2.1 Strongly Consistent Test

For testing a simple hypothesis versus a composite alternative, Györfi and van der Meulen (1990) introduced a related goodness of fit test statistic L_n defined as

$$L_n(\mu_{n,1},\mu_1) = \sum_{A\in\mathcal{P}_n}|\mu_{n,1}(A)-\mu_1(A)|.$$

Beirlant, Devroye, Györfi, and Vajda (2001), and Biau and Györfi (2005) proved that, for all $0 < \varepsilon$,

$$\mathbf{P}\{L_n(\mu_{n,1},\mu_1) > \varepsilon\} \leq 2^{m_n} e^{-n\varepsilon^2/2}. \tag{4}$$

We now describe a similar result for our L_1 independence statistic.

Theorem 1 *Under $\mathcal{H}_0$, for all $0 < \varepsilon_1$, $0 < \varepsilon_2$ and $0 < \varepsilon_3$,*

$$\mathbf{P}\{L_n(\nu_n,\mu_{n,1}\times\mu_{n,2}) > \varepsilon_1+\varepsilon_2+\varepsilon_3\} \leq 2^{m_n\cdot m'_n} e^{-n\varepsilon_1^2/2} + 2^{m_n} e^{-n\varepsilon_2^2/2} + 2^{m'_n} e^{-n\varepsilon_3^2/2}.$$

Proof We bound $L_n(\nu_n,\mu_{n,1}\times\mu_{n,2})$ according to

$$\begin{aligned}
L_n(\nu_n,\mu_{n,1}\times\mu_{n,2}) &= \sum_{A\in\mathcal{P}_n}\sum_{B\in\mathcal{Q}_n} |\nu_n(A\times B) - \mu_{n,1}(A)\cdot\mu_{n,2}(B)| \\
&\leq \sum_{A\in\mathcal{P}_n}\sum_{B\in\mathcal{Q}_n} |\nu_n(A\times B) - \nu(A\times B)| \\
&\quad + \sum_{A\in\mathcal{P}_n}\sum_{B\in\mathcal{Q}_n} |\nu(A\times B) - \mu_1(A)\cdot\mu_2(B)| \\
&\quad + \sum_{A\in\mathcal{P}_n}\sum_{B\in\mathcal{Q}_n} |\mu_1(A)\cdot\mu_2(B) - \mu_{n,1}(A)\cdot\mu_{n,2}(B)|.
\end{aligned}$$

Under the null hypothesis $\mathcal{H}_0$, we have that

$$\sum_{A\in\mathcal{P}_n}\sum_{B\in\mathcal{Q}_n} |\nu(A\times B) - \mu_1(A)\cdot\mu_2(B)| = 0.$$

Moreover

$$\begin{aligned}
&\sum_{A\in\mathcal{P}_n}\sum_{B\in\mathcal{Q}_n} |\mu_1(A)\cdot\mu_2(B) - \mu_{n,1}(A)\cdot\mu_{n,2}(B)| \\
\leq\ &\sum_{A\in\mathcal{P}_n}\sum_{B\in\mathcal{Q}_n} |\mu_1(A)\cdot\mu_2(B) - \mu_1(A)\cdot\mu_{n,2}(B)| \\
&+ \sum_{A\in\mathcal{P}_n}\sum_{B\in\mathcal{Q}_n} |\mu_1(A)\cdot\mu_{n,2}(B) - \mu_{n,1}(A)\cdot\mu_{n,2}(B)| \\
=\ &\sum_{B\in\mathcal{Q}_n} |\mu_2(B) - \mu_{n,2}(B)| + \sum_{A\in\mathcal{P}_n} |\mu_1(A) - \mu_{n,1}(A)| \\
=\ &L_n(\mu_{n,1},\mu_1) + L_n(\mu_{n,2},\mu_2).
\end{aligned}$$

Thus, (4) implies

$$\begin{aligned}
&\mathbf{P}\{L_n(\nu_n,\mu_{n,1}\times\mu_{n,2}) > \varepsilon_1+\varepsilon_2+\varepsilon_3\} \\
\leq\ &\mathbf{P}\{L_n(\nu_n,\nu) > \varepsilon_1\} + \mathbf{P}\{L_n(\mu_{n,1},\mu_1) > \varepsilon_2\} + \mathbf{P}\{L_n(\mu_{n,2},\mu_2) > \varepsilon_3\} \\
\leq\ &2^{m_n\cdot m'_n} e^{-n\varepsilon_1^2/2} + 2^{m_n} e^{-n\varepsilon_2^2/2} + 2^{m'_n} e^{-n\varepsilon_3^2/2}.
\end{aligned}$$

■

Theorem 1 yields a strong consistent test of independence, which rejects the null hypothesis if $L_n(\nu_n,\mu_{n,1}\times\mu_{n,2})$ becomes large. The test is distribution-free, that is, the probability distributions ν, μ_1 and μ_2 are completely arbitrary; and the threshold is universal, that is, it does not depend on the distribution.

Corollary 2 *Consider the test which rejects $\mathcal{H}_0$ when*

$$L_n(\nu_n, \mu_{n,1} \times \mu_{n,2}) > c_1 \left(\sqrt{\frac{m_n m'_n}{n}} + \sqrt{\frac{m_n}{n}} + \sqrt{\frac{m'_n}{n}} \right) \approx c_1 \sqrt{\frac{m_n m'_n}{n}},$$

where

$$c_1 > \sqrt{2 \ln 2} \approx 1.177. \tag{5}$$

Assume that conditions

$$\lim_{n \to \infty} \frac{m_n m'_n}{n} = 0, \tag{6}$$

and

$$\lim_{n \to \infty} \frac{m_n}{\ln n} = \infty, \qquad \lim_{n \to \infty} \frac{m'_n}{\ln n} = \infty, \tag{7}$$

are satisfied. Then under $\mathcal{H}_0$, the test makes a.s. no error after a random sample size. Moreover, if

$$\nu \neq \mu_1 \times \mu_2,$$

and for any sphere S centered at the origin,

$$\lim_{n \to \infty} \max_{A \in \mathcal{P}_n, A \cap S \neq 0} \operatorname{diam}(A) = 0 \tag{8}$$

and

$$\lim_{n \to \infty} \max_{B \in \mathcal{Q}_n, B \cap S \neq 0} \operatorname{diam}(B) = 0, \tag{9}$$

then after a random sample size the test makes a.s. no error.

Proof Under $\mathcal{H}_0$, we obtain from Theorem 1 a non-asymptotic bound for the tail of the distribution of $L_n(\nu_n, \mu_{n,1} \times \mu_{n,2})$, namely

$$\begin{aligned} & \mathbf{P}\left\{ L_n(\nu_n, \mu_{n,1} \times \mu_{n,2}) > c_1 \left(\sqrt{\frac{m_n m'_n}{n}} + \sqrt{\frac{m_n}{n}} + \sqrt{\frac{m'_n}{n}} \right) \right\} \\ \leq \;& 2^{m_n m'_n} e^{-c_1^2 m_n m'_n/2} + 2^{m_n} e^{-c_1^2 m_n/2} + 2^{m'_n} e^{-c_1^2 m'_n/2} \\ \leq \;& e^{-(c_1^2/2 - \ln 2) m_n m'_n} + e^{-(c_1^2/2 - \ln 2) m_n} + e^{-(c_1^2/2 - \ln 2) m'_n} \end{aligned}$$

as $n \to \infty$. Therefore the conditions (7) imply

$$\sum_{n=1}^{\infty} \mathbf{P}\left\{ L_n(\nu_n, \mu_{n,1} \times \mu_{n,2}) > c_1 \left(\sqrt{\frac{m_n m'_n}{n}} + \sqrt{\frac{m_n}{n}} + \sqrt{\frac{m'_n}{n}} \right) \right\} < \infty,$$

and the proof under the null hypothesis is completed by the Borel-Cantelli lemma.

For the result under the alternative hypothesis, we first apply the triangle inequality

$$\begin{aligned} L_n(\nu_n, \mu_{n,1} \times \mu_{n,2}) \quad \geq \quad & \sum_{A \in \mathcal{P}_n} \sum_{B \in \mathcal{Q}_n} |\nu(A \times B) - \mu_1(A) \cdot \mu_2(B)| \\ & - \sum_{A \in \mathcal{P}_n} \sum_{B \in \mathcal{Q}_n} |\nu_n(A \times B) - \nu(A \times B)| \\ & - \sum_{B \in \mathcal{Q}_n} |\mu_2(B) - \mu_{n,2}(B)| \\ & - \sum_{A \in \mathcal{P}_n} |\mu_1(A) - \mu_{n,1}(A)|. \end{aligned}$$

The condition in (6) implies the three last terms of the right hand side tend to 0 a.s. Moreover, using the technique from Barron, Györfi, and van der Meulen (1992) we can prove that by conditions (8) and (9),

$$\sum_{A\in\mathcal{P}_n}\sum_{B\in\mathcal{Q}_n}|\nu(A\times B)-\mu_1(A)\cdot\mu_2(B)|\to 2\sup_C|\nu(C)-\mu_1\times\mu_2(C)|>0$$

as $n\to\infty$, where the last supremum is taken over all Borel subsets C of $\mathbb{R}^d\times\mathbb{R}^{d'}$, and therefore

$$\liminf_{n\to\infty}L_n(\nu_n,\mu_{n,1}\times\mu_{n,2})\geq 2\sup_C|\nu(C)-\mu_1\times\mu_2(C)|>0$$

a.s. ■

2.2 Asymptotic α-level Test

Beirlant, Györfi, and Lugosi (1994) proved, under conditions

$$\lim_{n\to\infty}m_n=\infty,\qquad\lim_{n\to\infty}\frac{m_n}{n}=0, \tag{10}$$

and

$$\lim_{n\to\infty}\max_{j=1,\ldots,m_n}\mu_1(A_{nj})=0, \tag{11}$$

that

$$\sqrt{n}\left(L_n(\mu_{n,1},\mu_1)-\mathbf{E}\{L_n(\mu_{n,1},\mu_1)\}\right)/\sigma\xrightarrow{\mathcal{D}}\mathcal{N}(0,1),$$

where $\xrightarrow{\mathcal{D}}$ indicates convergence in distribution and $\sigma^2=1-2/\pi$. The technique of Beirlant, Györfi, and Lugosi (1994) involves a Poisson representation of the empirical process in conjunction with Bartlett's idea of partial inversion for obtaining characteristic functions of conditional distributions (see Bartlett, 1938). We apply these techniques in Appendix A to derive an asymptotic result for $L_n(\nu_n,\mu_{n,1}\times\mu_{n,2})$.

Theorem 3 *Assume that conditions (6) and*

$$\lim_{n\to\infty}\max_{A\in\mathcal{P}_n}\mu_1(A)=0,\quad\lim_{n\to\infty}\max_{B\in\mathcal{Q}_n}\mu_2(B)=0, \tag{12}$$

are satisfied. Then, under $\mathcal{H}_0$, there exists a centering sequence $(C_n)_{n\geq 1}$ depending on ν such that

$$\sqrt{n}\left(L_n(\nu_n,\mu_{n,1}\times\mu_{n,2})-C_n\right)/\sigma\xrightarrow{\mathcal{D}}\mathcal{N}(0,1),$$

where $\sigma^2=1-2/\pi$.

Theorem 3 yields the asymptotic null distribution of a consistent independence test, which rejects the null hypothesis if $L_n(\nu_n,\mu_{n,1}\times\mu_{n,2})$ becomes large. In contrast to Corollary 2, and because of condition (11), this new test is *not* distribution-free: the measures μ_1 and μ_2 have to be nonatomic.

Corollary 4 *Let $\alpha \in (0,1)$. Consider the test which rejects $\mathcal{H}_0$ when*

$$\begin{aligned} L_n(\nu_n, \mu_{n,1} \times \mu_{n,2}) &> c_2 \sqrt{\frac{m_n m_n'}{n}} + \frac{\sigma}{\sqrt{n}} \Phi^{-1}(1-\alpha) \\ &\approx c_2 \sqrt{\frac{m_n m_n'}{n}}, \end{aligned}$$

where

$$\sigma^2 = 1 - 2/\pi \quad \textit{and} \quad c_2 = \sqrt{2/\pi} \approx 0.798,$$

and Φ denotes the standard normal distribution function. Then, under the conditions of Theorem 3, the test has asymptotic significance level α. Moreover, under the additional conditions (8) and (9), the test is consistent.

Before proceeding to the proof, we examine how the above test differs from that in Corollary 2. In particular, comparing c_2 above with c_1 in (5), both tests behave identically with respect to $\sqrt{m_n m_n'/n}$ for large enough n, but c_2 is smaller.

Proof According to Theorem 3, under $\mathcal{H}_0$,

$$\mathbf{P}\{\sqrt{n}(L_n(\nu_n, \mu_{n,1} \times \mu_{n,2}) - C_n)/\sigma \le x\} \approx \Phi(x),$$

therefore the error probability with threshold x is

$$\alpha = 1 - \Phi(x).$$

Thus the α-level test rejects the null hypothesis if

$$L_n(\nu_n, \mu_{n,1} \times \mu_{n,2}) > C_n + \frac{\sigma}{\sqrt{n}} \Phi^{-1}(1-\alpha).$$

As C_n depends on the unknown distribution, we apply an upper bound

$$C_n \le \sqrt{2/\pi} \sqrt{\frac{m_n m_n'}{n}}$$

(see Equation (22) in Appendix A for the definition of C_n, and Equation (23) for the bound), so decreasing the error probability. ■

3. Log-likelihood Statistic

In the literature on goodness-of-fit testing the *I-divergence statistic*, *Kullback-Leibler divergence*, or *log-likelihood statistic*,

$$I_n(\mu_{n,1}, \mu_1) = \sum_{j=1}^{m_n} \mu_{n,1}(A_{n,j}) \log \frac{\mu_{n,1}(A_{n,j})}{\mu_1(A_{n,j})},$$

plays an important role. For testing independence, the corresponding log-likelihood test statistic is defined as

$$I_n(\nu_n, \mu_{n,1} \times \mu_{n,2}) = \sum_{A \in \mathcal{P}_n} \sum_{B \in \mathcal{Q}_n} \nu_n(A \times B) \log \frac{\nu_n(A \times B)}{\mu_{n,1}(A) \cdot \mu_{n,2}(B)}.$$

The large deviation and the limit distribution properties of $I_n(\nu_n, \mu_{n,1} \times \mu_{n,2})$ can be derived from the properties of

$$I_n(\nu_n, \nu) = \sum_{A \in \mathcal{P}_n} \sum_{B \in \mathcal{Q}_n} \nu_n(A \times B) \log \frac{\nu_n(A \times B)}{\nu(A \times B)}.$$

We have that under $\mathcal{H}_0$,

$$\begin{aligned}
& I_n(\nu_n, \nu) - I_n(\nu_n, \mu_{n,1} \times \mu_{n,2}) \\
= & \sum_{A \in \mathcal{P}_n} \sum_{B \in \mathcal{Q}_n} \nu_n(A \times B) \log \frac{\nu_n(A \times B)}{\nu(A \times B)} \\
& - \sum_{A \in \mathcal{P}_n} \sum_{B \in \mathcal{Q}_n} \nu_n(A \times B) \log \frac{\nu_n(A \times B)}{\mu_{n,1}(A) \cdot \mu_{n,2}(B)} \\
= & \sum_{A \in \mathcal{P}_n} \sum_{B \in \mathcal{Q}_n} \nu_n(A \times B) \log \frac{\mu_{n,1}(A) \cdot \mu_{n,2}(B)}{\nu(A \times B)} \\
= & \sum_{A \in \mathcal{P}_n} \sum_{B \in \mathcal{Q}_n} \nu_n(A \times B) \log \frac{\mu_{n,1}(A) \cdot \mu_{n,2}(B)}{\mu_1(A) \cdot \mu_2(B)},
\end{aligned}$$

therefore

$$\begin{aligned}
& I_n(\nu_n, \nu) - I_n(\nu_n, \mu_{n,1} \times \mu_{n,2}) \\
= & \sum_{A \in \mathcal{P}_n} \sum_{B \in \mathcal{Q}_n} \nu_n(A \times B) \left(\log \frac{\mu_{n,1}(A)}{\mu_1(A)} + \log \frac{\mu_{n,2}(B)}{\mu_2(B)} \right) \\
= & \sum_{A \in \mathcal{P}_n} \mu_{n,1}(A) \log \frac{\mu_{n,1}(A)}{\mu_1(A)} + \sum_{B \in \mathcal{Q}_n} \mu_{n,2}(B) \log \frac{\mu_{n,2}(B)}{\mu_2(B)} \\
= & I_n(\mu_{n,1}, \mu_1) + I_n(\mu_{n,1}, \mu_1) \\
\geq & 0.
\end{aligned}$$

3.1 Strongly Consistent Test

We refer to Tusnády (1977) and Barron (1989) who first discussed the exponential character of the tails of I_n. Kallenberg (1985), and Quine and Robinson (1985) proved that, for all $\varepsilon > 0$,

$$\mathbf{P}\{I_n(\mu_{n,1}, \mu_1) > \varepsilon\} \leq \binom{n + m_n - 1}{m_n - 1} e^{-n\varepsilon} \leq e^{m_n \log(n+m_n) - n\varepsilon}.$$

Note that using an alternative bound due to Barron (1989, Equation 3.5), we obtain under (10) and (11) that

$$\mathbf{P}\{I_n(\mu_{n,1}, \mu_1) > \varepsilon\} = e^{-n(\varepsilon + o(1))}, \tag{13}$$

such that

$$\lim_{n \to \infty} \frac{1}{n} \log \mathbf{P}\{I_n(\mu_{n,1}, \mu_1) > \varepsilon\} = -\varepsilon.$$

A large deviation based test can be introduced such that the test rejects the independence if

$$I_n(\nu_n, \mu_{n,1} \times \mu_{n,2}) \geq \frac{m_n m_n' (\log(n + m_n m_n') + 1)}{n}.$$

Under $\mathcal{H}_0$, we obtain a non-asymptotic bound for the tail of the distribution of $I_n(\nu_n, \mu_{n,1} \times \mu_{n,2})$:

$$\begin{aligned} & \mathbf{P}\left\{ I_n(\nu_n, \mu_{n,1} \times \mu_{n,2}) > \frac{m_n m'_n (\log(n + m_n m'_n) + 1)}{n} \right\} \\ \leq \; & \mathbf{P}\left\{ I_n(\nu_n, \nu) > \frac{m_n m'_n (\log(n + m_n m'_n) + 1)}{n} \right\} \\ \leq \; & e^{m_n m'_n \log(n + m_n m'_n) - n \frac{m_n m'_n (\log(n + m_n m'_n) + 1)}{n}} \\ = \; & e^{-m_n m'_n}. \end{aligned}$$

Therefore condition (7) implies

$$\sum_{n=1}^{\infty} \mathbf{P}\left\{ I_n(\nu_n, \mu_{n,1} \times \mu_{n,2}) > \frac{m_n m'_n (\log(n + m_n m'_n) + 1)}{n} \right\} < \infty,$$

and by the Borel-Cantelli lemma we have strong consistency under the null hypothesis.

Under the alternative hypothesis the proof of strong consistency follows from the inequality, also called Pinsker's inequality, which upper bounds the L_1 error in terms of I-divergence (cf. Csiszár, 1967; Kemperman, 1969; Kullback, 1967),

$$L_n(\nu_n, \mu_{n,1} \times \mu_{n,2})^2 \leq 2 I_n(\nu_n, \mu_{n,1} \times \mu_{n,2}).$$

Therefore,

$$\begin{aligned} \liminf_{n \to \infty} 2 I_n(\nu_n, \mu_{n,1} \times \mu_{n,2}) & \geq (\liminf_{n \to \infty} L_n(\nu_n, \mu_{n,1} \times \mu_{n,2}))^2 \\ & \geq 4 \sup_C |\nu(C) - \mu_1 \times \mu_2(C)|^2 > 0 \end{aligned}$$

a.s., where the supremum is taken over all Borel subsets C of $\mathbb{R}^d \times \mathbb{R}^{d'}$. In fact, under conditions (8), (9), and

$$I(\nu, \mu_1 \times \mu_2) < \infty,$$

one may get

$$\lim_{n \to \infty} I_n(\nu_n, \mu_{n,1} \times \mu_{n,2}) = I(\nu, \mu_1 \times \mu_2) > 0$$

a.s. (see Barron et al., 1992). Note that due to the form of the universal test threshold, strong consistency under $\mathcal{H}_1$ requires the condition

$$\lim_{n \to \infty} \frac{m_n m'_n}{n} \log(n + m_n m'_m) = 0,$$

as compared to (6).

3.2 Asymptotic α-level Test

Concerning the limit distribution, Inglot et al. (1990), and Györfi and Vajda (2002) proved that under (10) and (11),

$$\frac{2n I_n(\mu_{n,1}, \mu_1) - m_n}{\sqrt{2m_n}} \xrightarrow{\mathcal{D}} \mathcal{N}(0,1). \tag{14}$$

This implies that for any real valued x, under the conditions (6) and (12),

$$\begin{aligned}\mathbf{P}\left\{\frac{2nI_n(\nu_n,\mu_{n,1}\times\mu_{n,2})-m_nm_n'}{\sqrt{2m_nm_n'}}\geq x\right\} &\leq \mathbf{P}\left\{\frac{2nI_n(\nu_n,\nu)-m_nm_n'}{\sqrt{2m_nm_n'}}\geq x\right\}\\ &\to 1-\Phi(x),\end{aligned}$$

which results in a test rejecting the independence if

$$\frac{2nI_n(\nu_n,\mu_{n,1}\times\mu_{n,2})-m_nm_n'}{\sqrt{2m_nm_n'}}\geq\Phi^{-1}(1-\alpha),$$

or equivalently

$$I_n(\nu_n,\mu_{n,1}\times\mu_{n,2})\geq\frac{\Phi^{-1}(1-\alpha)\sqrt{2m_nm_n'}+m_nm_n'}{2n}.$$

Note that unlike the L_1 case, the ratio of the strong consistent threshold to the asymptotic threshold increases for increasing n.

4. Kernel-based Statistic

We now present a second class of approaches to independence testing, based on a kernel statistic. We can derive this statistic in a number of ways. The most immediate interpretation, introduced by Rosenblatt (1975), defines the statistic as the L_2 distance between the joint density estimate and the product of marginal density estimates. Let K and K' be density functions (called kernels) defined on $\mathbb{R}^d$ and on $\mathbb{R}^{d'}$, respectively. For the bandwidth $h>0$, define

$$K_h(x)=\frac{1}{h^d}K\left(\frac{x}{h}\right)\quad\text{and}\quad K_h'(y)=\frac{1}{h^{d'}}K'\left(\frac{y}{h}\right).$$

The Rosenblatt-Parzen kernel density estimates of the density of (X,Y) and X are respectively

$$f_n(x,y)=\frac{1}{n}\sum_{i=1}^n K_h(x-X_i)K_h'(y-Y_i)\text{ and }f_{n,1}(x)=\frac{1}{n}\sum_{i=1}^n K_h(x-X_i),\tag{15}$$

with $f_{n,2}(y)$ defined by analogy. Rosenblatt (1975) introduced the kernel-based independence statistic

$$T_n=\int_{\mathbb{R}^d\times\mathbb{R}^{d'}}(f_n(x,y)-f_{n,1}(x)f_{n,2}(y))^2dxdy.$$

Alternatively, defining

$$L_h(x)=\int_{\mathbb{R}^d}K_h(u)K_h(x-u)du=\frac{1}{h^d}\int_{\mathbb{R}^d}K(u)K(x-u)du$$

and $L_h'(y)$ by analogy, we may write the kernel test statistic

$$\begin{aligned}T_n=&\tfrac{1}{n^2}\textstyle\sum_{i=1}^n\sum_{j=1}^n L_h(X_i-X_j)L_h'(Y_i-Y_j)\\&-\tfrac{2}{n^3}\textstyle\sum_{i=1}^n\left(\sum_{j=1}^n L_h(X_i-X_j)\right)\left(\sum_{j=1}^n L_h'(Y_i-Y_j)\right)\\&+\left(\tfrac{1}{n^2}\textstyle\sum_{i=1}^n\sum_{j=1}^n L_h(X_i-X_j)\right)\left(\tfrac{1}{n^2}\textstyle\sum_{i=1}^n\sum_{j=1}^n L_h'(Y_i-Y_j)\right).\end{aligned}\tag{16}$$

Note that at independence, the expected value of the statistic is not zero, but

$$\begin{aligned}\mathbf{E}\{T_n\} &= \frac{n-1}{n^2}\left(L_h(0)-\mathbf{E}\{L_h(X_1-X_2)\}\right)\left(L'_h(0)-\mathbf{E}\{L'_h(Y_1-Y_2)\}\right) \\ &\leq n^{-1}L_h(0)L'_h(0) = (nh^d h^{d'})^{-1}\|K\|^2\|K'\|^2\end{aligned} \tag{17}$$

A second interpretation of the above statistic is as a smoothed difference between the joint characteristic function and the product of the marginals (Feuerverger, 1993; Kankainen, 1995; Ushakov, 1999). The characteristic function and Rosenblatt-Parzen window statistics can be quite similar: in fact, for appropriate smoothing and kernel choices and *fixed* n, they may be identical (Kankainen, 1995, p. 54, demonstrates this for a Gaussian kernel). That said, a number of important differences exist between the characteristic function-based statistic and that of Rosenblatt (1975). Most crucially, the kernel bandwidth is kept fixed for the characteristic function-based test, rather than decreasing as n rises (a decreasing bandwidth is needed to ensure consistency of the kernel density estimates), resulting in very different forms for the null distribution; and there are more restrictive conditions on the Rosenblatt-Parzen test statistic (Rosenblatt, 1975, conditions a.1-a.4). These issues are discussed in detail by Feuerverger (1993, Section 5) and Kankainen (1995, Section 5.4).

A further generalization of the statistic is presented by Gretton et al. (2005a, 2008), in terms of covariances between feature mappings of the random variables to reproducing kernel Hilbert spaces (RKHSs). We now briefly review this interpretation, beginning with some necessary terminology and definitions. Let $\mathcal{F}$ be an RKHS, with the continuous feature mapping $\phi(x) \in \mathcal{F}$ for each $x \in \mathbb{R}^d$, such that the inner product between the features is given by the positive definite kernel function $L_h(x,x') := \langle \phi(x), \phi(x') \rangle_{\mathcal{F}}$. Likewise, let $\mathcal{G}$ be a second RKHS on $\mathbb{R}^{d'}$ with kernel $L'_h(\cdot,\cdot)$ and feature map $\psi(y)$. Following Baker (1973) and Fukumizu et al. (2004), the cross-covariance operator $C_\nu : \mathcal{G} \to \mathcal{F}$ for the measure ν is defined such that for all $f \in \mathcal{F}$ and $g \in \mathcal{G}$,

$$\langle f, C_\nu g \rangle_{\mathcal{F}} = \mathbf{E}\left([f(X)-\mathbf{E}(f(X))]\,[g(Y)-\mathbf{E}(g(Y))]\right).$$

The cross-covariance operator can be thought of as a generalisation of a cross-covariance matrix between the (potentially infinite dimensional) feature mappings $\phi(x)$ and $\psi(y)$.

To see how this operator may be used to test independence, we recall the following characterization of independence (see, e.g., Jacod and Protter, 2000, Theorem 10.1e):

Theorem 5 *The random variables X and Y are independent if and only if* $\mathrm{cov}(f(X),g(Y)) = 0$ *for any pair (f,g) of bounded, continuous functions.*

While the bounded continuous functions are too rich a class to permit the construction of a covariance-based test statistic on a sample, Fukumizu et al. (2008) and Sriperumbudur et al. (2008) show that when $\widetilde{\mathcal{F}}$ is the unit ball in a *characteristic*[2] RKHS $\mathcal{F}$, and $\widetilde{\mathcal{G}}$ the unit ball in a characteristic RKHS $\mathcal{G}$, then

$$\sup_{f\in\widetilde{\mathcal{F}},g\in\widetilde{\mathcal{G}}} \mathbf{E}\left([f(X)-\mathbf{E}(f(X))]\,[g(Y)-\mathbf{E}(g(Y))]\right) = 0 \qquad \Longleftrightarrow \qquad \nu = \mu_1 \times \mu_2.$$

2. The reader is referred to Fukumizu et al. (2008) and Sriperumbudur et al. (2008) for conditions under which an RKHS is characteristic. We note here that the Gaussian kernel on $\mathbb{R}^d$ has this property, and provide further discussion below.

In other words, the spectral norm of the covariance operator C_ν between characteristic RKHSs is zero only at independence. Rather than the maximum singular value, we may use the squared Hilbert-Schmidt norm (the sum of the squared singular values), which has a population expression

$$\begin{aligned} \mathrm{H}(\nu;\mathcal{F},\mathcal{G}) &= \mathbf{E}\{L_h(X_1-X_2)L'_h(Y_1-Y_2)\} - 2\mathbf{E}\left\{\mathbf{E}\{L_h(X_1-X_2)|X_1\}\mathbf{E}\{L_h(Y_1-Y_2)|Y_1\}\right\} \\ &\quad +\mathbf{E}\{L_h(X_1-X_2)\}\mathbf{E}\{L'_h(Y_1-Y_2)\} \end{aligned}$$

(see Gretton et al., 2005a, Lemma 1): we call this the Hilbert-Schmidt independence criterion (HSIC).

The test statistic in (16) is then interpreted as a biased empirical estimate of $\mathrm{H}(\nu;\mathcal{F},\mathcal{G})$. Clearly, when K_h and K'_h are continuous and square integrable densities, the induced kernels L_h and L'_h are continuous positive definite RKHS kernels. However, as long as L_h and L'_h are characteristic kernels, then $\mathrm{H}(\nu;\mathcal{F},\mathcal{G}) = 0$ iff X and Y independent. The Gaussian and Laplace kernels are characteristic on $\mathbb{R}^d$ (Fukumizu et al., 2008), and universal kernels (in the sense of Steinwart, 2001) are characteristic on compact domains (Gretton et al., 2005a, Theorem 6). Sriperumbudur et al. (2008) provide a simple necessary and sufficient condition for a bounded continuous translation invariant kernel to be characteristic on $\mathbb{R}^d$: the Fourier spectrum of the kernel must be supported on the entire domain. Note that characteristic kernels need not be inner products of square integrable probability density functions: an example is the kernel

$$L_h(x_1,x_2) = \exp(x_1^T x_2/h)$$

from Steinwart (2001, Section 3, Example 1), which is universal, hence characteristic on compact subsets of $\mathbb{R}^d$. Moreover, an appropriate choice of kernels allows testing of dependence in non-Euclidean settings, such as distributions on strings and graphs (Gretton et al., 2008).

Finally, while we have focused on a kernel dependence measure based on the covariance, alternative kernel dependence measures exist based on the canonical correlation. Dauxois and Nkiet (1998) propose the canonical correlation between variables in a spline-based RKHS as a statistic for an independence test: this dependence measure follows the suggestion of Rényi (1959), but with a more restrictive pair of function classes used to compute the correlation (rather than the set of all square integrable functions). The variables are assumed in this case to be univariate. Likewise, Bach and Jordan (2002) use the canonical correlation between RKHS feature mappings as a measure of dependence between pairs of random variables (although they do not address the problem of hypothesis testing). Bach and Jordan employ a different regularization strategy to Dauxois and Nkiet, however, which is a roughness penalty on the canonical correlates, rather than projection on a finite basis. For an appropriate rate of decay of the regularization with increasing sample size, the empirical estimate of the canonical correlation converges in probability (Leurgans et al., 1993; Fukumizu et al., 2007). Fukumizu et al. (2008) provide a consistent RKHS-based estimate of the mean-square contingency, which is also based on the canonical correlation. This final independence measure is asymptotically independent of the kernel choice. When used as a statistic in an independence test, the kernel contingency was found empirically to have power superior to the HSIC-based test.

4.1 Strongly Consistent Test

The empirical statistic T_n was previously shown by Gretton et al. (2005a) to converge in probability to its expectation with rate $1/\sqrt{n}$. Given $0 \le L_h(0)L'_h(0) \le 1$, the corresponding result is

$$\mathbf{P}(T_n - \mathbf{E}(T_n) \ge \varepsilon^2) \le 3e^{-0.24n\varepsilon^4},$$

which follows from the straightforward application of a bound by Hoeffding (1963, p. 25). We now provide a more refined bound which scales better with ε, and is thus tighter when the bandwidth h decreases.

We will obtain our results for the semi-statistic

$$\tilde{T}_n = \|f_n(\cdot,\cdot) - \mathbf{E}f_n(\cdot,\cdot)\|^2,$$

since under the null hypothesis,

$$\begin{aligned}
\sqrt{T_n} &= \|f_n(\cdot,\cdot) - f_{n,1}(\cdot)f_{n,2}(\cdot)\| \\
&\leq \|f_n(\cdot,\cdot) - \mathbf{E}f_n(\cdot,\cdot)\| + \|f_{n,1}(\cdot)f_{n,2}(\cdot) - \mathbf{E}f_{n,1}(\cdot)\mathbf{E}f_{n,2}(\cdot)\| \\
&\leq \sqrt{\tilde{T}_n} + \|f_{n,1}(\cdot)(f_{n,2}(\cdot) - \mathbf{E}f_{n,2}(\cdot))\| + \|(f_{n,1}(\cdot) - \mathbf{E}f_{n,1}(\cdot))\mathbf{E}f_{n,2}(\cdot)\| \\
&= \sqrt{\tilde{T}_n} + \|f_{n,1}(\cdot)\|\,\|f_{n,2}(\cdot) - \mathbf{E}f_{n,2}(\cdot)\| + \|f_{n,1}(\cdot) - \mathbf{E}f_{n,1}(\cdot)\|\,\|\mathbf{E}f_{n,2}(\cdot)\| \\
&\approx \sqrt{\tilde{T}_n}.
\end{aligned}$$

Theorem 6 *For any* $\varepsilon > 0$,

$$\mathbf{P}\left\{\tilde{T}_n \geq \left(\varepsilon + \mathbf{E}\left\{\sqrt{\tilde{T}_n}\right\}\right)^2\right\} \leq e^{-n\varepsilon^2 \big/ (2L_h(0)L'_h(0))}.$$

Proof We apply the McDiarmid inequality (cf. McDiarmid, 1989): Let $Z_1, \ldots, Z_n$ be independent random variables taking values in a set A and assume that $f : A^n \to \mathbb{R}$ satisfies

$$\sup_{\substack{z_1,\ldots,z_n,\\ z'_i \in A}} |f(z_1,\ldots,z_n) - f(z_1,\ldots,z_{i-1},z'_i,z_{i+1},\ldots,z_n)| \leq c_i,\ 1 \leq i \leq n.$$

Then, for all $\varepsilon > 0$,

$$\mathbf{P}\{f(Z_1,\ldots,Z_n) - \mathbf{E}f(Z_1,\ldots,Z_n) \geq \varepsilon\} \leq e^{-2\varepsilon^2 \big/ \sum_{i=1}^n c_i^2}.$$

Because of

$$\begin{aligned}
\sqrt{\tilde{T}_n} &= \|f_n(\cdot,\cdot) - \mathbf{E}f_n(\cdot,\cdot)\| \\
&= \|\frac{1}{n}\sum_{i=1}^n K_h(\cdot - X_i)K'_h(\cdot - Y_i) - \mathbf{E}f_n(\cdot,\cdot)\| \\
&\leq \|\frac{1}{n}K_h(\cdot - X_1)K'_h(\cdot - Y_1)\| + \|\frac{1}{n}\sum_{i=2}^n K_h(\cdot - X_i)K'_h(\cdot - Y_i) - \mathbf{E}f_n(\cdot,\cdot)\|
\end{aligned}$$

we can apply McDiarmid inequality with

$$\frac{2}{n}\|K_h(\cdot - X_1)K'_h(\cdot - Y_1)\| = \frac{2}{n}\sqrt{L_h(0)L'_h(0)} =: c_i = c_1,$$

where we note that the c_i are independent of i, and can be replaced by a single c_1. Thus,

$$\begin{aligned}
\mathbf{P}\left\{\sqrt{\tilde{T}_n} - \mathbf{E}\left\{\sqrt{\tilde{T}_n}\right\} \geq \varepsilon\right\} &\leq e^{-2\varepsilon^2 \big/ \sum_{i=1}^n c_i^2} \\
&= e^{-2\varepsilon^2 \big/ (nc_1^2)} \\
&\leq e^{-n\varepsilon^2 \big/ (2L_h(0)L'_h(0))}.
\end{aligned}$$

This implies

$$\mathbf{P}\left\{\tilde{T}_n \geq \left(\varepsilon + \mathbf{E}\left\{\sqrt{\tilde{T}_n}\right\}\right)^2\right\} \leq e^{-n\varepsilon^2/(2L_h(0)L_h'(0))}.$$

■

From these inequalities we can derive a test of independence. Choose ε such that

$$n\varepsilon^2/(2L_h(0)L_h'(0)) = 2\ln n.$$

Because of

$$\mathbf{E}\{\tilde{T}_n\} \approx \mathbf{E}\{T_n\} \leq \frac{L_h(0)L_h'(0)}{n},$$

we choose the threshold

$$\left(\sqrt{\frac{L_h(0)L_h'(0)4\ln n}{n}} + \sqrt{\frac{L_h(0)L_h'(0)}{n}}\right)^2 = \frac{L_h(0)L_h'(0)}{n}(\sqrt{4\ln n}+1)^2,$$

that is, we reject the hypothesis of independence if

$$T_n > \frac{\|K\|^2\|K'\|^2}{nh^d h^{d'}}(\sqrt{4\ln n}+1)^2.$$

It follows from

$$\begin{aligned}
& \mathbf{P}\left\{T_n \geq \frac{L_h(0)L_h'(0)}{n}(\sqrt{4\ln n}+1)^2\right\} \\
\approx\ & \mathbf{P}\left\{\tilde{T}_n \geq \left(\sqrt{\frac{L_h(0)L_h'(0)4\ln n}{n}} + \sqrt{\frac{L_h(0)L_h'(0)}{n}}\right)^2\right\} \\
\leq\ & \mathbf{P}\left\{\tilde{T}_n \geq \left(\sqrt{\frac{L_h(0)L_h'(0)4\ln n}{n}} + \sqrt{\mathbf{E}\{\tilde{T}_n\}}\right)^2\right\} \\
\leq\ & \mathbf{P}\left\{\tilde{T}_n \geq \left(\sqrt{\frac{L_h(0)L_h'(0)4\ln n}{n}} + \mathbf{E}\left\{\sqrt{\tilde{T}_n}\right\}\right)^2\right\} \\
\leq\ & e^{-2\ln n}
\end{aligned}$$

that this test of independence is strongly consistent.

Under the alternative hypothesis, there are two cases:

- If $h \to 0$ and the density f exists and is square integrable, then

$$T_n \to \|f - f_1 f_2\|^2 > 0$$

a.s. The strong consistency is not distribution-free, since ν must have a square integrable density.

- If h is fixed, the strong law of large numbers implies

$$\begin{aligned} T_n &\rightarrow \mathbf{E}\{L_h(X_1-X_2)L'_h(Y_1-Y_2)\} - 2\mathbf{E}\{\mathbf{E}\{L_h(X_1-X_2)|X_1\}\mathbf{E}\{L_h(Y_1-Y_2)|Y_1\}\} \\ &\quad +\mathbf{E}\{L_h(X_1-X_2)\}\mathbf{E}\{L'_h(Y_1-Y_2)\} \\ &=: \mathrm{H}(\nu;\mathcal{F},\mathcal{G}) \end{aligned}$$

  If K_h and K'_h are continuous and square integrable densities, the induced kernels L_h and L'_h are continuous positive definite kernels: $\mathrm{H}(\nu;\mathcal{F},\mathcal{G})$ is then the squared Hilbert-Schmidt norm of the covariance operator for ν. We may replace L_h and L'_h with any *characteristic kernels* (in the sense of Fukumizu et al., 2008; Sriperumbudur et al., 2008), however, and retain the property $\mathrm{H}(\nu;\mathcal{F},\mathcal{G}) = 0$ iff X and Y independent. In this case, the strong consistency is distribution-free.

4.2 Approximately α-level Tests

We now describe the asymptotic limit distribution of the test statistic T_n in (16). We address two cases: first, when the kernel bandwidth decreases, and second, when it remains fixed.

Let us consider the case where $K_h(x)$ and $K'_h(y)$ are intended to be used in a Rosenblatt-Parzen density estimator, as in (15). The corresponding density estimates in T_n are mean square consistent if $h = h_n$ such that

$$h_n \rightarrow 0 \quad \text{and} \quad nh_n^d h_n^{d'} \rightarrow \infty. \tag{18}$$

Based on the results of Hall (1984), Cotterill and Csörgő (1985) and Beirlant and Mason (1995), we expect that, under these consistency conditions,

$$\frac{T_n - \mathbf{E}\{T_n\}}{\sqrt{\mathrm{var}(T_n)}} \xrightarrow{\mathcal{D}} \mathcal{N}(0,1).$$

We next calculate $\mathrm{var}(T_n) \approx \mathrm{var}(\tilde{T}_n)$. Under the null hypothesis,

$$\begin{aligned} \tilde{T}_n &= \|f_n(\cdot,\cdot) - \mathbf{E}f_n(\cdot,\cdot)\|^2 \\ &= \left\| \frac{1}{n}\sum_{i=1}^n (K_h(\cdot - X_i)K'_h(\cdot - Y_i) - \mathbf{E}\{K_h(\cdot - X)K'_h(\cdot - Y)\}) \right\|^2 \\ &= \frac{1}{n^2}\sum_{i=1}^n\sum_{j=1}^n \Big((K_h(\cdot - X_i)K'_h(\cdot - Y_i) - \mathbf{E}\{K_h(\cdot - X)K'_h(\cdot - Y)\}) \times \\ &\qquad (K_h(\cdot - X_j)K'_h(\cdot - Y_j) - \mathbf{E}\{K_h(\cdot - X)K'_h(\cdot - Y)\}) \Big) \\ &=: \frac{1}{n^2}\sum_{i=1}^n\sum_{j=1}^n M_h(X_i,Y_i,X_j,Y_j), \end{aligned}$$

and therefore

$$\mathrm{var}(\tilde{T}_n) = \frac{1}{n^4}\sum_{i=1}^n\sum_{j=1}^n\sum_{i'=1}^n\sum_{j'=1}^n \mathrm{cov}(M_h(X_i,Y_i,X_j,Y_j), M_h(X_{i'},Y_{i'},X_{j'},Y_{j'})).$$

One can check that

$$\mathrm{cov}(M_h(X_i,Y_i,X_j,Y_j), M_h(X_{i'},Y_{i'},X_{j'},Y_{j'})) = 0$$

unless $(i,j) = (i',j')$ or $(i,j) = (j',i')$. Thus,

$$\begin{aligned}\mathrm{var}(\tilde{T}_n) &= \frac{1}{n^4}\left(n\mathrm{var}(M_h(X_1,Y_1,X_1,Y_1)) + 2n(n-1)\mathrm{var}(M_h(X_1,Y_1,X_2,Y_2))\right)\\ &\approx \frac{2}{n^2}\mathrm{var}(M_h(X_1,Y_1,X_2,Y_2)).\end{aligned}$$

If $h \to 0$ then

$$\frac{2}{n^2}\mathrm{var}(M_h(X_1,Y_1,X_2,Y_2)) \approx \frac{2\|f\|^2}{n^2 h^d h^{d'}}, \tag{19}$$

therefore a possible form for the asymptotic normal distribution is

$$nh^{d/2}h^{d'/2}(T_n - \mathbf{E}\{T_n\})/\sigma \xrightarrow{\mathcal{D}} \mathcal{N}(0,1),$$

where

$$\sigma^2 = 2\|f\|^2.$$

Thus the asymptotic α-level test rejects the null hypothesis if

$$T_n > \mathbf{E}\{T_n\} + \frac{\sigma}{nh^{d/2}h^{d'/2}}\Phi^{-1}(1-\alpha),$$

where $\mathbf{E}\{T_n\}$ may be replaced by its upper bound,

$$L_h(0)L'_h(0)/n = \|K\|^2\|K'\|^2/(nh^d h^{d'}).$$

The only problem left is that the threshold is not distribution-free: σ depends on the unknown f. The simplest distribution-free bound for the variance,

$$\sigma^2 \leq \frac{\|K\|^4\|K'\|^4}{n^2 h^{2d} h^{2d'}}$$

is unsatisfactory since its performance as a function of h is worse than the result (19). An improved distribution-free bound on the variance (for both fixed and decreasing h) is a topic for future research: we give an empirical estimate below (Equation 20) for use in asymptotic hypothesis tests.

We now consider the case of fixed h. Following Feuerverger (1993); Serfling (1980), the distribution of T_n under $\mathcal{H}_0$ is

$$nT_n \xrightarrow{D} \sum_{l=1}^{\infty} \lambda_l z_l^2,$$

where $z_l \sim \mathcal{N}(0,1)$ i.i.d., and λ_l are the solutions to an eigenvalue problem depending on the unknown distribution of X and Y (see Gretton et al., 2008, Theorem 2 for details).

A difficulty in using the statistic (16) in a hypothesis test therefore arises due to the form of the null distribution of the statistic, which is a function of the unknown distribution over X and Y, whether or not h is fixed. In the case of h decreasing according to (18), we may use an empirical estimate of the variance of T_n under $\mathcal{H}_0$ due to Gretton et al. (2008, Theorem 4). Denoting by $\odot$ the entrywise matrix product and $A^{\cdot 2}$ the entrywise matrix power,

$$\mathrm{var}(T_n) = \mathbf{1}^\top\left(\mathbf{B} - \mathrm{diag}(\mathbf{B})\right)\mathbf{1}, \tag{20}$$

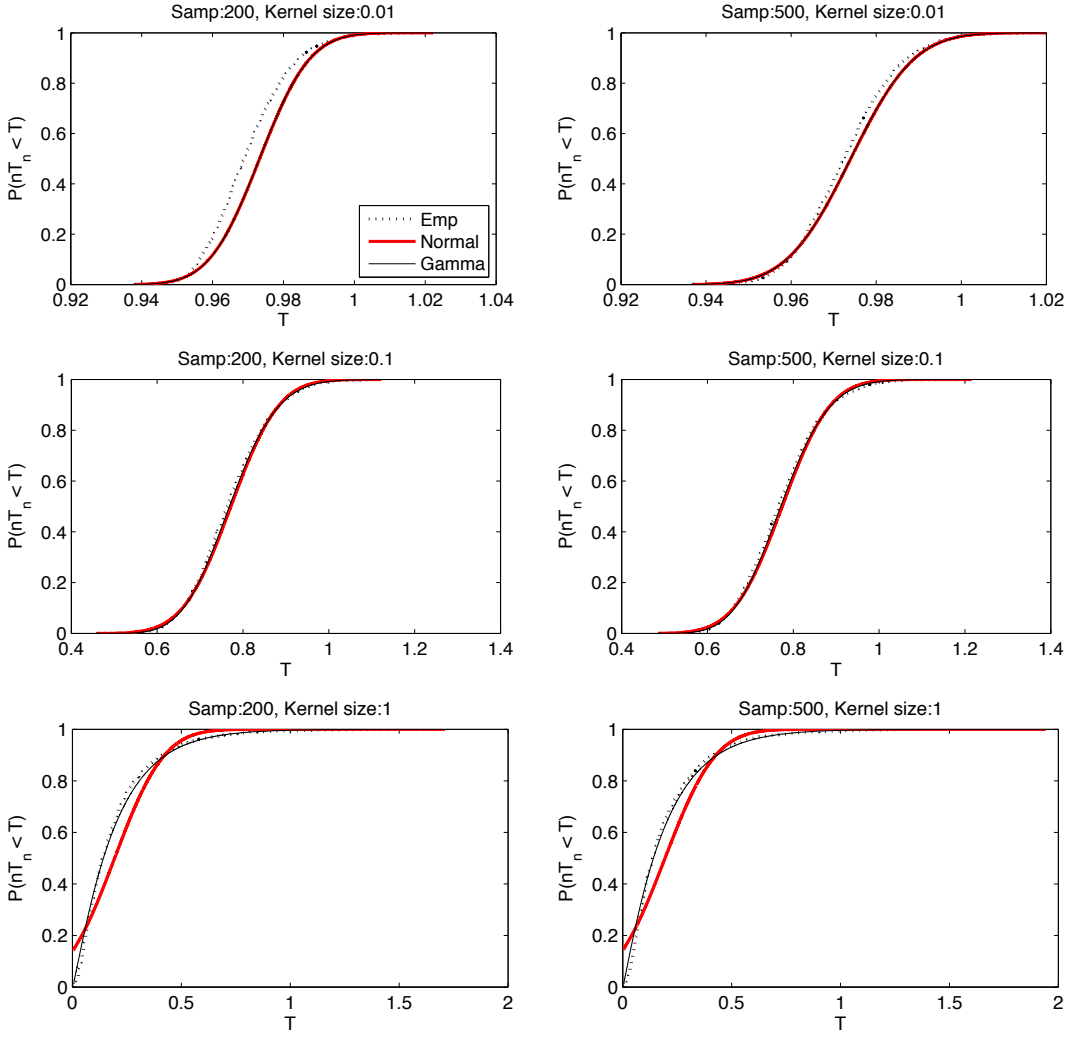

Figure 1: Simulated cumulative distribution function of T_n (*Emp*) under $\mathcal{H}_0$ for $n = 200$ (left column) and $n = 500$ (right column), compared with the two-parameter Gamma distribution (*Gamma*) and the Normal distribution (*Normal*). The empirical CDF was obtained empirically using 5000 independent draws of T_n. Both the parametric approximations are fit using the mean and variance in Equations (17) and (20). "Samp" is the number n of samples, and the bandwidth is h.

where

$$\mathbf{B} = \left((\mathbf{HLH}) \odot \left(\mathbf{HL}'\mathbf{H}\right)\right)^{\cdot 2},$$

$\mathbf{L}$ is a matrix with entries $L_h(X_i - X_j)$, $\mathbf{L}'$ is a matrix with entries $L'_h(Y_i - Y_j)$, $\mathbf{H} = \mathbf{I} - n^{-1}\mathbf{1}\mathbf{1}^\top$ is a centering matrix, and $\mathbf{1}$ an $n \times 1$ vector of ones.

Two approaches have been proposed in the case of fixed h to obtain appropriate quantiles of the null distribution for hypothesis testing: repeated shuffling of the sample (Feuerverger, 1993), and

approximation by a two-parameter Gamma density (Kankainen, 1995),

$$nT_n \sim \frac{x^{\alpha-1}e^{-x/\beta}}{\beta^\alpha \Gamma(\alpha)}$$
$$\text{where} \quad \alpha = \frac{(\mathbf{E}\{T_n\})^2}{\text{var}(T_n)}, \quad \beta = \frac{n\text{var}(T_n)}{\mathbf{E}\{T_n\}},$$

and $\mathbf{E}\{T_n\}$ is given in (17). This Gamma approximation was found by Gretton et al. (2008) to perform identically on the Section 5 benchmark data to the more computationally expensive approach of Feuerverger (1993). We emphasize, however, that this approximation is a heuristic: no guarantees are provided regarding the asymptotic performance of this approximation in terms of Type II error, nor is it established under what conditions the approximation fails.

We end this section with an empirical comparison between the Normal and two-parameter Gamma null distribution approximations, and the null CDF generated by repeated independent samples of T_n. We chose X and Y to be independent and univariate, with X having a uniform distribution and Y being a symmetric bimodal mixture of Gaussians. Both variables had zero mean and unit standard deviation. Results are plotted in Figure 1.

We observe that as the bandwidth increases, the Gamma approximation of T_n becomes more accurate (although it is always good for large quantiles, which is the region most important to a hypothesis test). The Normal approximation is very close to the Gamma approximation for small bandwidths, but is less accurate (with respect to both the Gamma distribution and the simulated CDF) for larger bandwidths. Finally, for the smallest bandwidth ($h = 0.01$), both approximate null distributions become more accurate for increasing n (for larger kernel sizes, the effect is too small to see on the plots). We will return to these points in the next section when analysing our experimental results.

5. Numerical Results

In comparing the independence tests, we made use of the multidimensional benchmark data proposed by Gretton et al. (2008). We tested the independence in two, four, and six dimensions (i.e., $d \in 1,2,3$ and $d = d'$). The data were constructed as follows. First, we generated n samples of two independent univariate random variables, each drawn at random from the ICA benchmark densities of Bach and Jordan (2002, Figure 5): these included super-Gaussian, sub-Gaussian, multimodal, and unimodal distributions, with the common property of zero mean and unit variance. The densities are described in Table 5, as reproduced from Gretton et al. (2005b, Table 3). Second, we mixed these random variables using a rotation matrix parametrised by an angle θ, varying from 0 to $\pi/4$ (a zero angle meant the data were independent, while dependence became easier to detect as the angle increased to $\pi/4$: see the two plots in Figure 2). Third, in the cases $d = 2$ and $d = 3$, independent Gaussian noise of zero mean and unit variance was used to fill the remaining dimensions, and the resulting vectors were multiplied by independent random two- or three-dimensional orthogonal matrices, to obtain random vectors X and Y dependent across all observed dimensions. We emphasise that classical approaches (such as Spearman's ρ or Kendall's τ) are unable to find this dependence, since the variables are uncorrelated; nor can we recover the subspace in which the variables are dependent using PCA, since this subspace has the same second order properties as the noise. We investigated sample sizes $n = 128, 512, 1024$, and 2048.

Table 1: Labels of distributions used in the independence test benchmarks, and their respective kurtoses. All distributions have zero mean and unit variance.

