Abstract

We consider regularized support vector machines (SVMs) and show that they are precisely equivalent to a new robust optimization formulation. We show that this equivalence of robust optimization and regularization has implications for both algorithms, and analysis. In terms of algorithms, the equivalence suggests more general SVM-like algorithms for classification that explicitly build in protection to noise, and at the same time control overfitting. On the analysis front, the equivalence of robustness and regularization provides a robust optimization interpretation for the success of regularized SVMs. We use this new robustness interpretation of SVMs to give a new proof of consistency of (kernelized) SVMs, thus establishing robustness as the *reason* regularized SVMs generalize well.

Keywords: robustness, regularization, generalization, kernel, support vector machine

1. Introduction

Support Vector Machines (SVMs for short) originated in Boser et al. (1992) and can be traced back to as early as Vapnik and Lerner (1963) and Vapnik and Chervonenkis (1974). They continue to be one of the most successful algorithms for classification. SVMs address the classification problem by finding the hyperplane in the feature space that achieves maximum sample margin when the training samples are separable, which leads to minimizing the norm of the classifier. When the samples are not separable, a penalty term that approximates the total training error is considered (Bennett and Mangasarian, 1992; Cortes and Vapnik, 1995). It is well known that minimizing the training error itself can lead to poor classification performance for new unlabeled data; that is, such an approach

∗. Also at the Department of Electrical Engineering, Technion, Israel.

may have poor generalization error because of, essentially, overfitting (Vapnik and Chervonenkis, 1991). A variety of modifications have been proposed to handle this, one of the most popular methods being that of minimizing a combination of the training-error and a regularization term. The latter is typically chosen as a norm of the classifier. The resulting regularized classifier performs better on new data. This phenomenon is often interpreted from a statistical learning theory view: the regularization term restricts the complexity of the classifier, hence the deviation of the testing error and the training error is controlled (see Smola et al., 1998; Evgeniou et al., 2000; Bartlett and Mendelson, 2002; Koltchinskii and Panchenko, 2002; Bartlett et al., 2005, and references therein).

In this paper we consider a different setup, assuming that the training data are generated by the true underlying distribution, but some non-i.i.d. (potentially adversarial) disturbance is then added to the samples we observe. We follow a robust optimization (see El Ghaoui and Lebret, 1997; Ben-Tal and Nemirovski, 1999; Bertsimas and Sim, 2004, and references therein) approach, that is, minimizing the worst possible empirical error under such disturbances. The use of robust optimization in classification is not new (e.g., Shivaswamy et al., 2006; Bhattacharyya et al., 2004b; Lanckriet et al., 2003), in which *box-type* uncertainty sets were considered. Moreover, there has not been an explicit connection to the regularized classifier, although at a high-level it is known that regularization and robust optimization are related (e.g., El Ghaoui and Lebret, 1997; Anthony and Bartlett, 1999). The main contribution in this paper is solving the robust classification problem for a class of non-box-typed uncertainty sets, and providing a linkage between robust classification and the standard regularization scheme of SVMs. In particular, our contributions include the following:

- We solve the robust SVM formulation for a class of non-box-type uncertainty sets. This permits finer control of the adversarial disturbance, restricting it to satisfy aggregate constraints across data points, therefore reducing the possibility of highly correlated disturbance.

- We show that the standard regularized SVM classifier is a special case of our robust classification, thus explicitly relating robustness and regularization. This provides an alternative explanation to the success of regularization, and also suggests new physically motivated ways to construct regularization terms.

- We relate our robust formulation to several probabilistic formulations. We consider a chance-constrained classifier (that is, a classifier with probabilistic constraints on misclassification) and show that our robust formulation can approximate it far less conservatively than previous robust formulations could possibly do. We also consider a Bayesian setup, and show that this can be used to provide a principled means of selecting the regularization coefficient without cross-validation.

- We show that the robustness perspective, stemming from a non-i.i.d. analysis, can be useful in the standard learning (i.i.d.) setup, by using it to prove consistency for standard SVM classification, *without using VC-dimension or stability arguments*. This result implies that generalization ability is a direct result of robustness to local disturbances; it therefore suggests a new justification for good performance, and consequently allows us to construct learning algorithms that generalize well by robustifying non-consistent algorithms.

1.1 Robustness and Regularization

We comment here on the explicit equivalence of robustness and regularization. We briefly explain how this observation is different from previous work and why it is interesting. Previous works on robust classification (e.g., Lanckriet et al., 2003; Bhattacharyya et al., 2004a,b; Shivaswamy et al., 2006; Trafalis and Gilbert, 2007) consider robustifying *regularized* classifications.[1] That is, they propose modifications to standard regularized classifications so that the new formulations are robust to input uncertainty. Furthermore, box-type uncertainty—a setup where the joint uncertainty is the Cartesian product of uncertainty in each input (see Section 2 for detailed formulation)—is considered, which leads to penalty terms on each *constraint* of the resulting formulation. The objective of these works was not to relate robustness and the standard regularization term that appears in the *objective function*. Indeed, research on classifier regularization mainly considers its effect on bounding the complexity of the function class (e.g., Smola et al., 1998; Evgeniou et al., 2000; Bartlett and Mendelson, 2002; Koltchinskii and Panchenko, 2002; Bartlett et al., 2005). Thus, although certain equivalence relationships between robustness and regularization have been established for problems other than classification (El Ghaoui and Lebret, 1997; Ben-Tal and Nemirovski, 1999; Bishop, 1995; Xu et al., 2009), the explicit equivalence between robustness and regularization in the SVM setup is novel.

The connection of robustness and regularization in the SVM context is important for the following reasons. First, it gives an alternative and potentially powerful explanation of the generalization ability of the regularization term. In the standard machine learning view, the regularization term bounds the complexity of the class of classifiers. The robust view of regularization regards the testing samples as a perturbed copy of the training samples. Therefore, when the total perturbation is given or bounded, the regularization term bounds the gap between the classification errors of the SVM on these two sets of samples. In contrast to the standard PAC approach, this bound depends neither on how rich the class of candidate classifiers is, nor on an assumption that all samples are picked in an i.i.d. manner.

Second, this connection suggests novel approaches to designing good classification algorithms, in particular, designing the regularization term. In the PAC structural-risk minimization approach, regularization is chosen to minimize a bound on the generalization error based on the training error and a complexity term. This approach is known to often be too pessimistic (Kearns et al., 1997), especially for problems with more structure. The robust approach offers another avenue. Since both noise and robustness are physical processes, a close investigation of the application and noise characteristics at hand, can provide insights into how to properly robustify, and therefore regularize the classifier. For example, it is known that normalizing the samples so that the variance among all features is roughly the same (a process commonly used to eliminate the scaling freedom of individual features) often leads to good generalization performance. From the robustness perspective, this has the interpretation that the noise is anisotropic (ellipsoidal) rather than spherical, and hence an appropriate robustification must be designed to fit this anisotropy.

We also show that using the robust optimization viewpoint, we obtain some probabilistic results that go beyond the PAC setup. In Section 3 we bound the probability that a noisy training sample is correctly labeled. Such a bound considers the behavior of *corrupted* samples and is hence different from the known PAC bounds. This is helpful when the training samples and the testing samples are

1. Lanckriet et al. (2003) is perhaps the only exception, where a regularization term is added to the covariance estimation rather than to the objective function.

drawn from different distributions, or some adversary manipulates the samples to prevent them from being correctly labeled (e.g., spam senders change their patterns from time to time to avoid being labeled and filtered). Finally, this connection of robustification and regularization also provides us with new proof techniques as well (see Section 5).

We need to point out that there are several different definitions of robustness in the literature. In this paper, as well as the aforementioned robust classification papers, robustness is mainly understood from a Robust Optimization (RO) perspective, where a min-max optimization is performed over all possible disturbances. An alternative interpretation of robustness stems from the rich literature on robust statistics (e.g., Huber, 1981; Hampel et al., 1986; Rousseeuw and Leroy, 1987; Maronna et al., 2006), which studies how an estimator or algorithm behaves under a small perturbation of the statistics model. For example, the *influence function* approach, proposed in Hampel (1974) and Hampel et al. (1986), measures the impact of an infinitesimal amount of contamination of the original distribution on the quantity of interest. Based on this notion of robustness, Christmann and Steinwart (2004) showed that many kernel classification algorithms, including SVM, are robust in the sense of having a finite Influence Function. A similar result for regression algorithms is shown in Christmann and Steinwart (2007) for smooth loss functions, and in Christmann and Van Messem (2008) for non-smooth loss functions where a relaxed version of the Influence Function is applied. In the machine learning literature, another widely used notion closely related to robustness is the *stability*, where an algorithm is required to be robust (in the sense that the output function does not change significantly) under a specific perturbation: deleting one sample from the training set. It is now well known that a stable algorithm such as SVM has desirable generalization properties, and is statistically consistent under mild technical conditions; see for example Bousquet and Elisseeff (2002), Kutin and Niyogi (2002), Poggio et al. (2004) and Mukherjee et al. (2006) for details. One main difference between RO and other robustness notions is that the former is constructive rather than analytical. That is, in contrast to robust statistics or the stability approach that measures the robustness of a *given* algorithm, RO can *robustify* an algorithm: it converts a given algorithm to a robust one. For example, as we show in this paper, the RO version of a naive empirical-error minimization is the well known SVM. As a constructive process, the RO approach also leads to additional flexibility in algorithm design, especially when the nature of the perturbation is known or can be well estimated.

1.2 Structure of the Paper

This paper is organized as follows. In Section 2 we investigate the correlated disturbance case, and show the equivalence between the robust classification and the regularization process. We develop the connections to probabilistic formulations in Section 3. The kernelized version is investigated in Section 4. Finally, in Section 5, we consider the standard statistical learning setup where all samples are i.i.d. draws and provide a novel proof of consistency of SVM based on robustness analysis. The analysis shows that duplicate copies of iid draws tend to be "similar" to each other in the sense that with high probability the total difference is small, and hence robustification that aims to control performance loss for small perturbations can help mitigate overfitting even though no explicit perturbation exists.

1.3 Notation

Capital letters are used to denote matrices, and boldface letters are used to denote column vectors. For a given norm $\|\cdot\|$, we use $\|\cdot\|^*$ to denote its dual norm, that is, $\|\mathbf{z}\|^* \triangleq \sup\{\mathbf{z}^\top \mathbf{x} | \|\mathbf{x}\| \leq 1\}$. For a vector $\mathbf{x}$ and a positive semi-definite matrix C of the same dimension, $\|\mathbf{x}\|_C$ denotes $\sqrt{\mathbf{x}^\top C \mathbf{x}}$. We use δ to denote disturbance affecting the samples. We use superscript r to denote the true value for an uncertain variable, so that δ_i^r is the true (but unknown) noise of the i^{th} sample. The set of non-negative scalars is denoted by $\mathbb{R}^+$. The set of integers from 1 to n is denoted by $[1:n]$.

2. Robust Classification and Regularization

We consider the standard binary classification problem, where we are given a finite number of training samples $\{\mathbf{x}_i, y_i\}_{i=1}^m \subseteq \mathbb{R}^n \times \{-1,+1\}$, and must find a linear classifier, specified by the function $h^{\mathbf{w},b}(\mathbf{x}) = \mathrm{sgn}(\langle \mathbf{w}, \mathbf{x} \rangle + b)$. For the standard regularized classifier, the parameters $(\mathbf{w}, b)$ are obtained by solving the following convex optimization problem:

$$\begin{aligned} \min_{\mathbf{w},b,\xi} : \quad & r(\mathbf{w},b) + \sum_{i=1}^m \xi_i \\ \text{s.t.} : \quad & \xi_i \geq \left[1 - y_i(\langle \mathbf{w}, \mathbf{x}_i \rangle + b)\right] \\ & \xi_i \geq 0, \end{aligned}$$

where $r(\mathbf{w},b)$ is a regularization term. This is equivalent to

$$\min_{\mathbf{w},b} \left\{ r(\mathbf{w},b) + \sum_{i=1}^m \max\left[1 - y_i(\langle \mathbf{w}, \mathbf{x}_i \rangle + b), 0\right] \right\}.$$

Previous robust classification work (Shivaswamy et al., 2006; Bhattacharyya et al., 2004a,b; Bhattacharyya, 2004; Trafalis and Gilbert, 2007) considers the classification problem where the input are subject to (unknown) disturbances $\vec{\delta} = (\delta_1, \ldots, \delta_m)$ and essentially solves the following min-max problem:

$$\min_{\mathbf{w},b} \max_{\vec{\delta} \in \mathcal{N}_{\text{box}}} \left\{ r(\mathbf{w},b) + \sum_{i=1}^m \max\left[1 - y_i(\langle \mathbf{w}, \mathbf{x}_i - \delta_i \rangle + b), 0\right] \right\}, \tag{1}$$

for a box-type uncertainty set $\mathcal{N}_{\text{box}}$. That is, let $\mathcal{N}_i$ denote the projection of $\mathcal{N}_{\text{box}}$ onto the δ_i component, then $\mathcal{N}_{\text{box}} = \mathcal{N}_1 \times \cdots \times \mathcal{N}_m$ (note that $\mathcal{N}_i$ need not be a "box"). Effectively, this allows simultaneous worst-case disturbances across many samples, and leads to overly conservative solutions. The goal of this paper is to obtain a robust formulation where the disturbances $\{\delta_i\}$ may be meaningfully taken to be correlated, that is, to solve for a non-box-type $\mathcal{N}$:

$$\min_{\mathbf{w},b} \max_{\vec{\delta} \in \mathcal{N}} \left\{ r(\mathbf{w},b) + \sum_{i=1}^m \max\left[1 - y_i(\langle \mathbf{w}, \mathbf{x}_i - \delta_i \rangle + b), 0\right] \right\}. \tag{2}$$

We briefly explain here the four reasons that motivate this "robust to perturbation" setup and in particular the min-max form of (1) and (2). First, it can explicitly incorporate prior problem knowledge of local invariance (e.g., Teo et al., 2008). For example, in vision tasks, a desirable classifier should provide a consistent answer if an input image slightly changes. Second, there are situations where

some adversarial opponents (e.g., spam senders) will manipulate the testing samples to avoid being correctly classified, and the robustness toward such manipulation should be taken into consideration in the training process (e.g., Globerson and Roweis, 2006). Or alternatively, the training samples and the testing samples can be obtained from different processes and hence the standard i.i.d. assumption is violated (e.g., Bi and Zhang, 2004). For example in real-time applications, the newly generated samples are often less accurate due to time constraints. Finally, formulations based on chance-constraints (e.g., Bhattacharyya et al., 2004b; Shivaswamy et al., 2006) are mathematically equivalent to such a min-max formulation.

We define explicitly the correlated disturbance (or uncertainty) which we study below.

Definition 1 *A set $\mathcal{N}_0 \subseteq \mathbb{R}^n$ is called an* Atomic Uncertainty Set *if*

$$\begin{aligned} &(I) \quad \mathbf{0} \in \mathcal{N}_0; \\ &(II) \quad \text{For any } \mathbf{w}_0 \in \mathbb{R}^n : \sup_{\delta \in \mathcal{N}_0} [\mathbf{w}_0^\top \delta] = \sup_{\delta' \in \mathcal{N}_0} [-\mathbf{w}_0^\top \delta'] < +\infty. \end{aligned}$$

We use "sup" here because the maximal value is not necessary attained since $\mathcal{N}_0$ may not be a closed set. The second condition of Atomic Uncertainty set basically says that the uncertainty set is bounded and symmetric. In particular, all norm balls and ellipsoids centered at the origin are atomic uncertainty sets, while an arbitrary polytope might not be an atomic uncertainty set.

Definition 2 *Let $\mathcal{N}_0$ be an atomic uncertainty set. A set $\mathcal{N} \subseteq \mathbb{R}^{n \times m}$ is called a* Sublinear Aggregated Uncertainty Set *of $\mathcal{N}_0$, if*

$$\mathcal{N}^- \subseteq \mathcal{N} \subseteq \mathcal{N}^+,$$

$$\text{where:} \quad \mathcal{N}^- \triangleq \bigcup_{t=1}^{m} \mathcal{N}_t^-; \qquad \mathcal{N}_t^- \triangleq \{(\delta_1, \cdots, \delta_m) | \delta_t \in \mathcal{N}_0;\ \delta_{i \neq t} = \mathbf{0}\}.$$

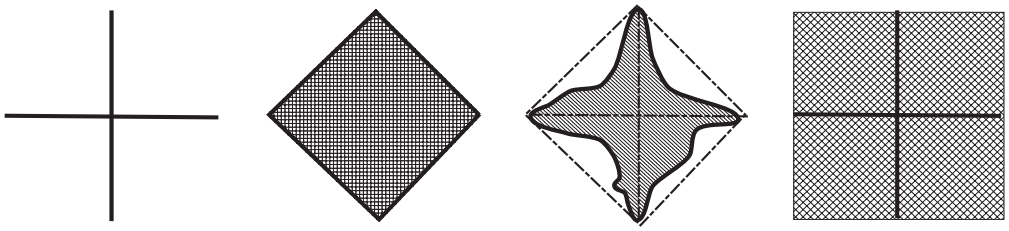
$$\mathcal{N}^+ \triangleq \{(\alpha_1 \delta_1, \cdots, \alpha_m \delta_m) | \sum_{i=1}^{m} \alpha_i = 1;\ \alpha_i \geq 0,\ \delta_i \in \mathcal{N}_0, i = 1, \cdots, m\}.$$

The Sublinear Aggregated Uncertainty definition models the case where the disturbances on each sample are treated identically, but their aggregate behavior across multiple samples is controlled. Some interesting examples include

$$\begin{aligned} &(1) \quad \{(\delta_1, \cdots, \delta_m) | \sum_{i=1}^{m} \|\delta_i\| \leq c\}; \\ &(2) \quad \{(\delta_1, \cdots, \delta_m) | \exists t \in [1:m];\ \|\delta_t\| \leq c;\ \delta_i = \mathbf{0}, \forall i \neq t\}; \\ &(3) \quad \{(\delta_1, \cdots, \delta_m) | \sum_{i=1}^{m} \sqrt{c\|\delta_i\|} \leq c\}. \end{aligned}$$

All these examples have the same atomic uncertainty set $\mathcal{N}_0 = \left\{\delta \middle| \|\delta\| \leq c\right\}$. Figure 1 provides an illustration of a sublinear aggregated uncertainty set for $n = 1$ and $m = 2$, that is, the training set consists of two univariate samples.

The following theorem is the main result of this section, which reveals that standard norm regularized SVM is the solution of a (non-regularized) robust optimization. It is a special case of Proposition 4 by taking $\mathcal{N}_0$ as the dual-norm ball $\{\delta | \|\delta\|^* \leq c\}$ for an arbitrary norm $\|\cdot\|$ and $r(\mathbf{w}, b) \equiv 0$.



a. $\mathcal{N}^-$ b. $\mathcal{N}^+$ c. $\mathcal{N}$ d. Box uncertainty

Figure 1: Illustration of a Sublinear Aggregated Uncertainty Set $\mathcal{N}$.

Theorem 3 *Let* $\mathcal{T} \triangleq \left\{(\delta_1, \cdots \delta_m) | \sum_{i=1}^m \|\delta_i\|^* \leq c\right\}$. *Suppose that the training sample* $\{\mathbf{x}_i, y_i\}_{i=1}^m$ *are non-separable. Then the following two optimization problems on* $(\mathbf{w}, b)$ *are equivalent*[2]

$$\begin{aligned} \min: \quad & \max_{(\delta_1,\cdots,\delta_m)\in\mathcal{T}} \sum_{i=1}^m \max\left[1 - y_i\big(\langle \mathbf{w}, \mathbf{x}_i - \delta_i\rangle + b\big), 0\right], \\ \min: \quad & c\|\mathbf{w}\| + \sum_{i=1}^m \max\left[1 - y_i\big(\langle \mathbf{w}, \mathbf{x}_i\rangle + b\big), 0\right]. \end{aligned} \tag{3}$$

Proposition 4 *Assume* $\{\mathbf{x}_i, y_i\}_{i=1}^m$ *are non-separable,* $r(\cdot) : \mathbb{R}^{n+1} \to \mathbb{R}$ *is an arbitrary function,* $\mathcal{N}$ *is a Sublinear Aggregated Uncertainty set with corresponding atomic uncertainty set* $\mathcal{N}_0$. *Then the following min-max problem*

$$\min_{\mathbf{w},b} \sup_{(\delta_1,\cdots,\delta_m)\in\mathcal{N}} \left\{ r(\mathbf{w}, b) + \sum_{i=1}^m \max\left[1 - y_i(\langle \mathbf{w}, \mathbf{x}_i - \delta_i\rangle + b), 0\right]\right\} \tag{4}$$

is equivalent to the following optimization problem on $\mathbf{w}, b, \xi$*:*

$$\begin{aligned} \min: \quad & r(\mathbf{w}, b) + \sup_{\delta\in\mathcal{N}_0} (\mathbf{w}^\top \delta) + \sum_{i=1}^m \xi_i, \\ \text{s.t.}: \quad & \xi_i \geq 1 - [y_i(\langle \mathbf{w}, \mathbf{x}_i\rangle + b)], \quad i = 1, \ldots, m; \\ & \xi_i \geq 0, \quad i = 1, \ldots, m. \end{aligned} \tag{5}$$

Furthermore, the minimization of Problem (5) is attainable when $r(\cdot, \cdot)$ *is lower semi-continuous.*

Proof Define:

$$v(\mathbf{w}, b) \quad \triangleq \quad \sup_{\delta\in\mathcal{N}_0} (\mathbf{w}^\top \delta) + \sum_{i=1}^m \max\left[1 - y_i(\langle \mathbf{w}, \mathbf{x}_i\rangle + b), 0\right].$$

2. The optimization equivalence for the linear case was observed independently by Bertsimas and Fertis (2008).

Recall that $\mathcal{N}^- \subseteq \mathcal{N} \subseteq N^+$ by definition. Hence, fixing any $(\hat{\mathbf{w}}, \hat{b}) \in \mathbb{R}^{n+1}$, the following inequalities hold:

$$\begin{aligned}
&\sup_{(\delta_1,\cdots,\delta_m)\in\mathcal{N}^-} \sum_{i=1}^{m} \max\left[1 - y_i(\langle \hat{\mathbf{w}}, \mathbf{x}_i - \delta_i\rangle + \hat{b}), 0\right] \\
\leq &\sup_{(\delta_1,\cdots,\delta_m)\in\mathcal{N}} \sum_{i=1}^{m} \max\left[1 - y_i(\langle \hat{\mathbf{w}}, \mathbf{x}_i - \delta_i\rangle + \hat{b}), 0\right] \\
\leq &\sup_{(\delta_1,\cdots,\delta_m)\in\mathcal{N}^+} \sum_{i=1}^{m} \max\left[1 - y_i(\langle \hat{\mathbf{w}}, \mathbf{x}_i - \delta_i\rangle + \hat{b}), 0\right].
\end{aligned}$$

To prove the theorem, we first show that $v(\hat{\mathbf{w}}, \hat{b})$ is no larger than the leftmost expression and then show $v(\hat{\mathbf{w}}, \hat{b})$ is no smaller than the rightmost expression.

Step 1: We prove that

$$v(\hat{\mathbf{w}}, \hat{b}) \leq \sup_{(\delta_1,\cdots,\delta_m)\in\mathcal{N}^-} \sum_{i=1}^{m} \max\left[1 - y_i(\langle \hat{\mathbf{w}}, \mathbf{x}_i - \delta_i\rangle + \hat{b}), 0\right]. \tag{6}$$

Since the samples $\{\mathbf{x}_i, y_i\}_{i=1}^m$ are not separable, there exists $t \in [1:m]$ such that

$$y_t(\langle \hat{\mathbf{w}}, \mathbf{x}_t\rangle + \hat{b}) < 0. \tag{7}$$

Hence,

$$\begin{aligned}
&\sup_{(\delta_1,\cdots,\delta_m)\in\mathcal{N}_t^-} \sum_{i=1}^{m} \max\left[1 - y_i(\langle \hat{\mathbf{w}}, \mathbf{x}_i - \delta_i\rangle + \hat{b}), 0\right] \\
&= \sum_{i\neq t} \max\left[1 - y_i(\langle \hat{\mathbf{w}}, \mathbf{x}_i\rangle + \hat{b}), 0\right] + \sup_{\delta_t\in\mathcal{N}_0} \max\left[1 - y_t(\langle \hat{\mathbf{w}}, \mathbf{x}_t - \delta_t\rangle + \hat{b}), 0\right] \\
&= \sum_{i\neq t} \max\left[1 - y_i(\langle \hat{\mathbf{w}}, \mathbf{x}_i\rangle + \hat{b}), 0\right] + \max\left[1 - y_t(\langle \hat{\mathbf{w}}, \mathbf{x}_t\rangle + \hat{b}) + \sup_{\delta_t\in\mathcal{N}_0} (y_t \hat{\mathbf{w}}^\top \delta_t), 0\right] \\
&= \sum_{i\neq t} \max\left[1 - y_i(\langle \hat{\mathbf{w}}, \mathbf{x}_i\rangle + \hat{b}), 0\right] + \max\left[1 - y_t(\langle \hat{\mathbf{w}}, \mathbf{x}_t\rangle + \hat{b}), 0\right] + \sup_{\delta_t\in\mathcal{N}_0} (y_t \hat{\mathbf{w}}^\top \delta_t) \\
&= \sup_{\delta\in\mathcal{N}_0} (\hat{\mathbf{w}}^\top \delta) + \sum_{i=1}^{m} \max\left[1 - y_i(\langle \hat{\mathbf{w}}, \mathbf{x}_i\rangle + \hat{b}), 0\right] = v(\hat{\mathbf{w}}, \hat{b}).
\end{aligned}$$

The third equality holds because of Inequality (7) and $\sup_{\delta_t\in\mathcal{N}_0}(y_t \hat{\mathbf{w}}^\top \delta_t)$ being non-negative (recall $\mathbf{0} \in \mathcal{N}_0$). Since $\mathcal{N}_t^- \subseteq \mathcal{N}^-$, Inequality (6) follows.

Step 2: Next we prove that

$$\sup_{(\delta_1,\cdots,\delta_m)\in\mathcal{N}^+} \sum_{i=1}^{m} \max\left[1 - y_i(\langle \hat{\mathbf{w}}, \mathbf{x}_i - \delta_i\rangle + \hat{b}), 0\right] \leq v(\hat{\mathbf{w}}, \hat{b}). \tag{8}$$

Notice that by the definition of $\mathcal{N}^+$ we have

$$\begin{aligned}
&\sup_{(\delta_1,\cdots,\delta_m)\in\mathcal{N}^+}\sum_{i=1}^m \max\left[1-y_i(\langle\hat{\mathbf{w}},\mathbf{x}_i-\delta_i\rangle+\hat{b}),0\right]\\
=&\sup_{\sum_{i=1}^m\alpha_i=1;\alpha_i\geq 0;\hat{\delta}_i\in\mathcal{N}_0}\sum_{i=1}^m \max\left[1-y_i(\langle\hat{\mathbf{w}},\mathbf{x}_i-\alpha_i\hat{\delta}_i\rangle+\hat{b}),0\right] \qquad (9)\\
=&\sup_{\sum_{i=1}^m\alpha_i=1;\alpha_i\geq 0;}\sum_{i=1}^m \max\Big[\sup_{\hat{\delta}_i\in\mathcal{N}_0}\left(1-y_i(\langle\hat{\mathbf{w}},\mathbf{x}_i-\alpha_i\hat{\delta}_i\rangle+\hat{b})\right),0\Big].
\end{aligned}$$

Now, for any $i\in[1:m]$, the following holds,

$$\begin{aligned}
&\max\Big[\sup_{\hat{\delta}_i\in\mathcal{N}_0}\left(1-y_i(\langle\hat{\mathbf{w}},\mathbf{x}_i-\alpha_i\hat{\delta}_i\rangle+\hat{b})\right),0\Big]\\
=&\max\left[1-y_i(\langle\hat{\mathbf{w}},\mathbf{x}_i\rangle+\hat{b})+\alpha_i\sup_{\hat{\delta}_i\in\mathcal{N}_0}(\hat{\mathbf{w}}^\top\hat{\delta}_i),0\right]\\
\leq&\max\left[1-y_i(\langle\hat{\mathbf{w}},\mathbf{x}_i\rangle+\hat{b}),0\right]+\alpha_i\sup_{\hat{\delta}_i\in\mathcal{N}_0}(\hat{\mathbf{w}}^\top\hat{\delta}_i).
\end{aligned}$$

Therefore, Equation (9) is upper bounded by

$$\begin{aligned}
&\sum_{i=1}^m\max\left[1-y_i(\langle\hat{\mathbf{w}},\mathbf{x}_i\rangle+\hat{b}),0\right]+\sup_{\sum_{i=1}^m\alpha_i=1;\alpha_i\geq 0;}\sum_{i=1}^m\alpha_i\sup_{\hat{\delta}_i\in\mathcal{N}_0}(\hat{\mathbf{w}}^\top\hat{\delta}_i)\\
=&\sup_{\delta\in\mathcal{N}_0}(\hat{\mathbf{w}}^\top\delta)+\sum_{i=1}^m\max\left[1-y_i(\langle\hat{\mathbf{w}},\mathbf{x}_i\rangle+\hat{b}),0\right]=v(\hat{\mathbf{w}},\hat{b}),
\end{aligned}$$

hence Inequality (8) holds.

Step 3: Combining the two steps and adding $r(\mathbf{w},b)$ on both sides leads to: $\forall(\mathbf{w},b)\in\mathbb{R}^{n+1}$,

$$\sup_{(\delta_1,\cdots,\delta_m)\in\mathcal{N}}\sum_{i=1}^m\max\left[1-y_i(\langle\mathbf{w},\mathbf{x}_i-\delta_i\rangle+b),0\right]+r(\mathbf{w},b)=v(\mathbf{w},b)+r(\mathbf{w},\mathbf{b}).$$

Taking the infimum on both sides establishes the equivalence of Problem (4) and Problem (5). Observe that $\sup_{\delta\in\mathcal{N}_0}\mathbf{w}^\top\delta$ is a supremum over a class of affine functions, and hence is lower semi-continuous. Therefore $v(\cdot,\cdot)$ is also lower semi-continuous. Thus the minimum can be achieved for Problem (5), and Problem (4) by equivalence, when $r(\cdot)$ is lower semi-continuous. ■

Before concluding this section we briefly comment on the meaning of Theorem 3 and Proposition 4. On one hand, they explain the widely known fact that the regularized classifier tends to be more robust (see for example, Christmann and Steinwart, 2004, 2007; Christmann and Van Messem, 2008; Trafalis and Gilbert, 2007). On the other hand, this observation also suggests that the appropriate way to regularize should come from a disturbance-robustness perspective. The above equivalence implies that standard regularization essentially assumes that the disturbance is spherical; if this is not true, robustness may yield a better regularization-like algorithm. To find a more effective regularization term, a closer investigation of the data variation is desirable, particularly if some a-priori knowledge of the data-variation is known. For example, consider an image

classification problem. Suppose it is known that these pictures are taken under significantly varying background light. Therefore, for a given sample (picture), the perturbation on each feature (pixel) is large. However, the perturbations across different features are almost identical since they are under the same background light. This can be represented by the following Atomic uncertainty set

$$\mathcal{N}_0 = \{\delta | \|\delta\|_2 \le c_1,\ \|\delta - (\frac{1}{n}\sum_{t=1}^{n}\delta_t)\mathbf{1}\|_2 \le c_2\},$$

where $c_2 \ll c_1$. By Proposition 4, this leads to the following regularization term

$$\begin{aligned} f(\mathbf{w}) = \ & \max : \mathbf{w}^\top \delta \\ & \text{s.t.} \ \|\delta\|_2 \le c_1 \\ & \quad \|(I - \frac{1}{n}\mathbf{1}\mathbf{1}^\top)\delta\|_2 \le c_2. \end{aligned}$$

Notice this is a second order cone programming which has a dual form

$$\begin{aligned} \min : \ & c_1 v_1 + c_2 v_2 \\ \text{s.t.} \ & \mathbf{u}_1 + (I - \frac{1}{n}\mathbf{1}\mathbf{1}^\top)\mathbf{u}_2 = \mathbf{w} \\ & \|\mathbf{u}_i\|_2 \le v_i,\ i = 1, 2. \end{aligned}$$

Substituting it to (5), the resulting classification problem is a second order cone program, which can be efficiently solved (Boyd and Vandenberghe, 2004).

3. Probabilistic Interpretations

Although Problem (4) is formulated without any probabilistic assumptions, in this section, we briefly explain two approaches to construct the uncertainty set and equivalently tune the regularization parameter c based on probabilistic information.

The first approach is to use Problem (4) to approximate an upper bound for a chance-constrained classifier. Suppose the disturbance $(\delta_1^r, \cdots \delta_m^r)$ follows a joint probability measure μ. Then the chance-constrained classifier is given by the following minimization problem given a confidence level $\eta \in [0, 1]$,

$$\begin{aligned} \min_{\mathbf{w},b,l} : \quad & l \\ \text{s.t.} : \quad & \mu\Big\{ \sum_{i=1}^{m} \max\left[1 - y_i(\langle \mathbf{w}, \mathbf{x}_i - \delta_i^r \rangle + b), 0\right] \le l \Big\} \ge 1 - \eta. \end{aligned} \tag{10}$$

The formulations in Shivaswamy et al. (2006), Lanckriet et al. (2003) and Bhattacharyya et al. (2004a) assume uncorrelated noise and require all constraints to be satisfied with high probability *simultaneously*. They find a vector $[\xi_1, \cdots, \xi_m]^\top$ where each ξ_i is the η-quantile of the hinge-loss for sample $\mathbf{x}_i^r$. In contrast, our formulation above minimizes the η-quantile of the average (or equivalently the sum of) empirical error. When controlling this average quantity is of more interest, the box-type noise formulation will be overly conservative.

Problem (10) is generally intractable. However, we can approximate it as follows. Let

$$c^* \triangleq \inf\{\alpha | \mu(\sum_i \|\delta_i\|^* \le \alpha) \ge 1 - \eta\}.$$

Notice that c^* is easily simulated given μ. Then for any $(\mathbf{w}, b)$, with probability no less than $1-\eta$, the following holds,

$$\sum_{i=1}^{m} \max\left[1 - y_i(\langle \mathbf{w}, \mathbf{x}_i - \delta_i^r \rangle + b), 0\right]$$
$$\leq \max_{\sum_i \|\delta_i\|^* \leq c^*} \sum_{i=1}^{m} \max\left[1 - y_i(\langle \mathbf{w}, \mathbf{x}_i - \delta_i \rangle + b), 0\right].$$

Thus (10) is upper bounded by (3) with $c = c^*$. This gives an additional probabilistic robustness property of the standard regularized classifier. Notice that following a similar approach but with the constraint-wise robust setup, that is, the box uncertainty set, would lead to considerably more pessimistic approximations of the chance constraint.

The second approach considers a Bayesian setup. Suppose the total disturbance $c^r \triangleq \sum_{i=1}^m \|\delta_i^r\|^*$ follows a prior distribution $\rho(\cdot)$. This can model for example the case that the training sample set is a mixture of several data sets where the disturbance magnitude of each set is known. Such a setup leads to the following classifier which minimizes the Bayesian (robust) error:

$$\min_{\mathbf{w},b}: \quad \int \left\{ \max_{\sum \|\delta_i\|^* \leq c} \sum_{i=1}^{m} \max\left[1 - y_i\big(\langle \mathbf{w}, \mathbf{x}_i - \delta_i \rangle + b\big), 0\right] \right\} d\rho(c). \tag{11}$$

By Theorem 3, the Bayes classifier (11) is equivalent to

$$\min_{\mathbf{w},b}: \quad \int \left\{ c\|\mathbf{w}\| + \sum_{i=1}^{m} \max\left[1 - y_i\big(\langle \mathbf{w}, \mathbf{x}_i \rangle + b\big), 0\right] \right\} d\rho(c),$$

which can be further simplified as

$$\min_{\mathbf{w},b}: \quad \overline{c}\|\mathbf{w}\| + \sum_{i=1}^{m} \max\left[1 - y_i\big(\langle \mathbf{w}, \mathbf{x}_i \rangle + b\big), 0\right],$$

where $\overline{c} \triangleq \int c\, d\rho(c)$. This thus provides us a justifiable parameter tuning method different from cross validation: simply using the expected value of c^r. We note that it is the equivalence of Theorem 3 that makes this possible, since it is difficult to imagine a setting where one would have a prior on regularization coefficients.

4. Kernelization

The previous results can be easily generalized to the kernelized setting, which we discuss in detail in this section. In particular, similar to the linear classification case, we give a new interpretation of the standard kernelized SVM as the min-max empirical hinge-loss solution, where the disturbance is assumed to lie in the feature space. We then relate this to the (more intuitively appealing) setup where the disturbance lies in the sample space. We use this relationship in Section 5 to prove a consistency result for kernelized SVMs.

The kernelized SVM formulation considers a linear classifier in the feature space $\mathcal{H}$, a Hilbert space containing the range of some feature mapping $\Phi(\cdot)$. The standard formulation is as follows,

$$\begin{aligned} \min_{\mathbf{w},b}: \quad & r(\mathbf{w}, b) + \sum_{i=1}^{m} \xi_i \\ \text{s.t.}: \quad & \xi_i \geq \left[1 - y_i(\langle \mathbf{w}, \Phi(\mathbf{x}_i) \rangle + b)\right], \\ & \xi_i \geq 0\,. \end{aligned}$$

It has been proved in Schölkopf and Smola (2002) that if we take $f(\langle \mathbf{w}, \mathbf{w} \rangle)$ for some increasing function $f(\cdot)$ as the regularization term $r(\mathbf{w}, b)$, then the optimal solution has a representation $\mathbf{w}^* = \sum_{i=1}^m \alpha_i \Phi(\mathbf{x}_i)$, which can further be solved without knowing explicitly the feature mapping, but by evaluating a kernel function $k(\mathbf{x}, \mathbf{x}') \triangleq \langle \Phi(\mathbf{x}), \Phi(\mathbf{x}') \rangle$ only. This is the well-known "kernel trick".

The definitions of Atomic Uncertainty Set and Sublinear Aggregated Uncertainty Set in the feature space are identical to Definition 1 and 2, with $\mathbb{R}^n$ replaced by $\mathcal{H}$. The following theorem is a feature-space counterpart of Proposition 4. The proof follows from a similar argument to Proposition 4, that is, for any fixed $(\mathbf{w}, b)$ the worst-case empirical error equals the empirical error plus a penalty term $\sup_{\delta \in \mathcal{N}_0} \big(\langle \mathbf{w}, \delta \rangle \big)$, and hence the details are omitted.

Theorem 5 *Assume $\{\Phi(\mathbf{x}_i), y_i\}_{i=1}^m$ are not linearly separable, $r(\cdot) : \mathcal{H} \times \mathbb{R} \to \mathbb{R}$ is an arbitrary function, $\mathcal{N} \subseteq \mathcal{H}^m$ is a Sublinear Aggregated Uncertainty set with corresponding atomic uncertainty set $\mathcal{N}_0 \subseteq \mathcal{H}$. Then the following min-max problem*

$$\min_{\mathbf{w}, b} \sup_{(\delta_1, \cdots, \delta_m) \in \mathcal{N}} \left\{ r(\mathbf{w}, b) + \sum_{i=1}^m \max \left[1 - y_i (\langle \mathbf{w}, \Phi(\mathbf{x}_i) - \delta_i \rangle + b), 0 \right] \right\}$$

is equivalent to

$$\begin{aligned} \min: \quad & r(\mathbf{w}, b) + \sup_{\delta \in \mathcal{N}_0} \big(\langle \mathbf{w}, \delta \rangle \big) + \sum_{i=1}^m \xi_i, \\ \text{s.t.}: \quad & \xi_i \geq 1 - y_i \big(\langle \mathbf{w}, \Phi(\mathbf{x}_i) \rangle + b \big), \quad i = 1, \cdots, m; \\ & \xi_i \geq 0, \quad i = 1, \cdots, m. \end{aligned} \tag{12}$$

Furthermore, the minimization of Problem (12) is attainable when $r(\cdot, \cdot)$ is lower semi-continuous.

For some widely used feature mappings (e.g., RKHS of a Gaussian kernel), $\{\Phi(\mathbf{x}_i), y_i\}_{i=1}^m$ are always separable. In this case, the worst-case empirical error may not be equal to the empirical error plus a penalty term $\sup_{\delta \in \mathcal{N}_0} \big(\langle \mathbf{w}, \delta \rangle \big)$. However, it is easy to show that for any $(\mathbf{w}, b)$, the latter is an upper bound of the former.

The next corollary is the feature-space counterpart of Theorem 3, where $\| \cdot \|_{\mathcal{H}}$ stands for the RKHS norm, that is, for $\mathbf{z} \in \mathcal{H}$, $\|\mathbf{z}\|_{\mathcal{H}} = \sqrt{\langle \mathbf{z}, \mathbf{z} \rangle}$. Noticing that the RKHS norm is self dual, we find that the proof is identical to that of Theorem 3, and hence omit it.

Corollary 6 *Let $\mathcal{T}_{\mathcal{H}} \triangleq \left\{ (\delta_1, \cdots \delta_m) \middle| \sum_{i=1}^m \|\delta_i\|_{\mathcal{H}} \leq c \right\}$. If $\{\Phi(\mathbf{x}_i), y_i\}_{i=1}^m$ are non-separable, then the following two optimization problems on $(\mathbf{w}, b)$ are equivalent*

$$\begin{aligned} \min: \quad & \max_{(\delta_1, \cdots, \delta_m) \in \mathcal{T}_{\mathcal{H}}} \sum_{i=1}^m \max \big[1 - y_i \big(\langle \mathbf{w}, \Phi(\mathbf{x}_i) - \delta_i \rangle + b \big), 0 \big], \\ \min: \quad & c \|\mathbf{w}\|_{\mathcal{H}} + \sum_{i=1}^m \max \big[1 - y_i \big(\langle \mathbf{w}, \Phi(\mathbf{x}_i) \rangle + b \big), 0 \big]. \end{aligned} \tag{13}$$

Equation (13) is a variant form of the standard SVM that has a squared RKHS norm regularization term, and it can be shown that the two formulations are equivalent up to changing of tradeoff parameter c, since both the empirical hinge-loss and the RKHS norm are convex. Therefore, Corollary 6

essentially means that the standard kernelized SVM is implicitly a robust classifier (without regularization) with disturbance in the feature-space, and the sum of the magnitude of the disturbance is bounded.

Disturbance in the feature-space is less intuitive than disturbance in the sample space, and the next lemma relates these two different notions.

Lemma 7 *Suppose there exists* $\mathcal{X} \subseteq \mathbb{R}^n$, $\rho > 0$, *and a continuous non-decreasing function* $f : \mathbb{R}^+ \to \mathbb{R}^+$ *satisfying* $f(0) = 0$, *such that*

$$k(\mathbf{x},\mathbf{x}) + k(\mathbf{x}',\mathbf{x}') - 2k(\mathbf{x},\mathbf{x}') \leq f(\|\mathbf{x}-\mathbf{x}'\|_2^2), \quad \forall \mathbf{x},\mathbf{x}' \in \mathcal{X}, \|\mathbf{x}-\mathbf{x}'\|_2 \leq \rho$$

then

$$\|\Phi(\hat{\mathbf{x}}+\delta) - \Phi(\hat{\mathbf{x}})\|_{\mathcal{H}} \leq \sqrt{f(\|\delta\|_2^2)}, \quad \forall \|\delta\|_2 \leq \rho,\ \hat{\mathbf{x}}, \hat{\mathbf{x}}+\delta \in \mathcal{X}.$$

In the appendix, we prove a result that provides a tighter relationship between disturbance in the feature space and disturbance in the sample space, for RBF kernels.

Proof Expanding the RKHS norm yields

$$\begin{aligned}
&\|\Phi(\hat{\mathbf{x}}+\delta) - \Phi(\hat{\mathbf{x}})\|_{\mathcal{H}} \\
=&\sqrt{\langle \Phi(\hat{\mathbf{x}}+\delta) - \Phi(\hat{\mathbf{x}}),\, \Phi(\hat{\mathbf{x}}+\delta) - \Phi(\hat{\mathbf{x}}) \rangle} \\
=&\sqrt{\langle \Phi(\hat{\mathbf{x}}+\delta),\, \Phi(\hat{\mathbf{x}}+\delta) \rangle + \langle \Phi(\hat{\mathbf{x}}),\, \Phi(\hat{\mathbf{x}}) \rangle - 2\langle \Phi(\hat{\mathbf{x}}+\delta),\, \Phi(\hat{\mathbf{x}}) \rangle} \\
=&\sqrt{k\big(\hat{\mathbf{x}}+\delta, \hat{\mathbf{x}}+\delta\big) + k\big(\hat{\mathbf{x}}, \hat{\mathbf{x}}\big) - 2k\big(\hat{\mathbf{x}}+\delta,\ \hat{\mathbf{x}}\big)} \\
\leq&\sqrt{f(\|\hat{\mathbf{x}}+\delta-\hat{\mathbf{x}}\|_2^2)} = \sqrt{f(\|\delta\|_2^2)},
\end{aligned}$$

where the inequality follows from the assumption. ■

Lemma 7 essentially says that under certain conditions, robustness in the feature space is a stronger requirement that robustness in the sample space. Therefore, a classifier that achieves robustness in the feature space (the SVM for example) also achieves robustness in the sample space. Notice that the condition of Lemma 7 is rather weak. In particular, it holds for any continuous $k(\cdot,\cdot)$ and bounded $\mathcal{X}$.

In the next section we consider a more foundational property of robustness in the sample space: we show that a classifier that is robust in the sample space is asymptotically consistent. As a consequence of this result for linear classifiers, the above results imply the consistency for a broad class of kernelized SVMs.

5. Consistency of Regularization

In this section we explore a fundamental connection between learning and robustness, by using robustness properties to re-prove the statistical consistency of the linear classifier, and then the kernelized SVM. Indeed, our proof mirrors the consistency proof found in Steinwart (2005), with the key difference that *we replace metric entropy, VC-dimension, and stability conditions used there, with a robustness condition*.

Thus far we have considered the setup where the training-samples are corrupted by certain set-inclusive disturbances. We now turn to the standard statistical learning setup, by assuming that all

training samples and testing samples are generated i.i.d. according to a (unknown) probability $\mathbb{P}$, that is, there does not exist explicit disturbance.

Let $\mathcal{X} \subseteq \mathbb{R}^n$ be bounded, and suppose the training samples $(\mathbf{x}_i, y_i)_{i=1}^{\infty}$ are generated i.i.d. according to an unknown distribution $\mathbb{P}$ supported by $\mathcal{X} \times \{-1, +1\}$. The next theorem shows that our robust classifier setup and equivalently regularized SVM asymptotically minimizes an upper-bound of the expected classification error and hinge loss.

Theorem 8 *Denote* $K \triangleq \max_{x \in \mathcal{X}} \|x\|_2$. *Then there exists a random sequence* $\{\gamma_{m,c}\}$ *such that:*

1. $\forall c > 0$, $\lim_{m\to\infty} \gamma_{m,c} = 0$ *almost surely, and the convergence is uniform in* $\mathbb{P}$*;*

2. *the following bounds on the Bayes loss and the hinge loss hold uniformly for all* $(\mathbf{w}, b)$*:*

$$\mathbb{E}_{(\mathbf{x},y)\sim\mathbb{P}}(\mathbf{1}_{y \neq sgn(\langle \mathbf{w}, \mathbf{x}\rangle + b)}) \leq \gamma_{m,c} + c\|\mathbf{w}\|_2 + \frac{1}{m}\sum_{i=1}^{m} \max\left[1 - y_i(\langle \mathbf{w}, \mathbf{x}_i\rangle + b), 0\right];$$

$$\mathbb{E}_{(\mathbf{x},y)\sim\mathbb{P}}\Big(\max(1 - y(\langle \mathbf{w}, \mathbf{x}\rangle + b), 0)\Big) \leq$$

$$\gamma_{m,c}(1 + K\|\mathbf{w}\|_2 + |b|) + c\|\mathbf{w}\|_2 + \frac{1}{m}\sum_{i=1}^{m} \max\left[1 - y_i(\langle \mathbf{w}, \mathbf{x}_i\rangle + b), 0\right].$$

Proof We briefly explain the basic idea of the proof before going to the technical details. We consider the testing sample set as a perturbed copy of the training sample set, and measure the magnitude of the perturbation. For testing samples that have "small" perturbations, $c\|\mathbf{w}\|_2 + \frac{1}{m}\sum_{i=1}^{m} \max\left[1 - y_i(\langle \mathbf{w}, \mathbf{x}_i\rangle + b), 0\right]$ upper-bounds their total loss by Theorem 3. Therefore, we only need to show that the ratio of testing samples having "large" perturbations diminishes to prove the theorem.

Now we present the detailed proof. Given a $c > 0$, we call a testing sample $(\mathbf{x}', y')$ and a training sample $(\mathbf{x}, y)$ a *sample pair* if $y = y'$ and $\|\mathbf{x} - \mathbf{x}'\|_2 \leq c$. We say a set of training samples and a set of testing samples form l pairings if there exist l sample pairs with no data reused. Given m training samples and m testing samples, we use $M_{m,c}$ to denote the largest number of pairings. To prove this theorem, we need to establish the following lemma.

Lemma 9 *Given a* $c > 0$, $M_{m,c}/m \to 1$ *almost surely as* $m \to +\infty$, *uniformly w.r.t.* $\mathbb{P}$.

Proof We make a partition of $\mathcal{X} \times \{-1, +1\} = \bigcup_{t=1}^{T_c} \mathcal{X}_t$ such that $\mathcal{X}_t$ either has the form $[\alpha_1, \alpha_1 + c/\sqrt{n}) \times [\alpha_2, \alpha_2 + c/\sqrt{n}) \cdots \times [\alpha_n, \alpha_n + c/\sqrt{n}) \times \{+1\}$ or $[\alpha_1, \alpha_1 + c/\sqrt{n}) \times [\alpha_2, \alpha_2 + c/\sqrt{n}) \cdots \times [\alpha_n, \alpha_n + c/\sqrt{n}) \times \{-1\}$ (recall n is the dimension of $\mathcal{X}$). That is, each partition is the Cartesian product of a rectangular cell in $\mathcal{X}$ and a singleton in $\{-1, +1\}$. Notice that if a training sample and a testing sample fall into $\mathcal{X}_t$, they can form a pairing.

Let N_t^{tr} and N_t^{te} be the number of training samples and testing samples falling in the t^{th} set, respectively. Thus, $(N_1^{tr}, \cdots, N_{T_c}^{tr})$ and $(N_1^{te}, \cdots, N_{T_c}^{te})$ are multinomially distributed random vectors following a same distribution. Notice that for a multinomially distributed random vector $(N_1, \cdots, N_k)$ with parameter m and $(p_1, \cdots, p_k)$, the following holds (Bretegnolle-Huber-Carol inequality, see for example Proposition A6.6 of van der Vaart and Wellner, 2000). For any $\lambda > 0$,

$$\mathbb{P}\Big(\sum_{i=1}^{k} \big|N_i - mp_i\big|) \geq 2\sqrt{m}\lambda\Big) \leq 2^k \exp(-2\lambda^2).$$

Hence we have

$$\begin{aligned}
& \mathbb{P}\Big(\sum_{t=1}^{T_c}\big|N_t^{tr}-N_t^{te}\big|\geq 4\sqrt{m}\lambda\Big)\leq 2^{T_c+1}\exp(-2\lambda^2),\\
\Longrightarrow\quad & \mathbb{P}\Big(\frac{1}{m}\sum_{t=1}^{T_c}\big|N_t^{tr}-N_t^{te}\big|\geq \lambda\Big)\leq 2^{T_c+1}\exp(\frac{-m\lambda^2}{8}),\\
\Longrightarrow\quad & \mathbb{P}\Big(M_{m,c}/m\leq 1-\lambda\Big)\leq 2^{T_c+1}\exp(\frac{-m\lambda^2}{8}). \qquad (14)
\end{aligned}$$

Observe that $\sum_{m=1}^{\infty}2^{T_c+1}\exp(\frac{-m\lambda^2}{8})<+\infty$, hence by the Borel-Cantelli Lemma (see, for example, Durrett, 2004), with probability one the event $\{M_{m,c}/m\leq 1-\lambda\}$ only occurs finitely often as $m\to\infty$. That is, $\liminf_m M_{m,c}/m\geq 1-\lambda$ almost surely. Since λ can be arbitrarily close to zero, $M_{m,c}/m\to 1$ almost surely. Observe that this convergence is uniform in $\mathbb{P}$, since T_c only depends on $\mathcal{X}$. ■

Now we proceed to prove the theorem. Given m training samples and m testing samples with $M_{m,c}$ sample pairs, we notice that for these paired samples, both the total testing error and the total testing hinge-loss is upper bounded by

$$\begin{aligned}
&\max_{(\delta_1,\cdots,\delta_m)\in\mathcal{N}_0\times\cdots\times\mathcal{N}_0}\sum_{i=1}^{m}\max\big[1-y_i\big(\langle\mathbf{w},\mathbf{x}_i-\delta_i\rangle+b\big),0\big]\\
\leq& cm\|\mathbf{w}\|_2+\sum_{i=1}^{m}\max\big[1-y_i(\langle\mathbf{w},\mathbf{x}_i\rangle+b),0\big],
\end{aligned}$$

where $\mathcal{N}_0=\{\delta\,|\,\|\delta\|\leq c\}$. Hence the total classification error of the m testing samples can be upper bounded by

$$(m-M_{m,c})+cm\|\mathbf{w}\|_2+\sum_{i=1}^{m}\max\big[1-y_i(\langle\mathbf{w},\mathbf{x}_i\rangle+b),0\big],$$

and since

$$\max_{\mathbf{x}\in\mathcal{X}}(1-y(\langle\mathbf{w},\mathbf{x}\rangle))\leq\max_{\mathbf{x}\in\mathcal{X}}\Big\{1+|b|+\sqrt{\langle\mathbf{x},\mathbf{x}\rangle\cdot\langle\mathbf{w},\mathbf{w}\rangle}\Big\}=1+|b|+K\|\mathbf{w}\|_2,$$

the accumulated hinge-loss of the total m testing samples is upper bounded by

$$(m-M_{m,c})(1+K\|\mathbf{w}\|_2+|b|)+cm\|\mathbf{w}\|_2+\sum_{i=1}^{m}\max\big[1-y_i(\langle\mathbf{w},\mathbf{x}_i\rangle+b),0\big].$$

Therefore, the average testing error is upper bounded by

$$1-M_{m,c}/m+c\|\mathbf{w}\|_2+\frac{1}{m}\sum_{i=1}^{n}\max\big[1-y_i(\langle\mathbf{w},\mathbf{x}_i\rangle+b),0\big],$$

and the average hinge loss is upper bounded by

$$(1-M_{m,c}/m)(1+K\|\mathbf{w}\|_2+|b|)+c\|\mathbf{w}\|_2+\frac{1}{m}\sum_{i=1}^{m}\max\big[1-y_i(\langle\mathbf{w},\mathbf{x}_i\rangle+b),0\big].$$

Let $\gamma_{m,c} = 1 - M_{m,c}/m$. The proof follows since $M_{m,c}/m \to 1$ almost surely for any $c > 0$. Notice by Inequality (14) we have

$$\mathbb{P}\Big(\gamma_{m,c} \geq \lambda\Big) \leq \exp\Big(-m\lambda^2/8 + (T_c+1)\log 2\Big), \tag{15}$$

that is, the convergence is uniform in $\mathbb{P}$.

We have shown that the average testing error is upper bounded. The final step is to show that this implies that in fact the random variable given by the conditional expectation (conditioned on the training sample) of the error is bounded almost surely as in the statement of the theorem. To make things precise, consider a fixed m, and let $\omega_1 \in \Omega_1$ and $\omega_2 \in \Omega_2$ generate the m training samples and m testing samples, respectively, and for shorthand let $\mathcal{T}^m$ denote the random variable of the first m training samples. Let us denote the probability measures for the training by ρ_1 and the testing samples by ρ_2. By independence, the joint measure is given by the product of these two. We rely on this property in what follows. Now fix a λ and a $c > 0$. In our new notation, Equation (15) now reads:

$$\begin{aligned}\int_{\Omega_1}\int_{\Omega_2} \mathbf{1}\big\{\gamma_{m,c}(\omega_1,\omega_2) \geq \lambda\big\}\, d\rho_2(\omega_2)\, d\rho_1(\omega_1) &= \mathbb{P}\Big(\gamma_{m,c}(\omega_1,\omega_2) \geq \lambda\Big) \\ &\leq \exp\Big(-m\lambda^2/8 + (T_c+1)\log 2\Big).\end{aligned}$$

We now bound $\mathbb{P}_{\omega_1}(\mathbb{E}_{\omega_2}[\gamma_{m,c}(\omega_1,\omega_2)\,|\,\mathcal{T}^m] > \lambda)$, and then use Borel-Cantelli to show that this event can happen only finitely often. We have:

$$\begin{aligned}
& \mathbb{P}_{\omega_1}(\mathbb{E}_{\omega_2}[\gamma_{m,c}(\omega_1,\omega_2)\,|\,\mathcal{T}^m] > \lambda) \\
= & \int_{\Omega_1} \mathbf{1}\Big\{ \int_{\Omega_2} \gamma_{m,c}(\omega_1,\omega_2)\, d\rho_2(\omega_2) > \lambda\Big\}\, d\rho_1(\omega_1) \\
\leq & \int_{\Omega_1} \mathbf{1}\Big\{ \Big[\int_{\Omega_2} \gamma_{m,c}(\omega_1,\omega_2)\mathbf{1}(\gamma_{m,c}(\omega_1,\omega_2) \leq \lambda)\, d\rho_2(\omega_2) + \\
& \int_{\Omega_2} \gamma_{m,c}(\omega_1,\omega_2)\mathbf{1}(\gamma_{m,c}(\omega_1,\omega_2) > \lambda)\, d\rho_2(\omega_2)\Big] \geq 2\lambda\Big\} d\rho_1(\omega_1) \\
\leq & \int_{\Omega_1} \mathbf{1}\Big\{ \Big[\int_{\Omega_2} \lambda\mathbf{1}(\lambda(\omega_1,\omega_2) \leq \lambda)\, d\rho_2(\omega_2) + \\
& \int_{\Omega_2} \mathbf{1}(\gamma_{m,c}(\omega_1,\omega_2) > \lambda)\, d\rho_2(\omega_2)\Big] \geq 2\lambda\Big\} d\rho_1(\omega_1) \\
\leq & \int_{\Omega_1} \mathbf{1}\Big\{ \Big[\lambda + \int_{\Omega_2} \mathbf{1}(\gamma_{m,c}(\omega_1,\omega_2) > \lambda)\, d\rho_2(\omega_2)\Big] \geq 2\lambda\Big\} d\rho_1(\omega_1) \\
= & \int_{\Omega_1} \mathbf{1}\Big\{ \int_{\Omega_2} \mathbf{1}(\gamma_{m,c}(\omega_1,\omega_2) > \lambda)\, d\rho_2(\omega_2) \geq \lambda\Big\} d\rho_1(\omega_1).
\end{aligned}$$

Here, the first equality holds because training and testing samples are independent, and hence the joint measure is the product of ρ_1 and ρ_2. The second inequality holds because $\gamma_{m,c}(\omega_1,\omega_2) \leq 1$ everywhere. Further notice that

$$\begin{aligned}
& \int_{\Omega_1}\int_{\Omega_2} \mathbf{1}\big\{\gamma_{m,c}(\omega_1,\omega_2) \geq \lambda\big\}\, d\rho_2(\omega_2)\, d\rho_1(\omega_1) \\
& \geq \int_{\Omega_1} \lambda\mathbf{1}\Big\{ \int_{\Omega_2} \mathbf{1}\big(\gamma_{m,c}(\omega_1,\omega_2) \geq \lambda\big)\, d\rho(\omega_2) > \lambda\Big\}\, d\rho_1(\omega_1).
\end{aligned}$$

Thus we have

$$\mathbb{P}(\mathbb{E}_{\omega_2}(\gamma_{m,c}(\omega_1,\omega_2))>\lambda)\leq \mathbb{P}\Big(\gamma_{m,c}(\omega_1,\omega_2)\geq\lambda\Big)/\lambda\leq \exp\Big(-m\lambda^2/8+(T_c+1)\log 2\Big)/\lambda.$$

For any λ and c, summing up the right hand side over $m=1$ to ∞ is finite, hence the theorem follows from the Borel-Cantelli lemma. ■

Remark 10 We note that M_m/m converges to 1 almost surely even if $\mathcal{X}$ is not bounded. Indeed, to see this, fix $\varepsilon>0$, and let $\mathcal{X}'\subseteq\mathcal{X}$ be a bounded set such that $\mathbb{P}(\mathcal{X}')>1-\varepsilon$. Then, with probability one,

$$\#(\text{unpaired samples in}\mathcal{X}')/m\to 0,$$

by Lemma 9. In addition,

$$\max\big(\#(\text{training samples not in }\mathcal{X}'),\#(\text{testing samples not in }\mathcal{X}')\big)/m\to\varepsilon.$$

Notice that

$$\begin{aligned}M_m\geq m&-\#(\text{unpaired samples in }\mathcal{X}')\\&-\max\big(\#(\text{training samples not in }\mathcal{X}'),\#(\text{testing samples not in }\mathcal{X}')\big).\end{aligned}$$

Hence

$$\lim_{m\to\infty}M_m/m\geq 1-\varepsilon,$$

almost surely. Since ε is arbitrary, we have $M_m/m\to 1$ almost surely.

Next, we prove an analog of Theorem 8 for the kernelized case, and then show that these two imply statistical consistency of linear and kernelized SVMs. Again, let $\mathcal{X}\subseteq\mathbb{R}^n$ be bounded, and suppose the training samples $(\mathbf{x}_i,y_i)_{i=1}^\infty$ are generated i.i.d. according to an unknown distribution $\mathbb{P}$ supported on $\mathcal{X}\times\{-1,+1\}$.

Theorem 11 *Denote* $K\triangleq\max_{\mathbf{x}\in\mathcal{X}}k(\mathbf{x},\mathbf{x})$. *Suppose there exists* $\rho>0$ *and a continuous non-decreasing function* $f:\mathbb{R}^+\to\mathbb{R}^+$ *satisfying* $f(0)=0$, *such that:*

$$k(\mathbf{x},\mathbf{x})+k(\mathbf{x}',\mathbf{x}')-2k(\mathbf{x},\mathbf{x}')\leq f(\|\mathbf{x}-\mathbf{x}'\|_2^2),\quad\forall\mathbf{x},\mathbf{x}'\in\mathcal{X},\|\mathbf{x}-\mathbf{x}'\|_2\leq\rho.$$

Then there exists a random sequence $\{\gamma_{m,c}\}$ *such that:*

1. $\forall c>0$, $\lim_{m\to\infty}\gamma_{m,c}=0$ *almost surely, and the convergence is uniform in* $\mathbb{P}$*;*
2. *the following bounds on the Bayes loss and the hinge loss hold uniformly for all* $(\mathbf{w},b)\in\mathcal{H}\times\mathbb{R}$

$$\begin{aligned}&\mathbb{E}_{\mathbb{P}}(\mathbf{1}_{y\neq sgn(\langle\mathbf{w},\Phi(\mathbf{x})\rangle+b)})\leq\gamma_{m,c}+c\|\mathbf{w}\|_{\mathcal{H}}+\frac{1}{m}\sum_{i=1}^m\max\big[1-y_i(\langle\mathbf{w},\Phi(\mathbf{x}_i)\rangle+b),0\big],\\&\mathbb{E}_{(\mathbf{x},y)\sim\mathbb{P}}\big(\max(1-y(\langle\mathbf{w},\Phi(\mathbf{x})\rangle+b),0)\big)\leq\\&\qquad\gamma_{m,c}(1+K\|\mathbf{w}\|_{\mathcal{H}}+|b|)+c\|\mathbf{w}\|_{\mathcal{H}}+\frac{1}{m}\sum_{i=1}^m\max\big[1-y_i(\langle\mathbf{w},\Phi(\mathbf{x}_i)\rangle+b),0\big].\end{aligned}$$

Proof As in the proof of Theorem 8, we generate a set of m testing samples and m training samples, and then lower-bound the number of samples that can form a *sample pair* in the feature-space; that is, a pair consisting of a training sample $(\mathbf{x}, y)$ and a testing sample $(\mathbf{x}', y')$ such that $y = y'$ and $\|\Phi(\mathbf{x}) - \Phi(\mathbf{x}')\|_{\mathcal{H}} \leq c$. In contrast to the finite-dimensional sample space, the feature space may be infinite dimensional, and thus our decomposition may have an infinite number of "bricks." In this case, our multinomial random variable argument used in the proof of Lemma 9 breaks down. Nevertheless, we are able to lower bound the number of sample pairs in the feature space by the number of sample pairs in the *sample space*.

Define $f^{-1}(\alpha) \triangleq \max\{\beta \geq 0 | f(\beta) \leq \alpha\}$. Since $f(\cdot)$ is continuous, $f^{-1}(\alpha) > 0$ for any $\alpha > 0$. Now notice that by Lemma 7, if a testing sample $\mathbf{x}$ and a training sample $\mathbf{x}'$ belong to a "brick" with length of each side $\min(\rho/\sqrt{n}, f^{-1}(c^2)/\sqrt{n})$ in the *sample space* (see the proof of Lemma 9), $\|\Phi(\mathbf{x}) - \Phi(\mathbf{x}')\|_{\mathcal{H}} \leq c$. Hence the number of *sample pairs* in the feature space is lower bounded by the number of pairs of samples that fall in the same brick in the sample space. We can cover $\mathcal{X}$ with finitely many (denoted as T_c) such bricks since $f^{-1}(c^2) > 0$. Then, a similar argument as in Lemma 9 shows that the ratio of samples that form pairs in a brick converges to 1 as m increases. Further notice that for M paired samples, the total testing error and hinge-loss are both upper-bounded by

$$cM\|\mathbf{w}\|_{\mathcal{H}} + \sum_{i=1}^{M} \max\left[1 - y_i(\langle \mathbf{w}, \Phi(\mathbf{x}_i)\rangle + b), 0\right].$$

The rest of the proof is identical to Theorem 8. In particular, Inequality (15) still holds. ■

Note that the condition in Theorem 11 is satisfied by most commonly used kernels, for example, homogeneous polynominal kernels and Gaussian radial basis functions. This condition requires that the feature mapping is "smooth" and hence preserves "locality" of the disturbance, that is, small disturbance in the sample space guarantees the corresponding disturbance in the feature space is also small. It is easy to construct non-smooth kernel functions which do not generalize well. For example, consider the following kernel:

$$k(\mathbf{x}, \mathbf{x}') = \begin{cases} 1 & \mathbf{x} = \mathbf{x}'; \\ 0 & \mathbf{x} \neq \mathbf{x}'. \end{cases}$$

A standard RKHS regularized SVM using this kernel leads to a decision function

$$\text{sign}(\sum_{i=1}^{m} \alpha_i k(\mathbf{x}, \mathbf{x}_i) + b),$$

which equals $\text{sign}(b)$ and provides no meaningful prediction if the testing sample $\mathbf{x}$ is not one of the training samples. Hence as m increases, the testing error remains as large as 50% regardless of the tradeoff parameter used in the algorithm, while the training error can be made arbitrarily small by fine-tuning the parameter.

5.1 Convergence to Bayes Risk

Next we relate the results of Theorem 8 and Theorem 11 to the standard consistency notion, that is, convergence to the Bayes Risk (Steinwart, 2005). The key point of interest in our proof is the use of a robustness condition in place of a VC-dimension or stability condition used in Steinwart (2005). The proof in Steinwart (2005) has 4 main steps. They show: (i) there always exists a minimizer to

the expected regularized (kernel) hinge loss; (ii) the expected regularized hinge loss of the minimizer converges to the expected hinge loss as the regularizer goes to zero; (iii) if a sequence of functions asymptotically have optimal expected hinge loss, then they also have optimal expected loss; and (iv) the expected hinge loss of the minimizer of the regularized *training* hinge loss concentrates around the empirical regularized hinge loss. In Steinwart (2005), this final step, (iv), is accomplished using concentration inequalities derived from VC-dimension considerations, and stability considerations.

Instead, we use our robustness-based results of Theorem 8 and Theorem 11 to replace these approaches (Lemmas 3.21 and 3.22 in Steinwart 2005) in proving step (iv), and thus to establish the main result.

Recall that a classifier is a rule that assigns to every training set $T = \{\mathbf{x}_i, y_i\}_{i=1}^m$ a measurable function f_T. The risk of a measurable function $f : \mathcal{X} \to \mathbb{R}$ is defined as

$$\mathcal{R}_{\mathbb{P}}(f) \triangleq \mathbb{P}(\{\mathbf{x}, y : \text{sign} f(\mathbf{x}) \neq y\}).$$

The smallest achievable risk

$$\mathcal{R}_{\mathbb{P}} \triangleq \inf\{\mathcal{R}_{\mathbb{P}}(f) | f : \mathcal{X} \to \mathbb{R} \,\text{measurable}\}$$

is called the *Bayes Risk* of $\mathbb{P}$. A classifier is said to be strongly uniformly consistent if for all distributions P on $\mathcal{X} \times [-1, +1]$, the following holds almost surely.

$$\lim_{m\to\infty} \mathcal{R}_{\mathbb{P}}(f_T) = \mathcal{R}_{\mathbb{P}}.$$

Without loss of generality, we only consider the kernel version. Recall a definition from Steinwart (2005).

Definition 12 *Let $C(\mathcal{X})$ be the set of all continuous functions defined on a compact metric space $\mathcal{X}$. Consider the mapping $I : \mathcal{H} \to C(\mathcal{X})$ defined by $I\mathbf{w} \triangleq \langle \mathbf{w}, \Phi(\cdot)\rangle$. If I has a dense image, we call the kernel* universal.

Roughly speaking, if a kernel is universal, then the corresponding RKHS is rich enough to satisfy the condition of step (ii) above.

Theorem 13 *If a kernel satisfies the condition of Theorem 11, and is universal, then the Kernel SVM with $c \downarrow 0$ sufficiently slowly is strongly uniformly consistent.*

Proof We first introduce some notation, largely following Steinwart (2005). For some probability measure μ and $(\mathbf{w}, b) \in \mathcal{H} \times \mathbb{R}$,

$$R_{L,\mu}((\mathbf{w}, b)) \triangleq \mathbb{E}_{(\mathbf{x},y)\sim\mu}\big\{\max(0, 1 - y(\langle \mathbf{w}, \Phi(\mathbf{x})\rangle + b))\big\},$$

is the expected hinge-loss under probability μ, and

$$R^c_{L,\mu}((\mathbf{w}, b)) \triangleq c\|\mathbf{w}\|_{\mathcal{H}} + \mathbb{E}_{(\mathbf{x},y)\sim\mu}\big\{\max(0, 1 - y(\langle \mathbf{w}, \Phi(\mathbf{x})\rangle + b))\big\}$$

is the regularized expected hinge-loss. Hence $R_{L,\mathbb{P}}(\cdot)$ and $R^c_{L,\mathbb{P}}(\cdot)$ are the expected hinge-loss and regularized expected hinge-loss under the generating probability $\mathbb{P}$. If μ is the empirical distribution of m samples, we write $R_{L,m}(\cdot)$ and $R^c_{L,m}(\cdot)$ respectively. Notice $R^c_{L,m}(\cdot)$ is the objective function of the SVM. Denote its solution by $f_{m,c}$, that is, the classifier we get by running SVM with m samples

and parameter c. Further denote by $f_{\mathbb{P},c} \in \mathcal{H} \times \mathbb{R}$ the minimizer of $R^c_{L,\mathbb{P}}(\cdot)$. The existence of such a minimizer is proved in Lemma 3.1 of Steinwart (2005) (step (i)). Let

$$\mathcal{R}_{L,\mathbb{P}} \triangleq \min_{f \text{ measurable}} \mathbb{E}_{\mathbf{x},y\sim\mathbb{P}}\Big\{ \max\big(1 - yf(\mathbf{x}), 0\big)\Big\},$$

that is, the smallest achievable hinge-loss for all measurable functions.

The main content of our proof is to use Theorems 8 and 11 to prove step (iv) in Steinwart (2005). In particular, we show: if $c \downarrow 0$ "slowly", we have with probability one

$$\lim_{m\to\infty} R_{L,\mathbb{P}}(f_{m,c}) = \mathcal{R}_{L,\mathbb{P}}. \tag{16}$$

To prove Equation (16), denote by $\mathbf{w}(f)$ and $b(f)$ as the weight part and offset part of any classifier f. Next, we bound the magnitude of $f_{m,c}$ by using $R^c_{L,m}(f_{m,c}) \le R^c_{L,m}(\mathbf{0},0) \le 1$, which leads to

$$\|\mathbf{w}(f_{m,c})\|_{\mathcal{H}} \le 1/c$$

and

$$|b(f_{m,c})| \le 2 + K\|\mathbf{w}(f_{m,c})\|_{\mathcal{H}} \le 2 + K/c.$$

From Theorem 11 (note that the bound holds uniformly for all $(\mathbf{w}, b)$), we have

$$\begin{aligned}
R_{L,\mathbb{P}}(f_{m,c}) &\le \gamma_{m,c}[1 + K\|\mathbf{w}(f_{m,c})\|_{\mathcal{H}} + |b|] + R^c_{L,m}(f_{m,c}) \\
&\le \gamma_{m,c}[3 + 2K/c] + R^c_{L,m}(f_{m,c}) \\
&\le \gamma_{m,c}[3 + 2K/c] + R^c_{L,m}(f_{\mathbb{P},c}) \\
&= \mathcal{R}_{L,\mathbb{P}} + \gamma_{m,c}[3 + 2K/c] + \big\{R^c_{L,m}(f_{\mathbb{P},c}) - R^c_{L,\mathbb{P}}(f_{\mathbb{P},c})\big\} + \big\{R^c_{L,\mathbb{P}}(f_{\mathbb{P},c}) - \mathcal{R}_{L,\mathbb{P}}\big\} \\
&= \mathcal{R}_{L,\mathbb{P}} + \gamma_{m,c}[3 + 2K/c] + \big\{R_{L,m}(f_{\mathbb{P},c}) - R_{L,\mathbb{P}}(f_{\mathbb{P},c})\big\} + \big\{R^c_{L,\mathbb{P}}(f_{\mathbb{P},c}) - \mathcal{R}_{L,\mathbb{P}}\big\}.
\end{aligned}$$

The last inequality holds because $f_{m,c}$ minimizes $R^c_{L,m}$.

It is known (Steinwart, 2005, Proposition 3.2) (step (ii)) that if the kernel used is rich enough, that is, universal, then

$$\lim_{c\to 0} R^c_{L,\mathbb{P}}(f_{\mathbb{P}}, c) = \mathcal{R}_{L,\mathbb{P}}.$$

For fixed $c > 0$, we have

$$\lim_{m\to\infty} R_{L,m}(f_{\mathbb{P},c}) = R_{L,\mathbb{P}}(f_{\mathbb{P},c}),$$

almost surely due to the strong law of large numbers (notice that $f_{\mathbb{P},c}$ is a fixed classifier), and $\gamma_{m,c}[3 + 2K/c] \to 0$ almost surely. Notice that neither convergence rate depends on $\mathbb{P}$. Therefore, if $c \downarrow 0$ sufficiently slowly,[3] we have almost surely

$$\lim_{m\to\infty} R_{L,\mathbb{P}}(f_{m,c}) \le \mathcal{R}_{L,\mathbb{P}}.$$

Now, for any m and c, we have $R_{L,\mathbb{P}}(f_{m,c}) \ge \mathcal{R}_{L,\mathbb{P}}$ by definition. This implies that Equation (16) holds almost surely, thus giving us step (iv).

Finally, Proposition 3.3. of Steinwart (2005) shows step (iii), namely, approximating hinge loss is sufficient to guarantee approximation of the Bayes loss. Thus Equation (16) implies that the risk

3. For example, we can take $\{c(m)\}$ be the smallest number satisfying $c(m) \ge m^{-1/8}$ and $T_{c(m)} \le m^{1/8}/\log 2 - 1$. Inequality (15) thus leads to $\sum_{m=1}^{\infty} P(\gamma_{m,c(m)}/c(m) \ge m^{1/4}) \le +\infty$ which implies uniform convergence of $\gamma_{m,c(m)}/c(m)$.

of function $f_{m,c}$ converges to Bayes risk. ■

Before concluding this section, we remark that although we focus in this paper the hinge-loss function and the RKHS norm regularizer, the robustness approach to establish consistency can be generalized to other regularization schemes and loss functions. Indeed, throughout the proof we only require that the regularized loss (that is, the training loss plus the regularization penalty) is an upper bound of the minimax error with respect to certain set-inclusive uncertainty. This is a property satisfied by many classification algorithms even though an exact equivalence relationship similar to the one presented in this paper may not exist. This suggests using the robustness view to derive sharp sample complexity bounds for a broad class of algorithms (e.g., Steinwart and Christmann, 2008).

6. Concluding Remarks

This work considers the relationship between robust and regularized SVM classification. In particular, we prove that the standard norm-regularized SVM classifier is in fact the solution to a robust classification setup, and thus known results about regularized classifiers extend to robust classifiers. To the best of our knowledge, this is the first explicit such link between regularization and robustness in pattern classification. The interpretation of this link is that norm-based regularization essentially builds in a robustness to sample noise whose probability level sets are symmetric unit balls with respect to the dual of the regularizing norm. It would be interesting to understand the performance gains possible when the noise does not have such characteristics, and the robust setup is used in place of regularization with appropriately defined uncertainty set.

Based on the robustness interpretation of the regularization term, we re-proved the consistency of SVMs without direct appeal to notions of metric entropy, VC-dimension, or stability. Our proof suggests that the ability to handle disturbance is crucial for an algorithm to achieve good generalization ability. In particular, for "smooth" feature mappings, the robustness to disturbance in the observation space is guaranteed and hence SVMs achieve consistency. On the other-hand, certain "non-smooth" feature mappings fail to be consistent simply because for such kernels the robustness in the feature-space (guaranteed by the regularization process) does not imply robustness in the observation space.

Acknowledgments

We thank the editor and three anonymous reviewers for significantly improving the accessibility of this manuscript. We also benefited from comments from participants in ITA 2008 and at a NIPS 2008 workshop on optimization. This research was partially supported by the Canada Research Chairs Program, by the Israel Science Foundation (contract 890015), by a Horev Fellowship, by NSF Grants EFRI-0735905, CNS-0721532, and a grant from DTRA.

Appendix A.

In this appendix we show that for RBF kernels, it is possible to relate robustness in the feature space and robustness in the sample space more directly.

Theorem 14 *Suppose the Kernel function has the form $k(\mathbf{x},\mathbf{x}') = f(\|\mathbf{x}-\mathbf{x}'\|)$, with $f:\mathbb{R}^+\to\mathbb{R}$ a decreasing function. Denote by $\mathcal{H}$ the RKHS space of $k(\cdot,\cdot)$ and $\Phi(\cdot)$ the corresponding feature mapping. Then we have for any $\mathbf{x}\in\mathbb{R}^n$, $\mathbf{w}\in\mathcal{H}$ and $c>0$,*

$$\sup_{\|\delta\|\le c}\langle \mathbf{w}, \Phi(\mathbf{x}-\delta)\rangle = \sup_{\|\delta_\phi\|_{\mathcal{H}}\le\sqrt{2f(0)-2f(c)}}\langle \mathbf{w}, \Phi(\mathbf{x})+\delta_\phi\rangle.$$

Proof We show that the left-hand-side is not larger than the right-hand-side, and vice versa.

First we show

$$\sup_{\|\delta\|\le c}\langle \mathbf{w}, \Phi(\mathbf{x}-\delta)\rangle \le \sup_{\|\delta_\phi\|_{\mathcal{H}}\le\sqrt{2f(0)-2f(c)}}\langle \mathbf{w}, \Phi(\mathbf{x})-\delta_\phi\rangle. \tag{17}$$

We notice that for any $\|\delta\|\le c$, we have

$$\begin{aligned}
&\langle \mathbf{w}, \Phi(\mathbf{x}-\delta)\rangle\\
=&\Big\langle \mathbf{w}, \Phi(\mathbf{x})+\big(\Phi(\mathbf{x}-\delta)-\Phi(\mathbf{x})\big)\Big\rangle\\
=&\langle \mathbf{w}, \Phi(\mathbf{x})\rangle + \langle \mathbf{w}, \Phi(\mathbf{x}-\delta)-\Phi(\mathbf{x})\rangle\\
\le&\langle \mathbf{w}, \Phi(\mathbf{x})\rangle + \|\mathbf{w}\|_{\mathcal{H}}\cdot\|\Phi(\mathbf{x}-\delta)-\Phi(\mathbf{x})\|_{\mathcal{H}}\\
\le&\langle \mathbf{w}, \Phi(\mathbf{x})\rangle + \|\mathbf{w}\|_{\mathcal{H}}\sqrt{2f(0)-2f(c)}\\
=&\sup_{\|\delta_\phi\|_{\mathcal{H}}\le\sqrt{2f(0)-2f(c)}}\langle \mathbf{w}, \Phi(\mathbf{x})-\delta_\phi\rangle.
\end{aligned}$$

Taking the supremum over δ establishes Inequality (17).

Next, we show the opposite inequality,

$$\sup_{\|\delta\|\le c}\langle \mathbf{w}, \Phi(\mathbf{x}-\delta)\rangle \ge \sup_{\|\delta_\phi\|_{\mathcal{H}}\le\sqrt{2f(0)-2f(c)}}\langle \mathbf{w}, \Phi(\mathbf{x})-\delta_\phi\rangle. \tag{18}$$

If $f(c)=f(0)$, then Inequality 18 holds trivially, hence we only consider the case that $f(c)<f(0)$. Notice that the inner product is a continuous function in $\mathcal{H}$, hence for any $\varepsilon>0$, there exists a δ'_ϕ such that

$$\langle \mathbf{w}, \Phi(\mathbf{x})-\delta'_\phi\rangle > \sup_{\|\delta_\phi\|_{\mathcal{H}}\le\sqrt{2f(0)-2f(c)}}\langle \mathbf{w}, \Phi(\mathbf{x})-\delta_\phi\rangle-\varepsilon;\quad \|\delta'_\phi\|_{\mathcal{H}}<\sqrt{2f(0)-2f(c)}.$$

Recall that the RKHS space is the completion of the feature mapping, thus there exists a sequence of $\{\mathbf{x}'_i\}\in\mathbb{R}^n$ such that

$$\Phi(\mathbf{x}'_i)\to\Phi(\mathbf{x})-\delta'_\phi, \tag{19}$$

which is equivalent to

$$\big(\Phi(\mathbf{x}'_i)-\Phi(\mathbf{x})\big)\to-\delta'_\phi.$$

This leads to

$$\begin{aligned}
&\lim_{i\to\infty}\sqrt{2f(0)-2f(\|\mathbf{x}'_i-\mathbf{x}\|)}\\
=&\lim_{i\to\infty}\|\Phi(\mathbf{x}'_i)-\Phi(\mathbf{x})\|_{\mathcal{H}}\\
=&\|\delta'_\phi\|_{\mathcal{H}}<\sqrt{2f(0)-2f(c)}.
\end{aligned}$$

Since f is decreasing, we conclude that $\|\mathbf{x}_i' - \mathbf{x}\| \leq c$ holds except for a finite number of i. By (19) we have

$$\langle \mathbf{w}, \Phi(\mathbf{x}_i') \rangle \to \langle \mathbf{w}, \Phi(\mathbf{x}) - \delta_\phi' \rangle > \sup_{\|\delta_\phi\|_{\mathcal{H}} \leq \sqrt{2f(0)-2f(c)}} \langle \mathbf{w}, \Phi(\mathbf{x}) - \delta_\phi \rangle - \varepsilon,$$

which means

$$\sup_{\|\delta\| \leq c} \langle \mathbf{w}, \Phi(\mathbf{x} - \delta) \rangle \geq \sup_{\|\delta_\phi\|_{\mathcal{H}} \leq \sqrt{2f(0)-2f(c)}} \langle \mathbf{w}, \Phi(\mathbf{x}) - \delta_\phi \rangle - \varepsilon.$$

Since ε is arbitrary, we establish Inequality (18).

Combining Inequality (17) and Inequality (18) proves the theorem. ■

Abstract

In the machine learning community, the Bayesian scoring criterion is widely used for model selection problems. One of the fundamental theoretical properties justifying the usage of the Bayesian scoring criterion is its consistency. In this paper we refine this property for the case of binomial Bayesian network models. As a by-product of our derivations we establish strong consistency and obtain the law of iterated logarithm for the Bayesian scoring criterion.

Keywords: Bayesian networks, consistency, scoring criterion, model selection, BIC

1. Introduction

Bayesian networks are graphical structures which characterize probabilistic relationships among variables of interest and serve as a ground model for doing probabilistic inference in large systems of interdependent components. A basic element of a Bayesian network is a directed acyclic graph (DAG) which is bound to an underlying joint probability distribution by the Markov condition. The absence of certain arcs (edges) in a DAG encodes conditional independences in this distribution. DAG's not only provide a starting point for implementation of inference and parameter learning algorithms, but they also, due to their graphical nature, offer an intuitive picture of the relationships among the variables. It happens too often that researchers have only a random sample from a probability distribution and face a problem of choosing the appropriate DAG between a large number of competing structures. This, effectively, constitutes the model selection problem in the space of Bayesian networks. The methodology which is concerned with solving such task is called Bayesian structure learning.

Suppose that the data consists of n i.i.d. random vectors $X_1, \ldots, X_n$ with each X_i having the unknown probability distribution P. We define a probability space Ω with measure Pr for infinite i.i.d. sequences $X_1, X_2, \ldots$ having distribution P. There are many structures which can form a Bayesian

network with the distribution P (see Section 2 for formal definitions and examples), however not all of them are optimal for future analysis. Indeed, since the presence of an arc (edge) does not necessarily guarantee direct dependency between corresponding variables, a complete DAG constitutes a Bayesian network with any probability distribution, yet provides no information about conditional independences in P. It is natural to seek structures which not only form a Bayesian network with P, but also entail only conditional independences in this distribution. These DAGs are called *faithful* to P or else *perfect maps* of P. Unfortunately, it turns out that not all probability distributions have an associated faithful structure. In this case it is desirable to identify a structure which satisfies certain "optimality" properties with respect to P. Roughly speaking, we want to include only those edges that are necessary for describing P.

A *scoring criterion* for DAGs is a function that assigns a value to each DAG under consideration based on the data. Suppose M is the set of all DAGs of a fixed size. Under the Bayesian approach to structure learning, the DAG m is chosen from M such that m maximizes the posterior probability given the observed data D:

$$p(m|D,\psi) = \frac{p(m|\psi)p(D|m,\psi)}{p(D|\psi)} = \frac{p(m|\psi)\int_{\Omega_m} p(D|m,\Theta_m,\psi)p(\Theta_m|m,\psi)d\Theta_m}{\sum_{m\in M} p(m|\psi)\int_{\Omega_m} p(D|m,\Theta_m,\psi)p(\Theta_m|m,\psi)d\Theta_m}, \quad (1)$$

where Θ_m denotes the set of parameters of the conditional distributions of each "node given its parents" for all the nodes of the DAG m, Ω_m denotes the domain of these parameters, and ψ denotes the system of parameter priors. The quantity $P(D|m,\psi)$ is called the *marginal likelihood*, *Bayesian scoring criterion* or else *Score* of the graph m. We denote it as $\texttt{score}_B(D|m)$. Assuming $\sum_{m\in M} p(m|\psi) = 1$ for all $m \in M$, the Bayesian scoring criterion provides a measure of posterior certainty of the graph m under the prior system ψ.

It is quite interesting to see if the Bayesian scoring criterion is *consistent*, that is, as the size of data D approaches infinity, the criterion is maximized at the DAG which forms a Bayesian network with P and has smallest dimension. Based on the fundamental results of Haughton (1988) and Geiger et al. (2001), the consistency of Bayesian scoring criterion has been established for the class of multinomial Bayesian networks. Chickering (2002) provides a detailed sketch of the proof. Further, for the same model class, if P admits a faithful DAG representation m, then m has the smallest dimension among all DAGs which form a Bayesian network with P (see, for example, Neapolitan, 2004, Corollary 8.1) . Therefore, due to consistency of the Bayesian scoring criterion, we can conclude that if P admits a faithful DAG representation m then, in the limit, the Bayesian scoring criterion will be maximized at m. This last result is naturally expected: as more information becomes available, a scoring criterion should recognize the properties of the underlying distribution P with increasing precision.

Although the consistency property provides insight into the limiting properties of the posterior distribution over the graph space, it is interesting to know at what rate (as a function of sample size) the graph(s) with the smallest dimension become favored by the Bayesian scoring criterion. In this article we address this question for the case of binomial Bayesian network models. We also show that in addition to being consistent for these models, the Bayesian scoring criterion is also *strongly consistent* (see Definition 4). Our proofs are mostly self-contained, relying mainly on well-known limit theorems of classical probability. At one point we require the input of Haughton (1988) and Geiger et al. (2001) mentioned in the preceding paragraph (but note that their results only deal with consistency, not strong consistency).

It may be possible to re-derive our results using the machinery of VC classes (Vapnik, 1998) or empirical process theory (e.g., van der Vaart and Wellner, 1996), but to our knowledge this has not yet been done. However, one point of our paper is to show that the results are amenable to fairly transparent and accessible proofs, and do not require the overhead of these well-developed theoretical frameworks. That being said, we note that our method assumes that the networks have fixed finite size, and other approaches may be better suited to handling the situation in which the network size gets large.

The rest of the paper is organized as follows. Background and notation appear in Section 2, with some illustrative examples. Our results are presented in Section 3. Section 4 contains some discussion. Proofs appear in the Appendix.

2. Background

A directed graph is a pair (V,E), where $V = \{1,\ldots,N\}$ is a finite set whose elements are called nodes (or vertices), and E is a set of ordered pairs of distinct components of V. Elements of E are called edges (or arcs). If $(i_1,i_2) \in E$ we say that there is an edge from i_1 to i_2. Given a set of nodes $\{i_1,i_2,\ldots,i_k\}$ where $k \geq 2$ and $(i_r,i_{r+1}) \in E$ for $1 \leq r \leq k-1$, we call a sequence of edges $((i_1,i_2),\ldots,(i_{k-1},i_k))$ a path from i_1 to i_k . A path from a node to itself is called a directed cycle. Additionally, a directed graph is called a directed acyclic graph (DAG) if it contains no directed cycles. Given a DAG $m = (V,E)$, a node i_2 is called a parent of i_1 if there is an edge from i_2 to i_1. We write $\mathrm{Pa}(i)$ to denote the set of parents of a node i. A node i_2 is called a descendant of i_1 if there is a path from i_1 to i_2, and i_2 is called a nondescendant of i_1 if i_2 is not a descendant of i_1.

Suppose $m = (V,E)$ is a DAG, and $X = \{\xi_1,\ldots,\xi_N\}$ is a random vector that follows a joint probability distribution P. For each i, let ξ_i correspond to the i^{th} node of V. For $A \subset V$, let ξ_A denote the collection of variables $\{\xi_i : i \in A\}$. (In the literature, sometimes this collection is written simply as A. We will occasionally following this convention, but in mathematical expressions about probabilities we usually prefer to distinguish clearly between the set of variables A and their values ξ_A.) In particular, $\xi_{\mathrm{Pa}(i)}$ describes the states of the parents of node i. We say that (m,P) satisfies the Markov condition if each component of X is conditionally independent of the set of all its nondescendants given the set of all its parents. Finally, if (m,P) satisfies the Markov condition, then we say that (m,P) is a Bayesian network, and that m forms a Bayesian network with P. See Neapolitan (2004) for more details.

The independence constraints encoded in a Bayesian network allow for a simplification of the joint probability distribution P which is captured by the factorization theorem (Neapolitan, 2004, Theorem 1.4):

Theorem 1 *If (m,P) satisfies the Markov condition, then P is equal to the product of its conditional distributions of all nodes given the values of their parents, whenever these conditional distributions exist:*

$$P(\xi_1,\ldots,\xi_N) = \prod_{i=1}^{N} P\left(\xi_i|\xi_{Pa(i)}\right).$$

Consider the following example (also see Neapolitan, 2004, Example 2.9). Rewrite the variables $(\xi_1,\xi_2,\xi_3,\xi_4) = (U,Y,Z,W)$. Suppose we have a Bayesian network (m,P) where m is shown in Figure 1 and the distribution P satisfies the conditions presented in Table 1 for some

$P(u_1) = a$	$P(y_1\|u_1) = 1-(b+c)$	$P(z_1\|y_1) = e$	$P(w_1\|z_1) = g$
$P(u_2) = 1-a$	$P(y_2\|u_1) = c$	$P(z_2\|y_1) = 1-e$	$P(w_2\|z_1) = 1-g$
	$P(y_3\|u_1) = b$	$P(z_1\|y_2) = e$	$P(w_1\|z_2) = h$
	$P(y_1\|u_2) = 1-(b+d)$	$P(z_2\|y_2) = 1-e$	$P(w_2\|z_2) = 1-h$
	$P(y_2\|u_2) = d$	$P(z_1\|y_3) = f$	
	$P(y_3\|u_2) = b$	$P(z_2\|y_3) = 1-f$	

Table 1: Constraints on distribution P

Figure 1: The DAG m for our first example.

$0 \leq a,b,c,\ldots,g,h \leq 1$. Note that, due to Theorem 1, the equations in Table 1 fully determine P as a function of $a,b,c,\ldots,g,h$. Further, since (m,P) satisfies the Markov condition, each node is conditionally independent of the set of all its nondescendants given its parents. For example, we see that Z and U are conditionally independent given Y (written $Z \perp\!\!\!\perp U\,|\,Y$). Do these conditional independences entail any other conditional independences, that is, are there any other conditional independences which P must satisfy other than the one based on a node's parents? The answer is positive. For example, if (m,P) satisfies the Markov condition, then

$$P(w|u,y) = \sum_u P(w|z,u,y)P(z|u,y) = \sum_u P(w|z,y)P(z|y) = P(w|y)$$

and hence $W \perp\!\!\!\perp U\,|\,Y$. Explicitly, the notion of "entailed conditional independence" is given in the following definition:

Definition 2 *Let $m = (V,E)$ be a DAG where V is a set of random variables, and let $A,B,C \subset V$. We say that, based on Markov condition, m entails conditional independence $A \perp\!\!\!\perp B\,|\,C$ if $A \perp\!\!\!\perp B\,|\,C$ holds for every $P \in P_m$, where P_m is the set of all probability distributions P such that (m,P) satisfies the Markov condition.*

We say that there is a *direct dependency* between variables A and B in P if A and B are not conditionally independent given any subset of V. Based on the Markov condition, the absence of an edge between A and B implies that there is no direct dependency between A and B. However, the Markov condition is not sufficient to guarantee that the presence of an edge means direct dependency. In general, given a Bayesian network (m,P), we would want an edge in m to mean there is a direct dependency. In this case the DAG would become what it is naturally expected to be—a graphical representation of the structure of relationships between variables. The faithfulness condition as defined below indeed reflects this.

Definition 3 *We say that a Bayesian network (m,P) satisfies the faithfulness condition if, based on the Markov condition, m entails all and only the conditional independences in P. When (m,P)*

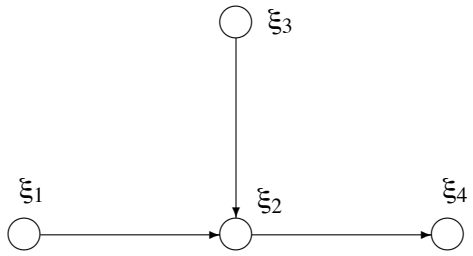

Figure 2: A second example of a DAG.

satisfies the faithfulness condition, we say that m and P are faithful to each other and we say m is a perfect map of P.

It is easy to see that the Bayesian network (m,P), where m is shown in Figure 1 and P satisfies the constraints in Table 1, does not satisfy the faithfulness condition. Indeed, Table 1 implies that $U \perp\!\!\!\perp Z$, but this independence is not entailed by m based on the Markov condition. As shown in Example 2.10 of Neapolitan (2004), the distribution P of this example has no perfect map. However, it is not hard to see that the DAG of Figure 1 is "optimal" in the sense that no DAG with fewer edges forms a Bayesian network with P.

In this paper we concentrate on Bayesian networks over a set of variables $X = \{\xi_1,\ldots,\xi_N\} \sim P$ where each variable takes values from the set $\{1,2\}$. Let m be a DAG with nodes $1,\ldots,N$. The probability distributions in P_m can be parameterized according to the conditional distributions of Theorem 1 as follows. For each node i, let $|\mathrm{Pa}(i)|$ be the number of parents of i and let $q_i(m) = 2^{|\mathrm{Pa}(i)|}$ be the number of possible states of the set of variables $\xi_{\mathrm{Pa}(i)}$. Consider a fixed list of the $q_i(m)$ possible states of $\xi_{\mathrm{Pa}(i)}$. For $j \in \{1,\ldots,q_i(m)\}$, we shall write "$\xi_{\mathrm{Pa}(i)} = j$" to mean that the parents of node i are in the states given by the j^{th} item in the list. For $k = 1,2$ and $j = 1,\ldots,q_i(m)$, we write $\theta_{ijk} = P(\xi_i = k \,|\, \xi_{\mathrm{Pa}(i)} = j)$. Observe that $\theta_{ij2} = 1 - \theta_{ij1}$. We shall write Θ_m to denote the vector of all θ_{ij1}'s for m:

$$\Theta_m \;=\; \big(\theta_{ij1} \,:\, i = 1,\ldots,N,\, j = 1,\ldots,q_i(m)\big) \;\in\; [0,1]^{k_m},$$

where $k_m = \sum_{i=1}^{N} q_i(m)$. Then each Θ_m in $[0,1]^{k_m}$ determines a probability measure $P = P_{\Theta_m}$ such that (m,P) is Bayesian network; and conversely, if (m,P) is a Bayesian network, then $P = P_{\Theta_m}$ for some $\Theta_m \in [0,1]^{k_m}$.

To illustrate this notation, consider the DAG m in Figure 2. Here, $\mathrm{Pa}(1) = \emptyset = \mathrm{Pa}(3)$, $\mathrm{Pa}(2) = \{1,3\}$, and $\mathrm{Pa}(4) = \{3\}$, and so $q_1(m) = 2^0 = q_3(m)$, $q_2(m) = 2^2$, and $q_4(m) = 2^1$. We could fix the list of possible states of $\xi_{\mathrm{Pa}(4)}$ to be "1,2", and the list for $\xi_{\mathrm{Pa}(2)}$ to be "(1,1), (1,2), (2,1), (2,2)" (with the understanding that the ordering is (ξ_1,ξ_3)). For the latter list, we have for example

$$\theta_{231} \;=\; P\big(\xi_2 = 1 \,|\, \xi_{\mathrm{Pa}(2)} = 3\big) \;=\; P\big(\xi_2 = 1 \,|\, (\xi_1,\xi_3) = (2,1)\big)\,.$$

Since $\mathrm{Pa}(3) = \emptyset$, $P(\xi_{\mathrm{Pa}(3)} = 1) = 1$, and θ_{311} is simply $P(\xi_3 = 1)$. We can write

$$\Theta_m \;=\; (\theta_{111},\theta_{211},\theta_{221},\theta_{231},\theta_{241},\theta_{311},\theta_{411},\theta_{421}),$$

and $k_m = 1+4+1+2 = 8$.

Let $D = D_n = \{X_1, ..., X_n\}$ be fully observed data of size n generated according to Pr, and let N_{ijk} be the number of cases in the database D such that node i takes value k while its parent set $\xi_{\mathrm{Pa}(i)}$ takes the values corresponding to j.

A *probabilistic model* $\mathcal{M}$ for a random vector $X = (\xi_1, \ldots, \xi_N)$ is a set of possible joint probability distributions of its components. If the probability distribution P is a member of a model $\mathcal{M}$, we say P is *included* in $\mathcal{M}$. Let m be a DAG (V,E). A *Bayesian network model* is a pair (m,F) where F is a set of possible parameter vectors Θ_m: each Θ_m in F determines conditional probability distributions for m, such that the joint probability distribution P_{Θ_m} of X (given by the product of these conditional distributions) satisfies the Markov condition with m. (E.g., for the DAG m of Figure 2, the most general choice of F is $[0,1]^8$, but F could also be a subset of $[0,1]^8$.) For simplicity, we shall usually omit F when referring to a Bayesian network model (m,F). In a given class of models, if $\mathcal{M}_2$ includes the probability distribution P, and if there exists no $\mathcal{M}_1$ (in the class) such that $\mathcal{M}_1$ includes P and $\mathcal{M}_1$ has smaller dimension than $\mathcal{M}_2$, then $\mathcal{M}_2$ is called a *parameter optimal map* of P. (E.g. the DAG of Figure 1 is a parameter optimal map of the distribution P of Table 1.) For the Bayesian network models we shall work with in this paper, the dimension of a model m is $k_m = \sum_{i=1}^{N} q_i(m)$. A detailed discussion of probabilistic model selection in the case of Bayesian networks could be found in Neapolitan (2004).

In order to proceed further we would also need a formal definition of consistency. In this definition we assume that the dimensions of the probabilistic models are well-defined. For a more detailed discussion of the definition of consistency see, for example, Neapolitan (2004), Grünwald (2007) and Lahiri (2001).

Definition 4 *Let D_n be a set of values (data) of a set of n mutually independent random vectors $X_1, \ldots, X_n$, each with probability distribution P. Furthermore, let* `score` *be a scoring criterion over some class of models for the random variables that constitute each vector. We say* `score` *is* ***consistent*** *for the class of models if the following two properties hold:*
1. If $\mathcal{M}_1$ includes P and $\mathcal{M}_2$ does not, then

$$\lim_{n\to\infty} Pr(\texttt{score}(D_n, \mathcal{M}_1) > \texttt{score}(D_n, \mathcal{M}_2)) = 1.$$

2. If $\mathcal{M}_1$ and $\mathcal{M}_2$ both include P and $\mathcal{M}_1$ has smaller dimension than $\mathcal{M}_2$, then

$$\lim_{n\to\infty} Pr(\texttt{score}(D_n, \mathcal{M}_1) > \texttt{score}(D_n, \mathcal{M}_2)) = 1.$$

Additionally, we say that the scoring criterion is ***strongly consistent*** *if, in both cases 1 and 2, it selects the appropriate model almost surely:*

$$Pr(\exists N : \forall n \geq N \;\; \texttt{score}(D_n, \mathcal{M}_1) > \texttt{score}(D_n, \mathcal{M}_2)) = 1.$$

As an example, let m_1 be the DAG of Figure 2, let m_2 be the DAG obtained from m_1 by adding an arc from node 3 to node 4, and let m_0 be the DAG obtained from m_1 by removing the arc from node 2 to node 4. For $i = 0,1,2$, let $\mathcal{M}_i$ be the probabilistic model consisting of all probability distributions with which m_i forms a Bayesian network. Let P be a probability distribution in $\mathcal{M}_1$ such the components of Θ_{m_1} are eight distinct numbers in $(0,1)$. Then $\mathcal{M}_0$ does not contain P (since ξ_4 is not independent of $\{\xi_1, \xi_2, \xi_3\}$), while $\mathcal{M}_1$ and $\mathcal{M}_2$ both contain P, and $\mathcal{M}_1$ has smaller

dimension that $\mathcal{M}_2$. If `score` is consistent, then in a situation with lots of data, `score` will be very likely to rank $\mathcal{M}_1$ over either $\mathcal{M}_0$ or $\mathcal{M}_2$. However, consider an infinite stream of data $X_1, X_2, \ldots$ sampled independently from P. Suppose that after each new observation, we ask `score` to choose among $\mathcal{M}_0$, $\mathcal{M}_1$ and $\mathcal{M}_2$. Consistency says that the expected proportion of `score`'s correct choices tends to 1 as n tends to infinity. But strong consistency says more: if `score` is strongly consistent, then with probability one it will make the correct choice for all but finitely many values of n.

3. Results

In this paper we consider the case of binomial Bayesian networks with independent $Beta(\alpha_{ij1}, \alpha_{ij2})$ priors for the parameters θ_{ij1} (note that $\theta_{ij2} = 1 - \theta_{ij1}$), where $\alpha_{ij1}, \alpha_{ij2} > 0$. We choose the beta family as it is the conjugate prior for the Binomial distribution. According to (1), the value of the Bayesian scoring criterion can be calculated as follows:

$$\begin{aligned} p(D_n|m) &= \int_{\Omega_m} p(D_n|m,\Theta_m)p(\Theta_m|m)d\Theta_m \\ &= \prod_{i=1}^{N}\prod_{j=1}^{q_i(m)} \int_0^1 \theta_{ij1}^{N_{ij1}+\alpha_{ij1}-1}(1-\theta_{ij1})^{N_{ij2}+\alpha_{ij2}-1}\frac{1}{Beta(\alpha_{ij1},\alpha_{ij2})}d\theta_{ij1} \\ &= \prod_{i=1}^{N}\prod_{j=1}^{q_i(m)} \frac{Beta(N_{ij1}+\alpha_{ij1}, N_{ij2}+\alpha_{ij2})}{Beta(\alpha_{ij1},\alpha_{ij2})} \\ &= \prod_{i=1}^{N}\prod_{j=1}^{q_i(m)} \frac{\Gamma(N_{ij1}+\alpha_{ij1})\Gamma(N_{ij2}+\alpha_{ij2})}{\Gamma(N_{ij1}+N_{ij2}+\alpha_{ij1}+\alpha_{ij2})}\cdot\frac{\Gamma(\alpha_{ij1}+\alpha_{ij2})}{\Gamma(\alpha_{ij1})\Gamma(\alpha_{ij2})}, \end{aligned} \quad (2)$$

which coincides with the well-known formula by Cooper and Herskovits (1992).

Throughout this paper we produce several asymptotic expansions "in probability" and "almost surely", always with respect to our probability measure Pr on Ω. We derive several properties of the marginal likelihood (2). We shall show that, for any model m,

$$\log p(D_n|m) = nC_m + \mathrm{O}(\sqrt{n\log\log n}) \qquad \text{a.s.}, \quad (3)$$

where C_m is a constant independent of n. We strengthen this result by showing how to obtain a positive constant σ_m such that

$$\limsup_{n\to\infty} \frac{\log p(D_n|m) - nC_m}{\sqrt{2n\mathrm{loglog}n}} = \sigma_m \quad \text{and} \quad \liminf_{n\to\infty} \frac{\log p(D_n|m) - nC_m}{\sqrt{2n\mathrm{loglog}n}} = -\sigma_m \quad \text{a.s.} \quad (4)$$

We note that "in probability" versions of the above statements also follow from our methods (as in the proofs of Corollaries 12 and 10):

$$\log p(D_n|m) \;=\; nC_m + O_p(\sqrt{n}), \quad (5)$$

$$\frac{\log p(D_n|m) - nC_m}{\sqrt{n}} \;\xrightarrow{\mathcal{D}}\; N(0,\sigma_m).$$

Additionally, we will be using the approximation of the Bayesian scoring criterion via maximum log-likelihood:

$$\log p(D_n|m) = \log\left(\prod_{i=1}^{N}\prod_{j=1}^{q_i(m)}\hat{\theta}_{ij1}^{N_{ij1}}(1-\hat{\theta}_{ij1})^{N_{ij2}}\right) - \frac{1}{2}k_m \log n + O_p(1), \tag{6}$$

where $\hat{\theta}_{ij1}$ is the MLE of θ_{ij1} and $k_m = \sum_{i=1}^{N} q_i(m)$ is the dimension of the model m. This is the efficient approximation of Bayesian score commonly known as BIC which was first derived in Schwarz (1978) for the case of linear exponential families. In Haughton (1988) his result was made more specific and extended to the case of curved exponential families—the type of model that includes Bayesian networks, as is shown in Geiger et al. (2001).

In this work, we attempt to get insight into the rate of convergence of the Bayes factor comparing two models m_1 and m_2. Our result strengthens the well known property of consistency of the Bayesian scoring criterion (e.g., see Chickering, 2002) and is expressed as the following theorem.

Theorem 5 *In the case of a binomial Bayesian network class, for the Bayesian scoring criterion based on independent beta priors, the following two properties hold:*

1. If m_2 includes P and m_1 does not, then there exists a positive constant $C(P,m_1,m_2)$ such that

$$\log\frac{\texttt{score}_B(D_n|m_2)}{\texttt{score}_B(D_n|m_1)} = C(P,m_1,m_2)n + O(\sqrt{n\log\log n}) \qquad a.s.$$

and

$$\log\frac{\texttt{score}_B(D_n|m_2)}{\texttt{score}_B(D_n|m_1)} = C(P,m_1,m_2)n + O_p(\sqrt{n}).$$

2. If m_1 and m_2 both include P and $\dim m_1 > \dim m_2$ where $\dim m_k = \sum_{i=1}^{N} q_i(m_k)$, $k = 1,2$, then

$$\log\frac{\texttt{score}_B(D_n|m_2)}{\texttt{score}_B(D_n|m_1)} = \frac{\dim m_1 - \dim m_2}{2}\log n + O(\log\log n) \qquad a.s.$$

and

$$\log\frac{\texttt{score}_B(D_n|m_2)}{\texttt{score}_B(D_n|m_1)} = \frac{\dim m_1 - \dim m_2}{2}\log n + O_p(1).$$

In particular, the Bayesian scoring criterion is strongly consistent.

It follows from the consistency property of the Bayesian scoring criterion that if P admits a faithful DAG representation, then the limit of the probability that a consistent scoring criterion chooses a model faithful to P, as the size of data approaches infinity, equals 1. Our result in Theorem 5 strengthens this claim as follows:

Corollary 6 *If (m_1,P) satisfies the faithfulness condition and (m_2,P) does not, then with probability 1, $\frac{\texttt{score}_B(D_n|m_1)}{\texttt{score}_B(D_n|m_2)}$ approaches infinity at exponential rate in n when m_2 does not include P, and approaches infinity at polynomial rate in n when m_2 includes P.*

The first result of Theorem 5 is optimal in the following sense:

Theorem 7 *If m_2 includes P and m_1 does not, then there exist $C_{m_1,m_2} > 0$ and $\sigma_{m_1,m_2} > 0$ such that:*

$$\limsup_{n\to\infty} \frac{\log \frac{\texttt{score}_B(D_n|m_2)}{\texttt{score}_B(D_n|m_1)} - nC_{m_1,m_2}}{\sigma_{m_1,m_2}\sqrt{2n\log\log n}} = 1 \qquad a.s.,$$

$$\liminf_{n\to\infty} \frac{\log \frac{\texttt{score}_B(D_n|m_2)}{\texttt{score}_B(D_n|m_1)} - nC_{m_1,m_2}}{\sigma_{m_1,m_2}\sqrt{2n\log\log n}} = -1 \qquad a.s.$$

and also

$$\frac{\log \frac{\texttt{score}_B(D_n|m_2)}{\texttt{score}_B(D_n|m_1)} - nC_{m_1,m_2}}{\sqrt{n}} \xrightarrow{\mathcal{D}} N(0,\sigma_{m_1,m_2}).$$

The constants C_{m_1,m_2} and σ_{m_1,m_2} from the above theorem could be defined as follows.

Definition 8 *Consider a single observation $X = (\xi_1,\ldots,\xi_N)$ from P. Define*

$$\phi_{ijk}(X) = \begin{cases} \log\theta_{ijk} & \text{if } \xi_i = k \text{ and } \xi_{Pa(i)} = j \\ 0 & \text{otherwise} \end{cases}$$

and define

$$\tau(X,m) = \sum_{i=1}^{N}\sum_{j=1}^{q_i(m)}\sum_{k=1}^{2}\phi_{ijk}(X).$$

Then define C_{m_1,m_2} and σ_{m_1,m_2} respectively to be the mean and the standard deviation of $\tau(X,m_1) - \tau(X,m_2)$. Also define

$$C_{i,m} = \prod_{j=1}^{q_i(m)}\left[\theta_{ij1}^{\theta_{ij1}}(1-\theta_{ij1})^{1-\theta_{ij1}}\right]^{P\left(\xi_{Pa(i)}=j\right)}.$$

Observe that we have

$$\tau(X,m) = \sum_{i=1}^{N}\log\theta_{i,\xi_{\mathrm{Pa}(i)},\xi_i}.$$

We shall show (see Lemma 13) that $\tau(X,m) = \log P(X)$, and (see proof of Lemma 9) that

$$C_{m_1,m_2} = \sum_{i=1}^{N}\log\frac{C_{i,m_2}}{C_{i,m_1}}. \tag{7}$$

Observe that for any i, the constant $C_{i,m}$ depends only on the conditional probabilities $P(\xi_i|\xi_{\mathrm{Pa}(i)})$ of the model m; therefore, if models m_1 and m_2 have the same set of parents of the i^{th} node, then $C_{i,m_1} = C_{i,m_2}$ and the i^{th} term in (7) is zero.

The quantities defined above will be extensively used throughout the Appendix.

4. Conclusion

In this paper we proved the strong consistency property of the Bayesian scoring criterion for the case of binomial Bayesian network models. We obtained asymptotic expansions for the logarithm of Bayesian score as well as the logarithm of the Bayes factor comparing two models. These results are important extensions of the consistency property of the Bayesian scoring criterion, providing insight into the rates at which the Bayes factor favors correct models. The asymptotic properties are found to be independent of the particular choice of beta parameter priors.

The methods we used are different from the mainstream. One typical way to investigate the properties of Bayesian score is to use BIC approximation and hence reduce the problem to investigation of the maximum log-likelihood term. In this paper we use expression (9) where the first term is the log-likelihood evaluated at the true parameter.

If we use the results of Theorem 5 in the approximation of Bayes scoring criterion by BIC (6), we can see that given two models m_1 and m_2, if both of them include the generating distribution P then their maximum log-likelihoods are within $O(\log\log n)$ of each other, and if one of the models does not include P then the maximum log-likelihoods differ by a leading order of $C(P,m_1,m_2)n$. These are the rates obtained by Qian and Field (2002, Theorems 2 and 3) for the case of model selection in logistic regression. This observation advocates for the existence of a unified approach for a very general class of models which can describe the rates at which Bayesian scoring criterion and its approximations favor correct model choices.

Appendix A.

In this section we provide proofs for the basic facts in this paper and for Theorems 5 and 7. Note that part 1 of Theorem 5 follows directly from Theorem 7. In our derivations we first assume that the parameter prior of every node follows a flat $Beta(1,1)$ distribution. At the end, we shall show how the results can be extended to the case of general beta priors.

We will start from the expression for the marginal likelihood (2). Noticing that $Beta(x+1,y+1) = \left[(x+y+1)\binom{x+y}{x}\right]^{-1}$ we obtain the expression for the Bayesian scoring criterion via binomial coefficients:

$$p(D_n|m) = \left[\prod_{i=1}^{N}\prod_{j=1}^{q_i(m)}(N_{ij1}+N_{ij2}+1)\binom{N_{ij1}+N_{ij2}}{N_{ij1}}\right]^{-1}. \tag{8}$$

Let $P(k,n,\theta) = \binom{n}{k}\theta^k(1-\theta)^{n-k}$. Substituting $\binom{n}{k} = \frac{P(k,n,\theta)}{\theta^k(1-\theta)^{n-k}}$ into (8) with θ taken as θ_{ij1} we obtain an expression for $\log p(D_n|m)$, which will be the fundamental core of our proof:

$$\log p(D_n|m) = \sum_{i=1}^{N}\sum_{j=1}^{q_i(m)}\left[\log\left(\theta_{ij1}^{N_{ij1}}(1-\theta_{ij1})^{N_{ij2}}\right) - \log P(N_{ij1}, N_{ij1}+N_{ij2}, \theta_{ij1}) - \log(N_{ij1}+N_{ij2}+1)\right]. \quad (9)$$

The rest of the Appendix is organized as follows. In Lemma 9 we derive the law of iterated logarithm for the first term of (9) by using the function $\tau(X,m)$ introduced in Definition 8. Lemma 11 states asymptotic expansions of each of three terms in (9) hence providing us with an opportunity to get an expansion for $p(D_n|m)$. Asymptotic expressions (3), (4) and (5) are immediate consequences of this lemma. Lemma 13 establishes a fundamental result regarding the log-likelihood evaluated at the true parameter value. It is followed by the proofs of Theorems 5 and 7.

Lemma 9 *Recall the notation of Section 2 and Definition 8. For model m, let $T(m) = T_n(m) = \sum_{i=1}^{N}\sum_{j=1}^{q_i(m)}\log\left(\theta_{ij1}^{N_{ij1}}(1-\theta_{ij1})^{N_{ij2}}\right)$. Then the following laws of the iterated logarithm hold almost surely:*

$$\limsup_{n\to\infty}\frac{T(m) - n\sum_{i=1}^{N}\log C_{i,m}}{\sigma_m\sqrt{2n\log\log n}} = 1, \qquad \liminf_{n\to\infty}\frac{T(m) - n\sum_{i=1}^{N}\log C_{i,m}}{\sigma_m\sqrt{2n\log\log n}} = -1, \quad (10)$$

$$\limsup_{n\to\infty}\frac{[T(m_1) - T(m_2)] - nC_{m_1,m_2}}{\sigma_{m_1,m_2}\sqrt{2n\log\log n}} = 1, \qquad \liminf_{n\to\infty}\frac{[T(m_1) - T(m_2)] - nC_{m_1,m_2}}{\sigma_{m_1,m_2}\sqrt{2n\log\log n}} = -1. \quad (11)$$

Proof It is not difficult to see that $T(m) = \sum_{r=1}^{n}\tau(X_r,m)$ and

$$E(\tau(X,m)) = \sum_{i=1}^{N}\sum_{j=1}^{q_i(m)}\sum_{k=1}^{2} P\left(\xi_{\mathrm{Pa}(i)} = j\right)\theta_{ijk}\log\theta_{ijk} = \sum_{i=1}^{N}\log C_{i,m}.$$

By the law of the iterated logarithm applied to $T(m)$ we conclude that

$$\limsup_{n\to\infty}\frac{T(m) - n\sum_{i=1}^{N}\log C_{i,m}}{\sigma_m\sqrt{2n\log\log n}} = 1,$$

where σ_m is the standard deviation of $\tau(X,m)$. Further, applying the law of the iterated logarithm to $T(m_1) - T(m_2)$, we obtain the equalities (11) where σ_{m_1,m_2} is the standard deviation of $\tau(X,m_1) - \tau(X,m_2)$. ■

Corollary 10 *The following expressions hold:*

$$T(m_1) - T(m_2) = nC_{m_1,m_2} + O(\sqrt{n \log\log n}) \qquad a.s., \tag{12}$$

$$\sum_{i=1}^{N} \sum_{j=1}^{q_i(m)} \log\left(\theta_{ij1}^{N_{ij1}} (1-\theta_{ij1})^{N_{ij2}}\right) = n \sum_{i=1}^{N} \log C_{i,m} + O_p(\sqrt{n}), \tag{13}$$

$$\frac{[T(m_1) - T(m_2)] - nC_{m_1,m_2}}{\sqrt{n}} \xrightarrow{\mathcal{D}} N(0, \sigma_{m_1,m_2}). \tag{14}$$

Proof Obviously, (12) is a direct consequence of (11). Applying the central limit theorem to $T(m)$ and $T(m_1) - T(m_2)$ in the proof of Lemma 9 instead of the law of the iterated logarithm we obtain (13) and (14). ■

Lemma 11 *The following asymptotic expansions hold:*

$$\sum_{i=1}^{N} \sum_{j=1}^{q_i(m)} \log\left(\theta_{ij1}^{N_{ij1}} (1-\theta_{ij1})^{N_{ij2}}\right) = n \sum_{i=1}^{N} \log C_{i,m} + O(\sqrt{n \log\log n}) \qquad a.s.,$$

$$N_{ij1} + N_{ij2} + 1 = n\left[P\left(\xi_{Pa(i)} = j\right) + o(1)\right] \qquad a.s., \tag{15}$$

$$\log P(N_{ij1}, N_{ij1} + N_{ij2}, \theta_{ij1}) = -\frac{1}{2} \log n + O(\log\log n) \qquad a.s., \tag{16}$$

$$\log P(N_{ij1}, N_{ij1} + N_{ij2}, \theta_{ij1}) = -\frac{1}{2} \log n + O_p(1). \tag{17}$$

Proof The first expression follows from (10). Further, note, that each of the variables N_{ijk} is a sum of i.i.d. Bernoulli variables. Based on the law of the iterated logarithm for the number of successes in n Bernoulli trials, as $n \to \infty$

$$N_{ijk} = n\theta_{ijk} P(\xi_{\mathrm{Pa}(i)} = j) + O(\sqrt{n \mathrm{loglog} n}) \qquad \text{a.s.}, \tag{18}$$

which immediately implies (15). Additionally, using the central limit theorem instead of the law of the iterated logarithm we obtain:

$$N_{ijk} = n\theta_{ijk} P(\xi_{\mathrm{Pa}(i)} = j) + O_p(\sqrt{n}). \tag{19}$$

Next, we will be using the following version of Local De Moivre-Laplace theorem (see for example p. 46 of Chow and Teicher 1978):

If $n \to \infty$ and $k = k_n \to \infty$ are such that $x_k n^{-\frac{1}{6}} \to 0$, where $x_k = \frac{k-np}{\sqrt{np(1-p)}}$, then

$$P(k,n,p) = \frac{1}{\sqrt{2\pi np(1-p)}} e^{-\frac{(k-np)^2}{2np(1-p)} + \mathrm{o}(1)}. \tag{20}$$

According to the law of the iterated logarithm, $x_k = \frac{k-np}{\sqrt{np(1-p)}} = \mathrm{O}(\sqrt{\log\log n})$ a.s., for the case where k is the number of successes in n i.i.d. Bernoulli trials of probability p. Notice that any such x_k satisfies the condition $x_k n^{-\frac{1}{6}} \to 0$. Therefore we can use (20) to approximate the binomial probability in (9), specifically:

$$\begin{aligned}&\log P(N_{ij1}, N_{ij1}+N_{ij2}, \theta_{ij1}) \\ &\quad = -\log\sqrt{2\pi(N_{ij1}+N_{ij2})\theta_{ij1}(1-\theta_{ij1})} - \frac{(N_{ij1}-(N_{ij1}+N_{ij2})\theta_{ij1})^2}{2(N_{ij1}+N_{ij2})\theta_{ij1}(1-\theta_{ij1})} + \mathrm{o}(1) \quad \text{a.s.} \quad (21)\end{aligned}$$

The first term in this expansion can be simplified based on (15):

$$-\log\sqrt{2\pi(N_{ij1}+N_{ij2})\theta_{ij1}(1-\theta_{ij1})} \;=\; -\frac{1}{2}\log n + O(1) \qquad \text{a.s.} \qquad (22)$$

Applying (18) to the second term we conclude that as $n \to \infty$:

$$-\frac{(N_{ij1}-(N_{ij1}+N_{ij2})\theta_{ij1})^2}{2(N_{ij1}+N_{ij2})\theta_{ij1}(1-\theta_{ij1})} \;=\; O(\log\log n) \qquad \text{a.s.} \qquad (23)$$

Now, (21) could be simplified further based on (22) and (23) to obtain (16). Finally, we can prove (17) analogously to (16) by using (19) instead of (18). Therefore the proof of the lemma is complete. ■

Now it is easy to derive the expansions announced in Sect. 3.

Corollary 12 *Properties (3), (4) and (5) of the marginal likelihood $P(D_n|m)$ hold.*

Proof Using (10), (15) and (16) in (9) and denoting $C_m \stackrel{def}{=} \sum_{i=1}^{N} \log C_{i,m}$ we get (4). Further, (3) is a direct consequence of (4). Finally, (5) can be proved by substituting (15), (13) and (16) into (9). ■

Lemma 13 *Suppose the probability distribution P is a member of the model m. Let $T(m) = \sum_{i=1}^{N}\sum_{j=1}^{q_i(m)} \log\left(\theta_{ij1}^{N_{ij1}}(1-\theta_{ij1})^{N_{ij2}}\right)$ for model m. Then $T(m) = \log P(D_n)$.*

Proof Since P is a member of the model m, we know that (m,P) satisfies the Markov condition. Therefore, by the factorization theorem (Theorem 1), we obtain

$$P(D_n) \;=\; \prod_{i=1}^{N}\prod_{j=1}^{q_i(m)} \theta_{ij1}^{N_{ij1}}(1-\theta_{ij1})^{N_{ij2}}$$

and the result follows. ■

Next, we will prove Theorems 5 and 7. Note that part 1 of Theorem 5 directly follows from Theorem 7.

Geiger et al. (2001) showed that each of the competing Bayesian network models m could be represented as a C^∞ connected manifold of dimension $\sum_{i=1}^N q_i(m)$ embedded in $\mathcal{R}^N$. In order to keep the notation simple we will be denoting this manifold as m. Every probability distribution for a finite sample space belongs to an exponential family. Therefore, there exists a set of ζ_i, $i = 1,2,\ldots,$ i.i.d. observations from an underlying distribution P_{θ_0} belonging to a full exponential family in standard form with densities $f(\zeta,\theta) = \exp(\zeta\theta - b(\theta))$ with respect to a finite measure on $\mathcal{R}^N$, with $\theta \in \Theta$ the natural parameter space, such that

$$\log\left(\prod_{i=1}^{N}\prod_{j=1}^{q_i(m)} \hat{\theta}_{ij1}^{N_{ij1}}(1-\hat{\theta}_{ij1})^{N_{ij2}}\right) = n \sup_{\phi\in m\cap\Theta}(Y_n\phi - b(\phi)), \tag{24}$$

where $Y_n = (1/n)\sum_{i=1}^n \zeta_i$.

Theorem 2.3 of Haughton (1988) provides an expansion of the logarithm of the Bayesian scoring criterion via maximum log-likelihood and, together with (24), guarantees (6). It follows from (3), (6) and (24) that

$$n \sup_{\phi\in m\cap\Theta}(Y_n\phi - b(\phi)) = C_m n + O_p(\sqrt{n\log\log n}). \tag{25}$$

Suppose m_2 includes P and m_1 does not. In this case, Haughton (1988, p.346) guarantees that as $n\to\infty$, we have

$$Pr\left(\sup_{\phi\in m_1\cap\Theta}(Y_n\phi - b(\phi)) + \varepsilon < \sup_{\phi\in m_2\cap\Theta}(Y_n\phi - b(\phi))\right) \to 1$$

for some $\varepsilon > 0$, and by (25) we obtain $C_{m_1} < C_{m_2}$. Hence, $\sum_{i=1}^N \log\frac{C_{i,m_2}}{C_{i,m_1}} > 0$. Now, the result of Theorem 7 can be obtained by using (15), (11) and (16) in (9), and by using (15), (14) and (16) in (9).

Now, suppose both m_1 and m_2 include the true distribution P and $k_{m_2} < k_{m_1}$. For part 2 of Theorem 5, direct application of Lemma 13, (16) and (15) provides the "almost surely" result, while Lemma 13, (17) and (15) prove the "in probability" result.

Finally, we shall show that the results of Theorems 5 and 7 hold for the case of general beta priors. It is not difficult to see that Stirling's approximation implies

$$\lim_{z\to\infty} z^{b-a}\frac{\Gamma(z+a)}{\Gamma(z+b)} = 1. \tag{26}$$

Denote as ψ_1 the flat $Beta(1,1)$ system of priors and denote as ψ_2 the system which, for each parameter θ_{ij1}, assumes the distribution $Beta(\alpha_{ij1},\alpha_{ij2})$, where $\alpha_{ij1},\alpha_{ij2} > 0$. It follows from (2) and (26) that:

$$\begin{aligned}
\frac{p(m|D,\psi_2)}{p(m|D,\psi_1)} &= \prod_{i=1}^{N}\prod_{j=1}^{q_i(m)} \frac{Beta(N_{ij1}+\alpha_{ij1}, N_{ij2}+\alpha_{ij2})}{Beta(N_{ij1}+1, N_{ij2}+1)} \cdot \frac{1}{Beta(\alpha_{ij1},\alpha_{ij2})} \\
&= \prod_{i=1}^{N}\prod_{j=1}^{q_i(m)} \frac{\Gamma(N_{ij1}+\alpha_{ij1})\Gamma(N_{ij2}+\alpha_{ij2})\Gamma(N_{ij1}+N_{ij2}+2)}{\Gamma(N_{ij1}+1)\Gamma(N_{ij2}+1)\Gamma(N_{ij1}+N_{ij2}+\alpha_{ij1}+\alpha_{ij2})} \cdot \frac{1}{Beta(\alpha_{ij1},\alpha_{ij2})} \\
&\sim \prod_{i=1}^{N}\prod_{j=1}^{q_i(m)} \frac{N_{ij1}^{\alpha_{ij1}-1} N_{ij2}^{\alpha_{ij2}-1}}{(N_{ij1}+N_{ij2})^{\alpha_{ij1}+\alpha_{ij2}-2}} \cdot \frac{1}{Beta(\alpha_{ij1},\alpha_{ij2})}.
\end{aligned}$$

Therefore, using (18) we can conclude that there exists a constant $c > 0$ such that:

$$\lim_{n\to\infty} \frac{p(m|D,\psi_2)}{p(m|D,\psi_1)} = c \quad \text{a.s.},$$

which implies that the results of Theorems 5 and 7 extend to the case of general beta parameter priors.

Abstract

We propose the recursive autonomy identification (RAI) algorithm for constraint-based (CB) Bayesian network structure learning. The RAI algorithm learns the structure by sequential application of conditional independence (CI) tests, edge direction and structure decomposition into autonomous sub-structures. The sequence of operations is performed recursively for each autonomous sub-structure while simultaneously increasing the order of the CI test. While other CB algorithms d-separate structures and then direct the resulted undirected graph, the RAI algorithm combines the two processes from the outset and along the procedure. By this means and due to structure decomposition, learning a structure using RAI requires a smaller number of CI tests of high orders. This reduces the complexity and run-time of the algorithm and increases the accuracy by diminishing the curse-of-dimensionality. When the RAI algorithm learned structures from databases representing synthetic problems, known networks and natural problems, it demonstrated superiority with respect to computational complexity, run-time, structural correctness and classification accuracy over the PC, Three Phase Dependency Analysis, Optimal Reinsertion, greedy search, Greedy Equivalence Search, Sparse Candidate, and Max-Min Hill-Climbing algorithms.

Keywords: Bayesian networks, constraint-based structure learning

1. Introduction

A Bayesian network (BN) is a graphical model that efficiently encodes the joint probability distribution for a set of variables (Heckerman, 1995; Pearl, 1988). The BN consists of a structure and a set of parameters. The structure is a directed acyclic graph (DAG) that is composed of nodes representing domain variables and edges connecting these nodes. An edge manifests dependence between the nodes connected by the edge, while the absence of an edge demonstrates independence between the nodes. The parameters of a BN are conditional probabilities (densities) that quantify the graph edges. Once the BN structure has been learned, the parameters are usually estimated (in the case of discrete variables) using the relative frequencies of all combinations of variable states as exemplified in the data. Learning the structure from data by considering all possible structures ex-

*. This work was done while the author was at the Department of Electrical and Computer Engineering, Ben-Gurion University of the Negev, Israel.

haustively is not feasible in most domains, regardless of the size of the data (Chickering et al., 2004), since the number of possible structures grows exponentially with the number of nodes (Cooper and Herskovits, 1992). Hence, structure learning requires either sub-optimal heuristic search algorithms or algorithms that are optimal under certain assumptions.

One approach to structure learning—known as search-and-score (S&S) (Chickering, 2002; Cooper and Herskovits, 1992; Heckerman, 1995; Heckerman et al., 1995)—combines a strategy for searching through the space of possible structures with a scoring function measuring the fitness of each structure to the data. The structure achieving the highest score is then selected. Algorithms of this approach may also require node ordering, in which a parent node precedes a child node so as to narrow the search space (Cooper and Herskovits, 1992). In a second approach—known as constraint-based (CB) (Cheng et al., 1997; Pearl, 2000; Spirtes et al., 2000)—each structure edge is learned if meeting a constraint usually derived from comparing the value of a statistical or information-theory-based test of conditional independence (CI) to a threshold. Meeting such constraints enables the formation of an undirected graph, which is then further directed based on orientation rules (Pearl, 2000; Spirtes et al., 2000). That is, generally in the S&S approach we learn structures, whereas in the CB approach we learn edges composing a structure.

Search-and-score algorithms allow the incorporation of user knowledge through the use of prior probabilities over the structures and parameters (Heckerman et al., 1995). By considering several models altogether, the S&S approach may enhance inference and account better for model uncertainty (Heckerman et al., 1999). However, S&S algorithms are heuristic and usually have no proof of correctness (Cheng et al., 1997) (for a counter-example see Chickering, 2002, providing an S&S algorithm that identifies the optimal graph in the limit of a large sample and has a proof of correctness). As mentioned above, S&S algorithms may sometimes depend on node ordering (Cooper and Herskovits, 1992). Recently, it was shown that when applied to classification, a structure having a higher score does not necessarily provide a higher classification accuracy (Friedman et al., 1997; Grossman and Domingos, 2004; Kontkanen et al., 1999).

Algorithms of the CB approach are generally asymptotically correct (Cheng et al., 1997; Spirtes et al., 2000). They are relatively quick and have a well-defined stopping criterion (Dash and Druzdzel, 2003). However, they depend on the threshold selected for CI testing (Dash and Druzdzel, 1999) and may be unreliable in performing CI tests using large condition sets and a limited data size (Cooper and Herskovits, 1992; Heckerman et al., 1999; Spirtes et al., 2000). They can also be unstable in the sense that a CI test error may lead to a sequence of errors resulting in an erroneous graph (Dash and Druzdzel, 1999; Heckerman et al., 1999; Spirtes et al., 2000). Additional information on the above two approaches, their advantages and disadvantages, may be found in Cheng et al. (1997), Cooper and Herskovits (1992), Dash and Druzdzel (1999), Dash and Druzdzel (2003), Heckerman (1995), Heckerman et al. (1995), Heckerman et al. (1999), Pearl (2000) and Spirtes et al. (2000). We note that Cowell (2001) showed that for complete data, a given node ordering and using cross-entropy methods for checking CI and maximizing logarithmic scores to evaluate structures, the two approaches are equivalent. In addition, hybrid algorithms have been suggested in which a CB algorithm is employed to create an initial ordering (Singh and Valtorta, 1995), to obtain a starting graph (Spirtes and Meek, 1995; Tsamardinos et al., 2006a) or to narrow the search space (Dash and Druzdzel, 1999) for an S&S algorithm.

Most CB algorithms, such as Inductive Causation (IC) (Pearl, 2000), PC (Spirtes et al., 2000) and Three Phase Dependency Analysis (TPDA) (Cheng et al., 1997), construct a DAG in two consecutive stages. The first stage is learning associations between variables for constructing an undi-

rected structure. This requires a number of CI tests growing exponentially with the number of nodes. This complexity is reduced in the PC algorithm to polynomial complexity by fixing the maximal number of parents a node can have and in the TPDA algorithm by measuring the strengths of the independences computed while CI testing along with making a strong assumption about the underlying graph (Cheng et al., 1997). The TPDA algorithm does not take direct steps to restrict the size of the condition set employed in CI testing in order to mitigate the curse-of-dimensionality.

In the second stage, most CB algorithms direct edges by employing orientation rules in two consecutive steps: finding and directing V-structures and directing additional edges inductively (Pearl, 2000). Edge direction (orientation) is unstable. This means that small errors in the input to the stage (i.e., CI testing) yield large errors in the output (Spirtes et al., 2000). Errors in CI testing are usually the result of large condition sets. These sets, selected based on previous CI test results, are more likely to be incorrect due to their size, and they also lead, for a small sample size, to poorer estimation of dependences due to the curse-of-dimensionality. Thus, we usually start learning using CI tests of low order (i.e., using small condition sets), which are the most reliable tests (Spirtes et al., 2000). We further note that the division of learning in CB algorithms into two consecutive stages is mainly for simplicity, since no directionality constraints have to be propagated during the first stage. However, errors in CI testing is a main reason for the instability of CB algorithms, which we set out to tackle in this research.

We propose the recursive autonomy identification (RAI) algorithm, which is a CB model that learns the structure of a BN by sequential application of CI tests, edge direction and structure decomposition into autonomous sub-structures that comply with the Markov property (i.e., the sub-structure includes all its nodes' parents). This sequence of operations is performed recursively for each autonomous sub-structure. In each recursive call of the algorithm, the order of the CI test is increased similarly to the PC algorithm (Spirtes et al., 2000). By performing CI tests of low order (i.e., tests employing small conditions sets) before those of high order, the RAI algorithm performs more reliable tests first, and thereby obviates the need to perform less reliable tests later. By directing edges while testing conditional independence, the RAI algorithm can consider parent-child relations so as to rule out nodes from condition sets and thereby to avoid unnecessary CI tests and to perform tests using smaller condition sets. CI tests using small condition sets are faster to implement and more accurate than those using large sets. By decomposing the graph into autonomous sub-structures, further elimination of both the number of CI tests and size of condition sets is obtained. Graph decomposition also aids in subsequent iterations to direct additional edges. By recursively repeating both mechanisms for autonomies decomposed from the graph, further reduction of computational complexity, database queries and structural errors in subsequent iterations is achieved. Overall, the RAI algorithm learns faster a more precise structure.

Tested using synthetic databases, nineteen known networks, and nineteen UCI databases, RAI showed in this study superiority with respect to structural correctness, complexity, run-time and classification accuracy over PC, Three Phase Dependency Analysis, Optimal Reinsertion, a greedy hill-climbing search algorithm with a Tabu list, Greedy Equivalence Search, Sparse Candidate, naive Bayesian, and Max-Min Hill-Climbing algorithms.

After providing some preliminaries and definitions in Section 2, we introduce the RAI algorithm and prove its correctness in Section 3. Section 4 presents experimental evaluation of the RAI algorithm with respect to structural correctness, complexity, run-time and classification accuracy in comparison to CB, S&S and hybrid structure learning algorithms. Section 5 concludes the paper with a discussion.

2. Preliminaries

A BN $B(\mathcal{G},\Theta)$ is a model for representing the joint probability distribution for a set of variables $\boldsymbol{X} = \{X_1 \ldots X_n\}$. The structure $\mathcal{G}(\boldsymbol{V},\boldsymbol{E})$ is a DAG composed of $\boldsymbol{V}$, a set of nodes representing the domain variables $\boldsymbol{X}$, and $\boldsymbol{E}$, a set of directed edges connecting the nodes. A directed edge $X_i \rightarrow X_j$ connects a child node X_j to its parent node X_i. We denote $\boldsymbol{Pa}(X,\mathcal{G})$ as the set of parents of node X in a graph $\mathcal{G}$. The set of parameters Θ holds local conditional probabilities over $\boldsymbol{X}$, $P(X_i|\boldsymbol{Pa}(X_i,\mathcal{G}))\forall i$ that quantify the graph edges. The joint probability distribution for $\boldsymbol{X}$ represented by a BN that is assumed to encode this distribution[1] is (Cooper and Herskovits, 1992; Heckerman, 1995; Pearl, 1988)

$$P(X_1 \ldots X_n) = \prod_{i=1}^{n} P(X_i|\boldsymbol{Pa}(X_i,\mathcal{G})). \tag{1}$$

Though there is no theoretical restriction on the functional form of the conditional probability distributions in Equation 1, we restrict ourselves in this study to discrete variables. This implies joint distributions which are unrestricted discrete distributions and conditional probability distributions which are independent multinomials for each variable and each parent configuration (Chickering, 2002).

We also make use of the term partially directed graph, that is, a graph that may have both directed and undirected edges and has at most one edge between any pair of nodes (Meek, 1995). We use this term while learning a graph starting from a complete undirected graph and removing and directing edges until uncovering a graph representing a family of Markov equivalent structures (pattern) of the true underlying BN[2] (Pearl, 2000; Spirtes et al., 2000). $\boldsymbol{Pa}_p(X,\mathcal{G})$, $\boldsymbol{Adj}(X,\mathcal{G})$ and $\boldsymbol{Ch}(X,\mathcal{G})$ are, respectively, the sets of potential parents, adjacent nodes[3] and children of node X in a partially directed graph $\mathcal{G}$, $\boldsymbol{Pa}_p(X,\mathcal{G}) = \boldsymbol{Adj}(X,\mathcal{G}) \backslash \boldsymbol{Ch}(X,\mathcal{G})$.

We indicate that X and Y are independent conditioned on a set of nodes $\boldsymbol{S}$ (i.e., the condition set) using $X \perp\!\!\!\perp Y \,|\, \boldsymbol{S}$, and make use of the notion of d-separation (Pearl, 1988). Thereafter, we define d-separation resolution with the aim to evaluate d-separation for different sizes of condition sets, d-separation resolution of a graph, an exogenous cause to a graph and an autonomous substructure. We concentrate in this section only on terms and definitions that are directly relevant to the RAI concept and algorithm, where other more general terms and definitions relevant to BNs can be found in Heckerman (1995), Pearl (1988), Pearl (2000), and Spirtes et al. (2000).

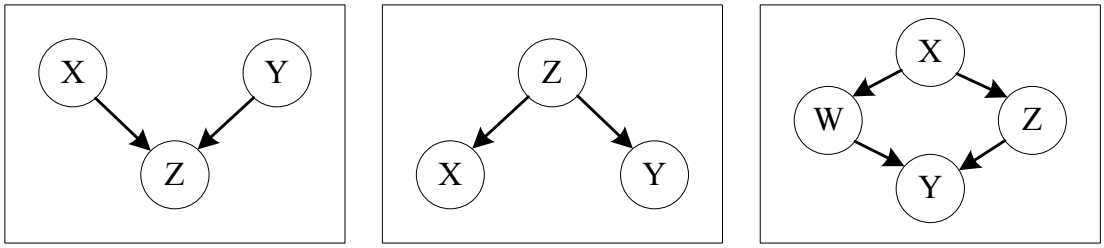
Definition 1 – *d-separation resolution*: The resolution of a d-separation relation between a pair of non-adjacent nodes in a graph is the size of the smallest condition set that d-separates the two nodes.

Examples of d-separation resolutions of 0, 1 and 2 between nodes X and Y are given in Figure 1.

Definition 2 – *d-separation resolution of a graph*: The d-separation resolution of a graph is the highest d-separation resolution in the graph.

The d-separation relations encoded by the example graph in Figure 2a and relevant to the determination of the d-separation resolution of this graph are: 1) $X_1 \perp\!\!\!\perp X_2 \,|\, \emptyset$; 2) $X_1 \perp\!\!\!\perp X_4 \,|\, \{X_3\}$; 3) $X_1 \perp\!\!\!\perp X_5 \,|\, \{X_3\}$; 4) $X_1 \perp\!\!\!\perp X_6 \,|\, \{X_3\}$; 5) $X_2 \perp\!\!\!\perp X_4 \,|\, \{X_3\}$; 6) $X_2 \perp\!\!\!\perp X_5 \,|\, \{X_3\}$; 7) $X_2 \perp\!\!\!\perp X_6 \,|\, \{X_3\}$; 8) $X_3 \perp\!\!\!\perp X_6 \,|\, \{X_4, X_5\}$ and 9) $X_4 \perp\!\!\!\perp X_5 \,|\, \{X_3\}$. Due to relation 8, exemplifying d-separation resolution

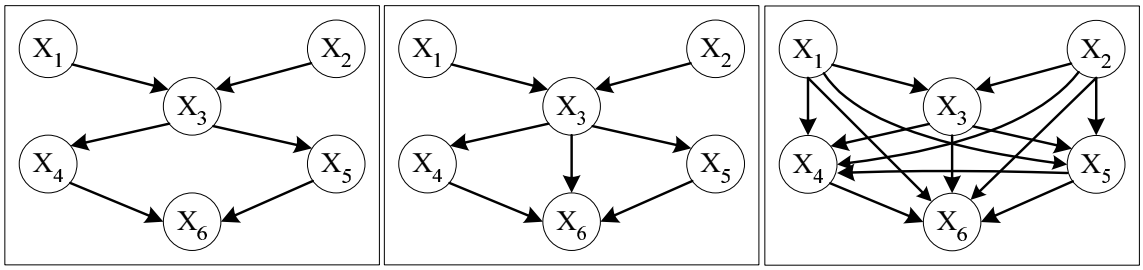
1. Throughout the paper, we assume faithfulness of the probability distribution to a DAG (Spirtes et al., 2000).
2. Two BNs are Markov equivalent if and only if they have the same sets of adjacencies and V-structures (Verma and Pearl, 1990).
3. Two nodes in a graph that are connected by an edge are adjacent.



(a) (b) (c)

Figure 1: Examples of d-separation resolutions of (a) 0, (b) 1 and (c) 2 between nodes X and Y.

of 2, the d-separation resolution of the graph is 2. Eliminating relation 8 by adding the edge $X_3 \rightarrow X_6$, we form a graph having a d-separation resolution of 1 (Figure 2b). By further adding edges to the graph, eliminating relations of resolution 1, we form a graph having a d-separation resolution of 0 (Figure 2c) that encodes only relation 1.



(a) (b) (c)

Figure 2: Examples of graph d-separation resolutions of (a) 2, (b) 1 and (c) 0.

Definition 3 – *exogenous cause*: A node Y in $\mathcal{G}(\boldsymbol{V},\boldsymbol{E})$ is an exogenous cause to $\mathcal{G}'(\boldsymbol{V}',\boldsymbol{E}')$, where $\boldsymbol{V}' \subset \boldsymbol{V}$ and $\boldsymbol{E}' \subset \boldsymbol{E}$, if $Y \notin \boldsymbol{V}'$ and $\forall X \in \boldsymbol{V}', Y \in \boldsymbol{Pa}(X,\mathcal{G})$ or $Y \notin \boldsymbol{Adj}(X,\mathcal{G})$ (Pearl, 2000).

Definition 4 – *autonomous sub-structure*: In a DAG $\mathcal{G}(\boldsymbol{V},\boldsymbol{E})$, a sub-structure $\mathcal{G}^{\mathrm{A}}(\boldsymbol{V}^{\mathrm{A}},\boldsymbol{E}^{\mathrm{A}})$ such that $\boldsymbol{V}^{\mathrm{A}} \subset \boldsymbol{V}$ and $\boldsymbol{E}^{\mathrm{A}} \subset \boldsymbol{E}$ is said to be autonomous in $\mathcal{G}$ given a set $\boldsymbol{V}_{ex} \subset \boldsymbol{V}$ of exogenous causes to $\mathcal{G}^{\mathrm{A}}$ if $\forall X \in \boldsymbol{V}^{\mathrm{A}}, \boldsymbol{Pa}(X,\mathcal{G}) \subset \{\boldsymbol{V}^{\mathrm{A}} \cup \boldsymbol{V}_{ex}\}$. If $\boldsymbol{V}_{ex}$ is empty, we say the sub-structure is (completely) autonomous[4].

We define sub-structure autonomy in the sense that the sub-structure holds the Markov property for its nodes. Given a structure $\mathcal{G}$, any two non-adjacent nodes in an autonomous sub-structure $\mathcal{G}^{\mathrm{A}}$ in $\mathcal{G}$ are d-separated given nodes either included in the sub-structure $\mathcal{G}^{\mathrm{A}}$ or exogenous causes to $\mathcal{G}^{\mathrm{A}}$. Figure 3 depicts a structure $\mathcal{G}$ containing a sub-structure $\mathcal{G}^{\mathrm{A}}$. Since nodes X_1 and X_2 are exogenous causes to $\mathcal{G}^{\mathrm{A}}$ (i.e., they are either parents of nodes in $\mathcal{G}^{\mathrm{A}}$ or not adjacent to them; see Definition 3), $\mathcal{G}^{\mathrm{A}}$ is said to be autonomous in $\mathcal{G}$ given nodes X_1 and X_2.

Proposition 1: If $\mathcal{G}^{\mathrm{A}}(\boldsymbol{V}^{\mathrm{A}},\boldsymbol{E}^{\mathrm{A}})$ is an autonomous sub-structure in a DAG $\mathcal{G}(\boldsymbol{V},\boldsymbol{E})$ given a set $\boldsymbol{V}_{ex} \subset \boldsymbol{V}$ of exogenous causes to $\mathcal{G}^{\mathrm{A}}$ and $X \perp\!\!\!\perp Y \,|\, \boldsymbol{S}$, where $X, Y \in \boldsymbol{V}^{\mathrm{A}}$, $\boldsymbol{S} \subset \boldsymbol{V}$, then $\exists \boldsymbol{S}'$ such that $\boldsymbol{S}' \subset \{\boldsymbol{V}^{\mathrm{A}} \cup \boldsymbol{V}_{ex}\}$ and $X \perp\!\!\!\perp Y \,|\, \boldsymbol{S}'$.

4. If $\mathcal{G}$ is a partially directed graph, then $\boldsymbol{Pa}_p(X,\mathcal{G})$ replaces $\boldsymbol{Pa}(X,\mathcal{G})$.

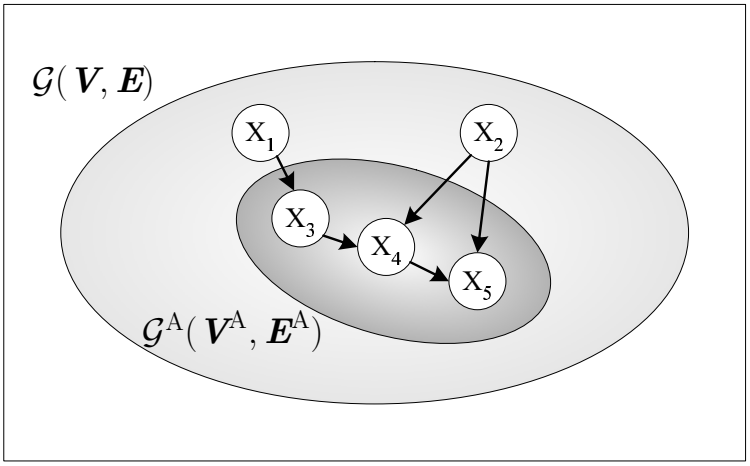


Figure 3: An example of an autonomous sub-structure.

Proof: The proof is based on Lemma 1.
Lemma 1: If in a DAG, X and Y are non-adjacent and X is not a descendant of Y,[5] then X and Y are d-separated given $\boldsymbol{Pa}(Y)$ (Pearl, 1988; Spirtes et al., 2000).

If in a DAG $\mathcal{G}(\boldsymbol{V},\boldsymbol{E})$, $X \perp\!\!\!\perp Y \,|\, \boldsymbol{S}$ for some set $\boldsymbol{S}$, where X and Y are non-adjacent, and if X is not a descendant of Y, then, according to Lemma 1, X and Y are d-separated given $\boldsymbol{Pa}(Y)$. Since X and Y are contained in the sub-structure $\mathcal{G}^{A}(\boldsymbol{V}^{A},\boldsymbol{E}^{A})$, which is autonomous given the set of nodes $\boldsymbol{V}_{ex}$, then, following the definition of an autonomous sub-structure, all parents of the nodes in $\boldsymbol{V}^{A}$—and specifically $\boldsymbol{Pa}(Y)$—are members in set $\{\boldsymbol{V}^{A} \cup \boldsymbol{V}_{ex}\}$. Then, $\exists \boldsymbol{S}'$ such that $\boldsymbol{S}' \subset \{\boldsymbol{V}^{A} \cup \boldsymbol{V}_{ex}\}$ and $X \perp\!\!\!\perp Y \,|\, \boldsymbol{S}'$, which proves Proposition 1. ■

3. Recursive Autonomy Identification

Starting from a complete undirected graph and proceeding from low to high graph d-separation resolution, the RAI algorithm uncovers the correct pattern[6] of a structure by performing the following sequence of operations: (1) test of CI between nodes, followed by the removal of edges related to independences, (2) edge direction according to orientation rules, and (3) graph decomposition into autonomous sub-structures. For each autonomous sub-structure, the RAI algorithm is applied recursively, while increasing the order of CI testing.

CI testing of order n between nodes X and Y is performed by thresholding the value of a criterion that measures the dependence between the nodes conditioned on a set of n nodes (i.e., the condition set) from the parents of X or Y. The set is determined by the Markov property (Pearl, 2000), for example, if X is directed into Y, then only Y's parents are included in the set. Commonly, this criterion is the χ^2 goodness of fit test (Spirtes et al., 2000) or conditional mutual information (CMI) (Cheng et al., 1997).

5. If X is a descendant of Y, we change the roles of X and Y and replace $\boldsymbol{Pa}(Y)$ with $\boldsymbol{Pa}(X)$.
6. In the absence of a topological node ordering, uncovering the correct pattern is the ultimate goal of BN structure learning algorithms, since a pattern represents the same set of probabilities as that of the true structure (Spirtes et al., 2000).

Directing edges is conducted according to orientation rules (Pearl, 2000; Spirtes et al., 2000). Given an undirected graph and a set of independences, both being the result of CI testing, the following two steps are performed consecutively. First, intransitive triplets of nodes (V-structures) are identified, and the corresponding edges are directed. An intransitive triplet $X \rightarrow Z \leftarrow Y$ is defined if 1) X and Y are non-adjacent neighbors of Z, and 2) Z is not in the condition set that separated X and Y. In the second step, also known as the inductive stage, edges are continually directed until no more edges can be directed, while assuring that no new V-structures and no directed cycles are created.

Decomposition into separated, smaller, autonomous sub-structures reveals the structure hierarchy. Decomposition also decreases the number and length of paths between nodes that are CI-tested, thereby diminishing, respectively, the number of CI tests and the sizes of condition sets used in these tests. Both reduce computational complexity. Moreover, due to decomposition, additional edges can be directed, which reduces the complexity of CI testing of the subsequent iterations. Following decomposition, the RAI algorithm identifies ancestor and descendant sub-structures; the former are autonomous, and the latter are autonomous given nodes of the former.

3.1 The RAI Algorithm

Similarly to other algorithms of structure learning (Cheng et al., 1997; Cooper and Herskovits, 1992; Heckerman, 1995), the RAI algorithm[7] assumes that all the independences entailed from the given data can be encoded by a DAG. Similarly to other CB algorithms of structure learning (Cheng et al., 1997; Spirtes et al., 2000), the RAI algorithm assumes that the data sample size is large enough for reliable CI tests.

An iteration of the RAI algorithm starts with knowledge produced in the previous iteration and the current d-separation resolution, n. Previous knowledge includes $\mathcal{G}_{\text{start}}$, a structure having a d-separation resolution of $n-1$, and $\mathcal{G}_{\text{ex}}$, a set of structures each having possible exogenous causes to $\mathcal{G}_{\text{start}}$. Another input is the graph $\mathcal{G}_{\text{all}}$, which contains $\mathcal{G}_{\text{start}}$, $\mathcal{G}_{\text{ex}}$ and edges connecting them. Note that $\mathcal{G}_{\text{all}}$ may also contain other nodes and edges, which may not be required for the learning task (e.g., edges directed from nodes in $\mathcal{G}_{\text{start}}$ into nodes that are not in $\mathcal{G}_{\text{start}}$ or $\mathcal{G}_{\text{ex}}$), and these will be ignored by the RAI. In the first iteration, $n=0$, $\mathcal{G}_{\text{ex}}=\emptyset$, $\mathcal{G}_{\text{start}}(\boldsymbol{V},\boldsymbol{E})$ is the complete undirected graph and the d-separation resolution is not defined, since there are no pairs of d-separated nodes. Since $\mathcal{G}_{\text{ex}}$ is empty, $\mathcal{G}_{\text{all}}=\mathcal{G}_{\text{start}}$.

Given a structure $\mathcal{G}_{\text{start}}$ having d-separation resolution $n-1$, the RAI algorithm seeks independences between adjacent nodes conditioned on sets of size n and removes the edges corresponding to these independences. The resulting structure has a d-separation resolution of n. After applying orientation rules so as to direct the remaining edges, a partial topological order is obtained in which parent nodes precede their descendants. Childless nodes have the lowest topological order. This order is partial, since not all the edges can be directed; thus, edges that cannot be directed connect nodes of equal topological order. Using this partial topological ordering, the algorithm decomposes the structure into ancestor and descendent autonomous sub-structures so as to reduce the complexity of the successive stages.

First, descendant sub-structures are established containing the lowest topological order nodes. A descendant sub-structure may be composed of a single childless node or several adjacent childless

7. The RAI algorithm and a preliminary experimental evaluation of the algorithm were introduced in Yehezkel and Lerner (2005).

nodes. We will further refer to a single descendent sub-structure, although such a sub-structure may consist of several non-connected sub-structures. Second, all edges pointing towards nodes of the descendant sub-structure are temporarily removed (together with the descendant sub-structure itself), and the remaining clusters of connected nodes are identified as ancestor sub-structures. The descendent sub-structure is autonomous, given nodes of higher topological order composing the ancestor sub-structures. To consider smaller numbers of parents (and thereby smaller condition set sizes) when CI testing nodes of the descendant sub-structure, the algorithm first learns ancestor sub-structures, then the connections between ancestor and descendant sub-structures, and finally the descendant sub-structure itself. Each ancestor or descendent sub-structure is further learned by recursive calls to the algorithm. Figures 4, 5 and 6 show, respectively, the RAI algorithm, a manifesting example and the algorithm execution order for this example.

The RAI algorithm is composed of four stages (denoted in Figure 4 as Stages A, B, C and D) and an exit condition checked before the execution of any of the stages. The purpose of the exit condition is to assure that a CI test of a required order can indeed be performed, that is, the number of potential parents required to perform the test is adequate. The purpose of Stage A1 is to thin the link between $\mathcal{G}_{\text{ex}}$ and $\mathcal{G}_{\text{start}}$, the latter having d-separation resolution of $n-1$. This is achieved by removing edges corresponding to independences between nodes in $\mathcal{G}_{\text{ex}}$ and nodes in $\mathcal{G}_{\text{start}}$ conditioned on sets of size n of nodes that are either exogenous to, or within, $\mathcal{G}_{\text{start}}$. Similarly, in Stage B1, the algorithm tests for CI of order n between nodes in $\mathcal{G}_{\text{start}}$ given sets of size n of nodes that are either exogenous to, or within, $\mathcal{G}_{\text{start}}$, and removes edges corresponding to independences. The edges removed in Stages A1 and B1 could not have been removed in previous applications of these stages using condition sets of lower orders. When testing independence between X and Y, conditioned on the potential parents of node X, those nodes in the condition set that are exogenous to $\mathcal{G}_{\text{start}}$ are X's parents whereas those nodes that are in $\mathcal{G}_{\text{start}}$ are either its parents or adjacents.

In Stages A2 and B2, the algorithm directs every edge from the remaining edges that can be directed. In Stage B3, the algorithm groups in a descendant sub-structure all the nodes having the lowest topological order in the derived partially directed structure, and following the temporary removal of these nodes, it defines in Stage B4 separate ancestor sub-structures. Due to the topological order, every edge from a node X in an ancestor sub-structure to a node Z in the descendant sub-structure is directed as $X \rightarrow Z$. In addition, there is no edge connecting one ancestor sub-structure to another ancestor sub-structure.

Thus, every ancestor sub-structure contains all the potential parents of its nodes, that is, it is autonomous (or if some potential parents are exogenous, then the sub-structure is autonomous given the set of exogenous nodes). The descendant sub-structure is, by definition, autonomous given nodes of ancestor sub-structures. Proposition 1 showed that we can identify all the conditional independences between nodes of an autonomous sub-structure. Hence, every ancestor and descendant sub-structure can be processed independently in Stages C and D, respectively, so as to identify conditional independences of increasing orders in each recursive call of the algorithm. Stage C is a recursive call for the RAI algorithm for learning each ancestor sub-structure with order $n+1$. Similarly, Stage D is a recursive call for the RAI algorithm for learning the descendant sub-structure with order $n+1$, while assuming that the ancestor sub-structures have been fully learned (having d-separation resolution of $n+1$).

Figure 5 and Figure 6, respectively, show diagrammatically the stages in learning an example graph and the execution order of the algorithm for this example. Figure 5a shows the true structure that we wish to uncover. Initially, $\mathcal{G}_{\text{start}}$ is the complete undirected graph (Figure 5b), $n=0$, $\mathcal{G}_{\text{ex}}$ is

Main function: $\mathcal{G}_{\text{out}} = \text{RAI}[n, \mathcal{G}_{\text{start}}(\boldsymbol{V}_{\text{start}}, \boldsymbol{E}_{\text{start}}), \mathcal{G}_{\text{ex}}(\boldsymbol{V}_{ex}, \boldsymbol{E}_{ex}), \mathcal{G}_{\text{all}}]$

Exit condition

If all nodes in $\mathcal{G}_{\text{start}}$ have fewer than $n+1$ potential parents, set $\mathcal{G}_{\text{out}} = \mathcal{G}_{\text{all}}$ and exit.

A. **Thinning the link between $\mathcal{G}_{\text{ex}}$ and $\mathcal{G}_{\text{start}}$ and directing $\mathcal{G}_{\text{start}}$**

1. For every node Y in $\mathcal{G}_{\text{start}}$ and its parent X in $\mathcal{G}_{\text{ex}}$, if $\exists \boldsymbol{S} \subset \{\boldsymbol{Pa}_p(Y, \mathcal{G}_{\text{start}}) \cup \boldsymbol{Pa}(Y, \mathcal{G}_{\text{ex}}) \backslash X\}$ and $|\boldsymbol{S}| = n$ such that $X \perp\!\!\!\perp Y \,|\, \boldsymbol{S}$, then remove the edge between X and Y from $\mathcal{G}_{\text{all}}$.
2. Direct the edges in $\mathcal{G}_{\text{start}}$ using orientation rules.

B. **Thinning, directing and decomposing $\mathcal{G}_{\text{start}}$**

1. For every node Y and its potential parent X both in $\mathcal{G}_{\text{start}}$, if $\exists \boldsymbol{S} \subset \{\boldsymbol{Pa}(Y, \mathcal{G}_{\text{ex}}) \cup \boldsymbol{Pa}_p(Y, \mathcal{G}_{\text{start}}) \backslash X\}$ and $|\boldsymbol{S}| = n$ such that $X \perp\!\!\!\perp Y \,|\, \boldsymbol{S}$, then remove the edge between X and Y from $\mathcal{G}_{\text{all}}$ and $\mathcal{G}_{\text{start}}$.
2. Direct the edges in $\mathcal{G}_{\text{start}}$ using orientation rules.
3. Group the nodes having the lowest topological order into a descendant sub-structure $\mathcal{G}_{\text{D}}$.
4. Remove $\mathcal{G}_{\text{D}}$ from $\mathcal{G}_{\text{start}}$ temporarily and define the resulting unconnected structures as ancestor sub-structures $\mathcal{G}_{\text{A}_1}, \ldots, \mathcal{G}_{\text{A}_k}$.

C. **Ancestor sub-structure decomposition**

For $i = 1$ to k, call $\text{RAI}[n+1, \mathcal{G}_{\text{A}_i}, \mathcal{G}_{\text{ex}}, \mathcal{G}_{\text{all}}]$.

D. **Descendant sub-structure decomposition**

1. Define $\mathcal{G}_{\text{ex}_{\text{D}}} = \{\mathcal{G}_{\text{A}_1}, \ldots, \mathcal{G}_{\text{A}_k}, \mathcal{G}_{\text{ex}}\}$ as the exogenous set to $\mathcal{G}_{\text{D}}$.
2. Call $\text{RAI}[n+1, \mathcal{G}_{\text{D}}, \mathcal{G}_{\text{ex}_{\text{D}}}, \mathcal{G}_{\text{all}}]$.
3. Set $\mathcal{G}_{\text{out}} = \mathcal{G}_{\text{all}}$ and exit.

Figure 4: The RAI algorithm.

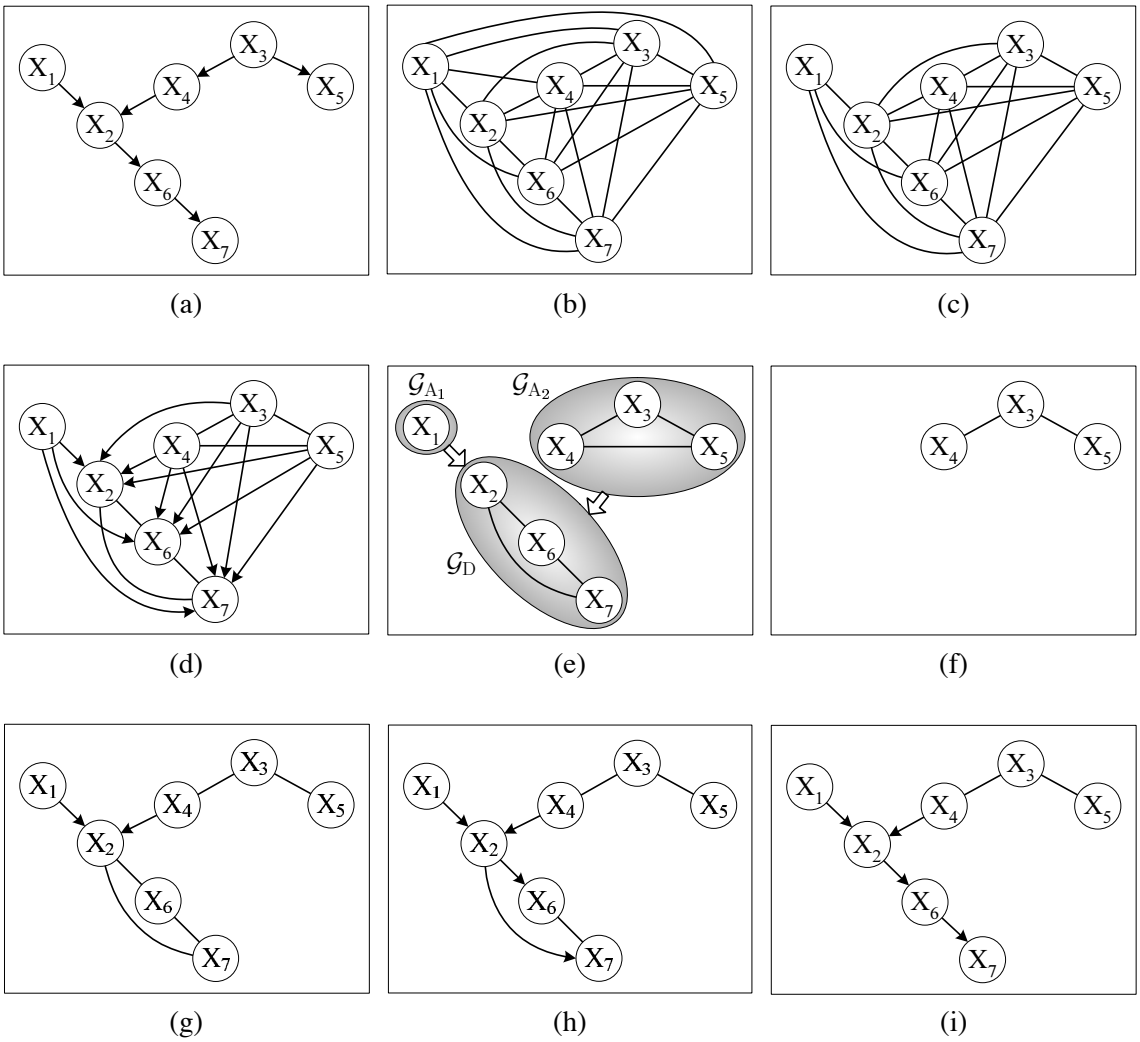

Figure 5: Learning an example structure. a) The true structure to learn, b) initial (complete) structure and structures learned by the RAI algorithm in Stages (see Figure 4) c) B1, d) B2, e) B3 and B4, f) C, g) D and A1, h) D and A2 and i) D, B1 and B2 (i.e., the resulting structure).

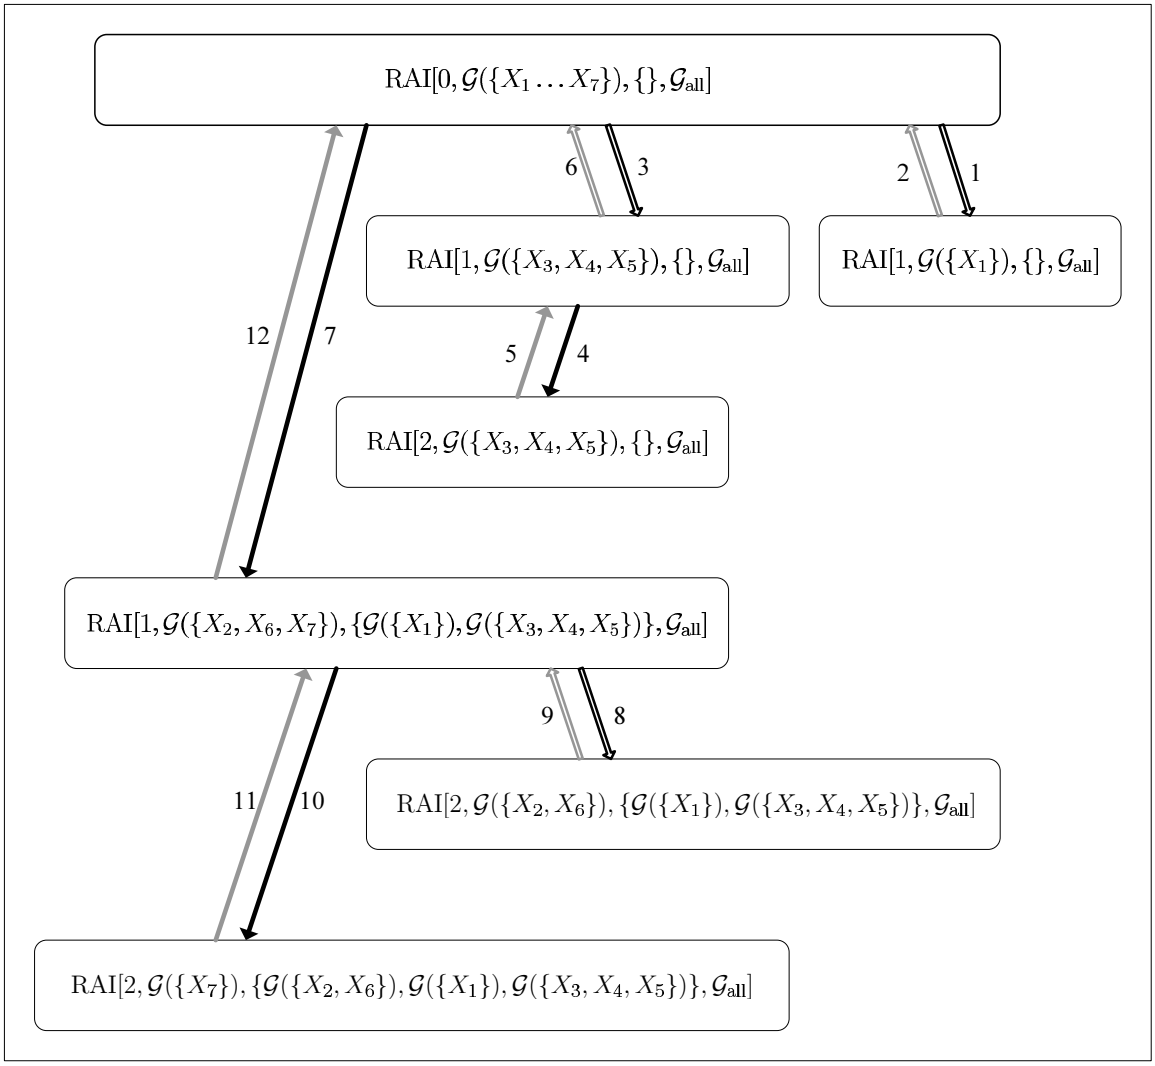

Figure 6: The execution order of the RAI algorithm for the example structure of Figure 5. Recursive calls of Stages C and D are marked with double and single arrows, respectively. The numbers annotating the arrows indicate the order of calls and returns of the algorithm.

empty and $\mathcal{G}_{\text{all}} = \mathcal{G}_{\text{start}}$, so Stage A is skipped. In Stage B1, any pair of nodes in $\mathcal{G}_{\text{start}}$ is CI tested given an empty condition set (i.e., checking marginal independence), which yields the removal of the edges between node X_1 and nodes X_3, X_4 and X_5 (Figure 5c). The edge directions inferred in Stage B2 are shown in Figure 5d. The nodes having the lowest topological order (X_2, X_6, X_7) are grouped into a descendant sub-structure $\mathcal{G}_{\text{D}}$ (Stage B3), while the remaining nodes form two unconnected ancestor sub-structures, $\mathcal{G}_{\text{A}_1}$ and $\mathcal{G}_{\text{A}_2}$ (Stage B4)(Figure 5e). Note that after decomposition, every edge between a node, X_i, in an ancestor sub-structure, and a node, X_j, in a descendant sub-structure is a directed edge $X_i \to X_j$. The set of all edges from an ancestor sub-structure to the descendant sub-structure is illustrated in Figure 5e by a wide arrow connecting the sub-structures. In Stage C, the algorithm is called recursively for each of the ancestor sub-structures with $n = 1$, $\mathcal{G}_{\text{start}} = \mathcal{G}_{\text{A}_i}$ $(i = 1,2)$ and $\mathcal{G}_{\text{ex}} = \emptyset$. Since sub-structure $\mathcal{G}_{\text{A}_1}$ contains a single node, the exit condition for this structure is satisfied. While calling $\mathcal{G}_{\text{start}} = \mathcal{G}_{\text{A}_2}$, Stage A is skipped, and in Stage B1 the algorithm identifies that $X_4 \perp\!\!\!\perp X_5 \,|\, X_3$, thus removing the edge $X_4 - X_5$. No orientations are identified (e.g., X_3 cannot be a collider, since it separated X_4 and X_5), so the three nodes have equal topological order and they are grouped to form a descendant sub-structure. The recursive call for this sub-structure with $n = 2$ is returned immediately, since the exit condition is satisfied (Figure 5f). Moving to Stage D, the RAI is called with $n = 1$, $\mathcal{G}_{\text{start}} = \mathcal{G}_{\text{D}}$ and $\mathcal{G}_{\text{ex}} = \{\mathcal{G}_{\text{A}_1}, \mathcal{G}_{\text{A}_2}\}$. Then, in Stage A1 relations $X_1 \perp\!\!\!\perp \{X_6, X_7\} \,|\, X_2$, $X_4 \perp\!\!\!\perp \{X_6, X_7\} \,|\, X_2$ and $\{X_3, X_5\} \perp\!\!\!\perp \{X_2, X_6, X_7\} \,|\, X_4$ are identified, and the corresponding edges are removed (Figure 5g). In Stage A2, X_6 and X_7 cannot collide at X_2 (since X_6 and X_7 are adjacent), and X_2 and X_6 (X_7) cannot collide at X_7 (X_6) (since X_2 and X_6 (X_7) are adjacent); hence, no additional V-structures are formed. Based on the inductive step and since X_1 is directed at X_2, X_2 should be directed at X_6 and at X_7. X_6 (X_7) cannot be directed at X_7 (X_6), because no new V-structures are allowed (Figure 5h). Stage B1 of the algorithm identifies the relation $X_2 \perp\!\!\!\perp X_7 \,|\, X_6$ and removes the edge $X_2 \to X_7$. In Stage B2, X_6 cannot be a collider of X_2 and X_7, since it has separated them. In the inductive step, X_6 is directed at X_7, $X_6 \to X_7$ (Figure 5i). In Stages B3 and B4, X_7 and $\{X_2, X_6\}$ are identified as a descendant sub-structure and an ancestor sub-structure, respectively. Further recursive calls (8 and 10 in Figure 6) are returned immediately, and the resulting partially directed structure (Figure 5i) represents a family of Markov equivalent structures (pattern) of the true structure (Figure 5a).

3.2 Minimality, Stability and Complexity

After describing the RAI algorithm (Section 3.1) and before proving its correctness (Section 3.3), we analyze in Section 3.2 three essential aspects of the algorithm—minimality, stability and complexity.

3.2.1 MINIMALITY

A structure recovered by the RAI algorithm in iteration m has a higher d-separation resolution and entails fewer dependences and thus is simpler and preferred[8] to a structure recovered in iteration $m-k$ where $0 < k \leq m$. By increasing the resolution, the RAI algorithm, similarly to the PC algorithm, moves from a complete undirected graph having maximal dependence relations between variables to structures having less (or equal) dependences than previous structures, ending in a structure having no edges between conditionally independent nodes, that is, a minimal structure.

8. We refer here to structures learned during algorithm execution and do not consider the empty graph that naturally has the lowest d-separation resolution (i.e., 0). This graph, having all nodes marginally independent of each other, will be found by the RAI algorithm immediately after the first iteration for graph resolution 0.

3.2.2 STABILITY

Similarly to Spirtes et al. (2000), we use the notion of stability informally to measure the number of errors in the output of a stage of the algorithm due to errors in the input to this stage. Similarly to the PC algorithm, the main sources of errors of the RAI algorithm are CI-testing and the identification of V-structures. Removal of an edge due to an erroneous CI test may lead to failure in correctly removing other edges, which are not in the true graph and also cause to orientation errors. Failure to remove an edge due to an erroneous CI test may prevent, or wrongly cause, orientation of edges. Missing or wrongly identifying a V-structure affect the orientation of other edges in the graph during the inductive stage and subsequent stages.

Many CI test errors (i.e., deciding that (in)dependence exists where it does not) in CB algorithms are the result of unnecessary large condition sets given a limited database size (Spirtes et al., 2000). Large condition sets are more likely to be inaccurate, since they are more likely to include unnecessary and erroneous nodes (erroneous due to errors in earlier stages of the algorithm). These sets may also cause poorer estimation of the criterion that measures dependence (e.g., CMI or χ^2) due to the curse-of-dimensionality, as typically there are only too few instances representing some of the combinations of node states. Either way, these condition sets are responsible for many wrong decisions about whether dependence between two nodes exists or not. Consequently, these errors cause structural inaccuracies and hence also poor inference ability.

Although CI-testing in the PC algorithm is more stable than V-structure identification (Spirtes et al., 2000), it is difficult to say whether this is also the case in the RAI algorithm. Being recursive, the RAI algorithm might be more unstable. However, CI test errors are practically less likely to occur, since by alternating between CI testing and edge direction the algorithm uses knowledge about parent-child relations before CI testing of higher orders. This knowledge permits avoiding some of the tests and decreases the size of conditions sets of some other tests (see Lemma 1). In addition, graph decomposition promotes decisions about well-founded orders of node presentation for subsequent CI tests, contrary to the common arbitrary order of presentation (see, e.g., the PC algorithm). Both mechanisms enhance stability and provide some means of error correction, as will be demonstrated shortly.

Let us now extensively describe examples that support our claim regarding the enhanced stability of the RAI algorithm. Suppose that following CI tests of some order both the PC and RAI algorithms identify a triplet of nodes in which two non-adjacent nodes, X and Y, are adjacent to a third node, Z, that is, $X - Z - Y$. In the immediate edge direction stage, the RAI algorithm identifies this triplet as a V-structure, $X \rightarrow Z \leftarrow Y$. Now, suppose that due to an unreliable CI test of a higher order the PC algorithm removes $X - Z$ and the RAI algorithm removes $X \rightarrow Z$. Eventually, both algorithms fail to identify the V-structure, but the RAI algorithm has an advantage over the PC algorithm in that the other arm of the V-structure is directed, $Z \leftarrow Y$. This contributes to the possibility to direct further edges during the inductive stage and subsequent recursive calls for the algorithm. The directed arm would also contribute to fewer CI tests and tests with smaller condition sets during CI testing with higher orders (e.g., if we later have to test independence between Y and another node, then we know that Z should not be included in the condition set, even though it is adjacent to Y). In addition, the direction of this edge also contributes to enhanced inference capability.

Now, suppose another example in which after removing all edges due to reliable CI tests using condition set sizes lower than or equal to n, the algorithm identifies the V-structure $X \rightarrow Z \leftarrow Y$ (Figure 7a). However, let assume that one of the V-structure arms, say $X \rightarrow Z$, is correctly removed

on a subsequent iteration using a larger condition set size (say $n+1$ without limiting the generality). We may be concerned that assuming a V-structure for the lower graph resolution, the RAI algorithm wrongly directs the second arm $Z - Y$ as $Z \leftarrow Y$. However, we demonstrate that the edge direction $Z \leftarrow Y$ remains valid even if there should be no edge $X - Z$ in the true graph. Suppose that $X \rightarrow Z$ was correctly removed conditioned on variable W, which is independent of Y given any condition set with a size smaller than or equal to n. Then, the possible underlying graphs are shown in Figures 7b-7d. The graph in Figure 7d is not possible, since it yields that X and Y are dependent given all condition sets of sizes smaller than or equal to n. In Figure 7b and Figure 7c, Z is a collider between W and Y, and thus the edge direction $Z \leftarrow Y$ remains valid. A different graph, $X \rightarrow W \leftarrow Z - Y$ (i.e., W is a collider), is not possible, since it means that $X \perp\!\!\!\perp Z \,|\, \boldsymbol{S}, |\boldsymbol{S}| \leq n, W \notin \boldsymbol{S}$ and then $X - Z$ should have been removed in a previous order (using condition set size of n or lower) and $X \rightarrow Z \leftarrow Y$ should not have been identified in the first place. Now, suppose that W and Y are dependant. In this case, the possible graphs are those shown in Figures 7e-7h. Similarly to the case in which W and Y are independent, W cannot be a collider of X and Z ($X \rightarrow W \leftarrow Z$) in this case as well. The graphs shown in Figures 7e-7g cannot be the underlying graphs since they entail dependency between X and Y given a condition set of size lower than or equal to n. The graph shown in Figure 7h exemplifies a V-structure $X \rightarrow W \leftarrow Y$. Since we assume that X and Z are independent given W (and thus $X - Z$ was removed), a V-structure $X \rightarrow W \leftarrow Z$ is not allowed. Since the edge $X \rightarrow W$ is already directed, the edge between W and Z must be directed as $W \rightarrow Z$. In this case, to avoid the cycle $Y \rightarrow W \rightarrow Z \rightarrow Y$, the edge between Y and Z must be directed as in the true graph, that is, $Y \rightarrow Z$.

Finally for the stability subsection, we note that the contribution of graph decomposition to structure learning using the RAI algorithm is threefold. First is the identification in early stages, using low-order, reliable CI tests, of the graph hierarchy, exemplifying the backbone of causal relations in the graph. For example, Figure 5e shows that learning our example graph (Figure 5a) from the complete graph (Figure 5b) demonstrates, immediately after the first iteration, that the graph is composed of three sub-structures—$\{X_1\}$, $\{X_2, X_6, X_7\}$ and $\{X_3, X_4, X_5\}$, where $\{X_1\} \rightarrow \{X_2, X_6, X_7\}$ and $\{X_3, X_4, X_5\} \rightarrow \{X_2, X_6, X_7\}$. This rough (low-resolution) partition of the graph is helpful in visualizing the problem and representing the current knowledge from the outset and along the learning. The second contribution of graph decomposition is the possibility to implement learning using a parallel processor for each sub-structure independently. This advantage may be further extended in the recursive calls for the algorithm.

Third is the contribution of graph decomposition to improved performance. Aiming at a low number of CI tests, decomposition provides a sound guideline for deciding on an educated order in which the edges should be CI tested. Based on this order, some tests can be considered redundant and thus be avoided. Several methods for selecting the right order for the PC algorithm were presented in Spirtes et al. (2000), but these methods are heuristic. Decomposition into ancestor and descendent sub-structures is followed by three levels of learning (Figure 4), that is, removing and directing edges 1) of ancestor sub-structures, 2) between ancestor and descendent sub-structures, and 3) of the descendent sub-structure. The second level has the greatest influence on further learning. The removal of edges between ancestor and descendent sub-structures and the sequential direction of edges in the descendant sub-structure assure that, first, fewer potential parents are considered, while learning the descendent sub-structure and second, more edges can be directed in this latter sub-structure. Moreover, these directed edges and the derived parent-child relations prevent an arbitrary selection order of nodes for CI testing and thereby enable employing smaller and more

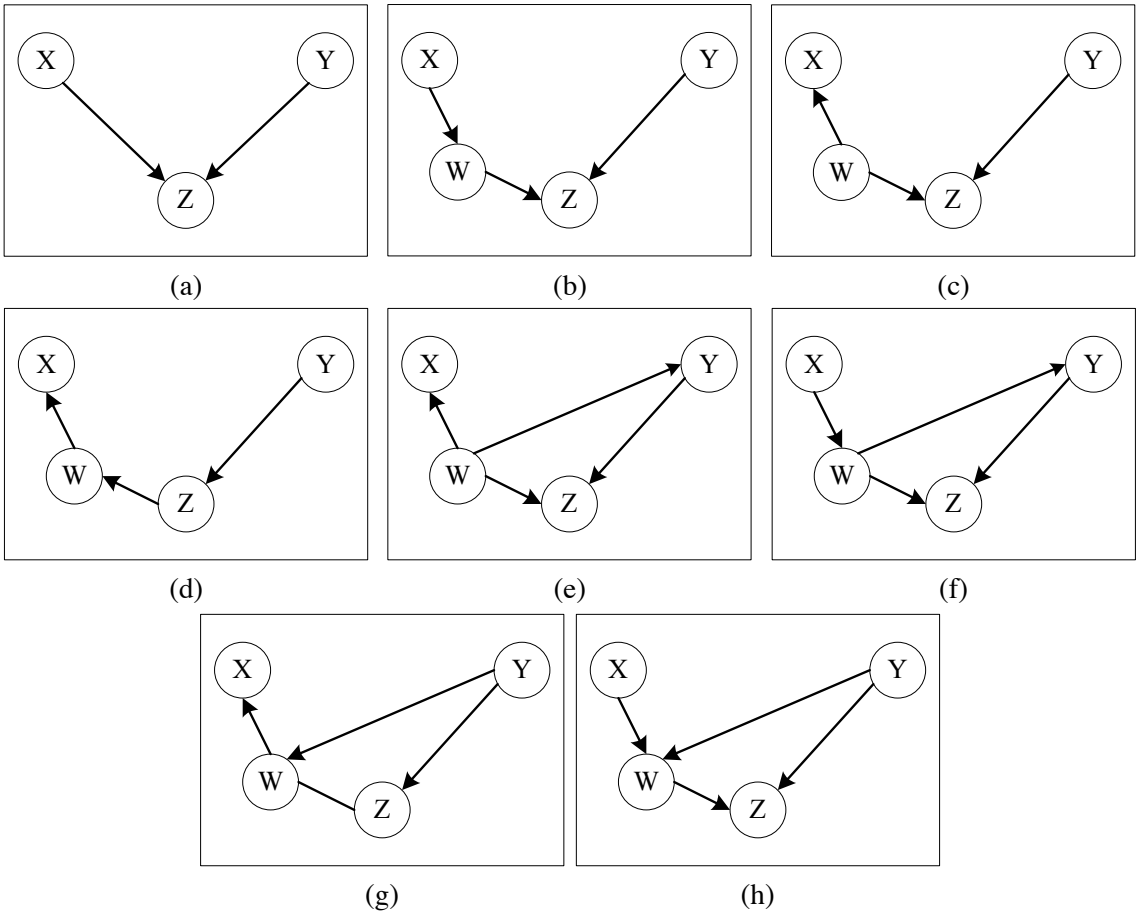

Figure 7: Graphs used to exemplify the stability of the RAI algorithm (see text).

accurate condition sets. Take, for example, CI testing for the redundant edge between X_2 and X_7 in our example graph (Figure 5i) if the RAI algorithm did not use decomposition. Graph decomposition for $n = 0$ (Figure 5e) enables the identification of two ancestor sub-structures, $\mathcal{G}_{\mathrm{A}_1}$ and $\mathcal{G}_{\mathrm{A}_2}$, as well as a descendent sub-structure $\mathcal{G}_{\mathrm{D}}$ that are each learned recursively. During Stage D (Figure 4) and while thinning the links between the ancestor sub-structures and $\mathcal{G}_{\mathrm{D}}$ (in Stage A1 of the recursion for $n = 1$), we identify the relations $X_1 \perp\!\!\!\perp \{X_6, X_7\} \,|\, X_2$, $X_4 \perp\!\!\!\perp \{X_6, X_7\} \,|\, X_2$ and $\{X_3, X_5\} \perp\!\!\!\perp \{X_2, X_6, X_7\} \,|\, X_4$ and remove the 10 corresponding edges (Figure 5g). The decision to test and remove these edges first was enabled by the decomposition of the graph to $\mathcal{G}_{\mathrm{A}_1}$, $\mathcal{G}_{\mathrm{A}_2}$ and $\mathcal{G}_{\mathrm{D}}$. In Stage A2 (Figure 5h), we direct the edge $X_2 \to X_6$ (as $X_1 \perp\!\!\!\perp X_6 \,|\, X_2$ and thus X_2 cannot be a collider between X_1 and X_6) and edge $X_2 \to X_7$ (as $X_1 \perp\!\!\!\perp X_7 \,|\, X_2$ and thus X_2 cannot be a collider between X_1 and X_7), and in Stage B (Figure 5i) we direct the edge $X_6 \to X_7$. The direction of these edges could not be assured without removing first the above edges, since the (redundant) edges pointing onto X_6 and X_7 would have allowed wrong edge direction, that is, $X_6 \to X_2$ and $X_7 \to X_2$. If we had been using the RAI algorithm with no decomposition (Figure 5d) (or the PC algorithm) and had decided to check the independence between X_2 and X_7, first, we would have had to consider condition sets containing the nodes X_1, X_3, X_4, X_5 or X_6 (up to 10 CI tests whether we start from

X_2 or X_7). Instead, we perform in Stage B1 only one test, $X_2 \perp\!\!\!\perp X_7 \,|\, X_6$. These benefits are the result of graph decomposition.

3.2.3 COMPLEXITY

CI tests are the major contributors to the (run-time) complexity of CB algorithms (Cheng and Greiner, 1999). In the worst case, the RAI algorithm will neither direct any edges nor decompose the structure and will thus identify the entire structure as a descendant sub-structure, calling Stages D and B1 iteratively while skipping all other stages. Then, the execution of the algorithm will be similar to that of the PC algorithm, and thus the complexity will be bounded by that of the PC algorithm. Given the maximal number of possible parents k and the number of nodes n, the number of CI tests is bounded by (Spirtes et al., 2000)

$$2\binom{n}{2}\cdot\sum_{i=0}^{k}\binom{n-1}{i}\leq\frac{n^2(n-1)^{k-1}}{(k-1)!},$$

which leads to complexity of $O(n^k)$.

This bound is loose even in the worst case (Spirtes et al., 2000) especially in real-world applications requiring graphs having V-structures. This means that in most cases some edges are directed and the structure is decomposed; hence, the number of CI tests is much smaller than that of the worst case. For example, by decomposing our example graph (Figure 5) into descendent and ancestor sub-structures in the first application of Stage B4 (Figure 5e), we avoid checking $X_6 \perp\!\!\!\perp X_7 \,|\, \{X_1, X_3, X_4, X_5\}$. This is because $\{X_1, X_3, X_4, X_5\}$ are neither X_6's nor X_7's parents and thus are not included in the (autonomous) descendent sub-structure. By checking only $X_6 \perp\!\!\!\perp X_7 \,|\, \{X_2\}$, the RAI algorithm saves CI tests that are performed by the PC algorithm. We will further elaborate on the RAI algorithm complexity in our forthcoming study.

3.3 Proof of Correctness

We prove the correctness of the RAI algorithm using Proposition 2. We show that only conditional independences (of all orders) entailed by the true underlying graph are identified by the RAI algorithm and that all V-structures are correctly identified. We then note on the correctness of edge direction.

Proposition 2: If the input data to the RAI algorithm are faithful to a DAG, $\mathcal{G}_{\text{true}}$, having any d-separation resolution, then the algorithm yields the correct pattern for $\mathcal{G}_{\text{true}}$.

Proof: We use mathematical induction to prove the proposition, where in each induction step, m, we prove that the RAI algorithm finds (a) all conditional independences of order m and lower, (b) no false conditional independences, (c) only correct V-structures and (d) all V-structures, that is, no V-structures are missing.

Base step ($m = 0$): If the input data to the RAI algorithm was generated from a distribution faithful to a DAG, $\mathcal{G}_{\text{true}}$, having d-separation resolution 0, then the algorithm yields the correct pattern for $\mathcal{G}_{\text{true}}$.

Given that the true underlying DAG has a d-separation resolution of 0, the data entail only marginal independences. In the beginning of learning, $\mathcal{G}_{\text{start}}$ is a complete graph and $m = 0$. Since

there are no exogenous causes, Stage A is skipped. In Stage B, the algorithm tests for independence between every pair of nodes with an empty condition set, that is, $X \perp\!\!\!\perp Y \,|\, \emptyset$ (marginal independence), removes the redundant edges and directs the remaining edges as possible. In the resulting structure, all the edges between independent nodes have been removed and no false conditional independences are entailed. Thus, all the identified V-structures are correct, as discussed in Section 3.2.2 on stability, and there are no missing V-structures, since the RAI algorithm has tested independence for all pair of nodes (edges). At the end of Stage B2 (edge direction), the resulting structure and $\mathcal{G}_{\text{true}}$ have the same set of V-structures and the same set of edges. Thus, the correct pattern for $\mathcal{G}_{\text{true}}$ is identified. Since the data entail only independences of zero order, further recursive calls with $m \geq 1$ will not find independences with condition sets of size m, and thus no edges will be removed, leaving the graph unchanged.

Inductive step $(m+1)$: Suppose that at induction step m, the RAI algorithm discovers all conditional independences of order m and lower, no false conditional independences are entailed, all V-structures are correct, and no V-structures are missing. Then, if the input data to the RAI algorithm was generated from a distribution faithful to a DAG, $\mathcal{G}_{\text{true}}$, having d-separation resolution $m+1$, then the RAI algorithm would yield the correct pattern for that graph.

In step m, the RAI algorithm discovers all conditional independences of order m and lower. Given input data faithful to a DAG, $\mathcal{G}_{\text{true}}$, having d-separation resolution $m+1$, there exists at least one pair of nodes, say $\{X,Y\}$, in the true graph, that has a d-separation resolution of $m+1$.[9] Since the RAI, by the recursive call $m+1$ (i.e., calling RAI$[m+1, \mathcal{G}_{\text{start}}, \mathcal{G}_{\text{ex}}, \mathcal{G}_{\text{all}}]$), has identified only conditional independences of order m and lower, an edge, $E_{XY} = (X - Y)$, exists in the input graph, $\mathcal{G}_{\text{start}}$. The smallest condition set required to identify the independence between X and Y is $\boldsymbol{S}_{XY}$ ($X \perp\!\!\!\perp Y \,|\, \boldsymbol{S}_{XY}$), such that $|\boldsymbol{S}_{XY}| \geq m+1$. Thus, $|\boldsymbol{Pa}_p(X) \backslash Y| \geq m+1$ or $|\boldsymbol{Pa}_p(Y) \backslash X| \geq m+1$, meaning that either node X or node Y has at least $m+2$ potential parents. Such an edge exists in at least one of the autonomous sub-structures decomposed from the graph yielded at the end of iteration m. When calling, in Stage C or Stage D, the algorithm recursively for this sub-structure with $m' = m+1$, the exit condition is not satisfied because either node X or node Y has at least $m'+1$ parents. Since Step m assured that the sub-structure is autonomous, it contains all the necessary node parents. Note that decomposition into ancestor, $\mathcal{G}_{\text{A}}$, and descendant, $\mathcal{G}_{\text{D}}$, sub-structures occurs after identification of all nodes having the lowest topological order, such that every edge from a node X in $\mathcal{G}_{\text{A}}$ to a node Y in $\mathcal{G}_{\text{D}}$ is directed, $X \rightarrow Y$. In the case that the sub-structure is an ancestor sub-structure, $\boldsymbol{S}_{XY}$ contains nodes of the sub-structure and its exogenous causes. In the case that the sub-structure is a descendant sub-structure, $\boldsymbol{S}_{XY}$ contains nodes from the ancestor sub-structures and the descendant sub-structure. Therefore, based on Proposition 1, the RAI algorithm tests all edges using condition sets of sizes m' and removes E_{XY} (and all similar edges) in either Stage A or Stage B, yielding a structure with d-separation resolution of m' and thereby yields the correct pattern for the true underlying graph of d-separation resolution $m+1$.

Spirtes (2001)—when introducing the anytime fast casual inference (AFCI) algorithm—proved the correctness of edge direction of AFCI. The AFCI algorithm can be interrupted at any stage (resolution), and the resultant graph at this stage is correct with probability one in the large sample

9. If the d-separation resolution of $\{X,Y\}$ is $m' > m+1$, then the RAI algorithm will not modify the graph until step m'.

limit, although possibly less informative[10] than if had been allowed to continue uninterrupted.[11] Recall that interrupting learning means that we avoid CI tests of higher orders. This renders the resultant graph more reliable. We use this proof here for proving the correctness of edge direction in the RAI algorithm. Completing CI testing with a specific graph resolution n in the RAI algorithm and interrupting the AFCI at any stage of CI testing are analogous. Furthermore, Spirtes (2001) proves that interrupting the algorithm at any stage is also possible during edge direction, that is, once an edge is directed, the algorithm never changes that direction. In Section 3.2.2, we showed that even if a directed edge of a V-structure is removed, the direction of the remaining edge is still correct. Since directing edges by the AFCI algorithm after interruption yields a correct (although less informative) graph (Spirtes, 2001), also the direction of edges by the RAI algorithm yields a correct graph. Having (real) parents in a condition set used for CI testing, instead of potential parents, which are the result of edge direction for resolutions lower than n, is a virtue, as was confirmed in Section 3.1. All that is required that all parents, either real or potential, be included within the corresponding condition set, and this is indeed guaranteed by the autonomy of each substructure, as was proved above. ■

4. Experiments and Results

We compare the RAI algorithm with other state-of-the-art algorithms with respect to structural correctness, computational complexity, run-time and classification accuracy when the learned structure is used in classification. The algorithms learned structures from databases representing synthetic problems, real decision support systems and natural classification problems. We present the experimental evaluation in four sections. In Section 4.1, the complexity of the RAI algorithm is measured by the number of CI tests required for learning synthetically generated structures in comparison to the complexity of the PC algorithm (Spirtes et al., 2000).

The order of presentation of nodes is not an input to the PC algorithm. Nevertheless, CI testing of orders higher than 0, and therefore also edge directing, which depends on CI testing, may be sensitive to that order. This may cause learning different graphs whenever the order is changed. Dash and Druzdzel (1999) turned this vice of the PC algorithm into a virtue by employing the partially directed graphs formed by using different orderings for the PC algorithm as the search space from which the structure having the highest value of the K2 metric (Cooper and Herskovits, 1992) is selected. For the RAI algorithm, sensitivity to the order of presentation of nodes is expected to be reduced compared to the PC algorithm, since the RAI algorithm, due to edge direction and graph decomposition, decides on the order of performing most of the CI tests and does not use an arbitrary order (Section 3.2.2). Nevertheless, to account for the possible sensitivity of the RAI and PC algorithms to this order, we preliminarily employed 100 different permutations[12] of the order for each of ten Alarm network (Beinlich et al., 1989) databases. Since the results of these experiments

10. Less informative in the sense that it answers "can't tell" for a larger number of questions; that is, identifying, for example, "$\circ$" edge endpoint (placing no restriction on the relation between the pair of nodes making the edge) instead of "$\rightarrow$" endpoint.
11. The AFCI algorithm is also correct if hidden and selection variables exist. A selection variable models the possibility of an observable variable having some missing data. We focus here on the case where neither hidden nor selection variables exist.
12. Dash and Druzdzel (1999) examined the relationships between the number of order permutations and the numbers of variables and instances. We fixed the number of order permutations at 100.

had showed that the difference in performance for different permutations is slight, we further limited the experiments with the PC and RAI algorithms to a single permutation.

In Section 4.2, we present our methodology of selecting a threshold for RAI CI testing. We propose selecting a threshold for which the learned structure has a maximum of a likelihood-based score value.

In Section 4.3, we use the Alarm network (Beinlich et al., 1989), which is a widely accepted benchmark for structure learning, to evaluate the structural correctness of graphs learned by the RAI algorithm. The correctness of the structure recovered by RAI is compared to those of structures learned using other algorithms—PC, TPDA (Cheng et al., 1997), GES (Chickering, 2002; Meek, 1997), SC (Friedman et al., 1999) and MMHC (Tsamardinos et al., 2006a). The PC and TPDA algorithms are the most popular CB algorithms (Cheng et al., 2002; Kennett et al., 2001; Marengoni et al., 1999; Spirtes et al., 2000); GES and SC are state-of-the-art S&S algorithms (Tsamardinos et al., 2006a); and MMHC is a hybrid algorithm that has recently been developed and showed superiority, with respect to different criteria, over all the (non-RAI) algorithms examined here (Tsamardinos et al., 2006a). In addition to correctness, the complexity of the RAI algorithm, as measured through the enumeration of CI tests and log operations, is compared to those of the other CB algorithms (PC and TPDA) for the Alarm network.

In Section 4.4, we extend the examination of RAI in structure learning to known networks other than the Alarm. Although the Alarm is a popular benchmark network, many algorithms perform well for this network. Hence, it is important to examine RAI performance on other networks for which the true graph is known. In the comparison of RAI to other algorithms, we included all the algorithms of Section 4.3, as well as the Optimal Reinsertion (OR) (Moore and Wong, 2003) algorithm and a greedy hill-climbing search algorithm with a Tabu list (GS) (Friedman et al., 1999). We compared algorithm performances with respect to structural correctness, run-time, number of statistical calls and the combination of correctness and run-time.

In Section 4.5, the complexity and run-time of the RAI algorithm are compared to those of the PC algorithm using nineteen natural databases. In addition, the classification accuracy of the RAI algorithm for these databases is compared to those of the PC, TPDA, GES, MMHC, SC and naive Bayesian classifier (NBC) algorithms. No structure learning is required for NBC and all the domain variables are used. This classifier is included in the study as a reference to a simple, yet accurate, classifier. Because we are interested in this section in classification, and a likelihood-based score does not reflect the importance of the class variable in structures used for classification (Friedman et al., 1997; Kontkanen et al., 1999; Grossman and Domingos, 2004; Yang and Chang, 2002), we prefer here the classification accuracy score in evaluating structure performance.

In the implementations of all sections, except Section 4.4, we were aided by the Bayes net toolbox (BNT) (Murphy, 2001), BNT structure learning package (Leray and François, 2004) and PowerConstructor software (Cheng, 1998) and evaluated all algorithms ourselves. In Section 4.4, we downloaded and used the results reported in Tsamardinos et al. (2006a) for the non-RAI algorithms and used the Causal Explorer algorithm library (Aliferis et al., 2003) (http://www.dsl-lab.org/causal_explorer/index.html). The Causal Explorer algorithm library makes use of methods and values of parameters for each algorithm as suggested by the authors of each algorithm (Tsamardinos et al., 2006a). For example, BDeu score (Heckerman et al., 1995) with equivalent sample size 10 for GS, GES, OR and MMHC; χ^2 p-values at the standard 5% for the MMHC's and PC's statistical thresholds; threshold of 1% for the TPDA mutual information test; the Bayesian scoring heuristic, equivalent sample size of 10 and maximum allowed sizes for the candidate parent

set of 5 and 10 for SC; and maximum number of parents allowed of 5, 10 and 20 and maximum allowed run time, which is one and two times the time used by MMHC on the corresponding data set, for OR. The only parameter that requires optimization in the RAI algorithm (similar to the other CB algorithms - PC and TPDA) is the CI testing threshold. We use no prior knowledge to find this threshold but a training set for each database (see Section 4.2 for details). Note, however that we do not account for the time required for selecting the threshold when reporting the execution time.

4.1 Experimentation with Synthetic Data

The complexity of the RAI algorithm was evaluated in comparison to that of the PC algorithm by the number of CI tests required to learn synthetically generated structures. Since the true graph is known for these structures, we could assume that all CI tests were correct and compare the numbers of CI tests required by the algorithms to learn the true independence relationships. In one experiment, all 29,281 possible structures having 5 nodes were learned using the PC and RAI algorithms. The average number of CI tests employed by each algorithm is shown in Figure 8a for increasing orders (condition set sizes). Figure 8b depicts the average percentages of CI tests saved by the RAI algorithm compared to the PC algorithm for increasing orders. These percentages were calculated for each graph independently and then averaged. It is seen that the advantage of the RAI algorithm over the PC algorithm is more prominent for high orders.

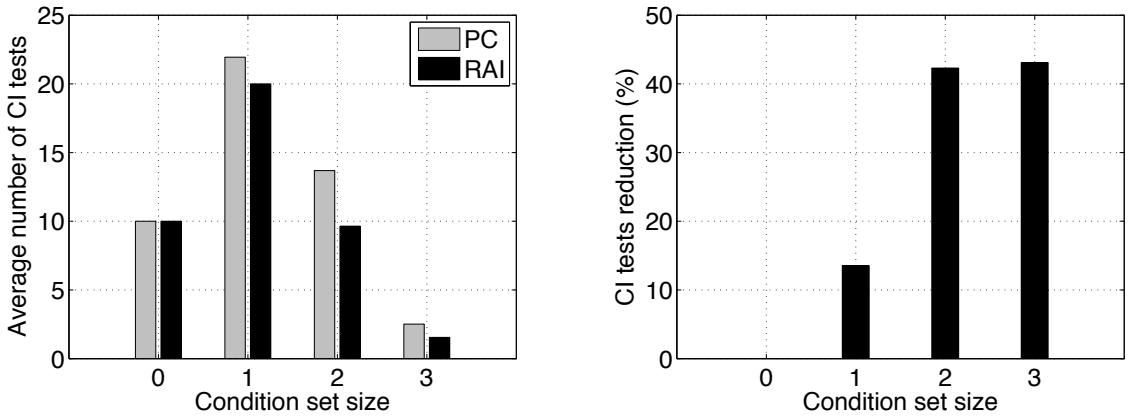

Figure 8: Measured for increasing orders, the (a) average number of CI tests required by the RAI and PC algorithms for learning all possible structures having five nodes and (b) average over all structures of the reduction percentage in CI tests achieved by the RAI algorithm compared to the PC algorithm.

In another experiment, we learned graphs of sizes (numbers of nodes) between 6 and 15. We selected from a large number of randomly generated graphs 3,000 graphs that were restricted by a maximal fan-in value of 3; that is, every node in such a graph has 3 parents at most and at least one node in the graph has 3 parents. This renders a practical learning task. Thus, the structures can theoretically be learned by employing CI tests of order 3 and below and should not use tests of orders higher than 3. In such a case, the most demanding test, having the highest impact on

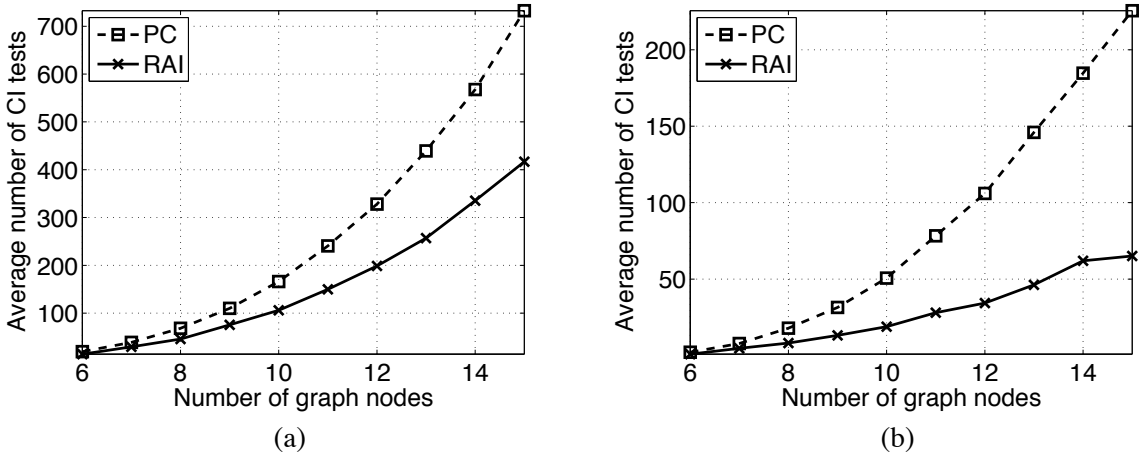

Figure 9: Average number of CI tests required by the PC and RAI algorithms for increasing graph sizes and orders of (a) 3 and (b) 4.

computational time, is of order 3. Figure 9a shows the average numbers of CI tests performed for this order by the PC and RAI algorithms for graphs with increasing sizes. Moreover, because the maximal fan-in is 3, all CI tests of order 4 are a priori redundant, so we can further check how well each algorithm avoids these unnecessary tests. Figure 9b depicts the average numbers of CI tests performed by the two algorithms for order 4 and graphs with increasing sizes. Both Figure 9a and Figure 9b show that the number of CI tests employed by the RAI algorithm increases more slowly with the graph size compared to that of the PC algorithm and that this advantage is much more significant for the redundant (and more costly) CI tests of order 4.

We further expanded the examination of the algorithms in CI testing for different graph sizes and CI test orders. Figure 10 shows the average number and percentage of CI tests saved using the RAI algorithm compared to the PC algorithm for different condition set sizes and graph sizes. The number of CI tests having an empty condition set employed by each of the algorithms is equal and is therefore omitted from the comparison. The figure shows that the percentage of CI tests saved using the RAI algorithm increases with both graph and condition set sizes. For example, the saving in CI tests when using the RAI algorithm instead of the PC algorithm for learning a graph having 15 nodes and using condition sets of size 4 is above 70% (Figure 10b). In Section 4.4, we will demonstrate the RAI quality of requiring relatively fewer tests of high orders than of low orders for graphs of larger sizes for real, rather than synthetic, data.

4.2 Selecting the Threshold for RAI CI Testing

CI testing for the RAI algorithm can be based on the χ^2 test as for the PC algorithm or the conditional mutual information (CMI) as for the TPDA algorithm. The CMI between nodes X and Y conditioned on a set of nodes $\boldsymbol{Z}$ (i.e., the condition set), is:

$$\mathrm{CMI}(X,Y|\boldsymbol{Z}) = \sum_{i=1}^{N_X}\sum_{j=1}^{N_Y}\sum_{k=1}^{N_Z}\left[P(x_i,y_j,\boldsymbol{z}_k)\cdot\log\frac{P(x_i,y_j|\boldsymbol{z}_k)}{P(x_i|\boldsymbol{z}_k)\cdot P(y_j|\boldsymbol{z}_k)}\right], \tag{2}$$

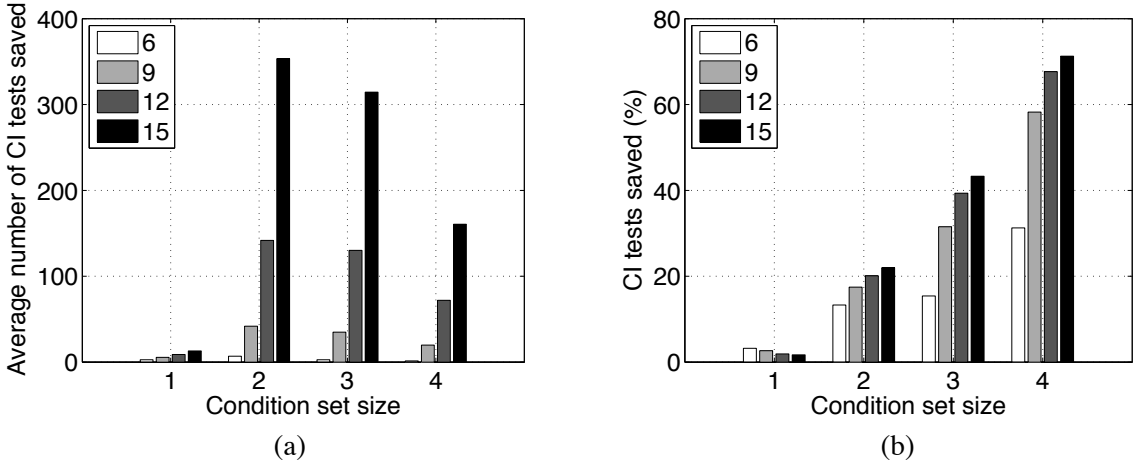

Figure 10: (a) Average number and (b) percentage of CI tests saved by using the RAI algorithm compared to the PC algorithm for graph sizes of 6, 9, 12 or 15 (gray shades) and orders between 1 and 4.

where x_i and y_j represent, respectively, states of X and Y, z_k represents a combination of states of all variables in $\boldsymbol{Z}$, and N_X, N_Y and N_Z are the numbers of states of X, Y and $\boldsymbol{Z}$, respectively.

In both CI testing methods, the value of interest (either χ^2 or CMI) is compared to a threshold. For example, CMI values that are higher or lower than the threshold indicate, respectively, conditional dependence or independence between X and Y given $\boldsymbol{Z}$. However, the optimal threshold is unknown beforehand. Moreover, the optimal threshold is problem and data-driven, that is, it depends, on the one hand, on the database and its size and, on the other hand, on the variables and the numbers of their states. Thus, it is not possible to set a "default" threshold value that will accurately determine conditional (in)dependence while using any database or problem.

To find an optimal threshold for a database, we propose to score structures learned using different thresholds by a likelihood-based criterion evaluated using the training (actually validation) set and to select the threshold leading to the structure achieving the highest score. Such a score may be BDeu (Heckerman et al., 1995), although other scores (Heckerman et al., 1995) may also be appropriate. Note that BDeu scores equally statistically indistinguishable structures. Figure 11 shows BDeu values for structures learned by RAI for the Alarm network using different CMI threshold values. The maximum BDeu value was achieved at a threshold value of 4e-3 that was selected as the threshold for RAI CI testing for the Alarm network.

To assess the threshold selected using the suggested method, we employed the Alarm network and computed the errors between structures learned using different thresholds and the pattern that corresponds to the true known graph. Following Spirtes et al. (2000) and Tsamardinos et al. (2006a), we define five types of structural errors to evaluate structural correctness. An extra edge (commission; EE) error is due to an edge learned by the algorithm although it does not exist in the true graph. A missing edge (omission; ME) error is due to an edge missed by the algorithm although exists in the true graph. An extra direction (ED) error is due to edge direction that appears in the learned graph but not in the true graph, whereas a missing direction (MD) error is due to edge direction that

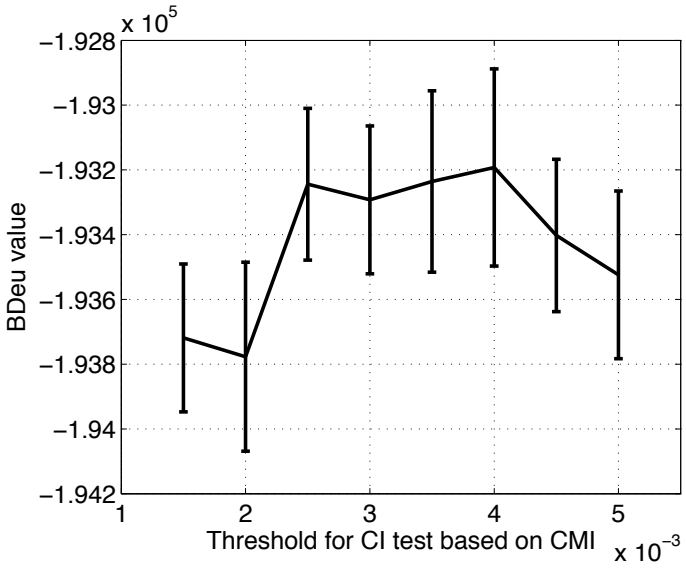

Figure 11: BDeu values averaged over ten validation sets consisting of 10,000 samples each drawn from the Alarm network for increasing CMI thresholds used in CI testing for the RAI algorithm.

appears in the true graph but not in the learned graph. Finally, a reversed direction (RD) error is due to edge direction in the learned graph that is opposite to the edge direction in the true graph.

Figure 12a shows the sensitivity of the five structural errors to the CMI threshold. Each point on the graph is the average error over ten validation databases containing 10,000 randomly sampled instances each. Figure 12a demonstrates that the MD, RD and ED errors are relatively constant in the examined range of thresholds and the ME error increases monotonically. The EE error is the highest error among the five error types, and it has a minimum at a threshold value of 3e-3.

In Figure 12b, we cast the three directional errors using the total directional error (DE), DE = ED + MD + RD, and plot this error together with the ME and EE errors. The impact of each error for increasing thresholds is now clearer; the contribution of the DE error is almost constant, that of the ME error increases with the threshold but is less than DE, and that of the EE error dominants for every threshold.

Tsamardinos et al. (2006a) suggested assessing the quality of a learned structure using the structural Hamming distance (SHD) metric, which is the sum of the five above errors. We plot in Figure 12c this error for the experiment with the Alarm network. Comparison of the threshold responsible for the minimum of the SHD error (2.5e-3) to that selected according to BDeu (4e-3 in Figure 11) shows only a small difference, especially as the maximum values of BDeu are obtained between thresholds of 2.5e-3 and 4e-3. This result motivates using the BDeu score, as measured on a validation set, as a criterion for finding good thresholds for RAI CI testing. Thresholds that are smaller than this range lead to too many pairs of variables that are wrongly identified as dependent and thus the edges between them are not removed, contributing to high EE errors (see, for example, Figure 12b). In addition, for thresholds higher than 3e-3, more edges are wrongly removed, contributing to high ME errors.

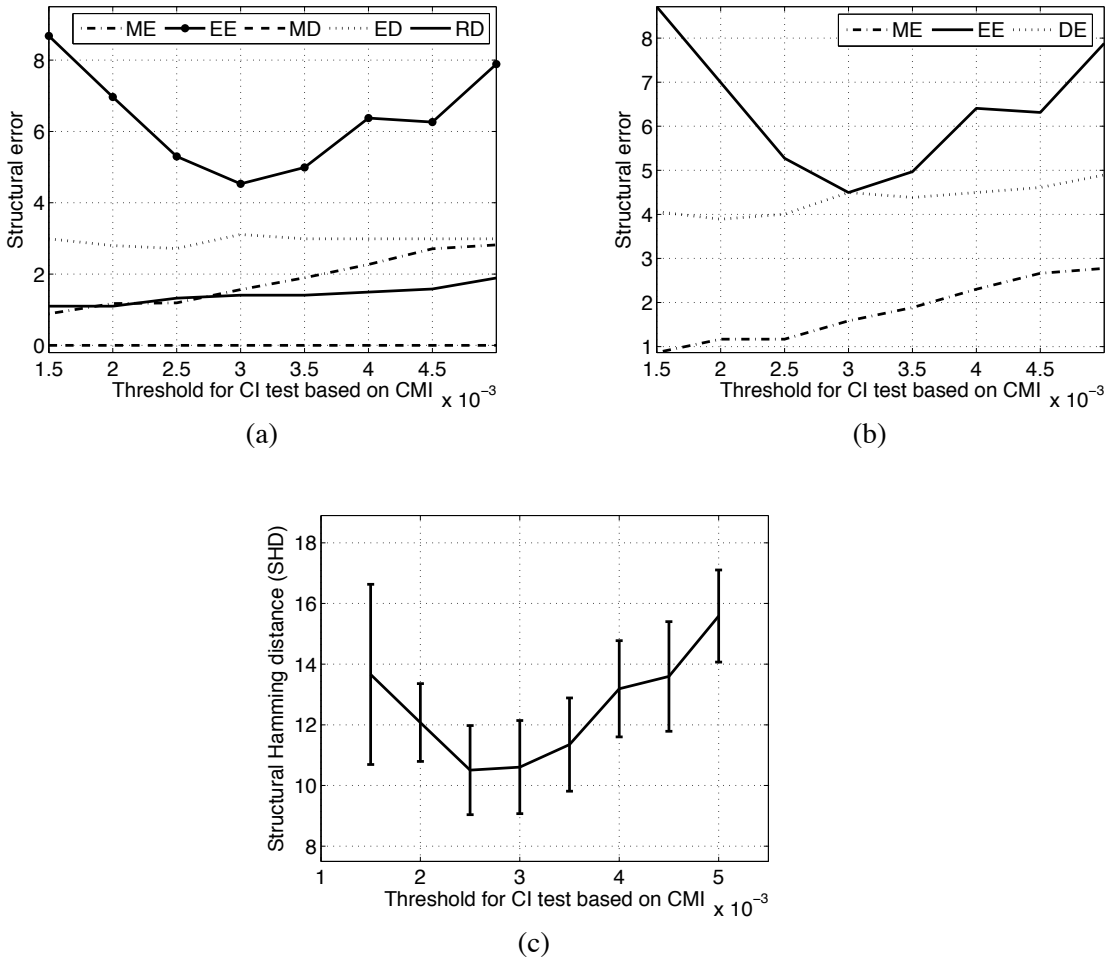

Figure 12: Structural errors of the RAI algorithm learning the Alarm network for different CMI thresholds as averaged over ten validation sets of 10,000 samples each. (a) Five types (ME, EE, MD, ED and RD) of structural errors, (b) EE, ME and DE errors, and (c) SHD error (mean and std).

4.3 Learning the Alarm Network

For evaluating the correctness of learned BN structures, we used the Alarm network, which is widely accepted as a benchmark for structure learning algorithms, since the true graph for this problem is known. The RAI algorithm was compared to the PC, TPDA, GES, SC and MMHC algorithms using ten databases containing 10,000 random instances each sampled from the network.

Structural correctness can be measured using different scores. However, some of the scores suggested in the literature are not always accurate or related to the true structure. For example, Tsamardinos et al. (2006a), who examined the BDeu score (Heckerman et al., 1995) and KL divergence (Kullback and Leibler, 1951) in evaluating learned networks, noted that it is not known in practice to what degree the assumptions (e.g., a Dirichlet distribution of the hyperparameters) in the

	Extra Direction (ED)	Missing Direction (MD)	Reversed Direction (RD)	Directional Error (DE)	Extra Edge (EE)	Missing Edge (ME)	SHD
SC	1	9.5	4.6	15.1	4.7	4.5	24.3
MMHC	0.8	3.3	5.7	9.8	2.6	**0.7**	13.1
GES	0.1	0.6	1.2	1.9	2.7	0.8	5.4
TPDA	**0**	4.2	**0**	4.2	2.4	2.9	9.5
PC	**0**	**0**	0.8	0.8	2.5	1.0	4.3
RAI	**0**	**0**	0.3	**0.3**	**1.8**	1.4	**3.5**

Table 1: Structural errors of several algorithms as averaged over 10 databases each containing 10,000 randomly generated instances of the Alarm network. The total directional error is the sum of three different directional errors, DE=ED+MD+RD, and the SHD error is DE+EE+ME. Bold font emphasizes the smallest error over all algorithms for each type of structural error.

basis of the BDeu score hold. Moreover, usually such a score is used in both learning and evaluation of a structure; hence the score favors algorithms that use it in learning. Tsamardinos et al. (2006a) also mentioned that both scores do not rely on the true structure. Thus, they suggested the SHD metric, which is directly related to structural correctness, since it is the sum of the five errors of Section 4.2. Nevertheless, since SHD can be measured only when the true graph is known, scores such as BDeu and KL divergence are of great value in practical situations, for example, in classification problems like those examined in Section 4.5 in which the true graph is not known. These scores are also beneficial in the determination of algorithm parameters. For example, in Section 4.2 we measured BDeu scores of structures learned using different thresholds in order to select a good threshold for RAI CI testing.

