}_3)$$

defines a norm on $\mathcal{B}$. It is clear that point evaluations are continuous on $\mathcal{B}$ under this norm. Furthermore, since the linear mapping $\Phi_u \to u^*$ is isometrically isomorphic from $\mathcal{B}$ to $\ell^{\frac{3}{2}}(\mathbb{N}_3)$, $\mathcal{B}$ is a uniformly convex and uniformly Fréchet differentiable Banach space. By this fact, we obtain that $\mathcal{B}$ is an s.i.p. RKBS with semi-inner-product

$$[\Phi_u, \Phi_v]_{\mathcal{B}} = [v, u]_{\ell^3(\mathbb{N}_3)}, \ \ u, v \in \ell^3(\mathbb{N}_3). \tag{46}$$

The above equation implies that the s.i.p. kernel G for $\mathcal{B}$ is

$$G(j,k) = [e_k, e_j]_{\ell^3(\mathbb{N}_3)}, \ \ j,k \in \mathbb{N}_3. \tag{47}$$

Recall that the reproducing kernel K for $\mathcal{B}$ satisfies the denseness condition (8). Consequently, to show that $G \neq K$, it suffices to show that

$$\operatorname{span}\{G(j,\cdot) : j \in \mathbb{N}_3\} \subsetneqq \mathcal{B}. \tag{48}$$

To this end, we notice by (45) that there exists a nonzero element $v \in \ell^3(\mathbb{N}_3)$ such that

$$[v, e_j]_{\ell^3(\mathbb{N}_3)} = (v, e_j^*)_{\ell^3(\mathbb{N}_3)} = 0, \ \ j \in \mathbb{N}_3.$$

As a result, the nonzero function Φ_v satisfies by (46) and (47) that

$$[G(j,\cdot), \Phi_v]_{\mathcal{B}} = [\Phi_{e_j}, \Phi_v]_{\mathcal{B}} = [v, e_j]_{\ell^3(\mathbb{N}_3)} = 0, \ \ j \in \mathbb{N}_3,$$

which proves (48), and implies that the s.i.p. kernel and reproducing kernel for $\mathcal{B}$ are different. By (45), this is essentially due to the reason that the second condition of (36) is not satisfied.

4.3 Properties of S.i.p. Reproducing Kernels

The existence of a semi-inner-product makes it possible to study properties of RKBS and their reproducing kernels. For illustration, we present below three of these properties.

4.3.1 NON-POSITIVE DEFINITENESS

An $n \times n$ matrix M over a number field $\mathbb{F}$ ($\mathbb{C}$ or $\mathbb{R}$) is said to be positive semi-definite if for all $(c_j : j \in \mathbb{N}_n) \in \mathbb{F}^n$

$$\sum_{j \in \mathbb{N}_n} \sum_{k \in \mathbb{N}_n} c_j \overline{c_k} M_{jk} \geq 0.$$

We shall consider positive semi-definiteness of matrices $G[\mathbf{x}]$ as defined in (1) for an s.i.p. reproducing kernel G on X.

Let $\Phi : X \to \mathcal{W}$ be a feature map for G, that is, (39) and (36) hold. By properties 3 and 4 in the definition of a semi-inner-product, we have that

$$G(x,x) \geq 0, \ \ x \in X \tag{49}$$

and

$$|G(x,y)|^2 \leq G(x,x)G(y,y), \ \ x,y \in X. \tag{50}$$

Notice that if a complex matrix is positive semi-definite then it must be hermitian. Since a semi-inner-product is in general not an inner product, we can not expect a complex s.i.p. kernel to be positive definite. In the real case, inequalities (49) and (50) imply that $G[\mathbf{x}]$ is positive semi-definite for all $\mathbf{x} \subseteq X$ with cardinality less than or equal to two. However, $G[\mathbf{x}]$ might stop being positive semi-definite if $\mathbf{x}$ contains more than two points. We shall give an explicit example to explain this phenomenon.

Set $p \in (1,+\infty)$ and $\mathcal{W} := \ell^p(\mathbb{N}_2)$. We let $X := \mathbb{R}_+ := [0,+\infty)$ and $\Phi(x) = (1,x), x \in X$. Thus,

$$\Phi^*(x) = \frac{(1,x^{p-1})}{(1+x^p)^{\frac{p-2}{p}}}, \ \ x \in X.$$

Clearly, Φ satisfies the denseness condition (36). The corresponding s.i.p. reproducing kernel G is constructed as

$$G(x,y) = [\Phi(x),\Phi(y)]_{\mathcal{W}} = \frac{1+xy^{p-1}}{(1+y^p)^{\frac{p-2}{p}}}, \ \ x,y \in X. \tag{51}$$

Proposition 12 *For the s.i.p. reproducing kernel G defined by (51), matrix $G[\mathbf{x}]$ is positive semi-definite for all $\mathbf{x} = \{x,y,z\} \subseteq X$ if and only if $p = 2$.*

Proof If $p = 2$ then $\mathcal{W}$ is a Hilbert space. As a result, G is a positive definite kernel. Hence, for all finite subsets $\mathbf{x} \subseteq X$, $G[\mathbf{x}]$ is positive semi-definite.

Assume that $G[\mathbf{x}]$ is positive semi-definite for all $\mathbf{x} = \{x,y,z\} \subseteq X$. Choose $\mathbf{x} := \{0,1,t\}$ where t is a positive number to be specified later. Then we have by (51) that

$$G[\mathbf{x}] = \begin{bmatrix} 1 & 2^{2/p-1} & \dfrac{1}{(1+t^p)^{1-2/p}} \\ 1 & 2^{2/p} & \dfrac{1+t^{p-1}}{(1+t^p)^{1-2/p}} \\ 1 & \dfrac{1+t}{2^{1-2/p}} & \dfrac{1+t^p}{(1+t^p)^{1-2/p}} \end{bmatrix}.$$

Let M be the symmetrization of $G[\mathbf{x}]$ given as

$$M = \begin{bmatrix} 1 & \dfrac{1}{2}+2^{2/p-2} & \dfrac{1}{2}+\dfrac{1}{2(1+t^p)^{1-2/p}} \\ \dfrac{1}{2}+2^{2/p-2} & 2^{2/p} & \dfrac{1+t}{2^{2-2/p}}+\dfrac{1+t^{p-1}}{2(1+t^p)^{1-2/p}} \\ \dfrac{1}{2}+\dfrac{1}{2(1+t^p)^{1-2/p}} & \dfrac{1+t}{2^{2-2/p}}+\dfrac{1+t^{p-1}}{2(1+t^p)^{1-2/p}} & \dfrac{1+t^p}{(1+t^p)^{1-2/p}} \end{bmatrix}.$$

Matrix M preserves the positive semi-definiteness of $G[\mathbf{x}]$. Therefore, its determinant $|M|$ must be nonnegative. Through an analysis of the asymptotic behavior of the component of M as t goes to infinity, we obtain that

$$|M| = -\frac{t^2}{8}\left(2^{\frac{2}{p}} - 2\right)^2 + \varphi(t), \;\; t > 0,$$

where φ is a function satisfying that

$$\lim_{t\to\infty} \frac{\varphi(t)}{t^2} = 0.$$

Therefore, $|M|$ being always nonnegative forces $2^{\frac{2}{p}} - 2 = 0$, which occurs only if $p = 2$. ■

By Proposition 12, non-positive semi-definiteness is a characteristic of s.i.p. reproducing kernels for RKBS that distincts them from reproducing kernels for RKHS.

4.3.2 POINTWISE CONVERGENCE

If f_n converges to f in an s.i.p. RKBS with its s.i.p. kernel G then $f_n(x)$ converges to $f(x)$ for any $x \in X$ and the limit is uniform on the set where $G(x,x)$ is bounded. This follows from (30) and the Cauchy-Schwartz inequality by

$$|f_n(x) - f(x)| = |[f_n - f, G(x,\cdot)]_{\mathcal{B}}| \leq \|f_n - f\|_{\mathcal{B}} \sqrt{[G(x,\cdot), G(x,\cdot)]_{\mathcal{B}}} = \sqrt{G(x,x)}\|f_n - f\|_{\mathcal{B}}.$$

4.3.3 WEAK UNIVERSALITY

Suppose that X is metric space and G is an s.i.p. reproducing kernel on X. We say that G is **universal** if G is continuous on $X \times X$ and for all compact subsets $\mathcal{Z} \subseteq X$, $\operatorname{span}\{G(x,\cdot) : x \in \mathcal{Z}\}$ is dense in $C(\mathcal{Z})$ (Micchelli et al., 2006; Steinwart, 2001). Universality of a kernel ensures that it can approximate any continuous target function uniformly on compact subsets of the input space. This is crucial for the consistence of the learning algorithms with the kernel. We shall discuss the case when X is itself a compact metric space. Here we are concerned with the ability of G to approximate any continuous target function on X uniformly. For this purpose, we call a continuous kernel G on a compact metric space X **weakly universal** if $\operatorname{span}\{G(x,\cdot) : x \in X\}$ is dense in $C(X)$. We shall present a characterization of weak universality. The results in the cases of positive definite kernels and vector-valued positive definite kernels have been established respectively in Micchelli et al. (2006) and Caponnetto et al. (2008).

Proposition 13 *Let Φ be a feature map from a compact metric space X to $\mathcal{W}$ such that both $\Phi : X \to \mathcal{W}$ and $\Phi^* : X \to \mathcal{W}^*$ are continuous. Then the s.i.p. reproducing kernel G defined by (39) is continuous on $X \times X$, and there holds in $C(X)$ the equality of subspaces*

$$\overline{\operatorname{span}}\{G(x,\cdot) : x \in X\} = \overline{\operatorname{span}}\{[u, \Phi(\cdot)]_{\mathcal{W}} : u \in \mathcal{W}\}.$$

Consequently, G is weakly universal if and only if

$$\overline{\operatorname{span}}\{[u, \Phi(\cdot)]_{\mathcal{W}} : u \in \mathcal{W}\} = C(X).$$

Proof First, we notice by

$$G(x,y) = [\Phi(x), \Phi(y)]_{\mathcal{W}} = (\Phi(x), \Phi^*(y))_{\mathcal{W}}, \;\; x,y \in X$$

that G is continuous on $X \times X$. Similarly, for each $u \in \mathcal{W}$, $[u, \Phi(\cdot)]_{\mathcal{W}} = (u, \Phi^*(\cdot))_{\mathcal{W}} \in C(X)$. Now since

$$G(x,\cdot) = [\Phi(x), \Phi(\cdot)]_{\mathcal{W}} \in \{[u, \Phi(\cdot)]_{\mathcal{W}} : u \in \mathcal{W}\},$$

we have the inclusion

$$\overline{\text{span}}\{G(x,\cdot) : x \in X\} \subseteq \overline{\text{span}}\{[u, \Phi(\cdot)]_{\mathcal{W}} : u \in \mathcal{W}\}.$$

On the other hand, let $u \in \mathcal{W}$. By denseness condition (36), there exists a sequence $v_n \in \text{span}\{\Phi(x) : x \in X\}$ that converges to u. Since G is continuous on the compact space $X \times X$, it is bounded. Thus, by the property of pointwise convergence discussed before, $[v_n, \Phi(\cdot)]_{\mathcal{W}}$ converges in $C(X)$ to $[u, \Phi(\cdot)]_{\mathcal{W}}$. Noting that

$$[v_n, \Phi(\cdot)]_{\mathcal{W}} \in \text{span}\{G(x,\cdot) : x \in X\}, \;\; n \in \mathbb{N},$$

we have the reverse inclusion

$$\overline{\text{span}}\{[u, \Phi(\cdot)]_{\mathcal{W}} : u \in \mathcal{W}\} \subseteq \overline{\text{span}}\{G(x,\cdot) : x \in X\},$$

which proves the result. ■

We remark that in the case that $\mathcal{W}$ is a Hilbert space, the idea in the above proof can be applied to show with less effort the main result in Caponnetto et al. (2008) and Micchelli et al. (2006), that is, for each compact subset $\mathcal{Z} \subseteq X$

$$\overline{\text{span}}\{G(x,\cdot) : x \in \mathcal{Z}\} = \overline{\text{span}}\{[u, \Phi(\cdot)]_{\mathcal{W}} : u \in \mathcal{W}\},$$

where the two closures are taken in $C(\mathcal{Z})$. A key element missing in the Banach space is the orthogonal decomposition in a Hilbert space $\mathcal{W}$:

$$\mathcal{W} = (\overline{\text{span}}\Phi(\mathcal{Z})) \oplus \Phi(\mathcal{Z})^{\perp}, \;\; \mathcal{Z} \subseteq X.$$

For a normed vector space V, we denote for each $A \subseteq V$ by $A^{\perp} := \{v^* \in V^* : (a, v^*)_V = 0, \; a \in A\}$, and for each $B \subseteq V^*$, ${}^{\perp}B := \{a \in V : (a, v^*)_V = 0, \; v^* \in B\}$. A Banach space $\mathcal{W}$ is in general not the direct sum of $\overline{\text{span}}\Phi(\mathcal{Z})$ and ${}^{\perp}\Phi^*(\mathcal{Z})$. In fact, closed subspaces in $\mathcal{W}$ may not always have an algebraic complement unless $\mathcal{W}$ is isomorphic to a Hilbert space (see, Conway, 1990, page 94).

Universality and other properties of s.i.p. reproducing kernels will be treated specially in future work. One of the main purposes of this study is to apply the tool of s.i.p. reproducing kernels to learning in Banach spaces. To be precise, we shall develop in the framework of s.i.p. RKBS several standard learning schemes.

5. Representer Theorems for Standard Learning Schemes

In this section, we assume that $\mathcal{B}$ is an s.i.p. RKBS on X with the s.i.p. reproducing kernel G defined by a feature map $\Phi : X \to \mathcal{W}$ as in (39). We shall develop in this framework several standard learning schemes including minimal norm interpolation, regularization network, support vector machines, and kernel principal component analysis. For introduction and discussions of these widely used algorithms in RKHS, see, for example, Cucker and Smale (2002), Evgeniou et al. (2000), Micchelli and Pontil (2005), Schölkopf and Smola (2002), Shawe-Taylor and Cristianini (2004) and Vapnik (1998).

5.1 Minimal Norm Interpolation

The minimal norm interpolation is to find, among all functions in $\mathcal{B}$ that interpolate a prescribed set of points, a function with the minimal norm. Let $\mathbf{x} := \{x_j : j \in \mathbb{N}_n\}$ be a fixed finite set of distinct points in X and set for each $\mathbf{y} := (y_j : j \in \mathbb{N}_n) \in \mathbb{C}^n$

$$I_{\mathbf{y}} := \{f \in \mathcal{B} : f(x_j) = y_j,\ j \in \mathbb{N}_n\}.$$

Our purpose is to find $f_0 \in I_{\mathbf{y}}$ such that

$$\|f_0\|_{\mathcal{B}} = \inf\{\|f\|_{\mathcal{B}} : f \in I_{\mathbf{y}}\} \tag{52}$$

provided that I_y is nonempty. Our first concern is of course the condition ensuring that $I_{\mathbf{y}}$ is nonempty. To address this issue, let us recall the useful property of the s.i.p. reproducing kernel G:

$$f(x) = [f, G(x,\cdot)]_{\mathcal{B}} = [G(\cdot,x), f^*]_{\mathcal{B}^*},\ \ x \in X,\ f \in \mathcal{B}. \tag{53}$$

Lemma 14 *The set $I_{\mathbf{y}}$ is nonempty for any $\mathbf{y} \in \mathbb{C}^n$ if and only if $G_{\mathbf{x}} := \{G(\cdot,x_j) : j \in \mathbb{N}_n\}$ is linearly independent in $\mathcal{B}^*$.*

Proof Observe that $I_{\mathbf{y}}$ is nonempty for any $\mathbf{y} \in \mathbb{C}^n$ if and only if $\operatorname{span}\{(f(x_j) : j \in \mathbb{N}_n) : f \in \mathcal{B}\}$ is dense in $\mathbb{C}^n$. Using the reproducing property (53), we have for each $(c_j : j \in \mathbb{N}_n) \in \mathbb{C}^n$ that

$$\sum_{j\in\mathbb{N}_n} c_j f(x_j) = \sum_{j\in\mathbb{N}_n} c_j [f, G(x_j,\cdot)]_{\mathcal{B}} = \left[\sum_{j\in\mathbb{N}_n} c_j G(\cdot,x_j), f^*\right]_{\mathcal{B}^*}.$$

Thus,

$$\sum_{j\in\mathbb{N}_n} c_j f(x_j) = 0, \quad \text{for all } f \in \mathcal{B}$$

if and only if

$$\sum_{j\in\mathbb{N}_n} c_j G(\cdot,x_j) = 0.$$

This implies that $G_{\mathbf{x}}$ is linearly independent in $\mathcal{B}^*$ if and only if $\operatorname{span}\{(f(x_j) : j \in \mathbb{N}_n) : f \in \mathcal{B}\}$ is dense in $\mathbb{C}^n$. Therefore, $I_{\mathbf{y}}$ is nonempty for any $\mathbf{y} \in \mathbb{C}^n$ if and only if $G_{\mathbf{x}}$ is linearly independent. ■

We next show that the minimal norm interpolation problem in $\mathcal{B}$ always has a unique solution under the hypothesis that $G_{\mathbf{x}}$ is linearly independent. The following useful property of a uniformly convex Banach space is crucial (see, for example, Istrăţescu, 1984, page 53).

Lemma 15 *If V is a uniformly convex Banach space, then for any nonempty closed convex subset $A \subseteq V$ and any $x \in V$ there exists a unique $x_0 \in A$ such that*

$$\|x - x_0\|_V = \inf\{\|x - a\|_V : a \in A\}.$$

Proposition 16 *If $G_{\mathbf{x}}$ is linearly independent in $\mathcal{B}^*$, then for any $\mathbf{y} \in \mathbb{C}^n$ there exists a unique $f_0 \in I_{\mathbf{y}}$ satisfying (52).*

Proof By Lemma 14, $I_{\mathbf{y}}$ is nonempty. Note also that it is closed and convex. Since $\mathcal{B}$ is uniformly convex, by Lemma 15, there exists a unique $f_0 \in I_{\mathbf{y}}$ such that

$$\|f_0\|_{\mathcal{B}} = \|0 - f_0\|_{\mathcal{B}} = \inf\{\|0 - f\|_{\mathcal{B}} = \|f\|_{\mathcal{B}} : f \in I_{\mathbf{y}}\}.$$

The above equation proves the result. ■

We shall establish a representation of the minimal norm interpolator f_0. For this purpose, a simple observation is made based on the following fact connecting orthogonality with best approximation in s.i.p. spaces (Giles, 1967).

Lemma 17 *If V is a uniformly Fréchet differentiable normed vector space, then $\|x + \lambda y\|_V \geq \|x\|_V$ for all $\lambda \in \mathbb{C}$ if and only if $[y, x]_V = 0$.*

Lemma 18 *If $I_{\mathbf{y}}$ is nonempty then $f_0 \in I_{\mathbf{y}}$ is the minimizer of (52) if and only if*

$$[g, f_0]_{\mathcal{B}} = 0, \quad \text{for all } g \in I_0. \tag{54}$$

Proof Let $f_0 \in I_{\mathbf{y}}$. It is obvious that f_0 is the minimizer of (52) if and only if

$$\|f_0 + g\|_{\mathcal{B}} \geq \|f_0\|_{\mathcal{B}}, \quad g \in I_0.$$

Since I_0 is a linear subspace of $\mathcal{B}$, the result follows immediately from Lemma 17. ■

The following result is of the representer theorem type. For the representer theorem in learning with positive definite kernels, see, for example, Argyriou et al. (2008), Kimeldorf and Wahba (1971) and Schölkopf et al. (2001).

Theorem 19 *(Representer Theorem) Suppose that $G_{\mathbf{x}}$ is linearly independent in $\mathcal{B}^*$ and f_0 is the solution of the minimal norm interpolation (52). Then there exists $\mathbf{c} = (c_j : j \in \mathbb{N}_n) \in \mathbb{C}^n$ such that*

$$f_0^* = \sum_{j \in \mathbb{N}_n} c_j G(\cdot, x_j). \tag{55}$$

Moreover, a function of the form in the right hand side above is the solution if and only if $\mathbf{c}$ satisfies

$$\left[G(\cdot, x_k), \sum_{j \in \mathbb{N}_n} c_j G(\cdot, x_j) \right]_{\mathcal{B}^*} = y_k, \quad k \in \mathbb{N}_n. \tag{56}$$

Proof Note that (54) is equivalent to $f_0^* \in I_0{}^\perp$ and that $I_0 = {}^\perp G_{\mathbf{x}}$. Therefore, f_0 satisfies (54) if and only if

$$f_0^* \in ({}^\perp G_{\mathbf{x}})^\perp.$$

Recall a consequence of the Hahn-Banach theorem that in a reflexive Banach space $\mathcal{B}$, for each $B \subseteq \mathcal{B}^*$,

$$({}^\perp B)^\perp = \overline{\operatorname{span}} B. \tag{57}$$

By this fact, (55) holds true for some $\mathbf{c} \in \mathbb{C}^n$.

Suppose that $f \in \mathcal{B}$ is of the form $f^* = \sum_{j\in\mathbb{N}_n} c_j G(\cdot, x_j)$ where $\mathbf{c}$ satisfies (56). Then $f^* \in \operatorname{span} G_{\mathbf{x}}$. By (57), f^* satisfies (54). Furthermore, (56) implies that

$$f(x_k) = [f, G(x_k,\cdot)]_{\mathcal{B}} = [G(\cdot,x_k), f^*]_{\mathcal{B}^*} = \left[G(\cdot,x_k), \sum_{j\in\mathbb{N}_n} c_j G(\cdot,x_j)\right]_{\mathcal{B}^*} = y_k, \ \ k \in \mathbb{N}_n. \tag{58}$$

That is, $f \in I_{\mathbf{y}}$. By Lemma 18, $f = f_0$. On the other hand, f_0 has the form (55). As shown in (58), (56) is simply the interpolation condition that $f_0(x_k) = y_k, k \in \mathbb{N}_n$. Thus, it must be true. The proof is complete. ■

Applying the inverse of the duality mapping to both sides of (55) yields a representation of f_0 in the space $\mathcal{B}$. However, since the duality mapping is nonadditive unless $\mathcal{B}$ is an RKHS, this procedure in general does not result in a linear representation.

We conclude that under the condition that $G_{\mathbf{x}}$ is linearly independent, the minimal norm interpolation problem (52) has a unique solution, and finding the solution reduces to solving the system (56) of equations about $\mathbf{c} \in \mathbb{C}^n$. The solution $\mathbf{c}$ of (56) is unique by Theorem 19. Again, the difference from the result for RKHS is that (56) is often nonlinear about $\mathbf{c}$ since by Proposition 6 a semi-inner-product is generally nonadditive about the second variable.

To see an explicit form of (56), we shall reformulate it in terms of the feature map Φ from X to $\mathcal{W}$. Let $\mathcal{B}$ and $\mathcal{B}^*$ be identified as in Theorem 10. Then (56) has the equivalent form

$$\left[\Phi^*(x_k), \sum_{j\in\mathbb{N}_n} c_j \Phi^*(x_j)\right]_{\mathcal{B}^*} = y_k, \ \ k \in \mathbb{N}_n.$$

In the particular case that $\mathcal{W} = L^p(\Omega,\mu)$, $p \in (1,+\infty)$ on some measure space $(\Omega, \mathcal{F}, \mu)$, and $\mathcal{W}^* = L^q(\Omega,\mu)$, the above equation is rewritten as

$$\int_\Omega \Phi^*(x_k) \overline{\sum_{j\in\mathbb{N}_n} c_j \Phi^*(x_j)} \left|\sum_{j\in\mathbb{N}_n} c_j \Phi^*(x_j)\right|^{q-2} d\mu = y_k \left\|\sum_{j\in\mathbb{N}_n} c_j \Phi^*(x_j)\right\|_{L^q(\Omega,\mu)}^{q-2}, \ \ k \in \mathbb{N}_n.$$

5.2 Regularization Network

We consider learning a predictor function from a finite sample data $\mathbf{z} := \{(x_j, y_j) : j \in \mathbb{N}_n\} \subseteq X \times \mathbb{C}$ in this subsection. The predictor function will yield from a regularized learning algorithm. Let $\mathcal{L} : \mathbb{C} \times \mathbb{C} \to \mathbb{R}_+$ be a *loss function* that is continuous and convex with respect to its first variable. For each $f \in \mathcal{B}$, we set

$$\mathcal{E}_{\mathbf{z}}(f) := \sum_{j\in\mathbb{N}_n} \mathcal{L}(f(x_j), y_j) \text{ and } \mathcal{E}_{\mathbf{z},\mu}(f) := \mathcal{E}_{\mathbf{z}}(f) + \mu \|f\|_{\mathcal{B}}^2,$$

where μ is a positive regularization parameter. The predictor function that we learn from the sample data $\mathbf{z}$ will be the function f_0 satisfying

$$\mathcal{E}_{\mathbf{z},\mu}(f_0) = \inf\{\mathcal{E}_{\mathbf{z},\mu}(f) : f \in \mathcal{B}\}. \tag{59}$$

One can always make this choice as we shall prove that the minimizer of (59) exists and is unique.

Theorem 20 *There exists a unique $f_0 \in \mathcal{B}$ satisfying (59).*

Proof We first show the existence. If $f \in \mathcal{B}$ satisfies $\|f\|_{\mathcal{B}}^2 > \frac{1}{\mu}\mathcal{E}_{\mathbf{z},\mu}(0)$ then

$$\mathcal{E}_{\mathbf{z},\mu}(f) \geq \mu\|f\|_{\mathcal{B}}^2 > \mathcal{E}_{\mathbf{z},\mu}(0).$$

Thus

$$\inf\{\mathcal{E}_{\mathbf{z},\mu}(f) : f \in \mathcal{B}\} = \inf\left\{\mathcal{E}_{\mathbf{z},\mu}(f) : f \in \mathcal{B},\ \|f\|_{\mathcal{B}}^2 \leq \frac{1}{\mu}\mathcal{E}_{\mathbf{z},\mu}(0)\right\}.$$

Let

$$e := \inf\left\{\mathcal{E}_{\mathbf{z},\mu}(f) : f \in \mathcal{B},\ \|f\|_{\mathcal{B}}^2 \leq \frac{1}{\mu}\mathcal{E}_{\mathbf{z},\mu}(0)\right\}$$

and

$$A := \left\{f \in \mathcal{B} : \|f\|_{\mathcal{B}}^2 \leq \frac{1}{\mu}\mathcal{E}_{\mathbf{z},\mu}(0)\right\}.$$

Then, there exists a sequence $f_k \in A$, $k \in \mathbb{N}$, such that

$$e \leq \mathcal{E}_{\mathbf{z},\mu}(f_k) \leq e + \frac{1}{k}. \tag{60}$$

Since $\mathcal{B}$ is reflexive, A is weakly compact, that is, we may assume that there exists $f_0 \in A$ such that for all $g \in \mathcal{B}$

$$\lim_{k\to\infty}[f_k, g]_{\mathcal{B}} = [f_0, g]_{\mathcal{B}}. \tag{61}$$

In particular, the choice $g := G(x_j, \cdot)$, $j \in \mathbb{N}_n$ yields that $f_k(x_j)$ converges to $f_0(x_j)$ as $k \to \infty$ for all $j \in \mathbb{N}_n$. Since the loss function $\mathcal{L}$ is continuous about the first variable, we have that

$$\lim_{k\to\infty}\mathcal{E}_{\mathbf{z}}(f_k) = \mathcal{E}_{\mathbf{z}}(f_0).$$

Also, choosing $g = f_0$ in (61) yields that

$$\lim_{k\to\infty}[f_k, f_0]_{\mathcal{B}} = \|f_0\|_{\mathcal{B}}^2.$$

By the above two equations, for each $\varepsilon > 0$ there exists some N such that for $k \geq N$

$$\mathcal{E}_{\mathbf{z}}(f_0) \leq \mathcal{E}_{\mathbf{z}}(f_k) + \varepsilon$$

and

$$\|f_0\|_{\mathcal{B}}^2 \leq \varepsilon\|f_0\|_{\mathcal{B}}^2 + |[f_k, f_0]_{\mathcal{B}}| \leq \varepsilon\|f_0\|_{\mathcal{B}}^2 + \|f_k\|_{\mathcal{B}}\|f_0\|_{\mathcal{B}}, \text{ if } f_0 \neq 0.$$

If $f_0 = 0$, then trivially we have

$$\|f_0\|_{\mathcal{B}} \leq \varepsilon\|f_0\|_{\mathcal{B}} + \|f_k\|_{\mathcal{B}}.$$

Combining the above three equations, we get for $k \geq N$ that

$$\mathcal{E}_{\mathbf{z},\mu}(f_0) \leq \frac{1}{(1-\varepsilon)^2}\mathcal{E}_{\mathbf{z},\mu}(f_k) + \varepsilon.$$

By (60) and the arbitrariness of ε, we conclude that f_0 is a minimizer of (59).

Since $\mathcal{L}$ is convex with respect to its first variable and $\|\cdot\|_{\mathcal{B}}^2$ is strictly convex, $\mathcal{E}_{\mathbf{z},\mu}$ is strictly convex on $\mathcal{B}$. This implies the uniqueness of the minimizer. ■

In the rest of this subsection, we shall consider the regularization network in $\mathcal{B}$, that is, the loss function $\mathcal{L}$ is specified as

$$\mathcal{L}(a,b) = |a-b|^2, \ \ a,b \in \mathbb{C}.$$

It is continuous and convex with respect to its first variable. Therefore, by Theorem 20, there is a unique minimizer for the regularization network:

$$\min_{f\in\mathcal{B}} \sum_{j\in\mathbb{N}_n} |f(x_j) - y_j|^2 + \mu\|f\|_{\mathcal{B}}^2. \tag{62}$$

We next consider solving the minimizer. To this end, we need the notion of strict convexity of a normed vector space. We call a normed vector space V **strictly convex** if whenever $\|x+y\|_V = \|x\|_V + \|y\|_V$ for some $x, y \neq 0$, there must hold $y = \lambda x$ for some $\lambda > 0$. Note that a uniformly convex normed vector space is automatically strictly convex. The following result was observed in Giles (1967).

Lemma 21 *An s.i.p. space V is strictly convex if and only if whenever $[x,y]_V = \|x\|_V\|y\|_V$ for some $x, y \neq 0$ there holds $y = \lambda x$ for some $\lambda > 0$.*

A technical result about s.i.p. spaces is required for solving the minimizer.

Lemma 22 *Let V be a strictly convex s.i.p. space. Then for all $u, v \in V$*

$$\|u+v\|_V^2 - \|u\|_V^2 - 2\,\mathrm{Re}\,[v,u]_V \geq 0.$$

Proof Assume that there exist $u, v \in V$ such that

$$\|u+v\|_V^2 - \|u\|_V^2 - 2\,\mathrm{Re}\,[v,u]_V < 0.$$

Then we have $u, v \neq 0$. We proceed by the above inequality and properties of semi-inner-products that

$$\begin{aligned} \|u\|_V^2 &= [u+v-v,u]_V = [u+v,u]_V - [v,u]_V \\ &= \mathrm{Re}\,[u+v,u]_V - \mathrm{Re}\,[v,u]_V \leq |[u+v,u]_V| - \mathrm{Re}\,[v,u]_V \\ &\leq \|u+v\|_V\|u\|_V - \frac{\|u+v\|_V^2 - \|u\|_V^2}{2}. \end{aligned}$$

The last inequality above can be simplified as

$$\|u+v\|_V^2 + \|u\|_V^2 \leq 2\|u+v\|_V\|u\|_V.$$

Thus, we must have

$$\|u+v\|_V = \|u\|_V \text{ and } [u+v,u]_V = \|u+v\|_V\|u\|_V.$$

Applying the strict convexity of V and Lemma 21, we obtain that $u+v=u$, namely, $v=0$. This is impossible. ■

Theorem 23 *(Representer Theorem) Let f_0 be the minimizer of (62). Then there exists some $\mathbf{c} \in \mathbb{C}^n$ such that*

$$f_0^* = \sum_{j\in\mathbb{N}_n} c_j G(\cdot,x_j). \tag{63}$$

If $G_{\mathbf{x}}$ is linearly independent then the right hand side of the above equation is the minimizer if and only if

$$\mu\overline{c_k} + \left[G(\cdot,x_k), \sum_{j\in\mathbb{N}_n} c_j G(\cdot,x_j)\right]_{\mathcal{B}^*} = y_k, \ \ k\in\mathbb{N}_n. \tag{64}$$

Proof Let $g\in\mathcal{B}$. Define the function $\phi:\mathbb{R}\to\mathbb{R}$ by $\phi(t) := \mathcal{E}_{\mathbf{z},\mu}(f_0+tg)$, $t\in\mathbb{R}$. We compute by Lemma 7 that

$$\phi'(t) = 2\,\mathrm{Re}\sum_{j\in\mathbb{N}_n} g(x_j)(\overline{f_0(x_j)-y_j} + t\overline{g(x_j)}) + 2\mu\,\mathrm{Re}\,[g,f_0+tg]_{\mathcal{B}}.$$

Since f_0 is the minimizer, $t=0$ is the minimum point of ϕ. Hence $\phi'(0)=0$, that is,

$$\sum_{j\in\mathbb{N}_n} g(x_j)\overline{f_0(x_j)-y_j} + \mu[g,f_0]_{\mathcal{B}} = 0, \ \text{ for all } g\in\mathcal{B}.$$

The above equation can be rewritten as

$$\sum_{j\in\mathbb{N}_n} [\overline{f_0(x_j)-y_j}G(\cdot,x_j),g^*]_{\mathcal{B}^*} + \mu[f_0^*,g^*]_{\mathcal{B}^*} = 0, \ \text{ for all } g\in\mathcal{B},$$

which is equivalent to

$$\mu f_0^* = \sum_{j\in\mathbb{N}_n} \overline{y_j - f_0(x_j)}G(\cdot,x_j). \tag{65}$$

Therefore, f_0^* has the form (63).

If $G_{\mathbf{x}}$ is linearly independent then $f_0^* = \sum_{j\in\mathbb{N}_n} c_j G(\cdot,x_j)$ satisfies (65) if and only if (64) holds. Thus, it remains to show that condition (65) is enough to ensure that f_0 is the minimizer. To this end, we check that (65) leads to

$$\mathcal{E}_{\mathbf{z},\mu}(f_0+g) - \mathcal{E}_{\mathbf{z},\mu}(f_0) = \mu\|f_0+g\|_{\mathcal{B}}^2 - \mu\|f_0\|_{\mathcal{B}}^2 - 2\mu\,\mathrm{Re}\,[g,f_0]_{\mathcal{B}} + \sum_{j\in\mathbb{N}_n}|g(x_j)|^2,$$

which by Lemma 22 is nonnegative. The proof is complete. ■

By Theorem 23, if $G_{\mathbf{x}}$ is linearly independent then the minimizer of (62) can be obtained by solving (64), which has a unique solution in this case. Using the feature map, the system (64) has the following form

$$\mu\overline{c_k} + \left[\Phi^*(x_k), \sum_{j\in\mathbb{N}_n} c_j\Phi^*(x_j)\right]_{\mathcal{B}^*} = y_k, \ \ k\in\mathbb{N}_n.$$

As remarked before, this is in general nonlinear about $\mathbf{c}$.

5.3 Support Vector Machines

In this subsection, we assume that all the spaces are over the field $\mathbb{R}$ of real numbers, and consider learning a classifier from the data $\mathbf{z} := \{(x_j, y_j) : j \in \mathbb{N}_n\} \subseteq X \times \{-1, 1\}$. We shall establish for this task two learning algorithms in RKBS whose RKHS versions are well-known (Evgeniou et al., 2000; Schölkopf and Smola, 2002; Shawe-Taylor and Cristianini, 2004; Vapnik, 1998; Wahba, 1999).

5.3.1 SOFT MARGIN HYPERPLANE CLASSIFICATION

We first focus on the soft margin hyperplane classification by studying

$$\inf\left\{\frac{1}{2}\|w\|_{\mathcal{W}}^2 + C\|\xi\|_{\ell^1(\mathbb{N}_n)} : w \in \mathcal{W},\ \xi := (\xi_j : j \in \mathbb{N}_n) \in \mathbb{R}_+^n,\ b \in \mathbb{R}\right\} \tag{66}$$

subject to

$$y_j([\Phi(x_j), w]_{\mathcal{W}} + b) \geq 1 - \xi_j, \quad j \in \mathbb{N}_n.$$

Here, C is a fixed positive constant controlling the tradeoff between margin maximization and training error minimization. If a minimizer $(w_0, \xi_0, b_0) \in \mathcal{W} \times \mathbb{R}_+^n \times \mathbb{R}$ exists, the classifier is taken as $\operatorname{sgn}([\Phi(\cdot), w_0]_{\mathcal{W}} + b_0)$.

Recall by Theorem 10 that functions in $\mathcal{B}^*$ are of the form

$$f^* = [\Phi(\cdot), w]_{\mathcal{W}}, \quad w \in \mathcal{W} \tag{67}$$

and

$$\|f^*\|_{\mathcal{B}^*} = \|w\|_{\mathcal{W}}.$$

Introduce the loss function

$$\mathcal{L}_b(a, y) := \max\{1 - ay - by, 0\}, \quad (a, y) \in \mathbb{R} \times \{-1, 1\}, \quad b \in \mathbb{R},$$

and the error functional on $\mathcal{B}^*$,

$$\mathcal{E}_{b,\mathbf{z},\mu}(f^*) := \mu\|f^*\|_{\mathcal{B}^*}^2 + \sum_{j \in \mathbb{N}_n} \mathcal{L}_b(f^*(x_j), y_j), \quad f^* \in \mathcal{B}^*$$

where $\mu := 1/(2C)$. Then we observe that (66) can be equivalently rewritten as

$$\inf\{\mathcal{E}_{b,\mathbf{z},\mu}(f^*) : f^* \in \mathcal{B}^*, \quad b \in \mathbb{R}\}. \tag{68}$$

When $b = 0$, (68) is also called the support vector machine classification (Wahba, 1999).

If a minimizer $(f_0^*, b_0) \in \mathcal{B}^* \times \mathbb{R}$ for (68) exists then by (67), the classifier followed from (66) will be taken as $\operatorname{sgn}(f_0^* + b_0)$. It can be verified that for every $b \in \mathbb{R}$, $\mathcal{L}_b$ is convex and continuous with respect to its first variable. This enables us to prove the existence of minimizers for (68) based on Theorem 20.

Proposition 24 *Suppose that $\{y_j : j \in \mathbb{N}_n\} = \{-1, 1\}$. Then there exists a minimizer $(f_0^*, b_0) \in \mathcal{B}^* \times \mathbb{R}$ for (68). Moreover, the first component f_0^* of the minimizer is unique.*

Proof The uniqueness of f_0^* follows from the fact that $\mathcal{E}_{b,\mathbf{z},\mu}$ is strictly convex with respect to its first variable. It remains to deal with the existence. Let e be the infimum (68). Then there exists a sequence $(f_k^*, b_k^*) \in \mathcal{B}^* \times \mathbb{R}, k \in \mathbb{N}$ such that

$$\lim_{k\to\infty} \mathcal{E}_{b_k,\mathbf{z},\mu}(f_k^*) = e. \tag{69}$$

Since $\{y_j : j \in \mathbb{N}_n\} = \{-1,1\}$, $\{b_k : k \in \mathbb{N}\}$ is bounded on $\mathbb{R}$. We may hence assume that b_k converges to some $b_0 \in \mathbb{R}$. By Theorem 20, $\min\{\mathcal{E}_{b_0,\mathbf{z},\mu}(f^*) : f^* \in \mathcal{B}^*\}$ has a unique minimizer f_0^*. The last fact we shall need is the simple observation that

$$\max\{1-ay-by,0\} - \max\{1-ay-b'y,0\} \le |b-b'| \text{ for all } a,b,b' \in \mathbb{R} \text{ and } y \in \{-1,1\}.$$

Thus, we get for all $k \in \mathbb{N}$ that

$$\mathcal{E}_{b_0,\mathbf{z},\mu}(f_0^*) \le \mathcal{E}_{b_0,\mathbf{z},\mu}(f_k^*) \le \mathcal{E}_{b_k,\mathbf{z},\mu}(f_k^*) + n|b_0 - b_k|,$$

which together with (69) and $\lim_{k\to\infty} b_k = b_0$ implies that (f_0^*, b_0) is a minimizer for (68). ■

Since the soft margin hyperplane classification (66) is equivalent to (68), we obtain by Proposition 24 that it has a minimizer $(w_0, \xi_0, b_0) \in \mathcal{W} \times \mathbb{R}_+^n \times \mathbb{R}$, where the first component w_0 is unique.

We shall prove a representer theorem for f_0^* using the following celebrated geometric consequence of the Hahn-Banach theorem (see, Conway, 1990, page 111).

Lemma 25 *Let A be a closed convex subset of a normed vector space V and b a point in V that is not contained in A. Then there exist $T \in V^*$ and $\alpha \in \mathbb{R}$ such that*

$$T(b) < \alpha < T(a), \text{ for all } a \in A.$$

Theorem 26 *(Representer Theorem) Let f_0^* be the minimizer of (68). Then f_0 lies in the closed convex cone $\operatorname{co} G_\mathbf{z}$ spanned by $G_\mathbf{z} := \{y_j G(x_j, \cdot) : j \in \mathbb{N}_n\}$, that is, there exist $\lambda_j \ge 0$ such that*

$$f_0 = \sum_{j\in\mathbb{N}_n} \lambda_j y_j G(x_j, \cdot). \tag{70}$$

Consequently, the minimizer w_0 of (66) belongs to the closed convex cone spanned by $y_j\Phi(x_j)$, $j \in \mathbb{N}_n$.

Proof Assume that $f_0 \notin \operatorname{co} G_\mathbf{z}$. By Lemmas 25 and 8, there exists $g \in \mathcal{B}$ and $\alpha \in \mathbb{R}$ such that for all $\lambda \ge 0$

$$[f_0, g]_\mathcal{B} < \alpha < [\lambda y_j G(x_j, \cdot), g]_\mathcal{B} = \lambda y_j g^*(x_j), \quad j \in \mathbb{N}_n.$$

Choosing $\lambda = 0$ above yields that $\alpha < 0$. That $\lambda y_j g^*(x_j) > \alpha$ for all $\lambda \ge 0$ implies $y_j g^*(x_j) \ge 0$, $j \in \mathbb{N}_n$. We hence obtain that

$$[f_0, g]_\mathcal{B} < 0 \le y_j g^*(x_j), \quad j \in \mathbb{N}_n.$$

We choose $f^* = f_0^* + tg^*, t > 0$. First, observe from $y_j g^*(x_j) \ge 0$ that

$$1 - y_j f^*(x_j) \le 1 - y_j f_0^*(x_j), \quad j \in \mathbb{N}_n. \tag{71}$$

By Lemma 7,

$$\lim_{t\to 0^+} \frac{\|f_0^* + tg^*\|_{\mathcal{B}^*}^2 - \|f_0^*\|_{\mathcal{B}^*}^2}{t} = 2[g^*, f_0^*]_{\mathcal{B}^*} = 2[f_0, g]_{\mathcal{B}} < 0.$$

Therefore, there exists $t > 0$ such that $\|f^*\|_{\mathcal{B}^*}^2 < \|f_0^*\|_{\mathcal{B}^*}^2$. This combined with (71) implies that $\mathcal{E}_{b,\mathbf{z},\mu}(f^*) < \mathcal{E}_{b,\mathbf{z},\mu}(f_0^*)$ for every $b \in \mathbb{R}$, contradicting the hypothesis that f_0^* is the minimizer. ■

To solve (68), by Theorem 26 one substitutes equation (70) into (68) to obtain a convex optimization problem about λ_j subject to the constraint that $\lambda_j \geq 0$, $j \in \mathbb{N}_n$.

5.3.2 HARD MARGIN HYPERPLANE CLASSIFICATION

Consider in the feature space $\mathcal{W}$ the following hard margin classification problem

$$\inf\{\|w\|_{\mathcal{W}} : w \in \mathcal{W},\ b \in \mathbb{R}\} \tag{72}$$

subject to

$$y_j([\Phi(x_j), w]_{\mathcal{W}} + b) \geq 1, \quad j \in \mathbb{N}_n.$$

Provided that the minimizer $(w_0, b_0) \in \mathcal{W} \times \mathbb{R}$ exists, the classifier is $\operatorname{sgn}([\Phi(\cdot), w_0]_{\mathcal{W}} + b_0)$.

Hard margin classification in s.i.p. spaces was discussed in Der and Lee (2007). Applying the results in our setting tells that if b is fixed then (72) has a unique minimizer w_0 and $w_0 \in \operatorname{co}\{y_j\Phi(x_j) : j \in \mathbb{N}_n\}$. As a corollary of Proposition 24 and Theorem 26, we obtain here that if $\{y_j : j \in \mathbb{N}_n\} = \{-1, 1\}$ then (72) has a minimizer (w_0, b_0), where w_0 is unique and belongs to the set $\operatorname{co}\{y_j\Phi(x_j) : j \in \mathbb{N}_n\}$.

We draw the conclusion that the support vector machine classifications in this subsection all reduce to a convex optimization problem.

5.4 Kernel Principal Component Analysis

Kernel principal component analysis (PCA) plays a foundational role in data preprocessing for other learning algorithms. We shall present an extension of kernel PCA for RKBS. To this end, let us briefly review the classical kernel PCA (see, for example, Schölkopf and Smola, 2002; Schölkopf et al., 1998).

Let $\mathbf{x} := \{x_j : j \in \mathbb{N}_n\} \subseteq X$ be a set of inputs. We denote by $d(w, V)$ the distance from $w \in \mathcal{W}$ to a closed subspace V of $\mathcal{W}$. Fix $m \in \mathbb{N}$. For each subspace $V \subseteq \mathcal{W}$ with dimension $\dim V = m$, we define the distance from V to $\Phi(\mathbf{x})$ as

$$\mathcal{D}(V, \Phi(\mathbf{x})) := \frac{1}{n} \sum_{j\in\mathbb{N}_n} (d(\Phi(x_j), V))^2.$$

Suppose that $\{u_j : j \in \mathbb{N}_m\}$ is a basis for V. Then for each $v \in \mathcal{W}$ the best approximation v_0 in V of v exists. Assume that $v_0 = \sum_{j\in\mathbb{N}_m} \lambda_j u_j$, $\lambda_j \in \mathbb{C}$, $j \in \mathbb{N}_m$. By Lemma 17, the coefficients λ_j's are uniquely determined by

$$\left[u_k, v - \sum_{j\in\mathbb{N}_m} \lambda_j u_j\right]_{\mathcal{W}} = 0, \quad k \in \mathbb{N}_m. \tag{73}$$

In the case when $\mathcal{W}$ is a Hilbert space, the system (73) of equations resulting from best approximation is linear about λ_j's. This enables us to construct a unique m-dimensional subspace $V_0 \subseteq \mathcal{W}$ such that

$$\mathcal{D}(V_0, \Phi(\mathbf{x})) = \min\{\mathcal{D}(V, \Phi(\mathbf{x})) : V \subseteq \mathcal{W} \text{ subspace, } \dim V = m\}. \tag{74}$$

Let T be the compact operator on $\mathcal{W}$ determined by

$$(Tu, v)_{\mathcal{W}} = \frac{1}{n} \sum_{j \in \mathbb{N}_n} (u, \Phi(x_j))_{\mathcal{W}} (\Phi(x_j), v)_{\mathcal{W}}, \quad u, v \in \mathcal{W}. \tag{75}$$

We let v_j, $j \in \mathbb{N}_m$ be the unit eigenvectors of T corresponding to its first m largest eigenvalues. Then v_j's form an orthonormal basis for V_0 and are called the *principal components* of $\Phi(\mathbf{x})$. For each $x \in X$, $((\Phi(x), v_j)_{\mathcal{W}} : j \in \mathbb{N}_m) \in \mathbb{C}^m$ is its new *feature*. Therefore, kernel PCA amounts to selecting the new feature map from X to $\mathbb{C}^m$. The dimension m is usually chosen to be much smaller than the original dimension of $\mathcal{W}$. Moreover, by (74), the new features of $\mathbf{x}$ are expected to become sparser under this mapping.

The analysis of PCA in Hilbert spaces breaks in s.i.p. spaces where (73) is nonlinear. To tackle this problem, we suggest using a class of linear functionals to measure the distance between two elements in $\mathcal{W}$. Specifically, we choose $B \subseteq \mathcal{W}^*$ and set for all $u, v \in \mathcal{W}$

$$d_B(u, v) := \left(\sum_{b \in B} |(u - v, b)_{\mathcal{W}}|^2 \right)^{1/2}.$$

The idea is that if $d_B(u, v)$ is small for a carefully chosen set B of linear functionals then $\|u - v\|_{\mathcal{W}}$ should be small, and vice versa. In particular, if $\mathcal{W}$ is a Hilbert space and B is an orthonormal basis for $\mathcal{W}$ then $d_B(u, v) = \|u - v\|_{\mathcal{W}}$. From the practical consideration, we shall use what we have at hand, that is, $\Phi(\mathbf{x})$. Thus, we define for each $u, v \in \mathcal{W}$

$$d_{\Phi(\mathbf{x})}(u, v) := \left(\sum_{j \in \mathbb{N}_n} \left| [u - v, \Phi(x_j)]_{\mathcal{W}} \right|^2 \right)^{1/2}.$$

This choice of distance is equivalent to mapping X into $\mathbb{C}^n$ by

$$\widetilde{\Phi}(x) := ([\Phi(x), \Phi(x_j)]_{\mathcal{W}} : j \in \mathbb{N}_n), \quad x \in X.$$

Consequently, new features of elements in X will be obtained by applying the classical PCA to $\widetilde{\Phi}(x_j)$, $j \in \mathbb{N}_n$ in the Hilbert space $\mathbb{C}^n$.

In our method the operator T defined by (75) on $\mathbb{C}^n$ is of the form

$$Tu = \frac{1}{n} \sum_{j \in \mathbb{N}_n} (\widetilde{\Phi}(x_j)^* u) \widetilde{\Phi}(x_j), \quad u \in \mathbb{C}^n,$$

where $\widetilde{\Phi}(x_j)^*$ is the conjugate transpose of $\widetilde{\Phi}(x_j)$. One can see that T has the matrix representation $Tu = M_{\mathbf{x}} u$, $u \in \mathbb{C}^n$, where

$$M_{\mathbf{x}} := \frac{1}{n} (G[\mathbf{x}]^* G[\mathbf{x}])^T.$$

Let $\lambda_k, k \in \mathbb{N}_n$, be the eigenvalues of $M_{\mathbf{x}}$ arranged in nondecreasing order. We find for each $k \in \mathbb{N}_m$ the unit eigenvector $\alpha^k := (\alpha_j^k : j \in \mathbb{N}_n) \in \mathbb{C}^n$ corresponding to λ_k, that is,

$$M_{\mathbf{x}}\alpha^k = \lambda_k \alpha^k.$$

Vectors $\alpha^k, k \in \mathbb{N}_m$, form an orthonormal sequence. The new feature for $x \in X$ is hence

$$((\widetilde{\Phi}(x), \alpha^k)_{\mathbb{C}^n} : k \in \mathbb{N}_m) \in \mathbb{C}^m.$$

We compute explicitly that

$$(\widetilde{\Phi}(x), \alpha^k)_{\mathbb{C}^n} = \sum_{j \in \mathbb{N}_n} \overline{\alpha_j^k} G(x, x_j), \quad k \in \mathbb{N}_m.$$

We remark that unlike the previous three learning algorithms, the kernel PCA presented here only makes use of the kernel G and is independent of the semi-inner-product on $\mathcal{W}$. The *kernel trick* can hence be applied to this algorithm.

6. Conclusion

We have introduced the notion of reproducing kernel Banach spaces and generalized the correspondence between an RKHS and its reproducing kernel to the setting of RKBS. S.i.p. RKBS were specially treated by making use of semi-inner-products and the duality mapping. A semi-inner-product shares many useful properties of an inner product. These properties and the general theory of semi-inner-products make it possible to develop many learning algorithms in RKBS. As illustration, we discussed in the RKBS setting the minimal norm interpolation, regularization network, support vector machines, and kernel PCA. Various representer theorems were established.

This work attempts to provide an appropriate mathematical foundation of kernel methods for learning in Banach spaces. Many theoretical and practical issues are left for future research. An immediate challenge is to construct a class of useful RKBS and the corresponding reproducing kernels. By the classical theory of RKHS, a function K is a reproducing kernel if and only if the finite matrix (1) is always hermitian and positive semi-definite. This function property characterization brings great convenience to the construction of positive definite kernels. Thus, we ask what characteristics a function must possess so that it is a reproducing kernel for some RKBS. Properties of RKBS and their reproducing kernels also deserve a systematic study. For the applications, we have seen that minimum norm interpolation and regularization network reduce to systems of nonlinear equations. Dealing with the nonlinearity requires algorithms specially designed for the underlying s.i.p. space. On the other hand, support vector machines can be reformulated into certain convex optimization problems. Finally, section 5.4 only provides a possible implementation of kernel PCA for RKBS. We are interested in further careful analysis and efficient algorithms for these problems. We shall return to these issues in future work.

Appendix A.

In this appendix, we provide proofs of two results stated in the previous sections of this paper. The first one is about the minimization problem (5) in the introduction.

Proposition 27 *If $\varphi : \mathbb{R}^d \to [0,+\infty)$ is strictly concave and $\mu > 0$, then every minimizer of*

$$\min\{\varphi(x) + \mu\|x\|_{\ell^1} : x \in \mathbb{R}^d\} \tag{76}$$

has at most one nonzero element.

Proof Assume to the contrary that $x_0 \in \mathbb{R}^d$ is a minimizer of (76) with more than one nonzero elements. Then x_0 is not an extreme points of the sphere $\{x \in \mathbb{R}^d : \|x\|_{\ell^1} = \|x_0\|_{\ell^1}\}$. In other words, there exist two distinct vectors $x_1, x_2 \in \mathbb{R}^d$ and some $\lambda \in (0,1)$ such that

$$x_0 = \lambda x_1 + (1-\lambda)x_2 \text{ and } \|x_1\|_{\ell^1} = \|x_2\|_{\ell^1} = \|x_0\|_{\ell^1}.$$

By the strict concavity of φ, we get that

$$\begin{aligned} \varphi(x_0) + \mu\|x_0\|_{\ell^1} &> \lambda\varphi(x_1) + (1-\lambda)\varphi(x_2) + \mu\|x_0\|_{\ell^1} \\ &= \lambda(\varphi(x_1) + \mu\|x_1\|_{\ell^1}) + (1-\lambda)(\varphi(x_2) + \mu\|x_2\|_{\ell^1}). \end{aligned}$$

Therefore, we must have either

$$\varphi(x_0) + \mu\|x_0\|_{\ell^1} > \varphi(x_1) + \mu\|x_1\|_{\ell^1}$$

or

$$\varphi(x_0) + \mu\|x_0\|_{\ell^1} > \varphi(x_2) + \mu\|x_2\|_{\ell^1}.$$

Either case contradicts the hypothesis that x_0 is a minimizer of (76). ■

The second result confirms that (27) indeed defines a semi-inner-product.

Proposition 28 *Let V be a normed vector space over $\mathbb{C}$. If for all $x, y \in V \setminus \{0\}$ the limit $\lim_{t\in\mathbb{R}, t\to 0} \frac{\|x+ty\|_V - \|x\|_V}{t}$ exists then $[\cdot,\cdot]_V : V \times V \to \mathbb{C}$ defined by*

$$[x,y]_V := \|y\|_V \left(\lim_{t\in\mathbb{R}, t\to 0} \frac{\|y+tx\|_V - \|y\|_V}{t} + i \lim_{t\in\mathbb{R}, t\to 0} \frac{\|iy+tx\|_V - \|y\|_V}{t} \right) \text{ if } x, y \neq 0 \tag{77}$$

and $[x,y]_V := 0$ if $x = 0$ or $y = 0$ is a semi-inner-product on V.

Proof First, we obtain for $x \neq 0$ that

$$\begin{aligned}[x,x]_V &= \|x\|_V \left(\lim_{t\in\mathbb{R},t\to 0} \frac{\|(1+t)x\|_V - \|x\|_V}{t} + i \lim_{t\in\mathbb{R},t\to 0} \frac{\|(i+t)x\|_V - \|x\|_V}{t} \right) \\ &= \|x\|_V^2 \left(\lim_{t\in\mathbb{R},t\to 0} \frac{|1+t|-1}{t} + i \lim_{t\in\mathbb{R},t\to 0} \frac{|i+t|-1}{t} \right) \\ &= \|x\|_V^2 (1+0) = \|x\|_V^2 > 0. \end{aligned} \tag{78}$$

We then deal with the remaining three conditions of a semi-inner-product. Clearly, they are true if one of the arguments involved is the zero vector. Let $x,y,z \in V \setminus \{0\}$. We start with the estimate:

$$\begin{aligned}\operatorname{Re}[x+y,z]_V &= \|z\|_V \lim_{t\in\mathbb{R},t\to 0^+} \frac{\|z+tx+ty\|_V - \|z\|_V}{t} \\ &\leq \|z\|_V \lim_{t\in\mathbb{R},t\to 0^+} \frac{\|\frac{z}{2}+tx\|_V + \|\frac{z}{2}+ty\|_V - \|z\|_V}{t} \\ &= \|z\|_V \left(\lim_{t\in\mathbb{R},t\to 0^+} \frac{\|\frac{z}{2}+tx\|_V - \|\frac{z}{2}\|_V}{t} + \lim_{t\in\mathbb{R},t\to 0^+} \frac{\|\frac{z}{2}+ty\|_V - \|\frac{z}{2}\|_V}{t} \right) \\ &= \|z\|_V \left(\lim_{t\in\mathbb{R},t\to 0^+} \frac{\|z+2tx\|_V - \|z\|_V}{2t} + \lim_{t\in\mathbb{R},t\to 0^+} \frac{\|z+2ty\|_V - \|z\|_V}{2t} \right). \end{aligned}$$

The above equation implies that

$$\operatorname{Re}[x+y,z]_V \leq \operatorname{Re}[x,z]_V + \operatorname{Re}[y,z]_V. \tag{79}$$

It can be easily verified that $[-x,y]_V = -[x,y]_V$. Replacing y with $x+y$, and x with $-x$ in the above equation yields that

$$\operatorname{Re}[y,z]_V \leq \operatorname{Re}[-x,z]_V + \operatorname{Re}[x+y,z]_V = -\operatorname{Re}[x,z]_V + \operatorname{Re}[x+y,z]_V. \tag{80}$$

Combining (79) and (80), we get that $\operatorname{Re}[x+y,z]_V = \operatorname{Re}[x,z]_V + \operatorname{Re}[y,z]_V$. Similar arguments lead to that $\operatorname{Im}[x+y,z]_V = \operatorname{Im}[x,z]_V + \operatorname{Im}[y,z]_V$. Therefore,

$$[x+y,z]_V = [x,z]_V + [y,z]_V. \tag{81}$$

Next we see for all $\lambda \in \mathbb{R} \setminus \{0\}$ that

$$[\lambda x,y]_V = \|y\|_V \lim_{t\in\mathbb{R},t\to 0} \frac{\|y+t\lambda x\|_V - \|y\|_V}{t} = \lambda \|y\|_V \lim_{t\in\mathbb{R},t\to 0} \frac{\|y+t\lambda x\|_V - \|y\|_V}{\lambda t} = \lambda [x,y]_V.$$

It is also clear from the definition (77) that $[ix,y]_V = i[x,y]_V$. We derive from these two facts and (81) for every $\lambda = \alpha + i\beta$, $\alpha,\beta \in \mathbb{R}$ that

$$\begin{aligned}[\lambda x,y]_V &= [\alpha x + i\beta x, y]_V = [\alpha x,y]_V + [i\beta x,y]_V = \alpha[x,y]_V + i[\beta x,y]_V \\ &= \alpha[x,y]_V + i\beta[x,y]_V = (\alpha+i\beta)[x,y]_V = \lambda[x,y]_V. \end{aligned} \tag{82}$$

We then proceed for $\lambda \in \mathbb{C} \setminus \{0\}$ by (82) that

$$\begin{aligned}[x,\lambda y]_V &= \|\lambda y\|_V \lim_{t\in\mathbb{R},t\to 0} \frac{\|\lambda y + tx\|_V - \|\lambda y\|_V}{t} = \|\lambda y\|_V |\lambda| \lim_{t\in\mathbb{R},t\to 0} \frac{\|y + t\frac{x}{\lambda}\|_V - \|y\|_V}{t} \\ &= |\lambda|^2 [\frac{x}{\lambda}, y]_V = \frac{|\lambda|^2}{\lambda} [x,y]_V = \overline{\lambda}[x,y]_V. \end{aligned} \tag{83}$$

Finally, we find some $\lambda \in \mathbb{C}$ such that $|\lambda| = 1$ and $\lambda[x,y]_V = |[x,y]_V|$, and then obtain by (82) and (77) that

$$\begin{aligned} |[x,y]_V| &= \lambda[x,y]_V = [\lambda x, y]_V = \|y\|_V \lim_{t\in\mathbb{R}, t\to 0^+} \frac{\|y + t\lambda x\|_V - \|y\|_V}{t} \\ &\leq \|y\|_V \lim_{t\in\mathbb{R}, t\to 0^+} \frac{\|y\|_V + t\|\lambda x\|_V - \|y\|_V}{t} = \|y\|_V \|\lambda x\|_V = \|x\|_V \|y\|_V. \end{aligned}$$

By (78), the above inequality has the equivalent form

$$|[x,y]_V| \leq [x,x]_V^{1/2} [y,y]_V^{1/2}. \tag{84}$$

Combining Equations (78), (81), (82), (83), and (84) proves the proposition. ■

Abstract

Many collective classification (CC) algorithms have been shown to increase accuracy when instances are interrelated. However, CC algorithms must be carefully applied because their use of estimated labels can in some cases decrease accuracy. In this article, we show that managing this label uncertainty through *cautious* algorithmic behavior is essential to achieving maximal, robust performance. First, we describe *cautious inference* and explain how four well-known families of CC algorithms can be parameterized to use varying degrees of such caution. Second, we introduce *cautious learning* and show how it can be used to improve the performance of almost any CC algorithm, with or without cautious inference. We then evaluate cautious inference and learning for the four collective inference families, with three local classifiers and a range of both synthetic and real-world data. We find that cautious learning and cautious inference typically outperform less cautious approaches. In addition, we identify the data characteristics that predict more substantial performance differences. Our results reveal that *the degree of caution used usually has a larger impact on performance than the choice of the underlying inference algorithm*. Together, these results identify the most appropriate CC algorithms to use for particular task characteristics and explain multiple conflicting findings from prior CC research.

Keywords: collective inference, statistical relational learning, approximate probabilistic inference, networked data, cautious inference

1. Introduction

Traditional methods for supervised learning assume that the instances to be classified are independent of each other. However, in many classification tasks, instances can be related. For example, hyperlinked web pages are more likely to have the same class label than unlinked pages. Such autocorrelation (correlation of class labels among interrelated instances) exists in a wide variety of data (Neville and Jensen, 2007; Macskassy and Provost, 2007), including situations where the relationships are implicit (e.g., email messages between two people are likely to share topics).

Collective classification (CC) is a method for jointly classifying related instances. To do so, CC methods employ a *collective inference* algorithm that exploits dependencies between instances (e.g., autocorrelation), enabling CC to often attain higher accuracies than traditional methods when instances are interrelated (Neville and Jensen, 2000; Taskar et al., 2002; Jensen et al., 2004; Sen et al., 2008). Several algorithms have been used for collective inference, including relaxation labeling (Chakrabarti et al., 1998), the iterative classification algorithm (*ICA*) (Lu and Getoor, 2003a), loopy belief propagation (*LBP*) (Taskar et al., 2002), Gibbs sampling (*Gibbs*) (Jensen et al., 2004), and variants of the weighted-vote relational neighbor algorithm (*wvRN*) (Macskassy and Provost, 2007).

During testing, all collective inference algorithms exploit relational features based on uncertain estimation of class labels. This test-time label uncertainty can diminish accuracy due to two related effects. First, an incorrectly predicted label during testing may negatively influence the predictions of its linked neighbors, possibly leading to cascading inference errors (cf., Neville and Jensen, 2008). Second, the training process may learn a poor model for test-time inference, because of the disparity between the training scenario (where labels are known and certain) and the test scenario (where labels are estimated and hence possibly incorrect). As a result, while CC has many potential advantages, in some cases CC's label uncertainty may actually cause accuracy to decrease compared to non-relational approaches (Neville and Jensen, 2007; Sen and Getoor, 2006; Sen et al., 2008).

In this article, we argue that managing this test-time label uncertainty through "cautious" algorithmic behavior is essential to achieving maximal, robust performance. We describe two complementary cautious strategies. Each addresses the fundamental problem of label uncertainty, but separately targets the two manifestations of the problem described above. First, *cautious inference* is an inference process that attends to the uncertainty of its intermediate label predictions. For example, existing algorithms such as *Gibbs* or *LBP* accomplish cautious inference by sampling from or directly reasoning with the estimated label distributions. These techniques are cautious because they prevent less certain label estimates from having substantial influence on subsequent estimations. Alternatively, we show how variants of a simpler algorithm, *ICA*, can perform cautious inference by appropriately favoring more certain information. Second, *cautious learning* refers to a training process that ameliorates the aforementioned train/test disparity. In particular, we introduce PLUL (Parameter Learning for Uncertain Labels), which uses standard cross-validation techniques, but in a way that is new for CC and that leads to significant performance advantages. In particular, PLUL is cautious because it prevents the algorithm from learning a model from the (correctly labeled) training set that overestimates how useful relational features will be when computed with uncertain labels from the test set.

We consider four frequently-studied families of CC algorithms: *ICA*, *Gibbs*, *LBP*, and *wvRN*. For each family, we describe algorithms that use varying degrees of cautious inference and explain how they all (except for the relational-only *wvRN*) can also exploit cautious learning via PLUL. We then evaluate the variants of these four families, with and without PLUL, over a wide range of synthetic and real-world data sets. To broaden the evidence for our results, we evaluate three local classifiers that are used by some of the CC algorithms, and also compare against a non-relational baseline.

While recent CC studies describe complementary results and make some related comparisons, they omit important variations that we consider here (see Section 3). Moreover, the scope and/or methodology of previous studies leaves several important questions unanswered. For instance, *Gibbs* is often regarded as one of the most accurate inference algorithms, and has been shown

to work well for CC (Jensen et al., 2004; Neville and Jensen, 2007). If so, why did Sen et al. (2008) find no significant difference between *Gibbs* and the much less sophisticated *ICA*? Second, we earlier reported that ICA_C (a cautious variant of *ICA*) outperforms both *Gibbs* and *ICA* on three real-world data sets (McDowell et al., 2007a). Why would ICA_C outperform *Gibbs*, and for what data characteristics are ICA_C's gains significant? We answer these questions and more in Section 8.

We hypothesize that *cautious CC algorithms will outperform more aggressive CC approaches when there exists a high probability of an "incorrect relational inference"*, which we define as a prediction error that is due to reasoning with relational features (i.e., an error that does not occur when relational features are removed). Two kinds of data characteristics increase the likelihood of such errors. First, when the data characteristics lead to lower overall classification accuracy (e.g., when the non-relational attributes are not highly predictive), then the computed relational feature values will be less reliable. Second, when a typical relational link is highly predictive (e.g., as occurs when the data exhibits high *relational autocorrelation*), then the potential effect of any incorrect prediction is magnified. As the magnitude of either of these data set characteristics increases, cautious algorithms should outperform more aggressive algorithms by an increasing amount.

Our contributions are as follows. First, we describe cautious inference and how four commonly-used families of existing CC inference algorithms can exhibit more or less caution. Second, we introduce cautious learning and explain how it can help compensate for the train/test disparity that occurs when a CC algorithm uses estimated class labels during testing. Third, we identify the data characteristics for which these cautious techniques should outperform more aggressive approaches, as introduced in the preceding paragraph and discussed in more detail in Section 6. Our experimental results confirm that cautious approaches typically do outperform less cautious variants, and that these effects grow larger when there is a greater probability of incorrect relational inference. Moreover, our results reveal that in most cases *the degree of caution used has a larger impact on performance than the choice of the underlying inference algorithm*. In particular, the cautious algorithms perform very similarly, regardless of whether ICA_C or *Gibbs* or *LBP* is used, although our results also confirm that, for some data characteristics, inference with *LBP* performs comparatively poorly. These results suggest that in many cases the higher computational complexity of *Gibbs* and *LBP* is unnecessary, and that the much faster ICA_C should be used instead. Finally, our results and analysis enable us to answer the previously mentioned questions regarding CC.

The next two sections summarize collective classification and related work. Section 4 then explains why CC needs to be cautious and describes cautious inference and learning in more detail. In Section 5, we describe how caution can be specifically used by the four families of CC inference algorithms. Section 6 then describes our methodology and hypotheses. Section 7 presents our results, which we discuss in Section 8. We conclude in Section 9.

2. Collective Classification: Description and Problem Definition

In this section, we first motivate and define collective classification (CC). We then describe different approaches to CC, different CC tasks, and our assumptions for this article.

2.1 Problem Statement and Example

In many domains, relations exist among instances (e.g., among hyperlinked web pages, social network members, co-cited publications). These relations may be helpful for classification tasks, such

as predicting the topic of a publication or the group membership of a person (Koller et al., 2007). More formally, we consider the following task (based on Macskassy and Provost, 2006):

Definition 1 *(Classification of Graph-based Data) Assume we are given a graph $G = (V, E, X, Y, C)$ where V is a set of nodes, E is set of (possibly directed) edges, each $\vec{x}_i \in X$ is an attribute vector for node $v_i \in V$, each $Y_i \in Y$ is a label variable for v_i, and C is the set of possible labels. Assume further that we are given a set of "known" values Y^K for nodes $V^K \subset V$, so that $Y^K = \{y_i | v_i \in V^K\}$. Then the task is to infer Y^U, the values of Y_i for the remaining nodes with "unknown" values ($V^U = V - V^K$), or a probability distribution over those values.*[1]

For example, consider the task of predicting whether a web page belongs to a professor or a student. Conventional supervised learning approaches ignore the link relations and classify each page using attributes derived from its content (e.g., words present in the page). We refer to this approach as *non-relational classification*. In contrast, a technique for *relational classification* would explicitly use the links to construct additional relational features for classification (e.g., for each page, including as features the words from hyperlinked pages). This additional information can potentially increase classification accuracy, though may sometimes decrease accuracy as well (Chakrabarti et al., 1998). Alternatively, even greater (and usually more reliable) increases can occur when the class *labels* of the linked pages are used instead to derive relevant relational features (Jensen et al., 2004). However, using features based on these labels is challenging, because some or all of the labels are initially unknown, and thus typically must be estimated and then iteratively refined in some way. This process of jointly inferring the labels of interrelated nodes is known as *collective classification* (CC).

Figure 1 summarizes an example execution of a simple CC algorithm, *ICA*, applied to the binary web page classification task. Each step in the sequence displays a graph of four nodes, where each node denotes a web page, and hyperlinks among them. Each node has a class label y_i; the set of possible class labels is $C = \{P, S\}$, denoting *professors* and *students*, respectively. Three nodes have *unknown* labels ($V^U = \{v_1, v_2, v_4\}$) and one node has a *known* label ($V^K = \{v_3\}$). In the initial state (step A), no label y_i has yet been estimated for the nodes in V^U, so each is set to *missing* (indicated by a question mark). Each node has three binary attributes (represented by $\vec{x}_i$). Nodes in V^U also have two relational features (one per class), represented by the vector $\vec{f}_i$. Each feature denotes the number of linked nodes (ignoring link direction) that have a particular class label.

In step B, some classifier (not shown) estimates class labels for nodes in V^U using only the (non-relational) attributes. These labels, along with the known label y_3, are used in step C to compute the relational feature value vectors. For instance, in step C, $\vec{f}_2 = (1\ 2)$ because v_2 links to nodes with one current *P* label and two current *S* labels. In step D, a classifier re-estimates the labels using both attributes and relational features, which changes the predicted label of v_2. In step E, relational feature values are re-computed using the new labels. Steps D and E then repeat until a termination criterion is satisfied (e.g., convergence, number of iterations).

This example exhibits how relational value uncertainty occurs with CC. For instance, the feature vector $\vec{f}_1$ is $(1\ 0)$ in step C but later becomes $(0\ 1)$. Thus, intermediate predictions use uncertain label estimates, motivating the need to cautiously use such estimates.

1. V^K may be empty. In addition, a separate training graph may be provided; see Section 2.3.

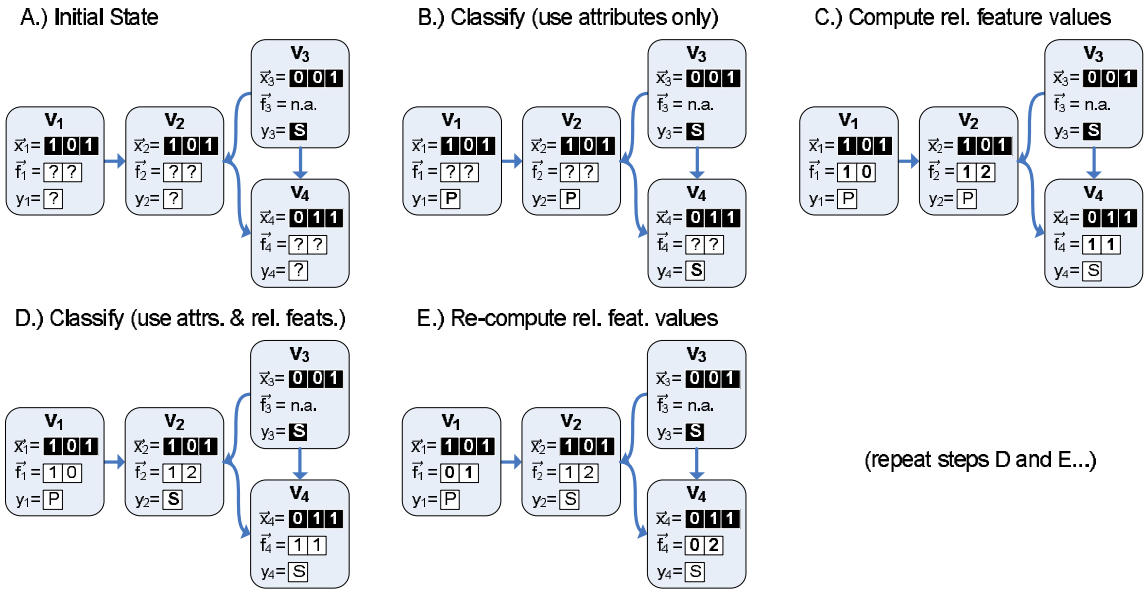

Figure 1: Example operation of *ICA*, a simple CC algorithm. Each step (A thru E) shows a graph of 4 linked nodes (i.e., web pages). "Known" values are are shown in white text on a black background; this includes all attribute values $\vec{x}_i$ and the class label y_3 for v_3. Estimated values are shown instead with a white background.

2.2 Algorithms for Collective Inference

For some collective inference tasks, exact methods such as junction trees (Huang and Darwiche, 1996) or variable elimination (Zhang and Poole, 1996) can be applied. However, these methods may be prohibitively expensive to use (e.g., summing over the remaining variable configurations is intractable for modest-sized graphs). Some research has focused on methods that further factorize the variables, and then apply an exact procedure such as belief propagation (Neville and Jensen, 2005), min-cut partition (Barzilay and Lapata, 2005), or methods for solving quadratic and linear programs (Triebel et al., 2007). In this article, we consider only approximate collective inference methods.

We consider three primary types of approximate collective inference algorithms, borrowing some terminology from Sen et al. (2008):

- **Local classifier-based methods.** For these methods, inference is an iterative process whereby a *local classifier* predicts labels for each node in V^U using both attributes and relational features (derived from the current label predictions), and then a *collective inference* algorithm recomputes the class labels, which will be used in the next iteration. Examples of this type of CC algorithm include *ICA* (used in the example above) and *Gibbs*. Local classifiers that have been used include Naive Bayes (Jensen et al., 2004), relational probability trees (Neville et al., 2003a), k-nearest neighbor (McDowell et al., 2007b), and logistic regression (Sen et al., 2008). Typically, a supervised learner induces the local classifier from the training set using both attributes and relational features.

- **Global formulation-based methods.** These methods train a classifier that seeks to optimize one global objective function, often based on a Markov random field (Dobrushin, 1968; Besag, 1974). As above, the classifier uses both attributes and relational features for inference. Examples of these algorithms include loopy belief propagation and relaxation labeling. These do not use a separate local classifier; instead, the entire algorithm is used for both training (e.g., to learn the clique potentials) and inference. See Taskar et al. (2002) and Sen et al. (2008) for more details.

- **Relational-only methods.** Recently, Macskassy and Provost (2007) demonstrated that, when some labels are known (i.e., $|V^K| > 0$), algorithms that use *only* relational information can in some cases perform very well. We consider several variants of the algorithm they described, $wvRN_{RL}$ (weighted-vote relational neighbor, with relaxation labeling). This algorithm computes a new label distribution for a node by averaging the current distributions of its neighbors. It does not require any training.

With local classifier methods, learning the classifier can often be done in a single pass over the data, does not require running collective inference, and in fact is independent of the collective inference procedure that will be used. In contrast, for global methods the local classifier and inference algorithm are effectively unified. As a result, learning for a global method requires committing to and actually executing a specific inference algorithm, and thus can be much slower than with a local classifier-based method.

All of these algorithms jointly classify interrelated nodes using some iterative process. Those that propagate from one iteration to the next a single label for each node are called *hard-labeling* methods. Methods that instead propagate a probability distribution over the possible class labels are called *soft-labeling* methods (cf., Galstyan and Cohen, 2007). All of the local classifier-based methods that we examine are hard-labeling methods.[2] Soft-labeling methods, such as variants of relaxation labeling, are also possible but require that the local classifier be able to reason directly with label distributions, which is more complex than the label aggregation for features typically done with approaches like *ICA* or *Gibbs*. Section 6.6 provides more detail on these features.

2.3 Task Definitions and Focus

Collective classification has been applied to two types of inference tasks, namely the **out-of-sample** task, where V^K is empty, and the **in-sample** task, where V^K is not empty. Both types of tasks may emerge in real-world situations (Neville and Jensen, 2005). Prior work on out-of-sample tasks (Neville and Jensen, 2000; Taskar et al., 2002; Sen and Getoor, 2006) assume that the algorithm is also provided with a training graph G_{Tr} that is disjoint from the test graph G. For instance, a model may be learned over the web-graph for one institution, and tested on the web-graph of another.

For in-sample tasks, where some labels in G are known, CC can be applied to the single graph G (Macskassy and Provost, 2007; McDowell et al., 2007a; Sen et al., 2008; Gallagher et al., 2008); *within-network* classification (Macskassy and Provost, 2006) involves training on the subset $G^K \subset G$ with known labels, and testing by running inference over the entire graph. This task simulates, for example, fraud detection in a single large telecommunication network where some entities/nodes are

2. We could also consider $wvRN_{RL}$, which is a soft-labeling method, to be a local classifier-based method, albeit a simple one that ignores attributes and does no learning. However, for explication we list relational-only methods as a separate category in the list above because our results will show they often have rather different performance trends.

known to be fraudulent. Another in-sample task (Neville and Jensen, 2007; Bilgic and Getoor, 2008; Neville and Jensen, 2008) assumes a separate training graph G_{Tr}, where a model is learned from G_{Tr} and inference is performed over the test graph G, which includes both labeled and unlabeled nodes. For both tasks, predictive accuracy is measured only for the unlabeled nodes.

In Section 6, we will address three types of tasks (i.e., out-of-sample, sparse in-sample, and dense in-sample). This is similar to the set of tasks addressed in some previous evaluations (e.g., Neville and Jensen, 2007, 2008; Bilgic and Getoor, 2008) and subsumes some others (e.g., Neville and Jensen, 2000; Taskar et al., 2002; Sen and Getoor, 2006). We will not directly address the within-network task, but the algorithmic trends observed from our in-sample evaluations should be similar.[3]

2.4 Assumptions and Limitations

In this broad investigation on the utility of caution in collective classification, we make several simplifying assumptions. First, we assume data is obtained passively rather than actively (Rattigan et al., 2007; Bilgic and Getoor, 2008). Second, we assume that nodes are homogeneous (e.g., all represent the same kind of object) rather than heterogeneous (Neville et al., 2003a; Neville and Jensen, 2007). Third, we assume that links are not missing, and need not be inferred (Bilgic and Getoor, 2008). Finally, we do not attempt to increase autocorrelation via techniques such as link addition (Gallagher et al., 2008), clustering (Neville and Jensen, 2005), or problem transformation (Tian et al., 2006; Triebel et al., 2007).

Our example in Figure 1 employs a simple relational feature (i.e., that counts the number of linked nodes with a specific class label). However, several other types of relations exist. For example, Gallagher and Eliassi-Rad (2008) describe a topology of feature types, including structural features that are independent of node labels (e.g., the number of linked neighbors of a given node). We focus on only three simple types of relational features (see Section 6.6), and leave broader investigations for future work. Likewise, for CC algorithms that learn, we assume that training is performed just once, which differs from some prior work where the learned model is updated in each iteration (Lu and Getoor, 2003b; Gurel and Kersting, 2005).

3. Related Work

Besag (1986) originally described the "Iterated Conditional Modes" (ICM) algorithm, which is a version of the *ICA* algorithm that we consider. Several researchers have reported that employing inter-instance relations in CC algorithms can significantly increase predictive accuracy (e.g., Chakrabarti et al., 1998; Neville and Jensen, 2000; Taskar et al., 2002; Lu and Getoor, 2003a). Furthermore, these algorithms have performed well on a variety of tasks, such as identifying securities fraud (Neville et al., 2005), ranking suspicious entities (Macskassy and Provost, 2005), and annotating semantic web services (Heß and Kushmerick, 2004).

In each iteration, a CC algorithm predicts a class label (or a class distribution) for each node and uses it to determine the next iteration's predictions. Although using label predictions from linked nodes (instead of using the larger number of attributes from linked nodes) encapsulates the influence of a linked node and simplifies learning (Jensen et al., 2004), it can be problematic. For example,

3. Indeed, we performed additional experiments where we reproduced the synthetic data of Sen et al. (2008), but then transformed the task from their within-network variant to a variant that uses a separate graph for training (as done in this article), and obtained results similar to those they reported.

iterating with incorrectly predicted labels can propagate and amplify errors (Neville and Jensen, 2007; Sen and Getoor, 2006; Sen et al., 2008), diminishing or even reducing accuracy compared to non-relational approaches. In this article, we examine the data characteristics (and algorithmic interactions) for which these issues are most serious and explain how cautious approaches can ameliorate them.

The performance of CC compared to non-relational learners depends greatly on the data characteristics. First, for CC to improve performance, the data must exhibit *relational autocorrelation* (Jensen et al., 2004; Neville and Jensen, 2005; Macskassy and Provost, 2007; Rattigan et al., 2007; Sen et al., 2008), which is correlation among the labels of related instances (Jensen and Neville, 2002). Complex correlations can be exploited by some CC algorithms, capturing for instance the notion "Professors primarily have out-links to Students." In contrast, the simplest kind of correlation is *homophily* (McPherson et al., 2001), in which links tend to connect nodes with the same label. To facilitate replication, Appendix A defines homophily more formally.

A second data characteristic that can influence CC performance is *attribute predictiveness*. For example, if the attributes are far less predictive than the selected relational features, then CC algorithms should perform comparatively well vs. traditional algorithms (Jensen et al., 2004). Third, *link density* plays a role (Jensen and Neville, 2002; Neville and Jensen, 2005; Sen et al., 2008); if there are few relations among the instances, then collective classification may offer little benefit. Alternatively, algorithms such as *LBP* are known to perform poorly when link density is very high (Sen and Getoor, 2006). Fourth, an important factor is the *labeled proportion* (the proportion of test nodes that have known labels). In particular, if some node labels are known ($|V^K| > 0$), these labels may help prevent CC estimation errors from cascading. In addition, if a substantial number of labels are known, simpler relational-only algorithms may be the most effective. Although additional data characteristics exist that can influence the performance of CC algorithms, such as *degree of disparity* (Jensen et al., 2003) and *assortativity* (Newman, 2003; Macskassy, 2007), we concentrate on these four in our later evaluations.