We compared three different asymptotic independence testing approaches based on space partitioning: the L_1 test, denoted *L1*; the log likelihood test *Like*; and a third test, *Pears*, based on a conjecture regarding the asymptotic distribution of the Pearson χ^2 statistic

$$\chi^2_n(\nu_n, \mu_{n,1} \times \mu_{n,2}) \quad = \quad \sum_{A \in \mathcal{P}_n} \sum_{B \in Q_n} \frac{(\nu_n(A \times B) - \mu_{n,1}(A) \cdot \mu_{n,2}(B))^2}{\mu_{n,1}(A) \cdot \mu_{n,2}(B)}$$

(see Appendix B for details, and for a further conjecture regarding a strongly consistent test for the χ^2_n statistic). The number of discretisations per dimension was set at $m_n = m'_n = 4$, besides in the $n = 128, d = 2$ case and the $d = 3$ cases, where it was set at $m_n = m'_n = 3$: for the latter values of n and d, there were too few samples per bin when a greater number of partitions were used, causing poor performance. We divided our spaces $\mathbb{R}^d$ and $\mathbb{R}^{d'}$ into roughly equiprobable bins. Further increases in the number of partitions per dimension, where sufficient samples were present to justify this (i.e., the $n = 512, d = 1$ case), resulted only in very minor shifts in performance.

We compared the partitioning approaches with the kernel approach from Section 4, using both the Gamma *Ker(g)* and Normal *Ker(n)* approximations to the null distribution. Our kernels were Gaussian for both X and Y, with bandwidths set to the median distance between samples of the respective variables. Note that a more sophisticated but computationally costly approach to bandwidth selection is described by Fukumizu et al. (2008), which involves matching the closed-form expression for the variance of T_n in (20) with an estimate obtained by data shuffling.

Results are plotted in Figure 3 (average over 500 independent generations of the data). The y-intercept on these plots corresponds to the acceptance rate of $\mathcal{H}_0$ at independence, or $1 - (\text{Type I error})$,

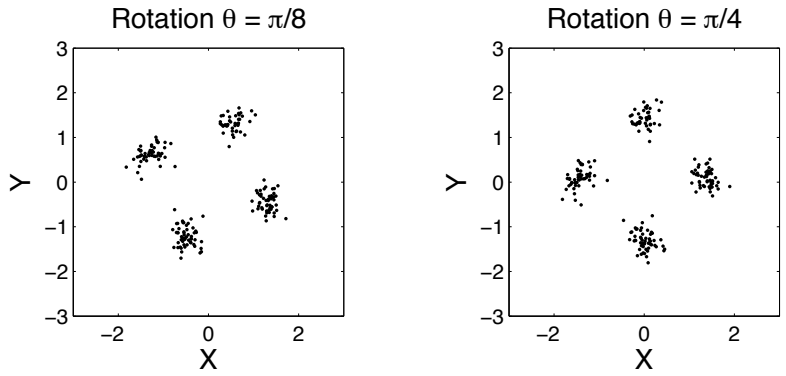

Figure 2: Example data set for $d = d' = 1, n = 200$, and rotation angles $\theta = \pi/8$ (left) and $\theta = \pi/4$ (right). In this case, both sources are mixtures of two Gaussians (source *(g)* in Gretton et al., 2005b, Table 3).

and should be close to the design parameter of $1 - \alpha = 0.95$. Elsewhere, the plots indicate acceptance of $\mathcal{H}_0$ where the underlying variables are dependent, that is, the Type II error.

As expected, we observe dependence becomes easier to detect as θ increases from 0 to $\pi/4$, when n increases, and when d decreases. Although no tests are reliable for small θ, several tests do well as θ approaches $\pi/4$ (besides the case of $n = 128,\ d = 2$). The L_1 test has a lower Type II error than the χ^2 test when the number of samples per partition is small ($n = 128, d = 1$, $n = 128, d = 2$, and $n = 1024, d = 3$), but this advantage is lessened for larger numbers of samples per partition. The log-likelihood test generally has the lowest Type II error of the three partition-based tests, however it gives a Type I error larger than the design parameter of 0.05 when the number of samples per bin is insufficient: this problem is severe in the case $n = 1024$ and $d = 3$, but can also be observed at $n = 2048, d = 3$ (for larger sample sizes $n = 3072, d = 3$ and $n = 4096, d = 3$, the Type I error of the log-likelihood test was at or below the design value). This suggests the log-likelihood test is more susceptible to bias for small numbers of samples per bin than the L_1 and χ^2 tests. In the remaining cases, performance of the log-likelihood test and the L_1 test is comparable, besides in the case $n = 512, d = 2$, where the log-likelihood test has an advantage.

The superior performance of the log-likelihood test compared with the χ^2 test (in the cases $d = 1$ and $d = 2$) might arise due to the different convergence properties of the two test statistics. In particular, we note the superior convergence behaviour of the goodness-of-fit statistic for the log likelihood (Equation 13), as compared with the χ^2 statistic (Equation 24 in Appendix B), in terms of the dependence of the latter on the number m_n of partitions used. By analogy, we anticipate the log-likelihood independence statistic $I_n(\nu_n, \mu_{n,1} \times \mu_{n,2})$ will also converge faster than the Pearson χ^2 independence statistic $\chi^2_n(\nu_n, \mu_{n,1} \times \mu_{n,2})$, and thus provide better test performance. A more formal discussion of this behaviour is a topic for future research.

In all cases, the kernel-based test has the lowest Type II error.[3] That said, one should bear in mind the kernel test thresholds require $\mathbf{E}\{T_n\}$ and $\mathrm{var}(T_n)$, which are unknown and must be estimated from the data using Equations (17) and (20), respectively. In other words, unlike the L_1

3. Aside from $n = 1024$ and $d = 3$, where the log-likelihood has a lower Type II error: we disregard this result since it is due to the log-likelihood test being affected by bias, as discussed above.

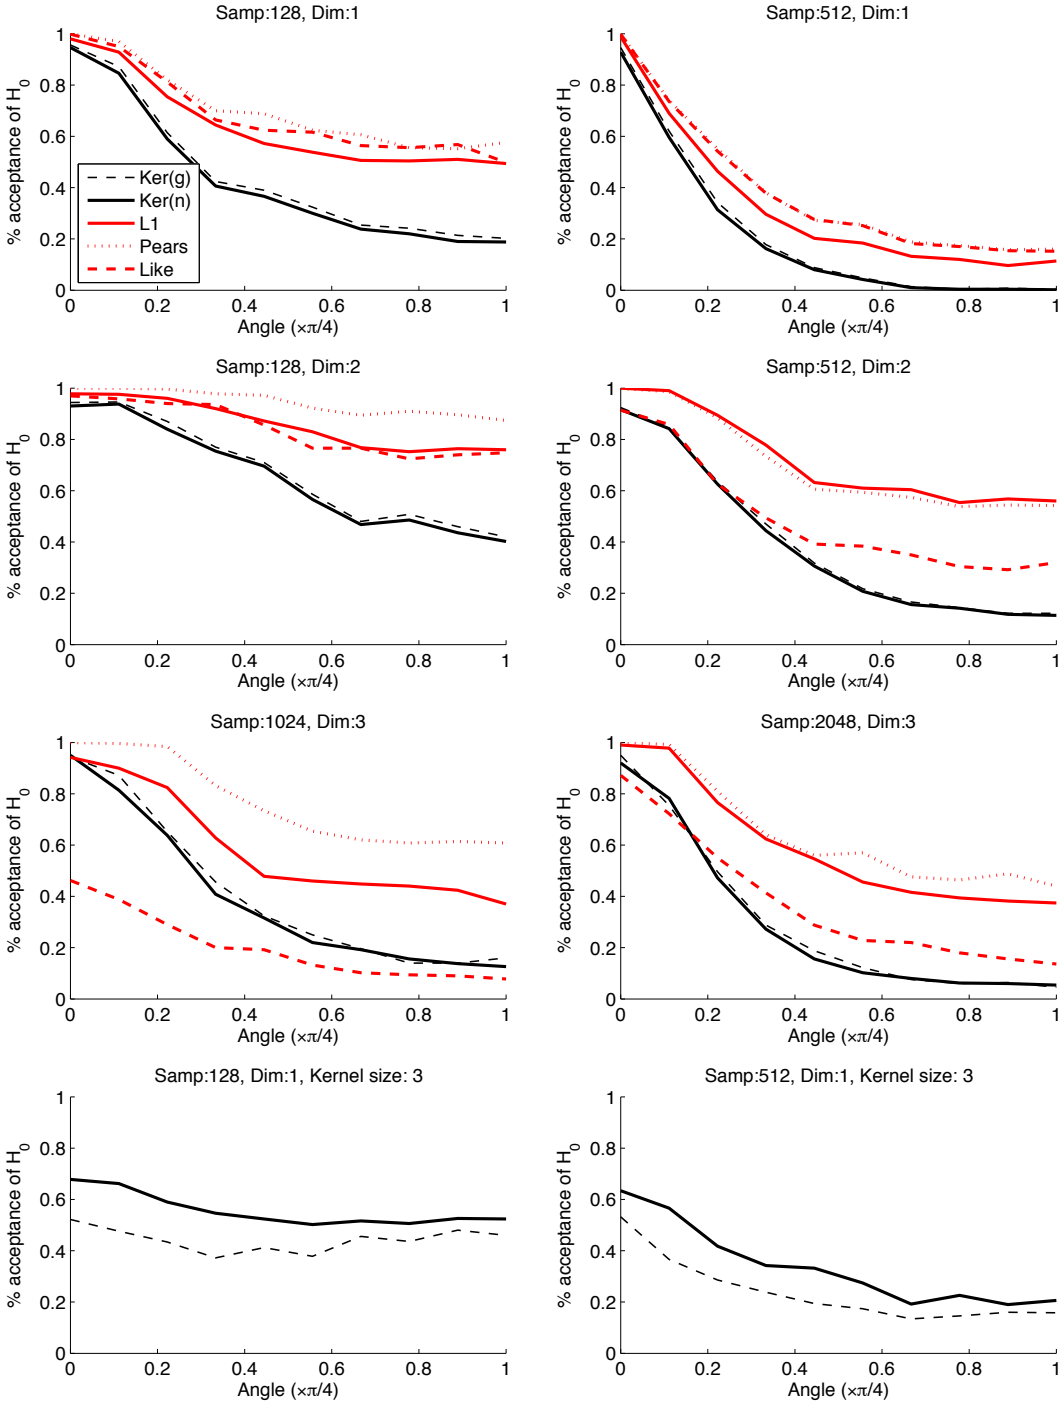

Figure 3: Rate of acceptance of $\mathcal{H}_0$ for the *Ker(g)*, *Ker(n)*, *L1*, *Pears*, and *Like* tests. "Samp" is the number n of samples, and "dim" is the dimension $d = d'$ of x and y. In the final row, the performance of the *Ker(g)* and *Ker(n)* tests is plotted for a large bandwidth $h = 3$, and $\tilde{\alpha} = 0.5$, to illustrate the difference between the Normal and two-parameter Gamma approximations to the null distribution.

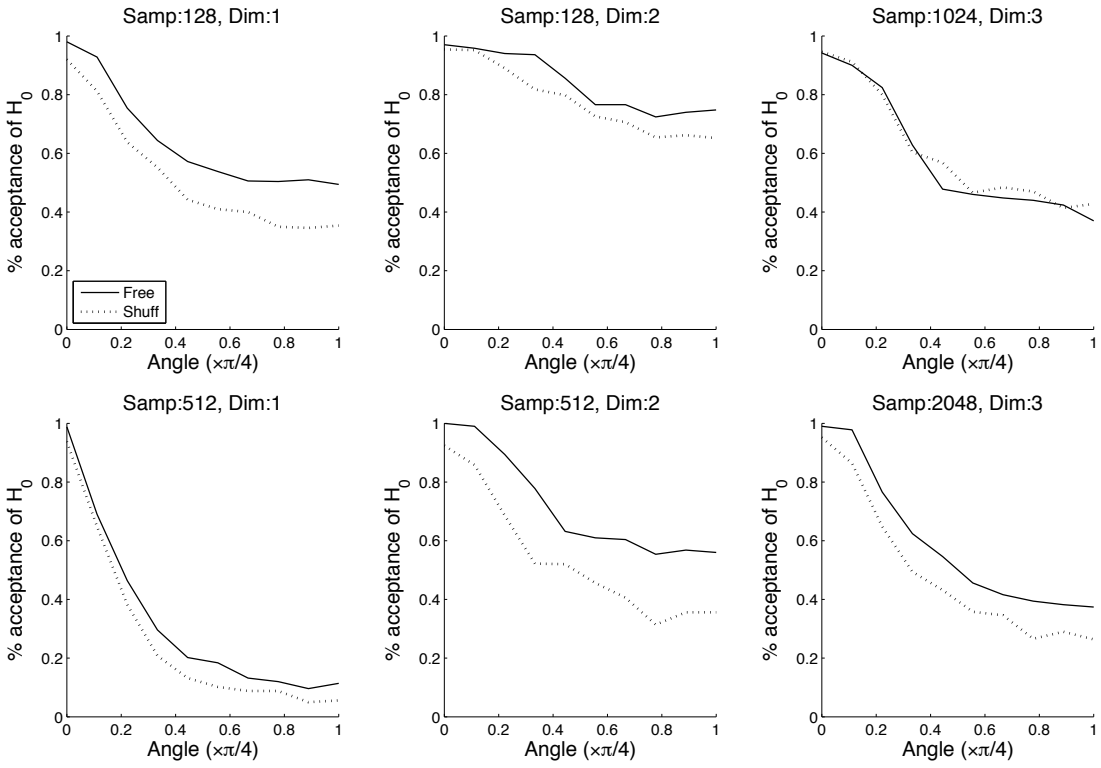

Figure 4: Rate of acceptance of $\mathcal{H}_0$ for the distribution-free (*Free*) and shuffling-based (*Shuff*) null distribution quantiles, using the L1 test statistic. "Samp" is the number n of samples, and "dim" is the dimension $d = d'$ of x and y.

and log likelihood tests, the kernel test thresholds in our experiments are themselves finite sample estimates (which we have not attempted to account for, and which could impact on test performance). Moreover, the Gamma approximation to the null distribution is simply a heuristic, with no asymptotic guarantees.

It is of interest to further investigate the null distribution approximation strategies for the kernel tests, and in particular to determine the effect on test performance of the observations made in Figure 1. Since the median distance between sample points was small enough in our previous experiments for the Normal and Gamma estimates to be very similar, we used an artificially high kernel bandwidth $h = 3$. In addition, we employed a much lower $\tilde{\alpha} = 0.5$, since this provided a more visible performance difference. The final row of Figure 3 shows the resulting test performance. We recall from Figure 1 that for large kernel sizes and $\tilde{\alpha} = 0.5$, the Gaussian approximation returns a larger threshold than the true CDF would require, and thus the Normal distribution has a lower Type I error (the error for very small values of α is in the opposite direction, but had a less pronounced effect in our experiments). The large bandwidth required to observe this behaviour results in a substantial performance penalty on the Type II error, however, and would not be used in practice.

An alternative approach to obtaining null distribution quantiles for test thresholds is via a shuffling procedure: the ordering of the $Y_1, \ldots, Y_n$ sample is permuted repeatedly while that of $X_1, \ldots, X_n$ sample is kept fixed, and the $1 - \alpha$ quantile is obtained from the resulting estimated cumulative distribution function of the test statistic. Again, we emphasize that unlike the asymptotic L1 and

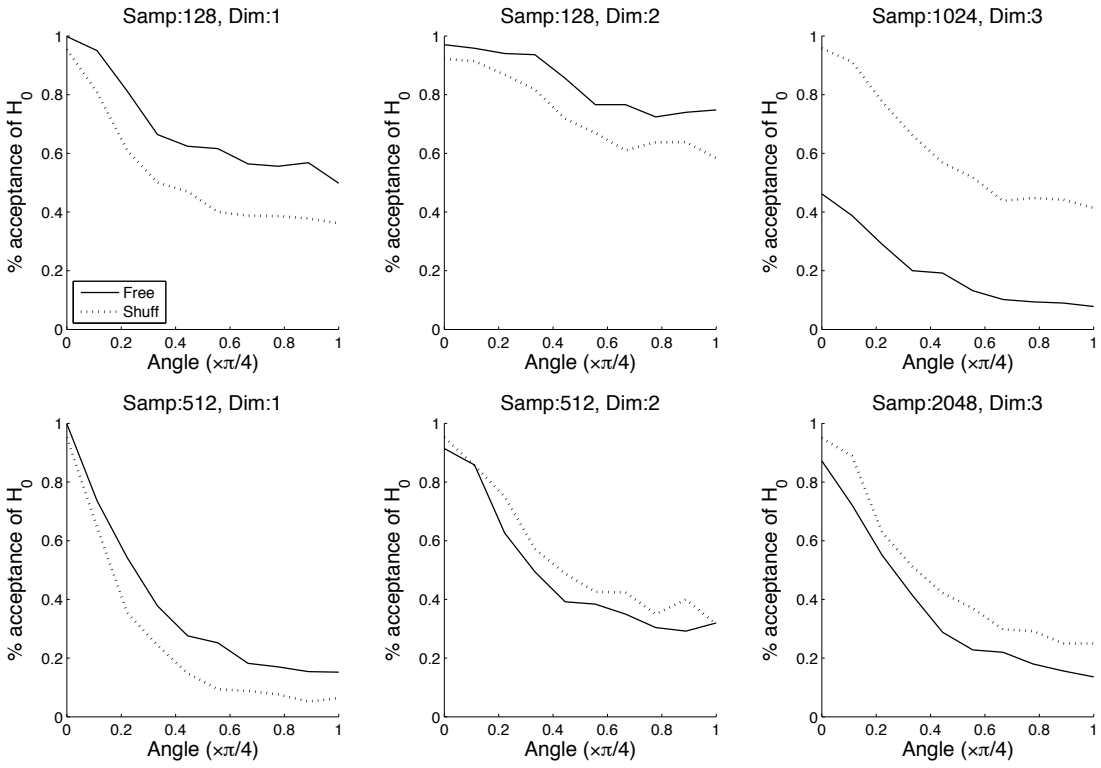

Figure 5: Rate of acceptance of $\mathcal{H}_0$ for the distribution-free (*Free*) and shuffling-based (*Shuff*) null distribution quantiles, using the log-likelihood test statistic. "Samp" is the number n of samples, and "dim" is the dimension $d = d'$ of x and y.

log-likelihood tests we have proposed, the resulting test threshold is an empirical estimate, and the convergence behaviour of this estimate is not accounted for. In our final experiments, we compared the performance of our asymptotic tests for *L1* and *Like* with this shuffling approach, for the same data as in our Figure 3 experiments.[4] We used $p = 200$ permutations in obtaining the approximation to the null distribution. Results for the *L1* case are plotted in Figure 4, and those for the *Like* case in Figure 5.

In the case of the *L1* statistic, we observe the distribution-free approach is conservative in terms of the Type I error, generally setting it slightly lower than the target value. The shuffling approach returns a lower Type II error, however it is notable that the performance difference is not particularly large with respect to our distribution-free threshold, and that apart from an offset, the error as a function of angle takes the same form. We should further bear in mind that the shuffling approach has a substantially greater computational cost (p times the cost of the distribution-free test). In the case of the *Like* statistic, we observe similar behaviour to *L1* in the cases $d = 1$ and $d = 2$. In the $d = 3$ case, however, the *Like* test gives too large a Type I error, and thus the Type II performance of the two approaches cannot be compared (although for $n = 2048$, the *Like* test is observed to approach the asymptotic regime, and the Type I performance is closer to the target value).

4. This comparison was made for the kernel statistic on these data by Gretton et al. (2008), and no performance difference was found.

6. Conclusion

We have described distribution-free strong consistent tests of independence, and asymptotically α-level tests, based on three statistics: the L_1 distance, the log-likelihood, and a kernel-based distance. The asymptotic L_1 and log-likelihood tests require that the distributions be non-atomic, but make no assumptions apart from this: in particular, the test thresholds are *not* functions of the distribution. The kernel statistic is interpretable as either an L_2 distance between kernel density estimates (if the kernel bandwidth shrinks for increasing sample size), or as the Hilbert-Schmidt norm of a covariance operator between reproducing kernel Hilbert spaces (if the kernel bandwidth is fixed). We have provided a novel strong consistent test for the kernel statistic, as well as reviewing two asymptotically α-level tests (for both fixed and shrinking kernel bandwidth). Unlike the L_1 and log-likelihood tests, the thresholds for the kernel asymptotic tests are distribution dependent. We also gave conjectures regarding the strong consistent test and asymptotically α-level test for the Pearson χ^2 distance.

Our experiments showed the asymptotic tests to be capable of detecting dependence for both univariate and multi-dimensional variables (of up to three dimensions each), for variables having no linear correlation. The kernel tests had lower Type II error than the L_1 and log-likelihood tests for a given Type I error, however we should bear in mind that the kernel test thresholds were finite sample estimates, and the resulting convergence issues have not been addressed. The log-likelihood test appeared to suffer more from bias than the L_1 test, in cases where there were few samples per partition (this effect was most visible in high dimensions).

This study raises a number of questions for future research. First, the χ^2 tests remain conjectures, and proofs should be established. Second, there is as yet no distribution-free asymptotic threshold for the kernel test, which could be based on a tighter bound on the variance of the test statistic under the null distribution. Third, the asymptotic distribution of the kernel statistic with fixed bandwidth is presently a heuristic: it would therefore be of interest to replace this with a null distribution estimate having appropriate convergence guarantees.

Appendix A. Proof of Theorem 3

The main difficulty in proving Theorem 3 is that it states the asymptotic normality of $L_n(\nu_n, \mu_{n,1} \times \mu_{n,2})$, which is a sum of *dependent* random variables. To overcome this problem, we use a "Poissonization" argument originating from the fact that an empirical process is equal in distribution to the conditional distribution of a Poisson process given the sample size (for more on Poissonization techniques, we refer the reader to Beirlant, Györfi, and Lugosi, 1994).

We begin by introducing the necessary terminology. For each $n \geq 1$, denote by N_n a Poisson(n) random variable, defined on the same probability space as the sequences $(X_i)_{i\geq 1}$ and $(Y_i)_{i\geq 1}$, and

independent of these sequences. Denote by ν_{N_n}, $\mu_{N_n,1}$ and $\mu_{N_n,2}$ the Poissonized version of the empirical measures associated with the samples $\{(X_i,Y_i)\}$, $\{X_i\}$ and $\{Y_i\}$, respectively, so that

$$\nu_{N_n}(A\times B)=\frac{\#\{i:(X_i,Y_i)\in A\times B, i=1,\ldots,N_n\}}{n},$$

$$\mu_{N_n,1}(A)=\frac{\#\{i:X_i\in A, i=1,\ldots,N_n\}}{n},$$

and

$$\mu_{N_n,2}(B)=\frac{\#\{i:Y_i\in B, i=1,\ldots,N_n\}}{n}$$

for any Borel subsets A and B. The Poissonized version $\tilde{L}_n(\nu_n,\mu_{n,1}\times\mu_{n,2})$ of $L_n(\nu_n,\mu_{n,1}\times\mu_{n,2})$ is then

$$\tilde{L}_n(\nu_n,\mu_{n,1}\times\mu_{n,2})=\sum_{A\in\mathcal{P}_n}\sum_{B\in\mathcal{Q}_n}|\nu_{N_n}(A\times B)-\mu_{N_n,1}(A)\cdot\mu_{N_n,2}(B)|.$$

Clearly,

$$n\nu_{N_n}(A\times B)=\#\{i:(X_i,Y_i)\in A\times B, i=1,\ldots,N_n\},$$

$$n\mu_{N_n,1}(A)=\#\{i:X_i\in A, i=1,\ldots,N_n\},$$

and

$$n\mu_{N_n,2}(B)=\#\{i:Y_i\in B, i=1,\ldots,N_n\}$$

are Poisson random variables.

Key to the proof of Theorem 3 is the following property, which is a slight extension of the proposition of Beirlant, Györfi, and Lugosi (1994, p. 311).

Proposition 7 *Let g_{njk} $(n\geq 1,\ j=1,\ldots,m_n, k=1,\ldots,m_n')$ be real measurable functions, and let*

$$M_n:=\sum_{j=1}^{m_n}\sum_{k=1}^{m_n'}g_{njk}\left(\nu_{N_n}(A_{nj}\times B_{nk})-\mu_{N_n,1}(A_{nj})\mu_{N_n,2}(B_{nk})\right).$$

Assume that, under the null hypothesis,

$$\mathbf{E}\{g_{njk}\left(\nu_{N_n}(A_{nj}\times B_{nk})-\mu_{N_n,1}(A_{nj})\mu_{N_n,2}(B_{nk})\right)\}=0,$$

and that

$$\left(M_n,\frac{N_n-n}{\sqrt{n}}\right)\xrightarrow{\mathcal{D}}\mathcal{N}\left(\begin{bmatrix}0\\0\end{bmatrix},\begin{bmatrix}\sigma^2&0\\0&1\end{bmatrix}\right) \tag{21}$$

as $n\to\infty$, where σ is a positive constant and $\mathcal{N}(\mathbf{m},\mathbf{C})$ is a normally distributed random variable with mean $\mathbf{m}$ and covariance matrix $\mathbf{C}$. Then

$$\frac{1}{\sigma}\sum_{j=1}^{m_n}\sum_{k=1}^{m_n'}g_{njk}\left(\nu_n(A_{nj}\times B_{nk})-\mu_{n,1}(A_{nj})\mu_{n,2}(B_{nk})\right)\xrightarrow{\mathcal{D}}\mathcal{N}(0,1).$$

Proof The proof is in sketch form, along the lines of Biau and Györfi (2005). Define the two characteristic functions

$$\Phi_n(t,v) := \mathbf{E}\left\{\exp\left(\imath t M_n + \imath v \frac{N_n - n}{\sqrt{n}}\right)\right\}$$

and

$$\Psi_n(t) := \mathbf{E}\left\{\exp\left(\imath t \sum_{j=1}^{m_n}\sum_{k=1}^{m'_n} g_{njk}\left(\nu_n(A_{nj}\times B_{nk}) - \mu_{n,1}(A_{nj})\mu_{n,2}(B_{nk})\right)\right)\right\}.$$

We begin with the result

$$\mathbf{E}\left\{\exp\left(\imath t M_n + \imath u N_n\right)\right\} = \sum_{l=0}^{\infty} \mathbf{E}\{\exp(\imath t M_n)|N_n = l\} e^{\imath u l} p_n(l),$$

where $p_n(l)$ is the probability distribution of the Poisson(n) random variable N_n,

$$p_n(l) = \mathbf{P}\{N_n = l\} = e^{-n} n^l / l!,$$

and

$$\Psi_n(t) = \mathbf{E}\{\exp(\imath t M_n)|N_n = n\}.$$

Taking the inverse Fourier transform,

$$\mathbf{E}\{\exp(\imath t M_n)|N_n = n\} = \frac{1}{2\pi p_n(n)} \int_{-\pi}^{\pi} e^{-\imath u n} \mathbf{E}\left\{\exp\left(\imath t M_n + \imath u N_n\right)\right\} du.$$

We now replace $n!$ with the Stirling approximation to obtain

$$2\pi p_n(n) = \frac{2\pi e^{-n} n^n}{n!} \approx \sqrt{\frac{2\pi}{n}} \quad \text{as} \quad n \to \infty.$$

Then, substituting $v = u\sqrt{n}$, we get

$$\Psi_n(t) = \frac{1}{\sqrt{2\pi}}(1 + o(1)) \int_{-\pi\sqrt{n}}^{\pi\sqrt{n}} \Phi_n(t,v) dv.$$

By assumption,

$$\Phi_n(t,v) \to e^{-t^2\sigma^2/2} e^{-v^2/2}$$

as $n \to \infty$. The result follows from Rao (1973, p. 136). ■

We now use Proposition 7 to prove

$$\frac{\sqrt{n}}{\sigma}\left(L_n(\nu_n, \mu_{n,1}\times\mu_{n,2}) - \mathbf{E}\{\tilde{L}_n(\nu_n, \mu_{n,1}\times\mu_{n,2})\}\right) \xrightarrow{\mathcal{D}} \mathcal{N}(0,1),$$

where we recall $\sigma^2 = 1 - 2/\pi$. This provides the result in Theorem 3 with the centering constant

$$C_n = \mathbf{E}\{\tilde{L}_n(\nu_n, \mu_{n,1}\times\mu_{n,2})\} = \sum_{A\in\mathcal{P}_n}\sum_{B\in\mathcal{Q}_n} \mathbf{E}\{|\nu_{N_n}(A\times B) - \mu_{N_n,1}(A)\cdot\mu_{N_n,2}(B)|\}. \tag{22}$$

To apply Proposition 7, we must prove assumption (21) holds. Define

$$g_{njk}(x) = \sqrt{n}\left(|x| - \mathbf{E}\left|\nu_{N_n}(A_{nj}\times B_{nk}) - \mu_{N_n,1}(A_{nj})\mu_{N_n,2}(B_{nk})\right|\right).$$

Let

$$\begin{aligned} S_n &:= t\sqrt{n}\sum_{j=1}^{m_n}\sum_{k=1}^{m_n'}\Big(\left|\nu_{N_n}(A_{nj}\times B_{nk}) - \mu_{N_n,1}(A_{nj})\mu_{N_n,2}(B_{nk})\right| \\ &\quad -\mathbf{E}\left|\nu_{N_n}(A_{nj}\times B_{nk}) - \mu_{N_n,1}(A_{nj})\mu_{N_n,2}(B_{nk})\right|\Big) \\ &\quad +v\sqrt{n}\left(\frac{N_n}{n}-1\right). \end{aligned}$$

Our goal is to prove the assumption in (21) holds. In particular, we require the variance of the Poissonized statistic S_n. After this variance is calculated, the asymptotic normality in (21) can be proved by verifying the Lyapunov conditions as in Beirlant, Györfi, and Lugosi (1994). From the definitions of ν_{N_n}, μ_1, and μ_2, we have

$$\frac{N_n}{n} - 1 = \sum_{A\in\mathcal{P}_n}\sum_{B\in\mathcal{Q}_n}\nu_{N_n}(A\times B) - \sum_{A\in\mathcal{P}_n}\sum_{B\in\mathcal{Q}_n}\mu_1(A)\mu_2(B),$$

and thus the variance of S_n is

$$\begin{aligned} \operatorname{var}(S_n) &= t^2 n\sum_{A\in\mathcal{P}_n}\sum_{B\in\mathcal{Q}_n}\operatorname{var}\left|\nu_{N_n}(A\times B) - \mu_{N_n,1}(A)\mu_{N_n,2}(B)\right| \\ &+ 2tvn\sum_{A\in\mathcal{P}_n}\sum_{B\in\mathcal{Q}_n}\mathbf{E}\big\{\left|\nu_{N_n}(A\times B) - \mu_{N_n,1}(A)\mu_{N_n,2}(B)\right| \\ &\quad \cdot\left(\nu_{N_n}(A\times B) - \mu_1(A)\mu_2(B)\right)\big\} \\ &+ v^2. \end{aligned}$$

One can check that there exist standard normal random variables $Z_{A\times B}$, Z_A, and Z_B such that

$$\nu_{N_n}(A\times B) \overset{\mathcal{D}}{\approx} Z_{A\times B}\sqrt{\frac{\mu_1(A)\mu_2(B)}{n}} + \mu_1(A)\mu_2(B),$$

$$\mu_{N_n,1}(A) \overset{\mathcal{D}}{\approx} Z_A\sqrt{\frac{\mu_1(A)}{n}} + \mu_1(A),$$

and

$$\mu_{N_n,2}(B) \overset{\mathcal{D}}{\approx} Z_B\sqrt{\frac{\mu_2(B)}{n}} + \mu_2(B),$$

which implies

$$\begin{aligned}
& \nu_{N_n}(A\times B)-\mu_{N_n,1}(A)\mu_{N_n,2}(B) \\
\overset{\mathcal{D}}{\approx} \; & Z_{A\times B}\sqrt{\frac{\mu_1(A)\mu_2(B)}{n}}+\mu_1(A)\mu_2(B) \\
& -\left(Z_A\sqrt{\frac{\mu_1(A)}{n}}+\mu_1(A)\right)\left(Z_B\sqrt{\frac{\mu_2(B)}{n}}+\mu_2(B)\right) \\
= \; & \sqrt{\frac{\mu_1(A)\mu_2(B)}{n}}\left(Z_{A\times B}-Z_AZ_B\frac{1}{\sqrt{n}}-Z_A\sqrt{\mu_2(B)}-Z_B\sqrt{\mu_1(A)}\right) \\
\approx \; & Z_{A\times B}\sqrt{\frac{\mu_1(A)\mu_2(B)}{n}}.
\end{aligned}$$

Thus,

$$\begin{aligned}
& \mathrm{var}(S_n) \\
\approx \; & t^2 n\sum_{A\in\mathcal{P}_n}\sum_{B\in\mathcal{Q}_n}\mathrm{var}\left|Z_{A\times B}\sqrt{\frac{\mu_1(A)\mu_2(B)}{n}}\right| \\
+ \; & 2tvn\sum_{A\in\mathcal{P}_n}\sum_{B\in\mathcal{Q}_n}\mathbf{E}\left\{\left|Z_{A\times B}\sqrt{\frac{\mu_1(A)\mu_2(B)}{n}}\right|\cdot\left(Z_{A\times B}\sqrt{\frac{\mu_1(A)\mu_2(B)}{n}}\right)\right\} \\
+ \; & v^2 \\
= \; & t^2\sum_{A\in\mathcal{P}_n}\sum_{B\in\mathcal{Q}_n}\mathrm{var}|Z_{A\times B}|\mu_1(A)\mu_2(B) \\
+ \; & 2tv\sum_{A\in\mathcal{P}_n}\sum_{B\in\mathcal{Q}_n}\mathbf{E}\{|Z_{A\times B}|Z_{A\times B}\}\mu_1(A)\mu_2(B) \\
+ \; & v^2 \\
= \; & t^2(1-2/\pi)+v^2.
\end{aligned}$$

Finally, we use the variable $Z_{A\times B}$ in defining a distribution-free upper bound on C_n, which we use in our asymptotically α-level independence test,

$$\begin{aligned}
C_n &= \sum_{A\in\mathcal{P}_n}\sum_{B\in\mathcal{Q}_n}\mathbf{E}\{|\nu_{N_n}(A\times B)-\mu_{N_n,1}(A)\cdot\mu_{N_n,2}(B)|\} \\
&\approx \sum_{A\in\mathcal{P}_n}\sum_{B\in\mathcal{Q}_n}\mathbf{E}\{|Z_{A\times B}|\}\sqrt{\mu_1(A)\mu_2(B)/n} \\
&\leq \sqrt{2/\pi}\sqrt{\frac{m_nm_n'}{n}} \qquad (23)
\end{aligned}$$

Appendix B. Conjectured Large Sample Properties of the Pearson χ^2 Statistic

For a real parameter λ, the *power divergence statistic* is defined as

$$D_{n,\lambda}(\mu_{n,1},\mu_1)=\frac{2}{\lambda(\lambda+1)}\sum_{j=1}^{m_n}\mu_{n,1}(A_{n,j})\left[\left(\frac{\mu_{n,1}(A_{n,j})}{\mu_1(A_{n,j})}\right)^{\lambda}-1\right]$$

provided $\lambda \neq 0$ and $\lambda \neq 1$ (cf. Read and Cressie, 1988). One can check that

$$\lim_{\lambda \to 0} D_{n,\lambda}(\mu_{n,1}, \mu_1) = I_n(\mu_{n,1}, \mu_1).$$

For $\lambda = 1$, we have the Pearson χ^2 statistic:

$$\chi_n^2(\mu_{n,1}, \mu_1) = D_{n,1}(\mu_{n,1}, \mu_1) = \sum_{j=1}^{m_n} \frac{(\mu_{n,1}(A_{n,j})) - \mu_1(A_{n,j}))^2}{\mu_1(A_{n,j})}.$$

For testing independence, we employ the Pearson χ^2 test statistic

$$\chi_n^2(\nu_n, \mu_{n,1} \times \mu_{n,2}) \quad = \quad \sum_{A \in \mathcal{P}_n} \sum_{B \in \mathcal{Q}_n} \frac{(\nu_n(A \times B) - \mu_{n,1}(A) \cdot \mu_{n,2}(B))^2}{\mu_{n,1}(A) \cdot \mu_{n,2}(B)}.$$

B.1 Strongly Consistent Test

Quine and Robinson (1985) proved that, for all $\varepsilon > 0$,

$$\mathbf{P}\{\chi_n^2(\mu_{n,1}, \mu_1) > \varepsilon\} \leq \binom{n + m_n - 1}{m_n - 1} e^{-\frac{n \log m_n}{2\sqrt{m_n}} \sqrt{\varepsilon}} \leq e^{m_n \log(n+m_n) - \frac{n \log m_n}{2\sqrt{m_n}} \sqrt{\varepsilon}}. \tag{24}$$

A large deviation-based test can be introduced that rejects independence if

$$\chi_n^2(\nu_n, \mu_{n,1} \times \mu_{n,2}) \geq \left(\frac{2(m_n m_n')^{3/2} (\log(n + m_n m_n') + 1)}{n \log(m_n m_n')} \right)^2.$$

Under $\mathcal{H}_0$, we conjecture a non-asymptotic bound for the tail of the distribution of $\chi_n^2(\nu_n, \mu_{n,1} \times \mu_{n,2})$,

$$\begin{aligned} & \mathbf{P}\left\{ \chi_n^2(\nu_n, \mu_{n,1} \times \mu_{n,2}) > \left(\frac{2(m_n m_n')^{3/2} (\log(n + m_n m_n') + 1)}{n \log(m_n m_n')} \right)^2 \right\} \\ \leq \; & e^{m_n m_n' \log(n + m_n m_n') - \frac{n \log(m_n m_n')}{2\sqrt{m_n m_n'}} \frac{2(m_n m_n')^{3/2} (\log(n + m_n m_n') + 1)}{n \log(m_n m_n')}} \\ = \; & e^{-m_n m_n'}. \end{aligned}$$

Therefore the conditions (7) imply

$$\sum_{n=1}^{\infty} \mathbf{P}\left\{ \chi_n^2(\nu_n, \mu_{n,1} \times \mu_{n,2}) > \left(\frac{2(m_n m_n')^{3/2} (\log(n + m_n m_n') + 1)}{n \log(m_n m_n')} \right)^2 \right\} < \infty,$$

and by the Borel-Cantelli lemma we have strong consistency under the null hypothesis.

Under the alternative hypothesis the proof strong consistency follows from the proof for the information divergence since

$$I_n(\nu_n, \mu_{n,1} \times \mu_{n,2})/2 \leq \chi_n^2(\nu_n, \mu_{n,1} \times \mu_{n,2})$$

(cf. Györfi et al., 1998).

B.2 Asymptotic α-level Test

Morris (1975), Inglot et al. (1990), and Györfi and Vajda (2002) proved that under (10) and (11),

$$\frac{n\chi_n^2(\mu_{n,1},\mu_1)-m_n}{\sqrt{2m_n}} \xrightarrow{\mathcal{D}} \mathcal{N}(0,1),$$

which is the same asymptotic normality result as for $2I_n(\mu_{n,1},\mu_1)$ (see Equation (14) in Section 3.2). We conjecture that under the conditions (6) and (12),

$$\frac{n\chi_n^2(\nu_n,\mu_{n,1}\times\mu_{n,2})-m_nm_n'}{\sqrt{2m_nm_n'}} \xrightarrow{\mathcal{D}} \mathcal{N}(0,1).$$

Thus, as for the log-likelihood statistic, the hypothesis of independence is rejected if

$$\chi_n^2(\nu_n,\mu_{n,1}\times\mu_{n,2}) \geq \frac{\Phi^{-1}(1-\alpha)\sqrt{2m_nm_n'}+m_nm_n'}{n}.$$

Abstract

We study hierarchical clustering schemes under an axiomatic view. We show that within this framework, one can prove a theorem analogous to one of Kleinberg (2002), in which one obtains an existence and uniqueness theorem instead of a non-existence result. We explore further properties of this unique scheme: stability and convergence are established. We represent dendrograms as ultrametric spaces and use tools from metric geometry, namely the Gromov-Hausdorff distance, to quantify the degree to which perturbations in the input metric space affect the result of hierarchical methods.

Keywords: clustering, hierarchical clustering, stability of clustering, Gromov-Hausdorff distance

1. Introduction

Clustering techniques play a very central role in various parts of data analysis. They can give important clues to the structure of data sets, and therefore suggest results and hypotheses in the underlying science. Many of the interesting methods of clustering available have been applied to good effect in dealing with various data sets of interest. However, despite being one of the most commonly used tools for unsupervised exploratory data analysis, and despite its extensive literature, very little is known about the theoretical foundations of clustering methods. These points have been recently made prominent by von Luxburg and Ben-David (2005); Ben-David et al. (2006).

The general question of which methods are "best", or most appropriate for a particular problem, or how significant a particular clustering is has not been addressed too frequently. This lack of theoretical guarantees can be attributed to the fact that many methods involve particular choices to be made at the outset, for example how many clusters there should be, or the value of a particular thresholding parameter. In addition, some methods depend on artifacts in the data, such as the particular order in which the observations are listed.

In Kleinberg (2002), Kleinberg proves a very interesting impossibility result for the problem of even defining a clustering scheme with some rather mild invariance properties. He also points out that his results shed light on the trade-offs one has to make in choosing clustering algorithms.

Standard clustering methods take as input a finite metric space (X,d) and output a partition of X. Let $\mathcal{P}(X)$ denote the set of all possible partitions of the set X. Kleinberg (2002) discussed

*. Corresponding author.

this situation in an axiomatic way and identified a set of reasonable properties of standard clustering schemes, namely, scale invariance, richness and consistency. Fix a standard clustering method f and a metric space (X,d) and let $f(X,d) = \Pi \in \mathcal{P}(X)$. Kleinberg identified the following desirable properties of a clustering scheme:

- **Scale Invariance**: For all $\alpha > 0$, $f(X, \alpha \cdot d) = \Pi$.
- **Richness**: Fix any finite set X. Then for all $\Pi \in \mathcal{P}(X)$, *there exists* d_Π, a metric on X s.t. $f(X,d_\Pi) = \Pi$.
- **Consistency**: Let $\Pi = \{B_1, \ldots, B_\ell\}$. Let $\widehat{d}$ be any metric on X s.t.
  1. for all $x, x' \in B_\alpha$, $\widehat{d}(x,x') \leqslant d(x,x')$ and
  2. for all $x \in B_\alpha, x' \in B_{\alpha'}$, $\alpha \neq \alpha'$, $\widehat{d}(x,x') \geqslant d(x,x')$.

  Then, $f(X,\widehat{d}) = \Pi$.

He then proved, in the same spirit of Arrow's impossibility theorem, that no clustering scheme satisfying these conditions simultaneously can exist.

Theorem 1 (Kleinberg, 2002) *There exists no clustering algorithm that satisfies scale invariance, richness and consistency.*

Then, in particular, Kleinberg's axioms rule out single, average and complete linkage (standard) clustering. Clusters in any of these three methods can be obtained by first constructing a hierachical decomposition of space (such as those provided by hierarchical clustering methods) and then selecting the partition that arises at a given, fixed, threshold.

A natural question is whether Kleinberg's impossibility results still holds when one admits clustering schemes that do not try to return a fixed partition of a space, but are allowed to return a *hierarchical decomposition*.

Furthermore, data sets can exhibit multiscale structure and this can render standard clustering algorithms inapplicable in certain situations, see Figure 1. This further motivates the use of **Hierarchical clustering methods.** Hierarchical methods take as input a finite metric space (X,d) and output a hierarchical family of partitions of X.

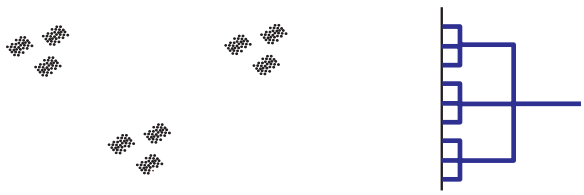

Figure 1: Data set with multiscale structure. Any standard clustering algorithm will fail to capture the structure of the data.

These hierarchical families of partitions that constitute the output of hierarchical methods receive the name of *dendrograms*. Dendrograms come in two versions: *proximity* and *threshold* dendrograms. These two types of dendrograms differ in whether they retain some proximity information about the underlying clusters that they represent or not: proximity dendrograms do retain

such information whereas threshold dendrograms do not. Practicioners of statistical data analysis seem to work almost exclusively with proximity dendrograms. For this reason we opt to carry out our analysis under the model that hierarchical methods take as input a finite metric space X and output a proximity dendrogram over X, see Remark 3.

We remind the reader that we are using the term standard clustering methods to refer to procedures that take a finite metric space as input and output a fixed single partition of the metric space.

In a similar spirit to Kleinberg's theorem, we prove in Theorem 18 that in the context of hierarchical methods, one obtains *uniqueness* instead of non-existence. We emphasize that our result can be interpreted as a *relaxation* of the theorem proved by Kleinberg, in the sense that allowing clustering schemes that output a nested family of partitions in the form of a proximity dendrogram, instead of a fixed partition, removes the obstruction to existence. The unique HC method characterized by our theorem turns out to be single linkage hierarchical clustering.

We stress the fact that our result assumes that outputs of hierarchical methods are proximity dendrograms, whereas Kleinberg's Theorem applies to flat/standard clustering, a situation in which the output contains no proximity information between clusters.

In order to state and prove our results we make use of the well known **equivalent representation** of dendrograms, the output of HC methods, using *ultrametrics*. This already appears in the book of Hartigan and others, see Hartigan (1985), Jain and Dubes (1988, §3.2.3) and references therein.

In recent years, the theme of studying the properties of metrics with prescribed generalized curvature properties has been studied intensively. In particular, the work of Gromov (1987) has been seminal, and many interesting results have been proved concerning objects other than metric spaces, such as finitely generated groups, depending on these methods. The curvature conditions can be formulated in terms of properties of triangles within the metric spaces, and the most extreme of these properties is that embodied in ultrametric spaces. A second idea of Gromov's is to make the collection of all metric spaces into its own metric space, and the resulting metric gives a very useful and natural way to distinguish between metric spaces (Gromov, 2007). This metric is known as the Gromov-Hausdorff distance and its restriction to the subclass of ultrametric spaces is therefore a very natural object to study.

1.1 Stability

Stability of some kind is clearly a desirable property of clustering methods and, therefore, a point of interest is studying whether results obtained by a given clustering algorithm are *stable* to perturbations in the input data. Since input data are modelled as finite metric spaces, and the output of hierarchical methods can be regarded as finite ultrametric spaces, the Gromov-Hausdorff distance provides a natural tool for studying *variability* or *perturbation* of the inputs and outputs of hierarchical clustering methods.

After observing in §3.6 that average and complete linkage clustering are not stable in the metric sense alluded to above, we prove in Proposition 26 that single linkage does enjoy a kind of stability:

Proposition 2 *Let (X,d_X) and (Y,d_Y) be two finite metric spaces and let (X,u_X) and (Y,u_X) be the two (finite metric ultrametric spaces) corresponding outputs yielded by single linkage HC. Then,*

$$d_{\mathcal{GH}}\big((X,u_X),(Y,u_Y)\big) \leqslant d_{\mathcal{GH}}\big((X,d_X),(Y,d_Y)\big).$$

Here, $d_{\mathcal{GH}}$ stands for the Gromov-Hausdorff distance.

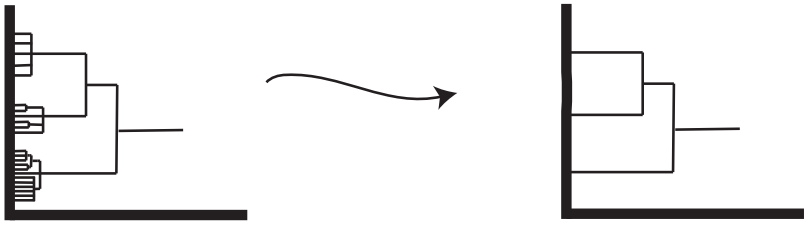

Figure 2: Convergence of dendrograms. We formalize this concept by equivalently representing dendrogram as ultrametrics and then computing the Gromov-Hausdorff distance between the resulting metrics. We prove in Theorem 30 that by taking increasingly many i.i.d. samples from a given probability distribution μ on a metric space,then with probability 1 one recovers a multiscale representation of the supprt of μ.

This result is very important for the convergence theorems which we prove in the later parts of the paper. These results describe in a very precise way the fact that for compact metric spaces X, the results of clustering the finite subsets of X yields a collection of dendrograms which ultimately converge to the dendrogram for X. In order for this to happen, one needs the metric on the ultrametric spaces as well as the behavior of the clustering construction on the Gromov-Hausdorff distance, which is what Proposition 2 does. The issue of stability is further explored in §5.

1.2 Probabilistic Convergence

Finally, in Theorem 30 we also prove that for random i.i.d. observations $\mathbb{X}_n = \{x_1, \ldots, x_n\}$ with probability distribution μ compactly supported in a metric space (X, d), the result $(\mathbb{X}_n, u_{\mathbb{X}_n})$ of applying single linkage clustering to $(\mathbb{X}_n, d)$ **converges almost surely** in the Gromov-Hausdorff sense to an ultrametric space that recovers the multiscale structure of the *support* of μ, see Figure 20. This can be interpreted as a refinement of a previous observation (Hartigan, 1985) that SLHC is insensitive to the distribution of mass of μ in its support.

1.3 Organization of the Paper

This paper is organized as follows: §A provides a list of all the notation defined and used throughout the paper; §2 introduces the terminology and basic concepts that we use in our paper; §3.2 reviews hierarchical clustering methods in general; §3.3 discusses the representation of dendrograms as ultrametric spaces and establishes the equivalence of both repersentations; and §3.5 delves into the issue of constructing a notion of distance between dendrograms which is based in the equivalence of dendrograms and ultrametrics; §3.6 comments on issues pertaining to the theoretical properties of HC methods. In §4 we present our characterization result, Theorem 18, for SL in a spirit similar to the axiomatic treatment of Kleinberg. We delve into the stability and convergence questions of SL in §5, where we introduce all the necessary concepts from Metric Geometry. Proposition 26 and Theorem 28 contain our results for the deterministic case. In §5.3 we prove a probabilistic convergence result Theorem 30 that hinges on a general sampling theorem for measure metric spaces, Theorem 34. Finally, we conclude the paper with a discussion on future directions.

For clarity of exposition, we have chosen to move most of the proofs in this paper to an appendix. The ones which remain in the main text are intended to provide intuition which would not otherwise be there.

2. Background and Notation

A **metric space** is a pair (X,d) where X is a set and $d : X \times X \to \mathbb{R}^+$ satisfies

1. For all $x,x' \in X$, $d(x',x) = d(x,x') \geqslant 0$ and $d(x,x') = 0$ if and only if $x = x'$.
2. For all $x,x',x'' \in X$, $d(x,x'') \leqslant d(x,x') + d(x',x'')$.

A metric space (X,u) is an **ultrametric space** if and only if for all $x,x',x'' \in X$,

$$\max(u(x,x'),u(x',x'')) \geqslant u(x,x''). \tag{1}$$

Ultrametric spaces are therefore metric spaces which satisfy a stronger type of triangle inequality. It is interesting to observe that this ultrametric triangle inequality (1) implies that all triangles are *isosceles*.[1]

Notice that by iterating the ultrametric property one obtains that if $x_1,x_2,\ldots,x_k$ is any set of k points in X, then

$$\max\left(u(x_1,x_2),u(x_2,x_3),\ldots,u(x_{k-1},x_k)\right) \geqslant u(x_1,x_k).$$

For a fixed finite set X, we let $\mathcal{U}(X)$ denote the collection of all ultrametrics on X. For $n \in \mathbb{N}$ let $\mathcal{X}_n$ (resp. $\mathcal{U}_n$) denote the collection of all metric spaces (resp. ultra-metric spaces) with n points. Let $\mathcal{X} = \bigsqcup_{n\geqslant 1} \mathcal{X}_n$ denote the collection of all finite metric spaces and $\mathcal{U} = \bigsqcup_{n\geqslant 1} \mathcal{U}_n$ all finite ultrametric spaces. For $(X,d) \in \mathcal{X}$ let

$$\mathrm{sep}(X,d) := \min_{x\neq x'} d(x,x') \quad \text{and} \quad \mathrm{diam}\,(X,d) := \max_{x,x'} d(x,x')$$

be the *separation* and the *diameter* of X, respectively.

We now recall the definition of an **equivalence relation**. Given a set A, a *binary relation* is a subset $S \subset A \times A$. One says that a and a' are *related* and writes $a \sim a'$ whenever $(a,a') \in S$. S is called an *equivalence relation* if and only if for all $a,b,c \in A$, all the following hold true:

- Reflexivity: $a \sim a$.
- Symmetry: if $a \sim b$ then $b \sim a$.
- Transitivity: if $a \sim b$ and $b \sim c$ then $a \sim c$.

The *equivalence class* of a under $\sim$, denoted $[a]$, is defined as all those a' which are related to a: $[a] = \{a' \in A, \text{s.t. } a' \sim a\}$. Finally, the *quotient space* $A\backslash\sim$ is the collection of all equivalence classes: $A\backslash\sim := \{[a], a \in A\}$.

We now construct our first example which will be crucial in our presentation.