Although SHD sums all five structural errors, we were first interested in examining the contribution of each individual error to the total error. Table 1 summarizes the five structural errors for each algorithm as averaged over 10 databases of 10,000 instances each sampled from the Alarm network. These databases are different from those validation databases used for threshold setting. The table also shows the total directional error, DE, which is the sum of the three directional errors. Table 1 demonstrates that the lowest EE and DE errors are achieved by the RAI algorithm and the lowest ME error is accomplished by the MMHC algorithm. Computing SHD shows the advantage of the RAI (3.5) algorithm over the PC (4.3), TPDA (9.5), GES (5.4), MMHC (13.1) and the SC (24.3) algorithms. Further, we propose such a table as Table 1 as a useful tool for the identification of the sources of structural errors of a given structure learning algorithm.

Note that the SHD error weighs each of the five error types equally. We believe that a score that weighs the five types based on their relative significance to structure learning will be a more accurate method to evaluate structural correctness; however, deriving such a score is a topic for future research.

Complexity was evaluated for each of the CB algorithms by measuring the number of CI tests employed for each order (condition set size) and the total number of log operations. The latter criterion is proportional to the total number of multiplications, divisions and logarithm evaluations that is required for calculating the CMI (Equation 2) during CI testing. Figure 13 depicts the average

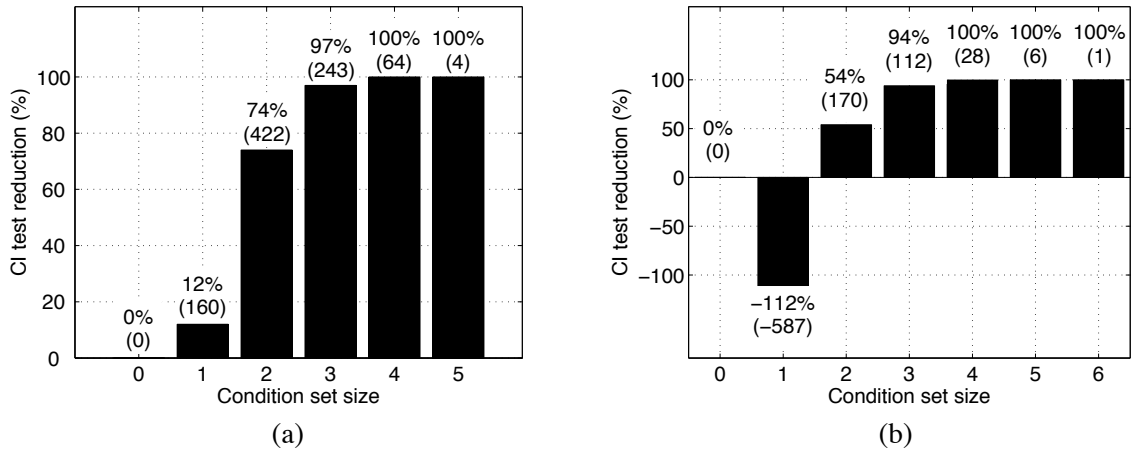

Figure 13: Average percentage (number) of CI tests reduced by using RAI compared to using (a) PC and (b) TPDA, as a function of the condition set size when learning the Alarm network.

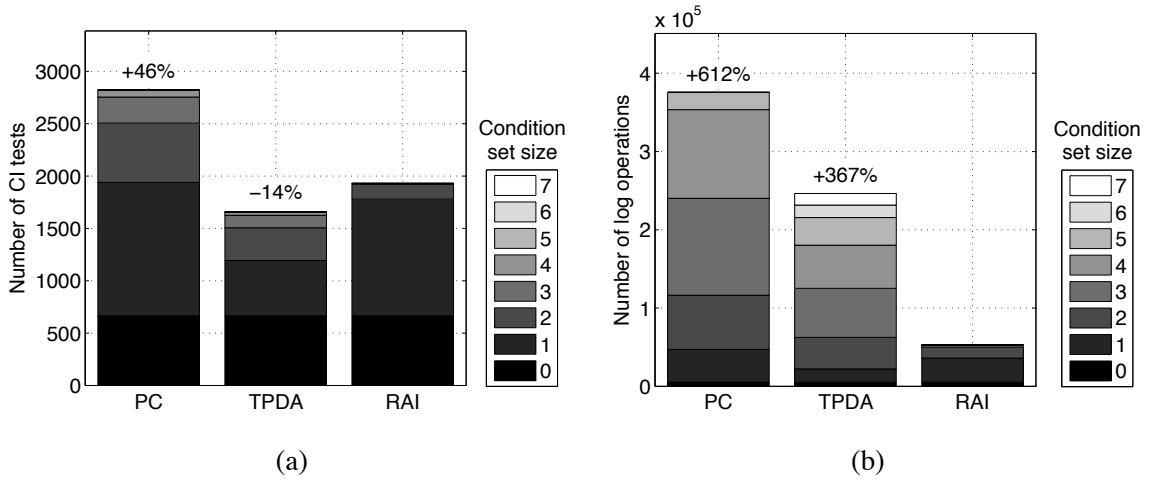
percentage (and number) of CI tests reduced by using the RAI algorithm compared to using the PC or TPDA algorithms for increasing sizes of the condition sets. The RAI algorithm reduces the number of CI tests of orders 1 and above required by the PC algorithm and those of orders 2 and above required by the TPDA algorithm. Moreover, the RAI algorithm completely avoids the use of CI tests of orders 4 and above and almost completely avoids CI tests of order 3 compared to both the PC and TPDA algorithms. However, the RAI algorithm performs more CI tests of order 1 than the TPDA algorithm.

Figure 14 summarizes the total numbers of CI tests and log operations over different condition set sizes required by each algorithm. The RAI algorithm requires 46% less CI tests than the PC algorithm and 14% more CI tests (of order 1) than the TPDA algorithm. However, the RAI algorithm significantly reduces the number of log operations required by the other two algorithms. The PC or TPDA algorithms require, respectively, an additional 612% or 367% of the number of log operations required by the RAI algorithm. The reason for this substantial advantage of the RAI algorithm over both the PC and TPDA algorithms is the saving in CI tests of high orders (see Figure 13). These tests make use of large condition sets and thus are very expensive computationally.

4.4 Learning Known Networks

In addition to the state-of-art algorithms that were compared in Section 4.3, we include in this section the OR and GS algorithms. We compare the performance of the RAI algorithm to these algorithms by learning the structures of known networks employed in real decision support systems from a wide range of applications. We use known networks described in Tsamardinos et al. (2006a), which include the Alarm (Beinlich et al., 1989), Barley (Kristensen and Rasmussen, 2002), Child (Cowell et al., 1999), Hailfinder (Jensen and Jensen, 1996), Insurance (Binder et al., 1997), Mildew (Jensen and Jensen, 1996) and Munin (Andreassen et al., 1989) networks. All these networks may be downloaded from the Causal Explorer webpage. The Pigs, Link and Gene networks, which were also evaluated in Tsamardinos et al. (2006a), are omitted from our experiment due to memory and



(a) (b)

Figure 14: Cumulative numbers of (a) CI tests and (b) log operations required by PC, TPDA, and RAI for learning the Alarm network. Different gray shades represent different sizes of condition sets. Percentages on tops of the bars are with reference to the RAI algorithm.

run-time limitations of the platform used in our experiment. These limitations are in the computation of the BDeu scoring function (part of the BNT toolbox) that is used for selecting a threshold for the RAI CI tests (Section 4.2).

The Casual Explorer webpage also contains larger networks that were created by tiling networks, such as the Alarm, Hailfinder, Child and Insurance, 3, 5 and 10 times. In the tiling method developed by Tsamardinos et al. (2006b), several copies (here 3, 5 and 10) of the same BN are tiled until reaching a network having a desired number of variables (e.g., Alarm5 has $5 \times 37 = 185$ variables). The method maintains the structural and probabilistic properties of the original network but allows the evaluation of the learning algorithm as the number of variables increases without increasing the complexity of the network. Overall, we downloaded and used nineteen networks, the most important details of which are shown in Table 2. Further motivation for using these networks and tiling is given in Tsamardinos et al. (2006a).

Throughout this experiment, we used for each network the same training and test sets as used in Tsamardinos et al. (2006a), so we could compare the performance of the RAI to all the algorithms reported in Tsamardinos et al. (2006a). The data in the Causal Explorer webpage are given for each network using five training sets and five test sets with 500, 1000 and 5,000 samples each. We picked and downloaded the data sets with the smallest sample size (500), which we believe challenge the algorithms the most. All the reported results for a network and a learning algorithm in this subsection are averages over five experiments in which a different training set was used for training the learning algorithm and a different test set was used for testing this algorithm.

The RAI algorithm was run by us. CMI thresholds for CI testing corresponded to the maximum BDeu values were obtained in five runs using five validation sets independent of the training and test sets, and performances were averaged over the five validation sets. We note that the thresholds selected according to the maximum BDeu values (Section 4.2) also led to the lowest SHD errors. The OR algorithm was examined with a maximum number of parents allowed for a node (k) of

#	Network	# nodes	# edges	Max fan-in	Max fan-out

Table 2: Nineteen networks with known structures that are used for the evaluation of the structure learning algorithms. The number that is attached to the network name (3, 5 or 10) indicates the number of tiles of this network. The # symbol on the first column represents the network ID for further use in the subsequent tables.

5, 10 and 20 and allowed run-time that is one and two times the time used by MMHC on the corresponding data set (OR1 and OR2, respectively). The SC algorithm was evaluated with $k = 5$ and $k = 10$ as recommended by its authors. Motivation for using these parameter values and parameter values used by the remaining algorithms are given in Tsamardinos et al. (2006a).

Following Tsamardinos et al. (2006a), we normalized all SHD results with the SHD results of the MMHC algorithm. For each network and algorithm, we report on the average ratio over the five runs. The normalized SHDs are presented in Table 3. A ratio smaller (larger) than 1 indicates that the algorithm learns a more (less) accurate structure than that learned using the MMHC algorithm. In addition, we average the ratios over all nineteen databases similarly to Tsamardinos et al. (2006a). Based on these averaged ratios, Tsamardinos et al. (2006a) found the MMHC algorithm to be superior to the PC, TPDA, GES, OR and SC algorithms with respect to SHD. Table 3 shows that the RAI algorithm is the only algorithm that achieves an average ratio that is smaller than 1, which means it learns structures that on average are more accurate than those learned by MMHC, and thus also more accurate than those learned by all other algorithms. Note the difference in SHD values for Alarm between Table 3 (as measured in Tsamardinos et al., 2006a, on databases of 500 samples) and Table 1 (as measured by us on databases of 10,000 samples).

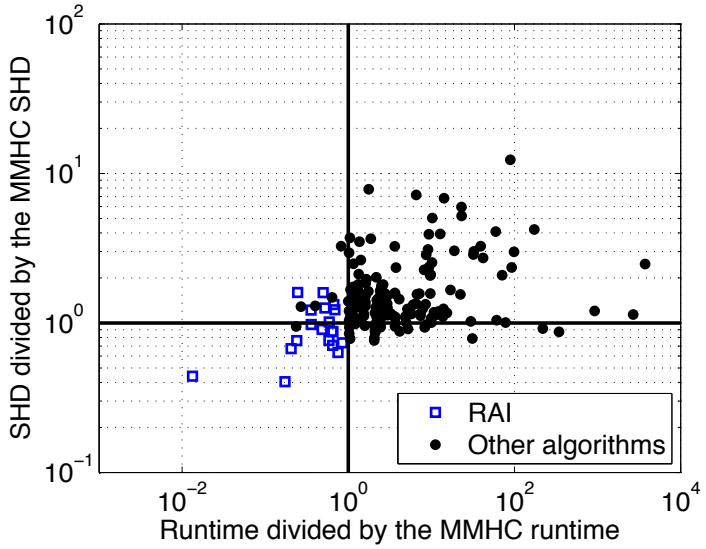
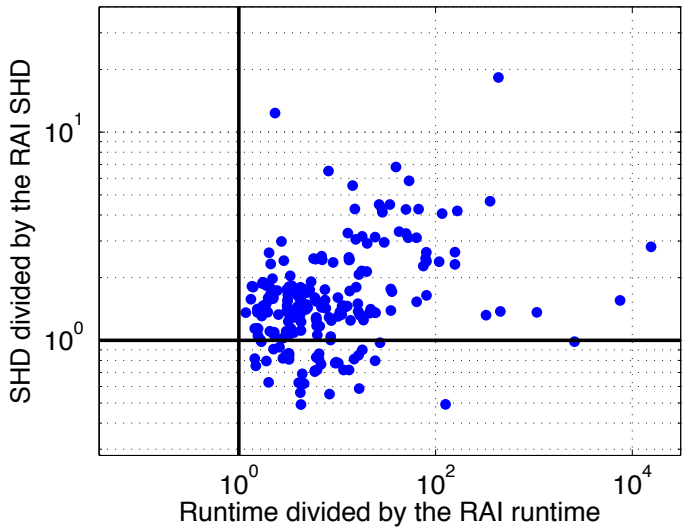
Table 3: Algorithm SHD errors normalized with respect to the MMHC SHD error for the nineteen networks detailed in Table 2. Average (avg.) for an algorithm is over all networks. Blank cells represent jobs that Tsamardinos et al. (2006a) reported that refused to run or did not complete their computations within two days running time.

Next, we compared the run-times of the algorithms in learning the nineteen networks. We note that the run-time of a structure learning algorithm depends, besides on its implementation, on the number of statistical calls (Tsamardinos et al., 2006a) it performs (e.g., CI tests in CB algorithms). For CB algorithms it also depends on the orders of the CI tests and the number of states of each variable that is included in the condition set. The run-time for each algorithm learning each network is presented in Table 4. Following Tsamardinos et al. (2006a), we normalized all run-time results with the run-time results of the MMHC algorithm and report on the average ratio for each algorithm and network over five runs. The run-time ratios for all algorithms except that for the RAI were taken from the Causal Explorer webpage. The ratio for the RAI was computed after running both the RAI and MMHC algorithms on our platform using the same data sets. According to Tsamardinos et al. (2006a), MMHC is the fastest algorithm among all algorithms (except RAI). Table 4 shows that RAI was the only algorithm that achieved an average ratio smaller than 1, which means it is the new fastest algorithm. The RAI average run-time was between 2.1 (for MMHC) and 2387 (for GES) times shorter than those of all other algorithms. Perhaps part of the inferiority of GES with respect to run-time can be related (Tsamardinos et al., 2006a) to many optimizations suggested in Chickering (2002) that were not implemented in Tetrad 4.3.1 that was used by Tsamardinos et al. (2006a) affecting their, and thus also our, results.

Accounting for both error and time, we plot in Figure 15 the SHD and run-time for all nineteen networks normalized with respect to either the MMHC algorithm (Figure 15a) or the RAI algorithm



(a)



(b)

Figure 15: Normalized SHD vs. normalized run-time for all algorithms learning all networks. (a) Normalization is with respect to the MMHC algorithm (thus MMHC results are at (1,1)) and (b) normalization is with respect to the RAI algorithm (thus RAI results are at (1,1)). The points in the graph correspond to 19 networks (average performance over 5 runs) and $14-1=13$ algorithms.

Table 4: Algorithm run-times normalized with respect to the MMHC run-time for the nineteen networks detailed in Table 2. Average (avg.) for an algorithm is over all networks. Blank cells represent jobs that Tsamardinos et al. (2006a) reported that refused to run or did not complete their computations within two days running time.

(Figure 15b). Figure 15 demonstrates that the advantage of RAI over all other algorithms is evident for both the SHD error and the run-time.

It is common to consider the statistical calls performed by an algorithm of structure learning as the major criterion of computational complexity (efficiency) and a major contributor to the algorithm run-rime. In CB algorithms (e.g., PC, TPDA and RAI), the statistical calls are due to CI tests, and in S&S algorithms (e.g., GS, GES, SC, OR) the calls are due to the computation of the score. Hybrid algorithms (e.g., MMHC) have both types of calls. In Table 5, we compare the numbers of calls for statistical tests performed by the RAI algorithm and computed by us to those of the MMHC, GS, PC and TPDA, as computed in Tsamardinos et al. (2006a), and downloaded from the Causal Explorer webpage. We find that for all networks the RAI algorithm performs fewer calls for statistical tests than all other algorithms. On average over all networks, the RAI algorithm performs only 53% of the calls for statistical tests performed by the MMHC algorithm, which is the algorithm that required the fewest calls of all algorithms examined in Tsamardinos et al. (2006a). Figure 16 demonstrates this advantage of RAI over MMHC graphically using a scatter plot. All points below the $x = y$ line represent data sets for which the numbers of calls for statistical tests of MMHC are larger than those of RAI.

Evaluating the statistical significance of the results in Tables 3-5 using Wilcoxon signed-ranks test (Demšar, 2006) with a confidence level of 0.05, we find the SHD errors of RAI and MMHC to be not significantly different from each other; however, the RAI run-times and numbers of statistical calls are significantly shorter than those of the MMHC algorithm.

Table 5: Number of statistical calls performed by each algorithm normalized by the number of statistical calls performed by the MMHC algorithm for the nineteen networks detailed in Table 2. Average (avg.) for an algorithm is over all networks. Blank cells represent jobs that Tsamardinos et al. (2006a) reported that refused to run or did not complete their computations within two days running time.

In continuation to Section 4.1, we further analyzed the complexity of RAI (as measured by the numbers of CI tests performed) according to the CI test orders and the graph size. However, here we used real rather than synthetic data. We examined the numbers of tests as performed for different orders for the Child, Insurance, Alarm and Hailfinder networks and their tiled networks. Using the tiled networks (Tsamardinos et al., 2006b), we could examine the impact of graph size on the number of tests. Figure 17 shows the cumulative percentage of CI tests for a specific order out of the total number of CI tests performed for each network. The figure demonstrates that the percentages of CI tests performed decrease with the CI test order and become small for orders higher than the max fan-in of the network (see Table 2). These percentages also decrease with the numbers of nodes in the network (validated on the tiled networks). This is due to a faster increase of the number of low-order CI tests compared with the number of high-order CI tests as the graph size increases for all networks except for Hailfinder. For Hailefinder (Figure 17d), the threshold for the network was different from those of the tiled networks. This led to an increase in the percentage of high-order CI tests and a decrease in CI tests of order 0 when comparing the Hailfinder network to its tiled versions. For all the tiled Alarm networks (Figure 17c), CI tests of order 0 nearly sufficed

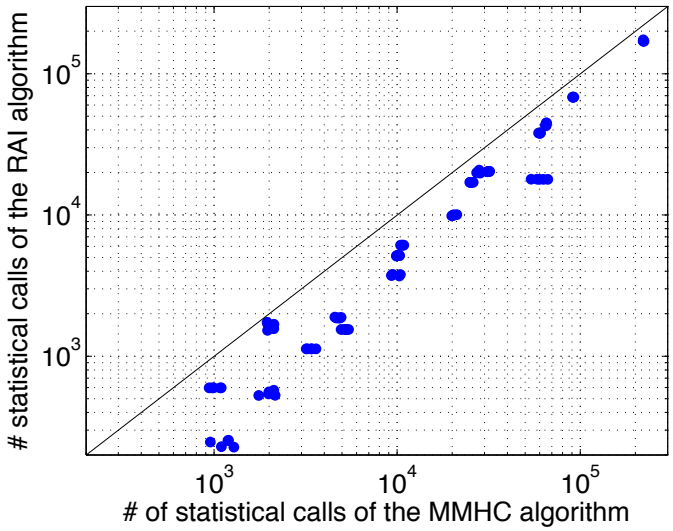

Figure 16: Number of statistical calls performed by the RAI algorithm vs. the number of statistical calls performed by the MMHC algorithm for all networks and data sets examined in this sub-section (5 data sets $\times$ 19 networks = 95 points).

for learning the network. Overall, the results support our preliminary results with synthetic data and "perfect" CI tests (Section 4.1). Thus, we can conclude that as the graph size increases, the RAI algorithm requires relatively fewer CI tests of high orders, especially of orders higher than the max fan-in, than tests of low orders. This result enhances the attractiveness in applying the RAI algorithm also to large problems.

4.5 Structure Learning for General BN Classifiers

Classification is one of the most fundamental tasks in machine learning (ML), and a classifier is primarily expected to achieve high classification accuracy. The Bayesian network classifier (BNC) is usually not considered as an accurate classifier compared to state-of-the-art ML classifiers, such as the neural network (NN) and support vector machine (SVM). However, the BNC has important advantages over the NN and SVM models. The BNC enhances model interpretability by exhibiting dependences, independences and causal relations between variables. It also allows the incorporation of prior knowledge during model learning so as to select a better model or to improve the estimation of its data-driven parameters. Moreover, the BNC naturally performs feature selection as part of model construction and permits the inclusion of hidden nodes that increase model representability and predictability. In addition, the BN has a natural way of dealing with missing inputs by marginalizing hidden variables. Finally, compared to NN and SVM, BNC can model very large, multi-class problems with different types of variables. These advantages are important in real-world classification problems, since they provide many insights into the problem at hand that are beyond the pure classification decisions provided by NN and SVM.

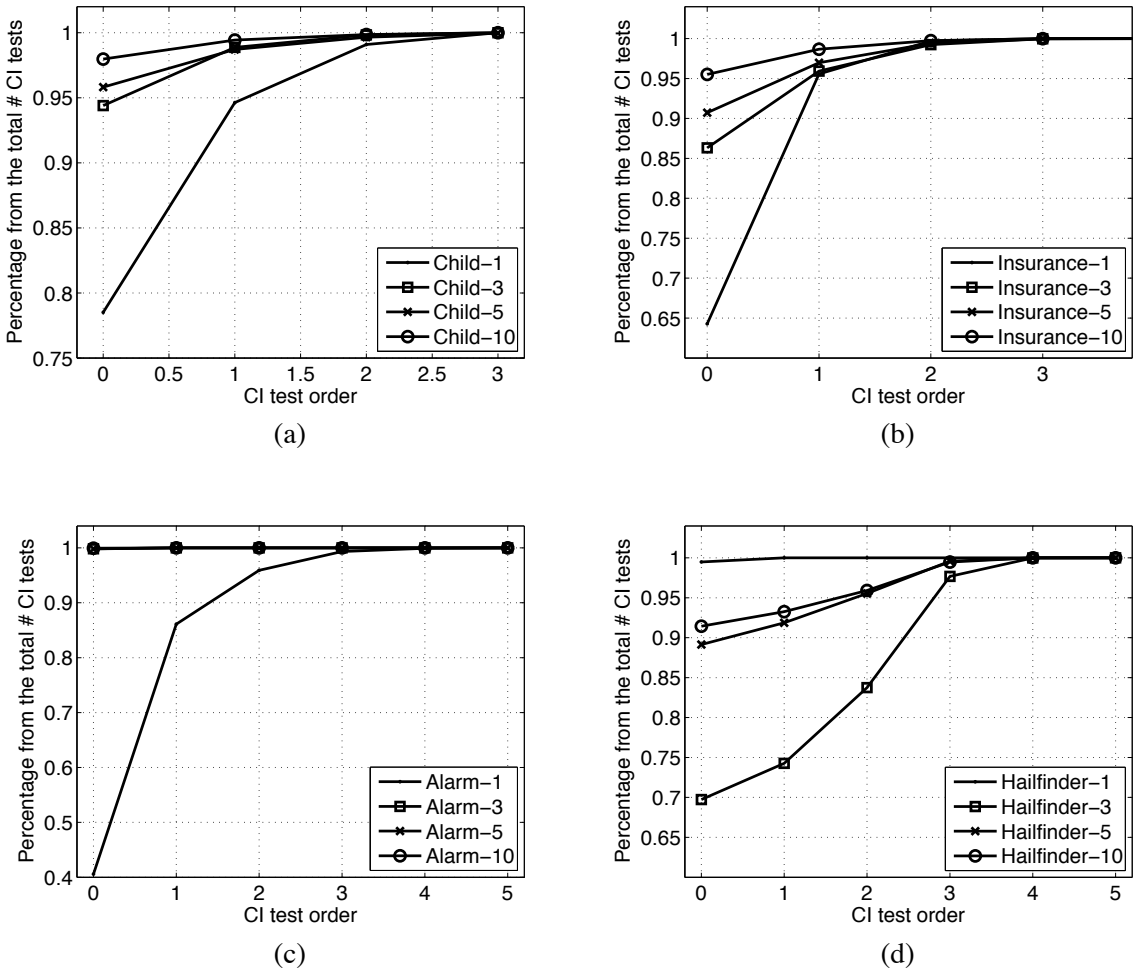

Figure 17: Cumulative percentages of CI tests out of the total numbers of tests for increasing orders as performed by the RAI algorithm for the (a) Child, (b) Insurance, (c) Alarm, and (d) Hailfinder networks including their tiled networks.

We evaluated the RAI complexity, run-time and accuracy when applied to learning a general BN classifier (Cheng and Greiner, 1999; Friedman et al., 1997) in comparison to other algorithms of structure learning using nineteen databases of the UCI Repository (Newman et al., 1998) and Kohavi and John (1997). These databases are detailed in Table 6 with respect to the numbers of variables, classes and instances in each database. All databases were analyzed using a CV5 experiment, except large databases (e.g., "chess", "nursery" and "shuttle"), which were analyzed using the holdout methodology and the common division to training and test sets (Newman et al., 1998; Friedman et al., 1997; Cheng et al., 1997) as detailed in Table 6. Continuous variables were discretized using the MLC++ library (Kohavi et al., 1994) and instances with missing values were removed, as is commonly done.

Table 6: Databases of the UCI repository (Newman et al., 1998) and of Kohavi and John (1997) used for evaluating the accuracy of a classifier learned using the RAI algorithm.

Generally for this sub-section, CI tests for RAI and PC were carried out using the χ^2 test (Spirtes et al., 2000) and those for TPDA using the CMI independence test (Equation 2). However, CI tests for RAI and PC for the "corral", "nursery" and "vehicle" databases were carried out using the CMI independence test. In the case of the large "nursery" database, the need to use the CMI test was due to a Matlab memory limitation in the completion of the χ^2 test using the BNT structure learning package (Leray and François, 2004). In the case of the "corral" and "vehicle" databases, the smallness of the database, together with either the large numbers of classes, variables or states for each variable, led to low frequencies of instances for many combinations of variable states. In this case, the implementation of the χ^2 test assumes variable dependence (Spirtes et al., 2000) that prevents the CB (PC, TPDA and RAI) algorithms from removing edges regardless of the order of the CI test, leading to erroneous decisions. Another test of independence, which is reported to be more reliable and robust, especially for small databases or large numbers of variables (Dash and Druzdzel, 2003), may constitute another solution in these cases.

Thresholds for the CI tests of the CB algorithms and parameter values for all other algorithms were chosen for each algorithm and database so as to maximize the classification accuracy on a validation set selected from the training set or based on the recommendation of the algorithm authors or of Tsamardinos et al. (2006a). Although using a validation set decreases the size of the training set, it also eliminates the chance of selecting a threshold or a parameter that causes the model to

overfit the training set at the expense of the test set. If several thresholds/parameters were found suitable for an algorithm, the threshold/parameter chosen was that leading to the fewest CI tests (in the case of CB algorithms). For GES and GS there are no parameters to set (except the equivalent sample size for the BDeu), and for MMHC we used the selections used by the authors in all their experiments.

Finally, parameter learning was performed by maximum likelihood estimation. Since we were interested in structure learning, no attempt was made to study estimation methods other than this simple and most popular generative method (Cooper and Herskovits, 1992; Heckerman, 1995; Yang and Chang, 2002). Nevertheless, we note that discriminative models for parameter learning have recently been suggested (Pernkopf and Bilmes, 2005; Roos et al., 2005). These models show an improvement over generative models when estimating the classification accuracy (Pernkopf and Bilmes, 2005). We expect that any improvement in classification accuracy gained by using parameter learning other than maximum likelihood estimation will be shared by classifiers induced using any algorithm of structure learning; however, the exact degree of improvement in each case should be further evaluated.

Complexity of the RAI algorithm was measured by the number of CI tests employed for each size of the condition set and the cumulative run-time of the CI tests. These two criteria of complexity were also measured for the PC algorithm, since both the RAI and PC algorithms use the same implementation of CI testing. Table 7 shows the average number and percentage of CI tests reduced by the RAI algorithm compared to the PC algorithm for different CI test orders and each database. An empty entry in the table means that no CI tests of this order are required. A 100% cut in CI tests for a specific order means that RAI does not need any of the CI tests employed by the PC algorithm for this order (e.g., orders 2 and above for the "led7" database). It can be seen that for almost all databases examined, the RAI algorithm avoids most of the CI tests of orders two and above that are required by the PC algorithm (e.g., the "chess" database). Table 7 also shows the reduction in the CI test run-time due to the RAI algorithm in comparison to the PC algorithm for all nineteen databases examined; except for the "australian" database, the cut is measured in tens of percentages for all databases and for six databases this cut is higher than 70%. Run-time differences between algorithms may be the result of different implementations. However, since in our case the run-time is almost entirely based on the number and order of CI tests and RAI has reduced most of the PC CI tests, especially those of high orders that are expensive in run-time, we consider the above run-time reduction results to be significant.

Classification accuracy using a BNC has recently been explored extensively in the literature (Friedman et al., 1997; Grossman and Domingos, 2004; Kontkanen et al., 1999; Pernkopf and Bilmes, 2005; Roos et al., 2005). By restricting the general inference task of BN to inference performed on the class variable, we turn a BN into a BNC. First, we use the training data to learn the structure and then transform the pattern outputted by the algorithm into a DAG (Dor and Tarsi, 1992). Thereafter, we identify the class node Markov blanket and remove from the graph all the nodes that are not part of this blanket. Now, we could estimate the probabilities comprising the class node posterior probability, $P(C|\boldsymbol{X})$, where $\boldsymbol{X}$ is the set of the Markov blanket variables. During the test, we inferred the state c of the class node C for each test instantiation, $\boldsymbol{X} = \boldsymbol{x}$, using the estimated posterior probability. The class $\hat{c}$ selected was the one that maximized the posterior probability, meaning that $\hat{c} = \arg\max_c P(C = c|\boldsymbol{X} = \boldsymbol{x})$. By comparing the class maximizing the posterior probability and the true class, we could compute the classification accuracy.

Table 7: Average number (and percentage) of CI tests reduced by the RAI algorithm compared to the PC algorithm for different databases and CI test orders and the cut (%) in the total CI test run-time.

In Table 8 we compared the classification accuracy due to the RAI algorithm to those due to the PC, TPDA, GES, MMHC, SC and NBC algorithms. We note the overall advantage of the RAI algorithm, especially for large databases. Since the reliability of the CI tests increased with the sample size, it seems that RAI benefits from this increase more than the other algorithms and excels in classifying large databases. RAI, when compared to the other structure learning algorithms, yielded the best classifiers on six ("flare C", "nursery", "led7", "mofn", "tic-tac-toe" and "vehicle") of the ten largest databases and among the best classifiers on the remaining four ("shuttle", "chess", "car" and "cmc") large databases. The other CB algorithms—PC and TPDA—also showed here, and in Tsamardinos et al. (2006a), better results on the large databases. However, the CB algorithms are less accurate on very small databases (e.g., "wine" and "zoo").

Overall, RAI was the best algorithm on 7 databases compared to 5, 2, 5, 4, 5 and 5 databases for the PC, TPDA, GES, MMHC, SC and NBC algorithms, respectively. RAI was the worst classifier on only a single database, whereas the PC, TPDA, GES, MMHC, SC and NBC algorithms were the worst classifiers on 2, 4, 6, 2, 2 and 7 databases, respectively. We believe that the poor results of the GES and MMHC algorithms on the "nursery" database may be attributed to the fact that these algorithms find the class node C as a child of many other variables, making the estimation of $P(C|\boldsymbol{X})$ unreliable due to the curse-of-dimensionality. The structures learned by the other algorithms required a smaller number of such connections and thereby reduced the curse.

Table 8: Mean (and standard deviation for CV5 experiments) of the classification accuracy of the RAI algorithm in comparison to those of the PC, TPDA, GES, MMHC, SC and NBC algorithms. **Bold** and *italic* fonts represent, respectively, the best and worst classifiers for a database.

In addition, we averaged the classification accuracies of the algorithms over the nineteen databases. Averaging accuracies over databases has no meaning in itself except that the average accuracies over many different problems of different algorithms may infer about the relative expected success of the algorithms in other classification problems. It is interesting to note that although the different algorithms in our study showed different degrees of success on various databases, most of the algorithms (i.e., PC, TPDA, MMHC, SC and NBC) achieved almost the same average accuracy (83.0%-83.5%). The GES average accuracy was a little inferior (81.9%) to that of the above algorithms, and the average accuracy of the RAI (85.3%) was superior to that of all algorithms. Concerning the standard deviation of the classification accuracy, RAI outperformed all classifiers implying to the robustness of the RAI-based classifier.

Superiority of one algorithm over another algorithm for each database was evaluated with a statistical significance test (Dietterich, 1998). We used a single-sided t-test to evaluate whether the mean difference between any pair of algorithms as measured on the five folds of the CV5 test was greater than zero. Table 9 summarizes the statistical significance results, measured at a significance level of 0.05, for any two classifiers and each database examined using cross validation. The number in each cell of Table 9 describes—for the corresponding algorithm and database—the number of

Table 9: Statistical significance using a t-test for the classification accuracy results of Table 8. For a given database, each cell indicates the number of algorithms found to be inferior at a significance level of 0.05 to the algorithm above the cell.

algorithms that are inferior to that algorithm for that databases. A "0" value indicates that the algorithm is either inferior to all the other algorithms or not significantly superior to any of them. For example, for the "car" database the PC, TPDA, GES, MMHC, SC, NBC and RAI algorithms were significantly superior to 1, 1, 0, 4, 6, 1 and 5 other algorithms, respectively. In total, the superiority of the RAI algorithm over the other algorithms was statistically significant 28 times, with an average of 1.87 algorithms per database. The second and third best algorithms were the MMHC and SC algorithms, with a total of 20 and 18 times of statistically significant superiority and averages of 1.33 and 1.2 per database, respectively. The least successful classifier, according to Tables 8 and 9, was the one that is learned using GES. We believe that this inferiority arises from the assumptions on the type of probabilities and their parameters made by the GES algorithm when computing the BDeu score (Heckerman et al., 1995), assumptions that probably do not hold for the examined databases.

Although this methodology of statistical tests between pairs of classifiers is the most popular in the machine learning community, there are other methodologies that evaluate statistical significance between several classifiers on several databases simultaneously. For example, Demšar (2006), recently suggested using Friedman test (Friedman, 1940) and some post-hoc tests for such an evaluation.

5. Discussion

The performance of a CB algorithm in BN structure learning depends on the number of conditional independence tests and the sizes of condition sets involved in these tests. The larger the condition set, the greater the number of CI tests of high orders that have to be performed and the smaller their accuracies.

We propose the CB RAI algorithm that learns a BN structure by performing the following sequence of operations: 1) test of CI between nodes and removal of edges related to independences, 2) edge direction employing orientation rules, and 3) structure decomposition into smaller autonomous sub-structures. This sequence of operations is performed recursively for each sub-structure, along with increasing the order of the CI tests. Thereby, the RAI algorithm deals with less potential parents for the nodes on a tested edge and thus uses smaller condition sets that enable the performance of fewer CI tests of higher orders. This reduces the algorithm run-time and increases its accuracy.

By introducing orientation rules through edge direction in early stages of the algorithm and following CI tests of lower orders, the graph "backbone" is established using the most reliable CI tests. Relying on this "backbone" and its directed edges in later stages obviates the need for unnecessary CI tests and enables RAI to be less complex and sensitive to errors.

In this study, we proved the correctness of the RAI algorithm. In addition, we demonstrated empirically, using synthetically generated networks, samples of nineteen known structures, and nineteen natural databases used in classification problems, the advantage of the RAI algorithm over state-of-the-art structure learning algorithms, such as PC, TPDA, GS, GES, OR, SC and MMHC, with respect to structural correctness, number of statistical calls, run-time and classification accuracy. We note that no attempt was made to optimize the parameters of the other algorithms and the effect of such optimization was not evaluated. This is due to the fact that some of the algorithms have more than one parameter to optimize and besides, no optimization methods were proposed by the algorithm inventors. We propose such an optimization method for the RAI algorithm that uses only the training (validation) data.

We plan to extend our study in several directions. One is the comparison of RAI-based classifiers to non-BN classifiers, such as the neural network and support vector machine. Second is the incorporation of different types of prior knowledge (e.g., related to classification) into structure learning. We also intend to study error correction during learning and to allow the inclusion of hidden variables to improve representation and facilitate learning with the RAI algorithm.

Acknowledgments

The authors thank the three anonymous reviewers for their thorough reviews and helpful comments that improved the quality and clarity of the manuscript. The authors also thank the Discovery Systems Laboratory (DSL) of the Vanderbilt University, TN, for making the Causal Explorer library of algorithms and the networks tested in Aliferis et al. (2003) freely available. Special thanks due to Ms. Laura Brown of DSL for the co-operation, helpful discussions and the provision of some missing results of Aliferis et al. (2003) for comparison. This work was supported, in part, by the Paul Ivanier Center for Robotics and Production Management, Ben-Gurion University of the Negev, Beer-Sheva, Israel.

Abstract

Beam search is commonly used to help maintain tractability in large search spaces at the expense of completeness and optimality. Here we study supervised learning of linear ranking functions for controlling beam search. The goal is to learn ranking functions that allow for beam search to perform nearly as well as unconstrained search, and hence gain computational efficiency without seriously sacrificing optimality. In this paper, we develop theoretical aspects of this learning problem and investigate the application of this framework to learning in the context of automated planning. We first study the computational complexity of the learning problem, showing that even for exponentially large search spaces the general consistency problem is in NP. We also identify tractable and intractable subclasses of the learning problem, giving insight into the problem structure. Next, we analyze the convergence of recently proposed and modified online learning algorithms, where we introduce several notions of problem margin that imply convergence for the various algorithms. Finally, we present empirical results in automated planning, where ranking functions are learned to guide beam search in a number of benchmark planning domains. The results show that our approach is often able to outperform an existing state-of-the-art planning heuristic as well as a recent approach to learning such heuristics.

Keywords: beam search, speedup learning, automated planning, structured classification

1. Introduction

Throughout artificial intelligence and computer science, heuristic search is a fundamental approach to solving complex problems. Unfortunately, when the heuristic is not accurate enough, memory and time constraints make pure heuristic search impractical. One common way to attempt to maintain tractability of heuristic search is through a pruning technique known as beam search. At each search step, beam search maintains a "beam" of the heuristically best b nodes, pruning all other nodes from the search queue. Due to this pruning, beam search is not guaranteed to be complete nor optimal. However, if the heuristic is good enough to keep a good solution path in the beam, then the solution will be found quickly.

The goal of this paper is to study the problem of learning heuristics, or ranking functions, that allow beam search to quickly find solutions, without seriously sacrificing optimality compared to unconstrained search. We consider this problem for the case of linear ranking functions, where each search node v is associated with a feature vector $f(v)$ and nodes are ranked according to $w \cdot f(v)$ where w is a weight vector. Each instance in our training set corresponds to a search space that is labeled by a set of target solutions, each solution being a (satisficing) path from the initial node to a goal node. Given a training set, our learning objective is to select a weight vector w such that a beam search of a specified beam width always maintains one of the target paths in the beam until finally reaching a goal node. Such a w effectively represents a ranking function that allows beam search to efficiently solve all of the training instances, and ideally new search problems for which the training set is representative.

Recent work (Daumé III and Marcu, 2005) has considered the problem of learning beam search ranking functions in the context of structured classification. Structured classification is the problem of learning a mapping from structured inputs (e.g., sentences) to structured outputs (e.g., syntactic parses) and there has been much recent work that extends traditional classification algorithms to this setting including conditional random fields (Lafferty et al., 2001), the generalized Perceptron algorithm (Collins, 2002), and margin optimization (Taskar et al., 2003). The approach of Daumé III and Marcu (2005) differs from prior approaches in that it explicitly views structured classification as a search problem, where given an input x, the problem of labeling x by a structured output y is treated as searching through an exponentially large set of candidate outputs. For example, in part-of-speech tagging where x is a sequence of words and y is a sequence of word tags, each node in the search space is a pair (x, y') where y' is a partial labeling of the words in x. Learning corresponds to inducing a ranking function that quickly guides the search to the search node (x, y^*) where y^* is the desired output. This framework, known as *learning as search optimization (LaSO)*, has demonstrated highly competitive performance on a number of structured classification problems.

This paper builds on the LaSO framework and makes two key contributions. First, we analyze the learning problem theoretically, in terms of its computational complexity and the convergence properties of various learning algorithms. Secondly, this paper provides an empirical evaluation in the context of automated planning, a problem that is qualitatively very different from structured classification.

Our complexity analysis considers a number of subclasses of the general beam-search learning problem. First, we provide an upper bound on the complexity of the general problem by showing that even for exponentially large search spaces, which are the norm, the consistency problem (i.e., finding a w that solves all training instances) remains in NP. Next, we identify several core tractable and intractable subclasses of the beam-search learning problem. Interestingly, some of these subclasses resemble more traditional "learning to rank" problems (Agarwal and Roth, 2005) with clear analogies to applications.

Our convergence analysis studies convergence properties of perceptron-style online learning algorithms. In prior work, Daumé III and Marcu (2005) proposed a notion of linear separability for this learning problem and proved convergence of the algorithm for linearly separable data. However, here we show that result to be inaccurate for subtle reasons and give a counter example. We then propose new notions of problem margin and show that convergence can be guaranteed for revised versions of the algorithm given positive margins. For the case where training data is ambiguous, that is, where many good solutions to a search problem are not included in the target solution set, we also give sufficient conditions on the minimum beam width to guarantee convergence. This result

also provides a formal characterization of the intuition that the learning problem should become easier as the beam width increases, by showing that the mistake bound decreases with increasing beam width.

While the LaSO framework has been empirically evaluated in structured classification, with impressive results, its utility in other types of search problems has not been demonstrated. Here we consider the application of a LaSO-style algorithm to automated planning, which is a problem that is qualitatively very different compared to structured classification. The planning problems we consider are most naturally viewed as goal-finding problems, where we must search for a short path to a goal node in an exponentially large graph. Rather, structured classification is most naturally viewed as an optimization problem, where we must search for a structured object that optimizes an objective function. While the two problem classes are related they differ in significant ways. For example, the search problems studied in structured classification typically have a single or small number of solution paths, whereas in automated planning there are often a large number of equally good solutions, which can contribute to ambiguous training data. Furthermore, the size of the search spaces encountered in automated planning are usually much larger than in structured classification, because of the larger depths and branching factors. These differences raise the empirical question of whether a LaSO-style approach will be effective in automated planning.

To evaluate this question we incorporated a LaSO-style learning mechanism into a forward state-space search planner in order to learn domain-specific heuristics, or ranking functions, from training examples. For a given planning domain, the training examples given to our learner include solution plans to a set of planning problems from the domain. The learned ranking function for a domain can then be used to guide beam search in order to solve new test problems from the same domain. We evaluate this approach on a number of benchmark planning domains and show that our learned ranking functions are often able to outperform both a state-of-the-art domain-independent planning heuristic and the heuristics learned by another recently proposed learning mechanism based on linear regression.

The remainder of this paper proceeds as follows. In Section 2, we introduce our formal setup of the beam-search learning problem and then, in Section 3, study the computational complexity of this learning problem. In Section 4, we describe two online learning mechanisms followed by their convergence analysis. In Section 5, we apply the learning problem to automated planning and present the experimental results. Finally Section 6 concludes and suggests future directions.

2. Problem Setup

In this section, we first describe two different beam search paradigms: breadth-first beam search and best-first beam search. We then introduce the learning problems that we study in these two paradigms, followed by an illustrative example from automated planning. Finally, we describe how our formulation, which was motivated by automated planning, relates to structured classification.

2.1 Beam Search

We first define breadth-first and best-first beam search, the two paradigms considered in this work. A *search space* is a tuple $\langle I, s(\cdot), f(\cdot), < \rangle$, where I is the initial search node, s is a successor function from search nodes to finite sets of search nodes, f is a feature function from search nodes to m-dimensional real-valued vectors, and $<$ is a total preference ordering on search nodes. We think of f as defining properties of search nodes that are useful for evaluating their relative goodness and $<$

as defining a canonical ordering on nodes, for example, lexicographic. In this work, we use f to define a linear ranking function $w \cdot f(v)$ on nodes where w is an m-dimensional weight vector, and nodes with larger values are considered to be higher ranked, or more preferred. Since a given w may assign two nodes the same rank, we use $<$ to break ties such that v is ranked higher than v' given $w \cdot f(v') = w \cdot f(v)$ and $v' < v$, arriving at a total rank ordering on search nodes. We denote this total rank ordering as $r(v', v|w, <)$, or just $r(v', v)$ when w and $<$ are clear from context, indicating that v is ranked higher than v'.

Given a search space $S = \langle I, s(\cdot), f(\cdot), < \rangle$, a weight vector w, and a beam width b, *breadth-first beam search* simply conducts breadth-first search, but at each search depth keeps only the b highest ranked nodes according to r. More formally, breadth-first beam search generates a unique *beam trajectory* $(B_0, B_1, \ldots)$ as follows,

- $B_0 = \{I\}$ is the initial beam;
- $C_{j+1} = \textbf{BreadthExpand}(B_j, s(\cdot)) = \bigcup_{v \in B_j} s(v)$ is the depth $j+1$ *candidate set* of the depth j beam;
- B_{j+1} is the unique set of b highest ranked nodes in C_{j+1} according to the total ordering r.

Note that for any j, $|C_j| \leq cb$ and $|B_j| \leq b$, where c is the maximum number of children of any search node.

Best-first beam search is almost identical to breadth-first beam search except that we replace the function **BreadthExpand** with $\textbf{BestExpand}(B_j, s(\cdot)) = B_j \cup s(v^*) - v^*$, where v^* is the unique highest ranking node in B_j. Thus, instead of expanding all nodes in the beam at each search step, best-first search is more conservative and only expands the single best node. Note that unlike breadth-first search this can result in beams that contain search nodes from different depths of the search space relative to I.

2.2 Learning Problems

Our learning problems provide training sets of pairs $\{\langle S_i, P_i \rangle\}$, where the $S_i = \langle I_i, s_i(\cdot), f_i(\cdot), <_i \rangle$ are search spaces constrained such that each f_i has the same dimension. As described in more detail below, the P_i encode sets of *target search paths* that describe desirable search paths through the corresponding search spaces. Roughly speaking the learning goal is to learn a ranking function that can produce a beam trajectory of a specified width for each search space that contains at least one of the corresponding target paths in the training data. For example, in the context of automated planning, the S_i would correspond to planning problems from a particular domain, encoding the state space and available actions, and the P_i would encode optimal or satisficing plans for those problems. A successfully learned ranking function would be able to quickly find at least one of the target solution plans for each training problem and ideally new target problems.

We represent each set of target search paths as a sequence $P_i = (P_{i,0}, P_{i,1}, \ldots, P_{i,d})$ of sets of search nodes where $P_{i,j}$ contains target nodes at depth j and $P_{i,0} = \{I_i\}$. It is useful to think about $P_{i,d}$ as encoding the *goal nodes* of the i'th search space. We will refer to the maximum size t of any target node set $P_{i,j}$ as the *target width* of P_i, which will be referred to in our complexity analysis. The generality of this representation for target paths allows for pathological targets where certain nodes do not lead to the goal. In order to arrive at convergence results, we rule out such possibilities by assuming that the training set is *dead-end free*. That is, for all i and $j < d$ each $v \in P_{i,j}$ has at

least one child node $v' \in P_{i,j+1}$. Note that in almost all real problems this property will be naturally satisfied. For our complexity analysis, we will not need to assume any special properties of the target search paths P_i.

Intuitively, for a dead-end free training set, each P_i represents a layered directed graph with at least one path from each target node to a goal node in $P_{i,d}$. Thus, the training set specifies not only a set of goals for each search space but also gives possible solution paths to the goals. For simplicity, we assume that all target solution paths have depth d, but all results easily generalize to non-uniform depths.

For breadth-first beam search we specify a learning problem by giving a training set and a beam width $\langle\{\langle S_i, P_i\rangle\}, b\rangle$. The objective is to find a weight vector w that generates a beam trajectory containing at least one of the target paths for each training instance. More formally, we are interested in the consistency problem:

Definition 1 (Breadth-First Consistency) *Given the input $\langle\{\langle S_i, P_i\rangle\}, b\rangle$ where b is a positive integer and $P_i = (P_{i,0}, P_{i,1}, \ldots, P_{i,d})$, the breadth-first consistency problem asks us to decide whether there exists a weight vector w such that for each S_i, the corresponding beam trajectory $(B_{i,0}, B_{i,1}, \ldots, B_{i,d})$, produced using w with a beam width of b, satisfies $B_{i,j} \cap P_{i,j} \neq \emptyset$ for each j?*

A weight vector that demonstrates a "yes" answer is guaranteed to allow a breath-first beam search of width b to uncover at least one goal node (i.e., a node in $P_{i,d}$) within d beam expansions for all training instances.

Unlike the case of breadth-first beam search, the length of the beam trajectory required by best-first beam search to reach a goal node can be greater than the depth d of the target paths. This is because best-first beam search, does not necessarily increase the maximum depth of search nodes in the beam at each search step. Thus, in addition to specifying a beam width for the learning problem, we also specify a maximum number of search steps, or horizon, h. The objective is to find a weight vector that allows a best-first beam search to find a goal node within h search steps, while always keeping some node from the target paths in the beam.

Definition 2 (Best-First Consistency) *Given the input $\langle\{\langle S_i, P_i\rangle\}, b, h\rangle$, where b and h are positive integers and $P_i = (P_{i,0}, \ldots, P_{i,d})$, the best-first consistency problem asks us to decide whether there is a weight vector w that produces for each S_i a beam trajectory $(B_{i,0}, \ldots, B_{i,k})$ of beam width b, such that $k \leq h$, $B_{i,k} \cap P_{i,d} \neq \emptyset$ (i.e., $B_{i,k}$ contains a goal node), and each $B_{i,j}$ for $j < k$ contains at least one node in $\bigcup_j P_{i,j}$?*

Again, a weight vector that demonstrates a "yes" answer is guaranteed to allow a best-first beam search of width b to find a goal node in h search steps for all training instances.

2.2.1 EXAMPLE FROM AUTOMATED PLANNING.

Figure 1, shows a pictorial example of a single training example from an automated planning problem. The planning domain in this example is Blocksworld where individual problems involve transforming an initial configuration of blocks to a goal configuration using simple actions such as picking up, putting down, and stacking the various blocks. The figure shows a search space S_i where each node corresponds to a configuration of blocks and the arcs indicate when it is possible to take an action that transitions from one configuration to another. The figure depicts, via highlighted nodes,

two target paths. The label P_i would encode these target paths by a sequence $P_i = (P_{i,0}, P_{i,1}, \ldots, P_{i,4})$ where $P_{i,j}$ contains the set of all highlighted target nodes at depth j. A solution weight vector, for this training example, would be required to keep at least one of the highlighted paths in the beam until uncovering the goal node.

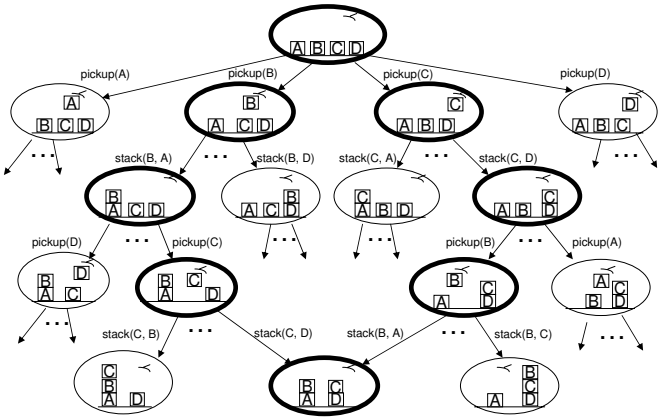

Figure 1: An example from automated planning.

2.2.2 EXAMPLE FROM STRUCTURED CLASSIFICATION

Daumé III and Marcu (2005) considered learning ranking functions to control beam search in the context of structured classification. Structured classification involves learning a function that maps structured inputs x to structured outputs y. As an example, consider part-of-speech tagging where the inputs correspond to English sentences and the correct output for a sentence is the sequence of part-of-speech tags for the words in the sentence. Figure 2 shows how Daumé III and Marcu (2005) formulated a single instance of part-of-speech tagging as a search problem. Each search node is a pair (x, y') where x is the input sentence and y' is a partial labeling of the words in x by part-of-speech tags. The arcs in this space correspond to search steps that label words in the sentence in a left-to-right order by extending y' in all possible ways by one element. The leaves, or terminal nodes, of this space correspond to all possible complete labelings of x. Given a ranking function and a beam width, Daumé III and Marcu (2005) return a predicted output for x by conducting a beam search until a terminal node becomes the highest ranked node in the beam, and then return the output component of that terminal node. This approach to making predictions suggests that the learning objective should require that we learn a ranking function such that the goal terminal node, is the first terminal node to become highest ranked in the beam. In the figure, there is a single goal terminal node (x, y) where y is the correct labeling of x and there is a unique target path to this goal.

From the above example, we see that there is a difference between the learning objective used by Daumé III and Marcu (2005) for structured classification and the learning objective under our formulation, which was motivated by automated planning. In particular, our formulation does not force the goal node to be the highest ranked node in the final beam, but rather only requires that a goal node appear somewhere in the final beam. While these formulations appear quite different, it turns out that they are polynomially reducible to one another, which we prove in Appendix A.

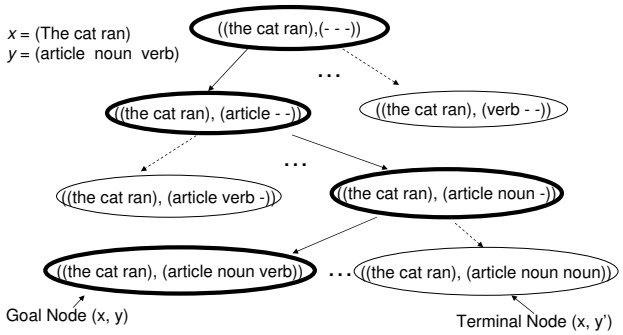

Figure 2: An example from structured classification.

Thus, all of the results in this paper apply equally well to the structured-classification formulation of Daumé III and Marcu (2005).

3. Computational Complexity

In this section, we study the computational complexity of the above consistency problems. We first focus on breadth-first beam search, and then give the corresponding best-first results at the end of this section. It is important to note that the size of the search spaces will typically be exponential in the encoding size of the learning problem. For example, in automated planning, standard languages such as PDDL (McDermott, 1998) are used to compactly encode planning problems that are potentially exponentially large, in terms of the number of states, with respect to the PDDL encoding size. Throughout this section we measure complexity in terms of the problem encoding size, not the potentially exponentially larger search space size. All discussions in this section apply to general search spaces and are not tied to a particular language for describing search space such as PDDL.

Our complexity analysis will consider various sub-classes of the breadth-first consistency problem, where the sub-classes will be defined by placing constraints on the following problem parameters: n - the number of training instances, d - the depth of target solution paths, c - the maximum number of children of any search node, t - the maximum target width of any P_i as defined in Section 2.2, and b - the beam width. Figure 3 gives a pictorial depiction of these key problem parameters. Throughout the complexity analysis we will restrict our attention to problem classes where the maximum number of children c and beam width b are polynomial in the problem size, which are necessary conditions to ensure that each beam search step requires only polynomial time and space. We will also assume that all feature functions can be evaluated in polynomial time in the problem size.

Note that restricting the number of children c may rule out the use of certain search space encodings for some problems. For example, in a multi-agent planning scenario, there are an exponential number of joint actions to consider from each state, and thus an exponential number of children. However, here it is possible to re-encode the search space by increasing the depth of the search tree, so that each joint action is encoded by a sequence of steps where each agent selects an action in turn followed by all of them executing the selected actions. The resulting search space has only a polynomial number of children and thus satisfies our assumption, though the required search depth

has increased. This form of re-encoding from a search space with exponentially many children to one with polynomially many children can be done whenever the actions in the original space have a compact, factored encoding, which is typically the case in practice.

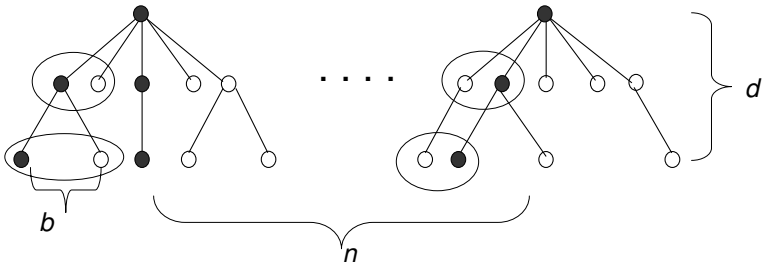

Figure 3: The key problem parameters: n - the number of training instances, d - the depth of target solution paths, b - the beam width. Not depicted in the figure are: c - maximum number of children of any node, t - the maximum target width of any example.

3.1 Hardness Upper Bounds

We first show an upper bound on the complexity of breadth-first consistency by proving that the general problem is in NP even for exponentially large search spaces.

Observe that given a weight vector w and beam width b, we can easily generate a unique depth d beam trajectory for each training instance. Our upper bound is based on considering the inverse problem of checking whether a set of hypothesized beam trajectories, one for each training instance, could have been generated by some weight vector. The algorithm *TestTrajectories* in Figure 4 efficiently carries out this check. The main idea is to observe that for any search space S it is possible to efficiently check whether there is a weight vector that starting with a beam B could generate a beam B' after one step of breadth-first beam search. This can be done by constructing an appropriate set of linear constraints on the weight vector w that are required to generate B' from B. In particular, we first generate the set of candidate nodes C from B by unioning all children of nodes in B. Clearly we must have $B' \subseteq C$ in order for there to be a solution weight vector. If this is the case then we create a linear constraint for each pair of nodes (u,v) such that $u \in B'$ and $v \in C - B'$, which forces u to be preferred to v:

$$w \cdot f(u) > w \cdot f(v)$$

where $w = (w_1, w_2, \ldots, w_m)$ are the constraint variables and $f(\cdot) = (f_1(\cdot), f_2(\cdot), \ldots, f_m(\cdot))$ is the vector of feature functions. Note that if u is more preferred than v in the total preference ordering, then we only need to require that $w \cdot f(u) \geq w \cdot f(v)$. The overall algorithm *TestTrajectories* simply creates this set of constraints for each consecutive pair of beams in each beam trajectory and then tests to see whether there is a w that satisfies all of the constraints.

Lemma 3 *Given a set of search spaces $\{S_i\}$ and a corresponding set of width b beam trajectories $\{(B_{i,0}, \ldots, B_{i,d})\}$, the algorithm TestTrajectories (Figure 4) decides in polynomial time whether there exists a weight vector w that can generate $(B_{i,0}, \ldots, B_{i,d})$ in S_i for all i.*

Proof It is straightforward to show that w satisfies the constraints generated by *TestTrajectories* iff for each i, j, $r(v', v| <_i, w)$ leads beam search to generate $B_{i,j+1}$ from $B_{i,j}$. The linear program contains m variables and at most $ndcb^2$ constraints. Since we are assuming that the maximum number of children of a node v is polynomial in the size of the learning problem, the size of the linear program is also polynomial and thus can be solved in polynomial time (Khachiyan, 1979). ■

This lemma shows that sets of beam trajectories can be used as efficiently-checkable certificates for breadth-first consistency, which leads to an upper bound on the problem's complexity.

Theorem 4 *Breadth-first consistency is in NP.*

Proof Given a learning problem $\langle \{\langle S_i, P_i \rangle\}, b \rangle$ our certificates correspond to sets of beam trajectories $\{(B_{i,0}, \ldots, B_{i,d})\}$ each of size at most $O(ndb)$ which is polynomial in the problem size. The certificate can then be checked in polynomial time to see if for each i, $(B_{i,0}, \ldots, B_{i,d})$ contains a target solution path encoded in P_i as required by Definition 1. If it is consistent then according to Lemma 3 we can efficiently decide whether there is a w that can generate $\{(B_{i,0}, \ldots, B_{i,d})\}$. ■

This result suggests an enumeration-based decision procedure for breadth-first consistency as given in Figure 4. In that procedure, the function **Enumerate** creates a list of all possible combinations of beam trajectories for the training data. Thus, each element of this list is a list of beam trajectories, one for each training example, where a beam trajectory is simply a sequence of sets of nodes that are selected from the given search space. For each enumerated combination of beam trajectories, the function **IsConsistent** checks whether the beam trajectory for each example contains a target path for that example and if so *TestTrajectories* will be called to determine whether there exists a weight vector that could produce those trajectories. The following gives us the worst case complexity of this algorithm in terms of the key problem parameters.

Theorem 5 *The procedure ExhaustiveAlgorithm (Figure 4) decides breadth-first consistency and returns a solution weight vector if there is a solution in time* $O\left((t + poly(m))\,(cb)^{bdn}\right)$.

Proof We first bound the number of certificates. Breadth-first beam search expands nodes in the current beam, resulting in at most cb nodes, from which b nodes are selected for the next beam. Enumerating these possible choices over d levels and n trajectories, one for each training instance, we can bound the number of certificates by $O\left((cb)^{bdn}\right)$. For each certificate the enumeration process checks consistency with the target paths $\{P_i\}$ in time $O(tbdn)$ and then calls *TestTrajectories* which runs in time $\text{poly}(m, ndcb^2)$. The total time complexity then is $O\left(\left(tbdn + \text{poly}(m, ndcb^2)\right)(cb)^{bdn}\right)$ $= O\left((t + \text{poly}(m))\,(cb)^{bdn}\right)$. ■

Not surprisingly the complexity is exponential in the beam width b, target path depth d, and number of training instances n. However, it is polynomial in the maximum number of children c and the maximum target width t. Thus, breadth-first consistency can be solved in polynomial time for any problem class where b, d, and n are constants. Of course, for most problems these constants would be too large for this result to be of practical interest. This leads to the question of whether we can do better than the exhaustive algorithm for restricted problem classes. For at least one problem class we can.

```
ExhaustiveAlgorithm ({⟨S_i, P_i⟩}, b)
Γ = Enumerate({⟨S_i, P_i⟩}, b)
// enumerates all possible sets of beam trajectories
for each {(B_{i,0} ..., B_{i,d})} ∈ Γ
    if IsConsistent({P_i}, {(B_{i,0} ..., B_{i,d})}) then
        w= TestTrajectories({S_i}, {(B_{i,0}, ..., B_{i,d})})
        if w ≠ false then
            return w
return false
```

```
TestTrajectories({S_i}, {(B_{i,0}, ..., B_{i,d})})
// S_i = ⟨I_i, s_i(·), f_i(·), <_i⟩
construct a linear programming problem LP as below
    the variables are w = {w_1, w_2, ..., w_m}
    for (i, j) ∈ {1, ..., n} × {1, ..., d}
        C_{i,j} =BreadthExpand(B_{i,j-1}, s_i(·))
        if B_{i,j} ⊆ C_{i,j} then
            for each u ∈ B_{i,j} and v ∈ C_{i,j} − B_{i,j}
                if v <_i u then
                    add a constraint w · f_i(u) ≥ w · f_i(v)
                else add a constraint w · f_i(u) > w · f_i(v)
        else return false
w = LPSolver(LP)
if LP is solved then
    return w
return false
```

Figure 4: The exhaustive algorithm for breadth-first consistency.

Theorem 6 *The class of breadth-first consistency problems where $b = 1$ and $t = 1$ is solvable in polynomial time.*

Proof Given a learning problem $\langle \{\langle S_i, P_i \rangle\}, b \rangle$ where $P_i = (P_{i,0}, \ldots, P_{i,d})$, $t = 1$ implies that each $P_{i,j}$ contains exactly one node. Since the beam width $b = 1$, then the only way that a beam trajectory $(B_{i,0}, \ldots, B_{i,d})$ can satisfy the condition $B_{i,j} \cap P_{i,j} \neq \emptyset$ for any i, j, is for $B_{i,j} = P_{i,j}$. Thus there is exactly one beam trajectory for each training example, equal to the target trajectory, and using Lemma 3 we can check for a solution weight vector for these trajectories in polynomial time. ■

This problem class, as depicted in Figure 5, corresponds to the case where each training instance is labeled by exactly a single solution path and we are asked to find a w that leads a greedy hill-climbing search, or reactive policy, to follow those paths. This is a common learning setting, for example, when attempting to learn reactive control policies based on demonstrations of target policies, perhaps from an expert, as in Khardon (1999).

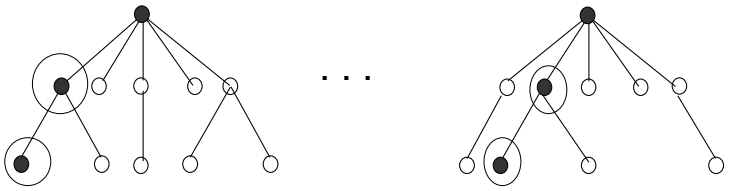

Figure 5: A tractable class of breadth-first consistency, where $b = 1$ and $t = 1$.

3.2 Hardness Lower Bounds

Unfortunately, outside of the above problem classes it appears that breadth-first consistency is computationally hard even under strict restrictions. In particular, the following three results show that if any one of b, d, or n are not bounded then the consistency problem is hard even when the other problem parameters are small constants.

First, we show that the problem class where $n = d = t = 1$ but $b \geq 1$ is NP-complete. That is, a single training instance involving a depth one search space is sufficient for hardness. This problem class, resembles more traditional ranking problems and has a nice analogy in the application domain of web-page ranking, where the depth 1 leaves of our search space correspond to possibly relevant web-pages for a particular query. One of those pages is marked as a target page, for example, the page that a user eventually went to. The learning problem is then to find a weight vector that will cause for the target page to be ranked among the top b pages. Our result shows that this problem is NP-complete and hence will be exponential in b unless $P = NP$.

Theorem 7 *The class of breadth-first consistency problems where $n = 1$, $d = 1$, $t = 1$, and $b \geq 1$ is NP-complete.*

Proof Our reduction is from the Minimum Disagreement problem for linear binary classifiers, which was proven to be NP-complete by Hoffgen et al. (1995). The input to this problem is a training set $T = \{x_1^+, \cdots, x_{r_1}^+, x_1^-, \cdots, x_{r_2}^-\}$ of positive and negative m-dimensional vectors and a positive integer k. A weight vector w classifies a vector as positive iff $w \cdot x \geq 0$ and otherwise as negative. The Minimum Disagreement problem is to decide whether there exists a weight vector that commits no more than k misclassification.

Given a Minimum Disagreement problem we construct an instance $\langle \langle S_1, P_1 \rangle, b \rangle$ of the breadth-first consistency problem as follows. Assume without loss of generality $S_1 = \langle I, s(\cdot), f(\cdot), < \rangle$. Let $s(I) = \{q_0, q_1, \cdots, q_{r_1+r_2}\}$. For each $i \in \{1, \cdots, r_1\}$, define $f(q_i) = -x_i^+ \in R^m$. For each $i \in \{1, \cdots, r_2\}$,define $f(q_{i+r_1}) = x_i^- \in R^m$. Define $f(q_0) = 0 \in R^m$, $P_1 = (\{I\}, \{q_0\})$ and $b = k+1$. Define the total ordering $<$ to be a total ordering in which $q_i < q_0$ for every $i = 1, \ldots, r_1$ and $q_0 < q_i$ for every $i = r_1 + 1, \ldots, r_1 + r_2$.We claim that there exists a linear classifier with at most k misclassifications if and only if there exists a solution to the corresponding consistency problem.

First, suppose there exists a linear classifier $w \cdot x \geq 0$ with at most k misclassifications. Using the weight vector w, we have

- $w \cdot f(q_0) = 0$;

- for $i = 1, \cdots, r_1$:
  if $w \cdot x_i^+ \geq 0, w \cdot f(q_i) = w \cdot (-x_i^+) \leq 0$;
  if $w \cdot x_i^+ < 0, w \cdot f(q_i) = w \cdot (-x_i^+) > 0$;

- for $i = r_1 + 1, \ldots, r_1 + r_2$:
  if $w \cdot x_i^- \geq 0, w \cdot f(q_i) = w \cdot x_i^- \geq 0$;
  if $w \cdot x_i^- < 0, w \cdot f(q_i) = w \cdot x_i^- < 0$.

For $i = 1, \cdots, r_1 + r_2$, the node q_i in the consistency problem is ranked lower than q_0 if and only if its corresponding example in the Minimum Disagreement problem is labeled correctly, is ranked higher than q_0 if and only if its corresponding example in the Minimum Disagreement problem is labeled incorrectly. Therefore, there are at most k nodes which are ranked higher than q_0. With beam width $b = k + 1$, the beam $B_{i,1}$ is guaranteed to contain node q_0, indicating that w is a solution to the consistency problem.

On the other hand, suppose there exists a solution w to the consistency problem. There are at most $b - 1 = k$ nodes that are ranked higher than q_0. That is, at least $r_1 + r_2 - k$ nodes are ranked lower than q_0. For $i = 1, \ldots, r_1$, q_i is ranked lower than q_0 if and only if $w \cdot f(q_i) \leq w \cdot f(q_0)$. For $i = r_1 + 1, \ldots, r_1 + r_2$, q_i is ranked lower than q_0 if and only if $w \cdot f(q_i) < w \cdot f(q_0)$. Since $w \cdot f(q_0) = 0$, we have

- for $i = 1, \cdots, r_1$:
  $w \cdot f(q_i) \leq 0 \Rightarrow w \cdot (-x_i^+) \leq 0 \Rightarrow w \cdot x_i^+ \geq 0$;

- for $i = r_1 + 1, \ldots, r_1 + r_2$:
  $w \cdot f(q_i) < 0 \Rightarrow w \cdot x_i^- < 0 \Rightarrow w \cdot x_i^- < 0$.

Therefore, using the linear classifier $w \cdot x \geq 0$, at least $r_1 + r_2 - k$ nodes are labeled correctly, that is, it makes at most k misclassifications.

Since the time required to construct the instance $\langle \langle S_1, P_1 \rangle, b \rangle$ from T, k is polynomial in the size of T, k, we conclude that the consistency problem is NP-Complete even restricted to $n = 1$, $d = 1$ and $t = 1$. ■

The next result shows that if we do not bound the number of training instances n, then the problem remains hard even when the target path depth and beam width are equal to one. Interestingly, this subclass of breadth-first consistency corresponds to the multi-label learning problem as defined in Jin and Ghahramani (2002). In multi-label learning each training instance can be viewed as a bag of m-dimensional vectors, some of which are labeled as positive, which in our context correspond to the target nodes. The learning goal is to find a w that for each bag, ranks one of the positive vectors as best.

Theorem 8 *The class of breadth-first consistency problems where $d = 1$, $b = 1$, $c = 6$, $t = 3$, and $n \geq 1$ is NP-complete.*

Proof The proof is by reduction from 3-SAT (Garey and Johnson, 1979), which is the following.

"Given a set U of boolean variables, a collection Q of clauses over U such that each clause $q \in Q$ has $|q| = 3$, decide whether there a satisfying truth assignment for C."

Let $U = \{u_1, \ldots, u_m\}$, $Q = \{q_{11} \vee q_{12} \vee q_{13}, \ldots, q_{n1} \vee q_{n2} \vee q_{n3}\}$ be an instance of the 3-SAT problem. Here, $q_{ij} = u$ or $\neg u$ for some $u \in U$. We construct from U, Q an instance $\langle \{\langle S_i, P_i \rangle\}, b \rangle$ of the breadth-first consistency problem as follows. For each clause $q_{i1} \vee q_{i2} \vee q_{i3}$, let $s_i(I_i) = \{p_{i,1}, \cdots, p_{i,6}\}$, $P_i = (\{I_i\}, \{p_{i,1}, p_{i,2}, p_{i,3}\})$, $b = 1$, and the total ordering $<_i$ is defined so that $p_{i,j} <_i p_{i,k}$ for $j = 1,2,3$ and $k = 4,5,6$. Let $e_k \in \{0,1\}^m$ denote a vector of zeros except a 1 in the k'th component. For each $i = 1, \ldots, n$, $j = 1,2,3$, if $q_{ij} = u_k$ for some k then $f_i(p_{i,j}) = e_k$ and $f_i(p_{i,j+3}) = -e_k/2$, otherwise if $q_{ij} = \neg u_k$ for some k then $f_i(p_{i,j}) = -e_k$ and $f_i(p_{i,j+3}) = e_k/2$. We claim that there exists a satisfying truth assignment if and only if there exists a solution to the corresponding consistency problem.

First, suppose that there exists a satisfying truth assignment. Let $w = (w_1, \cdots, w_m)$, where $w_k = 1$ if u_k is true, and $w_k = -1$ if u_k is false in the truth assignment. For each $i = 1, \ldots, n$, $j = 1, \ldots, 3$, we have:

- if q_{ij} is true, then
  $w \cdot f_i(p_{i,j}) = 1$ and $w \cdot f_i(p_{i,j+3}) = -1/2$;
- if q_{ij} is false, then
  $w \cdot f_i(p_{i,j}) = -1$ and $w \cdot f_i(p_{i,j+3}) = 1/2$.

Note that for each clause $q_{i1} \vee q_{i2} \vee q_{i3}$, at least one of the literals is true. Thus, for every set of nodes $\{p_{i,1}, p_{i,2}, p_{i,3}\}$, at least one of the nodes will have the highest rank value equal to 1, resulting in $B_{i,1} = \{v\}$ where $v \in \{p_{i,1}, p_{i,2}, p_{i,3}\}$. By the definition, the weight vector w is a solution to the consistency problem.

On the other hand, suppose that there exists a solution $w = (w_1, \ldots, w_m)$ to the consistency problem. Assume the beam trajectory for each i is $(\{I_i\}, \{v_i\})$. Then $v_i = p_{i,j}$ for some $j \in \{1,2,3\}$, and for this i and j, $q_{ij} = u_k$ or $\neg u_k$ for some k. Let u_k be true if $q_{ij} = u_k$ and be false if $q_{ij} = \neg u_k$. As long as there is no contradiction in this assignment, this is a satisfying truth assignment because at least one of $\{q_{i1}, q_{i2}, q_{i3}\}$ is true for every i, that is, every clause is true.

Now we will prove that there is no contradiction in this assignment, that is, any variable is assigned either true or false, but not both. Note that for any node $v \in \{p_{i,1}, p_{i,2}, p_{i,3}\}$, there always exists a node $v' \in \{p_{i,4}, \ldots, p_{i,6}\}$ such that:

- $w \cdot f_i(v) < 0 \Leftrightarrow w \cdot f_i(v') > 0$;
- $w \cdot f_i(v) > 0 \Leftrightarrow w \cdot f_i(v') < 0$;
- $w \cdot f_i(v) = 0 \Leftrightarrow w \cdot f_i(v') = 0$.

Then because of the total ordering $<_i$ we defined, the node $v_i = p_{i,j}$ appearing in the beam trajectory, must has $w \cdot f_i(v_i) > 0$. Assume without loss of generality that $q_{ij} = u_k$, then u_k is assigned to be true. Although $\neg u_k$ might appear in other clauses, for example, $q_{i'j'} = \neg u_k$, its corresponding node $p_{i',j'}$ can never appear in the beam trajectory because $w \cdot f_{i'}(p_{i',j'}) = w \cdot (-e_k) = -w \cdot e_k = -w \cdot f_i(p_{i,j}) < 0$. Therefore, u_k will never be assigned false. A similar proof can be given for the case of $q_{ij} = \neg u_k$.

Since the time required to construct the instance $\langle \{\langle S_i, P_i \rangle\}, b \rangle$ from U, Q is polynomial in the size of U, Q, we conclude that the consistency problem is NP-Complete for the case of $d = 1, b = 1$, $c = 6$ and $t = 3$.

■

Finally, we show that when the depth d is unbounded the consistency problem remains hard even when $b = n = 1$.

Theorem 9 *The class of breadth-first consistency problems where $n = 1$, $b = 1$, $c = 6$, $t = 3$, and $d \geq 1$ is NP-complete.*

Proof Assume $x = \langle \{\langle S_i, P_i \rangle | i = 1, \ldots, n\}, b \rangle$, where $S_i = \langle I_i, s_i(\cdot), f_i(\cdot), <_i \rangle$ and $P_i = (\{I_i\}, P_{i,1})$, is an instance of the consistency problem with $d = 1$, $b = 1$, $c = 6$ and $t = 3$. We can construct an instance y of the consistency problem with $n = 1, b = 1, c = 6$, and $t = 3$. Let $y = \langle \langle \bar{S}_1, \bar{P}_1 \rangle, b \rangle$ where $\bar{S}_1 = \langle I_1, \bar{s}(\cdot), \bar{f}(\cdot), \bar{<} \rangle$, and $\bar{P}_1 = (\{I_1\}, P_{1,1}, P_{2,1}, \ldots, P_{t,1})$. We define $\bar{s}(\cdot), \bar{f}(\cdot), \bar{<}$ as below.

- $\bar{s}(I_1) = s_1(I_1), \bar{f}(I_1) = f_1(I_1)$;
- for each $i = 1, \ldots, n-1$
  $\forall v \in s_i(I_i), \bar{f}(v) = f_i(v)$ and $\bar{s}(v) = s_{i+1}(I_{i+1})$;
  $\forall (v, v') \in s_i(I_i), \bar{<}(v, v') =<_i (v, v')$;
- $\forall v \in s_n(I_n), \bar{f}(v) = f_n(v)$;
  $\forall (v, v') \in s_n(I_n), \bar{<}(v, v') =<_n (v, v')$.

Obviously, a weight vector w is a solution for the instance x if and only if w is a solution for the constructed instance y. ■

b	n	d	c	t	Complexity
poly	≥ 1	≥ 1	poly	≥ 1	NP
K	K	K	poly	≥ 1	P
1	≥ 1	≥ 1	poly	1	P
poly	1	1	poly	1	NP-Complete
1	≥ 1	1	6	3	NP-Complete
1	1	≥ 1	6	3	NP-Complete

Figure 6: Complexity results for breadth-first consistency. Each row corresponds to a sub-class of the problem and indicates the computational complexity. K indicates a constant value and "poly" indicates that the quantity must be polynomially related to the problem size.

Figure 6 summarizes our main complexity results from this section for breadth-first consistency. For best-first beam search, most of these results can be carried over. Recall that for best-first consistency the problem specifies a search horizon h in addition to a beam width. Using a similar approach as above we can show that best-first consistency is in NP assuming that h is polynomial in the problem size, which is a reasonable assumption. Similarly, one can extend the polynomial time result for fixed b, n, and d. The remaining results in the table can be directly transferred to best-first search, since in each case either $b = 1$ or $d = 1$ and best-first beam search is equivalent to breadth-first beam search in either of these cases.

4. Convergence of Online Updates

In the previous section, we identified a limited set of tractable problem classes and saw that even very restricted classes remain NP-hard. We also saw that some of these hard classes had interesting application relevance. Thus, it is desirable to consider efficient learning mechanisms that work well in practice. Below we describe two such algorithms based on online perceptron updates.

4.1 Online Perceptron Updates

Figure 7 gives the LaSO-BR algorithm for learning ranking functions for breadth-first beam search. It resembles the *learning as search optimization (LaSO)* algorithm for best-first search by Daumé III and Marcu (2005). LaSO-BR iterates through all training instances $\langle S_i, P_i \rangle$ and for each one conducts a beam search of the specified width. After generating the depth j beam for the ith training instance, if at least one of the target nodes in $P_{i,j}$ are in the beam then no weight update occurs. Rather, if none of the target nodes in $P_{i,j}$ are in the beam then a search error is flagged and weights are updated according to the following perceptron-style rule,

$$w = w + \alpha \cdot \left(\frac{\sum_{v^* \in P_{i,j} \cap C} f(v^*)}{|P_{i,j} \cap C|} - \frac{\sum_{v \in B} f(v)}{b} \right)$$

where $0 < \alpha \leq 1$ is a learning rate parameter, B is the current beam and C is the candidate set from which B was generated (i.e., the beam expansion of the previous beam). For simplicity of notation, here we assume that f is a feature function for all training instances. Intuitively this weight update moves the weights in the direction of the average feature function of target nodes that appear in C, and away from the average feature function of non-target nodes in the beam. This has the effect of increasing the rank of target nodes in C and decreasing the rank of non-targets in the beam. Ideally, this will cause at least one of the target nodes to become preferred enough to remain on the beam next time through the search. Note that the use of averages over target and non-target nodes is important so as to account for the different sizes of these sets of nodes. After each weight update, the beam is reset to contain only the set of target nodes in C and the beam search then continues. Importantly, on each iteration, the processing of each training instance is guaranteed to terminate in d search steps.

Figure 8 gives the LaSO-BST algorithm for learning in best-first beam search, which is a slight modification of the original LaSO algorithm. The main difference compared to the original LaSO is in the weight update equation, a change that appears necessary for our convergence analysis. The algorithm is similar to LaSO-BR except that a best-first beam search is conducted, which means that termination for each training instance is not guaranteed to be within d steps. Rather, the number of search steps for a single training instance remains unbounded without further assumptions, which we will address later in this section. In particular, there is no bound on the number of search steps between weight updates for a given training example. This difference between LaSO-BR and LaSO-BST was of great practical importance in our automated planning application. In particular, LaSO-BST typically did not produce useful learning results due to the fact that the number of search steps between weight updates was extremely large. Note that in the case of structured classification, Daumé III and Marcu (2005) did not experience this difficulty due to the bounded-depth nature of their search spaces.

LaSO-BR $(\{\langle S_i, P_i \rangle\}, b)$
$w \leftarrow 0$
repeat until w is unchanged **or** a large number of iterations
  for every i
    Update-BR(S_i, P_i, b, w)
return w

Update-BR (S_i, P_i, b, w)
// $S_i = \langle I_i, s_i(\cdot), f(\cdot), <_i \rangle$ and $P_i = (P_{i,0}, \ldots, P_{i,d})$
$B \leftarrow \{I_i\}$ // initial beam
for $j = 1, \ldots, d$

    $H(v) \leftarrow w \cdot f(v)$ // compute heuristic value of v
  Order C according to H and the total ordering $<_i$
  $B \leftarrow$ the first b nodes in C
  if $B \cap P_{i,j} = \emptyset$ **then**
    $w \leftarrow w + \alpha \cdot \left(\frac{\sum_{v^* \in P_{i,j} \cap C} f(v^*)}{|P_{i,j} \cap C|} - \frac{\sum_{v \in B} f(v)}{b} \right)$
    $B \leftarrow P_{i,j} \cap C$
return

Figure 7: The LaSO-BR online algorithm for breadth-first beam search.

4.2 Previous Result and Counter Example

Adjusting to our terminology, Daumé III and Marcu (2005) defined a training set to be *linear separable* iff there is a weight vector that solves the corresponding consistency problem. Also for linearly separable data they defined a notion of margin of a weight vector, which we refer to here as the *search margin*. The formal definition of search margin is given below.

Definition 10 (Search Margin) *The search margin of a weight vector w for a linearly separable training set is defined as $\gamma = min_{\{(v^*,v)\}}(w \cdot f(v^*) - w \cdot f(v))$, where the set $\{(v^*, v)\}$ contains any pair where v^* is a target node and v is a non-target node that was compared during the beam search guided by w.*

Daumé III and Marcu (2005) state that the existence of a w with positive search margin, which implies linear separability, implies convergence of the original LaSO algorithm after a finite number of weight updates. On further investigation, we have found that a positive search margin is not sufficient to guarantee convergence for LaSO, LaSO-BR, or LaSO-BST. Intuitively, the key difficulty is that our learning problem contains hidden state in the form of the desired beam trajectory. Given the beam trajectory of a consistent weight vector one can compute the weights, and likewise given consistent weights one can compute the beam trajectory. However, we are given neither to begin with and our approach can be viewed as an online EM-style algorithm, which alternates between

LaSO-BST $(\{\langle S_i, P_i\rangle\}, b)$
$w \leftarrow 0$
repeat until w is unchanged **or** a large number of iterations
  for every i
    Update-BST(S_i, P_i, b, w)
return w

Update-BST (S_i, P_i, b, w)
// $S_i = \langle I_i, s_i(\cdot), f(\cdot), <_i\rangle$ and $P_i = (P_{i,0}, \ldots, P_{i,d})$
$B \leftarrow \{I_i\}$ // initial beam
$\bar{P} = P_{i,0} \cup P_{i,2} \cup \ldots \cup P_{i,d}$
while $B \cap P_{i,d} = \emptyset$
  $C \leftarrow$ **BestExpand**$(B, s_i(\cdot))$

  Order C according to H and the total ordering $<_i$
  $B \leftarrow$ the first b nodes in C
  if $B \cap \bar{P} = \emptyset$ **then**
    $w \leftarrow w + \alpha \cdot \left(\frac{\sum_{v^* \in \bar{P} \cap C} f(v^*)}{|\bar{P} \cap C|} - \frac{\sum_{v \in B} f(v)}{b} \right)$
    $B \leftarrow \bar{P} \cap C$
return

Figure 8: Online algorithm for best-first beam search.

updating weights given the current beam and recomputing the beam given the updated weights. Just as traditional EM is quite prone to local minima, so are the LaSO algorithms in general, and in particular even when there is a positive search margin as demonstrated in the following counter example. Note that the standard Perceptron algorithm for classification learning does not run into this problem since there is no hidden state involved.

Counter Example 1 *We give a training set for which the existence of a weight vector with positive search margin does not guarantee convergence to a solution weight vector for LaSO-BR or LaSO-BST. Consider a problem that consists of a single training instance with search space shown in Figure 9, preference ordering $C < B < F < E < D < H < G$, and single target path $P = (\{A\}, \{B\}, \{E\})$.*

First we will consider using breadth-first beam search with a beam width of $b = 2$. Using the weight vector $w = [\gamma, \gamma]$ the resulting beam trajectory will be (note that higher values of $w \cdot f(v)$ are better):

$$\{A\}, \{B,C\}, \{E,F\}.$$

The search margin of w, which is only sensitive to pairs of target and non-target nodes that were compared during the search, is equal to,

$$\gamma = w \cdot f(B) - w \cdot f(C) = w \cdot f(E) - w \cdot f(F)$$

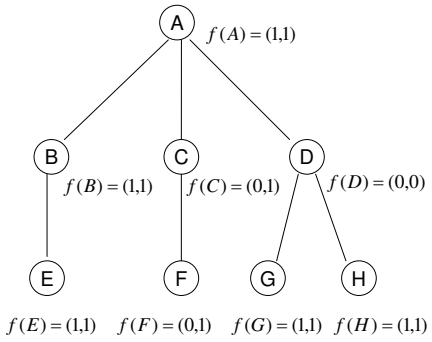

Figure 9: Counter example for convergence under positive search margin.

which is positive. We now show that the existence of w does not imply convergence under perceptron updates.

Consider simulating LaSO-BR starting from $w' = 0$. *The first search step gives the beam* $\{D,B\}$ *according to the given preference ordering. Since B is on the target path we continue expanding to the next level where we get the new beam* $\{G,H\}$. *None of the nodes are on the target path so we update the weights as follows:*

$$\begin{aligned} w' &= w' + f(E) - 0.5[f(G) + f(H)] \\ &= w' + [1,1] - [1,1] \\ &= w'. \end{aligned}$$

This shows that w' *does not change and we have converged to the weight vector* $w' = 0$, *which is not a solution to the problem.*

For the case of best-first beam search, the performance is similar. Given the weight vector $w = [\gamma, \gamma]$, *the resulting beam search with beam width 2 will generate the beam sequence,*

$$\{A\}, \{B,C\}, \{E,C\}$$

which is consistent with the target trajectory. From this we can see that w has a positive search margin of:

$$\gamma = w \cdot f(B) - w \cdot f(C) = w \cdot f(E) - w \cdot f(C).$$

However, if we follow the perceptron algorithm when started with the weight vector $w' = 0$ *we can again show that the algorithm does not converge to a solution weight vector. In particular, the first search step gives the beam* $\{D,B\}$ *and since B is on the target path, we do not update the weights and generate a new beam* $\{G,H\}$ *by expanding the node D. At this point there are no target nodes in the beam and the weights are updated as follows*

$$\begin{aligned} w' &= w' + f(B) - 0.5[f(G) + f(H)] \\ &= w' + [1,1] - [1,1] \\ &= w' \end{aligned}$$

showing that the algorithm has converged to $w' = 0$, which is not a solution to the problem.

Thus, we have shown that a positive search margin does not guarantee convergence for either LaSO-BR or LaSO-BST. This counter example also applies to the original LaSO algorithm, which is quite similar to LaSO-BST.

4.3 Convergence Under Stronger Notions of Margin

Given that linear separability, or equivalently a positive search margin, is not sufficient to guarantee convergence we consider a stronger notion of margin, the *level margin*, which measures by how much the target nodes are ranked above (or below) other non-target nodes at the same search level.

Definition 11 (Level Margin) *The level margin of a weight vector w for a training set is defined as $\gamma = min_{\{(v^*,v)\}}(w \cdot f(v^*) - w \cdot f(v))$, where the set $\{(v^*, v)\}$ contains any pair such that v^* is a target node at some depth j and v can be reached in j search steps from the initial search node—that is, v^* and v are at the same level.*

For breadth-first beam search, a positive level margin for w implies a positive search margin, but not necessarily vice versa, showing that level margin is a strictly stronger notion of separability. The following result shows that a positive level margin is sufficient to guarantee convergence of LaSO-BR. Throughout we will let R be a constant such that for all training instances, for all nodes v and v', $\|f(v) - f(v')\| \leq R$. The proof of this result follows similar lines as the Perceptron convergence proof for standard classification problems Rosenblatt (1962).

Theorem 12 *Given a dead-end free training set such that there exists a weight vector w with level margin $\gamma > 0$ and $\|w\| = 1$, LaSO-BR will converge with a consistent weight vector after making no more than $(R/\gamma)^2$ weight updates.*

Proof First note that the dead-end free property of the training data can be used to show that unless the current weight vector is a solution it will eventually trigger a "meaningful" weight update (one where the candidate set contains target nodes).

Let w^k be the weights before the k'th mistake is made. Then $w^1 = 0$. Suppose the k'th mistake is made for the training data $\langle S_i, P_i \rangle$, when $B \cap P_{i,j} = \emptyset$. Here, $P_{i,j}$ is the j'th element of P_i, B is the beam generated at depth j for S_i and C is the candidate set from which B is selected. Note that C is generated by expanding all nodes in the previous beam and at least one of them is in $P_{i,j-1}$. With the dead-end free property, we are guaranteed that $C' = P_{i,j} \cap C \neq \emptyset$. The occurrence of the mistake indicates that, $\forall v^* \in P_{i,j} \cap C, v \in B$, $w^k \cdot f(v^*) \leq w^k \cdot f(v)$, which lets us derive an upper bound for $\|w^{k+1}\|^2$.

$$
\begin{aligned}
\|w^{k+1}\|^2 &= \|w^k + \frac{\sum_{v^* \in C'} f(v^*)}{|C'|} - \frac{\sum_{v \in B} f(v)}{b}\|^2 \\
&= \|w^k\|^2 + \|\frac{\sum_{v^* \in C'} f(v^*)}{|C'|} - \frac{\sum_{v \in B} f(v)}{b}\|^2 \\
&\quad + 2w^k \cdot (\frac{\sum_{v^* \in C'} f(v^*)}{|C'|} - \frac{\sum_{v \in B} f(v)}{b}) \\
&\leq \|w^k\|^2 + \|\frac{\sum_{v^* \in C'} f(v^*)}{|C'|} - \frac{\sum_{v \in B} f(v)}{b}\|^2 \\
&\leq \|w^k\|^2 + R^2
\end{aligned}
$$

where the first equality follows from the definition of the perceptron-update rule, the first inequality follows because $w^k \cdot (f(v^*) - f(v)) < 0$ for all $v^* \in C', v \in B$, and the second inequality follows from the definition of R. Using this upper-bound we get by induction that

$$\|w^{k+1}\|^2 \leq kR^2.$$

Suppose there is a weight vector w such that $||w|| = 1$ and w has a positive level margin, then we can derive a lower bound for $w \cdot w^{k+1}$.

$$\begin{aligned} w \cdot w^{k+1} &= w \cdot w^k + w \cdot (\frac{\sum_{v^* \in C'} f(v^*)}{|C'|} - \frac{\sum_{v \in B} f(v)}{b}) \\ &= w \cdot w^k + \frac{\sum_{v^* \in C'} w \cdot f(v^*)}{|C'|} - \frac{\sum_{v \in B} w \cdot f(v)}{b} \\ &\geq w \cdot w^k + \gamma. \end{aligned}$$

This inequality follows from the definition of the level margin γ of the weight vector w.

By induction, we get that $w \cdot w^{k+1} \geq k\gamma$. Combining this result with the above upper bound on $\|w^{k+1}\|$ and the fact that $\|w\| = 1$ we get that

$$1 \geq \frac{w \cdot w^{k+1}}{\|w\|\|w^{k+1}\|} \geq \sqrt{k}\frac{\gamma}{R} \Rightarrow k \leq \frac{R^2}{\gamma^2}.$$

Without the dead-end free property, LaSO-BR might generate a candidate set that contains no target nodes, which would allow for a mistake that does not result in a weight update. However, for a dead-end free training set, it is guaranteed that the weights will be updated if and only if a mistake is made. Thus, the mistake bound is equal to the bound on the weight updates. ■

Note that for the example search space in Figure 9 there is no weight vector with a positive level margin since the final layer contains target and non-target nodes with identical weight vectors. Thus, the non-convergence of LaSO-BR on that example is consistent with the above result. Unlike LaSO-BR, LaSO-BST and LaSO do not have such a guarantee since their beams can contain nodes from multiple levels. This is demonstrated by the following counter example.

Counter Example 2 *We give a training set for which the existence of a w with positive level margin does not guarantee convergence for LaSO-BST. Consider a single training example with the search space in Figure 10, single target path $P = (\{A\}, \{B\}, \{E\})$, and preference ordering $C < B < E < F < G < D$.*

Given the weight vector $w = [2\gamma, \gamma]$, the level margin of w is equal to γ. However, starting with $w' = 0$ and running LaSO-BST the first search step gives the beam $\{D, B\}$. Since B is on the target path, we get the new beam $\{G, F\}$ by expanding the node D. This beam does not contain a target node, which triggers the following weight update:

$$\begin{aligned} w' &= w' + f(B) - [f(F) + f(G)]/2 \\ &= w' + [1,0] - [1,0] \\ &= w'. \end{aligned}$$

Since w' does not change the algorithm has converged to $w' = 0$, which is not a solution to this problem. This shows that a positive level margin is not sufficient to guarantee the convergence of LaSO-BST. The same can be shown for the original LaSO.

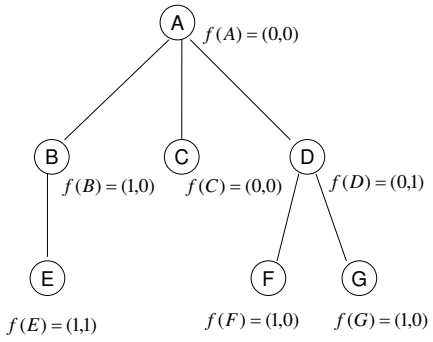

Figure 10: Counter example to convergence under positive level margin.

In order to guarantee convergence of LaSO-BST, we require an even stronger notion of margin, *global margin*, which measures the rank difference between any target node and any non-target node, regardless of search space level.

Definition 13 (Global Margin) *The global margin of a weight vector w for a training set is defined as* $\gamma = min_{\{(v^*,v)\}}(w \cdot f(v^*) - w \cdot f(v))$*, where the set* $\{(v^*,v)\}$ *contains any pair such that* v^* *is any target node and v is any non-target node in the search space.*

Note that if w has a positive global margin then it has a positive level margin. The converse is not necessarily true. The global margin is similar to the common definitions of margin used to characterize the convergence of linear perceptron classifiers (Novikoff, 1962).

To ensure convergence of LaSO-BST we also assume that the search spaces are all finite trees. This avoids the possibility of infinite best-first beam trajectories that never terminate at a goal node. Tree structures are quite common in practice and it is often easy to transform a finite search space into a tree. The structured classification experiments of Daumé III and Marcu (2005) and our own automated experiments both involve tree structured spaces.

Theorem 14 *Given a dead-end free training set of finite tree search spaces such that there exists a weight vector w with global margin* $\gamma > 0$ *and* $\|w\| = 1$*, LaSO-BST will converge with a consistent weight vector after making no more than* $(R/\gamma)^2$ *weight updates.*

The proof is similar to that of Theorem 12 except that the derivation of the lower bound makes use of the global margin and we must verify that the restriction to finite tree search spaces guarantees that each iteration of LaSO-BST will terminate with a goal node being reached. We were unable to show convergence for the original LaSO algorithm even under the assumptions of this theorem.

In summary, this section has introduced three different notions of margin: search margin, level margin, and global margin. Both algorithms converge for a positive global margin, which implies a positive search margin and a positive level margin. For LaSO-BR, but not LaSO-BST, convergence is guaranteed for a positive level margin, which implies a positive search margin. This shows that LaSO-BR converges under a strictly weaker notion of margin than LaSO-BST due to the fact that the ranking decisions of breadth-first search are restricted to nodes at the same level of the search space, as opposed to best-first search. This suggests that it may often be easier to define effective feature spaces for the breadth-first paradigm. Finally, a positive search margin corresponds exactly

to linear separability, but is not enough to guarantee convergence for either algorithm. This is in contrast to results for linear classifier learning, where linear separability implies convergence of perceptron updates.

4.4 Convergence for Ambiguous Training Data

Here we study convergence for linearly inseparable training data. Inseparability is often the result of training-data ambiguity, in the sense that many "good" solution paths are not included as target paths. For example, this is common in automated planning where there can be many (nearly) optimal solutions, many of which are inherently identical (e.g., differing in the orderings of unrelated actions). It is usually impractical to include all solutions in the training data, which can make it infeasible to learn a ranking function that strictly prefers the target paths over the inherently identical paths not included as targets. In these situations, the above notions of margin will all be negative. Here we consider the notion of *beam margin* that allows for some amount of ambiguity, or inseparability.

For each instance $\langle S_i, P_i \rangle$, where $S_i = \langle I_i, s_i(\cdot), f(\cdot), <_i \rangle$ and $P_i = (P_{i,1}, P_{i,2}, \ldots, P_{i,d_i})$, let D_{ij} be the set of nodes that can be reached in j search steps from I_i. That is, D_{ij} is the set of all possible non-target nodes that could be in beam $B_{i,j}$. A beam margin is a triple (b', δ_1, δ_2) where b' is a non-negative integer, and $\delta_1, \delta_2 \geq 0$.

Definition 15 (Beam Margin) *A weight vector w has beam margin (b', δ_1, δ_2) on a training set $\{\langle S_i, P_i \rangle\}$, if for each i, j there is a set $D'_{ij} \subseteq D_{ij}$ such that $|D'_{ij}| \leq b'$ and*

$$\forall v^* \in P_{i,j}, v \in D_{ij} - D'_{ij}, \;\; w \cdot f(v^*) - w \cdot f(v) \geq \delta_1 \text{ and,}$$
$$\forall v^* \in P_{i,j}, v \in D'_{ij}, \;\; \delta_1 > w \cdot f(v^*) - w \cdot f(v) \geq -\delta_2.$$

A weight vector w has beam margin (b', δ_1, δ_2) if at each search depth it ranks the target nodes better than most other non-target nodes (those in $D_{ij} - D'_{ij}$) by a margin of at least δ_1, and ranks at most b' non-target nodes (those in D'_{ij}) better than the target nodes by a margin no greater than δ_2. Whenever this condition is satisfied we are guaranteed that a beam search of width $b > b'$ guided by w will solve all of the training problems. The case where $b' = 0$ corresponds to the level margin, where the data is separable. By allowing $b' > 0$ we can consider cases where there is no "dominating" weight vector that ranks all targets better than all non-targets at the same level. The following result shows that for a large enough beam width, which is dependent on the beam margin, LaSO-BR will converge to a consistent solution.

Theorem 16 *Given a dead-end free training set, if there exists a weight vector w with beam margin (b', δ_1, δ_2) and $\|w\| = 1$, then for any beam width $b > (1 + \delta_2/\delta_1) b' = b^*$, LaSO-BR will converge with a consistent weight vector after making no more than $(R/\delta_1)^2 \left(1 - b^* b^{-1}\right)^{-2}$ weight updates.*

Proof Let w^k be the weights before the k'th mistake is made, so that $w^1 = 0$. Suppose that the k'th mistake is made when $B \cap P_{i,j} = \emptyset$ where B is the beam generated at depth j for the ith training instance. We can derive the upper bound of $\|w^{k+1}\|^2 \leq kR^2$ as in the proof of Theorem 12.

Next we derive a lower bound on $w \cdot w^{k+1}$. Denote by $B' \subseteq B$ the set of nodes in the beam such that $\delta_1 > w \cdot (f(v^*) - f(v)) \geq -\delta_2$ and let $C' = P_{i,j} \cap C$. By the definition of beam margin, we have $|B'| < b'$.

$$
\begin{aligned}
w \cdot w^{k+1} &= w \cdot w^k + w \cdot \left(\frac{\sum_{v* \in C'} f(v^*)}{|C'|} - \frac{\sum_{v \in B} f(v)}{b}\right) \\
&= w \cdot w^k + w \cdot \sum_{v \in B - B'} \frac{\frac{\sum_{v* \in C'} f(v^*)}{|C'|} - f(v)}{b} \\
&\quad + w \cdot \sum_{v \in B'} \frac{\frac{\sum_{v* \in C'} f(v^*)}{|C'|} - f(v)}{b} \\
&\geq w \cdot w^k + \frac{(b-b')\delta_1}{b} - \frac{b'\delta_2}{b}.
\end{aligned}
$$

By induction, we get that $w \cdot w^{k+1} \geq k\frac{(b-b')\delta_1 - b'\delta_2}{b}$. Combining this result with the above upper bound on $\|w^{k+1}\|$ and the fact that $\|w\| = 1$ we get that $1 \geq \frac{w \cdot w^{k+1}}{\|w\|\|w^{k+1}\|} \geq \sqrt{k}\frac{(b-b')\delta_1 - b'\delta_2}{bR}$. The mistake bound follows by noting that $b > b^*$ and algebra.

Similar to Theorem 12, the dead-end free property of the training set guarantees that the mistake bound is equal to the bound on the weight updates. ■

Note that when there is a positive level margin (i.e., $b' = 0$), the mistake bound here reduces to $(R/\delta_1)^2$, which does not depend on the beam width and matches the result for separable data. This is also the behavior when $b >> b^*$.

An interesting aspect of this result is that the mistake bound depends on the beam width. Rather, all of our previous convergence results were independent of the beam width and held even for beam width $b = 1$. Thus, those previous results did not provide any formalization of the intuition that the learning problem will often become easier as the beam width increases, or equivalently as the amount of search increases. Indeed, in the extreme case of exhaustive search, no learning is needed at all, whereas for $b = 1$ the ranking function has little room for error.

To get a sense for the dependence on the beam width consider two extreme cases. As noted above, for very large beam widths such that $b >> b^*$, the bound becomes $(R/\delta_1)^2$. On the other extreme, if we assume $\delta_1 = \delta_2$ and we use the smallest possible beam width allowed by the theorem $b = 2b' + 1$, then the bound becomes $((2b'+1)R/\delta_1)^2$, which is a factor of $(2b'+1)^2$ larger than when $b >> b'$. This shows that as we increase b (i.e., the amount of search), the mistake bound decreases, suggesting that learning becomes easier, agreeing with intuition.

It is also possible to define an analog to the beam margin for best first beam search. However, in order to guarantee convergence, the conditions on ambiguity would be relative to the global state space, rather than local to each level of the search space.

5. Application to Automated Planning

In this section, we present an empirical evaluation of beam-search learning in the context of automated planning. We first give related background, followed by the technical details regarding our application to automated planning. Then, we present the experimental results.

5.1 Background

Here we give background related to automated planning, the problem of learning to plan, and prior related work in the area of learning to plan.

5.1.1 AUTOMATED PLANNING

Planning is a subfield of artificial intelligence that studies algorithms for selecting sequences of actions in order to achieve goals. In this work, we consider planning domains and planning problems described using the STRIPS fragment of the planning domain description language (PDDL) (McDermott, 1998), which we now outline.

A planning domain $\mathcal{D}$ defines a set of possible actions $\mathcal{A}$ and a set of world states $\mathcal{W}$ in terms of a set of predicate symbols P, action types Y, and constants C. A state fact is the application of a predicate to the appropriate number of constants, with a state being a set of state facts. Each action $a \in \mathcal{A}$ consists of: 1) an action name, which is an action type applied to the appropriate number of constants, 2) a set of precondition state facts $\text{Pre}(a)$, 3) two sets of state facts $\text{Add}(a)$ and $\text{Del}(a)$ representing the add and delete effects respectively. An action a is applicable to a world state ω iff $\text{Pre}(a) \subseteq \omega$, and the application of an (applicable) action a to ω results in the new state $\omega' = (\omega \setminus \text{Del}(a)) \cup \text{Add}(a)$. That is, the application of an action adds the facts in the add list to the state and deletes facts in the delete list.

Given a planning domain, a planning problem is a tuple (ω, A, g), where $A \subseteq \mathcal{A}$ is a set of actions, $\omega \in \mathcal{W}$ is the initial state, and g is a set of state facts representing the goal. A solution plan for a planning problem is a sequence of actions $\langle a_1, \ldots, a_l \rangle$, where the sequential application of the sequence starting in state ω leads to a goal state ω' where $g \subseteq \omega'$. In this paper, we will view planning problems as directed graphs where the vertices represent states and the edges represent possible state transitions. Planning then reduces to graph search for a path from the initial state to goal.

Figure 1 shows an example of the search space corresponding to a problem from the Blocksworld planning domain. Here, the initial state is described by the facts

$$\begin{aligned}\omega_0 = \{&clear(A), clear(B), clear(C), clear(D), ontable(A),\\ &ontable(B), ontable(C), ontable(D), armempty\}.\end{aligned}$$

An example action from the domain is $pickup(A)$ with the following definition:

$$\begin{aligned} Pre(pickup(A)) &= \{clear(A), ontable(A), armempty\}\\ Add(pickup(A)) &= \{holding(A)\}\\ Del(pickup(A)) &= \{clear(A), ontable(A), armempty\}.\end{aligned}$$

Note that the precondition of this action is satisfied in ω_0 and hence can be applied from ω_0, which would result in the new state

$$\omega_1 = \{holding(A), clear(B), clear(C), clear(D), ontable(B), ontable(C), ontable(D)\}.$$

If the goal of the planning problem is $g = \{on(C,D), on(B,A), clear(C), clear(B)\}$, then one solution for the problem, as shown in Figure 1, is the action sequence $\langle pickup(B), stack(B,A), pickup(C), stack(C,D)\rangle$.

There has been much recent progress in automated planning. One of the most successful approaches, and the one most relevant to this paper, is to solve planning problems using forward state-space search guided by powerful domain-independent planning heuristics. A number of recent state-of-the-art planners have followed this approach including HSP (Bonet and Geffner, 1999), FF (Hoffmann and Nebel, 2001), and AltAlt (Nguyen et al., 2002) to name just a few.

5.1.2 LEARNING TO PLAN

It is common for planning systems to be asked to solve many problems from a particular domain. For example, the bi-annual international planning competition is organized around a number of planning domains and includes many problems of varying difficulty from each domain. Given that problems from the same domain share significant structure, it is natural to attempt to learn from past experience in a domain in order to solve future problems from the same domain more efficiently. However, most state-of-the-art planning systems do not have any such learning capability and rather solve each problem from the domain as if it were the first problem ever encountered by the planner. The goal of our work is to develop the capability for a planner to learn domain-specific knowledge in order to improve performance in a target domain of interest.

More specifically, we focus on developing learning capabilities within the simple, but highly successful, framework of heuristic state-space search planning. Our goal is to learn heuristics, or ranking functions, that can quickly solve problems using beam search with a small beam width. Given a representative training set of problems from a planning domain, our approach first solves the problems using potentially expensive search (e.g., using a large beam width), guided by an existing heuristic. These solutions are then used to learn a heuristic that can guide a small width beam search to the same solutions. The hope is that the learned heuristic will then generalize and allow for the quick solution of new problems that could not be practically solved before learning.

5.1.3 PRIOR WORK

There has been a long history of work on learning-to-plan, originating at least back to the original STRIPS planner (Fikes et al., 1972), which learned triangle tables or macros that could later be exploited by the planner. For a collection and survey of work on learning in AI planning see Minton (1993) and Zimmerman and Kambhampati (2003).

A number of learning-to-plan systems have been based on the explanation-based learning (EBL) paradigm, for example, Minton et al. (1989) among many others. EBL is a deductive learning approach, in the sense that the learned knowledge is provably correct. Despite the relatively large effort invested in EBL research, the best approaches typically did not consistently lead to significant gains, and even hurt performance in many cases. A primary way that EBL can hurt performance is by learning too many, overly specific control rules, which results in the planner spending too much time simply evaluating the rules at the cost of reducing the number of search nodes considered. This problem is commonly referred to as the EBL utility problem (Minton, 1988).

Partly in response to the difficulties associated with EBL-based approaches, there have been a number of systems based on inductive learning, sometimes combined with EBL. The inductive approach involves applying statistical learning mechanisms in order to find common patterns that can distinguish between good and bad search decisions. Unlike EBL, the learned control knowledge typical does not have guarantees of correctness, however, the knowledge is typically more general and hence more effective in practice. Some representative examples of such systems include

learning for partial-order planning (Estlin and Mooney, 1996), learning for planning as satisfiability (Huang et al., 2000), and learning for the Prodigy means-ends framework (Aler et al., 2002). While these systems typically showed better scalability than their EBL counterparts, the evaluations were typically conducted on only a small number of planning domains and/or small number of test problems. There is no empirical evidence that such systems are robust enough to compete against state-of-the-art non-learning planners across a wide range of domains.

More recently there have been several learning-to-plan systems based on the idea of learning reactive policies for planning domains (Khardon, 1999; Martin and Geffner, 2000; Yoon et al., 2002). These approaches use statistical learning techniques to learn policies, or functions, that map any state-goal pair from a given domain to an appropriate action. Given a good reactive policy for a domain, problems can be solved quickly, without search, by iterative application of the policy. Despite its simplicity, this approach has demonstrated considerable success. However, these approaches have still not demonstrated the robustness necessary to outperform state-of-the-art non-learning planners across a wide range of domains.

More closely related is work by La Rosa et al. (2007), which uses a case-based reasoning approach to obtained an improved heuristic for forward state-space search. It is likely that our weight learning approach could be combined with their system to harness the benefits of both approaches. The most closely related approach to our work is based on extending forward state-space search planners by learning improved heuristics (Yoon et al., 2006), an approach which is among the state-of-the-art among learning-based planners. That work focused on improving the relaxed plan length heuristic used by the state-of-the-art planner FF (Hoffmann and Nebel, 2001). Note that FF consists of two stages: an incomplete local search and a complete best first search. In particular, Yoon et al. (2006) applied linear regression to learn an approximation of the difference between FF's heuristic and the observed distances-to-goal of states in the training plans. The primary contribution of the work was to define a generic knowledge representation for features and a features-search procedure that allowed learning of good regression functions across a range of planning domains. While the approach showed promising results, the learning mechanism has a number of potential shortcomings. Most importantly, the mechanism does not consider the actual search performance of the heuristic during learning. That is, learning is based purely on approximating the observed distances-to-goal in the training data. Even if the learned heuristic performs poorly on the training data when used for search, the learner makes no attempt to correct the heuristic in response.

A primary motivation for this paper is to develop a heuristic learning mechanism that is more tightly integrated with the search process. Our LaSO-style algorithms for learning beam-search ranking functions do exactly that. Our learning approach can be viewed as error-driven in the sense that it directly attempts to correct errors as they arise in the search process, rather than attempting to precisely model the distance-to-goal. In many areas of machine learning, such error-driven methods have been observed to outperform their traditional passive counterparts. The experimental results presented here agree with that observation in a number of planning domains.

5.2 Experimental Setup

We present experiments in eight STRIPS domains: Blocksworld, Pipesworld, Pipesworld-with-tankage, PSR, Philosopher, DriverLog, Depots and FreeCell. All of these domains with the exception of Blocksworld were taken from the 3rd and 4th international planning competitions (IPC3 and IPC4). With only two exceptions, this is the same set of domains used to evaluate the approach of

Yoon et al. (2006), which is the only prior work that we are aware of for learning heuristics to improve forward state-space search in automated planning. The difference between our set of domains and theirs is that we include Blocksworld, while they did not, and we do not include the Optical Telegraph domain, while they did. Our reason for not showing results for Optical Telegraph is that none of the systems we evaluated were able to solve any of the problems.[1]

5.2.1 DOMAIN PROBLEM SETS

For each domain we needed to create a set of training problems and testing problems on which the learned heuristics would be trained and evaluated. In Blocksworld, all problems were generated using the BWSTATES generator (Slaney and Thiébaux, 2001), which produces random Blocksworld problems. Thirty problems with 10 or 20 blocks were used as training data, and 30 problems with 20, 30, or 40 blocks were used for testing. For DriverLog, Depots and FreeCell, the first 20 problems are taken from IPC3 and we generated 30 more problems of varying difficulty to arrive at a set of 50 problems, roughly ordered by difficulty. For each domain, we used the first 15 problems for training and the remaining 35 for testing. The other four domains are all taken from IPC4. Each domain includes 50 or 48 problems, roughly ordered by difficulty. In each case, we used the first 15 problems for training and the remaining problems for testing.

5.2.2 SEARCH SPACE DEFINITION

We now describe the mapping between the planning problem described in Section 5.1.1 and the general search spaces described in Section 2, which were the basis for describing our algorithms. Recall that a general search space is a tuple $\langle I, s(\cdot), f(\cdot), < \rangle$ giving the initial state, successor function, feature function, and preference ordering respectively. In the context of planning each search node is a state-goal pair (ω, g), where ω can be thought of as the current world state, g is the current goal, and both are represented as sets of facts. Note that it is important that nodes contain both state and goal information, rather than just state information, since the evaluation/ranking of a search node depends on how good ω is with respect to the particular goal g. The initial search node I is equal to (ω_0, g), where ω_0 is the initial state of the planning problem and g is the problem's goal. The successor function s maps a search node (ω, g) to the set of all nodes of the form (ω', g) where ω' is a state that can be reached from ω via the application of some action whose preconditions are satisfied in ω. Note that according to this definition all nodes in a search space contain the same goal component. The feature function $f((\omega, g)) = (f_1((\omega, g)), \ldots, f_m((\omega, g)))$ can be any function over world states and goals. The particular functions we use in this work are describe later in this section. Finally, the preference ordering $<$ is simply the default ordering used by the planner FF, which is the planner our implementation is based on.

5.2.3 TRAINING DATA GENERATION

The LaSO-style algorithms learn from target solution paths, which requires that we generate solution plans for all of the training problems. To do this, for each training problem, we selected the shortest plan out of those found by running the planner FF and beam search with various large beam

1. The results in Yoon et al. (2006) indicated that their linear regression learning method was effective in Optical Telescope. Our implementation of linear regression, however, was unable to solve any of the problems. After investigating this difference, we found that it is due to a subtle difference in the way that ties are broken during forward state-space search, indicating that the linear regression method was not particularly robust in this domain.

widths guided by FF's relaxed-plan heuristic. The resulting plans are totally ordered sequences of actions and one could simply label each training problem by its corresponding sequence of actions. However, in many cases, it is possible to produce equivalent plans by permuting the order of certain actions in the totally ordered plans. That is, there are usually many other equivalent totally ordered plans. Thus, including only the single plan found via the above approach in the training data results in significant ambiguity in the sense described in Section 4.4.

In order to help reduce the ambiguity it is desirable to try to include as many equivalent plans as possible as part of the target plan set for a particular problem. To do this, instead of using just a single totally ordered solution plan in the training data for each problem, we transform each such totally ordered plan into a partial-order plan, which contains the same set of actions but only includes action-ordering constraints that appear to be necessary. Finding minimal partial-order plans from total-order plans is an NP-hard problem and hence we use the heuristic algorithm described in Veloso et al. (1991). For each training problem, the resulting partial-order plan provides an implicit representation for a potentially exponentially large set of solution trajectories. By using these partial-order plans as the labels for our training problems we can significantly reduce the ambiguity in the training data. In preliminary experiments, the performance of our learning algorithms improved in a number of domains when using training data that included the partial-order plans rather than the original total-order plans.

5.2.4 HEURISTIC REPRESENTATION AND DOMAIN FEATURES

We consider learning heuristic functions that are represented as weighted linear combinations of features, that is, $H(v) = \Sigma_i w_i \cdot f_i(v)$ where v is a search node, f_i is a feature of search nodes, and w_i is the weight of feature f_i. One of the challenges with this representation is to define a generic feature space from which features can be selected for each domain. This space must be rich enough to capture important properties of a wide range of planning domains, but also be amenable to searching for those properties. For this purpose we will draw on prior work Yoon et al. (2008) that defined such a feature space using a first-order language.

Each feature in the above space is defined by a taxonomic class expression, which represents a set of constants/objects in the planning domain. For example, a simple taxonomic class expression for the Blocksworld planning domain is *clear*, which represents the set of blocks that are currently clear, that is, the set of blocks x such that $clear(x) \in \omega$ where the current search node is $v = (\omega, g)$. The respective feature value represented by a class expression is equals to the cardinality of the class expression when evaluated at a search node. For example, if we let f_1 be the feature represented by the class expression *clear* then $f_1((\omega, g))$ is simply the number of clear blocks in ω. So in the example states from Section 5.1.1, $f_1(v_0) = f_1((\omega_0, g)) = 4$ and $f_1(v_1) = f_1((\omega_1, g)) = 3$. A more complex example for this problem is $clear \cap gclear$, which represents the set of blocks that are clear in both the current state and the goal, that is, the set containing any block x such that $clear(x) \in \omega$ and $clear(x) \in g$. If f_2 represents the feature corresponding to this expression then in the example states from 5.1.1 we get that $f_2(v_0) = 2$ and $f_2(v_1) = 2$.

Since our work in this paper is focused on weight learning, we refer to Yoon et al. (2008) for the full definition of the taxonomic feature language. Here we simply use a set of taxonomic features that have been automatically learned in prior work (Yoon et al., 2008) and tune their weights. In our experiments, this prior work gave us 15 features in Blocksworld, 35 features in Pipesworld, 11 features in Pipesworld-with-tankage, 54 features in PSR, 19 features in Philosopher, 22 features in

DriverLog, 3 features in Depot and 3 features in FreeCell. In all cases, we include FF's relaxed-plan-length heuristic as an additional feature.

5.3 Experimental Results

For each domain, we use LaSO-BR to learn weights with a learning rate of 0.01 for beam widths 1, 10, 50, and 100 and we will denote LaSO-BR run with beam width b by LaSO-BR$_b$. The maximum number of LaSO-BR iterations was set to 5000. In the evaluation procedure, we set a time cut-off of 30 CPU minutes per problem and considered a problem to be unsolved if a solution was not found within the cut-off.

In preliminary work, we also tried to apply LaSO-BST to our problems. However, this turned out to be an impractical approach due to the large potential search depths of these problems. In particular, we found that in many cases LaSO-BST would become stuck processing training examples, in the sense that it would neither update the weights nor make progress with respect to following the target trajectories. This typically occurred because LaSO-BST would maintain an early target node in the beam and thus not trigger a weight update, but at the same time would not progress to include deeper nodes on the target trajectories and instead explore paths off the target trajectories. To help remedy this behavior, we experimented with a variant of LaSO-BST that forces progress along the target trajectories after a specified number of search steps. For the Blocksworld planning domain and preliminary experiments in the other domains, we found that the results tended to improve compared to the original LaSO-BST, but still were not competitive with LaSO-BR. Thus for the experiments reported below we focus on LaSO-BR.

Note that the experiments in Daumé III and Marcu (2005) for structured classification produced good results using an algorithm very similar to LaSO-BST. There, however, the search spaces have small maximum depths (e.g., the length of a sentence), which apparently helped to avoid the problem we experienced here.

5.3.1 TRAINING TIME

Figure 11 gives the average training time required by LaSO-BR per iteration in each of our domains for four different beam widths. Note that Pipesworld was the only domain for which LaSO-BR converged to a consistent weight vector using a learning beam width 100. For all other training sets LaSO-BR never converged and thus terminated after 5000 iterations. The training time varies widely across the domains and depends on various factors including: number of features, number of actions, number of state predicates, and the number and length of target trajectories per training example. As expected the training times increase with the training beam width across the domains. It is difficult, however, to predict the relative times between different domains due to the complicated interactions among the above factors. Note that while these training times can be significant in many domains, the cost of training needs to only be paid once and then it is amortorized over all future problems. Furthermore, as we can observe later in the experimental results, a small beam width of 10 typically performs as well as larger widths.

5.3.2 DESCRIPTION OF TABLES

Before presenting our results we will first provide an overview of the information contained in our results tables. Figure 12 compares the performance of LaSO-BR$_{10}$ to three other algorithms,

Domain	$b = 1$	$b = 10$	$b = 50$	$b = 100$
Blocksworld	3	15	66	128
Pipesworld	1	4	13	24
Pipesworld-with-tankage	3	17	76	149
PSR	53	127	403	690
Philosopher	3	24	121	260
DriverLog	1	5	22	44
Depots	5	32	160	320
FreeCell	10	68	315	654

Figure 11: The average training time required by LaSO-BR per iteration for all training instances (seconds).

- LEN : beam search using FF's relaxed plan length heuristic
- U : beam search using a heuristic with uniform weights for all features
- LR : beam search using the heuristic learned from linear regression following the approach in Yoon et al. (2006).

We selected LaSO-BR$_{10}$ here because its performance is on par or better than other training beam widths. Note that in practice one could select the best beam width to use via cross-validation with a validation set of problems.

There is one table for each of our domains and each column in the tables is labeled by the algorithm used to generate the results. The rows correspond to the beam width used to generate the results on the testing problems, with the last row corresponding to using full best-first search (BFS) with an infinite beam width, which is the native search procedure used by FF. The columns are divided into three sets. The first four data columns labeled "Problems solved" give the number of problems solved using the testing beam width corresponding to the row, where a problem is considered solved if a solution is found within 30 minutes. The second set of columns labeled "Median plan length" gives the median length of solutions to the planning problems that were solved. The last 4 columns labeled "Median runtime " give the median runtime of each solver on the problems it solved. So, for example, the table shows that the heuristic learned via LaSO-BR$_{10}$ solves 26 Blocksworld test problems with a median solution length of 139 and a median runtime of 58.8 seconds using a testing beam width of 50, and solved 19 problems with a median solution length of 142 and a median runtime of 20.9 seconds using BFS.

Figure 13 is similar in structure to Figure 12 but compares the performance of heuristics learned using LaSO-BR with a variety of training beam widths and evaluated using a variety of testing beam widths. Only the number of problems solved and the median length of solutions that are found are considered here. For example, the upper left-most data point gives the number of problems solved using a learning beam width of 1 and a testing beam width of 1, while the first entry in the last column gives the median plan length of solved problems when learning with beam width 100 and testing with beam width 1.

Figure 12: Experimental results for different planners. For each domain, we show the number of solved problems, the median plan length and median runtime of the solved problems. A dash in the table indicates that the planner was unable to solve any of the problems.

5.3.3 PERFORMANCE ACROSS TESTING BEAM WIDTHS

From Figure 12, in general, for all algorithms (learning and non-learning) we see that as the testing beam width begins to increase the number of solved problems and runtime increase and solution lengths improve. However, at some point as the beam width continues to increase the number of solved problems typically decreases. This behavior is typical for beam search, since as the testing beam width increases there is a greater chance of not pruning a solution trajectory, but the computational time and memory demands increase. Thus, for a fixed time cut-off we expect a decrease in performance as the beam width becomes large.

The median runtime typically increases as the test beam width increases, because more search nodes need to be evaluated. However, it is not always the case. The number of search nodes that are going to be evaluated also depends on the plan length. For example, while using LEN in the Depots planning domain, the median runtime of beam width 50 is smaller than that of beam width 10, because the median plan length improves from 195 to 25. Also note that it is not necessarily true that the plan lengths are strictly non-increasing with testing beam width. With large testing beam widths the number of candidates for the next beam increases, making it more likely for the heuristic to get confused by "bad" states. This is also one possible reason why performance tends to decrease with larger testing beam widths.

5.3.4 LASO-BR$_{10}$ VERSUS NO LEARNING

From Figure 12, we see that compared to LEN, the heuristic learned by LaSO-BR$_{10}$ tends to significantly improve the performance of beam search, especially for small beam widths. For example, in Blocksworld with beam width 1, LaSO-BR$_{10}$ solves almost twice as many problems as LEN. The median plan length has also been reduced significantly for beam width 1. As the beam width increases the gap between LaSO-BR$_{10}$ and LEN decreases but LaSO-BR$_{10}$ still solves more problems with comparable solution quality. In Pipesworld, LaSO-BR$_{10}$ has the best performance gap with beam width 50, solving 8 more problems than LEN. As the beam width increases, again the performance gap decreases, but LaSO-BR$_{10}$ consistently solves more problems than LEN. In this domain, the median plan lengths of LEN tend to be better, though a direct comparison of these lengths is not exactly fair since LaSO-BR$_{10}$ solves more problems, which are often the harder problems that result in longer plans. The trends with respect to number of solved problems are similar in other domains, with the exception of PSR and FreeCell. In PSR, LEN solves slightly more problems than LaSO-BR$_{10}$ at large beam widths. In FreeCell, LaSO-BR$_{10}$ is better than LEN for most case except for beam width 50.

These results show that LaSO-BR$_{10}$ is able to learn heuristics that significantly improve on the state-of-the-art heuristic LEN when using beam search. In general, the best performance was achieved for small beam widths close to those used for training, which is beneficial in terms of time and memory efficiency. Note that in practice one could use a validation set of problems in order to select the best combination of training beam width and testing beam width for a given domain. This is particularly natural in our current setting where our goal is to perform well relative to problems drawn from a given problem generator, in which case we can easily draw both training and evaluation problem sets.

5.3.5 COMPARING LASO-BR$_{10}$ WITH LINEAR REGRESSION

To compare with prior passive heuristic learning work we learned weights using linear regression following the approach of Yoon et al. (2006). To our knowledge this is the only previous system that addresses the heuristic learning problem in the context of forward state-space search in automated planning. In these experiments we used the linear regression tool available under Weka. The results for the resulting learned linear-regression heuristics are shown in the columns labeled LR in Figure 12.

For Blocksworld, LR solves fewer problems than LaSO-BR$_{10}$ with beam widths smaller than 500 but solves more problems than LaSO-BR$_{10}$ with beam width 500. The median plan length tends to favor LR except for the smallest beam width $b = 1$. For Pipesworld, DriverLog and Depots, LaSO-BR$_{10}$ always solves more problems than LR, with plan length again favoring LR to varying degrees. In Pipesworld-with-tankage, LaSO-BR$_{10}$ is better than LR for most case except for beam width 10, solving one less problem. In PSR and Philosopher, LR outperforms LaSO-BR$_{10}$ but LaSO-BR$_{10}$ achieves a comparable performance with small beam widths. In FreeCell, LaSO-BR$_{10}$ always solves more problems than LR with improved plan length.

These results indicate that error-driven learning can significantly improve over prior passive learning (here regression) in a number of domains. Indeed, there appears to be utility in integrating the learning process directly in the search procedure. However, the results also indicate that in some cases our current error-driven training method can fail to converge to a good solution in cases where regression happens to work well.

5.3.6 EFFECTS OF LEARNING BEAM WIDTH

Figure 13 compares the performance of LaSO-BR with different learning beam widths. For most domains, the performance doesn't change much as the learning beam width changes. Even with learning beam width 1, LaSO-BR can often achieve performance on par with larger learning beam widths. For example, in Blocksworld, LaSO-BR$_1$ results in the best performance at most testing beam widths except for beam width 500. For the other domains, LaSO-BR$_{10}$ typically is close to the performance of the best learning beam width. In a number of cases we see that LaSO-BR$_{10}$ performs significantly better than LaSO-BR$_{100}$, which suggests that learning with smaller beam widths can have some practical advantages. One reason for this might be due to the additional ambiguity in the weight updates when using larger beam widths. In particular, the weight update equations involve averages of all target and non-target nodes in the beams. The effect of this averaging is to effectively mix the feature vectors of large numbers of search nodes together. In many cases there will be a wide variety of non-target nodes in the beam, and this mixing can increase the difficulty of uncovering key patterns, which we conjecture might increase the requirements on training iterations and examples. In cases where the features are rich enough to support successful beam search with small width, it is then likely that learning with smaller widths will be better given a fixed number of iterations and examples. Note that the feature space we have used in this work has been previously demonstrated (Fern et al., 2006) to be particularly well suited to Blocksworld, which is perhaps one reason that $b = 1$ performed so well in that domain.

Finally note that contrary to what we originally expected it is not typically the case that the best performance for a particular testing beam width is achieved when learning with that same beam width. Rather the relationship between learning and testing beam widths is quite variable. Note that for most domains LaSO-BR never converged to a consistent weight vector in our experiments,

indicating that either the features were not powerful enough for consistency or the learning beam widths and/or number of iterations needed to be increased. In such cases, there is no clear technical reason to expect the best testing beam width to match the learning beam width. Thus, in general, we suggest the use of validation sets to select the best pair of learning and testing beam widths for a particular domain. Note that the lack of relationship between learning and test beam width is in contrast to that observed in Daumé III and Marcu (2005) for structured classification, where there appeared to be a small advantage to training and testing using the same width.

5.3.7 BEST FIRST SEARCH RESULTS

While our heuristic was learned for the purpose of controlling beam search we conducted one more experiment in each domain where we used the heuristics to guide Best First Search (*BFS*). We include these results primarily because BFS was the search procedure used to evaluate LR in Yoon et al. (2006) and is the native search strategy used by FF.[2] These results are shown in the bottom row of each table in Figure 12 and 13.

In Blocksworld, Pipesworld, PSR, LaSO-BR$_{10}$ was as good or better than the other three algorithms. Especially in Blocksworld, LaSO-BR$_{10}$ solves 19 problems while LEN only solves 5 problems. In Philosopher, neither LEN nor LaSO-BR$_{10}$ solves any problem. LEN is the best in Pipesworld-with-tankage, DriverLog and FreeCell, and LR works best in Depots. But for Pipesworld-with-tankage, Depots and FreeCell, the performance of LaSO-BR$_{10}$ is very close to the best planner.

These results indicate that the advantage of error-driven learning over regression is not just restricted to beam search, but appears to extend to other search approaches. That is, by learning in the context of beam search it is possible to extract problem solving information that is useful in other contexts.

5.3.8 PLAN LENGTH

LaSO-BR can significantly improve success rate at small beam widths, which is one of our main goals. However, the plan lengths at small widths are quite suboptimal, which is typical of beam search. Ideally we would like to obtain these success rates without paying a price in plan length. We are currently investigating ways to improve LaSO-BR in this direction. However, we note that typically one of the primary difficulties of automated planning is to simply find a path to the goal. After finding such a path, if it is significantly sub-optimal, incomplete plan analysis or plan rewriting rules can be used to significantly prune the plan, for example, see Ambite et al. (2000). Thus, despite the long plan lengths, the improved success rate of LaSO-BR at small beam widths could provide a good starting point for a fast plan length optimization.

6. Summary and Future Work

This paper presented a detailed study of the problem of learning ranking functions for beam search with an application to automated planning. On the theoretical side we first studied the computational complexity of this learning problem, highlighting the main dimensions of complexity by identifying core tractable and intractable subclasses. Next, we studied the convergence of recent online learning algorithms for this problem. The results clarified convergence issues, correcting and extending

2. FF actually uses two search strategies. In the first state it uses an incomplete strategy called enforced hill climbing. If that initial search does not find a solution then a best-first search is conducted.

Figure 13: Experimental results for various learning beam widths. For each domain, we show the number of solved problems and the median plan length of the solved problems. A dash in the table indicates that the planner was unable to solve any of the problems.

previous results. This included an analysis of convergence given ambiguous training data, giving a result that highlights the trade-off between the amount of allowed search and the difficulty of the resulting learning problem. Our experiments in the domain of automated planning showed that the approach has benefits compared to existing learning and non-learning state-space search planners. These results complement the positive empirical results in structured classification (Daumé III and Marcu, 2005) showing the general utility of the method.

In future work, we plan to extend the algorithms described here to allow for feature induction and more robust parameter estimation. We are also interested in studying learning in the context of search for other search strategies such as best-first and k-best-first search. In our initial investigations, we have found that the LaSO-style approach for these strategies has great difficulty in automated planning due to the very large depths of the search spaces, which makes it difficult to "assign credit" to search errors. This suggests that a key aspect of future work is to understand general credit-assignment mechanisms in the context of error-driven learning for search. Another important direction is to consider the application of these methods to new problem domains, in particular we are interested in more complex planning domains that include concurrency, durative actions, and uncertainty. It will also be interesting to consider learning beam-search heuristics for other search-based formulations of planning such as partial-order planning where the search is conducted directly in the space of partial-order plans.

Appendix A. Relation to Structured Classification

This Appendix assumes that the reader is familiar with the material in Section 3. The learning framework introduced in Section 2.2 is motivated by automated planning, with the objective of finding a goal node. It is important to note that the learning objective does not place a constraint on the rank of a goal node in the final beam compared to non-goal nodes, but rather only requires that there exists some goal node in the final beam. This is a natural formulation for automated planning where when solving test problems it is easy to test each beam to determine whether a goal node has been uncovered and to return a solution trajectory if one has. Thus, the exact ordering of the goal node in the final beam is not important with respect to finding solutions to planning problems.

In contrast, as described in the example at the end of Section 2.2, the formulation of structured classification as a search problem appears to require that we do pay attention to the rank of the goal nodes in the final beam. In particular, the formulation of Daumé III and Marcu (2005) requires the goal node to not only be contained in the final beam, but to be ranked higher than any other terminal node in the beam.

Since our formulation of the beam-search learning problem does not constrain the ranking of goal nodes relative to other nodes, it is not immediately clear how our formulation relates to structured classification. It turns out that these two formulations are polynomially equivalent, meaning that there is a polynomial reduction from each problem to the other. Thus, it is possible to compile away the explicit requirement that goal nodes have the highest rank in the final beam.

Below we adapt the definitions of the learning problems in Section 2.2 for structured classification. First, we introduce the notion of terminal node, which can be thought of as a possible solution to be returned by a structured classification algorithm, for example, a full parse tree for a sentence. We will denote the set of all terminal nodes as $\mathcal{T}$ and will assume a polynomial time test for determining whether a node is in this set. Note that some terminal nodes correspond to target solutions and others do not. When using beam search for structured classification the search is halted whenever a terminal node becomes highest ranked in the beam and the path leading to that terminal node is returned as the solution. Thus, successful learning must ensure both that no non-target terminal node ever becomes ranked first in any beam and also that eventually a target terminal node does become ranked first. This motivation leads to the following definitions for the breadth-first and best-first structured classification problems. Below, given the context of a weight vector w, we will denote the highest ranked node relative to w in a beam B by $B^{(1)}$.

Definition 17 (Breadth-First Structured Classification) *Given the input $\langle\{\langle S_i, P_i\rangle\}, b\rangle$, where b is a positive integer and $P_i = (P_{i,0}, \ldots, P_{i,d})$, the breadth-first structured classification problem asks us to decide whether there is a weight vector w such that for each S_i, the corresponding beam trajectory $(B_{i,0}, \ldots, B_{i,d})$, produced using w with a beam width of b, satisfies $B_{i,j} \cap P_{i,j} \neq \emptyset$ for each j, $B^{(1)}_{i,d} \in P_{i,d}$, and $B^{(1)}_{i,j} \notin \mathcal{T}$ for $j < d$?*

Definition 18 (Best-First Structured Classification) *Given the input $\langle\{\langle S_i, P_i\rangle\}, b\rangle$, where b is a positive integer and $P_i = (P_{i,0}, \ldots, P_{i,d})$, the best-first structured classification problem asks us to decide whether there is a weight vector w that produces for each S_i a beam trajectory $(B_{i,0}, \ldots, B_{i,k})$ of beam width b, such that $k \leq h$, each $B_{i,j}$ for $j < k$ contains at least one node in $\bigcup_j P_{i,j}$, $B^{(1)}_{i,k} \in P_{i,d}$, and $B^{(1)}_{i,j} \notin \mathcal{T}$ for $j < k$?*

We prove that these problems are polynomially equivalent to breadth-first and best-first consistency by showing that they are NP-complete. Since Section 3 proves that the consistency problems are also NP-complete we immediately get equivalence.

Theorem 19 *Breadth-first structured classification is NP-complete.*

Proof We can prove that the problem is in NP, following the structure of the proof of Theorem 4. Each certificate corresponds to a set of beam trajectories and has a size that is polynomial in the problem size. The certificate can be checked in polynomial time to see if for each i, it satisfies the conditions defined in Definition 17. From Lemma 3 in Section 3 we can then use the algorithm *TestTrajectories* in Figure 4 to decide whether there is a weight vector that generates the certificate in polynomial time. To show hardness we reduce from breadth-first consistency for the class of problems where $b = 1, d = 1, c = 6, t = 3$, and $n \geq 1$, which from Figure 6 is NP-complete. Since for this class the search spaces have depth 1 and the beam width is 1 it is easy to see that for any problem in this class, a weight vector is a solution to the consistency problem if and only if it is a solution to the structured classification problem. This shows that breadth-first structured classification is NP-hard and thus NP-complete. ■

Using an almost identical proof we can prove the same result for best-first structured classification.

Theorem 20 *Best-first structured classification is NP-complete.*

Abstract

Inference in Bayesian statistics involves the evaluation of marginal likelihood integrals. We present algebraic algorithms for computing such integrals exactly for discrete data of small sample size. Our methods apply to both uniform priors and Dirichlet priors. The underlying statistical models are mixtures of independent distributions, or, in geometric language, secant varieties of Segre-Veronese varieties.

Keywords: marginal likelihood, exact integration, mixture of independence model, computational algebra

1. Introduction

Evaluation of marginal likelihood integrals is central to Bayesian statistics. It is generally assumed that these integrals cannot be evaluated exactly, except in trivial cases, and a wide range of numerical techniques (e.g., MCMC) have been developed to obtain asymptotics and numerical approximations (Chickering and Heckerman, 1997). The aim of this paper is to show that exact integration is more feasible than is surmised in the literature. We examine marginal likelihood integrals for a class of mixture models for discrete data. Bayesian inference for these models arises in many contexts, including machine learning and computational biology. Recent work in these fields has made a connection to singularities in algebraic geometry (Drton, 2009; Geiger and Rusakov, 2005; Watanabe, 2001; Watanabe and Yamazaki, 2003, 2004). Our study augments these developments by providing tools for symbolic integration when the sample size is small.

The numerical value of the integral we have in mind is a rational number, and exact evaluation means computing that rational number rather than a floating point approximation. For a first example consider the integral

$$\int_{\Theta} \prod_{i,j \in \{\mathtt{A},\mathtt{C},\mathtt{G},\mathtt{T}\}} \left(\pi \lambda_i^{(1)} \lambda_j^{(2)} + \tau \rho_i^{(1)} \rho_j^{(2)}\right)^{U_{ij}} d\pi\, d\tau\, d\lambda\, d\rho, \tag{1}$$

where Θ is the 13-dimensional polytope $\Delta_1 \times \Delta_3 \times \Delta_3 \times \Delta_3 \times \Delta_3$. The factors are probability simplices,

$$\begin{aligned}
\Delta_1 &= \{(\pi,\tau) \in \mathbb{R}^2_{\geq 0} : \pi + \tau = 1\}, \\
\Delta_3 &= \{(\lambda_{\mathtt{A}}^{(k)}, \lambda_{\mathtt{C}}^{(k)}, \lambda_{\mathtt{G}}^{(k)}, \lambda_{\mathtt{T}}^{(k)}) \in \mathbb{R}^4_{\geq 0} \ : \textstyle\sum_i \lambda_i^{(k)} = 1\}, \quad k = 1,2, \\
\Delta_3 &= \{(\rho_{\mathtt{A}}^{(k)}, \rho_{\mathtt{C}}^{(k)}, \rho_{\mathtt{G}}^{(k)}, \rho_{\mathtt{T}}^{(k)}) \in \mathbb{R}^4_{\geq 0} \ : \textstyle\sum_i \rho_i^{(k)} = 1\}, \quad k = 1,2.
\end{aligned}$$

and we integrate with respect to Lebesgue probability measure on Θ. If we take the exponents U_{ij} to be the entries of the particular contingency table

$$U = \begin{pmatrix} 4 & 2 & 2 & 2 \\ 2 & 4 & 2 & 2 \\ 2 & 2 & 4 & 2 \\ 2 & 2 & 2 & 4 \end{pmatrix}, \tag{2}$$

then the exact value of the integral (1) is the rational number

$$\frac{571 \cdot 773426813 \cdot 17682039596993 \cdot 625015426432626533}{2^{31} \cdot 3^{20} \cdot 5^{12} \cdot 7^{11} \cdot 11^8 \cdot 13^7 \cdot 17^5 \cdot 19^5 \cdot 23^5 \cdot 29^3 \cdot 31^3 \cdot 37^3 \cdot 41^3 \cdot 43^2}. \tag{3}$$

The table (2) is taken from Example 1.3 of Pachter and Sturmfels (2005), where the integrand

$$\prod_{i,j \in \{\mathtt{A},\mathtt{C},\mathtt{G},\mathtt{T}\}} \bigl(\pi \lambda_i^{(1)} \lambda_j^{(2)} + \tau \rho_i^{(1)} \rho_j^{(2)}\bigr)^{U_{ij}} \tag{4}$$

was studied using the EM algorithm, and the problem of validating its global maximum over Θ was raised. See Feinberg et al. (2007, §4.2) and Sturmfels (2008, §3) for further discussions. That optimization problem, which was widely known as the 100 *Swiss Francs problem*, has in the meantime been solved by Gao et al. (2008).

The main difficulty in performing computations such as (1) = (3) lies in the fact that the expansion of the integrand has many terms. A first naive upper bound on the number of monomials in the expansion of (4) would be

$$\prod_{i,j \in \{\mathtt{A},\mathtt{C},\mathtt{G},\mathtt{T}\}} (U_{ij}+1) \quad = \quad 3^{12} \cdot 5^4 \ = \ 332,150,625.$$

However, the true number of monomials is only $3,892,097$, and we obtain the rational number (3) by summing the values of the corresponding integrals

$$\int_\Theta \pi^{a_1} \tau^{a_2} (\lambda^{(1)})^u (\lambda^{(2)})^v (\rho^{(1)})^w (\rho^{(2)})^x d\pi\, d\tau\, d\lambda\, d\rho \quad =$$
$$\frac{a_1! a_2!}{(a_1+a_2+1)!} \cdot \frac{3! \prod_i u_i!}{(\sum_i u_i + 3)!} \cdot \frac{3! \prod_i v_i!}{(\sum_i v_i + 3)!} \cdot \frac{3! \prod_i w_i!}{(\sum_i w_i + 3)!} \cdot \frac{3! \prod_i x_i!}{(\sum_i x_i + 3)!}.$$

The geometric idea behind our approach is that the Newton polytope of (4) is a *zonotope* and we are summing over its lattice points. Definitions for these geometric objects are given in Section 3.

This paper is organized as follows. In Section 2 we describe the class of algebraic statistical models to which our method applies, and we specify the problem. In Section 3 we examine the Newton zonotopes of mixture models, and we derive formulas for marginal likelihood evaluation using tools from geometric combinatorics. Our algorithms and their implementations are described

in detail in Section 4. Section 5 is concerned with applications in Bayesian statistics. We show how *Dirichlet priors* can be incorporated into our approach, we discuss the evaluation of *Bayes factors*, we compare our setup with that of Chickering and Heckerman (1997), and we illustrate the scope of our methods by computing an integral arising from a data set of Evans et al. (1989).

A preliminary draft version of the present article was published as Section 5.2 of the Oberwolfach lecture notes (Drton et al., 2009). We refer to that volume for further information on the use of computational algebra in Bayesian statistics.

2. Independence Models and their Mixtures

We consider a collection of discrete random variables

$$\begin{array}{cccc} X_1^{(1)}, & X_2^{(1)}, & \ldots, & X_{s_1}^{(1)}, \\ X_1^{(2)}, & X_2^{(2)}, & \ldots, & X_{s_2}^{(2)}, \\ \vdots & \vdots & \ddots & \vdots \\ X_1^{(k)}, & X_2^{(k)}, & \ldots, & X_{s_k}^{(k)}, \end{array}$$

where $X_1^{(i)},\ldots,X_{s_i}^{(i)}$ are identically distributed with values in $\{0,1,\ldots,t_i\}$. The independence model $\mathcal{M}$ for these variables is a toric model (Pachter and Sturmfels, 2005, §1.2) represented by an integer $d \times n$-matrix A with

$$d = t_1 + t_2 + \cdots + t_k + k \quad \text{and} \quad n = \prod_{i=1}^{k} (t_i+1)^{s_i}. \tag{5}$$

The columns of the matrix A are indexed by elements v of the state space

$$\{0,1,\ldots,t_1\}^{s_1} \times \{0,1,\ldots,t_2\}^{s_2} \times \cdots \times \{0,1,\ldots,t_k\}^{s_k}. \tag{6}$$

The rows of the matrix A are indexed by the model parameters, which are the d coordinates of the points $\theta = (\theta^{(1)},\theta^{(2)},\ldots,\theta^{(k)})$ in the polytope

$$P \;=\; \Delta_{t_1} \times \Delta_{t_2} \times \cdots \times \Delta_{t_k}, \tag{7}$$

and the model $\mathcal{M}$ is the subset of the simplex Δ_{n-1} given parametrically by

$$p_v \quad = \quad \text{Prob}\big(X_j^{(i)} = v_j^{(i)} \text{ for all } i,j\big) \quad = \quad \prod_{i=1}^{k} \prod_{j=1}^{s_i} \theta^{(i)}_{v_j^{(i)}}. \tag{8}$$

This is a monomial in d unknowns. The matrix A is defined by taking its column a_v to be the exponent vector of this monomial.

In algebraic geometry, the model $\mathcal{M}$ is known as *Segre-Veronese variety*

$$\mathbb{P}^{t_1} \times \mathbb{P}^{t_2} \times \cdots \times \mathbb{P}^{t_k} \quad \hookrightarrow \quad \mathbb{P}^{n-1}, \tag{9}$$

where the embedding is given by the line bundle $O(s_1,s_2,\ldots,s_k)$. The manifold $\mathcal{M}$ is the toric variety of the polytope P. Both objects have dimension $d-k$, and they are identified with each other via the moment map (Fulton, 1993, §4).

Example 1 *Consider three binary random variables where the last two random variables are identically distributed. In our notation, this corresponds to $k = 2$, $s_1 = 1$, $s_2 = 2$ and $t_1 = t_2 = 1$. We find that $d = 4, n = 8$, and*

$$A \quad = \quad \begin{array}{c} \\ \theta_0^{(1)} \\ \theta_1^{(1)} \\ \theta_0^{(2)} \\ \theta_1^{(2)} \end{array} \begin{array}{c} \begin{array}{cccccccc} p_{000} & p_{001} & p_{010} & p_{011} & p_{100} & p_{101} & p_{110} & p_{111} \end{array} \\ \begin{pmatrix} 1 & 1 & 1 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 1 & 1 & 1 \\ 2 & 1 & 1 & 0 & 2 & 1 & 1 & 0 \\ 0 & 1 & 1 & 2 & 0 & 1 & 1 & 2 \end{pmatrix} \end{array}.$$

The columns of this matrix represent the monomials in the parametrization (8). The model $\mathcal{M}$ lies in the 5-dimensional subsimplex of Δ_7 given by $p_{001} = p_{010}$ and $p_{101} = p_{110}$, and it consists of all rank one matrices

$$\begin{pmatrix} p_{000} & p_{001} & p_{100} & p_{101} \\ p_{010} & p_{011} & p_{110} & p_{111} \end{pmatrix}.$$

In algebraic geometry, the surface $\mathcal{M}$ is called a rational normal scroll.

The matrix A has repeated columns whenever $s_i \geq 2$ for some i. It is sometimes convenient to represent the model $\mathcal{M}$ by the matrix $\tilde{A}$ which is obtained from A by removing repeated columns. We label the columns of $\tilde{A}$ by elements $v = (v^{(1)}, \ldots, v^{(k)})$ of (6) whose components $v^{(i)} \in \{0, 1, \ldots, t_i\}^{s_i}$ are weakly increasing. Hence $\tilde{A}$ is a $d \times \tilde{n}$-matrix with

$$\tilde{n} \quad = \quad \prod_{i=1}^{k} \binom{s_i + t_i}{s_i}. \tag{10}$$

The model $\mathcal{M}$ and its mixtures are subsets of a subsimplex $\Delta_{\tilde{n}-1}$ of Δ_{n-1}.

We now introduce *marginal likelihood integrals*. All our domains of integration in this paper are polytopes that are products of standard probability simplices. On each such polytope we fix the standard Lebesgue probability measure. In other words, our discussion of Bayesian inference refers to the uniform prior on each parameter space. Naturally, other prior distributions, such as Dirichlet priors, are of interest, and our methods are extended to these in Section 5. In what follows, we simply work with uniform priors.

We identify the state space (6) with the set $\{1, \ldots, n\}$. A *data vector* $U = (U_1, \ldots, U_n)$ is thus an element of $\mathbb{N}^n$. The *sample size* of these data is $U_1 + U_2 + \cdots + U_n = N$. If the sample size N is fixed then the probability of observing these data is

$$\mathbf{L}_U(\theta) \quad = \quad \frac{N!}{U_1! U_2! \cdots U_n!} \cdot p_1(\theta)^{U_1} \cdot p_2(\theta)^{U_2} \cdot \cdots \cdot p_n(\theta)^{U_n}.$$

This expression is a function on the polytope P which is known as the *likelihood function* of the data U with respect to the independence model $\mathcal{M}$. The *marginal likelihood* of the data U with respect to the model $\mathcal{M}$ equals

$$\int_P \mathbf{L}_U(\theta)\, d\theta.$$

The value of this integral is a rational number which we now compute explicitly. The data U will enter this calculation by way of the *sufficient statistic* $b = A \cdot U$, which is a vector in $\mathbb{N}^d$. The

coordinates of this vector are denoted $b_j^{(i)}$ for $i = 1,\ldots,k$ and $j = 0,\ldots,t_k$. Thus $b_j^{(i)}$ is the total number of times the value j is attained by one of the random variables $X_1^{(i)},\ldots,X_{s_i}^{(i)}$ in the i-th group. Clearly, the sufficient statistics satisfy

$$b_0^{(i)} + b_1^{(i)} + \cdots + b_{t_i}^{(i)} \;=\; s_i \cdot N \qquad \text{for all } i = 1,2,\ldots,k. \tag{11}$$

The likelihood function $\mathbf{L}_U(\theta)$ is the constant $\frac{N!}{U_1!\cdots U_n!}$ times the monomial

$$\theta^b \;=\; \prod_{i=1}^{k}\prod_{j=0}^{t_i}(\theta_j^{(i)})^{b_j^{(i)}}.$$

The logarithm of this function is concave on the polytope P, and its maximum value is attained at the point $\hat{\theta}$ with coordinates $\hat{\theta}_j^{(i)} = b_j^{(i)}/(s_i \cdot N)$.

Lemma 1 *The integral of the monomial θ^b over the polytope P equals*

$$\int_P \theta^b d\theta \quad = \quad \prod_{i=1}^{k} \frac{t_i!\, b_0^{(i)}!\, b_1^{(i)}! \cdots b_{t_i}^{(i)}!}{(s_i N + t_i)!}.$$

The product of this number with the multinomial coefficient $N!/(U_1!\cdots U_n!)$ equals the marginal likelihood of the data U for the independence model $\mathcal{M}$.

Proof Since P is the product of simplices (7), this follows from the formula

$$\int_{\Delta_t} \theta_0^{b_0}\theta_1^{b_1}\cdots\theta_t^{b_t} d\theta \quad = \quad \frac{t!\cdot b_0!\cdot b_1!\cdots b_t!}{(b_0+b_1+\cdots+b_t+t)!} \tag{12}$$

for the integral of a monomial over the standard probability simplex Δ_t. ■

Our objective is to compute marginal likelihood integrals for the mixture model $\mathcal{M}^{(2)}$. The natural parameter space of this model is the polytope

$$\Theta \;=\; \Delta_1 \times P \times P.$$

Let $a_v \in \mathbb{N}^d$ be the column vector of A indexed by the state v, which is either in (6) or in $\{1,2,\ldots,n\}$. The parametrization (8) can be written simply as $p_v = \theta^{a_v}$. The mixture model $\mathcal{M}^{(2)}$ is defined to be the subset of Δ_{n-1} with the parametric representation

$$p_v \;=\; \sigma_0 \cdot \theta^{a_v} + \sigma_1 \cdot \rho^{a_v} \qquad \text{for } (\sigma,\theta,\rho) \in \Theta. \tag{13}$$

The likelihood function of a data vector $U \in \mathbb{N}^n$ for the model $\mathcal{M}^{(2)}$ equals

$$\mathbf{L}_U(\sigma,\theta,\rho) \quad = \quad \frac{N!}{U_1!U_2!\cdots U_n!}\, p_1(\sigma,\theta,\rho)^{U_1}\cdots p_n(\sigma,\theta,\rho)^{U_n}. \tag{14}$$

The *marginal likelihood* of the data U with respect to the model $\mathcal{M}^{(2)}$ equals

$$\int_\Theta \mathbf{L}_U(\sigma,\theta,\rho)\, d\sigma d\theta d\rho \;=\; \frac{N!}{U_1!\cdots U_n!}\int_\Theta \prod_v (\sigma_0\theta^{a_v} + \sigma_1\rho^{a_v})^{U_v} d\sigma d\theta d\rho. \tag{15}$$

The following proposition shows that we can evaluate this integral *exactly*.

Proposition 2 *The marginal likelihood (15) is a rational number.*

Proof The likelihood function $\mathbf{L}_U$ is a $\mathbb{Q}_{\geq 0}$-linear combination of monomials $\sigma^a\theta^b\rho^c$. The integral (15) is the same $\mathbb{Q}_{\geq 0}$-linear combination of the numbers

$$\int_\Theta \sigma^a\theta^b\rho^c d\sigma d\theta d\rho \quad = \quad \Big(\int_{\Delta_1}\sigma^a d\sigma\Big)\cdot\Big(\int_P \theta^b d\theta\Big)\cdot\Big(\int_P \rho^c d\rho\Big).$$

Each of the three factors is an easy-to-evaluate rational number, by (12). ■

Example 2 *The integral (1) expresses the marginal likelihood of a* 4×4*-table of counts* $U=(U_{ij})$ *with respect to the mixture model* $\mathcal{M}^{(2)}$*. Specifically, the marginal likelihood of the data (2) equals the normalizing constant* $40!\cdot(2!)^{-12}\cdot(4!)^{-4}$ *times the number (3). The model* $\mathcal{M}^{(2)}$ *consists of all non-negative* 4×4*-matrices of rank* ≤ 2 *whose entries sum to one. Here the parametrization (13) is not identifiable because* $\dim(\mathcal{M}^{(2)})=11$ *but* $\dim(\Theta)=13$*. In this example,* $k=2$*,* $s_1{=}s_2{=}1$*,* $t_1{=}t_2{=}3$*,* $d=8$*,* $n=16$*.*

In algebraic geometry, the model $\mathcal{M}^{(2)}$ is known as the first secant variety of the Segre-Veronese variety (9). We could also consider the higher secant varieties $\mathcal{M}^{(l)}$, which correspond to mixtures of l independent distributions, and much of our analysis can be extended to that case, but for simplicity we restrict ourselves to $l=2$. The variety $\mathcal{M}^{(2)}$ is embedded in the projective space $\mathbb{P}^{\tilde{n}-1}$ with $\tilde{n}$ as in (10). Note that $\tilde{n}$ can be much smaller than n. If this is the case, it is convenient to aggregate states whose probabilities are identical and represent the data by a vector $\tilde{U}\in\mathbb{N}^{\tilde{n}}$. Here is an example.

Example 3 *Let* $k{=}1$*,* $s_1{=}4$ *and* $t_1{=}1$*, so* $\mathcal{M}$ *is the independence model for four identically distributed binary random variables. Then* $d=2$ *and* $n=16$*. The corresponding integer matrix and its row and column labels are*

$$A \;=\; \begin{array}{c} \\ \theta_0 \\ \theta_1 \end{array}\!\!\begin{array}{c} \begin{array}{cccccccccc} p_{0000} & p_{0001} & p_{0010} & p_{0100} & p_{1000} & p_{0011} & \cdots & p_{1110} & p_{1111} \end{array} \\ \begin{pmatrix} 4 & 3 & 3 & 3 & 3 & 2 & \cdots & 1 & 0 \\ 0 & 1 & 1 & 1 & 1 & 2 & \cdots & 3 & 4 \end{pmatrix} \end{array}.$$

However, this matrix has only $\tilde{n}=5$ *distinct columns, and we instead use*

$$\tilde{A} \;=\; \begin{array}{c} \\ \theta_0 \\ \theta_1 \end{array}\!\!\begin{array}{c} \begin{array}{ccccc} p_0 & p_1 & p_2 & p_3 & p_4 \end{array} \\ \begin{pmatrix} 4 & 3 & 2 & 1 & 0 \\ 0 & 1 & 2 & 3 & 4 \end{pmatrix} \end{array}.$$

The mixture model $\mathcal{M}^{(2)}$ *is the subset of* Δ_4 *given by the parametrization*

$$p_i \quad = \quad \binom{4}{i}\cdot\big(\sigma_0\cdot\theta_0^{4-i}\cdot\theta_1^i \,+\, \sigma_1\cdot\rho_0^{4-i}\cdot\rho_1^i\big) \qquad \text{for } i=0,1,2,3,4.$$

In algebraic geometry, this threefold is the secant variety of the rational normal curve in $\mathbb{P}^4$*. This is the cubic hypersurface with the implicit equation*

$$\det\begin{bmatrix} 12p_0 & 3p_1 & 2p_2 \\ 3p_1 & 2p_2 & 3p_3 \\ 2p_2 & 3p_3 & 12p_4 \end{bmatrix} \quad = \quad 0.$$

In Hoşten et al. (2005, Example 9), the likelihood function (14) was studied for the data

$$\tilde{U} \quad = \quad (\tilde{U}_0, \tilde{U}_1, \tilde{U}_2, \tilde{U}_3, \tilde{U}_4) \quad = \quad (51, 18, 73, 25, 75).$$

It has three local maxima (modulo swapping θ *and* ρ*) whose coordinates are algebraic numbers of degree* 12*. Using the methods to be described in the next two sections, we computed the exact value of the marginal likelihood for the data* $\tilde{U}$ *with respect to* $\mathcal{M}^{(2)}$*. The rational number (15) is found to be the ratio of two relatively prime integers having* 530 *digits and* 552 *digits, and its numerical value is approximately* $0.77887163388386786113357 42 \cdot 10^{-22}$.

3. Summation over a Zonotope

Our starting point is the observation that the Newton polytope of the likelihood function (14) is a zonotope. Recall that the *Newton polytope* of a polynomial is the convex hull of all exponent vectors appearing in the expansion of that polynomial, and a polytope is a *zonotope* if it is the image of a standard cube under a linear map. See Cox et al. (2005, §7) and Ziegler (1995, §7) for further discussions. We are here considering the zonotope

$$Z_A(U) \;=\; \sum_{v=1}^{n} U_v \cdot [0, a_v],$$

where $[0, a_v]$ represents the line segment between the origin and the point $a_v \in \mathbb{R}^d$, and the sum is a Minkowski sum of line segments. We write $Z_A = Z_A(1, 1, \ldots, 1)$ for the basic zonotope spanned by the vectors a_v. Hence $Z_A(U)$ is obtained by stretching Z_A along those vectors by factors U_v respectively. Assuming that the counts U_v are all positive, we have

$$\dim(Z_A(U)) \;=\; \dim(Z_A) \;=\; \operatorname{rank}(A) \;=\; d-k+1. \tag{16}$$

The zonotope Z_A is related to the polytope $P = \operatorname{conv}(A)$ in (7) as follows. The dimension $d-k = t_1 + \cdots + t_k$ of P is one less than $\dim(Z_A)$, and P appears as the *vertex figure* of the zonotope Z_A at the distinguished vertex 0.

Remark 3 *For higher mixtures* $\mathcal{M}^{(l)}$*, the Newton polytope of the likelihood function is isomorphic to the Minkowski sum of* $(l-1)$*-dimensional simplices in* $\mathbb{R}^{(l-1)d}$*. Only when* $l = 2$*, this Minkowski sum is a zonotope.*

The marginal likelihood (15) we wish to compute is the integral

$$\int_{\Theta} \prod_{v=1}^{n} (\sigma_0 \theta^{a_v} + \sigma_1 \rho^{a_v})^{U_v} d\sigma d\theta d\rho \tag{17}$$

times the constant $N!/(U_1! \cdots U_n!)$. Our approach to this computation is to sum over the lattice points in the zonotope $Z_A(U)$. If the matrix A has repeated columns, we may replace A with the reduced matrix $\tilde{A}$ and U with the corresponding reduced data vector $\tilde{U}$. If one desires the marginal likelihood for the reduced data vector $\tilde{U}$ instead of the original data vector U, the integral remains the same while the normalizing constant becomes

$$\frac{N!}{\tilde{U}_1! \cdots \tilde{U}_{\tilde{n}}!} \cdot \alpha_1^{\tilde{U}_1} \cdots \alpha_{\tilde{n}}^{\tilde{U}_{\tilde{n}}},$$

where α_i is the number of columns in A equal to the i-th column of $\tilde{A}$. In what follows we ignore the normalizing constant and focus on computing the integral (17) with respect to the original matrix A.

For a vector $b \in \mathbb{R}^d_{\geq 0}$ we let $|b|$ denote its L^1-norm $\sum_{t=1}^d b_t$. Recall from (8) that all columns of the $d \times n$-matrix A have the same coordinate sum

$$a \ := \ |a_v| \ = \ s_1 + s_2 + \cdots + s_k, \ \text{ for all } v = 1,2,\ldots,n,$$

and from (11) that we may denote the entries of a vector $b \in \mathbb{R}^d$ by $b_j^{(i)}$ for $i = 1,\ldots,k$ and $j = 0,\ldots,t_k$. Also, let $\mathbb{L}$ denote the image of the linear map $A : \mathbb{Z}^n \to \mathbb{Z}^d$. Thus $\mathbb{L}$ is a sublattice of rank $d-k+1$ in $\mathbb{Z}^d$. We abbreviate $Z_A^{\mathbb{L}}(U) := Z_A(U) \cap \mathbb{L}$. Now, using the binomial theorem, we have

$$(\sigma_0\theta^{a_v} + \sigma_1\rho^{a_v})^{U_v} \ = \ \sum_{x_v=0}^{U_v} \binom{U_v}{x_v} \sigma_0^{x_v}\sigma_1^{U_v-x_v}\theta^{x_v \cdot a_v}\rho^{(U_v-x_v)\cdot a_v}.$$

Therefore, in the expansion of the integrand in (17), the exponents of θ are of the form of $b = \sum_v x_v a_v \in Z_A^{\mathbb{L}}(U)$, $0 \leq x_v \leq U_v$. The other exponents may be expressed in terms of b. This gives us

$$\prod_{v=1}^n (\sigma_0\theta^{a_v} + \sigma_1\rho^{a_v})^{U_v} \ = \sum_{\substack{b \in Z_A^{\mathbb{L}}(U) \\ c = AU-b}} \phi_A(b,U) \cdot \sigma_0^{|b|/a} \cdot \sigma_1^{|c|/a} \cdot \theta^b \cdot \rho^c. \tag{18}$$

Writing $\mathbf{D}(U) = \{(x_1,\ldots,x_n) \in \mathbb{Z}^n : 0 \leq x_v \leq U_v, v = 1,\ldots,n\}$, the coefficient in (18) equals

$$\phi_A(b,U) \ = \sum_{\substack{Ax=b \\ x \in \mathbf{D}(U)}} \prod_{v=1}^n \binom{U_v}{x_v}. \tag{19}$$

Thus, by formulas (12) and (18), the integral (17) evaluates to

$$\sum_{\substack{b \in Z_A^{\mathbb{L}}(U) \\ c = AU-b}} \phi_A(b,U) \cdot \frac{(|b|/a)!\,(|c|/a)!}{(|U|+1)!} \cdot \prod_{i=1}^k \left(\frac{t_i!\, b_0^{(i)}! \cdots b_{t_i}^{(i)}!}{(|b^{(i)}|+t_i)!} \, \frac{t_i!\, c_0^{(i)}! \cdots c_{t_i}^{(i)}!}{(|c^{(i)}|+t_i)!} \right). \tag{20}$$

We summarize the result of this derivation in the following theorem.

Theorem 4 *The marginal likelihood of the data U in the mixture model $\mathcal{M}^{(2)}$ is equal to the sum (20) times the normalizing constant $N!/(U_1!\cdots U_n!)$.*

Each individual summand in the formula (20) is a ratio of factorials and hence can be evaluated symbolically. The challenge in turning Theorem 4 into a practical algorithm lies in the fact that both of the sums (19) and (20) are over very large sets. We shall discuss these challenges and present techniques from both computer science and mathematics for addressing them.

We first turn our attention to the coefficients $\phi_A(b,U)$ of the expansion (18). These quantities are written as an explicit sum in (19). The first useful observation is that these coefficients are also the coefficients of the expansion

$$\prod_v (\theta^{a_v} + 1)^{U_v} \quad = \sum_{b \in Z_A^{\mathbb{L}}(U)} \phi_A(b,U) \cdot \theta^b, \tag{21}$$

which comes from substituting $\sigma_i = 1$ and $\rho_j = 1$ in (18). When the cardinality of $Z_A^{\mathbb{L}}(U)$ is sufficiently small, the quantity $\phi_A(b,U)$ can be computed quickly by expanding (21) using a computer algebra system. We used MAPLE for this and all other symbolic computations in this project.

If the expansion (21) is not feasible, then it is tempting to compute the individual $\phi_A(b,U)$ via the sum-product formula (19). This method requires summation over the set $\{x \in \mathbf{D}(U) : Ax = b\}$, which is the set of lattice points in an $(n-d+k-1)$-dimensional polytope. Even if this loop can be implemented, performing the sum in (19) symbolically requires the evaluation of many large binomials, causing the process to be rather inefficient.

An alternative is offered by the following recurrence formula:

$$\phi_A(b,U) \;=\; \sum_{x_n=0}^{U_n} \binom{U_n}{x_n} \phi_{A\setminus a_n}(b - x_n a_n, U \setminus U_n). \tag{22}$$

This is equivalent to writing the integrand in (17) as

$$\left(\prod_{v=1}^{n-1} (\sigma_0 \theta^{a_v} + \sigma_1 \rho^{a_v})^{U_v} \right) (\sigma_0 \theta^{a_n} + \sigma_1 \rho^{a_n})^{U_n}.$$

More generally, for each $0 < i < n$, we have the recurrence

$$\phi_A(b,U) = \sum_{b' \in Z_{A'}^{\mathbb{L}}(U')} \phi_{A'}(b',U') \cdot \phi_{A\setminus A'}(b-b', U \setminus U'),$$

where A' and U' consist of the first i columns and entries of A and U respectively. This corresponds to the factorization

$$\left(\prod_{v=1}^{i} (\sigma_0 \theta^{a_v} + \sigma_1 \rho^{a_v})^{U_v} \right) \left(\prod_{v=i+1}^{n} (\sigma_0 \theta^{a_v} + \sigma_1 \rho^{a_v})^{U_v} \right).$$

This formula gives flexibility in designing algorithms with different payoffs in time and space complexity, to be discussed in Section 4.

The next result records useful facts about the quantities $\phi_A(b,U)$.

Proposition 5 *Suppose $b \in \mathbb{Z}_A^{\mathbb{L}}(U)$ and $c = AU - b$. Then, the following quantities are all equal to $\phi_A(b,U)$:*
(1) $\#\{z \in \{0,1\}^N : A^U z = b\}$, where A^U is the extended matrix

$$A^U \;:=\; (\underbrace{a_1,\ldots,a_1}_{U_1}, \underbrace{a_2,\ldots,a_2}_{U_2}, \ldots, \underbrace{a_n,\ldots,a_n}_{U_n}),$$

(2) $\phi_A(c,U)$,
(3)

$$\sum_{\substack{Ax=b \\ l_j \le x_j \le u_j}} \prod_{v=1}^{n} \binom{U_v}{x_v},$$

where $u_j = \min\{U_j\} \cup \{b_m/a_{jm}\}_{m=1}^n$ and $l_j = U_j - \min\{U_j\} \cup \{c_m/a_{jm}\}_{m=1}^n$.

Proof (1) This follows directly from (21).
(2) For each $z \in \{0,1\}^N$ satisfying $A^U z = b$, note that $\bar{z} = (1,1,\ldots,1) - z$ satisfies $A^U \bar{z} = c$, and vice versa. The conclusion thus follows from (1).
(3) We require $Ax = b$ and $x \in \mathbf{D}(U)$. If $x_j > u_j = b_m/a_{jm}$ then $a_{jm}x_j > b_m$, which implies $Ax \neq b$. The lower bound is derived by a similar argument. ■

One aspect of our approach is the decision, for any given model A and data set U, whether or not to attempt the expansion (21) using computer algebra. This decision depends on the cardinality of the set $Z_A^{\mathbb{L}}(U)$. In what follows, we compute the number exactly when A is unimodular. When A is not unimodular, we obtain useful lower and upper bounds.

Let S be any subset of the columns of A. We call S *independent* if its elements are linearly independent in $\mathbb{R}^d$. With S we associate the integer

$$\text{index}(S) \;:=\; [\mathbb{R}S \cap \mathbb{L} : \mathbb{Z}S].$$

This is the index of the abelian group generated by S inside the possibly larger abelian group of all lattice points in $\mathbb{L} = \mathbb{Z}A$ that lie in the span of S. The following formula is due to R. Stanley and appears in Stanley (1991, Theorem 2.2):

Proposition 6 *The number of lattice points in the zonotope $Z_A(U)$ equals*

$$\#Z_A^{\mathbb{L}}(U) \;=\; \sum_{S \subseteq A \text{ indep.}} \text{index}(S) \cdot \prod_{a_v \in S} U_v. \tag{23}$$

In fact, the number of monomials in (18) equals $\#M_A(U)$, where $M_A(U)$ is the set $\{b \in Z_A^{\mathbb{L}}(U) : \phi_A(b,U) \neq 0\}$, and this set can be different from $Z_A^{\mathbb{L}}(U)$. For that number we have the following bounds. The proof, which uses the methods in Stanley (1991, §2), will be omitted here.

Theorem 7 *The number $\#M_A(U)$ of monomials in the expansion (18) of the likelihood function to be integrated satisfies the two inequalities*

$$\sum_{S \subseteq A \text{ indep.}} \prod_{v \in S} U_v \;\leq\; \#M_A(U) \;\leq\; \sum_{S \subseteq A \text{ indep.}} \text{index}(S) \cdot \prod_{v \in S} U_v. \tag{24}$$

By definition, the matrix A is *unimodular* if $\text{index}(S) = 1$ for all independent subsets S of the columns of A. In this case, the upper bound coincides with the lower bound, and so $M_A(U) = Z_A^{\mathbb{L}}(U)$. This happens in the classical case of two-dimensional contingency tables ($k = 2$ and $s_1 = s_2 = 1$). In general, $\#Z_A^{\mathbb{L}}(U)/\#M_A(U)$ tends to 1 when all coordinates of U tend to infinity. This is why we believe that for computational purposes, $\#Z_A^{\mathbb{L}}(U)$ is a good approximation of $\#M_A(U)$.

Remark 8 *There exist integer matrices A for which $\#M_A(U)$ does not agree with the upper bound in Theorem 7. However, we conjecture that $\#M_A(U) = \#Z_A^{\mathbb{L}}(U)$ holds for matrices A of Segre-Veronese type as in (8) and strictly positive data vectors U.*

Example 4 *Consider the* 100 Swiss Francs *example in Section 1. Here A is unimodular and it has* 16145 *independent subsets S. The corresponding sum of* 16145 *squarefree monomials in (23) gives the number of terms in the expansion of (4). For the data U in (2) this sum evaluates to* $3,892,097$.

Example 5 *We consider the matrix and data from Example 3.*

$$\begin{aligned} \tilde{A} &= \begin{pmatrix} 0 & 1 & 2 & 3 & 4 \\ 4 & 3 & 2 & 1 & 0 \end{pmatrix} \\ \tilde{U} &= (51, 18, 73, 25, 75) \end{aligned}$$

By Theorem 7, the lower bound is 22,273 and the upper bound is 48,646. Here the number $\#M_{\tilde{A}}(\tilde{U})$ *of monomials agrees with the latter.*

We next present a formula for $\text{index}(S)$ when S is any linearly independent subset of the columns of the matrix A. After relabeling we may assume that $S = \{a_1, \ldots, a_k\}$ consists of the first k columns of A. Let $H = VA$ denote the row Hermite normal form of A. Here $V \in SL_d(\mathbb{Z})$ and H satisfies

$$H_{ij} = 0 \text{ for } i > j \text{ and } 0 \leq H_{ij} < H_{jj} \text{ for } i < j.$$

Hermite normal form is a built-in function in computer algebra systems. For instance, in MAPLE the command is `ihermite`. Using the invertible matrix V, we may replace A with H, so that $\mathbb{R}S$ becomes $\mathbb{R}^k$ and $\mathbb{Z}S$ is the image over $\mathbb{Z}$ of the upper left $k \times k$-submatrix of H. We seek the index of that lattice in the possibly larger lattice $\mathbb{Z}A \cap \mathbb{Z}^k$. To this end we compute the column Hermite normal form $H' = HV'$. Here $V' \in SL_n(\mathbb{Z})$ and H' satisfies

$$H'_{ij} = 0 \text{ if } i > j \text{ or } j > d \text{ and } 0 \leq H_{ij} < H_{ii} \text{ for } i < j.$$

The lattice $\mathbb{Z}A \cap \mathbb{Z}^k$ is spanned by the first k columns of H', and this implies

$$\text{index}(S) \quad = \quad \frac{H_{11} H_{22} \cdots H_{kk}}{H'_{11} H'_{22} \cdots H'_{kk}}.$$

4. Algorithms

In this section we discuss algorithms for computing the integral (17) exactly, and we discuss their advantages and limitations. In particular, we examine four main techniques which represent the formulas (20), (21), (16) and (22) respectively. The practical performance of the various algorithms is compared by computing the integral in Example 3.

A MAPLE library which implements our algorithms is made available at

`http://math.berkeley.edu/~shaowei/integrals.html`.

The input for our MAPLE code consists of parameter vectors $s = (s_1, \ldots, s_k)$ and $t = (t_1, \ldots, t_k)$ as well as a data vector $U \in \mathbb{N}^n$. This input uniquely specifies the $d \times n$-matrix A. Here d and n are as in (5). The output features the matrices A and $\tilde{A}$, the marginal likelihood integrals for $\mathcal{M}$ and $\mathcal{M}^{(2)}$, as well as the bounds in (24).

We tacitly assume that A has been replaced with the reduced matrix $\tilde{A}$. Thus from now on we assume that A has no repeated columns. This requires some care concerning the normalizing constants. All columns of the matrix A have the same coordinate sum a, and the convex hull of the columns is the polytope $P = \Delta_{t_1} \times \Delta_{t_2} \times \cdots \times \Delta_{t_k}$. Our domain of integration is the following polytope of dimension $2d - 2k + 1$:

$$\Theta \;=\; \Delta_1 \times P \times P.$$

We seek to compute the rational number

$$\int_{\Theta} \prod_{v=1}^{n} (\sigma_0 \theta^{a_v} + \sigma_1 \rho^{a_v})^{U_v} d\sigma d\theta d\rho, \tag{25}$$

where integration is with respect to Lebesgue probability measure. Our MAPLE code outputs this integral multiplied with the statistically correct normalizing constant. That constant will be ignored in what follows. In our complexity analysis, we fix A while allowing the data U to vary. The complexities will be given in terms of the sample size $N = U_1 + \cdots + U_n$.

4.1 Ignorance is Costly

Given an integration problem such as (25), a first attempt is to use the symbolic integration capabilities of a computer algebra package such as MAPLE. We refer to this method as *ignorant integration*:

```
U  := [51, 18, 73, 25, 75]:
f  := (s*t^4        +(1-s)*p^4        )^U[1] *
      (s*t^3*(1-t)  +(1-s)*p^3*(1-p)  )^U[2] *
      (s*t^2*(1-t)^2+(1-s)*p^2*(1-p)^2)^U[3] *
      (s*t  *(1-t)^3+(1-s)*p  *(1-p)^3)^U[4] *
      (s    *(1-t)^4+(1-s)    *(1-p)^4)^U[5]:
II := int(int(int(f,p=0..1),t=0..1),s=0..1);
```

In the case of mixture models, recognizing the integral as the sum of integrals of monomials over a polytope allows us to avoid the expensive integration step above by using (20). To demonstrate the power of using (20), we implemented a simple algorithm that computes each $\phi_A(b,U)$ using the naive expansion in (19). We computed the integral in Example 3 with a small data vector $U = (2,2,2,2,2)$, which is the rational number

$$\frac{66364720654753}{5905738398721701533994000},$$

and summarize the run-times and memory usages of the two algorithms in the table below. All experiments reported in this section are done in MAPLE.

	Time(seconds)	Memory(bytes)
Ignorant Integration	16.331	155,947,120
Naive Expansion	0.007	458,668

For the remaining comparisons in this section, we no longer consider the ignorant integration algorithm because it is computationally too expensive.

4.2 Symbolic Expansion of the Integrand

While ignorant use of a computer algebra system is unsuitable for computing our integrals, we can still exploit its powerful polynomial expansion capabilities to find the coefficients of (21). A major advantage is that it is very easy to write code for this method. We compare the performance of this symbolic expansion algorithm against that of the naive expansion algorithm. The table below concerns computing the coefficients $\phi_A(b,U)$ for the original data $U = (51,18,73,25,75)$. The

column "Extract" refers to the time taken to extract the coefficients $\phi_A(b,U)$ from the expansion of the polynomial, while the column "Sum" shows the time taken to evaluate (20) after all the needed values of $\phi_A(b,U)$ had been computed and extracted.

	Time(seconds)				Memory
	$\phi_A(b,U)$	Extract	Sum	Total	(bytes)
Naive Expansion	2764.35	-	31.19	2795.54	10,287,268
Symbolic Expansion	28.73	962.86	29.44	1021.03	66,965,528

4.3 Storage and Evaluation of $\phi_A(b,U)$

Symbolic expansion is fast for computing $\phi_A(b,U)$, but it has two drawbacks: high memory usage and the long time it takes to extract the values of $\phi_A(b,U)$. One solution is to create specialized data structures and algorithms for expanding (21), rather using than those offered by MAPLE.

First, we tackle the problem of storing the coefficients $\phi_A(b,U)$ for $b \in Z_A^{\mathbb{L}}(U) \subset \mathbb{R}^d$ as they are being computed. One naive method is to use a d-dimensional array $\phi[\cdot]$. However, noting that A is not row rank full, we can use a d_0-dimensional array to store $\phi_A(b,U)$, where $d_0 = \text{rank}(A) = d-k+1$. Furthermore, by Proposition 5(2), the expanded integrand is a symmetric polynomial, so only half the coefficients need to be stored. We will leave out the implementation details so as not to complicate our discussions. In our algorithms, we will assume that the coefficients are stored in a d_0-dimensional array $\phi[\cdot]$, and the entry that represents $\phi_A(b,U)$ will be referred to as $\phi[b]$.

Next, we discuss how $\phi_A(b,U)$ can be computed. One could use the naive expansion (19), but this involves evaluating many binomials coefficients and products, so the algorithm is inefficient for data vectors with large coordinates. A more efficient solution uses the recurrence formula (22):

Algorithm 1 (RECURRENCE(A, U))
Input: *The matrix A and the vector* U.
Output: *The coefficients* $\phi_A(b,U)$.
Step 1*: Create a* d_0*-dimensional array* ϕ *of zeros.*
Step 2*: For each* $x \in \{0,1,\ldots,U_1\}$ *set*

$$\phi[xa_1] := \binom{U_1}{x}.$$

Step 3*: Create a new* d_0*-dimensional array* ϕ'.
Step 4*: For each* $2 \le j \le n$ *do*
1. Set all the entries of ϕ' *to* 0.
2. For each $x \in \{0,1,\ldots,U_j\}$ *do*
For each non-zero entry $\phi[b]$ *in* ϕ *do*
Increment $\phi'[b+xa_j]$ *by* $\binom{U_j}{x}\phi[b]$.
3. Replace ϕ *with* ϕ'.
Step 5*: Output the array* ϕ.

The space complexity of this algorithm is $O(N^{d_0})$ and its time complexity is $O(N^{d_0+1})$. By comparison, the naive expansion algorithm has space complexity $O(N^d)$ and time complexity $O(N^{n+1})$.

We now turn our attention to computing the integral (25). One major issue is the lack of memory to store all the terms of the expansion of the integrand. We overcome this problem by writing

the integrand as a product of smaller factors which can be expanded separately. In particular, we partition the columns of A into submatrices $A^{[1]},\ldots,A^{[m]}$ and let $U^{[1]},\ldots,U^{[m]}$ be the corresponding partition of U. Thus the integrand becomes

$$\prod_{j=1}^{m}\prod_{v}(\sigma_0\theta^{a_v^{[j]}}+\sigma_1\rho^{a_v^{[j]}})^{U_v^{[j]}},$$

where $a_v^{[j]}$ is the vth column in $A^{[j]}$. The resulting algorithm for evaluating the integral is as follows:

Algorithm 2 (Fast Integral)
Input: *The matrices $A^{[1]},\ldots,A^{[m]}$, vectors $U^{[1]},\ldots,U^{[m]}$ and the vector t.*
Output: *The value of the integral (25) in exact rational arithmetic.*
Step 1*: For $1\le j\le m$, compute $\phi^{[j]}:=\mathrm{RECURRENCE}(A^{[j]},U^{[j]})$.*
Step 2*: Set $I:=0$.*
Step 3*: For each non-zero entry $\phi^{[1]}[b^{[1]}]$ in $\phi^{[1]}$ do*

$$\vdots$$

For each non-zero entry $\phi^{[m]}[b^{[m]}]$ in $\phi^{[m]}$ do
Set $b:=b^{[1]}+\cdots+b^{[m]}$, $c:=AU-b$, $\phi:=\prod_{j=1}^{m}\phi^{[j]}[b^{[j]}]$.
Increment I by

$$\phi\cdot\frac{(|b|/a)!(|c|/a)!}{(|U|+1)!}\cdot\prod_{i=1}^{k}\frac{t_i!b_0^{(i)}!\cdots b_{t_i}^{(i)}!}{(|b^{(i)}|+t_i)!}\,\frac{t_i!c_0^{(i)}!\cdots c_{t_i}^{(i)}!}{(|c^{(i)}|+t_i)!}.$$

Step 4*: Output the sum I.*

The algorithm can be sped up by precomputing the factorials used in the product in Step 3. The space and time complexity of this algorithm is $O(N^S)$ and $O(N^T)$ respectively, where $S=\max_i \mathrm{rank}\,A^{[i]}$ and $T=\sum_i \mathrm{rank}A^{[i]}$. From this, we see that the splitting of the integrand should be chosen wisely to achieve a good pay-off between the two complexities.

In the table below, we compare the naive expansion algorithm and the fast integral algorithm for the data $U=(51,18,73,25,75)$. We also compare the effect of splitting the integrand into two factors, as denoted by $m=1$ and $m=2$. For $m=1$, the fast integral algorithm takes significantly less time than naive expansion, and requires only about 1.5 times more memory.

	Time(minutes)	Memory(bytes)
Naive Expansion	43.67	9,173,360
Fast Integral (m=1)	1.76	13,497,944
Fast Integral (m=2)	139.47	6,355,828

4.4 Limitations and Applications

While our algorithms are optimized for exact evaluation of integrals for mixtures of independence models, they may not be practical for applications involving large sample sizes. To demonstrate their limitations, we vary the sample sizes in Example 3 and compare the computation times. The data vectors U are generated by scaling $U=(51,18,73,25,75)$ according to the sample size N and rounding off the entries. Here, N is varied from 110 to 300 by increments of 10. Figure 1 shows a logarithmic plot of the results. The times taken for $N=110$ and $N=300$ are 3.3 and 98.2 seconds

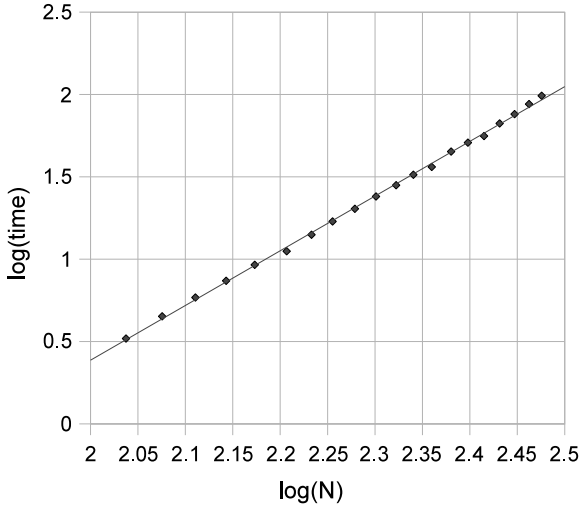

Figure 1: Comparison of computation time against sample size.

respectively. Computation times for larger samples may be extrapolated from the graph. Indeed, a sample size of 5000 could take more than 13 days.

For other models, such as the 100 *Swiss Francs* example in Section 1 and that of the schizophrenic patients in Example 9, the limitations are even more apparent. In the table below, for each example we list the sample size, computation time, rank of the corresponding A-matrix and the number of terms in the expansion of the integrand. Despite having smaller sample sizes, the computations for the latter two examples take a lot more time. This may be attributed to the higher ranks of the A-matrices and the larger number of terms that need to be summed up in our algorithm.

	Size	Time	Rank	#Terms
Coin Toss	242	45 sec	2	48,646
100 Swiss Francs	40	15 hrs	7	3,892,097
Schizophrenic Patients	132	16 days	5	34,177,836

Despite their high complexities, we believe our algorithms are important because they provide a gold standard with which approximation methods such as those studied in Chickering and Heckerman (1997) can be compared. Below, we use our exact methods to ascertain the accuracy of asymptotic formula derived in Watanabe (2001) and Watanabe and Yamazaki (2003, 2004) using desingularization methods from algebraic geometry.

Example 6 *Consider the model from Example 3. Choose data vectors* $U = (U_0, U_1, U_2, U_3, U_4)$ *with* $U_i = Nq_i$ *where* N *is a multiple of* 16 *and*

$$q_i = \frac{1}{16}\binom{4}{i}, \quad i = 0, 1, \ldots, 4.$$

Let $I_N(U)$ *be the integral (25). Define*

$$F_N(U) = N \sum_{i=0}^{4} q_i \log q_i - \log I_N(U).$$

According to Watanabe and Yamazaki (2004), for large N we have the asymptotics

$$\mathrm{E}_U[F_N(U)] \;=\; \frac{3}{4}\log N + O(1) \tag{26}$$

where the expectation E_U is taken over all U with sample size N under the distribution defined by $q = (q_0, q_1, q_2, q_3, q_4)$. Thus, we should expect

$$F_{16+N} - F_N \;\approx\; \frac{3}{4}\log(16+N) - \frac{3}{4}\log N =: g(N).$$

We compute $F_{16+N} - F_N$ using our exact methods and list the results below.

N	$F_{16+N} - F_N$	$g(N)$
16	*0.21027043*	*0.225772497*
32	*0.12553837*	*0.132068444*
48	*0.08977938*	*0.093704053*
64	*0.06993586*	*0.072682510*
80	*0.05729553*	*0.059385934*
96	*0.04853292*	*0.050210092*
112	*0.04209916*	*0.043493960*

Clearly, the table supports our conclusion. The coefficient $3/4$ of $\log N$ in the formula (26) is known as the real log-canonical threshold *of the statistical model. The example suggests that our method could be developed into a numerical technique for computing the real log-canonical threshold.*

5. Back to Bayesian Statistics

In this section we discuss how the exact integration approach presented here interfaces with issues in Bayesian statistics. The first concerns the rather restrictive assumption that our marginal likelihood integral be evaluated with respect to the uniform distribution (Lesbegue measure) on the parameter space Θ. It is standard practice to compute such integrals with respect to *Dirichlet priors*, and we shall now explain how our algorithms can be extended to Dirichlet priors. That extension is also available as a feature in our MAPLE implementation.

Recall that the *Dirichlet distribution* $\mathrm{Dir}(\alpha)$ is a continuous probability distribution parametrized by a vector $\alpha = (\alpha_0, \alpha_1, \ldots, \alpha_m)$ of positive reals. It is the multivariate generalization of the beta distribution and is conjugate prior (in the Bayesian sense) to the multinomial distribution. This means that the probability distribution function of $\mathrm{Dir}(\alpha)$ specifies the belief that the probability of the ith among $m+1$ events equals θ_i given that it has been observed $\alpha_i - 1$ times. More precisely, the probability density function $f(\theta;\alpha)$ of $\mathrm{Dir}(\alpha)$ is supported on the m-dimensional simplex

$$\Delta_m \;=\; \bigl\{(\theta_0,\ldots,\theta_m) \in \mathbb{R}^m_{\geq 0} \,:\, \theta_0 + \cdots + \theta_m = 1\bigr\},$$

and it equals

$$f(\theta_0,\ldots,\theta_m;\alpha_0,\ldots,\alpha_m) \quad = \quad \frac{1}{\mathbb{B}(\alpha)} \cdot \theta_0^{\alpha_0-1}\theta_1^{\alpha_1-1}\cdots\theta_m^{\alpha_m-1} \;=:\; \frac{\theta^{\alpha-1}}{\mathbb{B}(\alpha)}.$$

Here the normalizing constant is the multinomial beta function

$$\mathbb{B}(\alpha) \quad = \quad \frac{m!\Gamma(\alpha_0)\Gamma(\alpha_1)\cdots\Gamma(\alpha_m)}{\Gamma(\alpha_0+\alpha_1+\cdots+\alpha_m)}.$$

Note that, if the α_i are all integers, then this is the rational number

$$\mathbb{B}(\alpha) \;=\; \frac{m!(\alpha_0-1)!(\alpha_1-1)!\cdots(\alpha_m-1)!}{(\alpha_0+\cdots+\alpha_m-1)!}.$$

Thus the identity (12) is the special case of the identity $\int_{\Delta_m} f(\theta;\alpha)d\theta = 1$ for the density of the Dirichlet distribution when all $\alpha_i = b_i+1$ are integers.

We now return to the marginal likelihood for mixtures of independence models. To compute this quantity with respect to Dirichlet priors means the following. We fix positive real numbers α_0,α_1, and $\beta_j^{(i)}$ and $\gamma_j^{(i)}$ for $i=1,\ldots,k$ and $j=0,\ldots,t_i$. These specify Dirichlet distributions on Δ_1, P and P. Namely, the Dirichlet distribution on P given by the $\beta_j^{(i)}$ is the product probability measure given by taking the Dirichlet distribution with parameters $(\beta_0^{(i)},\beta_1^{(i)},\ldots,\beta_{t_i}^{(i)})$ on the i-th factor Δ_{t_i} in the product (7) and similarly for the $\gamma_j^{(i)}$. The resulting product probability distribution on $\Theta = \Delta_1\times P\times P$ is called the *Dirichlet distribution* with parameters (α,β,γ). Its probability density function is the product of the respective densities:

$$f(\sigma,\theta,\rho;\alpha,\beta,\gamma) \;=\; \frac{\sigma^{\alpha-1}}{\mathbb{B}(\alpha)}\cdot\prod_{i=1}^{k}\frac{(\theta^{(i)})^{\beta^{(i)}-1}}{\mathbb{B}(\beta^{(i)})}\cdot\prod_{i=1}^{k}\frac{(\rho^{(i)})^{\gamma^{(i)}-1}}{\mathbb{B}(\gamma^{(i)})}. \tag{27}$$

By the marginal likelihood with Dirichlet priors we mean the integral

$$\int_\Theta \mathbf{L}_U(\sigma,\theta,\rho)\, f(\sigma,\theta,\rho;\alpha,\beta,\gamma)d\sigma d\theta d\rho. \tag{28}$$

This is a modification of (15) and it depends not just on the data U and the model $\mathcal{M}^{(2)}$ but also on the choice of Dirichlet parameters (α,β,γ). When the coordinates of these parameters are arbitrary positive reals but not integers, then the value of the integral (28) is no longer a rational number. Nonetheless, it can be computed exactly as follows. We abbreviate the product of gamma functions in the denominator of the density (27) as follows:

$$\mathbb{B}(\alpha,\beta,\gamma) \;:=\; \mathbb{B}(\alpha)\cdot\prod_{i=1}^{k}\mathbb{B}(\beta^{(i)})\cdot\prod_{i=1}^{k}\mathbb{B}(\gamma^{(i)}).$$

Instead of the integrand (18) we now need to integrate

$$\sum_{\substack{b\in Z_A^{\mathbb{L}}(U)\\ c=AU-b}} \frac{\phi_A(b,U)}{\mathbb{B}(\alpha,\beta,\gamma)}\cdot\sigma_0^{|b|/a+\alpha_0-1}\cdot\sigma_1^{|c|/a+\alpha_1-1}\cdot\theta^{b+\beta-1}\cdot\rho^{c+\gamma-1}$$

with respect to Lebesgue probability measure on Θ. Doing this term by term, as before, we obtain the following modification of Theorem 4.

Corollary 9 *The marginal likelihood of the data U in the mixture model $\mathcal{M}^{(2)}$ with respect to Dirichlet priors with parameters (α,β,γ) equals*

$$\frac{N!}{U_1!\cdots U_n!\cdot\mathbb{B}(\alpha,\beta,\gamma)}\cdot\sum_{\substack{b\in Z_A^{\mathbb{L}}(U)\\ c=AU-b}}\phi_A(b,U)\,\frac{\Gamma(|b|/a+\alpha_0)\Gamma(|c|/a+\alpha_1)}{\Gamma(|U|+|\alpha|)}$$
$$\cdot\prod_{i=1}^{k}\Big(\frac{t_i!\Gamma(b_0^{(i)}+\beta_0^{(i)})\cdots\Gamma(b_{t_i}^{(i)}+\beta_{t_i}^{(i)})}{\Gamma(|b^{(i)}|+|\beta^{(i)}|)}\;\frac{t_i!\Gamma(c_0^{(i)}+\gamma_0^{(i)})\cdots\Gamma(c_{t_i}^{(i)}+\gamma_{t_i}^{(i)})}{\Gamma(|c^{(i)}|+|\gamma^{(i)}|)}\Big).$$

A well-known experimental study (Chickering and Heckerman, 1997) compares different methods for computing numerical approximations of marginal likelihood integrals. The model considered in the study is the *naive-Bayes model*, which, in the language of algebraic geometry, corresponds to arbitrary secant varieties of Segre varieties. In this paper we considered the first secant variety of arbitrary Segre-Veronese varieties. In what follows we restrict our discussion to the intersection of both classes of models, namely, to the first secant variety of Segre varieties. For the remainder of this section we fix

$$s_1 = s_2 = \cdots = s_k = 1$$

but we allow $t_1, t_2, \ldots, t_k$ to be arbitrary positive integers. Thus in the model of Chickering and Heckerman (1997, Equation 1), we fix $r_C = 2$, and the n there corresponds to our k.

To keep things as simple as possible, we shall fix the uniform distribution as in Sections 1–4 above. Thus, in the notation of Chickering and Heckerman (1997, §2), all Dirichlet hyperparameters α_{ijk} are set to 1. This implies that, for any data $U \in \mathbb{N}^n$ and any of our models, the problem of finding the maximum a posteriori (MAP) configuration is equivalent to finding the maximum likelihood (ML) configuration. To be precise, the *MAP configuration* is the point $(\hat{\sigma}, \hat{\theta}, \hat{\rho})$ in Θ which maximizes the likelihood function $\mathbf{L}_U(\sigma, \theta, \rho)$ in (14). This maximum may not be unique, and there will typically be many local maxima. Chickering and Heckerman (1997, §3.2) used the expectation maximization (EM) algorithm (Pachter and Sturmfels, 2005, §1.3) to approximate the MAP configuration numerically

The Laplace approximation and the BIC score (Chickering and Heckerman, 1997, §3.1) are predicated on the idea that the MAP configuration can be found with high accuracy and that the data U were actually drawn from the corresponding distribution $p(\hat{\sigma}, \hat{\theta}, \hat{\rho})$. Let $\mathbf{H}(\sigma, \theta, \rho)$ denote the Hessian matrix of the log-likelihood function $\log \mathbf{L}(\sigma, \theta, \rho)$. Then the Laplace approximation (Chickering and Heckerman, 1997, Equation 15) states that the logarithm of the marginal likelihood can be approximated by

$$\log \mathbf{L}(\hat{\sigma}, \hat{\theta}, \hat{\rho}) - \frac{1}{2} \log |\det \mathbf{H}(\hat{\sigma}, \hat{\theta}, \hat{\rho})| + \frac{2d - 2k + 1}{2} \log(2\pi). \tag{29}$$

The Bayesian information criterion (BIC) suggests the coarser approximation

$$\log \mathbf{L}(\hat{\sigma}, \hat{\theta}, \hat{\rho}) \; - \; \frac{2d - 2k + 1}{2} \log(N), \tag{30}$$

where $N = U_1 + \cdots + U_n$ is the sample size.

In algebraic statistics, we do not content ourselves with the output of the EM algorithm but, to the extent possible, we seek to actually solve the likelihood equations (Hoşten et al., 2005) and compute all local maxima of the likelihood function. We consider it a difficult problem to reliably find $(\hat{\sigma}, \hat{\theta}, \hat{\rho})$, and we are concerned about the accuracy of any approximation like (29) or (30).

Example 7 *Consider the* 100 Swiss Francs *table (2) discussed in the Introduction. Here* $k = 2$, $s_1 = s_2 = 1$, $t_1 = t_2 = 3$, *the matrix A is unimodular, and (9) is the Segre embedding* $\mathbb{P}^3 \times \mathbb{P}^3 \hookrightarrow \mathbb{P}^{15}$. *The parameter space* Θ *is* 13*-dimensional, but the model* $\mathcal{M}^{(2)}$ *is* 11*-dimensional, so the given parametrization is not identifiable (Feinberg et al., 2007). This means that the Hessian matrix* $\mathbf{H}$ *is singular, and hence the Laplace approximation (29) is not defined.*

Example 8 *We compute (29) and (30) for the model and data in Example 3. According to Hoşten et al. (2005, Example 9), the likelihood function* $p_0^{51}p_1^{18}p_2^{73}p_3^{25}p_4^{75}$ *has three local maxima* $(\hat{p}_0,\hat{p}_1,\hat{p}_2,\hat{p}_3,\hat{p}_4)$ *in the model* $\mathcal{M}^{(2)}$*, and these translate into six local maxima* $(\hat{\sigma},\hat{\theta},\hat{\rho})$ *in the parameter space* Θ*, which is the 3-cube. The two global maxima are*

$$(0.3367691969, 0.0287713237, 0.6536073424),$$
$$(0.6632308031, 0.6536073424, 0.0287713237).$$

Both of these points in Θ *give the same point in the model:*

$$(\hat{p}_0,\hat{p}_1,\hat{p}_2,\hat{p}_3,\hat{p}_4) \;=\; (0.12104, 0.25662, 0.20556, 0.10758, 0.30920).$$

The likelihood function evaluates to $0.1395471101 \times 10^{-18}$ *at this point. The following table compares the various approximations. Here, "Actual" refers to the base-10 logarithm of the marginal likelihood in Example 3.*

BIC	*-22.43100220*
Laplace	*-22.39666281*
Actual	*-22.10853411*

The method for computing the marginal likelihood which was found to be most accurate in the experimental study is the *candidate method* (Chickering and Heckerman, 1997, §3.4). This is a Monte-Carlo method which involves running a Gibbs sampler. The basic idea is that one wishes to compute a large sum, such as (20) by sampling among the terms rather than listing all terms. In the candidate method one uses not the sum (20) over the lattice points in the zonotope but the more naive sum over all 2^N hidden data that would result in the observed data represented by U. The value of the sum is the number of terms, 2^N, times the average of the summands, each of which is easy to compute. A comparison of the results of the candidate method with our exact computations, as well as a more accurate version of Gibbs sampling which is adapted for (20), will be the subject of a future study.

One of the applications of marginal likelihood integrals lies in model selection. An important concept in that field is that of *Bayes factors*. Given data and two competing models, the Bayes factor is the ratio of the marginal likelihood integral of the first model over the marginal likelihood integral of the second model. In our context it makes sense to form that ratio for the independence model $\mathcal{M}$ and its mixture $\mathcal{M}^{(2)}$. To be precise, given any independence model, specified by positive integers $s_1,\ldots,s_k,t_1,\ldots,t_k$ and a corresponding data vector $U \in \mathbb{N}^n$, the Bayes factor is the ratio of the marginal likelihood in Lemma 1 and the marginal likelihood in Theorem 4. Both quantities are rational numbers and hence so is their ratio.

Corollary 10 *The Bayes factor which discriminates between the independence model* $\mathcal{M}$ *and the mixture model* $\mathcal{M}^{(2)}$ *is a rational number. It can be computed exactly using Algorithm 2 (and our* MAPLE*-implementation).*

Example 9 *We conclude by applying our method to a data set taken from the Bayesian statistics literature. Evans, Gilula, and Guttman (1989, §3) analyzed the association between length of hospital stay (in years Y) of* 132 *schizophrenic patients and the frequency with which they are visited*

by relatives. Their data set is the following 3×3 *contingency table:*

			$2\le Y<10$	$10\le Y<20$	$20\le Y$	*Totals*
		Visited regularly	43	16	3	*62*
U	$=$	*Visited rarely*	6	11	10	*27*
		Visited never	9	18	16	*43*
		Totals	*58*	*45*	*29*	**132**

They present estimated posterior means and variances for these data, where "each estimate requires a 9-dimensional integration" *(Evans et al., 1989, p. 561). Computing their integrals is essentially equivalent to ours, for* $k=2, s_1=s_2=1, t_1=t_2=2$ *and* $N=132$. *The authors emphasize that* "the dimensionality of the integral does present a problem" *(Evans et al., 1989, p. 562), and they point out that* "all posterior moments can be calculated in closed form .... however, even for modest N these expressions are far to complicated to be useful" *(Evans et al., 1989, p. 559).*

We differ on that conclusion. In our view, the closed form expressions in Section 3 are quite useful for modest sample size N. *Using Algorithm 2, we computed the integral (25). It is the rational number with numerator*

$$\begin{aligned}&27801948853106338912064360032498932910387614080 5\\ &28524283958209256935726588667532284587409752803 3\\ &99493069713103633199906939405711180837568853737\end{aligned}$$

and denominator

$$\begin{aligned}&12288402873591935400678094796599848745442833177572204\\ &50448819979286456995185542195946815073112429169997801\\ &33503900169921912167352239204153786645029153951176422\\ &43298328046163472261962028461650432024356339706541132\\ &34375318471880274818667657423749120000000000000000.\end{aligned}$$

To obtain the marginal likelihood for the data U *above, that rational number (of moderate size) still needs to be multiplied with the normalizing constant*

$$\frac{132!}{43!\cdot 16!\cdot 3!\cdot 6!\cdot 11!\cdot 10!\cdot 9!\cdot 18!\cdot 16!}.$$

Abstract

The reinforcement learning paradigm is a popular way to address problems that have only limited environmental feedback, rather than correctly labeled examples, as is common in other machine learning contexts. While significant progress has been made to improve learning in a single task, the idea of *transfer learning* has only recently been applied to reinforcement learning tasks. The core idea of transfer is that experience gained in learning to perform one task can help improve learning performance in a related, but different, task. In this article we present a framework that classifies transfer learning methods in terms of their capabilities and goals, and then use it to survey the existing literature, as well as to suggest future directions for transfer learning work.

Keywords: transfer learning, reinforcement learning, multi-task learning

1. Transfer Learning Objectives

In *reinforcement learning* (RL) (Sutton and Barto, 1998) problems, leaning agents take sequential actions with the goal of maximizing a reward signal, which may be time-delayed. For example, an agent could learn to play a game by being told whether it wins or loses, but is never given the "correct" action at any given point in time. The RL framework has gained popularity as learning methods have been developed that are capable of handling increasingly complex problems. However, when RL agents begin learning *tabula rasa*, mastering difficult tasks is often slow or infeasible, and thus a significant amount of current RL research focuses on improving the speed of learning by exploiting domain expertise with varying amounts of human-provided knowledge. Common approaches include deconstructing the task into a hierarchy of subtasks (cf., Dietterich, 2000); learning with higher-level, temporally abstract, actions (e.g., *options*, Sutton et al. 1999) rather than simple one-step actions; and efficiently abstracting over the state space (e.g., via function approximation) so that the agent may generalize its experience more efficiently.

The insight behind *transfer learning* (TL) is that generalization may occur not only within tasks, but also *across tasks*. This insight is not new; transfer has long been studied in the psychological literature (cf., Thorndike and Woodworth, 1901; Skinner, 1953). More relevant are a number of

∗. The first author wrote the majority of this article while a graduate student at the University of Texas at Austin.

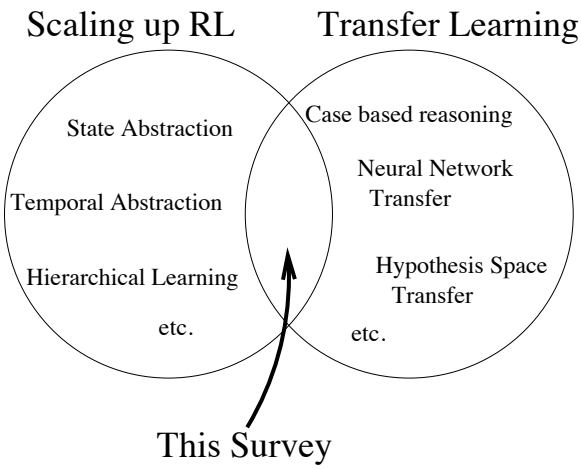

Figure 1: This article focuses on transfer between reinforcement learning tasks.

approaches that transfer between machine learning tasks (Caruana, 1995; Thrun, 1996), for planning tasks (Fern et al., 2004; Ilghami et al., 2005), and in the context of cognitive architectures (Laird et al., 1986; Choi et al., 2007). However, TL for RL tasks has only recently been gaining attention in the artificial intelligence community. Others have written surveys for reinforcement learning (Kaelbling et al., 1996), and for transfer across machine learning tasks (Thrun and Pratt, 1998), which we will not attempt to duplicate; this article instead focuses on transfer *between RL tasks* (see Figure 1) to provide an overview of a new, growing area of research.

Transfer learning in RL is an important topic to address at this time for three reasons. First, in recent years RL techniques have achieved notable successes in difficult tasks which other machine learning techniques are either unable or ill-equipped to address (e.g., TDGammon Tesauro 1994, job shop scheduling Zhang and Dietterich 1995, elevator control Crites and Barto 1996, helicopter control Ng et al. 2004, marble maze control Bentivegna et al. 2004, Robot Soccer Keepaway Stone et al. 2005, and quadruped locomotion Saggar et al. 2007 and Kolter et al. 2008). Second, classical machine learning techniques such as rule induction and classification are sufficiently mature that they may now easily be leveraged to assist with TL. Third, promising initial results show that not only are such transfer methods possible, but they can be very effective at speeding up learning. The 2005 DARPA Transfer Learning program (DARPA, 2005) helped increase interest in transfer learning. There have also been some recent workshops providing exposure for RL techniques that use transfer. The 2005 NIPS workshop, "Inductive Transfer: 10 Years Later," (Silver et al., 2005) had few RL-related transfer papers, the 2006 ICML workshop, "Structural Knowledge Transfer for Machine Learning," (Banerjee et al., 2006) had many, and the 2008 AAAI workshop, "Transfer Learning for Complex Tasks," (Taylor et al., 2008a) focused on RL.

1.1 Paper Overview

The goals of this survey are to introduce the reader to the transfer learning problem in RL domains, to organize and discuss current transfer methods, and to enumerate important open questions in RL transfer. In transfer, knowledge from one or more *source task(s)* is used to learn one or more *target task(s)* faster than if transfer was not used. The literature surveyed is structured primarily by grouping methods according to how they allow source and target tasks to differ. We further

distinguish methods according to five different dimensions (see Section 2.2). Some of the questions that distinguish transfer methods include:

- What are the goals of the transfer method? By what metric(s) will success be measured? Section 2 examines commonly used metrics, as well as different settings where transfer learning can improve learning.
- What assumptions, if any, are made regarding the similarity between the tasks? Section 3.2.1 enumerates common differences, such as changes to the space in which agents operate, allowing the agents to have different goals, or letting agents have different sets of actions.
- How does a transfer method identify what information can/should be transferable? Section 3.2.2 enumerates possibilities ranging from assuming *all* previously seen tasks are directly useful to autonomously learning which source task(s) are useful for learning in the current target task.
- What information is transferred between tasks? Section 3.2.3 discusses possibilities ranging from very low-level information (such as direct control knowledge) to high-level information (such as rules regarding how a particular domain functions).

The following section presents a discussion about how to best evaluate transfer in RL. There are many different situations in which transfer can be useful and these different situations may entail different metrics. This discussion will prepare the reader to better understand how transfer may be used. Section 3.1 will briefly discuss reinforcement learning and the notation used in the article. Section 3.2 enumerates the ways in which transfer methods can differ, providing a skeleton for the structure of this survey. Sections 3.3 and 3.4 provide additional high-level categorization of TL methods and Section 3.5 discusses related learning paradigms which are explicitly not discussed in this survey.

The bulk of the remainder of the article (Sections 4–8) discuss contemporary TL methods, arranged by the goals of, and methods employed by, the designers. Lastly, Section 9 discusses current open questions in transfer and concludes.

2. Evaluating Transfer Learning Methods

Transfer techniques assume varying degrees of autonomy and make many different assumptions. To be fully autonomous, an RL transfer agent would have to perform all of the following steps:

1. Given a target task, select an appropriate source task or set of tasks from which to transfer.
2. Learn how the source task(s) and target task are related.
3. Effectively transfer knowledge from the source task(s) to the target task.

While the mechanisms used for these steps will necessarily be interdependent, TL research has focused on each independently, and no TL methods are currently capable of robustly accomplishing all three goals.

A key challenge in TL research is to define evaluation metrics, precisely because there are many possible measurement options and algorithms may focus on any of the three steps above. This section focuses on how to best evaluate TL algorithms so that the reader may better understand the

different goals of transfer and the situations where transfer may be beneficial.[1] For instance, it is not always clear how to treat learning in the source task: whether to charge it to the TL algorithm or to consider it as a "sunk cost." On the one hand, a possible goal of transfer is to reduce the overall time required to learn a complex task. In this scenario, a *total time scenario*, which explicitly includes the time needed to learn the source task or tasks, would be most appropriate. On the other hand, a second reasonable goal of transfer is to effectively reuse past knowledge in a novel task. In this case, a *target task time scenario*, which only accounts for the time spent learning in the target task, is reasonable.

The total time scenario may be more appropriate when an agent is explicitly guided by a human. Suppose that a user wants an agent to learn to perform a task, but recognizes that the agent may be able to learn a sequence of tasks faster than if it directly tackled the difficult task. The human can construct a series of tasks for the agent, suggesting to the agent how the tasks are related. Thus the agent's TL method will easily accomplish steps 1 and 2 above, but it must efficiently transfer knowledge between tasks (step 3). To successfully transfer in this setting, the agent would have to learn the entire sequence of tasks faster than if it had spent its time learning the final target task directly (see the total time scenario in Figure 2).

The target task time scenario is more appropriate for a fully autonomous learner. A fully autonomous agent must be able to perform steps 1–3 on its own. However, metrics for this scenario do not need to take into account the cost of learning source tasks. The target task time scenario emphasizes the agent's ability to use knowledge from one or more previously learned source tasks without being charged for the time spent learning them (see the target task time scenario in Figure 2). In this survey we will see that the majority of existing transfer algorithms assume a human-guided scenario, but disregard time spent training in the source task. When discussing individual TL methods, we will specifically call attention to the methods that do account for the total training time and do not treat the time spent learning a source task as a sunk cost.

Many metrics to measure the benefits of transfer are possible (shown in Figure 3, replicated from our past transfer learning work, Taylor and Stone 2007b):

1. *Jumpstart*: The initial performance of an agent in a target task may be improved by transfer from a source task.

2. *Asymptotic Performance*: The final learned performance of an agent in the target task may be improved via transfer.

3. *Total Reward*: The total reward accumulated by an agent (i.e., the area under the learning curve) may be improved if it uses transfer, compared to learning without transfer.

4. *Transfer Ratio*: The ratio of the total reward accumulated by the transfer learner and the total reward accumulated by the non-transfer learner.

5. *Time to Threshold*: The learning time needed by the agent to achieve a pre-specified performance level may be reduced via knowledge transfer.

Metrics 1–4 are most appropriate in the fully autonomous scenario as they do not charge the agent for time spent learning any source tasks. To measure the total time, the metric must account for time

1. Evaluation is particularly important because there are very few theoretical results supporting TL for RL methods, as discussed further in Section 9.3. Instead, practitioners rely on empirical methods to evaluate the efficacy of their methods.

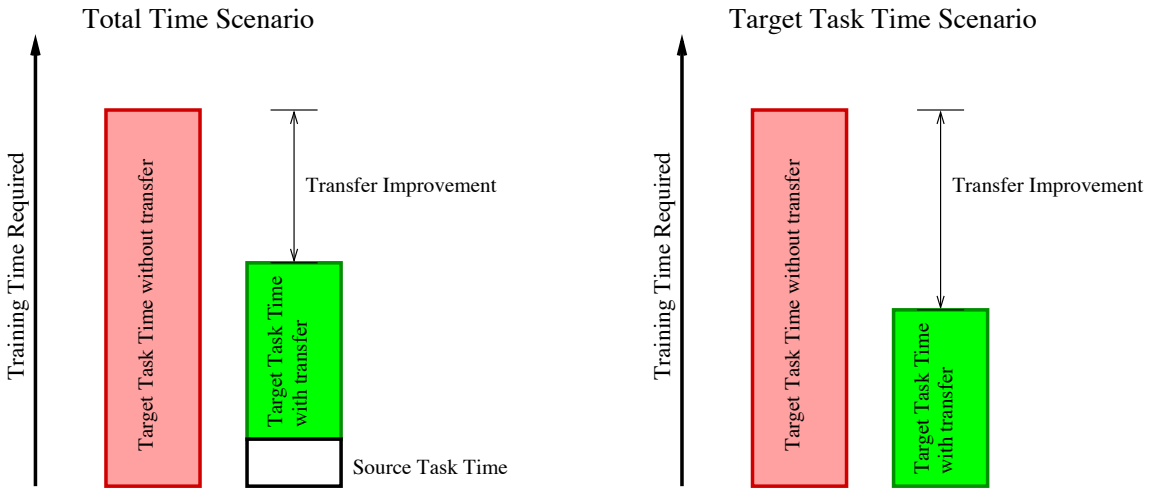

Figure 2: Successful TL methods may be able to reduce the total training time (left). In some scenarios, it is more appropriate to treat the source task time as a sunk cost and test whether the method can effectively reuse past knowledge to reduce the target task time (right).

spent learning one or more source tasks, which is natural when using metric 5. Other metrics have been proposed in the literature, but we choose to focus on these five because they are sufficient to describe the methods surveyed in this article.

For this article, we may think of learning time as a surrogate for *sample complexity*. Sample complexity (or data complexity) in RL refers to the amount of data required by an algorithm to learn. It is strongly correlated with learning time because RL agents only gain data by collecting it through repeated interactions with an environment.

2.1 Empirical Transfer Comparisons

The previous section enumerated five possible TL metrics, and while others are possible, these represent the methods most commonly used. However, each metric has drawbacks and none are sufficient to fully describe the benefits of any transfer method. Rather than attempting to create a total order ranking of different methods, which may indeed by impossible, we instead suggest that a multi-dimensional evaluation with multiple metrics is most useful. Specifically, some methods may "win" on a set of metrics relative to other methods, but "lose" on a different set. As the field better understands why different methods achieve different levels of success on different metrics, it should become easier to map TL methods appropriately to TL problems. Although the machine learning community has defined standard metrics (such as precision vs. recall curves for classification and mean squared error for regression), RL has no such standard. Empirically comparing two RL algorithms is a current topic of debate within the community, although there is some process towards standardizing comparisons (Whiteson et al., 2008). Theoretical comparisons are also not clear-cut, as samples to convergence, asymptotic performance, and the computational complexity are all valid axes along which to evaluate RL algorithms.

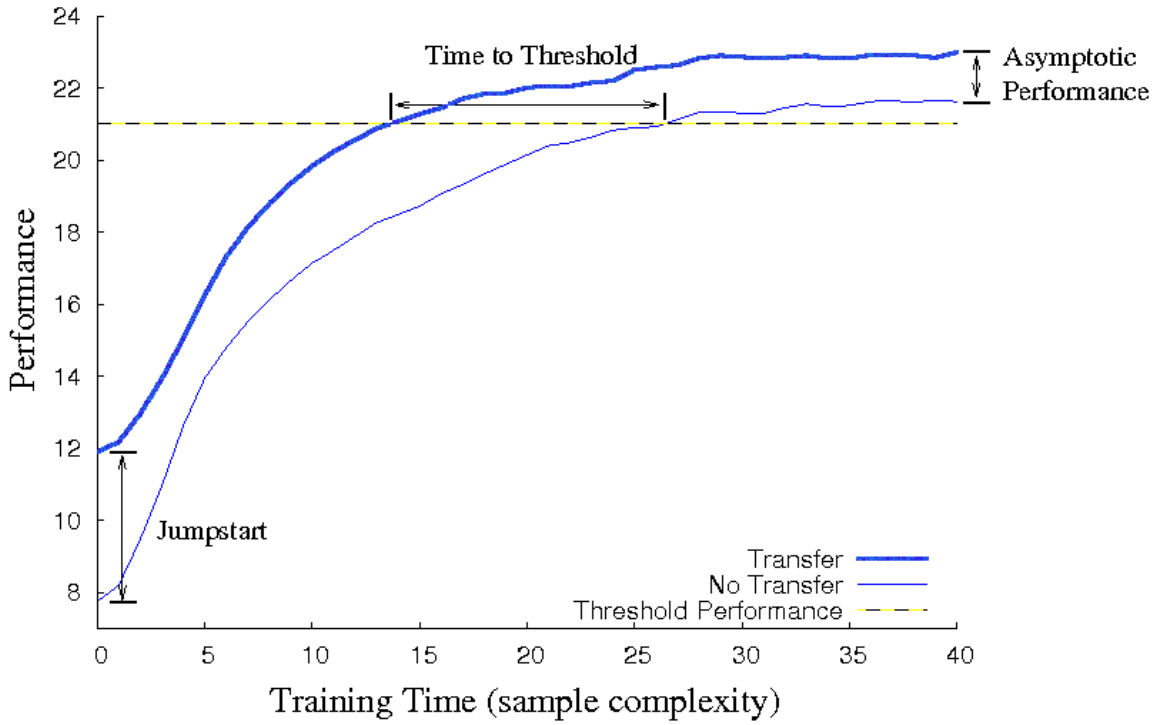

Figure 3: Many different metrics for measuring TL are possible. This graph show benefits to the jumpstart, asymptotic performance, time to threshold, and total reward (the area under the learning curve).

The first proposed transfer measure considers the agent's initial performance in a target task and answers the question, "can transfer be used so that the initial performance is increased relative to the performance of an initial (random) policy?" While such an initial jumpstart is appealing, such a metric fails to capture the behavior of *learning* in the target task and instead only focuses on the performance before learning occurs.

Asymptotic performance, the second proposed metric, compares the final performance of learners in the target task both with and without transfer. However, it may be difficult to tell when the learner has indeed converged (particularly in tasks with infinite state spaces) or convergence may take prohibitively long. In many settings the number of samples required to learn is most critical, not the performance of a learner with an infinite number of samples. Further, it is possible for different learning algorithms to converge to the same asymptotic performance but require very different numbers of samples to reach the same performance.

A third possible measure is that of the total reward accumulated during training. Improving initial performance and achieving a faster learning rate will help agents accumulate more on-line reward. RL methods are often not guaranteed to converge with function approximation and even when they do, learners may converge to different, sub-optimal performance levels. If enough samples are provided to agents (or, equivalently, learners are provided sufficient training time), a learning method which achieves a high performance relatively quickly will have less total reward than a learning method which learns very slowly but eventually plateaus at a slightly higher performance level. This metric is most appropriate for tasks that have a well-defined duration.

A fourth measure of transfer efficacy is that of the ratio of areas defined by two learning curves. Consider two learning curves in the target task where one uses transfer and one does not. Assuming that the transfer learner accrues more reward, the area under the transfer leaning curve will be greater than the area under the non-transfer learning curve. The ratio

$$r = \frac{\textit{area under curve with transfer - area under curve without transfer}}{\textit{area under curve without transfer}}$$

gives a metric that quantifies improvement from TL. This metric is most appropriate if the same final performance is achieved, or there is a predetermined time for the task. Otherwise the ratio will directly depend on how long the agents act in the target task.

While such a metric may be appealing as a candidate for inter-task comparisons, we note that the transfer ratio is not scale invariant. For instance, if the area under the transfer curve were 1000 units and the area under the non-transfer curve were 500, the transfer ratio would be 1.0. If all rewards were multiplied by a constant, this ratio would not change. But if an offset were added (e.g., each agent is given an extra +1 at the end of each episode, regardless of the final state), the ratio would change. The evaluation of a TL algorithm with the transfer ratio is therefore closely related to the reward structure of the target task being tested. Lastly, we note that although none of the papers surveyed in this article use such a metric, we hope that it will be used more often in the future.

The final metric, Time to Threshold, suffers from having to specify a (potentially arbitrary) performance agents must achieve. While there have been some suggestions how to pick such thresholds appropriately (Taylor et al., 2007a), the relative benefit of TL methods will clearly depend on the exact threshold chosen, which will necessarily be domain- and learning method-dependent. While choosing a range of thresholds to compare over may produce more representative measures (cf., Taylor et al., 2007b), this leads to having to generating a time vs. threshold curve rather than producing a single real valued number that evaluates a transfer algorithm's efficacy.

A further level of analysis that could be combined with any of the above methods would be to calculate a ratio comparing the performance of a TL algorithm with that of a human learner. For instance, a set of human subjects could learn a given target task with and without having first trained on a source task. By averaging over their performances, different human transfer metrics could be calculated and compared to that of a TL algorithm. However, there are many ways to manipulate such a meta-metric. For instance, if a target task is chosen that humans are relatively proficient at, transfer will provide them very little benefit. If that same target task is difficult for a machine learning algorithm, it will be relatively easy to show that the TL algorithm is quite effective relative to human transfer, even if the agent's absolute performance is extremely poor.

A major drawback of all the metrics discussed is that none are appropriate for inter-domain comparisons. The vast majority of papers in this survey compare learning with and without transfer—their authors often do not attempt to directly compare different transfer methods. Developing fair metrics that apply across multiple problem domains would facilitate better comparisons of methods. Such inter-domain metrics may be infeasible in practice, in which case standardizing on a set of test domains would assist in comparing different TL methods (as discussed further in Section 9). In the absence of either a set of inter-domain metrics or a standard benchmark suite of domains, we limit our comparisons of different TL methods in this survey to their applicability, assumptions, and algorithmic differences. When discussing different methods, we may opine on the method's relative

performance, but we remind the reader that such commentary is largely based on intuition rather than empirical data.