Compared to this article, prior studies provide complementary results and make some relevant comparisons, but do not examine important variations that we consider here. For instance, Jensen et al. (2004) only investigate a single collective inference algorithm, and Macskassy and Provost (2007) focus on relational-only (univariate) algorithms. Sen et al. (2008) assess several algorithms on real and synthetic data, but do not examine the impact of attribute predictiveness or labeled proportion. Likewise, Neville and Jensen (2007) evaluate synthetic and real data, but vary data characteristics (autocorrelation and labeled proportion) for only the synthetic data, do not consider *ICA*, and consider *LBP* only for the synthetic data. In addition, only one of these prior studies (Neville and Jensen, 2000) evaluates an algorithm related to ICA_C, which is a simple cautious variant of *ICA* that we show has promising performance. Moreover, these studies did not compare algorithms that vary only in their degree of cautious inference, or use cautious learning.

4. Types of Caution in CC and Why Caution is Important

Section 3 described how collective classification exploits label predictions to try to increase accuracy, but how iterating with incorrectly predicted labels can sometimes propagate and amplify errors. To address this problem, we recently proposed the use of cautious inference for CC (McDowell et al., 2007a). We defined an inference algorithm to be cautious if it sought to "explicitly identify and preferentially exploit the more certain relational information." In addition, we ex-

plained that a variant of *ICA* that we here call ICA_C is cautious because it selectively ignores class labels that were predicted with less confidence by the local classifier. Previously, Neville and Jensen (2000) introduced a simpler version[4] of ICA_C but compared it only with non-relational classifiers. We showed that ICA_C can outperform *ICA* and *Gibbs*, but did not identify the data conditions under which such gains hold.

In this article, we expand our original notion of caution in two ways. First, we broaden our idea of *cautious inference* to encompass several other existing CC inference techniques that seek the same goal (managing prediction uncertainty). Recognizing the behavioral similarities between these different algorithms helps us to better assess the strengths and weaknesses of each algorithm for a particular data set. Second, we introduce *cautious learning*, a technique that ameliorates prediction uncertainty even before inference is applied, which can substantially increase accuracy. Below we detail these two types of caution.

- A CC algorithm exhibits **cautious inference** if its inference process attends to the uncertainty of its intermediate label predictions. Usually, this uncertainty is approximated via the posterior probabilities associated with each predicted label. For instance, a CC algorithm may exercise cautious inference by favoring predicted information that has less uncertainty (higher confidence). This is the approach taken by ICA_C, which uses only the most certain labels at the beginning of its operation, then gradually incorporates less certain predictions in later iterations. Alternatively, instead of always selecting the most likely class label for each node (like *ICA* and ICA_C), *Gibbs* re-samples the label of each node based on its estimated distribution. This re-sampling leads to more stochastic variability (and less influence) for nodes with less certain predictions. Finally, soft-labeling algorithms like *LBP*, relaxation labeling, and $wvRN_{RL}$ directly reason with the estimated label distributions. For instance, $wvRN_{RL}$ averages the estimated distributions of a node's linked neighbors, which gives more influence to more certain predictions.

- A CC algorithm exhibits **cautious learning** if its training process is influenced by recognizing the disparity between the training set (where labels are known and certain) and the test scenario (where labels may be estimated and hence incorrect). In particular, a relational feature may appear to be highly predictive of the class when examining the training set (e.g., to learn conditional probabilities or feature weights), yet its use may actually decrease accuracy if its value is often incorrect during testing. In response, one approach is to ensure that appropriate training parameters are cross-validated using the actual testing conditions (e.g., with estimated test labels). We use PLUL to achieve this goal.

The next section describes how these general ideas can be applied. Later, our experimental results demonstrate when they lead to significant performance improvements.

5. Applying Cautious Inference and Learning to Collective Classification

The previous section described two types of caution for CC. Each attempts to alleviate potential estimation errors in labels during collective inference. Cautious inference and cautious learning can often be combined, and at least one is used or is applicable to every CC algorithm known to

4. Their algorithm is like ICA_C, except that it does not consider how to favor "known" labels from V^K.

us. In this section, we provide examples of how both types can be applied by describing specific CC algorithms that exploit cautious inference (Sections 5.1-5.4), and by describing how PLUL can complement these algorithms with cautious learning (Section 5.5). Section 5.6 then discusses the computational complexity of these algorithms.

We describe and evaluate four families of CC inference algorithms: *ICA*, *Gibbs*, *LBP*, and *wvRN*.[5] Among local classifier-based algorithms, we chose *ICA* and *Gibbs* because both have been frequently studied and often perform well. As a representative global formulation-based algorithm, we chose *LBP* instead of relaxation labeling because previous studies (Sen and Getoor, 2007; Sen et al., 2008) found similar performance, with in some cases a slight edge for *LBP*. Finally, we select *wvRN* because it is a good relational-only baseline for CC evaluations (Macskassy and Provost, 2007).

Table 1 summarizes the four CC families that we consider. Within each family, each variant use more cautious inference than the variant listed below it. Cautious variants of standard algorithms are given a "C" subscript (e.g., ICA_C), while non-cautious variants of standard algorithms are given a "NC" subscript (e.g., $Gibbs_{NC}$). For the latter case, our intent is not to demonstrate large performance "gains" for a standard algorithm vs. a new non-cautious variant, but to isolate the impact of a particular cautious algorithmic behavior on performance. While the result may not be a theoretically coherent algorithm (e.g., $Gibbs_{NC}$, unlike *Gibbs*, is not a MCMC algorithm), in every case the resultant algorithm *does* perform well under data set situations where caution is not critical (see Section 7). Thus, comparing the performance of the cautious vs. non-cautious variants allows us to investigate the data characteristics for which cautious behavior is more important.[6]

5.1 ICA Family of Algorithms

Figure 2 displays pseudocode for *ICA*, ICA_C, and ICA_{Kn}, depending on the setting of the parameter $AlgType$. We describe each in turn.

5.1.1 *ICA*

In Figure 2, step 1 is a "bootstrap" step that predicts the class label y_i of each node in V^U using only attributes ($conf_i$ records the confidence of this prediction, but *ICA* ignores this information). The algorithm then iterates (step 2). During each iteration, *ICA* selects all available labels (step 3), computes the relational features' values based on these labels (step 4), and then re-predicts the class label of each node using both attributes and relational features (step 5). After iterating, hopefully to convergence, step 6 returns the final set of estimated class labels.

Types of Caution Used: Steps 3-4 of *ICA* use all available labels for feature computation (including estimated, possibly incorrect labels) and step 5 picks the single most likely label for each node based on the new predictions. In these steps, uncertainty in the predictions is ignored. Thus, *ICA* does not

5. Technically, *wvRN* by itself is a local classifier, not an inference algorithm, but for brevity we refer to the family of algorithms based on this classifier (such as $wvRN_{RL}$) as *wvRN*.
6. Section 7 shows that the non-cautious variants *ICA*, $Gibbs_{NC}$, and LBP_{NC} perform similarly to each other. Thus, our empirical results would change little if we compared all of the cautious algorithms against the more standard *ICA*. However, the results for *Gibbs* and *LBP* would then concern performance differences between distinct algorithms, due to conjectured but unconfirmed differences in algorithmic properties. By instead comparing *Gibbs* vs. $Gibbs_{NC}$ and *LBP* vs. LBP_{NC}, we more precisely demonstrate that the cautious algorithms benefit from specifically identified cautious behaviors.

Name	Cautious Inf.?	Key Features	Type	Evaluated by?
Local classifier-based methods that iteratively classify nodes, yielding a final graph state				
ICA_C	Favors more conf. labels	Relational features depend only on "more confident" estimated labels; later iterations loosen confidence threshold.	Hard	Neville and Jensen (2000); McDowell et al. (2007a)
ICA_{Kn}	Favors known labels	First iteration: rel. features depend only on known labels. Later iterations: use all labels.	Hard	McDowell et al. (2007a)
ICA	Not cautious	Always use all labels, known and estimated.	Hard	Lu and Getoor (2003a); Sen and Getoor (2006); McDowell et al. (2007a,b)
Local classifier-based algorithms that compute conditional probabilities for each node				
Gibbs	Samples from estimated distribution	At each step, classifies using *all* neighbor labels, then samples new labels from the resultant distributions. Records new labels to produce final marginal statistics.	Hard	Jensen et al. (2004); Neville and Jensen (2007); Sen et al. (2008)
$Gibbs_{NC}$	Not cautious	Like *Gibbs*, but always pick most likely label instead of sampling.	Hard	None, but very similar to ICA.
Global formulation algorithms based on loopy belief propagation (LBP)				
LBP	Reasons with estimated distribution	Passes continuous-valued messages between linked neighbors until convergence.	Soft	Taskar et al. (2002); Neville and Jensen (2007); Sen et al. (2008)
LBP_{NC}	Not cautious	Like *LBP*, but each node always chooses single most likely label to use for next round of messages.	Hard	—
Relational-only algorithms				
$wvRN_{RL}$	Reasons with estimated distribution	Computes new distribution by averaging neighbors' label distributions; combines old and new distributions via relaxation labeling.	Soft	Macskassy and Provost (2007); Gallagher et al. (2008)
$wvRN_{ICA+C}$	Favors nodes closer to known labels	Initializes nodes in V^U to *missing*. Computes most likely label by averaging neighbors' labels, ignoring *missing* labels.	Hard	Macskassy and Provost (2007); similar to Galstyan and Cohen (2007)
$wvRN_{ICA+NC}$	Not cautious	Like $wvRN_{ICA+C}$, but no *missing* labels are used. Instead, initialize nodes in V^U by sampling from the prior label distribution.	Hard	—

Table 1: The ten collective inference algorithms considered in this article, divided into four families. Hard/soft refers to hard-labeling and soft-labeling (see Section 2.2).

perform cautious inference. However, it may exploit cautious learning to learn the classifier models that are used for inference (M_A and M_{AR}).

5.1.2 ICA_C

In steps 3-4 of Figure 2, *ICA* assumes that the estimated node labels are all equally likely to be correct. When *AlgType* instead selects ICA_C, the inference becomes more cautious by only considering more certain estimated labels. Specifically, step 3 "commits" into Y' only the best m of

ICA_classify $(V, E, X, Y^K, M_{AR}, M_A, n, AlgType)$=
// V=nodes, E=edges, X=attribute vectors, Y^K=labels of known nodes ($Y^K = \{y_i | v_i \in V^K\}$)
// M_{AR}=local classifier (uses attributes and relations), M_A=classifier that uses only attributes
// n=# of iterations, $AlgType$=ICA_C, ICA_{Kn}, or ICA

1 **for each** node $v_i \in V^U$ **do** // Bootstrap: estimate label y_i for each node
  $(y_i, conf_i) \leftarrow M_A(\vec{x}_i)$ // using attributes only
2 **for** $h = 0$ **to** n **do**
3 // Select node labels to use for computing relational feature values, store in Y'
  if $(AlgType = ICA_C)$ // For ICA_C: use known and m most confident
    $m \leftarrow |V^U| \cdot (h/n)$ // estimated labels, gradually increase m
    $Y' \leftarrow Y^K \cup \{y_i | v_i \in V^U \wedge rank(conf_i) \leq m\}$
  else if $(h = 0)$ and $(AlgType = ICA_{Kn})$
    $Y' \leftarrow Y^K$ // For ICA_{Kn}(first iteration): use *only* known labels
  else // For ICA_{Kn} (after first iteration) and ICA: use *all*
    $Y' \leftarrow Y^K \cup \{y_i | v_i \in V^U\}$ // labels (known and estimated)
4 **for each** node $v_i \in V^U$ **do**
    $\vec{f}_i \leftarrow calcRelatFeats(V, E, Y')$ // Compute feature values, using labels selected above
5 **for each** node $v_i \in V^U$ **do** // Re-predict most likely label, using attributes
    $(y_i, conf_i) \leftarrow M_{AR}(\vec{x}_i, \vec{f}_i)$ // and relational features
6 **return** $\{y_i | v_i \in V^U\}$ // Return predicted class label for each node

Figure 2: Algorithm for *ICA* family of algorithms. We use $n = 10$ iterations.

the current estimated labels; other labels are considered *missing* and thus ignored in the next step. Step 4 computes the relational features using only the committed labels, and step 5 classifies using this information. Step 3 gradually increases the fraction of estimated labels that are committed per iteration (e.g., if n=10, from 0%, 10%, 20%,..., up to 100%). Node label assignments committed in an iteration h are not necessarily committed again in iteration $h+1$ (and may in fact change).

ICA_C requires some kind of confidence measure ($conf_i$ in Figure 2) to determine the "best" m of the current label assignments (those with the highest confidence "rank"). We adopt the approach of Neville and Jensen (2000) and use the posterior probability of the most likely class for each node i as $conf_i$. In exploratory experiments, we found that alternative measures (e.g., probability difference of the top two classes) produced similar results.

Types of Caution Used: ICA_C favors more confident information by ignoring nodes whose labels are estimated with lower confidence. Step 3 executes this preference, which affects the algorithm in several ways. First, omitting the estimated labels for some nodes causes the relational feature value computation in step 4 to ignore those less certain labels. Since this computation favors more reliable label assignments, subsequent assignments should also be more reliable. Second, if any node links only to nodes with *missing* labels, then the computed value of the relational features for that node will also be *missing*; Section 6.5 describes how the classifier in Step 5 handles this case. Third, recall that a realistic CC scenario's test set may have links to nodes with known labels; these nodes, represented by V^K, provide the "most certain" labels and thus may aid classification. ICA_C exploits *only* these labels for iteration $h = 0$. In this case, step 3 ignores all estimated labels (every estimate for V^U), but step 4 can still compute some relational feature values based on known labels

Gibbs_classify $(V, E, X, Y^K, M_{AR}, M_A, n, n_B, C, AlgType)$=
// V=nodes, E=edges, X=attribute vectors, Y^K=labels of known nodes ($Y^K = \{y_i | v_i \in V^K\}$)
// M_{AR}=local classifier (uses attributes and relations), M_A=classifier that uses only attributes
// n=# of iterations, n_B= "burn-in" iters., C=set of class labels, $AlgType$=*Gibbs* or $Gibbs_{NC}$

1 **for each** node $v_i \in V^U$ **do** // Bootstrap: estimate label probs. $\vec{b}_i$
  $\vec{b}_i \leftarrow M_A(\vec{x}_i)$ // for each node, using attributes only
2 **for each** node $v_i \in V^U$ **do** // Initialize statistics
  for each $c \in C$
    $stats[i][c] \leftarrow 0$
3 **for** $h = 1$ **to** n **do** // Repeat for n iterations
  for each node $v_i \in V^U$ **do**
4 **switch** ($AlgType$):
    case ($Gibbs$): $y_i \leftarrow sampleDist(\vec{b}_i)$ // Sample next label from distribution
    case ($Gibbs_{NC}$): $y_i \leftarrow argmax_{c \in C}\ b_i(c)$ // Or, pick most likely label from dist.
5 **if** $(h > n_B)$ $stats[i, y_i] \leftarrow stats[i, y_i] + 1$ // Record stats. on chosen label
6 $Y' \leftarrow Y^K \cup \{y_i | v_i \in V^U\}$ // Compute feature values, using known
  for each node $v_i \in V^U$ **do** // labels and labels chosen in step 4
    $\vec{f}_i \leftarrow computeRelatFeatures(V, E, Y')$
7 **for each** node $v_i \in V^U$ **do** // Re-estimate label probs., using
    $\vec{b}_i \leftarrow M_{AR}(\vec{x}_i, \vec{f}_i)$ // attributes and relational features
8 **return** *stats* // Return marginal stats. for each node

Figure 3: Algorithm for Gibbs sampling. Thousands of iterations are typically needed.

from V^K. Thus, the known labels influence the first classification in step 5, before any estimated labels are used, and in subsequent iterations. Finally, ICA_C can also benefit from PLUL.

5.1.3 ICA_{Kn}

The above discussion highlighted two different effects from ICA_C: favoring more confident estimated labels vs. favoring known labels from V^K. An interesting variant is to favor the known labels in the first iteration (just like ICA_C), but then use all labels for subsequent iterations (just like *ICA*). We call this algorithm ICA_{Kn} ("ICA+Known").

Types of Caution Used: ICA_{Kn} favors only known nodes. It is thus more cautious than *ICA*, but less cautious than ICA_C. It can also benefit from cautious learning via PLUL.

5.2 Gibbs Family of Algorithms

Figure 3 displays pseudocode for Gibbs sampling (*Gibbs*) and the non-cautious variant $Gibbs_{NC}$. We describe each in turn.

5.2.1 *Gibbs*

In Figure 3, step 1 (bootstrapping) is identical to step 1 of the *ICA* algorithms, except that for each node v_i the classifier must output a distribution $\vec{x}_i$ containing the likelihood of each class, not just

the most likely class. Step 2 initializes the statistics that will be used to compute the marginal class probabilities for each node. In step 4, within the loop, the algorithm probabilistically samples the current class label distribution of each node and assigns a single label y_i based on this distribution. This label is also recorded in the statistics during Step 5 (after the first n_B iterations are ignored for "burn-in"). Step 6 then selects all labels (known labels and those just sampled) and uses them to compute the relational features' values. Step 7 re-estimates the posterior class label probabilities given these relational features. The process then repeats. When the process terminates, the statistics recorded in step 5 approximate the marginal distribution of class labels, and are returned by step 8.
Types of Caution Used: Like ICA_C, *Gibbs* is cautious in its use of estimated labels, but in a different way. In particular, ICA_C exercises caution in step 3 by ignoring (at least for some iterations) labels that have lower confidence. In contrast, *Gibbs* exercises caution by sampling, in step 4, values from each node's predicted label distribution—causing nodes with lower prediction confidence to reflect that uncertainty via higher fluctuation in their assigned labels, yielding less predictive influence on their neighbors. Gibbs can also benefit from cautious learning via PLUL.

We expect *Gibbs* to perform better than ICA_C, since it makes use of more information, but this requires careful confirmation. In addition, *Gibbs* is considerably more time intensive than ICA_C or *ICA* (see Section 5.6).

5.2.2 $Gibbs_{NC}$

$Gibbs_{NC}$ is identical to *Gibbs* except that instead of sampling in step 4, it always selects the most likely label. This change makes $Gibbs_{NC}$ deterministic (unlike *Gibbs*), and makes $Gibbs_{NC}$ behave almost identically to *ICA*. In particular, observe that after any number of iterations h ($1 \leq h \leq n$), *ICA* and $Gibbs_{NC}$ will have precisely the same set of current label assignments for every node. However, *ICA*'s result is the final set of label assignments, whereas $Gibbs_{NC}$'s result is the marginal statistics computed from these time-varying assignments. For a given data set, if *ICA* converges to an an unchanging set of label assignments, then for sufficiently large n $Gibbs_{NC}$'s final result (in terms of accuracy) will be identical to *ICA*'s. If, however, some nodes' labels continue to oscillate with *ICA*, then *ICA* and $Gibbs_{NC}$ will have different results for some of those nodes.
Types of Caution Used: Just like *ICA*, $Gibbs_{NC}$ uses all available labels for relational feature computation, and always picks the single most likely label based on the new predictions. Thus, $Gibbs_{NC}$ does not perform cautious inference, though it can benefit from cautious learning to learn the classifiers M_A and M_{AR}.

5.3 LBP Family of Algorithms

This section describes loopy belief propagation (*LBP*) and the non-cautious variant LBP_{NC}.

5.3.1 *LBP*

LBP has been a frequently studied technique for performing approximate inference, and has been used both in early work on CC (Taskar et al., 2002) and in more recent evaluations (Sen and Getoor, 2006; Neville and Jensen, 2007; Sen et al., 2008). Most works that study *LBP* for CC treat the entire graph, including attributes, as a pairwise Markov random field (e.g., Sen and Getoor, 2006; Sen et al., 2008) and then justify *LBP* as an example of a variational method (cf., Yedidia et al., 2000). The basic inference algorithm is derived from belief propagation (Pearl, 1988), but applied to graphs with cycles (McEliece et al., 1998; Murphy et al., 1999).

LBP performs inference via passing messages from node to node. In particular, $m_{i\to j}(c)$ represents node v_i's assessment of how likely it is that node v_j has a true label of class c. In addition, $\phi_i(c)$ represents the "non-relational evidence" (e.g., based only on attributes) for v_i having class c, and $\psi_{ij}(c',c)$ represents the "compatibility function" which describes how likely two nodes of class c and c' are linked together (in terms of Markov networks, this represents the potential functions defined by the pairwise cliques of linked class nodes). Given these two sets of functions, Yedidia et al. (2000) show the belief that node i has class c can be calculated as follows:

$$b_i(c) = \alpha\phi_i(c)\prod_{k\in N_i} m_{k\to i}(c) \tag{1}$$

where α is a normalizing factor to ensure that $\sum_{c\in C} b_i(c) = 1$ and N_i is the neighborhood function defined as:

$$N_i = \{v_j | \exists (v_i, v_j) \in E\} .$$

The messages themselves are computed recursively as:

$$m'_{i\to j}(c) = \alpha \sum_{c'\in C}\left(\phi_i(c')\psi_{ij}(c',c)\prod_{k\in N_i\setminus j} m_{k\to i}(c')\right) . \tag{2}$$

Observe that the message from i to j incorporates the beliefs of all the neighbors of i (N_i) *except* j itself. $m'_{i\to j}(c)$ is the "new" value of $m_{i\to j}(c)$ to be used in the next iteration.

For CC, we need a model that generalizes from the training nodes to the test nodes. The above equations do not provide this, since they have node-specific potential functions (i.e., ψ_{ij} is specific to nodes i and j). Fortunately, we can represent each potential function as a log-linear combination of generalizable features, as commonly done for such Markov networks (e.g., Della Pietra et al., 1997; McCallum et al., 2000a). More specifically for CC, Taskar et al. (2002) used a log-linear combination of functions that indicate the presence or absence of particular attributes or other features. Several papers (e.g., Sen and Getoor, 2006; Sen et al., 2008) have described a general model on how to accomplish this, but do not completely explain how to perform the computation. For a slight loss in generality (e.g., assuming that our nodes are represented by a simple attribute vector), we now describe how to perform *LBP* for CC on an undirected graph. In particular, let N_A be the number of attributes, $\mathcal{D}_h$ be the domain of attribute h, and $w_{c,h,k}$ be a learned weight indicating how strongly a value of k for attribute h indicates that a given node has class c. In addition, let $f_i(h,k)$=1 iff the h^{th} attribute of node i is k (i.e., $x_{ih} = k$). Then

$$\phi_i(c) = exp\left(\sum_{h\in\{1..N_A\}}\sum_{k\in\mathcal{D}_h} exp(w_{c,h,k})f_i(h,k))\right)$$

which is a special case of logistic regression. We likewise define similar learned weights of the form $w_{c,c'}$ that indicate how likely a node with label c is linked to a node with label c', yielding the compatibility function

$$\psi_{ij}(c,c') = exp(w_{c,c'}) .$$

LBP_classify $(V,E,X,Y^K,w,C,N,AlgType)$=
// V=nodes, E=edges, X=attribute vectors, Y^K=labels of known nodes ($Y^K = \{y_i | v_i \in V^K\}$)
// w=learned params., C=set of class labels, N=neighborhood funct., $AlgType$=*LBP* or LBP_{NC}

1 **for each** $(v_i, v_j) \in E$ such that $v_j \in V^U$ **do** // Initialize all messages
  for each $c \in C$ **do**
    if $(v_i \in V^K)$ // If class is known (y_i), set message to its
      $m_{i\to j}(c) \leftarrow \alpha \cdot exp(w_{y_i,c})$ // final, class-specific value
    else // Otherwise, message starts with same value
      $m_{i\to j}(c) \leftarrow \alpha$ // for every class, but will vary later

2 **while** (messages are still changing)

3 **for each** $(v_i, v_j) \in E$ such that $v_j \in V^U$ **do** // Perform message passing
    for each $c \in C$ **do**
      $m'_{i\to j}(c) \leftarrow \alpha \sum_{c' \in C} \left(\phi_i(c') exp(w_{c',c}) \prod_{k \in N_i \setminus j} m_{k\to i}(c')\right)$

4 **for each** $(v_i, v_j) \in E$ such that $v_j \in V^U$ **do**
    if $(AlgType = LBP)$ // For *LBP*, copy new messages for use in
      $m_{i\to j}(c) \leftarrow m'_{i\to j}(c)$ // next iteration
    else
      $c' \leftarrow argmax_{c \in C}(m'_{i\to j}(c))$ // For LBP_{NC}, select most likely label for node
      for each $c \in C$ **do** // Treat selected label the same as a "known"
        $m_{i\to j}(c) \leftarrow exp(w_{c',c})$ // label for use in the next iteration

5 **for each** node $v_i \in V^U$ **do** // Compute final beliefs
  for each $c \in C$ **do**
    $b_i(c) \leftarrow \alpha \phi_i(c) \prod_{k \in N_i} m_{k\to i}(c)$

6 **return** $\{\vec{b}_i\}$ // Return final beliefs

Figure 4: Algorithm for loopy belief propagation (LBP). α is a normalization factor.

As desired, the compatibility function is now independent of specific node identifiers, that is, it depends only upon the class labels c and c', not i and j. We use conjugate gradient descent to learn the weights (cf., Taskar et al., 2002; Neville and Jensen, 2007; Sen et al., 2008).

Finally, we must consider how to handle messages from nodes with a "known" class label. Suppose node v_i has known class y_i. This is equivalent to having a node where the non-relational evidence $\phi_i(c) = 1$ if c is y_i and zero otherwise. Since y_i is known, node v_i is not influenced by its neighbors. In that case, using Equation 2 (with an empty neighborhood for the product) yields:

$$m_{i\to j}(c) = \alpha \sum_{c' \in C} \phi_i(c') \psi_{ij}(c', c) = \alpha \cdot \psi_{ij}(y_i, c) = \alpha \cdot exp(w_{y_i,c}) \; . \tag{3}$$

Given these formulas, we can now present the complete algorithm in Figure 4. In Step 1, the messages are initialized, using Equation 3 if v_i is a known node; otherwise, each value is set to α (creating a uniform distribution). Steps 2-4 performs message passing until convergence, based on Equation 2. Finally, step 5 computes the final beliefs using Equation 1 and step 6 returns the results.
Types of Caution Used: Like *Gibbs*, *LBP* exercises caution by reasoning based on the estimated label uncertainty, but in a different manner. Instead of sampling from the estimated distribution, *LBP* in step 3 directly updates its beliefs using all of its current beliefs, so that the new beliefs reflect the underlying uncertainty of the old beliefs. In particular, this uncertainty is expressed

WVRN_RL_classify $(V, Y^K, n, C, \vec{b}_{prior}, N, \Gamma)$=
// V=nodes, Y^K=labels of known nodes ($Y^K = \{y_i | v_i \in V^K\}$), n=# of iterations
// C=set of class labels, $\vec{b}_{prior}$=class priors, N=neighborhood funct., Γ=decay factor

1 **for each** node $v_i \in V^K$ **do** // Create belief vector for each known label
  $\vec{b}_i \leftarrow makeBeliefsFromKnownClass(|C|, y_i)$ // (all zeros except at index for class y_i)
  for each node $v_i \in V^U$ **do** // Create initial beliefs for unknown labels
  $\vec{b}_i \leftarrow \vec{b}_{prior}$ // (using class priors as initial setting)
2 **for** $h = 0$ **to** n **do** // Iteratively re-compute beliefs
3 **for each** node $v_i \in V^U$ **do** // Compute new distribution for each node
  $\vec{b'}_i \leftarrow \frac{1}{|N_i|} \sum_{v_j \in N_i} \vec{b}_j$ // by averaging neighbors' distributions
4 **for each** node $v_i \in V^U$ **do** // Perform simulated annealing
  $\vec{b}_i \leftarrow \Gamma^h \vec{b'}_i + (1 - \Gamma^h)\vec{b}_i$
5 **return** $\{\vec{b}_i | v_i \in V^U\}$ // Return belief distribution for each node

Figure 5: Algorithm for $wvRN_{RL}$. Based on Macskassy and Provost (2007), we use $n = 100$ iterations with a decay factor of $\Gamma = 0.99$.

by the continuous-valued numbers that represent each message $m_{i \to j}$. *LBP* can also benefit from cautious learning with PLUL; in this case, PLUL influences the $w_{c,h,k}$ and $w_{c,c'}$ weights that are learned (see Section 6.4).

5.3.2 LBP_{NC}

LBP_{NC} is identical to *LBP* except that after the new messages are computed in step 3, in step 4 LBP_{NC} picks the single most likely label c' to represent the message from v_i to v_j. LBP_{NC} then treats c' as equivalent to a "known" label y_i for v_i and re-computes the appropriate message $m_{i \to j}(c)$ using Equation 3.

Types of Caution Used: Like *ICA* and $Gibbs_{NC}$, LBP_{NC} is non-cautious because it uses all available labels for relational feature computation and always picks the single most likely label based on the new predictions. In essence, the "pick most likely" step transforms the soft-labeling *LBP* algorithm into the hard-labeling LBP_{NC} algorithm, removing cautious inference just as the "pick most likely" step did for $Gibbs_{NC}$. However, LBP_{NC}, like *LBP*, can still benefit from cautious learning with PLUL.

5.4 wvRN Family of Algorithms

Figure 5 displays pseudocode for $wvRN_{RL}$, a soft-labeling algorithm. For simplicity, we present the related, hard-labeling variants $wvRN_{ICA+C}$ and $wvRN_{ICA+NC}$ separately in Figure 6. Each of these is a relational-only algorithm; Section 7.9 will discuss variants that incorporate attribute information.

5.4.1 $wvRN_{RL}$

$wvRN_{RL}$(Weighted-Vote Relational Neighbor, with relaxation labeling) is a relational-only CC algorithm that Macskassy and Provost (2007) argued should be considered as a baseline for all CC

WVRN_ICA_classify $(V, Y^K, n, C, \vec{b}_{prior}, N, AlgType)$=
// V=nodes, Y^K=labels of known nodes ($Y^K = \{y_i | v_i \in V^K\}$), n=# of iters., C=class labels
// $\vec{b}_{prior}$=class priors, N=neighborhood function, $AlgType$=$wvRN_{ICA+C}$ or $wvRN_{ICA+NC}$

1 **for each** node $v_i \in V^U$ **do**
  switch ($AlgType$): // Set initial value for unknown labels...
    case ($wvRN_{ICA+C}$): $y_i \leftarrow$ '?' // ...start labels as *missing*
    case ($wvRN_{ICA+NC}$): $y_i \leftarrow sampleDist(\vec{b}_{prior})$ // ...or sample label from class priors
2 **for** $h = 0$ **to** n **do** // Iteratively re-label the nodes
3 **for each** node $v_i \in V^U$ **do**
    $N'_i \leftarrow \{v_j \in N_i | y_j \neq$ '?' $\}$ // Find all non-*missing* neighbors
    if ($|N'_i| > 0$) // New label is the most common label
      $y'_i \leftarrow argmax_{c \in C} | \{v_j \in N'_i | y_j = c\} |$ // amongst those neighbors
    else $y'_i = y_i$ // If no such neighbors, keep same label
4 **for each** node $v_i \in V^U$ **do** // After all new labels are computed,
    $y_i \leftarrow y'_i$ // update to store the new labels
5 **return** $\{y_i | v_i \in V^U\}$ // Return est. class label for each node

Figure 6: Algorithm for $wvRN_{ICA+C}$ and $wvRN_{ICA+NC}$. This is a "hard labeling" version of $wvRN_{RL}$; each of the 5 steps corresponds to the same numbered step in Figure 5. We use $n = 100$ iterations.

evaluations. At each iteration, each node i updates its estimated class distribution by averaging the current distributions of each of its linked neighbors. $wvRN_{RL}$ ignores all attributes (non-relational features). Thus, $wvRN_{RL}$ is useful only if the test set links to some nodes with known labels to "seed" the inference process. Macskassy and Provost showed that this simple algorithm can work well if the nodes exhibit strong homophily and enough labels are known.

Step 1 of $wvRN_{RL}$ (Figure 5) initializes a belief vector for every node, using the known labels for nodes in V^K, and a class prior distribution for nodes in V^U. For each node, step 3 averages the current distributions of its neighbors, while step 4 performs simulated annealing to ensure convergence. Step 5 returns the final beliefs. For simplicity, we omit edge weights from the algorithm's description, since our experiments do not use them.

Types of Caution Used: Since $wvRN_{RL}$ computes directly with the estimated label distributions, it exercises cautious inference in the same manner as *LBP*. However, unlike the other CC algorithms, it does not learn from a training set, and thus cautious learning with PLUL does not apply.

5.4.2 $wvRN_{ICA+C}$ AND $wvRN_{ICA+NC}$

Figure 6 presents a hard-labeling alternative to $wvRN_{RL}$. Each of the five steps mirror the corresponding step in the description of $wvRN_{RL}$. In particular, for node v_i, step 3 computes the most common label among the neighbors of v_i (the hard-labeling equivalent of averaging the distributions), and step 4 commits the new labels without annealing.

However, with a hard-labeling algorithm, the initial labels for each node become very important. The simplest approach would be to initialize every node to have the most common label from the prior distribution. However, that approach could easily produce interlinked regions of labels that

that were incorrect but highly self-consistent; leading to errors even when many known labels were provided. Instead, Macskassy and Provost (2007) suggest initializing each node $v_i \in V^U$ to *missing* (indicated in Figure 6 by a question mark), a value that is ignored during calculations. They call the resulting algorithm wvRN-ICA; here we refer to it as $wvRN_{ICA+C}$. A *missing* label remains for node v_i after iteration h if during that iteration every neighbor of v_i was also *missing*.

Alternatively, a simpler algorithm is to always compute with all neighbor labels (do not initialize any to *missing*), but initialize each label in V^U by sampling from the prior distribution. We call this algorithm $wvRN_{ICA+NC}$. This process is the hard-labeling analogue of $wvRN_{RL}$'s approach: instead of initializing *each* node with the prior distribution, with $wvRN_{ICA+NC}$ sampling initializes the *entire set* so that it represents, in aggregate, the prior distribution.

Types of Caution Used: $wvRN_{ICA+NC}$ always uses the estimated label of every node, without regard for how certain that estimate is. Thus, it does not exhibit cautious inference. However, $wvRN_{ICA+C}$ does exhibit cautious inference, although this effect was not discussed by prior work with this algorithm. In particular, during the first iteration $wvRN_{ICA+C}$ uses only the certain labels from Y^K, since all nodes in Y^U are marked *missing*. These known labels are used to estimate labels for every node in V^U that is directly adjacent to some node in V^K. In subsequent iterations, $wvRN_{ICA+C}$ uses both labels from Y^K and labels from Y^U that have been estimated so far. However, the labels estimated so far are likely to be more reliable than later estimations, since the former labels are from nodes that were closer to at least one known label. Thus, in a manner similar to ICA_C's gradual commitment of labels based on confidence, $wvRN_{ICA+C}$ gradually incorporates more and more estimated labels into its computation, where more confident labels (those closer to known nodes) are incorporated sooner. This effect causes $wvRN_{ICA+C}$ to exploit estimated labels more cautiously.

5.5 Parameter Learning for Uncertain Labels (PLUL)

CC algorithms typically train a local classifier on a fully-labeled training set, then use that local classifier with some collective inference algorithm to classify the test set. Unfortunately, this results in asymmetric training and test phases: since all labels are known in the training phase, the learning process sees no uncertainty in relational feature values, unlike the reality of testing. Moreover, the classifier's training is unaffected by the type of collective inference algorithm used, and how (if at all) that collective algorithm attempts to compensate for the uncertainty of estimated labels during testing. Consequently, the learned classifier may tend to produce poor estimates of important parameters related to the relational features (e.g., feature weights, conditional probabilities). Even for CC algorithms that do not use a local classifier, but instead take a global approach that learns over the entire training graph (as with *LBP* and relaxation labeling), the same fundamental problem occurs: if autocorrelation is present, then parameters learned over the fully labeled training set tend to overstate the usefulness of relational features for testing, where estimated labels must be used.

To address these problems, we developed PLUL (Parameter Learning for Uncertain Labels). PLUL is based on standard cross-validation techniques for performing automated parameter tuning (e.g., Kohavi and John, 1997). The key novelty is not in the cross-validation mechanism, but in the selection of *which* parameters should be tuned and *why*. To use PLUL, we must first select or create an appropriate parameter that controls the amount of impact that relational features have on the resultant classifications. In principle, PLUL could search a multi-dimensional parameter space, but for tractability we select a single parameter that affects all relational features. For instance, when

PLUL_learn ($CCtype, P, lp, V_{Tr}, E_{Tr}, X_{Tr}, Y_{Tr}, V_H, E_H, X_H, Y_H$)=
// $CCtype$=CC alg. to use, P=set of parameter values to consider, lp=labeled proportion to use
// $V_{Tr}, E_{Tr}, X_{Tr}, Y_{Tr}$ = vertices, edges, attributes, and labels from training graph
// V_H, E_H, X_H, Y_H = vertices, edges, attributes, and labels from holdout graph

1 $Y'_H = keepSomeLabels(lp, Y_H)$ // Randomly select lp% of labels to keep; discard others

2 $bestParam \leftarrow \emptyset$ // Initialize variables to track best parameter so far
$bestAcc \leftarrow -1$

3 **for each** $p \in P$ **do** // Iterate over every parameter value

4 // Learn complete CC classifier from fully-labeled training data, influenced by p
$cc = learn\_CC\_classifier(CCtype, V_{Tr}, E_{Tr}, X_{Tr}, Y_{Tr}, p)$

5 // Run CC on holdout graph (with some known labels Y'_H) and evaluate accuracy
$acc \leftarrow execute\_CC\_inference(cc, V_H, E_H, X_H, Y'_H)$

6 // Remember this parameter if it's the best so far
if $(acc > bestAcc)$
$bestParam \leftarrow p$
$bestAcc \leftarrow acc$

7 **return** $bestParam$ // Return best parameter found over the holdout graph

Figure 7: Algorithm for Parameter Learning for Uncertain Labels (PLUL). The holdout graph is derived from the original training data and is disjoint from the graph that is used later for testing.

using a k-nearest-neighbor rule as the local classifier, we employ PLUL to adjust the weight w_R of relational features in the node similarity function. PLUL performs automated tuning by repeatedly evaluating different values of the selected parameter, as used by the local classifier, together with the collective inference algorithm (or the entire learned model for *LBP*). For each parameter value, accuracy is evaluated on a holdout set (a subset of the training set). PLUL then selects the parameter value that yields the best accuracy to use for testing.

Figure 7 summarizes these key steps of PLUL and some additional details. First, note that proper use of PLUL requires a holdout set that reflects the test set conditions. Thus, step 1 of the algorithm removes some or all of the labels from the holdout set, leaving only the same percentage of labels (lp%) that are expected in the test set. Second, running CC inference with a new parameter value may require re-learning the local classifier (for *ICA* or *Gibbs*) or the entire learned model (for *LBP*). This is shown in step 4 of Figure 7. Alternatively, for Naive Bayes or k-nearest-neighbor local classifiers, the existing classifier can simply be updated to reflect the new parameter value.

We expect PLUL's utility to vary based upon the fraction of known labels (lp) that are available to the test set. If there are few such labels, there is more discrepancy between the training and test environments, and hence more need to apply PLUL. However, if there are many such labels, then PLUL may not be useful.

Because almost all CC algorithms learn parameters based in some way on relational features, PLUL is widely applicable. In particular, Table 2 shows how we select an appropriate relational parameter to apply PLUL for different CC algorithms. The top of the table describes how to apply PLUL to a local classifier that is designed to be used with a CC algorithm like *ICA* or *Gibbs*. The

Local Classifier (or CC algorithm)	**Parameter set by PLUL (per relational feature)**	**Values tested by PLUL (default in bold)**
Naive Bayes (NB)	Hyperparameter α for Dirichlet prior	**1**, 2, 4, 8, 16, 32, 64, 128, 256, 512, 1024, 2048, 4096
Logistic Regression (LR)	Variance σ^2 of Gaussian prior	5, **10**, 20, 40, 80, 160, 320, 640, 1280, 2560, 512
k-Nearest Neighbor (kNN)	Weight w_R	0.01, 0.03, 0.0625, 0.125, 0.25, 0.5, 0.75, **1.0**, 2.0
LBP	Variance σ^2 of Gaussian prior	5, **10**, 20, 100, 200, 1000, 10000, 100000, 1000000

Table 2: The classifiers (NB, LR, and kNN) and CC algorithm (*LBP*) used in our experiments for which PLUL can be applied to improve performance. The second column lists the key relational parameters that we identified for PLUL to learn, while the last column shows the values that PLUL considers in its cross-validation.

last row demonstrates how it can instead be applied to a global algorithm like *LBP*. For instance, for the NB classifier, most previous research has used either no prior or a simple Laplacian ("add one") prior for each conditional probability. By instead using a Dirichlet prior (Heckerman, 1999), we can adjust the "hyperparameter" α of the prior for each relational feature. Larger values of α translate to less extreme conditional probabilities, thus tempering the impact of relational features. For the kNN classifier, reducing the weight of relational features has a similar net effect. For the LR classifier and the *LBP* algorithm, both techniques involve iterative MAP estimation. Increasing the value of the variance of the Gaussian prior for relational features causes the corresponding parameter to "fit" less closely to the training data, again making the algorithm more cautious in its use of such relational features.

While the core mechanism of PLUL—cross-validation tuning—is common, techniques like PLUL to explicitly compensate for the bias incurred from training on a fully-labeled set while testing using estimated labels have not been previously used for CC. A possible exception is Lu and Getoor (2003a), who appear to have used a similar technique to tune a relational parameter, but, in contrast to this work, they did not discuss its need, the specific procedure, or the performance impact.

PLUL attempts to compensate for the bias incurred from training on the correctly-labeled training set. Alternatively, Kou and Cohen (2007) describe a "stacked model" that learns based on estimated, rather than true labels. While the original goal of this stacked approach was to produce a more time-efficient algorithm, Fast and Jensen (2008) recently demonstrated that this technique, by eliminating the bias between training and testing, does indeed reduce "inference bias." This reduced bias enables the stacked models to perform comparably to Gibbs sampling, even though the stacked model is a simpler, non-iterative algorithm that consequently has higher learning bias. Interestingly, Fast and Jensen (2008) note that the stacked model performs an "implicit weighting of local and relational features," as with PLUL. The stacked model accomplishes this by varying the learning and inference procedure, whereas PLUL modifies only the learning procedure, and thus works with any inference algorithm that relies on a learned model.

5.6 Computational Complexity and the Cost of Caution

For learning and inference, all of the CC algorithms (variants of *ICA*, *Gibbs*, *wvRN*, and *LBP*) use space that is linear in the number of nodes/instances (N_I). *ICA* and *Gibbs* have significant similarities, so we consider their time complexity first. For these two algorithms, the dominant computation costs for inference stem from the time to compute relational features and the time to classify each node with the local classifier. Typically, nodes are connected to a small number of other instances, so the first cost is $O(N_I)$ per iteration. For the second cost, the time per iteration is $O(N_I)$ for NB and LR, and $O(N_I^2)$ for kNN. However, the number of iterations varies significantly. Based on previous work (Neville and Jensen, 2000; McDowell et al., 2007a), we set $n = 10$ for variants of *ICA*; more iterations did not improve performance. In contrast, *Gibbs* typically requires *thousands* of iterations.

Adding or removing cautious inference to *ICA* and *Gibbs* does not significantly change their time complexity. In particular, $Gibbs_{NC}$ has the same complexity as *Gibbs*. ICA_C introduces an additional cost, compared to *ICA*, of $O(N_I log N_I)$ per iteration to sort the nodes by confidence. However, in practice classification time usually dominates. Therefore, the overall computational cost per iteration for all variants of *ICA* and *Gibbs* are roughly the same, but the larger number of iterations for variants of *Gibbs* makes them much more time-expensive than *ICA*, ICA_{Kn}, or ICA_C.

LBP does not explicitly compute relational features, but its main loop iterates over all neighbors of each node, thus again yielding a cost of $O(N_I)$ per iteration under the same assumptions as above. We found that *LBP* inference was comparable in cost to that of *ICA*, which agrees with Sen and Getoor (2007). However, training the *LBP* classifier is much more expensive than training the other algorithms. *ICA* and *Gibbs* only require training the local classifier, which involves zero to one passes over the data for kNN and NB, and a relatively simple optimization for LR. On the other hand, training *LBP* with conjugate gradient requires executing *LBP* inference many times. We found this training to be at least an order of magnitude slower than the other algorithms, as also reported by Sen and Getoor (2007). LBP_{NC} has the same theoretical and practical time results as *LBP*.

wvRN is the simplest CC algorithm, since it requires no feature computation and the key step of each iteration is a simple average over the neighbors of each node. As with previous algorithms, assuming a small number of neighbors for each node yields a total time per iteration of $O(N_I)$. Prior work (Macskassy and Provost, 2007) suggested using a somewhat larger number of iterations (100) than with *ICA*. Nonetheless, in practice *wvRN*'s simplicity makes it the fastest algorithm.

Finally, all of the algorithms, except for *wvRN*, can be augmented with cautious learning via PLUL. Executing PLUL requires repeatedly running the CC algorithm with different values of the selected parameter. We used 9-13 different parameter values, and hence the cost of PLUL vs. not using PLUL is about one order of magnitude.

6. Evaluation Methodology

This section describes our hypotheses and the method that we use to evaluate them.

6.1 Hypotheses

Table 3 summarizes our five hypotheses. As described in Section 1, we expect cautious behaviors to be more important when there is a higher probability of incorrect relational inference. Thus, each

Data characteristic	**Type of caution considered**	**Hypothesis:** relative gain of caution will increase as value of characteristic...
Autocorrelation	Inference	...increases (H1)
Attribute predictiveness	Inference	...decreases (H2)
Link density	Inference	...decreases (H3)
Labeled proportion	Inference	...decreases (H4)
Labeled proportion	Learning	...decreases (H5)

Table 3: The five hypotheses that we investigate.

hypothesis varies one data characteristic that impacts the likelihood of such errors. In particular, hypotheses H1-H4 vary a data characteristic to measure the impact of cautious inference, which Section 7 will evaluate for different pairs of cautious and non-cautious inference algorithms. We define the "relative gain of cautious inference" as the difference between the accuracies of two such algorithms (e.g., *Gibbs* vs. $Gibbs_{NC}$). Hypothesis H5 also varies a data characteristic, but does so to measure the "relative gain of cautious learning" (i.e., comparing performance with vs. without PLUL).

- **H1: The relative gain of cautious inference increases with increasing autocorrelation**. Larger autocorrelation implies that relations are more predictive, and will be learned as such by the classifier. This magnifies the impact that an error in a predicted label can have on linked nodes. Therefore, we expect cautious inference algorithms to improve classification by a greater margin in such cases.

- **H2: The relative gain of cautious inference increases with decreasing attribute predictiveness (*ap*)**. Decreased *ap* implies a greater potential of errors/uncertainty in the predicted labels. The effect of cautiously using uncertain labels should be greater in such cases.

- **H3: The relative gain of cautious inference increases with decreasing link density (*ld*).** When the number of links is high, a single mispredicted label has relatively little impact on its neighbors. As the number of links decreases, however, a single misprediction can cause larger relational feature uncertainty, increasing the need for caution.

- **H4: The relative gain of cautious inference increases with decreasing labeled proportion (*lp*).** When *lp* is high, only a few of each node's neighbors have estimated labels (most are known with certainty). Consequently, there is less uncertainty in relational feature values, and less need to use estimated labels cautiously.

- **H5: The relative gain of cautious learning with PLUL increases with decreasing labeled proportion(*lp*).** As with H4, when *lp* is high there is less uncertainty in the relational features. Thus there is less disparity between the fully correct training set (where classifier parameters were learned) and the test set. Consequently, we expect PLUL, which compensates for any such disparity, to matter less when *lp* is high.

6.2 Tasks

We will evaluate three general tasks (see Section 2.3):

Parameter	Abbrev.	Values tested (defaults in bold)
Nodes per graph	N_I	250
Number of class labels	N_C	5
Number of attributes	N_A	10
Degree of homophily	*dh*	0.1, 0.2, 0.3, 0.4, 0.5, 0.6, **0.7**, 0.8, 0.9
Link density	*ld*	0.1, **0.2**, 0.3, 0.4, 0.5, 0.6, 0.7, 0.8, 0.9
Attribute predictiveness	*ap*	0.1, 0.2, 0.3, 0.4, 0.5, **0.6**, 0.7, 0.8, 0.9
Labeled proportion	*lp*	**0%**, **10%**, 20%, 40%, **50%**, 60%, 80%

Table 4: Synthetic data parameters. Defaults were chosen based on averages from Cora and Citeseer, two commonly studied data sets for CC.

1. **Out-of-sample task:** Here the test set does not contain or link to any known nodes, as with Neville and Jensen (2000), Taskar et al. (2002), and Sen and Getoor (2006).

2. **Sparse in-sample task:** Here some of the test nodes, but only a few, have known labels (we use 10%). We focus particularly on this task, because some researchers argue that it is the most realistic scenario, since often networks are large, and acquiring known labels is expensive (Bilgic and Getoor, 2008). This was the primary scenario considered by the recent work of McDowell et al. (2007a,b), Bilgic and Getoor (2008), and Gallagher et al. (2008).

3. **Dense in-sample task:** Here a substantial number of test nodes may have known labels (we use 50%). This task was the one recently evaluated by Sen et al. (2008).

6.3 Data

We evaluate the hypotheses over both synthetic and real-world data sets, which we describe below. We use the synthetic data to highlight how different data characteristics affect the relative gain of cautious behaviors, then the real-world data sets to validate these findings.

6.3.1 SYNTHETIC DATA

We use a synthetic data generator (see Table 4) with two components: a Graph Generator and an Attribute Generator. The Graph Generator has four inputs: N_I (the number of nodes/instances), N_C (the number of classes), *ld* (the link density), and *dh* (the degree of homophily). For each link, *dh* controls the probability that the linked nodes have the same class label; higher values yield higher autocorrelation (see Appendix A for details). The final number of links is approximately $N_I/(1-ld)$, and the final link degrees follow a power law distribution, which is common in real networks (Bollobás et al., 2003). The Graph Generator is identical to that used by Sen et al. (2008); see that article for more detail.

To make this a practical study, we chose default parameter values that mimic characteristics of two frequently studied CC data sets, Cora and Citeseer (McDowell et al., 2007a; Neville and Jensen, 2007; Sen et al., 2008). In particular, N_C=5 classes and Table 4 shows additional default values. We chose N_I=250 nodes, a smaller value than with Cora/Citeseer, to reduce CC execution time, but larger values did not change the performance trends.

The Attribute Generator generates 10 (N_A) binary attributes. Our design for it is motivated by our observations of common CC data sets. We found that, unlike synthetic models used in prior studies, different attributes vary in their utility for class prediction. To simulate this, we associate each attribute h with a particular class c_m, where $m = h \ mod \ N_C$, and vary the strength of each attribute's predictiveness based on the value of h. In particular, for node v_i with class y_i, the probability that v_i's h^{th} attribute x_{ih} has value 1 depends upon the class y_i as follows:

$$P(x_{ih} = 1 | y_i = c_k) = \begin{cases} 0.15 + (ap - 0.15) \cdot \frac{h}{N_A - 1} & \text{if } k = h \ mod \ N_C \\ 0.1 & \text{if } k = (h-1) \ mod \ N_C \\ 0.05 & \text{if } k = (h+1) \ mod \ N_C \\ 0.02 & \text{otherwise.} \end{cases}$$

The first line indicates that, when y_i $(= c_k)$ is the class associated with attribute h (i.e., $k = h \ mod \ N_C$), then $P(x_{ih} = 1 | y_i = c_k)$ ranges from 0.15 for $h = 0$ to ap (a constant representing the strength of attribute predictiveness) for $h = 9$. As a result, each of the five classes has two attributes associated with that class, but some classes have associated attributes that are more useful for prediction. However, x_{ih} may also be 1 when y_i is some other class besides an "associated class"; the next three lines encode this class ambiguity. This ambiguity/noise is based on our observations of Cora and Citeseer and is similar to the binomial distribution used by Sen et al. (2008).

Finally, we use a parameter for test set generation called lp (labeled proportion), which is the proportion of test nodes with known labels. We use default values of lp=0%, lp=10%, and lp=50% for the three tasks defined in Section 6.2. Nodes to be labeled are selected uniformly at random from the test set until the desired value of lp is reached. In contrast, some real data sets are likely to exhibit non-uniform clustering of known nodes. We conjecture that such data sets will have a smaller "effective" lp, since each known node will have, on average, fewer direct connections to unknown nodes. For instance, a data set with lp=10% may behave more like a data set with lp=5% where the labels are more uniformly distributed. Such effects should be examined in future work.

6.3.2 "REAL-WORLD" DATA SETS

We consider the following five "real-world" data sets (see Table 5). "Real-world" is a somewhat subjective term; however, all of the data sets are based on naturally arising networks and have been used in some form for previous research on relational learning.

1. **Cora (McCallum et al., 2000b):** A collection of machine learning publications categorized into seven classes. The relational links are (directed) citations.

2. **Citeseer (Lu and Getoor, 2003a):** A collection of research publications drawn from CiteSeer. The relational links are (directed) citations.

3. **WebKB (Craven et al., 1998):** A collection of web pages from four computer science departments categorized into six classes (Faculty, Student, Staff, Course, ResearchProject, or Other). "Other" is problematic because it is too general, representing 74% of the pages. Like Taskar et al. (2002), we discarded all "Other" pages that did not have at least three outgoing links, yielding a total of 1541 instances of which 30% are Other. The relational links are the (directed) hyperlinks among these pages.

	Cora	CiteSeer	WebKB	HepTH	Terror
Characteristics of entire graph					
Instances/nodes	2708	3312	1541	2194	645
Attributes (non-relat. feats.) available	1433	3703	100	387	106
Attributes used (max)	100	100	100	100	100
Attributes used (default)	20	20	40	40	2
Link/relation directedness	directed	directed	directed	directed	undirected
Type of relational features used	in,out	in,out	in,out,co	in,out	linksto
Class labels	7	6	6	7	6
Total relational features used	14	12	18	14	6
Links per node	3.9	2.7	5.8(64.6)	8.9	9.8
Autocorrelation	0.88	0.83	0.30(0.53)	0.54	0.16
Characteristics of each test set (on average)					
Instances/nodes	400	400	335-469	300	150
Number of folds	5	5	4	5	3
Links per node	2.7	2.7	5.7(61.0)	4.3	12.3
Approx. link density	0.23	0.23	0.64(0.97)	0.53	0.79
Autocorrelation	0.85	0.84	0.38(0.53)	0.64	0.24
Label consistency	0.78	0.75	0.21(0.90)	0.61	0.56
Approximate homophily	0.74	0.70	0.05(0.88)	0.54	0.47

Table 5: Summary of the five real-world data sets used. *in* and *out* features compute separate values based on incoming or outgoing links, while *linksto* features make no such distinction. *co* features are based on virtual co-citation links; nodes A and B are linked via a *co* link if there exists some node C with outgoing links to both A and B. For WebKB, the first statistic listed is computed ignoring co-links, while the statistic in parentheses is computed using *only* co-links. Label consistency is the percentage of links connecting nodes with the same label; Appendix A defines this and approximate homophily. Section 6.9 describes the "default" number of attributes used.

4. **HepTH:** A collection of journal articles in the field of theoretical high-energy physics, derived from the Proximity Hep-Th database (http://kdl.cs.umass.edu/data/hepth). The original data set did not have any single class label, but some pages were classified into topic subtypes. Among pages with one such subtype, we selected all articles belonging to the six most common subtypes, yielding 1404 articles. To create a more connected graph, we also selected all articles with a date after 2001 that linked to at least two of the 1404 pre-selected articles. There were 790 such articles, which we treated as having a class label of "Other." The relational links are the (directed) citations among all 2194 articles.

5. **Terror (Zhao et al., 2006):** A collection of terrorist incidents, drawn from the Profile in Terror project (http://profilesinterror.mindswap.org). The incidents are non-uniformly distributed into six categories: Bombing (44%), WeaponAttack (38%), Kidnapping (14%), Arson (2%), NBCRAttack (1%), and OtherAttack (1%). The relational links indicate (undirected) geographical co-location.

These data sets are intended to demonstrate CC performance on a range of data characteristics. For instance, CC would be expected to be very helpful for Cora and CiteSeer, where autocorrelation is high, but not very helpful for Terror.

6.4 CC Algorithms

We evaluate the ten algorithms listed in Table 1, plus *Content Only* (*CO*), a non-relational baseline that uses only attributes. For each of the four main sections in Table 1, there is one non-cautious variant (*ICA*, $Gibbs_{NC}$, LBP_{NC}, and $wvRN_{ICA+NC}$) and one or two cautious variants (ICA_C, ICA_{Kn}, *Gibbs*, *LBP*, $wvRN_{RL}$, and $wvRN_{ICA+C}$). The *wvRN* algorithms also serve as a collective, relational-only baseline.

Based on previous work (Neville and Jensen, 2000; McDowell et al., 2007a), the *ICA*-based algorithms used $n = 10$ iterations; more iterations did not improve performance. For *Gibbs*, we used 1500 iterations, with a random restart every 300 iterations, and ignored the first 100 iterations after a restart for burn-in. Additional iterations did not improve performance. $Gibbs_{NC}$ converged in far fewer iterations because it does not sample and is deterministic; we used $n = 50$.

For *LBP*, we assumed that each parameter was a priori independent and had a zero-mean Gaussian prior with a default uniform prior variance of $\sigma^2 = 10$, which is similar to the values reported in previous work (e.g., Sen and Getoor 2006; Neville and Jensen 2007). We used MAP estimation to estimate these parameters based on conjugate gradient. σ^2 controls how tightly the parameters fit to the training data; Table 2 shows the alternative values of σ^2 considered by PLUL to constrain this fitting for the relational parameters.

6.5 Classifiers

To account for possible variations in overall CC performance trends due to the effect of the underlying classifier, we tested three local classifiers with each CC algorithm wherever applicable (this excludes *LBP* and *wvRN*). Section 5.5 already described, for each classifier, the key relational feature whose value is learned by PLUL; we now provide more detail on each classifier and its application of PLUL.

The first classifier is Naive Bayes (NB). PLUL was used to learn α for the Dirichlet prior of each relational feature. The second classifier is Logistic Regression (LR). We used MAP estimation with Gaussian priors to learn the parameters for LR; PLUL learned an appropriate variance σ^2 for the prior of each relational feature. The final classifier is k-Nearest Neighbor (kNN); we used k=11. When computing similarity, attributes were assigned a weight of 1. PLUL learned the weight w_R for each relational feature. Weighted similarity was used for voting.

For each classifier, Table 2 shows the specific values considered by PLUL. The "default" value shown (e.g., $\alpha = 1.0$ for NB) was used in two ways. First, the default was used as the parameter value for all attributes. Second, the default was used for a manual setting for the parameter value for all relational features when PLUL is not being used. When PLUL was used, the learned value was used instead for the relational features.

The ICA_C algorithm requires a classifier that can ignore *missing* relational feature values. kNN and NB can do this easily: kNN by dropping the feature from the similarity calculation and NB by skipping the feature in probability computation. For LR, however, dealing with missing values is a current research topic (e.g., Fung and Wrobel 1989), with typical techniques including mean value substitution or multiple imputation. However, for CC the situation is less complex than the more general case, because missing values occur only for the test set, only for relational features, and typically only when all neighbors of a node have missing labels. Thus, we can learn several LR classifiers: one that uses all relational features, and one for each combination of features that may be missing simultaneously (for our data, this is at most 4). Experimentally, we found this

to perform better than mean value substitution, though the difference was slight because missing values were rare. These results are consistent with those of Saar-Tsechansky and Provost (2007) on non-relational data. Section 7.8 discusses this effect in more detail.

6.6 Node Representation

Each node is represented by a set of (non-relational) attributes and relational features. Algorithms based on *LBP* and *wvRN* reason directly with each individual link, and their algorithms thus directly define the effective relational features used. Approaches based on *ICA* and *Gibbs*, however, use some kind of aggregation function to compute their relational feature values. We first describe the possible aggregation functions for these features, then separately describe the complete representation for the synthetic and real data.

6.6.1 RELATIONAL FEATURES CONSIDERED

We considered three different types of relational features:

- **Count**: This type represents the number of neighbors that belong to a particular class. For each node i, there is one such feature $f_i(c)$ per class label c. The value of $f_i(c) = Neighbors_i(c)$, which is the number of nodes linked to node i that have a known or current estimated label of c. For instance, in step C of Figure 1, $f_2(P) = 1$ and $f_2(S) = 2$.

- **Proportion**: This feature is like "count", except that the feature value represents the proportion of neighbors that have a particular label, rather than the raw number of such neighbors. For this feature, $f_i(c) = Neighbors_i(c)/Neighbors_i(*)$, where $Neighbors_i(*)$ is the number of nodes linked to node i that have any current label (known or estimated, but, for ICA_C, excluding those nodes whose label was set to *missing* because of low confidence). If $Neighbors_i(*)$ is zero, then $f_i(c)$ is set to *missing*. For example, if proportion features were being used, then the feature values for step C of Figure 1 would be $f_2(P) = 1/3$ and $f_2(S) = 2/3$.

- **Multiset**: Proportion and count features aggregate the labels of a node's neighborhood to produce a single numerical value for each possible label. During inference, this aggregate value is then compared against the mean value from the training set (with NB or LR), or compared against the aggregate values for nodes in the training set (with kNN). In contrast, a "multiset" feature uses a single multiset to represent the current labels of a node's neighbors. For instance, if multiset features were used, then for step C of Figure 1, $f_2 = \{P,S,S\}$. This has the same information content as with count features, but can be exploited differently by some local classifiers. In particular, during NB inference, each label in the multiset (excluding *missing* labels) is separately used to update the conditional probability that a node has true label c. This is the "independent value" approach introduced by Neville et al. (2003b) and used by Neville and Jensen (2007). However, this approach does not directly apply to LR or kNN.

6.6.2 SYNTHETIC DATA NODE REPRESENTATION

Each node is represented by ten binary attributes and some relational features. Because representation choices can affect how well a CC algorithm handles the uncertainty of estimated labels, for each local classifier-based algorithm we considered count and proportion relational features, as well

as multiset features when using NB. For each trial, we evaluated the two or three possible types of relational features with cross-validation (evaluating accuracy on the holdout set), then selected the feature type with the highest accuracy to use for testing. When PLUL was used, PLUL was also applied to each feature type; the best performance (on the holdout set) reported by PLUL for each feature type was then used for this feature selection. Section 7.8 describes which feature types were chosen most often for each local classifier. Since there are 5 class labels for the synthetic data and links are undirected, there were 5 relational features when using count or proportion features, and 1 relational feature (whose value is a multiset) when using multiset.

6.6.3 REAL-WORLD DATA NODE REPRESENTATION

For all five data sets we used binary attributes that indicated the presence or absence of a particular word. For WebKB, these words were from the body of each HTML page; we selected the 100 most frequent such words, which was all that was available in our version of the data set. For symmetry, and because adding more words had a small impact on performance, we likewise set up the remaining data sets to select 100 words as attributes. For Cora and CiteSeer, these words were taken from the body of the publications; as with previous work (McDowell et al., 2007a) we selected the 100 words with the highest information gain in the training set to use. For Terror, the words come from hand-written descriptions of each incident provided with the data set; we selected the first 100 of the 106 available attributes. For HepTH, we selected, based on information gain, the 100 highest-scoring words from the article title or the name of the corresponding journal.

For relational features, we again considered the proportion, multiset, and count features, and selected the best feature type using cross-validation as described above. All of the data sets except Terror had directed links. For these data sets, we computed separate relational feature values based on incoming and outgoing links. In addition, previous work has shown WebKB to have much stronger autocorrelation based on co-citation links than on direct links (see Table 5). However, using such links can sometimes be problematic. Thus, we evaluate two data sets: "WebKB" and "WebKB+co". For WebKB, algorithms use in and out links ("direct" links). For WebKB+co, algorithms use in, out, and co-links, except *wvRN* uses only co-links, as suggested by Macskassy and Provost (2007) (see Section 7.6).

6.7 Training/Test Splits Generation

For the synthetic data, we generate training, holdout, and test graphs that are disjoint. Likewise, for WebKB, the data was already divided into four splits (one for each department) that can be used for cross-validation.

For the other real data sets, we must manually construct training and test splits from the original graph. Sen et al. (2008) suggest a technique based on snowball sampling that involves picking a random starting node and iteratively growing a split around that node, where the class of the next node to be selected is sampled from the overall class distribution. However, we found that low graph connectivity often prevented the algorithm from producing a final subgraph whose class distribution resembled the whole graph's. Instead, we created the following technique, *similarity-driven snowball sampling*: given the whole graph G, pick a random starting node and add it to the split G_1. At each step, consider the *frontier* F of G_1 (all those nodes not in G_1 that link to some node in G_1). Among all labels c that exist in F, select the class label c' such that adding some node of label c' to G_1 would maximize the similarity (inverse Euclidean distance) of the class distributions

of G_1 and G. Given this c', randomly select some node in F of class c' and add it to G_1. Repeat this random selection and insertion until G_1 is of the desired size.

We run this algorithm in parallel for N_S different subgraphs, using N_S different seeds, and permit each node to be inserted into only one subgraph. This results in N_S disjoint splits that have similar class distributions and that can be used for N_S-fold cross validation. We set $N_S = 5$ for Cora, Citeseer, and HepTH, and $N_S = 3$ for the smaller Terror.

Table 5 shows some of the characteristics of the generated test sets vs. the original, complete graphs. In general, the autocorrelation and number of links per node are similar, indicating that the sampling procedure did not dramatically change the average characteristics of the graph. While the splitting procedure effectively removes links, the average degree of the test sets may still be greater than with the original graph if high-degree subsets of the original are selected.

6.8 Test Procedure

We first consider the synthetic data. For each control condition (i.e., data generated with a combination of *dh*, *ap*, *ld*, and *lp* values, see Table 4) we ran 25 random trials. For each trial, we generated training, holdout, and test data sets of 250 nodes each. All training is performed on the fully labeled training set. The holdout set, when not used for PLUL, was merged with the training set. We measured classification accuracy on the test set, excluding all nodes with "known" labels.

For the real-world data sets, each experiment involves using all of the relational features shown in Table 5 and a fixed number of attributes (N_A). We vary N_A from 2 to 100 (recall that for all data sets 100 attributes were selected for experimentation). For each setting of N_A, we perform N_S-fold cross-validation, where N_S is 3, 4, or 5, depending on the data set. Each one of these 3 to 5 trials is associated with one subgraph (the test set), and the remaining 2-4 subgraphs comprise the training set. We then apply PLUL by training on half of the training set and using the other half as the holdout set. After PLUL selects the best parameter setting, we re-train on the whole training set and evaluate accuracy on the test set. If PLUL is not used, training likewise uses the whole training set.

We report results with accuracy in order to ease comprehension of the results and to facilitate comparison with some of the most relevant related work (e.g., Sen et al., 2008; Macskassy and Provost, 2007). Results with area under the ROC curve (AUC) for the majority class demonstrated similar trends.

6.9 Statistical Analysis

We conducted two distinct types of analysis. First, to compare algorithms for a single control condition, we used a one-tailed paired t-test accepted at the 95% confidence level. For every such test each "test point" is the accuracy over a single trial's test graph. For example, for the synthetic data there are 25 trials for each control condition, and thus a single t-test compares 25 pairs of accuracies (e.g., ICA_C vs. ICA). In all cases the test graphs used by these t-tests are disjoint, for both the synthetic and the real data.

Second, we performed linear regression slope tests. In particular, for hypotheses H1-H4, we compared two algorithms (e.g., ICA_C vs. ICA) for each independent variable X (e.g., *ld*) as follows: For each trial, we computed the difference in the algorithms' classification accuracies (e.g., for the synthetic data, 225 such differences for 25 trials and 9 values of *ld*). We performed linear regression ($Y = a + bX$), where the accuracy difference is the dependent variable Y and X is the independent variable (e.g., *ld*). The estimated value of slope b, when non-zero, indicates an increasing (+)

or decreasing ($-$) trend. Regression produces a p value associated with the slope that indicates the significance level for hypothesis testing; we accept when $p < 0.05$. For hypothesis H5, the equations are the same but we compare a single CC algorithm with and without PLUL.

For the synthetic data, the analysis is straight-forward and we use the data generation parameters *dh*, *ap*, *ld*, and *lp* as the independent variable for regression. Analysis for the real data sets requires more explanation. For instance, each computed subgraph of a data set has similar autocorrelation, so regression for H1 (where autocorrelation is the X value) cannot be performed on a single data set. Instead, we combine the trials of all the real data sets into one analysis, where the independent variable is the measured autocorrelation of the corresponding data set (we include WebKB, but exclude WebKB+co because it's not clear how to compute its autocorrelation with direct links combined with co-citation links). In addition, our results show that when attribute predictiveness is high, there is less need for caution. Thus, to prevent any interactions between autocorrelation and caution from being obscured by high attribute predictiveness, we use fewer than 100 attributes for these experiments. In particular, for each data set we evaluated the baseline *CO* algorithm with varying numbers of attributes N_A, and selected the number that yields an average accuracy closest to 50%. Table 5 shows the resulting default number of attributes for each data set.

For H2 (attribute predictiveness), we can directly vary the number of attributes, so we can perform regression for each data set separately. However, attribute predictiveness is typically not a linear function of the number of attributes. Thus, for H2 we perform regression where the dependent variable is the accuracy of *CO* for each trial (as a surrogate for attribute predictiveness).

We do not directly evaluate H3 for the real data sets (see Section 7).

For H4 and H5 (varying labeled proportion), we directly vary *lp*, so we can compute separate results for each data set. Moreover, *lp* is suitable for direct use as the dependent variable. As with H1, we use the default number of attributes for each data set in order to avoid having high attribute predictiveness obscure the interaction of caution and *lp*. We omit nonsensical points (e.g., *wvRN* when *lp*=0%) from all of the analyses.

Finally, for each hypothesis we also perform a *pooled analysis*. For the synthetic data, this involves pooling the results of all the cautious CC algorithms, then performing the slope regression test. For the real-world data, we pool the results across both the CC algorithms and each of the real data sets. In addition, to account for differences in the data sets, we perform a multiple regression analysis that includes autocorrelation as one of the input variables (except for H1). In particular, we fit the data to the line $Y = a + b_1X_1 + b_2X_2$, where X_1 is the variable in question (e.g., *lp* for H4 or H5) and X_2 is the autocorrelation of the data set. The X_2 term factors out differences due only to autocorrelation, thus making the other trends more clear. The p-value corresponding to b_1 is then used for hypothesis testing.

6.10 Implementation Validation

To validate the implementation of our algorithms, we replicated three different synthetic data generators: those used by Sen and Getoor (2006), Neville and Jensen (2007), and Sen et al. (2008). We then replicated some of the experiments from these papers. While several of our CC algorithm variants were not evaluated in any of these earlier papers, we were able to compare results for *ICA*, *Gibbs*, and *LBP*, with the LR and NB classifiers as appropriate, and found very consistent results. Section 8.4 discusses one exception.

LBP is the most challenging algorithm to implement and to get to converge. To deal with such problems, Sen et al. (2008) seeded *LBP*'s learning process with weights learned from *ICA*. Alternatively, we found that seeding with values estimated from empirical counts over the data, combined with limiting the maximum step size of the search to prevent oscillation, worked well. With these enhancements, *LBP* achieved equivalent accuracy to that reported by Sen and Getoor (2006), and, when PLUL was applied, significantly improved it for the cases of high homophily and link density (where *LBP*'s accuracy had been very poor). In contrast, we found that *LBP* could replicate the performance of Sen et al. (2008), but that in this case PLUL had little effect. Section 8.4 explains the data characteristics of that study (effectively high *lp*) that led to this result.

7. Evaluation Results

This section presents our experimental results. Section 7.1 presents a summary of the results, Section 7.2 explains how we present the detailed results, and subsequent sections discuss these detailed results for each hypothesis. We focus on the sparse in-sample task, so *we accept a hypothesis if it is confirmed, for the* lp=*10% case, by the pooled analysis on both the synthetic data and the real-world data*. Hypotheses H4-H5 involve varying *lp*; here we accept the hypothesis if confirmed on both the synthetic and real data.

When a local classifier is needed, all results below use NB by default. We found that NB's performance was better or equivalent to that of LR and kNN in almost every case (see Section 8.4), for both the synthetic and real data sets, and that using LR or kNN led to very similar performance trends. Below we mention some of the results for LR and kNN; see the online appendix for more detail. In addition, PLUL is used everywhere unless otherwise specified; see analysis and motivation in Section 7.7.

7.1 Summary of Results

Tables 6-8 summarize our overall results for hypotheses H1-H5. Each table presents results for the synthetic data on the left and (where applicable) for the real data sets on the right. Each reported value represents the estimated slope of the line measuring the difference between a cautious and a non-cautious CC algorithm as the corresponding x-parameter (e.g., autocorrelation) is varied (see Section 6.9). Only values that were statistically different from zero are reported; otherwise a dash is shown. Bold values indicate a significant slope that supports the corresponding hypothesis. For instance, H2 predicted that caution becomes more important as attribute predictiveness *decreases* (a negative slope). Thus, Table 7 shows a minus sign for the expected slope and all significant, negative slopes are shown in bold. Where possible, we show separate results for the out-of-sample, sparse in-sample, and dense in-sample tasks (using $lp = 0\%$, 10%, and 50%). However, to simplify the table the real-world data results for H2 are shown only with lp=10%; Section 7.4 describes other results.

The tables show strong support for hypotheses H1, H2, and H4. In particular, we accept H1, H2, and H4 because the pooled analyses find significant slopes in the expected direction; non-pooled results also demonstrate consistent support. Thus, the data support the claims that each cautious inference algorithm outperforms[7] its non-cautious variant by increasing amounts when autocorrelation

7. Technically, the slope results don't by themselves show that the cautious algorithms "outperform" the non-cautious algorithms—only that the relative performance of the cautious algorithms is improving in the hypothesized direction.

Table 8: Summary of results for hypotheses H4 and H5, which both vary the labeled proportion (lp). As before, all values shown represent a slope that is significantly different from zero; values in bold support the corresponding hypothesis. For H4, all algorithms used PLUL where applicable.

the dependence (the magnitude of the slope) generally decreases as the labeled proportion increases from 10% to 50% (Section 7.4 discusses the differences between lp=0% and 10% in more detail).

Table 7 shows weaker support for H3 (cautious inference gain increases as link density decreases). H3 is supported by most of the synthetic data cases and by the pooled analysis for lp=10% and lp=50%, but the magnitude of the slopes indicates a weaker effect. Moreover, Section 7.5 examines these results more closely and proposes that a more appropriate hypothesis would state that the cautious inference gain is greatest when link density is moderate. This conclusion is also tentatively supported by a per-node degree analysis of the real data.

Table 8 also shows weaker support for H5. The synthetic data results supported H5 for every algorithm except *ICA*. In addition, for 18 of the 29 possible cases shown for the real data sets, the computed slope was negative, as predicted by H5. However, the magnitude of these slopes indicate a weaker effect than with H1, H2, or H4. This decreased magnitude, in conjunction with the smaller number of trials for the real data, leads to only 4 of those 18 slopes reaching statistical significance. Nonetheless, by combining trials across algorithms and data sets, the pooled analysis does find significant (but small) negative slopes for both the synthetic and real data, so we accept H5. This indicates, as expected, that cautious learning with PLUL is most important when lp is small; Section 7.7 also demonstrates that in this case PLUL can provide substantial performance gains.

In addition to these results for each hypothesis, regarding relative performance trends as data characteristics vary, our results also show statistically significant differences between the cautious and non-cautious algorithms for at least some of the data conditions. These differences are consistent with the accepted hypotheses. For instance, using the default synthetic data characteristics, each cautious algorithm showed a significant performance gain over its non-cautious variant, and the amount of this gain increased as autocorrelation increased, attribute predictiveness decreased, or labeled proportion decreased.

7.2 Explanation of Results Presentation

In the following sections, we present several figures that compare CC algorithmic performance. In these figures some controllable parameter is the x-axis and the y-axis is the resultant accuracy for a given algorithmic variant, averaged over all trials. For instance, Figure 8 plots accuracy vs. the degree of homophily (*dh*). Each figure compares cautious and non-cautious variants of a particular CC algorithm: *ICA*, *Gibbs*, *LBP*, or *wvRN*. In addition, for the CC algorithms that use a local classifier (*ICA* and *Gibbs*), we often include results for the non-relational algorithm *CO* for comparison.

In each section below, we use these results to describe two kinds of analysis. First, we accept or reject a hypothesis, based on the pooled regression slope test. This analysis confirms or fails to confirm that the importance of the cautious techniques *does change* in the expected direction as some data parameter varies, but does not evaluate *how important* the cautious techniques are in improving performance. To answer the latter question, we report on a second analysis that evaluates, using paired t-tests, whether the cautious techniques perform significantly better than the non-cautious alternatives (see Section 6.9).

Each figure has embedded statistical information corresponding to some of these t-tests. In particular, each non-cautious CC variant is plotted with a $\times$ marker, while cautious CC variants are plotted with a triangle (where multiple cautious variants exist, two triangle orientations are used: $\bigtriangledown$ and $\bigtriangleup$). For a particular x-value, if the plotted triangle is filled in (solid color), then that cautious variant had accuracy that was significantly different from the accuracy *of the corresponding non-cautious variant*. Hollow triangles instead indicate no significant difference. This notation does *not* directly indicate other significance comparisons (e.g., between the two cautious variants ICA_C and ICA_{Kn}); where necessary we describe such results in the text. For example, in Figure 8, the graph in the third column of the first row (*LBP* at *lp*=0%) shows that *LBP* significantly outperforms LBP_{NC} when *dh*=0.6 (note the filled triangle). However, for *dh*=0.5, *LBP*'s small gain is not statistically significant (hollow triangle).

When *lp*=0%, ICA_{Kn} is equivalent to *ICA*, so results for ICA_{Kn} are not shown. Also, *LBP* with WebKB+co did not converge due to the very high number of links, so results for that case are not considered (cf., Taskar et al., 2002).

7.3 Result 1: The Relative Gain of Cautious Inference Increases with Increasing Autocorrelation

Table 6 reports that for H1, for the sparse in-sample task (*lp*=10%), the pooled regression analyses found all significant positive values for the slope B. Thus, we accept H1. In addition, all the non-pooled analyses found significant positive values. The only exception was *LBP* on the real data sets, which had a positive, non-significant slope ($b = +0.03$).

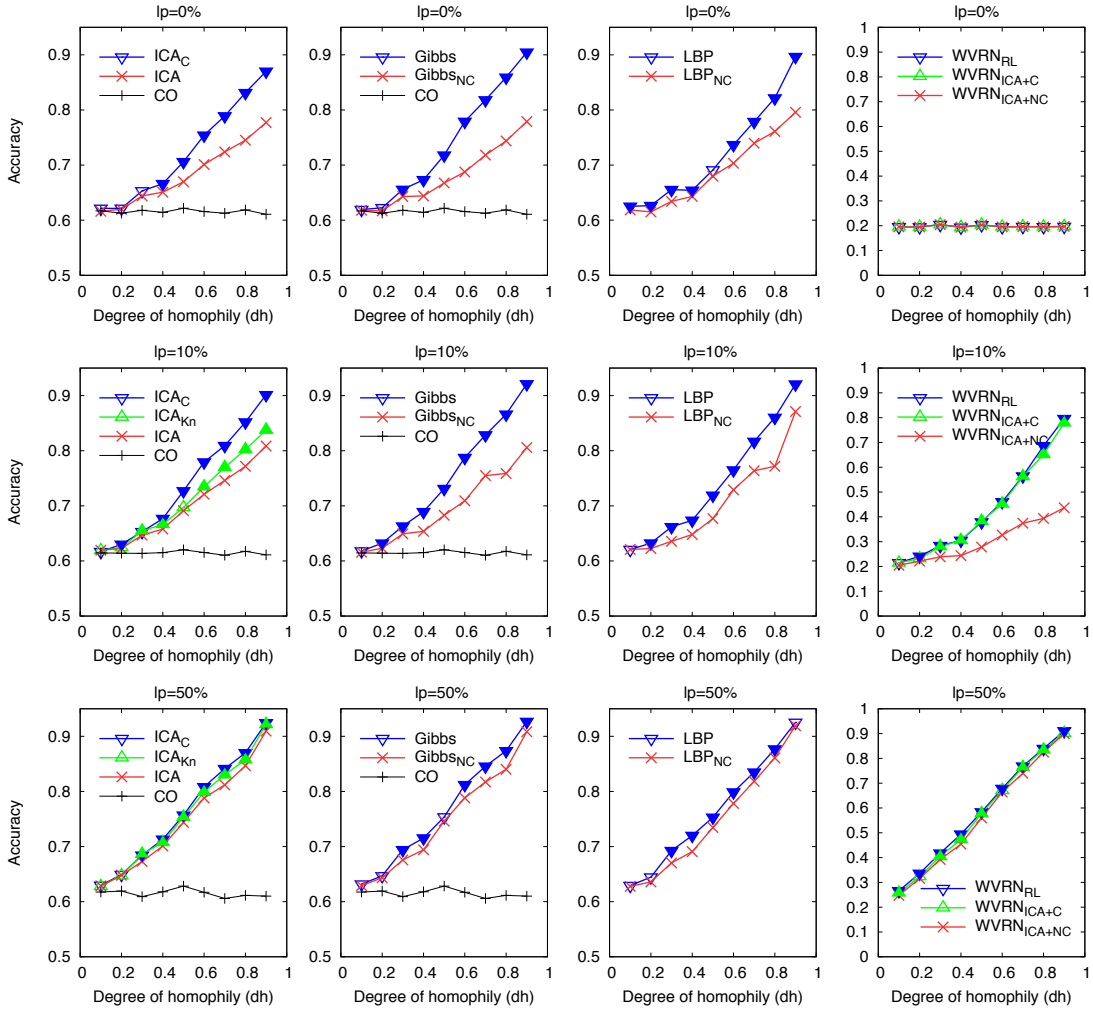

Figure 8: Results for the synthetic data as the degree of homophily (*dh*) varies. Section 7.2 explains how filled triangles indicate statistical significance. Some of the gains are small but consistent, leading to significance, as in the bottom right graph.

For *lp*=0% and *lp*=50%, the pooled analyses and most individual analyses show the same positive slopes (on the real data for ICA_C vs. *ICA* at *lp*=0%, the slope was $b = +0.11$, but the p-value was just over the significance threshold), as we also found with LR and kNN. The reduced significance and magnitude of the slopes when *lp*=50% is also consistent with our expectations, since the overall importance of caution should decrease as *lp* increases (see hypotheses H4 and H5). Section 7.4 explains more for the *lp*=0% case.

Figure 8 shows detailed performance trends for the synthetic data. Here each column presents results for different variants of a single CC algorithm (*ICA*, *Gibbs*, *LBP*, and *wvRN*), and each row shows results for a different value of *lp*. The x-axis varies homophily (which directly increases autocorrelation) and the y-axis reports average accuracy.