Example 1 (r-equivalence) *Given a finite metric space (X,d) and $r \geqslant 0$ we say that points $x,x' \in X$ are* **r-equivalent** *(denoted $x \sim_r x'$) if and only if there exists points $x_0,x_1,\ldots,x_t \in X$ with $x_0 = x$,*

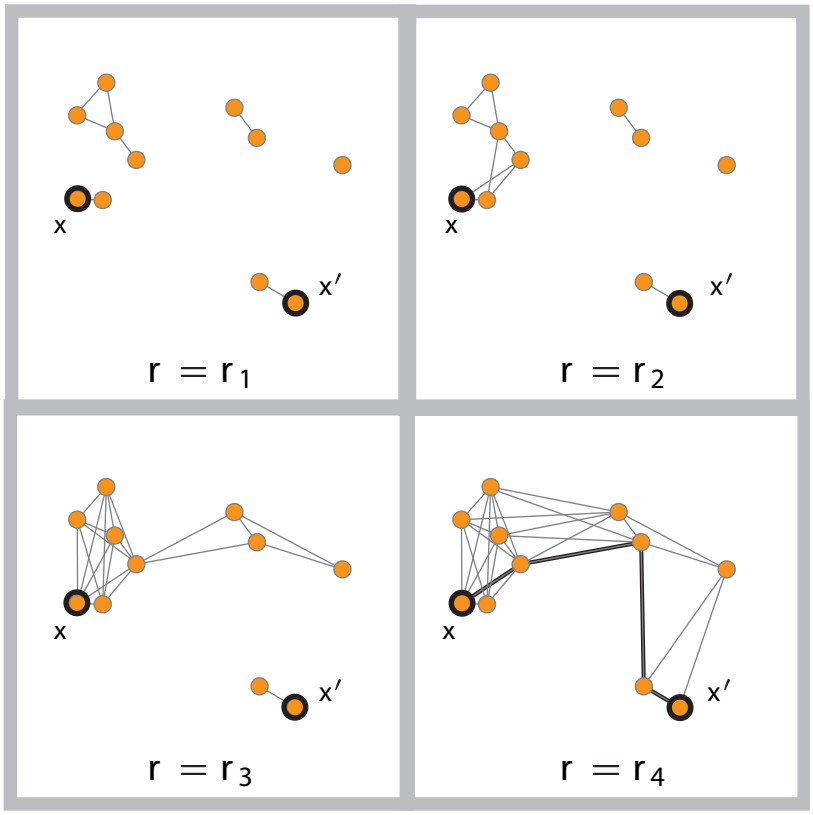

Figure 3: Illustration of the equivalence relation $\sim_r$. A finite metric space X is specified by the points in orange which are endowed with the Euclidean distance. This construction can be understood as allowing the creation of edges joining two points whenever the distance between them does not exceed r. Then, two points x and x' in black are deemed r-equivalent if one can find a sequence of edges on the resulting graph connecting x to x'. From left to right and top to bottom we show the resulting graph one obtains for 4 increasing values of r. The points x and x' are not r-equivalent when $r = r_1, r_2$ or r_3, but they are r_4-equivalent.

$x_t = x'$ *and* $d(x_i, x_{i+1}) \leqslant r$ *for* $i = 0, \ldots, t-1$. *It is easy to see that* $\sim_r$ *is indeed an equivalence relation on* X.

This definition embodies the simple idea of partitioning a finite metric space into path connected components, where the granularity of this partitioning is specified by the parameter $r \geqslant 0$, *see Figure 1.*

1. Indeed, assume that all sides a, b, c of a triangle in a given ultrametric space are different. Then, without loss of generality $a > b > c$. But then, $a > \max(a, b)$ which violates (1). Hence, there must be at least two equal sides in every triangle in an ultrametric space.

For a finite set X, and a symmetric function $W : X \times X \to \mathbb{R}^+$ let $\mathcal{L}(W)$ denote the *maximal metric* on X less than of equal to W (Bridson and Haefliger, 1999), that is,

$$\mathcal{L}(W)(x,x') = \min\left\{ \sum_{i=0}^{m-1} W(x_i,x_{i+1}) \Big| x = x_0,\ldots,x_m = x \right\}$$

for $x,x' \in X$.

For a finite set X, we let $\mathcal{C}(X)$ denote the collection of all non-empty subsets of X. By $\mathcal{P}(X)$ we denote the set of all partitions of X. For a given partition $\Pi \in \mathcal{P}(X)$ we refer to each $\mathcal{B} \in \Pi$ as a *block* of Π. For partitions $\Pi, \Pi' \in \mathcal{P}(X)$, we say that Π is *coarser* than Π', or equivalently that Π' is a *refinement* of Π, if for every block $\mathcal{B}' \in \Pi'$ there exists a block $\mathcal{B} \in \Pi$ s.t. $\mathcal{B}' \subset \mathcal{B}$.

For $k \in \mathbb{N}$ and $r > 0$ let $S^{k-1}(r) \subset \mathbb{R}^k$ denote the $(k-1)$ dimensional sphere with radius r. By $((a))$ we will denote a matrix of elements a_{ij}.

3. Hierarchical Clustering: Formulation

In this section we formaly define hierarchical clustering methods as maps that assign a dendrogram to a finite metric space. First, in §3.1 formalize the standard concept of dendrogram; then, in §3.2 we present a formal treatment of HC methods which emphasizes the need for a formulation that is insensitive to arbitrary choices such as the labels given to the points in the data set. Finally, in §3.3 we prove that the collection of all dendrograms over a finite set is in a one to one correspondence with the collection of all ultrametrics on this set. We then redefine HC methods as maps from the collection of finite metric spaces to the collection all finite ultrametric spaces. This change in perspective permits a natural formulation and study of the *stability* and *convergence* issues in later sections of the paper. In particular, in §3.5, we discuss the construction of notions of *distance between dendrograms* by appealing to the ultrametric representation. These notions are instrumental for the arguments in §5.

Finally, in §3.6, we disgress on some critiques to the classical HC methods. The situation with HC methods is seemingly paradoxical in that SL is the one that seems to enjoys the best theoretical properties while CL and AL, despite exhibiting some undesirable behaviour, are the usual choices of practicioners.

3.1 Dendrograms

A **dendrogram** over a finite set X is defined to be nested family of partitions, usually represented graphically as a rooted tree. Dendrograms are meant to represent a hierarchical decompositions of the underlying set X, such as those that are produced by hierarchical clustering algorithms, and therefore the nested family of partitions provided must satisfy certain conditions. We formally describe dendrograms as pairs (X,θ), where X is a finite set and $\theta : [0,\infty) \to \mathcal{P}(X)$. The parameter of θ usually represents a certain notion of *scale* and it is reflected in the height of the different levels, see Figure 3.1. We require that θ satisfies:

1. $\theta(0) = \{\{x_1\},\ldots,\{x_n\}\}$. This condition means that the initial decomposition of space is the finest possible: the space itself.

2. There exists t_0 s.t. $\theta(t)$ is the *single block partition* for all $t \geqslant t_0$. This condition encondes the fact that for large enough t, the partition of the space becomes trivial.

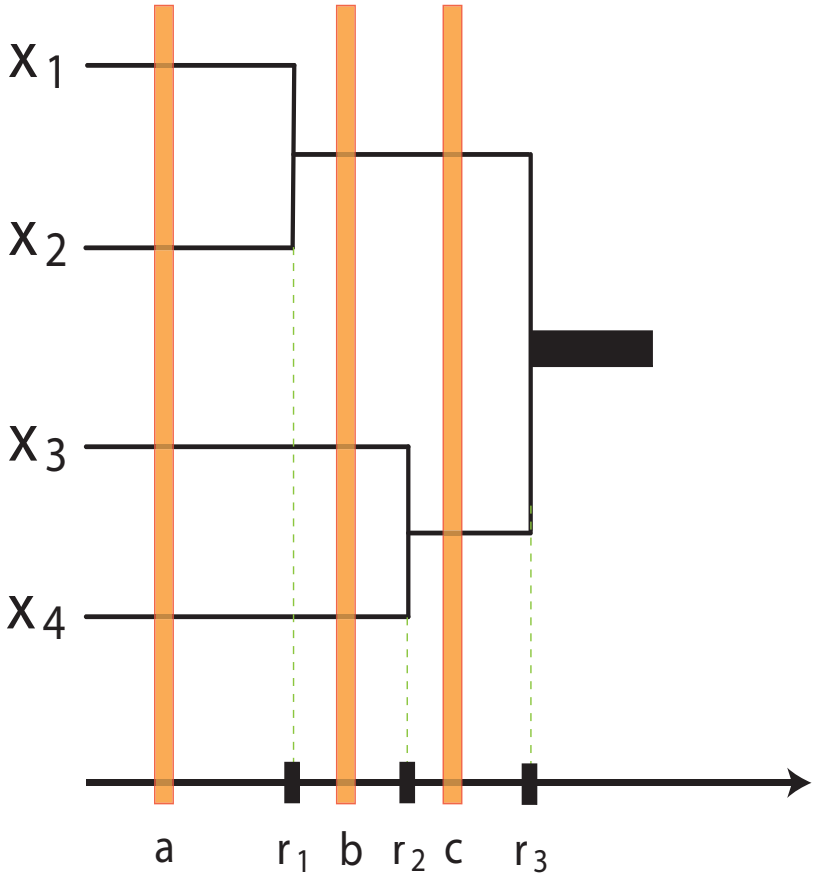

Figure 4: A graphical representation of a dendrogram over the set $X = \{x_1, x_2, x_3, x_4\}$. Let θ denote the dendrogram. Notice for example that $\theta(a) = \big\{\{x_1\},\{x_2\},\{x_3\},\{x_4\}\big\}$; $\theta(b) = \big\{\{x_1,x_2\},\{x_3\},\{x_4\}\big\}$; $\theta(c) = \big\{\{x_1,x_2\},\{x_3,x_4\}\big\}$; and $\theta(t) = \big\{x_1,x_2,x_3,x_4\big\}$ for any $t \geqslant r_3$.

3. If $r \leqslant s$ then $\theta(r)$ *refines* $\theta(s)$. This condition ensures that the family of partitions provided by the dendrogram is indeed nested.

4. For all r there exists $\varepsilon > 0$ s.t. $\theta(r) = \theta(t)$ for $t \in [r, r+\varepsilon]$. (technical condition)

Let $\mathcal{D}(X)$ denote the collection of all possible dendrograms over a given finite set X. When understood from context, we will omit the first component of a dendrogram $(X,\theta) \in \mathcal{D}(X)$ and refer to θ as a dendrogram over X.

Remark 3 (About our definition of dendrogram) *Our definition coincides with what Jain and Dubes call* ***proximity dendrograms*** *in Jain and Dubes (1988, §3.2). We stress that we view the parameter t in our definition as part of the information about the hierarchical clustering. Jain and Dubes also discuss a simpler version of dendrograms, which they call* threshold dendrograms, *which retain merely the order in which succesive partitions are created. These of course can be viewed as functions from $\mathbb{N}$ into $\mathcal{P}(X)$ satisfying the constraints (1), (2) and (3) above, instead of having the domain $[0,\infty)$.*

It seems that proximity dendrograms are the type of dendrograms that are most often employed by practicioners and statisticians, see for example the dendrograms provided by the statistical software R[2] *and by Matlab's statistics toolbox,*[3] *whereas threshold dendrograms are more popular in the Machine Learning and Computer Science communities.*

Usually, Hierarchical Clustering methods are defined as those maps that to each finite metric space (X,d) assign a dendrogram over X.

Using the definitions above we now construct our first example.

Example 2 *For each finite metric space (X,d) let $(X,\theta^*) \in \mathcal{D}(X)$ be given by $\theta^*(r) = X\setminus\sim_r$. In other words, for each $r \geqslant 0$, $\theta^*(r)$ returns the partition of X into $\sim_r$-equivalence classes. Recall (Example 1) that two points x amd x' are $\sim_r$ equivalent if and only if one can find a sequence of points $x_0, x_1, \ldots, x_k$ s.t. the first of them is x and the last one is x' and all the hops are smaller than r: $\max_i d_X(x_i, x_{i+1}) \leqslant r$. We will see below that this definition coincides with single linkage hierarchical clustering. See Figure 2 for an illustration of this concept.*

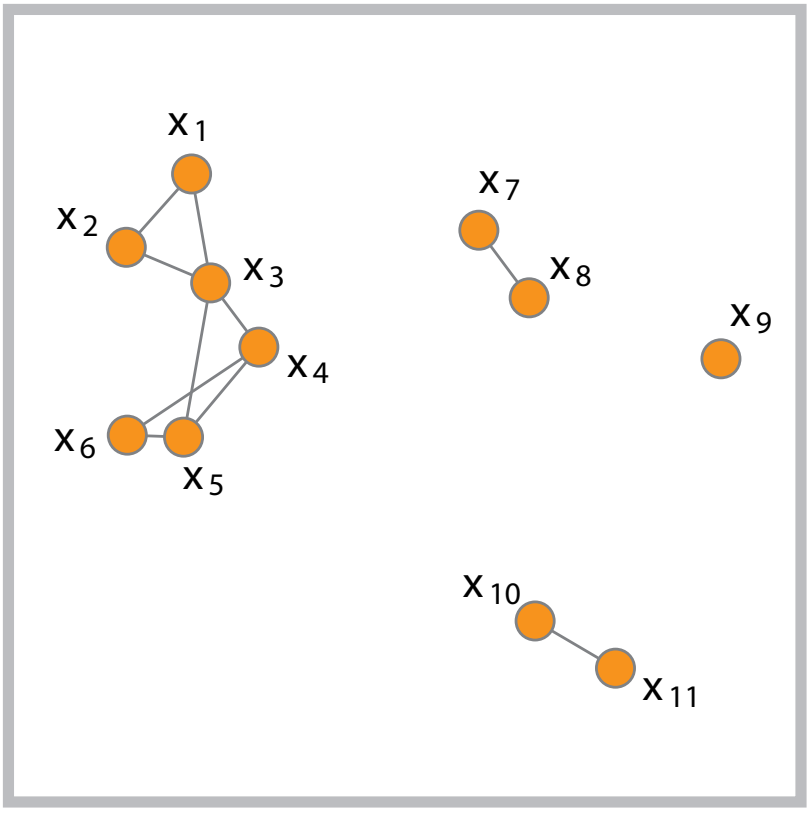

Figure 5: For the same finite metric space X of Example 1 and the value $r = r_2$, $X\setminus\sim_{r_2} = \big\{\{x_1,x_2,x_3,x_4,x_5,x_6\},\{x_7,x_8\},\{x_9\},\{x_{10},x_{11}\}\big\}$, that is, $\sim_{r_2}$ splits X into four path connected components.

2. Available at `http://www.r-project.org/`.
3. Available at `http://www.mathworks.com/products/statistics/`.

In order to build up intuition about our definitions, we prove that (X,θ^*) is indeed a dendrogram. Since X is a metric space, $x \sim_0 x'$ if and only if $x = x'$. Thus condition (1) above is satisfied. Clearly, for $t \geqslant diam(X,d)$, $x \sim_t x'$ for all x,x', and thus condition (2) holds. Fix $0 \leqslant r \leqslant s$ and let $\mathcal{B}$ be a maximal connected component of $\theta^*(r)$ and let $x,x' \in \mathcal{B}$. Then, by definition of $\theta^*(r)$, $x \sim_r x'$. But it follows from the definition of $\sim_r$ that if $x \sim_r x'$, then $x \sim_s x'$ for all $s \geqslant r$. Hence, x,x' are in the same block of $\theta^*(s)$ and condition (3) holds. Condition (4) holds since clearly θ^* is right continuous, has finitely many discontinuity points, and is piecewise constant.

We now need to discuss a formal description of agglomerative HC methods.

3.2 A General Description of Agglomerative Hierarchical Clustering Methods

In this section we give a description of agglomerative HC methods that is suitable for our theoretical analyses. Standard algorithmic descriptions of HC methods typically make the assumption that in the merging process there are only two points at minimal linkage value of eachother. For example, the formulation of Lance and Williams (1967) does not specifically explain how to deal with the case when more than two points are candidates for merging. In practice one could argue that if at a certain stage, say, three points are at minimal linkage value of eachother, then one could proceed to merge them two at a time, according to some predefined rule that depends on the indices of the points.

Whereas this *tie breaking* strategy seems reasonable from a computational point of view, it invariably leads to dendrograms that depend on the ordering of the points. This is no doubt an undesirable feature that can be translated into, for example, that the results of the clustering methods depend on the order in which the data samples were obtained. Single linkage HC is exempted from this problem however, because of the fact that at each stage only *minimal distances* are taken into account. In contrast, complete and average linkage will produce results that do not behave well under reordering of the points.

The problems arising from ad hoc tie breaking are often not even mentioned in books on clustering. A notable exception is the book Jain and Dubes (1988), especially Section §3.2.6, where the reader can find a careful exposition of these issues.

Below, we formulate HC methods in a way that is independent of these extraneous features. In order to do so , we need to have some kind of **invariance** in the formulation. More precisely, let (X,d_X) be the input metric space, where we assume that $X = \{1,\ldots,n\}$ consists of exactly n points. Write (X,θ_X) is the output dendrogram of a given HC method applied to (X,d_X). Let π be a permutation of the indices $\{1,2,\ldots,n\}$, and (Y,d_Y) be the metric space with points $\{1,\ldots,n\}$ and permuted metric: $d_Y(i,j) := d_X(\pi_i,\pi_j)$ for all $i,j \in \{1,\ldots,n\}$; further, denote by (Y,θ_Y) the output dendrogram of the same HC method applied on (Y,d_Y). Then, we require that for all permutations π, the result of computing the dendrogram first and then permuting the result **is the same** as the result of first permuting the input distance matrix and then computing the output dendrogram:

$$\pi \circ \theta_X(t) = \theta_Y(t), \text{ for all } t \geqslant 0. \tag{2}$$

Formally, the action of a permutation π over a partition (such as $\theta_X(t)$) above must be understood in the following sense: if $P = \{\mathcal{B}_1,\ldots,\mathcal{B}_r\}$ is a partition of $\{1,2,\ldots,n\}$, then $\pi \circ P$ is the partition with blocks $\{\pi \circ \mathcal{B}_i,\, 1 \leqslant i \leqslant r\}$, where in turn $\pi \circ \mathcal{B}_i$ consists of all those indices π_j for $j \in \mathcal{B}_i$.

We elaborate on this in the next example. We first recall the usual definition of CLHC, and then construct a simple metric space consisting of five points where this usual formulation of CL fails to exhibit invariance to permutations.

3.2.1 THE STANDARD FORMULATION OF COMPLETE LINKAGE HC

We assume $(X,((d)))$ is a given finite metric space. In this example, we use the formulas for CL but the structure of the iterative procedure in this example is common to all HC methods (Jain and Dubes, 1988, Chapter 3). Let θ be the dendrogram to be constructed in this example.

1. Set $X_0 = X$ and $D_0 = ((d))$ and set $\theta(0)$ to be the partition of X into singletons.

2. Search the matrix D_0 for the smallest non-zero value, that is, find $\delta_0 = \mathrm{sep}(X_0)$, and find all pairs of points $\{(x_{i_1},x_{j_1}),(x_{i_2},x_{j_2})\ldots,(x_{i_k},x_{j_k})\}$ at distance δ_0 from eachother, that is, $d(x_{i_\alpha},x_{j_\alpha}) = \delta_0$ for all $\alpha = 1,2,\ldots,k$, where one orders the indices s.t. $i_1 < i_2 < \ldots < i_k$.

3. Merge the first pair of elements in that list, (x_{i_1},x_{j_1}), into a single group. The procedure now removes (x_{i_1},x_{j_1}) from the initial set of points and adds a point c to represent the cluster formed by both: define $X_1 = \big(X_0\backslash\{x_{i_1},x_{j_1}\}\big)\cup\{c\}$. Define the dissimilarity matrix D_1 on $X_1\times X_1$ by $D_1(a,b) = D_0(a,b)$ for all $a,b\neq c$ and $D_1(a,c) = D_1(c,a) = \max\big(D_0(x_{i_1},a),D_0(x_{j_1},a)\big)$ (this step is the only one that depends on the choice corresponding to CL). Finally, set

$$\theta(\delta) = \{x_{i_1},x_{j_1}\}\cup\bigcup_{i\neq i_1,j_1}\{x_i\}.$$

4. The construction of the dendrogram θ is completed by repeating the previous steps until all points have been merged into a single cluster.

Example 3 (about the standard formulation of complete linkage) *The crux of the problem lies in step 3 of the procedure outlined above. The choice to merge just the first pair of points in the list causes the procedure to not behave well under relabeling of the points in the sense of (2).*

An explicit example is the following: consider the metric space $\big(\{1,2,3,4,5\},((d))\big)$ *with five points and distance matrix*

$$((d)) = \begin{array}{c} \\ 1\\2\\3\\4\\5\end{array}\!\!\begin{array}{c}\begin{array}{ccccc}1&2&3&4&5\end{array}\\\begin{pmatrix}0&1&2&5&5\\1&0&3&6&6\\2&3&0&3&7\\5&6&3&0&4\\6&7&4&6&0.\end{pmatrix}\end{array}$$

This metric space arises from considering the graph metric on the graph depicted in Figure 6. Under CLHC (as defined in §3.2.1), and under the action of all possible permutations of the labels of its 5 points, this metric space produces 3 different ***non-equivalent*** *dendrograms, see Figure 7. This is an undesirable feature, as discussed at length in Jain and Dubes (1988, Chapter 3).*

We now re-define general HC methods in a way that they satisfy (2).

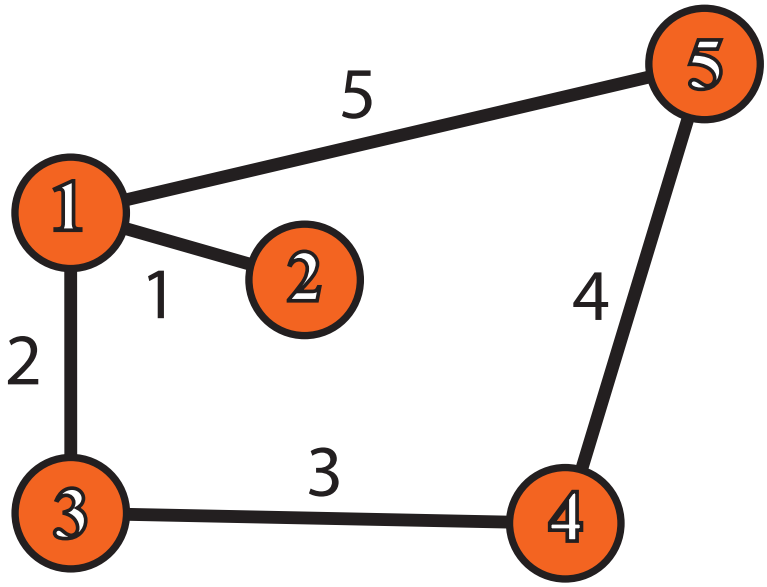

Figure 6: A finite metric space that under permutations leads to different outputs of the usual CL HC algorithm, see text for details. The metric is defined by the graph distance on the weighted graph shown.

3.2.2 THE PERMUTATION INVARIANT FORMULATION

Here we consider the family of Agglomerative Hierarchical clustering techniques (Jain and Dubes, 1988, Chapter 3). We define these by the recursive procedure described next. The main difference with §3.2.1 lies that in Step 3 we will allow for more than just two points into the same cluster and also, it could happen, for example, that four points A,B,C,D merge into two different clusters $\{A,B\}$ and $\{C,D\}$ at the same time.

Let the finite metric space (X,d) be given where $X = \{x_1,\ldots,x_n\}$ and let L denote a family of *linkage functions* on X:

$$L := \{\ell : \mathcal{C}(X)\times\mathcal{C}(X) \to \mathbb{R}^+\}$$

with the property all that $\ell \in L$ are bounded non-negative functions. These functions assign a non-negative value to each pair of non-empty subsets of X, and provide a certain measure of *distance* between two clusters. Let $\mathcal{B},\mathcal{B}' \in \mathcal{C}(X)$, then, some possible standard choices for ℓ are:

- *Single linkage*: $\ell^{\mathrm{SL}}(\mathcal{B},\mathcal{B}') = \min_{x\in\mathcal{B}} \min_{x'\in\mathcal{B}'} d(x,x')$;
- *Complete linkage*: $\ell^{\mathrm{CL}}(\mathcal{B},\mathcal{B}') = \max_{x\in\mathcal{B}} \max_{x'\in\mathcal{B}'} d(x,x')$; and
- *Average linkage*: $\ell^{\mathrm{AL}}(\mathcal{B},\mathcal{B}') = \frac{\sum_{x\in\mathcal{B}}\sum_{x'\in\mathcal{B}'} d(x,x')}{\#\mathcal{B}\cdot\#\mathcal{B}'}$.
- *Hausdorff linkage*: $\ell^{\mathrm{HL}}(\mathcal{B},\mathcal{B}') = d_{\mathcal{H}}(\mathcal{B},\mathcal{B}')$.[4]

The permutation invariant formulation is as follows:

4. The Hausdorff distance is defined in Definition 21.

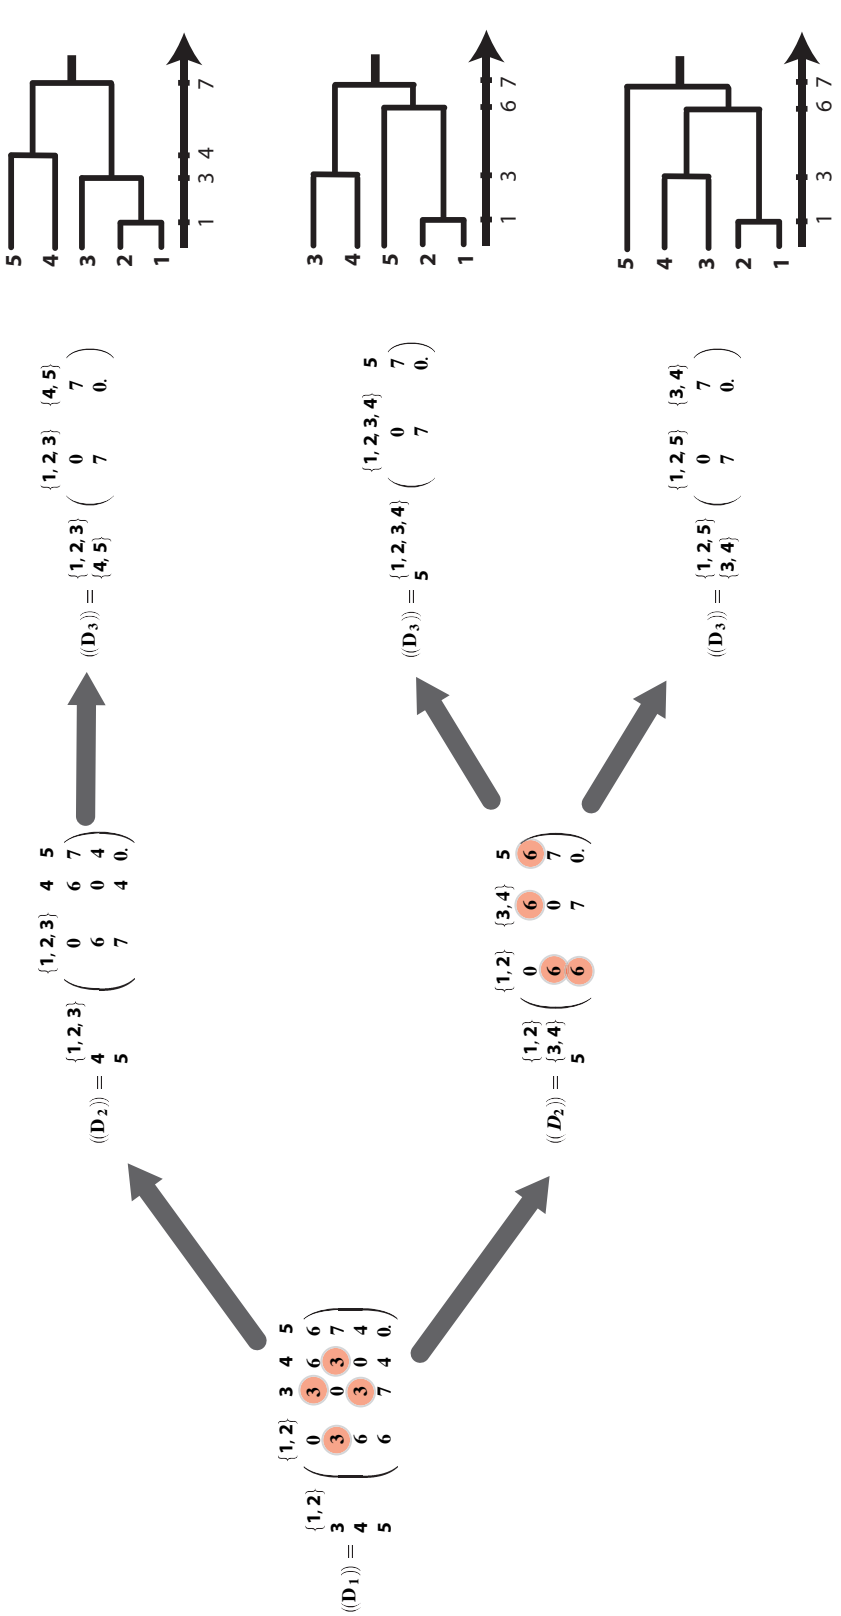

Figure 7: The five point metric space of Example 3 leads to 3 non-equivalent CL-dendrograms. Here we show the agglomerative procedure corresponding to the usual order dependent definition of CL HC, see text in Example 3 for details. Notice that in D_1, there are two pairs at minimal linkage value (this value is 3, in red circles): $\big(\{1,2\},3\big)$ on one hand, and $\big(3,4\big)$ on the other. The top row shows the agglomeration process that follows after merging $\{1,2\}$ with 3. The bottom row shows that when one instead chooses to merge 3 and 4 instead, then at the next step there is again ambiguity (represented again by the red circles). The three dendrograms shown on the right are the three possible outputs one finds when choosing different orders for the agglomeration processes. Clearly, these three dendrograms are not equivalent under permutations of the labels of their base points.

1. Fix $\ell \in L$. For each $R > 0$ consider the equivalence relation $\sim_{\ell,R}$ on blocks of a partition $\Pi \in \mathcal{P}(X)$, given by $\mathcal{B} \sim_{\ell,R} \mathcal{B}'$ if and only if there is a sequence of blocks $\mathcal{B} = \mathcal{B}_1, \ldots, \mathcal{B}_s = \mathcal{B}'$ in Π with $\ell(\mathcal{B}_k, \mathcal{B}_{k+1}) \leqslant R$ for $k = 1, \ldots, s-1$.

2. Consider the sequences $R_1, R_2, \ldots \in [0, \infty)$ and $\Theta_1, \Theta_2, \ldots \in \mathcal{P}(X)$ given by $\Theta_1 := \{x_1, \ldots, x_n\}$, and recursively for $i \geqslant 1$ by $\Theta_{i+1} = \Theta_i / \sim_{\ell,R_i}$ where

$$R_i := \min\{\ell(\mathcal{B}, \mathcal{B}'); \mathcal{B}, \mathcal{B}' \in \Theta_i, \mathcal{B} \neq \mathcal{B}'\}.$$

   Note that this process necessarily ends in finitely many steps. This construction reflects the fact that at step i one agglomerates those clusters at distance $\leqslant R_i$ from eachother (as measured by the linkage function ℓ). More than two clusters could be merged at any given step.

3. Finally, we define $\theta^\ell : [0, \infty) \to \mathcal{P}(X)$ by $r \mapsto \theta^\ell(r) := \Theta_{i(r)}$ where $i(r) := \max\{i | R_i \leqslant r\}$.

Remark 4 (About our definition of HC methods) *Note that, unlike the usual definition of agglomerative hierarchical clustering §3.2.1 (Jain and Dubes, 1988, §3.2), at each step of the inductive definition we allow for more than two clusters to be merged. Of course, the standard formulation can be recovered if one assumes that at each step i of the algorithm, there exist* only *two blocks $\mathcal{B}$ and $\mathcal{B}'$ in Θ_i s.t. $R_i = \ell(\mathcal{B}, \mathcal{B}')$. Then, at each step, only two blocks will be merged.*

Example 4 *Note for example that for the five point metric space in Example 3, the result of applying CL (according to the permutation invariant formulation) is the dendrogram in Figure 8 (a). It also follows, for example, that when applied to the metric space* $L_3 := \left(\{a,b,c\}, \begin{pmatrix} 0 & 1 & 2 \\ 1 & 0 & 1 \\ 2 & 1 & 0 \end{pmatrix} \right)$, *which can be represented by three points on a line:* 
, *SL, AL and CL all yield the same dendrogram, which is shown in Figure 8 (b).*

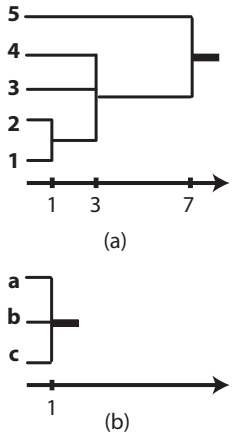

Figure 8: (a) shows the result of applying the permutation invariant formulation of CL to the five point metric space of Example 3 (see also Figure 6). (b) shows the dendrogram that one obtains as output of (the permutation invariant formulation of) SL, AL and CL applied to the metric space L_3.

Proposition 5 *We have the following properties of the construction above:*

- *For $i = 1, 2, \ldots$, Θ_{i+1} is coarser than Θ_i and*
- $R_{i+1} \geqslant R_i$.
- θ^ℓ *is a dendrogram over* X.

Proof The only non trivial claim is that $R_{i+1} \geqslant R_i$, which can be proved by induction on i. ■

Remark 6 *From this point forward, all references to SL, AL, and CL clustering will be to the permutation invariant formulation, in which more than two clusters can be merged at a given step.*

The following result is clear, and we omit its proof.

Proposition 7 *The above construction of hierarchical clustering algorithms (including SL, AL, and CL) yields algorithms which are permutation invariant.*

A simplification for SL HC. In the particular case of SL, there is an alternative formulation that uses the equivalence relation introduced in Example 1 and its associated dendrogram (Example 2). The proof of the following Proposition is deferred to the appendix.

Proposition 8 *Let (X,d) be a finite metric space and θ^{SL} be the dendrogram over X obtained by the single linkage agglomerative procedure described above, and let θ^* be the dendrogram over X constructed in Example 2. Then, $\theta^{SL}(r) = \theta^*(r)$ for all $r \geqslant 0$.*

3.3 Dendrograms as Ultrametric Spaces

The representation of dendrograms as ultrametrics is well known and it appears in the book by Jardine and Sibson (1971), it has already been used in the work of Hartigan (1985), and is touched upon in the classical reference of Jain and Dubes (1988, §3.2.3).

We now present the main ideas regarding this change in perspective which we will adopt for all subsequent considerations. The formulation of the output of hierarchical clustering algorithms as ultrametric spaces is powerful when one is proving stability results, as well as results about the approximation of the dendrograms of metric spaces by their finite subspaces. This is so because of the fact that once a dendrogram is regarded as a metric space, the Gromov-Hausdorff metric provides a very natural notion of distance on the output, in which the right kind of stability results are easily formulated. We state these theorems in §5.

The main result in this section is that dendrograms and ultrametrics are **equivalent**.

Theorem 9 *Given a finite set X, there is a bijection $\Psi : \mathcal{D}(X) \to \mathcal{U}(X)$ between the collection $\mathcal{D}(X)$ of all dendrograms over X and the collection $\mathcal{U}(X)$ of all ultrametrics over X such that for any dendrogram $\theta \in \mathcal{D}(X)$ the ultrametric $\Psi(\theta)$ over X generates the same hierarchical decomposition as θ, that is,*

$$(*) \quad \text{for each } r \geqslant 0,\ x, x' \in \mathcal{B} \in \theta(r) \iff \Psi(\theta)(x,x') \leqslant r.$$

Furthermore, this bijection is given by

$$\Psi(\theta)(x,x') = \min\{r \geqslant 0 \,|\, x, x' \text{ belong to the same block of } \theta(r)\}.$$

In order to establish the above theorem, we first construct certain natural mappings from $\mathcal{D}(X)$ to $\mathcal{U}(X)$ and from $\mathcal{U}(X)$ to $\mathcal{D}(X)$, and we then prove they are inverses of eachother and satisfy $(*)$.

3.3.1 FROM DENDROGRAMS TO ULTRAMETRICS

Let X be a finite set and $\theta : [0,\infty) \to \mathcal{P}(X)$ a dendrogram over X. Consider the symmetric map $u_\theta : X \times X \to \mathbb{R}^+$ given by

$$(x,x') \mapsto \min\{r \geqslant 0 \,|\, x,x' \text{belong to the same block of } \theta(r)\}. \tag{3}$$

See Figure 9 for an illustration of this definition. Note that condition (4) in the definition of dendrograms guarantees that u_θ is well defined. It is easy to see that u_θ defines an ultrametric on X:

Lemma 10 *Let X be a finite set and $(X,\theta) \in \mathcal{D}(X)$. Then $u_\theta : X \times X \to \mathbb{R}^+$ defined in (3) is an ultrametric.*

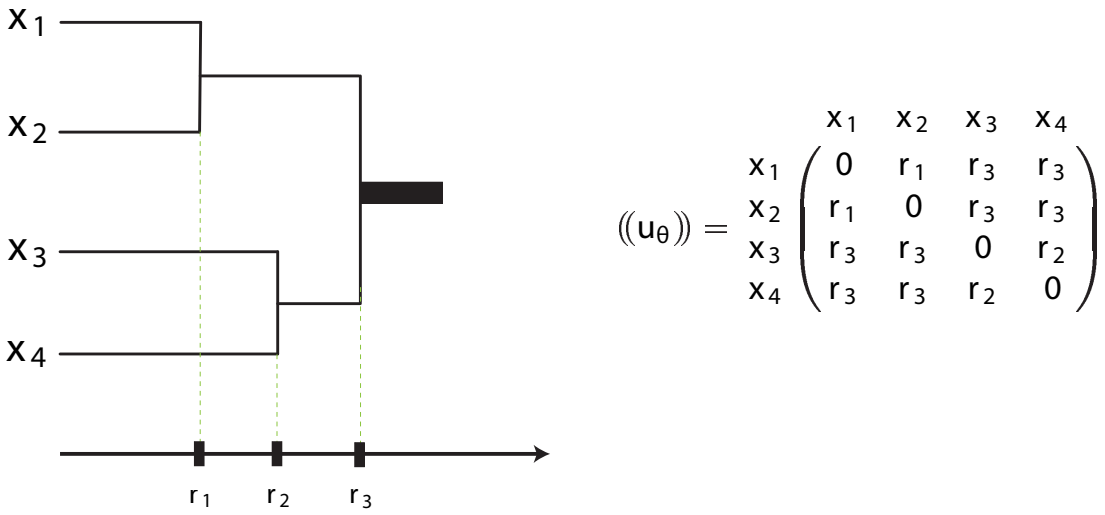

Figure 9: A graphical representation of a dendrogram θ over $X = \{x_1,x_2,x_3,x_3\}$ and the ultrametric u_θ. Notice for example, that according to (3), $u_\theta(x_1,x_2) = r_1$ since r_1 is the first value of the (scale) parameter for which x_1 and x_2 are merged into the same cluster. Similarly, since x_1 and x_3 are merged into the same cluster for the first time when the parameter equals r_3, then $u_\theta(x_1,x_3) = r_3$.

3.3.2 FROM ULTRAMETRICS TO DENDROGRAMS

Conversely, given an ultrametric $u : X \times X \to \mathbb{R}^+$, its associated dendrogram

$$\theta^u : [0,\infty) \to \mathcal{P}(X)$$

can be obtained as follows: for each $r \geqslant 0$ let $\theta^u(r)$ be the collection of equivalence classes of X under the relation $x \sim x'$ if and only if $u(x,x') \leqslant r$. That this defines an equivalence relation follows immediately from the fact that u is an ultrametric. Indeed, assume that $x \sim x'$ and

$x' \sim x''$ for some $r \geqslant 0$. Then, $u(x,x') \leqslant r$ and $u(x',x'') \leqslant r$. Now, by the ultrametric property, $\max\big(u(x,x'),u(x',x'')\big) \geqslant u(x,x'')$ and hence $u(x,x'') \leqslant r$ as well. We conclude that $x \sim x''$ thus establishing the transitivity of $\sim$.

Example 5 *Consider the ultrametric u on* $X = \{x_1,x_2,\ldots,x_6\}$ *given by*

$$((u)) = \begin{array}{c} \\ x_1 \\ x_2 \\ x_3 \\ x_4 \\ x_5 \\ x_6 \end{array} \begin{array}{c} \begin{array}{cccccc} x_1 & x_2 & x_3 & x_4 & x_5 & x_6 \end{array} \\ \begin{pmatrix} 0 & 2 & 2 & 5 & 6 & 6 \\ 2 & 0 & 2 & 5 & 6 & 6 \\ 2 & 2 & 0 & 5 & 6 & 6 \\ 5 & 5 & 5 & 0 & 6 & 6 \\ 6 & 6 & 6 & 6 & 0 & 4 \\ 6 & 6 & 6 & 6 & 4 & 0. \end{pmatrix} \end{array}$$

Then, for example $\theta^u(0) = \big\{\{x_1\},\{x_2\},\{x_3\},\{x_4\},\{x_5\},\{x_6\}\big\}$, $\theta^u(3) = \big\{\{x_1,x_2,x_3\},\{x_4\},\{x_5\},\{x_6\}\big\}$, $\theta^u(4.5) = \big\{\{x_1,x_2,x_3\},\{x_4\},\{x_5,x_6\}\big\}$, $\theta^u(5.5) = \big\{\{x_1,x_2,x_3,x_4\},\{x_5,x_6\}\big\}$ *and* $\theta^u(7) = \big\{x_1,x_2,x_3,x_4,x_5,x_6\big\}$. *A graphical representation of the dendrogram* θ^u *is given in Figure 10.*

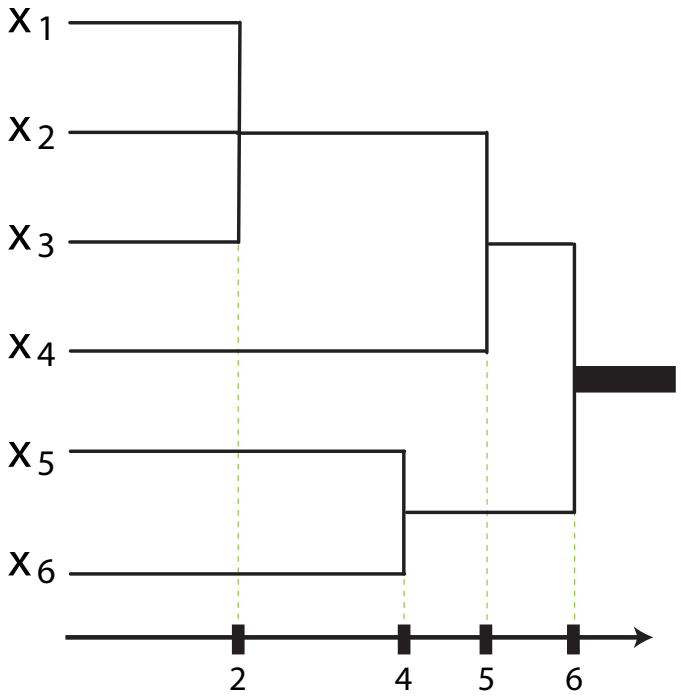

Figure 10: A graphical representation of the dendrogram θ^u of Example 5, see the text for details.

3.3.3 THE CONCLUSION OF THE PROOF OF THEOREM 9.

It is easy to check that (1) given any dendrogram θ on X, $\theta^{u_\theta} = \theta$ and (2) given any ultrametric u on X, $u_{\theta^u} = u$. Now, let $\Psi : \mathcal{D}(X) \to \mathcal{U}(X)$ be defined by $\theta \mapsto \Psi(\theta) := u_\theta$. By construction we see that

$\Psi : \mathcal{D}(X) \to \mathcal{U}(X)$ is a bijection and that Ψ^{-1} is given by $u \mapsto \theta^u$. From (3) we see that Ψ satisfies $(*)$. Hence, we obtain Theorem 9.

From now, whenever given a dendrogram θ_X over a set X, we will be using the notation $\Psi(\theta_X)$ for the ultrametric associated to X given by Theorem 9. In a similar manner, given an ultrametric u on X, $\Psi^{-1}(u)$ will denote the dendrogram over X given by Theorem 9.

3.4 Reformulation of Hierarchical Clustering using Ultrametrics

In the sequel, appealing to Theorem 9 which states the **equivalence between ultrametrics and dendrograms**, we represent dendrograms as *ultrametric* spaces. Then, any hierarchical clustering method can be regarded as a map from finite metric spaces into finite ultrametric spaces. This motivates the following definition:

Definition 11 *A* hierarchical clustering method *is defined to be a map*

$$\mathfrak{T} : \mathcal{X} \to \mathcal{U} \quad s.t. \quad \mathcal{X}_n \ni (X,d) \mapsto (X,u) \in \mathcal{U}_n,\ n \in \mathbb{N}.$$

Example 6 *For a given finite metric space (X,d) consider the HC method $\mathfrak{T}^{\mathrm{SL}}$ given by $\mathfrak{T}^{\mathrm{SL}}(X,d) = (X, \Psi(\theta^{\mathrm{SL}}))$, where θ^{SL} is the single linkage dendrogram over X defined in §3.2. Similarly, we define $\mathfrak{T}^{\mathrm{CL}}$ and $\mathfrak{T}^{\mathrm{AL}}$.*

Example 7 (maximal sub-dominant ultrametric) *There is a canonical construction: Let $\mathfrak{T}^* : \mathcal{X} \to \mathcal{U}$ be given by $(X,d) \mapsto (X,u^*)$ where*

$$u^*(x,x') := \min \left\{ \max_{i=0,\ldots,k-1} d(x_i, x_{i+1}),\ s.t.\ x = x_0, \ldots, x_k = x' \right\}. \tag{4}$$

We remark that the minimum above is taken over $k \in \mathbb{N}$ and all $k+1$-tuples of points $x_0, x_1, \ldots, x_k$ in X s.t. $x_0 = x$ and $x_k = x'$. Notice that for all $x, x' \in X$, $u^*(x,x') \leqslant d(x,x')$.

*This construction is sometimes known as the **maximal sub-dominant ultrametric** and it has the property that if $u \leqslant d$ is any other ultrametric on X, then $u \leqslant u^*$. The Lemma below proves that this canonical construction is equivalent to the ultrametric induced by the equivalence relation in Example 1.*

Lemma 12 *For $(X,d) \in \mathcal{X}$ write $\mathfrak{T}^*(X,d) = (X,u^*)$ and let $(X,\theta^*) \in \mathcal{D}(X)$ be the dendrogram arising from the construction in Example 2. Then, $u^* = \Psi(\theta^*)$.*

Remark 13 *Notice that another way of stating the Lemma above is that $x \sim_r x'$ if and only if $u^*(x,x') \leqslant r$.*

It turns out that T* yields **exactly** *single linkage clustering* as defined in §3.2.

Corollary 14 *One has that $\mathfrak{T}^{SL} = \mathfrak{T}^*$.*

Equivalently, for any finite metric space X, the single linkage dendrogram θ^{SL} on X agrees with $\Psi^{-1}(u^*)$.

Proof The proof follows easily from Proposition 8 and Lemma 12. ■

We emphasize that, as it follows from Corollary 14, $\mathfrak{T}^*$ produces ultrametric outputs which are exactly those corresponding to SLHC. We will use this fact strongly in the sequel.

3.4.1 INTERPRETATION OF THE ULTRAMETRIC

For a HC method $\mathfrak{T}$ and $(X,d) \in \mathcal{X}$, let $\mathfrak{T}(X,d) = (X,u)$. The intuition that arises from (3) is that for two points $x,x' \in X$, $u(x,x')$ measures the minimal **effort** method $\mathfrak{T}$ makes in order to join x to x' into the same cluster.

We note in particular that a desirable property of a HC algorithm should be that upon shrinking some of the distances in the input metric space, the corresponding "efforts" also decrease. This property is exactly verified by $\mathfrak{T}^*$. Indeed, let X be a finite set and d_1 and d_2 two metrics on X s.t. $d_1 \geqslant d_2$. Write $\mathfrak{T}^*(X,d_1) = (X,u_1^*)$ and $\mathfrak{T}^*(X,d_2) = (X,u_2^*)$. Then, it follows immediately from Equation (4) that $u_1^* \geqslant u_2^*$ (compare with Kleinberg's *consistency* property, pp 1425).

Observe that CL and AL HC *fail to satisfy this property*. An example is provided in Figure 19.

We see in Theorem 18 that a condition of this type, together with two more natural normalizing conditions, *completely characterizes SLHC*.

3.5 Comparing results of Hierarchical Clustering Methods

One of the goals of this paper is to study the stability of clustering methods to perturbations in the input metric space. In order to do so one needs to define certain suitable notions of distance between dendrograms. We choose to do this by appealing to the ultrametric representation of dendrograms, which provides a natural way of defining a distance between hierarchical clusterings. We now delve into the construction.

Consider first the simple case of two different dendrograms (X,α) and (X,β) over the same fixed finite set X. In this case, as a tentative measure of dissimilarity between the dendrograms we look at the maximal difference between the associated ultrametrics given by Theorem 9: $u_\alpha = \Psi(\alpha)$ and $u_\beta = \Psi(\beta)$: $\max_{x,x' \in X} |u_\alpha(x,x') - u_\beta(x,x')|$. There is a natural interpretation of the condition that $\max_{x,x' \in X} |u_\alpha(x,x') - u_\beta(x,x')| \leqslant \varepsilon$: if we look at the graphical representation of the dendrograms α and β, then the transition horizontal lines in Figure 11 have to occur within ε of eachother.[5] This is easy to see by recalling that by (3),

$$u_\alpha(x,x') = \min\{r \geqslant 0 \,|\, x,x' \text{belong to the same block of } \alpha(r)\}$$

and

$$u_\beta(x,x') = \min\{r \geqslant 0 \,|\, x,x' \text{belong to the same block of } \beta(r)\}.$$

For the example in Figure 11, we then obtain that $\max_i |r_i - r_i'| \leqslant \varepsilon$, which is not surprising since $r_2 = u_\alpha(x_1,x_2)$, $r_2' = u_\beta(x_1,x_2)$, etc.

5. These lines represent values of the scale parameter for which there is a merging of blocks of the partitions encoded by the dendrograms.

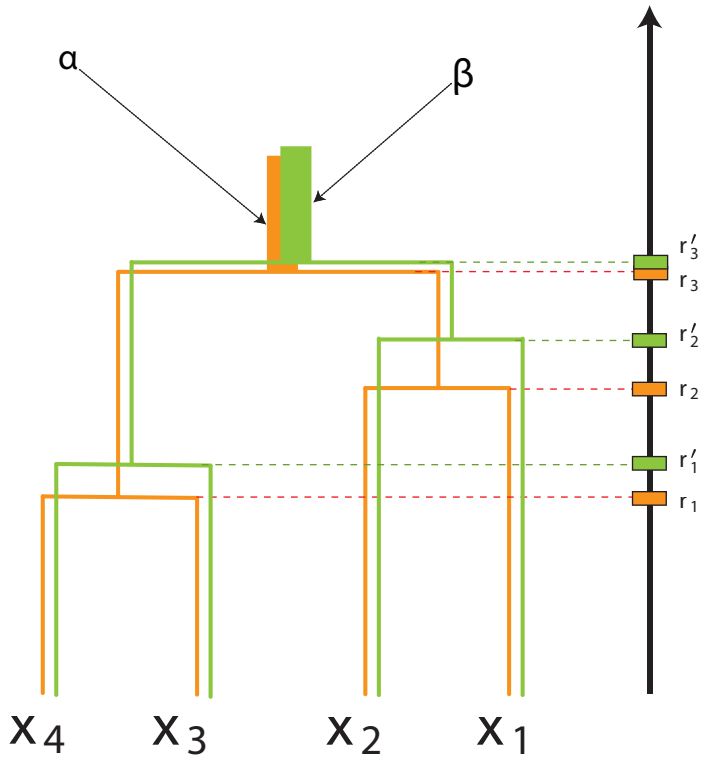

Figure 11: Two different dendrograms (X,α) and (X,β) over the same underlying set $X = \{x_1,x_2,x_3,x_4\}$. The condition that $\|u_\alpha - u_\beta\|_{L^\infty(X\times X)} \leqslant \varepsilon$ is equivalent to the horizontal dotted lines corresponding to r_i and r'_i $(i = 1,2,3)$ being within ε of eachother.

Now, in a slightly more general situation we may be faced with the task of comparing two different dendrograms α and β without knowing (or caring about) the exact labels of the points. In this case, a natural solution is to look at the minimum of the maximum difference of the corresponding ultrametrics under all possible permutations, namely:

$$\min_{\pi\in P_n} \max_{x,x'\in X} |u_\alpha(x,x') - u_\beta(\pi(x),\pi(x'))|, \tag{5}$$

where n is the cardinality of X and P_n is the collection of all permutations of n elements.

The most general case arises when we do not know whether the dendrograms come from the same underlying set or not. This situation may arise, for example, when comparing the results of clustering two different samples, of possibly different sizes, coming from the same data set. One may want to be able to compare two such clusterings as a way to ascertain whether the sample size is sufficient for capturing the structure of the underlying data set.