2.2 Dimensions of Comparison

In addition to differing on evaluation metrics, we categorize TL algorithms along five dimensions, which we use as the main organizing framework for our survey of the literature:

I *Task difference assumptions*: What assumptions does the TL method make about how the source and target are allowed to differ? Examples of things that can differ between the source and target tasks include different system dynamics (i.e., the target task becomes harder to solve is some incremental way), or different sets of possible actions at some states. Such assumptions define the types of source and target tasks that the method can transfer between. Allowing transfer to occur between less similar source and target tasks gives more flexibility to a human designer in the human-guided scenario. In the fully autonomous scenario, more flexible methods are more likely to be able to successfully apply past knowledge to novel target tasks.

II *Source task selection*: In the simplest case, the agent assumes that a human has performed source task selection (the human-guided scenario), and transfers from one or more selected tasks. More complex methods allow the agent to select a source task or set of source tasks. Such a selection mechanism may additionally be designed to guard against *negative transfer*, where transfer hurts the learner's performance. The more robust the selection mechanism, the more likely it is that transfer will be able to provide a benefit. While no definitive answer to this problem exists, successful techniques will likely have to account for specific target task characteristics. For instance, Carroll and Seppi (2005) motivate the need for general task similarity metrics to enable robust transfer, propose three different metrics, and then proceed to demonstrate that none is always "best," just as there is never a "best" inductive bias in a learning algorithm.

III *Task Mappings*: Many methods require a mapping to transfer effectively: in addition to knowing that a source task and target task are related, they need to know *how* they are related. *Inter-task mappings* (discussed in detail later in Section 3.4) are a way to define how two tasks are related. If a human is in the loop, the method may assume that such task mappings are provided; if the agent is expected to transfer autonomously, such mappings have to be learned. Different methods use a variety of techniques to enable transfer, both on-line (while learning the target task) and offline (after learning the source task but before learning the target task). Such learning methods attempt to minimize the number of samples needed and/or the computational complexity of the learning method, while still learning a mapping to enable effective transfer.

IV *Transferred Knowledge*: What type of information is transferred between the source and target tasks? This information can range from very low-level information about a specific task (i.e., the expected outcome when performing an action in a particular location) to general heuristics that attempt to guide learning. Different types of knowledge may transfer better or worse depending on task similarity. For instance, low-level information may transfer across closely related tasks, while high-level concepts may transfer across pairs of less similar tasks. The mechanism that transfers knowledge from one task to another is closely related to what

is being transferred, how the task mappings are defined (III), and what assumptions about the two tasks are made (I).

V *Allowed Learners*: Does the TL method place restrictions on what RL algorithm is used, such as applying only to temporal difference methods? Different learning algorithms have different biases. Ideally an experimenter or agent would select the RL algorithm to use based on characteristics of the task, not on the TL algorithm. Some TL methods require that the source and target tasks be learned with the same method, other allow a class of methods to be used in both tasks, but the most flexible methods decouple the agents' learning algorithms in the two tasks.

An alternate TL framework may be found in the related work section of Lazaric (2008), a recent PhD thesis on TL in RL tasks. Lazaric compares TL methods in terms of the type of benefit (jumpstart, total reward, and asymptotic performance), the allowed differences between source and target (different goal states, different transition functions but the same reward function, and different state and action spaces) and the type of transferred knowledge (experience or structural knowledge). Our article is more detailed both in the number of approaches considered, the depth of description about each approach, and also uses a different organizational structure. In particular, we specify which of the methods improve which of five TL metrics, we note which of the methods account for source task training time rather than treating it as a sunk cost, and we differentiate methods according to five dimensions above.

3. Transfer for Reinforcement Learning

In this section we first give a brief overview of notation. We then summarize the methods discussed in this survey using the five dimensions previously discussed, as well as enumerating the possible attributes for these dimensions. Lastly, learning paradigms with goals similar to transfer are discussed in Section 3.5.

3.1 Reinforcement Learning Background

RL problems are typically framed in terms of *Markov decision processes* (MDPs) (Puterman, 1994). For the purposes of this article, *MDP* and *task* are used interchangeably. In an MDP, there is some set of possible perceptions of the current *state* of the world, $s \in S$, and a learning agent has one or more initial starting states, $s_{initial}$. The *reward function*, $R : S \mapsto \mathbb{R}$, maps each state of the environment to a single number which is the instantaneous reward achieved for reaching the state. If the task is *episodic*, the agent begins at a start state and executes actions in the environment until it reaches a terminal state (one or more of the states in s_{final}, which may be referred to as a *goal state*), at which point the agent is returned to a start state. An agent in an episodic task typically attempts to maximize the average reward per episode. In non-episodic tasks, the agent attempts to maximize the total reward, which may be discounted. By using a discount factor, γ, the agent can weigh immediate rewards more heavily than future rewards, allowing it to maximize a non-infinite sum of rewards.

An agent knows its current state in the environment, $s \in S$.[2] TL methods are particularly relevant in MDPs that have a large or continuous state, as these are the problems which are slow to learn *tabula rasa* and for which transfer may provide substantial benefits. Such tasks typically factor the state using *state variables* (or *features*), so that $s = \langle x_1, x_2, \ldots, x_n \rangle$ (see Figure 4). The agent's observed state may be different from the true state if there is perceptual noise. The set A describes the *actions* available to the agent, although not every action may be possible in every state.[3] The *transition function*, $T : S \times A \mapsto S$, takes a state and an action and returns the state of the environment after the action is performed. Transitions may be non-deterministic, making the transition function a probability distribution function. A learner senses the current state, s, and typically knows A and what state variables comprise S; however, it is generally not given R or T.

A *policy*, $\pi : S \mapsto A$, fully defines how a learner interacts with the environment by mapping perceived environmental states to actions. The success of an agent is determined by how well it maximizes the total reward it receives in the long run while acting under some policy π. An *optimal policy*, π^*, is a policy which does maximize the expectation of this value. Any reasonable learning algorithm attempts to modify π over time so that the agent's performance approaches that of π^* in the limit.

There are many possible approaches to learning such a policy (depicted as a black box in Figure 4), including:

- *Temporal difference* (TD) methods, such as *Q-learning* (Sutton, 1988; Watkins, 1989) and *Sarsa* (Rummery and Niranjan, 1994; Singh and Sutton, 1996), learn by backing up experienced rewards through time. An estimated *action-value function*, $Q : S \times A \mapsto \mathbb{R}$ is learned, where $Q(s,a)$ is the expected return found when executing action a from state s, and greedily following the current policy thereafter. The current best policy is generated from Q by simply selecting the action that has the highest value for the current state. *Exploration*, when the agent chooses an action to learn more about the environment, must be balanced with *exploitation*, when the agent selects what it believes to be the best action. One simple approach that balances the two is ε-greedy action selection: the agent selects an random action with chance ε, and the current best action is selected with probability $1 - \varepsilon$ (where ε is in [0,1]).

- *Policy search* methods, such as policy iteration (dynamic programming), policy gradient (Williams, 1992; Baxter and Bartlett, 2001), and direct policy search (Ng and Jordan, 2000), are in some sense simpler than TD methods because they directly modify a policy over time to increase the expected long-term reward by using search or other optimization techniques.

- *Dynamic programming* (Bellman, 1957) approaches assume that a full model of the environment is known (i.e., S, A, T, and R are provided to the agent and are correct). No interaction with the environment is necessary, but the agent must iteratively compute approximations for the true value or action-value function, improving them over time.

- *Model-based* or *Model-learning* methods (Moore and Atkeson, 1993; Kearns and Singh, 1998) attempt to estimate the true model of the environment (i.e., T and R) by interacting

2. If the agent only receives *observations* and does not know the true state, the agent may treat approximate its true state as the observation (cf., Stone et al., 2005), or it may learn using the Partially Observable Markov Decision Process (POMDP) (cf., Kaelbling et al., 1998) problem formulation, which is beyond the scope of this survey.
3. Although possible in principle, we are aware of no TL methods currently address MDPs with continuous actions.

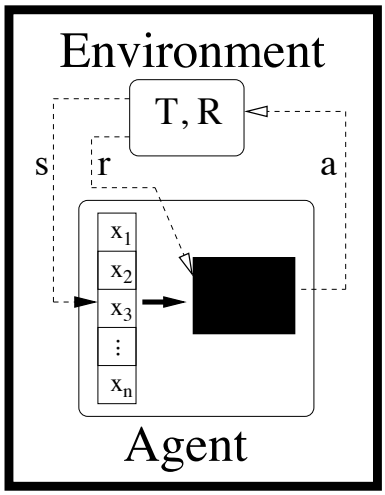

Figure 4: An agent interacts with an environment by sequentially selecting an action in an observed state, with the objective of maximizing an environmental reward signal.

with the environment over time. *Instance based methods* (Ormoneit and Sen, 2002) save observed interactions with the environment and leverage the instance directly to predict the model. *Bayesian RL* (Dearden et al., 1999) approaches use a mathematical model to explicitly represent uncertainty in the components of the model, updating expectations over time. The learned model is then typically used to help the agent decide how to efficiently explore or plan trajectories so that it can accrue higher rewards. While very successful in small tasks, few such methods handle continuous state spaces (cf., Jong and Stone, 2007), and they generally have trouble scaling to tasks with many state variables due to the "curse of dimensionality."

- *Relational reinforcement learning* (RRL) (Dzeroski et al., 2001) uses a different learning algorithm as well as a different state representation. RRL may be appropriate if the state of an MDP can be described in a relational or first-order language. Such methods work by reasoning over individual objects (e.g., a single block in a Blocksworld task) and thus may be robust to changes in numbers of objects in a task.

- *Batch* learning methods (e.g., *Least Squares Policy Iteration* (Lagoudakis and Parr, 2003) and Fitted-Q Iteration (Ernst et al., 2005) are offline and do not attempt to learn as the agent interacts with the environment. Batch methods are designed to be more sample efficient, as they can store a number of interactions with the environment and use the data multiple times for learning. Additionally, such methods allow a clear separation of the learning mechanism from the exploration mechanism (which much decide whether to attempt to gather more data about the environment or exploit the current best policy).

In tasks with small, discrete state spaces, Q and π can be fully represented in a table. As the state space grows, using a table becomes impractical, or impossible if the state space is continuous. In such cases, RL learning methods use *function approximators*, such as artificial neural networks, which rely on concise, parameterized functions and use supervised learning methods to set these parameters. Function approximation is used in large or continuous tasks to better generalize experience. Parameters and biases in the approximator are used to abstract the state space so that observed

data can influence a region of state space, rather than just a single state, and can substantially increase the speed of learning.

Some work in RL (Dean and Givan, 1997; Li et al., 2006; Mahadevan and Maggioni, 2007) has experimented with more systematic approaches to state abstractions (also called structural abstraction). Temporal abstractions have also been successfully used to increase the speed of learning. These macro-actions or *options* (Sutton et al., 1999) may allow the agent to leverage the sequence of actions to learn its task with less data. Lastly, hierarchical methods, such as MAXQ (Dietterich, 2000), allow learners exploit a task that is decomposed into different sub-tasks. The decomposition typically enables an agent to learn each subtask relatively quickly and then combine them, resulting in an overall learning speed improvement (compared to methods that do not leverage such a sub-task hierarchy).

3.2 Transfer Approaches

Having provided a brief overview of the RL notation used in this survey, we now enumerate possible approaches for transfer between RL tasks. This section lists attributes of methods used in the TL literature for each of the five dimensions discussed in Section 2.2, and summarizes the surveyed works in Table 1. The first two groups of methods apply to tasks which have the same state variables and actions. (Section 4 discusses the TL methods in the first block, and Section 5 discusses the multi-task methods in the second block.) Groups three and four consider methods that transfer between tasks with different state variables and actions. (Section 6 discusses methods that use a representation that does not change when the underlying MDP changes, while Section 7 presents methods that must explicitly account for such changes.) The last group of methods (discussed in Section 8) learns a mapping between tasks like those used by methods in the fourth group of methods. Table 2 concisely enumerates the possible values for the attributes, as well as providing a key to Table 1.

In this section the *mountain car* task (Moore, 1991; Singh and Sutton, 1996), a standard RL benchmark, will serve as a running example. In mountain car, an under-powered car moves along a curve and attempts to reach a goal state at the top of the right "mountain" by selecting between three actions on every timestep: {`Forward`, `Neutral`, `Backward`}, where `Forward` accelerates the car in the positive x direction and `Backward` accelerates the car in the negative x direction. The agent's state is described by two state variables: the horizontal position, x, and velocity, $\dot{x}$. The agent receives a reward of -1 on each time step. If the agent reaches the goal state the episode ends and the agent is reset to the start state (often the bottom of the hill, with zero velocity).

3.2.1 ALLOWED TASK DIFFERENCES

TL methods can transfer between MDPs that have different transition functions (denoted by t in Table 1), state spaces (s), start states (s_i), goal states (s_f), state variables (v), reward functions (r), and/or action sets (a). For two of the methods, the agent's representation of the world (the *agent-space*, describing physical sensors and actuators) remains the same, while the true state variables and actions (the *problem-space*, describing the task's state variables and macro-actions) can change (p in Table 1, discussed further in Section 6). There is also a branch of work that focuses on transfer between tasks which are composed of some number of objects that may change between the source and the target task, such as when learning with RRL (# in Table 1). When summarizing the allowed task differences, we will concentrate on the most salient features. For instance, when the source task

and target task are allowed to have different state variables and actions, the state space of the two tasks is different because the states are described differently, and the transition function and reward function must also change, but we only indicate "a" and "v."

These differences in the example mountain car task could be exhibited as:

- t: using a more powerful car motor or changing the surface friction of the hill
- s: changing the range of the state variables
- s_i: changing where the car starts each episode
- s_f: changing the goal state of the car
- v: describing the agent's state only by its velocity
- r: rather than a reward of -1 on every step, the reward could be a function of the distance from the goal state
- a: disabling the `Neutral` action
- p: the agent could describe the state by using extra state variables, such as the velocity on the previous timestep, but the agent only directly measures its current position and velocity
- #: the agent may need to control two cars simultaneously on the hill

3.2.2 SOURCE TASK SELECTION

The simplest method for selecting a source task for a given target task is to assume that only a single source task has been learned and that a human has picked it, assuring that the agent should use it for transfer (h in Table 1). Some TL algorithms allow the agent to learn multiple source tasks and then use them all for transfer (all). More sophisticated algorithms build a library of seen tasks and use only the most relevant for transfer (lib). Some methods are able to automatically modify a single source task so that the knowledge it gains from the modified task will likely be more useful in the target task (mod). However, none of the existing TL algorithms for RL can guarantee that the source tasks will be useful; a current open question is how to robustly avoid attempting to transfer from an irrelevant task.

3.2.3 TRANSFERRED KNOWLEDGE

The type of knowledge transferred can be primarily characterized by its specificity. Low-level knowledge, such as $\langle$ s, a, r, s$'$ $\rangle$ instances (I in Table 1), an action-value function (Q), a policy (π), a full task model (model), or prior distributions (pri), could all be directly leveraged by the TL algorithm to initialize a learner in the target task. Higher level knowledge, such as what action to use in some situations (A: a subset of the full set of actions), partial policies or options (π_p), rules or advice (rule), important features for learning (fea), proto-value functions (pvf: a type of learned feature), shaping rewards (R), or subtask definitions (sub) may not be directly used by the algorithm to fully define an initial policy, but such information may help guide the agent during learning in the target task.

3.2.4 TASK MAPPINGS

The majority of TL algorithms in this survey assume that no explicit task mappings are necessary because the source and target task have the same state variables and actions. In addition to having the same labels, the state variables and actions need to have the same semantic meanings in both tasks. For instance, consider again the mountain car domain. Suppose that the source task had the actions $A = \{$`Forward, Neutral, Backward`$\}$. If the target task had the actions $A = \{$`Right, Neutral, Left`$\}$, a TL method would need some kind of mapping because the actions had different labels. Furthermore, suppose that the target task had the same actions as the source ($A = \{$`Forward, Neutral, Backward`$\}$) but the car was facing the opposite direction, so that `Forward` accelerated the car in the negative `x` direction and `Backward` accelerated the car in the positive `x` direction. If the source and target task actions have different semantic meanings, there will also need to be some kind of inter-task mapping to enable transfer.

Methods that do not use a task mapping are marked as "N/A" in Table 1. TL methods which aim to transfer between tasks with different state variables or actions typically rely on a task mapping to define how the tasks are related (as defined in Section 3.4). Methods that use mappings and assume that they are human-supplied mappings are marked as "sup" in Table 1. A few algorithms leverage experience gained in the source task and target task (exp) or a high-level description of the MDPs in order to learn task mappings.

Methods using description-level knowledge differ primarily in what assumptions they make about what will be provided. One method assumes a qualitative understanding of the transition function (T), which would correspond to knowledge like "taking the action Neutral tends to have a positive influence on the velocity in the positive x direction." Two methods assume knowledge of one mapping (M_a: the "action mapping") to learn a second mapping (the "state variable mapping" in Section 3.4). Three methods assume that the state variables are "grouped" together to describe objects (sv_g). An example of the state variable grouping can be demonstrated in a mountain car task with multiple cars: if the agent knew which position state variables referred to the same car as certain velocity state variables, it would know something about the grouping of state variables. These different assumptions are discussed in detail in Section 8.

3.2.5 ALLOWED LEARNERS

The type of knowledge transferred directly affects the type of learner that is applicable (as discussed in Section 3.1). For instance, a TL method that transfers an action-value function would likely require that the target task agent use a temporal difference method to exploit the transferred knowledge. The majority of methods in the literature use a standard form of temporal difference learning (TD in Table 1), such as Sarsa. Other methods include Bayesian learning (B), hierarchical approaches (H), model-based learning (MB), direct policy search (PS), and relational reinforcement learning (RRL). Some TL methods focus on batch learning (Batch), rather than on-line learning. Two methods use *case based reasoning* (CBR) (Aamodt and Plaza, 1994) to help match previously learned instances with new instances, and one uses linear programming (LP) to calculate a value function from a given model (as part of a dynamic programming routine).

3.3 Multi-Task Learning

Closely related to TL algorithms, and discussed in Section 5, are *multi-task learning* (MTL) algorithms. The primary distinction between MTL and TL is that multi-task learning methods assume

Table 1: This table lists all the TL methods discussed in this survey and classifies each in terms of the five transfer dimensions (the key for abbreviations is in Table 2). Two entries, marked with a $\star$, are repeated due to multiple contributions. Metrics that account for source task learning time, rather than ignoring it, are marked with a †.

Allowed Task Differences	
a	action set may differ
p	problem-space may differ (agent-space must be identical)
r	reward function may differ
s_i	the start state may change
s_f	goal state may move
t	transition function may differ
v	state variables may differ
#	number of objects in state may differ

Source Task Selection	
all	all previously seen tasks are used
h	one source task is used (human selected)
lib	tasks are organized into a library and one or more may be used
mod	a human provides a source task that the agent automatically modifies

Task Mappings	
exp	agent learns the mappings from experience
M_a	the method must be provided with an action mapping (learns state variable mapping)
N/A	no mapping is used
sup	a human supplies the task mappings
sv_g	method is provided groupings of state variables
T	higher-level knowledge is provided about transfer functions to learn mapping

Transferred Knowledge	
A	an action set
fea	task features
I	experience instances
model	task model
π	policies
π_p	partial policies (e.g., options)
pri	distribution priors
pvf	proto-value function
Q	action-value function
R	shaping reward
rule	rules or advice
sub	subtask definitions

Allowed Learners	
B	Bayesian learner
Batch	batch learner
CBR	case based reasoning
H	hierarchical value-function learner
LP	linear programming
MB	model based learner
PS	policy search learner
RRL	relational reinforcement learning
TD	temporal difference learner

TL Metrics	
ap	asymptotic performance increased
j	jumpstart demonstrated
tr	total reward increased
tt	task learning time reduced

Table 2: This key provides a reference to the abbreviations in Table 1.

all problems experienced by the agent are drawn from the same distribution, while TL methods may allow for arbitrary source and target tasks. For example, a MTL task could be to learn a series of mountain car tasks, each of which had a transition function that was drawn from a fixed distribution of functions that specified a range of surface frictions. Because of this assumption, MTL methods generally do not need task mappings (dimension III in Section 2.2). MTL algorithms may be used to transfer knowledge between learners, similar to TL algorithms, or they can attempt to learn how to act on the entire class of problems.

When discussing supervised multitask learning (cf., Caruana, 1995, 1997), data from multiple tasks can be considered simultaneously. In an RL setting, rather than trying to learn multiple problems simultaneously (i.e., acting in multiple MDPs), agents tackle a sequence of tasks which are more closely related than in TL settings. It is possible that RL agents could learn multiple tasks simultaneously in a multiagent setting (Stone and Veloso, 2000), but this has not yet been explored in the literature. For the purposes of this survey, we will assume, as in other transfer settings, that tasks are learned in a sequential order.

Sutton et al. (2007) motivate this approach to transfer by suggesting that a single large task may be most appropriately tackled as a sequential series of subtasks. If the learner can track which subtask it is currently in, it may be able to transfer knowledge between the different subtasks, which are all presumably related because they are part of the same overall task. Such a setting may provide a well-grounded way of selecting a distribution of tasks to train over, either in the context of transfer or for multi-task learning. Note also that the additional assumptions in an MTL setting may be leveraged to allow a more rigorous theoretical analysis than in TL (cf., Kalmár and Szepesvári, 1999).

3.4 Inter-Task Mappings

Transfer methods that assume the source and target tasks use the same state variables and actions, as is the case in MTL, typically do not need an explicit mapping between task. In order to enable TL methods to transfer between tasks that do have such differences, the agent must know how the tasks are related. This section provides a brief overview of *inter-task mappings* (Taylor et al., 2007a), one formulation of task mappings. Task mappings like these are used by transfer methods discussed in Section 7.

To transfer effectively, when an agent is presented with a target task that has a set of actions (A'), it must know how those actions are related to the action set in the source task (A). (For the sake of exposition we focus on actions, but an analogous argument holds for state variables.) If the TL method knows that the two action sets are identical, no action mapping is necessary. However, if this is not the case, the agent needs to be told, or learn, how the two tasks are related. For instance, if the agent learns to act in a source task with the actions `Forward` and `Backward`, but the target task uses the actions `Right` and `Left`, the correspondence between these action sets may not be obvious. Even if the action labels were the same, if the actions had different semantic meanings, the default correspondence may be incorrect. Furthermore, if the cardinality of A and A' are not equal, there are actions without exact equivalences.

One option is to define an *action mapping* (χ_A) such that actions in the two tasks are mapped so that their effects are "similar," where similarity depends on the transfer and reward functions in the two MDPs.[4] Figure 5 depicts an action mapping as well as a *state-variable mapping* (χ_X) between two tasks. A second option is to define a *partial mapping* (Taylor et al., 2007b), such that any novel actions in the target task are ignored. Consider adding an action in a mountain car target task, `pull hand brake`, which did not have an analog in the source task. The partial mapping could map `Forward` to `Forward`, and `Backward` to `Backward`, but not map `pull hand brake` to any source task action. Because inter-task mappings are not functions, they are typically assumed to be easily invertible (i.e., mapping source task actions into target task actions, rather than target task actions to source task actions).

It is possible that mappings between states, rather than between state variables, could be used for transfer, although no work has currently explored this formulation.[5] Another possible extension is to link the mappings rather than making them independent. For instance, the action mapping could depend on the state that the agent is in, or the state variable mapping could depend on the action

4. An inter-task mapping often maps multiple entities in the target task to single entities in the source task because the target task is more complex than the source, but the mappings may be one-to-many, one-to-one, or many-to-many.
5. However, there are many possibilities for using this approach for transfer learning, such as through bisimulation (see Section 9).

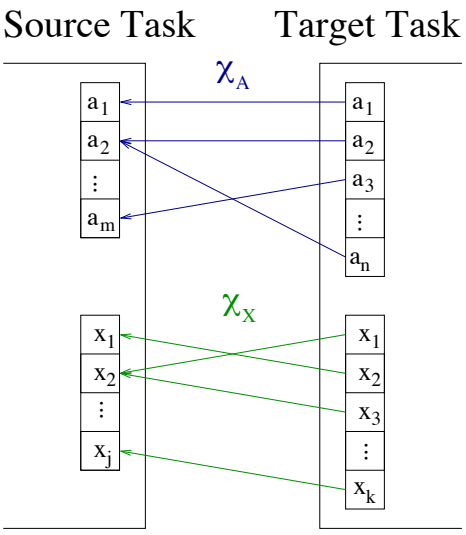

Figure 5: χ_A and χ_X are independent mappings that describe similarities between two MDPs. These mappings describe how actions in the target task are similar to actions in the source task and how state variables in the target task are similar to state variables in the source task, respectively.

selected. Though these extensions may be necessary based on the demands of particular MDPs, current methods have functioned well in a variety of tasks without such enhancements.

For a given pair of tasks, there could be many ways to formulate inter-task mappings. Much of the current TL work assumes that a human has provided a (correct) mapping to the learner. Work that attempts to learn a mapping that can be effectively used for transfer is discussed in Section 8.

3.5 Related Paradigms

In this survey, we consider transfer learning algorithms that use one or more source tasks to better learn in a different, but related, target task. There is a wide range of methods designed to improve the learning speed of RL methods. This section discusses four alternate classes of techniques for speeding up learning and differentiates them from transfer. While some TL algorithms may reasonably fit into one or more of the following categories, we believe that enumerating the types of methods *not* surveyed in this article will help clarify our subject of interest.

3.5.1 LIFELONG LEARNING

Thrun (1996) suggested the notion of lifelong learning where an agent may experience a sequence of tasks. Others (cf., Sutton et al., 2007) later extended this idea to the RL setting, suggesting than an agent interacting with the world for an extended period of time will necessarily have to perform in a sequence of tasks. Alternately, the agent may discover a series of spatially, rather than temporally, separated sub-tasks. Transfer would be a key component of any such system, but the lifelong learning framework is more demanding than that of transfer. First, transfer algorithms may reasonably focus on transfer between a single pair of related tasks, rather than attempting to account for any future task that an agent could encounter. Second, transfer algorithms are typically

told when a new task has begun, whereas in lifelong learning, agents may be reasonably expected to automatically identify new sub-tasks within the global MDP (i.e., the real world).

3.5.2 IMITATION LEARNING

The primary motivations for imitation methods are to allow agents to learn by watching another agent with similar abilities (Price and Boutilier, 2003; Syed and Schapier, 2007) or a human (Abbeel and Ng, 2005; Kolter et al., 2008) perform a task. Such algorithms attempt to learn a policy by observing an outside actor, potentially improving upon the inferred policy. In contrast, our definition of transfer learning focuses on agents successfully reusing internal knowledge on novel problems.

3.5.3 HUMAN ADVICE

There is a growing body of work integrating human advice into RL learners. For instance, a human may provide action suggestions to the agent (cf., Maclin and Shavlik, 1996; Maclin et al., 2005) or guide the agent through on-line feedback (cf., Knox and Stone, 2008). Leveraging humans' background and task-specific knowledge can significantly improve agents' learning ability, but it relies on a human being tightly integrated into the learning loop, providing feedback in an on-line manner. This survey instead concentrates on transfer methods in which a human is not continuously available and agents must learn autonomously.

3.5.4 SHAPING

Reward shaping (Colombetti and Dorigo, 1993; Mataric, 1994) in an RL context typically refers to allowing agent to train on an artificial reward signal rather than R. For instance, in the mountain car task, the agent could be given a higher reward as it gets closer to the goal state, rather then receiving -1 at every state except the goal. However, if the human can compute such a reward, s/he would probably already know the goal location, knowledge that the agent typically does not have. Additionally, the constructed reward function must be a potential function. If it is not, the optimal policy for the new MDP could be different from that of the original (Ng et al., 1999). A second definition of shaping follows Skinner's research (Skinner, 1953) where the reward function is modified over time in order to direct the behavior of the learner. This method, as well as the approach of using a static artificial reward, are ways of injecting human knowledge into the task definition to improve learning efficacy.

Erez and Smart (2008) have argued for a third definition of shaping as any supervised, iterative, process to assist learning. This includes modifying the dynamics of the task over time, modifying the internal learning parameters over time, increasing the actions available to the agent, and extending the agent's policy time horizon (e.g., as done in value iteration). All of these methods rely on a human to intelligently assist the agent in its learning task and may leverage transfer-like methods to successfully reuse knowledge between slightly different tasks. When discussing transfer, we will emphasize how knowledge is successfully reused rather than how a human may modify tasks to achieve the desired agent behavior improve agent learning performance.

3.5.5 REPRESENTATION TRANSFER

Transfer learning problems are typically framed as leveraging knowledge learned on a source task to improve learning on a related, but different, target task. Taylor and Stone (2007a) examine the

complimentary task of transferring knowledge between agents with different internal *representations* (i.e., the function approximator or learning algorithm) of the *same* task. Allowing for such shifts in representation gives additional flexibility to an agent designer; past experience may be transferred rather than discarded if a new representation is desired. A more important benefit is that changing representations partway through learning can allow agents to achieve better performance in less time. Selecting a representation is often key for solving a problem (cf., the *mutilated checkerboard problem* McCarthy 1964 where humans' internal representations of a problem drastically changes the problem's solvability) and different representations may make transfer more or less difficult. However, representation selection is a difficult problem in RL in general and discussions of representation selection (or its applications to transfer efficacy) are beyond the scope of this article.

4. Transfer Methods for Fixed State Variables and Actions

To begin our survey of TL methods, we examine the first group of methods in Table 1, reproduced in Table 3. These techniques may be used for transfer when the source and target tasks use the same state variables and when agents in both tasks have the same set of actions (see Figure 6).

In one of the earliest TL works for RL, Selfridge et al. (1985) demonstrated that it was faster to learn to balance a pole on a cart by changing the task's transition function, T, over time. The learner was first trained on a long and light pole. Once it successfully learned to balance the pole the task was made harder: the pole was shortened and made heavier. The total time spent training on a sequence of tasks and reusing the learned function approximator was faster than training on the hardest task directly.[6]

Similarly, the idea of *learning from easy missions* (Asada et al., 1994) also relies on a human constructing a set of tasks for the learner. In this work, the task (for example, a maze) is made incrementally harder not by changing the dynamics of the task, but by moving the agent's initial

6. As discussed in Section 3.5.3, we classify this work as transfer rather than as a "human advice" method; while the human may assist the agent in task selection, s/he does not provide direct on-line feedback while the agent learns.

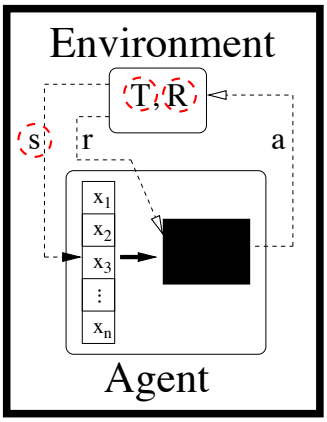

Figure 6: Methods in Section 4 are able to transfer between tasks that have different state spaces, different transition functions, and different reward functions, but only if the source and target tasks have the same actions and state variables. Dashed circles indicate the MDP components which may differ between the source task and target task.

state, $s_{initial}$, further and further from the goal state. The agent incrementally learns how to navigate to the exit faster than if it had tried to learn how to navigate the full maze directly. This method relies on having a known goal state from which a human can construct a series of source tasks of increasing difficulty.

Selfridge et al. (1985) and Asada et al. (1994) provide useful methods for improving learning, which follow from Skinner's animal training work. While they require a human to be in the loop, and to understand the task well enough to provide the appropriate guidance to the learner, these methods are relatively easy ways to leverage human knowledge. Additionally, they may be combined with many of the transfer methods that follow.

Rather than change a task over time, one could consider breaking down a task into a series of smaller tasks. This approach can be considered a type of transfer in that a single large target task can be treated as a series of simpler source tasks. Singh (1992) uses a technique he labels *compositional learning* to discover how to separate temporally sequential subtasks in a monolithic task. Each subtask has distinct beginning and termination conditions, and each subtask will be significantly easier to learn in isolation than in the context of the full task. Only the reward function, R, is allowed to change between the different subtasks and none of the other MDP components may vary, but the total reward can be increased. If subtasks in a problem are recognizable by state features, such subtasks may be automatically identified via vision algorithms (Drummond, 2002). Again, breaking a task into smaller subtasks can improve both the total reward and the asymptotic performance. This particular method is only directly applicable to tasks in which features clearly define subtasks due to limitations in the vision algorithm used. For instance, in a 2D navigation task each room may be a subtask and the steep value function gradient between impassable walls is easily identifiable. However, if the value function gradient is not distinct between different subtasks, or the subtask regions of state space are not polygonal, the algorithm will likely fail to automatically identify subtasks.

In Atkeson and Santamaria (1997), transfer between tasks in which only the reward function can differ are again considered. Their method successfully transfers a locally weighted regression

model of the transition function, which is learned in a source task, by directly applying it to a target task. Because their model enables planning over the transition function and does not account for the reward function, they show significant improvement to the jumpstart and total reward, as well as the asymptotic performance.

The next three methods transfer partial policies, or options, between different tasks. First, Asadi and Huber (2007) have the agent identify states that "locally form a significantly stronger 'attractor' for state space trajectories" as subgoals in the source task (i.e., a doorway between rooms that is visited relatively often compared to other parts of the state space). The agent then learns options to reach these subgoals via a learned action-value function, termed the *decision-level* model. A second action-value function, the *evaluation-level* model, includes all actions and the full state space. The agent selects actions by only considering the decision-level model but uses discrepancies between the two models to automatically increase the complexity of the decision-level model as needed. The model is represented as a *Hierarchical Bounded Parameter SMDP*, constructed so that the performance of an optimal policy in the simplified model will be within some fixed bound of the performance of the optimal policy on the initial model. Experiments show that transferring both the learned options and the decision-level representation allow the target task agent to learn faster on a task with a different reward function. In the roughly 20,000 target task states, only 81 distinct states are needed in the decision-level model, as most states do not need to be distinguished when selecting from learned options.

Second, Andre and Russell (2002) transfer learned subroutines between tasks, which are similar to options. The authors assume that the source and target tasks have a hierarchical structure, such as in the *taxi domain* (Dietterich, 2000). On-line analysis can uncover similarities between two tasks if there are only small differences in the state space (e.g., the state variables do not change) and then directly copy over the subroutine, which functions as a partial policy, thereby increasing the total reward in the target task. This method highlights the connection between state abstraction and transfer; if similarities can be found between parts of the state space in the two tasks, it is likely that good local controllers or local policies can be directly transferred.

Third, Ravindran and Barto (2003b) learn *relativized options* in a small, human selected source task. When learning in the target task, the agent is provided these options and a set of possible transformations it could apply to them so that they were relevant in the target task. For instance, if the source task were a small grid navigation task, the target task could be a large grid composed of rooms with similar shape to the source task and the transformations could be rotation and reflection operators. The agent uses experience in the target and Bayesian parameter estimation to select which transformations to use so that the target task's total reward is increased. Learning time in the source task is ignored, but is assumed to be small compared to the target task learning time.

Next, Ferguson and Mahadevan (2006) take a unique approach to transfer information about the source task's structure. *Proto-value functions* (PVFs) (Mahadevan and Maggioni, 2007) specify an ortho-normal set of basis functions, without regard to R, which can be used to learn an action-value function. After PVFs are learned in a small source task, they can be transferred to another discrete MDP that has a different goal or small changes to the state space. The target task can be learned faster and achieve higher total reward with the transferred PVFs than without. Additionally, the PVF can be scaled to larger tasks. For example, the target maze could have twice the width and height of the source maze: R, S, and T are all scaled by the same factor. In all cases only the target task time is counted.

The goal of learning PVFs is potentially very useful for RL in general and TL in particular. It makes intuitive sense that high-level information about how to best learn in a domain, such as appropriate features to reason over, may transfer well across tasks. There are few examples of meta-learners where TL algorithms learn high level knowledge to assist the agent in learning, rather than lower-level knowledge about how to act. However, we believe that there is ample room for such methods, including methods to learn other domain-specific learning parameters, such as learning rates, function approximator representations, an so on.

Instead of biasing the target task agent's learning representation by transferring a set of basis functions, Sherstov and Stone (2005) consider how to bias an agent by transferring an appropriate action set. If tasks have large action sets, all actions could be considered when learning each task, but learning would be much faster if only a subset of the actions needed to be evaluated. If a reduced action set is selected such that using it could produce near-optimal behavior, learning would be much faster with very little loss in final performance. The standard MDP formalism is modified so that the agent reasons about *outcomes* and *classes*. Informally, rather than reasoning over the probability of reaching a given state after an action, the learner reasons over the actions' effect, or outcome. States are grouped together in classes such that the probability of a given outcome from a given action will be the same for any state in a class. The authors then use their formalism to bound the value lost by using their abstraction of the MDP. If the source and target are very similar, the source task can be learned with the full action set, the optimal action set can be found from the learned Q-values, and learning the target with this smaller action set can speed up learning in the target task. The authors also introduce *random task perturbation* (RTP) which creates a *series* of source tasks from a single source task, thereby producing an action set which will perform well in target tasks that are less similar to the source task. Transfer with and without RTP is experimentally compared to learning without transfer. While direct action transfer can perform worse than learning without transfer, RTP was able to handle misleading source task experience so that performance was improved relative to no transfer in all target tasks and performance using the transferred actions approaches that of the optimal target task action set. Performance was judged by the total reward accumulated in the target task. Leffler et al. (2007) extends the work of Sherstov and Stone by applying the outcome/class framework to learn a *single* task significantly faster, and provides empirical evidence of correctness in both simulated and physical domains.

The idea of RTP is not only unique in this survey, but it is also potentially a very useful idea for transfer in general. While a number of TL methods are able to learn from a set of source tasks, no others attempt to automatically generate these source tasks. If the goal of an agent is perform as well as possible in a novel target task, it makes sense that the agent would try to train on many source tasks, even if they are artificial. How to best generate such source tasks so that they are most likely to be useful for an arbitrary target task in the same domain is an important area of open research.

Similar to previously discussed work (Selfridge et al., 1985; Asada et al., 1994), *Progressive RL* (Madden and Howley, 2004) is a method for transferring between a progression of tasks of increasing difficulty, but is limited to discrete MDPs. After learning a source task, the agent performs *introspection* where a symbolic learner extracts rules for acting based on learned Q-values from all previously learned tasks. The RL algorithm and introspection use different state features. Thus the two learning mechanisms learn in different state spaces, where the state features for the symbolic learner are higher-level and contain information otherwise hidden from the agent. When the agent acts in a novel task, the first time it reaches a novel state it initialize the Q-values of that state so that the action suggested by the learned rule is preferred. Progressive RL allows agents to learn infor-

mation in a set of tasks and then abstract the knowledge to a higher-level representation, allowing the agent to achieve higher total reward and reach the goal state for the first time faster. Time spent in the source task(s) is not counted.

Finally, Lazaric (2008) demonstrates that source task *instances* can be usefully transferred between tasks. After learning one or more source tasks, some experience is gathered in the target task, which may have a different state space or transition function. Saved instances (that is, observed $\langle s, a, r, s' \rangle$ tuples) are compared to instances from the target task. Instances from the source tasks that are most similar, as judged by their distance and alignment with target task data, are transferred. A batch learning algorithm then uses both source instances and target instances to achieve a higher reward and a jumpstart. *Region transfer* takes the idea one step further by looking at similarity with the target task per-sample, rather than per task. Thus, if source tasks have different regions of the state space which are more similar to the target, only those most similar regions can be transferred. In these experiments, time spent training in the target task is not counted towards the TL algorithm.

Region transfer is the only method surveyed which explicitly reasons about task similarity in *different parts* of the state space, and then selects source task(s) to transfer from. In domains where target tasks have regions of the state space that are similar to one or more source tasks, and other areas which are similar to other source tasks (or are similar to no source tasks), region transfer may provide significant performance improvements. As such, this method provides a unique approach to measuring, and exploiting, task similarity on-line. It is likely that this approach will inform future transfer methods, and is one possible way of accomplishing step # 1 in Section 2: Given a target task, select an appropriate source task from which to transfer, if one exists.

Taken together, these TL methods show that it is possible to efficiently transfer many different types of information between tasks with a variety of differences. It is worth re-emphasizing that many TL methods may be combined with other speedup methods, such as reward shaping, or with other transfer methods. For instance, when transferring between maze tasks, basis functions could be learned (Ferguson and Mahadevan, 2006) in the source task, a set of actions to transfer could be selected after training on a set of additional generated source tasks (Sherstov and Stone, 2005), and then parts of different source tasks could be leveraged to learn a target task (Lazaric, 2008). A second example would be to start with a simple source task and change it over time by modifying the transition function (Selfridge et al., 1985) and start state (Asada et al., 1994), while learning options (Ravindran and Barto, 2003b), until a difficult target task is learned. By examining how the source and target task differ and what base learning method is used, RL practitioners may select one or more TL method to apply to their domain of interest. However, in the absence of theoretical guarantees of transfer efficacy, any TL method has the potential to be harmful, as discussed further in Section 9.2.

5. Multi-Task Learning Methods

This section discusses scenarios where the source tasks and target task have the same state variables and actions. However, these methods (see Table 4, reproduced from Table 1) are explicitly MTL, and all methods in this section are designed to use multiple source tasks (see Figure 7). Some methods leverage all experienced source tasks when learning a novel target task and others are able to choose a subset of previously experienced tasks. Which approach is most appropriate depends on the assumptions about the task distribution: if tasks are expected to be similar enough that all past experience is useful, there is no need to select a subset. On the other hand, if the distribution of

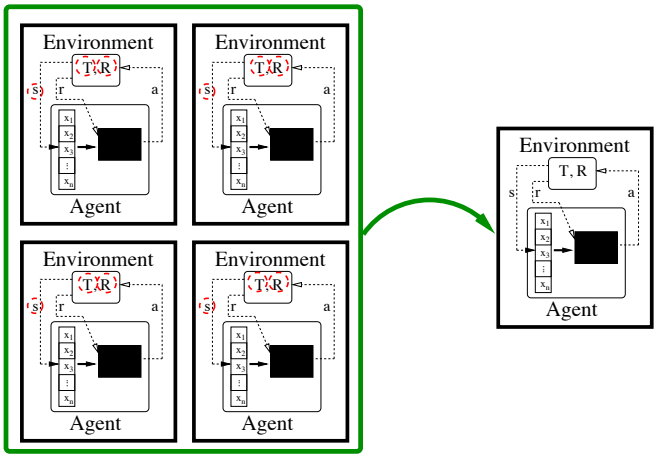

Figure 7: Multi-task learning methods assume tasks are chosen from a fixed distribution, use one or more source tasks to help learn the current task, and assume that all the tasks have the same actions and state variables. Dashed circles indicate the MDP components which may differ between tasks.

tasks is multi-modal, it is likely that transferring from all tasks is sub-optimal. None of the methods account for time spent learning in the source task(s) as the primary concern is effective learning on the next task chosen at random from an unknown (but fixed) distribution of MDPs.

Variable-reward hierarchical reinforcement learning (Mehta et al., 2008) assumes that the learner will train on a sequence of tasks which are identical except for different *reward weights*. The reward weights define how much reward is assigned via a linear combination of *reward features*. The authors provide the reward features to the agent for a given set of tasks. For instance, in a real-time strategy domain different tasks could change the reward features, such as the benefit from collecting units of gold or from damaging the enemy. However, it is unclear how many domains of interest have reward features, which are provided to the agent at the start of each task. Using a hierarchical RL method, subtask policies are learned. When a novel target task is encountered, the agent sets the initial policy to that of the most similar source task, as determined by the dot product with previ-

ously observed reward weight vectors. The agent then uses an ε-greedy action selection method at each level of the task hierarchy to decide whether to use the best known sub-task policy or explore. Some sub-tasks, such as navigation, will never need to be relearned for different tasks because they are unaffected by the reward weights, but any suboptimal sub-task policies will be improved. As the agent experiences more tasks, the total reward in each new target task increases, relative to learning the task without transfer.

A different problem formulation is posed by Perkins and Precup (1999) where the transition function, T, may change after reaching the goal. Upon reaching the goal, the agent is returned to the start state and is not told if, or how, the transition function has changed, but it knows that T is drawn randomly from some fixed distribution. The agent is provided a set of hand-coded options which assist in learning on this set of tasks. Over time, the agent learns an accurate action-value function over these options. Thus, a single action-value function is learned over a set of tasks, allowing the agent to more quickly reach the goal on tasks with novel transition functions.

Instead of transferring options, Foster and Dayan (2004) aim to identify sub-tasks in a source task and use this information in a target task, a motivation similar to that of Singh (1992). Tasks are allowed to differ in the placement of the goal state. As optimal value functions are learned in source tasks, an *expectation-maximization* algorithm (Dempster et al., 1977) identifies different "fragmentations," or sub-tasks, across all learned tasks. Once learned, the fragmentations are used to augment the state of the agent. Each sub-problem can be learned independently; when encountering a new task, much of the learning is already complete because the majority of sub-problems are unchanged. The fragmentations work with both a flat learner (i.e., TD) and an explicitly hierarchical learner to improve the jumpstart and total reward.

Probabilistic policy reuse (Fernandez and Veloso, 2006) also considers a distribution of tasks in which only the goal state differs, but is one of the most robust MTL methods in terms of appropriate source task selection. Although the method allows a single goal state to differ between the tasks, it requires that S, A, and T remain constant. If a newly learned policy is significantly different from existing policies, it is added to a policy library. When the agent is placed in a novel task, on every timestep, it can choose to: exploit a learned source task policy, exploit the current best policy for the target task, or randomly explore. If the agent has multiple learned policies in its library, it probabilistically selects between policies so that over time more useful policies will be selected more often. While this method allows for probabilistic mixing of the policies, it may be possible to treat the past policies as options which can be executed until some termination condition is met, similar to a number of previously discussed methods. By comparing the relative benefits of mixing past policies and treating them as options, it may be possible to better understand when each of the two approaches is most useful.

The idea of constructing an explicit policy library is likely to be useful in future TL research, particularly for agents that train on a number of source tasks that have large qualitative differences (and thus very different learned behaviors). Although other methods also separately record information from multiple source tasks (cf., Mehta et al., 2008; Lazaric, 2008), Fernandez and Veloso explicitly reason about the library. In addition to reasoning over the amount of information stored, as a function of number and type of source tasks, it will be useful to understand how many target task samples are needed to select the most useful source task(s).

Unlike probabilistic policy reuse, which selectively transfers information from a single source task, Tanaka and Yamamura (2003) gather statistics about *all* previous tasks and use this amalgamated knowledge to learn novel tasks faster. Specifically, the learner keeps track of the average

and the deviation of the action value for each (s,a) pair observed in all tasks. When the agent encounters a new task, it initializes the action-value function so that every (s,a) pair is set to the current average for that pair, which provides a benefit relative to uninformed initialization. As the agent learns the target task with Q-learning and prioritized sweeping,[7] the agent uses the standard deviation of states' Q-values to set priorities on TD backups. If the current Q-value is far from the average for that (s,a) pair, its value should be adjusted more quickly, since it is likely incorrect (and thus should be corrected before affecting other Q-values). Additionally, another term accounting for the variance within individual trials is added to the priority; Q-values that fluctuate often within a particular trial are likely wrong. Experiments show that this method, when applied to sets of discrete tasks with different transition functions, can provide significant improvement to jumpstart and total reward.

The next two methods consider how priors can be effectively learned by a Bayesian MTL agent. First, Sunmola and Wyatt (2006) introduce two methods that use instances from source tasks to set priors in a Bayesian learner. Both methods constrain the probabilities of the target task's transition function by using previous instances as a type of prior. The first method uses the working prior to generate possible models which are then tested against data in the target task. The second method uses a probability perturbation method in conjunction with observed data to improve models generated by the prior. Initial experiments show that the jumpstart and total reward can be improved if the agent has an accurate estimation of the prior distributions of the class from which the target is drawn. Second, Wilson et al. (2007) consider learning in a hierarchical Bayesian RL setting. Setting the prior for Bayesian models is often difficult, but in this work the prior may be transferred from previously learned tasks, significantly increasing the learning rate. Additionally, the algorithm can handle "classes" of MDPs, which have similar model parameters, and then recognize when a novel class of MDP is introduced. The novel class may then be added to the hierarchy and a distinct prior may be learned, rather than forcing the MDP to fit into an existing class. The location of the goal state and the parameterized reward function may differ between the tasks. Learning on subsequent tasks shows a clear performance improvement in total reward, and some improvement in jumpstart.

While Bayesian methods have been shown to be successful when transferring between classification tasks (Roy and Kaelbling, 2007), and in non-transfer RL (Dearden et al., 1999), only the two methods above use it in RL transfer. The learner's bias is important in all machine learning settings. However, Bayesian learning makes such bias explicit. Being able to set the bias through transfer from similar tasks may prove to be a very useful heuristic—we hope that additional transfer methods will be developed to initialize Bayesian learners from past tasks.

Walsh et al. (2006) observe that "deciding what knowledge to transfer between environments can be construed as determining the correct state abstraction scheme for a set of source [tasks] and then applying this compaction to a target [task]." Their suggested framework solves a set of MDPs, builds abstractions from the solutions, extracts relevant features, and then applies the feature-based abstraction function to a novel target task. A simple experiment using tasks with different state spaces and reward functions shows that the time to learn a target task is decreased by using MTL. Building upon their five defined types of state abstractions (as defined in Li et al. 2006), they give theoretical results showing that when the number of source tasks is large (relative to the differences

7. Prioritized sweeping (Moore and Atkeson, 1993) is an RL method that orders adjustments to the value function based on their "urgency," which can lead to faster convergence than when updating the value function in the order of visited states.

between the different tasks), four of the five types of abstractions are guaranteed to produce the optimal policy in a target task using Q-learning.

Similar to Walsh et al. (2006), Lazaric (2008) also discovers features to transfer. Rather than learning tasks sequentially, as in all the papers above, one could consider learning different tasks in parallel and using the shared information to learn the tasks better than if each were learned in isolation. Specifically, Lazaric (2008) learns a set of tasks with different reward functions using the batch method *Fitted Q-iteration* (Ernst et al., 2005). By leveraging a multi-task feature learning algorithm (Argyrious et al., 2007), the problem can be formulated as a joint optimization problem to find the best features and learning parameters across observed data in all tasks. Experiments demonstrate that this method can improve the total reward and can help the agent to ignore irrelevant features (i.e., features which do not provide useful information). Furthermore, since it may be possible to learn a superior representation, asymptotic performance may be improved as well, relative to learning tasks in isolation.

The work in this section, as summarized in the second section of Table 1, explicitly assumes that all MDPs an agent experiences are drawn from the same distribution. Different tasks in a single distribution could, in principal, have different state variables and actions, and future work should investigate when allowing such flexibility would be beneficial.

6. Transferring Task-Invariant Knowledge Between Tasks with Differing State Variables and Actions

This section, unlike the previous two, discusses methods that allow the source task and target task to have different state variables and actions (see Figure 8 and the methods in Table 5). These methods formulate the problem so that no explicit mapping between the tasks is needed. Instead the agent reasons over abstractions of the MDP that are invariant when the actions or state variables change.

For example, Konidaris and Barto (2006) have separated the standard RL problem into *agent-space* and *problem-space* representations. The agent-space is determined by the agent's capabilities, which remain fixed (e.g., physical sensors and actuators), although such a space may be non-Markovian.[8] The problem-space, on the other hand, may change between source and target

8. A standard assumption is that a task is Markovian, meaning that the probability distribution over next states is independent of the agent's state and action history. Thus, saving a history would not assist the agent when selecting actions, and it can consider each state in isolation.

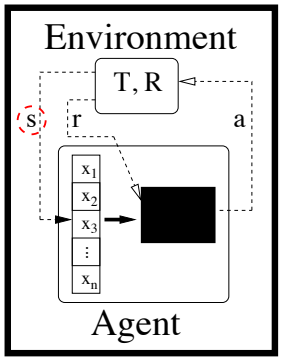

Figure 8: Methods in Section 6 are able to transfer between tasks with different state spaces. Although T, R, A, and the state variables may also technically change, the agent's internal representation is formulated so that they remain fixed between source and target tasks. MDP components with a dashed circle may change between the source task and target task.

problems and is assumed to be Markovian. The authors' method learns a shaping reward on-line in agent-space while learning a source task. If a later target task has a similar reward structure and action set, the learned shaping reward will help the agent achieve a jumpstart and higher total reward. For example, suppose that one of the agent's sensors measures the distance between it and a particular important state (such as a beacon located near the goal state). The agent may learn a shaping reward that assigns reward when the state variable describing its distance to the beacon is reduced, even in the absence of an environmental reward. The authors assume that there are no novel actions (i.e., actions which are not in the source task's problem-space) but any new state variables can be handled if they can be mapped from the novel problem-space into the familiar agent-space. Additionally, the authors acknowledge that the transfer must be between *reward-linked* tasks, where "the reward function in each environment consistently allocates rewards to the same types of interactions across environments." Determining whether or not a sequence of tasks meet this criterion is left for future work.

In later work (Konidaris and Barto, 2007), the authors assume knowledge of "pre-specified salient events," which make learning options tractable. While it may be possible to learn options without requiring such events to be specified, the paper focuses on how to use such options rather than option learning. Specifically, when the agent achieves one of these subgoals, such as unlocking a door or moving through a doorway, it may learn an option to achieve the event again in the future. As expected, problem-space options speed up learning a single task. More interesting, when the agent trains on a series of tasks, options in both agent-space and problem-space significantly increase the jumpstart and total reward in the target task (time spent learning the source task is discounted). The authors suggest that agent-space options will likely be more portable than problem-space options in cases where the source and target tasks are less similar—indeed, problem-space options will only be portable when source and target tasks are very similar.

In our opinion, agent- and problem-space are ideas that should be further explored as they will likely yield additional benefits. Particularly in the case of physical agents, it is intuitive that agent sensors and actuators will be static, allowing information to be easily reused. Task-specific items,

such as features and actions, may change, but should be faster to learn if the agent has already learned something about its unchanging agent-space.

If transfer is applied to game trees, changes in actions and state variables may be less problematic. Banerjee and Stone (2007) are able to transfer between games by focusing on this more abstract formulation. For instance, in experiments the learner identified the concept of a *fork*, a state where the player could win on the subsequent turn regardless of what move the opponent took next. After training in the source task, analyzing the source task data for such features, and then setting the value for a given feature based on the source task data, such features of the game tree were used in a variety of target tasks. This analysis focuses on the effects of actions on the game tree and thus the actions and state variables describing the source and target game can differ without requiring an inter-task mapping. Source task time is discounted, but jumpstart, total reward, and asymptotic performance are all improved via transfer. Although the experiments in the paper use only temporal difference learning, it is likely that this technique would work well with other types of learners.

Guestrin et al. (2003) examine a similar problem in the context of planning in what they term a *relational MDP*. Rather than learning a standard value function, an agent-centered value function for each *class* of agents is calculated in a source task, forcing all agents of a given class type to all have the same value function. However, these class value functions are defined so that they are independent of the number of agents in a task, allowing them to be directly used in a target task which has additional (or fewer) agents. No further learning is done in the target task, but the transferred value functions perform better than a handcoded strategy provided by the authors, despite having additional friendly and adversarial agents. However, the authors note that the technique will not perform well in heterogeneous environments or domains with "strong and constant interactions between many objects."

Relational Reinforcement Learning may also be used for effective transfer. Rather than reasoning about states as input from an agent's sensors, an RRL learner typically reasons about a state in propositional form by constructing first-order rules. The learner can easily abstract over specific object identities as well as the number of objects in the world; transfer between tasks with different number of objects is simplified. For instance, Croonenborghs et al. (2007) first learn a source task policy with RRL. The learned policy is used to create examples of state-action pairs, which are then used to build a relational decision tree. This tree predicts, for a given state, which action would be executed by the policy. Lastly, the trees are mined to produce *relational options*. These options are directly used in the target task with the assumption that the tasks are similar enough that no translation of the relational options is necessary. The authors consider three pairs of source/target tasks where relational options learned in the source directly apply to the target task (only the number of objects in the tasks may change), and learning is significantly improved in terms of jumpstart, total reward, and asymptotic performance.

Other work using RRL for transfer (Ramon et al., 2007) introduces the TGR algorithm, a relational decision tree algorithm. TGR incrementally builds a decision tree in which internal nodes use first-order logic to analyze the current state and where the tree's leaves contain action-values. The algorithm uses four tree-restructuring operators to effectively use available memory and increase sample efficacy. Both target task time and total time are reduced by first training on a simple source task and then on a related target task. Jumpstart, total reward, and asymptotic performance also appear to improve via transfer.

RRL is a particularly attractive formulation in the context of transfer learning. In RRL, agents can typically act in tasks with additional objects without reformulating their, although additional

training may be needed to achieve optimal (or even acceptable) performance levels. When it is possible to frame a domain of interest as an RRL task, transfer between tasks with different numbers of objects or agents will likely be relatively straightforward.

With motivation similar to that of RRL, some learning problems can be framed so that agents choose between high-level actions that function regardless of the number of objects being reasoned about. Sharma et al. (2007) combines case-based reasoning with RL in the *CAse-Based Reinforcement Learner* (CARL), a multi-level architecture includes three modules: a planner, a controller, and a learner. The tactical layer uses the learner to choose between high-level actions which are independent of the number of objects in the task. The cases are indexed by: high-level state variables (again independent of the number of objects in the task), the actions available, the Q-values of the actions, and the cumulative contribution of that case on previous timesteps. Similarity between the current situation and past cases is determined by Euclidean distance. Because the state variables and actions are defined so that the number of objects in the task can change, the source and target tasks can have different numbers of objects (in the example domain, the authors use different numbers of player and opponent troops in the source and target tasks). Time spent learning the source task is not counted, but the target task performance is measured in terms of jumpstart, *asymptotic gain* (a metric related to the improvement in average reward over learning), and *overall gain* (a metric based on the total reward accrued).

In summary, methods surveyed in this section all allow transfer between tasks with different state variables and actions, as well as transfer functions, state spaces, and reward functions. By framing the task in an agent-centric space, limiting the domain to game trees, or using a learning method that reasons about variable numbers of objects, knowledge can be transferred between tasks with relative ease because problem representations do not change from the learner's perspective. In general, not all tasks may be formulated so that they conform to the assumptions made by TL methods presented in this section.

7. Explicit Mappings to Transfer between Different Actions and State Representations

This section of the survey focuses on a set of methods which are more flexible than those previously discussed as they allow the state variables and available actions to differ between source and target tasks (see Table 6 and Figure 9). All methods in this section use inter-task mappings, enabling transfer between pairs of tasks that could not be addressed by methods in the previous section. Note that because of changes in state variables and actions, R, S, and T, all technically change as well (they are functions defined over actions and state variables). However, as we elaborate below, some of the methods allow for significant changes in reward functions between the tasks, while most do not.

In Taylor et al. (2007a), the authors assume that a mapping between the source and target tasks is provided to the learner. The learner first trains in a source task using a value-function-learning method. Before learning begins in the target task, every action-value for each state in the target task is initialized via learned source task values. This work experimentally demonstrates that value-function transfer can cause significant speedup by transferring between tasks that have different state variables and actions. Additionally, different methods for performing the value-function transfer are examined, different function approximators are successfully used, and multi-step transfer is demonstrated (i.e., transfer from task A to task B to task C). This TL method demonstrates that when

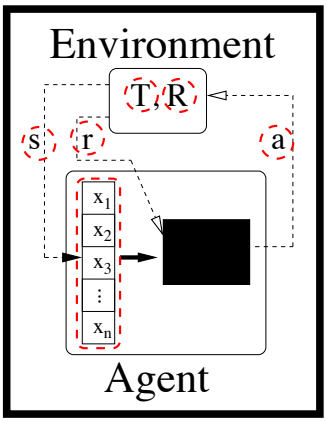

Figure 9: Methods in Section 7 focus on transferring between tasks with different state features, action sets, and possible reward functions (which, in turn, causes the state space and transition function to differ as well). As in previous figures, MDP components with a dashed circle may change between the source task and target task.

faced with a difficult task, it may be faster overall to first train on an artificial source task or tasks and then transfer the knowledge to the target task, rather than training on the target task directly. The authors provide no theoretical guarantees about their method's effectiveness, but hypothesize conditions under which their TL method will and will not perform well, and provide examples of when their method fails to reduce the training time via transfer.

In subsequent work, Taylor et al. (2007b) transfer entire policies between tasks with different state variables and actions, rather than action-value functions. A set of policies is first learned via a genetic algorithm in the source task and then transformed via inter-task mappings. Additionally, partial inter-task mappings are introduced, which may be easier for a human to intuit in many domains. Specifically, those actions and state variables in the target which have "very similar" actions and state variables in the source task are mapped, while novel state variables and actions in the target task are left unmapped. Policies are transformed using one of the inter-task mappings and then used to seed the learning algorithm in the target task. As in the previous work, this TL method can successfully reduce both the target task time and the total time.

Later, Taylor et al. (2008b) again consider pairs of tasks where the actions differ, the state variables differ, and inter-task mappings are available to the learner. In this work, the authors allow transfer between model-learning methods by transferring instances, which is similar in spirit to Lazaric (2008). Fitted R-MAX (Jong and Stone, 2007), an instance-based model-learning method capable of learning in continuous state spaces, is used as the base RL method, and source task instances are transferred into the target task to better approximate the target task's model. Experiments in a simple continuous domain show that transfer can improve the jumpstart, total reward, and asymptotic performance in the target task.

Another way to transfer is via learned *advice* or preferences. Torrey et al. (2005) automatically extract such advice from a source task by identifying actions which have higher Q-values than other available actions.[9] Such advice is mapped via human-provided inter-task mappings to the target task as preferences given to the target task learner. In this work, Q-values are learned via support vector regression, and then *Preference Knowledge Based Kernel Regression* (KBKR) (Maclin et al., 2005) adds the advice as soft constraints in the target, setting relative preferences for different actions in different states. The advice is successfully leveraged by the target task learner and decreases the target task learning time, even when the source task has different state variables and actions. Additionally, the reward structure of the tasks may differ substantially: their experiments use a source task whose reward is an unbounded score based on episode length, while the target task's reward is binary, depending on if the agents reached a goal state or not. Source task time is discounted and the target task learning is improved slightly in terms of total reward and asymptotic performance.

Later work (Torrey et al., 2006) improves upon this method by using *inductive logic programming* (ILP) to identify *skills* that are useful to the agent in a source task. A trace of the agent in the source task is examined and both positive and negative examples are extracted. Positive and negative examples are identified by observing which action was executed, the resulting outcome, the Q-value of the action, and the relative Q-value of other available actions. Skills are extracted using the ILP engine Aleph (Srinivasan, 2001) by using the F_1 score (the harmonic mean of precision and recall). These skills are then mapped by a human into the target task, where they improve learning via KBKR. Source task time is not counted towards the target task time, jumpstart may be improved, and the total reward is improved. The source and target tasks again differ in terms of state variables, actions, and reward structure. The authors also show how human-provided advice may be easily incorporated in addition to advice generated in the source task. Finally, the authors experimentally demonstrate that giving bad advice to the learner is only temporarily harmful and that the learner can "unlearn" bad advice over time, which may be important for minimizing the impact of negative transfer.

Torrey et al. (2007) further generalize their technique to transfer *strategies*, which may require composing several skills together, and are defined as a finite-state machine (FSM). The *structure learning* phase of their algorithm analyzes source task data to find sequences of actions that distinguish between successful and unsuccessful games (e.g., whether or not a goal was reached), and composes the actions into a FSM. The second phase, *ruleset learning*, learns when each action in the strategy should be taken based on state features, and when the FSM should transition to the next state. Experience in the source task is again divided into positive and negative sequences for Aleph. Once the strategies are re-mapped to the target task via a human-provided mapping, they are used to *demonstrate* a strategy to the target task learner. Rather than explore randomly, the target

9. While this survey focuses on automatically learned knowledge in a source task, rather than human-provided knowledge, Torrey et al. (2005) show that both kinds of knowledge can be effectively leveraged.

task learner always executes the transferred strategies for the first 100 episodes and thus learns to estimate the Q-values of the actions selected by the transferred strategies. After this demonstration phase, the learner chooses from the MDP's actions, not the high-level strategies, and can learn to improve on the transferred strategies. Experiments demonstrate that strategy transfer significantly improves the jumpstart and total reward in the target task when the source and target tasks have different state variables and actions (source task time is again discounted).

Similar to strategy transfer, Taylor and Stone (2007b) learn *rules* with RIPPER (Cohen, 1995) that summarize a learned source task policy. The rules are then transformed via handcoded inter-task mappings so that they could apply to a target task with different state variables and actions. The target task learner may then bootstrap learning by incorporating the rules as an extra action, essentially adding an ever-present option "take the action suggested by the source task policy," resulting in an improved jumpstart and total reward. By using rules as an intermediary between the two tasks, the authors argue that the source and target tasks can use different learning methods, effectively de-coupling the two learners. Similarities with Torrey et al. (2007) include a significant improvement in initial performance and no provision to automatically handle scale differences.[10] The methods differ primarily in how advice is incorporated into the target learner and the choice of rule learner.

Additionally, Taylor and Stone (2007b) demonstrated that *inter-domain* transfer is possible. The two source tasks in this paper were discrete, fully observable, and one was deterministic. The target task, however, had a continuous state space, was partially observable, and had stochastic actions. Because the source tasks required orders of magnitude less time, the total time was roughly equal to the target task time. Our past work has used the term "inter-domain transfer" for transfer between qualitatively different domains, such as between a board game and a soccer simulation. However, this term is not well defined, or even agreed upon in the community. For instance, Swarup and Ray (2006) use the term "cross-domain transfer" to describe the reuse of a neural network structure between classification tasks with different numbers of boolean inputs and a single output. However, our hope is that researchers will continue improve transfer methods so that they may usefully transfer from very dissimilar tasks, similar to the way that humans may transfer high level ideas between very different domains.

This survey has discussed examples of of low- and high-level knowledge transfer. For instance, learning general rules or advice may be seen as relatively high level, whereas transferring specific Q-values or observed instances is quite task-specific. Our intuition is that higher-level knowledge may be more useful when transferring between very dissimilar tasks. For instance, it is unlikely that Q-values learned for a checkers game will transfer to chess, but the concept of a fork may transfer well. This has not been definitely shown, however, nor is there a quantitative way to classify knowledge in terms of low- or high-level. We hope that future work will confirm or disconfirm this hypothesis, as well as generate guidelines as to when different types of transferred knowledge is most appropriate.

All methods in this section use some type of inter-task mapping to allow transfer between MDPs with very different specifications. While these results show that transfer can provide a significant benefit, they presuppose that the mappings are provided to the learner. The following section considers methods that work to autonomously learn such inter-task mappings.

10. To our knowledge, there is currently no published method to automatically scale rule constants. Such scaling would be necessary if, for instance, source task distances were measured in feet, but target task distances were measured in meters.

8. Learning Task Mappings

The transfer algorithms considered thus far have assumed that a hand-coded mapping between tasks was provided, or that no mapping was needed. In this section we consider the less-well explored question of how a mapping between tasks can be learned, such that source task knowledge may be exploited in a novel target task with different state variables and actions (see Figure 10 and the final group in Table 1). Note that in this section, all but one of the methods have N/A for transfer method—with the exception of Kuhlmann and Stone (2007), the papers covered in this section introduce mapping-learning methods and then use existing methods to validate the mapping efficacy.

One current challenge of TL research is to reduce the amount of information provided to the learner about the relationship between the source and target tasks. If a human is directing the learner through a series of tasks, the similarities (or analogies) between the tasks will likely be provided by the human's intuition. If transfer is to succeed in an autonomous setting, however, the learner must first determine how (and whether) two tasks are related, and only then may the agent leverage its past knowledge to learn in a target task. Learning task relationships is critical if agents are to transfer without human input, either because the human is outside the loop, or because the human is *unable* to provide similarities between tasks. Methods in this section differ primarily in what information must be provided. At one end of the spectrum, Kuhlmann and Stone (2007) assume that a complete description of R, S, and T are given, while at the other, Taylor et al. (2008c) learn the mapping exclusively from experience gathered via environmental interactions.

Given a complete description of a game (i.e., the full model of the MDP), Kuhlmann and Stone (2007) analyze the game to produce a *rule graph*, an abstract representation of a deterministic, full information game. A learner first trains on a series of source task games, storing the rule graphs and learned value functions. When a novel target task is presented to the learner, it first constructs the target task's rule graph and then attempts to find a source task that has an isomorphic rule graph. The learner assumes that a transition function is provided and uses value-function-based learning to estimate values for *afterstates* of games. Only state variables need to be mapped between source and target tasks, and this is exactly the mapping found by graph matching. For each state in the target task, initial Q-values are set by finding the value of the corresponding state in the source task. Three types of transfer are considered: direct, which copies afterstate values over without modification; inverse, which accounts for a reversed goal or switched roles; and average, with copies the average

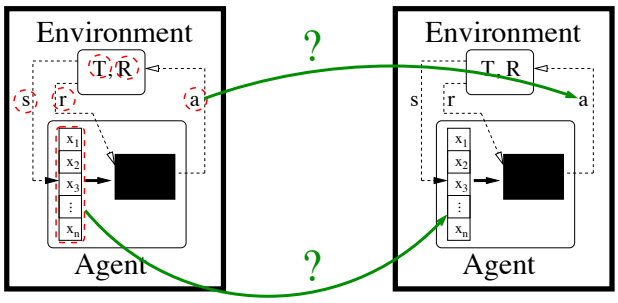

Figure 10: Section 8 presents methods to learn the relationship between tasks with different state variables and actions. As in previous figures, MDP components with a dashed circle may change between the source task and target task.

of a set of Q-values and can be used for boards with different sizes. Source task time is ignored but jumpstart and total reward can both be improved in the target task.

The previous work assumes full knowledge of a transition function. A more general approach could assume that the agent has only a qualitative understanding of the transition function. For instance, *qualitative dynamic Bayes networks* (QDBNs) (Liu and Stone, 2006), summarize the effects of actions on state variables but are not precise (for instance, they could not be used as a generative model for planning). If QDBNs are provided to an agent, a graph mapping technique can automatically find a mapping between actions and state variables in two tasks with relatively little computational cost. The authors show that mappings can be learned autonomously, effectively enabling value function transfer between tasks with different state variables and actions. However, it remains an open question as to whether or not QDBNs are learnable from experience, rather than being hand-coded.

The next three methods assume knowledge about how state variables are used to describe objects in a multi-player task. For instance, an agent may know that a pair of state variables describe "distance to teammate" and "distance from teammate to marker," but the agent is not told *which* teammate the state variables describe. First, Soni and Singh (2006) supply an agent with a series of possible state transformations and an inter-task action mapping. There is one such transformation, X, for every possible mapping of target task variables to source task variables. After learning the source task, the agent's goal is to learn the correct transformation: in each target task state s, the agent can randomly explore the target task actions, or it may choose to take the action $\pi_{source}(X(s))$. This method has a similar motivation to that of Fernandez and Veloso (2006), but here the authors are learning to select between possible mappings rather than possible previous policies. Over time the agent uses Q-learning to select the best state variable mapping as well as learn the action-values for the target task. The jumpstart, total reward, and asymptotic performance are all slightly improved when using this method, but its efficacy will be heavily dependent on the number of possible mappings between any source and target task.

Second, *AtEase* (Talvitie and Singh, 2007) also generates a number of possible state variable mappings. The action mapping is again assumed and the target task learner treats each of the possible mappings as an arm on a multi-armed bandit (Bellman, 1956). The authors prove their algorithm learns in time proportional to the number of possible mappings rather than the size of the problem: "in time polynomial in T, [the algorithm] accomplishes an actual return close to the

asymptotic return of the best expert that has mixing time at most T." This approach focuses efficient selection of a proposed state variable mappings and does not allow target task learning.

Third, these assumptions are relaxed slightly by Taylor et al. (2007b), who show that it is possible to learn both the action and state variable mapping simultaneously by leveraging a classification technique, although it again relies on the pre-specified state variable groupings (i.e., knowing that "distance to teammate" refers to a teammate, but not which teammate). Action and state variable classifiers are trained using recorded source task data. For instance, the source task agent records s_{source}, a_{source}, s'_{source} tuples as it interacts with the environment. An action classifier is trained so that $C(s_{source,object}, s'_{source,object}) = a_{source}$ for each object present in the source task. Later, the target task agent again records s_{target}, a_{target}, s'_{target} tuples. Then the action classifier can again be used for to classify tuples for every target task object: $C(s_{target,object}, s'_{target,object}) = a_{source}$, where such a classification would indicate a mapping between a_{target} and a_{source}. Relatively little data is needed for accurate classification; the number of samples needed to learn in the target task far outweighs the number of samples used by the mapping-leaning step. While the resulting mappings are not always optimal for transfer, they do serve to effectively reduce target task training time as well as the total training time.

The MASTER algorithm (Taylor et al., 2008c) was designed to further relax the knowledge requirements of Taylor et al. (2007b): no state variable groupings are required. The key idea of MASTER is to save experienced source task instances, build an approximate transition model from a small set of experienced target task instances, and then test possible mappings offline by measuring the prediction error of the target-task models on source task data. This approach is sample efficient at the expense of high computational complexity, particularly as the number of state variables and actions increase. The method uses an exhaustive search to find the inter-task mappings that minimize the prediction error, but more sophisticated (e.g., heuristic) search methods could be incorporated. Experiments show that the learned inter-task mappings can successfully improve jumpstart and total reward. A set of experiments also shows how the algorithm can assist with source task selection by selecting the source task which is best able to minimize the offline prediction error. The primary contribution of MASTER is to demonstrate that autonomous transfer is possible, as the algorithm can learn inter-task mappings autonomously, which may then be used by any of the TL methods discussed in the previous section of this survey (Section 7).

In summary, this last section of the survey has discussed several methods able to learn inter-task mappings with different amounts of data. Although all make some assumptions about the amount of knowledge provided to the learner or the similarity between source and target tasks, these approaches represent an important step towards achieving fully autonomous transfer.

The methods in the section have been loosely ordered in terms of increasing autonomy. By learning inter-task mappings, these algorithms try to enable a TL agent to use past knowledge on a novel task without human intervention, even if the state variables or actions change. However, the question remains whether fully autonomous transfer would ever be useful in practice. Specifically, if there are no restrictions on the type of target task that could be encountered, why would one expect that past knowledge (a type of bias) would be useful when learning an encountered task, or even on the majority of tasks that could be encountered? This question is directly tied to the ability of TL algorithms to recognize when tasks are similar and when negative transfer may occur, both of which are discussed in more detail in the following section.

9. Open Questions

Although transfer learning in RL has made significant progress in recent years, there are still a number of open questions to be addressed. This section presents a selection of questions that we find particularly important. Section 9.1 discusses ways in which methods in the survey could potentially be extended and serves to highlight some of the methods most promising for future work. Section 9.2 then discusses the problem of negative transfer, currently one of the most troubling open questions. Lastly, Section 9.3 presents a set of possible research directions that the authors' believe will be most beneficial to the field of TL.

9.1 Potential Enhancements

One apparent gap in our taxonomy is a dearth of model-learning methods. Because model-learning algorithms are often more sample efficient than model-free algorithms, it is likely that TL will have a large impact on sample complexity when coupled with such efficient RL methods. Moreover, when a full model of the environment is learned in a source task, it may be possible for the target task learner to explicitly reason about how to refine or extend the model as it encounters disparities between it and the target task.

As mentioned in Section 5, transfer is an appealing way to set priors in a Bayesian setting. When in a MTL setting, it may be possible to accurately learn priors over a distribution of tasks, enabling a learner to better avoid negative transfer. One of the main benefits of transfer learning is the ability to bias learners so that they may find better solutions with less data; making these biases explicit through Bayesian priors may allow more efficient (and human-understandable) transfer methods. While there will likely be difficulties associated with scaling up current methods to handle complex tasks, possibly with a complex distribution hierarchy, it seems like Bayesian methods are particularly appropriate for transfer.

The idea of automatically modifying source tasks (cf., RTP Sherstov and Stone 2005, and suggested by Kuhlmann and Stone 2007) has not yet been widely adopted. However, such methods have the potential to improving transfer efficacy in settings where the target task learning performance is paramount. By developing methods that allow training on a sequence of automatically generated variations, TL agents may be able to train autonomously and gain experience that is exploitable in a novel task. Such an approach would be particularly relevant in the multi-task learning setting where the agent could leverage some assumptions about the distribution of the target task(s) it will see in the future.

None of the transfer methods in this survey are able to explicitly take advantage of any knowledge about changes in the reward function between tasks, and it may be particularly easy for humans to identify qualitative changes in reward functions. For example, if it was known that the target task rewards were twice that of the source task, it is possible that value-function methods may be able to automatically modify the source task value function with this background knowledge to enhance learning. As a second example, consider a pair of tasks where the goal state were moved from one edge of the state space to the opposite edge. While the learned transition information could be reused, the policy or value-function would need to be significantly altered to account for the new reward function. It is possible that inter-task mappings could be extended to account for changes in R between tasks, in addition to changes in A and in state variables.

Ideas from *theory revision* (Ginsberg, 1988) (also *theory refinement*) may help inform the automatic construction of inter-task mappings. For example, many methods initialize a target task

agent to have Q-values similar to those in the source task agent. Transfer is likely to be successful (Taylor et al., 2007a) if the target task Q-values are close enough to the optimal Q-values that learning is improved, relative to not using transfer. There are also situations where a *syntactic* change to the knowledge would produce better transfer. For instance, if the target task's reward function were the inverse of the source task function, direct transfer of Q-values would be far from optimal. However, a TL algorithm that could recognize the inverse relationship may be able to use the source task knowledge more appropriately (such as initializing its behavior so that $\pi_{target}(s_{target}) \neq \pi_{source}(\chi_X(s_{target}))$.

Given a successful application of transfer, there are potentially two distinct benefits for the agent. First, transfer may help improve the agent's exploration so that it discovers higher-valued states more quickly. Secondly, transfer can help bias the agent's internal representation (e.g., its function approximator) so that it may learn faster. It will be important for future work to better distinguish between these two effects; decoupling the two contributions should allow for a better understanding of TL's benefits, as well as provide avenues for future improvements.

Of the thirty-four transfer methods discussed, only five (Tanaka and Yamamura, 2003; Sunmola and Wyatt, 2006; Ferguson and Mahadevan, 2006; Lazaric, 2008; Wilson et al., 2007) attempt to discover internal learning parameters (e.g., appropriate features or learning rate) so that future tasks in the same domain may be learned more efficiently. It is likely that other "meta-learning" methods could be useful. For instance, it may be possible to learn to use an appropriate function approximator, an advantageous learning rate, or even the most appropriate RL method. Although likely easier to accomplish in a MTL setting, such meta-learning may also be possible in transfer, given sufficiently strong assumptions about task similarity. Multiple heuristics regarding the best way to select RL methods and learning parameter settings for a particular domain exist, but typically such settings are chosen in an ad hoc manner. Transfer may be able to assist when setting such parameters, rather than relying on human intuition.

Section 8 discussed methods that learned an inter-task mapping, with the motivation that such a mapping could enable autonomous transfer. However, it is unclear if fully autonomous TL is realistic in an RL setting, or indeed is useful. In the majority of situations, a human will be somewhere in the loop and full autonomy is not necessary. Instead, it could be that mappings may be learned to *supplement* a human's intuition regarding appropriate mappings, or that a set of learned mappings could be proposed and then one selected by a human. It would be worthwhile to define realistic scenarios when fully autonomous transfer will be necessary, or to instead specify how (limited) human interaction will be coupled with mapping-learning methods.

Lastly, we hope that the idea of task-invariant knowledge will be extended. Rather than learning an appropriate representation across tasks, agent-space (Konidaris and Barto, 2007) and RRL techniques attempt to discover knowledge about the agent or the agent's actions which can be directly reused in novel tasks. The better techniques can successfully compartmentalize knowledge, separating what will usefully transfer and what will not will not, the easier it will be to achieve successful transfer without having to un-learn irrelevant biases.

9.2 Negative Transfer

The majority of TL work in the literature has concentrated on showing that a particular transfer approach is plausible. None, to our knowledge, has a well-defined method for determining *when* an approach will fail according to one or more metrics. While we can say that it is possible to improve

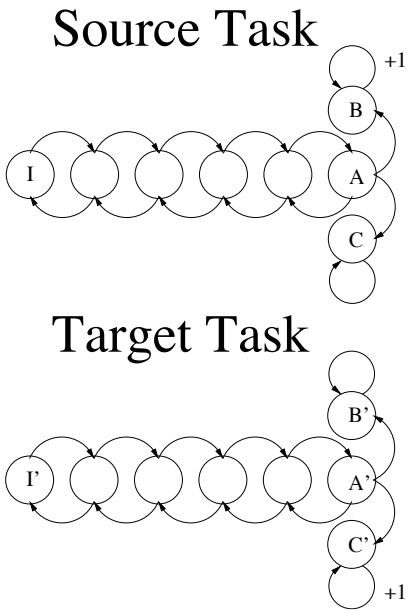

Figure 11: This figure depicts a pair of tasks that are likely to result in negative transfer for TL methods.

learning in a target task faster via transfer, we cannot currently decide if an arbitrary pair of tasks are appropriate for a given transfer method. Therefore, transfer may produce incorrect learning biases and result in negative transfer.

Methods such as MASTER (Taylor et al., 2008c), which can measure task similarity via model prediction error, or region transfer (Lazaric, 2008), which examines the similarity of tasks at a local level rather than at a per-task level, can help assist when deciding if the agent should transfer or what the agent should transfer. However, neither method provides any theoretical guarantees about its effectiveness.

As an example of why it is difficult to define a metric for task similarity, consider the pair of tasks shown in Figure 11, which are extremely similar, but where direct transfer of a policy or action-value function will be detrimental. The source task in Figure 11 (top) is deterministic and discrete. The agent begins in state I and has one action available: `East`. Other states in the "hallway" have two applicable actions: `East` and `West`, except for state A, which also has the actions `North` and `South`. Once the agent executes `North` or `South` in state A, it will remain in state B or C (respectively) and continue self-transitioning. No transition has a reward, except for the self-transition in state B.

Now consider the target task in Figure 11 (bottom), which is the same as the source task, except that the self-transition from C′ is the only rewarded transition in the MDP. $Q^\star$(I′,`East`) in the target task (the optimal action-value function, evaluated at the state I′) is the same as $Q^\star$(I, `East`) in the source task. Indeed, the optimal policy in the target task differs at only a single state, A′, and the optimal action-value functions differ only at states A′, B′, and C′.

One potential method for avoiding negative transfer is to leverage the ideas of *bisimulation* (Milner, 1982). Ferns et al. (2006) point out that:

> In the context of MDPs, bisimulation can roughly be described as the largest equivalence relation on the state space of an MDP that relates two states precisely when for every action, they achieve the same immediate reward and have the same probability of transitioning to classes of equivalent states. This means that bisimilar states lead to essentially the same long-term behavior.

However, bisimulation may be too strict because states are either equivalent or not, and may be slow to compute in practice. The work of Ferns et al. (2005, 2006) relaxes the idea of bisimulation to that of a (pseudo)metric that can be computed much faster, and gives a similarity measure, rather than a boolean. It is possible, although not yet shown, that bisimulation approximations can be used to discover regions of state space that can be transferred from one task to another, or to determine how similar two tasks are *in toto*. In addition to this, or perhaps because of it, there are currently no methods for automatically *constructing* a source task given a target task.[11]

Homomorphisms (Ravindran and Barto, 2002) are a different abstraction that can define transformations between MDPs based on transition and reward dynamics, similar in spirit to inter-task mappings, and have been used successfully for transfer (Soni and Singh, 2006). However, discovering homomorphisms is NP-hard (Ravindran and Barto, 2003a) and homomorphisms are generally supplied to a learner by an oracle. While these two theoretical frameworks may be able to help avoid negative transfer, or determine when two tasks are "transfer compatible," significant work needs to be done to determine if such approaches are feasible in practice, particularly if the agent is fully autonomous (i.e., is not provided domain knowledge by a human) and is not provided a full model of the MDP.

9.3 New Directions

As suggested above, TL in RL domains is one area of machine learning where the empirical work has outpaced the theoretical. While there has been some work on the theory of transfer between classification tasks (cf., Baxter, 2000; Ben-David and Borbely, 2008), such analyses do not directly apply to RL settings. To our knowledge, there is only a single work analyzing the theoretical properties of transfer in RL (Phillips, 2006), where the authors use the Kantorovich and full models of two MDPs to calculate how well an optimal policy in one task will perform in a second task. Unfortunately, this calculation of policy performance may require more computation than directly learning in the target task. There is considerable room, and need for, more theoretical work in RL (cf., Bowling and Veloso, 1999). For example:

1. Provides guarantees about whether a particular source task can improve learning in a target task (given a particular type of knowledge transfer).

2. Correlates the amount of knowledge transferred (e.g., the number of samples) with the improvement in the source task.

3. Defines what an optimal inter-task mapping is, and demonstrates how transfer efficacy is impacted by the inter-task mapping used.

11. We distinguish this idea from Sherstov and Stone's 2005 approach. Their paper shows it is possible to construct source task perturbations and then allow an agent to spend time learning the set of tasks to attempt to improve learning on an (unknown) source task. Instead, it may be more effective to tailor a source task to a specific target task, effectively enabling an agent to reduce the total number of environmental interactions needed to learn.

The remainder of this section suggests other open areas.

Concept drift (Widmer and Kubat, 1996) in RL has not been directly addressed by any work in this survey. The idea of concept drift is related to a non-stationary environment: at certain points in time, the environment may change arbitrarily. As Ramon et al. (2007) note, "for transfer learning, it is usually known when the context change takes place. For concept drift, this change is usually unannounced." Current on-line learning methods may be capable of handling such changes by continually learning. However, it is likely that RL methods developed specifically to converge to a policy and then re-start learning when the concept changes will achieve higher performance, whether such drift is announced or unannounced.

Another question no work in this survey directly addresses is how to determine the optimal amount of source task training to minimize the target task training time or total training time. If the source task and target task were identical, the goal of reducing the target task training time would be trivial (by maximizing the source task training time) and the goal of minimizing total training time would be impossible. On the other hand, if the source task and target task were unrelated, it would be impossible to reduce the target task training time through transfer and the total training time would be minimized by not training in the source task at all. It is likely that a calculation or heuristic for determining the optimal amount of source task training time will have to consider the structure of the two tasks, their relationship, and what transfer method is used. This optimization becomes even more difficult in the case of multi-step transfer, as there are two or more tasks that can be trained for different amounts of time.

Transfer methods in this survey have used source task knowledge in many forms to better learn in a target task. However, none explicitly account for scaling differences between the two tasks. For instance, if a source task measured distance in meters and the target task measured distance in inches, constants would have to be updated manually rather than learned.

Another question not addressed is how to best explore in a source task if the explicit purpose of the agent is to speed up learning in a target task. One could imagine that a non-standard learning or exploration strategy may produce better transfer results, relative to standard strategies. For instance, it may be better to explore more of the source task's state space than to learn an accurate action-value function for only part of the state space. While no current TL algorithms take such an approach, there has been some work on the question of learning a policy that is exploitable (without attempt to maximize the on-line reward accrued while learning) in non-transfer contexts (Şimşek and Barto, 2006).

Similarly, instead of always transferring information from the end of learning in the source task, an agent that knows its information will be used in a target task may decide to record information to transfer partway through training in the source task. For instance Taylor et al. (2007b) showed that transfer may be more effective when using policies trained for less time in the source task than when using those trained for more time. Although others have also observed similar behavior Mihalkova and Mooney (2008), the majority of work shows that increased performance in the source task is correlated with increased target task performance. Understanding how and why this effect occurs will help determine the most appropriate time to transfer information from one task to another.

We now present four possibilities for extending the current RL transfer work to different learning settings in which transfer has not been successfully applied.

- First, although two of the papers (Banerjee and Stone, 2007; Kuhlmann and Stone, 2007) in this survey have examined extensive games, none consider repeated normal form games or stochastic games (Shapley, 1953). For instance, one could consider learning how to play

against a set of opponents so that when a new opponent is introduced, the learner may quickly adapt one of its previous strategies rather than completely re-learning a strategy. Another option would be for an agent to learn how to play one game and then transfer the knowledge to a different stochastic game. Due to similarities between RL and these two game playing settings, transfer methods described in this survey may be applied with relatively little modification.

- A second possibility for extending transfer is into the realm of partially observable MDPs (POMDPs). It may possible to learn a source POMDP and then use knowledge gained to heuristically speed up planning in a target POMDP. Additionally, because it is typically assumed that POMDP planners are given a complete and accurate model of a task, it may be possible to analytically compare source and target tasks before learning in order to determine if transfer would be beneficial, and if so, how best to use the past knowledge.

- Third, multi-agent MDP and POMDP learners may also be able to successfully exploit transfer. None of the work surveyed in this article focuses on explicit multi-agent learning (i.e., learning over the joint action space, or in an (adaptive) adversarial setting, as in Stone and Veloso 2000), but it is likely existing methods may be extended to the cooperative multi-agent setting. For instance, when formulating a problem as an MMDP or DEC-MDP, the agents must either reason over a joint action space or explicitly reason about how their actions affect others. It may be possible for agents to learn over a subset of actions first, and then gradually add actions (or joint actions) over time, similar to transferring between tasks with different action sets. The need for such speedups is particularly critical in distributed POMDPs, as solving them optimally as been shown to be NEXP-Complete (Bernstein et al., 2002). Transfer is one possible approach to making such problems more tractable, but to our knowledge, no such methods have yet been proposed.

- Fourth, as mentioned in Section 3.3, MTL methods in RL consider a sequence of tasks that are drawn sequentially from the same distribution. However, in supervised learning, multi-task learning typically involves learning multiple tasks *simultaneously*. There may be contexts in which an agent must learn multiple tasks concurrently, such as in hierarchical RL or when the agent has multiple reward functions or goals. Fully specifying such a scenario, and extending MTL methods to encompass this setting, could bring additional tools to RL researchers and help move TL in RL closer to TL in classification.

Lastly, in order to better evaluate TL methods, it would be helpful to have a standard set of domains and metrics. Ideally there would be a domain-independent metric for transfer learning, but it is unclear that such a metric can exist (see Section 2). Furthermore, it is unclear what *optimal transfer* would mean, but would likely depend on the scenario considered. Classification and regression have long benefited from standard metrics, such as precision and recall, and it is likely that progress in transfer will be likewise enhanced once standard metrics are agreed upon.

Standard test sets, such as the Machine Learning Repository at the University of California, Irvine (Asuncion and Newman, 2007), have also assisted the growth and progress of supervised learning, but there are currently no equivalents for RL. Furthermore, while there are some standard data sets for for transfer learning in classification,[12] none exist for transfer in RL. While there is

12. Found at `http://multitask.cs.berkeley.edu`.

some work in the RL community to standardize on a common interface and set of benchmark tasks (Tanner et al., 2008; Whiteson et al., 2008), no such standardization has been proposed for the transfer learning in RL community. Even in the absence of such a framework, we suggest that it is important for authors working in this area to:

- Clearly specify the setting: Is the source task learning time discounted? What assumptions are made about the relationship between the source target and target task?
- Evaluate the algorithm with a number of metrics: No one metric captures all possible benefits from transfer.
- Empirically or theoretically compare the performance of novel algorithms: To better evaluate novel algorithms, existing algorithms should be compared using standard metrics on a single task task.[13]

As discussed in Section 2.1, we do not think that TL for RL methods can be strictly ordered in terms of efficacy, due to the many possible goals of transfer. However, by standardizing on reporting methodology, TL algorithms can be more easily compared, making it easier to select an appropriate method in a given experimental setting.

Our hope is that TL questions, such as those presented in this section, will be addressed in the near future; our expectation is that transfer learning will become an increasingly powerful tool for the machine learning community.

Acknowledgments

We would like to thank Cynthia Matuszek and the anonymous reviewers for helpful comments and suggestions over multiple revisions. This work has taken place in the Learning Agents Research Group (LARG) at the Artificial Intelligence Laboratory, The University of Texas at Austin. LARG research is supported in part by grants from the National Science Foundation (CNS-0615104), DARPA (FA8750-05-2-0283 and FA8650-08-C-7812), the Federal Highway Administration (DTFH61-07-H-00030), and General Motors.

13. One of the difficulties inherent in this proposal is that small variations in domain implementation may result in very different learning performances. While machine learning practitioners are able to report past results verbatim when using the same data set, many RL domains used in papers are not released. In order to compare with past work, RL researchers must reimplement, tune, and test past algorithms to compare with their algorithm on their domain implementation.

Abstract

We consider the problem of classification using high dimensional features' space. In a paper by Bickel and Levina (2004), it is recommended to use naive-Bayes classifiers, that is, to treat the features as if they are statistically independent.

Consider now a sparse setup, where only a few of the features are informative for classification. Fan and Fan (2008), suggested a variable selection and classification method, called FAIR. The FAIR method improves the design of naive-Bayes classifiers in sparse setups. The improvement is due to reducing the noise in estimating the features' means. This reduction is since that only the means of a few selected variables should be estimated.

We also consider the design of naive Bayes classifiers. We show that a good alternative to variable selection is estimation of the means through a certain non parametric empirical Bayes procedure. In sparse setups the empirical Bayes implicitly performs an efficient variable selection. It also adapts very well to non sparse setups, and has the advantage of making use of the information from many "weakly informative" variables, which variable selection type of classification procedures give up on using.

We compare our method with FAIR and other classification methods in simulation for sparse and non sparse setups, and in real data examples involving classification of normal versus malignant tissues based on microarray data.

Keywords: non parametric empirical Bayes, high dimension, classification

1. Introduction

We consider the problem of finding a classifier for a response variable $Y \in \{-1,1\}$ based on a vector $(X_1,...,X_p) \in \mathbb{R}^p$ of explanatory variables.

Suppose we have a 'training set' (or a sample) of n_1 examples $(Y_i,X_{i1},...,X_{ip})$, $i = 1,...,n_1$, for which $Y_i = -1$, and additional n_2 examples $(Y_i,X_{i1},...,X_{ip})$, $i = n_1+1,...,n_1+n_2$, for which $Y_i = 1$. We assume that the n_1+n_2 observations are independent. In what follows we assume for simplicity that $n_1 = n_2 \equiv n$.

Our study is aimed to understand and suggest a good classification procedure in a high dimensional setup. Here, by high dimensionality we mean $p \gg n$. There are many examples in

contemporary statistical applications where $p \gg n$. We mention that of microarray data where the dimensionality is typically of thousands, while the sample size is of the order of dozens or hundreds.

In particular we focus on linear predictors for Y, which are of the form:

$$\hat{Y} = \text{sign}\left(\sum_{j=1}^{p} a_j X_j + a_0\right),$$

where $a_0, a_1, ..., a_p$ are constants.

Suppose the distribution of the explanatory variables, conditional on $Y = -1$ and on $Y = 1$, is G_1 and G_2 correspondingly, where G_i are multivariate normals $i = 1, 2$. Assume that the covariance matrices of G_i, $i = 1, 2$ are the same. Then the optimal classifier is Fisher's rule. However when the common covariance matrix as well as the vectors of means under G_1 and G_2 are unknown, we can not apply Fisher's rule. When $n \gg p$, the naive approach, of estimating the unknown quantities and plug-in to Fisher's rule, would work well. It is impractical when $p \gg n$. A practical solution, called 'naive Bayes' is to neglect estimation of the off diagonal elements in the covariance matrix (or to estimate them trivially) by setting those values to be 0. Then apply Fisher's rule by plugging in the estimated diagonal covariance matrix and the estimated vectors of means. Bickel and Levina (2004) showed that in many cases, by this trivial estimation of the covariance matrix, one does not lose too much in terms of classification error, relative to incorporating the true covariance matrix, and suggested this practice. Note, the bottom line of this practice is to treat the explanatory variables as if they are independent, or act "assuming" independence of the explanatory variables. We will also refer in the sequel to Fisher's rule as the Independence Rule, or IR.

It was pointed out independently by Fan and Fan (2008) and by Greenshtein et al. (2009), that even in the independent case, when $p \gg n$, estimating the vector of means under G_1 and under G_2 by the corresponding sample averages, could lead to a very weak estimator, resulting in a corresponding classifier with virtually no classification power (see Theorem 1 in Fan and Fan 2008, and Proposition 1 of Greenshtein et al. 2009). This is also in cases where there exists a good linear classifier. In other words, often, attempting to estimate the $2p$ coordinates of the two mean vectors, by the corresponding averages of n observations on each, is already "too much", and leads to overfit. The FAIR approach suggested by Fan and Fan (2008), and the conditional MLE approach suggested by Greenshtein et al. (2009), are based on variable selection techniques followed by estimation of the mean of the selected explanatory variables, while ignoring the others (i.e., setting the corresponding coefficients of the linear classifier to be equal to zero). The FAIR method estimates the means of the selected variables by the corresponding sample means (the MLE), while the conditional MLE method estimates by the conditional MLE, conditional on the event that the variables were selected.

The above approaches are helpful especially in a high dimensional sparse setup, while the non parametric Empirical Bayes approach that we will present is helpful also in non-sparse setups. Let μ and τ be the vectors of means under G_1 and G_2 correspondingly; here 'sparse' setup means that the vector

$$\nu \equiv \mu - \tau$$

is sparse. A 'sparse' setup is such, that relatively few of the explanatory variables are informative for the classification.

1.1 On Types of Sparsity

The term sparse vector is only loosely defined in the literature, and we will keep some of the ambiguity. However, by a sparse vector ν we mean that most of its coordinates are *exactly* zero. Throughout our study we consider only vectors ν such that their l_2 norm $||\nu||$, is much smaller than their dimension, say, $||\nu|| = o(p)$. The last condition *does not* imply sparsity under our terminology.

We concentrate on configurations such that $||\nu|| = o(p)$, since that as $p \to \infty$, when letting $||\nu|| = O(p)$, any reasonable procedure would achieve asymptotically (virtually) zero misclassification rate. We are interested in the cases when there is not enough signal to make nearly perfect classification, that is, $p \gg ||\nu||$. In our simulation, we achieve $p \gg ||\nu||$, by considering the following three types of configurations for vectors $||\nu||$:

(a) Very few non-zero coordinates of a large/moderate magnitude (i.e., sparse vectors)

(b) Very few coordinates of a large magnitude, mixed with many very small coordinates (i.e., non-sparse vectors).

(c) Many coordinates of a very small magnitude (i.e., non-sparse vectors).

In sparse configurations, our EB procedure is comparable to the other procedures. Specifically, it is better in moderately sparse setups, while in extremely sparse cases, it is inferior. Indeed, when there are only a few relevant variables, naturally methods which are based on variable selection would do well. In non-sparse configurations our EB procedure is clearly advantageous in simulations. This is in line with the theoretical results in Brown and Greenshtein (2009), and in Jiang and Zhang (2007), on optimality of non-parametric empirical Bayes in estimation of high dimensional not extremely sparse normal mean vectors, coupled with the relation between estimation and classification as explained in Section 2.

The above mentioned results, join a huge body of literature on Empirical Bayes starting with Robbins (1951), see the surveys by Copas (1969) and by Zhang (2003). See also a recent paper by Greenshtein and Rotov (2009) on efficiency of compound and empirical Bayes procedures with respect to the class of permutation invariant procedures. A recent comprehensive study and performance comparison, of various methods for estimating a vector of normal means under squared error loss, was conducted by Brown (2008), the very good performance of non parametric empirical Bayes methods is demonstrated also there. Our approach is related to (and independent of) the approach in Efron (2009), where EB estimation method is used to obtain good classifiers.

We will introduce and explain the virtues of our empirical Bayes classification method and provide simulation evidence as well as real data evidence to its excellent performance. We will compare the performance of our Empirical Bayes classifiers to that of FAIR (Fan and Fan, 2008), conditional MLE (Greenshtein et al. , 2009), NSC (Tibshirani et al. , 2002), and plug in Fisher's rule.

The outline is the following. In the next section we introduce our formal setup and explain the relation between estimating a vector of means under a squared loss and classification. In Section 3 we introduce a class of non-parametric empirical Bayes estimators of a vector of normal means and define our classifier. In Section 4 we demonstrate the performance of our classifier on simulated as well as real data.

2. Preliminaries

Assume a multivariate normal distribution of the vector $(X_1,...,X_p)$ conditional on the value of Y. Specifically, we assume $(X_j|Y=-1) \sim N(\mu_j, s^2)$ and $(X_j|Y=1) \sim N(\tau_j, s^2)$ independently, $j=1,...,p$. We will assume that the variance s^2 is known. Denote $\mu=(\mu_1,...,\mu_p), \tau=(\tau_1,...,\tau_p)$.

In considering linear classifiers, when both p and n are large it is robust to assume normality of $(X_1,...,X_p)$ by the central limit theorem. Due to Lindberg's CLT, large p implies that $\sum a_j X_j$ will be close to normal, when a_j are comparable in size, even if the individual X_j are not normal. In addition, large n implies that averages of independent X_{ij}, $i=1,...,n$ (as in Z_j, which is defined in the sequel) are close to normal. The CLT arguments are problematic when the X_js have heavy tails. In Table 5 of Section 4 some simulations are carried to demonstrate the effect of heavy tailed distributions.

When searching for values $a \equiv (a_1,...,a_p)$ that determine a 'good' linear classifier, we assume w.l.o.g. that $\|a\|^2 = \sum_{j=1}^p a_j^2 = 1$. In this case the optimal choice of $(a_1,...,a_p)$ is the vector that maximizes $|\sum a_j\mu_j - \sum a_j\tau_j|$. Note that the optimal choice of $a_1,...,a_p$ is the same regardless of the misclassification loss (the value of a_0 does depend on the loss). In order to see it, observe that $\sum a_j X_j \sim N(\sum a_j\mu_j, s^2) \equiv N(\theta_1, s^2)$ conditional on $Y=-1$ and $\sum a_j X_j \sim N(\sum a_j\tau_j, s^2) \equiv N(\theta_2, s^2)$ conditional on $Y=1$; here $\theta_i, = 1,2$ are implicitly defined. Hence, an optimal choice of $a_1,...a_p$ is such that

$$V = V(a_1,...,a_n) \equiv |\sum_j a_j\mu_j - \sum_j a_j\tau_j| = |\theta_1 - \theta_2| \tag{1}$$

is maximized. This implies that the coordinates a_j^{opt} of the optimal choice satisfy:

$$a_j^{opt} = \frac{\nu_j}{\sqrt{\sum \nu_j^2}},\ j=1,...p; \tag{2}$$

recall $\nu_j = \mu_j - \tau_j$.

Under a 0-1 loss, given any choice of $(a_1,...,a_p)$, the corresponding minmax choice of a_0 is

$$a_0 = -\frac{\theta_2+\theta_1}{2}.$$

This is also the Bayes solution assuming a prior $\pi_i = 0.5$ for each class. The optimal choice of a_0 for none-equal losses and priors is straightforward.

A formal argument showing that the optimal $a_1,...,a_p$ is the same regardless of the misclassification loss may be obtained using the theory of comparison of experiments, implying that the experiment that consists of the distributions $N(\theta_1, s^2)$ and $N(\theta_2, s^2)$, dominates the experiment that consists of the distributions $N(\theta_1', s^2)$ and $N(\theta_2', s^2)$ if and only if $|\theta_1 - \theta_2| \geq |\theta_1' - \theta_2'|$. See Lehmann (1986, p. 86), for some basic theory on comparison of experiments and some additional references.

By the above discussion there is a natural order relation $\preceq$ between two classifiers determined by a and a'. We say that $a \preceq a'$ if for the corresponding θ_i and θ_i',

$$V = |\theta_1' - \theta_2'| \geq |\theta_1 - \theta_2| = V' \tag{3}$$

Note, here $V \equiv V(a_1,...,a_p)$, is a function of $(a_1,...,a_p)$.

By (2), $V(a_1^{opt},...,a_p^{opt}) = ||\nu||$, consequently for the optimal choice a_0^{opt}, the Bayes risk is:

$$\Phi(-\frac{||\nu||}{2s}) \tag{4}$$

where Φ is the cumulative distribution of a standard normal distribution.

2.1 Summary

The goal of finding the optimal classifier when $\nu_j,\ j=1,...,p$ are unknown, is not practical. However we want to find a classifier with a corresponding 'large' value of V.

Note, in statistical inference the choice of $a_j,\ j=1,...,p$ depends on the data. The dependence on the data is through the vector

$Z=(Z_1,...,Z_p)$; here, for $n=n_1=n_2$

$$Z_j=\frac{\sum_{i=1}^{n}X_{ij}}{n}-\frac{\sum_{i=n+1}^{2n}X_{ij}}{n},\ j=1,...,p, \tag{5}$$

are independent normal random variables with $EZ_j=\nu_j$ and variance, denoted σ^2,

$$\sigma^2=\frac{2s^2}{n}. \tag{6}$$

Thus, depending on the particular procedure the selected value of a_j depends on $Z_1,...,Z_p$, and it is a random variable denoted $\hat{a}_j,\ j=1,...,p$.

Equation (3), motivates us to search for procedures with high value of

$$E(V)=E|\sum_{j=1}^{p}\hat{a}_j\nu_j|.$$

Thus we extend the definition of the order relation, to apply to two statistical procedures $\{\hat{a}_j\},\ j=1,...,p$, and $\{\hat{a}'_j\},\ j=1,...,p$.

Definition 1: We say that $\{\hat{a}'_j\},\ j=1,...,p$, dominates $\{\hat{a}_j\},\ j=1,...,p$, if for the corresponding V' and V, $E(V')\geq E(V)$.

Remark 1: Evaluating a procedure $\hat{a}_j\ j=1,...,p$, by its corresponding value $E(V)$, is simplistic, for example, it ignores the effect of the standard deviation of V on the classification error. However, in high dimensional setup one might hope that the standard deviation of V is small compare to $E(V)$. Otherwise, one might perceive it as a convenient approximate evaluation. Note however, that for two procedures with very accurate classification rate, ignoring the variability of V might be significantly misleading even if $E(V)$ is large compare to the standard deviation of V, this is due to the thin tail of the normal distribution.

2.2 On the Relation Between Estimating the Mean Under a Squared Loss and Classification

Since the optimal choice of $a_j,\ j=1,...,p$, is $a_j^{opt}=\frac{\nu_j}{\sqrt{\sum\nu_j^2}}$, a natural way to proceed is to estimate ν_j by a 'good' estimator $\hat{\nu}_j$ for ν_j, and then plug-in, that is, let $\hat{a}_j=\frac{\hat{\nu}_j}{\sqrt{\sum\hat{\nu}_j^2}}$. A formal definition of 'good' in the above, depends on the loss function. In the sequel we will indicate why the squared error loss function is especially appropriate.

First we state the obvious. In general, the fact that $\hat{\nu}$ is a good estimator for ν under a squared error loss, does not indicate that $T(\hat{\nu})$ is a good estimator for $T(\nu)$ under (say) a squared loss. For example in the case $T(\nu)=\sum\nu_j$, plugging in the MLE for ν will often be better than plugging in the James-Stein estimator because of the bias of the J-S estimator which is accumulated. This is although the J-S estimator dominates the MLE in estimating ν under a squared error loss. Hence good properties of the Empirical Bayes as an estimator for ν under squared loss in high dimensions,

do not automatically indicate that it should be plugged-in in order to obtain good estimators for a_j^{opt}, and thus provide good classifiers.

Consider the collection of all vectors $(a_1,...,a_p)$ with l_2 norm 1. Define the function

$$L((a_1,...,a_p)) = \sum(\nu_j - a_j)^2$$

Then, one may check that on the surface of the p dimensional unit ball,

$$L(a) = -2 \times V(a) + C,$$

where $C = 1 + \sum \nu_j^2$, and V is defined in (1).

The last equation motivates the particular choice of a squared error loss when evaluating an estimator $\hat{\nu}_j$. This is because of the direct relation between minimizing $E(L)$ to that of maximizing $E(V)$. Maximizing V is crucial in obtaining a good classifier, as explained in the first part of this section.

An estimator with particularly appealing properties, in estimation of a vector of means under a squared loss in high dimensions, is the non-parametric empirical Bayes estimator, see Brown and Greenshtein (2009). We describe it in the following section and then define our procedure.

For a given ν the success in obtaining a good classifier has to do with two aspects. The larger is the l_2 norm of ν the smaller is the misclassification rate of the Bayes procedure, as may be seen in (4), and typically also the misclassification rate of our EB procedure. The more difficult is the task of estimating ν by our non parametric empirical Bayes method in terms of MSE, the less successful is our classification method. As pointed by a referee, the difficulty/MSE in estimating ν by EB is invariant under translation, while (obviously) the l_2 norm is not. When the vector ν is identically zero (i.e., no signal) the corresponding misclassification rate is 0.5. The corresponding rates for various translations of the zero-vector may be found in Table 4.

3. Empirical Bayes Classification

In this section, we define our linear classifier for the cases of known homoscedastic variances and unknown heteroscedastic variances.

3.1 Known Homoscedastic Variance

In the sequel we rescale X_j, so that Z_j defined in (5) will have variance $\sigma^2 = 1$, $j = 1,...,p$. This is possible since s, the common standard deviation of X_j, is known see (6). When the variances are unknown (and not assumed equal) we simply standardize the variables using the sample variance. The extension of this subsection for the latter case and for non equal samples n_1 and n_2 is explicitly given in the next subsection.

Under the non-parametric empirical Bayes approach for estimating a vector of means, we consider the means $\nu_i = E(Z_i)$, $i = 1,...,p$, as realizations of i.i.d random variables $M_1,...,M_p$ distributed G, where G is completely unknown. Still, we attempt to approximate the Bayes estimator of the mean, denoted $\delta^G(z)$, by $\hat{\delta}(z)$. Then we estimate ν_i by $\hat{\nu}_i = \hat{\delta}(Z_i)$.

More formally it is described in the following. Let $Z \sim N(M,1)$ where $M \sim G, G \in \mathcal{G}$. We want to emulate the Bayes procedure δ^G based on a sample $Z_1,...,Z_p$, $Z_i \sim N(M_i,1)$, $i = 1,...,p$, where $M_i \sim G$ and the Z_i are independent conditional on $M_1,...,M_p$, $i = 1,...,p$.

Let g^* be the mixture density

$$g^*(z) = \int \phi(z-\nu) dG(\nu).$$

Then from Brown (1971) equation (1.2.2), we have that the Bayes procedure, denoted δ^G, satisfies

$$\delta^G(z) = z + \frac{g^{*'}(z)}{g^*(z)};$$

here $g^{*'}(z)$ is the derivative of $g^*(z)$. The estimator that we suggest for δ^G, is of the form

$$\hat{\delta}_h(z) = z + \frac{\hat{g}_h^{*'}(z)}{\hat{g}_h^*(z)}$$

where $\hat{g}_h^{*'}(z)$ and $\hat{g}_h^*(z)$ are appropriate kernel estimators for the density $g^*(z)$ and its derivative $g^{*'}(z)$. The subscript h denotes the bandwidth of the kernel estimator. We will use a normal kernel.

Let $h > 0$ be a bandwidth constant. Then define the kernel estimator

$$\hat{g}_h^*(z) = \frac{1}{nh} \sum \phi(\frac{z - Z_i}{h}).$$

Its derivative is:

$$\hat{g}_h^{*'}(z) = \frac{1}{nh} \sum \frac{Z_i - z}{h} \times \phi(\frac{z - Z_i}{h}).$$

In Brown and Greenshtein (2009), it is suggested to let the bandwidth converge slowly to zero as $p \to \infty$, they suggested that h^2 should approach zero 'just faster' than $1/\log(p)$. In the simulations and real data analysis in this paper, we applied $h = 0.3 \approx 1/\sqrt{\log(p)}$, which is in agreement with that suggestion for the range of features' dimensions p that we study. The choice $h = 1/\sqrt{\log(p)}$ is also suggested in Brown and Greenshtein (2009) as a 'default' choice. A more careful choice could involve, for example, cross validation. However, the results are not too sensitive to the choice.

3.2 The Empirical Bayes Classifier

We now define our Empirical Bayes classifier.

Let

$$\hat{\nu}_i = \hat{\delta}_h(Z_i), \;\; i = 1, ..., p.$$

Let

$$\hat{a}_i = \frac{\hat{\nu}_i}{\sqrt{\sum_j \hat{\nu}_j^2}} \;\; i = 1, ..., p.$$

In order to fully define our classifier, we should still define the parameter $\hat{a}_0$, given $\hat{a}_1, ..., \hat{a}_p$. We do it for the case of 0-1 loss and equal prior probabilities for each class. An obvious way is the following. Let $\hat{\theta}_1 = \frac{1}{n} \sum_{i=1}^n \sum_{j=1}^p \hat{a}_j X_{ij}$, where the summation is over the n examples $(Y_i, X_{i1}, ..., X_{ip})$ for which $Y_i = -1$. Similarly define $\hat{\theta}_2$.

Let,

$$\hat{a}_0 = -\frac{\hat{\theta}_2 + \hat{\theta}_1}{2}.$$

where we assume w.l.o.g. that $\hat{\theta}_1 < \hat{\theta}_2$.

3.3 Unknown Heteroscedastic Variances

Consider now the case where the standard deviation, denoted s_j, of X_j are unknown $j = 1,...,p$. We now introduce a superscript $k = 1,2$ to denote quantities associated with the data corresponding to $Y = -1$ and $Y = 1$. Denote by $\hat{s}_j^k$ the usual estimates of the standard deviation of X_j^k. The estimates are based on the corresponding X_{ij}^k, $k = 1,2$, $i = 1,...,n_k$, $j = 1,...,p$. Denote $\bar{X}_j^1$ and $\bar{X}_j^2$ the corresponding means.

Let

$$\hat{S}_j = \sqrt{\frac{(\hat{s}_j^1)^2}{n_1} + \frac{(\hat{s}_j^2)^2}{n_2}},$$

thus $\hat{S}_j$ is our estimator for the standard deviation of $\bar{X}_j^1 - \bar{X}_j^2$.

Let

$$Z_j = \frac{\bar{X}_j^1 - \bar{X}_j^2}{\hat{S}_j};$$

note, we expect that the variance of Z_j is approximately 1, $j = 1,...,p$.

As before let $\hat{\nu}_i$ be the empirical Bayes estimators of $E(Z_i)$, and let $\hat{a}_i = \frac{\hat{\nu}_i}{\sqrt{\sum_j \hat{\nu}_j^2}}$, $i = 1,...,p$.

In the following we proceed in terms of the variables

$$U_j = \frac{X_j}{\hat{S}_j} \quad j = 1,...,p.$$

We will represent our linear classifiers as linear functions of U_j, $j = 1,...,p$.

Let

$$\hat{\theta}_k = \frac{1}{n_k} \sum_{i=1}^{n_k} \sum_{j=1}^{p} \hat{a}_j U_{ij}^k, \; k = 1,2.$$

Let

$$\hat{a}_0 = -\frac{\hat{\theta}_2 + \hat{\theta}_1}{2}.$$

Finally, our classifier is:

$$\text{sign}(\sum_{j=1}^{p} \hat{a}_j U_j + \hat{a}_0).$$

4. Simulations and Data Analysis

In this section, we present numerical studies including simulations and application to three sets of real data.

4.1 Simulations

The simulation study in this subsection is based on the procedure described in Section 3.1. We present simulations for $p = 10^5$ and for $p = 10^4$, under various configurations in which $\tau_j = 0$, $j = 1,...,p$. We study sparse configurations where for l variables the corresponding mean is fixed $\nu_j = \Delta$, while the remaining $p - l$ variables have $\nu_j = 0$, $p \gg l$. We also study a non-sparse version of the above where the remaining $p - l$ variables have means ν_j which are randomly selected from

$N(0,0.1^2)$. The small variance of the normal distribution is in order to control the magnitude of $||\nu||$; recall from the introduction, we want $p \gg ||\nu||$. Thus a configuration is determined by (Δ, l), the corresponding p, and whether the $p-l$ coordinates, whose means are not equal to Δ, are set to be equal to zero or, alternatively get their values randomly based on a $N(0,0.1^2)$ distribution.

We consider the case where $n = 25$, and a rescale under which the variance of Z_j is $\sigma^2 = 1$, $j = 1,...,p$. Thus, the variance of X_j is $s^2 = 25/2$, and the same for the variance of $\sum a_j X_j$, when $\sum a_j^2 = 1$. The distribution X_j is normal throughout this section, except for the simulations reported in Table 5. In Table 5 the effect of a heavy tailed distribution variables X_j is studied.

Table 1 shows the misclassification rates of the empirical Bayes, conditional MLE, FAIR, and the plug in Fisher's rule which is also termed IR (Independence Rule). The plug in Fisher's refers to plugging in Z_j for ν_j, $j = 1,...,p$, in Fisher's rule. We see that the empirical Bayes approach produces the best results for non-sparse and for moderately sparse configurations. The CMLE is better for strongly sparse configurations. The version of FAIR we are using is described in Theorem 4 of Fan and Fan (2008). It performs similar to IR, since it selects too many variables. Fan and Fan (2008) describe another version of FAIR in their equation (4.3), this other version screens variables more aggressively and involves computation of eigenvalues of the empirical covariance matrix. That more aggressive version might perform better in our simulation, yet it is motivated for cases where it is not known that the covariance matrix is of the form $\sigma^2 I$ (which is used in most of our simulations). In addition, computing eigenvalues for empirical covariance matrix with $p = 10^5$ is computationally intensive. In the real data analysis, with unknown covariance matrix, the other version of FAIR is used.

Each entry is based on simulated $Z_1,...,Z_p$, and on calculating the exact theoretical misclassification rate. Note, given the estimators $\hat{a}_j$ $j = 0,1,...,p$, for a given simulated realization, the theoretical misclassification error, under equal prior probability for each class, is $\frac{1}{2}\Phi((-\sum_{j=1}^{p}\hat{a}_j\mu_j - \hat{a}_0)/s) + \frac{1}{2}(1-\Phi((-\sum_{j=1}^{p}\hat{a}_j\tau_j - \hat{a}_0))/s)$.

In order to demonstrate the effect of dependence and to compare the methods for correlated variables, we also consider correlated normal variables where the correlation of X_i and X_j, namely ρ_{ij}, has the form of $\rho^{|i-j|}$ known as AR(1) model. Here, the corresponding misclassification probabilities are $\frac{1}{2}\Phi((-\sum_{j=1}^{p}\hat{a}_j\mu_j - \hat{a}_0)/\sqrt{\hat{\mathbf{a}}'S\hat{\mathbf{a}}}) + \frac{1}{2}(1-\Phi((-\sum_{j=1}^{p}\hat{a}_j\tau_j - \hat{a}_0))/\sqrt{\hat{\mathbf{a}}'S\hat{\mathbf{a}}})$, for the appropriate covariance matrix S.

Table 2 presents misclassification rates under different values of ρ. The empirical Bayes still achieves the lowest error rates for all those non-sparse configurations. The reported entries are averages of the 100 error rates corresponding to 100 realizations and corresponding estimators $\hat{a}_j$ for the particular configuration (Δ, l) or $(\Delta_1, l_1, \Delta_2, l_2)$ where $(\Delta_1, l_1, \Delta_2, l_2)$ means that l_1 and l_2 coordinates in ν are all valued Δ_1 and Δ_2 correspondingly, while the remaining entries are all zero.

In Table 3 we present simulation results under the following correlation structure which is much heavier than that of AR(1). We consider correlations $corr(X_i, X_j) = \rho_{ij} = \alpha_i\alpha_j$ for $i \neq j$ which is easily implemented by letting $X_i = \tau_i(\text{or } \mu_i) + \sqrt{1-\alpha_i^2}W_i + \alpha_i U$ where W_i's $1 \leq i \leq p$ and U are generated independently from $N(0,s^2)$. In our simulations, all $\alpha_i's$ are generated from $U(-a,a)$ where $a = 0.3, 0.5, 0.7$ and 0.9 are considered. As a increases, variables are more correlated. Table 3 shows misclassification probabilities for configurations of (Δ, l) or $(\Delta_1, l_1, \Delta_2, l_2)$ as in Table 2.

In general the effect of correlation (especially heavy positive correlation) on the EB classification method is stronger than on the other methods. This is partially because the EB uses more

Table 1: Misclassification error rates by Empirical Bayes, conditional MLE (Greenshtein et al. 2009), FAIR (Fan and Fan 2008) and Fisher's rule (i.e., without variable selection)) . Error rate with * represents minimum error rate in the row for the corresponding configuration.

variables, so more correlations are in effect, relative to variable selection methods that screen variables and consequently their correlations do not effect.

In Table 4, we compare the above mentioned procedures in non sparse setups where there are many small signals. In all the configurations there is 'enough overall signal' to make virtually no classification error if μ and τ were known. In those configurations the optimal (unknown) linear classifiers uses most (or all) of the variables. However, attempting to estimate the corresponding means by FAIR or Fisher's plug-in and the Conditional MLE methods yield poor classifiers, while the non parametric empirical Bayes method yields classifiers with excellent performance in some cases.

In Table 5, we present simulation studies for X_js with a heavy tailed distribution. As before $n_1 = n_2 = 25$. Under G_1 the distribution of X_j is $c \times t(3)$ (i.e., t with 3 degrees of freedom), $j = 1,...,p$ where c is chosen so that the variance of X_j is $s^2 = 25/2$. Under G_2 the distribution of X_j is $\nu_j + c \times X_j$, where X_j is distributed $t(3)$, $j = 1,...,p$. Thus, the corresponding Z_j has variance 1 and it is only approximately normal. We study the configurations $(\Delta, l) = (1,2000), (2.5,100), (3.5,50)$ and $(4,40)$, which were also studied in Table 1. The misclassification rates are obtained based on test sets of size $1000, 500$ from each G_i, $i = 1,2$. As seen in Table 5, the EB method and CMLE still

produce smaller error rates compared to FAIR and IR. However, compared to the results in Table 1, the EB method and CMLE have a worst performance which is caused by some sensitivity to the heavy tailed distribution of the X_js.

Summary: The most important advantage of the EB classifier, demonstrated in the above simulations, is its ability to use the information provided by many small signals in order to improve the classification. This is unlike variable-selection type of classifiers, that give up on using the information from variables with small ν_j, in order to reduce the variability in estimation. This advantage is not on the expanse of being a good classifier also under moderately sparse configurations.

4.2 Real Data Analysis

The following analysis of real date sets is based on the procedure described in Section 3.2. We consider three real data sets and compare the empirical Bayes approach with nearest centroid shrunken (henceforth NSC), and FAIR. The NSC was proposed by Tibshirani et al. (2002). The three data sets were studied by Fan and Fan (2008), and all the misclassification rates, other than that of the empirical Bayes method, are cited from that paper.

The first example is of a leukemia data set, which was previously analyzed in Golub et al. (1999). The data set can be obtained in `http://www.broad.mit.edu/cgi-bin/cancer/datasets.cgi`. There are $p = 7129$ genes and 72 samples generated from two classes, ALL (acute lymphocytic leukemia) and AML (acute mylogenous leukemia). Among the 72 samples, the training data

Table 3: Dependent case II : $Corr(X_i, X_j) = \rho_{ij} = \alpha_i \alpha_j$ for $i \neq j$ where α_i and α_j are generated from $Unif(-a, a)$ for $a = 0.3, 0.5, 0.7$ and 0.9. $(\Delta_1, l_1, \Delta_2, l_2)$ represents l_1 and l_2 coordinates in ν are Δ_1 and Δ_2 respectively.

set has 38 ($n_1 = 27$ in ALL and $n_2 = 11$ in AML) and the test data set has 34 (20 in ALL and 14 in AML). Table 6 shows the results of the nearest shrunken centroid, FAIR, and empirical Bayes methods.

The empirical Bayes approach misclassified 3 out of 34 test samples which is the same result as NSC, but slightly worse than FAIR. Figure 1 shows histograms of $\sum_j \hat{a}_j U_j$ corresponding to the two groups, under the training and under the test sets.

The second example is of lung cancer data which were previously analyzed by Gordon et al. (2002) and analyzed using FAIR in Fan and Fan (2008). The data is available at `http://www.chestsurg.org`. There are $p = 12533$ genes and 181 samples coming from two classes, MPM(malignant pleural mesothelioma) and ADCA(adenocarcinoma). The training sample set consists of 32 samples($n_1 = 16$ from MPM and $n_2 = 16$ from ADCA) and the test has 149 samples (15 from MPM and 134 from ADCA). As displayed in Table 7, the empirical Bayes method classified all the training samples correctly and 148 out of 149 test samples correctly, which is a significant improvement compared to NSC and FAIR. In Figure 2, we show histograms of $\sum \hat{a}_j U_j$ under the two groups, for the training and for the test sets.

The last example is of prostate cancer data studied by Singh et al. (2002), which is available at `http://www.broad.mit.edu/cgi-bin/cancer/datasets.cgi`. The training data set has 102 samples, $n_1 = 52$ of which are prostate tumor samples and $n_2 = 50$ of which are normal samples. An

Two panels in the first columns are histograms for normal and tumor from training sets and two in the second columns are for normal and tumor from test sets. Red vertical lines in all histograms represent cut off value which is $-a_0 = (\hat{\theta}_{normal} + \hat{\theta}_{tumor})/2 = 213.68$.

independent test data set, from a different experiment, has 25 tumor and 9 normal samples. There are $p = 12600$ genes.

As displayed in Table 8, for the prostate cancer data, the empirical Bayes approach has a very large training error compared to NSC and FAIR, but the test error is smaller than both NSC and FAIR. The *pessimism* of the misclassification error, reflected by our training set, may be attributed to two facts. One is the difference in the proportion of tumor and normal samples in the training versus the test set. The other reason is that the test set seems to be less noisy. It seems that the empirical Bayes method succeed in estimating ν_j and hence deriving good coefficients $\hat{a}_j$ from the large training data although it is noisy; yet, the classification of the individual data points of the noisy training set is still difficult, while the classification is easier for the test set data points. Figure 3 might be helpful in assessing it. In the histograms of $\sum_j \hat{a}_j U_j$ corresponding to the normal and tumor groups from the training data, we may see that the two training sets look noisier.

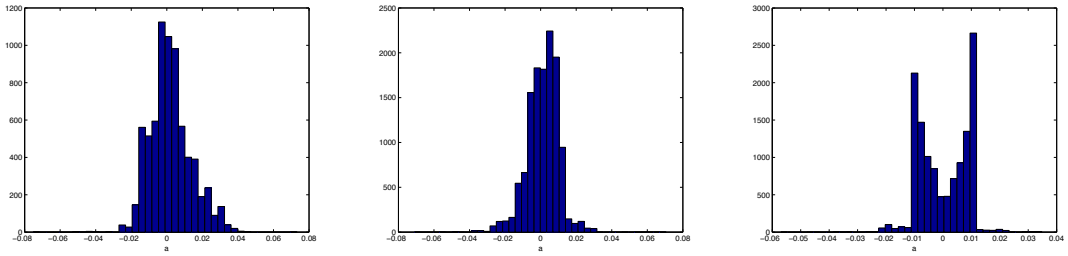

Figure 4: Histograms of $\hat{a}_j$, $j = 1, ..., p$, for the leukemia, lung cancer, and prostate cancer data sets.

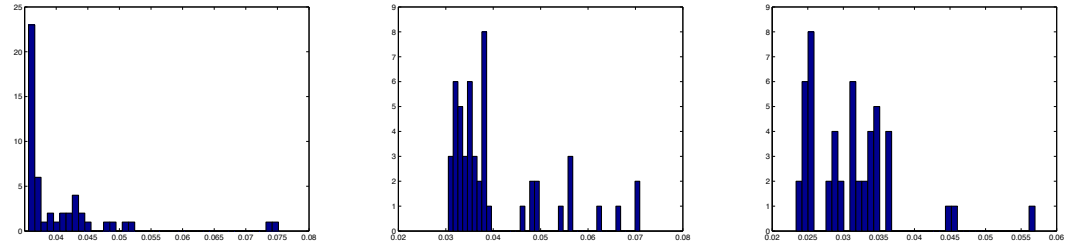

Figure 5: Histograms of the first 50 largest $|\hat{a}_j|$ for the leukemia, lung cancer, and prostate cancer data sets.

4.3 Number of Selected Variables

Figure 4 shows the histograms of $\hat{a}_j$, $j = 1, ..., p$ for each data set. In Figure 5 we see three histograms corresponding to the fifty largest $|\hat{a}_j|$, $j = 1, ..., p$, in each of the three data sets. Our empirical Bayes method uses many variables for the classification. In fact, formally it uses all the variables, since none of the $\hat{a}_j$ is exactly 0. In comparison the FAIR uses 11, 31, and 2 variables corresponding to the above three cases in the order they presented, while the NSC uses 21, 26, 6.

Obviously a method which is based on a few variables is easy to implement and to interpret. Our suggested classifiers are meant only to produce good classification and thus use many variables if necessary. Using many variables and somewhat complicated classifiers is in the spirit of data mining approach. However, selecting a subset of variables following an empirical Bayes estimation of the means, makes much sense, for producing simpler classifiers. It might even reduce noise and will produce over all better classifiers.

Acknowledgments

We are grateful to Yingying Fan for providing us some of the data analyzed in Fan and Fan (2008). We also thanks the AE and three reviewers for helpful comments for improvement of the paper.

Abstract

We give an algorithm for the on-line learning of permutations. The algorithm maintains its uncertainty about the target permutation as a doubly stochastic weight matrix, and makes predictions using an efficient method for decomposing the weight matrix into a convex combination of permutations. The weight matrix is updated by multiplying the current matrix entries by exponential factors, and an iterative procedure is needed to restore double stochasticity. Even though the result of this procedure does not have a closed form, a new analysis approach allows us to prove an optimal (up to small constant factors) bound on the regret of our algorithm. This regret bound is significantly better than that of either Kalai and Vempala's more efficient Follow the Perturbed Leader algorithm or the computationally expensive method of explicitly representing each permutation as an expert.

Keywords: permutation, ranking, on-line learning, Hedge algorithm, doubly stochastic matrix, relative entropy projection, Sinkhorn balancing

1. Introduction

Finding a good permutation is a key aspect of many problems such as the ranking of search results or matching workers to tasks. In this paper we present an efficient and effective on-line algorithm for learning permutations in a model related to the on-line allocation model of learning with experts (Freund and Schapire, 1997). In each trial, the algorithm probabilistically chooses a permutation and then incurs a linear loss based on how appropriate the permutation was for that trial. The *regret* is the total expected loss of the algorithm on the whole sequence of trials minus the total loss of the best permutation chosen in hindsight for the whole sequence, and the goal is to find algorithms that have provably small worst-case regret.

For example, one could consider a commuter airline which owns n airplanes of various sizes and flies n routes.[1] Each day the airline must match airplanes to routes. If too small an airplane is assigned to a route then the airline will loose revenue and reputation due to unserved potential passengers. On the other hand, if too large an airplane is used on a long route then the airline could have larger than necessary fuel costs. If the number of passengers wanting each flight were known ahead of time, then choosing an assignment is a weighted matching problem. In the on-line

*. An earlier version of this paper appears in *Proceedings of the Twentieth Annual Conference on Computational Learning Theory* (COLT 2007), published by Springer as LNAI 4539.
†. Manfred K. Warmuth acknowledges the support of NSF grant IIS 0325363.
1. We assume that each route starts and ends at the airline's home airport.

allocation model, the airline first chooses a distribution over possible assignments of airplanes to routes and then randomly selects an assignment from the distribution. The *regret* of the airline is the earnings of the single best assignment for the whole sequence of passenger requests minus the total expected earnings of the on-line assignments. When airplanes and routes are each numbered from 1 to n, then an assignment is equivalent to selecting a permutation. The randomness helps protect the on-line algorithm from adversaries and allows one to prove good bounds on the algorithm's regret for arbitrary sequences of requests.

Since there are $n!$ permutations on n elements, it is infeasible to simply treat each permutation as an expert and apply one of the expert algorithms that uses exponential weights. Previous work has exploited the combinatorial structure of other large sets of experts to create efficient algorithms (see Helmbold and Schapire, 1997; Takimoto and Warmuth, 2003; Warmuth and Kuzmin, 2008, for examples). Our solution is to make a simplifying assumption on the loss function which allows the new algorithm, called PermELearn, to maintain a sufficient amount of information about the distribution over $n!$ permutations while using only n^2 weights.

We represent a permutation of n elements as an $n \times n$ *permutation matrix* Π where $\Pi_{i,j} = 1$ if the permutation maps element i to position j and $\Pi_{i,j} = 0$ otherwise. As the algorithm randomly selects a permutation $\widehat{\Pi}$ at the beginning of a trial, an adversary simultaneously selects an arbitrary *loss matrix* $L \in [0,1]^{n \times n}$ which specifies the loss of all permutations for the trial. Each entry $L_{i,j}$ of the loss matrix gives the loss for mapping element i to j, and the loss of any whole permutation is the sum of the losses of the permutation's mappings, that is, the loss of permutation Π is $\sum_i L_{i,\Pi(i)} = \sum_{i,j} \Pi_{i,j} L_{i,j}$. Note that the per-trial expected losses can be as large as n, as opposed to the common assumption for the expert setting that the losses are bounded in $[0,1]$. In Section 3 we show how a variety of intuitive loss motifs can be expressed in this matrix form.

This assumption that the loss has a linear matrix form ensures the expected loss of the algorithm can be expressed as $\sum_{i,j} W_{i,j} L_{i,j}$, where $W = \mathbb{E}(\widehat{\Pi})$. This expectation W is an $n \times n$ *weight matrix* which is *doubly stochastic*, that is, it has non-negative entries and the property that every row and column sums to 1. The algorithm's uncertainty about which permutation is the target is summarized by W; each weight $W_{i,j}$ is the probability that the algorithm predicts with a permutation mapping element i to position j. It is worth emphasizing that the W matrix is only a *summary* of the distribution over permutations used by any algorithm (it doesn't indicate which permutations have non-zero probability, for example). However, this summary is *sufficient* to determine the algorithm's expected loss when the losses of permutations have the assumed loss matrix form.

Our PermELearn algorithm stores the weight matrix W and must convert W into an efficiently sampled distribution over permutations in order to make predictions. By Birkhoff's Theorem, every doubly stochastic matrix can be expressed as the convex combination of at most $n^2 - 2n + 2$ permutations (see, e.g., Bhatia, 1997). In Appendix A we show that a greedy matching-based algorithm efficiently decomposes any doubly stochastic matrix into a convex combination of at most $n^2 - 2n + 2$ permutations. Although the efficacy of this algorithm is implied by standard dimensionality arguments, we give a new combinatorial proof that provides independent insight as to why the algorithm finds a convex combination matching Birkhoff's bound. Our algorithm for learning permutations predicts with a random $\widehat{\Pi}$ sampled from the convex combination of permutations created by decomposing weight matrix W. It has been applied recently for pricing combinatorial markets when the outcomes are permutations of objects (Chen et al., 2008).

The PermELearn algorithm updates the entries of its weight matrix using exponential factors commonly used for updating the weights of experts in on-line learning algorithms (Littlestone and

Warmuth, 1994; Vovk, 1990; Freund and Schapire, 1997): each entry $W_{i,j}$ is multiplied by a factor $e^{-\eta L_{i,j}}$. Here η is a positive learning rate that controls the "strength" of the update (When $\eta = 0$, than all the factors are one and the update is vacuous). After this update, the weight matrix no longer has the doubly stochastic property, and the weight matrix must be projected back into the space of doubly stochastic matrices (called "Sinkhorn balancing", see Section 4) before the next prediction can be made.

In Theorem 4 we bound the expected loss of PermELearn over any sequence of trials by

$$\frac{n \ln n + \eta \mathcal{L}_{\text{best}}}{1 - e^{-\eta}}, \tag{1}$$

where n is the number of elements being permuted, η is the learning rate, and $\mathcal{L}_{\text{best}}$ is the loss of the best permutation on the entire sequence. If an upper bound $\mathcal{L}_{\text{est}} \geq \mathcal{L}_{\text{best}}$ is known, then η can be tuned (as in Freund and Schapire, 1997) and the expected loss bound becomes

$$\mathcal{L}_{\text{best}} + \sqrt{2\mathcal{L}_{\text{est}} n \ln n} + n \ln n, \tag{2}$$

giving a bound of $\sqrt{2\mathcal{L}_{\text{est}} n \ln n} + n \ln n$ on the worst case expected regret of the tuned PermELearn algorithm. We also prove a matching lower bound (Theorem 6) of $\Omega(\sqrt{\mathcal{L}_{\text{best}} n \ln n})$ for the expected regret of any algorithm solving our permutation learning problem.

A simpler and more efficient algorithm than PermELearn maintains the sum of the loss matrices on the the previous trials. Each trial it adds random perturbations to the cumulative loss matrix and then predicts with the permutation having minimum perturbed loss. This "Follow the Perturbed Leader" algorithm (Kalai and Vempala, 2005) has good regret bounds for many on-line learning settings. However, the regret bound we can obtain for it in the permutation setting is about a factor of n worse than the bound for PermELearn and the lower bound.

Although computationally expensive, one can also consider running the Hedge algorithm while explicitly representing each of the $n!$ permutations as an expert. If T is the sum of the loss matrices over the past trials and F is the $n \times n$ matrix with entries $F_{i,j} = e^{-\eta T_{i,j}}$, then the weight of each permutation expert Π is proportional to the product $\prod_i F_{i,\Pi(i)}$ and the normalization constant is the permanent of the matrix F. Calculating the permanent is a known #P-complete problem and sampling from this distribution over permutations is very inefficient (Jerrum et al., 2004). Moreover since the loss range of a permutation is $[0, n]$, the standard loss bound for the algorithm that uses one expert per permutation must be scaled up by a factor of n, becoming

$$\mathcal{L}_{\text{best}} + n\sqrt{2\frac{\mathcal{L}_{\text{est}}}{n} \ln(n!)} + n \ln(n!) \approx \mathcal{L}_{\text{best}} + \sqrt{2\mathcal{L}_{\text{est}} n^2 \ln n} + n^2 \ln n.$$

This expected loss bound is similar to our expected loss bound for PermELearn in Equation (2), except that the $n \ln n$ terms are replaced by $n^2 \ln n$. Our method based on Sinkhorn balancing bypasses the estimation of permanents and somehow PermELearn's implicit representation and prediction method exploit the structure of permutations and lets us obtain the improved bound. We also give a matching lower bound that shows PermELearn has the optimum regret bound (up to a small constant factor). It is an interesting open question whether the structure of permutations can be exploited to prove bounds like (2) for the Hedge algorithm with one expert per permutation.

PermELearn's weight updates belong to the Exponentiated Gradient family of updates (Kivinen and Warmuth, 1997) since the components $L_{i,j}$ of the loss matrix that appear in the exponential

factor are the derivatives of our linear loss with respect to the weights $W_{i,j}$. This family of updates usually maintains a probability vector as its weight vector. In that case the normalization of the weight vector is straightforward and is folded directly into the update formula. Our new algorithm PermELearn for learning permutations maintains a doubly stochastic matrix with n^2 weights. The normalization alternately normalizes the rows and columns of the matrix until convergence (Sinkhorn balancing). This may require an unbounded number of steps and the resulting matrix does not have a closed form. Despite this fact, we are able to prove bounds for our algorithm.

We first show that our update minimizes a tradeoff between the loss and a relative entropy between doubly stochastic matrices. This relative entropy becomes our measure of progress in the analysis. Luckily, the un-normalized multiplicative update already makes enough progress (towards the best permutation) to achieve the loss bound quoted above. Finally, we interpret the iterations of Sinkhorn balancing as Bregman projections with respect to the same relative entropy and show using the properties of Bregman projections that these projections can only increase the progress and thus don't hurt the analysis (Herbster and Warmuth, 2001).

Our new insight of splitting the update into an un-normalized step followed by a normalization step also leads to a streamlined proof of the loss bound for the Hedge algorithm in the standard expert setting that is interesting in its own right. Since the loss in the allocation setting is linear, the bounds can be proven in many different ways, including potential based methods (see, e.g., Kivinen and Warmuth, 1999; Gordon, 2006; Cesa-Bianchi and Lugosi, 2006). For the sake of completeness we reprove our main loss bound for PermELearn using potential based methods in Appendix B. We show how potential based proof methods can be extended to handle linear equality constraints that don't have a solution in closed form, paralleling a related extension to linear *in*equality constraints in Kuzmin and Warmuth (2007). In this appendix we also discuss the relationship between the projection and potential based proof methods. In particular, we show how the Bregman projection step corresponds to plugging in suboptimal dual variables into the potential.

The remainder of the paper is organized as follows. We introduce our notation in the next section. Section 3 presents the permutation learning model and gives several intuitive examples of appropriate loss motifs. Section 4 gives the PermELearn algorithm and discusses its computational requirements. One part of the algorithm is to decompose the current doubly stochastic matrix into a small convex combination of permutations using a greedy algorithm. The bound on the number of permutations needed to decompose the weight matrix is deferred to Appendix A. We then bound PermELearn's regret in Section 5 in a two-step analysis that uses a relative entropy as a measure of progress. To exemplify the new techniques, we also analyze the basic Hedge algorithm with the same methodology. The regret bounds for Hedge and PermELearn are re-proven in Appendix B using potential based methods. In Section 6, we apply the "Follow the Perturbed Leader" algorithm to learning permutations and show that the resulting regret bounds are not as good. In Section 7 we prove a lower bound on the regret when learning permutations that is within a small constant factor of our regret bound on the tuned PermELearn algorithm. The concluding section describes extensions and directions for further work.

2. Notation

All matrices will be $n \times n$ matrices. When A is a matrix, $A_{i,j}$ denotes the entry of A in row i, and column j. We use $A \bullet B$ to denote the dot product between matrices A and B, that is, $\sum_{i,j} A_{i,j} B_{i,j}$. We use single superscripts (e.g., A^k) to identify matrices/permutations from a sequence.

Permutations on n elements are frequently represented in two ways: as a bijective mapping of the elements $\{1,\ldots,n\}$ into the positions $\{1,\ldots,n\}$ or as a permutation matrix which is an $n \times n$ binary matrix with exactly one "1" in each row and each column. We use the notation Π (and $\widehat{\Pi}$) to represent a permutation in either format, using the context to indicate the appropriate representation. Thus, for each $i \in \{1,\ldots,n\}$, we use $\Pi(i)$ to denote the position that the ith element is mapped to by permutation Π, and matrix element $\Pi_{i,j} = 1$ if $\Pi(i) = j$ and 0 otherwise.

If L is a matrix with n rows then the product ΠL permutes the rows of L:

$$\underset{\text{perm. } (2,4,3,1) \text{ as matrix}}{\Pi = \begin{pmatrix} 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 1 & 0 \\ 1 & 0 & 0 & 0 \end{pmatrix}} \qquad \underset{\text{an arbitrary matrix}}{L = \begin{pmatrix} 11 & 12 & 13 & 14 \\ 21 & 22 & 23 & 24 \\ 31 & 32 & 33 & 34 \\ 41 & 42 & 43 & 44 \end{pmatrix}} \qquad \underset{\text{permuting the rows}}{\Pi L = \begin{pmatrix} 21 & 22 & 23 & 24 \\ 41 & 42 & 43 & 44 \\ 31 & 32 & 33 & 34 \\ 11 & 12 & 13 & 14 \end{pmatrix}}.$$

Convex combinations of permutations create *doubly stochastic* or *balanced* matrices: non-negative matrices whose n rows and n columns each sum to one. Our algorithm maintains its uncertainty about which permutation is best as a doubly stochastic weight matrix W and needs to randomly select a permutation from some distribution whose expectation is W. By Birkhoff's Theorem (see, e.g., Bhatia, 1997), for every doubly stochastic matrix W there is a decomposition into a convex combination of at most $n^2 - 2n + 2$ permutation matrices. We show in Appendix A how a decomposition of this size can be found effectively. This decomposition gives a distribution over permutations whose expectation is W that now can be effectively sampled because its support is at most $n^2 - 2n + 2$ permutations.

3. On-line Protocol

We are interested in learning permutations in a model related to the on-line allocation model of learning with experts (Freund and Schapire, 1997). In that model there are N experts and at the beginning of each trial the algorithm allocates a probability distribution w over the experts. The algorithm picks expert i with probability w_i and then receives a loss vector $\ell \in [0,1]^N$. Each expert i incurs loss ℓ_i and the expected loss of the algorithm is $w \cdot \ell$. Finally, the algorithm updates its distribution w for the next trial.

In case of permutations we could have one expert per permutation and allocate a distribution over the $n!$ permutations. Explicitly tracking this distribution is computationally expensive, even for moderate n. As discussed in the introduction, we assume that the losses in each trial can be specified by a loss matrix $L \in [0,1]^{n \times n}$ where the loss of each permutation Π has the linear form $\sum_i L_{i,\Pi(i)} = \Pi \bullet L$. If the algorithm's prediction $\widehat{\Pi}$ is chosen probabilistically in each trial then the algorithm's expected loss is $\mathbb{E}[\widehat{\Pi} \bullet L] = W \bullet L$, where $W = \mathbb{E}[\widehat{\Pi}]$. This expected prediction W is an $n \times n$ doubly stochastic matrix and algorithms for learning permutations under the linear loss assumption can be viewed as implicitly maintaining such a doubly stochastic weight matrix.

More precisely, the on-line algorithm follows the following protocol in each trial:

- The learner (probabilistically) chooses a permutation $\widehat{\Pi}$, and let $W = \mathbb{E}(\widehat{\Pi})$.
- Nature simultaneously chooses a loss matrix $L \in [0,1]^{n \times n}$ for the trial.
- At the end of the trial, the algorithm is given L. The loss of $\widehat{\Pi}$ is $\widehat{\Pi} \bullet L$ and the expected loss of the algorithm is $W \bullet L$.

- Finally, the algorithm updates its distribution over permutations for the next trial, implicitly updating matrix W.

Although our algorithm can handle arbitrary sequences of loss matrices $L \in [0,1]^{n\times n}$, nature could be significantly more restricted. Many ranking applications have an associated loss motif M and nature is constrained to choose (row) permutations of M as its loss matrix L. In effect, at each trial nature chooses a "correct" permutation Π and uses the loss matrix $L = \Pi M$. Note that the permutation left-multiplies the loss motif, and thus permutes the rows of M. If nature chooses the identity permutation then the loss matrix L is the motif M itself. When M is known to the algorithm, it suffices to give the algorithm only the permutation Π at the end of the trial, rather than the loss matrix L itself. Figure 1 gives examples of loss motifs.

The last loss in Figure 1 is related to a competitive List Update Problem where an algorithm services requests to a list of n items. In the List Update Problem the cost of a request is the requested item's current position in the list. After each request, the requested item can be moved forward in the list for free, and additional rearrangement can be done at a cost of one per transposition. The goal is for the algorithm to be cost-competitive with the best static ordering of the elements in hindsight. Note that the transposition cost for additional list rearrangement is not represented in the permutation loss motif. Blum et al. (2003) give very efficient algorithms for the List Update Problem that do not do additional rearranging of the list (and thus do not incur the cost neglect by the loss motif). In our notation, their bound has the same form as ours (1) but with the $n\ln n$ factors replaced by $O(n)$. However, our lower bound (see Section 7) shows that the $n\ln n$ factors in (2) are necessary in the general permutation setting.

Note that many compositions of loss motifs are possible. For example, given two motifs with their associated losses, any convex combination of the motifs creates a new motif for the same convex combination of the associated losses. Other component-wise combinations of two motifs (such as product or max) can also produce interesting loss motifs, but the combination usually cannot be distributed across the matrix dot-product calculation, and so cannot be expressed as a simple linear function of the original losses.

4. PermELearn Algorithm

Our permutation learning algorithm uses exponenential weights and we call it PermELearn. It maintains an $n \times n$ doubly stochastic weight matrix W as its main data structure, where $W_{i,j}$ is the probability that PermELearn predicts with a permutation mapping element i to position j. In the absence of prior information it is natural to start with uniform weights, that is, the matrix with $\frac{1}{n}$ in each entry.

In each trial PermELearn does two things:

1. Choose a permutation $\widehat{\Pi}$ from some distribution such that $\mathbb{E}[\widehat{\Pi}] = W$.

2. Create a new doubly stochastic matrix $\widetilde{W}$ for use in the next trial based on the current weight matrix W and loss matrix L.

loss $\mathcal{L}(\widehat{\Pi}, \Pi)$	motif M
the number of elements i where $\widehat{\Pi}(i) \neq \Pi$	$\begin{pmatrix} 0 & 1 & 1 & 1 \\ 1 & 0 & 1 & 1 \\ 1 & 1 & 0 & 1 \\ 1 & 1 & 1 & 0 \end{pmatrix}$
$\frac{1}{n-1}\sum_{i=1}^{n} \lvert\widehat{\Pi}(i) - \Pi(i)\rvert$, how far the elements are from their "correct" positions (the division by $n-1$ ensures that the entries of M are in $[0,1]$.)	$\frac{1}{3}\begin{pmatrix} 0 & 1 & 2 & 3 \\ 1 & 0 & 1 & 2 \\ 2 & 1 & 0 & 1 \\ 3 & 2 & 1 & 0 \end{pmatrix}$
$\frac{1}{n-1}\sum_{i=1}^{n} \frac{\lvert\widehat{\Pi}(i)-\Pi(i)\rvert}{\Pi(i)}$, a position weighted version of the above emphasizing the early positions in Π	$\frac{1}{3}\begin{pmatrix} 0 & 1 & 2 & 3 \\ 1/2 & 0 & 1/2 & 1 \\ 2/3 & 1/3 & 0 & 1/3 \\ 3/4 & 1/2 & 1/4 & 0 \end{pmatrix}$
the number of elements mapped to the first half by Π but the second half by $\widehat{\Pi}$, or vice versa	$\begin{pmatrix} 0 & 0 & 1 & 1 \\ 0 & 0 & 1 & 1 \\ 1 & 1 & 0 & 0 \\ 1 & 1 & 0 & 0 \end{pmatrix}$
the number of elements mapped to the first two positions by Π that fail to appear in the top three position of $\widehat{\Pi}$	$\begin{pmatrix} 0 & 0 & 0 & 1 & 1 \\ 0 & 0 & 0 & 1 & 1 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \end{pmatrix}$
the number of links traversed to find the first element of Π in a list ordered by $\widehat{\Pi}$	$\frac{1}{3}\begin{pmatrix} 0 & 1 & 2 & 3 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix}$

Figure 1: Loss motifs

Choosing a permutation is done by Algorithm 1. The algorithm greedily decomposes W into a convex combination of at most $n^2 - 2n + 2$ permutations (see Theorem 7), and then randomly selects one of these permutations for the prediction.[2]

Our decomposition algorithm uses a Temporary matrix A initialized to the weight matrix W. Each iteration of Algorithm 1 finds a permutation Π where each $A_{i,\Pi(i)} > 0$. This can be done by finding a perfect matching on the $n \times n$ bipartite graph containing the edge i, j whenever $A_{i,j} > 0$. We shall soon see that each matrix A is a constant times a doubly stochastic matrix, so the existence of a suitable permutation Π follows from Birkhoff's Theorem. Given such a permutation Π, the algorithm updates A to $A - \alpha\Pi$ where $\alpha = \min_i A_{i,\Pi(i)}$. The updated matrix A has non-negative entries and has strictly more zeros than the original A. Since the update decreases each row and

2. The decomposition is usually not unique and the implementation may have a bias as to exactly which convex combination is chosen.

Algorithm 1 PermELearn: Selecting a permutation

Require: a doubly stochastic $n \times n$ matrix W

$A := W$; $q = 0$;

repeat

$q := q + 1$;

Find permutation Π^q such that $A_{i,\Pi^q(i)}$ is positive for each $i \in \{1,\ldots,n\}$

$\alpha_q := \min_i A_{i,\Pi^q(i)}$

$A := A - \alpha_q \Pi^q$

until All entries of A are zero $\quad \{$at end of loop $W = \sum_{k=1}^{q} \alpha_k \Pi^k\}$

Randomly select and return a $\widehat{\Pi} \in \{\Pi^1,\ldots,\Pi^q\}$ using probabilities $\alpha_1,\ldots,\alpha_q$.

Algorithm 2 PermELearn: Weight Matrix Update

Require: learning rate η, loss matrix L, and doubly stochastic weight matrix W

Create W' where each $W'_{i,j} = W_{i,j} e^{-\eta L_{i,j}}$ (3)

Create doubly stochastic $\widetilde{W}$ by re-balancing the rows and columns of W' (Sinkhorn balancing) and update W to $\widetilde{W}$.

column sum by α and the original matrix W was doubly stochastic, each matrix A will have rows and columns that sum to the same amount. In other words, each matrix A created during Algorithm 1 is a constant times a doubly stochastic matrix, and thus (by Birkhoff's Theorem) is a constant times a convex combination of permutations.

After at most $n^2 - n$ iterations the algorithm arrives at a matrix A having exactly n non-zero entries, so this A is a constant times a permutation matrix. Therefore, Algorithm 1 decomposes the original doubly stochastic matrix into the convex combination of (at most) $n^2 - n + 1$ permutation matrices. The more refined arguments in Appendix A shows that the Algorithm 1 never uses more than $n^2 - 2n + 2$ permutations, matching the bound given by Birkhoff's Theorem.

Several improvements are possible. In particular, we need not compute each perfect matching from scratch. If only z entries of A are zeroed by a permutation, then that permutation is still a matching of size $n - z$ in the graph for the updated matrix. Thus we need to find only z augmenting paths to complete the perfect matching. The entire process thus requires finding $O(n^2)$ augmenting paths at a cost of $O(n^2)$ each, for a total cost of $O(n^4)$ to decompose weight matrix W into a convex combination of permutations.

4.1 Updating the Weights

In the second step, Algorithm 2 updates the weight matrix by multiplying each $W_{i,j}$ entry by the factor $e^{-\eta L_{i,j}}$. These factors destroy the row and column normalization, so the matrix must be re-balanced to restore the doubly-stochastic property. There is no closed form for the normalization step. The standard iterative re-balancing method for non-negative matrices is called *Sinkhorn balancing*. This method first normalizes each row of the matrix to sum to one, and then normalizes the columns. Since normalizing the columns typically destroys the row normalization, the process must be iterated until convergence (Sinkhorn, 1964).

$$\begin{pmatrix} \frac{1}{2} & \frac{1}{2} \\ \frac{1}{2} & 1 \end{pmatrix} \xrightarrow{\text{Sinkhorn balancing}} \begin{pmatrix} \frac{\sqrt{2}}{1+\sqrt{2}} & \frac{1}{1+\sqrt{2}} \\ \frac{1}{1+\sqrt{2}} & \frac{\sqrt{2}}{1+\sqrt{2}} \end{pmatrix}$$

Figure 2: Example where Sinkhorn balancing requires infinitely many steps.

Normalizing the rows corresponds to pre-multiplying by a diagonal matrix. The product of these diagonal matrices thus represents the combined effect of the multiple row normalization steps. Similarly, the combined effect of the column normalization steps can be represented by post-multiplying the matrix by a diagonal matrix. Therefore we get the well known fact that Sinkhorn balancing a matrix A results in a doubly stochastic matrix RAC where R and C are diagonal matrices. Each entry $R_{i,i}$ is the positive multiplier applied to row i, and each entry $C_{j,j}$ is the positive multiplier of column j needed to convert A into a doubly stochastic matrix.

In Figure 2 we give a rational matrix that balances to an irrational matrix. Since each row and column balancing step creates rationals, Sinkhorn balancing produces irrationals only in the limit (after infinitely many steps). Multiplying a weight matrix from the left and/or right by non-negative diagonal matrices (e.g., row or column normalization) preserves the ratio of product weights between permutations. That is if $A' = RAC$, then for any two permutations Π_1 and Π_2,

$$\frac{\prod_i A'_{i,\Pi_1(i)}}{\prod_i A'_{i,\Pi_2(i)}} = \frac{\prod_i A_{i,\Pi_1(i)} R_{i,i} C_{\Pi_1(i),\Pi_1(i)}}{\prod_i A_{i,\Pi_2(i)} R_{i,i} C_{\Pi_2(i),\Pi_2(i)}} = \frac{\prod_i A_{i,\Pi_1(i)}}{\prod_i A_{i,\Pi_2(i)}}.$$

Therefore $\begin{pmatrix} 1/2 & 1/2 \\ 1/2 & 1 \end{pmatrix}$ must balance to a doubly stochastic matrix $\begin{pmatrix} a & 1-a \\ 1-a & a \end{pmatrix}$ such that the ratio of the product weight between the two permutations $(1,2)$ and $(2,1)$ is preserved. This means $\frac{1/2}{1/4} = \frac{a^2}{(1-a)^2}$ and thus $a = \frac{\sqrt{2}}{1+\sqrt{2}}$.

This example leads to another important observation: PermELearn's predictions are different than Hedge's when each permutation is treated as an expert. If each permutation is explicitly represented as an expert, then the Hedge algorithm predicts permutation Π with probability proportional to the product weight, $\prod_i e^{-\eta \sum_t L^t_{i,\Pi(i)}}$. However, algorithm PermELearn predicts differently. With the weight matrix in Figure 4.1, Hedge puts probability $\frac{2}{3}$ on permutation $(1,2)$ and probability $\frac{1}{3}$ on permutation $(2,1)$ while PermELearn puts probability $\frac{\sqrt{2}}{1+\sqrt{2}} \approx 0.59$ on permutation $(1,2)$ and probability $\frac{\sqrt{1}}{1+\sqrt{2}} \approx 0.41$ on permutation (2,1).

There has been much written on the balancing of matrices, and we briefly describe only a few of the results here. Sinkhorn showed that this procedure converges and that the RAC balancing of any matrix A into a doubly stochastic matrix is unique (up to canceling multiples of R and C) if it exists[3] (Sinkhorn, 1964).

A number of authors consider balancing a matrix A so that the row and column sums are $1 \pm \varepsilon$. Franklin and Lorenz (1989) show that $O(\text{length}(A)/\varepsilon)$ Sinkhorn iterations suffice, where length(A) is the bit-length of matrix A's binary representation. Kalantari and Khachiyan (1996) show that

3. Some non-negative matrices, like $\begin{pmatrix} 1 & 1 & 0 \\ 0 & 1 & 0 \\ 0 & 1 & 1 \end{pmatrix}$, cannot be converted into doubly stochastic matrices because of their pattern of zeros. The weight matrices we deal with have strictly positive entries, and thus can always be made doubly stochastic with an RAC balancing.

$O(n^4 \ln \frac{n}{\varepsilon} \ln \frac{1}{\min A_{i,j}})$ operations suffice using an interior point method. Linial et al. (2000) give a preprocessing step after which only $O((n/\varepsilon)^2)$ Sinkhorn iterations suffice. They also present a strongly polynomial time iterative procedure requiring $\tilde{O}(n^7 \log(1/\varepsilon))$ iterations. Balakrishnan et al. (2004) give an interior point method with complexity $O(n^6 \log(n/\varepsilon))$. Finally, Fürer (2004) shows that if the row and column sums of A are $1 \pm \varepsilon$ then every matrix entry changes by at most $\pm n\varepsilon$ when A is balanced to a doubly stochastic matrix.

4.2 Dealing with Approximate Balancing

With slight modifications, Algorithm PermELearn can handle the situation where its weight matrix is imperfectly balanced (and thus not quite doubly stochastic). As before, let W be the fully balanced doubly stochastic weight matrix, but we now assume that only an approximately balanced $\widehat{W}$ is available to predict from. In particular, we assume that each row and column of $\widehat{W}$ sum to $1 \pm \varepsilon$ for some $\varepsilon < \frac{1}{3}$. Let $s \geq 1 - \varepsilon$ be the smallest row or column sum in $\widehat{W}$.

We modify Algorithm 1 in two ways. First, A is initialized to $\frac{1}{s}\widehat{W}$ rather than W. This ensures every row and column in the initial A sums to at least one, to at most $1 + 3\varepsilon$, and at least one row or column sums to exactly 1. Second, the loop exits as soon as A has an all-zero row or column. Since the smallest row or column sum starts at 1, is decreased by α_k each iteration k, and ends at zero, we have that $\sum_{k=1}^{q} \alpha_k = 1$ and the modified Algorithm 1 still outputs a convex combination of permutations $C = \sum_{k=1}^{q} \alpha_k \Pi^k$. Furthermore, each entry $C_{i,j} \leq \frac{1}{s}\widehat{W}_{i,j}$. We now bound the additional loss of this modified algorithm.

Lemma 1 *If the weight matrix $\widehat{W}$ is approximately balanced so each row and column sum is in $1 \pm \varepsilon$ (for $\varepsilon \leq \frac{1}{3}$) then the modified Algorithm 1 has an expected loss $C \bullet L$ at most $3n^3\varepsilon$ greater than the expected loss $W \bullet L$ of the original algorithm that uses the completely balanced doubly stochastic matrix W.*

Proof Let s be the smallest row or column sum in $\widehat{W}$. Since each row and column sum of $\frac{1}{s}\widehat{W}$ lies in $[1, 1+3\varepsilon]$, each entry of $\frac{1}{s}\widehat{W}$ is close to the corresponding entry of the fully balanced W. In particular each $\frac{1}{s}\widehat{W}_{i,j} \leq W_{i,j} + 3n\varepsilon$ (Fürer, 2004). This allows us to bound the expected loss when predicting with the convex combination C in terms of the expected loss using a decomposition of the perfectly balanced W:

$$\begin{aligned} C \bullet L &\leq \frac{1}{s}\widehat{W} \bullet L \\ &= \sum_{i,j} \frac{\widehat{W}_{i,j}}{s} L_{i,j} \\ &\leq \sum_{i,j} (W_{i,j} + 3n\varepsilon) L_{i,j} \\ &\leq W \bullet L + 3n^3\varepsilon. \end{aligned}$$

Therefore the extra loss incurred by using a ε-approximately balanced weight matrix at a particular trial is at most $3n^3\varepsilon$, as desired. ■

If in a sequence of T trials the matrices $\widehat{W}$ are $\varepsilon = 1/(3Tn^3)$ balanced (so that each row and column sum is $1 \pm 1/(3Tn^3)$) then Lemma 1 implies that the total additional expected loss for using approximate balancing is at most 1. The algorithm of Balakrishnan et al. (2004) ε-balances a matrix in $O(n^6 \log(n/\varepsilon))$ time (note that this dominates the time for the loss update and constructing the convex combination). This balancing algorithm with $\varepsilon = 1/(3Tn^3)$ together with the modified prediction algorithm give a method requiring $O(Tn^6 \log(Tn))$ total time over the T trials and having a bound of $\sqrt{2\mathcal{L}_{\text{est}} n \ln n} + n \ln n + 1$ on the worst-case regret.

If the number of trials T is not known in advance then setting ε as a function of t can be helpful. A natural choice is $\varepsilon_t = 1/(3t^2n^3)$. In this case the total extra regret for not having perfect balancing is bounded by $\sum_{t=1}^{T} 1/t^2 \leq 5/3$ and the total computation time over the T trials is still bounded by $O(Tn^6 \log(Tn))$.

One might be concerned about the effects of approximate balancing propagating between trials. However this is not an issue. In the following section we show that the loss updates and balancing can be arbitrarily interleaved. Therefore the modified algorithm can either keep a cumulative loss matrix $L^{\leq t} = \sum_{i=1}^{t} L^i$ and create its next $\widehat{W}$ by (approximately) balancing the matrix with entries $\frac{1}{n} e^{-\eta L_{i,j}^{\leq t}}$, or apply the multiplicative updates to the previous approximately balanced $\widehat{W}$.

5. Bounds for PermELearn

Our analysis of PermELearn follows the entropy-based analysis of the exponentiated gradient family of algorithms (Kivinen and Warmuth, 1997). This style of analysis first shows a per-trial progress bound using relative entropy to a comparator as a measure of progress, and then sums this invariant over the trials to bound the expected total loss of the algorithm. We also show that PermELearn's weight update belongs to the exponentiated gradient family of updates (Kivinen and Warmuth, 1997) since it is the solution to a minimization problem that trades of the loss (in this case a linear loss) against a relative entropy regularization.

Recall that the expected loss of PermELearn on a trial is a linear function of its weight matrix W. Therefore the gradient of the loss is independent of the current value of W. This property of the loss greatly simplifies the analysis. Our analysis for this setting provides a good foundation for learning permutation matrices and lays the groundwork for the future study of other permutation loss functions.

We start our analysis with an attempt to mimic the standard analysis (Kivinen and Warmuth, 1997) for the exponentiated gradient family updates which multiply by exponential factors and re-normalize. The per-trial invariant used to analyze the exponentiated gradient family bounds the decrease in relative entropy from any (normalized) vector u to the algorithm's weight vector by a linear combination of the algorithm's loss and the loss of u on the trial. In our case the weight vectors are matrices and we use the following (un-normalized) relative entropy between matrices A and B with non-negative entries:

$$\Delta(A,B) = \sum_{i,j} A_{i,j} \ln \frac{A_{i,j}}{B_{i,j}} + B_{i,j} - A_{i,j} \ .$$

Note that this is just the sum of the relative entropies between the corresponding rows (or equivalently, between the corresponding columns):

$$\Delta(A,B) = \sum_{i} \Delta(A_{i,\star}, B_{i,\star}) = \sum_{j} \Delta(A_{\star,j}, B_{\star,j})$$

(here $A_{i,\star}$ is the ith row of A and $A_{\star,j}$ is its jth column).

Unfortunately, the lack of a closed form for the matrix balancing procedure makes it difficult to prove bounds on the loss of the algorithm. Our solution is to break PermELearn's update (Algorithm 2) into two steps, and use only the progress made to the intermediate un-balanced matrix in our per-trial bound (8). After showing that balancing to a doubly stochastic matrix only increases the progress, we can sum the per-trial bound to obtain our main theorem.

5.1 A Dead End

In each trial, PermELearn multiplies each entry of its weight matrix by an exponential factor and then uses one additional factor per row and column to make the matrix doubly stochastic (Algorithm 2 described in Section 4.1):

$$\widetilde{W}_{i,j} := r_i c_j W_{i,j} e^{-\eta L_{i,j}} \tag{4}$$

where the r_i and c_j factors are chosen so that all rows and columns of the matrix $\widetilde{W}$ sum to one.

We now show that PermELearn's update (4) gives the matrix A solving the following minimization problem:

$$\begin{array}{l} \operatorname{argmin} \\ \forall i : \sum_j A_{i,j} = 1 \\ \forall j : \sum_i A_{i,j} = 1 \end{array} \quad (\Delta(A,W) + \eta\,(A \bullet L)). \tag{5}$$

Since the linear constraints are feasible and the divergence is strictly convex, there always is a unique solution, even though the solution does not have a closed form.

Lemma 2 *PermELearn's updated weight matrix* $\widetilde{W}$ (4) *is the solution of* (5).

Proof We form a Lagrangian for the optimization problem:

$$l(A,\rho,\gamma) = \Delta(A,W) + \eta\,(A \bullet L) + \sum_i \rho_i (\sum_j A_{i,j} - 1) + \sum_j \gamma_j (\sum_i A_{i,j} - 1).$$

Setting the derivative with respect to $A_{i,j}$ to 0 yields $A_{i,j} = W_{i,j} e^{-\eta L_{i,j}} e^{-\rho_i} e^{-\gamma_j}$. By enforcing the row and column sum constraints we see that the factors $r_i = e^{-\rho_i}$ and $c_j = e^{-\gamma_j}$ function as row and column normalizers, respectively. ■

We now examine the progress $\Delta(U,W) - \Delta(U,\widetilde{W})$ towards an arbitrary stochastic matrix U. Using Equation (4) and noting that all three matrices are doubly stochastic (so their entries sum to n), we see that

$$\Delta(U,W) - \Delta(U,\widetilde{W}) = -\eta\, U \bullet L + \sum_i \ln r_i + \sum_j \ln c_j.$$

Making this a useful invariant requires lower bounding the sums on the rhs by a constant times $W \bullet L$, the loss of the algorithm. Unfortunately we are stuck because the r_i and c_j normalization factors don't even have a closed form.

5.2 Successful Analysis

Our successful analysis splits the update (4) into two steps:

$$W'_{i,j} := W_{i,j} e^{-\eta L_{i,j}} \quad \text{and} \quad \widetilde{W}_{i,j} := r_i c_j W'_{i,j}, \tag{6}$$

where (as before) r_i and c_j are chosen so that each row and column of the matrix $\widetilde{W}$ sum to one. Using the Lagrangian (as in the proof of Lemma 2), it is easy to see that these W' and $\widetilde{W}$ matrices solve the following minimization problems:

$$W' = \operatorname*{argmin}_A \left(\Delta(A,W) + \eta\,(A \bullet L)\right) \quad \text{and} \quad \widetilde{W} := \operatorname*{argmin}_{\substack{\forall i: \sum_j A_{i,j} = 1 \\ \forall j: \sum_i A_{i,j} = 1}} \Delta(A,W'). \tag{7}$$

The second problem shows that the doubly stochastic matrix $\widetilde{W}$ is the projection of W' onto to the linear row and column sum constraints. The strict convexity of the relative entropy between non-negative matrices and the feasibility of the linear constraints ensure that the solutions for both steps are unique.

We now lower bound the progress $\Delta(U,W) - \Delta(U,W')$ in the following lemma to get our per-trial invariant.

Lemma 3 *For any $\eta > 0$, any doubly stochastic matrices U and W and any trial with loss matrix $L \in [0,1]^{n \times n}$*

$$\Delta(U,W) - \Delta(U,W') \geq (1 - e^{-\eta})(W \bullet L) - \eta(U \bullet L),$$

where W' is the unbalanced intermediate matrix (6) *constructed by PermELearn from W.*

Proof The proof manipulates the difference of relative entropies and uses the inequality $e^{-\eta x} \leq 1 - (1 - e^{-\eta})x$, which holds for any η and any $x \in [0,1]$:

$$\begin{aligned}
\Delta(U,W) - \Delta(U,W') &= \sum_{i,j} \left(U_{i,j} \ln \frac{W'_{i,j}}{W_{i,j}} + W_{i,j} - W'_{i,j} \right) \\
&= \sum_{i,j} \left(U_{i,j} \ln(e^{-\eta L_{i,j}}) + W_{i,j} - W_{i,j} e^{-\eta L_{i,j}} \right) \\
&\geq \sum_{i,j} \left(-\eta L_{i,j} U_{i,j} + W_{i,j} - W_{i,j}(1 - (1 - e^{-\eta}) L_{i,j}) \right) \\
&= -\eta (U \bullet L) + (1 - e^{-\eta})(W \bullet L).
\end{aligned}$$

■

Relative entropy is a Bregman divergence, so the Generalized Pythagorean Theorem (Bregman, 1967) applies. Specialized to our setting, this theorem states that if S is a closed convex set containing some matrix U with non-negative entries, W' is any matrix with strictly positive entries, and $\widetilde{W}$ is the relative entropy projection of W' onto S then

$$\Delta(U,W') \geq \Delta(U,\widetilde{W}) + \Delta(\widetilde{W},W').$$

Furthermore, this holds with equality when S is affine, which is the case here since S is the set of matrices whose rows and columns each sum to 1. Rearranging and noting that $\Delta(A,B)$ is non-negative yields Corollary 3 of Herbster and Warmuth (2001), which is the inequality we need:

$$\Delta(U,W') - \Delta(U,\widetilde{W}) = \Delta(\widetilde{W},W') \geq 0.$$

Combining this with the inequality of Lemma 3 gives the critical per-trial invariant:

$$\Delta(U,W) - \Delta(U,\widetilde{W}) \geq (1-e^{-\eta})(W \bullet L) - \eta(U \bullet L). \tag{8}$$

We now introduce some notation and bound the expected total loss by summing the above inequality over a sequence of trials. When considering a sequence of trials, L^t is the loss matrix at trial t, W^{t-1} is PermELearn's weight matrix W at the start of trial t (so W^0 is the initial weight matrix) and W^t is the updated weight matrix $\widetilde{W}$ at the end of the trial.

Theorem 4 *For any learning rate $\eta > 0$, any doubly stochastic matrices U and initial W^0, and any sequence of T trials with loss matrices $L^t \in [0,1]^{n\times n}$ (for $1 \leq t \leq T$), the expected loss of PermELearn is bounded by:*

$$\sum_{t=1}^{T} W^{t-1} \bullet L^t \leq \frac{\Delta(U,W^0) - \Delta(U,W^T) + \eta \sum_{t=1}^{T} U \bullet L^t}{1-e^{-\eta}} \ .$$

Proof Applying (8) to trial t gives:

$$\Delta(U,W^{t-1}) - \Delta(U,W^t) \geq (1-e^{-\eta})(W^{t-1} \bullet L^t) - \eta(U \bullet L^t).$$

By summing the above over all T trials we get:

$$\Delta(U,W^0) - \Delta(U,W^T) \geq (1-e^{-\eta}) \sum_{t=1}^{T} W^{t-1} \bullet L^t - \eta \sum_{t=1}^{T} U \bullet L^t.$$

The bound then follows by solving for the total expected loss, $\sum_{t=1}^{T} W^{t-1} \bullet L^t$, of the algorithm. ■

When the entries of W^0 are all initialized to $\frac{1}{n}$ and U is a permutation then $\Delta(U,W^0) = n\ln n$. Since each doubly stochastic matrix U is a convex combination of permutation matrices, at least one minimizer of the total loss $\sum_{t=1}^{T} U \bullet L$ will be a permutation matrix. If $\mathcal{L}_{\text{best}}$ denotes the loss of such a permutation U^*, then Theorem 4 implies that the total loss of the algorithm is bounded by

$$\frac{\Delta(U^*,W^0) + \eta \mathcal{L}_{\text{best}}}{1-e^{-\eta}}.$$

If upper bounds $\Delta(U^*,W^0) \leq D_{\text{est}} \leq n\ln n$ and $\mathcal{L}_{\text{est}} \geq \mathcal{L}_{\text{best}}$ are known, then by choosing $\eta = \ln\left(1+\sqrt{\frac{2D_{\text{est}}}{\mathcal{L}_{\text{est}}}}\right)$, and the above bound becomes (Freund and Schapire, 1997):

$$\mathcal{L}_{\text{best}} + \sqrt{2\mathcal{L}_{\text{est}} D_{\text{est}}} + \Delta(U^*,W^0). \tag{9}$$

A natural choice for D_{est} is $n\ln n$. In this case the tuned bound becomes

$$\mathcal{L}_{\text{best}} + \sqrt{2\mathcal{L}_{\text{est}} n\ln n} + n\ln n.$$

5.3 Approximate Balancing

The preceding analysis assumes that PermELearn's weight matrix is perfectly balanced each iteration. However, balancing techniques are only capably of approximately balancing the weight matrix in finite time, so implementations of PermELearn must handle approximately balanced matrices. In Section 4.2, we describe an implementation that uses an approximately balanced $\widehat{W}^{t-1}$ at the start of iteration t rather than the completely balanced W^{t-1} of the preceding analysis. Lemma 1 shows that when this implementation of PermELearn uses an approximately balanced $\widehat{W}^{t-1}$ where each row and column sum is in $1 \pm \varepsilon_t$, then the expected loss on trial t is at most $W^{t-1} \bullet L^t + 3n^3\varepsilon_t$. Summing over all trials and using Theorem 4, this implementation's total loss is at most

$$\sum_{t=1}^{T} \left(W^{t-1} \bullet L^t + 3n^3\varepsilon_t\right) \leq \frac{\Delta(U,W^0) - \Delta(U,W^T) + \eta \sum_{t=1}^{T} U \bullet L^t}{1-e^{-\eta}} + \sum_{t=1}^{T} 3n^3\varepsilon_t \ .$$

As discussed in Section 4.2, setting $\varepsilon_t = 1/(3n^3t^2)$ leads to an additional loss of less than $5/3$ over the bound of Theorem 4 and its subsequent tunings while incurring a total running time (over all T trials) in $O(Tn^6 \log(Tn))$. In fact, the additional loss for approximate balancing can be made less than any positive c by setting $\varepsilon_t = c/(5n^3t^2)$. Since the time to approximately balance depends only logarithmically on $1/\varepsilon$, the total time taken over T trials remains in $O(Tn^6 \log(Tn))$.

5.4 Split Analysis for the Hedge Algorithm

Perhaps the simplest case where the loss is linear in the parameter vector is the on-line allocation setting of Freund and Schapire (1997). It is instructive to apply our method of splitting the update in this simpler setting. There are N experts and the algorithm keeps a probability distribution w over the experts. In each trial the algorithm picks expert i with probability w_i and then gets a loss vector $\ell \in [0,1]^N$. Each expert i incurs loss ℓ_i and the algorithm's expected loss is $w \cdot \ell$. Finally w is updated to $\widetilde{w}$ for the next trial.

The Hedge algorithm (Freund and Schapire, 1997) updates its weight vector to $\tilde{w}_i = \frac{w_i e^{-\eta \ell_i}}{\sum_j w_j e^{-\eta \ell_j}}$. This update can be motivated by a tradeoff between the un-normalized relative entropy to the old weight vector and expected loss in the last trial (Kivinen and Warmuth, 1999):

$$\widetilde{w} := \operatorname*{argmin}_{\sum_i \widehat{w}_i = 1} \left(\Delta(\widehat{w}, w) + \eta \ \widehat{w} \cdot \ell\right).$$

For vectors, the relative entropy is simply $\Delta(\widehat{w}, w) := \sum_i \widehat{w}_i \ln \frac{\widehat{w}_i}{w_i} + w_i - \widehat{w}_i$. As in the permutation case, we can split this update (and motivation) into two steps: setting each $w'_i = w_i e^{-\eta \ell_i}$ then $\widetilde{w} = w' / \sum_i w'_i$. These are the solutions to:

$$w' := \operatorname*{argmin}_{\widehat{w}} \left(\Delta(\widehat{w}, w) + \eta \ \widehat{w} \cdot \ell\right) \ \text{ and } \ \widetilde{w} := \operatorname*{argmin}_{\sum_i \widehat{w}_i = 1} \Delta(\widehat{w}, w').$$

The following lower bound has been shown on the progress towards any probability vector u serving as a comparator:[4]

$$\begin{aligned}\Delta(u,w)-\Delta(u,\widetilde{w}) &= -\eta\, u\cdot\ell-\ln\sum_i w_i e^{-\eta\ell_i}\\ &\geq -\eta\, u\cdot\ell-\ln\sum_i w_i(1-(1-e^{-\eta})\ell_i)\\ &\geq -\eta\, u\cdot\ell+w\cdot\ell\,(1-e^{-\eta})\,, \end{aligned}\tag{10}$$

where the first inequality uses $e^{-\eta x}\leq 1-(1-e^{-\eta})x$, for any $x\in[0,1]$, and the second uses $-\ln(1-x)\geq x$, for $x\in[0,1]$. Surprisingly the same inequality already holds for the un-normalized update:[5]

$$\Delta(u,w)-\Delta(u,w')=-\eta\, u\cdot\ell+\sum_i w_i(1-e^{-\eta\ell_i})\geq w\cdot\ell\,(1-e^{-\eta})-\eta\, u\cdot\ell.$$

Since the normalization is a projection w.r.t. a Bregman divergence onto a linear constraint satisfied by the comparator u, $\Delta(u,w')-\Delta(u,\widetilde{w})\geq 0$ by the Generalized Pythagorean Theorem (Herbster and Warmuth, 2001). The total progress for both steps is again Inequality (10).

With the key Inequality (10) in hand, it is easy to introduce trial dependent notation and sum over trails (as done in the proof of Theorem 4, arriving at the familiar bound for Hedge (Freund and Schapire, 1997): For any $\eta>0$, any probability vectors w^0 and u, and any loss vectors $\ell^t\in[0,1]^n$,

$$\sum_{t=1}^{T} w^{t-1}\bullet\ell^t\leq\frac{\Delta(u,w^0)-\Delta(u,w^T)+\eta\sum_{t=1}^{T}u\bullet\ell^t}{1-e^{-\eta}}\quad.\tag{11}$$

Note that the r.h.s. is actually constant in the comparator u (Kivinen and Warmuth, 1999), that is, for all u,

$$\frac{\Delta(u,w^0)-\Delta(u,w^T)+\eta\sum_{t=1}^{T}u\bullet\ell^t}{1-e^{-\eta}}=\frac{-\ln\sum_i w_i^0 e^{-\eta\ell_i^{\leq T}}}{1-e^{\eta}}.$$

The r.h.s. of the above equality is often used as a potential in proving bounds for expert algorithms. We discuss this further in Appendix B.

5.5 When to Normalize?

Probably the most surprising aspect about the proof methodology is the flexibility about how and when to project onto the constraints. Instead of projecting a nonnegative matrix onto all $2n$ constraints at once (as in optimization problem (7)), we could mimic the Sinkhorn balancing algorithm by first projecting onto the row constraints and then the column constraints and alternating until convergence. The Generalized Pythagorean Theorem shows that projecting onto *any* convex constraint that is satisfied by the comparator class of doubly stochastic matrices brings the weight matrix closer to *every* doubly stochastic matrix.[6] Therefore our bound on $\sum_t W^{t-1}\bullet L^t$ (Theorem 4) holds if the exponential updates are interleaved with any sequence of projections to some subsets of the

4. This is essentially Lemma 5.2 of Littlestone and Warmuth (1994). The reformulation of this type of inequality with relative entropies goes back to Kivinen and Warmuth (1999)
5. Note that if the algorithm does not normalize the weights then w is no longer a distribution. When $\sum_i w_i<1$, the loss $w\cdot L$ amounts to incurring 0 loss with probability $1-\sum_i w_i$, and predicting as expert i with probability w_i.
6. There is a large body of work on finding a solution subject to constraints via iterated Bregman projections (see, e.g., Censor and Lent, 1981).

constraints. However, if the normalization constraints are not enforced then W is no longer a convex combination of permutations. Furthermore, the exponential update factors only decrease the entries of W and without any normalization all of the entries of W can get arbitrarily small. If this is allowed to happen then the "loss" $W \bullet L$ can approach 0 for any loss matrix, violating the spirit of the prediction model.

There is a direct argument that shows that the same final doubly stochastic matrix is reached if we interleave the exponential updates with projections to any of the constraints as long as all $2n$ constraints hold at the end. To see this we partition the class of matrices with positive entries into equivalence classes. Call two such matrices A and B *equivalent* if there are diagonal matrices R and C with positive diagonal entries such that $B = RAC$. Note that $[RAC]_{i,j} = R_{i,i}A_{i,j}C_{j,j}$ and therefore B is just a rescaled version of A. Projecting onto any row and/or column sum constraints amounts to pre- and/or post-multiplying the matrix by some positive diagonal matrices R and C. Therefore if matrices A and B are equivalent then the projection of A (or B) onto a set of row and/or column sum constraints results in another matrix equivalent to both A and B.

The importance of equivalent matrices is that they balance to the same doubly stochastic matrix.

Lemma 5 *For any two equivalent matrices A and RAC, where the entries of A and the diagonal entries of R and C are positive,*

$$\underset{\substack{\forall i: \sum_j \widehat{A}_{i,j} = 1 \\ \forall j: \sum_i \widehat{A}_{i,j} = 1}}{\operatorname{argmin}} \Delta(\widehat{A}, A) \quad = \quad \underset{\substack{\forall i: \sum_j \widehat{A}_{i,j} = 1 \\ \forall j: \sum_i \widehat{A}_{i,j} = 1}}{\operatorname{argmin}} \Delta(\widehat{A}, RAC).$$

Proof The strict convexity of the relative entropy implies that both problems have a unique matrix as their solution. We will now reason that the unique solutions for both problems are the same. By using a Lagrangian (as in the proof of Lemma 2) we see that the solution of the left optimization problem is a square matrix with $\dot{r}_i A_{i,j} \dot{c}_j$ in position i, j. Similarly the solution of the problem on the right has $\ddot{r}_i R_{i,i} A_{i,j} C_{j,j} \ddot{c}_j$ in position i, j. Here the factors $\dot{r}_i, \ddot{r}_i$ function as row normalizers and $\dot{c}_j, \ddot{c}_j$ as column normalizers. Given a solution matrix $\dot{r}_i, \dot{c}_j$ to the left problem, then $\dot{r}_i / R_{i,i}, \dot{c}_j / C_{j,j}$ is a solution of the right problem of the same value. Also if $\ddot{r}_i, \ddot{c}_j$ is a solution of right problem, then $\ddot{r}_i R_{i,i}, \ddot{c}_j C_{j,j}$ is a solution to the left problem of the same value.

This shows that both minimization problems have the same value and the matrix solutions for both problems are the same and unique (even though the normalization factors $\dot{r}_i, \dot{c}_j$ of say the left problem are not necessarily unique). Note that its crucial for the above argument that the diagonal entries of R, C are positive. ■

The analogous phenomenon is much simpler in the weighted majority case: Two non-negative vectors a and b are *equivalent* if $a = cb$, where c is any nonnegative scalar, and again each equivalence class has exactly one normalized weight vector.

PermELearn's intermediate matrix $W'_{i,j} := W_{i,j} e^{-\eta L_{i,j}}$ can be written $W \circ M$ where $\circ$ denotes the *Hadamard* (entry-wise) *Product* and $M_{i,j} = e^{-\eta L_{i,j}}$. Note that the Hadamard product commutes with matrix multiplication by diagonal matrices, if C is diagonal and $P = (A \circ B)C$ then $P_{i,j} = (A_{i,j} B_{i,j}) C_{j,j} = (A_{i,j} C_{j,j}) B_{i,j}$ so we also have $P = (AC) \circ B$. Similarly, $R(A \circ B) = (RA) \circ B$ when R is diagonal.

Hadamard products also preserve equivalence. For equivalent matrices A and $B = RAC$ (for diagonal R and C) the matrices $A \circ M$ and $B \circ M$ are equivalent (although they are not likely to be equivalent to A and B) since $B \circ M = (RAC) \circ M = R(A \circ M)C$.

This means that any two runs of PermELearn-like algorithms that have the same bag of loss matrices and equivalent initial matrices end with equivalent final matrices even if they project onto different subsets of the constraints at the end of the various trials.

In summary the proof method discussed so far uses a relative entropy as a measure of progress and relies on Bregman projections as its fundamental tool. In Appendix B we re-derive the bound for PermELearn using the value of the optimization problem (5) as a potential. This value is expressed using the dual optimization problem and intuitively the application of the Generalized Pythagorean Theorem now is replaced by plugging in a non-optimal choice for the dual variables. Both proof techniques are useful.

5.6 Learning Mappings

We have an algorithm that has small regret against the best permutation. Permutations are a subset of all mappings from $\{1,\ldots,n\}$ to $\{1,\ldots,n\}$. We continue using Π for a permutation and introduce Ψ to denote an arbitrary mapping from $\{1,\ldots,n\}$ to $\{1,\ldots,n\}$. Mappings differ from permutations in that the n dimensional vector $(\Psi(i))_{i=1}^n$ can have repeats, that is, $\Psi(i)$ might equal $\Psi(j)$ for $i \neq j$. Again we alternately represent a mapping Ψ as an $n \times n$ matrix where $\Psi_{i,j} = 1$ if $\Psi(i) = j$ and 0 otherwise. Note that such square[7] *mapping matrices* have the special property that they have exactly one 1 in each row. Again the loss is specified by a loss matrix L and the loss of mapping Ψ is $\Psi \bullet L$.

It is straightforward to design an algorithm *MapELearn* for learning mappings with exponential weights: Simply run n independent copies of the Hedge algorithm for each of the n rows of the received loss matrices. That is, the r'th copy of Hedge always receives the r'th row of the loss matrix L as its loss vector. Even though learning mappings is easy, it is nevertheless instructive to discuss the differences with PermELearn.

Note that MapELearn's combined weight matrix is now a convex combination of mappings, that is, a "singly" stochastic matrix with the constraint that each row sums to one. Again, after the exponential update (3), the constraints are typically not satisfied any more, but they can be easily reestablished by simply normalizing each row. The row normalization only needs to be done once in each trial: no iterative process is needed. Furthermore, no fancy decomposition algorithm is needed in MapELearn: for (singly) stochastic weight matrix W, the prediction $\Psi(i)$ is simply a random element chosen from the row distribution $W_{i,*}$. This sampling procedure produces a mapping Ψ such that $W = \mathbb{E}(\Psi)$ and thus $\mathbb{E}(\Psi \bullet L) = W \bullet L$ as needed.

We can use the same relative entropy between the single stochastic matrices, and the lower bound on the progress for the exponential update given in Lemma 3 still holds. Also our main bound (Theorem 4) is still true for MapELearn and we arrive at the same tuned bound for the total loss of MapELearn:

$$\mathcal{L}_{\text{best}} + \sqrt{2\mathcal{L}_{\text{est}} D_{\text{est}}} + \Delta(U^*, W^0),$$

where $\mathcal{L}_{\text{best}}$, $\mathcal{L}_{\text{est}}$, and D_{est} are now the total loss of the best mapping, a known upper bound on $\mathcal{L}_{\text{best}}$, and an upper bound on $\Delta(U^*, W^0)$, respectively. Recall that $\mathcal{L}_{\text{est}}$ and D_{est} are needed to tune the η parameter.

7. In the case of mappings the restriction to square matrices is not essential.

Our algorithm PermElearn for permutations may be seen as the above algorithm for mappings while enforcing the column sum constraints in addition to the row constraints used in MapELearn. Since PermELearn's row balancing "messes up" the column sums and vice versa, an interactive procedure (i.e., Sinkhorn Balancing) is needed to create to a matrix in which each row *and* column sums to one. The enforcement of the additional column sum constraints results in a doubly stochastic matrix, an apparently necessary step to produce predictions that are permutations (and an expected prediction equal to the doubly stochastic weight matrix).

When it is known that the comparator is a permutation, then the algorithm always benefits from enforcing the additional column constraints. In general we should always make use of any constraints that the comparator is known to satisfy (see, e.g., Warmuth and Vishwanathan, 2005, for a discussion of this).

As discussed in Section 4.1, if A' is a Sinkhorn-balanced version of a non-negative matrix A, then

$$\text{for any permutations } \Pi_1 \text{ and } \Pi_2, \quad \frac{\prod_i A_{i,\Pi_1(i)}}{\prod_i A_{i,\Pi_2(i)}} = \frac{\prod_i A'_{i,\Pi_1(i)}}{\prod_i A'_{i,\Pi_2(i)}}. \tag{12}$$

An analogous invariant holds for mappings: If A' is a row-balanced version of a non-negative matrix A, then

$$\text{for any mappings } \Psi_1 \text{ and } \Psi_2, \quad \frac{\prod_i A_{i,\Psi_1(i)}}{\prod_i A_{i,\Psi_2(i)}} = \frac{\prod_i A'_{i,\Psi_1(i)}}{\prod_i A'_{i,\Psi_2(i)}}.$$

However it is important to note that column balancing does not preserve the above invariant for mappings. In fact, permutations are the subclass of mappings where invariant 12 holds.

There is another important difference between PermELearn and MapELearn. For MapELearn, the probability of predicting mapping Ψ with weight matrix W is always the product $\prod_i W_{i,\Psi(i)}$. The analogous property does *not* hold for PermELearn. Consider the balanced 2×2 weight matrix W on the right of Figure 2. This matrix decomposes into $\frac{\sqrt{2}}{1+\sqrt{2}}$ times the permutation $(1,2)$ plus $\frac{1}{1+\sqrt{2}}$ times the permutation $(2,1)$. Thus the probability of predicting with permutation $(1,2)$ is $\sqrt{2}$ times the probability of permutation $(2,1)$ for the PermELearn algorithm. However, when the probabilities are proportional to the intuitive product form $\prod_i W_{i,\Pi(i)}$, then the probability ratio for these two permutations is 2. Notice that this intuitive product weight measure is the distribution used by the Hedge algorithm that explicitly treats each permutation as a separate expert. Therefore PermELearn is clearly different than a concise implementation of Hedge for permutations.

6. Follow the Perturbed Leader Algorithm

Perhaps the simplest on-line algorithm is the *Follow the Leader* (FL) algorithm: at each trial predict with one of the best models on the data seen so far. Thus FL predicts at trial t with an expert in $\operatorname{argmin}_i \ell_i^{<t}$ or any permutation in $\operatorname{argmin}_\Pi \Pi \bullet L^{<t}$, where "$<t$" indicates that we sum over the past trials, that is, $\ell_i^{<t} := \sum_{q=1}^{t-1} \ell_i^q$. The FL algorithm is clearly non-optimal; in the expert setting there is a simple adversary strategy that forces FL to have loss at least n times larger than the loss of the best expert in hindsight.

The expected total loss of tuned Hedge is one times the loss of the best expert plus lower order terms. Hedge achieves this by randomly choosing experts. The probability w_i^{t-1} for choosing expert i at trial t is proportional to $e^{-\eta \ell_i^{<t}}$. As the learning rate $\eta \to \infty$, Hedge becomes FL (when there are

no ties) and the same holds for PermELearn. Thus the exponential weights with moderate η may be seen as a soft min calculation: the algorithm hedges its bets and does not put all its probability on the expert with minimum loss so far.

The "Follow the Perturbed Leader" (FPL) algorithm of Kalai and Vempala (2005) is an alternate on-line prediction algorithm that works in a very general setting. It adds random perturbations to the total losses of the experts incurred so far and then predicts with the expert of minimum perturbed loss. Their FPL* algorithm has bounds closely related to Hedge and other multiplicative weight algorithms and in some cases Hedge can be simulated exactly (Kuzmin and Warmuth, 2005) by judiciously choosing the distribution of perturbations. However, for the permutation problem the bounds we were able to obtain for FPL* are weaker than the the bound we obtained bounds for PermELearn that uses exponential weights despite the apparent similarity between our representations and the general formulation of FPL*.

The FPL setting uses an abstract k-dimensional decision space used to encode predictors as well as a k-dimensional state space used to represent the losses of the predictors. At any trial, the current loss of a particular predictor is the dot product between that predictor's representation in the decision space and the state-space vector for the trial. This general setting can explicitly represent each permutation and its loss when $k = n!$. The FPL setting also easily handles the encodings of permutations and losses used by PermELearn by representing each permutation matrix Π and loss matrix L as n^2-dimensional vectors.

The FPL* algorithm (Kalai and Vempala, 2005) takes a parameter ε and maintains a cumulative loss matrix C (initially C is the zero matrix) At each trial, FPL*:

1. Generates a random perturbation matrix P where each $P_{i,j}$ is proportional to $\pm r_{i,j}$ where $r_{i,j}$ is drawn from the standard exponential distribution.

2. Predicts with a permutation Π minimizing $\Pi \bullet (C+P)$.

3. After getting the loss matrix L, updates C to $C+L$.

Note that FPL* is more computationally efficient than PermELearn. It takes only $O(n^3)$ time to make its prediction (the time to compute a minimum weight bipartite matching) and only $O(n^2)$ time to update C. Unfortunately the generic FPL* loss bounds are not as good as the bounds on PermELearn. In particular, they show that the loss of FPL* on any sequence of trials is at most[8]

$$(1+\varepsilon)\mathcal{L}_{\text{best}} + \frac{8n^3(1+\ln n)}{\varepsilon}$$

where ε is a parameter of the algorithm. When the loss of the best expert is known ahead of time, ε can be tuned and the bound becomes

$$\mathcal{L}_{\text{best}} + 4\sqrt{2\mathcal{L}_{\text{best}} n^3(1+\ln n)} + 8n^3(1+\ln n) \quad .$$

Although FPL* gets the same $\mathcal{L}_{\text{best}}$ leading term, the excess loss over the best permutation grows as $n^3 \ln n$ rather the $n \ln n$ growth of PermELearn's bound. Of course, PermELearn pays for the improved bound by requiring more computation.

8. The n^3 terms in the bounds for FPL are n times the sum of the entries in the loss matrix. So if the application has a loss motif whose entries sum to only n, then the n^3 factors become n^2.

It is important to note that Kalai and Vempala also present a refined analysis of FPL* when the perturbed leader changes only rarely. This analysis leads to bounds that are similar to the bounds given by the entropic analysis of the Hedge algorithm (although the constant on the square-root term is not quite as good). However, this refined analysis cannot be directly applied with the efficient representations of permutations because the total perturbations associated with different permutations are no longer independent exponentials. We leave the adaptation of the refined analysis to the permutation case as an open problem.

7. Lower Bounds

In this section we prove lower bounds on the worst-case regret of any algorithm for our permutation learning problem by reducing the expert allocation problem for n experts with loss range $[0,n]$ to the permutation learning problem. We then show in Appendix C a lower bound for this n expert allocation problem that uses a known lower bound in the expert advice setting with losses in $[0,1]$.

For the reduction we choose any set of n permutations $\{\Pi^1,\ldots,\Pi^n\}$ that use disjoint positions, that is, $\sum_{i=1}^n \Pi^i$ is the $n\times n$ matrix of all ones. Using disjoint positions ensures that the losses of these n permutations can be set independently. Each Π^i matrix in this set corresponds to the ith expert in the n-expert allocation problem. To simulate an n-expert trial with loss vector $\ell\in[0,n]^n$ we use a loss matrix L s.t. $\Pi^i\bullet L=\ell_i$. This is done by setting all entries in $\{L_{q,\Pi^i(q)} : 1\le q\le n\}$ to $\ell_i/n\in[0,1]$, that is, $L=\sum_i \Pi^i(\ell_i/n)$. Now for any doubly stochastic matrix W,

$$W\bullet L=\sum_i \frac{\Pi^i\bullet W}{n}\,\ell_i.$$

Note that the n dimensional vector with the components $(\Pi^i\bullet W)/n$ is a probability vector and therefore any algorithm for the n-element permutation problem can be used as an algorithm for the n-expert allocation problem with losses in the range $[0,n]$. Thus any lower bound for the latter model is also a lower bound on the n-element permutation problem.

We first prove a lower bound for the case when at least one expert has loss zero for the entire sequence of trials. If the algorithm allocates any weight to experts that have already incurred positive loss, then the adversary can assign loss only to those experts and force the algorithm increase its expected loss without reducing the number of experts of loss zero. Thus we can assume w.l.o.g. that the algorithm allocates positive weight only to experts of zero loss. The algorithm minimizes its expected loss and the adversary maximizes it. We get a lower bound by fixing the adversary: This adversary assigns loss n to one of the experts which received the highest probability by the algorithm and all other experts are assigned loss zero. Clearly the optimal allocation against such an adversary uses the uniform distribution over those experts with zero loss. The number of experts with loss zero is reduced by one in each trial. At trial $t=1,\ldots,n-1$, $n+1-t$ experts are left and the expected loss is $\frac{n}{n+1-t}$. In the first $n-1$ trials the algorithm incurs expected loss

$$\sum_{i=2}^{n}\frac{n}{i}\approx n\ln n.$$

When the loss of the best expert is large then the following theorem follows from Corollary 11:

Theorem 6 *There exists n_0 such that for each dimension $n \geq n_0$, there is a T_n where for any number of trials $T \geq T_n$ the following holds for any algorithm A for learning permutations of n elements in the allocation setting: there is a sequence S of T trials such that*

$$\mathcal{L}_{\text{best}}(S) \leq nT/2 \quad \textit{and} \quad \mathcal{L}_A(S) - \mathcal{L}_{\text{best}}(S) \geq \sqrt{(nT/2)\, n \ln n}.$$

These two lower bounds can be combined to the following lower bound on the expected regret for our permutation learning problem:

$$\max\left(\sqrt{\mathcal{L}_{\text{best}} n \ln n}, n \ln n\right) \geq \frac{\sqrt{\mathcal{L}_{\text{best}} n \ln n} + n \ln n}{2}.$$

This means that the tuned upper bound on the expected regret of PermELearn given after Theorem 4 cannot be improved by more than a small ($2\sqrt{2}$) constant factor.

8. Conclusions

We considered the problem of learning a permutation on-line, when the per-trial loss is specified by a matrix $L \in [0,1]^{n \times n}$ and the loss of a permutation matrix Π is the linear loss $\Pi \bullet L$. The standard approach would treat each permutation as an expert. However this is computationally inefficient and introduces an additional factor of n in the regret bounds (since the per-trial loss of a permutation is $[0,n]$ rather than $[0,1]$). We do not know if this factor of n is necessary for permutations, and it remains open whether their special structure allows better regret bounds on the standard expert algorithms when the experts are permutations.

We developed a new algorithm called PermELearn that uses a doubly stochastic matrix to maintain its uncertainty over the hidden permutation. PermELearn decomposes this doubly stochastic matrix into a small mixture of permutation matrices and predicts with a random permutation from this mixture. A similar decomposition was used by Warmuth and Kuzmin (2008) to learn as well as the best fixed-size subset of experts.

PermELearn belongs to the Exponentiated Gradient family of updates and the analysis uses a relative entropy as a measure of progress. The main technical insight is that the per-trial progress bound already holds for the un-normalized update and that re-balancing the matrix only increases the progress. Since the re-balancing step does not have a closed form, accounting for it in the analysis would otherwise be problematic. We also showed that the update for the Hedge algorithm can be split into an un-normalized update and a normalization. In this more basic setting the per trial progress bound also holds for the un-normalized update.

Our analysis techniques rely on Bregman projection methods[9] and the regret bounds hold not only for permutations but also for mixtures of permutations. This means that if we have additional convex constraints that are satisfied by the mixture that we compare against, then we can project the algorithm's weight matrix onto these constraints without hurting the analysis (Herbster and Warmuth, 2001). With these kinds of side constraints we can enforce some relationships between the parameters, such as $W_{i,j} \geq W_{i,k}$ (i is more likely mapped to j than k).

Our main contribution is showing how to apply the analysis techniques from the expert advice setting to the problem of efficiently learning a permutation. This means that many of the tools from

9. Following Kuzmin and Warmuth (2007), we also showed in Appendix B that the regret bounds proven in this paper can be reproduced with potential based methods.

the expert setting are likely to carry over to permutations: lower bounding the weights when the comparator is shifting (Herbster and Warmuth, 1998), long-term memory when shifting between a small set of comparators (Bousquet and Warmuth, 2002), capping the weights from the top if the goal is to be close to the best set of disjoint permutations of fixed size (Warmuth and Kuzmin, 2008), adapting the updates to the multi-armed bandit setting when less feedback is provided (Auer et al., 2002),[10] and PAC Bayes analysis of the exponential updates (McAllester, 2003).

We also applied the "Follow the Perturbed Leader" techniques to our permutation problem. This algorithm adds randomness to the total losses and then predicts with a minimum weighted matching which costs $O(n^3)$ whereas our more complicated algorithm is at least $O(n^4)$ and has precision issues. However the bounds currently provable for the FPL* algorithm of Kalai and Vempala (2005) are much worse than for our PermELearn algorithm. The key open problem is whether we can have the best of both worlds: add randomness to the loss matrix so that the expected minimum weighted matching is the stochastic matrix produced by the PermELearn update (4). This would mean that we could use the faster algorithm together with our tighter analysis. In the simpler weighted majority setting this has been done already (Kuzmin and Warmuth, 2005; Kalai, 2005). However we do not yet know how to simulate the PermELearn update this way.

Our on-line learning problem requires that the learner's prediction to be an actual permutation. This requirement makes sense for the linear loss we focus on in this paper, but may be less appropriate for on-line regression problems. Consider the case where on each trial the algorithm selects a doubly stochastic matrix M while nature simultaneously picks a matrix $X \in [0,1]^{n\times n}$ and a real number y. The prediction is $\hat{y} = M \bullet X$ and the loss on the trial is $(\hat{y}-y)^2$. With this convex quadratic loss, it is generally better for the algorithm to hedge its bets between competing permutations and select its doubly stochastic parameter matrix W as M instead of a random permutation matrix Π chosen s.t. $\mathbb{E}(\Pi) = W$. The Exponentiated Gradient algorithm can be applied to this type of non-linear regression problem (see, e.g., Helmbold et al., 1999) and Sinkhorn Balancing can project the parameter matrix W onto the row and column sum constraints.

We close with an open problem involving higher order loss functions. In this paper we considered linear losses specified by a square matrix L where $L_{i,j}$ gives the loss when entry (i, j) is used in the permutation. Can one prove good regret bounds when the loss depends on how the permutation assigns multiple elements? A pairwise loss could be represented with a four-dimensional matrix L where $L_{i,j,k,l}$ is added to the loss only when the predicted permutation maps *both* i to j *and* k to l. The recently developed Fourier analysis techniques for permutations (Kondor et al., 2007; Huang et al., 2009) may be helpful in generalizing our techniques to this kind of higher order loss.

Acknowledgments

We thank Vishy Vishwanathan for helping us simplify the lower bounds, and David DesJardins for helpful discussions and pointers to the literature on Sinkhorn Balancing.

10. Recently, a less efficient algorithm which explicitly maintains one expert per permutation has been analyzed in the bandit setting by Cesa-Bianchi and Lugosi (2009). However the bounds they obtain have the loss range as an additional factor in the regret bound (a factor of n for permutations).

Appendix A. Size of the Decomposition

Here we show that the iterative matching method of Algorithm 1 requires most n^2-2n+2 permutations to decompose an doubly stochastic matrix. This matches the bound provided by Birkhoff's Theorem. Note that the discussion in Section 4 shows why Algorithm 1 can always find a suitable permutation.

Theorem 7 *Algorithm 1 decomposes any doubly stochastic matrix into a convex combination of at most n^2-2n+2 permutations.*

Proof Let W be a doubly stochastic matrix and let $\Pi_1,\ldots,\Pi_\ell$ and $\alpha_1,\ldots,\alpha_\ell$ be any sequence of permutations and coefficients created by Algorithm 1 on input W. For $0\le j\le\ell$, define $M^j = W-\sum_{i=1}^{j}\alpha_i\Pi_i$. By permuting rows and columns we can assume without loss of generality that Π_ℓ is the identity permutation. Let G^j (for $1\le j\le\ell$) be the (undirected) graph on the n vertices $\{1,\ldots n\}$ where the undirected edge $\{p,q\}$ between nodes $p\neq q$ is present if and only if either $M^j_{p,q}$ or $M^j_{q,p}$ is non-zero. Thus both $G^{\ell-1}$ and G^ℓ are the empty graph and each G^{j+1} has a (not necessarily strict) subset of the edges in G^j. Note the natural correspondences between vertices in the graphs and rows and columns in the matrices.

The proof is based in the following key invariant:

$$\#\text{ of zero entries in } M^j \ge j + (\#\text{ connected components in } G^j) - 1.$$

This holds for the initial M^0. Furthermore, when the connected components of G^j and G^{j+1} are the same, the algorithm insures that M^{j+1} has at least one more zero than M^j. We now analyze the case when new connected components are created.

Let vertex set V be a connected component in G^{j+1} that was split off a larger connected component in G^j. We overload the notation, and use V also for the set of matrix rows and/or columns associated with the vertices in the connected component.

Since V is a connected component of G^{j+1} there are no edges going between V and the rest of the graph, so if M^{j+1} is viewed as a (conserved) flow, there is no flow either into or out of V:

$$\sum_{r\in V}\sum_{c\notin V} M^{j+1}_{r,c} = \sum_{r\notin V}\sum_{c\in V} M^{j+1}_{r,c} = 0.$$

Thus all entries of M^j in the sets $\{M^j_{r,c}>0 : r\in V, c\notin V\}$ and $\{M^j_{r,c}>0 : r\notin V, c\in V\}$ are set to zero in M^{j+1}. Since V was part of a larger connected component in G^j, at least one of these sets must be non-empty. We now show that both these sets of entries are non-empty.

Each row and column of M^j sum to $1-\sum_{i=1}^{j}\alpha_i$. Therefore

$$\left(1-\sum_{i=1}^{j}\alpha_i\right)|V| = \sum_{r\in V}\sum_{c=1}^{n} M^j_{r,c} = \sum_{c\in V}\sum_{r=1}^{n} M^j_{r,c}.$$

By splitting the inner sums we get:

$$\sum_{r\in V}\sum_{c\in V} M^j_{r,c} + \sum_{r\in V}\sum_{c\notin V} M^j_{r,c} = \sum_{c\in V}\sum_{r\in V} M^j_{r,c} + \sum_{c\in V}\sum_{r\notin V} M^j_{r,c}.$$

By canceling the first sums and viewing M^j as a flow in G^j we conclude that the total flow out of V in M^j equals the total flow into V in M^j, that is,

$$\sum_{r\in V}\sum_{c\notin V} M^j_{r,c} = \sum_{c\in V}\sum_{r\notin V} M^j_{r,c}$$

and both sets $\{M^j_{r,c} > 0 : r \in V, c \notin V\}$ and $\{M^j_{r,c} > 0 : r \notin V, c \in V\}$ sum to the same positive total, and thus are non-empty.

This establishes the following fact that we can use in the remainder of the proof: for each new connected component V in G^{j+1}, some entry $M^j_{r,c}$ from a row r in V was set to zero.

Now let k_j (and k_{j+1}) be the number of connected components in graph G^j (and G^{j+1} respectively). Since the edges in G^{j+1} are a subset of the edges in G^j, $k_{j+1} \geq k_j$. We already verified the invariant when $k_j = k_{j+1}$, so we proceed assuming $k_{j+1} > k_j$. In this case at most $k_j - 1$ components of G^j survive when going to G^{j+1}, and at least $k_{j+1} - (k_j - 1)$ new connected components are created. The vertex sets of the new connected components are disjoint, and in the rows corresponding to each new connected component there is at least one non-zero entry in M^j that is zero in M^{j+1}. Therefore, M^{j+1} has at least $k_{j+1} - k_j + 1$ more zeros than M^j, verifying the invariant for the case when $k_{j+1} > k_j$.

Since $G^{\ell-1}$ has n connected components, the invariant shows that the number of zeros in $M^{\ell-1}$ is at least $\ell - 1 + n - 1$. Furthermore, M^ℓ has n more zeros than $M^{\ell-1}$, so M^ℓ has at least $\ell + 2n - 2$ zeros. Since M^ℓ has only n^2 entries, $n^2 \geq \ell + 2n - 2$ and $\ell \leq n^2 - 2n + 2$ as desired. ■

The fact that Algorithm 1 uses at most $n^2 - 2n + 2$ permutations can also be established with a dimensionality argument like that in Section 2.7 of Bazaraa et al. (1977).

Appendix B. Potential Based Bounds

Let us begin with the on-line allocation problem in the simpler expert setting. There are always two ways to motivate on-line updates. One trades the divergence to the last weight vector against the loss in the last trial, and the other trades the divergence to the initial weight vector against the loss in all past trials (Azoury and Warmuth, 2001):

$$w^t := \operatorname*{argmin}_{\sum_i w_i = 1} \left(\Delta(w, w^{t-1}) + \eta\, w \cdot \ell^t\right), \quad w^t := \operatorname*{argmin}_{\sum_i w_i = 1} \left(\Delta(w, w^0) + \eta\, w \cdot \ell^{\leq t}\right).$$

By differentiating the Lagrangian for each optimization problem we obtain the solutions to both minimization problems:

$$w^t_i = w^{t-1}_i e^{-\eta \ell^t_i + \widetilde{\beta}^t}, \quad w^t_i = w^0_i e^{-\eta \ell^{\leq t}_i + \beta^t},$$

where the signs of the Lagrange multipliers $\widetilde{\beta}^t$ and β^t are unconstrained and their values are chosen so that the equality constraints are satisfied. The left update can be unrolled to obtain

$$w^t_i = w^0_i e^{-\eta \ell^{\leq t}_i + \sum_{q=1}^t \widetilde{\beta}^q}.$$

This means the Lagrangian multipliers for both problems are related by the equality $\sum_{q=1}^t \widetilde{\beta}^q = \beta^t$ and both problems have the same solution:[11] $w^t_i = \frac{w^0_i e^{-\eta \ell^{\leq t}_i}}{\sum_{j=1}^n w^0_j e^{-\eta \ell^{\leq t}_j}}$. We use the value of the right convex

11. The solutions can differ if the minimization is over linear inequality constraints (Kuzmin and Warmuth, 2007).

optimization problem's objective function as our potential v^t. Its Lagrangian is

$$\sum_i \left(w_i \ln \frac{w_i}{w_i^0} + w_i^0 - w_i + \eta w_i \ell_i^{\leq t} \right) + \beta \left(\sum_i w_i - 1 \right)$$

and since there is no duality gap:[12]

$$v^t := \min_{\sum_i w_i = 1} \left(\Delta(w, w^0) + \eta \, w \cdot \ell_{\leq t} \right) = \max_{\beta} \underbrace{\sum_i w_i^0 (1 - e^{-\eta \ell_i^{\leq t} - \beta}) - \beta}_{\text{dual function } \theta^t(\beta)}.$$

Here β is the (unconstrained) dual variable for the primal equality constraint and the w_i's have been optimized out. By differentiating we can optimize β in the dual problem and arrive at

$$v^t = -\ln \sum_i w_i^0 e^{-\eta \ell_i^{\leq t}}.$$

This form of the potential has been used extensively for analyzing expert algorithms (see, e.g., Kivinen and Warmuth, 1999; Cesa-Bianchi and Lugosi, 2006). One can easily show the following key inequality (essentially Lemma 5.2 of Littlestone and Warmuth, 1994):

$$\begin{aligned} v^t - v^{t-1} &= -\ln \sum_i w_i^0 e^{-\eta \ell_i^{\leq t}} + \ln \sum_i w_i^0 e^{-\eta \ell_i^{<t}} \\ &= -\ln \sum_i w_i^{t-1} e^{-\eta \ell_i^t} \\ &\geq -\ln \sum_i w_i^{t-1} (1 - (1 - e^{-\eta}) \ell_i^t) \\ &\geq (1 - e^{-\eta}) \, w^{t-1} \cdot \ell^t. \end{aligned} \tag{13}$$

Summing over all trials and using $v^0 = 0$ gives the familiar bound:

$$\sum_{t=1}^{T} w^{t-1} \cdot \ell^t \leq \frac{v^T}{1 - e^{-\eta}} = \frac{1}{1 - e^{-\eta}} \min_{\sum_i w_i = 1} \left(\Delta(w, w^0) + \eta \, w \cdot \ell^{\leq T} \right).$$

Note that by Kivinen and Warmuth (1999)

$$v^t - v^{t-1} = -\ln \left(\sum_i w_i^{t-1} e^{-\eta \ell_i^t} \right) = \Delta(u, w^{t-1}) - \Delta(u, w^t) + \eta \, u \cdot \ell^t,$$

and therefore the Inequality (13) is the same as Inequality (10). Since

$$\sum_{t=1}^{T} (v^t - v^{t-1}) = v^T = -\ln \left(\sum_i w_i^0 e^{-\eta \ell_i^{\leq t}} \right),$$

summing the bound (13) over t coincides with the bound (11).

12. There is no duality gap in this case because the primal problem is a feasible convex optimization problem subject to linear constraints.

We now reprove the key inequality (13) using the dual function $\theta^t(\beta)$. Note β^t maximizes this function, that is, $v^t = \theta^t(\beta^t)$, and the optimal primal solution is $w_i^t = w_i^0 e^{-\eta \ell_i^{\leq t} - \beta^t}$. Now,

$$\begin{aligned} v^t - v^{t-1} &= \theta^t(\beta^t) - \theta^{t-1}(\beta^{t-1}) \\ &\geq \theta^t(\beta^{t-1}) - \theta^{t-1}(\beta^{t-1}) \\ &= \sum_i \underbrace{w_i^0 e^{-\eta \ell_i^{<t} - \beta^{t-1}}}_{w_i^{t-1}} (1 - e^{-\eta \ell_i^t}) \\ &\geq \sum_i w_i^{t-1} (1 - (1 - (1 - e^{-\eta})\ell_i^t)) \\ &= (1 - e^{-\eta})\, w^{t-1} \cdot \ell_t \end{aligned}$$

where we used $e^{-\eta \ell_i^t} \leq 1 - (1 - e^{-\eta})\ell_i^t$ to get the fourth line. Notice that in the first inequality above we used $\theta^t(\beta^t) \geq \theta^t(\beta^{t-1})$. This is true because β^t maximizes $\theta^t(\beta)$ and the old choice β^{t-1} is non-optimal. The dual parameter β^{t-1} assures that w^{t-1} is normalized and $\theta^t(\beta^{t-1})$ is related to plugging the intermediate unnormalized weights $w'^t_i := w_i^0 e^{-\eta \ell_i^{\leq t} - \beta^{t-1}}$ into the primal problem for trial t. This means that the inequality $\theta^t(\beta^t) \geq \theta^t(\beta^{t-1})$ corresponds to the Bregman projection of the unnormalized update onto the equality constraint. The difference $\theta^t(\beta^{t-1}) - \theta^{t-1}(\beta^{t-1})$ in the second line above is the progress in the value when going from w^{t-1} at the end of trial $t-1$ to the intermediate unnormalized update w'^t at trial t. Therefore this proof also does not exploit the normalization.

The bound for the permutation problem follows the same outline. We use the value of the following optimization problem as our potential:

$$\begin{aligned} v_{t+1} &:= \min_{\substack{\forall i : \sum_j A_{i,j} = 1 \\ \forall j : \sum_i A_{i,j} = 1}} \left(\Delta(A, W^0) + \eta\, (A \bullet L^{\leq t})\right) \\ &= \max_{\alpha_i, \beta_j} \underbrace{\sum_{i,j} W_{i,j}^0 (1 - e^{-\eta L_{i,j}^{\leq t} - \alpha_i - \beta_j}) - \sum_i \alpha_i - \sum_j \beta_j}_{\theta^t(\alpha, \beta)}. \end{aligned}$$

The α_i and β_j are the dual variables for the row and column constraints. Now we can't optimize out the dual variables in the dual function $\theta^t(\alpha, \beta)$ does not have a maximum in closed form. Nevertheless the above proof technique based on duality still works. Let α^t and β^t be the optimizers of $\theta^t(\alpha, \beta)$. Then the optimum primal solution (the parameter vector of PermELearn) becomes

$$W_{i,j}^t = W_{i,j}^0 e^{-\eta L_{i,j}^{\leq t} - \alpha_i^t - \beta_j^t}$$

and we can analyze the increase in value as before:

$$\begin{aligned} v^t - v^{t-1} &= \theta^t(\alpha^t, \beta^t) - \theta^{t-1}(\alpha^{t-1}, \beta^{t-1}) \\ &\geq \theta^t(\alpha_{t-1}, \beta_{t-1}) - \theta^{t-1}(\alpha^{t-1}, \beta^{t-1}) \\ &= \sum_{i,j} \underbrace{W_{i,j}^0 e^{-\eta L_{i,j}^{<t} - \alpha_i^{t-1} - \beta_j^{t-1}}}_{W_{i,j}^{t-1}} (1 - e^{-\eta L_{i,j}^{t-1}}) \\ &\geq \sum_{i,j} W_{i,j}^{t-1} (1 - (1 - e^{-\eta}) L_{i,j}^t) \\ &= (1 - e^{-\eta})\, W^{t-1} \bullet L^t. \end{aligned}$$

Summing over trials in the usual way gives the bound

$$\sum_{t=1}^{T} W^{t-1} \bullet L^t \leq \frac{v_T}{1-e^{-\eta}} = \frac{1}{1-e^{-\eta}} \min_{\substack{\forall i: \sum_j A_{i,j}=1 \\ \forall j: \sum_i A_{i,j}=1}} \left(\Delta(A, W^0) + \eta\, (A \bullet L_{\leq T})\right)$$

which is the same as the bound of Theorem 4.

Appendix C. Lower Bounds for the Expert Advice Setting

We first modify a known lower bound from the expert advice setting with the absolute loss (Cesa-Bianchi et al., 1997). We begin by describing that setting and show how it relates to the allocation setting for experts.

In the expert advice setting there are n experts. Each trial t starts with nature selecting a *prediction* x_i^t in [0,1] for each expert $i \in \{1,\ldots,n\}$. The algorithm is given these predictions and then produces its own prediction $\hat{y}^t \in [0,1]$. Finally, nature selects a *label* $y^t \in \{0,1\}$ for the trial. The algorithm is charged loss $|\hat{y}^t - y^t|$ and expert i gets loss $|x_i^t - y^t|$.

Any algorithm in the allocation setting leads to an algorithm in the above expert advice setting: keep the weight update unchanged, predict with the weighted average (i.e., $\hat{y}^t = w^{t-1} \cdot \mathbf{x}^t$) and define the loss vector in $\ell^t \in [0,1]^n$ in terms of the absolute loss:

$$|\underbrace{w^{t-1} \cdot \mathbf{x}^t}_{\hat{y}^t} - y^t| \;=\; \sum_i w_i^{t-1} \underbrace{|x_i^t - y^t|}_{\ell_i^t} \;=\; w^{t-1} \cdot \ell^t,$$

where the first equality holds because $x_i^t \in [0,1]$ and $y^t \in \{0,1\}$. This means that any lower bound on the regret in the above expert advice setting immediately leads to a lower bound on the expected loss in the allocation setting for experts when the loss vectors lie in $[0,1]^n$.

We now introduce some more notation and state the lower bound from the expert advice setting that we build on. Let $\mathcal{S}_{n,T}$ be the set of all sequences of T trials with n experts in the expert advice setting with the absolute loss. Let $V_{n,T}$ be the minimum over algorithms of the worst case regret over sequences in $\mathcal{S}_{n,T}$.

Theorem 8 *(Cesa-Bianchi et al., 1997, Theorem 4.5.2)*

$$\lim_{n\to\infty} \lim_{T\to\infty} \frac{V_{n,T}}{\sqrt{(T/2)\ln n}} = 1.$$

This means that for all $\varepsilon > 0$ there exists n_ε such that for each $n \geq n_\varepsilon$, there is a $T_{\varepsilon,n}$ where for all $T \geq T_{\varepsilon,n}$,

$$V_{n,T} \geq (1-\varepsilon)\sqrt{(T/2)\ln n}.$$

By further expanding the definition of $V_{n,T}$ we get the following version of the above lower bound that avoids the use of limits:

Corollary 9 *For all $\varepsilon > 0$ there exists n_ε such that for each number of experts $n \geq n_\varepsilon$, there is a $T_{\varepsilon,n}$ where for any number of trials $T \geq T_{\varepsilon,n}$ the following holds for any algorithm A in the expert advice setting with the absolute loss: there is a sequence S of T trials with n experts such that*

$$\mathcal{L}_A(S) - \mathcal{L}_{\text{best}}(S) \geq (1-\varepsilon)\sqrt{(T/2)\ln n}.$$

This lower bound on the regret depends on the number of trials T. We now use a reduction to bound $\mathcal{L}_{\text{best}}(S)$ by $T/2$. Define $R(S^-)$ as the transformation that takes a sequence S^- of trials in $\mathcal{S}_{n-1,T}$ and produces a sequence of trials in $\mathcal{S}_{n,T}$ by adding an extra expert whose predictions are simply 1 minus the predictions of the first expert. On each trial the absolute loss of the additional expert on sequence $R(S^-)$ is 1 minus the loss of the first expert. Therefore either the first expert or the additional expert will have loss at most $T/2$ on $R(S^-)$.

Theorem 10 *For all $\varepsilon > 0$ there exists n_ε such that for each number of experts $n \geq n_\varepsilon$, there is a $T_{\varepsilon,n}$ where for any number of trials $T \geq T_{\varepsilon,n}$ the following holds for any algorithm A in the expert advice setting with the absolute loss: there is a sequence S of T trials with n experts such that*

$$\mathcal{L}_{\text{best}}(S) \leq T/2 \quad \textit{and} \quad \mathcal{L}_A(S) - \mathcal{L}_{\text{best}}(S) \geq (1-\varepsilon)\sqrt{(T/2)\ln n}.$$

Proof We begin by showing that the regret on a transformed sequence in $\{R(S^-) : S^- \in \mathcal{S}_{n-1,T}\}$ is at least $(1-\varepsilon/2)\sqrt{(T/2)\ln(n-1)}$.