This figure confirms that when homophily is very low, CC offers little gain, and thus the cautious variants perform equivalently to the non-cautious variants (and, except for *wvRN*, to the non-

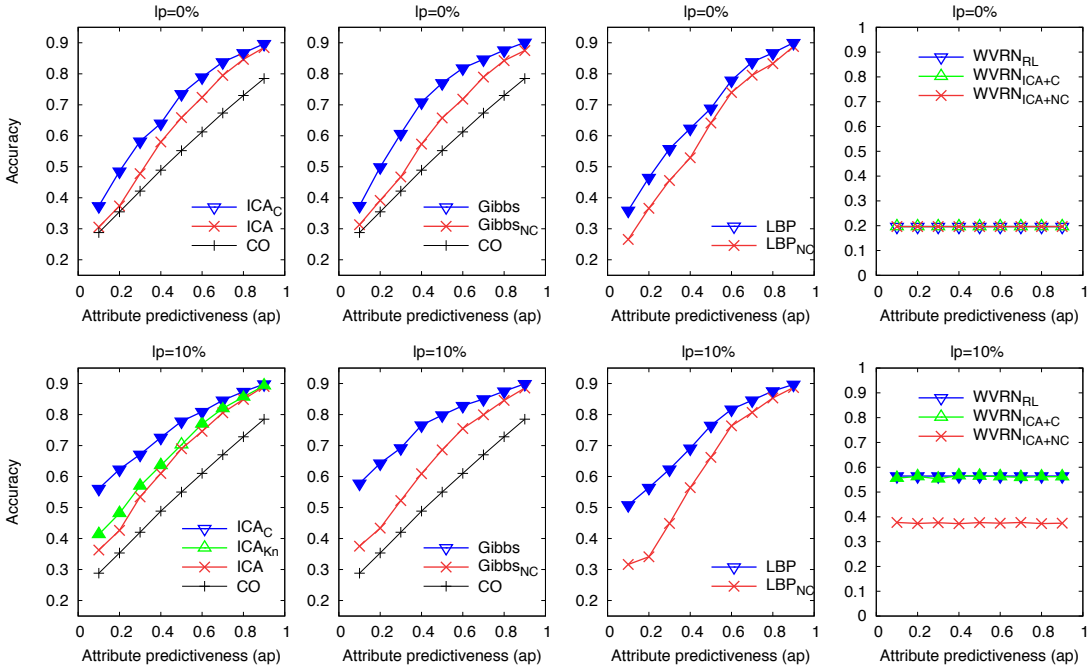

Figure 9: Results for the synthetic data as attribute predictiveness (*ap*) varies.

relational baseline *CO*). As the strength of relational influence (as well as the potential for incorrect relational inference) increases with higher homophily, the relative gain of the cautious methods increases substantially (e.g., at *lp*=10%, gains for NB-based algorithms rise from 4-5% at *dh*=0.5 to 9-12% at *dh*=0.9). The gains from caution are statistically significant in most cases when $dh \geq 0.3$. Results with LR and kNN show very similar trends (see online appendix).

Figure 8 also confirms that as *lp* increases, the cautious and non-cautious variants perform more similarly. However, even for *lp*=50%, the cautious variants maintain a significant, though smaller, advantage. In the other results discussed below, the same trend of very similar performances at *lp*=50% was evident. Likewise, the graphs for *lp*=0% are similar to those for *lp*=10%. Thus, we defer most results for *lp*=0% or 50% to the online appendix.

7.4 Result 2: The Relative Gain of Cautious Inference Increases as Attribute Predictiveness (*ap*) Decreases

Table 7 reports that, for *lp*=10%, the regression analyses found all significant negative slopes (as expected) for the synthetic data. Likewise, in almost all cases we found significant negative slopes for the real data sets that have substantial autocorrelation (Cora, Citeseer, HepTH, and WebKB+co), except for WebKB+co (which had very erratic performance with all the algorithms). We accept H2, because the pooled analysis found negative slopes at *lp*=10% for both synthetic and real data; this result also holds at *lp*=0% and 50%.

Figure 9 shows detailed performance trends for the synthetic data as the x-axis varies *ap*. For instance, for *lp*=10%, when the attribute predictiveness (*ap*) is 0.6 (the default), ICA_C and *Gibbs* outperform their non-cautious variants by 6-7%. However, as *ap* decreases to 0.2, label uncertainty

increases (as evidenced by the drop for *CO*), causing the relative gain of caution to increase to 20%. *LBP* shows very similar results.

Results for *lp*=0% are mostly similar, but with an interesting twist. In this case, the relative gain of cautious CC increases as *ap* decreases, as with *lp*=10%. However, this gain peaks at *ap*=0.2 or 0.3, then declines as *ap* continues to decrease. When attribute predictiveness is very low, and there are no known labels to help seed the inference (i.e., *lp*=0%), then even the cautious algorithms have difficulty exploiting relational information, and achieve accuracy only moderately above the baseline *CO*. However, even in this case the cautious algorithms maintain some small, statistically significant advantage over the their non-cautious variants (which at *ap*=0.1 do little better than *CO*). Also, observe that ICA_C, *Gibbs*, and *LBP* all improve substantially for the *lp*=10% case (compared to *lp*=0%), even though only ICA_C explicitly favors the provided known labels in its inference process. In this case, using caution appears to be the important performance factor, regardless of what specific behavior provides that caution.

Figures 10 and 11 provide similar results for the real data sets with *lp*=10%, where the x-axis is now the number of attributes used, which correlates with overall attribute predictiveness. In general, the trends shown are similar to those already observed for the synthetic data. In particular, the graphs for Cora, Citeseer, HepTH, and WebKB all follow the same pattern: cautious algorithms outperform non-cautious algorithms more when the number of attributes is low (and cautious ICA_C outperforms the somewhat cautious ICA_{Kn}). Consistent with H1, the magnitude of these gains varies with autocorrelation: larger for Cora and Citeseer, smaller for HepTH and WebKB, and non-existent for Terror (where autocorrelation is very weak).

There are two exceptions to the similarities of these results with the synthetic data. First, for some data sets *Gibbs* and/or *LBP* perform noticeably worse than ICA_C; we discuss this separately in Section 8.1. Second, WebKB+co shows fairly erratic performance for all algorithms except ICA_{Kn}. In general, the co-citation links used by WebKB+co appear to be very informative (peak accuracy is much higher than with WebKB), but also potentially misleading. This may be a function of the WebKB graph structure: Table 5 shows that co-citation links have a very high label consistency of 0.90 (implying that classifiers will learn a strong relational dependence), but this may be biased by the presence of some very high degree nodes. During learning the co-citation links may appear very informative on average, but this strong dependency may lead to mispredictions for low-degree nodes, leading to the observed erratic behavior.

We now briefly return to the slope analysis of Table 7. For the synthetic data, the negative slopes for H2 are significant in all cases, but generally largest for *lp*=10%. This behavior is consistent with our previously discussed analyses of the synthetic data: when *lp*=0%, the performance of cautious algorithms for very low *ap* is diminished, thus producing a smaller slope magnitude than when *lp*=10%. On the other hand, the more general observation that caution is less useful when *lp* is high explains why the magnitude of the slopes is less for *lp*=50% than for *lp*=10%. We found similar trends for the real-world data sets: while Table 7 shows significant negative slopes for H2 for most cases (excluding the erratic WebKB+co and the low autocorrelation Terror) when *lp*=10%, results (not shown) with *lp*=0% or 50% indicate slopes of reduced magnitude and/or slopes that do not reach statistical significance. However, in both cases the pooled analysis still indicates significant negative slopes for H2 (-0.05 for *lp*=0% and -0.13 for *lp*=50%).

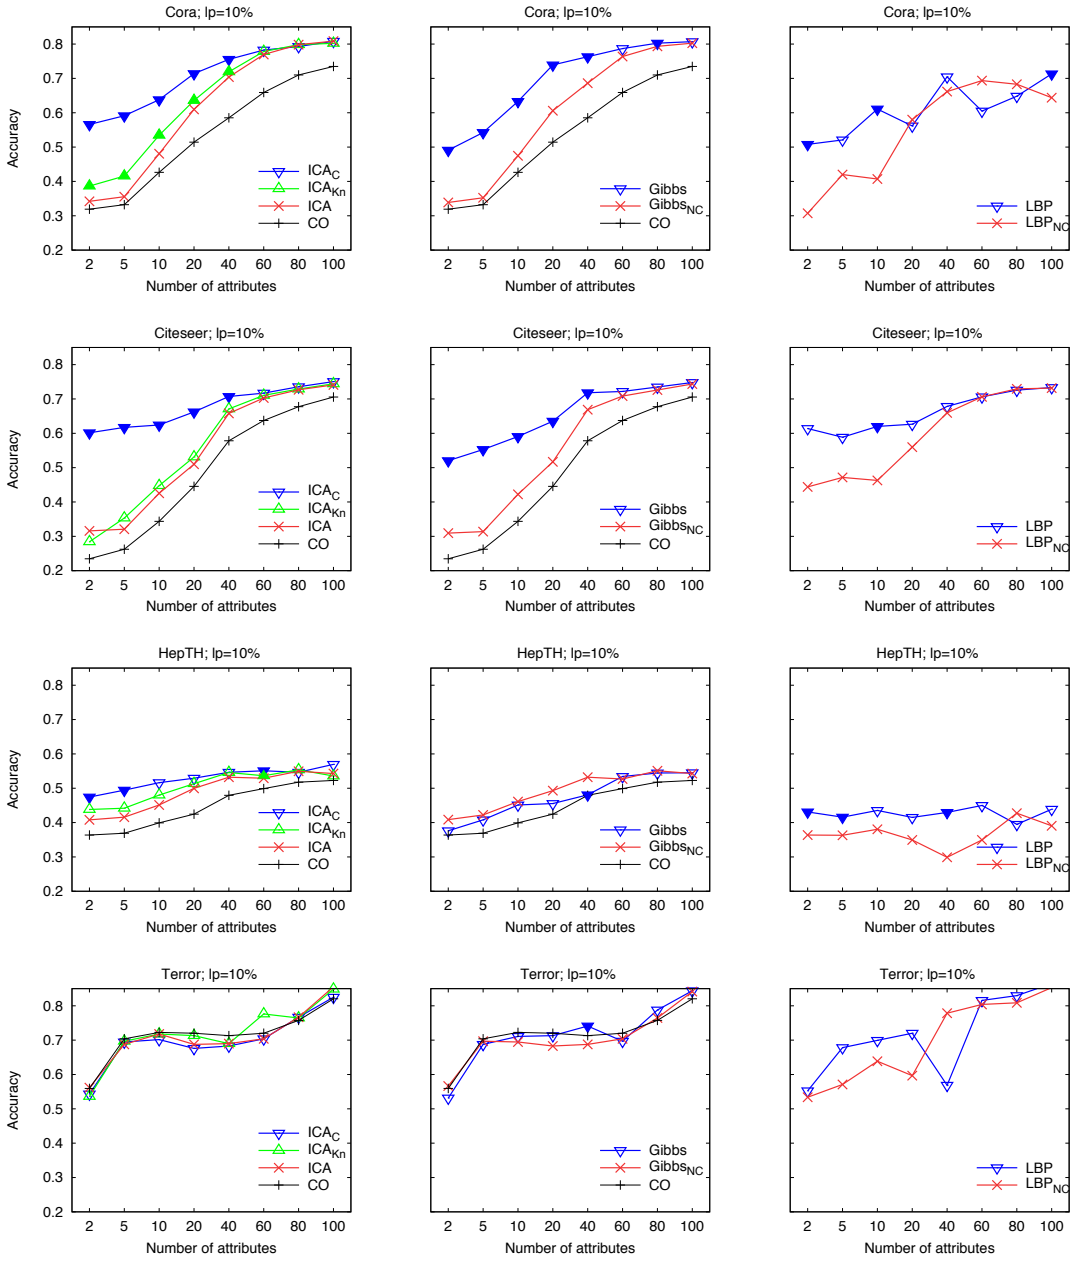

Figure 10: Results for four of the real data sets as the number of attributes is varied. The x-axis is not to scale; this is to improve readability and to yield a more linear curve for the baseline *CO* algorithm, thus facilitating comparison with Figure 9. Because there are only 3-5 trials for the real data, high variance sometimes causes substantial gains to not be statistically significant.

7.5 Result 3: The More Cautious Algorithms Outperform Non-Cautious Algorithms when Link Density (*ld*) is Moderate, But Have Mixed Results When *ld* is High

For the synthetic data, the results in Table 7 support H3 for all algorithms when *lp*=50%, for most algorithms when *lp*=10%, and for only two algorithms when *lp*=0%. The pooled analysis finds,

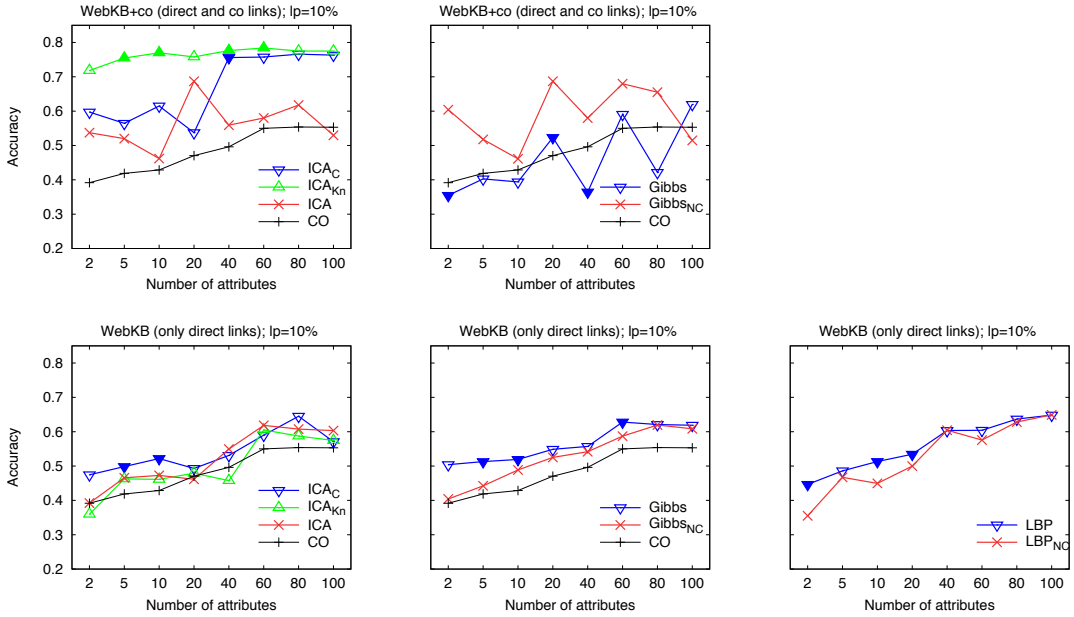

Figure 11: Results for the WebKB data sets as the number of attributes is varied. With WebKB+co, *LBP* did not converge, so results are not shown.

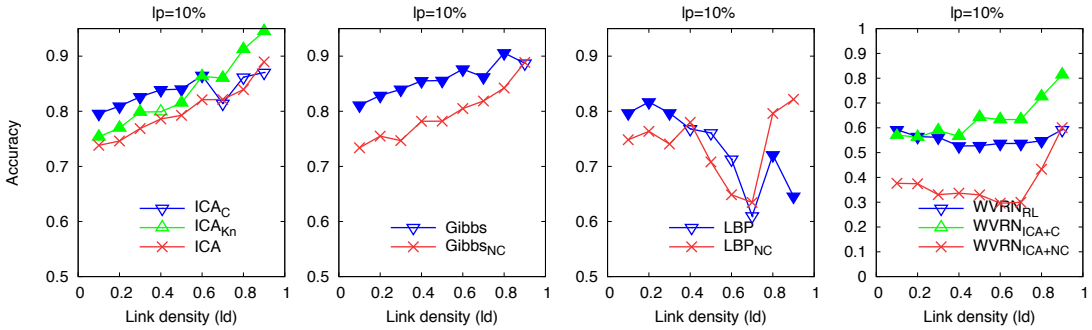

Figure 12: Results for the synthetic data as link density (*ld*) varies.

as expected, significant negative slopes for *lp*=10% and *lp*=50%. However, without corresponding pooled results for the real data, we cannot accept H3. Moreover, the results we present below will suggest a revision to H3.

Figure 12 shows the results as *ld* is varied, for *lp*=10%. When *ld* is low to moderate (up to *ld*=0.6), the cautious algorithms consistently and significantly outperform their non-cautious variants. We had hypothesized that this advantage would decrease as link density increased, because when the link graph is dense, the relational features are relatively unaffected by a few incorrect labels, and thus using such labels cautiously matter less; Figure 12 generally reflects this trend. In some cases the non-cautious algorithm even outperforms the cautious algorithm at very high *ld*. For instance, at *ld*=0.9 *ICA* outperforms the more cautious ICA_C (though not significantly). At such high link density, simply using all available information with *ICA* may work better than ICA_C's

cautious but partial use of estimated labels—provided that accuracy is high enough that errors are few. In separate experiments we confirmed that if the attribute predictiveness (and thus accuracy) was lower, ICA_C maintained it's advantage over *ICA* even when *ld* was very high.

While these results generally indicate, as expected, that the gain from caution decreases as *ld* becomes high, closer examination indicates that this gain from caution peaks not at very low *ld*, but at moderate *ld*. In particular, the gain from caution peaks when *ld* is 0.2 or 0.3 for ICA_C, ICA_{Kn}, or *Gibbs*, and when *ld* is 0.6 for $wvRN_{RL}$ and $wvRN_{ICA+C}$. In hindsight, this effect makes sense: as the number of links decrease, there is less relational influence, and thus less probability of incorrect relational influence, so caution matters less. Another effect is that with fewer links, there are fewer opportunities for a cautious algorithm to favor one node's predictions over another's.

To further analyze these trends, we turn to the real data. We did not attempt to directly vary the link density of the real data sets, because it's not clear how to realistically add links to an existing data set, as would be necessary to create a reasonable range of link densities for experimentation. However, Table 9 examines our previous results for the real data sets, showing the amount of cautious gain broken down by the link degree of each node. This approach does not directly correlate to varying the overall link density, so our conclusions are tentative, but it does provide some insight. We focus primarily on ICA_C; trends with other algorithms were similar.

The results support our previous conjectures. In particular, the cautious gain generally decreases for the highest link degrees, even going negative in some cases. Moreover, in most cases the cautious gain also decreases for the lowest link degrees, resulting in a peak for the cautious gain (shown in bold if present) at moderate link degrees. These effects generally hold true for the synthetic data and for the real data sets that have substantial autocorrelation.

We now return to Figure 12 to consider a few possible exceptions. First, with *LBP*, accuracy decreases with increasing *ld*, is erratic, and is sometimes better with LBP_{NC} than with *LBP*. This is not surprising: the short graph cycles caused by high *ld* produces great problems for *LBP* (e.g., Sen and Getoor, 2006; Sen et al., 2008). Even these *LBP* accuracies are much better than those achieved without PLUL (see Section 7.7).

Second, two of the cautious algorithms (ICA_{Kn} and $wvRN_{ICA+C}$) performed unexpectedly well, continuing to significantly outperform the non-cautious variants (and even alternative cautious variants) at very high link density. Interestingly, these effects also occur with WebKB+co (see Figures 11 and 14), which has by far the highest link density of the real data sets.[8] In addition, the superior performance of ICA_{Kn} at high *ld* remains even when the local classifier is changed to LR or kNN (see Figure 19 in the online appendix). We suspect that ICA_{Kn}'s advantage arises because it both achieves a better starting point than *ICA* (by favoring known labels in its first iteration) and exploits more information than ICA_C (by using all estimated labels in subsequent iterations—and when *ld* is high using a few erroneous labels doesn't harm performance). For $wvRN_{ICA+C}$, its advantage over $wvRN_{RL}$ must arise from the key algorithmic difference: since $wvRN_{ICA+C}$ is a hard-labeling algorithm, it gives all labeled nodes equal weight in the neighborhood average that determines the next label for a node. When link density is high, relying on this simple average may be better than $wvRN_{RL}$'s soft-labeling estimation, which implicitly gives more weight to nodes with more extreme

8. At first, these strong performances seem to conflict with Macskassy and Provost (2007), who generally find $wvRN_{RL}$ outperforms $wvRN_{ICA+C}$. However, two-thirds of their data sets are variants of WebKB, but where all "Other" pages have been removed from the classification task. This change makes the classification problem easier, and thus may explain the discrepancy. In addition, on the only other data set used in that work and this article (Cora), our performance trends are very similar.

	Degree 1-2	Degree 3-5	Degree 6-10	Degree 11-20

Table 9: Per-node degree results showing the amount of gain from caution (ICA_C vs. *ICA* or *Gibbs* vs. $Gibbs_{NC}$). Each value indicates the average accuracy gain from caution for all nodes in the test set within the given link degree range (nodes with degree greater than 20 were rare, and ignored for simplicity). Within each row, a value is in bold if it represents a clear peak, with monotonically decreasing accuracies to both the left and right of that value. The synthetic data used the default settings. The real data sets used the default number of attributes and lp=10%.

estimated distributions. In both cases, however, extending *ld* to even more extreme values (e.g., *ld*=0.95) does confirm the overall trend of the amount of cautious gain decreasing at high *ld*.

As expected, we found that these performance differences disappeared when many known labels were provided. In particular, at high link density and lp=50%, there were only small differences between ICA_C, ICA_{Kn}, and *ICA*, or between $wvRN_{RL}$, $wvRN_{ICA+C}$, and $wvRN_{ICA+NC}$. In addition, when PLUL was used, even *LBP* and LBP_{NC} performed on par with ICA_C and *Gibbs* when lp=50%, despite the challenges of *LBP* with high *ld*.

Overall, our results suggest that a more appropriate rendering of H3 should indicate that *the relative gain from caution will peak at some moderate value of* ld, with the precise value depending on the CC algorithm and the other data conditions. We leave confirmation of this revised hypothesis to future work.

7.6 Result 4: The Relative Gain of Cautious Inference Increases as the Labeled Proportion (*lp*) Decreases

Table 8 reports that, as *lp* varies, the regression analyses found all significant negative slopes (as expected) for the synthetic data. Likewise, in almost all cases we found significant negative slopes

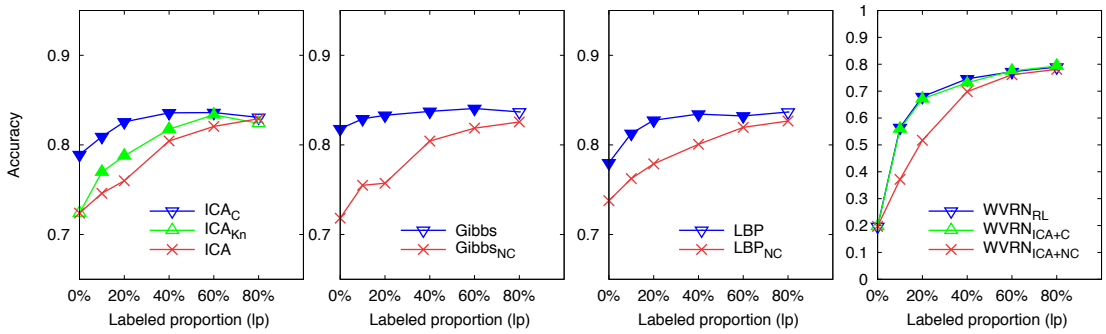

Figure 13: Results for the synthetic data as the labeled proportion (*lp*) varies.

for the real data sets with substantial autocorrelation (all except Terror and WebKB). We accept H4, because the pooled analyses find all negative, significant slopes.

For the real data, the exceptions to H4's stated trend were primarily WebKB+co, which had very erratic performance with all the algorithms, and WebKB, where none of the slopes attained statistical significance. In addition, *LBP* had highly variable behavior so that only for Citeseer did the slope approach statistical significance ($p = .053$, just over the threshold).

Figure 13, for the synthetic data, shows the performance of the cautious and non-cautious algorithms converging as *lp* increases. The cautious algorithms maintain a significant advantage until *lp*=80%. Observe that ICA_{Kn}'s curve lies between that of the more cautious ICA_C and the non-cautious *ICA*, while $wvRN_{RL}$ and $wvRN_{ICA+C}$ obtain the same results with their two different approaches to caution.

Figure 14 shows results for the real data sets as *lp* is varied. This figure show results only for *wvRN*, since results were previously presented for the other algorithms for varying numbers of attributes, and the *lp* graphs don't add additional insight for those algorithms.

The results in Figure 14 mirror those of the synthetic data, with a few exceptions. First, $wvRN_{ICA+C}$ does poorly on Terror, perhaps because of the low autocorrelation. Second, with WebKB+co, $wvRN_{ICA+C}$ outperforms $wvRN_{RL}$ when *lp* is low, though the gains are not quite significant; this effect was discussed in Section 7.5. Finally, the accuracy of *wvRN* for WebKB goes *down* with increasing *lp*. WebKB with just direct links has some autocorrelation but very low label consistency (see Table 5), because each node tends to link in certain patterns to nodes with a *different* label from itself (cf., Macskassy and Provost, 2007). Algorithms based on *wvRN* assume homophily, not such more complex forms of autocorrelation. Consequently, increasing *lp* only serves to reduce accuracy below the majority class baseline. Running *wvRN* with only co-citation links, as done for WebKB+co, works much better.

7.7 Result 5: The Relative Gain of Cautious Learning With PLUL Increases as the Labeled Proportion (*lp*) Decreases

The previous results compared cautious vs. non-cautious variants of a particular CC algorithm, in all cases using PLUL. We now justify the use of PLUL and examine its impact.

The bottom of Table 8 shows the regression slope results for H5, where the x-axis varies the labeled proportion (*lp*), and each table row compares a single CC algorithmic variant when using PLUL vs. not using PLUL. As expected, the slope analysis found all significant negative slopes for

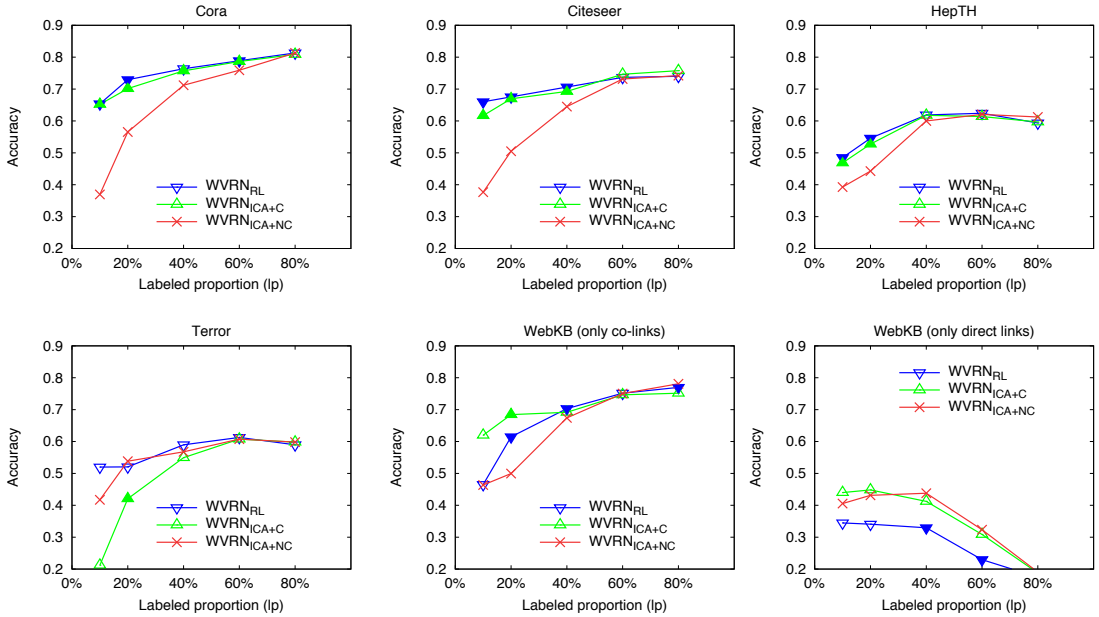

Figure 14: Results for variants of *wvRN* on the real data sets, as *lp* is varied. For the first WebKB results, *wvRN* uses *only* co-citation links (unlike previous results with other algorithms, where WebKB+co used direct links and co-links together; see Section 6.6.3). Recall that filled triangles indicate statistical significance, but only for comparing the cautious variant (here, $wvRN_{RL}$ or $wvRN_{ICA+C}$) vs. the non-cautious variant ($wvRN_{ICA+NC}$).

the synthetic data (with one exception where the p-value was close to the threshold), although the magnitude of the slopes suggests a weak trend. For the real data sets, while 18 of the 29 possible slopes were in the expected direction, only 4 of these slopes were statistically significant (recall that the real data sets have available only 3-5 trials, making significance harder to achieve). However, pooling the results across the data sets and algorithms yields a significant negative slope for both the synthetic and real data, so we accept H5.

Thus, while the effect (as *lp* varies) is smaller than with previous hypotheses, H5 indicates the PLUL provides the most gain when *lp* is small. To measure the magnitude of this gain, Table 10 shows the impact of PLUL when *lp*=0%. Each row shows the results for a different collective algorithm. Results are given for each algorithm both with and without PLUL, along with the overall gain from PLUL. Because PLUL interacts closely with the local classifier, we show results here for NB, LR, and kNN for the CC algorithms that use a local classifier. *CO* and *wvRN* are unaffected by PLUL, and thus are not shown.

In general, we found that PLUL improved performance, sometimes substantially, but the data regions where such substantial gains occur vary by classifier and/or CC algorithm. For instance, Column A of Table 10 shows results for the default synthetic data settings. Here, PLUL improves performance for almost all algorithms. In particular, the gains range from -0.3% to 10.8%, with an average of 4.0%, and are significant in 9 of the 14 cases. Column B shows results where the attribute predictiveness is 0.3 (instead of the default 0.6). In this case, the gains due to PLUL are almost

Table 10: Impact of PLUL on accuracy with the synthetic data, for CC algorithms where PLUL applies, at lp=0%. Gains in bold are statisticaly significant.

all larger, ranging from 0.7% to 27.8% (average of 8.6%), and are significant in 11 of 14 cases. These results are consistent with H2: when attributes are less predictive of the class label, cautious techniques, including PLUL, become more important. Finally, column C shows results where the link density is now 0.7 (instead of the default 0.2); here the gains due to PLUL are more varied. For ICA_C, PLUL remains important and matters even more than with the default data settings. We conjecture that this is because with so many links, relational influence can spread very quickly in the graph, and thus the PLUL process is very important to ensuring that ICA_C's confidence measure selects the most reliable predictions during the first few iterations. Indeed, when lp is instead set to 10% (thus providing more certain estimates for the early iterations), PLUL became much less important for ICA_C. *LBP* has known issues with high link density, but PLUL helps substantially to ameliorate them. For the other algorithms, the increased link density leads to PLUL having a minor impact, consistent with H3.

Table 11 shows similar results for the real data sets, where results for all six data sets have been pooled together. Since we cannot directly vary link density, we instead show results with two conditions. On the left is the "fewer attributes" case; here each data set uses its default number of attributes, as explained in Section 6.9. On the right is the case where each data set uses 100 attributes.

Compared to results with the synthetic data, Table 11 shows less evidence for the effectiveness of PLUL with the real data sets. While all algorithms show a gain from using PLUL, only about half of the gains are statistically significant. To explain, consider that PLUL works best when the

	Fewer attributes(default)			More attributes(100)

LBP_{NC}	46.0	42.1	3.9	63.5	56.4	**7.1**

Table 11: Accuracy results showing the impact of using PLUL with the real data. Each value shows results pooled over the six real data sets, at lp=0%, using NB where applicable. Gains in bold are statistically significant.

holdout set used for learning is most similar to the test set. With the synthetic data, such similarity is likely, because the two graphs are generated from the same distribution. However, with the real data, splitting an arbitrary graph into multiple subgraphs, even while seeking to maintain similar class distributions, may nonetheless produce subgraphs with important differences (e.g., in auto-correlation), leading to sub-optimal parameter choices by PLUL. Future work is needed to explore these issues.

Nonetheless, the evidence suggests that in most cases for the real and synthetic data PLUL improves performance. Moreover, for every algorithm there was some type of data for which not using PLUL led to very poor performance. Thus, applying PLUL in all of our other experiments seemed advisable for maximizing performance and for ensuring the most equitable comparisons.

7.8 Choice of Relational Feature Types

Section 6.6 described how each trial selected a type of relational feature to use. For completeness, Table 12 summarizes how often each type of feature was chosen. In general, the best feature type (as chosen by cross-validation) varied based on the local classifier used and the data conditions. However, Table 12 shows that for NB, multiset features were dominant, especially for the more cautious algorithms (chosen 76-96% of the time for ICA_C and *Gibbs*). With kNN, proportion features were dominant, while with LR count features were chosen most often but proportion features were also fairly common, especially with high ld. These results suggest that an analyst should most likely use multiset with NB, use proportion with kNN, and consider the data conditions to select a feature type for LR.

The superiority of multiset features, when they were applicable, is interesting because they are "cautious" features that simply ignore nodes with no known or predicted label (see Section 6.6.1). Likewise, Section 6.5 reported that LR with ICA_C performed best when missing feature values were ignored (by using a separate classifier trained without the missing features). These results are consistent with Saar-Tsechansky and Provost (2007), who found (for non-relational data) this "reduced-feature model" approach to be superior to commonly used approaches based on imputation. For a non-relational setting, their results thus demonstrate the superiority of a more "cautious" approach to handling missing values during testing. For relational domains, we could imagine taking this idea of ignoring missing/estimated values even further, e.g., using a classifier that ignored

Table 12: The relational feature type (multiset, count, or proportion) chosen by cross-validation. For the synthetic data, results are shown with the default settings, with low attribute predictiveness (*ap*=0.3), and with high link density (*ld*=0.7). For the real data, results are shown averaged across all the data points shown in Figures 10 and 11.

the estimated label of a linked node but instead directly used its non-relational features. However, Jensen et al. (2004) demonstrated that such an approach is generally inferior to the approaches we consider in this article (label-based features with collective inference), because of the much larger number of model parameters that must be learned for the former case.

7.9 Variants of *wvRN*

Most prior research involving *wvRN* has used $wvRN_{RL}$, the variant suggested as a relational-only baseline by Macskassy and Provost (2007). However, algorithms based on *wvRN* need not necessarily be relational-only. For instance, Macskassy (2007) described a technique for adding additional links to the graph between nodes that appeared similar based on their attributes. Alternatively, we could imagine, for $wvRN_{RL}$, initializing each node's predicted label probabilities based upon the output of an attribute-only local classifier (instead of using class priors as done in Figure 5). Unfortunately, this idea does not work well for a "soft" algorithm such as $wvRN_{RL}$, because after iterating many times the current state is almost completely determined by the known labels, independent

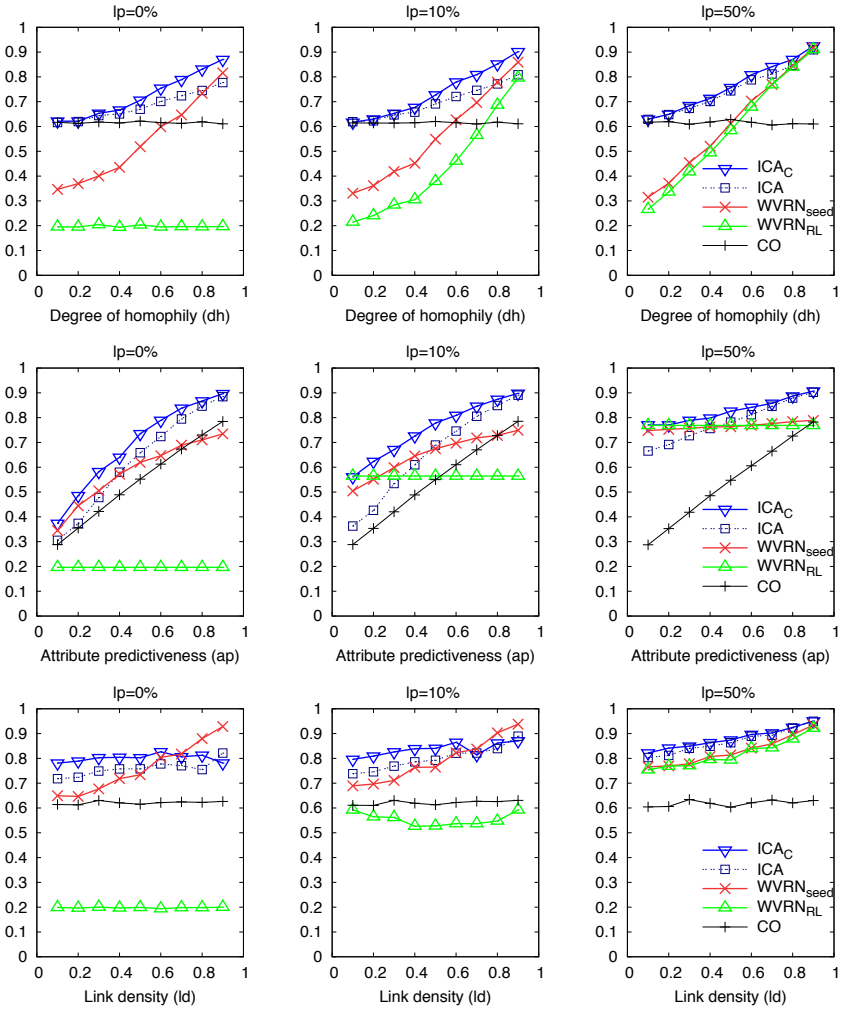

Figure 15: Results for the synthetic data where $wvRN_{seed}$ is added for comparison. Because of the multiple possible comparisons, filled triangles are not used here to indicate statistical significance.

of the starting state (Macskassy and Provost, 2005). While in principle this problem could be addressed via learning an appropriate decay parameter Γ and stopping point, this forfeits much of the simplicity of *wvRN*.

In contrast to $wvRN_{RL}$, with a hard-labeling algorithm such as $wvRN_{ICA+C}$, the initial conditions do matter. In particular, we evaluated $wvRN_{seed}$, an algorithm that behaves just like $wvRN_{ICA+C}$, except that each node's predicted label is initialized to the most likely label predicted by an attribute-only NB classifier. Non-relational information thus "seeds" the inference process but is then not explicitly used again. To the best of our knowledge, this algorithm has not been previously considered for CC.

Figure 15 shows a variety of results for the synthetic data; results with the real data showed similar trends. Overall, $wvRN_{seed}$ outperforms $wvRN_{RL}$ (especially when *lp* is low), which is to be expected since $wvRN_{seed}$ uses more information. $wvRN_{seed}$ generally underperforms ICA_C, which

is also to be expected since ICA_C both uses predicted labels cautiously (while $wvRN_{seed}$ treats all predictions equally) and continues to use both attribute and relational information after the first iteration. The differences with ICA_C are largest when *dh* is low (where *wvRN*'s homophily assumption is violated) or when attribute predictiveness is high (since $wvRN_{seed}$ uses the attributes only at initialization). However, $wvRN_{seed}$ outperforms all of the other shown algorithms when link density is high. This case is analogous to the results with ICA_{Kn} from Section 7.5: if accuracy and link density are high (and homophily is present), then caution with relational information may not be necessary, and this case shows that continuing to use non-relational information after initialization may also not be necessary. Overall, the results indicate that $wvRN_{seed}$ is not likely to be a strong contender as a general purpose CC algorithm, but they do demonstrate an effective way to add non-relational information to *wvRN*-based algorithms.

7.10 Impact of the Default Values for Synthetic Data Generation

The synthetic data evaluated above was generated with the default parameters described in Table 4. Conceivably, our choice of default values could have an important effect on the results. While our evaluation of multiple real data sets has already helped to validate the synthetic data results, we also carried out an extensive exploration with other default values. For instance, when varying *ld*, we experimented with all combinations of *ap*= $\{0.4, 0.6, 0.8\}$, *dh*= $\{0.5, 0.7, 0.9\}$, and *lp*=$\{0\%, 10\%, 50\%\}$. For tractability, we only evaluated variants of *ICA*, since the above results show that ICA_C produced the best or nearly the best results for all synthetic and real data sets, and that other cautious algorithms usually behaved like ICA_C.

The trends were highly consistent with the results we report and agree with our accepted hypotheses. For instance, if the default *ap* is very high, the results for varying *dh* showed a much smaller slope for the relative impact of cautious ICA_C vs *ICA*. The only default value that noticeably changed any result was already reported in Section 7.5: when *ap* was small (e.g., 0.4), the unusual advantage of *ICA* over ICA_C observed at very high *ld* disappeared. Thus, we believe the trends in our results are robust over a wide range of data characteristics.

8. Discussion

In this section we compare results with different families of algorithms, examine the overall effectiveness of caution, and use our results to explain the findings of some previous research.

8.1 Comparisons Across Algorithmic Families

Section 7 focused on comparing cautious vs. non-cautious variants within the same algorithmic family. We now briefly compare across these families. We focus on the algorithms that have been most frequently used in previous work: *ICA*, *Gibbs*, *LBP*, and $wvRN_{RL}$. We also include the less studied ICA_C, since our results show that it has very strong performance. We report specific results for *lp*=10%; comparisons were similar for *lp*=0%, while all of the algorithms perform very similarly when *lp*=50%.

$wvRN_{RL}$'s performance depends on homophily, link density, and *lp*. In our study, $wvRN_{RL}$ was thus competitive with the other CC algorithms when homophily and/or *lp* was high, or when the attributes were not very predictive. On the other hand, $wvRN_{RL}$ requires that some labels are known

in the test set, so it is not applicable when *lp*=0% (the out-of-sample task). $wvRN_{seed}$ would be an alternative.

For the synthetic data, the cautious algorithms ICA_C, *Gibbs*, and *LBP* had remarkably similar performance. Among the three, *Gibbs* had a small but sometimes significant performance advantage. For instance, across the results for varying *dh* at *lp*=10% shown in Figure 8, *Gibbs* outperformed ICA_C by an average of 1.0% (significantly for $dh \geq 0.6$) and *LBP* by an average of 0.7% (significantly for $0.4 \leq dh \leq 0.7$). Neither ICA_C nor *LBP* had consistent, significant gains over the other, except that both *Gibbs* and ICA_C had substantial, significant gains over *LBP* when attribute strength was very low (gains of 5-8%) or when link density was high (gains of 14-25%). However, all three algorithms did have substantial, significant gains vs. *ICA*, except for when *dh* was very low or when *ld* was very high. For instance, across the various *dh* levels, *Gibbs* outperformed *ICA* by 0.9-11.2% (all significantly) except for a loss of 0.1% at *dh*=0.1. Thus, based on the synthetic data results, ICA_C, *Gibbs*, and *LBP* usually achieve similar accuracies, despite their use of very different approaches to caution.

On the real data sets, ICA_C, *Gibbs*, and *LBP* likewise performed similarly. However, there are two kinds of differences that should be noted. First, there were a few data sets on which *LBP* and/or *Gibbs* performed noticeably worse than ICA_C. In particular, *Gibbs* has poor performance on HepTH and WebKB+co. In both cases, this is likely due to issues of high link density (WebKB has very many co-citation links; HepTH has fewer links but some nodes have very high degree). High link density can lead to extreme probabilities, where *Gibbs* is known to perform poorly. While this was not a particular problem with the synthetic data (perhaps because the training and test graphs were more similar), NB is well known for producing polarized probabilities in some cases. PLUL does help, for instance, improving performance on HepTH and WebKB+co by an average of 4% and 15%, respectively, in Figures 10 and 11. Nonetheless, performance with *Gibbs* lags that of ICA_C or *ICA*, which are not so influenced by extreme probabilities. We experimented with more and/or longer *Gibbs* chains but this did not improve performance. However, this is one case where the LR classifier performed better than NB: it appears to produce less polarized probabilities than NB, leading to improved performance with *Gibbs* (see Figures 24 and 27 in the online appendix). Similarly, *LBP*, which struggles with high link density, also has problems with HepTH (and likely would have low performance with WebKB+co, had it ever converged) and with Cora. Its difficulty with Cora is surprising and possibly indicates that the conjugate gradient training did not perform adequately, despite our attempts (cf., Sen et al., 2008). However, *LBP* did perform well on Citeseer, which has similar characteristics.

Second, in contrast to the small advantage for *Gibbs* on the synthetic data, for the real data ICA_C holds a small advantage. For instance, in Figure 10, ICA_C outperforms *Gibbs* on average by 1% for Cora and 2.4% for Citeseer, though not significantly. For HepTH and WebKB+co, where *Gibbs* had trouble, the gains averaged 5.4% and 21.0%, respectively, and were significant for HepTH when the number of attributes was small. ICA_C was also robust: it was the only algorithm to outperform *ICA* on average for every real data set considered. Moreover, using results pooled over all six data sets, ICA_C had moderate gains vs. *ICA*, *Gibbs*, *LBP*, and $wvRN_{RL}$, both at the default number of attributes (where the gains were significant) and using 100 attributes for each data set. Comparing to just *Gibbs* and *LBP*, ICA_C had a pooled gain of 4.9% and 7.8%, respectively, with the default number of attributes, and 1.8% and 4.5%, respectively, with 100 attributes.

8.2 Cautious Behavior as a Predictor of Performance

The previous section identified some of the situations in which the algorithms performed similarly or differently. However, if we exclude the extreme data conditions such as very low attribute predictiveness or high link density, a more remarkable finding emerges: *the amount of cautious inference used by an algorithm strongly predicts its relative performance*. This finding is especially interesting because the precise type of cautious inference seems to matter little. On both the synthetic and the real data sets, in most cases ICA_C, *Gibbs*, and *LBP* perform alike, while the non-cautious *ICA*, $Gibbs_{NC}$, and LBP_{NC} also perform similarly to each other (and at lower accuracy levels than the cautious algorithms). However, when many test labels are known (high *lp*), the need for caution decreases, and the differences between these two groups greatly diminish.

This effect can also be seen in other CC variants. For instance, $wvRN_{RL}$ and $wvRN_{ICA+C}$ perform similarly, despite their very different approaches to caution, and they both outperform the non-cautious $wvRN_{ICA+NC}$. Likewise, in almost every case the somewhat-cautious ICA_{Kn} attained an accuracy between that of the more cautions ICA_C and the non-cautious *ICA*.

Thus, the amount of cautious inference seems to be the biggest factor differentiating those algorithms that use attributes, much more so than whether some kind of *ICA* or *Gibbs* or *LBP* is used. Likewise, when attributes are not used, as with the variants of *wvRN*, caution also appears to be the largest factor in predicting relative performance.

8.3 Limitations of Cautious Inference

While our results show that the cautious use of relational information can significantly boost performance, adding more caution to an algorithm is not always beneficial. In particular, the most extreme form of relational caution is to not use any relational information (i.e., *CO*), but that is seldom optimal. Instead, an algorithm must seek to cautiously avoid errors from noisy predictions while still leveraging informative relations.

To illustrate these effects, Figure 16 shows accuracy results for three synthetic data conditions: low attribute predictiveness (*ap*=0.3), the default settings, and high link density (*ld*=0.9). Here the x-axis indicates the algorithm used, with the amount of relational caution used increasing to the right. We focus on variants of *ICA*, but add three new algorithms for further analysis. ICA_{70} is just like ICA_C, except that it stops after it has "committed" and used the most certain 70% of the predicted labels (i.e., after the iteration when $h = 7$ in Figure 2). ICA_{30} and ICA_0 likewise stop after accepting and using 30% and 0% of the predicted labels, respectively. Note that ICA_0 is identical to ICA_{Kn} during the very first iteration (when both use only the "known" labels for relational features), but that ICA_0 stops after that iteration, while ICA_{Kn} continues for 10 more iterations, using all available predictions during those iterations.

For the default and low attribute predictiveness data conditions, the trends are very similar: amongst *ICA*, ICA_{Kn}, and ICA_C, the most cautious ICA_C performs best. Adding more caution to ICA_C, however, consistently decreases performance, as ICA_{70}, ICA_{30}, and ICA_0 use less and less relational information, until the lowest performance is found with the non-relational *CO*. These results make sense: for this data, relational links *are* informative, so completely ignoring any (or all) of them is non-optimal. Indeed, using all of them without any caution (*ICA*) is much better than cautiously ignoring all relations (*CO*), but the cautious algorithm that eventually uses all relations (ICA_C) performs best. Note that this property of (eventually) using all available relational informa-

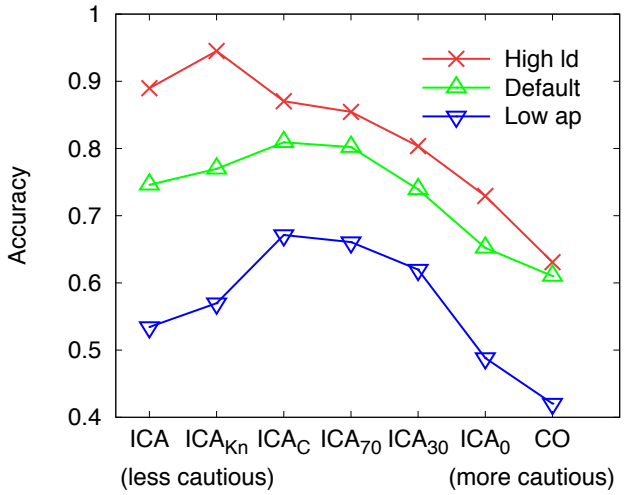

Figure 16: Accuracy as a function of the amount of relational caution used. ICA_{70}, ICA_{30}, and ICA_0 are (even more cautious) variants of ICA_C that stop iterating before some of the less certain relational information has been used.

tion is true of all of the more cautious algorithms that we considered in this article (ICA_C, *Gibbs*, *LBP*, $wvRN_{RL}$, and $wvRN_{ICA+C}$).

The high link density case provides an interesting contrast. Here the general shape of the curve is similar, but the peak performance is observed with ICA_{Kn}, not with the more cautious ICA_C. This effect was already discussed in Section 7.5: if the baseline accuracy is high and there are many links, simply using all available information after the first iteration is best. Similarly, for situations where caution is not very important (e.g., when *lp* is high), the curve would show similar results for *ICA*, ICA_{Kn}, and ICA_C. Thus, in most cases being cautious with relational information is best, but the algorithm should eventually use all available information (relational and non-relational), and in some cases using more caution may be less important or even harmful.

8.4 Explanation of Prior Results

Our investigation enables us to explain the questions from Section 1, among others:

1. **Why did Sen et al. (2008) find no consistent difference between *Gibbs* and *ICA*?** In contrast, *Gibbs* had worked well in other work, and in this article we found that *Gibbs* (and ICA_C) often significantly increases accuracy vs. *ICA*. However, our results and careful study of Sen et al.'s methodology explains the discrepancy: to generate the test set, they used a snowball sampling method that we found produces an effective labeled proportion (*lp*) of at least 0.5—a region where the use of caution has little impact. Also, their study did not vary attribute predictiveness, which we show is a significant factor in the relative performance of more cautious CC algorithms.

2. **Why did McDowell et al. (2007a) find that ICA_C significantly outperforms *Gibbs*, even though attribute predictiveness was high, while here we find that *Gibbs* performs on**

par or better than ICA_C in such cases? To investigate, we re-ran our experiments from our earlier paper, but with two variations informed by our now-refined understanding of CC. First, we used PLUL with both the NB and kNN classifiers. Second, we changed the NB classifier to use multiset relational features (instead of proportion), which use more information and which Section 7.8 shows is the feature of choice when using NB (it didn't apply for kNN). With these enhancements, *Gibbs*'s relative performance improved, so that ICA_C and *Gibbs* both significantly outperformed *ICA*, but the results for *Gibbs* and ICA_C did not significantly differ. Thus, more careful learning and representation choices resolves the discrepancy. This also suggests that not using PLUL could potentially have an important effect on performance comparisons. As an additional example, Sen and Getoor (2006) experimented with a wide range of link densities but did not use a technique like PLUL; our results suggest that using PLUL could have significantly improved their results with *LBP* for high *ld*.

3. **Why did Galstyan and Cohen (2007) find that a soft-labeling version of *wvRN* fails to consistently outperform a hard "label propagation" (LP) version?** Most authors have expected that, for relational-only classification, the soft-labeling algorithm that directly reasons with probabilities (thus exercising cautious inference) should outperform a hard-labeling version that only reasons with the single most likely label for each linked node. However, closer examination of their LP algorithm reveals that it includes elements of caution. In particular, after each iteration, LP labels a non-known node only if the estimated score for that node is among the *highest* of any such nodes. Thus, in a way similar to $wvRN_{ICA+C}$, nodes that are closest to known nodes are labeled first, and the algorithm effectively favors label information that was either known or is closer to other known nodes. This cautious behavior enables LP to be competitive with (and sometimes outperform) the soft-labeling algorithm.

4. **Why did Sen et al. (2008) find that *ICA* and *Gibbs* perform better with LR than with NB, while we find the reverse?** We replicated the synthetic data of their paper, and reproduced their results. A key point, however, is that Sen et al. used count relational features for both NB and LR, while we used cross-validation on a holdout set to select the best relational feature type (see Section 6.6). This procedure predominantly selected multiset features for NB (see Section 7.8), which we found in separate experiments to consistently improve NB performance compared to using count features. Consequently, in our results CC algorithms that use NB almost always outperformed those that use LR. While not a focus of our work, such differences can be seen in Table 10. The superior performance of multiset features also confirms the finding of Neville et al. (2003b).

5. **When will cautious algorithms outperform their aggressive variants?** We found that using more cautious CC frequently and sometimes dramatically increased accuracy. In general, cautious CC performs comparatively well whenever relational inference errors are more likely. These errors occur more frequently when there is more uncertainty in the estimated relational feature values (e.g., when the attribute predictiveness is low) or when the effect of any such uncertainty is magnified (e.g., when autocorrelation is high). In some cases, such as when the test set links to many known labels (high *lp*), using a more cautious CC algorithm may be unnecessary. However, in many cases (and with most previous work) *lp* is small or zero, and thus caution may be important.

9. Conclusion

Collective classification's greatest strength—making inferences based on the inferred labels of related nodes—can also be a significant weakness, since this use of uncertain labels may reduce accuracy when the estimates are incorrect. In this article, we demonstrated that managing this estimation uncertainty through "cautious" algorithmic behavior is essential to achieving maximal, robust performance. We showed how varying degrees of cautious inference could be manifested in four different collective inference families, and explained how to use cautious learning with PLUL to further improve performance. Our experimental results with both synthetic and real-world data sets showed that cautious algorithms did outperform their non-cautious variants. By exploring a wide range of data, we identified some data characteristics for which this performance advantage grew larger. In particular, cautious behavior is especially important when there is a higher probability of incorrect relational inference—which occurs when autocorrelation is higher, when link density is moderate, and/or when attribute predictiveness or the labeled proportion is lower. In addition, our study enabled us to answer several important questions from previous work.

Across a wide range of data, we found that an algorithm's degree of caution was a significant predictor of relative performance—in most cases a more important one than the specific collective inference algorithm used. This reinforces the fundamental importance of cautious behavior for CC. However, the cautious CC algorithms were not always comparable. *Gibbs* and (especially) *LBP* sometimes struggled (e.g., when the data had high link density). In contrast, ICA_C was a very reliable performer and almost always had maximal or near-maximal performance, especially for the real-world data. This finding is interesting because this article is the first to consider ICA_C in depth. Moreover, ICA_C is a simple modification to *ICA*, making it much more time-efficient than *Gibbs* or *LBP*. This suggests that ICA_C is a strong contender for general CC tasks, and should be used as a baseline for future CC performance comparisons.

Regarding cautious learning, we found that PLUL generally increased accuracy, sometimes substantially. Parameter tuning is known to be important for learning non-relational classifiers. We show that it can be especially critical for CC due to CC's reliance on uncertain labels during testing. For example, further results showed that for the synthetic data when link density was high, *Gibbs*+NB with a naive α (prior hyperparameter) of 1.0 attained 99% of the accuracy attainable with any α—*if* most test labels were known (e.g., *lp*=80%). However, when *lp*=0% this strategy's accuracy was just 61% of optimal. Using PLUL to set α instead increased accuracy. In addition, our results in Section 7.7 showed PLUL helping both cautious and non-cautious inference algorithms. Thus, using PLUL for cautious learning improves performance, and adding cautious inference helps even more.

Future work is needed to compare the algorithms considered here with alternative methods, such as Markov Logic Networks (Richardson and Domingos, 2006) and the "ghost edge" approach of Gallagher et al. (2008), and to compare PLUL to the alternative "stacked models" discussed in Section 5.5. In addition, further studies to consider the effect of training set size, noise in the known labels, and link uncertainty would be useful. Finally, techniques are needed to further improve the performance of cautious inference on data with high link density or other extreme conditions.

Acknowledgments

Thanks to Doug Downey, Lise Getoor, David Jensen, and Sofus Macskassy for helpful comments on this work, to Prithviraj Sen for the Cora and Citeseer data sets, to Jennifer Neville for helpful discussions and for code that implements LBP, and to Prithviraj Sen and Mustafa Bilgic for clarifications on their work. Thanks also to the anonymous reviewers for many helpful comments that helped to improve this article. Luke McDowell's funding for this research was partly supported by the U.S. Naval Academy Cooperative Program for Scientific Interchange, which is a component of NRL's General Laboratory Scientific Interchange Program. Portions of this analysis were conducted using Proximity, an open-source software environment developed by the Knowledge Discovery Laboratory at the University of Massachusetts Amherst (http://kdl.cs.umass.edu/proximity/). The HepTH data was derived from the Proximity HEP-Th database, which is based on data from the arXiv archive and the Stanford Linear Accelerator Center SPIRES-HEP database provided for the 2003 KDD Cup competition, with additional preparation performed by the Knowledge Discovery Lab.

Appendix A. Measuring the Strength of Relational Dependence

Data sets used for CC are often measured for their autocorrelation. Alternatively, *label consistency* is the percentage of links connecting nodes with the same label. A closely related measure is the *degree of homophily* (*dh*) used by Sen et al. (2008). To see the difference, suppose that a data set has five labels that occur with equal frequency. Sen et al. argue that, if *dh* is zero, the target of a link from a node labeled *A* should be to another node labeled *A* 20% of the time (random chance), not 0% of the time (Sen, 2008). Thus, for a uniform class distribution, the actual probability of a link connecting two nodes i and j of the same label is defined as:

$$\text{label consistency} = P(y_i = y_j | (i,j) \in E) = dh + \frac{1-dh}{|C|}. \tag{4}$$

To facilitate comparison, we adopt this definition to generate synthetic data with varying levels of *dh*. However, for real data sets, we can only directly compute label consistency. Thus, to facilitate comparison we also compute *approximate homophily* from the measured label consistency by assuming a uniform distribution of labels and solving for *dh* using Equation 4.

Appendix B. Information on Additional Results

In Section 7, we omitted some results for alternate local classifiers (LR and kNN) and/or alternate settings of *lp*, since they did not noticeably change our reported trends. These results are available in an online appendix that accompanies this article on the JMLR website.

Abstract

In the context of multiple hypothesis testing, the proportion π_0 of true null hypotheses in the pool of hypotheses to test often plays a crucial role, although it is generally unknown *a priori*. A testing procedure using an implicit or explicit estimate of this quantity in order to improve its efficency is called *adaptive*. In this paper, we focus on the issue of false discovery rate (FDR) control and we present new adaptive multiple testing procedures with control of the FDR. In a first part, assuming independence of the *p*-values, we present two new procedures and give a unified review of other existing adaptive procedures that have provably controlled FDR. We report extensive simulation results comparing these procedures and testing their robustness when the independence assumption is violated. The new proposed procedures appear competitive with existing ones. The overall best, though, is reported to be Storey's estimator, albeit for a specific parameter setting that does not appear to have been considered before. In a second part, we propose adaptive versions of step-up procedures that have provably controlled FDR under positive dependence and unspecified dependence of the *p*-values, respectively. In the latter case, while simulations only show an improvement over non-adaptive procedures in limited situations, these are to our knowledge among the first theoretically founded adaptive multiple testing procedures that control the FDR when the *p*-values are not independent.

Keywords: multiple testing, false discovery rate, adaptive procedure, positive regression dependence, *p*-values

1. Introduction

The topic of multiple testing, which enjoys a long history in the statistics literature, has generated a renewed, growing attention in the recent years, spurred by an increasing number of application fields, in particular bioinformatics. For example, when processing microarray data, a common goal is to detect which genes (among several ten of thousands) exhibit a significantly different level of expression in two different experimental conditions. Each gene represents a "hypothesis" to be tested in the statistical sense. The genes' expression levels fluctuate naturally (not to speak of other sources of fluctuation introduced by the experimental protocol), and, because the number of candidate genes is large, it is important to control precisely what can be deemed a significant

observed difference. Generally, it is assumed that the natural fluctuation distribution of a *single* gene is known and the problem is to take into account the number of genes involved (for more details, see for instance Dudoit et al., 2003).

1.1 Adaptive Multiple Testing Procedures

In this work, we focus on building multiple testing procedures with a control of the false discovery rate (FDR). This quantity is defined as the expected proportion of type I errors, that is, the proportion of true null hypotheses among all the null hypotheses that have been rejected (i.e., declared as false) by the procedure. In their seminal work on this topic, Benjamini and Hochberg (1995) proposed the celebrated *linear step-up* (LSU) procedure, which was proved to control the FDR under the assumption of independence between the p-values. Later, it was proved (Benjamini and Yekutieli, 2001) that the LSU procedure still controls the FDR when the p-values have positive dependence (or more precisely, a specific form of positive dependence called positive regression dependence from a subset, PRDS). Under completely unspecified dependence, the same authors have shown that the FDR control still holds if the threshold collection of the LSU procedure is divided by a factor $1+1/2+\cdots+1/m$, where m is the total number of null hypotheses to test. More recently, the latter result has been generalized (Blanchard and Fleuret, 2007; Blanchard and Roquain, 2008; Sarkar, 2008a,b), by showing that there is in fact a family of step-up procedures (depending on the choice of a kind of prior distribution) that control the FDR under unspecified dependence between the p-values.

However, all of these procedures, which are built in order to control the FDR at a level α, can be shown to have actually their FDR upper bounded by $\pi_0\alpha$, where π_0 is the proportion of true null hypotheses in the initial pool. Therefore, when most of the hypotheses are false (i.e., π_0 is small), these procedures are inevitably conservative, since their FDR is in actuality much lower than the fixed target α. In this context, the challenge of *adaptive control* of the FDR (e.g., Benjamini and Hochberg, 2000; Black, 2004) is to integrate an estimation of the unknown proportion π_0 in the threshold of the previous procedures and to prove that the corresponding FDR is still rigorously controlled by α.

Of course, adaptive procedures are of practical interest if it is expected that π_0 is, or can be, significantly smaller than 1. An example of such a situation occurs when using hierarchical procedures (e.g., Benjamini and Heller, 2007) which first selects some clusters of hypotheses that are likely to contain false nulls, and then apply a multiple testing procedure on the selected hypotheses. Since a large part of the true null hypotheses is expected to be false in the second step, an adaptive procedure is needed in order to keep the FDR close to the target level.

A number of adaptive procedures have been proposed in the recent literature and can loosely be divided into the following categories:

- *plug-in* procedures, where some initial estimator of π_0 is directly plugged in as a multiplicative level correction to the usual procedures. In some cases (e.g., Storey's estimator, see Storey, 2002), the resulting plug-in adaptive procedure (or a variation thereof) has been proved to control the FDR at the desired level (Benjamini et al., 2006; Storey et al., 2004). A variety of other estimators of π_0 have been proposed (e.g., Meinshausen and Rice, 2006; Jin and Cai, 2007; Jin, 2008); while their asymptotic consistency (as the number of hypotheses tends to infinity) is generally established, their use in plug-in adaptive procedures has not always been studied.

- *two-stage* procedures: in this approach, a first round of multiple hypothesis testing is performed using some fixed algorithm, then the results of this first round are used in order to tune the parameters of a second round in an adaptive way. This can generally be interpreted as using the output of the first stage to estimate π_0. Different procedures following this general approach have been proposed (Benjamini et al., 2006; Sarkar, 2008a; Farcomeni, 2007); more generally, multiple-stage procedures can be considered.

- *one-stage* procedures, which perform a single round of multiple testing (generally step-up or step-down), based on a particular (deterministic) threshold collection that renders it adaptive (Finner et al., 2009; Gavrilov et al., 2009).

In addition, some works (Genovese and Wasserman, 2004; Storey et al., 2004; Finner et al., 2009) have studied the question of adaptivity to the parameter π_0 from an *asymptotic* viewpoint. In this framework, the more specific *random effects* model is—most generally, though not always—considered, in which p-values are assumed independent, each hypothesis has a probability π_0 of being true, and all false null hypotheses share the same alternate distribution. The behavior of different procedures is then studied under the limit where the number of tested hypotheses grows to infinity. One advantage of this approach and specific model is that it allows to derive quite precise results (see Neuvial, 2008, for a precise study of limiting behaviors of central limit type under this model, including some of the new procedures introduced in the present paper). However, we emphasize that in the present work our focus is decidedly on the nonasymptotic side, using finite samples and arbitrary alternate hypotheses.

To complete this overview, let us also mention another interesting and different direction opened up recently, that of adaptivity to the alternate distribution. If the alternate distributions are known *a priori*, the optimal testing statistics are generally likelihood ratios between each null and each alternate, which (possibly after standardization under the form of p-values) can be combined using a multiple testing algorithm in order to control some measure of type I error while minimizing a measure of type II error (see, e.g., Spjøtvoll, 1972, Wasserman and Roeder, 2006, Genovese et al., 2006, Storey, 2007, Roquain and van de Wiel, 2009). In situations where the alternate is unknown, though, one can hope to estimate, implicitly or explicitly, the alternate distributions from the observed data, and consequently approximate the optimal test statistics and the associated multiple testing procedure (Sun and Cai, 2007 proposed an asymptotically consistent approach to this end). Interestingly, this point of view is also intimately linked to some traditional topics in statistical learning such as classification and of optimal novelty detection (see, e.g., Scott and Blanchard, 2009). However, in the present paper we will focus on adaptivity to the parameter π_0 only.

1.2 Overview of this Paper

The contributions of the present paper are the following. A first goal of the paper is to introduce a number of novel adaptive procedures:

1. We introduce a new *one-stage* step-up procedure that is more powerful than the standard LSU procedure in a large range of situations, and provably controls the FDR under independence (and in a nonasymptotic sense). This procedure is called one-stage adaptive, because the estimation of π_0 is performed implicitly.

2. Based on this, we then build a new *two-stage* adaptive procedure, which is more powerful in general than the procedure proposed by Benjamini et al. (2006), while provably controlling the FDR under independence.

3. Under the assumption of positive or arbitrary dependence of the p-values, we introduce new two-stage adaptive versions of known step-up procedures (namely, of the LSU under positive dependence, and of the family of procedures introduced by Blanchard and Fleuret, 2007, under unspecified dependence). These adaptive versions provably control the FDR and result in an improvement of power over the non-adaptive versions in some situations (namely, when the number of hypotheses rejected in the first stage is large, typically more than 60%).

A second goal of this work is to present a review of several existing adaptive step-up procedures with provable FDR control under independence. For this, we present the theoretical FDR control as a consequence of a single general theorem, which was first established by Benjamini et al. (2006). Here, we give a short self-contained proof of this result that is of independent interest. The latter is based on some tools introduced earlier (Blanchard and Roquain, 2008; Roquain, 2007), aimed at unifying FDR control proofs. Related results and tools also appear independently in Finner et al. (2009) and Sarkar (2008b).

A third goal is to compare both the existing and our new adaptive procedures in an extensive simulation study under both independence and dependence, following the simulation model and methodology used by Benjamini et al. (2006):

- Concerning the new one- and two- stage procedures with theoretical FDR control under independence, these are generally quite competitive in comparison to existing ones. However we also report that the best procedure overall (in terms of power, among procedures that are robust enough to the dependent case) appears to be the plug-in procedure based on the well-known Storey estimator (Storey, 2002) used with the somewhat nonstandard parameter setting $\lambda = \alpha$. This outcome was in part unexpected since to the best of our knowledge, this fact had never been pointed out so far (the usual default recommended choice is $\lambda = \frac{1}{2}$ and turns out to be very unstable in dependent situations); this is therefore an important conclusion of this paper regarding practical use of these procedures.

- Concerning the new two-stage procedures with theoretical FDR control under dependence, simulations show an (admittedly limited) improvement over their non-adaptive counterparts in favorable situations which correspond to what was expected from the theoretical study (i.e., large proportion of false hypotheses). The observed improvement is unfortunately not striking enough to be able to recommend using these procedures in practice.

The paper is organized as follows: in Section 2, we introduce the mathematical framework, and we recall the existing non-adaptive results for FDR control. In Section 3, we deal with the setup of independent p-values. We expose our new procedures and review the existing ones, and compare them theoretically and in a simulation study. The case of positive dependent and arbitrarily dependent p-values is examined in Section 4 where we introduce our new adaptive procedures in this context. A conclusion is given in Section 5. Section 6 and 7 contain proofs of the results and lemmas, respectively. Some technical remarks and discussions of links to other work are gathered at the end of each relevant subsection, and can be skipped by the non-specialist reader.

2. Preliminaries

In this paper, we stick to the traditional statistical framework for multiple testing, which we first briefly recall below.

2.1 Multiple Testing Framework

Let $(\mathcal{X}, \mathfrak{X}, \mathbb{P})$ be a probability space; we aim at inferring a decision on $\mathbb{P}$ from an observation x in $\mathcal{X}$ drawn from $\mathbb{P}$. Let $\mathcal{H}$ be a finite set of null hypotheses for $\mathbb{P}$, that is, each null hypothesis $h \in \mathcal{H}$ corresponds to some subset of distributions on $(\mathcal{X}, \mathfrak{X})$ and "$\mathbb{P}$ satisfies h" means that $\mathbb{P}$ belongs to this subset of distributions. The number of null hypotheses $|\mathcal{H}|$ is denoted by m, where $|.|$ is the cardinality function. The underlying probability $\mathbb{P}$ being fixed, we denote $\mathcal{H}_0 = \{h \in \mathcal{H} \mid \mathbb{P} \text{ satisfies } h\}$ the set of the true null hypotheses and $m_0 = |\mathcal{H}_0|$ the number of true null hypotheses. We let also $\pi_0 := m_0/m$ the proportion of true null hypotheses. We stress that $\mathcal{H}_0$, m_0, and π_0 are unknown and implicitly depend on the unknown $\mathbb{P}$. All the results to come are always implicitly meant to hold for any generating distribution $\mathbb{P}$.

We suppose further that there exists a set of *p-value* functions $\mathbf{p} = (p_h, h \in \mathcal{H})$, meaning that each $p_h : (\mathcal{X}, \mathfrak{X}) \mapsto [0,1]$ is a measurable function and that for each $h \in \mathcal{H}_0$, p_h is bounded stochastically by a uniform distribution, that is,

$$\forall h \in \mathcal{H}_0, \qquad \forall t \in [0,1],\ \mathbb{P}[p_h \leq t] \leq t. \tag{1}$$

Typically, each p-value is obtained from a statistic Z that has a known distribution P_0 under the corresponding null hypothesis. In this case, $p_h = \overline{\Phi}_0(Z)$ satisfies (1) in general, where $\overline{\Phi}_0(z) = P_0([z, +\infty))$. Here, we are however not concerned with how these p-values are precisely constructed and only assume that they exist and are known (this is the standard setting in multiple testing).

2.2 Multiple Testing Procedure and Errors

A *multiple testing procedure* is a function

$$R : x \in \mathcal{X} \mapsto R(x) \in \mathcal{P}(\mathcal{H}),$$

such that for any $h \in \mathcal{H}$, the function $x \mapsto \mathbf{1}\{h \in R(x)\}$ is measurable. It takes as input an observation x and returns a subset of $\mathcal{H}$, corresponding to the rejected hypotheses. As it is commonly the case, we will focus here on multiple testing procedure based on p-values, that is, we will implicitly assume that R is of the form $R(\mathbf{p})$.

A multiple testing procedure R can make two kinds of errors: a *type I error* occurs for h when h is true and is rejected by R, that is, $h \in \mathcal{H}_0 \cap R$. Conversely, *a type II error* occurs for h when h is false and is not rejected by R, that is $h \in \mathcal{H}_0^c \cap R^c$. Following the Neyman-Pearson general philosophy for hypothesis testing, the primary concern is to control the quantity of type I errors of a testing procedure. For this, the most traditional way is to upper bound the "Family-wise error rate" (FWER), which is the probability that one or more true null hypotheses are rejected. However, procedures with a controlled FWER are (by definition) very "cautious" not to make even a single error, and thus reject only few hypotheses. This conservative way of measuring the type I error for multiple hypothesis testing can be a serious hindrance in practice, since it requires to collect large enough data sets so that significant evidence can be found under this strict error control criterion.

More recently, a more liberal measure of type I errors has been introduced in multiple testing (Benjamini and Hochberg, 1995): the *false discovery rate* (FDR), which is the averaged proportion of true null hypotheses in the set of all the rejected hypotheses:

Definition 1 (False discovery rate) *The* false discovery rate *of a multiple testing procedure R for a generating distribution $\mathbb{P}$ is given by*

$$\mathrm{FDR}(R) := \mathbb{E}\left[\frac{|R \cap \mathcal{H}_0|}{|R|}\mathbf{1}\{|R| > 0\}\right]. \tag{2}$$

A classical aim, then, is to build procedures R with FDR upper bounded at a given, fixed level α. Of course, if we choose $R = \emptyset$, meaning that R rejects no hypotheses, trivially $\mathrm{FDR}(R) = 0 \leq \alpha$. Therefore, it is desirable to build procedures R satisfying $\mathrm{FDR}(R) \leq \alpha$ while at the same time having as few type II errors as possible. As a general rule, provided that $\mathrm{FDR}(R) \leq \alpha$, we want to build procedures that reject as many false hypotheses as possible. The absolute power of a multiple testing procedure is defined as the average proportion of false hypotheses correctly rejected, $\mathbb{E}\left[\left|R \cap \mathcal{H}_0^c\right|\right] / \left|\mathcal{H}_0^c\right|$. Given two procedures R and R', a particularly simple sufficient condition for R to be more powerful than R' is when R' if $R' \subset R$ holds pointwise. We will say in this case that R is *(uniformly) less conservative* than R'.

Remark 2 *Throughout this paper we will use the following convention: whenever there is an indicator function inside an expectation, this has logical priority over any other factor appearing in the expectation. What we mean is that if other factors include expressions that may not be defined (such as the ratio $\frac{0}{0}$) outside of the set defined by the indicator, this is safely ignored. This results in more compact notation, such as in Definition 1. Note also again that the dependence of the FDR on the unknown $\mathbb{P}$ is implicit.*

2.3 Self-Consistency, Step-Up Procedures, FDR Control and Adaptivity

We first define a general class of multiple testing procedures called *self-consistent procedures* (Blanchard and Roquain, 2008).

Definition 3 (Self-consistency, nonincreasing procedure) *Let $\Delta : \{0, 1, \ldots, m\} \to \mathbb{R}^+$, $\Delta(0) = 0$, be a nondecreasing function called* threshold collection*; a multiple testing procedure R is said to satisfy the self-consistency condition with respect to Δ if the inclusion*

$$R \subset \{h \in \mathcal{H} \mid p_h \leq \Delta(|R|)\}$$

holds almost surely. Furthermore, we say that R is nonincreasing if for all $h \in \mathcal{H}$ the function $p_h \mapsto |R(\mathbf{p})|$ is nonincreasing, that is if $|R|$ is nonincreasing in each p-value.

The class of self-consistent procedures includes well-known types of procedures, notably step-up and step-down. The assumption that a procedure is nonincreasing, which is required in addition to self-consistency in some of the results to come, is relatively natural as a lower p-value means we have more evidence to reject the corresponding hypothesis. We will mainly focus on the *step-up* procedure, which we define now. For this, we sort the p-values in increasing order using the notation $p_{(1)} \leq \cdots \leq p_{(m)}$ and putting $p_{(0)} = 0$. This order is of course itself random since it depends on the observation.

Definition 4 (Step-up procedure) *The step-up procedure with threshold collection Δ is defined as*

$$R = \{h \in \mathcal{H} \mid p_h \leq p_{(k)}\}, \text{ where } k = \max\{0 \leq i \leq m \mid p_{(i)} \leq \Delta(i)\}.$$

A trivial but important property of a step-up procedure is the following.

Lemma 5 *The step-up procedure with threshold collection Δ is nonincreasing and self-consistent with respect to Δ.*

Therefore, a result valid for any nonincreasing self-consistent procedure w.r.t. Δ holds in particular for the corresponding step-up procedure. This will be used extensively through the paper and thus should be kept in mind by the reader.

Among all procedures that are self-consistent with respect to Δ, the step-up is uniformly less conservative than any other (Blanchard and Roquain, 2008) and is therefore of primary interest. However, to recover procedures of a more general form (including step-down for instance), the statements of this paper will be preferably expressed in terms of self-consistent procedures when it is possible.

Threshold collections are generally scaled by the target FDR level α. Once correspondingly rewritten under the normalized form $\Delta(i) = \alpha\beta(i)/m$, we will call β the *shape function* for threshold collection Δ. In the particular case where the shape function β is the identity function, the procedure is called the *linear step-up* (LSU) *procedure* (at level α).

The LSU plays a prominent role in multiple testing for FDR control; it was the first procedure for which FDR control was proved and it is probably the most widely used procedure in this context. More precisely, when the p-values are assumed to be independent, the following theorem holds.

Theorem 6 *Suppose that the family of p-values $\mathbf{p} = (p_h, h \in \mathcal{H})$ is independent. Then any nonincreasing self-consistent procedure with respect to threshold collection $\Delta(i) = \alpha i/m$ has FDR upper bounded by $\pi_0\alpha$, where $\pi_0 = m_0/m$ is the proportion of true null hypotheses. (In particular, this is the case for the linear step-up procedure.) Moreover, if the p-values associated to true null hypotheses are exactly distributed like a uniform distribution, the linear step-up procedure has FDR exactly equal to $\pi_0\alpha$.*

For the specific case of the LSU, the first part of this result was proved in the landmark paper of Benjamini and Hochberg (1995); the second part was proved by Benjamini and Yekutieli (2001) and Finner and Roters (2001). Benjamini and Yekutieli (2001) extended the first part by proving that the LSU procedure still controls the FDR in the case of p-values with a certain form of positive dependence called *positive regression dependence from a subset* (PRDS). We skip a formal definition for now (we will get back to this topic in Section 4). The extension of these results to self-consistent procedures (in the independent as well as PRDS case) was established by Blanchard and Roquain (2008) and Finner et al. (2009).

However, when no particular assumption is made on the dependence between the p-values, it can be shown that the above FDR control does not hold in general. This situation is called *unspecified* or *arbitrary* dependence. A modification of the LSU was first proposed by Benjamini and Yekutieli (2001), and proved to have a controlled FDR under arbitrary dependence. This result was extended by Blanchard and Fleuret (2007) and Blanchard and Roquain (2008) (see also a related result of Sarkar, 2008a,b). Namely, it can be shown that self-consistent procedures (not necessarily nonincreasing) based on a particular class of shape functions have controlled FDR:

Theorem 7 *Under unspecified dependence of the family of p-values* $\mathbf{p} = (p_h, h \in \mathcal{H})$*, let* β *be a shape function of the form:*

$$\beta(r) = \int_0^r u d\nu(u), \tag{3}$$

where ν *is some fixed a priori probability distribution on* $(0,\infty)$*. Then any self-consistent procedure with respect to threshold collection* $\Delta(i) = \alpha\beta(i)/m$ *has FDR upper bounded by* $\alpha\pi_0$ *.*

To recap, in all of the above cases, the FDR is actually controlled at the level $\pi_0\alpha$ instead of the target α. Hence, a direct corollary of both of the above theorems is that the step-up procedure with shape function $\beta^*(x) = \pi_0^{-1}\beta(x)$ has FDR upper bounded by α in either of the following situations:

- $\beta(x) = x$ when the p-value family is independent or PRDS,
- the shape function β is of the form (3) when the p-values have unspecified dependence.

Since $\pi_0 \leq 1$, using β^* always gives rise to a less conservative procedure than using β (especially when π_0 is small). However, since π_0 is unknown, the shape function β^* is not directly accessible. We therefore call the step-up procedure using β^* the *Oracle step-up procedure* based on shape function β (in each of the above cases).

Simply put, the role of adaptive step-up procedures is to mimic the latter oracle in order to obtain more powerful procedures. Adaptive procedures are often step-up procedures using the modified shape function $G\beta$, where G is some estimator of π_0^{-1}:

Definition 8 (Plug-in adaptive step-up procedure) *Given a level* $\alpha \in (0,1)$*, a shape function* β *and an estimator* $G : [0,1]^{\mathcal{H}} \to (0,\infty)$ *of the quantity* π_0^{-1} *, the plug-in adaptive step-up procedure of shape function* β *and using estimator* G *(at level* α*) is defined as*

$$R = \{h \in \mathcal{H} \mid p_h \leq p_{(k)}\}, \text{ where } k = \max\{0 \leq i \leq m \mid p_{(i)} \leq \alpha\beta(i)G(\mathbf{p})/m\}.$$

The (data-dependent) function $\Delta(\mathbf{p}, i) = \alpha\beta(i)G(\mathbf{p})/m$ *is called the adaptive threshold collection corresponding to the procedure. In the particular case where the shape function* β *is the identity function on* $\mathbb{R}^+$*, the procedure is called an adaptive linear step-up procedure using estimator* G *(and at level* α*).*

Following the previous definition, an adaptive plug-in procedure is composed of two different steps:

1. Estimate π_0^{-1} with an estimator G .
2. Take the step-up procedure of shape function $G\beta$.

A subclass of plug-in adaptive procedures is formed by so-called *two-stage procedures*, when the estimator G is actually based on a first, non-adaptive, multiple testing procedure. This can obviously be possibly iterated and leads to multi-stage procedures. The distinction between generic plug-in procedures and two-stage procedures is somewhat informal and generally meant only to provide some kind of nomenclature between different possible approaches.

The main theoretical task is to ensure that an adaptive procedure of this type still correctly controls the FDR. The mathematical difficulty obviously comes from the additional random variations of the estimator G in the procedure.

3. Adaptive Procedures with Provable FDR Control under Independence

In this section, we introduce two new adaptive procedures that provably control the FDR under independence. The first one is one-stage and does not include an explicit estimator of π_0^{-1}, hence it is not explicitly a plug-in procedure. We then propose to use this as the first stage in a new two-stage procedure, which constitutes the second proposed method.

For clarity, we first introduce the new one-stage procedure; we then discuss several possible plug-in procedures, including our new proposition and several procedures proposed by other authors. FDR control for these various plug-in procedures can be studied under independence using a general theoretical device introduced by Benjamini et al. (2006) which we reproduce here with a self-contained and somewhat simplified proof. Finally, we compare these different approaches; first with a theoretical study of the robustness under a very specific case of maximal dependence; second by extensive simulations, where we inspect both the performance under independence and the robustness under a wide range of positive correlations.

3.1 New Adaptive One-Stage Step-Up Procedure

We present here our first main contribution, a one-stage adaptive step-up procedure. This means that the estimation step is implicitly included in the (deterministic) threshold collection.

Theorem 9 *Suppose that the p-value family* $\mathbf{p} = (p_h, h \in \mathcal{H})$ *is independent and let* $\lambda \in (0,1)$ *be fixed. Define the adaptive threshold collection*

$$\Delta(i) = \min\left((1-\lambda)\frac{\alpha i}{m-i+1}, \lambda\right). \tag{4}$$

Then any nonincreasing self-consistent procedure with respect to Δ *has FDR upper bounded by* α. *In particular, this is the case of the corresponding step-up procedure, denoted by BR-1S-*λ.

The above result is proved in Section 6. Our proof is in part based on Lemma 1 of Benjamini et al. (2006). Note that an alternate proof of Theorem 9 is established in Sarkar (2008b) without using this lemma, while nicely connecting the FDR upper-bound to the false non-discovery rate.

3.1.1 COMPARISON TO THE LSU

Below, we will mainly focus on the choice $\lambda = \alpha$, leading to the threshold collection

$$\Delta(i) = \alpha \min\left((1-\alpha)\frac{i}{m-i+1}, 1\right). \tag{5}$$

For $i \leq (m+1)/2$, the threshold (5) is $\alpha\frac{(1-\alpha)i}{m-i+1}$, and thus our approach differs from the threshold collection of the standard LSU procedure threshold by the factor $\frac{(1-\alpha)m}{m-i+1}$.

It is interesting to note that the correction factor $\frac{m}{m-i+1}$ appears in Holm's step-down procedure (Holm, 1979) for FWER control. The latter is a well-known improvement of Bonferroni's procedure (which corresponds to the fixed threshold α/m), taking into account the proportion of true nulls, and defined as the step-down procedure[1] with threshold collection $\alpha/(m-i+1)$. Here we therefore

1. The step-down procedure with threshold collection Δ rejects the hypotheses corresponding to the k smallest p-values, where $k = \max\{0 \leq i \leq m \mid \forall j \leq i,\ p_{(j)} \leq \Delta(j)\}$. It is self-consistent with respect to Δ but uniformly more conservative than the step-up procedure with the same threshold collection, compare with Definition 4.

prove that this correction is suitable as well for the linear step-up procedure, in the framework of FDR control.

If r denotes the final number of rejections of the new one-stage procedure, we can interpret the ratio $\frac{(1-\alpha)m}{m-r+1}$ between the adaptive threshold and the LSU threshold at the same point as an *a posteriori* estimate for π_0^{-1} . In the next section we propose to use this quantity in a plug-in, two-stage adaptive procedure.