Assume then that we are given (X_1,α) and (X_2,β), two different dendrograms, defined possibly over two *different sets* X_1 and X_2 of different cardinality. This potential difference in cardinality in the two sets forces us to consider transformations other than mere permutations. A natural solution, which can be interpreted as a *relaxation* of the permutation based distance (5) discussed above, is to consider maps $f : X_1 \to X_2$ and $g : X_2 \to X_1$ and look at their *distortions*:

$$\operatorname{dis}(f) := \max_{x,x' \in X_1} |u_\alpha(x,x') - u_\beta(f(x),f(x'))|,$$

$$\operatorname{dis}(g) := \max_{x,x' \in X_2} |u_\alpha(g(x),g(x')) - u_\beta(x,x)|.$$

The next natural step would be to optimize over the choice of f and g, for example by minimizing the maximum of the two distortions:

$$\min_{f,g} \max\big(\operatorname{dis}(f), \operatorname{dis}(g)\big).$$

This construction is depicted in Figure 12. Roughly speaking, this idea leads to the Gromov-Hausdorff distance. The difference lies in the fact that in standard definition of the Gromov-Hausdorff distance, one also considers a term that measures the degree to which f and g are inverses of eachother. Being more precise, given the maps f and g, this term, called the *joint distortion* of f and g is given by

$$\operatorname{dis}(f,g) := \max_{x \in X, y \in Y} \big|u_\alpha(x,g(y)) - u_\beta(y,f(x))\big|.$$

One defines the Gromov-Hausdorff distance between (X_1,u_α) and (X_2,u_β) by

$$d_{\mathcal{GH}}\big(X_1,X_2\big) := \frac{1}{2} \min_{f,g} \max\big(\operatorname{dis}(f), \operatorname{dis}(g), \operatorname{dis}(f,g)\big).^{6} \tag{6}$$

We now see exactly how the inclusion of the new term enforces f and g to be approximate inverses of eachother. Assume that for some $\varepsilon > 0$ $d_{\mathcal{GH}}\big(X_1,X_2\big) < \varepsilon$, then, in particular, there exist maps f and g such that $\big|u_\alpha(x,g(y)) - u_\beta(y,f(x))\big| \leqslant 2\varepsilon$ for all $x \in X_1$ and $y \in X_2$. Choosing $y = f(x)$, in particular, we obtain that $u_\alpha(x,g(f(x))) \leqslant 2\varepsilon$ for all $x \in X_1$. Similarly one obtains that $u_\beta(y,f(g(y))) \leqslant 2\varepsilon$ for all $y \in X_2$. These two inequalities measure the degree to which $f \circ g$ and $g \circ f$ differ from the identities, and thus, measure the degree to which f and g fail to be inverses of eachother. This is a useful feature when one considers *convergence issues* such as we do in §5.

3.5.1 INTERPRETATION OF THE GROMOV-HAUSDORFF DISTANCE IN TERMS OF DENDROGRAMS

Assume that $d_{\mathcal{GH}}\big((X_1,u_\alpha),(X_2,u_\beta)\big) \leqslant \frac{\eta}{2}$ for some $\eta \geqslant 0$. Then there exist maps $f : X \to Y$ and $g : Y \to X$ such that the following conditions hold (see Figure 13):

- If x,x' fall in the same block of $\alpha(t)$ then $f(x), f(x')$ belong to the same block of $\beta(t')$ for all $t' \geqslant t + \eta$.
- If y,y' fall in the same block of $\beta(t)$ then $g(y), g(y')$ belong to the same block of $\alpha(t')$ for all $t' \geqslant t + \eta$.

For the next section we do not need to make use of the full generality in these considerations: there we only compare dendrograms defined over the same underlying set. A more detailed use and additional material about the Gromov-Hausdorff ideas is given in §5.

We finish this section with a precise result regarding the stability of dendrograms arising from SLHC.

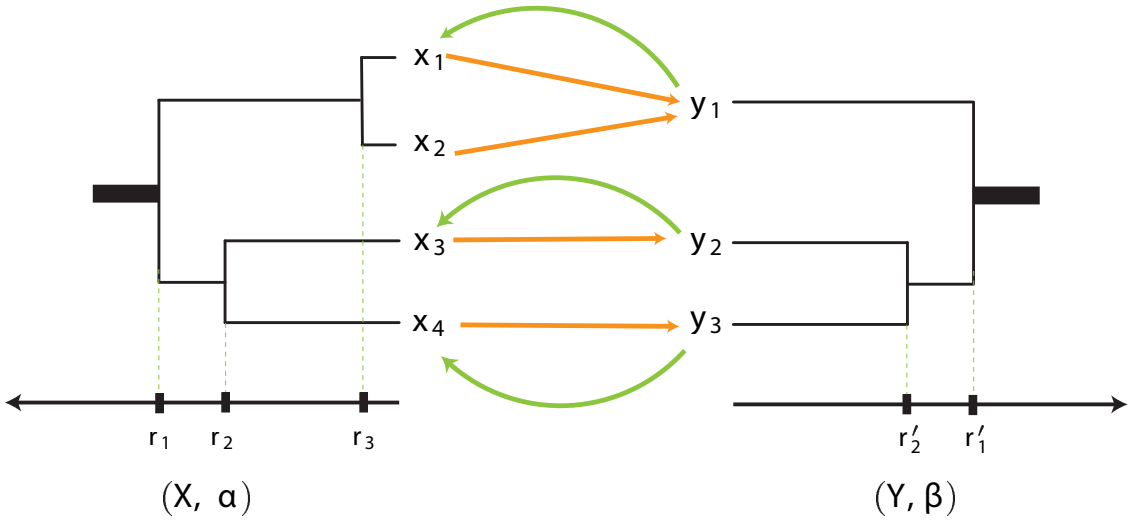

Figure 12: In this example, two different dendrograms, (X,α) and (Y,β), are given. The (straight) arrows pointing from left to right show a map $f : X \to Y$, and the (curved) arrows pointing from right to left show the map $g : Y \to X$. With simple explicit computations one sees that these choices of maps f and g incur distortions $\mathrm{dis}(f) = \mathrm{dis}(f,g) = \max\left(r_3, |r_1 - r_1'|, |r_2 - r_2'|\right)$ and $\mathrm{dis}(g) = \max\left(|r_1 - r_1'|, |r_2 - r_2'|\right)$, respectively. Hence, we see that $d_{\mathcal{GH}}\big((X,\Psi(\alpha)),(Y,\Psi(\beta))\big) \leqslant \frac{1}{2}\max\left(r_3, |r_1 - r_1'|, |r_2 - r_2'|\right)$.

The following Lemma deals with the situation when we have a fixed finite set P and two different metrics on P and then we compute the result of applying $\mathfrak{T}^*$ each of these metrics. This lemma is a particular case of our main stability result, Proposition 26 in §5. In the interest of clarity, we prove it here to provide some intuition about the techniques.

Lemma 15 *Let P be a fixed finite set and let d_1, d_2 be two metrics on P. Write $\mathfrak{T}^*(P,d_i) = (P,u_i)$, $i = 1,2$. Then,*

$$\max_{p,q\in P} |u_1(p,q) - u_2(p,q)| \leqslant \max_{p,q\in P} |d_1(p,q) - d_2(p,q)|.$$

Proof Let $\eta = \max_{p,q\in P} |d_1(p,q) - d_2(p,q)|$. Let $p_0,\ldots,p_k \in P$ be s.t. $p_0 = p$, $p_k = q$ and $\max_i d_1(p_i,p_{i+1}) = u_1(p,q)$. Then, by definition of u_2 (which is the minimum over all chains of the maximal hop measured with metric d_2) and the fact that $d_2 \leqslant d_1 + \eta$:

$$u_2(p,q) \leqslant \max_i d_2(p_i,p_{i+1}) \leqslant \max_i (\eta + d_1(p_i,p_{i+1})) = \eta + u_1(p,q).$$

Similarly, $u_1(p,q) \leqslant \eta + u_2(p,q)$, and hence $|u_1(p,q) - u_2(p,q)| \leqslant \eta$. The claim follows since $p,q \in P$ are arbitrary. ■

6. The factor $\frac{1}{2}$ is of course inmaterial but kept here for coherence with the standard definition.

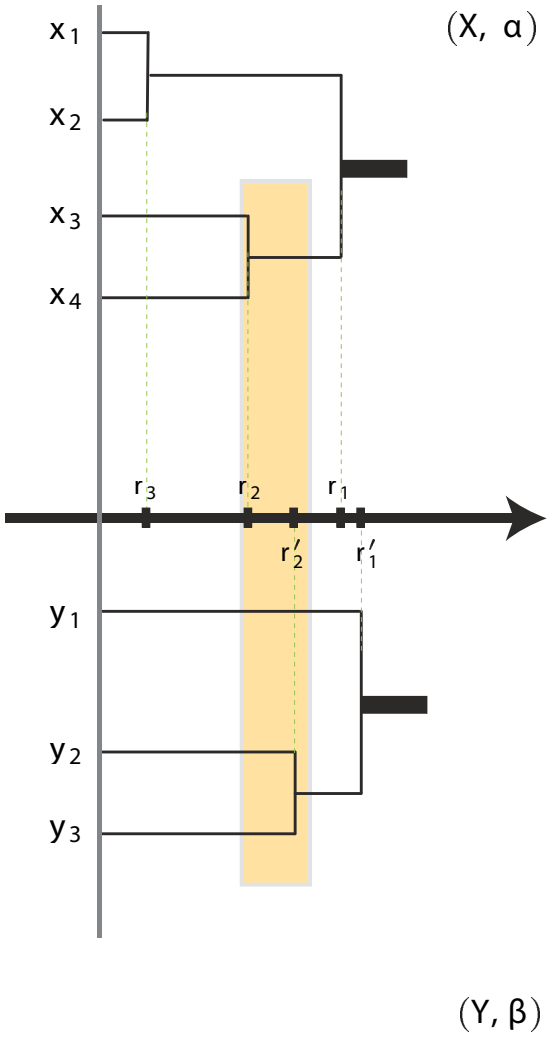

Figure 13: These are the same dendrograms as in Figure 12. Let $r_1 = \frac{5}{3}, r_2 = 1, r_3 = \frac{1}{3}, r'_1 = \frac{11}{6}$ and $r'_2 = \frac{4}{3}$. For the maps f and g s.t. $f(x_1) = f(x_2) = y_1$, $f(x_3) = y_2$, $f(x_4) = y_3$, $g(y_1) = x_1$, $g(y_2) = x_3$ and $g(y_3) = x_4$, using the formulas computed in Figure 12 we see that $\mathrm{dis}(f) = \mathrm{dis}(g) = \mathrm{dis}(f,g) = \frac{1}{3}$ and hence $d_{\mathcal{GH}}\big((X,\Psi(\alpha)),(Y,\Psi(\beta))\big) \leqslant \frac{1}{6}$. Now notice for instance that x_3 and x_4 fall in the same block of $\alpha(r_2) = \alpha(1)$ and that $y_2 = f(x_3)$ and $y_3 = f(x_4)$ fall in the same block of $\beta(t')$ for all $t' \geqslant r_2 + 2 \cdot \frac{1}{6} = 1 + \frac{1}{3} = \frac{4}{3} = r'_2$.

3.6 Some Remarks about Hierarchical Clustering Methods

Practitioners of clustering often prefer AL and CL to SL because it is perceived that the former two methods tend to produce clusters which are more coherent conceptually, and which are in a non-technical sense viewed as more compact. In fact, SL exhibits the so called **chaining effect** which makes it more likely to produce clusterings which separate items which conceptually should be together. We view these observations as evidence for the idea that good clustering schemes need to take some notion of density into account, rather than straightforward geometric information alone.

One can loosely argue that given the actual definition of the linkage functions used by AL and CL, these two methods do enjoy some sort of sensitivity to density. Unfortunately, AL and CL are **unstable**, and in particular, **discontinuous** in a very precise sense (see Remark 16 below), whereas SL enjoys all the nice theoretical properties that the other two methods lack.

In this section we review this seemingly paradoxical situation.

For each $n \in \mathbb{N}$ let L_n be a metric space with n points $P = \{p_1, \ldots, p_n\}$ and metric $d_{L_n}(p_i, p_j) = |i-j|$, $i, j \in \{1, \ldots, n\}$. Similarly, let Δ_n be the metric space with the same underlying set and metric $d_{\Delta_n}(p_i, p_j) = 1$, $i, j \in \{1, \ldots, n\}$, $i \neq j$. Clearly, the metric space L_n is isometric to points equally spaced on a line in Euclidean space whereas (s.t. two adjacent points are at distance 1 from eachother) Δ_n is isometric to the $(n-1)$-unit-simplex as a subset of $\mathbb{R}^{n-1}$.

Clearly, the outputs of Single Linkage HC applied to both L_n and Δ_n coincide for all $n \in \mathbb{N}$:

$$\mathfrak{T}^*(P, d_{L_n}) = \mathfrak{T}^*(P, d_{\Delta_n}) = \big(P, ((\gamma))\big) \tag{7}$$

where $\gamma_{ij} = 0$ if $i = j$ and $\gamma_{ij} = 1$ if $i \neq j$, for all $n \in \mathbb{N}$, see Figure 14.

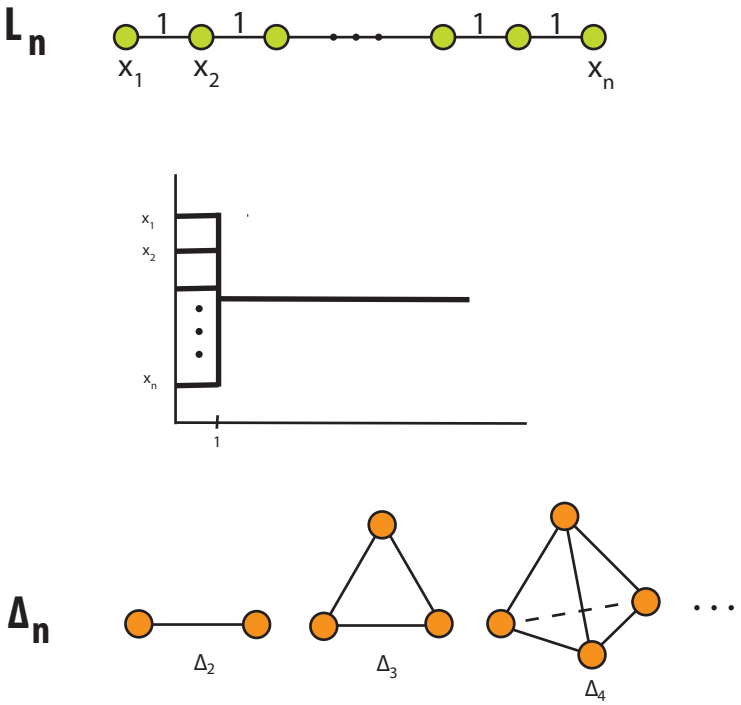

Figure 14: The metric spaces L_n and Δ_n both have n points. Single linkage HC applied to either of them yields the dendrogram in the center.

By appealing to the Euclidean realizations of L_n and Δ_n, one can define *perturbed* versions of these two metric spaces. Indeed, fix $\varepsilon > 0$ and let $\{a_1, \ldots, a_n\} \subset [0, \varepsilon/2]$ and $\{b_1, \ldots, b_n\} \subset S^{n-1}(\varepsilon/2)$. Define L_n^ε to be the metric space with underlying set P and metric $d_{L_n^\varepsilon}(p_i, p_j) = |i-j+$

$a_i - a_j|$. Similarly, define Δ_n^ε to be the metric space with underlying set P and metric $d_{\Delta_n^\varepsilon}(p_i,p_j) = \|s_i - s_j + b_i - b_j\|$.

Notice that by construction,

$$\max_{i,j} \left| d_{L_n}(p_i,p_j) - d_{L_n^\varepsilon}(p_i,p_j) \right| \leqslant \varepsilon \tag{8}$$

and

$$\max_{i,j} \left| d_{\Delta_n}(p_i,p_j) - d_{\Delta_N^\varepsilon}(p_i,p_j) \right| \leqslant \varepsilon. \tag{9}$$

We thus say that the spaces $(P, d_{L_n^\varepsilon})$ and $(P, d_{\Delta_n^\varepsilon})$ are perturbed versions of (P, d_{L_n}) and (P, d_{Δ_n}), respectively.

Remark 16 (About a critique to SL) *Single linkage is generally regarded as a poor choice in practical applications. The reason for this is the so called* chaining *effect observed experimentally, which is central to the criticism to SL made in Lance and Williams (1967) (see also the discussion in Wishart, 1969, pp. 296). The following two observations are important:*

(O1) *It is generally argued that since $(P, d_{L_n^\varepsilon})$ corresponds to points on the vicinity of a line, whereas $(P, d_{\Delta_n^\varepsilon})$ corresponds to points in the close vicinity of a $(n-1)$-simplex, then the cluster formed by points on the latter metric space is more* compact *or* denser *than the one formed by the former, and thus more meaningful.*

(O2) *The outputs of SL to the spaces $(P, d_{L_n^\varepsilon})$ and $(P, d_{\Delta_n^\varepsilon})$ are very similar and this similarity is of order ε.*

Indeed, if we write $\mathfrak{T}^*(P, d_{L_n^\varepsilon}) = (P, u_{L_n^\varepsilon})$ and $\mathfrak{T}^*(P, d_{\Delta_n^\varepsilon}) = (P, u_{\Delta_n^\varepsilon})$, then, by the triangle inequality for the L^∞ norm,

$$\begin{aligned} \|u_{L_n^\varepsilon} - u_{\Delta_n^\varepsilon}\|_{L^\infty(P\times P)} &\leqslant \|u_{L_n^\varepsilon} - u_{L_n^0}\|_{L^\infty(P\times P)} \\ &+ \|u_{L_n^0} - u_{\Delta_n^0}\|_{L^\infty(P\times P)} \\ &+ \|u_{\Delta_n^0} - u_{\Delta_n^\varepsilon}\|_{L^\infty(P\times P)}. \end{aligned} \tag{10}$$

As we pointed out in (7) at the beginning of Section §3.6,

$$u_{L_n^0} = u_{L_n} = ((\gamma)) = u_{\Delta_n} = u_{\Delta_n^0},$$

thus, (10) simplifies into:

$$\begin{aligned} \|u_{L_n^\varepsilon} - u_{\Delta_n^\varepsilon}\|_{L^\infty(P\times P)} &\leqslant \|u_{L_n^\varepsilon} - u_{L_n^0}\|_{L^\infty(P\times P)} \\ &+ \|u_{\Delta_n^\varepsilon} - u_{\Delta_n^0}\|_{L^\infty(P\times P)} \\ &\quad \textit{(and by Lemma 15:)} \\ &\leqslant \|d_{L_n^\varepsilon} - d_{L_n^0}\|_{L^\infty(P\times P)} \\ &+ \|d_{\Delta_n^\varepsilon} - d_{\Delta_n^0}\|_{L^\infty(P\times P)}. \end{aligned} \tag{11}$$

Hence, by (11) and the construction of $d_{L_n^\varepsilon}$ and $d_{\Delta_n^\varepsilon}$ (Equations (8) and (9)), we conclude that

$$\|u_{L_n^\varepsilon} - u_{\Delta_n^\varepsilon}\|_{L^\infty(P\times P)} \leqslant 2\varepsilon.$$

This means that for any small perturbations of L_n and Δ_n, the output of SL to these perturbations are at a small distance from eachother, as we claimed.

*When put together, observations **(O1)** and **(O2)** suggest that SL is unable to pick denser associations of data, such as cliques, over sparser ones, such as linear structures. This feature is undesirable in practical applications where often times one would like to regard clusters as modes of an underlying distribution (Wishart, 1969; Hartigan, 1981).*

It is then the case that in practical applications, CL and especially AL are preferred over SL. These two methods have the property that they indeed somehow favor the association of compact subsets of points. For CL this can be explained easily using the concept of maximal clique *(maximally connected sub-graphs of a given graph) (Jain and Dubes, 1988, Section 3.2.1). Let d_k be the diameter of the cluster created in step k of CL clustering and define a graph $G(k)$ as the graph that links all data points with a distance of at most d_k. Then the clusters after step k are the maximal cliques of $G(k)$. This observation reinforces the perception that CL yields clusters that are dense as measured by the presence of cliques. The sensitivity of AL to density has been discussed by Hartigan in Hartigan (1985, Section 3) and is basically due to the averaging performed in the definition of its linkage function.*

*A more principled way of taking density into account, that does not depend on ad hoc constructions which destroy the stability property, would be to explicitly build the density into the method. In Carlsson and Mémoli (2009) we study **multiparameter clustering methods**, which are similar to HC methods but we* track *connected components in a multiparameter landscape. We also study the classification and stability properties of multiparameter clustering methods.*

Remark 17 (Instability of CL and AL) *It turns out that CL and AL, despite not exhibiting the undesirable feature of the chaining effect, and despite being regarded as more sensitive to density, are **unstable** in a precise sense. Consider for example CL and let $n = 3$. In the construction of (P, d_L^ε) above let $a_1 = a_2 = 0$ and $a_3 = \varepsilon$, then*

$$((d_L)) = \begin{array}{c} \\ p_1 \\ p_2 \\ p_3 \end{array} \begin{array}{c} \begin{array}{ccc} p_1 & p_2 & p_3 \end{array} \\ \begin{pmatrix} 0 & 1 & 2 \\ 1 & 0 & 1 \\ 2 & 1 & 0 \end{pmatrix} \end{array} \quad \textit{and} \quad ((d_L^\varepsilon)) = \begin{array}{c} \\ p_1 \\ p_2 \\ p_3 \end{array} \begin{array}{c} \begin{array}{ccc} p_1 & p_2 & p_3 \end{array} \\ \begin{pmatrix} 0 & 1 & 2+\varepsilon \\ 1 & 0 & 1+\varepsilon \\ 2+\varepsilon & 1+\varepsilon & 0 \end{pmatrix} \end{array}.$$

Write $\mathfrak{T}^{CL}(P, d_L) = (P, u_L)$ and $\mathfrak{T}^{CL}(P, d_L^\varepsilon) = (P, u_L^\varepsilon)$. Clearly,

$$((u_L)) = \begin{array}{c} \\ p_1 \\ p_2 \\ p_3 \end{array} \begin{array}{c} \begin{array}{ccc} p_1 & p_2 & p_3 \end{array} \\ \begin{pmatrix} 0 & 1 & 1 \\ 1 & 0 & 1 \\ 1 & 1 & 0 \end{pmatrix} \end{array} \quad \textit{and} \quad ((u_L^\varepsilon)) = \begin{array}{c} \\ p_1 \\ p_2 \\ p_3 \end{array} \begin{array}{c} \begin{array}{ccc} p_1 & p_2 & p_3 \end{array} \\ \begin{pmatrix} 0 & 1 & 2+\varepsilon \\ 1 & 0 & 2+\varepsilon \\ 2+\varepsilon & 2+\varepsilon & 0 \end{pmatrix} \end{array}.$$

Notice that despite $\max_{i,j} |d_L(p_i, p_j) - d_L^\varepsilon(p_i, p_j)| = \varepsilon$, $\max_{i,j} |u_L(p_i, p_j) - u_L^\varepsilon(p_i, p_j)| = 1 + \varepsilon > 1$ for all $\varepsilon > 0$. *We thus conclude that CL is not stable under small perturbations of the metric. Note that in particular, it follows that CL is **not continuous**. The same construction can be adapted for AL. See Figure 15.*

4. A Characterization Theorem for SL Hierarchical Clustering

In this section we obtain a **characterization** of SL hierarchical clustering in terms of some simple axioms. The main axiom, (II) below, says that the clustering scheme has a prescribed behavior

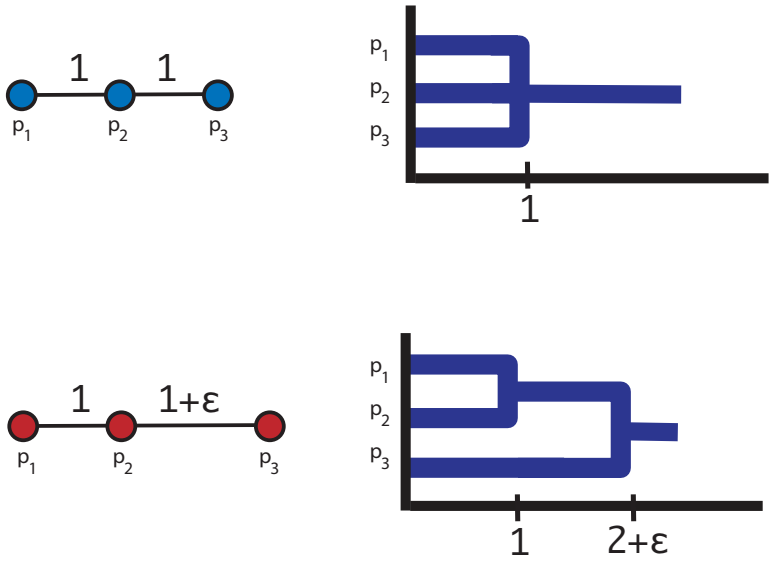

Figure 15: Complete Linkage is not stable to small perturbations in the metric. On the left we show two metric spaces that are metrically very similar. To the right of each of them we show their CL dendrogram outputs. Regardless of $\varepsilon > 0$, the two outputs are always very dissimilar. We make the notion of *similarity* between dendrogram precise in §5 by interpreting dendrograms as ultrametric spaces and by computing the Gromov-Hausdorff distance between these ultrametric spaces.

under distance non-increasing maps of metric space. The behavior is that the map of metric spaces should induce a map of clusters, that is, that if two points in the domain space belong to the same cluster, then so do their images in the clustering of the image metric space. This notion, referred to as **functoriality** in the mathematics literature, appears to us to be a very natural one, and it is closely related to Kleinberg's consistency property (cf. pp. 1425) for ordinary clustering methods; see Remark 19 for an interpretation of our axioms.

Theorem 18 *Let $\mathfrak{T}$ be a hierarchical clustering method s.t.*

(I) $\mathfrak{T}\left(\{p,q\},\left(\begin{smallmatrix}0&\delta\\ \delta&0\end{smallmatrix}\right)\right)=\left(\{p,q\},\left(\begin{smallmatrix}0&\delta\\ \delta&0\end{smallmatrix}\right)\right)$ *for all* $\delta>0$.

(II) *Whenever $X,Y\in\mathcal{X}$ and $\phi:X\to Y$ are such that $d_X(x,x')\geqslant d_Y(\phi(x),\phi(x'))$ for all $x,x'\in X$, then*

$$u_X(x,x')\geqslant u_Y(\phi(x),\phi(x'))$$

also holds for all $x,x'\in X$, where $\mathfrak{T}(X,d_X)=(X,u_X)$ and $\mathfrak{T}(Y,d_Y)=(Y,u_Y)$. prop

(III) *For all $(X,d)\in\mathcal{X}$,*

$$u(x,x')\geqslant sep(X,d)\text{ for all }x\neq x'\in X$$

where $\mathfrak{T}(X,d)=(X,u)$.

Then $\mathfrak{T}=\mathfrak{T}^*$, that is, $\mathfrak{T}$ is exactly single linkage hierarchical clustering.

Remark 19 (Interpretation of the conditions) *Let $(X,d) \in \mathcal{X}$ and write $\mathfrak{T}(X,d) = (X,u)$. The intuition is that $u(x,x')$ measures the* effort *method $\mathfrak{T}$ makes in order to join x to x' into the same cluster.*

Condition (I) is clear, the two-point metric space contains only one degree of freedom which has to determine unambiguously the behavior of any clustering method $\mathfrak{T}$. In terms of dendrograms, this means that the two point metric space $\left(\{A,B\}, \left(\begin{smallmatrix} 0 & \delta \\ \delta & 0 \end{smallmatrix}\right)\right)$ must be mapped to the dendrogram where A and B are merged at parameter value δ, see Figure 16.

Condition (II) is crucial and roughly says that whenever one shrinks some distances (even to zero) to obtain a new (pseudo) metric space, then the corresponding efforts in this new space have to be smaller than the efforts in the original metric space. This is consistent with the notion that reducing the distance between two points (without increasing all other distances) makes them more likely to belong to the same cluster.

Let $\theta_X = \Psi^{-1}(u_X)$ and $\theta_Y = \Psi^{-1}(u_Y)$ be the dendrograms associated to u_X and u_Y. In terms of dendrograms, this means that if two points $x,x' \in X$ are in the same block of $\theta_X(t)$ for some $t > 0$, then $\phi(x)$ and $\phi(x')$ must be *in the same block of $\theta_Y(t)$. see Figure 17.*

Condition (III) expresses the fact that in order to join two points $x,x' \in X$, any clustering method $\mathfrak{T}$ has to make an effort of at least the separation $sep(X,d)$ of the metric space. In terms of dendrograms, this means that $\theta_X(t)$ has to equal the partition of X into singletons for all $0 \leqslant t < sep(X,d)$. See Figure 18.

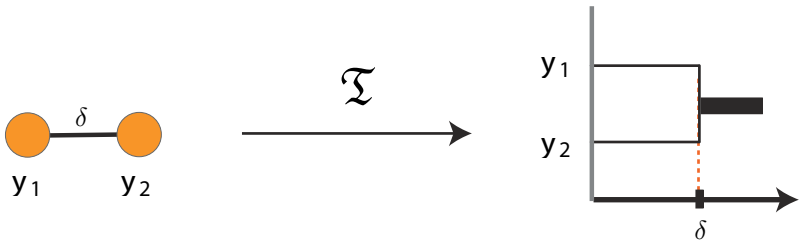

Figure 16: **Interpretation of Condition I**: For all $\delta > 0$ the two point metric space on the left must be mapped by $\mathfrak{T}$ into the dendrogram on the right.

Remark 20 *It is interesting to point out why complete linkage and average linkage hierarchical clustering, as defined in §3.2.2, fail to satisfy the conditions in Theorem 18. It is easy to see that conditions (I) and (III) are always satisfied by CL and AL.*

Consider the metric spaces $X = \{A,B,C\}$ with metric given by the edge lengths $\{4,3,5\}$ and $Y = (A',B',C')$ with metric given by the edge lengths $\{4,3,2\}$, as given in Figure 19. Obviously, the map ϕ from X to Y with $\phi(A) = A'$, $\phi(B) = B'$ and $\phi(C) = C'$ is s.t.

$$d_Y(\phi(x),\phi(x')) \leqslant d_X(x,x') \quad \text{for all } x,x' \in \{A,B,C\}.$$

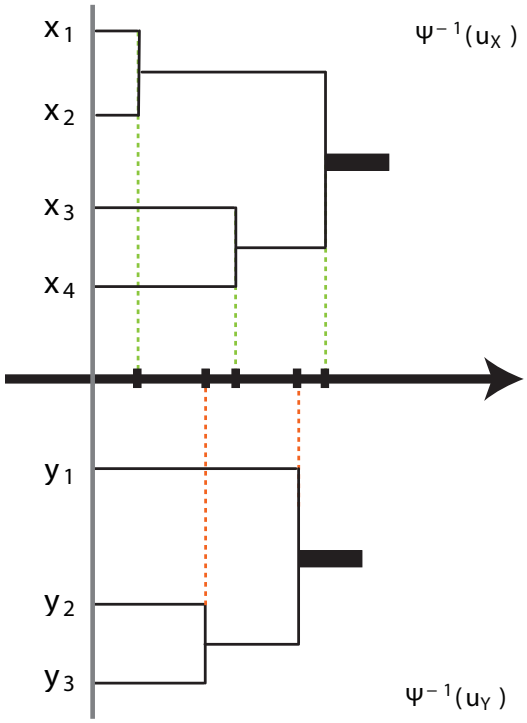

Figure 17: **Interpretation of Condition II**: Assume that $\phi : X \to Y$ is a distance non-increasing map such that $\phi(x_1) = \phi(x_2) = y_1$, $\phi(x_3) = y_2$ and $\phi(x_4) = y_3$. Then, Condition (II) requires that if $x, x' \in X$ are merged into the same cluster of $\Psi^{-1}(u_X)$ at parameter value t, then $\phi(x)$ and $\phi(x')$ must merge into the same cluster of $\Psi^{-1}(u_Y)$ for some parameter value $\leqslant t$. In the Figure, this translates into the condition that vertical dotted lines corresponding to mergings of pairs of points in X should happen at parameter values greater than or equal than the parameter values for which correponding points in Y (via ϕ) are merged into the same cluster. For example, $\phi(x_1), \phi(x_2)$ merge into the same cluster at parameter value 0. The condition is clearly verified for this pair since by definition of ϕ, $\phi(x_1) = \phi(x_2) = y_1$. Take now x_3 and x_4: clearly the vertical line that shows the parameter value for which they merge is to the right of the vertical line showing the parameter value for which $y_2 = \phi(x_3)$ and $y_3 = \phi(x_4)$ merge.

It is easy to check that

$$((u_X)) = \begin{array}{c} \\ A \\ B \\ C \end{array} \begin{array}{c} \begin{array}{ccc} A & B & C \end{array} \\ \begin{pmatrix} 0 & 5 & 3 \\ 5 & 0 & 5 \\ 3 & 5 & 0 \end{pmatrix} \end{array} \quad \textit{and} \quad ((u_Y)) = \begin{array}{c} \\ A' \\ B' \\ C' \end{array} \begin{array}{c} \begin{array}{ccc} A' & B' & C' \end{array} \\ \begin{pmatrix} 0 & 2 & 4 \\ 2 & 0 & 4 \\ 4 & 4 & 0 \end{pmatrix} \end{array}.$$

Note that for example $3 = u_X(A,C) < u_Y(\phi(A),\phi(C)) = u_Y(A',C') = 4$ *thus violating property (II). The same construction yields a counter-example for average linkage.*

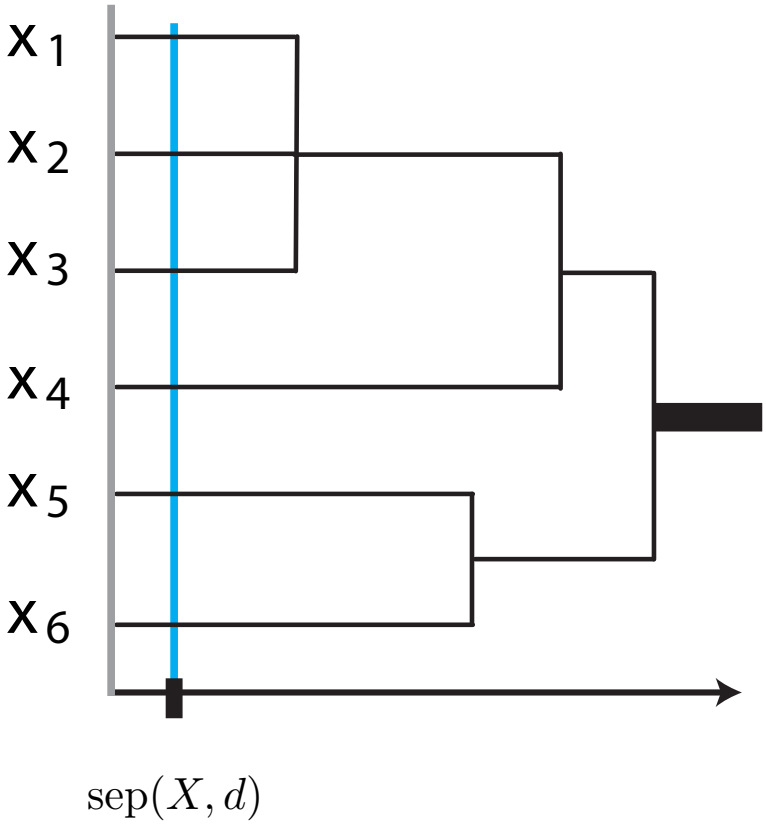

Figure 18: **Interpretation of Condition III**: The vertical line at parameter value $t = \mathrm{sep}(X,d)$ must intersect the horizontal lines of the dendrogram before any two points are merged.

5. Metric Stability and Convergence of $\mathfrak{T}^*$

The Proposition and Theorem below assert the metric stability and consistency/convergence of the method $\mathfrak{T}^*$ (i.e., of SLHC, by virtue of Proposition 14. We use the notion of Gromov-Hausdorff distance between metric spaces (Burago et al., 2001). This notion of distance permits regarding the collection of all compact metric spaces as a metric space in itself.

This seemingly abstract construction is in fact very useful. Finite metric spaces are by now ubiquitous in virtually all areas of data analysis, and the idea of assigning a metric to the collection of all of them is in fact quite an old one. For Euclidean metric spaces, for example, the idea of constructing a metric was used by Kendall et al. (1999) and Bookstein et al. (1985) in constructing a *statistical shape theory*, motivated by the ideas about form of biological organisms developed by D'Arcy Thompson.

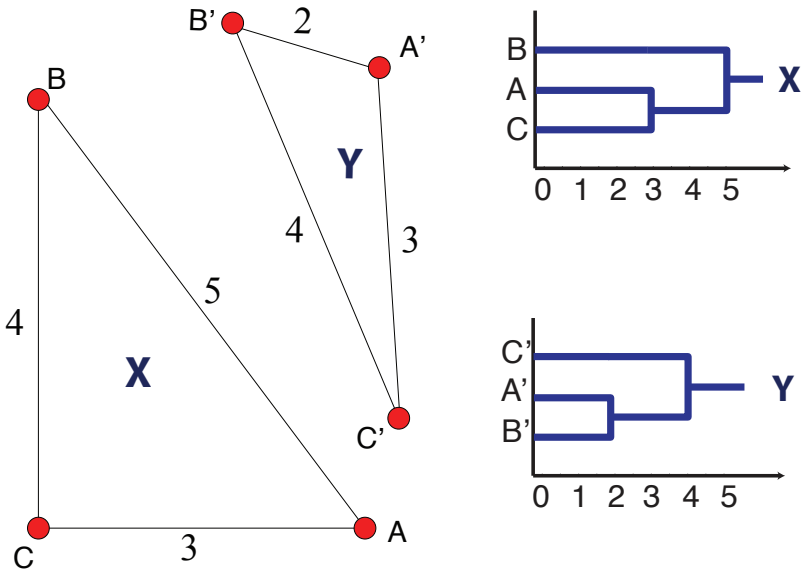

Figure 19: An example that shows why complete linkage fails to satisfy condition (2) of Theorem 18.

5.1 The Gromov-Hausdorff Distance and Examples

Definition 21 *Let (Z,d_Z) be a compact metric space. The Hausdorff distance between any two compact subsets A,B of Z is defined by*

$$d_{\mathcal{H}}^Z(A,B) := \max\left(\max_{a\in A}\min_{b\in B} d_Z(a,b), \max_{b\in B}\min_{a\in A} d_Z(a,b)\right).$$

Remark 22 *Let $\mathbb{Z} = \{z_1,\ldots,z_n\} \subset Z$. Then, $d_{\mathcal{H}}^Z(\mathbb{Z},Z) \leqslant \delta$ for some $\delta \geqslant 0$ if and only if $Z \subset \bigcup_{i=1}^n \overline{B(z_i,\delta)}$. In other words, $d_{\mathcal{H}}^Z(\mathbb{Z},Z)$ describes the minimal δ s.t. $\mathbb{Z}$ is a δ-net for Z and therefore measures how well $\mathbb{Z}$ covers Z.*

The Gromov-Hausdorff distance $d_{\mathcal{GH}}(X,Y)$ between compact metric spaces (X,d_X) and (Y,d_Y) was orignally defined to be the infimal $\varepsilon > 0$ s.t. there exists a metric d on $X \bigsqcup Y$ with $d_{|X\times X} = d_X$ and $d_{|Y\times Y} = d_Y$ for which the Hausdorff distance between X and Y (as subsets of $(X\bigsqcup Y,d)$) is less than ε (Gromov, 1987). There is, however, an alternative expression for the GH distance that is better suited for our purposes which we now recall.

Definition 23 (Correspondence) *For sets A and B, a subset $R \subset A\times B$ is a* correspondence *(between A and B) if and and only if*

- $\forall\, a\in A$, *there exists* $b\in B$ *s.t.* $(a,b)\in R$
- $\forall\, b\in B$, *there exists* $a\in X$ *s.t.* $(a,b)\in R$

Let $\mathcal{R}(A,B)$ denote the set of all possible correspondences between A and B.

We now give several examples to illustrate this definition.

Example 8 *Let $A=\{a_1,a_2\}$ and $B=\{b_1,b_2,b_3\}$. In this case, $R_1=\{(a_1,b_1),(a_2,b_2),(a_1,b_3)\}$ is a correspondence but $R_2=\{(a_1,b_1),(a_2,b_2)\}$ is not.*

Example 9 *Let A and B be finite s.t. $\#A=\#B=n$. In this case, if π is any permutation matrix of size n, then $\{(a_i,b_{\pi_i}),\, i=1,\ldots,n\}\in\mathcal{R}(A,B)$.*

Example 10 *Let $\phi:X\to Y$ and $\psi:Y\to X$ be given maps. Then, one can construct a correspondence out of these maps, call it $R(\phi,\psi)$ given by*

$$\big\{(x,\phi(x)),\, x\in X\big\}\bigcup\big\{(\psi(y),y),\; y\in Y\big\}.$$

For metric spaces (X,d_X) and (Y,d_Y). Let $\Gamma_{X,Y}:X\times Y\times X\times Y\to\mathbb{R}^+$ be given by

$$(x,y,x',y')\mapsto\big|d_X(x,x')-d_Y(y,y')\big|.$$

Then, by (Burago et al., 2001, Theorem 7.3.25) the **Gromov-Hausdorff distance** between X and Y is equal to

$$d_{\mathcal{GH}}\big(X,Y\big):=\frac{1}{2}\inf_{R\in\mathcal{R}(X,Y)}\sup_{(x,y),(x',y')\in R}\Gamma_{X,Y}(x,y,x',y'). \tag{12}$$

It can be seen (it is an easy computation) that in (12) one can restrict the infimum to those correspondences that arise from maps ϕ and ψ such as those constructed in Example 10. Then, one recovers expression (6) which we gave in §3.5, namely, that actually

$$d_{\mathcal{GH}}\big(X,Y\big):=\frac{1}{2}\inf_{\phi,\psi}\max\big(\mathrm{dis}(\phi),\mathrm{dis}(\psi),\mathrm{dis}(\phi,\psi)\big). \tag{13}$$

Remark 24 *Expression (13) defines a **distance** on the set of (isometry classes of) finite metric spaces (Burago et al., 2001, Theorem 7.3.30). From now on let $\mathcal{G}$ denote the collection of all (isometry classes of) compact metric spaces. We say that $\{(X_n,d_{X_n})\}_{n\in\mathbb{N}}\subset\mathcal{G}$ Gromov-Hausdorff converges to $X\in\mathcal{G}$ if and only if $d_{\mathcal{GH}}\big(X_n,X\big)\to 0$ as $n\uparrow\infty$.*

Example 11 *Fix $(X,d_X)\in\mathcal{G}$. Consider the sequence $\{(X,\frac{1}{n}\cdot d_X)\}_{n\in\mathbb{N}}\subset\mathcal{G}$. Then, X_n Gromov-Hausdorff converges to the metric space consisting of a single point.*

Remark 25 (Gromov-Hausdorff distance and Hausdorff distance) *Let (X,d_X) be a compact metric space. Then, if $X'\subset X$ is compact and we endow X' with the metric $d_{X'}$ equal to the restriction of d_X, then*

$$d_{\mathcal{GH}}\big((X,d_X),(X',d_{X'})\big)\leqslant d_{\mathcal{H}}^X\big(X',X\big).$$

This is easy to see by defining the correspondence R between X and X' given by

$$R=\{(x',x'),x'\in X'\}\cup\{(x,x'),x\in V(x'),x'\in X'\},$$

where $V(x'):=\{x\in X,\, d_X(x,x')\leqslant d_X(x,z),\, z\in X'\backslash\{x'\}\}$. Indeed, since then, for all $(x_1,x_1'),(x_2,x_2')\in R$,

$$\frac{1}{2}\big|d_X(x_1,x_2)-d_X(x_1',x_2')\big|\leqslant\frac{1}{2}\left(d_X(x_1,x_1')+d_X(x_2,x_2')\right)\leqslant\max_{x\in X}\min_{x'\in X'}d_X(x,x')=d_{\mathcal{H}}^X\big(X,X'\big).$$

Example 12 *Consider a finite set M and $d, d' : M \times M \to \mathbb{R}^+$ two metrics on M. Then, the GH distance between (M,d) and (M,d') is bounded above by the L^∞ norm of the difference between d and d':*

$$d_{\mathcal{GH}}\big((M,d),(M,d')\big) \leqslant \frac{1}{2}\|d - d'\|_{L^\infty(M\times M)}.$$

To prove this it is enough to consider the correspondence $R \in \mathcal{R}(M,M)$ given by $R = \{(m,m), m \in M\}$.

Notice that as an application, for the metric spaces $(P, d_{L_n^\varepsilon})$ and $(P, d_{\Delta_n^\varepsilon})$ discussed in §3.6, one has that

$$d_{\mathcal{GH}}\big((P,d_{L_n}),(P,d_{L_n^\varepsilon})\big) \leqslant \frac{\varepsilon}{2} \text{ and}$$

$$d_{\mathcal{GH}}\big((P,d_{\Delta_n}),(P,d_{\Delta_n^\varepsilon})\big) \leqslant \frac{\varepsilon}{2}.$$

5.2 Stability and Convergence Results

Our first result states that SL HC is stable in the Gromov-Hausdorff sense and it is a generalization of Lemma 15.

Proposition 26 *For any two finite metric spaces (X,d_X) and (Y,d_Y)*

$$d_{\mathcal{GH}}\big((X,d_X),(Y,d_Y)\big) \geqslant d_{\mathcal{GH}}\big(\mathfrak{T}^*(X,d_X),\mathfrak{T}^*(Y,d_Y)\big).$$

Remark 27 *This Proposition generalizes Lemma 15. Notice for example that in case X and Y are finite, they need not have the same number of points. This feature is important in order to be able to make sense of situations such as the one depicted in Figure 2 in pp. 1428, where one is trying to capture the connectivity (i.e., clustering) properties of an underlying 'continuous' space by taking finitely (but increasingly) many samples from this space and applying some form of HC to this finite set. Theorem 28 below deals with exactly this situation. See Figure 20.*

Let (Z,d_Z) be a compact metric space. Given a finite index set A and a (finite) collection of disjoint compact subsets of Z, $\{U^{(\alpha)}\}_{\alpha\in A}$, let $W_A : A \times A \to \mathbb{R}^+$ be given by

$$(\alpha,\alpha') \mapsto \min_{\substack{z\in U^{(\alpha)}\\ z'\in U^{(\alpha')}}} d_Z(z,z').$$

A metric space (A,d_A) arises from this construction, where $d_A = \mathcal{L}(W_A)$. We say that (A,d_A) is the metric space with underlying set A **arising** from $\{U^{(\alpha)}\}_{\alpha\in A}$. Notice that $\mathrm{sep}(A,d_A)$ equals the minimal separation between any two sets $U^{(\alpha)}$ and $U^{(\alpha')}$ ($\alpha \neq \alpha'$). More precisely,

$$\mathrm{sep}(A,d_A) = \min_{\substack{\alpha,\alpha'\in A,\\ \alpha\neq\alpha'}} \min_{\substack{z\in U^{(\alpha)}\\ z'\in U^{(\alpha')}}} d_Z(z,z').$$

We now state a metric stability and convergence result, see Figure 20. The proof of this result is deferred to §B.

Theorem 28 *Assume (Z,d_Z) is a compact metric space. Let X and X' be any two finite subsets of Z and let $d_X = d_{Z|_{X\times X}}$ and $d_{X'} = d_{Z|_{X'\times X'}}$. Write $\mathfrak{T}^*(X,d_X) = (X,u_X)$ and $\mathfrak{T}^*(X',d_{X'}) = (X',u_{X'})$. Then,*

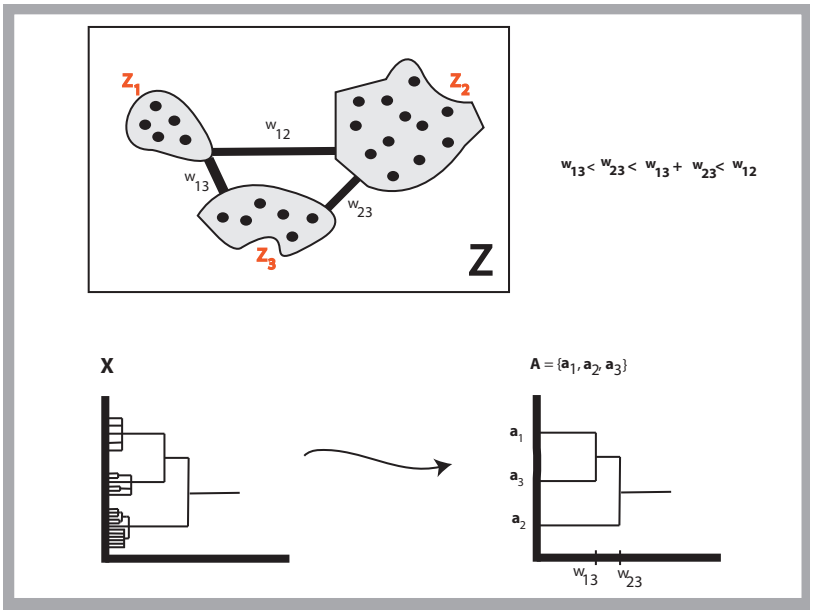

Figure 20: Illustration of Theorem 28. *Top*: A space Z composed of 3 disjoint path connected parts, $Z^{(1)}, Z^{(2)}$ and $Z^{(3)}$. The black dots are the points in the finite sample X. In the figure, $w_{ij} = W(i,j)$, $1 \leqslant i \neq j \leqslant 3$. *Bottom Left*: The dendrogram representation of (X, u_X). *Bottom Right* The dendrogram representation of (Z, u_Z). Note that $d_Z(z_1, z_2) = w_{13} + w_{23}$, $d_Z(z_1, z_3) = w_{13}$ and $d_Z(z_2, z_3) = w_{23}$. As $r \to 0$, $(X, u_X) \to (Z, u_Z)$ in the Gromov-Hausdorff sense, see text for details.

1. *(Finite Stability)* $d_{\mathcal{GH}}\big((X,u_X),(X',u_{X'})\big) \leqslant d_{\mathcal{H}}^Z\big(X,Z\big) + d_{\mathcal{H}}^Z\big(X',Z\big)$.

2. *(Approximation bound) Assume in addition that* $Z = \bigsqcup_{\alpha\in A} Z^{(\alpha)}$ *where* A *is a finite index set and* $Z^{(\alpha)}$ *are compact, disjoint and path-connected sets. Let* (A, d_A) *be the finite metric space with underlying set* A *arising from* $\{Z^{(\alpha)}\}_{\alpha\in A}$. *Let* $\mathfrak{T}^*(A,d_A) = (A,u_A)$. *Then, if* $d_{\mathcal{H}}^Z\big(X,Z\big) < sep(A,d_A)/2$,
$$d_{\mathcal{GH}}\big((X,u_X),(A,u_A)\big) \leqslant d_{\mathcal{H}}^Z\big(X,Z\big).$$

3. *(Convergence) Under the hypotheses of (2), let* $\{X_n\}_{n\in\mathbb{N}}$ *be a sequence of finite subsets of* Z *s.t.* $d_{\mathcal{H}}^Z\big(X_n,Z\big) \to 0$ *as* $n \to \infty$, *and* d_{X_n} *be the metric on* X_n *given by the restriction of* d_Z *to* $X_n \times X_n$. *Then, one has that*
$$d_{\mathcal{GH}}\big(\mathfrak{T}^*(X_n,d_{X_n}),(A,u_A)\big) \to 0 \text{ as } n \to \infty.$$

Remark 29 (Interpretation of the statement) *Assertion (1) guarantees that if* X, X' *are both dense samples of* Z, *then the result of applying* $\mathfrak{T}^*$ *to both sets are very close in the Gromov-Hausdorff sense.*

Assertions (2) and (3) identify the limiting behavior of the construction $\mathfrak{T}^*(X_n, d_{X_n})$ *as* X_n *becomes denser and denser in* X, *see Figure 20.*

5.3 A Probabilistic Convergence Result

In this section, we prove a precise result which describes how the dendrograms attached to compact metric spaces by single linkage clustering can be obtained as the limits of the dendrograms attached to finite subsets of the metric space. The result is by necessity probabilistic in nature. This kind of result is of great importance, since we are often interested in infinite metric spaces but typically do not have access to more than finitely many random samples from the metric space.

Theorem 30 and Corollary 32 below proves that for random i.i.d. observations $\mathbb{X}_n = \{x_1, \ldots, x_n\}$ with probability distribution μ compactly supported in a metric space (X, d), the result $(\mathbb{X}_n, u_{\mathbb{X}_n})$ of applying single linkage clustering to $(\mathbb{X}_n, d)$ converges almost surely in the Gromov-Hausdorff sense to an ultrametric space that recovers the multiscale structure of the *support* of μ, see Figure 20. This is a refinement of a previous observation of Hartigan (1985) that SLHC is insensitive to the distribution of mass of μ in its support.

The proof of this theorem relies on Theorem 34, a probabilistic covering theorem of independent interest. In order to state and prove our theorems we make use of the formalism of **metric measure spaces**.

A triple (X, d_X, μ_X), where (X, d_X) is a metric space and μ_X is a Borel probability measure on X with compact support will be called an **mm-space** (short for measure metric space). The support $\mathrm{supp}[\mu_X]$ of a measure μ_X on X is the minimal closed set A (w.r.t. inclusion) s.t. $\mu_X(X \backslash A) = 0$. Measure metric spaces are considered in the work of Gromov and are useful in different contexts, see (Gromov, 2007, Chapter $3\frac{1}{2}$). For a mm-space X let $f_X : \mathbb{R}^+ \to \mathbb{R}^+$ be defined by

$$r \mapsto \min_{x \in \mathrm{supp}[X]} \mu_X(B_X(x, r)).$$

Note also that by construction $f_X(\cdot)$ in non-decreasing and $f_X(r) > 0$ for all $r > 0$. Let also $F_X : \mathbb{N} \times \mathbb{R}^+ \to \mathbb{R}^+$ be defined by $(n, \delta) \mapsto \frac{e^{-n f_X(\delta/4)}}{f_X(\delta/4)}$. Note that for fixed $\delta_0 > 0$, (1) $F_X(\cdot, \delta_0)$ is decreasing in its argument, and (2) $\sum_{n \in \mathbb{N}} F_X(n, \delta_0) < \infty$.