Note that for all $R(S^-)$, $\mathcal{L}_{\text{best}}(R(S^-)) \leq T/2$ and assume to the contrary that some algorithm A has regret strictly less than $(1-\varepsilon/2)\sqrt{(T/2)\ln(n-1)}$ on every sequence in $\{R(S^-) : S^- \in \mathcal{S}_{n-1,T}\}$. We then create an algorithm A^- that runs transformation $R(\cdot)$ on-the-fly and predicts as A does on the transformed sequence. Therefore A^- on S^- and A on $R(S^-)$ make the same predictions and have the same total loss. On every sequence $S^- \in \mathcal{S}_{n-1,T}$ we have $\mathcal{L}_{\text{best}}(S^-) \geq \mathcal{L}_{\text{best}}(R(S))$ and therefore

$$\begin{aligned}
\mathcal{L}_{A^-}(S^-) - \mathcal{L}_{\text{best}}(S^-) &\leq \mathcal{L}_{A^-}(S^-) - \mathcal{L}_{\text{best}}(R(S^-)) \\
&= \mathcal{L}_A(R(S^-)) - \mathcal{L}_{\text{best}}(R(S^-)) \\
&< (1-\varepsilon/2)\sqrt{(T/2)\ln(n-1)}.
\end{aligned}$$

Now if $n-1$ is at least the $n_{\varepsilon/2}$ of Corollary 9 and T is at least the $T_{\varepsilon/2,n-1}$ of the same corollary, then this contradicts that corollary.

This means that for any algorithm A and large enough n and T, there is a sequence S for which the algorithm has regret at least $(1-\varepsilon/2)\sqrt{(T/2)\ln(n-1)}$ and $\mathcal{L}_{\text{best}}(S) \leq T/2$. By choosing the lower bound on n large enough,

$$(1-\varepsilon/2)\sqrt{(T/2)\ln(n-1)} \geq (1-\varepsilon)\sqrt{(T/2)\ln n}$$

and the theorem follows. ■

Note that the tuned upper bounds in the allocation setting (9) have an additional factor of $\sqrt{2}$. This is due to the fact that in the allocation setting the algorithm predicts with the weighted average and this is non-optimal. In the expert setting with the absolute loss, the upper bound (based on a different prediction function) and the lower bound on the regret are asymptotically tight (See Theorem 8). We are now ready to prove our lower bound for the allocation setting with experts when the losses of the experts are in $[0,n]^n$ instead of $[0,1]^n$.

Corollary 11 *There exists n_0 such that for each dimension $n \geq n_0$, there is a T_n where for any number of trials $T \geq T_n$ the following holds for any algorithm A for allocation setting with n experts: there is a sequence S of T trials with loss vectors in $[0,n]^n$ such that*

$$\mathcal{L}_{\text{best}}(S) \leq nT/2 \quad \textit{and} \quad \mathcal{L}_A(S) - \mathcal{L}_{\text{best}}(S) \geq \sqrt{(nT/2)n\ln n}.$$

Proof Via the reduction we stated at the beginning of the section, the following lower bound for the allocation setting with n experts immediately follows from the previous theorem: For any algorithm in the allocation setting for n experts there is a sequence $\widetilde{S}$ of T trials where the losses of the experts lie in $[0,1]$ such that

$$\mathcal{L}_{\text{best}}(\widetilde{S}) \leq T/2 \quad \text{and} \quad \mathcal{L}_A(\widetilde{S}) - \mathcal{L}_{\text{best}}(\widetilde{S}) \geq \sqrt{(T/2)\ln n}.$$

Now we simply scale the loss vectors by the factor n, that is, the scaled sequences S have loss vectors in the range $[0,n]^n$ and $\mathcal{L}_{\text{best}}(S) \leq nT/2$. The lower bound becomes $n\sqrt{(T/2)\ln n} = \sqrt{(nT/2)n\ln n}$. ■

Abstract

The SGD-QN algorithm is a stochastic gradient descent algorithm that makes careful use of second-order information and splits the parameter update into independently scheduled components. Thanks to this design, SGD-QN iterates nearly as fast as a first-order stochastic gradient descent but requires less iterations to achieve the same accuracy. This algorithm won the "Wild Track" of the first PASCAL Large Scale Learning Challenge (Sonnenburg et al., 2008).

Keywords: support vector machine, stochastic gradient descent

1. Introduction

The last decades have seen a massive increase of data quantities. In various domains such as biology, networking, or information retrieval, fast classification methods able to scale on millions of training instances are needed. Real-world applications demand learning algorithms with low time and memory requirements. The first PASCAL Large Scale Learning Challenge (Sonnenburg et al., 2008) was designed to identify which machine learning techniques best address these new concerns. A generic evaluation framework and various data sets have been provided. Evaluations were carried out on the basis of various performance curves such as training time versus test error, data set size versus test error, and data set size versus training time.[1]

Our entry in this competition, named SGD-QN, is a carefully designed *Stochastic Gradient Descent* (SGD) for *linear Support Vector Machines* (SVM).

Nonlinear models could in fact reach much better generalization performance on most of the proposed data sets. Unfortunately, even in the Wild Track case, the evaluation criteria for the competition reward good scaling properties and short training durations more than they punish suboptimal test errors. Nearly all the competitors chose to implement linear models in order to avoid the

1. This material and its documentation can be found at `http://largescale.first.fraunhofer.de/`.

additional penalty implied by nonlinearities. Although SGD-QN can work on nonlinear models,[2] we only report its performance in the context of linear SVMs.

Stochastic algorithms are known for their poor optimization performance. However, in the large scale setup, when the bottleneck is the computing time rather than the number of training examples, Bottou and Bousquet (2008) have shown that stochastic algorithms often yield the best generalization performances in spite of being worst optimizers. SGD algorithms were therefore a natural choice for the "Wild Track" of the competition which focuses on the relation between training time and test performance.

SGD algorithms have been the object of a number of recent works. Bottou (2007) and Shalev-Shwartz et al. (2007) demonstrate that the plain Stochastic Gradient Descent yields particularly effective algorithms when the input patterns are very sparse, taking less than $O(d)$ space and time per iteration to optimize a system with d parameters. It can greatly outperform sophisticated batch methods on large data sets but suffers from slow convergence rates especially on ill-conditioned problems. Various remedies have been proposed: *Stochastic Meta-Descent* (Schraudolph, 1999) heuristically determines a learning rate for each coefficient of the parameter vector. Although it can solve some ill-conditioning issues, it does not help much for linear SVMs. *Natural Gradient Descent* (Amari et al., 2000) replaces the learning rate by the inverse of the Riemannian metric tensor. This quasi-Newton stochastic method is statistically efficient but is penalized in practice by the cost of storing and manipulating the metric tensor. *Online BFGS* (oBFGS) and *Online Limited storage BFGS* (oLBFGS) (Schraudolph et al., 2007) are stochastic adaptations of the Broyden-Fletcher-Goldfarb-Shanno (BFGS) optimization algorithm. The limited storage version of this algorithm is a quasi-Newton stochastic method whose cost by iteration is a small multiple of the cost of a standard SGD iteration. Unfortunately this penalty is often bigger than the gains associated with the quasi-Newton update. *Online Dual Solvers* for SVMs (Bordes et al., 2005; Hsieh et al., 2008) have also shown good performance on large scale data sets. These solvers can be applied to both linear and nonlinear SVMs. In the linear case, these dual algorithms are surprising close to SGD but do not require fiddling with learning rates. Although this is often viewed as an advantage, we feel that this aspect restricts the improvement opportunities.

The contributions of this paper are twofold:

1. We conduct an analysis of different factors, ranging from algorithmic refinements to implementation details, which can affect the learning speed of SGD algorithms.

2. We present a novel algorithm, denoted SGD-QN, that carefully exploits these speedup opportunities. We empirically validate its properties by benchmarking it against state-of-the-art SGD solvers and by summarizing its results at the PASCAL Large Scale Learning Challenge (Sonnenburg et al., 2008).

The paper is organized as follows: Section 2 analyses the potential gains of quasi-Newton techniques for SGD algorithms. Sections 3 and 4 discuss the sparsity and implementation issues. Finally Section 5 presents the SGD-QN algorithm, and Section 6 reports experimental results.

2. Stochastic gradient works well in models with nonlinear parametrization. For SVMs with nonlinear kernels, we would prefer dual methods, (e.g., Bordes et al., 2005), which can exploit the sparsity of the kernel expansion.

2. Analysis

This section describes our notations and summarizes theoretical results that are relevant to the design of a fast variant of stochastic gradient algorithms.

2.1 SGD for Linear SVMs

Consider a binary classification problem with examples $z = (\mathbf{x}, y) \in \mathbb{R}^d \times \{-1, +1\}$. The linear SVM classifier is obtained by minimizing the primal cost function

$$\mathcal{P}_n(\mathbf{w}) \;=\; \frac{\lambda}{2}\|\mathbf{w}\|^2 + \frac{1}{n}\sum_{i=1}^{n} \ell(y_i \mathbf{w}^\top \mathbf{x}_i) \;=\; \frac{1}{n}\sum_{i=1}^{n}\left(\frac{\lambda}{2}\|\mathbf{w}\|^2 + \ell(y_i \mathbf{w}^\top \mathbf{x}_i)\right), \tag{1}$$

where the hyper-parameter $\lambda > 0$ controls the strength of the regularization term. Although typical SVMs use mildly non regular convex loss functions, we assume in this paper that the loss $\ell(s)$ is convex and twice differentiable with continuous derivatives ($\ell \in C^2[\mathbb{R}]$). This could be simply achieved by smoothing the traditional loss functions in the vicinity of their non regular points.

Each iteration of the SGD algorithm consists of drawing a random training example $(\mathbf{x}_t, y_t)$ and computing a new value of the parameter $\mathbf{w}_t$ as

$$\mathbf{w}_{t+1} \;=\; \mathbf{w}_t - \frac{1}{t+t_0}\mathbf{B}\,\mathbf{g}_t(\mathbf{w}_t) \quad \text{where} \quad \mathbf{g}_t(\mathbf{w}_t) = \lambda \mathbf{w}_t + \ell'(y_t \mathbf{w}_t^\top \mathbf{x}_t)\, y_t\, \mathbf{x}_t \tag{2}$$

where the *rescaling matrix* $\mathbf{B}$ is positive definite. Since the SVM theory provides simple bounds on the norm of the optimal parameter vector (Shalev-Shwartz et al., 2007), the positive constant t_0 is heuristically chosen to ensure that the first few updates do not produce a parameter with an implausibly large norm.

- The traditional first-order SGD algorithm, with decreasing learning rate, is obtained by setting $\mathbf{B} = \lambda^{-1}\mathbf{I}$ in the generic update (2):

$$\mathbf{w}_{t+1} \;=\; \mathbf{w}_t - \frac{1}{\lambda(t+t_0)}\,\mathbf{g}_t(\mathbf{w}_t)\,. \tag{3}$$

- The second-order SGD algorithm is obtained by setting $\mathbf{B}$ to the inverse of the Hessian Matrix $\mathbf{H} = [\,\mathcal{P}_n''(\mathbf{w}_n^*)\,]$ computed at the optimum $\mathbf{w}_n^*$ of the primal cost $\mathcal{P}_n(\mathbf{w})$:

$$\mathbf{w}_{t+1} \;=\; \mathbf{w}_t - \frac{1}{t+t_0}\mathbf{H}^{-1}\,\mathbf{g}_t(\mathbf{w}_t)\,. \tag{4}$$

Randomly picking examples could lead to expensive random accesses to the slow memory. In practice, one simply performs sequential passes over the randomly shuffled training set.

2.2 What Matters Are the Constant Factors

Bottou and Bousquet (2008) characterize the asymptotic learning properties of stochastic gradient algorithms in the *large scale regime*, that is, when the bottleneck is the computing time rather than the number of training examples.

The first three columns of Table 2.2 report the time for a single iteration, the number of iterations needed to reach a predefined accuracy ρ, and their product, the time needed to reach accuracy ρ.

Stochastic Gradient Algorithm	Cost of one iteration	Iterations to reach ρ	Time to reach accuracy ρ	Time to reach $\mathcal{E} \leq c\,(\mathcal{E}_{\text{app}} + \varepsilon)$
1^{st} Order SGD	$O(d)$	$\frac{\nu\kappa^2}{\rho} + o\left(\frac{1}{\rho}\right)$	$O\left(\frac{d\nu\kappa^2}{\rho}\right)$	$O\left(\frac{d\nu\kappa^2}{\varepsilon}\right)$
2^{nd} Order SGD	$O(d^2)$	$\frac{\nu}{\rho} + o\left(\frac{1}{\rho}\right)$	$O\left(\frac{d^2\nu}{\rho}\right)$	$O\left(\frac{d^2\nu}{\varepsilon}\right)$

Table 1: Asymptotic results for stochastic gradient algorithms, reproduced from Bottou and Bousquet (2008). Compare the second last column (time to optimize) with the last column (time to reach the excess test error ε). *Legend*: n number of examples; d parameter dimension; c positive constant that appears in the generalization bounds; κ condition number of the Hessian matrix $\mathbf{H}$; $\nu = \mathbf{tr}\left(\mathbf{G}\mathbf{H}^{-1}\right)$ with $\mathbf{G}$ the Fisher matrix (see Theorem 1 for more details). The implicit proportionality coefficients in notations $O()$ and $o()$ are of course independent of these quantities.

The excess test error $\mathcal{E}$ measures how much the test error is worse than the best possible error for this problem. Bottou and Bousquet (2008) decompose the test error as the sum of three terms $\mathcal{E} = \mathcal{E}_{\text{app}} + \mathcal{E}_{\text{est}} + \mathcal{E}_{\text{opt}}$. The *approximation error* $\mathcal{E}_{\text{app}}$ measures how closely the chosen family of functions can approximate the optimal solution, the *estimation error* $\mathcal{E}_{\text{est}}$ measures the effect of minimizing the empirical risk instead of the expected risk, the *optimization error* $\mathcal{E}_{\text{opt}}$ measures the impact of the approximate optimization on the generalization performance.

The fourth column of Table 2.2 gives the time necessary to reduce the excess test error $\mathcal{E}$ below a target that depends on $\varepsilon > 0$. This is the important metric because the test error is the measure that matters in machine learning.

Both the first-order and the second-order SGD require a time inversely proportional to ε to reach the target test error. Only the constants differ. The second-order algorithm is insensitive to the condition number κ of the Hessian matrix but suffers from a penalty proportional to the dimension d of the parameter vector. Therefore, algorithmic changes that exploit the second-order information in SGD algorithms are unlikely to yield superlinear speedups. We can at best improve the constant factors.

This property is not limited to SGD algorithms. To reach an excess error ε, the most favorable generalization bounds suggest that one needs a number of examples proportional to $1/\varepsilon$. Therefore, the time complexity of any algorithm that processes a non vanishing fraction of these examples cannot scale better than $1/\varepsilon$. In fact, Bottou and Bousquet (2008) obtain slightly worse scaling laws for typical non-stochastic gradient algorithms.

2.3 Limited Storage Approximations of Second-Order SGD

Since the second-order SGD algorithm is penalized by the high cost of performing the update (2) using a full rescaling matrix $\mathbf{B} = \mathbf{H}^{-1}$, it is tempting to consider matrices that admit a sparse representation and yet approximate the inverse Hessian well enough to reduce the negative impact of the condition number κ.

The following theorem describes how the convergence speed of the generic SGD algorithm (2) is related to the spectrum of matrix $\mathbf{HB}$.

Theorem 1 *Let $\mathbb{E}_\sigma$ denote the expectation with respect to the random selection of the examples $(\mathbf{x}_t, y_t)$ drawn independently from the training set at each iteration. Let $\mathbf{w}_n^* = \arg\min_{\mathbf{w}} \mathcal{P}_n(\mathbf{w})$ be an optimum of the primal cost. Define the Hessian matrix $\mathbf{H} = \partial^2 \mathcal{P}_n(\mathbf{w}_n^*)/\partial \mathbf{w}^2$ and the Fisher matrix $\mathbf{G} = \mathbf{G}_t = \mathbb{E}_\sigma\left[\mathbf{g}_t'(\mathbf{w}_n^*)\,\mathbf{g}_t'(\mathbf{w}_n^*)^\top\right]$. If the eigenvalues of $\mathbf{HB}$ are in range $\lambda_{\max} \geq \lambda_{\min} > 1/2$, and if the SGD algorithm* (2) *converges to $\mathbf{w}_n^*$, the following inequality holds:*

$$\frac{\mathbf{tr}\,(\mathbf{HBGB})}{2\lambda_{\max}-1}\,t^{-1} + \mathrm{o}\left(t^{-1}\right) \leq \mathbb{E}_\sigma\left[\mathcal{P}_n(\mathbf{w}_t) - \mathcal{P}_n(\mathbf{w}_n^*)\right] \leq \frac{\mathbf{tr}\,(\mathbf{HBGB})}{2\lambda_{\min}-1}\,t^{-1} + \mathrm{o}\left(t^{-1}\right).$$

The proof of the theorem is provided in the appendix. Note that the theorem assumes that the generic SGD algorithm converges. Convergence in the first-order case holds under very mild assumptions (e.g., Bottou, 1998). Convergence in the generic SGD case holds because it reduces to the first-order case with a the change of variable $\mathbf{w} \to \mathbf{B}^{-\frac{1}{2}}\,\mathbf{w}$. Convergence also holds under slightly stronger assumptions when the rescaling matrix $\mathbf{B}$ changes over time (e.g., Driancourt, 1994).

The following two corollaries recover the maximal number of iterations listed in Table 2.2 with $\nu = \mathbf{tr}\left(\mathbf{GH}^{-1}\right)$ and $\kappa = \lambda^{-1}\|\mathbf{H}\|$. Corollary 2 gives a very precise equality for the second-order case because the lower bound and the upper bound of the theorem take identical values. Corollary 3 gives a much less refined bound in the first-order case.

Corollary 2 *Assume $\mathbf{B} = \mathbf{H}^{-1}$ as in the second-order SGD algorithm* (4)*. Under the assumptions of Theorem 1, we have*

$$\mathbb{E}_\sigma\left[\mathcal{P}_n(\mathbf{w}_t) - \mathcal{P}_n(\mathbf{w}_n^*)\right] \;=\; \mathbf{tr}\left(\mathbf{GH}^{-1}\right)\,t^{-1} + \mathrm{o}\left(t^{-1}\right) \;=\; \nu t^{-1} + \mathrm{o}\left(t^{-1}\right).$$

Corollary 3 *Assume $\mathbf{B} = \lambda^{-1}\,\mathbf{I}$ as in the first-order SGD algorithm* (3)*. Under the assumptions of Theorem 1, we have*

$$\mathbb{E}_\sigma\left[\mathcal{P}_n(\mathbf{w}_t) - \mathcal{P}_n(\mathbf{w}_n^*)\right] \;\leq\; \lambda^{-2}\,\mathbf{tr}\left(\mathbf{H}^2\mathbf{GH}^{-1}\right)\,t^{-1} + \mathrm{o}\left(t^{-1}\right) \;\leq\; \kappa^2 \nu t^{-1} + \mathrm{o}\left(t^{-1}\right).$$

An often rediscovered property of second order SGD provides an useful point of reference:

Theorem 4 (Fabian, 1973; Murata and Amari, 1999; Bottou and LeCun, 2005)
Let $\mathbf{w}^* = \arg\min \frac{\lambda}{2}\|\mathbf{w}\|^2 + \mathbb{E}_{\mathbf{x},y}\left[\,\ell(y\,\mathbf{w}^\top\mathbf{x})\,\right]$. Given a sample of n independent examples $(\mathbf{x}_i, y_i)$, define $\mathbf{w}_n^* = \arg\min_{\mathbf{w}} \mathcal{P}_n(\mathbf{w})$ and compute $\mathbf{w}_n$ by applying the second-order SGD update (4) *to each of the n examples. If they converge, both $n\mathbb{E}\left[\,\|\mathbf{w}_n - \mathbf{w}^*\|^2\right]$ and $n\mathbb{E}\left[\,\|\mathbf{w}_n^* - \mathbf{w}^*\|^2\right]$ converge to a same positive constant K when n increases.*

This result means that, asymptotically and on average, the parameter $\mathbf{w}_n$ obtained after one pass of second-order SGD is as close to the infinite training set solution $\mathbf{w}^*$ as the true optimum of the primal $\mathbf{w}_n^*$. Therefore, when the training set is large enough, we can expect that a single pass of second-order SGD (n iterations of (4)) optimizes the primal accurately enough to replicate the test error of the actual SVM solution.

When we replace the full second-order rescaling matrix $\mathbf{B} = \mathbf{H}^{-1}$ by a more computationally acceptable approximation, Theorem 1 indicates that we lose a constant factor k on the required number of iterations to reach that accuracy. In other words, we can expect to replicate the SVM test error after k passes over the randomly reshuffled training set.

On the other hand, a well chosen approximation of the rescaling matrix can save a large constant factor on the computation of the generic SGD update (2). The best training times are therefore obtained by carefully trading the quality of the approximation for sparse representations.

	Frequency	Loss
Special example:	$\frac{n}{\texttt{skip}}$	$\frac{\lambda\texttt{skip}}{2}\|\mathbf{w}\|^2$
Examples 1 to n:	1	$\ell(y_i\mathbf{w}^\top\mathbf{x}_i)$

Table 2: The regularization term in the primal cost can be viewed as an additional training example with an arbitrarily chosen frequency and a specific loss function.

2.4 More Speedup Opportunities

We have argued that carefully designed quasi-Newton techniques can save a constant factor on the training times. There are of course many other ways to save constant factors:

- *Exploiting the sparsity of the patterns* (see Section 3) can save a constant factor in the cost of each first-order iteration. The benefits are more limited in the second-order case, because the inverse Hessian matrix is usually not sparse.
- *Implementation details* (see Section 4) such as compiler technology or parallelization on a predetermined number of processors can also reduce the learning time by constant factors.

Such opportunities are often dismissed as engineering tricks. However they should be considered on an equal footing with quasi-Newton techniques. Constant factors matter regardless of their origin. The following two sections provide a detailed discussion of sparsity and implementation.

3. Scheduling Stochastic Updates to Exploit Sparsity

First-order SGD iterations can be made substantially faster when the patterns $\mathbf{x}_t$ are sparse. The first-order SGD update has the form

$$\mathbf{w}_{t+1} \;=\; \mathbf{w}_t - \alpha_t\mathbf{w}_t - \beta_t\mathbf{x}_t\,, \tag{5}$$

where α_t and β_t are scalar coefficients. Subtracting $\beta_t\mathbf{x}_t$ from the parameter vector involves solely the nonzero coefficients of the pattern $\mathbf{x}_t$. On the other hand, subtracting $\alpha_t\mathbf{w}_t$ involves all d coefficients. A naive implementation of (5) would therefore spend most of the time processing this first term. Shalev-Shwartz et al. (2007) circumvent this problem by representing the parameter $\mathbf{w}_t$ as the product $s_t\mathbf{v}_t$ of a scalar and a vector. The update (5) can then be computed as $s_{t+1} = (1-\alpha_t)s_t$ and $\mathbf{v}_{t+1} = \mathbf{v}_t - \beta\mathbf{x}_t/s_{t+1}$ in time proportional to the number of nonzero coefficients in $\mathbf{x}_t$.

Although this simple approach works well for the first order SGD algorithm, it does not extend nicely to quasi-Newton SGD algorithms. A more general method consists of treating the regularization term in the primal cost (1) as an additional training example occurring with an arbitrarily chosen frequency with a specific loss function.

Consider examples with the frequencies and losses listed in Table 2 and write the average loss:

$$\frac{1}{\frac{n}{\texttt{skip}}+n}\left[\frac{n}{\texttt{skip}}\left(\frac{\lambda\texttt{skip}}{2}\|\mathbf{w}\|^2\right) \;+\; \sum_{i=1}^{n}\ell(y_i\mathbf{w}^\top\mathbf{x}_i)\right] = \frac{\texttt{skip}}{1+\texttt{skip}}\left[\frac{\lambda}{2}\|\mathbf{w}\|^2 + \frac{1}{n}\sum_{i=1}^{n}\ell(y_i\mathbf{w}^\top\mathbf{x}_i)\right].$$

SGD	SVMSGD2
Require: $\lambda, \mathbf{w}_0, t_0, T$	**Require:** $\lambda, \mathbf{w}_0, t_0, T$, `skip`
1: $t = 0$	1: $t = 0$, `count` $=$ `skip`

11: **return** $\mathbf{w}_T$	11: **return** $\mathbf{w}_T$

Figure 1: Detailed pseudo-codes of the SGD and SVMSGD2 algorithms.

Minimizing this loss is of course equivalent to minimizing the primal cost (1) with its regularization term. Applying the SGD algorithm to the examples defined in Table 2 separates the regularization updates, which involve the special example, from the pattern updates, which involve the real examples. The parameter `skip` regulates the relative frequencies of these updates. The SVMSGD2 algorithm (Bottou, 2007) measures the average pattern sparsity and picks a frequency that ensures that the amortized cost of the regularization update is proportional to the number of nonzero coefficients. Figure 1 compares the pseudo-codes of the naive first-order SGD and of the first-order SVMSGD2. Both algorithms handle the real examples at each iteration (line 3) but SVMSGD2 only performs a regularization update every `skip` iterations (line 6).

Assume s is the average proportion of nonzero coefficients in the patterns $\mathbf{x}_i$ and set `skip` to c/s where c is a predefined constant (we use $c = 16$ in our experiments). Each pattern update (line 3) requires sd operations. Each regularization update (line 6) requires d operations but occurs s/c times less often. The average cost per iteration is therefore proportional to $O(sd)$ instead of $O(d)$.

4. Implementation

In the optimization literature, a superior algorithm implemented with a slow scripting language usually beats careful implementations of inferior algorithms. This is because the superior algorithm minimizes the training error with a higher order convergence.

This is no longer true in the case of large scale machine learning because we care about the test error instead of the training error. As explained above, algorithm improvements do not improve the order of the test error convergence. They can simply improve constant factors and therefore *compete evenly with implementation improvements*. Time spent refining the implementation is time well spent.

- There are lots of methods for representing sparse vectors with sharply different computing requirement for sequential and random access. Our C++ implementation always uses a full

	Full	**Sparse**
Random access to a single coefficient:	$\Theta(1)$	$\Theta(s)$
In-place addition into a full vector of dimension d':	$\Theta(d)$	$\Theta(s)$
In-place addition into a sparse vector with s' nonzeros:	$\Theta(d+s')$	$\Theta(s+s')$

Table 3: Costs of various operations on a vector of dimension d with s nonzero coefficients.

vector for representing the parameter $\mathbf{w}$, but handles the patterns $\mathbf{x}$ using either a full vector representation or a sparse representation as an ordered list of index/value pairs.

Each calculation can be achieved directly on the sparse representation or after a conversion to the full representation (see Table 3). Inappropriate choices have outrageous costs. For example, on a dense data set with 500 attributes, using sparse vectors increases the training time by 50%; on the sparse RCV1 data set (see Table 4), using a sparse vector to represent the parameter $\mathbf{w}$ increases the training time by more than 900%.

- Modern processors often sport specialized instructions to handle vectors and multiple cores. Linear algebra libraries, such as `BLAS`, may or may not use them in ways that suit our purposes. Compilation flags have nontrivial impacts on the learning times.

Such implementation improvements are often (but not always) orthogonal to the algorithmic improvements described above. The main issue consists of deciding how much development resources are allocated to implementation and to algorithm design. This trade-off depends on the available competencies.

5. SGD-QN: A Careful Diagonal Quasi-Newton SGD

As explained in Section 2, designing an efficient quasi-Newton SGD algorithm involves a careful trade-off between the sparsity of the scaling matrix representation $\mathbf{B}$ and the quality of its approximation of the inverse Hessian $\mathbf{H}^{-1}$. The two obvious choices are diagonal approximations (Becker and Le Cun, 1989) and low rank approximations (Schraudolph et al., 2007).

5.1 Diagonal Rescaling Matrices

Among numerous practical suggestions for running SGD algorithm in multilayer neural networks, Le Cun et al. (1998) emphatically recommend to rescale each input space feature in order to improve the condition number κ of the Hessian matrix. In the case of a linear model, such preconditioning is similar to using a constant diagonal scaling matrix.

Rescaling the input space defines transformed patterns $\mathbf{X}_t$ such that $[\mathbf{X}_t]_i = b_i [\mathbf{x}_t]_i$ where the notation $[\mathbf{v}]_i$ represents the i-th coefficient of vector $\mathbf{v}$. This transformation does not change the classification if the parameter vectors are modified as $[\mathbf{W}_t]_i = [\mathbf{w}_t]_i / b_i$. The first-order SGD update on these modified variable is then

$$\begin{aligned} \forall i = 1 \dots d \qquad [\mathbf{W}_{t+1}]_i &= [\mathbf{W}_t]_i - \eta_t \left(\lambda [\mathbf{W}_t]_i + \ell'(y_t \mathbf{W}_t^\top \mathbf{X}_t)\, y_t\, [\mathbf{X}_t]_i, \right) \\ &= [\mathbf{W}_t]_i - \eta_t \left(\lambda [\mathbf{W}_t]_i + \ell'(y_t \mathbf{w}_t^\top \mathbf{x}_t)\, y_t\, b_i [\mathbf{x}_t]_i \right) . \end{aligned}$$

Multiplying by b_i shows how the original parameter vector $\mathbf{w}_t$ is affected:

$$\forall i = 1 \dots d \qquad [\mathbf{w}_{t+1}]_i = [\mathbf{w}_t]_i - \eta_t \left(\lambda [\mathbf{w}_t]_i + \ell'(y_t \mathbf{w}_t^\top \mathbf{x}_t) \, y_t \, b_i^2 \, [\mathbf{x}_t]_i \right) .$$

We observe that rescaling the input is equivalent to multiplying the gradient by a fixed diagonal matrix $\mathbf{B}$ whose elements are the squares of the coefficients b_i.

Ideally we would like to make the product $\mathbf{BH}$ spectrally close the identity matrix. Unfortunately we do not know the value of the Hessian matrix $\mathbf{H}$ at the optimum $\mathbf{w}_n^*$. Instead we could consider the current value of the Hessian $\mathbf{H}_{\mathbf{w}_t} = \mathcal{P}''(\mathbf{w}_t)$ and compute the diagonal rescaling matrix $\mathbf{B}$ that makes $\mathbf{BH}_{\mathbf{w}_t}$ closest to the identity. This computation could be very costly because it involves the full Hessian matrix. Becker and Le Cun (1989) approximate the optimal diagonal rescaling matrix by inverting the diagonal coefficients of the Hessian. The method relies on the analytical derivation of these diagonal coefficients for multilayer neural networks. This derivation does not extend to arbitrary models. It certainly does not work in the case of traditional SVMs because the hinge loss has zero curvature almost everywhere.

5.2 Low Rank Rescaling Matrices

The popular LBFGS optimization algorithm (Nocedal, 1980) maintains a low rank approximation of the inverse Hessian by storing the k most recent rank-one BFGS updates instead of the full inverse Hessian matrix. When the successive full gradients $\mathcal{P}_n'(\mathbf{w}_{t-1})$ and $\mathcal{P}_n'(\mathbf{w}_t)$ are available, standard rank one updates can be used to directly estimate the inverse Hessian matrix $\mathbf{H}^{-1}$. Using this method with stochastic gradient is tricky because the full gradients $\mathcal{P}_n'(\mathbf{w}_{t-1})$ and $\mathcal{P}_n'(\mathbf{w}_t)$ are not readily available. Instead we only have access to the stochastic estimates $\mathbf{g}_{t-1}(\mathbf{w}_{t-1})$ and $\mathbf{g}_t(\mathbf{w}_t)$ which are too noisy to compute good rescaling matrices.

The oLBFGS algorithm (Schraudolph et al., 2007) compares instead the derivatives $\mathbf{g}_{t-1}(\mathbf{w}_{t-1})$ and $\mathbf{g}_{t-1}(\mathbf{w}_t)$ for the same example $(\mathbf{x}_{t-1}, y_{t-1})$. This reduces the noise to an acceptable level at the expense of the computation of the additional gradient vector $\mathbf{g}_{t-1}(\mathbf{w}_t)$.

Compared to the first-order SGD, each iteration of the oLBFGS algorithm computes the additional quantity $\mathbf{g}_{t-1}(\mathbf{w}_t)$ and updates the list of k rank one updates. The most expensive part however remains the multiplication of the gradient $\mathbf{g}_t(\mathbf{w}_t)$ by the low-rank estimate of the inverse Hessian. With $k = 10$, each iteration of our oLBFGS implementation runs empirically 11 times slower than a first-order SGD iteration.

5.3 SGD-QN

The SGD-QN algorithm estimates a *diagonal rescaling matrix* using a technique inspired by oLBFGS. For any pair of parameters $\mathbf{w}_{t-1}$ and $\mathbf{w}_t$, a Taylor series of the gradient of the primal cost $\mathcal{P}$ provides the secant equation:

$$\mathbf{w}_t - \mathbf{w}_{t-1} \approx \mathbf{H}_{\mathbf{w}_t}^{-1} \left(\mathcal{P}_n'(\mathbf{w}_t) - \mathcal{P}_n'(\mathbf{w}_{t-1}) \right) . \tag{6}$$

We would then like to replace the inverse Hessian matrix $\mathbf{H}_{\mathbf{w}_t}^{-1}$ by a diagonal estimate $\mathbf{B}$

$$\mathbf{w}_t - \mathbf{w}_{t-1} \approx \mathbf{B} \left(\mathcal{P}_n'(\mathbf{w}_t) - \mathcal{P}_n'(\mathbf{w}_{t-1}) \right) .$$

Since we are designing a stochastic algorithm, we do not have access to the full gradient $\mathcal{P}_n'$. Following oLBFGS, we replace them by the local gradients $\mathbf{g}_{t-1}(\mathbf{w}_t)$ and $\mathbf{g}_{t-1}(\mathbf{w}_{t-1})$ and obtain

$$\mathbf{w}_t - \mathbf{w}_{t-1} \approx \mathbf{B} \left(\mathbf{g}_{t-1}(\mathbf{w}_t) - \mathbf{g}_{t-1}(\mathbf{w}_{t-1}) \right) .$$

Since we chose to use a diagonal rescaling matrix $\mathbf{B}$, we can write the term-by-term equality

$$[\mathbf{w}_t - \mathbf{w}_{t-1}]_i \approx \mathbf{B}_{ii} [\mathbf{g}_{t-1}(\mathbf{w}_t) - \mathbf{g}_{t-1}(\mathbf{w}_{t-1})]_i ,$$

where the notation $[\mathbf{v}]_i$ still represents the i-th coefficient of vector $\mathbf{v}$. This leads to computing $\mathbf{B}_{ii}$ as the average of the ratio $[\mathbf{w}_t - \mathbf{w}_{t-1}]_i / [\mathbf{g}_{t-1}(\mathbf{w}_t) - \mathbf{g}_{t-1}(\mathbf{w}_{t-1})]_i$. An online estimation is easily achieved during the course of learning by performing a leaky average of these ratios,

$$\mathbf{B}_{ii} \leftarrow \mathbf{B}_{ii} + \frac{2}{r} \left(\frac{[\mathbf{w}_t - \mathbf{w}_{t-1}]_i}{[\mathbf{g}_{t-1}(\mathbf{w}_t) - \mathbf{g}_{t-1}(\mathbf{w}_{t-1})]_i} - \mathbf{B}_{ii} \right) \qquad \forall i = 1 \ldots d ,$$

and where the integer r is incremented whenever we update the matrix $\mathbf{B}$.

The weights of the scaling matrix $\mathbf{B}$ are initialized to λ^{-1} because this corresponds to the exact setup of first-order SGD. Since the curvature of the primal cost (1) is always larger than λ, the ratio $[\mathbf{g}_{t-1}(\mathbf{w}_t) - \mathbf{g}_{t-1}(\mathbf{w}_{t-1})]_i / [\mathbf{w}_t - \mathbf{w}_{t-1}]_i$ is always larger than λ. Therefore the coefficients $\mathbf{B}_{ii}$ never exceed their initial value λ^{-1}. Basically these scaling factors slow down the convergence along some axes. The speedup does not occur because we follow the trajectory faster, but because we follow a better trajectory.

Performing the weight update (2) with a diagonal rescaling matrix $\mathbf{B}$ consists in performing term-by-term operations with a time complexity that is marginally greater than the complexity of the first-order SGD (3) update. The computation of the additional gradient vector $\mathbf{g}_{t-1}(\mathbf{w}_t)$ and the reestimation of all the coefficients $\mathbf{B}_{ii}$ essentially triples the computing time of a first-order SGD iteration with non-sparse inputs (3), and is considerably slower than a first-order SGD iteration with sparse inputs implemented as discussed in Section 3.

Fortunately this higher computational cost per iteration can be nearly avoided by scheduling the reestimation of the rescaling matrix with the same frequency as the regularization updates. Section 5.1 has shown that a diagonal rescaling matrix does little more than rescaling the input variables. Since a fixed diagonal rescaling matrix already works quite well, there is little need to update its coefficients very often.

Figure 2 compares the SVMSGD2 and SGD-QN algorithms. Whenever SVMSGD2 performs a regularization update, we set the flag `updateB` to schedule a reestimation of the rescaling coefficients during the next iteration. This is appropriate because both operations have comparable computing times. Therefore the rescaling matrix reestimation schedule can be regulated with the same `skip` parameter as the regularization updates. In practice, we observe that each SGD-QN iteration demands less than twice the time of a first-order SGD iteration.

Because SGD-QN reestimates the rescaling matrix after a pattern update, special care must be taken when the ratio $[\mathbf{w}_t - \mathbf{w}_{t-1}]_i / [\mathbf{g}_{t-1}(\mathbf{w}_t) - \mathbf{g}_{t-1}(\mathbf{w}_{t-1})]_i$ has the form $0/0$ because the corresponding input coefficient $[\mathbf{x}_{t-1}]_i$ is zero. Since the secant Equation (6) is valid for any two values of the parameter vector, one can compute the ratios with parameter vectors $\mathbf{w}_{t-1}$ and $\mathbf{w}_t + \varepsilon$ and derive the correct value by continuity when $\varepsilon \to 0$. When $[\mathbf{x}_{t-1}]_i = 0$, we can write

$$\begin{aligned}
\frac{[(\mathbf{w}_t+\varepsilon)-\mathbf{w}_{t-1}]_i}{[\mathbf{g}_{t-1}(\mathbf{w}_t+\varepsilon)-\mathbf{g}_{t-1}(\mathbf{w}_{t-1})]_i} &= \frac{[(\mathbf{w}_t+\varepsilon)-\mathbf{w}_{t-1}]_i}{\lambda[(\mathbf{w}_t+\varepsilon)-\mathbf{w}_{t-1}]_i + \left(\ell'(y_{t-1}(\mathbf{w}_t+\varepsilon)^\top \mathbf{x}_{t-1}) - \ell'(y_{t-1}\mathbf{w}_{t-1}^\top \mathbf{x}_{t-1})\right) y_{t-1} [\mathbf{x}_{t-1}]_i} \\
&= \left(\lambda + \frac{\left(\ell'(y_{t-1}(\mathbf{w}_t+\varepsilon)^\top \mathbf{x}_{t-1}) - \ell'(y_{t-1}\mathbf{w}_{t-1}^\top \mathbf{x}_{t-1})\right) y_{t-1} [\mathbf{x}_{t-1}]_i}{[(\mathbf{w}_t+\varepsilon)-\mathbf{w}_{t-1}]_i} \right)^{-1} \\
&= \left(\lambda + \frac{0}{[\varepsilon]_i} \right)^{-1} \quad \stackrel{\varepsilon \to 0}{\longrightarrow} \quad \lambda^{-1} .
\end{aligned}$$

6. Experiments

We demonstrate the good scaling properties of SGD-QN in two ways: we present a detailed comparison with other stochastic gradient methods, and we summarize the results obtained on the PASCAL Large Scale Challenge.

Table 4 describes the three binary classification tasks we used for comparative experiments. The Alpha and Delta tasks were defined for the PASCAL Large Scale Challenge (Sonnenburg et al., 2008). We train with the first 100,000 examples and test with the last 50,000 examples of the official training sets because the official testing sets are not available. Alpha and Delta are dense data sets with relatively severe conditioning problems. The third task is the classification of RCV1 documents belonging to class CCAT (Lewis et al., 2004). This task has become a standard benchmark for linear SVMs on sparse data. Despite its larger size, the RCV1 task is much easier than the Alpha and Delta tasks. All methods discussed in this paper perform well on RCV1.

	ALPHA	RCV1
SGD	0.13	36.8
SVMSGD2	0.10	0.20
SGD-QN	0.21	0.37

Table 5: Time (sec.) for performing one pass over the training set.

The experiments reported in Section 6.4 use the hinge loss $\ell(s) = \max(0, 1-s)$. All other experiments use the squared hinge loss $\ell(s) = \frac{1}{2}(\max(0, 1-s))^2$. In practice, there is no need to make the losses twice differentiable by smoothing their behavior near $s = 0$. Unlike most batch optimizer, stochastic algorithms do not not aim directly for nondifferentiable points, but randomly hop around them. The stochastic noise implicitly smoothes the loss.

The SGD, SVMSGD2, oLBFGS, and SGD-QN algorithms were implemented using the same C++ code base.[3] All experiments are carried out in single precision. We did not experience numerical accuracy issues, probably because of the influence of the regularization term. Our implementation of oLBFGS maintains a rank 10 rescaling matrix. Setting the oLBFGS gain schedule is rather delicate. We obtained fairly good results by replicating the gain schedule of the VieCRF package.[4] We also propose a comparison with the online dual linear SVM solver (Hsieh et al., 2008) implemented in the LibLinear package.[5] We did not reimplement this algorithm because the LibLinear implementation has proved as simple and as efficient as ours.

The t_0 parameter is determined using an automatic procedure: since the size of the training set does not affect results of Theorem 1, we simply pick a subset containing 10% of the training examples, perform one SGD-QN pass over this subset with several values for t_0, and pick the value for which the primal cost decreases the most. These values are given in Table 4.

6.1 Sparsity Tricks

Table 5 illustrates the influence of the scheduling tricks described in Section 3. The table displays the training times of SGD and SVMSGD2. The only difference between these two algorithms are the scheduling tricks. SVMSGD2 trains 180 times faster than SGD on the sparse data set RCV1. This table also demonstrates that iterations of the quasi-newton SGD-QN are not prohibitively expensive.

6.2 Quasi-Newton

Figure 3 shows how the primal cost $\mathcal{P}_n(\mathbf{w})$ of the Alpha data set evolves with the number of passes (left) and the training time (right). Compared to the first-order SVMSGD2, both the oLBFGS and SGD-QN algorithms dramatically decrease the number of passes required to achieve similar values of the primal. Even if it uses a more precise approximation of the inverse Hessian, oLBFGS does not perform better after a single pass than SGD-QN. Besides, running a single pass of oLBFGS is much slower than running multiple passes of SVMSGD2 or SGD-QN. The benefits of its second-order approximation are canceled by its greater time requirements per iteration. On the other hand,

3. Implementations and experiment scripts are available in the `libsgdqn` library on `http://www.mloss.org`.
4. This can be found at `http://www.ofai.at/~jeremy.jancsary`.
5. This can be found at `http://www.csie.ntu.edu.tw/~cjlin/liblinear`.

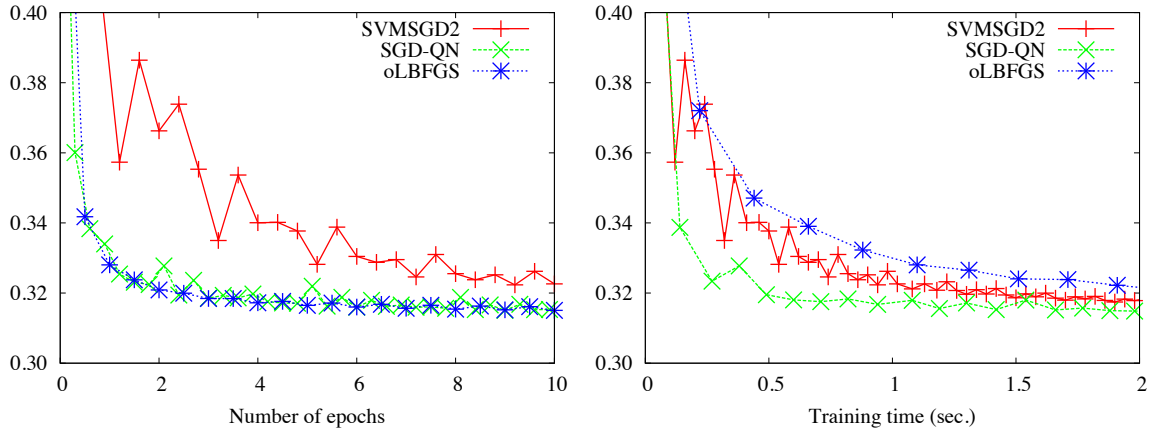

Figure 3: Primal costs according to the number of epochs (left) and the training duration (right) on the Alpha data set.

each SGD-QN iteration is only marginally slower than a SVMSGD2 iteration; the reduction of the number of iterations is sufficient to offset this cost.

6.3 Training Speed

Figure 4 displays the test errors achieved on the Alpha, Delta and RCV1 data sets as a function of the number of passes (left) and the training time (right). These results show again that both oLBFGS and SGD-QN require less iterations than SVMSGD2 to achieve the same test error. However, oLBFGS suffers from the relatively high complexity of its update process. The SGD-QN algorithm is competitive with the dual solver LibLinear on the dense data sets Alpha and Delta; it runs significantly faster on the sparse RCV1 data set.

According to Theorem 4, given a large enough training set, a perfect second-order SGD algorithm would reach the batch test error after a single pass. One pass learning is attractive when we are dealing with high volume streams of examples that cannot be stored and retrieved quickly. Figure 4 (left) shows that oLBFGS is a little bit closer to that ideal than SGD-QN and could become attractive for problems where the example retrieval time is much greater than the computing time.

6.4 PASCAL Large Scale Challenge Results

The SGD-QN algorithm has been submitted to the "Wild Track" of the PASCAL Large Scale Challenge. Wild Track contributors were free to do anything leading to more efficient and more accurate methods. Forty two methods have been submitted to this track. Table 6 shows the SGD-QN ranks determined by the organizers of the challenge according to their evaluation criteria. The SGD-QN algorithm always ranks among the top five submissions and ranks first in overall score (tie with another Newton method).

Table 6: Parameters and final ranks obtained by SGD-QN in the "Wild Track" of the first PASCAL Large Scale Learning Challenge. All competing algorithms were run by the organizers. (Note: the competition results were obtained with a preliminary version of SGD-QN. In particular the λ parameters listed above are different from the values used for all experiments in this paper and listed in Table 4.)

7. Conclusion

The SGD-QN algorithm strikes a good compromise for large scale application because it has low time and memory requirements per iteration and because it reaches competitive test errors after a small number of iterations. We have shown how this performance is the result of a careful design taking into account the theoretical knowledge about second-order SGD and a precise understanding of its computational requirements.

Finally, although this contribution presents SGD-QN as a solver for linear SVMs, this algorithm can be easily extended to nonlinear models for which we can analytically compute the gradients. We plan to further investigate the performance of SGD-QN in this context.

Appendix A. Proof of Theorem 1

Define $\mathbf{v}_t = \mathbf{w}_t - \mathbf{w}_n^*$ and observe that a second-order Taylor expansion of the primal gives

$$\mathcal{P}_n(\mathbf{w}_t) - \mathcal{P}_n(\mathbf{w}_n^*) \;=\; \mathbf{v}_t^\top \mathbf{H} \mathbf{v}_t + \mathrm{o}\left(t^{-2}\right) \;=\; \mathbf{tr}\left(\mathbf{H}\mathbf{v}_t\mathbf{v}_t^\top\right) + \mathrm{o}\left(t^{-2}\right).$$

Let $\mathbb{E}_{t-1}$ representing the conditional expectation over the choice of the example at iteration $t-1$ given all the choices made during the previous iterations. Since we assume that convergence takes

place, we have

$$\begin{aligned}\mathbb{E}_{t-1}\left[\mathbf{g}_{t-1}(\mathbf{w}_{t-1})\,\mathbf{g}_{t-1}(\mathbf{w}_{t-1})^\top\right] &= \mathbb{E}_{t-1}\left[\mathbf{g}_{t-1}(\mathbf{w}_n^*)\,\mathbf{g}_{t-1}(\mathbf{w}_n^*)^\top\right] + \mathrm{o}(1) \;=\; \mathbf{G} + \mathrm{o}(1)\\ \text{and } \mathbb{E}_{t-1}\left[\mathbf{g}_{t-1}(\mathbf{w}_{t-1})\right] &= \mathcal{P}_n'(\mathbf{w}_{t-1}) \;=\; \mathbf{H}\mathbf{v}_{t-1} + \mathrm{o}(\mathbf{v}_{t-1}) \;=\; \mathbf{I}_\varepsilon \mathbf{H}\mathbf{v}_{t-1}\end{aligned}$$

where notation $\mathbf{I}_\varepsilon$ is a shorthand for $\mathbf{I} + \mathrm{o}(1)$, that is, a matrix that converges to the identity. Expressing $\mathbf{H}\mathbf{v}_t\mathbf{v}_t^\top$ using the generic SGD update (2) gives

$$\begin{aligned}\mathbf{H}\mathbf{v}_t\mathbf{v}_t^\top &= \mathbf{H}\mathbf{v}_{t-1}\mathbf{v}_{t-1}^\top - \frac{\mathbf{H}\mathbf{v}_{t-1}\,\mathbf{g}_{t-1}(\mathbf{w}_{t-1})^\top\mathbf{B}}{t+t_0} - \frac{\mathbf{H}\mathbf{B}\,\mathbf{g}_{t-1}(\mathbf{w}_{t-1})\,\mathbf{v}_{t-1}^\top}{t+t_0}\\ &\quad + \frac{\mathbf{H}\mathbf{B}\,\mathbf{g}_{t-1}(\mathbf{w}_{t-1})\,\mathbf{g}_{t-1}(\mathbf{w}_{t-1})^\top\mathbf{B}}{(t+t_0)^2}\\ \mathbb{E}_{t-1}\left[\mathbf{H}\mathbf{v}_t\mathbf{v}_t^\top\right] &= \mathbf{H}\mathbf{v}_{t-1}\mathbf{v}_{t-1}^\top - \frac{\mathbf{H}\mathbf{v}_{t-1}\,\mathbf{v}_{t-1}^\top\mathbf{H}\mathbf{I}_\varepsilon\mathbf{B}}{t+t_0} - \frac{\mathbf{H}\mathbf{B}\mathbf{I}_\varepsilon\mathbf{H}\mathbf{v}_{t-1}\,\mathbf{v}_{t-1}^\top}{t+t_0} + \frac{\mathbf{H}\mathbf{B}\mathbf{G}\mathbf{B}}{(t+t_0)^2} + \mathrm{o}\left(t^{-2}\right)\\ \mathbb{E}_{t-1}\left[\mathbf{tr}\left(\mathbf{H}\mathbf{v}_t\mathbf{v}_t^\top\right)\right] &= \mathbf{tr}\left(\mathbf{H}\mathbf{v}_{t-1}\mathbf{v}_{t-1}^\top\right) - \frac{2\,\mathbf{tr}\left(\mathbf{H}\mathbf{B}\mathbf{I}_\varepsilon\mathbf{H}\mathbf{v}_{t-1}\,\mathbf{v}_{t-1}^\top\right)}{t+t_0} + \frac{\mathbf{tr}\left(\mathbf{H}\mathbf{B}\mathbf{G}\mathbf{B}\right)}{(t+t_0)^2} + \mathrm{o}\left(t^{-2}\right)\\ \mathbb{E}_\sigma\left[\mathbf{tr}\left(\mathbf{H}\mathbf{v}_t\mathbf{v}_t^\top\right)\right] &= \mathbb{E}_\sigma\left[\mathbf{tr}\left(\mathbf{H}\mathbf{v}_{t-1}\mathbf{v}_{t-1}^\top\right)\right] - \frac{2\mathbb{E}_\sigma\left[\mathbf{tr}\left(\mathbf{H}\mathbf{B}\mathbf{I}_\varepsilon\mathbf{H}\mathbf{v}_{t-1}\,\mathbf{v}_{t-1}^\top\right)\right]}{t+t_0} + \frac{\mathbf{tr}\left(\mathbf{H}\mathbf{B}\mathbf{G}\mathbf{B}\right)}{(t+t_0)^2} + \mathrm{o}\left(t^{-2}\right).\end{aligned}$$

Let $\lambda_{\max} \geq \lambda_{\min} > 1/2$ be the extreme eigenvalues of $\mathbf{HB}$. Since, for any positive matrix $\mathbf{X}$,

$$\left(\lambda_{\min} + \mathrm{o}(1)\right)\mathbf{tr}\left(\mathbf{X}\right) \;\leq\; \mathbf{tr}\left(\mathbf{H}\mathbf{B}\mathbf{I}_\varepsilon\mathbf{X}\right) \;\leq\; \left(\lambda_{\max} + \mathrm{o}(1)\right)\mathbf{tr}\left(\mathbf{X}\right)$$

we can bracket $\mathbb{E}_\sigma\left[\mathbf{tr}\left(\mathbf{H}\mathbf{v}_t\mathbf{v}_t^\top\right)\right]$ between the expressions

$$\left(1 - \frac{2\lambda_{\max}}{t} + \mathrm{o}\left(\frac{1}{t}\right)\right)\mathbb{E}_\sigma\left[\mathbf{tr}\left(\mathbf{H}\mathbf{v}_{t-1}\mathbf{v}_{t-1}^\top\right)\right] + \frac{\mathbf{tr}\left(\mathbf{H}\mathbf{B}\mathbf{G}\mathbf{B}\right)}{(t+t_0)^2} + \mathrm{o}\left(t^{-2}\right)$$

and

$$\left(1 - \frac{2\lambda_{\min}}{t} + \mathrm{o}\left(\frac{1}{t}\right)\right)\mathbb{E}_\sigma\left[\mathbf{tr}\left(\mathbf{H}\mathbf{v}_{t-1}\mathbf{v}_{t-1}^\top\right)\right] + \frac{\mathbf{tr}\left(\mathbf{H}\mathbf{B}\mathbf{G}\mathbf{B}\right)}{(t+t_0)^2} + \mathrm{o}\left(t^{-2}\right)$$

By recursively applying this bracket, we obtain

$$u_{\lambda_{\max}}(t+t_0) \;\leq\; \mathbb{E}_\sigma\left[\mathbf{tr}\left(\mathbf{H}\mathbf{v}_t\mathbf{v}_t^\top\right)\right] \;\leq\; u_{\lambda_{\min}}(t+t_0)$$

where the notation $u_\lambda(t)$ represents a sequence of real satisfying the recursive relation

$$u_\lambda(t) \;=\; \left(1 - \frac{2\lambda}{t} + \mathrm{o}\left(\frac{1}{t}\right)\right)u_\lambda(t-1) + \frac{\mathbf{tr}\left(\mathbf{H}\mathbf{B}\mathbf{G}\mathbf{B}\right)}{t^2} + \mathrm{o}\left(\frac{1}{t^2}\right).$$

From (Bottou and LeCun, 2005, Lemma 1), $\lambda > 1/2$ implies $t\,u_\lambda(t) \longrightarrow \frac{\mathbf{tr}(\mathbf{HBGB})}{2\lambda-1}$. Then

$$\frac{\mathbf{tr}\left(\mathbf{H}\mathbf{B}\mathbf{G}\mathbf{B}\right)}{2\lambda_{\max}-1}t^{-1} + \mathrm{o}\left(t^{-1}\right) \leq \mathbb{E}_\sigma\left[\mathbf{tr}\left(\mathbf{H}\mathbf{v}_t\mathbf{v}_t^\top\right)\right] \leq \frac{\mathbf{tr}\left(\mathbf{H}\mathbf{B}\mathbf{G}\mathbf{B}\right)}{2\lambda_{\min}-1}t^{-1} + \mathrm{o}\left(t^{-1}\right)$$

and

$$\frac{\mathbf{tr}\left(\mathbf{H}\mathbf{B}\mathbf{G}\mathbf{B}\right)}{2\lambda_{\max}-1}t^{-1} + \mathrm{o}\left(t^{-1}\right) \leq \mathbb{E}_\sigma\left[\mathcal{P}_n(\mathbf{w}_t) - \mathcal{P}_n(\mathbf{w}_n^*)\right] \leq \frac{\mathbf{tr}\left(\mathbf{H}\mathbf{B}\mathbf{G}\mathbf{B}\right)}{2\lambda_{\min}-1}t^{-1} + \mathrm{o}\left(t^{-1}\right). \qquad \blacksquare$$

Dlib-ml: A Machine Learning Toolkit

Davis E. King DAVISKING@USERS.SOURCEFORGE.NET
Northrop Grumman ES, ATR and Image Exploitation Group
Baltimore, Maryland, USA

Editor: Soeren Sonnenburg

Abstract

There are many excellent toolkits which provide support for developing machine learning software in Python, R, Matlab, and similar environments. Dlib-ml is an open source library, targeted at both engineers and research scientists, which aims to provide a similarly rich environment for developing machine learning software in the C++ language. Towards this end, dlib-ml contains an extensible linear algebra toolkit with built in BLAS support. It also houses implementations of algorithms for performing inference in Bayesian networks and kernel-based methods for classification, regression, clustering, anomaly detection, and feature ranking. To enable easy use of these tools, the entire library has been developed with contract programming, which provides complete and precise documentation as well as powerful debugging tools.

Keywords: kernel-methods, svm, rvm, kernel clustering, C++, Bayesian networks

1. Introduction

Dlib-ml is a cross platform open source software library written in the C++ programming language. Its design is heavily influenced by ideas from design by contract and component-based software engineering. This means it is first and foremost a collection of independent software components, each accompanied by extensive documentation and thorough debugging modes. Moreover, the library is intended to be useful in both research and real world commercial projects and has been carefully designed to make it easy to integrate into a user's C++ application.

There are a number of well known machine learning libraries. However, many of these libraries focus on providing a good environment for doing research using languages other than C++. Two examples of this kind of project are the Shogun (Sonnenburg et al., 2006) and Torch (Collobert and Bengio, 2001) toolkits which, while they are implemented in C++, are not focused on providing support for developing machine learning software in that language. Instead they are primarily intended to be used with languages like R, Python, Matlab, or Lua. Then there are toolkits such as Shark (Igel et al., 2008) and dlib-ml which are explicitly targeted at users who wish to develop software in C++. Given these considerations, dlib-ml attempts to help fill some of the gaps in tool support not already filled by libraries such as Shark. It is hoped that these efforts will prove useful for researchers and engineers who wish to develop machine learning software in this language.

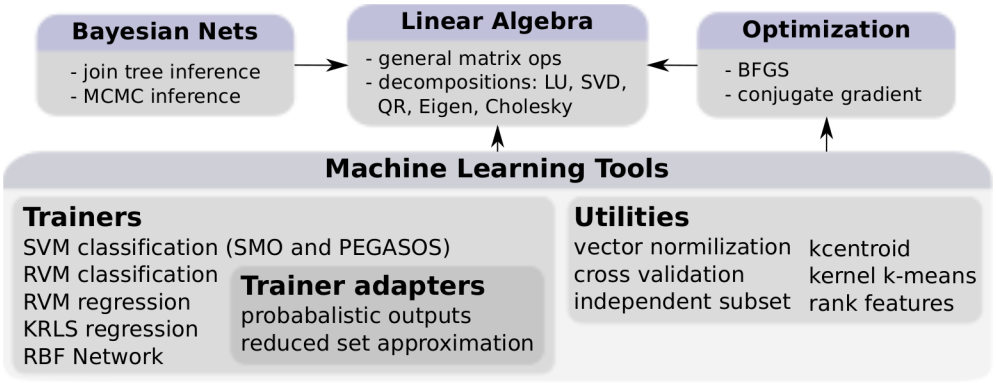

Figure 1: Elements of dlib-ml. Arrows show dependencies between components.

2. Elements of the Library

The library is composed of the four distinct components shown in Figure 1. The linear algebra component provides a set of core functionality while the other three implement various useful tools. This paper addresses the two main components, linear algebra and machine learning tools.

2.1 Linear Algebra

The design of the linear algebra component of the library is based on the template expression techniques popularized by Veldhuizen and Ponnambalam (1996) in the Blitz++ numerical software. This technique allows an author to write simple Matlab-like expressions that, when compiled, execute with speed comparable to hand-optimized C code. The dlib-ml implementation extends this original design in a number of ways. Most notably, the library can use the BLAS when available, meaning that the performance of code developed using dlib-ml can gain the speed of highly optimized libraries such as ATLAS or the Intel MKL while still using a very simple syntax. Consider the following example involving matrix multiplies, transposes, and scalar multiplications:

```
(1) result = 3*trans(A*B + trans(A)*2*B);
(2) result = 3*trans(B)*trans(A) + 6*trans(B)*A;
```

The result of expression (1) could be computed using only two calls to the matrix multiply routine in BLAS but first it is necessary to reorder the terms into form (2) to fit the form expected by the BLAS routines. Performing these transformations by hand is tedious and error prone. Dlib-ml automatically performs these transformations on all expressions and invokes the appropriate BLAS calls. This enables the user to write equations in the form most intuitive to them and leave these details of software optimization to the library. This is a feature not found in the supporting tools of other C++ machine learning libraries.

2.2 Machine Learning Tools

A major design goal of this portion of the library is to provide a highly modular and simple architecture for dealing with kernel algorithms. In particular, each algorithm is parameterized to allow a user to supply either one of the predefined dlib-ml kernels, or a new user defined kernel. Moreover, the implementations of the algorithms are totally separated from the data on which they operate.

This makes the dlib-ml implementation generic enough to operate on any kind of data, be it column vectors, images, or some other form of structured data. All that is necessary is an appropriate kernel.

This is a feature unique to dlib-ml. Many libraries allow arbitrary precomputed kernels and some even allow user defined kernels but have interfaces which restrict them to operating on column vectors. However, none allow the flexibility to operate *directly* on arbitrary objects, making it much easier to apply custom kernels in the case where the kernels operate on objects other than fixed length vectors.

The library provides implementations of popular algorithms such as RBF networks and support vector machines for classification. It also includes algorithms not present in other major ML toolkits such as relevance vector machines for classification and regression (Tipping and Faul, 2003). All of these algorithms are implemented as generic trainer objects with a standard interface. This design allows trainer objects to be used by a number of generic meta-algorithms that do tasks such as performing cross validation, reducing the number of output support vectors (Suttorp and Igel, 2007), or fitting a sigmoid to the output decision function to make decisions interpretable in probabilistic terms (Platt, 1999). This generic trainer interface, along with the contract programming approach, makes the library easily extensible by other developers.

Another good example of a generic kernel algorithm provided by the library is the kernel RLS technique introduced by Engel et al. (2004). It is a kernelized version of the famous recursive least squares filter, and functions as an excellent online regression method. With it, Engel introduced a simple but very effective technique for producing sparse outputs from kernel learning algorithms.

Engel's sparsification technique is also used by one of dlib-ml's most versatile tools, the kcentroid object. It is a general utility for representing a weighted sum of sample points in a kernel induced feature space. It can be used to easily kernelize any algorithm that requires only the ability to perform vector addition, subtraction, scalar multiplication, and inner products.

The kcentroid object enables the library to provide a number of useful kernel-based machine learning algorithms. The most straightforward of which is online anomaly detection, which simply marks data samples as novel if their distance from the centroid of a previously observed body of data is large (e.g., 3 standard deviations from the mean distance). A similarly simple but still powerful application is in feature ranking, where features are considered good if their inclusion results in a large distance between the centroids of different classes of data.

Another straightforward application of this technique is in kernelized cluster analysis. Using the kcentroid it is easy to create sparse kernel clustering algorithms. To demonstrate this, the library comes with a sparse kernel k-means algorithm.

Finally, dlib-ml contains two SVM solvers. One is essentially a reimplementation of LIBSVM (Chang and Lin, 2001) but with the generic parameterized kernel approach used in the rest of the library. This solver has roughly the same CPU and memory utilization characteristics as LIBSVM. The other SVM solver is a kernelized version of the Pegasos algorithm introduced by Shalev-Shwartz et al. (2007). It is built using the kcentroid and thus produces sparse outputs.

3. Availability and Requirements

The library is released under the Boost Software License, allowing it to be incorporated into both open-source and commercial software. It requires no additional libraries, does not need to be configured or installed, and is frequently tested on MS Windows, Linux and MacOS X but should work with any ISO C++ compliant compiler.

Note that dlib-ml is a subset of a larger project named dlib hosted at http://dclib.sourceforge.net. Dlib is a general purpose software development library containing a graphical application for creating Bayesian networks as well as tools for handling threads, network I/O, and numerous other tasks. Dlib-ml is available from the dlib project's download page on SourceForge.

Abstract

Judea Pearl's Causal Model is a rich framework that provides deep insight into the nature of causal relations. As yet, however, the Pearl Causal Model (PCM) has had a lesser impact on economics or econometrics than on other disciplines. This may be due in part to the fact that the PCM is not as well suited to analyzing structures that exhibit features of central interest to economists and econometricians: optimization, equilibrium, and learning. We offer the settable systems framework as an extension of the PCM that permits causal discourse in systems embodying optimization, equilibrium, and learning. Because these are common features of physical, natural, or social systems, our framework may prove generally useful for machine learning. Important features distinguishing the settable system framework from the PCM are its countable dimensionality and the use of partitioning and partition-specific response functions to accommodate the behavior of optimizing and interacting agents and to eliminate the requirement of a unique fixed point for the system. Refinements of the PCM include the settable systems treatment of attributes, the causal role of exogenous variables, and the dual role of variables as causes and responses. A series of closely related machine learning examples and examples from game theory and machine learning with feedback demonstrates some limitations of the PCM and motivates the distinguishing features of settable systems.

Keywords: causal models, game theory, machine learning, recursive estimation, simultaneous equations

1. Introduction

Judea Pearl's work on causality, especially as embodied in his landmark book *Causality* (Pearl, 2000), represents a rich framework in which to understand, analyze, and explain causal relations. This framework has been adopted and applied in a broad array of disciplines, but so far it has had a lesser impact in economics. This may be due in part to the fact that the Pearl causal model (PCM) is not as explicit about or well suited to analyzing structures that exhibit features of central interest to economists and econometricians: optimization, equilibrium, and learning. Here, we offer the

settable systems framework as an extension of the PCM that permits causal discourse in systems embodying these features.

Because optimization, equilibrium, and learning are features not only of economic systems, but also of physical, natural, or social systems more generally, our extended framework may prove useful elsewhere, especially in areas where empirical analysis, whether observational or experimental, has a central role to play. In particular, settable systems offer a number of advantages relative to the PCM for machine learning. To show this, we provide a detailed examination of the features and limitations of the PCM relevant to machine learning. This examination provides key insight into the PCM and helps to motivate features of the settable systems framework we propose.

Roughly speaking, a settable system is a mathematical framework describing an environment in which multiple agents interact under uncertainty. In particular, the settable systems framework is explicit about the principles underlying how agents make decisions, the equilibria (if any) resulting from agents' decisions, and learning from repeated interactions. Because it is explicit about agents' decision making, the settable systems framework extends the PCM by providing a decision-theoretic foundation for causal analysis (see, e.g., Heckerman and Shachter, 1995) in the spirit of influence diagrams (Howard and Matheson, 1984). However, unlike influence diagrams, the settable systems framework preserves the spirit of the PCM and its appealing features for empirical analysis, including its use of response functions and the causal notions that these support.

As Koller and Milch (2003, pp. 189-190) note in motivating their study of multi-agent influence diagrams (MAIDs), "influence diagrams [...] have been investigated almost entirely in a single-agent setting." The settable systems framework also permits the study of multiple agent interactions. Nevertheless, a number of settable systems features distinguishes them from MAIDs, as we discuss in Section 6.4. Among other things, settable systems permit causal discourse in systems with multi-agent interactions.

Some features of settable systems are entirely unavailable in the PCM. These include (1) accommodating an infinite number of agents; and (2) the absence of a unique fixed point requirement. Other features of settable systems rigorously formalize and refine or extend related PCM features, thereby permitting a more explicit causal discourse. These features include (3) the notion of attributes, (4) definitions of interventions and direct effects, (5) the dual role of variables as causes and responses, and (6) the causal role of exogenous variables.

For instance, for a given system, the PCM's common treatment of attributes and background variables rules out a causal role for background variables. Specifically, this rules out structurally exogenous causes, whether observed or unobserved. This also limits the role of attributes in characterizing systems of interest. Because the status of a variable in the PCM is relative to the analysis and is entirely up to the researcher, a background variable may be treated as an endogenous variable in an alternative system if deemed sensible by the researcher, thereby permitting it to have a causal role. Nevertheless, the PCM is silent about how to distinguish between attributes, background variables, and endogenous variables. In contrast, in settable systems one or more governing principles, such as optimization or equilibrium, provide a formal and explicit way to distinguish between structurally exogenous and endogenous variables, permitting explicitly causal roles not only for endogenous but also for exogenous variables. Attributes are unambiguously defined as constants (numbers, sets, functions) associated with the system units that define fundamental aspects of the decision problem represented by the settable system.

The Rubin treatment effect approach to causal inference (e.g., as formalized by Holland, 1986) also relates to settable systems. We leave a careful study of the relations between these two ap-

proaches to other work in order to keep a sharp and manageable focus for this paper. Thus, our goal here is to compare and contrast our approach with the PCM, which, along with structural equation systems in econometrics, comprise the frameworks that primarily motivate settable systems. Nevertheless, some brief discussion of the relation of settable systems to Rubin's treatment effect approach is clearly warranted. In our view, the main feature that distinguishes settable systems (and the PCM) from the Rubin model is the explicit representation of the full causal structure. This has significant implications for the selection of covariates and for providing primitive conditions that deliver unconfoundedness conditions as consequences in settable systems, rather than introducing these as maintained assumptions in the Rubin model. Explicit representation of the full causal structure also has important implications for the analysis of "simultaneous" systems and mutually causal relations, which are typically suppressed in the Rubin approach. Finally, the allowance for a countable number of system units, the partitioning device of settable systems, and settable systems' more thorough exploitation of attributes also represent useful differences with Rubin's model.

The plan of this paper is as follows. In Section 2, we give a succinct statement of the elements of the PCM and of a generalization due to Halpern (2000) relevant for motivating and developing our settable systems extension.

Section 3 contains a series of closely related machine learning examples in which we examine the features and limitations of the PCM. These in turn help motivate features of the settable systems framework. Our examples involve least squares-based machine learning algorithms for simple artificial neural networks useful for making predictions. We consider learning algorithms with and without weight clamping and network structures with and without hidden units. Because learning is based on principles of optimization (least squares), our discussion relates to decision problems generally.

Our examples in Section 3 show that although the PCM applies to key aspects of machine learning, it also fails to apply to important classes of problems. One source of these limitations is the PCM's unique fixed point requirement. Although Halpern's (2000) generalization does not impose this requirement, it has other limitations. We contrast these with settable systems, where there is no fixed point requirement, but where fixed points may help determine system outcomes. The feature of settable systems delivering this flexibility is partitioning, an analog of the submodel and do operator devices of the PCM.

The examples of Section 3 do not involve randomness. We introduce randomness in Section 4, using our machine learning examples to discuss heuristic aspects of stochastic settable systems. We compare and contrast these with aspects of Pearl's probabilistic causal model. An interesting feature of stochastic settable systems is that attributes can determine the governing probability measure. In contrast, attributes are random variables in the PCM. Straightforward notions of counterfactuals, interventions, direct causes, direct effects, and total effects emerge naturally from stochastic settable systems.

Section 5 integrates the features of settable systems motivated by our examples to provide a rigorous formal definition of stochastic settable systems.

In Section 6 we use a series of examples from game theory to show how settable systems apply to groups of interacting and strategically competitive decision-making agents. Game theoretic structures have broad empirical relevance; they also present interesting opportunities for distributed and emergent computation of important quantities, such as prices. The decision-making agents may be consumers, firms, or government entities; they may also be biological systems or artificial intelligences, as in automated trading systems. Our demonstrations thus provide foundations for causal

analysis of systems where optimization and equilibrium mechanisms both operate to determine system outcomes. We relate our results to multi-agent influence diagrams (Koller and Milch, 2003) in Section 6.4.

In Section 7 we close the loop by considering examples from a general class of machine learning algorithms with feedback introduced by Kushner and Clark (1978) and extended by Chen and White (1998). These systems contain not only learning methods involving possibly hidden states, such as the Kalman filter (Kalman, 1960) and recurrent neural networks (e.g., Elman, 1990; Jordan, 1992; Kuan, Hornik, and White, 1994), but also systems of groups of strategically interacting and learning decision makers, as shown by Chen and White (1998). These systems exhibit optimization, equilibrium, and learning and map directly to settable systems, providing foundations for causal analysis in such systems.

Section 8 contains a summary and a discussion of research relying on the foundations provided here as well as discussion of directions for future work. An Appendix contains supplementary material; specifically, we give a formal definition of nonstochastic settable systems.

In a recent review of Pearl's book for economists and econometricians, Neuberg (2003) expresses a variety of reservations and concerns. Nevertheless, Neuberg (2003, p. 685) recommends that "econometricians should read *Causality* and start contributing to the cross-disciplinary discussion of the subject that Pearl has begun. Hopefully mutual enlightenment will be the effect of our reading and talking about the book among ourselves and with the Bayesian causal network thinkers." By examining aspects of what can and cannot be accommodated within Pearl's framework, and by proposing settable systems as an extension of this framework designed to accommodate features of central interest to economists, namely optimization, equilibrium, and learning, we offer this paper as part of this dialogue.

2. Pearl's Causal Model

Pearl's definition of a *causal model* (Pearl, 2000, Def. 7.1.1, p. 203) provides a formal statement of the elements essential to causal reasoning. According to this definition, a causal model is a triple $M := (u, v, f)$, where $u := \{u_1, ..., u_m\}$ is a collection of "background" variables determined outside the model, $v := \{v_1, ..., v_n\}$ is a collection of "endogenous" variables determined within the model, and $f := \{f_1, ..., f_n\}$ is a collection of "structural" functions that specify how each endogenous variable is determined by the other variables of the model, so that $v_i = f_i(v_{(i)}, u), \quad i = 1, ..., n$. Here $v_{(i)}$ denotes the vector containing every element of v except v_i. The integers m and n are finite. We refer to the elements of u and v as system "units."

Finally, the definition requires that f yields a unique fixed point for each u, so that there exists a unique collection $g := \{g_1, ..., g_n\}$ such that for each u,

$$v_i = g_i(u) = f_i(g_{(i)}(u), u), \quad i = 1, ..., n.$$

The unique fixed point requirement is a crucial aspect of the PCM, as this ensures existence of the *potential response function* (Pearl, 2000, Def. 7.1.4). This provides the foundation for discourse about causal relations between endogenous variables; this discourse is not possible in the PCM otherwise. A variant of the PCM analyzed by Halpern (2000) does not require a fixed point, but if any exist, there may be multiple collections of functions g yielding a fixed point. We refer to such a model as a Generalized Pearl Causal Model (GPCM). We note that GPCMs do not possess an analog of the potential response function, due to the lack of a unique fixed point.

In presenting the elements of the PCM, we have adapted Pearl's original notation somewhat to facilitate the discussion to follow, but all essential elements of the definition are present and complete.

3. Machine Learning, the PCM, and Settable Systems

We now consider how machine learning can be viewed in the context of the PCM. We consider machine learning examples that fundamentally involve optimization, a feature of a broad range of physical, natural, and social systems.[1] Specifically, optimization lies at the heart of most decision problems, as these problems typically involve deciding which of a range of possible options delivers the best expected outcome given the available information. When machine learning is based on optimization, it represents a prototypical decision problem. As we show, certain important aspects of machine learning map directly to the PCM. This permits us to investigate which causal questions are meaningful for machine learning within the PCM, and it motivates the modifications and refinements that lead to settable systems and the more extensive causal discourse possible there.

3.1 A Least-Squares Learning Example

Our first example considers predicting a random variable Y using a single random predictor X and an artificial neural network. In particular, we study the causal consequences for the optimal network weights of interventions to certain parameters of the joint distribution of the randomly generated X and Y.

More specifically, the output of an artificial neural network having a simple linear architecture is given by

$$f(X;\alpha,\beta) = \alpha + \beta X.$$

We suppose that Y and X are randomly generated according to a joint distribution F_γ indexed by a vector of parameters γ belonging to the parameter space Γ. We thus view γ as a variable whose values may range over Γ. For clarity, we suppose that γ is not influenced by our prediction (e.g., a weather forecast or an economic growth forecast).

We evaluate network performance in terms of expected squared prediction error loss,

$$\begin{aligned} L(\alpha,\beta,\gamma) &:= E_\gamma([Y - f(X;\alpha,\beta)]^2) \\ &= \int [y - f(x;\alpha,\beta)]^2 dF_\gamma(x,y), \end{aligned}$$

where $E_\gamma(\cdot)$ denotes expectation taken with respect to the distribution F_γ. Our goal is to obtain the best possible predictions according to this criterion. Accordingly, we seek loss-minimizing network weights, which solve the optimization problem

$$\min_{\alpha,\beta} L(\alpha,\beta,\gamma).$$

This makes it explicit that the governing principle in this example is optimization.

Under mild conditions, least squares-based machine learning algorithms converge to the optimal weights as the size of the training data set grows. For clarity, we work for now with the optimal network weights.

1. The great mathematician Leonhard Euler once wrote, "nothing at all takes place in the Universe in which some rule of maximum or minimum does not appear" (as quoted in Marsden and Tromba, 2003).

For our linear network, the first order conditions necessary for an optimum are

$$\begin{aligned}(\partial/\partial\alpha)L(\alpha,\beta,\gamma) &= -2E_\gamma([Y-\alpha-\beta X]) = 0,\\ (\partial/\partial\beta)L(\alpha,\beta,\gamma) &= -2E_\gamma(X[Y-\alpha-\beta X]) = 0.\end{aligned}$$

Letting $\mu_X := E_\gamma(X)$, $\mu_Y := E_\gamma(Y)$, $\mu_{XX} := E_\gamma(X^2)$, and $\mu_{XY} := E_\gamma(XY)$, we can conveniently parameterize F_γ in terms of the moments $\gamma := (\mu_X, \mu_Y, \mu_{XX}, \mu_{XY})$. (This parameterization need not uniquely determine F_γ; that is, there may be multiple distributions F_γ for a given γ. Nevertheless, this γ is the only aspect of the distribution that matters here.) We can then express the first order conditions equivalently as

$$\begin{aligned}\mu_Y - \alpha - \beta\mu_X &= 0,\\ \mu_{XY} - \alpha\mu_X - \beta\mu_{XX} &= 0.\end{aligned}$$

Now consider how this system fits into Pearl's causal model. Pearl's model requires a system of equations in which the left-hand side variables are structurally determined by the right-hand side variables. The first order conditions are not in this form, but, provided $\mu_{XX} - \mu_X^2 > 0$, they can be transformed to this form by solving jointly for α and β :

$$\begin{aligned}\alpha^* &= \mu_Y - [\mu_{XX} - \mu_X^2]^{-1}(\mu_{XY} - \mu_X\mu_Y)\mu_X,\\ \beta^* &= [\mu_{XX} - \mu_X^2]^{-1}(\mu_{XY} - \mu_X\mu_Y).\end{aligned} \tag{1}$$

We write (α^*, β^*) to distinguish optimized values from generic values (α, β).

This representation demonstrates that the PCM applies directly to this machine learning problem. The equations in (1) form a system in which the background (or "structurally exogenous") variables $u := (u_1, u_2, u_3, u_4) = (\mu_X, \mu_Y, \mu_{XX}, \mu_{XY}) =: \gamma$ determine the endogenous variables $v := (v_1, v_2) = (\alpha^*, \beta^*)$. The structural functions (f_1, f_2) are defined by

$$\begin{aligned}f_1(u) &= u_2 - [u_3 - u_1^2]^{-1}(u_4 - u_1u_2)u_1,\\ f_2(u) &= [u_3 - u_1^2]^{-1}(u_4 - u_1u_2).\end{aligned}$$

We observe that by the conventions of the PCM, the background variables u do not have formal status as causes, as we further discuss below.

In discussing the PCM, Pearl (2000, p. 203) notes that the background variables are often unobservable, but this is not a formal requirement of the PCM. In our example, we may view the γ variables as either observable or unobservable, depending on the context. For example, suppose we are given a linear least-squares learning machine as a black box: we know that it is a learning machine, but we don't know of what kind. To attempt to determine what is inside the black box, we can conduct computer experiments in which we set γ to various known values and observe the resulting values of (α^*, β^*). In this case, γ is observable.

Alternatively, we may have a least-squares learning machine that we apply to a variety of data sets obeying the distribution F_γ for differing unknown values of γ. In each case, γ is unobservable, but we can generate as much data as we want from F_γ.

Intermediate cases are also possible, in which some elements of γ are known and others are not. For example, in the multiple data set example, we could have knowledge of a subvector of γ, for example, we might know μ_X.

3.2 Learning with Clamping

Next, we study the effects on one of the optimal network weights of interventions to the other weight. For this, we consider the optimal network weights that arise when one or the other of the network weights is clamped, that is, set to an arbitrary fixed value. Specifically, consider

$$\min_{\alpha} L(\alpha,\beta,\gamma) \text{ and } \min_{\beta} L(\alpha,\beta,\gamma).$$

Clamping is useful in "nested" or multi-stage optimization, as

$$\begin{aligned} \min_{\alpha,\beta} L(\alpha,\beta,\gamma) &= \min_{\beta}[\min_{\alpha} L(\alpha,\beta,\gamma)] \text{ and} \\ \min_{\alpha,\beta} L(\alpha,\beta,\gamma) &= \min_{\alpha}[\min_{\beta} L(\alpha,\beta,\gamma)]. \end{aligned}$$

See, for example, Sergeyev and Grishagin (2001). Clamping is a central feature of a variety of powerful machine learning algorithms, for example, the restricted Boltzmann machine (e.g., Ackley et al., 1985; Hinton and Sejnowski, 1986; Hinton et al., 2006; Hinton and Salakhutdinov, 2006). Learning in stages is particularly useful in cases involving complex optimizations, as in the EM algorithm (Dempster, Laird, and Rubin, 1977).

The first order condition necessary for the β-clamped optimum $\min_\alpha L(\alpha,\beta,\gamma)$ is

$$(\partial/\partial\alpha)L(\alpha,\beta,\gamma) = -2E_\gamma([Y-\alpha-\beta X]) = 0.$$

Equivalently, $\mu_Y - \alpha - \beta\mu_X = 0$. Solving for the optimal α weight gives

$$\tilde{\alpha}^* = \mu_Y - \beta\mu_X. \tag{2}$$

We use the tilde notation to distinguish between the optimal weights with clamping and the jointly optimal weights obtained above.

Similarly, the first order condition necessary for the α-clamped optimum $\min_\beta L(\alpha,\beta,\gamma)$ is

$$(\partial/\partial\beta)L(\alpha,\beta,\gamma) = -2E_\gamma(X[Y-\alpha-\beta X]) = 0.$$

Equivalently, $\mu_{XY} - \alpha\mu_X - \beta\mu_{XX} = 0$. Given $\mu_{XX} > 0$, the optimal weight with clamping is

$$\tilde{\beta}^* = \mu_{XX}^{-1}(\mu_{XY} - \alpha\mu_X). \tag{3}$$

Writing Equations (2) and (3) as a system, we have

$$\tilde{\alpha}^* = \mu_Y - \beta\mu_X \qquad \tilde{\beta}^* = \mu_{XX}^{-1}(\mu_{XY} - \alpha\mu_X). \tag{4}$$

This resembles a structural system in the form of the PCM, except that here $\tilde{\alpha}^*$ and $\tilde{\beta}^*$ appear on the left, instead of α and β. This difference is significant; we address this shortly.

Nevertheless, suppose for the moment that we ignore this difference and modify the system above to conform to the PCM by replacing $\tilde{\alpha}^*$ and $\tilde{\beta}^*$ with α and β :

$$\alpha = \mu_Y - \beta\mu_X \qquad \beta = \mu_{XX}^{-1}(\mu_{XY} - \alpha\mu_X). \tag{5}$$

We take $u = \gamma$ as above, but in keeping with our conforming modification, we now take $(v_1, v_2) = (\alpha, \beta)$. The structural functions become

$$\tilde{f}_1(u, v_2) = u_2 - v_2 u_1 \qquad \tilde{f}_2(u, v_1) = u_3^{-1}(u_4 - v_1 u_1).$$

This system falls into the PCM, with consequent causal status for v, provided there is a unique fixed point for each u.

Unfortunately, this fixed point requirement fails here. As is apparent from the equations in (5), the only necessary restriction on u is that $u_3 = \mu_{XX} > 0$. This is the requirement that X is not equal to 0 with probability one. Nevertheless, it is readily verified that even with this restriction, the fixed point requirement fails for all u such that

$$u_3 - u_1^2 = \mu_{XX} - \mu_X^2 = 0.$$

This is the condition that $X = \mu_X$ with probability one, and μ_X can take any value, not just zero. When this condition holds, there is an uncountable infinity of fixed point solutions to the equations in (5). Stated another way, the solution to the system is set-valued in this circumstance.

Because of the lack of a fixed point, the PCM does not apply and therefore cannot provide causal meaning for such a system. The inability of the PCM to apply to this simple example of machine learning with clamping is an unfortunate limitation. Because Halpern's (2000) GPCM does not require a unique fixed point, it does apply here. Nevertheless, the lack of the potential response function in the GPCM prevents the desired causal discourse.

3.3 Settable Systems and Learning with Clamping

We now consider how these issues can be addressed. Our intent is to encompass this example while preserving the spirit of the PCM. This motivates and helps illustrate various features of our settable systems framework.

3.3.1 SETTABLE VARIABLES

We begin by taking seriously the difference in roles between (α, β) and $(\tilde{\alpha}^*, \tilde{\beta}^*)$ appearing in the equations in (4). In the simplest sense, the difference is that $(\tilde{\alpha}^*, \tilde{\beta}^*)$ and (α, β) appear on different sides of the equal signs: (α, β) appears on the right and $(\tilde{\alpha}^*, \tilde{\beta}^*)$ on the left. In the PCM, this difference is fundamentally significant, in that causal relations are asymmetric, with structurally determined (endogenous) variables on the left and all other variables on the right. In settable systems, we formalize these dual roles by defining *settable variables* as mappings $\mathcal{X}$ with a dual aspect:

$$\begin{aligned} \mathcal{X}_1(0) &:= \tilde{\alpha}^*, \quad \mathcal{X}_1(1) := \alpha, \\ \mathcal{X}_2(0) &:= \tilde{\beta}^*, \quad \mathcal{X}_2(1) := \beta. \end{aligned} \tag{6}$$

We call the $0-1$ argument of the settable variables $\mathcal{X}$ the "role indicator." When this is 0, the value of the variable is that determined by its structural equation. We call these values *responses*. In contrast, when the role indicator is 1, the value is not determined by its structural equation, but is instead set to one of its admissible values. We call these values *settings*. We require that a setting has *more than one* admissible value. That is, settings are variable.

Formally distinguishing between responses and settings makes explicit the dual roles played by variables in a causal system, entirely in the spirit of the PCM. Settable variables represent a formal

implementation, alternative to that of the "do operator" in the PCM, of the "wiping out" operation first proposed by Strotz and Wold (1960) and later used by Fisher (1970).

Once we make explicit the dual roles of the system variables, several benefits become apparent. First, the equal sign no longer has to serve in an asymmetric manner. This makes possible *implicit* representations of causal relations in settable systems that are either not possible in the PCM, because the required closed-form expressions do not exist; or that are possible in the PCM only under restrictions permitting application of the implicit function theorem. Such implicit representations are often natural for responses satisfying first order conditions arising from optimization. To illustrate, consider how explicit representation of the dual roles of system variables modifies the learning with clamping system. The first order condition necessary for the β-clamped optimum $\min_\alpha L(\alpha,\beta,\gamma)$ is now

$$\mu_Y - \tilde{\alpha}^* - \beta\mu_X = 0.$$

That for the α-clamped optimum $\min_\beta L(\alpha,\beta,\gamma)$ is now

$$\mu_{XY} - \alpha\mu_X - \tilde{\beta}^*\mu_{XX} = 0.$$

The structural system thus has the implicit representation

$$\mu_Y - \tilde{\alpha}^* - \beta\mu_X = 0, \tag{7}$$

$$\mu_{XY} - \alpha\mu_X - \tilde{\beta}^*\mu_{XX} = 0. \tag{8}$$

3.3.2 SETTABLE SYSTEMS AND THE ROLE OF FIXED POINTS

A second benefit of making explicit the dual roles of the system variables is that unique fixed points do not have a crucial role to play in settable systems. This enables us to dispense with the unique fixed point requirement prohibiting the PCM from encompassing our learning with clamping example. This is not to say that fixed points have no role to play. Instead, that role is removed from the structural representation of the system and, to the extent relevant, operates according to the governing principle, for example, optimization or equilibrium. We discuss this further below.

To illustrate, consider the learning with clamping system above where the dual roles of the system variables are made explicit. Now there is no necessity of finding a fixed point for Equations (7) and (8). Each equation stands on its own, representing its associated clamped optimum.

The simplest case is that for $\tilde{\alpha}^*$. For every μ_X, μ_Y, and β, there is a unique solution,

$$\tilde{\alpha}^* = \mu_Y - \beta\mu_X =: \tilde{r}_1(\beta,\gamma).$$

We call $\tilde{r}_1$ the *response function* for $\mathcal{X}_1$.

Next consider $\tilde{\beta}^*$. Provided $\mu_{XX} > 0$, Equation (8) determines a unique value for $\tilde{\beta}^*$,

$$\tilde{\beta}^* = \mu_{XX}^{-1}(\mu_{XY} - \alpha\mu_X).$$

But what happens when $\mu_{XX} = 0$? This further implies $\mu_X = \mu_{XY} = 0$. Consequently, *any* value will do for $\tilde{\beta}^*$, as any value of $\tilde{\beta}^*$ delivers the best possible prediction. To arrive at a unique value for $\tilde{\beta}^*$, we can apply criteria supplemental to predictive optimality. For example, we may choose a value that has the simplest representation. This reduces the viable choices to $\tilde{\beta}^* \in \{0,1\}$, as either of these requires only one bit to represent. Finally, by selecting $\tilde{\beta}^* \in \{0\}$, so that we set $\tilde{\beta}^* = 0$ when

$\mu_{XX} = 0$, we achieve a prediction, $f(X;\alpha,\tilde{\beta}^*) = \alpha$, that requires the fewest operations to compute. Formally, this gives

$$\tilde{\beta}^* = 1_{\{\mu_{XX}>0\}}\mu_{XX}^{-1}(\mu_{XY} - \alpha\mu_X) =: \tilde{r}_2(\alpha,\gamma),$$

where $1_{\{\mu_{XX}>0\}}$ is the indicator function taking the value one when $\mu_{XX} > 0$, and zero otherwise. We call $\tilde{r}_2$ the response function for $\mathcal{X}_2$.

This example demonstrates that even when structural equations conforming to the PCM (i.e., Equation 5) do not have a fixed point, we can find unique response functions for each settable variable of the analogous settable system. We do this by applying the governing principle for the system (e.g., optimization), supplemented when necessary by further appropriate principles (e.g., parsimony of memory and computation).

Applying the settable variable representation in the equations in (6), we obtain a settable variables representation for our learning with clamping example:

$$\mathcal{X}_1(0) = \tilde{r}_1(\mathcal{X}_2(1),\gamma), \qquad \mathcal{X}_2(0) = \tilde{r}_2(\mathcal{X}_1(1),\gamma).$$

So far, the variable γ has not been given status as a settable variable. Although it does not have a dual aspect, it can be set to any of several admissible values (those in Γ), so it does have the aspect of a setting. Accordingly, we can define $\mathcal{X}_0(1) := \gamma$. To ensure that $\mathcal{X}_0$ is a well-defined settable variable, we must also specify a value for $\mathcal{X}_0(0)$. By convention, we simply put $\mathcal{X}_0(0) := \mathcal{X}_0(1)$. We call $\mathcal{X}_0$ *fundamental* settable variables. As these are determined outside the system, they are structurally exogenous.

We can now give an explicit settable system representation for our present example, that is, a representation solely in terms of settable variables:

$$\mathcal{X}_1(0) = \tilde{r}_1(\mathcal{X}_2(1),\mathcal{X}_0(1)) \qquad \mathcal{X}_2(0) = \tilde{r}_2(\mathcal{X}_1(1),\mathcal{X}_0(1)).$$

3.4 Causes and Effects: Settable Systems and the PCM

This section introduces causal notions appropriate to settable systems.

3.4.1 DIRECT CAUSALITY

We begin by considering our learning with clamping example, where

$$\tilde{\alpha}^* = \tilde{r}_1(\beta,\gamma), \quad \tilde{\beta}^* = \tilde{r}_2(\alpha,\gamma).$$

In particular, consider the equation $\tilde{\beta}^* = \tilde{r}_2(\alpha,\gamma)$. In settable systems, settings are variable, that is, they can take any of a range of admissible values. We view this as sufficient to endow them with potential causal status. Thus, we call α and γ *potential causes* of $\tilde{\beta}^*$.

We say that a given element of (α,γ) *does not directly cause* $\tilde{\beta}^*$ if $\tilde{r}_2(\alpha,\gamma)$ defines a function constant in the given element for all admissible values of the other elements of (α,γ). Otherwise, that element is a *direct cause* of $\tilde{\beta}^*$. According to this definition, μ_Y does not directly cause $\tilde{\beta}^*$, whereas $\mu_X, \mu_{XX}, \mu_{XY}$, and α are direct causes of $\tilde{\beta}^*$.

3.4.2 INTERVENTIONS AND DIRECT EFFECTS IN SETTABLE SYSTEMS

In settable systems, an *intervention to a settable variable* is a pair of distinct admissible setting values. In our clamped learning example, let α_1 and α_2 be different admissible values for α.

Then $\alpha_1 \to \alpha_2 := (\alpha_1, \alpha_2)$ is an intervention to α, or, more formally, to $\mathcal{X}_1$. Similarly, $(\alpha_1, \gamma_1) \to (\alpha_2, \gamma_2) := ((\alpha_1, \gamma_1), (\alpha_2, \gamma_2))$ is an intervention to (α, γ) (i.e., to $(\mathcal{X}_1, \mathcal{X}_0)$). The *direct effect* on a given settable variable of a specified intervention is the response difference arising from the intervention. In our clamped learning example, the direct effect on $\mathcal{X}_2$ of the intervention $\alpha_1 \to \alpha_2$ is

$$\begin{aligned} \Delta\tilde{r}_2(\alpha_1, \alpha_2; \gamma) &:= \tilde{r}_2(\alpha_2, \gamma) - \tilde{r}_2(\alpha_1, \gamma) \\ &= 1_{\{\mu_{XX} > 0\}} \mu_{XX}^{-1} (\alpha_1 - \alpha_2) \mu_X. \end{aligned}$$

We emphasize that interventions are always well defined, as settings necessarily have more than one admissible value. Indeed, a key reason that we require settings to be variable is precisely to ensure that interventions to settable variables are always meaningful.

PCM notions related to the settable systems notion of intervention are the do operator and the "effect of action" defined in definition 7.1.3 of Pearl (2000); these specify a submodel associated with a given realization x for a given subset of the endogenous variables v.

3.4.3 EXOGENOUS AND ENDOGENOUS CAUSES

The notion of causality just defined contrasts in an interesting way with that formally given in the PCM. We have just seen that γ can serve in the settable system as a direct cause of $\tilde{\beta}^*$. Above, we saw that γ corresponds to background variables u in the PCM. In the PCM, the formal concept of *submodel* and the *do operator* necessary to define causal relations are meaningful only for endogenous variables v. None of these concepts are defined for u; that is, u is not subject to counterfactual variation in the PCM.[2] Consequently, u does not have formal causal status in the PCM as defined in Pearl (2000, Chap. 7).

In the PCM, u thus has four explicit distinguishing features: it is (i) a vector of variables that (ii) are determined outside the system, (iii) determine the endogenous variables, and (iv) are not subject to counterfactual variation. An optional but common feature of u is: (v) it is unobservable. As a result, background variables cannot act as causes in the PCM; in particular, for a given system, the PCM formally rules out structurally exogenous unobserved causes.

In settable systems, we drop requirement (iv) for structurally exogenous variables. Thus, we allow for observed structurally exogenous causes such as a treatment of interest in a controlled experiment, which is typically directly set (and observed) by the researcher. We also allow for unobservable structurally exogenous causes, ensuring a causal framework that is not relative to the capabilities of the observer, as is appropriate to the macroscopic, non-quantum mechanical systems that are the strict focus of our attention here. Unobserved common causes are particularly relevant for the analysis of confounding, that is, the existence of hidden causal relations that may prevent the identification of causal effects of interest (see Pearl, 2000, Chap. 3.3-3.5). Also, unobserved structurally exogenous causes are central to errors-in-variables models where a structurally exogenous cause of interest cannot be observed. Instead, one observes an version of this cause contaminated by measurement error. These models are the subject of a vast literature in statistics and econometrics (see, e.g., van Huffel and Lemmerling, 2002, and the references there).

Dropping (iv) in settable systems creates no difficulties in defining causal relations, as direct causality is a property solely of the response function on its domain. Moreover, by requiring that settings have more than one admissible value, we ensure that these domains contain at least two

2. We are grateful to two of the referees for emphasizing this.

points, making possible the interventions supporting definitions of effects in settable systems. We will return to this point shortly.

In the PCM, endogenous variables are usually observable, although this is not formally required. Structurally endogenous settable variables X may also be observable or not.

Fortunately, the PCM treats a variable as a background variable or an endogenous variable relative to the analysis. If the effects of a variable are of interest, it can be converted to an endogenous variable in an alternative PCM. Nevertheless, the PCM does not provide guidance on whether to treat a variable as a background variable or an endogenous one. This decision is entirely left to the researcher's discretion. For example, the "disturbances" in the Markovian PCM "represent background variables that the investigator chooses not to include in the analysis" (Pearl, 2000, p. 68), but the PCM does not specify how an investigator chooses to include variables in the analysis. Nor is it clear that background variables are necessary to the analysis in the first place. For example, Dawid (2002, p. 183) states that "when the additional variables are pure mathematical fictions, introduced merely so as to reproduce the desired probabilistic structure of the domain variables, there seems absolutely no good reason to include them in the model."

Settable systems permit but do not require background variables. Further, and of particular significance, in a settable system a governing principle such as optimization provides a formal way to distinguish between fundamental settable variables (exogenous variables) and other settable variables (endogenous variables). In particular, the decision problem determines if a variable is exogenous or endogenous. For instance, in our clamped learning example, the optimal network weights $\tilde{\alpha}^*$ and $\tilde{\beta}^*$ minimize the loss function $L(\alpha, \beta, \gamma)$. On the other hand, although the elements of γ are variables, our learning example does not specify a decision problem that determines how these are generated. This distinction endows the variables $\tilde{\alpha}^*$ and $\tilde{\beta}^*$ with the status of endogenous variables and the elements of γ with the status of structurally exogenous variables.

Thus, carefully and explicitly specifying the decision problems and governing principles in settable systems provides a systematic way to distinguish between exogenous and endogenous variables. This formalizes and extends the distinctions between the PCM endogenous and exogenous variables.

The PCM has been fruitfully applied in the sciences (e.g., Shipley, 2000). Nevertheless, because the PCM is agnostic concerning the status of variables, two researchers may employ two possibly inconsistent PCMs to study the same scientific phenomena. To resolve such inconsistencies, one may use the fact that under suitable assumptions, causal relations imply empirically testable conditional independence relations among system variables (Pearl, 2000; Chalak and White, 2008b). This yields procedures for falsifying causal structures that are inconsistent with data. Such procedures at best identify a class of observationally equivalent causal models, so resolution of inconsistencies by this means is not guaranteed. On the other hand, specifying the decision problems underlying the phenomena of interest may, among other things, offer guidance as to which (if either) model is more suitable to the analysis. The settable systems framework provides the foundation necessary for this in the context of optimally interacting agents under uncertainty. We emphasize that agents and their decision problems may be defined in such a way as to apply even to physical or biological systems not usually thought of in these terms; any system involving optimizing (e.g., least energy, maximum entropy) and/or equilibrium falls into this framework.

3.5 Unclamped Learning and Settable Systems

Now consider how our original unclamped learning example is represented using settable systems. We begin by recognizing that the solution to a given optimization problem need not be unique, but is in general a set. When the solution depends on other variables, the solution is in general a correspondence, not a function (see, e.g., Berge, 1963). Thus, we write the solution to the unclamped learning problem as

$$(\mathbb{A}^*(\gamma), \mathbb{B}^*(\gamma)) := \arg\min_{\alpha,\beta} L(\alpha, \beta, \gamma),$$

where $\mathbb{A}^*(\gamma)$ and $\mathbb{B}^*(\gamma)$ define correspondences.

Due to the linear network architecture, we can explicitly represent $\mathbb{A}^*(\gamma)$ and $\mathbb{B}^*(\gamma)$ as

$$\begin{aligned} \mathbb{A}^*(\gamma) &= \{\alpha : [\mu_{XX} - \mu_X^2](\alpha - \mu_Y) + (\mu_{XY} - \mu_X\mu_Y)\mu_X = 0\}, \\ \mathbb{B}^*(\gamma) &= \{\beta : [\mu_{XX} - \mu_X^2]\beta - (\mu_{XY} - \mu_X\mu_Y) = 0\}. \end{aligned}$$

When $\mu_{XX} - \mu_X^2 > 0$, $\mathbb{A}^*(\gamma)$ and $\mathbb{B}^*(\gamma)$ each have a unique element, namely

$$\begin{aligned} \alpha^* &= \mu_Y - [\mu_{XX} - \mu_X^2]^{-1}(\mu_{XY} - \mu_X\mu_Y)\mu_X, \\ \beta^* &= [\mu_{XX} - \mu_X^2]^{-1}(\mu_{XY} - \mu_X\mu_Y). \end{aligned}$$

When $\mu_{XX} - \mu_X^2 = 0$, we can select a unique value from each of $\mathbb{A}^*(\gamma)$ and $\mathbb{B}^*(\gamma)$. Choosing the simplest representation and the simplest computation of the prediction yields $\alpha^* = \mu_Y$ and $\beta^* = 0$. We thus represent optimal weights using response functions r_1 and r_2 as

$$\begin{aligned} \alpha^* &= r_1(\gamma) := \mu_Y - 1_{\{\mu_{XX} - \mu_X^2 > 0\}}[\mu_{XX} - \mu_X^2]^{-1}(\mu_{XY} - \mu_X\mu_Y)\mu_X, \\ \beta^* &= r_2(\gamma) := 1_{\{\mu_{XX} - \mu_X^2 > 0\}}[\mu_{XX} - \mu_X^2]^{-1}(\mu_{XY} - \mu_X\mu_Y). \end{aligned}$$

These response functions do represent fixed points of the equations in (5). This illustrates the role that fixed points can play in determining the response functions. Observe, however, that we do not require a *unique* fixed point.

Applying the settable system definition of direct causality, we have that a given element of γ, say γ_i, does not directly cause α^* (resp. β^*) if $r_1(\gamma)$ (resp. $r_2(\gamma)$) defines a function constant in γ_i for all admissible values of the other elements of γ. Otherwise, that element is a direct cause of α^* (resp. β^*). Here, each element of γ directly causes both α^* and β^*.

In this example, we have the settable system representation

$$\mathcal{X}_1(0) = r_1(\mathcal{X}_0(1)), \qquad \mathcal{X}_2(0) = r_2(\mathcal{X}_0(1)),$$

where $\mathcal{X}_0(0) := \mathcal{X}_0(1) := \gamma, \mathcal{X}_1(1) := \alpha, \mathcal{X}_2(1) := \beta$ as before, but now $\mathcal{X}_1(0) := \alpha^*$ and $\mathcal{X}_2(0) := \beta^*$.

Finally, we note that the system outputs of the clamped and unclamped systems are *mutually consistent*, in the sense that if we plug the responses of the unclamped system into the response functions $(\tilde{r}_1, \tilde{r}_2)$ of the clamped system as settings, we obtain clamped responses that replicate the responses of the unclamped system. That is, putting $\mathcal{X}_1^c(1) = \mathcal{X}_1^u(0)$ and $\mathcal{X}_2^c(1) = \mathcal{X}_2^u(0)$, where we now employ the superscripts c and u to clearly distinguish clamped and unclamped system settable variables, we have

$$\mathcal{X}_1^u(0) = \tilde{r}_1(\mathcal{X}_2^u(0), \mathcal{X}_0(1)), \qquad \mathcal{X}_2^u(0) = \tilde{r}_2(\mathcal{X}_1^u(0), \mathcal{X}_0(1)),$$

as some simple algebra will verify. This mutual consistency is ensured by the governing principle of optimization.

3.6 Partitioning in Settable Systems

In the PCM, the role of submodels (Pearl, 2000, Def. 7.1.2) is to specify which endogenous variables are subject to manipulation; the do operator specifies which values the manipulated variables take. In settable systems, submodels and the do operator are absent. Nevertheless, settable systems do have an analog of submodels, but instead of specifying which variables are to be manipulated, a settable system specifies which system variables are free to respond to the others. In our learning examples, settable systems specify which variables are unclamped. In our first example, both variables are unclamped. In the second example, the variables are considered one at a time, and each variable is unclamped in turn.

3.6.1 PARTITIONING

A formal mathematical implementation of these specifications is achieved by *partitioning*. Partitioning operates on an index set I whose elements are in one-to-one correspondence to the structurally endogenous (non-fundamental) settable variables. In our learning examples, there are two such variables, so the index set can be chosen to be $I = \{1,2\}$.

Let I be any set with a countable number of elements. A partition Π is a collection of subsets $\Pi_1, \Pi_2, ...$ of I that are mutually exclusive ($\Pi_a \cap \Pi_b = \varnothing, a \neq b$) and exhaustive ($\cup_b \, \Pi_b = I$). Examples are the *elementary partition*, $\Pi^e := \{\Pi^e_1, ..., \Pi^e_n\}$, where $\Pi^e_1 := \{1\}, \Pi^e_2 := \{2\}, ...$, and the *global partition* $\Pi^g := \{\Pi^g_1\}$, where $\Pi^g_1 := I$.

When $I = \{1,2\}$, these are the only two possible partitions: $\Pi^e = \{\Pi^e_1, \Pi^e_2\}$, where $\Pi^e_1 = \{1\}$ and $\Pi^e_2 = \{2\}$; and $\Pi^g = \{\Pi^g_1\}$, where $\Pi^g_1 = \{1,2\}$.

We interpret the partition elements as specifying which of the system variables are jointly free to respond to the remaining variables of the system, according to the governing principle of the system (e.g., optimization). In our machine learning examples with $I = \{1,2\}$, the element $\Pi^e_1 = \{1\}$ of the elementary partition Π^e specifies that variable 1 (i.e., $\tilde{\alpha}^*$) is free to respond to all other variables of the system (i.e., (β, γ)), whereas $\Pi^e_2 = \{2\}$ specifies that variable 2 (i.e., $\tilde{\beta}^*$) is free to respond to all other variables of the system (i.e., (α, γ)). The element $\Pi^g_1 = \{1,2\}$ of the global partition specifies that variables 1 and 2 (i.e., (α^*, β^*)) are jointly free to respond to all other variables of the system (i.e., γ).

In settable systems, response functions are partition specific. With Π^e, we have

$$\tilde{\alpha}^* = \tilde{r}_1(\beta, \gamma), \quad \tilde{\beta}^* = \tilde{r}_2(\alpha, \gamma);$$

with Π^g, we have

$$\alpha^* = r_1(\gamma), \quad \beta^* = r_2(\gamma)$$

for the response functions $(\tilde{r}_1, \tilde{r}_2)$ and (r_1, r_2) defined above. This implies that the settable variables and the resulting causal relations are *partition specific*.

We note that the distinction between the response functions $(\tilde{r}_1, \tilde{r}_2)$ and (r_1, r_2) is not due to additional constraints imposed on the optimization problem per se. Instead, the distinction follows from whether learning occurs with or without clamping and hence on whether or not alpha and beta respond jointly. Thus, different optimization problems yield different corresponding partitions and response functions.

These partitioning concepts and principles extend to systems with any number of structurally endogenous variables. We discuss further examples below.

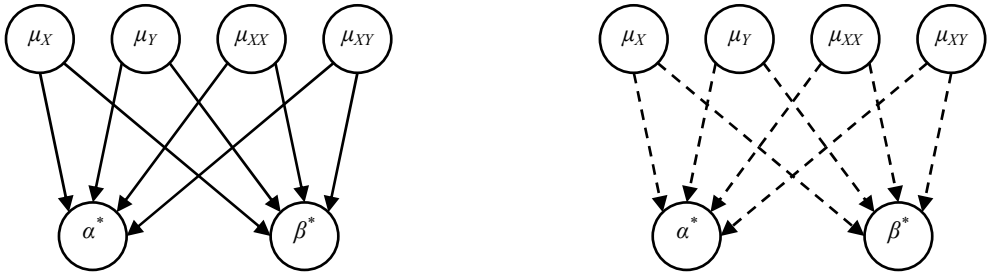

Figure 1: PCM Directed Acyclic Graphs

3.6.2 SETTABLE SYSTEM CAUSAL GRAPHS

Given the applicability of the PCM to the unclamped learning example, this system has an associated PCM directed acyclic graph (DAG). The particular representation of this graph depends on whether or not the background variables are observable or not. Figure 1(a) depicts the case of observable γ and Figure 1(b) that of unobservable γ. The solid arrows in Figure 1(a) indicate that the background variables are observable, whereas the dashed arrows in Figure 1(b) indicate that the background variables are not observable.

In interpreting these graphs, note that the arrows, whether solid or dashed, represent the functional relationships present. They do not, however, represent causal relations, as in the PCM these are defined to hold only between endogenous variables, and no arrows link the endogenous variables here. Pearl (2000) often uses the term "influence" to refer to situations involving functional dependence, but not causal dependence. In this sense, the arrows in these DAGs represent "influences."

In contrast, due to the lack of a fixed point, the PCM does not apply to the learning with clamping example. Necessarily, the PCM cannot supply a causal graph.

In settable systems, partitions play a key role in constructing causal graphs that represent direct causality relations. To see how, consider our clamped learning example. Here, μ_Y (i.e., $\mathcal{X}_{0,2}(1)$) does not directly cause $\tilde{\beta}^*$ ($\mathcal{X}_2(0)$), whereas $\mu_X, \mu_{XX}, \mu_{XY}$, and α ($\mathcal{X}_{0,1}(1), \mathcal{X}_{0,3}(1), \mathcal{X}_{0,4}(1)$, and $\mathcal{X}_1(1)$) are direct causes of $\tilde{\beta}^*$ ($\mathcal{X}_2(0)$). We can succinctly and unambiguously state these causal relations in terms of settable variables by saying that $\mathcal{X}_{0,2}$ does not directly cause $\mathcal{X}_2$, whereas $\mathcal{X}_{0,1}, \mathcal{X}_{0,3}, \mathcal{X}_{0,4}$, and $\mathcal{X}_1$ are direct causes of $\mathcal{X}_2$.

For each block Π_b of a partition $\Pi = \{\Pi_b\}$, we construct a settable system causal graph by letting nodes correspond to settable variables. If one settable variable directly causes another, we draw an arrow from the node representing the cause to that representing the responding settable variable. Note that in contrast to the DAGs for the PCM, we represent all direct causal links as solid arrows, letting dashed nodes represent unobservable settable variables. The motivation for this is that unobservability is a property of the settable variable (the node), not the links between nodes.

Figures 2(a) and 2(b) depict the causal graphs for our clamped learning example. There are two causal graphs, as the clamped learning example expresses the elementary partition $\Pi^e = \{\{1\}, \{2\}\}$. For purposes of illustration, we depict the case in which γ is unobserved.

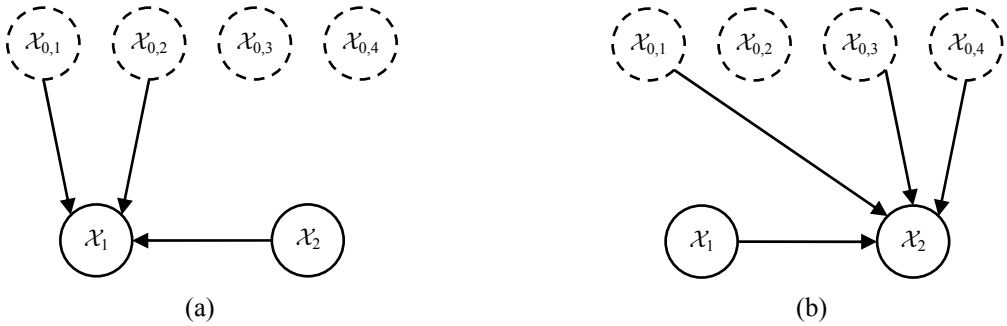

Figure 2: Block-specific Settable System Causal Graphs for the Elementary Partition

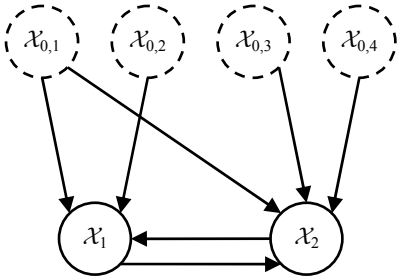

Figure 3: Settable System Superimposed Causal Graph for the Elementary Partition

For convenience, we may superimpose settable system causal graphs. Superimposing Figures 2(a) and 2(b) gives Figure 3. This is a cyclic graph. Nevertheless, this cyclicality does not represent true simultaneity; it is instead an artifact of the superimposition.

The settable system causal graph for the global partition $\Pi^g = \{\{1,2\}\}$ representing unclamped learning is depicted in Figure 4. Observe that this reproduces the connectivity of Figure 1. Note that in Figure 4, the nodes represent settable variables and the arrows represent direct causes. In Figure 1, the nodes represent background or endogenous variables and the arrows represent non-causal "influences."

We emphasize that the causal graphs associated with settable systems are not necessary to the analysis. Rather, they are sometimes helpful in succinctly representing and studying causal relations.

3.7 Further Examples Motivating Settable System Features

We now introduce two further features of settable systems, countable dimension and attributes, using examples involving machine learning algorithms and networks with hidden units. This provides further interesting contrasts between settable systems and the PCM.

3.7.1 A MACHINE LEARNING ALGORITHM AND COUNTABLE DIMENSIONALITY

So far, we have restricted attention to the optimal network weights for linear least-squares machine learning. Now consider the machine learning algorithm itself. For this, let

$$\hat{\mu}_{x,0} = \hat{\mu}_{y,0} = \hat{\mu}_{xx,0} = \hat{\mu}_{xy,0} = \hat{\alpha}_0 = \hat{\beta}_0 = 0,$$

and perform the recursion

$$\begin{aligned}
\hat{\mu}_{x,n} &= \hat{\mu}_{x,n-1} + n^{-1}(x_n - \hat{\mu}_{x,n-1}) \\
\hat{\mu}_{y,n} &= \hat{\mu}_{y,n-1} + n^{-1}(y_n - \hat{\mu}_{y,n-1}) \\
\hat{\mu}_{xx,n} &= \hat{\mu}_{xx,n-1} + n^{-1}(x_n^2 - \hat{\mu}_{xx,n-1}) \\
\hat{\mu}_{xy,n} &= \hat{\mu}_{xy,n-1} + n^{-1}(x_n y_n - \hat{\mu}_{xy,n-1}) \\
\hat{\beta}_n &= 1_{\{\hat{\mu}_{xx,n} - \hat{\mu}_{x,n}^2 > 0\}}[\hat{\mu}_{xx,n} - \hat{\mu}_{x,n}^2]^{-1}(\hat{\mu}_{xy,n} - \hat{\mu}_{x,n}\hat{\mu}_{y,n}) \\
\hat{\alpha}_n &= \hat{\mu}_{y,n} - \hat{\beta}_n \hat{\mu}_{x,n}, \quad n = 1, 2, ...
\end{aligned} \tag{9}$$

Variables determined outside the system are the observed data sequences $x := (x_1, x_2, ...)$ and $y := (y_1, y_2, ...)$. Variables determined within the system are $\hat{\mu}_x := (\hat{\mu}_{x,0}, \hat{\mu}_{x,1}, ...), \hat{\mu}_y := (\hat{\mu}_{y,0}, \hat{\mu}_{y,1}, ...), \hat{\mu}_{xx} := (\hat{\mu}_{xx,0}, \hat{\mu}_{xx,1}, ...), \hat{\mu}_{xy} := (\hat{\mu}_{xy,0}, \hat{\mu}_{xy,1}, ...), \hat{\alpha} = (\hat{\alpha}_0, \hat{\alpha}_1, ...)$, and $\hat{\beta} := (\hat{\beta}_0, \hat{\beta}_1, ...)$. Under mild conditions, $\hat{\alpha}_n$ converges to α^* and $\hat{\beta}_n$ converges to β^*.

We now ask whether this system falls into the PCM. The answer is no, because the PCM requires the dimensions of the background and endogenous variables to be finite. Here these dimensions are countably infinite. The PCM does not apply. (As a referee notes, however, a countably infinite version of the PCM has recently been discussed by Eichler and Didelez, 2007).

In contrast, settable systems encompass this learning system by permitting the settable variables to be of countably infinite dimension. The definitions of direct causality and the notion of partitioning operate identically in either the finite or the countably infinite case. Settable systems generally accommodate any recursive learning algorithm involving data sequences of arbitrary length.

3.7.2 LEARNING WITH A HIDDEN UNIT NETWORK AND ATTRIBUTES

To motivate the next feature of settable systems, we return to considering the effect on an optimal network weight of interventions to distributional parameters, γ, and another network weight. Now, however, we modify the prediction function to be that defined by

$$f(X; \alpha, \beta) = \alpha\, \phi(\beta X).$$

This is a single hidden layer feedforward network with a single hidden unit having the activation function ϕ. For concreteness, let ϕ be the standard normal density. This activation function often appears in radial basis function networks. For clarity, we consider only a single input X, a single

input-to-hidden weight β, and a single hidden-to-output weight α. This elementary structure suffices to make our key points and keeps our notation simple.

Now the expected squared prediction error is

$$L(\alpha,\beta,\gamma;\phi) := E_\gamma([Y-\alpha\,\phi(\beta X)]^2).$$

Here, γ reverts to representing the general parameter indexing F_γ. The choice $\gamma := (\mu_X,\mu_Y,\mu_{XX},\mu_{XY})$ considered above is no longer appropriate, due to the nonlinearity in network output induced by ϕ. Further, note the presence of the hidden unit activation function ϕ in the argument list of L. We make this explicit, as ϕ certainly helps determine prediction performance, and it has a key role to play in our subsequent discussion.

Now consider the clamped optimization problems corresponding to the elementary partition Π^e. This yields solutions

$$\begin{aligned}\widetilde{\mathbb{A}}^*(\beta,\gamma;\phi) &:= \arg\min_{\alpha\in\mathbb{A}} L(\alpha,\beta,\gamma;\phi),\\ \widetilde{\mathbb{B}}^*(\alpha,\gamma;\phi) &:= \arg\min_{\beta\in\mathbb{B}} L(\alpha,\beta,\gamma;\phi).\end{aligned}$$

We ensure the existence of compact-valued correspondences $\widetilde{\mathbb{A}}^*(\beta,\gamma;\phi)$ and $\widetilde{\mathbb{B}}^*(\alpha,\gamma;\phi)$ by (among other things) taking $\mathbb{A}$ and $\mathbb{B}$ to be compact subsets of $\mathbb{R}$. Elements $\tilde\alpha^*$ of $\widetilde{\mathbb{A}}^*(\beta,\gamma;\phi)$ and $\tilde\beta^*$ of $\widetilde{\mathbb{B}}^*(\alpha,\gamma;\phi)$ satisfy the necessary first order conditions

$$\begin{aligned}E_\gamma([\phi(\beta X)]^2)\tilde\alpha^* - E_\gamma(\phi(\beta X)Y) &= 0,\\ E_\gamma(D\phi(\tilde\beta^* X)Y) - \alpha E_\gamma[D\phi(\tilde\beta^* X)\phi(\tilde\beta^* X)] &= 0,\end{aligned}$$

where $D\phi$ denotes the first derivative of the ϕ function. We caution that although these relations necessarily hold for elements of $\widetilde{\mathbb{A}}^*(\beta,\gamma;\phi)$ and $\widetilde{\mathbb{B}}^*(\alpha,\gamma;\phi)$, not all (α,β) values jointly satisfying these implicit equations are members of $\widetilde{\mathbb{A}}^*(\beta,\gamma;\phi)$ and $\widetilde{\mathbb{B}}^*(\alpha,\gamma;\phi)$. Some solutions to these equations may be local minima, inflection points, or (local) maxima.

The PCM does not apply here, due (among other things) to the absence of a unique fixed point. Nevertheless, settable systems do apply, using a principled selection of elements from $\widetilde{\mathbb{A}}^*(\beta,\gamma;\phi)$ and $\widetilde{\mathbb{B}}^*(\alpha,\gamma;\phi)$, respectively. We write these selections

$$\tilde\alpha^* = \tilde r_1(\beta,\gamma;\phi), \quad \tilde\beta^* = \tilde r_2(\alpha,\gamma;\phi).$$

The feature distinguishing this example from our earlier examples is the appearance in the response functions of the hidden unit activation function ϕ. The key feature of ϕ is that it takes one and only one value: ϕ is the standard normal density. It is therefore not a variable. Consequently, it cannot be a setting, and it is distinct from any of the other objects we have previously examined. We define an *attribute* to be any object specified a priori that helps determine responses but is not variable. We associate attributes with the system units. Any attribute of the system itself is a *system attribute*; we formally associate system attributes to each system unit. Here, ϕ is a system attribute. Because a unit's associated attributes are constant, they are not subject to counterfactual variation. Nevertheless, attributes may differ across units.

One generally useful attribute is the attribute of *identity*. This is a label assigned to each unit of a given system that can take only the assigned value, and whose value is shared by no other unit

of the system. The identity attribute is required by settable systems, as the identity labels are those explicitly used in the partitioning operation. The identity attribute is also a feature of the PCM, as background and endogenous variables are distinct types of objects, and elements of each distinct type have identifying subscripts.

When attributes beyond identity are present, they need not be distinct across units. For example, the quantity n appearing in several of the response functions in the learning algorithm of Equation (9) is an attribute shared by those units.

We emphasize that attributes are relative to the particular structural system, not somehow absolute. Some objects may be taken as attributes solely for convenience. For example, one might consider several different possible activation functions and attempt to learn the best one for a given problem. In such systems, the hidden unit activation is no longer an attribute but is an endogenous variable. In other cases, it may be more convenient to treat the activation function as hard-wired, in which case the activation function is an attribute. Indeed, any hard-wired aspect of the system is properly an attribute. Convenience may even dictate treating as attributes objects that are in principle variable, but whose degree of variation is small relative to that of other system variables of interest.

Other system aspects are more inherently attributes. Because of their fundamental role and their invariance, such attributes are easily taken for granted and thus overlooked. Our least-squares learning example is a case in point. Specifically, the loss function itself is properly viewed as an attribute.

A useful way to appreciate this is to consider the loss functions

$$L_p(\alpha,\beta,\gamma) := \int |y - f(x;\alpha,\beta)|^p dF_\gamma(x,y), \quad p > 0.$$

In our examples so far, we always take $p = 2$, so $L = L_2$. Different choices are possible, yielding different loss functions. A leading example is the choice $p = 1$. Whereas $p = 2$ yields forecasts that approximate the conditional mean of Y given X, $p = 1$ yields forecasts that approximate the conditional median of Y given X.

Because p is a constant specified a priori and because p helps determine the optimal responses, p is an attribute. When the forecaster's goal is explicitly to provide a forecast based on the conditional mean, it makes little sense to consider values of p other than 2, because no other value of p is guaranteed to generally deliver an approximation to the conditional expectation. Put somewhat differently, it may not make much sense to attempt to endogenize p and choose an "optimal" value of p from some set of admissible values because the result of choosing different values for p is to modify the very goal of the learning exercise. Nor can one escape from attributes by endogenizing p; as long as there is some optimality criterion at work, this criterion is properly an attribute of the system.

Another important example of inherent attributes is provided by the sets $\mathbb{S}_i$ that specify the admissible values taken by the settings $\mathcal{X}_i(1)$ and responses $\mathcal{X}_i(0)$. These are properly specified a priori; they take one and only one value for each unit i; and they play a fundamental role in determining system responses.

Because attributes in settable systems are fixed a priori for a given unit, they take values in a (non-empty) degenerate set. Accordingly, attributes cannot be settings, and thus can never be potential causes, much less direct causes. This formal distinction between attributes and potential causes is unambiguous in settable systems.

3.7.3 ATTRIBUTES IN THE PCM

In contrast, a somewhat ambiguous situation prevails in the PCM. Viewing attributes as a subset of those objects having no causal status, Pearl (2000, p. 98) states that attributes can be treated as elements of u, the background variables.[3] This overlooks the key property we wish to assign to attributes: for a given unit, they are fixed, not variable. Such objects thus cannot belong to u if one takes the word "variable" at face value. In our view, assigning attributes to u misses the opportunity to make an important distinction between invariant aspects of the system units on the one hand and counterfactual variation admissible for the system unit values on the other. Among other things, assigning attributes to u interferes with assigning natural causal roles to structurally exogenous variables.

Further, just as for endogenous and exogenous variables, the PCM does not provide guidance about how to select attributes. In contrast, settable systems clearly identify attributes as invariant features of the system units that embody fundamental aspects of the decision problem represented by the settable system.

Below, we will further distinguish attributes from variables when we discuss stochastic settable systems.

3.8 A Comparative Review of PCM and Settable System Features

At this point, it is helpful to take stock of the features of settable systems that we have so far introduced and contrast these with corresponding features of the PCM.

(1) Settable systems explicitly represent the dual roles of the variables of structural systems using settable variables. These dual roles are present but implicit in the PCM. Settable variables can be responses, or they can be set to given values (settings). The explicit representation of these dual roles in settable systems makes possible implicitly defined structural relations that may not be representable in the PCM. Further, these implicit structural relations may involve correspondences rather than functions. Principled selections from these correspondences yield unique response functions in settable systems.

(2) In settable systems, all variables of the system, structurally exogenous or endogenous, have causal status, in that they can be potential causes or direct causes. Further, no assumptions are made as to the observability of system variables: structurally exogenous variables may be either observable or unobservable; the same is true for structurally endogenous variables. In particular, this permits settable systems to admit unobserved causes and results in causal relations that are not relative to an observer. In contrast, the PCM admits causal status only for endogenous variables. For the PCM, structurally exogenous unobserved causes are ruled out. Although the PCM does permit treating background variables as endogenous variables in alternative systems, it is silent as to how to distinguish between exogenous and endogenous variables. On the other hand, the governing principles in settable systems provide a formal and explicit means for distinguishing between endogenous and exogenous variables.

(3) Settable systems admit straightforward definitions of interventions and direct effects. These notions, while present, are less direct in the formal PCM.

(4) In settable systems, partitioning permits specification of different mutually consistent versions of a given structural system in which different groups of variables are jointly free to respond to the other variables of the system. In particular, system variables can respond either singly or jointly

3. This possibility is also suggested by two referees.

to the other variables of the system, as illustrated by our examples of learning with or without clamping. Similar exercises are possible in the PCM using submodels and the do operator, but the PCM requirement of a unique fixed point limits its applicability. Specifically, we saw that learning with clamping falls outside the PCM. Halpern's (2000) GPCM does apply to such systems, but causal discourse is problematic, due to the absence of the potential response function. In settable systems, fixed points are not required, and causal notions obtain without requiring the potential response function. This permits settable systems to provide causal meaning in our examples of learning with or without clamping.

(5) Settable systems can have a countable infinity of units, whereas the PCM requires a finite number of units.

(6) In settable systems, attributes are a priori constants associated with the units that help determine responses. In the PCM, attributes are not necessarily linked to the system units. Further, they are treated not as constants, but as background variables, resulting in potential ambiguity. The PCM is silent as to how to distinguish between attributes and variables.

Some features of settable systems, such as relaxing the assumption of unique fixed points (point 4) and accommodating an infinity of agents (point 5), are entirely unavailable in the PCM. The remaining settable systems features above rigorously formalize and extend or refine related PCM features and thus permit more explicit causal inference.

4. Stochastic Settable Systems: Heuristics

In the PCM, randomness does not formally appear until definition 7.1.6 (*probabilistic causal model*). Nevertheless, Pearl's (2000) definitions 7.1.1 through 7.1.5 (*causal model*, *submodel*, *effect of action*, *potential response,* and *counterfactual*) explicitly refer to "realizations" *pa* or *x* of endogenous variables *PA* or X. These references make sense only if *PA* and X are interpreted as random vectors. Although *u* is not explicitly called a realization, the language of definition 7.1.1 further suggests that *u* is viewed as a realization of random background variables, U. This becomes explicit in definition 7.1.6, where PCM background variables U become governed by a probability measure *P*. Randomness of endogenous variables is then induced by their dependence on U. In this sense, definitions 7.1.1 through 7.1.5 do not have fully defined content until definition 7.1.6 resolves the meaning of U, V, PA, and X. Nevertheless, definitions 7.1.1 through 7.1.5 are perfectly meaningful, simply viewing the referenced variables as real numbers.

The settable systems discussed so far are entirely non-stochastic: the settings and responses defined in Section 3 are real numbers, not random variables. Nevertheless, we can connect causal and stochastic structures in settable systems by viewing settings and responses as realizations of random variables, in much the same spirit as the PCM. In this section we discuss some specifics of this connection.

4.1 Introducing Randomness into Settable Systems

First, instead of only the background variables *u* representing realizations of random variables, in settable systems *all* settings represent realizations of random variables governed by an underlying probability measure. For example, in our hidden unit clamped learning example, (α, β, γ) are realizations of random variables (A, B, C) governed by a probability measure P on an underlying measurable space $(\Omega, \mathcal{F})$. The randomness of the responses is induced by their dependence on the

settings. Thus, in the hidden unit clamped learning example, we have random responses

$$\tilde{A}^* = \tilde{r}_1(B,C;\phi), \qquad \tilde{B}^* = \tilde{r}_2(A,C;\phi).$$

Second, the underlying probability measure for settable systems can depend on the attribute vector, call it $\mathbf{a}$, of the system. Whereas in the PCM attributes are "lumped together" with other background variables, and may therefore be random, this is not permitted in settable systems. In settable systems, attributes are specified a priori and take one and only one value, $\mathbf{a}$. Because of its a priori status, this value is non-random.

It follows that the probability measure governing the settable system can be indexed by $\mathbf{a}$. This is not an empty possibility; it has clear practical value. One context in which this practical value arises is when attention focuses only on the units of some subsystem of a larger system. For example, consider the least squares machine learning algorithm of the equations in (9), and focus attention on the subsystem

$$\begin{aligned} \hat{B} &= 1_{\{\hat{M}_{xx}-\hat{M}_x^2>0\}}[\hat{M}_{xx}-\hat{M}_x^2]^{-1}(\hat{M}_{xy}-\hat{M}_x\hat{M}_y), \\ \hat{A} &= \hat{M}_y - \hat{B}\hat{M}_x. \end{aligned}$$

Note that we have modified the notation to reflect the fact that the settings $\hat{M}_x, \hat{M}_y, \hat{M}_{xx}$, and $\hat{M}_{xy}$ are now random variables. These generate realizations $\hat{\mu}_{x,n}, \hat{\mu}_{y,n}, \hat{\mu}_{xx,n}$, and $\hat{\mu}_{xy,n}$ under a probability measure P_n, which is that induced by the probability measure governing the random fundamental settings $\{(X_1,Y_1),...,(X_n,Y_n)\}$. Note the explicit dependence of the probability measure P_n on the attribute n. The fact that this probability measure can depend on attributes underscores their nature as a priori constants in settable systems.

4.2 Some Formal Properties of Stochastic Settable Systems

Given attributes $\mathbf{a}$, we let $(\Omega, \mathcal{F}, P_\mathbf{a})$ denote the complete probability space on which the settings and responses are defined. Here, Ω is a set (the "universe") whose elements ω index possible outcomes ("possibilities"); $\mathcal{F}$ is a $\sigma-$field of measurable subsets of Ω whose elements represent events; and $P_\mathbf{a}$ is a probability measure (indexed by $\mathbf{a}$) on the measurable space $(\Omega, \mathcal{F})$ that assigns a number $P_\mathbf{a}(F)$ to each event $F \in \mathcal{F}$. See, for example, White (2001, Chap. 3) for an introductory discussion of measurable spaces and probability spaces.

We decompose ω as $\omega := (\omega_r, \omega_s)$, with $\omega_r \in \Omega_r, \omega_s \in \Omega_s$, so that $\Omega = \Omega_r \times \Omega_s$. As we discuss next, this enables distinct components of ω to underlie responses (ω_r) and settings (ω_s). This facilitates straightforward and rigorous definitions of counterfactuals and interventions. These notions in turn support a definition of direct effect.

To motivate the foundations for defining counterfactuals, again consider the hidden unit clamped learning example. Formally, the random settings (A,B,C) are measurable functions $A : \Omega_s \to \mathbb{R}$, $B : \Omega_s \to \mathbb{R}$, and $C : \Omega_s \to \mathbb{R}^m$, $m \in \mathbb{N}$. Letting ω_s belong to Ω_s, we take the setting values to be the realizations

$$\begin{aligned} \alpha &= A(\omega_s) =: \mathcal{X}_1(\omega,1), \\ \beta &= B(\omega_s) =: \mathcal{X}_2(\omega,1), \\ \gamma &= C(\omega_s) =: \mathcal{X}_0(\omega,1). \end{aligned}$$

Observe that the settings depend only on the ω_s component of ω. We make this explicit in $A(\omega_s)$, $B(\omega_s)$, and $C(\omega_s)$, but leave this implicit in writing $\mathcal{X}_0(\omega,1)$, $\mathcal{X}_1(\omega,1)$, and $\mathcal{X}_2(\omega,1)$ for notational convenience.

The responses are determined similarly:

$$\begin{aligned}\tilde{A}^*(\omega) &= \tilde{r}_1(B(\omega_s),C(\omega_s),\omega_r;\phi) = \tilde{r}_1(\mathcal{X}_2(\omega,1),\mathcal{X}_0(\omega,1),\omega_r;\phi) =: \mathcal{X}_1(\omega,0),\\ \tilde{B}^*(\omega) &= \tilde{r}_2(A(\omega_s),C(\omega_s),\omega_r;\phi) = \tilde{r}_2(\mathcal{X}_1(\omega,1),\mathcal{X}_0(\omega,1),\omega_r;\phi) =: \mathcal{X}_2(\omega,0).\end{aligned}$$

Note that we now make explicit the possibility that the response functions may depend directly on ω_r. This dependence was absent in all our previous examples but is often useful in applications, as this dependence permits responses to embody an aspect of "pure" randomness. From now on, we will include ω_r as an explicit argument of the response functions.

In the deterministic systems previously considered, we viewed the fundamental setting $\mathcal{X}_0(1)$ as a primitive object and adopted the convention that $\mathcal{X}_0(0) := \mathcal{X}_0(1)$. Once settings and responses depend on ω, it becomes necessary to modify our conventions regarding the fundamental settable variables $\mathcal{X}_0$, as $\mathcal{X}_0$ is no longer determined outside the system. The role of the system primitive is now played by ω, the *primary setting*. We represent this as the settable variable defined by $\mathcal{X}_*(\omega,0) := \mathcal{X}_*(\omega,1) := \omega$. We now view $\mathcal{X}_0(\omega,0)$ as a response to ω_s and we take $\mathcal{X}_0(\cdot,1) := \mathcal{X}_0(\cdot,0)$.

In the current stochastic framework, the feature that distinguishes $\mathcal{X}_0$ from other settable variables is that the response $\mathcal{X}_0(\omega,0)$ depends only on ω_s, whereas responses of other settable variables can depend directly on other settings and on ω_r. Given the availability of $\mathcal{X}_*$, there is no guarantee or requirement that such a settable variable $\mathcal{X}_0$ exists. Nevertheless, such *fundamental stochastic settable variables* $\mathcal{X}_0$ are often an important and useful feature in applications, as our machine learning examples demonstrate.

The definition of direct causality in stochastic settable systems is closely parallel to that in the non-stochastic case. Specifically, consider the partition $\Pi = \{\Pi_b\}$, and suppose i belongs to the partition element Π_b. Let $\mathcal{X}_{(b)}(\omega,1)$ denote setting values for the settable variables whose indexes do not belong to Π_b, together with the settings $\mathcal{X}_0(\omega,1)$. Then the response $\mathcal{X}_i(\omega,0)$ is given by

$$\mathcal{X}_i(\omega,0) := r_i(\mathcal{X}_{(b)}(\omega,1),\omega_r;\mathbf{a}) = r_i(z_{(b)},\omega_r;\mathbf{a}),$$

where r_i is the associated response function, $\mathbf{a}$ is the attribute vector, and for convenience we write $z_{(b)} := \mathcal{X}_{(b)}(\omega_s,1)$. Then we say that $\mathcal{X}_j$ *does not directly cause* $\mathcal{X}_i$ if $r_i(z_{(b)},\omega_r;\mathbf{a})$ defines a function constant in the element z_j of $(z_{(b)},\omega_r)$ for all values of the other elements of $(z_{(b)},\omega_r)$. Otherwise, we say that $\mathcal{X}_j$ *directly causes* $\mathcal{X}_i$. Thus, $\mathcal{X}_*$ can directly cause $\mathcal{X}_i$; for this, take $z_j = \omega_r$. If $\mathcal{X}_0(\omega,0)$ does not define a constant function of ω_s, we also say that $\mathcal{X}_*$ directly causes $\mathcal{X}_0$. As always, direct causality is relative to the specified partition.

4.3 Counterfactuals, Interventions, and Direct Effects

We now have the foundation necessary to specify "counterfactuals." We begin by defining what is meant by "factual." Suppose for now that all setting and response values apart from ω_r are observable. Specifically, suppose we have realizations of setting values (β,γ) and response value $\tilde{\alpha}^* = \tilde{r}_1(\beta,\gamma,\omega_r;\phi)$, and that ω is such that $\beta = B(\omega_s)$, $\gamma = C(\omega_s)$, and $\tilde{\alpha}^* = \tilde{A}^*(\omega)$, where

$$\tilde{A}^*(\omega) = \tilde{r}_1(B(\omega_s),C(\omega_s),\omega_r;\phi).$$

Then we say that $(\tilde{\alpha}^*, \beta, \gamma)$ are *factual* and that $\omega = (\omega_r, \omega_s)$ is *factual*. Otherwise, we say that $(\tilde{\alpha}^*, \beta, \gamma)$ and ω are *counterfactual*. Specifically, if the realization $(\tilde{\alpha}^*, \beta, \gamma)$ does not obtain, then we say that $(\tilde{\alpha}^*, \beta, \gamma)$ is counterfactual, whereas if we have the realizations $(\tilde{\alpha}^*, \beta, \gamma)$, but ω is such that $\beta \neq B(\omega_s)$, $\gamma \neq C(\omega_s)$, or $\tilde{\alpha}^* \neq \tilde{A}^*(\omega)$ then we say that ω is counterfactual.

There need not be a unique factual ω since it is possible that multiple ω's yield the same realizations of random variables; this creates no logical or conceptual difficulties. Also, we need not observe all settings and responses; an observable subset of these may be factual or counterfactual. To the extent that a given ω generates realizations compatible with factual observables, it may also be viewed as factual to that degree. An ω generating realizations incompatible with factual observables is necessarily counterfactual.

In non-stochastic settable systems, we defined an intervention to a settable variable as a pair of distinct admissible setting values for that settable variable. For example, $\alpha_1 \to \alpha_2 := (\alpha_1, \alpha_2)$. In stochastic settable systems, we express interventions similarly. Specifically, again consider the partition $\Pi = \{\Pi_b\}$, and suppose i belongs to the partition element Π_b, so that

$$\mathcal{X}_i(\omega, 0) := r_i(\mathcal{X}_{(b)}(\omega, 1), \omega_r; \mathbf{a}) = r_i(z_{(b)}, \omega_r; \mathbf{a}).$$

Then an *intervention* $(z_{(b),1}, \omega_{r,1}) \to (z_{(b),2}, \omega_{r,2})$ is a pair $((z_{(b),1}, \omega_{r,1}), (z_{(b),2}, \omega_{r,2}))$ whose elements are admissible and distinct.

Interventions necessarily involve counterfactuals: at most, only one setting can be factual; and for an intervention to be well defined, the other setting value must be distinct. We note that the notion of counterfactuals is helpful mainly for describing interventions. Although our definitions of causality, interventions, or, as we see next, direct effects implicitly involve counterfactuals, they do not formally require this notion.

The *direct effect on $\mathcal{X}_i$ of the intervention* $(z_{(b),1}, \omega_{r,1}) \to (z_{(b),2}, \omega_{r,2})$ is the associated response difference

$$r_i(z_{(b),2}, \omega_{r,2}; \mathbf{a}) - r_i(z_{(b),1}, \omega_{r,1}; \mathbf{a}).$$

Our definitions of interventions and direct effects permit *ceteris paribus* interventions and direct effects. For these, only some finite number (e.g., one) of the settings differs between $(z_{(b),1}, \omega_{r,1})$ and $(z_{(b),2}, \omega_{r,2})$; the other elements are "held constant."

Under suitable conditions (specifically, that the settings $\mathcal{X}_{(b)}(\cdot, 1)$ are an "onto" function), the interventions $(z_{(b),1}, \omega_{r,1}) \to (z_{(b),2}, \omega_{r,2})$ can be equivalently represented as a *primary intervention*

$$\omega_1 \to \omega_2 := (\omega_1, \omega_2) = ((\omega_{r,1}, \omega_{s,1}), (\omega_{r,2}, \omega_{s,2})).$$

That is, primary interventions are pairs (ω_1, ω_2) of elements of Ω. This representation is ensured by specifying that $\omega = (\omega_r, \omega_s)$, permitting ω_r and ω_s to be variation free (i.e., ω_r can vary without inducing any necessary variation in ω_s, and vice versa).

Primary interventions yield a definition of *total effect* as a response difference. In our hidden unit clamped learning example, the total effect on $\mathcal{X}_1$ of $\omega_1 \to \omega_2$ is

$$\begin{aligned} \Delta\mathcal{X}_1(\omega_1, \omega_2, 0) \ &: = \mathcal{X}_1(\omega_2, 0) - \mathcal{X}_1(\omega_1, 0) \\ &= \ \tilde{r}_1(B(\omega_{s,2}), C(\omega_{s,2}), \omega_{r,2}; \phi) - \tilde{r}_1(B(\omega_{s,1}), C(\omega_{s,1}), \omega_{r,1}; \phi). \end{aligned}$$

This is also the direct effect on $\mathcal{X}_1$ of $(Z_{(1)}(\omega_{s,1}), \omega_{r,1}) \to (Z_{(1)}(\omega_{s,2}), \omega_{r,2})$. We emphasize that these effects are, as always, relative to the governing partition. The total effect above is relative to the elementary partition, corresponding to clamped learning.

4.4 Review of Stochastic Settable System Features

In stochastic settable systems, all settings are governed by the underlying probability measure, whereas in the PCM, only the background variables are subject to random variation. Because of their status as a priori constants, attributes can index the settable system probability measure. Stochastic settable systems distinguish between primary settings and, when they exist, fundamental settable variables. Responses may contain an element of pure randomness. The structure of stochastic settable systems also supports straightforward rigorous definitions of direct causes, counterfactuals, interventions, direct effects, and total effects.

5. Stochastic Settable Systems: A Formal Definition

In Sections 3 and 4, we motivated the features of settable systems using a series of closely related machine learning examples. Here we integrate these features to provide a rigorous formal definition of a stochastic settable system $\mathcal{S}^{\Pi} := \{(\mathbf{A},\mathbf{a}),(\Omega,\mathcal{F},P_{\mathbf{a}}),(\Pi,\mathcal{X}^{\Pi})\}$.

To give a concise definition, we first introduce some convenient notation. We write the positive integers as $\mathbb{N}^+$; we also write $\bar{\mathbb{N}}^+ = \mathbb{N}^+ \cup \{\infty\}$. When $n = \infty$, we interpret $i = 1,...,n$ as $i = 1,2,....$ We also write $\mathbb{N} := \{0\} \cup \mathbb{N}^+$, and $\bar{\mathbb{N}} = \mathbb{N} \cup \{\infty\}$. When $m = 0$, we interpret $k = 1,...,m$ as being omitted; thus, when $m = 0$, terms like $\times_{k=1}^{m} A$ or $\times_{k=1}^{m} \mathbb{S}_{0,k}$ are ignored. The notation $\#\Pi$ denotes the number of elements (the cardinality) of the set Π.

Definition 1 (Stochastic Settable System) *Let $n \in \bar{\mathbb{N}}^+$, and let the* unit attribute space *A be a non-empty set. For each* unit *$i = 1,...,n$, let a* unit attribute *a_i be a fixed element of A, such that a_i includes a component of* admissible settings *$\mathbb{S}_i$, a multi-element Borel-measurable subset of $\mathbb{R}$.*

Let $m \in \bar{\mathbb{N}}$. For each $k = 1,...,m$, let a fundamental unit attribute *$a_{0,k}$ be a fixed element of A, such that $a_{0,k}$ includes a component of* admissible fundamental settings *$\mathbb{S}_{0,k}$, a multi-element Borel-measurable subset of $\mathbb{R}$. Write $a_0 := (a_{0,1},...,a_{0,m})$ and $\mathbf{a} := (a_0,a_1,...,a_n) \in \mathbf{A} := (\times_{k=1}^{m} A) \times (\times_{i=1}^{n} A)$, the* joint attribute space.

Let $(\Omega_r,\mathcal{F}_r)$ and $(\Omega_s,\mathcal{F}_s)$ be measurable spaces such that Ω_r and Ω_s each contain at least two elements, and let $(\Omega,\mathcal{F},P_{\mathbf{a}})$ be a complete probability space, where $\Omega := \Omega_r \times \Omega_s$, $\mathcal{F} := \mathcal{F}_r \otimes \mathcal{F}_s$, and $P_{\mathbf{a}}$ is a probability measure indexed by $\mathbf{a} \in \mathbf{A}$.

For each $k = 1,...,m$, let a fundamental response *$Y_{0,k} : \Omega_s \to \mathbb{S}_{0,k}$ be a measurable function and let the corresponding* fundamental setting *be $Z_{0,k} := Y_{0,k}$. Write fundamental settings and responses as $Z_0 := (Z_{0,1},...,Z_{0,m})$ and $Y_0 = Z_0$.*

Let $\Pi = \{\Pi_b\}$ be a partition of $\{1,...,n\}$, with $B := \#\Pi \in \bar{\mathbb{N}}^+$, let $\ell_b := \#\Pi_b$, and let $\mathbf{a}$ determine the multi-element Borel measurable set $\mathbb{S}^{\Pi}_{(b)}(\mathbf{a}) \subset \times_{j \notin \Pi_b} \mathbb{S}_j \times_{k=1}^{m} \mathbb{S}_{0,k}$, $b = 1,...,B$. Suppose there exist measurable functions called settings, *$Z_i^{\Pi} : \Omega_s \to \mathbb{S}_i, i = 1,\ldots,n$, measurable functions called* responses, *$Y_i^{\Pi} : \Omega \to \mathbb{S}_i, i = 1,\ldots,n$, and measurable functions called* joint response functions,

$$r^{\Pi}_{[b]}(\,\cdot\,;\mathbf{a}) : \times_{i \in \Pi_b} \mathbb{S}_i \times \mathbb{S}^{\Pi}_{(b)}(\mathbf{a}) \times \Omega_r \to \mathbb{R}^{\ell_b} \quad b = 1,...,B,$$

such that

$$r^{\Pi}_{[b]}(Y^{\Pi}_{[b]}(\omega), Z^{\Pi}_{(b)}(\omega_s), \omega_r; \mathbf{a}) = \mathbf{0}, \;\; b = 1,...,B,$$

for each $\omega := (\omega_r,\omega_s) \in \Omega_r \times \Omega^{\Pi}_{(b)}(\mathbf{a})$, $\Omega^{\Pi}_{(b)}(\mathbf{a}) := \{\omega_s : Z^{\Pi}_{(b)}(\omega_s) \in \mathbb{S}^{\Pi}_{(b)}(\mathbf{a})\}$, where $Z^{\Pi}_{(b)}$ is the vector containing $Z^{\Pi}_j, j \notin \Pi_b$ and $Y^{\Pi}_{[b]}$ is the vector containing $Y^{\Pi}_i, i \in \Pi_b$. Write

$$\mathcal{X}^{\Pi}_0(\omega;0) \;:= Y_0(\omega_s), \quad \mathcal{X}^{\Pi}_0(\omega;1) := Z_0(\omega_s),$$

$$\mathcal{X}_i^{\Pi}(\omega;0) \ := Y_i^{\Pi}(\omega), \quad \mathcal{X}_i^{\Pi}(\omega;1) := Z_i^{\Pi}(\omega_s),\ i = 1,...,n,$$

so that the fundamental settable variables $\mathcal{X}_0^{\Pi}$ *and* settable variables $\mathcal{X}_i^{\Pi}$, $i = 1,...,n$ *are mappings such that:*

$$\mathcal{X}_0^{\Pi} : \Omega \times \{0,1\} \to \times_{k=1}^{m} \mathbb{S}_{0,k} \text{ and } \mathcal{X}_i^{\Pi} : \Omega \times \{0,1\} \to \mathbb{S}_i,\ i = 1,...,n.$$

Finally, write

$$\mathcal{X}^{\Pi} := (\mathcal{X}_0^{\Pi}, \mathcal{X}_1^{\Pi},,...,\mathcal{X}_n^{\Pi}).$$

Then $\mathcal{S}^{\Pi} := \{(\mathbf{A},\mathbf{a}),(\Omega,\mathcal{F},P_{\mathbf{a}}),(\Pi,\mathcal{X}^{\Pi})\}$ *is a* stochastic settable system.

A stochastic settable system consists of *units* $i = 1,...,n$ with *unit attributes* a_i belonging to *unit attribute space* A. When $m > 0$, the system has optional *fundamental units* $k = 1,...,m$ with fundamental unit attributes $a_{0,k}$ also belonging to A. The *joint attributes* $\mathbf{a} := (a_{0,1},...,a_{0,m},a_1,...,a_n)$ belong to the *joint attribute space* $\mathbf{A}$. By construction, the unit attributes include the *admissible settings* $\mathbb{S}_i$ for each unit ($\mathbb{S}_{0,k}$ for any fundamental units). $\mathbb{S}_i$ must contain at least two values, necessary to ensuring that interventions are well defined.

The probability space $(\Omega,\mathcal{F},P_{\mathbf{a}})$ embodies the stochastic structure of the system. By representing the *primary settings* as elements $\omega := (\omega_r,\omega_s)$ of $\Omega := \Omega_r \times \Omega_s$, we provide explicit means for variation-free interventions to primary setting values ω_r and the remaining setting values (via ω_s). By "variation-free", we mean that we can consider interventions $(\omega_1,\omega_2) = ((\omega_{r,1},\omega_s),(\omega_{r,2},\omega_s))$ in which only the ω_r component differs or interventions $(\omega_1,\omega_2) = ((\omega_r,\omega_{s,1}),(\omega_r,\omega_{s,2}))$ in which only the ω_s component differs. Requiring that Ω_r and Ω_s each have at least two elements ensures that interventions to ω_r and ω_s are well defined.

The probability measure $P_{\mathbf{a}}$ is indexed by the attributes $\mathbf{a}$ and governs the joint distribution of the random settings and responses. $P_{\mathbf{a}}$ may be determined by nature, determined by a researcher, or determined in part by nature and in part by a researcher. $P_{\mathbf{a}}$ can embody any probabilistically meaningful dependence or independence for events involving ω_r and ω_s. Completeness of the probability space is a technical requirement ensuring that the collection of events $\mathcal{F}$ contains every subset of any event having $P_{\mathbf{a}}-$probability zero.

We call the random variables $Z_i^{\Pi}(\cdot)$ *settings* and realizations $Z_i^{\Pi}(\omega_s)$ *setting values*. By suitably choosing Ω_s and Z_i^{Π}, we also achieve variation-free interventions for the individual setting values. Specifically, let $\Omega_s := (\times_{k=1}^{m}\mathbb{S}_{0,k}) \times (\times_{i=1}^{n}\mathbb{S}_i)$, so that Ω_s has typical element $\omega_s := (z_{0,1},...,z_{0,m}, z_1,...,z_n)$. Further, let $Z_{0,k}(\omega_s) = z_{0,k}$ and $Z_i^{\Pi}(\omega_s) = z_i$ be the projection functions that select the specified component of ω_s. By construction, these functions are surjective (onto). That is, the range $Z_i^{\Pi}(\Omega_s)$ equals the co-domain $\mathbb{S}_i$, so that there is (at least) one ω_s corresponding to each admissible value in $\mathbb{S}_i$. With a suitable choice of $\mathcal{F}_s$ (e.g., that generated by the measurable finite dimensional product cylinders), these choices for $Z_{0,k}$ and Z_i^{Π} are also measurable, as required. (White (2001, Section 3.3) provides relevant background and discussion.) Thus, different values $\omega_{s,1}$ and $\omega_{s,2}$ can generate interventions referencing just a single settable variable, so that $Z_i^{\Pi}(\omega_{s,1}) \neq Z_i^{\Pi}(\omega_{s,2})$, but $Z_j^{\Pi}(\omega_{s,1}) = Z_j^{\Pi}(\omega_{s,2})$ for $j \neq i$. Further, when surjectivity holds, it ensures that the primary interventions $(\omega_{s,1},\omega_{s,2})$ can represent every admissible intervention to the setting values.

When the system has fundamental units, these units have *fundamental responses* $Y_{0,k}$; these are random variables whose values $Y_{0,k}(\omega_s)$ are determined solely by $\omega_s \in \Omega_s$. By convention, *fundamental settings* $Z_{0,k}$ are random variables identical to $Y_{0,k}$. When $Y_{0,k}$ is surjective, then so is $Z_{0,k}$.

Each element Π_b of the partition $\Pi = \{\Pi_b\}$ identifies a group of (non-fundamental) units. The *joint response function* $r^{\Pi}_{[b]}$ specifies how these identified units jointly and freely respond to given jointly admissible setting values of all units not belonging to Π_b.

The given values are setting values $Z^{\Pi}_j(\omega_s)$ for j not belonging to Π_b, including $Z_0(\omega_s)$ and ω_r, represented here by $(Z^{\Pi}_{(b)}(\omega_s), \omega_r)$. The values $Z^{\Pi}_{(b)}(\omega_s)$ belong to the set of *jointly admissible setting values* $\mathbb{S}^{\Pi}_{(b)}(\mathbf{a})$, a subset of $\times_{j\notin\Pi_b}\mathbb{S}_j \times^m_{k=1}\mathbb{S}_{0,k}$. In the absence of constraints, we have $\mathbb{S}^{\Pi}_{(b)}(\mathbf{a}) = \times_{j\notin\Pi_b}\mathbb{S}_j \times^m_{k=1}\mathbb{S}_{0,k}$. Often, however, applications place joint restrictions on the admissible setting values. For example, when the settings represent probabilities (as in the mixed strategy games considered shortly), the constraint that probabilities add to one jointly restricts admissible setting values. The constraints are encoded in $\mathbf{a}$, and implemented by $\mathbb{S}^{\Pi}_{(b)}(\mathbf{a})$.

The *response values* are $Y^{\Pi}_{[b]}(\omega)$, the vector containing unit i's response value $Y^{\Pi}_i(\omega)$ for each i in Π_b, satisfying

$$r^{\Pi}_{[b]}(Y^{\Pi}_{[b]}(\omega), Z^{\Pi}_{(b)}(\omega_s), \omega_r; \mathbf{a}) = \mathbf{0}. \tag{10}$$

Note that we do not explicitly require that $Y^{\Pi}_{[b]}(\omega)$ is the unique solution to the equations in (10). As discussed in our machine learning examples, the governing principles of the system (e.g., optimization and/or equilibrium) operate to deliver a selected system response satisfying these equations. By including the governing principles (including appropriate selection operators) among the attributes $\mathbf{a}$, as is fully rigorous and proper, the presence of $\mathbf{a}$ in the response function can ensure a unique response value. Note that the response function depends on the full system attribute vector $\mathbf{a}$, not just the attributes associated with the units of the given block b. This has been a common feature of our examples. We call the random variables $Y^{\Pi}_i(\cdot)$ *responses*.

Our expression for the responses is in implicit form, as is appropriate for solutions of optimization problems. Nevertheless, it is often convenient to abuse notation somewhat and write response values explicitly as

$$Y^{\Pi}_{[b]}(\omega) = r^{\Pi}_{[b]}(Z^{\Pi}_{(b)}(\omega_s), \omega_r; \mathbf{a}).$$

Because the partition is exhaustive, the collection of response functions $r^{\Pi} := (r^{\Pi}_{[1]}, ..., r^{\Pi}_{[B]})$ provides a description of how each unit in the system responds when it is free to do so in the company of other specified freely responding units. In given circumstances, it may be that only one of these sets of responses is factual; the others are then counterfactual.

Settable variables $\mathcal{X}^{\Pi}_i : \Omega \times \{0,1\} \to \mathbb{S}_i$ embody the dual aspects of settings and responses. Responses $\mathcal{X}^{\Pi}_i(\,\cdot\,,0) := Y^{\Pi}_i$ are random variables taking values in $\mathbb{S}_i$ in response to settings of other settable variables of the system outside the block to which i belongs, say Π_b. The settings $\mathcal{X}^{\Pi}_i(\,\cdot\,,1) := Z^{\Pi}_i$ are random variables taking values in $\mathbb{S}_i$ whose realized values determine the realized responses of other settable variables. The optional fundamental settable variables $\mathcal{X}^{\Pi}_0 : \Omega \times \{0,1\} \to \times^m_{k=1}\mathbb{S}_{0,k}$ yield identical random responses and settings whose values drive responses of other settable variables. We collect together all settable variables of the system by writing $\mathcal{X}^{\Pi} := (\mathcal{X}^{\Pi}_{0,1}, ..., \mathcal{X}^{\Pi}_{0,m}, \mathcal{X}^{\Pi}_1, ..., \mathcal{X}^{\Pi}_n)$. Observe that $\mathcal{X}^{\Pi}$ actually depends on $\mathbf{a}$ through the response functions r^{Π}, so it would be formally correct and more explicit to write $\mathcal{X}^{\Pi}_{\mathbf{a}}$ instead of $\mathcal{X}^{\Pi}$. We forego this for notational simplicity, but this dependence should not be overlooked.

Our notation for the stochastic settable system, $\mathcal{S}^{\Pi} := \{(\mathbf{A}, \mathbf{a}), (\Omega, \mathcal{F}, P_{\mathbf{a}}), (\Pi, \mathcal{X}^{\Pi})\}$, references each component of the system in a way that expresses the hierarchy of these components. At the lowest level is the *attribute structure*, $(\mathbf{A}, \mathbf{a})$; next comes the *stochastic structure*, $(\Omega, \mathcal{F}, P_{\mathbf{a}})$; resting on these is the *causal structure*, $(\Pi, \mathcal{X}^{\Pi})$.

6. Game Theory, Settable Systems, and the PCM

So far, our machine learning examples have shown how settable systems apply to decision problems where optimization operates as a governing principle. We now discuss examples showing how settable systems apply to groups of interacting and strategically competitive decision-making agents. In economics, these agents are usually viewed as consumers, firms, and/or government entities. Of direct relevance to machine learning is that agents may also be artificial intelligences, as in automated trading systems. In addition to their empirical relevance (e.g., the analysis of FCC spectrum auctions or U.S. Treasury Bill auctions), such environments present the opportunity for emergent and distributed computation of otherwise difficult to compute quantities, like prices.

Game theory, the study of multi-agent decision problems, provides a rich formal framework in which to understand and explain the behavior of interacting decision makers. Gibbons (1992) provides an excellent introduction. By showing how the structures of game theory map to settable systems, we establish the foundations for causal analysis of such systems. A central feature of such structures is that their outcomes are determined by suitable equilibrium mechanisms, specifically *Nash equilibrium* and its refinements. Among other things, these mechanisms play a key role in ensuring the mutual consistency of various partitions relevant to the analysis of a given game.

6.1 Pure-Strategy Games and Pure-Strategy Nash Equilibria

The simplest games are static games of complete information (Gibbons, 1992, Chap. 1). In these games, each of n players has: (i) a number of playable strategies (let player i have K_i playable strategies, $s_{i,1},...,s_{i,K_i}$); and (ii) a utility (or "payoff") function u_i that describes the payoff π_i to that player when each player plays one of their given strategies. That is, $\pi_i = u_i(s_1,...,s_n)$, where $s_j \in S_j := \{s_{j,1},...,s_{j,K_j}\}$, $j = 1,...,n$. The players simultaneously choose their strategies; then each receives the payoff specified by the collection of the jointly chosen strategies and the players' payoff functions. Such games are "static" because of the simultaneity of choice. They are "complete information" games because the players' possible strategies and payoff functions are known to all players. (Thus, each player can assess the game from every other player's viewpoint.) An n-player static game of complete information is formally represented in "normal form" as $\mathcal{G} = \{S_1,...,S_n; u_1,...,u_n\}$.

These games map directly and explicitly to the settable system framework. Specifically, the players correspond to units $i = 1,...,n$. The unit attributes a_i include the identity attribute i, the strategies $\mathbb{S}_i = S_i$ available to player i, and the player's utility function $u_i : S_1 \times ... \times S_n \to \mathbb{R}$. When a strategy for player i is set arbitrarily, we denote its value as $z_i \in S_i$; when player i chooses a strategy (a response) we represent its value as $y_i \in S_i$. For concreteness and without loss of generality, we take $S_i := \{1,...,K_i\}$. The players' utility functions implicitly account for the possibility that strategy 1 for player i may represent a different action than that of strategy 1 for player j.

Each player seeks to maximize their payoff given the strategies of the others, so that

$$y_i = r_i^e(z_{(i)};\mathbf{a}) = \arg\max_{z_i \in S_i} u_i(z_1,...,z_n).$$

In economics, this goal-seeking behavior is called "rationality;" an equally fitting (or perhaps superior) term is "intelligence." Thus, game theory analyzes rational or intelligent agents.

Here, we write the responses r_i^e using the superscript e to denote that these response are those for the elementary partition, $\Pi^e := \{\Pi_1^e,...,\Pi_n^e\}$ with $\Pi_i^e = \{i\}$, as each response takes the strategies of all other players as fixed.

For convenience, we assume that for each player there is a unique utility-maximizing response, but just as in our previous machine learning examples, we can generally make a principled selection when the optimal decision is a set. Below, we discuss this further.

In game theory, r_i^e is called a "best-response" function. In settable systems, we refer generically to functions like r_i^e as "response" functions, in part motivated by this usage. Because in game theory the specific game $\mathcal{G}$ under consideration is almost always clear, there is usually no need to explicitly reflect its elements in the players' best response functions. The explicit appearance of players' joint attributes $\mathbf{a}$ (which characterize the game) in the response functions $r_i^e(\,\cdot\,;\mathbf{a})$ emphasizes their role in determining player responses.

Now consider the PCM representation of this game. In the PCM, the attributes become background variables u. The attributes $a_i = (i, S_i, u_i)$ do not map directly to PCM background variables, as S_i is a set and u_i is a function; the PCM requires the background variables to be real numbers. Nevertheless, some simple modifications deliver a conforming representation: we can replace S_i with the integers 1 through K_i and u_i with the vector of values taken by $\pi_i = u_i(s_1,...,s_n)$ as the strategies range over all possible values. We collect these values together across all players and write them as u. Endogenous variables $v = \{s_1,...,s_n\}$ represent player strategies, and the structural functions $f = \{f_1,...,f_n\}$ represent the best response for agent i as $s_i = f_i(s_{(i)}, u), \quad i = 1,...,n$.

The final condition required by the PCM is that there exists a unique fixed point, defined by functions g_i such that $s_i = s_i^* := g_i(u), i = 1,...,n$. When such a unique fixed point exists, it represents a *pure-strategy Nash equilibrium* (Nash, 1950). By definition this satisfies

$$u_i(s_1^*,...,s_i^*,...,s_n^*) \geq u_i(s_1^*,...,s_i,...,s_n^*) \;\; for\ all\ s_i \in S_i, i = 1,...,n.$$

Gibbons (1992, p. 8) provides further discussion of pure-strategy Nash equilibrium.

Just as we saw in Section 3, the PCM faces difficulties arising from its requirement of a unique fixed point. A first difficulty for the PCM is that there are important games for which a pure-strategy Nash equilibrium does not exist; the PCM therefore has nothing to say about such games. A leading example of such games is known as *matching pennies* (Gibbons, 1992, p. 29). In this game, each of two players has a penny that they can choose to display face up (heads) or face down (tails). If the pennies match, player 2 gets both; otherwise player 1 gets both. This game applies to any situation in which one player would like to outguess the other, as in *poker* (bluffing), *baseball* (pitcher vs. hitter), and *battle*.

Given the interest attaching to such games, one would like to have an applicable causal model. This need is met by the settable system framework. Because this framework imposes no fixed point requirement, it applies regardless of the existence of a unique pure-strategy Nash equilibrium. For games with no pure-strategy Nash equilibrium, the response functions $r_i^e(z_{(i)};\mathbf{a})$ of the elementary partition $\Pi^e := \{\{1\},...,\{n\}\}$ readily provide complete information about the best response for all counterfactual strategy combinations of the other players.

If a unique pure-strategy Nash equilibrium exists, it has settable system representation

$$s_i^* = r_i^g(\mathbf{a}), \quad i = 1,...,n,$$

where r_i^g is the response function for the global partition, $\Pi^g := \{\{1,...,n\}\}$. An interesting feature of these response functions is that they depend only on the attributes $\mathbf{a}$; no fundamental or even primary settings appear. Observe also that the Nash equilibrium condition ensures the mutual consistency of the elementary and global partitions.

When there is no pure strategy Nash equilibrium, as in the matching pennies game, there need not exist a valid settable system for the global partition. This provides an interesting example in which we have a well-defined settable system for the elementary partition, but not for the global partition. In contrast, the PCM does not apply at all.

Another difficulty for the PCM is that the unique fixed point requirement prevents it from applying to games with multiple pure-strategy Nash equilibria. An example is the game known as *battle of the sexes* (Gibbons, 1992, p. 11). In this game, two players (Ralph and Alice) are trying to decide on what to do on their next night out: attend a boxing match or attend an opera. Each would rather spend the evening together than apart, but Ralph prefers boxing and Alice prefers the opera. With the payoffs suitably arranged (symmetric), there is a unique best response for each player, given the strategy of the other. Nevertheless, this game has two pure-strategy Nash equilibria: (i) both select boxing; (ii) both select the opera. Thus, the PCM does not apply.

In contrast, the settable system framework does apply, as it does not impose a unique fixed point requirement. The elementary partition describes each agent's unique best response to a given strategy of the other. Further, when multiple Nash equilibria exist, the global partition can yield a well-defined settable system by selecting one of the possible equilibria. As Gibbons (1992, p. 12) notes, "In some games with multiple Nash equilibria one equilibrium stands out as the compelling solution to the game," leading to the development of "conventions" that provide standard means for selecting a unique equilibrium from the available possibilities.

An example is the classic *coordination game*, in which there are two pure-strategy Nash equilibria, but one yields greater payoffs to both players. The convention is to select the higher payoff equilibrium. If such a convention exists, the global partition can specify the response functions r_i^g to deliver this. In such cases, the global partition responses satisfy not only a fixed-point property, but also embody equilibrium selection.

Interestingly, battle of the sexes is not a game with such a convention, as both equilibria seem equally compelling. A more elaborate version of this game, involving incomplete information, does possess a unique equilibrium, however (Gibbons, 1992, pp. 152-154).

6.2 Mixed-Strategy Games and Mixed-Strategy Nash Equilibria

As just suggested, one can modify the character of a game's equilibrium set by elaborating the game. Specifically, consider "mixed-strategy" static games of complete information. Instead of optimally choosing a pure strategy, each player h now chooses a vector of probabilities $p_h := (p_{h,1}, ..., p_{h,K_h})$ (a mixed strategy) over their available pure strategies, say $S_h := \{1, ..., K_h\}$, so that $p_{h,j}$ is the probability that player h plays strategy $j \in S_h$. For example, the probability vector $(1, 0..., 0)$ for player h represents playing the pure strategy $s_h = 1$.

Note that we have modified the notation for the player index from i to h. This enables us to continue to index units using i. Here, the units i correspond to *agent-decision pairs* (h, j). The values h and j become part of the unit attributes, a_i. When referencing i, we may for convenience reference the corresponding h, j, so, for example, we may write a_i or $a_{h,j}$, whichever is more convenient.

Each player h now behaves rationally or intelligently by choosing mixed-strategy probabilities to maximize their expected payoff given other players' strategies,

$$\bar{\pi}_h = \upsilon_h(p^n) := \sum_{s^n \in S^n} u_h(s^n) \Pr(s^n; p^n),$$

where for conciseness we now write $s^n := (s_1, ..., s_n)$, $S^n := S_1 \times ... \times S_n$, and $p^n := (p_1, ..., p_n)$. (Maximizing expected payoff is not the only possibility, but we focus on this case for concreteness.) The strategies are chosen independently, so that $\Pr(s^n; p^n)$, the probability that the agents jointly choose the configuration of strategies s^n, is given by $\Pr(s^n; p^n) = \prod_{h=1}^{n} p_{h,s_h}$.

It is a famous theorem of Nash (1950) that if n is finite and if K_h is finite, $h = 1, ..., n$, then there must exist at least one Nash equilibrium for $\mathcal{G}$, possibly involving mixed strategies (e.g., Gibbons, 1992, p. 45).

We map mixed-strategy games to settable systems as follows. As mentioned above, units i are agent-decision pairs (h, j), so that unit attributes a_i include the agent and decision designators, h and j. Because settings and responses are now probabilities, unit attributes also specify admissible settings $\mathbb{S}_{h,j}$ as a subset of $[0, 1]$. We further discuss $a_{h,j}$ below.

For each agent h, there is a $K_h \times 1$ vector of settings and responses. We denote the probabilities of the mixed strategy for agent h as $z_{h,j}, j = 1, ..., K_h$, when these are set, and as $y_{h,j}, j = 1, ..., K_h$, when these constitute the agent's best response. Let z_h be the $K_h \times 1$ vector with elements $z_{h,j}$, and let y_h be the $K_h \times 1$ vector with elements $y_{h,j}$. Given all other player's mixed strategies $z_{(h)}$, agent h's best response is

$$y_h = r_h^a(z_{(h)}; \mathbf{a}) = \sigma_h(\arg\max_{z_h \in \mathbf{S}_h} \upsilon_h(z_1, ..., z_n)),$$

where the maximization is taken over the simplex $\mathbf{S}_h := \{z \in [0, 1]^{K_h} : \sum_{j=1}^{K_h} z_j = 1\}$. The operator σ_h performs a measurable selection, discussed below.

Several aspects of this representation are notable. First, we write the response function r_h^a to denote that it is the response function for the *agent partition* $\Pi^a := \{\Pi_h^a, h = 1, ..., n\}$, where $\Pi_h^a = \{(h, 1), ..., (h, K_h)\}$. In contrast, the elementary partition is $\Pi^e := \{\Pi_{h,j}^e, j = 1, ..., K_h; h = 1, ..., n\}$, with $\Pi_{h,j}^e := \{(h, j)\}$. The response functions $r_{h,j}^e$ for the elementary partition describe the best response for agent h's strategy j given not only all other agents' strategies, but also all other strategies for agent h. The elementary partition is usually not of particular interest; the agent partition and the global partition are typically the main objects of interest in this context.

The superscript ^{a} in r_h^a and elsewhere to denote the agent partition creates no confusion with the joint attributes $\mathbf{a}$, as the former is always a superscript, and the latter never is.

Next, we note that the unit attributes $a_{h,j}$ contain admissible values $\mathbb{S}_{h,j} \subset [0, 1]$, so that $0 \leq z_{h,j} \leq 1$. This is not enough to fully specify the admissible values for the vector z_h, however, as the probabilities must add up to 1. This means that z_h must belong to the simplex $\mathbf{S}_h$. We enforce this constraint by making $\mathbf{S}_h$ a component of each unit attribute $a_{h,j}, j = 1, ..., K_h$. Just as an attribute common to all system units is a system attribute, any attribute common to a given subset of units is an attribute of that subset. Thus, $\mathbf{S}_h$ is an attribute of agent h; agent h is that subset of the units with agent designator equal to h.

An interesting feature of mixed-strategy games is that the set $\arg\max_{z_h \in \mathbf{S}_h} \upsilon_h(z_1, ..., z_n)$ can easily fail to have a unique element. This set thus defines the player's best-response correspondence, rather than simply giving a best-response function. We obtain a best-response function by applying a measurable selection operator σ_h to the set of maximizers. The operator σ_h is an attribute, specifically of agent h; thus, we include it as a component of the unit attributes $a_{h,j}, j = 1, ..., K_h$.

By definition, the agent is indifferent between elements of the arg-max set; the choice of selection operator is not crucial. In fact, the selection may be random, implemented by letting σ_h depend

on $\omega_r \in \Omega_r$, so that one has

$$y_h = r_h^a(z_{(h)}, \omega_r; \mathbf{a}) = \sigma_h(\arg\max_{z_h \in \mathbf{S}_h} \upsilon_h(z_1, ..., z_n), \omega_r).$$

Now consider how this game maps to the PCM. Again, the attributes map to the background variables u, although now the attributes are, among other things, sets with a continuum of values and correspondences. Mapping these to a vector of real numbers is problematic, so we simply view u as a general vector whose elements may be numbers, sets, functions, or correspondences. The endogenous variables are most appropriately represented as $K_h \times 1$ vectors p_h such that $v = \{p_1, ..., p_n\}$. The elements of $f := \{f_1, ..., f_n\}$ are correspondingly vector-valued. These must satisfy $p_h = f_h(p_{(h)}, u) := \sigma_h(\arg\max_{p_h \in \mathbf{S}_h} \upsilon_h(p_1, ..., p_n))$.

In order to apply the PCM, we require a unique fixed point. Even when a unique Nash equilibrium exists, to obtain this as the fixed point requires choosing the selection operators σ_h so that they specifically produce the Nash equilibrium response. In the usual situation, the properties of f determine whether or not a fixed point exists. Here, however, knowledge of the unique fixed point is required to properly specify σ_h, hence f_h, an awkward reversal signaling that the PCM is not well-suited to this application. Indeed, the selection cannot be random, a plausible response when the player is indifferent between different strategies.

An interesting feature of this example is that when the PCM applies, it does so with vector-valued units rather than the scalar-valued units formally treated by Pearl (2000) or Halpern (2000). The PCM is thus necessarily silent about what happens when components of an agent's strategy are arbitrarily set. In contrast, settable systems apply to partitions both finer and coarser than the agent partition. (The elements (sets of unit indexes) of a "coarser" partition are unions of the elements of a "finer" partition. Thus, the agent partition is coarser than the elementary partition and finer than the global partition.)

Unlike the case of pure-strategy games, there must always be at least one mixed-strategy Nash equilibrium, so the PCM does not run into the difficulty that there may be no equilibrium. Nevertheless, mixed-strategy games can also have multiple Nash equilibria, so the PCM does not apply there. For a given game, the GPCM does apply to the agent partition, but it does not incorporate equilibrium selection mechanisms. In contrast, the settable system framework permits causal analysis at the level of the agent partition (as well as coarser or finer partitions); represents the unique Nash equilibrium at the level of the global partition without requiring a selection operator when a unique equilibrium exists; and otherwise represents the desired responses when a unique mixed-strategy Nash equilibrium does not exist but conventions or other plausible selection mechanisms apply.

Static games of complete information are the beginning of a sequence of increasingly richer games, including dynamic games of complete information, static games of incomplete information, and dynamic games of incomplete information. Each of these games employs progressively stronger equilibrium concepts that rule out implausible equilibria that would survive under equilibrium concepts suitable for simpler games (Gibbons, 1992, p. 173). These implausible equilibria all satisfy fixed-point (simple Nash equilibrium) requirements.

The unique fixed point requirement of the PCM thus acts to severely limit its applicability in game theory, due to the many opportunities for multiple Nash equilibria. Although GPCMs formally apply, they cannot support discourse about causal relations between endogenous variables, due to the lack of an analog of the potential response function. In contrast, by exploiting attributes and partitioning, settable systems permit implementation of whichever stronger and/or more re-

fined equilibria criteria are natural for a given game, together with any natural equilibrium selection mechanism.

6.3 Infinitely Repeated Dynamic Games

Dynamic games are played sequentially. For example, two players can repeatedly play *prisoner's dilemma*. In infinitely repeated games, play proceeds indefinitely. Clearly, infinite repetition cannot be handled in a finite system, so the PCM cannot apply.

In infinitely repeated dynamic games of complete and perfect information (see Gibbons, 1992, Section 2.3.B), players play a given static game in "stages" or periods $t = 1, 2, ...$ The period t payoff to player h is $\pi_{h,t} = u_{h,t}(\alpha_{1,t}, ..., \alpha_{n,t})$, where $u_{h,t}$ is player h's payoff function for period t, whose arguments are the "actions" $\alpha_{j,t}$ at time t of all n players. (The strategies of static games correspond to the actions of dynamic games.) Information is "complete," as each player knows the others' possible actions and payoff functions. Information is "perfect," as at every t, each player knows the entire history of play up to that period.

Rational players act to maximize their average present discounted value of payoff,

$$\bar{\pi}_h = \bar{u}_h(\alpha_1, ..., \alpha_n) := (1-\delta)\sum_{t=1}^{\infty} \delta^{t-1} u_{h,t}(\alpha_{1,t}, ..., \alpha_{n,t}),$$

where $\alpha_j := \{\alpha_{j,t}\}$ denotes player j's countable sequence of actions, and $0 < \delta < 1$ is a "discount rate" (common across players, for simplicity) that converts payoffs $\pi_{h,t}$ in period t to a value in period 1 as $\delta^{t-1}\pi_{h,t}$. A player's best response to any collective sequence of actions by the others is a solution to the problem

$$\max_{s_h \in S_h} \bar{u}_h(\alpha_1, ..., \alpha_n) \;\; subject\ to \;\; \alpha_{h,t} = s_{h,t}(\alpha_1^{t-1}, ..., \alpha_n^{t-1}), \;\; t = 1, 2, ...,$$

where S_h is player h's set of all admissible sequences $s_h := \{s_{h,t}\}$ of "strategy functions" $s_{h,t}$. These represent player h's action in period t as a function only of the prior histories of player actions, $\alpha_1^{t-1}, ..., \alpha_n^{t-1}$. (For $t = 1$, $s_{h,t}$ is a constant function.) Player h's best responses are $\alpha_{h,t}^* = s_{h,t}^*(\alpha_1^{t-1}, ..., \alpha_h^{*t-1}, ..., \alpha_n^{t-1})$, $t = 1, 2, ...$, where $s_h^* := \{s_{h,t}^*\}$ is a sequence of best response strategy functions. (These need not be unique, so $s_{h,t}^*$ may be a correspondence. The player is indifferent among the different possibilities.)

Such games generally have multiple Nash equilibria. Many of these are implausible, however, as they involve non-credible threats; and credibility is central to all dynamic games (see Gibbons, 1992, p. 55). Non-credible equilibria can be eliminated by retaining only "subgame perfect" Nash equilibria. These are Nash equilibria that solve not only the game beginning at time 1, but also the same game beginning at any time $t > 1$ (Gibbons, 1992, pp. 94-95). A celebrated result by James Friedman (1971) ensures the existence of one or more subgame perfect Nash equilibria, provided δ is close enough to one (see, e.g.. Gibbons, 1992, pp. 97-102). Significantly, such equilibria permit *tacit cooperation*, yielding outcomes superior to what players can achieve in the static game played at each stage.

We now map this game to settable systems. The units i now correspond to *agent-time pairs* (h,t). As $t = 1, 2, ...$, there is a countable infinity of units. Agent attributes include their admissible actions and their payoff functions for each period. That is, a_i (equivalently $a_{h,t}$) includes the admissible sequence of functions S_h, the utility function $u_{h,t}$, and the discount factor δ. When player actions

$\alpha_{h,t}$ are set arbitrarily, the settable system represents them as $z_{h,t}$. When players intelligently choose their actions, they are denoted $y_{h,t}$.

The agent partition $\Pi^a := \{\Pi^a_h, h = 1,...,n\}$, where $\Pi^a_h := \{(h,1),(h,2),...\}$, represents agents' best responses recursively as

$$y_{h,t} = \sigma_{h,t}(s^*_{h,t}(z_1^{t-1},...,y_h^{t-1},...,z_n^{t-1}),\omega_r), \;\; t = 1,2,...;h = 1,...,n,$$

where $\sigma_{h,t}$ is a measurable selection operator; $s^*_{h,t}$ is the agent's best response correspondence, which depends on the action histories of other agents, $z^{t-1}_{(h)}$, and agent h's history of prior best responses, y_h^{t-1}; and the realization ω_r determines random selections from the best response correspondence for agent h in period t. Recursive substitution for the elements of the history y_h^{t-1} yields a representation in terms of an agent-partition response function, $r^a_{h,t}$, namely

$$y_{h,t} = r^a_{h,t}(z^{t-1}_{(h)},\omega_r;\mathbf{a}), \;\; t = 1,2,...;h = 1,...,n.$$

The global partition represents whatever selection of the collection of subgame perfect Nash equilibria is natural or compelling. Equilibrium agent responses are given by the global-partition response functions $r^g_{h,t}$ as

$$y_{h,t} = r^g_{h,t}(\omega_r;\mathbf{a}) \quad t = 1,2,...;h = 1,...,n.$$

Notably, this example exploits each feature of stochastic settable systems, including countable dimension, attributes, partitioning, and pure randomness.

6.4 Settable Systems and Multi-Agent Influence Diagrams

Causal models other than the PCM are available in the machine learning literature. We focus here on the PCM because of its prevalence and to maintain a sharp focus for this paper.

A framework particularly related to the preceding discussion is that of Koller and Milch (2003) (KM), who introduce multi-agent influence diagrams (MAIDs) to represent noncooperative games. In particular, KM provide a graphical criterion for determining a notion of "strategic relevance." KM's "relevance graphs" are related to causal graphs. By casting games in the settable system framework, we can immediately construct causal graphs for games by applying the conventions of Section 3.6.2.

The most immediate similarity between settable systems and MAIDs is that they are both capable of modeling environments in which multiple agents interact. In contrast, "influence diagrams [...] have been investigated almost entirely in a single-agent setting" (KM, 2003, p. 189-190). Nevertheless, several features of settable systems distinguish them from MAIDs:

(i) A settable system is an explicit causal framework in which notions of partitioning, settings, interventions, responses, and causality are formally defined. Furthermore, the interrelations between these causal notions on the one hand and the notions of optimization, equilibrium, and learning on the other are made precise. In contrast, there is no formal mention of causality in KM.

(ii) MAIDs build on the "chain rule for Bayesian Networks" (KM, definition 2.2, p. 186). This is equivalent to assuming a set of (conditional) independence relations involving chance and decision variables and is necessary for the applicability of the "s-reachability" graphical criterion. On the other hand, settable systems permit but do not require any assumptions on the joint distribution of

settings and responses. In particular, responses may admit an aspect of "pure randomness" due to their direct dependence on the primary variable.

(*iii*) In KM, an agent's utility is additive (KM, p. 189-190). Settable systems do not impose this requirement.

(*iv*) The KM algorithm for finding Nash equilibria outputs one Nash equilibrium. It selects an equilibrium arbitrarily if multiple equilibria are found. Further, the algorithm cannot produce certain equilibria, such as a nonsubgame-perfect equilibrium (KM, p. 216). The settable system framework can represent principled selections from all relevant Nash equilibria.

We emphasize that the results in KM are very helpful for representing and studying games. In particular, under the MAID assumptions, the KM results permit an explicit representation of games and can lead to computational savings.

7. Machine Learning, Optimization, and Equilibrium

A general learning algorithm introduced by Kushner and Clark (1978) (KC) has the form

$$\hat{\theta}_{t+1} = \hat{\theta}_t + \lambda_t M_t(\hat{\xi}_t, \hat{\theta}_t, \zeta_{t+1}), \tag{11}$$

$$\hat{\xi}_{t+1} = R_t(\hat{\xi}^t, \hat{\theta}^{t+1}, \zeta_{t+1}), \quad t = 0, 1, 2, ..., \tag{12}$$

where $\hat{\theta}_t$ and $\hat{\xi}_t$ are random vectors, λ_t is a random scalar, M_t and R_t are known vector functions, $\hat{\xi}^t := (\hat{\xi}_0, ..., \hat{\xi}_t)$, $\hat{\theta}^{t+1} := (\hat{\theta}_0, ..., \hat{\theta}_{t+1})$, and ζ_t is an observable random vector. Initial values $\hat{\xi}_0$ and $\hat{\theta}_0$ are random vectors independent of $\{\zeta_t\}$. KC call this a Robbins and Monro (1951) (RM) algorithm with feedback (RMF). Equation (11) is an RM procedure; Equation (12) supplies the feedback. A main focus of interest is the convergence behavior of $\hat{\theta}_t$ as $t \to \infty$.

Chen and White (1998) analyze a version of RMF where each vector takes values in a real separable infinite-dimensional Hilbert space. We call this an HRMF algorithm. Because of the flexibility this affords, the HRMF supports nonparametric learning.

The RM procedure emerges when $\hat{\xi}_t$ has dimension zero, so $\hat{\theta}_{t+1} = \hat{\theta}_t + \lambda_t M_t(\hat{\theta}_t, \zeta_{t+1})$, $t = 0, 1, 2, ...$ This contains recursive least squares (e.g., back-propagation), recursive maximum likelihood, and recursive method of moments procedures (e.g., Ljung and Soderstrom, 1983). The estimated weights are $\hat{\theta}_t$; $\{\zeta_t\}$ is the data sequence; λ_t is the "learning rate," for example, $\lambda_t = 1/t$; and M_t determines the learning method (least squares, maximum likelihood, etc.). By permitting feedback, the RMF accommodates the evolution of internal, possibly hidden states $\hat{\xi}_t$; thus, Kalman filter methods (Kalman, 1960) are a special case.

The RMF also describes learning in recurrent artificial neural networks (ANNs) (e.g., Elman, 1990; Jordan, 1992; Kuan, Hornik, and White, 1994). Here, the input sequence is $\{\zeta_t\}$; after t input observations, network weights are $\hat{\theta}_t$, and hidden unit activations are $\hat{\xi}_t$. The learning function is M_t, the learning rate is λ_t, and R_t determines hidden unit activations. The allowed randomness of λ_t accommodates simulated annealing.

The RMF and HRMF contain systems with learning by one or more optimizing agents. When there are multiple agents, the system can embody convergence to equilibrium. Specifically, Chen and White (1998) provide conditions ensuring system convergence as $t \to \infty$ to Nash equilibria or to "rational expectations" equilibria. As examples, Chen and White (1998) consider, among others, a learning agent solving a *stochastic dynamic programming* problem and the game of *fictitious play with continuum strategies* (an infinitely repeated dynamic game of incomplete information). The applications of the (H)RMF are thus broad; further, the settable systems framework contains both.

The units i are *time-agent-generalized decision triples*, (t,h,j). Specifically, at time t, agent h has generalized decisions indexed by j. Generalized decisions are *knowledge* (or in Bayesian frameworks, *beliefs*) denoted $\hat{\theta}_{t,h,k}$, $k = 1,...,k_h$, or *generalized actions*, denoted $\hat{\xi}_{t,h,\ell}$, $\ell = 1,...,\ell_h$. Generalized actions may be *actions* (as in Section 6.3) or *states*, as in the Kalman filtering and recurrent ANN examples. We write $\hat{\theta}_t := (\hat{\theta}'_{t,1},...,\hat{\theta}'_{t,n})'$, where $\hat{\theta}_{t,h} := (\hat{\theta}_{t,h,1},...,\hat{\theta}_{t,h,k_h})'$ takes values in Θ_h, a subset of $\mathbb{R}^{k_h}$, and $\hat{\xi}_t := (\hat{\xi}'_{t,1},...,\hat{\xi}'_{t,n})'$, where $\hat{\xi}_{t,h} := (\hat{\xi}_{t,h,1},...,\hat{\xi}_{t,h,\ell_h})'$ takes values in Ξ_h, a subset of $\mathbb{R}^{\ell_h}$, $h = 1,...,n$.

In addition to the time-agent-generalized decision indicators (t,h,j), attributes $a_{t,h,j}$ include as components the spaces Θ_h and Ξ_h and the function $\lambda_t : \Omega_r \to \mathbb{R}$. They can also include the functions $M_{t,h,k}$ or $R_{t,h,\ell}$, as appropriate. We write $M_t := (M'_{t,1},...,M'_{t,n})'$, with $M_{t,h} := (M_{t,h,1},...,M_{t,h,k_h})'$, and $R_t := (R'_{t,1},...,R'_{t,n})'$, with $R_{t,h} := (R_{t,h,1},...,R_{t,h,\ell_h})'$. The functions $M_{t,h,k}$ may be a consequence of an underlying optimization principle, as in our machine learning examples of Section 3. The same may be true of the functions $R_{t,h,\ell}$.

For the RMF, in Equations (11) and (12), n is finite, as are k_h and ℓ_h. Because t takes a countable infinity of values, we require a countably infinite settable system. For the HRMF, n may be countably infinite; similarly, k_h and/or ℓ_h may be countably infinite.

Equations (11) and (12) form a recursive or acyclic system. In such systems, there is a natural hierarchy of units, in which *predecessor* units drive *successor* units. The system evolves naturally (i.e., without intervention) when the response values at a given level of the hierarchy act as setting values for successors. Stochastic settable systems are sufficiently flexible to permit this. That is, given recursivity, for every ω_r in Ω_r, there exists ω_s in Ω_s such that $Z_i(\omega_s) = Y_i(\omega_r,\omega_s)$ for all i. When $\omega = (\omega_r,\omega_s)$ has this property, we call ω *canonical*, and we let $\Omega_c \subset \Omega$ denote the set of canonical primary settings ω. Response and setting values for a given unit thus coincide on Ω_c, implementing the natural evolution. In the present example, $Y_{t,h,j}$ and $Z_{t,h,j}$ correspond to an element of either $\hat{\theta}_t$ or $\hat{\xi}_t$. Fundamental settings are $\hat{\xi}_0, \hat{\theta}_0$, and $\{\zeta_t\}$, corresponding to elements of $\mathcal{X}_0(\,\cdot\,,1) := \mathcal{X}_0(\,\cdot\,,0)$.

Substituting Equation (11) into Equation (12) yields response functions for the *time partition*, $\Pi^t := \{\Pi^t_1,\Pi^t_2,...\}$, where $\Pi^t_b := \{(b,h,k), k = 1,...,k_h; (b,h,\ell), \ell = 1,...,\ell_h; h = 1,...,n\}$.

In the HRMF, agents' generalized decisions take values in real separable infinite-dimensional Hilbert spaces, so generalized decisions are not just vector-valued; their values may be suitably well-behaved functions. First, consider how a countably dimensioned settable system accommodates such objects when there is a single agent with a single action, a function, and a single knowledge element, also a function. We represent such functions by a countable vector whose elements are coefficients of terms in a suitable series representation, for example, a Fourier series. Further, this same approach applies without exhausting the dimensionality of the settable system, even when there is a countable infinity of agents, each having a countable infinity of knowledge elements and actions, which are themselves elements of real separable infinite-dimensional Hilbert spaces.

8. Summary and Concluding Remarks

This paper introduces settable systems, an extension of Pearl's (2000) causal model. Settable systems and the PCM share many common features. For example, in both frameworks the variables of the system have a dual role (set or free), there are mechanisms for specifying which variables are set or free (submodels and the do operator in the PCM, partitioning in settable systems), and attributes

may be accommodated (as background variables in the PCM and as a priori constants in settable systems).

The key difference between the PCM and settable systems is the way these common features interrelate to one another. Although we point out a number of limitations of the PCM in motivating settable systems, settable systems strictly build on the percepts of the PCM. Our intent is to show how modest reconfiguration and refinement of the elements of the PCM considerably enhance its explanatory power.

As we demonstrate, the PCM encounters obstacles when we attempt to apply it to certain machine learning examples. These limitations motivate particular features of settable systems. For example, the unique fixed point requirement of the PCM is a significant limitation. Like Halpern's (2000) GPCM, settable systems do not require the existence of a unique fixed point. The structure of settable systems nevertheless leads to natural notions of counterfactuals, interventions, direct causes, direct effects, and total effects. In contrast, the absence of the potential response function in the GPCM precludes causal discourse.

Another appealing feature of settable systems relative to the PCM is its ability to provide a causal role for structurally exogenous variables. This capability arises because settable systems distinguish between attributes and fundamental settings. In contrast, the PCM lumps together attributes and background variables, so neither can play a causal role. The PCM is silent on whether to treat variables as exogenous or endogenous and on how to specify attributes. In settable systems, the governing principles (e.g., optimization and equilibrium) provide explicit guidance for distinguishing exogenous variables and endogenous variables. Attributes are unambiguously defined as constants (numbers, functions, sets, etc.) associated with system units that define fundamental aspects of the decision problem represented by the settable system.

Our examples in game theory (Section 6) and machine learning with feedback (Section 7) further show that settable systems apply directly to systems where learning and/or optimizing agents interact in a process where outcomes satisfy or converge to appropriate equilibria. Settable systems thus provide rigorous foundations for causal analysis in these empirically relevant and computationally important systems.

These foundations are only a first step in analyzing phenomena conforming to settable systems. A particularly important research area is the study of general primitive conditions ensuring the identification of specific causal effects of interest under varying assumptions about the observability of causes of interest and other ancillary causes and under particular patterns of causal relation. In this context, identification means the equality of causally meaningful objects (e.g., expected effects) with corresponding stochastically meaningful objects, that is, quantities expressible solely as a functional of the joint distribution of observable random variables. When identification holds, it becomes possible to estimate various causal effects from data. Recent work of White (2006), White and Chalak (2007), Schennach et al. (2008), Chalak and White (2008a), and White and Kennedy (2009) provides results for identification and estimation of causal effects under varying assumptions.

Key to ensuring identification of effects of interest in all of these studies are specific independence or conditional independence conditions, for example, the conditional independence of causes of interest from unobservable ancillary causes given other observable variables (covariates). Chalak and White (2008b) provide primitive conditions on recursive settable system structures (in particular the response functions) that either ensure or rule out such independence or conditional independence relations. In pursuing this goal, notions of indirect and total effects of non-primary causes

emerge naturally and play key roles. These results also have direct implications for d-separation and D-separation (e.g., Geiger, Verma, and Pearl, 1990; Pearl, 2000, pp. 16-17).

These studies by no means exhaust the opportunities for deeper understanding and application of settable systems. For example, all of the studies of identification and estimation just mentioned are for recursive structures. Obtaining analogous results for non-recursive structures is of particular interest.

At the outset, we offered this paper as part of a cross-disciplinary dialog between the economics/econometrics community and the machine learning community, with the hope that both communities might gain thereby. For economists, the benefits are clear and precise notions of causal effects that apply broadly to economic structures and, in particular, to the powerful structures of game theory. These causal notions draw heavily on concepts at the heart of the PCM, but surmount a number of limitations that may have held back economists' acceptance of the PCM. For those in the machine learning community, one benefit is the extension of causal notions to systems fundamentally involving optimization, equilibrium, and learning, features common to a broad range of application domains relevant to machine learning. We also hope that the machine learning community, which has so far paid only limited attention to game theory, may begin to consider the possibilities it offers for understanding empirical phenomena and for distributed and emergent computation.

Acknowledgments

The authors are grateful for discussion and comments on previous work by Judea Pearl that stimulated this work, and for the comments and suggestions of James Heckman, Philip Neary, Douglas R. White, Scott White, the editor, and five referees. Any errors are solely the author's responsibility. The present paper is an expanded version of the foundational and definitional material contained in our earlier unpublished paper "A Unified Framework for Defining and Identifying Causal Effects."

Appendix A.

For completeness, we provide a formal definition of a non-stochastic settable system.

Definition 2 (Nonstochastic Settable System) *Let $n \in \bar{\mathbb{N}}^+$, and let A be a non-empty set. For each $i = 1,...,n$, let a_i be a fixed element of A, such that a_i includes a component $\mathbb{S}_i$, a multi-element Borel-measurable subset of $\mathbb{R}$.*

Let $m \in \bar{\mathbb{N}}$. For each $k = 1,...,m$, let $a_{0,k}$ be a fixed element of A, such that $a_{0,k}$ includes a component $\mathbb{S}_{0,k}$, a multi-element Borel-measurable subset of $\mathbb{R}$. Write $a_0 := (a_{0,1},...,a_{0,m})$ and $\mathbf{a} := (a_0, a_1, ..., a_n) \in \mathbf{A} := (\times_{k=1}^{m} A) \times (\times_{i=1}^{n} A)$.

For each $k = 1,...,m$, let $z_{0,k} \in \mathbb{S}_{0,k}$, and put $y_{0,k} := z_{0,k}$. Write $z_0 := (z_{0,1},...,z_{0,m})$ and $y_0 := z_0$.

Let $\Pi = \{\Pi_b\}$ be a partition of $\{1,...,n\}$, with $B := \#\Pi \in \bar{\mathbb{N}}^+$, let $\ell_b := \#\Pi_b$, and let $\mathbf{a}$ determine the multi-element Borel measurable set $\mathbb{S}^{\Pi}_{(b)}(\mathbf{a}) \subset \times_{j \notin \Pi_b} \mathbb{S}_j \times_{k=1}^{m} \mathbb{S}_{0,k}$, $b = 1,...,B$. Suppose there exist measurable functions

$$r^{\Pi}_{[b]}(\,\cdot\,;\mathbf{a}) : \times_{i \in \Pi_b} \mathbb{S}_i \times \mathbb{S}^{\Pi}_{(b)}(\mathbf{a}) \to \mathbb{R}^{\ell_b} \quad b = 1,...,B,$$

and real vectors $y^{\Pi}_{[b]} \in \times_{i \in \Pi_b} \mathbb{S}_i$ *such that for each* $z^{\Pi}_{(b)} \in \mathbb{S}^{\Pi}_{(b)}(\mathbf{a})$,

$$r^{\Pi}_{[b]}(y^{\Pi}_{[b]}, z^{\Pi}_{(b)}; \mathbf{a}) = \mathbf{0}, \;\; b = 1, ..., B.$$

Write $\mathcal{X}^{\Pi}_0(0) := y_0$, $\mathcal{X}^{\Pi}_0(1) := z_0$, $\mathcal{X}^{\Pi}_i(0) := y^{\Pi}_i$, $\mathcal{X}^{\Pi}_i(1) := z^{\Pi}_i$, $i = 1, ..., n$, *so that* $\mathcal{X}^{\Pi}_0 : \{0,1\} \to \times^m_{k=1} \mathbb{S}_{0,k}$ *and* $\mathcal{X}^{\Pi}_i : \{0,1\} \to \mathbb{S}_i, i = 1, ..., n$. *Finally, write*

$$\mathcal{X}^{\Pi} := (\mathcal{X}^{\Pi}_0, \mathcal{X}^{\Pi}_1, , ..., \mathcal{X}^{\Pi}_n).$$

Then $\mathcal{S}^{\Pi} := \{(\mathbf{A}, \mathbf{a}), (\Pi, \mathcal{X}^{\Pi})\}$ *is a* nonstochastic settable system.

Abstract

We describe distributed algorithms for two widely-used topic models, namely the Latent Dirichlet Allocation (LDA) model, and the Hierarchical Dirichet Process (HDP) model. In our distributed algorithms the data is partitioned across separate processors and inference is done in a parallel, distributed fashion. We propose two distributed algorithms for LDA. The first algorithm is a straightforward mapping of LDA to a distributed processor setting. In this algorithm processors concurrently perform Gibbs sampling over local data followed by a global update of topic counts. The algorithm is simple to implement and can be viewed as an approximation to Gibbs-sampled LDA. The second version is a model that uses a hierarchical Bayesian extension of LDA to directly account for distributed data. This model has a theoretical guarantee of convergence but is more complex to implement than the first algorithm. Our distributed algorithm for HDP takes the straightforward mapping approach, and merges newly-created topics either by matching or by topic-id. Using five real-world text corpora we show that distributed learning works well in practice. For both LDA and HDP, we show that the converged test-data log probability for distributed learning is indistinguishable from that obtained with single-processor learning. Our extensive experimental results include learning topic models for two multi-million document collections using a 1024-processor parallel computer.

Keywords: topic models, latent Dirichlet allocation, hierarchical Dirichlet processes, distributed parallel computation

1. Introduction

Very large data sets, such as collections of images or text documents, are becoming increasingly common, with examples ranging from collections of online books at Google and Amazon, to the large collection of images at Flickr. These data sets present major opportunities for machine learning, such as the ability to explore richer and more expressive models than previously possible, and provide new and interesting domains for the application of learning algorithms.

However, the scale of these data sets also brings significant challenges for machine learning, particularly in terms of computation time and memory requirements. For example, a text corpus with one million documents, each containing one thousand words, will require approximately eight GBytes of memory to store the billion words. Adding the memory required for parameters, which usually exceeds memory for the data, creates a total memory requirement that exceeds that available

on a typical desktop computer. If one were to assume that a simple operation, such as computing a probability vector over categories using Bayes rule, takes on the order of 10^{-6} seconds per word, then a full pass through the billion words would take 1000 seconds. Thus, algorithms that make multiple passes through the data, for example clustering and classification algorithms, will have run times in days for this sized corpus. Furthermore, for small to moderate sized document sets where memory is not an issue, it would be useful to have algorithms that could take advantage of desktop multiprocessor/multicore technology to learn models in near real-time.

An obvious approach for addressing these time and memory issues is to distribute the learning algorithm over multiple processors. In particular, with P processors, it is somewhat trivial to address the memory issue by distributing $\frac{1}{P}$ of the total data to each processor. However, the computation problem remains non-trivial for a fairly large class of learning algorithms, namely how to combine local processing on each processor to arrive at a useful global solution.

In this general context we investigate distributed algorithms for two widely-used unsupervised learning models: the Latent Dirichlet Allocation (LDA) model, and the Hierarchical Dirichet Process (HDP) model. LDA and HDP models are arguably among the most successful recent learning algorithms for analyzing discrete data such as bags of words from a collection of text documents. However, they can take days to learn for large corpora, and thus, distributed learning would be particularly useful.

The rest of the paper is organized as follows: In Section 2 we review the standard derivation of LDA and HDP. Section 3 presents our two distributed algorithms for LDA and one distributed algorithm for HDP. Empirical results are provided in Section 4. Scalability results are presented in Section 5, and further analysis of distributed LDA is provided in Section 6. A comparison with related models is given in Section 7. Finally, Section 8 concludes the paper.

2. Latent Dirichlet Allocation and Hierarchical Dirichlet Process Model

We start by reviewing the LDA and HDP models. Both LDA and HDP are generative probabilistic models for discrete data such as bags of words from text documents—in this context these models are often referred to as topic models. To illustrate the notation, we refer the reader to the graphical models for LDA and HDP shown in Figure 1.

LDA models each of D documents in a collection as a mixture over K latent topics, with each topic being a multinomial distribution over a vocabulary of W words. For document j, we first draw a mixing proportion θ_j from a Dirichlet with parameter α. For the i^{th} word in the document, a topic $z_{ij} = k$ is drawn with probability $\theta_{k|j}$. Word x_{ij} is then drawn from topic z_{ij}, with x_{ij} taking on value w with probability $\phi_{w|z_{ij}}$. A Dirichlet prior with parameter β is placed on the word-topic distributions ϕ_k.

Thus, the generative process for LDA is given by

$$\theta_j \sim \mathcal{D}[\alpha], \quad \phi_k \sim \mathcal{D}[\beta], \quad z_{ij} \sim \theta_j, \quad x_{ij} \sim \phi_{z_{ij}}. \tag{1}$$

To avoid clutter we denote sampling from a Dirichlet $\theta_j \sim \mathcal{D}[\alpha]$ as shorthand for $[\theta_{1|j}, \ldots, \theta_{K|j}] \sim \mathcal{D}[\alpha, \ldots, \alpha]$, and likewise for ϕ. In this paper, we use symmetric Dirichlet priors for simplicity, unless specified otherwise. The full joint distribution over all parameters and variables is

$$p(\mathbf{x}, \mathbf{z}, \theta, \phi | \alpha, \beta) = \prod_j \frac{\Gamma(K\alpha)}{\Gamma(\alpha)^K} \prod_k \theta_{k|j}^{N_{kj}+\alpha-1} \prod_k \frac{\Gamma(W\beta)}{\Gamma(\beta)^W} \prod_w \phi_{w|k}^{N_{wk}+\beta-1}, \tag{2}$$

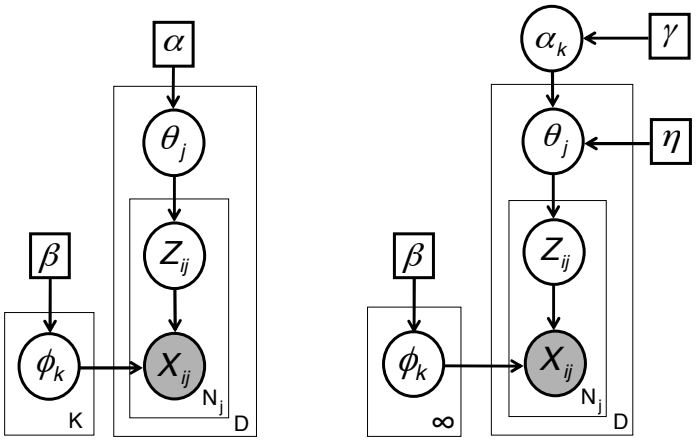

Figure 1: Graphical models for LDA (left) and HDP (right). Observed variables (words) are shaded, and hyperparameters are shown in squares.

	Description
D	Number of documents in collection
W	Number of distinct words in vocabulary
N	Total number of words in collection
K	Number of topics
x_{ij}	i^{th} observed word in document j
z_{ij}	Topic assigned to x_{ij}
N_{wk}	Count of word assigned to topic
N_{kj}	Count of topic assigned in document
ϕ_k	Probability of word given topic k
θ_j	Probability of topic given document j

Table 1: Description of commonly used variables.

where $N_{wkj} = \#\{i : x_{ij} = w, z_{ij} = k\}$, and we use the convention that missing indices are summed out. $N_{kj} = \sum_w N_{wkj}$ and $N_{wk} = \sum_j N_{wkj}$ are the two primary count arrays used in computations, representing the number of words assigned to topic k in document j, and the number of times word w is assigned to topic k in the corpus, respectively. For ease of reading we list commonly used variables in Table 1.

Given the observed words $\mathbf{x} = \{x_{ij}\}$, the task of Bayesian inference for LDA is to compute the posterior distribution over the latent topic assignments $\mathbf{z} = \{z_{ij}\}$, the mixing proportions θ_j, and the topics ϕ_k. Approximate inference for LDA can be performed either using variational methods (Blei et al., 2003) or Markov chain Monte Carlo methods (Griffiths and Steyvers, 2004). In this paper we focus on Markov chain Monte Carlo algorithms for approximate inference. MCMC is widely used as an inference method for a variety of topic models, for example Rosen-Zvi et al. (2004), Li and McCallum (2006), and Chemudugunta et al. (2007) all use MCMC for inference. In the MCMC context, the usual procedure is to integrate out the mixtures θ and topics ϕ in (2)—a procedure called collapsing—and just sample the latent variables $\mathbf{z}$. Given the current state of all but one variable z_{ij},

the conditional probability of z_{ij} is

$$p(z_{ij} = k|\mathbf{z}^{\neg ij}, \mathbf{x}, \alpha, \beta) \propto \frac{N_{wk}^{\neg ij} + \beta}{\sum_w N_{wk}^{\neg ij} + W\beta} \left(N_{kj}^{\neg ij} + \alpha \right), \tag{3}$$

where the superscript $\neg ij$ means that the corresponding word is excluded in the counts.

HDP is a collection of Dirichlet Processes which share the same topic distributions and can be viewed as the non-parametric extension of LDA. The advantage of HDP is that the number of topics is determined by the data. The HDP model is obtained by taking the following model in the limit as K goes to infinity. Let α_k be top level Dirichlet variables sampled from a Dirichlet with parameter γ/K. The topic mixture for each document, θ_j, is drawn from a Dirichlet with parameters $\eta\alpha_k$. The word-topic distributions ϕ_k are drawn from a base Dirichlet distribution with parameter β. As in LDA, z_{ij} is sampled from θ_j, and word x_{ij} is sampled from the corresponding topic $\phi_{z_{ij}}$. The generative process is given by

$$\alpha_k \sim \mathcal{D}[\gamma/K], \qquad \theta_j \sim D[\eta\alpha_k], \qquad \phi_k \sim D[\beta], \qquad z_{ij} \sim \theta_j, \qquad x_{ij} \sim \phi_{z_{ij}}.$$

The posterior distribution is sampled using the direct assignment sampler for HDP described in Teh et al. (2006). As was done for LDA, both θ and ϕ are integrated out, and z_{ij} is sampled from the following conditional distribution:

$$p(z_{ij} = k|\mathbf{z}^{\neg ij}, \mathbf{x}, \alpha, \beta, \eta) \propto \begin{cases} \frac{N_{wk}^{\neg ij} + \beta}{\sum_w N_{wk}^{\neg ij} + W\beta} \left(N_{kj}^{\neg ij} + \eta\alpha_k \right), & \text{if } k \text{ previously used} \\ \frac{\eta\alpha_{\text{new}}}{W}, & \text{if } k \text{ is new.} \end{cases} \tag{4}$$

The sampling scheme for α_k is also detailed in Teh et al. (2006). Note that a small amount of probability mass proportional to α_{new} is reserved for the instantiation of new topics. While HDP is defined to have infinitely many topics, the sampling algorithm only instantiates topics as needed.

2.1 Need for Distributed Algorithms

One could argue that it is trivial to distribute non-collapsed Gibbs sampling, because sampling of z_{ij} can happen independently given θ_j and ϕ_k, and therefore can be done concurrently. In the non-collapsed Gibbs sampler, one samples z_{ij} given θ_j and ϕ_k, and then samples θ_j and ϕ_k given z_{ij}. Furthermore, if individual documents are not spread across different processors, one can marginalize over just θ_j, since θ_j is processor-specific. In this partially collapsed scheme, the latent variables z_{ij} on each processor can be concurrently sampled, where the concurrency is over processors.

Unfortunately, the non-collapsed and partially collapsed Gibbs samplers exhibit slow convergence due to the strong dependencies between the parameters and latent variables. Generally, we expect faster mixing as more variables are collapsed (Liu et al., 1994; Casella and Robert, 1996). Figure 2 shows, using one of the data sets used throughout our paper, that the log probability of test data (measured as perplexity, which is defined in Section 4) of the non-collapsed and partially collapsed samplers converges more slowly than the fully collapsed sampler.

The slow convergence of partially collapsed and non-collapsed Gibbs samplers motivates the need to devise distributed algorithms for fully collapsed Gibbs samplers. In the following section we introduce distributed topic modeling algorithms that take advantage of the benefits of collapsing both θ and ϕ.

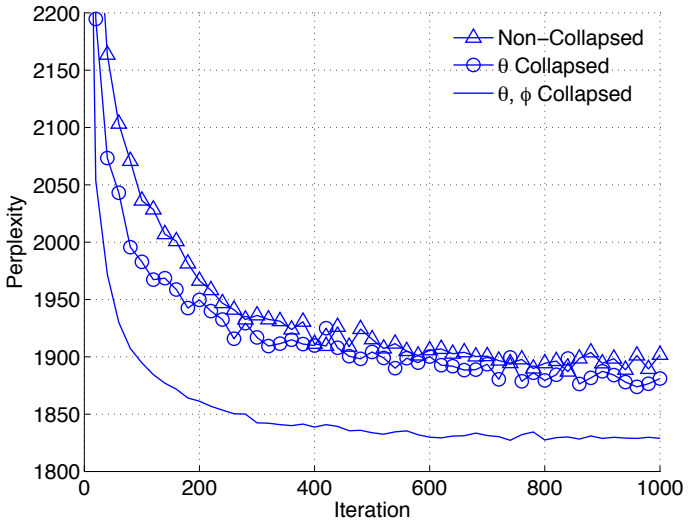

Figure 2: On the NIPS data set using $K = 20$ topics, the fully collapsed Gibbs sampler (solid line) converges faster than the partially collapsed (circles) and non-collapsed (triangles) samplers.

3. Distributed Algorithms for Topic Models

We introduce algorithms for LDA and HDP where the data, parameters, and computation are distributed over distinct processors. We distribute the D documents over P processors, with approximately $D_P = \frac{D}{P}$ documents on each processor. Documents are randomly assigned to processors, although as we will see later, the assignment of documents to processors—ranging from random to highly non-random or adversarial—appears to have little influence on the results. This indifference is somewhat understandable given that converged results from Gibbs sampling are independent of sampling order.

We partition the words from the D documents into $\mathbf{x} = \{\mathbf{x}_1, \ldots, \mathbf{x}_p, \ldots, \mathbf{x}_P\}$ and the corresponding topic assignments into $\mathbf{z} = \{\mathbf{z}_1, \ldots, \mathbf{z}_p, \ldots, \mathbf{z}_P\}$, where processor p stores $\mathbf{x}_p$, the words from documents $j = (p-1)D_P + 1, \ldots, pD_P$, and $\mathbf{z}_p$, the corresponding topic assignments. Topic-document counts N_{kj} are likewise distributed as N_{kjp}. The word-topic counts N_{wk} are also distributed, with each processor keeping a separate local copy N_{wkp}.

3.1 Approximate Distributed Latent Dirichlet Allocation

The difficulty of distributing and parallelizing over Gibbs sampling updates (3) lies in the fact that Gibbs sampling is a strictly sequential process. To asymptotically sample from the posterior distribution, the update of any topic assignment z_{ij} can not be performed concurrently with the update of any other topic assignment $z_{i'j'}$. But given the typically large number of word tokens compared to the number of processors, to what extent will the update of one topic assignment z_{ij} depend on the update of any other topic assignment $z_{i'j'}$? Our hypothesis is that this dependence is weak, and therefore we should be able to relax the requirement of sequential sampling of topic assignments and still learn a useful model. One can see this weak dependence in the following common situation. If two processors are concurrently sampling, but sampling different words in different documents

Algorithm 1 AD-LDA

repeat
  for each processor p in parallel **do**
    Copy global counts: $N_{wkp} \leftarrow N_{wk}$
    Sample $\mathbf{z}_p$ locally: LDA-Gibbs-Iteration($\mathbf{x}_p, \mathbf{z}_p, N_{kjp}, N_{wkp}, \alpha, \beta$)
  end for
  Synchronize
  Update global counts: $N_{wk} \leftarrow N_{wk} + \sum_p (N_{wkp} - N_{wk})$
until termination criterion satisfied

(i.e., $w_{ij} \neq w_{i'j'}$), then concurrent sampling will be very close to sequential sampling because the only term affecting the order of operations is the total count of topics $\sum_w N_{wk}$ in the denominator of (3).

The pseudocode for our Approximate Distributed LDA (AD-LDA) algorithm is shown in Algorithm 1. After distributing the data and parameters across processors, AD-LDA performs simultaneous LDA Gibbs sampling on each of the P processors. After processor p has swept through its local data and updated topic assignments $\mathbf{z}_p$, the processor has modified count arrays N_{kjp} and N_{wkp}. The topic-document counts N_{kjp} are distinct because of the document index, j, and will be consistent with the topic assignments $\mathbf{z}$. However, the word-topic counts N_{wkp} will in general be different on each processor, and not globally consistent with $\mathbf{z}$. To merge back to a single and consistent set of word-topic counts, we perform a reduce operation on N_{wkp} across all processors to update the global counts. After the synchronization and update operations, each processor has the same values in the N_{wkp} array which are consistent with the global vector of topic assignments $\mathbf{z}$. Note that N_{wkp} is not the result of P separate LDA models running on separate data. In particular, each word-topic count array reflects all the counts, not just those local to that processor, so for every processor $\sum_{wk} N_{wkp} = N$, where N is the total number of words in the corpus. As in LDA, the algorithm can terminate either after a fixed number of iterations, or based on some suitable MCMC convergence metric.

We chose the name *Approximate* Distributed LDA because in this algorithm we are no longer asymptotically sampling from the true posterior, but to an approximation of the true posterior. Nonetheless, we will show in our experimental results that the approximation made by Approximate Distributed LDA works very well.

3.2 Hierarchical Distributed Latent Dirichlet Allocation

In AD-LDA we constructed an algorithm where each processor is independently computing an LDA model, but at the end of each sweep through a processor's data, a consistent global array of topic counts N_{wk} is reconstructed. This global array of topic counts could be thought of as a parent topic distribution, from which each processor draws its own local topic distribution.

Using this intuition, we created a Bayesian model reflecting this structure, as shown in Figure 3. Our Hierarchical Distributed LDA model (HD-LDA) places a hierarchy over word-topic distributions, with Φ_k being the global or parent word-topic distribution and φ_{kp} the local word-topic distributions on each processor. The local word-topic distributions φ_{kp} are drawn from Φ_k according to a Dirichlet distribution with a topic-dependent strength parameter β_k, for each topic $k = 1 \ldots K$. The model on each processor is simply an LDA model. The generative process is given

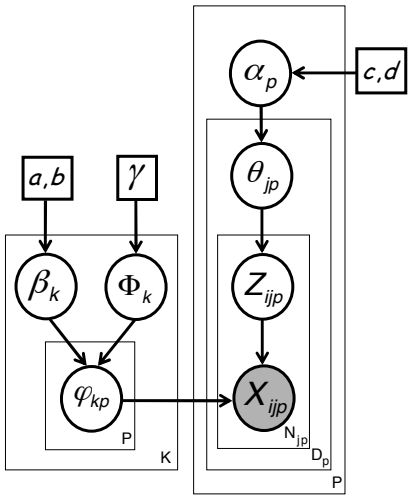

Figure 3: Graphical model for Hierarchical Distributed Latent Dirichlet Allocation.

by:

$$\beta_k \sim \mathcal{G}[a,b], \qquad \alpha_p \sim \mathcal{G}[c,d], \qquad \theta_{jp} \sim \mathcal{D}[\alpha_p], \qquad \Phi_k \sim \mathcal{D}[\gamma], \qquad \varphi_{kp} \sim \mathcal{D}[\beta_k \Phi_k], \qquad (5)$$
$$z_{ijp} \sim \theta_{jp}, \qquad x_{ijp} \sim \varphi_{z_{ijp}p}.$$

From this generative process, we derive Gibbs sampling equations for HD-LDA. The derivation is based on the Teh et al. (2006) sampling schemes for Hierarchical Dirichlet Processes. As was done for LDA, we start by integrating out φ and θ. The collapsed distribution of $\mathbf{z}_p$ and $\mathbf{x}_p$ on processor p is given by:

$$p(\mathbf{z}_p, \mathbf{x}_p | \alpha_p, \beta, \Phi) = \prod_j \left[\frac{\Gamma(K\alpha_p)}{\Gamma(N_{jp} + K\alpha_p)} \prod_k \frac{\Gamma(N_{kjp} + \alpha_p)}{\Gamma(\alpha_p)} \right] \prod_k \left[\frac{\Gamma(\beta_k)}{\Gamma(N_{kp} + \beta_k)} \prod_w \frac{\Gamma(N_{wkp} + \beta_k \Phi_{w|k})}{\Gamma(\beta_k \Phi_{w|k}))} \right]. \qquad (6)$$

From this we derive the conditional probability for sampling a topic assignment z_{ijp}. Unlike AD-LDA, the topic assignments on any processor are now conditionally independent of the topic assignments on the other processors given Φ, thus allowing each processor to sample $\mathbf{z}_p$ concurrently. The conditional probability of z_{ijp} is

$$p(z_{ijp} = k | \mathbf{z}_p^{\neg ijp}, \mathbf{x}, \alpha_p, \beta, \Phi) = (N_{kjp}^{\neg ijp} + \alpha_p) \frac{(N_{wkp}^{\neg ijp} + \beta_k \Phi_{w|k})}{(N_{kp}^{\neg ijp} + \beta_k)}.$$

The full derivation of the Gibbs sampling equations for HD-LDA is provided in Appendix A, which lists the complete set of sampling equations for α_p, β_k, and Φ_k.

The pseudocode for our Hierarchical Distributed LDA algorithm is given in Algorithm 2. Each variable in this model is either local or global, depending on whether inference for the variable is computed locally on a processor or globally, requiring information from all processors. Local variables include α, θ, φ, z, and x. Global variables include β and Φ. Each processor uses Gibbs

sampling to sample its local variables concurrently. After each sweep through the processor's data, the global variables are sampled. Note that, unlike AD-LDA, HD-LDA is performing strictly correct sampling for its model.

HD-LDA can be viewed as a mixture model with P LDA mixture components with equal mixing weights. In this view the data have been hard-assigned to their respective clusters (i.e., processors), and the parameters of the clusters are generated from a shared prior distribution.

Algorithm 2 HD-LDA

repeat
  for each processor p in parallel **do**
    Sample $\mathbf{z}_p$ locally: LDA-Gibbs-Iteration($\mathbf{x}_p, \mathbf{z}_p, N_{kjp}, N_{wkp}, \alpha_p, \beta_k \Phi_k$)
    Sample α_p locally
  end for
  Synchronize
  Sample: β_k, Φ_k
  Broadcast: β_k, Φ_k
until termination criterion satisfied

3.3 Approximate Distributed Hierarchical Dirichlet Processes

Our third distributed algorithm, Approximate Distributed HDP, takes the same approach as AD-LDA. Processors concurrently run HDP for a single sweep through their local data. After all of the processors sweep through their data, a synchronization and update step is performed to create a single set of globally-consistent word-topic counts N_{wk}. We refer to the distributed version of HDP as AD-HDP, and provide the pseudocode in Algorithm 3.

Unlike AD-LDA, which uses a fixed number of topics, individual processors in AD-HDP may instantiate new topics during the sampling phase, according to the HDP sampling Equation (4). During the synchronization and update step, instead of treating each processor's new topics as distinct, we merge new topics that were instantiated on different processors. Merging new topics helps limit unnecessary growth in the total number of topics and allows AD-HDP to produce more of a global model.

Algorithm 3 AD-HDP

repeat
  for each processor p in parallel **do**
    Sample z_p locally: HDP-Gibbs-Iteration($x_p, z_p, N_{kjp}, N_{wkp}, \alpha_{kp}, \beta, \gamma, \eta$)
    Report N_{wkp}, α_{kp} to master node
  end for
  Synchronize
  Update global counts (and merge new topics): $N_{wk} \leftarrow N_{wk} + \sum_p (N_{wkp} - N_{wk})$
  $\alpha_k \leftarrow (\sum_p \alpha_{kp})/P$
  Sample: η, α_k, γ
  Broadcast: $N_{wk}, \alpha_k, \gamma, \eta$
until termination criterion satisfied

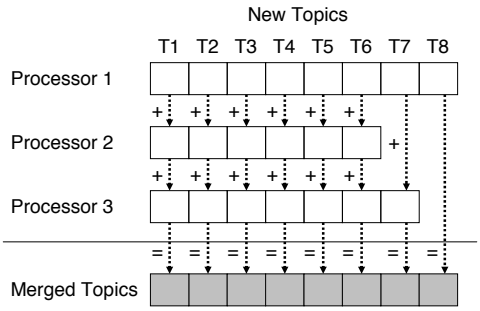

Figure 4: The simplest method to merge new topics in AD-HDP is by integer topic label.