As Figure 1 illustrates, our procedure is generally less conservative than the (non-adaptive) linear step-up procedure (LSU). Precisely, the new procedure can only be more conservative than the LSU procedure in the marginal case where the factor $\frac{(1-\alpha)m}{m-i+1}$ is smaller than one. This happens only when the proportion of null hypotheses rejected by the LSU procedure is positive but less than $\alpha + 1/m$ (and even in this region the ratio of the two threshold collections is never less than $(1-\alpha)$). Roughly speaking, this situation with only few rejections can only happen if there are few false hypotheses to begin with (π_0 close to 1) or if the false hypotheses are very difficult to detect (the distribution of false p-values is close to being uniform).

In the interest of being more specific, we briefly investigate this issue in the next lemma, considering the particular *Gaussian random effects* model (which is relatively standard in the multiple testing literature, see, for example, Genovese and Wasserman, 2004) in order to give a quantitative answer from an asymptotical point of view (when the number of tested hypotheses grows to infinity). In the random effect model, hypotheses are assumed to be randomly true or false with probability π_0 , and the false null hypotheses share a common distribution P_1 . Globally, the p-values then are i.i.d. drawn according to the mixture distribution $\pi_0 U[0,1] + (1-\pi_0)P_1$.

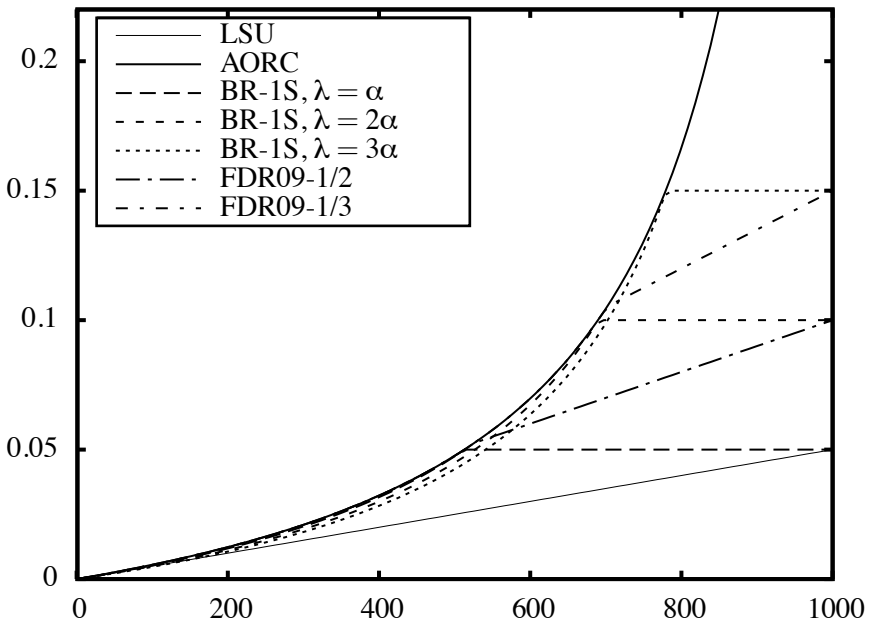

Figure 1: For $m = 1000$ null hypotheses and $\alpha = 5\%$: comparison of the new threshold collection *BR-1S*-λ given by (4) to that of the LSU, the AORC and *FDR09*-η .

Lemma 10 *Consider the random effects model where the p-values are i.i.d. with common cumulative distribution function* $t \mapsto \pi_0 t + (1-\pi_0)F(t)$. *Assume that the true null hypotheses are standard Gaussian with zero mean and that the alternative hypotheses are standard Gaussian with mean* $\mu > 0$. *In this case* $F(t) = \overline{\Phi}(\overline{\Phi}^{-1}(t) - \mu)$, *where* $\overline{\Phi}$ *is the standard Gaussian upper tail function. Assuming* $\pi_0 < (1+\alpha)^{-1}$, *define*

$$\mu^\star = \overline{\Phi}^{-1}(\alpha^2) - \overline{\Phi}^{-1}\left(\frac{\alpha^{-1}-\pi_0}{1-\pi_0}\alpha^2\right).$$

Then if $\mu > \mu^*$, *the probability that the LSU rejects a proportion of null hypotheses less than* $1/m+\alpha$ *tends to 0 as m tends to infinity. On the other hand, if* $\pi_0 > (1+\alpha)^{-1}$, *or* $\mu < \mu^*$, *then this probability tends to one.*

Lemma 10 is proved in Section 6. Taking for instance in this lemma the values $\pi_0 = 0.5$ and $\alpha = 0.05$, results in the critical value $\mu^\star \simeq 1.51$. This lemma delineates clearly in a particular case in which situation we can expect an improvement from the adaptive procedure BR-1S over the standard LSU.

3.1.2 COMPARISON TO OTHER ADAPTIVE ONE-STAGE PROCEDURES

Very recently, other adaptive one-stage procedures with important similarities to *BR-1S-*λ have been proposed by other authors. (The present work was developed independently.)

Starting with some heuristic motivations, Finner et al. (2009) proposed the threshold collection $t(i) = \frac{\alpha i}{m-(1-\alpha)i}$, which they dubbed the *asymptotically optimal rejection curve* (AORC). However, the step-up procedure using this threshold collection as is does not have controlled FDR (since $t(m) = 1$, the corresponding step-up procedure would always reject all the hypotheses), and several suitable modifications were proposed by Finner et al. (2009), the simplest one being

$$t'_\eta(i) = \min\left(t(i), \eta^{-1}\alpha i/m\right),$$

which is denoted by *FDR09-*η in the following.

The theoretical FDR control proved in Finner et al. (2009) is studied asymptotically as the number of hypotheses grows to infinity. In that framework, asymptotical control at level α is shown to hold for any $\eta < 1$. On Figure 1, we represented the thresholds *BR-1S-*λ and *FDR09-*η for comparison, for several choices of the parameters. The two families appear quite similar, initially following the AORC curve, then branching out or capping at a point depending on the parameter. One noticeable difference in the initial part of the curve is that while *FDR09-*η exactly coincides with the AORC, *BR-1S-*λ is arguably sligthly more conservative. This reflects the nature of the corresponding theoretical result—nonasymptotic control of the FDR requires a somewhat more conservative threshold as compared to the only asymptotic control of *FDR-*η . Additionally, we can use *BR-1S-*λ as a first step in a 2-step procedure, as will be argued in the next section.

The ratio between *BR-1S-*λ and the AORC (before the capping point) is a factor which, assuming $\alpha \geq (m+1)^{-1}$, is lower bounded by $(1-\lambda)(1-\frac{1}{m+1})$. This suggests that the value for λ should be kept small, this is why we propose $\lambda = \alpha$ as a default choice.

Finally, the *step-down* procedure based on the AORC threshold collection (under the slightly modified form $\widetilde{t}(i) = \frac{\alpha i}{m-(1-\alpha)i+1}$, but with no further modification) is proposed and studied by Gavrilov et al. (2009). Using specific properties of step-down procedures, these authors proved the nonasymptotic FDR control of this procedure.

3.2 Adaptive Plug-In Methods

In this section, we consider different adaptive step-up procedures of the plug-in type, that is, based on an explicit estimator of π_0^{-1}. We first review a general method proposed by Benjamini et al. (2006) in order to derive FDR control for such plug-in procedures (see also Theorem 4.3 of Finner et al., 2009, for a similar result, as well as Theorem 3.3 of Sarkar, 2008b). We propose here a self-contained proof of this result, which notably extends the original result from step-up procedures to more general self-consistent procedures. Based on this result, we review the different plug-in estimators considered by Benjamini et al. (2006) and add a new one to the lot, based on the one-stage adaptive procedure introduced in the previous section.

Let us first introduce the following notation: for each $h \in \mathcal{H}$, we denote by $\mathbf{p}_{-h}$ the collection of p-values $\mathbf{p}$ restricted to $\mathcal{H} \setminus \{h\}$, that is, $\mathbf{p}_{-h} = (p_{h'}, h' \neq h)$. We also denote $\mathbf{p}_{0,h} = (\mathbf{p}_{-h}, 0)$ the collection $\mathbf{p}$ where p_h has been replaced by 0.

Theorem 11 (Benjamini, Krieger, Yekutieli 2006) *Suppose that the p-value family $\mathbf{p} = (p_h, h \in \mathcal{H})$ is independent. Let $G : [0,1]^{\mathcal{H}} \to (0,\infty)$ be a measurable, coordinate-wise nonincreasing function. Consider a nonincreasing multiple testing procedure R which is self-consistent with respect to the adaptive linear threshold collection $\Delta(\mathbf{p}, i) = \alpha G(\mathbf{p}) i/m$. Then the following holds:*

$$\mathrm{FDR}(R) \leq \frac{\alpha}{m} \sum_{h \in \mathcal{H}_0} \mathbb{E}\left[G(\mathbf{p}_{0,h})\right]. \tag{6}$$

In particular, if for any $h \in \mathcal{H}_0$, it holds that $\mathbb{E}\left[G(\mathbf{p}_{0,h})\right] \leq \pi_0^{-1}$, then $\mathrm{FDR}(R) \leq \alpha$.

The proof is given in Section 6. Since we assumed G to be nonincreasing, the quantity $\mathbb{E}\left[G(\mathbf{p}_{0,h})\right]$ in bound (6) is maximized when the p-values associated to true nulls have a uniform distribution (p_h excepted), while the p-values associated to false nulls are all set to zero. Following Finner et al. (2009), this *least favorable configuration* for the distribution of p-values is referred to as the Dirac-Uniform distribution and gives rise to the following corollary:

Corollary 12 *Consider the same conditions as for Theorem 11, and assume moreover that G is invariant by permutation of the p-values. Then it holds that*

$$\mathrm{FDR}(R) \leq \gamma(G,m)\,\alpha,$$

with $\gamma(G,m) = \max_{1 \leq m_0 \leq m} \left\{ \frac{m_0}{m} \mathbb{E}_{\mathbf{p} \sim DU(m, m_0 - 1)}\left[G(\mathbf{p})\right] \right\}$, where $DU(m,j)$ is the distribution of $\mathbf{p}$ where the j first p-values are independent uniform in $[0,1]$ and the $m-j$ others are identically equal to zero.

(While the proof is standard, it is given for completeness in Section 6). The interest of the last result is that for *any* choice of nonincreasing (permutation invariant) function G, it is possible in principle to evaluate $\gamma(G,m)$ by a Monte Carlo method, namely by estimating the expected value of G under the $m-1$ possible least favorable configurations. This leads to a practical control of the FDR valid for any value of m_0, obtained by dividing the target level α by $\gamma(G,m)$ before applying the procedure.

However, when m is large, this method can be computationally demanding, and a more convenient approach for practical use is to obtain explicit bounds for specific estimators. We now

concentrate on this goal and apply the result of Theorem 11 (or alternatively of Corollary 12) to the following estimators, depending on a fixed parameter $\lambda \in (0,1)$ or $k_0 \in \{1,\dots,m\}$:

$$\text{[Storey-}\lambda\text{]} \qquad G_1(\mathbf{p}) = \frac{(1-\lambda)m}{\sum_{h\in\mathcal{H}} \mathbf{1}\{p_h > \lambda\}+1};$$

$$\text{[Quant-}\frac{k_0}{m}\text{]} \qquad G_2(\mathbf{p}) = \frac{(1-p_{(k_0)})m}{m-k_0+1};$$

$$\text{[BKY06-}\lambda\text{]} \qquad G_3(\mathbf{p}) = \frac{(1-\lambda)m}{m-|R_0(\mathbf{p})|+1}, \text{ where } R_0 \text{ is the standard LSU at level } \lambda;$$

$$\text{[BR-2S-}\lambda\text{]} \qquad G_4(\mathbf{p}) = \frac{(1-\lambda)m}{m-|R'_0(\mathbf{p})|+1}, \text{ where } R'_0 \text{ is BR-1S-}\lambda \text{ (see Theorem 9).}$$

Above, the notation "Storey-λ", "Quant-$\frac{k_0}{m}$", "BKY06-λ" and "BR-2S-λ" refer to the plug-in adaptive linear step-up procedures associated to G_1, G_2, G_3 and G_4, respectively.

Estimator G_1 is usally called *modified Storey's estimator* and was initially introduced by Storey (2002) from an heuristics on the p-values histogram (originally without the "+1", hence the name "modified"). Its intuitive justification is as follows: denoting by S_λ the set of p-values larger than the threshold λ, the average number of true nulls having a p-value in S_λ is $m_0(1-\lambda)$. Hence, a natural estimator of π_0^{-1} is $(1-\lambda)m/|S_\lambda \cap \mathcal{H}_0| \geq (1-\lambda)m/|S_\lambda| \simeq G_1(\mathbf{p})$. In particular, we expect that Storey's estimator is generally an underestimate of π_0^{-1}, which is in accordance with the condition of Theorem 11. A standard choice is $\lambda = 1/2$ (as in the SAM software of Storey and Tibshirani, 2003). FDR control for the corresponding plug-in step-up procedure was proved by Storey et al. (2004) (more precisely, for the modification $\widetilde{\Delta}(\mathbf{p},i) = \min(\alpha G_1(\mathbf{p})i/m, \lambda)$) and by Benjamini et al. (2006).

Estimator G_2 was introduced by Benjamini and Hochberg (2000) and Efron et al. (2001), from a slope heuristics on the p-values c.d.f. Roughly speaking, G_2 appears as Storey's estimator with the data-dependent parameter choice $\lambda = p_{(k_0)}$, and can therefore be interpreted as the quantile version of Storey's estimator. A standard value for k_0 is $\lfloor m/2 \rfloor$, resulting in the so-called median adaptive LSU (see Benjamini et al., 2006, and the references therein).

Estimator G_3 was introduced by Benjamini et al. (2006) for the particular choice $\lambda = \alpha/(1+\alpha)$. More precisely, a slightly less conservative version, without the "+1" in the denominator, was used in Benjamini et al. (2006). We forget about this refinement here, noting that it results only in a very slight improvement.

Finally, the estimator G_4 is new and follows exactly the same philosophy as G_3, that is, uses a step-up procedure as a first stage in order to estimate π_0^{-1}, but this time based on our adaptive one-stage step-up procedure introduced in the previous section, rather than the standard LSU. Note that since R'_0 is less conservative than R_0 (except in marginal cases), we generally have $G_3 \leq G_4$ pointwise and our estimator improves over the one of Benjamini et al. (2006).

These different estimators all satisfy the sufficient condition mentioned in Theorem 11, and we thus obtain the following corollary:

Corollary 13 *Assume that the family of p-values* $\mathbf{p} = (p_h, h \in \mathcal{H})$ *is independent. For* $i = 1,2,3,4$, *and any* $h \in \mathcal{H}_0$, *it holds that* $\mathbb{E}[G_i(\mathbf{p}_{0,h})] \leq \pi_0^{-1}$. *Therefore, the plug-in adaptive linear step-up procedure at level* α *using estimator* G_i *has FDR smaller than or equal to* α.

The above result for G_1, G_2 and G_3 (for the specific parameter setting $\lambda = \alpha/(1+\alpha)$) was proved by Benjamini et al. (2006). In Section 6, we shortly reproduce their arguments, and prove the result for G_4.

To sum up, Corollary 13 states that under independence, for any λ and k_0, the plug-in adaptive procedures Storey-λ, Quant-$\frac{k_0}{m}$, BKY06-λ and BR-2S-λ all control the FDR at level α.

Remark 14 *The result proved by Benjamini et al. (2006) is actually slightly sharper than Theorem 11. Namely, if $G(\cdot)$ is moreover supposed to be coordinate-wise left-continuous, it is possible to prove that Theorem 11 still holds when $\mathbf{p}_{0,h}$ in the RHS of* (6) *is replaced by the slightly better $\widetilde{\mathbf{p}}_h = (\mathbf{p}_{-h}, \widetilde{p}_h(\mathbf{p}_{-h}))$, defined as the collection of p-values $\mathbf{p}$ where p_h has been replaced by $\widetilde{p}_h(\mathbf{p}_{-h}) = \max\left\{p \in [0,1] \;\middle|\; p \leq \alpha |R(\mathbf{p}_{-h}, p)| G(\mathbf{p}_{-h}, p)\right\}$. This improvement then permits to get rid of the "+1" in the denominator of G_3. Here, we opted for simplicity and a more straightforward statement, noting that this improvement is not crucial.*

Remark 15 *The one-stage step-up procedure of Finner et al. (2009) (see previous discussion in Section 3.1.2)—for which there is no result proving nonasymptotic FDR control up to our knowledge—can also be interpreted intuitively as an adaptive version of the LSU using estimator G_2, where the choice of parameter k_0 is data-dependent. Namely, assume that we want to reject at least i null hypotheses whenever $p_{(i)}$ is lower than the standard LSU threshold times the estimator G_2 wherein parameter $k_0 = i$ is used. This corresponds to the inequality $p_{(i)} \leq \frac{k(1-p_{(i)})}{m-i+1}$, which, solved in $p_{(i)}$, gives the threshold collection of Finner et al. (2009). Remember from Section 3.1.2 that this threshold collection must actually be modified in order to be useful, since it otherwise always leads to reject all hypotheses. The modification leading to FDR09-η consists in capping the estimated π_0^{-1} at a level η, that is, using $\min(\eta, G_2)$ instead of G_2 in the above reasoning. In fact, the proof of Finner et al. (2009) relies on a result which is essentially a reformulation of Theorem 11 for a specific form of estimator.*

Remark 16 *The estimators G_i, $i = 1,2,3,4$ are not necessarily larger than 1, and to this extent can in some unfavorable cases result in the final procedure being actually more conservative than the standard LSU. This can only happen in the situation where either π_0 is close to 1 ("sparse signal") or the alternative hypotheses are difficult to detect ("weak signal"); if such a situation is anticipated, it is more appropriate to use the regular non-adaptive LSU.*

For the Storey-λ estimator, we can control precisely the probability that such an unfavorable case arises by using Hoeffding's inequality (Hoeffding, 1963): assuming the true nulls are i.i.d. uniform on $(0,1)$ and the false nulls i.i.d. of c.d.f. $F(\cdot)$, we write by definition of G_1

$$\begin{aligned}\mathbb{P}[G_1(\mathbf{p}) < 1] &= \mathbb{P}\left[\frac{1}{m}\sum_{h\in\mathcal{H}}^{m}(\mathbf{1}\{p_h > \lambda\} - \mathbb{P}[p_h > \lambda]) > (1-\pi_0)(F(\lambda)-\lambda) - m^{-1}\right] \\ &\leq \exp(-2(mc^2+1)),\end{aligned}$$

where we denoted $c = (1-\pi_0)(F(\lambda)-\lambda)$, and assumed additionally $c > m^{-1}$. The behavior of the bound mainly depends on c, which can get small only if π_0 is close to 1 (sparse signal) or $F(\lambda)$ is close to λ (weak signal), illustrating the above point. In general, provided $c > 0$ does not depend on m, the probability that the Storey procedure fails to outperform the LSU vanishes exponentially as m tends to infinity.

3.3 Theoretical Robustness of the Adaptive Procedures under Maximal Dependence

For the different procedures proposed above, the theory only provides the correct FDR control under independence between the p-values. An important issue is to know how robust this control is when dependence is present (as it is often the case in practice). However, the analytic computation of the FDR under dependence is generally a difficult task, and this issue is often tackled empirically through simulations in a pre-specified model (we will do so in Section 3.4).

In this short section, we present theoretical computations of the FDR for the previously introduced adaptive step-up procedures, under the maximally dependent model where all the p-values are in fact equal, that is $p_h \equiv p_1$ for all $h \in \mathcal{H}$ (and $m_0 = m$). It corresponds to the case where we perform m times the same test, with the same p-value. Albeit relatively trivial and limited, this case leads to very simple FDR computations and provides at least some hints concerning the robustness under dependence of the different procedures studied above.

Proposition 17 *Suppose that we observe m identical p-values $\mathbf{p} = (p_1, ..., p_m) = (p_1, ..., p_1)$ with $p_1 \sim U([0,1])$ and assume $m = m_0$. Then, the following holds:*

$$\begin{aligned}
\mathrm{FDR}(\textit{BR-1S-}\lambda) &= \min\big(\lambda, \alpha(1-\lambda)m\big),\\
\mathrm{FDR}(\textit{FDR09-}\eta) &= \alpha\eta^{-1},\\
\mathrm{FDR}(\textit{Storey-}\lambda) &= \min\big(\lambda, \alpha(1-\lambda)m\big) + \big(\alpha(1-\lambda)(1+m^{-1}) - \lambda\big)_+,\\
\mathrm{FDR}(\textit{Quant-}k_0/m) &= \frac{\alpha}{(1+\alpha) - (k_0-1)m^{-1}},\\
\mathrm{FDR}(\textit{BKY06-}\lambda) &= \mathrm{FDR}(\textit{BR-2S-}\lambda) = \mathrm{FDR}(\textit{Storey-}\lambda).
\end{aligned}$$

Interestingly, the above proposition suggests specific choices of the parameters λ, η and k_0 to ensure control of the FDR at level α under maximal dependence:

- For BR-1S-λ, putting $\lambda_2 = \alpha/(\alpha + m^{-1})$, Proposition 17 gives that $\mathrm{FDR}(\textit{BR-1S-}\lambda) = \lambda$ whenever $\lambda \leq \lambda_2$. This suggests to take $\lambda = \alpha$, and is thus in accordance with the default choice proposed in Section 3.1.

- For FDR09-η, no choice of $\eta < 1$ will lead to the correct FDR control under maximal dependence. However, the larger η , the smaller the FDR in this situation. Note that $\mathrm{FDR}(\textit{FDR09-}\frac{1}{2}) = 2\alpha$.

- For Storey-λ, BKY06-λ and BR-2S-λ, putting $\lambda_1 = \alpha/(1+\alpha+m^{-1})$, we have FDR $= \lambda$ for $\lambda_1 \leq \lambda \leq \lambda_2$. This suggests to choose $\lambda = \alpha$ within these three procedures. Furthermore, note that the standard choice $\lambda = 1/2$ for Storey-λ leads to a very poor control under maximal dependence: $\mathrm{FDR}(\textit{Storey-}\frac{1}{2}) = \min(\alpha m, 1)/2$.

- For Quant-k_0/m, we see that the value of k_0 maximizing the FDR while maintaining it below α is $k_0 = \lfloor \alpha m \rfloor + 1$. Remark also that the standard choice $k_0 = \lfloor m/2 \rfloor$ leads to $\mathrm{FDR}(\textit{Quant-}k_0/m) = 2\alpha/(1+2\alpha+2m^{-1}) \simeq 2\alpha$.

Nevertheless, we would like to underline that the above computations should be interpreted with caution, as the maximal dependence case is very specific and cannot possibly give an accurate idea of the behavior of the different procedures when the correlation between the p-values are strong

but not equal to 1 . For instance, it is well-known that the LSU procedure has FDR far below α for strong positive correlations, but its FDR is equal to α in the above extreme model (see Finner et al., 2007, for a comprehensive study of the LSU under positive dependence). Conversely, the FDR of some adaptive procedures can be higher under moderate dependence than under maximal dependence. This behavior appears in the simulations of the next section, illustrating the complexity of the issue.

3.4 Simulation Study

How can we compare the different adaptive procedures defined above? For a fixed λ, it holds pointwise that $G_1 \geq G_4 \geq G_3$, which shows that the adaptive procedure [Storey-λ] is always less conservative than [BR-2S-λ], itself less conservative than [BKY06-λ] (except in the marginal cases where the one-stage adaptive procedure is more conservative than the standard step-up procedure, as delineated earlier for example in Lemma 10). It would therefore appear that one should always choose [Storey-λ] and disregard the other ones. However, an important point made by Benjamini et al. (2006) for introducing G_3 as a better alternative to the (already known earlier) G_1 is that, on simulations with positively dependent test statistics, the plug-in procedure using G_1 with $\lambda = 1/2$ had very poor control of the FDR, while the FDR was still controlled for the plug-in procedure based on G_3. While the positively dependent case is not covered by the theory, it is of course very important to ensure that a multiple testing procedure is sufficiently robust in practice so that the FDR does not vary too much in this situation.

In order to assess the quality of our new procedures, we compare here the different methods on a simulation study following the setting used by Benjamini et al. (2006). Let $X_i = \mu_i + \varepsilon_i$, for $i, 1 \leq i \leq m$, where ε is a $\mathbb{R}^m$-valued centred Gaussian random vector such that $\mathbb{E}(\varepsilon_i^2) = 1$ and for $i \neq j$, $\mathbb{E}(\varepsilon_i \varepsilon_j) = \rho$, where $\rho \in [0,1]$ is a correlation parameter. Thus, when $\rho = 0$ the X_i's are independent, whereas when $\rho > 0$ the X_i's are positively correlated (with a constant pairwise correlation). For instance, the ε_i's can be constructed by taking $\varepsilon_i := \sqrt{\rho}\, U + \sqrt{1-\rho}\, Z_i$, where Z_i, $1 \leq i \leq m$ and U are all i.i.d $\sim \mathcal{N}(0,1)$.

Considering the one-sided null hypotheses h_i : "$\mu_i \leq 0$" against the alternatives "$\mu_i > 0$" for $1 \leq i \leq m$, we define the p-values $p_i = \overline{\Phi}(X_i)$, for $1 \leq i \leq m$, where $\overline{\Phi}$ is the standard Gaussian distribution tail. We choose a common mean $\bar{\mu}$ for all false hypotheses, that is, for $i, 1 \leq i \leq m_0$, $\mu_i = 0$ and for $i, m_0 + 1 \leq i \leq m, \mu_i = \bar{\mu}$; the p-values corresponding to the null means follow exactly a uniform distribution.

Note that the case $\rho = 1$ and $m = m_0$ (i.e., $\pi_0 = 1$) corresponds to the maximally dependent case studied in Section 3.3.

We compare the following step-up multiple testing procedures: first, the one-stage step-up procedures defined in Section 3.1:

- [BR08-1S-α] The new procedure of Theorem 9, with parameter $\lambda = \alpha$,
- [FDR09-$\frac{1}{2}$] The procedure proposed in Finner et al. (2009) and described in Section 3.1.2, with $\eta = \frac{1}{2}$.

Secondly, the adaptive plug-in step-up procedures defined in Section 3.2:

- [Median LSU] The procedure [Quant-$\frac{k_0}{m}$] with the choice $\frac{k_0}{m} = \frac{1}{2}$,
- [BKY06-α] The procedure [BKY06-λ] with the parameter choice $\lambda = \alpha$,

- [BR08-2S-α] The procedure [BR08-2S-λ] with the parameter choice $\lambda = \alpha$,
- [Storey-λ] With the choices $\lambda = 1/2$ and $\lambda = \alpha$.

Finally, we used as oracle reference [LSU Oracle], the step-up procedure with the threshold collection $\Delta(i) = \alpha i/m_0$, using "oracle" prior knowledge of π_0.

The parameter choice $\lambda = \alpha$ for [Storey-λ] comes from the relationship (delineated in Section 3.1) of G_3, G_4 to G_1, and from the discussion of the maximally dependent case in Section 3.3. Note that the procedure studied by Benjamini et al. (2006) is actually [BKY06-$\alpha/(1+\alpha)$] in our notation (up to a minor modification explained in Remark 14). Thefore, the procedure [BKY06-α] used in our simulations is not srictly the same as in Benjamini et al. (2006), but it is very close.

The three most important parameters in the simulation are the correlation coefficient ρ, the proportion of true null hypotheses π_0, and the alternative mean $\bar{\mu}$ which represents the signal-to-noise ratio, or how easy it is to distinguish alternative hypotheses. We present in Figures 2, 3, and 4 results of the simulations for one varying parameter (π_0, $\bar{\mu}$ and ρ, respectively), the others being kept fixed. Reported are, for the different methods: the FDR, and the power relative to the reference [LSU-Oracle]. Remember the absolute power is defined as the mean proportion of false null hypotheses that are correctly rejected; for each procedure the relative power is the ratio of its absolute power to that of [LSU-Oracle]. Each point is estimated by an average of 10^5 simulations, with fixed parameters $m = 100$ and $\alpha = 5\%$.

3.4.1 UNDER INDEPENDENCE ($\rho = 0$)

Remember that under independence of the p-values, the procedure [LSU] has a FDR equal to $\alpha\pi_0$ and that the procedure [LSU Oracle] has a FDR equal to α (provided that $\alpha \leq \pi_0$). The other procedures have their FDR upper bounded by α (in an asymptotical sense only for [FDR09-$\frac{1}{2}$]).

The situation where the p-values are independent corresponds to the first row of Figures 2 and 3 and the leftmost point of each graph in Figure 4. It appears that in the independent case, the following procedures can be consistently ordered in terms of (relative) power over the range of parameters studied here:

$$[\text{Storey-}\tfrac{1}{2}] \succ [\text{Storey-}\alpha] \succ [\text{BR08-2S-}\alpha] \succ [\text{BKY06-}\alpha],$$

the symbol "$\succ$" meaning "is (uniformly over our experiments) more powerful than".

Next, the procedures [median-LSU] and [FDR09-$\frac{1}{2}$] appear both consistently less powerful than [Storey-$\frac{1}{2}$], and [FDR09-$\frac{1}{2}$] is additionally also consistently less powerful than [Storey-α]. Their relation to the remaining procedures depends on the parameters; both [median-LSU] and [FDR09-$\frac{1}{2}$] appear to be more powerful than the remaining procedures when $\pi_0 > \frac{1}{2}$, and less efficient otherwise. We note that [median-LSU] also appears to perform better when $\bar{\mu}$ is low (i.e., the alternative hypotheses are harder to distinguish).

Concerning our one-stage procedure [BR08-1S-α], we note that it appears to be indistinguishable from its two-stage counterpart [BR08-2S-α] when $\pi_0 > \frac{1}{2}$, and significantly less powerful otherwise. This also corresponds to our expectations, since in the situation $\pi_0 < \frac{1}{2}$, there is a much higher likelihood that more than 50% hypotheses are rejected, in which case our one-stage threshold family hits its "cap" at level α (see, e.g., Fig. 1; a similar qualitative explanation applies to understand the behavior of [FDR09-$\frac{1}{2}$]). This is precisely to improve on this situation that we introduced the two-stage procedure, and we see that the latter does in fact improve substantially the one-stage version in that specific region.

The fact that [Storey-$\frac{1}{2}$] is uniformly more powerful than the other procedures in the independent case corroborates the simulations reported in Benjamini et al. (2006). Generally speaking, under independence we obtain a less biased estimate for π_0^{-1} when considering Storey's estimator based on a "high" threshold like $\lambda = \frac{1}{2}$. Namely, higher p-values are less likely to be "contaminated" by false null hypotheses; conversely, if we take a lower threshold λ, there will be more false null hypotheses included in the set of p-values larger than λ , leading to a pessimistic bias in the estimation of π_0^{-1} . This qualitative reasoning is also consistent with the observed behavior of [median-LSU], since the set of p-values larger than the median is much more likely to be "contaminated" when $\pi_0 < \frac{1}{2}$.

However, the problem with [Storey-$\frac{1}{2}$] is that the corresponding estimation of π_0^{-1} exhibits much more variability than its competitors when there is a substantial correlation between the p-values. As a consequence it is a very fragile procedure. This phenomenon was already pinpointed in Benjamini et al. (2006) and we study it next.

3.4.2 UNDER POSITIVE DEPENDENCE ($\rho > 0$)

Under positive dependence, remember that it is known theoretically from Benjamini and Yekutieli (2001) that the FDR of the procedure [LSU] (resp. [LSU Oracle]) is still bounded by $\alpha\pi_0$ (resp. α), but without equality in general. However, we do not know from a theoretical point of view if the adaptive procedures have their FDR upper bounded by α. In fact, it was pointed out by Farcomeni (2007), in another work reporting simulations on adaptive procedures, that one crucial point to this respect seems to be the variability of estimate of π_0^{-1}. Estimates of this quantity that are not robust with respect to positive dependence will result in failures for the corresponding multiple testing procedure.

The situation where the p-values are positively dependent corresponds to the second and third rows ($\rho = 0.2, 0.5$, respectively) of Figures 2 and 3 and to all the graphs of Figure 4 (except the leftmost points corresponding to $\rho = 0$).

The most striking fact is that [Storey-$\frac{1}{2}$] does not control the FDR at the desired level any longer under positive dependence, and can even be off by quite a large factor. This is in accordance with the experimental findings of Benjamini et al. (2006). Therefore, although this procedure was the favorite in the independent case, it turns out to be not robust, which is very undesirable for practical use where it is generally impossible to guarantee that the p-values are independent. The procedure [median-LSU] appears to have higher power than the remaining ones in the situations studied in Figure 3, especially with a low signal-to-noise ratio. Unfortunately, other situations appearing in Figures 2 and 4 show that [median-LSU] can exhibit a poor FDR control in some parameter regions, most notably when π_0 is close to 1 and positive dependence is present (see, e.g., Figure 4, bottom row). In a majority of practical situations, this is an important drawback since it is difficult to rule out *a priori* that π_0 is close to 1 (i.e., there is only a small proportion of false hypotheses), or that dependence is present. Additionally, from the inspection of the behavior of the power of [median-LSU] in Figures 2 and 4, it appears that the parameter setting $\pi_0 = 0.5$ (which is the fixed value used in Figure 3) is actually noticeably the most favorable for [median-LSU] under dependence. For other values of π_0, this procedure is often clearly outperformed in terms of power, in particular by [Storey-α] and [BR-2S-α]. (At this point we have no satisfying explanation to this peculiar "peak of power" at $\pi_0 = 0.5$ observed specifically for the [median-LSU] procedure under dependence.) For all of these reasons, our conclusion is that [median-LSU] is also not robust enough in general to be reliable.

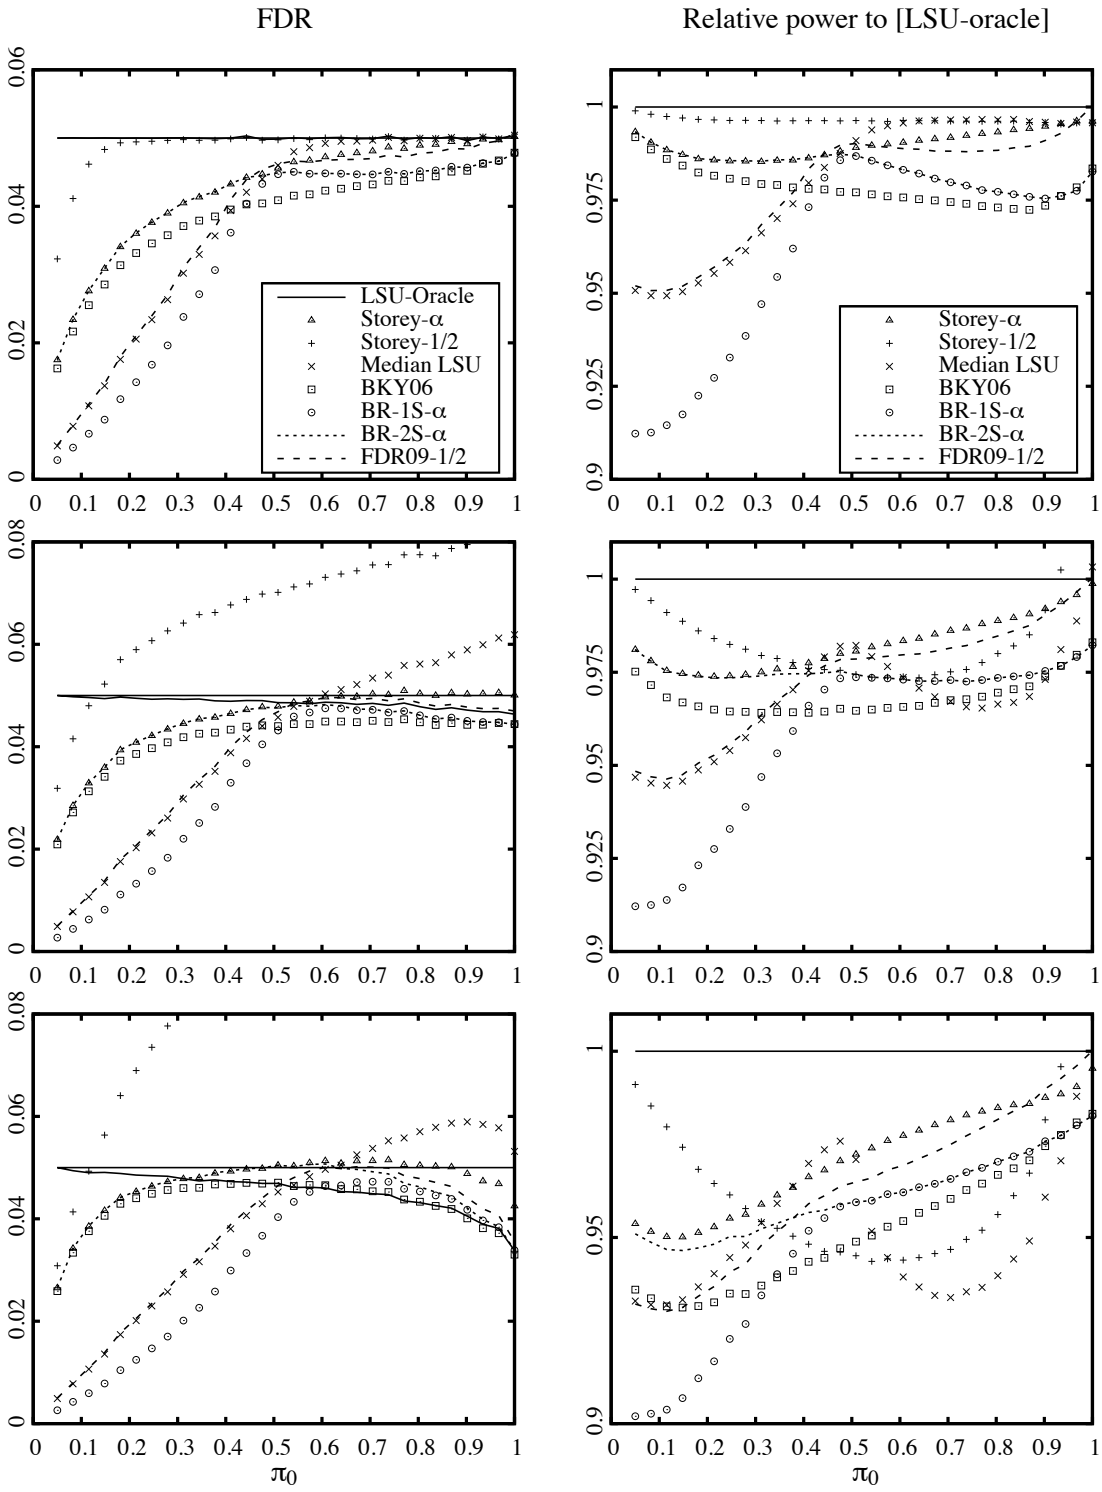

Figure 2: FDR and power relative to oracle as a function of the true proportion π_0 of null hypotheses . Target FDR is $\alpha = 5\%$, total number of hypotheses $m = 100$. The mean for the alternatives is $\bar{\mu} = 3$. From top to bottom: pairwise correlation coefficient $\rho \in \{0, 0.2, 0.5\}$.

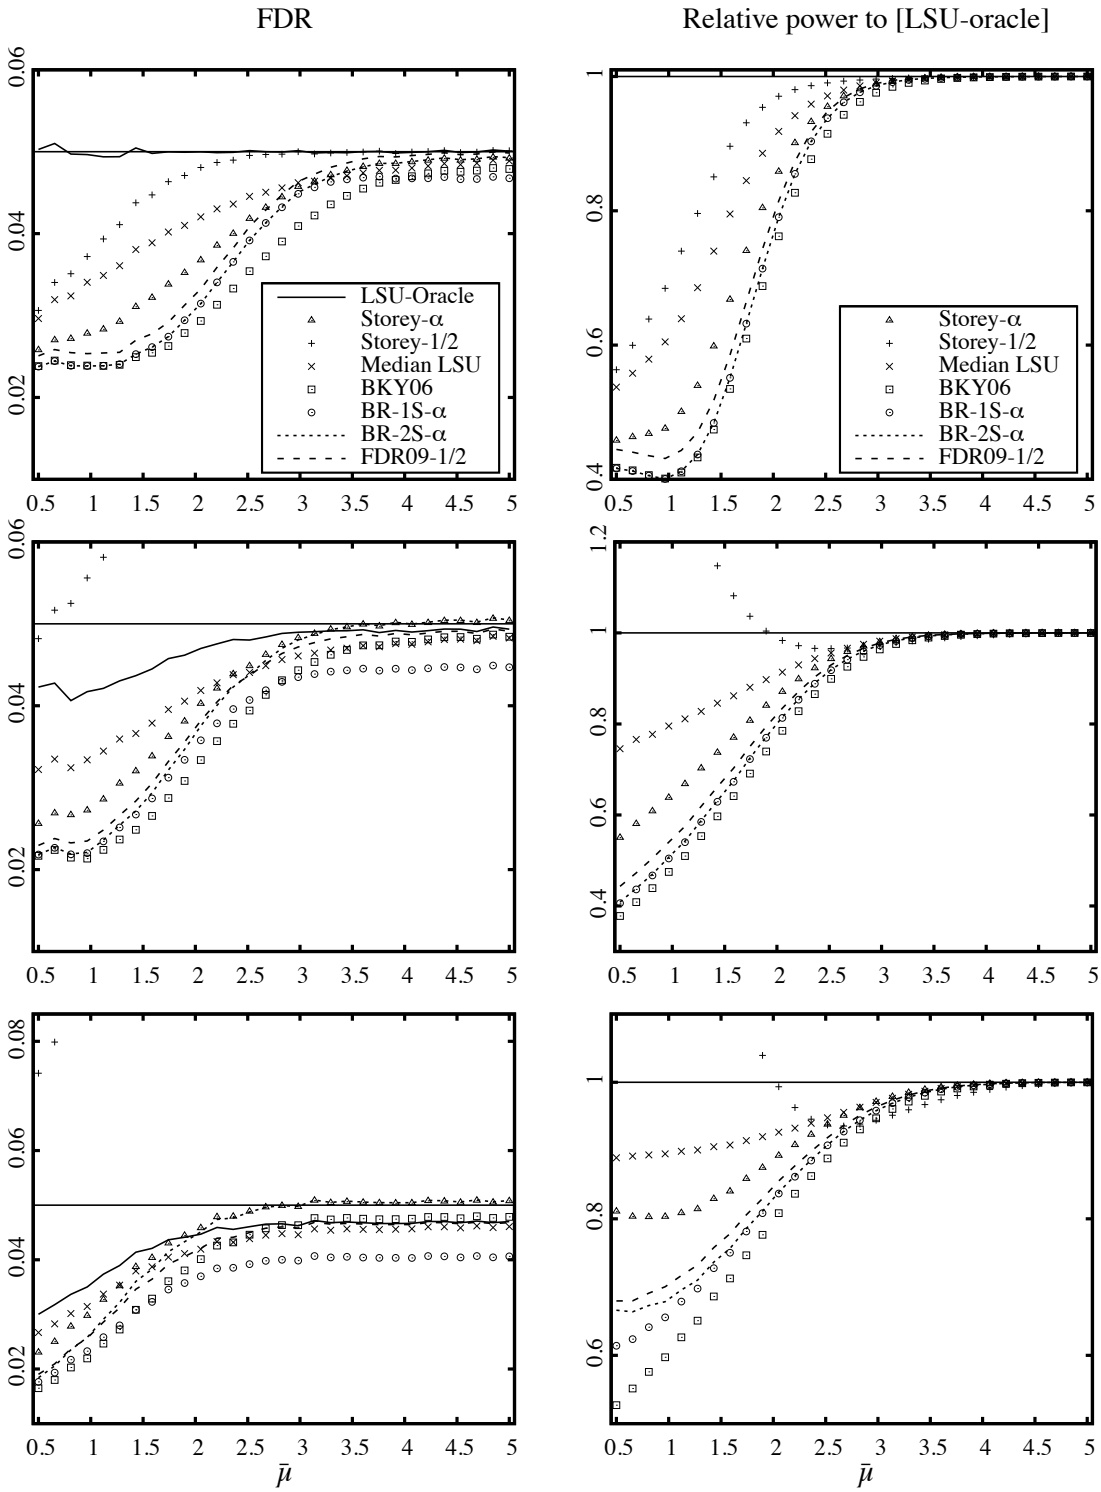

Figure 3: FDR and power relative to oracle as a function of the common alternative hypothesis mean $\bar{\mu}$. Target FDR is $\alpha = 5\%$, total number of hypotheses $m = 100$. The proportion of true null hypotheses is $\pi_0 = 0.5$. From top to bottom: pairwise correlation coefficient $\rho \in \{0, 0.2, 0.5\}$.

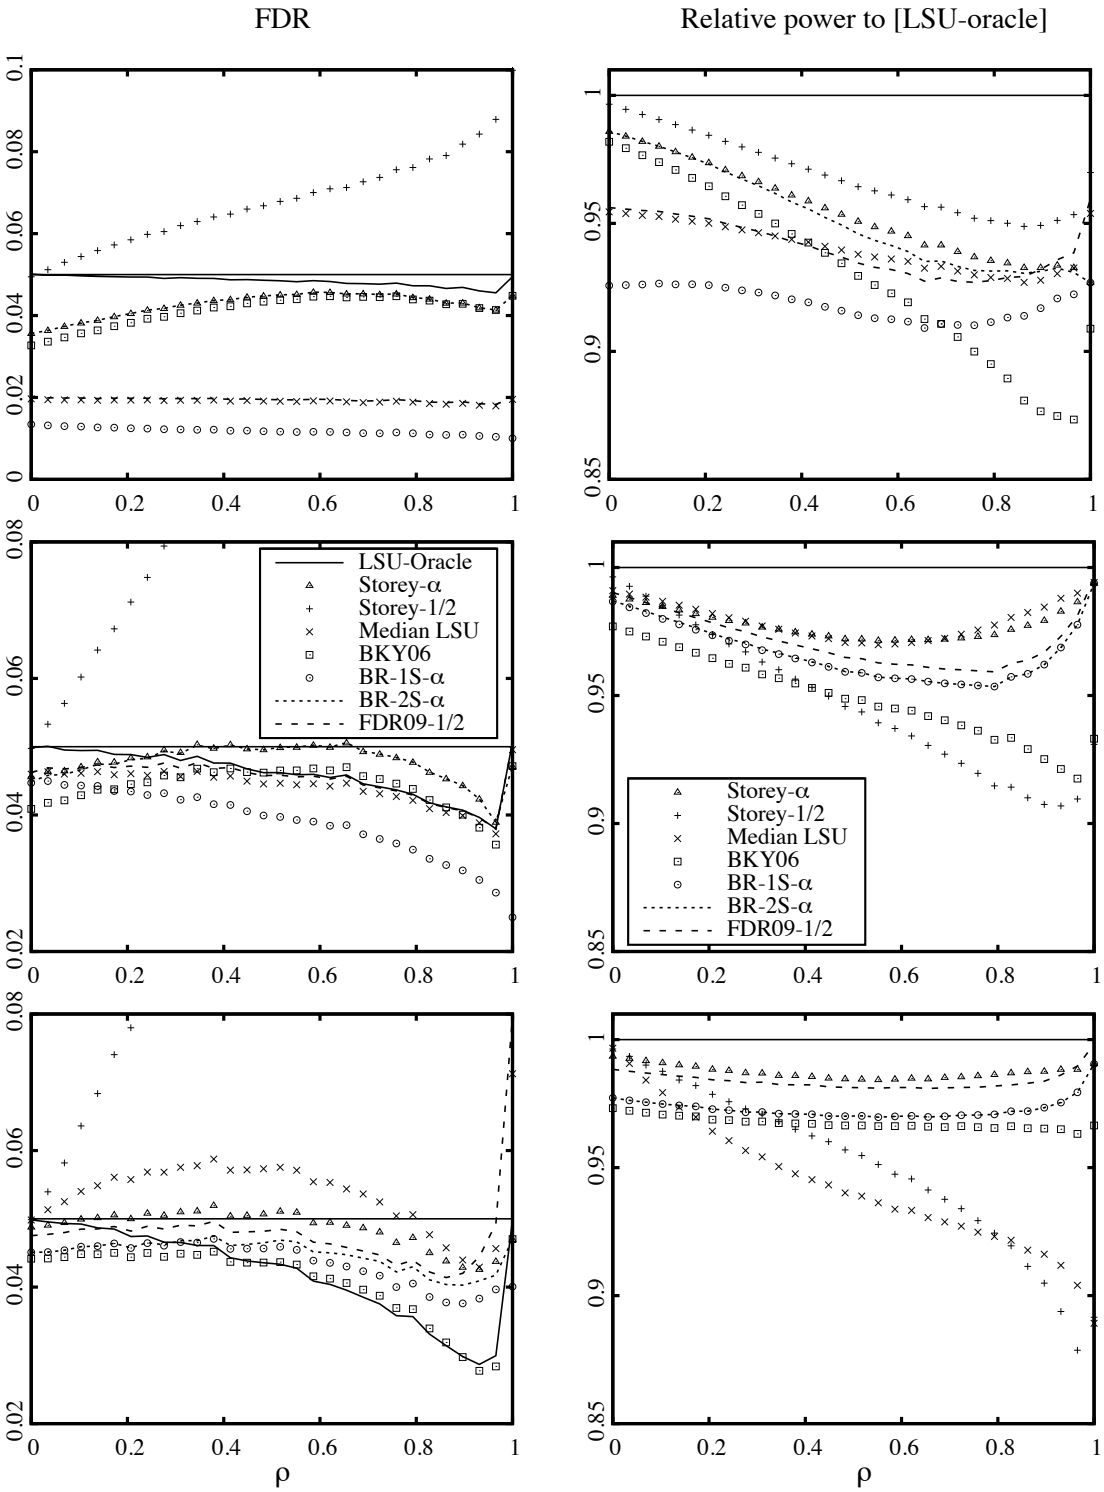

Figure 4: FDR and power relative to oracle as a function of the pairwise correlation coefficient ρ .Target FDR is $\alpha = 5\%$, total number of hypotheses $m = 100$. The mean for the alternatives is $\bar{\mu} = 3$. From top to bottom: proportion of true null hypotheses $\pi_0 \in \{0.2, 0.5, 0.8\}$.

The other remaining procedures seem to exhibit a robust control of the FDR under dependence, or at least their FDR appears to be very close to the target level (except for [FDR09-$\frac{1}{2}$] when ρ and π_0 are close to 1). For these procedures, it seems that the qualitative conclusions concerning power comparison found in the independent case remain true. To sum up:

- the best overall procedure seems to be [Storey-α]: its FDR seems to be under or only slightly over the target level in all situations, and it exhibits globally a power superior to other procedures.
- then come in order of power, our two-stage procedure [BR08-2S-α], then [BKY06-α].
- like in the dependent case, [FDR09-$\frac{1}{2}$] ranks second when $\pi_0 > \frac{1}{2}$ but tends to perform noticeably poorer if π_0 gets smaller. Its FDR is also not controlled if very strong correlations are present.

The overall conclusion we draw from these experiments is that for practical use, we recommend in priority [Storey-α], then as close seconds [BR08-2S-α] or [FDR09-$\frac{1}{2}$] (the latter when it is expected that $\pi_0 > 1/2$, and that there are no very strong correlations present). The procedudre [BKY06-α] is also competitive but appears to be in most cases noticeably outperformed by the above ones. These procedures all exhibit good robustness to dependence for FDR control as well as comparatively good power. The fact that [Storey-α] performs so well and seems to hold the favorite position has up to our knowledge not been reported before (it was not included in the simulations of Benjamini et al., 2006) and came somewhat as a surprise to us.

Remark 18 *As pointed out earlier, the fact that [FDR09-$\frac{1}{2}$] performs sub-optimally for $\pi_0 < \frac{1}{2}$ appears to be strongly linked to the choice of parameter $\eta = \frac{1}{2}$. Namely, the implicit estimator of π_0^{-1} in the procedure is capped at η (see Remark 15). Choosing a higher value for η will reduce the sub-optimality region but increase the variability of the estimate and thus decrease the overall robustness of the procedure (if dependence is present; and also under independence if only a small number m of hypotheses are tested, as for this procedure the convergence of the FDR towards its asymptotically controlled value becomes slower as η grows towards 1).*

Remark 19 *Another two-stage adaptive procedure was introduced in Sarkar (2008a), which is very similar to a plug-in procedure using [Storey-λ]. In fact, in the experiments presented in Sarkar (2008a), the two procedures are almost equivalent, corresponding to $\lambda = 0.995$. We decided not to include this additional procedure in our simulations to avoid overloading the plots. Qualitatively, we observed that the procedures of Sarkar (2008a) or [Storey-0.995] are very similar in behavior to [Storey-$\frac{1}{2}$]: very performant in the independent case but very fragile with respect to deviations from independence.*

Remark 20 *One could formulate the concern that the observed FDR control for [Storey-α] could possibly fail with other parameters settings, for example when π_0 and/or ρ are close to one. We performed additional simulations to this respect (a more detailed report is available on the authors' web pages), which we summarize briefly here. We considered the following cases: $\pi_0 = 0.95$ and varying $\rho \in [0,1]$; $\rho = 0.95$ and varying $\pi_0 \in [0,1]$; finally (π_0, ρ) varying both in $[0.8,1]^2$, using a finer discretization grid to cover this region in more detail. In all the above cases Storey-α still had its FDR very close to (or below) α. Note also that the case $\rho \simeq 1$ and $\pi_0 \simeq 1$ is in accordance with*

the result of Section 3.3, stating that $\mathrm{FDR}(\textit{Storey-}\alpha) = \alpha$ *when* $\rho = 1$ *and* $\pi_0 = 1$. *Finally, we also performed additional experiments for different choices of the number of hypotheses to test (*$m = 20$ *and* $m = 10^4$*) and different choices of the target level (*$\alpha = 10\%, 1\%$*). In all of these cases were the results qualitatively in accordance with the ones already presented here.*

4. New Adaptive Procedures with Provable FDR Control under Arbitrary Dependence

In this section, we consider from a theoretical point of view the problem of constructing multiple testing procedures that are adaptive to π_0 under arbitrary dependence conditions of the *p*-values. The derivation of adaptive procedures that have provably controlled FDR under dependence appears to have been only studied scarcely (see Sarkar, 2008a, and Farcomeni, 2007). Here, we propose to use a two-stage procedure where the first stage is a multiple testing with either controlled FWER or controlled FDR. The first option is relatively straightfoward and is intended as a reference. In the second case, we use Markov's inequality to estimate π_0^{-1}. Since Markov's inequality is general but not extremely precise, the resulting procedures are obviously quite conservative and are arguably of a limited practical interest. However, we will show that they still provide an improvement, in a certain regime, with respect to the (non-adaptive) LSU procedure in the PRDS case and with respect to the family of (non-adaptive) procedures proposed in Theorem 7 in the arbitrary dependence case.

For the purposes of this section, we first recall the formal definition for PRDS dependence of Benjamini and Yekutieli (2001):

Definition 21 (PRDS condition) *Remember that a set* $D \subset [0,1]^{\mathcal{H}}$ *is said to be nondecreasing if for all* $x, y \in [0,1]^{\mathcal{H}}$*, if* $x \leq y$ *coordinate-wise,* $x \in D$ *implies* $y \in D$*. Then, the p-value family* $\mathbf{p} = (p_h, h \in \mathcal{H})$ *is said to be positively regression dependent on each one from* $\mathcal{H}_0$ *(PRDS on* $\mathcal{H}_0$ *in short) if for any nondecreasing measurable set* $D \subset [0,1]^{\mathcal{H}}$ *and for all* $h \in \mathcal{H}_0$*, the function* $u \in [0,1] \mapsto \mathbb{P}[\mathbf{p} \in D \mid p_h = u]$ *is nondecreasing.*

On the one hand, it was proved by Benjamini and Yekutieli (2001) that the LSU still has controlled FDR at level $\pi_0\alpha$ (i.e., Theorem 6 still holds) under the PRDS assumption. On the other hand, under totally arbitrary dependence this result does not hold, and Theorem 7 provides a family of threshold collection resulting in controlled FDR at the same level in this case.

Our first result concerns a two-stage procedure where the first stage R_0 is any multiple testing procedure with controlled FWER, and where we (over-) estimate m_0 via the straightforward estimator $(m - |R_0|)$. This should be considered as a form of baseline reference for this type of two-stage procedure.

Theorem 22 *Let* R_0 *be a nonincreasing multiple testing procedure and assume that its FWER is controlled at level* α_0 *, that is,* $\mathbb{P}[R_0 \cap \mathcal{H}_0 \neq \emptyset] \leq \alpha_0$ *. Then the adaptive step-up procedure R with data-dependent threshold collection* $\Delta(i) = \alpha_1 (m - |R_0|)^{-1} \beta(i)$ *has FDR controlled at level* $\alpha_0 + \alpha_1$ *in either of the following dependence situations:*

- *the p-value family* $(p_h, h \in \mathcal{H})$ *is PRDS on* $\mathcal{H}_0$ *and the shape function is the identity function.*
- *the p-values have unspecified dependence and* β *is a shape function of the form (3).*

Here it is clear that the price for adaptivity is a certain loss in FDR control for being able to use the information of the first stage. If we choose $\alpha_0 = \alpha_1 = \alpha/2$, then this procedure will outperform its

non-adaptive counterpart (using the same shape function) only if there are more than 50% rejected hypotheses in the first stage. Only if it is expected that this situation will occur does it make sense to employ this procedure, since it will otherwise perform worse than the non-adaptive procedure.

Our second result is a two-stage procedure where the first stage has controlled FDR. First introduce, for a fixed constant $\kappa \geq 2$, the following function: for $x \in [0,1]$,

$$F_\kappa(x) = \begin{cases} 1 & \text{if } x \leq \kappa^{-1} \\ \frac{2\kappa^{-1}}{1-\sqrt{1-4(1-x)\kappa^{-1}}} & \text{otherwise} \end{cases}.$$

If R_0 denotes the first stage, we propose using $F_\kappa(|R_0|/m)$ as an (under-)estimation of π_0^{-1} at the second stage. We obtain the following result:

Theorem 23 *Let β be a fixed shape function, and $\alpha_0, \alpha_1 \in (0,1)$ such that $\alpha_0 \leq \alpha_1$. Denote by R_0 the step-up procedure with threshold collection $\Delta_0(i) = \alpha_0\beta(i)/m$. Then the adaptive step-up procedure R with data-dependent threshold collection $\Delta_1(i) = \alpha_1\beta(i)F_\kappa(|R_0|/m)/m$ has FDR upper bounded by $\alpha_1 + \kappa\alpha_0$ in either of the following dependence situations:*

- *the p-value family $(p_h, h \in \mathcal{H})$ is PRDS on $\mathcal{H}_0$ and the shape function is the identity function.*
- *the p-values have unspecified dependence and β is a shape function of the form (3).*

For instance, in the PRDS case, the procedure R of Theorem 23, used with $\kappa = 2$, $\alpha_0 = \alpha/4$ and $\alpha_1 = \alpha/2$, corresponds to the adaptive linear step-up procedure at level $\alpha/2$ with the following estimator for π_0^{-1} :

$$\frac{1}{1-\sqrt{(2|R_0|/m-1)_+}},$$

where $|R_0|$ is the number of rejections of the LSU procedure at level $\alpha/4$.

Whether in the PRDS or arbitrary dependence case, with the above choice of parameters, we note that R is less conservative than the non-adaptive step-up procedure with threshold collection $\Delta(i) = \alpha\beta(i)/m$ if $F_2(|R_0|/m) \geq 2$ or equivalently when R_0 rejects more than $F_2^{-1}(2) = 62,5\%$ of the null hypotheses. Conversely, R is more conservative otherwise, and we can lose up to a factor 2 in the threshold collection with respect to the standard one-stage version. Therefore, here again this adaptive procedure is only useful in the cases where it is expected that a "large" proportion of null hypotheses can easily be rejected. In particular, when we use Theorem 23 under unspecified dependence, it is relevant to choose the shape function β from a distribution ν concentrated on the large numbers of $\{1,\ldots,m\}$. Finally, note that it is not immediate to see if this procedure will improve on the one of Theorem 22. Namely, with the above choice of parameters, procedure of Theorem 22 has the advantage of using a better estimator of π_0^{-1} of the form $(1-x)^{-1} \geq (1-\sqrt{(2x-1)_+})^{-1}$ in the second round (with $x = |R_0|/m$ coming from the first round), but it has the drawback to use a first round controlling the FWER at level $\alpha/2$ which can be much more conservative than controlling the FDR at level $\alpha/4$.

To explore this issue, we performed the two above procedures, in a favorable situation where π_0 is small. Namely, we considered the simulation setting of Section 3.4 with $\rho = 0.1$, $m_0 = 100$ and $m = 1000$ (hence $\pi_0 = 10\%$) and $\alpha = 5\%$. The common value $\bar{\mu}$ of the positive means varies in the range $[0,5]$. Larger values of $\bar{\mu}$ correspond to a very large proportion of hypotheses that are easy to

reject, which favors the first stage of the two above procedures. A positively correlated family of Gaussians satisfies the PRDS assumption (see Benjamini and Yekutieli, 2001), so that we use the identity shape function (linear step-up), and compare our procedures against the standard LSU. For the FWER-controlled first stage of Theorem 22, we chose a standard Holm procedure (see Holm, 1979), which is a step-down procedure with threshold collection $t(i) = \alpha m/(m-i+1)$. In Figure 5, we report the relative power to the oracle LSU, and the False Non-discovery Rate (FNR), which is the converse of the FDR for type II errors, that is, the average of the ratio of non-rejected false hypotheses over the total number of non-rejected hypotheses. Since we are in a situation where π_0 is small, the FNR might actually be a more relevant criterion than the raw power: in this situation, because of the small number of non-rejected hypotheses, two different procedures could have their power very similar and close to 1, but noticeably different FNRs.

The conclusion is that there exists an (unfortunately relatively small) region where the adaptive procedures improve over the standard LSU in terms of power. In terms of FNR, the improvement is more noticeable and over a larger region. Finally, our two-stage adaptive procedure of Theorem 23 appears to outperform consistently the baseline of Theorem 22. These results are still unsatisfying to the extent that the adaptive procedure improves over the non-adaptive one only in a region limited to some quite particular cases, and underperforms otherwise. Nevertheless, this demonstrates theoretically the possibility of provably adaptive procedures under dependence. Again, this theme appears to have been theoretically studied in only a handful of previous works until now, and improving significantly the theory in this setting is still an open challenge.

Remark 24 *Some theoretical results for two-stage procedures under possible dependence using a first stage with controlled FWER or controlled FDR appeared earlier (Farcomeni, 2007). However, it appears that in this reference, it is implicitly assumed that the two stages are actually independent, because the proof relies on a conditioning argument wherein FDR control for the second stage still holds conditionally on the first stage output. This is the case for example if the two stages are performed on separate families of p-values corresponding to a new independent observation. Here we specifically wanted to take into account that we use the same collection of p-values for the two stages, and therefore that the two stages cannot assumed to be independent. In this sense the result of Theorem 22 is novel with respect to that of Farcomeni (2007).*

Remark 25 *The theoretical problem of adaptive procedures under arbitrary dependence was also considered by Sarkar (2008a) using two-stage procedures. However, the procedures proposed there were reported not to yield any significant improvement over non-adaptive procedures.*

5. Conclusion and Discussion

We proposed several adaptive multiple testing procedures that provably control the FDR under different hypotheses on the dependence of the p-values. Firstly, we introduced the one- and two-stage procedures *BR-1S* and *BR-2S* and we proved their theoretical validity when the p-values are independent. The procedure *BR-2S* is less conservative in general (except in marginal situations) than the adaptive procedure proposed by Benjamini et al. (2006). Extensive simulations showed that these new procedures appear to be robustly controlling the FDR even in a positive dependence situation, which is a very desirable property in practice. This is an advantage with respect to the [Storey-$\frac{1}{2}$] procedure, which is less conservative but breaks down under positive dependence. Moreover, our simulations showed that the choice of parameter $\lambda = \alpha$ instead of $\lambda = 1/2$ in the Storey procedure

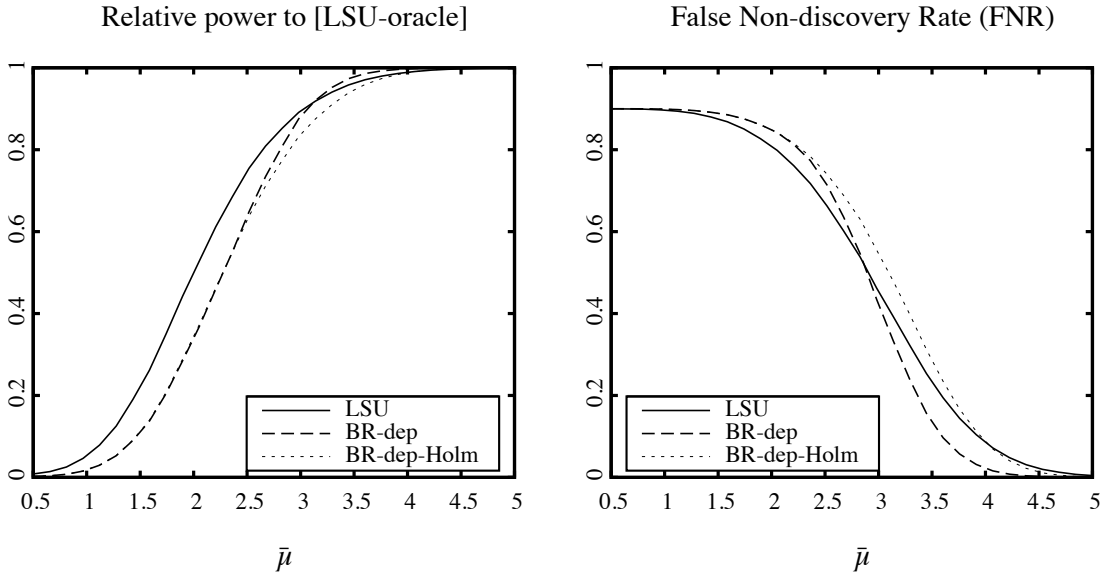

Figure 5: Relative power to oracle and false non-discovery rate (FNR) of the different procedures, as a function of the common alternative hypothesis mean $\bar{\mu}$. Parameters are $\alpha = 5\%$, $m = 1000$, $\pi_0 = 10\%$, $\rho = 0.1$. "BR08-dep-Holm" corresponds to the procedure of Theorem 22 using $\alpha_1 = \alpha_0 = \alpha/2$ and Holm's step-down for the first step, and "BR08-dep" to the procedure of Theorem 23 with $\kappa = 2$, $\alpha_0 = \alpha/4$ and $\alpha_1 = \alpha/2$. The shape function β is the identity function. Each point is estimated by an average over 10^4 independent repetitions.

resulted in a much more robust procedure under positive dependence, at the price of being slightly more conservative. This fact is supported by a theoretical investigation of the maximally dependent case. These properties do not appear to have been reported before, and put forward Storey-α as a procedure of considerable practical interest.

Secondly, we presented what we think is among the first examples of adaptive multiple testing procedures with provable FDR control in the PRDS case and under unspecified dependence. An important difference with respect to earlier works on this topic is that the procedures we introduced here are both theoretically founded and can be shown to improve over non-adaptive procedures in certain (admittedly limited) circumstances. Although their interest at this point is mainly theoretical, this shows in principle that adaptivity can improve performance in a theoretically rigorous way even without the independence assumption.

The proofs of the results have been built upon the notion of *self-consistency* and other technical tools introduced in a previous work (Blanchard and Roquain, 2008). We believe these tools allow for a more unified approach than in the classical adaptive multiple testing literature, avoiding in particular to deal explicitly with the reordered p-values, which can be somewhat cumbersome.

Another advantage of this approach is that it can be extended in a relatively straightforward manner to the case of *weighted FDR*, that is, the quantity (2) where the cardinality measure $|.|$ has been replaced by a general measure $W(R) = \sum_{h \in R} w_h$ (with $W(\mathcal{H}) = \sum_{h \in \mathcal{H}} w_h = m$). This allows

in particular to recover results very similar to those of Benjamini and Heller (2007) and can also be used to prove that a (generalized) Storey estimator can be used to control the weighted FDR. The modifications needed to include this generalizations are relatively minor; we omit the details here and refer the reader to Blanchard and Roquain (2008) to see how the case of weighted FDR can be handled using the same technical tools.

There remains a vast number of open issues concerning adaptive procedures. We first want to underline once more that the theory for adaptive procedures under dependence is still underdeveloped. It might actually be too restrictive to look for procedures having theoretically controlled FDR uniformly over arbitrary dependence situations such as what we studied in Section 4. An interesting future theoretical direction could be to prove that some of the adaptive procedures showing good robustness in our simulations actually have controlled FDR under some types of dependence, at least when the p-values are in some sense not too far from being independent.

6. Proofs

This section collects proofs for all the stated results, following their order of appearance in the text.

6.1 Proofs for Section 3

The following proofs use the notation $\mathbf{p}_{0,h}$ and $\mathbf{p}_{-h}$ defined at the beginning of Section 3.2.

6.1.1 PROOF OF THEOREM 9

Let R denote a nonincreasing self-consistent procedure with respect to Δ defined in (4). By definition, R satisfies

$$R \subset \left\{ h \in \mathcal{H} \mid p_h \leq \min\left((1-\lambda)\frac{\alpha|R|}{m-|R|+1}, \lambda \right) \right\}.$$

Therefore, we have

$$\begin{aligned}
\mathrm{FDR}(R) &= \sum_{h\in\mathcal{H}_0} \mathbb{E}\left[\frac{\mathbf{1}\{h \in R(\mathbf{p})\}}{|R(\mathbf{p})|} \right] \\
&\leq \sum_{h\in\mathcal{H}_0} \mathbb{E}\left[\frac{\mathbf{1}\left\{ p_h \leq (1-\lambda)\frac{\alpha|R(\mathbf{p})|}{m-|R(\mathbf{p})|+1} \right\}}{|R(\mathbf{p})|} \right] \\
&\leq \sum_{h\in\mathcal{H}_0} \mathbb{E}\left[\frac{\mathbf{1}\left\{ p_h \leq (1-\lambda)\frac{\alpha|R(\mathbf{p})|}{m-|R(\mathbf{p}_{0,h})|+1} \right\}}{|R(\mathbf{p})|} \right] \\
&= \sum_{h\in\mathcal{H}_0} \mathbb{E}\left[\mathbb{E}\left[\frac{\mathbf{1}\left\{ p_h \leq (1-\lambda)\frac{\alpha|R(\mathbf{p})|}{m-|R(\mathbf{p}_{0,h})|+1} \right\}}{|R(\mathbf{p})|} \middle| \mathbf{p}_{-h} \right] \right] \\
&\leq (1-\lambda)\alpha \sum_{h\in\mathcal{H}_0} \mathbb{E}\left[\frac{1}{m-|R(\mathbf{p}_{0,h})|+1} \right],
\end{aligned}$$

The second inequality above comes from $|R(\mathbf{p})| \leq |R(\mathbf{p}_{0,h})|$, which itself holds because $|R|$ is coordinate-wise nonincreasing in each p-value. The last inequality is obtained with Lemma 27

of Section 7 with $U = p_h$, $g(U) = |R(\mathbf{p}_{-h}, U)|$ and $c = \frac{(1-\lambda)\alpha}{m-|R(\mathbf{p}_{0,h})|+1}$, because the distribution of p_h conditionally on $\mathbf{p}_{-h}$ is (by independence) identical to its marginal distribution, hence stochastically lower bounded by a uniform variable on $[0,1]$; $|R|$ is coordinate-wise nonincreasing; and because $\mathbf{p}_{0,h}$ depends only on the p-values of $\mathbf{p}_{-h}$. Finally, since the threshold collection of R is upper bounded by λ, we get

$$(1-\lambda)\mathbb{E}\left[m/(m-|R(\mathbf{p}_{0,h})|+1)\right] \leq \mathbb{E}G_1(\mathbf{p}_{0,h}),$$

where G_1 is the Storey estimator with parameter λ. We then use $\mathbb{E}G_1(\mathbf{p}_{0,h}) \leq \pi_0^{-1}$ (see proof of Corollary 13) to conclude. ■

6.1.2 PROOF OF LEMMA 10

Denote $G(t) = \pi_0 t + (1-\pi_0)F(t)$ the c.d.f. of the p-values under the random effects mixture model. Let us denote by $\hat{t}_m$ the threshold of the LSU procedure. The proportion of rejected hypotheses from the initial pool is then exactly $\widehat{G}_m(\hat{t}_m)$, where $\widehat{G}_m$ is the empirical cdf of the p-values. It was proved by Genovese and Wasserman (2002) under the random effects model, that as m tends to infinity the LSU threshold $\hat{t}_m$ converges in probability to $t^\star$, which is the largest point $t \in [0,1]$ such that $G(t) = \alpha^{-1}t$. Since $\widehat{G}_m$ converges in probability uniformly to G , we deduce that the proportion of rejected hypotheses converges to $\alpha^{-1}t^*$ in probability; hence, if $t^* > \alpha^2$, the probability that the proportion of rejected hypotheses is less that $\alpha + 1/m$ converges to zero; and conversely converges to 1 if $t^* < \alpha^2$.

The definition of t^* and the expression for G in the Gaussian mean shift model imply the following relation whenever $t^* > 0$:

$$\mu = \overline{\Phi}^{-1}(t^\star) - \overline{\Phi}^{-1}\left(\frac{\alpha^{-1}-\pi_0}{1-\pi_0}t^\star\right).$$

It is easily seen that if $\pi_0 < (1+\alpha)^{-1}$, the quantity μ^* in the statement of the lemma is well defined and we have $t^* > \alpha^2$ for $\mu > \mu^*$. This gives the first part of the result.

Conversely, if $\pi_0 > (1+\alpha)^{-1}$ we have $t^* = 0$, and if $\pi_0 < (1+\alpha)^{-1}$ but $\mu < \mu^*$, we have $t^* < \alpha^2$; this leads to the second part of the result. ■

6.1.3 PROOF OF THEOREM 11

By definition of self-consistency, the procedure R satisfies

$$R \subset \{h \in \mathcal{H} \mid p_h \leq \alpha |R| G(\mathbf{p})/m\}.$$

Therefore,

$$\mathrm{FDR}(R) = \sum_{h\in\mathcal{H}_0} \mathbb{E}\left[\frac{\mathbf{1}\{h \in R(\mathbf{p})\}}{|R(\mathbf{p})|}\right] \leq \sum_{h\in\mathcal{H}_0} \mathbb{E}\left[\frac{\mathbf{1}\{p_h \leq \alpha |R(\mathbf{p})| G(\mathbf{p})/m\}}{|R(\mathbf{p})|}\right].$$

Since G is nonincreasing, we get:

$$\begin{aligned}
\mathrm{FDR}(R) &\leq \sum_{h\in\mathcal{H}_0} \mathbb{E}\left[\frac{\mathbf{1}\{p_h \leq \alpha |R(\mathbf{p})| G(\mathbf{p}_{0,h})/m\}}{|R(\mathbf{p})|}\right] \\
&= \sum_{h\in\mathcal{H}_0} \mathbb{E}\left[\mathbb{E}\left[\frac{\mathbf{1}\{p_h \leq \alpha |R(\mathbf{p})| G(\mathbf{p}_{0,h})/m\}}{|R(\mathbf{p})|}\middle| \mathbf{p}_{-h}\right]\right] \leq \frac{\alpha}{m}\sum_{h\in\mathcal{H}_0} \mathbb{E}G(\mathbf{p}_{0,h}).
\end{aligned}$$

The last step is obtained with Lemma 27 of Section 7 with $U = p_h$, $g(U) = |R(\mathbf{p}_{-h}, U)|$ and $c = \alpha G(\mathbf{p}_{0,h})/m$, because the distribution of p_h conditionally on $\mathbf{p}_{-h}$ is (by independence) identical to its marginal distribution, hence stochastically lower bounded by a uniform variable; $|R|$ is coordinate-wise nonincreasing; and $\mathbf{p}_{0,h}$ depends only on the p-values of $\mathbf{p}_{-h}$. ■

6.1.4 PROOF OF COROLLARY 12

Assuming $\mathcal{H}_0 \neq \emptyset$ without loss of generality, for $h_0 \in \mathcal{H}_0$ we want to upper bound $\mathbb{E}[G(\mathbf{p}_{0,h_0})]$ appearing in the bound of Theorem 11. Let $\widetilde{\mathbf{p}}_{0,h_0}$ denote the family of p-values $\mathbf{p}_{0,h_0}$ where all p-values p_h , $h \in \mathcal{H} \setminus \mathcal{H}_0$ have been replaced by zero. Since G is nonincreasing, we have $\mathbb{E}[G(\mathbf{p}_{0,h_0})] \leq \mathbb{E}[G(\widetilde{\mathbf{p}}_{0,h_0})]$. Now, for any $h \in \mathcal{H}_0 \setminus \{h_0\}$, denote $\widetilde{\mathbf{p}}'_{0,h_0}$ the family $\widetilde{\mathbf{p}}_{0,h_0}$, where the variable p_h has been replaced by u_h , an independent uniform variable on $[0,1]$. Since both p_h and u_h are independent of the other p-values, p_h is stochastically lower bounded by u_h and G is nonincreasing, we have

$$\mathbb{E}\left[G(\widetilde{\mathbf{p}}_{0,h_0})\middle|\mathbf{p}_{-h}\right] \leq \mathbb{E}\left[G(\widetilde{\mathbf{p}}'_{0,h_0})\middle|\mathbf{p}_{-h}\right] ,$$

hence also in unconditional expectation. Iterating this reasoning in succession for all $h \in \mathcal{H}_0 \setminus \{h_0\}$, we have finally replaced $\mathbf{p}_{0,h_0}$ by a family of $m_0 - 1$ independent uniform variables and $m - m_0 + 1$ zeros, while only increasing the expected value, so that (now using that G is permutation invariant)

$$\mathbb{E}[G(\mathbf{p}_{0,h_0})] \leq \mathbb{E}_{\mathbf{p}\sim DU(m,m_0-1)}[G(\mathbf{p})] ,$$

which, combined with (6), entails the desired result. ■

6.1.5 PROOF OF COROLLARY 13

First, we prove that the sufficient condition of Theorem 11 holds for the nonincreasing estimators G_i, $i = 1,3,4$. To that end, we reproduce here without major changes the arguments used by Benjamini et al. (2006). The bound for G_1 is obtained using Lemma 30 (see below) with $k = m_0$ and $q = 1-\lambda$: for all $h \in \mathcal{H}_0$,

$$\mathbb{E}[G_1(\mathbf{p}_{0,h})] \leq m(1-\lambda)\mathbb{E}\left[\left(\sum_{h' \in \mathcal{H}_0 \setminus \{h\}} \mathbf{1}\{p_{h'} > \lambda\} + 1\right)^{-1}\right] \leq \pi_0^{-1}.$$

The proof for G_3 and G_4 is deduced from the one of G_1 because G_3 and G_4 are smaller than G_1 pointwise.

Secondly, for G_2 we use a somewhat more direct argument than Benjamini et al. (2006), namely using Corollary 12 and proving that $\gamma(G_2, m) \leq 1$. Take $\mathbf{p} \sim DU(m, m_0 - 1)$. On the one hand, if $k_0 \leq m - m_0 + 1$, we have $p_{(k_0)} = 0$, and therefore $\pi_0 G_2(\mathbf{p}) = \pi_0 m/(m - k_0 + 1) \leq 1$ pointwise. On the other hand, if $k_0 \geq m - m_0 + 2$, we have $p_{(k_0)} = q_{(k_0 - m + m_0 - 1)}$, where $q_{(1)} \leq \ldots \leq q_{(m_0-1)}$ are the $(m_0 - 1)$ ordered p-values of $\mathbf{p}$ corresponding to uniform variables. Thus,

$$\pi_0 \mathbb{E}[G_2(\mathbf{p})] = m\pi_0 \frac{1 - \mathbb{E}\left[q_{(k_0-m+m_0-1)}\right]}{m - k_0 + 1} = m\pi_0 \frac{1 - (k_0 - m + m_0 - 1)/m_0}{m - k_0 + 1} = 1.$$

6.1.6 PROOF OF PROPOSITION 17

Let us first consider adaptive one-stage procedures: for any step-up procedure R of threshold $\Delta(i) = \alpha\beta(i)/m$ we easily derive that the probability that R makes any rejection is

$$\mathbb{P}[\exists i \mid p_i \leq \Delta(i)] = \mathbb{P}[\exists i \mid p_1 \leq \Delta(i)] = \mathbb{P}[p_1 \leq \Delta(m)] = \Delta(m),$$

which is FDR(R) because $m_0 = m$. The results for *BR-1S*-λ and *FDR09*-η follow.

With the same reasoning, we find that for any plug-in adaptive linear step-up procedure R that uses an estimator $G(\mathbf{p})$,

$$\mathrm{FDR}(R) = \mathbb{P}\left[p_1 \leq \alpha G(\mathbf{p})\right]. \tag{7}$$

Next, for the Storey plug-in procedure, we have $G_1(p_1,...,p_1) = (1-\lambda)m/(m\mathbf{1}\{p_1 > \lambda\}+1)$, so that applying (7), we get

$$\begin{aligned}\mathrm{FDR}(\textit{Storey-}\lambda) &= \mathbb{P}\left[p_1 \leq \alpha G_1(\mathbf{p})\right] \\ &= \mathbb{P}\left[p_1 \leq \lambda,\, p_1 \leq \alpha(1-\lambda)m\right] + \mathbb{P}\left[p_1 > \lambda,\, p_1 \leq \alpha(1-\lambda)m/(m+1)\right] \\ &= \min\left(\lambda, \alpha(1-\lambda)m\right) + \left(\frac{\alpha(1-\lambda)m}{m+1} - \lambda\right)_+ .\end{aligned}$$

For the quantile procedure, we have

$$\mathbb{P}\left[p_1 \leq \alpha(1-p_1)m/(m-k_0+1)\right] = \mathbb{P}\left[p_1((1+\alpha)m-k_0+1) \leq \alpha m\right] = \frac{\alpha}{1+\alpha-(k_0-1)/m}.$$

For the BKY06 procedure, we simply remark that since the linear step-up procedure of level λ rejects all the hypotheses when $p_1 \leq \lambda$ and rejects no hypothesis otherwise, the estimator G_1 and G_3 are equal in this case. The proof for *BR-2S*-λ is similar. ■

6.2 Proofs for Section 4

We begin with a technical lemma that will be useful for proving both Theorem 22 and 23. It is related to techniques previously introduced by Blanchard and Roquain (2008).