Theorem 30 *Let (Z, d_Z, μ_Z) be a mm-space and write $\mathrm{supp}[\mu_Z] = \bigcup_{\alpha \in A} U^{(\alpha)}$ for a finite index set A and $\mathbf{U} = \{U^{(\alpha)}\}_{\alpha \in A}$ a collection of disjoint, compact, path-connected subsets of Z. Let (A, d_A) be the metric space arising from $\mathbf{U}$ and let $\delta_A := sep(A, d_A)/2$.*

For each $n \in \mathbb{N}$, let $\mathbb{Z}_n = \{z_1, z_2, \ldots, z_n\}$ be a collection of n independent random variables (defined on some probability space Ω with values in Z) with distribution μ_Z, and let $d_{\mathbb{Z}_n}$ be the restriction of d_Z to $\mathbb{Z}_n \times \mathbb{Z}_n$. Then, for $\zeta \geqslant 0$ and $n \in \mathbb{N}$,

$$\mathbf{P}_{\mu_Z}\left(d_{\mathcal{GH}}\big(\mathfrak{T}^*(\mathbb{Z}_n, d_{\mathbb{Z}_n}), \mathfrak{T}^*(A, d_A)\big) > \zeta \right) \leqslant F_Z\big(n, \min(\zeta, \delta_A/2)\big).$$

Corollary 31 *Under the hypotheses of Theorem 30, for any pre-specified probability level $p \in (0,1)$ and tolerance $\zeta \geqslant 0$, if*

$$n \geqslant \frac{\ln \frac{1}{1-p} - \ln f_X(\delta/4)}{f_X(\delta/4)},$$

then $\mathbf{P}_{\mu_Z}\left(d_{\mathcal{GH}}\big(\mathfrak{T}^*(\mathbb{Z}_n, d_{\mathbb{Z}_n}), \mathfrak{T}^*(A, d_A)\big) \leqslant \zeta \right) \geqslant p$, where $\delta := \min(\zeta, \delta_A/2)$.

Corollary 32 *Under the hypotheses of Theorem 30,* $\mathfrak{T}^*(\mathbb{Z}_n, d_{\mathbb{Z}_n}) \xrightarrow{n} \mathfrak{T}^*(A, d_A)$ *in the Gromov-Hausdorff sense* μ_Z*-almost surely.*

Proof [Proof of Corollary 32] The proof follows immediately from the expression for F_X and the Borel-Cantelli Lemma. ■

Remark 33 *Note that the convergence theorem above implies that in the limit,* $\mathfrak{T}^*(X_n, d_{X_n})$ *only retains information about the support of the probability measure but not about the way the mass is distributed inside the support, compare to Hartigan (1985).*

Example 13 ($Z \subset \mathbb{R}^d$**)** *Let* $\rho : \mathbb{R}^d \to \mathbb{R}^+$ *be a density function with compact, support* Z *and* μ *be its associated probability measure. Then* $(\mathbb{R}^d, \|\cdot\|, \mu)$ *satisfies the assumptions in the theorem. If one makes additional smoothness assumptions on* ρ*, in this particular case one can relate* $F_Z(n, \zeta)$ *to geometrical properties of the boundary of supp* $[\rho]$*.*

Example 14 (Z **is a Riemannian manifold)** *In more generality,* Z *could be a Riemannian manifold and* μ *a probability measure absolutely continuous w.r.t. to the Riemannian area measure on* Z*.*

6. Discussion

We have obtained novel characterization, stability and convergence theorems for SL HC. Our theorems contemplate both the deterministic and the stochastic case. Our characterization theorem can be interpreted as a relaxation of Kleinberg's impossibility result for standard clustering methods in that by allowing the output of clustering methods to be hierarchical, one obtains existence and uniqueness.

Our stability results seem to be novel and complement classical observations that CL and AL are discontinuous as maps from finite metric spaces into dendrograms.

Our convergence results also seem to be novel and they refine a previous observation by Hartigan about the information retained about an underlying density by SL clustering of an i.i.d. collection of samples from that density. Our setting for the stochastic convergence results is quite general in that we do not assume the underlying space to be a smooth manifold and we do not assume the underlying probability measure to have a density with respect to any reference measure.

We understand that SL HC is not sensitive to variations in the density (see also Hartigan, 1981). In our future work we will be looking at ways of further relaxing the notions of clustering that can cope with the problem of detecting "dense" clusters, in the same spirit as Wishart (1969); Stuetzle (2003). A follow up paper (Carlsson and Mémoli, 2009) presents a systematic treatment of this with a more general framework.

Some recent works have also addressed the characterization of clustering schemes in the hierarchical case. The authors of the present paper reported a characterization for proximity dendrograms (Carlsson and Mémoli, 2008) using the language of category theory. Zadeh and Ben-David (2009) gave a characterization for threshold dendrograms.[7] More classical is the work of Jardine and Sibson (1971) who also ultimately view HC methods as maps form finite metric spaces to finite ultrametric spaces.

7. Recall that the difference between these two types of dendrograms is that proximity dendrograms retain the linkage value at which mergings take place whereas threshold dendrograms only record the order, see Remark 3.

It is interesting to consider the situation when one requires the map ϕ in our characterization theorem (Theorem 18) to be 1 to 1 on points. In this case, a much wider class of hierarchical schmemes becomes possible including for example a certain version of *clique clustering*. The restriction on the nature of ϕ would be called restriction of *functoriality* by a mathematician. The classification question of clustering methods that arises becomes mathematically interesting and we are currently exploring it (Carlsson and Mémoli, Stanford, 2009; Carlsson and Mémoli, 2008).

Appendix A. Notation

Symbol	Meaning
$\mathbb{R}$	Real numbers.
$\mathbb{R}^d$	d-dimensional Euclidean space.
$\mathbb{N}$	Natural numbers.
$((a))$	A square symmetric matrix with elements a_{ij} which are usually distances.
(X,d)	Metric space X with metric d, page 1429.
(X,u)	Ultrametric space X with ultrametric u, page 1429.
$\mathcal{X}$, $\mathcal{X}_n$	Collection of all finite (resp. n point) metric spaces, page 1429.
$\mathcal{U}$, $\mathcal{U}_n$	Collection of all finite (resp. n point) ultrametric spaces, page 1429.
$\mathcal{C}(X)$	Collection of all non-empty subsets of the set X, page 1429.
$\mathcal{U}(X)$	Collection of all ultrametrics over the finite set X, page 1429.
$\mathcal{P}(X)$	Collection of all partitions of the finite set X, page 1429.
$\Pi, \mathcal{B}, \mathcal{A}$	A partition of a finite set and blocks of that partition, respectively, page 1429.
$\sim, [a], A\backslash\sim$	An equivalence relation, the equivalence class of a point and the quotient space, page 1429.
$\sim_r$	An equivalence relation with a parameter $r \geqslant 0$, page 1429.
$S^{k-1}(r)$	Sphere of radius r and dimension $k-1$ embedded in $\mathbb{R}^k$, page 1429.
$\mathcal{L}(W)$	Maximal metric $\leqslant W$, page 1429.
$\theta : [0,\infty) \to \mathcal{P}(X)$	A dendrogram over the finite set X, 1431.
$\mathcal{D}(X)$	Collection of all dendrograms over the finite set X, page 1431.
θ^*	Dendrogram over the finite set X arising from $\sim_r$, 1433.
$\ell^{\mathrm{SL}}, \ell^{\mathrm{CL}}, \ell^{\mathrm{AL}}$	Linkage functions, page 1434.
$\theta^{\mathrm{SL}}, \theta^{\mathrm{AL}}, \theta^{\mathrm{CL}}$	Dendrograms arising from linkage functions, 1434.
$\mathfrak{T}$	A hierarchical clustering method seen as a map $\mathfrak{T} : \mathcal{X} \to \mathcal{U}$, page 1442.
$\mathfrak{T}^*$	A HC method arising from the maximal sub-dominant ultrametric, page 1442.
u_θ	An ultrametric obtained from the dendrogram θ, page 1440.
θ^u	A dendrogram obtained from the ultrametric u, page 1441.
Ψ	A bijective map between $\mathcal{D}(X)$ and $\mathcal{U}(X)$, page 1439.
Δ_n	Metric space isometric to an n point unit simplex, page 1447.

L_n	Metric space isometric to n points on a line, page 1447.
$d_{\mathcal{H}}^Z$	Hausdorff distance between subsets of the metric space Z, page 1455.
$\mathfrak{T}^{\mathrm{SL}}, \mathfrak{T}^{\mathrm{CL}}, \mathfrak{T}^{\mathrm{CL}}$	Standard linkage based HC methods seen as maps from $\mathcal{X}$ to $\mathcal{U}$, page 1442.
$\mathrm{dis}(f), \mathrm{dis}(f,g)$	Distortion of a map f and joint distortion of a pair of maps f and g, page 1445.
$d_{\mathcal{GH}}$	Gromov-Hausdorff distance between metric spaces, pages 1445, 1456.
$\mathrm{sep}(X)$	Separation of the metric space X, page 1429.
$\mathrm{diam}\,(X)$	Diameter of the metric space X, page 1429.
P_n	All the $n!$ permutations of elements of the set $\{1,\ldots,n\}$.
$\Gamma_{X,Y}$	A function used to measure metric distortion, page 1456.
(X,d,μ)	An mm-space, (X,d) a compact metric space, μ a Borel probability measure, page 1459.
$\mathrm{supp}\,[\mu]$	Support of the probability measure μ, page 1459.
$\mathbf{P}_\mu$	Probability with respect to the law μ.

Appendix B. Proofs

Proof [Proof of Proposition 8] The claim follows from the following claim, which we prove by induction on i:

Claim: For all $i \geqslant 2, x, x' \in X$ are s.t. there exists $\mathcal{B} \in \Theta_i$ with $x, x' \in \mathcal{B}$ if and only if $x \sim_{R_{i-1}} x'$.

Proof [Proof of the Claim] For $i = 2$ the claim is clearly true. Fix $i > 2$.

Assume that $x, x' \in X$ and $\mathcal{B} \in \Theta_{i+1}$ are such that $x, x' \in \mathcal{B}$. If x, x' belong to the same block of Θ_i there is nothing to prove. So, assume that $x \in \mathcal{A}$ and $x' \in \mathcal{A}'$ with $\mathcal{A} \neq \mathcal{A}'$ and $\mathcal{A}, \mathcal{A}' \in \Theta_i$. Then, it must be that there exist blocks $\mathcal{A} = \mathcal{A}_1, \mathcal{A}_2, \ldots, \mathcal{A}_s = \mathcal{A}'$ of Θ_i s.t. $\ell^{\mathrm{SL}}(\mathcal{A}_t, \mathcal{A}_{t+1}) \leqslant R_i$ for $t = 1, \ldots, s-1$. Pick $x_1, y_1 \in \mathcal{A}_1, x_2, y_2 \in \mathcal{A}_2, \ldots, x_s, y_s \in \mathcal{A}_s$ s.t. $x_1 = x$ and $y_s = x'$ and $d(y_t, x_{t+1}) = \ell^{\mathrm{SL}}(\mathcal{A}_t, \mathcal{A}_{t+1}) \leqslant R_i$ for $t = 1, \ldots, s-1$, see the Figure 21.

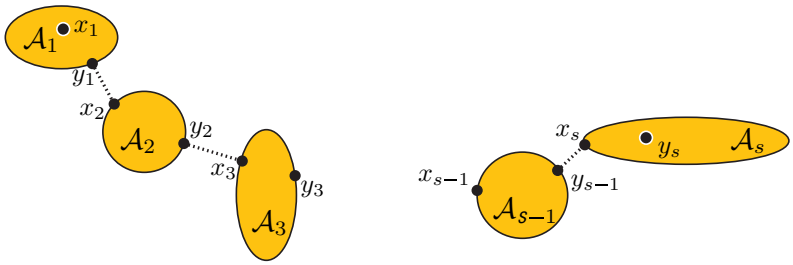

Figure 21: Construction used in the proof of Proposition 8.

Notice that by the inductive hypothesis we have $x_t \sim_{R_{i-1}} y_t$ for $t = 1, \ldots, s$. It follows that $x \sim_r x'$ for $r = \max(R_i, R_{i-1})$. By Proposition 5, $r = R_i$ and hence $x \sim_{R_i} x'$.

Assume now that $x \sim_{R_i} x'$. If x, x' belong to the same block of Θ_i there's nothing to prove since Θ_{i+1} is coarser than Θ_i and hence x, x' will also belong to the same block of Θ_{i+1}. Assume then that $x \in \mathcal{B}$ and $x' \in \mathcal{B}'$ for $\mathcal{B}, \mathcal{B}' \in \Theta_i$ with $\mathcal{B} \neq \mathcal{B}'$. Let $x = x_1, x_2, \ldots, x_s = x'$ be points in X with $d(x_t, x_{t+1}) \leqslant R_i$ for $t = 1, \ldots, s-1$. Also, for $t = 1, \ldots, s-1$ let $\mathcal{B}_t$ be the block of Θ_i to which x_t

belongs. But then, by construction

$$R_i \geqslant d(x_t, x_{t+1}) \geqslant \min_{z\in\mathcal{B}_t, z'\in\mathcal{B}_{t+1}} d(z,z') = \ell^{\mathrm{SL}}(\mathcal{B}_t, \mathcal{B}_{t+1}) \quad \text{for } t = 1,\ldots,s-1,$$

and hence $\mathcal{B}_1 \sim_{\ell^{\mathrm{SL}},R_i} \mathcal{B}_s$. In particular, $\mathcal{B}_1 \cup \mathcal{B}_s \subset \mathcal{A}$ for some $\mathcal{A} \in \Theta_{i+1}$ and thus x, x' belong to the same block in Θ_{i+1}. ■

■

Proof [Proof of Lemma 10] Obviously u_θ is non-negative. Pick $x, x', x'' \in X$ and let $r_1, r_2 \geqslant 0$ be s.t. x, x' belong to the same block of $\theta(r_1)$ and x', x'' belong to the same block of $\theta(r_2)$. These numbers clearly exist by condition (2) in the definition of dendrograms. Then, there exist a block $\mathcal{B}$ of $\theta\big(\max(r_1, r_2)\big)$ s.t. $x, x'' \in \mathcal{B}$ and hence $u_\theta(x, x'') \leqslant max(r_1, r_2)$. The conclusion follows since $r_1 \geqslant u_\theta(x, x')$ and $r_2 \geqslant u_\theta(x', x'')$ are arbitrary.

Now, let $x, x' \in X$ be such that $u_\theta(x, x') = 0$. Then x, x' are in the same block of $\theta(0)$. Condition (1) in the definition of dendrograms implies that $x = x'$. ■

Proof [Proof of Lemma 12] Pick $x, x' \in X$ and let $r := u_{\theta*}(x, x')$. Then, according to (3), there exist $x_0, x_1, \ldots, x_t \in X$ with $x_0 = x$, $x_t = x'$ and $\max_i d(x_i, x_{i+1}) \leqslant r$. From (4) we conclude that then $u^*(x, x') \leqslant r$ as well. Assume now that $u^*(x, x') \leqslant r$ and let $x_0, x_1, \ldots, x_t \in X$ be s.t. $x_0 = x$, $x_t = x'$ and $\max_i d(x_i, x_{i+1}) \leqslant r$. Then, $x \sim_r x'$ and hence again by recalling (3), $u_{\theta*}(x, x') \leqslant r$. This finishes the proof. ■

Proof [Proof of Theorem 18] Pick $(X, d) \in \mathcal{X}$. Write $\mathfrak{T}(X, d) = (X, u)$ and $\mathfrak{T}^*(X, d) = (X, u^*)$.
(A) We prove that $u^*(x, x') \geqslant u(x, x')$ for all $x, x' \in X$. Pick $x, x' \in X$ and let $\delta := u^*(x, x')$. Let $x = x_0, \ldots, x_n = x'$ be s.t.

$$\max_i d(x_i, x_{i+1}) = u^*(x, x') = \delta.$$

Consider the two point metric space $(Z, e) := (\{p, q\}, \left(\begin{smallmatrix} 0 & \delta \\ \delta & 0 \end{smallmatrix}\right))$. Fix $i \in \{0, \ldots, n-1\}$. Consider $\phi : \{p, q\} \to X$ given by $p \mapsto x_i$ and $q \mapsto x_{i+1}$. By condition (I) we have $\mathfrak{T}(Z_\delta) = Z_\delta$. Note that $\delta = e(p, q) \geqslant d(\phi(p), \phi(q)) = d(x_i, x_{i+1})$ and hence by condition (II),

$$\delta \geqslant u(x_i, x_{i+1}).$$

Then, since i was arbitrary, we obtain $\delta \geqslant \max_i u(x_i, x_{i+1})$. Now, since u is an ultrametric on X, we know that $\max_i u(x_i, u_{i+1}) \geqslant u(x, x')$ and hence $\delta \geqslant u(x, x')$.
(B) We prove that $u^*(x, x') \leqslant u(x, x')$ for all $x, x' \in X$. Fix $r > 0$. Let (X_r, d_r) be the metric space with underlying set X_r given by the equivalence classes of X under the relation $x \sim_r x'$. Let $\phi_r : X \to X_r$ be given by $x \mapsto [x]_r$ where $[x]_r$ denotes the equivalence class of x under $\sim_r$. Let $\tilde{d}_r : X_r \times X_r \to \mathbb{R}^+$ be given by

$$\tilde{d}_r(z, z') = \min_{\substack{x \in \phi_r^{-1}(z) \\ x' \in \phi_r^{-1}(z')}} d(x, x')$$

and let $d_r = \mathcal{L}(\tilde{d}_r)$. Note that, by our construction, ϕ_r is such that for all $x,x' \in X$,

$$d(x,x') \geqslant d_r(\phi_r(x),\phi_r(x')).$$

Indeed, assume the contrary. Then for some $x,x' \in X$ one has that $d(x,x') < d_r(\phi_r(x),\phi_r(x'))$. But, from the definition of d_r it follows that $d(x,x') < d_r(\phi_r(x),\phi_r(x')) \leqslant \tilde{d}_r(\phi_r(x),\phi_r(x')) = \min\{d(\bar{x},\bar{x}'), \text{s.t. } \bar{x} \sim_r x; \bar{x}' \sim_r x'\}$. This is a contradiction since $x \sim_r x$ and $x' \sim_r x'$.

Write $\mathfrak{T}(X_r,d_r) = (X_r,u_r)$. Then, by condition (III),

$$u(x,x') \geqslant u_r(\phi_r(x),\phi_r(x')) \tag{14}$$

for all $x,x' \in X$. Note that

$$\operatorname{sep}(X_r,d_r) > r. \tag{15}$$

Indeed, for otherwise, there would be two points $x,x' \in X$ with $[x]_r \neq [x']_r$ and $r \geqslant d(x,x') \geqslant u^*(x,x')$. But this gives a contradiction by Remark 13.
Claim: $u^*(x,x') > r$ implies that $u_r(\phi_r(x),\phi_r(x')) > r$.
Assuming the claim, let $x,x' \in X$ be s.t. $u^*(x,x') > r$, then by Equation (14),

$$u(x,x') \geqslant u_r(\phi_r(x),\phi_r(x')) > r.$$

That is, we have obtained that for any $r > 0$,

$$\{(x,x') \,\text{s.t.}\, u^*(x,x') > r\} \subseteq \{(x,x') \,\text{s.t.}\, u(x,x') > r\},$$

which implies that $u^*(x,x') \leqslant u(x,x')$ for all $x,x' \in X$.
Proof of the claim. Let $x,x' \in X$ be s.t. $u^*(x,x') > r$. Then, $[x]_r \neq [x']_r$. By definition of ϕ_r, also, $\phi_r(x) \neq \phi_r(x')$ and hence, by condition (III) and Equation (15):

$$u_r(\phi_r(x),\phi_r(x')) \geqslant \operatorname{sep}(X_r,d_r) > r.$$

■

Proof [Proof of Proposition 26] Write $\mathfrak{T}^*(X,d_X) = (X,u_X)$ and $\mathfrak{T}^*(Y,d_Y) = (Y,u_Y)$. Let $\eta = d_{\mathcal{GH}}\big((X,d_X),(Y,d_Y)\big)$ and $R \in \mathcal{R}(X,Y)$ s.t. $|d_X(x,x') - d_Y(y,y')| \leqslant 2\eta$ for all $(x,y),(x',y') \in R$. Fix (x,y) and $(x',y') \in R$. Let $x_0,\ldots,x_m \in X$ be s.t. $x_0 = x$, $x_m = x'$ and $d_X(x_i,x_{i+1}) \leqslant u_X(x,x')$ for all $i = 0,\ldots,m-1$. Let $y = y_0,y_1,\ldots,y_{m-1},y_m = y' \in Y$ be s.t. $(x_i,y_i) \in R$ for all $i = 0,\ldots,m$ (this is possible by definition of R). Then, $d_Y(y_i,y_{i+1}) \leqslant d_X(x_i,x_{i+1}) + \eta \leqslant u_X(x,x') + \eta$ for all $i = 0,\ldots,m-1$ and hence $u_Y(y,y') \leqslant u_X(x,x') + 2\eta$. By exchanging the roles of X and Y one obtains the inequality $u_X(x,x') \leqslant u_Y(y,y') + 2\eta$. This means $|u_X(x,x') - u_Y(y,y')| \leqslant 2\eta$. Since $(x,y),(x',y') \in R$ are arbitrary, and upon recalling the expression of the Gromov-Hausdorff distance given by (12) we obtain the desired conclusion. ■

Proof [Proof of Theorem 28] By Proposition 26 and the triangle inequality for the Gromov-Hausdorff distance,

$$d_{\mathcal{GH}}\big(X,Z\big) + d_{\mathcal{GH}}\big(X',Z\big) \geqslant d_{\mathcal{GH}}\big((X,u_X)),(X',u_{X'}))\big).$$

Now, (1) follows from Remark 25.

We now prove the second claim. Let $\delta > 0$ be s.t. $\min_{\alpha\neq\beta} W_A(\alpha,\beta) \geqslant \delta$. For each $z \in Z$ let $\alpha(z)$ denote the index of the path connected component of Z s.t. $z \in Z^{(\alpha(z))}$. Since $r := d_{\mathcal{H}}^{Z}\big(X,Z\big) < \frac{\delta}{2}$, it is clear that $\#\left(Z^{(\alpha)} \cap X\right) \geqslant 1$ for all $\alpha \in A$. It follows that $R = \{(x,\alpha(x))|x \in X\}$ belongs to $\mathcal{R}(X,A)$. We prove below that for all $x,x' \in X$,

$$u_A(\alpha(x),\alpha(x')) \overset{\text{(I)}}{\leqslant} u_X(x,x') \overset{\text{(II)}}{\leqslant} u_A(\alpha(x),\alpha(x')) + 2r.$$

By putting (I) and (II) together we will have $d_{\mathcal{GH}}\big((X,u_X),(A,u_A)\big) \leqslant r$.

Let's prove (I). It follows immediately from the definition of d_A and W_A that for all $y,y' \in X$,

$$W_A(\alpha(y),\alpha(y')) \leqslant d_X(y,y').$$

From the definition of d_A it also follows that $W_A(\alpha,\alpha') \geqslant d_A(\alpha,\alpha')$ for all $\alpha,\alpha' \in A$. Then, in order to prove (I) pick $x_0,\ldots,x_m$ in X with $x_0 = x, x_m = x'$ and $\max_i d_X(x_i,x_{i+1}) \leqslant u_X(x,x')$. Consider the points in A given by

$$\alpha(x) = \alpha(x_0),\alpha(x_1),\ldots,\alpha(x_m) = \alpha(x').$$

Then,

$$d_A(\alpha(x_i),\alpha(x_{i+1})) \leqslant W_A(\alpha(x_i),\alpha(x_{i+1})) \leqslant d_X(x_i,x_{i+1}) \leqslant u_X(x,x')$$

for $i = 0,\ldots,m-1$ by the observations above. Then, $\max_i d_A(\alpha(x_i),\alpha(x_{i+1})) \leqslant d_X(x,x')$ and by recalling the definition of $u_A(\alpha(x),\alpha(x'))$ we obtain (I).

We now prove (II). Assume first that $\alpha(x) = \alpha(x') = \alpha$. Fix $\varepsilon_0 > 0$ small. Let $\gamma : [0,1] \to Z^{(\alpha)}$ be a continuous path s.t. $\gamma(0) = x$ and $\gamma(1) = x'$. Let $z_1,\ldots,z_m$ be points on image(γ) s.t. $z_0 = x, z_m = x'$ and $d_X(z_i,z_{i+1}) \leqslant \varepsilon_0$, $i = 0,\ldots,m-1$. By hypothesis, one can find $x = x_0,x_1,\ldots,x_{m-1},x_m = x'$ s.t. $d_Z(x_i,z_i) \leqslant r$. Thus,

$$\max_i d_X(x_i,x_{i+1}) \leqslant \varepsilon_0 + 2r$$

and hence $u_X(x,x') \leqslant \varepsilon_0 + 2r$. Let $\varepsilon_0 \to 0$ to obtain the desired result.

Now if $\alpha = \alpha(x) \neq \alpha(x') = \beta$, let $\alpha_0,\alpha_1,\ldots,\alpha_l \in A$ be s.t. $\alpha_0 = \alpha(x), \alpha_l = \alpha(x')$ and $d_A(\alpha_j,\alpha_{j+1}) \leqslant u_A(\alpha,\beta)$ for $j = 0,\ldots,l-1$.

By definition of d_A, for each $j = 0,\ldots,l-1$ one can find a *chain*

$$C_j = \left\{\alpha_j^{(0)},\ldots,\alpha_j^{(r_j)}\right\} \quad \text{s.t. } \alpha_j^{(0)} = \alpha_j, \alpha_j^{(r_j)} = \alpha_{j+1}$$

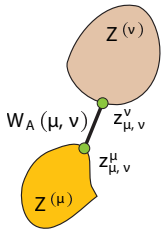
and

$$\sum_{i=0}^{r_j-1} W_A\left(\alpha_j^{(i)},\alpha_j^{(i+1)}\right) = d_A(\alpha_j,\alpha_{j+1}) \leqslant u_A(\alpha,\beta).$$

Since W_A takes non-negative values, then, for fixed $j \in \{0,\ldots,l-1\}$, it follows that

$$W_A(\alpha_j^{(i)},\alpha_j^{(i+1)}) \leqslant u_A(\alpha,\beta) \quad \text{for all } i = 0,\ldots,r_j-1.$$

Consider the chain $C = \{\widehat{\alpha}_0,\ldots,\widehat{\alpha}_s\}$ in A joining α to β given by the concatenation of all the C_j. By eliminating repeated consecutive elements in C, if necessary, one can assume that $\widehat{\alpha}_i \neq \widehat{\alpha}_{i+1}$. By construction $W_A(\widehat{\alpha}_i,\widehat{\alpha}_{i+1}) \leqslant u_A(\alpha,\beta)$ for $i \in \{0,\ldots,s-1\}$, and $\widehat{\alpha}_0 = \alpha$, $\widehat{\alpha}_s = \beta$. We will now lift C into a chain in Z joining x to x'. Note that by compactness, for all $\nu,\mu \in A, \nu \neq \mu$ there exist $z_{\nu,\mu}^{\nu} \in Z^{(\nu)}$ and $z_{\nu,\mu}^{\mu} \in Z^{(\mu)}$ s.t. $W_A(\nu,\mu) = d_Z(z_{\nu,\mu}^{\nu}, z_{\nu,\mu}^{\mu})$.



Consider the chain G in Z given by

$$G = \left\{x, z^{\hat{\alpha}_0}_{\hat{\alpha}_0,\hat{\alpha}_1}, z^{\hat{\alpha}_1}_{\hat{\alpha}_0,\hat{\alpha}_1}, \ldots, z^{\hat{\alpha}_s}_{\hat{\alpha}_{s-1},\hat{\alpha}_s}, x'\right\}.$$

For each point $g \in G \subset Z$ pick a point $x(g) \in X$ s.t. $d_Z(g, x(g)) \leqslant r$. Note that this is possible by definition of r and also, that $x(g) \in Z^{(\alpha(g))}$ since $r < \delta/2$.

Let $G' = \{x_0, x_1, \ldots, x_t\}$ be the resulting path in X. Notice that if $\alpha(x_k) \neq \alpha(x_{k+1})$ then

$$d_X(x_k, x_{k+1}) \leqslant 2r + W_A(\alpha(x_k), \alpha(x_{k+1})) \tag{16}$$

by the triangle inequality. Also, by construction, for $k \in \{0, \ldots, t-1\}$,

$$W_A(\alpha(x_k), \alpha(x_{k+1})) \leqslant u_A(\alpha, \beta). \tag{17}$$

Now, we claim that

$$u_X(x, x') \leqslant \max_k W_A(\alpha(x_k), \alpha(x_{k+1})) + 2r. \tag{18}$$

This claim will follow from (16) and the simple observation that

$$u_X(x, x') \leqslant \max_k u_X(x_k, x_{k+1}) \leqslant \max_k d_X(x_k, x_{k+1})$$

which in turn follows from the fact that u_X is the ultrametric on X defined by (4), see remarks in Example 7. If $\alpha(x_k) = \alpha(x_{k+1})$ we already proved that $u_X(x_k, x_{k+1}) \leqslant 2r$. If on the other hand $\alpha(x_k) \neq \alpha(x_{k+1})$ then (18) holds. Hence, we have that without restriction, for all $x, x' \in X$,

$$u_X(x, x') \leqslant \max_k W_A(\alpha(x_k), \alpha(x_{k+1})) + 2r.$$

and hence the claim. Combine this fact with (17) to conclude the proof of (II). Claim (3) follows immediately from (2).

■

B.1 The Proof of Theorem 30

We will make use of the following general covering theorem in the proof of Theorem 30.

Theorem 34 *Let (X, d, μ) be an mm-space and $\mathbb{X}_n = \{x_1, x_2, \ldots, x_n\}$ a collection of n independent random variables (defined on some probability space Ω, and with values in X) and identically distributed with distribution μ. Then, for any $\delta > 0$,*

$$\mathbf{P}_\mu\left(d^X_{\mathcal{H}}\left(\mathbb{X}_n, supp\left[\mu_X\right]\right) > \delta\right) \leqslant F_X(n, \delta).$$

Proof Consider first a fixed point $x \in \operatorname{supp}[\mu_X]$ and $h > 0$. Then, since $x_1, \ldots, x_n$ are i.i.d., for all i, $\mathbf{P}_\mu(x_i \in B_X(x,h)) = \mu(B_X(x,h))$. We then have:

$$\begin{aligned}
\mathbf{P}_\mu\left(\left\{x \notin \bigcup_{i=1}^n B_X(x_i,h)\right\}\right) &= \mathbf{P}_\mu\left(\bigcap_{i=1}^n \{x \notin B_X(x_i,h)\}\right) \\
&= \mathbf{P}_\mu\left(\bigcap_{i=1}^n \{x_i \notin B_X(x,h)\}\right) \\
&= \prod_{i=1}^n \mathbf{P}_\mu(\{x_i \notin B_X(x,h)\}) \quad \text{(by independence)} \\
&= (1-\mu_X(B_X(x,h)))^n \\
&\leqslant (1-f_X(h)))^n. \qquad (19)
\end{aligned}$$

We now obtain a similar bound for the probability that a ball of radius $\delta/2$ around x is within δ of a point in $\mathbb{X}_n$. Notice that the following inclusion of events holds:

$$\left\{B_X(x,\delta/2) \subset \bigcup_{i=1}^n B_X(x_i,\delta)\right\} \supseteq \left\{x \in \bigcup_{i=1}^n B_X(x_i,\delta/2)\right\}. \qquad (20)$$

Indeed, assume that the event $\{x \in \bigcup_{i=1}^n B_X(x_i,\delta/2)\}$ holds. Then, $x \in B_X(x_i,\delta/2)$ for some $i \in \{1,\ldots,n\}$. Pick any $x' \in B_X(x,\delta/2)$, then by the triangle inequality, $d_X(x',x_i) \leqslant d_X(x',x) + d_X(x,x_i) < \delta/2 + \delta/2 = \delta$, thus $x' \in B_X(x_i,\delta)$. Since x' is an arbitrary point in $B_X(x,\delta/2)$ we are done. Now, from (20) and (19) (for $h = \delta/2$) above, we find

$$\mathbf{P}_\mu\left(\left\{B_X(x,\delta/2) \nsubseteq \bigcup_{i=1}^n B_X(x_i,\delta)\right\}\right) \leqslant (1-f_X(\delta/2))^n. \qquad (21)$$

Now, consider a maximal $\delta/4$-packing of $\operatorname{supp}[\mu_X]$ by balls with centers $\{p_1,\ldots,p_N\}$. Then, clearly, $\operatorname{supp}[\mu_X] = \bigcup_{j=1}^N B_X(p_j,\delta/2)$. Such a packing always exists since $\operatorname{supp}[\mu_X]$ is assumed to be compact (Burago et al., 2001). Notice that N, the cardinality of the packing, can be bounded by $1/f_X(\delta/4)$. Indeed, since $B_X(p_\alpha,\delta/4) \cap B_X(p_\beta,\delta/4) = \varnothing$ for $\alpha \neq \beta$, we have

$$\begin{aligned}
1 = \mu_X(\operatorname{supp}[\mu_X]) &= \mu_X\left(\bigcup_{j=1}^N B_X(p_j,\delta/2)\right) \\
&\geqslant \mu_X\left(\bigcup_{j=1}^N B_X(p_j,\delta/4)\right) \\
&= \sum_{j=1}^N \mu_X(B_X(p_j,\delta/4)) \\
&\geqslant N \cdot f_X(\delta/4)
\end{aligned}$$

and the claim follows. Now, we finish the proof by first noting that since $\mathbb{X}_n \subset \mathrm{supp}\,[\mu_X]$, the following inclusion of events holds:

$$\{d_{\mathcal{H}}^X(\mathbb{X}_n, \mathrm{supp}\,[\mu_X]) > \delta\} \subseteq \left\{ X \nsubseteq \bigcup_{i=1}^n B_X(x_i, \delta) \right\}$$

and hence, using the union bound, then (21) and the bound on N, we find:

$$\begin{aligned}
\mathbf{P}_\mu\left(d_{\mathcal{H}}^X(\mathbb{X}_n, \mathrm{supp}\,[\mu_X]) > \delta\right) &\leqslant \mathbf{P}_\mu\left(X \nsubseteq \bigcup_{i=1}^n B_X(x_i,\delta)\right) \\
&= \mathbf{P}_\mu\left(\bigcup_{j=1}^N \left\{ B_X(p_j,\delta/2) \nsubseteq \bigcup_{i=1}^n B_X(x_i,\delta)\right\}\right) \\
&\leqslant N \cdot \max_{j=1,\ldots,N} \mathbf{P}_\mu\left(B_X(p_j,\delta/2) \nsubseteq \bigcup_{i=1}^n B_X(x_i,\delta)\right) \\
&\leqslant \frac{1}{f_X(\delta/4)} \cdot (1 - f_X(\delta/2))^n \\
&\leqslant \frac{1}{f_X(\delta/4)} \cdot (1 - f_X(\delta/4))^n \quad \text{(since } f_X(\cdot) \text{ is non-decreasing)} \\
&\leqslant \frac{1}{f_X(\delta/4)} e^{-n f_X(\delta/4)} \quad \text{(by the inequality } (1-t) \leqslant e^{-t}, \forall t \in \mathbb{R}) \\
&= F_X(n,\delta)
\end{aligned}$$

thus concluding the proof. ■

Proof [Proof of Theorem 30] For each $n \in \mathbb{N}$, introduce the random variables $r_n := d_{\mathcal{H}}^Z(\mathbb{Z}_n, \mathrm{supp}\,[\mu_Z])$ and $g_n := d_{\mathcal{GH}}(\mathfrak{T}^*(\mathbb{Z}_n, d_{\mathbb{Z}_n}), \mathfrak{T}^*(A, d_A))$. Fix $\zeta' = \delta_A/2$. Note that by Theorem 28 (2) once $r_n \leqslant \zeta$ for some $\zeta \leqslant \zeta'$ we know that $g_n \leqslant r_n$ a.s. Hence, we have

$$\mathbf{P}(g_n > \zeta) \leqslant \mathbf{P}(r_n > \zeta) \leqslant F_X(n,\zeta), \tag{22}$$

where the last inequality follows from Lemma 34.

Meanwhile, if $\zeta \geqslant \zeta'$ is arbitrary, then $\mathbf{P}(g_n > \zeta) \leqslant \mathbf{P}(g_n > \zeta')$. By (22) (for $\zeta = \zeta'$) we find $\mathbf{P}(g_n > \zeta) \leqslant \mathbf{P}(r_n > \zeta') \leqslant F_X(n,\zeta')$ for all $\zeta \geqslant \zeta'$. Thus, we have found that

$$\mathbf{P}(g_n > \zeta) \leqslant \begin{cases} F_X(n,\zeta') & \text{for } \zeta \geqslant \zeta'. \\ F_X(n,\zeta) & \text{for } \zeta \leqslant \zeta'. \end{cases}$$

The conclusion now follows. ■

Abstract

Kernel techniques have long been used in SVM to handle linearly inseparable problems by transforming data to a high dimensional space, but training and testing large data sets is often time consuming. In contrast, we can efficiently train and test much larger data sets using linear SVM without kernels. In this work, we apply fast linear-SVM methods to the explicit form of polynomially mapped data and investigate implementation issues. The approach enjoys fast training and testing, but may sometimes achieve accuracy close to that of using highly nonlinear kernels. Empirical experiments show that the proposed method is useful for certain large-scale data sets. We successfully apply the proposed method to a natural language processing (NLP) application by improving the testing accuracy under some training/testing speed requirements.

Keywords: decomposition methods, low-degree polynomial mapping, kernel functions, support vector machines, dependency parsing, natural language processing

1. Introduction

Support vector machines (SVMs) (Boser et al., 1992; Cortes and Vapnik, 1995) have been popular for data classification. An SVM often maps data to a high dimensional space and then employs kernel techniques. We refer to such an approach as nonlinear SVM. Training nonlinear SVM is usually performed through the use of popular decomposition methods. However, these decomposition approaches require considerable time for large data sets. In addition, the testing procedure is slow due to the kernel calculation involving support vectors and testing instances.

For some applications with data in a rich dimensional space (e.g., document classification), people have shown that testing accuracy is similar with/without a nonlinear mapping. If data are not

mapped, recently some methods have been proposed to efficiently train much larger data sets. We refer to such cases as linear SVM.

Among the recent advances in training large linear SVM, Hsieh et al. (2008) discuss decomposition methods for training linear and nonlinear SVM. If l is the number of training data, $\bar{n}$ is the average number of non-zero features per instance, and each kernel evaluation takes $O(\bar{n})$ time, then the cost per decomposition iteration for nonlinear SVM is $O(l\bar{n})$. Taking the property of linear SVM, Hsieh et al.'s approach runs one iteration in only $O(\bar{n})$. If the number of iterations is not significantly more than that for the nonlinear case, their method is very efficient for training linear SVM.

Motivated by the above $O(l\bar{n})$ and $O(\bar{n})$ difference, in this work, we investigate the performance of applying linear-SVM methods to low-degree data mappings. By considering the explicit form of the mapping, we directly train a linear SVM. The cost per decomposition iteration is $O(\hat{n})$, where $\hat{n}$ is the new average number of non-zero elements in the mapped vector. If $\hat{n} < l\bar{n}$, the new strategy may be faster than the training using kernels.

Currently, polynomial kernels are less widely used than the RBF (Gaussian) kernel, which maps data to an infinite dimensional space. This might be because under similar training and testing cost, a polynomial kernel may not give higher accuracy. We show for some data, the testing accuracy of using low-degree polynomial mappings is only slightly worse than RBF, but training/testing via linear-SVM strategies is much faster. Therefore, our approach takes advantages of linear methods, while still preserves a certain degree of nonlinearity. Some early works (e.g., Gertz and Griffin, 2005; Jung et al., 2008; Moh and Buhmann, 2008) have employed this idea in their experiments. Here we aim at a more detailed study on large-scale scenarios.

An exception where polynomial kernels have been popular is NLP (natural language processing). Some have explored the fast calculation of low-degree polynomial kernels to save the testing time (e.g., Isozaki and Kazawa, 2002; Kudo and Matsumoto, 2003; Goldberg and Elhadad, 2008). However, these works still suffer from the slow training because of not applying some recently developed training techniques.

This paper is organized as follows. We introduce SVM in Section 2. In Section 3, we discuss the proposed method for efficiently training and testing SVM for low-degree polynomial data mappings. A particular emphasis is on the degree-2 polynomial mapping. Section 4 presents the empirical studies. We give an NLP application on dependency parsing in Section 5. Conclusions are in Section 6.

Notation: we list some notation related to the number of features.

n: number of features (dimensionality of data); $\mathbf{x}_i \in R^n$ is the ith training instance

n_i: number of non-zero feature values of $\mathbf{x}_i$

$\bar{n}$: average number of non-zero elements in $\mathbf{x}_i$; see (9)

$\hat{n}$: average number of non-zero elements in the mapped vector $\phi(\mathbf{x}_i)$

$\tilde{n}$: number of non-zero elements in the weight vector $\mathbf{w}$

2. Linear and Nonlinear SVM

Assume training instance-label pairs are $(\mathbf{x}_i, y_i)$, $i = 1, \ldots, l$, where $\mathbf{x}_i \in R^n$ and $y_i \in \{1, -1\}$. We consider the following SVM problem with a penalty parameter $C > 0$:

$$\min_{\mathbf{w}} \quad \frac{1}{2}\mathbf{w}^T\mathbf{w} + C\sum_{i=1}^{l} \max(1 - y_i\mathbf{w}^T\phi(\mathbf{x}_i), 0). \tag{1}$$

The function $\phi(\mathbf{x})$ maps an instance to a higher dimensional space for handling linearly inseparable data. We refer to such a setting as nonlinear SVM. For some applications, $\phi(\mathbf{x}) = \mathbf{x}$ can already properly separate data; we call such cases linear SVM. Many SVM studies consider $\mathbf{w}^T\mathbf{x}_i + b$ instead of $\mathbf{w}^T\mathbf{x}_i$ in (1). In general this bias term b does not affect the performance much, so here we omit it for the simplicity.

Due to the high dimensionality of $\phi(\mathbf{x})$ and the possible difficulty of obtaining the explicit form of $\phi(\mathbf{x})$, SVM is often solved through the dual problem with the kernel trick:

$$\begin{aligned} \min_{\alpha} \quad & \frac{1}{2}\alpha^T Q\alpha - \mathbf{e}^T\alpha \\ \text{subject to} \quad & 0 \le \alpha_i \le C, i = 1,\ldots,l, \end{aligned} \tag{2}$$

where $Q_{ij} = y_i y_j K(\mathbf{x}_i,\mathbf{x}_j) = y_i y_j \phi(\mathbf{x}_i)^T\phi(\mathbf{x}_j)$ and $\mathbf{e} = [1,\ldots,1]^T$. $K(\mathbf{x}_i,\mathbf{x}_j)$ is called the kernel function and α is the dual variable.

The matrix Q in the dual problem (2) is dense and may be too large to be stored in the computer memory. Currently, decomposition methods (e.g., Joachims, 1998; Keerthi et al., 2001; Chang and Lin, 2001) are the major approach to solve (2). However, if linear SVM is considered, we can more easily solve both the primal and the dual problems. Early studies (e.g., Mangasarian and Musicant, 1999; Ferris and Munson, 2003) have demonstrated that many traditional optimization methods can be applied. They focus on data with many instances but a small number of features. Recently, an active research topic is to train linear SVM with both large numbers of instances and features (e.g., Joachims, 2006; Shalev-Shwartz et al., 2007; Bottou, 2007; Hsieh et al., 2008; Langford et al., 2009).

3. Using Linear SVM for Low-degree Polynomial Data Mappings

In this section, we discuss the methods and issues in training/testing low-degree data mappings using linear SVM. We are interested in when the training via linear-SVM techniques is faster than nonlinear SVM. We put an emphasis on the degree-2 polynomial mapping.

3.1 Low-degree Polynomial Mappings

A polynomial kernel takes the following form

$$K(\mathbf{x}_i,\mathbf{x}_j) = (\gamma\mathbf{x}_i^T\mathbf{x}_j + r)^d, \tag{3}$$

where γ and r are parameters and d is the degree. The polynomial kernel is the product between two vectors $\phi(\mathbf{x}_i)$ and $\phi(\mathbf{x}_j)$. For example, if $d = 2$ and $r = 1$, then

$$\phi(\mathbf{x}) = [1, \sqrt{2\gamma}x_1,\ldots,\sqrt{2\gamma}x_n, \gamma x_1^2,\ldots,\gamma x_n^2, \sqrt{2}\gamma x_1x_2,\ldots,\sqrt{2}\gamma x_{n-1}x_n]^T. \tag{4}$$

The coefficient $\sqrt{2}$ in (4) is only used to make $\phi(\mathbf{x}_i)^T\phi(\mathbf{x}_j)$ have a simple form. Without using kernels, we can consider more flexible mapping vectors. For example, if $\gamma = 1$, removing $\sqrt{2}$ in (4) results in a simple mapping vector:

$$\phi(\mathbf{x}) = [1, x_1,\ldots,x_n, x_1^2,\ldots,x_n^2, x_1x_2,\ldots,x_{n-1}x_n]^T. \tag{5}$$

For the polynomial kernel (3), the dimensionality of $\phi(\mathbf{x})$ is

$$C(n+d,d) = \frac{(n+d)(n+d-1)\cdots(n+1)}{d!},$$

which is obtained by counting the number of terms in (3).

3.2 Training by Linear SVM Methods

The training time for SVM depends on the number of data instances and the number of features. Due to the high dimensionality of $\phi(\mathbf{x})$, we must judge whether it is better to choose an explicit mapping or an implicit way by kernels. We explore this issue by investigating the difference between applying decomposition methods to solve the dual problem of linear and nonlinear SVM. Though many optimization methods have been applied to train SVM, we discuss decomposition methods because of the following reasons. First, they are the major approach for nonlinear SVM. Second, efficient decomposition methods for linear SVM have been developed (e.g., Hsieh et al., 2008).

A decomposition method iteratively updates a small subset of variables. We consider the situation of updating one variable at a time.[1] If α is the current solution and the ith component is selected for update, then we minimize the following one-variable problem:

$$\begin{aligned} \min_d \quad & \frac{1}{2}(\alpha + d\mathbf{e}_i)^T Q(\alpha + d\mathbf{e}_i) - \mathbf{e}^T(\alpha + d\mathbf{e}_i) \\ & = \frac{1}{2}Q_{ii}d^2 + (Q\alpha - \mathbf{e})_i d + \text{constant} \\ \text{subject to} \quad & 0 \le \alpha_i + d \le C. \end{aligned} \tag{6}$$

This minimization is easy, but to construct (6), we must calculate

$$(Q\alpha - \mathbf{e})_i = \sum_{j=1}^{l} Q_{ij}\alpha_j - 1 = \sum_{j=1}^{l} y_i y_j K(\mathbf{x}_i, \mathbf{x}_j)\alpha_j - 1. \tag{7}$$

If each kernel element costs $O(\bar{n})$, where $\bar{n}$ is the average number of non-zero features, then (7) needs $O(l\bar{n})$ operations.

If using the explicit mapping vectors, we can calculate $(Q\alpha - \mathbf{e})_i$ by

$$\sum_{j=1}^{l} Q_{ij}\alpha_j - 1 = y_i \mathbf{w}^T \phi(\mathbf{x}_i) - 1, \text{ where } \mathbf{w} = \sum_{j=1}^{l} y_j \alpha_j \phi(\mathbf{x}_j). \tag{8}$$

If $\mathbf{w}$ is available, (8) requires $O(\hat{n})$ operations, where $\hat{n}$ is the average number of non-zero elements in $\phi(\mathbf{x}_i), \forall i$. To maintain $\mathbf{w}$, Hsieh et al. (2008) use

$$\mathbf{w} \leftarrow \mathbf{w} + y_i(\alpha_i^{\text{new}} - \alpha_i^{\text{old}})\phi(\mathbf{x}_i),$$

so the cost is also $O(\hat{n})$. Therefore, the above discussion indicates the tradeoff between $O(l\bar{n})$ and $O(\hat{n})$ cost by implicit and explicit mappings, respectively.

Practical implementations of decomposition methods involve other issues. For example, if using the kernel trick, we may develop better techniques for selecting the working variable at each iteration. Then the number of iterations is smaller. More details can be found in Hsieh et al. (2008, Section 4). Nevertheless, checking $O(l\bar{n})$ and $O(\hat{n})$ can roughly indicate if using an explicit mapping leads to faster training.

1. If using standard SVM with the bias b, the dual form contains an equality and at least two variables must be considered.

3.3 Number of Non-zero Features per Instance

From the discussion in Section 3.2, it is important to know the value $\hat{n}$. If the input data are dense, then the number of non-zero elements in $\phi(\mathbf{x})$ is $O(n^d)$, where d is the degree of the polynomial mapping.

If the input data are sparse, the number of non-zero elements is smaller than the dimensionality. Assume n_i is the number of non-zero elements of the ith training instance. Then the average number in $\mathbf{x}_i$ $\forall i$ is

$$\bar{n} = \frac{n_1 + \cdots + n_l}{l}. \tag{9}$$

If $d = 2$, the average number of non-zero elements in $\phi(\mathbf{x}_i)$, $\forall i$ is

$$\hat{n} = \frac{1}{l}\sum_{i=1}^{l} \frac{(n_i+2)(n_i+1)}{2} \approx \frac{1}{l}\sum_{i=1}^{l} \frac{n_i^2}{2} = \frac{1}{2}\bar{n}^2 + \frac{1}{2l}\sum_{i=1}^{l}(n_i - \bar{n})^2. \tag{10}$$

The second term in (10) is the variance of $n_1, \ldots, n_l$. If the variance is small, comparing $l\bar{n}$ and $\bar{n}^2/2$ can possibly indicate if one should train a linear or a nonlinear SVM. In Section 4, we give more analysis on real data.

3.4 Implementation Issues

Due to the high dimensionality of $\phi(\mathbf{x}_i)$, some implementation issues must be addressed. To begin, we discuss various ways to handle the new data $\phi(\mathbf{x}_1), \ldots, \phi(\mathbf{x}_l)$. A vector $\phi(\mathbf{x})$ now contains terms like $x_r x_s$, which can be calculated using $\mathbf{x}$. We consider three methods:

1. Calculate and store $\phi(\mathbf{x}_1), \ldots, \phi(\mathbf{x}_l)$ as the new input data.
2. Use $\mathbf{x}_1, \ldots, \mathbf{x}_l$ as the input data and calculate all $\phi(\mathbf{x}_1), \ldots, \phi(\mathbf{x}_l)$ before training.
3. Use $\mathbf{x}_1, \ldots, \mathbf{x}_l$ as the input data and calculate $\phi(\mathbf{x}_i)$ in a training algorithm (e.g., decomposition method).

These methods have advantages/disadvantages. The first method does not require any modification of linear-SVM solvers, but needs a large $O(l\hat{n})$ disk/memory space to store $\phi(\mathbf{x}_i)$, $\forall i$. The second method also needs extra memory spaces, but avoids the long time for loading data from disk. The third method does not need extra memory, but requires some modifications of the decomposition implementation. That is, we need to calculate $\phi(\mathbf{x}_i)$ in (8). These three methods are useful under different circumstances. In Section 4.3, we experimentally show that for data with not too large n, the third way is the fastest. Although $\phi(\mathbf{x}_i)$ $\forall i$ can be stored in memory, accessing data from memory to cache and then CPU may be slower than performing the calculation. However, for an application with very large n and very small $\bar{n}$, we demonstrate that the first or the second method may be more suitable. See the discussion later in this section.

While we may avoid storing $\phi(\mathbf{x}_i)$, one memory bottleneck remains. The vector $\mathbf{w}$ has a huge number of $O(n^d)$ components. If some features of $\phi(\mathbf{x}_i)$, $\forall i$ are zero, their corresponding elements in $\mathbf{w}$ are useless. Hence we can implement a sparse $\mathbf{w}$ to save the storage. In the following we analyze the possibility of having a sparse $\mathbf{w}$ by considering $d = 2$ and assuming that features of an instance have an equal opportunity to be zeros. The probability that $(\mathbf{x}_i)_r(\mathbf{x}_i)_s$ is zero for all $\phi(\mathbf{x}_i)$, $i = 1, \ldots, l$ is

$$\prod_{i=1}^{l}\left(1 - \frac{n_i(n_i-1)}{n(n-1)}\right).$$

Note that $n_i(n_i-1)/n(n-1)$ is the probability that $(\mathbf{x}_i)_r(\mathbf{x}_i)_s$ is non-zero. Then the expected number of non-zero elements in $\mathbf{w}$ can be approximated by

$$C(n+2,2)-\frac{n(n-1)}{2}\prod_{i=1}^{l}\left(1-\frac{n_i(n_i-1)}{n(n-1)}\right), \tag{11}$$

where $n(n-1)/2$ is the number of $x_r x_s$ terms in (4). This number is usually close to $C(n+2,2)$ due to the product of l values in (11). Moreover, this estimate is only accurate if features are independent. The assumption may hold for data sets with features from bitmaps or word frequencies, but is wrong for data with exclusive features (e.g., binary representation of a nominal feature). For data with known structures of features, in Section 4.2 we use real examples to illustrate how to more accurately estimate the number of $\mathbf{w}$'s non-zero elements.