There are several ways to merge newly created topics on each processor. A simple way—inspired by AD-LDA—is to merge new topics based on their integer topic label. A more complicated way is to match new topics across processors based on topic similarity.

In the first merging scheme, new topics are merged based on their integer topic label. For example, assume that we have three processors, and at the end of a sweep through the data, processor one has 8 new topics, processor two has 6 new topics, and processor three has 7 new topics. Then during synchronization, all these new topics would be aligned by topic label and their counts summed, producing 8 new global topics, as shown in Figure 4.

While this merging of new topics by topic-id may seem suboptimal, it is computationally simple and efficient. We will show in the next section that this merging generally works well in practice, even when processors only have a small amount of data. We suggest that even if the merging by topic-id is initially quite random, the subsequent dynamics align the topics in a sensible manner. We will also show that AD-HDP ultimately learns models with similar perplexity to HDP, irrespective of how new topics are merged.

We also investigate more complicated schemes for merging new topics in AD-HDP, beyond the simple approach of merging by topic-id. Instead of aligning new topics based topic-id it is possible to align new topics using a similarity metric such as symmetric Kullback-Leibler divergence. However, finding the optimal matching of topics in the case where $P > 2$ is NP-hard (Burkard and Çela, 1999). Thus, we consider approximate schemes: bipartite matching using a reference processor, and greedy matching.

In the bipartite matching scheme, we select a reference processor and perform bipartite matching between every processor's new topics and the set of new topics of the reference processor. The bipartite match is computed using the Hungarian algorithm, which runs in $O(T^3)$, producing an overall complexity of $O(PT^3)$ where T is the maximum number of new topics on a processor. We implemented this scheme but did not find any improvement over AD-HDP with merging by topic-id.

In the greedy matching scheme, new topics on each processor are sequentially compared to a global set of new topics. This global set is initialized to the first processor's set of new topics. If a new topic is sufficiently different from every topic in the global set, the number of topics in the global set is incremented; otherwise, the counts for that new topic are added to those from the closest match in the global set. A threshold is used to determine whether a new topic is sufficiently different from another topic. The worst case complexity of this algorithm is $O(P^2T^2)$—this is the case where every new topic is found to be different from every other new topic in the global set. Increasing this threshold will make it more likely for new topics to merge with the topics already in the global set (instead of incrementing the set), causing the expected running time of this merging algorithm to

Algorithm 4 Greedy Matching of New Topics for AD-HDP

```
Initialize global set of new topics, G, to be processor 1's set of new topics
for p = 2 to P do
  for topic t in processor p's set of new topics do
    Initialize score array
    for topic g in G do
      score[g] = symmetric-KL-divergence(t,g)
    end for
    if min(score) < threshold then
      Add t's counts to the topic in G corresponding to min(score)
    else
      Augment G with the new topic t
    end if
  end for
end for
```

be linear in the number of processors. The pseudocode of this greedy matching scheme is shown in Algorithm 4. This algorithm is run after each iteration of AD-HDP to produce a global set of new topics. We show in the next section that this greedy matching scheme significantly improves the rate of convergence for AD-HDP.

4. Experiments

The purpose of our experiments is to investigate how our distributed topic model algorithms, AD-LDA, HD-LDA and AD-HDP, perform when compared to their sequential counterparts, LDA and HDP. We are interested in two aspects of performance: the quality of the model learned, measured by log probability of test data; and the time taken to learn the model. Our primary data sets for these experiments were KOS blog entries, from dailykos.com, and NIPS papers, from books.nips.cc. We chose these relatively small data sets to allow us to perform a large number of experiments. Both data sets were split into a training set and a test set. Size parameters for these data sets are shown in Table 2. For each corpus, D is the number of documents, W is the vocabulary size and N is the total number of words. Two larger data sets WIKIPEDIA, from en.wikipedia.org, and PUBMED, from pubmed.gov were used for speedup experiments, described in Section 5. For precision-recall experiments we used the NEWSGROUPS data set, taken from the UCI Machine Learning Repository. All the data sets used in this paper can be downloaded from the UCI Machine Learning Repository (Asuncion and Newman, 2007).

Using the KOS and NIPS data sets, we computed test set perplexities for a range of topics K, and for numbers of processors, P, ranging from 1 to 3000. The distributed algorithms were initialized by first randomly assigning topics to words in $\mathbf{z}$, then counting topics in documents, N_{kjp}, and words in topics, N_{wkp}, for each processor. For each run of LDA, AD-LDA, and HD-LDA, a sample was taken at 500 iterations of the Gibbs sampler, which is well after the typical burn-in period of the initial 200-300 iterations. For each run of HDP and AD-HDP, we allow the Gibbs sampler to run for 3000 iterations, to allow the number of topics to grow. In our perplexity experiments, multiple processors were simulated in software by separating data, running sequentially through each processor, and simulating the global synchronization and update steps. For the speedup experiments, computations were run on 64 to 1024 processors on a 2000+ processor parallel supercomputer.

The following set of hyperparameters was used for the experiments, where hyperparameters are shown as variables in squares in the graphical models in Figures 1 and 3. For AD-LDA we set $\alpha = 0.1$ and $\beta = 0.01$. For AD-HDP we set $\beta = 0.01$, $\eta \sim \text{Gamma}(2,1)$ and $\gamma \sim \text{Gamma}(10,1)$. While η and γ could have also been fixed, resampling these hyperparameters allows for more robust topic growth, as described by Teh et al. (2006). For LDA and AD-LDA we fixed the hyperparameters α and β, but these priors could also be learned using sampling.

Selection of hyperparameters for HD-LDA was guided by our experience with AD-LDA. For AD-LDA, $\sum_w N_{wkp} \approx \frac{N}{K}$, but for HD-LDA $\sum_w N_{wkp} \approx \frac{N}{PK}$, so we choose a and b to make the mode of $\beta_k = \frac{(P-1)N}{PK}$ to simulate the inclusion of global counts in N_{wkp} as is done in AD-LDA. We set $\gamma = 2/K$, because it is important to scale γ by the number of topics to prevent oversmoothing when the counts are spread thinly among many topics. Finally, we choose c and d to make the mode of $\alpha_p = 0.1$, matching the value of α used in our LDA and AD-LDA experiments. Specifically, we set: $a = \frac{(P-1)N}{PK}$, $b = 1$, $c = 0.1 * 10 + 1$ and $d = 0.1$.

To systematically evaluate our distributed topic model algorithms, AD-LDA, HD-LDA and AD-HDP, we measured performance using test set perplexity, which is computed as $\text{Perp}(\mathbf{x}^{\text{test}}) = \exp(-\frac{1}{N^{\text{test}}} \log p(\mathbf{x}^{\text{test}}))$. For every test document, half the words at random are designated for fold-in, and the remaining words are used as test. The document mixture θ_j is learned using the fold-in part, and log probability of the test words is computed using this mixture, ensuring that the test words are not used in estimation of model parameters. For AD-LDA, the perplexity computation exactly follows that of LDA, since a single set of topic counts N_{wk} are saved when a sample is taken. In contrast, all P copies of N_{wkp} are required to compute perplexity for HD-LDA. Except where stated, perplexities are computed for all algorithms using $S = 10$ samples from the posterior from ten independent chains using

$$\log p(\mathbf{x}^{\text{test}}) = \sum_{j,w} N_{jw}^{\text{test}} \log \frac{1}{S} \sum_s \sum_k \theta_{k|j}^s \phi_{w|k}^s, \qquad \theta_{k|j}^s = \frac{\alpha + N_{kj}^s}{K\alpha + N_j^s}, \qquad \phi_{w|k}^s = \frac{\beta + N_{wk}^s}{W\beta + N_k^s}. \tag{7}$$

This perplexity computation follows the standard practice of averaging over multiple chains when making predictions with LDA models trained via Gibbs sampling, as discussed in Griffiths and Steyvers (2004). Averaging over ten samples significantly reduces perplexity compared to using a single sample from one chain. While we perform averaging over multiple samples to improve the estimate of perplexity, we have also observed similar relative results across our algorithms when we use a single sample to compute perplexity.

Analogous perplexity calculations are used for HD-LDA and AD-HDP. With HD-LDA we additionally compute processor-specific responsibilities, since test documents do not belong to any

particular processor, unlike the training documents. Each processor learns a document mixture θ_{jp} using the fold-in part for each test document. For each processor, the likelihood is calculated over the words in the fold-in part in a manner analogous to (7), and these likelihoods are normalized to form the responsibilities, r_p. To compute perplexity, we compute the likelihood over the test words, using a responsibility-weighted average of probabilities over all processors:

$$\log p(\mathbf{x}^{\text{test}}) = \sum_{j,w} N_{jw}^{\text{test}} \log \sum_p \frac{r_p}{S} \sum_s \sum_k \theta_{k|jp}^s \phi_{w|kp}^s$$

$$\text{where} \quad \theta_{k|jp}^s = \frac{\alpha_p + N_{kjp}^s}{K\alpha_p + N_{jp}^s}, \qquad \phi_{w|kp}^s = \frac{\beta_k \Phi_{w|k} + N_{wkp}^s}{\beta_k + N_{kp}^s}.$$

Computing perplexity in this manner prevents the possibility of seeing or using test words during the training and fold-in phases.

4.1 Perplexity

The perplexity results for KOS and NIPS in Figure 5 clearly show that the model perplexity is essentially the same for the distributed models AD-LDA and AD-HDP at $P = 10$ and $P = 100$ as their single-processor versions at $P = 1$. The figures show the test set perplexity, versus number of processors, P, for different numbers of topics K for the LDA-type models, and also for the HDP-models which learn the number of topics. The $P = 1$ perplexity is computed by LDA (circles) and HDP (triangles), and we use our distributed algorithms—AD-LDA (crosses), HD-LDA (squares), and AD-HDP (stars)—to compute the $P = 10$ and $P = 100$ perplexities. The variability in perplexity as a function of the number of topics is much greater than the variability due to the number of processors. Note that there is essentially no perplexity difference between AD-LDA and HD-LDA.

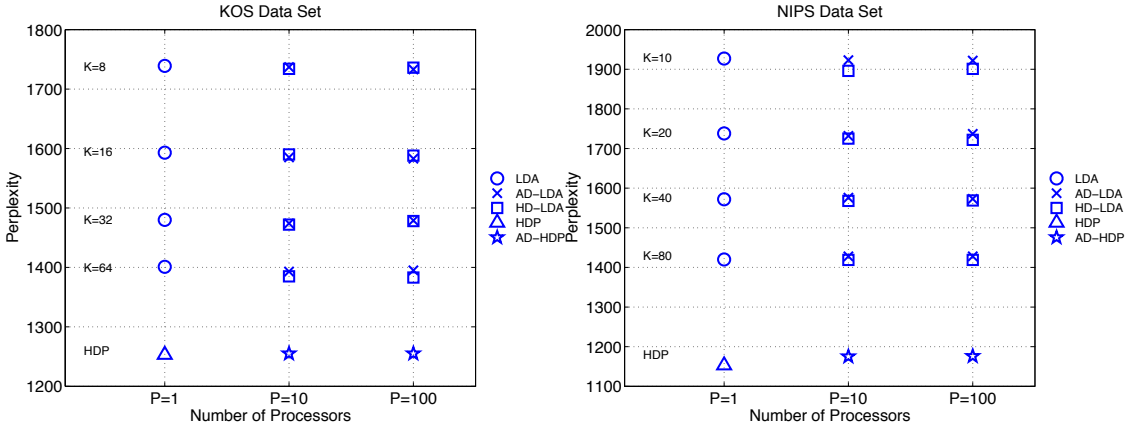

Figure 5: Test perplexity on KOS (left) and NIPS (right) data versus number of processors P. $P = 1$ corresponds to LDA and HDP. At $P = 10$ and $P = 100$ we show AD-LDA, HD-LDA and AD-HDP.

Even in the limit of a large number of processors, the perplexity for the distributed algorithms matches that for the sequential version. In fact, in the limiting case of just one document per processor, $P = 3000$ for KOS and $P = 1500$ for NIPS, we see that the perplexities of AD-LDA are generally no different to those of LDA, as shown in the rightmost point in each curve in Figure 6.

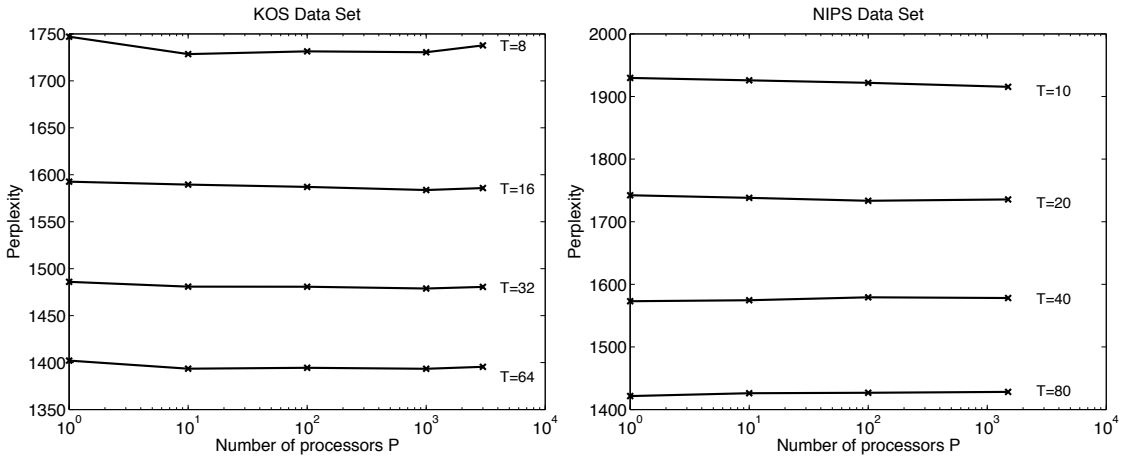

Figure 6: AD-LDA test perplexity versus number of processors up to the limiting case of number of processors equal to number of documents in collection. Left plot shows perplexity for KOS and right plot shows perplexity for NIPS.

AD-HDP instantiates fewer topics but produces a similar perplexity to HDP. The average number of topics instantiated by HDP on KOS was 669 while the average number of topics instantiated by AD-HDP was 490 ($P = 10$) and 471 ($P = 100$). For NIPS, HDP instantiated 687 topics while AD-HDP instantiated 569 ($P = 10$) and 569 ($P = 100$) topics. AD-HDP instantiates fewer topics because of the merging across processors of newly-created topics. The similar perplexity results for AD-HDP compared to HDP, despite the fewer topics, is partly due to the relatively small probability mass in many of the topics.

Despite no formal convergence guarantees, the approximate distributed algorithms, AD-LDA and AD-HDP, converged to good solutions in every single experiment (of the more than one hundred) we conducted using multiple real-world data sets. We also tested both our distributed LDA algorithms with adversarial/non-random distributions of topics across processors using synthesized data. One example of an adversarial distribution of documents is where each document only uses a single topic, and these documents are distributed such that processor p only has documents that are about topic p. In this case the distributed topic models have to learn the correct set of P topics, even though each processor only sees local documents that pertain to just one of the topics. We ran multiple experiments, starting with 1000 documents that were hard-assigned to $K = 10$ topics (i.e., each document is only about one topic), and distributing the 1000 documents over $P = 10$ processors, where each processor contained documents belonging to the same topic (an analogy is one processor only having documents about sports, the next processor only having documents about arts, and so on). The perplexity performance of AD-LDA and HD-LDA under these adversarial/non-random distribution of documents was as good as the performance when the documents were distributed randomly, and as good as the performance of single-processor LDA.

To demonstrate that the low perplexities obtained from the distributed algorithms with $P = 100$ processors are not just due to averaging effects, we split the NIPS corpus into one hundred 15-document collections, and ran LDA separately on each of these hundred collections. The test perplexity at $K = 40$ computed by averaging 100-separate LDA models was 2117, significantly

higher than the $P = 100$ test perplexity of 1575 for AD-LDA and HD-LDA. This shows that a baseline approach of simple averaging of results from separate processors performs much worse than the distributed coordinated learning algorithms that we propose in this paper.

4.2 Convergence

One could imagine that distributed algorithms, where each processor only sees its own local data, may converge more slowly than single-processor algorithms where the data is global. Consequently, we performed experiments to see whether our distributed algorithms were converging at the same rate as their sequential counterparts. If the distributed algorithms were converging slower, the computational gains of parallelization would be reduced. Our experiments consistently showed that the convergence rate for the distributed LDA algorithms was just as fast as those for the single processor case. As an example, Figure 7 shows test perplexity versus iteration of the Gibbs sampler for the NIPS data at $K = 20$ topics. During burn-in, up to iteration 200, the distributed algorithms are actually converging slightly faster than single processor LDA. Note that one iteration of AD-LDA or HD-LDA on a parallel multi-processor computer only takes a fraction (at best $\frac{1}{P}$) of the wall-clock time of one iteration of LDA on a single processor computer.

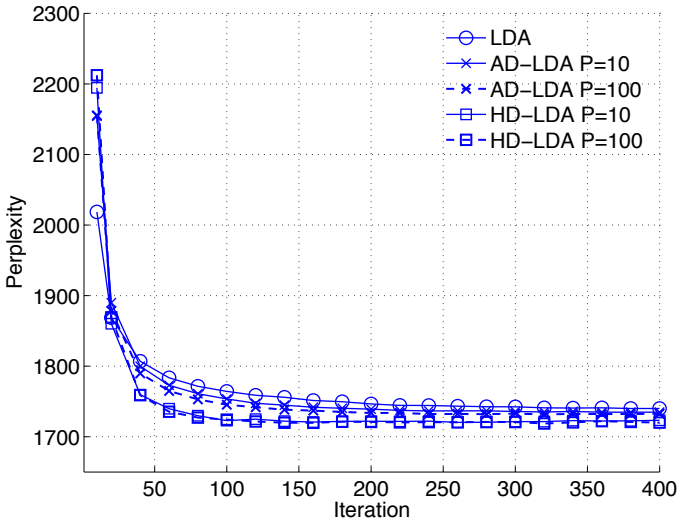

Figure 7: Convergence of test perplexity versus iteration for the distributed algorithms AD-LDA and HD-LDA using the NIPS data set and $K = 20$ topics.

We see slightly different convergence behavior in the non-parametric topic models. AD-HDP converges more slowly than HDP, as shown in Figure 8, due to AD-HDP's heavy averaging of new topics resulting from merging by topic-id (i.e., no matching). This slower convergence may partially be a result of the lower number of topics instantiated. The number of new topics instantiated in one pass of AD-HDP is limited to the maximum number of new topics instantiated on any one processor. For example, in the right plot, after 500 iterations, HDP has instantiated 360 topics, whereas AD-HDP has instantiated 210 ($P = 100$) and 250 ($P = 10$) topics. Correspondingly, at 500 iterations, the perplexity of HDP is lower than the perplexity of AD-HDP. After three thousand iterations, AD-HDP produces the same perplexity as HDP, which is reassuring because it indicates that AD-HDP

is ultimately producing a model that has the same predictive ability as HDP. We observe a similar result for the NIPS data set.

One way to accelerate the rate of convergence for AD-HDP is to match newly generated topics by similarity instead of by topic-id. Figure 9 shows that performing the greedy matching scheme for new topics as described in Algorithm 4 significantly improves the rate of convergence for AD-HDP. In this experiment, we used a threshold of 2 for determining topic similarity. The number of topics increases at a faster rate for AD-HDP with matching, since the greedy matching scheme is more flexible in that the number of new topics at each iteration is not limited to the maximum number of new topics instantiated on any one processor. The results show that the greedy matching scheme enables AD-HDP $P = 100$ to converge almost as quickly as HDP. In practice, only a few new topics are generated locally on each processor each iteration, and so the computational overhead of this heuristic matching scheme is minimal relative to the time for Gibbs sampling.

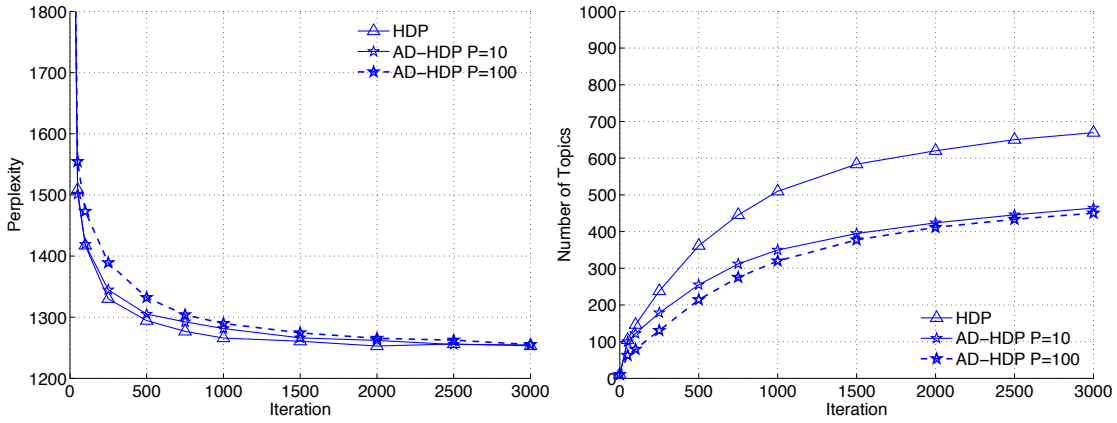

Figure 8: Results for HDP versus AD-HDP with no matching. Left plot shows test perplexity versus iteration for HDP and AD-HDP. Right plot shows number of topics versus iteration for HDP and AD-HDP. Results are for the KOS data set.

To further check that the distributed algorithms were performing comparably to their single processor counterparts, we ran experiments to investigate whether the results were sensitive to the number of topics used in the models, in case the distributed algorithms' performance worsens when the number of topics becomes very large. Figure 10 shows the test perplexity computed on the NIPS data set, as a function of the number of topics, for the LDA algorithms and a fixed number of processors $P = 10$ (the results for the KOS data set were quite similar and therefore not shown). The perplexities of the different algorithms closely track each other as number of topics, K, increases. In fact, in some cases HD-LDA produces slightly lower perplexities than those of single processor LDA. This lower perplexity may be due to the fact that in HD-LDA test perplexity is computed using P sets of topic parameters, thus it has more parameters than AD-LDA to better fit the data.

4.3 Precision and Recall

In addition to our experiments measuring perplexity, we also performed precision/recall calculations using the NEWSGROUPS data set, where each document's corresponding newsgroup is the class label. In this experiment we use LDA and AD-LDA to learn topic models on the training data. Once

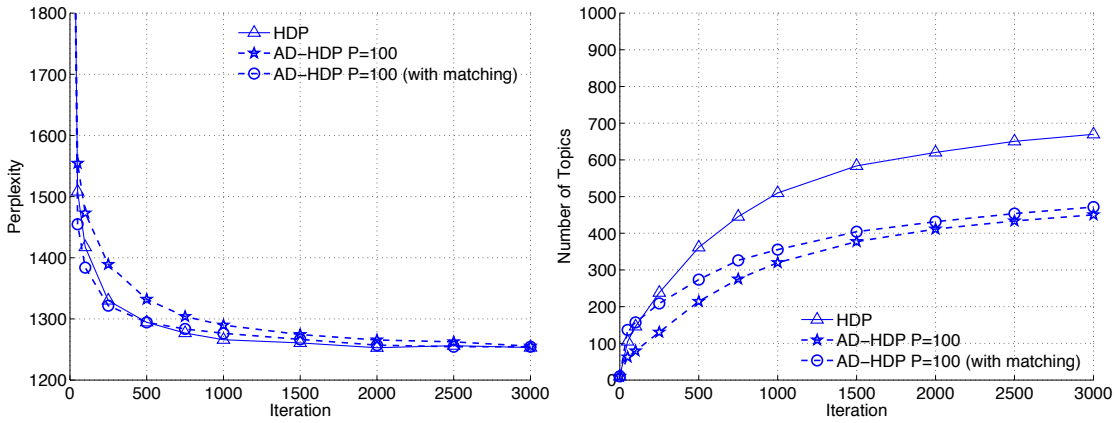

Figure 9: Results for HDP versus AD-HDP with greedy matching. Left plot shows test perplexity versus iteration for HDP and AD-HDP. Right plot shows number of topics versus iteration for HDP and AD-HDP. Results are for the KOS data set.

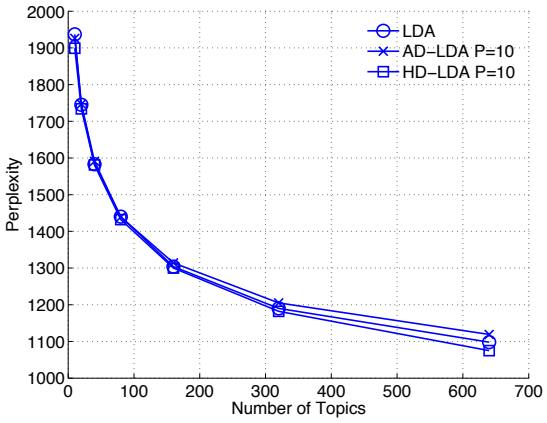

Figure 10: Test perplexity versus number of topics using the NIPS data set (S=5).

the model is learned, each test document can be treated as a "query", where the goal is to retrieve relevant documents from the training set. For each test document, the training documents are ranked according to how probable the test document is under each training document's mixture θ_j and the set of topics ϕ. From this ranking, one can calculate mean average precision and area under the ROC curve.

Figure 11 shows the mean average precision and the area under the ROC curve achieved by LDA and AD-LDA, plotted versus iteration. LDA performs slightly better than AD-LDA for the first 20 iterations, but AD-LDA catches up and converges to the same mean average precision and area under the ROC curve as LDA. This again shows that our distributed/parallel version of LDA produces a very similar result to the single-processor version.

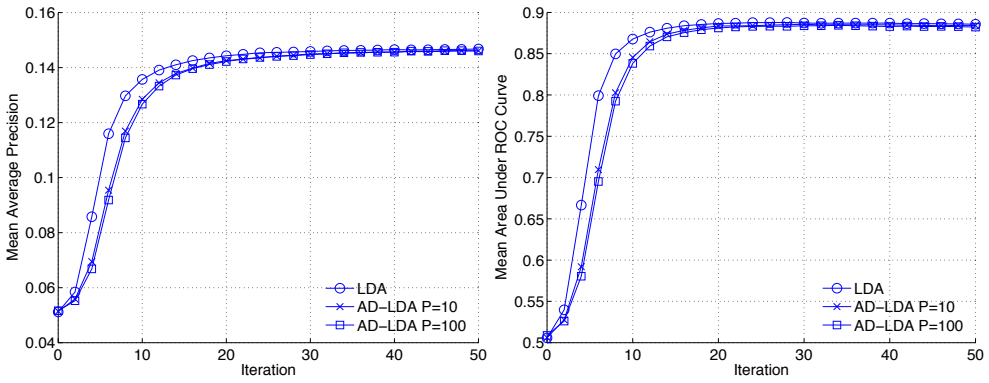

Figure 11: Precision/recall results: (left) Mean average precision for LDA/AD-LDA. (right) Area under the ROC curve for LDA/AD-LDA.

5. Scalability

The primary motivation for developing distributed algorithms for LDA and HDP is to have highly scalable algorithms, in terms of memory and computation time. Memory requirements depend on both memory for data and memory for model parameters. The memory for the data scales with N, the total number of words in the corpus. The memory for the parameters is linear in the number of topics K, which is either fixed for the LDA models or learned for the HDP models. The per-processor per-iteration time and space complexity of LDA and AD-LDA are shown in Table 3. AD-LDA's memory requirement scales well as collection sizes grow, because while corpus size (N and D) can get arbitrarily large, which can be offset by increasing the number of processors, P, the vocabulary size W will tend to asymptote, or at least grow more slowly. Similarly the time complexity scales well since the leading order term NK is divided by P.

The communication cost of the reduce operation, denoted by C in the table, represents the time taken to perform the global sum of the count difference $\sum_p (N_{wkp} - N_{wk})$. This is executed in $\log P$ stages and can be implemented efficiently in standard language/protocols such as MPI, the Message Passing Interface. Because of the additional KW term, parallel efficiency will depend on $\frac{N}{PW}$, with increasing efficiency as this ratio increases. Space and time complexity of HD-LDA are similar to that of AD-LDA, but HD-LDA has bigger constants. For a given number of topics, K, we argue that AD-HDP has similar time complexity as AD-LDA.

We performed large-scale speedup experiments with just AD-LDA instead of all three of our distributed topic modeling algorithms because AD-LDA produces very similar results to HD-LDA, but with significantly less computation. We expect that relative speedup performance for HD-LDA and AD-HDP should follow that for AD-LDA.

	LDA	AD-LDA
Space	$N+K(D+W)$	$\frac{1}{P}(N+KD)+KW$
Time	NK	$\frac{1}{P}NK+KW+C$

Table 3: Space and time complexity of LDA and AD-LDA.

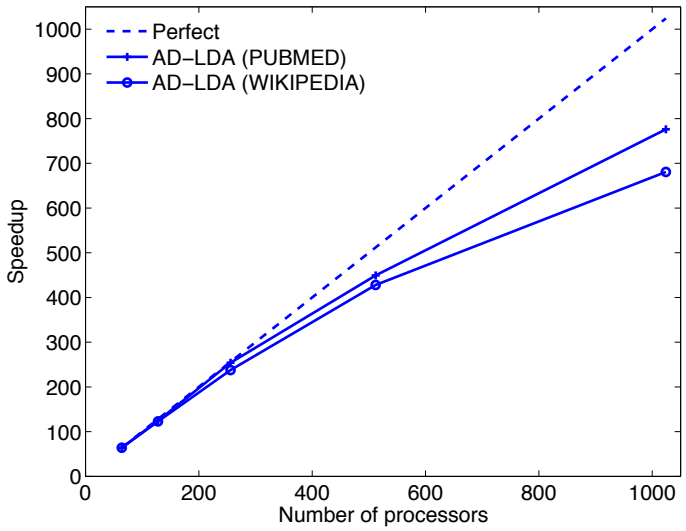

Figure 12: Parallel speedup results for 64 to 1024 processors on multi-million document data sets WIKIPEDIA and PUBMED.

We used two multi-million document data sets, WIKIPEDIA and PUBMED, for speedup experiments on a large-scale supercomputer. The supercomputer used was DataStar, a 15.6 TFlop terascale machine at San Diego Supercomputer Center built from 265 IBM P655 8-way compute nodes. We implemented a parallel version of AD-LDA using the Message Passing Interface protocol. We ran AD-LDA on WIKIPEDIA using $K = 1000$ topics and PUBMED using $K = 2000$ topics distributed over $P = 64, 128, 256, 512$ and 1024 processors. The speedup results, shown in Figure 12, show relatively high parallel efficiency, with approximately 700 times speedup for WIKIPEDIA and 800 times speedup for PUBMED when using $P = 1024$ processors, corresponding to parallel efficiencies of approximately 0.7 and 0.8 respectively. This speedup is computed relative to the time per iteration when using $P = 64$ processors (i.e., at $P = 64$ processors speedup=64), since it is not possible, due to memory limitations, to run these models on a single processor. Multiple runs were timed for both WIKIPEDIA and PUBMED, and the resulting variation in timing was less than 1%, so error bars are not shown in the figure. We see slightly higher parallel efficiency for PUBMED versus WIKIPEDIA because PUBMED has a larger amount of computation per unit data communicated, $\frac{N}{PW}$.

This speedup dramatically reduces the learning time for large topic models. If we were to learn a $K = 2000$ topic model for PUBMED using LDA on a single processor, it would require over 300 days instead of the 10 hours required to learn the same model using AD-LDA on 1024 processors. In our speedup experiments on these large data sets, we did not directly investigate latency or communication bandwidth effects. Nevertheless, one could expect that if the communication time becomes very long compared to the computation time, then it may be worth doing multiple Gibbs sampling sweeps on a processor's local data before performing the synchronization and global update step. In Section 6 we further examine this question of frequency of synchronizations. The relative time for communication versus computation also effects the weak scaling of parallelization, where the problem size increases linearly with the number of processors. We expect that parallel efficiency will be relatively constant for weak scaling since $\frac{N}{PW}$ is constant.

In addition to the large-scale speedup experiments run on the 1024-processor parallel supercomputer, we also performed small-scale speedup experiments for AD-HDP on an 8-node parallel cluster running MPI. Using the NIPS data set we measured parallel efficiencies of 0.75 and 0.5 for $P = 4$ and $P = 8$. The latter result on 8 processors means that the HDP model for NIPS can be learned four times faster than on a single processor.

6. Analysis of Approximate Distributed LDA

Finally, we investigate the dynamics of AD-LDA learning using toy data to get further insight into how AD-LDA is working. While we have shown experimental results showing that AD-LDA produces models with similar perplexity and similar convergence rates to LDA, it is not obvious why this algorithm works so well in practice. Our toy example has $W = 3$ words and $K = 2$ topics. We generated document collections according to the LDA generative process given by (1). We chose a low dimension vocabulary, W, so that we could plot the evolution of the Gibbs sampler on a two-dimensional word-topic simplex. We first generated data, then learned models using LDA and AD-LDA.

The left plot of Figure 13 shows the L_1 distance between the model's estimate of a particular topic-word distribution and the true distribution, as a function of Gibbs iteration, for both single-processor LDA and AD-LDA with $P = 2$. LDA and AD-LDA have qualitatively the same three-phase learning dynamics. The first four or so iterations (labeled *initialize*) correspond to somewhat random movement close to the randomly initialized starting point. In the next phase (labeled *burn-in*) both algorithms rapidly move in parameter space toward the posterior mode. And finally after burn-in (labeled *stationary*) both are sampling around the mode. In the right plot we show the similarity between AD-LDA and LDA samples taken from the equilibrium distribution—here plotted on the two-dimensional planar simplex corresponding to the three-word topic distribution.

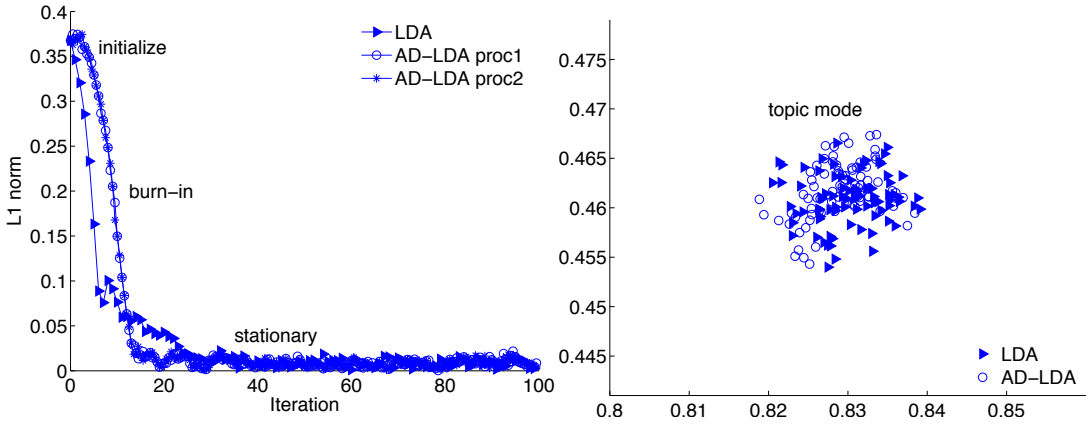

Figure 13: (Left) L_1 distance to the mode for LDA and for $P = 2$ AD-LDA. (Right) Closeup of 50 samples of ϕ (projected onto the topic simplex) taken from the equilibrium distribution, showing the similarity between LDA and $P = 2$ AD-LDA. Note the zoomed scale in this figure.

The left plot of Figure 14 depicts the same trajectory shown in Figure 13 left, projected onto the topic simplex. This plot shows the paths in parameter space of each model, and the same three-phase

learning dynamics: taking a few small steps near the starting point, moving up to the true solution, and then sampling near the posterior mode for the rest of the iterations. For each Gibbs iteration, the parameters corresponding to each of the two individual processors, and those parameters after merging, are shown for AD-LDA. One can see the alternating pattern of two separate (but close) parameter estimates on each processor, followed by a merged estimate. We observed that after the initial few iterations, the individual processor steps and the merge step each resulted in a move closer to the mode. One might worry that the AD-LDA algorithm would get trapped close to the initial starting point, for example, due to repeated label switching or oscillatory behavior of topic labeling across processors. In practice we have consistently observed that the algorithm quickly discards such configurations due to the stochastic nature of the moves and latches onto a consistent and stable labeling that rapidly moves it toward the posterior mode. The figure clearly illustrates that LDA and AD-LDA have qualitatively similar learning dynamics. The right plot in Figure 14 illustrates the same qualitative behavior as in the left plot, but now for $P = 10$ processors.

Interestingly, across a wide range of experiments, we observed that the variance in the AD-LDA word-topic distribution samples is typically only about 70% of the variance in LDA topic samples. Since the samplers are not the same it makes sense that the posterior variance differs (i.e., is underestimated) by the parallel sampler. We expect less variance because AD-LDA ignores fluctuations in the bulk of N_{wk}. Nonetheless, all of our experiments indicate that the posterior mode and means found by the parallel sampler are essentially the same as those found by the sequential sampler.

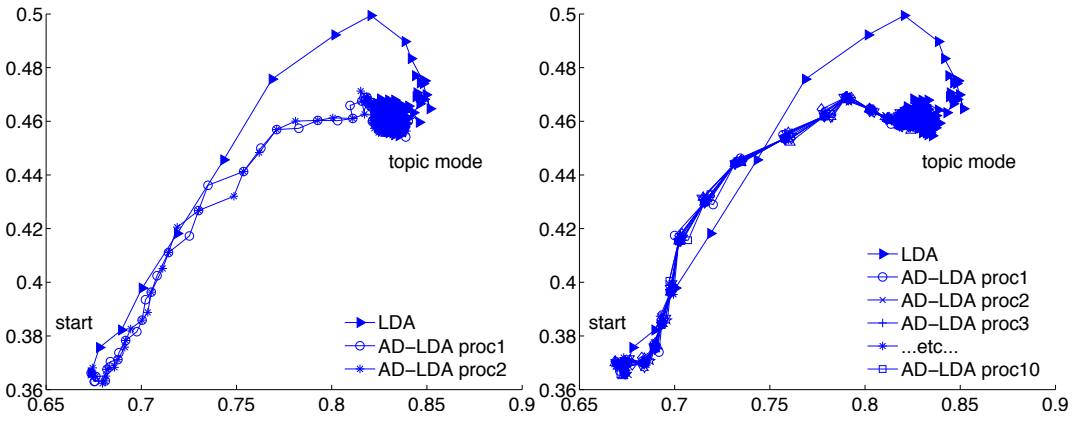

Figure 14: (Left) Projection of topics onto simplex, showing convergence to mode for $P = 2$. (Right) Same as left plot, but with $P = 10$.

Another insight can be gained by thinking of LDA as an approximation to stochastic descent in the space of assignment variables $\mathbf{z}$. On a single processor, one can view Gibbs sampling during burn-in as a stochastic algorithm to move up the likelihood surface. With multiple processors, each processor computes an upward direction in its own subspace, keeping all other directions fixed. The global update step then recombines these directions by vector-addition, in the same way as one would compute a gradient using finite differences. This is expected to be accurate as long as the surface is locally convex or concave, but will break down at saddle-points. We conjecture AD-LDA works reliably because saddle points are unstable and rare because the posterior is usually highly peaked for LDA models and high-dimensional count data sets.

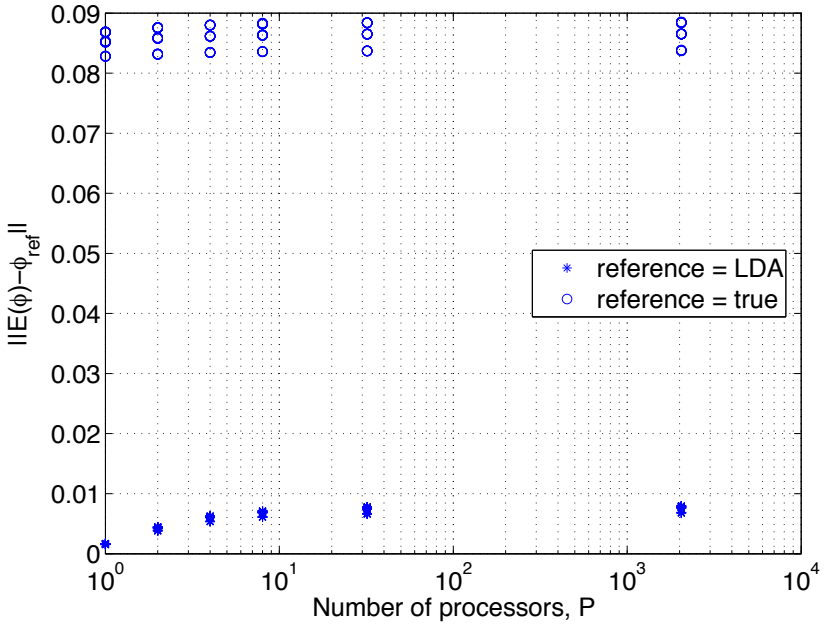

Figure 15: Average L_1 error in word-topic distribution versus P for AD-LDA.

While we see similar perplexities for AD-LDA compared to LDA, we could further ask if the AD-LDA algorithm is producing any bias in its estimates of the model parameters. To test this, we performed a series of experiments where we generated synthetic data sets according to the LDA generative process, with known word-topic distributions ϕ^*. We then learned LDA and AD-LDA models from each of the simulated data sets. We computed the expected value of the AD-LDA topics $E(\phi)$ and compared this to two reference values, ϕ_{ref} one based on the true distribution, $\phi_{\text{ref}} = \phi^*$, the other based on multiple LDA samples, $\phi_{\text{ref}} = E[\phi_{\text{LDA}}]$. Figure 15 shows that AD-LDA is much closer to the LDA topics $E[\phi_{\text{LDA}}]$ than either are to the true topics ϕ^*, telling us that the sampling variation in learning LDA models from finite data sets is much greater than the variation between LDA and AD-LDA on the same data sets.

6.1 When Does AD-LDA Fail?

In all of our experiments thus far, we have seen that our distributed algorithms learn models with equivalent predictive power as their non-distributed counterparts. However, when global synchronizations are done less frequently (i.e., when the synchronization step is performed after multiple Gibbs sampling sweeps through local data), the distributed algorithms may converge to suboptimal solutions.

When the synchronization interval is increased dramatically, it is possible for AD-LDA to converge to a suboptimal solution. This can happen because the topics (with the same integer label) on each processor can drift far apart, so that topic k on one processor diverges from topic k on another processor. In Figure 16, we show the results of an experiment on KOS where synchronizations only occur once every 100 iterations. For $P = 2$ processors, AD-LDA performs significantly worse than LDA. The $P = 2$ processor case is the worst case for AD-LDA, since one half of the total words on

each processor have the freedom to drift. In contrast, when $P = 100$ processors, each processor can only locally modify $1/100^{th}$ of the topic assignments, and so the topics on each processor can not drift far from the global set of topic counts at the previous iteration. Bipartite matching significantly improves the perplexity in the $P = 2$ processor case, suggesting that the lack of communication has indeed caused the topics to drift apart. Fortunately, topic drifting becomes less of a problem as more processors are used, and can be eliminated by frequent synchronization. It is also important to note that AD-LDA $P = 2$, where processors synchronize after every iteration, gives essentially identical results as LDA. Our recommendation in practice is to perform the synchronization and count updates after each iteration of the Gibbs sampler. As shown earlier in the paper, this leads to performance that is essentially indistinguishable from LDA. Since most multi-processor computing hardware will tend to have communication bandwidth matched to processor speed (i.e., faster and/or more processors usually come with a faster communication network), synchronizing after each iteration of the Gibbs sampler will usually be the optimal strategy.

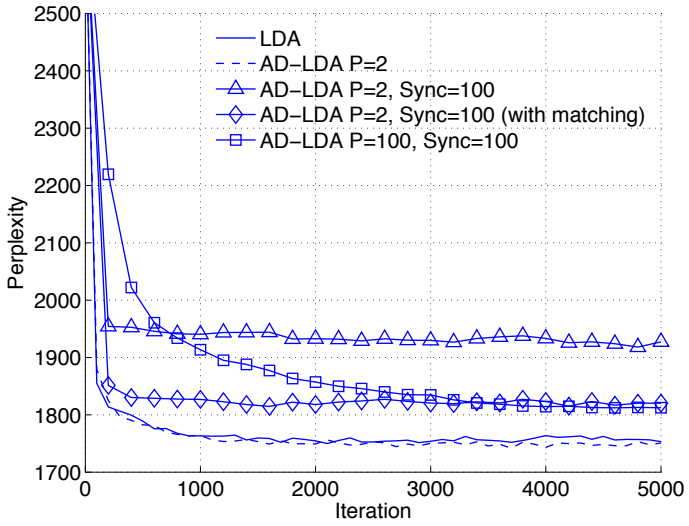

Figure 16: Test perplexity versus iteration where synchronizations between processors only occur every 100 iterations, KOS, $K = 16$.

7. Related Work

Approximate inference for topic models such as LDA and HDP can be carried out using a variety of methods, the most common being variational methods and Markov chain Monte Carlo methods. Previous efforts to parallelize these algorithms have focused on variational methods, which are often straightforward to cast in a distributed framework. For example, Blei et al. (2002) and Nallapati et al. (2007) describe distributed variational EM methods for LDA. In their distributed variational approach, the computationally expensive E-step is easily parallelized because the document-specific variational parameters are independent. Wolfe et al. (2008) investigate the parallelization of both the E and M-steps of variational EM for LDA, under a variety of computer network topologies. In these cases the distributed version of LDA produces identical results to the sequential version of the algorithm. However, memory for variational inference in LDA scales as MK, where M is

the number of distinct document-word pairs in the corpus. For typical English-language corpora, the total number of words in the corpus is less than twice the number of distinct document-word pairs ($N < 2M$), so M can be considered on the order of N. Since M is usually much larger than the number of documents, D, this memory requirement of MK is not nearly as scalable as that the memory requirement of $N + DK$ for MCMC methods.

Parallelized versions of various machine learning algorithms have also been developed. Forman and Zhang (2000) describe a parallel k-means algorithm, and W. Kowalczyk and N. Vlassis (2005) describe an asynchronous parallel EM algorithm for Gaussian mixture learning. A parallel EM algorithm for Probabilistic Latent Semantic Analysis, implemented using Google's MapReduce framework, was described in Das et al. (2007). A review of how to parallelize an array of standard machine learning algorithms using MapReduce was presented by Chu et al. (2007). Rossini et al. (2007) presents a framework for statisticians that allows for the parallel computing of independent tasks within the R language.

While many of these EM algorithms are readily parallelizable, Gibbs sampling of dependent variables (such as topic assignments) is fundamentally sequential and therefore difficult to parallelize. One way to parallelize Gibbs sampling is to run multiple independent chains in parallel to obtain multiple samples; however, this multiple-chain approach does not address the fact that the burn-in within each chain may take a long time. Furthermore, for some applications, one is not interested in multiple samples from independent chains. For example, if we wish to learn topics for a very large document collection, one is usually satisfied with mean values of word-topic distributions taken from a single chain.

One can parallelize a single MCMC chain by decomposing the variables into independent non-interacting blocks that can be sampled concurrently (Kontoghiorghes, 2005). However, when the variables are not independent, sampling variables in parallel is not possible. Brockwell (2006) presents a general parallel MCMC algorithm based on pre-fetching, but it is not practical for learning topic models because it discards most of its computations which makes it relatively inefficient. It is possible to construct partially parallel Gibbs samplers, in which the samples are independently accepted with some probability. In the limit as this probability goes to zero, this sampler will approach the sequential Gibbs sampler, as explained in P. Ferrari et al. (1993). However, this method is also not practical when learning topic models because it is computationally inefficient. Younes (1998) shows the existence of exact parallel samplers that make use of periodic synchronous random fields. However there is no known method for constructing such a sampler.

Our HD-LDA model is similar to the DCM-LDA model presented by Mimno and McCallum (2007). There the authors perform topic modeling on a collection of books by learning a different topic model for each book and then clustering these learned topics together to find global topics. In this model, the concept of a book is directly analogous to our concept of a processor. DCM-LDA uses Stochastic EM along with agglomerative clustering to learn topics, while our HD-LDA follows a fully Bayesian approach for inference. HD-LDA also differs from other topic hierarchies found in the literature. The Hierarchical Dirichlet Process model of Teh et al. (2006) places a deeper hierarchical prior on the topic mixture, instead of on the word-topic distributions. The Pachinko Allocation Model presented by Li and McCallum (2006) deals with a document-specific hierarchy of topic-assignments. These types of hierarchies do not directly facilitate proper parallel Gibbs sampling as is done in HD-LDA.

8. Conclusions

We have proposed three different algorithms for distributing across multiple processors Gibbs sampling for LDA and HDP. With our approximate distributed algorithm, AD-LDA, we sample from an approximation to the posterior distribution by allowing different processors to concurrently sample topic assignments on their local subsets of the data. Despite having no formal convergence guarantees, AD-LDA works very well empirically and is easy to implement. With our hierarchical distributed model, HD-LDA, we adapt the underlying LDA model to map to the distributed processor architecture. This model is more complicated than AD-LDA, but it inherits the usual convergence properties of Markov chain Monte Carlo. We discovered that careful selection of hyperparameters was critical to making HD-LDA work well, but this selection was clearly informed by AD-LDA. Our distributed algorithm AD-HDP followed the same approach as AD-LDA, but with an additional step to merge newly instantiated topics.

Our proposed distributed algorithms learn LDA models with predictive performance that is no different than single-processor LDA. On each processor they burn-in and converge at the same rate as LDA, yielding significant speedups in practice. For HDP, our distributed algorithm eventually produced the same perplexity as the single-processor version of HDP. Prior to reaching the converged perplexity result, AD-HDP had higher perplexity than HDP since the merging of new topics by label slows the rate of topic growth. We also discovered that matching new topics by similarity significantly improves AD-HDP's rate of convergence.

The space and time complexity of these distributed algorithms make them scalable to run very large data sets, for example, collections with billions to trillions of words. Using two multi-million document data sets, and running computations on a 1024-processor parallel supercomputer, we showed how one can achieve a 700-800 times reduction in wall-clock time by using our distributed approach.

There are several potentially interesting research directions that can be pursued using the algorithms proposed here as a starting point. One research direction is to use more complex schemes that allow data to adaptively move from one processor to another. The distributed schemes presented in this paper can also be used to parallelize topic models that are based on or derived from LDA and HDP, and beyond that a potentially larger class of graphical models.

Appendix A.

The auxiliary variable method explained in Escobar and West (1995) and Teh et al. (2006) is used to sample α, β, and Φ. To derive Gibbs sampling equations, we use the following expansions:

$$\frac{\Gamma(u)}{\Gamma(u+n)} = \frac{1}{\Gamma(n)} B(u,n) = \frac{1}{\Gamma(n)} \int_0^1 t^{u-1}(1-t)^{n-1}\,dt \tag{8}$$

$$\frac{\Gamma(u+n)}{\Gamma(u)} = \sum_{s=0}^{n} S(n,s)(u)^s \qquad \text{(S is Stirling number of first kind)} \tag{9}$$

The first expansion follows from the definition of the Beta function, and the second expansion makes use of the Stirling number of the first kind to rewrite the factorial (see Abramowitz and Stegun, 1964).

Now we derive the sampling equation for α_p. Combining the collapsed distribution (6) with the prior on α_p (5) gives the posterior distribution for α_p:[1]

$$P(\alpha_p|_-) \propto \prod_j \left[\frac{\Gamma(K\alpha_p)}{\Gamma(N_{jp}+K\alpha_p)} \prod_k \frac{\Gamma(N_{kjp}+\alpha_p)}{\Gamma(\alpha_p)}\right] \alpha_p^{c-1} e^{-d\alpha_p}.$$

Using the expansions (8,9) we introduce the auxiliary variables $\mathbf{t}$ and $\mathbf{s}$:

$$P(\alpha_p, \mathbf{t}, \mathbf{s}|_-) \propto \left[\prod_j t_j^{K\alpha_p - 1}(1-t_j)^{N_{jp}-1}\,dt_j\right] \left[\prod_j \prod_k S(N_{kjp}, s_{kjp}) \alpha_p^{s_{kjp}}\right] \alpha_p^{c-1} e^{-d\alpha_p}.$$

The joint distribution above allows us to create sampling equations for α_p, $\mathbf{t}$, and $\mathbf{s}$:

$$\begin{aligned} P(\alpha_p|\mathbf{t},\mathbf{s},_-) &\propto \left[\prod_j t_j^{K\alpha_p}\right] \left[\prod_j \prod_k \alpha_p^{s_{kjp}}\right] \alpha_p^{c-1} e^{-d\alpha_p} \\ &= \text{Gamma}\left[c + \sum_j \sum_k s_{kjp}; d - K\sum_j \log(t_j)\right], \end{aligned}$$

$$\begin{aligned} P(t_j|\alpha_p,\mathbf{s},_-) &\propto t_j^{K\alpha_p - 1}(1-t_j)^{N_{jp}-1} \\ &= \text{Beta}\,[K\alpha_p, N_{jp}], \end{aligned}$$

$$\begin{aligned} P(s_{kjp}|\alpha_p,\mathbf{t},_-) &\propto S(N_{kjp}, s_{kjp}) \alpha_p^{s_{kjp}} \\ &= \text{Antoniak}\,[N_{kjp}, \alpha_p]. \end{aligned}$$

The Antoniak distribution is the distribution of the number of occupied tables if N_{kjp} customers are sent into a restaurant that follows the Chinese restaurant process with strength parameter α_p. Sampling from the Antoniak distribution is done by sampling N_{kjp} Bernoulli variables:

1. To avoid notational clutter, we denote conditioned-upon variables and parameters by a dash. These variables can be inferred from context.

$$s^l_{kjp} \sim \text{Bernoulli}\left[\frac{\alpha_p}{\alpha_p + l - 1}\right] \qquad l = 1 \ldots N_{kjp},$$
$$s_{kjp} = \sum_l s^l_{kjp}.$$

Using the same auxiliary variable techniques, we derive sampling equations for β and Φ. These variables are sampled jointly because they are dependent. The posterior distribution for β and Φ and the joint distribution with the auxiliary variables $\mathbf{t}$ and $\mathbf{s}$ are given by:

$$P(\beta_k, \Phi_k|\_) \propto \prod_p \left[\frac{\Gamma(\beta_k)}{\Gamma(N_{kp}+\beta_k)} \prod_w \frac{\Gamma(N_{wkp}+\beta_k\Phi_{w|k})}{\Gamma(\beta_k\Phi_{w|k})}\right] \left[\prod_w \Phi^{\gamma-1}_{w|k}\right] \beta_k^{a-1} e^{-b\beta_k},$$
$$P(\beta_k, \Phi_k, \mathbf{t}, \mathbf{s}|\_) \propto \left[\prod_p t_{kp}^{\beta_k - 1}(1-t_{kp})^{N_{kp}-1}\right] \left[\prod_p \prod_w S(N_{wkp}, s_{wkp})(\beta_k\Phi_{w|k})^{s_{wkp}}\right]$$
$$\left[\prod_k \prod_w \Phi^{\gamma-1}_{w|k}\right] \beta_k^{a-1} e^{-b\beta_k}.$$

Note that the set of variables ($\mathbf{t}$ and $\mathbf{s}$) is unrelated to the set of auxiliary variables introduced for α_p. The sampling equations for β, Φ, $\mathbf{t}$, and $\mathbf{s}$ are:

$$P(\beta_k|\Phi, \mathbf{t}, \mathbf{s}, \_) \propto \left[\prod_p t_{kp}^{\beta_k}\right] \left[\prod_p \prod_w (\beta_k)^{s_{wkp}}\right] \beta_k^{a-1} e^{-b\beta_k}$$
$$= \text{Gamma}\left[a + \sum_p \sum_w s_{wkp}; b - \sum_p log(t_{kp})\right],$$

$$P(\Phi_k|\beta_k, \mathbf{t}, \mathbf{s}, \_) \propto \left[\prod_p \prod_w \Phi^{s_{wkp}}_{w|k}\right] \left[\prod_w \Phi^{\gamma-1}_{w|k}\right]$$
$$= \text{Dirichlet}\left[\gamma + \sum_p s_{wkp}\right],$$

$$P(t_{kp}|\beta_k, \Phi_k, \mathbf{s}, \_) \propto t_{kp}^{\beta_k - 1}(1-t_{kp})^{N_{kp}-1}$$
$$= \text{Beta}\left[\beta_k, N_{kp}\right],$$

$$P(s_{wkp}|\beta_k, \Phi_k, \mathbf{t}, \_) \propto S(N_{wkp}, s_{wkp})(\beta_k\Phi_{w|k})^{s_{wkp}}$$
$$= \text{Antoniak}\left[N_{wkp}, \beta_k\Phi_{w|k}\right].$$

Abstract

We introduce a new nonlinear model for classification, in which we model the joint distribution of response variable, y, and covariates, x, non-parametrically using Dirichlet process mixtures. We keep the relationship between y and x linear within each component of the mixture. The overall relationship becomes nonlinear if the mixture contains more than one component, with different regression coefficients. We use simulated data to compare the performance of this new approach to alternative methods such as multinomial logit (MNL) models, decision trees, and support vector machines. We also evaluate our approach on two classification problems: identifying the folding class of protein sequences and detecting Parkinson's disease. Our model can sometimes improve predictive accuracy. Moreover, by grouping observations into sub-populations (i.e., mixture components), our model can sometimes provide insight into hidden structure in the data.

Keywords: mixture models, Dirichlet process, classification

1. Introduction

In regression and classification models, estimation of parameters and interpretation of results are easier if we assume that distributions have simple forms (e.g., normal) and that the relationship between a response variable and covariates is linear. However, the performance of such a model depends on the appropriateness of these assumptions. Poor performance may result from assuming wrong distributions, or regarding relationships as linear when they are not. In this paper, we introduce a new model based on a Dirichlet process mixture of simple distributions, which is more flexible in capturing nonlinear relationships.

A Dirichlet process, $\mathcal{D}(G_0, \gamma)$, with baseline distribution G_0 and scale parameter γ, is a distribution over distributions. Ferguson (1973) introduced the Dirichlet process as a class of prior distributions for which the support is large, and the posterior distribution is manageable analytically. Using the Polya urn scheme, Blackwell and MacQueen (1973) showed that the distributions sampled from a Dirichlet process are discrete almost surely.

The idea of using a Dirichlet process as the prior for the mixing proportions of a simple distribution (e.g., Gaussian) was first introduced by Antoniak (1974). In this paper, we will describe the Dirichlet process mixture model as a limit of a finite mixture model (see Neal, 2000, for further description). Suppose exchangeable random values $y_1, ..., y_n$ are drawn independently from some

unknown distribution. We can model the distribution of y as a mixture of simple distributions, with probability or density function

$$P(y) \quad = \quad \sum_{c=1}^{C} p_c F(y, \phi_c).$$

Here, p_c are the mixing proportions, and $F(y,\phi)$ is the probability or density for y under a distribution, $F(\phi)$, in some simple class with parameters ϕ—for example, a normal in which $\phi = (\mu, \sigma)$. We first assume that the number of mixing components, C, is finite. In this case, a common prior for p_c is a symmetric Dirichlet distribution, with density function

$$P(p_1, ..., p_C) \quad = \quad \frac{\Gamma(\gamma)}{\Gamma(\gamma/C)^C} \prod_{c=1}^{C} p_c^{(\gamma/C)-1},$$

where $p_c \geq 0$ and $\sum p_c = 1$. The parameters ϕ_c are independent under the prior, with distribution G_0. We can use mixture identifiers, c_i, and represent this model as follows:

$$\begin{aligned} y_i | c_i, \phi &\sim F(\phi_{c_i}), \\ c_i | p_1, ..., p_C &\sim \mathit{Discrete}(p_1, ..., p_C), \\ p_1, ..., p_C &\sim \mathit{Dirichlet}(\gamma/C, ..., \gamma/C), \\ \phi_c &\sim G_0. \end{aligned} \tag{1}$$

By integrating over the Dirichlet prior, we can eliminate the mixing proportions, p_c, and obtain the following conditional distribution for c_i:

$$P(c_i = c | c_1, ..., c_{i-1}) \quad = \quad \frac{n_{ic} + \gamma/C}{i - 1 + \gamma}. \tag{2}$$

Here, n_{ic} represents the number of data points previously (i.e., before the i^{th}) assigned to component c. As we can see, the above probability becomes higher as n_{ic} increases.

When C goes to infinity, the conditional probabilities (2) reach the following limits:

$$\begin{aligned} P(c_i = c | c_1, ..., c_{i-1}) &\rightarrow \frac{n_{ic}}{i - 1 + \gamma}, \\ P(c_i \neq c_j \text{ for all } j < i | c_1, ..., c_{i-1}) &\rightarrow \frac{\gamma}{i - 1 + \gamma}. \end{aligned}$$

As a result, the conditional probability for θ_i, where $\theta_i = \phi_{c_i}$, becomes

$$\theta_i | \theta_1, ..., \theta_{i-1} \quad \sim \quad \frac{1}{i - 1 + \gamma} \sum_{j<i} \delta_{\theta_j} + \frac{\gamma}{i - 1 + \gamma} G_0, \tag{3}$$

where δ_θ is a point mass distribution at θ. Since the observations are assumed to be exchangeable, we can regard any observation, i, as the last observation and write the conditional probability of θ_i given the other θ_j for $j \neq i$ (written θ_{-i}) as follows:

$$\theta_i | \theta_{-i} \quad \sim \quad \frac{1}{n - 1 + \gamma} \sum_{j \neq i} \delta_{\theta_j} \; + \; \frac{\gamma}{n - 1 + \gamma} G_0. \tag{4}$$

The above conditional probabilities are equivalent to the conditional probabilities for θ_i according to the Dirichlet process mixture model (as presented by Blackwell and MacQueen, 1973, using the Polya urn scheme), which has the following form:

$$\begin{aligned} y_i|\theta_i &\sim F(\theta_i), \\ \theta_i|G &\sim G, \\ G &\sim \mathcal{D}(G_0,\gamma). \end{aligned} \tag{5}$$

That is, If we let $\theta_i = \phi_{c_i}$, the limit of model (1) as $C \to \infty$ becomes equivalent to the Dirichlet process mixture model (Ferguson, 1983; Neal, 2000). In model (5), G is the distribution over θ's, and has a Dirichlet process prior, $\mathcal{D}$. Phrased this way, each data point, i, has its own parameters, θ_i, drawn independently from a distribution that is drawn from a Dirichlet process prior. But since distributions drawn from a Dirichlet process are discrete (almost surely) as shown by Blackwell and MacQueen (1973), the θ_i for different data points may be the same.

The parameters of the Dirichlet process prior are G_0, a distribution from which θ's are sampled, and γ, a positive scale parameter that controls the number of components of the mixture that will be represented in the sample, such that a larger γ results in a larger number of components. To illustrate the effect of γ on the number of mixture components in a sample of size 200, we generated samples from four different Dirichlet process priors with $\gamma = 0.1, 1, 5, 10$, and the same baseline distribution $G_0 = N_2(0, 10I_2)$ (where I_2 is a 2×2 identity matrix). For a given value of γ, we first sample θ_i, where $i = 1, ..., 200$, according to the conditional probabilities (3), and then we sample $y_i|\theta_i \sim N_2(\theta_i, 0.2I_2)$. The data generated according to these priors are shown in Figure 1. As we can see, the (prior) expected number of components in a finite sample increases as γ becomes larger.

With a Dirichlet process prior, we can we find conditional distributions of the posterior distribution of model parameters by combining the conditional prior probability of (4) with the likelihood $F(y_i, \theta_i)$, obtaining

$$\theta_i|\theta_{-i}, y_i \sim \sum_{j \neq i} q_{ij}\delta_{\theta_j} + r_i H_i, \tag{6}$$

where H_i is the posterior distribution of θ based on the prior G_0 and the single data point y_i, and the values of the q_{ij} and r_i are defined as follows:

$$\begin{aligned} q_{ij} &= bF(y_i, \theta_j), \\ r_i &= b\gamma \int F(y_i, \theta) dG_0(\theta). \end{aligned}$$

Here, b is such that $r_i + \sum_{j \neq i} q_{ij} = 1$. These conditional posterior distributions are what are needed when sampling the posterior using MCMC methods, as discussed further in Section 2.

Bush and MacEachern (1996), Escobar and West (1995), MacEachern and Müller (1998), and Neal (2000) have used Dirichlet process mixture models for density estimation. Müller et al. (1996) used this method for curve fitting. They model the joint distribution of data pairs (x_i, y_i) as a Dirichlet process mixture of multivariate normals. The conditional distribution, $P(y|x)$, and the expected value, $E(y|x)$, are estimated based on this distribution for a grid of x's (with interpolation) to obtain a nonparametric curve. The application of this approach (as presented by Müller et al., 1996) is restricted to continuous variables. Moreover, this model is feasible only for problems with a small number of covariates, p. For data with moderate to large dimensionality, estimation of the joint

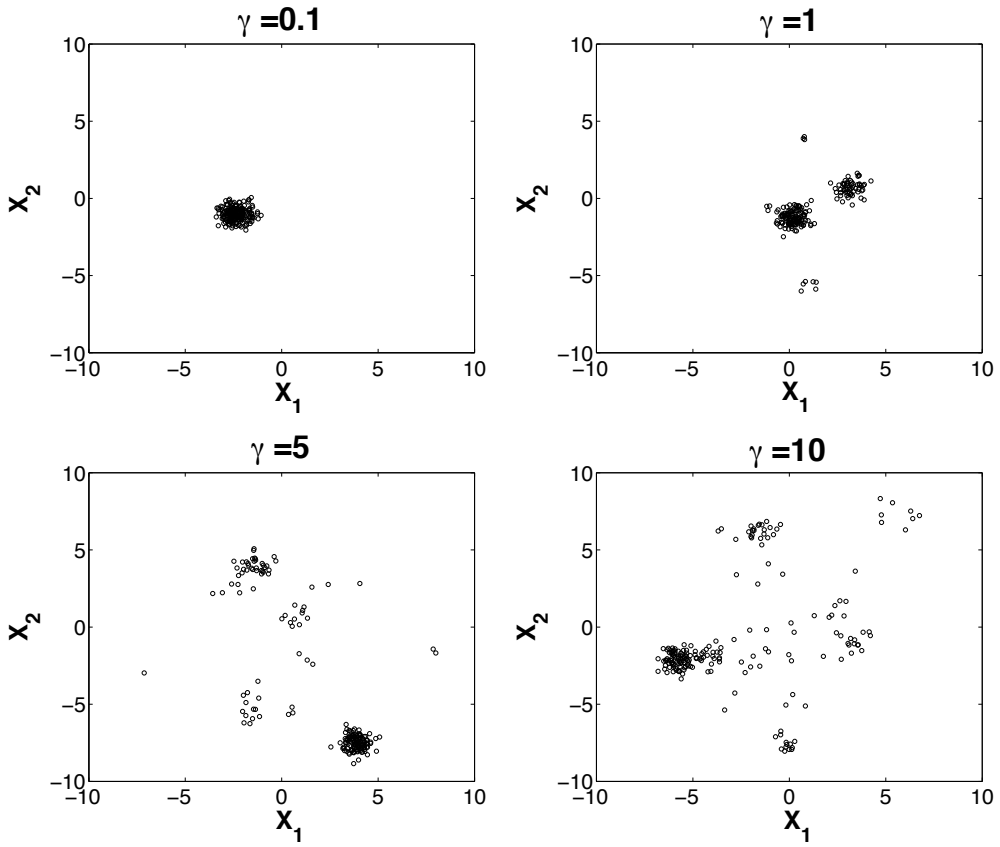

Figure 1: Data sets of size $n = 200$ generated according to four different Dirichlet process mixture priors, each with the same baseline distribution, $G_0 = N_2(0, 10I_2)$, but different scale parameters, γ. As γ increases, the expected number of components present in the sample becomes larger. (Note that, as can be seen above, when γ is large, many of these components have substantial overlap.)

distribution is very difficult both statistically and computationally. This is mostly due to the difficulties that arise when simulating from the posterior distribution of large full covariance matrices. In this approach, if a mixture model has C components, the set of full covariance matrices have $Cp(p+1)/2$ parameters. For large p, the computational burden of estimating these parameters might be overwhelming. Estimating full covariance matrices can also cause statistical difficulties since we need to assure that covariance matrices are positive semidefinite. Conjugate priors based the inverse Wishart distribution satisfy this requirement, but they lack flexibility (Daniels and Kass, 1999). Flat priors may not be suitable either, since they can lead to improper posterior distributions, and they can be unintentionally informative (Daniels and Kass, 1999). A common approach to address these issues is to use decomposition methods in specifying priors for full covariance matrices (see for example, Daniels and Kass, 1999; Cai and Dunson, 2006). Although this approach has demonstrated some computational advantages over direct estimation of full covariance matrices, it is not yet feasible for high-dimensional variables. For example, Cai and Dunson (2006) recommend their approach only for problems with less than 20 covariates.

We introduce a new nonlinear Bayesian model, which also nonparametrically estimates $P(x,y)$, the joint distribution of the response variable y and covariates x, using Dirichlet process mixtures. Within each component, we assume the covariates are independent, and model the dependence between y and x using a linear model. Therefore, unlike the method of Müller et al. (1996), our approach can be used for modeling data with a large number of covariates, since the covariance matrix for one mixture component is highly restricted. Using the Dirichlet process as the prior, our method has a built-in mechanism to avoid overfitting since the complexity of the nonlinear model is controlled. Moreover, this method can be used for categorical as well as continuous response variables by using a generalized linear model instead of the linear model.

The idea of building a nonlinear model based on an ensemble of simple linear models has been explored extensively in the field of machine learning. Jacobs et al. (1991) introduced a supervised learning procedure for models that are comprised of several local models (experts) each handling a subset of data. A gating network decides which expert should be used for a given data point. For inferring the parameters of such models, Waterhouse et al. (1996) provided a Bayesian framework to avoid over-fitting and noise level under-estimation problems associated with traditional maximum likelihood inference. Rasmussen and Ghahramani (2002) generalized mixture of experts models by using infinitely many nonlinear experts. In their approach, each expert is assumed to be a Gaussian process regression model, and the gating network is based on an input-dependent adaptation of Dirichlet process. Meeds and Osindero (2006) followed the same idea, but instead of assuming that the covariates are fixed, they proposed a joint mixture of experts model over covariates and response variable.

Our focus here is on classification models with a multi-category response, in which we have observed data for n cases, (x_1,y_1),...,(x_n,y_n). Here, the class y_i has J possible values, and the covariates x_i can in general be a vector of p covariates. We wish to classify future cases in which only the covariates are observed. For binary ($J = 2$) classification problems, a simple logistic model can be used, with class probabilities defined as follows (with the case subscript dropped from x and y):

$$P(y = 1|x,\alpha,\beta) \quad = \quad \frac{\exp(\alpha + x^T\beta)}{1+\exp(\alpha + x^T\beta)}.$$

When there are three or more classes, we can use a generalization known as the multinomial logit (MNL) model (called "softmax" in the machine learning literature):

$$P(y = j|x,\alpha,\beta) \quad = \quad \frac{\exp(\alpha_j + x^T\beta_j)}{\sum_{j'=1}^{J}\exp(\alpha_{j'} + x^T\beta_{j'})}.$$

MNL models are *discriminative*, since they model the conditional distribution $P(y|x)$, but not the distribution of covariates, $P(x)$. In contrast, our dpMNL model is *generative*, since it estimates the joint distribution of response and covariates, $P(x,y)$. The joint distribution can be decompose into the product of the marginal distribution $P(x)$ and the conditional distribution $P(y|x)$; that is, $P(x,y) = P(x)P(y|x)$.

Generative models have several advantages over discriminative models (see for example, Ulusoy and Bishop, 2005). They provide a natural framework for handling missing data or partially labeled data. They can also augment small quantities of expensive labeled data with large quantities of cheap unlabeled data. This is especially useful in applications such as document labeling and image analysis, where it may provide better predictions for new feature patterns not present in the data at

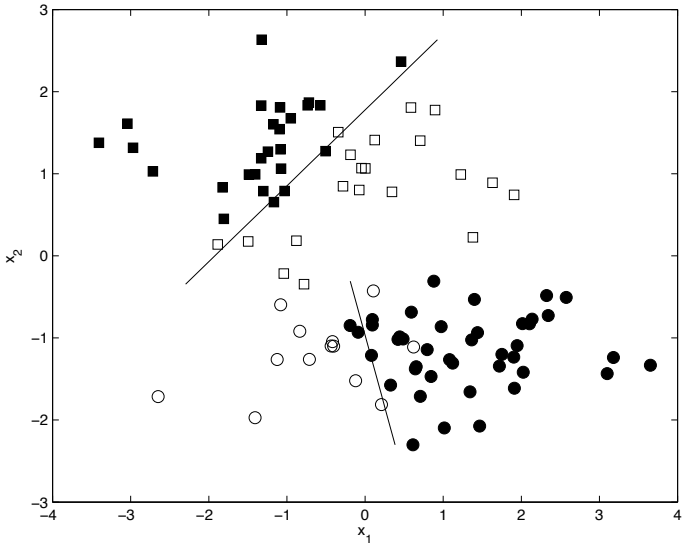

Figure 2: An illustration of our model for a binary (black and white) classification problem with two covariates. Here, the mixture has two components, which are shown with circles and squares. In each component, an MNL model separates the two classes into "black" or "white" with a linear decision boundary. The overall decision boundary, which is a smooth function, is not shown in this figure.

the time of training. For example, the Latent Dirichlet Allocation (LDA) model proposed by Blei et al. (2003) is a well-defined generative model that performs well in classifying documents with previously unknown patterns.

While generative models are quite successful in many problems, they can be computationally intensive. Moreover, finding a good (but not perfect) estimate for the joint distribution of all variables (i.e., x and y) does not in general guarantee a good estimate of decision boundaries. By contrast, discriminative models are often computationally fast and are preferred when the covariates are in fact non-random (e.g., they are fixed by an experimental design).

Using a generative model in our proposed method provides an additional benefit. Modeling the distribution of covariates jointly with y allows us to implicitly model the dependency of covariates on each other through clustering (i.e., assigning data points to different components), which could provide insight into hidden structure in the data. To illustrate this concept, consider Figure 2 where the objective is to classify cases into black or white. To improve predictive accuracy, our model has divided the data into two components, shown as squares and circles. These components are distinguished primarily by the value of the second covariate, x_2, which is usually positive for squares and negative for circles. For cases in the squares group, the response variable strongly depends on both x_1 and x_2 (the linear separator is almost diagonal), whereas, for cases in the circles group, the model mainly depends on x_1 alone (the linear model is almost vertical). Therefore, by grouping the data into sub-populations (e.g., circles and squares in this example), our model not only improves classification accuracy, but also discovers hidden structure in the data (i.e., by clustering covariate observations). This concept is briefly discussed in Section 5, where we use our model to predict Parkinson's disease. A more detailed discussion on using our method to detect hidden structure in

data is provided elsewhere (Shahbaba, 2009), where a Dirichlet process mixture of autoregressive models us used to analyze time-series processes that are subject to regime changes, with no specific economic theory about the structure of the model.

The next section describes our methodology. In Section 3, we illustrate our approach and evaluate its performance on simulated data. In Section 4, we present the results of applying our model to an actual classification problem, which attempts to identify the folding class of a protein sequence based on the composition of its amino acids. Section 5 discusses another real classification problem, where the objective is to detect Parkinson's disease. This example is provided to show how our method can be used not only for improving prediction accuracy, but also for identifying hidden structure in the data. Finally, Section 6 is devoted to discussion and future directions.

2. Methodology

We now describe our classification model, which we call dpMNL, in detail. We assume that for each case we observe a vector of continuous covariates, x, of dimension p. The response variable, y, is categorical, with J classes. To model the relationship between y and x, we non-parametrically model the joint distribution of y and x, in the form $P(x,y) = P(x)P(y|x)$, using a Dirichlet process mixture. Within each component of the mixture, the relationship between y and x (i.e., $P(y|x)$) is expressed using a linear function. The overall relationship becomes nonlinear if the mixture contains more than one component. This way, while we relax the assumption of linearity, the flexibility of the relationship is controlled.

Each component in the mixture model has parameters $\theta = (\mu, \sigma^2, \alpha, \beta)$. The distribution of x within a component is multivariate normal, with mean vector μ and diagonal covariance, with the vector σ^2 on the diagonal. The distribution of y given x within a component is given by a multinomial logit (MNL) model—for $j = 1, \ldots, J$,

$$P(y = j|x, \alpha, \beta) \quad = \quad \frac{\exp(\alpha_j + x^T \beta_j)}{\sum_{j'=1}^{J} \exp(\alpha_{j'} + x^T \beta_{j'})}.$$

The parameter α_j is scalar, and β_j is a vector of length p. Note that given x, the distribution of y does not depend on μ and σ. This representation of the MNL model is redundant, since one of the β_j's (where $j = 1, ..., J$) can be set to zero without changing the set of relationships expressible with the model, but removing this redundancy would make it difficult to specify a prior that treats all classes symmetrically. In this parameterization, what matters is the difference between the parameters of different classes.

In addition to the mixture view, which follows Equation (1) with $C \to \infty$, one can also view each observation, i, as having its own parameter, θ_i, drawn independently from a distribution drawn from a Dirichlet process, as in Equation (5):

$$\begin{aligned} \theta_i | G &\sim G, \text{ for } i = 1, \ldots, n, \\ G &\sim \mathcal{D}(G_0, \gamma). \end{aligned}$$

Since G will be discrete, many groups of observations will have identical θ_i, corresponding to components in the mixture view.

Although the covariates in each component are assumed to be independent with normal priors, this independence of covariates exists only locally (within a component). Their global (over all

components) dependency is modeled by assigning data to different components (i.e., clustering). The relationship between y and x within a component is captured using an MNL model. Therefore, the relationship is linear locally, but nonlinear globally.

We could assume that y and x are independent within components, and capture the dependence between the response and the covariates by clustering too. However, this may lead to poor performance (e.g., when predicting the response for new observations) if the dependence of y on x is difficult to capture using clustering alone. Alternatively, we could also assume that the covariates are dependent within a component. For continuous response variables, this becomes equivalent to the model proposed by Müller et al. (1996). If the covariates are in fact dependent, using full covariance matrices (as suggested by Müller et al., 1996) could result in a more parsimonious model since the number of mixture component would be smaller. However, as we discussed above, this approach may be practically infeasible for problems with a moderate to large number of covariates. We believe that our method is an appropriate compromise between these two alternatives.

We define G_0, which is a distribution over $\theta = (\mu, \sigma^2, \alpha, \beta)$, as follows:

$$\begin{aligned} \mu_l|\mu_0,\sigma_0 &\sim N(\mu_0,\sigma_0^2), \\ \log(\sigma_l^2)|M_\sigma,V_\sigma &\sim N(M_\sigma,V_\sigma^2), \\ \alpha_j|\tau &\sim N(0,\tau^2), \\ \beta_{jl}|\nu &\sim N(0,\nu^2). \end{aligned}$$

The parameters of G_0 may in turn depend on higher level hyperparameters. For example, we can regard the variances of coefficients as hyperparameters with the following priors:

$$\begin{aligned} \log(\tau^2)|M_\tau,V_\tau &\sim N(M_\tau,V_\tau^2), \\ \log(\nu^2)|M_\nu,V_\nu &\sim N(M_\nu,V_\nu^2). \end{aligned}$$

We use MCMC algorithms for posterior sampling. We could use Gibbs sampling if G_0 is the conjugate prior for the likelihood given by F. That is, we would repeatedly draw samples from $\theta_i|\theta_{-i},y_i$ (where $i = 1,...,n$) using the conditional distribution (6). Neal (2000) presented several algorithms for sampling from the posterior distribution of Dirichlet process mixtures when non-conjugate priors are used. Throughout this paper, we use Gibbs sampling with auxiliary parameters (Neal's algorithm 8).

This algorithm uses a Markov chain whose state consists of $c_1,...,c_n$ and $\phi = (\phi_c : c \in \{c_1,...,c_n\})$, so that $\theta_i = \phi_{c_i}$. In order to allow creation of new clusters, the algorithm temporarily supplements the ϕ_c parameters of existing clusters with m (or $m-1$) additional parameter values drawn from the prior, where m a postive integer that can be adjusted to give good performance. Each iteration of the Markov chain simulation operates as follows:

- For $i = 1,...,n$: Let k^- be the number of distinct c_j for $j \neq i$ and let $h = k^- + m$. Label these c_j with values in $\{1,...,k^-\}$. If $c_i = c_j$ for some $j \neq i$, draw values independently from G_0 for those ϕ_c for which $k^- < c \leq h$. If $c_i \neq c_j$ for all $j \neq i$, let c_i have the label $k^- + 1$, and draw values independently from G_0 for those ϕ_c where $k^- + 1 < c \leq h$. Draw a new value for c_i from $\{1,...,h\}$ using the following probabilities:

$$P(c_i = c|c_{-i},y_i,\phi_1,...,\phi_h) = \begin{cases} b\,\dfrac{n_{-i,c}}{n-1+\gamma}F(y_i,\phi_c) & \text{for } 1 \leq c \leq k^-, \\ \\ b\,\dfrac{\gamma/m}{n-1+\gamma}F(y_i,\phi_c) & \text{for } k^- < c \leq h, \end{cases}$$

where $n_{-i,c}$ is the number of c_j for $j \neq i$ that are equal to c, and b is the appropriate normalizing constant. Change the state to contain only those ϕ_c that are now associated with at least to one observation.

- For all $c \in \{c_1, ..., c_n\}$ draw a new value from the distribution $\phi_c \mid \{y_i \text{ such that } c_i = c\}$, or perform some update that leaves this distribution invariant.

Throughout this paper, we set $m = 5$. This algorithm resembles one proposed by MacEachern and Müller (1998), with the difference that the auxiliary parameters exist only temporarily, which avoids an inefficiency in MacEachern and Müller's algorithm.

Samples simulated from the posterior distribution are used to estimate posterior predictive probabilities. For a new case with covariates x', the posterior predictive probability of the response variable, y', is estimated as follows:

$$P(y' = j|x') = \frac{P(y' = j, x')}{P(x')},$$

where

$$\begin{aligned} P(y' = j, x') &= \frac{1}{S}\sum_{s=1}^{S} P(y' = j, x'|G_0, \theta^{(s)}), \\ P(x') &= \frac{1}{S}\sum_{s=1}^{S} P(x'|G_0, \theta^{(s)}). \end{aligned}$$

Here, S is the number of post-convergence samples from MCMC, and $\theta^{(s)}$ represents the set of parameters obtained at iteration s. Alternatively, we could predict new cases using $P(y' = j, x') = \frac{1}{S}\sum_{s=1}^{S} P(y' = j|x', G_0, \theta^{(s)})$. While this would be computationally faster, the above approach allows us to learn from the covariates of test cases when predicting their response values. Note also that the above predictive probabilities include the possibility that the test case is from a new cluster.

We use these posterior predictive probabilities to make predictions for test cases, by assigning each test case to the class with the highest posterior predictive probability. This is the optimal strategy for a simple 0/1 loss function. In general, we could use more problem-specific loss functions and modify our prediction strategy accordingly.

Implementations for all our models were coded in MATLAB, and are available online at `http://www.ics.uci.edu/~babaks/codes`.

3. Results for Simulated Data

In this section, we illustrate our dpMNL model using synthetic data, and compare it with other models as follows:

- A simple MNL model, fitted by maximum likelihood or Bayesian methods.
- A Bayesian MNL model with quadratic terms (i.e., $x_l x_k$, where $l = 1, ..., p$ and $k = 1, ..., p$), referred to as qMNL.
- A decision tree model (Breiman et al., 1993) that uses 10-fold cross-validation for pruning, as implemented by the MATLAB "treefit", "treetest" (for cross-validation) and "treeprune" functions.

- Support Vector Machines (SVMs) (Vapnik, 1995), implemented with the MATLAB "svmtrain" and "svmclassify" functions from the Bioinformatics toolbox. Both a linear SVM (LSVM) and a nonlinear SVM with radial basis function kernel (RBF-SVM) were tried.

When the number of classes in a classification problem was bigger than two, LSVM and RBF-SVM used the all-vs-all scheme as suggested by Allwein et al. (2000), Fürnkranz (2002), and Hsu and Lin (2002). In this scheme, $\binom{J}{2}$ binary classifiers are trained where each classifier separates a pair of classes. The predicted class for each test case is decided by using a majority voting scheme where the class with the highest number of votes among all binary classes wins. For RBF-SVM, the scaling parameter, λ, in the RBF kernel, $k(x,x') = \exp(-||x-x'||/2\lambda)$, was optimized based on a validation set comprised of 20% of training samples.

The models are compared with respect to their accuracy rate and the F_1 measure. Accuracy rate is defined as the percentage of the times the correct class is predicted. F_1 is a common measurement in machine learning defined as:

$$F_1 = \frac{1}{J}\sum_{j=1}^{J}\frac{2A_j}{2A_j+B_j+C_j},$$

where A_j is the number of cases which are correctly assigned to class j, B_j is the number cases incorrectly assigned to class j, and C_j is the number of cases which belong to the class j but are assigned to other classes.

We do two tests. In the first test, we generate data according to the dpMNL model. Our objective is to evaluate the performance of our model when the distribution of data is comprised of multiple components. In the second test, we generate data using a smooth nonlinear function. Our goal is to evaluate the robustness of our model when data actually come from a different model.

3.1 Simulation 1

The first test was on a synthetic four-way classification problem with five covariates. Data are generated according to our dpMNL model, except the number of components was fixed at two. Two hyperparameters defining G_0 were given the following priors:

$$\begin{aligned}\log(\tau^2) &\sim N(0,0.1^2),\\ \log(\nu^2) &\sim N(0,2^2).\end{aligned}$$

The prior for component parameters $\theta = (\mu,\sigma^2,\alpha,\beta)$ defined by this G_0 was

$$\begin{aligned}\mu_l &\sim N(0,1),\\ \log(\sigma_l^2) &\sim N(0,2^2),\\ \alpha_j|\tau &\sim N(0,\tau^2),\\ \beta_{jl}|\nu &\sim N(0,\nu^2),\end{aligned}$$

where $l = 1,...,5$ and $j = 1,...,4$. We randomly draw parameters θ_1 and θ_2 for two components as described from this prior. For each component, we then generate 5000 data points by first drawing $x_{il} \sim N(\mu_l,\sigma_l)$ and then sampling y using the following MNL model:

$$P(y=j|x,\alpha,\beta) = \frac{\exp(\alpha_j+x\beta_j)}{\sum_{j'=1}^{J}\exp(\alpha_{j'}+x\beta_{j'})}.$$

Model	Accuracy (%)	F_1 (%)
Baseline	45.57 (1.47)	15.48 (1.77)
MNL (Maximum Likelihood)	77.30 (1.23)	66.65 (1.41)
MNL	78.39 (1.32)	66.52 (1.72)
qMNL	83.60 (0.99)	74.16 (1.30)
Tree (Cross Validation)	70.87 (1.40)	55.82 (1.69)
LSVM	78.61 (1.17)	67.03 (1.51)
RBF-SVM	79.09 (0.99)	63.65 (1.44)
dpMNL	89.21 (0.65)	81.00 (1.23)

Table 1: Simulation 1: the average performance of models based on 50 simulated data sets. The Baseline model assigns test cases to the class with the highest frequency in the training set. Standard errors of estimates (based on 50 repetitions) are provided in parentheses.

The overall sample size is 10000. We randomly split the data into a training set, with 100 data points, and a test set, with 9900 data points. We use the training set to fit the models, and use the independent test set to evaluate their performance. The regression parameters of the Bayesian MNL model with Bayesian estimation and the qMNL model have the following priors:

$$\begin{aligned} \alpha_j|\tau &\sim N(0,\tau^2), \\ \beta_{jl}|\nu &\sim N(0,\nu^2), \\ \log(\tau) &\sim N(0,1^2), \\ \log(\nu) &\sim N(0,2^2). \end{aligned}$$

The above procedure was repeated 50 times. Each time, new hyperparameters, τ^2 and ν^2, and new component parameters, θ_1 and θ_2, were sampled, and a new data set was created based on these θ's.

We used Hamiltonian dynamics (Neal, 1993) for updating the regression parameters (the α's and β's). For all other parameters, we used single-variable slice sampling (Neal, 2003) with the "stepping out" procedure to find an interval around the current point, and then the "shrinkage" procedure to sample from this interval. We also used slice sampling for updating the concentration parameter γ, We used $\log(\gamma) \sim N(-3,2^2)$ as the prior, which, encourages smaller values of γ, and hence a smaller number of components. Note that the likelihood for γ depends only on C, the number of unique components (Neal, 2000; Escobar and West, 1995). For all models we ran 5000 MCMC iterations to sample from the posterior distributions. We discarded the initial 500 samples and used the rest for prediction.

Our dpMNL model has the highest computational cost compared to all other methods. Simulating the Markov chain took about 0.15 seconds per iteration using a MATLAB implementation on an UltraSPARC III machine (approximately 12.5 minutes for each simulated data set). Each MCMC iteration for the Bayesian MNL model took about 0.1 second (approximately 8 minutes for each data set). Training the RBF-SVM model (with optimization of the scale parameter) took approximately 1 second for each data set. Therefore, SVM models have a substantial advantage over our approach in terms of computational cost.

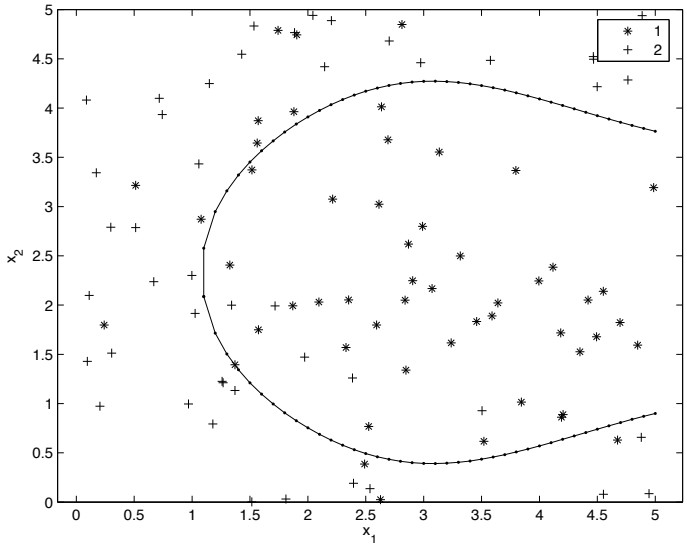

Figure 3: A random sample generated according to Simulation 2, with $a_3 = 0$. The dotted line is the optimal boundary function.

The average results (over 50 repetitions) are presented in Table 1. As we can see, our dpMNL model provides better results compared to all other models. The improvements are statistically significant (p-values < 0.001) for comparisons of accuracy rates using a paired t-test with $n = 50$.

3.2 Simulation 2

In the above simulation, since the data were generated according to the dpMNL model, it is not surprising that this model had the best performance compared to other models. In fact, as we increase the number of components, the amount of improvement using our model becomes more and more substantial (results not shown). To evaluate the robustness of the dpMNL model, we performed another test. This time, we generated x_{i1}, x_{i2}, x_{i3} (where $i = 1, ..., 10000$) from the $Uniform(0,5)$ distribution, and generated a binary response variable, y_i, according the following model:

$$P(y = 1|x) = \frac{1}{1 + \exp[a_1 \sin(x_1^{1.04} + 1.2) + x_1 \cos(a_2 x_2 + 0.7) + a_3 x_3 - 2]},$$

where a_1, a_2 and a_3 are randomly sampled from $N(1, 0.5^2)$. The function used to generate y is a smooth nonlinear function of covariates. The covariates are not clustered, so the generated data do not conform with the assumptions of our model. Moreover, this function includes a completely arbitrary set of constants to ensure the results are generalizable. Figure 3 shows a random sample from this model except that a_3 is fixed at zero (so x_3 is ignored). In this figure, the dotted line is the optimal decision boundary.

Table 2 shows the results for this simulation, which are averages over 50 data sets. For each data set, we generated 10000 cases by sampling new values for a_1, a_2, and a_3, new covariates, x, for each case, and new values for the response variable, y, in each case. As before, models were trained on 100 cases, and tested on the remaining 9900. As before, the dpMNL model provides significantly

Model	Accuracy (%)	F_1 (%)
Baseline	61.96 (1.53)	37.99 (0.57)
MNL (Maximum Likelihood)	73.58 (0.96)	68.33 (1.17)
MNL	73.58 (0.97)	67.92 (1.41)
qMNL	75.60 (0.98)	70.12 (1.36)
Tree (Cross Validation)	73.47 (0.95)	66.94 (1.43)
LSVM Linear	73.09 (0.99)	64.95 (1.71)
RBF-SVM	76.06 (0.94)	68.46 (1.77)
dpMNL	77.80 (0.86)	73.13 (1.26)

Table 2: Simulation 2: the average performance of models based on 50 simulated data sets. The Baseline model assigns test cases to the class with the highest frequency in the training set. Standard errors of estimates (based on 50 repetitions) are provided in parentheses.

(all p-values are smaller than 0.001) better performance compared to all other models. This time, however, the performances of qMNL and RBF-SVM are closer to the performance of the dpMNL model.

4. Results on Real Classification Problems

In this section, we first apply our model the problem of predicting a protein's 3D structure (i.e., folding class) based on its sequence. We then use our model to identify patients with Parkinson's disease (PD) based on their speech signals.

4.1 Protein Fold Classification

When predicting a protein's 3D structure, it is common to presume that the number of possible folds is fixed, and use a classification model to assign a protein to one of these folding classes. There are more than 600 folding patterns identified in the SCOP (Structural Classification of Proteins) database (Lo Conte et al., 2000). In this database, proteins are considered to have the same folding class if they have the same major secondary structure in the same arrangement with the same topological connections.

We apply our model to a protein fold recognition data set provided by Ding and Dubchak (2001). The proteins in this data set are obtained from the PDB_select database (Hobohm et al., 1992; Hobohm and Sander, 1994) such that two proteins have no more than 35% of the sequence identity for aligned subsequences larger than 80 residues. Originally, the resulting data set included 128 unique folds. However, Ding and Dubchak (2001) selected only the 27 most populated folds (311 proteins) for their analysis. They evaluated their models based on an independent sample (i.e., test set) obtained from PDB-40D (Lo Conte et al., 2000). PDB-40D contains the SCOP sequences with less than 40% identity with each other. Ding and Dubchak (2001) selected 383 representatives of the same 27 folds in the training set with no more than 35% identity to the training sequences. The training and test data sets are available online at `http://crd.lbl.gov/~cding/protein/`.

The covariates in these data sets are the length of the protein sequence, and the percentage composition of the 20 amino acids. While there might exist more informative covariates to predict protein folds, we use these so that we can compare the results of our model to that of Ding

and Dubchak (2001), who trained several Support Vector Machines (SVM) with nonlinear kernel functions.

We centered the covariates so they have mean zero, and used the following priors for the MNL model and qMNL model (with no interactions, only x_i and x_i^2 as covariates):

$$\begin{aligned}
\alpha_j|\eta &\sim N(0,\eta^2),\\
\log(\eta^2) &\sim N(0,2^2),\\
\beta_{jl}|\xi,\sigma_l &\sim N(0,\xi^2\sigma_l^2),\\
\log(\xi^2) &\sim N(0,1),\\
\log(\sigma_l^2) &\sim N(-3,4^2).
\end{aligned}$$

Here, the hyperparameters for the variances of regression parameters are more elaborate than in the previous section. One hyperparameter, σ_l, is used to control the variance of all coefficients, β_{jl} (where $j = 1,...,J$), for covariate x_l. If a covariate is irrelevant, its hyperparameter will tend to be small, forcing the coefficients for that covariate to be near zero. This method, termed Automatic Relevance Determination (ARD), has previously been applied to neural network models by Neal (1996). We also used another hyperparameter, ξ, to control the overall magnitude of all β's. This way, σ_l controls the relevance of covariate x_l compared to other covariates, and ξ controls the overall usefulness of all covariates in separating all classes. The standard deviation of β_{jl} is therefore equal to $\xi\sigma_l$.

The above scheme was also used for the dpMNL model. Note that in this model, one σ_l controls all β_{jlc}, where $j = 1,...,J$ indexes classes, and $c = 1,...,C$ indexes the unique components in the mixture. Therefore, the standard deviation of β_{jlc} is $\xi\sigma_l\nu_c$. Here, ν_c is specific to each component c, and controls the overall effect of coefficients in that component. That is, while σ and ξ are global hyperparameters common between all components, ν_c is a local hyperparameter within a component. Similarly, the standard deviation of intercepts, α_{jc} in component c is $\eta\tau_c$. We used $N(0,1)$ as the prior for ν_c and τ_c.

We also needed to specify priors for μ_l and σ_l, the mean and standard deviation of covariate x_l, where $l = 1,...,p$. For these parameters, we used the following priors:

$$\begin{aligned}
\mu_{lc}|\mu_{0,l},\sigma_{0,l} &\sim N(\mu_{0,l},\sigma_{0,l}^2),\\
\mu_{0,l} &\sim N(0,5^2),\\
\log(\sigma_{0,l}^2) &\sim N(0,2^2),\\
\log(\sigma_{lc}^2)|M_{\sigma,l},V_{\sigma,l} &\sim N(M_{\sigma,l},V_{\sigma,l}^2),\\
M_{\sigma,l} &\sim N(0,1^2),\\
\log(V_{\sigma,l}^2) &\sim N(0,2^2).
\end{aligned}$$

These priors make use of higher level hyperparameters to provide flexibility. For example, if the components are not different with respect to covariate x_l, the corresponding variance, $\sigma_{0,l}^2$, becomes small, forcing μ_{lc} close to their overall mean, $\mu_{0,l}$.

The MCMC chains for MNL, qMNL, and dpMNL ran for 10000 iterations. Simulating the Markov chain took about 2.1 seconds per iteration (5.8 hours in total) for dpMNL and 0.5 seconds per iteration (1.4 hours in total) for MNL using a MATLAB implementation on an UltraSPARC III machine. Training the RBF-SVM model took about 2.5 minutes.

Model	Accuracy (%)	F_1 (%)
MNL	50.0	41.2
qMNL	50.5	42.1
SVM (Ding and Dubchak, 2001)	49.4	-
LSVM	50.5	47.3
RBF-SVM	53.1	49.5
dpMNL	58.6	53.0

Table 3: Performance of models based on protein fold classification data.

The results for MNL, qMNL, LSVM, RBF-SVM, and dpMNL are presented in Table 3, along with the results for the best SVM model developed by Ding and Dubchak (2001) on the exact same data set. As we can see, the nonlinear RBF-SVM model that we fit has better accuracy than the linear models. Our dpMNL model provides an additional improvement over the RBF-SVM model. This shows that there is in fact a nonlinear relationship between folding classes and the composition of amino acids, and our nonlinear model could successfully identify this relationship.

4.2 Detecting Parkinson's Disease

The above example shows that our method can potentially improve prediction accuracy, though of course other classifiers, such as SVM and neural networks, may do better on some problems. However, we believe the application of our method is not limited to simply improving prediction accuracy—it can also be used to discover hidden structure in data by identifying subgroups (i.e., mixture components) in the population. This section provides an example to illustrate this concept.

Neurological disorders such as Parkinson's disease (PD) have profound consequences for patients, their families, and society. Although there is no cure for PD at this time, it is possible to alleviate its symptoms significantly, especially at the early stages of the disease (Singh et al., 2007). Since approximately 90% of patients exhibit some form of vocal impairment (Ho et al., 1998), and research has shown that vocal impairment could be one of the earliest indicators of onset of the illness (Duffy, 2005), voice measurement has been proposed as a reliable tool to detect and monitor PD (Sapir et al., 2007; Rahn et al., 2007; Little et al., 2008). For example, patients with PD commonly display a symptom known as *dysphonia*, which is an impairment in the normal production of vocal sounds.

In a recent paper, Little et al. (2008) show that by detecting *dysphonia*, we could identify patients with PD. Their study used data on sustained vowel phonations from 31 subjects, of whom 23 were diagnosed with PD. The 22 covariates used include traditional variables, such as measures of vocal fundamental frequency and measures of variation in amplitude of signals, as well as a novel measurement referred to as *pitch period entropy* (PPE). See Little et al. (2008) for a detailed description of these variables. This data set is publicly available at UCI Machine Learning Repository (`http://archive.ics.uci.edu/ml/datasets/Parkinsons`).

Little et al. (2008) use an SVM classifier with Gaussian radial basis kernel functions to identify patients with PD, chosing the SVM penalty value and kernel bandwidth by an exhaustive search over a range of values. They also perform an exhaustive search to select the optimal subset of features (10 features were selected). Their best model provides a 91.4% ($\pm$4.4) accuracy rate based on a bootstrap algorithm. This of course does not reflect the true prediction accuracy rate of the model for future observations since the model is trained and evaluated on the same sample. Here, we use

Model	Accuracy (%)	F_1 (%)
MNL	85.6 (2.2)	79.1 (2.8)
qMNL	86.1 (1.5)	79.7 (2.1)
LSVM	87.2 (2.3)	80.6 (2.8)
RBF-SVM	87.2 (2.7)	79.9 (3.2)
dpMNL	87.7 (3.3)	82.6 (2.5)

Table 4: Performance of models based on detecting Parkinson's disease. Standard errors of estimates (based on 5 cross-validation folds) are provided in parentheses.

Group	Frequency	Age Average	Male Proportion
1	107	66 (0.7)	0.86 (0.03)
2	12	72 (1.1)	0.83 (0.11)
3	36	63 (1.8)	0.08 (0.04)
4	40	65 (2.2)	0.40 (0.08)
Population	195	66 (0.7)	0.60 (0.03)

Table 5: The age average and male proportion for each cluster (i.e., mixture component) identified by our model. Standard errors of estimates are provided in parentheses.

a 5-fold cross validation scheme instead in order to obtain a more accurate estimate of prediction accuracy rate and avoid inflating model performance due to overfitting. As a result, our models cannot be directly compared to that of Little et al. (2008).

We apply our dpMNL model to the same data set, along with MNL and qMNL (no interactions, only x_i and x_i^2 as covariates). Although the observations from the same subject are not independent, we assume they are, as done by Little et al. (2008). Instead of selecting an optimum subset of features, we used PCA and chose the first 10 principal components. The MCMC algorithm for MNL, qMNL, and dpMNL ran for 3000 iterations (the first 500 iterations were discarded). Simulating the Markov chain took about 0.7 second per iteration (35 minutes per data set) for dpMNL and 0.1 second per iteration (5 minutes per data set) for MNL using a MATLAB implementation on an UltraSPARC III machine. Training the RBF-SVM model took 38 seconds for each data set.

Using the dpMNL model, the most probable number of components in the posterior is four (note that might change from one iteration to another). Table 4 shows the average and standard errors (based on 5-fold cross validation) of the accuracy rate and the F_1 measure for MNL, LSVM, RBF-SVM, and dpMNL. (But note that the standard errors assume independence of cross-validation folds, which is not really correct.)

While dpMNL provides slightly better results, the improvement is not statistically significant. However, examining the clusters (i.e., mixture components) identified by dpMNL reveals some information about the underlying structure in the data. Table 5 shows the average age of subjects and male proportion for the four clusters (based on the most probable number of components in the posterior) identified by our model. Note that age and gender are not available from the UCI Machine Learning Repository, and they are not included in our model. They are, however, available from Table 1 in Little et al. (2008). The first two groups include substantially higher percentages of male subjects than female subjects. The average age in the second of these groups is higher compared to the first group. Most of the subjects in the third group are female (only 8% are male).

The fourth group also includes more female subjects than male subjects, but the disproportionality is not as high as for the third group.

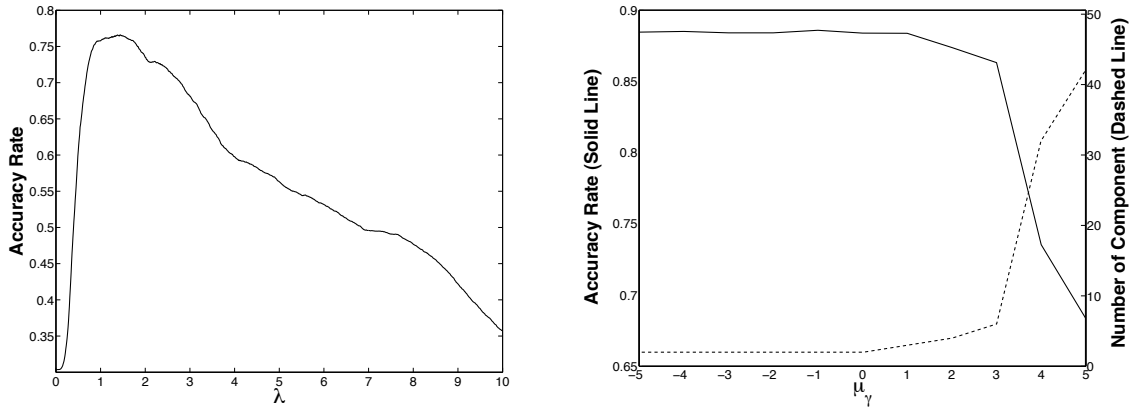
When identifying Parkinson's disease by detecting dysphonia, it has been shown that gender has a confounding effect (Cnockaert et al., 2008). By grouping the data into clusters, our model has identified (to some extent) the heterogeneity of subjects due to age and gender, even though these covariates were not available to the model. Moreover, by fitting a separate linear model to each component (i.e., conditioning on mixture identifiers), our model approximates the confounding effect of age and gender. For this example, we could have simply taken the age and gender of subjects from Table 1 in Little et al. (2008) and included them in our model. In many situations, however, not all the relevant factors are measured. This could result in unobservable changes in the structure of data. We discuss this concept in more detail elsewhere (Shahbaba, 2009).

5. Discussion and Future Directions

We introduced a new nonlinear classification model, which uses Dirichlet process mixtures to model the joint distribution of the response variable, y, and the covariates, x, non-parametrically. We compared our model to several linear and nonlinear alternative methods using both simulated and real data. We found that when the relationship between y and x is nonlinear, our approach provides substantial improvement over alternative methods. One advantage of this approach is that if the relationship is in fact linear, the model can easily reduce to a linear model by using only one component in the mixture. This way, it avoids overfitting, which is a common challenge in many nonlinear models.

We believe our model can provide more interpretable results. In many real problems, the identified components may correspond to a meaningful segmentation of data. Since the relationship between y and x remains linear in each segment, the results of our model can be expressed as a set of linear patterns for different data segments.

Hyperparameters such as λ in RBF-SVM and γ in dpMNL can substantially influence the performance of the models. Therefore, it is essential to choose these parameters appropriately. For RBF-SVM, we optimized λ using a validation set that includes 20% of the training data. Figure 4 (a) shows the effect of λ on prediction accuracy for one data set. The value of λ with the highest accuracy rate based on the validation set was used to train the RBF-SVM model. The hyperparameters in our dpMNL model are not fixed at some "optimum" values. Instead, we use hyperpriors that reflect our opinion regarding the possible values of these parameters before observing the data, with the posterior for these parameters reflecting both this prior opinion and the data. Hyperpriors for regression parameters, β, facilitate their shrinkage towards zero if they are not relevant to the classification task. The hyperprior for the scale parameter γ affects how many mixture components are present in the data. Instead of setting γ to some constant number, we allow the model to decide the appropriate value of γ, using a hyperprior that encourages a small number of components, but which is not very restrictive, and hence allows γ to become large in the posterior if required to fit the data. Choosing unreasonably restrictive priors could have a negative effect on model performance and MCMC convergence. Figure 4 (b) illustrates the negative effect of unreasonable priors for γ. For this data set, the correct number of components is two. We gradually increase μ_γ, where $\log(\gamma) \sim N(\mu_\gamma, 2)$, in order to put higher probability on larger values of γ and lower probability on smaller values. As we can see, setting $\mu_\gamma \geq 4$, which makes the hyperprior very restrictive, results in



(a) (b)

Figure 4: Effects of scale parameters when fitting a data set generated according to Simulation 1. (a) The effect of λ in the RBF-SVM model. (b) The effect of the prior on the scale parameter, $\gamma \sim \text{log-N}(\mu_\gamma, 2^2)$, as μ_γ changes in the dpMNL model.

a substantial decline in accuracy rate (solid line) due to overfitting with a large number of mixture components (dashed line).

The computational cost for our model is substantially higher compared to other methods such as MNL and SVM. This could be a preventive factor in applying our model to some problems. The computational cost of our model could be reduced by using more efficient methods, such as the "split-merge" approach introduced by Jain and Neal (2007). This method uses a Metropolis-Hastings procedure that resamples clusters of observations simultaneously rather than incrementally assigning one observation at a time to mixture components. Alternatively, it might be possible to reduce the computational cost by using a variational inference algorithm similar to the one proposed by Blei and Jordan (2005). In this approach, the posterior distribution P is approximated by a tractable variational distribution Q, whose free variational parameters are adjusted until a reasonable approximation to P is achieved.

We expect our model to outperform other nonlinear models such as neural networks and SVM (with nonlinear kernel functions) when the population is comprised of subgroups each with their own distinct pattern of relationship between covariates and response variable. We also believe that our model could perform well if the true function relating covariates to response variable contains sharp changes.

The performance of our model could be negatively affected if the covariates are highly correlated with each other. In such situations, the assumption of diagonal covariance matrix for x adopted by our model could be very restrictive. To capture the interdependencies between covariates, our model would attempt to increase the number of mixture components (i.e., clusters). This however is not very efficient. To address this issue, we could use mixtures of factor analyzers, where the covariance structure of high dimensional data is model using a small number of latent variables (see for example, Rubin and Thayer, 2007; Ghahramani and Hinton, 1996).

In this paper, we considered only continuous covariates. Our approach can be easily extended to situations where the covariate are categorical. For these problems, we need to replace the nor-

mal distribution in the baseline, G_0, with a more appropriate distribution. For example, when the covariate x is binary, we can assume $x \sim Bernoulli(\mu)$, and specify an appropriate prior distribution (e.g., *Beta* distribution) for μ. Alternatively, we can use a continuous latent variable, z, such that $\mu = \exp(z)/\{1+\exp(z)\}$. This way, we can still model the distribution of z as a mixture of normals. For categorical covariates, we can either use a Dirichlet prior for the probabilities of the K categories, or use K continuous latent variables, $z_1, ..., z_K$, and let the probability of category j be $\exp(z_j)/\sum_{j'}^{K}\exp(z_{j'})$.

Throughout this paper, we assumed that the relationship between y and x is linear within each component of the mixture. It is possible of course to relax this assumption in order to obtain more flexibility. For example, we can include some nonlinear transformation of the original variables (e.g., quadratic terms) in the model.

Our model can also be extended to problems where the response variable is not multinomial. For example, we can use this approach for regression problems with continuous response, y, which could be assumed normal within a component. We would model the mean of this normal distribution as a linear function of covariates for cases that belong to that component. Other types of response variables (i.e., with Poisson distribution) can be handled in a similar way.

In the protein fold prediction problem discussed in this paper, classes were regarded as a set of unrelated entities. However, these classes are not completely unrelated, and can be grouped into four major structural classes known as α, β, α/β, and $\alpha+\beta$. Ding and Dubchak (2001) show the corresponding hierarchical scheme (Table 1 in their paper). We have previously introduced a new approach for modeling hierarchical classes (Shahbaba and Neal, 2006, 2007). In this approach, we use a Bayesian form of the multinomial logit model, called corMNL, with a prior that introduces correlations between the parameters for classes that are nearby in the hierarchy. Our dpMNL model can be extend to classification problems where classes have a hierarchical structure (Shahbaba, 2007). For this purposse, we use a corMNL model, instead of MNL, to capture the relationship between the covariates, x, and the response variable, y, within each component. The results is a nonlinear model which takes the hierarchical structure of classes into account.

Finally, our approach provides a convenient framework for semi-supervised learning, in which both labeled and unlabeled data are used in the learning process. In our approach, unlabeled data can contribute to modeling the distribution of covariates, x, while only labeled data are used to identify the dependence between y and x. This is a quite useful approach for problems where the response variable is known for a limited number of cases, but a large amount of unlabeled data can be generated. One such problem is classification of web documents.

Abstract

The growth of information available to learning systems and the increasing complexity of learning tasks determine the need for devising algorithms that scale well with respect to all learning parameters. In the context of supervised sequential learning, the Viterbi algorithm plays a fundamental role, by allowing the evaluation of the best (most probable) sequence of labels with a time complexity linear in the number of time events, and quadratic in the number of labels.

In this paper we propose CarpeDiem, a novel algorithm allowing the evaluation of the best possible sequence of labels with a sub-quadratic time complexity.[1] We provide theoretical grounding together with solid empirical results supporting two chief facts. CarpeDiem always finds the optimal solution requiring, in most cases, only a small fraction of the time taken by the Viterbi algorithm; meantime, CarpeDiem is never asymptotically worse than the Viterbi algorithm, thus confirming it as a sound replacement.

Keywords: Viterbi algorithm, sequence labeling, conditional models, classifiers optimization, exact inference

1. Introduction

In supervised learning systems, classifiers are learnt from sets of labeled examples and then used to predict the "correct" labeling for new objects. According to how relations between objects are exploited to build and evaluate the classifier, different categories of learning systems can be individuated. When the learning system deals with examples as isolated individuals, thus disregarding any relation among them, the system is said to work in a *propositional* setting. In this case classifiers can optimize the assignment of labels individually. Instead, in the setting of supervised sequential learning (SSL) the objects are assumed to be arranged in a sequence: relationships between previous and subsequent objects exist, and are used to improve the classification accuracy. SSL classifiers are then required to find the globally optimum sequence of labels, rather than the sequence of locally optimal labels. For instance, in the optical character recognition task, the labelling "*learning*" is probably better than "*learn1ng*", even though the description of the sixth character taken in isolation might suggest otherwise. A SSL classifier may deal with such ambiguities by exploiting the

higher sequential correlation, in the English language, of the bigram *in* with respect to *1n*. Conceptually, given a sequence of T observations and K possible labels, K^T possible combinations of labels are to be considered by SSL classifiers. Most systems deal with such complexity by assuming that relations may span only over nearby objects and use the Viterbi algorithm (Viterbi, 1967) to find the globally optimal sequence of labels in $\Theta(TK^2)$ time.

In the last few years it has become increasingly important for supervised sequential learning algorithms to handle problems with large state spaces (Dietterich et al., 2008). Unfortunately, even the drastic reduction in complexity achieved by the Viterbi algorithm may be not sufficient in such domains. For instance, this is the case of web-logs related tasks (Felzenszwalb et al., 2003), music analysis (Radicioni and Esposito, 2007), and activity monitoring through body sensors (Siddiqi and Moore, 2005), where the number of possible labels is so large that the classification time can grow prohibitively high.

Some recent works propose techniques that under precise assumptions allow faster execution time of classifiers based on hidden Markov models (HMMs) (Rabiner, 1989). One feature shared by these approaches is the assumption that the transition matrix has a specific form allowing one to rule out most transitions. Such approaches are highly valuable when the problem naturally fits the assumption; *vice versa* they either lose the optimal solution or cannot be applied at all, when it does not. Moreover, they assume the transition matrix to be known beforehand and fixed over time. While this is a natural assumption in HMMs, recent algorithms based on the boolean features framework (McCallum et al., 2000) allow for more general settings where the transition matrix is itself a function of the observations around the object to be labelled. In such cases it is hard to figure out how the aforementioned approaches apply.

In this paper we introduce `CarpeDiem`. It is a parameter-free algorithm, sporting best case sub-quadratic complexity, devised as a replacement for the Viterbi algorithm. `CarpeDiem` avoids considering a transition whenever local observations make it impossible for the transition to be part of the optimal path. `CarpeDiem` preserves the optimality of the result, never being asymptotically worse than the Viterbi algorithm. Moreover, `CarpeDiem` automatically adapts to the sequence being evaluated, so that its complexity degrades to the Viterbi algorithm complexity in case the underlying assumption is not met. Interestingly, in contrast with alternative approaches, the assumption made by `CarpeDiem` needs not be "always" valid. On the contrary, the algorithm is able to take advantage of the assumption even when it holds for small portions of the sequence. This implies that the worst case complexity is hit only in the very unlikely situation where the assumption does not hold for the entire sequence. Finally, `CarpeDiem` can be directly applied in any sequential learning system based on the Viterbi algorithm, even in those where the transition matrix changes over time.

The present work is structured as follows: we briefly recall the Viterbi algorithm and state the problem (Section 2). After surveying related work (Section 3), we illustrate `CarpeDiem` in full detail, and an execution example on a toy problem is provided (Section 4). We then show how `CarpeDiem` can be embodied in the voted perceptron algorithm (Section 5) and, in Section 6, we report the experimental results and discuss the results as well as several related algorithms, and elaborate on future directions of research. The soundness of the algorithm as well as its complexity are formally proved in Appendices A and B, respectively.

2. Preliminaries

The problem of finding the best sequence of labels is often represented as a search for the optimal path in a layered and weighted graph (Figure 1).

Definition 1 Layered graph. *A layered graph is a connected graph where vertices are partitioned into a set of "layers" such that:* i*) edges connect only vertices in adjacent layers;* ii*) any vertex in a given layer is connected to all vertices of the successive layer.*

We adopt the convention of indicating the layer to which a vertex belongs as a subscript to the vertex name, so that y_t denotes a vertex in layer t. We associate to each vertex y_t a weight $S^0_{y_t}$, and to each edge (y_{t-1}, y_t) a weight $S^1_{y_t, y_{t-1}}$ (Figure 1). In the following we use the term "vertical" in referring to "per node" properties. For instance, we will use the expressions "vertical weight" of y_t and "vertical information" to refer to $S^0_{y_t}$ and to the information provided by evidence related to vertices, respectively. Similarly, we use the term "horizontal" in referring to "per edge" properties. For instance, we will use the expression "horizontal weight" in referring to the weight associated to a given transition. The distinction between vertical and horizontal information is important in the present work, the key idea in `CarpeDiem` is to exploit vertical information to avoid considering the horizontal one.

Given a layered and weighted graph with T layers and K vertices per layer, a *path* is a sequence of vertices $y_1, y_2, \ldots, y_t$ ($1 \leq t \leq T$). The reward for a path is the sum of the vertical and horizontal weights associated to the path:

$$\text{reward}(y_1, y_2, \ldots, y_t) = \left(\sum_{u=1}^{t-1} S^0_{y_u} + S^1_{y_{u+1}, y_u} \right) + S^0_{y_t}.$$

We define $\gamma(y_t)$ as the maximal reward associated to any path from any node in layer 1 to y_t:

$$\gamma(y_t) = \max_{y_1, y_2, \ldots, y_{t-1}} \text{reward}(y_1, y_2, \ldots, y_{t-1}, y_t).$$

We consider the problem of picking the maximal path from the leftmost layer to the rightmost layer. The *naive* solution considers all the K^T possible paths, and returns the maximal one. The Viterbi algorithm (Viterbi, 1967) solves the problem in $\Theta(TK^2)$ time by exploiting a dynamic programming strategy. The main idea stems from noticing that the reward of the best path to node y_t can be recursively computed as: *i)* the reward of the best path to the predecessor $\pi(y_t)$ on the optimal path to y_t; *ii)* plus the reward for transition $S^1_{y_t, \pi(y_t)}$; *iii)* plus the weight of node y_t. In formulae:

$$\gamma(y_t) = \begin{cases} S^0_{y_t} & \text{if } t = 1 \\ \gamma(\pi(y_t)) + S^1_{y_t, \pi(y_t)} + S^0_{y_t} & \text{otherwise.} \end{cases} \quad (1)$$

We will also make use of the equivalent formulation obtained by noticing that $\pi(y_t)$ is the best predecessor for y_t. That is, $\pi(y_t)$ is the vertex y_{t-1} (in layer $t-1$) that maximizes the quantity $\gamma(y_{t-1}) + S^1_{y_t, y_{t-1}}$. Then:

$$\gamma(y_t) = \begin{cases} S^0_{y_t} & \text{if } t = 1 \\ \max_{y_{t-1}} \left(\gamma(y_{t-1}) + S^1_{y_t, y_{t-1}} + S^0_{y_t} \right) & \text{otherwise.} \end{cases} \quad (2)$$

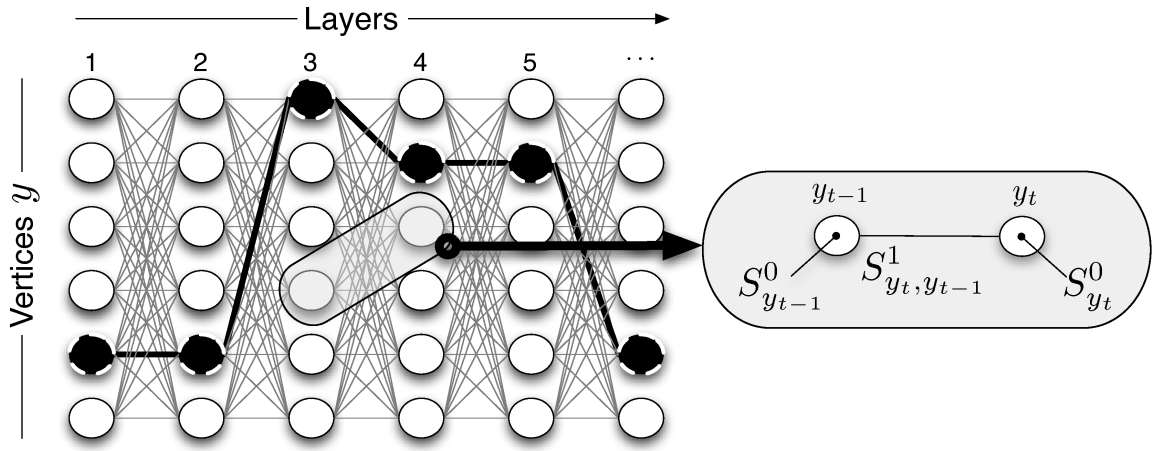

Figure 1: $S^0_{y_t}$ and $S^0_{y_{t-1}}$ denote per vertex (vertical) weights. $S^1_{y_t,y_{t-1}}$ denotes per edge (horizontal) weights.

The Viterbi algorithm proceeds from left to right storing the values of γ into an array $\mathbb{G}$ as soon as such values are computed. Assuming that $\forall y_{t-1} : \mathbb{G}(y_{t-1}) = \gamma(y_{t-1})$, then $\mathbb{G}(y_t)$ is computed as:

$$\mathbb{G}(y_t) = \max_{y_{t-1}} \left(\mathbb{G}(y_{t-1}) + S^1_{y_t,y_{t-1}} + S^0_{yt} \right).$$

The pseudo code for the algorithm is reported in Algorithm 1. Since the maximization at the line marked with label number 1 (henceforth simply "line 1 ") requires $\Theta(K)$ time, the time needed for processing each layer is in the order of $\Theta(K^2)$. The total time required by Viterbi is then $\Theta(K^2T)$. The standard formulation of the Viterbi algorithm would also store the optimal path information as it becomes available. Since this can be done using standard techniques (Cormen et al., 1990, page 520) without affecting the complexity of the algorithm, we do not explicitly report that in the pseudo-code.

Let us now consider how the above definitions instantiate in the context of a learning environment. The symbol $S^0_{y_t}$ conveys information about label y_t provided by observing the data at time t. In hidden Markov models terminology, $S^0_{y_t}$ corresponds to probability $b_{y_t}(x_t)$ of observing symbol x_t in state y_t (Rabiner, 1989, definition of $b_j(k)$ pag. 261, Eq. 8). More generally, $S^0_{y_t}$ is a quantity that depends on both the label y_t predicted for time (layer) t and the observations at and *around* time t. Likewise, in HMMs terminology, $S^1_{y',y}$ corresponds to the probability $a_{yy'}$ of transiting from state y to state y' (Rabiner, 1989, definition of a_{ij} pag. 260, Eq. 7). More in general, $S^1_{y',y}$ may depend on both the labels (y',y) *and* on the observations at and around the current layer. We note that since $S^1_{y',y}$ may vary over time (which motivates the notation $S^1_{y_t,y_{t-1}}$), the setup considered here is more general than the one of HMMs, where the transition matrix does not depend on the time instant.

```
begin
    forall y_1 do
        G(y_1) ← S^0_{y_1};
    end
    for t = 2 to T do
        forall y_t do
1           G(y_t) ← max_{y_{t-1}} ( G(y_{t-1}) + S^1_{y_t,y_{t-1}} + S^0_{y_t} );
        end
    end
    y*_T ← arg max_{y_T} G(y_T);
    return y*_T;
end
```

Algorithm 1: The Viterbi algorithm.

3. Related Work

As we illustrated in Section 1, in cases where hundreds or thousands of labels are to be handled, the quadratic dependence on the number of labels is still a high burden that limits the applicability of sequential learning techniques.

In other fields (e.g., telecommunications) there exist *ad hoc* solutions that allow one to tame the complexity of the Viterbi algorithm by means of hardware implementations (Austin et al., 1990) or methods for approximating the optimum path (Fano, 1963). For instance, in the research field of speech recognition, the Viterbi algorithm is routinely applied to huge problems. This is a typical case where approximate solutions really pay off: suboptimal paths could be tolerated (to some extent) and tight time constraints prevent exhaustive search. A popular approach in this field is the *Viterbi beam search* (VBS) (Lowerre and Reddy, 1980; Spohrer et al., 1980; Bridle et al., 1982): essentially, VBS performs a breadth-first suboptimal search in which only the most promising solutions are retained at each step. Many improvements over this basic strategy have been proposed to refine either the computational performance or the accuracy of the solution (e.g., Ney et al., 1992). In most cases domain-based knowledge (such as language constraints) is used to restrict the search efforts to some relevant regions of the search space (Ney et al., 1987). Also, in recent years, several algorithms have been proposed that overcome the difficulties inherent in heuristic ranking strategies by learning ranking functions specifically optimized for the problem at hand (Xu and Fern, 2007).

Although promising, the VBS approach does not come without difficulties. For instance, Collins and Roark (2004) propose Viterbi beam search to improve the performances of the perceptron algorithm on the particular problem of natural language parsing. Interestingly, the authors note how the sub-optimality of the beam search can negatively affect the learning performances. The problem arises when a sub-optimal sequence is used instead of the optimal one to update the weights of the features (please refer to Section 5). In order to alleviate this issue, the authors stop the search—during learning—as soon as the beam does not contain the optimal solution. In such case only the partial sequence, up to when the stopping occurred, is used to update the weights. This prevents from training the perceptron using "bad" predictions, but it still has the drawback of exploiting only partially the training sequences. In such system, then, the sub-optimality of Viterbi beam search

has *two* drawbacks: at learning time, it hinders the process of finding better classifiers (or at least it slows the process down); at testing time, it yields sub-optimal classifications.

In recent years, despite a widespread usage of the Viterbi algorithm within the sequential learning field, only few works addressed the problem of reducing its time complexity and at the same time retaining the optimal result. In Felzenszwalb et al. (2003), linear (and near linear) algorithms are proposed to compute the optimal labels sequence. Their algorithms work under the assumption that the reward for the transition between states number i and j is a "simple" function of $|i-j|$.[2]

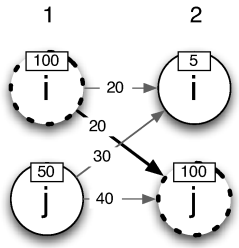
In Siddiqi and Moore (2005) it is assumed that the transition matrix is well approximated by a particular one where, for each vertex, the probability mass is concentrated on the k highest transitions leaving it. Then, the weights associated to the other transitions are approximated by a constant, and the optimal path is evaluated with $\Theta(kKT)$ time complexity. Clearly, the smaller k, the faster the algorithm.

Both techniques provide significant time savings with respect to the Viterbi algorithm. However, they are both based on assumptions about the entries in the transition matrix that are not guaranteed to hold in practice. More in particular, the assumption by Felzenszwalb et al. (2003) does not seem to easily fit general cases. Also, the investigation needed to devise the correct parameter space may require knowledge and efforts that are not always at disposal of the average practitioner. The assumption underlying the work of Siddiqi and Moore (2005) is, in our opinion, simpler to be fulfilled in practice. However, the extent to which it holds (which determines the magnitude of k) cannot be easily forecasted. Again, the extra efforts needed to assess the applicability of the approach may be detrimental to its application. Moreover, both approaches require *homogeneous* transition matrices: that is, transition matrices that do not vary over time. This is a common assumption, but unfortunately it cannot be guaranteed in some recently developed approaches, as those based on the boolean feature framework (McCallum et al., 2000). `CarpeDiem` can be safely applied even in this more complex scenario. In the experimentation, we successfully apply `CarpeDiem` in both settings, the one where the transition matrix is not constant (Section 6.1), as well as the one where it is (Sections 6.2 and 6.3).

In a recent paper Mozes et al. (2007) propose an *exact* compression-based technique to speed up the Viterbi algorithm. The authors propose to use three well known compression schemes achieving significant speed-ups whose magnitude depends on which compression algorithm is adopted. Interestingly the cited approach is not a search scheme, rather it is a preprocessing step. As such, it qualifies as an orthogonal technique amenable to be used together with `CarpeDiem` obtaining the advantages of both techniques.

In facts, to the best of our knowledge, the algorithms `CarpeDiem` and (Mozes et al., 2007) are the only exact ones, capable of speeding up the Viterbi algorithm when the assumption of homogeneous matrices is dropped. We would also argue that the other approaches presented above are not easily adapted to work in this, more complex, scenario. In Siddiqi and Moore (2005) the transition matrix needs to be traversed in advance in order to obtain the highest ranking frequencies. If those frequencies change over time, this operation needs to be repeated for each t, and the algorithm would require $O(TK^2)$ only to compute this preprocessing step. In Felzenszwalb et al. (2003) it is necessary to express the weights of the transition from label i to label j in terms of a function of $|i-j|$. The effectiveness of the approach depends on particular properties of this function. It could be argued that, in very particular situations, those properties could be shown to hold even when

2. One whose maximum can be calculated in (nearly) constant time.



Vertical weights	$S^0_{i_1}$	100	$S^0_{j_1}$	50	$S^0_{i_2}$	5	$S^0_{j_2}$	100
Horizontal weights	$S^1_{i_1,i_2}$	20	$S^1_{i_1,j_2}$	20	$S^1_{j_1,i_2}$	30	$S^1_{j_1,j_2}$	40

Figure 2: Sometimes horizontal weights can be disregarded without loosing the optimal path.

the transition matrix varies with t. However, it is hard to figure out a general way to enforce this property without inspecting the whole transition matrix at each time step.

`CarpeDiem` enjoys the desirable property of smoothly scaling to the Viterbi algorithm complexity when the underlying assumptions soften (as argued in Section 4.5). This has two consequences: 1) the algorithm adapts to the problem *and* to the sequence at hand, and 2) the algorithm can be universally applied (even when one is unsure about whether the problem fits `CarpeDiem` assumptions or not). In contrast with other state-of-the-art algorithms, no domain knowledge is to be given, nor any parameter needs to be set. This makes `CarpeDiem` well suited to be used on a regular basis as a *drop-in* replacement of the Viterbi algorithm: in the worst case, with no time saving.

4. The `CarpeDiem` Algorithm

In the general case, in order to determine the end point of the best path to a given layer, one can avoid inspecting all vertices in that layer. In particular, after sorting the vertices in layer t according to their vertical weight, the search can be stopped when the difference in vertical weight of the best node so far and the next vertex in the ordering is big enough to counterbalance any advantage that can be possibly derived from exploiting a better transition and/or a better ancestor.

To clarify this point, it is interesting to consider the minimal example reported in Figure 2. Let us assume that the reward for the maximal weight for any transition is 60. Our objective is to find the endpoint of the best path to each layer. For layer 1 we have no incoming paths, the best endpoint is simply the vertex with the maximal vertical weight: in the example, i_1. In our approach, we consider vertices with highest vertical weight first. Hence we start by calculating the reward of the optimal path to node j_2: in the example, the path i_1, j_2 (with score $S^0_{i_1} + S^1_{j_2,i_1} + S^0_{j_2} = 100 + 20 + 100 = 220$). We notice that the reward attainable by reaching i_2 cannot be higher than 165, computed as the sum of the reward for the best path to layer 1 (i.e., 100), plus the maximal weight for any transition (i.e., 60), plus the vertical weight of i_2 (i.e., 5). Therefore the endpoint of the best path to layer 2 must be j_2 and it is not necessary to calculate the reward for reaching i_2. In the course of the algorithm (hopefully) many vertices will be left unexplored by means of the above strategy. We note, however, that this does not prevent from the need of exploring those vertices in the following steps. When necessity arises `CarpeDiem` goes back through the previous layers gathering the required information. This is why `CarpeDiem` makes use of two procedures: one that finds the best vertex in

each layer (Algorithm 3), and one that finds the reward for reaching a given node by traversing the graph from right to left (Algorithm 4).

We say that a vertex is *open* if the reward of its best incoming path has been computed; otherwise the vertex is said to be *closed*. `CarpeDiem` finds the best vertex for each layer by calling Algorithm 3 (also referred to as *forward search strategy*), which leaves closed as many vertices as possible. The *backward search strategy* is called to open vertices whenever necessary.

The main procedure of `CarpeDiem` is presented in Algorithm 2; the forward and the backward search strategies are presented in Algorithms 3 and 4, respectively. Before detailing the algorithm, we need to introduce several definitions.

Definition 2 *Let us define:*

S^{1*} *: an upper bound to the maximal transition weight in the current graph*

$$S^{1*} \geq \max_{y_t, y_{t-1}} S^1_{y_t, y_{t-1}}; \tag{3}$$

γ^*_t *: the reward of the best path to any vertex in layer t (including the vertical weight of the ending vertex)*

$$\gamma^*_t = \max_{y_t} \gamma(y_t);$$

β_t *: an upper bound to the reward that can be obtained in reaching layer t* ($2 \leq t \leq T$)

$$\beta_t = \gamma^*_{t-1} + S^{1*}; \tag{4}$$

$\sqsupseteq_t$ *: a total ordering—based on vertical weights—of vertices at layer t.*

$$\sqsupseteq_t \equiv \{(y_t, y'_t) | S^0_{y_t} \geqslant S^0_{y'_t}\}. \tag{5}$$

Also, we say that vertex y_t is more promising *than vertex y'_t iff $y_t \sqsupseteq_t y'_t$.*

During execution, `CarpeDiem` calculates several values that are strictly connected to the definitions above. In particular $\mathbb{G}$ is a vector of $K \times T$ elements. $\mathbb{G}(y_t)$ contains the value of $\gamma(y_t)$ as calculated by `CarpeDiem`. Also, $\mathbb{B}$ is a vector of T elements. $\mathbb{B}_t$ contains the value of β_t as calculated by `CarpeDiem`. To a good extent, proving `CarpeDiem` correct will involve proving that, indeed, $\mathbb{G}(y_t) = \gamma(y_t)$ and $\mathbb{B}_t = \beta_t$.

4.1 Algorithm 2 – Main Procedure

Algorithm 2 initializes $\mathbb{G}(y_1)$ and $\mathbb{B}_2$ values and calls Algorithm 3 on all layers $2 \ldots T$. More specifically, $\mathbb{G}(y_1)$ is set to S^0_1 (as required by Equation 1). Also $\mathbb{B}_2$ is set to the maximal vertical weight found plus S^{1*} (as required by Equation 4).

4.2 Algorithm 3 – Forward search strategy

The forward strategy searches for the best vertex for layer t stopping as soon as this vertex can be determined unambiguously.

At the beginning of the analysis of each layer all vertices in the layer are *closed*. The algorithm scans vertices in the order given by $\sqsupseteq_t$. As mentioned at the beginning of Section 4, in the general

begin
  foreach y_1 { Initialization Step } **do**
2 $\mathbb{G}(y_1) \leftarrow S^0_{y_1}$; { Opens vertex y_1 }
  end
3 $y^*_1 \leftarrow \arg\max_{y_1}(\mathbb{G}(y_1))$;
  $\mathbb{B}_2 \leftarrow \mathbb{G}(y^*_1) + S^{1*}$;
  foreach *layer* $t \in 2 \dots T$ **do**
    $y^*_t \leftarrow$ result of Algorithm 3 on layer t;
  end
  return path to y^*_T;
end

Algorithm 2: `CarpeDiem`.

begin
  $y^*_t \leftarrow$ most promising vertex;
  $y'_t \leftarrow$ next vertex in the $\sqsupseteq_t$ ordering;
  Open vertex y^*_t {call Algorithm 4};
  while $\mathbb{G}(y^*_t) < \mathbb{B}_t + S^0_{y'_t}$ **do**
4   Open vertex y'_t {call Algorithm 4};
5    $y^*_t \leftarrow \arg\max_{y'' \in \{y^*_t, y'_t\}} [\mathbb{G}(y'')]$;
    $y'_t \leftarrow$ next vertex in the $\sqsupseteq_t$ ordering;
  end
6 $\mathbb{B}_{t+1} \leftarrow \mathbb{G}(y^*_t) + S^{1*}$;
  return y^*_t;
end

Algorithm 3: Forward search strategy.

case, the algorithm can avoid opening all vertices in every layer. The search is stopped when the difference in vertical weight of y^*_t and y'_t is big enough to counterbalance any advantage that can be possibly derived from exploiting a better transition and/or a better ancestor. In formulae, let $\pi(y^*_t)$ be the best predecessor for y^*_t, the (forward) search is stopped when the currently best vertex y^*_t and the next vertex y'_t in the $\sqsupseteq_t$ ordering satisfy:

$$\overbrace{S^0_{y^*_t} - S^0_{y'_t}}^{\substack{\text{accounts for a better vertical} \\ \text{weight of } y^*_t \text{ w.r.t. } y_t}} \geq \overbrace{\left(\gamma^*_{t-1} - \gamma(\pi(y^*_t))\right)}^{\substack{\text{accounts for a possibly bet-} \\ \text{ter predecessor of } y'_t \text{ w.r.t. } y^*_t}} + \overbrace{\left(S^{1*} - S^1_{y^*_t, \pi(y^*_t)}\right)}^{\substack{\text{accounts for a possibly bet-} \\ \text{ter transition from } y'_t \text{ prede-} \\ \text{cessor}}} . \tag{6}$$

The above formula is a direct consequence of the exit condition of the *while* loop of Algorithm 3, and it can be obtained by substituting[3] $\mathbb{B}$ and $\mathbb{G}$ with β and γ, and then expanding β and γ using their definitions (we repeat the relevant definitions in Table 1-*a* and *b*).

3. The soundness of the substitution is guaranteed by Theorems 1 and 2.

a)	Definition of β	$\beta_t = \gamma^*_{t-1} + S^{1*}$
b)	Definition of γ (see Eq. 1)	$\gamma(y^*_t) = \gamma(\pi(y^*_t)) + S^1_{y^*_t,\pi(y^*_t)} + S^0_{y^*_t}$

Table 1: Summary of few useful quantities

In case the stop criterion is not met, the algorithm calls Algorithm 4 (also referred to as the *backward strategy*) which sets $\mathbb{G}(y'_t) = \gamma(y'_t)$. If necessary, the "maximal" vertex y^*_t (the vertex that, so far, has associated maximal reward) is updated. Before exiting, $\mathbb{B}_{t+1}$ is readied for later use, and the best vertex is returned.

4.3 Algorithm 4 – Backward search strategy

The backward search strategy opens a vertex y_t by finding its best ancestor and setting $\mathbb{G}(y_t)$ accordingly. In much the same spirit as in the forward strategy, the algorithm saves some computation *i*) by exploiting $\sqsupseteq_{t-1}$ in order to inspect first the most promising vertices, and *ii*) by taking advantage of β_{t-1} in order to stop the search as soon as possible.

Data: A vertex y_t to be opened
begin
  $y^*_{t-1} \leftarrow$ most promising vertex;
  $y'_{t-1} \leftarrow$ next vertex in the $\sqsupseteq_{t-1}$ ordering;
  while y'_{t-1} *is open* **do**
    $y^*_{t-1} \leftarrow \arg\max_{y'' \in \{y'_{t-1}, y^*_{t-1}\}} \left[\mathbb{G}(y'') + S^1_{y_t,y''}\right]$;
    $y'_{t-1} \leftarrow$ next vertex in the $\sqsupseteq_{t-1}$ ordering;
  end
  while $\left(\mathbb{G}(y^*_{t-1}) + S^1_{y_t,y^*_{t-1}} < \mathbb{B}_{t-1} + S^0_{y'_{t-1}} + S^{1*}\right)$ **do**
    Open y'_{t-1} {call Algorithm 4};
    $y^*_{t-1} \leftarrow \arg\max_{y'' \in \{y'_{t-1}, y^*_{t-1}\}} \left[\mathbb{G}(y'') + S^1_{y_t,y''}\right]$;
    $y'_{t-1} \leftarrow$ next vertex in the $\sqsupseteq_{t-1}$ ordering;
  end
7 $\mathbb{G}(y_t) \leftarrow \mathbb{G}(y^*_{t-1}) + S^1_{y_t,y^*_{t-1}} + S^0_{y_t}$;
end

Algorithm 4: Backward search strategy to open y_t.

The first loop finds the best predecessor among the open vertices of layer $t-1$. In the second loop, we exploit the same idea behind the forward strategy. Let us inspect the exit condition of the second loop:

$$\mathbb{G}(y^*_{t-1}) + \mathbf{S^1_{y_t,y^*_{t-1}}} < \mathbb{B}_{t-1} + S^0_{y'_{t-1}} + \mathbf{S^{1*}}.$$

With the exception of the symbols in bold font, the formula is the same as the one in the exit condition of the while loop in Algorithm 3. The bold symbols take into account the transition to the target vertex. Namely, $\mathbf{S^1_{y_t,y^*_{t-1}}}$ takes into account the transition from the current best vertex (y^*_{t-1})

to the target vertex y_t and $\mathbf{S^{1*}}$ accounts for the maximal reward that a transition from y'_{t-1} to y_t can possibly obtain.

Also the internal working of the second loop is very similar to the one in the forward strategy. After opening (through a recursive call) y'_{t-1}, the current best vertex is set to the best of y'_{t-1} and y^*_{t-1}.

4.4 Example

In the following we provide a description of an execution of `CarpeDiem` over a toy problem. The problem consists of labeling a sequence containing four events and two labels (named *i* and *j*). The example is reported in Figure 3. The weight shown on the edge between labels y_{t-1} and y_t corresponds to $S^1_{y_t,y_{t-1}}$. The bound S^{1*} on the maximum horizontal reward is 60. Two further quantities are reported in the figure, and shown graphically by means of boxes placed on vertices: within rectangular boxes, we report the vertical weight of the vertex. Within rounded boxes, we report:

- $\mathbb{G}(y_t)$, if y_t is open;
- $\mathbb{B}_t + S^0_{y_t}$, if y_t is closed and $\mathbb{B}_t$ has already been computed;
- 0, otherwise.

Here we give a detailed description of the algorithm execution over the given graph.

step (a) At the beginning of the execution, all vertices are closed. The initialization steps in Algorithm 2 open all vertices in layer 1. Clearly, there is no reward for arriving at vertices in layer 0 and no incoming transitions to be taken into account. The best vertex in layer 1 is thus the vertex having the maximum vertical weight.

step (b) The analysis of layer 2 starts by opening the most promising vertex in that layer (vertex *j*). Since all vertices at layer 1 are open, the backward strategy already has complete information at disposal, and it does not need to enter the second loop to open j_2. Once $\mathbb{G}(j_2)$ has been computed, the algorithm compares this value to the bound on the weight of the best path to i_2. Since $S^0_{i_2} + \mathbb{B}_2 = 165$ cannot outperform $\mathbb{G}(j_2) = 220$, there is no need to open vertex i_2.

step (c) To open i_3, the backward strategy goes back to layer 2 and searches for the best path to that vertex. Again, vertex i_2 can be left closed, since there is no chance that the best path to i_3 traverses it. In fact,

$$\mathbb{B}_2 + S^0_{i_2} + S^{1*} = (100+60) + 5 + 60 = 225$$

cannot outperform the reward

$$\mathbb{G}(j_2) + S^1_{i_3,j_2} = 220 + 15 = 235$$

obtained by passing through j_2. Then $\mathbb{G}(i_3)$ is set to $235 + 100 = 335$.

Unfortunately, this does not allow to make a definitive decision about whether this is the best vertex of layer 3, since $\mathbb{B}_3 + S^0_{j_3}$ is $(220+60)+70 = 350$. Next step will thereby settle the question by opening vertex j_3.

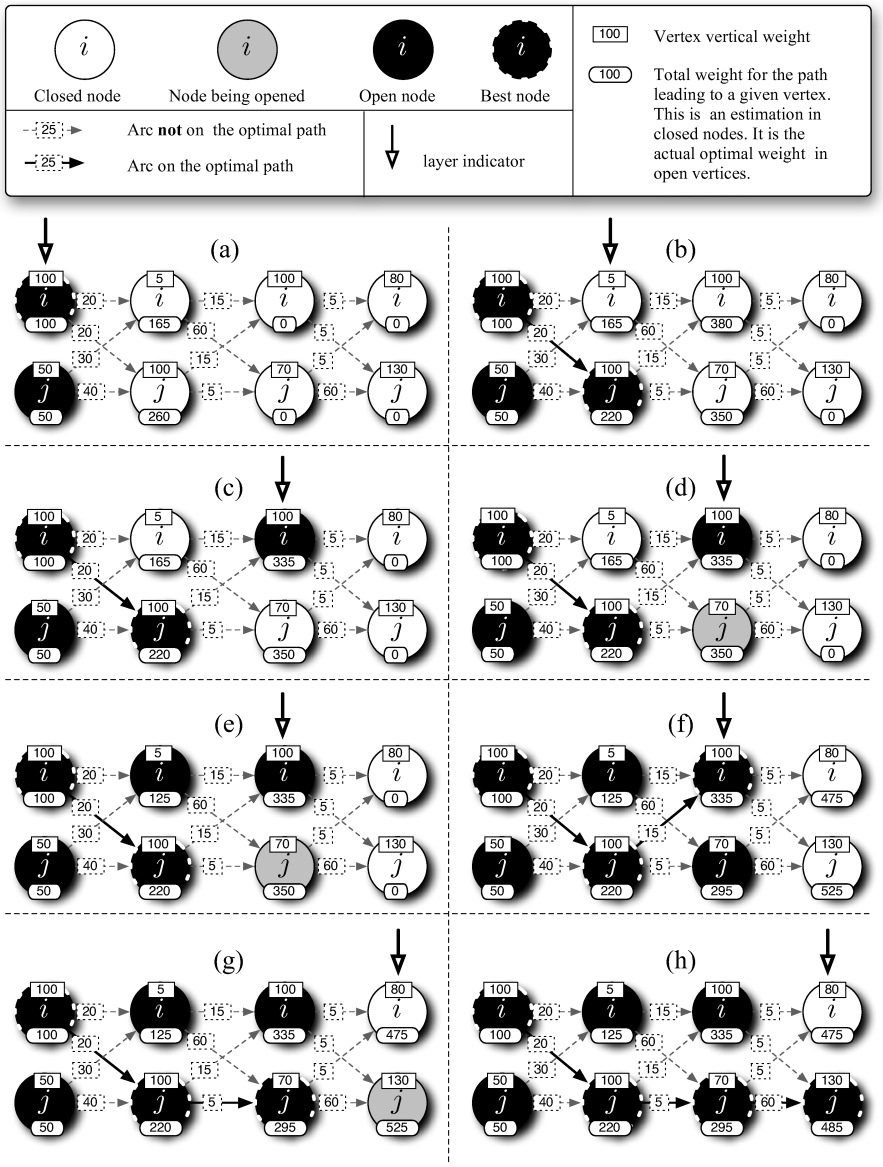


Figure 3: `CarpeDiem` in action on a toy problem.

step (d) The goal is, at this point, to find the best path to j_3. Even though j_2 has a clear advantage over i_2, this does not suffice to exclude that the latter one is on the optimal path to j_3 (since $\mathbb{G}(j_2) + S^1_{j_3,j_2} \not< \mathbb{B}_2 + S^0_{i_2} + S^{1*}$): the backward strategy is then forced to recursively call itself to open i_2.

step (e) By opening i_2, the algorithm sets $\mathbb{G}(i_2)$ to 125 (the best path being $i_1 \rightarrow i_2$), thus ruling it out as a candidate for being on the optimal path to j_3.

step (f) In returning to consider layer 3, we are back to the path $i_1 \rightarrow j_2 \rightarrow i_3$. To open vertices i_2 and j_3 has been wasteful, though unavoidable.

step (g) The first vertex to be opened in its layer is j_4. Interestingly, the best path to j_4 is not through the best vertex in layer 3. In fact, while the highest reward for a three steps walk is on vertex i_3, it is more convenient to go through vertex j_3 to reach vertex j_4.

step (h) Since $\mathbb{G}(j_4) = 485$ is larger than $\mathbb{B}_4 + S^0_{i_4}$, the algorithm terminates leaving i_4 closed.

In Section 6 real world problems are considered, and much larger optimizations obtained.

4.5 Algorithm Properties

An intuitive way of characterizing the algorithm complexity is to consider Formula 6, where the exit condition of Algorithm 3 is rewritten in order to point out why in some cases it is safe to stop inspecting the current layer. Clearly, the sooner the loop exit condition is satisfied, the faster the algorithm.

Arguably, the worst case happens when vertical rewards, being equal for each label, do not provide any discriminative power. In such a case, the left term in Formula 6 is zero, the inequality is never satisfied, and Algorithm 3 calls Algorithm 4 over all K vertices in every layer. In this case, for each one of the k vertices to be opened in a new layer, the first loop of Algorithm 4 iterates over all K predecessors. However, no recursive call takes place. Overall, in the worst case hypothesis, `CarpeDiem` has order of $O(TKK + TK\log(K)) = O(TK^2)$ time complexity.[4] `CarpeDiem` is never asymptotically worse than the Viterbi algorithm.

The best case happens when horizontal rewards, being equal for each transition, do not provide any discriminative power. In such a case the right hand side of the inequality in Formula 6 is zero and the inequality is guaranteed to be satisfied immediately. Moreover, being the backward strategy based on a bound similar to the one that leads to Formula 6, it will never open any other vertex. Then, a single vertex per layer is opened and `CarpeDiem` has order of $O(T + TK\log(K)) = O(TK\log(K))$ time complexity. A more formal argument about `CarpeDiem` complexity is stated by Theorem 3 and proved in Appendix B.

Theorem 3 `CarpeDiem` *has* $O(TK^2)$ *worst case time complexity and* $O(TK\log K)$ *best case time complexity.*

`CarpeDiem` finds the optimal sequence of labels. By using standard book-keeping techniques, the optimal sequence of labels can be tracked back by starting from the optimal end point. Then, the optimality of `CarpeDiem` can be proved by showing that the vertex returned by the forward strategy at the end of the algorithm is the end-point of the optimal path through the graph. This property, stated by Theorem 1, is formally proved in Appendix A.

Theorem 1 *Let us consider a sequence of calls to Algorithm 3 on layers* $2,3,\ldots,t$ $(t \leq T)$. *When Algorithm 3 terminates on layer* t*, the returned vertex* y^*_t *is the endpoint of the optimal path to layer* t*. Formally,*

$$\forall y_t : \gamma(y^*_t) \geq \gamma(y_t).$$

Beside the theoretical properties of the algorithm, it is important for the practitioner to consider its actual performances over real world problems. In the general case the algorithm will open some, but not all vertices: the exact number of the vertices that will be inspected depends on the particular

4. The $O(TK\log(K))$ term in the formula accounts for the time needed to sort vertices according to $\sqsupseteq_t$.

application and on how the features have been engineered. Empirical evidence (Section 6) suggests that many problems are closer to the best case than to the worst. Before introducing the experimentation, we show how `CarpeDiem` can be instantiated in the context of a supervised sequential learning system and, more in particular, in a system based on the voted perceptron algorithm.

5. Grounding the Voted Perceptron Algorithm on `CarpeDiem`

The supervised sequential learning problem can be formulated as follows (Dietterich, 2002).

> Let $\{(\vec{x}_i, \vec{y}_i)\}_{i=1}^{N}$ be a set of N training examples. Each example is a pair of sequences $(\vec{x}_i, \vec{y}_i)$, where $\vec{x}_i = \langle x_{i,1}, x_{i,2}, \ldots, x_{i,T_i} \rangle$ and $\vec{y}_i = \langle y_{i,1}, y_{i,2}, \ldots, y_{i,T_i} \rangle$. The goal is to construct a classifier H that can correctly predict a new label sequence $\vec{y} = H(\vec{x})$ given an input sequence $\vec{x}$.

The SSL problem has been approached with many different techniques. Among others, we recall Sliding Windows (Dietterich, 2002), hidden Markov models (Rabiner, 1989), Maximum Entropy Markov Models (McCallum et al., 2000), Conditional Random Fields (Lafferty et al., 2001), Dynamic Conditional Random Fields (Sutton et al., 2007), and the voted perceptron algorithm (Collins, 2002).

The voted perceptron uses the Viterbi algorithm at both learning and classification time. It is then particularly appropriate for the application of our technique. Moreover, it relies on the *boolean features framework* (McCallum et al., 2000) which is more general than the HMMs model with respect to representing the graph. In this framework, depending on how features are implemented, both static (homogeneous) and *dynamic* transition matrices can be modeled. We use the term *dynamic* transition matrix to indicate that weights associated to edges may change from time point to time point, depending on the observations.

In the boolean features framework the learnt classifier is built in terms of a set of boolean features. Each feature ϕ reports about a salient aspect of the sequence to be labelled in a given time instant. More formally, given a time point t, a boolean feature is a $1/0$-valued function of the whole sequence of feature vectors $\vec{x}$, and of a restricted neighborhood of y_t. The function is meant to return 1 if the characteristics of the sequence $\vec{x}$ around time step t support the classifications given at and around y_t. Under a first order Markov assumption, each ϕ depends only on y_t and y_{t-1}. Let us denote with w_ϕ the weight associated to feature ϕ. The classifier learnt by the voted perceptron algorithm has the form

$$H(\vec{x}) = \arg\max_{\vec{y}} \sum_{t=1}^{T} \sum_{\phi} w_\phi \cdot \phi(\vec{x}, y_t, y_{t-1}, t)$$

and is suitable to be evaluated using the Viterbi algorithm.

In practice, not all boolean features depend on both y_t and y_{t-1}. Let us distinguish features depending on both y_t and y_{t-1} from those depending only on y_t. We denote with Φ^0 the set of features that depends only on y_t and thus models per vertex (vertical) information. Analogously, we denote with Φ^1 the set of features that depend on both y_t and y_{t-1} modeling, thus, per edge (horizontal) information. The vertical and horizontal weights can be then calculated as:

$$S^0_{y_t} = \sum_{\phi \in \Phi^0} w_\phi \phi(\vec{x}, y_t, t)$$

and

$$S^1_{y_t,y_{t-1}} = \sum_{\phi \in \Phi^1} w_\phi \phi(\vec{x}, y_t, y_{t-1}, t).$$

In general, the bound on the maximal transition weight S^{1*} can be set to the sum of all positive horizontal weights:

$$S^{1*} = \sum_{\phi \in \Phi^1} J(w_\phi)$$

where $J(x)$ is x if $x > 0$, and 0 otherwise. It is noteworthy that this quantity can be computed without any extra—domain specific—knowledge.

Often, however, better bounds can be given based on specific domain knowledge. An example of such improvements (one that we exploit throughout our experimentation) consists in partitioning the horizontal features into sets of mutually exclusive features. Then the bound can be computed as the sum of the maximal weight of each partition. In case the partitions degenerate to a single set (i.e., all horizontal features are mutually exclusive), the maximal horizontal weight can be used. For instance, in many domains where HMMs are routinely applied, horizontal features are used only to check the last two predicted labels. In such domains, if a horizontal feature is asserted, no other feature can and we can appropriately set

$$S^{1*} = \max_{\phi \in \Phi^1} J(w_\phi). \tag{7}$$

6. Experimentation

To figure out whether and how `CarpeDiem` can be applied to actual tasks, we tested it on three different problems: the problem of music harmony analysis (Radicioni and Esposito, 2007), the frequently asked questions (FAQs) segmentation problem (McCallum et al., 2000), and a text recognition problem built starting from the "letter recognition" data set from the UCI machine learning repository (Frey and Slate, 1991).

The running time of an execution of `CarpeDiem` depends on how the weights of vertical and horizontal features compare: the more discriminative are vertical features with respect to horizontal features, the larger is the edge `CarpeDiem` has over the Viterbi algorithm.

Overall the three experiments cover three situations that are likely to occur in practice. The music analys problem represents a situation where S^{1*} has been selected by exploiting detailed domain knowledge: horizontal features have been divided into sets of non trivial partitions and the bound has been set accordingly (see end of Section 5). Features of the FAQs segmentation problem have been developed by McCallum et al. (2000) on a different system, and then imported into ours without modifications. Features used in the text recognition task didn't go through a real engineering process; on the contrary, they can be seen as a first, to some extent *naive*, attempt to tackle the problem. In these last two cases, we have set S^{1*} using Formula 7.

6.1 Tonal Harmony Analysis

Given a musical flow, the task of music harmony analysis consists in associating a label to each time point (Temperley, 2001; Pardo and Birmingham, 2002). Such labels reveal the underlying harmony by indicating a fundamental note (*root*) and a *mode*, using chord names such as 'C minor'.

Music analysis task can be naturally represented as a supervised sequential learning problem. In fact, by considering only the "vertical" aspects of musical structure, one would hardly produce reasonable analyses. Experimental evidences about human cognition reveal that in order to disambiguate unclear cases, composers and listeners refer to "horizontal" features of music as well: in these cases, context plays a fundamental role, and contextual cues can be useful to the analysis system.

The system relies on 39 features. They have been engineered so that they take into account the prescriptions from music harmony theory, a field where vertical and horizontal features naturally arise. *Vertical* features report about simultaneous sounds and their correlation with the currently predicted chord. *Horizontal* features capture metric patterns and chordal successions. This is a case where not all horizontal features are mutually exclusive (i.e., S^{1*} is not the maximal of positive horizontal weights) and where horizontal weights may change over time. For instance, the same transition between two chords can receive different weights according to whether it falls on accented/unaccented beats.

The training set is composed of 30 chorales (3,020 events) by J.S. Bach (1675-1750). The classifiers have been tested on 42 separate chorales (3,487 events) from the same author.

6.2 FAQs Segmentation

We experimented on the FAQs segmentation problem as introduced by McCallum et al. (2000). It basically consists of segmenting Usenet FAQs into four distinct sections: 'head', 'question', 'answer', and 'tail'.

In this data set, events correspond to text lines and sequences correspond to FAQs. McCallum et al. define 24 boolean features. Each one is coupled with each possible label for a total of 96 features. Additionally, 16 features are used to take into account the possible transitions between labels.

The data set consists of a learning set containing 26 sequences (29,406 events) and a test set containing 22 sequences (33,091 events).

6.3 Text Recognition

Our third experiment deals with the problem of recognizing printed text. We trained the classifiers on the "The Frog King" tale (122 sequences, 6,931 events) by Grimm brothers, and tested over the "Cinderella" tale (240 sequences, 13,354 events) by the same authors. The classifier is called to recognize each letter composing the tale. The data set has been built as follows. Each letter (corresponding to an individual event) in the tales has been encoded by picking at random one of its possible descriptions as provided by the *letters* UCI data set[5] (Frey and Slate, 1991). Each sentence corresponds to a distinct sequence.

We briefly recall here the characteristics of the letters data set as originally proposed by the authors. The data set contains 20,000 letters described using 16 integer valued features. Such attributes capture highly heterogeneous facets of the scanned raw image such as: horizontal and vertical position, the width and height, the mean number of edges per pixel row. The images have been obtained by randomly distorting 16 fonts taken from the US National Bureau of Standards. The features used by the learning system are:

5. It can be found at `ftp://ftp.ics.uci.edu/pub/machine-learning-databases/letter-recognition`.

Experiment	Viterbi	CarpeDiem	Time Saved (%)
music Analysis	13,582	1,507	88.90%
FAQs segmentation	537	144	73.15%
letter recognition	961,969	34,244	96.44%

Table 2: CPU Time (expressed in seconds) and percentage of time saved by CarpeDiem.

1. $26 \times (16 \times 16) = 6,656$ vertical features, obtained by the original attributes devised by Frey and Slate (1991). The reported figure is explained as follows. We consider each of the 16 values of the 16 attributes in the original data set, thus resulting in 256 possible combinations. Each such combination is still to be coupled with the 26 letters of the English alphabet.

2. the $27 \times 27 = 729$ horizontal features, obtained by considering $\mathcal{A} \times \mathcal{A}$, where $\mathcal{A}$ is the set of letters in the english alphabet, plus a sign for blanks.

6.4 Procedure

We compare the performances of CarpeDiem against those provided by the Viterbi algorithm. To this aim, we embedded CarpeDiem in a SSL system implementing the voted perceptron learning algorithm (Collins, 2002). The learnt weights have been then used to build two classifiers: one based on the Viterbi algorithm, the other one based on CarpeDiem.

For each one of the three problems we divided the data into a learning set and a test set. Each learning set has been further divided into ten data sets of increasing sizes (the first one contains 10% of the data, the second one 20% of the data, and so forth). Also, each experiment has been repeated by varying the number of learning iterations from 1 to 10, for a grand total of 100 classifiers per problem. We tested each learnt classifier on the appropriate test set recording the classification time obtained by using first CarpeDiem and then Viterbi.

In the following we will indicate each one of the 100 classifiers by using two numbers separated by a colon: the former number corresponds to the size of the training set (1 standing for 10%, 2 for 20%, ..., 10 for 100%), the latter one indicates the number of iterations. For instance, the classifier 8:1 has been acquired by iterating once on 80% of the learning set.

6.5 Results

As earlier mentioned (and implied by Theorem 1), CarpeDiem performs exact inference: classifiers built on CarpeDiem provide the same answers as those built on the Viterbi algorithm.

We measured the total classification time spent by the algorithms as well as the average time *saved* by CarpeDiem with respect to the Viterbi algorithm. They are provided in Table 2: average time savings range from about 73% (FAQs segmentation) to over 96% (letter recognition). Figures 4, 5 and 6 graphically report a detailed account of each experiment. Classification times for each problem were obtained using a fixed size test set. By observing the profiles reported in the figures, it is apparent that, while the Viterbi algorithm runs in approximately constant time, CarpeDiem performances depend on the particular classifier used.

In all trials of all experiments CarpeDiem runs in a small fraction of the time needed by Viterbi.

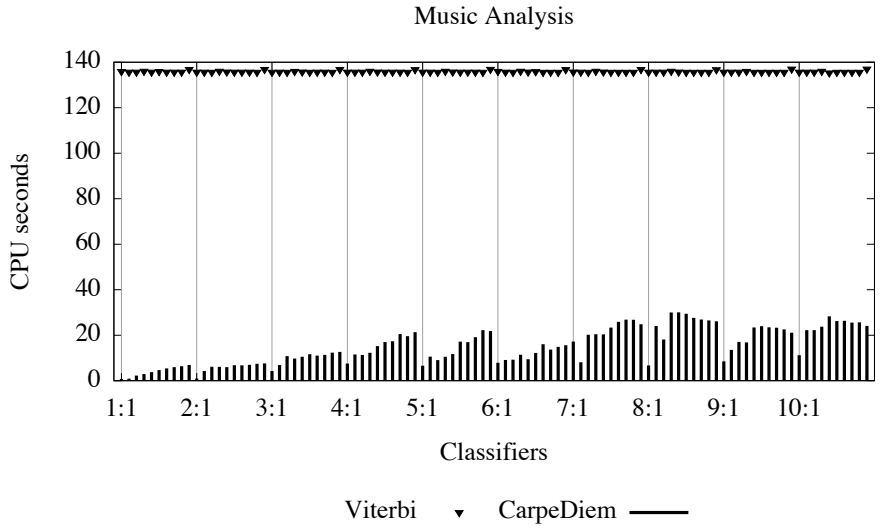

Figure 4: Results on the music analysis problem. We report on the abscissas the learnt classifiers indicating $i{:}j$ for classifier acquired using $(10 \cdot i)\%$ of the training set and j iterations. Labels on the abscissas refer only to the first classifier for each block of experiments; the following nine bars refer to the remaining ones. For instance, label 3:1 is positioned below the bar corresponding to the classifier trained on the 30% of the training set and using 1 iteration. The following nine bars refer to classifiers $3{:}2, 3{:}3, \ldots, 3{:}10$. We report on the ordinates the CPU seconds needed for the classification of the test set. Vertical bars refer to the time spent by `CarpeDiem`. Triangles refer to the time spent by Viterbi.

One interesting fact is unveiled by the profile of the classification time. Since—in each one of the three experiments—classification is performed on a data set of fixed size, one would expect roughly constant classification time. By converse, at least in the first two experiments (Figures 4 and 5), the emerging patterns are similar to those usually observed at learning time. We remark that the hundred runs of each experiment differ only in the set of weights used by the classifier. Then it is apparent that, as the voted perceptron learns, it somehow modifies the weights in a way that proves to be detrimental to the work of `CarpeDiem`.

To explain the observed patterns, let us consider an informative vertical feature $\phi_\bullet$ and examine the first iteration of the voted perceptron on a sequence of length $T = 100$. Also, we assume that $\phi_\bullet$ is asserted 60 times, and that it votes for the correct label 50 times out of 60. Even though this example may seem unrealistic, it is not.[6] The first iteration on the first sequence the voted perceptron chooses labels at random. Then, the vast majority of them will be incorrectly assigned, thus implying a large number of feature weights updates. If all the labels for which $\phi_\bullet$ is asserted are actually mislabelled, due to the way the update rule acts, the weight associated to $\phi_\bullet$ will be increased[7] by 40. This large increase occurs all at once at the end of the first iteration on the first sequence, and it is likely to overestimate the weight of $\phi_\bullet$. The voted perceptron will spend the rest of learning trying to compensate for this overestimation. However, subsequent updates will be

6. For instance, in the music analysis problem, this could be the case for the feature that votes for the chord that has exactly 3 notes asserted in the current event.

7. That is, $50 - (60 - 50) = 40$.

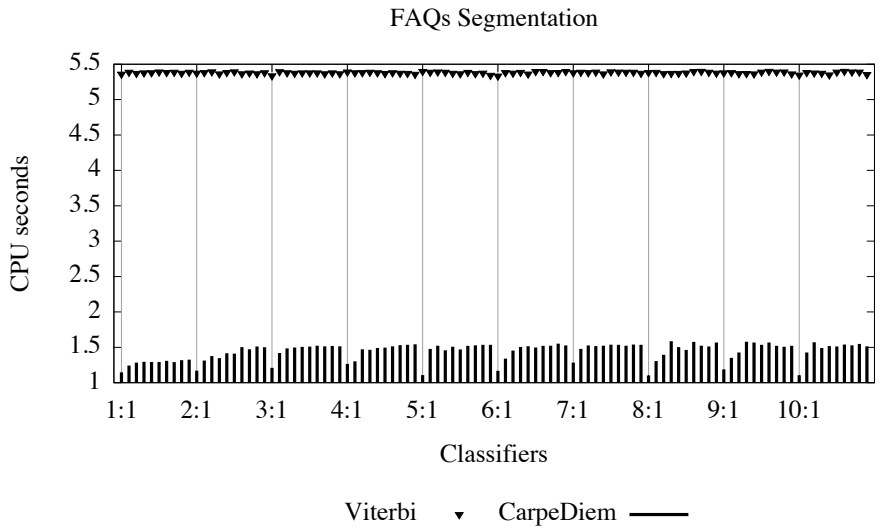

Figure 5: Results on the FAQs Segmentation problem. The conventions adopted are the same as for Figure 4.

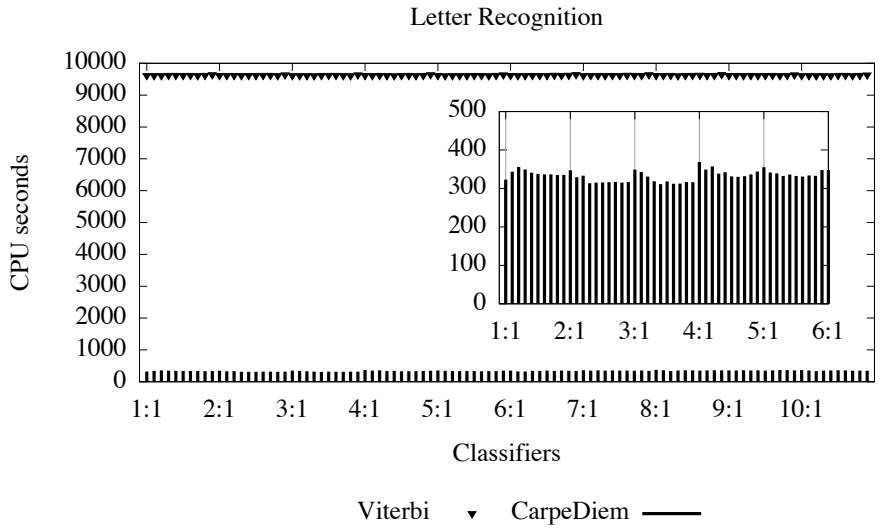

Figure 6: Results on the letter recognition problem. In the inner frame we detail the time spent by `CarpeDiem` using the first fifty classifiers. The conventions adopted are the same as for Figure 4.

of smaller magnitude. In fact, the following predicted labeling will not be randomly guessed, thus implying a reduced number of updates.

By summarizing, highly predictive features have their weights initially set to very large values; such weights slowly decrease in the following. The behavior described clearly emerges in Figure 7, where the individual weights of vertical features (for the music analysis problem) are plotted as the updates occur. Then, since `CarpeDiem` is efficient when vertical features are discriminative compared to horizontal ones, the algorithm is particularly well-suited to be used during the early

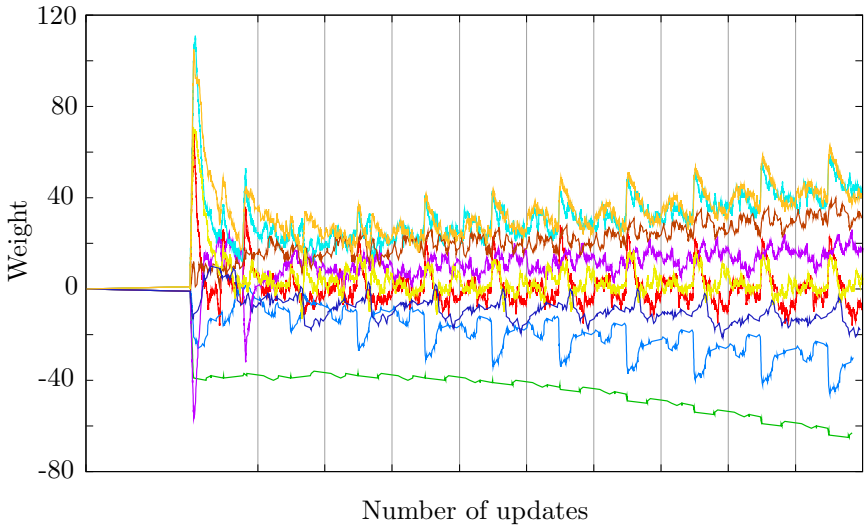

Figure 7: Evolution of vertical weights throughout learning. Each line corresponds to an individual vertical feature; vertical lines correspond to the beginning of new iterations. The plot refers to the music analysis data set.

learning steps of the voted perceptron where the time saved by `CarpeDiem` reaches peaks of 99.47% (music analysis, classifier 1:1) and 78.60% (FAQs segmentation, classifier 1:1).

Lastly, one might wonder why the observed pattern wasn't seen in the text recognition problem. Notwithstanding that the problem itself is a sequential one, to model only bigrams probabilities proved—against our expectations—to be not enough to provide sufficient discrimination power to horizontal features. In other words, the horizontal features we devised contribute to the correct classification only in a marginal way. This is a setting where `CarpeDiem` can, and actually does, attain exceptional time savings (Figure 6).

Prompted by such time savings, we re-ran the same experiments using no horizontal features: the accuracy does not drop down as significantly as in the other two problems. This fact explains why the pattern observed in Figures 4 and 5 is not observed in Figure 6: since vertical features remain predictive with respect to horizontal ones throughout the learning process the performances of `CarpeDiem` do not change over time. Here we note one important property of `CarpeDiem`: `CarpeDiem` time performances reflect the degree of sequentiality inherent to the problem at hand. Actually, by tracking the number of vertices opened in each layer, one can even measure how important sequential information is in different parts of the same sequence.

6.6 Comparison with Related Algorithms

In the following we present a brief discussion about two technologies that, if not directly comparable with `CarpeDiem`, are much related to the algorithm. We start by reporting the results of implementing the `CarpeDiem` heuristic for the A^* algorithm. Then, we report about a performance comparison with non-optimal search algorithms based on the Viterbi beam search approach.

6.6.1 RELATIONS WITH A^*

It could be argued that the `CarpeDiem` algorithm looks interestingly similar to the A^* algorithm (Hart et al., 1968). In order to investigate this similarity let us consider the following heuristic, based on the same ideas underlying `CarpeDiem`:

$$h(y_t) = \sum_{t'>t} \left[\max_{y_{t'}} \left(S^0_{y_{t'}} \right) + S^{1*} \right] = (T-t)S^{1*} + \sum_{t'>t} \left[\max_{y_{t'}} \left(S^0_{y_{t'}} \right) \right].$$

The heuristic estimates the distance to the goal by summing the best vertical weight in each layer and the best possible transition between any two layers.

Even though the heuristic is intuitively connected to the strategy implemented in `CarpeDiem`, the differences are indeed remarkable. A first important difference is in the choice criteria implemented in Algorithms 3 and 4 (we will focus only on Algorithm 3 for the sake of exposition). The criterion in Algorithm 3 states: *do not consider any further node in this layer if*

$$\mathbb{G}(y^*_t) >= \mathbb{B}_t + S^0_{y'_t}.$$

Since $\mathbb{B}_t = \mathbb{G}(y^*_{t-1}) + S^{1*}$, the above criterion approximates the reward of the optimal path by means of S^{1*} only once rather than the $T-t$ times taken by $h(y_t)$. Hence, A^* incurs an high risk of opening vertices in layers far from the goal only because of the cumulation of these approximations.

Another important difference between the two algorithms is in the fact that `CarpeDiem` implements two different heuristics: one is used by Algorithm 3 and one is used by Algorithm 4. On the contrary A^* uses the same criterion throughout the computation. Finally, the data structures needed by `CarpeDiem` are simpler (and faster) than those needed to implement A^*.

In order to empirically assess whether A^* could be competitive with respect to `CarpeDiem`, we implemented the above heuristic and paid particular attention to tuning the data structures. The resulting algorithm turned out to be even less efficient than the Viterbi algorithm.

Of course, this does not mean that the same principles implemented by `CarpeDiem` could not be plugged into A^* by means of a carefully chosen heuristic. Rather, it shows that the problem is not trivial, and deserves *ad-hoc* research efforts.

6.6.2 VITERBI BEAM SEARCH

To compare `CarpeDiem` with algorithms based on the Viterbi beam search (VBS) strategy presents several difficulties. On the one hand, we have an algorithm that guarantees optimality, but not computational performances; on the other hand, we have VBS approaches that guarantee computational performances abdicating optimality.

In VBS approaches the width of the beam (hereafter b) is particularly important in that it affects the tradeoff between computational gain and result optimality. For very small b, VBS would most probably lead to crude approximations; in this case VBS is likely to run faster than CarpeDiem just because it disregards most of the possibly-optimal paths. By converse, if we were to choose the beam size almost equal to the number of possible labels K (i.e., $b \simeq K$), then VBS would run in almost the same time as the Viterbi algorithm. In between there are all other options. Also, the quality of the solution found by VBS approaches highly depends on the heuristic adopted. In the following we will disregard any accuracy concern, so that the two approaches could be compared in terms of execution times solely.

Let ξ be the ratio between the time spent by `CarpeDiem` and the time spent by the Viterbi algorithm for solving a given problem: that is, the time savings reported in Table 2 are computed as $[(1-\xi)\times 100]\%$. Given that the time spent by a Viterbi beam search algorithm is in the order of b^2T, the time saved by a VBS algorithm w.r.t. the Viterbi algorithm is in the order of:

$$\frac{(K^2-b^2)T}{K^2T} = 1 - \frac{b^2}{K^2}\ .$$

By equating the time saved by `CarpeDiem` (i.e., $1-\xi$) and the time saved via the VBS approach, we have that by setting:

$$b = \sqrt{\xi K^2} \tag{8}$$

an algorithm based on the VBS approach will run in about the same time as `CarpeDiem`.

We implemented a basic VBS algorithm and measured its running time over the data set described in Section 6 and experimented with different settings of b. The results show that to obtain the same running times as `CarpeDiem`, the beam size needs to be set as follows:

- $b = 25$ for the Tonal Harmony Analysis data set. Being $K = 78$, this amounts to consider 32% of the possible labels;
- $b = 2$ for the FAQ Segmentation data set. Being $K = 4$, this amounts to consider 50% of the possible labels;
- $b = 5$ for the text recognition data set. Being $K = 27$, this amounts to consider 18.5% of the possible labels;

Two aspects are remarkable in the above results: *i)* the reported figures have been observed empirically rather than determined using the above formula. It is immediate to verify that they are very close to the ones returned by using Formula 8; *ii)* we omitted to implement a heuristic to guide the VBS search. Since computing the heuristic would require additional efforts, the timings used to derive such numbers are optimistic approximations of the actual time needed by a full fledged VBS algorithm.

In summary, `CarpeDiem` runs at least as fast as a VBS approach when a small to medium beam size is used while providing some additional benefits. Again, investigating the conditions that make appropriate one approach over the other one, deserves further deepening the research.

7. Conclusions

In this paper we have proposed `CarpeDiem`, a replacement of the Viterbi algorithm. On average, `CarpeDiem` allows evaluating the best path in a layered and weighted graph in a fraction of the time needed by the Viterbi algorithm. `CarpeDiem` is based on a property exhibited by most tasks commonly tackled by means of sequential learning techniques: the observations at and around a time instant t are very relevant for determining the t-th label, while information about the succession of labels is mainly useful in order to disambiguate unclear cases. The extent to which the property holds determines the performances of the algorithm. We formally proved that `CarpeDiem` finds the best possible sequence of labels *and* that the algorithm complexity ranges between $O(TK\log K)$ in the best case, and $O(TK^2)$ in the worst case. The fact that the worst case complexity is the same as the Viterbi algorithm complexity suggests that, by and large, `CarpeDiem` is suitable for substituting the Viterbi algorithm.

In Section 3, we reviewed recently proposed alternatives and pointed out the following advantages of CarpeDiem with respect to the competitors:

- it is parameter free;
- it does not require any prior knowledge or tuning;
- it never compromises on optimality.

At the present time, the main strength of other approaches with respect to ours is that they have been devised to improve the forward-backward algorithm as well. We defer the extension of our approach in that direction to future work.

In addition to the theoretical grounding of CarpeDiem complexity, we provided an experimentation on three real world problems, and compared its execution time with that of the Viterbi algorithm. The experiments show that large time savings can be obtained. The reported figures show time savings ranging from 73% to 96% with respect to the Viterbi algorithm.

A further interesting facet of CarpeDiem is that its execution trace provides clues about the problems at hand. It can then be used to understand how salient sequential information is. Also, within the same sequence, it is often interesting to investigate the time steps where sequential information gets crucial thus implying higher classification time. For instance, in Radicioni and Esposito (2007) we used this fact to find where musical excerpts get more difficult.

In a world where the quantity of information as well as its complexity is ever increasing, there is the need for sophisticated tools to analyse it in reasonable time. Our perception is that, in most problems, long chains of dependencies are useful to reach top results, but their influence on the correct labelling decreases with the length of the chain. In a probabilistic setting, the length of the chain of dependencies would be called the 'order of the Markov assumption'. In such a context, it would be appropriate to say that what we call 'vertical' features are actually features making a zero order Markov assumption (no dependency at all), while horizontal features are features making a first order Markov assumption. The higher the order of the Markov assumption we want to plug into the model, the slower the algorithm that evaluates the sequential classifier. If our guess is correct, however, the higher the Markov assumption, the less informative are the features that use it. Should this be the case, CarpeDiem strategy could be extended to efficiently handle higher order Markov assumptions, thereby allowing to use sequential classifiers to tackle a larger set of problems.

Acknowledgments

We wish to thank Luca Anselma, Guido Boella, Leonardo Lesmo, and Lorenza Saitta for their precious advices on preliminary versions of the work. We also want to thank the anonymous reviewers for their helpful comments and suggestions.

Appendix A. Soundness

A proof of soundness for CarpeDiem consists in showing that y_T^* is the endpoint of the optimal path through the graph of interest. Although the whole algorithm is concerned with finding out the optimal path, we presently restrict ourselves to find the optimal endpoint, since standard book

symbol	description
$S^0_{y_t}$	vertical weight of vertex y_t
$S^1_{y_t,y_{t-1}}$	horizontal weight for transition from y_{t-1} and y_t
S^{1*}	maximal transition reward (fixed for the whole graph)
$\gamma(y_t)$	the weight of the best path to y_t
γ^*_t	the weight of the best path to the best vertex in level t
β_t	$\gamma^*_{t-1} + S^{1*}$
$\mathbb{G}(y_t)$	$\gamma(y_t)$ as calculated by `CarpeDiem`
$\mathbb{B}_t$	β_t as calculated by `CarpeDiem`

Table 3: Summary of the notation adopted.

keeping techniques can be used during the search to store path information. The path can be then be retrieved in $O(T)$ time.

The proof consists in two Theorems and one Lemma; in particular, Theorem 1 directly implies the soundness of `CarpeDiem`, while Theorem 2 and Lemma 1 are necessary in the proof of Theorem 1.

Before entering the core of the proof, let us summarize the notation adopted. We distinguish between values that are calculated by `CarpeDiem`, and those representing properties of the graph. We will use blackboard characters ($\mathbb{G}$ and $\mathbb{B}$) to denote the former ones and greek letters (γ and β) for the latter ones. A summary of important definitions is reported in Table 3.

We start by stating and proving Lemma 1, which ensures the soundness of the main bound used by `CarpeDiem`.

Lemma 1 *If $\mathbb{B}_t = \beta_t$ then the bound exploited by CarpeDiem does not underestimate the reward of the optimal path to any vertex. Formally,*

$$\mathbb{B}_t = \beta_t \Rightarrow \mathbb{B}_t + S^0_{y_t} \geq \gamma(y_t).$$

Proof Let us consider the optimal path to y_t and denote with $\pi(y_t)$ the predecessor of y_t. Then, by definition we have: $\gamma^*_{t-1} \geq \gamma(\pi(y_t))$, and $S^{1*} \geq S^1_{y_t,\pi(y_t)}$. It immediately follows that:

$$\gamma^*_{t-1} + S^{1*} + S^0_{y_t} \geq \gamma(\pi(y_t)) + S^1_{y_t,\pi(y_t)} + S^0_{y_t}.$$

By definition $\beta_t = \gamma^*_{t-1} + S^{1*}$ and $\gamma(y_t) = \gamma(\pi(y_t)) + S^1_{y_t,\pi(y_t)} + S^0_{y_t}$, which yields:

$$\beta_t + S^0_{y_t} \geq \gamma(y_t)$$

and by assumption, this implies:

$$\mathbb{B}_t + S^0_{y_t} \geq \gamma(y_t).$$

■

Theorem 1 *Let us consider a sequence of calls to Algorithm 3 on layers $2,3,\ldots,t$ $(t \leq T)$. When Algorithm 3 terminates on layer t, the returned vertex y^*_t is the endpoint of the optimal path to layer t. Formally,*

$$\forall y_t : \gamma(y^*_t) \geq \gamma(y_t).$$

Proof We prove the stronger fact

$$\mathbb{B}_t = \beta_t \wedge \forall y_t : \gamma(y_t^*) \geq \gamma(y_t).$$

The proof is by induction on t. The base case for the induction is guaranteed by the initialization step in Algorithm 2 where $\mathbb{B}_2$ and $\gamma(y_1^*)$ are set. We start by showing that

$$\forall y_1 : \gamma(y_1^*) \geq \gamma(y_1) \tag{9}$$

as follows:

$$\begin{array}{rcl}
\gamma(y_1^*) = & \gamma\left(\arg\max_{y_1} \mathbb{G}(y_1)\right) & \rightarrow \text{by line 3 (Algorithm 2)} \\
= & \gamma\left(\arg\max_{y_1} S^0_{y_1}\right) & \rightarrow \text{by line 2 (Algorithm 2)} \\
= & \gamma\left(\arg\max_{y_1} \gamma(y_1)\right) & \rightarrow \text{by Equation 2} \\
= & \max_{y_1} \gamma(y_1) & \\
& \Downarrow & \\
& \forall y_1 : \gamma(y_1^*) \geq \gamma(y_1). &
\end{array}$$

In order to prove $\mathbb{B}_2 = \beta_2$, we note that Algorithm 2 sets $\mathbb{B}_2$ to $\mathbb{G}(y_1^*) + S^{1*}$:

$$\begin{array}{rcl}
\mathbb{B}_2 = & \mathbb{G}(y_1^*) + S^{1*} & \\
= & S^0_{y_1^*} + S^{1*} & \rightarrow \text{by line 2 (Algorithm 2)} \\
= & \gamma(y_1^*) + S^{1*} & \rightarrow \text{by Equation 2} \\
= & \gamma_1^* + S^{1*} & \rightarrow \text{by definition of } \gamma_1^* \text{ (Table 3) and Equation 9} \\
= & \beta_2 & \rightarrow \text{by definition of } \beta_2 \text{ (Table 3).}
\end{array}$$

Let us now assume that for all $\hat{t}$, $1 \leq \hat{t} < t$:[8]

$$\begin{array}{c}
\mathbb{B}_{\hat{t}} = \beta_{\hat{t}} \\
\forall y_{\hat{t}} : \gamma(y_{\hat{t}}^*) \geq \gamma(y_{\hat{t}})
\end{array}$$

then we prove $\mathbb{B}_t = \beta_t$ as follows:

$$\begin{array}{rcl}
\mathbb{B}_t = & \mathbb{G}(y_{t-1}^*) + S^{1*} & \rightarrow \text{by instruction 6 (Algorithm 3)} \\
= & \gamma(y_{t-1}^*) + S^{1*} & \rightarrow \text{by Theorem 2} \\
= & \gamma_{t-1}^* + S^{1*} & \rightarrow \text{by Equation 10 and definition of } \gamma_{t-1}^* \\
= & \beta_t & \rightarrow \text{by definition of } \beta_t \text{ (Table 3).}
\end{array}$$

In order to prove $\forall y_t : \gamma(y_t^*) \geq \gamma(y_t)$ we start by noting that at the end of the main loop of Algorithm 3 it holds $\mathbb{G}(y_t^*) \geq \mathbb{B}_t + S^0_{y_t'}$. Also, for any $y_t \sqsubseteq_t y_t'$ we have (by Definition 2–Equation 5): $\mathbb{B}_t + S^0_{y_t} \leq \mathbb{B}_t + S^0_{y_t'}$. It follows that $y_t \sqsubseteq_t y_t' \Rightarrow \mathbb{G}(y_t^*) \geq \mathbb{B}_t + S^0_{y_t}$. Using Lemma 1 we have

$$y_t \sqsubseteq_t y_t' \Rightarrow \mathbb{G}(y_t^*) \geq \gamma(y_t). \tag{10}$$

8. We note that our definitions give no meaning to $\mathbb{B}_1$ and β_1. We define them to be equal regardless their value: this simplifies the discussion allowing an easier formulation of the properties being stated and proved. They are not used in the algorithm nor in the argument anyway; the definition is thus safe.

Moreover, since the algorithm scans the vertices in the order given by $\sqsupseteq_t$, all vertices y_t, $y_t \sqsupseteq_t y'_t$ have been considered by the main loop. Then by line 4 (Algorithm 3), by our inductive hypothesis ($\forall \hat{t} < t : \mathbb{B}_{\hat{t}} = \beta_{\hat{t}}$) and Theorem 2, we have that for each such vertex $\mathbb{G}(y_t) = \gamma(y_t)$. Moreover, due to line 5 (Algorithm 3), $\mathbb{G}(y_t^*) \geq \mathbb{G}(y_t)$. Putting together the two statements, we conclude that

$$y_t \sqsupseteq_t y'_t \Rightarrow \mathbb{G}(y_t^*) \geq \gamma(y_t). \tag{11}$$

Equation 10, Equation 11, and the fact that $\sqsupseteq_t$ is a total order, yield

$$\forall y_t : \mathbb{G}(y_t^*) \geq \gamma(y_t).$$

By noting that y_t^* is open (and exploiting again Theorem 2), we have:

$$\forall y_t : \gamma(y_t^*) \geq \gamma(y_t).$$

■

Theorem 2 *Let us assume $\forall \hat{t} < t : \mathbb{B}_{\hat{t}} = \beta_{\hat{t}}$, then after opening vertex y_t, $\mathbb{G}(y_t) = \gamma(y_t)$.*

Proof By line 7 (Algorithm 4), $\mathbb{G}(y_t) = \mathbb{G}(y_{t-1}^*) + S^1_{y_t, y_{t-1}^*} + S^0_{y_t}$. Then, our main goal is to prove

$$\mathbb{G}(y_{t-1}^*) + S^1_{y_t, y_{t-1}^*} + S^0_{y_t} = \gamma(y_t).$$

Replacing $\gamma(y_t)$ with its definition (Equation 2) yields:

$$\mathbb{G}(y_{t-1}^*) + S^1_{y_t, y_{t-1}^*} + S^0_{y_t} = \max_{y_{t-1}} \left(\gamma(y_{t-1}) + S^1_{y_t, y_{t-1}} + S^0_{y_t} \right).$$

The above equality is satisfied if the following two properties hold:

$$y_{t-1}^* = \arg\max_{y_{t-1}} \left(\gamma(y_{t-1}) + S^1_{y_t, y_{t-1}} \right) \tag{12}$$

$$\mathbb{G}(y_{t-1}^*) = \gamma(y_{t-1}^*). \tag{13}$$

The proof, by induction on t, proves that the Equations 12 and 13 are satisfied at the moment (and after) $\mathbb{G}(y_t)$ is set. `CarpeDiem` starts by opening the most promising vertex in layer 2, this is the first time Algorithm 4 is called and hence the base case of the induction. Let us consider what happens when a node y_2 is opened. Since all vertices in layer 1 have been opened by the initialization step, the first loop in Algorithm 4 iterates on all of them and the second loop is never entered. Then, just before line 7, it holds

$$y_1^* = \arg\max_{y_1} \left(\mathbb{G}(y_1) + S^1_{y_2, y_1} \right).$$

Since the initialization step guarantees $\forall y_1 : \mathbb{G}(y_1) = \gamma(y_1)$, then properties 12 and 13 are satisfied.

Let us now assume by induction that after opening a vertex y_{t-1} in layer $t-1$ ($t > 2$) it holds $\mathbb{G}(y_{t-1}) = \gamma(y_{t-1})$. We focus on the execution of Algorithm 4 on a vertex y_t in layer t. Let us denote with O_{t-1} the set of vertices presently open in layer $t-1$, and with C_{t-1} the set of closed ones. When the first loop ends, it holds:

$$y_{t-1}^* = \arg\max_{y_{t-1} \in \mathsf{O}_{t-1}} \left(\mathbb{G}(y_{t-1}) + S^1_{y_t, y_{t-1}} \right).$$

Also, since all vertices for which we have taken the arg max are in layer $t-1$ and open, we apply the inductive hypothesis and conclude that:

$$y^*_{t-1} = \arg \max_{y_{t-1} \in \mathsf{O}_{t-1}} \left(\gamma(y_{t-1}) + S^1_{y_t, y_{t-1}} \right). \tag{14}$$

The second loop moves some vertices from C_{t-1} to O_{t-1}. At the same time, however, it updates y^*_{t-1} so that the above equality is preserved. Then, on exit we can conclude (14) and (for the particular y'_{t-1} that caused the loop to exit):

$$\mathbb{G}(y^*_{t-1}) + S^1_{y_t, y^*_{t-1}} \geq \mathbb{B}_{t-1} + S^0_{y'_{t-1}} + S^{1*}. \tag{15}$$

Also, by definition of $\sqsupseteq_{t-1}$ (Definition 2–Equation 5), $\forall y_{t-1} : y'_{t-1} \sqsupseteq_{t-1} y_{t-1}$ implies:

$$\mathbb{B}_{t-1} + S^0_{y'_{t-1}} + S^{1*} \geq \mathbb{B}_{t-1} + S^0_{y_{t-1}} + S^{1*}. \tag{16}$$

Since vertices are considered in $\sqsupseteq_{t-1}$ order and since y'_{t-1} is the first vertex that has not been opened, it follows that all closed vertices follow y'_{t-1} in the $\sqsupseteq_{t-1}$ order. Using this fact along with (15) and (16), it follows:

$$\forall y_{t-1} \in \mathsf{C}_{t-1} : \mathbb{G}(y^*_{t-1}) + S^1_{y_t, y^*_{t-1}} \geq \mathbb{B}_{t-1} + S^0_{y_{t-1}} + S^{1*}.$$

By induction, $\mathbb{G}(y^*_{t-1}) = \gamma(y^*_{t-1})$. Moreover, Lemma 1 implies $\mathbb{B}_{t-1} + S^0_{y_{t-1}} \geq \gamma(y_{t-1})$. Using these facts, along with $\forall y_t, y_{t-1} : S^{1*} \geq S^1_{y_t, y_{t-1}}$ (Definition 2–Equation 3) we obtain:

$$\forall y_{t-1} \in \mathsf{C}_{t-1} : \gamma(y^*_{t-1}) + S^1_{y_t, y^*_{t-1}} \geq \gamma(y_{t-1}) + S^1_{y_t, y_{t-1}}$$

Which yields:

$$\gamma(y^*_{t-1}) + S^1_{y_t, y^*_{t-1}} \geq \max_{y_{t-1} \in \mathsf{C}_{t-1}} \left(\gamma(y_{t-1}) + S^1_{y_t, y_{t-1}} \right).$$

This and (14) yield:

$$y^*_{t-1} = \arg \max_{y_{t-1}} \left(\gamma(y_{t-1}) + S^1_{y_t, y_{t-1}} \right).$$

Also, the fact that y^*_{t-1} is open and the inductive hypothesis, yield $\mathbb{G}(y^*_{t-1}) = \gamma(y^*_{t-1})$.

■

Appendix B. Complexity

Theorem 3 `CarpeDiem` *has $O(TK^2)$ worst case time complexity and $O(TK \log K)$ best case time complexity.*

Proof Let us consider the final step of an execution of `CarpeDiem`, and assume that for each layer t, exactly k_t vertices have been opened. In our proof we separately consider the time spent to process each layer of the graph. We define the quantity $\mathcal{T}(t)$ to represent the overall time spent by Algorithms 3 and 4 to process layer t. Let us define:

$a(y_t)$**:** the number of steps needed by Algorithm 3 to process vertex y_t;

$b(y_t)$: the number of steps needed by Algorithm 4 to find the best parent for node y_t.

We note that $a(y_t)$ does not include the time spent by Algorithm 4 since such time is accounted for by $b(y_t)$. Similarly, $b(y_t)$ does not include neither the time spent by Algorithm 3, nor the time spent by recursive calls to Algorithm 4. In fact, the time spent in recursive calls is taken into account by b values of vertices in previous layers. Then we can compute $\mathcal{T}(t)$ as:

$$\mathcal{T}(t) = \sum_{y_t} a(y_t) + b(y_t)$$

The total complexity of `CarpeDiem` is then:

$$\mathcal{T}(\texttt{CarpeDiem}) = \text{time for initialization} + \sum_{t=2}^{T} (O(1) + \mathcal{T}(t))$$

where the "time for initialization" includes the $O(K)$ time spent in the first loop of Algorithm 2 plus the $O(TK \log K)$ time needed to sort each layer according to $\sqsupseteq_t$. It follows:

$$\mathcal{T}(\texttt{CarpeDiem}) = O(TK \log K) + \sum_{t=2}^{T} (O(1) + \mathcal{T}(t)). \tag{17}$$

Let us now note that $a(y_t)$ is at worst $O(k_t)$. In fact, since only k_t vertices have been opened at the end of the algorithm, it follows that the steps needed to analyse a vertex y_t by (the loop in) Algorithm 3 is at most k_t. We notice that we are overestimating the cost to analyze each node since k_t is the *overall* number of iterations performed by the mentioned loop. However this overestimation simplifies the following argument without hindering the result.

$b(y_t)$ is, at worst, $O(k_{t-1})$. In fact, since only k_{t-1} vertices have been opened at the end of the algorithm, it follows that the two loops in Algorithm 4 iterate altogether at most k_{t-1} times. Moreover, since the steps performed by recursive calls are not to be included in $b(y_t)$, it follows that all operations are $O(1)$, and the complexity accounted for by $b(y_t)$ is $O(k_{t-1})$. In both cases no computational effort is spent to process closed nodes.

From the above discussion it follows that:

$$\begin{aligned}
\mathcal{T}(t) &= \sum_{y_t} a(y_t) + b(y_t) \\
&= \sum_{y_t \text{ in open vertices}} O(k_t) + O(k_{t-1}) \\
&= k_t \cdot (O(k_t) + O(k_{t-1})) \\
&= O(k_t^2 + k_t k_{t-1}).
\end{aligned}$$

Putting together the above equation and Equation 17 we have:

$$\begin{aligned}
\mathcal{T}(\texttt{CarpeDiem}) &= O(TK \log K) + \sum_{t=2}^{T} \left(O(1) + O(k_t^2 + k_t k_{t-1})\right) \\
&= O(TK \log K) + \sum_{t=2}^{T} O(k_t^2 + k_t k_{t-1}).
\end{aligned}$$

The worst case occurs when `CarpeDiem` opens every node in every layer. In such case: $k_t = K$ for each t and the above formula reduces to $O(TK^2)$. In the best case `CarpeDiem` opens only one node per layer, $k_t = 1$ for each t and the complexity is $O(TK \log K)$. ■

Abstract

We define a model of learning probabilistic acyclic circuits using value injection queries, in which fixed values are assigned to an arbitrary subset of the wires and the value on the single output wire is observed. We adapt the approach of using test paths from the Circuit Builder algorithm (Angluin et al., 2009) to show that there is a polynomial time algorithm that uses value injection queries to learn acyclic Boolean probabilistic circuits of constant fan-in and log depth. We establish upper and lower bounds on the attenuation factor for general and transitively reduced Boolean probabilistic circuits of test paths versus general experiments. We give computational evidence that a polynomial time learning algorithm using general value injection experiments may not do much better than one using test paths. For probabilistic circuits with alphabets of size three or greater, we show that the test path lemmas (Angluin et al., 2009, 2008b) fail utterly. To overcome this obstacle, we introduce function injection queries, in which the values on a wire may be mapped to other values rather than just to themselves or constants, and prove a generalized test path lemma for this case.

Keywords: nonadaptive learning algorithms, probabilistic circuits, causal Bayesian networks, value injection queries, test paths

1. Introduction

Probabilistic networks are used as models in a variety of domains, for example, gene interaction networks, social networks and causal reasoning. In a binary model of gene interaction, the state of each gene is either active or inactive, and the state of each gene is determined as a function of the states of some number of other genes, its inputs. In a probabilistic variant of the model, the activation function specifies, for each possible combination of the states of the inputs, the probability that the

gene will be active (Friedman et al., 2000). In the independent cascade model of social networks, the state of each agent is active or inactive and for each pair (u,v) of agents, there is a probability that the activation of u will cause v to become active. Kempe, Kleinberg, and Tardos (2003, 2005) study the problem of maximizing influence in this and related models of social networks. In a Bayesian network there is an acyclic directed graph and a joint probability distribution over the node values such that the joint distribution is the product of each of the marginal distributions for each node given the values of the parents (in-neighbors) of the node.

A fundamental question is how much we can infer about the properties and structure of such networks from observing and experimenting with their behaviors. Prior research gives evidence from cryptography that there may be no polynomial time algorithm to learn Boolean functions represented by acyclic circuits of constant fan-in and depth $O(\log n)$ when we can set only the inputs of the circuit and observe only the output (Angluin and Kharitonov, 1995). In this paper we consider a different setting, **value injection queries**, in which we can fix the values on any subset of wires in the target circuit, but still only observe the output of the circuit.

The concept of value injection queries was inspired by models of gene suppression and gene overexpression in the study of gene interaction networks (Akutsu et al., 2003; Ideker et al., 2000) and was introduced by Angluin et al. (2009). In a causal Bayesian network there is an additional action $\mathrm{do}(X = x)$ that forces a node X to take on a value x (Pearl, 2000). A value injection query may also be viewed as a set of such actions, one for each wire fixed to a value.

Angluin et al. (2009) investigate the learnability of deterministic circuits using value injection queries and behavioral equivalence queries. Polynomial time learning algorithms using just value injection queries are given for two classes of acyclic circuits. Circuit Builder uses value injection queries to learn acyclic deterministic circuits with constant-size alphabets, constant fan-in and depth $O(\log n)$ up to behavioral equivalence in polynomial time. Another algorithm is given that learns constant-depth acyclic Boolean circuits with NOT gates and unbounded fan-in AND, OR, NAND and NOR gates up to behavioral equivalence in polynomial time using value injection queries. Negative results include an exponential lower bound on the number of value injection queries to learn acyclic Boolean circuits of unbounded depth and unbounded fan-in, and the **NP**-hardness of learning acyclic Boolean circuits of unbounded depth and constant fan-in using value injection queries.

In extending these results to analog circuits, Angluin et al. (2008b) consider circuits with polynomial-size alphabets. They give evidence of the computational hardness of learning acyclic circuits over a polynomial-size alphabet even if the depth is restricted to $O(\log n)$, motivating structural restrictions on the graphs of the circuits to achieve polynomial time learnability. They give the Distinguishing Paths Algorithm, which uses value injection queries and learns acyclic deterministic circuits that are transitively reduced and have polynomial-size alphabets, constant fan-in and unbounded depth up to behavioral equivalence in polynomial time. They also give a generalization to circuits with a constant bound on shortcut width.

In this paper we seek to extend some of these positive learnability results to the case of acyclic probabilistic circuits. The key technique in the previous work has been the idea of a **test path** for an arbitrary wire w in the circuit. Informally speaking, a test path is a directed path of wires from w to the output wire in which each wire is an input of the next wire on the path, and the other (non-path) inputs of wires on the path are fixed to constant values, thus isolating the wires along the path from the rest of the circuit. Ideally, the choice of constant values is made in such a way as to maximize the effect on the output of the circuit of changing w from one value to another. A test path thus functions as a kind of "microscope" for viewing the effects of assigning different values to the

wire w. The primary focus of this paper is to understand the properties of test paths in probabilistic circuits, and the extent to which they can be used to give polynomial time algorithms for learning probabilistic acyclic circuits.

In Section 2 we formally define our model of acyclic probabilistic circuits, value injection queries and distribution injection queries, behavioral equivalence, and the learning problem that we consider. In Section 3 we establish some basic results about probabilistic circuits and value and distribution injection experiments. In Section 4 we review the test path lemma used in previous work to establish the ability of a learner to infer circuit behavior from a small subset of experiments and show that it fails utterly in probabilistic circuits with alphabet size greater than two. However, for Boolean probabilistic circuits, we show that the test path lemma holds with an attenuation factor that depends on the structure of the circuit. (Lemma 10 treats general acyclic circuits and Corollary 11 specializes the bound to transitively reduced circuits.) In Section 5 we apply the test path lemma in the Boolean case to adapt the Circuit Builder algorithm (Angluin et al., 2009) to find using value injection queries, with high probability, in time polynomial in n and $1/\varepsilon$, a circuit that is ε-behaviorally equivalent to a target acyclic Boolean probabilistic circuit of size n with constant fan-in and depth bounded by a constant times $\log n$. In Section 6, we consider lower bounds on the attenuation of paths; Theorem 16 shows that our bound is tight for transitively reduced circuits and Theorem 18 gives a lower bound for the case of general acyclic circuits. In Section 7 we give evidence that polynomial time algorithms using general value injection experiments may not do significantly better than algorithms that use test paths. In Section 8 we introduce a stronger kind of query, a **function injection query**, and show that test paths with function injections overcome the limitations of test paths for circuits with alphabets of size greater than two.

2. Model

We extend the circuit learning model (Angluin et al., 2008b, 2009) to probabilistic gates. An unusual feature of this model is that circuits do not have distinguished inputs—since the learning algorithm seeks to predict the output behavior of value injection experiments that override the values on an arbitrary subset of wires, each wire is a potential input.

2.1 Probabilistic Circuits

A **probabilistic circuit** C of **size** $n \geq 1$ has n **wires**, of which one is the distinguished **output wire**. We call the set of C's wires W, and these wires take values in a finite **alphabet** Σ with $|\Sigma| \geq 2$. If $\Sigma = \{0,1\}$, then C is **Boolean**. The value on a wire is ordinarily determined by the output of an associated probabilistic gate, whose distribution is a function of the values on other wires.

Formally, a **value distribution** D is a probability distribution over Σ, that is, a map from Σ to the real interval $[0,1]$ such that $\sum_{\sigma\in\Sigma} D(\sigma) = 1$. The probability of σ is $D(\sigma)$. The **support** of D is the set of values $\sigma \in \Sigma$ such that $D(\sigma) > 0$. When the support of D is a singleton $\{\sigma\}$, we say D is **deterministic**. For a nonempty set of values $S \subseteq \Sigma$, the **uniform distribution** $U(S)$ is the distribution such that $U(S)(\sigma) = [\sigma \in S]/|S|$, that is, has value 0 on $\sigma \notin S$ and $1/|S|$ for $\sigma \in S$.

A k-ary **probabilistic gate function** f maps each k-tuple of values $(\sigma_1, \ldots, \sigma_k) \in \Sigma^k$ to a value distribution. When C is Boolean, we can specify f by a truth table giving the expected value for each Boolean vector of inputs. A probabilistic gate function is **deterministic** if it maps k-tuples to deterministic value distributions only.

A **probabilistic gate** g of **fan-in** k pairs a k-ary probabilistic gate function f with a k-tuple $(w_1,\ldots,w_k) \in W^k$ of **input wires**. The gate g is **deterministic** if its gate function f is deterministic. When $k = 0$, the gate g has no inputs, and we can regard it as specifying a value distribution, or, when C is Boolean, a biased coin flip.

A **probabilistic circuit** C maps wires to probabilistic gates. C is **deterministic** if all of its gates are deterministic. The **fan-in** of C is the maximum fan-in over C's gates. The **circuit graph** of C has a node for each wire in W and a directed edge (u,w) if u is one of the input wires of the gate associated with w. It is important to distinguish between wires in the circuit and edges in the circuit graph. For example, if wire u is an input of wires v and w, then there will be two directed edges, (u,v) and (u,w), in the circuit graph.

Wire w is **reachable** from wire u if there is a directed path from u to w in the circuit graph. A wire is **relevant** if the output wire is reachable from it. The **depth** of a wire w is the number of edges in the longest simple path from w to the output wire in the circuit graph. The **depth** of the circuit is the maximum depth of any relevant wire. The circuit is **acyclic** if the circuit graph contains no directed cycles. The circuit is **transitively reduced** if its circuit graph is transitively reduced, that is, if it contains no edge (u,w) such that there is a directed path of length at least two from u to w. In this paper we assume all circuits are acyclic.

2.2 Experiments

In an experiment some wires are constrained to be particular values or value distributions and the other wires are left free to take on values according to their gate functions and the values of their input wires. The behavior of a circuit consists of its responses to all possible experiments. For probabilistic circuits we consider both value injection experiments and distribution injection experiments.

A **distribution injection experiment** e is a function with domain W that maps each wire w to a special symbol $*$ or to a value distribution. A **value injection experiment** e is a distribution injection experiment for which every value distribution assigned is deterministic—that is, always generates the same symbol. To simplify notation, we think of a value injection experiment as a mapping from W to $(\Sigma \cup \{*\})$. If e is either kind of experiment, we say that e leaves w **free** if $e(w) = *$; otherwise we say that e **constrains** w to $e(w)$. If $e(w)$ is a single symbol, then we say e **fixes** w to $e(w)$.

We define a partial ordering $\leq$ on the set containing $*$ and all value distributions D as follows: $D \leq *$ for every value distribution D, and for two value distributions, $D_1 \leq D_2$ if the support of D_1 is a subset of the support of D_2. This ordering is extended to experiments on the same set of wires W as follows: $e_1 \leq e_2$ if for every $w \in W$, $e_1(w) \leq e_2(w)$. The intuitive meaning of $e_1 \leq e_2$ is that e_1 is at least as constraining as e_2 for every wire.

If e is any experiment, w is a wire, and a is $*$ or an element of Σ or a value distribution, then the experiment $e|_{w=a}$ is defined to be the experiment e' such that $e'(w) = a$ and $e'(u) = e(u)$ for all $u \in W$ such that $u \neq w$. If e is any experiment then a **free path** in e is a path in the circuit graph containing only wires w that are free in e.

2.3 Behavior

Let C be a probabilistic circuit. Then a distribution injection experiment e determines a joint distribution over assignments of elements of Σ to all of the wires of the circuit, as follows. If wire w

is constrained then w is randomly and independently assigned a value in Σ drawn according to the value distribution $e(w)$; in the case of a value injection experiment, this just assigns a fixed element of Σ to w. If wire w is free and has probabilistic gate function f, and its inputs $u_1, \ldots, u_k$ have been assigned the values $\sigma_1, \ldots, \sigma_k$, then w is randomly and independently assigned a value from Σ according to the value distribution determined by the gate function on these inputs, that is, according to the value distribution $f(\sigma_1, \ldots, \sigma_k)$.

Constrained gates and gates of fan-in zero give the base cases for the above recursive definition, which assigns an element of Σ to every wire because the circuit is acyclic. Let $C(e,w)$ denote the (marginal) value distribution of the assignments of values to w for the above process. The **output distribution** of the circuit, denoted $C(e)$, is the distribution $C(e,z)$, where z is the output wire of the circuit. The **behavior** of a circuit C is the function that maps value injection experiments e to output distributions $C(e)$.

We note that even when the circuit is Boolean and the only non-deterministic gates are uniform coin flips, the problem of exactly computing $C(e)$ is #**P**-hard because we can arrange for $C(e)$ to be the fraction of assignments satisfying a given Boolean formula.

2.4 Example: C_1

We give an example of a simple Boolean probabilistic circuit, which we also refer to later. The 2-input **averaging gate function** $A(b_1, b_2)$ outputs 1 with probability $(b_1 + b_2)/2$. Thus, if both inputs are 0, the output is deterministically 0, if both inputs are 1, the output is deterministically 1, and if its inputs disagree, the output is an unbiased coin flip, $U(\{0,1\})$. Another characterization of the averaging gate function A is that it randomly and equiprobably selects one of its inputs and copies it to the output.

We define a circuit C_1 of 4 wires as follows: $w_4 = A(w_2, w_3)$, $w_3 = w_1$, $w_2 = w_1$, and $w_1 = U(\{0,1\})$. The output wire is w_4. C_1 is depicted in Figure 1.

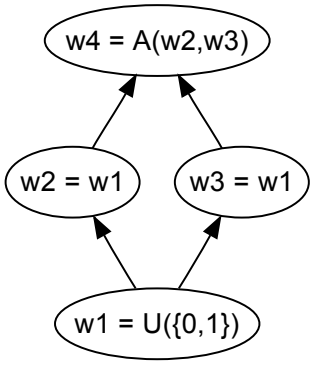

Figure 1: The circuit C_1; w_4 is the output wire.

To illustrate the behavior of this circuit, we consider two value injection experiments. Define the experiment e to leave every wire in C_1 free, that is, $e(w_i) = *$ for $1 \leq i \leq 4$. Given e, we construct one random outcome as follows. The wire w_1 is assigned a value as the result of an unbiased coin flip—say it is assigned 0. Then the values assigned to w_2 and w_3 are determined because they are each the output of an identity gate with w_1 as input: both are 0. Finally, because both its input wires have been assigned values, w_4 can be assigned a value according to $A(0,0)$, which is deterministically

0. It is easy to see that this is one of two possible outcomes for experiment e; either all wires are assigned 0 or all wires are assigned 1, and these each occur with probability $1/2$. The output distribution $C_1(e)$ is just an unbiased coin flip.

Now consider experiment $e' = e|_{w_2=1}$ that fixes w_2 to 1 and leaves the other wires free. Once again, the value of w_1 is determined by a coin flip—say it is assigned 0. Since w_2 is fixed to 1, that is its assignment. Wire w_3 is free, and is therefore assigned the value of w_1, that is 0. Now the inputs of w_4 have been assigned values, so we consider $A(1,0)$, which randomly and equiprobably selects 0 or 1. If, instead, the coin flip for w_1 had returned 1, all wires would be assigned 1. There are three possible assignments to (w_1,w_2,w_3,w_4) for experiment e': $(1,1,1,1)$ with probability $1/2$, $(0,1,0,0)$ with probability $1/4$ and $(0,1,0,1)$ with probability $1/4$. The output distribution $C_1(e')$ is a biased coin flip that is 1 with probability $3/4$.

2.5 Behavioral Equivalence

Two circuits C and C' are **behaviorally equivalent** if they have the same set of wires, the same output wire and the same behavior, that is, for every value injection experiment $e, C(e) = C'(e)$. We also need a concept of approximate equivalence. The **(statistical) distance** between value distributions D and D' is $d(D,D') = (1/2)\sum_\sigma |D(\sigma) - D'(\sigma)|$, which takes values in $[0,1]$. Note that when D and D' are deterministic, $d(D,D')$ is 0 if $D = D'$ and 1 otherwise. For $\varepsilon \geq 0, C$ is **ε-behaviorally equivalent** to C' if they contain the same wires and the same output wire, and for every value injection experiment e, $d(C(e),C'(e)) \leq \varepsilon$, where d is the statistical distance between value distributions.

In Lemma 2 we show that the behavioral equivalence of C and C' implies $C(e) = C'(e)$ for all distribution injection experiments as well. However, behavioral equivalence is not sufficient to guarantee that two circuits have the same topology; even when all the gates are Boolean, deterministic and relevant, the circuit graph of the target circuit may not be uniquely determined by its behavior (Angluin et al., 2009).

2.6 Queries

The learning algorithm gets information about the target circuit by specifying a value injection experiment e and observing the element of Σ assigned to the output wire. Such an action is termed a **value injection query**, abbreviated VIQ. A value injection query does not return complete information about the value distribution $C(e)$, but instead returns an element of Σ selected according to the distribution $C(e)$. Thus, in order to approximate the distribution $C(e)$, the learner must repeatedly make value injection queries with experiment e. In this case, the goal of learning is approximate behavioral equivalence.

2.7 The Learning Problem

The learning problem is ε-**approximate learning**: by making value injection queries to a target circuit C drawn from a known class of probabilistic circuits, the goal is to find a circuit C' that is ε-behaviorally equivalent to C. The inputs to the learning algorithm are the names of the wires in C, the name of the output wire and positive numbers ε and δ, where the learning algorithm is required to succeed with probability at least $(1-\delta)$.

We note that acyclic deterministic circuits are a subclass of acyclic probabilistic circuits. If the target circuit C is deterministic and we learn a probabilistic circuit C' that is $1/3$-behaviorally

equivalent to C, then we can compute the behavior of C on any value-injection experiment e with high probability by sampling the behavior of $C'(e)$. The negative results concerning learning deterministic circuits using value injection queries shown by Angluin et al. (2009) carry over to learning probabilistic circuits. In particular, for $\varepsilon = 1/3$ and $\delta = 1/2$, with no bound on fan-in or depth, the worst-case expected number of value injection queries necessary to learn acyclic probabilistic Boolean circuits is exponential, while with constant fan-in and no bound on depth, no polynomial time algorithm can learn acyclic probabilistic Boolean circuits if **NP** is not equal to **BPP**.

3. Preliminary Results

In this section we establish some basic results about probabilistic circuits, value injection experiments and distribution injection experiments. The reader may choose to skip this section and return to it as needed for proofs in subsequent sections.

We first note that if C is a probabilistic circuit, e is a distribution injection experiment and either $e(w)$ is a value distribution or e deterministically fixes all the input wires of w, then there is a value distribution D such that the value of w in $C(e)$ is determined by a random choice according to D, independent of the values chosen for any other wires. We make systematic use of this observation to reduce the number of experiments under consideration.

We start by considering two circuits C_1 and C_2 over the same wires, and distribution injection experiments e_1 and e_2 that agree on the distribution assigned to a wire w and that show a certain distance between $C_1(e_1)$ and $C_2(e_2)$. The following lemma says that we may modify e_1 and e_2 to fix w to a particular value $\sigma \in \Sigma$ while preserving (or increasing) the distance they show.

Lemma 1 *Let C_1 and C_2 be probabilistic circuits on wires W with the same output wire, let $w \in W$ be a wire, let D be a value distribution, and let e_1 and e_2 be distribution injection experiments such that $e_1(w) = e_2(w) = D$. Then there exists a value $\sigma \in \text{support}(D)$ such that*

$$d(C_1(e_1|_{w=\sigma}), C_2(e_2|_{w=\sigma})) \geq d(C_1(e_1), C_2(e_2)).$$

Proof We have

$$\begin{aligned}
d(C_1(e_1), C_2(e_2)) &= \frac{1}{2} \sum_{\tau \in \Sigma} \left| C_1(e_1)(\tau) - C_2(e_2)(\tau) \right| \\
&= \frac{1}{2} \sum_{\tau \in \Sigma} \left| \sum_{\rho \in \Sigma} C_1(e_1|_{w=\rho})(\tau) D(\rho) - \sum_{\rho \in \Sigma} C_2(e_2|_{w=\rho})(\tau) D(\rho) \right| \\
&\leq \frac{1}{2} \sum_{\rho \in \Sigma} D(\rho) \sum_{\tau \in \Sigma} \left| C_1(e_1|_{w=\rho})(\tau) - C_2(e_2|_{w=\rho})(\tau) \right| \\
&= \sum_{\rho \in \Sigma} D(\rho) d(C(e_1|_{w=\rho}), C(e_2|_{w=\rho})),
\end{aligned}$$

by the triangle inequality. Let

$$\sigma = \operatorname*{arg\,max}_{\rho \in \text{support}(D)} d(C(e_1|_{w=\rho}), C(e_2|_{w=\rho})),$$

so that

$$d(C(e_1|_{w=\sigma}), C(e_2|_{w=\sigma})) \geq d(C(e_1), C(e_2))$$

by an averaging argument. ■

By successively replacing each value distribution by a particular value, we may convert a distribution injection experiment that shows a certain distance between two circuits into a value injection experiment that shows at least that distance between the two circuits.

Lemma 2 *Let C_1 and C_2 be probabilistic circuits on wires W with the same output wire and let e be a distribution injection experiment. Then there exists a value injection experiment $e' \leq e$ such that*

$$d(C_1(e'),C_2(e')) \geq d(C_1(e),C_2(e)).$$

Proof By induction on $|V|$, where $V \subseteq W$ is the set of wires that e constrains to distributions that are not deterministic. If $|V| > 0$, then let $w \in V$. By Lemma 1, there exists a value $\sigma \in \Sigma$ such that

$$d(C_1(e|_{w=\sigma}),C_2(e|_{w=\sigma})) \geq d(C_1(e),C_2(e)).$$

Since $e|_{w=\sigma}$ constrains one fewer wire to a nonconstant distribution, the existence of e' follows from the inductive hypothesis. ■

Thus, value injection experiments suffice to establish approximate behavioral equivalence with respect to distribution injection experiments.

Corollary 3 *If circuits C_1 and C_2 are ε-behaviorally equivalent with respect to value injection experiments, then C_1 and C_2 are ε-behaviorally equivalent with respect to distribution injection experiments.*

Suppose that C is a probabilistic circuit and e_1 and e_2 are distribution injection experiments. For each wire w, we say that e_1 and e_2 **agree** on w if either

- e_1 and e_2 constrain w to the same distribution, or
- w is free in e_1 and e_2, and e_1 and e_2 agree on all of w's inputs.

It is clear that if e_1 and e_2 agree on a wire w, then the marginal distributions of w in e_1 and e_2 are identical, that is, $C(e_1,w) = C(e_2,w)$.

Lemma 4 *Let C be a probabilistic circuit on wires W and let e_1 and e_2 be distribution injection experiments that agree on wires $V \subseteq W$. Then there exist distribution injection experiments $e'_1 \leq e_1$ and $e'_2 \leq e_2$ such that for each wire $w \in V$, there exists a value $\sigma \in \Sigma$ such that $e'_1(w) = e'_2(w) = \sigma$, and*

$$d(C(e'_1),C(e'_2)) \geq d(C(e_1),C(e_2)).$$

Proof By induction on the number of unfixed wires $w \in V$. If there is such a wire, choose v by the acyclicity of the circuit to be one that is not reachable from the others. If $e_1(v) = e_2(v) = *$, then e_1 and e_2 agree on all of v's inputs, and by the choice of v, all of v's inputs are fixed. As

such, we may assume without loss of generality that e_1 and e_2 in fact constrain v to the distribution $D = C(e_1, v) = C(e_2, v)$. By Lemma 1, there exists a value $\sigma \in \text{support}(D)$ such that

$$d(C(e_1|_{v=\sigma}), C(e_2|_{v=\sigma})) \geq d(C(e_1), C(e_2)).$$

The existence of e_1' and e_2' follows from the inductive hypothesis. ■

The following lemma shows that constraining a wire w does not change the behavior of wires that are not reachable from w.

Lemma 5 *Let C be a probabilistic circuit on wires W, let e be a distribution injection experiment, let $w \in W$ be a wire free in e, and let D be a value distribution. Then e and $e|_{w=D}$ agree on all wires $u \in W$ such that there is no free path from w to u in e.*

Proof If u is constrained, then the conclusion follows. Otherwise, let $u \in W$ be a wire free in e such that there is no free path from w to u in e. Then no input v of u has a free path from w to v in e. We proceed by induction on the length of the longest path to u. If this length is zero, then u does not have any inputs. Otherwise, the inductive hypothesis applies to all of u's inputs, on which e and $e|_{w=D}$ then must agree. It follows that they also agree on u. ■

If we consider the distance between the behavior of a circuit with a wire constrained to two different value distributions, the following lemma allows us to move to a situation in which the wire is constrained to two different value distributions whose supports are disjoint. In the special case of Boolean circuits, the property of disjoint supports means that the resulting value distributions are deterministic. Later we see that this fundamentally distinguishes between alphabet size two and larger alphabets.