Lemma 26 *Assume R is a multiple testing procedure satisfying the self-consistency condition:*

$$R \subset \left\{h \in \mathcal{H} \mid p_h \leq \alpha G(\mathbf{p})\beta(|R|)/m\right\},$$

where $G(\mathbf{p})$ is a data-dependent factor. Then the following inequality holds:

$$FDR(R) \leq \alpha + \mathbb{E}\left[\frac{|R\cap\mathcal{H}_0|}{|R|}\mathbf{1}\{|R|>0\}\mathbf{1}\left\{G(\mathbf{p}) > \pi_0^{-1}\right\}\right], \tag{8}$$

under either of the following conditions:

- *the p-value family $(p_h, h \in \mathcal{H})$ is PRDS on $\mathcal{H}_0$, R is nonincreasing and β is the identity function.*
- *the p-values have unspecified dependence and β is a shape function of the form (3).*

Proof. We have

$$\begin{aligned}\mathrm{FDR}(R) &= \mathbb{E}\left[\frac{|R\cap\mathcal{H}_0|}{|R|}\mathbf{1}\{|R|>0\}\right] \\ &= \mathbb{E}\left[\frac{|R\cap\mathcal{H}_0|}{|R|}\mathbf{1}\{|R|>0\}\mathbf{1}\left\{G \leq \pi_0^{-1}\right\}\right] + \mathbb{E}\left[\frac{|R\cap\mathcal{H}_0|}{|R|}\mathbf{1}\{|R|>0\}\mathbf{1}\left\{G > \pi_0^{-1}\right\}\right] \\ &\leq \sum_{h\in\mathcal{H}_0}\mathbb{E}\left[\frac{\mathbf{1}\{p_h \leq \alpha\beta(|R|)/m_0\}}{|R|}\right] + \mathbb{E}\left[\frac{|R\cap\mathcal{H}_0|}{|R|}\mathbf{1}\{|R|>0\}\mathbf{1}\left\{G > \pi_0^{-1}\right\}\right].\end{aligned}$$

The desired conclusion will therefore hold if we establish that for any $h \in \mathcal{H}_0$, and $c > 0$:

$$\mathbb{E}\left[\frac{\mathbf{1}\{p_h \leq c\beta(|R|)\}}{|R|}\right] \leq c\,.$$

Under unspecified dependence, this is a direct consequence of Lemma 29 of Section 7 with $U = p_h$ and $V = \beta(|R|)$. For the PRDS case, we note that since $|R(\mathbf{p})|$ is coordinate-wise nonincreasing in each p-value, for any $v > 0$, $D = \{\mathbf{z} \in [0,1]^{\mathcal{H}} \mid |R(\mathbf{z})| < v\}$ is a measurable nondecreasing set, so that the PRDS property implies that $u \mapsto \mathbb{P}[|R| < v \mid p_h = u]$ is nondecreasing. This implies that $u \mapsto \mathbb{P}[|R| < v \mid p_h \leq u]$ by the following argument (see also Lehmann, 1966, cited by Benjamini and Yekutieli, 2001, and Blanchard and Roquain, 2008): putting $\gamma = \mathbb{P}[p_h \leq u \mid p_h \leq u']$,

$$\begin{aligned}\mathbb{P}\left[\mathbf{p} \in D \mid p_h \leq u'\right] &= \mathbb{E}\left[\mathbb{P}[\mathbf{p} \in D \mid p_h] \mid p_h \leq u'\right] \\ &= \gamma\mathbb{E}[\mathbb{P}[\mathbf{p} \in D \mid p_h] \mid p_h \leq u] + (1-\gamma)\mathbb{E}\left[\mathbb{P}[\mathbf{p} \in D \mid p_h] \mid u < p_h \leq u'\right] \\ &\geq \mathbb{E}[\mathbb{P}[\mathbf{p} \in D \mid p_h] \mid p_h \leq u] = \mathbb{P}[\mathbf{p} \in D \mid p_h \leq u]\,.\end{aligned}$$

We can then apply Lemma 28 of Section 7 with $U = p_h$ and $V = |R|$. ■

6.2.1 PROOF OF THEOREM 22

By definition of a step-up procedure, the two-stage procedure R satisfies the assumption of Lemma 26 for $G(\mathbf{p}) = (1 - \frac{|R_0|}{m})^{-1}$, where R_0 is the first stage with FWER controlled at level α_0 . Furthermore, it is easy to check that $|R|$ is nonincreasing as a function of each p-value (since $|R_0|$ is). Then, we can apply Lemma 26, and from inequality (8) we deduce

$$\begin{aligned}FDR(R) &\leq \alpha_1 + \mathbb{E}\left[\frac{|R \cap \mathcal{H}_0|}{|R|}\mathbf{1}\left\{1 - \frac{|R_0|}{m} < \pi_0\right\}\right] \\ &\leq \alpha_1 + \mathbb{P}[R_0 \cap \mathcal{H}_0 \neq \emptyset] \\ &\leq \alpha_0 + \alpha_1\,.\end{aligned}$$

In the case where R_0 rejects all hypotheses, we assumed implicitly that the second stage also does. ■

6.2.2 PROOF OF THEOREM 23

Assume $\pi_0 > 0$ (otherwise the result is trivial). By definition of a step-up procedure, the two-stage procedure R satisfies the assumption of Lemma 26 for $G(\mathbf{p}) = F_\kappa(|R_0|/m)$, where R_0 is the first stage. Furthermore, it is easy to check that $|R|$ is nonincreasing as a function of each p-value (since $|R_0|$ is). Then, we can apply Lemma 26, and from inequality (8) we deduce

$$\begin{aligned}\mathrm{FDR}(R) &\leq \alpha_1 + \mathbb{E}\left[\frac{|R \cap \mathcal{H}_0|}{|R|}\mathbf{1}\left\{F_\kappa(|R_0|/m) > \pi_0^{-1}\right\}\right] \\ &\leq \alpha_1 + m_0\mathbb{E}\left[\frac{\mathbf{1}\left\{F_\kappa(|R_0|/m) > \pi_0^{-1}\right\}}{|R_0|}\right].\end{aligned}$$

For the second inequality, we have used the two following facts:

(i) $F_\kappa(|R_0|/m) > \pi_0^{-1}$ implies $|R_0| > 0$,

(ii) because of the assumption $\alpha_0 \leq \alpha_1$ and $F_\kappa \geq 1$, the output of the second step is necessarily a set containing at least the output of the first step. Hence $|R| \geq |R_0|$.

Let us now concentrate on further bounding this second term. For this, first consider the generalized inverse of F_κ, $F_\kappa^{-1}(t) = \inf\{x \mid F_\kappa(x) > t\}$. Since F_κ is a nondecreasing left-continuous function, we have $F_\kappa(x) > t \Leftrightarrow x > F_\kappa^{-1}(t)$. Furthermore, the expression of F_κ^{-1} is given by: $\forall t \in [1,+\infty), F_\kappa^{-1}(t) = \kappa^{-1}t^{-2} - t^{-1} + 1$ (providing in particular that $F_\kappa^{-1}(\pi_0^{-1}) > 1 - \pi_0$). Hence

$$m_0 \mathbb{E}\left[\frac{\mathbf{1}\left\{F_\kappa(|R_0|/m) > \pi_0^{-1}\right\}}{|R_0|}\right] \leq m_0 \mathbb{E}\left[\frac{\mathbf{1}\left\{|R_0|/m > F_\kappa^{-1}(\pi_0^{-1})\right\}}{|R_0|}\right] \leq \frac{\pi_0}{F_\kappa^{-1}(\pi_0^{-1})} \mathbb{P}\left[|R_0|/m \geq F_\kappa^{-1}(\pi_0^{-1})\right]. \tag{9}$$

Now, by assumption, the FDR of the first step R_0 is controlled at level $\pi_0\alpha_0$, so that

$$\begin{aligned}
\pi_0\alpha_0 &\geq \mathbb{E}\left[\frac{|R_0 \cap \mathcal{H}_0|}{|R_0|}\mathbf{1}\{|R_0| > 0\}\right] \\
&\geq \mathbb{E}\left[\frac{|R_0| + m_0 - m}{|R_0|}\mathbf{1}\{|R_0| > 0\}\right] \\
&= \mathbb{E}\left[\left(1 + (\pi_0 - 1)Z^{-1}\right)\mathbf{1}\{Z > 0\}\right],
\end{aligned}$$

where we denoted by Z the random variable $|R_0|/m$. Hence by Markov's inequality, for all $t > 1 - \pi_0$,

$$\mathbb{P}[Z \geq t] \leq \mathbb{P}\left[\left(1 + (\pi_0 - 1)Z^{-1}\right)\mathbf{1}\{Z > 0\} \geq 1 + (\pi_0 - 1)t^{-1}\right] \leq \frac{\pi_0\alpha_0}{1 + (\pi_0 - 1)t^{-1}};$$

choosing $t = F_\kappa^{-1}(\pi_0^{-1})$ and using this into (9), we obtain

$$m_0 \mathbb{E}\left[\frac{\mathbf{1}\left\{F_\kappa(|R_0|/m) > \pi_0^{-1}\right\}}{|R_0|}\right] \leq \alpha_0 \frac{\pi_0^2}{F_\kappa^{-1}(\pi_0^{-1}) - 1 + \pi_0}.$$

If we want this last quantity to be less than $\kappa\alpha_0$, this yields the condition $F_\kappa^{-1}(\pi_0^{-1}) \geq \kappa^{-1}\pi_0^2 - \pi_0 + 1$, and this is true from the expression of F_κ^{-1} (note that this is how the formula for F_κ was determined in the first place). ■

7. Probabilistic Lemmas

The three following lemmas have been established in a previous work (see Blanchard and Roquain, 2008, Lemma 3.2).

Lemma 27 *Let $g : [0,1] \to (0,\infty)$ be a nonincreasing function. Let U be a random variable which is stochastically lower bounded by a uniform variable on $[0,1]$, that is, $\forall u \in [0,1]$, $\mathbb{P}[U \leq u] \leq u$. Then, for any constant $c > 0$, we have*

$$\mathbb{E}\left[\frac{\mathbf{1}\{U \leq cg(U)\}}{g(U)}\right] \leq c.$$

Lemma 28 *Let U, V be two nonnegative real variables. Assume the following:*

1. *U is stochastically lower bounded by a uniform variable on $[0,1]$, that is, $\forall u \in [0,1]$, $\mathbb{P}[U \leq u] \leq u$.*
2. *The conditional distribution of V given $U \leq u$ is stochastically decreasing in u, that is,*

$$\forall v \geq 0, \qquad \forall 0 \leq u \leq u', \qquad \mathbb{P}[V < v \mid U \leq u] \leq \mathbb{P}\left[V < v \mid U \leq u'\right].$$

Then, for any constant $c > 0$, we have

$$\mathbb{E}\left[\frac{\mathbf{1}\{U \leq cV\}}{V}\right] \leq c.$$

Lemma 29 *Let U, V be two nonnegative real variables and β be a function of the form (3). Assume that U is stochastically lower bounded by a uniform variable on $[0,1]$, that is, $\forall u \in [0,1]$, $\mathbb{P}[U \leq u] \leq u$. Then, for any constant $c > 0$, we have*

$$\mathbb{E}\left[\frac{\mathbf{1}\{U \leq c\beta(V)\}}{V}\right] \leq c.$$

The following lemma was stated by Benjamini et al. (2006). It is a major point when we estimate π_0^{-1} in the independent case. The proof is left to the reader.

Lemma 30 *For any $k \geq 2$, $q \in (0,1]$, let Y be a binomial random variable with parameters $(k-1, q)$; then the following holds:*

$$\mathbb{E}[1/(1+Y)] \leq 1/kq.$$

Abstract

Learning algorithms are based on samples which are often drawn independently from an identical distribution (i.i.d.). In this paper we consider a different setting with samples drawn according to a non-identical sequence of probability distributions. Each time a sample is drawn from a different distribution. In this setting we investigate a fully online learning algorithm associated with a general convex loss function and a reproducing kernel Hilbert space (RKHS). Error analysis is conducted under the assumption that the sequence of marginal distributions converges polynomially in the dual of a Hölder space. For regression with least square or insensitive loss, learning rates are given in both the RKHS norm and the L^2 norm. For classification with hinge loss and support vector machine q-norm loss, rates are explicitly stated with respect to the excess misclassification error.

Keywords: sampling with non-identical distributions, online learning, classification with a general convex loss, regression with insensitive loss and least square loss, reproducing kernel Hilbert space

1. Introduction

In the literature of learning theory, samples for algorithms are often assumed to be drawn independently from an identical distribution. Here we consider a setting with samples drawn from non-identical distributions. Such a framework was introduced in Smale and Zhou (2009) and Steinwart et al. (2008) where online learning for least square regression and off-line support vector machines are investigated. We shall follow this framework and study a kernel based online learning algorithm associated with a general convex loss function. Our analysis can be applied for various purposes including regression and classification.

1.1 Sampling with Non-identical Distributions

Let (X,d) be a metric space called an input space for the learning problem. Let Y be a compact subset of $\mathbb{R}$ (output space) and $Z = X \times Y$.

In our online learning setting, at each step $t = 1,2,\ldots$, a pair $z_t = (x_t, y_t)$ is drawn from a probability distribution $\rho^{(t)}$ on Z. The sampling sequence of probability distributions $\{\rho^{(t)}\}_{t=1,2,\cdots}$ is not identical. For convergence analysis, we shall assume that the sequence $\{\rho_X^{(t)}\}_{t=1,2,\cdots}$ of marginal distributions on X converges polynomially in the dual of the Hölder space $C^s(X)$ for some $0 < s \leq 1$.

Here the Hölder space $C^s(X)$ is defined to be the space of all continuous functions on X with the norm $\|f\|_{C^s(X)} = \|f\|_{C(X)} + |f|_{C^s(X)}$ finite, where $|f|_{C^s(X)} := \sup_{x\neq y} \frac{|f(x)-f(y)|}{(d(x,y))^s}$.

Definition 1 *We say that the sequence $\{\rho_X^{(t)}\}_{t=1,2,\cdots}$ converges polynomially to a probability distribution ρ_X in $(C^s(X))^*$ ($0 \le s \le 1$) if there exist $C > 0$ and $b > 0$ such that*

$$\|\rho_X^{(t)} - \rho_X\|_{(C^s(X))^*} \le Ct^{-b}, \qquad t \in \mathbb{N}. \tag{1}$$

By the definition of the dual space $(C^s(X))^*$, decay condition (1) can be expressed as

$$\left| \int_X f(x) d\rho_X^{(t)} - \int_X f(x) d\rho_X \right| \le Ct^{-b} \|f\|_{C^s(X)}, \qquad \forall f \in C^s(X), t \in \mathbb{N}. \tag{2}$$

What measures quantitatively differences between our non-identical setting and the i.i.d. case is the power index b. Its impact on performance of online learning algorithms will be studied in this paper. The i.i.d. case corresponds to $b = \infty$.

We describe three situations in which decay condition (1) is satisfied. The first is when a distribution ρ_X is perturbed by some noise and the noise level decreases as t increases.

Example 1 *Let $\{h^{(t)}\}$ be a sequence of bounded functions on X such that $\sup_{x\in X} |h^{(t)}(x)| \le Ct^{-b}$. Then the sequence $\{\rho_X^{(t)}\}_{t=1,2,\cdots}$ defined by $d\rho_X^{(t)} = d\rho_X + h^{(t)}(x)d\rho_X$ satisfies (1) for any $0 \le s \le 1$.*

The proof follows from $\left|\int_X f(x)h^{(t)}(x)d\rho_X\right| \le \sup_{x\in X} |h^{(t)}(x)| \|f\|_{C(X)} \le Ct^{-b}\|f\|_{C^s(X)}$. In this example, $h^{(t)}$ is the density function of the noise distribution and we assume its bound (noise level) to decay polynomially as t increases.

The second situation when decay condition (1) is satisfied is generated by iterative actions of an integral operator associated with a stochastic density kernel. We demonstrate this situation by an example on $X = S^{n-1}$, the unit sphere of $\mathbb{R}^n$ with $n \ge 2$. Let dS be the normalized surface element of S^{n-1}. The corresponding space $L^2(S^{n-1})$ has an orthonormal basis $\{Y_{\ell,k} : \ell \in \mathbb{Z}_+, k = 1, \ldots, N(n,\ell)\}$ with $N(n,0) = 1$ and $N(n,\ell) = \frac{2\ell+n-2}{\ell} \frac{(\ell+n-3)!(n-2)!}{(\ell-1)!}$. Here $Y_{\ell,k}$ is a spherical harmonic of order ℓ which is the restriction onto S^{n-1} of a homogeneous polynomial in $\mathbb{R}^n$ of degree ℓ satisfying the Laplace equation $\Delta f = 0$. In particular, $Y_{0,0} \equiv 1$.

Example 2 *Let $X = S^{n-1}$, $0 < \alpha < 1$, and $\psi \in C(X \times X)$ be given by*

$$\psi(x,u) = 1 + \sum_{\ell=1}^{\infty} \sum_{k=1}^{N(n,\ell)} a_{\ell,k} Y_{\ell,k}(x) Y_{\ell,k}(u) \quad \textit{where} \quad 0 \le a_{\ell,k} \le \alpha, \ \sum_{\ell=1}^{\infty} \sum_{k=1}^{N(n,\ell)} a_{\ell,k} \|Y_{\ell,k}\|_{C(X)}^2 < 1.$$

If $h^{(1)}$ is a square integrable density function on X and a sequence of density functions $\{h^{(t)}\}$ is defined by

$$h^{(t+1)}(x) = \int_X \psi(x,u) h^{(t)}(u) dS(u), \qquad x \in X, \ t \in \mathbb{N},$$

then we know $h^{(t)} = Y_{0,0} + \sum_{\ell=1}^{\infty} \sum_{k=1}^{N(n,\ell)} a_{\ell,k}^{t-1} \langle h^{(1)}, Y_{\ell,k} \rangle_{L^2(S^{n-1})} Y_{\ell,k}$ and $\|h^{(t)} - Y_{0,0}\|_{L^2(S^{n-1})} \le \alpha^{t-1} \|h^{(1)}\|_{L^2(S^{n-1})}$. It follows that the sequence $\{\rho_X^{(t)} = h^{(t)}(x)dS\}_{t=1,2,\cdots}$ of probability distributions on X converges polynomially to the uniform distribution $d\rho_X = dS$ on X and satisfies (1) for any $0 \le s \le 1$.

In general, if ν is a strictly positive probability distribution on X, and if $\psi \in C(X \times X)$ is strictly positive satisfying $\int_X \psi(x,u)d\nu(u) = 1$ for each $x \in X$, then the sequence $\{\rho_X^{(t)}\}$ defined by

$$\rho_X^{(t)}(\Gamma) = \int_\Gamma \left\{ \int_X \psi(x,u) d\rho_X^{(t-1)}(x) \right\} d\nu(u) \qquad \text{on Borel sets} \quad \Gamma \subseteq X$$

satisfies $\|\rho_X^{(t)} - \rho_X\|_{(C(X))^*} \leq C\alpha^t$ for some (strictly positive) probability distribution ρ_X on X and constants $C > 0, 0 < \alpha < 1$. Hence decay condition (1) is valid for any $0 \leq s \leq 1$. For details, see Smale and Zhou (2009).

The third situation to realize decay condition (1) is to induce distributions by dynamical systems. Here we present a simple example.

Example 3 *Let $X = [-1/2, 1/2]$ and for each $t \in \mathbb{N}$, the probability distribution $\rho_X^{(t)}$ on X has support $[-2^{-t}, 2^{-t}]$ and uniform density 2^{t-1} on its support. Then with δ_0 being the delta distribution at the origin, for each $0 < s \leq 1$ we have*

$$\left| \int_X f(x) d\rho_X^{(t)} - \int_X f(x) d\delta_0 \right| \leq 2^{t-1} \int_{-2^{-t}}^{2^{-t}} |f(x) - f(0)| dx \leq \left(2^{-s}\right)^t \|f\|_{C^s(X)}.$$

Remark 2 *Since $\|f\|_{C(X)} \leq \|f\|_{C^s(X)}$, we see from (2) that decay condition (1) with any $0 < s \leq 1$ is satisfied when this polynomial convergence requirement is valid in the case $s = 0$. This happens in Examples 1 and 2. Note that when $s = 0$, the dual space $(C(X))^*$ is exactly the space of signed finite measures on X. Each signed finite measure μ on X lies in $(C(X))^* \subset (C^s(X))^*$ and satisfies $\|\mu\|_{(C^s(X))^*} \leq \|\mu\|_{(C(X))^*} \leq \int_X d|\mu|$.*

1.2 Fully Online Learning Algorithm

In this paper we study a family of online learning algorithms associated with reproducing kernel Hilbert spaces and a general convex loss function.

A *reproducing kernel Hilbert space* (RKHS) is induced by a *Mercer kernel* $K : X \times X \to \mathbb{R}$ which is a continuous and symmetric function such that the matrix $(K(x_i, x_j))_{i,j=1}^\ell$ is positive semidefinite for any finite set of points $\{x_1, \cdots, x_\ell\} \subset X$. The RKHS $\mathcal{H}_K$ is the completion (Aronszajn, 1950) of the span of the set of functions $\{K_x = K(x, \cdot) : x \in X\}$ with the inner product given by $\langle K_x, K_y \rangle_K = K(x,y)$.

Definition 3 *We say that $V : Y \times \mathbb{R} \to \mathbb{R}_+$ is a convex loss function if for each $y \in Y$, the univariate function $V(y, \cdot) : \mathbb{R} \to \mathbb{R}_+$ is convex.*

The convexity tells us (Rockafellar, 1970) that for each $f \in \mathbb{R}$ and $y \in Y$, the left derivative $\lim_{\delta \to 0-}(V(y, f+\delta) - V(y,f))/\delta$ exists and is no more than the right derivative $\lim_{\delta \to 0+}(V(y, f+\delta) - V(y,f))/\delta$. An arbitrary number between them (which is a gradient) will be taken and denoted as $\partial V(y,f)$ in our algorithm.

For the least square regression problem, we can take $V(y,f) = (y-f)^2$. For the binary classification problem, we can take $V(y,f) = \phi(yf)$ with $\phi : \mathbb{R} \to \mathbb{R}_+$ a convex function.

The online algorithm associated with the RKHS $\mathcal{H}_K$ and the convex loss V is a stochastic gradient descent method (Cesa-Bianchi et al., 1996; Kivinen et al., 2004; Smale and Yao, 2006; Ying and Zhou, 2006; Ying, 2007).

Definition 4 *The fully online learning algorithm is defined by* $f_1 = 0$ *and*

$$f_{t+1} = f_t - \eta_t \{\partial V(y_t, f_t(x_t))K_{x_t} + \lambda_t f_t\}, \text{ for } t = 1, 2, \ldots, \tag{3}$$

where $\lambda_t > 0$ *is called the regularization parameter and* $\eta_t > 0$ *the step size.*

In this fully online algorithm, the regularization parameter λ_t changes with the learning step t. Throughout the paper we assume that $\lambda_{t+1} \leq \lambda_t$ for each $t \in \mathbb{N}$. When the regularization parameter $\lambda_t \equiv \lambda_1$ does not change as the step t develops, we call scheme (3) *partially online*.

The goal of this paper is to investigate the fully online learning algorithm (3) when the sampling sequence is not identical. We will show that learning rates in the non-identical setting can be the same as those in the i.i.d. case when the power index b in polynomial decay condition (1) is large enough, that is, $\{\rho_X^{(t)}\}$ converges fast to ρ_X. When b is small, the non-identical effect becomes crucial and the learning rates will depend essentially on b.

2. Error Bounds for Regression and Classification

As in the work on least square regression (Smale and Zhou, 2009), we assume for the sampling sequence $\{\rho^{(t)}\}_{t=1,2,\cdots}$ that the conditional distribution $\rho^{(t)}(y|x)$ of each $\rho^{(t)}$ at $x \in X$ is independent of t, denoted as ρ_x.

Throughout the paper we assume independence of the sampling, that is, $\{z_t = (x_t, y_t)\}_t$ is a sequence of samples drawn from the product probability space $\Pi_{t=1,2,\cdots}(Z, \rho^{(t)})$.

Error analysis will be conducted for fully online learning algorithm (3) under polynomial decay condition (1) for the sequence of marginal distributions $\{\rho_X^{(t)}\}$. Let ρ be the probability distribution on Z given by the marginal distribution ρ_X and the conditional distributions ρ_x. Essential difficulty in our non-identical setting is caused by the deviation of $\{\rho^{(t)}\}$ from ρ.

The first novelty of our analysis is to deal with an error quantity Δ_t involving $\rho^{(t)} - \rho$ (defined by (15) below) which occurs only in the non-identical setting. This is handled for a general loss function V and output space Y by Lemma 18 in Section 3 under decay condition (1) for marginal distributions $\{\rho_X^{(t)}\}$ and Lipschitz s continuity of conditional distributions $\{\rho_x : x \in X\}$.

Definition 5 *We say that the set of distributions* $\{\rho_x : x \in X\}$ *is Lipschitz* s *in* $(C^s(Y))^*$ *if there exists a constant* $C_\rho \geq 0$ *such that*

$$\|\rho_x - \rho_u\|_{(C^s(Y))^*} \leq C_\rho (d(x,u))^s, \qquad \forall x, u \in X. \tag{4}$$

Notice that on the compact subset Y of $\mathbb{R}$, the Hölder space $C^s(Y)$ and its dual $(C^s(Y))^*$ are well defined. Each ρ_x belongs to $(C^s(Y))^*$.

The second novelty of our analysis is to show for the least square loss (described in Section 3) and binary classification that Lipschitz s continuity (4) of $\{\rho_x : x \in X\}$ is the same as requiring $f_\rho \in C^s(X)$ where f_ρ is the *regression function* defined by

$$f_\rho(x) = \int_Y y d\rho_x(y), \qquad x \in X. \tag{5}$$

Proposition 6 *Let* $0 < s \leq 1$. *Condition (4) implies* $f_\rho \in C^s(X)$ *with* $|f_\rho|_{C^s(X)} \leq C_\rho(1 + 2^{1-s}) \sup_{y \in Y} |y|$. *When* $Y = \{1, -1\}$, $f_\rho \in C^s(X)$ *also implies (4) and* $C_\rho \leq |f_\rho|_{C^s(X)}$.

The two-point nature of the output space Y for binary classification plays a crucial role in our observation. The second statement of Proposition 6 is not true for general output space Y. Here is one example.

Example 4 *Let $0 < s \leq 1$ and $Y = \{1, -1, 0\}$. Then condition (4) holds if and only if $f_\rho \in C^s(X)$ and $f_{\rho,-1} \in C^s(X)$ where $f_{\rho,-1}$ is the function on X given by $f_{\rho,-1}(x) = \rho_x(\{-1\})$.*

Proofs of Proposition 6 and Example 4 will be given in the appendix.

Our third novelty is to understand some essential differences between our non-identical setting and the classical i.i.d. setting by pointing out the key role played by the power index b of polynomial decay condition $\|\rho_X^{(t)} - \rho_X\|_{(C^s(X))^*} \leq Ct^{-b}$ in derived convergence rates in Theorems 7 and 10 for regression and Theorem 11 for classification. Even for least square regression our result improves the error analysis in Smale and Zhou (2009) where a stronger exponential decay condition $\|\rho_X^{(t)} - \rho_X\|_{(C^s(X))^*} \leq C\alpha^t$ is assumed.

Our error bounds for fully online algorithm (3) are comparable with those for a batch learning algorithm generated by the off-line regularization scheme in $\mathcal{H}_K$ defined with a sample $\mathbf{z} := \{z_t = (x_t, y_t)\}_{t=1}^T$ and a regularization parameter $\lambda > 0$ as

$$f_{\mathbf{z},\lambda} = \arg\min_{f \in \mathcal{H}_K} \left\{ \frac{1}{T} \sum_{t=1}^{T} V(y_t, f(x_t)) + \frac{\lambda}{2} \|f\|_K^2 \right\}. \tag{6}$$

Let us demonstrate our error analysis by learning rates for regression with least square loss and insensitive loss and for binary classification with hinge loss.

2.1 Learning Rates for Least Square Regression

Here we take $Y = [-M, M]$ for some $M > 0$ and the least square loss $V = V_{ls}$ as $V_{ls}(y, f) = (y - f)^2$. Then the algorithm takes the form

$$f_{t+1} = f_t - 2\eta_t \left\{ (f_t(x_t) - y_t) K_{x_t} + \frac{\lambda_t}{2} f_t \right\}, \text{ for } t = 1, 2, \ldots$$

The following learning rates are derived by the procedure in Smale and Zhou (2009) where an exponential decay condition is assumed. Here we only impose a much weaker polynomial decay condition (1). We also assume the regularity condition (of order $r > 0$)

$$f_\rho = L_K^r(g_\rho) \text{ for some } g_\rho \in L^2_{\rho_X}(X), \tag{7}$$

where L_K is the integral operator $L^2_{\rho_X}$ defined by

$$L_K f(x) = \int_X K(x, v) f(v) d\rho_X(v), \qquad x \in X$$

with L_K^r well-defined as a compact operator.

Theorem 7 *Let $0 < s \leq \frac{1}{2}$ and $\frac{1}{2} < r \leq \frac{3}{2}$. Assume $K \in C^{2s}(X \times X)$, regularity condition (7) for f_ρ and (1) with $b > \frac{2r+2}{2r+1}$ for $\{\rho_X^{(t)}\}$. Take*

$$\lambda_t = \lambda_1 t^{-\frac{1}{2r+1}}, \quad \eta_t = \eta_1 t^{-\frac{2r}{2r+1}}$$

with $\lambda_1\eta_1 > \frac{2r-1}{4r+2}$, *then*

$$\mathbb{E}_{z_1,\ldots,z_T}\left(\|f_{T+1}-f_\rho\|_K\right) \le \widetilde{C}T^{-\frac{2r-1}{4r+2}},$$

where $\widetilde{C}$ *is a constant independent of* T.

Denote the constant $\kappa = \max_{x\in X}\sqrt{K(x,x)}$. From the reproducing property

$$\langle K_x, f\rangle_K = f(x), \qquad x\in X,\ f\in\mathcal{H}_K \tag{8}$$

of the RKHS $\mathcal{H}_K$, we see that

$$\|f\|_{C(X)} \le \kappa\|f\|_K, \qquad \forall x\in X, f\in\mathcal{H}_K.$$

Most error analysis in the literature of least square regression (Zhang, 2004; De Vito et al., 2005; Smale and Yao, 2006; Wu et al., 2007) is about the L^2-norm $\|f_{T+1}-f_\rho\|_{L^2_{\rho_X}}$ or risk in the i.i.d. case. From a predictive viewpoint, in the non-identical setting, the error $f_{T+1}-f_\rho$ should be measured with respect to the distribution $\rho_X^{(T)}$, not the limit ρ_X. This can be done by bounding $\|f_{T+1}-f_\rho\|_{C(X)}$ (since $\rho_X^{(T)}$ changes with T), which follows from estimates for $\|f_{T+1}-f_\rho\|_K$. So our bounds for the error in the $\mathcal{H}_K$-norm provides useful predictive information about learning ability of fully online algorithm (3) in the non-identical setting.

Remark 8 *When* $X\subset\mathbb{R}^n$ *and* $K\in C^{2m}(X\times X)$ *for some* $m\in\mathbb{N}$, *we know from Zhou (2003, 2008) and Theorem 7 that* $\mathbb{E}_{z_1,\ldots,z_T}\left(\|f_{T+1}-f_\rho\|_{C^m(X)}\right) = O(T^{-\frac{2r-1}{4r+2}})$. *So the regression function is learned efficiently by the online algorithm not only in the usual* $L^2_{\rho_X}$ *space, but also strongly in the space* $C^m(X)$ *implying the learning of gradients (Mukherjee and Wu, 2006).*

In the special case of $r=\frac{3}{2}$, the learning rate in Theorem 7 is $\mathbb{E}_{z_1,\ldots,z_T}\left(\|f_{T+1}-f_\rho\|_K\right) = O(T^{-\frac{1}{4}})$, the same as those in the literature (Smale and Zhou, 2009; Tarrès and Yao, 2005; Smale and Zhou, 2007). Here we assume polynomial convergence condition (1) with a large index $b > \frac{2r+2}{2r+1}$. So the influence of the non-identical distributions $\{\rho_X^{(t)}\}$ does not appear in the learning rates (it is involved in the constant $\widetilde{C}$). Instead of refining the analysis for smaller b in Theorem 7, we shall show the influence of the index b on learning rates by the settings of regression with insensitive loss and binary classification.

2.2 Learning Rates for Regression with Insensitive Loss

A large family of loss functions for regression take the form $V(y,f)=\psi(y-f)$ where $\psi:\mathbb{R}\to\mathbb{R}_+$ is an even, convex and continuous function satisfying $\psi(0)=0$. One example is the ε-insensitive loss (Vapnik, 1998) with $\varepsilon\ge 0$ where $\psi(u)=\max\{|u|-\varepsilon,0\}$. We consider the case when $\varepsilon=0$. In this case the loss is called least absolute deviation or least absolute error in the literature of statistics and finds applications in some important problems because of robustness.

Definition 9 *The insensitive loss* $V=V_{in}$ *is given by* $V_{in}(y,f)=|y-f|$.

Algorithm (3) now takes the form

$$f_{t+1} = \begin{cases} (1-\eta_t\lambda_t)f_t - \eta_t K_{x_t}, & \text{if } f_t(x_t)\ge y_t,\\ (1-\eta_t\lambda_t)f_t + \eta_t K_{x_t}, & \text{if } f_t(x_t)< y_t. \end{cases}$$

The following learning rates are new and will be proved in Section 5.

Theorem 10 *Let $0 < s \le \frac{1}{2}$ and $K \in C^{2s}(X \times X)$. Assume regularity condition (7) for f_ρ with $r > \frac{1}{2}$, and polynomial convergence condition (1) for $\{\rho_X^{(t)}\}$. Suppose that for each $x \in X$, ρ_x is the uniform distribution on the interval $[f_\rho(x) - 1, f_\rho(x) + 1]$. If $\lambda_1 \le (\kappa \|g_\rho\|_{L^2_{\rho_X}})^{2/(1-2r)}/2$ and $\eta_1 > 0$, then with a constant $\widetilde{C}$ independent of T, when $1 < r \le \frac{3}{2}$ we have*

$$\mathbb{E}_{z_1,\dots,z_T}\left(\|f_{T+1} - f_\rho\|_K\right) \le \widetilde{C} T^{-\min\{\frac{2r-1}{6r+1}, \frac{b}{2} - \frac{2}{6r+1}\}} \quad \text{by taking } \lambda_t = \lambda_1 t^{-\frac{2}{6r+1}},\ \eta_t = \eta_1 t^{-\frac{4r}{6r+1}}$$

and when $\frac{1}{2} < r \le 1$, we have

$$\mathbb{E}_{z_1,\dots,z_T}\left(\|f_{T+1} - f_\rho\|_{L^2_{\rho_X}}\right) \le \widetilde{C} T^{-\min\{\frac{r}{3r+2}, \frac{b}{2} - \frac{1}{3r+2}\}} \quad \text{with } \lambda_t = \lambda_1 t^{-\frac{1}{3r+2}},\ \eta_t = \eta_1 t^{-\frac{2r+1}{3r+2}}.$$

Again, when $b > \frac{4r+2}{6r+1}$, $X \subset \mathbb{R}^n$ and $K \in C^{2m}(X \times X)$ for some $m \in \mathbb{N}$, Theorem 10 tells us that $\mathbb{E}_{z_1,\dots,z_T}\left(\|f_{T+1} - f_\rho\|_{C^m(X)}\right) = O(T^{-\frac{2r-1}{6r+1}})$. So the regression function is learned efficiently by the online algorithm not only with respect to the risk, but also strongly in the space $C^m(X)$ implying the learning of gradients.

Consider the case $r = \frac{3}{2}$. When $\{\rho_X^{(i)}\}$ converges slowly with $b < \frac{4}{5}$, we see that $\mathbb{E}_{z_1,\dots,z_T}\left(\|f_{T+1} - f_\rho\|_K\right) = O(T^{-(\frac{b}{2} - \frac{1}{5})})$ which heavily depends on the index b representing quantitatively the deviation of $\{\rho_X^{(t)}\}$ from ρ_X. When b is large enough with $b \ge \frac{4}{5}$, the learning rate $\mathbb{E}_{z_1,\dots,z_T}\left(\|f_{T+1} - f_\rho\|_K\right)$ is of order $T^{-\frac{1}{5}}$ which is independent of b.

It would be interesting to extend Theorem 10 to situations when $\{\rho_x : x \in X\}$ are more general bounded symmetric distributions.

2.3 Learning Rates for Binary Classification

The output space Y for the binary classification problem is $Y = \{1, -1\}$ representing the set of two classes. A binary *classifier* $C : X \to Y$ makes a prediction $y = C(x) \in Y$ for each point $x \in X$.

A real valued function $f : X \to \mathbb{R}$ can be used to generate a classifier $C(x) = \operatorname{sgn}(f(x))$ where $\operatorname{sgn}(f(x)) = 1$ if $f(x) \ge 0$ and $\operatorname{sgn}(f(x)) = -1$ if $f(x) < 0$. A classifying convex loss $\phi : \mathbb{R} \to \mathbb{R}_+$ is often used for the real valued function f, to measure the local error $\phi(yf(x))$ suffered from the use of $\operatorname{sgn}(f)$ as a model for the process producing y at $x \in X$. Take $V(y, f) = \phi(yf)$ in out setting. Off-line classification algorithm (6) has been extensively studied in the literature. In particular, the error analysis is well done when the sample $\mathbf{z}$ is assumed to be an identical and independent drawer from a probability measure ρ on Z. See, for example, Evgeniou et al. (2000), Steinwart (2002), Zhang (2004) and Wu et al. (2007). Some analysis for off-line support vector machines with dependent samples can be found in Steinwart et al. (2008).

When the sample size T is very large, algorithm (6) might be practically challenging. Then online learning algorithms can be applied, which provide more efficient methods for classification. These algorithms are generalizations of the perceptron which has a long history. The error analysis for online algorithm (3) has also been conducted for classification in the i.i.d. setting, see, for example, Cesa-Bianchi et al. (2004), Ying and Zhou (2006), Ying (2007) and Ye and Zhou (2007).

Here we are interested in the error analysis for fully online algorithm (3) in the non-identical setting. The error is measured by the *misclassification error* $\mathcal{R}(C)$ defined to be the probability of the event $\{C(x) \ne y\}$ for a classifier C

$$\mathcal{R}(C) = \int_X \rho_x(y \ne C(x)) d\rho_X(x) = \int_X \rho_x(\{-C(x)\}) d\rho_X(x).$$

The best classifier minimizing the misclassification error is called the *Bayes rule* (e.g., Devroye et al. 1997) and can be expressed as $f_c = \mathrm{sgn}(f_\rho)$.

We are interested in the classifier $\mathrm{sgn}(f_{T+1})$ produced by the real valued function f_{T+1} using fully online learning algorithm (3). So our error analysis aims at the *excess misclassification error* $\mathcal{R}(\mathrm{sgn}(f_{T+1})) - \mathcal{R}(f_c)$.

We demonstrate our error analysis by a result, proved in Section 5, for the *hinge loss* $\phi(x) = (1-x)_+ = \max\{1-x, 0\}$. For this loss, the online algorithm (3) can be expressed as $f_1 = 0$ and

$$f_{t+1} = \begin{cases} (1-\eta_t\lambda_t)f_t, & \text{if } y_t f_t(x_t) > 1, \\ (1-\eta_t\lambda_t)f_t + \eta_t y_t K_{x_t}, & \text{if } y_t f_t(x_t) \le 1. \end{cases}$$

Theorem 11 *Let $V(y,f) = (1-yf)_+$ and $K \in C^{2s}(X \times X)$ for some $0 < s \le \frac{1}{2}$. Assume $f_\rho \in C^s(X)$ and the triple (ρ_X, f_c, K) satisfies*

$$\inf_{f \in \mathcal{H}_K} \{\|f - f_c\|_{L^1_{\rho_X}} + \frac{\lambda}{2}\|f\|_K^2\} \le \mathcal{D}_0 \lambda^\beta \qquad \forall \lambda > 0 \tag{9}$$

for some $0 < \beta \le 1$ and $\mathcal{D}_0 > 0$. Take

$$\lambda_t = \lambda_1 t^{-\frac{1}{4}}, \eta_t = \eta_1 t^{-(\frac{1}{2}+\frac{\beta}{12})}$$

where $\lambda_1 > 0$ and $0 < \eta_1 \le \frac{1}{2\kappa^2+\lambda_1}$. If $\{\rho_X^{(t)}\}_{t=1,2,\cdots}$ satisfies (1) with $b > \frac{1}{2}$, then

$$\mathbb{E}_{z_1,\ldots,z_T}\left(\mathcal{R}(sgn(f_{T+1})) - \mathcal{R}(f_c)\right) \le C_{\beta,s,b} T^{-\min\{\frac{\beta}{4}, \frac{1}{8}+\frac{\beta}{24}, \frac{b}{2}-\frac{1}{4}\}}, \tag{10}$$

where $C_{\beta,s,b} = C_{\eta_1,\lambda_1,\kappa,\mathcal{D}_0,\beta,s}$ is a constant depending on $\eta_1, \lambda_1, \kappa, \mathcal{D}_0, \beta, s$ and b.

In the i.i.d. case with $b = \infty$, the learning rate for fully online algorithm (3) we state in Theorem 11 is of form $O(T^{-\min\{\frac{\beta}{4}, \frac{1}{8}+\frac{\beta}{24}\}})$ which is better than that in Ye and Zhou (2007) of order $O(T^{-\min\{\frac{\beta}{4}, \frac{1}{8}-\frac{\varepsilon}{2}\}})$ with an arbitrarily small $\varepsilon > 0$. This improvement is realized by technical novelty in our error analysis, as pointed out in Remark 27. So even in the i.i.d. case, our learning rate for fully online classification with the hinge loss under approximation error assumption (9) is the best in the literature.

Let us discuss the role of the power index b for the convergence of $\{\rho_X^{(t)}\}$ to ρ_X played in the learning rate in Theorem 11. Consider the case $\beta \le \frac{3}{5}$. When $b \ge \frac{1+\beta}{2}$ meaning fast convergence of $\{\rho_X^{(t)}\}$ to ρ_X, learning rate (10) takes the form $O(T^{-\frac{\beta}{4}})$ which depends only on the approximation ability of $\mathcal{H}_K$ with respect to the function f_c and ρ_X. When $\frac{1}{2} < b < \frac{1+\beta}{2}$ representing some slow convergence of $\{\rho_X^{(t)}\}$ to ρ_X, the learning rate takes the form $O(T^{-\frac{2b-1}{4}})$ which depends only on b.

When $\beta > \frac{3}{5}$, learning rate (10) is of order $T^{-(\frac{1}{8}+\frac{\beta}{24})}$ for $b > \frac{3}{4} + \frac{\beta}{12}$ (fast convergence of $\{\rho_X^{(t)}\}$) and of order $T^{-(\frac{b}{2}-\frac{1}{4})}$ for $\frac{1}{2} < b \le \frac{3}{4} + \frac{\beta}{12}$ (slow convergence of $\{\rho_X^{(t)}\}$). It would be interesting to know how online learning algorithms adapt when the time dependent distribution drifts sufficiently slowly (corresponding to very small b).

2.4 Approximation Error Involving a General Loss

Condition (9) concerns the approximation of the function f_c in the space $L^1_{\rho_X}$ by functions from the RKHS $\mathcal{H}_K$. In particular, when $\mathcal{H}_K$ is a dense subset of $C(X)$ (i.e., K is a universal kernel), the quantity on the left-hand side of (9) tends to 0 as $\lambda \to 0$. So (9) is a reasonable assumption, which can be characterized by an interpolation space condition (Smale and Zhou, 2003; Chen et al., 2004).

Assumptions like (9) are necessary to determine the regularization parameter for achieving learning rate (10). This can be seen from the literature (Wu et al., 2007; Zhang, 2004; Caponnetto et al., 2007) of off-line algorithm (6): learning rates are obtained by suitable choices of the regularization parameter $\lambda \equiv \lambda_1 = \lambda_1(T)$, according to the behavior of the approximation error estimated from a priori conditions on the distribution ρ and the space $\mathcal{H}_K$.

For a general loss function V, conditions like (9) can be stated as the approximation error or regularization error.

Definition 12 *The approximation error $\mathcal{D}(\lambda)$ associated with the triple (K,V,ρ) is*

$$\mathcal{D}(\lambda) = \inf_{f\in\mathcal{H}_K} \left\{ \mathcal{E}(f) - \mathcal{E}(f_\rho^V) + \frac{\lambda}{2}\|f\|_K^2 \right\}, \tag{11}$$

where we define the generalization error for $f : X \to \mathbb{R}$ as

$$\mathcal{E}(f) = \int_Z V(y,f(x))d\rho = \int_X \int_Y V(y,f(x))d\rho_x(y)d\rho_X$$

and f_ρ^V is a minimizer of $\mathcal{E}(f)$.

The approximation error measures the approximation ability of the space $\mathcal{H}_K$ with respect to the learning process involving V and ρ. The denseness of $\mathcal{H}_K$ in $C(X)$ implies $\lim_{\lambda\to 0}\mathcal{D}(\lambda) = 0$. A natural assumption would be

$$\mathcal{D}(\lambda) \le \mathcal{D}_0\lambda^\beta \qquad \text{for some } 0 \le \beta \le 1 \text{ and } \mathcal{D}_0 > 0. \tag{12}$$

Throughout the paper we assume for the general loss function V that $\|V\| := \sup_{y\in Y} V(y,0) + \sup\{|V(y,f) - V(y,0)|/|f| : y \in Y, |f| \le 1\} < \infty$.

Remark 13 *Since $\mathcal{D}(\lambda) \le \mathcal{E}(0) + 0 \le \|V\|$ for any $\lambda > 0$, we see that (12) always holds with $\beta = 0$ and $\mathcal{D}_0 = \|V\|$.*

For the least square loss $V(y,f) = (y-f)^2$, the minimizer f_ρ^V of $\mathcal{E}(f)$ is exactly the regression function defined by (5) and approximation error (11) takes the from $\mathcal{D}(\lambda) = \inf_{f\in\mathcal{H}_K}\{\|f - f_\rho\|^2_{L^2_{\rho_X}} + \frac{\lambda}{2}\|f\|_K^2\}$ which measures the approximation of f_ρ in $L^2_{\rho_X}$ by functions from the RKHS $\mathcal{H}_K$.

For a general loss function V, the minimizer f_ρ^V of $\mathcal{E}(f)$ is in general different from f_ρ. Moreover, the approximation error $\mathcal{D}(\lambda)$ involves the approximation of f_ρ^V by $\mathcal{H}_K$ in some function spaces which need not be $L^2_{\rho_X}$.

Example 5 *For the hinge loss $V(y,f) = (1-yf)_+$, the minimizer f_ρ^V is the Bayes rule $f_\rho^V = f_c$ (Devroye et al., 1997). Moreover the uniform Lipschitz continuity of $V(\cdot,f)$ implies (Chen et al., 2004)*

$$\mathcal{E}(f) - \mathcal{E}(f_\rho^V) = \int_Z \phi(yf(x)) - \phi(yf_c(x))d\rho \le \int_X |f(x) - f_c(x)|d\rho_X = \|f - f_c\|_{L^1_{\rho_X}}.$$

So approximation error (11) can be estimated by approximation in the space $L^1_{\rho_X}$ and condition (9) implies (12).

Consider the insensitive loss $V = V_{in}$. We can easily see that for each $x \in X$, $f_\rho^{V_{in}}(x)$ equals the median of the probability distribution ρ_x on Y. That is, $f_\rho^{V_{in}}(x)$ is uniquely determined by

$$\rho_x(\{y \in Y : y \le f_\rho^{V_{in}}(x)\}) \ge \frac{1}{2} \quad \text{and} \quad \rho_x(\{y \in Y : y \ge f_\rho^{V_{in}}(x)\}) \ge \frac{1}{2}.$$

When ρ_x is symmetric about its mean $f_\rho(x)$, we have $f_\rho^{V_{in}}(x) = f_\rho(x)$.

Example 6 *Let $V = V_{in}$, $f_\rho \in C(X)$ and $p \ge 1$. If for each $x \in X$, the conditional distribution ρ_x is given by*

$$d\rho_x(y) = \begin{cases} \frac{p}{2}|y - f_\rho(x)|^{p-1}dy, & \text{if } |y - f_\rho(x)| \le 1, \\ 0, & \text{if } |y - f_\rho(x)| > 1, \end{cases}$$

then we have

$$\begin{aligned} \mathcal{E}(f) - \mathcal{E}(f_\rho^{V_{in}}) &= \frac{1}{p+1}\|f - f_\rho\|^{p+1}_{L^{p+1}_{\rho_X}} - \frac{1}{p+1}\int_{\{x \in X : |f(x) - f_\rho(x)| > 1\}} \\ &\quad |f(x) - f_\rho(x)|^{p+1} + p - (1+p)|f(x) - f_\rho(x)|d\rho_X. \end{aligned}$$

It follows that

$$\mathcal{D}(\lambda) \le \inf_{f \in \mathcal{H}_K} \left\{ \|f - f_\rho\|^{p+1}_{L^{p+1}_{\rho_X}} + \frac{\lambda}{2}\|f\|^2_K \right\}.$$

The conclusion of Example 6 will be proved in the appendix. The following general result follows from the same argument as in Wu et al. (2006).

Proposition 14 *If the loss function V satisfies $|V(y, f_1) - V(y, f_2)| \le |f_1 - f_2|^c$ for some $0 < c \le 1$ and any $y \in Y, f_1, f_2 \in \mathbb{R}$, then*

$$\mathcal{D}(\lambda) \le \inf_{f \in \mathcal{H}_K} \{\|f - f_\rho^V\|^c_{L^1_{\rho_X}} + \frac{\lambda}{2}\|f\|^2_K\} \le \inf_{f \in \mathcal{H}_K} \{\|f - f_\rho^V\|^c_{L^2_{\rho_X}} + \frac{\lambda}{2}\|f\|^2_K\}.$$

If the univariate function $V(y, \cdot)$ is C^1 and satisfies $|\partial V(y, f_1) - \partial V(y, f_2)| \le |f_1 - f_2|^c$ for some $0 < c \le 1$ and any $y \in Y, f_1, f_2 \in \mathbb{R}$, then

$$\mathcal{D}(\lambda) \le \inf_{f \in \mathcal{H}_K} \{\|f - f_\rho^V\|^{1+c}_{L^{1+c}_{\rho_X}} + \frac{\lambda}{2}\|f\|^2_K\} \le \inf_{f \in \mathcal{H}_K} \{\|f - f_\rho^V\|^{1+c}_{L^2_{\rho_X}} + \frac{\lambda}{2}\|f\|^2_K\}.$$

3. Key Analysis for the Fully Online Non-identical Setting

Learning rates for fully online learning algorithm (3) such as those stated in the last section for regression and classification are obtained through analysis for approximation error and sample error. The approximation error has been well understood (Smale and Zhou, 2003; Chen et al., 2004). The sample error for (3) will be estimated in the following two sections. It is expressed as $\|f_{T+1} - f^V_{\lambda_T}\|_K$ where $f^V_{\lambda_T}$ is a regularizing function.

Definition 15 *For $\lambda > 0$ the regularizing function $f_\lambda^V \in \mathcal{H}_K$ is defined by*

$$f_\lambda^V = \arg \inf_{f \in \mathcal{H}_K} \left\{ \mathcal{E}(f) + \frac{\lambda}{2} \|f\|_K^2 \right\}. \tag{13}$$

Observe that f_λ^V is a sample-free limit of $f_{\mathbf{z},\lambda}$ defined by (6). It is natural to expect that the function f_{T+1} produced by online algorithm (3) approximates the regularizing function $f_{\lambda_T}^V$ well. This is actually the case. Our main result on sample error analysis estimates the difference $f_{T+1} - f_{\lambda_T}^V$ in the $\mathcal{H}_K$-norm for quite general situations. The estimation follows from an iteration procedure, developed for online classification algorithms in Ying and Zhou (2006), Ying (2007) and Ye and Zhou (2007), together with some novelty provided in the proof of Theorem 26 in the next section. It is based on a one-step iteration bounding $\|f_{t+1} - f_{\lambda_t}^V\|_K$ in terms of $\|f_t - f_{\lambda_{t-1}}^V\|_K$. The goal of this section is to present our key analysis for one-step iteration in tackling two barriers arising from the fully online non-identical setting.

3.1 Bounding Error Term Caused by Non-identical Sequence of Distributions

The first part of our key analysis for one-step iteration is to tackle an extra error term Δ_t caused by the non-identical sequence of distributions when bounding $\|f_{t+1} - f_{\lambda_t}^V\|_K$ by means of $\|f_t - f_{\lambda_t}^V\|_K$ with the fixed regularization parameter λ_t.

Lemma 16 *Define $\{f_t\}$ by (3). Then we have*

$$\mathbb{E}_{z_t}(\|f_{t+1} - f_{\lambda_t}^V\|_K^2) \le (1 - \eta_t\lambda_t)\|f_t - f_{\lambda_t}^V\|_K^2 + 2\eta_t\Delta_t + \eta_t^2 \mathbb{E}_{z_t} \|\partial V(y_t, f_t(x_t))K_{x_t} + \lambda_t f_t\|_K^2, \tag{14}$$

where Δ_t is defined by

$$\Delta_t = \int_Z \left\{ V(y, f_{\lambda_t}^V(x)) - V(y, f_t(x)) \right\} d\left[\rho^{(t)} - \rho\right]. \tag{15}$$

Lemma 16 follows from the same procedure as in the proof of Lemma 3 in Ying and Zhou (2006) and Ye and Zhou (2007). A crucial estimate is

$$\langle \partial V(y_t, f_t(x_t))K_{x_t} + \lambda_t f_t, f_{\lambda_t}^V - f_t \rangle_K \le [V(y_t, f_{\lambda_t}^V(x_t)) + \frac{\lambda_t}{2}\|f_{\lambda_t}^V\|_K^2] - [V(y_t, f_t(x_t)) + \frac{\lambda_t}{2}\|f_t\|_K^2].$$

When we take the expectation with respect to $z_t = (x_t, y_t)$, we get $\int_Z V(y, f_{\lambda_t}^V(x))d\rho^{(t)}$ (and $\int_Z V(y, f_t(x))d\rho^{(t)}$) on the right-hand side, not $\mathcal{E}(f_{\lambda_t}^V) = \int_Z V(y, f_{\lambda_t}^V(x))d\rho$. So compared with results in the i.i.d. case (Smale and Yao, 2006; Ying and Zhou, 2006; Ying, 2007; Tarrès and Yao, 2005; Ye and Zhou, 2007), an extra term Δ_t involving the difference measure $\rho^{(t)} - \rho$ appears. This is the first barrier we need to tackle here.

When V is the least square loss, it can be easily handled by assuming $f_\rho \in C^s(X)$. In fact, from $V(y, f) = (y - f)^2$, we see that

$$\begin{aligned} \Delta_t &= \int_X \left\{ \int_Y [f_{\lambda_t}^V(x)) - f_t(x)][f_{\lambda_t}^V(x) + f_t(x) - 2y] d\rho_x(y) \right\} d\left[\rho_X^{(t)} - \rho_X\right] \\ &= \int_X [f_{\lambda_t}^V(x)) - f_t(x)][f_{\lambda_t}^V(x) + f_t(x) - 2f_\rho(x)] d\left[\rho_X^{(t)} - \rho_X\right]. \end{aligned}$$

This together with the relation $\|hg\|_{C^s(X)} \le \|h\|_{C^s(X)}\|g\|_{C^s(X)}$ yields the following bound.

Proposition 17 *Let $V(y,f) = (y-f)^2$ and $f_\rho \in C^s(X)$. Then we have*

$$\Delta_t \le \left\{ \|f_{\lambda_t}^V\|_{C^s(X)} + \|f_t\|_{C^s(X)} + 2\|f_\rho\|_{C^s(X)} \right\} \|\rho_X^{(t)} - \rho_X\|_{(C^s(X))^*} \|f_{\lambda_t}^V - f_t\|_{C^s(X)}.$$

For a general loss function and output space, Δ_t can be bounded under assumption (4). It is a special case of the following general result when $h = f_{\lambda_t}^V$ and $g = f_t$.

Lemma 18 *Let $h, g \in C^s(X)$. If (4) holds, then we have*

$$\begin{aligned} &\left| \int_Z V(y,h(x)) - V(y,g(x)) d\left[\rho^{(t)} - \rho\right] \right| \\ &\quad \le \left\{ B_{h,g} \left(\|h\|_{C^s(X)} + \|g\|_{C^s(X)} \right) + 2C_\rho \widetilde{B}_{h,g} \right\} \|\rho_X^{(t)} - \rho_X\|_{(C^s(X))^*}, \end{aligned}$$

where $B_{h,g}$ and $\widetilde{B}_{h,g}$ are constants given by

$$B_{h,g} = \sup\left\{ |\partial V(y,f)| : y \in Y, |f| \le \max\{\|h\|_{C(X)}, \|g\|_{C(X)}\} \right\}$$

and

$$\widetilde{B}_{h,g} = \sup\left\{ \|V(\cdot,f)\|_{C^s(Y)} : |f| \le \max\{\|h\|_{C(X)}, \|g\|_{C(X)}\} \right\}.$$

Proof By decomposing the probability distributions on Z into marginal and conditional distributions, we see

$$\int_Z V(y,h(x)) - V(y,g(x)) d\left[\rho^{(t)} - \rho\right] = \int_X \int_Y V(y,h(x)) - V(y,g(x)) d\rho_x(y) d\left[\rho_X^{(t)} - \rho_X\right].$$

By the definition of the norm in $(C^s(X))^*$, we obtain

$$\left| \int_Z V(y,h(x)) - V(y,g(x)) d\left[\rho^{(t)} - \rho\right] \right| \le \|\rho_X^{(t)} - \rho_X\|_{(C^s(X))^*} \|J\|_{C^s(X)},$$

where J is a function on X defined by

$$J(x) = \int_Y V(y,h(x)) - V(y,g(x)) d\rho_x(y), \qquad x \in X.$$

The notion of $B_{h,g}$ tells us that $|V(y,h(x)) - V(y,g(x))| \le B_{h,g}|h(x) - g(x)|$ for each $y \in Y$. Hence $\|J\|_{C(X)} \le B_{h,g}\|h - g\|_{C(X)}$.

To bound $|J|_{C^s(X)}$, let $x, u \in X$. We can decompose $J(x) - J(u)$ as

$$\begin{aligned} J(x) - J(u) &= \int_Y \{[V(y,h(x)) - V(y,g(x))] - [V(y,h(u)) - V(y,g(u))]\} d\rho_x(y) \\ &\quad + \int_Y [V(y,h(u)) - V(y,g(u))] d[\rho_x - \rho_u](y). \end{aligned}$$

By the notion $B_{h,g}$, part of the first term above can be bounded as

$$|V(y,h(x)) - V(y,h(u))| \le B_{h,g}|h(x) - h(u)| \le B_{h,g}|h|_{C^s(X)}(d(x,u))^s.$$

The same bound holds for the other part of the first term. So we get

$$\left|\int_Y \{[V(y,h(x))-V(y,g(x))]-[V(y,h(u))-V(y,g(u))]\}\,d\rho_x(y)\right| \le B_{h,g}\left\{|h|_{C^s(X)}+|g|_{C^s(X)}\right\}(d(x,u))^s.$$

For the other term of the expression for $J(x)-J(u)$, we apply condition (4) to

$$\left|\int_Y [V(y,h(u))-V(y,g(u))]d[\rho_x-\rho_u](y)\right| \le \|\rho_x-\rho_u\|_{(C^s(Y))^*}\|V(y,h(u))-V(y,g(u))\|_{C^s(Y)}$$

and find that

$$\left|\int_Y [V(y,h(u))-V(y,g(u))]d[\rho_x-\rho_u](y)\right| \le C_\rho (d(x,u))^s 2\widetilde{B}_{h,g}.$$

Combining the above two bounds, we see that

$$|J|_{C^s(X)} = \sup_{x\neq u\in X}\frac{|J(x)-J(u)|}{(d(x,u))^s} \le B_{h,g}\left\{|h|_{C^s(X)}+|g|_{C^s(X)}\right\}+2C_\rho\widetilde{B}_{h,g}.$$

Then the desired bound follows and the lemma is proved. ■

3.2 Bounding Error Term Caused by Varying Regularization Parameters

The second part of our key analysis is to estimate the error term called drift error $\|f^V_{\lambda_t}-f^V_{\lambda_{t-1}}\|_K$ caused by the change of the regularization parameter from λ_{t-1} to λ_t in our fully online algorithm. This is the second barrier we need to tackle here.

Definition 19 *The drift error is defined as*

$$d_t = \|f^V_{\lambda_t}-f^V_{\lambda_{t-1}}\|_K.$$

The drift error can be estimated by the approximation error, which has been studied for regression (Smale and Zhou, 2009) and for classification (Ye and Zhou, 2007).

Theorem 20 *Let V be a convex loss function, f^V_λ by (13) and $\mu>\lambda>0$. We have*

$$\|f^V_\lambda-f^V_\mu\|_K \le \frac{\mu}{2}\left(\frac{1}{\lambda}-\frac{1}{\mu}\right)\left(\|f^V_\lambda\|_K+\|f^V_\mu\|_K\right) \le \frac{\mu}{2}\left(\frac{1}{\lambda}-\frac{1}{\mu}\right)\left(\sqrt{\frac{2\mathcal{D}(\lambda)}{\lambda}}+\sqrt{\frac{2\mathcal{D}(\mu)}{\mu}}\right).$$

In particular, if with some $0<\gamma\le 1$ we take $\lambda_t=\lambda_1 t^{-\gamma}$ for $t\ge 1$, then

$$d_{t+1} \le 2t^{\frac{\gamma}{2}-1}\sqrt{\mathcal{D}(\lambda_1 t^{-\gamma})/\lambda_1}.$$

Proof Taking derivative of the functional $\mathcal{E}(f)+\frac{\lambda}{2}\|f\|^2_K$ at the minimizer f^ϕ_λ defined in (13), we see that

$$\int_Z \partial V(y,f^V_\lambda(x))K_x d\rho+\lambda f^V_\lambda = 0.$$

It follows that

$$f_\lambda^V - f_\mu^V = \frac{1}{\mu}\int_Z \partial V(y, f_\mu^V(x))K_x d\rho - \frac{1}{\lambda}\int_Z \partial V(y, f_\lambda^V(x))K_x d\rho.$$

Combining with the reproducing property (8), we know $\|f_\lambda^V - f_\mu^V\|_K^2 = \langle f_\lambda^V - f_\mu^V, f_\lambda^V - f_\mu^V\rangle_K$ can be expressed as

$$\|f_\lambda^V - f_\mu^V\|_K^2 = \frac{1}{\mu}\int_Z \partial V(y, f_\mu^V(x))\left(f_\lambda^V - f_\mu^V\right)(x)d\rho - \frac{1}{\lambda}\int_Z \partial V(y, f_\lambda^V(x))\left(f_\lambda^V - f_\mu^V\right)(x)d\rho.$$

The convexity of the function $V(y,\cdot)$ on $\mathbb{R}$ tells us that

$$\partial V(y, f_\mu^V(x))\left(f_\lambda^V - f_\mu^V\right)(x) \le V(y, f_\lambda^V(x)) - V(y, f_\mu^V(x))$$

and

$$\partial V(y, f_\lambda^V(x))\left(f_\mu^V - f_\lambda^V\right)(x) \le V(y, f_\mu^V(x)) - V(y, f_\lambda^V(x)).$$

Hence

$$\|f_\lambda^V - f_\mu^V\|_K^2 \le (\frac{1}{\lambda} - \frac{1}{\mu})(\mathcal{E}(f_\mu^V) - \mathcal{E}(f_\lambda^V)).$$

¿From the definition of f_μ^V, we see that $\mathcal{E}(f_\mu^V) + \frac{\mu}{2}\|f_\mu^V\|_K^2 - (\mathcal{E}(f_\lambda^V) + \frac{\mu}{2}\|f_\lambda^V\|_K^2) \le 0$. It follows that

$$\mathcal{E}(f_\mu^V) - \mathcal{E}(f_\lambda^V) \le \frac{\mu}{2}(\|f_\lambda^V\|_K^2 - \|f_\mu^V\|_K^2) \le \frac{\mu}{2}\|f_\lambda^V - f_\mu^V\|_K(\|f_\lambda^V\|_K + \|f_\mu^V\|_K).$$

Then the desired inequality follows. ■

4. Bounds for Sample Error in $\mathcal{H}_K$-norm

We are in a position to present our main result on the sample error measured with the $\mathcal{H}_K$-norm of the difference $f_{T+1} - f_{\lambda_T}^V$. This will be done by applying iteratively the key analysis in Lemma 16, Lemma 18 and Theorem 20.

When applying Lemma 18, we need to bound $\|g\|_{C^s(X)}$ in terms of $\|g\|_K$.

Definition 21 *We say that the Mercer kernel K satisfies the kernel condition of order s if $K \in C^s(X\times X)$ and for some $\kappa_{2s} > 0$,*

$$|K(x,x) - 2K(x,u) + K(u,u)| \le \kappa_{2s}^2 (d(x,u))^{2s}, \qquad \forall x,u \in X. \tag{16}$$

When $0 < s \le \frac{1}{2}$ and $K \in C^{2s}(X\times X)$, (16) holds true. The following result follows directly from Zhou (2003), Zhou (2008) and Smale and Zhou (2009).

Lemma 22 *If K satisfies the kernel condition of order s with (16) valid, then we have*

$$\|g\|_{C^s(X)} \le (\kappa + \kappa_{2s})\|g\|_K, \qquad \forall g \in \mathcal{H}_K.$$

When using Lemma 16 and Lemma 18, we need incremental behaviors of the loss function V to bound $\|f_t\|_K$.

Definition 23 *Denote*

$$N(\lambda) = \sup\left\{|\partial V(y,f)| : y \in Y, |f| \le \max\left\{\kappa^2\|V\|/\lambda, \kappa\sqrt{2\|V\|/\lambda}\right\}\right\}$$

and

$$\widetilde{N}(\lambda) = \sup\left\{\|V(\cdot,f)\|_{C^s(Y)} : y \in Y, |f| \le \max\left\{\kappa^2\|V\|/\lambda, \kappa\sqrt{2\|V\|/\lambda}\right\}\right\}.$$

We say that V has incremental exponent $p \ge 0$ if for some $N_1 > 0$ and $\lambda_1 > 0$ we have

$$N(\lambda) \le N_1(\frac{1}{\lambda})^p \quad \text{and} \quad \widetilde{N}(\lambda) \le N_1(\frac{1}{\lambda})^{p+1} \qquad \forall 0 < \lambda \le \lambda_1. \tag{17}$$

We say that ∂V is locally Lipschitz at the origin if

$$M_0 := \sup\left\{\frac{|\partial V(y,f) - \partial V(y,0)|}{|f|} : y \in Y, |f| \le 1\right\} < \infty. \tag{18}$$

The following result can be proved by exactly the same procedure as those in Ying and Zhou (2006), Ying (2007) and Ye and Zhou (2007).

Lemma 24 *Assume that ∂V is locally Lipschitz at the origin. Define $\{f_t\}$ by (3). If*

$$\eta_t\left(\kappa^2(M_0 + 2N(\lambda_t)) + \lambda_t\right) \le 1 \tag{19}$$

for $t = 1, \ldots, T$, then we have

$$\|f_t\|_K \le \frac{\kappa\|V\|}{\lambda_t}, \qquad t = 1, \ldots, T+1. \tag{20}$$

For the insensitive loss, (18) is not satisfied, but $\partial V(y,f)$ is uniformly bounded by 1. For such loss functions we can apply the following bound.

Lemma 25 *Assume $\|\partial V(y,f)\|_\infty := \sup_{y\in Y, f\in\mathbb{R}} |\partial V(y,f)| < \infty$. Define $\{f_t\}$ by (3). If for some $\lambda_1, \eta_1 > 0$ and $\gamma, \alpha > 0$ with $\lambda + \alpha < 1$, we take $\lambda_t = \lambda_1 t^{-\gamma}, \eta_t = \eta_1 t^{-\alpha}$ with $t = 1, \ldots, T$, then we have*

$$\|f_t\|_K \le \frac{C_{V,\gamma,\alpha}}{\lambda_t}, \qquad t = 1, \ldots, T+1, \tag{21}$$

where $C_{V,\gamma,\alpha}$ is the constant given by

$$C_{V,\gamma,\alpha} = \kappa\|\partial V(y,f)\|_\infty\left\{\lambda_1\eta_1 + \lambda_1\left(2^{\gamma+2\alpha}/(\lambda_1\eta_1) + \left((1+\alpha)/[e\lambda_1\eta_1(1-2^{\gamma+\alpha-1})]\right)^{\frac{1+\alpha}{1-\gamma-\alpha}}\right)\right\}.$$

Proof By taking norms in (3) we see that

$$\|f_{t+1}\|_K \le (1 - \eta_t\lambda_t)\|f_t\|_K + \eta_t\kappa\|\partial V(y,f)\|_\infty.$$

By iterating and the choice $f_1 = 0$ we find

$$\|f_{t+1}\|_K \le \sum_{i=1}^{t} \Pi_{j=i+1}^{t}(1 - \eta_j\lambda_j)\eta_i\kappa\|\partial V(y,f)\|_\infty.$$

But $1-\eta_j\lambda_j \le \exp\{-\eta_j\lambda_j\}$. It follows that

$$\|f_{t+1}\|_K \le \sum_{i=1}^{t} \Pi_{j=i+1}^{t} \exp\left\{-\sum_{j=i+1}^{t}\eta_j\lambda_j\right\}\eta_i\kappa\|\partial V(y,f)\|_\infty.$$

Now we need the following elementary inequality with $c>0, q_2\ge 0$ and $0<q_1<1$:

$$\sum_{i=1}^{t-1} i^{-q_2}\exp\left\{-c\sum_{j=i+1}^{t} j^{-q_1}\right\} \le \left(\frac{2^{q_1+q_2}}{c}+\left(\frac{1+q_2}{ec(1-2^{q_1-1})}\right)^{\frac{1+q_2}{1-q_1}}\right)t^{q_1-q_2}. \tag{22}$$

This elementary inequality can be found in, for example, Smale and Zhou (2009). Taking $q_2=\alpha, q_1=\gamma+\alpha$ and $c=\lambda_1\eta_1$ we know that $\|f_{t+1}\|_K$ is bounded by

$$\kappa\|\partial V(y,f)\|_\infty\left\{\eta_1 t^{-\alpha}+\left(2^{\gamma+2\alpha}/(\lambda_1\eta_1)+\left((1+\alpha)/[e\lambda_1\eta_1(1-2^{\gamma+\alpha-1})]\right)^{\frac{1+\alpha}{1-\gamma-\alpha}}\right)t^{\gamma}\right\}.$$

Then our desired bound holds true. ■

Now we can present our bound for the sample error $\|f_{T+1}-f_{\lambda_T}^V\|_K$.

Theorem 26 *Suppose the following assumptions hold:*

1. *the kernel K satisfies the kernel condition of order s ($0<s\le 1$) with (16) valid.*
2. *V has incremental exponent $p\ge 0$ with (17) valid and ∂V satisfies (18).*
3. *$\{\rho_X^{(t)}\}_{t=1,2,\cdots}$ converges polynomially to ρ_X in $(C^s(X))^*$ with (1) valid.*
4. *the distributions $\{\rho_x : x\in X\}$ is Lipschitz s in $(C^s(Y))^*$ with (4) valid.*
5. *the triple (K,V,ρ) has the approximation ability of power $0<\beta\le 1$ stated by (12).*

Take

$$\lambda_t=\lambda_1 t^{-\gamma}, \eta_t=\eta_1 t^{-\alpha} \tag{23}$$

with some $\lambda_1,\eta_1>0$ and γ,α satisfying

$$0<\gamma<\frac{2}{5+4p-\beta},\ (2p+1)\gamma<\alpha<1-\frac{\gamma(3-\beta)}{2},\ \eta_1\le\frac{1}{\kappa^2M_0+2\kappa^2N_1\lambda_1^{-p}+\lambda_1}. \tag{24}$$

Then we have

$$\mathbb{E}_{z_1,z_2,\cdots,z_T}(\|f_{T+1}-f_{\lambda_T}^V\|_K^2)\le C_{K,V,\rho,b,\beta,s}T^{-\theta} \tag{25}$$

where the power index θ is given by

$$\theta:=\min\left\{2-\gamma(3-\beta)-2\alpha,\alpha-\gamma(2p+1),b-\gamma(2+p)\right\}, \tag{26}$$

and $C_{K,V,\rho,b,\beta,s}$ is a constant independent of T given explicitly in the proof.

Proof We divide the proof into four steps.

First we bound Δ_t. Since λ_t and η_t take the form (23), we see from the lower bound for α in (24) that $p\gamma \le (2p+1)\gamma \le \alpha$. Hence for $t \in \mathbb{N}$,

$$\eta_t(\kappa^2(M_0+2N(\lambda_t))+\lambda_t) \le \eta_1 t^{-\alpha}(\kappa^2 M_0 + 2\kappa^2 N_1 \lambda_1^{-p} t^{p\gamma} + \lambda_1 t^{-\gamma}) \le \eta_1(\kappa^2 M_0 + 2\kappa^2 N_1 \lambda_1^{-p} + \lambda_1).$$

So the last restriction of (24) implies (19), and by Lemma 24, we know that (20) holds true.

Taking $f = 0$ in (13) yields

$$\|f_{\lambda_t}^V\|_K^2 \le \frac{2\|V\|}{\lambda_t}, \qquad t = 1, \ldots, T.$$

Putting these bounds into the definition of constant $B_{h,g}, \widetilde{B}_{h,g}$, we see by the notion $N(\lambda)$ that

$$B_{f_{\lambda_t}^V, f_t} \le N(\lambda_t), \qquad \widetilde{B}_{f_{\lambda_t}^V, f_t} \le N(\lambda_t).$$

So by Lemma 18 and Lemma 22,

$$\Delta_t \le B_t^* := \left\{(\kappa+\kappa_{2s})(\sqrt{2\|V\|/\lambda_t}+\kappa\|V\|/\lambda_t)N(\lambda_t) + 2C_\rho \widetilde{N}(\lambda_t)\right\} \|\rho_X^{(t)} - \rho_X\|_{(C^s(X))^*}.$$

Putting this bound and (20) into (14) yields

$$\mathbb{E}_{z_1,z_2,\cdots,z_t}(\|f_{t+1} - f_{\lambda_t}^V\|_K^2) \le (1-\eta_t\lambda_t)\mathbb{E}_{z_1,z_2,\cdots,z_{t-1}}\left(\|f_t - f_{\lambda_t}^V\|_K^2\right) + \kappa^2\eta_t^2(N(\lambda_t)+\|V\|)^2 + 2\eta_t B_t^*.$$

Next we derive explicit bounds for the one-step iteration.

Recall that $d_t = \|f_{\lambda_t}^V - f_{\lambda_{t-1}}^V\|_K$. It gives $\|f_t - f_{\lambda_t}^V\|_K^2 \le \|f_t - f_{\lambda_{t-1}}^V\|_K^2 + 2\|f_t - f_{\lambda_{t-1}}^V\|_K d_t + d_t^2$.

Take $\tau = \frac{\gamma+\alpha}{1-\gamma(1-\beta)/2}$. By the upper bound for α in (24), we find $0 < \tau < 1$.

Take $A_1 = \frac{\eta_1 \lambda_1^{1+\tau(1-\beta)/2}}{2^{1+2\tau}\mathcal{D}_0^{\tau/2}} > 0$. Applying the elementary inequality

$$2ab = 2[\sqrt{A_1}ab^{\tau/2}][b^{1-\tau/2}/\sqrt{A_1}] \le A_1 a^2 b^\tau + b^{2-\tau}/A_1 \tag{27}$$

to $a = \|f_t - f_{\lambda_{t-1}}^V\|_K$ and $b = d_t$, we know that

$$\mathbb{E}_{z_1,z_2,\cdots,z_{t-1}}\left(\|f_t - f_{\lambda_t}^V\|_K^2\right) \le (1+A_1 d_t^\tau)\mathbb{E}_{z_1,z_2,\cdots,z_{t-1}}\left(\|f_t - f_{\lambda_{t-1}}^V\|_K^2\right) + d_t^{2-\tau}/A_1 + d_t^2.$$

Using this bound and noticing the inequality $(1-\eta_t\lambda_t)(1+A_1 d_t^\tau) \le 1 + A_1 d_t^\tau - \eta_t\lambda_t$, we obtain

$$\begin{aligned}\mathbb{E}_{z_1,z_2,\cdots,z_t}(\|f_{t+1} - f_{\lambda_t}^V\|_K^2) \le (1+A_1 d_t^\tau - \eta_t\lambda_t)\mathbb{E}_{z_1,z_2,\cdots,z_{t-1}}\left(\|f_t - f_{\lambda_{t-1}}^V\|_K^2\right) \\ + d_t^{2-\tau}/A_1 + d_t^2 + \kappa^2\eta_t^2(N(\lambda_t)+\|V\|)^2 + 2\eta_t B_t^*.\end{aligned}$$

By Theorem 20, condition (12) for the approximation error yields

$$d_t \le 2\sqrt{\mathcal{D}_0}\lambda_1^{(\beta-1)/2}(t-1)^{\gamma(1-\beta)/2-1} \le A_2 t^{\gamma(1-\beta)/2-1} \quad \text{where } A_2 = 4\sqrt{\mathcal{D}_0}\lambda_1^{(\beta-1)/2}.$$

Inserting the parameter form $\lambda_t = \lambda_1 t^{-\gamma}$ into assumption (17) and applying condition (1), we can bound B_t^* as

$$B_t^* \le A_3 t^{\gamma(1+p)-b} \quad \text{where } A_3 = \left\{(\kappa+\kappa_{2s})(\sqrt{2\|V\|/\lambda_1}+\kappa\|V\|/\lambda_1) + 2C_\rho/\lambda_1\right\} N_1 \lambda_1^{-p} C.$$

Therefore, for the one-step iteration, by denoting $f_{\lambda_1}^V$ as $f_{\lambda_0}^V$ when $t=1$, we have for each $t=1,\ldots,T$,

$$\mathbb{E}_{z_1,z_2,\cdots,z_t}(\|f_{t+1}-f_{\lambda_t}^V\|_K^2) \le (1+A_1 d_t^{\tau}-\eta_t\lambda_t)\mathbb{E}_{z_1,z_2,\cdots,z_{t-1}}\left(\|f_t-f_{\lambda_{t-1}}^V\|_K^2\right)+A_4 t^{-\widetilde{\theta}}, \tag{28}$$

where

$$\widetilde{\theta}=\min\left\{2-\gamma(2-\beta)-\alpha,\ 2(\alpha-p\gamma),\ \alpha+b-\gamma(1+p)\right\}$$

and

$$A_4=A_2^{2-\tau}/A_1+A_2^2+\kappa^2\eta_1^2(N_1\lambda_1^{-p}+\|V\|)^2+2\eta_1 A_3.$$

Then we iterate the above one-step analysis. Inserting the parameter forms for λ_t and η_t, we see from the definition of the constant A_1 that

$$1+A_1 d_t^{\tau}-\eta_t\lambda_t \le 1+A_1A_2^{\tau}t^{\tau(\gamma(1-\beta)/2-1)}-\eta_1\lambda_1 t^{-\gamma-\alpha}=1-\frac{\eta_1\lambda_1}{2}t^{-\gamma-\alpha}. \tag{29}$$

So the one-step analysis (28) yields

$$\mathbb{E}_{z_1,z_2,\cdots,z_t}(\|f_{t+1}-f_{\lambda_t}^V\|_K^2) \le \left(1-\frac{\eta_1\lambda_1}{2}t^{-\gamma-\alpha}\right)\mathbb{E}_{z_1,z_2,\cdots,z_{t-1}}\left(\|f_t-f_{\lambda_{t-1}}^V\|_K^2\right)+A_4t^{-\widetilde{\theta}}.$$

Applying this bound iteratively for $t=1,\ldots,T$ implies

$$\begin{aligned}\mathbb{E}_{z_1,z_2,\cdots,z_T}(\|f_{T+1}-f_{\lambda_T}^V\|_K^2) &\le A_4\sum_{t=1}^{T}\Pi_{j=t+1}^{T}(1-\frac{\eta_1\lambda_1}{2}j^{-\gamma-\alpha})t^{-\widetilde{\theta}}\\ &+\left\{\Pi_{t=1}^{T}(1-\frac{\eta_1\lambda_1}{2}t^{-\gamma-\alpha})\right\}\|f_1-f_{\lambda_1}^V\|_K^2.\end{aligned}$$

Finally we bound the above expressions by two elementary inequalities. The first one is (22). Applying this inequality with $c=\frac{\eta_1\lambda_1}{2}, q_1=\gamma+\alpha$ and $q_2=\widetilde{\theta}$, since $1-u\le e^{-u}$ for any $u\ge 0$, the first expression above can be bounded as

$$\sum_{t=1}^{T}\Pi_{j=t+1}^{T}(1-\frac{\eta_1\lambda_1}{2}j^{-\gamma-\alpha})t^{-\widetilde{\theta}} \le \sum_{t=1}^{T}\exp\left\{-\frac{\eta_1\lambda_1}{2}\sum_{j=t+1}^{T}j^{-\gamma-\alpha}\right\}t^{-\widetilde{\theta}} \le A_5T^{\gamma+\alpha-\widetilde{\theta}},$$

where A_5 is the constant given by

$$A_5=\frac{2^{\gamma+\alpha+\widetilde{\theta}+1}}{\eta_1\lambda_1}+1+\left(\frac{2+2\widetilde{\theta}}{e\eta_1\lambda_1(1-2^{\gamma+\alpha-1})}\right)^{\frac{1+\widetilde{\theta}}{1-\gamma-\alpha}}.$$

For the second expression above, we have

$$\begin{aligned}&\Pi_{t=1}^{T}(1-\frac{\eta_1\lambda_1}{2}t^{-\gamma-\alpha}) \le \exp\left\{-\frac{\eta_1\lambda_1}{2}\sum_{j=1}^{T}t^{-\gamma-\alpha}\right\} \le \exp\left\{-\frac{\eta_1\lambda_1}{2}\int_1^{T+1}x^{-\gamma-\alpha}dx\right\}\\ &\le \exp\left\{\frac{\lambda_1\eta_1}{2(1-\gamma-\alpha)}\right\}\exp\left\{-\frac{\lambda_1\eta_1}{2(1-\gamma-\alpha)}(T+1)^{1-\gamma-\alpha}\right\}.\end{aligned}$$

Applying another elementary inequality

$$\exp\{-cx\} \le \left(\frac{a}{ec}\right)^a x^{-a}, \qquad \forall c,a,x>0$$

with $c=\frac{\lambda_1\eta_1}{2(1-\gamma-\alpha)}$, $a=\frac{2}{1-\gamma-\alpha}$ and $x=(T+1)^{1-\gamma-\alpha}$ yields

$$\Pi_{t=1}^T(1-\frac{\eta_1\lambda_1}{2}t^{-\gamma-\alpha}) \le \exp\left\{\frac{\lambda_1\eta_1}{2(1-\gamma-\alpha)}\right\}\left(\frac{4}{e\lambda_1\eta_1}\right)^{\frac{2}{1-\gamma-\alpha}} T^{-2}.$$

The above two estimates give the desired bound (25) with $\theta=\widetilde{\theta}-\gamma-\alpha$ and the constant $C_{K,V,\rho,b,\beta,s}$ given by

$$C_{K,V,\rho,b,\beta,s} = A_4A_5 + \exp\left\{\frac{\lambda_1\eta_1}{2(1-\gamma-\alpha)}\right\}\left(\frac{4}{e\lambda_1\eta_1}\right)^{\frac{2}{1-\gamma-\alpha}}\frac{2\|V\|}{\lambda_1}.$$

This proves the theorem. ■

Remark 27 *Some ideas in the above proof are from Ying and Zhou (2006), Ye and Zhou (2007) and Smale and Zhou (2009). Two novel points are presented for the first time here. One is the bound for Δ_t, dealing with $\rho_X^{(t)}-\rho_X$, given in the first step of our proof in order to tackle the technical difficulty arising from the non-identical sampling process. The same difficulty for the least square regression was overcome in Smale and Zhou (2009) by the special linear feature and explicit expressions offered by the least square loss. The second technical novelty is to introduce a parameter A_1 into elementary inequality (27). With this parameter, we can bound $1+A_1d_t^\tau-\eta_t\lambda_t$ by $1-\frac{1}{2}\eta_t\lambda_t$, shown in (29). This improves the error bound even in the i.i.d. case presented in Ye and Zhou (2007) for the fully online algorithm.*

Let us discuss the role of parameters in Theorem 26. When γ is small enough and $b>\frac{2}{3}$, fully online algorithm (3) becomes very close to the partially online scheme with $\lambda_t\equiv\lambda_1$. By taking $\alpha=\frac{2}{3}$, the rates in (25) are of order $O(T^{-(\frac{2}{3}-\varepsilon)})$ with ε arbitrarily small, which is a nice bound for the sample error $\|f_{T+1}-f_{\lambda_T}^V\|_K$. In this case, the difference between $f_{\lambda_T}^V$ and f_ρ^V, measured by the approximation error, increases since $\lambda_T=\lambda_1T^{-\gamma}$. To estimate the total error between f_{T+1} and f_ρ^V, we should take a balance for the index γ of the regularization parameter, as shown in Theorem 11.

For the insensitive loss, (18) is not satisfied. We can apply Lemma 25 and obtain bounds for $\|f_{T+1}-f_{\lambda_T}^V\|_K$ by the same proof as that for Theorem 26.

Proposition 28 *Assume $\|\partial V(y,f)\|_\infty<\infty$ and all the conditions of Theorem 26 except (18). Take $\{\lambda_t,\eta_t\}$ by (23) with the restriction (24) without the last inequality. Then the same convergence rate (25) holds true with the power index θ given by (26).*

5. Bounds for Binary Classification and Regression with Insensitive Loss

We demonstrate how to apply Theorem 26 by deriving learning rates of fully online algorithm (3) for binary classification and regression with insensitive loss.