In Section 5, we present an example of using a sparse $\mathbf{w}$. The dimensionality of the input data is $n = 46,155$. If $d = 2$, then storing $\mathbf{w}$ as a dense vector takes almost 20 GBytes of memory (assuming double precision). This problem has a very small $n_i \approx 13.3, \forall i$. Many $x_r x_s$ terms are zero in all $\phi(\mathbf{x}_i), i = 1,\ldots,l$, so $\mathbf{w}$ is very sparse. However, a naive implementation can be very inefficient. Assume $\tilde{n}$ is the number of non-zero elements in $\mathbf{w}$, where for this example $\tilde{n} = 1,438,456$. Accessing an element in a sparse vector requires an expensive $O(\tilde{n})$ linear search. We can use a hash table to store $\mathbf{w}$, but experiments show that the access time of $\mathbf{w}$ is still high. If $\phi(\mathbf{x}_i)$, $\forall i$ can be stored in memory, we construct a hash mapping from (r,s) to $j \in \{1,\ldots,\tilde{n}\}$ and re-generate training data using feature index j. That is, we construct a condensed representation for $\phi(\mathbf{x}_i), \forall i$ and train a linear SVM with a dense $\mathbf{w} \in R^{\tilde{n}}$. The training is much more efficient because we can easily access any element of $\mathbf{w}$. In prediction, for any testing instance $\mathbf{x}$, we use the same hash table to conduct the inner product $\mathbf{w}^T\phi(\mathbf{x})$. This strategy corresponds to the first/second methods in the above discussion of handling $\phi(\mathbf{x}_i)\ \forall i$.

The above technique to condense $\phi(\mathbf{x}_i)$ has been used in recent works on hash kernels (e.g., Shi et al., 2009). They differ from us in several aspects. First, their condensed representation is an approximation to $\phi(\mathbf{x}_i)$. Second, with an online setting, they may not accurately solve the problem (1).

3.5 Relations with the RBF kernel

RBF kernel (Gaussian kernel) may be the most used kernel in training nonlinear SVM. It takes the following form:

$$K(\mathbf{x}_i,\mathbf{x}_j) = e^{\frac{-\|\mathbf{x}_i-\mathbf{x}_j\|^2}{2\sigma^2}}.$$

Keerthi and Lin (2003) show that, as $\sigma^2 \to \infty$, SVM with the RBF kernel and the penalty parameter C approaches linear SVM with the penalty parameter $C/(2\sigma^2)$. This result implies that with a suitable parameter selection, the testing accuracy of using the RBF kernel is at least as good as using the linear kernel.

For polynomial kernels, Lippert and Rifkin (2006) discuss the relation with RBF. They consider the penalty parameter $(1/(2\sigma^2))^{-2d}C$ and check the situation as $\sigma^2 \to \infty$. For a positive integer d, the limit of SVM with the RBF kernel approaches SVM with a degree-d polynomial mapping of data. The polynomial mapping is related only to the degree d. This result seems to indicate that RBF is again at least as good as polynomial kernels. However, the polynomial mapping for (3) is more general due to two additional parameters γ and r. Thus the situation is unclear if parameter

Data set	n	$\bar{n}$	l	# testing
a9a	123	13.9	32,561	16,281

webspam	254	85.1	280,000	70,000

Table 1: Summary of the data sets. n is the number of features, and $\bar{n}$ is the average number of non-zero features for each data instance. l is the number of data instances. The last column shows the number of testing data.

selections have been applied to both kernels. In Section 4, we give a detailed comparison between degree-2 polynomial mappings and RBF.

3.6 Parameter Selection

The polynomial kernel defined in (3) has three parameters (d, γ, and r). Now we intend to use low-degree mappings so d should be 2 or 3. Selecting the two remaining parameters is still complicated. Fortunately, we show in Appendix A that r can be fixed to one, so the number of parameters is the same as that of the RBF kernel. This result is obtained by proving that a polynomial kernel

$$\bar{K}(\mathbf{x}_i, \mathbf{x}_j) = (\bar{\gamma}\mathbf{x}_i^T\mathbf{x}_j + r)^d \text{ with parameters } (\bar{C}, \bar{\gamma}, r) \tag{12}$$

results in the same model as the polynomial kernel

$$K(\mathbf{x}_i, \mathbf{x}_j) = (\gamma\mathbf{x}_i^T\mathbf{x}_j + 1)^d \text{ with parameters } \gamma = \frac{\bar{\gamma}}{r} \text{ and } C = r^d\bar{C}. \tag{13}$$

3.7 Prediction

Assume a degree-d polynomial mapping is considered and #SV is the number of support vectors. For any testing data $\mathbf{x}$, the prediction time with/without kernels is

$$\sum_{i:\alpha_i>0} \alpha_i y_i K(\mathbf{x}_i, \mathbf{x}) \quad \Rightarrow \quad O(\#\text{SV} \cdot \bar{n}), \tag{14}$$

$$\mathbf{w}^T\phi(\mathbf{x}) \quad \Rightarrow \quad O(\hat{n}), \tag{15}$$

where $\bar{n}$ and $\hat{n}$ are respectively the average number of non-zero elements in $\mathbf{x}$ and $\phi(\mathbf{x})$. If $\hat{n} \leq \#\text{SV} \cdot \bar{n}$, then (15) is more efficient than (14). Several NLP studies (e.g., Isozaki and Kazawa, 2002) have used (15) for efficient testing.

4. Experiments

In this section, we experimentally analyze the proposed approach for degree-2 polynomial mappings. We use two-class data sets, but in Section 5, we consider multi-class problems from an NLP application. We briefly discuss extensions to L1-regularized SVM in Section 4.5.

Except programs used in Section 5, all sources for experiments are available at `http://www.csie.ntu.edu.tw/~cjlin/liblinear/exp.html`.

4.1 Data Sets and Implementations

We select the following problems from LIBSVM tools[2] for experiments: a9a, real-sim, news20, ijcnn1, MNIST, covtype and webspam. The summary of data sets is in Table 1. Problems real-sim, news20, covtype and webspam have no original test sets, so we use a 80/20 split for training and testing. MNIST is a 10-class problem; we consider classes 3 and 8 to form a two-class data set MNIST38. While covtype is originally multi-class, we use a two-class version at LIBSVM tools.

We do not further scale these data sets as some of them have been pre-processed. Problems real-sim, news20 and webspam are document sets and each instance is normalized to unit length. We use a scaled version of covtype at LIBSVM tools, where each feature is linearly scaled to $[0,1]$. The original MNIST data have all feature values in the range $[0,255]$, but the version we download is scaled to $[0,1]$ by dividing every value by 255.

We compare implicit mappings (kernel) and explicit mappings of data by LIBSVM (Chang and Lin, 2001) and an extension of LIBLINEAR (Fan et al., 2008), respectively. The two packages use similar stopping conditions, and we set the same stopping tolerance 0.1. Experiments are conducted on a 2.5G Xeon L5420 machine with 16G RAM using gcc compiler. Our experiments are run on a single CPU.

4.2 Analysis of $\phi(\mathbf{x})$ and $\mathbf{w}$

Following the discussion in Section 3.2, we check $l\bar{n}$ and $\hat{n}$ to see if using the explicit mapping of data may be helpful. Table 2 presents these two values for the degree-2 polynomial mapping. We also present $\bar{n}^2/2$ as from (10) it can be a rough estimate of $\hat{n}$.

From Table 2, except document data real-sim and news20, $\bar{n}^2/2$ is close to $\hat{n}$. The huge difference between $\hat{n}$ and $l\bar{n}$ indicates that using explicit mappings is potentially faster.

Next we investigate the number of non-zero elements in $\mathbf{w}$. Table 2 presents the dimensionality of $\mathbf{w}$, two estimated numbers of non-zero elements and the actual number. For most data, the first estimation by (11) pessimistically predicts that $\mathbf{w}$ is fully dense. Two exceptions are real-sim and

2. LIBSVM tools can be found at `http://www.csie.ntu.edu.tw/~cjlin/libsvmtools/datasets/`.

webspam[4]	45.07	1.30e+11	4,219.3	3.20e+09	3,228.1

Table 3: A comparison between storing and calculating $\phi(\mathbf{x}_i)$. The column $\hat{n}/\bar{n}$ indicates the ratio between the memory consumption for storing $\phi(\mathbf{x}_i)$ and $\mathbf{x}_i$. Time is in seconds.

news20, where (11) is quite accurate. These two sparse document sets seem to have independent features (word occurrence) so that the assumption for (11) holds. For data with known structures, we demonstrate that a better estimate than (11) can be achieved. The problem a9a contains 14 groups of features[3] and each group contains several exclusive binary features (e.g., age in various ranges). Within each group, $x_r x_s = 0$ if $r \neq s$, so an upper bound of $\mathbf{w}$'s number of non-zero elements is

$$C(n+2,2) - \sum_{\text{feature groups}} C(\#\text{features in each group}, 2). \tag{16}$$

We show in Table 2 that (16) is closer to the actual number. The situation for two other problems (ijcnn1 and covtype) is similar.

As storing news20's non-zero $\mathbf{w}$ elements requires more memory than our machine's capacity, we do not include this set in subsequent experiments.

4.3 Calculating or Storing $\phi(\mathbf{x}_i)$

In Section 3.4, we discuss three methods to handle $\phi(\mathbf{x}_i)$. Table 3 compares the first/second and the third methods. We select C and kernel parameters by a validation procedure and present the training time of using optimal parameters. For the first/second methods, we count CPU time after all $\phi(\mathbf{x}_i)$ have been loaded/generated. For the third, we show CPU time after loading all $\mathbf{x}_i$, as this method calculates $\phi(\mathbf{x}_i), \forall i$ in the middle of the training procedure.

Table 3 lists $\hat{n}/\bar{n}$ to show the ratio between two methods' memory consumption on storing $\phi(\mathbf{x}_i)$ and $\mathbf{x}_i$, $\forall i$. In the same table we present each method's number of L2 cache misses and training time. The number of L2 cache misses is obtained by the simulation tool cachegrind in valgrind.[5] The method by calculating $\phi(\mathbf{x}_i)$ is faster in all cases. Moreover, it has a smaller number of L2 cache misses. Data can be more easily located in the cache when $\phi(\mathbf{x}_i)$ is not stored. We consider the method of calculating $\phi(\mathbf{x}_i)$ for subsequent experiments in this section.

3. See descriptions in the beginning of each file from `http://research.microsoft.com/en-us/um/people/jplatt/adult.zip`.
4. For webspam, as $\phi(\mathbf{x}_i)$ $\forall i$ require more memory than what our machine has, we use single precision floating-point numbers to store the data. All other experiments in this work use double precision.
5. cachegrind can be found at `http://valgrind.org/`.

4.4 Accuracy and Time of Using Linear, Degree-2 Polynomial, and RBF

We compare training time, testing time, and testing accuracy of using three mappings: linear, degree-2 polynomial, and RBF. We use LIBLINEAR for linear, LIBSVM for RBF, and both for degree-2 polynomial. For each data set, we choose parameters C and γ by a five-fold cross validation on a grid of points. The best (C,γ) are then used to train the whole training set and obtain the testing accuracy. To reduce the training time, LIBSVM allocates some memory space, called kernel cache, to store recently used kernel elements. In contrast, LIBLINEAR does not require this space. All it needs is to store $\mathbf{w}$. In this work, we run LIBSVM using 1 GBytes of kernel cache.

Using linear and RBF mappings, Table 4 presents the training time, testing accuracy, and the correspondent parameters. Linear and RBF have similar testing accuracy on data sets a9a and real-sim. The set real-sim contains document data with many features. Linear classifiers have been observed to perform well on such data with much less training time. For other data sets, the testing accuracy of using linear is clearly inferior to that of using RBF. Degree-2 polynomial mappings may be useful for these data. We can possibly improve the accuracy over linear while achieving faster training time than RBF.

We then explore the performance of the degree-2 polynomial mapping. The first part of Table 5 shows the training time, testing accuracy, and optimal parameters using LIBLINEAR. As a com-

Data set	LIBLINEAR		LIBSVM

Table 6: Testing time (in seconds) using decomposition methods for linear and nonlinear SVM. Parameters in Tables 4 and 5 are used to build SVM models for prediction. NA: SVM models are not available due to lengthy training time (see Table 5).

parison, we run LIBSVM with the same parameters and report training time.[6] Table 5 also presents the testing accuracy difference between degree-2 polynomial and linear/RBF. It is observed that for nearly all problems, the performance of the degree-2 polynomial mapping can compete with RBF, while for covtype, the performance is only similar to the linear mapping. Apparently, a degree-2 mapping does not give rich enough information to separate data in covtype.

Regarding the training time, LIBLINEAR with degree-2 polynomial mappings is faster than LIBSVM with RBF. Therefore, the proposed method may achieve fast training, while preserving some benefits of nonlinear mappings. Next, we compare the training time between LIBLINEAR and LIBSVM when the same degree-2 polynomial mapping is used. From Table 5, LIBLINEAR is much faster than LIBSVM. Thus for applications needing to use low-degree polynomial kernels, the training time can be significantly reduced.

We present testing time in Table 6. The explicit mapping approach is much faster as it calculates only $\mathbf{w}^T\mathbf{x}$ or $\mathbf{w}^T\phi(\mathbf{x})$.

4.5 L1-regularized SVM with Linear and Degree-2 Polynomial Mappings

Recently, L1-regularized SVM has gained attention because it can produce a sparse model (see, for example, the survey by Yuan et al., 2009, and references therein). An L1-regularized SVM[7] solves

$$\min_{\mathbf{w}} \quad \|\mathbf{w}\|_1 + C\sum_{i=1}^{l} \max(1 - y_i\mathbf{w}^T\phi(\mathbf{x}_i), 0)^2, \tag{17}$$

where $\|\cdot\|_1$ denotes the 1-norm. As discussed in Section 3.4, after a degree-2 polynomial mapping the number of features may be very large. A sparse $\mathbf{w}$ reduces the memory consumption. In this section, we conduct a preliminary investigation on training degree-2 polynomial mappings via (17).

Due to the non-differentiable term $\|\mathbf{w}\|_1$, optimization techniques for (17) are different from those for L2-regularized SVM. If we pre-compute $\phi(\mathbf{x}_i), \forall i$ (i.e., methods 1 and 2 in Section 3.4 for handling $\phi(\mathbf{x}_i)$), then any optimization technique for (17) can be directly applied. Recall that Section 4.3 shows that method 3 (calculating $\phi(\mathbf{x}_i)$ in the training algorithm) is faster if n is not large. We show an interesting example where this method significantly increases the number of operations. In

6. LIBSVM solves SVM with bias b, but LIBLINEAR solves (1). As the difference is minor, we run LIBSVM with the same parameters for LIBLINEAR. Moreover, the testing accuracy of LIBSVM is almost the same as LIBLINEAR.

7. We consider L2-loss in (17) by following Yuan et al. (2009).

Data set	Linear			Degree-2 polynomial				
	Time (s)	Sparsity (%)	Accuracy (%)	Time (s): $\phi(\mathbf{x}_i)$ is stored	Time (s): $\phi(\mathbf{x}_i)$ is calculated	Sparsity (%)	Accuracy (%)	L2 SVM Sparsity

webspam	47.08	38.98	92.55	772.92	1,296.40	12.60	98.32	28.96

Table 7: L1-regularized SVM: a comparison between linear and degree-2 polynomial mappings. Time is in seconds. Sparsity is the percentage of non-zero elements in $\mathbf{w}$. For the degree-2 polynomial mapping, we show the training time of both calculating and storing $\phi(\mathbf{x})$.

Yuan et al. (2009), a primal decomposition (coordinate descent) method is considered the fastest for solving (17). It updates one element of $\mathbf{w}$ at a time. If $\mathbf{w}$ is the current solution and the jth element is selected, the following one-variable problem is minimized:

$$\min_d \quad |w_j + d| + C\sum_{i=1}^{l} \max\left(1 - y_i \mathbf{w}^T \phi(\mathbf{x}_i) - y_i d\phi(\mathbf{x}_i)_j, 0\right)^2.$$

Assume $\phi(\mathbf{x})_j$ involves $x_r x_s$. To obtain all $\phi(\mathbf{x}_i)_j, \forall i$, we must go through non-zero elements of the rth and the sth features of the original data. This operation costs $O(\bar{l})$, where $\bar{l}$ is the average number of non-zero elements per feature of $\mathbf{x}_i$, $\forall i$. However, the expected number of non-zero elements of $\phi(\mathbf{x}_i)_j, \forall i$ is only

$$\left(\bar{l}/l\right)^2 \cdot l = \bar{l}^2/l.$$

If data are sparse, $\bar{l}^2/l$ is much smaller than $\bar{l}$. Therefore, the cost by using methods 1 and 2 to pre-compute $\phi(\mathbf{x}_i), \forall i$ is less than method 3. This is mainly because the primal coordinate descent approach accesses data in a feature-based way. The sparse patterns of two features are needed. In contrast, decomposition methods used earlier for solving the dual problem of L2-regularized SVM is instance-based. To obtain $x_r x_s$, one needs only the sparse pattern of an instance $\mathbf{x}$. Some optimization approaches discussed in Yuan et al. (2009) for (17) are instance-based. An interesting future study would be to investigate their performances.

We extend a primal decomposition implementation for (17) in LIBLINEAR to handle degree-2 polynomial mappings. We use default settings (e.g., stopping tolerance) in LIBLINEAR. Table 7 compares linear and degree-2 polynomial mappings by showing training time, $\mathbf{w}$'s sparsity, and testing accuracy. For the training time of using degree-2 polynomials, we present results by storing and calculating $\phi(\mathbf{x}_i)$. Clearly, calculating $\phi(\mathbf{x}_i)$ is much slower, a result consistent with our analysis. The training time for real-sim is much longer than that in Table 5 (L2-regularized SVM). This result is due to the huge number of variables in solving the primal problem (17). There are some tricks to improve the training speed for this problem though we do not get into details. For sparsity, we also show the result using L2-regularized SVM as a comparison.[8] L1-regularized SVM gives excellent

8. The sparsity of L2-regularized SVM is in fact the column of "real" numbers of non-zero elements in Table 2 divided by the dimensionality $C(n+2,2)$.

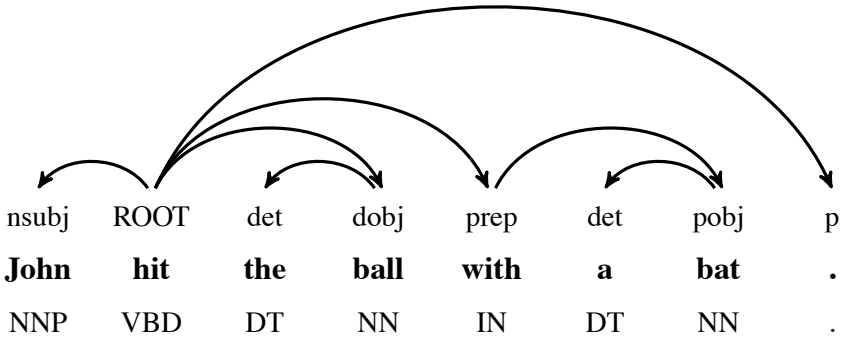

Figure 1: A dependency graph with arc labels and part-of-speech tags for a sentence.

sparsity for some problems. For example, MNIST38 has $n = 752$ features. By solving (17) with linear mapping, 420 features remain. If using a degree-2 polynomial mapping, the dimensionality is $C(n+2,2) = 283,881$. Solving an L2-regularized SVM gives a $\mathbf{w}$ with 153,564 non-zero elements, but using L1 regularization $\mathbf{w}$ has only a very small number of 650 non-zero elements. Finally, for testing accuracy, results are similar to (or slightly lower than) those in Tables 4-5.

Due to the nice sparsity results, L1 regularization for low-degree polynomial mappings may be a promising future direction.

5. An NLP Application: Data-driven Dependency Parsing

In this section we study a real-world natural language processing (NLP) task on dependency parsing. Given a sentence, a dependency graph represents each word and its syntactic modifiers through labeled directed edges. Figure 1 shows an example. Data-driven dependency parsing is a common method to construct dependency graphs. Different from grammar-based parsing, it learns to produce the dependency graph solely by using the training data. Data-driven dependency parsing has become popular because it is chosen as the shared task at CONLL-X[9] and CONLL2007.[10] More information about dependency parsing can be found in, for example, McDonald and Nivre (2007).

Dependency parsing appears in many online NLP applications. In such cases testing (parsing) speed is very important. We will see that this requirement for testing speed makes our approach very useful for this application.

5.1 A Multi-class Problem

We study a transition-based parsing method proposed by Nivre (2003). The parsing algorithm builds a labeled dependency graph in one left-to-right pass over the input with a stack to store partially processed tokens. At each step, we need to decide which transition to perform. As in Nivre et al. (2007), we use the following transitions:

- SHIFT: Pushes the next input token to the top of the stack and advances to the next input token.
- REDUCE: Pops the top element from the stack.

9. CONLL-X can be found at `http://nextens.uvt.nl/~conll/`.
10. CONLL2007 can be found at `http://nextens.uvt.nl/depparse-wiki/SharedTaskWebsite`.

input(1).tag	stack.tag	stack.leftmost-child.label
input(2).tag	stack(1).tag	stack.rightmost-child.label
input(3).tag	stack.label	input.leftmost-child.label
input.word	stack.word	
input(1).word	stack.head.word	

Table 8: Feature types used by the dependency parser.

- LEFT-ARC(r): Adds an arc with label r from the next input token to the token on top of the stack and pops the top element off the stack.

- RIGHT-ARC(r): Adds an arc with label r from the top token on the stack to the next input token. Then pushes the current input token to the stack and advances to the next input token.

The parser decides the next transition by extracting features from the current parse state. The parse state consists of the stack, the remaining input tokens, and the partially built dependency graph. We use the standard method for converting symbolic features into numerical features by binarization. For each feature type F (see Table 8), that has value v in the current state, we generate a feature predicate, $F = v$. These feature predicates are used as binary features in the classifier. It is this expansion of feature types to binary feature predicates that leads to the large number of features in the classifiers. Especially the lexicalized (i.e., word-based) features generate large numbers of sparse features.

Thus the core of the parser is a multi-class classification problem, which maps features to transitions. Nivre et al. (2006) use LIBSVM with a degree-2 polynomial kernel to train the multi-class classification problems, and get good results at CONLL-X.

In this experiment, we use data from the English Penn Treebank (Marcus et al., 1993). The treebank is converted to dependency format using Penn2Malt,[11] and the data is split into sections 02–21 for training and section 23 for testing. During training we construct a canonical transition sequence from the dependency graph of each sentence in the training corpus, adopting an arc-eager approach for disambiguation. For each transition, we extract the features in Table 8 from the current parse state, and use this for training the classifiers.

When parsing a sentence, the classifiers are used for predicting the next transition, based on the features extracted from the current parse state. When all the input tokens have been processed the dependency graph is extracted from the transition sequence.

In order to reduce training time the data is split into multiple sets. For example, if a feature j takes two values a and b, we can divide the training data into $\{\mathbf{x} \mid x_j = a\}$ and $\{\mathbf{x} \mid x_j = b\}$, and get two models M^a and M^b. Then in the prediction phase, we decide to use M^a or M^b according to x_j of the testing instance. Yamada and Matsumoto (2003) mention that applying this method reduces the training time without a significant loss in accuracy. We divide the training data into 125 smaller training sets according to the part-of-speech tag of the current input token. Also, the label for RIGHT-ARC and LEFT-ARC transitions is predicted separately from the transition. The number of classes ranges from 2 to 12. Table 9 lists the statistics of the largest multi-class problem among 125.

11. See `http://w3.msi.vxu.se/~nivre/research/Penn2Malt.html`

n	$\bar{n}$	l	#nz
46,155	13.3	294,582	3,913,845

Table 9: Summary of the dependency parsing data set. We show statistics of the largest problem among the 125 sets divided from the training data. The column #nz ($= l\bar{n}$) indicates the total number of non-zero feature values in the training set.

5.2 Implementations

We consider the degree-2 polynomial mapping in (5). Since the original $\mathbf{x}_i, \forall i$ have 0/1 feature values, we use (5) instead of (4) to preserve this property.[12] In our implementation, by extending LIBLINEAR, 0/1 values are still stored as double-precision numbers. However, for large data sets, we can save memory by storing only non-zero indices. Due to using (5), the only parameter is C.

The dimensionality of using the degree-2 polynomial mapping is huge. We discussed in Section 3.4 that 20 GBytes memory is needed to store a dense $\mathbf{w}$. Assume the "one-against-the rest" approach is applied for multi-class classification. We need 125 $\times$ (# classes) vectors of $\mathbf{w}$ in the prediction (parsing) stage as training data are separated into 125 sets. Obviously we do not have enough memory for them. As the data are very sparse, the actual number of non-zero elements in $\mathbf{w}$ is merely 1,438,456 (considering the largest of the 125 training sets). Only these non-zero features in $\phi(\mathbf{x})$ and $\mathbf{w}$ are needed in training/testing, so the memory issue is solved. In the practical implementation, we construct a hash table to collect non-zero features of $\phi(\mathbf{x}_i), i = 1, \ldots, l$ as a new set for training.[13] In prediction, we use the same hash map to calculate $\mathbf{w}^T\phi(\mathbf{x})$. This implementation corresponds to the first/second methods discussed in Section 3.4. See more details in the end of Section 3.4.

Other settings (e.g., stopping tolerance and LIBSVM's kernel cache) are the same as those in Section 4. LIBSVM uses the "one-against-one" approach for training multi-class problems, while LIBLINEAR uses "one-against-the rest." We use a dependency parsing system at Google, which calls LIBSVM/LIBLINEAR for training/testing. Parts of this experiment were performed when some authors worked at Google.

As the whole parsing system is quite complex, we have not conducted a complete parameter optimization. Instead, we have roughly tuned each parameter to produce good results.

5.3 Experiments

We compare two approaches. The first uses kernels, while the second does not.

- LIBSVM: RBF and degree-2 polynomial kernels.
- LIBLINEAR: linear mapping (i.e., the original input data) and the degree-2 polynomial mapping via (5).

12. In fact, if using (4), we can still use some ways so that $\sqrt{2}$ is not stored. However, the implementation is more complicated.
13. For a fair comparison, the reported training time includes time for this pre-processing stage.

	LIBSVM		LIBLINEAR	
	RBF	Poly ($d=2$)	Linear	Poly: Eq. (5)
Parameters	$C=0.5$ $1/(2\sigma^2)=0.18$	$C=0.5$ $\gamma=0.18$ $r=0.3$	$C=0.5$	$C=0.05$
Training time	3h34m53s	3h21m51s	3m36s	3m43s
Parsing speed	0.7x	1x	1652x	103x
UAS	89.92	91.67	89.11	91.71
LAS	88.55	90.60	88.07	90.71

Table 10: Accuracy, training time, and parsing speed (relative to LIBSVM with polynomial kernel) for the dependency parsing.

Table 10 lists parameters for various kernels, training/testing time, and testing accuracy. Training and testing are done using gold standard part-of-speech tags, and only non-punctuation tokens are used for scoring. The accuracy of dependency parsing is measured by two evaluation metrics:

1. Labeled attachment score (LAS): the percentage of tokens with correct dependency head and dependency label.

2. Unlabeled attachment score (UAS): the percentage of tokens with correct dependency head.

For LIBSVM the polynomial kernel gives better accuracy than the RBF kernel, consistent with previous observations, that polynomial mappings are important for parsing (Kudo and Matsumoto, 2000; McDonald and Pereira, 2006; Yamada and Matsumoto, 2003; Goldberg and Elhadad, 2008). Moreover, LIBSVM using degree-2 polynomial kernel produces better results in terms of UAS/LAS than LIBLINEAR using just a linear mapping of features. However, parsing using LIBSVM is slow compared to LIBLINEAR. We can speed up parsing by a factor of 1,652 with only a 2.5% drop in accuracy. With a degree-2 polynomial mapping (5), we achieve UAS/LAS results similar to LIBSVM, while still maintaining high parsing speed, 103 times faster than LIBSVM.

From Table 10, training LIBLINEAR is a lot faster than LIBSVM. This large reduction in training time allows us to easily conduct experiments and improve the settings. Some may criticize that the comparison on training time is not fair as LIBSVM uses "one-against-one" for multi-class classification, while LIBLINEAR uses "one-against-the rest." It is known (e.g., Hsu and Lin, 2002) that for nonlinear SVM, LIBSVM with "one-against-one" is faster than "one-against-the rest." Thus even if we modify LIBSVM to perform "one-against-the rest," its training is still much slower than LIBLINEAR.

5.4 Related Work

Earlier works have improved the testing speed of SVM with low-degree polynomial kernels. Most of them target natural language processing (NLP) applications. Isozaki and Kazawa (2002) propose an approach similar to obtaining $\mathbf{w}$ by the expression in (8).[14] A direct implementation of their

14. They do not really form $\mathbf{w}$, but their result by expanding the degree-2 polynomial kernel leads to something very similar.

method requires a memory space as large as the dimensionality of $\mathbf{w}$, but we cannot afford such a space for our application. Kudo and Matsumoto (2003) consider the expression of $\mathbf{w}$ in (8) and propose an approximate prediction scheme using only a sub-vector of $\mathbf{w}$. Their method is useful for data with 0/1 features. Goldberg and Elhadad (2008) propose speeding up the calculation of low-degree polynomial kernels by separating features to rare and common ones. Goldberg and Elhadad's approach is motivated by some observations of NLP data. It avoids the memory problem, but the effectiveness on general data is not clear yet.

The above existing works focus on improving testing speed. They suffer from the slow training of using traditional SVM solvers. For example, Kudo and Matsumoto (2000) mention that "the experiments . . . have actually taken long training time," so they must select a subset using properties of dependency parsing. Our approach considers linear SVM on explicitly mapped data, applies state of the art training techniques, and can simultaneously achieve fast training and testing.

6. Discussions and Conclusions

Past research has shown that SVM using linear and highly nonlinear mappings of data has the following properties:

Linear	Highly nonlinear
Fast training/testing	Slow training/testing via kernels
Low accuracy	High accuracy

Many have attempted to develop techniques in the between. Most start from the nonlinear side. They propose methods to manipulate the kernels (e.g., Lee and Mangasarian, 2001; Keerthi et al., 2006). In contrast, ours is from the linear side. The strategy is simple and requires only minor modifications of existing packages for linear SVM.

This work focuses on the degree-2 polynomial mapping. An interesting future study is the efficient implementation for degree-3 mappings. Considering other mapping functions to expand data vectors could be investigated as well. As kernels are not used, we might have a greater flexibility to design the mapping function.

Table 2 shows that storing $\mathbf{w}$ may require a huge amount of memory. For online training, some (e.g., Langford et al., 2009) have designed feature hashing techniques to control the memory use of $\mathbf{w}$. Recently, feature hashing has been popular for projecting a high dimensional feature vector to a lower dimensional one (e.g., Weinberger et al., 2009; Shi et al., 2009). For certain sequence data, one can consider n-gram (i.e., n consecutive features) instead of general polynomial mappings. Then not only the number of features becomes smaller, but also controlling $\mathbf{w}$'s sparsity is easier. Existing experiments on document data can be found in, for example, Ifrim et al. (2008) and Shi et al. (2009).

We successfully apply the proposed procedure to an NLP application. It has certain requirements on the training and testing speed, but we also hope to achieve better testing accuracy. The proposed procedure is very useful for applications of this type.

Appendix A. Connection Between (12) and (13)

We prove the result by showing that the dual optimization problems of using (12) and (13) are the same. Since

$$(\bar{\gamma}\mathbf{x}_i^T\mathbf{x}_j + r)^d = r^d\left(\frac{\bar{\gamma}}{r}\mathbf{x}_i^T\mathbf{x}_j + 1\right)^d,$$

we have

$$\bar{Q}_{ij} = y_i y_j \bar{K}(\mathbf{x}_i, \mathbf{x}_j) = r^d Q_{ij}.$$

The dual optimization problem of using $\bar{Q}$ can be written as

$$\begin{aligned} \min_{\bar{\alpha}} \quad & \frac{1}{r^d}\left(\frac{1}{2}(r^d\bar{\alpha})^T Q(r^d\bar{\alpha}) - \mathbf{e}^T r^d\bar{\alpha}\right) \\ \text{subject to} \quad & 0 \le r^d\bar{\alpha}_i \le r^d\bar{C}, \quad i = 1\ldots, l. \end{aligned}$$

Using $\alpha = r^d\bar{\alpha}$ and $C = r^d\bar{C}$, this problem becomes the dual problem when using Q.

Abstract

Identifying a subset of features that preserves classification accuracy is a problem of growing importance, because of the increasing size and dimensionality of real-world data sets. We propose a new feature selection method, named Quadratic Programming Feature Selection (QPFS), that reduces the task to a quadratic optimization problem. In order to limit the computational complexity of solving the optimization problem, QPFS uses the Nyström method for approximate matrix diagonalization. QPFS is thus capable of dealing with very large data sets, for which the use of other methods is computationally expensive. In experiments with small and medium data sets, the QPFS method leads to classification accuracy similar to that of other successful techniques. For large data sets, QPFS is superior in terms of computational efficiency.

Keywords: feature selection, quadratic programming, Nyström method, large data set, high-dimensional data

1. Introduction

The task of feature selection is to reduce the number of variables used in training a classifier. Three main benefits can be drawn from successful feature selection: first, a substantial gain in computational efficiency (especially important for any application that requires classifier execution in real-time); second, scientific discovery by determining which features are most correlated with the class labels (which may in turn reveal unknown relationships among features); and, third, reduction of the risk of overfitting if too few training instances are available (a serious problem particularly in situations with high dimensionalities relative to training set sizes). Document categorization (Forman, 2008), prosthesis control (Momen et al., 2007; Shenoy et al., 2008), cardiac arrhythmia classifica-

tion (Rodriguez et al., 2005), fMRI analysis, gene selection from microarray data (Ding and Peng, 2005; Li et al., 2004; Zhang et al., 2008), real-time identification of polymers (Leitner et al., 2003), and credit card fraud detection are some real-life domains where these gains are especially meaningful.

Many methods have been suggested to solve the variable selection problem. They can be categorized into three groups. *Filter* methods perform feature selection that is independent of the classifier (Bekkerman et al., 2003; Forman, 2003, 2008). *Wrapper* methods use search techniques to select candidate subsets of variables and evaluate their fitness based on classification accuracy (John et al., 1994; Kohavi and John, 1997; Langley, 1994). Finally, *embedded* methods incorporate feature selection in the classifier objective function or algorithm (Breiman et al., 1984; Weston et al., 2001).

Filter methods are often preferable to other selection methods because of their usability with alternative classifiers, their computational speed, and their simplicity (Guyon, 2003; Yu and Liu, 2003). But filter algorithms often score variables separately from each other, so they do not achieve the goal of finding combinations of variables that give the best classification performance. It has been shown that simply combining good variables does not necessary lead to good classification accuracy (Cover, 1974; Cover and Thomas, 1991; Jain et al., 2000). Therefore, one common improvement direction for filter algorithms is to consider dependencies among variables. In this direction approaches based on mutual information, in particular Maximal Dependency (MaxDep) and minimal-Redundancy-Maximum-Relevance (mRMR), have been significant advances (Peng et al., 2005).

The central idea of the MaxDep approach is to find a subset of features which jointly have the largest dependency on the target class. However, it is often infeasible to compute the joint density functions of all features and of all features with the class. One approach to making the MaxDep approach practical is Maximal Relevance (MaxRel) feature selection (Peng et al., 2005). This approach selects those features that have highest relevance (mutual information) to the target class. The main limitation of MaxRel is not accounting for redundancy among features. The mRMR criterion is another version of MaxDep that chooses a subset of features with both minimum redundancy (approximated as the mean value of the mutual information between each pair of variables in the subset) and maximum relevance (estimated as the mean value of the mutual information between each feature and the target class). Given the prohibitive cost of considering all possible subsets of features, the mRMR algorithm selects features greedily, minimizing their redundancy with features chosen in previous steps and maximizing their relevance to the class.

The new method proposed in this paper aims at dealing with very large data sets with high dimensionality providing a time complexity improvement respect to current methods.We show how to build on well-established mathematical methods to reduce time and space complexity. The new method is named Quadratic Programming Feature Selection (QPFS) because it is based on efficient quadratic programming (Bertsekas, 1999). We introduce an objective function with quadratic and linear terms. The quadratic term captures the dependence (that is, similarity, correlation, or mutual information) between each pair of variables, whereas the linear term captures the relationship between each feature and the class label. For large data sets, solving a quadratic programming problem can have high time and space complexity. Therefore, we show how to reformulate the optimization problem in a lower dimensional subspace using the Nyström method for matrix diagonalization (Fowlkes et al., 2001). The Nyström approximation allows the variables to be sampled, without losing much information but with a great improvement in the speed of the algorithm. Ex-

perimental results show that the QPFS method achieves accuracy similar to that of other methods on medium-size data sets, while on the well-known large MNIST data set, QPFS is more efficient than its predecessors.

The present manuscript is organized as follows. Section 2 presents the QPFS algorithm, including the Nyström approximation, error estimation, theoretical complexity, and implementation issues. Section 3 provides a description of data sets, and experimental results in terms of classification accuracy and running time.

2. The QPFS Algorithm

Our goal is to develop a feature selection method capable of succeeding with very large data sets. To achieve this goal, our first contribution is a novel formulation of the task. The new formulation uses quadratic programming, a methodology that has previously been successful for a broad range of other quite different applications (Bertsekas, 1999). Assume the classifier learning problem involves N training samples and M variables (also called attributes or features). A quadratic programming problem is to minimize a multivariate quadratic function subject to linear constraints as follows:

$$\min_x \left\{ \frac{1}{2} x^T Q x - F^T x \right\} . \tag{1}$$

Above, x is an M-dimensional vector, $Q \in \mathbb{R}^{M \times M}$ is a symmetric positive semidefinite matrix, and F is a vector in $\mathbb{R}^M$ with non-negative entries. Applied to the feature selection task, Q represents the similarity among variables (redundancy), and F measures how correlated each feature is with the target class (relevance).

After the quadratic programming optimization problem has been solved, the components of x represent the weight of each feature. Features with higher weights are better variables to use for subsequent classifier training. Since x_i represents the weight of each variable, it is reasonable to enforce the following constraints:

$$\begin{aligned} x_i &\geqslant 0 \text{ for all } i = 1, \ldots, M \\ \sum_{i=1}^{M} x_i &= 1 . \end{aligned}$$

Depending on the learning problem, the quadratic and linear terms can have different relative purposes in the objective function. Therefore, we introduce a scalar parameter α as follows:

$$\min_x \left\{ \frac{1}{2}(1-\alpha) x^T Q x - \alpha F^T x \right\} \tag{2}$$

where x, Q and F are defined as before and $\alpha \in [0,1]$. If $\alpha = 1$, only relevance is considered; the quadratic programming problem becomes linear and equivalent to the MaxRel criterion. On the contrary, if $\alpha = 0$, then only independence between features is considered that is, features with higher weights are those which have lower similarity coefficients with the rest of features. Every data set has its best choice of α to extract the minimum number of features for classification purposes. Nevertheless, a reasonable choice of α must balance the linear and quadratic terms of Equation 2. Thus, we estimate the mean value $\bar{q}$ of the elements of the matrix Q and on the mean value $\bar{f}$ of the

elements of the vector F as

$$\bar{q} = \frac{1}{M^2}\sum_{i=1}^{M}\sum_{j=1}^{M} q_{ij} ,$$
$$\bar{f} = \frac{1}{M}\sum_{i=1}^{M} f_i .$$

Since the relevance and redundancy terms in Equation 2 are balanced when $(1-\hat{\alpha})\bar{q} = \hat{\alpha}\bar{f}$, a reasonable initial estimate of α is

$$\hat{\alpha} = \frac{\bar{q}}{\bar{q}+\bar{f}} .$$

The goal of balancing both terms in the QPFS objective function, Equation 2, is to ensure that both redundancy and relevance are taken into account. If features are only slightly redundant, that is, they have low correlation with each other, then the linear term in Equation 1 is dominant: $\bar{f} \gg \bar{q}$. Making α small reduces this dominance. On the other hand, if the features have a high level of redundancy relative to relevance ($\bar{q} \gg \bar{f}$), then the quadratic term in Equation 1 can dominate the linear one. In this case, overweighting the linear term (α close to 1) makes the objective function be balanced.

Experimental results in Section 3 show that using $\hat{\alpha}$ leads to good results. Alternatively, it is possible to use a validation subset to determine an appropriate value for α. However, that approach requires evaluating the accuracy of the underlying classifier for each point in a grid of α values. In this case, QPFS would become a wrapper feature selection method instead of a filter method because it would need the classifier accuracy to determine the proper value of α.

2.1 Similarity Measures

One advantage of the problem formulation above is that it is sufficiently general to permit any symmetric similarity measure to be used. In the remainder of this paper, the Pearson correlation coefficient and mutual information are chosen, because they are conventional and because they are representative ways to measure similarity.

The Pearson correlation coefficient is simple and has been shown to be effective in a wide variety of feature selection methods, including correlation based feature selection (CFS) (Hall, 2000) and principal component analysis (PCA) (Duda et al., 2000). Formally, the Pearson correlation coefficient is defined as

$$\rho_{ij} = \frac{cov(v_i, v_j)}{\sqrt{var(v_i)var(v_j)}}$$

where *cov* is the covariance of variables and *var* is the variance of each variable. The sample correlation is calculated as

$$\hat{\rho}_{ij} = \frac{\sum_{k=1}^{N}(v_{ki}-\bar{v}_i)(v_{kj}-\bar{v}_j)}{\sqrt{\sum_{k=1}^{N}(v_{ki}-\bar{v}_i)^2 \sum_{k=1}^{N}(v_{kj}-\bar{v}_j)^2}} \tag{3}$$

where N is the number of samples, v_{ki} is the k-th sample of random variable v_i, and $\bar{v}_i$ is the sample mean of the random variable v_i.

Each matrix element q_{ij} is defined to be the absolute value of the Pearson correlation coefficient of the pair of variables v_i and v_j, that is, $q_{ij} = |\hat{\rho}_{ij}|$. Suppose a classifier learning problem with C classes, the relevance weight of variable v_i, F_i, is computed using a modified correlation coefficient (Hall, 2000) which is an extension to the C-class classification scenario. The modified definition is

$$F_i = \sum_{k=1}^{C} \hat{p}(K=k)|\hat{\rho}_{iC_k}|$$

where K is the target class variable, C_k is a binary variable taking the value 1 when $K = k$ and 0 otherwise, $\hat{p}(K=k)$ is the empirical prior probability of class k, and $\hat{\rho}_{iC_k}$ is the correlation between feature v_i and binary variable C_k, computed according to Equation 3.

Because the correlation coefficient only measures the *linear* relationship between two random variables, it may not be suitable for some classification problems. Mutual information can capture nonlinear dependencies between variables. Formally, the mutual information between two random variables v_i and v_j is defined as

$$I(v_i;v_j) = \int\int p(v_i,v_j)\log\frac{p(v_i,v_j)}{p(v_i)p(v_j)}dv_i dv_j \ .$$

Computing mutual information is based on estimating the probability distributions $p(v_i)$, $p(v_j)$ and $p(v_i,v_j)$. These distributions can be either discretized or estimated by density function methods (Duda et al., 2000). When mutual information is used, the quadratic term is $q_{ij} = I(v_i,v_j)$ and the linear one is $F_i = I(v_i,c)$.

QPFS using mutual information as its similarity measure resembles mRMR, but there is an important difference. The mRMR method selects features greedily, as a function of features chosen in previous steps. In contrast, QPFS is not greedy and provides a ranking of features that takes into account simultaneously the mutual information between all pairs of features and the relevance of each feature to the class label.

2.2 Approximate Solution of the Quadratic Programming Problem

In high-dimensional domains, it is likely that the feature space is redundant. If so, the symmetric matrix Q is singular. We show now how Equation 2 can then be simplified and solved in a space of dimension less than M, thus reducing the computational cost.

Given the diagonalization $Q = U\Lambda U^T$ in decreasing order of eigenvalues, Equation 2 is equivalent to

$$\min_x \left\{ \frac{1}{2}(1-\alpha)x^T U\Lambda U^T x - \alpha F^T x \right\} . \tag{4}$$

If the rank of Q is $k \ll M$, then the diagonalization $Q = U\Lambda U^T$ can be written as $Q = \bar{U}\bar{\Lambda}\bar{U}^T$, where $\bar{\Lambda}$ is a diagonal square matrix consisting of the highest k eigenvalues of Q in decreasing order and $\bar{U}$ is a $M \times k$ matrix consisting of the first k eigenvectors of Q. Then, Equation 4 can be rewritten as

$$\min_x \left\{ \frac{1}{2}(1-\alpha)x^T \bar{U}\bar{\Lambda}\bar{U}^T x - \alpha F^T x \right\} .$$

Let $y = \bar{U}^T x$ be a vector in $\mathbb{R}^k$. The optimization problem is reduced to minimizing a derived quadratic function in a k-dimensional space:

$$\min_y \left\{ \frac{1}{2}(1-\alpha) y^T \bar{\Lambda} y - \alpha F^T \bar{U} y \right\}$$

under $M+1$ constraints:

$$\begin{aligned} \bar{U} y &\geq \overrightarrow{0} \\ \sum_{i=1}^{M} \sum_{j=1}^{k} \bar{u}_{ij} y_j &= 1. \end{aligned}$$

We can approximate the original vector x as $x \approx \bar{U} y$.

The matrix Q is seldom precisely singular for real world data sets. However, Q can normally be reasonably approximated by a low-rank matrix formed from its $\tilde{k}$ eigenvectors whose eigenvalues are greater than a fixed threshold $\delta > 0$ (Fine et al., 2001). More precisely, let $\tilde{Q} = U \Gamma U^T$ be the $\tilde{k}$-rank approximation of Q, where $\Gamma \in \mathbb{R}^{M \times M}$ is a diagonal matrix consisting of the $\tilde{k}$ highest eigenvalues of Q and the rest of diagonal entries are zero. Then, the approximate quadratic programming problem is formulated as

$$\min_x \left\{ \frac{1}{2}(1-\alpha) x^T U \Gamma U^T x - \alpha F^T x \right\} .$$

Equivalently,

$$\min_y \left\{ \frac{1}{2}(1-\alpha) y^T \widetilde{\Gamma} y - \alpha F^T \widetilde{U} y \right\} \tag{5}$$

where $y = \widetilde{U}^T x \in \mathbb{R}^{\tilde{k}}$, $\widetilde{\Gamma} \in \mathbb{R}^{\tilde{k} \times \tilde{k}}$ is a diagonal matrix with the nonzero eigenvalues of Γ and $\widetilde{U} \in \mathbb{R}^{M \times \tilde{k}}$ the first $\tilde{k}$ eigenvectors of U. The $M+1$ constraints of the optimization problem are defined as

$$\begin{aligned} \widetilde{U} y &\geq \overrightarrow{0} \\ \sum_{i=1}^{M} \sum_{j=1}^{\tilde{k}} \tilde{u}_{ij} y_j &= 1 . \end{aligned}$$

Given the solutions x^* of Equation 2 and $\tilde{x}^*$ of Equation 5, the error of the approximation can be estimated using the following theorem.

Theorem 1 *(Fine et al., 2001) Given $\tilde{Q}$ a $\tilde{k}$-rank approximation of Q, if $(Q - \tilde{Q})$ is positive semidefinite and $tr(Q - \tilde{Q}) \leq \varepsilon$ then the optimal value of the original problem is larger than the optimal objective value of the perturbed problem and their difference is bounded by*

$$\tilde{g}(\tilde{x}^*) \leq g(x^*) \leq \tilde{g}(\tilde{x}^*) + \frac{d^2 l \varepsilon}{2} \tag{6}$$

where l is the number of active constraints in the perturbed problem and d is an upper bound for the coefficients of the original solution.

In our case, $0 \leq x_i \leq 1$ and $d = 1$. The matrix $(Q - \tilde{Q})$ is positive semidefinite since $(Q - \tilde{Q}) = U(\Lambda - \Gamma)U^T$ and $(\Lambda - \Gamma)$ is a diagonal matrix with positive eigenvalues upper bounded by δ. Moreover $\varepsilon \leq (M - \tilde{k})\delta$ and $l \leq M + 1$, so

$$g(x^*) - \tilde{g}(\tilde{x}^*) \leq \frac{l(M-\tilde{k})\delta}{2} \leq \frac{(M+1)(M-\tilde{k})\delta}{2} = \gamma$$

where $g(x)$ and $\tilde{g}(x)$ are defined as

$$g(x) = \frac{1}{2}(1-\alpha)x^T Q x - \alpha F^T x \text{ for } x \in \mathbb{R}^M \tag{7}$$

$$\tilde{g}(x) = \frac{1}{2}(1-\alpha)x^T \tilde{\Gamma} x - \alpha F^T \tilde{U} x \text{ for } x \in \mathbb{R}^{\tilde{k}} . \tag{8}$$

Although the quadratic programming formulation of the feature selection problem is elegant and provides insight, the formulation by itself does not significantly reduce the computational complexity of feature selection. Thus we introduce the idea of applying a Nyström approximation to take advantage of the redundancy that typically makes the matrix Q almost singular. When this is true, the rank of Q is much smaller than M and the Nyström method can approximate eigenvalues and eigenvectors of Q by solving a smaller eigenproblem using only a subset of rows and columns of Q (Fowlkes et al., 2001). Suppose that $k < M$ is the rank of Q which is represented as

$$Q = \begin{pmatrix} A & B \\ B^T & E \end{pmatrix}$$

where $A \in \mathbb{R}^{k \times k}$, $B \in \mathbb{R}^{k \times (M-k)}$, $E \in \mathbb{R}^{(M-k)\times(M-k)}$, and the rows of $[A\ B]$ are independent. Then, the eigenvalues and eigenvectors of Q can be calculated exactly from the submatrix $[A\ B]$ and the diagonalization of A. Let $S = A + A^{-\frac{1}{2}} B B^T A^{-\frac{1}{2}}$ and its diagonalization $S = R\hat{\Sigma}R^T$ then, the highest k eigenvalues of Q are given by $\tilde{\Lambda} = \hat{\Sigma}$ and its associated eigenvectors $\tilde{U}$ are calculated as,

$$\tilde{U} = \begin{pmatrix} A \\ B^T \end{pmatrix} A^{-\frac{1}{2}} R \hat{\Sigma}^{-\frac{1}{2}} .$$

The application of the Nyström method entails some practical issues. First, a prior knowledge of the rank k of Q is, in general, unfeasible and it is necessary to estimate the number of subsamples r to be used in the Nyström approximation. Second, the r rows of $[A\ B]$ should be, ideally, linearly independent. If the rank of Q is greater than r or the rows of $[A\ B]$ are not linearly independent, an approximation of the diagonalization of Q is obtained whose error can be quantified, in general, as $\|E - B^T A^{-1} B\|$. Although the Nyström approximation is not error-free, if the redundancy of the feature space is large enough, then good approximations can be achieved, as shown in the following sections.

When QPFS+Nyström is used, the rule for setting the value of the α parameter is slightly different. In this case, only the the $[A\ B]$ submatrix of Q is known, and it is necessary to use the Nyström approximation $\hat{Q}$ of the original matrix Q,

$$\hat{Q} = (\hat{q_{ij}}) = \begin{pmatrix} A & B \\ B^T & B^T A^{-1} B \end{pmatrix} .$$

Therefore, the mean value of $\hat{Q}$ is computed as

$$\bar{\hat{q}} = \frac{1}{M^2} \sum_{i=1}^{M} \sum_{j=1}^{M} \hat{q_{ij}}.$$

The mean value $\bar{f}$ of the vector F is still calculated using Equation 3, since QPFS+Nyström needs to know all coordinates of F. To sum up, the value of α for the QPFS+Nyström method is

$$\hat{\alpha} = \frac{\bar{\hat{q}}}{\bar{\hat{q}} + \bar{f}}. \tag{9}$$

The algorithm QPFS+Nyström has two levels of approximation.

1. The first level is to approximate the eigenvalues and eigenvectors of the original matrix Q based on only a subset of rows, applying the Nyström method: $\hat{Q} = \hat{U}\hat{\Lambda}\hat{U}^T$. One of the critical issues with the Nyström method is how to choose the subset of rows to use (Fowlkes et al., 2001). Ideally, the number of linearly independent rows of $[A\,B]$ should be the rank of Q. We use uniform sampling without replacement. This technique has been used successfully in other applications (Fowlkes et al., 2001; Williams and Seeger, 2001). Moreover, theoretical performance bounds for the Nyström method with uniform sampling without replacement are known (Kumar et al., 2009). In particular, we use the following theorem.

   Theorem 2 *(Kumar et al., 2009) Let $Q \in \mathbb{R}^{M\times M}$ be a symmetric positive semidefinite Gram (or kernel) matrix. Assume that r columns of Q are sampled uniformly at random without replacement ($r > k$), let $\hat{Q}$ be the rank-k Nyström approximation to Q, and let $\tilde{Q}$ the best rank-k approximation to Q. For $\varepsilon > 0$, if $r \geq \frac{64k}{\varepsilon^4}$, then*

$$E\left[\|Q - \hat{Q}\|_F\right] \leq \|Q - \tilde{Q}\|_F + \varepsilon \left[\left(\frac{M}{r} \sum_{i \in D(r)} Q_{ii}\right) \sqrt{M \sum_{i=1}^{M} Q_{ii}^2}\right]^{\frac{1}{2}} \tag{10}$$

   where $\sum_{i\in D(r)} Q_{ii}$ is the sum of the largest r diagonal entries of Q and $\|\cdot\|_F$ represents the Frobenius norm.