Lemma 6 *Let C be a probabilistic circuit on wires W, let $w \in W$ be a wire, and let D_1, D_2 be value distributions. There exist value distributions D_1', D_2' with $\text{support}(D_1') \cap \text{support}(D_2') = \emptyset$ such that for all experiments e,*

$$d(C(e|_{w=D_1}), C(e|_{w=D_2})) = d(D_1, D_2) d(C(e|_{w=D_1'}), C(e|_{w=D_2'})).$$

Proof Intuitively, we couple D_1 and D_2 so that $D_1 = D_2$ as often as possible and let $\widehat{D_i}$ be the distribution of D_i given that $D_1 \neq D_2$. It can be shown that $\widehat{D_1}$ and $\widehat{D_2}$ have disjoint support. Formally, we have

$$\begin{aligned} d(C(e|_{w=D_1}), C(e|_{w=D_2})) &= \frac{1}{2} \sum_{\sigma \in \Sigma} \left| C(e|_{w=D_1})(\sigma) - C(e|_{w=D_2})(\sigma) \right| \\ &= \frac{1}{2} \sum_{\sigma \in \Sigma} \left| \sum_{\tau \in \Sigma} C(e|_{w=\tau})(\sigma)(D_1(\tau) - D_2(\tau)) \right|. \end{aligned}$$

If we let

$$\begin{aligned} \widehat{D_1}(\tau) &= D_1(\tau) - \min(D_1(\tau), D_2(\tau)) \\ \widehat{D_2}(\tau) &= D_2(\tau) - \min(D_1(\tau), D_2(\tau)), \end{aligned}$$

then

$$d(C(e|_{w=D_1}),C(e|_{w=D_2})) = \frac{1}{2}\sum_{\sigma\in\Sigma}\left|\sum_{\tau\in\Sigma} C(e|_{w=\tau})(\sigma)(\widehat{D_1}(\tau)-\widehat{D_2}(\tau))\right|.$$

Since $\sum_{\tau\in\Sigma}\widehat{D_1}(\tau) = 1-\sum_{\tau\in\Sigma}\min(D_1(\tau),D_2(\tau))$ and likewise for D_2,

$$\begin{aligned} d(D_1,D_2) &= \frac{1}{2}\sum_{\tau\in\Sigma}\left|D_1(\tau)-D_2(\tau)\right| \\ &= \frac{1}{2}\sum_{\tau\in\Sigma}\left|\widehat{D_1}(\tau)-\widehat{D_2}(\tau)\right| \\ &= \sum_{\tau\in\Sigma}\widehat{D_1}(\tau) = \sum_{\tau\in\Sigma}\widehat{D_2}(\tau). \end{aligned}$$

If $d(D_1,D_2)>0$, then the distributions D_1' and D_2' where

$$\begin{aligned} D_1'(\tau) &= \widehat{D_1}(\tau)/d(D_1,D_2) \\ D_2'(\tau) &= \widehat{D_2}(\tau)/d(D_1,D_2) \end{aligned}$$

satisfy the requisite properties. Otherwise, any two distributions with disjoint support will do. ■

4. Test Paths

The concept of a test path has been central in previous work on learning deterministic circuits by means of value injection queries (Angluin et al., 2008b, 2009). A **test path** for a wire w, or **w-test path**, is a value injection experiment in which the free gates form a directed path in the circuit graph from w to the output wire. All the other wires in the circuit are fixed; this includes the inputs of w. A **side wire** with respect to a test path p is a wire fixed by p that is input to a free wire in p.

As an example, suppose that $\Sigma = \{0,1\}$ and the target circuit has a circuit graph as shown in Figure 2. There are four directed paths from w_1 to the output wire: w_1w_5, $w_1w_3w_5$, $w_1w_2w_4w_5$ and $w_1w_3w_4w_5$. A w_1-test path is a value injection experiment that sets the wires of one of these paths to $*$ and the other wires to 0 or 1, for example, $*011*$ or $**0**$. For the test path $*011*$, the side wires are w_3 and w_4, while for the test path $**0**$ the side wire is w_3. The value injection experiments $*****$ and $*01**$ are not test paths.

A test path may help the learning algorithm determine the effects of assigning different values to the wire w. The test path lemmas (Angluin et al., 2008b, 2009) may be re-stated as follows.

Lemma 7 *Let C be a deterministic circuit. If for some value injection experiment e, wire w free in e and alphabet symbols σ and τ it is the case that*

$$C(p|_{w=\sigma}) = C(p|_{w=\tau})$$

for every test path $p \le e$ then also

$$C(e|_{w=\sigma}) = C(e|_{w=\tau}).$$

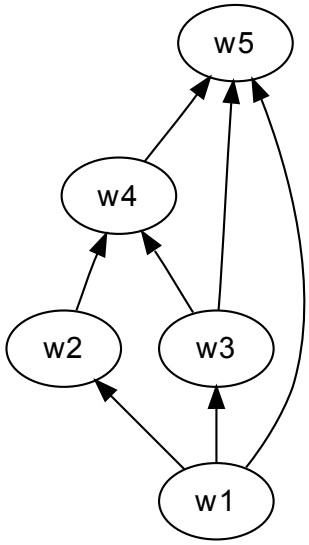

Figure 2: A circuit graph; w_5 is the output wire.

Nontrivial complications arise in attempting to carry over this test path lemma to general probabilistic circuits, as we now show. The following lemma shows that for alphabets of size at least three, there are transitively reduced probabilistic circuits for which the test-path lemma fails completely.

Lemma 8 *If $|\Sigma| \geq 3$, there exists a probabilistic circuit C, value injection experiment e, wire w free in e and alphabet symbols σ and τ such that although for every test path $p \leq e$ for w, $d(C(p|_{w=\sigma}), C(p|_{w=\tau})) = 0$, it is nevertheless the case that $d(C(e|_{w=\sigma}), C(e|_{w=\tau})) = 1/2$.*

Proof Assume that $\Sigma = \{0,1,2\}$, and define probabilistic gate functions T and X as follows.

$$\begin{aligned} T(0) &= T(1) = U(\{0,1\}) \\ T(2) &= 2 \\ X(b_1,b_2) &= b_1 \oplus b_2 \text{ if } b_1, b_2 \in \{0,1\} \\ X(b_1,b_2) &= U(\{0,1\}) \text{ if } b_1 = 2 \text{ or } b_2 = 2, \end{aligned}$$

where $\oplus$ is sum modulo 2. The gate function T flips a coin on input 0 or 1, and passes 2 through unaltered. The gate function X is exclusive or if neither input is 2, and a coin flip otherwise.

The circuit C has 5 wires, connected as in Figure 3. The output wire is w_5; note that C is transitively reduced.

Consider the experiment e that leaves all the wires free. In this experiment, we have $C(e|_{w_1=0}) = C(e|_{w_1=1}) = 0$ because w_2 is a coin flip and w_5 is the exclusive or of two copies of the coin flip. On the other hand, $C(e|_{w_1=2}) = U(\{0,1\})$ because $w_4 = w_3 = w_2 = 2$ and w_5 is therefore a coin flip. Thus $d(C(e|_{w_1=0}), C(e|_{w_1=2})) = 1/2$.

However, the only test paths for w_1 fix w_3 and leave all other wires free, or fix w_4 and leave all other wires free, and the two cases are symmetric. If w_3 is fixed to any value and all other wires are free, then w_5 is a coin flip when $w_1 = 2$. If w_3 is fixed to 2 and all other wires are free, then w_5 is also a coin flip. If w_3 is fixed to $b \in \{0,1\}$ and all other wires are free, then when $w_1 \in \{0,1\}$, w_2 is a coin

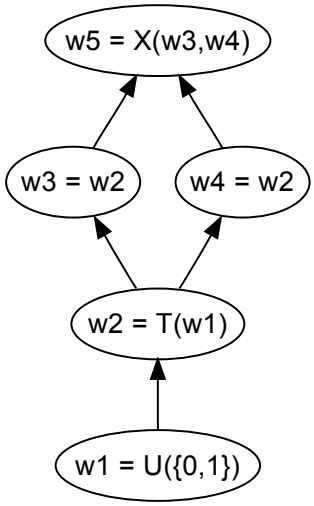

Figure 3: The circuit C; w_5 is the output wire.

flip, and w_5 is the exclusive or of b and that coin flip, that is, w_5 is also coin flip. Hence, for any test path $p \leq e$ for w_1, we have $C(p|_{w_1=0}) = C(p|_{w_1=2}) = U(\{0,1\})$ and $d(C(p_{w_1=0}), C(p_{w_1=2})) = 0$.

For alphabets Σ of size larger than 3, we can treat three of the symbols as 0, 1 and 2 in the above construction, and the other symbols as "tilt," where each function outputs a tilt value if any of its inputs is a tilt value. ■

4.1 A Bound for Boolean Probabilistic Circuits

Surprisingly, the case of $|\Sigma| = 2$ is different; for Boolean probabilistic circuits there is a useful quantitative relationship between the difference exposed by an arbitrary experiment e and the differences exposed by test paths $p \leq e$. The bound we give depends on the structure of directed paths on free wires in e.

Let e be an experiment and w a wire. Define $\Pi(e,w)$ to be the set of all directed paths from w to the output wire on free wires in e. Let $S(e)$ be the set of wires that originate a free shortcut, that is, the set of free wires w such that there exists a path $p \in \Pi(e,w)$ with two free wires to which w is an input. Define

$$\kappa(e,w) = \sum_{p \in \Pi(e,w)} 2^{|p \cap S(e)|}.$$

Thus, $\kappa(e,w)$ is the sum over paths in $\Pi(e,w)$ of 2 raised to the number of wires on the path that originate free shortcuts in e. If there are no wires that originate free shortcuts in e, then this is just the number of free paths in e. As an example, if the target circuit has the circuit graph shown in Figure 2 and the experiment e leaves all wires free then $\Pi(e,w_1)$ contains the four paths w_1w_5, $w_1w_3w_5$, $w_1w_2w_4w_5$ and $w_1w_3w_4w_5$, $S(e) = \{w_1, w_3\}$, and $\kappa(e,w)$ is $2+4+2+4 = 12$.

The following technical lemma gives a useful recurrence for $\kappa(e,w)$.

Lemma 9 *Let C be a probabilistic circuit, e be a distribution injection experiment, w and u be free wires where w is an input to u, and D_0 be a value distribution. Let $\beta = 2$ if $w \in S(e)$ and $\beta = 1$*

otherwise. Then

$$\kappa(e,w) = \kappa(e|_{u=D_0},w) + \kappa(e|_{w=1},u)\cdot\beta.$$

Proof The first term of the sum counts paths that don't contain u, and the second counts paths that do. Let $e' = e|_{u=D_0}$ and $e'' = e|_{w=1}$. We have

$$\begin{aligned}
\kappa(e,w) &= \sum_{p\in\Pi(e,w)} 2^{|p\cap S(e)|} \\
&= \sum_{\substack{p\in\Pi(e,w)\\ u\notin p}} 2^{|p\cap S(e)|} + \sum_{\substack{p\in\Pi(e,w)\\ u\in p}} 2^{|p\cap S(e)|} \\
&= \sum_{p\in\Pi(e',w)} 2^{|p\cap S(e')|} + \sum_{p\in\Pi(e'',u)} 2^{|p\cap S(e'')|}\beta \\
&= \kappa(e',w) + \kappa(e'',u)\cdot\beta,
\end{aligned}$$

since each path $p \ni u$ from w corresponds to the path $p\setminus\{w\}$ from u. ■

Next is the key lemma relating the difference exposed by e to the differences exposed by paths $p \le e$ for Boolean probabilistic circuits.

Lemma 10 *Let C be a Boolean probabilistic circuit, e be a distribution injection experiment, w be a wire free in e and D_1, D_2 be value distributions. If there exists $\varepsilon \ge 0$ such that for all w-test paths $p \le e$,*

$$d(C(p|_{w=D_1}), C(p|_{w=D_2})) \le \varepsilon,$$

then

$$d(C(e|_{w=D_1}), C(e|_{w=D_2})) \le \kappa(e,w)\cdot\varepsilon.$$

Proof By induction on $\phi(e)$, the number of free wires in e. By Lemma 6, assume that $\text{support}(D_1)\cap\text{support}(D_2) = \emptyset$. The critical feature of the Boolean case is that it follows that $D_1 = 0$ and $D_2 = 1$ without loss of generality—it is important to the following proof that D_1 and D_2 be deterministic.

If $\phi(e) = 1$, then either

$$d(C(e|_{w=0}), C(e|_{w=1})) = 0,$$

or w is the output, e is a w-test path, and $\kappa(e,w) = 1$. Otherwise, the inductive hypothesis is that the lemma holds for all experiments e' with $\phi(e') < \phi(e)$.

Except for w, the experiments $e|_{w=0}$ and $e|_{w=1}$ agree on all constrained wires, so by Lemmas 4 and 5, assume without loss of generality that every wire with no free path from w is in fact fixed. Since C is acyclic, there exists a free wire $u \ne w$ whose only unfixed input is w. Let g be the gate assigned by C to u and let $B_0 = g(e|_{w=0})$ and $B_1 = g(e|_{w=1})$, so that

$$\begin{aligned}
C(e|_{w=0}) &= C(e|_{w=0,u=B_0}) \\
C(e|_{w=1}) &= C(e|_{w=1,u=B_1}).
\end{aligned}$$

By the triangle inequality,

$$\begin{aligned}
d(C(e|_{w=0}), C(e|_{w=1})) \le\ & d(C(e|_{w=0,u=B_0}), C(e|_{w=1,u=B_0})) \\
& + d(C(e|_{w=1,u=B_0}), C(e|_{w=1,u=B_1})).
\end{aligned}$$

Letting $e' = e|_{u=B_0}$, any test path $p \leq e'$ also satisfies $p \leq e$ since $e' \leq e$. The experiment e' has one fewer free wire, as u is free in e, so using the inductive hypothesis, we can bound the first term of the sum by $\kappa(e', w) \cdot \varepsilon$. We now derive a bound on u-test paths so that the inductive hypothesis applies to the second term as well. Let $\beta = 2$ if $w \in S(e)$ and $\beta = 1$ otherwise. Let $e'' = e|_{w=1}$ and suppose $p \leq e''$ is a u-test path. Then

$$\begin{aligned}
&d(C(p|_{u=B_0}), C(p|_{u=B_1})) \\
&\leq d(C(p|_{w=1,u=B_0}), C(p|_{w=0,u=B_0})) + d(C(p|_{w=0,u=B_0}), C(p|_{w=1,u=B_1})) \\
&\text{[by the triangle inequality]} \\
&= d(C(p|_{w=1,u=B_0}), C(p|_{w=0,u=B_0})) + d(C(p|_{w=0,u=*}), C(p|_{w=1,u=*})) \\
&\text{[by the definitions of } B_0 \text{ and } B_1\text{]}.
\end{aligned}$$

Since w is an input to u, both $p|_{w=*,u=B_0}$ and $p|_{w=*,u=*}$ are w-test paths. Therefore, both terms of the sum are bounded by ε, and the first is nonzero only if w is an input to some free wire in p other than u. It follows that

$$d(C(p|_{u=B_0}), C(p|_{u=B_1})) \leq \beta\varepsilon,$$

and thus that

$$d(C(e''|_{u=0}), C(e''|_{u=1})) \leq \kappa(e'', u) \cdot \beta\varepsilon,$$

so by Lemma 9,

$$\begin{aligned}
d(C(e|_{w=0}), C(e|_{w=1})) &\leq \kappa(e', w) \cdot \varepsilon + \kappa(e'', u) \cdot \beta\varepsilon \\
&= \kappa(e, w) \cdot \varepsilon.
\end{aligned}$$

■

In the case of transitively reduced circuits, $S(e) = \emptyset$, and $\kappa(e, w) = \pi(e, w)$, where $\pi(e, w) = |\Pi(e, w)|$, the number of directed paths on free wires in e from w to the output wire.

Corollary 11 *Let C be a transitively reduced Boolean probabilistic circuit, e be a distribution injection experiment, and w be a wire free in e. If there exists $\varepsilon \geq 0$ such that for all w-test paths $p \leq e$,*

$$d(C(p|_{w=0}), C(p|_{w=1})) \leq \varepsilon,$$

then

$$d(C(e|_{w=0}), C(e|_{w=1})) \leq \pi(e, w) \cdot \varepsilon.$$

5. Learning Boolean Probabilistic Circuits

The amount of attenuation given by Lemma 10 allows us to adapt the Circuit Builder algorithm (Angluin et al., 2009) to learn Boolean probabilistic circuits with constant fan-in and log depth in polynomial time. For this class of circuits, the attenuation factor $\kappa(e, w)$ is bounded by a polynomial in n.

Theorem 12 *Given constants c and k there is a nonadaptive learning algorithm that with probability at least $(1-\delta)$ successfully ε-approximately learns any Boolean probabilistic circuit with n wires, gates of fan-in at most k and depth at most $c\log n$ using value injection queries in time bounded by a polynomial in n, $1/\varepsilon$ and $\log(1/\delta)$.*

The rest of the section is devoted to proving this theorem. Let the target circuit be C with $\Sigma = \{0,1\}$ and let positive constants δ, ε, k and c be given such that the fan-in of C is bounded by k and the depth of C is bounded by $c\log n$. For such a circuit, $\pi(e,w)$ is bounded above by $k^{c\log n}$, so the quantity $\kappa(e,w)$ is bounded above by

$$\kappa(n) = k^{c\log n} \cdot 2^{c\log n} = n^{c(\log k+1)} = n^{O(1)}.$$

We now describe our Probabilistic Circuit Builder algorithm (PCB). PCB is nonadaptive: first it computes a set U of value injection experiments such that every test path is equivalent to some experiment in U. It then repeats each value injection query $e \in U$ enough times that with probability at least $(1-\delta)$, the distribution $C(e)$ is estimated with sufficient accuracy for every $e \in U$. Finally, it uses these estimates to build a circuit C' by repeatedly adding a sufficiently accurate gate all of whose inputs are in the partially constructed circuit. If the estimates of $C(e)$ are all sufficiently accurate, then C' is ε-behaviorally equivalent to C.

5.1 Constructing U

In choosing the experiments U, the goal is that for every potential test path, U includes an equivalent experiment. The structure of the circuit, however, is not known *a priori*, a difficulty that we overcome by the same method as used by Angluin et al. (2009). Let U_* be a universal set of value injection experiments such that for every set of $kc\log n$ wires and every assignment of symbols from $\Sigma \cup \{*\}$ to those wires, some experiment $e \in U_*$ agrees with the values assigned to those wires. There is a deterministic construction of such a set U_* of size

$$2^{O(kc\log n)}\log n = n^{O(kc)}$$

in time polynomial in its size (Angluin et al., 2009). (For intuition, a set of $n^{O(kc)}$ independent random uniform assignments of $*$, 0 and 1 to the wires has this property with high probability.) For every wire w and test path p for w, there is an experiment in U_* that leaves the path wires of p free and fixes the side wires of p to their values in p. Consequently, p and this experiment agree on the output wire. In order to have experiments in which each free wire is also set to 0 and 1, for $b = 0,1$ let U_b contain every experiment $e|_{w=b}$ such that $e \in U_*$ and w is free in e. The final set of experiments is $U = U_* \cup U_0 \cup U_1$.

5.2 Estimating $C(e)$ for $e \in U$

For each $e \in U$, PCB repeatedly makes a value injection query with e to estimate the value distribution $C(e)$; let $\widehat{C}(e)$ denote this estimate. By Hoeffding's bound, we have that

$$m = O((n\kappa(n)/\varepsilon)^2 \log(|U|/\delta))$$

trials per experiment e suffice to guarantee that with probability at least $1-\delta$, for all $e \in U$,

$$d(C(e), \widehat{C}(e)) \leq \varepsilon/(4n\kappa(n)). \tag{1}$$

Let $e \in U_*$ be a value injection experiment, w be a wire that e leaves free, and D be a value distribution. We define

$$\widehat{C}(e|_{w=D}) = \sum_{\sigma \in \Sigma} D(\sigma)\widehat{C}(e|_{w=\sigma}).$$

Note that this is computed from the values of $\widehat{C}(e|_{w=\sigma})$ and does not require new experiments.

If (1) holds for all $e \in U$, then we have

$$\begin{aligned} d(C(e|_{w=D}), \widehat{C}(e|_{w=D})) &\leq \sum_{\sigma \in \Sigma} D(\sigma) d(C(e|_{w=\sigma}), \widehat{C}(e|_{w=\sigma})) \\ &\leq \varepsilon/(4n\kappa(n)). \end{aligned} \tag{2}$$

5.3 Building the Circuit C'

PCB builds the circuit C' one gate at a time. Let W' denote the set of wires of C' that have already been assigned a gate by PCB; initially W' is empty. While $W' \neq W$, PCB attempts to add another gate to C' by searching for a wire $w \in (W - W')$ and a probabilistic gate g' all of whose inputs are in W' such that for each experiment $e \in U_*$ that leaves w free and fixes all inputs of g',

$$d(\widehat{C}(e), \widehat{C}(e|_{w=g'(e)})) \leq 2\varepsilon/(4n\kappa(n)).$$

If no such gate can be found or $W' = W$, PCB outputs C' and halts. We will later show that a gate can be found as long as $W \neq W'$.

The search for g' iterates over every wire $w \in (W - W')$ and every choice of an r-tuple of distinct wires $w_1, \ldots, w_r$ from W' as the inputs of w, where $0 \leq r \leq k$. For each such choice, PCB attempts to define a probabilistic gate function f as follows. For each $(\sigma_1, \ldots, \sigma_r) \in \Sigma^r$, PCB seeks a number $x \in [0,1]$ such that if D_x is the distribution that is 1 with probability x and 0 with probability $(1-x)$ then

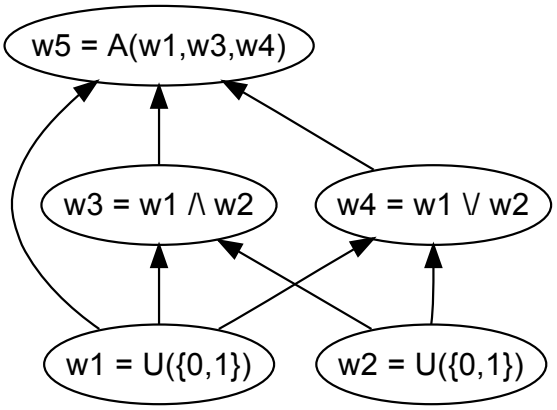
$$d(\widehat{C}(e), \widehat{C}(e|_{w=D_x})) \leq 2\varepsilon/(4n\kappa(n))$$

for all experiments $e \in U_*$ that leave w free and fix w_i to σ_i for $i = 1, \ldots, r$. Since the left hand side is a convex function of x, every such e constrains the possible values of x to an interval, and any x in the intersection of $[0,1]$ and the intervals for all such e suffices. If the intersection is empty, then the attempt to define f fails; otherwise, $f(\sigma_1, \ldots, \sigma_r)$ is defined to be D_x. If PCB succeeds in defining f for all possible r-tuples $(\sigma_1, \ldots, \sigma_r)$, then the gate g' with inputs $w_1, \ldots, w_r$ and probabilistic gate function f is assigned to w.

5.4 An Illustration

For some intuition about the operation of PCB, consider the probabilistic Boolean circuit shown in Figure 4. Wires w_1 and w_2 are determined by random coin flips, w_3 is the AND of w_1 and w_2, w_4 is the OR of w_1 and w_2, and w_5 is determined by the 3-input averaging gate applied to w_1, w_3 and w_4. The table shows the probability that $w_5 = 1$ for a selected set of value injection experiments.

Suppose that these experiments are contained in U when PCB attempts to add the first gate to C'. Of course, PCB will only have repeated sampling estimates of these probabilities, but suppose for a moment that the exact values were available. Because W' is empty, the first gate added must



#	Experiment	$\Pr[w_5 = 1]$
1.	* * * * *	1/2
2.	0 * * * *	1/6
3.	1 * * * *	5/6
4.	* * 0 * *	5/12
5.	* * 1 * *	3/4
6.	* 1 * 0 *	1/3
7.	0 1 * 0 *	0
8.	1 1 * 0 *	2/3
9.	* 1 0 0 *	1/6
10.	* 1 1 0 *	1/2

Figure 4: A Boolean circuit with output wire w_5, and some of its behavior.

have no inputs and must be determined by a coin flip that is 1 with some probability x. In this group of experiments, there are two constraints for wire w_1 for the possible values of x. Experiments 1, 2 and 3 give the constraint $(1/6)(1-x)+(5/6)x = 1/2$, which implies $x = 1/2$, and experiments 6, 7 and 8 give the constraint $0(1-x)+(2/3)x = 1/3$, which also implies $x = 1/2$, consistent with the gate computing w_1 in the target circuit. There are also two constraints on the possible values of x for the wire w_3. Experiments 1, 4 and 5 give the constraint $(5/12)(1-x)+(3/4)x = 1/2$, which implies $x = 1/4$, and experiments 6, 9 and 10 give the constraint $(1/6)(1-x)+(1/2)x = 1/3$, which implies $x = 1/2$. Thus there is no consistent value of x that would allow the first gate to be chosen for wire w_3. Rather than exact values, PCB considers intervals determined by error tolerances, but when these are small enough, the constraint intervals for w_3 will not overlap, and PCB will not choose the first gate for wire w_3.

5.5 Correctness

With probability at least $(1-\delta)$, the estimates $\widehat{C}(e)$ satisfy (1) for all $e \in U$. We now assume that the estimates satisfy these bounds and show that PCB successfully builds a circuit C' that is ε-behaviorally equivalent to C.

We first establish two lemmas connecting gates, paths and experiments. Given a Boolean probabilistic circuit C and a probabilistic gate g, g is **η-correct** for wire w with respect to C if for every value injection experiment e that fixes the input wires for g we have $d(C(e), C(e|_{w=g(e)})) \leq \eta$, where $g(e)$ denotes the value distribution determined by g when its inputs are fixed as in e. Recall that $\phi(e)$ denotes the number of free wires in experiment e, and therefore $\phi(e) \leq n$ for all e.

Lemma 13 *Let C and C' be probabilistic circuits on wires W, and let e be a distribution injection experiment. If for every wire w, the gate for w in C' is η-correct for w with respect to C, then*

$$d(C(e), C'(e)) \leq \phi(e) \cdot \eta.$$

Proof By induction on $\phi(e)$, the number of free wires in e. If $\phi(e) = 0$, then e constrains the output wire, and trivially, $d(C(e), C'(e)) = 0$. Otherwise, the inductive hypothesis is that

$$d(C(e'), C'(e')) \leq \phi(e') \cdot \eta$$

for all experiments e' with fewer than $\phi(e)$ free gates.

By Lemma 2, assume that e is in fact a value injection experiment. Since C' is acyclic, there exists a free wire w in e such that the inputs to w in C' are fixed in e to some k-tuple $(\sigma_1,\ldots,\sigma_k) \in \Sigma^k$. Let f denote the probabilistic gate function for w in C', and let D denote the value distribution $f(\sigma_1,\ldots,\sigma_k)$. Then we have $C'(e) = C'(e|_{w=D})$, and

$$\begin{aligned} d(C(e),C'(e)) &\le d(C(e),C(e|_{w=D})) + d(C(e|_{w=D}),C'(e|_{w=D})) \\ &\le \eta + (\phi(e)-1)\cdot\eta \\ &= \phi(e)\cdot\eta \end{aligned}$$

by the inductive hypothesis and the fact that f is η-correct for w. ■

Corollary 14 *Let C and C' be probabilistic circuits on wires W where $|W| = n$. If for every wire w, the gate g for w in C' is η-correct for w with respect to C, then*

$$d(C(e),C'(e)) \le n\cdot\eta.$$

Proof By the definition of approximate behavioral equivalence and the bound $\phi(e) \le n$. ■

Next we show that test paths are sufficient to determine whether a gate is η-correct for a wire in C.

Lemma 15 *Let C be a Boolean probabilistic circuit, w a wire and g' a probabilistic gate. If for every test path p for w that fixes all the inputs of g', $d(C(p),C(p|_{w=g'(p)})) \le \eta/K_w$, where K_w is the maximum value of $\kappa(e,w)$ for C over all experiments e, then g' is η-correct for w with respect to C.*

Proof Let g be the actual gate that C assigns to w. Let e be a value injection experiment that fixes every input of g'. Then e may not fix all of g's inputs, but because C is acyclic, g's inputs are not reachable from w. By Lemmas 4 and 5, there exists an experiment $e' \le e$ that fixes g's inputs, with

$$d(C(e'),C(e'|_{w=g'(e')})) \ge d(C(e),C(e|_{w=g'(e)})).$$

Since e' fixes all of g's inputs, $C(e') = C(e'|_{w=g(e')})$. It is given that for all test paths p that fix all inputs of g' that

$$d(C(p|_{w=g(p)}),C(p|_{w=g'(p)})) \le \eta/K_w,$$

so it follows by Lemma 10 that

$$d(C(e'|_{w=g(e')}),C(e'|_{w=g'(e')})) \le \kappa(e',w)\cdot\eta/K_w \le \eta,$$

and g' is η-correct for w. ■

To prove that PCB constructs a circuit C' that is ε-behaviorally equivalent to the target circuit C, we show that for each wire $w \in W$, PCB assigns a gate that is ε/n-correct for w in C.

Assume that $W' \neq W$, that is, that not all wires have been assigned gates, and consider PCB as it attempts to add another gate to C'. PCB looks for a wire $w \in (W - W')$ and probabilistic gate $g' \in G$ with all of its inputs in W' such that for each experiment $e \in U_*$ that leaves w free and fixes all inputs of g',

$$d(\widehat{C}(e), \widehat{C}(e|_{w=g'(e)})) \leq 2\varepsilon/(4n\kappa(n)).$$

If this search succeeds, then by (1),

$$d(C(e), \widehat{C}(e)) \leq \varepsilon/(4n\kappa(n)) d(\widehat{C}(e|_{w=g'(e)}), C(e|_{w=g'(e)})) \leq \varepsilon/(4n\kappa(n)),$$

and thus by the triangle inequality we have

$$d(C(e|_{w=g'(e)}), C(e)) \leq \varepsilon/(n\kappa(n)),$$

It follows by Lemma 15 and the choice of $\kappa(n)$ that g' is ε/n-correct for w in C.

To see that the search for a gate will succeed as long as $W' \neq W$, we note that because C is acyclic, there is some wire $w \in (W - W')$ such that all of w's inputs in C are in W'. Let g denote the gate assigned by C to w, with inputs $w_1, \ldots, w_r$ and probabilistic gate function f. By the existence of g, there is at least one feasible gate-wire assignment for PCB to make, ensuring the continued progress of PCB. Consider any experiment $e \in U_*$ that leaves w free and fixes the inputs of g to $(\sigma_1, \ldots, \sigma_r)$. Let D be the value distribution $f(\sigma_1, \ldots, \sigma_r)$. Then $C(e) = C(e|_{w=D})$ and by (1) and (2) we have

$$\begin{aligned} d(\widehat{C}(e), C(e)) &\leq \varepsilon/(4n\kappa(n)) \\ d(C(e|_{w=D}), \widehat{C}(e|_{w=D})) &\leq \varepsilon/(4n\kappa(n)), \end{aligned}$$

so by the triangle inequality,

$$d(\widehat{C}(e), \widehat{C}(e|_{w=D})) \leq 2\varepsilon/(4n\kappa(n)).$$

Therefore, PCB will continue to make progress until it has assigned a gate to every wire in W, and every such gate will be ε/n-correct for its wire in C, which means that C' will be ε-behaviorally equivalent to C.

5.6 Running Time

To bound the running time of PCB we argue as follows. The set U of experiments is of cardinality $n^{O(kc)}$ and can be constructed in time polynomial in its size. To estimate $C(e)$, each experiment in U is repeated

$$O((n\kappa(n)/\varepsilon)^2 \log(|U|/\delta))$$

times; recall that $\kappa(n) = O(n^{c(\log k+1)})$. PCB then chooses a gate for a wire n times. For each choice, it must at worst iterate over $O(n)$ wires in $(W - W')$, over all $O(n^k)$ choices of k or fewer input wires from W', over all $|\Sigma|^k$ assignments of values to the input wires, and all experiments in U. Thus the running time of PCB is polynomial in n, $1/\varepsilon$ and $1/\delta$.

6. Lower Bounds on Path Attenuation

The path attenuation bound $\kappa(n)$ is a significant factor in the running time of the PCB algorithm. In this section we consider lower bounds on path attenuation for Boolean probabilistic circuits. The following theorem shows that the bound of $\pi(e,w)$ for transitively reduced Boolean probabilistic circuits in Corollary 11 is tight infinitely often.

Theorem 16 *There is an infinite set of transitively reduced probabilistic Boolean circuits such that for each circuit C in the family, there exists a value injection experiment e and a wire w free in e such that*

$$d(C(e|_{w=0}),C(e_{w=1})) = 1$$

and for every test path p for w we have

$$d(C(p|_{w=0}),C(p|_{w=1})) = 1/\pi(e,w).$$

Proof For each positive integer ℓ, define the circuit C_ℓ to be a chain of ℓ copies of the circuit C_1 in Figure 1 with wire w_4 of one copy identified with wire w_1 of the next copy. More formally, the $3\ell+1$ wires are $w_{0,4}$ and $w_{i,j}$ for $i = 1,\ldots,\ell$ and $j = 2,3,4$. The output wire is $w_{\ell,4}$. The wire $w_{0,4}$ has no inputs and is determined by an unbiased coin flip, that is, $U(\{0,1\})$. The wires $w_{i,2}$ and $w_{i,3}$ are the outputs of deterministic identity gates with input $w_{i-1,4}$. The wire $w_{i,4} = A(w_{i,2},w_{i,3})$ is the result of applying the two-input averaging probabilistic gate function A to the wires $w_{i,2}$ and $w_{i,3}$. The circuit C_3 is depicted in Figure 5.

To understand the operation of this circuit in response to a value injection experiment e, we may view each averaging gate as choosing one of its inputs to copy to its output. Starting at the output wire, this determines a path back to the first wire whose value has been fixed, or to the wire $w_{0,4}$ (which has no inputs) and the output of the circuit is the value of the wire so reached.

Define experiment e to leave all of the wires free. Let w denote the wire $w_{0,4}$. Clearly there are 2^ℓ paths on free gates in e from w to the output gate, that is, $\pi(w,e) = 2^\ell$. For experiment e every possible path starts at wire w and we have $C(e|_{w=0}) = 0$ and $C(e|_{w=1}) = 1$, so $d(C(e|_{w=0}),C(e|_{w=1})) = 1$. However, any test path p for w must fix one of the wires $w_{i,2}$ or $w_{i,3}$ for each $i = 1,\ldots,\ell$. Thus, there is exactly one path that leads back to wire w, and this path is the one chosen by the averaging gates with probability $1/2^\ell$. Thus the result for any test path p for w is $d(C(p|_{w=0}),C(p|_{w=1})) = 1/2^\ell = 1/\pi(e,w)$. ■

This lower bound also holds for general transitively reduced circuit topologies, as follows. (Note that this result was incorrectly stated in the preliminary version of this paper (Angluin et al., 2008a).)

Theorem 17 *Let G be a transitively reduced acyclic directed graph with a designated output node z that is reachable from every node. For each node w there exists a Boolean probabilistic circuit C whose circuit graph is G with output wire z such that for every value injection experiment e that leaves w free and for every test path $p \leq e$ for wire w we have*

$$d(C(e|_{w=1}),C(e|_{w=0})) \geq \pi(e,w) \cdot d(C(p|_{w=1}),C(p|_{w=0})).$$

Proof Let w be given. To construct C, each node v of G is assigned a probabilistic gate whose inputs are the in-neighbors of v in G, as follows. For each node v, let $P(v)$ denote the number of

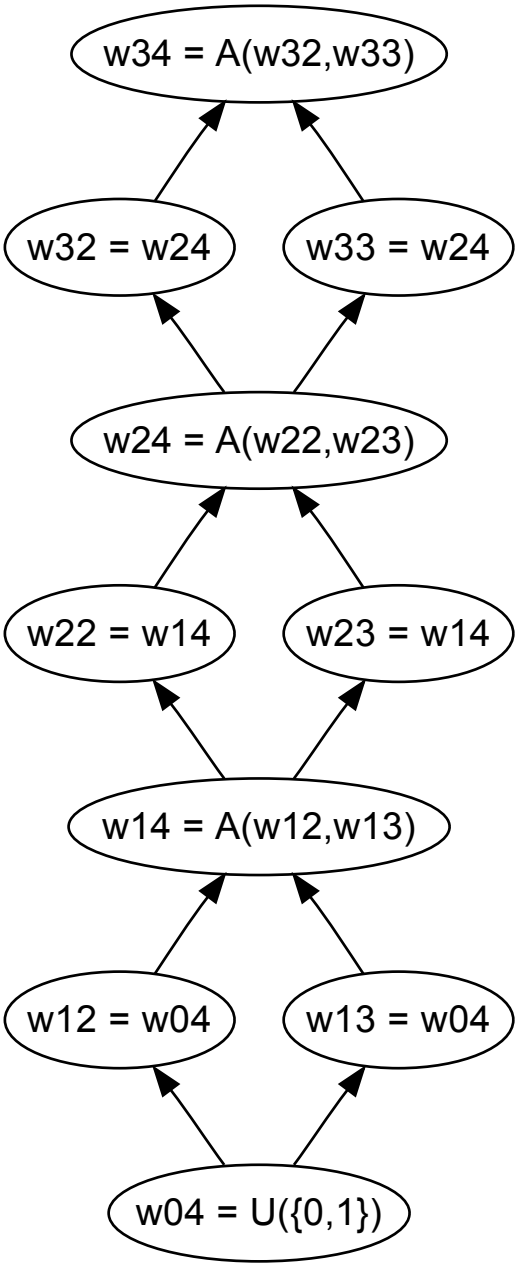


Figure 5: The circuit C_3; $w_{3,4}$ is the output wire.

distinct directed paths from w to z that include node v, and for each edge (u,v), let $P(u,v)$ denote the number of distinct directed paths from w to z that include edge (u,v). If there are no paths from w to z through v (that is, $P(v) = 0$) then we let the probabilistic gate function for v be the constant function 0. The probabilistic gate function for w is a coin flip, $U(\{0,1\})$.

Otherwise, if node v has inputs $u_1, \ldots, u_r$ then it is assigned the probabilistic gate function specified by

$$A_v(b_1, \ldots, b_r) = \sum_{i=1}^{r} b_i \cdot P(u_i, v)/P(v)$$

This generalizes the two-input averaging gate A, weighting input u_i by the fraction of paths from w to z passing through v that also pass through u_i. We may view A_v as performing a random weighted selection of one of its inputs to copy to its output. The weights have been chosen so that each directed path from w to z is selected with probability $1/P(w)$.

Let e be any value injection experiment that leaves w free. If there is no path on free wires in e from w to the output, then $\pi(e,w) = 0$, and the bound in the conclusion of the lemma holds trivially. Otherwise, the output of the circuit in response to e is determined by tracing from the output wire, following the choices of the averaging gates, until either the first wire fixed by e, or w, is reached. Thus

$$d(C(e|_{w=1}), C(e|_{w=0})) = \pi(e,w)/P(w),$$

because there are $\pi(e,w)$ paths from w to the output wire in e. Let $p \leq e$ be any test path for w; now there is just one choice of path that leads back to w, so

$$d(C(p|_{w=1}), C(p|_{w=0})) = 1/P(w),$$

establishing the conclusion of the lemma. ■

Can the general bound in Lemma 10 be improved to the bound for transitively reduced circuits in Corollary 11? The following example shows that the better bound is in general not attainable if the circuit is not transitively reduced. It gives a family of circuits of depth 2ℓ for which the worst-case ratio of the differences shown for w by an experiment e and the best path for w is $(5/4)^\ell \pi(e,w)$.

Theorem 18 *There exists an infinite set of Boolean probabilistic circuits $D_1, D_2, \ldots$ such that for each ℓ there exists a value injection experiment e and a wire w free in e such that $\pi(e,w) = 4^\ell$ and*

$$d(D_\ell(e|_{w=0}), D_\ell(e|_{w=1})) = (5/7)^\ell,$$

but for any test path p for w,

$$d(D_\ell(p|_{w=0}), D_\ell(p|_{w=1})) = (1/7)^\ell.$$

Proof We first define a Boolean probabilistic circuit D_1 and then connect ℓ copies of it in series to get D_ℓ. The wires of D_1 are $w_1, \ldots, w_5$. They are connected as in Figure 6; the output wire is w_5. Note that the edge (w_1, w_5) means that the circuit graph is not transitively reduced. The gate

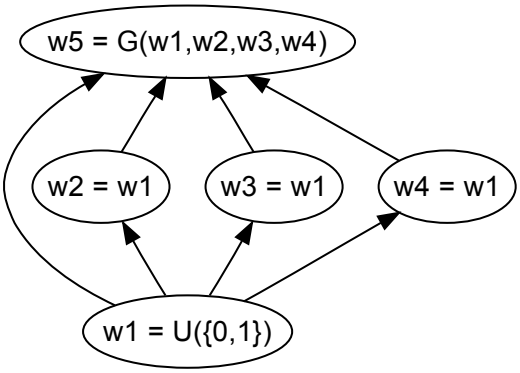

Figure 6: The circuit D_1; w_5 is the output wire.

function G is defined by giving its expected value as a function of its inputs:

$$E[G(w_1,w_2,w_3,w_4)] = ((1-w_1)+2w_2+2w_3+2w_4)/7.$$

Let e be the experiment that leaves all five wires free. It is clear that

$$d(D_1(e|_{w_1=0}),D_1(e|_{w_1=1})) = 5/7.$$

We now show that for any test path p for w_1,

$$d(D_1(p|_{w_1=0}),D_1(p|_{w_1=1})) = 1/7.$$

The possible test paths p for w_1 either fix all of w_2,w_3,w_4 or all but one of them. Thus, as we change from $w_1 = 0$ to $w_1 = 1$ in such a test path, the assignments to wires (w_1,w_2,w_3,w_4) change in one of four possible ways:

$(0,b_2,b_3,b_4)$ to $(1,b_2,b_3,b_4)$

$(0,0,b_3,b_4)$ to $(1,1,b_3,b_4)$

$(0,b_2,0,b_4)$ to $(1,b_2,1,b_4)$

$(0,b_2,b_3,0)$ to $(1,b_2,b_3,1)$

Checking each of these possible changes against the definition of G, we see that each change produces a difference of $1/7$, as claimed. (This example can be modified to give a difference of 1 versus $1/5$.) Thus, setting $w = w_1$, the circuit D_1 gives the base case of the claim in the lemma.

To construct D_ℓ, we take ℓ copies of D_1 and identify wire w_5 in one copy with wire w_1 in the next copy, making the wire w_5 of the final copy the output wire of the whole circuit. Let w denote the wire w_1 in the first such copy. Then $\pi(e,w) = 4^\ell$ and

$$d(D_\ell(e|_{w=0}),D_\ell(e_{w=1})) = (5/7)^\ell.$$

For any test path p, the signal is attenuated by a factor of $1/7$ for each level, and we have

$$d(D_\ell(p|_{w=0}),D_\ell(p|_{w=1})) = 1/7^\ell.$$

■

This construction can be generalized to $k+1$ wires for any odd $k+1$, which increases the attenuation. In the base circuit there are k paths and an attenuation factor of $1/(2k-3)$, and the worst-case ratio of differences for an experiment and its test paths in D_ℓ approaches $2^\ell \pi(e,w)$ as k goes to infinity.

7. Exponential Dependence on Depth

The bounds on path attenuation show that test paths may be much less informative than general value injection experiments, resulting in the exponential dependence of the number of experiments and the running time of PCB on the depth of the target circuit. It is natural to ask whether we might do better by using selected general experiments. In this section, we give computational evidence to the contrary. The following result contrasts with the case of deterministic circuits, where the Distinguishing Paths algorithm uses value injection queries to learn arbitrary transitively reduced acyclic deterministic circuits of constant fan-in over polynomial size alphabets in polynomial time (Angluin et al., 2008b).

Theorem 19 *If* **BPP** $\neq$ **NP** *and* $k \geq 4$ *then there is no polynomial time algorithm using value injection queries that approximately learns all acyclic transitively reduced Boolean probabilistic circuits with fan-in bounded by* k.

Proof Suppose L is a polynomial time algorithm that approximately learns the behavior of every transitively reduced acyclic Boolean probabilistic circuit of fan-in bounded by 4 using value injection queries. The hard computational problem we consider is the following: given a satisfiable 3-CNF formula ϕ over the variables $x_1,\ldots,x_n$ with clauses $c_1,\ldots,c_m$, find an assignment to the variables that satisfies significantly more than seven-eights of the clauses of the formula. Finding such an assignment is **NP**-hard by a result of Håstad (2001). We show how to transform the 3-CNF formula ϕ into a pair of transitively reduced circuits C_0 and C_1 with maximum fan-in 4 such that value injection experiments show a difference that is exponentially small in the depth of the circuits unless we can find a variable assignment that satisfies significantly more than seven-eighths of the clauses of the formula.

The efficiency of our construction depends on the existence of a family of graphs with an expansion property. Specifically, there exists a constant $\alpha < 1$ such that for sufficiently large m, there exists a directed graph G_m on m nodes with constant out-degree 3 such that the second largest eigenvalue λ_2 of the transition matrix for a random walk on G_m satisfies $\lambda_2 \leq \alpha$. Such a family can be constructed by the probabilistic method and explicit constructions are also known; these are surveyed by Hoory, Linial, and Wigderson (2006). Let r be the smallest integer such that $\alpha^r \leq 1/40$.

Let ℓ be a positive integer. The two circuits C_0 and C_1 differ only in their default assignments to a subset of their wires, so we describe their common structure as follows. The circuit consists of a stack of ℓ repetitions of a block consisting of r expander layers above one gadget layer for a total depth of $(2r+1)\ell$. Figure 7 illustrates a block consisting of one expander layer ($r=1$) above a gadget layer. Recall that $x_1,\ldots,x_n$ are the variables of ϕ and $c_1,\ldots,c_m$ are the clauses of ϕ.

A **gadget layer** has three types of wires: inputs $\mathrm{gIn}_1,\ldots,\mathrm{gIn}_m$, variables $\mathrm{x}_1,\ldots,\mathrm{x}_n$, and outputs $\mathrm{gOut}_1,\ldots,\mathrm{gOut}_m$. The input wire gIn_j of each gadget layer except the initial one is identified with

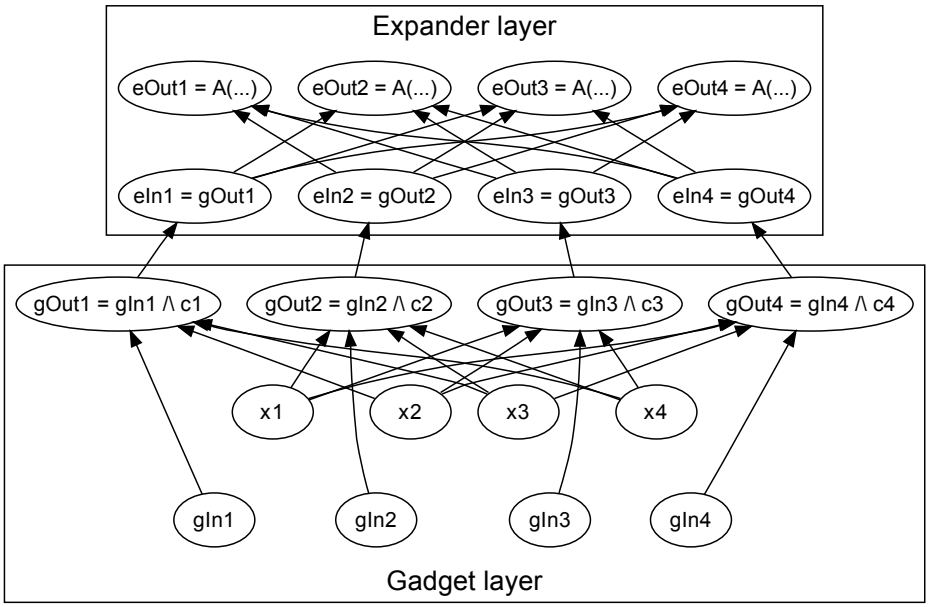

Figure 7: A block with $r = 1$ for the Boolean formula $c_1 \wedge c_2 \wedge c_3 \wedge c_4$, where $c_1 = x_2 \vee \overline{x_3} \vee x_4$ and $c_2 = \overline{x_1} \vee x_3 \vee \overline{x_4}$ and $c_3 = x_1 \vee \overline{x_2} \vee x_4$ and $c_4 = \overline{x_1} \vee x_2 \vee \overline{x_3}$.

the corresponding output wire eOut_j of the expander layer just below it. The variable wires x_i of each gadget layer have no inputs and default to the constant 0. Each output wire gOut_j has four inputs: the corresponding gadget input wire gIn_j and the three variable wires for the variables of the clause c_j of ϕ. Its gate function computes the conjunction of gIn_j and the value of the clause c_j given its three variable values.

Thus, if the learner sets the variable wires x_i in a gadget layer according to a satisfying assignment of ϕ, the signals propagate from the gadget inputs gIn_j to their corresponding outputs gOut_j with perfect fidelity. Otherwise, any unsatisfied clause blocks the signal for the corresponding output.

An **expander layer** averages the outputs of the layer below to be the inputs for the layer above, according to the expander graph G_m. Each input eIn_j of an expander layer is set equal to the corresponding output of the gadget or expander layer immediately below it. The three inputs to eOut_j are eIn_k for the three out-neighbors k of j in the expander graph G_m. The gate function for each eOut_j is the three-input averaging gate $A(x,y,z)$, which is 1 with probability $(x+y+z)/3$. The output of the whole circuit is the first output wire of the final (topmost) expander layer.

The **initial inputs** are the input wires gIn_j of the initial gadget layer. They have no inputs; for the circuit C_0 they are all assigned the default value 0, and for the circuit C_1 they are all assigned the default value 1. Note that C_0 and C_1 are transitively reduced and have a maximum fan-in of 4.

The challenge for the learner is to determine which of C_0 and C_1 is the target circuit. If a value injection experiment succeeds in setting the variable wires in every gadget layer to (possibly different) satisfying assignments for the formula ϕ and leaves all other wires free, then the output of C_0 is 0 and the output of C_1 is 1. If not all the clauses of ϕ are satisfied, then this distance is reduced.

Intuitively, the learner's strategy must be to fix the variable wires in each gadget layer to prevent the signal from the initial inputs from getting blocked; fixing the input or output wires of gadget or expander layers would not help, because they would then have the same value regardless of their inputs. Without a good variable assignment, however, the signal strength drops by a constant factor for each layer, as we now show.

Let e be a value injection experiment. The experiment e induces an assignment to the variables of ϕ for each gadget layer, either by fixing the value of each variable wire or letting it default to 0. The effect of an averaging gate is to select one of its inputs at random and copy the value of that input to the output. Thus, the output of the circuit for experiment e is in effect determined by a random walk backward from the output wire until the walk reaches a wire whose value is fixed by e (and the output is the fixed value), or a gadget layer output wire corresponding to an unsatisfied clause (and the output is 0), or an initial input wire (and the output is the value of that wire.) Suppose that for each gadget layer e encodes a variable assignment that satisfies at most $(9/10)m$ of the clauses of ϕ. We show that the probability that the random walk hits an initial input wire is bounded above by $(39/40)^\ell\sqrt{m}$.

Without loss of generality we may assume that e fixes no wires other than variable wires and initial input wires, because any other fixed wires reduce the probability of reaching an initial input. For $i = 1,\ldots,\ell$, let W_i be the $m \times m$ diagonal matrix with 1s for each satisfied clause in the ith gadget layer and 0s for each unsatisfied clause. Let B be the transition matrix for an r-step random walk on G_m and let $e_1 = (1,0,\ldots,0)$. The probabilities of the random walk hitting the initial inputs are given by the vector $e_1BW_\ell BW_{\ell-1}\cdot BW_2BW_1$. By the following argument, for all i and vectors v, we have $\|vBW_i\| \le (39/40)\|v\|$.

Write $v = cu + w$, where c is a scalar and $u = (1,\ldots,1)$ and w is a vector such that $u \perp w$. Then u is an eigenvector of B with eigenvalue 1 and multiplying w by B shrinks its length to at most the second eigenvalue of B times its original length. By Pythagoras, $\|cu\| \le \|v\|$ and $\|w\| \le \|v\|$. We have $vBW_i = (cu+w)BW_i$. On one hand, $\|cuBW_i\| = \|cuW_i\| \le \sqrt{9/10}\|cu\| \le (19/20)\|v\|$. On the other hand, $\|wB\| \le (1/40)\|w\| \le (1/40)\|v\|$, because the second eigenvalue of B is no larger than $1/40$, and $\|wBW_i\| \le (1/40)\|v\|$, because W_i does not increase the L_2 norm. The resulting $(39/40)^\ell$ bound on the L_2 norm of the probability vector gives a bound of $(39/40)^\ell\sqrt{m}$ on the L_1 norm, which is an upper bound on the probability that any initial input is reached.

Suppose the learning algorithm L runs in time $f(N,1/\varepsilon,1/\delta)$, for some nondecreasing polynomial f, where N is the number of wires in the target circuit. Let $N(\ell)$ denote the number of wires in C_0 (or C_1) as a function of the number ℓ of blocks in the stack. Then $N(\ell) = O(\ell(n+rm))$. We choose ℓ sufficiently large that

$$((39/40)^\ell\sqrt{m})f(N(\ell),4,4) < 1/4,$$

clearly $N(\ell)$ is bounded by a polynomial in m and n.

We randomly and equiprobably choose the target circuit C to be C_0 or C_1 and simulate L with target circuit C and $\varepsilon = \delta = 1/4$. When L makes a value injection experiment e, we check whether any of the induced variable assignments of e satisfies more than $(9/10)m$ clauses of ϕ. If so, we output the assignment and halt. Otherwise, we use a random walk from the output wire in the circuit C to give an output for e. If no experiment e satisfies more than $(9/10)m$ of the clauses of ϕ, then the probability that any of them reaches an initial input in C is less than $1/4$. If none of them reaches an initial input, then L cannot distinguish between C_0 and C_1, and must output a circuit that is not $1/4$-approximately behaviorally equivalent to C with probability at least $3/8 > 1/4$, violating the

requirements of approximate learning. ■

We conclude that if **BPP** $\neq$ **NP**, any polynomial time learning algorithm requires in expectation exponentially many queries in ℓ to learn the default settings of the initial inputs and therefore, PCB is within a polynomial of optimal.

8. Non-Boolean Circuits Revisited

The sharp contrast in results for transitively reduced circuits with alphabet size at least three, for which test paths may show no difference (Lemma 8) and those with alphabet size two, for which test paths must show a significant difference (Lemma 10) motivate us to consider a generalization of the kinds of experiments we consider, to function injection experiments. This generalization allows us to extend the results of Lemma 10 to non-Boolean alphabets.

In a value injection experiment, each wire is either fixed to a constant value or left free. In a function injection experiment for a wire w, these possibilities are expanded to permit a transformation of the value that the wire w would take if it were left free. As an example, consider a transformation in which the values that w could attain are linearly ordered and all values below a certain threshold are mapped to the minimum value and all other values are mapped to the maximum value. It is conceivable that this kind of transformation could be feasible in some domains; in any case, the theoretical consequences are quite interesting. We first give a general definition of function injection, but in the results below we are primarily concerned with 2-partitions, that is, transformations that are like the above example in that they partition the values into at most two blocks and map each block to a fixed element of the block.

An **alphabet transformation** is a function f that maps symbols to distributions over symbols. An alphabet transformation is **deterministic** if it assigns only deterministic distributions, in which case we think of it as a map from symbols to symbols. A deterministic alphabet transformation f is a k-**partition** if there exists a partition of Σ into at most k disjoint nonempty sets Σ_i such that for each i there exists $\sigma_i \in \Sigma_i$ such that $f(\Sigma_i) = \{\sigma_i\}$. Note that if $k_1 \leq k_2$, every k_1-partition is also a k_2-partition.

A 1-partition is a constant function, achieving the same result as fixing the wire to a value in a value injection experiment. We use 2-partitions to reduce the case of larger alphabets to the binary case. Note that the 2-partitions of a binary alphabet include the identity and the two constant functions, but not the negation function.

If D is a value distribution and f is an alphabet transformation, then $f(D)$ is the value distribution in which

$$(f(D))(\sigma) = \sum_{\tau \in \Sigma} D(\tau)(f(\tau))(\sigma).$$

A **function injection experiment** is a mapping e with domain W that assigns to each wire the symbol $*$ or a symbol from Σ or an alphabet transformation f. Then e leaves w **free** if $e(w) = *$, **fixes** w if $e(w) \in \Sigma$, and **transforms** w if $e(w)$ is an alphabet transformation f. We extend the ordering $\leq$ on experiments by stipulating that each alphabet transformation $f \leq *$. A **2-partition experiment** is a function injection experiment in which every alphabet transformation is a 2-partition.

We now define the joint probability distribution on assignments of symbols from Σ to wires determined by a function injection experiment e. If e fixes w, then w is just assigned $e(w)$. Otherwise,

if the inputs of w have been assigned the values $\sigma_1, \ldots, \sigma_k$ and f is the gate function for w, we randomly and independently choose a symbol σ according to the value distribution $f(\sigma_1, \ldots, \sigma_k)$. If w is free in e, then σ is the symbol assigned to w; however, if $e(w)$ is an alphabet transformation, then a symbol τ is chosen randomly and independently according to the value distribution $e(\sigma)$ and assigned to w. That is, when $e(w)$ is an alphabet transformation, we generate the symbol for w as though it were free, and then use the distribution $e(w)$ to transform that symbol. Because C is acyclic, this process assigns a symbol to every wire of C.

In a **function injection query** (FIQ), the learning algorithm gives a function injection experiment e and receives a symbol σ assigned to the output wire of C by the probability distribution defined above. A **functional test path** for a wire w is a function injection experiment in which the free and transformed wires are a directed path in the circuit graph from w to the output wire, and all other wires are fixed.

As an example of how functional test paths help in learning non-Boolean probabilistic circuits, consider again the circuit in the proof of Lemma 8, depicted in Figure 3. We specify a functional test path p by $p(w_1) = p(w_4) = p(w_5) = *$, $p(w_3) = 0$ and $p(w_2)$ is the alphabet transformation $0 \to 0$, $1 \to 0$, and $2 \to 2$. Note that the alphabet transformation is a 2-partition. Then $C(p|_{w_1=0}) = 0$ but $C(p|_{w_1=2}) = U(\{0,1\})$, so this functional test path witnesses a difference of $1/2$, as large as the experiment that leaves all the wires free. Test paths with functions allow us to carry over the results of Lemma 10 to non-Boolean alphabets.

Lemma 20 *Let C be a probabilistic circuit, e be a function injection experiment, w be a wire free in e and D_1, D_2 be value distributions. If there exists $\varepsilon \geq 0$ such that for all functional w-test paths $p \leq e$ that are 2-partitions,*

$$d(C(p|_{w=D_1}), C(p|_{w=D_2})) \leq \varepsilon,$$

then

$$d(C(e|_{w=D_1}), C(e|_{w=D_2})) \leq \kappa(e,w) \cdot \varepsilon.$$

Proof The obstacle in Lemma 10 is that when the alphabet is non-Boolean, we may assume only that D_1 and D_2 have disjoint support, not that they are deterministic. This obstacle can be overcome by injecting a 2-partition at w. Let $\Sigma_1 = \text{support}(D_1)$ and $\Sigma_2 = \text{support}(D_2)$ and assume $\Sigma_1 \cap \Sigma_2 = \emptyset$. Then

$$d(C(e|_{w=D_1}), C(e|_{w=D_2})) \leq \sum_{\substack{\rho_1 \in \Sigma_1 \\ \rho_2 \in \Sigma_2}} D_1(\rho_1) D_2(\rho_2) d(C(e|_{w=\rho_1}), C(e|_{w=\rho_2}))$$

by the triangle inequality. Let

$$(\sigma, \tau) = \arg\max_{\substack{\rho_1 \in \Sigma_1 \\ \rho_2 \in \Sigma_2}} d(C(e|_{w=\rho_1}), C(e|_{w=\rho_2}))$$

so that

$$d(C(e|_{w=D_1}), C(e|_{w=D_2})) \leq d(D_1, D_2) d(C(e|_{w=\sigma}), C(e|_{w=\tau})).$$

Let f be an alphabet transformation that maps Σ_1 to σ and Σ_2 to τ and all other symbols to either σ or τ. Then f is a 2-partition, and

$$d(C(e|_{w=D_1}), C(e|_{w=D_2})) \leq d(C(e|_{w=f(D_1)}), C(e|_{w=f(D_2)})).$$

Since $f(D_1) = \sigma$ and $f(D_2) = \tau$, the rest of the proof goes through. ■

Corollary 21 *Let C be a transitively reduced probabilistic circuit, e be a function injection experiment, w be a wire, and D_1, D_2 be value distributions. If there exists $\varepsilon \geq 0$ such that for all functional w-test paths $p \leq e$,*

$$d(C(p|_{w=D_1}), C(p|_{w=D_2})) \leq \varepsilon,$$

then

$$d(C(e|_{w=D_1}), C(e|_{w=D_2})) \leq \pi(e,w) \cdot \varepsilon.$$

We expect that a further generalization of the Probabilistic Circuit Builder algorithm to use function injection experiments can learn non-Boolean circuits of logarithmic depth and constant fan in in polynomial time. The universal set would map wires to the set containing all alphabet symbols from Σ and all 2-partitions of Σ, of which there are fewer than $|\Sigma|^2 2^{|\Sigma|}$. Thus, the universal set will still be of size $n^{O(1)}$, suggesting that a polynomial time algorithm may be attainable in this case.

Certain other natural questions arise in response to the idea of function injection experiments. We can define circuits C and C' to be **strongly behaviorally equivalent** if $C(e) = C'(e)$ for every function injection query e. Does behavioral equivalence imply strong behavioral equivalence? Once again, alphabet size determines the answer: no for alphabet size greater than two, yes for alphabet size two.

Lemma 22 *For $\Sigma = \{0,1,2\}$, there exist deterministic circuits C_1 and C_2 that are behaviorally equivalent but not strongly behaviorally equivalent.*

Proof In both C_1 and C_2 there are two wires w_1 and w_2, where w_2 is the output wire. In both circuits the gate for w_2 has input w_1 and deterministically maps 0 to 0 and maps 1 and 2 to 1. In C_1, w_1 is the constant 1 and C_2 it is the constant 2.

Then if e is the value injection experiment that leaves both wires free, $C_1(e) = 1 = C_2(e)$. If e fixes either w_1 or w_2, then also $C_1(e) = C_2(e)$. Thus C_1 is behaviorally equivalent to C_2.

However, the 2-partition function injection experiment e that leaves w_2 free and maps the output of w_1 according to the transformation $0 \to 0$, $1 \to 0$, $2 \to 2$ yields $C_1(e) = 0$ and $C_2(e) = 1$. Thus C_1 is not strongly behaviorally equivalent to C_2. ■

However, 2-partition function experiments suffice to establish strong behavioral equivalence.

Lemma 23 *Let C and C' be probabilistic circuits with the same alphabet Σ, the same set of wires and the same output wire. If $C(e) = C'(e)$ for every 2-partition function experiment e then C and C' are strongly behaviorally equivalent.*

Proof By a generalization of the Probabilistic Circuit Builder algorithm to functional test paths. ■

Because in the Boolean case every 2-partition function injection query is a value injection query, we then have the following.

Corollary 24 *For Boolean probabilistic circuits C and C', if C is behaviorally equivalent to C' then C is strongly behaviorally equivalent to C'.*

9. Discussion and Open Problems

These results concern general probabilistic acyclic gates, with no restriction other than fan-in on the kinds of probabilistic gate functions considered. Particular domains may warrant specific assumptions about the gate functions, which may make the learning problems more tractable. For example, for the problem of learning the structure of an independent cascade social network using exact value injection queries, a query-optimal algorithm is presented by Angluin et al. (2008c). Note that social networks may in general contain cycles, which complicates their analysis.

The Distinguishing Paths algorithm (Angluin et al., 2008b) learns transitively reduced acyclic deterministic circuits over polynomial size alphabets with constant fan-in and no depth bound using value injection queries in polynomial time, and relies on a version of the test path lemma. Theorem 19 shows that if **BPP** $\neq$ **NP** then this algorithm does not generalize to arbitrary transitively reduced Boolean probabilistic circuits, but there is a possibility that it might generalize to transitively reduced Boolean probabilistic circuits with a polynomial bound on the total number of directed paths in the circuit graph. A somewhat technical open question is whether in the case of general Boolean probabilistic circuits, the ability to inject the NOT function might reduce the maximum path attenuation to just the number of paths, as it does in the case of the circuit in Figure 6.

Abstract

In this paper, we present an automated approach to discover patterns that can distinguish between sequences belonging to different labeled groups. Our method searches for approximately conserved motifs that occur with varying statistical properties in positive and negative training examples. We propose a two-step process to discover such patterns. Using locality sensitive hashing (LSH), we first estimate the frequency of all subsequences and their approximate matches within a given Hamming radius in labeled examples. The discriminative ability of each pattern is then assessed from the estimated frequencies by concordance and rank sum testing. The use of LSH to identify approximate matches for each candidate pattern helps reduce the runtime of our method. Space requirements are reduced by decomposing the search problem into an iterative method that uses a single LSH table in memory. We propose two further optimizations to the search for discriminative patterns. Clustering with redundancy based on a 2-approximate solution of the k-center problem decreases the number of overlapping approximate groups while providing exhaustive coverage of the search space. Sequential statistical methods allow the search process to use data from only as many training examples as are needed to assess significance. We evaluated our algorithm on data sets from different applications to discover sequential patterns for classification. On nucleotide sequences from the Drosophila genome compared with random background sequences, our method was able to discover approximate binding sites that were preserved upstream of genes. We observed a similar result in experiments on ChIP-on-chip data. For cardiovascular data from patients admitted with acute coronary syndromes, our pattern discovery approach identified approximately conserved sequences of morphology variations that were predictive of future death in a test population. Our data showed that the use of LSH, clustering, and sequential statistics improved the running time of the search algorithm by an order of magnitude without any noticeable effect on accuracy. These results suggest that our methods may allow for an unsupervised approach to efficiently learn interesting dissimilarities between positive and negative examples that may have a functional role.

Keywords: pattern discovery, motif discovery, locality sensitive hashing, classification

1. Introduction

Pattern discovery has been studied extensively in the context of data mining and knowledge discovery (Han and Kamber, 2005) and causal inference in statistics (Pearl, 2000). The search for patterns is typically guided by classification. The focus is on discovering activity that can distinguish members of a family from non-members (Duda et al., 2000) by identifying activity that is unlikely to occur purely by chance and may have a functional role (Syed et al., 2007).

Pattern discovery has been applied to data from a variety of applications, for example, world wide web transactions (Mobasher et al., 1996), marketing information (Shaw et al., 2001), and medical signals (Li et al., 2005). More recently, there has been an increased interest in applying techniques for discovering patterns to sequences corresponding to genomic data (Wang et al., 1999). Of particular importance in computational biology is the problem of discovering subsequences, that is, motifs, which regulate important biological processes (Kellis et al., 2004). Pattern discovery has been proposed in this context as a machine learning problem (Brazma et al., 1998):

> Given two sets of sequences S^+ and S^- drawn randomly from families F^+ and F^- respectively such that $F^+ \cap F^- = \oslash$, find the pattern W of length L that has high likelihood in F^+ but not in F^-.

This formulation is sufficiently general to apply to a wide variety of applications where sequential data exists. Furthermore, an extensive literature on symbolization (Daw et al., 2003) allows for a large set of time-series signals to be abstracted into sequential data for analysis. We make the notion of a pattern more explicit by refining the goal of pattern discovery described above as follows:

> Given two sets of sequences S^+ and S^- drawn randomly from families F^+ and F^- respectively such that $F^+ \cap F^- = \oslash$, find the subsequence W of length L that occurs with a Hamming distance of at most d with high likelihood in F^+ but not in F^-.

In this paper, we propose a method to efficiently carry out the search for such approximate patterns. A variety of techniques have been proposed to address this problem statement (Lawrence et al., 1993; Bailey and Elkan, 1994; Grundy et al., 1997; Tavazoie et al., 1999; Liu et al., 2001; Pavesi et al., 2001; Sinha and Tompa, 2003). The common strategy adopted by these methods is to approach the problem of pattern discovery by finding activity that is statistically unlikely but occurs consistently in positive examples. Negative examples are primarily used for evaluation. This process means that discriminative patterns in negatively labeled sequences are not explored for classification. Other algorithms for pattern discovery (Delcher et al., 1999; Batzoglou et al., 2000) enumerate all exact patterns across both positive and negative examples to identify sequences that can discriminate between these two cases, but become computationally intractable when allowing subsequences to have an approximate form.

We describe a locality sensitive hashing (LSH) based algorithm to efficiently estimate the frequencies of all approximately conserved subsequences with a certain Hamming radius in both positive and negative examples. The search process attempts to identify patterns that allow maximum discrimination between the two groups. In this way, our method unifies the broad areas of existing work in sequential pattern detection for classification by proposing a way to discover patterns that are both approximate and derived using the additional information available in negative instances.

LSH forms a key component of our method. The use of LSH has been proposed earlier in the context of pattern discovery to identify interesting activity in positive examples (Buhler, 2001; Buhler and Tompa, 2002). We supplement this work by allowing for information from negative examples to be factored into the search and by proposing different optimizations to the search process. In particular, we expand the use of LSH in pattern discovery from indexing to fast counting and approximate clustering. While LSH provides runtime efficiency to the search process, it imposes significant space requirements, and we describe an iterative method that uses a single LSH table in memory to address this issue. We also explore the idea of using clustering as part of pattern discovery to reduce approximate subsequences with significantly overlapping Hamming radii to a small number. This aspect of our work resembles efforts for web clustering (Haveliwala et al., 2000). We explore similar ideas within the context of approximate pattern discovery. This decreases the number of motifs to be evaluated while still providing a fairly exhaustive coverage of the search space. We describe a clustering method based on a 2-approximate solution of the k-center problem to achieve this goal.

In addition to LSH and clustering, we also draw upon sequential statistical methods to make the search for interesting patterns more efficient. The process of identifying patterns with discriminative ability makes use of concordance and rank sum testing. In many cases, the goodness of approximate patterns can be assessed without using data from all training sequences. We propose a further optimization to address these cases. The runtime and space requirements of the pattern discovery process can be reduced by using sequential statistical methods that allow the search process for patterns to terminate after using data from only as many training examples as are needed to assess significance.

We address a similar goal to earlier work on using hypergeometric significance testing to discover patterns that are enriched in a positive set relative to a negative set (Barash et al., 2001). The focus of this work is to generate seeds of short lengths that can be expanded using an expectation-maximization (EM)-like process to produce a position specific scoring matrix of the desired length. However, in contrast to our work, this method is based on the assumption that a pattern occurs at most once in each sequence. This leads it to disregard multiple copies of a match within the same sequence. Moreover, the use of a testing function based on hypergeometric analysis may affect the accuracy of this method (Leung and Chin, 2006).

Our algorithm to find approximate discriminative patterns is also related to previous work on the use of profile hidden Markov models (Krogh, 1994; Jaakkola et al., 1999) to optimize recognition of positively and negatively labeled sequences. This work focuses on learning the parameters of a hidden Markov model that can represent approximations of subsequences. Generally, this approach requires large amounts of data or sophisticated priors to train the hidden Markov model. Computing forward and backward probabilities from the Baum-Welch algorithm is also very computationally intensive. Subsequent work in this area focuses on mismatch tree-based kernels (Leslie et al., 2003) for use in a support vector machine (SVM) classifier. This work focuses on efficiently calculating a kernel based on the mismatch tree data structure (Eskin and Pevzner, 2002), which quantifies how different two sequences are based on the approximate occurrence of the fixed L-length subsequences within them. The mismatch kernel is used to train an SVM and assign labels to unknown query sequences.

Our algorithm supplements this work by measuring how frequently each subsequence occurs in an approximate form in the data. In contrast to the mismatch kernel, which focuses on quantifying the difference between two sequences and does not report the frequency of individual approximate

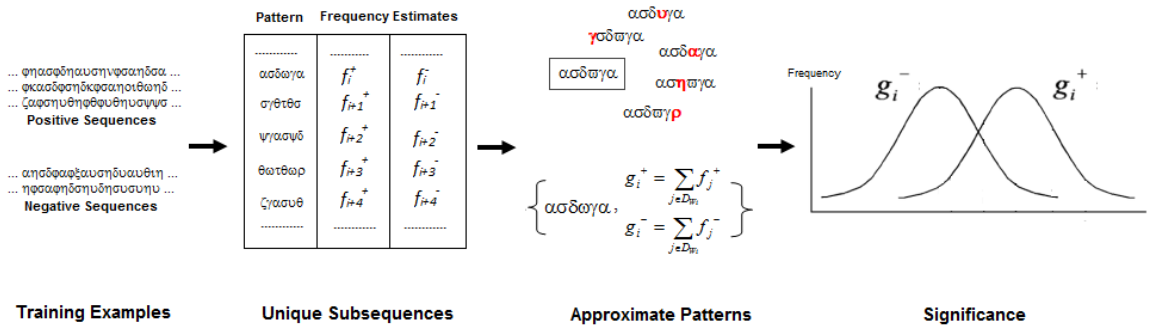

Figure 1: Overview of the pattern discovery process.

subsequences in the data, our algorithm focuses on identifying the specific approximate patterns with discriminative value. This approach can be integrated more easily with the use of sequential statistics, that is, since the frequencies of each approximate pattern are retained during analysis, this information can be used to determine if patterns are good or bad discriminators without analyzing all the available data.

We evaluated our algorithm on data sets from different applications to discover sequential patterns for classification. On nucleotide sequences from the Drosophila genome, our method was able to discover binding sites for genes that are preserved across the genome and do not occur in random background sequences. On symbolized electrocardiographic time-series from patients with acute coronary syndromes, our pattern discovery approach identified approximately conserved sequences of morphology variations that were predictive of future death in a test population. These results suggest that our methods may allow for an unsupervised approach to learn interesting dissimilarities between positive and negative examples that may have a functional role.

The rest of this paper is organized as follows: Section 2 gives an overview of our algorithm. Section 3 describes a locality sensitive hashing scheme to find approximate matches to all subsequences in the data set. Section 4 proposes the use of clustering to reduce the number of approximate patterns analyzed during pattern discovery. Section 5 discusses the statistical approaches used in assessing the goodness of patterns. Section 6 details the evaluation methodology of our pattern discovery algorithm on data from different real-world applications. Section 7 reports the results of this study. Section 8 concludes with a discussion.

2. Overview

The process of discovering discriminative patterns of a specified length L from positive and negative sequences is carried out in two stages: frequency estimation and pattern ranking. Figure 1 presents an overview of this approach.

2.1 Frequency Estimation

Given a set of positive examples $S^+ = \{S_x^+ | x = 1, \ldots, N^+\}$ and a set of negative examples $S^- = \{S_y^- | y = 1, \ldots, N^-\}$ the frequency estimation step measures the frequency of every unique subse-

quence W_i for $i = 1, \ldots, M$ in sequences belonging to S^+ and S^-. The resulting frequency for W_i in positive and negative examples is denoted as:

$$f_i^+ = \{f_{i,z}^+ | z \in S^+\},$$
$$f_i^- = \{f_{i,z}^- | z \in S^-\}$$

where $f_{i,z}^+$ and $f_{i,z}^-$ are the frequencies with which W_i appears in sequences z drawn from S^+ and S^-, and f_i^+ and f_i^- are vectors measuring the frequency of W_i in all positive and negative sequences.

To allow for approximate patterns, unique subsequences are then matched to all other subsequences at a Hamming distance of at most d from W_i. Denoting this group of subsequences as D_{W_i}, the resulting frequency for the subsequence W_i and its approximate matches is defined as:

$$g_i^+ = \sum_{j \in D_{W_i}} f_j^+,$$
$$g_i^- = \sum_{j \in D_{W_i}} f_j^-$$

where g_i^+ and g_i^- are vectors obtained by summing up the vectors f_i^+ and f_i^- for all subsequences within a given Hamming radius d of W_i.

In Section 3, we describe an LSH-based solution that allows for efficient discovery of the subsequences D_{W_i} matching W_i. We also present a clustering approach in Section 4 to reduce overlapping approximate patterns for which frequencies are estimated to a smaller number with less redundancy for subsequent analysis.

2.2 Pattern Ranking

The goal of the search process is to identify approximately matching subsequences that can discriminate between positive and negative training examples. The pattern ranking stage therefore scores each candidate approximate pattern according to its discriminative ability. We use two measures to assess the goodness of patterns.

The first approach to score patterns is to use rank sum testing. This technique is a non-parametric approach for assessing whether two samples of observations come from the same distribution. Patterns are ordered based on the significance of separation (as measured by the p-value) obtained by rank sum testing. A second scoring criterion used by our work is the C-statistic, which corresponds to the area under the receiver operating characteristic (ROC) curve. Details of these techniques are provided in Section 5. We further describe how sequential methods can be used to reduce the search process to only process as many training examples as are needed to determine if a candidate pattern has high or low discriminative ability.

3. Locality Sensitive Hashing

In this section, we describe the use of locality sensitive hashing in our algorithm.

3.1 Finding Approximate Matches for a Subsequence

Locality sensitive hashing (Indyk and Motwani, 1998) has been proposed as a randomized approximation algorithm to solve the nearest neighbor problem. Given a set of subsequences, the goal of

LSH is to pre-process the data so that future queries searching for closest points under some l_p norm can be answered efficiently. A brief review of LSH is presented here.

Given two subsequences S_x and S_y of length L, we describe them as being similar if they have a Hamming distance of at most d. To detect similarity, we choose K indices $i_1, \ldots, i_K$ at random with replacement from the set $\{1, \ldots, L\}$. The locality sensitive hash function $LSH(S)$ is then defined as:

$$LSH(S) = < S[i_1], \ldots, S[i_k] >$$

where $< \ldots >$ corresponds to the concatenation operator. Under this scheme, S_x and S_y are declared to be similar if:

$$LSH(S_x) = LSH(S_y). \tag{1}$$

The equality in Equation 1 corresponds to an exact match. However, since the indices used by the locality sensitive hash function $LSH(S)$ may not span the entire subsequences S_x and S_y, an exact match in Equation 1 may be obtained if S_x and S_y match approximately.

Practically, LSH is implemented by creating a hash table using the $LSH(S)$ values for all subsequences as the keys. Searching for the approximate neighbors of a query subsequence corresponds to a two-step process. The locality sensitive hash function is first applied to the query. Following this, the bucket to which the query is mapped is searched for all original subsequences with a Hamming distance of at most d.

Two subsequences with a Hamming distance of d or less may not match for a random choice of K indices if one of the K indices chosen corresponds to a position in which S_x and S_y differ. The probability of such a miss is bounded by (Indyk and Motwani, 1998):

$$Pr[LSH(S_x) \neq LSH(S_y)] \leq [1 - (1 - \frac{d}{L})^K].$$

By repeating the process of choosing K indices T times this probability can be reduced further to:

$$Pr[LSH(S_x) \neq LSH(S_y)] \leq [1 - (1 - \frac{d}{L})^K]^T. \tag{2}$$

Effectively, Equation 2 corresponds to constructing a data structure comprising T hash tables using different locality sensitive hash functions $LSH_1(S), \ldots, LSH_T(S)$. Approximate neighbors for a query are detected by searching for matches in each of these hash tables as described earlier.

The intuition underlying LSH is that the problem of searching through all possible subsequences in the data set for a match can be reduced to the more feasible problem of first rapidly identifying a small set of potential matches with a bounded error, and then searching through this smaller set to remove false positives. The lower the desired error bound for false negatives affecting correctness (i.e., by choosing K and T), the higher the corresponding false positive rate affecting the runtime of the algorithm. The choice between these two parameters depends on the application and the underlying data set.

3.2 Finding Approximate Matches Between All Subsequences

LSH provides an efficient mechanism to find the nearest neighbors of a given subsequence. To find the nearest neighbors for all M subsequences in the data set, each member of the set can be passed

through the entire LSH data structure comprising T hash tables for matches. Unfortunately, this process is both computationally and memory intensive. In what follows, we describe a strategy to reduce the space requirements of LSH-based search for all approximate matches between subsequences. Section 4 further addresses runtime issues by proposing a clustering amendment to the search process.

Different approaches have been proposed recently to reduce the space requirements of LSH. In particular, the use of multi-probe LSH (Lv et al., 2007) has been shown to substantially reduce the memory requirements for traditional LSH by searching each LSH hash table (i.e., corresponding to a random selection of K indices) more thoroughly for misses. This additional work translates into fewer LSH hash tables being needed to bound the given error rate. As a result, the space of the LSH data structure decreases.

In our work, the memory requirements of LSH are reduced by organizing the approximate matching process as T iterations. Each iteration makes use of a single locality sensitive hash function and maintains only a single hash table in memory at any time. To preserve state across iterations, the search process maintains a list of matching pairs found during each loop after removing false positives. The subsequences D_{W_i} matching W_i are found as:

$$D_{W_i} = \bigcup_{t=1}^{T} \{W_j | LSH_t(W_j) = LSH_t(W_i)\}.$$

4. Clustering Subsequences

The runtime of the pattern discovery process as described so far is dominated by the approximate matching of all subsequences. Every subsequence is first used to create the LSH data structure, and then passed through the LSH data structure to find matches with a Hamming distance of at most d. This process is associated with considerable redundancy, as matches are sought individually for subsequences that are similar to each other. The overlap between approximate patterns increases the computational needs of the pattern discovery process and also makes it more challenging to interpret the results as good patterns may appear many times in the output.

To address this issue, we reduce patterns to a much smaller group that still collectively spans the search space. This is done by making use of a clustering method based on a 2-approximate solution to the k-center problem. The focus of this clustering is to group together the original subsequences falling into the same hash bucket during the first LSH iteration. Each of the clusters obtained at the end of this process corresponds to an approximate pattern that is retained. During subsequent iterations, while all subsequences are still used to construct the LSH tables, only the cluster centroids are passed through the LSH data structure. This reduces the runtime of the search by reducing the number of times subsequences have to be passed through the LSH tables to find true and false positives. It also reduces the memory requirements of the search by reducing the number of subsequences for which we need to maintain state about approximate matches.

The traditional k-center problem can be formally posed as follows. Given a complete graph $G = (V,E)$ with edge weights $\omega_e \geq 0$, $e \in E$ and $\omega(v,v) = 0$, $v \in V$, the k-center problem is to find a subset $Z \in V$ of size at most k such that the following quantity is minimized:

$$W(Z) = \max_{i \in V} \min_{j \in Z} \omega_{(i,j)}.. \tag{3}$$

The k-center problem is NP-hard, but a 2-approximate solution has been proposed (Hochbaum and Shmoys, 1985) for the case where the triangular inequality holds:

$$\omega_{(i,j)} + \omega_{(j,k)} \geq \omega_{(i,k)}.$$

The Hamming distance metric obeys the triangular inequality. Under this condition, the process of clustering can be decomposed into two stages. During the first LSH iteration, we identify subsequences that serve as cluster seeds using the 2-approximate solution to the k-center problem. Subsequent LSH iterations are used to grow the clusters till the probability that any subsequence within a Hamming distance at most d of the cluster centroid is missed becomes small. This approach can be considered as being identical to choosing a set of subsequences during the first LSH iteration, and finding their approximate matches by multiple LSH iterations.

More formally, during the first LSH iteration, for each bucket b_i in the hash table for $i = 1, \ldots, B$, we solve the k-center problem using the 2-approximate method (Hochbaum and Shmoys, 1985) with a Hamming distance metric. The number of subsequences forming centers k_i for the i-th hash table bucket is determined alongside the specific centroid subsequences from:

$$k_i = \min\{k | W(z_i(k)) \leq d\} \tag{4}$$

where $W(Z)$ is defined as in Equation 3 and $z_{i(k)}$ denotes the subsequence centers chosen for a particular choice of k in Equation 4, that is:

$$k_i = \min\{k | \max_{j \in b_i} \min_{z_i(k)} \omega_{(j,z_i(k))} \leq d\}.$$

The final set of subsequences chosen as centroids at the end of the first LSH iteration then corresponds to:

$$\Phi = \bigcup_{i=1}^{B} z_i(k_i).$$

The LSH iterations that follow find approximate matches to the subsequences in Φ. It is important to note that while clustering reduces a large number of overlapping approximate patterns to a much smaller group, the clusters formed during this process may still overlap. This overlap corresponds to missed approximate matches that do not hash to a single bucket during the first LSH iteration. Techniques to merge clusters can be used at the end of the first LSH iteration to reduce overlap. In our work, we tolerate small amounts of overlap between clusters analogous to the use of sliding windows to more thoroughly span the search space. Figure 2 illustrates the clustering process.

5. Pattern Ranking

Given the frequencies g_i^+ and g_i^- of an approximate pattern corresponding to all subsequences within a Hamming distance d of the subsequence W_i, a score can be assigned to the pattern by using concordance statistics and rank sum testing.

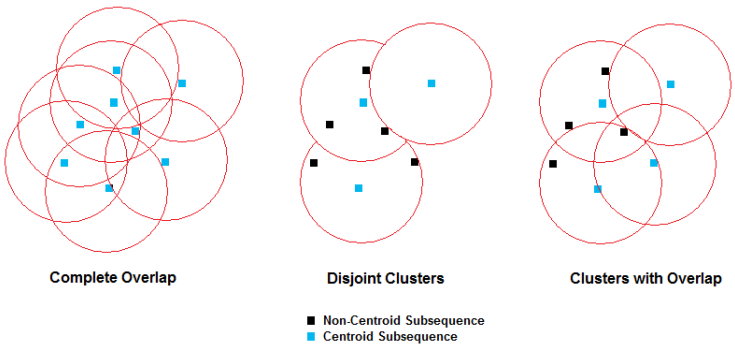

Figure 2: In the absence of clustering there is significant redundancy between the Hamming radii of approximate patterns. Partitioning the data into disjoint clusters can help address this issue. In our work, we reduce the original approximate patterns into a small group with some overlap to span the search space.

5.1 Concordance Statistic

The concordance statistic (C-statistic) (Hanley and McNeil, 1982) measures the discriminative ability of a feature to classify binary endpoints. The C-statistic corresponds to the area under the receiver operating characteristic (ROC) curve, which describes the inherent trade-off between sensitivity and specificity. As opposed to measuring the performance of a particular classifier, the C-statistic directly measures the goodness of a feature (in this case the frequency with which an approximate pattern occurs) by evaluating its average sensitivity over all possible specificities.

The C-statistic ranges from 0-1. A pattern that is randomly associated with the labels would have a C-statistic of 0.5. Conversely, good discriminators would correspond to either low or high C-statistic values.

5.2 Rank Sum Testing

An alternate approach to assess the goodness of patterns is to make use of rank sum testing (Wilcoxon, 1945; Lehmann, 1975). This corresponds to a non-parametric method to test whether a pattern occurs with statistically different frequencies in both positive and negative examples.

Given the frequencies g_i^+ and g_i^- of an approximate pattern in both positive and negative examples, the null and alternate hypotheses correspond to:

$$H_0 : \mu_{g_i^+} = \mu_{g_i^-},$$
$$H_1 : \mu_{g_i^+} \neq \mu_{g_i^-}.$$

Rank sum testing calculates the statistic U whose distribution under H_0 is known. This is done by arranging the g_i^+ and g_i^- into a single ranked series. The ranks for the observations from the g_i^+ series are added up. Denoting this value as R^+ and the number of positive examples by N^+, the statistic U is given by:

$$U = R^+ - \frac{N^+(N^+ + 1)}{2}.$$

The obtained value of U is compared to the known distribution under H_0 and a probability for this observation corresponding to the null hypothesis is obtained (i.e., the p-value). For large samples, U is approximately normally distributed and its standardized value can be checked in tables of the normal distribution (Gibbons, 1985; Hollander and Wolfe, 1999). The lower the p-value obtained through rank sum testing, the more probable it is that g_i^+ and g_i^- have distributions with different means, that is, that the approximate pattern is distributed differently in positive and negative examples.

5.3 Sequential Statistical Tests

The runtime and space requirements of the pattern discovery process can be reduced by analyzing only a subset of the training data. For example, it may be possible to recognize patterns with high discriminative ability without the need to analyze all positive and negative examples.

Our pattern discovery algorithm starts out by using a small subset of the initial training data for batch analysis. This helps identify candidate approximate patterns that occur in the data set and collectively span the search space. The remaining training examples are used for scoring purposes only. These examples are added in an online manner and during each iteration, the occurrence of outstanding candidate patterns in positive and negative examples is updated. Patterns may then be marked as being good or bad (and consequently removed from further analysis) or studied further to resolve uncertainty. The number of candidate patterns is therefore monotonically non-increasing with iteration number. As a result, the analysis of training examples becomes faster as more data is added, since fewer patterns need to be scored.

A sequential formulation for rank sum testing has been proposed (Phatarfod and Sudbury, 1988) that adds positive and negative examples in pairs. The frequencies of an approximate pattern in positive and negative examples at the end of iteration n can be denoted as $g_i^+(j)$ and $g_i^-(j)$ where $j = 1, \ldots, n$. The corresponding statistic for rank sum testing is:

$$U_n = \sum_{x=1}^{n} \sum_{y=1}^{n} I(g_i^+(x) > g_i^-(y)). \tag{5}$$

The operator $I(.)$ is equal to one when the inequality holds and zero otherwise. Using this statistic, the decision at the end of the n-th iteration corresponds to accepting H_0 if:

$$\frac{U_n}{n} < \frac{n}{2} - \lambda \log(\frac{1-\beta}{\alpha}) \tag{6}$$

while H_1 is accepted if:

$$\frac{U_n}{n} > \frac{n}{2} - \lambda \log(\frac{\beta}{1-\alpha})$$

where λ is defined as Phatarfod and Sudbury (1988):

$$\lambda = \frac{1 - \frac{\delta^2}{2} - \frac{\delta^3}{3\sqrt{3}} - \frac{\delta^4}{48}}{2\sqrt{3}\delta - \frac{\delta^2}{2}}. \tag{7}$$

In Equations 6 to 7, α and β correspond to desired false positive and false negative rates for the sequential rank sum testing process, while δ is a user-specified parameter that reflects the preferences of the user regarding how fine or coarse a difference the distributions are allowed to have under the alternate hypothesis. If both inequalities are not met, the process of adding data continues until there are no more training examples to add. In this case, all outstanding candidate patterns are rejected.

This formulation of sequential rank sum testing adds data in pairs of positive and negative examples. In cases where there is a skew in the training examples (without loss of generalization we assume a much larger number of negative examples than positive ones), we use a different formulation of sequential testing (Reynolds, 1975). Denoting the mean frequency in positive training samples as:

$$\mu_i^+ = \sum_{x=1}^{N^+} g_i^+(x).. \tag{8}$$

The alternate hypothesis can be redefined as the case where $h_i = g_i^- - \mu_i^+$ is asymmetrically distributed about the origin. This can be identified using the statistic:

$$U_n = \sum_{x=1}^{n} \frac{1}{x+1} \text{sgn}(h_i(x)) R_{xx} \tag{9}$$

where R_{xy} is defined as the rank of $|h_i(x)|$ in the set $\{|h_i(1)|, \ldots, |h_i(y)|\}$ with $x \leq y$ and $\text{sgn}(|h_i(x)|)$ is 1 if $h_i(x) \geq 0$ and -1 otherwise. The test procedure using the statistic continues taking observations as long as $U_n \in (-\delta, \delta)$ where δ is a user-specified parameter.

Traditional formulations of sequential significance testing remove good patterns from analysis when the test statistic is first found to lie above or below a given threshold. Patterns with potentially low discriminative ability are retained for further analysis and are discarded if they do not meet any of the admission criteria during any iteration of the search process. Since there may be a large number of such patterns with low discriminative value, we make use of a modified approach to reject poor hypotheses while retaining patterns that may have value in classification. This strategy improves efficiency, while also ensuring that good patterns are ranked using the available training data. Given the typical goal of pattern discovery to return the best patterns found during the search process, this technique naturally addresses the problem statement.

Given the test statistics in Equations 5 and 9, we remove all patterns that have a test statistic:

$$U_n < \lambda U_{\max}$$

where $U_{\max}$ is the maximum test statistic for any pattern and λ is a user-specific fraction (e.g., 0.2).

5.4 Multiple Hypothesis Correction

While assessing a large number of approximate patterns, M, the statistical significance required for goodness must be adjusted for Type I (i.e., false positive) errors. If we declare a pattern to be significant for some probability of the null hypothesis less than θ, then the overall false positive rate for the experiment assuming independence of patterns is given by:

$$FP = 1 - (1-\theta)^M.$$

If we do not assume that the patterns are independent, the false positive rate can be bounded by:

$$FP \leq \theta M.$$

To account for this condition, a more restrictive level of significance must be set consistent with the number of unique patterns being evaluated (in our case, the clusters obtained earlier). If c clusters are assessed for goodness, the Bonferroni correction (Bland and Altman, 1995) suggests that the level of significance be set at:

$$\theta' = \frac{\theta}{c}.$$

This addresses the issue of increasing false positives caused by the evaluation of a large number of clusters by correspondingly lowering the p-value required to accept a pattern.

6. Evaluation

All experiments were carried out on a 3.2 GHz P4 with 2 GB of RAM running Linux Fedora Core4. The algorithms to be evaluated were implemented in Java.

6.1 Regulatory Motifs in Drosophila Genome

We evaluated our pattern discovery algorithm on data from the Assessment of Computational Motif Discovery Tools project (Li and Tompa, 2006; Tompa et al., 2005). The focus of this project was to compare 13 motif discovery tools on nucleotide sequences from the human, mouse, fly and yeast genomes to see if they could successfully identify known regulatory elements such as binding sites for genes. These tools differed from each other mainly in their definition of a motif, and in the method used to search for statistically overrepresented motifs. Authors with specific expertise were chosen to test each tool and avoid the disadvantage of being run with an uninformed set of parameters. The expert predictions were then compared with known binding sites in the TRANSFAC database (Wingender et al., 1996) using various statistics to assess the correctness of the predictions.

In our work, we focused on nucleotide sequences from the *Drosophila melanogaster* genome comprising 43 kb base pairs (Li and Tompa, 2006; Tompa et al., 2005). These sequences were divided into 8 data sets, each corresponding to a different binding site. The Drosophila genome was the smallest (in terms of the available data) of the four genomes used in the project, allowing us to compare our method with more computationally intensive algorithms that do not use LSH or clustering. To use our method, we generated random negative sequences with the same background frequencies and lengths as the positive examples, and supplemented both positive and negative sequences with their reverse complements. Our method predicted binding sites in the original data corresponding to all subsequences in the group D_{W_i} with maximum discriminative value. While our algorithm has been designed to use additional information in negative examples when available, this approach presents an example of how our method can be used even in cases where only positive training data is present and negative examples are generated using a simple approach.

The pattern discovery process attempted to find approximate subsequences of lengths 8, 12 and 16. We investigated Hamming radii of 1-3 for patterns of length 8, 2-4 for those of length 12 and 3-5 for length 16. Parameters were chosen using the inequality in Equation 2 so that the LSH probability of false negatives in each case was below 0.005. For each of these cases, we ran our algorithm three

times and consistent with the other motif discovery algorithms evaluated, we chose only the best pattern discovered (where best corresponded to lowest rank sum p-value or no result if a pattern with a p-value less than 0.05 was not found).

We compared our method to the 13 motif discovery tools evaluated on the same data set using the *nPC* and *nCC* summary statistics (Li and Tompa, 2006; Tompa et al., 2005). Given the number of nucleotide positions in both known sites and predicted sites (*nTP*), the number of nucleotide positions in neither known sites nor predicted sites (*nTN*), the number of nucleotide positions not in known sites but in predicted sites (*nFP*) and the number of nucleotide positions in known sites but not in predicted sites (*nFN*), the nucleotide level performance coefficient (*nPC*) (Pevzner and Sze, 2000) was defined as:

$$nPC = \frac{nTP}{nTP + nFN + nFP}.$$

The nucleotide level correlation coefficient (*nCC*) (Burset and Guigo, 1996) was defined as:

$$nCC = \frac{nTP.nTN - nFN.nFP}{\sqrt{(nTP+nFN)(nTN+nFP)(nTP+nFP)(nTN+nFN)}}.$$

In addition to comparing our method with results from the 13 motif discovery algorithms evaluated in the Assessment of Computational Motif Discovery Tools project, we also explored the runtime and accuracy of two variations of our algorithm. These variations were meant to assess the contribution of clustering and LSH-based approximate matching to the performance of our method. The first variation we examined did not make use of the clustering process described in Section 4 to reduce overlapping approximate patterns to a smaller group. The second variation further avoided the use of LSH to match subsequences and was based instead on an exhaustive search.

While comparing the three approaches, we use the following notation: *LSHCS* for our original algorithm using clustering and sequential statistics, *NoClust* for the variation that did not use clustering, and *ExhSearch* for the exhaustive search algorithm that further avoided the use of LSH to match subsequences.

For some binding site data sets *NoClust* and *ExhSearch* did not terminate even after very long processing times. We terminated algorithms if they did not produce results within 24 hours of CPU time. These cases are annotated where included.

6.2 Regulatory Motifs in ChIP-on-chip Yeast Data

We evaluated the ability of our method to discover yeast transcription factor binding motifs in ChIP-on-chip data (Harbison et al., 2004). The "gold standard" motifs for this data set were generated by applying a suite of six motif-finding algorithms to intergenic regions from *Saccharomyces cerevisiae* and clustering the results to arrive at a consensus motif for each transcription factor. When no motif was found computationally for the intergenic regions, a literature-based consensus motif was used.

In our experiments, we focused on the 21 transcription factors in the data set for which the six motif-finding algorithms in Harbison et al. (2004) failed to find a significant motif and the reported motif had to be based on a consensus obtained from the literature. For all tests, we used the output from the *LSHCS* algorithm with the lowest rank sum p-value (or no result if a motif with p-value less than 0.05 was not found), with the motif width chosen to match the width of the literature consensus motif. This approach was analogous to earlier work on ChIP-on-chip data to evaluate motif discovery methods (Siddharthan et al., 2005).

For each experiment, we defined positive examples as the set of probe sequences found to bind the transcription factor and set negative examples to be randomly selected non-binding probe sequences. The positive and negative sets contained the same number of sequences. This approach was also chosen to be consistent with earlier studies to evaluate motif discovery tools (Redhead and Bailey, 2007).

6.3 Predictive Morphology Variations in Electrocardiogram Signals

We evaluated our method on 24-hour electrocardiographic (ECG) signals from patients admitted with non-ST-elevation acute coronary syndromes (NSTEACS) to discover patterns of morphology changes associated with future cardiovascular death. Earlier studies suggest that increased beat-to-beat variations in ECG morphology may be associated with instability in the conduction system of the heart and could help identify high risk patients (Syed et al., 2008). We applied our pattern discovery algorithm to discover specific sequences of beat-to-beat changes that had predictive value.

Given a 24-hour ECG signal, we first converted the data recorded during the course of hospitalization into a time-series of morphology changes between pairs of consecutive heart beats (Syed et al., 2008). Morphology changes between beats were measured using a dynamic time-warping algorithm (Rabiner et al., 1978) that calculates the time-aligned energy difference between beats. The morphology change time-series was then converted into a sequence using symbolic aggregate approximation (SAX) (Lin et al., 2003) with an alphabet size of 10. In this manner, multiple ECG signals were transformed into sequences that could be analyzed by our method. On average, each sequence corresponding to 24 hours of ECG was almost 100,000 symbols long.

On a training set of 765 patients, where 15 patients died over a 90 day period following NSTEACS (i.e., 15 positive examples and 750 negative examples), we used our pattern discovery algorithm to learn sequences of morphology changes in the ECG signal that were predictive of death. We searched for patterns of length 8 with a Hamming distance of at most 2. Parameters were chosen using the inequality in Equation 2 so that the LSH probability of false negatives was less than 0.01. We selected patterns that showed a C-statistic greater than 0.7 and a rank sum test p-value of 0.05 corrected for multiple hypotheses using the Bonferroni correction. These were evaluated on a test set of 250 patients with 10 deaths.

We also studied the runtime performance of our algorithm on this data set with and without the use of sequential statistics to find significant patterns. Given the large number of negative examples in the training data, we employed the sequential formulation in Equations 8 and 9 with $\lambda = 0.2$. Consistent with the notation proposed in Section 6 we denote our original algorithm using sequential statistics as *LSHCS* while the variation that avoids sequential statistics is denoted by *NoSeqStats*.

7. Results

The results of our experiments are as follow.

7.1 Regulatory Motifs in Drosophila Genome

Table 1 presents the results of the 13 different motif discovery algorithms evaluated by the Assessment of Computational Motif Discovery Tools project. The results of using our method are given in Table 2.

Algorithm	*nPC*	*nCC*

Table 1: Performance of 13 different motif discovery methods on the Drosophila genome (*nPC*=performance coefficient, *nCC*=correlation coefficient) in the Assessment of Computational Motif Discovery Tools project (Tompa et al., 2005).

Parameter	*nPC*	*nCC*
$L = 8, d = 1$	0.021	0.031
$L = 8, d = 2$	0.007	-0.009
$L = 8, d = 3$	0.013	-0.002
$L = 12, d = 2$	0.013	0.018
$L = 12, d = 3$	0.039	0.062
$L = 12, d = 4$	0.013	0.018
$L = 16, d = 3$	0	-0.011
$L = 16, d = 4$	0.032	0.055
$L = 16, d = 5$	0.056	0.093

Table 2: Performance of the *LSHCS* pattern discovery method on the Drosophila genome using different input parameters (*nPC*=performance coefficient, *nCC*=correlation coefficient, L=pattern length, d=maximum Hamming distance allowed in pattern).

Our *LSHCS* algorithm compared favorably with the other motif discovery algorithms evaluated on the same data by experts. In particular, for two of the parameter settings evaluated (i.e., $L = 12, d = 3$ and $L = 16, d = 5$), our algorithm had both a higher performance coefficient and a higher correlation coefficient than any of the other methods. The $L = 16, d = 4$ case also had a higher correlation coefficient than the motif discovery algorithms previously reported, although the performance coefficient for this choice of parameters was exceeded by *SeSiMCMC*.

We note that these findings help only to validate the ability of our pattern discovery approach to identify potentially interesting activity. Since these results hold on a specific genome, we caution against interpreting the results as a more general comparison of *LSHCS* with nucleotide motif discovery methods. In particular, we observe that the nucleotide motif discovery methods in Table 1 were tested blindly on a single pre-determined choice of parameters. It is possible that with different choices of input parameters (i.e., similar to the evaluation of *LSHCS* using different values of L and d), these methods would have yielded significantly better results.

Tables 3 and 4 present the performance and correlation coefficients for the *NoClust* and *ExhSearch* algorithms. For both these variations, the algorithms did not terminate for the largest choice of Hamming radius d. Investigation revealed that the slow processing times in these cases were associated with insufficient memory to store the neighborhoods for all approximate patterns (i.e., in the absence of clustering for both algorithms). For large choices of the maximum allowed Hamming radius, the neighborhood for each pattern is more extensive and storing this information for all overlapping patterns imposes significant space requirements. Conversely, by using clustering, *LSHCS* is able to reduce the number of overlapping patterns and avoid references to disk.

We found some of the results in Tables 3 and 4 comparing *LSHCS* to *NoClust* and *ExhSearch* to be surprising. In contrast to *LSHCS*, the *NoClust* variation explores all overlapping patterns while *ExhSearch* uses an exhaustive search to find nearest neighbors (i.e., avoiding the small false negative probability associated with LSH). Since both variations use strictly more data and explore the outputs of *LSHCS* as well as other alternatives, we expected the results to improve uniformly between *LSHCS* and *ExhSearch* for all parameter selections. While this was generally the case, for some parameter choices (e.g., $L = 16, d = 4$) the best results were obtained by *LSHCS*. Examining the outputs by all three algorithms revealed these inconsistencies to be the result of resolving ties between patterns with identical rank sum p-values arbitrarily. While presenting the results in this section, we explicitly note this limitation of the objective function (i.e., the rank sum p-value) used for evaluation.

Ignoring parameter choices for which *NoClust* and *ExhSearch* did not terminate, the performance of all three methods was similar as shown in Table 5. A comparison of the running time for all three algorithms is also presented in Table 6. The running time increased significantly both as all overlapping approximate patterns were studied, and when an exhaustive search was used to replace LSH. The increase in runtime due to exhaustive search was considerably more than the effect of examining all overlapping approximate patterns.

7.2 Regulatory Motifs in ChIP-on-chip Yeast Data

The results of applying the *LSHCS* algorithm on the ChIP-on-chip data set for the 21 transcription factors for which the six motif-finding algorithms failed to find a significant motif are shown in Table 7.

Table 7: Results of *LSHCS* on the ChIP-on-chip data set for transcription factors (TF) where common motif-finding algorithms failed to find a significant motif.

Pattern (Centroid)	Rank Sum P-Value	C-statistic
ABCCDFGJ	0.025	0.71
FFJJJJCC	0.004	0.70

Table 8: Statistical significance of approximate patterns found on a training set of 765 post-NSTEACS patients (15 deaths over a 90 day follow-up period) when evaluated on a test population of 250 patients (10 deaths).

In 6 of the 21 experiments conducted, the discriminative motif with the lowest p-value found by the *LSHCS* algorithm corresponded to the consensus motif in the literature, but was not found by any of the six motif-finding algorithms evaluated earlier. *LSHCS*, as well as the other six motif-finding algorithms, failed to find the discriminative motif in the remaining 15 cases although motifs are described in the literature.

7.3 Predictive Morphology Variations in Electrocardiogram Signals

Our pattern discovery method returned 2 approximate patterns that were assessed to have discriminative value in the training set (i.e., a C-statistic of more than 0.7 and a p-value of less than 0.05 after accounting for the Bonferroni correction). Representing the symbols obtained using SAX by the letters *A*-*J*, where *A* corresponds to the symbol class for the least beat-to-beat change in morphology and *J* denotes the symbol for the greatest change, the centroids for the approximate pattern can be written as:

$$ABCCDFGJ$$

$$FFJJJJCC$$

The first of these patterns is equivalent to increasing time-aligned energy changes between successive beats. This may suggest increased instability in the conduction system of the heart. The second pattern corresponds to a run of instability followed by a return to baseline. This pattern can be interpreted as a potential arrhythmia.

The results of testing both patterns on previously unseen data from 250 patients (with 10 deaths over a 90 day follow-up period) are shown in Table 8. Both patterns found by our approximate pattern discovery algorithm showed statistical significance in predicting death according to the C-statistic and rank sum criteria.

A comparison of the running times for the *LSHCS* and *NoSeqStats* algorithms is presented in Table 9. While the outputs produced by both algorithms were identical, the use of sequential statistics helped our *LSHCS* method decrease the runtime of the search process to almost half of what we encountered for the variation not using the methods proposed in Section 5.3. We also note that the *NoSeqStats* variation used considerably more memory than the *LSHCS* approach. This effect was due to *LSHCS* purging state for patterns that did not obey the inequality in Equation 9. In the absence of sequential statistics, *NoSeqStats* had to retain ranking information for all patterns till the training data set was completely analyzed.

Algorithm	Time
LSHCS	5:08:24
NoSeqStats	9:43:09

Table 9: Time taken by the *LSHCS* and *NoSeqStats* pattern discovery algorithms on the cardiovascular training data set.

8. Summary and Discussion

This paper presents an approach to efficiently learn patterns in labeled sequences that can be used for classification. We define patterns as groups of approximately matching subsequences, that is, all variations of a subsequence within a given Hamming radius. Our method represents a fully automated approach for unsupervised pattern discovery, where the goodness of patterns is assessed by measuring differences in their frequency of occurrence in positive and negative training examples.

We designed our pattern discovery algorithm to make it both accurate and efficient in terms of space and computation. We briefly review the central ideas of our work.

First, we include patterns from both positive and negative training sets in our search for discriminative activity. In many applications, we can consider positive examples as being associated with some physical phenomenon. Patterns that occur mainly in positive examples can be considered as potentially regulatory activity that may cause the phenomenon being studied. Conversely, patterns that occur mainly in negative examples (i.e., are absent in positive examples) can be considered as potentially supressive activity. The absence of these suppressive patterns in positive examples may promote the observed phenomenon. We allow for the discovery of both types of activity. This approach has a further advantage in that it reduces the need for prior knowledge. In the absence of negative examples, activity in positive training samples must be assessed through some assumption of statistical over-representation. By being able to directly compare positive examples against negative ones, we attempt to remove the need for such assumptions.

Second, to efficiently search for approximate patterns, we make use of locality sensitive hashing. LSH has been proposed as a randomized approximation algorithm to solve the nearest neighbor problem. We employ an iterative LSH method that is able to efficiently find groups of matching subsequences for subsequent analysis as candidate patterns.

Third, we explore the idea of clustering together subsequences, so that the number of candidate patterns can be reduced. This abstraction is intended to decrease the redundancy associated with evaluating a large number of approximate patterns with significant overlap. Reducing this redundancy, while still spanning the search space, provides an improvement in efficiency and also allows for more clarity in interpreting the results of the search process.

Finally, we make use of non-parametric statistical methods that have been designed to identify patterns with different distributions in both positive and negative examples. An extension of this work is the use of sequential methods, which only use as much of the training data as is needed to make a decision about a candidate pattern.

We evaluated the use of our pattern discovery algorithm on data from different real-world applications. On nucleotide sequences from the Drosophila genome, our method was able to discover approximate binding sites that were preserved upstream of genes. A similar result was seen for ChIP-on-chip data from the yeast genome. For cardiovascular data from patients admitted with

acute coronary syndromes, our pattern discovery approach identified approximately conserved sequences of morphology changes that were predictive of future death in a test population. Our data showed that the use of LSH, clustering, and sequential statistics improved the running time of the search algorithm by an order of magnitude without any noticeable effect on accuracy. These results suggest that our methods may allow for an efficient unsupervised approach to learn interesting dissimilarities between positive and negative examples, which may have a functional role.

Acknowledgments

We would like to thank Dorothy Curtis for helping with the computational needs for this project, Murtaza Zafar and Ebad Ahmed for their technical input regarding sequential statistics, and Manolis Kellis for suggesting the genomic data set for validation. We also thank the editors and anonymous reviewers for their feedback.

Abstract

Support vector machines are a powerful machine learning technology, but the training process involves a dense quadratic optimization problem and is computationally challenging. A parallel implementation of linear Support Vector Machine training has been developed, using a combination of MPI and OpenMP. Using an interior point method for the optimization and a reformulation that avoids the dense Hessian matrix, the structure of the augmented system matrix is exploited to partition data and computations amongst parallel processors efficiently. The new implementation has been applied to solve problems from the PASCAL Challenge on Large-scale Learning. We show that our approach is competitive, and is able to solve problems in the Challenge many times faster than other parallel approaches. We also demonstrate that the hybrid version performs more efficiently than the version using pure MPI.

Keywords: linear SVM training, hybrid parallelism, largescale learning, interior point method

1. Introduction

Support vector machines (SVMs) are powerful machine learning techniques for classification and regression. They were developed by Vapnik (1998), and are based on statistical learning theory. They have been applied to a wide range of applications, with excellent results, and so they have received significant interest.

Like many machine learning techniques, SVMs involve a training stage, where the machine learns a pattern in the data from a *training data set*, and a separate test or validation stage where the ability of the machine to correctly predict labels is evaluated using a previously unseen *test data set*. This process allows parameters to be adjusted towards optimal values, while guarding against overfitting.

The training stage for Support Vector Machines involves at its core a dense convex quadratic optimization problem (QP). Solving this optimization problem is computationally expensive, primarily due to the dense Hessian matrix. Solving the QP with a general-purpose QP solver would result in the time taken to scale cubically with the number of data points ($O(n^3)$). Such a complexity result means that, in practise, the SVM training problem cannot be solved by general purpose optimization solvers.

Several schemes have been developed where a solution is built by solving a sequence of small-scale problems, where only a few data points (an *active set*) are considered at a time. Examples include decomposition (Osuna et al., 1997) and sequential minimal optimization (Platt, 1999), and state-of-the-art software use these techniques. Active-set techniques work well when the data is clearly separable by a hyperplane, so that the separation into active and non-active variables is clear. With noisy data, however, finding a good separating hyperplane between the two classes is not so clear, and the performance of these algorithms deteriorates (Woodsend and Gondzio, 2007).

In addition, the active set techniques used by standard software are essentially sequential—they choose a small subset of variables to form the active set at each iteration, and this selection is based upon the results of the previous iteration. It is not clear how to efficiently implement such an algorithm in parallel, due to the large number of iterations required and the dependencies between each iteration and the next.

Few approaches have been developed for training SVMs in parallel, yet multiple-core computers are becoming the norm, and data sets are becoming ever larger. It is notable that of the 44 submissions to compete in the PASCAL Challenge on Large-scale Learning (Sonnenburg et al., 2008), only 3 entries were parallel methods.

Parallelization schemes so far proposed have involved splitting the training data to give smaller, separable optimization sub-problems which can be distributed amongst the processors. Dong et al. (2003) used a block-diagonal approximation of the kernel matrix to derive independent optimization problems. The resulting SVMs were used to filter out samples that were likely not to be support vectors. A SVM was then trained on the remaining samples, using the standard serial algorithm. Collobert et al. (2002) proposed a mixture of multiple SVMs where single SVMs are trained on subsets of the training set and a neural network is used to assign samples to different subsets.

Another approach is to use a variation of the standard SVM algorithm that is better suited to a parallel architecture. Tveit and Engum (2003) developed an exact parallel implementation of the Proximal SVM (Fung and Mangasarian, 2001), which classifies points by assigning them to the closest of two parallel planes. Compared to the standard SVM formulation, the single constraint is removed and the result is an unconstrained QP; this is substantially different from the linear SVM task set in the PASCAL Challenge.

There have only been a few parallel methods in the literature which train a standard SVM on the whole of the data set. We briefly survey the methods of Zanghirati and Zanni (2003), Graf et al. (2005), Durdanovic et al. (2007) and Chang et al. (2008).

The algorithm of Zanghirati and Zanni (2003) decomposes the SVM training problem into a sequence of smaller, though still dense, QP sub-problems. Zanghirati and Zanni implement the inner solver using a technique called variable projection method, which is able to work efficiently on relatively large dense inner problems, and is suitable for implementing in parallel. The performance of the inner QP solver was improved in Zanni et al. (2006).

In the cascade algorithm introduced by Graf et al. (2005), the SVMs are layered. The support vectors given by the SVMs of one layer are combined to form the training sets of the next layer. The support vectors of the final layer are re-inserted into the training sets of the first layer at the next iteration, until the global KKT conditions are met. The authors show that this feedback loop corresponds to standard SVM training.

The algorithm of Durdanovic et al. (2007), implemented in the Milde software, is a parallel implementation of the sequential minimal optimization. The objective function of the dual form (see Equation 3 below) is expressed in terms of partial gradients. Variables are selected to enter

the working set, based on the steepest descent direction, and whether the variables are free to move within their box constraints. A second working set method considers pairwise contributions. Very large data sets can be split across processors. When a variable z_i enters the working set, the owner processor broadcasts the corresponding data vector x_i. All nodes calculate kernel functions and update their portion of the gradient vector. Although many of the operations within an iteration are parallelizable, a very large number of sequential outer iterations are still required. The authors use a hybrid approach to parallelization similar to ours described below, involving a multi-core BLAS library, but its use is limited to Layer 1 and 2 operations.

Another family of approaches to QP optimization are based on interior point method (IPM) technology, which works by delaying the split between active and inactive variables for as long as possible. IPMs generally work well on large-scale problems, largely because the number of iterations tends to grow very slowly with the problem dimension. Unfortunately each iteration requires the solving of a large system of linear equations. A straight-forward implementation of the standard SVM dual formulation has a per iteration complexity of $O(n^3)$, and would be unusable for anything but the smallest problems. Several sequential implementations of IPMs for support vector machines address this difficulty (Ferris and Munson, 2003; Fine and Scheinberg, 2002; Woodsend and Gondzio, 2007). Returning to parallel implementations, Chang et al. (2008) use parallel IPM technology for the optimizer, and avoid the problem of inverting the dense Hessian matrix by generating a low-rank approximation of the kernel matrix using partial Cholesky decomposition with pivoting. The dense Hessian matrix can then be efficiently inverted implicitly using the low-rank approximation and the Sherman-Morrison-Woodbury (SMW) formula. Moreover, a large part of the calculations at each iteration can be distributed amongst the processors effectively. The SMW formula has been widely used in interior point methods; however, sometimes it runs into numerical difficulties. Fine and Scheinberg (2002) constructed data sets where an SMW-based algorithm required many more iterations to terminate, and in some cases stalled before achieving an accurate solution. They also showed that this situation arises in real-world data sets.

Most of the previous approaches (Durdanovic et al. 2007 is the exception) have considered the parallel computer system as a cluster of independent processors, communicating through a message passing scheme such as MPI (MPI-Forum, 1995). Advances in technology have resulted in systems where several processing cores have access to a single memory space, and such symmetric multiprocessing (SMP) architectures are becoming prevalent. OpenMP (OpenMP Architecture Review Board, 2008) has proven to work effectively on shared memory systems, while MPI can be used for message passing between nodes. It can also be used to communicate between processors within an SMP node, but it is not immediately clear that this is the most efficient technique.

Most high performance computing systems are now clusters of SMP nodes. On such hybrid systems, a combination of message passing between SMP nodes and shared memory techniques inside each node could potentially offer the best parallelization performance from the architecture, although previous investigations have revealed mixed results (Smith and Bull, 2001; Rabenseifner and Wellein, 2003). A standard approach to combining the two schemes involves OpenMP parallelization inside each MPI process, while communication between the MPI processes is made only outside of the OpenMP regions. Rabenseifner and Wellein (2003) refer to this style as "master-only".

In this paper, we propose a parallel linear SVM algorithm that adopts this hybrid approach to parallelization. It trains the SVM using the full data set, using an interior point method to give efficient optimization, and Cholesky decomposition to give good numerical stability. MPI is used to

communicate between clusters, while within clusters we take advantage of the availability of highly efficient OpenMP-based BLAS implementations. Data is distributed evenly amongst the processors. Our approach directly tackles the most computationally expensive part of the optimization, namely the inversion of the dense Hessian matrix, through providing an efficient implicit inverse representation. By exploiting the structure of the problem, we show how this can be parallelized with excellent parallel efficiency. The resulting implementation is significantly faster at SVM training than active set methods, and it allows SVMs to be trained on data sets that would be impossible to fit within the memory of a single processor.

The structure of the rest of this paper is as follows. Section 2 gives an outline of interior point method for optimizing quadratic programs. Section 3 provides a short description of support vector machines and the formulation we use. Then in Section 4 we describe our approach to training linear SVMs, exploiting the structure of the QP and accessing memory efficiently. Numerical performance results are given in Section 5. Section 6 contains some concluding remarks.

We now briefly describe the notation used in this paper. x_i is the attribute vector for the i^{th} data point, and it consists of the observation values directly. There are n observations in the training set, and m attributes in each vector x_i. X is the $m \times n$ matrix whose columns are the attribute vectors x_i associated with each point. The classification label for each data point is denoted by $y_i \in \{-1, 1\}$. The variables $w \in \mathbb{R}^m$ and $z \in \mathbb{R}^n$ are used for the primal variables ("weights") and dual variables (α in SVM literature) respectively, and $w_0 \in \mathbb{R}$ for the bias of the hyperplane. Scalars and column vectors are denoted using lower case letters, while upper case letters denote matrices. D, S, U, V, Y and Z are the diagonal matrices of the corresponding lower case vectors.

2. Interior Point Methods

Interior point methods represent state-of-the-art techniques for solving linear, quadratic and nonlinear optimization programmes. In this section the key issues of implementation for QPs are discussed very briefly; for more details, see Wright (1997).

For the purposes of this paper, we need a method to solve the box and equality-constrained convex quadratic problem

$$\begin{aligned} \min_z \quad & \frac{1}{2} z^T Q z + c^T z \\ \text{s.t.} \quad & Az = b \\ & 0 \le z \le u, \end{aligned}$$

where u is a vector of upper bounds, and the constraint matrix A is assumed to have full row rank. Dual feasibility requires that $A^T \lambda + s - v - Qz = c$, where λ is the Lagrange multiplier associated with the linear constraint $Az = b$ and $s, v > 0$ are the Lagrange multipliers associated with the lower and upper bounds of z respectively.

At each iteration, an interior point method makes a damped Newton step towards satisfying the primal feasibility, dual feasibility and complementarity product conditions,

$$\begin{aligned} ZSe &= \mu e \\ (U - Z)Ve &= \mu e, \end{aligned}$$

for a given $\mu > 0$. e is the vector of all ones. We follow a common practice in interior point literature and denote with a capital letter (Z, S, U, V) a diagonal matrix with elements of the corresponding

vector (z,s,u,v) on the diagonal. The algorithm decreases μ before making another iteration, and continues until both infeasibilities and the duality gap (which is proportional to μ) fall below required tolerances.

The Newton system to be solved at each iteration can be transformed into the *augmented system equations*:

$$\begin{bmatrix} -(Q+\Theta^{-1}) & A^T \\ A & 0 \end{bmatrix} \begin{bmatrix} \Delta z \\ \Delta\lambda \end{bmatrix} = \begin{bmatrix} r_c \\ r_b \end{bmatrix}, \tag{1}$$

where $\Delta z, \Delta\lambda$ are components of the Newton direction in the primal and dual spaces respectively, $\Theta^{-1} \equiv Z^{-1}S + (U-Z)^{-1}V$, and r_c and r_b are appropriately defined residuals. If the block $(Q+\Theta^{-1})$ is diagonal, an efficient method to solve such a system is to form the Schur complement $C = A(Q+\Theta^{-1})^{-1}A^T$, solve the smaller system $C\Delta\lambda = r_b + A(Q+\Theta^{-1})^{-1} r_c$ for $\Delta\lambda$, and back-substitute into (1) to calculate Δz. Unfortunately, as we shall see in the next section, for the case of SVM training the Hessian matrix Q is a completely dense matrix.

3. Support Vector Machines

In this section we briefly outline the standard SVM binary classification primal and dual formulations, and summarise how they can be reformulated as a separable QP (for more details, see Woodsend and Gondzio, 2007).

A Support vector machine (SVM) is a classification learning machine that learns a mapping between the features and the target label of a set of data points known as the *training set*, and then uses a hyperplane $w^T x + w_0 = 0$ to separate the data set and predict the class of further data points. The labels are the binary values "yes" or "no", which we represent using the values $+1$ and -1. The objective is based on the *structural risk minimization* principle, which aims to minimize the risk functional with respect to both the empirical risk (the quality of the approximation to the given data, by minimising the misclassification error) and maximize the confidence interval (the complexity of the approximating function, by maximising the separation margin) (Vapnik, 1998).

For a *linear kernel*, the attributes in the vector x_i for the i^{th} data point are the observation values directly, while for a *non-linear kernel* the observation values are transformed by means of a (possibly infinite dimensional) non-linear mapping Φ.

Concentrating on the linear SVM classifier, and using a 2-norm for the hyperplane weights w and a 1-norm for the misclassification errors $\xi \in \mathbb{R}^n$, the QP that forms the core of training the SVM takes the form:

$$\begin{aligned} \min_{w,w_0,\xi} \quad & \frac{1}{2} w^T w + \tau e^T \xi \\ \text{s.t.} \quad & Y(X^T w + w_0 e) \geq e - \xi \\ & w, w_0 \text{ free}, \quad \xi \geq 0, \end{aligned} \tag{2}$$

where τ is a positive constant that parameterizes the problem.

Due to the convex nature of the problem, a Lagrangian function associated with (2) can be formulated, and the solution will be at the saddle point. Partially differentiating the Lagrangian function gives relationships between the primal variables (w, w_0 and ξ) and the dual variables ($z \in \mathbb{R}^n$) at optimality, and substituting these relationships back into the Lagrangian function gives the

standard dual problem formulation

$$\begin{array}{ll} \min\limits_{z} & \frac{1}{2} z^T Y X^T X Y z - e^T z \\ \text{s.t.} & y^T z = 0 \\ & 0 \le z \le \tau e. \end{array} \tag{3}$$

However, using one of the optimality relationships, $w = XYz$, we can rewrite the quadratic objective in terms of w. Consequently, we can state the classification problem (3) as a separable QP:

$$\begin{array}{ll} \min\limits_{w,z} & \frac{1}{2} w^T w - e^T z \\ \text{s.t.} & w - XYz = 0 \\ & y^T z = 0 \\ & w \,\text{free}, \quad 0 \le z \le \tau e. \end{array} \tag{4}$$

The Hessian is simplified to the diagonal matrix $Q = \text{diag}\left(\begin{bmatrix} e_m \\ 0_n \end{bmatrix} \right)$ where $e_m = (1, 1, \ldots, 1) \in \mathbb{R}^m$, while the constraint matrix becomes:

$$A = \begin{bmatrix} I_m & -XY \\ 0 & y^T \end{bmatrix} \in \mathbb{R}^{(m+1)\times(m+n)}. \tag{5}$$

As described in Section 2, the Schur complement,

$$\begin{aligned} C &\equiv A(Q + \Theta^{-1})^{-1} A^T \\ &= \begin{bmatrix} I_m + XY\Theta_z YX^T & -XY\Theta_z y \\ -y^T \Theta_z YX^T & y^T \Theta_z y \end{bmatrix} \in \mathbb{R}^{(m+1)\times(m+1)}, \end{aligned}$$

can be formed efficiently from such matrices and used to determine the Newton step. The operation of building the matrix C is of order $O(n(m+1)^2)$, while inverting the resulting matrix is an operation of order $O((m+1)^3)$. The formulation (4) is the basis of our parallel algorithm, where building matrix C is split between the processors. This approach is efficient if $n \gg m$ (as was true with all the Challenge data sets), since building C is the most expensive operation, but it would not be suitable for data sets with a large number of features and $m \gg n$.

4. Implementing the QP for Parallel Computation

To apply (4) to truly large-scale data sets, it is necessary to employ linear algebra operations that exploit the block structure of the formulation (Gondzio and Sarkissian, 2003; Gondzio and Grothey, 2007). Between clusters, the emphasis is on partitioning the linear algebra operations to minimize interdependencies between processors. Within clusters, the emphasis is on accessing memory in the most efficient manner.

The approach described below was implemented using the OOPS interior point solver (Gondzio and Grothey, 2007).[1] We should note here that, as the parallel track of the Challenge was focused on shared memory algorithms, our submission to the Challenge used only the techniques described in Section 4.2.

1. Our implementation is available for academic use at `http://www.maths.ed.ac.uk/ERGO/software.html`.

4.1 Linear Algebra Operations Between Nodes

We use the augmented system matrix $H = \begin{bmatrix} -Q-\Theta^{-1} & A^T \\ A & 0 \end{bmatrix}$ corresponding to system (4), where $Q = \text{diag}\begin{bmatrix} e_m \\ 0 \end{bmatrix}$, Θ was described in Section 2 and A is given by Equation (5). This results in H having a symmetric bordered block diagonal structure. We can break H into blocks:

$$H = \begin{bmatrix} H_1 & & & & A_1^T \\ & H_2 & & & A_2^T \\ & & \ddots & & \vdots \\ & & & H_p & A_p^T \\ A_1 & A_2 & \dots & A_p & 0 \end{bmatrix},$$

where $H_i = -(Q_i + \Theta_i^{-1})$ are actually diagonal and A_i result from partitioning the data set evenly across the p processors. Due to the "arrow-head" structure of H, a block-based Cholesky decomposition of the matrix $H = LDL^T$ will be guaranteed to have the structure:

$$H = \begin{bmatrix} L_1 & & & \\ & \ddots & & \\ & & L_p & \\ L_{A_1} & \dots & L_{A_p} & L_C \end{bmatrix} \begin{bmatrix} D_1 & & & \\ & \ddots & & \\ & & D_p & \\ & & & D_C \end{bmatrix} \begin{bmatrix} L_1^T & & & L_{A_1}^T \\ & \ddots & & \vdots \\ & & L_p^T & L_{A_p}^T \\ & & & L_C^T \end{bmatrix}.$$

Exploiting this structure allows us to compute the blocks L_i, D_i and L_{A_i} in parallel. Terms that form the Schur complement can be calculated in parallel but must then be gathered, and the corresponding blocks L_C and D_C computed serially. This requires the exchange of matrices of size $(m+1)\times(m+1)$ between processors.

$$H_i = L_i D_i L_i^T \quad \Rightarrow D_i = -(Q_i + \Theta_i^{-1}), L_i = I, \tag{6}$$

$$L_{A_i} = A_i L_i^{-T} D_i^{-1} = A_i H_i^{-1}, \tag{7}$$

$$C = -\sum_{i=1}^{p} A_i H_i^{-1} A_i^T, \tag{8}$$

$$= L_C D_C L_C^T. \tag{9}$$

Matrix C is a dense matrix of relatively small size $(m+1)\times(m+1)$, and the Cholesky decomposition $C = L_C D_C L_C^T$ is performed in the normal way on a single processor. It is possible that a coarse-grained parallel implementation of Cholesky decomposition could give better performance (Luecke et al., 1992), but we did not include this in our implementation as the time taken to perform the decomposition is negligible compared to computing C.

Once the representation $H = LDL^T$ above is known, we can use it to compute the solution of the system $H\begin{bmatrix} \Delta z \\ \Delta\lambda \end{bmatrix} = \begin{bmatrix} r_c \\ r_b \end{bmatrix}$ through back-substitution. $\Delta z'$, $\Delta\lambda'$ and $\Delta\lambda''$ are vectors used for

intermediate calculations, with the same dimensions as Δz and $\Delta\lambda$.

$$\Delta\lambda'' = L_C^{-1}(r_b - \sum_i^p L_{A_i} r_{c_i}), \tag{10}$$

$$\Delta\lambda' = D_C^{-1}\Delta\lambda'', \tag{11}$$

$$\Delta\lambda = L_C^{-T}\Delta\lambda', \tag{12}$$

$$\Delta z_i' = D_i^{-1} r_{c_i}, \tag{13}$$

$$\Delta z_i = \Delta z_i' - L_{A_i}^T \Delta\lambda. \tag{14}$$

For the formation of LDL^T, Equations (6) and (7) can be calculated on each processor individually. Outer products (8) are then calculated, and the results gathered onto a single master processor to form C; this requires each processor to transfer approximately $\frac{1}{2}(m+1)^2$ elements. The master processor performs the Cholesky decomposition of C (9). Each processor needs to calculate $L_{A_i} r_{c_i}$, which again can be performed without any inter-processor communication, and the results are gathered onto the master processor. The master processor then performs the calculations in Equations (10), (11) and (12) of the back-substitution. Vector $\Delta\lambda$ is broadcast to all processors for them to calculate Equations (13) and (14) locally.

4.2 Linear Algebra Operations Within Nodes

Within each node, the bulk of operations are due to the contribution of each processor $A_i H_i^{-1} A_i^T$ to the calculation of the Schur complement in (8), and to a lesser extent the calculation of L_{A_i} in (7).

The standard technology for dense linear algebra operations is the BLAS library. Much of the effort to produce highly efficient implementations of BLAS Layer 3 (matrix-matrix operations) have concentrated on the routine GEMM, for good reason: Kågström et al. (1998) showed that it is possible to develop an entire BLAS Layer 3 implementation based on a highly optimized GEMM routine and a small amount of BLAS Layer 1 and Layer 2 routines. Their approach focused on efficiently organizing the accessing of memory, both through structuring the data for locality and through ordering operations within the algorithm. Matrices are partitioned into *panels* (block rows or block columns) and further partitioned into blocks of a size that fits in the processor's cache, where access times to the data are much shorter. Herrero (2006) has pursued these concepts further, showing that it is possible to develop an implementation offering competitive performance without the need for hand-optimized routines.

Goto and van de Geijn (2008) have shown that another limiting factor is the process of looking up mappings in the page table between virtual and physical addresses of memory. A more efficient approach ensures that the mappings for all the required data reside in the Translation Look-aside Buffer, effectively a cache for the page table. In practice, the best way of achieving this is to recast the matrix-matrix multiplications as a sum of panel-panel multiplications, repacking each panel into a contiguous buffer. This is the approach implemented in GotoBLAS, the library used in our implementation.

To perform GEMM $C := AB + C$, the algorithm described in Goto and van de Geijn (2008) divides the matrices into panels and uses three optimized components.

1. Divide matrix B into block row panels. Each panel $B_{p\bullet}$ contains all the columns we need, but fewer rows than the original matrix B. As required, pack $B_{p\bullet}$ into a contiguous buffer.

2. Divide matrix A into block column panels $A_{\cdot p}$, so that the inner dimensions of $A_{\cdot p}$ and $B_{p\cdot}$ match. Further divide A into blocks A_{ip}. As required, pack block A_{ip} into a contiguous buffer, so that by the end it is transposed and in the L2 cache.

3. Considering each block A_{ip} in turn, perform the multiplication $C_{i\cdot} := A_{ip}B_{p\cdot} + C_{i\cdot}$, with $B_{p\cdot}$ brought into the cache in column strips.

Additionally, it is possible in a multi-core system to coordinate the packing of $B_{p\cdot}$ between the processors, avoiding redundancy and improving performance.

Similar techniques using panels and blocks can be applied to Cholesky factorization (Buttari et al., 2009), but again these are not included in our implementation as the factorization of C is a relatively small part of the algorithm.

Returning to the SVM training problem, by casting the main computation of our algorithm in terms of matrix-matrix multiplications, we can take advantage of the above improvements for a multi-threaded architecture:

1. Consider a subblock of the constraint matrix A, consisting of all rows and the number of columns around the same size as $m+1$. Call this A_i.

2. Calculate L_{A_i} for this subblock, using (7). This involves Layer 1 operations, but these can be vectorized by the compiler.

3. Calculate $C := C + L_{A_i}A_i^T$ using the GEMM algorithm described above.

The performance gain of this approach is investigated in the next section.

5. Performance

In this section we compare the hybrid OpenMP/MPI version of our software with one using only MPI, and also our implementation against three other parallel SVM solvers. Data sets are taken from the PASCAL Challenge on Large-scale Learning, and the sizes we used are shown in Table 1. Due to memory restrictions, we reduced the number of samples in the FD and DNA data sets. Additionally, the DNA data set was modified from categories to binary features, increasing m by a factor of 4. The data sets were converted into a simple feature representation in SVM-light format. The software was run on a cluster of quad-core 3GHz Intel Xeon processors, each with 2GB RAM. The GotoBLAS library was used for BLAS functions, with the number of OpenMP threads set to 4, to match the number of cores. We also used the LAM implementation of the MPI library.

To compare the hybrid approach (using the techniques described in Sections 4.1 and 4.2) with pure MPI (using Section 4.1 only), we used the data sets alpha to zeta. The results are shown in Figure 1. They consistently show that, although the pure MPI approach has better properties in terms of parallel efficiency, the hybrid approach is always computationally more efficient. We believe this is a result of the multi-core processor architecture. The cores are associated with relatively small local cache memories, and such an architecture demands a fine-grained parallelism where, to reduce bus traffic, an operation is split into tasks that operate on small portions of data (Buttari et al., 2009). OpenMP is better suited to this fine-grained parallelism.

We made a comparison with other parallel software PGPDT (Zanni et al., 2006), PSVM (Chang et al., 2008), and Milde (Durdanovic et al., 2007). All of them are able to handle nonlinear as well as linear kernels, unlike our implementation. Using a linear kernel in each case, the results are shown

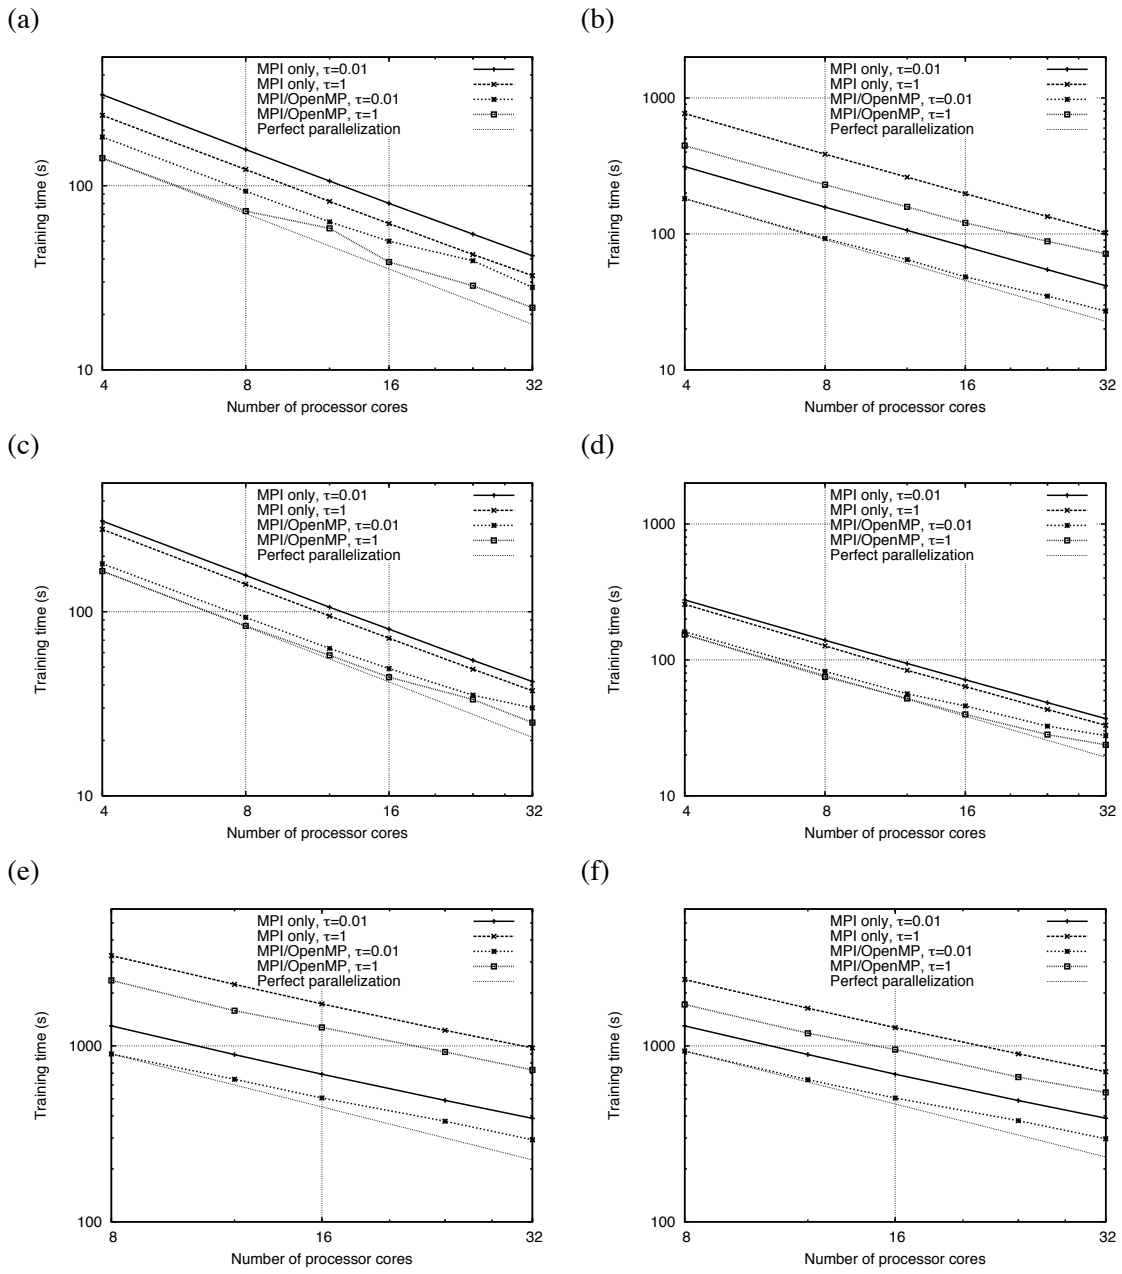

Figure 1: SVM training time with respect to the number of processors, for the PASCAL data sets (a) alpha, (b) beta, (c) gamma, (d) delta, (e) epsilon and (f) zeta. For each data set we trained using two values of τ. The results show that, although the pure MPI approach shows better parallel efficiency properties, the hybrid approach is always computationally more efficient.

Table 2: Comparison of parallel SVM training software on PASCAL data sets. Times are in seconds. In all cases except the DNA data set, the Milde software ran but did not terminate within 24 hours of runtime, so the numbers in brackets show when it was within 1% of its final objective value; — indicates that the software failed to load the problem.

in Table 2. With the exception of Milde (which has its own message passing implementation), the LAM implementation of the MPI library was used.

We required an objective value accuracy of $\varepsilon = 0.01$, and chose two values for τ within the range set in the Challenge, so we believe the training tasks are representative. In keeping with the evaluation method of the Challenge, the timings shown are for training and do not include time spent reading the data. The PSVM algorithm includes an additional partial Cholesky factorization

Table 3: Comparison of our SVM training software OOPS, in parallel and on a single processor, with linear SVM software LibLinear and LaRank, again on PASCAL data sets. Times for training are in seconds. For the parallel software OOPS, each core had access to 2GB memory. The single processor codes had access to 4 cores and 8GB memory, and the larger data sets were reduced in size to fit. For LibLinear, brackets indicate that the iteration limit was reached. For LaRank, — indicates that the software did not terminate within 24 hours.

Data Set	OOPS	LibLinear	LaRank
Alpha	**0.1345**	0.1601	0.1606
Beta	**0.4988**	**0.4988**	0.5001
Gamma	**0.1174**	0.1185	0.1187
Delta	**0.1344**	0.1346	0.1355
Epsilon	**0.0341**	0.4935	0.4913
Zeta	**0.0115**	0.4931	0.4875
FD	**0.2274**	0.2654	0.3081
OCR	**0.1595**	0.1660	0.1681

Table 4: Accuracy measured using area under precision recall curve. These values are taken from the test results tables of the Evaluation pages of the PASCAL Challenge website.

procedure, which we also do not include in the training times. To make the training equivalent, the rank of the factorization was set to be the number of features m. The Milde software includes a number of termination criteria but not one based on the objective. Using the default criteria of maximum gradient below ε resulted in the software never terminating in all but one case within a 24

hour runtime limit. To be closer to the spirit of the Challenge, we show the time taken to be within 1% of the objective value at the end of 24 hours when the program was terminated prematurely, although in many cases the output indicated that the method was not yet converging.

The results show that our approach described in this paper and implemented in OOPS is typically one to two orders of magnitude faster than the other parallel SVM solvers, terminates reliably, and training times are reasonably consistent for different values of τ.

Unfortunately there were no other linear SVM implementations in the Parallel track of the PASCAL Challenge. Instead, we show in Table 3 training time results for two linear SVM codes that did participate in the PASCAL Challenge: LibLinear (Fan et al., 2008) which won the linear SVM track, and LaRank (Bordes et al., 2007) specialised for linear SVMs. Both codes ran serially, using the memory of 4 processor cores (8GB RAM in total), although it should be noted that as we used the GotoBLAS library when building LibLinear, it was able to use all four processor cores during BLAS operations. To make training possible, it was necessary to reduce the size of the larger data sets from the sizes given in Table 1; the number of samples used each time are shown as n in Table 3.

The presentation of the results is slightly unusual in that training times are not directly connected to accuracy results against a test set. This is because labelled validation and test data sets have not been made publicly available. Performance statistics related to the precision recall curve were evaluated on the Challenge website, and so instead we reproduce in Table 4 the results from the website for area under the precision recall curve results for the test data set. In general the precision of our method is consistent with the best of the other linear SVM methods that participated.

Taking the results in Tables 3 and 4 together, it is clear that LibLinear in particular is a very efficient implementation, even in the cases Alpha to Delta where it is working with the full data set. Table 4 clearly indicates that our approach consistently finds a high-quality solution to the separating hyperplane, measured in terms of classification accuracy, whereas for LibLinear the quality of the solution is lower. In many cases, the reduction in prediction accuracy is only small. The results in Table 4 for the Epsilon and Zeta data sets in particular show, however, that for some problems the quality of the solution from OOPS can be substantially better.

6. Conclusions

In this paper, we have shown how to develop a hybrid parallel implementation of linear Support Vector Machine training. The approach allows the entire data set to be used, and consists of the following steps:

1. Reformulating the problem to remove the dense Hessian matrix.
2. Using interior point method to solve the optimization problem in a predictable time, and Cholesky decomposition to give good numerical stability of implicit inverses.
3. Exploiting the block structure of the augmented system matrix, to partition the data and linear algebra computations amongst parallel processing nodes efficiently.
4. Within SMP nodes, casting the main computations as matrix-matrix multiplication where possible, partitioning the matrices to obtain better data locality, and using highly efficient BLAS implementation for a multi-threaded architecture.

The above steps were implemented in OOPS. Our results show that, for all cases, the hybrid implementation was faster than one using purely MPI, even though the MPI version had better parallel

efficiency. We used the hybrid implementation to solve very large problems from the PASCAL Challenge on Large-scale Learning, of up to a few million data samples. On these problems the approach described in this paper was highly competitive, and showed that even on data sets of this size, training times in the order of minutes are possible.

In this paper we have focused on linear kernels. It is possible to extend the techniques described above to handle non-linear kernels, by approximating the positive semidefinite kernel matrix K with a low-rank outer product representation such as partial Cholesky factorization $LL^T \approx K$ (Fine and Scheinberg, 2002). This approach produces the first r columns of the matrix L (corresponding to the r largest pivots) and leaves the other columns as zero, giving an approximation of the matrix K of rank r. Extending the work of Fine and Scheinberg, the diagonal $D \in \mathbb{R}^{n\times n}$ of the residual matrix $(K - LL^T)$ can be determined at no extra expense and included in a separable formulation for non-linear kernels:

$$\begin{aligned} \min_{w,z} \quad & \frac{1}{2}(w^T w + z^T D z) - e^T z \\ \text{s.t.} \quad & w - (YL)^T z = 0 \\ & -y^T z = 0 \\ & 0 \le z \le \tau e. \end{aligned}$$

Chang et al. (2008) describe how to perform partial Cholesky decomposition in a parallel environment. Data is segmented between the processors. All diagonal elements are calculated to determine pivot candidates. Then, for each of the r columns, the largest diagonal element is located. The corresponding pivot row of L and the original features need to be known by all processors, so this information is broadcast by the owner processor. With this information, all processors can update the section of the new column of L for which they are responsible, and also update corresponding diagonal elements. Although the algorithm requires the processors to be synchronised at each iteration, little of the data needs to be shared amongst the processors: the bulk of the communication between processors is limited to a vector of length m and a vector of at most length r. Note that matrix K is known only implicitly, through the kernel function, and calculating its values is an expensive process. The algorithm therefore calculates each kernel element required to form L only once, giving a complexity of $O(nr^2 + nmr)$ for the initial Cholesky factorization, and $O(nr^2 + r^3)$ for each IPM iteration of our algorithm.

The method described in this paper requires all sample data to be loaded into memory, and this clearly has an impact on the size of problem that can be tackled. It is possible to improve data handling and increase the storage capacity somewhat, for instance storing the data compactly and expanding sections into floating point numbers when needed by the BLAS routines (Durdanovic et al., 2007), but the scaling is still $O(nm^2)$. The direction of our further research is to develop methods that are able to safely ignore or remove data points from consideration as the algorithm progresses. In conjunction with exploiting the structure of the optimization problem as described in this paper, we believe this will offer further significant improvements to the overall training time.

Acknowledgments

Abstract

To quickly achieve good performance, reinforcement-learning algorithms for acting in large continuous-valued domains must use a representation that is both sufficiently powerful to capture important domain characteristics, and yet simultaneously allows generalization, or sharing, among experiences. Our algorithm balances this tradeoff by using a stochastic, switching, parametric dynamics representation. We argue that this model characterizes a number of significant, real-world domains, such as robot navigation across varying terrain. We prove that this representational assumption allows our algorithm to be probably approximately correct with a sample complexity that scales polynomially with all problem-specific quantities including the state-space dimension. We also explicitly incorporate the error introduced by approximate planning in our sample complexity bounds, in contrast to prior Probably Approximately Correct (PAC) Markov Decision Processes (MDP) approaches, which typically assume the estimated MDP can be solved exactly. Our experimental results on constructing plans for driving to work using real car trajectory data, as well as a small robot experiment on navigating varying terrain, demonstrate that our dynamics representation enables us to capture real-world dynamics in a sufficient manner to produce good performance.

Keywords: reinforcement learning, provably efficient learning

1. Introduction

Reinforcement learning (RL) (Sutton and Barto, 1998) has had some impressive real-world successes, including model helicopter flying (Ng et al., 2004) and expert software backgammon players (Tesauro, 1994). Two of the key challenges in reinforcement learning are scaling up to larger, richer domains, and developing principled approaches for quickly learning to perform well. Our interest lies in developing algorithms for large continuous-valued environments, including problems such as

learning the best route to drive to work, or how a remote robotic rover can learn to traverse different types of terrain. To perform learning efficiently in such environments, we will assume that the world dynamics can be compactly described by a small set of simple parametric models, such as one for driving on highways and another for driving on small roads. We will prove that this assumption allows our algorithm to require an amount of experience that only scales polynomially with the state space dimension. We will also empirically demonstrate that these assumptions are realistic for several real world data sets, indicating that our Continuous-Offset Reinforcement Learning (CORL) algorithm may be well suited for large, high-dimensional domains.

A critical choice in the construction of a reinforcement-learning algorithm is how to balance between actions that gather information about the world environment (exploration) versus actions that are expected to yield high reward given the agent's current estimates of the world environment (exploitation). In early work, algorithms such as Q-learning were shown to perform optimally in the limit of infinite data (Watkins, 1989), but no finite-sample guarantees were known. More recently there have been three main branches of model-based reinforcement learning research concerned with the exploration problem. The first consists of heuristic approaches, some of which perform very well in practice, but lack performance guarantees (for example Jong and Stone 2007). The second branch strives to perform the action that optimally balances exploration and exploitation at each step. Such Bayesian approaches include the model parameters inside the state space of the problem. Poupart et al. (2006) assumed a fully observed discrete state space and modeled the underlying model parameters as hidden states, effectively turning the problem into a continuous-state partially observable Markov decision process (POMDP). Castro and Precup (2007) also assumed a fully observed discrete state space but represented the model parameters as counts over the different transitions and reward received, thereby keeping the problem fully observable. Doshi et al. (2008) considered a Bayesian approach for learning when the discrete state space is only partially observable, and Ross et al. (2008) considered learning in a partially-observed continuous-valued robot navigation problem. Approaches in the Bayesian RL framework run into inherent complexity problems and typically produce algorithms that only approximately solve their target optimality criteria.

In our work we will focus on achieving near optimality, making precise guarantees on when, and with what probability, it will be achieved. This type of approach to reinforcement learning was commenced by Kearns and Singh (2002) and Brafman and Tennenholtz (2002) who created algorithms that were guaranteed to achieve near optimal performance on all but a small number of samples, with high probability. We will refer to work in this line of research as "probably approximately correct" (PAC-MDP), as introduced by Strehl et al. (2006), and will discuss it further in the sections that follow. One of the appealing aspects of this area over a Bayesian RL approach is that it allows one to make precise statements about the efficiency and performance of algorithms: if the MDP or POMDP used in the Bayesian RL approach could be solved exactly with an informative prior, then this approach would likely outperform PAC-MDP approaches. However, when a Bayesian RL problem is only approximately solved or when the prior information is incorrect, it is unknown how far the resulting solution is from the optimal behavior. Our work lies within this third PAC-MDP approach, and draws upon the past advances made in this subfield, including our own initial work in this area (Brunskill et al., 2008). The current work makes a significant theoretical generalization of our initial results which requires different proof techniques, and presents a number of new experiments and discussions.

Within the PAC-MDP line of research, there has been little work on directly considering continuous-valued states. One exception is the work of Strehl and Littman (2008), who considered learning in continuous-valued state-action spaces. Their work assumed that a single dynamics representation was shared among all states, and that the noise parameter of the dynamics representation was known. The focus of their paper was slightly different than the current work, in that the authors presented a new online regression algorithm for determining when enough information was known to make accurate predictions.

An alternate approach to handling continuous state spaces is to discretize the space into a grid. This step enables prior PAC-MDP algorithms such as R-max (Brafman and Tennenholtz, 2002) to be applied directly to the discretized space. However, their representation of the world may not fully exploit existing structure. In particular, such a representation requires that the dynamics model for each state-action tuple is learned independently. Since each state-action can have entirely different dynamics, this approach has a great deal of representational power. However, as there is no sharing of dynamics information among states, it has a very low level of generalization. In contrast, the work of Strehl and Littman (2008) and the classic linear quadratic Gaussian regulator model (Burl, 1998) assume that the dynamics model is the same for all states, greatly restricting the representational power of these models in return for higher generalization and fast learning.

Recently, there have been several approaches that explore the middle ground of representational power and generalization ability. Jong and Stone (2007) assumed that the dynamics model between nearby states was likely to be similar, and used an instance-based approach to solve a continuous-state RL problem. Their experimental results were encouraging but no theoretical guarantees were provided, and the amount of data needed would typically scale exponentially with the state-space dimension. A stronger structural assumption is made in the work of Leffler et al. (2007), which focused on domains in which the discrete state space is divided into a set of types. States within the same type were assumed to have the same dynamics. The authors proved that a typed representation can require significantly less experience to achieve good performance compared to a standard R-max algorithm that learns each state-action dynamics model separately.

Our work draws on the recent progress and focuses on continuous-state, discrete-action, typed problems. By using a parametric model to represent the dynamics of each of a discrete set of types, we sacrifice some of the representational power of prior approaches (Leffler et al., 2007; Brafman and Tennenholtz, 2002) in return for improved generalization, but still retain a much more flexible representation than approaches that assume a single dynamics model that is shared across all states. In particular, we prove that restricting our representational power enables our algorithm to have a sample complexity that scales *polynomially* with the state-space dimension. An alternate approach is to place a uniformly spaced grid over the state space and solve the problem using the existing algorithms from Leffler et al. (2007) or Brafman and Tennenholtz (2002). However, this strategy results in an algorithm whose computational complexity scales exponentially with the state-space dimension.

Our algorithm involves a subroutine for solving a continuous-state MDP using the current model estimates. Outside of special cases like the linear Gaussian quadratic regulator problem (Burl, 1998), planning cannot be performed exactly for generic continuous-state MDPs. Therefore we explicitly incorporate the error introduced by approximate planning in our sample complexity bounds. This is in contrast to prior PAC-MDP approaches, which typically assume the estimated MDP can be solved exactly.

In particular, our dynamics representation is a simple noisy offset model, where the next state is presumed to be a function of the prior state, plus an offset and some Gaussian distributed noise. The offset and Gaussian parameters are assumed to be specified by the type t of the state and action a, thereby allowing all states of the same type to share dynamics parameters. More formally,

$$s' = s + \beta_{at} + \varepsilon_{at}, \tag{1}$$

where s is the current state, s' is the next state, $\varepsilon_{at} \sim \mathcal{N}(0, \Sigma_{at})$ is drawn from a zero-mean Gaussian with covariance Σ_{at}, and β_{at} is the offset.

In our experimental section we first demonstrate our algorithm on the standard RL PuddleWorld problem of Boyan and Moore (1995). We next illustrate the importance of learning the variance of different types by an example of an agent with a hard time deadline. The third example is a simulated decision problem in which an agent is trying to learn the best route for driving to work. The simulator uses real car-trajectory data to generate its trajectories. In the final experiment, a real robot car learns to navigate varying terrain. These experiments demonstrate that the noisy offset dynamics model, while simple, is able to capture real world dynamics for two different domains sufficiently adequately to allow the agent to quickly learn a good strategy.

At a high level, our work falls into the category of model-based reinforcement-learning algorithms in which the MDP model (Equation 1) can be *KWIK-learned* (Li et al., 2008; Li, 2009), and thus it is efficient in exploring the world. The Knows Whats It Knows (KWIK) framework is an alternate learning framework which incorporates characteristics of the Probably Approximately Correct (PAC) learning framework, which will be discussed further below, and the mistake bound framework. Though our theoretical development will follow a PAC-style approach, the KWIK framework provides another justification of the soundness and effectiveness of our algorithm.

The focus of this paper is on the sample complexity of the CORL algorithm. CORL assumes an approximate MDP planner to solve the current estimated MDP, and several such approximate planners with guarantees on the resulting solution involve a discretizaton that results in an exponential tiling of the state space. In such cases the computational complexity of CORL will scale exponentially with the number of dimensions. However, the experimental results demonstrate that CORL exhibits computational performance competitive with or better than existing approaches.

The rest of the paper proceeds as follows. In Section 2, we will briefly discuss the background to our work and then present the CORL algorithm. Section 3 presents our theoretical analysis of our algorithm. In Section 4 we present experimental results, and in Section 5 we conclude and discuss future work.

2. A Continuous-state Offset-dynamics Reinforcement Learner

This section introduces terminology and then presents our algorithm, CORL.

2.1 Background

The world is characterized by a continuous-state discounted MDP $M = \langle S, A, p(s'|s,a), R, \gamma \rangle$ where $S \subseteq \mathbb{R}^N$ is the N-dimensional state space, A is a set of discrete actions, $p(s'|s,a)$ is the transition dynamics, $\gamma \in [0,1)$ is the discount factor and $R : S \times A \to [0,1]$ is the reward function. In addition to the standard MDP formulation, each state s is associated with a single observable type $t \in T$. The total number of types is N_T and the mapping from states to types $S \to T$ is assumed to be known.

Algorithm 1 CORL

Input: N (dimension of the state space),$|A|$ (number of actions), N_T (number of types), R (reward model), γ (discount factor), N_{at} (minimum number of samples per state-action pair)
Set all type-action tuples $\langle t,a\rangle$ to be unknown and initialize the dynamics models (see text) to create an empirical known-type MDP model $\hat{M}_K$.
Start in a state s_0.
loop
  Solve MDP $\hat{M}_K$ using approximate solver and denote its optimal value function by Q_t.
  Select action $a = \text{argmax}_a Q_t(s,a)$.
  Increment the appropriate n_{at} count (where t is the type of state s).
  Observe transition to the next state s'.
  If n_{at} exceeds N_{at} then mark $\langle a,t\rangle$ as "known" and estimate the dynamics model parameters for this tuple.
end loop

The dynamics of the environment are determined by the current state type t and action a taken:

$$p(s'|s,a) = \mathcal{N}(s';s+\beta_{at},\Sigma_{at}).$$

Therefore, types partition the state space into regions, and each region is associated with a particular pair of dynamics parameters.

In this work, we focus on when the reward model is provided[1] and the dynamics model parameters are hidden. The parameters of the dynamics model, β_{at} and Σ_{at}, are assumed to be unknown for all types t and actions a at the start of learning. This model is a departure from prior related work (Abbeel and Ng, 2005; Strehl and Littman, 2008), which focuses on a more general linear dynamics model but assumes a single type and that the variance of the noise Σ_{at} is known. We argue that in many interesting problems, the variance of the noise is unknown and estimating this noise may provide the key distinction between the dynamics models of different types.

In reinforcement learning, the agent must learn to select an action a given its current state s. At each time step, it receives an immediate reward r based on its current state.[2] The agent then moves to a next state s' according to the dynamics model. The goal is to learn a policy $\pi : S \to A$ that allows the agent to choose actions to maximize the expected total reward it will receive. The value of a particular policy π is the expected discounted sum of future rewards that will be received from following this policy, and is denoted $V^\pi(s) = E_\pi[\sum_{j=0}^{\infty}\gamma^j r_j|s_0 = s]$, where r_j is the reward received on the j-th time step and s_0 is the initial state of the agent. Let π^* be the optimal policy, and its associated value function be $V^*(s)$.

2.2 Algorithm

Our algorithm (*c.f.*, Algorithm 1) is derived from the R-max algorithm of Brafman and Tennenholtz (2002). We first form a set of $\langle t,a\rangle$ tuples, one for each type-action pair. Note that each tuple

1. As long as the reward can be KWIK-learned (Li et al., 2008) then the results are easily extended to when the reward is unknown. KWIK-learnable reward functions include, for instance, Gaussian, linear and tabular rewards.
2. For simplicity, the reward is assumed to be only a function of state in this paper. It is straightforward to extend our results to the case when the reward function also depends on the action taken.

corresponds to a particular pair of dynamics model parameters, $\langle \beta_{at}, \Sigma_{at} \rangle$. A tuple is considered to be "known" if the agent has been in type t and taken action a a number N_{at} times. At each time step, we construct a new MDP $\hat{M}_K$ as follows, using the same state space, action space, and discount factor as the original MDP. If the number of times a tuple has been experienced, n_{at}, is greater than or equal to N_{at}, then we estimate the parameters for this dynamics model using maximum-likelihood estimation:

$$\tilde{\beta}_{at} = \frac{\sum_{i=1}^{n_{at}} (s'_i - s_i)}{n_{at}}, \quad (2)$$

$$\tilde{\Sigma}_{at} = \frac{\sum_{i=1}^{n_{at}} (s'_i - s_i - \tilde{\beta}_{at})(s'_i - s_i - \tilde{\beta}_{at})^T}{n_{at}} \quad (3)$$

where the sum ranges over all state-action pairs experienced for which the type of s_i was t, the action taken was a, and s'_i was the successor state. Note that while Equation 3 is a biased estimator, it is also popular and consistent, and becomes extremely close to the unbiased estimate when the number of samples n_{at} is large. We choose it because it makes our later analysis simpler.

Otherwise, we set the dynamics model for all states and the action associated with this type-action tuple to be a transition with probability 1 back to the same state. We also modify the reward function for all states associated with an unknown type-action tuple $\langle t_u, a_u \rangle$ so that all state-action values $Q(s_{t_u}, a_u)$ have a value of $V_{\max}$ (the maximum value possible, $1/(1-\gamma)$). We then seek to solve $\hat{M}_K$. This MDP includes switching dynamics with continuous states, and we are aware of no planners guaranteed to return the optimal policy for such MDPs in general. CORL assumes the use of an approximate solver to provide a solution for a MDP. There are a variety of existing MDP planners, such as discretizing or using a linear function approximation, and we will consider particular planner choices in the following sections. At each time step, the agent chooses the action that maximizes the estimate of its current approximate value according to Q_t: $a = \text{argmax}_a Q_t(s,a)$. The complete algorithm is shown in Algorithm 1.

3. Learning Complexity

In this section we will first introduce relevant background and then provide a formal analysis of the CORL algorithm.

3.1 Preliminaries and Framework

When analyzing the performance of an RL algorithm $\mathcal{A}$, there are many potential criteria to use. In our work, we will focus predominantly on sample complexity with a brief mention of computational complexity. Computational complexity refers to the number of operations executed by the algorithm for each step taken by the agent in the environment. We will follow Kakade (2003) and use *sample complexity* as shorthand for the *sample complexity of exploration*. It is the number of time steps at which the algorithm, when viewed as a non-stationary policy π, is not ε-optimal at the current state; that is, $Q^*(s,a) - Q^\pi(s,a) > \varepsilon$ where Q^* is the optimal state-action value function and Q^π is the state-action value function of the non-stationary policy π. Following Strehl et al. (2006), we are interested in showing, for a given ε and δ, that with probability at least $1-\delta$ the sample complexity of the algorithm is less than or equal to a polynomial function of MDP parameters. Note that we only consider the number of samples to ensure the algorithm will learn and execute a near-optimal

policy with high probability. As the agent acts in the world, it may be unlucky and experience a series of state transitions that poorly reflect the true dynamics due to noise.

Prior work by Strehl et al. (2006) provided a framework for analyzing the sample complexity of R-max-style RL algorithms. This framework has since been used in several other papers (Leffler et al., 2007; Strehl and Littman, 2008) and we will also adopt the same approach. We first briefly discuss the structure of this framework.

Strehl et al. (2006) defined an RL algorithm to be greedy if it chooses its action to be the one that maximizes the value of the current state s ($a = \text{argmax}_{a \in A} Q(s,a)$). Their main result goes as follows: let $\mathcal{A}(\varepsilon, \delta)$ denote a greedy learning algorithm. Maintain a list K of "known" state-action pairs. At each new time step, this list stays the same unless during that time step a new state-action pair becomes known. MDP $\hat{M}_K$ is the agent's current estimated MDP, consisting of the agent's estimated models for the known state-action pairs, and self loops and optimistic rewards (as in our construction described in the prior section) for unknown state-action pairs. MDP M_K is an MDP which consists of the true (underlying) reward and dynamics models for the known state-action pairs, and again self loops and optimistic rewards for the unknown state-action pairs. To be clear, the only difference between MDP $\hat{M}_K$ and MDP M_K is that the first uses the agent's experience to generate estimated models for the known state-action pairs, and the second uses the true model parameters. π is the greedy policy with respect to the current state-action values $Q_{\hat{M}_K}$ obtained by solving MDP $\hat{M}_K$: $V^{\pi}_{\hat{M}_K}$ is the associated value function for $Q_{\hat{M}_K}$ and may equivalently be viewed as the value of policy π computed using the estimated model parameters. $V^{\pi}_{M_K}$ is the value of policy π computed using the true model parameters. Assume that ε and δ are given and the following three conditions hold for all states, actions and time steps:

1. $Q^*(s,a) - Q_{\hat{M}_K}(s,a) \leq \varepsilon$.
2. $V^{\pi}_{\hat{M}_K}(s) - V^{\pi}_{M_K}(s) \leq \varepsilon$.
3. The total number of times the agent visits a state-action tuple that is not in K is bounded by $\zeta(\varepsilon, \delta)$ (the *learning complexity*).

Then, Strehl et al. (2006) show for any MDP M, $\mathcal{A}(\varepsilon, \delta)$ will follow a 4ε-optimal policy from its initial state on all but N_{total} time steps with probability at least $1 - 2\delta$, where N_{total} is polynomial in the problem's parameters $(\zeta(\varepsilon, \delta), \frac{1}{\varepsilon}, \frac{1}{\delta}, \frac{1}{1-\gamma})$.

The majority of our analysis will focus on showing that our algorithm fulfills these three criteria. In our approach, we will define the known state-action pairs to be all those state-actions for which the type-action pair $\langle t(s), a \rangle$ is known. We will assume that the absolute values of the components in Σ_{at} are upper bounded by a known constant B_σ which is, without loss of generality, assumed to be greater than or equal to 1. This assumption is often true in practice. We denote the determinant of matrix D by $\det D$, the trace of a matrix D by $\text{tr}(D)$, the absolute value of a scalar d by $|d|$ and the p-norm of a vector v by $\|v\|_p$. Full proofs, when omitted, can be found in the Appendix.

3.2 Analysis

Our analysis will serve to prove the main result:

Theorem 1 *For any given δ and ε in a continuous-state noisy offset dynamics MDP with N_T types where the covariance along each dimension of all the dynamics models is bounded by $[-B_\sigma, B_\sigma]$,*

on all but N_{total} time steps, our algorithm will follow a 4ε-optimal policy from its current state with probability at least $1-2\delta$, where N_{total} is polynomial in the problem parameters $(N, |A|, N_T, \frac{1}{\varepsilon}, \frac{1}{\delta}, \frac{1}{1-\gamma}, \frac{1}{\lambda_N}, B_\sigma)$ where λ_N is the smallest eigenvalue of the dynamics covariance matrices.

Proof To prove this, we need to demonstrate that the three criteria of Strehl et al. (2006) hold. The majority of our effort will focus on the second criterion. This criterion states that the value of states under the estimated known-state MDP $\hat{M}_K$ must be very close to the value of states under the known-state MDP M_K that uses the true model parameters for all known type-action pairs. To prove this we must bound how far away the model parameters estimated from the agent's experience can be from the true underlying parameters, and how this relates to error in the resulting value function. We must also consider the error induced by approximately solving the estimated MDP $\hat{M}_K$. Achieving a given accuracy level in the final value function creates constraints on how close the estimated model parameters must be to the true model parameters. We will illustrate how these constraints relate to the amount of experience required to achieve these constraints. This in turn will give us an expression for the number of samples required for a type-action pair to be known, or the learning complexity for our algorithm. Once we have proved the second criterion we will discuss how the other two conditions are also met.

Therefore we commence by formally relating how the amount of experience (number of transitions) of the agent corresponds to the accuracy in the estimated dynamics model parameters.

Lemma 2 *Given any $\varepsilon, \delta > 0$, then after $T = \frac{12N^2B_\sigma^2}{\varepsilon^2\delta}$ transition samples (s,a,s') with probability at least $1-\frac{2\delta}{3}$, the estimated offset parameter $\tilde{\beta}$, computed by Equation 2, and estimated covariance parameters $\tilde{\sigma}_{ij}$, computed by Equation 3, will deviate from the true parameters β and σ_{ij} by at most ε: $\Pr(\|\tilde{\beta}-\beta\|_2 \leq \varepsilon) \geq 1-\frac{\delta}{3}$ and $\Pr(\max_i |\tilde{\sigma}_{ij}-\sigma_{ij}| \leq \varepsilon) \geq 1-\frac{\delta}{3}$.*

Proof T will be the maximum of the number of samples to guarantee the above bounds for the offset parameter β and the number of samples needed for a good estimate of the variance parameter. We first examine the offset parameter:

Lemma 3 *Given any $\varepsilon, \delta > 0$, define $T_\beta = \frac{3N^2B_\sigma}{\varepsilon^2\delta}$. If there are T_β transition samples (s,a,s'), then with probability at least $1-\frac{\delta}{3}$, the estimated offset parameter $\tilde{\beta}$, computed by Equation 2, will deviate from the true offset parameter β by no more than ε along any dimension d; formally, $\Pr(\max_d \|\tilde{\beta}_d - \beta_d\|_2 \geq \frac{\varepsilon}{\sqrt{N}}) \leq \frac{\delta}{3N}$.*

Proof From Chebyshev's inequality, we know

$$P(|(s'_{id}-s_{id})-\beta_d| \geq \frac{\varepsilon}{\sqrt{N}}) \leq \frac{\sigma_d^2 N}{\varepsilon^2},$$

where s_{id} and σ_d^2 are the value of the i-th state and variance of the offset along dimension d, respectively. Using the fact that the variance of a sum of T_β i.i.d. variables is just T_β multiplied by the variance of a single variable, we obtain

$$\begin{aligned}
\Pr(|\sum_{i=1}^{T_\beta}(s'_{id}-s_{id}) - T_\beta\beta_d| \geq T_\beta\frac{\varepsilon}{\sqrt{N}}) &\leq \frac{T_\beta\sigma_d^2 N}{T_\beta^2\varepsilon^2} \\
\Pr(|\tilde{\beta}_d - \beta_d| \geq \frac{\varepsilon}{\sqrt{N}}) &\leq \frac{\sigma_d^2 N}{T_\beta\varepsilon^2}.
\end{aligned}$$

We require the right-hand side above be at most $\frac{\delta}{3N}$ and solve for T_β:

$$T_\beta = \frac{3\sigma_d^2 N^2}{\delta\varepsilon^2}.$$

We know that the variance along any dimension is bounded above by B_σ so we can substitute this in the above expression to derive a bound on the number of samples required:

$$T_\beta \geq \frac{3B_\sigma N^2}{\delta\varepsilon^2}.$$

■

Lemma 3 immediately implies a bound on the L_2 norm between the estimated offset parameter vector and the true offset parameter vector, as follows:

Lemma 4 *Given any* $\varepsilon, \delta > 0$, *if* $\Pr(\max_d |\tilde{\beta}_d - \beta_d| \geq \frac{\varepsilon}{\sqrt{N}}) \leq \frac{\delta}{3N}$, *then* $\Pr(\|\tilde{\beta} - \beta\|_2 \geq \varepsilon) \leq \frac{\delta}{3}$.

Proof By a union bound, the probability that any of the dimensions exceeds an estimation error of at most $\frac{\varepsilon}{\sqrt{N}}$ is at most $\frac{\delta}{3}$. Given this, with probability at least $1 - \frac{\delta}{3}$ all dimensions will simultaneously have an estimation error of less than $\frac{\varepsilon}{\sqrt{N}}$ and from the definition of the L2 norm this immediately implies that $\|\tilde{\beta} - \beta\|_2 \leq \varepsilon$. ■

We next analyze the number of samples needed to estimate the covariance accurately.

Lemma 5 *Assume* $\max_d |\tilde{\beta}_d - \beta_d| \leq \varepsilon$ *for* $\varepsilon < 1/4$. *Given any* $\delta > 0$, *define* $T_\sigma = \frac{12N^2 B_\sigma^2}{\delta\varepsilon^2}$. *If there are* T_σ *transition samples* (s, a, s'), *then with probability at most* $\frac{\delta}{3}$, *the estimated covariance parameter* $\tilde{\sigma}_{ij}$, *computed by Equation 3, deviates from the true covariance parameter* σ_{ij} *by more than* ε *over all entries* ij; *formally,* $\Pr(\max_{i,j} |\tilde{\sigma}_{ij} - \sigma_{ij}| \geq \varepsilon) \leq \frac{\delta}{3}$.

We provide the proof of Lemma 5 in the appendix: briefly, we again use Chebyshev's inequality which requires us to bound the variance of the sample covariance.

Combining Lemmas 4 and 5 gives a condition on the minimum number of samples necessary to ensure, with high probability, that the estimated parameters of a particular type-action dynamics model are close to the true parameters. Without loss of generality, assume $B_\sigma \geq 1$, then

$$T = \max\{T_\beta, T_\sigma\} = \max\left\{\frac{3N^2 B_\sigma}{\varepsilon^2\delta}, \frac{12N^2 B_\sigma^2}{\varepsilon^2\delta}\right\} = \frac{12N^2 B_\sigma^2}{\varepsilon^2\delta}.$$

■

From Lemma 2 we now have an expression that relates how much experience the agent needs in order to have precise estimates of each model parameter. We next need to establish the distance between two dynamics models which have different offset and covariance parameters. This distance will later be important for bounding the value function difference between the estimated model MDP $\hat{M}_K$ and the true model MDP M_K.

Following Abbeel and Ng (2005), we choose to use the variational distance between two dynamics models P and Q:

$$d_{var}(P(x),Q(x)) = \frac{1}{2}\int_{\mathcal{X}} |P(x)-Q(x)|dx.$$

In our algorithm, β_1 and Σ_1 are the true offset parameter and covariance matrix of the Gaussian distribution, and β_2 and Σ_2 are the offset parameter and covariance matrix estimated from data. Since we can guarantee that they can be made arbitrarily close (element-wise), we will be able to bound the variational distance between two Gaussians, one defined with the true parameters and the other with the estimated parameters. The real-valued, positive eigenvalues of Σ_1 and Σ_2 are denoted by $\lambda_1 \geq \lambda_2 \geq \cdots \geq \lambda_N > 0$ and $\lambda'_1 \geq \lambda'_2 \geq \cdots \geq \lambda'_N > 0$, respectively. Because of symmetry and positive definiteness of Σ_1 and Σ_2, λ_i and λ'_i must be real as well as positive. Since all eigenvalues are positive, they are also the singular values of their respective matrices.

Lemma 6 *Assume* $\max_{i,j} |\Sigma_1(i,j) - \Sigma_2(i,j)| \leq \varepsilon$, *and* $N\varepsilon \left\|\Sigma_1^{-1}\right\|_\infty < 1$, *then,*

$$d_{var}(\mathcal{N}(s'-s|\beta_1,\Sigma_1),\mathcal{N}(s'-s|\beta_2,\Sigma_2)) \leq \frac{||\beta_1-\beta_2||_2}{\sqrt{\lambda_N}} + \sqrt{\frac{N^2\varepsilon}{\lambda_N} + \frac{2N^3 B_\sigma \varepsilon}{\lambda_N^2 - N^{1.5}\varepsilon\lambda_N}}.$$

Proof We will use $\mathcal{N}(\beta,\Sigma)$ as an abbreviation for $\mathcal{N}(s'-s|\beta,\Sigma)$. Then

$$\begin{aligned} d_{var}(\mathcal{N}(\beta_1,\Sigma_1),\mathcal{N}(\beta_2,\Sigma_2)) &\leq d_{var}(\mathcal{N}(\beta_1,\Sigma_1),\mathcal{N}(\beta_2,\Sigma_1)) + d_{var}(\mathcal{N}(\beta_2,\Sigma_1),\mathcal{N}(\beta_2,\Sigma_2)) \\ &= \frac{||(\mathcal{N}(\beta_1,\Sigma_1),\mathcal{N}(\beta_2,\Sigma_1))||_1}{2} + \frac{||(\mathcal{N}(\beta_2,\Sigma_1),\mathcal{N}(\beta_2,\Sigma_2))||_1}{2} \\ &\leq \sqrt{2\mathrm{d_{KL}}(\mathcal{N}(\beta_1,\Sigma_1)\,\|\,\mathcal{N}(\beta_2,\Sigma_1))} + \sqrt{2\mathrm{d_{KL}}(\mathcal{N}(\beta_2,\Sigma_1)\,\|\,\mathcal{N}(\beta_2,\Sigma_2))} \end{aligned}$$

where $\mathrm{d_{KL}}(\|)$ is the Kullback-Leibler divergence. The first step follows from the triangle inequality and the last step follows from Kullback (1967) (included for completeness in Lemma 14 in the appendix).

The KL divergence between two N-variate Gaussians has the closed form expression

$$\mathrm{d_{KL}}(\mathcal{N}(\beta_1,\Sigma_1)\,\|\,\mathcal{N}(\beta_2,\Sigma_2)) = \frac{1}{2}\left((\beta_1-\beta_2)^T\Sigma_1^{-1}(\beta_1-\beta_2) + \ln\frac{\det\Sigma_2}{\det\Sigma_1} + \mathrm{tr}\left(\Sigma_2^{-1}\Sigma_1\right) - N\right).$$

Substituting this expression into the above bound on d_{var} we get

$$d_{var}(\mathcal{N}(\beta_1,\Sigma_1),\mathcal{N}(\beta_2,\Sigma_2)) \leq \sqrt{(\beta_1-\beta_2)^T\Sigma_1^{-1}(\beta_1-\beta_2)} + \sqrt{\ln\left(\frac{\det\Sigma_2}{\det\Sigma_1}\right) + \mathrm{tr}\left(\Sigma_2^{-1}\Sigma_1\right) - N}. \quad (4)$$

Our proof relies on bounding both terms of Equation 4. Note that this expression reduces (up to a constant) to the bound proved by Abbeel and Ng (2005) when the variance is known.

We now start with the first term of Equation 4:

Lemma 7

$$(\beta_1-\beta_2)^T\Sigma_1^{-1}(\beta_1-\beta_2) \leq \frac{1}{\lambda_N}||\beta_1-\beta_2||_2^2.$$

Proof First note that since Σ_1^{-1} is a Hermitian matrix,

$$\frac{(\beta_1-\beta_2)^T\Sigma_1^{-1}(\beta_1-\beta_2)}{||\beta_1-\beta_2)||_2^2}$$

is a Rayleigh quotient which is bounded by the maximum eigenvalue of Σ_1^{-1}. The eigenvalues of Σ_1^{-1} are precisely the reciprocals of the eigenvalues of Σ_1. Therefore, the Rayleigh quotient above is at most $\frac{1}{\lambda_N}$:

$$(\beta_1-\beta_2)^T\Sigma_1^{-1}(\beta_1-\beta_2) \leq \frac{||\beta_1-\beta_2||_2^2}{\lambda_N}.$$

■

We now provide lemmas that bound the components of the second term of Equation 4: proofs are provided in the appendix.

Lemma 8 *If* $\max_{i,j}|\Sigma_1(i,j)-\Sigma_2(i,j)| \leq \varepsilon$ *for any* $1 \leq i,j \leq N$, *then*

$$\left|\ln\frac{\det\Sigma_2}{\det\Sigma_1}\right| \leq N\varepsilon\left(\frac{1}{\lambda_1}+\frac{1}{\lambda_2}+\cdots+\frac{1}{\lambda_N}\right) \leq \frac{N^2\varepsilon}{\lambda_N}.$$

Lemma 9 *If* $\max_{i,j}|\Sigma_1(i,j)-\Sigma_2(i,j)| \leq \varepsilon$ *and* $N\varepsilon\left\|\Sigma_1^{-1}\right\|_1 < 1$, *then*

$$\mathrm{tr}\left(\Sigma_2^{-1}\Sigma_1\right)-N \leq \frac{2N^3\varepsilon B_\sigma}{\lambda_N^2-(N)^{1.5}\lambda_N\varepsilon}.$$

Combining the results of Lemmas 7, 8, and 9 completes the proof of Lemma 6. ■

Note this bound is tight when the means and the variances are the same.

At this point we can relate the number of experiences (samples) of the agent to a distance measure between the estimated dynamics model (for a particular type-action) and the true dynamics model.

We now bound the error between the state-action values of the true MDP model M_K solved exactly and the approximate state-action values of our estimated model MDP $\hat{M}_K$ obtained using an approximate planner, as a function of the error in the dynamics model estimates. This is a departure from most related PAC-MDP work which typically assumes the existence of a planning oracle for choosing actions given the estimated model.

Lemma 10 ***(Simulation Lemma)*** *Let* $M_1=\langle S,A,p_1(\cdot|\cdot,\cdot),R,\gamma\rangle$ *and* $M_2=\langle S,A,p_2(\cdot|\cdot,\cdot),R,\gamma\rangle$ *be two MDPs*[3] *with dynamics as characterized in Equation 1 and non-negative rewards bounded above by 1. Given an* ε *(where* $0<\varepsilon\leq V_{\max}$*), assume that for all state-action tuples* (s,a), $d_{var}(p_1(\cdot|s,a),p_2(\cdot|s,a)) \leq (1-\gamma)^2\varepsilon/(2\gamma)$ *and the error incurred by approximately solving a MDP, defined as* ε_{plan} *is also at most* $(1-\gamma)^2\varepsilon/(2\gamma)$ *(to be precise,* $\varepsilon_{plan}=||V^*-\tilde{V}^*||_\infty \leq (1-\gamma)^2\varepsilon/(2\gamma)$ *where* $\tilde{V}^*$ *is the value computed by the approximate solver). Let* π *be a policy that can be applied to both* M_1 *and* M_2. *Then, for any stationary policy* π, *for all states* s *and actions* a, $|Q_1^\pi(s,a)-\tilde{Q}_2^\pi(s,a)| \leq \varepsilon$, *where* $\tilde{Q}_2^\pi$ *denotes the state-action value obtained by using an approximate MDP solver on MDP* M_2 *and* Q_1^π *denotes the true state-action value for MDP* M_1 *for policy* π.

3. For simplicity we present the results here without reference to types. In practice, each dynamics parameter would be subscripted by its associated MDP, type, and action.

Proof Let $\Delta_Q = \max_{s,a} |Q_1^\pi(s,a) - \tilde{Q}_2^\pi(s,a)|$ and define $\tilde{V}_2^\pi$ to be the approximate value of policy π computed using an approximate MDP solver on MDP M_2, and V_1^π be the exact value of policy π on MDP M_1. Note that since we are taking the max over all actions, Δ_Q is also equal to or greater than $\max_s |V_1^\pi(s) - \tilde{V}_2^\pi(s)|$. Let $Lp_2(s'|s,a)$ denote an approximate backup for MDP M_2.

Since these value functions are the fixed-point solutions to their respective Bellman operators, we have for every (s,a) that

$$
\begin{aligned}
&|Q_1^\pi(s,a) - \tilde{Q}_2^\pi(s,a)| \\
&= \left| \left(R(s,a) + \gamma \int_{s' \in S} p_1(s'|s,a) V_1^\pi(s') ds' \right) - \left(R(s,a) + \gamma \int_{s' \in S} Lp_2(s'|s,a) \tilde{V}_2^\pi(s') ds' \right) \right| \\
&\leq \gamma \left| \int_{s' \in S} p_1(s'|s,a) V_1^\pi(s') - Lp_2(s'|s,a) \tilde{V}_2^\pi(s') ds' \right| \\
&\leq \gamma \left| \int_{s' \in S} p_1(s'|s,a) V_1^\pi(s') - p_1(s'|s,a) \tilde{V}_2^\pi(s') + p_1(s'|s,a) \tilde{V}_2^\pi(s') - Lp_2(s'|s,a) \tilde{V}_2^\pi(s') ds' \right| \\
&\leq \gamma \left| \int_{s' \in S} \left[p_1(s'|s,a)(V_1^\pi(s') - \tilde{V}_2^\pi(s')) + p_1(s'|s,a) \tilde{V}_2^\pi(s') - p_2(s'|s,a) \tilde{V}_2^\pi(s') \right. \right. \\
&\quad \left. \left. + p_2(s'|s,a) \tilde{V}_2^\pi(s') - Lp_2(s'|s,a) \tilde{V}_2^\pi(s') \right] ds' \right| \\
&\leq \gamma \left| \int_{s' \in S} p_1(s'|s,a)(V_1^\pi(s') - \tilde{V}_2^\pi(s')) ds' \right| + \gamma \left| \int_{s' \in S} (p_1(s'|s,a) - p_2(s'|s,a)) \tilde{V}_2^\pi(s') ds' \right| \\
&\quad + \gamma \left| \int_{s' \in S} p_2(s'|s,a) \tilde{V}_2^\pi(s') - Lp_2(s'|s,a) \tilde{V}_2^\pi(s') ds' \right|
\end{aligned}
$$

where the final expression was obtained by repeatedly adding and subtracting identical terms and using the triangle inequality. This expression must hold for all states s and actions a, so it must also hold for the maximum error over all states and actions:

$$
\begin{aligned}
\max_s \max_a |Q_1^\pi(s,a) - \tilde{Q}_2^\pi(s,a)| &\leq \gamma \int_{s' \in S} p_1(s'|s,a) \Delta_Q ds' + \gamma \left| \int_{s' \in S} (p_1(s'|s,a) - p_2(s'|s,a)) \tilde{V}_2^\pi(s') ds' \right| \\
&\quad + \gamma \left| \int_{s' \in S} \left(p_2(s'|s,a) \tilde{V}_2^\pi(s') - Lp_2(s'|s,a) \tilde{V}_2^\pi(s') \right) ds' \right| \\
\Delta_Q &\leq \gamma \Delta_Q + \gamma \left| \int_{s' \in S} (p_1(s'|s,a) - p_2(s'|s,a)) \tilde{V}_2^\pi(s') ds' \right| \\
&\quad + \gamma \left| \int_{s' \in S} \left(p_2(s'|s,a) \tilde{V}_2^\pi(s') - Lp_2(s'|s,a) \tilde{V}_2^\pi(s') \right) ds' \right| \\
&\leq \gamma \Delta_Q + \gamma V_{max} \left| \int_{s' \in S} p_1(s'|s,a) - p_2(s'|s,a) ds' \right| \\
&\quad + \gamma \left| \int_{s' \in S} \left(p_2(s'|s,a) \tilde{V}_2^\pi(s') - Lp_2(s'|s,a) \tilde{V}_2^\pi(s') \right) ds' \right| \\
&\leq \gamma \Delta_Q + \gamma V_{max} d_{var}(p_1(s'|s,a), p_2(s'|s,a)) + \gamma \varepsilon_{plan}
\end{aligned}
$$

where we have again used the triangle inequality. Therefore

$$\begin{aligned}\Delta_Q &\leq \gamma\Delta_Q + \gamma V_{\max} d_{var} + \gamma\varepsilon_{plan} \\ &= \frac{\gamma\frac{d_{var}}{1-\gamma}}{1-\gamma} + \frac{\gamma\varepsilon_{plan}}{1-\gamma},\end{aligned}$$

where we have used d_{var} as shorthand for $d_{var}(p_1(s'|s,a), p_2(s'|s,a))$

We have now expressed the error in the value function as the sum of the error due to the model approximation and the error due to using an approximate MDP planner. Using the assumptions in the lemma, the result immediately follows. ■

We can now use the prior lemmas to prove Theorem 1. First we need to examine under what conditions the two assumptions of the Simulation Lemma hold. The first assumption requires that $d_{var}(p_1(\cdot|s,a), p_2(\cdot|s,a)) \leq (1-\gamma)^2\varepsilon/(2\gamma)$ for all state-action tuples. From Lemma 6 this holds for a particular type-action tuple (which encompasses all state-action tuples where the state belongs to that type) if

$$\frac{||\beta_2 - \beta_1||_2}{\sqrt{\lambda_N}} + \sqrt{\frac{N^2\varepsilon}{\lambda_N} + \frac{2N^3 B_\sigma \varepsilon}{\lambda_N^2 - (N)^{1.5}\max_{ij}|\tilde{\sigma}_{ij} - \sigma_{ij}|\lambda_N}} \leq \frac{(1-\gamma)^2\varepsilon}{2\gamma} \tag{5}$$

and

$$\max_{ij}|\tilde{\sigma}_{ij} - \sigma_{ij}| \leq \varepsilon. \tag{6}$$

We can ensure Equation 5 holds by splitting the error into three terms:

$$\begin{aligned}\frac{\|\beta_2 - \beta_1\|_2}{\sqrt{\lambda_N}} &\leq \frac{(1-\gamma)^2\varepsilon}{4\gamma} \\ \frac{N^2\varepsilon}{\lambda_N} &\leq \frac{(1-\gamma)^4\varepsilon^2}{32\gamma^2} \\ \frac{2N^3 B_\sigma\varepsilon}{\lambda_N^2 - (N)^{1.5}\max_{ij}|\tilde{\sigma}_{ij} - \sigma_{ij}|\lambda_N} &\leq \frac{(1-\gamma)^4\varepsilon^2}{32\gamma^2}.\end{aligned}$$

Given these three equations, and Equation 6, we can obtain bounds on the error in the dynamics parameter estimates:

$$\|\tilde{\beta} - \beta\|_2 \leq \frac{(1-\gamma)^2\varepsilon\lambda_N^{0.5}}{4\gamma} \tag{7}$$

$$\max_{ij}|\tilde{\sigma}_{ij} - \sigma_{ij}| \leq \frac{(1-\gamma)^4\varepsilon^2\lambda_N}{32\gamma^2 N^2} \tag{8}$$

$$\max_{ij}|\tilde{\sigma}_{ij} - \sigma_{ij}| \leq \frac{(1-\gamma)^4\varepsilon^2\lambda_N^2}{16\gamma^2 N^3 B_\sigma + (1-\gamma)^4\varepsilon^2(N)^{1.5}\lambda_N}. \tag{9}$$

Assume[4] that $\lambda_N \leq 1, N > 1$ and $B_\sigma \geq 1$. In this case the upper bound in Equation 9 will be at least as small as the upper bounds in Equations 7 and 8.

4. This is just a simplifying assumption and it is trivial to show the bounds will have a similar polynomial dependence on the parameters if the assumptions do not hold.

We therefore require that the error ε in the model parameters be bounded by

$$\varepsilon \leq \frac{(1-\gamma)^4\varepsilon^2\lambda_N^2}{16\gamma^2N^3B_\sigma + (1-\gamma)^4\varepsilon^2(N)^{1.5}\lambda_N} \tag{10}$$

(from Equation 9). Lemma 2 provides a guarantee on the number of samples $T = \frac{12N^2B_\sigma^2}{\varepsilon^2 g}$ required to ensure with probability at least $1-g$ that all the model parameters have error of most ε. In order to ensure that the model parameters for all actions and types simultaneously fulfill this criteria with probability δ, it is sufficient to require that $g = \delta/(|A|N_T)$, from the union bound. We can then substitute this expression for g and Equation 10 into the expression for the number of samples T:

$$T = \frac{12N^2B_\sigma^2}{\left(\frac{(1-\gamma)^4\varepsilon^2\lambda_N^2}{16\gamma^2N^3B_\sigma+(1-\gamma)^4\varepsilon^2(N)^{1.5}\lambda_N}\right)\frac{\delta}{|A|N_T}} = \frac{12N^2|A|N_TB_\sigma^2(16\gamma^2N^3B_\sigma + N^1.5\lambda_N(1-\gamma)^4\varepsilon^2)^2}{(1-\gamma)^8\varepsilon^2\delta\lambda_N^4}.$$

Given this analysis, the first assumption of the Simulation Lemma holds with probability at least $1-\delta$ after

$$O\left(\frac{N^8|A|N_TB_\sigma^4}{(1-\gamma)^8\varepsilon^4\delta(\lambda_N)^4}\right)$$

samples.

The second assumption in the Simulation Lemma requires that we have access to an MDP planner than can produce an approximate solution to our typed-offset-dynamics continuous-state MDP. At least one such planner exists if the reward model is Lipschitz continuous; under a set of four conditions, Chow and Tsitsiklis (1991) proved that the optimal value function V_ε of a discrete-state MDP formed by discretizing a continuous-state MDP into $\Theta(\varepsilon)$-length (per dimension)[5] grid cells is an ε-close approximation of the optimal continuous-state MDP value function, denoted by V^*:

$$||V_\varepsilon - V^*||_\infty \leq \varepsilon.$$

The first condition used to prove the above result is that the reward function is Lipschitz-continuous. In our work, the reward function is assumed to be given, so this condition is a prior condition on the problem specification. The second condition is that the transition function is piecewise Lipschitz continuous. In other words, the transition model is Lipschitz-continuous over each of a set of finite subsets that cover the state space, and that the boundary between each subset region is piecewise smooth. For each type and action our transition model is a Gaussian distribution, which is Lipschitz-continuous, and there are a finite number of different types so it is piecewise Lipschitz-continuous. As long as our domain fulfills our earlier stated assumption that there are a finite number of different type regions, and the boundaries between each are piecewise smooth, then Chow and Tsitsiklis's second assumption is satisfied. The third condition is that the dynamics probabilities represent a true probability measure that sums to one ($\int_{s'} p(s'|s,a) = 1$), though the authors show that this assumption can be relaxed to $\int_{s'} p(s'|s,a) \leq 1$ and the main results still hold.

5. More specifically, the grid spacing h_g must satisfy $h_g \leq \frac{(1-\gamma)^2\varepsilon}{K_1+2KK_2}$ and $h_g \leq \frac{1}{2K}$ where K is the larger of the Lipschitz constants arising from the assumptions discussed in the text, and K_1 and K_2 are constants discussed in Chow and Tsitsiklis (1991). For small ε any h_g satisfying the first condition will automatically satisfy the second condition.

In our work, our dynamics models are defined to be true probability models. Chow and Tsitsiklis's final condition is that there must be a bounded difference between any two controls. In our case we consider only finite controls, so this property holds directly. Assuming the reward model fulfills the first condition, our framework satisfies all four conditions made by Chow and Tsitsiklis, and we can use their result.

By selecting fixed grid points at a regular spacing of $\frac{(1-\gamma)^2\varepsilon}{2\gamma}$, and by requiring that there exist at least one grid point placed in each contiguous single-type region, we can ensure that the maximum error in the approximate value function compared to the exactly solved value function is at most $\frac{(1-\gamma)^2\varepsilon}{2\gamma}$. This provides a mechanism for ensuring the second assumption of the Simulation Lemma holds. In other words, if the grid width used is the minimum of $\frac{(1-\gamma)^2\varepsilon}{2\gamma}$ and the minimum contiguous length of a single-type region, then the resulting value function using this discrete approximate planner is no more than $\frac{(1-\gamma)^2\varepsilon}{2\gamma}$-worse in value than the optimal exact planner for the continuous-state MDP.[6]

Type-action tuples with at least T samples are defined to be "known." From the analysis above, the estimated dynamics model for such types have a d_{var} value from the true known type-action dynamics model of at most $(1-\gamma)^2\varepsilon/(2\gamma)$. All unknown type-action tuples are defined to be self-loops. Therefore the dynamics models of our known-type, estimated dynamics MDP $\hat{M}_K$ relative to a known-type MDP with the true dynamics parameters M_K have a d_{var} of zero for all the unknown type-action tuples (since these are always defined as self loops) and at most $(1-\gamma)^2\varepsilon/(2\gamma)$ for all the known type-action tuples. Hence the first assumption of the Simulation Lemma holds. The second assumption of the Simulation Lemma is fulfilled given the analysis in the prior paragraph. Given these two assumptions are satisfied, the Simulation Lemma guarantees that the approximate value of our known-type MDP $\hat{M}_K$ under its greedy policy π ($\pi(s) = \text{argmax}_a Q_{\hat{M}_K}(s,a)$) is ε-close to the optimal value of the known-type MDP with the true dynamics parameters M_K under policy π: $||\tilde{V}^{\pi}_{\hat{M}_K} - V^{\pi}_{M_K}||_\infty \leq \varepsilon$. This fulfills condition 2 of Strehl et al. (2006).

The first condition of Strehl et al. (2006) can be re-expressed as:

$$Q^*(s,a) - Q_{\hat{M}_K}(s,a) = (Q^*(s,a) - Q_{M_K}(s,a)) + (Q_{M_K}(s,a) - Q_{\hat{M}_K}(s,a)) \leq \varepsilon.$$

We start by considering the first expression, $Q^*(s,a) - Q_{M_K}(s,a)$. If all type-action pairs are known, then M_K is the same as the original MDP, and this expression equals 0. If some type-action pairs are unknown, then the value of states of that type, associated with that action, becomes $V_{\max}$ under MDP M_K. As all known type-action pairs have the same reward and dynamics model as the original MDP, this implies that the value Q_{M_K} must be either equal or greater than Q^*, since all the value of all unknown state-actions is at least as great in Q_{M_K} as their real value Q^*. For this reason, $Q^*(s,a) - Q_{M_K}(s,a)$ is always less than or equal to 0.

We next consider $Q_{M_K}(s,a) - Q_{\hat{M}_K}(s,a)$. The variational distanced_{var} between the dynamics models of M_K and $\hat{M}_K$ for all unknown type-action tuples is zero, because all the dynamics of unknown tuples are self loops. As discussed above, the d_{var} between all known type-action tuples is at most $(1-\gamma)^2\varepsilon/(2\gamma)$. We can then apply the Simulation Lemma to guarantee that $|Q^{\pi}_{M_K}(s,a) - Q^{\pi}_{\hat{M}_K}(s,a)| \leq \varepsilon$. As a result, the first condition of Strehl et al. (2006) holds.

The third condition limits the number of times the algorithm may experience an unknown type-action tuple. Since there are a finite number of types and actions, this quantity is bounded above by

6. The condition of the extent of a typed region is a requirement in order to ensure that the discrete-representation doesn't skip over a smaller region of a different type, that may have a different optimal policy.

$N_{at}N_T|A|$, which is a polynomial in the problem parameters $(N, |A|, N_T, \frac{1}{\varepsilon}, \frac{1}{\delta}, \frac{1}{1-\gamma}, \frac{1}{\lambda_N}, B_\sigma)$. Therefore, our algorithm fulfills the three specified criteria and the result follows. ■

3.3 Discussion

Prior PAC-MDP work has focused predominantly on discrete-state, discrete-action environments. The sample complexity of the R-max algorithm by Brafman and Tennenholtz (2002) scales with the number of actions and the square of the number of discrete states, since a different dynamics model is learned for each discrete state-action tuple. In environments in which states of the same type share the same dynamics, Leffler et al. (2007) proved that the sample complexity scales with the number of actions, number of discrete states, and number of types. Assuming the number of types is typically much less than the number of states, this can result in significantly faster learning, as Leffler et al. (2007) demonstrate empirically. However, a naïve application of either technique to a continuous-state domain involves uniformly discretizing the continuous-state space. This procedure that results in a number of states that grows exponentially with the dimension of the state space. In this scenario the approaches of both Brafman and Tennenholtz (2002) and Leffler et al. (2007) will have a sample complexity that scales exponentially with the state space dimension, though the approach of Leffler et al. (2007) will scale better if there are a small number of types.

In contrast, the sample complexity of our approach scales polynomially in the numbers of actions and types as well as state space dimension, suggesting that it is more suitable for high dimensional environments. Our results follow the results of Strehl and Littman (2008), who gave an algorithm for learning in continuous-state and continuous-action domains that has a sample complexity that is polynomial in the state space dimension and the action space dimension. Our work demonstrates that we can get similar bounds when we use a more powerful dynamics representation (allowing states to have different dynamics, but sharing dynamics within the same types), learn from experience the variance of the dynamics models, and incorporate the error due to approximate planning.

Our analysis presented so far considers the discounted, infinite-horizon learning setting. However, our results can be extended to the H-step finite horizon case fairly directly using the results of Kakade (2003). Briefly, Kakade considers the scenario where a learning algorithm $\mathcal{A}$ is evaluated in a cycling H-step periods. The H-step normalized undiscounted value U of an algorithm is defined to be the sum of the rewards received during a particular H-step cycle, divided by H. Kakade defines $\mathcal{A}$ to be ε-optimal if the value over a state-action trajectory, until the end of the current H-step period, is within ε of the optimal value U. Using this alternate definition of value requires a modification of the Simulation Lemma which results in a bound on Δ_Q of $(H-1)V_{max}d_{var} + (H-1)\varepsilon_{plan}$. In short, the $\gamma/(1-\gamma)$ terms has been replaced with $H-1$. The earlier results on the number of samples required to obtain good estimates of the model parameters are unchanged, and the final result follows largely as before, except we now have a polynomial dependence on the horizon H of the undiscounted problem, compared to a polynomial dependence on the discount factor $1/\gamma$.

Finally, though our focus is on sample complexity, it is also important to briefly consider computational complexity. To ensure the approximate planner produces highly accurate results, our algorithm's worst-case computational complexity is exponential in the number of state dimensions. While this fact prevents it from being theoretically computationally efficient, in the next section we

present experimental results that demonstrate our algorithm performs well empirically compared to a related approach in a real-life robot problem.

4. Experiments

First we demonstrate the benefit of using domain knowledge about the structure of the dynamics model on the standard reinforcement-learning benchmark, PuddleWorld (Boyan and Moore, 1995). Then we illustrate the importance of explicitly learning the variance parameters of the dynamics in a simulated "catching a plane" experiment. This is in contrast to some past approaches which assume the variance parameters to be provided, such as Strehl and Littman (2008).

Our central hypothesis is that offset dynamics are a simple model that reasonably approximate several real world scenarios. In our third experiment, we applied our algorithm to a simulated problem using in which an agent needs to learn the best route to drive to work, and used date collected from real cars to simulate the dynamics. In our final experiment we applied our algorithm to a real-world robot car task in which the car most cross varying terrain (carpet and rocks) to reach a goal location.

CORL requires a planner to solve the estimated continuous-state MDP. Planning in continuous-state MDPs is an active area of research in its own right, and is known to be provably hard (Chow and Tsitsiklis, 1989). In all our experiments we used a standard technique, Fitted Value Iteration (FVI), to approximately solve the current MDP. In FVI, the value function is represented explicitly at only a fixed set of states. In our experiments these fixed states are uniformly spaced in a grid over the state space. Planning requires performing Bellman backups for each grid point; the value function over points not in this set is computed by function interpolation. We used Gaussian kernel functions as the interpolation method. Using sufficiently small kernel widths relative to the spacing of the grid points will make the approach equivalent to using a nearest neighbour standard discretization. However, there are some practical advantages in coarse grids to more smooth methods of interpolation. We discuss this issue in more depth in the next section.

In each experiment, N_{at} was tuned based on informal experimentation.

4.1 Puddle World

Puddle world is a standard continuous-state reinforcement-learning problem introduced by Boyan and Moore (1995). The domain is a two-dimensional square of width 1 with two oval puddles, which consist of the area of radius 0.1 around two line segments, one from $(0.1, 0.75)$ to $(0.45, 0.75)$ and the other from $(0.45, 0.4)$ to $(0.45, 0.8)$. The action space consists of the four cardinal directions. Upon taking an action the agent moves 0.05 in the specified cardinal direction with added Gaussian noise $\mathcal{N}(0, 0.001 * I)$, where I is a two-by-two identity matrix. The episode terminates when the agent reaches the goal region which is defined as the area in which $x + y \geq 1.9$. All actions receive a reward of -1 unless the agent is inside a puddle, in which case it then receives a reward of -400 times the distance inside the puddle. Figure 1 provides a graphical depiction of the puddle world environment.

We expect CORL will outperform prior approaches on this problem for two reasons. The first is that we assume the reward is given. However even if the reward model is provided, most past work still has to learn the dynamics model for this world, which is still a significant undertaking. The second reason is a feature of the CORL algorithm: its dynamics model uses the additional information that the dynamics for one action for all states of the same type are identical. Here there

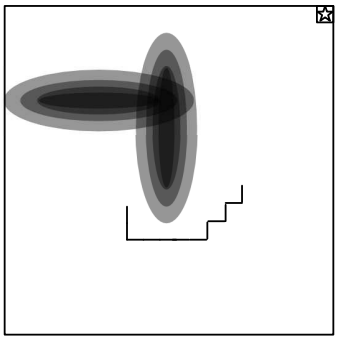

Figure 1: Puddle world. The small square with a star in it denotes the goal region. The black ovals represent the puddles and the black line represents a sample partial trajectory of an agent navigating around this world.

is only a single type, so CORL must learn only 4 sets of transition parameters, one for each action. Our goal here is simply to demonstrate that this additional information can lead to significantly faster learning over other more general techniques.

Puddle world has previously been used in reinforcement-learning competitions, and our evaluation follows the procedure of the second bakeoff (Dutech et al., 2005). We initially generated 50 starting locations, and cycled through these when initializing each episode. Each episode goes until the agent reaches the goal, or has taken 300 actions. We report results from taking the average reward within fifty sequential episodes (so the first point is the average reward of episodes 1-50, the second point is the average of episodes 51-100, etc.). We set N_{at} to be 15, and solved the approximate MDP model using Fitted Value Iteration with Gaussian kernel functions. The kernel means were spaced uniformly in a 20x20 grid across the state space (every 0.05 units), and their standard deviation was set to 0.01. Note that in the limit as the standard deviation goes to 0 the function interpolation becomes equivalent to nearest neighbour. Nearest neighbour is the interpolation method used in the approximate continuous-state MDP solver by Chow and Tsitsiklis (1991) which provides guarantees on the resulting value function approximation. However, since computational complexity scales exponentially with the grid discretization, practical application can require the use of coarse grids. In this case, we found that using a smoother function interpolation method empirically outperformed a nearest neighbour approach. In particular, we found that a kernel width, which is a measure of the standard deviation, of 0.01 gave the best empirical performance. This value lies in the middle of kernel widths which are smaller than the variance of the dynamics models and the grid spacing and those widths larger than the grid spacing and dynamics models.

We compare our results to the reported results of Jong and Stone (2007)'s Fitted R-max and to Lagoudakis and Parr (2003)'s Least Squares Policy Iteration (LSPI).[7] Fitted R-max is an instance-based approach that smoothly interpolates the dynamics of unknown states with previously observed transitions, and takes a similar approach for modeling the reward function. LSPI is a policy iteration approach which uses a linear basis function representation of the state-action values, and uses a set of sample transitions to compute the state-action values.

7. Both results reported come from the paper of Jong and Stone (2007).

Algorithm	Number of episodes			
	50	100	200	400
CORL	−19.9	−18.4	−20.3	−18.7
Fitted R-max	−130	−20	20	−20
LSPI	−500	−330	−310	−80

Table 1: PuddleWorld results. Each entry is the average reward/episode received during the prior 50 episodes. Results for the other algorithms are as reported by Jong and Stone (2007).

On the first 50 episodes, Fitted R-max had an average reward of approximately -130, though on the next 50 episodes it had learnt sufficiently good models that it reached its asymptotic performance of an average reward of approximately -20. In contrast, CORL learned a good model of the world dynamics within the very first episode, since it has the advantage of knowing that the dynamics across the entire state space are the same. This meant that CORL performed well on all subsequent episodes, leading to an average reward on the first 50 episodes of -19.9. Least Squares Policy Iteration (Lagoudakis and Parr, 2003) learned slower than Fitted R-max. Results are summarized in Table 1.

It is worth a short remark on the comparability of the reported results, as LSPI and Fitted R-max were run without knowing the reward model. LSPI's performance on a deterministic reward reinforcement-learning problem such as PuddleWorld will be identical to its performance in the known-reward case, as the rewards in the sampled transitions will be the same in either situation. Given this, assuming known reward, as we do for CORL, will not change the LSPI results. In contrast we do expect that Fitted R-max will be slightly faster if it does not have to learn the reward model. This is because a wider interpolation width can be selected if the reward is known and only the dynamics are unknown, since all states share the same dynamics. However, even in this case, Fitted R-max will be approximating the Gaussian dynamics by a set of observed transitions, and so it appears likely that CORL will still be faster than Fitted R-max since CORL assumes the (true) parametric representation of the transition model.

In summary, given the reward function, CORL can learn a good dynamics model extremely quickly in PuddleWorld, since the dynamics are typed-offset with a single type. This additional information enables CORL to learn a good policy for puddle world much faster than Fitted R-max and LSPI. This experiment illustrates the advantage of CORL when the transition dynamics are known to be identical across the state space, and to follow a noisy offset model.

4.2 Catching a Plane

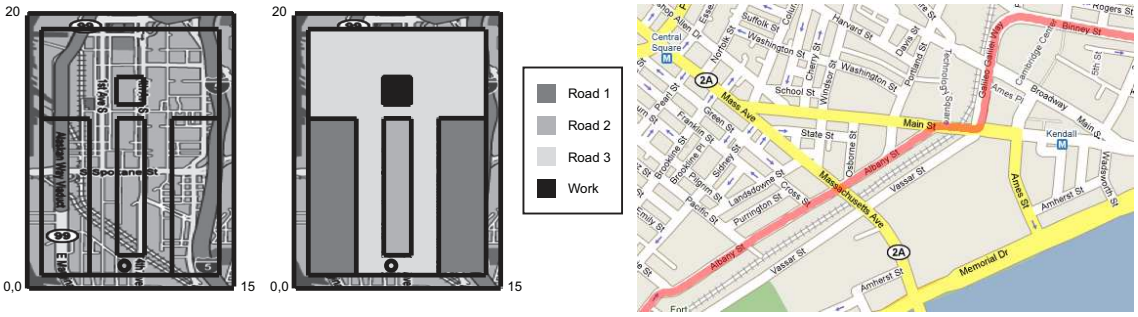
We next consider some examples with multiple types. Thousands of people now rely on internet maps or GPS units to do efficient trip planning, and better traffic prediction is an area of recent research (Horvitz et al., 2005). In many street systems, there exist a number of different classes of road types according to the designated speed limits associated with these roads. These different road types are often also associated with different variances. For example, while highways have mean speeds that are faster than small side streets, highways typically have a very large variance; rush hour highway speeds may often be slower than smaller side streets.

Figure 2: Motivating example where an agent must drive from a start location (designated with an S) to a goal area (shown with a highlighted rectangle) in time for a deadline, and can choose to take large high speed and variance roads, or slower small variance roads.

In our first experiment we considered a scenario in which learning this variance is critical: an agent must learn the best way to drive to an airport in time to catch a plane. A similar real-world environment is depicted in Figure 2. The agent starts from home and can either drive directly along a small side street, or cross over to the left or right to reach a main highway. The agent goes forward more quickly on the highway (with a mean offset of 2 units), but the highway also has a high variance of 0.49. In contrast, on the small side streets the agent goes forward more slowly (a mean offset of 1 unit) but with very small variance (0.00001). The state space is four dimensional, consisting of the agent's current x and y location, its orientation, and the amount of time that has passed. On each step five minutes pass. The agent can drive in a 14 by 19 region: outside of this is considered to be too far away.[8] If the agent exits this region it receives a reward of -1. The cost for each step is -0.05, the reward for reaching the airport in time for check in is $+1$ and the cost for not making the airport in time is -1. The discount factor is set to 1.0. N_{at} was set to 10. An episode starts when the agent takes its first step and lasts until the agent reaches the goal, exits the allowed region, or reaches the time at which check in for the plane closes. The agent starts at location $7,3$ facing north, and must figure out a way to reach the goal region which spans $[6.5-8.5, 15.5\text{-}17.5]$. To solve the underlying MDP, fitted value iteration was used. The fixed points were regularly spaced grid points with 15 across the x dimension, 20 across the y dimension, 4 orientation angles, and 21 time intervals. This yielded over 25,000 fixed points.

The correct path to take depends on the amount of time left. Here we explored three different deadline scenarios: when the agent has 60 minutes remaining (*RunningLate*), 70 minutes remaining (*JustEnough*), or 90 minutes remaining until check in closes for the plane (*RunningEarly*). In all three scenarios, the agent learned a good enough model of the dynamics within 15 episodes to compute a good policy. Note that using a naïve discretization of the space with the FVI fixed points as states and applying R-max would be completely intractable, as a different model would have to be learned for each of over 25,000 states. We display results for all three scenarios in Table 2. In

8. Note that this could be a reasonable assumption in some cases, such as when doctors had to stay within a certain radius of a hospital when on call.



(a) (b) (c)

Figure 3: (a) Simulated world map showing example environment. (b) World divided into a set of discrete types. Agent starts at driveway (black circle) and tries to learn a good route to reach work. (c) An example section of a car trajectory (constructed from a set of GPS locations).

the *RunningLate* scenario the agent learned that the side streets are too slow to allow it to ever reach the airport in time. Instead it took the higher variance highway which enables it to reach the airport in time in over half the episodes after N_{at} is reached for all types: its average reward is -0.4833 and it takes on average 56.62 minutes for it to reach the airport. In *JustEnough* the agent learned that the speed of side streets is sufficiently fast for the agent to reach the airport consistently in time, whereas the higher speed and variance highway would result in the agent failing to reach the check in time in some cases. Here the agent always reached the goal and receives an average reward of 0.45. In the *RunningEarly* scenario, the agent has enough time so that it can take either route and reliably reach the airport in time. In this scenario it learned to always take the highway, since in expectation that route will be faster. The average reward here was 0.4629.

This simulation serves to illustrate that our algorithm can quickly learn to perform well, in situations in which learning the variance is critical to ensure good performance.

4.3 Driving to Work

In our second experiment we again consider a simulated trip routing problem, but we now generate transitions in the simulator by sampling from real traffic data distributions. Here an agent must learn the best series of actions to drive from home to work in a small simulated world (see Figure 3(a) and 3(b)). The state consists of the current coordinates (x, y) and the orientation of the agent. There are three road types and each road type is associated with a different distribution of speeds. The

Scenario	Deadline (min)	Mean Reward/Episode	Mean Time to Reach Goal (min)
RunningLate	60	-0.4833	56.62
JustEnough	70	0.45	60
RunningEarly	90	0.4629	58.6

Table 2: Catching a plane: results after N_{at} has been reached for all types.

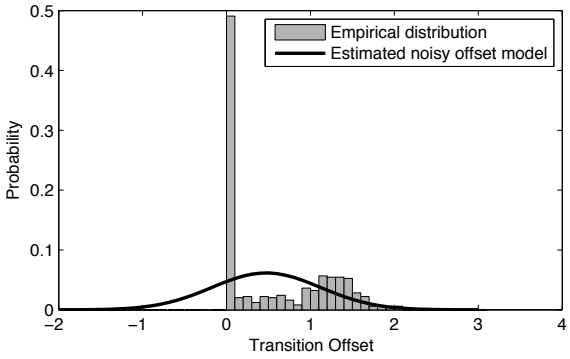


Figure 4: A histogram of car speeds on small roads that is used to generate transitions on road type 2 and the estimated dynamics model parameters found during the experiment

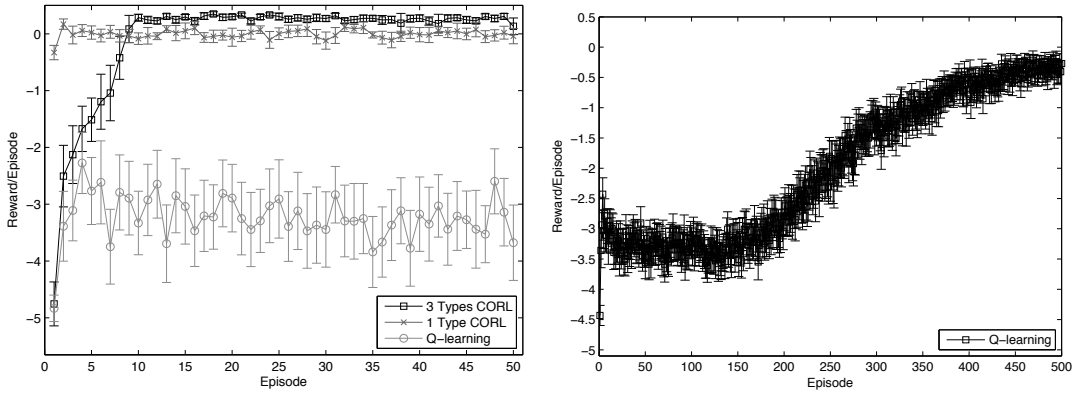
distributions were obtained from the CarTel project (Eriksson et al., 2008), which consists of a set of car trajectories from the Boston, Massachusetts area. GPS locations and time stamps are stored approximately every second from a fleet of 27 cars.[9] A section from one car trajectory is shown in Figure 3(c). Using this data set we extracted car trajectories on an interstate highway, small side streets and a local highway: these constitute types 1, 2 and 3 respectively in the simulation world. Each car trajectory consisted of a set of D GPS+time data points, which was converted into a set of $D-1$ transitions. Each transition in the simulation was sampled from these real-world transitions; for example, transitions in the simulator on road type 2 were sampled from real-world transitions on small side streets. Transitions from all three road types were all rescaled by the same constant in order to make the distances reasonable for the simulated world.[10] Figure 4 displays a histogram of rescaled transitions associated with small side streets. This figure shows that the speed distribution for small side streets was not Gaussian: the speed distribution for the other two street types was also not Gaussian. In particular, in no trajectories used does the car ever go backwards, whereas in some Gaussian models there will be small probability of this occurring. In this experiment we sought to investigate how well a noisy offset model could function in this environment, and the benefit of directly modelling different types of roads. Each transition in the simulated environment was sampled from the histogram of speeds associated with the road type at the agent's current position. Therefore, the data from the simulator is closer to the real environment than to the Gaussian distributions assumed by the learning algorithm.

The agent received a reward of 1 for reaching the work parking lot, -0.05 for each step, and -1 if it left the local area. Each episode finished when the agent either reached the goal, left the local area, or had taken 100 steps. An agent can go left, right or straight at each step. The transition induced by a straight action was determined by the road type as specified in the prior paragraph, and going left or right changed the orientation of the agent by 90 degrees with a very small amount of noise. The number of samples needed until a type-action tuple is known, N_{at}, was set to be 20. The discount factor was 1. The agent was always started in the same location and was allowed to learn across a set of 50 episodes. Results were averaged across 20 rounds of 50 episodes per

9. See more information about the project at `http://cartel.csail.mit.edu/`.
10. We also removed outlier transitions, as extremely fast speeds/transitions were likely to be errors in the log file.



(a) (b)

Figure 5: Reward versus episode. (a) Compares CORL with 3 types and 1 type to Q-learning. Results are averaged over 20 rounds (50 episodes per round). Error bars show 95% confidence intervals. (b) Shows Q-learning with 500 episodes per round, averaged over 100 rounds.

round. In one experiment the agent was given full knowledge of the three world types, and learned a different dynamics model for each type and action. In the second experiment the agent assumed there was only a single type and learned a dynamics model for each action. We also compared our approach to *Q*-learning over a uniformly-spaced discrete grid over the environment with an ε-greedy policy. We used a discretization that was identical to the fixed points used in the fitted value iteration planner of CORL. Points were mapped to their nearest neighbors. Q-learning requires specifying two parameters: the learning rate α which determines how much to adjust the state-action value estimates after each update, and ε which specifies how often to take a random action instead of the action that maximizes the current Q values. In this experiment α was set to 1.0 and decreased by multiplying by a factor of 0.9999 at each step.[11] We set ε to be 0.1.

The CORL results are displayed in Figure 5(a). This figure displays three encouraging results. The first is that in both CORL algorithms the agent learned to consistently reach the goal: the only way that the agent can receive a reward greater than -1 is to reach the goal, and all confidence intervals lie above -1 for all episodes after 10, indicating that the agent in both cases was successfully reaching the goal. This is promising because even though the underlying dynamics models were not exactly Gaussian noisy offset dynamics, a noisy offset model approximation was sufficient for the agent to learn a good policy in this environment. The estimated parameters computed for one type and action are displayed in Figure 4.

The second result is that the policy found by the agent that models all three types differently resulted in significantly higher reward than modeling the world with a single type: its performance suffered initially because it takes longer to learn a model of the world dynamics, but from about episode 10-50 modelling all types separately resulted in significantly higher reward per episode than modelling all types as the same. Table 3 displays the average reward of both approaches on episodes 10-50. These results demonstrate that traffic data does exhibit different speed distributions

11. We tried different decay factors for the α parameter but found that this worked better than decaying α more rapidly.

Algorithm	Average reward/episode
CORL with 3 types	0.27
CORL with 1 type	0.00
Q-learning	−3.2485

Table 3: Average reward on episodes 10-50 for the driving to work example.

on different types of roads, and that by considering such differences CORL can improve route directions even in a small simulated example.

The third result is that both CORL algorithms significantly outperformed Q-learning: again see Table 3 for comparing the short term performance of Q-learning to the CORL algorithm. This is not surprising since Q-learning is a model-free approach that trades off speed of computation per step in return for not requiring consistency between its state values through learned reward and dynamics models. Here in particular there is a large amount of structure in the domain that Q-learning cannot use. Q-learning does eventually begin to consistently reach the goal but this is only after about 500 episodes, more than an order of magnitude longer than the CORL algorithms took to find a good policy. These results are displayed in Figure 5(b). Such results argue that in situations where data is costly to gather, using a model can be extremely helpful.

4.4 Robot Navigation Over Varying Terrain

We also tried our algorithm in a real-life robotic environment involving a navigation task where a robotic car must traverse multiple surface types to reach a goal location. This experiment is a second example where a noisy offset dynamics model provides a sufficiently good representation of the real-world dynamics to allow our algorithm to learn good policies. We compared to the RAM-Rmax algorithm (Leffler et al., 2007), a provably efficient RL algorithm for learning in discrete-state worlds with types. The authors demonstrated that, by explicitly representing the types, they could get a significant learning speedup compared to R-max, which learns a separate dynamics model for each state. The RAM-Rmax algorithm represents the dynamics model using a list of possible next outcomes for a given type. CORL works directly with continuous-valued states, resulting in the improved sample complexity discussed earlier. This is achieved through assuming a fixed parametric representation of the dynamics, which is a less flexible model than the one used in RAM-Rmax. In this experiment we were interested in whether our representation was still rich enough to capture the real world dynamics involved in varying terrain traversal. We also investigated the computational load of CORL compared to RAM-Rmax, since by restricting our representation size we hoped to also achieve computational savings.

In this experiment we ran a LEGO® Mindstorms NXT robot (see Figure 6(b)) on a multi-surface environment. A tracking pattern was placed on the top of the robot and an overhead camera was used to determine the robot's current position and orientation. The domain, shown in Figure 6(a), consisted of two types of terrain: rocks embedded in wax and a carpeted area. The goal was for the agent to begin in the start location (indicated in the figure by an arrow) and end in the goal without going outside the environmental boundaries. The rewards were -1 for going out of

(a) (b)

Figure 6: (a) Image of the environment. The start location and orientation is marked with an arrow. The goal location is indicated by the circle.(b) LEGO® robot.

bounds, $+1$ for reaching the goal, and -0.01 for taking an action. Reaching the goal and going out of bounds ended the episode and resulted in the agent getting moved back to the start location.[12]

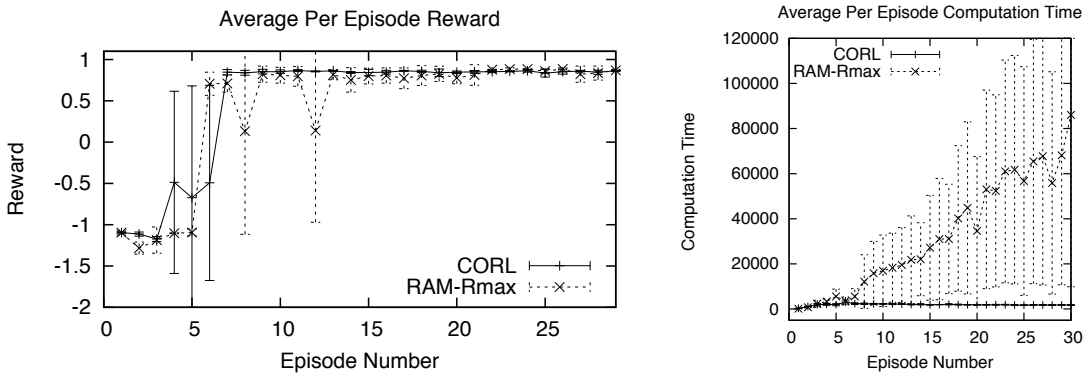
Due to the close proximity of the goal to the boundary, the agent needs an accurate dynamics model to reliably reach the goal. Part of the difficultly of this task is that the actions were going forward, turning left, and turning right. Without the ability to move backwards, the robot needed to approach the goal accurately to avoid falling out of bounds.