Theorem 29 *Let $V(y,f)=\phi(yf)$ where $\phi:\mathbb{R}\to\mathbb{R}_+$ is a convex function satisfying*

$$|\phi'_-(u)|\le N_\phi|u|^p,\quad \phi(u)\le N_\phi u^{p+1}\qquad \forall |u|\ge 1 \tag{30}$$

for some $p\ge 0$ and $N_\phi>0$. Suppose $M_\phi:=\sup\{|\phi'_-(u)-\phi'_-(0)|/|u| : |u|\le 1\}<\infty$. Assume (16) for K, (1) for $\{\rho_X^{(t)}\}$, and (12) for (K,ϕ,ρ). If $f_\rho\in C^s(X)$ and we choose $\{\lambda_t,\eta_t\}$ as (23) with $0<\gamma<\frac{2}{5+10p-\beta},\alpha=\frac{2+\gamma(2p-2+\beta)}{3}$ and $b>\gamma(2+p)$, and $\eta_1<\eta_0$, $\lambda_1\le\kappa^2(\phi(0)+\|\phi'_-\|_{L^\infty[-1,1]})/2$, then we have

$$\mathbb{E}_{z_1,\dots,z_T}\left(\mathcal{E}(f_{T+1})-\mathcal{E}(f_\rho^V)\right)\le \widetilde{C}_{\phi,\beta,\gamma}T^{-\min\left\{\frac{2-\gamma(5+10p-\beta)}{6},\frac{b-\gamma(2+3p)}{2},\gamma\beta\right\}},$$

where $\eta_0:=\frac{1}{\kappa^2M_\phi+2\kappa^2N_1\lambda_1^{-p}+\lambda_1}$ with $N_1=(M_\phi+N_\phi+\phi(0)+\|\phi'_-\|_{L^\infty[-1,1]})\kappa^{2p}(\phi(0)+\|\phi'_-\|_{L^\infty[-1,1]})^p$ and $\widetilde{C}_{\phi,\beta,\gamma}$ is a constant depending on $\eta_1,\lambda_1,\kappa,\mathcal{D}_0,\beta,\phi,\beta$ and s.

Proof By the bounds for $\|f_{\lambda_T}^V\|_K$ and $\|f_{T+1}\|_K$, we know from (30) that

$$\begin{aligned}\left|\mathcal{E}(f_{T+1})-\mathcal{E}(f_{\lambda_T}^V)\right| &= \left|\int_Z\phi(yf_{T+1}(x))-\phi(yf_{\lambda_T}^V(x))d\rho\right|\\ &\le C_{K,\phi}\lambda_T^{-p}\|f_{T+1}-f_{\lambda_T}^V\|_\infty\le\kappa C_{K,\phi}\lambda_T^{-p}\|f_{T+1}-f_{\lambda_T}^V\|_K,\end{aligned}$$

where $C_{K,\phi}$ is a constant depending on K and ϕ.

It is easy to check that the loss $V(y,f)=\phi(yf)$ satisfies (17) with incremental exponent p.

By Theorem 26 with $0<\gamma<\frac{2}{5+10p-\beta},\alpha=\frac{2+\gamma(2p-2+\beta)}{3}$ and $b>\gamma(2+p)$, we have

$$\mathbb{E}_{z_1,z_2,\cdots,z_T}\left(\left\|f_{T+1}-f_{\lambda_T}^V\right\|_K\right)\le\sqrt{C_{K,V,\rho,b,\beta,s}}T^{-\min\{[2-\gamma(5+4p-\beta)]/6,[b-\gamma(2+p)]/2\}}.$$

Also, we have $\mathcal{E}(f_{\lambda_T}^\phi)-\mathcal{E}(f_\rho^V)\le\mathcal{D}(\lambda_T)\le\mathcal{D}_0\lambda_T^\beta$. Thus we get a bound for the excess generalization error

$$\mathbb{E}_{z_1,\dots,z_T}(\mathcal{E}(f_{T+1})-\mathcal{E}(f_\rho^V))\le\widetilde{C}_{\phi,\beta,\gamma}T^{-\min\{[2-\gamma(5+10p-\beta)]/6,\gamma\beta,[b-\gamma(2+3p)]/2\}},$$

where $\widetilde{C}_{\phi,\beta,\gamma}=\kappa C_{K,\phi}\lambda_1^{-p}\sqrt{C_{K,V,\rho,b,\beta,s}}+\mathcal{D}_0\lambda_1^\beta$. This verifies the desired bound. ■

Theorem 29 yields concrete learning rates with various loss functions. When ϕ is chosen to be the hinge loss $\phi(x)=(1-x)_+$, we can prove Theorem 11.

5.1 Proof of Theorem 11

When $0<s\le\frac{1}{2}$ and $K\in C^{2s}(X\times X)$, (16) holds true.

The loss function $\phi(x)=(1-x)_+$ satisfies $\phi'_-(x)=-1$ for $x\le 1$ and 0 otherwise. It follows that (17) holds true with $p=0$ and $M_\phi=0$. By Example 5, (9) implies (12).

Thus all conditions in Theorem 29 are satisfied and by taking $p=0$ and $\gamma=\frac{1}{4}$, we have

$$\mathbb{E}_{z_1,\dots,z_T}\left(\mathcal{E}(f_{T+1})-\mathcal{E}(f_\rho^V)\right)\le\widetilde{C}_{\phi,\beta,\gamma}T^{-\min\left\{\frac{1}{8}+\frac{\beta}{24},\frac{\beta}{4},\frac{b}{2}-\frac{1}{4}\right\}}.$$

An important relation concerning the hinge loss is the one (Zhang, 2004) between the excess misclassification error and the excess generalization error given for any measurable function $f : X \to \mathbb{R}$ as

$$\mathcal{R}(\mathrm{sgn}(f)) - \mathcal{R}(f_c) \le \mathcal{E}(f) - \mathcal{E}(f_c).$$

Combining this relation with the above bound for the excess generalization error proves the conclusion of Theorem 11. ■

Turn to the general loss ϕ. We give an additional assumption that $\phi''(0)$ exists and is positive. Under this assumption it was proved in Chen et al. (2004) and Bartlett et al. (2006) that there exists a constant depending c_ϕ only on ϕ such that for any measurable function $f : X \to \mathbb{R}$,

$$\mathcal{R}(\mathrm{sgn}(f)) - \mathcal{R}(f_c) \le c_\phi \sqrt{\mathcal{E}(f) - \mathcal{E}(f_\rho^\phi)}.$$

Then Theorem 29 gives the following learning rate.

Corollary 30 *Let ϕ be a loss function such that $\phi''(0)$ exists and is positive. Under the assumptions of Theorem 29, if $\gamma = \frac{2}{5+10p+5\beta}$, we have*

$$\mathbb{E}_{z_1,\dots,z_T}\left(\mathcal{R}(sgn(f_{T+1})) - \mathcal{R}(f_c)\right) \le \widetilde{C}_{\phi,\beta} T^{-\min\{\frac{\beta}{5+10p+5\beta}, \frac{b}{4} - \frac{2+3p}{10+20p+10\beta}\}},$$

where $\tilde{C}_{\phi,\beta}$ is a constant independent of T.

As an example, the q-norm SVM loss $\phi(x) = ((1-x)_+)^q$ with $q > 1$ satisfies $\phi''(0) > 0$ and (17) with $p = q - 1$. So Corollary 30 yields the following rates.

Example 7 *Let $\phi(x) = ((1-x)_+)^q$ with $q > 1$. Under the assumptions of Theorem 29, if $\gamma = \frac{2}{10q-5+5\beta}$, $\alpha = \frac{8q-6+4\beta}{10q-5+5\beta}$ and $b > \frac{6q-2}{10q-5+5\beta}$, then*

$$\mathbb{E}_{z_1,\dots,z_T}\left(\mathcal{R}(sgn(f_{T+1})) - \mathcal{R}(f_c)\right) = O\left(T^{-\min\{\frac{\beta}{10q-5+5\beta}, \frac{b}{4} - \frac{3q-1}{20q-10+10\beta}\}}\right).$$

Finally we verify the learning rates for regression with insensitive loss stated in Section 2.

5.2 Proof of Theorem 10

We need the regularizing function $f_\lambda^{V_{ls}}$ defined by (13) with the least square loss $V = V_{ls}$. It can be found, for example, in Smale and Zhou (2007) that regularity condition (7) implies

$$\|f_\lambda^{V_{ls}} - f_\rho\|_K \le \left(\frac{\lambda}{2}\right)^{r-\frac{1}{2}} \|g_\rho\|_{L^2_{\rho_X}}, \qquad \text{when } \frac{1}{2} < r \le \frac{3}{2}$$

and

$$\|f_\lambda^{V_{ls}} - f_\rho\|_{L^2_{\rho_X}} \le \left(\frac{\lambda}{2}\right)^{r} \|g_\rho\|_{L^2_{\rho_X}}, \qquad \text{when } 0 < r \le 1.$$

It follows that when $\lambda \le 2(\kappa\|g_\rho\|_{L^2_{\rho_X}})^{2/(1-2r)}$, we have $\|f_\lambda^{V_{ls}} - f_\rho\|_{C(X)} \le 1$. Thus by the special form of the conditional distribution ρ_x, we see from the conclusion of Example 6 with $p = 1$ that

$f_\lambda^{V_{in}} = f_{2\lambda}^{V_{ls}}$ and bounds for $\|f_\lambda^{V_{in}} - f_\rho\|_K$ and $\|f_\lambda^{V_{in}} - f_\rho\|_{L^2_{\rho_X}}$ follow. Moreover, condition (12) for $\mathcal{D}(\lambda)$ is valid with $\beta = 1$.

Now we check other conditions of Proposition 28.

Condition (16) is valid because $K \in C^{2s}(X \times X)$ with $0 < s \le \frac{1}{2}$.

By a simple computation, incremental condition (17) is verified with exponent $p = 0$.

Note that $\|f_\rho\|_K \le \kappa^{2r-1}\|g_\rho\|_{L^2_{\rho_X}}$ and $\|f_\rho\|_{C^s(X)} \le (\kappa + \kappa_{2s})\|f_\rho\|_K$. Then for any $x, u \in X$ and $g \in C^s(Y)$, we see from the uniform distribution ρ_x and ρ_u that

$$\begin{aligned}\left|\int_Y g(y)d(\rho_x - \rho_u)\right| &= \frac{1}{2}\left|\int_{f_\rho(x)-1}^{f_\rho(x)+1} g(y)dy - \int_{f_\rho(u)-1}^{f_\rho(u)+1} g(y)dy\right| \le \|g\|_{C(Y)}|f_\rho(x) - f_\rho(u)| \\ &\le \|g\|_{C(Y)}(\kappa + \kappa_{2s})\kappa^{2r-1}\|g_\rho\|_{L^2_{\rho_X}}(d(x,u))^s.\end{aligned}$$

This verifies Lipschitz s continuous condition (4) for $\{\rho_x\}$ with constant $C_\rho = (\kappa + \kappa_{2s})\kappa^{2r-1}\|g_\rho\|_{L^2_{\rho_X}}$.

Thus all conditions of Proposition 28 are satisfied and we obtain

$$\mathbb{E}_{z_1,z_2,\cdots,z_T}(\|f_{T+1} - f_{\lambda_T}^{V_{in}}\|_K^2) \le C_{K,V,\rho,b,\beta,s}T^{-\theta}$$

where

$$\theta := \min\left\{2 - 2\gamma - 2\alpha, \alpha - \gamma, b - 2\gamma\right\}.$$

Finally we get

$$\mathbb{E}_{z_1,z_2,\cdots,z_T}(\|f_{T+1} - f_\rho\|_K) \le \sqrt{C_{K,V,\rho,b,\beta,s}}T^{-\theta/2} + \left(\frac{\lambda_{T+1}}{2}\right)^{r-\frac{1}{2}}\|g_\rho\|_{L^2_{\rho_X}}, \quad \text{when } \frac{1}{2} < r \le \frac{3}{2}$$

and

$$\mathbb{E}_{z_1,z_2,\cdots,z_T}(\|f_{T+1} - f_\rho\|_{L^2_{\rho_X}}) \le \kappa\sqrt{C_{K,V,\rho,b,\beta,s}}T^{-\theta/2} + \left(\frac{\lambda_{T+1}}{2}\right)^{r}\|g_\rho\|_{L^2_{\rho_X}}, \quad \text{when } 0 < r \le 1.$$

Then our desired learning rates follow. ■

This appendix includes some detailed proofs.

A.1 Proof of Proposition 6

The first statement follows by taking $g(y) = y$ on Y because

$$|f_\rho(x) - f_\rho(u)| = \left| \int_Y g(y) d(\rho_x - \rho_u)(y) \right| \le \|\rho_x - \rho_u\|_{(C^s(Y))^*} \|g\|_{C^s(Y)}$$

and $\|g\|_{C^s(Y)} = \|g\|_{C(Y)} + |g|_{C^s(Y)} \le \sup_{y\in Y} |y| + 2^{1-s} \sup_{y\in Y} |y|$. Actually the above estimates tell us that f_ρ is continuous and belongs to $C^s(X)$ with $|f_\rho|_{C^s(X)} \le C_\rho(1 + 2^{1-s}) \sup_{y\in Y} |y|$.

For the second statement, since $Y = \{1, -1\}$, we have $f_\rho(x) = \rho_x(\{1\}) - \rho_x(\{-1\})$. It follows that for each $y \in Y$ and $x \in X$, there holds $\rho_x(\{y\}) = \frac{1+yf_\rho(x)}{2}$. So for any $g \in C^s(Y)$ and $x, u \in X$,

$$\int_Y g(y) d(\rho_x - \rho_u)(y) = \sum_{y\in Y} g(y) \frac{y[f_\rho(x) - f_\rho(u)]}{2} = \sum_{y\in Y} \frac{yg(y)}{2} [f_\rho(x) - f_\rho(u)].$$

Now the conclusion follows from

$$\left| \int_Y g(y) d(\rho_x - \rho_u)(y) \right| \le \|g\|_{C(Y)} |f_\rho(x) - f_\rho(u)| \le |f_\rho|_{C^s(X)} (d(x,u))^s \|g\|_{C^s(Y)}.$$

This proves Proposition 6. ■

A.2 Proof of Example 4

For $x \in X$, we have $\rho_x(\{1\}) = f_{\rho,-1}(x) + f_\rho(x)$ and $\rho_x(\{0\}) = 1 - 2f_{\rho,-1}(x) - f_\rho(x)$. Hence for any $g \in C^s(Y)$,

$$\int_Y g(y) d\rho_x = f_{\rho,-1}(x) \{g(1) - 2g(0) + g(-1)\} + f_\rho(x) \{g(1) - g(0)\} + g(0)$$

and for $u \in X$,

$$\int_Y g(y) d(\rho_x - \rho_u) = [f_{\rho,-1}(x) - f_{\rho,-1}(u)] \{g(1) - 2g(0) + g(-1)\} + [f_\rho(x) - f_\rho(u)] \{g(1) - g(0)\}.$$

Then our statement follows from the first part of Proposition 6. This proves the conclusion of Example 4. ■

A.3 Proof of Example 6

Let $x \in X$. When $f(x) \ge f_\rho^{V_{in}}(x)$, we see from the explicit form of the insensitive loss V_{in} that

$$\begin{aligned} & \int_Y V_{in}(y, f(x)) d\rho_x(y) - \int_Y V_{in}(y, f_\rho^{V_{in}}(x)) d\rho_x(y) \\ = & \int_{y \ge f(x)} f_\rho^{V_{in}}(x) - f(x) d\rho_x + \int_{y \le f_\rho^{V_{in}}(x)} f(x) - f_\rho^{V_{in}}(x) d\rho_x \\ & + \int_{f_\rho^{V_{in}}(x) < y < f(x)} f(x) + f_\rho^{V_{in}}(x) - 2y d\rho_x. \end{aligned}$$

It follows that

$$\mathcal{E}(f) - \mathcal{E}(f_\rho^{V_{in}}) = \int_X \left\{ |f(x) - f_\rho^{V_{in}}(x)| \Delta_x + 2 \int_{I_x} |f(x) - y| d\rho_x \right\} d\rho_X \tag{31}$$

where

$$\Delta_x := \left|\rho_x\left(\{y \in Y : y \le f_\rho^{V_{in}}(x)\}\right) - \rho_x\left(\{y \in Y : y > f_\rho^{V_{in}}(x)\}\right)\right|$$

and I_x in the open interval between $f_\rho^{V_{in}}(x)$ and $f(x)$. The same relation (31) also holds when $f(x) < f_\rho^{V_{in}}(x)$.

Now we use the special assumption on the conditional distributions and see that the median and mean of ρ_x are equal: $f_\rho^{V_{in}}(x) = f_\rho(x)$ for each $x \in X$. Moreover, $\Delta_x = 0$ and when $f_\rho(x) \le f(x) \le f_\rho(x) + 1$, we have

$$2\int_{I_x} |f(x) - y| d\rho_x = 2\int_0^{f(x)-f_\rho(x)} (f(x) - f_\rho(x) - u)\frac{p}{2}u^{p-1}du = \frac{|f(x) - f_\rho(x)|^{p+1}}{p+1}.$$

The same expression holds true when $f_\rho(x) - 1 \le f(x) < f_\rho(x)$. When $|f(x) - f_\rho(x)| > 1$, since ρ_x vanishes outside $[-f_\rho(x) - 1, f_\rho(x) + 1]$, we have $2\int_{I_x} |f(x) - y| d\rho_x = |f(x) - f_\rho(x)| - \frac{p}{p+1}$. Therefore, (31) is the same as

$$\begin{aligned}\mathcal{E}(f) - \mathcal{E}(f_\rho^{V_{in}}) &= \int_{\{x \in X : |f(x) - f_\rho(x)| \le 1\}} \frac{|f(x) - f_\rho(x)|^{p+1}}{p+1} d\rho_X \\ &\quad + \int_{\{x \in X : |f(x) - f_\rho(x)| > 1\}} |f(x) - f_\rho(x)| - \frac{p}{p+1} d\rho_X.\end{aligned}$$

This proves the desired expression for $\mathcal{E}(f) - \mathcal{E}(f_\rho^{V_{in}})$ and hence the bound for $\mathcal{D}(\lambda)$. ■

Abstract

We describe, analyze, and experiment with a framework for empirical loss minimization with regularization. Our algorithmic framework alternates between two phases. On each iteration we first perform an *unconstrained* gradient descent step. We then cast and solve an instantaneous optimization problem that trades off minimization of a regularization term while keeping close proximity to the result of the first phase. This view yields a simple yet effective algorithm that can be used for batch penalized risk minimization and online learning. Furthermore, the two phase approach enables sparse solutions when used in conjunction with regularization functions that promote sparsity, such as ℓ_1. We derive concrete and very simple algorithms for minimization of loss functions with ℓ_1, ℓ_2, ℓ_2^2, and ℓ_∞ regularization. We also show how to construct efficient algorithms for mixed-norm ℓ_1/ℓ_q regularization. We further extend the algorithms and give efficient implementations for very high-dimensional data with sparsity. We demonstrate the potential of the proposed framework in a series of experiments with synthetic and natural data sets.

Keywords: subgradient methods, group sparsity, online learning, convex optimization

1. Introduction

Before we begin, we establish notation for the content of this paper. We denote scalars by lower case letters and vectors by lower case bold letters, for example, $\boldsymbol{w}$. The inner product of two vectors $\boldsymbol{u}$ and $\boldsymbol{v}$ is denoted $\langle \boldsymbol{u}, \boldsymbol{v} \rangle$. We use $\|\boldsymbol{x}\|_p$ to denote the p-norm of the vector $\boldsymbol{x}$ and $\|\boldsymbol{x}\|$ as a shorthand for $\|\boldsymbol{x}\|_2$.

The focus of this paper is an algorithmic framework for regularized convex programming to minimize the following sum of two functions:

$$f(\boldsymbol{w}) + r(\boldsymbol{w}), \tag{1}$$

where both f and r are convex bounded below functions (so without loss of generality we assume they are into $\mathbb{R}_+$). Often, the function f is an empirical loss and takes the form $\sum_{i \in S} \ell_i(\boldsymbol{w})$ for a sequence of loss functions $\ell_i : \mathbb{R}^n \to \mathbb{R}_+$, and $r(\boldsymbol{w})$ is a regularization term that penalizes for excessively complex vectors, for instance $r(\boldsymbol{w}) = \lambda \|\boldsymbol{w}\|_p$. This task is prevalent in machine learning, in which a learning problem for decision and prediction problems is cast as a convex optimization problem. To that end, we investigate a general and intuitive algorithm, known as *forward-backward splitting*, to minimize Eq. (1), focusing especially on derivations for and use of non-differentiable regularization functions.

Many methods have been proposed to minimize general convex functions such as that in Eq. (1). One of the most general is the subgradient method (see, e.g., Bertsekas, 1999), which is elegant and very simple. Let $\partial f(\boldsymbol{w})$ denote the subgradient set of f at $\boldsymbol{w}$, namely,

$$\partial f(\boldsymbol{w}) = \left\{ \boldsymbol{g} \mid \forall \boldsymbol{v} : f(\boldsymbol{v}) \geq f(\boldsymbol{w}) + \langle \boldsymbol{g}, \boldsymbol{v} - \boldsymbol{w} \rangle \right\}.$$

Sub-gradient procedures then minimize the function $f(\boldsymbol{w})$ by iteratively updating the parameter vector $\boldsymbol{w}$ according to the update rule

$$\boldsymbol{w}_{t+1} = \boldsymbol{w}_t - \eta_t \boldsymbol{g}_t^f \quad ,$$

where η_t is a constant or diminishing a step size and $\boldsymbol{g}_t^f \in \partial f(\boldsymbol{w}_t)$ is an arbitrary vector from the subgradient set of f evaluated at $\boldsymbol{w}_t$. A more general method than the above is the projected gradient method, which iterates

$$\boldsymbol{w}_{t+1} \; = \; \Pi_\Omega\left(\boldsymbol{w}_t - \eta_t \boldsymbol{g}_t^f\right) \; = \; \operatorname*{argmin}_{\boldsymbol{w}\in\Omega} \left\{ \left\| \boldsymbol{w} - (\boldsymbol{w}_t - \eta_t \boldsymbol{g}_t^f) \right\|_2^2 \right\}$$

where $\Pi_\Omega(\boldsymbol{w})$ is the Euclidean projection of $\boldsymbol{w}$ onto the set Ω. Standard results (Bertsekas, 1999) show that the (projected) subgradient method converges at a rate of $O(1/\varepsilon^2)$, or equivalently that the error $f(\boldsymbol{w}) - f(\boldsymbol{w}^\star) = O(1/\sqrt{T})$, given some simple assumptions on the boundedness of the subdifferential set and Ω (we have omitted constants dependent on $\|\partial f\|$ or $\dim(\Omega)$).

If we use the subgradient method to minimize Eq. (1), the iterates are simply $\boldsymbol{w}_{t+1} = \boldsymbol{w}_t - \eta_t \boldsymbol{g}_t^f - \eta_t \boldsymbol{g}_t^r$, where $\boldsymbol{g}_t^r \in \partial r(\boldsymbol{w}_t)$. A common problem in subgradient methods is that if r or f is non-differentiable, the iterates of the subgradient method are very rarely at the points of non-differentiability. In the case of regularization functions such as $r(\boldsymbol{w}) = \|\boldsymbol{w}\|_1$, however, these points (zeros in the case of the ℓ_1-norm) are often the true minima of the function. Furthermore, with ℓ_1 and similar penalties, zeros are desirable solutions as they tend to convey information about the structure of the problem being solved, and in the case of statistical inference, can often yield the correct sparsity structure of the parameters (Zhao and Yu, 2006; Meinshausen and Bühlmann, 2006).

There has been a significant amount of work related to minimizing Eq. (1), especially when the function r is a sparsity-promoting regularizer, and much of it stems from the machine learning, statistics, and optimization communities. We can hardly do justice to the body of prior work, and we provide a few references here to the research we believe is most directly related. The approach we pursue below is known as *forward-backward splitting* in the optimization literature, which is closely related to the proximal method.

The forward-backward splitting method was first proposed by Lions and Mercier (1979) and has been analyzed by several researches in the context of maximal monotone operators in the optimization literature. Chen and Rockafellar (1997) and Tseng (2000) give conditions and modifications of forward-backward splitting to attain linear convergence rates. Combettes and Wajs (2005) give proofs of convergence for forward-backward splitting in Hilbert spaces under asymptotically negligible perturbations, though without establishing strong rates of convergence. Prior work on convergence of the method often requires an assumption of strong monotonicity of the maximal monotone operators (equivalent to strong convexity of at least one of the functions in Eq. (1)), and as far as we know, all analyses assume that f is differentiable with Lipschitz-continuous gradient. The analyses have also been carried out in a non-stochastic and non-online setting.

More recently, Wright et al. (2009) suggested the use of the method for sparse signal reconstruction, where $f(\boldsymbol{w}) = \|\boldsymbol{y} - A\boldsymbol{w}\|^2$, though they note that the method can apply to suitably smooth convex functions f. Nesterov (2007) gives analysis of convergence rates using gradient mapping techniques when f has Lipschitz continuous gradient, which was inspired by Wright et al. In the special case that $r(\boldsymbol{w}) = \lambda\|\boldsymbol{w}\|_1$, similar methods to the algorithms we investigate have been proposed and termed iterative thresholding (Daubechies et al., 2004) or truncated gradient (Langford et al., 2008) in signal processing and machine learning, but the authors were apparently unaware of the connection to splitting methods.

Similar projected-gradient methods, when the regularization function r is no longer part of the objective function but rather cast as a constraint so that $r(\boldsymbol{w}) \leq \lambda$, are also well known (Bertsekas, 1999). In signal processing, the problem is often termed as an inverse problem with sparsity constraints, see for example, Daubechies et al. (2008) and the references therein. Duchi et al. (2008) give a general and efficient projected gradient method for ℓ_1-constrained problems. We make use of one of Duchi et al.'s results in obtaining an efficient algorithm for the case when $r(\boldsymbol{w}) = \|\boldsymbol{w}\|_\infty$ (a setting useful for mixed-norm regularization). There is also a body of literature on regret analysis for online learning and online convex programming with convex constraints, which we build upon here (Zinkevich, 2003; Hazan et al., 2006; Shalev-Shwartz and Singer, 2007). Learning sparse models generally is of great interest in the statistics literature, specifically in

the context of consistency and recovery of sparsity patterns through ℓ_1 or mixed-norm regularization across multiple tasks (Meinshausen and Bühlmann, 2006; Obozinski et al., 2008; Zhao et al., 2006).

In this paper, we describe a general gradient-based framework for online and batch convex programming. To make our presentation a little simpler, we call our approach FOBOS, for FOrward-Backward Splitting.[1] Our proofs are made possible through the use of "forward-looking" subgradients, and FOBOS is a distillation of some the approaches mentioned above for convex programming. Our alternative view lends itself to unified analysis and more general settings, efficient implementation, and provides a flexible tool for the derivation of algorithms for old and new convex programming settings.

The paper is organized as follows. In the next section, we begin by introducing and formally defining the method, giving some simple preliminary analysis. We follow the introduction by giving in Sec. 3 rates of convergence for batch (offline) optimization. We then extend the results to stochastic gradient descent and provide regret bounds for online convex programming in Sec. 4. To demonstrate the simplicity and usefulness of the framework, we derive in Sec. 5 algorithms for several different choices of the regularizing function r, though most of these results are known. We then extend these methods to be efficient in very high dimensional learning settings where the input data is sparse in Sec. 6. Finally, we conclude in Sec. 7 with experiments examining various aspects of the proposed framework, in particular the runtime and sparsity selection performance of the derived algorithms.

2. Forward-Looking Subgradients and Forward-Backward Splitting

Our approach to Forward-Backward Splitting is motivated by the desire to have the iterates $\boldsymbol{w}_t$ attain points of non-differentiability of the function r. The method alleviates the problems of non-differentiability in cases such as ℓ_1-regularization by taking analytical minimization steps interleaved with subgradient steps. Put informally, FOBOS can be viewed as analogous to the *projected* subgradient method while replacing or augmenting the projection step with an instantaneous minimization problem for which it is possible to derive a closed form solution. FOBOS is succinct as each iteration consists of the following two steps:

$$\boldsymbol{w}_{t+\frac{1}{2}} = \boldsymbol{w}_t - \eta_t \boldsymbol{g}_t^f, \tag{2}$$

$$\boldsymbol{w}_{t+1} = \operatorname*{argmin}_{\boldsymbol{w}} \left\{ \frac{1}{2} \left\| \boldsymbol{w} - \boldsymbol{w}_{t+\frac{1}{2}} \right\|^2 + \eta_{t+\frac{1}{2}} r(\boldsymbol{w}) \right\} . \tag{3}$$

In the above, $\boldsymbol{g}_t^f$ is a vector in $\partial f(\boldsymbol{w}_t)$ and η_t is the step size at time step t of the algorithm. The actual value of η_t depends on the specific setting and analysis. The first step thus simply amounts to an unconstrained subgradient step with respect to the function f. In the second step we find a new vector that interpolates between two goals: (i) stay close to the interim vector $\boldsymbol{w}_{t+\frac{1}{2}}$, and (ii) attain a low complexity value as expressed by r. Note that the regularization function is scaled by an interim step size, denoted $\eta_{t+\frac{1}{2}}$. The analyses we describe in the sequel determine the specific value of $\eta_{t+\frac{1}{2}}$, which is either η_t or η_{t+1}.

A key property of the solution of Eq. (3) is the necessary condition for optimality and gives the reason behind the name FOBOS. Namely, the zero vector must belong to subgradient set of the objective at the optimum $\boldsymbol{w}_{t+1}$, that is,

$$\mathbf{0} \in \partial \left\{ \frac{1}{2} \left\| \boldsymbol{w} - \boldsymbol{w}_{t+\frac{1}{2}} \right\|^2 + \eta_{t+\frac{1}{2}} r(\boldsymbol{w}) \right\} \Bigg|_{\boldsymbol{w}=\boldsymbol{w}_{t+1}} .$$

Since $\boldsymbol{w}_{t+\frac{1}{2}} = \boldsymbol{w}_t - \eta_t \boldsymbol{g}_t^f$, the above property amounts to

$$\mathbf{0} \in \boldsymbol{w}_{t+1} - \boldsymbol{w}_t + \eta_t \boldsymbol{g}_t^f + \eta_{t+\frac{1}{2}} \partial r(\boldsymbol{w}_{t+1}). \tag{4}$$

1. An earlier draft of this paper referred to our algorithm as FOLOS, for FOrward LOoking Subgradients. In order not to confuse readers of the early draft, we attempt to stay close to the earlier name and use the acronym FOBOS rather than Fobas.

The property $\mathbf{0} \in \boldsymbol{w}_{t+1} - \boldsymbol{w}_t + \eta_t \boldsymbol{g}_t^f + \eta_{t+\frac{1}{2}} \partial r(\boldsymbol{w}_{t+1})$ implies that so long as we choose $\boldsymbol{w}_{t+1}$ to be the minimizer of Eq. (3), we are guaranteed to obtain a vector $\boldsymbol{g}_{t+1}^r \in \partial r(\boldsymbol{w}_{t+1})$ such that

$$\mathbf{0} = \boldsymbol{w}_{t+1} - \boldsymbol{w}_t + \eta_t \boldsymbol{g}_t^f + \eta_{t+\frac{1}{2}} \boldsymbol{g}_{t+1}^r \ .$$

The above equation can be understood as an update scheme where the new weight vector $\boldsymbol{w}_{t+1}$ is a linear combination of the previous weight vector $\boldsymbol{w}_t$, a vector from the subgradient set of f evaluated at $\boldsymbol{w}_t$, and a vector from the subgradient of r evaluated at the yet to be determined $\boldsymbol{w}_{t+1}$, hence the name Forward-Looking Subgradient. To recap, we can write $\boldsymbol{w}_{t+1}$ as

$$\boldsymbol{w}_{t+1} = \boldsymbol{w}_t - \eta_t \, \boldsymbol{g}_t^f - \eta_{t+\frac{1}{2}} \, \boldsymbol{g}_{t+1}^r, \tag{5}$$

where $\boldsymbol{g}_t^f \in \partial f(\boldsymbol{w}_t)$ and $\boldsymbol{g}_{t+1}^r \in \partial r(\boldsymbol{w}_{t+1})$. Solving Eq. (3) with r above has two main benefits. First, from an algorithmic standpoint, it enables sparse solutions at virtually no additional computational cost. Second, the forward-looking gradient allows us to build on existing analyses and show that the resulting framework enjoys the formal convergence properties of many existing gradient-based and online convex programming algorithms.

3. Convergence Analysis of FOBOS

Upon first look FOBOS looks substantially different from sub-gradient and online convex programming methods. However, the fact that FOBOS actually employs a forward-looking subgradient of the regularization function lets us build nicely on existing analyses. In this section we modify known results while using the forward-looking property of FOBOS to provide convergence rate analysis for FOBOS. To do so we will set $\eta_{t+\frac{1}{2}}$ properly. As we show in the sequel, it is sufficient to set $\eta_{t+\frac{1}{2}}$ to η_t or η_{t+1}, depending on whether we are doing online or batch optimization, in order to obtain convergence and low regret bounds. We start with an analysis of FOBOS in a batch setting. In this setting we use the subgradient of f, set $\eta_{t+\frac{1}{2}} = \eta_{t+1}$ and update $\boldsymbol{w}_t$ to $\boldsymbol{w}_{t+1}$ as prescribed by Eq. (2) and Eq. (3).

Throughout the section we denote by $\boldsymbol{w}^\star$ the minimizer of $f(\boldsymbol{w}) + r(\boldsymbol{w})$. In what follows, define $\|\partial f(\boldsymbol{w})\| \triangleq \sup_{\boldsymbol{g} \in \partial f(\boldsymbol{w})} \|\boldsymbol{g}\|$. We begin by deriving convergence results under the fairly general assumption (see, e.g., Langford et al. 2008 or Shalev-Shwartz and Tewari 2009) that the subgradients are bounded as follows:

$$\|\partial f(\boldsymbol{w})\|^2 \leq A f(\boldsymbol{w}) + G^2, \quad \|\partial r(\boldsymbol{w})\|^2 \leq A r(\boldsymbol{w}) + G^2 \ . \tag{6}$$

For example, any Lipschitz loss (such as the logistic loss or hinge loss used in support vector machines) satisfies the above with $A = 0$ and G equal to the Lipschitz constant. Least squares estimation satisfies Eq. (6) with $G = 0$ and $A = 4$. The next lemma, while technical, provides a key tool for deriving all of the convergence results in this paper.

Lemma 1 (Bounding Step Differences) *Assume that the norms of the subgradients of the functions f and r are bounded as in Eq. (6):*

$$\|\partial f(\boldsymbol{w})\|^2 \leq A f(\boldsymbol{w}) + G^2, \quad \|\partial r(\boldsymbol{w})\|^2 \leq A r(\boldsymbol{w}) + G^2 \ .$$

Let $\eta_{t+1} \leq \eta_{t+\frac{1}{2}} \leq \eta_t$ and suppose that $\eta_t \leq 2\eta_{t+\frac{1}{2}}$. If we use the FOBOS *update of Eqs. (2) and (3), then for a constant $c \leq 4$ and any vector $\boldsymbol{w}^\star$,*

$$\begin{aligned} & 2\eta_t(1 - cA\eta_t) f(\boldsymbol{w}_t) + 2\eta_{t+\frac{1}{2}}(1 - cA\eta_{t+\frac{1}{2}}) r(\boldsymbol{w}_{t+1}) \\ & \quad \leq \quad 2\eta_t f(\boldsymbol{w}^\star) + 2\eta_{t+\frac{1}{2}} r(\boldsymbol{w}^\star) + \|\boldsymbol{w}_t - \boldsymbol{w}^\star\|^2 - \|\boldsymbol{w}_{t+1} - \boldsymbol{w}^\star\|^2 + 7\eta_t \eta_{t+\frac{1}{2}} G^2 \ . \end{aligned}$$

Proof We begin with a few simple properties of the forward-looking subgradient steps before proceeding with the core of the proof. Note first that for some $\boldsymbol{g}_t^f \in \partial f(\boldsymbol{w}_t)$ and $\boldsymbol{g}_{t+1}^r \in \partial r(\boldsymbol{w}_{t+1})$, we have as in Eq. (5)

$$\boldsymbol{w}_{t+1} - \boldsymbol{w}_t = -\eta_t \boldsymbol{g}_t^f - \eta_{t+\frac{1}{2}} \boldsymbol{g}_{t+1}^r \ . \tag{7}$$

The definition of a subgradient implies that for any $\boldsymbol{g}_{t+1}^r \in \partial r(\boldsymbol{w}_{t+1})$ (and similarly for any $\boldsymbol{g}_t^f \in \partial f(\boldsymbol{w}_t)$ with $f(\boldsymbol{w}_t)$ and $f(\boldsymbol{w}^\star)$)

$$r(\boldsymbol{w}^\star) \geq r(\boldsymbol{w}_{t+1}) + \left\langle \boldsymbol{g}_{t+1}^r, \boldsymbol{w}^\star - \boldsymbol{w}_{t+1} \right\rangle \quad \Rightarrow \quad -\left\langle \boldsymbol{g}_{t+1}^r, \boldsymbol{w}_{t+1} - \boldsymbol{w}^\star \right\rangle \leq r(\boldsymbol{w}^\star) - r(\boldsymbol{w}_{t+1}). \tag{8}$$

From the Cauchy-Shwartz Inequality and Eq. (7), we obtain

$$\begin{aligned}
\left\langle \boldsymbol{g}_{t+1}^r, (\boldsymbol{w}_{t+1} - \boldsymbol{w}_t) \right\rangle &= \left\langle \boldsymbol{g}_{t+1}^r, (-\eta_t \boldsymbol{g}_t^f - \eta_{t+\frac{1}{2}} \boldsymbol{g}_{t+1}^r) \right\rangle \\
&\leq \|\boldsymbol{g}_{t+1}^r\| \|\eta_{t+\frac{1}{2}} \boldsymbol{g}_{t+1}^r + \eta_t \boldsymbol{g}_t^f\| \leq \eta_{t+\frac{1}{2}} \|\boldsymbol{g}_{t+1}^r\|^2 + \eta_t \|\boldsymbol{g}_{t+1}^r\| \|\boldsymbol{g}_t^f\| \\
&\leq \eta_{t+\frac{1}{2}} \left(A r(\boldsymbol{w}_{t+1}) + G^2 \right) + \eta_t \left(A \max\{f(\boldsymbol{w}_t), r(\boldsymbol{w}_{t+1})\} + G^2 \right) \ .
\end{aligned} \tag{9}$$

We now proceed to bound the difference between $\boldsymbol{w}^\star$ and $\boldsymbol{w}_{t+1}$, and using a telescoping sum we will eventually bound $f(\boldsymbol{w}_t) + r(\boldsymbol{w}_t) - f(\boldsymbol{w}^\star) - r(\boldsymbol{w}^\star)$. First, we expand norm squared of the difference between $\boldsymbol{w}_t$ and $\boldsymbol{w}_{t+1}$,

$$\begin{aligned}
\|\boldsymbol{w}_{t+1} - \boldsymbol{w}^\star\|^2 &= \|\boldsymbol{w}_t - (\eta_t \boldsymbol{g}_t^f + \eta_{t+\frac{1}{2}} \boldsymbol{g}_{t+1}^r) - \boldsymbol{w}^\star\|^2 \\
&= \|\boldsymbol{w}_t - \boldsymbol{w}^\star\|^2 - 2\left[\eta_t \left\langle \boldsymbol{g}_t^f, \boldsymbol{w}_t - \boldsymbol{w}^\star \right\rangle + \eta_{t+\frac{1}{2}} \left\langle \boldsymbol{g}_{t+1}^r, \boldsymbol{w}_t - \boldsymbol{w}^\star \right\rangle \right] + \|\eta_t \boldsymbol{g}_t^f + \eta_{t+\frac{1}{2}} \boldsymbol{g}_{t+1}^r\|^2 \\
&= \|\boldsymbol{w}_t - \boldsymbol{w}^\star\|^2 - 2\eta_t \left\langle \boldsymbol{g}_t^f, \boldsymbol{w}_t - \boldsymbol{w}^\star \right\rangle + \|\eta_t \boldsymbol{g}_t^f + \eta_{t+\frac{1}{2}} \boldsymbol{g}_{t+1}^r\|^2 \\
&\quad -2\eta_{t+\frac{1}{2}} \left[\left\langle \boldsymbol{g}_{t+1}^r, \boldsymbol{w}_{t+1} - \boldsymbol{w}^\star \right\rangle - \left\langle \boldsymbol{g}_{t+1}^r, \boldsymbol{w}_{t+1} - \boldsymbol{w}_t \right\rangle \right] \ .
\end{aligned} \tag{10}$$

We can bound the third term above by noting that

$$\begin{aligned}
&\|\eta_t \boldsymbol{g}_t^f + \eta_{t+\frac{1}{2}} \boldsymbol{g}_{t+1}^r\|^2 \\
&= \eta_t^2 \|\boldsymbol{g}_t^f\|^2 + 2\eta_t \eta_{t+\frac{1}{2}} \left\langle \boldsymbol{g}_t^f, \boldsymbol{g}_{t+1}^r \right\rangle + \eta_{t+\frac{1}{2}}^2 \|\boldsymbol{g}_{t+1}^r\|^2 \\
&\leq \eta_t^2 A f(\boldsymbol{w}_t) + 2\eta_t \eta_{t+\frac{1}{2}} A \max\{f(\boldsymbol{w}_t), r(\boldsymbol{w}_{t+1})\} + \eta_{t+\frac{1}{2}}^2 A r(\boldsymbol{w}_{t+1}) + 4\eta_t^2 G^2 \ .
\end{aligned}$$

We now use Eq. (9) to bound the last term of Eq. (10) and the above bound on $\eta_t \boldsymbol{g}_t^f + \eta_{t+\frac{1}{2}} \boldsymbol{g}_{t+1}^r$ to get that

$$\begin{aligned}
&\|\boldsymbol{w}_{t+1} - \boldsymbol{w}^\star\|^2 \\
&\leq \|\boldsymbol{w}_t - \boldsymbol{w}^\star\|^2 - 2\eta_t \left\langle \boldsymbol{g}_t^f, \boldsymbol{w}_t - \boldsymbol{w}^\star \right\rangle - 2\eta_{t+\frac{1}{2}} \left\langle \boldsymbol{g}_{t+1}^r, \boldsymbol{w}_{t+1} - \boldsymbol{w}^\star \right\rangle + \|\eta_t \boldsymbol{g}_t^f + \eta_{t+\frac{1}{2}} \boldsymbol{g}_{t+1}^r\|^2 \\
&\quad + 2\eta_{t+\frac{1}{2}} \left(\eta_{t+\frac{1}{2}} A r(\boldsymbol{w}_{t+1}) + 2\eta_t A \max\{f(\boldsymbol{w}_t), r(\boldsymbol{w}_{t+1})\} + 2\eta_t G^2 \right) \\
&\leq \|\boldsymbol{w}_t - \boldsymbol{w}^\star\|^2 + 2\eta_t \left(f(\boldsymbol{w}^\star) - f(\boldsymbol{w}_t) \right) + 2\eta_{t+\frac{1}{2}} \left(r(\boldsymbol{w}^\star) - r(\boldsymbol{w}_t) \right) + 7\eta_t^2 G^2 \\
&\quad + \eta_t^2 A f(\boldsymbol{w}_t) + 3\eta_t \eta_{t+\frac{1}{2}} A \max\{f(\boldsymbol{w}_t), r(\boldsymbol{w}_t)\} + 2\eta_{t+\frac{1}{2}}^2 A r(\boldsymbol{w}_{t+1}) \qquad (11) \\
&\leq \|\boldsymbol{w}_t - \boldsymbol{w}^\star\|^2 + 7\eta_t^2 G^2 \\
&\quad + 2\eta_t \left(f(\boldsymbol{w}^\star) - (1 - c\eta_t A) f(\boldsymbol{w}_t) \right) + 2\eta_{t+\frac{1}{2}} \left(r(\boldsymbol{w}^\star) - (1 - c\eta_{t+\frac{1}{2}} A) r(\boldsymbol{w}_{t+1}) \right) \ . \qquad (12)
\end{aligned}$$

To obtain Eq. (11) we used the standard convexity bounds established earlier in Eq. (8). The final bound given by Eq. (12) is due to the fact that $3A\eta_t \eta_{t+\frac{1}{2}} \leq 6A\eta_t^2$ and that for any $a, b \geq 0$, $\max\{a, b\} \leq a + b$. Rearranging

the terms $f(\cdot)$ and $r(\cdot)$ yields the desired inequality. ■

The lemma allows a proof of the following theorem, which constitutes the basis for deriving concrete convergence results for FOBOS. It is also demonstrates the ease of proving convergence results based on the lemma and the forward looking property.

Theorem 2 *Assume the following hold: (i) the norm of any subgradient from ∂f and the norm of any subgradient from ∂r are bounded as in Eq. (6), (ii) the norm of $\boldsymbol{w}^\star$ is less than or equal to D, (iii) $r(\mathbf{0}) = 0$, and (iv) $\frac{1}{2}\eta_t \leq \eta_{t+1} \leq \eta_t$. Then for a constant $c \leq 4$ with $\boldsymbol{w}_1 = \mathbf{0}$ and $\eta_{t+\frac{1}{2}} = \eta_{t+1}$,*

$$\sum_{t=1}^{T} \left[\eta_t \left((1 - cA\eta_t) f(\boldsymbol{w}_t) - f(\boldsymbol{w}^\star)\right) + \eta_t \left((1 - cA\eta_t) r(\boldsymbol{w}_t) - r(\boldsymbol{w}^\star)\right)\right] \leq D^2 + 7G^2 \sum_{t=1}^{T} \eta_t^2 \ .$$

Proof Rearranging the $f(\boldsymbol{w}^\star)$ and $r(\boldsymbol{w}^\star)$ terms from the bound in Lemma 1, we sum the loss terms over t from 1 through T and get a canceling telescoping sum:

$$\begin{aligned}
&\sum_{t=1}^{T} \left[\eta_t \left((1 - cA\eta_t) f(\boldsymbol{w}_t) - f(\boldsymbol{w}^\star)\right) + \eta_{t+1} \left((1 - cA\eta_{t+1}) r(\boldsymbol{w}_{t+1}) - r(\boldsymbol{w}^\star)\right)\right] \\
&\quad \leq \quad \|\boldsymbol{w}_1 - \boldsymbol{w}^\star\|^2 - \|\boldsymbol{w}_{T+1} - \boldsymbol{w}^\star\|^2 + 7G^2 \sum_{t=1}^{T} \eta_t^2 \ \leq \ \|\boldsymbol{w}_1 - \boldsymbol{w}^\star\|^2 + 7G^2 \sum_{t=1}^{T} \eta_t^2 \ . \qquad (13)
\end{aligned}$$

We now bound the time-shifted $r(\boldsymbol{w}_{t+1})$ terms by noting that

$$\begin{aligned}
&\sum_{t=1}^{T} \eta_{t+1} \left((1 - cA\eta_{t+1}) r(\boldsymbol{w}_{t+1}) - r(\boldsymbol{w}^\star)\right) \\
&\quad = \quad \sum_{t=1}^{T} \eta_t \left((1 - cA\eta_t) r(\boldsymbol{w}_t) - r(\boldsymbol{w}^\star)\right) + \eta_{T+1} \left((1 - cA\eta_{T+1}) r(\boldsymbol{w}_{t+1}) - r(\boldsymbol{w}^\star)\right) + \eta_1 r(\boldsymbol{w}^\star) \\
&\quad \geq \quad \sum_{t=1}^{T} \eta_t \left((1 - cA\eta_t) r(\boldsymbol{w}_{t+1}) - r(\boldsymbol{w}^\star)\right) + r(\boldsymbol{w}^\star)(\eta_1 - \eta_{T+1}) \\
&\quad \geq \quad \sum_{t=1}^{T} \eta_t \left((1 - cA\eta_t) r(\boldsymbol{w}_t) - r(\boldsymbol{w}^\star)\right) \ . \qquad (14)
\end{aligned}$$

Finally, we use the fact that $\|\boldsymbol{w}_1 - \boldsymbol{w}^\star\| = \|\boldsymbol{w}^\star\| \leq D$, along with with Eq. (13)) and Eq. (14) to get the desired bound. ■

In the remainder of this section, we present a few corollaries that are consequences of the theorem. The first corollary underscores that the rate of convergence in general is approximately $1/\varepsilon^2$, or, equivalently, $1/\sqrt{T}$.

Corollary 3 (Fixed step rate) *Assume that the conditions of Thm. 2 hold and that we run* FOBOS *for a predefined T iterations with $\eta_t = \frac{D}{\sqrt{7T}G}$ and that $(1 - cA\frac{D}{\sqrt{7T}G}) > 0$. Then*

$$\min_{t \in \{1,\ldots,T\}} f(\boldsymbol{w}_t) + r(\boldsymbol{w}_t) \leq \frac{1}{T} \sum_{t=1}^{T} f(\boldsymbol{w}_t) + r(\boldsymbol{w}_t) \leq \frac{3DG}{\sqrt{T}\left(1 - \frac{cAD}{G\sqrt{7T}}\right)} + \frac{f(\boldsymbol{w}^\star) + r(\boldsymbol{w}^\star)}{1 - \frac{cAD}{G\sqrt{7T}}}.$$

Proof Since we have $\eta_t = \eta$ for all t, the bound on the convergence rate from Thm. 2 becomes

$$\begin{aligned}
&\eta(1-cA\eta)T \min_{t\in\{1,\ldots,T\}} [f(\boldsymbol{w}_t) + r(\boldsymbol{w}_t) - f(\boldsymbol{w}^\star) - r(\boldsymbol{w}^\star)] \\
&\leq \quad \eta(1-cA\eta) \sum_{t=1}^{T} [f(\boldsymbol{w}_t) - f(\boldsymbol{w}^\star)] + [r(\boldsymbol{w}_t) - r(\boldsymbol{w}^\star)] \;\leq\; D^2 + 7G^2 T\eta^2 \;\; .
\end{aligned}$$

Plugging in the specified value for η gives the bound. ■

Another direct consequence of Thm. 2 is convergence of the minimum over t when running FOBOS with $\eta_t \propto 1/\sqrt{t}$ or with non-summable step sizes decreasing to zero.

Corollary 4 (Convergence of decreasing step sizes) *Assume that the conditions of Thm. 2 hold and the step sizes η_t satisfy $\eta_t \to 0$ and $\sum_{t=1}^{\infty} \eta_t = \infty$. Then*

$$\liminf_{t\to\infty} f(\boldsymbol{w}_t) + r(\boldsymbol{w}_t) - (f(\boldsymbol{w}^\star) + r(\boldsymbol{w}^\star)) = 0.$$

Finally, when f and r are Lipschitz with Lipschitz constant G, we immediately have

Corollary 5 *In addition to the conditions of Thm. 2, assume that the norm of any subgradient from ∂f and the norm of any subgradient from ∂r are bounded by G. Then*

$$\min_{t\in\{1,\ldots,T\}} (f(\boldsymbol{w}_t) + r(\boldsymbol{w}_t)) - (f(\boldsymbol{w}^\star) + r(\boldsymbol{w}^\star)) \leq \frac{D^2 + 7G^2 \sum_{t=1}^{T} \eta_t^2}{2\sum_{t=1}^{T} \eta_t}. \tag{15}$$

Bounds of the above form, where we obtain convergence for one of the points in the sequence $\boldsymbol{w}_1, \ldots, \boldsymbol{w}_T$ rather than the last point $\boldsymbol{w}_T$, are standard in subgradient optimization. The main reason that this weaker result occurs is due to the fact that we cannot guarantee a strict descent direction when using arbitrary subgradients (see, for example, Theorem 3.2.2 from Nesterov 2004). Another consequence of using non-differentiable functions means that analyses such as those carried out by Tseng (2000) and Chen and Rockafellar (1997) are difficult to apply, as the stronger rates rely on the existence and Lipschitz continuity of $\nabla f(\boldsymbol{w})$. However, it is possible to show linear convergence rates under suitable smoothness and strong convexity assumptions. When $\nabla f(\boldsymbol{w})$ is Lipschitz continuous, a more detailed analysis yields convergence rates of $1/\varepsilon$ (namely, $1/T$ in terms of number of iterations needed to be ε close to the optimum). A more complicated algorithm related to Nesterov's "estimate functions" (Nesterov, 2004) leads to $O(1/\sqrt{\varepsilon})$ convergence (Nesterov, 2007). For completeness, we give a simple proof of $1/T$ convergence in Appendix C. Finally, the above proof can be modified slightly to give convergence of the stochastic gradient method. In particular, we can replace $\boldsymbol{g}_t^f$ in the iterates of FOBOS with a stochastic estimate of the gradient $\tilde{\boldsymbol{g}}_t^f$, where $E[\tilde{\boldsymbol{g}}_t^f] \in \partial f(\boldsymbol{w}_t)$. We explore this approach in slightly more depth after performing a regret analysis for FOBOS below in Sec. 4 and describe stochastic convergence rates in Corollary 10.

We would like to make further comments on our proof of convergence for FOBOS and the assumptions underlying the proof. It is often not necessary to have a Lipschitz loss to guarantee boundedness of the subgradients of f and r, so in practice an assumption of bounded subgradients (as in Corollary 5 and in the sequel for online analysis) is not restrictive. If we know that an optimal $\boldsymbol{w}^\star$ lies in some compact set Ω and that $\Omega \subseteq \mathrm{dom}(f+r)$, then Theorem 24.7 of Rockafellar (1970) guarantees that ∂f and ∂r are bounded. The lingering question is thus whether we can guarantee that such a set Ω exists and that our iterates $\boldsymbol{w}_t$ remain in Ω. The following simple setting shows that ∂f and ∂r are indeed often bounded.

If $r(\boldsymbol{w})$ is a norm (possibly scaled) and f is lower bounded by 0, then we know that $r(\boldsymbol{w}^\star) \leq f(\boldsymbol{w}^\star) + r(\boldsymbol{w}^\star) \leq f(\boldsymbol{w}_1) + r(\boldsymbol{w}_1)$. Using standard bounds on norms, we get that for some $\gamma > 0$

$$\|\boldsymbol{w}^\star\|_\infty \leq \gamma r(\boldsymbol{w}^\star) \leq \gamma(f(\boldsymbol{w}_1) + r(\boldsymbol{w}_1)) = \gamma f(\boldsymbol{w}_1) \;\; ,$$

where for the last inequality we used the assumption that $r(\boldsymbol{w}_1) = 0$. Thus, we obtain that $\boldsymbol{w}^\star$ lies in a hypercube. We can easily project onto this box by truncating elements of $\boldsymbol{w}_t$ lying outside it at any iteration without affecting the bounds in Eq. (12) or Eq. (15). This additional Euclidean projection Π_Ω to an arbitrary convex set Ω with $\boldsymbol{w}^\star \in \Omega$ satisfies $\|\Pi_\Omega(\boldsymbol{w}_{t+1}) - \boldsymbol{w}^\star\| \leq \|\boldsymbol{w}_{t+1} - \boldsymbol{w}^\star\|$. Furthermore, so long as Ω is an ℓ_p-norm ball, we know that

$$r(\Pi_\Omega(\boldsymbol{w}_{t+1})) \leq r(\boldsymbol{w}_{t+1}) \ . \tag{16}$$

Thus, looking at Eq. (11), we notice that $r(\boldsymbol{w}^\star) - r(\boldsymbol{w}_{t+1}) \leq r(\boldsymbol{w}^\star) - r(\Pi_\Omega(\boldsymbol{w}_{t+1}))$ and the series of inequalities through Eq. (12) still hold (so long as $c\eta_{t+\frac{1}{2}}A \leq 1$, which it will if Ω is compact so that we can take $A = 0$). In general, so long as Eq. (16) holds and $\boldsymbol{w}^\star \in \Omega$, we can project $\boldsymbol{w}_{t+1}$ into Ω without affecting convergence guarantees. This property proves to be helpful in the regret analysis below.

4. Regret Analysis of FOBOS

In this section we provide regret analysis for FOBOS in online settings. In an online learning problem, we are given a sequence of functions $f_t : \mathbb{R}^n \to \mathbb{R}$. The learning goal is for the sequence of predictions $\boldsymbol{w}_t$ to attain low regret when compared to a single optimal predictor $\boldsymbol{w}^\star$. Formally, let $f_t(\boldsymbol{w})$ denote the loss suffered on the t^{th} input loss function when using a predictor $\boldsymbol{w}$. The regret of an online algorithm which uses $\boldsymbol{w}_1, \ldots, \boldsymbol{w}_t, \ldots$ as its predictors w.r.t. a fixed predictor $\boldsymbol{w}^\star$ while using a regularization function r is

$$R_{f+r}(T) = \sum_{t=1}^{T} \left[f_t(\boldsymbol{w}_t) + r(\boldsymbol{w}_t) - (f_t(\boldsymbol{w}^\star) + r(\boldsymbol{w}^\star))\right].$$

Ideally, we would like to achieve 0 regret to a stationary $\boldsymbol{w}^\star$ for arbitrary length sequences.

To achieve an online bound for a sequence of convex functions f_t, we modify arguments of Zinkevich (2003). Using the bound from Lemma 1, we can readily state and prove a theorem on the online regret of FOBOS. It is possible to avoid the boundedness assumptions in the proof of the theorem (getting a bound similar to that of Theorem 2 but for regret), however, we do not find it significantly more interesting. Aside from its reliance on Lemma 1, this proof is quite similar to Zinkevich's, so we defer it to Appendix A.

Theorem 6 *Assume that $\|\boldsymbol{w}_t - \boldsymbol{w}^\star\| \leq D$ for all iterations and the norm of the subgradient sets ∂f_t and ∂r are bounded above by G. Let $c > 0$ an arbitrary scalar. Then, the regret bound of* FOBOS *with $\eta_t = c/\sqrt{t}$ satisfies*

$$R_{f+r}(T) \leq 2GD + \left(\frac{D^2}{2c} + 7G^2c\right)\sqrt{T} \ .$$

The following Corollary is immediate from Theorem 6.

Corollary 7 *Assume the conditions of Theorem 6 hold. Then, setting $\eta_t = \frac{D}{4G\sqrt{t}}$, the regret of* FOBOS *is*

$$R_{f+r}(T) \leq 2GD + 4GD\sqrt{T} \ .$$

We can also obtain a better regret bound for FOBOS when the sequence of loss functions $f_t(\cdot)$ or the function $r(\cdot)$ is strongly convex. As demonstrated by Hazan et al. (2006), with the projected gradient method and strongly convex functions, it is possible to achieve regret on the order of $O(\log T)$ by using the curvature of the sequence of functions f_t rather than simply using convexity and linearity as in Theorems 2 and 6. We can extend these results to FOBOS for the case in which $f_t(\boldsymbol{w}) + r(\boldsymbol{w})$ is strongly convex, at least over the domain $\|\boldsymbol{w} - \boldsymbol{w}^\star\| \leq D$. For completeness, we recap a few definitions and provide the logarithmic regret bound for FOBOS. A function f is called H-strongly convex if

$$f(\boldsymbol{w}) \geq f(\boldsymbol{w}_t) + \langle \nabla f(\boldsymbol{w}_t), \boldsymbol{w} - \boldsymbol{w}_t \rangle + \frac{H}{2}\|\boldsymbol{w} - \boldsymbol{w}_t\|^2.$$

Thus, if r and the sequence of functions f_t are strongly convex with constants $H_f \geq 0$ and $H_r \geq 0$, we have $H = H_f + H_r$ and H-strong convexity gives

$$f_t(\boldsymbol{w}_t) - f(\boldsymbol{w}^\star) + r(\boldsymbol{w}_t) - r(\boldsymbol{w}^\star) \leq \left\langle \boldsymbol{g}_t^f + \boldsymbol{g}_t^r, \boldsymbol{w}_t - \boldsymbol{w}^\star \right\rangle - \frac{H}{2}\|\boldsymbol{w}_t - \boldsymbol{w}^\star\|^2 \ . \tag{17}$$

We do not need to assume that both f_t and r are strongly convex. We only need assume that at least one of them attains a positive strong convexity constant. For example, if $r(\boldsymbol{w}) = \frac{\lambda}{2}\|\boldsymbol{w}\|^2$, then $H \geq \lambda$ so long as the functions f_t are convex. With Eq. (17) in mind, we can readily build on Hazan et al. (2006) and prove a stronger regret bound for the online learning case. The proof is similar to that of Hazan et al., so we defer it also to Appendix A.

Theorem 8 *Assume as in Theorem 6 that $\|\boldsymbol{w}_t - \boldsymbol{w}^\star\| \leq D$ and that ∂f_t and ∂r are bounded above by G. Assume further that $f_t + r$ is H-strongly convex for all t. Then, when using step sizes $\eta_t = 1/Ht$, the regret of* FOBOS *is*

$$R_{f+r}(T) = O\left(\frac{G^2}{H}\log T\right).$$

We now provide an easy lemma showing that for Lipschitz losses with ℓ_2^2 regularization, the boundedness assumptions above hold. This, for example, includes the interesting case of support vector machines. The proof is not difficult but relies tacitly on a later result, so we leave it to Appendix A.

Lemma 9 *Let the functions f_t be G-Lipschitz so that $\|\partial f_t(\boldsymbol{w})\| \leq G$. Let $r(\boldsymbol{w}) = \frac{\lambda}{2}\|\boldsymbol{w}\|^2$. Then $\|\boldsymbol{w}^\star\| \leq G/\lambda$ and the iterates $\boldsymbol{w}_t$ generated by* FOBOS *satisfy $\|\boldsymbol{w}_t\| \leq G/\lambda$.*

Using the regret analysis for online learning, we are able to return to learning in a batch setting and give stochastic convergence rates for FOBOS. We build on results of Shalev-Shwartz et al. (2007) and assume as in Sec. 3 that we are minimizing $f(\boldsymbol{w}) + r(\boldsymbol{w})$. Indeed, suppose that on each step of FOBOS, we choose instead of some $\boldsymbol{g}_t^f \in \partial f(\boldsymbol{w}_t)$ a stochastic estimate of the gradient $\tilde{\boldsymbol{g}}_t^f$ where $E[\tilde{\boldsymbol{g}}_t^f] \in \partial f(\boldsymbol{w}_t)$. We assume that we still use the true r (which is generally easy, as it is simply the regularization function). It is straightforward to use theorems 6 and 8 above as in the derivation of theorems 2 and 3 from Shalev-Shwartz et al. (2007) to derive the following corollary on the expected convergence rate of FOBOS as well as a guarantee of convergence with high probability.

Corollary 10 *Assume that the conditions on ∂f, ∂r, and $\boldsymbol{w}^\star$ hold as in the previous theorems and let* FOBOS *be run for T iterations. Let s be an integer chosen uniformly at random from $\{1, \ldots, T\}$. If $\eta_t = \frac{D}{4G\sqrt{t}}$, then*

$$E_s[f(\boldsymbol{w}_s) + r(\boldsymbol{w}_s)] \leq f(\boldsymbol{w}^\star) + r(\boldsymbol{w}^\star) + \frac{2GD + 4GD\sqrt{T}}{T}.$$

With probability at least $1 - \delta$,

$$f(\boldsymbol{w}_s) + r(\boldsymbol{w}_s) \leq f(\boldsymbol{w}^\star) + r(\boldsymbol{w}^\star) + \frac{2GD + 4GD\sqrt{T}}{\delta T}.$$

If $f + r$ is H-strongly convex and we choose $\eta_t \propto 1/t$, we have

$$E_s[f(\boldsymbol{w}_s) + r(\boldsymbol{w}_s)] = f(\boldsymbol{w}^\star) + r(\boldsymbol{w}^\star) + O\left(\frac{G^2 \log T}{HT}\right)$$

and with probability at least $1 - \delta$,

$$f(\boldsymbol{w}_s) + r(\boldsymbol{w}_s) = f(\boldsymbol{w}^\star) + r(\boldsymbol{w}^\star) + O\left(\frac{G^2 \log T}{H\delta T}\right).$$

5. Derived Algorithms

In this section we derive a few variants of FOBOS by considering different regularization functions. The emphasis of the section is on non-differentiable regularization functions, such as the ℓ_1 norm of $\boldsymbol{w}$, which lead to sparse solutions. We also derive simple extensions to mixed-norm regularization (Zhao et al., 2006) that build on the first part of this section.

First, we make a few changes to notation. To simplify our derivations, we denote by $\boldsymbol{v}$ the vector $\boldsymbol{w}_{t+\frac{1}{2}} = \boldsymbol{w}_t - \eta_t \boldsymbol{g}_t^f$ and let $\tilde{\lambda}$ denote $\eta_{t+\frac{1}{2}} \cdot \lambda$. Using this newly introduced notation the problem given in Eq. (3) can be rewritten as

$$\operatorname*{minimize}_{\boldsymbol{w}} \frac{1}{2}\|\boldsymbol{w}-\boldsymbol{v}\|^2 + \tilde{\lambda} r(\boldsymbol{w}). \tag{18}$$

Let $[z]_+$ denote $\max\{0,z\}$. For completeness, we provide full derivations for all the regularization functions we consider, but for brevity we do not state formally well established technical lemmas. We note that many of the following results were given tacitly by Wright et al. (2009).

5.1 FOBOS with ℓ_1 Regularization

The update obtained by choosing $r(\boldsymbol{w}) = \lambda\|\boldsymbol{w}\|_1$ is simple and intuitive. First note that the objective is decomposable as we can rewrite Eq. (18) as

$$\operatorname*{minimize}_{\boldsymbol{w}} \sum_{j=1}^{n} \left(\frac{1}{2}(w_j - v_j)^2 + \tilde{\lambda}|w_j|\right).$$

Let us focus on a single coordinate of $\boldsymbol{w}$ and for brevity omit the index j. Let $w^\star$ denote the minimizer of $\frac{1}{2}(w-v)^2 + \tilde{\lambda}|w|$. Clearly, $w^\star \cdot v \geq 0$. If it were not, then we would have $w^\star \cdot v < 0$, however $\frac{1}{2}v^2 < \frac{1}{2}v^2 - w^\star \cdot v + \frac{1}{2}(w^\star)^2 < \frac{1}{2}(v-w^\star)^2 + \tilde{\lambda}|w^\star|$, contradicting the supposed optimality of $w^\star$. The symmetry of the objective in v also shows us that we can assume that $v \geq 0$; we therefore need to minimize $\frac{1}{2}(w-v)^2 + \tilde{\lambda}w$ subject to the constraint that $w \geq 0$. Introducing a Lagrange multiplier $\beta \geq 0$ for the constraint, we have the Lagrangian $\frac{1}{2}(w-v)^2 + \tilde{\lambda}w - \beta w$. By taking the derivative of the Langrangian with respect to w and setting the result to zero, we get that the optimal solution is $w^\star = v - \tilde{\lambda} + \beta$. If $w^\star > 0$, then from the complimentary slackness condition that the optimal pair of $w^\star$ and β must have $w^\star\beta = 0$ (Boyd and Vandenberghe, 2004) we must have $\beta = 0$, and therefore $w^\star = v - \tilde{\lambda}$. If $v < \tilde{\lambda}$, then $v - \tilde{\lambda} < 0$, so we must have $\beta > 0$ and again by complimentary slackness, $w^\star = 0$. The case when $v \leq 0$ is analogous and amounts to simply flipping signs. Summarizing and expanding notation, the components of the optimal solution $\boldsymbol{w}^\star = \boldsymbol{w}_{t+1}$ are computed from $\boldsymbol{w}_{t+\frac{1}{2}}$ as

$$w_{t+1,j} = \operatorname{sign}\left(w_{t+\frac{1}{2},j}\right)\left[|w_{t+\frac{1}{2},j}| - \tilde{\lambda}\right]_+ = \operatorname{sign}\left(w_{t,j} - \eta_t g_{t,j}^f\right)\left[\left|w_{t,j} - \eta_t g_{t,j}^f\right| - \eta_{t+\frac{1}{2}} \cdot \lambda\right]_+. \tag{19}$$

Note that this update can lead to sparse solutions. Whenever the absolute value of a component of $\boldsymbol{w}_{t+\frac{1}{2}}$ is smaller than $\tilde{\lambda}$, the corresponding component in $\boldsymbol{w}_{t+1}$ is set to zero. Thus, Eq. (19) gives a simple online and offline method for minimizing a convex f with ℓ_1 regularization.

Such soft-thresholding operations are common in the statistics literature and have been used for some time (Donoho, 1995; Daubechies et al., 2004). Langford et al. (2008) recently proposed and analyzed the same update, terming it the "truncated gradient." The analysis presented here is different from the analysis in the aforementioned paper as it stems from a more general framework. Indeed, as illustrated in this section, the derivation and method is also applicable to a wide variety of regularization functions. Nevertheless, both analyses merit consideration as they shed light from different angles on the problem of learning sparse models using gradients, stochastic gradients, or online methods. This update can also be implemented very efficiently when the support of $\boldsymbol{g}_t^f$ is small (Langford et al., 2008), but we defer details to Sec. 6, where we give a unified view that facilitates efficient implementation for all the norm regularization functions we discuss.

5.2 FOBOS with ℓ_2^2 Regularization

When $r(\boldsymbol{w}) = \frac{\lambda}{2}\|\boldsymbol{w}\|_2^2$, we obtain a very simple optimization problem,

$$\underset{\boldsymbol{w}}{\text{minimize}}\ \frac{1}{2}\|\boldsymbol{w}-\boldsymbol{v}\|^2 + \frac{1}{2}\tilde{\lambda}\|\boldsymbol{w}\|^2,$$

where for conciseness of the solution we replace $\tilde{\lambda}$ with $\frac{1}{2}\tilde{\lambda}$. Differentiating the above objective and setting the result equal to zero, we have $\boldsymbol{w}^\star - \boldsymbol{v} + \tilde{\lambda}\boldsymbol{w}^\star = 0$, which, using the original notation, yields the update

$$\boldsymbol{w}_{t+1} = \frac{\boldsymbol{w}_t - \eta_t \boldsymbol{g}_t^f}{1+\tilde{\lambda}}. \tag{20}$$

Informally, the update simply shrinks $\boldsymbol{w}_{t+1}$ back toward the origin after each gradient-descent step. In Sec. 7 we briefly compare the resulting FOBOS update to modern stochastic gradient techniques and show that the FOBOS update exhibits similar empirical behavior.

5.3 FOBOS with ℓ_2 Regularization

A lesser used regularization function is the ℓ_2 norm of the weight vector. By setting $r(\boldsymbol{w}) = \tilde{\lambda}\|\boldsymbol{w}\|$ we obtain the following problem,

$$\underset{\boldsymbol{w}}{\text{minimize}}\ \frac{1}{2}\|\boldsymbol{w}-\boldsymbol{v}\|^2 + \tilde{\lambda}\|\boldsymbol{w}\|. \tag{21}$$

The solution of Eq. (21) must be in the direction of $\boldsymbol{v}$ and takes the form $\boldsymbol{w}^\star = s\boldsymbol{v}$ where $s \geq 0$. To show that this is indeed the form of the solution, let us assume for the sake of contradiction that $\boldsymbol{w}^\star = s\boldsymbol{v} + \boldsymbol{u}$ where $\boldsymbol{u}$ is in the null space of $\boldsymbol{v}$ (if $\boldsymbol{u}$ has any components parallel to $\boldsymbol{v}$, we can add those to $s\boldsymbol{v}$ and obtain an orthogonal $\boldsymbol{u}'$) and s may be negative. Since $\boldsymbol{u}$ is orthogonal to $\boldsymbol{v}$, the objective function can be expressed in terms of s, $\boldsymbol{v}$, and $\boldsymbol{u}$ as

$$\frac{1}{2}(1-s)^2\|\boldsymbol{v}\|^2 + \frac{1}{2}\|\boldsymbol{u}\|^2 + \tilde{\lambda}(\|\boldsymbol{v}\| + \|\boldsymbol{u}\|) \geq \frac{1}{2}(1-s)^2\|\boldsymbol{v}\|^2 + \tilde{\lambda}\|\boldsymbol{v}\|.$$

Thus, $\boldsymbol{u}$ must be equal to the zero vector, $\boldsymbol{u} = \boldsymbol{0}$, and we can write the optimization problem as

$$\underset{s}{\text{minimize}}\ \frac{1}{2}(1-s)^2\|\boldsymbol{v}\|^2 + \tilde{\lambda}s\|\boldsymbol{v}\| \ .$$

Next note that a negative value for s cannot constitute the optimal solution. Indeed, if $s < 0$, then

$$\frac{1}{2}(1-s)^2\|\boldsymbol{v}\|^2 + \tilde{\lambda}s\|\boldsymbol{v}\| \ < \ \frac{1}{2}\|\boldsymbol{v}\|^2 \ .$$

This implies that by setting $s = 0$ we can obtain a lower objective function, and this precludes a negative value for s as an optimal solution. We therefore end again with a constrained scalar optimization problem, $\text{minimize}_{s\geq 0}\ \frac{1}{2}(1-s)^2\|\boldsymbol{v}\|^2 + \tilde{\lambda}s\|\boldsymbol{v}\|$. The Lagrangian of this problem is

$$\frac{1}{2}(1-s)^2\|\boldsymbol{v}\|^2 + \tilde{\lambda}s\|\boldsymbol{v}\| - \beta s \ ,$$

where $\beta \geq 0$. By taking the derivative of the Langrangian with respect to s and setting the result to zero, we get that $(s-1)\|\boldsymbol{v}\|^2 + \tilde{\lambda}\|\boldsymbol{v}\| - \beta = 0$ which gives the following closed form solution: $s = 1 - \tilde{\lambda}/\|\boldsymbol{v}\| + \beta/\|\boldsymbol{v}\|^2$. Whenever $s > 0$ then the complimentary slackness conditions imply that $\beta = 0$ and s can be further simplified and written as $s = 1 - \tilde{\lambda}/\|\boldsymbol{v}\|$. The last expression is positive iff $\|\boldsymbol{v}\| > \tilde{\lambda}$. If $\|\boldsymbol{v}\| < \tilde{\lambda}$, then β must be positive and complimentary slackness implies that $s = 0$.

Summarizing, the second step of the FOBOS update with ℓ_2 regularization amounts to

$$\boldsymbol{w}_{t+1} = \left[1 - \frac{\tilde{\lambda}}{\|\boldsymbol{w}_{t+\frac{1}{2}}\|}\right]_+ \boldsymbol{w}_{t+\frac{1}{2}} \ = \ \left[1 - \frac{\tilde{\lambda}}{\|\boldsymbol{w}_t - \eta_t \boldsymbol{g}_t^f\|}\right]_+ (\boldsymbol{w}_t - \eta_t \boldsymbol{g}_t^f) \ .$$

Thus, the ℓ_2 regularization results in a zero weight vector under the condition that $\|\boldsymbol{w}_t - \eta_t \boldsymbol{g}_t^f\| \leq \tilde{\lambda}$. This condition is rather more stringent for sparsity than the condition for ℓ_1 (where a weight is sparse based only on its value, while here, sparsity happens only if the entire weight vector has ℓ_2-norm less than $\tilde{\lambda}$), so it is unlikely to hold in high dimensions. However, it does constitute a very important building block when using a mixed ℓ_1/ℓ_2-norm as the regularization function, as we show in the sequel.

5.4 FOBOS with ℓ_∞ Regularization

We now turn to a less explored regularization function, the ℓ_∞ norm of $\boldsymbol{w}$. This form of regularization is not capable of providing strong guarantees against over-fitting on its own as many of the weights of $\boldsymbol{w}$ may not be penalized. However, there are settings in which it is desirable to consider blocks of variables as a group, such as ℓ_1/ℓ_∞ regularization. We continue to defer the discussion on mixing different norms and focus merely on the ℓ_∞ norm as it serves as a building block. That is, we are interested in obtaining an efficient solution to the following problem,

$$\operatorname*{minimize}_{\boldsymbol{w}} \frac{1}{2}\|\boldsymbol{w} - \boldsymbol{v}\|^2 + \tilde{\lambda}\|\boldsymbol{w}\|_\infty \quad . \tag{22}$$

It is possible to derive an efficient algorithm for finding the minimizer of Eq. (22) using properties of the subgradient set of $\|\boldsymbol{w}\|_\infty$. However, a solution to the dual form of Eq. (22) is well established. Recalling that the conjugate of the quadratic function is a quadratic function and the conjugate of the ℓ_∞ norm is the ℓ_1 barrier function, we immediately obtain that the dual of the problem given by Eq. (22) is

$$\operatorname*{maximize}_{\boldsymbol{\alpha}} -\frac{1}{2}\|\boldsymbol{\alpha} - \boldsymbol{v}\|_2^2 \;\; \text{s.t.} \;\; \|\boldsymbol{\alpha}\|_1 \leq \tilde{\lambda} \;\; . \tag{23}$$

Moreover, the vector of dual variables $\boldsymbol{\alpha}$ satisfies the relation $\boldsymbol{\alpha} = \boldsymbol{v} - \boldsymbol{w}$. Thus, by solving the dual form in Eq. (23) we can readily obtain a solution for Eq. (22). The problem defined by Eq. (23) is equivalent to performing Euclidean projection onto the ℓ_1 ball and has been studied by numerous authors. The solution that we overview here is based on recent work of Duchi et al. (2008). The maximizer of Eq. (23), denoted $\boldsymbol{\alpha}^\star$, is of the form

$$\alpha_j^\star = \operatorname{sign}(v_j)\left[|v_j| - \theta\right]_+ \quad , \tag{24}$$

where θ is a non-negative scalar. Duchi et al. (2008) describe a linear time algorithm for finding θ. We thus skip the analysis of the algorithm and focus on its core properties that affect the solution of the original problem Eq. (22). To find θ we need to locate a pivot element in $\boldsymbol{v}$, denoted by the ρ^{th} order statistic $v_{(\rho)}$ (where $v_{(1)}$ is the largest magnitude entry of $\boldsymbol{v}$), with the following property, $v_{(\rho)}$ is the smallest magnitude element in $\boldsymbol{v}$ such that

$$\sum_{j:|v_j|>|v_{(\rho)}|} \left(|v_j| - |v_{(\rho)}|\right) < \tilde{\lambda} \;\; .$$

If all the elements in $\boldsymbol{v}$ (assuming that we have added an extra 0 element to handle the smallest entry of $\boldsymbol{v}$) satisfy the above requirement then the optimal choice for θ is 0. Otherwise,

$$\theta = \frac{1}{\rho}\left(\sum_{j:|v_j|>|v_{(\rho)}|} |v_j| - \tilde{\lambda}\right) \quad .$$

Thus, the optimal choice of θ is zero when $\sum_{j=1}^n |v_j| \leq \tilde{\lambda}$ (this is, not coincidentally, simply the subgradient condition for optimality of the zero vector in Eq. (22)).

Using the linear relationship $\boldsymbol{\alpha} = \boldsymbol{v} - \boldsymbol{w} \Rightarrow \boldsymbol{w} = \boldsymbol{v} - \boldsymbol{\alpha}$ along with the solution of the dual problem as given by Eq. (24), we obtain the following solution for Eq. (22),

$$w_{t+1,j} = \operatorname{sign}\left(w_{t+\frac{1}{2},j}\right)\min\left\{\left|w_{t+\frac{1}{2},j}\right| \, , \, \theta\right\} \quad . \tag{25}$$

As stated above, $\theta = 0$ iff $\|\boldsymbol{w}_{t+\frac{1}{2}}\|_1 \leq \tilde{\lambda}$ and otherwise $\theta > 0$ and can be found in $O(n)$ steps. In words, the components of the vector $\boldsymbol{w}_{t+1}$ are the result of capping all of the components of $\boldsymbol{w}_t$ at θ where θ is zero when the 1-norm of $\boldsymbol{w}_{t+\frac{1}{2}}$ is smaller than $\tilde{\lambda}$. Interestingly, this property shares a duality resemblance with the ℓ_2-regularized update, which results in a zero weight vector when the 2-norm (which is self-dual) of $\boldsymbol{v}$ is less than $\tilde{\lambda}$. We can exploit these properties in the context of mixed-norm regularization to achieve sparse solutions for complex prediction problems, which we describe in the sequel and for which we present preliminary results in Sec. 7. Before doing so, we present one more norm-related regularization.

5.5 FOBOS with Berhu Regularization:

We now consider a regularization function which is a hybrid of the ℓ_1 and ℓ_2 norms. Similar to ℓ_1 regularization, Berhu (for inverse Huber) regularization results in sparse solutions, but its hybridization with ℓ_2^2 regularization prevents the weights from being excessively large. Berhu regularization (Owen, 2006) is defined as

$$r(\boldsymbol{w}) = \lambda \sum_{j=1}^{n} b(w_j) = \lambda \sum_{j=1}^{n} \left[|w_j| \left[\!\left[|w_j| \leq \gamma \right]\!\right] + \frac{w_j^2 + \gamma^2}{2\gamma} \left[\!\left[|w_j| > \gamma \right]\!\right] \right].$$

In the above, $[\![\cdot]\!]$ is 1 if its argument is true and is 0 otherwise. The positive scalar γ controls the value for which the Berhu regularization switches from ℓ_1 mode to ℓ_2 mode. Formally, when $w_j \in [-\gamma, \gamma]$, $r(\boldsymbol{w})$ behaves as ℓ_1, and for w_j outside this region, the Berhu penalty behaves as ℓ_2^2. The Berhu penalty is convex and differentiable except at 0, where it has the same subdifferential set as $\lambda \|\boldsymbol{w}\|_1$.

To find a closed form update from $\boldsymbol{w}_{t+\frac{1}{2}}$ to $\boldsymbol{w}_{t+1}$, we minimize in each variable $\frac{1}{2}(w-v) + \tilde{\lambda} b(w)$; the derivation is fairly standard but technical and is provided in Appendix B. The end result is aesthetic and captures the ℓ_1 and ℓ_2 regions of the Berhu penalty,

$$w_{t+1,j} = \begin{cases} 0 & \left| w_{t+\frac{1}{2},j} \right| \leq \tilde{\lambda} \\ \operatorname{sign}(w_{t+\frac{1}{2},j}) \left[|w_{t+\frac{1}{2},j}| - \tilde{\lambda} \right] & \tilde{\lambda} < |w_{t+\frac{1}{2},j}| \leq \tilde{\lambda} + \gamma \\ \frac{w_{t+\frac{1}{2},j}}{1 + \tilde{\lambda}/\gamma} & \gamma + \tilde{\lambda} < \left| w_{t+\frac{1}{2},j} \right| \end{cases} . \tag{26}$$

Indeed, as Eq. (26) indicates, the update takes one of two forms, depending on the magnitude of the coordinate of $w_{t+\frac{1}{2},j}$. If $|w_{t+\frac{1}{2},j}|$ is greater than $\gamma + \tilde{\lambda}$, the update is identical to the update for ℓ_2^2-regularization of Eq. (20), while if the value is no larger than $\gamma + \tilde{\lambda}$, the resulting update is equivalent to the update for ℓ_1-regularization of Eq. (19).

5.6 Extension to Mixed Norms

We saw above that when using either the ℓ_2 or the ℓ_∞ norm as the regularization function, we obtain an all zeros vector if $||\boldsymbol{w}_{t+\frac{1}{2}}||_2 \leq \tilde{\lambda}$ or $||\boldsymbol{w}_{t+\frac{1}{2}}||_1 \leq \tilde{\lambda}$, respectively. The zero vector does not carry any generalization properties, which surfaces a concern regarding the usability of the these norms as a form of regularization. This seemingly problematic phenomenon can, however, be useful in the setting we discuss now. In many applications, the set of weights can be grouped into subsets where each subset of weights should be dealt with uniformly. For example, in multiclass categorization problems each class r may be associated with a different weight vector $\boldsymbol{w}^r$. The prediction for an instance $\boldsymbol{x}$ is a vector $\langle \boldsymbol{w}^1, \boldsymbol{x} \rangle, \ldots, \langle \boldsymbol{w}^k, \boldsymbol{x} \rangle$ where k is the number of different classes. The predicted class is the index of the inner-product attaining the largest of the k values, $\operatorname{argmax}_j \langle \boldsymbol{w}^j, \boldsymbol{x} \rangle$. Since all the weight vectors operate over the same instance space, in order to achieve a sparse solution, it may be beneficial to tie the weights corresponding to the same input feature. That is, we would like to employ a regularization function that tends to zero the row of weights $w_j^1, \ldots, w_j^k$ *simultaneously*. In these circumstances, the nullification of the entire weight vector by ℓ_2 and ℓ_∞ regularization becomes a powerful tool.