   As $\left(Q - \tilde{Q}\right)$ is a real symmetric positive semidefinite matrix, it is easy to prove that $\|Q - \tilde{Q}\|_F \leq \text{trace}\left(Q - \tilde{Q}\right)$.
   Equation 10 shows that the error in the Nyström approximation decreases with the number of sampled rows, r.

2. The second level of approximation is to solve the quadratic programming problem using the Nyström approximation. As stated in Section 2.2, only eigenvalues higher than a fixed threshold $\delta > 0$ are considered in the rank of matrix $\hat{Q}$. Then, these top $\tilde{k}$ eigenvalues of matrix $\hat{Q}$ are taken to make up a diagonal matrix $\hat{\tilde{\Lambda}} \in \mathbb{R}^{\tilde{k}\times\tilde{k}}$ and let $\hat{\tilde{U}} \in \mathbb{R}^{M\times\tilde{k}}$ the matrix consisting of the eigenvectors associated to $\hat{\tilde{\Lambda}}$. Therefore, the QPFS+Nyström method approximates Q by $\hat{\tilde{Q}} = \hat{\tilde{U}}\hat{\tilde{\Lambda}}\hat{\tilde{U}}^T$ and the quadratic programming problem is defined as,

$$\hat{\tilde{g}}(x) \quad = \quad \frac{1}{2}(1-\alpha)x^T\hat{\tilde{\Lambda}}x - \alpha F^T\hat{\tilde{U}}x \text{ for } x \in \mathbb{R}^{\tilde{k}}$$

and let $\hat{\hat{x}}^*$ be its optimal solution, and $g(x)$ and $\tilde{g}(x)$ be as described in Equations 7 and 8, respectively. The best rank-$\tilde{k}$ approximation to Q is $\tilde{Q} = U\Gamma U^T$ as given in Section 2.2. A bound on the total error in the QPFS+Nyström approximation is obtained following the reasoning in Fine et al. (2001):

$$\begin{aligned} E\left[g(x^*) - \hat{\hat{g}}(\hat{\hat{x}}^*)\right] &\leq E\left[g(\hat{\hat{x}}^*) - \hat{\hat{g}}(\hat{\hat{x}}^*)\right] \\ &\leq \frac{1}{2}(1-\alpha)E\left[(\hat{\hat{x}}^*)^T\left(Q - \hat{\hat{Q}}\right)(\hat{\hat{x}}^*)\right] \\ &\leq \frac{1}{2}E\left[\|Q - \hat{\hat{Q}}\|_2 \|\hat{\hat{x}}^*\|_2^2\right] \\ &\leq \frac{1}{2}(M+1)\,E\left[\|Q - \hat{\hat{Q}}\|_F\right]. \end{aligned}$$

Applying the bound for the Nyström method with uniform sampling without replacement (Equation 10) and the inequality $\|Q - \tilde{Q}\|_F \leq \text{trace}\left(Q - \tilde{Q}\right) \leq (M - \tilde{k})\delta$ yields

$$\begin{aligned} E\left[g(x^*) - \hat{\hat{g}}(\hat{\hat{x}}^*)\right] &\leq \frac{1}{2}(M+1)\left((M-\tilde{k})\delta + \varepsilon\left[\left(\frac{M}{r}\sum_{i\in D(r)} Q_{ii}\right)\sqrt{M\sum_{i=1}^{M} Q_{ii}^2}\right]^{\frac{1}{2}}\right) \\ &\leq \gamma + \frac{\varepsilon}{2}(M+1)\left[\left(\frac{M}{r}\sum_{i\in D(r)} Q_{ii}\right)\sqrt{M\sum_{i=1}^{M} Q_{ii}^2}\right]^{\frac{1}{2}}. \end{aligned}$$

The total error is the sum of the error γ obtained from the approximation of the quadratic programming problem in a subspace (Equation 6) and the error due to the Nyström method.

2.3 Summary of the QPFS+Nyström Method

Figure 1 shows a diagram of the proposed feature selection method, which can be summarized as follows:

1. Compute the F vector representing the dependence of each variable with the class.
2. Choose r rows of Q according to some criterion (typically, uniform sampling without replacement). Arrange the Q matrix so that these r rows are the first ones. Define the $[A\,B]$ matrix to be the first r rows of Q.
3. Set the value of the α parameter according to Equation 9.
4. Apply the Nyström method knowing $[A\,B]$. Obtain an approximation of the eigenvalues and eigenvectors of Q, $\hat{Q} = \hat{U}\hat{\Lambda}\hat{U}^T$.
5. Formulate the quadratic programming (QP) problem in the lower dimensional space $\hat{\hat{Q}} = \hat{\hat{U}}\hat{\hat{\Lambda}}\hat{\hat{U}}^T$.
6. Solve the QP in the subspace to obtain the solution vector y.
7. Return to the original space via $x = \hat{\hat{U}}y$.
8. Rank the variables according to the coefficients of vector x. In case of equal coefficients, rank them by decreasing relevance F_k to the class.

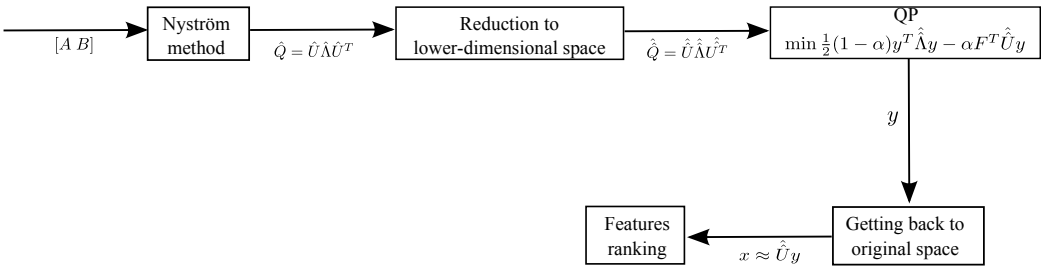

Figure 1: Diagram of the QPFS algorithm using the Nyström method. $[A\ B]$ is the upper $r \times M$ submatrix of Q.

2.4 Complexity Analysis

As already mentioned, the mRMR method is one of the most successful previous methods for feature selection. The main advantage of the QPFS+Nyström method versus mRMR is the time complexity reduction. The time complexities of mRMR and QPFS both have two components, the time needed to compute the matrices Q and F *(Similarity)*, and the time needed to perform variable ranking *(Rank)*. The computational cost of evaluating correlations or mutual information for all variable pairs is $O(NM^2)$ for both mRMR and QPFS. Table 1 shows the time complexities of the three algorithms mRMR, QPFS and QPFS+Nyström.

	mRMR		**QPFS**		**QPFS+Nyström**	
	Similarity	Rank	Similarity	Rank	Similarity	Rank
M large $N \ll pM$	$\mathbf{O(NM^2)}$	$O(M^2)$	$O(NM^2)$	$\mathbf{O(M^3)}$	$O(NpM^2)$	$\mathbf{O(p^2M^3)}$
M medium $N \gg pM$	$\mathbf{O(NM^2)}$	$O(M^2)$	$O(NM^2)$	$\mathbf{O(M^3)}$	$\mathbf{O(NpM^2)}$	$O(p^2M^3)$
M small $N \gg M$	$\mathbf{O(NM^2)}$	$O(M^2)$	$\mathbf{O(NM^2)}$	$O(M^3)$	$\mathbf{O(NpM^2)}$	$O(p^2M^3)$

Table 1: Time complexity of algorithms as a function of training set size N, number of variables M, and Nyström sampling rate p. The predominant cost term is indicated in boldface.

The order-of-magnitude time complexity of QPFS is greater than or similar to that of mRMR. However, the QPFS+Nyström time complexity is lower for $N \gg pM$ and $N \gg M$. When $N \ll pM$, QPFS+Nyström is faster than mRMR if $p^2M^3 \ll NM^2$, that is, when $N \gg p^2M$. For example, if $p = 10^{-2}$ then QPFS+Nyström is more efficient than mRMR if $N \gg 10^{-4}M$, that is, if the size of the training set is greater than 10^{-4} times the number of variables.

2.5 Implementation

We implemented QPFS and mRMR in C using *LAPACK* for matrix operations (Anderson et al., 1990). Quadratic optimization is performed by the Goldfarb and Idnani algorithm implemented in Fortran and used in the R *quadprog* package (Goldfarb and Idnani, 1983; Turlach and Weingessel, 2000).

As mentioned in Section 2.1, in general mutual information computation requires estimating density functions for continuous variables. For simplicity, each variable is discretized in three segments $(-\infty, \mu-\sigma]$, $(\mu-\sigma, \mu+\sigma]$, and $(\mu+\sigma, +\infty)$, where μ is the sample mean of training data and σ its standard deviation. The linear SVM provided by the *LIBSVM* package (Chang and Lin, 2001) was the underlying classifier in all experiments. A linear kernel is used to reduce the number of SVM parameters, thus making meaningful results easier to obtain. Note that mRMR and QPFS can be used with any classifier learning algorithms. We expect results obtained with linear SVMs to be representative.

3. Experiments

The aim of the experiments described here is twofold: first, to compare classification accuracy achieved using mRMR versus QPFS; and second, to compare their computational cost.

3.1 Experimental Design

The data sets used for experiments are shown in Table 2. These data sets were chosen because they are representative of multiple types of classification problems. with respect to the number of samples, the number of features, and the achievable classification accuracy. Moreover, these data sets have been used in other research on the feature selection task (Hua et al., 2009; Lauer et al., 2007; Lecun et al., 1998; Li et al., 2004; Peng et al., 2005; Zhang et al., 2008; Zhu et al., 2008).

In order to estimate classification accuracy, for the ARR, NCI60, SRBCT and GCM data sets 10-fold cross-validation (10CV) and 100 runs were used (Duda et al., 2000). Mean error rates are comparable to the results reported in Li et al. (2004), Peng et al. (2005), Zhang et al. (2008) and Zhu et al. (2008). In the case of the RAT data set, 120 training samples (61 for test) and 300 runs were used, following Hua et al. (2009). The MNIST data set is divided into training and testing subsets as proposed by Chang and Lin (2001), with 60000 and 10000 patterns respectively. Therefore, cross-validation is not done with MNIST.

Time complexity is measured as a function of training set size (N), dimensionality (M), and the Nyström sampling rate ($p = \frac{r}{M}$). In all cases, times are averages over 50 runs. In order to measure time complexity as a function of training set size, the number of SRBCT examples was artificially increased 4 times ($N = 332$) and dimensionality reduced to $M = 140$. Time complexity as a function of dimensionality was measured using the original SRBCT data set, that is, with $N = 83$ and $M = 2308$.

As mentioned above, MaxRel, mRMR and QPFS are all filter methods that can be used with any classifier. Figure 2 shows that the choice of the SVM regularization parameter c does not influence the comparison between mRMR and QPFS. This figure displays the performance of mRMR and QPFS for the ARR data set and different c values. Our goal is not to determine the optimal c value for each data set, but to compare mRMR and QPFS. Therefore, c is set to 1.0 in all experiments.

Data Set	N	M	C	Baseline Error Rate	References
ARR	422	278	2	21.81%	(Peng et al., 2005; Zhang et al., 2008)
NCI60	60	1123	9	38.67%	(Li et al., 2004; Zhang et al., 2008) (Zhu et al., 2008)
SRBCT	83	2308	4	0.22%	(Li et al., 2004; Zhu et al., 2008)
GCM	198	16063	14	33.85%	(Li et al., 2004; Zhang et al., 2008) (Zhu et al., 2008)
RAT	181	8460	2	8.61%	(Hua et al., 2009)
MNIST	60000	780	10	6.02%	(Lauer et al., 2007; Lecun et al., 1998)

Table 2: Description of the data sets used in experiments. N is the number of examples, M is the number of variables, and C is the number of classes. Baseline error rate is the rate obtained taking into account all variables. The last column cites papers where the data sets have been mentioned.

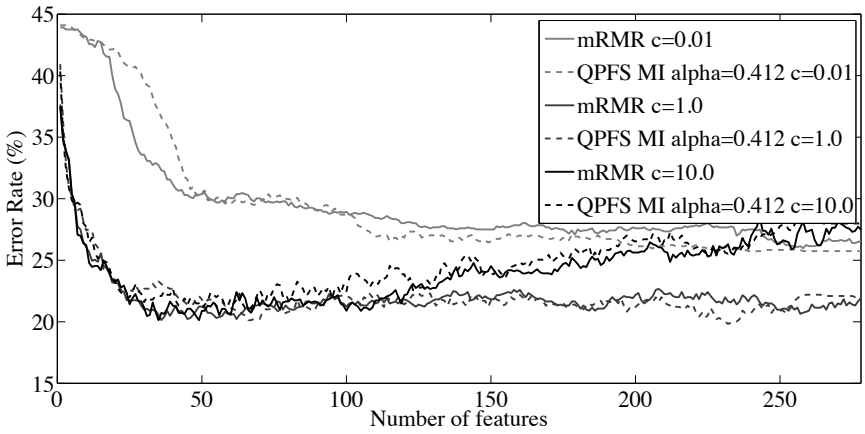

Figure 2: Classification error as a function of the number of features for the ARR data set and different regularization parameter values c in linear SVM. The figure shows that for $c = 0.01$, the SVM is too regularized. The effect when $c = 10.0$ is the opposite and the SVM overfits the training data. A value of $c = 1.0$ is a good tradeoff.

The value of the α parameter chosen for each data set is shown in Table 3. This value is obtained according to Equations 3 and 9. Our hypothesis is that high values of α are better for data sets with high redundancy among variables. On the other hand, if there is low redundancy then small α should yield better results. The Nyström sampling rate p is chosen as large as possible while still yielding a reasonable running time, since larger values reduce error in the approximation of the Q matrix. Other values of the α parameter, $\alpha \in \{0.0, 0.1, 0.3, 0.5, 0.7, 0.9\}$, were considered in all experiments in order to verify that the proposed method of setting α provides good results.

Data Set	p	$\bar{q}$	$\bar{f}$	$\hat{\alpha}$
ARR (cor)	-	0.0889	0.0958	0.481
NCI60 (cor)	-	0.267	0.165	0.618
ARR (MI)	-	0.0106	0.0152	0.411
NCI60 (MI)	-	0.0703	0.253	0.217
SRBCT (MI)	-	0.0188	0.0861	0.179
GCM (MI)	0.05	0.0284	0.158	0.152
RAT (MI)	0.1	0.0346	0.0187	0.649
MNIST (MI)	-	0.0454	0.0515	0.469

Table 3: Values of the α parameter for each data set. Correlation (cor) and mutual information (MI) were used as similarity measures for ARR and NCI60 data sets. Only mutual information was used for SRBCT, GCM, RAT and MNIST data sets. p is the subsampling rate in the Nyström method, $\bar{q}$ is the mean value of the elements of the matrix Q (similarity among each pair of features), and $\bar{f}$ is the mean value of the elements of the F vector (similarity of each feature with the target class). For the MNIST data set only nonzero values have been considered for the statistics due to the high level of sparsity of its features (80.78% sparsity in average).

3.2 Classification Accuracy Results

The aim of the experiments described in this section is to compare classification accuracy achieved with mRMR and with QPFS, with and without Nyström approximation. The MaxRel algorithm (Peng et al., 2005) is also included in the comparison. Two similarity measures, mutual information (MI) and correlation are considered. Classification error is measured as a function of the number of features. We also give results from a baseline method that does random selection of features, in order to determine the absolute advantage of using any feature selection method.

Figure 3 shows the average classification error rate for the ARR data set as a function of the number of features. In Figure 3a, correlation is the similarity measure while mutual information (MI) is applied for Figure 3b. In both cases, the best accuracy is obtained with $\alpha = 0.5$, which means that an equal tradeoff between relevance and redundancy is best. However, accuracies using the values of α specified by our heuristic are similar.

Better accuracy is obtained when MI is used, in which case (Figure 3b) the error rate curve for $\alpha = 0.5$ is similar to that obtained with mRMR. The random selection method yields results significantly worse than those obtained with other algorithms. Comparison with this method shows that the other methods provide a significant benefit up to about 150 features.

For the NCI60 data set (Figure 4), the best accuracy is obtained when mutual information is used (Figure 4b) and α is set to 0.217 according to Table 3. In this case, the accuracy of QPFS is slightly better than the accuracy of mRMR. The value of α close to zero indicates that it is appropriate to give more weight to the quadratic term in QPFS. When correlation is used (Figure 4a), the best accuracy is obtained when α is set according to Equation 3.

Generally, MI as similarity measure leads to better accuracy than correlation. This finding is reasonable given that MI can capture nonlinear relationships between variables. MI is used in the experiments described in the remainder of this section.

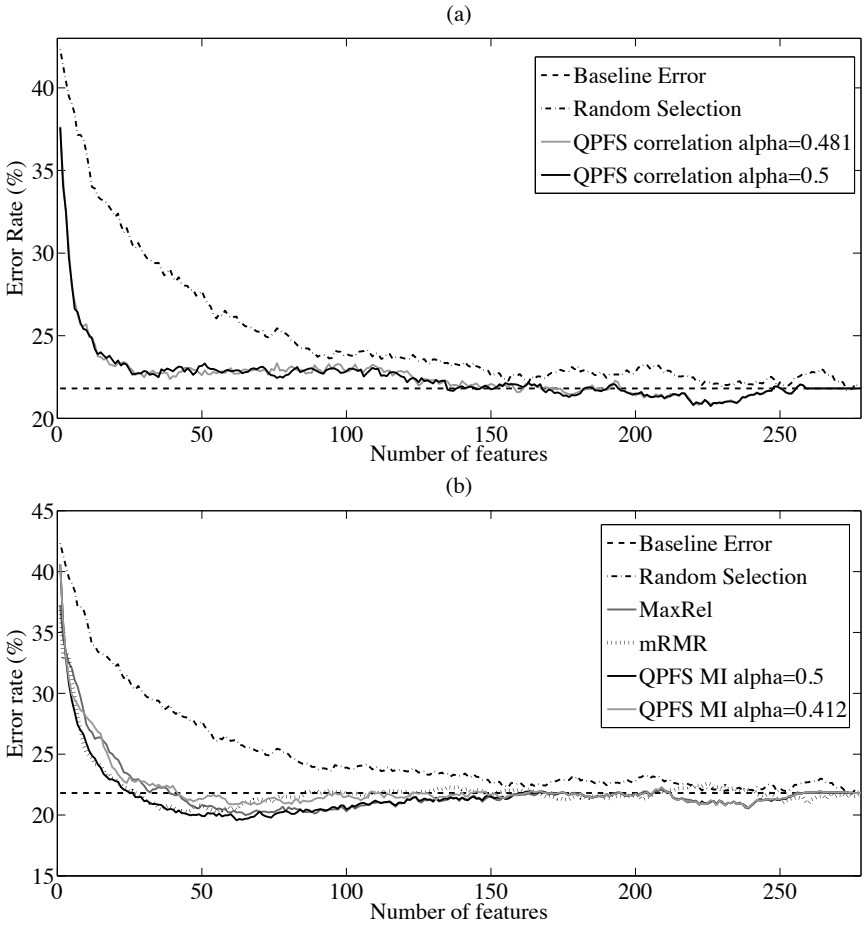

Figure 3: Classification error as a function of the number of features for the ARR data set. **(a)** QPFS results using correlation as similarity measure with different α values. **(b)** MaxRel, mRMR and QPFS results using mutual information as similarity measure and different values of α for QPFS.

Average error rate for the SRBCT data set and different sampling rates as a function of the number of features is shown in Figure 5. Results for the best α value in the grid $\{0, 0.1, 0.3, 0.5, 0.7, 0.9\}$, $\alpha = 0.1$, and the estimated $\hat{\alpha} = 0.179$ are shown in Figure 5a. Accuracies for both α values are similar. The fact that a low value of α is best indicates low redundancy among variables compared to their relevance with the target class. QPFS classification accuracy is similar to that of mRMR. As shown in Figure 5b, when the QPFS+Nyström method is used, the higher the parameter p, the closer the Nyström approximation is to complete diagonalization. QPFS+Nyström gives classification accuracy similar to that of QPFS when $p > 0.1$.

Figure 6 shows error rates for the GCM data set using the algorithms MaxRel, mRMR, and QPFS+Nyström with $\alpha = 0.1$ and $\hat{\alpha} = 0.152$. When the number of features is over 60, accuracy achieved with QPFS+Nyström is better than with mRMR. A sampling rate of 3% is adequate for

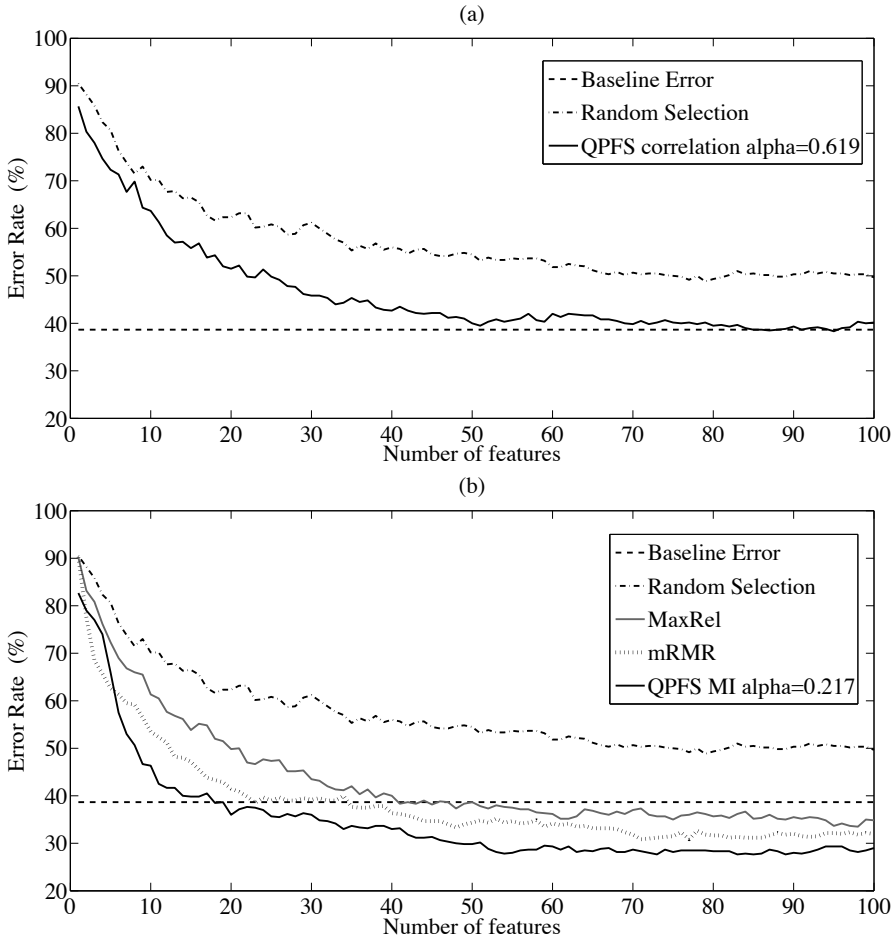

Figure 4: Classification error as a function of number of features for the NCI60 data set. **(a)** QPFS results using correlation as similarity measure with different α values. **(b)** MaxRel, mRMR and QPFS results using mutual information as similarity measure and different values of α for QPFS.

this data set, which represents a major time complexity reduction given a feature space of 16063 variables.

Another data set with many features is the RAT data set, for which Figure 7 shows results. In this case, QPFS+Nyström gives classification accuracy similar to that of mRMR when the subset size is over 80 and the sampling rate is 10%. Given the good performance of the MaxRel algorithm for this data set, it is not surprising that a large α value $\alpha = 0.9$ or $\hat{\alpha} = 0.649$ is best, considering also that QPFS with $\alpha = 1.0$ is equivalent to MaxRel.

The MNIST data set has a high number of training examples. Results for it are shown in Figure 8 for the QPFS with $\alpha = 0.3$, the estimation $\hat{\alpha} = 0.469$ and the QPFS+Nyström with $\hat{\alpha}$ and $p \in \{0.1, 0.2, 0.5\}$. Our C code of mRMR is used instead of the code on the mRMR web site (Peng et al., 2005) which takes a long time to read the training file. The error rate for all algorithms

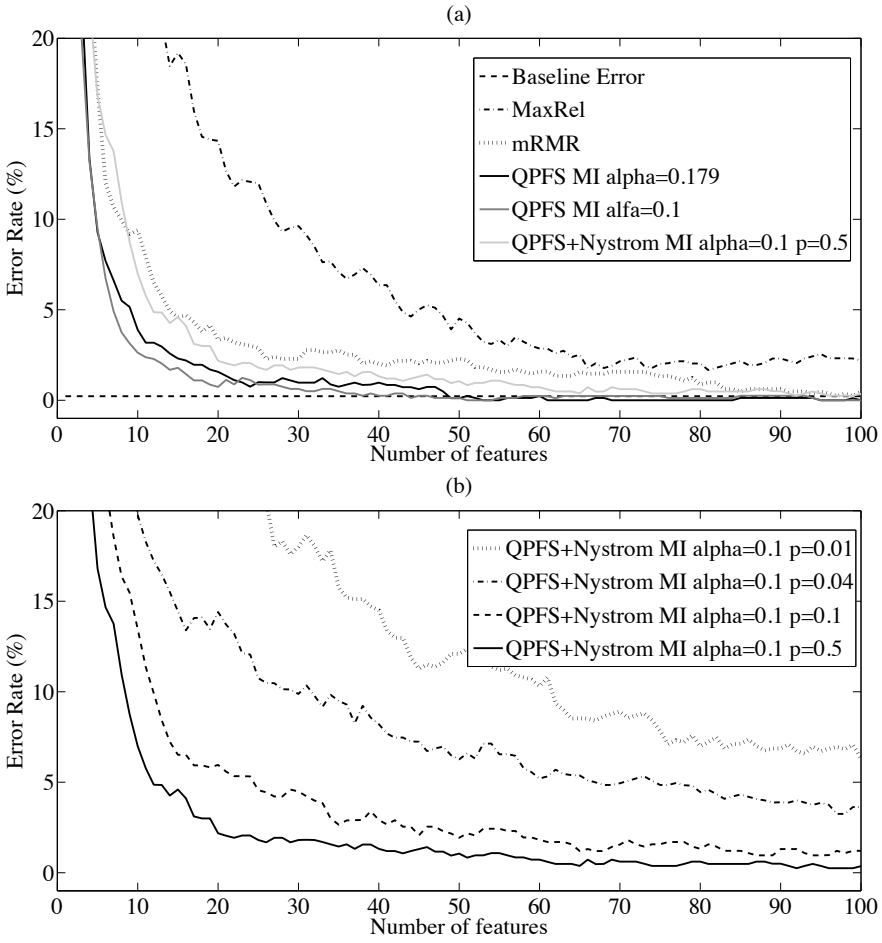

Figure 5: Error rates using MaxRel, mRMR and QPFS+Nyström methods, with mutual information as similarity measure for the SRBCT data set.

reaches a minimum when about 350 features are selected. This is not a surprising fact: analyzing the sparsity of the MNIST features, approximately 400 of them have a level of sparsity higher than 70%. But if the feature space needs a greater reduction, significant differences appears between the studied methods as shown in Figure 8. mRMR and QPFS with $\hat{\alpha} = 0.469$ have similiar performance and close to the best results obtained by QPFS with $\alpha = 0.3$. For this data set, the number of samples is much greater than the number of features, $N \gg M$, and therefore , the time complexity of mRMR and QPFS is the same ($O(NM^2)$). When QPFS+Nyström is applied with $p = 0.2$, the error rate is competitive and the MNIST provides an example of the ability of QPFS+Nyström to handle large data sets reducing the computational cost of mRMR and QPFS by a factor of 5. Note that the error rates shown for the MNIST data set are obtained using a linear kernel. The radial basis function kernel for SVM classifiers is known to lead to lower error rates for the full MNIST data set, but the choice of kernel is an issue separate from feature selection, which is the focus of this paper.

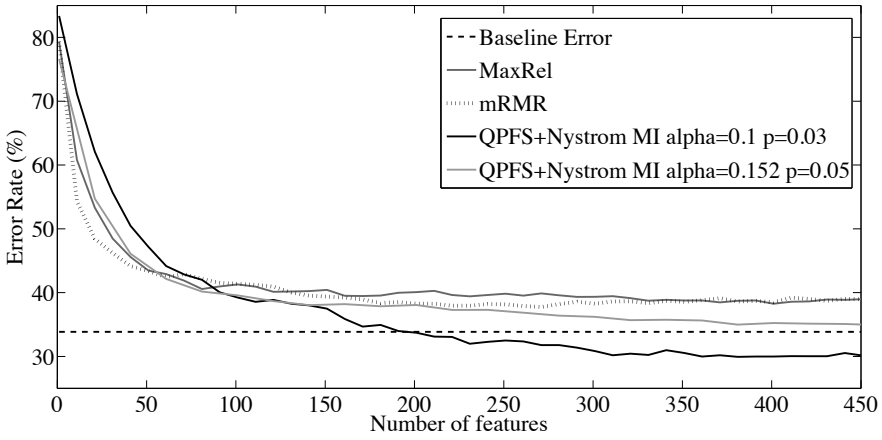

Figure 6: Error rates using MaxRel, mRMR and QPFS+Nyström methods, with mutual information as similarity measure for the GCM data set.

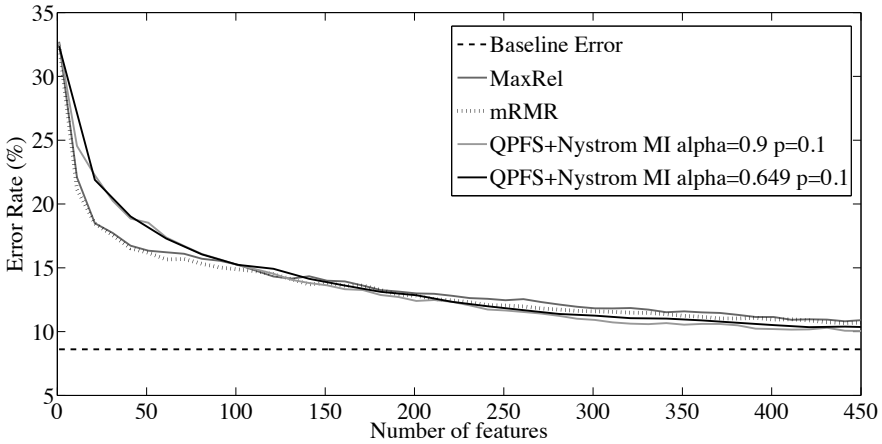

Figure 7: Error rates using MaxRel, mRMR and QPFS+Nyström methods, with mutual information as similarity measure for the RAT data set.

Figure 9 shows a grid of 780 pixels arrayed in the same way as the images in the MNIST data sets. A pixel is black if it corresponds to one of the top 100 (Figure 9a) and 350 (Figure 9b) selected features, and white otherwise. Black pixels are more dense towards the middle of the grid, because that is where the most informative features are. Pixels sometimes appear in a black/white/black checkerboard pattern, because neighboring pixels tend to make each other redundant.

Table 4 evaluates the statistical significance of error rate differences. For each data set, 100 classifiers were trained using the stated number M of selected features. The 100 classifiers arise

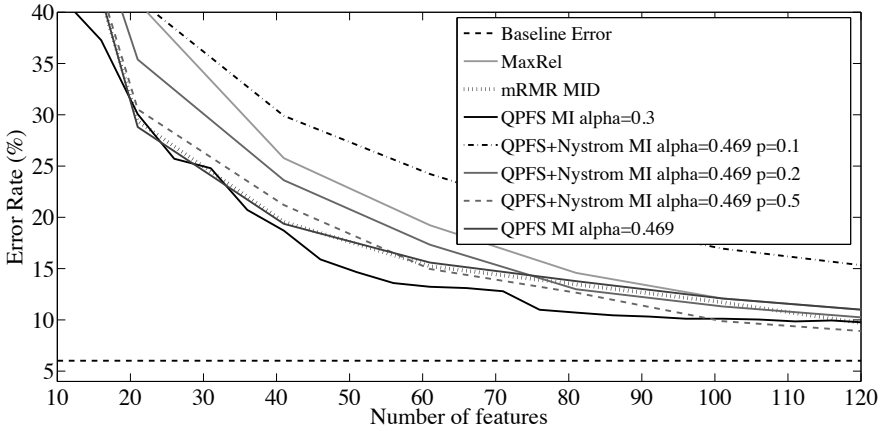

Figure 8: Error rates using MaxRel, mRMR and QPFS+Nyström methods, with mutual information as similarity measure for the MNIST data set.

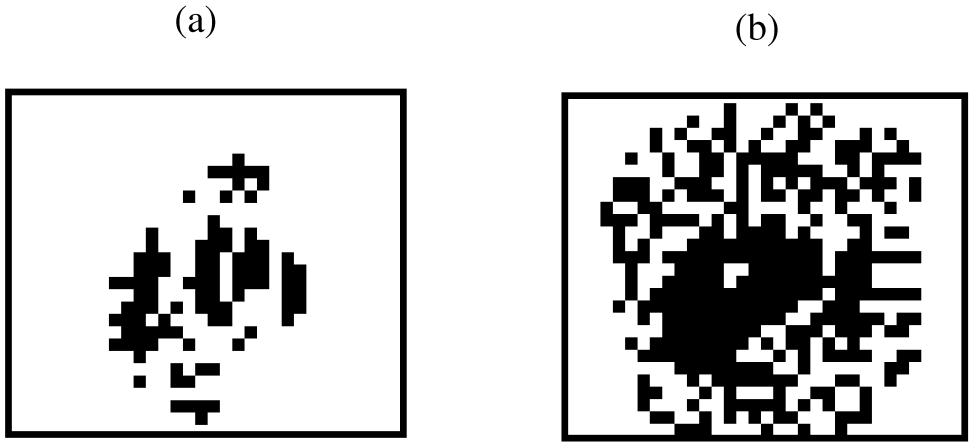

Figure 9: First **(a)** 100 and **(b)** 350 features selected by QPFS+Nyström ($\hat{\alpha} = 0.469$ and $p = 0.5$) for the MNIST data set (black pixels).

from 10 repetitions of 10-fold cross-validation, so which M features are used may be different for each classifier. The one-tailed paired t-test for equal means is applied to the two sets of error rates, one set for mRMR and one set for QPFS. The test is one-tailed because the null hypothesis is that the mRMR method is as good or better than the QPFS method. The test is paired because both methods were applied to the same 100 data set versions. Results of the test are given in the row labeled *significant?*.

For the NCI60 and SRBCT data sets, the best result is obtained when QPFS is used and it is statistically significantly better than mRMR. When 200 to 400 variables are considered, mRMR and QPFS are not statistically significantly different but the accuracy is not as good as in the case of 100 features, probably due to overfitting. In the case of the GCM data set, the mRMR method is statistically significantly better when fewer than 50 variables are considered. If the number of features is over 100, the accuracy with QPFS is significantly better than with mRMR, and the best performance is obtained in this case. For the ARR data set, mRMR is statistically significantly better than QPFS if fewer than 10 features are considered but the error rate obtained can be improved if more features are taken into account. When more than 50 featues are selected, the two methods are not statistically significantly different. The RAT data set behavior is quite similar. When fewer than 100 features are used, the mRMR algorithm is satatistically better than QPFS, but the error rate can be reduced adding more features. The two algorithms are not statistically significantly different in the other cases, except if more than 400 features are involved in which case QPFS is statistically significantly better than mRMR. Note that the error rates shown for QPFS are obtained with the proposed estimation of $\hat{\alpha}$. In some cases, as shown in Figures 3 to 7, this α value is not the best choice.

Beyond simple binary statistical significance, Table 4 indicates that the QPFS method is statistically significantly better when the value of $\hat{\alpha}$ is small. A possible explanation for this finding is the following. When $\hat{\alpha}$ is small, features are highly correlated with the label ($\bar{f} \gg \bar{q}$). The mRMR method is greedy, and only takes into account redundancy among features selected in previous iterations. When features are highly correlated with the label, then mRMR selects features with high relevance and mostly ignores redundancy. In contrast, QPFS evaluates all variables simultaneously, and always balances relevance and redundancy.

3.2.1 COMPARISON WITH OTHER FEATURE SELECTION METHODS

The experiments of this work are focused in comparing QPFS with the greedy filter-type method mRMR (difference form, named MID) which also takes into account the difference between redundancy and relevance. Nevertheless, other feature selection methods independent of the classifier have been considered in the described experiments:

- **mRMR (quotient form, named MIQ)** (Ding and Peng, 2005). While in mRMR (MID form) the difference between the estimation of redundancy and relevance is considered, in the case of mRMR (MIQ form) the quotient of both approximations is calculated.

- **reliefF** (Robnik-Šikonja and Kononenko, 2003). The main idea of ReliefF is to evaluate the quality of a feature according to how well it distinguishes between instances that are near to each other. This algorithm is efficient in problems with strong dependencies between attributes.

- **Streamwise Feature Selection (SFS)** (Zhou et al., 2006). SFS selects a feature if the *benefit* of adding it to the model is greater than the increase in the model complexity. The algorithm scales well to large feature sets and considers features sequentially for addition to a model making unnecessary to know all the features in advance.

Average error rates for MaxRel, mRMR (MID), mRMR (MIQ), reliefF and QPFS using linear SVM ($c = 1.0$) and different number of features are shown in Table 5. Table 6 shows the error rate

and the average number of features selected by Streamwise Feature Selection. SFS was applied to the binary data sets ARR and RAT and was used only as a feature selection method (a feature generation step was not included).

Table 5 shows that for ARR, NCI60, SRBCT and GCM data sets, the best selector is mRMR or QPFS. A statistical study of the performance of both methods is given in Table 4. In the case of the RAT data set, the best methods are MaxRel and reliefF. The fact that the best results are obtained with methods which only consider relevance with the target class fits in with the analysis of Figure 7. Finally, for the MNIST data set the best choice is the mRMR (MIQ) algorithm. Nevertheless, the

performance of MIQ in some data sets is not competitive (see, for instance, the ARR and NCI60 results). The accuracy of QPFS+Nyström ($p = 0.2$) is good if a high enough number of features is used, and it has lower computational cost than mRMR and QPFS.

Regarding SFS, Table 6 shows that SFS provides a competitive error rate for the ARR data set with few features (around 11) but its effectiveness in the RAT data set is improved by other feature selection algorithms when more than 6 attributes are considered. It is noticeable the efficiency of SFS getting acceptable accuracies using a small number of features.

ReliefF and SFS are feature selection methods which need to establish the value of some parameters like in QPFS. In ReliefF all instances were used (not random subsampling) and the number of neighbors was set to 3 for all data sets, except for MNIST where 10 neighbors were considered. In the case of the SFS algorithm, the default values (wealth $= 0.5$ and $\triangle\ \alpha = 0.5$) were used.

3.3 Time Complexity Results

Since the previous subsection has established the effectiveness of the QPFS method, it is useful now to compare mRMR and QPFS experimentally with respect to time complexity. As stated in Table 1 in Section 2.4, the running times of mRMR and QPFS with and without Nyström all depend linearly on N when M and p are fixed. In order to confirm experimentally this theoretical dependence, time consumption as a function of the number of training examples is measured on the SRBCT data set.

Figure 10a shows the time consumed for the modified SRBCT data set, averaged over 50 runs, as a function of the number of samples, N, for the mRMR, QPFS and QPFS+Nyström methods.

As expected, both mRMR and QPFS show a linear dependence on the number of patterns. For QPFS+Nyström, Table 1 shows that the slope of this linear dependence is proportional to the sampling rate p. Over the range $p = 0.01$ to $p = 0.5$, a decrease in p leads to a decrease in the slope of the linear dependence on N. Therefore, although all algorithms are linearly dependent on N, the QPFS+Nyström is computationally the most efficient. The time cost advantage increases with increasing number of training examples because the slope is greater for mRMR than for QPFS.

The next question is the impact on performance of the number of features, M. Table 1 shows that mRMR and QPFS have quadratic and cubic dependence on M, respectively. However, the QPFS+Nyström cubic coefficient is proportional to the square of the sampling rate. When small value of p are sufficient, which is the typical case, the cubic terms are not dominant.

These results are illustrated in the experiments shown in Figure 10b. This figure shows the average time cost for the SRBCT data set as a function of the problem dimension, M, for the mRMR, QPFS, and QPFS+Nyström methods. As expected from Table 1, mRMR and QPFS empirically show quadratic and cubic dependence on problem dimension. QPFS+Nyström shows only quadratic dependence on problem dimension, with a decreasing coefficient for decreasing p values. In all cases, a t-test has been used to verify the order of the polynomial that best fits each curve by least-squares fitting (Neter and Wasserman, 1974). Overall, for small Nyström sampling rates, QPFS+Nyström is computationally the most efficient.

Last but not least important, Table 1 shows there should be a quadratic dependence on sampling rate for the QPFS+Nyström algorithm. Figure 10c shows the empirical average time cost for the SRBCT data set as a function of the sampling rate p. As expected, there is quadratic dependence on p and cubic dependence on the problem dimension M.

Data Set	Method	M

4. Conclusions

This paper has presented and studied a new feature selection method for multiclass classifier learning problems. The new method, named Quadratic Programming Feature Selection (QPFS), is based

Data Set	Number of Selected Features (average)	Error rate (%)
ARR	10.75 ± 0.155	23.34 ± 0.63
RAT	6.12 ± 0.13	22.87 ± 0.33

Table 6: Streamwise Feature Selection error rates.

on the optimization of a quadratic function that is reformulated in a lower-dimensional space using the Nyström approximation (QPFS+Nyström). The QPFS+Nyström method, using either Pearson correlation coefficient or mutual information as the underlying similarity measure, is computationally more efficient than the leading previous methods, mRMR and MaxRel.

With respect to classification accuracy, the QPFS method is similar to MaxRel and mRMR when mutual information is used, and yields slightly better results if there is high redundancy. In all experiments, mutual information yields better classification accuracy than correlation, presumably because mutual information better captures nonlinear dependencies. Small sampling rates in the Nyström method still lead to reasonable approximations of exact matrix diagonalization, sharply reducing the time complexity of QPFS. In summary, the new QPFS+Nyström method for selecting a subset of features is a competitive and efficient filter-type feature selection algorithm for high-dimensional classifier learning problems.

Abstract

A Hilbert space embedding for probability measures has recently been proposed, with applications including dimensionality reduction, homogeneity testing, and independence testing. This embedding represents any probability measure as a mean element in a reproducing kernel Hilbert space (RKHS). A pseudometric on the space of probability measures can be defined as the distance between distribution embeddings: we denote this as γ_k, indexed by the kernel function k that defines the inner product in the RKHS.

We present three theoretical properties of γ_k. First, we consider the question of determining the conditions on the kernel k for which γ_k is a metric: such k are denoted *characteristic kernels*. Unlike pseudometrics, a metric is zero only when two distributions coincide, thus ensuring the RKHS embedding maps all distributions uniquely (i.e., the embedding is injective). While previously published conditions may apply only in restricted circumstances (e.g., on compact domains), and are difficult to check, our conditions are straightforward and intuitive: *integrally strictly positive definite kernels* are characteristic. Alternatively, if a bounded continuous kernel is translation-invariant on $\mathbb{R}^d$, then it is characteristic if and only if the support of its Fourier transform is the entire $\mathbb{R}^d$. Second, we show that the distance between distributions under γ_k results from an interplay between the properties of the kernel and the distributions, by demonstrating that distributions are close in the embedding space when their differences occur at higher frequencies. Third, to understand the

nature of the topology induced by γ_k, we relate γ_k to other popular metrics on probability measures, and present conditions on the kernel k under which γ_k metrizes the weak topology.

Keywords: probability metrics, homogeneity tests, independence tests, kernel methods, universal kernels, characteristic kernels, Hilbertian metric, weak topology

1. Introduction

The concept of distance between probability measures is a fundamental one and has found many applications in probability theory, information theory and statistics (Rachev, 1991; Rachev and Rüschendorf, 1998; Liese and Vajda, 2006). In statistics, distances between probability measures are used in a variety of applications, including hypothesis tests (homogeneity tests, independence tests, and goodness-of-fit tests), density estimation, Markov chain monte carlo, etc. As an example, homogeneity testing, also called the two-sample problem, involves choosing whether to accept or reject a null hypothesis $H_0 : \mathbb{P} = \mathbb{Q}$ versus the alternative $H_1 : \mathbb{P} \neq \mathbb{Q}$, using random samples $\{X_j\}_{j=1}^m$ and $\{Y_j\}_{j=1}^n$ drawn i.i.d. from probability distributions $\mathbb{P}$ and $\mathbb{Q}$ on a topological space $(M, \mathcal{A})$. It is easy to see that solving this problem is equivalent to testing $H_0 : \gamma(\mathbb{P}, \mathbb{Q}) = 0$ versus $H_1 : \gamma(\mathbb{P}, \mathbb{Q}) > 0$, where γ is a metric (or, more generally, a semi-metric[1]) on the space of all probability measures defined on M. The problems of testing independence and goodness-of-fit can be posed in an analogous form. In non-parametric density estimation, $\gamma(p_n, p_0)$ can be used to study the quality of the density estimate, p_n, that is based on the samples $\{X_j\}_{j=1}^n$ drawn i.i.d. from p_0. Popular examples for γ in these statistical applications include the *Kullback-Leibler divergence*, the *total variation distance*, the *Hellinger distance* (Vajda, 1989)—these three are specific instances of the generalized ϕ-divergence (Ali and Silvey, 1966; Csiszár, 1967)—the *Kolmogorov distance* (Lehmann and Romano, 2005, Section 14.2), the *Wasserstein distance* (del Barrio et al., 1999), etc.

In probability theory, the distance between probability measures is used in studying limit theorems, the popular example being the central limit theorem. Another application is in metrizing the weak convergence of probability measures on a separable metric space, where the *Lévy-Prohorov distance* (Dudley, 2002, Chapter 11) and *dual-bounded Lipschitz distance* (also called the *Dudley metric*) (Dudley, 2002, Chapter 11) are commonly used.

In the present work, we will consider a particular pseudometric[1] on probability distributions which is an instance of an *integral probability metric* (IPM) (Müller, 1997). Denoting $\mathscr{P}$ the set of all Borel probability measures on $(M, \mathcal{A})$, the IPM between $\mathbb{P} \in \mathscr{P}$ and $\mathbb{Q} \in \mathscr{P}$ is defined as

$$\gamma_{\mathcal{F}}(\mathbb{P}, \mathbb{Q}) = \sup_{f \in \mathcal{F}} \left| \int_M f \, d\mathbb{P} - \int_M f \, d\mathbb{Q} \right|, \tag{1}$$

where $\mathcal{F}$ is a class of real-valued bounded measurable functions on M. In addition to the general application domains discussed earlier for metrics on probabilities, IPMs have been used in proving central limit theorems using Stein's method (Stein, 1972; Barbour and Chen, 2005), and are popular in empirical process theory (van der Vaart and Wellner, 1996). Since most of the applications listed

1. Given a set M, a *metric* for M is a function $\rho : M \times M \to \mathbb{R}_+$ such that *(i)* $\forall x, \rho(x,x) = 0$, *(ii)* $\forall x, y, \rho(x,y) = \rho(y,x)$, *(iii)* $\forall x, y, z, \rho(x,z) \leq \rho(x,y) + \rho(y,z)$, and *(iv)* $\rho(x,y) = 0 \Rightarrow x = y$. A semi-metric only satisfies *(i)*, *(ii)* and *(iv)*. A pseudometric only satisfies *(i)-(iii)* of the properties of a metric. Unlike a metric space (M, ρ), points in a pseudometric space need not be distinguishable: one may have $\rho(x,y) = 0$ for $x \neq y$.

Now, in the two-sample test, though we mentioned that γ is a metric/semi-metric, it is sufficient that γ satisfies *(i)* and *(iv)*.

above require $\gamma_{\mathcal{F}}$ to be a metric on $\mathscr{P}$, the choice of $\mathcal{F}$ is critical (note that irrespective of $\mathcal{F}$, $\gamma_{\mathcal{F}}$ is a pseudometric on $\mathscr{P}$). The following are some examples of $\mathcal{F}$ for which $\gamma_{\mathcal{F}}$ is a metric.

(a) $\mathcal{F} = C_b(M)$, the space of bounded continuous functions on (M,ρ), where ρ is a metric (Shorack, 2000, Chapter 19, Definition 1.1).

(b) $\mathcal{F} = C_{bu}(M)$, the space of bounded ρ-uniformly continuous functions on (M,ρ)—Portmonteau theorem (Shorack, 2000, Chapter 19, Theorem 1.1).

(c) $\mathcal{F} = \{f : \|f\|_\infty \leq 1\} =: \mathcal{F}_{TV}$, where $\|f\|_\infty = \sup_{x\in M} |f(x)|$. $\gamma_{\mathcal{F}}$ is called the *total variation distance* (Shorack, 2000, Chapter 19, Proposition 2.2), which we denote as TV, that is, $\gamma_{\mathcal{F}_{TV}} =: TV$.

(d) $\mathcal{F} = \{f : \|f\|_L \leq 1\} =: \mathcal{F}_W$, where $\|f\|_L := \sup\{|f(x) - f(y)|/\rho(x,y) : x \neq y \text{ in } M\}$. $\|f\|_L$ is the Lipschitz semi-norm of a real-valued function f on M and $\gamma_{\mathcal{F}}$ is called the *Kantorovich metric*. If (M,ρ) is separable, then $\gamma_{\mathcal{F}}$ equals the *Wasserstein distance* (Dudley, 2002, Theorem 11.8.2), denoted as $W := \gamma_{\mathcal{F}_W}$.

(e) $\mathcal{F} = \{f : \|f\|_{BL} \leq 1\} =: \mathcal{F}_\beta$, where $\|f\|_{BL} := \|f\|_L + \|f\|_\infty$. $\gamma_{\mathcal{F}}$ is called the *Dudley metric* (Shorack, 2000, Chapter 19, Definition 2.2), denoted as $\beta := \gamma_{\mathcal{F}_\beta}$.

(f) $\mathcal{F} = \{\mathbb{1}_{(-\infty,t]} : t \in \mathbb{R}^d\} =: \mathcal{F}_{KS}$. $\gamma_{\mathcal{F}}$ is called the *Kolmogorov distance* (Shorack, 2000, Theorem 2.4).

(g) $\mathcal{F} = \{e^{\sqrt{-1}\langle \omega, \cdot \rangle} : \omega \in \mathbb{R}^d\} =: \mathcal{F}_c$. This choice of $\mathcal{F}$ results in the maximal difference between the characteristic functions of $\mathbb{P}$ and $\mathbb{Q}$. That $\gamma_{\mathcal{F}_c}$ is a metric on $\mathscr{P}$ follows from the *uniqueness theorem* for characteristic functions (Dudley, 2002, Theorem 9.5.1).

Recently, Gretton et al. (2007b) and Smola et al. (2007) considered $\mathcal{F}$ to be the unit ball in a reproducing kernel Hilbert space (RKHS) $\mathcal{H}$ (Aronszajn, 1950), with k as its reproducing kernel (r.k.), that is, $\mathcal{F} = \{f : \|f\|_{\mathcal{H}} \leq 1\} =: \mathcal{F}_k$ (also see Chapter 4 of Berlinet and Thomas-Agnan, 2004, and references therein for related work): we denote $\gamma_{\mathcal{F}_k} =: \gamma_k$. While we have seen many possible $\mathcal{F}$ for which $\gamma_{\mathcal{F}}$ is a metric, $\mathcal{F}_k$ has a number of important advantages:

- **Estimation of $\gamma_{\mathcal{F}}$:** In applications such as hypothesis testing, $\mathbb{P}$ and $\mathbb{Q}$ are known only through the respective random samples $\{X_j\}_{j=1}^m$ and $\{Y_j\}_{j=1}^n$ drawn i.i.d. from each, and $\gamma_{\mathcal{F}}(\mathbb{P},\mathbb{Q})$ is estimated based on these samples. One approach is to compute $\gamma_{\mathcal{F}}(\mathbb{P},\mathbb{Q})$ using the empirical measures $\mathbb{P}_m = \frac{1}{m}\sum_{j=1}^m \delta_{X_j}$ and $\mathbb{Q}_n = \frac{1}{n}\sum_{j=1}^n \delta_{Y_j}$, where δ_x represents a Dirac measure at x. It can be shown that choosing $\mathcal{F}$ as $C_b(M)$, $C_{bu}(M)$, $\mathcal{F}_{TV}$ or $\mathcal{F}_c$ results in this approach not yielding consistent estimates of $\gamma_{\mathcal{F}}(\mathbb{P},\mathbb{Q})$ for all $\mathbb{P}$ and $\mathbb{Q}$ (Devroye and Györfi, 1990). Although choosing $\mathcal{F} = \mathcal{F}_W$ or $\mathcal{F}_\beta$ yields consistent estimates of $\gamma_{\mathcal{F}}(\mathbb{P},\mathbb{Q})$ for all $\mathbb{P}$ and $\mathbb{Q}$ when $M = \mathbb{R}^d$, the rates of convergence are dependent on d and become slow for large d (Sriperumbudur et al., 2009b). On the other hand, $\gamma_k(\mathbb{P}_m,\mathbb{Q}_n)$ is a $\sqrt{mn/(m+n)}$-consistent estimator of $\gamma_k(\mathbb{P},\mathbb{Q})$ if k is measurable and bounded, for all $\mathbb{P}$ and $\mathbb{Q}$. If k is translation invariant on $M = \mathbb{R}^d$, the rate is independent of d (Gretton et al., 2007b; Sriperumbudur et al., 2009b), an important property when dealing with high dimensions. Moreover, $\gamma_{\mathcal{F}}$ is not straightforward to compute when $\mathcal{F}$ is $C_b(M)$, $C_{bu}(M)$, $\mathcal{F}_W$ or $\mathcal{F}_\beta$ (Weaver, 1999, Section 2.3): by contrast, $\gamma_k^2(\mathbb{P},\mathbb{Q})$ is simply a sum of expectations of the kernel k (see (9) and Theorem 1).