For the experiments, we compared our algorithm ("CORL") and the RAM-Rmax algorithm ("RAM"). The fixed points for the fitted value iteration portion of our algorithm were set to the discretized points of the RAM-Rmax algorithm. Both algorithms used an EDISON image segmentation system to uniquely identify the current surface type. The reward function was provided to both algorithms.

The state space is three dimensional: x, y position and orientation. Our algorithm implementation for this domain used a full covariance matrix to model the dynamics variance. For the RAM-Rmax agent, the world was discretized to a forty-by-thirty-by-ten state space. In our algorithm, we used a function approximator of a weighted sum of Gaussians, as described in Section 2. We used the same number of Gaussians to represent the value function as the size of the state space used in the discretized algorithm, and placed these fixed Gaussians at the same locations. The variance over the x and y variables was independent of each other and of orientation, and was set to be 16. To average orientation vectors correctly (so that -180° degrees and 180° do not average to 0) we converted orientations θ to a Cartesian coordinate representation $x_\theta = \cos(\theta), y_\theta = \sin(\theta)$. The variance over these two was set to be 9 for each variable (with zero covariance). For our algorithm and the RAM-Rmax algorithm, the value of N_{at} was set to four and five, respectively, which was determined after informal experimentation. The discount factor was set to 1.

Figure 7(a) shows the average reward with standard deviation for each of the algorithms over three runs. Both algorithms are able to receive near-optimal reward on a consistent basis, choosing

12. A video of the task can be seen at `http://people.csail.mit.edu/emma/corl/SuccessfulRun.mov` and `http://people.csail.mit.edu/emma/corl/SuccessfulRun.wmv`.



(a) (b)

Figure 7: (a) Reward received by algorithms averaged over three runs. Error bars show one standard deviation. (b) Total time taken by algorithms averaged over three runs. Error bars show one standard deviation.

similar paths to the goal. Our dynamics representation is sufficient to allow our algorithm to learn well in this real-life environment.

In addition, by using a fixed size (parametric) dynamics representation, the computational time per episode of our algorithm is roughly constant (Figure 7(b)). In the implementation of RAM-Rmax, the computational time grew with the number of episodes due to its dynamics model representation. This suggests that using a fixed size dynamics representation can have significant computation benefits. Overall CORL performed well in this domain, both in terms of reward achieved and computation required.

5. Conclusion and Future Work

In this paper we have presented CORL, an algorithm for efficiently learning to act in typed, continuous-state environments. CORL has a sample complexity that scales polynomially with the state space dimension and the number of types: this bound also directly incorporates the error due to approximate planning. Experiments on a simulated driving example using real world car data, and a small robot navigation task, suggest that noisy offset dynamics are a sufficiently rich representation to allow CORL to perform well in some real-world environments.

Due to the approximate MDP planning, we cannot currently guarantee both polynomial sample complexity and polynomial computational complexity. There are a number of recent advances in continuous-state MDP planning (Kocsis and Szepesvári, 2006; Kveton and Hauskrecht, 2006; Marecki and Tambe, 2008) as well as alternate approaches such as forward search techniques. In the future it would be interesting to investigate whether there exist alternate MDP planners that can provide ε-close approximations to the exact solutions with a computational complexity that scales polynomially with the number of state dimensions. Such approaches would enable CORL to achieve the appealing goal of polynomial dependence on the number of state dimension for both sample complexity and computational complexity.

Finally, the bounds provided remain overly large for many practical applications. We are broadly interested in developing techniques that can tighten the gap between the theoretical bounds and those needed for practical performance in real-world reinforcement learning.

Appendix A.

Lemma 5 *Assume* $\max_d |\tilde{\beta}_d - \beta_d| \leq \varepsilon$ *for* $\varepsilon < 1/4$. *Given any* $\delta > 0$, *define* $T_\sigma = \frac{12N^2B_\sigma^2}{\delta\varepsilon^2}$. *If there are* T_σ *transition samples* (s,a,s'), *then with probability at most* $\frac{\delta}{3}$, *the estimated covariance parameter* $\tilde{\sigma}_{ij}$, *computed by Equation 3, deviates from the true covariance parameter* σ_{ij} *by more than* ε *over all entries* ij; *formally,* $\Pr(\max_i |\tilde{\sigma}_{ij} - \sigma_{ij}| \geq \varepsilon) \leq \frac{\delta}{3}$.

Proof First recall that σ_{ij} represents the covariance between dimensions i and j. We are interested in the probability that the estimated covariance $\tilde{\sigma}_{ij}$ differs from the true parameter σ_{ij}: $\Pr(|\tilde{\sigma_{ij}} - \sigma_{ij}| \geq \varepsilon)$. From Chebyshev's inequality, we can bound this expression as

$$\Pr(|\tilde{\sigma_{ij}} - \sigma_{ij}| \geq \varepsilon) \quad \leq \quad \frac{Var(\tilde{\sigma}_{ij})}{\varepsilon^2}, \tag{11}$$

where $Var(\tilde{\sigma}_{ij})$ is the variance of the sample variance.

We therefore require an upper bound on the variance of the sample covariance. We will derive a bound on this below in the general case of the covariance between two variables x and y both of which are Gaussian distributed.

$$\begin{aligned} Var(\tilde{\sigma}_{xy}) &= E[(\tilde{\sigma}_{xy} - \sigma_{xy})^2] \\ &= E\left[\left(\frac{1}{T_\sigma}\sum_{k=1}^{T_\sigma}(x_k - \bar{x})(y_k - \bar{y}) - \sigma_{xy}\right)^2\right] \end{aligned}$$

where $\bar{x}$ and $\bar{y}$ are the respective sample means, and in the second line we have written out the definition of the sample covariance. We can then use the linearity of expectation to derive

$$\begin{aligned} Var(\tilde{\sigma}_{xy}) &= \frac{1}{T_\sigma^2}\sum_{k=1}^{T_\sigma}\sum_{m=1}^{T_\sigma} E[(x_k - \bar{x})(x_m - \bar{x})(y_k - \bar{y})(y_m - \bar{y})] \\ &\quad -2\sigma_{xy}\frac{1}{T_\sigma}\sum_{k=1}^{T_\sigma} E[(x_m - \bar{x})(y_m - \bar{y})] + E[(\sigma_{xy})^2] \\ &= \frac{1}{T_\sigma^2}\sum_{k=1}^{T_\sigma}\sum_{m=1}^{T_\sigma} E[(x_k - \bar{x})(x_m - \bar{x})(y_k - \bar{y})(y_m - \bar{y})] - (\sigma_{xy})^2 \end{aligned}$$

where the second line follows from the definition of the covariance σ_{xy}. We next divide the summation into two expressions, when $m = k$ and when $m \neq k$, and use the property that the expectation of independent variables is the product of their expectations:

$$\begin{aligned} Var(\tilde{\sigma}_{xy}) &= \frac{1}{T_\sigma} E[(x_k - \bar{x})^2 (y_k - \bar{y})^2] + \frac{T_\sigma (T_\sigma - 1)}{T_\sigma^2} E[(x_k - \bar{x})(y_k - \mu_k)] E[(x_m - \bar{x})(y_m - \bar{y})] - (\sigma_{xy})^2 \\ &= \frac{1}{T_\sigma} E[(x_k - \bar{x})^2 (y_k - \bar{y})^2] + \frac{T_\sigma (T_\sigma - 1)}{T_\sigma^2} (\sigma_{xy})^2 - (\sigma_{xy})^2. \end{aligned}$$

We can now use the Cauchy-Schwarz inequality on the first term to get

$$\begin{aligned} Var(\tilde{\sigma}_{xy}) &\leq \frac{1}{T_\sigma} \sqrt{E[(x_k - \bar{x})^4] E[(y_k - \bar{y})^4]} + \frac{T_\sigma (T_\sigma - 1)}{T_\sigma^2} (\sigma_{xy})^2 - (\sigma_{xy})^2 \\ &= \frac{1}{T_\sigma} \sqrt{E[(x_k + \mu_x - \mu_x - \bar{x})^4] E[(y_k + \mu_y - \mu_y - \bar{y})^4]} + \frac{T_\sigma (T_\sigma - 1)}{T_\sigma^2} (\sigma_{xy}^2)^2 - (\sigma_{xy}^2)^2 \\ &= \frac{1}{T_\sigma} \sqrt{(3\sigma_{xx}^4 + 6\sigma_{xx}^2 (\bar{x} - \mu_x)^2 + (\bar{x} - \mu_x)^4)(3\sigma_{yy}^4 + 6\sigma_{yy}^2 (\bar{y} - \mu_y)^2 + (\bar{y} - \mu_y)^4)} \\ &\quad + \frac{T_\sigma (T_\sigma - 1)}{T_\sigma^2} (\sigma_{xy})^2 - (\sigma_{xy})^2 \end{aligned}$$

where we have used the fact that the fourth central moment of a Gaussian distribution is $3\sigma_{xx}^2$ in the final line. Next we make use of the assumptions that B_σ is an upper bound to all covariance matrix elements and the bound on the maximum error in the parameter offset estimates:

$$\begin{aligned} Var(\tilde{\sigma}_{xy}^2) &\leq \frac{(\varepsilon^4 + 6\varepsilon^2 B_\sigma + 3B_\sigma^2)}{T_\sigma} + \frac{T_\sigma (T_\sigma - 1)}{T_\sigma^2} (\sigma_{xy})^2 - (\sigma_{xy})^2 \\ &\leq \frac{4B_\sigma^2}{T_\sigma} \end{aligned}$$

where the last line follows because $\varepsilon < 1/4$ and $B_\sigma \geq 1$. We can then substitute this result into Equation 11 which yields

$$P(|\tilde{\sigma}_{ij} - \sigma_{ij}| \geq \varepsilon) \leq \frac{4B_\sigma^2}{\varepsilon^2 T_\sigma}.$$

To ensure that this bound holds simultaneously with probability $\frac{\delta}{3}$ for all N^2 covariance matrix elements it suffices by the union bound to require that each covariance entry exceeds its expected value by more than ε with probability at most $\frac{\delta}{3N^2}$:

$$\frac{4B_\sigma^2}{\varepsilon^2 T_\sigma} \leq \frac{\delta}{3N^2}.$$

Re-arranging yields the bound for the required number of samples:

$$T_\sigma \geq \frac{12N^2 B_\sigma^2}{\delta \varepsilon^2}.$$

■

Lemma 8 *If* $\max_{i,j}|\Sigma_1(i,j)-\Sigma_2(i,j)| \le \varepsilon$ *for any* $1 \le i,j \le N$, *then*

$$\left|\ln\frac{\det\Sigma_2}{\det\Sigma_1}\right| \le N\varepsilon\left(\frac{1}{\lambda_1}+\frac{1}{\lambda_2}+\cdots+\frac{1}{\lambda_N}\right) \le \frac{N^2\varepsilon}{\lambda_N}.$$

Proof Define $E=\Sigma_2-\Sigma_1$. Clearly, E is symmetric since both Σ_1 and Σ_2 are symmetric. Its eigenvalues are denoted by $\psi_1 \ge \psi_2 \ge \cdots \ge \psi_N$, which are real (but can be negative or positive). First, it is known that

$$\det\Sigma_1=\prod_{i=1}^{N}\lambda_i \quad \& \quad \det\Sigma_2=\prod_{i=1}^{N}\lambda_i'.$$

Therefore,

$$\ln\frac{\det\Sigma_2}{\det\Sigma_1}=\ln\prod_{i=1}^{N}\frac{\lambda_i'}{\lambda_i}=\sum_{i=1}^{N}\ln\frac{\lambda_i'}{\lambda_i}.$$

From Geršgorin's theorem (Horn and Johnson, 1986, Theorem 6.1.1), the eigenvalues of E must be small as the elements of E are small. Specifically, each ψ_i must lie in one of the n Geršgorin discs:

$$\forall 1 \le j \le N : D_j=\{x \in R \mid |x-E(j,j)| \le \sum_{j' \ne j}\left|E(j,j')\right|\}.$$

It follows immediately that

$$|\psi_i| \le \sum_{j=1}^{N}|E(i,j)| \le N\varepsilon$$

as every component in E lies in $[-\varepsilon,\varepsilon]$.

On the other hand, from Weyl's theorem (Horn and Johnson, 1986, Theorem 4.3.1), we have

$$\psi_1 \ge \lambda_i'-\lambda_i \ge \psi_N.$$

We have just proved that both $|\psi_1|$ and $|\psi_N|$ are at most $N\varepsilon$, and thus

$$\left|\lambda_i'-\lambda_i\right| \le N\varepsilon.$$

Consequently,

$$\frac{\lambda_i'}{\lambda_i} \le \frac{\lambda_i+N\varepsilon}{\lambda_i}=1+\frac{N\varepsilon}{\lambda_i}.$$

Therefore, we have

$$\ln\frac{\det\Sigma_2}{\det\Sigma_1}=\sum_{i=1}^{N}\ln\frac{\lambda_i'}{\lambda_i} \le \sum_{i=1}^{N}\ln\left(1+\frac{N\varepsilon}{\lambda_i}\right) \le \sum_{i=1}^{N}\frac{N\varepsilon}{\lambda_i} \le \frac{(N)^2\varepsilon}{\lambda_N}$$

where the second to last inequality uses the inequality $\ln(1+x) \le x$ for $x \ge 0$. ■

The following lemmas will be useful to prove Lemma 9.

Lemma 11 ***(Lemma 2.7.1 and Theorem 2.7.2 from Golub and Van Loan 1996)*** *Suppose $Ax = b$ and $(A + \Delta A)y = b + \Delta b$ with $\|\Delta A\| \leq \varepsilon \|A\|$ and $\|\Delta b\| \leq \varepsilon \|b\|$. If $\varepsilon\kappa(A) < 1$, then $A + \Delta A$ is nonsingular, and*

$$\frac{\|y - x\|}{\|x\|} \leq \frac{2\varepsilon\kappa(A)}{1 - \varepsilon\kappa(A)},$$

where $\|\cdot\|$ can be any ℓ_p matrix/vector norm, and $\kappa(A) = \|A\| \left\|A^{-1}\right\|$ is the corresponding condition number.

Lemma 12 ***(A trace inequality of von Neumann 1937)*** *Let A and B be two symmetric matrices of order n, whose singular values are $\xi_1 \geq \xi_2 \geq \cdots \geq \xi_n \geq 0$ and $\zeta_1 \geq \zeta_2 \geq \cdots \geq \zeta_n \geq 0$, respectively. Then*

$$|\mathrm{tr}\,(AB)| \leq \sum_{i=1}^{n} \xi_i \zeta_i.$$

Lemma 13 *Suppose the covariance matrix Σ_1 is non-singular; that is its eigenvalues $\lambda_1 : \lambda_N > 0$. Then*

$$\begin{aligned} \mathrm{tr}\left(\Sigma_1^{-1}\right) &= \sum_{i=1}^{N} \frac{1}{\lambda_i} \leq \frac{N}{\lambda_N} \\ \max_{ij} |\Sigma_1^{-1}(i,j)| &\leq ||\Sigma_1^{-1}||_1 \\ ||\Sigma_1^{-1}||_1 \leq \sqrt{N}||\Sigma_1^{-1}||_2 &= \frac{\sqrt{N}}{\lambda_N}. \end{aligned}$$

Proof We prove the three upper bounds one by one:

1. It is a known fact that the trace of a matrix equals the sum of its eigenvalues. The first equality follows from the observation that the eigenvalues of Σ_1^{-1} are $\frac{1}{\lambda_1}, \frac{1}{\lambda_2}, \ldots, \frac{1}{\lambda_N}$.

2. This inequality follows from the definition of $||\Sigma_1^{-1}||_1$: it is the maximum absolute row sum of the matrix Σ_1^{-1}, and therefore is not less than the largest absolute component of the matrix.

3. It is known that $||A||_1 \leq \sqrt{N}||A||_2$ for any $N \times N$ matrix A (see, eg. theorem 5.6.18 in Horn and Johnson 1986). On the other hand, $||\Sigma_1^{-1}||_2$ equals the largest eigenvalue of Σ_1^{-1}, which is $\frac{1}{\lambda_N}$.

■

Lemma 9 *If $\max_{i,j} |\Sigma_1(i,j) - \Sigma_2(i,j)| \leq \varepsilon$ and $N\varepsilon \left\|\Sigma_1^{-1}\right\|_1 < 1$, then*

$$\mathrm{tr}\left(\Sigma_2^{-1}\Sigma_1\right) - N \leq \frac{2N^3\varepsilon B_\sigma}{\lambda_N^2 - (N)^{1.5}\lambda_N\varepsilon}.$$

Proof The i-th row (or column) of Σ_1^{-1} is the solution to the system of linear equations: $\Sigma_1 x = e_i$ where e_i has $N - 1$ zero components except a 1 in the i-th component. Similarly, the i-th row (or

column) of Σ_2^{-1} is the solution to $\Sigma_2 y = e_i$. Since Σ_1 and Σ_2 differ by at most ε in every component, we have

$$\frac{\|\Sigma_1 - \Sigma_2\|_1}{\|\Sigma_1\|_1} \leq \frac{N\varepsilon}{\|\Sigma_1\|_1}.$$

For convenience, denote the right-hand side above by ε'. It follows from Lemma 11 that

$$\|x - y\|_1 \leq \frac{2\varepsilon'\kappa(\Sigma_1)\,\|x\|_1}{1 - \varepsilon'\kappa(\Sigma_1)}.$$

The above inequality holds for all N possible e values. Note that $\|x-y\|_1$ is the absolute sum of the i-th row (or column) of $\Sigma_1^{-1} - \Sigma_2^{-1}$ for e_i. Let $\psi_1 \geq \psi_2 \geq \cdots \geq \psi_N \geq 0$ be the singular values of $\Sigma_1^{-1} - \Sigma_2^{-1}$. From Geršgorin's theorem, it follows that for all i,

$$\psi_i \leq \max_e \|x-y\|_1 \leq \frac{2\varepsilon'\kappa(\Sigma_1)}{1-\varepsilon'\kappa(\Sigma_1)} \max_e \|x\|_1 = \frac{2\varepsilon'\kappa(\Sigma_1)}{1-\varepsilon'\kappa(\Sigma_1)} \left\|\Sigma_1^{-1}\right\|_1 \tag{12}$$

where $\kappa(\Sigma_1) = \|\Sigma_1\| \left\|\Sigma_1^{-1}\right\|$ the condition number of Σ_1. We can now complete the proof:

$$\begin{aligned}
\operatorname{tr}\left(\Sigma_2^{-1}\Sigma_1\right) - N &= \operatorname{tr}\left((\Sigma_2^{-1} - \Sigma_1^{-1})\Sigma_1\right) && (13)\\
&\leq \sum_{i=1}^{N} \psi_i \lambda_i && (14)\\
&\leq \frac{2\varepsilon'\kappa(\Sigma_1)\left\|\Sigma_1^{-1}\right\|_1}{1-\varepsilon'\kappa(\Sigma_1)} \sum_{i=1}^{N} \lambda_i && (15)\\
&= \frac{2\varepsilon'\kappa(\Sigma_1)\left\|\Sigma_1^{-1}\right\|_1}{1-\varepsilon'\kappa(\Sigma_1)} \operatorname{tr}(\Sigma_1) && (16)\\
&= \frac{2N\varepsilon\left\|\Sigma_1^{-1}\right\|_1^2}{1-N\varepsilon\left\|\Sigma_1^{-1}\right\|_1} \operatorname{tr}(\Sigma_1) && (17)\\
&= \frac{2N^2 B_\sigma \varepsilon\left\|\Sigma_1^{-1}\right\|_1^2}{1-N\varepsilon\left\|\Sigma_1^{-1}\right\|_1}, && (18)\\
&\leq \frac{2N^3\varepsilon B_\sigma}{\lambda_N^2 - (N)^{1.5}\lambda_N\varepsilon}. && (19)
\end{aligned}$$

The first equality (Equation 13) is due to the identity $\operatorname{tr}\left(\Sigma_1^{-1}\Sigma_1\right) = \operatorname{tr}(I) = N$, and the first inequality (Equation 14) is a direct application of von Neumann's inequality (Lemma 12) which can be used since the eigenvalues λ_i are also the singular values in this case. The second inequality (Equation 15) follows from the result of Equation 12, the second equality (Equation 16) follows by the definition of matrix traces, and the third equality (Equation 17) is obtained by noting that $\kappa(\Sigma_1) = \|\Sigma_1\|_1 \left\|\Sigma_1^{-1}\right\|_1$. Since each term in the covariance matrix is known to be bounded by B_σ then the trace is bounded by NB_σ which allows us to generate the fourth equality (Equation 18). The final result is obtained using the result of Lemma 13.

■

Lemma 14 ***(Theorem from Kullback 1967)*** *Let p_1 and p_2 be two probability density functions defined over $\mathcal{X}$. Define*

$$\Omega = \{x \in \mathcal{X} \mid p_1(x) \geq p_2(x)\}.$$

If p_1 and p_2 are both measurable (integrable) over Ω, then

$$d_{KL}(p_1 \,\|\, p_2) \geq \frac{1}{8} \|p_1 - p_2\|_1^2.$$

Abstract

Nearest neighbor graphs are widely used in data mining and machine learning. A brute-force method to compute the exact kNN graph takes $\Theta(dn^2)$ time for n data points in the d dimensional Euclidean space. We propose two divide and conquer methods for computing an approximate kNN graph in $\Theta(dn^t)$ time for high dimensional data (large d). The exponent $t \in (1,2)$ is an increasing function of an internal parameter α which governs the size of the common region in the divide step. Experiments show that a high quality graph can usually be obtained with small overlaps, that is, for small values of t. A few of the practical details of the algorithms are as follows. First, the divide step uses an inexpensive Lanczos procedure to perform recursive spectral bisection. After each conquer step, an additional refinement step is performed to improve the accuracy of the graph. Finally, a hash table is used to avoid repeating distance calculations during the divide and conquer process. The combination of these techniques is shown to yield quite effective algorithms for building kNN graphs.

Keywords: nearest neighbors graph, high dimensional data, divide and conquer, Lanczos algorithm, spectral method

1. Introduction

Building nearest neighbor graphs is often a necessary step when dealing with problems arising from applications in such areas as data mining (Brito et al., 1997; Dasarathy, 2002), manifold learning (Belkin and Niyogi, 2003; Roweis and Saul, 2000; Saul and Roweis, 2003; Tenenbaum et al., 2000), robot motion planning (Choset et al., 2005), and computer graphics (Sankaranarayanan et al., 2007). Given a set of n data points $X = \{x_1, \ldots, x_n\}$, a nearest neighbor graph consists of the vertex set X and an edge set which is a subset of $X \times X$. The edges are defined based on a *proximity* measure $\rho(x_i, x_j)$ between two data points x_i and x_j, where a small ρ value means that the two points are

close. Two types of nearest neighbor graphs (Belkin and Niyogi, 2003; He and Niyogi, 2004) are often used:

1. ε-graph: This is an undirected graph whose edge set consists of pairs (x_i, x_j) such that $\rho(x_i, x_j)$ is less than some pre-defined threshold $\varepsilon \in \mathbb{R}^+$.

2. kNN graph: This is a directed graph (in general). There is an edge from x_i to x_j if and only if $\rho(x_i, x_j)$ is among the k smallest elements of the set $\{\rho(x_i, x_\ell) \mid \ell = 1, \ldots, i-1, i+1, \ldots, n\}$.

The ε-graph is geometrically motivated, and many efficient algorithms have been proposed for computing it (see, e.g., Bentley et al., 1977; Chazelle, 1983). However, the ε-graph easily results in disconnected components (Belkin and Niyogi, 2003) and it is difficult to find a good value of ε which yields graphs with an appropriate number of edges. Hence, they are not suitable in many situations. On the other hand, kNN graphs have been shown to be especially useful in practice. Therefore, this paper will focus on the construction of kNN graphs, for the case when $\rho(\cdot, \cdot)$ is the Euclidean distance between two points in the $\mathbb{R}^d$.

When $k = 1$, only the nearest neighbor for each data point is considered. This particular case, the *all nearest neighbors* problem, has been extensively studied in the literature. To compute the 1NN graph, Bentley (1980) proposed a multidimensional divide-and-conquer method that takes $O(n \log^{d-1} n)$ time, Clarkson (1983) presented a randomized algorithm with expected $O(c^d n \log n)$ time (for some constant c), and Vaidya (1989) introduced a deterministic worst-case $O((c'd)^d n \log n)$ time algorithm (for some constant c'). These algorithms are generally adaptable to $k > 1$. Thus, Paredes et al. (2006) presented a method to build a kNN graph, which was empirically studied and reported to require $O(n^{1.27})$ distance calculations for low dimensional data and $O(n^{1.90})$ calculations for high dimensional data. Meanwhile, several parallel algorithms have also been developed (Callahan, 1993; Callahan and Rao Kosaraju, 1995; Plaku and Kavraki, 2007). Despite a rich existing literature, efficient algorithms for high dimensional data are still under-explored. In this paper we propose two methods that are especially effective in dealing with high dimensional data.

Note that the problem of constructing a kNN graph is different from the problem of *nearest neighbor(s) search* (see, e.g., Indyk, 2004; Shakhnarovich et al., 2006, and references therein), where given a set of data points, the task is to find the k nearest points for any query point. Usually, the nearest neighbors search problem is handled by first building a data structure (such as a search tree) for the given points in a preprocessing phase. Then, queries can be answered efficiently by exploiting the search structure. Of course, the construction of a kNN graph can be viewed as a nearest neighbors search problem where each data point itself is a query. However, existing search methods in general suffer from an unfavorable trade-off between the complexity of the search structure and the accuracy of the query retrieval: either the construction of the search structure is expensive, or accurate searches are costly. The spill-tree (sp-tree) data structure (Liu et al., 2004) is shown to be empirically effective in answering queries, but since some heuristics (such as the hybrid scheme) are introduced to ensure search accuracy, the construction time cost is difficult to theoretically analyze. On the other hand, many $(1+\varepsilon)$ nearest neighbor search methods[1] have been proposed with guaranteed complexity bounds (Indyk, 2004). These methods report a point within $(1+\varepsilon)$ times the distance from the query to the actual nearest neighbor. Kleinberg (1997) presented two algorithms. The first one has a $O((d \log^2 d)(d + \log n))$ query time complexity but requires a data structure of

1. The ε parameter here is different from that in the "ε-graph".

size $O(n\log d)^{2d}$, whereas the second algorithm uses a nearly linear (to dn) data structure and responds to a query in $O(n+d\log^3 n)$ time. By using locality sensitive hashing, Indyk and Motwani (1998) gave an algorithm that uses $O(n^{1+1/(1+\varepsilon)}+dn)$ preprocessing time and requires $O(dn^{1/(1+\varepsilon)})$ query time. Another algorithm given in Indyk and Motwani (1998) is a $O(d\,\mathrm{poly}\log(dn))$ search algorithm that uses a $O(n(1/\varepsilon)^{O(d)}\,\mathrm{poly}\log(dn))$ data structure. Kushilevitza et al. (2000) proposed a $O((dn)^2(n\log(d\log n/\varepsilon))^{O(\varepsilon^{-2})}\,\mathrm{poly}(1/\varepsilon)\,\mathrm{poly}\log(dn/\varepsilon))$ data structure that can answer a query in $O(d^2\,\mathrm{poly}(1/\varepsilon)\,\mathrm{poly}\log(dn/\varepsilon))$ time. In general, most of the given bounds are theoretical, and have an inverse dependence on ε, indicating expensive costs when ε is small. Some of these methods can potentially be applied for the purpose of efficient kNN graph construction, but many aspects, such as appropriate choices of the parameters that control ε, need to be carefully considered before a practically effective algorithm is derived. Considerations of this nature will not be explored in the present paper.

The rest of the paper is organized as follows. Section 2 proposes two methods for computing approximate kNN graphs, and Section 3 analyzes their time complexities. Then, we show a few experiments to demonstrate the effectiveness of the methods in Section 4, and discuss two applications in Section 5. Finally, conclusions are given in Section 6.

2. Divide and Conquer kNN

Our general framework for computing an approximate kNN graph is as follows: We divide the set of data points into subsets (possibly with overlaps), recursively compute the (approximate) kNN graphs for the subsets, then conquer the results into a final kNN graph. This divide and conquer framework can clearly be separated in two distinct sub-problems: how to divide and how to conquer. The conquer step is simple: If a data point belongs to more than one subsets, then its k nearest neighbors are selected from its neighbors in each subset. However, the divide step can be implemented in many different ways, resulting in different qualities of graphs. In what follows two methods are proposed which are based on a spectral bisection (Boley, 1998; Juhász and Mályusz, 1980; Tritchler et al., 2005) of the graph obtained from an inexpensive Lanczos procedure (Lanczos, 1950).

2.1 Spectral Bisection

Consider the data matrix

$$X = [x_1, \ldots, x_n] \in \mathbb{R}^{d\times n}$$

where each column x_i represents a data point in $\mathbb{R}^d$. When the context is clear, we will use the same symbol X to also denote the set of data points. The data matrix X is centered to yield the matrix:

$$\hat{X} = [\hat{x}_1, \ldots, \hat{x}_n] = X - ce^T,$$

where c is the centroid and e is a column of all ones. A typical spectral bisection technique splits $\hat{X}$ into halves using a hyperplane. Let (σ, u, v) denote the largest singular triplet of $\hat{X}$ with

$$u^T\hat{X} = \sigma v^T. \tag{1}$$

Then, the hyperplane is defined as $\langle u, x-c\rangle = 0$, that is, it splits the set of data points into two subsets:

$$X_+ = \{x_i \mid u^T\hat{x}_i \geq 0\} \quad \text{and} \quad X_- = \{x_i \mid u^T\hat{x}_i < 0\}.$$

This hyperplane maximizes the sum of squared distances between the centered points $\hat{x}_i$ to the hyperplane that passes through the centroid. This is because for any hyperplane $\langle w, x-c\rangle = 0$, where w is a unit vector, the squared sum is

$$\sum_{i=1}^{n} (w^T \hat{x}_i)^2 = \left\| w^T \hat{X} \right\|_2^2 \leq \left\| \hat{X} \right\|_2^2 = \sigma^2,$$

while $w = u$ achieves the equality.

By a standard property of the SVD (Equation 1), this bisection technique is equivalent to splitting the set by the following criterion:

$$X_+ = \{x_i \mid v_i \geq 0\} \quad \text{and} \quad X_- = \{x_i \mid v_i < 0\}, \tag{2}$$

where v_i is the i-th entry of the right singular vector v. If it is preferred that the sizes of the two subsets be balanced, an alternative is to replace the above criterion by

$$X_+ = \{x_i \mid v_i \geq \mathrm{m}(v)\} \quad \text{and} \quad X_- = \{x_i \mid v_i < \mathrm{m}(v)\}, \tag{3}$$

where $\mathrm{m}(v)$ represents the median of the entries of v.

The largest singular triplet (σ, u, v) of $\hat{X}$ can be computed using the Lanczos algorithm (Lanczos, 1950; Berry, 1992). In short, we first compute an orthonormal basis of the Krylov subspace $\mathrm{span}\{q_1, (\hat{X}^T\hat{X})q_1, \ldots, (\hat{X}^T\hat{X})^{s-1}q_1\}$ for an arbitrary initial unit vector q_1 and a small integer s. Let the basis vectors form an orthogonal matrix

$$Q_s = [q_1, \ldots, q_s].$$

An equality resulting from this computation is

$$Q_s^T (\hat{X}^T\hat{X}) Q_s = T_s,$$

where T_s is a symmetric tridiagonal matrix of size $s \times s$. Then we compute the largest eigenvalue $\theta^{(s)}$ and corresponding eigenvector y_s of T_s:

$$T_s y_s = \theta^{(s)} y_s.$$

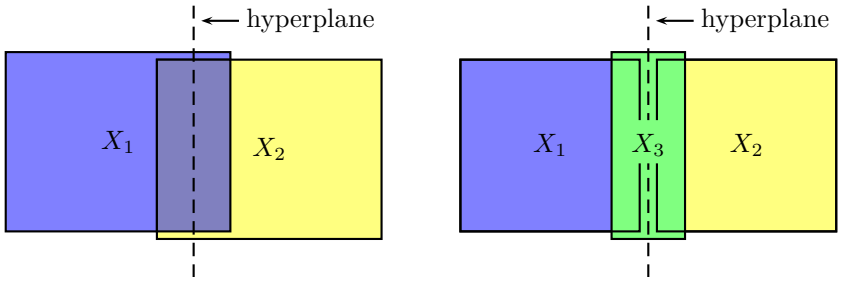
Therefore, $\theta^{(s)}$ is an approximation to the square of the largest singular value σ, while the vector $\tilde{v}_s \equiv Q_s y_s$ is an approximation of the right singular vector v of $\hat{X}$. The acute angle $\angle(\tilde{v}_s, v)$, between $\tilde{v}_s$ and v decays rapidly with s, as is shown in an error bound established in Saad (1980):

$$\sin\angle(\tilde{v}_s, v) \leq \frac{K}{C_{s-1}(1+\gamma_1)}$$

where K is a constant, C_k denotes the Chebyshev polynomial of degree k of the first kind, and $\gamma_1 = (\lambda_1 - \lambda_2)/(\lambda_2 - \lambda_n)$ in which the λ_i's denote the eigenvalues of $\hat{X}^T\hat{X}$, that is, the squared singular values of $\hat{X}$, ordered decreasingly. Note that we have $C_{s-1}(1+\gamma_1) = \cosh[(s-1)\cosh^{-1}(1+\gamma_1)]$, in which cosh is the hyperbolic cosine. Therefore, a small value of s will generally suffice to yield an accurate approximation. Note that an exact singular vector is not needed to perform a bisection, so we usually set a fixed value, say $s = 5$, for this purpose. The computation of the orthonormal basis takes time $\Theta(sdn)$, while the time to compute $\theta^{(s)}$ and y_s is negligible, since T_s is symmetric tridiagonal and s is very small. Hence the time for computing the largest singular triplet of $\hat{X}$ is bounded by $O(sdn)$.

2.2 The Divide Step: Two Methods

Based on the above general bisection technique, we propose two ways to perform the divide step for computing an approximate kNN graph. The first, called the *overlap* method, divides the current set into two overlapping subsets. The second, called the *glue* method, divides the current set into two disjoint subsets, and uses a third set called the gluing set to help merge the two resulting disjoint kNN graphs in the conquer phase. See Figure 1. Both methods create a common region, whose size is an α-portion of that of the current set, surrounding the dividing hyperplane. Details are given next.



(a) The overlap method. (b) The glue method.

Figure 1: Two methods to divide a set X into subsets. The size of the common region in the middle surrounding the hyperplane is an α-portion of the size of X.

2.2.1 THE OVERLAP METHOD

In this method, we divide the set X into two overlapping subsets X_1 and X_2:

$$\begin{cases} X_1 \cup X_2 = X, \\ X_1 \cap X_2 \neq \emptyset. \end{cases}$$

Since σv_i is the signed distance from $\hat{x}_i$ to the hyperplane, let the set V be defined as

$$V = \{|v_i| \mid i = 1, 2, \ldots, n\}.$$

Then we use the following criterion to form X_1 and X_2:

$$X_1 = \{x_i \mid v_i \geq -h_\alpha(V)\} \quad \text{and} \quad X_2 = \{x_i \mid v_i < h_\alpha(V)\}, \tag{4}$$

where $h_\alpha(\cdot)$ is a function which returns the element that is only larger than $(100\alpha)\%$ of the elements in the input set. The purpose of criterion (4) is to ensure that the overlap of the two subsets consists of $(100\alpha)\%$ of all the data, that is, that[2]

$$|X_1 \cap X_2| = \lceil \alpha |X| \rceil .$$

2. Here, we assume that the distances between points and the hyperplane are all different. Ties are broken arbitrarily. The same is done for the glue method.

2.2.2 THE GLUE METHOD

In this method, we divide the set X into two disjoint subsets X_1 and X_2 with a gluing subset X_3:

$$\begin{cases} X_1 \cup X_2 = X, \\ X_1 \cap X_2 = \emptyset, \\ X_1 \cap X_3 \neq \emptyset, \\ X_2 \cap X_3 \neq \emptyset. \end{cases}$$

The criterion to build these subsets is as follows:

$$X_1 = \{x_i \mid v_i \geq 0\}, \quad X_2 = \{x_i \mid v_i < 0\},$$
$$X_3 = \{x_i \mid -h_\alpha(V) \leq v_i < h_\alpha(V)\}.$$

Note that the gluing subset X_3 in this method is exactly the intersection of the two subsets in the overlap method. Hence, X_3 also contains $(100\alpha)\%$ of the data.

2.3 Refinement

In order to improve the quality of the resulting graph, during each recursion after the conquer step, the graph can be refined at a small cost. The idea is to update the k nearest neighbors for each point by selecting from a pool consisting of its neighbors and the neighbors of its neighbors. Formally, if $N(x)$ is the set of current nearest neighbors of x before refinement, then, for each point x, we re-select its k nearest neighbors from

$$N(x) \cup \left(\bigcup_{z \in N(x)} N(z) \right).$$

2.4 The Algorithms

We are ready to present the complete algorithms for both methods; see Algorithms 1 and 2. These algorithms share many similarities: They both fall in the framework of divide and conquer; they both call the brute-force procedure kNN-BRUTEFORCE to compute the graph when the size of the set is smaller than a threshold (n_k); they both recursively call themselves on smaller subsets; and they both employ a CONQUER procedure to merge the graphs computed for the subsets and a REFINE procedure to refine the graph during each recursion. The difference is that Algorithm 1 calls DIVIDE-OVERLAP to divide the set into two subsets (Section 2.2.1), while Algorithm 2 calls DIVIDE-GLUE to divide the set into three subsets (Section 2.2.2). For the sake of completeness, pseudocodes of all the mentioned procedures are given in Appendix A.

2.5 Storing Computed Distances in a Hash Table

The brute-force method computes $\Theta(n^2)$ pairs of distances, each of which takes $\Theta(d)$ time. One advantage of the methods presented in this paper over brute-force methods is that the distance calculations can be significantly reduced thanks to the divide and conquer approach. The distances are needed/computed in: (1) the kNN-BRUTEFORCE procedure which computes all the pairwise distances and selects the k smallest ones for each point, (2) the CONQUER procedure which selects

Algorithm 1 Approximate kNN Graph Construction: The Overlap Method

  end if
end function

Algorithm 2 Approximate kNN Graph Construction: The Glue Method

function $G = k$NN-GLUE(X, k, α)
  if $|X| < n_k$ **then**
    $G \leftarrow k$NN-BRUTEFORCE(X, k)
  else
    $(X_1, X_2, X_3) \leftarrow$ DIVIDE-GLUE(X, α) ▷ Section 2.2.2
    $G_1 \leftarrow k$NN-GLUE(X_1, k, α)
    $G_2 \leftarrow k$NN-GLUE(X_2, k, α)
    $G_3 \leftarrow k$NN-GLUE(X_3, k, α)
    $G \leftarrow$ CONQUER(G_1, G_2, G_3, k) ▷ Section 2, beginning
    REFINE(G, k) ▷ Section 2.3
  end if
end function

k smallest distances from at most $2k$ candidates for each point, and (3) the REFINE procedure which selects the k smallest distances from at most $k + k^2$ candidates for each point. Many of the distances computed from kNN-BRUTEFORCE and REFINE are reused in CONQUER and REFINE, with probably more than once for some pairs. A naive way is to allocate memory for an $n \times n$ matrix that stores all the computed distances to avoid duplicate calculations. However this consumes too much memory and is not necessary. A better approach is to use a hash table to store the computed distances. This will save a significant amount of memory, as a later experiment shows that only a small portion of the n^2 pairs are actually computed. Furthermore the computational time will not be affected since hash tables are efficient for both retrieving wanted items from and inserting new items into the table (we do not need the delete operation).

The ideal hash function maps (the distance between) a pair of data points (x_i, x_j) to a bucket such that the probability of collision is low. For simplicity of implementations, we use a hash function that maps the key (x_i, x_j) to i (and at the same time to j). Collisions easily occur since many distances between the point x_i and other points are computed during the whole process. However, this naive hashing has already shown rather appealing results in run time. More elaborate implementations should consider more effective hashing (e.g., double hashing) schemes.

3. Complexity Analysis

A thorough analysis shows that the time complexities for the overlap method and the glue method are sub-quadratic (in n), and the glue method is always asymptotically faster than the overlap method. To this end we assume that in each divide step the subsets X_1 and X_2 (in both methods) are balanced. This assumption can always be satisfied by using the Equation (3) to bisect the data set, instead of the criterion (2). Hence, the time complexity $T_{\rm o}$ for the overlap method and $T_{\rm g}$ for the glue method satisfy the following recurrence relations:

$$T_{\rm o}(n) = 2T_{\rm o}((1+\alpha)n/2) + f(n), \tag{5}$$

$$T_{\rm g}(n) = 2T_{\rm g}(n/2) + T_{\rm g}(\alpha n) + f(n), \tag{6}$$

where $f(n)$ is the combined time for the divide, conquer, and refine steps.

3.1 The Complexity of f

The function $f(n)$ consists of the following three components.

3.1.1 THE TIME FOR THE DIVIDE STEP

This includes the time to compute the largest right singular vector v of the centered matrix $\hat{X}$, and the time to divide points into subsets X_1 and X_2 (in the overlap method) or subsets X_1, X_2 and X_3 (in the glue method). The former has been shown to be $O(sdn)$ in Section 2.1, where the number of Lanczos steps $s = 5$ is fixed in the implementation, while for the latter we can use a linear time selection method to find the value $h_\alpha(V)$. Therefore the overall time for this step is $O(dn)$.

3.1.2 THE TIME FOR THE CONQUER STEP

This step only involves the points in $X_1 \cap X_2$ in the overlap method or X_3 in the glue method. For each of the αn points in these subsets, k nearest neighbors are chosen from at most $2k$ candidates. Therefore the time is $O(k\alpha n)$.

3.1.3 THE TIME FOR THE REFINE STEP

For each point, k nearest neighbors are chosen from at most $k+k^2$ candidates. If all these distances need to be computed, the overall time is $O(k^2dn)$. To the other extreme, if none of them are computed, the factor d can be omitted, which results in $O(k^2n)$. In practice, by using a hash table, only a very small fraction of the $k+k^2$ distances are actually computed in this step; see also Table 3. Hence, the best cost estimate for this step is $O(k^2n)$.

Indeed, the ultimate useful information from this estimate is that the time for the refinement is much less than that for the division (which has a $O(dn)$ cost), or at best is of the same order as the latter. This can be seen from another perspective: Let the number of neighbors k be a constant. Then even if all the distances are computed, the time is $O(k^2dn) = O(dn)$.

From the above three components and the fact that the dimension d dominates k, we conclude that $f(n)$ is bounded by $O(dn)$.

3.2 The Complexities of T_o and T_g

By substituting $f(n) = O(dn)$ into (5) and (6), we derive the closed form solutions to $T_o(n)$ and $T_g(n)$, which are stated in the following two theorems.

Theorem 1 *The time complexity for the overlap method is*

$$T_o(n) = \Theta(dn^{t_o}),$$

where

$$t_o = \log_{2/(1+\alpha)} 2 = \frac{1}{1-\log_2(1+\alpha)}.$$

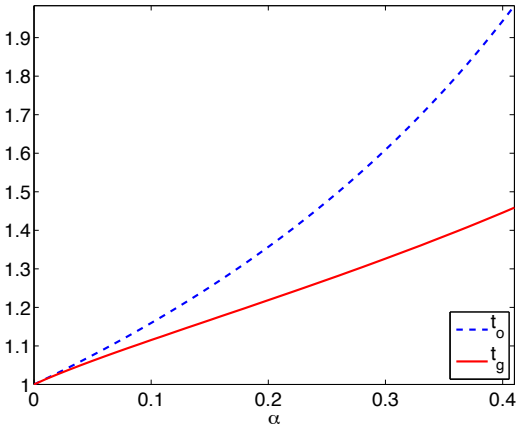
Theorem 2 *The time complexity for the glue method is*

$$T_g(n) = \Theta(dn^{t_g}/\alpha),$$

where t_g is the solution to the equation

$$\frac{2}{2^t} + \alpha^t = 1.$$

The proofs will be given in Appendix B. Figure 2 plots the two curves of t_o and t_g as functions of α, together with a table that lists some of their values. Figure 2 suggests that the glue method is asymptotically faster than the overlap method. Indeed, this is true for any choice of α.



α	0.05	0.10	0.15	0.20	0.25	0.30
t_o	1.08	1.16	1.25	1.36	1.47	1.61
t_g	1.06	1.12	1.17	1.22	1.27	1.33

Figure 2: The exponents t_o and t_g as functions of α.

Theorem 3 *When $0 < \alpha < 1$, the exponents t_o in Theorem 1 and t_g in Theorem 2 obey the following relation:*

$$1 < t_g < t_o. \tag{7}$$

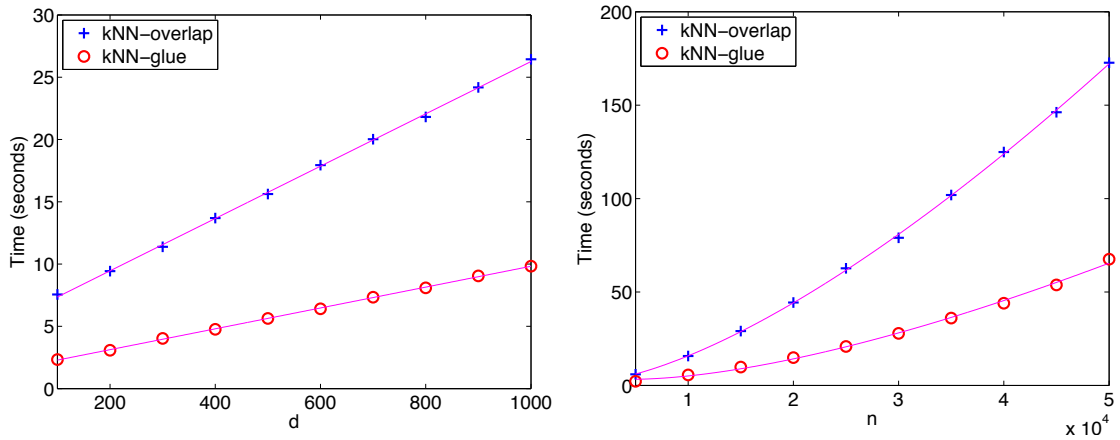
The proof of the above theorem will be given in Appendix B. We remark that when $\alpha > \sqrt{2} - 1 \approx 0.41$, $t_o > 2$. In this situation the overlap method becomes asymptotically slower than the brute-force method. Similarly, when $\alpha > 1/\sqrt{2} \approx 0.71$, $t_g > 2$. Hence, a large α (> 0.41) is not useful in practice.

4. Experiments

In this section we show a few experimental results to illustrate the running times of the two proposed methods compared with the brute-force method, and the qualities of the resulting graphs. The experiments were performed under a Linux workstation with two P4 3.20GHz CPUs and 2GB memory. The algorithms were all implemented using C/C++, and the programs were compiled using g++ with -O2 level optimization. The divide and conquer methods were implemented according to Algorithms 1 and 2, and the brute-force method was exactly as in the procedure kNN-BRUTEFORCE given in Appendix A.

4.1 Running Time

Figure 3 plots the running times versus the dimension d and the number of data points n on a synthetic data set. Since the distribution of the data should have little impact on the running times of the methods, we used random data (drawn from the uniform distribution over $[0,1]^d$) for this experiment. From Figure 3(a), it is clear that the running time is linear with respect to the dimension d. This is expected from the complexity analysis. In Figure 3(b), we used $\alpha = 0.2$, which corresponds to the theoretical values $t_o = 1.36$ and $t_g = 1.22$. We used curves in the form $c_1 n^{1.36} + c_2 n + c_3$ and $c_4 n^{1.22} + c_5 n + c_6$ to fit the running times of the overlap method and the glue method, respectively. The fitted curves are also shown in Figure 3. It can be seen that the experimental results match the theoretical analysis quite well.



(a) $n = 10000, \alpha = 0.2, d$ varying (b) $d = 500, \alpha = 0.2, n$ varying

Figure 3: The running times for randomly generated data.

4.2 Quality

In another experiment, we used four real-life data sets to test the qualities of the resulting kNN graphs: The FREY[3] face video frames (Roweis and Saul, 2000), the extYaleB[4] database (Lee et al.,

3. FREY can be found at http://www.cs.toronto.edu/~roweis/data.html.
4. extYaleB can be found at http://vision.ucsd.edu/~leekc/ExtYaleDatabase/ExtYaleB.html.

2005), the MNIST[5] digit images (LeCun et al., 1998), and the PIE[6] face database (Sim et al., 2003). These data sets are all image sets that are widely used in the literature in the areas of face recognition, dimensionality reduction, etc. For MNIST, we used only the test set. Table 1 gives some characteristics of the data. The number of images is equal to n and the size of each image, that is, the total number of pixels for each image, is the dimension d. The dimensions vary from about 500 to 10,000. Since some of these data sets were also used later to illustrate the practical usefulness of our methods in real applications, for each one we used a specific k value that was used in the experiments of past publications. These values are typically around 10.

	FREY	extYaleB	MNIST	PIE
# imgs (n)	1,965	2,414	10,000	11,554
img size (d)	20×28	84×96	28×28	32×32

Table 1: Image data sets.

The qualities of the resulting graphs versus the running times are plotted in Figure 4. Each plotted point in the figure corresponds to a choice of α ($= 0.05, 0.10, 0.15, 0.20, 0.25, 0.30$). The running times of the brute-force method are also indicated. We use two quality criteria: *accuracy* and *average rank*. The *accuracy* of an approximate kNN graph G' (with regard to the exact graph G) is defined as

$$\text{accuracy}(G') = \frac{|E(G') \cap E(G)|}{|E(G)|},$$

where $E(\cdot)$ means the set of directed edges in the graph. Thus, the accuracy is within the range $[0,1]$, and higher accuracy means better quality. The rank $r_u(v)$ of a vertex v with regard to a vertex u is the position of v in the vertex list sorted in ascending order of the distance to u. (By default, the rank of the nearest neighbor of u is 1.) Thus, the *average rank* is defined as

$$\text{ave-rank}(G') = \frac{1}{kn} \sum_u \sum_{v \in N(u)} r_u(v),$$

where $N(u)$ means the neighborhood of u in the graph G'. The exact kNN graph has the average rank $(1+k)/2$.

It can be seen from Figure 4 that the qualities of the resulting graphs exhibit similar trends by using both measures. Take the graph accuracy for example. The larger α, the more accurate the resulting graph. However, larger values of α lead to more time-consuming runs. In addition, the glue method is much faster than the overlap method for the same α, while the latter yields more accurate graphs than the former. The two methods are both significantly faster than the brute-force method when an appropriate α is chosen, and they can yield high quality graphs even when α is small.

It is interesting to note that in all the plots, the red circle-curve and the blue plus-curve roughly overlap. This similar quality-time trade-off seems to suggest that neither of the method is superior to the other one; the only difference is the α value used to achieve the desired quality. However, we note that different approximate graphs can yield the same accuracy value or average rank value, hence the actual quality of the graph depends on real applications.

5. MNIST can be found at `http://yann.lecun.com/exdb/mnist`.
6. PIE can be found at `http://www.cs.uiuc.edu/homes/dengcai2/Data/FaceData.html`.

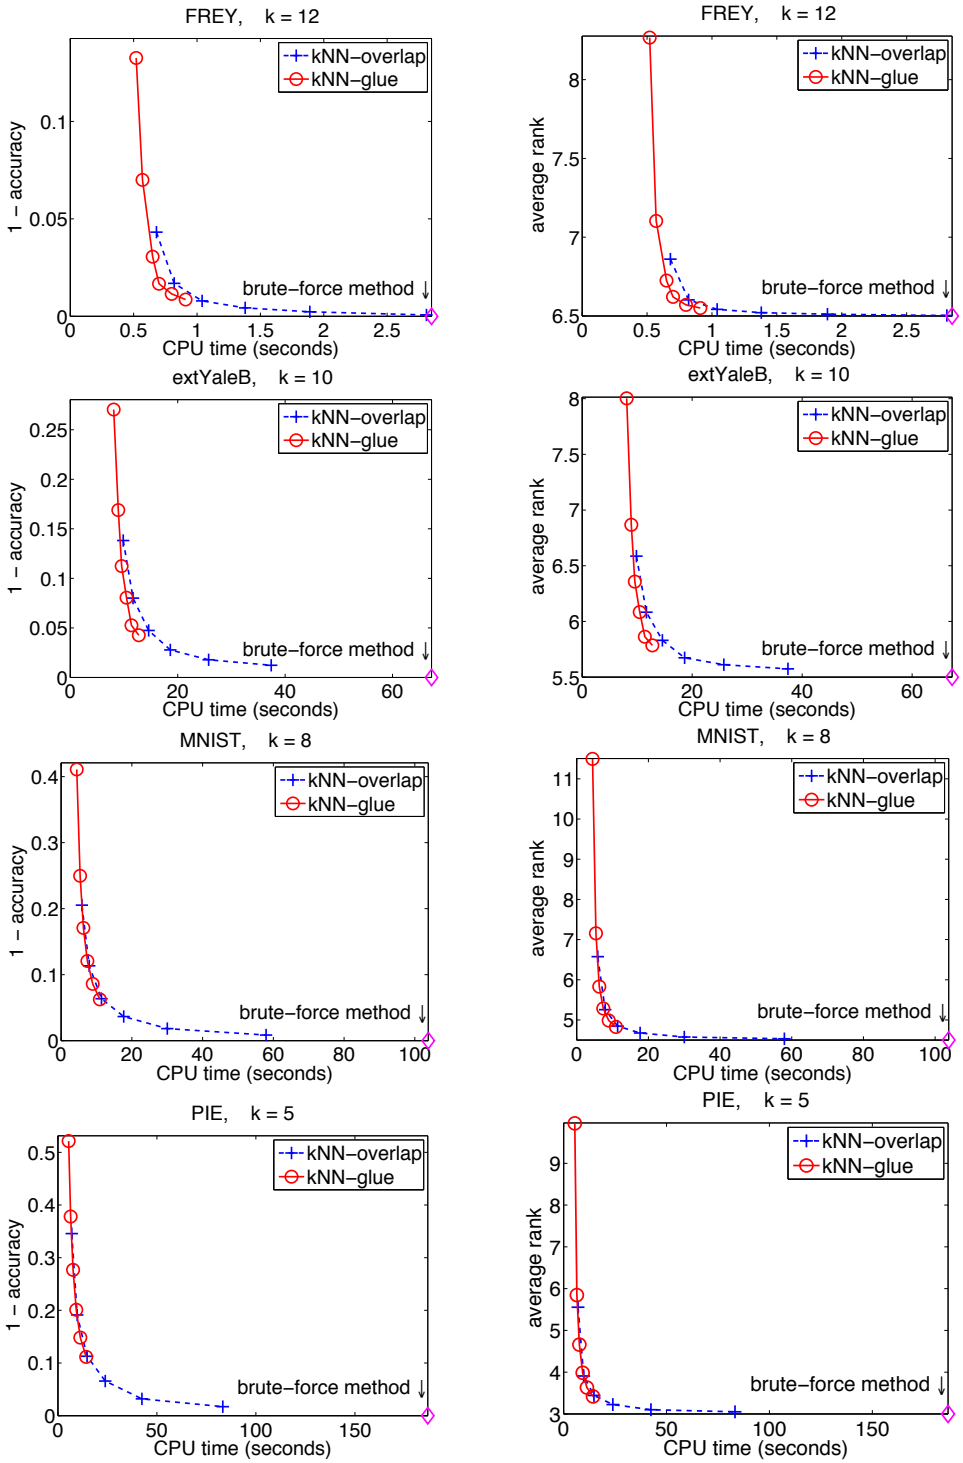


Figure 4: Graph quality versus running time for different data sets. Each row of the plots corresponds to one data set. The left column of plots shows the 1−accuracy measure. The right column shows the average-rank measure. Each plotted point corresponds to a choice of α. From left to right on each curve, the α values are $0.05, 0.10, 0.15, 0.20, 0.25, 0.30$, respectively.

4.3 Distance Calculations and Refinements

We also report the percentage of the distance calculations, which is one of the dominant costs of the graph construction. The superior efficiency of our methods lies in two facts. First, for n data points, the brute-force method must compute distances between $n(n-1)/2$ pairs of points, while our methods compute only a small fraction of this number. Second, the use of a (hash) table brings the benefit of avoiding repeating distance calculations if the evaluations of the same distance are required multiple times. Tables 2 and 3 confirm these two claims. As expected, the larger the common region (α) is, the more distances need to be calculated, while the benefit of the hashing becomes more significant. It can also be seen that the savings in distance calculations are more remarkable when n becomes larger and k becomes smaller, for example, $k = 5$ for the data set PIE.

	FREY ($k = 12$)		extYaleB ($k = 10$)		MNIST ($k = 8$)		PIE ($k = 5$)	
α	overlap	glue	overlap	glue	overlap	glue	overlap	glue
0.05	6.07%	5.10%	5.13%	4.42%	1.19%	0.94%	0.45%	0.35%
0.10	6.55%	5.80%	5.58%	5.08%	1.42%	1.22%	0.60%	0.47%
0.15	7.48%	6.35%	6.05%	5.46%	1.74%	1.36%	0.78%	0.56%
0.20	8.28%	6.57%	6.66%	5.66%	2.20%	1.52%	1.06%	0.66%
0.25	9.69%	7.00%	7.36%	6.02%	2.92%	1.71%	1.48%	0.77%
0.30	11.48%	7.46%	8.34%	6.26%	4.04%	1.91%	2.07%	0.90%

Table 2: Percentages of distance calculations (with respect to $n(n-1)/2$), for different data sets, different methods, and different α's.

	FREY ($k = 12$)		extYaleB ($k = 10$)		MNIST ($k = 8$)		PIE ($k = 5$)	
α	overlap	glue	overlap	glue	overlap	glue	overlap	glue
0.05	9.44%	12.15%	11.46%	14.80%	9.56%	11.55%	6.85%	7.01%
0.10	7.07%	12.09%	8.46%	14.36%	6.82%	11.76%	5.27%	8.14%

0.20	3.65%	9.12%	4.35%	11.04%	2.98%	8.49%	2.15%	6.40%
0.05	2.62%	7.52%	2.90%	9.55%	1.77%	6.85%	1.23%	5.19%
0.30	1.83%	6.44%	1.88%	7.89%	0.96%	5.41%	0.62%	4.13%

Table 3: Percentages of actual distance calculations with respect to the total number of needed distances in the refine step, for different data sets, different methods, and different α's. This is equivalent to the failure rate of hash table lookups.

The final experiment illustrates the importance of the refine step. Figure 5 shows the decrease in quality if the REFINE procedure is not invoked. The refinement greatly improves the accuracy of the approximate graph (especially for α less than 0.2) at some additional cost in the execution time. This additional expense is worthwhile if the goal is to compute a high quality kNN graph.

5. Applications

kNN graphs have been widely used in various data mining and machine learning applications. This section discusses two scenarios where the approximate kNN graphs resulting from our proposed techniques can provide an effective replacement for the exact kNN graph.

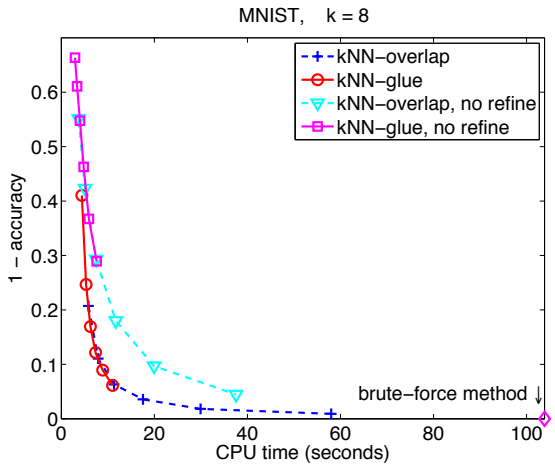

Figure 5: The refine step boosts the accuracy of the graph at some additional computational cost. Data set: MNIST. The settings are the same as in Figure 4.

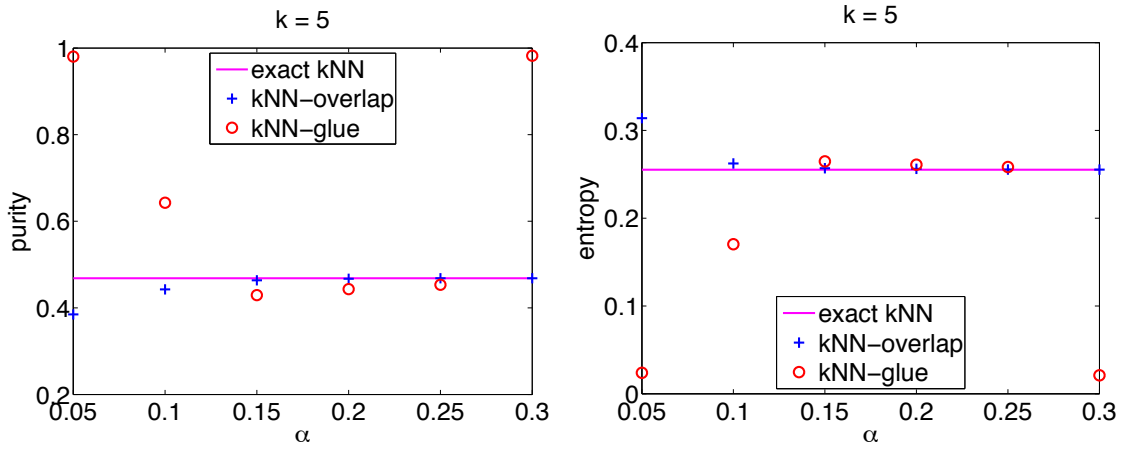
5.1 Agglomerative Clustering

Agglomerative clustering (Ward, 1963) is a clustering method which exploits a hierarchy for a set of data points. Initially each point belongs to a separate cluster. Then, the algorithm iteratively merges a pair of clusters that has the lowest merge cost, and updates the merge costs between the newly merged cluster and the rest of the clusters. This process terminates when the desired number of clusters is reached (or when all the points belong to the single final cluster). A straightforward implementation of the method takes $O(n^3)$ time, since there are $O(n)$ iterations, each of which takes $O(n^2)$ time to find the pair with the lowest merge cost (Shanbehzadeh and Ogunbona, 1997). Fränti et al. (2006) proposed, at each iteration, to maintain the kNN graph of the clusters, and merge two clusters that are the nearest neighbors in the graph. Let the number of clusters at the present iteration be m. Then this method takes $O(km)$ time to find the closest clusters, compared with the $O(m^2)$ cost of finding the pair with the lowest merge cost. With a delicate implementation using a doubly linked list, they showed that the overall running time of the clustering process reduces to $O(\tau n \log n)$, where τ is the number of nearest neighbor updates at each iteration. Their method greatly speeds up the clustering process, while the clustering quality is not much degraded.

However, the quadratic time to create the initial kNN graph eclipses the improvement in the clustering time. One solution is to use an approximate kNN graph that can be inexpensively created. Virmajoki and Fränti (2004) proposed a divide-and-conquer algorithm to create an approximate kNN graph, but their time complexity was overestimated. Our approach also follows the common framework of divide and conquer. However, we bring three improvements over previous work: (1) Two methods to perform the divide step are proposed, (2) an efficient way to compute the separating hyperplane is described, and (3) a detailed and rigorous analysis on the time complexity is provided. This analysis in particular makes the proposed algorithms practical, especially in the presence of high dimensional data (e.g., when d is in the order of hundreds or thousands).

We performed an experiment on the data set PIE with 68 classes (see Figure 6). Since class labels are known, we used the purity and the entropy (Zhao and Karypis, 2004) as quality measures.



(a) Purity.

(b) Entropy.

(c) Sum of squared errors.

Figure 6: Agglomerative clustering using kNN graphs on the image data set PIE (68 human subjects).

They are defined as

$$\text{Purity} = \sum_{i=1}^{q} \frac{n_i}{n} \text{Purity}(i), \qquad \text{where} \qquad \text{Purity}(i) = \frac{1}{n_i} \max_j \left(n_i^j \right),$$

and

$$\text{Entropy} = \sum_{i=1}^{q} \frac{n_i}{n} \text{Entropy}(i), \qquad \text{where} \qquad \text{Entropy}(i) = -\sum_{j=1}^{q} \frac{n_i^j}{n_i} \log_q \frac{n_i^j}{n_i}.$$

Here, q is the number of classes/clusters, n_i is the size of cluster i, and n_i^j is the number of class j data that are assigned to the i-th cluster. The purity and the entropy both range from 0 to 1. In Figure 6 we show the purities, the entropies, and the values of the objective function for a general purpose clustering (sum of squared errors, SSE), for different methods and different α's. In general,

a higher purity, a lower entropy, and/or a lower SSE means a better clustering quality. As can be seen the qualities of the clusterings obtained from the approximate kNN graphs are very close to those resulting from the exact graph, with a few being even much better. It is interesting to note that the clustering results seem to have little correlation with the qualities of the graphs governed by the value α.

5.2 Dimensionality Reduction

Many dimensionality reduction methods, for example, locally linear embedding (LLE) (Roweis and Saul, 2000), Laplacian eigenmaps (Belkin and Niyogi, 2003), locality preserving projections (LPP) (He and Niyogi, 2004), and orthogonal neighborhood preserving projections (ONPP) (Kokiopoulou and Saad, 2007), compute a low dimensional embedding of the data by preserving the local neighborhoods for each point. For example, in LLE, a weighted adjacency matrix W is first computed to minimize the following objective:

$$\mathcal{E}(W) = \sum_i \left\| x_i - \sum_{x_j \in N(x_i)} W_{ij} x_j \right\|^2, \qquad \text{subject to } \sum_j W_{ij} = 1,\ \forall i,$$

where $N(\cdot)$ means the neighborhood of a point. Then, a low dimensional embedding $Y = [y_1, \ldots, y_n]$ is computed such that it minimizes the objective:

$$\Phi(Y) = \sum_i \left\| y_i - \sum_{y_j \in N(y_i)} W_{ij} y_j \right\|^2, \qquad \text{subject to } YY^T = I.$$

The final solution, Y, is the matrix whose column-vectors are the r bottom right singular vectors of the Laplacian matrix $L_{\text{LLE}} = I - W$. As another example, in Laplacian eigenmaps, the low dimensional embedding $Y = [y_1, \ldots, y_n]$ is computed so as to minimize the cost function:

$$\Psi(Y) = \sum_{i,j} W_{ij} \left\| y_i - y_j \right\|^2, \qquad \text{subject to } YDY^T = I,$$

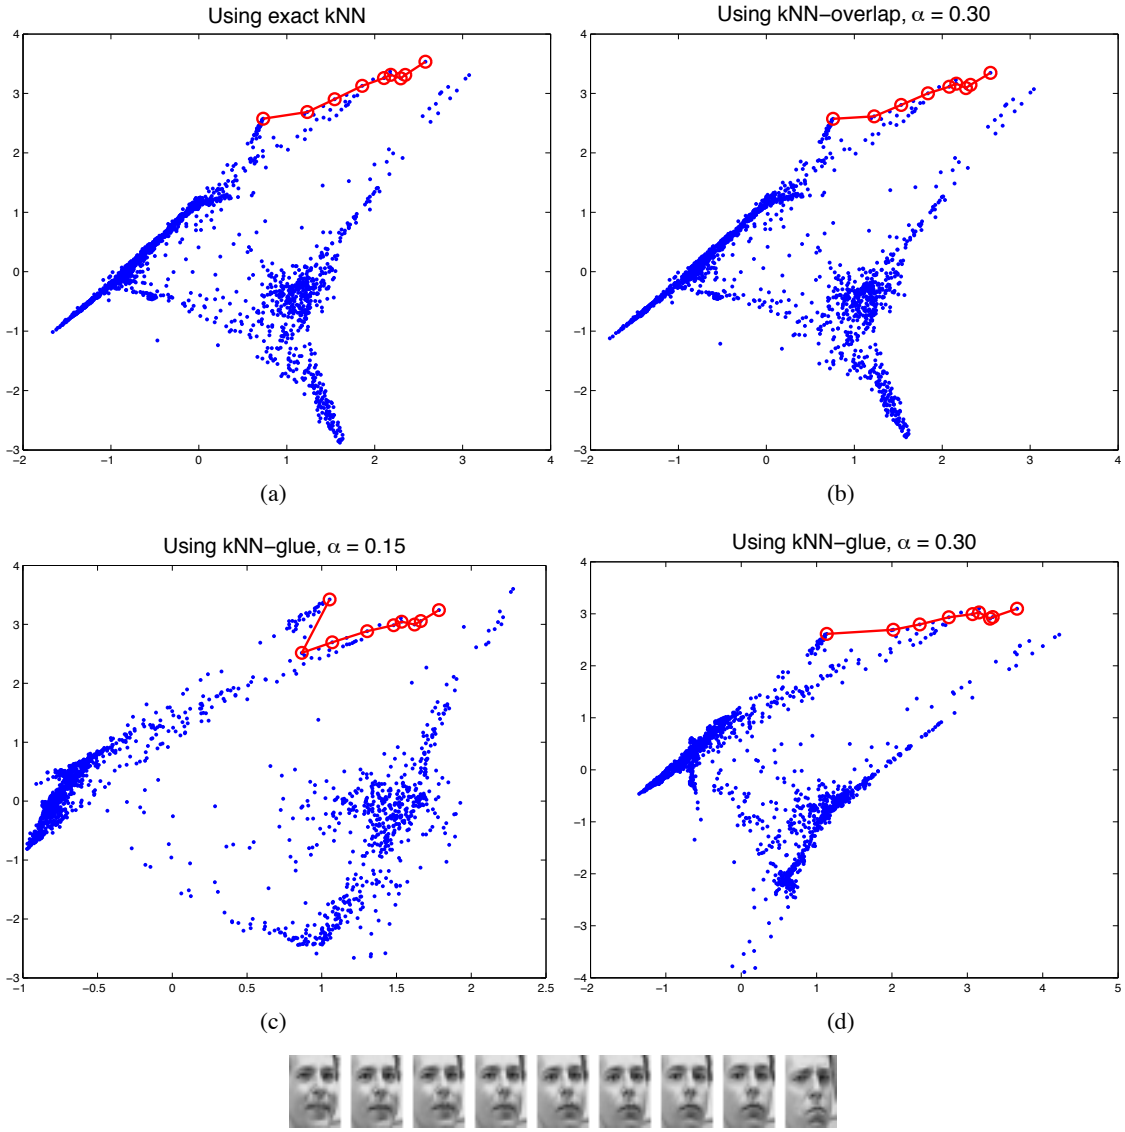
where D is the diagonal degree matrix. Here, the weighted adjacency matrix W is defined in a number of ways, one of the most popular being the weights of the heat kernel

$$W_{ij} = \begin{cases} \exp(-\left\| x_i - x_j \right\|^2 / \sigma^2) & \text{if } x_i \in N(x_j) \text{ or } x_j \in N(x_i), \\ 0 & \text{otherwise.} \end{cases}$$

The solution, Y, is simply the matrix of r bottom eigenvectors of the normalized Laplacian matrix $L_{\text{eigenmaps}} = I - D^{-1/2} W D^{-1/2}$ (subject to scaling).

A thorn in the nicely motivated formulations for the above approaches, is that they all begin with a rather expensive computation to obtain the neighborhood graph of the data. On the other hand, the cost of computing the solution Y via, for example, the Lanczos algorithm, is relatively inexpensive, and can be summarized as[7] $O(rkn)$, which is independent of the dimension d. The methods discussed in this paper are suitable alternatives to the expensive brute-force approach to

7. To be more exact, the dominant cost of computing r singular vectors/eigenvectors of a sparse matrix by the Lanczos method is $O(r' \cdot \text{nnz})$, where r' is the number of Lanczos steps and nnz is the number of nonzeros in the matrix. The value r' is in practice a few times of r, and in our situation, the matrix is the (normalized) graph Laplacian, hence $\text{nnz} = O(kn)$.



(e) Images on the circle path. Facial expressions gradually change.

Figure 7: Dimensionality reduction on the data set FREY by LLE.

extract the exact *k*NN graph, since the approximate graphs are accurate enough for the purpose of dimensionality reduction, while the time costs are significantly smaller. Figures 7 and 8 provide two illustrations of this.

In Figure 7 are the plots of the dimensionality reduction results of LLE applied to the data set FREY, where we used $k = 12$ as that in Roweis and Saul (2000, Figure 3). Figure 7(a) shows the result when using the exact *k*NN graph, while Figure 7(b) shows the result when using the approximate *k*NN graph by the overlap method with $\alpha = 0.30$. It is clear that the two results are almost identical. Figures 7(c) and 7(d) give two plots when the glue method is used. Although the

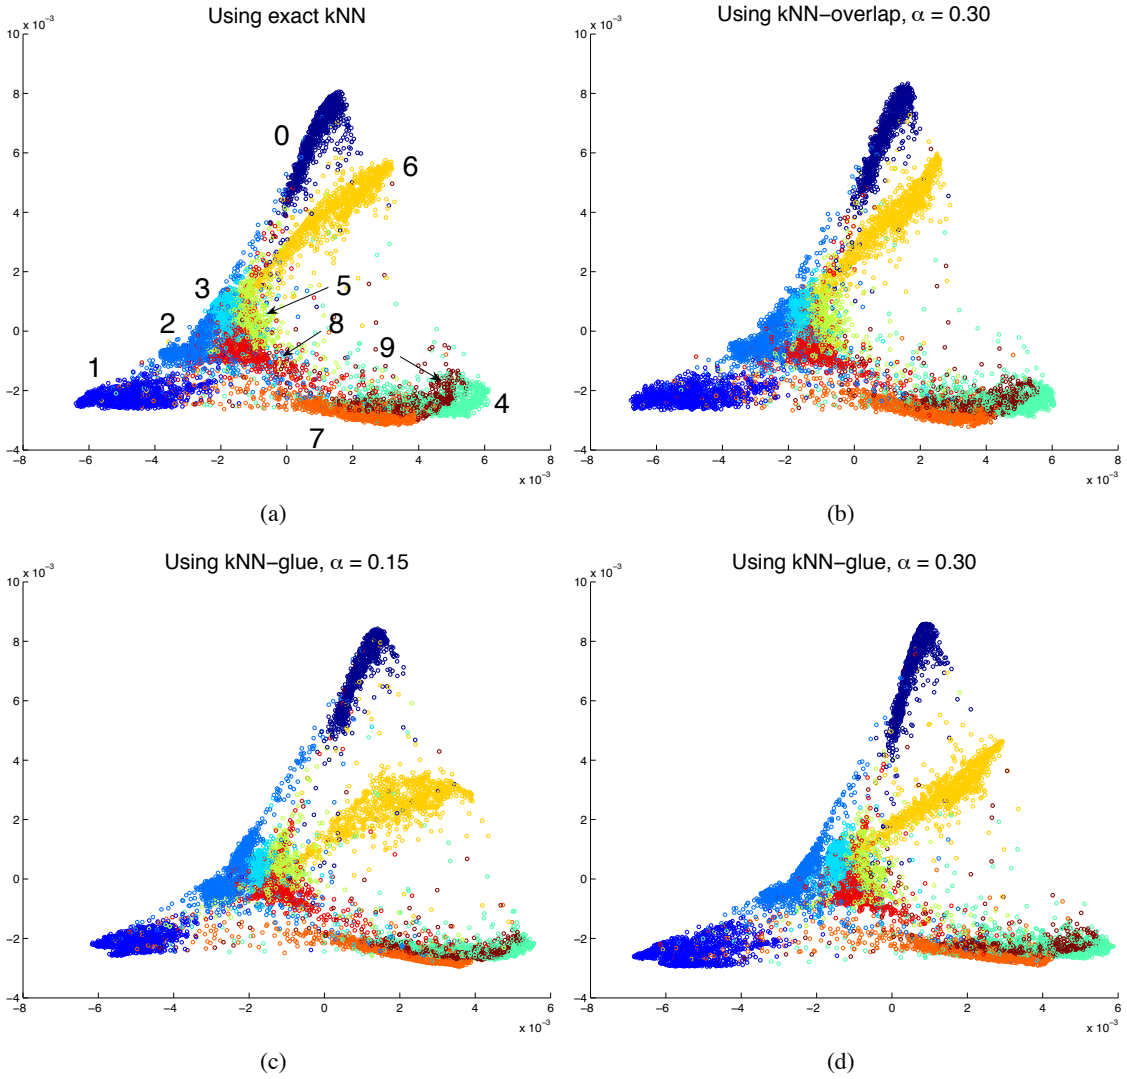


Figure 8: Dimensionality reduction on the data set MNIST by Laplacian eigenmaps.

embeddings are different from those of the exact kNN graph in Figure 7(a), they also represent the original data manifold quite well. This can be seen by tracking the relative locations of the sequence of images (as shown in 7(e)) in the two dimensional space.

Figure 8 shows the plots of the dimensionality reduction results of Laplacian eigenmaps applied to the data set MNIST, where we used $k = 5$. Figure 8(a) shows the original result by using the exact kNN graph, while 8(b), 8(c) and 8(d) show the results by using the overlap method with $\alpha = 0.30$, the glue method with $\alpha = 0.15$, and the glue method with $\alpha = 0.30$, respectively. The four plots all show clear clusterings of the ten classes (digits from 0 to 9), and the localization patterns of the clusterings are very similar.

6. Conclusions

We have proposed two sub-quadratic time methods under the framework of divide and conquer for computing approximate kNN graphs for high dimensional data. The running times of the methods, as well as the qualities of the resulting graphs, depend on an internal parameter that controls the overlap size of the subsets in the divide step. Experiments show that in order to obtain a high quality graph, a small overlap size is usually sufficient and this leads to a small exponent in the time complexity. An avenue of future research is to theoretically analyze the quality of the resulting graphs in relation to the overlap size. The resulting approximate graphs have a wide range of applications as they can be safely used as alternatives to the exact kNN graph. We have shown two such examples: one in agglomerative clustering and the other in dimensionality reduction. Thus, replacing the exact kNN graph construction with one produced by the methods proposed here, can significantly alleviate what currently constitutes a major bottleneck in these applications.

Appendix B. Proofs

Theorem 1 follows from the Master Theorem (Cormen et al., 2001, Chapter 4.3). Theorem 2 is an immediate consequence of the following lemma, which is straightforward to verify.

Lemma 4 *The recurrence relation*

$$T(n) = 2T(n/2) + T(\alpha n) + n$$

with $T(1) = 1$ *has a solution*

$$T(n) = \left(1 + \frac{1}{\alpha}\right) n^t - \frac{n}{\alpha}$$

where t *is the solution to the equation*

$$\frac{2}{2^t} + \alpha^t = 1.$$

The proof of Theorem 3 requires two lemmas.

Lemma 5 *When* $0 < x < 1$,

$$\log_2(1-x^2) > \Big(\log_2(1-x)\Big)\Big(\log_2(1+x)\Big).$$

Proof By Taylor expansion,

$$\begin{aligned}
&\Big(\ln(1-x)\Big)\Big(\ln(1+x)\Big)\\
&= \left(-\sum_{n=1}^{\infty}\frac{x^n}{n}\right)\left(\sum_{n=1}^{\infty}\frac{(-1)^{n+1}x^n}{n}\right)\\
&= -\sum_{n=1}^{\infty}\left(\sum_{m=1}^{2n-1}\frac{(-1)^{m-1}}{m(2n-m)}\right)x^{2n}\\
&= -\sum_{n=1}^{\infty}\left(\frac{1}{2n}\left(\frac{1}{1}+\frac{1}{2n-1}\right)-\frac{1}{2n}\left(\frac{1}{2}+\frac{1}{2n-2}\right)+\cdots+\frac{(-1)^{n-1}}{n^2}\right.\\
&\qquad\left.+\cdots-\frac{1}{2n}\left(\frac{1}{2n-2}+\frac{1}{2}\right)+\frac{1}{2n}\left(\frac{1}{2n-1}+\frac{1}{1}\right)\right)x^{2n}\\
&= -\sum_{n=1}^{\infty}\left(\frac{1}{n}\left(1-\frac{1}{2}+\frac{1}{3}+\cdots+\frac{1}{2n-1}\right)\right)x^{2n}\\
&< -\sum_{n=1}^{\infty}\left(\frac{\ln 2}{n}\right)x^{2n}\\
&= (\ln 2)\cdot\ln(1-x^2).
\end{aligned}$$

The inequality in the lemma follows by changing the bases of the logarithms. ■

Lemma 6 *The following inequality*

$$\log_2(ab) > (\log_2 a)(\log_2 b)$$

holds whenever $0 < a < 1 < b < 2$ *and* $a+b \geq 2$.

Proof By using $b \geq 2-a$, we have the following two inequalities

$$\log_2(ab) \geq \log_2(a(2-a)) = \log_2(1-(1-a))(1+(1-a)) = \log_2(1-(1-a)^2)$$

and

$$(\log_2 a)(\log_2 b) \leq (\log_2 a)(\log_2(2-a)) = \log_2(1-(1-a))\times\log_2(1+(1-a)).$$

Then by applying Lemma 5 with $1-a=x$, we have

$$\log_2(1-(1-a)^2) > \log_2(1-(1-a))\times\log_2(1+(1-a)).$$

Thus, the inequality of the lemma holds. ■

Proof of Theorem 3 From Theorem 2 we have

$$t_{\mathrm{g}} = 1 - \log_2(1-\alpha^{t_{\mathrm{g}}}) > 1.$$

Then

$$\begin{aligned} t_{\mathrm{o}} - t_{\mathrm{g}} &= \frac{1}{1-\log_2(1+\alpha)} - 1 + \log_2(1-\alpha^{t_{\mathrm{g}}}) \\ &= \frac{\log_2(1+\alpha) + \log_2(1-\alpha^{t_{\mathrm{g}}}) - \log_2(1+\alpha)\times\log_2(1-\alpha^{t_{\mathrm{g}}})}{1-\log_2(1+\alpha)}. \end{aligned}$$

Since $0 < \alpha < 1$, the denominator $1-\log_2(1+\alpha)$ is positive. By Lemma 6 the numerator is also positive. Hence $t_{\mathrm{o}} > t_{\mathrm{g}}$. ■

Abstract

Variable selection in high-dimensional space characterizes many contemporary problems in scientific discovery and decision making. Many frequently-used techniques are based on independence screening; examples include correlation ranking (Fan & Lv, 2008) or feature selection using a two-sample t-test in high-dimensional classification (Tibshirani et al., 2003). Within the context of the linear model, Fan & Lv (2008) showed that this simple correlation ranking possesses a sure independence screening property under certain conditions and that its revision, called iteratively sure independent screening (ISIS), is needed when the features are marginally unrelated but jointly related to the response variable. In this paper, we extend ISIS, without explicit definition of residuals, to a general pseudo-likelihood framework, which includes generalized linear models as a special case. Even in the least-squares setting, the new method improves ISIS by allowing feature deletion in the iterative process. Our technique allows us to select important features in high-dimensional classification where the popularly used two-sample t-method fails. A new technique is introduced to reduce the false selection rate in the feature screening stage. Several simulated and two real data examples are presented to illustrate the methodology.

Keywords: classification, feature screening, generalized linear models, robust regression, feature selection

1. Introduction

The remarkable development of computing power and other technology has allowed scientists to collect data of unprecedented size and complexity. Examples include data from microarrays, proteomics, brain images, videos, functional data and high-frequency financial data. Such a demand from applications presents many new challenges as well as opportunities for those in statistics and machine learning, and while some significant progress has been made in recent years, there remains a great deal to do.

A very common statistical problem is to model the relationship between one or more output variables Y and their associated covariates (or features) $X_1, \ldots, X_p$, based on a sample of size n. A characteristic feature of many of the modern problems mentioned in the previous paragraph is that the dimensionality p is large, potentially much larger than n. Mathematically, it makes sense to consider p as a function of n, which diverges to infinity. The dimensionality grows very rapidly when interactions of the features are considered, which is necessary for many scientific endeavors. For example, in disease classification using microarray gene expression data (Tibshirani et al., 2003; Fan & Ren, 2006), the number of arrays is usually in the order of tens or hundreds while the number of gene expression profiles is in the order of tens of thousands; in the study of protein-protein interactions, the sample size may be in the order of thousands, but the number of features can be in the order of millions.

The phenomenon of noise accumulation in high-dimensional classification and regression has long been observed by statisticians and computer scientists (see Vapnik 1995, Hastie et al. 2009 and references therein) and has been analytically demonstrated by Fan & Fan (2008). Various feature selection techniques have been proposed in both the statistics and machine learning literature, and introductions and overviews written for the machine learning community can be found in, for example, Liu & Motoda (1998), Guyon & Elisseeff (2003) and Guyon et al. (2006). Specific algorithms proposed include but are not restricted to FCBF (Yu & Li, 2003), CFS (Hall, 2000), ReliefF (Kononenko, 1994), FOCUS (Almuallim & Dietterich, 1994) and INTERACT (Zhao & Liu, 2007). See also the special issue published by JMLR on "variable and feature selection", including Bi et al. (2003), Bengio & Chapados (2003) and Guyon & Elisseeff (2003).

One particularly popular family of methods is based on penalized least-squares or, more generally, penalized pseudo-likelihood. Examples include the LASSO (Tibshirani, 1996), SCAD (Fan & Li, 2001), the Dantzig selector (Candes & Tao, 2007), and their related methods. These methods have attracted a great deal of theoretical study and algorithmic development recently. See Donoho & Elad (2003), Efron et al. (2004), Zou (2006), Meinshausen & Bühlmann (2006), Zhao & Yu (2006), Zou & Li (2008), Bickel et al. (2009), and references therein. However, computation inherent in those methods makes them hard to apply directly to ultrahigh-dimensional statistical learning problems, which involve the simultaneous challenges of computational expediency, statistical accuracy, and algorithmic stability.

A method that takes up the aforementioned three challenges is the idea of independent learning, proposed and demonstrated by Fan & Lv (2008) in the regression context. The method can be derived from an empirical likelihood point of view (Hall et al., 2009) and is related to supervised principal component analysis (Bair et al., 2006; Paul et al., 2008). In the important, but limited, context of the linear model, Fan & Lv (2008) proposed a two-stage procedure to deal with this problem. First, so-called independence screening is used as a fast but crude method of reducing the dimensionality to a more moderate size (usually below the sample size); then, a more sophisticated technique, such as a penalized likelihood method based on the smoothly clipped absolute deviation (SCAD) penalty, can be applied to perform the final feature selection and parameter estimation simultaneously.

Independence screening recruits those features having the best marginal utility, which corresponds to the largest marginal correlation with the response in the context of least-squares regression. Under certain regularity conditions, Fan & Lv (2008) show surprisingly that this fast feature selection method has a 'sure screening property'; that is, with probability very close to 1, the independence screening technique retains all of the important features in the model. A remarkable

feature of this theoretical result is that the dimensionality of the model is allowed to grow exponentially in the sample size; for this reason, we refer to the method as an 'ultrahigh' dimensional feature selection technique, to distinguish it from other 'high' dimensional methods where the dimensionality can grow only polynomially in the sample size. The sure screening property is described in greater detail in Section 3.2, and as a result of this theoretical justification, the method is referred to as Sure Independence Screening (SIS).

An important methodological extension, called Iterated Sure Independence Screening (ISIS), covers cases where the regularity conditions may fail, for instance if a feature is marginally uncorrelated, but jointly correlated with the response, or the reverse situation where a feature is jointly uncorrelated but has higher marginal correlation than some important features. Roughly, ISIS works by iteratively performing feature selection to recruit a small number of features, computing residuals based on the model fitted using these recruited features, and then using the working residuals as the response variable to continue recruiting new features. The crucial step is to compute the working residuals, which is easy for the least-squares regression problem but not obvious for other problems. The improved performance of ISIS has been documented in Fan & Lv (2008).

Independence screening is a commonly used techniques for feature selection. It has been widely used for gene selection or disease classification in bioinformatics. In those applications, the genes or proteins are called statistically significant if their associated expressions in the treatment group differ statistically from the control group, resulting in a large and active literature on the multiple testing problem. See, for example, Dudoit et al. (2003) and Efron (2008). The selected features are frequently used for tumor/disease classification. See, for example, Tibshirani et al. (2003), and Fan & Ren (2006). This screening method is indeed a form of independence screening and has been justified by Fan & Fan (2008) under some ideal situations. However, common sense can carry us only so far. As indicated above and illustrated further in Section 4.1, it is easy to construct features that are marginally unrelated, but jointly related with the response. Such features will be screened out by independent learning methods such as the two-sample t test. In other words, genes that are screened out by test statistics can indeed be important in disease classification and understanding molecular mechanisms of the disease. How can we construct better feature selection procedures in ultrahigh dimensional feature space than the independence screening popularly used in feature selection?

The first goal of this paper is to extend SIS and ISIS to much more general models. One challenge here is to make an appropriate definition of a residual in this context. We describe a procedure that effectively sidesteps this issue and therefore permits the desired extension of ISIS. In fact, our method even improves the original ISIS of Fan & Lv (2008) in that it allows variable deletion in the recruiting process. Our methodology applies to a very general pseudo-likelihood framework, in which the aim is to find the parameter vector $\beta = (\beta_1, \ldots, \beta_p)^T$ that is sparse and minimizes an objective function of the form

$$Q(\beta_0, \beta) = \sum_{i=1}^{n} L(Y_i, \beta_0 + \mathbf{x}_i^T \beta),$$

where $(\mathbf{x}_i^T, Y_i)$ are the covariate vector and response for the i^{th} individual. Important applications of this methodology, which is outlined in greater detail in Section 2, include the following:

1. **Generalized linear models**: All generalized linear models, including logistic regression and Poisson log-linear models, fit very naturally into our methodological framework. See McCullagh & Nelder (1989) for many applications of generalized linear models. Note in particular

that logistic regression models yield a popular approach for studying classification problems. In Section 4, we present simulations in which our approach compares favorably with the competing LASSO technique (Tibshirani, 1996).

2. **Classification**: Other common approaches to classification assume the response takes values in $\{-1,1\}$ and also fit into our framework. For instance, support vector machine classifiers (Vapnik, 1995) use the hinge loss function $L(Y_i, \beta_0 + \mathbf{x}_i^T\beta) = \{1 - Y_i(\beta_0 + \mathbf{x}_i^T\beta)\}_+$, while the boosting algorithm AdaBoost (Freund & Schapire, 1997) uses $L(Y_i, \beta_0 + \mathbf{x}_i^T\beta) = \exp\{-Y_i(\beta_0 + \mathbf{x}_i^T\beta)\}$.

3. **Robust fitting**: In a high-dimensional linear model setting, it is advisable to be cautious about the assumed relationship between the features and the response. Thus, instead of the conventional least squares loss function, we may prefer a robust loss function such as the L_1 loss $L(Y_i, \beta_0 + \mathbf{x}_i^T\beta) = |Y_i - \beta_0 - \mathbf{x}_i^T\beta|$ or the Huber loss (Huber, 1964), which also fits into our framework.

Any screening method, by default, has a large false selection rate (FSR), namely, many unimportant features are selected after screening. A second aim of this paper, covered in Section 3, is to present two variants of the SIS methodology, which reduce significantly the FSR. Both are based on partitioning the data into (usually) two groups. The first has the desirable property that in high-dimensional problems the probability of incorrectly selecting unimportant features is small. Thus this method is particularly useful as a means of quickly identifying features that should be included in the final model. The second method is less aggressive, and for the linear model has the same sure screening property as the original SIS technique. The applications of our proposed methods are illustrated in Section 5.

2. ISIS Methodology in a General Framework

Let $\mathbf{y} = (Y_1, \ldots, Y_n)^T$ be a vector of responses and let $\mathbf{x}_1, \ldots, \mathbf{x}_n$ be their associated covariate (column) vectors, each taking values in $\mathbb{R}^p$. The vectors $(\mathbf{x}_1^T, Y_1), \ldots, (\mathbf{x}_n^T, Y_n)$ are assumed to be independent and identically distributed realizations from the population $(X_1, \ldots, X_p, Y)^T$. The $n \times p$ design matrix is $\mathbf{X} = (\mathbf{x}_1, \ldots, \mathbf{x}_n)^T$.

2.1 Feature Ranking by Marginal Utilities

The relationship between Y and $(X_1, \ldots, X_p)^T$ is often modeled through a parameter vector $\beta = (\beta_1, \ldots, \beta_p)^T$, and the fitting of the model amounts to minimizing a negative pseudo-likelihood function of the form

$$Q(\beta_0, \beta) = n^{-1} \sum_{i=1}^{n} L(Y_i, \beta_0 + \mathbf{x}_i^T\beta).$$

Here, L can be regarded as the loss of using $\beta_0 + \mathbf{x}_i^T\beta$ to predict Y_i. The marginal utility of the j^{th} feature is

$$L_j = \min_{\beta_0, \beta_j} n^{-1} \sum_{i=1}^{n} L(Y_i, \beta_0 + X_{ij}\beta_j),$$

which minimizes the loss function, where $\mathbf{x}_i = (X_{i1}, \ldots, X_{ip})^T$. The idea of SIS in this framework is to compute the vector of marginal utilities $\mathbf{L} = (L_1, \ldots, L_p)^T$ and rank them according to the

marginal utilities: the smaller the more important. Note that in order to compute L_j, we need only fit a model with two parameters, β_0 and β_j, so computing the vector $\mathbf{L}$ can be done very quickly and stably, even for an ultrahigh dimensional problem. The feature X_j is selected by SIS if L_j is one of the d smallest components of $\mathbf{L}$. Typically, we may take $d = \lfloor n/\log n \rfloor$, though the choice of d is discussed in greater detail in Section 4.

The procedure above is an independence screening method. It uses only a marginal relation between features and the response variable to screen variables. When d is large enough, it has high probability of selecting all of the important features. For this reason, we call the method *Sure Independence Screening* (SIS). For classification problems with quadratic loss L, Fan & Lv (2008) show that SIS reduces to feature screening using a two-sample t-statistic. See also Hall et al. (2009) for a derivation from an empirical likelihood point of view and §3.2 for some theoretical results on the sure screening property.

2.2 Penalized Pseudo-likelihood

With features crudely selected by SIS, variable selection and parameter estimation can further be carried out simultaneously using a more refined penalized (pseudo)-likelihood method, as we now describe. The approach takes joint information into consideration. By reordering the features if necessary, we may assume without loss of generality that $X_1, \ldots, X_d$ are the features recruited by SIS. We let $\mathbf{x}_{i,d} = (X_{i1}, \ldots, X_{id})^T$ and redefine $\beta = (\beta_1, \ldots, \beta_d)^T$. In the penalized likelihood approach, we seek to minimize

$$\ell(\beta_0, \beta) = n^{-1} \sum_{i=1}^{n} L(Y_i, \beta_0 + \mathbf{x}_{i,d}^T \beta) + \sum_{j=1}^{d} p_\lambda(|\beta_j|). \tag{1}$$

Here, $p_\lambda(\cdot)$ is a penalty function and $\lambda > 0$ is a regularization parameter, which may be chosen by five-fold cross-validation, for example. The penalty function should satisfy certain conditions in order for the resulting estimates to have desirable properties, and in particular to yield sparse solutions in which some of the coefficients may be set to zero; see Fan & Li (2001) for further details.

Commonly used examples of penalty functions include the L_1 penalty $p_\lambda(|\beta|) = \lambda|\beta|$ (Tibshirani, 1996; Park & Hastie, 2007), the smoothly clipped absolute deviation (SCAD) penalty (Fan & Li, 2001), which is a quadratic spline with $p_\lambda(0) = 0$ and

$$p'_\lambda(|\beta|) = \lambda \left\{ \mathbb{1}_{\{|\beta| \le \lambda\}} + \frac{(a\lambda - |\beta|)_+}{(a-1)\lambda} \mathbb{1}_{\{|\beta| > \lambda\}} \right\},$$

for some $a > 2$ and $|\beta| > 0$, and the minimum concavity penalty (MCP), $p'_\lambda(|\beta|) = (\lambda - |\beta|/a)_+$ (Zhang, 2009). The choice $a = 3.7$ has been recommended in Fan & Li (2001). Unlike the L_1 penalty, SCAD and MC penalty functions have flat tails, which are fundamental in reducing biases due to penalization (Antoniadis & Fan, 2001; Fan & Li, 2001). Park & Hastie (2007) describe an iterative algorithm for minimizing the objective function for the L_1 penalty, and Zhang (2009) propose a PLUS algorithm for finding solution paths to the penalized least-squares problem with a general penalty $p_\lambda(\cdot)$. On the other hand, Fan & Li (2001) have shown that the SCAD-type of penalized loss function can be minimized iteratively using a local quadratic approximation, whereas Zou & Li (2008) propose a local linear approximation, taking the advantage of recently developed

algorithms for penalized L_1 optimization (Efron et al., 2004). Starting from $\beta^{(0)} = 0$ as suggested by Fan & Lv (2008), using the local linear approximation

$$p_\lambda(|\beta|) \approx p_\lambda(|\beta^{(k)}|) + p'_\lambda(|\beta^{(k)}|)(|\beta| - |\beta^{(k)}|),$$

in (1), at the $(k+1)^{th}$ iteration we minimize the weighted L_1 penalty

$$n^{-1}\sum_{i=1}^{n} L(Y_i, \beta_0 + \mathbf{x}_{i,d}^T\beta) + \sum_{j=1}^{d} w_j^{(k)}|\beta_j|, \tag{2}$$

where $w_j^{(k)} = p'_\lambda(|\beta_j^{(k)}|)$. Note that with initial value $\beta^{(0)} = 0$, $\beta^{(1)}$ is indeed a LASSO estimate for the SCAD and MC penalties, since $p'_\lambda(0+) = \lambda$. In other words, zero is not an absorbing state. Though motivated slightly differently, a weighted L_1 penalty is also the basis of the adaptive Lasso (Zou, 2006); in that case $w_j^{(k)} \equiv w_j = 1/|\hat{\beta}_j|^\gamma$, where $\widehat{\beta} = (\hat{\beta}_1, \ldots, \hat{\beta}_d)^T$ may be taken to be the maximum likelihood estimator, and $\gamma > 0$ is chosen by the user. The drawback of such an approach is that zero is an absorbing state when (2) is iteratively used—components being estimated as zero at one iteration will never escape from zero.

For a class of penalty functions that includes the SCAD penalty and when d is fixed as n diverges, Fan & Li (2001) established an oracle property; that is, the penalized estimates perform asymptotically as well as if an oracle had told us in advance which components of β were non-zero. Fan & Peng (2004) extended this result to cover situations where d may diverge with $d = d_n = o(n^{1/5})$. Zou (2006) shows that the adaptive LASSO possesses the oracle property too, when d is finite. See also further theoretical studies by Zhang & Huang (2008) and Zhang (2009). We refer to the two-stage procedures described above as SIS-Lasso, SIS-SCAD and SIS-AdaLasso.

2.3 Iterative Feature Selection

The SIS methodology may break down if a feature is marginally unrelated, but jointly related with the response, or if a feature is jointly uncorrelated with the response but has higher marginal correlation with the response than some important features. In the former case, the important feature has already been screened at the first stage, whereas in the latter case, the unimportant feature is ranked too high by the independent screening technique. ISIS seeks to overcome these difficulties by using more fully the joint covariate information while retaining computational expedience and stability as in SIS.

In the first step, we apply SIS to pick a set $\widehat{\mathcal{A}}_1$ of indices of size k_1, and then employ a penalized (pseudo)-likelihood method such as Lasso, SCAD, MCP or the adaptive Lasso to select a subset $\widehat{\mathcal{M}}_1$ of these indices. This is our initial estimate of the set of indices of important features. The screening stage solves only bivariate optimizations (2.1) and the fitting part solves only a optimization problem (1) with moderate size k_1. This is an attractive feature in ultrahigh dimensional statistical learning.

Instead of computing residuals, as could be done in the linear model, we compute

$$L_j^{(2)} = \min_{\beta_0, \beta_{\widehat{\mathcal{M}}_1}, \beta_j} n^{-1}\sum_{i=1}^{n} L(Y_i, \beta_0 + \mathbf{x}_{i,\widehat{\mathcal{M}}_1}^T\beta_{\widehat{\mathcal{M}}_1} + X_{ij}\beta_j), \tag{3}$$

for $j \in \widehat{\mathcal{M}}_1^c = \{1, \ldots, p\} \setminus \widehat{\mathcal{M}}_1$, where $\mathbf{x}_{i,\widehat{\mathcal{M}}_1}$ is the sub-vector of $\mathbf{x}_i$ consisting of those elements in $\widehat{\mathcal{M}}_1$. This is again a low-dimensional optimization problem which can easily be solved. Note that

$L_j^{(2)}$ [after subtracting the constant $\min_{\beta_0,\beta_{\widehat{\mathcal{M}}_1}} n^{-1}\sum_{i=1}^n L(Y_i,\beta_0+\mathbf{x}_{i,\widehat{\mathcal{M}}_1}^T\beta_{\widehat{\mathcal{M}}_1})$ and changing the sign of the difference] can be interpreted as the additional contribution of variable X_j given the existence of variables in $\widehat{\mathcal{M}}_1$. After ordering $\{L_j^{(2)} : j \in \widehat{\mathcal{M}}_1^c\}$, we form the set $\widehat{\mathcal{A}}_2$ consisting of the indices corresponding to the smallest k_2 elements, say. In this screening stage, an alternative approach is to substitute the fitted value $\widehat{\beta}_{\widehat{\mathcal{M}}_1}$ from the first stage into (3) and the optimization problem (3) would only be bivariate. This approach is exactly an extension of Fan & Lv (2008) as we have

$$L(Y_i,\beta_0+\mathbf{x}_{i,\widehat{\mathcal{M}}_1}^T\widehat{\beta}_{\widehat{\mathcal{M}}_1}+X_{ij}\beta_j)=(\hat{r}_i-\beta_0-X_{ij}\beta_j)^2,$$

for the quadratic loss, where $\hat{r}_i = Y_i - \mathbf{x}_{i,\widehat{\mathcal{M}}_1}^T\widehat{\beta}_{\widehat{\mathcal{M}}_1}$ is the residual from the previous step of fitting. The conditional contributions of features are more relevant in recruiting variables at the second stage, but the computation is more expensive. Our numerical experiments in Section 4.4 shows the improvement of such a deviation from Fan & Lv (2008).

After the prescreening step, we use penalized likelihood to obtain

$$\widehat{\beta}_2 = \underset{\beta_0,\beta_{\widehat{\mathcal{M}}_1},\beta_{\mathcal{A}_2}}{\operatorname{argmin}} \; n^{-1}\sum_{i=1}^n L(Y_i,\beta_0+\mathbf{x}_{i,\widehat{\mathcal{M}}_1}^T\beta_{\widehat{\mathcal{M}}_1}+\mathbf{x}_{i,\widehat{\mathcal{A}}_2}^T\beta_{\widehat{\mathcal{A}}_2})+\sum_{j\in\widehat{\mathcal{M}}_1\cup\widehat{\mathcal{A}}_2} p_\lambda(|\beta_j|).$$

Again, the penalty term encourages a sparse solution. The indices of $\widehat{\beta}_2$ that are non-zero yield a new estimated set $\widehat{\mathcal{M}}_2$ of active indices. This step also deviates importantly from the approach in Fan & Lv (2008) even in the least-squares case. It allows the procedure to delete variables from the previously selected features with indices in $\widehat{\mathcal{M}}_1$.

The process, which iteratively recruits and deletes features, can then be repeated until we obtain a set of indices $\widehat{\mathcal{M}}_\ell$ which either has reached the prescribed size d, or satisfies $\widehat{\mathcal{M}}_\ell = \widehat{\mathcal{M}}_{\ell-1}$. Of course, we also obtain a final estimated parameter vector $\widehat{\beta}_\ell$. The above method can be considered as an analogue of the least squares ISIS procedure (Fan & Lv, 2008) without explicit definition of the residuals. In fact, it is an improvement even for the least-squares problem.

In general, choosing larger values of each k_r decreases the computational cost and the probability that the ISIS procedure will terminate prematurely. However, it also makes the procedure more like its non-iterated counterpart, and so may offer less improvement in the awkward cases for SIS described in Section 1. In our implementation, we chose $k_1 = \lfloor 2d/3 \rfloor$, and thereafter at the rth iteration, we took $k_r = d - |\widehat{\mathcal{M}}_{r-1}|$. This ensures that the iterated versions of SIS take at least two iterations to terminate; another possibility would be to take, for example, $k_r = \min(5, d - |\widehat{\mathcal{M}}_{r-1}|)$.

Fan & Lv (2008) showed empirically that for the linear model ISIS improves significantly the performance of SIS in the difficult cases described above. The reason is that the fitting of the residuals from the $(r-1)^{th}$ iteration on the remaining features significantly weakens the priority of those unimportant features that are highly correlated with the response through their associations with $\{X_j : j \in \widehat{\mathcal{M}}_{r-1}\}$. This is due to the fact that the features $\{X_j : j \in \widehat{\mathcal{M}}_{r-1}\}$ have lower correlation with the residuals than with the original responses. It also gives those important features that are missed in the previous step a chance to survive.

2.4 Generalized Linear Models

Recall that we say that Y is of exponential dispersion family form if its density can be written in terms of its mean μ and a dispersion parameter ϕ as

$$f_Y(y;\mu,\phi) = \exp\left\{\frac{y\theta(\mu) - b(\theta(\mu))}{\phi} + c(y,\phi)\right\},$$

from some known functions $\theta(\cdot)$, $b(\cdot)$ and $c(\cdot,\cdot)$. In a generalized linear model for independent responses $Y_1,\ldots,Y_n$, we assert that the conditional density of Y_i given the covariate vector $\mathbf{X}_i = \mathbf{x}_i$ is of exponential dispersion family form, with the conditional mean response μ_i related to $\mathbf{x}_i$ through $g(\mu_i) = \mathbf{x}_i^T\beta$ for some known link function $g(\cdot)$, and where the dispersion parameters are constrained by requiring that $\phi_i = \phi a_i$, for some unknown dispersion parameter ϕ and known constants $a_1,\ldots,a_n$. For simplicity, throughout the paper, we take a constant dispersion parameter.

It is immediate from the form of the likelihood function for a generalized linear model that such a model fits within the pseudo-likelihood framework of Section 4. In fact, we have in general that

$$L(Y_i,\beta_0+\mathbf{x}_i^T\beta) = \sum_{i=1}^n \big\{b\big(\theta(g^{-1}(\beta_0+\mathbf{x}_i^T\beta)\big) - Y_i\theta\big(g^{-1}(\beta_0+\mathbf{x}_i^T\beta)\big)\big\}. \tag{4}$$

If we make the canonical choice of link function, $g(\cdot) = \theta(\cdot)$, then (4) simplifies to

$$L(Y_i,\beta_0+\mathbf{x}_i^T\beta) = \sum_{i=1}^n \big\{b(\beta_0+\mathbf{x}_i^T\beta) - Y_i(\beta_0+\mathbf{x}_i^T\beta)\big\}.$$

An elegant way to handle classification problems is to assume the class label takes values 0 or 1, and fit a logistic regression model. For this particular generalized linear model, we have

$$L(Y_i,\beta_0+\mathbf{x}_i^T\beta) = \sum_{i=1}^n \{\log(1+e^{\beta_0+\mathbf{x}_i^T\beta}) - Y_i(\beta_0+\mathbf{x}_i^T\beta)\},$$

while for Poisson log-linear models, we may take

$$L(Y_i,\beta_0+\mathbf{x}_i^T\beta) = \sum_{i=1}^n \big\{e^{\beta_0+\mathbf{x}_i^T\beta} - Y_i(\beta_0+\mathbf{x}_i^T\beta)\big\}.$$

3. Reduction of False Selection Rates

Sure independence screening approaches are simple and quick methods to screen out irrelevant features. They are usually conservative and include many unimportant features. In this section, we outline two possible variants of SIS and ISIS that have attractive theoretical properties in terms of reducing the FSRs. The first is an aggressive feature selection method that is particularly useful when the dimensionality is very large relative to the sample size; the second is a more conservative procedure.

3.1 First Variant of ISIS

It is convenient to introduce some new notation. We write $\mathcal{A}$ for the set of active indices—that is, the set containing those indices j for which $\beta_j \neq 0$ in the true model. Write $X_{\mathcal{A}} = \{X_j : j \in \mathcal{A}\}$ and $X_{\mathcal{A}^c} = \{X_j : j \in \mathcal{A}^c\}$ for the corresponding sets of active and inactive variables respectively.

Assume for simplicity that n is even, and split the sample into two halves at random. Apply SIS or ISIS separately to the data in each partition (with $d = \lfloor n/\log n \rfloor$ or larger, say), yielding two estimates $\widehat{\mathcal{A}}^{(1)}$ and $\widehat{\mathcal{A}}^{(2)}$ of the set of active indices $\mathcal{A}$. Both of them should have large FSRs, as they are constructed from a crude screening method. Assume that both sets have the satisfy

$$P(\mathcal{A} \subset \widehat{\mathcal{A}}^{(j)}) \to 1, \quad \text{for } j = 1 \text{ and } 2.$$

Then, the active features should appear in both sets with probability tending to one. We thus construct $\widehat{\mathcal{A}} = \widehat{\mathcal{A}}^{(1)} \cap \widehat{\mathcal{A}}^{(2)}$ as an estimate of $\mathcal{A}$. This estimate also satisfies

$$P(\mathcal{A} \subset \widehat{\mathcal{A}}) \to 1.$$

However, this estimate contains many fewer indices corresponding to inactive features, as such indices have to appear twice at random in the sets $\widehat{\mathcal{A}}^{(1)}$ and $\widehat{\mathcal{A}}^{(2)}$. This is indeed shown in Theorem 1 below.

Just as in the original formulation of SIS in Section 2, we can now use a penalized (pseudo)-likelihood method such as SCAD to perform final feature selection from $\widehat{\mathcal{A}}$ and parameter estimation. We can even proceed without the penalization since the false selection rate is small.

In our theoretical support for this variant of SIS, we will make use of the following condition:

(A1) Let $r \in \mathbb{N}$, the set of natural numbers. We say the model satisfies the exchangeability condition at level r if the set of random vectors

$$\{(Y, X_{\mathcal{A}}, X_{j_1}, \ldots, X_{j_r}) : j_1, \ldots, j_r \text{ are distinct elements of } \mathcal{A}^c\}$$

is exchangeable.

This condition ensures that each inactive feature is equally likely to be recruited by SIS. Note that (**A1**) certainly allows inactive features to be correlated with the response, but does imply that each inactive feature has the same marginal distribution. In Theorem 1 below, the case $r = 1$ is particularly important, as it gives an upper bound on the probability of recruiting any inactive features into the model. Note that this upper bound requires only the weakest version (level 1) of the exchangeability condition.

Theorem 1 *Let $r \in \mathbb{N}$, and assume the model satisfies the exchangeability condition **(A1)** at level r. If $\widehat{\mathcal{A}}$ denotes the estimator of $\mathcal{A}$ from the above variant of SIS, then*

$$P(|\widehat{\mathcal{A}} \cap \mathcal{A}^c| \geq r) \leq \frac{\binom{d}{r}^2}{\binom{p-|\mathcal{A}|}{r}} \leq \frac{1}{r!}\Big(\frac{d^2}{p-|\mathcal{A}|}\Big)^r,$$

where, for the second inequality, we require $d^2 \leq p - |\mathcal{A}|$ and d is the prescribed number of selected features in $\widehat{\mathcal{A}}^{(1)}$ or $\widehat{\mathcal{A}}^{(2)}$.

Proof Fix $r \in \mathbb{N}$, and let $\mathcal{J} = \{(j_1, \ldots, j_r) : j_1, \ldots, j_r \text{ are distinct elements of } \mathcal{A}^c\}$. Then

$$\begin{aligned} P(|\widehat{\mathcal{A}} \cap \mathcal{A}^c| \geq r) &\leq \sum_{(j_1,\ldots,j_r)\in\mathcal{J}} P(j_1 \in \widehat{\mathcal{A}}, \cdots, j_r \in \widehat{\mathcal{A}}) \\ &= \sum_{(j_1,\ldots,j_r)\in\mathcal{J}} P(j_1 \in \widehat{\mathcal{A}}^{(1)}, \cdots, j_r \in \widehat{\mathcal{A}}^{(1)})^2, \end{aligned}$$

in which we use the random splitting in the last equality. Obviously, the last probability is bounded by

$$\max_{(j_1,\ldots,j_r)\in\mathcal{J}} P(j_1 \in \widehat{\mathcal{A}}^{(1)},\cdots,j_r \in \widehat{\mathcal{A}}^{(1)}) \sum_{(j_1,\ldots,j_r)\in\mathcal{J}} P(j_1 \in \widehat{\mathcal{A}}^{(1)},\cdots,j_r \in \widehat{\mathcal{A}}^{(1)}). \tag{5}$$

Since there are at most d inactive features from $\mathcal{A}^c$ in the set $\widehat{\mathcal{A}}^{(1)}$, the number of r-tuples from $\mathcal{J}$ falling in the set $\widehat{\mathcal{A}}^{(1)}$ can not be more than the total number of such r-tuples in $\widehat{\mathcal{A}}^{(1)}$, that is,

$$\sum_{(j_1,\ldots,j_r)\in\mathcal{J}} \mathbb{1}_{\{j_1\in\widehat{\mathcal{A}}^{(1)},\cdots,j_r\in\widehat{\mathcal{A}}^{(1)}\}} \leq \binom{d}{r}.$$

Thus, we have

$$\sum_{(j_1,\ldots,j_r)\in\mathcal{J}} P(j_1 \in \widehat{\mathcal{A}}^{(1)},\cdots,j_r \in \widehat{\mathcal{A}}^{(1)}) \leq \binom{d}{r}. \tag{6}$$

Substituting this into (5), we obtain

$$P(|\widehat{\mathcal{A}}\cap\mathcal{A}^c| \geq r) \leq \binom{d}{r} \max_{(j_1,\ldots,j_r)\in\mathcal{J}} P(j_1 \in \widehat{\mathcal{A}}^{(1)},\cdots,j_r \in \widehat{\mathcal{A}}^{(1)}).$$

Now, under the exchangeability condition (**A1**), each r-tuple of distinct indices in $\mathcal{A}^c$ is equally likely to be recruited into $\widehat{\mathcal{A}}^{(1)}$. Hence, it follows from (6) that

$$\max_{(j_1,\ldots,j_r)\in\mathcal{J}} P(j_1 \in \widehat{\mathcal{A}}^{(1)},\cdots,j_r \in \widehat{\mathcal{A}}^{(1)}) \leq \frac{\binom{d}{r}}{\binom{p-|\mathcal{A}|}{r}},$$

and the first result follows. The second result follows from the simple fact that

$$\frac{(d-i)^2}{p^*-i} \leq \frac{d^2}{p^*}, \quad \text{for all } 0 \leq i \leq d,$$

where $p^* = p - |\mathcal{A}|$, and the simple calculation that

$$\frac{\binom{d}{r}^2}{\binom{p^*}{r}} = \frac{1}{r!}\frac{d^2(d-1)^2\cdots(d-r+1)^2}{p^*(p^*-1)\cdots(p^*-r+1)} \leq \frac{1}{r!}\left(\frac{d}{p^*}\right)^r.$$

This completes the proof. ■

Theorem 1 gives a nonasymptotic bound, using only the symmetry arguments, and this bound is expected to be reasonably tight especially when p is large. From Theorem 1, we see that if the exchangeability condition at level 1 is satisfied and if p is large by comparison with n^2, then when the number of selected features d is smaller than n, we have with high probability this variant of SIS reports no 'false positives'; that is, it is very likely that any index in the estimated active set also belongs to the active set in the true model. Intuitively, if p is large, then each inactive feature has small probability of being included in the estimated active set, so it is very unlikely indeed that it will appear in the estimated active sets from both partitions. The nature of this result is a little unusual in that it suggests a 'blessing of dimensionality'—the bound on the probability of false

positives decreases with p. However, this is only part of the full story, because the probability of missing elements of the true active set is expected to increase with p.

Of course, it is possible to partition the data into $K > 2$ groups, say, each of size n/K, and estimate $\mathcal{A}$ by $\widehat{\mathcal{A}}^{(1)} \cap \widehat{\mathcal{A}}^{(2)} \cap \ldots \cap \widehat{\mathcal{A}}^{(K)}$, where $\widehat{\mathcal{A}}^{(k)}$ represents the estimated set of active indices from the kth partition. Such a variable selection procedure would be even more aggressive than the $K = 2$ version; improved bounds in Theorem 1 could be obtained, but the probability of missing true active indices would be increased. As the $K = 2$ procedure is already quite aggressive, we consider this to be the most natural choice in practice.

In the iterated version of this first variant of SIS, we apply SIS to each partition separately to obtain two sets of indices $\widehat{\mathcal{A}}_1^{(1)}$ and $\widehat{\mathcal{A}}_1^{(2)}$, each having k_1 elements. After forming the intersection $\widehat{\mathcal{A}}_1 = \widehat{\mathcal{A}}_1^{(1)} \cap \widehat{\mathcal{A}}_1^{(2)}$, we carry out penalized likelihood estimation as before to give a first approximation $\widehat{\mathcal{M}}_1$ to the true active set of features. We then perform a second stage of the ISIS procedure, as outlined in Section 2, to each partition separately to obtain sets of indices $\widehat{\mathcal{M}}_1 \cup \widehat{\mathcal{A}}_2^{(1)}$ and $\widehat{\mathcal{M}}_1 \cup \widehat{\mathcal{A}}_2^{(2)}$. Taking the intersection of these sets and re-estimating parameters using penalized likelihood as in Section 2 gives a second approximation $\widehat{\mathcal{M}}_2$ to the true active set. This process can be continued until we reach an iteration ℓ with $\widehat{\mathcal{M}}_\ell = \widehat{\mathcal{M}}_{\ell-1}$, or we have recruited d indices.

3.2 Second Variant of ISIS

Our second variant of SIS is a more conservative feature selection procedure and also relies on random partitioning the data into $K = 2$ groups as before. Again, we apply SIS to each partition separately, but now we recruit as many features into equal-sized sets of active indices $\widetilde{\mathcal{A}}^{(1)}$ and $\widetilde{\mathcal{A}}^{(2)}$ as are required to ensure that the intersection $\widetilde{\mathcal{A}} = \widetilde{\mathcal{A}}^{(1)} \cap \widetilde{\mathcal{A}}^{(2)}$ has d elements. We then apply a penalized pseudo-likelihood method to the features $X_{\tilde{\mathcal{A}}} = \{X_j : j \in \widetilde{\mathcal{A}}\}$ for final feature selection and parameter estimation.

Theoretical support for this method can be provided in the case of the linear model; namely, under certain regularity conditions, this variant of SIS possesses the sure screening property. More precisely, if Conditions (1)–(4) of Fan & Lv (2008) hold with $2\kappa + \tau < 1$, and we choose $d = \lfloor n/\log n \rfloor$, then there exists $C > 0$ such that

$$P(\mathcal{A} \subseteq \tilde{\mathcal{A}}) = 1 - O\{\exp(-Cn^{1-2\kappa}/\log n + \log p)\}.$$

The parameter $\kappa \geq 0$ controls the rate at which the minimum signal $\min_{j\in\mathcal{A}} |\beta_j|$ is allowed to converge to zero, while $\tau \geq 0$ controls the rate at which the maximal eigenvalue of the covariance matrix $\Sigma = \mathrm{Cov}(X_1, \ldots, X_p)$ is allowed to diverge to infinity. In fact, we insist that $\min_{j\in\mathcal{A}} |\beta_j| \geq n^{-\kappa}$ and $\lambda_{\max}(\Sigma) \leq n^{\tau}$ for large n, where $\lambda_{\max}(\Sigma)$ denotes the maximal eigenvalue of Σ. Thus, these technical conditions ensure that any non-zero signal is not too small, and that the features are not too close to being collinear, and the dimensionality is also controlled via $\log p = o(n^{1-2\kappa}/\log n)$, which is still of an exponential order. See Fan & Lv (2008) for further discussion of the sure screening property.

Recently, Fan & Song (2009) extended the result of Fan & Lv (2008) to generalized linear models. Let $\hat{L}_0 = \min_{\beta_0} n^{-1} \sum_{i=1}^n L(Y_i, \beta_0)$ be the baseline value to (2.1). The feature ranking procedure is equivalent to the thresholding method: $\widehat{\mathcal{M}}_{\nu_n} = \{j : L_j - L_0 \geq \nu_n\}$, in which ν_n is a given thresholding value. Under certainly regularity conditions, if

$$\min_{j\in\mathcal{A}} |\mathrm{cov}(X_j, Y)| \geq c_1 n^{-\kappa}, \qquad \text{for some } c_1 > 0 \text{ and } \kappa < 1/2$$

and $\nu_n = c_0 n^{-2\kappa}$ for a sufficiently small c_0, then we have

$$P(\mathcal{A} \subset \widehat{\mathcal{M}}_{\nu_n}) \to 1,$$

exponentially fast, provided that $\log p_n = o(n^{1-2\kappa})$. The sure screening property does not depend on the correlation of the features, as expected. However, the selected model size does depend on the correlation structure: The more correlated the features, the larger the selected model size. In fact, Fan & Song (2009) demonstrated further that with probability tending to one exponentially fast, $|\widehat{\mathcal{M}}_{\nu_n}| = O(\nu_n^{-2}\lambda_{\max}(\Sigma))$. When $\lambda_{\max}(\Sigma) = O(n^{\tau})$ and $\lambda_{\max}(\Sigma) = O(n^{-2\kappa})$, the selected model size is $|\widehat{\mathcal{M}}_{\nu_n}| = O(n^{2\kappa+\tau})$. In particularly, if the condition $2\kappa+\tau < 1$ is imposed as in Fan & Lv (2008), we can reduce safely the model size to $o(n)$ by independence learning.

An iterated version of this second variant of SIS is also available. At the first stage we apply SIS, taking enough features in equal-sized sets of active indices $\widetilde{\mathcal{A}}_1^{(1)}$ and $\widetilde{\mathcal{A}}_1^{(2)}$ to ensure that the intersection $\widetilde{\mathcal{A}}_1 = \widetilde{\mathcal{A}}_1^{(1)} \cap \widetilde{\mathcal{A}}_1^{(2)}$ has k_1 elements. Applying penalized likelihood to the features with indices in $\widetilde{\mathcal{A}}_1$ gives a first approximation $\widetilde{\mathcal{M}}_1$ to the true set of active indices. We then carry out a second stage of the ISIS procedure of Section 2 to each partition separately to obtain equal-sized new sets of indices $\widetilde{\mathcal{A}}_2^{(1)}$ and $\widetilde{\mathcal{A}}_2^{(2)}$, taking enough features to ensure that $\widetilde{\mathcal{A}}_2 = \widetilde{\mathcal{A}}_2^{(1)} \cap \widetilde{\mathcal{A}}_2^{(2)}$ has k_2 elements. Penalized likelihood applied to $\widetilde{\mathcal{M}}_1 \cap \widetilde{\mathcal{A}}_2$ gives a second approximation $\widetilde{\mathcal{M}}_2$ to the true set of active indices. As with the first variant, we continue until we reach an iteration ℓ with $\widetilde{\mathcal{M}}_\ell = \widetilde{\mathcal{M}}_{\ell-1}$, or we have recruited d indices.

4. Numerical Results

We illustrate the breadth of applicability of (I)SIS and its variants by studying its performance on simulated data in four different contexts: logistic regression, Poisson regression, robust regression (with a least absolute deviation criterion) and multi-class classification with support vector machines. We will consider three different configurations of the $p = 1000$ features $X_1, \ldots, X_p$:

Case 1: $X_1, \ldots, X_p$ are independent and identically distributed $N(0,1)$ random variables

Case 2: $X_1, \ldots, X_p$ are jointly Gaussian, marginally $N(0,1)$, and with $\mathrm{corr}(X_i, X_4) = 1/\sqrt{2}$ for all $i \neq 4$ and $\mathrm{corr}(X_i, X_j) = 1/2$ if i and j are distinct elements of $\{1, \ldots, p\} \setminus \{4\}$

Case 3: $X_1, \ldots, X_p$ are jointly Gaussian, marginally $N(0,1)$, and with $\mathrm{corr}(X_i, X_5) = 0$ for all $i \neq 5$, $\mathrm{corr}(X_i, X_4) = 1/\sqrt{2}$ for all $i \notin \{4,5\}$, and $\mathrm{corr}(X_i, X_j) = 1/2$ if i and j are distinct elements of $\{1, \ldots, p\} \setminus \{4,5\}$.

Case 1, with independent features, is the most straightforward for variable selection. In Cases 2 and 3, however, we have serial correlation such that $\mathrm{corr}(X_i, X_j)$ does not decay as $|i-j|$ increases. We will see later that for both Case 2 and Case 3 the true coefficients are chosen such that the response is marginally uncorrelated with X_4. We therefore expect feature selection in these situations to be more challenging, especially for the non-iterated versions of SIS. Notice that in the asymptotic theory of SIS in Fan & Lv (2008), this type of dependence is ruled out by their Condition (4).

Regarding the choice of d, the asymptotic theory of Fan & Lv (2008) shows that in the linear model there exists $\theta^* > 0$ such that we may obtain the sure screening property with $\lfloor n^{1-\theta^*} \rfloor <$

$d < n$. However, θ^* is unknown in practice, and therefore Fan and Lv recommend $d = \lfloor n/\log n \rfloor$ as a sensible choice. Of course, choosing a larger value of d increases the probability that SIS will include all of the correct variables, but including more inactive variables will tend to have a slight detrimental effect on the performance of the final variable selection and parameter estimation method. We have found that this latter effect is most noticeable in models where the response provides less information. In particular, the binary response of a logistic regression model and, to a lesser extent, the integer-valued response in a Poisson regression model are less informative than the real-valued response in a linear model. We therefore used $d = \lfloor \frac{n}{4\log n} \rfloor$ in the logistic regression and multicategory classification settings of Sections 4.1 and 4.5, $d = \lfloor \frac{n}{2\log n} \rfloor$ in the Poisson regression settings of Section 4.2 and $d = \lfloor \frac{n}{2} \rfloor$ in Section 4.4. These model-based, rather than data-adaptive, choices of d seem to be satisfactory, as the performance of the procedures is quite robust to different choices of d (in fact using $d = \lfloor \frac{n}{\log n} \rfloor$ for all models would still give good performance).

4.1 Logistic Regression

In this example, the data $(\mathbf{x}_1^T, Y_1), \ldots, (\mathbf{x}_n^T, Y_n)$ are independent copies of a pair $(\mathbf{x}^T, Y)$, where Y is distributed, conditional on $\mathbf{X} = \mathbf{x}$, as $\text{Bin}(1, p(\mathbf{x}))$, with $\log\big(\frac{p(\mathbf{x})}{1-p(\mathbf{x})}\big) = \beta_0 + \mathbf{x}^T\beta$. We choose $n = 400$.

As explained above, we chose $d = \lfloor \frac{n}{4\log n} \rfloor = 16$ in both the vanilla version of SIS outlined in Section 2 (Van-SIS), and the second variant (Var2-SIS) in Section 3.2. For the first variant (Var1-SIS), however, we used $d = \lfloor \frac{n}{\log n} \rfloor = 66$; note that since this means the selected features are in the intersection of two sets of size d, we typically end up with far fewer than d features selected by this method.

For the logistic regression example, the choice of final regularization parameter λ for the SCAD penalty (after all (I)SIS steps) was made by means of an independent validation data set of size n (generated from the same model as the original data, used only for tuning the parameters), rather than by cross-validation. This also applies for the LASSO and Nearest Shrunken Centroid (NSC, Tibshirani et al., 2003) methods which we include for comparison; instead of using SIS, this method regularizes the log-likelihood with an L_1-penalty. The reason for using the independent tuning data set is that the lack of information in the binary response means that cross-validation is particularly prone to overfitting in logistic regression, and therefore perfoms poorly for all methods.

The coefficients used in each of the three cases were as follows:

Case 1: $\beta_0 = 0, \beta_1 = 1.2439, \beta_2 = -1.3416, \beta_3 = -1.3500, \beta_4 = -1.7971, \beta_5 = -1.5810, \beta_6 = -1.5967$, and $\beta_j = 0$ for $j > 6$. The corresponding Bayes test error is 0.1368.

Case 2: $\beta_0 = 0, \beta_1 = 4, \beta_2 = 4, \beta_3 = 4, \beta_4 = -6\sqrt{2}$, and $\beta_j = 0$ for $j > 4$. The Bayes test error is 0.1074.

Case 3: $\beta_0 = 0, \beta_1 = 4, \beta_2 = 4, \beta_3 = 4, \beta_4 = -6\sqrt{2}, \beta_5 = 4/3$, and $\beta_j = 0$ for $j > 5$. The Bayes test error is 0.1040.

In Case 1, the coefficients were chosen randomly, and were generated as $(4\log n/\sqrt{n} + |Z|/4)U$ with $Z \sim N(0,1)$ and $U = 1$ with probability 0.5 and -1 with probability -0.5, independent of Z. For Cases 2 and 3, the choices ensure that even though $\beta_4 \neq 0$, we have that X_4 and Y are independent. The fact that X_4 is marginally independent of the response is designed to make it difficult for a popular method such as the two-sample t test or other independent learning methods

to recognize this important feature. Furthermore, for Case 3, we add another important variable X_5 with a small coefficient to make it even more difficult to identify the true model. For Case 2, the ideal variables picked up by the two sample test or independence screening technique are X_1, X_2 and X_3. Using these variables to build the ideal classifier, the Bayes risk is 0.3443, which is much larger than the Bayes error 0.1074 of the true model with X_1, X_2, X_3, X_4. In fact one may exaggerate Case 2 to make the Bayes error using the independence screening technique close to 0.5, which corresponds to random guessing, by setting $\beta_0 = 0$, $\beta_1 = \beta_2 = \beta_3 = a$, $\beta_m = a$ for $m = 5, 6, \cdots, j$, $\beta_4 = -a(j-1)\sqrt{2}/2$, and $\beta_m = 0$ for $m > j$. For example, the Bayes error using the independence screening technique, which deletes X_4, is 0.4290 when $j = 20$ and $a = 4$ while the corresponding Bayes error using X_m, $m = 1, 2, \cdots, 20$ is 0.0445.

In the tables below, we report several performance measures, all of which are based on 100 Monte Carlo repetitions. The first two rows give the median L_1 and squared L_2 estimation errors $\|\beta - \widehat{\beta}\|_1 = \sum_{j=0}^{p} |\beta_j - \hat{\beta}_j|$ and $\|\beta - \widehat{\beta}\|_2^2 = \sum_{j=0}^{p} (\beta_j - \hat{\beta}_j)^2$. The third row gives the proportion of times that the (I)SIS procedure under consideration includes all of the important features in the model, while the fourth reports the corresponding proportion of times that the final features selected, after application of the SCAD or LASSO penalty as appropriate, include all of the important ones. The fifth row gives the median final number of features selected. Measures of fit to the training data are provided in the sixth, seventh and eighth rows, namely the median values of $2Q(\hat{\beta}_0, \widehat{\beta})$, defined in (2.1), Akaike's information criterion (Akaike, 1974), which adds twice the number of features in the final model, and the Bayesian information criterion (Schwarz, 1978), which adds the product of $\log n$ and the number of features in the final model. Finally, an independent test data set of size $100n$ was used to evaluate the median value of $2Q(\hat{\beta}_0, \widehat{\beta})$ on the test data (Row 9), as well as to report the median 0-1 test error (Row 10), where we observe an error if the test response differs from the fitted response by more than $1/2$.

Table 1 compares five methods, Van-SIS, Var1-SIS, Var2-SIS, LASSO, and NSC. The most noticeable observation is that while the LASSO always includes all of the important features, it does so by selecting very large models—a median of 94 variables, as opposed to the correct number, 6, which is the median model size reported by all three SIS-based methods. This is due to the bias of the LASSO, as pointed out by Fan & Li (2001) and Zou (2006), which encourages the choice of a small regularization parameter to make the overall mean squared error small. Consequently, many unwanted features are also recruited. This is also evidenced by comparing the differences between L_1 and L_2 losses in the first two rows. Thus the LASSO method has large estimation error, and while $2Q(\hat{\beta}_0, \widehat{\beta})$ is small on the training data set, this is a result of overfit, as seen by the large values of AIC/BIC, $2Q(\hat{\beta}_0, \widehat{\beta})$ on the test data and the 0-1 test error.

As the features are independent in Case 1, it is unsurprising to see that Van-SIS has the best performance of the three SIS-based methods. Even with the larger value of d used for Var1-SIS, it tends to miss important features more often than the other methods. Although the method appears to have value as a means of obtaining a minimal set of features that should be included in a final model, we will not consider Var1-SIS further in our simulation study.

Table 2 displays the results of repeating the Case 1 simulations for Van-SIS, Var1-SIS and Var2-SIS under the same conditions, but using the LASSO penalty function rather than the SCAD penalty function after the SIS step. These versions are called Van-SIS-LASSO, Var1-SIS-LASSO and Var2-SIS-LASSO respectively. We see that, as well as decreasing the computational cost, using any of the three versions of SIS before the LASSO improves performance substantially compared with

applying the LASSO to the full set of features. On the other hand, the results are less successful than applying SIS and its variants in conjuction with the SCAD penalty for final feature selection and parameter estimation. We therefore do not consider Van-SIS-LASSO, Var1-SIS-LASSO and Var2-SIS-LASSO further.

Table 2: Logistic regression, Case 1

In Cases 2 and 3, we also consider the iterated versions of Van-SIS and Var2-SIS, which we denote Van-ISIS and Var2-ISIS respectively. At each intermediate stage of the ISIS procedures, the Bayesian information criterion was used as a fast way of choosing the SCAD regularization parameter.

From Tables 3 and 4, we see that the non-iterated SIS methods fail badly in these awkward cases. Their performance is similar to that of the LASSO method. On the other hand, both of the iterated methods Van-ISIS and Var2-ISIS perform extremely well (and similarly to each other).

4.2 Poisson Regression

In our second example, the generic response Y is distributed, conditional on $\mathbf{X} = \mathbf{x}$, as Poisson$(\mu(\mathbf{x}))$, where $\log \mu(\mathbf{x}) = \beta_0 + \mathbf{x}^T\beta$.

Table 4: Logistic regression, Case 3

Due to the extra information in the count response, we choose $n = 200$, and apply all versions of (I)SIS with $d = \lfloor \frac{n}{2 \log n} \rfloor = 37$. We also use 10-fold cross-validation to choose the final regularization parameter for the SCAD and LASSO penalties. The coefficients used were as follows:

Case 1: $\beta_0 = 5, \beta_1 = -0.5423, \beta_2 = 0.5314, \beta_3 = -0.5012, \beta_4 = -0.4850, \beta_5 = -0.4133, \beta_6 = 0.5234$, and $\beta_j = 0$ for $j > 6$.

Case 2: $\beta_0 = 5, \beta_1 = 0.6, \beta_2 = 0.6, \beta_3 = 0.6, \beta_4 = -0.9\sqrt{2}$, and $\beta_j = 0$ for $j > 4$.

Case 3: $\beta_0 = 5, \beta_1 = 0.6, \beta_2 = 0.6, \beta_3 = 0.6, \beta_4 = -0.9\sqrt{2}, \beta_5 = 0.15$, and $\beta_j = 0$ for $j > 5$.

In Case 1, the magnitudes of the coefficients $\beta_1, \ldots, \beta_6$ were generated as $(\frac{\log n}{\sqrt{n}} + |Z|/8)U$ with $Z \sim N(0,1)$ and $U = 1$ with probability 0.5 and -1 with probability 0.5, independently of Z. Again, the choices in Cases 2 and 3 ensure that, even though $\beta_4 \neq 0$, we have $\mathrm{corr}(X_4, Y) = 0$. The coefficients are a re-scaled version of those in the logistic regression model, except that $\beta_0 = 5$ is used to control an appropriate signal-to-noise ratio.

The results are shown in Tables 5, 6 and 7. Even in Case 1, with independent features, the ISIS methods outperform SIS, so we chose not to present the results for SIS in the other two cases. Again,

both Van-ISIS and Var2-ISIS perform extremely well, almost always including all the important features in relatively small final models. The LASSO method continues to suffer from overfitting, particularly in the difficult Cases 2 and 3.

Table 7: Poisson regression, Case 3

4.3 Robust Regression

We have also conducted similar numerical experiments using L_1-regression for the three cases in an analogous manner to the previous two examples. We obtain similar results. Both versions of ISIS are effective in selecting important features with relatively low false positive rates. Hence, the prediction errors are also small. On the other hand, LASSO missed the difficult variables in cases 2 and 3 and also selected models with a large number of features to attenuate the bias of the variable selection procedure. As a result, its prediction errors are much larger. To save space, we omit the details of the results.

4.4 Linear Regression

Note that our new ISIS procedure allows feature deletion in each step. It is an important improvement over the original proposal of Fan & Lv (2008) even in the ordinary least-squares setting. To demonstrate this, we choose Case 3, the most difficult one, with coefficients given as follows.

Case 3: $\beta_0 = 0, \beta_1 = 5, \beta_2 = 5, \beta_3 = 5, \beta_4 = -15\sqrt{2}/2, \beta_5 = 1$, and $\beta_j = 0$ for $j > 5$.

The response Y is set as $Y = \mathbf{x}^T\beta + \varepsilon$ with independent $\varepsilon \sim N(0,1)$. This model is the same as Example 4.2.3 of Fan & Lv (2008). Using $n = 70$ and $d = n/2$, our new ISIS method includes all five important variables for 91 out of the 100 repetitions, while the original ISIS without feature deletion includes all the important features for only 36 out of the 100 repetitions. The median model size of our new variable selection procedure with variable deletion is 21, whereas the median model size corresponding to the original ISIS of Fan & Lv (2008) is 19.

We have also conducted the numerical experiment with a different sample size $n = 100$ and $d = n/2 = 50$. For 97 out of 100 repetitions, our new ISIS includes all the important features while ISIS without variable deletion includes all the important features for only 72 repetitions. Their median model sizes are both 26. This clearly demonstrates the improvement of allowing feature deletion in this example.

4.5 Multicategory Classification

Our final example in this section is a four-class classification problem. Here we study two different feature configurations, both of which depend on first generating independent $\tilde{X}_1, \ldots, \tilde{X}_p$ such that $\tilde{X}_1, \ldots, \tilde{X}_4$ are uniformly distributed on $[-\sqrt{3}, \sqrt{3}]$, and $\tilde{X}_5, \ldots, \tilde{X}_p$ are distributed as $N(0,1)$. We use these random variables to generate the following cases:

Case 1: $X_j = \tilde{X}_j$ for $j = 1, \ldots, p$

Case 2: $X_1 = \tilde{X}_1 - \sqrt{2}\tilde{X}_5, X_2 = \tilde{X}_2 + \sqrt{2}\tilde{X}_5, X_3 = \tilde{X}_3 - \sqrt{2}\tilde{X}_5, X_4 = \tilde{X}_4 + \sqrt{2}\tilde{X}_5$, and $X_j = \sqrt{3}\tilde{X}_j$ for $j = 5, \ldots, p$.

Conditional on $\mathbf{X} = \mathbf{x}$, the response Y was generated according to $P(Y = k|\widetilde{\mathbf{X}} = \tilde{\mathbf{x}}) \propto \exp\{f_k(\tilde{\mathbf{x}})\}$, for $k = 1, \ldots, 4$, where $f_1(\tilde{\mathbf{x}}) = -a\tilde{x}_1 + a\tilde{x}_4$, $f_2(\tilde{\mathbf{x}}) = a\tilde{x}_1 - a\tilde{x}_2$, $f_3(\tilde{\mathbf{x}}) = a\tilde{x}_2 - a\tilde{x}_3$ and $f_4(\tilde{\mathbf{x}}) = a\tilde{x}_3 - a\tilde{x}_4$ with $a = 5/\sqrt{3}$.

In both Case 1 and Case 2, all features have the same standard deviation since $\mathrm{sd}(X_j) = 1$ for $j = 1, 2, \cdots, p$ in Case 1 and $\mathrm{sd}(X_j) = \sqrt{3}$ for $j = 1, 2, \cdots, p$ in Case 2. Moreover, for this case, the variable X_5 is marginally unimportant, but jointly significant, so it represents a challenge to identify this as an important variable. For both Case 1 and Case 2, the Bayes error is 0.1373.

For the multicategory classification we use the loss function proposed by Lee, Lin and Wahba (2004). Denote the coefficients for the kth class by β_{0k} and β_k for $k = 1,2,3,4$, and let $\mathbf{B} = ((\beta_{01}, \beta_1^T)^T,$
$(\beta_{02}, \beta_2^T)^T, (\beta_{03}, \beta_3^T)^T, (\beta_{04}, \beta_4^T)^T)$. Let $f_k(\mathbf{x}) \equiv f_k(\mathbf{x}, \beta_{0k}, \beta_k) = \beta_{0k} + \mathbf{x}^T\beta_k$, $k = 1,2,3,4$, and

$$\mathbf{f}(\mathbf{x}) \equiv \mathbf{f}(\mathbf{x}, \mathbf{B}) = (f_1(\mathbf{x}), f_2(\mathbf{x}), f_3(\mathbf{x}), f_4(\mathbf{x}))^T.$$

The loss function is given by $L(Y, \mathbf{f}(\mathbf{x})) = \sum_{j \neq Y} [1 + f_j(\mathbf{x})]_+$, where $[\psi]_+ = \psi$ if $\psi \geq 0$ and 0 otherwise. Deviating slightly from our standard procedure, the marginal utility of the j^{th} feature is defined by

$$L_j = \min_{\mathbf{B}} \sum_{i=1}^{n} L(Y_i, \mathbf{f}(X_{ij}, \mathbf{B})) + \frac{1}{2} \sum_{k=1}^{4} \beta_{jk}^2$$

to avoid possible unidentifiablity issues due to the hinge loss function. Analogous modification is applied to (3) in the iterative feature selection step. With estimated coefficients $\hat{\beta}_{0k}$ and $\widehat{\beta}_k$, and $\hat{f}_k(\mathbf{x}) = \hat{\beta}_{0k} + \mathbf{x}^T\widehat{\beta}_k$ for $k = 1,2,3,4$, the estimated classification rule is given by $\text{argmax}_k \hat{f}_k(\mathbf{x})$. There are some other appropriate multi-category loss functions such as the one proposed by Liu, Shen and Doss (2005).

As with the logistic regression example in Section 4.1, we use $n = 400$, $d = \lfloor \frac{n}{4 \log n} \rfloor = 16$ and an independent validation data set of size n to pick the final regularization parameter for the SCAD penalty.

The results are given in Table 8. The mean estimated testing error was based on a further testing data set of size $200n$, and we also report the standard error of this mean estimate. In the case of independent features, all (I)SIS methods have similar performance. The benefits of using iterated versions of the ISIS methodology are again clear for Case 2, with dependent features.

5. Real Data Examples

In this section, we apply our proposed methods to two real data sets. The first one has a binary response while the second is multi-category. We treat both as classification problems and use the

hinge loss discussed in Section 4.5. We compare our methods with two alternatives: the LASSO and NSC.

5.1 Neuroblastoma Data

We first consider the neuroblastoma data used in Oberthuer et al. (2006). The study consists of 251 patients of the German Neuroblastoma Trials NB90-NB2004, diagnosed between 1989 and 2004. At diagnosis, patients' ages range from 0 to 296 months with a median age of 15 months. They analyzed 251 neuroblastoma specimens using a customized oligonucleotide microarray with the goal of developing a gene expression-based classification rule for neuroblastoma patients to reliably predict courses of the disease. This also provides a comprehensive view on which set of genes is responsible for neuroblastoma.

The complete data set, obtained via the MicroArray Quality Control phase-II (MAQC-II) project, includes gene expression over 10,707 probe sites. Of particular interest is to predict the response labeled "3-year event-free survival" (3-year EFS) which is a binary variable indicating whether each patient survived 3 years after the diagnosis of neuroblastoma. Excluding five outlier arrays, there are 246 subjects out of which 239 subjects have 3-year EFS information available with 49 positives and 190 negatives. We apply SIS and ISIS to reduce dimensionality from $p = 10,707$ to $d = 50$. On the other hand, our competitive methods LASSO and NSC are applied directly to $p = 10,707$ genes. Whenever appropriate, five-fold cross validation is used to select tuning parameters. We randomly select 125 subjects (25 positives and 100 negatives) to be the training set and the remainder are used as the testing set. Results are reported in the top half of Table 9. Selected probes for LASSO and all different (I)SIS methods are reported in Table 10.

In MAQC-II, a specially designed end point is the gender of each subject, which should be an easy classification. The goal of this specially designed end point is to compare the performance of different classifiers for simple classification jobs. The gender information is available for all the non-outlier 246 arrays with 145 males and 101 females. We randomly select 70 males and 50 females to be in the training set and use the others as the testing set. We set $d = 50$ for our SIS and ISIS as in the case of the 3-year EFS end point. The results are given in the bottom half of Table 9. Selected probes for all different methods are reported in Table 11.

End point		SIS	ISIS	var2-SIS	var2-ISIS	LASSO	NSC
3-year EFS	No. of features	5	23	10	12	57	9413
	Testing error	19/114	22/114	22/114	21/114	22/114	24/114
Gender	No. of features	6	2	4	2	42	3
	Testing error	4/126	4/126	4/126	4/126	5/126	4/126

Table 9: Results from analyzing two endpoints of the neuroblastoma data

We can see from Table 9 that our (I)SIS methods compare favorably with the LASSO and NSC. Especially for the end point 3-year EFS, our methods use fewer features while giving smaller testing error. For the end point GENDER, Table 11 indicates that the most parsimonious model given by ISIS and Var2-ISIS is a sub model of others.

5.2 SRBCT Data

In this section, we apply our method to the children cancer data set reported in Khan et al. (2001). Khan et al. (2001) used artificial neural networks to develop a method of classifying the small, round

Table 11: Selected probe for Gender end point

blue cell tumors (SRBCTs) of childhood to one of the four categories: neuroblastoma (NB), rhabdomyosarcoma (RMS), non-Hodgkin lymphoma (NHL), and the Ewing family of tumors (EWS) using cDNA gene expression profiles. Accurate diagnosis of SRBCTs to these four distinct diagnostic categories is important in that the treatment options and responses to therapy are different from one category to another.

After filtering, 2308 gene profiles out of 6567 genes are given in the SRBCT data set. It is available online at http://research.nhgri.nih.gov/microarray/Supplement/. It includes a training set

of size 63 (12 NBs, 20 RMSs, 8 NHLs, and 23 EWS) and an independent test set of size 20 (6 NBs, 5 RMSs, 3 NHLs, and 6 EWS).

Before performing classification, we standardize the data sets by applying a simple linear transformation to both the training set and the test set. The linear transformation is based on the training data so that, after standardizing, the training data have mean zero and standard deviation one. Our (I)SIS reduces dimensionality from $p = 2308$ to $d = \lfloor 63/\log 63 \rfloor = 15$ first while alternative methods LASSO and NSC are applied to $p = 2308$ gene directly. Whenever appropriate, a four-fold cross validation is used to select tuning parameters.

ISIS, var2-ISIS, LASSO and NSC all achieve zero test error on the 20 samples in the test set. NSC uses 343 genes and LASSO requires 71 genes. However ISIS and var2-ISIS use 15 and 14 genes, respectively.

This real data application delivers the same message that our new ISIS and var2-ISIS methods can achieve competitive classification performance using fewer features.

Abstract

Due to the scale and computational complexity of currently used simulation codes, global surrogate (metamodels) models have become indispensable tools for exploring and understanding the design space. Due to their compact formulation they are cheap to evaluate and thus readily facilitate visualization, design space exploration, rapid prototyping, and sensitivity analysis. They can also be used as accurate building blocks in design packages or larger simulation environments. Consequently, there is great interest in techniques that facilitate the construction of such approximation models while minimizing the computational cost and maximizing model accuracy. Many surrogate model types exist (Support Vector Machines, Kriging, Neural Networks, etc.) but no type is optimal in all circumstances. Nor is there any hard theory available that can help make this choice. In this paper we present an automatic approach to the model type selection problem. We describe an adaptive global surrogate modeling environment with adaptive sampling, driven by speciated evolution. Different model types are evolved cooperatively using a Genetic Algorithm (heterogeneous evolution) and compete to approximate the iteratively selected data. In this way the optimal model type and complexity for a given data set or simulation code can be dynamically determined. Its utility and performance is demonstrated on a number of problems where it outperforms traditional sequential execution of each model type.

Keywords: model type selection, genetic algorithms, global surrogate modeling, function approximation, active learning, adaptive sampling

1. Introduction

For many problems from science and engineering it is impractical to perform experiments on the physical world directly (e.g., airfoil design, earthquake propagation). Instead, complex, physics-based simulation codes are used to run experiments on computer hardware. While allowing scientists more flexibility to study phenomena under controlled conditions, computer experiments require a substantial investment of computation time. One simulation may take many minutes, hours, days or even weeks. A simpler approximation of the simulator is needed to make sensitivity analysis, visualization, design space exploration, etc. feasible (Forrester et al., 2008; Simpson et al., 2008).

As a result researchers have turned to various approximation methods that mimic the behavior of the simulation model as closely as possible while being computationally cheap(er) to evaluate. Different types of approximation methods exist, each with their relative strengths. This work con-

centrates on the use of data-driven, global approximations using compact surrogate models (also known as emulators, metamodels or response surface models) in the context of computer experiments. The objective is to construct a high fidelity approximation model that is as accurate as possible over the *complete* design space of interest using as little simulation points as possible. Once constructed, the global surrogate model (also referred to as a replacement metamodel[1]) is reused in other stages of the computational science and engineering pipeline. So optimization is not the main goal, but rather a useful post processing step.

The primary users of global surrogate modeling methods are domain experts, few of which will be experts in the intricacies of efficient sampling and modeling strategies. Their primary concern is obtaining an accurate replacement metamodel for their problem as fast as possible and with minimal overhead. Model (type) selection, model parameter optimization, sampling strategy, etc. are of lesser or no interest to them. Thus, this paper explores an automated way to help answer the always recurring question from domain experts *"Which approximation method is best for my data?"*. An evolutionary algorithm is presented that combines automatic model *type* selection, automatic model parameter optimization, and sequential design exploration.

In the next Section we describe the problem of global surrogate modeling followed by an in depth discussion of the motivation for this work in Section 3. The core approach presented in this paper is discussed in Section 5 followed by a critical analysis in Section 6. Section 7 describes a number of surrogate modeling problems we shall use to demonstrate the proposed approach, followed by their discussion in Section 10 (the experimental setup is described in Section 9). We conclude in Section 12 with pointers to future work.

2. Global Surrogate Modeling

The mathematical formulation of the problem is as follows: approximate an unknown multivariate function $f : \Omega \mapsto \mathbb{C}^n$, defined on some domain $\Omega \subset \mathbb{R}^d$, whose function values $f(X) = \{f(x_1), ..., f(x_k)\} \subset \mathbb{C}^n$ are known at a fixed set of pairwise distinct sample points $X = \{x_1, ..., x_k\} \subset \Omega$. Constructing an approximation requires finding a suitable function s from an approximation space S such that $s : \Omega \mapsto \mathbb{C}^n \in S$ and s closely resembles f as measured by some criterion ξ, where ξ constitutes three parts:

$$\xi = (\Lambda, \varepsilon, \tau).$$

Λ is the generalization estimator, ε the error (or loss) function, and τ is the target value required by the user. This means that the global surrogate model generation problem (i.e., finding the best approximation $s^* \in S$) for a given set of data points $D = (X, f(X))$ can be formally defined as

$$s^* = \arg\min_{t \in T} \arg\min_{\theta \in \Theta} \Lambda(\varepsilon, s_{t,\theta}, D) \tag{1}$$

such that

$$\Lambda(\varepsilon, s^*_{t,\theta}, D) \leqslant \tau$$

where $s_{t,\theta}$ is the parametrization θ (from a parameter space Θ) of s and $s_{t,\theta}$ is of model type t (from a set of model types T).

1. The terms surrogate model and metamodel are used interchangeably.

The first minimization over $t \in T$ is the task of selecting a suitable approximation model type, that is, a rational function, a neural network, a spline, etc. This is the model type selection problem. In practice, one typically considers only a single $t \in T$, though others may be included for comparison. Then given a particular approximation type t, the task is to find the hyperparameter assignment θ that minimizes the generalization estimator Λ (e.g., determine the optimal order of a polynomial model). This is the hyperparameter optimization problem, though generally both minimization's are simply referred to as the model selection problem. Many implementations of Λ have been described: the hold-out, bootstrap, cross validation, jack-knife, Akaike's Information Criterion (AIC), etc. Different criteria may also be combined in a multi-objective fashion. In this case ξ is really a matrix

$$\xi = \begin{bmatrix} \Lambda_1 & \varepsilon_1 & \tau_1 \\ \Lambda_2 & \varepsilon_2 & \tau_2 \\ \dots & \dots & \dots \\ \Lambda_m & \varepsilon_m & \tau_m \end{bmatrix}$$

with m the number of objectives. A simple example is minimizing the average relative cross validation error together with the maximum absolute deviation in the training points. An additional assumption is that f is expensive to compute. Thus the number of function evaluations $|f(X)|$ needs to be minimized and data points must be selected iteratively, at points where the information gain will be the greatest (Turner et al., 2007). Mathematically this means defining a sampling function

$$\phi(X_{j-1}) = X_j\,,\; j = 1,..,N$$

that constructs a data hierarchy

$$X_0 \subset X_1 \subset X_2 \subset ... \subset X_N \subset X$$

of nested subsets of X, where N is the number of levels. X_0 is referred to as the *initial experimental design* and is constructed using one of the many algorithms available from the theory of Design and Analysis of Computer Experiments (Kleijnen et al., 2005). Once the initial design X_0 is available it can be used to seed the sampling function ϕ. An important requirement of ϕ is to minimize the number of sample points $|X_j| - |X_{j-1}|$ selected each iteration, yet maximize the information gain of each successive data level. Depending on the problem, ϕ can take into account different criteria (non-linearity of the response, smoothness/uncertainty of the model, location of the optima, etc.). This process is referred to as adaptive sampling, active learning, model updating, or sequential design.

An important consequence of the adaptive sampling procedure is that the task of finding the best approximation s^* (cfr. Equation 1) becomes a dynamic problem instead of a static one. Since the optimal model parameters will change as the amount and distribution of data points changes. This of course makes the problem more difficult.

3. Motivation

While the mathematical formulation of global surrogate modeling is clear cut, its practical implementation raises an obvious question: How should the minimization over $t \in T$ and $\theta \in \Theta$ in Equation 1 be performed? We discuss both cases in the following subsections.

3.1 Problem 1: Model Type Selection

The first minimization over $t \in T$ is the model type selection problem. Many model types exist: rational functions, Artificial Neural Networks (ANN), Support Vector Machines (SVM), Gaussian Process (GP) models, Multivariate Adaptive Regression Splines (MARS), Radial Basis Function (RBF) models, projection pursuit regression, rational functions, etc.

3.1.1 BACKGROUND

From a theoretic standpoint, selecting the most suitable approximation method for a given response is a difficult problem that depends on the data characteristics (dimensionality, number of points, distribution, noise level, periodicity, etc) and the application constraints (accuracy, smoothness, ability to capture poles or discontinuities, execution speed, interpretability, extrapolation requirements, etc). Different application domains prefer different model types. For example rational functions are widely used by the electrical engineering community (Deschrijver and Dhaene, 2005) while ANN are preferred for hydrological modeling (Solomatine and Ostfeld, 2008). Differences in model type usage are often due to practical reasons. This is particularly true in industrial settings. For example: the designer adheres to common practice within his field, the final application restricts the designer to one particular type (e.g., rational models for EM systems), or the expertise is not available to properly try other methods.

Of course, this need not always be the case. The choice of the metamodel type can also be motivated by knowledge of the underlying physics[2] (Triverio et al., 2007) or by the special features the model provides: for example the uncertainty prediction based on random process assumption in Kriging methods[3] (Xiong et al., 2007). So remark there is no such thing as an inherently 'good' or 'bad' model. A model is only as good as the data it is based on and the expertise of the user that built it.

3.1.2 CLASSIC APPROACH

If multiple model types are considered, the classic approach is to simply to try out different types and select the best one according to one or more accuracy criteria. There is ample literature available that benchmarks model types in this way (Simpson et al., 2001; Jin et al., 2001; Queipo et al., 2005; Yang et al., 2005; Chen et al., 2006; Wang and Shan, 2007; Chung and Alonso, 2000; Gano et al., 2006; Gu, 2001; Santner et al., 2003; Lim et al., 2007; Fang et al., 2005; Gorissen et al., 2009c). But claims that a particular model type is superior to others should always be met with some skepticism.

In order for the different benchmarking studies to be truly useful for a domain expert, the results of such studies must be collected and compiled into a general set of rules, recipe, or flowchart. To ease the discussion, let us denote such a compilation into a learning algorithm by L. L is then essentially a classifier that can predict which model type $t \in T$ to use based on data D and application requirements Γ:

2. Knowledge of the physics of the underlying system can make a particular model type to be preferred. For example, rational functions are popular for all kinds of Linear Time-Invariant systems since theory is available that can be used to prove that rational pole-residue models conserve certain physical quantities (Triverio et al., 2007).
3. Kriging models are closely related to GP models and and often Kriging and GP models are used as labels for the same techniques. Great similarities between GP models, SVM models, RBF models, and RBF Neural Networks exist as well, as has been discussed in Rasmussen and Williams (2006).

$$L(D,\Gamma) = t.$$

When executed L should then be able to give a specific recommendation as to which model type to use for a given problem. This recommendation should be more specific than the general rules of thumb that are available now. Experience shows this to be exactly what an application engineer wants. However, constructing such a learner L for any but the most restricted class of problems is a daunting undertaking for obvious practical reasons. Firstly, deciding which problem/application features to train the classifier on is far from trivial. Also even if this is done, the number of features can be expected to be high thus gathering the necessary data (by manually solving Equation 1) to train L accurately will be very computationally expensive.

Secondly, as mentioned above, the success of a model type largely depends on the expertise of the user, the quality of the data, and even the quality of the software implementation of the technique. Neural networks are a good example in this respect. In the right hands they are able to perform very well on many problems. However, if poor choices are made with regard to training function, topology selection, generalization control, training parameters, software library, etc. they may seem to perform poorly. How to take into account this information in L?

Thirdly, a more fundamental problem with this approach is that data must be available in order for the reasoner to work. However, if only a simulation code is available (as is often the case) data must be collected, and the optimal data collection strategy that minimizes the number of points depends on the model type. Also, the optimal model type will change depending on how much data is available. One could argue to instead train L only on the data characteristics which are known in advance (e.g., dimensionality, noise level, etc.). The question is then again, which characteristics are most important? Furthermore, in many cases not much is known about the true behavior of the response thus there will typically not be enough information to train L accurately.

This brings us to the final point. A main reason for turning towards global surrogate modeling methods is that little is known about the behavior of the response (Simpson et al., 2008). The goal is to get insight into that behavior in a computationally cheap way by applying surrogate methods. Another reason why information about the data may be scarce is that the source of the data is confidential or proprietary and very little information is disclosed. In these situations using or training L becomes very difficult.

Finally, we must stress that we do ***not*** say that this problem is too difficult and not worth trying to solve. Indeed many such problems exist and are currently being tackled, particularly in medicine. Instead we argue that users of global surrogate modeling methods can benefit from a more dynamic approach that is flexible, can be easily applied to a wide range of different problems, can easily incorporate new fitting techniques and process knowledge, and naturally integrates with an adaptive data collection procedure. We shall revisit this point in sections 3.3 and 6.

3.2 Problem 2: Model Parameter Selection

Assuming the model type selection problem has been solved, there remains the model parameter selection problem (the minimization over $\theta \in \Theta$ in Equation 1). For example, finding the optimal C, ε and σ parameters in the case of RBF SVMs. This is the classic hyperparameter optimization problem that also depends on the data characteristics (for example the optimal correlation function and correlations parameters of a Kriging model will depend on the data distribution (Gorissen et al., 2008b; Toal et al., 2008). Some models are more sensitive to changes in their parameters than others

and usually it takes a great deal of experience to know how all parameters should be set. Sometimes this problem is solved through trial and error, but usually it is tackled as an optimization problem and classic optimization algorithms are used guided by a performance metric.

A huge amount of research has been done on this topic, particularly in the machine learning community (see Section 4). This particular problem is not the main focus of this work. Rather we are more interested in tackling the first problem.

3.3 Proposed Solution

While we are primarily interested in the first problem, the approach described in this paper naturally incorporates problem 2 as well. In both cases there is little theory that can be used as a guide. It is in this setting that the evolutionary approach can be expected to do well. We describe the application of a single GA with speciation to both problems: the selection of the surrogate type and the optimization of the surrogate model parameters (= hyperparameter optimization). In addition, we do not assume all data is available at once but must be sampled incrementally since it is expensive (active learning).

The idea is to maintain a heterogeneous population of surrogate model types and let them evolve cooperatively and dynamically with the changing data distribution. The details will be presented in Section 5 and a critique in Section 6. In addition, an implementation in the form of a Matlab toolbox is available for download from `http://www.sumo.intec.ugent.be`.

4. Related Work

The evolutionary generation of regression models for given input-output data has been widely studied in the genetic programming community (Vladislavleva et al., 2009; Streeter and Becker, 2003; Yeun et al., 2004). Given a set of mathematical primitives (+, *sin*, *exp*, /, *x*, *y*, etc.) the space of symbolic expression trees is searched to find the best function approximation. The application of GAs to the optimization of model parameters of a single model type (homogeneous evolution) has also been common (Chen et al., 2004; Lessmann et al., 2006; Tomioka et al., 2007; Friedrichs and Igel, 2005; Zhang et al., 2000) and the extensive work by Yao (1999); Yao and Xu (2006). Integration with adaptive sampling has also been discussed (Busby et al., 2007). However, these efforts do not tackle the model *type* selection problem, they restrict themselves to a particular method (e.g., SVMs or neural networks). As Knowles and Nakayama (2008) state "*Little is known about which types of model accord best with particular features of a landscape and, in any case, very little may be known to guide this choice*.". Likewise, Solomatine and Ostfeld (2008) note: "*...it is important to stress that there are always situations when one model type cannot be applied or suffers from inadequacies and can be well complemented or replaced by another one*". Thus an algorithm to help solve this problem in a dynamic, automated way is very useful (Keys et al., 2007). This is also noticed by Voutchkov and Keane (2006) who compare different surrogate models for approximating each objective during optimization. They note that in theory their approach allows the use of a different model type for each objective. However, such an approach will still require an a priori model type selection and does not allow for dynamic switching of the model type or the generation of hybrids.

There has also been much research on the use of surrogate models in evolutionary optimization of expensive simulators (to approximate the fitness function). References include Jin et al. (2002), Regis and Shoemaker (2004), Paenke et al. (2006) and Emmerich et al. (2006), the work by Ong et al. (2006), and more recently by Lim et al. (2007). In general the theory is referred to as Surrogate

Based Optimization or Metamodel Assisted Optimization. A good overview reference is given by Eldred and Dunlavy (2006) and Queipo et al. (2005). For example, Lim et al. (2007) compare the utility of different local surrogate modeling techniques (quadratic polynomials, GP, RBF, ...) including the use of (fixed) ensembles, for optimization of computationally expensive simulation codes. Local surrogates are used together with a trust region framework to quickly and robustly identify the optimum. As noted in the introduction, the contrast with this work is that references such as Lim et al. (2007) are interested in the optimum and not the surrogate itself (they make only a "*mild assumption on the accuracy of the metamodeling technique*"). In addition the model parameters are taken as fixed and there is no integration with active learning. In contrast we place very strong emphasis on the surrogate model accuracy, the automatic setting of the hyperparameters, and the efficient sampling of the *complete* design space.

The work of Sanchez et al. (2006) and Goel et al. (2007) is more useful in our context since they provide new algorithms for generating an optimal set of ensemble members for a fixed set of data points (no sampling). Unfortunately, though, the parameters of the models involved must still be chosen manually. Nevertheless, their approaches are interesting, and can be used to further enhance the approach presented here. For example, instead of returning the single final best model, an optimal ensemble member selection algorithm can be used to return a potentially much better model based on the final population or Pareto front.

From machine learning the work in B. et al. (2004) is also related. The authors describe an interesting classification algorithm *COMB* that combines online an ensemble of active learners so as to expedite the learning progress in pool-based active learning. In their terminology an active learner is a combination of a model type and a sampling algorithm. A weighted ensemble of active learners is maintained and each learner is allowed to express interest in a pool of unlabeled training points. Depending on the interests of the active learners, an unlabeled point is selected, labeled by the teacher, and based on the added value of that point the different active learners are punished or rewarded. Internally the active learners are SVM models whose parameters are chosen manually. In principle, with a number of approximations one could adapt the algorithm to the regression case. If one then also included hyperparameter optimization, the result would be very similar to the SUMO-Toolbox (cfr. Section 5.2) configured with one or more of the *Error*, LRM, or EGO (Jones et al., 1998) sample selection algorithms, but without the ability to combine different criteria. However, a problem would be that *COMB* assumes a pool of unlabeled training data is given. However, when modeling a simulation code in regression no such pool is available. Some external algorithm would still be needed to generate it in order for *COMB* to work. *COMB* does also naturally allow for different model types but in a more static way than the algorithm in Section 5.3: there is no hyperparameter optimization, the number of each active learning type remains fixed (though the weights can change) leading to a potentially high computational cost, and hybrid models are not considered. The extension to the multi-objective case is also non-trivial. Of course *COMB* could be extended to incorporate such features, but the result would be very similar to the work presented here. Nevertheless, the specific scoring functions, probability weightings, and ensemble weight updates, seem very useful and could be implemented in the SUMO-Toolbox to complement the approach presented here.

Finally, the work by Escalante et al. (2008) is most similar to the topic of this paper. Escalante et al. (2008) consider the problem of finding the optimal classifier and associated hyperparameters for a given classification problem (active learning is not considered). A solution is encoded as a vector and Particle Swarm Optimization (PSO) is used to search for good classifiers. Good results

are shown on various benchmarks. Unlike the GA approach, however, it is less straightforward to cater for multiple sub-populations, giving models room to mature independently before entering competition. The use of operators tuned to specific models is also difficult (to increase the search efficiency). In effect, the PSO approach takes a top-down view, using a high level encoding in a high dimensional space, a typical particle has 25 dimensions (Escalante et al., 2007). In contrast the GA approach is bottom up, the model specific operators result in a much smaller search space, different for each method (e.g., 1 for the spline models and 2 for the SVM models). This leads to a more efficient search requiring less fitness evaluations and facilitates the incorporation of prior knowledge. In addition, by using PSO there is no natural way of enabling hybrid solutions (ensembles) without extending the encoding and further increasing the search space. In contrast, the hybrid solutions arise very naturally in the GA framework and do not impact the search space of the other model types. The same is true of the extension to the multi-objective case, a very natural step in the GA case.

In sum, in by far the majority of the related work considered by the authors, speciation was always constrained to one particular model type, for example neural networks in Stanley and Miikkulainen (2002). The model type selection problem was still left as an a-priori choice for the user. Or, if multiple model types are used, the hyperparameters are typically kept fixed and there is no tie-in with the active learning process.

5. Heterogeneous Evolution of Surrogate Models

This Section discusses how different surrogate models may be evolved cooperatively in order perform model type selection.

5.1 Speciated Evolution

Since GAs are population-based they easily lend themselves to parallelism. The terms Parallel Genetic Algorithms (PGA) or Distributed Genetic Algorithms (DGA) refer to the case whenever the population is divided up in some way, be it to improve the computational efficiency or search efficiency. Unfortunately though, the terminology varies between authors and can be confusing (Nowostawski and Poli, 1999; Alba and Tomassini, 2002). From a biological standpoint it makes sense to consider *speciation:* genomes that differ considerably from the rest of the population are segregated and continue to evolve semi-independently, forming a new species.

The *island model* (Whitley et al., 1999.; Hocaoglu and Sanderson, 2001; Giannakoglou et al., 2006) is probably the most well known PGA. Different sub-populations, called *demes*, exist (initialized differently) and sporadic migration can occur between islands allowing for the exchange of genetic material between species and inter-species competition for resources. Selection and recombination are restricted per deme, such that each sub-population may evolve towards different locally optimal regions of the search space (also called *niches*). An advantage of using migration is that it allows sub-species to mature in semi-isolation without being forced to consistently engage in competition. This is particularly useful for the application of this paper. The island model introduces five new parameters: the migration topology, the migration frequency, the number of individuals to migrate, a strategy to select the emigrants, and a replacement strategy to incorporate the immigrants. The island model is illustrated in Figure 1 for two topologies.

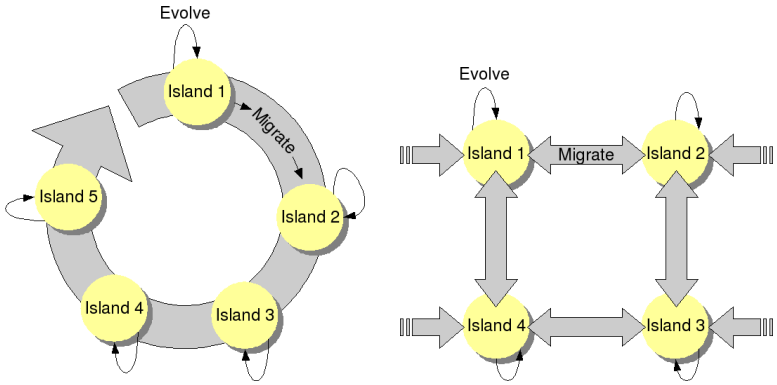

Figure 1: Ring (left) and grid (right) migration topologies in the Island Model

5.2 Global Surrogate Modeling Control Flow

Before we can discuss the concrete implementation of the automatic model type selection algorithm it is important to revisit the general global surrogate modeling methodology described in Section 2. It is important to understand the general control flow since it forms the basis for the evolutionary algorithm described in the next Section.

The general methodology is as follows: Initially, a small initial set of samples is chosen according to some experimental design (e.g., Latin hypercube, Box-Behnken, etc.). Based on this initial set, one or more surrogate models are constructed and their hyperparameters optimized according to a chosen hyperparameter optimization algorithm (e.g., BFGS, Particle Swarm Optimization (PSO), Genetic Algorithm (GA), DIRECT, NSGA-II, etc.). Models are assigned a score based on one or more measures (e.g., cross validation, Akaike's Information Criterion (AIC), etc.) and the optimization continues until no further improvement is possible. The models are then ranked according to their score and new samples are selected based on the best performing models and the behavior of the response (the exact criteria depend on the active learning algorithm used). The hyperparameter optimization process is continued or restarted intelligently and the whole process repeats itself until one of the following three conditions is satisfied: (1) the maximum number of samples has been reached, (2) the maximum allowed time has been exceeded, or (3) the user required accuracy has been met.

Recall that the adaptive sampling procedure has an important effect on the hyperparameter optimization. The non-stationary data distribution makes the model parameter optimization surface dynamic instead of static (as is typically assumed).

A readily available implementation of the control flow described in this Section, and the one we shall use for the experiments in this paper, is available as the **SU**rrogate **MO**deling Toolbox (SUMO Toolbox) (Gorissen et al., 2009c) from `http://www.sumo.intec.ugent.be`.

5.3 Algorithm

Algorithm 1 Automatic global surrogate modeling with heterogeneous evolution and active learning

01. $X_0 = initialExperimentalDesign()$;
02. $X = X_0$;
03 . $f|_X = evaluateSamples(X)$;
04 .$T = \{t_1, ..., t_h\}$;
05. $M_i = \text{createInitialModels}(t_i, popsize_i); i = 1, .., h$
06. $M = \bigcup_{i=1}^{h} M_i$;

07 . **while** (ξ not reached) **do**
08. $scores = \{\}$; $gen = 1$;
09 . **while** ($termination\_criteria$ not reached) **do**
10. **foreach** $M_i \subseteq M$ **do**
11. $scores_i = \text{fitness}(M_i, X, f|_X, \xi)$;
12. $elite = \text{sort}([scores_i; M_i])|_{1:el}$;
13. $parents = \text{select}(scores_i, M_i)$;
14. $parents_{xo} = \text{selectXOParents}(parents, p_c)$;
15. $offspring_{xo} = \text{crossover}(parents_{xo}, ES_{diff}, ES_{max})$;
16. $parents_{mut} = parents \backslash parents_{xo}$;
17. $offspring_{mut} = \text{mutate}(parents_{mut})$;
18. $M_i = elite \bigcup offspring_{mut} \bigcup offspring_{xo}$;
19. $scores = scores_i \cup scores$;
20. **end**
21. **if** $(mod(gen, m_i) = 0)$
22. $M = \text{migrate}(M, scores, m_f, m_d)$
23. **end**
24. $M = \text{extinctionPrevention}(M, T_{min})$;
25. $gen = gen + 1$;
26. **end**
27 . $X_{new} = \text{selectSamples}(X, f|_X, M)$;
28 . $f|_{X_{new}} = \text{evaluateSamples}(X_{new})$;
29 . $[X, f|_X] = merge(X, f|_X, X_{new}, f|_{X_{new}})$;
30 . **end**

31 . **return**bestModel(M);

We now present the concrete GA for heterogeneous evolution as it is embedded (as a plugin) in the SUMO Toolbox. The speciation model used is the island model since we found it the most natural way of evolving multiple model types while still allowing for hybrid solutions. The algorithm is based on the Matlab GADS toolbox and works as follows (see Algorithm 1 and reference (Gorissen, 2007) for more details): After the initial DOE has been calculated (cfr. the control flow in Section 5.2), an initial sub-population M_i is created for each model type $t \in T$ ($i = 1, .., h$). The exact creation algorithm is different for each model type so that model specific knowledge can be exploited.

Subsequently, each deme is allowed to evolve according to an elitist GA. Parents are selected according a selection algorithm (e.g., tournament selection) and offspring undergo either crossover (with probability p_c) or mutation (with probability $1 - p_c$). The models M_i are implemented as Matlab objects (with full polymorphism) thus each model type can choose its own representation and mutation/crossover implementations (this implements the minimization over $\theta \in \Theta$ of Equation 1). While mutation is straightforward, the crossover operator is more involved (see Section 5.5 below).

The fitness function calculates the quality of the model fit, according to criteria ξ. The current deme population is then replaced with its offspring together with *el* elite individuals. Once every deme has gone through a generation, migration between individuals is allowed to occur at migration interval m_i, with migration fraction m_f and migration direction m_d (a ring topology is used). The migration strategy is as follows: the $l = (|M_i| \cdot m_f)$ fittest individuals of M_i replace the l worst individuals in the next deme (defined by m_d). As in Pei and Goodman (2001), migrants are duplicated, not removed from the source population. Note that in this contribution we are primarily concerned with inter-model speciation (speciation as in different model types). Intra-model speciation (e.g., through the use of fitness sharing within one model type) is something which was not done but could easily be incorporated.

Once the GA has terminated, control passes back to the main global surrogate modeling algorithm of the SUMO Toolbox. At that point M contains the best set of models that can be constructed for the given data. If the accuracy of the models is sufficient the main loop terminates. If not, a new set of maximally informative sample points is selected based on several criteria (quality of the models, non-linearity of the response, etc.) and scheduled for evaluation. Once new simulations become available the GA is resumed.

Note that sample evaluation and model construction/hyperparameter optimization run in parallel. For clarity, algorithm 1 shows them running sequentially but this is not what happens in practice. In reality both are interleaved to allow an optimal use of computational resources.

5.4 Extinction Prevention

Initial versions of this algorithm exposed a major shortcoming, specifically due to the fact that models are being evolved. Since not all data is available at once but trickles in, $|X_j| - |X_{j-1}|$ samples at a time, models that need a reasonable-to-large number of samples to work well will be at a huge disadvantage initially. Since they perform badly at first, they may get overwhelmed by other models who are less sensitive to this problem. In the extreme case where they are driven extinct, they will never have had a fair chance to compete when sufficient data *does* become available. They may even have been the superior choice had they still been around.[4] Therefore an Extinction Prevention (EP) algorithm was introduced that ensures a model type can never disappear completely.

EP works by monitoring the population and each generation recording the number of individuals of each model type. If this number falls below a certain threshold T_{min} for a certain model type, the EP algorithm steps in and ensures the model type has its numbers replenished up to the threshold. This is done by re-inserting the last models that disappeared for that type (making copies if necessary). The re-inserted models replace the worst individuals of the other model types (who do have sufficient numbers) evenly.

Strictly speaking, EP goes completely against the survival of the fittest principle in evolutionary algorithms. By using it we are manually working against selection, preserving model types which

4. As an example, this observation was often made when using rational models on electro-magnetic data.

give poor results at that point in time. However, in this setting it seems a fair measure to take (we do not want to risk loosing a model type completely) and improves results in most cases (*see* Section 10). At the same time it is straightforward to implement and understand, needing no special control parameters. All it has to ensure is that a species is never driven extinct.

5.5 Heterogeneous Recombination

The attentive reader will have noticed that one major problem remains with the implementation as discussed so far. The problem lies in the genetic operators, more specifically in the crossover operator. Migration between demes means that model types will mix. This means that a set of parents selected for reproduction may contain more than one model type. The question then arises: how to perform recombination between two models of completely different types. For example, how to meaningfully cross an Artificial Neural Network with a rational function? The solution we propose here is to use ensembles (behavioral recombination). If two models of different types are selected to recombine, an ensemble is created with the models as ensemble members. Thus, as soon as migration occurs, model types start mixing, and ensemble models arise as a result. These are treated as a distinct model type just as the other model types.

However, the danger with this approach is that the population may quickly be overwhelmed by large ensembles containing duplicates of the best models (as was noticed during initial tests). To counter this phenomenon we apply the similarity idea from Holland's sharing concept (Holland, 1975). Individual models will try to mate only with individuals of the same type. Only in the case where selection has made this impossible shall different model types combine to form an ensemble. In addition we enforce a maximum ensemble size ES_{max} and require that ensemble members must differ ES_{diff} percent in their response (their 'behavior'). This is calculated by evaluating the models on a dense grid.

This leaves us with only three cases left to explain:

1. *ensemble - ensemble* recombination: a single-point crossover is made between the ensemble member lists of each model (note that the type of the ensemble members is irrelevant)

2. *ensemble - model* recombination: the model replaces a randomly selected ensemble member with probability p_{swap} or gets absorbed into the ensemble with probability $1 - p_{swap}$ (respecting ES_{max} and ES_{diff}).

3. *ensemble* mutation: one ensemble member is randomly deleted

Besides enabling hybrid solutions, using ensembles has the additional benefit of allowing a model to lie 'dormant' in an ensemble with the possibility of re-emerging later (e.g., if after mutation only one ensemble member remains). Note that, in contrast to Lim et al. (2007) for example, the type of the ensemble members is not fixed in any way but varies dynamically.

We have not yet mentioned what type of ensemble will be used. There are several methods for combining the outputs of models, such as average, weighted average, Dempster-Shafer methods, using rank-based information, supra-Bayesian approach, stacked generalization, etc (Sharkey, 1996). To keep the implementation straightforward and the complexity (number of parameters) low we have opted for a simple average ensemble. Of course different, more powerful combination methods could be used instead and they will only improve results. The exact method used is of lesser importance since it does not change the methodology. The advantage of a simple average

ensemble is that it works in all cases: It makes no assumption on the model types involved, nor does it mandate any changes to the models or training algorithms (for example, like negative correlation learning) since this is not always possible (e.g., when using proprietary, application specific, modeling code).

5.6 Multi-objective Model Selection

A crucial aspect of the model generation algorithm is the choice of a suitable criteria ξ. In practice it turns out that selecting an appropriate function for Λ, ε and a target value for τ is difficult. Particularly if little is known about the structure of the response. This is related to the "*The 5 percent problem*" (Gorissen et al., 2009b). The fundamental reason for this difficulty is that an approximation task inherently involves multiple, conflicting, criteria (Li and Zhao, 2006). Thus a multi-objective approach is very useful here since it enables the use of multiple criteria during the hyperparameter optimization process (see Jin and Sendhoff 2008 for an excellent overview of this line of research).

Secondly, it is not uncommon that a simulation engine has multiple outputs that all need to be modeled (Conti and O'Hagan, 2007). The direct approach is to model each output independently with separate models (possibly sharing the same data). This, however, leaves no room for trade-offs nor gives any information about the correlation between different outputs. Instead of performing two modeling runs (doing a separate hyperparameter optimization for each output) both outputs can be modeled simultaneously if models with multiple outputs are used in conjunction with a multi-objective optimization routine.

In both cases such a multi-objective approach can be integrated with the automatic surrogate model type selection algorithm described here. This means that the best model type can vary per criteria or, more interestingly, that it enables automatic selection of the best model type for each output without having to resort to multiple runs. A full discussion of these topics is out of scope for this paper. However, details and some initial results can already be found in Gorissen et al. (2009a) and Gorissen et al. (2009b).

6. Critique

The algorithm presented so far has a number of strengths and weaknesses. The obvious advantage is the ability to perform automatic selection of the model type and complexity for a given data source (no need to do multiple parallel runs or train a complex classifier). In addition the algorithm is generic in that it is independent of the data origin (application), model type, and data collection strategy. New approximation methods can easily be incorporated without changing the algorithm. Problem specific knowledge and model type specific optimizations based on expert knowledge can also be incorporated if needed (i.e., by customizing the genetic operators). Furthermore, the algorithm naturally integrates with the data collection strategy, allowing the best model type to change dynamically and naturally allows for hybrid solutions. Finally, it naturally extends to the multi-objective case (Section 5.6) and can be easily parallelized to allow for faster computations (though the computational cost is still outweighed by the simulation cost).

The main disadvantage is due to the fact that the approach is based on evolutionary algorithms: full determinism can not be guaranteed. This raises the obvious question of how stable the convergence is over multiple runs. The same can be said of standard approaches towards hyperparameter optimization (which typically include randomization) or for any algorithm involving a GA for that

matter. Formulating theoretical foundations in order to come to convergence guarantees for GAs is a difficult undertaking and has been the topic of intense research ever since their inception in the late 80s. Characterizing the performance of genetic algorithms is complex and depends on the application domain as well as the implementation parameters (Rawlins, 1991). Most theoretic work has been done on schema theorems for the Canonical Genetic Algorithm (CGA), which try to prove convergence in a simplified framework using a binary representation. However prediction of the future behavior of a GA turns out to be very difficult and much controversy remains over the usefulness of these theorems (Poli, 2001; Goldberg, 1989). Theoretical work on other classes of GAs or using specific operators has also been done (Nakama, 2008; Neubauer, 1997; Rawlins, 1991; Qi and Palmieri, 1994a,b) but is unfortunately of little practical use here. For example, the work in Ankenbrandt (1990) requires the calculation of fitness ratios, but this is impractical (and computationally expensive) to do in this situation and the results will vary with the application.

Thus, for the purposes of this paper a full mathematical treatment of algorithm 1 and its convergence is out of scope. Due to the island model, sampling procedure, and heterogeneous representation/operators used, such a treatment will be far from trivial to construct and distract from the main theme of the paper. In addition its practical usefulness would remain questionable due to the many assumptions that will be required. However, gaining a deeper theoretical insight into the robustness of the algorithm is still very important. A sensitivity study of the main GA parameters involved will shed more light on this issue.

Theoretical remarks aside, the authors have found that in practice the approach works quite well. If reasonable population sizes are used together with migration and the extinction prevention algorithm described in Section 5.4, the results of the algorithm are quite robust and give useful results and insights into the modeling problem. Besides the results given in this paper, good results have also been reported on various real world problems from aerodynamics (Gorissen et al., 2009a), electronics (Gorissen et al., 2008a), hydrology (Couckuyt et al., 2009), and chemistry (Gorissen, 2007).

In sum, this approach is useful if: little information is known about the expected structure of the response, if it is unclear which model type is most suited to the problem, data is expensive and must be collected iteratively, and hybrid solutions are useful. In other cases, for example it is clear from a priori knowledge which model type will be the most suitable (e.g., based on existing rules of thumb for a well defined, restricted problem), this approach should not be applied, save as a comparison.

7. Test Problems

We now consider five test problems to which we apply the heterogeneous GA (from now on abbreviated by HGA). The objective is to validate if the best model type can indeed be determined automatically, and in a way that is cheaper and better than the simple brute force method: doing multiple, single model type runs in parallel. The problems include 2 predefined mathematical functions, and real-world problems from electronics and aerodynamics.

The dimensionality of the examples ranges from 2 to 13. This is no inherent limit but simply depends on the model types used. For example if only SVM-type models are used the number of dimensions can be arbitrarily high, while for smoothing spline models the dimensionality should be kept low. It all depends on which model types make up the population.

We also hope to see evidence of a 'battle' between model types. While initially one species may have the upper hand, as more data becomes available (dynamically changing hyperparameter optimization landscape) a different species may become dominant. This should result in clearly noticeable population dynamics, a kind of oscillatory stage before convergence. We briefly discuss each of the test problems in turn.

7.1 Ackley Function (AF)

The first test problem is Ackley's Path, a well known benchmark problem from optimization. Its mathematical definition for d dimensions is:

$$\begin{aligned} F(\vec{x}) &= -20 \cdot \exp\left(-0.2\sqrt{\frac{1}{d}\cdot\sum_{i=1}^{d} x_i^2}\right) \\ &\quad -\exp\left(\frac{1}{d}\cdot\sum_{i=1}^{d}\cos(2\pi\cdot x_i)\right)+20+e \end{aligned}$$

with $x_i \in [-2,2]$ for $i = 1,...,d$. For easy visualization we take $d = 2$. For this function a validation set and a test set of 5000 random points each is available. Although this is a function from optimization we are not interested in optimizing it, rather in reproducing it using a regression method with minimal data.

7.2 Kotanchek Function (KF)

The second predefined function is the Kotanchek function (Smits and Kotanchek, 2004). Its mathematical definition is given as:

$$F(x_1,x_2,u_1,u_2,u_3) = \frac{e^{-x_2^2}}{1.2+x_1^2}+\varepsilon$$

with $x_1 \in [-2.5,1.5]$, $x_2 \in [-1.0,3.0]$, and with ε uniform random simulated numeric noise with mean 0 and variance 10^{-4}. As you can see only the first two variables are relevant. For this function a validation set and a test set of 5000 scattered points each is available.

7.3 EM Example (EE)

The fourth example is a 3D Electro-Magnetic (EM) simulator problem (Lehmensiek, 2001). Two perfectly conducting round posts, centered in the E-plane of a rectangular waveguide, are modeled, as shown in Figure 2. The 3 inputs to the simulation code are: the signal frequency f, the diameter of the posts d, and the distance between the two posts w. The outputs are the complex reflection and transmission coefficients S_{11} and S_{21}. The simulation model was constructed for a standard WR90 rectangular waveguide with $f \in$[7 GHz, 13 GHz], $d \in$[1 mm, 5 mm] and $w \in$[4 mm, 18 mm]. In addition, a 25^3 data set is available for testing purposes.

7.4 LGBB Example (LE)

NASA's Langley Research Center is developing a small launch vehicle (SLV) (Pamadi et al., 2004; Rogers et al., 2003) that can be used for rapid deployment of small payloads to low earth orbit

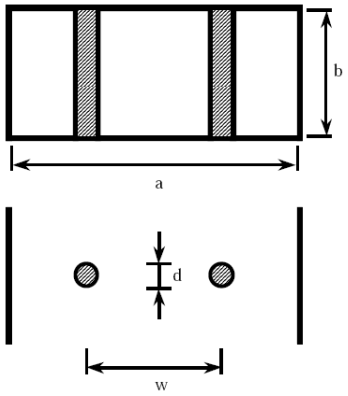

Figure 2: Cross sectional view and top view of the inductive posts (Lehmensiek, 2001)

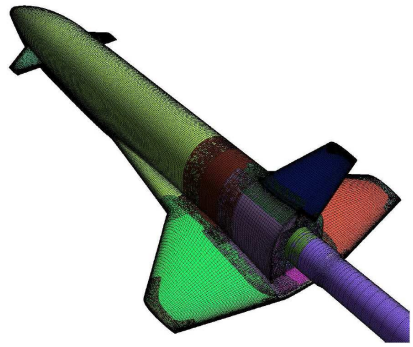
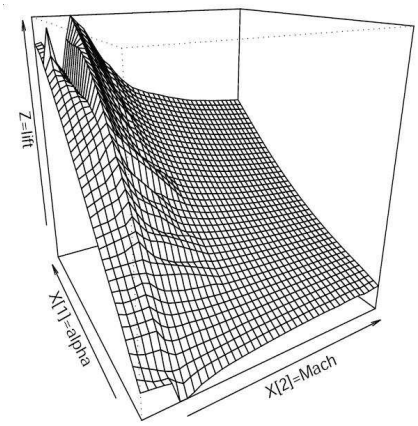


(a) LGBB geometry (Rogers et al., 2003)



(b) Lift plotted as a function of speed and angle of attack with side-slip angle fixed to zero (Gramacy et al., 2004).

Figure 3: LGBB Example

at significantly lower launch costs, improved reliability and maintainability. The vehicle is a three-stage system with a reusable first stage and expendable upper stages. The reusable first stage booster, which glides back to launch site after staging around Mach 3 is named the Langley Glide-Back Booster (LGBB). In particular, NASA is interested in the aerodynamic characteristics of the LGBB from subsonic to supersonic speeds when the vehicle reenters the atmosphere during its gliding phase.

More concretely, the goal is to gain insight about the response in lift, drag, pitch, side-force, yaw, and roll of the LGBB as a function of three inputs: Mach number, angle of attack, and side slip angle. For each of these input configurations the Cart3D flow solver is used to solve the inviscid Euler equations over an unstructured mesh of 1.4 million cells. Each run of the Euler solver takes on the order of 5-20 hours on a high end workstation (Rogers et al., 2003). The geometry of the LGBB used in the experiments is shown in Figure 3a.

Figure 3b shows the lift response plotted as a function of speed (Mach) and angle of attack (alpha) with the side-slip angle (beta) fixed at zero. The ridge at Mach 1 separates subsonic from supersonic cases. From the figure it can be seen there is a marked phase transition between flows at subsonic and supersonic speeds. This transition is distinctly non-linear and may even be non-differentiable or non-continuous (Gramacy et al., 2004). Given the computational cost of the CFD solvers, the LGBB example is an ideal application for metamodeling techniques. Unfortunately access to the original simulation code is restricted. Instead a data set of 780 points chosen adaptively according to the method described in Gramacy et al. (2004) was used.

7.5 Boston Housing Example (BH)

The Boston Housing data set contains census information for 506 housing tracts in the Boston area and is a classic data set used in statistical analysis. It was collected by Harrison et al. and described in Harrison and Rubinfeld (1978). In the case of regression the objective is to predict the Median value of owner-occupied homes (in $1000's) from 13 input variables (e.g., per capita crime rate by town, nitric oxide concentration, pupil-teacher ratio by town, etc.).

8. Model Types

For the tests the following model types are used: Artificial Neural Networks (ANN), rational functions, RBF models, Kriging models, LS-SVMs, and for the AF example: also smoothing splines. For the EM example only the model types that support complex valued outputs directly (rational functions, RBF, Kriging) were included. Each type has its own representation and genetic operator implementation (thanks to the polymorphism as a result of the object oriented design). As stated in subsection 5.5 the result of a heterogeneous recombination will be an averaged ensemble. So in total up to seven model types will be competing to approximate the data. Remember that all model parameters are chosen automatically as part of the GA. No user input is required, the models and data points are generated automatically.

The ANN models are based on the Matlab Neural Network Toolbox and are trained with Levenberg Marquard backpropagation with Bayesian regularization (MacKay; Foresee and Hagan, 1997) (300 epochs). The topology and initial weights are determined by the GA. When run alone (without the HGA) this results in high quality models with a much faster run time than training the weights by evolution as well. Nevertheless, the high level Matlab code and complex training function do make the ANNs much slower than any of the other model types.

The LS-SVM models are based on the implementation from Suykens et al. (2002), the kernel type is fixed to RBF, leaving c and σ to be chosen by the GA. The Kriging model implementation is based on Lophaven et al. (2002) (except for the EM example) and the correlation parameters are set by the GA (the regression function is set to linear and the correlation function to Gaussian). The RBF models (and the Kriging models for the EM example, since the data is complex valued) are based on a custom implementation where the regression function, correlation function, and correlation parameters are all evolved. The rational functions are also based on a custom implementation, the free parameters being the orders of the two polynomials, the weights of each parameter, and which parameters belong in the denominator. The spline models are based on the Matlab Splines Toolbox and only have one free parameter: the smoothness.

Remember that the specific model types chosen for the different tests is less important. This can be freely chosen by the user. What is important is rather how these different model types are used

together in a single algorithm. Thus a full explanation of the virtues of each model types, as well as the representation and genetic operators used is out of scope for this paper and would consume too much space. Details can be found in Gorissen (2007) or in the implementation that is available as part of the SUMO Toolbox.

9. Experimental Setup

The following subsections describe the configuration settings used (and their motivation) for performing the experiments.

9.1 Sample Selection Settings

For the LE and BH examples only a fixed, small size, data set is available. Thus, selecting samples adaptively makes little sense. So for these examples the adaptive sampling loop was switched off. For the other examples the settings were as follows: an initial optimized Latin hypercube design, using the method from Ye et al. (2000), of size 50 is used augmented with the corner points. Modeling is allowed to commence once at least 90% of the initial samples are available. Each iteration a maximum of 50 new samples are selected using the Local Linear (LOLA) adaptive sampling algorithm (Crombecq et al., 2009). LOLA identifies new sample locations by making a tradeoff between eploration (covering the design space evenly) and exploitation (concentrating on regions where true response is nonlinear). LOLA's strengths are that it scales well with the number of dimensions, makes no assumptions about the underlying problem or surrogate model type, and works in both the $\mathbb{R}$ and $\mathbb{C}$ domains. LOLA is able to automatically identify non-linear regions in the domain and sample these more densely compared to more linear, 'flatter' regions.

By default LOLA does not rely on the (possibly misleading) approximation model, but only on the true response. This is useful here since it allows us to consider the model selection results independent from the sample selection settings. I.e., the final distribution of points chosen by LOLA is the same across all runs and model types. This means that any difference in performance between models can not be due to differences in sample distribution. However, in many cases it may be desirable to also include information about the surrogate model itself when choosing potential sample locations. In this case the LOLA algorithm can be combined with one or more other sampling criteria that do depend on model characteristics (for example the *Error*, LRM, and EGO algorithms available in SUMO).

9.2 GA Settings

The GA is run for a maximum of 15 generations between each sampling iteration (after sampling, the GA continues with the final population of the previous iteration). It terminates if one of the following conditions is satisfied: (1) the maximum number of generations is reached, or (2) 8 generations with no improvement. The size of each deme is set to 15. The migration interval m_i is set to 7, the migration fraction m_f to 0.1 and the migration direction is *both* (copies of the m_f best individuals from island i replace the worst individuals in islands $i-1$ *and* $i+1$). A stochastic uniform selection function was used. Since we want to find the best approximation over the *complete* design space, the fitness of an individual is defined as the root relative square error (RRSE):

$$RRSE(y_i, \tilde{y}_i) = \sqrt{\frac{\sum_{i=1}^{n}(y_i - \tilde{y}_i)^2}{\sum_{i=1}^{n}(y_i - \bar{y})^2}}$$

where $y_i, \tilde{y}_i, \bar{y}$ are the true, predicted, and mean true response values respectively. Intuitively the *RRSE* indicates how much better an approximation is than the most simple approximation possible (the mean) (Ganser et al., 2007). In the case of the BH and LE examples no separate validation set is available, instead 20% of the available data is reserved for this purpose (taking care to ensure the validation set is representative of the full data set by maximizing the minimum distance between validation points). Note that we are using a validation set since it is cheap and we have enough data available. In the case where data is scarce we would most likely use the more expensive k-fold cross validation as a fitness measure. This is the case for the EM example.

The remaining parameters are set as follows: $p_m = 0.2, p_c = 0.7, k = 1, p_{swap} = 0.8, el = 1, ES_{max} = 3, ES_{diff} = 0.1, T_{min} = 2$. The random generator seed was set to Matlab's default initial seed.

9.3 Termination Criteria

In case of adaptive modeling only (no sample selection), the objective is to see what the most accurate model is that can be found in a limited period of time (= a typical use case). Thus the required accuracy (= target fitness value) is set to 0. For the LE the timeout is set to 180 minutes. For the BH example the timeout is significantly extended to 1200 minutes. Given the high dimensionality, the noise and discontinuities in the input domain it is a hard problem to fit accurately. In this case we are more interested to see how the population would evolve over such an extended period of time.

In case of adaptive sampling, the criteria are: a target accuracy (RRSE) of 0.01, and for the AF example a maximum number of 500 data points is enforced (to see what performance can be reached with a limited sample budget).

9.4 Others

Each problem was modeled twice with the heterogeneous evolution algorithm (once with $EP = true$, once with $EP = false$) and once with homogeneous evolution (a single model type run for each model type in the HGA). To smooth out random effects each run was repeated 15 times. This resulted in a total of 516 runs which used up a total of at least 130 days worth of CPU time (excluding initial tests and failed runs). All experiments were run on CalcUA, the cluster available at the University of Antwerp, which consists of 256 Sun Fire V20z nodes (dual AMD Opteron with 4 or 8 GB RAM), running SUSE linux, and Matlab 7.6 R2008a. Due to space considerations, only the results for the *S11* (EE), and *lift* (LE) outputs are considered in this paper. For all examples the input space is normalized to the interval $[-1, 1]$.

10. Discussion

We now discuss the results of each problem separately in the following subsections.

10.1 Ackley Function

The composition of the final population for each run is shown in Figure 4 for Extinction Prevention (EP) equal to *true* and *EP=false*. The title above each sub figure shows the average and standard

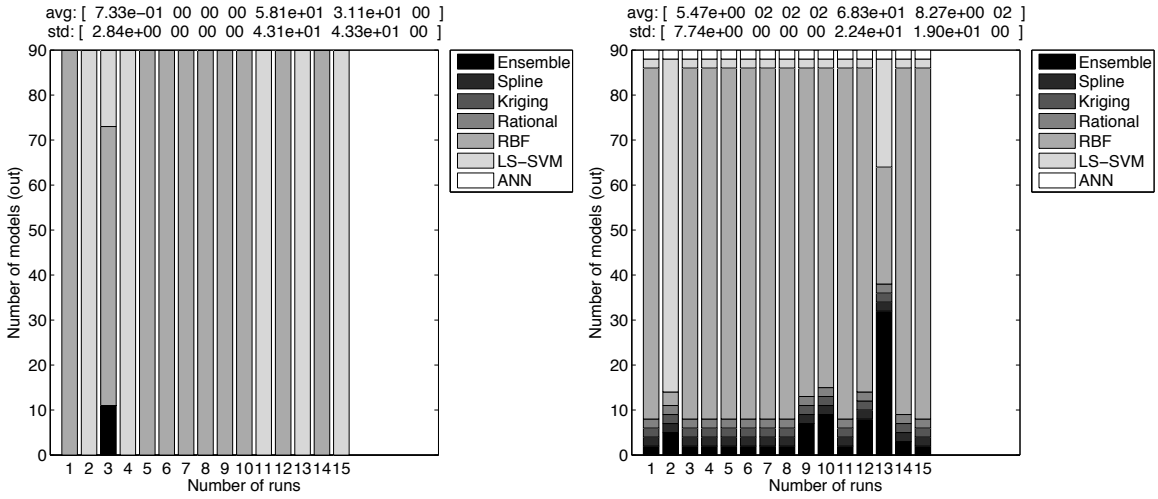


Figure 4: AF: Composition of the final population (Left: *EP=false*, Right: *EP=true*)

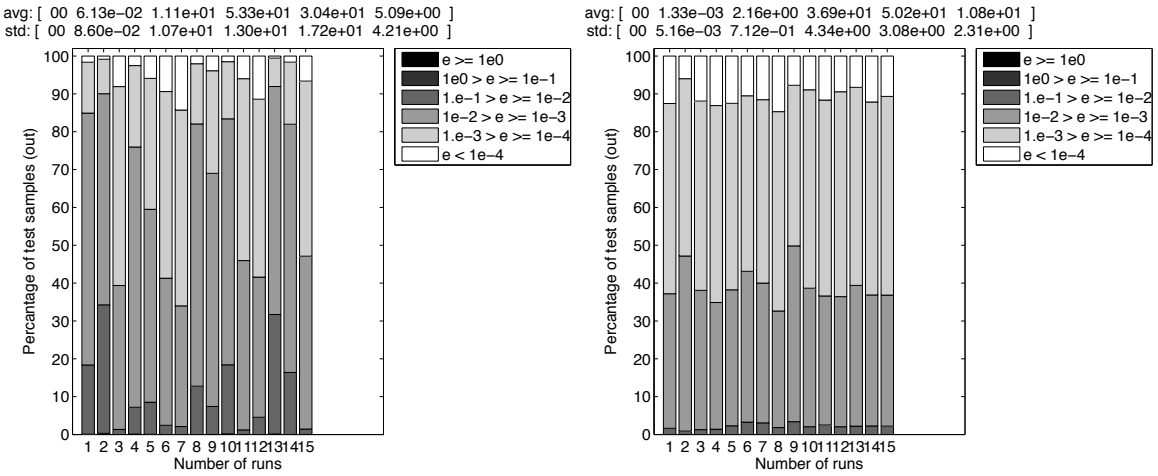

Figure 5: AF: Error histogram of the final best model in each run (Left: *EP=false*, Right: *EP=true*)

deviation over all runs. The first element of each vector corresponds to the first (top) legend entry. The error histogram of the final model of each run on the test data is shown in Figure 5. The population evolution for the run that produced the best model in both cases is shown in Figure 6. Figure 7 then depicts the evolution of the relative error (calculated according to Equation 2) on the test set as modeling progresses (again in both cases, for the run that produced the best model). The lighter the regions in Figure 7, the larger the percentage of test samples that have low relative error (RE) (according to Equation 2).

$$RE(y,\tilde{y}) = \frac{|y-\tilde{y}|}{1+|y|}. \tag{2}$$

Finally, a summary of the results for each run is shown in Table 1. The table shows the number of samples used ($|X|$), the validation error (*VE*), the test set error (*TE*), and the run time for each

Table 1: AF: Comparison with homogeneous evolution

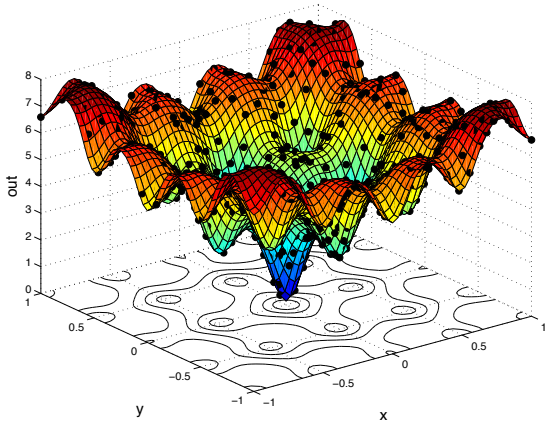

Figure 8: AF: normalized plot of the best model overall ($HGA_{EP=true}$)

experiment. All entries are averaged over 15 runs with the standard deviation shown in the adjacent column. The plot of the best model found overall is shown in Figure 8.

Regarding the composition of the final population in Figure 4, we see that the results are somewhat mixed for *EP=false*. In some runs RBF models perform best, in others LS-SVM models. This is also reflected in the corresponding error histogram plot in Figure 5. The quality of the best model found in each run differs considerably between runs. In contrast, for *EP=true*, the results are more clear cut, RBF models dominate in 14 of the 15 runs. This already demonstrates the usefulness of extinction prevention. Due to randomness in the initial population and genetic operators a model type may be driven extinct, unable to return. EP prevents this. In this particular case LS-SVM models generally perform best initially, pushing the RBF models out of the population. However, as more data becomes available (active learning), and as the hyperparameter optimization continues, superior RBF models are discovered and quickly take over the population. This is also nicely shown in Figure 6. In both cases the RBF models are driven out of the population around generation 50. Though in the *EP=true* case the RBF models are able to make a re-appearance around generation 100.

Of course nothing prevents this process from recurring. The fact that the optimal solution changes with time is not a disadvantage and should actually be expected since the optimization landscape is dynamic (due to the incremental sampling). Without EP these oscillations are impossible and everything depends on the initial conditions. As a result the danger of converging to a poor local optimum is considerably greater. Given the form of the Ackley function, we should really not be surprised that the RBF models end on top. The different radial basis functions that make up the RBF model (= a local model) can be expected to match up quite well with the 'bumps' of the Ackley function.

If we assess the quality of the final models (Figure 7) we see that it performs very well. After 500 samples the model has an error smaller than 0.01 on 98% of the test samples. More importantly, these results are consistent as can be seen from the *EP=true* plot in Figure 5. Actually, from an application standpoint consistency at this level (accuracy) is more important than consistency in model type selection. Since at the end of the day, from an application perspective, the accuracy of the model is typically most important, not its type.

Table 2: KF: Comparison with homogeneous evolution

The natural question that remains, is how do these results compare with simply doing multiple homogeneous evolution (single model type, using the same GA settings) runs, one for each type separately? Those results are shown in Table 1. Studying the table we see that the HGA compares favorably. The accuracy of the final models are the essentially the same as those found by the best performing single model type run, while the variance on the results tends to be lower (EP=true). Of course this is paid for by an increase in computation time due to the increased population size of the HGA. Still, the HGA has a factor of 6 larger population size (90 vs 15) but requires only double the running time of the best performing homogeneous run (ANN). Also the total HGA running time is still less than the combined run time of all homogeneous runs.

10.2 Kotanchek Function

The composition of the final population and final error histograms for each run are shown in Figures 9 and 10. The population evolution and corresponding error evolution for the best run are shown in Figures 11 and 12. The comparison with homogeneous evolution is shown in Table 2.

The Kotanchek function is an interesting example since the GA has to 'discover' that 3 of the 5 variables are irrelevant. Considering the composition of the final population the Kriging functions

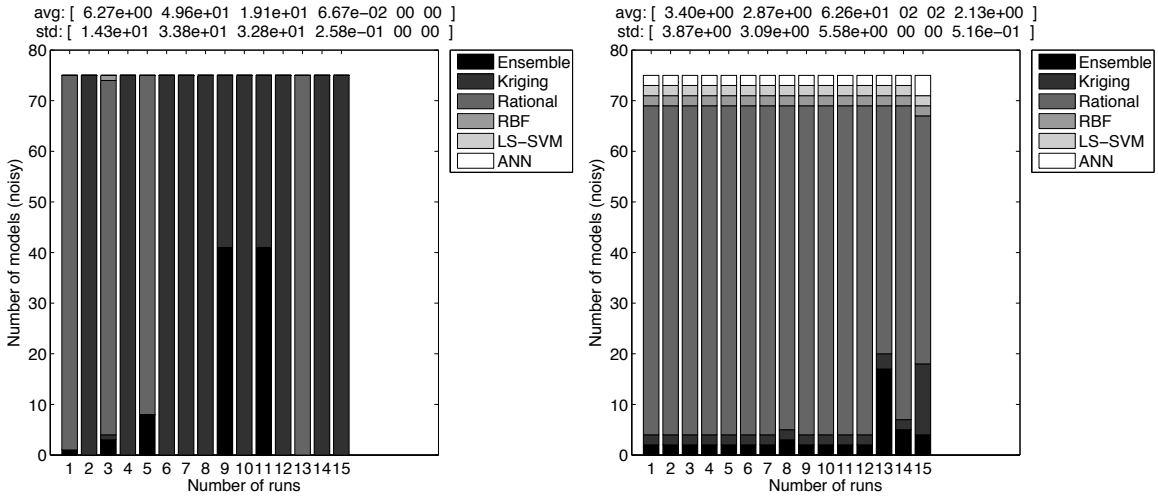

Figure 10: KF: Composition of the final population (Left: *EP=false*, Right: *EP=true*)

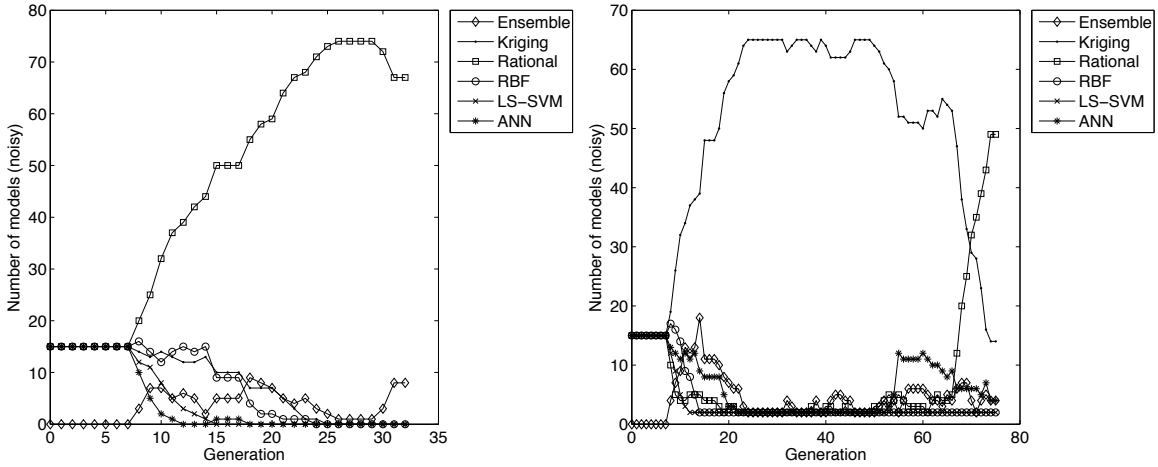

Figure 11: KF: Population evolution of the best run (Left: *EP=false*, Right: *EP=true*)

seem to be able to do this best in the *EP=false* case, with sporadic 'wins' for rational functions. In the *EP=true* case the situation is different, rational functions dominating all 15 runs. The fact that the rational functions succeed in doing this is thanks to a weighting scheme used in the genetic operators and described further in Hendrickx et al. (2006).

The usefulness of EP is demonstrated again as well. While the results of the best run for *EP=false* are better than the best run for *EP=true* (less samples), the former is much more a product of chance than the latter (which has lower variance). *EP=true* should still be preferred as it is more robust. Finally, the quality of the final models is excellent in all runs, and the performance and running time of the HGA remains competitive with the single model type runs.

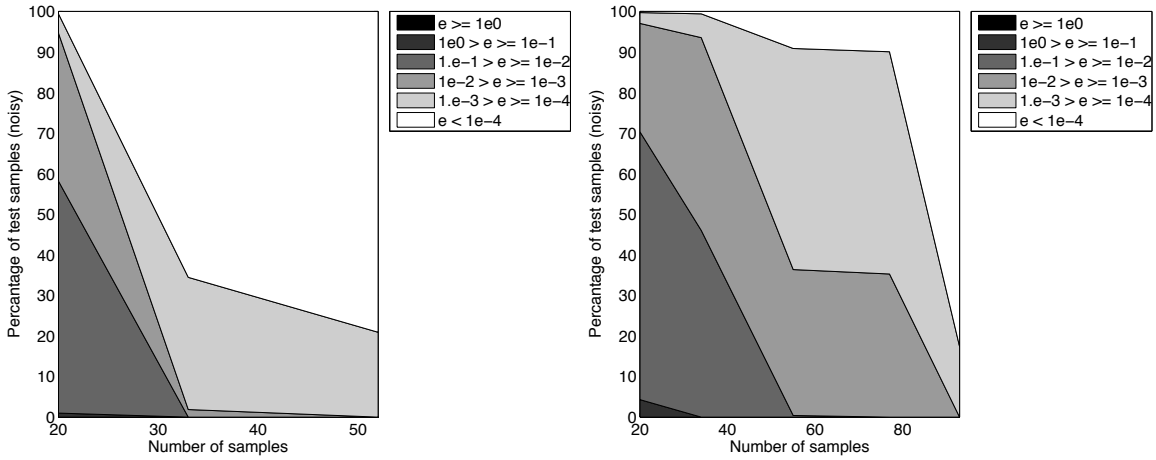

Figure 12: KF: Error evolution of the best run (Left: *EP=false*, Right: *EP=true*)

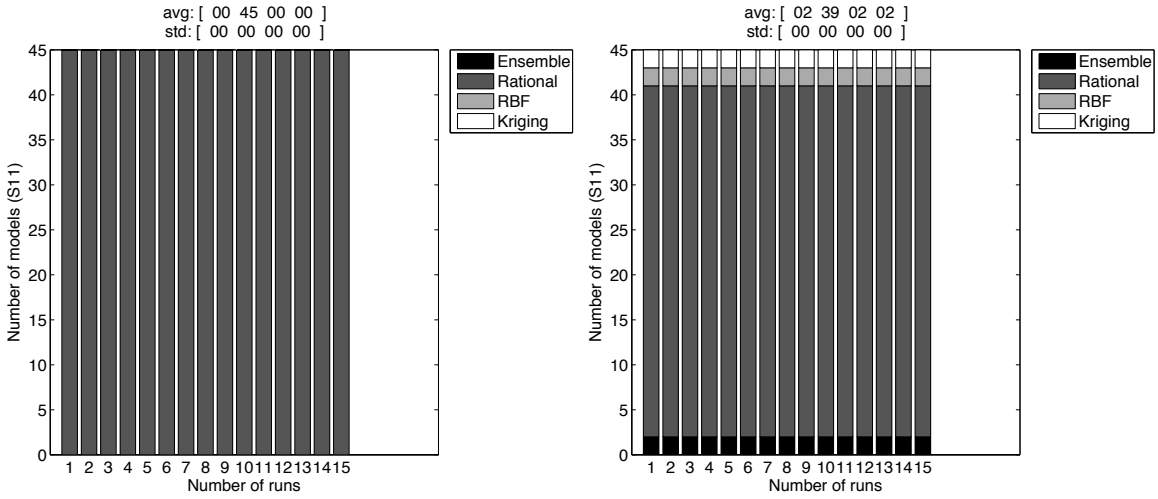

Figure 13: EE: Composition of the final population (Left: *EP=false*, Right: *EP=true*)

10.3 EM Example

The composition of the final population for each run is shown in Figure 13, and the associated error histogram in Figure 14. The population evolution and corresponding error evolution for the best run are shown in Figures 15 and 16. Table 3 summarizes the results and a plot of the best model can be found in Figure 17. Note that Table 3 shows the cross validation error (*CV*) instead of the validation error.

The results are very clear cut, rational functions dominate in every run, easily reaching the accuracy requirements in about 200 data points (with the *EP=true* runs generally reaching higher accuracies). This is to be expected. The physical behavior of two inductive posts in a rectangular waveguide is well described by a quotient of two differential multinomials (= the transfer function) and it is this function that needs to be modeled. Thus it is not surprising that rational functions do well since their form fits the underlying function.

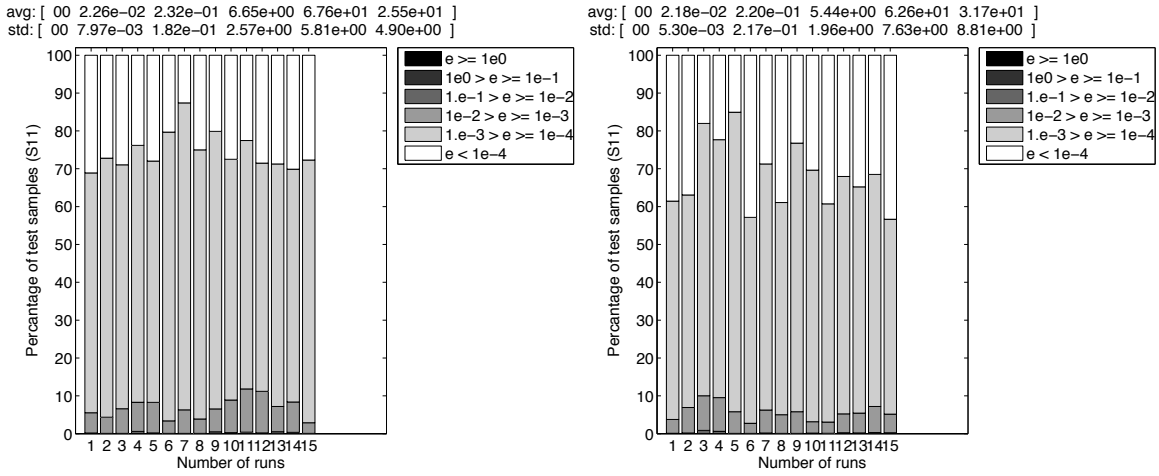

Figure 14: EE: Error histogram of the final best model in each run (Left: *EP=false*, Right: *EP=true*)

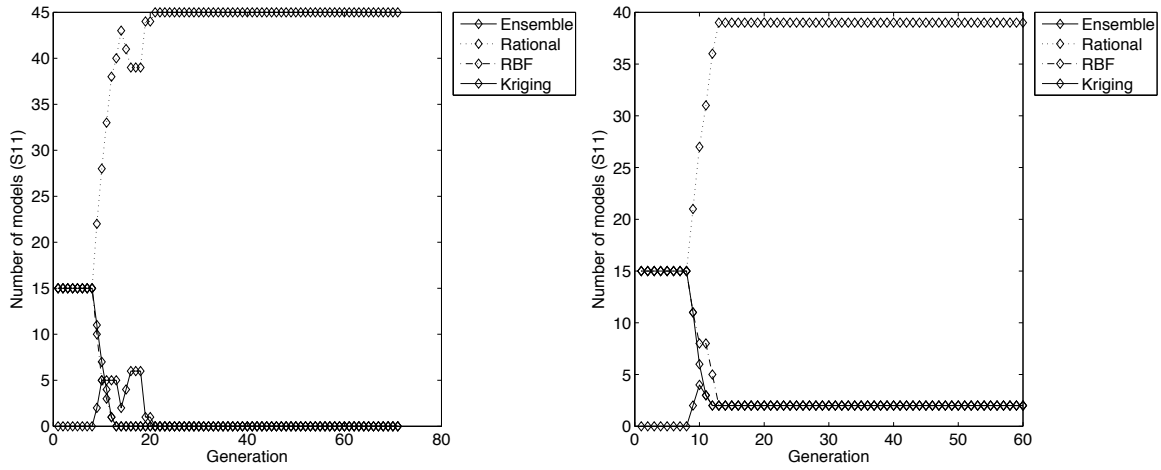

Figure 15: EE: Population evolution of the best run (Left: *EP=false*, Right: *EP=true*)

If we compare the HGA runs with the single model type runs we see significant improvements. Interestingly, the HGA runs need roughly 33-25% less sample evaluations to reach the target accuracy, and do so in a fraction of the time (less then 8 minutes vs. an average of 43 minutes for the homogeneous runs). Thus here we have a strong case for the use of the HGA.

10.4 LGBB Example

The composition of the final population for each run is shown in Figure 18 and the associated error histogram in Figure 19. The population evolution of the best run is shown in Figure 20. Table 4 shows the comparison with the homogeneous runs. A plot of the response can be found in Figure 21.

Adaptive sampling was switched off for the LGBB example. The objective was to see what accuracy can be reached and what model type prevails within a fixed time budget. The LGBB

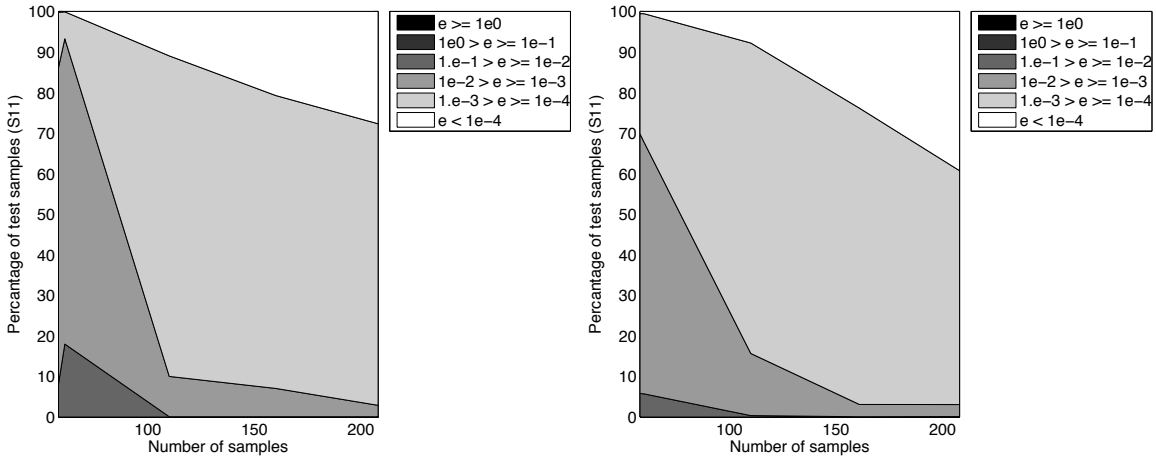

Figure 16: EE: Error evolution of the best run (Left: *EP=false*, Right: *EP=true*)

$HGA_{EP=true}$	1.980E+02	2.070E+01	6.733E-03	1.457E-03	2.227E-02	1.149E-02	7.722E+00	1.079E+00

Table 3: EE: Comparison with homogeneous evolution

example consists of a 3 dimensional data set and unlike the AF and EE examples there are no clues as to which model type is most adequate. Running the heterogeneous evolutionary algorithm it turns out that ANNs give the best fit overall (see Figure 18), achieving excellent accuracy. Changing the *EP* setting does not influence this, though the variance is lower for the *EP=true* case.