Formally, let W represent a $n \times k$ matrix where the j^{th} column of the matrix is the weight vector $\boldsymbol{w}^j$ associated with class j. Thus, the i^{th} row corresponds to the weight of the i^{th} feature with respect to all classes. The mixed ℓ_r/ℓ_s-norm (Obozinski et al., 2007) of W, denoted $\|W\|_{\ell_r/\ell_s}$, is obtained by computing the ℓ_s-norm of each row of W and then applying the ℓ_r-norm to the resulting n dimensional vector, for instance, $\|W\|_{\ell_1/\ell_\infty} = \sum_{j=1}^{n} \max_j |W_{i,j}|$. Thus, in a mixed-norm regularized optimization problem (such as multiclass learning), we seek the minimizer of the objective function

$$f(W) + \lambda \|W\|_{\ell_r/\ell_s} .$$

Given the specific variants of various norms described above, the FOBOS update for the ℓ_1/ℓ_∞ and the ℓ_1/ℓ_2 mixed-norms is readily available. Let $\bar{\boldsymbol{w}}^r$ denote the r^{th} row of W. Analogously to the standard norm-based regularization, we let $V = W_{t+\frac{1}{2}}$ be a shorthand for the result of the gradient step. For the ℓ_1, ℓ_p mixed-norm, where $p = 2$ or $p = \infty$, we need to solve the problem

$$\operatorname*{minimize}_{W} \frac{1}{2}\|W - V\|_{\mathrm{Fr}}^2 + \tilde{\lambda}\|W\|_{\ell_1/\ell_2} \equiv \operatorname*{minimize}_{\bar{\boldsymbol{w}}^1,\ldots,\bar{\boldsymbol{w}}^k} \sum_{i=1}^{n} \left(\frac{1}{2}\left\|\bar{\boldsymbol{w}}^i - \bar{\boldsymbol{v}}^i\right\|_2^2 + \tilde{\lambda}\left\|\bar{\boldsymbol{w}}^i\right\|_p \right) , \tag{27}$$

where $\bar{\boldsymbol{v}}^i$ is the i^{th} row of V. It is immediate to see that the problem given in Eq. (27) is decomposable into n separate problems of dimension k, each of which can be solved by the procedures described in the prequel. The end result of solving these types of mixed-norm problems is a sparse matrix with numerous zero rows. We demonstrate the merits of FOBOS with mixed-norms in Sec. 7.

6. Efficient Implementation in High Dimensions

In many settings, especially online learning, the weight vector $\boldsymbol{w}_t$ and the gradients $\boldsymbol{g}_t^f$ reside in a very high-dimensional space, but only a relatively small number of the components of $\boldsymbol{g}_t^f$ are non-zero. Such settings are prevalent, for instance, in text-based applications: in text categorization, the full dimension corresponds to the dictionary or set of tokens that is being employed while each gradient is typically computed from a single or a few documents, each of which contains words and bigrams constituting only a small subset of the full dictionary. The need to cope with gradient sparsity becomes further pronounced in mixed-norm problems, as a single component of the gradient may correspond to an entire row of W. Updating the entire matrix because a few entries of $\boldsymbol{g}_t^f$ are non-zero is clearly undesirable. Thus, we would like to extend our methods to cope efficiently with gradient sparsity. For concreteness, we focus in this section on the efficient implementation of ℓ_1, ℓ_2, and ℓ_∞ regularization, recognizing that the extension to mixed-norms (as in the previous section) is straightforward. The upshot of following proposition is that when $\boldsymbol{g}_t^f$ is sparse, we can use lazy evaluation of the weight vectors and defer to later rounds the update of components of $\boldsymbol{w}_t$ whose corresponding gradient entries are zero. We detail this after the proposition, which is technical so the interested reader may skip the proof to see the simple algorithms for lazy evaluation.

Proposition 11 *Let $\boldsymbol{w}_T$ be the end result of solving a succession of T self-similar optimization problems for $t = 1, \ldots, T$,*

$$\mathcal{P}.1: \quad \boldsymbol{w}_t = \operatorname*{argmin}_{\boldsymbol{w}} \frac{1}{2}\|\boldsymbol{w} - \boldsymbol{w}_{t-1}\|^2 + \lambda_t \|\boldsymbol{w}\|_q \ . \tag{28}$$

Let $\boldsymbol{w}^\star$ be the optimal solution of the following optimization problem:

$$\mathcal{P}.2: \quad \boldsymbol{w}^\star = \operatorname*{argmin}_{\boldsymbol{w}} \frac{1}{2}\|\boldsymbol{w} - \boldsymbol{w}_0\|^2 + \left(\sum_{t=1}^{T} \lambda_t \right) \|\boldsymbol{w}\|_q \ .$$

Then for $q \in \{1, 2, \infty\}$ the vectors $\boldsymbol{w}_T$ and $\boldsymbol{w}^\star$ are identical.

Proof It suffices to show that the proposition is correct for $T = 2$ and then use an inductive argument, because the proposition trivially holds for $T = 1$. We provide here a direct proof for each norm separately by examining the updates we derived in Sec. 5 and showing that $\boldsymbol{w}_2 = \boldsymbol{w}^\star$.

Note that the objective functions are separable for $q = 1$. Therefore, for ℓ_1-regularization it suffices to prove the proposition for any component of the vector $\boldsymbol{w}$. We omit the index of the component and denote by $w_0, w_1, w_2, w_3, \ldots$ one coordinate of $\boldsymbol{w}$ along the iterations of $\mathcal{P}.1$ and by $w^\star$ the result for the same component when solving $\mathcal{P}.2$. We need to show that $w^\star = w_2$. Expanding the ℓ_1-update of Eq. (19) over two iterations we get the following,

$$w_2 = \text{sign}(w_1)\,[|w_1| - \lambda_2]_+ = \text{sign}(w_1)\left[\left|\text{sign}(w_0)\,[|w_0| - \lambda_1]_+\right| - \lambda_2\right]_+ = \text{sign}(w_0)\,[|w_0| - \lambda_1 - \lambda_2]_+ \quad ,$$

where we used the positivity of $|\cdot|$. Examining $\mathcal{P}.2$ and using Eq. (19) again we get

$$w^\star = \text{sign}(w_0)\,[|w_0| - \lambda_1 - \lambda_2]_+ \quad .$$

Therefore, $w^\star = w_2$ as claimed.

Next we prove the proposition for ℓ_2, returning to using the entire vector for the proof. Using the explicit ℓ_2-update from Eq. (20), we can expand the norm of the vector $\boldsymbol{w}_1$ due to the program $\mathcal{P}.1$ as follows,

$$\|\boldsymbol{w}_1\| \;=\; \left[1 - \frac{\lambda_1}{\|\boldsymbol{w}_0\|}\right]_+ \|\boldsymbol{w}_0\| \;=\; [\|\boldsymbol{w}_0\| - \lambda_1]_+ \quad .$$

Similarly, we get that $\|\boldsymbol{w}_2\| = [\|\boldsymbol{w}_1\| - \lambda_2]_+$. Combining the norm equalities we see that the norm of $\boldsymbol{w}_2$ due to the succession of the two updates is

$$\|\boldsymbol{w}_2\| \;=\; \left[[\|\boldsymbol{w}_0\| - \lambda_1]_+ - \lambda_2\right]_+ \;=\; [\|\boldsymbol{w}_0\| - \lambda_1 - \lambda_2]_+ \quad .$$

Computing directly the norm of $\boldsymbol{w}^\star$ due to the update given by Eq. (20) yields

$$\|\boldsymbol{w}^\star\| \;=\; \left[1 - \frac{\lambda_1 + \lambda_2}{\|\boldsymbol{w}_0\|}\right]_+ \|\boldsymbol{w}_0\| \;=\; [\|\boldsymbol{w}_0\| - \lambda_1 - \lambda_2]_+ \quad .$$

Thus, $\boldsymbol{w}^\star$ and $\boldsymbol{w}_2$ have the same norm. Since the update itself retains the direction of the original vector $\boldsymbol{w}_0$, we get that $\boldsymbol{w}^\star = \boldsymbol{w}_2$ as needed.

We now turn to the most complicated update and proof of the three norms, the ℓ_∞ norm. We start by recapping the programs $\mathcal{P}.1$ and $\mathcal{P}.2$ for $T = 2$ and $q = \infty$,

$$\mathcal{P}.1: \quad \boldsymbol{w}_1 \;=\; \underset{\boldsymbol{w}}{\text{argmin}} \left\{ \frac{1}{2}\|\boldsymbol{w} - \boldsymbol{w}_0\|^2 + \lambda_1 \|\boldsymbol{w}\|_\infty \right\} \tag{29}$$

$$\boldsymbol{w}_2 \;=\; \underset{\boldsymbol{w}}{\text{argmin}} \left\{ \frac{1}{2}\|\boldsymbol{w} - \boldsymbol{w}_1\|^2 + \lambda_2 \|\boldsymbol{w}\|_\infty \right\} \quad , \tag{30}$$

$$\mathcal{P}.2: \quad \boldsymbol{w}^\star \;=\; \underset{\boldsymbol{w}}{\text{argmin}} \left\{ \frac{1}{2}\|\boldsymbol{w} - \boldsymbol{v}\|_2^2 + (\lambda_1 + \lambda_2) \|\boldsymbol{w}\|_\infty \right\} \quad . \tag{31}$$

We prove the equivalence of the two programs in two stages. First, we examine the case $\|\boldsymbol{w}_0\|_1 > \lambda_1 + \lambda_2$, and then consider the complement case $\|\boldsymbol{w}_0\|_1 \leq \lambda_1 + \lambda_2$. For concreteness and simplicity, we assume that $\boldsymbol{w}_0 \succeq \boldsymbol{0}$, since, clearly, the objective is symmetric in $\boldsymbol{w}_0$ and $-\boldsymbol{w}_0$. We thus can assume that all entries of $\boldsymbol{w}_0$ are non-negative. In the proof we use the following operators: $[\boldsymbol{v}]_+$ now denotes the positive component of each entry of $\boldsymbol{v}$, $\min\{\boldsymbol{v}, \theta\}$ denotes the component-wise minimum between the elements of $\boldsymbol{v}$ and θ, and likewise $\max\{\boldsymbol{v}, \theta\}$ is the component-wise maximum. Starting with the case $\|\boldsymbol{w}_0\|_1 > \lambda_1 + \lambda_2$, we examine Eq. (29). From Lagrange duality we know that that $\boldsymbol{w}_1 = \boldsymbol{w}_0 - \boldsymbol{\alpha}_1$, where $\boldsymbol{\alpha}_1$ is the solution of

$$\underset{\boldsymbol{\alpha}}{\text{minimize}} \frac{1}{2}\|\boldsymbol{\alpha} - \boldsymbol{w}_0\|_2^2 \;\text{ s.t. }\; \|\boldsymbol{\alpha}\|_1 \leq \lambda_1 \quad .$$

As described by Duchi et al. (2008) and reviewed above in Sec. 5, $\boldsymbol{\alpha}_1 = [\boldsymbol{w}_0 - \theta_1]_+$ for some $\theta_1 \in \mathbb{R}_+$. The form of $\boldsymbol{\alpha}_1$ readily translates to the following form for $\boldsymbol{w}_1$: $\boldsymbol{w}_1 = \boldsymbol{w}_0 - \boldsymbol{\alpha}_1 = \min(\boldsymbol{w}_0, \theta_1)$. Applying similar reasoning to the second step of $\mathcal{P}.1$ yields $\boldsymbol{w}_2 = \boldsymbol{w}_1 - \boldsymbol{\alpha}_2 = \boldsymbol{w}_0 - \boldsymbol{\alpha}_1 - \boldsymbol{\alpha}_2$, where $\boldsymbol{\alpha}_2$ is the minimizer of

$$\frac{1}{2}\|\boldsymbol{\alpha} - \boldsymbol{w}_1\|_2^2 = \frac{1}{2}\|\boldsymbol{\alpha} - (\boldsymbol{w}_0 - \boldsymbol{\alpha}_1)\|_2^2 \quad \text{s.t. } \|\boldsymbol{\alpha}\|_1 \leq \lambda_2 \quad .$$

Again, we have $\boldsymbol{\alpha}_2 = [\boldsymbol{w}_1 - \theta_2]_+ = [\boldsymbol{w}_0 - \boldsymbol{\alpha}_1 - \theta_2]_+$ for some $\theta_2 \in \mathbb{R}_+$. The successive steps then imply that

$$\boldsymbol{w}_2 = \min\{\boldsymbol{w}_1, \theta_2\} = \min\left\{\min\{\boldsymbol{w}_0, \theta_1\}, \theta_2\right\} \ .$$

We next show that regardless of the ℓ_1-norm of $\boldsymbol{w}_0$, $\theta_2 \leq \theta_1$. Intuitively, if $\theta_2 > \theta_1$, the second minimization step of $\mathcal{P}.1$ would perform no shrinkage of $\boldsymbol{w}_1$ to get $\boldsymbol{w}_2$. Formally, assume for the sake of contradiction that $\theta_2 > \theta_1$. Under this assumption, we would have that $\boldsymbol{w}_2 = \min\{\min\{\boldsymbol{w}_0, \theta_1\}, \theta_2\} = \min\{\boldsymbol{w}_0, \theta_1\} = \boldsymbol{w}_1$. In turn, we obtain that $\mathbf{0}$ belongs to the subgradient set of Eq. (30) when evaluated at $\boldsymbol{w} = \boldsymbol{w}_1$, thus,

$$\mathbf{0} \in \boldsymbol{w}_1 - \boldsymbol{w}_1 + \lambda_2 \partial \left\|\boldsymbol{w}_1\right\|_\infty = \lambda_2 \partial \left\|\boldsymbol{w}_1\right\|_\infty \ .$$

Clearly, the set $\partial \left\|\boldsymbol{w}_1\right\|_\infty$ can contain $\mathbf{0}$ only when $\boldsymbol{w}_1 = \mathbf{0}$. Since we assumed that $\lambda_1 < \left\|\boldsymbol{w}_0\right\|_1$, and hence that $\boldsymbol{\alpha}_1 \preceq \boldsymbol{w}_0$ and $\boldsymbol{\alpha}_1 \neq \boldsymbol{w}_0$, we have that $\boldsymbol{w}_1 = \boldsymbol{w}_0 - \boldsymbol{\alpha}_1 \neq \mathbf{0}$. This contradiction implies that $\theta_2 \leq \theta_1$.

We now examine the solution vectors to the dual problems of $\mathcal{P}.1$, $\boldsymbol{\alpha}_1$ and $\boldsymbol{\alpha}_2$. We know that $\left\|\boldsymbol{\alpha}_1\right\|_1 = \lambda_1$ so that $\left\|\boldsymbol{w}_0 - \boldsymbol{\alpha}_1\right\|_1 > \lambda_2$ and hence $\boldsymbol{\alpha}_2$ is at the boundary $\left\|\boldsymbol{\alpha}_2\right\|_1 = \lambda_2$ (see again Duchi et al. 2008). Furthermore, the sum of the these vectors is

$$\boldsymbol{\alpha}_1 + \boldsymbol{\alpha}_2 = [\boldsymbol{w}_0 - \theta_1]_+ + \left[\boldsymbol{w}_0 - [\boldsymbol{w}_0 - \theta_1]_+ - \theta_2\right]_+ \ . \tag{32}$$

Let v denote a component of $\boldsymbol{w}_0$ greater than θ_1. For any such component the right hand side of Eq. (32) amounts to

$$[v - (v - \theta_1) - \theta_2]_+ + [v - \theta_1]_+ = [\theta_1 - \theta_2]_+ + v - \theta_1 = v - \theta_1 = [v - \theta_1]_+ \ ,$$

where we used the fact that $\theta_2 \leq \theta_1$ to eliminate the term $[\theta_1 - \theta_2]_+$. Next, let u denote a component of $\boldsymbol{w}_0$ smaller than θ_1. In this case, the right hand side of Eq. (32) amounts to $[u - 0 - \theta_2]_+ + 0 = [u - \theta_2]_+$. Recapping, the end result is that the vector sum $\boldsymbol{\alpha}_1 + \boldsymbol{\alpha}_2$ equals $[\boldsymbol{w}_0 - \theta_2]_+$. Moreover, $\boldsymbol{\alpha}_1$ and $\boldsymbol{\alpha}_2$ are in $\mathbb{R}^n_+$ as we assumed that $\boldsymbol{w}_0 \succeq \mathbf{0}$, and thus

$$\left\|\,[\boldsymbol{w}_0 - \theta_2]_+\,\right\|_1 = \left\|\boldsymbol{\alpha}_1 + \boldsymbol{\alpha}_2\right\|_1 = \lambda_1 + \lambda_2 \ . \tag{33}$$

We now show that $\mathcal{P}.2$ has the same dual solution as the sequential updates above. The dual of $\mathcal{P}.2$ is

$$\underset{\boldsymbol{\alpha}}{\text{minimize}} \ \frac{1}{2}\left\|\boldsymbol{\alpha} - \boldsymbol{w}_0\right\|_2^2 \ \text{ s.t. } \ \left\|\boldsymbol{\alpha}\right\|_1 \leq \lambda_1 + \lambda_2.$$

Denoting by $\boldsymbol{\alpha}_0$ the solution of the above dual problem, we have $\boldsymbol{w}^\star = \boldsymbol{w}_0 - \boldsymbol{\alpha}_0$ and $\boldsymbol{\alpha}_0 = [\boldsymbol{w}_0 - \theta]_+$ for some $\theta \in \mathbb{R}_+$. Examining the norm of $\boldsymbol{\alpha}_0$ we obtain that

$$\left\|\boldsymbol{\alpha}_0\right\|_1 = \left\|[\boldsymbol{w}_0 - \theta]_+\right\|_1 = \lambda_1 + \lambda_2 \tag{34}$$

because we assumed that $\left\|\boldsymbol{w}_0\right\|_1 > \lambda_1 + \lambda_2$. We can view the terms $\left\|[\boldsymbol{w}_0 - \theta_2]_+\right\|_1$ from Eq. (33) and $\left\|[\boldsymbol{w}_0 - \theta]_+\right\|_1$ from Eq. (34) as functions of θ_2 and θ, respectively. The functions are strictly decreasing functions of θ and θ_2 over the interval $[0, \left\|\boldsymbol{w}_0\right\|_\infty]$. Therefore, they are invertible for $0 < \lambda_1 + \lambda_2 < \left\|\boldsymbol{w}_0\right\|_1$. Since $\left\|[\boldsymbol{w}_0 - \theta]_+\right\|_1 = \left\|[\boldsymbol{w}_0 - \theta_2]_+\right\|_1$, we must have $\theta_2 = \theta$. Recall that the solution of Eq. (31) is $\boldsymbol{w}^\star = \min\{\boldsymbol{w}_0, \theta\}$, and the solution of the sequential update induced by Eq. (29) and Eq. (30) is $\min\{\min\{\boldsymbol{w}_0, \theta_1\}, \theta_2\} = \min\{\boldsymbol{w}_0, \theta_2\}$. The programs $\mathcal{P}.1$ and $\mathcal{P}.2$ therefore result in the same vector $\min\{\boldsymbol{w}_0, \theta_2\} = \min\{\boldsymbol{w}_0, \theta\}$ and their induced updates are equivalent.

We now examine the case when $\left\|\boldsymbol{w}_0\right\|_1 \leq \lambda_1 + \lambda_2$. If the 1-norm of $\boldsymbol{w}_0$ is also smaller than λ_1, $\left\|\boldsymbol{w}_0\right\|_1 \leq \lambda_1$, then the dual solution for the first step of $\mathcal{P}.1$ is $\boldsymbol{\alpha}_1 = \boldsymbol{w}_0$, which makes $\boldsymbol{w}_1 = \boldsymbol{w}_0 - \boldsymbol{\alpha}_1 = \mathbf{0}$ and hence $\boldsymbol{w}_2 = \mathbf{0}$. The dual solution for the combined problem is clearly $\boldsymbol{\alpha}_0 = \boldsymbol{w}_0$; again, $\boldsymbol{w}^\star = \boldsymbol{w}_0 - \boldsymbol{\alpha}_0 = \mathbf{0}$. We are thus left with the case $\lambda_1 < \left\|\boldsymbol{w}_0\right\|_1 \leq \lambda_1 + \lambda_2$. We straightforwardly get that the solution to Eq. (31) is $\boldsymbol{w}^\star = \mathbf{0}$. We now prove that the iterated solution obtained by $\mathcal{P}.1$ results in the zero vector as well. First, consider the dual solution $\boldsymbol{\alpha}_1$, which is the minimizer of $\left\|\boldsymbol{\alpha} - \boldsymbol{w}_0\right\|^2$ subject to $\left\|\boldsymbol{\alpha}\right\|_1 \leq \lambda_1$. Since $\boldsymbol{\alpha}_1 = [\boldsymbol{w}_0 - \theta_1]_+$ for

some $\theta_1 \geq 0$, we know that each component of $\boldsymbol{\alpha}_1$ is between zero and its corresponding component in $\boldsymbol{w}_0$, therefore, $\|\boldsymbol{w}_0 - \boldsymbol{\alpha}_1\|_1 = \|\boldsymbol{w}_0\|_1 - \|\boldsymbol{\alpha}\|_1 = \|\boldsymbol{w}_0\|_1 - \lambda_1 \leq \lambda_2$. The dual of the second step of $\mathcal{P}.1$ distills to the minimization $\frac{1}{2}\|\boldsymbol{\alpha} - (\boldsymbol{w}_0 - \boldsymbol{\alpha}_1)\|^2$ subject to $\|\boldsymbol{\alpha}\|_1 \leq \lambda_2$. Since we showed that $\|\boldsymbol{w}_0 - \boldsymbol{\alpha}\|_1 \leq \lambda_2$, we get $\boldsymbol{\alpha}_2 = \boldsymbol{w}_0 - \boldsymbol{\alpha}_1$. This means that $\theta_2 = 0$. Recall that the solution of $\mathcal{P}.1$ is $\min\{\boldsymbol{w}_0, \theta_2\}$, which amounts to the zero vector when $\theta_2 = 0$. We have thus showed that both optimization problems result in the zero vector. This proves the equivalence of $\mathcal{P}.1$ and $\mathcal{P}.2$ for $q = \infty$. ■

The algorithmic consequence of Proposition 11 is that it is possible to perform a lazy update on each iteration by omitting the terms of $\boldsymbol{w}_t$ (or whole rows of the matrix W_t when using mixed-norms) that are outside the support of $\boldsymbol{g}_t^f$, the gradient of the loss at iteration t. However, we do need to maintain the step-sizes used on each iteration and have them readily available on future rounds when we need to update coordinates of $\boldsymbol{w}$ or W that were not updated in previous rounds. Let Λ_t denote the sum of the step sizes times regularization multipliers $\lambda\eta_t$ used from round 1 through t. Then a simple algebraic manipulation yields that instead of solving

$$\boldsymbol{w}_{t+1} = \operatorname*{argmin}_{\boldsymbol{w}} \left\{ \frac{1}{2}\|\boldsymbol{w} - \boldsymbol{w}_t\|_2^2 + \lambda\eta_t \|\boldsymbol{w}\|_q \right\}$$

repeatedly when $\boldsymbol{w}_t$ is not being updated, we can simply cache the last time t_0 that $\boldsymbol{w}$ (or a coordinate in $\boldsymbol{w}$ or a row from W) was updated and, when it is needed, solve

$$\boldsymbol{w}_{t+1} = \operatorname*{argmin}_{\boldsymbol{w}} \left\{ \frac{1}{2}\|\boldsymbol{w} - \boldsymbol{w}_t\|_2^2 + (\Lambda_t - \Lambda_{t_0})\|\boldsymbol{w}\|_q \right\} \quad .$$

The advantage of the lazy evaluation is pronounced when using mixed-norm regularization as it lets us avoid updating entire rows so long as the row index corresponds to a zero entry of the gradient $\boldsymbol{g}_t^f$. We would like to note that the lazy evaluation due to Proposition 11 includes as a special case the efficient implementation for ℓ_1-regularized updates first outlined by Langford et al. (2008). In sum, at the expense of keeping a time stamp t for each entry of $\boldsymbol{w}$ or row of W and maintaining a list of the cumulative sums $\Lambda_1, \Lambda_2, \ldots$, we can get $O(s)$ updates of $\boldsymbol{w}$ when the gradient $\boldsymbol{g}_t^f$ is s-sparse, that is, it has only s non-zero components.

7. Experiments

In this section we describe the results of experiments we performed whose goal are to demonstrate the merits and underscore a few weaknesses of FOBOS. To that end, we also evaluate specific instantiations of FOBOS with respect to several state-of-the-art optimizers and projected subgradient methods on different learning problems. In the experiments that focus on efficiency and speed of convergence, we evaluate the methods in terms of their number of operations, which is approximately the number of floating point operations each method performs. We believe that this metric offers a fair comparison of the different algorithms as it lifts the need to cope with specific code optimization such as cache locality or different costs per iteration of each of the methods.

7.1 Sensitivity Experiments

We begin our experiments by performing a sensitivity analysis of FOBOS. We perform some of the analysis in later sections during our comparisons to other methods, but we discuss the bulk of it here. We focus on two tasks in our sensitivity experiments: minimizing the hinge loss (used in Support Vector Machines) with ℓ_2^2 regularization and minimizing the ℓ_1-regularized logistic loss. These set the loss function f as

$$f(\boldsymbol{w}) = \frac{1}{n}\sum_{i=1}^{n} [1 - y_i \langle \boldsymbol{x}_i, \boldsymbol{w} \rangle]_+ + \frac{\lambda}{2}\|\boldsymbol{w}\|_2^2 \quad \text{and} \quad f(\boldsymbol{w}) = \frac{1}{n}\sum_{i=1}^{n} \log\left(1 + e^{-y_i \langle \boldsymbol{x}_i, \boldsymbol{w} \rangle}\right) + \lambda\|\boldsymbol{w}\|_1$$

respectively. Note that both loss functions have subgradient sets bounded by $\frac{1}{n}\sum_{i=1}^{n}\|y_i \boldsymbol{x}_i\|_2$. Therefore, if all the instances are of bounded norm, so are the subgradients of the empirical loss functions.

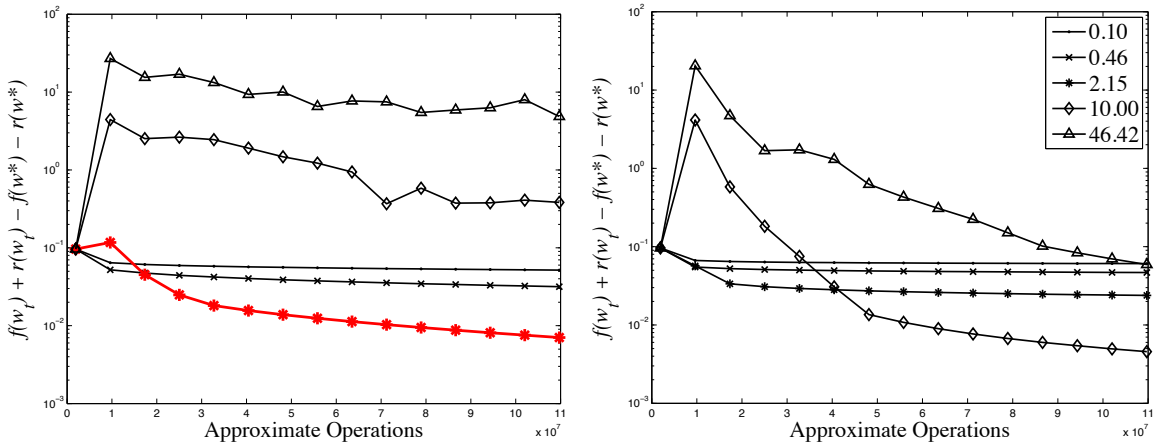

Figure 1: Sensitivity of deterministic FOBOS to initial step size on logistic regression. Key is initial step size. Left: $\eta_t \propto 1/\sqrt{t}$. Right: $\eta_t \propto 1/t$.

We perform analysis using dimensions $d \in \{50, 100, 200, 400, 800\}$ and data set sizes $n \in \{200, 400\}$. We investigate the effect of correlation of the features x_{ij} with one another by generating uncorrelated, moderately correlated, and highly correlated features. Specifically, to generate feature vectors $\boldsymbol{x}_i \in \mathbb{R}^d$, we sample n random vectors $\boldsymbol{z}_i \sim N(0, I)$, $\boldsymbol{z}_i \in \mathbb{R}^d$. We then construct a random covariance matrix Σ whose correlations $|\rho_{ij}| = |\Sigma_{ij}|/\sqrt{\Sigma_{ii}\Sigma_{jj}}$ have mean .2 for the moderately correlated experiments and .3 for the highly correlated experiments (on the highly correlated data, more than one-tenth of the features were more than 80% correlated). To get $\boldsymbol{x}$, we then set $\boldsymbol{x}_i = L\boldsymbol{z}_i$, where L is the Cholesky decomposition of Σ (the identity in the uncorrelated case), and normalize $\boldsymbol{x}_i$ to have $\|\boldsymbol{x}_i\|_\infty = 1$. We compared different stochastic gradient estimators that were based on varying sample sizes: a single example, 10% of the training set, 20% of the training set, and deterministic gradient using the entire data set. We also tested ten different initial step sizes. However, we give in the graphs results for only a subset of the initial steps that reveals the overall dependency on the step size. Further, we also checked three schemes for decaying the step size: $\eta_t \propto 1/t$, $\eta_t \propto 1/\sqrt{t}$, and $\eta_t \propto 1$ (constant step size). We discuss the results attained by constant step sizes only qualitatively, though, to keep the clarity of the figures. When η_t was a constant we divided the initial step size by $\sqrt{T}$, the total number of iterations being taken. We performed each experiment 10 times and averaged the results.

We distill the large number of experiments into a few figures here, deferring some of the analysis to the sequel. Thus in this section we focus on the case when $n = 400$ and $d = 800$, since the experiments with other training set sizes and dimensions gave qualitatively similar results. Most of the results in this section focus on the consequences of the initial step size η_1, though we also discuss different schedules of the learning rate and the sample size for computing the subgradients. In each experiment, we set $\lambda = .25/\sqrt{n}$, which in the logistic case gave roughly 50% sparsity. Before our discussion, we note that we can bound the ℓ_2-norm of $\boldsymbol{w}^\star$ for both the logistic and the hinge loss. In the case of the logistic, we have $\lambda\|\boldsymbol{w}^\star\|_2 \le \lambda\|\boldsymbol{w}^\star\|_1 \le f(\boldsymbol{0}) = \log 2$. Similarly, for the hinge loss we have $\frac{\lambda}{2}\|\boldsymbol{w}^\star\|_2^2 \le f(\boldsymbol{0}) = 1$. In both cases we can bound G by the norm of the $\|\boldsymbol{x}_i\|$, which is in our settings approximately 9. Thus, looking at the bounds from Sec. 3 and Sec. 4, when $\eta_t \propto 1/\sqrt{T}$, the initial step size amounts to $\eta_1 \approx D/\sqrt{7}G \approx 2.3$ and when $\eta_t \propto 1/\sqrt{t}$, the initial step should be $\eta_1 \approx D/4G \approx 1.5$ for logistic regression. For the hinge loss, when $\eta_t \propto 1/\sqrt{t}$, and the initial step ends being $\eta_1 \approx D/4G \approx .35$. We see in the sequel that these approximate step sizes yield results competitive with the best initial step sizes, which can be found only in hindsight.

We begin by considering the effect of initial step size for ℓ_1-regularized logistic regression. We plot results for the moderately correlated data sets, as we investigate the effect of correlation later on. The results are given in Figures 1 and 2, where we plot the objective value at each time step minus the optimal objective

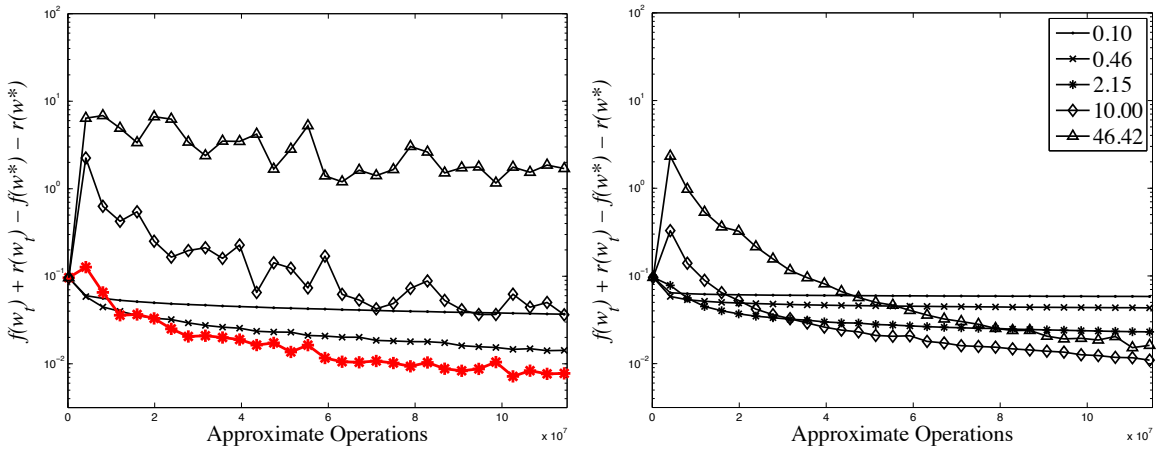

Figure 2: Sensitivity of stochastic FOBOS to initial step size on logistic regression. Key is initial step size. Left: $\eta_t \propto 1/\sqrt{t}$. Right: $\eta_t \propto 1/t$.

value attained, $f(\boldsymbol{w}_t) + r(\boldsymbol{w}_t) - f(\boldsymbol{w}^\star) - r(\boldsymbol{w}^\star)$. We plot the function values of the initial step size that was chosen automatically, by estimating D and G as described above, in bold red in the figures. Interestingly, the left side of Fig. 1 suggests that the best performing initial steps when $\eta_t \propto 1/\sqrt{t}$ are near 1.5: $\eta_1 = 2.15$ gives good regret (we also saw that $\eta_1 = 4.6$ performed well, but do not include it in the plot). In Fig. 2, we see similar behavior for stochastic FOBOS when using 10% of the samples to estimate the gradient. Though we do not plot these results, the stochastic case with constant step sizes also performs well when the step sizes are $\eta_t \approx 2.2/\sqrt{T}$. The deterministic variant of FOBOS could not not take as many steps in the allotted time as the stochastic versions, so its performance was not competitive. All methods are somewhat sensitive to initial step size. Nonetheless, for these types of learning problems it seems plausible to estimate an initial step size based on the arguments given in the previous paragraph, especially when using the step rate of $\eta_t \propto 1/\sqrt{t}$ that was suggested by the analysis in Sec. 4.

We performed similar experiments with the hinge loss with ℓ_2^2 regularization. As the objective is strongly convex,[2] our analysis from Sec. 4 and Theorem 8 suggests a step rate of $\eta_t = 1/\lambda t$. From the right plot in Fig. 3, we see that the best performing step sizes where the two largest, which is consistent with our analysis since $1/\lambda = 80$. For the the $1/\sqrt{t}$ steps, which we present on the left of Fig. 3 respectively, such initial step sizes are too large. However, we can see again that the approximation suggested by our arguments above gives good performance. In sum, it seems that while FOBOS and stochastic FOBOS are fairly sensitive to initial step sizes and rate schedule, our theoretical results from the previous sections give relatively good initial step size heuristics. We will see similar behavior in the sequel.

7.2 Comparison to Subgradient Optimizers

We now move on to the description of experiments using FOBOS to solve ℓ_2^2-regularized learning problems, focusing on comparison to the state-of-the-art subgradient optimizer Pegasos (Shalev-Shwartz et al., 2007). Pegasos was originally implemented and evaluated on Support Vector Machine (SVM) problems by using the hinge-loss as the empirical loss function along with an ℓ_2^2 regularization term. Nonetheless, Pegasos can be rather simply extended to the binary logistic loss function. We thus experimented with both the hinge and logistic loss functions. To generate data for our experiments, we chose a vector $\boldsymbol{w}$ with entries distributed normally with a zero mean and unit variance, while randomly zeroing 50% of the entries in the vector. The

2. We assume there is no bias term in the objective, since any optimization method must deal with this so we find it outside the scope of the paper.

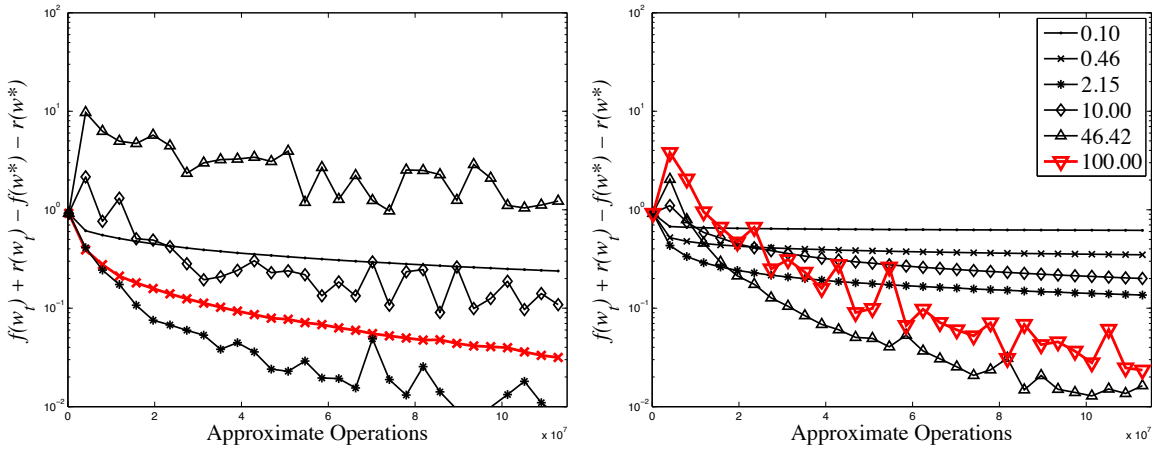

Figure 3: Sensitivity of stochastic methods to initial step size on hinge loss minimization with ℓ_2^2-regularization. Key is initial step size. Left: $\eta_t \propto 1/\sqrt{t}$. Right: $\eta_t \propto 1/t$.

examples $\boldsymbol{x}_i \in \mathbb{R}^d$ were also chosen at random with entries i.i.d. normally distributed. We also performed experiments using correlated data. The results attained on correlated data were similar, so we do not report them in our comparison to Pegasos. To generate target values, we set $y_i = \text{sign}(\langle \boldsymbol{x}_i, \boldsymbol{w} \rangle)$, and negated the sign of 10% of the examples to add label noise. In all experiments, we used $n = 1000$ training examples of dimension $d = 400$.

The graphs of Fig. 4 show (on a log-scale) the objective function, namely, the regularized empirical loss of the algorithms, minus the optimal value of the objective function. These results were averaged over 20 independent runs of the algorithms. In all experiments with a regularization of the form $\frac{1}{2}\lambda\|\boldsymbol{w}\|_2^2$, we used step sizes of the form $\eta_t = 1/(\lambda t)$ to achieve the logarithmic regret bound of Sec. 4. The left graph of Fig. 4 conveys that FOBOS performs comparably to Pegasos on hinge (SVM) loss. Both algorithms quickly approach the optimal value. In this experiment we let both Pegasos and FOBOS employ a projection after each gradient step onto a ℓ_2 norm ball in which $\boldsymbol{w}^\star$ must lie (see Shalev-Shwartz et al. 2007 and the discussion following the proof of Theorem 2). However, in the experiment corresponding to the right plot of Fig. 4, we eliminated the additional projection step and ran the algorithms with the logistic loss. In this case, FOBOS slightly outperforms Pegasos. We hypothesize that the slightly faster rate of FOBOS is due to the explicit shrinkage that FOBOS performs in the ℓ_2^2 update (see Eq. (20) and Lemma 9).

7.3 Comparison to Other Methods for Smooth Problems

As mentioned in our discussion of related work, many methods have been proposed in the optimization and machine learning literature for minimizing Eq. (1) when f is smooth, particularly when f has a Lipschitz-continuous gradient. For the case of ℓ_1-regularized logistic regression, Koh et al. (2007) propose an efficient interior point method. Tseng and Yun (2007) give analysis of a (block) coordinate descent method that uses approximations to the Hessian matrix and an Armijo-type backtracking line search to solve non-smooth regularized problems with smooth objectives; their method was noted to be effective for ℓ_1/ℓ_2-regularized logistic regression, for example, by Meier et al. (2008). We also compare FOBOS and its stochastic variants to the SPARSA method of Wright et al. (2009), which shares the same update as FOBOS but uses a simple line search strategy to choose the its steps. Note that none of these methods apply when f is non-smooth. Lastly, we compare FOBOS to projected-gradient methods. For ℓ_1-regularized problems, Duchi et al. (2008) show how to compute projections to an ℓ_1-ball in linear time, and Schmidt et al. (2009) extend the method to show that projection of a matrix $W \in \mathbb{R}^{d \times k}$ to an ℓ_1/ℓ_2-constraint can be computed in $O(dk)$ time. To compare

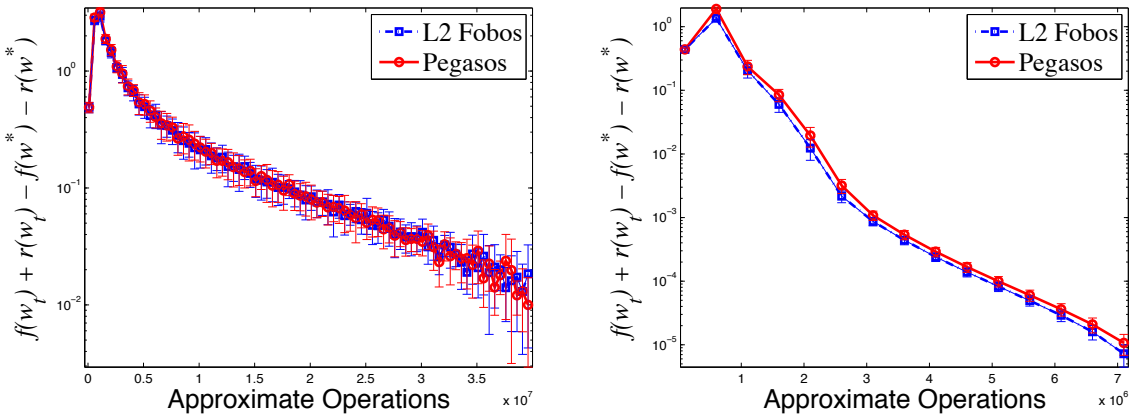

Figure 4: Comparison of FOBOS with Pegasos on the SVM (left) and logistic regression (right). The right hand side plot shows the performance of the algorithms without a projection step.

our methods to projected gradient methods, we first solve the regularized version of the problem. We then constrain the norm of $\boldsymbol{w}$ or the mixed-norm of W to lie within a ball of radius $\lambda\|\boldsymbol{w}^\star\|_1$ or $\lambda\|W^\star\|_{\ell_1/\ell_2}$.

We compared FOBOS to each of the above methods on many different synthetic data sets, and we report a few representative results. In our experiments, SPARSA seemed to outperform FOBOS and the projected gradient methods when using full (deterministic) gradient information. The additional function evaluations incurred by the line search in SPARSA seem to be insignificant to runtime, which is a plausible explanation for SPARSA's superior performance. We therefore do not report results for the deterministic versions of FOBOS and projected gradient methods to avoid clutter in the figures.

In the first set of experiments, we compare FOBOS's performance on ℓ_1-regularized logistic regression to each of the above methods. That is, we set $f(\boldsymbol{w})$ to be the average logistic loss and $r(\boldsymbol{w}) = \lambda\|\boldsymbol{w}\|_1$ and use a data set with $n = 1000$ examples and $d = 400$ dimensions. We compare the performance of stochastic FOBOS to the other algorithms in terms of two aspects. The first is the value of λ, which we set to five logarithmically spaced values that gave solution vectors $\boldsymbol{w}^\star$ ranging from 100% non-zero entries to only 5% non-zero entries. The second aspect is on the correlation of the features. We generated random data sets with uncorrelated features, features that were on average 20% correlated with one another, and features that were on average 30% correlated with one another. In the latter case about 350 pairs of features had above 80% correlation (see the description of feature generation at the beginning of the section). We normalized each example $\boldsymbol{x}$ to have features in the range $[-1,1]$. We assigned labels for each example by randomly choosing a 50% sparse vector $\boldsymbol{w}$, setting $y_i = \text{sign}(\langle \boldsymbol{w}, \boldsymbol{x}_i \rangle)$, and negating 5% of the y values.

The results comparing FOBOS to the other algorithms for different settings of the regularizer λ are in Fig. 5. The y-axis is $f(\boldsymbol{w}_t) + r(\boldsymbol{w}_t) - f(\boldsymbol{w}^\star) - r(\boldsymbol{w}^\star)$, the distance of the current value from the optimal value, and the x-axis is the approximate number of operations (FLOPs) for each method. We used the approximation we derived based on Corollary 7 in our earlier discussion of sensitivity to set the initial step size and used $\eta_t \propto 1/\sqrt{t}$. Tseng and Yun's method requires setting of constants for the backtracking-based line search. We thus use the settings in Meier et al. (2008). In attempt to make the comparisons as fair as possible, we used some of Tseng and Yun's code yet reimplemented the method to take advantage of the specific structure of logistic regression. Similarly, we used the line-search parameters in Wright et al.'s publicly available Matlab code for SPARSA, though we slightly modified their code to handle arbitrary loss functions. From the figure, we see that as λ grows, yielding sparser solutions for $\boldsymbol{w}^\star$, the performance of coordinate descent and especially the interior point method start to degrade relative to the stochastic methods and SPARSA.

In our experiments we found that the stochastic methods were quite resilient to overly-large initial step-sizes, as they quickly took a large number of steps. SPARSA employs an easy to implement and efficient line search, and in general yielded good performance. The coordinate descent method, with its somewhat

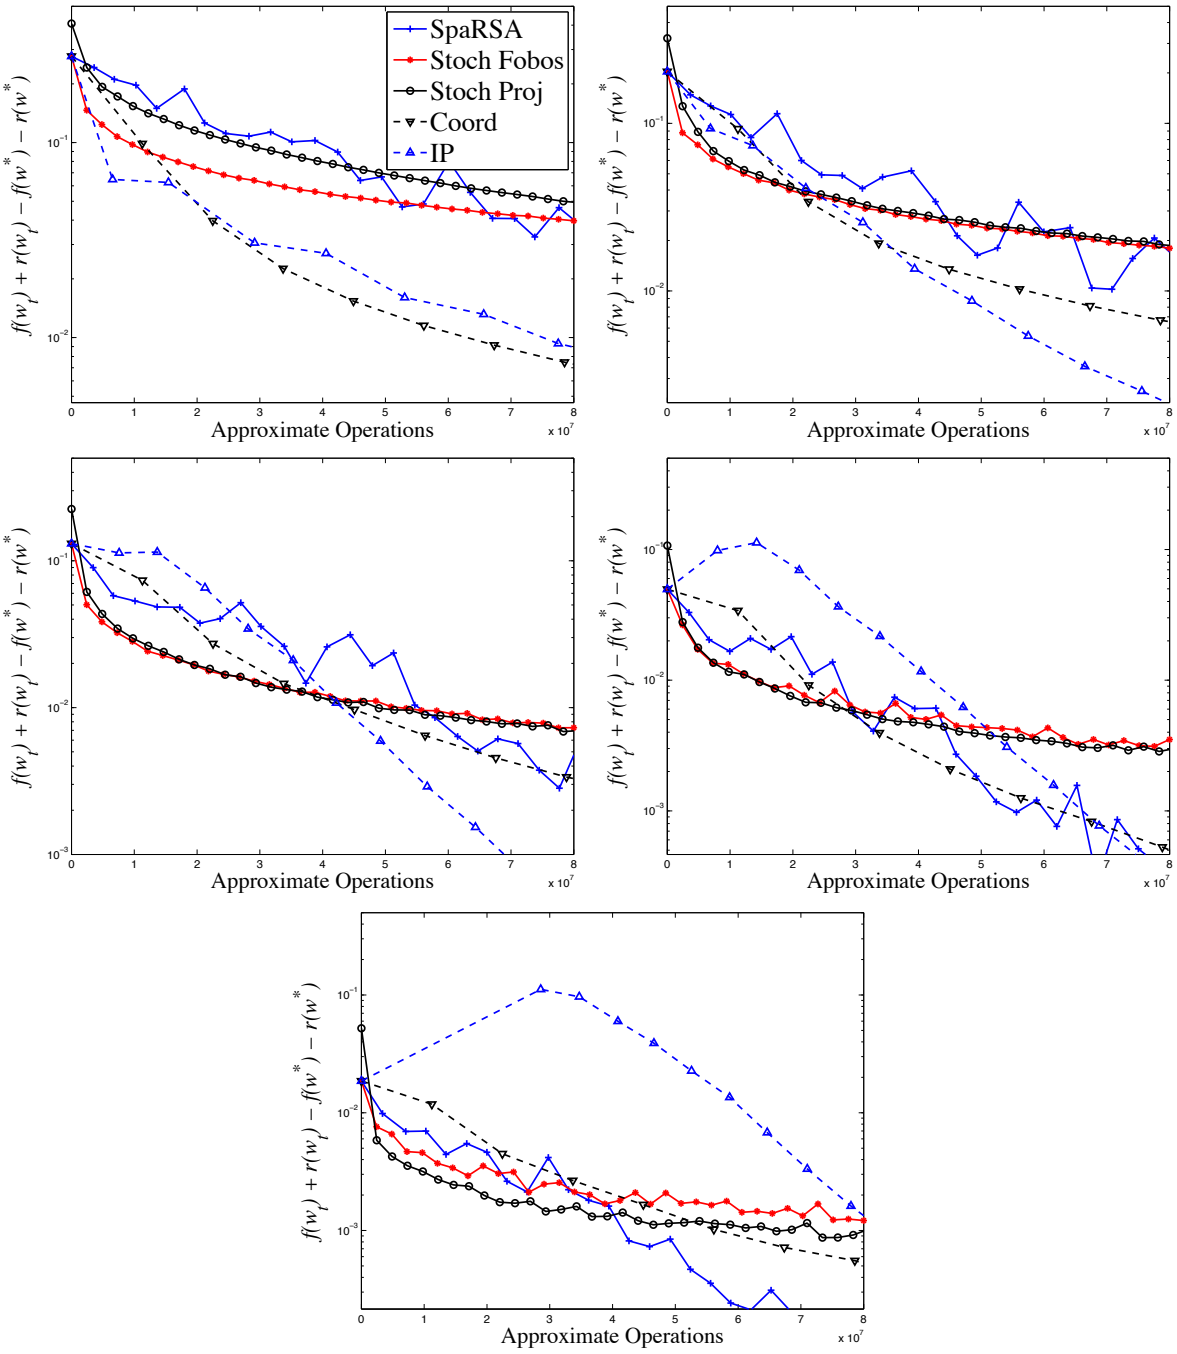

Figure 5: Performance of ℓ_1-regularized logistic regression methods with different settings of λ on correlated synthetic data. Left to right, top to bottom: $\boldsymbol{w}^\star$ has 0% sparsity, $\boldsymbol{w}^\star$ has 25% sparsity, $\boldsymbol{w}^\star$ has 40% sparsity, $\boldsymbol{w}^\star$ has 70% sparsity, and $\boldsymbol{w}^\star$ has 95% sparsity.

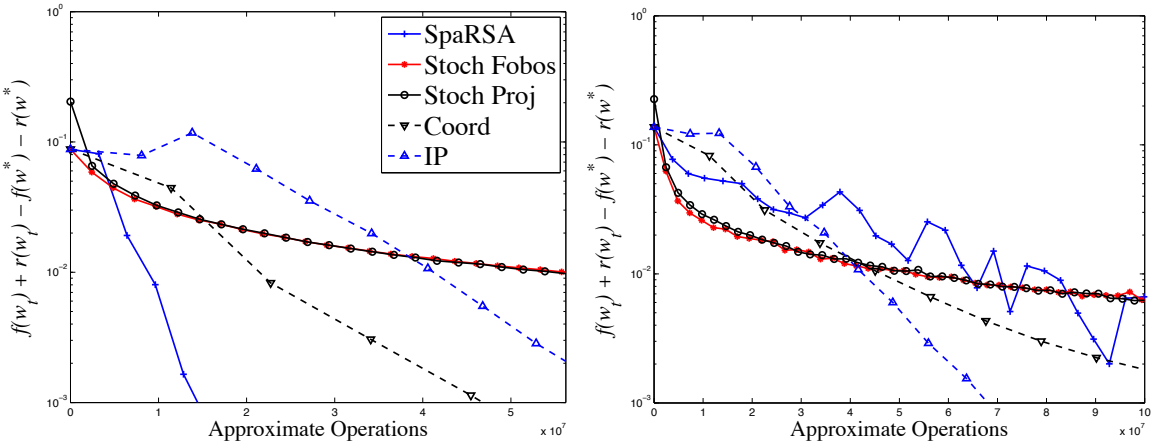

Figure 6: Performance of ℓ_1-regularized logistic regression methods with different correlations on synthetic data. Left: uncorrelated data. Right: highly correlated data.

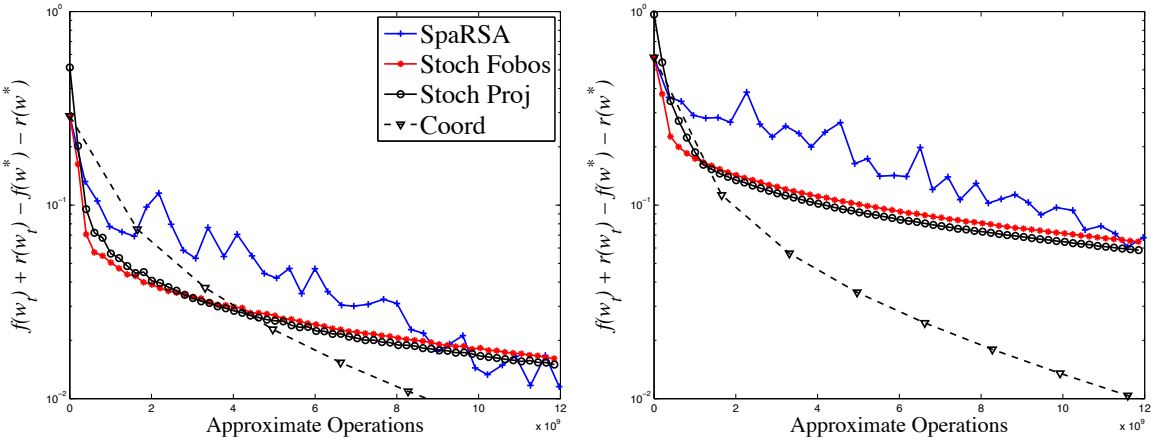

Figure 7: Performance of ℓ_1/ℓ_2-regularized multiclass logistic regression methods with different settings of λ on correlated synthetic data. Left: $\boldsymbol{w}^\star$ has 60% sparsity. Right: $\boldsymbol{w}^\star$ has 30% sparsity.

complicated backtracking line search, was difficult to implement correctly. Therefore, our experiments and experience suggest that SPARSA is likely to be preferred for smooth problems. Nonetheless, stochastic FOBOS quickly obtains a solution within about 10^{-2} of the optimal value. Since the regularized empirical loss serves as a proxy for attaining good generalization performance, we found that in numerous cases this accuracy sufficed to achieve competitive *test* loss.

In Fig. 6 we compare FOBOS to the other methods on data with uncorrelated, moderately correlated, and very correlated features. These plots all have λ set so that $\boldsymbol{w}^\star$ has approximately 40% sparsity. From the plots, we see that stochastic FOBOS and projected gradient actually perform very well on the more correlated data, very quickly getting to within 10^{-2} of the optimal value, though after this they essentially jam. As in the earlier experiments, SPARSA seems to perform quite well for these moderately sized experiments, though the interior point method's performance improves as the features become more correlated.

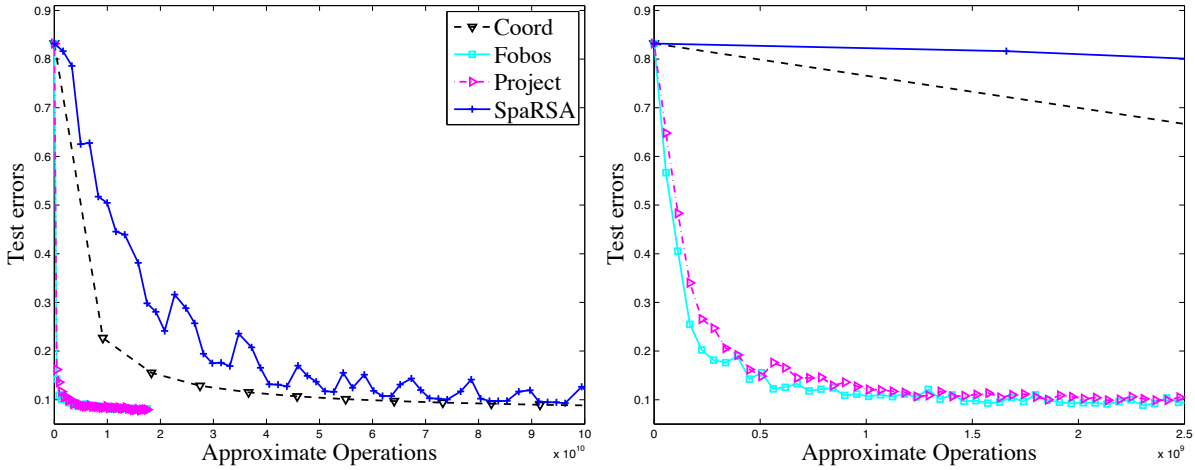

Figure 8: Comparison test error rate of FOBOS, SPARSA, projected gradient, and coordinate descent on MNIST digit recognition data set. Right: magnified view of left plot.

The last set of experiments with synthetic data sets was on mixed-norm-regularized multiclass logistic regression. The objective that we used in this case is

$$\frac{1}{n}\sum_{i=1}^{n}\log\left(1+\sum_{j\neq y_i}e^{\langle x_i, w^j - w^{y_i}\rangle}\right)+\lambda\|W\|_{\ell_1/\ell_q} \quad . \tag{35}$$

In the above equation q represents the norm over rows of the matrix W, and in our experiments it is either 1, 2, or ∞ (in this section, $q=2$). The goal is to classify correctly examples whose labels are in $\{1,\ldots,k\}$ while jointly regularizing entries of the vectors w^j. We used $n=5000$ datapoints of dimension $d=1000$ with $k=10$ classes, meaning we minimize a loss over a matrix $W\in\mathbb{R}^{d\times k}$ with 10000 parameters. To generate data, we sample examples x_i from a normal distribution with moderate correlation, randomly choose a matrix W, and set $y_i=\operatorname{argmax}_j\langle x_i, w^j\rangle$ with 5% label noise. We show results in Fig. 7. In the three figures, vary λ to give solutions $W^\star$ with roughly 60% zero rows, 30% zero rows, and completely non-sparse $W^\star$. From the figures, it is apparent that the stochastic methods, both FOBOS and projected gradient, exhibit very good initial performance but eventually lose to the coordinate descent method in terms of optimization speed. As before, if one is willing to use full gradient information, SPARSA seems a better choice than the deterministic counterpart of FOBOS and projected gradient algorithms. We thus again do not present results for deterministic FOBOS without any line search.

7.4 Experiments with Real Data Sets

Though in the prequel we focus on optimization speed, the main goal in batch learning problems is attaining good test-set error rates rather than rapid minimization of $f(w)+r(w)$. In order to better understand the merits of different optimization methods, we compared the performance of different optimizers on achieving a good test-set error rate on different data sets. Nonetheless, for these tests the contours for the training objective value were qualitatively very similar to the test-set error rate curves. We used the StatLog LandSat Satellite data set (Spiegelhalter and Taylor, 1994), the MNIST handwritten digit database, and a sentiment classification data set (Blitzer et al., 2007).

The MNIST database consists of 60,000 training examples and a 10,000 example test set with 10 classes. We show average results over ten experiments using random 15,000 example subsamples of the training set. For MNIST, each digit is a 28×28 gray scale image z which is represented as a $28^2=784$ dimensional

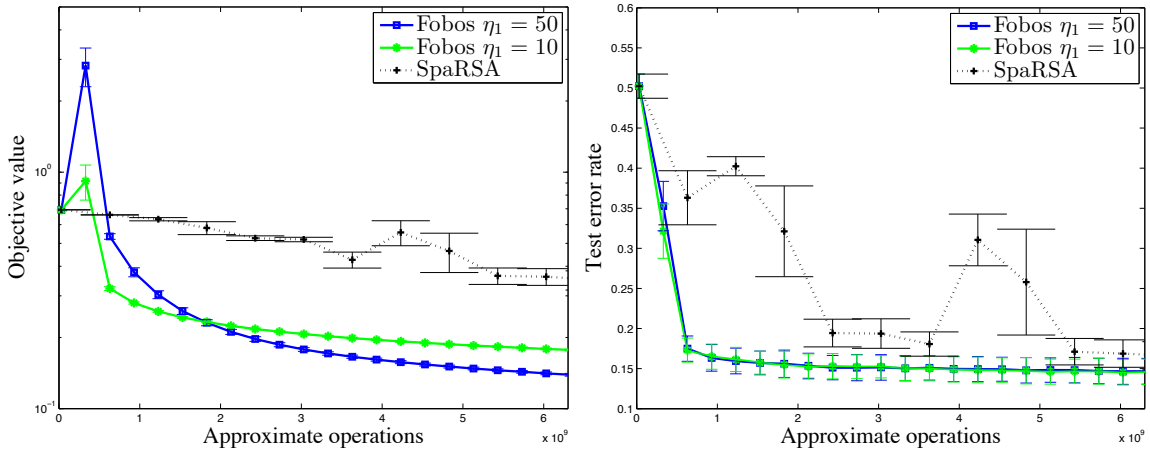

Figure 9: Comparison of FOBOS and SPARSA on sentiment classification task.

vector. Direct linear classifiers do not perform well on this data set. Thus, rather than learning weights for the original features, we learn the weights for a kernel machine with Gaussian kernels, where the value of the j^{th} feature for the i^{th} example is

$$x_{ij} = K(\boldsymbol{z}_i, \boldsymbol{z}_j) \triangleq e^{-\frac{1}{2}\|\boldsymbol{z}_i - \boldsymbol{z}_j\|^2} \quad .$$

We used ℓ_1/ℓ_2 regularization and compared FOBOS, SPARSA, coordinate descent, and projected gradient methods on this test (as well as stochastic gradient versions of FOBOS and projected gradient). The results for deterministic FOBOS and projected gradient were similar to SPARSA, so we do not present them. We also experimented with stochastic group sizes of 100 and 200 examples for FOBOS, but the results were similar, so we plot only the results from the 100 example runs. As before, we used the ℓ_1/ℓ_2 norm of the solution vectors for FOBOS, SPARSA, and coordinate descent as the constrained value for the projected gradient method. For each of the gradient methods, we estimated the diameter D and maximum gradient G as in the synthetic experiments, which led us to use a step size of $\eta_t = 30/\sqrt{t}$. The test set error rate as a function of number of operations for each of the methods are shown in Fig. 8. From Fig. 8, it is clear that the stochastic gradient methods (FOBOS and projected gradient) were significantly faster than any of the other methods. Before the coordinate descent method has even visited every coordinate once, stochastic FOBOS (and similarly stochastic projected gradient) have attained the minimal test-set error. The inferior performance of coordinate descent and deterministic gradient methods can be largely attributed to the need to exhaustively scan the data set. Even if we use only a subset of 15,000 examples, it takes a nontrivial amount of time to simply handle each example. Moreover, the objective values attained during training are qualitatively very similar to the test loss, so that stochastic FOBOS *much* more quickly reduces the training objective than the deterministic methods.

We also performed experiments on a data set that was very qualitatively different from the MNIST and LandSAT data sets. For this experiment, we used the multi-domain sentiment data set of Blitzer et al. (2007), which consists of product reviews taken from Amazon.com for many product types. The prediction task is to decide whether an article is a positive or negative review. The features are bigrams that take values in $\{0,1\}$, totalling about 630,000 binary features. In any particular example, at most a few thousand features are non-zero. We used 10,000 examples in each experiment and performed 10 repetitions while holding out 1000 of the examples as a test set and using 9000 of the examples for training. We used ℓ_1-regularized logistic regression and set $\lambda = 3 \cdot 10^{-5}$, which gave the best generalization performance and resulted in roughly 5% non-zeros in the final vector $\boldsymbol{w}$. We compare stochastic FOBOS to SPARSA in Fig. 9, since the projected gradient method is much slower than FOBOS (detailed in the sequel). For FOBOS we use 900 examples to compute each stochastic gradient. We use two different initial step sizes, one estimated using the approximation described earlier and a second where we scale it by $1/5$. The left plot in Fig. 9 shows the

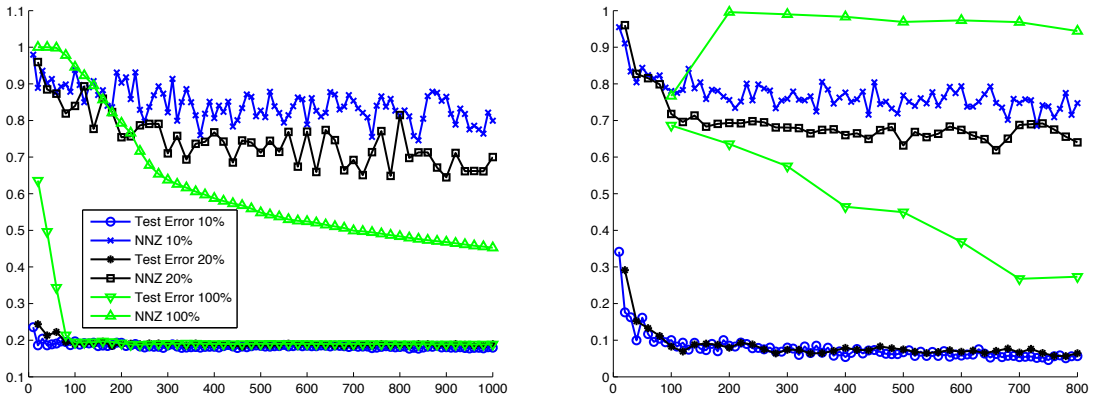

Figure 10: Left: FOBOS sparsity and test error for LandSat data set with ℓ_1-regularization. Right: FOBOS sparsity and test error for MNIST data set with ℓ_1/ℓ_2-regularization. Key is identical for both plots.

training objective value as a function of the number of operations for each of the three methods as well as error bars equal to the standard deviation of the objective. The right plot shows the error rates on the test sets. The behavior in the experiment is similar to that in Fig. 8, where the stochastic methods very quickly attain a small test error. Effectively, before SPARSA finishes two steps, the stochastic methods have arrived at approximate solutions that attain the minimal test set error rates.

We now change our focus from training time to the attained sparsity levels for multiclass classification with ℓ_1, ℓ_1/ℓ_2, and ℓ_1/ℓ_∞ regularization on MNIST and the StatLog LandSat data set. For the LandSat data set we attempt to classify 3×3 neighborhoods of pixels in a satellite image as a particular type of ground, and we expanded the input 36 features into 1296 features by taking the product of all features.

In the left plot of Fig. 10, we show the test set error and sparsity level of W as a function of training time (100 times the number of single-example gradient calculations) for the ℓ_1-regularized multiclass logistic loss with 720 training examples. The green lines show results for using all 720 examples to calculate the gradient, black using 20% of the examples, and blue using 10% of the examples to perform stochastic gradient. Each used the same learning rate $\eta_t \propto 1/\sqrt{t}$, and the reported results are averaged over 5 independent runs with different training data sets. The righthand figure shows a similar plot for training FOBOS on the MNIST data set with ℓ_1/ℓ_2-regularization. The objective value in training has a similar contour to the test loss. As expected, FOBOS with stochastic gradient descent gets to its minimum test classification error, and as the training set size increases this behavior is consistent. However, the deterministic version increases the level of sparsity throughout its run, while the stochastic-gradient version has highly variable sparsity levels and does not give solutions as sparse as the deterministic counterpart. We saw similar behavior when using stochastic versus deterministic projected gradient methods. The slowness of the deterministic gradient means that we do not see the sparsification immediately in larger tests; nonetheless, for longer training times similar sparsifying behavior emerges.

As yet, we do not have a compelling justification for the difference in sparsity levels between stochastic and deterministic gradient FOBOS. We give here some intuitive arguments, leaving a more formal analysis to future work. We develop one possible explanation by exploring the effect of taking a stochastic gradient step starting from the true solution vector $\boldsymbol{w}^\star$. Consider ℓ_1-regularized FOBOS with regularization multiplier λ. Let $\boldsymbol{g}^f$ be the gradient of $f(\boldsymbol{w}^\star)$. For j such that $w_j^\star > 0$, we have $g_j^f = -\lambda$, for j with $w_j^\star < 0$, $g_j^f = \lambda$, and for zero entries in $\boldsymbol{w}^\star$, we have $g_j^f \in [-\lambda, \lambda]$. The FOBOS step then amounts to

$w_j^+ = \text{sign}(w_j^\star)\left[|w_j^\star - \eta_t g_j^f| - \eta_t\lambda\right]_+$, which by inspection simply yields $\boldsymbol{w}^\star$. Now suppose that instead of $\boldsymbol{g}^f$, we use a stochastic estimate $\tilde{\boldsymbol{g}}^f$ of $\boldsymbol{g}^f$. Then the probability that the update w_j^+ of $w_j^\star$ is zero is

$$\mathbb{P}\left(\left|w_j^\star - \eta_t \tilde{g}_j^f\right| \leq \eta_t\lambda\right) = \mathbb{P}\left(\tilde{g}_j^f \in \left[\frac{w_j^\star}{\eta_t} - \lambda, \frac{w_j^\star}{\eta_t} + \lambda\right]\right) \quad .$$

When $w_j^\star = 0$, the probability is simply $\mathbb{P}(\tilde{g}_j^f \in [-\lambda, \lambda])$, which does not change as a function of η_t. However, when $w_j^\star > 0$, we have $E[\tilde{g}_j^f] = -\lambda$, while $w_j^\star/\eta_t \to \infty$ as η_t shrinks (and analogously for $w_j^\star < 0$). In essence, the probability of a non-zero parameter staying non-zero is high, however, the probability of a zero parameter staying zero is constant. Intuitively, then, we expect that stochastic gradient descent will result in more non-zero coefficients than the deterministic variant of FOBOS.

7.5 Experiments with Sparse Gradient Vectors

In this section, we consider the implications of Proposition 11 for learning with sparse data. We show that it is much more efficient to use the updates described in Proposition 11 than to maintain ℓ_1-constraints on $\boldsymbol{w}$ as in Duchi et al. (2008). Intuitively, the former requires rather simple bookkeeping for maintaining the sum Λ_t discussed in Sec. 6, and it is significantly easier to implement and more efficient than Duchi et al.'s red-black tree-based implementation. Indeed, whereas a red-black tree requires at least a thousand of lines of code for its balancing, joining, and splitting operations, the efficient FOBOS updates require fewer than 100 lines of code.

We simulated updates to a weight vector $\boldsymbol{w}$ with a sparse gradient $\boldsymbol{g}_t^f$ for different dimensions d of $\boldsymbol{w} \in \mathbb{R}^d$ and different sparsity levels s for $\boldsymbol{g}_t^f$ with $\text{card}(\boldsymbol{g}_t^f) = s$. To do so, we generate a completely dense $\boldsymbol{w}$ whose ℓ_1-norm is at most a pre-specified value b and add a random vector $\boldsymbol{g}$ to $\boldsymbol{w}$ with s non-zeros. We then either project $\boldsymbol{w} + \boldsymbol{g}$ back to the constraint $\|\boldsymbol{w}\|_1 \leq b$ using the algorithm of Duchi et al. (2008) or perform a FOBOS update to $\boldsymbol{w} + \boldsymbol{g}$ using the algorithm in Sec. 6. We chose λ in the FOBOS update to give approximately the same sparsity as the constraint on b. In Table 1 we report timing results averaged over 100 independent experiments for different dimensions d of $\boldsymbol{w}$ and different cardinalities s of $\boldsymbol{g}$. Though theoretically the sparse FOBOS updates should have no dependence on the dimension d, we found that cache locality can play a factor when performing updates to larger dimensional vectors. Nonetheless, it is clear from the table that the efficient FOBOS step is on the order of ten to twenty times faster than its projected counterpart. Furthermore, the sparse FOBOS updates apply equally as well to mixed norm regularization, and while there are efficient algorithms for both projection to both ℓ_1/ℓ_2 and ℓ_1/ℓ_∞ balls (Schmidt et al., 2009; Quattoni et al., 2009), they are more complicated than the FOBOS steps. Lastly, though it may be possible to extend the efficient data structures of Duchi et al. (2008) to the ℓ_1/ℓ_2 case, there is no known algorithm for efficient projections with sparse updates to an ℓ_1/ℓ_∞ constraint.

Dimension d	$s = 5000$		$s = 10000$		$s = 20000$	
	Project	FOBOS	Project	FOBOS	Project	FOBOS
$5 \cdot 10^4$	0.72	0.07	2.12	0.12	4.53	0.23
$2 \cdot 10^5$	0.80	0.10	2.06	0.16	5.09	0.34
$8 \cdot 10^5$	0.86	0.15	2.22	0.17	5.34	0.39
$3.2 \cdot 10^6$	1.07	0.13	2.75	0.16	6.31	0.52
$6.4 \cdot 10^6$	1.20	0.10	2.83	0.29	6.62	0.48

Table 1: Comparison of the average time (in hundredths of a second) required to compute projection of $\boldsymbol{w} + \boldsymbol{g}$ onto an ℓ_1-constraint to the analogous update required by the FOBOS step.

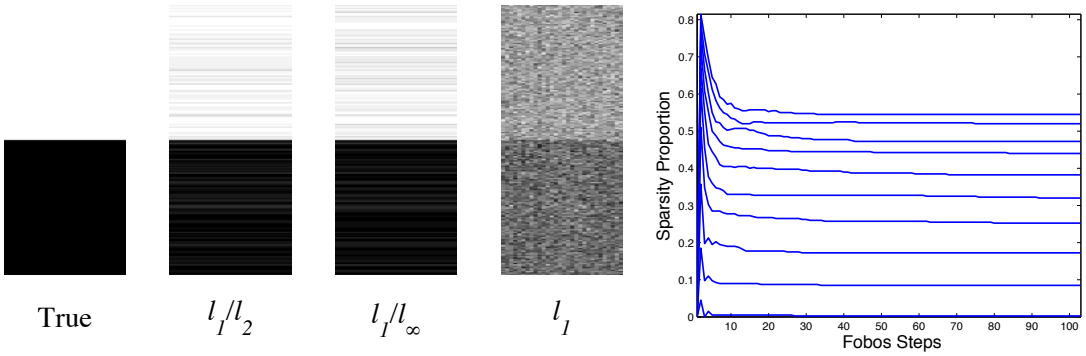

Figure 11: The sparsity patterns attained by FOBOS using mixed-norm and ℓ_1 regularization for a multiclass logistic regression problem.

7.6 Effects of Regularization

Our final experiments focus mostly on sparsity recovery of the different regularizers and their effects on test-set performance. While these are somewhat orthogonal to the previous experiments, we believe there is a relative paucity of investigation of the effects of mixed-norm regularization on classifier performance.

As a verification experiment of FOBOS with a mixed-norm regularizer, we solved a multiclass logistic regression problem whose objective is given in Eq. (35). To solve this task, we randomly generated a matrix W of dimension 200×30. The instances had $d = 200$ dimensions, the number of classes was $k = 30$, and we zeroed out the first 100 rows of W. We next generated $n = 1000$ samples $\boldsymbol{x}_i \in \mathbb{R}^d$ with zero mean and unit variance. We set $y_i = \operatorname{argmax}_j \left\langle \boldsymbol{x}_i, \boldsymbol{w}^j \right\rangle$ and added 10% label noise. We then used FOBOS to find an approximate minimizer of the objective defined by Eq. (35).

To compare the effects of different regularizers, we minimized Eq. (35) using ℓ_1/ℓ_1, ℓ_1/ℓ_2, and ℓ_1/ℓ_∞ regularization. We repeated the experiment 20 times with different randomly selected W that had the same sparsity pattern. On the left side of Fig. 11 we illustrate the sparsity pattern (far left) of the weight vector that generated the data and color-coded maps of the sparsity patterns learned using FOBOS with the different regularization schemes. The colors indicate the fraction of times a weight of W was set to be zero. A white color indicates that the weight was found (or selected) to be zero in all of the experiments while a black color means that it was never zero. The regularization value λ was set so that the learned matrix W would have approximately 50% zero weights. From Fig. 11, we see that both ℓ_1/ℓ_2 and ℓ_1/ℓ_∞ were capable of zeroing entire rows of parameters and often learned a sparsity pattern that was close to the sparsity pattern of the matrix that was used to generate the examples. The standard ℓ_1 regularizer (far right) performed very poorly in terms of structure recovery. In fact, the ℓ_1-regularizer did not yield a single row of zeros in any of the experiments, underscoring one of the merits of using mixed-norm regularization in structured problems. Quantitatively, 96.3% and 94.5% of the zero rows of W were correctly identified when using FOBOS with ℓ_1/ℓ_2 and ℓ_1/ℓ_∞ regularization, respectively. In contrast, not one of the zero rows of W was identified correctly as an all zero row using pure ℓ_1 regularization.

The right plot in Fig. 11 shows the sparsity levels (fraction of non-zero weights) achieved by FOBOS as a function of the number of iterations of the algorithm. Each line represents a different synthetic experiment as λ is modified to give more or less sparsity to the solution vector $\boldsymbol{w}^\star$. The results demonstrate that FOBOS quickly selects the sparsity pattern of $\boldsymbol{w}^\star$, and the level of sparsity persists throughout its execution. We found this sparsity pattern common to all problems we tested, including mixed-norm problems. This is not particularly surprising, as Hale et al. (2007) recently gave an analysis showing that after a finite number of iterations, FOBOS-like algorithms attain the sparsity of the true solution $\boldsymbol{w}^\star$.

% Non-zero	ℓ_1 Test	ℓ_1/ℓ_2 Test	ℓ_1/ℓ_∞ Test

40	**.08**	**.08**	.16

Table 3: MNIST classification error versus sparsity

For comparison of the different regularization approaches, we report in Table 2 and Table 3 the test set error as a function of row sparsity of the learned matrix W. For the LandSat data, we see that using the block ℓ_1/ℓ_2 regularizer yields better performance for a given level of structural sparsity. However, on the MNIST data the ℓ_1 regularization and the ℓ_1/ℓ_2 achieve comparable performance for each level of structural sparsity. Moreover, for a given level of structural sparsity, the ℓ_1-regularized solution matrix W attains significantly higher overall sparsity, roughly 90% of the entries of each non-zero row are zero. The different performance on the different data sets might indicate that structural sparsity is effective only when the set of parameters indeed exhibit natural grouping.

For our final experiment, we show the power of FOBOS with mixed-norm regularization in the context of image compression. For this experiment, we represent each image as a set of patches where each patch is in turn represented as a 79 dimensional vector as described by Grangier and Bengio (2008). The goal is to jointly describe the set of patches by a single high-dimensional yet sparse set of dictionary features. Each of the dictionary terms is also in $\mathbb{R}^{79}$. Let $\boldsymbol{x}_j$ denote the j^{th} patch of an image with k patches to be compressed and $\boldsymbol{c}_i$ be the i^{th} dictionary vector from a dictionary of n vectors. The regularized objective is thus

$$\frac{1}{2}\sum_{j=1}^{k}\left\|\boldsymbol{x}_j-\sum_{i=1}^{n}w_{ij}\boldsymbol{c}_i\right\|_2^2+\lambda\sum_{i=1}^{n}\|\bar{\boldsymbol{w}}^i\|_q \ .$$

In our experiments, the number of dictionary vectors n was 1000 and the number of patches k was around 120 on average. We report results averaged over 100 different images. We experiment with the three settings for q we have used in prior experiments, namely $q \in \{1,2,\infty\}$. In Fig. 12 we report the average reconstruction error as a function of the fraction of dictionary vectors actually used. As one would expect, the mixed-norm regularizers (ℓ_1/ℓ_2 and ℓ_1/ℓ_∞) achieve lower reconstruction error as a function of dictionary sparsity than strict ℓ_1-regularization. The ℓ_1/ℓ_2-regularization also gives a slight, but significant, reconstruction improvement over ℓ_1/ℓ_∞-regularization. We hypothesize that this is related to the relative efficiency of ℓ_1/ℓ_∞ as a function of the geometry of the input space, as was theoretically discussed in Negahban and Wainwright (2008). Further investigation is required to shed more light into this type of phenomenon, and we leave it for future research.

8. Conclusions and Future Work

In this paper we analyzed a framework for online and batch convex optimization with a diverse class of regularization functions. We provided theoretical justification for a type of convex programming method we call

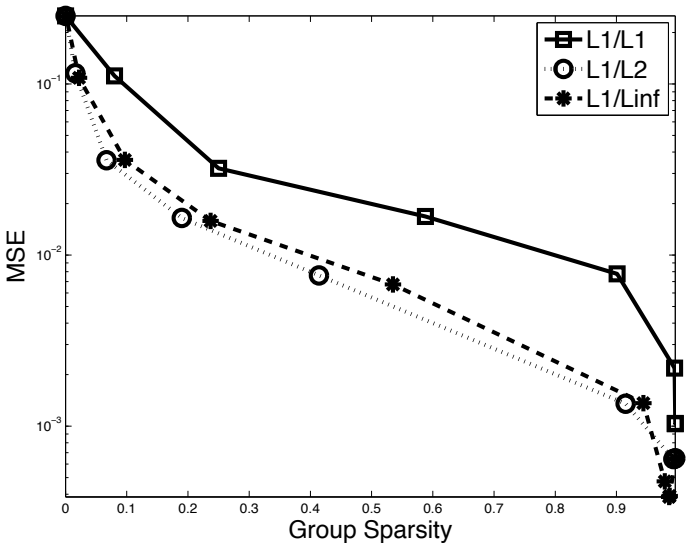

Figure 12: Image reconstruction error as a function of group sparsity.

FOBOS, which is known also as forward-backward splitting, iterative shrinkage and thresholding for the special case of ℓ_1-regularized problems, or SPARSA. Specifically, we described both offline convergence rates for arbitrary convex functions with regularization as well as regret bounds for online convex programming of regularized losses. Our derivation includes as a corollary the case of ℓ_1 regularization, which was concretely studied by Langford et al. (2008). Our approach provides a simple mechanism for solving online convex programs with many regularization functions, giving sparsity in parameters and different types of block or group regularization straightforwardly. Furthermore, the FOBOS framework is general and able to minimize any convex subdifferentialable function f so long as the forward looking step of Eq. (3) can be computed.

We have also provided a good deal of empirical evaluation of the method in comparison to other modern optimization methods for similar problems. Our practical experience suggests that for small to medium problems, SPARSA is effective and simple to implement (as opposed to more complicated coordinate descent methods), while for large scale problems, performing stochastic FOBOS is probably preferable. We have also shown that FOBOS is efficient for online learning with sparse data.

A few directions for further research suggest themselves, but we list here only two. The first is the question of whether we can modify the algorithm to work with arbitrary Bregman divergences of a function h instead of squared Euclidean distance, that is, we would like to form a generalized FOBOS update which is based on instantaneous optimization problems with Bregman divergences for convex differentiable h, where $B_h(\boldsymbol{u}, \boldsymbol{v}) = h(\boldsymbol{u}) - h(\boldsymbol{v}) - \langle \nabla h(\boldsymbol{v}), \boldsymbol{u} - \boldsymbol{v} \rangle$. We assume the generalized update would, loosely speaking, be analogous to nonlinear projected subgradient methods and the mirror descent (see, e.g., Beck and Teboulle 2003). This might allow us to give bounds for our algorithms in terms of other dual norms, such as ℓ_1/ℓ_∞ norms on the gradients or diameter of the space, rather than simply ℓ_2. We believe the attainment and rate of sparsity when using stochastic gradient information, as suggested by the discussion of Fig. 10, merits deeper investigation that will be fruitful and interesting.