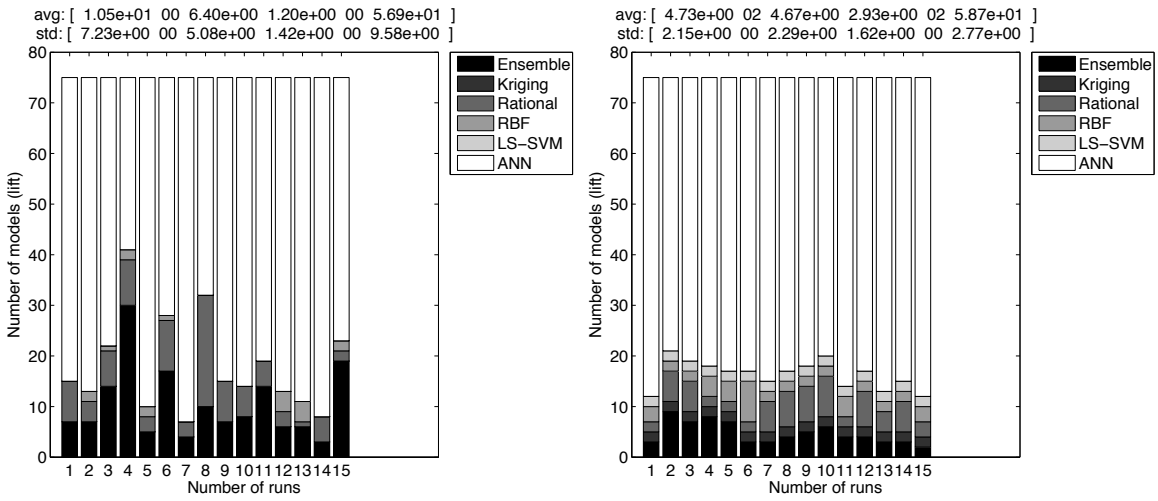

Figure 18: LE: Composition of the final population (Left: *EP=false*, Right: *EP=true*)

$HGA_{EP=false}$	7.800E+02	7.68E-003	4.38E-004	3.00E+002
$HGA_{EP=true}$	7.800E+02	7.59E-003	4.26E-004	3.00E+002

Table 4: LE: Comparison with homogeneous evolution

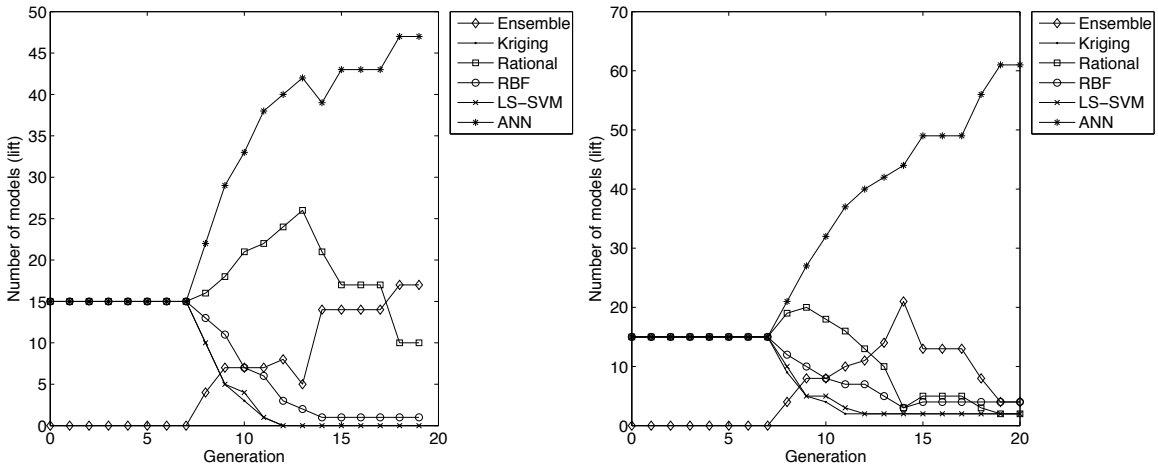

Figure 20: LE: Population evolution of the best run (Left: *EP=false*, Right: *EP=true*)

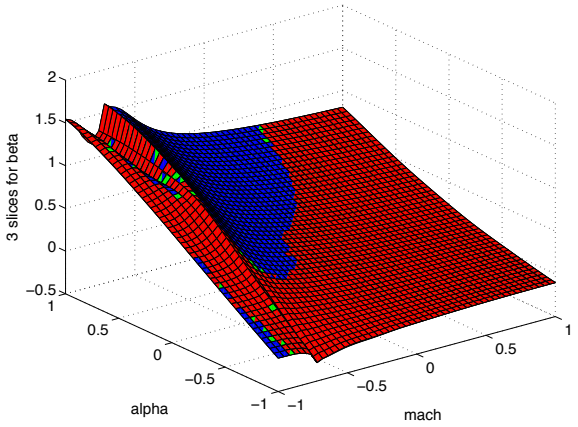

Figure 21: LE: normalized lot of the best model overall ($HGA_{EP=true}$, 3 slices for *beta*)

Within the same time limits the models produced by the HGA are comparable in accuracy to the best performing homogeneous runs, which again demonstrates the usefulness of the HGA.

Interestingly it turns out that the third dimension is negligible, the three slices in Figure 21 almost coincide. This was confirmed by using the SUMO model browser to fully explore the response. Thus we can safely conclude that side-slip angle has little or no effect on the lift on re-entry of the LGBB into the atmosphere.

10.5 Boston Housing Example

The final example is the Boston Housing data set, adaptive sampling was also switched off. The composition of the final population for each run is shown in Figure 22 and the associated error histogram in Figure 23. The population evolution of the best run is shown in Figure 24. Table 5 shows the comparison with the homogeneous runs.

$HGA_{EP=true}$	5.060E+02	2.735E-01	1.372E-02	1.200E+03

Table 5: BH: Comparison with homogeneous evolution

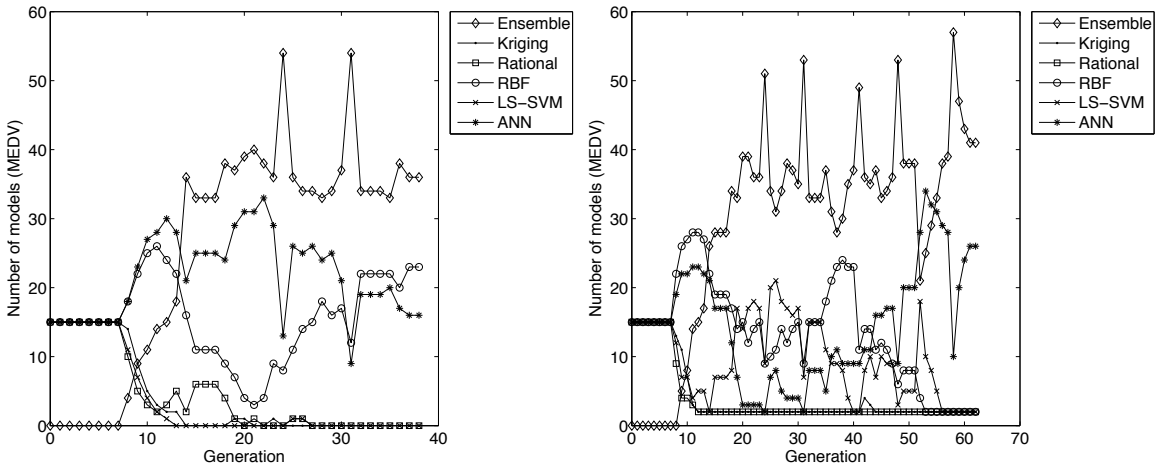

Figure 24: BH: Population evolution of the best run (Left: *EP=false*, Right: *EP=true*)

This is a somewhat curious example since it has high dimensionality (13), small support (506 tuples), and the types and ranges of the different inputs parameters vary greatly (e.g., input 4 (CHAS) is a boolean variable that is 1 if the tract borders the river and 0 otherwise while input 5 (NOX) is the nitric oxide concentration). Consequently, any analysis of this data should be preceded by a thorough statistical treatment (feature selection, variance analysis, etc.). We explicitly chose not to do this but take the data as is and treat is as black box regression problem.

The results are mixed (*see* Figure 22), though the HGA runs again outperform the homogeneous runs. (LS-)SVM and ANN models seem to be preferred over Kriging and RBF models but there is no evidence to distinguish between the models any further. Striking, though, is that about half of the final population consists of ensembles and that most of these ensembles turn out to be {ANN, RBF} pairs or multiple ANNs. Figure 25 shows the evolution of the composition of the best performing ensemble. The popularity of ensembles in this case is in line with the authors' previous experiences. When the individual model types are having trouble to fit a difficult response with none really performing much better than the other, hybrids (ensembles) tend to do well since they can produce more complicated responses. It is a signal that none of the included model types are really fit for the approximation problem.

Also striking (and interesting) are the oscillations in the population evolution (*see* Figure 24, or Figure 26 for a more marked example). It turns out that every run shows these oscillations between ensembles and one or two other model types. Interestingly these 'spikes' occur every 10 or 7 generations. It remains unclear to the authors how these oscillations may be explained. This is an issue that is being investigated in more detail.

11. Summary

In summary the results for the different test problems are very promising and in line with previous results (Gorissen, 2007; Gorissen et al., 2008a; Couckuyt et al., 2009; Gorissen et al., 2009a). The results show a consensus about which model type to use in all test cases (ignoring the BH example for the moment). In the case the consensus is not absolute (e.g., the *EP=true* run for the AF in Figure 4) the final model accuracies are essentially the same thus this is not really a problem from

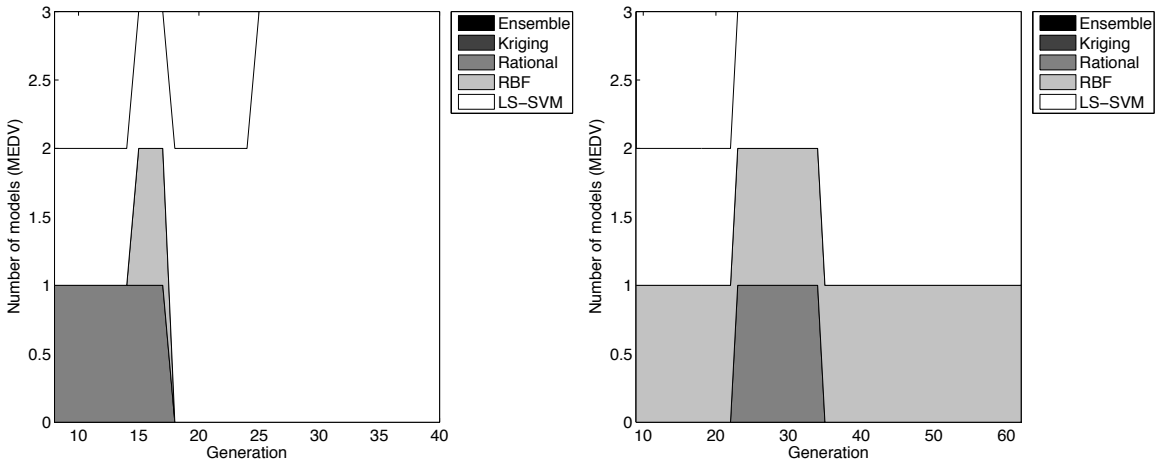

Figure 25: BH: Composition of the best performing ensemble of the best run (Left: *EP=false*, Right: *EP=true*)

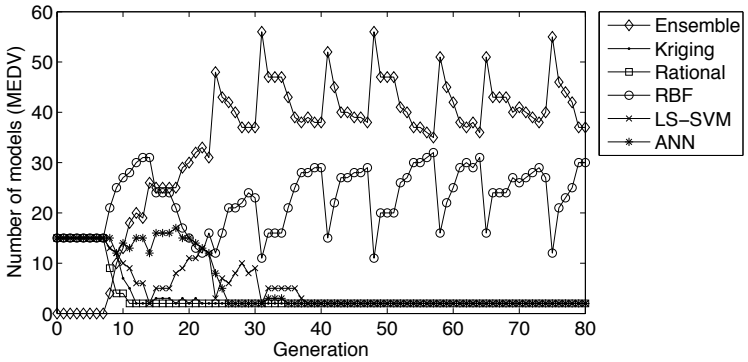

Figure 26: BH: Oscillations in the population evolution ($HGA_{EP=true}$)

an application standpoint. More important is that the target accuracy has been reached and that all model types have been given a fair chance without having to resort to a brute force approach.

In general we found the algorithm to be quite consistent across many runs. When variation does show up in the model selection results it typically is because two or more model types can fit the data equally well with only a minor difference in accuracy. This means that the GA may alternate between the different local optima, giving different model selection results, but still reaching the targets. The other reason is if the data is simply too difficult to fit using the methods included in the evolution. In this case ensembles may tend to do well. The BH example seems indicative of this situation.

It is important to remind the reader, though, that the overall performance of the HGA will of course depend on the quality of the model types themselves, and more importantly, on the quality of the creation function and genetic operators (and adequacy of the chosen representation). Good results have already been obtained with the current implementations though there is still room for

improvement with respect to the application by an expert in any one type.[5] Luckily, an advantage of the HGA based approach is that since the general algorithm is now in place, it becomes possible to focus on such improvements without requiring changes to the HGA itself. Specific improvements (e.g., devised by an expert in a certain model type) are straightforward to integrate into the existing genetic operators allowing an accumulation knowledge that will improve the overall quality of the models produced by the HGA.

A next step is to further increase the number of test problems and, more importantly, investigate the influence of the different parameters involved. In this respect the migration interval and migration topology parameters are particularly important since they determine how the different model types interact. For example, if the migration interval is set too high, each deme will produce high quality models (most of the time is spent optimizing the parameters of a single model type) but there will have been very little competition between models. If it is set too low, the converse is true. More research is needed to to better understand this balance and investigate the impact of genetic drift.

12. Conclusion and Future Work

Due to the computational complexity of current simulation codes, the use of global surrogate modeling techniques (adaptive sampling, adaptive modeling) has become standard practice among scientists and engineers alike. However, a recurring problem is selecting the most adequate surrogate model type and associated complexity. In this contribution we explored an approach based on the evolutionary migration model that can help tackle this problem in an automatic way if little information is known about the true response behavior and there are no a priori model type requirements. In addition, we have illustrated the usefulness of extinction prevention and ensemble based recombination. Extinction prevention is a straightforward algorithm that prevents a species from disappearing from the gene pool at the expense of a minor cost (keeping 2 extra individuals per species 'alive'). As a result, the optimal solution is able to change with time, making for a more flexible and adaptive system which, as demonstrated in the different examples, gives better and more consistent results.

Future work will consist of investigating the oscillations in the BH example, exploring different GA parameter values (role of the migration frequency, migration topology, etc.), incorporating more model types, and more advanced ensemble methods (e.g., stronger constraints on ensemble composition). As mentioned above, improvements to the genetic operators are ongoing in order to get more out of each model type. The utility of adding a penalty to the fitness function proportional to the model complexity and/or training time will also be investigated. Furthermore, we have been experimenting with sampling strategies that vary dynamically depending on the remaining sample budget and quality & type of surrogate currently used in the modeling process. The idea is to work towards an optimal interplay between sampling and modeling. E.g., initially the focus should be on exploration of the design space while, as accuracy of the models improves, the focus should shift towards refining the model in places where it is uncertain and ensuring the optima it exhibits are really true optima. Likewise, we are experimenting with dynamic model selection criteria. For example, if only little data is available cross validation type measures may be unreliable and it makes little sense enforcing problem specific constraints (e.g., the model response should be bounded between given bounds). However, when the data density is sufficiently high the opposite will be true. Thus there seems to be some intuition advocating the use of annealing type strategies.

5. There is a trade-off involved here. Expert application of a surrogate model type will invariably lead to problem specific bias, reducing the performance on other problems.

In addition to the global modeling use case. We are also experimenting with linking the HGA described here with the EGO framework from Jones et al. (1998). The structure of the SUMO Toolbox allows natural linking of these two components. This allows for automatic model type switching during optimization (any model type that supports prediction variance can be used) and may be beneficial for computational expensive codes.

Finally it should be noted that all the algorithms and examples described here are available for download at `http://www.sumo.intec.ugent.be`.

Acknowledgments

The authors would like to thank NASA and Robert Gramacy from the University of California, Santa Cruz for providing the data on the LGBB example. Special thanks also to Robert Lehmensiek and Petrie Meyer from the University of Stellenbosch, South Africa, for providing the simulation code for the EM example.

This work was supported by the Fund for Scientific Research Flanders (FWO Vlaanderen) and the Science and Innovation Administration Flanders (BSTC project).

Abstract

We present a method for training support vector machine (SVM)-based classification systems for combination with other classification systems designed for the same task. Ideally, a new system should be designed such that, when combined with existing systems, the resulting performance is optimized. We present a simple model for this problem and use the understanding gained from this analysis to propose a method to achieve better combination performance when training SVM systems. We include a regularization term in the SVM objective function that aims to reduce the average class-conditional covariance between the resulting scores and the scores produced by the existing systems, introducing a trade-off between such covariance and the system's individual performance. That is, the new system "takes one for the team", falling somewhat short of its best possible performance in order to increase the diversity of the ensemble. We report results on the NIST 2005 and 2006 speaker recognition evaluations (SREs) for a variety of subsystems. We show a gain of 19% on the equal error rate (EER) of a combination of four systems when applying the proposed method with respect to the performance obtained when the four systems are trained independently of each other.

Keywords: system combination, ensemble diversity, multiple classifier systems, support vector machines, speaker recognition, kernel methods

∗. This author performed part of the work presented in this paper while at the Information Systems Laboratory, Department of Electrical Engineering, Stanford University.

1. Introduction

The work presented in this paper is motivated by our work on the task of speaker verification. In the last decade, many successful speaker verification systems have relied on the combination of various component systems to achieve superior performance. In many cases, as in Ferrer et al. (2006) and Brummer et al. (2007), the combination leads to significant improvements. However, there are cases in which combining several comparably good systems does not result in improvements over the single best system (Reynolds et al., 2005). Most of these systems perform the combination of information sources at the score level[1] (Reynolds et al., 2003; Ferrer et al., 2006; Brummer et al., 2007; Huenupán et al., 2007; Dehak et al., 2007): systems that model each type of feature using a certain model are independently developed and their scores are combined to produce the final score and the decision. When training each individual system, all other systems available for combination are usually ignored while, in fact, the ultimate goal of the systems is to perform well in combination with all the other systems and not necessarily individually.

It is easy to see that system combination at the score level is not guaranteed to give strictly better performance than those of the individual systems being combined. In the extreme case, if all classifiers were generating exactly the same output for each sample, the combined classifier would not have better performance than the individual ones, independently of the combination procedure used. Intuitively, what we wish is to have enough diversity across systems such that classifiers contribute complementary information leading to a better final decision when systems are combined. System diversity has been the subject of a large amount of research in recent years, with two main goals: defining a measure of diversity that can predict the performance of the combination, and designing procedures for achieving diversity in an ensemble of systems. With the goal of motivating and placing our work in perspective, in the next section we present a discussion focused on existing techniques for measuring and designing for system diversity.

The contributions of this paper are: (1) the development of a simple model for the combination problem for a binary classification task under the assumption that the distribution of scores for each of the classes is Gaussian, and (2) a procedure for improving diversity in an ensemble including SVM classifiers. We find an upper bound on the EER of an ensemble combination and show that, for a two-system combination, this upper bound is a function of the performance of the individual systems and the correlation coefficient obtained from the average class-conditional covariance matrix of the scores from the two systems. Based on this result, we propose the inclusion of a regularization term in the SVM objective function when training a new SVM system for combination with a set of preexisting systems, which introduces a trade-off between the performance of the resulting model and its average class-conditional covariance with the preexisting systems. Ferrer et al. (2008b) presented empirical results using the proposed method. Here, we extend this previous work by developing a framework under which to understand the method, considering the cases of multiple preexisting systems and nonlinear kernels, and including new results on simulated and on the NIST 2005 and 2006 speaker-verification evaluation data. Results show that a gain of 19% on EER can be achieved when using the proposed method with respect to the results obtained when systems are trained without knowledge of the others.

The paper is organized as follows. Section 2 gives a review of the related research. Section 3 describes a simple model for the system combination problem under consideration. Using the

1. The term *score* is commonly used in the speaker verification community to refer to the numerical output of a system, which may or may not be a probability measure.

conclusions obtained from this development, Section 4 proposes a method for achieving improved combination performance. In Sections 5 and 6 we present results on simulated data and speaker verification data, respectively. Section 7 presents our conclusions.

2. Multiple Classifier Systems

In this section we review the literature related to our work, motivating and putting in perspective the research presented in the rest of the paper.

2.1 Measuring Diversity

For regression problems, the measures of ensemble diversity are well developed. Krogh and Vedelsby (1995) showed that the quadratic error for a certain input value of a convex combination of estimators trained on a single data set is guaranteed to be less than or equal to the weighted average quadratic error of the component estimators. The difference between the two is given by an ambiguity term that measures the variability among ensemble members for the particular input. On a related development, Ueda and Nakano (1996) give a decomposition of the mean square error of an ensemble classifier into three terms: average bias, variance and covariance of the ensemble members. One would then wish to reduce the covariance term without affecting the bias and variance terms by reducing the correlation between the members. This term can, in fact, be negative.

Classification problems where ensemble members output an estimate of the posterior probabilities of the classes (as opposed to just the estimated label) can also be considered regression problems. Tumer and Ghosh (1996) and, later, Fumera and Roli (2005) present a framework for studying this case. They consider the probability of error as the measure of performance. If the actual posterior probabilities of the classes given the features were known, the probability of error could be minimized by choosing, for each value of the input features, the class that has the highest posterior. This rule determines a boundary between the regions where each class is predicted and results in a certain probability of error that is called the *Bayes error*. In practice, the posterior probabilities are not known. Tumer and Ghosh assume an additive error model where the individual classifiers output, for each class w_k, a function of the features x such that $f_k(x) = P(w_k|x) + \varepsilon_k(x)$. The predictions are now made based on the output of the classifier instead of the actual posterior probabilities. Tumer and Ghosh consider the case in which the effect of using the predictions is a shift in the boundary by a certain amount b. This results in the probability of error being larger than the Bayes error by a certain amount they call the *added error*. An expression for the expected value of the added error is computed assuming that the ε_k are random variables with a certain mean and variance independent of the value of x, that they are uncorrelated across classes, that the b is small such that first-order approximations can be used and that the posterior probabilities are monotonic around the decision boundaries. Using the expression derived for the added error of a single classifier, they derive the corresponding expression for a classifier formed by the average estimates obtained from a set of N individual classifiers. Their final expression depends monotonically on the pairwise correlations between the error functions of the individual classifiers, supporting the intuition that good combination performance can be achieved if the classifiers being combined have complementary information such that when one classifier makes a mistake, some other classifier has the right answer. Fumera and Roli generalize Tumer and Ghosh's work by allowing the combination to be a weighted average instead of simple average and arrive at an optimization problem for the

combination weights. This problem is solved explicitly for the case of unbiased and uncorrelated estimation errors.

Two assumptions made by Tumer and Ghosh, as well as Fumera and Roli, are not well suited for the problem of interest in this paper but can be easily replaced for other assumptions without much consequence on the theory: the use of the classification error as measure of performance and the uncorrelatedness of the estimation errors across classes. Classification error is usually considered inappropriate for problems in which the prior probabilities of the classes are very different (as is the case in most speaker verification applications). For these cases, cost functions are usually defined where each type of error is assigned a different cost and the expected value of the cost function is used as performance measure. Derivations in Tumer and Ghosh (1996) can be easily modified to allow for cost functions. The Bayes classifier would now choose the class for which the loss is minimized instead of the posterior probability maximized. As for the estimation errors, the assumption of zero correlation can be easily relaxed when only two classes are considered. In fact, in our case we can assume that only one of the posteriors is estimated and the other one is calculated so that the sum is equal to one. In that case, the estimation errors would also sum to one. Hence, only one estimation error stays in the derivations and the zero correlation assumption is not needed.

Even though the results described above could be considered enough motivation for our development of the anticorrelation method in Section 4, in the next section we propose a different development that we believe presents an interesting alternative for the above framework. First, we do not use the additive error model with fixed bias and variance for the posterior probability estimates. In binary problems like speaker verification one can train classifiers that output a score instead of a probability. This score can be, for example, the output of a support vector machine or the logarithm of the ratio between the class likelihoods. These scores are assumed to be monotonically related to the posterior probability of one of the two classes and, hence, could be easily converted into this posterior. Nevertheless, in our speaker verification experiments we have found that combining the scores directly leads to better results than combining the estimated posteriors when using a linear combiner. In a combination experiment of all pairs of systems from a set of 13 systems, an average relative gain of 7.6% was found when combining scores versus posterior probabilities (obtained by learning a logit mapping of the scores) using linear logistic regression. The best performance across all combinations including any number of systems is obtained when combining the scores of six systems and this combination is 12% better than the best combination of posterior probabilities. Considering these results, we eliminate the assumption that the output of the classifiers is a posterior probability, allowing it to be a general continuous value (score). We then replace the additive error assumption with an assumption that the distribution of the scores for each class is Gaussian, which, as we will see, is a good approximation for most speaker verification scores.[2] Finally, we focus on a different measure of performance, the equal error rate, which is widely used on binary classification problems for its simplicity and for being independent of the class priors. This measure of performance depends on the overall shape of the posterior probabilities and not just on the difference between them, as is the case for the probability of error or the expected cost. Hence, no simple extension of the Tumer and Ghosh derivations could be made for this measure even if we

2. We believe this is the reason for the scores combining better with a linear combiner than the mapped posterior probabilities since when class distributions are Gaussian, the Bayes classifier is linear. Hence, the linear combiner is a good choice when combining speaker verification scores. The Gaussian approximation, on the other hand, is not good after the scores have been mapped to posterior probabilities making a linear combiner on the posterior probabilities suboptimal.

were willing to consider the system output to be a probability. Under these assumptions we arrive at an explicit expression for an upper bound on the optimal EER of the combination that is a function of the EER of the ensemble members and the pairwise class-conditional correlations.

2.2 Creating Diversity

The work described above, including the development we will show in Section 3, defines ways of quantifying the diversity in the ensemble and how this diversity affects the performance of the combined classifier under different sets of assumptions, but does not describe ways of achieving this diversity. Brown et al. (2005a) present a taxonomy of the methods for creating diversity found in the literature as of 2005. They divide the methods into implicit and explicit, where implicit methods are those that try to create diversity using randomization methods, while explicit methods do the same by directly taking into account some measure of the diversity being achieved. They further divide the methods into three groups based on how they affect the learners to create diversity: (1) by modifying the starting point in the hypothesis space, (2) by changing the set of accessible hypotheses or, (3) by defining how the hypothesis space is traversed. Modifying the starting point in the hypothesis space is applicable only for learners for whom the final hypothesis reached depends on some random initialization component, as is the case for neural networks. SVMs, on the other hand, do not fall into this category. Bagging (Breiman, 1996) and boosting (Freund and Schapire, 1997) are diversity creation methods of type 2, since each member of the ensemble is obtained by changing the training data, resulting in a different set of accessible hypotheses. In the case of bagging, the method is implicit since the training data for each ensemble is chosen randomly from the original set, while in the case of boosting, the training samples are weighted when training a new member of the ensemble in a way that ensures diversity, making it an explicit method of diversity creation. Allowing each member of the ensemble to use only a subset of features falls into the type 2 methods (Oza and Tumer, 2001). Finally, type 3 methods are those that directly aim at improving diversity by including a term measuring diversity in the objective function of the learner. The negative correlation (NC) learning algorithm is a notable example in this category (Liu, 1999; Rosen, 1996).

The goal of NC Learning is to minimize the squared error of an ensemble output computed as the average of the individual outputs in a regression context. This is done by adding a penalty term in the objective function of each individual neural network forming the ensemble. This penalty was shown (Brown et al., 2005b) to directly control the covariance term in the bias-variance-covariance trade-off. Zanda et al. (2007) extend the NC learning framework to classification problems by reinterpreting the Tumer and Ghosh model in a regression context. Our proposed anticorrelation method follows the spirit of the NC learning technique of explicitly creating diversity through the modification of the learner's objective function when the learners are SVMs instead of neural networks.

Much of the work on diversity creation has focused on the generation of large ensembles, where the number of classifiers is part of the design choices. The size of the ensemble is in fact another variable to be optimized. In this paper, we constrain the ensemble to contain a relatively small number of systems. These systems are different in nature, using different sets of features and different modeling methods and can be quite complex. Each of them might have been developed over several months or years of research. Hence, we do not take the size of the ensemble as a variable. The individual systems are fixed before hand, and all we are allowed to do is (perhaps only slightly) modify the training procedure of one or more of them in order to increase the diversity of the ensemble. The

speaker verification system described in this paper can, in fact, be considered as a cascade of two diversity creation methods. Given an enormous set of highly heterogeneous features coming from a few different sources in the speech signal (for example, prosodic or spectral information), we train separate classifiers for each type of feature, perhaps also varying the type of classifier used. This can be seen as a type 2 diversity creation method. The second stage of diversity creation focuses on making each new classifier added to the ensemble as new as possible. To achieve this we use a type 3 diversity creation method, where we add a penalty term in the SVM objective function, which explicitly aims at reducing the correlation between the new classifier and the preexisting ensemble. The proposed method is shown to be equivalent to defining a new kernel that we call the *anticorrelation kernel*.

Kocsor et al. (2004) introduced a method called *margin maximizing discriminant analysis* (MMDA) to obtain sucessive, mutually orthogonal, SVMs for a certain feature vector. In this method, presented as a nonparametric extension of linear discriminant analysis, the SVM optimization problem is modified by adding an orthogonality constraint with respect to the weight vectors from previous SVMs. The MMDA method can be seen as a particular case of the one proposed in this paper when the penalty coefficient is set to infinity. Furthermore, the constraints used here are more general, reducing to the ones used in MMDA when all systems in the ensemble are SVMs, use the same input features, and these features have identity within-class covariance matrices. Kernel-based methods for ensemble systems have also been used, for example, in Pavlidis et al. (2002) and Lanckriet et al. (2004). Pavlidis et al. compare three methods for combination of heterogeneous information for gene function detection: early, intermediate and late integration. Early integration (what we here call *feature-level combination*) consists of concatenating the features from the two different information sources into a single feature vector. Intermediate integration performs the combination at the kernel level, and late integration performs the combination at the last stage. This is what we are calling *score-level combination*. No explicit attempt at increasing diversity is made in the paper. Lanckriet et al. (2004) propose a method for combining kernel classifiers by learning a new kernel matrix that is a linear combination of the kernel matrices of the classifiers in the ensemble. This method requires prior knowledge of the test data, since instead of learning a function, they learn the labels on the set of unlabeled samples. This particular scenario is not applicable to speaker recognition where the speaker models are usually trained before any test sample is available.

2.3 System Combination

Once a diverse ensemble has been trained, the output of the individual classifiers must be combined into a single decision or score. Linear combiners are the most widely used methods for fusion of classifier outputs. In many cases the weights of the linear combination are determined based on the classification performance of the classifiers. For a survey of these methods, see Kuncheva (2004), Chapter 5. Obtaining the weights by training a "supra" classifier or combiner that takes the output of the individual classifiers as input is in many cases a better option. The main problem with this approach is that using the output of the individual classifiers on the data used for training them as training data for the combiner may result in suboptimal performance. The stacked generalization method (Kuncheva, 2004, Chapter 3) can be used in these cases to generate the training data for the combiner.

The focus in this paper is on diversity creation rather than on the methods used for combining the ensemble. Hence, we choose a simple but effective combination method: a linear supra-classifier

trained with data generated by the stacked generalization method using logistic regression. Linear logistic regression was shown in our previous work (Ferrer et al., 2008a) to perform comparably to or better than other linear and nonlinear classifiers for the combination of speaker verification scores, and it is one of the most commonly used methods for combining speaker verification systems (Brummer et al., 2007). Other common combination procedures used in speaker verification include neural networks (Reynolds et al., 2003; Ferrer et al., 2006), support vector machines (SVM) (Ferrer et al., 2006), and weighted summation using empirically determined weights (Dehak et al., 2007).

3. A Simple Model for System Combination

Consider a binary classification task with classes $y \in \{a,b\}$ for which N separate classifiers are available. In speaker verification, class a corresponds to *impostor* and b to *true-speaker*. Classifier i produces a score, f_i, which can be thresholded to obtain the final decision. That is, the estimated class $\hat{y}$ is given by

$$\hat{y} = \begin{cases} a & \text{if } f_i < t_i \\ b & \text{if } f_i \geq t_i, \end{cases} \tag{1}$$

where t_i is a tunable threshold.

Here, we consider a setup where the scores from the individual classifiers are combined into a single score $f_c = f_c(f_1, \ldots, f_N)$. This final score is the one that is later thresholded to obtain the estimated class for the sample. The goal is then to optimize the performance of the final combination, not that of the individual systems.

In this section we develop a simple model for this problem, which will lead us to an intuitive conclusion about what could be done to improve the final performance when training a new system for combination with others.

3.1 Mahalanobis Distance as a Surrogate for EER

Consider for now a single score f, corresponding to a random variable, F.[3] A usual way of measuring performance of a score when Equation (1) is used to estimate the class of the samples is equal error rate (EER), the false acceptance rate when the false rejection and false acceptance rates are equal. In speaker verification, a false acceptance (which we will call $e_{b|a}$) is an impostor trial accepted by the system as the target speaker, and a false rejection ($e_{a|b}$) is a true-speaker trial considered an impostor trial by the system.

If we make the assumption that the conditional distribution of the scores for each class is Gaussian, we can obtain an explicit bound for the EER as a function of the Mahalanobis distance between the class-conditional means. Figure 1 shows how to calculate the EER for this case. We assume that the class-conditional distribution of the scores is given by

$$F \mid Y = y \sim \mathcal{N}(\mu_y, \sigma_y^2), \text{ for } y = a,b,$$

where Y is the random variable corresponding to the trial's class. We further assume, without loss of generality, that $\mu_b \geq \mu_a$, so that (1) is the best way of assigning the labels for a given threshold.

3. Throughout the paper we will adopt the notation of using lower case letters for the samples of the random variable noted by the corresponding capital letter.

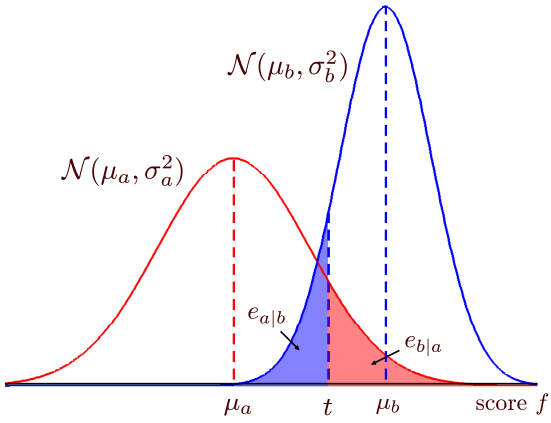

Figure 1: EER calculation when the class-conditional distributions are Gaussian. The EER is equal to $e_{a|b}$ when t is chosen such that $e_{a|b} = e_{b|a}$.

With these assumptions we can compute $e_{a|b}$ and $e_{b|a}$ for a certain value of the threshold t as

$$e_{a|b}(t) = \phi\left(\frac{t-\mu_b}{\sigma_b}\right), \tag{2}$$

$$e_{b|a}(t) = 1-\phi\left(\frac{t-\mu_a}{\sigma_a}\right), \tag{3}$$

where ϕ is the cumulative distribution function of the standard normal distribution $\mathcal{N}(0,1)$.

The EER is given by $e_{b|a}(t^*)$ when t^* is chosen such that $e_{b|a}(t^*) = e_{a|b}(t^*)$. In the appendix we prove the following upper bound on the EER:

$$\text{EER} = e_{b|a}(t^*) = e_{a|b}(t^*) \leq \phi(-\frac{1}{2}\frac{\delta\mu}{\sigma}), \tag{4}$$

where $\delta\mu = \mu_b - \mu_a$, and σ is any value that satisfies $\sigma \geq (\sigma_a + \sigma_b)/2$. Equality is achieved for $\sigma = (\sigma_a + \sigma_b)/2$, but this value of σ does not result in a nice expression later on, when we want to use it to optimize the combination performance. On the other hand,

$$\sigma = \sqrt{(\sigma_a^2 + \sigma_b^2)/2}$$

also satisfies the inequality and does result in a nice expression that we can later use. In the rest of the paper we will use

$$\mathcal{M}^2 = \frac{2\delta\mu^2}{\sigma_a^2 + \sigma_b^2} \tag{5}$$

as a surrogate for the EER of the system. $\mathcal{M}$ is the Mahalanobis distance between two Gaussian distributions with distance between the means $\delta\mu$ and variance $(\sigma_a^2 + \sigma_b^2)/2$. Using (4), we get that

$$\text{EER} \leq \phi(-\frac{\mathcal{M}}{2}).$$

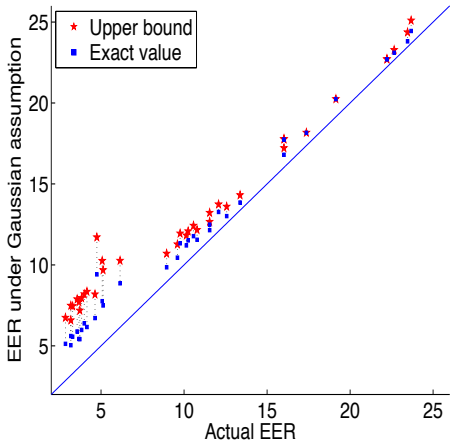

Figure 2: Actual EER for a set of 37 systems versus the upper bound and the exact value under Gaussian assumptions.

Our strategy in the remainder of the paper will be to reduce the value of the upper bound, with the hope that this will result in a reduction of the EER. Since ϕ is monotonically increasing in its argument, decreasing the value of $-\mathcal{M}$ (or increasing the value of $\mathcal{M}$) will decrease the value of the upper bound.

Figure 2 shows a scatter plot of the actual EER for a set of 37 different individual systems using different features or different modeling techniques (some of these systems are described by Ferrer et al. (2006)) versus the upper bound on the EER under Gaussian assumption given by $\phi(-\delta\mu/\sqrt{2(\sigma_a^2+\sigma_b^2)})$ and the exact value of the EER, also under Gaussian assumption, given by $\phi(-\delta\mu/(\sigma_a+\sigma_b))$. We can see that the upper bound is tight for high EER values. When the difference between the class-conditional covariance for both classes is large (which, in our experiments, is the case for the better systems), the upper bound becomes looser. We see that the exact estimation under the Gaussian assumption performs significantly better in this case. The remainder of the error is due to the inaccuracy of the Gaussian assumption. Figure 3 shows the actual distribution of two of the systems used in this paper compared to their Gaussian approximation. Figure 3.a corresponds to one of the low EER systems that drifts away from the diagonal in Figure 2, while 3.b corresponds to a system with EER around 12%. We can clearly see that the Gaussian approximation in this case is inaccurate, which in turn explains the inaccuracy of the upper bound and the exact formula developed in this section. Interestingly, even when the Gaussian approximation is inaccurate, (4) seems to still hold. Our procedure of trying to minimize this upper bound in the hope that the actual EER will be pushed down would then still be valid.

3.2 Maximum Mahalanobis Distance Combination

Returning to the problem of combining the output of several subsystems into a single score, we use the results from the previous section and maximize (5) to find the optimal parameters of the combiner. This will result in a simple formula that can predict the performance of the combination of

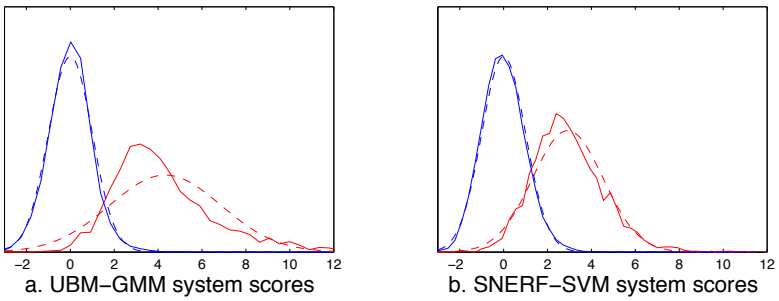

Figure 3: Distribution of scores for two individual systems compared to their Gaussian approximation.

several subsystems given their individual EERs (or $\mathcal{M}$s) and the average class-conditional covariance matrix for the vector of scores. To do this we further assume that the combination is performed with a linear function of the individual scores. This is not a very restrictive assumption for speaker verification since for this task we have repeatedly found that linear combination procedures perform as well (or better) than nonlinear ones (Ferrer et al., 2008a). The form of the combined scores as a function of N individual scores is then

$$f_c = \sum_{i=1}^{N} \alpha_i f_i = \alpha^t f,$$

where $\alpha = (\alpha_1 \dots \alpha_N)^t$ is the vector of weights and $f = (f_1 \dots f_N)^t$ the vector of individual scores. We assume that the class-conditional distribution of the f_i's is jointly Gaussian. Hence, each of the individual scores and the combined score satisfy the assumptions made in the previous section. The class-conditional distributions of F_c, the random variable corresponding to the combined score, are given by

$$F_c \mid Y = y \sim \mathcal{N}(\alpha^t \mu_y, \alpha^t \Sigma_y \alpha), \text{ for } y = a, b,$$

where $\mu_y = (\mu_{y1} \dots \mu_{yN})$ is the vector of means and $\Sigma_y = E[(F - \mu_y)(F - \mu_y)^t | Y = y]$ the covariance matrix for class y for random variable F corresponding to vector f. We can now compute $\mathcal{M}^2$ (Equation 5) for the combined score as a function of the parameters α:

$$\mathcal{M}^2 = \frac{2(\alpha^t \mu_b - \alpha^t \mu_a)^2}{\alpha^t \Sigma_a \alpha + \alpha^t \Sigma_b \alpha} = \frac{\alpha^t \Delta \Delta^t \alpha}{\alpha^t \Sigma \alpha}, \tag{6}$$

where $\Delta = \mu_b - \mu_a$ and

$$\Sigma = 1/2(\Sigma_a + \Sigma_b). \tag{7}$$

We wish to find the α that maximizes this expression. Define $\beta = \Sigma^{1/2}\alpha$, where $\Sigma^{1/2}$ is a symmetric matrix square root of Σ (which can be computed from the eigendecomposition of Σ, which exists and can be chosen to be symmetric since Σ is symmetric). Replacing this in (6), and using the Cauchy-Schwarz inequality,

$$\begin{aligned} \mathcal{M}^2 &= \frac{\beta^t \Sigma^{-1/2} \Delta \Delta^t \Sigma^{-1/2} \beta}{\beta^t \beta} = \frac{\|\Delta^t \Sigma^{-1/2} \beta\|^2}{\|\beta\|^2} \\ &\leq \|\Delta^t \Sigma^{-1/2}\|^2 = \Delta^t \Sigma^{-1} \Delta, \end{aligned}$$

with equality when $\beta \propto \Sigma^{-1/2}\Delta$. Hence, the optimal α is a vector in the direction of $\Sigma^{-1}\Delta$.[4]

Note that we have arrived at the definition of the Mahalanobis distance in multiple dimensions ($\Delta^t\Sigma^{-1}\Delta$), which is an intuitive result. We now know that the EER of the combination of the individual systems will be at most $\phi(-\sqrt{\Delta^t\Sigma^{-1}\Delta}/2)$. If we can devise a way of increasing $\Delta^t\Sigma^{-1}\Delta$, this upper bound will decrease.

Anderson and Bahadur (1962) consider the problem of finding all the admissible linear procedures for classifying into two multivariate normal distributions. They show that $\alpha = (t_a\Sigma_a + t_b\Sigma_b)^{-1}\Delta$ corresponds to an admissible procedure for any t_a and t_b (that is, no other linear procedure will have, simultaneously, strictly better $e_{b|a}$ and $e_{a|b}$) as long as $t_a\Sigma_a + t_b\Sigma_b$ is positive definite. Unfortunately, the values for t_a and t_b that correspond to the EER have to be numerically obtained. No explicit expression is available for the general case. Since our purpose here is to obtain a simple explicit expression for the EER (as a function of the EERs of the individual systems and some other parameters) that we can use to analyze the problem, we have settled for a bound on the EER instead of using the implicit expression developed by Anderson and Bahadur.

3.3 Analysis for Combination of Two Systems

We now focus on the case $N = 2$. In this case, we have that the optimal $\mathcal{M}^2$ ($\Delta^t\Sigma^{-1}\Delta$) is given by

$$\begin{aligned}\mathcal{M}^2 &= \frac{\delta_1^2\sigma_{22} + \delta_2^2\sigma_{11} - 2\delta_1\delta_2\sigma_{12}}{\sigma_{11}\sigma_{22} - \sigma_{12}^2} \\ &= \frac{\mathcal{M}_1^2 + \mathcal{M}_2^2 - 2\rho\mathcal{M}_1\mathcal{M}_2}{1-\rho^2},\end{aligned} \tag{8}$$

where δ_i is component i of vector Δ, σ_{ij} is component ij of matrix Σ, $\mathcal{M}_1 = \delta_1/\sqrt{\sigma_{11}}$ and $\mathcal{M}_2 = \delta_2/\sqrt{\sigma_{22}}$ are the Mahalanobis distances for the individual systems, and

$$\rho = \sigma_{12}/\sqrt{\sigma_{11}\sigma_{22}}. \tag{9}$$

Note that ρ is *not* the correlation between the two systems in the usual sense, since Σ is not the covariance matrix of F, but the average class-conditional covariance.

Let us call the upper bound on the EER, $\hat{e}$, that is, $\hat{e} = \phi(-\mathcal{M}/2)$. Figure 4 shows some curves of $\hat{e}_c$, the upper bound on the performance of the combination for two systems, as a function of ρ. To create these plots we take two actual systems (the MLLR-SVM and the SNERF-SVM, as described in Section 6.2) and compute the upper bound on the EERs based on their Gaussian approximation. We also compute matrix Σ and from there, ρ. This gives a single point in this graph (marked with a star). We can now vary ρ, keeping $\hat{e}_1$ and $\hat{e}_2$ (the upper bound on the performance of the individual systems) fixed, to obtain a curve. We can also obtain curves for different values of $\hat{e}_2$. These curves show us the relation between the performance of system 2, the value of ρ between the two systems, and the performance of their combination. We can see that for this particular set of systems, we could degrade the second system 100% (that is, from 15.6% to 31.3%) and still get a gain in the

4. Note that this is the same direction one would obtain with linear discriminant analysis (LDA). As mentioned in the introduction, for the experiments in this paper we will use linear logistic regression (LLR) to train the combination weights. The reason for using LLR instead of LDA, despite the result obtained in this section, is that the results in this section are obtained under the assumption of class-conditional Gaussianity. When Gaussianity is not closely satisfied, LLR is believed to be a safer choice being more robust to outliers (Hastie et al., 2001, Section 4.4). In fact, a set of initial experiments showed that LLR was significantly better than LDA on our speaker verification data.

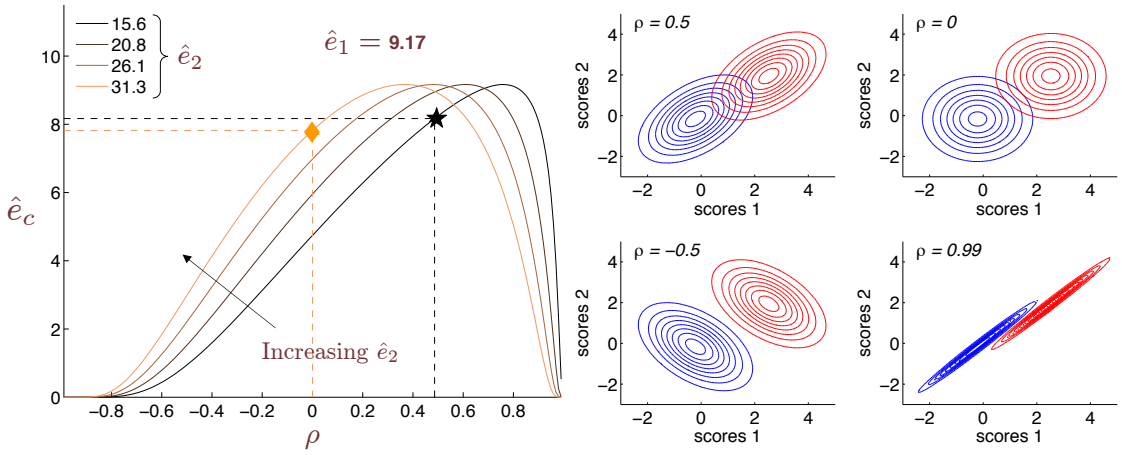

Figure 4: Left: Curves of $\hat{e}_c$ (the upper bound on the EER of the combination) for two systems as a function of ρ, for $\hat{e}_1$ fixed and various values of $\hat{e}_2$, where $\hat{e}_i$ denotes the upper bound on the EER of system i. Right: Simulated contour plots for the scores of two systems assuming class-conditional distributions are Gaussian with equal covariance matrix. Marginal distributions are kept fixed for all four figures, only ρ is changed. These plots correspond to four different points in the darker curve from the left plot.

performance of the combination (or at least in the upper bound) over what we get with the original pair of systems if, at the same time, we were able to decrease the ρ from 0.48 to 0 (this point is denoted by a diamond in the graph).

At first sight, these curves may seem to go against intuition, since when ρ increases, after reaching a peak (occurring at the minimum of $\mathcal{M}_1/\mathcal{M}_2$ and $\mathcal{M}_2/\mathcal{M}_1$), they go down again. That is, very high values of ρ result in extremely good combination performance. Similarly, when ρ turns negative, the combination performance improves, reaching zero EER for $\rho = -1$. All these cases can be easily understood using contour plots of the scores from two systems for varying values of ρ. The right plot of Figure 4 shows four different cases. Here we keep the marginal distributions of the systems fixed and vary only ρ, which implies that the performance of the two individual systems stays fixed for the four different plots. That is, the four plots correspond to four different points in a single curve like the ones in the left plot. Furthermore, we set the covariance matrix between the two systems to be the same for both classes. In this way, the upper bound (4) is exact and ρ is the within-class correlation (assuming both classes have the same prior). We can see that the separation between the two classes is highly dependent on the value of ρ. The first plot shows a typical case, where $\rho = 0.5$. The second plot shows the case of $\rho = 0$. We can already see that the overlap between the two classes has been significantly reduced, even though the marginal distributions have not changed. The third plot shows the case of negative ρ. This implies that both systems produce errors in a negatively correlated way, which makes the combination of those two systems extremely effective at reducing the error rate. The fourth plot illustrates the case in which ρ is larger than the value for which the $\hat{e}_c$ curve peaks, showing good separation between the two classes. Perfect classification with $\rho = 1$ is possible only when both classes have exactly the same

covariance matrix except possibly for a scalar factor (so that the contour plots become parallel lines) and the mean vectors for both systems are different. This case corresponds to a zero value in the denominator of (8) and a nonzero at the numerator.

In practice, if we take pairs of all 37 systems plotted in Figure 2 and compute the actual ρ and the ρ at the peak (that is, $\rho_{peak} = \min(\mathcal{M}_1/\mathcal{M}_2, \mathcal{M}_2/\mathcal{M}_1)$) we find that, on average, the actual ρ is 0.26 to the left of ρ_{peak}. Considering this empirical fact it seems unreasonable to try to increase ρ in order to improve the combination performance, since it would require a large increase in order to go past the peak into an area where the combination performance is better than the original. Furthermore, this would work only if the class-conditional covariance matrices were equal, which is usually not the case. Hence, in this paper, our strategy will be to try to decrease the value of ρ. Of course, we also require that the performance of each individual system stays reasonably close to its original performance, which we hope will result in a new point (in a plot like the one in the left of Figure 4) located toward the left and lower than the original point. In the next section we introduce our method for achieving this goal.

4. Anticorrelation Kernel

Suppose that two separate classifiers S and B are available, where S is required to be an SVM, but B can be any classifier that produces a score for each sample. We will consider B to be a black box from which we have only the scores that it produces. As we have been assuming, the final classification decision will be made based on a combination of the outputs generated by both classifiers. Our strategy will be to train system S using information about system B in order to improve the combination performance over the one obtained when system S is designed with no knowledge of system B.

4.1 Support Vector Machines

Consider a labeled training set with m samples, $T = \{(x_j, y_j) \in \mathcal{R}^d \times \{-1,+1\}; j = 1,...,m\}$, where x_j is the feature and y_j the class corresponding to sample j. The goal is to find a function $f(x) = w^t x + c$, such that $\text{sign}(f(x))$ is the predicted class for feature vector x. The standard (primal) SVM formulation for classification is given by Vapnik (1999):

$$\begin{array}{lll} \text{minimize} & J(w,\varepsilon) = \dfrac{1}{2} w^t w + C \displaystyle\sum_{j=1}^{m} \varepsilon_j & \\ \text{subject to} & y_j(w^t x_j + c) \geq 1 - \varepsilon_j & j = 1,...,m \\ & \varepsilon_j \geq 0 & j = 1,...,m. \end{array} \tag{10}$$

Minimizing the norm of the weight vector is equivalent to maximizing the margin between the samples and the hyperplane. The *slack* variables ε_j allow for some samples to be at a distance smaller than the margin to the separating hyperplane or even on the wrong side of the hyperplane. The parameter C controls the trade-off between the size of the margin and the total amount of error. By deriving the dual form of the optimization problem above we find that input vectors appear only as inner products with each other. Hence, if we wish to transform the input features with a certain function $\phi(x)$ we only need to be able to compute the inner products between the transforms for any pair of samples, that is, we only need to know the function $K(x_k, x_l) = \phi(x_k)^t \phi(x_l)$. This fact is what allows for complex transforms of the input features to be used, as long as the kernel

function $K(x_k, x_l)$ can be easily computed. In the next section we will develop the proposed method considering an inner product kernel. The general case will be treated in Section 4.5.

The above setup corresponds to a classification problem. The regression problem can also be posed as a convex optimization problem by choosing an appropriate distance measure (Vapnik, 1999; Smola and Schölkopf, 1998) with the objective function given by the sum of the square norm of the weight vector and an error term, as in the classification case. The dual of this problem again takes a form in which features appear only in inner products with other features, which again allows for the kernel trick to be used. Hence, even though the derivations in this paper will be done considering a classification problem for simplicity, the method described and the interpretations given can be equally applied to SVM regression problems.

4.2 Modified Support Vector Machines

As we saw in Section 3.3, reducing the ρ value between system S and system B could lead to an improvement in combination performance as long as the performance of the individual systems does not degrade too greatly. We propose to add a term in the SVM objective function ($J(w, \varepsilon)$ in Equation (10) that introduces a cost for a model that results in high value of ρ. Ideally, we would like this term to be given by $\lambda\rho$ so that low values of ρ are encouraged, including negative ones. Unfortunately, this term would make the new objective function nonconvex, making the optimization problem much more complex. To see this, let us derive an expression for ρ as a function of the SVM weights. Let $S = w^t X + c$, where w and c are the SVM parameters. We can compute $\sigma_{12} = \sigma_{SB}$ (component $1,2$ of Equation 7) as[5]

$$\sigma_{SB} = \frac{1}{2} \sum_{y=\{a,b\}} E[(B-\mu_{b,y})(S-\mu_{s,y})|Y=y] = w^t K,$$

where we are using the notation $\mu_{v,y} = E[V|Y=y]$ for any random variable V (scalar or vectorial), and where

$$K = \frac{1}{2} \sum_{y=\{a,b\}} E[(B-\mu_{b,y})(X-\mu_{x,y})|Y=y]. \tag{11}$$

K is simply the vector of average class-conditional covariances between each input feature and the scores from system B. The value of vector K can be estimated from the training set T as

$$\tilde{K} = \frac{1}{2} \sum_{y=\{a,b\}} \frac{1}{m_y} \sum_{j|y_j=y} (b_j - \tilde{\mu}_{b,y})(x_j - \tilde{\mu}_{x,y}), \tag{12}$$

where b_j is the score generated by system B for sample j, m_y is the number of samples in T from class y, $\tilde{\mu}_{b,y} = \frac{1}{m_y} \sum_{j|y_j=y} b_j$, and $\tilde{\mu}_{x,y} = \frac{1}{m_y} \sum_{j|y_j=y} x_j$.

Similarly, we can compute $\sigma_{11} = \sigma_{SS}$ (component $1,1$ of Equation 7) as $w^t M w$, where M is the average class-conditional covariance matrix for the feature vector X; and $\sigma_{22} = \sigma_{BB}$ (component $2,2$ of Equation 7) as the average class-conditional variance for the B scores that we will call v. We can now write ρ^2 as

$$\rho^2 = \frac{\sigma_{SB}^2}{\sigma_{SS}\sigma_{BB}} = \frac{w^t K K^t w}{v\, w^t M w}.$$

5. We use B and S to refer to the systems and the random variables corresponding to the scores produced by these systems. The actual meaning should be clear from the context.

This expression and its square root are nonconvex functions of w. Hence, adding the term $\lambda\rho$ to the objective function of the SVM problem would make the optimization problem nonconvex. On the other hand, the numerator of ρ^2, σ_{SB}^2 is a convex function of w and, using it as a regularization term results in a new problem that is equivalent to a standard SVM problem with a new kernel function. To see this, write

$$\begin{aligned} J_\sigma(w,\varepsilon) &= \frac{1}{2}w^t w + \frac{\lambda}{2}w^t KK^t w + C\sum_i \varepsilon_i \\ &= \frac{1}{2}w^t Aw + C\sum_i \varepsilon_i, \end{aligned}$$

where $A = I + \lambda KK^t$ is a symmetric positive semidefinite matrix. We can now change variables $\tilde{w} = Bw$, with B symmetric and $B^tB = A$ (i.e., B is a matrix square root of A and, since A is a positive definite symmetric matrix, it always exists and can be chosen to be real and symmetric) and write it as

$$\begin{aligned} &\text{minimize} && J_\sigma(\tilde{w},\varepsilon) = \tfrac{1}{2}\tilde{w}^t\tilde{w} + C\textstyle\sum_j \varepsilon_j \\ &\text{subject to} && y_j(\tilde{w}^t z_j + c) \geq 1 - \varepsilon_j && j = 1,\ldots,m \\ &&& \varepsilon_j \geq 0 && j = 1,\ldots,m, \end{aligned}$$

where

$$z_j = B^{-1}x_j. \tag{13}$$

We see that the appropriate choice of regularization term led us to a very simple new optimization problem. The disadvantage of this choice is that it does not *directly* achieve our goal of minimizing ρ. For example, negative values of ρ corresponding to negative values of σ_{SB} will generally not be encouraged by the new objective function because the maximum margin (that is, the minimum value of w^tw) corresponds, in most practical cases, to positive values of σ_{SB}. Hence, in practice, for each negative value of σ_{SB} the corresponding positive one will result in a smaller value of the objective function and will be preferred to the negative one. Furthermore, minimizing σ_{SB} does not imply minimization of ρ, even for positive values, since the denominator is not being taken into account. Nevertheless, we empirically find that the new optimization problem achieves its goal of reducing ρ. In particular, when λ is large, σ_{SB} is pushed toward zero, forcing ρ to become zero.

Directly finding the matrix B^{-1} in (13) is computationally expensive since in general the dimension d of the feature vectors x_i can be very large and the matrix B is a full matrix of size $d \times d$. Nevertheless, since matrix A has a very particular structure, we can find an expression for its inverse using the matrix inversion lemma, by which $A^{-1} = I - \frac{\lambda}{1+\lambda K^tK}KK^t$. Hence, one way of implementing the proposed method is to define a kernel $K(x_k,x_l) = x_k^tB^{-t}B^{-1}x_l = x_k^tA^{-1}x_l$ to be used by the SVM. This kernel satisfies the mercer conditions (i.e., it is a valid kernel) since A is a positive semidefinite matrix. Using the expression for A^{-1} above we get

$$K(x_k,x_l) = x_k^tx_l - \frac{\lambda}{1+\lambda K^tK}x_k^tKx_l^tK. \tag{14}$$

We call this kernel the *anticorrelation kernel*. The computation of $K(x_k,x_l)$ in Equation (14) requires only the calculation of three inner products, which makes the method computationally feasible. Another approach is to transform directly the features using (13). This is also computationally feasible because the inverse of the matrix B has a simple expression. To find this expression we first

note that the matrix B^{-1} is a matrix square root of A^{-1}. Hence, we need to find a matrix that when multiplied by its transpose results in $A^{-1} = I - \frac{\lambda}{1+\lambda K^t K} K K^t$. It is easy to show that

$$B^{-1} = I - \frac{\alpha}{K^t K} K K^t$$

satisfies this condition when $\alpha = 1 \pm \frac{1}{\sqrt{1+\lambda K^t K}}$. Hence, given a certain value for λ we can find the corresponding α and transform each feature vector using (13). This means that we can implement the proposed method by transforming the input features using the following expression:

$$z_i = x_i - \alpha \frac{K^t x_i}{K^t K} K. \tag{15}$$

In the case of speaker verification, a separate K vector is computed for each target model being trained. Hence, doing the transformation in the feature domain is inefficient, since there is not a single transformation for each feature vector x_i, but one for each target model. The kernel implementation might be preferable in this case. Furthermore, as we will see in Section 4.5, when the original SVM problem uses a kernel other than the inner-product one, implementing the anticorrelation method as a kernel may be the only feasible option.

4.3 Interpretation of the Modified Problem

To give an interpretation of the new SVM problem, we first need to understand the meaning of the direction given by the vector K. The average class-conditional covariance between the scores from system B and the scores from system S is given by $w^t K$. For a fixed value of $\|w\| = c$, the w that maximizes the absolute value of $w^t K$ is given by $w = cK/\|K\|$. Hence, K gives the direction for the vector w of SVM weights for which the average class-conditional covariance between the two systems is maximum. A w orthogonal to K would result in zero average class-conditional covariance between the two systems. The term $\|w^t K\|^2$ that we have added to the objective function of the SVM problem has the effect of penalizing any w vector with a large component in the direction of K. Our goal is to find a w as orthogonal to K as possible without degrading the performance of the system so much that the overall combination starts to degrade. This balance can be achieved by tuning the parameter λ.

We can interpret the kernel given by (14) in a similar way. When λ is small this kernel is close to the linear kernel. When λ grows to infinity the kernel subtracts the product of the projections of the points x_k and x_l into the vector K from the linear kernel. The resulting value of the kernel will be small if x_k and x_l are both aligned with K. Since the SVM will make an effort to separate only points from different classes that give a high kernel value (that is, that are more "similar"), this means that we consider vectors whose directions are close to that of K to be unimportant and, consequently, we emphasize the importance of the vectors whose directions are orthogonal from that of K. This results in a more effective usage of the features, ignoring those directions that would lead to high average class-conditional covariance between the systems and taking advantage of the rest.

Finally, if we choose to implement the method as a feature transform instead of a kernel function, the resulting features have a very simple interpretation. When $\lambda = \infty$, Equation (15) becomes $z_j = x_j - \frac{K^t x_j}{K^t K} K$, which is the expression for subtracting from x_j its component on direction K. If λ is not ∞ then only a part of the component is subtracted.

4.4 Extension for Multiple Preexisting Scores

An extension to the presented method can be considered where N previous systems are available, $B_1,\ldots,B_N$, and we wish to train S to combine well with them. A generalization of the formulas above can be derived for this setup. We rewrite the objective function as

$$\begin{aligned} J_\sigma(w,\varepsilon) &= \frac{1}{2}w^t w + \sum_{k=1}^{N}\frac{\lambda_k}{2}w^t K_k K_k^t w + C\sum_i \varepsilon_i \\ &= \frac{1}{2}w^t A w + C\sum_i \varepsilon_i, \end{aligned}$$

where now A is given by $I+\sum_{k=1}^{N}\lambda_k K_k K_k^t$ and it is still positive definite and symmetric. The same approach used above can be used here to simplify the problem to a standard SVM problem. We can still use the inversion lemma by considering matrices

$$\begin{aligned} K &= [K_1 \ldots K_N], \\ \Lambda &= \mathrm{diag}(\lambda_1 \ldots \lambda_N), \end{aligned}$$

so that $I+\sum_{k=1}^{N}\lambda_k K_k K_k^t = I + K\Lambda K^t$. We can then use the lemma to get $A^{-1} = I - K(\Lambda^{-1} + K^tK)^{-1}K^t$. When $\lambda_k = \infty$ for all k, $A^{-1} = I - K(K^tK)^{-1}K^t$. This matrix is idempotent (and symmetric), hence $B^{-1} = A^{-1}$. The transformed features z_i for this case are then given by $z_i = x_i - K(K^tK)^{-1}K^t x_i$, which is the projection of x_i on the complementary space to that spanned by vectors K_1 through K_N.

4.5 Extension for General Kernels

The development on Section 4.2 was done using inner-product kernel SVMs as the starting point. In this section we show that the method can be implemented for any kernel function.

Consider a problem for which $K_0(x,y) = \phi_0(x)^t\phi_0(y)$ has been found to perform better than the inner-product kernel. One way of implementing the anticorrelation method in this case is to simply transform the features using $\phi_0(x)$ and then treat the transformed features as the feature vectors x in Section 4.2. This is conceptually simple, but could be extremely costly computationally if the dimension of $\phi_0(x)$ is large compared to the dimension of x, or impossible if the transformation ϕ_0 is infinite dimensional (as in the case of the Gaussian kernel). Luckily, there is a way of implementing the anticorrelation method without ever computing the transform but only the kernel function between pairs of features.

In Section 4.2 we found that one way of implementing the proposed method is by the use of the *anticorrelation* kernel, defined by Equation (14). In practice, vector K in that equation is computed from data. We call this empirical value for K, $\tilde{K}$ (Equation 12). We can write $\tilde{K}$ as a linear function of the features x_j used to compute it. That is, $\tilde{K} = \sum_j c_j x_j$, where the c_j depend on the m_y's and all the b_i's. If we now replace every x in Equation (14) by $\phi_0(x)$ and K by $\sum_j c_j\phi_0(x_j)$, we get

$$\begin{aligned} K(x_k,x_l) &= \phi_0(x_k)^t\phi_0(x_l) - \frac{\lambda\sum_j c_j\phi_0(x_j)^t\phi_0(x_k)\sum_j c_j\phi_0(x_j)^t\phi_0(x_l)}{1+\lambda\sum_j\sum_i c_j c_j\phi_0(x_i)^t\phi_0(x_j)} \\ &= K_0(x_k,x_l) - \frac{\lambda\sum_j c_j K_0(x_j,x_k)\sum_j c_j K_0(x_j,x_l)}{1+\lambda\sum_j\sum_i c_j c_j K_0(x_i,x_j)}. \end{aligned}$$

The anticorrelation kernel can then be computed exclusively as a function of the original kernel K_0. The processing time is now significantly increased, though, since two sums over the samples used to obtain K are needed every time the kernel is computed (the denominator in the second term can be precomputed and reused, since it does not involve x_k or x_l). The extension for multiple preexisting scores follows the same steps as above. In this paper, the inner-product kernel is used for all experiments.

4.6 Other Approaches

Our goal is to obtain the best possible combination performance given the available systems. The approach presented above is one path toward this goal. Two other ways of approaching this problem are considered here.

4.6.1 FEATURE-LEVEL COMBINATION

When system B is also an SVM system and the features corresponding to the samples used for training system S are also available for system B, an SVM using the features from both systems concatenated into a single vector can be trained. The resulting SVM is in itself a combination procedure, which, ideally, should make optimal use of the features from both systems. This may not be true in practice, though, since a larger feature vector increases the complexity of the system, making it more prone to overfitting the training data. A further refinement of this approach consists of weighting the vector components, assigning weight α to the features from one of the original systems and weight $1-\alpha$ to the other features. This is done by multiplying the components of the square-norm of w in the SVM objective function by the inverse of the corresponding feature weight. That is, we replace $\|w\|^2 = \sum_i w_i^2$ with $\sum_i w_i^2/\beta_i$, where $\beta_i = \alpha$ for the features from one set and $1-\alpha$ for the features from the other set. This allows us to compensate for different lengths in the original vectors or to bias the training procedure to make more use of the features from the better-performing system. Feature-level combination is usually costly and sometimes even infeasible, given the large size of the original feature vectors, and can be considered only if both systems being combined are SVM systems.

4.6.2 FEATURE+SCORE COMBINATION

Another method can be considered in which we present the scores generated by system B as input features to the SVM, along with all the features from system S. Again, a larger weight can be given to the component corresponding to the score from system B than to the features from S.

5. Experiments on Artificial Data

To test the proposed kernel on a simple task, we generated data for two classes with model

$$Z = C\tilde{Z} + m_Y,$$

where $\tilde{Z}$ is a vector of size d where the components are generated independently with normal distribution with zero mean and unit variance. C is a square random matrix intended to create correlation between the features. Its components are drawn from a uniform distribution, and a scaling factor is

applied to force the maximum variance of Z to be 1. The class-dependent mean vector is given by

$$m_Y = \begin{cases} (0\ldots0)^t & \text{if } Y = a \\ (m\ldots m)^t & \text{if } Y = b. \end{cases}$$

We take half of the features and train a linear SVM (inner-product kernel), which serves as system B. The remaining features are used to train system S starting with an inner-product kernel. The anticorrelation kernel is implemented for varying values of λ. We create two separate sets, one for training, with 900 examples of class a and N examples of class b, and one for testing, with 10 times more data than in the training set.

The combination is performed using a linear logistic regression model, trained on the training set with the scores from the two SVM systems, B and S, for each value of λ. Since the scores obtained on the training set are overly optimistic, we use 10-fold cross-validation on the training set to create the B and S scores used to train the combiner (Kuncheva, 2004, Section 3.2.2). The scores from cross-validation for system B are also used to estimate the vector $\tilde{K}$ as in (12). When only a few samples from one of the classes are available, the estimation of $\tilde{K}$ can be noisy. In our simulation we vary the number of samples available for class b, keeping the number for a fixed; hence, in order to keep the variance of the estimator stable across experiments, we use only samples from class a to estimate $\tilde{K}$.

Figure 5 shows the error rates for the test data for system S, system B, and the score-level combination as a function of the value of λ, for $m = 3.0, N = 900$ and $d = 250$. The figure also shows results for the feature-level and the feature+score combination procedures, explained in Section 4.6. The weight α for these two systems was tuned using 10-fold cross-validation on the training set. For these two cases and for system B, the error does not depend on λ. On the other hand, the value of ρ between S and B decreases with λ (reaching a value close to zero). We see that, in practice, ρ is effectively reduced as λ increases, even though we use $\lambda\sigma^2_{SB}$ as regularization term instead of $\lambda\rho^2$. The error for system S also varies with λ. The degradation in performance is expected since we are trading off poorer performance in exchange for a lower value of ρ. The small improvement at moderate values of λ, though, is not too surprising. If the direction K corresponded to one that is especially noisy, reducing the importance of that direction can lead to improved performance. We will see more on this in Section 6.5.

The feature-level and feature+score combination methods perform approximately equal at around 1% EER, while, for $\lambda = 0$, the score-level combination has a significantly worse performance of 1.58%. Nevertheless, as λ grows, the performance of the score-level combination using the anticorrelation kernel improves significantly (from 1.58% to 0.56% when λ goes from 0 to 10^4), making it the best-performing system. Overall, we see a reduction in EER of around 50%, relative to the EER of the best combined system when the anticorrelation kernel is not used.

Figure 6 shows the scatter plot of scores (on the training data) for both systems corresponding to $\lambda = 0$ and $\lambda = 10000$. We can see that for the large value of λ, the within-class covariances have been largely reduced. We can also see that the separation of the two classes is better for the larger λ, which explains the performance improvement observed in Figure 5.

Figure 7 shows the results for the score-level combination of systems B and S with $\lambda = 0$ (that is, without using the proposed method), the score-level combination with $\lambda = \infty$, the feature-level combination, and the feature+score combination, for several settings of the simulation parameters N, m, and d. For the score-level combination with $\lambda = \infty$ we also present the results obtained when computing K using our knowledge of the model that generated the data. Since we are creating

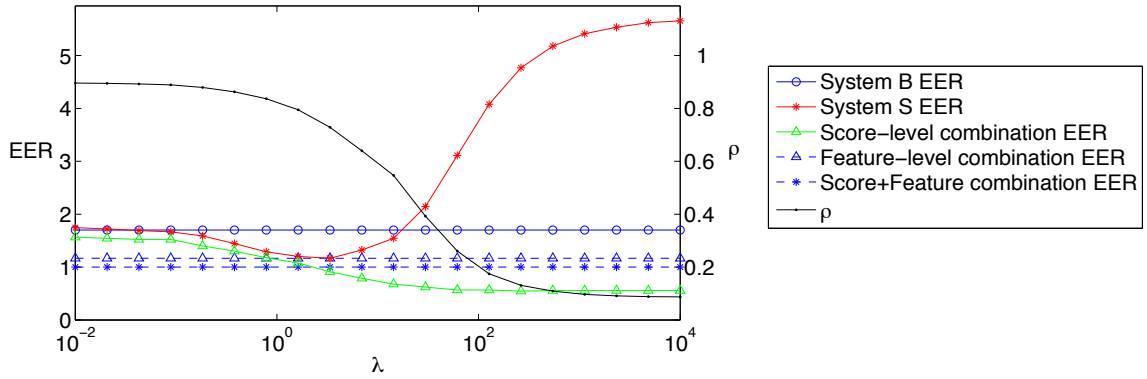

Figure 5: Error of individual systems and their combination, and value of the ρ coefficient as a function of λ for an artificial problem. The EER of the combination is reduced from 1.58% to 0.56% as λ increases.

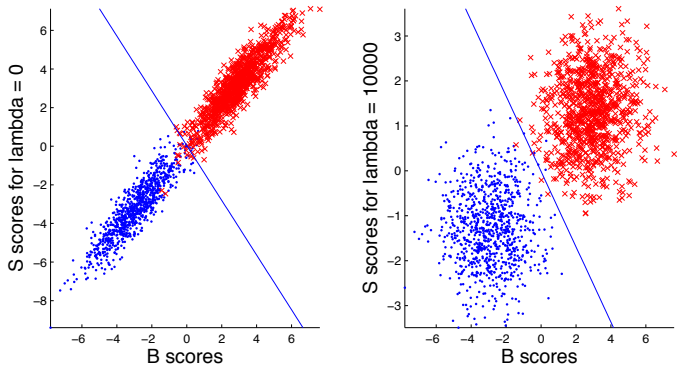

Figure 6: Scores from system B versus scores from system S for two values of λ.

the data ourselves according to a model, we can compute K exactly using (11) instead of (12). It can be shown that, for our setup, $K = \frac{1}{2}\sum_{y=\{a,b\}}(C_{12}C_{11}^t + C_{22}C_{12}^t)w_B$, where w_B is the SVM weight vector for system B and C_{ij} is block ij of size $d/2 \times d/2$ of matrix C. For each set of parameters, 10 different random seeds were used to generate the data, keeping matrix C equal for all 10 experiments. Each bar shows the first quartile, the median, and the third quartile of the set of EERs obtained from the 10 simulations.

The figure shows that feature+score combination is significantly better than score-level or feature-level combinations only when the task is easier ($m = 3.0$) and many samples are available for training ($N = 900$). Feature-level combination is optimal when the task is harder ($m = 1.8$) and the number of features is small ($d = 250$) particularly when enough samples are available for training ($N \geq 300$). Plain score-level combination (without anticorrelation) performs comparably to feature-level combination when the number of training samples is small and the number of features is large, in which case the feature-level combination suffers from the additional complexity. In all cases, though, the anticorrelation method (last two bars) is either comparable or significantly better than

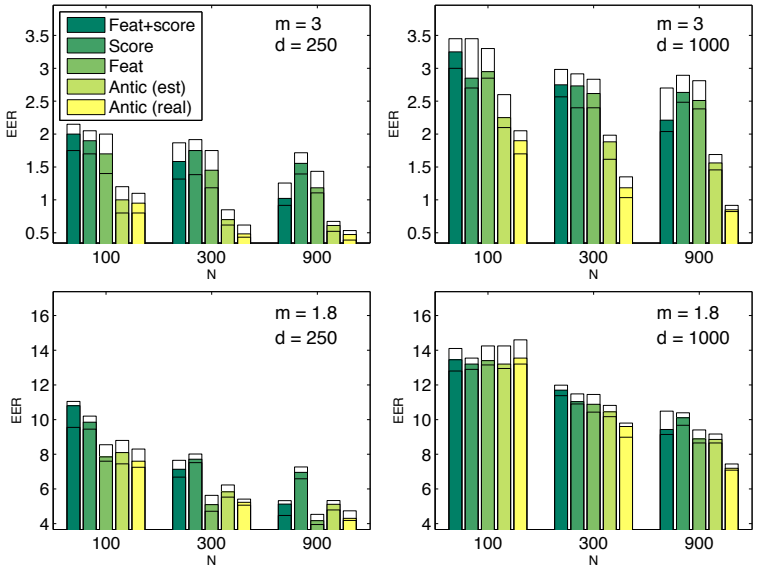

Figure 7: Comparison of EER on simulated data for the score-level combination of system B with S with $\lambda = 0$ (called *Score* in the legend), the score-level combination with $\lambda = \infty$ (*Antic*) using the estimated value for K (*est*) or the value obtained from the model (*real*), the feature-level combination (*Feat*), and the feature+score combination (*Feat+score*) for several values of the simulation parameters. For each pair of m (distance between means) and d (feature vector dimension), three values of N (number of samples from class b) are explored.

plain score-level, feature+score and feature-level combinations. For $m = 3.0$, the anticorrelation method significantly outperforms all other combination methods for both values of d and the three values of N. Gains are smaller or disappear when the task becomes harder ($m = 1.8$).

The difference between the fourth and the fifth bars in each set is due only to the difference in the K vector used. The K is estimated using the data (Equation 12) for the fourth bar and using the model (Equation 11) for the fifth bar. We can see that when the dimension of the feature vector Z_2 is large, the difference between the fourth and the fifth bars becomes larger, indicating that in these situations the estimation of K is noisier. This is also evident from looking at the reduction in ρ achieved for the different values of d when using the data to estimate K. For $d = 250$, the reduction is around 90%, while for $d = 1000$ the reduction is only around 60%. In most experiments with $d = 1000$ the value of ρ when using the estimated value of K does not go under 0.30. This means that for higher-dimensional vectors, the estimation of K is harder than for lower-dimensional ones. Nevertheless, even in those cases, the combination using the anticorrelated system with the estimated K is, in most cases, better than the original score-level combination.

6. Experiments on Speaker Verification

Speaker verification is the task of deciding whether or not a speech sample was produced by a certain target speaker. It is a binary classification task where the two classes are *true-speaker* and *impostor*. To test the proposed method we use a standard UBM-GMM system, a cepstral supervector SVM system, an MLLR-based system, and a prosodic system. We show results using the proposed kernel on all possible combinations involving two systems (two-way combinations) and a variety of combinations involving three and four systems (three-way and four-way combinations).

6.1 Databases and Error Measures

Experiments were conducted using data from the NIST speaker recognition evaluations (SRE) from 2005 and 2006. Each speaker verification trial consists of a test sample and a speaker model. The samples are one side of a telephone conversation with approximately 2.5 minutes of speech. We consider the 1-side training conditions in which we are given 1 conversation side to train the speaker model. This conversation corresponds to a positive example when training the SVM model for the speaker. The data used as negative examples for the SVM training and to estimate the K vectors is taken from 2003 and 2004 NIST evaluations along with some FISHER data, resulting in a total of 4355 samples. The tasks contain 26,270 trials for SRE05, and 21,343 for SRE06. In both cases around 1/10th of the trials are target trials. Trials are created by reusing the conversations from a few hundred speakers as train and test samples, sometimes as target speakers, sometimes as impostors. A total of 598 distinct models for SRE05 and 584 for SRE06 are created, some of them corresponding to different conversations from the same speaker.

The performance measures used in this section are the EER and NIST's detection cost function (DCF). The DCF is defined as the Bayesian risk with probability of target equal to 0.01, cost of false alarm equal to 1, and cost of miss equal to 10. The DCF is affected both by the discrimination power of the system and its calibration, given by the choice of threshold that is believed to minimize it (Brummer and du Preez, 2006). In this paper, we will not explore the calibration issue, which is, in itself, a large field of study in the biometrics community. We will present results in terms of the DCF achieved when choosing the threshold that minimizes it on the test data. This measure is commonly called *minimum* DCF and it measures *how much information the detector could have delivered to the user, if the calibration had been perfect* (Brummer and du Preez, 2006).

The EER and the DCF are two points in the receiver operating characteristic (ROC) curve of a system and they give a more complete picture of the behavior of the system for different operating points than the EER alone. Even though the theory in Section 3 was developed for EER, we will see that improvements are obtained for both performance measures.

6.2 Individual System Descriptions

The systems chosen to run the experiments in this paper are representative of the systems being used in most state-of-the-art speaker recognition systems. Somewhat simplified versions of the best-performing systems were used, in order to facilitate the large amount of computationally costly experiments that were run. A brief description for each of the systems follows.

6.2.1 UBM-GMM SYSTEM (G)

This is probably the most widely used paradigm for speaker verification. A Gaussian mixture model (GMM) is trained using data from many different speakers and recording conditions to create a *universal* background model (UBM). The target speaker models are trained by maximum a posteriori adaptation of the background model to the training data. For a given test sample the logarithm of the ratio of the likelihoods for the target model and the background model is used as a score. The system used here is based on 13 mel frequency cepstral coefficients (MFCCs) without the zeroth-order coefficient, and first-, second-, and third-order difference features, resulting in 52-dimensional feature vectors. The features are modeled by 2048 mixture component GMMs. Only the GMM means are adapted to the observed data, leaving variances and weights untouched. For implementation details on this system see Shriberg et al. (2005).

6.2.2 SUPERVECTOR-SVM SYSTEM (V)

This system (Campbell et al., 2006) is a variation of the UBM-GMM system, where SVMs are used to obtain scores. For each sample, the means of the UBM-GMM are adapted to the sample's data and stacked together in a single high-dimensional feature vector. A set of held-out samples (generally the same samples used to create the UBM-GMM) is used as negative examples when training the SVM, while the target sample is used as the positive example. These features are used to train a model using support vector regression with an inner-product kernel. The signed distance to the hyperplane is then used as the output of the system. For this system we use a 512-component background model. Since the dimension of the original space is 52, the final dimension of the feature vectors is given by $512 \times 52 = 26,624$. Larger background models have been found to give slightly better performance but increase the computational cost of the experiments. We found 512 components to give a good balance between performance and computational cost of the system.

6.2.3 MLLR-SVM SYSTEM (M)

The MLLR-SVM system (Stolcke et al., 2007, 2006) uses the speaker adaptation transforms used in the speech recognition system as features for speaker verification. A total of four affine 39x40 transforms is used to map the Gaussian mean vectors from speaker-independent to speaker-dependent speech models; two transforms each are estimated relative to male and female recognition models, respectively. The transforms are estimated using maximum-likelihood linear regression (MLLR) and can be viewed as a text-invariant encapsulation of the speaker's acoustic properties. The transform coefficients form a 6,240-dimensional feature space. Each feature dimension is rank normalized by replacing the value with its rank in the background data, and scaling ranks to lie in the interval $[0, 1]$. The resulting normalized feature vectors are then modeled using the same procedure as for the supervector-SVM system. The system described in this paragraph is a simplified version of our best performing MLLR-SVM system which uses a total of 16 transforms and has approximately 25% lower EER than the 4-transform system (Stolcke et al., 2007). Initial experiments (not shown here) indicate that improvements from the anticorrelation method are still obtained when the more complex MLLR system is used, with similar relative gains as the ones shown here.

6.2.4 SNERF-SVM SYSTEM (S)

This system models syllable-based prosodic NERFs (nonuniform extraction region features) (Shriberg et al., 2005). Features are based on estimated F_0, energy, and duration information extracted over syllables inferred via automatic syllabification based on automatic speech recognition output. Prosodic feature sequences are transformed into fixed-length vectors by a particular implementation of the Fisher score (Ferrer et al., 2007). In this paper, only features modeling sequences of two syllables are used. In previous work we have found that these features by themselves yield a performance almost as good as using features extracted for sequences of 1, 2, and 3 syllables together. The resulting feature vector, of dimension 13,343, is first rank-normalized (as in the MLLR system) and modeled using the same procedure as for the supervector-SVM system.

6.3 Application of the Proposed Method to the Speaker Verification Problem

Most speaker verification systems that use SVMs as models consider each train or test utterance as a single sample. If necessary, as in the case of the SNERF features and many other cases presented in the literature (Ferrer et al., 2006; Brummer et al., 2007; Reynolds et al., 2005), a transform is applied to the input features prior to SVM modeling in order to convert them into a single fixed-length vector. In other cases, such as the MLLR system, the features are directly generated as a single fixed-length vector. In our experiments, since we are presenting results on the 1-side training condition from NIST evaluations, this implies that only one positive sample is available during training for each speaker model. This means that the estimation of K in (12) will be given only by impostor samples. These impostor samples are extracted from a held-out set. For each target model in the task definition we require a separate vector K. This results in significant overhead during training since each model from system B must be tested against the held-out set used to compute K. Nevertheless, this has no effect at test time. Once the vector K for each target model is computed, obtaining the score for a new test is almost as fast as for a linear kernel SVM.

6.4 Results

Table 1 shows the results on SRE05 and SRE06 data for the individual systems. Each system is represented by a single letter: **G** for the GMM-UBM, **V** for the Supervector-SVM, **M** for the MLLR-SVM, and **S** for the SNERF-SVM. For the SVM systems (Supervector, MLLR, and SNERFs), we show the baseline results (training the SVM with an inner product kernel) and the results obtained by training the target SVMs using the kernel in (14) with K computed using the scores corresponding to each of the other three systems. This is indicated by the use of a subindex corresponding to the system with respect to which the anticorrelation is performed. For example, $\mathrm{M_G}$ corresponds to a system that uses the MLLR features and anticorrelation kernel with respect to the GMM-UBM system (that is, with K given by the vector of average class-conditional covariances between the MLLR features and the scores from the GMM-UBM system). A list of subindices corresponds to performing anticorrelation with respect to more than one system as described in Section 4.4. Hence, system $\mathrm{S_{M,V_M}}$ corresponds to system S anticorrelated with respect to systems M and $\mathrm{V_M}$. In all cases the anticorrelation results shown correspond to $\lambda = \infty$, which implies that the resulting weight vector will not have a component in the direction of K. This was shown to be optimal in the simulated experiments and in several preliminary experiments with the systems from this table.

System	SRE05		SRE06	
	DCF	EER%	DCF	EER%
G	0.303	7.259	0.306	5.639
M	0.266	7.096	0.221	4.979

S_{M,V_M}	0.588	16.150	0.592	14.157

Table 1: Results for individual systems (G: GMM-UBM, V: Supervector-SVM, M: MLLR-SVM, S: SNERF-SVM) with inner product kernel and anticorrelation kernel. When the anticorrelation kernel is used, a subindex indicates the name of the system or systems with respect to which the anticorrelation is performed.

It can be seen that in most cases, using the anticorrelation kernel results in a degradation in performance in the system. A notable exception is the result for system V_M (Supervector features using anticorrelation kernel with respect to the MLLR-SVM system). In this case, preventing the use of the direction given by K results in a significant gain in performance. This could happen if vector K corresponded to some noisy direction that, when ignored, allowed for other more robust directions to be used. This effect was also observed in the simulations and will be discussed in more detail in Section 6.5.

Table 2 shows results for all the possible two-way combinations of the four individual systems. For the score-level combinations (indicated with "+") we used a linear model trained on SRE05 data using logistic regression. Feature-level and feature+score combinations are indicated with "$\cup$". The symbol indicates feature concatenation. In the case of feature-level combination, features from both systems are directly concatenated. In the case of feature+score combination, the features from one system are concatenated with the scores from the other (this is indicated with the subscript "scores"). Whenever feature concatenation is performed, a weight is used (as described in Section 4.6) to emphasize the features from one set versus the other. This weight is tuned on SRE05. Since tuning this weight is extremely demanding computationally (it requires running a full classification experiment for each value of the weight), only feature+score combination experiments involving the MLLR systems are run. All possible feature-level combinations are shown, since there are only three of them.

We can see that every time a score-level combination (+) is done between systems X and Y_X,[6] the performance is better than that for the combination of X and Y (with the single exception of SRE05's EER for $V + S_V$). That is, applying the anticorrelation kernel to system *Y* always gives a gain in the combination performance, even though in most cases system Y_X has worse individual performance than system Y. Feature-level combinations, $X \cup Y$, do not show any advantage over the much simpler score-level combination $X + Y$. This simply indicates that the increased model complexity of the feature-level combination cannot be properly handled with the available amount of training samples. Similarly, the feature+score combinations, $X \cup Y_{\text{scores}}$, do not give any consistent improvement over the score-level combinations $X + Y$.

The most notable gain from using the anticorrelation kernel is found for the combination $M + V_M$. The relative gain in EER with respect to system $M + V$ is 16%. As mentioned above, system V_M is in fact better performing than system V. That is, anticorrelating with respect to M does not degrade its performance but improves it. This fact, together with a reduced impostor correlation between the systems, explains the observed large gain.

The last column in Table 2 shows the class-conditional correlation between the two systems being combined for the impostor and the target samples in SRE06 data. As we can see, the impostor correlation is significantly reduced when the proposed method is used, even though it does not reach a zero value. (This problem was also observed in the simulated experiments for large values of the feature vector dimension d.) This could mean that the amount of data used for the computation of K (4355 samples) is not enough to obtain a robust estimation of the statistics in the test data or that the statistics in the test data are not the same as those in the held-out set used to compute K. Furthermore, we can see that the target correlation remains almost unchanged by the application of the anticorrelation kernel. This is reasonable, since the vector K is computed without the use of any target data. The fact that the target correlation is not reduced when K is computed only over impostor samples suggests that the correlations in both populations are not equal and one cannot be predicted from the other. Nevertheless, a reduction in either of the class-conditional correlation coefficients can result in a reduction of ρ as given by (9).

Finally, Table 3 shows some three-way and four-way combination results. The first four results correspond to the combination of the three SVM systems. The three combinations shown that use the anticorrelation kernel on the V and S systems perform very similarly, resulting in a performance improvement of 18.9% on the SRE06 EER with respect to the baseline combination. We can see that using multiple anticorrelation on the S system with respect to the other two systems already in the combination (M and V_M) does not lead to further improvements (line $M + V_M + S_{M,V_M}$). This is, in fact, good news, since doing the multiple anticorrelation involves a significant amount of extra computation to obtain the K vector of system S with respect to the scores from V_M.

The last three lines in Table 3 show the results on some four-way score-level combinations. We see a large improvement of 19.2% when a successive anticorrelation procedure is used, where each new model is anticorrelated with the one previously added to the combination. The best three- and four-way combinations all include the V_M system. This was expected since the two-way gain from using anticorrelation on that system was the largest among all two-way combinations.

An overall observation from this table is that the proposed method performs better on SRE06 data than on SRE05 data, even though the combiner is trained on SRE05 data, making the SRE05 results slightly optimistic. We believe that this might be a consequence of a better statistical match

6. Letters X and Y are used in this section to indicate any two systems. Hence, $X, Y \in \{G, M, V, S\}$.

Table 2: Results for two-way combinations of the systems in Table 1. Symbol "$\cup$" indicates feature concatenation. Hence, $M \cup S$ corresponds to feature-level combination, while $M \cup S_{scores}$ corresponds to feature+score combination of systems M and S. Symbol "$+$" indicates score-level combination. The last column shows the correlations between the pair of systems being combined, for the impostor (CorI) and the target (CorT) samples.

between SRE04 data (used to compute the *K* vectors) and SRE06 data than between SRE04 and SRE05 data.

Evidently, the behavior found in these experiments cannot be expected to generalize to all possible sets of features and tasks. For example, if much smaller sets of features were used and enough training data was available for both classes, feature-level combination might result in better performance than score-level combination (as seen in the simulated experiments). Nevertheless, the systems used here are representative of the kinds of systems used for speaker recognition on state-of-the-art systems, where very large feature vectors have been found to outperform smaller ones. Furthermore, the small amount of positive training examples is an inherent characteristic of the speaker recognition task. Finally, these characteristics are found in many other modern machine learning tasks, a notable example being classification of microarray expression data, where the

number of features is in tens of thousands, and the number of samples for most studies is limited to tens or at most hundreds.

6.5 Interaction with Intersession Variability Compensation

The variability found across different recordings of the same speaker is commonly called *intersession variability* (ISV). This effect can be caused by a mismatch in channel conditions, emotional state, phonetic content, and so on, and it is one of the biggest sources of errors in speaker verification. Several methods have been developed to reduce the effect of intersession variability.

In the realm of SVMs, the most widely used ISV compensation (ISVC) method is nuisance attribute projection (NAP) (Solomonoff et al., 2004; Campbell, 2006). NAP consists of estimating the directions in the feature space that vary with the sessions and then projecting the samples on the complement of the space determined by those directions. The *noisy* directions are calculated as the first few eigenvectors of the within-speaker covariance matrix. This matrix is in turn estimated from held-out data for which several samples of each speaker are available. All speakers are pulled together and a single within-speaker covariance matrix is estimated. The number of directions to be eliminated from the feature vectors is determined empirically. Both NAP and the anticorrelation method presented here transform the features by eliminating certain directions. In the case of NAP these directions are the ones estimated to have information superfluous to the task of speaker verification. In the anticorrelation procedure, a single direction is eliminated: the one that maximizes the average class-conditional covariance between the two systems being combined.

In the case of UBM-GMM systems and systems like the supervector-SVM, which are based on the UBM-GMM models, a different type of ISVC based on the factor analysis method can be applied (Kenny and Dumouchel, 2004; Kenny et al., 2007). The method is based on the assumption that a supervector m corresponding to a certain sample can be decomposed into a speaker-dependent and a channel-dependent component. That is, $m = s + c$, where s is a speaker supervector and c a channel supervector. Furthermore, c is assumed to be given by ux, where u is a low-rank matrix and x is a normally distributed random vector. The components of vector x are called the *channel factors* and the columns of matrix u the *eigenchannels*. In order to estimate the matrix u, a database with several samples for each speaker (as the one required for NAP) is needed. In some models, s is further decomposed into different terms. Many different methods have been used to estimate and

Table 4: Results for individual systems and their combinations after ISVC.

compensate for the channel factors. The method used in this paper for the supervector system is described by Matrouf et al. (2007).

Table 4 shows a subset of results for two of the systems described in Section 6.2 when ISVC is applied. Factor analysis is used for the Supervector-SVM system, and NAP is used for the MLLR-SVM system. We can see that, for these systems, the anticorrelation kernel does not reduce the class-dependent correlations between pairs of systems enough to result in a gain in the combination performance. The fact that applying the anticorrelation kernel does not result in a significant reduction of the class-dependent correlations between the systems indicates that the K vectors computed from the held-out data are not a good estimation of the K vectors in the test data. If we compare the impostor correlation between the same pair of systems when no ISVC is applied (Table 2) versus the impostor correlation when ISVC is applied (Table 4) we see that ISVC'ed systems are much less correlated. Furthermore, the correlation when the anticorrelation method is applied results in similar values for ISVC'ed and non-ISVC'ed systems. This suggests that much of the correlation between the non-ISVC'ed systems is due to intersession variability effects. This intuition is confirmed by computing the projection of the K direction on the NAP directions, which shows that K is mostly in the direction of the first few NAP directions (when they are sorted by the size of the corresponding eigenvalue). Hence, when ISVC is applied to a system, the ISV effects are eliminated (or reduced), resulting on less-correlated systems that combine better with each other. For example, the performance for combination $M+V$ for non-ISVC'ed systems (3.299% from Table 2) is only 3.5% better than the best of the two individual performances (3.419% from Table 1), while the performance for that same combination but using ISVC'ed systems (2.639% from Table 4) is 6.4% better than the best of the two individual performances (2.819% from Table 4).

These observations explain the reduction in class-conditional correlation between pairs of systems when ISVC is applied to them, since a large part of the class-conditional correlation is due to the intersession variability. On the other hand, it does not explain why the correlation cannot be further reduced after the intersession variability noise has been eliminated. The reason for this is simply that the vector K estimated for each target model does not predict the direction of maximum impostor covariance on the test data. On the training data, we know that the covariance for the impostor cloud is necessarily pushed to zero when $\lambda = \infty$, but we do not observe the same behavior on the test data. This is because, as we saw in the simulations, the estimation of the direction K

gets noisier for larger feature vectors. Hence, only a very noticeable effect (like the intersession variability one) can be robustly estimated.

We believe that the observations presented in this section do not invalidate the usefulness of the method for the speaker verification task. As mentioned in Kenny et al. (2007), for ISVC to work, a well-balanced database is required where samples from several different recording conditions for each speaker are available. This kind of database is not easy to obtain. When such a database is not available, ISVC cannot be applied to the systems. In these cases, the anticorrelation method proposed here would be able to bring back some of the gain that ISVC would result in if the right database was available.

7. Conclusions

While speaker verification systems have seen large gains in performance from *ad hoc* combination of several component systems, a unified framework for joint development of a combined system that ensures system diversity has been lacking. The component systems are trained in isolation to maximize individual performance rather than the overall system being trained to maximize combined performance. In this work, we presented a simple model for the system combination problem and found the performance of the combined system to be a function of the performance of the individual systems being combined and a "correlation coefficient" obtained from the average class-condition covariance of the vector of scores. Based on this result we presented a technique for taking into account the characteristics of the scores from a set of fixed existing systems during the development of a new SVM system in order to improve the combined system performance. This is realized through a modification of the SVM optimization problem via the introduction of a regularization term involving the covariance between the scores of the previously existing systems and the input features to the SVM, explicitly encouraging diversity of the resulting system ensemble. The trade-off between the individual performance of the SVM system and the inter-system average class-conditional covariance is reflected in the optimization through the introduction of the Lagrange multiplier λ. The technique can be implemented cheaply through the use of a simple kernel function, which we call *anticorrelation* kernel.

We show the effectiveness of the anticorrelation technique in a series of simulated experiments and in speaker verification experiments on the 2005 and 2006 NIST SRE tasks using four component systems: a standard UBM-GMM system, a cepstral supervector system, an MLLR-based system, and a prosodic system. We show results using the proposed kernel on all possible combinations involving two systems (two-way combinations) and on some combinations involving three and four systems. We demonstrate a performance gain of around 19% for a four-way combination using the anticorrelation kernel with respect to the performance of the combination obtained without anticorrelation. When the same four speaker verification systems are compensated for intersession variability, the gains from the anticorrelation method disappear. Our analysis indicates that the reason for this is that much of the correlation between the systems is, in fact, due to the intersession variability. Once systems are compensated for this variability, the remaining correlation is too hard to estimate robustly. The anticorrelation method can then be seen as a replacement for intersession variability compensation methods when the right databases are not available for the estimation of the matrices needed for those methods.

The fact that, in our experiments, the combination performance improves monotonically as λ grows and ρ decreases indicates that the optimal trade-off between the performance of the individual

system and the value of ρ probably occurs at a negative value of ρ. Since we are using $\lambda\sigma_{SB}^2$ as our regularization term, σ_{SB} and, with it, ρ are forced toward zero and negative values will be unlikely to occur in our setup. Using a linear term $\lambda\rho$ in the objective function would allow ρ to become negative, perhaps leading to better combination results. Solving this optimization problem, though, requires the use of general-purpose convex optimization software, which would be too slow for our purposes, or the development of a solver specifically designed for it. This is a direction we plan to explore.

We note that the anticorrelation technique is general in that it can be applied to any binary classification task for which more than one system can be trained and at least one of them is an SVM. Many modern machine learning problems have these characteristics, among them microarray gene expression classification problems (Brown et al., 2000), biometric tasks (Roy and Bhattacharya, 2005; Heisele et al., 2003), and a variety of other classification tasks (Sebastiani, 2002). The proposed method has the potential to lead to significant gains on some of those tasks and many others depending on the nature of the features used, their dimension, the number of samples available for training, the absolute performance of the systems, and so on. Finally, since the implementation of the proposed method simply reduces to the use of a specific kernel function, any statistical procedure that can be kernelized (of which SVMs are simply one example) could potentially benefit from it.

Acknowledgments

We thank Robert M. Gray and Robert Tibshirani for helpful comments and discussions. We also thank our colleagues at SRI's Speech Technology and Research Laboratory. In particular, we thank Sachin Kajarekar, Andreas Stolcke, and Nicolas Scheffer for providing some of the features and systems used in these experiments. We are also grateful to the anonymous reviewers who provided valuable feedback that greatly improved the paper. Appendix A. Proof of Upper Bound on EER (Equation 4)

We wish to prove that if a set of scores F is distributed such that $F \mid Y = y \sim \mathcal{N}(\mu_y, \sigma_y^2)$, for $y = a, b$ (that is, the class-conditional distributions are Gaussian), the EER obtained when the class is estimated as in (1) is upper bounded by $\phi(-\frac{1}{2}\frac{\delta\mu}{\sigma})$, where $\delta\mu = \mu_b - \mu_a$, and σ satisfies $\sigma \geq (\sigma_a + \sigma_b)/2$.

For the case in which $\sigma_a = \sigma_b = \sigma$, the threshold t^* corresponding to EER is given by $t_s^* = (\mu_a + \mu_b)/2$ (s here stands for *same* variance) since this is the value that results in the rate of false acceptances ($e_{b|a}$) being equal to the rate of false rejections ($e_{a|b}$). Replacing this threshold in (2) or (3), we get that $\mathrm{EER}_s = \phi(-\frac{1}{2}\frac{\delta\mu}{\sigma})$. The upper plot in Figure 8 illustrates this case.

When variances are not equal, the EER threshold is no longer at half the distance between the two means. Nevertheless, we can find the approximate location of the threshold by mapping the value of t_s^* to two new locations, t_{db} and t_{da} (d stands for *different* variance) such that in one case the rate of false rejections is equal to EER_s and in the other case the rate of false acceptances is equal to EER_s. The EER threshold for the unequal variance case, t_d^*, will then be somewhere between these two points, since being to the left or to the right of both of them would result in the rates of false rejections and false acceptances being different from each other.

The values t_{da} and t_{db} are determined such that $e_{b|a}(t_{da}) = \text{EER}_s$ and $e_{a|b}(t_{db}) = \text{EER}_s$, respectively (with $e_{a|b}$ and $e_{b|a}$ defined in (2) and (3)), and they are given by

$$\begin{aligned} t_{db} &= \sigma_b/\sigma(t_s^* - \mu_b) + \mu_b \\ t_{da} &= \sigma_a/\sigma(t_s^* - \mu_a) + \mu_a. \end{aligned}$$

If $t_{da} \leq t_{db}$ then there will be a threshold t_d^* between t_{da} and t_{db} for which $e_{a|b}(t_d^*) = e_{b|a}(t_d^*) = \text{EER}_d \leq \text{EER}_s$. This is the case illustrated in Figure 8. So, if we can find some σ such that $t_{da} \leq t_{db}$, we can replace this value in $\text{EER}_s = \phi(-\frac{1}{2}\frac{\delta\mu}{\sigma})$ to get the desired upper bound. Now,

$$t_{da} - t_{db} = \frac{\sigma_a}{\sigma}(t_s^* - \mu_a) + \mu_a - \frac{\sigma_b}{\sigma}(t_s^* - \mu_b) - \mu_b = \delta\mu\left(\frac{\sigma_b + \sigma_a}{2\sigma} - 1\right).$$

Since we are assuming that $\delta\mu > 0$, we see that $t_{da} \leq t_{db}$ if and only if $\sigma \geq (\sigma_a + \sigma_b)/2$. When $\sigma = (\sigma_a + \sigma_b)/2$ we get $t_{da} = t_{db}$, which implies that $\text{EER}_d = \text{EER}_s$. Hence, we can always compute EER_d as $\phi(-\frac{\delta\mu}{\sigma_a+\sigma_b})$. It is easy to prove that $\sigma = \sqrt{(\sigma_a^2 + \sigma_b^2)/2}$ (the square root of the average variance instead of the average of the standard deviations) also satisfies $\sigma \geq (\sigma_a + \sigma_b)/2$.

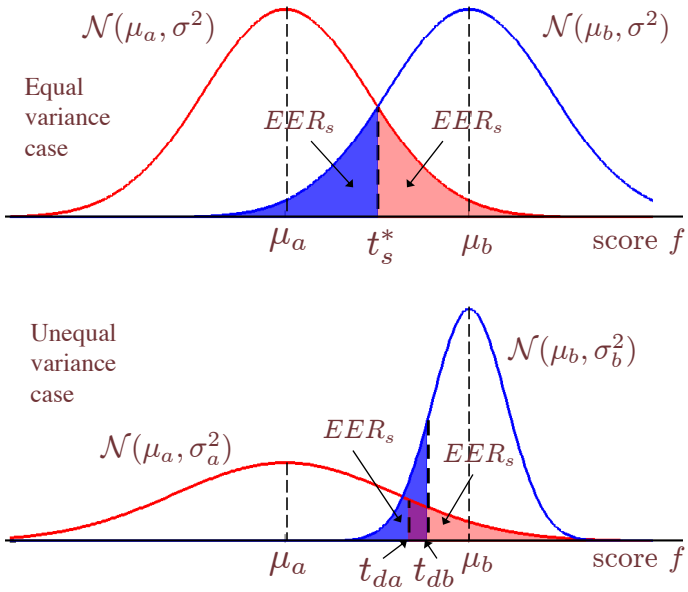

Figure 8: Proof of (4). The upper figure illustrates the computation of EER_s, the EER for the equal variance case. In the lower figure, the unequal variance case is considered. The x-axis values t_{da} and t_{db} are computed such that the area of the two shaded regions coincides with the area of the respective shaded regions in the upper plot. All four shaded areas are then equal to EER_s. The figure illustrates the case in which $t_{da} \leq t_{db}$. In this case, there will be a threshold t_d^* somewhere between t_{da} and t_{db} which corresponds to EER_d, the EER for the unequal variance distributions. From this, we conclude that, if $t_{da} \leq t_{db}$, then $\text{EER}_d \leq \text{EER}_s$.

Editor: Bernhard Schölkopf

Abstract

We introduce a new technique for the analysis of kernel-based regression problems. The basic tools are sampling inequalities which apply to all machine learning problems involving penalty terms induced by kernels related to Sobolev spaces. They lead to explicit deterministic results concerning the worst case behaviour of ε- and ν-SVRs. Using these, we show how to adjust regularization parameters to get best possible approximation orders for regression. The results are illustrated by some numerical examples.

Keywords: sampling inequality, radial basis functions, approximation theory, reproducing kernel Hilbert space, Sobolev space

1. Introduction

Support Vector (SV) machines and related kernel-based algorithms are modern learning systems motivated by results of statistical learning theory as introduced by Vapnik (1995). The concept of SV machines is to provide a prediction function which is accurate on the given training data and which is sparse in the sense that it can be written in terms of a typically small subset of all samples, called the support vectors, as stated by Schölkopf et al. (1995). Therefore, SV regression and classification algorithms are closely related to regularized problems from classical approximation theory as pointed out by Girosi (1998) and Evgeniou et al. (2000) who had applied techniques from functional analysis to derive probabilistic error bounds for SV regression.
This paper provides a theoretical framework to derive deterministic error bounds for some popular SV machines. We show how a sampling inequality by Wendland and Rieger (2005) can be used to bound the worst-case generalization error for the ν- and the ε-regression without making any statistical assumptions on the inaccuracy of the training data. In contrast to the literature, our error bounds explicitly depend on the pointwise noise in the data. Thus they can be used for any subsequent probabilistic analysis modelling certain assumptions on the noise distribution.
The paper is organized as follows. In the next section we recall some basic facts about reproducing kernels in Hilbert spaces. Section 3 deals with regularized approximation problems in Hilbert spaces with reproducing kernels and outlines the connection to classical SV regression (SVR) al-

gorithms. We provide a deterministic error analysis for the ν- and the ε-SVR for both exact and inexact training data. Our analytical results showing optimal convergence orders in Sobolev spaces are illustrated by numerical experiments.

2. Reproducing Kernels in Hilbert Spaces

We suppose that K is a positive definite kernel on some domain $\Omega \subset \mathbb{R}^d$ which should contain at least one point. To start with, we briefly recall the well known definition of a reproducing kernel in a Hilbert space. In the following we shall use the notation that bold letters denote vectors, that is $\mathbf{v} = (v_1, \ldots, v_d)^T \in \mathbb{R}^d$.

Definition 1 *Let $\mathcal{H}(\Omega)$ be a Hilbert space of functions $f : \Omega \to \mathbb{R}$. A function $K : \Omega \times \Omega \to \mathbb{R}$ is called reproducing kernel of $\mathcal{H}(\Omega)$, if*

- *$K(\mathbf{y}, \cdot) \in \mathcal{H}(\Omega)$ for all $\mathbf{y} \in \Omega$ and*
- *$f(\mathbf{y}) = (f, K(\mathbf{y}, \cdot))_{\mathcal{H}(\Omega)}$ for all $f \in \mathcal{H}(\Omega)$ and all $\mathbf{y} \in \Omega$.*

For each positive definite kernel $K : \Omega \times \Omega \to \mathbb{R}$ there exists a unique Hilbert space $\mathcal{N}_K(\Omega)$ of functions $f : \Omega \to \mathbb{R}$, such that K is the reproducing kernel of $\mathcal{N}_K(\Omega)$ (see Wendland, 2005, Theorems 10.1 and 10.11). This Hilbert space $\mathcal{N}_K(\Omega)$ is called the *native space of K*. Though this definition of a native space is rather abstract, it can be shown that in some cases the native spaces coincide with classical function spaces.
From now on we shall only consider *radial* kernels K, that is,

$$K(\mathbf{x}, \mathbf{y}) = K(\|\mathbf{x} - \mathbf{y}\|) \text{ for all } \mathbf{x}, \mathbf{y} \in \mathbb{R}^d ,$$

where we use the same notation for the kernel $K : \mathbb{R}^d \times \mathbb{R}^d \to \mathbb{R}$ and for the function $K : \mathbb{R}^d \to \mathbb{R}$. We hope that this does not cause any confusion. We shall mainly focus on continuous kernels $K \in L_1(\Omega)$, that is,

$$\|K\|_{L_1(\Omega)} := \int_\Omega |K(\mathbf{x})| \, d\mathbf{x} < \infty .$$

For $K \in L_1(\mathbb{R}^d)$, we define the Fourier transform $\hat{K}$ by

$$\hat{K}(\omega) := (2\pi)^{-\frac{d}{2}} \int_{\mathbb{R}^d} K(\mathbf{x}) \, e^{-i\mathbf{x}\cdot\omega} d\mathbf{x} , \ \omega \in \mathbb{R}^d .$$

For the case $\Omega = \mathbb{R}^d$ there is the following characterization of native spaces of certain radial kernels $K : \Omega \to \mathbb{R}^d$ (Wendland, 2005, Theorem 10.12).

Theorem 2 *Suppose that $K \in C(\mathbb{R}^d) \cap L_1(\mathbb{R}^d)$ is a real-valued and positive definite radial kernel. Then the native space of K is given by*

$$\begin{aligned} \mathcal{N}_K(\mathbb{R}^d) &= \left\{ f \in L_2(\mathbb{R}^d) \cap C(\mathbb{R}^d) \ : \ \frac{\hat{f}}{\sqrt{\hat{K}}} \in L_2(\mathbb{R}^d) \right\} , \\ (f, g)_{\mathcal{N}_K(\mathbb{R}^d)} &= (2\pi)^{-d/2} \left(\frac{\hat{f}}{\sqrt{\hat{K}}}, \frac{\hat{g}}{\sqrt{\hat{K}}} \right)_{L_2(\mathbb{R}^d)} , \end{aligned}$$

where $\hat{f}$ denotes the Fourier transform of f.

We recall that the Sobolev spaces $W_2^s(\mathbb{R}^d)$ on $\mathbb{R}^d$ with $s \geq 0$ are given by

$$W_2^s(\mathbb{R}^d) := \left\{ f \in L_2(\mathbb{R}^d) \ : \ \hat{f}(\cdot)(1+\|\cdot\|_2^2)^{s/2} \in L_2(\mathbb{R}^d) \right\} . \tag{1}$$

Therefore for a radial kernel function K whose Fourier transform decays like

$$c_1(1+\|\cdot\|_2^2)^s \leq \hat{K} \leq c_2(1+\|\cdot\|_2^2)^s \ \ , s > d/2 \tag{2}$$

for some constants $c_1, c_2 > 0$, the associated native space $\mathcal{N}_K(\mathbb{R}^d)$ is $W_2^s(\mathbb{R}^d)$ with an equivalent norm. There are several examples of kernels satisfying the condition (2). One famous example for fixed $s \in (d/2, \infty)$ is the *Matern kernel* (Wendland, 2005)

$$K_s(\mathbf{x}) := \frac{2^{1-s}}{\Gamma(s)} \|\mathbf{x}\|_2^{s-d/2} \, \mathcal{K}_{d/2-s}(\|\mathbf{x}\|_2) ,$$

where $\mathcal{K}$ denotes the Bessel function of the third kind. In our examples, however, we focus on *Wendland's functions* (Wendland, 2005). They are very convenient to implement since they are compactly supported and piecewise polynomials. Such nice reproducing kernels are so far only available for certain choices of the space dimension d and the decay parameter s (see Wendland, 2005), but a recent result by Schaback (2009) covers almost all cases of practical interest. We shall explain some more properties of these kernels in the experimental part, see Section 10, and refer to the recent monograph by Wendland (2005) for details.
In order to establish the equivalence of native spaces and Sobolev spaces on bounded domains one needs certain extension theorems for Sobolev functions on bounded domains (see Wendland, 2005).

Definition 3 *Let $\Omega \subset \mathbb{R}^d$ be a domain. We define the Sobolev spaces of integer orders $k \in \mathbb{N}$ as*

$$W_2^k(\Omega) = \{ f \in L_2(\Omega) \ : \ f \text{ has weak derivatives } D^\alpha f \in L_2(\Omega) \text{ of order } |\alpha| \leq k \}$$

with the norm

$$\|u\|_{W_2^k(\Omega)} := \left(\sum_{|\alpha| \leq k} \|D^\alpha u\|_{L_2(\Omega)}^2 \right)^{1/2} .$$

For fractional smoothness $s = k + \sigma$ with $0 < \sigma < 1$ and $k \in \mathbb{N}$ we define the semi-norm

$$|u|_{W_2^s(\Omega)} := \left(\sum_{|\alpha|=k} \int_\Omega \int_\Omega \frac{|D^\alpha u(\mathbf{x}) - D^\alpha u(\mathbf{y})|^2}{\|\mathbf{x}-\mathbf{y}\|_2^{d+2\sigma}} d\mathbf{x} d\mathbf{y} \right)^{1/2} ,$$

and set

$$W_2^s(\Omega) := \left\{ u \in L_2(\Omega) \ : \ \left(\|u\|_{W_2^k(\Omega)}^2 + |u|_{W_2^s(\Omega)}^2 \right)^{1/2} < \infty \right\} .$$

In the case $\Omega = \mathbb{R}^d$ this space is known to be equivalent to the space given by (1) in terms of Fourier transforms (for more details on these spaces, see Wloka, 1982). Finally, Wendland (2005) proves the following equivalence for domains having Lipschitz boundaries. Roughly speaking, a set $\Omega \subset \mathbb{R}^d$ has a Lipschitz boundary if its boundary is locally (in a suitable direction) the graph of a Lipschitz function such that Ω lies completely on one hand-side of this graph (see Brenner and Scott, 1994). Then there is the following theorem (see Wendland, 2005, Cor. 10.48).

Theorem 4 *Suppose that $K \in L_1(\mathbb{R}^d)$ has a Fourier transform that decays as $(1+\|\cdot\|_2^2)^{-s}$ for $s > d/2$. Suppose that Ω has a Lipschitz boundary. Then*

$$\mathcal{N}_K(\Omega) \cong W_2^s(\Omega)$$

with equivalent norms.

3. Regularized Problems in Native Hilbert Spaces

In the native Hilbert spaces we consider the following learning or recovery problem. We assume that we are given (possibly only approximate) function values $y_1,\dots,y_N \in \mathbb{R}$ of an unknown function $f \in \mathcal{N}_K(\Omega)$ on some scattered points $X := \{\mathbf{x}^{(1)},\dots,\mathbf{x}^{(N)}\} \subset \Omega$, that is $f(\mathbf{x}^{(j)}) \approx y_j$ for $j = 1,\dots,N$. In the following we shall use the notation that bold letters denote vectors, that is $\mathbf{v} = (v_1,\dots,v_d)^T \in \mathbb{R}^d$.

To control accuracy and complexity of the reconstruction simultaneously, we use the optimization problem

$$\min_{\substack{s\in\mathcal{N}_K(\Omega)\\ \varepsilon\in\mathbb{R}^+}} \frac{1}{N}\sum_{j=1}^{N} V_\varepsilon\left(\left|s\left(\mathbf{x}^{(j)}\right) - y_j\right|\right) + \frac{1}{2C}\|s\|^2_{\mathcal{N}_K(\Omega)}\ , \tag{3}$$

where $C > 0$ is a positive parameter and V_ε denotes a positive function which may be parametrized by a positive real number ε. We point out that V_ε need not be a classical loss function. Therefore we shall give some proofs of results which were formulated by Schölkopf and Smola (2002) in the case of V_ε being a loss function.

Theorem 5 (Representer theorem) *If $(s_{X,\mathbf{y}}, \varepsilon^*)$ is a solution of the optimization problem (3), then there exists a vector $\mathbf{w} \in \mathbb{R}^N$ such that*

$$s_{X,\mathbf{y}}(\cdot) = \sum_{j=1}^{N} w_j K\left(\mathbf{x}^{(j)},\cdot\right)\ ,$$

that is $s_{X,\mathbf{y}} \in span\left\{K\left(\mathbf{x}^{(1)},\cdot\right),\dots,K\left(\mathbf{x}^{(N)},\cdot\right)\right\}$.

Proof For the readers' convenience, we repeat the proof from Schölkopf and Smola (2002) in our specific situation. Every $s \in \mathcal{N}_K(\Omega)$ can be decomposed into two parts $s = s_{||} + s_\perp$, where $s_{||}$ is contained in the linear span of $\left\{K\left(\mathbf{x}^{(1)},\cdot\right),\dots,K\left(\mathbf{x}^{(N)},\cdot\right)\right\}$, and $s_\perp$ is contained in the orthogonal complement, that is $\left\langle s_{||}, s_\perp\right\rangle_{\mathcal{N}_K(\Omega)} = 0$. By the reproducing property of the kernel K in the native space, the problem (3) can be rewritten as

$$\min_{\substack{s=s_{||}+s_\perp\\ \varepsilon\in\mathbb{R}^+}} \frac{1}{N}\sum_{j=1}^{N} V_\varepsilon\left(\left|\left\langle s_{||}, K\left(\mathbf{x}^{(j)},\cdot\right)\right\rangle - y_j\right|\right) + \frac{1}{2C}\left\|s_{||}\right\|^2_{\mathcal{N}_K(\Omega)} + \frac{1}{2C}\|s_\perp\|^2_{\mathcal{N}_K(\Omega)}\ .$$

Therefore a solution $(s_{X,\mathbf{y}}, \varepsilon^*)$ of the optimization problem (3) satisfies $(s_{X,\mathbf{y}})_\perp = 0$, which implies $s_{X,\mathbf{y}} \in \operatorname{span}\left\{K\left(\mathbf{x}^{(1)},\cdot\right),\dots,K\left(\mathbf{x}^{(N)},\cdot\right)\right\}$. ■

Since the proof of Theorem 5 does not depend on the minimality with respect to ε this result holds also true if ε is a fixed parameter instead of a primal variable. To be precise we state this result as a corollary.

Corollary 6 *If $s_{X,\mathbf{y}}$ is a solution of the optimization problem*

$$\min_{s\in\mathcal{N}_K(\Omega)} \frac{1}{N}\sum_{j=1}^{N} V_\varepsilon\left(\left|s\left(\mathbf{x}^{(j)}\right)-y_j\right|\right)+\frac{1}{2C}\|s\|^2_{\mathcal{N}_K(\Omega)}\ , \tag{4}$$

with $\varepsilon\in\mathbb{R}^+$ being a fixed parameter, then $s_{X,\mathbf{y}}\in span\left\{K\left(\mathbf{x}^{(1)},\cdot\right),\ldots,K\left(\mathbf{x}^{(N)},\cdot\right)\right\}$.

The representer theorems can be used to reformulate infinite-dimensional optimization problems of the forms (3) or (4) in a finite-dimensional setting (see Schölkopf and Smola, 2002).

4. Support Vector Regression

As a first optimization problem of the form (3) we consider the ν-SVR which was introduced by Schölkopf et al. (2000). The function $V_\varepsilon(\mathbf{x})=|\mathbf{x}|_\varepsilon+\varepsilon\nu$ is related to Vapnik's ε-intensive loss function (Vapnik, 1995)

$$|\mathbf{x}|_\varepsilon=\begin{cases}0 & if\ |\mathbf{x}|\le\varepsilon\\ |\mathbf{x}|-\varepsilon & if\ |\mathbf{x}|>\varepsilon\end{cases}\ ,$$

but has an additional term with a positive parameter ν. The associated optimization problem is called ν-SVR and takes the form

$$\min_{\substack{s\in\mathcal{N}_K(\Omega)\\ \varepsilon\in\mathbb{R}^+}} \frac{1}{N}\sum_{j=1}^{N}\left|s\left(\mathbf{x}^{(j)}\right)-y_j\right|_\varepsilon+\varepsilon\nu+\frac{1}{2C}\|s\|^2_{\mathcal{N}_K(\Omega)}\ . \tag{5}$$

Theorem 7 *The optimization problem (5) possesses a solution $\left(s^{(\nu)}_{X,\mathbf{y}},\varepsilon^*\right)$.*

Proof This follows from a general result by Micchelli and Pontil (2005). The problem (5) is equivalent to the optimization problem

$$\min_{\substack{s\in\mathcal{N}_K(\Omega)\\ \delta\in\mathbb{R}}} \frac{1}{N}\sum_{j=1}^{N}\left|s\left(\mathbf{x}^{(j)}\right)-y_j\right|_{\delta^2}+\delta^2\nu+\frac{1}{2C}\|s\|^2_{\mathcal{N}_K(\Omega)}\ . \tag{6}$$

If we set $\mathcal{H}:=\mathcal{N}_K(\Omega)\times\mathbb{R}$ we can define an inner product on $\mathcal{H}$ by

$$\langle h_1,h_2\rangle_{\mathcal{H}}:=\langle f_1,f_2\rangle_{\mathcal{N}_K(\Omega)}+2C\nu\langle r_1,r_2\rangle_{\mathbb{R}}$$

for $h_j=(f_j,r_j)$, $j=1,2$. To make $\mathcal{H}$ a space of functions we use the canonical identification of $\mathbb{R}$ with the space of constant functions $\mathbb{R}\to\mathbb{R}$. The Hilbert space $\mathcal{H}$ then has the reproducing kernel $\tilde{K}:=\left(K,\frac{1}{2C\nu}\mathbf{1}\right)$ where $\mathbf{1}$ denotes the constant function which maps everything to 1, that is $\tilde{K}((\mathbf{x},r),(\mathbf{y},s))=K(\mathbf{x},\mathbf{y})+1/(2C\nu)$ for all $r,s\in\mathbb{R}$. With this notation the problem (6) can be rewritten as

$$\min_{(s,\delta)\in\mathcal{H}} Q^{\mathbf{y}}\left(I_X(s,\delta)\right)+\frac{1}{2C}\|(s,\delta)\|^2_{\mathcal{H}}\ , \tag{7}$$

where

$$I_X(s,\delta):=\left(s(\mathbf{x}^{(1)}),\ldots,s(\mathbf{x}^{(N)}),\delta\right)^T\in\mathbb{R}^{N+1}$$

and

$$Q^{\mathbf{y}} : \mathbb{R}^{N+1} \to \mathbb{R}, \quad Q^{\mathbf{y}}(\mathbf{p}, \delta) = \frac{1}{N} \sum_{j=1}^{N} \left| p_j - y_j \right|_{\delta^2} .$$

Since $Q^{\mathbf{y}}$ is continuous on $\mathbb{R}^{N+1}$ for all $\mathbf{y} \in \mathbb{R}^N$, the problem (7) possesses a solution as shown by Micchelli and Pontil (2005). ■

If we introduce the slack variables $\xi, \xi^* \in \mathbb{R}^N$, the representer theorem gives us an equivalent finite-dimensional problem which was considered by Schölkopf et al. (2000).

$$\min_{\substack{\mathbf{w} \in \mathbb{R}^{\mathbf{N}} \\ \xi^*, \xi \in \mathbb{R}^N \\ \varepsilon \in \mathbb{R}^+}} \frac{1}{2} \mathbf{w}^T \mathbf{K} \mathbf{w} + C \left(\nu\varepsilon + \frac{1}{N} \sum_{j=1}^{N} \left(\xi_j + \xi_j^* \right) \right)$$

$$\begin{aligned} \text{subject to} \quad (\mathbf{K}\mathbf{w})_j - y_j &\leq \varepsilon + \xi_j , \\ (-\mathbf{K}\mathbf{w})_j + y_j &\leq \varepsilon + \xi_j^* , \\ \xi_j^*, \xi_j \geq 0 , \qquad \varepsilon &\geq 0 \quad \text{for } 1 \leq j \leq N , \end{aligned} \tag{8}$$

where

$$\mathbf{K} = \left(K\left(\mathbf{x}^{(i)}, \mathbf{x}^{(j)} \right) \right)_{i,j=1\ldots N}$$

denotes the Gram matrix of the kernel K. We will use this equivalent problem for implementation and our numerical tests.

A particularly interesting problem arises if we skip the parameter ν and let ε be fixed. Then the optimization problem (8) takes the form

$$\min_{\substack{\mathbf{w} \in \mathbb{R}^{\mathbf{N}} \\ \xi^*, \xi \in \mathbb{R}^N}} \frac{1}{2} \mathbf{w}^T \mathbf{K} \mathbf{w} + C \frac{1}{N} \sum_{j=1}^{N} \left(\xi_j + \xi_j^* \right)$$

$$\begin{aligned} \text{subject to} \quad (\mathbf{K}\mathbf{w})_j - y_j &\leq \varepsilon + \xi_j , \\ (-\mathbf{K}\mathbf{w})_j + y_j &\leq \varepsilon + \xi_j^* , \\ \xi_j^*, \xi_j &\geq 0 \quad \text{for } 1 \leq j \leq N . \end{aligned} \tag{9}$$

Schölkopf et al. (2000) called this problem ε-SVR. Similarly to the ν-SVR, the problem (9) can be formulated as a regularized minimization problem in a Hilbert space (Evgeniou et al., 2000), namely

$$\min_{s \in \mathcal{N}_K(\Omega)} \frac{1}{N} \sum_{j=1}^{N} \left| s\left(\mathbf{x}^{(j)} \right) - y_j \right|_{\varepsilon} + \frac{1}{2C} \left\| s \right\|_{\mathcal{N}_K(\Omega)}^2 . \tag{10}$$

Like the ν-SVR, this optimization problem possesses a solution (see Micchelli and Pontil, 2005, Lemma 1).

5. A Sampling Inequality

We shall employ a special case of a *sampling inequality* introduced by Wendland and Rieger (2005). It requires the following assumptions which we need from now on. Let $\Omega \subset \mathbb{R}^d$ be a bounded

domain with Lipschitz boundary that satisfies an interior cone condition. A domain Ω is said to satisfy an interior cone condition with radius $r > 0$ and angle $\theta \in \left(0, \frac{\pi}{2}\right)$ if for every $\mathbf{x} \in \Omega$ there is a unit vector $\xi(\mathbf{x})$ such that the cone

$$C(\mathbf{x}, \xi(\mathbf{x}), \theta, r) := \left\{ \mathbf{x} + \lambda \mathbf{y} \ : \ \mathbf{y} \in \mathbb{R}^d, \|\mathbf{y}\|_2 = 1, \mathbf{y}^T \xi(\mathbf{x}) \geq \cos(\theta), \lambda \in [0, r] \right\}$$

is contained in Ω. In particular, a domain which satisfies an interior cone condition cannot have any outward cusps. We shall assume for the rest of this paper that Ω satisfies an interior cone condition with radius $R_{\max}$ and angle θ. We shall derive estimates that are valid only if the training points are sufficiently dense in Ω. To make this condition precise, we will need a slightly unhandy constant which depends only on the geometry of Ω, namely (see Wendland, 2005)

$$C_\Omega := \frac{\sin\left(2\arcsin\left(\frac{\sin\theta}{4(1+\sin\theta)}\right)\right)\sin\theta}{8\left(1+\sin\left(2\arcsin\left(\frac{\sin\theta}{4(1+\sin\theta)}\right)\right)\right)(1+\sin\theta)} R_{\max} \ .$$

Suppose that K is a radial kernel function such that the native Hilbert space of K is norm-equivalent to a Sobolev space, that is $\mathcal{N}_K(\Omega) = W_2^\tau(\Omega)$. Here we assume that $\lfloor \tau - \frac{1}{2} \rfloor > d/2$, where we use the notation $\lfloor t \rfloor := \max\{n \in \mathbb{N}_0 : n \leq t\}$ for $t \geq 0$. Furthermore, let $X = \left\{\mathbf{x}^{(1)}, \ldots, \mathbf{x}^{(N)}\right\} \subset \Omega$ be a finite set with sufficiently small fill distance

$$h := h_{X,\Omega} := \sup_{\mathbf{x} \in \Omega} \min_{\mathbf{x}^{(j)} \in X} \left\| \mathbf{x} - \mathbf{x}^{(j)} \right\|_2 \ .$$

The fill distance can be interpreted geometrically as the radius of the largest ball with center in $\bar{\Omega}$ that does not contain any of the points $\mathbf{x}^{(1)}, \ldots, \mathbf{x}^{(N)}$. It is a useful quantity for the deterministic error analysis in Sobolev spaces. The case $h = 0$ implies that $X = \left\{\mathbf{x}^{(1)}, \ldots, \mathbf{x}^{(N)}\right\}$ is dense in Ω, and therefore convergence is studied for the limit $h \to 0$ which means that the domain Ω is equally filled with points from X. Let us explain the relation to the usual error bounds in terms of the number of points N. In the case of regularly distributed points we have that $h = cN^{-\frac{1}{d}}$ with some constant $c > 0$ (Wendland, 2005). Therefore the limit $h \to 0$ is equivalent to the limit $N \to \infty$ which is the more intuitive meaning of asymptotic convergence. But there is a drawback, since the error bounds in terms of N depend crucially on the space dimension d, while error bounds in terms of the fill distance h are dominated by the smoothness of the function to be learned. We will comment on this again later for the special error bounds we consider here. We shall use the following result by Wendland and Rieger (2005).

Theorem 8 *Suppose $\Omega \subset \mathbb{R}^d$ is a bounded domain with Lipschitz boundary that satisfies an interior cone condition. Let τ be a positive real number with $\lfloor \tau - \frac{1}{2} \rfloor > \frac{d}{2}$, and let $1 \leq q \leq \infty$. Then there exists a positive constant $C > 0$ such that for all discrete sets $X \subset \Omega$ with sufficiently small fill distance $h := h_{X,\Omega} \leq C_\Omega \tau^{-2}$ the inequality*

$$\|u\|_{L_q(\Omega)} \leq C\left(h^{\tau - d\left(\frac{1}{2} - \frac{1}{q}\right)_+} \|u\|_{W_2^\tau(\Omega)} + \|u|_X\|_{\ell_\infty(X)}\right)$$

holds for all $u \in W_2^\tau(\Omega)$, where we use the notation $(t)_+ := \max\{0, t\}$.

We shall apply this theorem to the residual function $f - s_{X,\mathbf{y}}$ of the function $f \in W_2^\tau(\Omega)$ to be recovered and a solution $s_{X,\mathbf{y}} \in W_2^\tau(\Omega)$ of the regression problem. In our applications we shall focus on the two main cases $q = \infty$ and $q = 2$. Other cases can be treated analogously. It will turn out that we get optimal convergence rates in the noiseless case. In presence of noise the resulting error will explicitly be bounded in terms of the noise in the data.

6. ν-SVR with Exact Data

In order to derive error bounds for the ν-SVR optimization problem (5) we shall apply Theorem 8 to the residual $f - s^{(\nu)}_{X,\mathbf{y}}$, where $\left(s^{(\nu)}_{X,\mathbf{y}}, \varepsilon^*\right)$ denotes a solution to the problem (5) for $X := \left\{\mathbf{x}^{(1)}, \ldots, \mathbf{x}^{(N)}\right\} \subset \Omega$ and $\mathbf{y} \in \mathbb{R}^N$. In this section we consider exact data, that is

$$f\left(\mathbf{x}^{(j)}\right) = y_j \quad \text{for } j = 1, \ldots, N \tag{11}$$

for a function $f \in W_2^\tau(\Omega) \cong \mathcal{N}_K(\Omega)$. As pointed out by Wendland and Rieger (2005) we first need a stability and a consistency estimate for the solution $s^{(\nu)}_{X,\mathbf{y}}$.

Lemma 9 *Under the assumption (11) concerning the data, we find that for every X a solution $\left(s^{(\nu)}_{X,\mathbf{y}}, \varepsilon^*\right)$ to problem (5) satisfies*

$$\begin{aligned} \left\|s^{(\nu)}_{X,\mathbf{y}}\right\|_{\mathcal{N}_K(\Omega)} &\leq \|f\|_{\mathcal{N}_K(\Omega)} \quad \textit{and} \\ \left\|s^{(\nu)}_{X,\mathbf{y}}|_X - \mathbf{y}\right\|_{\ell_\infty(X)} &\leq \frac{N}{2C}\|f\|^2_{\mathcal{N}_K(\Omega)} + \varepsilon^* \cdot (1 - N\nu) \ . \end{aligned}$$

Proof We denote the objective function of the optimization problem (5) by

$$H^{\mathbf{y}}_{C,\nu}(s,\varepsilon) := \frac{1}{N}\sum_{j=1}^{N}\left|s\left(\mathbf{x}^{(j)}\right) - y_j\right|_\varepsilon + \nu\varepsilon + \frac{1}{2C}\|s\|^2_{\mathcal{N}_K(\Omega)} \ , \tag{12}$$

and the interpolant to f with respect to X and K with I_f, that is $I_f|_X = \mathbf{y}$ and $I_f \in \operatorname{span}\left\{K\left(\mathbf{x}^{(1)}, \cdot\right), \ldots, K\left(\mathbf{x}^{(N)}, \cdot\right)\right\}$. With this notation we have

$$\frac{1}{2C}\left\|s^{(\nu)}_{X,\mathbf{y}}\right\|^2_{\mathcal{N}_K(\Omega)} \leq H^{\mathbf{y}}_{C,\nu}\left(s^{(\nu)}_{X,\mathbf{y}}, \varepsilon^*\right) \leq H^{\mathbf{y}}_{C,\nu}(I_f, 0) = \frac{1}{2C}\left\|I_f\right\|^2_{\mathcal{N}_K(\Omega)} \leq \frac{1}{2C}\|f\|^2_{\mathcal{N}_K(\Omega)}$$

since $\left\|I_f\right\|_{\mathcal{N}_K(\Omega)} \leq \|f\|_{\mathcal{N}_K(\Omega)}$ (Wendland, 2005), which implies the first claim.
Furthermore we have for $i = 1, \ldots, N$

$$\begin{aligned} \left|s^{(\nu)}_{X,\mathbf{y}}\left(\mathbf{x}^{(i)}\right) - y_i\right| &\leq \sum_{j=1}^{N}\left|s^{(\nu)}_{X,\mathbf{y}}\left(\mathbf{x}^{(j)}\right) - y_j\right|_{\varepsilon^*} + \varepsilon^* \leq N H^{\mathbf{y}}_{C,\nu}\left(s^{(\nu)}_{X,\mathbf{y}}, \varepsilon^*\right) + \varepsilon^*(1 - N\nu) \\ &\leq N H^{\mathbf{y}}_{C,\nu}(I_f, 0) + \varepsilon^*(1 - N\nu) \leq \frac{N}{2C}\left\|I_f\right\|^2_{\mathcal{N}_K(\Omega)} + \varepsilon^*(1 - N\nu) \\ &\leq \frac{N}{2C}\|f\|^2_{\mathcal{N}_K(\Omega)} + \varepsilon^*(1 - N\nu) \ , \end{aligned}$$

which finishes the proof. ■

With Theorem 8 we find immediately the following result.

Theorem 10 *Suppose $\Omega \subset \mathbb{R}^d$ is a bounded domain with Lipschitz boundary that satisfies an interior cone condition. Let τ be a positive real number with $\lfloor \tau - \frac{1}{2} \rfloor > \frac{d}{2}$ and $1 \leq q \leq \infty$. We suppose*

$f \in W_2^\tau(\Omega)$ with $f(\mathbf{x}^{(i)}) = y_i$. Let $\left(s_{X,\mathbf{y}}^{(\nu)}, \varepsilon^*\right)$ be a solution of the ν-SVR. Then there is a constant $\tilde{C} > 0$, which depends on τ, d and Ω but not on f or X, such that the approximation error can be bounded by

$$\left\| f - s_{X,\mathbf{y}}^{(\nu)} \right\|_{L_q(\Omega)} \leq \tilde{C} \left(2h^{\tau - d\left(\frac{1}{2} - \frac{1}{q}\right)_+} \|f\|_{W_2^\tau(\Omega)} + \frac{N}{2C} \|f\|^2_{W_2^\tau(\Omega)} + (1 - N\nu) \cdot \varepsilon^* \right)$$

for all discrete sets $X \subset \Omega$ with fill distance $h := h_{X,\Omega} \leq C_\Omega \tau^{-2}$.

Proof Combining Lemma 9 and Theorem 8 leads to

$$\begin{aligned}
\left\| f - s_{X,\mathbf{y}}^{(\nu)} \right\|_{L_q(\Omega)} &\leq \tilde{C} \left(h^{\tau - d\left(\frac{1}{2} - \frac{1}{q}\right)_+} \left\| f - s_{X,\mathbf{y}}^{(\nu)} \right\|_{W_2^\tau(\Omega)} + \left\| \mathbf{y} - s_{X,\mathbf{y}}^{(\nu)}|_X \right\|_{\ell_\infty(X)} \right) \\
&\leq \tilde{C} \left(h^{\tau - \left(\frac{d}{2} - \frac{d}{q}\right)_+} \left(\|f\|_{W_2^\tau(\Omega)} + \left\| s_{X,\mathbf{y}}^{(\nu)} \right\|_{W_2^\tau(\Omega)} \right) + \left\| \mathbf{y} - s_{X,\mathbf{y}}^{(\nu)}|_X \right\|_{\ell_\infty(X)} \right) \\
&\leq \tilde{C} \left(2h^{\tau - \left(\frac{d}{2} - \frac{d}{q}\right)_+} \|f\|_{W_2^\tau(\Omega)} + \frac{N}{2C} \|f\|^2_{W_2^\tau(\Omega)} + (1 - N\nu)\, \varepsilon^* \right) .
\end{aligned}$$

■

At first glance the term containing ε^* seems to be odd because it could be uncontrollable. But according to Chang and Lin (2002) we can at least assume ε^* to be bounded by

$$\varepsilon^* \leq \frac{1}{2} \left(\max_{i=1,\ldots,N} y_i - \min_{i=1,\ldots,N} y_i \right) .$$

If this inequality is not satisfied, the problem (8) possesses only the trivial solution $s \equiv 0$ which is not interesting. Furthermore, we see that the ε^*-term occurs with a factor $(1 - N\nu)$, which can be used to control this term. If we choose $\nu \geq \frac{1}{N}$, the term $(1 - N\nu)\,\varepsilon^*$ vanishes or is even negative. The parameter ν is a lower bound on the fraction of support vectors (see Schölkopf et al., 2000), and hence $\nu = 1/N$ means to get at least one support vector, that is a non-trivial solution. Since we are not interested in the case of trivial solutions, the condition $\nu \geq 1/N$ is a reasonable assumption. On the other hand, we can use the results from Lemma 9 to derive a more explicit upper bound on $\varepsilon^* = \varepsilon^*(C, \nu, f)$ by

$$0 \leq \left\| s_{X,\mathbf{y}}^{(\nu)}|_X - \mathbf{y} \right\|_{\ell_\infty(X)} \leq \frac{N}{2C} \|f\|^2_{\mathcal{N}_K(\Omega)} + \varepsilon^* (1 - N\nu) .$$

If we assume $\nu > 1/N$, this leads to

$$\varepsilon^* = \varepsilon^*(C, \nu, f) \leq \frac{N}{2C(N\nu - 1)} \|f\|^2_{\mathcal{N}_K(\Omega)} .$$

Note that these bounds cannot be used for a better parameter choice, since we would need to rearrange this inequality and solve for C or ν. This would only be possible if there were lower bounds on ε^* as well. Moreover, the parameter C appears in our error bound as a factor $\frac{N}{2C}$ which implies that we expect convergence only in the case $C \to \infty$. In this case ε^* will be small, as can be deduced from problem (8).

We shall now make our bounds more explicit for the case of quasi-uniformly distributed points. In this case the number of points N and the fill distance h are related to each other by

$$c_1 N^{-1/d} \leq h \leq c_2 N^{-1/d} \,, \tag{13}$$

where c_1 and c_2 denote positive constants (see Wendland, 2005, Proposition 14.1).

Corollary 11 *In case of quasi-uniform exact data we can choose the problem parameters as*

$$C = \frac{N \|f\|_{W_2^\tau(\Omega)}}{2h^\tau} \approx h^{-(\tau+d)} \|f\|_{W_2^\tau(\Omega)} \text{ and } \nu \geq \frac{1}{N}$$

to get

$$\left\| f - s^{(\nu)}_{X,\mathbf{y}} \right\|_{L_2(\Omega)} \leq \tilde{C} h^\tau \|f\|_{W_2^\tau(\Omega)} \leq \tilde{C} N^{-\frac{\tau}{d}} \|f\|_{W_2^\tau(\Omega)} \,;$$

or as

$$C = \frac{N \|f\|_{W_2^\tau(\Omega)}}{2h^{\tau-\frac{d}{2}}} \approx h^{-\left(\tau+\frac{d}{2}\right)} \|f\|_{W_2^\tau(\Omega)} \text{ and } \nu \geq \frac{1}{N}$$

to get

$$\left\| f - s^{(\nu)}_{X,\mathbf{y}} \right\|_{L_\infty(\Omega)} \leq \tilde{C} h^{\tau-\frac{d}{2}} \|f\|_{W_2^\tau(\Omega)} \leq \tilde{C} N^{-\frac{\tau}{d}+\frac{1}{2}} \|f\|_{W_2^\tau(\Omega)}$$

for all discrete sets $X \subset \Omega$ with fill distance $h := h_{X,\Omega} \leq C_\Omega \tau^{-2}$, with generic positive constants $\tilde{C}$ which depend on τ, d, Ω but not on f or X.

Note that these bounds yield arbitrarily high convergence orders, provided that the functions are smooth enough, that is τ is large enough. Therefore they are in this setting better than the usual minimax rate $N^{-\frac{2\tau}{2\tau+d}}$ (see Stone, 1982). In the following we shall only give our error estimates in terms of the fill distance h rather than in terms of the number of points N. This is due to the fact that the approximation rate τ in h is independent of the space dimension d. However it should be clear how the approximation rates translate into error estimates in terms of N in the case of quasi-uniform data due to the inequality (13). Note that the parameter choice in the case of arbitrary, non-uniformly distributed data can be treated analogously.
Corollary 11 shows, that the solution of the ν-SVR leads to the same approximation orders with respect to the fill distance h as classical kernel-based interpolation (see Wendland, 2005). But the ν-SVR allows for much more flexibility and less complicated solutions. Our numerical results will confirm these convergence rates.

7. ν-SVR with Inexact Data

In this section we denote again by $\left(s^{(\nu)}_{X,\mathbf{y}}, \varepsilon^*\right)$ the solution to the problem (5) for a set of points $X := \left\{\mathbf{x}^{(1)}, \ldots, \mathbf{x}^{(N)}\right\} \subset \Omega$ and $\mathbf{y} \in \mathbb{R}^N$, but we allow the given data to be corrupted by some additive error $\mathbf{r} = (r_1, \ldots, r_N)$, that means

$$f\left(\mathbf{x}^{(j)}\right) = y_j + r_j \quad \text{for } j = 1, \ldots, N, \tag{14}$$

where is $f \in W_2^\tau(\Omega) \cong \mathcal{N}_K(\Omega)$. Note that there are no assumptions concerning the error distribution. As in the previous section we have to show a stability and a consistency estimate of the following form.

Lemma 12 *Under the assumption (14) concerning the data* $\mathbf{y}$*, a solution* $\left(s^{(\nu)}_{X,\mathbf{y}}, \varepsilon^*\right)$ *to the optimization problem (5) satisfies for every* X *and for all* $\varepsilon \geq 0$

$$\begin{aligned}
\left\| s^{(\nu)}_{X,\mathbf{y}} \right\|_{\mathcal{N}_K(\Omega)} &\leq \sqrt{\frac{2C}{N} \sum_{j=1}^{N} \left| r_j \right|_\varepsilon + 2C\nu\varepsilon + \|f\|^2_{\mathcal{N}_K(\Omega)}} \quad \textit{and} \\
\left\| s^{(\nu)}_{X,\mathbf{y}} - \mathbf{y} \right\|_{\ell_\infty(X)} &\leq \sum_{j=1}^{N} \left| r_j \right|_\varepsilon + \nu N\varepsilon + (1 - N\nu)\,\varepsilon^* + \frac{N}{2C} \|f\|^2_{\mathcal{N}_K(\Omega)} .
\end{aligned}$$

Proof Again, we denote the interpolant to f with respect to X and K by I_f and use $H^{\mathbf{y}}_{C,\nu}$ as defined in Equation (12). Then we have for all $\varepsilon > 0$

$$\frac{1}{2C} \left\| s^{(\nu)}_{X,\mathbf{y}} \right\|^2_{\mathcal{N}_K(\Omega)} \leq H^{\mathbf{y}}_{C,\nu}\left(s^{(\nu)}_{X,\mathbf{y}}, \varepsilon^*\right) \leq H^{\mathbf{y}}_{C,\nu}(I_f, \varepsilon) \leq \frac{1}{N} \sum_{j=1}^{N} \left| r_j \right|_\varepsilon + \nu\varepsilon + \frac{1}{2C} \|f\|^2_{\mathcal{N}_K(\Omega)}$$

which implies

$$\left\| s^{(\nu)}_{X,\mathbf{y}} \right\|_{\mathcal{N}_K(\Omega)} \leq \sqrt{\frac{2C}{N} \sum_{j=1}^{N} \left| r_j \right|_\varepsilon + 2C\nu\varepsilon + \|f\|^2_{\mathcal{N}_K(\Omega)}} .$$

Moreover we have for all $i = 1, \ldots, N$ and all $\varepsilon > 0$

$$\begin{aligned}
\left| s^{(\nu)}_{X,\mathbf{y}}\left(\mathbf{x}^{(i)}\right) - y_i \right| &\leq \sum_{j=1}^{N} \left| s^{(\nu)}_{X,\mathbf{y}}\left(\mathbf{x}^{(j)}\right) - y_j \right|_{\varepsilon^*} + \varepsilon^* \\
&\leq N H^{\mathbf{y}}_{C,\nu}\left(s^{(\nu)}_{X,\mathbf{y}}, \varepsilon^*\right) + (1 - N\nu)\,\varepsilon^* \\
&\leq \sum_{j=1}^{N} \left| r_j \right|_\varepsilon + \nu N\varepsilon + (1 - N\nu)\,\varepsilon^* + \frac{N}{2C} \|f\|^2_{\mathcal{N}_K(\Omega)} .
\end{aligned}$$

■

Again we can use the results from Lemma 12 to derive a more explicit upper bound on $\varepsilon^* = \varepsilon^*(C, \nu, f, \varepsilon)$. Note that ε^* depends now also on the free parameter ε.

$$0 \leq \left\| s^{(\nu)}_{X,\mathbf{y}|X} - \mathbf{y} \right\|_{\ell_\infty(X)} \leq \frac{N}{2C} \|f\|^2_{\mathcal{N}_K(\Omega)} + \varepsilon^*(1 - N\nu) + \sum_{j=1}^{N} \left| r_j \right|_\varepsilon + \nu N\varepsilon .$$

If we assume $\nu > 1/N$, this leads to

$$\varepsilon^*(C, \nu, f, \varepsilon) \leq \frac{1}{N\nu - 1} \left(\frac{N}{2C} \|f\|^2_{\mathcal{N}_K(\Omega)} + \sum_{j=1}^{N} \left| r_j \right|_\varepsilon + \nu N\varepsilon \right) .$$

Using the sampling inequality as in the case of exact data leads to the following result on L_q-norms.

Theorem 13 *We suppose $f \in W_2^\tau(\Omega)$ with $f\left(\mathbf{x}^{(i)}\right) = y_i + r_i$. Let $\left(s_{X,\mathbf{y}}^{(\nu)}, \varepsilon^*\right)$ be a solution of the ν-SVR, that is the optimization problem (5). Then there is a constant $\tilde{C} > 0$, which depends on τ, d and Ω but not on f or X, such that for all $\varepsilon > 0$ the approximation error can be bounded by*

$$\left\|f - s_{X,\mathbf{y}}^{(\nu)}\right\|_{L_q(\Omega)} \leq \tilde{C}\left(h^{\tau-\left(\frac{d}{2}-\frac{d}{q}\right)_+}\left(\|f\|_{W_2^\tau(\Omega)} + \sqrt{\frac{2C}{N}\sum_{j=1}^{N}\left|r_j\right|_\varepsilon + 2C\nu\varepsilon + \|f\|_{W_2^\tau(\Omega)}^2}\right)\right.$$
$$\left. + \sum_{j=1}^{N}\left|r_j\right|_\varepsilon + \nu N\varepsilon + \varepsilon^*(1-N\nu) + \frac{N}{2C}\|f\|_{W_2^\tau(\Omega)}^2 + \|\mathbf{r}\|_{\ell_\infty(X)}\right)$$

for all discrete sets $X \subset \Omega$ with fill distance $h := h_{X,\Omega} \leq C_\Omega \tau^{-2}$.

Note that the choice of the "optimal" ε leading to the best bound, depends dramatically on the problem. We now want to assume that the data errors do not exceed the data itself. For this we suppose

$$\|\mathbf{r}\|_{\ell_\infty(X)} \leq \delta \leq \|f\|_{W_2^\tau(\Omega)}$$

for a parameter $\delta > 0$.

Corollary 14 *If we choose the parameters as*

$$C = \frac{N\|f\|_{W_2^\tau(\Omega)}^2}{2\delta},$$
$$\varepsilon = \delta, \quad \textit{and} \quad \nu = \frac{1}{N},$$

we get

$$\left\|f - s_{X,\mathbf{y}}^{(\nu)}\right\|_{L_2(\Omega)} \leq \tilde{C}\left(h^\tau\|f\|_{W_2^\tau(\Omega)} + \delta\right)$$

and

$$\left\|f - s_{X,\mathbf{y}}^{(\nu)}\right\|_{L_\infty(\Omega)} \leq \tilde{C}\left(h^{\tau-d/2}\|f\|_{W_2^\tau(\Omega)} + \delta\right)$$

for all discrete sets $X \subset \Omega$ with fill distance $h := h_{X,\Omega} \leq C_\Omega \tau^{-2}$, with a generic positive constant $\tilde{C}$ which depends on τ, d and Ω but not on f or X.

8. ε-SVR with Exact Data

Since our arguments for the ν-SVR apply similarly to the ε-SVR, we skip over details and just state the results. Note that in this case the non-negative parameter ε is fixed in contrast to the free variable in the ν-SVR. Analogously to the notation introduced in the previous sections, we denote by $s_{X,\mathbf{y}}^{(\varepsilon)}$ the solution to the problem (10) for $X := \left\{\mathbf{x}^{(1)}, \ldots, \mathbf{x}^{(N)}\right\} \subset \Omega$ and $\mathbf{y} \in \mathbb{R}^N$. The stability and consistency estimates take the following form.

Lemma 15 *Under the assumption (11) concerning the data, we find that for every X and every fixed $\varepsilon \in \mathbb{R}^+$ a solution $s_{X,\mathbf{y}}^{(\varepsilon)}$ to problem (10) satisfies*

$$\left\|s_{X,\mathbf{y}}^{(\varepsilon)}\right\|_{\mathcal{N}_K(\Omega)} \leq \|f\|_{\mathcal{N}_K(\Omega)} \quad \textit{and}$$
$$\left\|s_{X,\mathbf{y}}^{(\varepsilon)}|_X - \mathbf{y}\right\|_{\ell_\infty(X)} \leq \frac{N}{2C}\|f\|_{\mathcal{N}_K(\Omega)}^2 + \varepsilon.$$

Again this leads to the following result on continuous L_q-norms.

Theorem 16 *We suppose $f \in W_2^\tau(\Omega)$ with $f\left(\mathbf{x}^{(i)}\right) = y_i$. Let $s_{X,\mathbf{y}}^{(\varepsilon)}$ be a solution of the ε-SVR, that is the optimization problem (10). Then there is a constant $\tilde{C} > 0$, which depends on τ, d and Ω but not on ε, f or X, such that the approximation error can be bounded by*

$$\left\| f - s_{X,\mathbf{y}}^{(\varepsilon)} \right\|_{L_q(\Omega)} \leq \tilde{C} \left(2h^{\tau - d\left(\frac{1}{2} - \frac{1}{q}\right)_+} \|f\|_{W_2^\tau(\Omega)} + \frac{N}{2C} \|f\|^2_{W_2^\tau(\Omega)} + \varepsilon \right) \tag{15}$$

for all discrete sets $X \subset \Omega$ with fill distance $h := h_{X,\Omega} \leq C_\Omega \tau^{-2}$.

Applying the same arguments as in the ν-SVR case we obtain the following corollary.

Corollary 17 *If we choose*

$$C = \frac{N \|f\|_{W_2^\tau(\Omega)}}{2h^\tau} \quad \text{, respectively } \; C = \frac{N \|f\|_{W_2^\tau(\Omega)}}{2h^{\tau - d/2}}$$

the inequality (15) turns into

$$\left\| f - s_{X,\mathbf{y}}^{(\varepsilon)} \right\|_{L_2(\Omega)} \leq \tilde{C} \left(3h^\tau \|f\|_{W_2^\tau(\Omega)} + \varepsilon \right) ,$$

respectively

$$\left\| f - s_{X,\mathbf{y}}^{(\varepsilon)} \right\|_{L_\infty(\Omega)} \leq \tilde{C} \left(3h^{\tau - \frac{d}{2}} \|f\|_{W_2^\tau(\Omega)} + \varepsilon \right)$$

for all discrete sets $X \subset \Omega$ with fill distance $h := h_{X,\Omega} \leq C_\Omega \tau^{-2}$, with a generic positive constant $\tilde{C}$ which depends on τ, d and Ω but not on $f \in W_2^\tau(\Omega)$ or X.

The rôle of the parameter C is similar to the one in case of the ν-SVR. But unlike in the case of the ν-SVR we are free to choose the parameter ε. We see that exact data implies that we should choose $\varepsilon \approx 0$. The case $C \to \infty$ and $\varepsilon \to 0$ leads to exact interpolation, and the well known error bounds for kernel-based interpolation (see Wendland, 2005) are attained.
We point out that the ε-SVR is closely related to the squared ε-loss,

$$\min_{s \in \mathcal{N}_K(\Omega)} \frac{1}{N} \sum_{j=1}^{N} \left| s\left(\mathbf{x}^{(j)}\right) - y_j \right|_\varepsilon^2 + \frac{1}{2C} \|s\|^2_{\mathcal{N}_K(\Omega)} \ . \tag{16}$$

This is important because for $\varepsilon = 0$ we get the square loss. Proceeding along the lines of this section, we find for a solution $s_{X,\mathbf{y}}^{(s\ell\varepsilon)}$ of (16) for exact data the stability bound

$$\left\| s_{X,\mathbf{y}}^{(s\ell\varepsilon)} \right\|_{\mathcal{N}_K(\Omega)} \leq \|f\|_{\mathcal{N}_K(\Omega)}$$

and the consistency estimate

$$\left\| s_{X,\mathbf{y}}^{(s\ell\varepsilon)}|_X - \mathbf{y} \right\|_{\ell_\infty(X)} \leq \sqrt{2} \left(\frac{N}{2C} \|f\|^2_{\mathcal{N}_K(\Omega)} + \varepsilon^2 \right)^{1/2} \leq \frac{\sqrt{N}}{\sqrt{C}} \|f\|_{\mathcal{N}_K(\Omega)} + \sqrt{2}\varepsilon \ .$$

Therefore, we obtain similar approximation results for the ε-squared loss as for the ε-SVR by inserting the estimates into the sampling inequalities. Similarly, the results of Section 9 can be adapted to the ε-squared loss. For the special case $\varepsilon = 0$, we obtain the usual least squares, which was analyzed by Wendland and Rieger (2005) in the case of exact data, and by Riplinger (2007) in the case of inexact data.

9. ε-SVR with Inexact Data

In this section we denote again by $s^{(\varepsilon)}_{X,\mathbf{y}}$ the solution to the problem (10) for a set of points $X := \{\mathbf{x}^{(1)},\dots,\mathbf{x}^{(N)}\} \subset \Omega$ and $\mathbf{y} \in \mathbb{R}^N$, but we allow the given data to be corrupted by some additive error according to assumption (14).

Lemma 18 *Under the assumption (14) concerning the data, for every X and every fixed $\varepsilon \in \mathbb{R}^+$ a solution $s^{(\varepsilon)}_{X,\mathbf{y}}$ to problem (10) satisfies*

$$\begin{aligned} \left\| s^{(\varepsilon)}_{X,\mathbf{y}} \right\|_{\mathcal{N}_K(\Omega)} &\leq \sqrt{\|f\|^2_{\mathcal{N}_K(\Omega)} + \frac{2C}{N}\sum_{i=1}^N |r_i|_\varepsilon} \quad \text{and} \\ \left\| s^{(\varepsilon)}_{X,\mathbf{y}}|_X - \mathbf{y} \right\|_{\ell_\infty(X)} &\leq \frac{N}{2C}\|f\|^2_{\mathcal{N}_K(\Omega)} + \sum_{i=1}^N |r_i|_\varepsilon + \varepsilon \,. \end{aligned}$$

These bounds shall now be plugged into the sampling inequality.

Theorem 19 *We suppose $f \in W_2^\tau(\Omega)$ with $f\left(\mathbf{x}^{(i)}\right) = y_i$. Let $s^{(\varepsilon)}_{X,\mathbf{y}}$ be a solution of the ε-SVR, that is the optimization problem (10). Then there is a constant $\tilde{C} > 0$, which depends on τ, d and Ω but not on ε, f or X, such that the approximation error can be bounded by*

$$\begin{aligned} \left\| f - s^{(\varepsilon)}_{X,\mathbf{y}} \right\|_{L_q(\Omega)} \leq\ & \tilde{C} \left(2h^{\tau - d\left(\frac{1}{2}-\frac{1}{q}\right)_+} \left(\|f\|_{W_2^\tau(\Omega)} + \sqrt{\|f\|^2_{W_2^\tau(\Omega)} + \frac{2C}{N}\sum_{i=1}^N |r_i|_\varepsilon} \right) \right. \\ & \left. + \frac{N}{2C}\|f\|^2_{W_2^\tau(\Omega)} + \sum_{i=1}^N |r_i|_\varepsilon + \varepsilon + \|\mathbf{r}\|_{\ell_\infty(X)} \right) \end{aligned}$$

for all discrete sets $X \subset \Omega$ with fill distance $h := h_{X,\Omega} \leq C_\Omega \tau^{-2}$.

If we again assume that the error level δ does not overrule the native space norm of the generating function,

$$\|\mathbf{r}\|_{\ell_\infty(X)} \leq \delta \leq \|f\|_{W_2^\tau(\Omega)} \,,$$

we get the following convergence orders, for our specific choices of the parameters.

Corollary 20 *Again we assume that the error satisfies (14). If we choose $\varepsilon = \delta$ and $C = \frac{N\|f\|_{W_2^\tau}}{2h^\tau}$ respectively $C = \frac{N\|f\|_{W_2^\tau}}{2h^{\tau-d/2}}$ then we find*

$$\begin{aligned} \left\| f - s^{(\varepsilon)}_{X,\mathbf{y}} \right\|_{L_2(\Omega)} &\leq \tilde{C}\left(h^\tau \|f\|_{W_2^\tau(\Omega)} + \delta \right) \quad \text{and} \\ \left\| f - s^{(\varepsilon)}_{X,\mathbf{y}} \right\|_{L_\infty(\Omega)} &\leq \tilde{C}\left(h^{\tau-d/2} \|f\|_{W_2^\tau(\Omega)} + \delta \right) \end{aligned}$$

for all discrete sets $X \subset \Omega$ with fill distance $h := h_{X,\Omega} \leq C_\Omega \tau^{-2}$, with a generic positive constant $\tilde{C}$ which depends on τ, d, and Ω but not on f or X.

10. Numerical Results

In this section we present some numerical examples to support our analytical results, in particular the rates of convergence in case of exact training data, and the detection of the error levels in case of noisy data.

10.1 Exact Training Data

Figure 1 illustrates the approximation orders in case of exact given data as considered in Sections 6 and 8. For that, we used regular data sets generated by the respective functions to be reconstructed and employed the ε- and the ν-SVR with the parameter choices provided in Corollaries 17 and 11, respectively. We implemented the finite dimensional formulations of the associated optimization problems as described in Equations (9) and (8). As kernel functions we used Wendland's functions for two reasons: On the one hand side they yield rather sparse kernel matrices $\mathbf{K}$ due to their compact support, on the other hand side they are easy to implement since they are piecewise polynomials. Furthermore Wendland's functions may be scaled to improve their numerical behaviour. An unscaled function K has support $\mathrm{supp}(K) \subset B(0,1) \subset \mathbb{R}^d$. The scaling is done in such a way that the decay of the Fourier transform is preserved, that is,

$$K^{(c)}(\mathbf{x}) = c^{-d} K\left(\frac{\mathbf{x}}{c}\right) , \quad \mathbf{x} \in \mathbb{R}^d . \tag{17}$$

By construction we have $supp\left(K^{(c)}\right) \subset B(0,c)$, such that small choices of the scaling parameter c imply rather sparse kernel matrices $\mathbf{K^{(c)}} = \left(K^{(c)}\left(\left\|\mathbf{x}^{(i)} - \mathbf{x}^{(j)}\right\|_2\right)\right)_{i,j=1\ldots N}$. On the other hand side it is known that the constant factor in our error estimates increases with decreasing c. This is a typical trade-off situation between good approximation properties and good condition numbers of the kernel matrices $\mathbf{K^{(c)}}$ (Wendland, 2005). We chose a scaling $c = 0.1$ in all one-dimensional examples and a scaling $c = 2$ in all two-dimensional examples. Since these standard choices already work well, there was no need for a more careful choice. To our knowledge, there are so far no theoretical results on the optimal scaling.

The double logarithmic plots in Figure 1 visualize the convergence orders in terms of the fill distance. For that, the L_∞-approximation error $\|f - s_{X,\mathbf{y}}\|_{L_\infty}$ is plotted versus the fill distance h. The convergence rates can be found as the slopes of the lines.

In subfigure 1(a) the data was generated by

$$f(x) = (x - 0.5)_+^{2.5+eps} \in W_2^3([0,1]) ,$$

where *eps* denotes the relative machine precision in the sense of MATLAB. We use the notation $(t)_+ := \max\{0,t\}$ for all $t \in \mathbb{R}$. This function f is sampled on regular grids in the unit interval $I := [0,1]$ with 30 to 96 points. Note that in this case the fill distance is given by $h \approx 1/N$. We use two different kernel functions, namely (see Wendland, 2005)

- $K_1(x) = (1 - |x|)_+^3 (3|x| + 1)$ with native space $W_2^2([0,1])$, and
- $K_2(x) = (1 - |x|)_+^5 \left(8|x|^2 + 5|x| + 1\right)$ with native space $W_2^3([0,1])$.

The scaling parameter according to Equation (17) is chosen as $c = 0.1$. We employed the ε- and the ν- SVR with the parameter choices provided in Corollaries 17 and 11. The respective corollaries

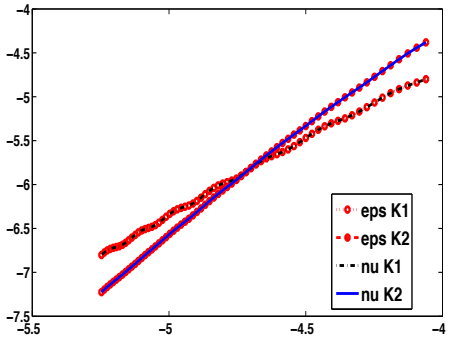
predict convergence rates of 1.5 for K_1, and 2.5 for K_2. In subfigure 1(a) the plots for the ε- and ν-SVR (almost identical) both show orders 1.7 for K_1 and 2.4 for K_2.
Subfigure 1(b) shows a 2-dimensional example. The data is generated by the smooth function

$$f(\mathbf{x}) = \sin(x_1 + x_2) \ .$$

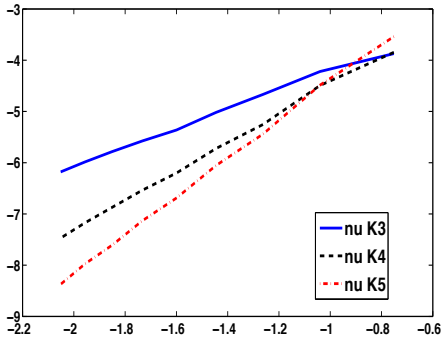
This function f is sampled on regular grids in the unit interval $I := [0,1]^2$ with 16 to 144 points. Note that in this case the fill distance is given by $h \approx \frac{1}{\sqrt{N}}$. We use three different kernel functions, namely (see Wendland, 2005)

- $K_3(\mathbf{x}) = (1 - \|\mathbf{x}\|)_+^4 (4\|\mathbf{x}\| + 1)$ with native space $W_2^{2.5}([0,1]^2)$,
- $K_4(\mathbf{x}) = (1 - \|\mathbf{x}\|)_+^6 \left(35\|\mathbf{x}\|^2 + 18\|\mathbf{x}\| + 3\right)$ with native space $W_2^{3.5}([0,1]^2)$, and
- $K_5(\mathbf{x}) = (1 - \|\mathbf{x}\|)_+^8 \left(32\|\mathbf{x}\|^3 + 25\|\mathbf{x}\|^2 + 8\|\mathbf{x}\| + 1\right)$ with native space $W_2^{4.5}([0,1]^2)$.

The kernel functions were scaled by $c = 2$ according to Equation (17). For the sake of simplicity we employed only the ν-SVR with the parameter choices provided in Corollary 11. The predicted convergence rates in the fill distance h are 1.5 for K_3, 2.5 for K_4 and 3.5 for K_5. The numerical experiments show orders 1.8 for K_3, 2.8 for K_4 and 3.7 for K_5. Therefore, the numerical examples support our analytical results.



(a) Data generated by $f \in W_2^3(I)$ on regular grids in I. ν- and ε-SVR yield orders 1.7 for K_1, and 2.4 for K_2. Scaling parameter $c = 0.1$.



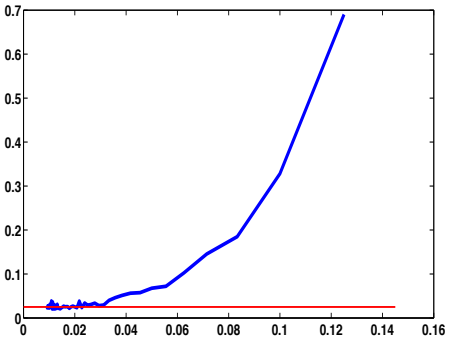
(b) Data generated by smooth function on regular grids in I^2. ν-SVR yields orders 1.8 for K_3, 2.8 for K_4, and 3.7 for K_5. Scaling parameter $c = 2$.

Figure 1: Logarithm of the L_∞-approximation error plotted versus the logarithm of the fill distance h for exact training data.

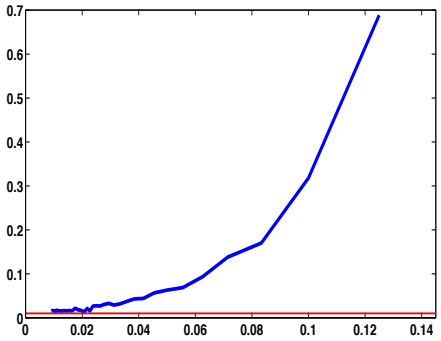
10.2 Inexact Data

Figure 2 shows examples for the case of noisy data. The plots show the L_∞-approximation error $\|f - s_{X,\mathbf{y}}\|_{L_\infty}$ versus the fill distance h. For simplicity we concentrated on the case of the ν-SVR in the one dimensional setting. We used the noise model given by Equation (14), that is $y = f + r$. In Subfigure 2(a) the function $f(x) = \sin(10x)$ is sampled on regular grids of 2 to 56 points in $[0,1]$. The data is disturbed by an error r which is normally distributed with mean zero and standard deviation 0.01. As kernel function we use K_1, and the parameters of the ν-SVR are chosen as in

Corollary 14. The plot shows that for $h \to 0$ the error remains of the same order of magnitude as the error level $\|r\|_{\ell_\infty}$.
In Subfigure 2(b) the function $f(x) = \sin(10x)$ is sampled on regular grids of 5 to 56 points in the unit interval $I = [0,1]$. Here, the data is corrupted by an error of ± 0.01, where the sign of the error is chosen randomly with equal likelihood for plus and minus. As kernel function we use K_1 with $c = 0.3$, and the parameters of the ν-SVR are chosen as in Corollary 14. The plot shows that the L_∞-approximation error converges to a constant of the order of magnitude of the error level for $h \to 0$.



(a) Data disturbed by random error with mean zero and standard deviation 0.01. Approximation error for $h \to 0$ reaches the error level and remains bounded of the same order of magnitude as the error level.



(b) Data disturbed by random sign deterministic error ± 0.01. Approximation error converges to a constant of the order of magnitude of the error level for $h \to 0$.

Figure 2: L_∞-approximation error versus fill distance in case of inexact data.

11. Summary and Outlook

We proved deterministic worst-case error estimates for kernel-based regression algorithms. The main ingredient are sampling inequalities. We provided a detailed analysis only for the ν- and the ε-SVR for both exact and inexact training data. However, the same techniques apply to all machine learning problems involving penalty terms induced by kernels related to Sobolev spaces. If the function to be reconstructed lies in the reproducing kernel Hilbert space (RKHS) of an infinitely smooth kernel such as the Gaussian or an infinite dot product kernel, a similar analysis based on sampling inequalities can be done, leading to exponential convergence rates (see Rieger and Zwicknagl 2008 and Zwicknagl 2009 for first results in this direction).
So far, our error estimates depend explicitly on the pointwise noise in the data, and we do not make any assumptions on the noise distribution. Future work should incorporate probabilistic models on the noise distribution to yield estimates for the expected error.

Abstract

RL-Glue is a standard, language-independent software package for reinforcement-learning experiments. The standardization provided by RL-Glue facilitates code sharing and collaboration. Code sharing reduces the need to re-engineer tasks and experimental apparatus, both common barriers to comparatively evaluating new ideas in the context of the literature. Our software features a minimalist interface and works with several languages and computing platforms. RL-Glue compatibility can be extended to any programming language that supports network socket communication. RL-Glue has been used to teach classes, to run international competitions, and is currently used by several other open-source software and hardware projects.

Keywords: reinforcement learning, empirical evaluation, standardization, open source

1. Introduction and Motivation

Reinforcement learning is an embodied, trial-and-error problem formulation for artificial intelligence (Sutton and Barto, 1998; Kaelbling et al., 1996; Bertsekas and Tsitsiklis, 1996). At a series of time steps, the *agent* emits actions in response to observations and rewards generated by the *environment*. The agent's objective is to select actions that maximize the future rewards. Reinforcement-learning methods have been successfully applied to many problems including backgammon (Tesauro, 1994), elevator control (Crites and Barto, 1998), and helicopter control (Ng et al., 2004). Reinforcement-learning models and formalisms have influenced a number of fields, including operations research, cognitive science, optimal control, psychology, neuroscience, and others.

Reinforcement-learning practitioners create their agents and environments using various incompatible software frameworks, making collaboration inconvenient and thus slowing progress in our community. It can be time consuming, difficult, and sometimes even impossible to exactly reproduce the work of others. A conference or journal article is not the appropriate medium to share a sufficiently detailed specification of the environment, agent and overall experimental apparatus. We need a convenient way to share source code.

We believe that a standard programming interface for reinforcement-learning experiments will remove some barriers to collaboration and accelerate the pace of research in our field. To encourage widespread adoption, this interface should be easy to adhere to, and it should not force users to abandon their favorite tools or languages. With these goals in mind, we have developed RL-Glue: language independent software for reinforcement-learning experiments.

2. RL-Glue

Reinforcement-learning environments cannot be stored as fixed data-sets, as is common in conventional supervised machine learning. The environment generates observations and rewards in response to actions selected by the agent, making it more natural to think of the environment and agent as interactive *programs*. Sutton and Barto describe one prevalent view of agent-environment interactions in their introductory text (1998). Their view, shown in Figure 1, clearly separates the agent and environment into different components which interact in a particular way, following a particular sequence.

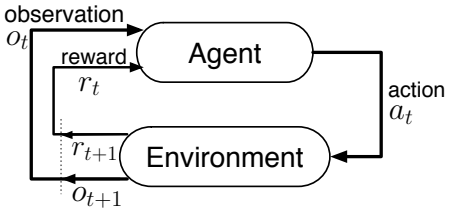

Figure 1: Sutton and Barto's agent-environment interface, with states generalized to observations.

White's RL-Glue Protocol (2006) formalizes Sutton and Barto's interface for online, single-agent reinforcement learning. The RL-Glue Protocol describes how the different aspects of a reinforcement-learning experiment should be arranged into programs, and the etiquette they should follow when communicating with each other. These programs (Figure 2) are the agent, the environment, the experiment, and RL-Glue. The agent program implements the learning algorithm and action-selection mechanism. The environment program implements the dynamics of the task and generates the observations and rewards. The experiment program directs the experiment's execution, including the sequence of agent-environment interactions and agent performance evaluation. The RL-Glue program mediates the communication between the agent and environment programs in response to commands from the experiment program. Our RL-Glue software (RL-Glue) implements White's protocol.[1]

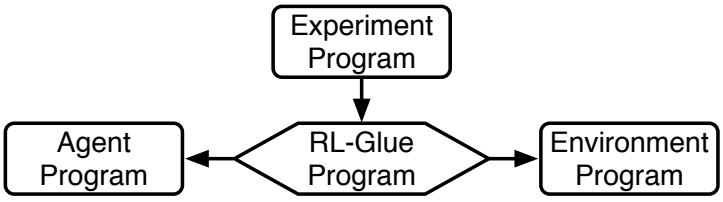

Figure 2: The four programs specified by the RL-Glue Protocol. Arrows indicate the direction of the flow of control.

RL-Glue can be used either in internal or external mode. In *internal* mode, the agent, environment and experiment are linked into a single program, and their communication is through function calls. Internal mode is currently an option if the agent, environment, and experiment are written exclusively in Java or C/C++. In *external* mode, the agent, environment and experiment are linked

1. This can be found at `http://glue.rl-community.org/protocol`.

into separate programs. Each program connects to the RL-Glue server program, and all communication is over TCP/IP socket connections. External mode allows these programs to be written in any programming language that supports socket communication. External mode is currently supported for C/C++, Java, Python, Lisp, and Matlab.

Each mode has its strengths and weaknesses. Internal mode has less overhead, so it can execute more steps per second. External mode is more flexible and portable. The performance difference between the two modes vanishes as the agent or environment becomes complex enough that computation dominates the socket overhead in terms of time per step. The agent and environment are indifferent and unaware of their execution mode; the difference in modes lies only in how the agent and environment are linked or loaded.

3. RL-Glue in Practice

RL-Glue's provides a common interface for a number of software and hardware projects in the reinforcement-learning community. For example, there is the annual RL-Competition, where teams from around the world compare their agents on a variety of challenging environments. The competition software uses the API, called RL-Viz, that is layered on top of RL-Glue to dynamically load agent and environment programs, modify parameters at runtime and visualize interaction and performance. All of the environments and sample agents created by the competition organizers are added to the RL-Library, a public, community-supported repository of RL-Glue compatible code. The RL-Library is also available as an archive of top competition agents, challenge problems, project code from academic publications, or any other RL-Glue compatible software that members of our community would like to share.

The socket architecture of RL-Glue allows diverse software and hardware platforms to be connected as RL-Glue environment programs. There are ongoing projects that connect a mobile robot platform, a keepaway soccer server, a real-time strategy game, and an Atari emulator to RL-Glue. Our socket architecture helps lower the barriers for researchers wishing to work on larger scale environments by providing a simple and familiar interface.

RL-Glue has been used for teaching reinforcement learning in several university courses and to create experiments for scientific articles published in leading conferences. See our *RL-Glue in practice* web page for an updated list of projects and papers that have used RL-Glue.[2]

4. Other Reinforcement-Learning Software Projects

RL-Glue is not the first software project that aims to standardize empirical reinforcement learning or to make agent and environment programs more accessible within our community. However, RL-Glue is the only project that offers a standardized language-independent interface, rich actions and observations, and fine-grained control of the experiment.

Other projects, most notably: CLSquare,[3] PIQLE,[4] RL Toolbox,[5] JRLF,[6] and LibPG,[7] offer significant value to the reinforcement-learning community by offering agents and environments,

intuitive visualizations, programming tools, etc. Users should not be forced to choose between RL-Glue and these alternative projects. Our design makes it relatively easy to interface existing frameworks with RL-Glue. We are currently offering our assistance in bridging other frameworks to RL-Glue, with the hope of improving access to all of these tools for all members of our community.

5. RL-Glue Open Source Project

Website: http://glue.rl-community.org **License:** `Apache 2.0`

RL-Glue is more than an interface; it connects a family of community projects, with many levels of possible participation. Members of the community are invited to submit agent, environment and experiment programs to the RL-Library. Developers can also extend the reach of RL-Glue compatibility by writing external-mode or internal-mode interfaces for their favorite programming language. The RL-Glue software project also welcomes submissions and improvements for all parts of the software and documentation.

Acknowledgments

We would like to thank the users, testers, and developers for their contributions to RL-Glue 3.0. Special thanks to Gábor Balázs, José Antonio Martin H., Scott Livingston, Marc Bellemare, István Szita, Marc Lanctot, Anna Koop, Dan Lizotte, Richard Sutton, Monica Dinculescu, Jordan Frank, and Andrew Butcher. Of course, we also owe a great debt to all of the talented people responsible for the historic and ongoing development of RL-Glue.[8]

Abstract

We address classification problems for which the training instances are governed by an input distribution that is allowed to differ arbitrarily from the test distribution—problems also referred to as classification under covariate shift. We derive a solution that is purely discriminative: neither training nor test distribution are modeled explicitly. The problem of learning under covariate shift can be written as an integrated optimization problem. Instantiating the general optimization problem leads to a kernel logistic regression and an exponential model classifier for covariate shift. The optimization problem is convex under certain conditions; our findings also clarify the relationship to the known kernel mean matching procedure. We report on experiments on problems of spam filtering, text classification, and landmine detection.

Keywords: covariate shift, discriminative learning, transfer learning

1. Introduction

Most machine learning algorithms are constructed under the assumption that the training data is governed by the exact same distribution which the model will later be exposed to. In practice, control over the data generation process is often less perfect. Training data may be obtained under laboratory conditions that cannot be expected after deployment of a system; spam filters may be used by individuals whose distribution of inbound emails diverges from the distribution reflected in public training corpora; image processing systems may be deployed to foreign geographic regions where vegetation and lighting conditions result in a distinct distribution of input patterns.

The case of distinct training and test distributions in a learning problem has been referred to as *covariate shift* and *sample selection bias*—albeit the term sample selection bias actually refers to a case in which each training instance is originally drawn from the test distribution, but is then selected into the training sample with some probability, or discarded otherwise.

The covariate shift model and the *missing at random* case in the sample selection bias model allow for differences between the training and test distribution of instances; the conditional distribution of the class variable given the instance is constant over training and test set.

In the *covariate shift* problem setting, a training sample is available in matrix $\mathbf{X}_L$ with row vectors $\mathbf{x}_1, \ldots, \mathbf{x}_m$. This training sample is governed by an unknown distribution $p(\mathbf{x}|\lambda)$. Vector $\mathbf{y}$ with elements $y_1, \ldots, y_m$ are the labels for training examples and are drawn according to an unknown target concept $p(y|\mathbf{x})$. In addition, unlabeled test data becomes available in matrix $\mathbf{X}_T$ with rows

$\mathbf{x}_{m+1}, \ldots, \mathbf{x}_{m+n}$. The test data is governed by a different unknown distribution, $p(\mathbf{x}|\theta)$. Training and test distribution may differ arbitrarily, but there is only one unknown target conditional class distribution $p(y|\mathbf{x})$.

In discriminative learning tasks such as classification, the classifier's goal is to produce the correct output given the input. It is widely accepted that this is best performed by discriminative learners that directly maximize a quality measure of the produced output. Model-based optimization criteria such as the joint likelihood of input and output, by contrast, additionally assess how well the classifier models the distribution of input values. This amounts to adding a term to the criterion that is irrelevant for the task at hand.

We contribute a discriminative model for learning under different training and test distributions. The model directly characterizes the divergence between training and test distribution, without the intermediate—intrinsically model-based—step of estimating training and test distribution. We formulate the search for all model parameters as an integrated optimization problem. This complements the predominant procedure of first estimating the bias of the training sample, and then learning the classifier on a weighted version of the training sample. We show that the integrated optimization can be convex, depending on the model type; it is convex for the exponential model. We derive a Newton gradient descent procedure, leading to a kernel logistic regression and an exponential model classifier for covariate shift.

After reviewing models for differing training and test distributions in Section 2, we introduce our integrated model in Section 3. We derive primal and kernelized classifiers for differing training and test distributions in Sections 4 and 5. In Section 6, we analyze the convexity of the integrated optimization problem. Section 7 describes an approximation to the joint optimization problem and Section 8 reveals a new interpretation of kernel mean matching and analyzes the relationship to our model. In Section 9 we discuss different tuning procedures for learning under covariate shift. Section 10 provides empirical results and Section 11 concludes.

The discriminative model for the logistic loss is described in a prior conference publication (Bickel et al., 2007). Our original results showed that the resulting optimization problem is not convex. New findings (Section 6) show that the integrated optimization problem can in fact be convex when the loss function is chosen appropriately. Section 7 describes a two-stage approximation that allows to train virtually any type of classifier under covariate shift. The new Section 8 characterizes the relation to kernel mean matching. New experiments include the exponential target model. Section 10 uses an experimental setting that differs from the setting of Bickel et al. (2007) in the parameter tuning process. In some cases, the new setting has improved the performance of baseline methods.

2. Prior Work

If training and test distributions were known, then the loss on the test distribution could be minimized by weighting the loss on the training distribution with an instance-specific factor. Proposition 1 (Shimodaira, 2000) illustrates that the scaling factor has to be $\frac{p(\mathbf{x}|\theta)}{p(\mathbf{x}|\lambda)}$.

Proposition 1 *The expected loss with respect to* θ *equals the expected loss with respect to* λ *with weights* $\frac{p(\mathbf{x}|\theta)}{p(\mathbf{x}|\lambda)}$ *for the loss incurred by each* $\mathbf{x}$*, provided that the support of* $p(\mathbf{x}|\theta)$ *is contained in the*

support of $p(\mathbf{x}|\lambda)$*:*

$$\mathbf{E}_{(\mathbf{x},y)\sim\theta}[\ell(f(\mathbf{x}),y)] \quad = \quad \mathbf{E}_{(\mathbf{x},y)\sim\lambda}\left[\frac{p(\mathbf{x}|\theta)}{p(\mathbf{x}|\lambda)}\ell(f(\mathbf{x}),y)\right]. \tag{1}$$

After expanding the expected value into its integral $\int \ell(f(\mathbf{x}),y)p(\mathbf{x},y|\theta)d\theta$, the joint distribution $p(\mathbf{x},y|\lambda)$ is decomposed into $p(\mathbf{x}|\lambda)p(y|\mathbf{x},\lambda)$. Since $p(y|\mathbf{x},\lambda) = p(y|\mathbf{x}) = p(y|\mathbf{x},\theta)$ is the global conditional distribution of the class variable given the instance, Proposition 1 follows. All instances $\mathbf{x}$ with positive $p(\mathbf{x}|\theta)$ are integrated over. Hence, Equation 1 holds as long as each $\mathbf{x}$ with positive $p(\mathbf{x}|\theta)$ also has a positive $p(\mathbf{x}|\lambda)$; otherwise, the denominator vanishes. This shows that covariate shift can only be compensated for as long as the training distribution covers the entire support of the test distribution. If a test instance had zero density under the training distribution, the test-to-training density ratio which it would need to be scaled with would incur a zero denominator.

Both, $p(\mathbf{x}|\theta)$ and $p(\mathbf{x}|\lambda)$ are unknown, but $p(\mathbf{x}|\theta)$ is reflected in $\mathbf{X}_T$, as is $p(\mathbf{x}|\lambda)$ in $\mathbf{X}_L$. A straightforward approach to compensating for covariate shift is to first obtain estimates $\hat{p}(\mathbf{x}|\theta)$ and $\hat{p}(\mathbf{x}|\lambda)$ from the test and training data, respectively, using kernel density estimation (Shimodaira, 2000; Sugiyama and Müller, 2005). In a second step, the estimated density ratio is used to re-sample the training instances, or to train with weighted examples.

This method decouples the problem. First, it estimates training and test distributions. This step is intrinsically model-based and only loosely related to the ultimate goal of accurate classification. In a subsequent step, the classifier is derived given fixed weights. Since the parameters of the final classifier and the parameters that control the weights are not independent, this decomposition into two optimization steps cannot generally find the optimal setting of the *joint* parameter vector.

A line of work on learning under sample selection bias has meandered from the statistics and econometrics community into machine learning (Heckman, 1979; Zadrozny, 2004). Sample selection bias relies on a model of the data generation process. Test instances are drawn under $p(\mathbf{x}|\theta)$. Training instances are drawn by first sampling $\mathbf{x}$ from the test distribution $p(\mathbf{x}|\theta)$. A selector variable σ then decides whether $\mathbf{x}$ is moved into the training set ($\sigma = 1$) or moved into the rejected set ($\sigma = -1$). For instances in the training set ($\sigma = 1$) a label is drawn from $p(y|\mathbf{x})$, for the instances in the rejected set the labels are unknown. A typical scenario for sample selection bias is credit scoring. The labeled training sample consists of customers who where given a loan in the past and the rejected sample are customers that asked for but where not given a loan. New customers asking for a loan reflect the test distribution.

In the *missing at random* case, the selector variable is only dependent on $\mathbf{x}$, but not on y; that is, $p(\sigma = 1|\mathbf{x},y,\theta,\lambda) = p(\sigma = 1|\mathbf{x},\theta,\lambda)$. The distribution of the selector variable then maps the test onto the training distribution:

$$p(\mathbf{x}|\lambda) \propto p(\mathbf{x}|\theta)p(\sigma = 1|\mathbf{x},\theta,\lambda).$$

Proposition 2 (Zadrozny, 2004; Bickel and Scheffer, 2007) says that minimizing the loss on instances weighted by $p(\sigma|\mathbf{x},\theta,\lambda)^{-1}$ in fact minimizes the expected loss with respect to θ.

Proposition 2 *The expected loss with respect to* θ *is proportional to the expected loss with respect to* λ *with weights* $p(\sigma = 1|\mathbf{x},\theta,\lambda)^{-1}$ *for the loss incurred by each* $\mathbf{x}$*, provided that the support of* $p(\mathbf{x}|\theta)$ *is contained in the support of* $p(\mathbf{x}|\lambda)$*:*

$$\mathbf{E}_{(\mathbf{x},y)\sim\theta}[\ell(f(\mathbf{x}),y)] \quad \propto \quad \mathbf{E}_{(\mathbf{x},y)\sim\lambda}\left[\frac{1}{p(\sigma = 1|\mathbf{x},\theta,\lambda)}\ell(f(\mathbf{x}),y)\right].$$

When the model is implemented, $p(\sigma = 1|\mathbf{x},\theta,\lambda)$ is learned by discriminating the training against the rejected examples; in a second step the target model is learned by following Proposition 2 and weighting training examples by $p(\sigma|\mathbf{x},\theta,\lambda)^{-1}$. No test examples drawn directly from $p(\mathbf{x}|\theta)$ are needed to train the model, only labeled selected and unlabeled rejected examples are required. This is in contrast to the covariate shift model that requires samples drawn from the test distribution, but no selection process is assumed and no rejected examples are needed. Covariate shift models can be applied to learning under sample selection bias in the missing at random setting by treating the selected examples as labeled sample and the union of selected (ignoring the labels) and rejected examples as unlabeled sample.

Propensity scores (Rosenbaum and Rubin, 1983; Lunceford and Davidian, 2004) are applied in settings related to sample selection bias; the training data is again assumed to be drawn from the test distribution $p(\mathbf{x}|\theta)$ followed by a selection process. The difference to the setting of sample selection bias is that the selected *and* the rejected examples are labeled. Weighting the selected examples by the inverse of the propensity score $p(\sigma = 1|\mathbf{x},\lambda,\theta)^{-1}$ and weighting the rejected examples by $p(\sigma = -1|\mathbf{x},\lambda,\theta)^{-1}$ results in two unbiased samples with respect to the test distribution.

Propensity scoring can precede a variety of analysis steps. This can be the training of a target model on re-weighted data or just a statistical analysis of the two re-weighted samples. A typical application for propensity scores is the analysis of the success of a medical treatment. Patients are selected to be given the treatment and some other patients are selected into the control group. If the selector variable is not independent of $\mathbf{x}$ (patients may be chosen for an experimental therapy only if they meet specific requirements), the outcome (e.g., ratio of cured patients) of the two groups cannot be compared directly, propensity scores have to be applied.

Maximum entropy density estimation under sample selection bias has been studied by Dudik et al. (2005). Bickel and Scheffer (2007) impose a Dirichlet process prior on several learning problems with related sample selection bias. Elkan (2001) and Japkowicz and Stephen (2002) investigate the case of training data that is only biased with respect to the class ratio, this can be seen as sample selection bias where the selection only depends on y.

Kernel mean matching (Huang et al., 2007) is a two-step method that first finds weights for the training instances such that the first momentum of training and test sets—that is, their mean value—matches in feature space. The subsequent training step uses these weights. Matching the means in feature space is equivalent to matching all moments of the distributions if a universal kernel is used. Huang et al. (2007) derive a quadratic program from Equation 2 that can be solved with standard optimization tools. $\Phi(\cdot)$ is a mapping into a feature space and B is a regularization parameter.

$$\begin{aligned} &\min_{\boldsymbol{\alpha}} \left\| \tfrac{1}{m}\sum_{i=1}^{m} \alpha_i \Phi(\mathbf{x}_i) - \tfrac{1}{n}\sum_{i=m+1}^{m+n} \Phi(\mathbf{x}_i) \right\|^2 \\ &\text{subject to } \alpha_i \in [0,B] \text{ and } \left| \tfrac{1}{m}\sum_{i=1}^{m} \alpha_i - 1 \right| \leq \varepsilon \end{aligned} \tag{2}$$

Cortes et al. (2008) theoretically analyze the error that gets introduced by estimating sample selection bias from data. Their analysis covers the kernel mean matching procedure and a cluster-based estimation technique.

KLIEP (Sugiyama et al., 2008) estimates resampling weights for the training examples by minimizing the Kullback-Leibler divergence between the test distribution and the weighted training distribution. Tsuboi et al. (2008) derive an extension to KLIEP for large-scale applications and reveal a close relationship to kernel mean matching.

3. Integrated Model

Our goal is to find model parameters $\mathbf{w}$ for a probabilistic classification model $f(\mathbf{x}) = \text{argmax}_y\, p(y|\mathbf{x};\mathbf{w})$. The model should correctly predict labels of the test data $\mathbf{X}_T$ drawn from $p(\mathbf{x}|\theta)$. A regular *maximum a posteriori* estimation $\mathbf{w}' = \text{argmax}_\mathbf{w}\, p(\mathbf{y}|\mathbf{X}_L;\mathbf{w})p(\mathbf{w})$, would only use the training data $(\mathbf{y},\mathbf{X}_L)$ governed by $p(\mathbf{x}|\lambda)$. By ignoring the test data, this estimate will not generally result in a model that predicts the missing labels of the test data with a minimum error because the training distribution $p(\mathbf{x}|\lambda)$ is different from the test distribution $p(\mathbf{x}|\theta)$.

In the following we devise a probabilistic model that accounts for the difference between training and test distribution. Before we describe the model we define a joint data matrix $\mathbf{X}$ that is a concatenation of the matrices $\mathbf{X}_L$ and $\mathbf{X}_T$. The model is based on a binary selector variable s: Given an instance vector $\mathbf{x}$ from the joint matrix $\mathbf{X}$ of all available instances, selector variable s decides whether $\mathbf{x}$ is drawn into the test data $\mathbf{X}_T$ ($s=-1$) or into the training data $\mathbf{X}_L$ ($s=1$) in which case $\mathbf{y}$ is determined. The variable s is governed by the distribution $p(s|\mathbf{x};\mathbf{v})$. Parameter $\mathbf{v}$ characterizes the discrepancy between the training and test distribution. Based on the model for s we can now describe the generative process underlying our model:

1. Draw parameter vectors $\mathbf{v}$ and $\mathbf{w}$ from prior distributions $p(\mathbf{v})$ and $p(\mathbf{w})$;
2. For each row $\mathbf{x}$ in matrix $\mathbf{X}$ draw binary variable s from distribution $p(s|\mathbf{x};\mathbf{v})$; accordingly, the likelihood of the vector of all selector variables $\mathbf{s}$ is $p(\mathbf{s}|\mathbf{X};\mathbf{v}) = \prod_{i=1}^{m+n} p(s_i|\mathbf{x}_i;\mathbf{v})$;
3. For all selected training examples (all examples $\mathbf{x}_i$ with $s_i = 1$) draw vector $\mathbf{y}$ of all labels from $p(\mathbf{y}|\mathbf{s},\mathbf{X};\mathbf{w},\mathbf{v})$.

This generative process corresponds to the following factorization of the joint probability of the vector of labels $\mathbf{y}$, vector of selector variables $\mathbf{s}$, and parameter vectors $\mathbf{v}$ and $\mathbf{w}$:

$$p(\mathbf{y},\mathbf{s},\mathbf{w},\mathbf{v}|\mathbf{X}) \;=\; p(\mathbf{y}|\mathbf{s},\mathbf{X};\mathbf{w},\mathbf{v})p(\mathbf{s}|\mathbf{X};\mathbf{v})p(\mathbf{w})p(\mathbf{v}). \tag{3}$$

3.1 Maximum A Posteriori Parameter Inference

For parameter inference we want to find parameters $\mathbf{w}$ that maximize the posterior probability given all available data (Equation 4). The available data are the data matrix $\mathbf{X}$, the label vector $\mathbf{y}$, and the selection vector $\mathbf{s}$, that splits the data matrix into training and test data. Because the parameter $\mathbf{v}$ is unknown and is not needed for the final classifier the best we can do is to integrate it out (Equation 5).

$$\mathbf{w}^* \;=\; \text{argmax}_\mathbf{w}\, p(\mathbf{w}|\mathbf{y},\mathbf{s},\mathbf{X}) \tag{4}$$

$$\;=\; \text{argmax}_\mathbf{w} \int p(\mathbf{w},\mathbf{v}|\mathbf{y},\mathbf{s},\mathbf{X})d\mathbf{v}. \tag{5}$$

Integrating over $\mathbf{v}$ is computationally infeasible. In Equation 6, the integral is therefore approximated by the single assignment of values to the parameters which maximizes the posterior—the *maximum a posteriori* (MAP) estimator. In our case, the MAP estimator naturally assigns values to all parameters, $\mathbf{w}$ and $\mathbf{v}$.

$$(\mathbf{w}_{\text{MAP}},\mathbf{v}_{\text{MAP}}) \;=\; \text{argmax}_{\mathbf{w},\mathbf{v}}\, p(\mathbf{w},\mathbf{v}|\mathbf{y},\mathbf{s},\mathbf{X}) \tag{6}$$

$$\;=\; \text{argmax}_{\mathbf{w},\mathbf{v}}\, p(\mathbf{y},\mathbf{s},\mathbf{w},\mathbf{v}|\mathbf{X}) \tag{7}$$

$$\;=\; \text{argmax}_{\mathbf{w},\mathbf{v}}\, p(\mathbf{y}|\mathbf{s},\mathbf{X};\mathbf{w},\mathbf{v})p(\mathbf{s}|\mathbf{X};\mathbf{v})p(\mathbf{w})p(\mathbf{v}). \tag{8}$$

Equation 7 follows from multiplication with a constant $p(\mathbf{y},\mathbf{s}|\mathbf{X})$ and from application of the chain rule. Equation 8 applies the factorization from the generative process of Equation 3.

The class-label posterior $p(y|\mathbf{x};\mathbf{w}_{\text{MAP}})$ is conditionally independent of $\mathbf{v}_{\text{MAP}}$ given $\mathbf{w}_{\text{MAP}}$. However, $\mathbf{w}_{\text{MAP}}$ and $\mathbf{v}_{\text{MAP}}$ are dependent. Assigning a single MAP value to $[\mathbf{w},\mathbf{v}]$ instead of integrating over $\mathbf{v}$ is a common approximation. However, sequential maximization of $p(\mathbf{s}|\mathbf{X};\mathbf{v})$ over parameters $\mathbf{v}$ followed by maximization of $p(\mathbf{y}|\mathbf{s},\mathbf{X};\mathbf{w},\mathbf{v})$ over parameters $\mathbf{w}$ with fixed $\mathbf{v}$ would amount to an additional degree of approximation and will not generally coincide with the maximum of the product in Equation 8. Such a sequential maximization corresponds to the predominant two-step procedure for learning under covariate shift.

In the next sections we will discuss the likelihood functions $p(\mathbf{y}|\mathbf{s},\mathbf{X};\mathbf{w},\mathbf{v})$ and $p(\mathbf{s}|\mathbf{X};\mathbf{v})$ and the optimization problem for parameter inference based on maximization of Equation 8.

3.2 Label Likelihood and Discriminative Weighting Factors

In order to define the label likelihood we first derive a discriminative expression for $\frac{p(\mathbf{x}|\theta)}{p(\mathbf{x}|\lambda)}$ which will no longer include any density on instances. When $p(s=-1)>0$, which is implied by the test set not being empty, the definition of s allows us to rewrite the test distribution as $p(\mathbf{x}|\theta)=p(\mathbf{x}|s=-1,\theta)$. Since test instances are only dependent on parameter θ but not on parameter λ, equation $p(\mathbf{x}|s=-1,\theta)=p(\mathbf{x}|s=-1,\theta,\lambda)$ follows. By an analogous argument, $p(\mathbf{x}|\lambda)=p(\mathbf{x}|s=1,\theta,\lambda)$ when $p(s=1)>0$. This implies Equation 9.

In Equation 10, Bayes' rule is applied twice; the two terms of $p(\mathbf{x}|\theta,\lambda)$ cancel each other out in Equation 11. Since $p(s=-1|\mathbf{x},\theta,\lambda)=1-p(s=1|\mathbf{x},\theta,\lambda)$, Equation 12 follows.

The conditional $p(s=1|\mathbf{x},\theta,\lambda)$ discriminates training ($s=1$) against test instances ($s=-1$).

$$\frac{p(\mathbf{x}|\theta)}{p(\mathbf{x}|\lambda)} = p(\mathbf{x}|s=-1,\theta,\lambda)\frac{1}{p(\mathbf{x}|s=1,\theta,\lambda)} \tag{9}$$

$$= \frac{p(s=-1|\mathbf{x},\theta,\lambda)p(\mathbf{x}|\theta,\lambda)}{p(s=-1|\theta,\lambda)}\frac{p(s=1|\theta,\lambda)}{p(s=1|\mathbf{x},\theta,\lambda)p(\mathbf{x}|\theta,\lambda)} \tag{10}$$

$$= \frac{p(s=1|\theta,\lambda)}{p(s=-1|\theta,\lambda)}\frac{p(s=-1|\mathbf{x},\theta,\lambda)}{p(s=1|\mathbf{x},\theta,\lambda)} \tag{11}$$

$$= \frac{p(s=1|\theta,\lambda)}{p(s=-1|\theta,\lambda)}\left(\frac{1}{p(s=1|\mathbf{x},\theta,\lambda)}-1\right). \tag{12}$$

The significance of Equation 12 is that it shows how the optimal example weights, the test-to-training ratio $\frac{p(\mathbf{x}|\theta)}{p(\mathbf{x}|\lambda)}$, can be determined without knowledge of either training or test density. The right hand side of Equation 12 can be evaluated based on a model that discriminates training against test examples and outputs how much more likely an instance is to occur in the test data than it is to occur in the training data. Instead of potentially high-dimensional densities $p(\mathbf{x}|\theta)$ and $p(\mathbf{x}|\lambda)$, a conditional distribution of the single binary variable s needs to be modeled.

The expression $p(s|\mathbf{x},\theta,\lambda)$ in Equation 12 corresponds to the parametric model $p(s|\mathbf{x};\mathbf{v})$ of Equation 3. With this model we can predict test-to-training density ratios for the training data in $\mathbf{X}_L$ according to Equation 12.

Since our goal is discriminative training, the likelihood function $p(\mathbf{y}|\mathbf{X}_L;\mathbf{w})$ (not taking training-test difference $\mathbf{v}$ into account) would be $\prod_i p(y_i|\mathbf{x}_i;\mathbf{w})$. By using this likelihood $p(\mathbf{y}|\mathbf{X}_L;\mathbf{w})$ instead of $p(\mathbf{y}|\mathbf{s},\mathbf{X};\mathbf{w},\mathbf{v})$, one would wrongly assume that the training data $\mathbf{X}_L$ was governed by the test

distribution. Intuitively, $\frac{p(\mathbf{x}|\theta)}{p(\mathbf{x}|\lambda)}$ dictates how many times, on average, $\mathbf{x}$ should occur in $\mathbf{X}_L$ if $\mathbf{X}_L$ was governed by the test distribution θ. When the individual conditional likelihood of $\mathbf{x}$ is $p(y|\mathbf{x};\mathbf{w})$, then the likelihood of $\frac{p(\mathbf{x}|\theta)}{p(\mathbf{x}|\lambda)}$ occurrences of $\mathbf{x}$ is $p(y|\mathbf{x};\mathbf{w})^{\frac{p(\mathbf{x}|\theta)}{p(\mathbf{x}|\lambda)}}$. Using a parametric model $p(s|\mathbf{x};\mathbf{v})$, according to Equation 12 the test-to-training ratio $\frac{p(\mathbf{x}|\theta)}{p(\mathbf{x}|\lambda)}$ can be expressed as [1]

$$\frac{p(s=1)}{p(s=-1)}\left(\frac{1}{p(s=1|\mathbf{x};\mathbf{v})}-1\right).$$

Therefore, we define the likelihood function as [2]

$$p(\mathbf{y}|\mathbf{s},\mathbf{X};\mathbf{w},\mathbf{v}) = \prod_{i=1}^{m} p(y_i|\mathbf{x}_i;\mathbf{w})^{\frac{p(s=1)}{p(s=-1)}\left(\frac{1}{p(s_i=1|\mathbf{x}_i;\mathbf{v})}-1\right)}. \tag{13}$$

As an immediate corollary of Manski and Lerman (1977), the likelihood function of Equation 13 has the property that when the true value $\mathbf{v}^*$ is given, its maximizer over $\mathbf{w}$ is a consistent estimator of the true parameter $\mathbf{w}^*$ that has produced labels for the test data under the test distribution θ. That is, as the sample grows, the maximizer of Equation 13 converges in probability to the true value $\mathbf{w}^*$ of parameter $\mathbf{w}$.

For the statistical analysis of case-control studies, Prentice and Pyke (1979) estimate the ratio of two odds ratios with a discriminative model using a formula similar to Equation 12. This double odds ratio is a statistical measure of the relative risk of an incidence (e.g., lung cancer) given a specific exposure (e.g., cigarette smoking) based on data from a retrospective study.

3.3 Optimization Problem for Integrated Model

The likelihood function $p(\mathbf{s}|\mathbf{X};\mathbf{v})$ resolves to $p(s_i=1|\mathbf{x}_i;\mathbf{v})$ for all training instances and $p(s_i=-1|\mathbf{x}_i;\mathbf{v})$ for all test instances:

$$p(\mathbf{s}|\mathbf{X};\mathbf{v}) = \prod_{i=1}^{m} p(s_i=1|\mathbf{x}_i;\mathbf{v}) \prod_{i=m+1}^{m+n} p(s_i=-1|\mathbf{x}_i;\mathbf{v}). \tag{14}$$

Equation 15 summarizes Equations 6 to 8 and Equation 16 inserts the likelihood models (Equations 13 and 14).

$$\begin{aligned} p(\mathbf{w},\mathbf{v}|\mathbf{y},\mathbf{s},\mathbf{X}) &\propto p(\mathbf{y}|\mathbf{s},\mathbf{X};\mathbf{w},\mathbf{v})p(\mathbf{s}|\mathbf{X};\mathbf{v})p(\mathbf{w})p(\mathbf{v}) && (15)\\ &= \left(\prod_{i=1}^{m} p(y_i|\mathbf{x}_i;\mathbf{w})^{\frac{p(s=1)}{p(s=-1)}\left(\frac{1}{p(s_i=1|\mathbf{x}_i;\mathbf{v})}-1\right)}\right) && (16)\\ &\quad \left(\prod_{i=1}^{m} p(s_i=1|\mathbf{x}_i;\mathbf{v}) \prod_{i=m+1}^{m+n} p(s_i=-1|\mathbf{x}_i;\mathbf{v})\right) p(\mathbf{w})p(\mathbf{v}). \end{aligned}$$

Using a logistic model for $p(s=1|\mathbf{x};\mathbf{v})$, we notice that Equation 12 can be simplified as in Equation 17.

$$\frac{p(s=1)}{p(s=-1)}\left(\frac{1}{1/(1+\exp(-\mathbf{v}^\mathsf{T}\mathbf{x}))}-1\right) = \frac{p(s=1)}{p(s=-1)}\exp(-\mathbf{v}^\mathsf{T}\mathbf{x}). \tag{17}$$

1. For a simplified presentation we drop the conditioning in the prior ratio, that is, $p(s|\theta,\lambda) = p(s)$.

2. The variable s in the prior ratio $\frac{p(s=1)}{p(s=-1)}$ does not need an index i because at this point it is not conditioned on $\mathbf{x}_i$.

Optimization Problem 1 is derived from Equation 16 in logarithmic form, using linear models $\mathbf{v}^\mathsf{T}\mathbf{x}_i$ and $\mathbf{w}^\mathsf{T}\mathbf{x}_i$ and a logistic model for $p(s=1|\mathbf{x};\mathbf{v})$. Negative log-likelihoods are abbreviated $\ell_\mathbf{w}(y_i\mathbf{w}^\mathsf{T}\mathbf{x}_i) = -\log p(y_i|\mathbf{x}_i;\mathbf{w})$ and $\ell_\mathbf{v}(s_i\mathbf{v}^\mathsf{T}\mathbf{x}_i) = -\log p(s_i|\mathbf{x}_i;\mathbf{v})$, respectively; this notation emphasizes the duality between likelihoods and empirical loss functions. The regularization terms correspond to Gaussian priors on $\mathbf{v}$ and $\mathbf{w}$ with variances $\sigma_\mathbf{v}^2$ and $\sigma_\mathbf{w}^2$.

Optimization Problem 1 *Over all* $\mathbf{w}$ *and* $\mathbf{v}$, *minimize*

$$\sum_{i=1}^{m} \frac{p(s=1)}{p(s=-1)} \exp(-\mathbf{v}^\mathsf{T}\mathbf{x}_i)\ell_\mathbf{w}(y_i\mathbf{w}^\mathsf{T}\mathbf{x}_i) + \sum_{i=1}^{m+n} \ell_\mathbf{v}(s_i\mathbf{v}^\mathsf{T}\mathbf{x}_i) + \frac{1}{2\sigma_\mathbf{w}^2}\mathbf{w}^\mathsf{T}\mathbf{w} + \frac{1}{2\sigma_\mathbf{v}^2}\mathbf{v}^\mathsf{T}\mathbf{v}.$$

4. Primal Learning Algorithm

We derive a Newton gradient descent method that directly minimizes Optimization Problem 1 in the attribute space. To this end, we need to derive the gradient and the Hessian of the objective function. The update rule assumes the form of a set of linear equations that have to be solved for the update vector $[\Delta_\mathbf{v}, \Delta_\mathbf{w}]^\mathsf{T}$. It depends on the current parameters $[\mathbf{v}, \mathbf{w}]^\mathsf{T}$, all combinations of training and test data, and resulting coefficients. In order to express the update rule as a single equation in matrix form, we define

$$\mathbf{X} = \begin{bmatrix} \mathbf{X}_L & \mathbf{X}_T & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{X}_L \end{bmatrix},$$

where $\mathbf{X}_L$ and $\mathbf{X}_T$ are the matrices of training vectors and test vectors, respectively.

Theorem 3 *The update step for the Newton gradient descent minimization of Optimization Problem 1 is* $[\mathbf{v}', \mathbf{w}']^\mathsf{T} \leftarrow [\mathbf{v}, \mathbf{w}]^\mathsf{T} + [\Delta_\mathbf{v}, \Delta_\mathbf{w}]^\mathsf{T}$ *with*

$$(\mathbf{X}\mathbf{\Lambda}\mathbf{X}^\mathsf{T} + \mathbf{S}) \begin{bmatrix} \Delta_\mathbf{v} \\ \Delta_\mathbf{w} \end{bmatrix} = -\mathbf{X}\mathbf{g} - \mathbf{S} \begin{bmatrix} \mathbf{v} \\ \mathbf{w} \end{bmatrix}. \tag{18}$$

The definitions of coefficients $\mathbf{\Lambda}$, $\mathbf{S}$, and $\mathbf{g}$—and the proof of the theorem—can be found in Appendix A.

Given the parameter $\mathbf{w}$, a test instance $\mathbf{x}$ is classified as $f(\mathbf{x};\mathbf{w}) = \text{sign}(\mathbf{w}^\mathsf{T}\mathbf{x})$.

5. Kernelized Learning Algorithm

We derive a kernelized version of the integrated classifier for differing training and test distributions. A transformation Φ maps instances into a target space in which a kernel function $k(\mathbf{x}_i, \mathbf{x}_j)$ calculates the inner product $\Phi(\mathbf{x}_i)^\mathsf{T}\Phi(\mathbf{x}_j)$. The update rule (Equation 18) thus becomes

$$(\Phi(\mathbf{X})\mathbf{\Lambda}\Phi(\mathbf{X})^\mathsf{T} + \mathbf{S}) \begin{bmatrix} \Delta_\mathbf{v} \\ \Delta_\mathbf{w} \end{bmatrix} = -\Phi(\mathbf{X})\mathbf{g} - \mathbf{S} \begin{bmatrix} \mathbf{v} \\ \mathbf{w} \end{bmatrix}. \tag{19}$$

$\Phi(\mathbf{X})$ is defined by

$$\Phi(\mathbf{X}) = \begin{bmatrix} \Phi(\mathbf{X}_L) & \Phi(\mathbf{X}_T) & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \Phi(\mathbf{X}_L) \end{bmatrix}.$$

According to the Representer Theorem, the optimal separator is a linear combination of examples. Parameter vectors $\boldsymbol{\alpha}$ and $\boldsymbol{\beta}$ in the dual space weight the influence of all examples:

$$\begin{bmatrix}\mathbf{v}\\ \mathbf{w}\end{bmatrix} = \Phi(\mathbf{X})\begin{bmatrix}\boldsymbol{\alpha}\\ \boldsymbol{\beta}\end{bmatrix}.$$

Equation 19 can therefore be rewritten as Equation 20. We now multiply $\Phi(\mathbf{X})^\mathsf{T}$ from the left to both sides and obtain Equation 21. We replace all resulting occurrences of $\Phi(\mathbf{X})^\mathsf{T}\Phi(\mathbf{X})$ by the kernel matrix $\mathbf{K}$ and arrive at Equation 22; $\mathbf{S}$ is replaced by $\mathbf{S}'$ such that $\Phi(\mathbf{X})^\mathsf{T}\mathbf{S}\Phi(\mathbf{X}) = \Phi(\mathbf{X})^\mathsf{T}\Phi(\mathbf{X})\mathbf{S}'$, that is, $S'_{i,i} = \sigma_\mathbf{v}^{-2}$ for $i = 1,\ldots,m+n$ and $S'_{m+n+i,m+n+i} = \sigma_\mathbf{w}^{-2}$ for $i = 1,\ldots,m$. Equation 22 is satisfied when Equation 23 is satisfied. Equation 23 is the update rule for the dual Newton gradient descent.

$$(\Phi(\mathbf{X})\boldsymbol{\Lambda}\Phi(\mathbf{X})^\mathsf{T}+\mathbf{S})\Phi(\mathbf{X})\begin{bmatrix}\Delta_{\boldsymbol{\alpha}}\\ \Delta_{\boldsymbol{\beta}}\end{bmatrix} = -\Phi(\mathbf{X})\mathbf{g} - \mathbf{S}\Phi(\mathbf{X})\begin{bmatrix}\boldsymbol{\alpha}\\ \boldsymbol{\beta}\end{bmatrix}, \tag{20}$$

$$\Phi(\mathbf{X})^\mathsf{T}(\Phi(\mathbf{X})\boldsymbol{\Lambda}\Phi(\mathbf{X})^\mathsf{T}+\mathbf{S})\Phi(\mathbf{X})\begin{bmatrix}\Delta_{\boldsymbol{\alpha}}\\ \Delta_{\boldsymbol{\beta}}\end{bmatrix} = -\Phi(\mathbf{X})^\mathsf{T}\Phi(\mathbf{X})\mathbf{g} - \Phi(\mathbf{X})^\mathsf{T}\mathbf{S}\Phi(\mathbf{X})\begin{bmatrix}\boldsymbol{\alpha}\\ \boldsymbol{\beta}\end{bmatrix}, \tag{21}$$

$$(\mathbf{K}\boldsymbol{\Lambda}\mathbf{K}+\mathbf{K}\mathbf{S}')\begin{bmatrix}\Delta_{\boldsymbol{\alpha}}\\ \Delta_{\boldsymbol{\beta}}\end{bmatrix} = -\mathbf{K}\mathbf{g} - \mathbf{K}\mathbf{S}'\begin{bmatrix}\boldsymbol{\alpha}\\ \boldsymbol{\beta}\end{bmatrix}, \tag{22}$$

$$(\boldsymbol{\Lambda}\mathbf{K}+\mathbf{S}')\begin{bmatrix}\Delta_{\boldsymbol{\alpha}}\\ \Delta_{\boldsymbol{\beta}}\end{bmatrix} = -\mathbf{g} - \mathbf{S}'\begin{bmatrix}\boldsymbol{\alpha}\\ \boldsymbol{\beta}\end{bmatrix}. \tag{23}$$

Given the parameters, test instance $\mathbf{x}$ is classified by $f(\mathbf{x};\boldsymbol{\beta}) = \operatorname{sign}(\sum_{i=1}^m \beta_i k(\mathbf{x},\mathbf{x}_i))$.

6. Convexity Analysis and Solving the Optimization Problems

The following theorem specifies sufficient conditions for convexity of Optimization Problem 1. With this theorem we can easily check whether the integrated classifier for covariate shift is convex for specific models of the negative log-likelihood functions. The negative log-likelihood function $\ell_\mathbf{w}$ itself and its first and second derivatives are needed. Equations 31 and 32 in Appendix A define shorthand notation which we will use in the following.

Theorem 4 *Optimization Problem 1 is convex if the loss function $\ell_\mathbf{v}$ is convex and $\ell_\mathbf{w}$ is log-convex and non-negative. The log-convexity condition is equivalent to*

$$\ell_\mathbf{w}\ell''_\mathbf{w} - \ell'^2_\mathbf{w} \geq 0. \tag{24}$$

Proof Looking at Optimization Criterion 1 we immediately see that the regularizers are convex. If $\ell_\mathbf{v}$ is convex, the second term is convex as well. We therefore only need to analyze the convexity of the term

$$\sum_{i=1}^m \frac{p(s=1)}{p(s=-1)}\exp(-\mathbf{v}^\mathsf{T}\mathbf{x}_i)\ell_\mathbf{w}(y_i\mathbf{w}^\mathsf{T}\mathbf{x}_i).$$

A sum is convex if the single summands are convex. And a sufficient condition for convexity of a function is that it is non-negative and log-convex. The above expression is non-negative as $\ell_\mathbf{w}$ is non-negative. This means we only need to check whether

$$\log\frac{p(s=1)}{p(s=-1)} - \mathbf{v}^\mathsf{T}\mathbf{x}_i + \log\ell_{\mathbf{w},i}$$

is convex. The prior ratio is assumed to be constant. The second term is linear and therefore convex and the third term is the log-convexity condition of $\ell_{\mathbf{w}}$. The second derivative of $\log \ell_{\mathbf{w}}$ is

$$\ell_{\mathbf{w}}^{-1}\ell_{\mathbf{w}}'' + \ell_{\mathbf{w}}^{-2}\ell_{\mathbf{w}}'^2,$$

thus $\log \ell_{\mathbf{w}}$ is convex if $\ell_{\mathbf{w}}\ell_{\mathbf{w}}'' - \ell_{\mathbf{w}}'^2$ is non-negative. ■

In order to check Optimization Criterion 1 for convexity we need to choose models of the negative log-likelihood $\ell_{\mathbf{v}}$ and $\ell_{\mathbf{w}}$ and derive their first and second derivatives. These derivations are also needed to actually minimize Optimization Criterion 1 with the Newton update steps derived in the last section.

We use a logistic model $\ell_{\mathbf{v}}(s_i\mathbf{v}^\mathsf{T}\mathbf{x}) = \log(1+\exp(-s_i\mathbf{v}^\mathsf{T}\mathbf{x}))$; the abbreviations of Appendix A can now be expanded:

$$\ell'_{\mathbf{v},i}s_ix_{ij} = -\frac{\exp(-s_i\mathbf{v}^\mathsf{T}\mathbf{x}_i)}{1+\exp(-s_i\mathbf{v}^\mathsf{T}\mathbf{x}_i)}s_ix_{ij}; \quad \ell''_{\mathbf{v},i}x_{ij}x_{ik} = \frac{\exp(-s_i\mathbf{v}^\mathsf{T}\mathbf{x}_i)}{(1+\exp(-s_i\mathbf{v}^\mathsf{T}\mathbf{x}_i))^2}x_{ij}x_{ik}.$$

For the target classifier, we detail the derivations for logistic and for exponential models of $\ell_{\mathbf{w}}$. For the logistic model the derivatives of $\ell_{\mathbf{w}}$ are the same as for $\ell_{\mathbf{v}}$, only $\mathbf{v}$ needs to be replaced by $\mathbf{w}$ and s_i by y_i. For an exponential model with $\ell_{\mathbf{w}}(y_i\mathbf{w}^\mathsf{T}\mathbf{x}) = \exp(-y_i\mathbf{w}^\mathsf{T}\mathbf{x})$ the abbreviations are expanded as follows:

$$\ell'_{\mathbf{w},i}y_ix_{ij} = -\exp(-y_i\mathbf{w}^\mathsf{T}\mathbf{x}_i)y_ix_{ij}; \quad \ell''_{\mathbf{w},i}x_{ij}x_{ik} = \exp(-y_i\mathbf{w}^\mathsf{T}\mathbf{x}_i)x_{ij}x_{ik}.$$

Using Theorem 4 we can now easily check the convexity of the integrated classifier with logistic model and with exponential model for $\ell_{\mathbf{w}}$.

Corollary 5 *With a logistic model for $\ell_{\mathbf{w}}$, the condition of Equation 24 is violated and therefore Optimization Problem 1 with logistic model for $\ell_{\mathbf{w}}$ may not convex in general.*

Proof Inserting the logistic function into Equation 24 we get the following solution.

$$\ell_{\mathbf{w},i}\ell''_{\mathbf{w},i} - \ell'^2_{\mathbf{w},i} = \frac{\exp(-y_i\mathbf{w}^\mathsf{T}\mathbf{x}_i)}{(1+\exp(-y_i\mathbf{w}^\mathsf{T}\mathbf{x}))^2}\left(\log(1+\exp(-y_i\mathbf{w}^\mathsf{T}\mathbf{x})) - \exp(-y_i\mathbf{w}^\mathsf{T}\mathbf{x}_i)\right). \tag{25}$$

The fraction in Equation 25 is always positive, the difference term is always negative which violates the condition of Equation 24. ■

Empirically, we find that it is a good choice to select the parameters of a regular, *iid* logistic regression classifier as starting point for the Newton gradient search.

One can easily show that the condition of Equation 24 is violated when $\ell_{\mathbf{w}}$ is chosen as hinge loss or quadratic loss.

Corollary 6 *Optimization Problem 1 with exponential model for $\ell_{\mathbf{w}}$ is convex.*

Proof The exponential loss is non-negative and its logarithm is linear and therefore convex. ■

This means the global optimum of Optimization Problem 1 with exponential model for $\ell_{\mathbf{w}}$ can easily be found by Newton gradient descent.

7. Two-Stage Approximation to Integrated Model

The previous sections describe a complete solution to the learning problem under covariate shift. Optimization Problem 1 is convex for the exponential model; solving it using the efficient procedures derived in Sections 4 and 5 produces a globally optimal solution.

For the logistic model, unfortunately, convexity cannot be guaranteed. Furthermore, the regularized regression classifier is deeply embedded in Optimization Problem 1. It would not be easy to replace it by a different type of classifier such as, for instance, a decision tree. We will now discuss an approximation to Optimization Problem 1 which solves two consecutive optimization problems. The first optimization problem produces example-specific weights; the second step generates a classifier from the weighted examples. Both optimization problems are convex for exponential, logistic, and hinge loss as well as for many other loss functions. But most significantly, the two-stage approximation is conceptually simple: the second optimization step can be carried out by any learning procedure that is able to scale the loss incurred by each example using prescribed weight factors. Example-specific weights can easily be incorporated into virtually any learning method. Furthermore, as a result of the decomposition into two optimization problems parameter tuning becomes much easier because cross-validation can be used (cf. Section 9).

The derivation in Section 3.1 approximates the integral over $\mathbf{v}$ by simultaneously selecting a pair of values which maximize the posterior. This leads to the joint MAP hypothesis over $\mathbf{v}$ and $\mathbf{w}$. In the resulting optimization problem, $\mathbf{v}$ and $\mathbf{w}$ are free parameters. At a higher degree of approximation, one may factorize the posterior (Equation 26) and at first approximate the integral over $\mathbf{v}$ by the maximum of $p(\mathbf{v}|\mathbf{y},\mathbf{s},\mathbf{X})$ (Equations 29 and 30). Subsequently, the posterior over $\mathbf{w}$ is maximized given fixed parameters $\mathbf{v}_{\text{MAP}'}$ (Equations 27 and 28).

$$\begin{aligned}
\mathbf{w}^* &= \operatorname{argmax}_{\mathbf{w}} \int p(\mathbf{w},\mathbf{v}|\mathbf{y},\mathbf{s},\mathbf{X}) d\mathbf{v} \\
&= \operatorname{argmax}_{\mathbf{w}} \int p(\mathbf{w}|\mathbf{y},\mathbf{s},\mathbf{X};\mathbf{v}) p(\mathbf{v}|\mathbf{y},\mathbf{s},\mathbf{X}) d\mathbf{v} && (26) \\
&\approx \operatorname{argmax}_{\mathbf{w}} p(\mathbf{w}|\mathbf{y},\mathbf{s},\mathbf{X};\mathbf{v}_{\text{MAP}'}) && (27) \\
&= \operatorname{argmax}_{\mathbf{w}} p(\mathbf{y}|\mathbf{s},\mathbf{X};\mathbf{w},\mathbf{v}_{\text{MAP}'}) p(\mathbf{w}) && (28) \\
\text{with} \quad \mathbf{v}_{\text{MAP}'} &= \operatorname{argmax}_{\mathbf{v}} p(\mathbf{v}|\mathbf{y},\mathbf{s},\mathbf{X}) && (29) \\
&= \operatorname{argmax}_{\mathbf{v}} p(\mathbf{s}|\mathbf{y},\mathbf{X};\mathbf{v}) p(\mathbf{v}). && (30)
\end{aligned}$$

This results in two optimization problems. Only parameter $\mathbf{v}$ is free in the first stage (Optimization Problem 2). The test-to-training ratio (Equation 17) can be derived from the resulting value of $\mathbf{v}$.

Optimization Problem 2 *Over* $\mathbf{v}$*, minimize*

$$\sum_{i=1}^{m+n} \ell_{\mathbf{v}}(s_i \mathbf{v}^\mathsf{T} \mathbf{x}_i) + \frac{1}{2\sigma_{\mathbf{v}}^2} \mathbf{v}^\mathsf{T} \mathbf{v}.$$

In the second stage (Optimization Problem 3), the target model parameters $\mathbf{w}$ are optimized with constant parameters $\mathbf{v}$ and constant example weights. The parameters $\mathbf{v}$ are the result of Optimization Problem 2.

Optimization Problem 3 *Over* $\mathbf{w}$ *(*$\mathbf{v}$ *is constant), minimize*