Acknowledgments

We would like to thank Sam Roweis and Samy Bengio for helpful discussions and Shai Shalev-Shwartz and Tong Zhang for useful feedback on earlier drafts. We also would like to thank the anonymous reviewers and

editor Yoav Freund for their constructive comments and guidance. A large portion of John Duchi's work was performed at Google.

Appendix A. Online Regret Proofs

Proof of Theorem 6 Looking at Lemma 1, we immediately see that if $\|\partial f\|$ and $\|\partial r\|$ are bounded by G,

$$f_t(\boldsymbol{w}_t) - f_t(\boldsymbol{w}^\star) + r(\boldsymbol{w}_{t+1}) - r(\boldsymbol{w}^\star) \leq \frac{1}{2\eta_t}\left(\|\boldsymbol{w}_t - \boldsymbol{w}^\star\|^2 - \|\boldsymbol{w}_{t+1} - \boldsymbol{w}^\star\|^2\right) + \frac{7}{2}G^2\eta_t. \tag{36}$$

Now we use Eq. (36) to obtain that

$$\begin{aligned} R_{f+r}(T) &= \sum_{t=1}^{T}\left(f_t(\boldsymbol{w}_t) - f_t(\boldsymbol{w}^\star) + r(\boldsymbol{w}_t) - r(\boldsymbol{w}^\star)\right) + r(\boldsymbol{w}_{T+1}) - r(\boldsymbol{w}^\star) - r(\boldsymbol{w}_1) + r(\boldsymbol{w}^\star) \\ &\leq GD + \sum_{t=1}^{T}\frac{1}{2\eta_t}\left(\|\boldsymbol{w}_t - \boldsymbol{w}^\star\|^2 - \|\boldsymbol{w}_{t+1} - \boldsymbol{w}^\star\|^2\right) + \frac{7G^2}{2}\sum_{t=1}^{T}\eta_t \end{aligned}$$

since $r(\boldsymbol{w}) \leq r(\mathbf{0}) + G\|\boldsymbol{w}\| \leq GD$. We can rewrite the above bound and see

$$\begin{aligned} R_{f+r}(T) &\leq GD + \frac{1}{2\eta_1}\|\boldsymbol{w}_1 - \boldsymbol{w}^\star\|^2 + \frac{1}{2}\sum_{t=2}^{T}\|\boldsymbol{w}_t - \boldsymbol{w}^\star\|^2\left(\frac{1}{\eta_t} - \frac{1}{\eta_{t-1}}\right) + \frac{7G^2}{2}\sum_{t=1}^{T}\eta_t \\ &\leq GD + \frac{D^2}{2\eta_1} + \frac{D^2}{2}\sum_{t=2}^{T}\left(\frac{1}{\eta_t} - \frac{1}{\eta_{t-1}}\right) + \frac{7G^2}{2}\sum_{t=1}^{T}\eta_t \ , \end{aligned}$$

where we used again the bound on the distance of each $\boldsymbol{w}_t$ to $\boldsymbol{w}^\star$ for the last inequality. Lastly, we use the fact that the sum $\frac{1}{\eta_1} + \sum_{t=2}^{T}(\frac{1}{\eta_t} - \frac{1}{\eta_{t-1}})$ telescopes and get that

$$R_{f+r}(T) \ \leq \ GD + \frac{D^2}{2\eta_T} + \frac{7G^2}{2}\sum_{t=1}^{T}\eta_t \ .$$

Setting $\eta_t = c/\sqrt{t}$ and recognizing that $\sum_{t=1}^{T}\eta_t \leq 2c\sqrt{T}$ concludes the proof. ■

Proof of Theorem 8 The proof builds straightforwardly on Theorem 1 from Hazan et al. (2006) and our proof of Theorem 6. We sum Eq. (17) from $t = 1$ to T and get

$$\begin{aligned} R_{f+r}(T) &\leq \sum_{t=1}^{T}\left(\left\langle \boldsymbol{g}_t^f + \boldsymbol{g}_t^r, \boldsymbol{w}_t - \boldsymbol{w}^\star\right\rangle - \frac{H}{2}\|\boldsymbol{w}_t - \boldsymbol{w}^\star\|^2\right) \\ &\leq 2GD + \frac{1}{2}\sum_{t=1}^{T-1}\left(\frac{1}{\eta_t}\|\boldsymbol{w}_t - \boldsymbol{w}^\star\|^2 - \frac{1}{\eta_t}\|\boldsymbol{w}_{t+1} - \boldsymbol{w}^\star\|^2 - H\|\boldsymbol{w}_t - \boldsymbol{w}^\star\|^2\right) + \frac{7G^2}{2}\sum_{t=1}^{T-1}\eta_t \\ &\leq 2GD + \frac{1}{2}\sum_{t=2}^{T-1}\|\boldsymbol{w}_t - \boldsymbol{w}^\star\|^2\left(\frac{1}{\eta_t} - \frac{1}{\eta_{t-1}} - H\right) + \frac{1}{\eta_1}\|\boldsymbol{w}_1 - \boldsymbol{w}^\star\|^2 + \frac{7G^2}{2}\sum_{t=1}^{T-1}\eta_t. \end{aligned}$$

The second inequality follows from Eq. (36) and the third inequality from a rearrangement of the sum and removal of the negative term $(1/\eta_{T-1})\|\boldsymbol{w}_T - \boldsymbol{w}^\star\|^2$. Taking $\eta_t = \frac{1}{Ht}$, we see that $1/\eta_t - 1/\eta_{t-1} - H = Ht - H(t-1) - H = 0$, so we can bound the regret by

$$R_{f+r}(T) \leq 2GD + HD^2 + \frac{7G^2}{2}\sum_{t=1}^{T-1}\frac{1}{Ht} \leq 2GD + HD^2 + \frac{7G^2}{2H}(1 + \log T) = O\left(\frac{G^2}{H}\log T\right) \ .$$

■

Proof of Lemma 9 The triangle inequality implies that

$$\left\|\sum_{t=1}^{T} \partial f_t(\boldsymbol{w}_t)\right\| \leq \sum_{t=1}^{T} \|\partial f_t(\boldsymbol{w}_t)\| \leq TG \ .$$

Let $\boldsymbol{g}_t^\star \in \partial f_t(\boldsymbol{w}^\star)$ be such that

$$\mathbf{0} = \sum_{t=1}^{T} \boldsymbol{g}_t^\star + T\lambda \boldsymbol{w}^\star \in \sum_{t=1}^{T} \partial f_t(\boldsymbol{w}^\star) + T\partial r(\boldsymbol{w}^\star)$$

so $\|\boldsymbol{w}^\star\| = \|\sum_{t=1}^{T} \boldsymbol{g}_t^\star\|/(T\lambda) \leq G/\lambda$.

For the second part, assume that $\boldsymbol{w}_0 = \mathbf{0}$, and for our induction that $\boldsymbol{w}_t$ satisfies $\|\boldsymbol{w}_t\| \leq G/\lambda$. Then computing the FOBOS update from Eq. (20),

$$\|\boldsymbol{w}_{t+1}\| = \frac{\|\boldsymbol{w}_t - \eta_t \boldsymbol{g}_t^f\|}{1+\lambda\eta_t} \leq \frac{\|\boldsymbol{w}_t\| + \eta_t\|\boldsymbol{g}_t^f\|}{1+\lambda\eta_t} \leq \frac{G/\lambda + \eta_t G}{1+\lambda\eta_t} = \frac{G(1+\lambda\eta_t)}{\lambda(1+\lambda\eta_t)} \ .$$

■

Appendix B. Update for Berhu Regularization

Recalling the Berhu regularizer and combining it with Eq. (18) for one variable, we see that we want to minimize

$$\frac{1}{2}(w-v)^2 + \tilde{\lambda} b(w) = \frac{1}{2}(w-v)^2 + \tilde{\lambda}\left[|w|\,[\![|w| \leq \gamma]\!] + \frac{w^2+\gamma^2}{2\gamma}\,[\![|w| > \gamma]\!]\right].$$

First, if $|v| \leq \tilde{\lambda}$, then exactly reasoning to that for minimization of the ℓ_1-regularized minimization step implies that the optimal solution is $w = 0$.

When $|v| > \tilde{\lambda}$, there are two remaining cases to check. Let us assume without loss of generality that $v > \tilde{\lambda}$. It is immediate to verify that $w \geq 0$ at the optimum. Now, suppose that $v - \tilde{\lambda} \leq \gamma$. Taking $w = v - \tilde{\lambda} \leq \gamma$ (so that $w > 0$) gives us that $\partial b(w) = \{\tilde{\lambda}\}$. Thus, the subgradient set of our objective contains a single element, $w - v + \tilde{\lambda}\partial|w| = v - \tilde{\lambda} - v + \tilde{\lambda}1 = 0$. Therefore, when $v - \tilde{\lambda} \leq \gamma$ the optimal value of w is $v - \tilde{\lambda}$. The last case we need to examine is when $v - \tilde{\lambda} > \gamma$, which we as we show shortly puts the solution $w^\star$ in the ℓ_2^2 realm of $b(w)$. By choosing $w = \frac{v}{1+\frac{\tilde{\lambda}}{\gamma}}$ we get that,

$$w = \frac{v}{1+\frac{\tilde{\lambda}}{\gamma}} = \frac{v\gamma}{\gamma+\tilde{\lambda}} > \frac{(\gamma+\tilde{\lambda})\gamma}{\gamma+\tilde{\lambda}} = \gamma \ .$$

Therefore, $w > \gamma$ and thus w is in the ℓ_2^2 region of the Berhu penalty $b(w)$. Furthermore, for this choice of w the derivative of the penalty is

$$w - v + \tilde{\lambda}\frac{w}{\gamma} = \frac{v\gamma}{\gamma+\tilde{\lambda}} - v + \tilde{\lambda}\frac{v\gamma}{\gamma(\gamma+\tilde{\lambda})} = \frac{v\gamma}{\gamma+\tilde{\lambda}} - \frac{v(\gamma+\tilde{\lambda})}{\gamma+\tilde{\lambda}} + \tilde{\lambda}\frac{v}{\gamma+\tilde{\lambda}} = 0.$$

Combining the above results, inserting the conditions on the sign, and expanding $v = w_{t+\frac{1}{2},j}$ gives Eq. (26).

Appendix C. Fast Convergence Rate for Smooth Objectives

In this appendix, we describe an analysis of FOBOS which yields an $O(1/T)$ rate of convergence when f has Lipschitz-continuous gradient. Our analysis is by no means new. It is a distilled and simplified adaptation of the analysis of Nesterov (2007) to our setting.

Throughout the appendix we assume that $\nabla f(\boldsymbol{w})$ is Lipschitz continuous with a constant L, that is, $\|\nabla f(\boldsymbol{w}) - \nabla f(\boldsymbol{v})\| \leq L\|\boldsymbol{w} - \boldsymbol{v}\|$. The fundamental theorem of calculus then readily implies that (Nesterov, 2004, Lemma 1.2.3)

$$|f(\boldsymbol{w}) - f(\boldsymbol{v}) - \langle \nabla f(\boldsymbol{v}), \boldsymbol{w} - \boldsymbol{v}\rangle| \leq \frac{L}{2}\|\boldsymbol{w} - \boldsymbol{v}\|^2 \ . \tag{37}$$

To see that Eq. (37) holds, add and subtract $\langle \nabla f(\boldsymbol{v}), \boldsymbol{w} - \boldsymbol{v}\rangle$ to note that

$$\begin{aligned} f(\boldsymbol{w}) - f(\boldsymbol{v}) &= \int_0^1 \langle \nabla f(\boldsymbol{v} + t(\boldsymbol{w} - \boldsymbol{v})), \boldsymbol{w} - \boldsymbol{v}\rangle \, dt \\ &= \langle \nabla f(\boldsymbol{v}), \boldsymbol{w} - \boldsymbol{v}\rangle + \int_0^1 \langle \nabla f(\boldsymbol{v} + t(\boldsymbol{w} - \boldsymbol{v})) - \nabla f(\boldsymbol{v}), \boldsymbol{w} - \boldsymbol{v}\rangle \, dt \end{aligned}$$

which, by using Cauchy-Shwartz inequality, yields

$$\begin{aligned} |f(\boldsymbol{w}) - f(\boldsymbol{v}) - \langle \nabla f(\boldsymbol{v}), \boldsymbol{w} - \boldsymbol{v}\rangle| \ &\leq \ \int_0^1 |\langle \nabla f(\boldsymbol{v} + t(\boldsymbol{w} - \boldsymbol{v})) - \nabla f(\boldsymbol{v}), \boldsymbol{w} - \boldsymbol{v}\rangle| \, dt \\ \leq \ \int_0^1 \|\nabla f(\boldsymbol{v} + t(\boldsymbol{w} - \boldsymbol{v})) - \nabla f(\boldsymbol{v})\| \|\boldsymbol{w} - \boldsymbol{v}\| dt \ &\leq \ \int_0^1 tL\|\boldsymbol{w} - \boldsymbol{v}\|^2 dt \ = \ \frac{L}{2}\|\boldsymbol{w} - \boldsymbol{v}\|^2 \ . \end{aligned}$$

For the remainder of this section, we assume that $f(\boldsymbol{w}) + r(\boldsymbol{w})$ is coercive, so that as $\|\boldsymbol{w}\| \to \infty$, $f(\boldsymbol{w}) + r(\boldsymbol{w}) \to \infty$. We thus have that the level sets of $f(\boldsymbol{w}) + r(\boldsymbol{w})$ are bounded: $\|\boldsymbol{w} - \boldsymbol{w}^\star\| \leq D$ for all $\boldsymbol{w}$ such that $f(\boldsymbol{w}) + r(\boldsymbol{w}) \leq f(\boldsymbol{0}) + r(\boldsymbol{0})$. Consider the "composite gradient mapping" (Nesterov, 2007)

$$m(\boldsymbol{v}, \boldsymbol{w}) = f(\boldsymbol{v}) + \langle \nabla f(\boldsymbol{v}), \boldsymbol{w} - \boldsymbol{v}\rangle + \frac{L}{2}\|\boldsymbol{w} - \boldsymbol{v}\|^2 + r(\boldsymbol{w}) \ . \tag{38}$$

Before proceeding with the proof of fast convergence rate, we would like to underscore the equivalence of the FOBOS update and the composite gradient mapping. Formally, minimizing $m(\boldsymbol{v}, \boldsymbol{w})$ with respect to $\boldsymbol{w}$ is completely equivalent to taking a FOBOS step with $\eta = 1/L$ and $\boldsymbol{v} = \boldsymbol{w}_t$. To obtain the FOBOS update from Eq. (38) we simply need to divide $m(\boldsymbol{v}, \boldsymbol{w})$ by $L = 1/\eta$, omit terms that solely depend on $\boldsymbol{v} = \boldsymbol{w}_t$, and use the fact that $\boldsymbol{w}_{t+\frac{1}{2}} = \boldsymbol{w}_t - \eta_t \boldsymbol{g}_t^f = \boldsymbol{v} - \nabla f(\boldsymbol{v})/L$.

For notational convenience, let $\phi(\boldsymbol{w}) = f(\boldsymbol{w}) + r(\boldsymbol{w})$. Denote by $\boldsymbol{w}^+$ the vector minimizing $m(\boldsymbol{v}, \boldsymbol{w})$. Then from Eq. (37) we get that

$$\phi(\boldsymbol{w}^+) = f(\boldsymbol{w}^+) + r(\boldsymbol{w}^+) \leq f(\boldsymbol{v}) + \left\langle \nabla f(\boldsymbol{v}), \boldsymbol{w}^+ - \boldsymbol{v}\right\rangle + \frac{L}{2}\|\boldsymbol{w}^+ - \boldsymbol{v}\|^2 + r(\boldsymbol{w}^+) = \inf_{\boldsymbol{w}} m(\boldsymbol{v}, \boldsymbol{w}). \tag{39}$$

Further, because $f(\boldsymbol{v}) + \langle \nabla f(\boldsymbol{v}), \boldsymbol{w} - \boldsymbol{v}\rangle \leq f(\boldsymbol{w})$ for all $\boldsymbol{w}$, we have

$$\inf_{\boldsymbol{w}} m(\boldsymbol{v}, \boldsymbol{w}) \leq \inf_{\boldsymbol{w}} \left[f(\boldsymbol{w}) + \frac{L}{2}\|\boldsymbol{w} - \boldsymbol{v}\|^2 + r(\boldsymbol{w}) \right] = \inf_{\boldsymbol{w}} \left[\phi(\boldsymbol{w}) + \frac{L}{2}\|\boldsymbol{w} - \boldsymbol{v}\|^2 \right] \ . \tag{40}$$

Now we consider the change in function value from $\boldsymbol{w}_t$ to $\boldsymbol{w}_{t+1}$ for the FOBOS update with $\eta = 1/L$. To do this, we take an arbitrary optimal point $\boldsymbol{w}^\star$ and restrict $\boldsymbol{w}_{t+1}$ to lie on the line between $\boldsymbol{w}_t$ and $\boldsymbol{w}^\star$, which constrains the set of infimum values above and allows us to carefully control them. With this construction,

along with Eqs. (39) and (40) we get that

$$\begin{aligned}
\phi(\boldsymbol{w}_{t+1}) &\leq \inf_{\boldsymbol{w}} \left[\phi(\boldsymbol{w}) + \frac{L}{2} \|\boldsymbol{w} - \boldsymbol{w}_t\|^2 \right] \\
&\leq \inf_{\alpha \in [0,1]} \left[\phi(\alpha \boldsymbol{w}^\star + (1-\alpha)\boldsymbol{w}_t) + \frac{L}{2} \|\alpha \boldsymbol{w}^\star + (1-\alpha)\boldsymbol{w}_t - \boldsymbol{w}_t\|^2 \right] \\
&\leq \inf_{\alpha \in [0,1]} \left[\alpha \phi(\boldsymbol{w}^\star) + (1-\alpha)\phi(\boldsymbol{w}_t) + \frac{\alpha^2 L}{2} \|\boldsymbol{w}^\star - \boldsymbol{w}_t\|^2 \right] . \qquad (41)
\end{aligned}$$

The bound in Eq. (41) follows due to the convexity of ϕ. One immediate consequence of Eq. (41) is that $\phi(\boldsymbol{w}_{t+1}) \leq \phi(\boldsymbol{w}_t)$, since at $\alpha = 0$ we obtain the same objective for ϕ. Thus, all iterates of the method satisfy $\|\boldsymbol{w}_t - \boldsymbol{w}^\star\| \leq D$. We therefore can distill the bound to be

$$\phi(\boldsymbol{w}_{t+1}) \leq \inf_{\alpha \in [0,1]} \left[\phi(\boldsymbol{w}_t) + \alpha \left(\phi(\boldsymbol{w}^\star) - \phi(\boldsymbol{w}_t) \right) + \alpha^2 \frac{LD^2}{2} \right] .$$

The argument of the infimum of the equation above is a quadratic equation in α. We need to analyze two possible cases for the optimal solution. In the first case when $\phi(\boldsymbol{w}_t) - \phi(\boldsymbol{w}^\star) > LD^2$, the optimal value of α is 1 and $\phi(\boldsymbol{w}_{t+1}) \leq \phi(\boldsymbol{w}^\star) + LD^2/2$. Therefore, we will never encounter again this case in future iterations. The second occurs when $\phi(\boldsymbol{w}_t) - \phi(\boldsymbol{w}^\star) \leq LD^2$, so we have $\alpha = (\phi(\boldsymbol{w}_t) - \phi(\boldsymbol{w}^\star))/LD^2 \in [0,1]$, which yields

$$\phi(\boldsymbol{w}_{t+1}) \leq \phi(\boldsymbol{w}_t) - \frac{\left(\phi(\boldsymbol{w}_t) - \phi(\boldsymbol{w}^\star)\right)^2}{2LD^2} . \qquad (42)$$

To obtain the form of the convergence rate let us define the inverse residual value $\rho_t = 1/(\phi(\boldsymbol{w}_t) - \phi(\boldsymbol{w}^\star))$. By analysing the rate at which ρ_t tends to infinity we obtain our desired convergence rate. From the definition of ρ_t and the bound of Eq. (42) we get that

$$\begin{aligned}
\rho_{t+1} - \rho_t &= \frac{1}{\phi(\boldsymbol{w}_{t+1}) - \phi(\boldsymbol{w}^\star)} - \frac{1}{\phi(\boldsymbol{w}_t) - \phi(\boldsymbol{w}^\star)} = \frac{\phi(\boldsymbol{w}_t) - \phi(\boldsymbol{w}^\star) - \phi(\boldsymbol{w}_{t+1}) + \phi(\boldsymbol{w}^\star)}{(\phi(\boldsymbol{w}_{t+1}) - \phi(\boldsymbol{w}^\star))(\phi(\boldsymbol{w}_t) - \phi(\boldsymbol{w}^\star))} \\
&= \rho_t \rho_{t+1} (\phi(\boldsymbol{w}_t) - \phi(\boldsymbol{w}_{t+1})) \geq \rho_t \rho_{t+1} \frac{\left(\phi(\boldsymbol{w}_t) - \phi(\boldsymbol{w}^\star)\right)^2}{2LD^2} = \frac{\rho_t \rho_{t+1}}{2\rho_t^2 LD^2} \geq \frac{1}{LD^2} ,
\end{aligned}$$

where the last inequality is due to the fact that $\rho_{t+1} \geq \rho_t$ and therefore $\rho_t \rho_{t+1}/\rho_t^2 \geq 1$. Summing the differences $\rho_{t+1} - \rho_t$ from $t = 0$ through $T-1$, we get $\rho_T \geq T/2LD^2$. Thus, for $t \geq 1$ we have

$$\phi(\boldsymbol{w}_t) - \phi(\boldsymbol{w}^\star) = 1/\rho_t \leq \frac{2LD^2}{t} .$$

To recap, by setting $\eta = 1/L$ while relaying on the fact that f has Lipschitz continuous gradient with constant L, we obtain a $1/T$ rate of convergence

$$f(\boldsymbol{w}_T) + r(\boldsymbol{w}_T) \leq f(\boldsymbol{w}^\star) + r(\boldsymbol{w}^\star) + \frac{2LD^2}{T} .$$

Abstract

Recommender systems are now popular both commercially and in the research community, where many algorithms have been suggested for providing recommendations. These algorithms typically perform differently in various domains and tasks. Therefore, it is important from the research perspective, as well as from a practical view, to be able to decide on an algorithm that matches the domain and the task of interest. The standard way to make such decisions is by comparing a number of algorithms offline using some evaluation metric. Indeed, many evaluation metrics have been suggested for comparing recommendation algorithms. The decision on the proper evaluation metric is often critical, as each metric may favor a different algorithm. In this paper we review the proper construction of offline experiments for deciding on the most appropriate algorithm. We discuss three important tasks of recommender systems, and classify a set of appropriate well known evaluation metrics for each task. We demonstrate how using an improper evaluation metric can lead to the selection of an improper algorithm for the task of interest. We also discuss other important considerations when designing offline experiments.

Keywords: recommender systems, collaborative filtering, statistical analysis, comparative studies

1. Introduction

Recommender systems can now be found in many modern applications that expose the user to a huge collections of items. Such systems typically provide the user with a list of recommended items they might prefer, or supply guesses of how much the user might prefer each item. These systems help users to decide on appropriate items, and ease the task of finding preferred items in the collection.

For example, the DVD rental provider Netflix[1] displays predicted ratings for every displayed movie in order to help the user decide which movie to rent. The online book retailer Amazon[2] provides average user ratings for displayed books, and a list of other books that are bought by users who buy a specific book. Microsoft provides many free downloads for users, such as bug fixes, products and so forth. When a user downloads some software, the system presents a list

1. This can be found at `www.netflix.com`.
2. This can be found at `www.amazon.com`.

of additional items that are downloaded together. All these systems are typically categorized as recommender systems, even though they provide diverse services.

In the past decade, there has been a vast amount of research in the field of recommender systems, mostly focusing on designing new algorithms for recommendations. An application designer who wishes to add a recommendation system to her application has a large variety of algorithms at her disposal, and must make a decision about the most appropriate algorithm for her application. Typically, such decisions are based on offline experiments, comparing the performance of a number of candidate algorithms over real data. The designer can then select the best performing algorithm, given structural constraints. Furthermore, most researchers who suggest new recommendation algorithms also compare the performance of their new algorithm to a set of existing approaches. Such evaluations are typically performed by applying some evaluation metric that provides a ranking of the candidate algorithms (usually using numeric scores).

Many evaluation metrics have been used to rank recommendation algorithms, some measuring similar features, but some measuring drastically different quantities. For example, methods such as the Root of the Mean Square Error (RMSE) measure the distance between predicted preferences and true preferences over items, while the Recall method computes the portion of favored items that were suggested. Clearly, it is unlikely that a single algorithm would outperform all others over all possible methods.

Therefore, we should expect different metrics to provide different rankings of algorithms. As such, selecting the proper evaluation metric to use has a crucial influence on the selection of the recommender system algorithm that will be selected for deployment. This survey reviews existing evaluation metrics, suggesting an approach for deciding which evaluation metric is most appropriate for a given application.

We categorize previously suggested recommender systems into three major groups, each corresponding to a different *task*. The first obvious task is to recommend a set of good (interesting, useful) items to the user. In this task it is assumed that all good items are interchangeable. A second, less discussed, although highly important task is utility optimization. For example, many e-commerce websites use a recommender system, hoping to increase their revenues. In this case, the task is to present a set of recommendations that will optimize the retailer revenue. Finally, a very common task is the prediction of user opinion (e.g., rating) over a set of items. While this may not be an explicit act of recommendation, much research in recommender systems focuses on this task, and so we address it here.

For each such task we review a family of common evaluation metrics that measure the performance of algorithms on that task. We discuss the properties of each such metric, and why it is most appropriate for a given task.

In some cases, applying incorrect evaluation metrics may result in selecting an inappropriate algorithm. We demonstrate this by experimenting with a wide collection of data sets, comparing a number of algorithms using various evaluation metrics, showing that the metrics rank the algorithms differently.

We also discuss the proper design of an offline experiment, explaining how the data should be split, which measurements should be taken, how to determine if differences in performance are statistically significant, and so forth. We also describe a few common pitfalls that may produce results that are not statistically sound.

The paper is structured as follows: we begin with some necessary background on recommender approaches (Section 2). We categorize recommender systems into a set of three tasks in Section 3.

We then discuss evaluation protocols, including online experimentation, offline testing, and statistical significance testing of results in Section 4. We proceed to review a set of existing evaluation metrics, mapping them to the appropriate task (Section 5). We then provide (Section 6) some examples of applying different metrics to a set of algorithms, resulting in questionable rankings of these algorithms when inappropriate measures are used. Following this, we discuss some additional relevant topics that arise (Section 7) and some related work (Section 8), and then conclude (Section 9).

2. Algorithmic Approaches

There are two dominant approaches for computing recommendations for the *active user*—the user that is currently interacting with the application and the recommender system. First, the *collaborative filtering* approach (Breese et al., 1998) assumes that users who agreed on preferred items in the past will tend to agree in the future too. Many such methods rely on a matrix of user-item ratings to predict unknown matrix entries, and thus to decide which items to recommend.

A simple approach in this family (Konstan et al., 2006), commonly referred to as *user based collaborative filtering*, identifies a neighborhood of users that are similar to the *active user*. This set of neighbors is based on the similarity of observed preferences between these users and the active user. Then, items that were preferred by users in the neighborhood are recommended to the active user. Another approach (Linden et al., 2003), known as *item based collaborative filtering* recommends items also prefered by users that prefer a particular *active item* to other users that also prefer that active item. In collaborative filtering approaches, the system only has access to the item and user identifiers, and no additional information over items or users is used. For example, websites that present recommendations titled "users who preferred this item also prefer" typically use some type of collaborative filtering algorithm.

A second popular approach is the *content-based* recommendation. In this approach, the system has access to a set of item features. The system then learns the user preferences over features, and uses these computed preferences to recommend new items with similar features. Such recommendations are typically titled "similar items". User's features, if available, such as demographics (e.g., gender, age, geographic location) can also provide valuable information.

Each approach has advantages and disadvantages, and a multitude of algorithms from each family, as well as a number of hybrid approaches have been suggested. This paper, though, makes no distinction between the underlying recommendation algorithms when evaluating their performance. Just as users should not need to take into account the details of the underlying algorithm when using the resulting recommendations, it is inappropriate to select different evaluation metrics for different recommendation approaches. In fact, doing so would make it difficult to decide which approach to employ in a particular application.

3. Recommender Systems Tasks

Providing a single definition for recommender systems is difficult, mainly because systems with different objectives and behaviors are grouped together under that name. Below, we categorize recommender systems into three classes, based on the recommendation task that they are designed for McNee et al. (2006). In fact, there have been several previous attempts to classify existing recommenders (see, e.g., Montaner et al. 2003 and Schafer et al. 1999). We, however, are interested

in the proper evaluation of such algorithms, and our classification is derived from that goal. While there may be recommender systems that do not fit well into the classes that we suggest, we believe that the vast majority of the recommender systems attempt to achieve one of these tasks, and can thus be classified as we suggest.

3.1 Recommending Good Items

Perhaps the most common task of recommendation engines is to recommend good items to users (Herlocker et al., 2004; McNee et al., 2006). Such systems typically present a list of items that the user is predicted to prefer. The user can then select (add to the shopping basket, view, ...) one or more of the suggested items. There are many examples of such systems. In the Amazon website, for instance, when the user is looking at an item, the system presents below a list of other items that the user may be interested in. Another example can be found in Netflix—when a user adds a movie to her queue, the system displays a list of other recommended movies that the user may want to add to the queue too. There are several considerations when creating recommendation lists. We identify below two sub-tasks that comply with different requirements.

3.1.1 RECOMMENDING SOME GOOD ITEMS

In this sub-task, we make the assumption that there is a large number of good items that may appeal to the user, and the user does not have enough resources (time, money) to select all items. In this case we can only present a part of the preferred item set. Thus, it is likely that many preferred items will be missing from the list. In this sub-task, it is more important not to present any disliked item than to find all the good items.

This is typically the case in recommender systems that suggest media items, such as movies, books, or news items. In all these cases the number of alternatives is huge, and the user cannot possibly watch all the recommended movies, or read all the relevant books.

3.1.2 RECOMMENDING ALL GOOD ITEMS

A less popular case is when the system should recommend all important items. Examples of such systems are recommenders that predict which scientific papers should be cited, or legal databases (Herlocker et al., 2004; McNee et al., 2006), where it is important not to overlook any possible case. In this sub-task, the system can present longer lists of items, trying to avoid missing a relevant item.

3.2 Optimizing Utility

With the rise of e-commerce websites, another recommendation task became highly important—maximizing the profits of the website. Online retailers are willing to invest in recommender systems hoping to increase their revenue. There are many ways by which a recommender system can increase revenue. The simplest way is through cross-selling; by suggesting additional items to the users, we increase the probability that the user will buy more than he originally intended. In an online news provider, where most revenue comes from display advertisements, the system can increase profit by keeping the users in the website for longer time periods, as the performance of an advertising campaign is often measured in terms of "x-minute reach," which is the number of consumers in a particular market that are exposed to the ad for x minutes. In such cases, it is in the best interest of the system to suggest items in order to lengthen the session. In a subscription

service, where revenue comes from users paying a regular subscription, the goal may be to allow users to easily reach items of interest. In this case, the system should suggest items such that the user reaches items of interest with minimal effort.

The utility function to be optimized can be more complicated, and in particular, may be a function of the entire set of recommendations and their presentation to the user. For example, in pay-per-click search advertising, the system must recommend advertisements to be displayed on search results pages. Each advertiser bids a fixed amount that is paid only when the user clicks on their ad. If we wish to optimize the expected system profit, both the bids and the probability that the user will click on each ad must be taken into account. This probability depends on the relevance of each ad to the user and the placement of the different ads on the page. Since the different ads displayed compete for the user's attention, the utility function depends on the entire set of ads displayed, and is not additive over the set (Gunawardana and Meek, 2008).

In all of these cases, it may be suboptimal to suggest items based solely on their predicted rating. While it is certainly beneficial to recommend relevant items, other considerations are also important. For example, in the e-commerce scenario, given two items that the system perceives as equally relevant, suggesting the item with the higher profit can further increase revenue. In the online news agency case, recommending longer stories may be beneficial, because reading them will keep the user in the website longer. In the subscription service, recommending items that are harder for the user to reach without the recommender system may be beneficial.

Another common practice of recommendation systems is to suggest recommendations that provide the most "value" to the user. For example, recommending popular items can be redundant, as the user is probably already familiar with them. A recommendation of a preferred, yet unknown item can provide a much higher value for the user.

Such approaches can be viewed as instances of providing recommendations that maximize some utility function that assigns a value to each recommendation. Defining the correct utility function for a given application can be difficult (Braziunas and Boutilier, 2005), and typically system designers make simplifying assumptions about the user utility function. In the e-commerce case the utility function is typically the profit resulting from recommending an item, and in the news scenario the utility can be the expected time for reading a news item, but these choices ignore the effect of the resulting recommendations on long-term profits. When we are interested in novel recommendations, the utility can be the log of the inverse popularity of an item, modeling the amount of new information in a recommended item (Shani et al., 2005), but this ignores other aspects of user-utility such as the diversity of recommendations.

In fact, it is possible to view many recommendation tasks, such as providing novel or serendipitious recommendations as maximizing some utility function. Also, the "recommend good items" of the previous section can be considered as optimizing for a utility function assigning a value of 1 to each successful recommendation. In this paper, due to the popularity of the former task, we choose to keep the two tasks distinct.

3.3 Predicting Ratings

In some cases, a system is required to predict the user ratings over a given set of items. For example, in the Netflix website, when the user is browsing the list of new releases, the system assigns a predicted rating for each movie. In CNET,[3] a website offering electronic product reviews, users can

3. This can be found at `www.cnet.com`.

search for, say, laptops that cost between $400 and $700. The system adds to some laptops in the list an automatically computed rating, based on the laptop features.

It is arguable whether this task is indeed a recommendation task. However, many researchers in the recommendations system community attempting to find good algorithms for this task. Examples include the Netflix competition, which was warmly embraced by the research community, and the numerous papers on predicting ratings on the Netflix or MovieLens[4] data sets.

While such systems do not provide lists of recommended items, predicting that the user will rate an item highly can be considered an act of recommendation. Furthermore, one can view a predicted high rating as a recommendation to use the item, and a predicted low rating as a recommendation to avoid the item. Indeed, it is common practice to use predicted ratings to generate a list of recommendations. Below, we will present several arguments of cases where this common practice may be undesirable.

4. Evaluation Protocols

We now discuss an experimental protocol for evaluating and choosing recommendation algorithms. We review several requirements to ensure that the results of the experiments are statistically sound. We also describe several common pitfalls in such experimental settings. This section reviews the evaluation protocols in related areas such as machine learning and information retrieval, highlighting practices relevant to evaluating recommendation systems. The reader is referred to publications in these fields for more detailed discussions (Salzberg, 1997; Demšar, 2006; Voorhees, 2002a).

We begin by discussing online experiments, which can measure the real performance of the system. We then argue that offline experiments are also crucial, because online experiments are costly in many cases. Therefore, the bulk of the section discusses the offline experimental setting in detail.

4.1 Online Evaluation

In the recommendation and utility optimization tasks, the designer of the system wishes to influence the behavior of users. We are therefore interested in measuring the change in user behavior when interacting with different recommendation systems. For example, if users of one system follow the recommendations more often (in the case of the "recommend good items" task), or if the utility gathered from users of one system exceeds utility gathered from users of the other system (in the utility optimization task), then we can conclude that one system is superior to the other, all else being equal. In the case of ratings prediction tasks, the goal is to provide information to support user browsing and search. Once again, the value of such predictions can depend on a variety of factors such as the user's intent (e.g., how specific their information needs are, how much novelty vs. how much risk they are seeking), the user's context (e.g., what items they are already familiar with, how much they trust the system), and the interface through which the predictions are presented.

For this reason, many real world systems employ an online testing system (Kohavi et al., 2009), where multiple algorithms can be compared. Typically, such systems redirect a small percentage of the traffic to each different recommendation engine, and record the users interactions with the different systems. There are a few considerations that must be made when running such tests. For example, it is important to sample (redirect) users randomly, so that the comparisons between

4. This can be found at `www.movielens.org`.

alternatives are fair. It is also important to single out the different aspects of the recommenders. For example, if we care about algorithmic accuracy, it is important to keep the user interface fixed. On the other hand, if we wish to focus on a better user interface, it is best to keep the underlying algorithm fixed.

However, in a multitude of cases, such experiments are very costly, since creating online testing systems may require much effort. Furthermore, we would like to evaluate our algorithms before presenting their results to the users, in order to avoid a negative user experience for the test users. For example, a test system that provides irrelevant recommendations, may discourage the test users from using the real system ever again. Finally, designers that wish to add a recommendation system to their application before its deployment do not have an opportunity to run such tests.

For these reasons, it is important to be able to evaluate the performance of algorithms in an offline setting, assuming that the results of these offline tests correlate well with the online behavior of users.

4.2 Offline Experimental Setup

As described above, the goal of the offline evaluation is to filter algorithms so that only the most promising need undergo expensive online tests. Thus, the data used for the offline evaluation should match as closely as possible the data the designer expects the recommender system to face when deployed online. Care must be exercised to ensure that there is no bias in the distributions of users, items and ratings selected. For example, in cases where data from an existing system (perhaps a system without a recommender) is available, the experimenter may be tempted to pre-filter the data by excluding items or users with low counts, in order to reduce the costs of experimentation. In doing so, the experimenter should be mindful that this involves a trade-off, since this introduces a systematic bias in the data. If necessary, randomly sampling users and items may be a preferable method for reducing data, although this can also introduce other biases into the experiment (e.g., this could tend to favor algorithms that work better with more sparse data).

In order to evaluate algorithms offline, it is necessary to simulate the online process where the system makes predictions or recommendations, and the user corrects the predictions or uses the recommendations. This is usually done by recording historical user data, and then hiding some of these interactions in order to simulate the knowledge of how a user will rate an item, or which recommendations a user will act upon.

There are a number of ways to choose the ratings/selected items to be hidden. Once again, it is preferable that this choice be done in a manner that simulates the target application as closely as possible. We discuss these concerns explicitly for the case of selecting used items for hiding in the evaluation of recommendation tasks, and note that the same considerations apply when selecting ratings to hide for evaluation of ratings prediction tasks.

Our goal is to simulate sets of past user selections that are representative of what the system will face when deployed. Ideally, if we have access to time-stamps for user selections, we can randomly sample test users, randomly sample a time just prior to a user action, hide all selections (of all users) after that instant, and then attempt to recommend items to that user. This protocol requires changing the set of given information prior to each recommendation, which can be computationally quite expensive. A cheaper alternative is to sample a set of test users, then sample a single test time, and hide all items after the sampled test time for each test user. This simulates a situation where the recommender system is "trained" as of the test time, and then makes recommendations without

taking into account any new data that arrives after the test time. Another alternative is to sample a test time for each test user, and hide the test user's items after that time, without maintaining time consistency across users. This effectively assumes that it is the sequence in which items are selected, and not the absolute times when they are selected that is important. A final alternative is to ignore time; We sample a set of test users, then sample the number n_a of items to hide for each user a, then sample n_a items to hide. This assumes that the temporal aspects of user selections are unimportant. All three of the latter alternatives partition the data into a single training set and single test set. It is important to select an alternative that is most appropriate for the domain and task of interest, rather than the most convenient one.

A common protocol used in many research papers is to use a fixed number of known items or a fixed number of hidden items per test user (so called "given n" or "all but n" protocols). This protocol is useful for diagnosing algorithms and identifying in which cases they work best. However, when we wish to make decisions on the algorithm that we will use in our application, we must ask ourselves whether we are truly interested in presenting recommendations for users who have rated exactly n items, or are expected to rate exactly n items more. If that is not the case, then results computed using these protocol have biases that make them difficult to use in predicting the outcome of using the algorithms online.

The evaluation protocol we suggest above generates a test set (Duda and Hart, 1973) which is used to obtain held-out estimates for algorithm performance, using performance measures which we discuss below. Another popular alternative is to use cross-validation (Stone, 1974), where the data is divided into a number of partitions, and each partition in turn is used as a test set. The advantages of the cross-validation approach are to allow the use of more data in ranking algorithms, and to take into account the effect of training set variation. In the case of recommender systems, the held-out approach usually yields enough data to make reliable decisions. Furthermore, in real systems, the problem of variation in training data is avoided by evaluating systems trained on the historical data specific to the task at hand. In addition, there is a risk that since the results on the different data partitions are not independent of each other, pooling the results across partitions for ranking algorithms can lead to statistically unjustified decisions (Bengio and Grandvalet, 2004).

4.3 Making Reliable Choices

When choosing between algorithms, it is important that we can be confidant that the algorithm that we choose will also be a good choice for the yet unseen data the system will be faced with in the future. As we explain above, we should exercise caution in choosing the data so that it would be most similar to the online application. Still, there is a possibility that the algorithm that performed best on this test set did so because the test set was fortuitously suitable for that algorithm. To reduce the possibility of such statistical mishaps, we must perform significance testing on the results.

Typically we compute a significance level or p-value—the probability that the obtained results were due to luck. Generally, we will reject the null hypothesis that algorithm A is no better than algorithm B if the p-value is above 0.05 (or below 95% confidence). That is, if the probability that the observed ranking is achieved by chance exceeds 0.05. More stringent significance levels (e.g., 0.01 or even lower) can be used in cases where the cost of making the wrong choice is higher.

In order to perform a significance test that algorithm A is indeed better than algorithm B, we require the results of several independent experiments comparing A and B. The protocol we have chosen in generating our test data ensures that we will have this set of results. Assuming that test

users are drawn independently from some population, the performance measures of the algorithms for each test user give us the independent comparisons we need. However, when recommendations or predictions of multiple items are made to the same user, it is unlikely that the resulting per-item performance metrics are independent. Therefore, it is better to compare algorithms on a per-user case. Approaches for use when users have not been sampled independently also exist, and attempt to directly model these dependencies (see, e.g., Larocque et al. 2007). Care should be exercised when using such methods, as it can be difficult to verify that the modeling assumptions that they depend on hold in practice.

Given such paired per-user performance measures for algorithms A and B the simplest test of significance is the sign test (Demšar, 2006). In this test, we count the number of users for whom algorithm A outperforms algorithm B (n_A) and the number of users for whom algorithm B outperforms algorithm A (n_B). The probability that A is not truly better than B is estimated as the probability of at least n_A out of $n_A + n_B$ 0.5-probability Binomial trials succeeding (that is, n_A out of $n_A + n_B$ fair coin-flips coming up "heads").

$$pr(successes \geq n_A | A = B) = 0.5^{n_A+n_B} \sum_{k=n_A}^{n_a+n_B} \frac{(n_A+n_B)!}{k!(n_i+n_B-k)!}.$$

The sign test is an attractive choice due to its simplicity, and lack of assumptions over the distribution of cases. Still this test may lead to mislabeling of significant results as insignificant when the number of test points is small. In these cases, the more sophisticated Wilcoxon signed rank test can be used (Demšar, 2006). As mentioned in Section 4.2, cross-validation can be used to increase the amount of data, and thus the significance of results, but in this case the results obtained on the cross-validated test sets are no longer independent, and care must be exercised to ensure that our decisions account for this (Bengio and Grandvalet, 2004). Also, model-based approaches (e.g., Goutte and Gaussier, 2005) may be useful when the amount of data is small, but once again, care must be exercised to ensure that the model assumptions are reasonable for the application at hand.

Another important consideration is the effect of evaluating multiple versions of algorithms. For example, an experimenter might try out several variants of a novel recommender algorithm and compare them to a baseline algorithm until they find one that passes a sign test at the $p = 0.05$ level and therefore infer that their algorithm improves upon the baseline with 95% confidence. However, this is not a valid inference. Suppose the experimenter evaluated ten different variants all of which are statistically the same as the baseline. If the probability that any one of these trials passes the sign test mistakenly is $p = 0.05$, the probability that at least one of the ten trials passes the sign test mistakenly is $1-(1-0.05)^{20} = 0.40$. This risk is colloquially known as "tuning to the test set" and can be avoided by separating the test set users into two groups—a development (or tuning) set, and an evaluation set. The choice of algorithm is done based on the development test, and the validity of the choice is measured by running a significance test on the evaluation set.

A similar concern exists when ranking a number of algorithms, but is more difficult to circumvent. Suppose the best of $N+1$ algorithms is chosen on the development test set. We can have a confidence $1-p$ that the chosen algorithm is indeed the best, if it outperforms the N other algorithms on the evaluation set with significance $1-(1-p)^{1/N}$. This is known as the Bonferroni correction, and should be used when pair-wise significant tests are used multiple times. Alternatively, the Friedman test for ranking can be used (Demšar, 2006).

5. Evaluating Tasks

An application designer that wishes to employ a recommendation system typically knows the purpose of the system, and can map it into one of the tasks defined above—recommendation, utility optimization, and ratings prediction. Given such a mapping, the designer must now decide which evaluation metric to use in order to rank a set of candidate recommendation algorithms. It is important that the metric match the task, to avoid an inappropriate ranking of the candidates.

Below we provide an overview of a large number of evaluation metrics that have been suggested in the recommendation systems literature. For each such metric we identify its important properties and explain why is it most appropriate for the given task. For each task we also explain a possible evaluation scenario that can be used to evaluate the various algorithms.

5.1 Predicting Ratings

In this task, the system must provide a set of predicted ratings, and is evaluated on the accuracy of these predictions. This is the most common scenario in the evaluation of regression and classification algorithms in the machine learning and statistics literature (Duda and Hart, 1973; Stone, 1974; Bengio and Grandvalet, 2004). Many evaluation metrics that originated in that literature have been applied here.

Most notably, the Root of the Mean Square Error (RMSE) is a popular method for scoring an algorithm. If $p_{i,j}$ is the predicted rating for user i over item j, and $v_{i,j}$ is the true rating, and $K = \{(i,j)\}$ is the set of hidden user-item ratings then the RMSE is defined as:

$$\sqrt{\frac{\sum_{(i,j)\in K}(p_{i,j}-v_{i,j})^2}{n}}.$$

Other variants of this family are the Mean Square Error (which is equivalent to RMSE) and Mean Average Error (MAE), and Normalized Mean Average Error (NMAE) (Herlocker et al., 2004). RMSE tends to penalize larger errors more severely than the other metrics, while NMAE normalizes MAE by the range of the ratings for ease of comparing errors across domains.

RMSE is suitable for the prediction task, because it measures inaccuracies on all ratings, either negative or positive. However, it is most suitable for situations where we do not differentiate between errors. For example, in the Netflix rating prediction, it may not be as important to properly predict the difference between 1 and 2 stars as between 2 and 3 stars. If the system predicts 2 instead of the true 1 rating, it is unlikely that the user will perceive this as a recommendation. However, a predicted rating of 3 may seem like an encouragement to rent the movie, while a prediction of 2 is typically considered negative. It is arguable that the space of ratings is not truly uniform, and that it can be mapped to a uniform space to avoid such phenomena.

5.2 Recommending Good Items

For the task of recommending items, typically we are only interested in binary ratings, that is, either the item was selected (1) or not (0). Compared to ratings data sets, where users typically rate only a very small number of items, making the data set extremely sparse, binary selection data sets are dense, as each item was either selected or not by the user. An example of such data sets are news story click streams, where we set a value of 1 for each item that was visited, and a value of 0

	Recommended	Not recommended
Preferred	True-Positive (tp)	False-Negative (fn)
Not preferred	False-Positive (fp)	True-Negative (tn)

Table 1: Classification of the possible result of a recommendation of an item to a user.

elsewhere. The task is to provide, given an existing list of items that were viewed, a list of additional items that the user may want to visit.

As we have explained above, these scenarios are typically not symmetric. We are not equally interested in good and bad items; the task of the system is to suggest good items, not to discourage the use of bad items. We can classify the results of such recommendations using Table 1.

We can now count the number of examples that fall into each cell in the table and compute the following quantities:

$$\begin{aligned} \text{Precision} &= \frac{\#\text{tp}}{\#\text{tp}+\#\text{fp}}, \\ \text{Recall (True Positive Rate)} &= \frac{\#\text{tp}}{\#\text{tp}+\#\text{fn}}, \\ \text{False Positive Rate (1 - Specificity)} &= \frac{\#\text{fp}}{\#\text{fp}+\#\text{tn}}. \end{aligned}$$

Typically we can expect a trade off between these quantities—while allowing longer recommendation lists typically improves recall, it is also likely to reduce the precision. In some applications, where the number of recommendations that are presented to the user is not preordained, it is therefore preferable to evaluate algorithms over a range of recommendation list lengths, rather than using a fixed length. Thus, we can compute curves comparing precision to recall, or true positive rate to false positive rate. Curves of the former type are known simply as precision-recall curves, while those of the latter type are known as a Receiver Operating Characteristic[5] or ROC curves.

While both curves measure the proportion of preferred items that are actually recommended, precision-recall curves emphasize the proportion of recommended items that are preferred while ROC curves emphasize the proportion of items that are not preferred that end up being recommended.

We should select whether to use precision-recall or ROC based on the properties of the domain and the goal of the application; suppose, for example, that an online video rental service recommends DVDs to users. The precision measure describes what proportion of their recommendations were actually suitable for the user. Whether the unsuitable recommendations represent a small or large fraction of the unsuitable DVDs that could have been recommended (that is, the false positive rate) may not be as relevant.

On the other hand, consider a recommender system for an online dating site. Precision describes what proportion of the suggested pairings for a user result in matches. The false positive rate describes what proportion of unsuitable candidates are paired with the active user. Since presenting unsuitable candidates can be especially undesirable in this setting, the false positive rate could be the most important factor.

5. A reference to their origins in signal detection theory.

Given two algorithms, we can compute a pair of such curves, one for each algorithm. If one curve completely dominates the other curve, the decision about the winning algorithm is easy. However, when the curves intersect, the decision is less obvious, and will depend on the application in question. Knowledge of the application will dictate which region of the curve the decision will be based on. For example, in the "recommend some good items" task it is likely that we will prefer a system with a high precision, while in the "recommend all good items" task, a higher recall rate is more important than precision.

Measures that summarize the precision recall of ROC curve such as F-measure (Rijsbergen, 1979) and the area under the ROC curve (Bamber, 1975) are useful for comparing algorithms independently of application, but when selecting an algorithm for use in a particular task, it is preferable to make the choice based on a measure that reflects the specific needs at hand.

5.2.1 PRECISION-RECALL AND ROC FOR MULTIPLE USERS

When evaluating precision-recall or ROC curves for multiple test users, a number of strategies that can be employed in aggregating the results. The simplest is to aggregate the hidden ratings from the test set into a set of user-item pairs, generate a ranked list of user-item pairs by combining the recommendation lists for the test users, and then compute the precision-recall or ROC curve on this aggregated data.

This aggregation process assumes that we have a means of comparing recommendations made to different users in order to combine the recommendation lists into a single ranked list. Computing ROC curves in this manner treats the recommendations of different items to each user as being independent detection or classification tasks, and the resulting curve is termed a global ROC (GROC) curve (Schein et al., 2002).

A second approach is to compute the precision and recall (or true positive rate and false positive rate) at each recommendation list length N for each user, and then compute the average precision and recall (or true positive rate and false positive rate) at each N(Sarwar et al., 2000). The resulting curves are particularly valuable because they prescribe a value of N for each achievable precision and recall (or true positive rate and false positive rate), and conversely, can be used to estimate performance at a given N. Thus, this approach is useful in the "recommend some good items" scenario, where one important decision is the length of the recommendation list, by comparing performances along different candidate points along the curves. An ROC curve obtained in this manner is termed a Customer ROC (CROC) curve (Schein et al., 2002).

A third approach is to compute a precision-recall curve (or ROC curve) for each user and then average the resulting curves over users. This is the usual manner in which precision-recall curves are computed in the information retrieval community, and in particular in the influential TREC competitions (Voorhees, 2002b). This method is more relevant in the "recommend all good items" sub-task, if the system provides the user with all available recommendations and the user then scans the list linearly, marking each scanned item as relevant or not. The system can then compute the precision of the items scanned so far, and use the precision recall curve to give the user an estimate of what proportion of the good items have yet to be found.

5.3 Optimize Utility

Estimating the utility of a list of recommendations requires a model of the way users interact with the recommendations. For example, if a movie recommender system presents the DVD cover im-

ages of the top five recommendations prominently arranged horizontally across the top of the screen, the user will probably observe them all and select the items of interest. However, if all the recommendations are presented in a textual list several pages long, the user will probably scan down the list and abandon their scan at some point. In the first case, utility delivered by the top five recommendations actually selected would be a good estimate of expected utility, while in the second case, we would have to model the way users scan lists.

The half-life utility score of Breese et al. (1998) suggested such a model. It postulates that the probability that the user will select a relevant item drops exponentially down the list.

This approach evaluates an unbounded recommendation list, that potentially contains all the items in the catalog. Given such a list we assume that the user looks at items starting from the top. We then assume that an item at position k has a probability of $\frac{1}{2^{(k-1)/(\alpha-1)}}$ of being viewed, where α is a half life parameter, specifying the location of the item in the list with 0.5 probability of being viewed.

In the binary case of the recommendation task the half-life utility score is computed by:

$$\begin{aligned} R_a &= \sum_j \frac{1}{2^{(idx(j)-1)/(\alpha-1)}}, \\ R &= \frac{\sum_a R_a}{\sum_a R_a^{max}}, \end{aligned}$$

where the summation in the first equation is over the preferred items only, $idx(j)$ is the index of item j in the recommendation list, and R_a^{max} is the score of the best possible list of recommendations for user a.

More generally, we can plug any utility function $u(a, j)$ that assigns a value to a user item pair into the half-life utility score, obtaining the following formula:

$$R_a = \sum_j \frac{u(a, j)}{2^{(idx(j)-1)/(\alpha-1)}}.$$

Now, R_a^{max} is the score for the list of the recommendation where all the observed items are ordered by decreasing utility. In applications where the probability that a user will select the idxth item if it is relevant is known, a further generalization would be to use these known probabilities instead of the exponential decay.

5.4 Fixed Recommendations Lists

When users add movies to their queues in Netflix, the system presents a list of 10 movies that they may like. However, when users choose to see recommendations (by clicking "movies that you will love") the system presents all the possible recommendations. If there are too many recommended movies to fit a single page, the system allows the user to move to the next page of recommendations.

These two different usage scenarios illustrate a fundamental difference between recommendation applications—in the first, the system is allowed to show a small, fixed number of recommendations. In the second, the system provides as many recommendations as it can. Even though the two cases match a single task—the "recommend good items" task—there are several important distinctions that arise. It is important to evaluate the two cases properly.

When the system is required to present a list with a small, fixed size, that is known *a priori*, methods that present curves (precision-recall), or methods that evaluate the entire list (half-life

utility score), become less appropriate. For example, a system may get a relatively high half-life utility score, only due to items that fall outside the fixed list, while another system that selects all the items in the list correctly, and uninteresting items elsewhere, might get a lower score. Precision-recall curves are typically used to help us select the proper list length, where the precision and recall reach desirable values.

Another important difference, is that for a small list, the order of items in the list is less important, as we can assume that the user looks at all the items in the list. Moreover, may of these lists are presented in a horizontal direction, which also reduces the importance of properly ordering the items.

In these cases, therefore, a more appropriate way to evaluate the recommendation system should focus on the first N movies only. In the "recommend good items" task this can be done, for example, by measuring the precision at N—the number of items that are interesting out of the recommended N items. In the "optimize utility" task, we can do so by measuring the aggregated utility (e.g., sum of utility) of the items that are indeed interesting within the N recommendations.

A final case is when we have unlimited recommendation lists in the "recommend good items" scenario, and we wish to evaluate the entire list. In this case, one can use the half-life utility score with a binary utility of 1 when the (hidden) item was indeed selected by the user, and 0 otherwise. In that case, the half-life utility score prefers a recommender system that places interesting items closer to the head of the list, but provides an evaluation for the entire list in a single score.

6. Empirical Evaluation

In some cases, two metrics may provide a different ranking of two algorithms. When one metric is more appropriate for the task at hand, using the other metric may result in selecting the wrong algorithm. Therefore, it is important to choose the appropriate evaluation metric for the task at hand.

In this section we provide some empirical examples of the phenomenon we describe above, that is, where different metrics rank algorithms differently. Below, we present examples where algorithms are ranked differently by two metrics, one of which is more appropriate for the task of interest.

6.1 Data Sets

We selected publicly available data sets which were naturally suited to the different recommendation tasks we have described above. We begin by describing the properties of each data set we used.

6.1.1 PREDICTION TASK

For the prediction task we selected two data sets that contained ratings over items—the Netflix data set and the BookCrossing data set. In both cases, the prediction task is quite natural. Users of both systems may want to browse the collection of movies or books, and we would want to offer these users an estimated rating for the presented items.

Netflix: In 2004, the online movie rental company Netflix[6] announced a competition for improving its recommendation system. For the purpose of the competition, Netflix has released a data set containing 480,000 users ratings over 17,700 movies. Ratings are between 1 and 5 stars for each movie. The data set is very sparse—users mostly rated a small fraction of the available movies. In

6. This can be found at `www.netflix.com`.

our experiments, as we are working with simple algorithms, we have reduced the data set to users who rated more than 100 movies, leaving us with 21,179 users, 17,415 movies, and 117 ratings per user on average. Thus, our results are not comparable to results published in the online competition scoreboard.

BookCrossing: The BookCrossing website[7] allows a community of book readers to share their interests in books, and to review and discuss books. Within that system users can provide ratings on the scale of 1 to 10 stars. The specific data set that we used was collected by a 4 week crawl during August and September 2004 (Ziegler et al., 2005). The data set contains 105,283 users and 340,556 books (we used just the subset containing explicit ratings). Average ratings for a user is 10. This data set is even more sparse than the Netflix data set that we used, as there are more items and less ratings per user.

Both data sets share some common properties. First, people watch many movies and read many books, compared with other domains. For example, most people experience with only a handful of laptop computers, and so cannot form an opinion on most laptops. Ratings are also skewed towards positive ratings in both cases, as people are likely to watch movies that they think they will like, and even more so in the case of books, which require a heavier investment of time.

There are also some distinctions between the data sets. Some people feel compelled to share their opinion about books and movies, without asking for a compensation. However, in the Netflix domain, providing ratings makes it easier to navigate the system and rent movies. Therefore, all users of Netflix have an incentive for providing ratings, while only people who like to share their views of books use the BookCrossing system. We can therefore expect that the ratings of the BookCrossing are less representative of the general population of book readers, than the ratings of Netflix user from the general population of DVD renters.

6.1.2 RECOMMENDATION TASK

One instance of the "recommend good items" task is the case where, given a set of items that the user has used (bought, viewed), we wish to recommend a set of items that are likely to be used. Typically, data sets of usage are binary—an item was either used or wasn't used by the user, and the data set is not sparse, because every item is either used or not used by every user. We used here a data set of purchases from supermarket retailer, and a stream of articles that were viewed in a news website.

Belgian retailer: This data set was collected from an anonymous Belgian retail supermarket store, collected over approximately 5 months, in three non-consecutive periods during 1999 and 2000. The data set is divided into baskets, and we cannot detect return users. There are 88,162 baskets, 16,470 distinct items, and 10 items in an average basket. We do not have access for item prices or profits, so we cannot optimize the retailer revenue. Therefore the task is to recommend more items that the user may want to add to the basket.

News click stream: This is a log of click-stream data of an Hungarian online news portal (Bodon, 2003). The data contains 990,002 sessions, 41,270 news stories, and an average of 8 stories for session. The task is, given the news items that a user has read so far, recommend more news items that the user will likely read.

7. This can be found at `www.bookcrossing.com`.

6.1.3 OPTIMIZING UTILITY TASK

Ta-Feng supermarket: A natural example for an application where optimizing utility is important is maximizing the revenues of a retail company. Such companies may provide recommendation for items, hoping that customers following these recommendations will produce higher revenue. In this case, a natural utility function is the revenue (or profit) from the purchase of an item. The Ta-Feng data set (Hsu et al., 2004) contains transaction information collected over 4 months from November, 2000 to February, 2001. There are $32,266$ users and $23,812$ items, where the average number of items bought by a user is 23. In this task, the utility function is the accumulated profit from selling an item—taking into account both the quantity and the profit per item.

6.2 Recommendation Algorithms

As the focus of this survey is on the correct evaluation of recommender systems, and not on sophisticated algorithms for computing recommendation lists, we limit ourselves to a set of very simple collaborative filtering algorithms. We do this because collaborative filtering is by far the most popular recommendation approach, and because we do not believe that it is appropriate to select the evaluation metric based on the recommendation approach (e.g., collaborative filtering vs. content based).

Moreover, we carefully selected algorithms that are better suited for different tasks, so that we could demonstrate that inappropriate choice of evaluation metric can lead to a bad choice of algorithm. As the algorithms that we choose are computationally intensive, we reduced the size of the data set in some cases, in order to reduce the computation time. This should not be done if it was important to realistically simulate the online case. Below, we present the different algorithms and our prior assumptions about their properties.

6.2.1 PEARSON CORRELATION

Typically, the input for a prediction task is a data set consisting of the ratings provided by n users for m items, where $v_{i,j}$ is the rating of user i for item j. Given such a data set, the simplest collaborative filtering method computes the similarity of the active user a to all other users i in the data set, resulting in a score $w(a,i)$. Then, the predicted rating $p_{a,j}$ for a over item j can be computed by:

$$p_{a,j} = \bar{v}_a + \kappa \sum_{i=1}^{n} w(a,i)(v_{i,j} - \bar{v}_i). \tag{1}$$

Perhaps the most popular method for computing the weights $w(a,i)$ is by using the Pearson correlation coefficient (Resnick and Varian, 1997):

$$w(a,i) = \frac{\sum_j (v_{a,j} - \bar{v}_a)(v_{i,j} - \bar{v}_i)}{\sqrt{\sum_j (v_{a,j} - \bar{v}_a)^2 \sum_j (v_{i,j} - \bar{v}_i)^2}}$$

where the summations are only over the items that both a and i have rated. To reduce the computational overhead, we use in Equation 1 a neighborhood of size N.

This method is specifically designed for the prediction task, as it computes only a predicted score for each item of interest. However, in many cases people used this method for the recommendation task. This is typically done by predicting the scores for all possible items, and then ordering the items by decreasing predicted scores.

This popular usage may not be appropriate. For example, in the movie domain people may associate ratings with quality, as opposed to enjoyment, which is dependent on external factors such as mood, time of day, and so forth. As such, 5 stars movies may be complicated, requiring a substantial effort from the viewer. Thus, a user may rent many light effortless romantic comedies, which may only get a score of 3 stars, and only a few 5 star movies. While it is difficult to measure this effect without owning a rental store, we computed the average number of ratings for movies with different average rating (Figure 6.2.1). This figure may suggest that movies with higher ratings are not always watched more often than movies with lower ratings. If our assumption is true, a system that recommends items to add to the rental queue by order of decreasing predicted rating, may not do as well as a system that predicts the probability of adding a movie to the queue directly.

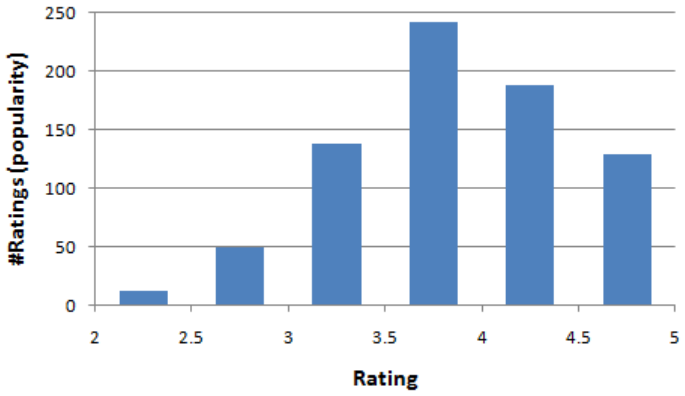

Figure 1: Computing the average number of ratings (popularity) of movies binned given their average ratings.

6.2.2 COSINE SIMILARITY

A second popular collaborative filtering method is the vector similarity metric (Salton, 1971) that measures the cosine angle formed by the two ratings vectors:

$$w(a,i) = \sum_{j \in I_{a,i}} \frac{v_{a,j}}{\sqrt{\sum k \in I_a v_{a,k}^2}} \frac{v_{i,j}}{\sqrt{\sum k \in I_i v_{i,k}^2}}.$$

When computing the cosine similarity, only positive ratings have a role, and negative ratings are discarded. Thus, I_i is the set of items that user i has rated positively and $I_{a,i}$ is the set of items that both users rated positively. Also, the predicted score for a user is computed by:

$$p_{a,j} = \kappa \sum_{i=1}^{n} w(a,i) v_{i,j}.$$

In the case of binary data sets, such as the usage data sets that we selected for the recommendation task, the vector similarity method becomes:

$$w(a,i) = \frac{|I_{a,i}|}{\sqrt{|I_a|} \cdot \sqrt{|I_i|}}$$

where I_a is the set of items that a used, and $I_{a,i}$ is the set of items that both a and i used. The resulting aggregated score can be considered as a non-calibrated measurement of the conditional probability $pr(j|a)$—the probability that user a will choose item j.

In binary usage data sets, the Pearson correlation method would compute similarity using all the items, as each item always has a rating. Therefore, the system would use all the negative "did not use" scores, which typically greatly outnumber the "used" scores. We can therefore expect that Pearson correlation in these cases will result in lower accuracy.

6.2.3 ITEM TO ITEM

The above two methods focused on computing a similarity between users, but another possible collaborative filtering alternative is to focus on the similarity between items. The simplest method for doing so is to use the maximum likelihood estimate for the conditional probabilities of items. Specifically, for the binary usage case, this translates to:

$$pr(j_1|j_2) = \frac{|J_{j_1,j_2}|}{|J_{j_2}|}$$

where J_j is the number of users who used item j, and J_{j_1,j_2} is the number of users that used both j_1 and j_2. While this seems like a very simple estimation, similar estimations are successfully used in deployed commercial applications (Linden et al., 2003).

Typically, an algorithm is given as an input a set of items, and needs to produce a list of recommendations. In that case, we can compute for the conditional probability of each target item given each observed item, and then aggregate the results over the set of given items. In many cases, choosing the maximal estimate has given the best results (Kadie et al., 2002), so we aggregate estimations using a max operator in our experiments.

6.2.4 EXPECTED UTILITY

As optimizing utilities is by far the least explored recommendation task, we choose here to propose a new algorithm that is designed specifically for this task. Intuitively, if the task requires lists that optimize a utility function $u(a, j)$, an obvious method is to order the recommendation by decreasing expected utility:

$$E[j|a] = \tilde{pr}(j|a) \cdot \tilde{u}(a, j)$$

where $\tilde{pr}$ is a conditional probability estimate and $\tilde{u}$ is a utility estimate.

One way to compute the two estimates is by using two different algorithms—a recommendation algorithm for estimating $\tilde{pr}$ and a prediction algorithm for estimating $\tilde{u}$, and then combining their output.

6.3 Experimental Results

Below, we present several examples where different evaluation metrics rank two algorithms differently. We argue that in these cases, using an improper evaluation metric will lead to the selection of an inferior algorithm.

	Netflix	BookCrossing
Pearson	1.07	3.58
Cosine	1.90	4.5

Table 2: RMSE scores for Pearson correlation and Cosine similarity on the Netflix domain (ratings from 1 to 5) and the BookCrossing domain (ratings from 1 to 10).

6.3.1 PREDICTION VS. RECOMMENDATION

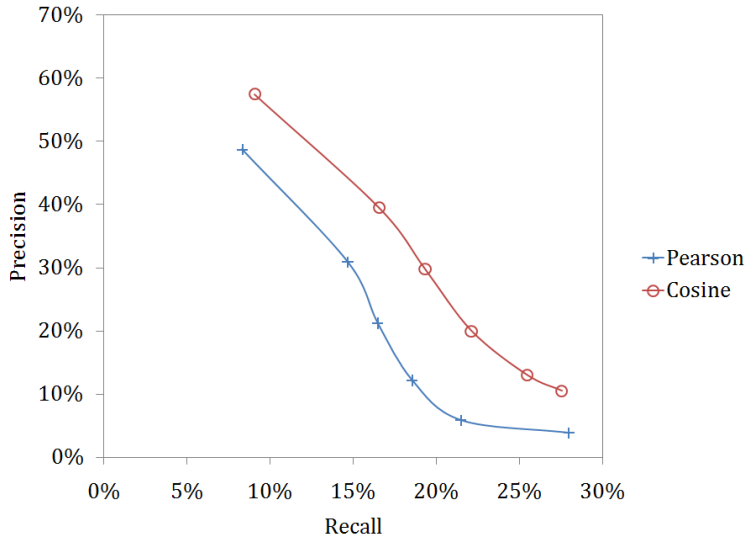
We begin by comparing Pearson correlation and Cosine similarity collaborative filtering algorithms over two tasks—the prediction task and the "recommend good items" task. Both algorithms used neighborhoods consisting of the closest 25 users.

First we evaluated the algorithms in predicting ratings on the Netflix and BookCrossing data sets, where we sampled 2000 test users and a randomly chosen number of test items per test user on each data set. Given Table 2, the algorithm of choice is clear—on both data sets, the predictions given by the Pearson correlation algorithm have lower RMSE scores, and the differences pass a sign test with $p < 0.0001$.

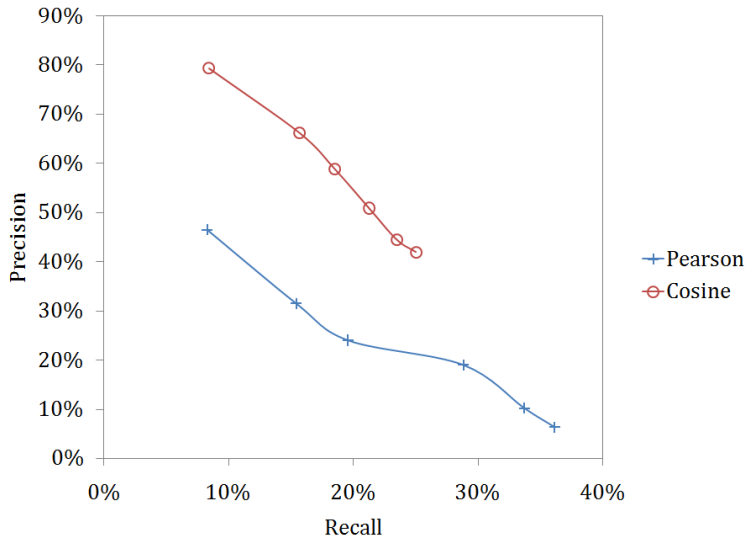
We then evaluated the two algorithms on the recommendation task on the Belgian retailer and news click stream data sets, where we again sampled 2000 test users and a randomly chosen number of test items per test user on each data set. Let us now evaluate the two algorithms on recommendation tasks. To do that, we computed precision-recall curves for the two algorithms on the Belgian retailer data set and the news click stream data set. This was done by computing precision and recall at 1, 3, 5, 10, 25, and 50 recommendations, and averaging the precisions and recalls at each number of recommendations. As Figure 2 shows, in both cases the recommendation lists generated by the Cosine similarity dominate the recommendation lists generated by the Pearson correlation algorithm in terms of precision. In the Belgian retailer data, Cosine similarity also has better recall than Pearson correlation across the board. On the news click stream data, Cosine similarity has better recall than Pearson correlation for 1, 3, and 5, recommendations. All these comparisons were significant according to a sign test with $p < 0.0001$. Therefore, in these cases, one would select the Cosine algorithm as the most appropriate choice.

This experiment shows that an algorithm that is uniformly better at predicting ratings on ratings data sets is not necessarily better at making recommendations on usage data sets. This suggests that it is possible that an algorithm that is better at predicting ratings could be worse at predicting usage in the same domain as well. An interesting experiment would be, given both ratings and usage data over the same users and items, to see whether algorithms that generate recommendation lists by decreasing order of predicted ratings do as well in the recommendation task over the usage data. Unfortunately, we are unaware of any public data set that contains both types of information. Nevertheless, companies such as Amazon or Netflix collect data both of user purchases and of user ratings over items. These companies can therefore make the appropriate decision for the recommendation task at hand.

It is also possible that websites that support multiple recommendation tasks should use different algorithms for the different tasks. For example, the Netflix website contains a prediction task (e.g., for new releases), and two recommendation tasks—a fixed list of recommendations when adding items to the rental queue, and an unlimited list of recommendations in the "movie you will like"



(a) Belgian retailer recommendations



(b) News click stream recommendations

Figure 2: Comparing recommendations generated by Pearson correlation and Cosine similarity. In both cases, the recommendation list is ordered by decreasing predicted score.

section. It may well be that different algorithms that were trained over different data sets (ratings vs. rentals) may rank differently in different tasks. Deciding on the best recommendation engine based solely on RMSE in the prediction task may lead to worse recommendation lists in the two other cases.

6.3.2 RECOMMENDATION VS. UTILITY MAXIMIZATION

In many retail applications, where the retailer is interested in maximizing profits, people may still train their algorithm on usage data solely, and evaluate them using recommendation oriented metrics, such as precision-recall. For example, even though a retailer website wishes to maximize its profit, it may use a binary data set of items that were bought by users to generate recommendations of the type "people who bought this item also bought ...".

To evaluate the performance of such an approach, we used an item-item recommendation system to generate recommendations for the Ta-Feng data set. Alternatively, one can order the items by expected utility. To compute an estimate of expected utility, we interpreted the normalized predicted score of each recommended item as the probability that the user would actually buy that item. In the case where the recommender predicts numerical ratings, we normalize by the highest possible rating and treat the result as a probability distribution. For example, if the highest rating is 5 and the algorithm predicts a score of 4.5 for a specific user we assume the the probability that the user will use the item is 0.9. We then use the average profit earned from each item to predict the profit that would be obtained from each item if the active user bought it. Multiplying the probability that the user would buy an item buy the profit that would result if the user bought the item yielded the required estimate of expected utility.

We then evaluated the two algorithms by comparing their precision-recall curves, which are shown in Figure 3. The curves were generated by evaluating precision and recall at $1, 3, 5, 10, 25$, and 50 recommendations, and averaging the precisions and recalls at each number of recommendations. The averages were computed over 2000 users, and the item-item recommender outperformed the expected profit recommender in terms of both precision and recall at all points with $p < 0.0001$.

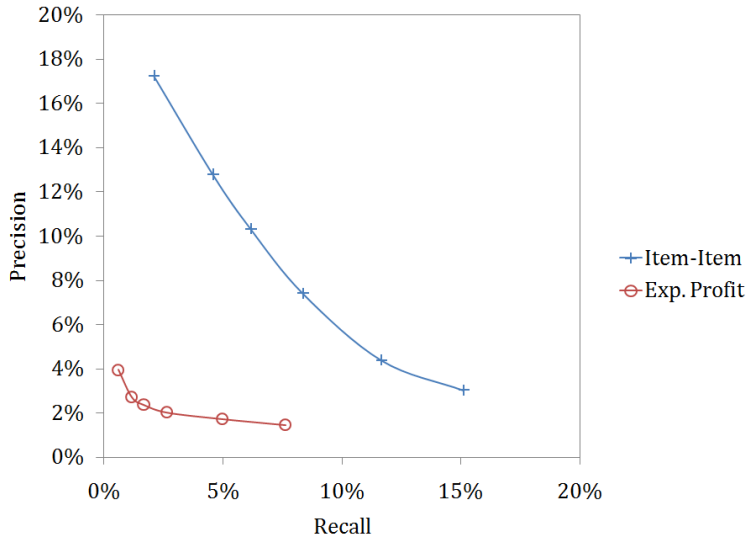


Figure 3: Comparing recommendations generated by the item-item recommender and the expected profit recommender on the Ta-Feng data set.

We then measured an half-life utility score where the utility of a correct recommendation was the profit from selling the correctly recommended item to the user. The results are shown in Table 3.

	Score
Item-Item	0.01
Exp. Profit	0.05

Table 3: Comparing item-item vs. expected utility recommendations on the Ta-Feng data set with the half-life utility score. The utility of a correct recommendation was the profit from selling that item to that user, while the half-life was 5. The trends were similar for other choices of the half-life parameter.

Choosing a recommender based on classification performance would have resulted in an half-life utility score (expected profit) that was 20% of what could have been achieved with the correct choice. This difference is statistically significant with $p < 0.001$.

These results are, of course, not surprising—using a recommender that explicitly attempts to optimize expected profit gives a better expected profit measure. However, occasionally people that are interested in maximizing profit, providing maximum value to the users, or minimizing user effort, use precision-recall to choose a recommendation algorithm.

7. Discussion

Above, we discussed the major considerations that one should make when deciding on the proper evaluation metric for a given task. We now add some discussion, illustrating other conclusions that can be derived, and illuminating some other relevant topics.

7.1 Evaluating Complete Recommender Systems

This survey focuses on the evaluation of recommendation algorithms. However, the success of a recommendation system does not depend solely on the quality of the recommendation algorithm. Such systems typically attempt to modify user behavior which is influenced by many other parameters, most notably, by the user interface. The success of the deployed system in influencing users can be measured through the change in user behavior, such as the number of recommendations that are followed, or the change in revenue.

Decisions about the interface by which users view recommendations are critical to the success of the system. For example, recommendations can be located in different places in the page, can be displayed horizontally or vertically, can be presented through images or text, and so forth. These decisions can make a significant impact, no smaller than the quality of the underlying algorithm, on the success of a system.

When the application is centered around the recommendation system, it is important to select the user interface together with the recommendation algorithm. In other cases, the recommendation system is only a supporting system for the application. For example, an e-commerce website is centered around the item purchases, and a news website is centered around the delivery of news stories. In both cases, a recommender system may be employed to help the users navigate, or to increase sales. It is likely that the recommendations are not the major method for browsing the collection of items.

When the recommender system is only a supporting system, the designer of the application will probably make the decision about the user interface without focusing on positioning recommendations where they have the most influence. In such cases, which we believe to be very common, the developer of the recommender system is constrained by the pre-designed interface, and in many cases can therefore only decide on the best recommendation algorithm, and in some cases perhaps the length of the recommendation list. This paper is targeted at researchers and developers who are making decisions about algorithms, not about the user interface. Designing a good user interface is an interesting and challenging problem, but it is outside the scope of this survey (see, e.g., Pu and Chen 2006).

7.2 Eliciting Utility Functions

A simple way to avoid the need to classify recommendation algorithms, is to assume that we are always optimizing some utility function. This utility function can be the user utility for items (see, e.g., Kumar et al. 1998, Price and Messinger 2005 and Hu and Pu 2009), or it can be the application utility. We can then ask users about their true utility function, or design a utility function that captures the goal of the application, and always choose the algorithm that maximizes this utility.

However, such a view is misleading; eliciting user utilities can be a very difficult task (see, e.g., Braziunas and Boutilier 2005, citealtChajewska and Huang 2008). For example, the value that the user is willing to invest in a laptop depends on a multitude of elements, such as her income, her technical knowledge, the intended use of the laptop and so forth. Indeed, eliciting such functions is the focus of active research, for example by presenting users with forced choices. Therefore, expecting that we will have access to a good estimate of the user utility function is unrealistic— estimating this function may be no easier than coming up with good recommendations.

Furthermore, even when the application designer understands the application utility function, gathering utilities from users may be very difficult. For example, in the Netflix domain, the business model may be to keep the users subscribed. Therefore, the utility of an movie for a user (from the website perspective) is not whether the user enjoys the movie, but rather whether the user will maintain her subscription if the movie is suggested to her. Clearly, most users will not want to answer such questions, and many may not know the answer themselves.

For this reason, when the utility function is unclear, the best we can do is to maximize the number of useful items that we suggest to the user. As such, the recommendation task cannot be viewed as a sub-task for utility optimization.

7.3 Implicit vs. Explicit ratings

Our classification of recommendation tasks sheds some light over another, commonly discussed subject in recommender systems, namely, implicit ratings (Claypool et al., 2001; Oard and Kim, 1998). In many applications, people refer to data that was automatically collected, such as logs of web browsing, or records of product purchases, as an implicit indication for positive opinions over the items that were visited or purchased.

However, this perspective is appropriate only if the task is the prediction task, where we would like to know whether the user will have a positive or negative opinion over certain items. If the task is to recommend more items that the user may buy, given the items that the user has already bought, purchase data becomes an explicit indication. In this case, using ratings that users provide over items is an implicit indication to whether the user will buy the item.

For example, a user may have a positive opinion over many laptop computers, and may rate many laptops highly. However, most people buy only one laptop. In that case, recommending more laptops, based on the co-occurring high ratings, will be inappropriate. However, if we predict the probability of buying a laptop given that another laptop has already been bought, we can expect this probability to be low, and the other laptop will not be recommended.

8. Related Work

In the past, different researchers discussed various topics relevant to the evaluation of recommender systems.

Breese et al. (1998) were probably the first to provide a sound evaluation of a number of recommendation approaches over a collection of different data sets, setting the general framework of evaluating algorithms on more than a single real world data set, and a comparison of several algorithms in identical experiments. The practices that were illustrated in that paper are used in many modern publications.

Herlocker et al. (2004) provide an extensive survey of possible metrics for evaluation. They then compare a set of metrics, concluding that for some pairs of metrics, using both together will give very little additional information compared to using just one.

Another interesting contribution of that paper is a classification of recommendation engines from the user task perspective, namely, what are the reasons and motivations that a user has when interacting with a recommender system. As they are interested in user tasks, and we are interested in the system tasks, our classification is different, yet we share some similar tasks, such as the "recommend some good items" and "recommend all good items" tasks.

Finally, their survey attempted to cover as many evaluation metrics and user task variations as possible, we focus here on the appropriate metrics for the most popular recommendation tasks only.

Mcnee et al. (2003) explain why accuracy metrics alone are insufficient for selecting the correct recommendation algorithm. For example, users may be interested in the serendipity of the recommended items. One way to model serendipity is through a utility function that assigns higher values to "unexpected" suggestions. They also discuss the "usefulness" of recommendations. Many utility functions, such as the inverse log of popularity (Shani et al., 2005) attempt to capture this "usefulness".

Ziegler et al. (2005) focus on another aspect of evaluation—considering the entire list together. This would allow us to consider aspects of a set of recommendations, such as diversification between items in the same list. Our suggested metrics consider only single items, and thus could not be used to evaluate entire lists. It would be interesting to see more evaluation metrics that provide observations over complete lists.

Celma and Herrera (2008) suggest looking at topological properties of the recommendation graph—the graph that connects recommended items. They explain how by looking at the recommendation graph one may understand properties such as the novelty of recommendations. It is still unclear how these properties correlate with the true goal of the recommender system, may it be to optimize revenue or to recommend useful items.

McLaughlin and Herlocker (2004) argue, as we do, that MAE is not appropriate for evaluating recommendation tasks, and that ratings are not necessarily indicative of whether a user is likely to watch a movie. The last claim can be explained by the way we view implicit and explicit ratings.

Some researchers have suggested taking a more holistic approach, and considering the recommendation algorithm within the complete recommendation system. For example, del Olmo and Gaudioso (2008), suggest that systems be evaluated only after deployment, through counting the number of successful recommendations. As we argue above, even in these cases, one is likely to evaluate algorithms offline, to avoid presenting recommendations that have poor quality for users, thus losing their trust.

9. Conclusion

In this paper we discussed how recommendation algorithms should be evaluated in order to select the best algorithm for a specific task from a set of candidates. This is an important step in the research attempt to find better algorithms, as well as in application design where a designer chooses an existing algorithm for their application. As such, many evaluation metrics have been used for algorithm selection in the past.

We review three core tasks of recommendation systems—the prediction task, the recommendation task, and the utility maximization task. Most evaluation metrics are naturally appropriate for one task, but not for the others. We discuss for each task a set of metrics that are most appropriate for selecting the best of the candidate algorithms.

We empirically demonstrate that in some cases two algorithms can be ranked differently by two metrics over the same data set, emphasizing the importance of choosing the appropriate metric for the task, so as not to choose an inferior algorithm.

We also describe the concerns that need to be addressed when designing offline and online experiments. We outline a few important measurements that one must take in addition to the score that the metric provides, as well as other considerations that should be taken into account when designing experiments for recommendation algorithms.