- **Comparison to ϕ-divergences:** Instead of using $\gamma_{\mathcal{F}}$ in statistical applications, one can also use ϕ-divergences. However, the estimators of ϕ-divergences (especially the Kullback-Leibler divergence) exhibit arbitrarily slow rates of convergence depending on the distributions (see Wang et al., 2005; Nguyen et al., 2008, and references therein for details), while, as noted above, $\gamma_k(\mathbb{P}_m, \mathbb{Q}_n)$ exhibits good convergence behavior.

- **Structured domains:** Since γ_k is dependent only on the kernel (see Theorem 1) and kernels can be defined on arbitrary domains M (Aronszajn, 1950), choosing $\mathcal{F} = \mathcal{F}_k$ provides the flexibility of measuring the distance between probability measures defined on structured domains (Borgwardt et al., 2006) like graphs, strings, etc., unlike $\mathcal{F} = \mathcal{F}_{KS}$ or $\mathcal{F}_c$, which can handle only $M = \mathbb{R}^d$.

The distance measure γ_k has appeared in a wide variety of applications. These include statistical hypothesis testing, of homogeneity (Gretton et al., 2007b), independence (Gretton et al., 2008), and conditional independence (Fukumizu et al., 2008); as well as in machine learning applications including kernel independent component analysis (Bach and Jordan, 2002; Gretton et al., 2005a; Shen et al., 2009) and kernel based dimensionality reduction for supervised learning (Fukumizu et al., 2004). In these applications, kernels offer a linear approach to deal with higher order statistics: given the problem of homogeneity testing, for example, differences in higher order moments are encoded as differences in the means of nonlinear features of the variables. To capture all nonlinearities that are relevant to the problem at hand, the embedding RKHS therefore has to be "sufficiently large" that differences in the embeddings correspond to differences of interest in the distributions. Thus, a natural question is how to guarantee k provides a sufficiently rich RKHS so as to detect *any* difference in distributions. A second problem is to determine what properties of distributions result in their being proximate or distant in the embedding space. Finally, we would like to compare γ_k to the classical integral probability metrics listed earlier, when used to measure convergence of distributions. In the following section, we describe the contributions of the present paper, addressing each of these three questions in turn.

1.1 Contributions

The contributions in this paper are three-fold and explained in detail below.

1.1.1 WHEN IS $\mathcal{H}$ CHARACTERISTIC?

Recently, Fukumizu et al. (2008) introduced the concept of a *characteristic kernel*, that is, a reproducing kernel for which $\gamma_k(\mathbb{P}, \mathbb{Q}) = 0 \Leftrightarrow \mathbb{P} = \mathbb{Q}$, $\mathbb{P}, \mathbb{Q} \in \mathscr{P}$, that is, γ_k is a metric on $\mathscr{P}$. The corresponding RKHS, $\mathcal{H}$ is referred to as a *characteristic RKHS*. The following are two characterizations for characteristic RKHSs that have already been studied in literature:

1. When M is compact, Gretton et al. (2007b) showed that $\mathcal{H}$ is characteristic if k is *universal* in the sense of Steinwart (2001, Definition 4), that is, $\mathcal{H}$ is dense in the Banach space of bounded continuous functions with respect to the supremum norm. Examples of such $\mathcal{H}$ include those induced by the Gaussian and Laplacian kernels on every compact subset of $\mathbb{R}^d$.

2. Fukumizu et al. (2008, 2009a) extended this characterization to non-compact M and showed that $\mathcal{H}$ is characteristic if and only if the direct sum of $\mathcal{H}$ and $\mathbb{R}$ is dense in the Banach space of r-integrable (for some $r \geq 1$) functions. Using this characterization, they showed

that the RKHSs induced by the Gaussian and Laplacian kernels (supported on the entire $\mathbb{R}^d$) are characteristic.

In the present study, we provide alternative conditions for characteristic RKHSs which address several limitations of the foregoing. First, it can be difficult to verify the conditions of denseness in both of the above characterizations. Second, universality is in any case an overly restrictive condition because universal kernels assume M to be compact, that is, they induce a metric only on the space of probability measures that are supported on compact M.

In Section 3.1, we present the simple characterization that *integrally strictly positive definite* (pd) kernels (see Section 1.2 for the definition) are characteristic, that is, the induced RKHS is characteristic (also see Sriperumbudur et al., 2009a, Theorem 4). This condition is more natural—strict pd is a natural property of interest for kernels, unlike the denseness condition—and much easier to understand than the characterizations mentioned above. Examples of integrally strictly pd kernels on $\mathbb{R}^d$ include the Gaussian, Laplacian, inverse multiquadratics, Matérn kernel family, B_{2n+1}-splines, etc.

Although the above characterization of integrally strictly pd kernels being characteristic is simple to understand, it is only a sufficient condition and does not provide an answer for kernels that are not integrally strictly pd,[2] for example, a Dirichlet kernel. Therefore, in Section 3.2, we provide an easily checkable condition, after making some assumptions on the kernel. We present a complete characterization of characteristic kernels when the kernel is translation invariant on $\mathbb{R}^d$. We show that a bounded continuous translation invariant kernel on $\mathbb{R}^d$ is characteristic if and only if the support of the Fourier transform of the kernel is the entire $\mathbb{R}^d$. This condition is easy to check compared to the characterizations described above. An earlier version of this result was provided by Sriperumbudur et al. (2008): by comparison, we now present a simpler and more elegant proof. We also show that all compactly supported translation invariant kernels on $\mathbb{R}^d$ are characteristic. Note, however, that the characterization of integral strict positive definiteness in Section 3.1 does not assume M to be $\mathbb{R}^d$ nor k to be translation invariant.

We extend the result of Section 3.2 to M being a d-Torus, that is, $\mathbb{T}^d = S^1 \times \overset{d}{\ldots} \times S^1 \equiv [0, 2\pi)^d$, where S^1 is a circle. In Section 3.3, we show that a translation invariant kernel on $\mathbb{T}^d$ is characteristic if and only if the Fourier series coefficients of the kernel are positive, that is, the support of the Fourier spectrum is the entire $\mathbb{Z}^d$. The proof of this result is similar in flavor to the one in Section 3.2. As examples, the Poisson kernel can be shown to be characteristic, while the Dirichlet kernel is not.

Based on the discussion so far, it is clear that the characteristic property of k can be determined in many ways. In Section 3.4, we summarize the relations between various kernel families (e.g., the universal kernels and the strictly pd kernels), and show how they relate in turn to characteristic kernels. A summary is depicted in Figure 1.

1.1.2 DISSIMILAR DISTRIBUTIONS WITH SMALL γ_k

As we have seen, the characteristic property of a kernel is critical in distinguishing between distinct probability measures. Suppose, however, that for a given characteristic kernel k and for any $\varepsilon > 0$, there exist $\mathbb{P}$ and $\mathbb{Q}$, $\mathbb{P} \neq \mathbb{Q}$, such that $\gamma_k(\mathbb{P}, \mathbb{Q}) < \varepsilon$. Though k distinguishes between such $\mathbb{P}$ and $\mathbb{Q}$, it can be difficult to tell the distributions apart in applications (even with characteristic kernels), since $\mathbb{P}$ and $\mathbb{Q}$ are then replaced with finite samples, and the distance between them may not be

2. It can be shown that integrally strictly pd kernels are strictly pd (see Footnote 4). Therefore, examples of kernels that are not integrally strictly pd include those kernels that are not strictly pd.

statistically significant (Gretton et al., 2007b). Therefore, given a characteristic kernel, it is of interest to determine the properties of distributions $\mathbb{P}$ and $\mathbb{Q}$ that will cause their embeddings to be close. To this end, in Section 4, we show that given a kernel k (see Theorem 19 for conditions on the kernel), for any $\varepsilon > 0$, there exists $\mathbb{P} \neq \mathbb{Q}$ (with non-trivial differences between them) such that $\gamma_k(\mathbb{P},\mathbb{Q}) < \varepsilon$. These distributions are constructed so as to differ at a sufficiently high frequency, which is then penalized by the RKHS norm when computing γ_k.

1.1.3 WHEN DOES γ_k METRIZE THE WEAK TOPOLOGY ON $\mathscr{P}$?

Given γ_k, which is a metric on $\mathscr{P}$, a natural question of theoretical and practical importance is "how is γ_k related to other probability metrics, such as the Dudley metric (β), Wasserstein distance (W), total variation metric (TV), etc?" For example, in applications like density estimation, where the unknown density is estimated based on finite samples drawn i.i.d. from it, the quality of the estimate is measured by computing the distance between the true density and the estimated density. In such a setting, given two probability metrics, ρ_1 and ρ_2, one might want to use the *stronger*[3] of the two to determine this distance, as the convergence of the estimated density to the true density in the stronger metric implies the convergence in the weaker metric, while the converse is not true. On the other hand, one might need to use a metric of weaker topology (i.e., coarser topology) to show convergence of some estimators, as the convergence might not occur w.r.t. a metric of strong topology. Clarifying and comparing the topology of a metric on the probabilities is, thus, important in the analysis of density estimation. Based on this motivation, in Section 5, we analyze the relation between γ_k and other probability metrics, and show that γ_k is weaker than all these other metrics.

It is well known in probability theory that β is weaker than W and TV, and it metrizes the weak topology (we will provide formal definitions in Section 5) on $\mathscr{P}$ (Shorack, 2000; Gibbs and Su, 2002). Since γ_k is weaker than all these other probability metrics, that is, the topology induced by γ_k is coarser than the one induced by these metrics, the next interesting question to answer would be, "When does γ_k metrize the weak topology on $\mathscr{P}$?" In other words, for what k, does the topology induced by γ_k coincide with the weak topology? Answering this question would show that γ_k is equivalent to β, while it is weaker than W and TV. In probability theory, the metrization of weak topology is of prime importance in proving results related to the weak convergence of probability measures. Therefore, knowing the answer to the above question will help in using γ_k as a theoretical tool in probability theory. To this end, in Section 5, we show that universal kernels on compact (M,ρ) metrize the weak topology on $\mathscr{P}$. For the non-compact setting, we assume $M = \mathbb{R}^d$ and provide sufficient conditions on the kernel such that γ_k metrizes the weak topology on $\mathscr{P}$.

In the following section, we introduce the notation and some definitions that are used throughout the paper. Supplementary results used in proofs are collected in Appendix A.

1.2 Definitions and Notation

For a measurable space, M and μ a Borel measure on M, $L^r(M,\mu)$ denotes the Banach space of r-power ($r \geq 1$) μ-integrable functions. We will also use $L^r(M)$ for $L^r(M,\mu)$ and dx for $d\mu(x)$ if μ is

3. Two metrics $\rho_1 : Y \times Y \to \mathbb{R}_+$ and $\rho_2 : Y \times Y \to \mathbb{R}_+$ are said to be equivalent if $\rho_1(x,y) = 0 \Leftrightarrow \rho_2(x,y) = 0, \forall x,y \in Y$. On the other hand, ρ_1 is said to be stronger than ρ_2 if $\rho_1(x,y) = 0 \Rightarrow \rho_2(x,y) = 0, \forall x,y \in Y$ but not vice-versa. If ρ_1 is stronger than ρ_2, then we say ρ_2 is weaker than ρ_1. Note that if ρ_1 is stronger (*resp.* weaker) than ρ_2, then the topology induced by ρ_1 is finer (*resp.* coarser) than the one induced by ρ_2.

the Lebesgue measure on $M \subset \mathbb{R}^d$. $C_b(M)$ denotes the space of all bounded, continuous functions on M. The space of all r-continuously differentiable functions on M is denoted by $C^r(M), 0 \leq r \leq \infty$. For $x \in \mathbb{C}$, $\bar{x}$ represents the complex conjugate of x. We denote as i the imaginary unit $\sqrt{-1}$.

For a measurable function f and a signed measure $\mathbb{P}$, $\mathbb{P}f := \int f \, d\mathbb{P} = \int_M f(x) \, d\mathbb{P}(x)$. δ_x represents the Dirac measure at x. The symbol δ is overloaded to represent the Dirac measure, the Dirac-delta distribution, and the Kronecker-delta, which should be distinguishable from the context. For $M = \mathbb{R}^d$, the characteristic function, $\phi_{\mathbb{P}}$ of $\mathbb{P} \in \mathscr{P}$ is defined as $\phi_{\mathbb{P}}(\omega) := \int_{\mathbb{R}^d} e^{i\omega^T x} \, d\mathbb{P}(x)$, $\omega \in \mathbb{R}^d$.

Support of a Borel measure: The support of a finite regular Borel measure, μ on a Hausdorff space, M is defined to be the closed set,

$$\text{supp}(\mu) := M \backslash \bigcup \{U \subset M : U \text{ is open}, \, \mu(U) = 0\}. \tag{2}$$

Vanishing at infinity and $C_0(M)$: A complex function f on a locally compact Hausdorff space M is said to *vanish at infinity* if for every $\varepsilon > 0$ there exists a compact set $K \subset M$ such that $|f(x)| < \varepsilon$ for all $x \notin K$. The class of all continuous f on M which vanish at infinity is denoted as $C_0(M)$.

Holomorphic and entire functions: Let $D \subset \mathbb{C}^d$ be an open subset and $f : D \to \mathbb{C}$ be a function. f is said to be *holomorphic* (or *analytic*) at the point $z_0 \in D$ if

$$f'(z_0) := \lim_{z \to z_0} \frac{f(z_0) - f(z)}{z_0 - z}$$

exists. Moreover, f is called holomorphic if it is holomorphic at every $z_0 \in D$. f is called an *entire function* if f is holomorphic and $D = \mathbb{C}^d$.

Positive definite and strictly positive definite: A function $k : M \times M \to \mathbb{R}$ is called *positive definite* (pd) if, for all $n \in \mathbb{N}$, $\alpha_1, \ldots, \alpha_n \in \mathbb{R}$ and all $x_1, \ldots, x_n \in M$, we have

$$\sum_{i,j=1}^{n} \alpha_i \alpha_j k(x_i, x_j) \geq 0. \tag{3}$$

Furthermore, k is said to be *strictly pd* if, for mutually distinct $x_1, \ldots, x_n \in X$, equality in (3) only holds for $\alpha_1 = \cdots = \alpha_n = 0$. ψ is said to be a positive definite function on $\mathbb{R}^d$ if $k(x, y) = \psi(x - y)$ is positive definite.

Integrally strictly positive definite: Let M be a topological space. A measurable and bounded kernel, k is said to be integrally strictly positive definite if

$$\int\int_M k(x, y) \, d\mu(x) \, d\mu(y) > 0,$$

for all finite non-zero signed Borel measures μ defined on M.

The above definition is a generalization of *integrally strictly positive definite functions* on $\mathbb{R}^d$ (Stewart, 1976, Section 6): $\int\int_{\mathbb{R}^d} k(x, y) f(x) f(y) \, dx \, dy > 0$ for all $f \in L^2(\mathbb{R}^d)$, which is the strictly positive definiteness of the integral operator given by the kernel. Note that the above definition is *not* equivalent to the definition of strictly pd kernels: if k is integrally strictly pd, then it is strictly pd, while the converse is not true.[4]

4. Suppose k is not strictly pd. This means for some $n \in \mathbb{N}$ and for mutually distinct $x_1, \ldots, x_n \in M$, there exists $\mathbb{R} \ni \alpha_j \neq 0$ for some $j \in \{1, \ldots, n\}$ such that $\sum_{j,l=1}^{n} \alpha_j \alpha_l k(x_j, x_l) = 0$. By defining $\mu = \sum_{j=1}^{n} \alpha_j \delta_{x_j}$, it is easy to see that there exists $\mu \neq 0$ such that $\int\int_M k(x, y) \, d\mu(x) \, d\mu(y) = 0$, which means k is not integrally strictly pd. Therefore, if k is integrally strictly pd, then it is strictly pd. However, the converse is not true. See Steinwart and Christmann (2008, Proposition 4.60, Theorem 4.62) for an example.

Fourier transform in $\mathbb{R}^d$: For $f \in L^1(\mathbb{R}^d)$, $\widehat{f}$ and $f^\vee$ represent the Fourier transform and inverse Fourier transform of f respectively, defined as

$$\widehat{f}(y) := \frac{1}{(2\pi)^{d/2}} \int_{\mathbb{R}^d} e^{-iy^T x} f(x)\, dx,\ y \in \mathbb{R}^d, \tag{4}$$

$$f^\vee(x) := \frac{1}{(2\pi)^{d/2}} \int_{\mathbb{R}^d} e^{ix^T y} f(y)\, dy,\ x \in \mathbb{R}^d. \tag{5}$$

Convolution: If f and g are complex functions in $\mathbb{R}^d$, their convolution $f * g$ is defined by

$$(f * g)(x) := \int_{\mathbb{R}^d} f(y) g(x-y)\, dy,$$

provided that the integral exists for almost all $x \in \mathbb{R}^d$, in the Lebesgue sense. Let μ be a finite Borel measure on $\mathbb{R}^d$ and f be a bounded measurable function on $\mathbb{R}^d$. The convolution of f and μ, $f * \mu$, which is a bounded measurable function, is defined by

$$(f * \mu)(x) := \int_{\mathbb{R}^d} f(x-y)\, d\mu(y).$$

Rapidly decaying functions, $\mathscr{D}_d$ and $\mathscr{S}_d$: Let $\mathscr{D}_d$ be the space of compactly supported infinitely differentiable functions on $\mathbb{R}^d$, that is, $\mathscr{D}_d = \{f \in C^\infty(\mathbb{R}^d) \,|\, \mathrm{supp}(f) \text{ is bounded}\}$, where $\mathrm{supp}(f) = \mathrm{cl}\left(\{x \in \mathbb{R}^d \,|\, f(x) \neq 0\}\right)$. A function $f : \mathbb{R}^d \to \mathbb{C}$ is said to decay rapidly, or be rapidly decreasing, if for all $N \in \mathbb{N}$,

$$\sup_{\|\alpha\|_1 \leq N} \sup_{x \in \mathbb{R}^d} (1 + \|x\|_2^2)^N |(T_\alpha f)(x)| < \infty,$$

where $\alpha = (\alpha_1, \ldots, \alpha_d)$ is an ordered d-tuple of non-negative α_j, $\|\alpha\|_1 = \sum_{j=1}^d \alpha_j$ and $T_\alpha = \left(\frac{1}{i}\frac{\partial}{\partial x_1}\right)^{\alpha_1} \cdots \left(\frac{1}{i}\frac{\partial}{\partial x_d}\right)^{\alpha_d}$. $\mathscr{S}_d$, called the Schwartz class, denotes the vector space of rapidly decreasing functions. Note that $\mathscr{D}_d \subset \mathscr{S}_d$. Also, for any $p \in [1, \infty]$, $\mathscr{S}_d \subset L^p(\mathbb{R}^d)$. It can be shown that for any $f \in \mathscr{S}_d$, $\widehat{f} \in \mathscr{S}_d$ and $f^\vee \in \mathscr{S}_d$ (see Folland, 1999, Chapter 9 and Rudin, 1991, Chapter 6 for details).

Distributions, $\mathscr{D}'_d$: A linear functional on $\mathscr{D}_d$ which is continuous with respect to the Fréchet topology (see Rudin, 1991, Definition 6.3) is called a *distribution* in $\mathbb{R}^d$. The space of all distributions in $\mathbb{R}^d$ is denoted by $\mathscr{D}'_d$.

As examples, if f is *locally integrable* on $\mathbb{R}^d$ (this means that f is Lebesgue measurable and $\int_K |f(x)|\, dx < \infty$ for every compact $K \subset \mathbb{R}^d$), then the functional D_f defined by

$$D_f(\varphi) = \int_{\mathbb{R}^d} f(x)\varphi(x)\, dx,\ \varphi \in \mathscr{D}_d, \tag{6}$$

is a distribution. Similarly, if μ is a Borel measure on $\mathbb{R}^d$, then

$$D_\mu(\varphi) = \int_{\mathbb{R}^d} \varphi(x)\, d\mu(x),\ \varphi \in \mathscr{D}_d,$$

defines a distribution D_μ in $\mathbb{R}^d$, which is identified with μ.

Support of a distribution: For an open set $U \subset \mathbb{R}^d$, $\mathscr{D}_d(U)$ denotes the subspace of $\mathscr{D}_d$ consisting of the functions with support contained in U. Suppose $D \in \mathscr{D}'_d$. If U is an open set of $\mathbb{R}^d$ and if

$D(\varphi) = 0$ for every $\varphi \in \mathscr{D}_d(U)$, then D is said to *vanish* or be *null* in U. Let W be the union of all open $U \subset \mathbb{R}^d$ in which D vanishes. The complement of W is the *support* of D.

Tempered distributions, $\mathscr{S}'_d$ and Fourier transform on $\mathscr{S}'_d$: A linear continuous functional (with respect to the Fréchet topology) over the space $\mathscr{S}_d$ is called a *tempered distribution* and the space of all tempered distributions in $\mathbb{R}^d$ is denoted by $\mathscr{S}'_d$. For example, every compactly supported distribution is tempered.

For any $f \in \mathscr{S}'_d$, the Fourier and inverse Fourier transforms are defined as

$$\begin{aligned} \widehat{f}(\varphi) &:= f(\hat{\varphi}), \varphi \in \mathscr{S}_d, \\ f^{\vee}(\varphi) &:= f(\varphi^{\vee}), \varphi \in \mathscr{S}_d, \end{aligned}$$

respectively. The Fourier transform is a linear, one-to-one, bicontinuous mapping from $\mathscr{S}'_d$ to $\mathscr{S}'_d$.

For complete details on distribution theory and Fourier transforms of distributions, we refer the reader to Folland (1999, Chapter 9) and Rudin (1991, Chapter 6).

2. Hilbert Space Embedding of Probability Measures

Embeddings of probability distributions into reproducing kernel Hilbert spaces were introduced in the late 70's and early 80's, generalizing the notion of mappings of individual points: see Berlinet and Thomas-Agnan (2004, Chapter 4) for a survey. Following Gretton et al. (2007b) and Smola et al. (2007), γ_k can be alternatively expressed as a pseudometric between such distribution embeddings. The following theorem describes this relation.

Theorem 1 *Let $\mathscr{P}_k := \{\mathbb{P} \in \mathscr{P} : \int_M \sqrt{k(x,x)}\, d\mathbb{P}(x) < \infty\}$, where k is measurable on M. Then for any $\mathbb{P}, \mathbb{Q} \in \mathscr{P}_k$,*

$$\gamma_k(\mathbb{P}, \mathbb{Q}) = \left\| \int_M k(\cdot, x)\, d\mathbb{P}(x) - \int_M k(\cdot, x)\, d\mathbb{Q}(x) \right\|_{\mathcal{H}} =: \|\mathbb{P}k - \mathbb{Q}k\|_{\mathcal{H}}, \tag{7}$$

where $\mathcal{H}$ is the RKHS generated by k.

Proof Let $T_{\mathbb{P}} : \mathcal{H} \to \mathbb{R}$ be the linear functional defined as $T_{\mathbb{P}}[f] := \int_M f(x)\, d\mathbb{P}(x)$ with $\|T_{\mathbb{P}}\| := \sup_{f \in \mathcal{H}, f \neq 0} \frac{|T_{\mathbb{P}}[f]|}{\|f\|_{\mathcal{H}}}$. Consider

$$|T_{\mathbb{P}}[f]| = \left| \int_M f\, d\mathbb{P} \right| \leq \int_M |f(x)|\, d\mathbb{P}(x) = \int_M |\langle f, k(\cdot, x)\rangle_{\mathcal{H}}|\, d\mathbb{P}(x) \leq \int_M \sqrt{k(x,x)} \|f\|_{\mathcal{H}}\, d\mathbb{P}(x),$$

which implies $\|T_{\mathbb{P}}\| < \infty, \forall \mathbb{P} \in \mathscr{P}_k$, that is, $T_{\mathbb{P}}$ is a bounded linear functional on $\mathcal{H}$. Therefore, by the Riesz representation theorem (Reed and Simon, 1980, Theorem II.4), for each $\mathbb{P} \in \mathscr{P}_k$, there exists a unique $\lambda_{\mathbb{P}} \in \mathcal{H}$ such that $T_{\mathbb{P}}[f] = \langle f, \lambda_{\mathbb{P}}\rangle_{\mathcal{H}}, \forall f \in \mathcal{H}$. Let $f = k(\cdot, u)$ for some $u \in M$. Then, $T_{\mathbb{P}}[k(\cdot, u)] = \langle k(\cdot, u), \lambda_{\mathbb{P}}\rangle_{\mathcal{H}} = \lambda_{\mathbb{P}}(u)$, which implies $\lambda_{\mathbb{P}} = \int_M k(\cdot, x)\, d\mathbb{P}(x) =: \mathbb{P}k$. Therefore, with

$$|\mathbb{P}f - \mathbb{Q}f| = |T_{\mathbb{P}}[f] - T_{\mathbb{Q}}[f]| = |\langle f, \lambda_{\mathbb{P}}\rangle_{\mathcal{H}} - \langle f, \lambda_{\mathbb{Q}}\rangle_{\mathcal{H}}| = |\langle f, \lambda_{\mathbb{P}} - \lambda_{\mathbb{Q}}\rangle_{\mathcal{H}}|,$$

we have

$$\gamma_k(\mathbb{P}, \mathbb{Q}) = \sup_{\|f\|_{\mathcal{H}} \leq 1} |\mathbb{P}f - \mathbb{Q}f| = \|\lambda_{\mathbb{P}} - \lambda_{\mathbb{Q}}\|_{\mathcal{H}} = \|\mathbb{P}k - \mathbb{Q}k\|_{\mathcal{H}}.$$

Note that this holds for any $\mathbb{P}, \mathbb{Q} \in \mathscr{P}_k$. ■

Given a kernel, k, (7) holds for all $\mathbb{P} \in \mathscr{P}_k$. However, in practice, especially in statistical inference applications, it is not possible to check whether $\mathbb{P} \in \mathscr{P}_k$ as $\mathbb{P}$ is not known. Therefore, one would prefer to have a kernel such that

$$\int_M \sqrt{k(x,x)}\, d\mathbb{P}(x) < \infty, \forall \mathbb{P} \in \mathscr{P}. \tag{8}$$

The following proposition shows that (8) is equivalent to the kernel being bounded. Therefore, combining Theorem 1 and Proposition 2 shows that if k is measurable and bounded, then $\gamma_k(\mathbb{P},\mathbb{Q}) = \|\mathbb{P}k - \mathbb{Q}k\|_{\mathcal{H}}$ for any $\mathbb{P},\mathbb{Q} \in \mathscr{P}$.

Proposition 2 *Let f be a measurable function on M. Then $\int_M f(x)\, d\mathbb{P}(x) < \infty$ for all $\mathbb{P} \in \mathscr{P}$ if and only if f is bounded.*

Proof One direction is straightforward because if f is bounded, then $\int_M f(x)\, d\mathbb{P}(x) < \infty$ for all $\mathbb{P} \in \mathscr{P}$. Let us consider the other direction. Suppose f is not bounded. Then there exists a sequence $\{x_n\} \subset M$ such that $f(x_n) \overset{n\to\infty}{\longrightarrow} \infty$. By taking a subsequence, if necessary, we can assume $f(x_n) > n^2$ for all n. Then, $A := \sum_{n=1}^{\infty} \frac{1}{f(x_n)} < \infty$. Define a probability measure $\mathbb{P}$ on M by $\mathbb{P} = \sum_{n=1}^{\infty} \frac{1}{Af(x_n)} \delta_{x_n}$, where δ_{x_n} is a Dirac measure at x_n. Then, $\int_M f(x)\, d\mathbb{P}(x) = \frac{1}{A}\sum_{n=1}^{\infty} \frac{f(x_n)}{f(x_n)} = \infty$, which means if f is not bounded, then there exists a $\mathbb{P} \in \mathscr{P}$ such that $\int_M f(x)\, d\mathbb{P}(x) = \infty$. ■

The representation of γ_k in (7) yields the embedding,

$$\Pi : \mathscr{P} \to \mathcal{H} \qquad \mathbb{P} \mapsto \int_M k(\cdot,x)\, d\mathbb{P}(x),$$

as proposed by Berlinet and Thomas-Agnan (2004, Chapter 4, Section 1.1) and Gretton et al. (2007b); Smola et al. (2007). Berlinet and Thomas-Agnan derived this embedding as a generalization of $\delta_x \mapsto k(\cdot,x)$, while Gretton et al. arrived at the embedding by choosing $\mathcal{F} = \mathcal{F}_k$ in (1). Since $\gamma_k(\mathbb{P},\mathbb{Q}) = \|\Pi[\mathbb{P}] - \Pi[\mathbb{Q}]\|_{\mathcal{H}}$, the question "When is γ_k a metric on $\mathscr{P}$?" is equivalent to the question "When is Π injective?" Addressing these questions is the central focus of the paper and is discussed in Section 3.

Before proceeding further, we present a number of equivalent representations of γ_k, which will improve our understanding of γ_k and be helpful in its computation. First, Gretton et al. have shown the reproducing property of k leads to

$$\begin{aligned}
\gamma_k^2(\mathbb{P},\mathbb{Q}) &= \left\| \int_M k(\cdot,x)\, d\mathbb{P}(x) - \int_M k(\cdot,x)\, d\mathbb{Q}(x) \right\|_{\mathcal{H}}^2 \\
&= \left\langle \int_M k(\cdot,x)\, d\mathbb{P}(x) - \int_M k(\cdot,x)\, d\mathbb{Q}(x), \int_M k(\cdot,y)\, d\mathbb{P}(y) - \int_M k(\cdot,y)\, d\mathbb{Q}(y) \right\rangle_{\mathcal{H}} \\
&= \left\langle \int_M k(\cdot,x)\, d\mathbb{P}(x), \int_M k(\cdot,y)\, d\mathbb{P}(y) \right\rangle_{\mathcal{H}} + \left\langle \int_M k(\cdot,x)\, d\mathbb{Q}(x), \int_M k(\cdot,y)\, d\mathbb{Q}(y) \right\rangle_{\mathcal{H}} \\
&\qquad -2\left\langle \int_M k(\cdot,x)\, d\mathbb{P}(x), \int_M k(\cdot,y)\, d\mathbb{Q}(y) \right\rangle_{\mathcal{H}} \\
&\overset{(a)}{=} \iint_M k(x,y)\, d\mathbb{P}(x)\, d\mathbb{P}(y) + \iint_M k(x,y)\, d\mathbb{Q}(x)\, d\mathbb{Q}(y) \\
&\qquad -2\iint_M k(x,y)\, d\mathbb{P}(x)\, d\mathbb{Q}(y) \qquad (9) \\
&= \iint_M k(x,y)\, d(\mathbb{P}-\mathbb{Q})(x)\, d(\mathbb{P}-\mathbb{Q})(y), \qquad (10)
\end{aligned}$$

where (a) follows from the fact that $\int_M f(x)\,d\mathbb{P}(x) = \langle f, \int_M k(\cdot,x)\,d\mathbb{P}(x)\rangle_{\mathcal{H}}$ for all $f \in \mathcal{H}$, $\mathbb{P} \in \mathscr{P}$ (see proof of Theorem 1), applied with $f = \int_M k(\cdot,y)\,d\mathbb{P}(y)$. As motivated in Section 1, γ_k^2 is a straightforward sum of expectations of k, and can be computed easily, for example, using (9) either in closed form or using numerical integration techniques, depending on the choice of k, $\mathbb{P}$ and $\mathbb{Q}$. It is easy to show that, if k is a Gaussian kernel with $\mathbb{P}$ and $\mathbb{Q}$ being normal distributions on $\mathbb{R}^d$, then γ_k can be computed in a closed form (see Song et al., 2008 and Sriperumbudur et. al., 2009b, Section III-C for examples). In the following corollary to Theorem 1, we prove three results which provide a nice interpretation for γ_k when $M = \mathbb{R}^d$ and k is translation invariant, that is, $k(x,y) = \psi(x-y)$, where ψ is a positive definite function. We provide a detailed explanation for Corollary 4 in Remark 5. Before stating the results, we need a famous result due to Bochner, that characterizes ψ. We quote this result from Wendland (2005, Theorem 6.6).

Theorem 3 (Bochner) *A continuous function $\psi : \mathbb{R}^d \to \mathbb{R}$ is positive definite if and only if it is the Fourier transform of a finite nonnegative Borel measure Λ on $\mathbb{R}^d$, that is,*

$$\psi(x) = \int_{\mathbb{R}^d} e^{-ix^T\omega}\,d\Lambda(\omega),\ x \in \mathbb{R}^d. \tag{11}$$

Corollary 4 (Different interpretations of γ_k) *(i) Let $M = \mathbb{R}^d$ and $k(x,y) = \psi(x-y)$, where $\psi : M \to \mathbb{R}$ is a bounded, continuous positive definite function. Then for any $\mathbb{P}, \mathbb{Q} \in \mathscr{P}$,*

$$\gamma_k(\mathbb{P},\mathbb{Q}) = \sqrt{\int_{\mathbb{R}^d} |\phi_{\mathbb{P}}(\omega) - \phi_{\mathbb{Q}}(\omega)|^2\,d\Lambda(\omega)} =: \|\phi_{\mathbb{P}} - \phi_{\mathbb{Q}}\|_{L^2(\mathbb{R}^d,\Lambda)}, \tag{12}$$

where $\phi_{\mathbb{P}}$ and $\phi_{\mathbb{Q}}$ represent the characteristic functions of $\mathbb{P}$ and $\mathbb{Q}$ respectively.

(ii) Suppose $\theta \in L^1(\mathbb{R}^d)$ is a continuous bounded positive definite function and $\int_{\mathbb{R}^d}\theta(x)\,dx = 1$. Let $\psi(x) := \psi_t(x) = t^{-d}\theta(t^{-1}x)$, $t > 0$. Assume that p and q are bounded uniformly continuous Radon-Nikodym derivatives of $\mathbb{P}$ and $\mathbb{Q}$ w.r.t. the Lebesgue measure, that is, $d\mathbb{P} = p\,dx$ and $d\mathbb{Q} = q\,dx$. Then,

$$\lim_{t\to 0}\gamma_k(\mathbb{P},\mathbb{Q}) = \|p-q\|_{L^2(\mathbb{R}^d)}. \tag{13}$$

In particular, if $|\theta(x)| \le C(1+\|x\|_2)^{-d-\varepsilon}$ for some $C, \varepsilon > 0$, then (13) holds for all bounded p and q (not necessarily uniformly continuous).

(iii) Suppose $\psi \in L^1(\mathbb{R}^d)$ and $\sqrt{\widehat{\psi}} \in L^1(\mathbb{R}^d)$. Then,

$$\gamma_k(\mathbb{P},\mathbb{Q}) = (2\pi)^{-d/4}\|\Phi * \mathbb{P} - \Phi * \mathbb{Q}\|_{L^2(\mathbb{R}^d)}, \tag{14}$$

where $\Phi := \left(\sqrt{\widehat{\psi}}\right)^{\vee}$ and $d\Lambda = (2\pi)^{-d/2}\widehat{\psi}\,d\omega$. Here, $\Phi * \mathbb{P}$ represents the convolution of Φ and $\mathbb{P}$.

Proof *(i)* Let us consider (10) with $k(x,y) = \psi(x-y)$. Then, we have

$$\begin{aligned}
\gamma_k^2(\mathbb{P},\mathbb{Q}) &= \iint_{\mathbb{R}^d} \psi(x-y)\,d(\mathbb{P}-\mathbb{Q})(x)\,d(\mathbb{P}-\mathbb{Q})(y)\\
&\overset{(a)}{=} \iiint_{\mathbb{R}^d} e^{-i(x-y)^T\omega}\,d\Lambda(\omega)\,d(\mathbb{P}-\mathbb{Q})(x)\,d(\mathbb{P}-\mathbb{Q})(y)\\
&\overset{(b)}{=} \iint_{\mathbb{R}^d} e^{-ix^T\omega}\,d(\mathbb{P}-\mathbb{Q})(x)\int_{\mathbb{R}^d} e^{iy^T\omega}\,d(\mathbb{P}-\mathbb{Q})(y)\,d\Lambda(\omega)\\
&= \int_{\mathbb{R}^d}(\phi_{\mathbb{P}}(\omega)-\phi_{\mathbb{Q}}(\omega))\left(\overline{\phi_{\mathbb{P}}(\omega)} - \overline{\phi_{\mathbb{Q}}(\omega)}\right)d\Lambda(\omega) = \int_{\mathbb{R}^d}|\phi_{\mathbb{P}}(\omega)-\phi_{\mathbb{Q}}(\omega)|^2\,d\Lambda(\omega),
\end{aligned}$$

where Bochner's theorem (Theorem 3) is invoked in (a), while Fubini's theorem (Folland, 1999, Theorem 2.37) is invoked in (b).

(ii) Consider (9) with $k(x,y) = \psi_t(x-y)$,

$$\begin{aligned}\gamma_k^2(\mathbb{P},\mathbb{Q}) &= \iint_{\mathbb{R}^d} \psi_t(x-y)p(x)p(y)\,dx\,dy + \iint_{\mathbb{R}^d} \psi_t(x-y)q(x)q(y)\,dx\,dy \\ &\qquad -2\iint_{\mathbb{R}^d} \psi_t(x-y)p(x)q(y)\,dx\,dy \\ &= \int_{\mathbb{R}^d} (\psi_t * p)(x)p(x)\,dx + \int_{\mathbb{R}^d} (\psi_t * q)(x)q(x)\,dx - 2\int_{\mathbb{R}^d} (\psi_t * q)(x)p(x)\,dx. \qquad (15)\end{aligned}$$

Note that $\lim_{t\to 0}\int_{\mathbb{R}^d}(\psi_t * p)(x)p(x)\,dx = \int_{\mathbb{R}^d}\lim_{t\to 0}(\psi_t * p)(x)p(x)\,dx$, by invoking the dominated convergence theorem. Since p is bounded and uniformly continuous, by Theorem 25 (see Appendix A), we have $p * \psi_t \to p$ uniformly as $t \to 0$, which means $\lim_{t\to 0}\int_{\mathbb{R}^d}(\psi_t * p)(x)p(x)\,dx = \int_{\mathbb{R}^d} p^2(x)\,dx$. Using this in (15), we have

$$\lim_{t\to 0}\gamma_k^2(\mathbb{P},\mathbb{Q}) = \int_{\mathbb{R}^d}(p^2(x)+q^2(x)-2p(x)q(x))\,dx = \|p-q\|^2_{L^2(\mathbb{R}^d)}.$$

Suppose $|\theta(x)| \le (1+\|x\|_2)^{-d-\varepsilon}$ for some $C, \varepsilon > 0$. Since $p \in L^1(\mathbb{R}^d)$, by Theorem 26 (see Appendix A), we have $(p * \psi_t)(x) \to p(x)$ as $t \to 0$ for almost every x. Therefore $\lim_{t\to 0}\int_{\mathbb{R}^d}(\psi_t * p)(x)p(x)\,dx = \int_{\mathbb{R}^d} p^2(x)\,dx$ and the result follows.

(iii) Since ψ is positive definite, $\widehat{\psi}$ is nonnegative and therefore $\sqrt{\widehat{\psi}}$ is valid. Since $\sqrt{\widehat{\psi}} \in L^1(\mathbb{R}^d)$, Φ exists. Define $\phi_{\mathbb{P},\mathbb{Q}} := \phi_{\mathbb{P}} - \phi_{\mathbb{Q}}$. Now, consider

$$\begin{aligned}\|\Phi * \mathbb{P} - \Phi * \mathbb{Q}\|^2_{L^2(\mathbb{R}^d)} &= \int_{\mathbb{R}^d} |(\Phi * (\mathbb{P}-\mathbb{Q}))(x)|^2\,dx \\ &= \int_{\mathbb{R}^d}\left|\int_{\mathbb{R}^d}\Phi(x-y)\,d(\mathbb{P}-\mathbb{Q})(y)\right|^2 dx \\ &= \frac{1}{(2\pi)^d}\int_{\mathbb{R}^d}\left|\iint_{\mathbb{R}^d}\sqrt{\widehat{\psi}(\omega)}\,e^{i(x-y)^T\omega}\,d\omega\,d(\mathbb{P}-\mathbb{Q})(y)\right|^2 dx \\ &\overset{(c)}{=} \frac{1}{(2\pi)^d}\int_{\mathbb{R}^d}\left|\int_{\mathbb{R}^d}\sqrt{\widehat{\psi}(\omega)}(\overline{\phi_{\mathbb{P}}(\omega)} - \overline{\phi_{\mathbb{Q}}(\omega)})\,e^{ix^T\omega}\,d\omega\right|^2 dx \\ &= \frac{1}{(2\pi)^d}\iiint_{\mathbb{R}^d}\sqrt{\widehat{\psi}(\omega)}\sqrt{\widehat{\psi}(\xi)}\,\overline{\phi_{\mathbb{P},\mathbb{Q}}(\omega)}\,\phi_{\mathbb{P},\mathbb{Q}}(\xi)\,e^{i(\omega-\xi)^Tx}\,d\omega\,d\xi\,dx \\ &\overset{(d)}{=} \iint_{\mathbb{R}^d}\sqrt{\widehat{\psi}(\omega)}\sqrt{\widehat{\psi}(\xi)}\,\overline{\phi_{\mathbb{P},\mathbb{Q}}(\omega)}\,\phi_{\mathbb{P},\mathbb{Q}}(\xi)\left[\frac{1}{(2\pi)^d}\int_{\mathbb{R}^d}e^{i(\omega-\xi)^Tx}\,dx\right]d\omega\,d\xi \\ &= \iint_{\mathbb{R}^d}\sqrt{\widehat{\psi}(\omega)}\sqrt{\widehat{\psi}(\xi)}\,\overline{\phi_{\mathbb{P},\mathbb{Q}}(\omega)}\,\phi_{\mathbb{P},\mathbb{Q}}(\xi)\,\delta(\omega-\xi)\,d\omega\,d\xi \\ &= \int_{\mathbb{R}^d}\widehat{\psi}(\omega)\,|\phi_{\mathbb{P}}(\omega)-\phi_{\mathbb{Q}}(\omega)|^2\,d\omega \\ &= (2\pi)^{d/2}\gamma_k^2(\mathbb{P},\mathbb{Q}),\end{aligned}$$

where (c) and (d) are obtained by invoking Fubini's theorem. ■

Remark 5 *(a) (12) shows that γ_k is the L^2-distance between the characteristic functions of $\mathbb{P}$ and $\mathbb{Q}$ computed w.r.t. the non-negative finite Borel measure, Λ, which is the Fourier transform of ψ. If $\psi \in L^1(\mathbb{R}^d)$, then (12) rephrases the well known fact (Wendland, 2005, Theorem 10.12) that for any $f \in \mathcal{H}$,*

$$\|f\|_{\mathcal{H}}^2 = \int_{\mathbb{R}^d} \frac{|\widehat{f}(\omega)|^2}{\widehat{\psi}(\omega)}\, d\omega. \tag{16}$$

Choosing $f = (\mathbb{P} - \mathbb{Q}) * \psi$ in (16) yields $\widehat{f} = (\phi_{\mathbb{P}} - \phi_{\mathbb{Q}})\widehat{\psi}$ and therefore the result in (12).

(b) Suppose $d\Lambda(\omega) = (2\pi)^{-d}\, d\omega$. Assume $\mathbb{P}$ and $\mathbb{Q}$ have p and q as Radon-Nikodym derivatives w.r.t. the Lebesgue measure, that is, $d\mathbb{P} = p\, dx$ and $d\mathbb{Q} = q\, dx$. Using these in (12), it can be shown that $\gamma_k(\mathbb{P}, \mathbb{Q}) = \|p - q\|_{L^2(\mathbb{R}^d)}$. However, this result should be interpreted in a limiting sense as mentioned in Corollary 4(ii) because the choice of $d\Lambda(\omega) = (2\pi)^{-d}\, d\omega$ implies $\psi(x) = \delta(x)$, which does not satisfy the conditions of Corollary 4(i). It can be shown that $\psi(x) = \delta(x)$ is obtained in a limiting sense (Folland, 1999, Proposition 9.1): $\psi_t \to \delta$ in $\mathscr{D}_d'$ as $t \to 0$.

(c) Choosing $\theta(x) = (2\pi)^{-d/2} e^{-\|x\|_2^2/2}$ in Corollary 4(ii) corresponds to ψ_t being a Gaussian kernel (with appropriate normalization such that $\int_{\mathbb{R}^d} \psi_t(x)\, dx = 1$). Therefore, (13) shows that as the bandwidth, t of the Gaussian kernel approaches zero, γ_k approaches the L^2-distance between the densities p and q. The same result also holds for choosing ψ_t as the Laplacian kernel, B_{2n+1}-spline, inverse multiquadratic, etc. Therefore, $\gamma_k(\mathbb{P}, \mathbb{Q})$ can be seen as a generalization of the L^2-distance between probability measures, $\mathbb{P}$ and $\mathbb{Q}$.

(d) The result in (13) holds if p and q are bounded and uniformly continuous. Since any condition on $\mathbb{P}$ and $\mathbb{Q}$ is usually difficult to check in statistical applications, it is better to impose conditions on ψ rather than on $\mathbb{P}$ and $\mathbb{Q}$. In Corollary 4(ii), by imposing additional conditions on ψ_t, the result in (13) is shown to hold for all $\mathbb{P}$ and $\mathbb{Q}$ with bounded densities p and q. The condition, $|\theta(x)| \leq C(1 + \|x\|_2)^{-d-\varepsilon}$ for some $C, \varepsilon > 0$, is, for example, satisfied by the inverse multiquadratic kernel, $\theta(x) = \widetilde{C}(1 + \|x\|_2^2)^{-\tau}$, $x \in \mathbb{R}^d$, $\tau > d/2$, where $\widetilde{C} = \left(\int_{\mathbb{R}^d} (1 + \|x\|_2^2)^{-\tau}\, dx\right)^{-1}$.

(e) The result in Corollary 4(ii) has connections to the kernel density estimation in L^2-sense using Parzen windows (Rosenblatt, 1975), where ψ can be chosen as the Parzen window: see Gretton et al. (2007a, Section 7.1) for further discussion. Note in particular that when γ_k is used in a homogeneity test, a constant kernel bandwidth results in a faster decrease of the Type II error with increasing sample size (Anderson et al., 1994, p. 43). A decreasing bandwidth is required for a consistent estimate of $\|p - q\|_{L^2(\mathbb{R}^d)}$, however.

(f) (14) shows that γ_k is proportional to the L^2-distance between $\Phi * \mathbb{P}$ and $\Phi * \mathbb{Q}$. Let Φ be such that Φ is nonnegative and $\Phi \in L^1(\mathbb{R}^d)$. Then, defining $\widetilde{\Phi} := \left(\int_{\mathbb{R}^d} \Phi(x)\, dx\right)^{-1} \Phi = \Phi / \sqrt{\widehat{\psi}(0)} = \left(\int_{\mathbb{R}^d} \psi(x)\, dx\right)^{-1/2} \Phi$ and using this in (14), we have

$$\gamma_k(\mathbb{P}, \mathbb{Q}) = (2\pi)^{-d/4} \sqrt{\widehat{\psi}(0)} \left\| \widetilde{\Phi} * \mathbb{P} - \widetilde{\Phi} * \mathbb{Q} \right\|_{L^2(\mathbb{R}^d)}. \tag{17}$$

The r.h.s. of (17) can be interpreted as follows. Let X, Y and N be independent random variables such that $X \sim \mathbb{P}$, $Y \sim \mathbb{Q}$ and $N \sim \widetilde{\Phi}$. This means γ_k is proportional to the L^2-distance computed between the densities associated with the perturbed random variables, $X + N$ and $Y + N$. Note that $\|p - q\|_{L^2(\mathbb{R}^d)}$ is the L^2-distance between the densities of X and Y. Examples of ψ that satisfy the conditions in Corollary 4(iii) in addition to the conditions on Φ as mentioned here include the

Gaussian and Laplacian kernels on $\mathbb{R}^d$. The result in (14) holds even if $\sqrt{\widehat{\psi}} \notin L^1(\mathbb{R}^d)$ as the proof of (iii) can be handled using distribution theory. However, we assumed $\sqrt{\widehat{\psi}} \in L^1(\mathbb{R}^d)$ to keep the proof simple, without delving into distribution theory.

Although we will not be using all the results of Corollary 4 in deriving our main results in the following sections, Corollary 4 was presented to provide a better intuitive understanding of γ_k. To summarize, the core results of this section are Theorem 1 (combined with Proposition 2), which provides a closed form expression for γ_k in terms of the measurable and bounded k, and Corollary 4*(i)*, which provides an alternative representation for γ_k when k is bounded, continuous and translation invariant on $\mathbb{R}^d$.

3. Conditions for Characteristic Kernels

In this section, we address the question, "When is γ_k a metric on $\mathscr{P}$?". In other words, "When is Π injective?" or "Under what conditions is k characteristic?". To this end, we start with the definition of characteristic kernels and provide some examples where k is such that γ_k is not a metric on $\mathscr{P}$. As discussed in Section 1.1.1, although some characterizations are available for k so that γ_k is a metric on $\mathscr{P}$, they are difficult to check in practice. In Section 3.1, we provide the characterization that if k is integrally strictly pd, then γ_k is a metric on $\mathscr{P}$. In Section 3.2, we present more easily checkable conditions wherein we show that if $\text{supp}(\Lambda) = \mathbb{R}^d$ (see (2) for the definition of the support of a Borel measure), then γ_k is a metric on $\mathscr{P}$. This result is extended in a straightforward way to $\mathbb{T}^d$ (d-Torus) in Section 3.3. The main results of this section are summarized in Table 1.

We start by defining characteristic kernels.

Definition 6 (Characteristic kernel) *A bounded measurable positive definite kernel k is characteristic to a set $\mathscr{Q} \subset \mathscr{P}$ of probability measures defined on $(M, \mathcal{A})$ if for $\mathbb{P}, \mathbb{Q} \in \mathscr{Q}$, $\gamma_k(\mathbb{P}, \mathbb{Q}) = 0 \Leftrightarrow \mathbb{P} = \mathbb{Q}$. k is simply said to be characteristic if it is characteristic to $\mathscr{P}$. The RKHS $\mathcal{H}$ induced by such a k is called a characteristic RKHS.*

As mentioned before, the injectivity of Π is related to the characteristic property of k. If k is characteristic, then $\gamma_k(\mathbb{P}, \mathbb{Q}) = \|\Pi[\mathbb{P}] - \Pi[\mathbb{Q}]\|_{\mathcal{H}} = 0 \Rightarrow \mathbb{P} = \mathbb{Q}$, which means $\mathbb{P} \mapsto \int_M k(\cdot, x)\, d\mathbb{P}(x)$, that is, Π is injective. Therefore, when $M = \mathbb{R}^d$, the embedding of a distribution to a characteristic RKHS can be seen as a generalization of the characteristic function, $\phi_{\mathbb{P}} = \int_{\mathbb{R}^d} e^{i\langle \cdot, x\rangle}\, d\mathbb{P}(x)$. This is because, by the uniqueness theorem for characteristic functions (Dudley, 2002, Theorem 9.5.1), $\phi_{\mathbb{P}} = \phi_{\mathbb{Q}} \Rightarrow \mathbb{P} = \mathbb{Q}$, which means $\mathbb{P} \mapsto \int_{\mathbb{R}^d} e^{i\langle \cdot, x\rangle}\, d\mathbb{P}(x)$ is injective. So, in this context, intuitively $e^{i\langle y, x\rangle}$ can be treated as the characteristic kernel, k, although, formally, this is not true as $e^{i\langle y, x\rangle}$ is not a pd kernel.

Before we get to the characterization of characteristic kernels, the following examples show that there exist bounded measurable kernels that are not characteristic.

Example 1 (Trivial kernel) *Let $k(x, y) = \psi(x - y) = C$, $\forall x, y \in \mathbb{R}^d$ with $C > 0$. Using this in (9), we have $\gamma_k^2(\mathbb{P}, \mathbb{Q}) = C + C - 2C = 0$ for any $\mathbb{P}, \mathbb{Q} \in \mathscr{P}$, which means k is not characteristic.*

Example 2 (Dot product kernel) *Let $k(x, y) = x^T y$, $x, y \in \mathbb{R}^d$. Using this in (9), we have*

$$\gamma_k^2(\mathbb{P}, \mathbb{Q}) = \mu_{\mathbb{P}}^T \mu_{\mathbb{P}} + \mu_{\mathbb{Q}}^T \mu_{\mathbb{Q}} - 2\mu_{\mathbb{P}}^T \mu_{\mathbb{Q}} = \|\mu_{\mathbb{P}} - \mu_{\mathbb{Q}}\|_2^2,$$

where $\mu_{\mathbb{P}}$ and $\mu_{\mathbb{Q}}$ represent the means associated with $\mathbb{P}$ and $\mathbb{Q}$ respectively, that is, $\mu_{\mathbb{P}} := \int_{\mathbb{R}^d} x\, d\mathbb{P}(x)$. It is clear that k is not characteristic as $\gamma_k(\mathbb{P}, \mathbb{Q}) = 0 \Rightarrow \mu_{\mathbb{P}} = \mu_{\mathbb{Q}} \not\Rightarrow \mathbb{P} = \mathbb{Q}$ for all $\mathbb{P}, \mathbb{Q} \in \mathscr{P}$.

Summary of Main Results				
Domain	Property	$\mathscr{Q}$	Characteristic	Reference
M	k is integrally strictly pd	$\mathscr{P}$	Yes	Theorem 7
$\mathbb{R}^d$	$\Omega = \mathbb{R}^d$	$\mathscr{P}$	Yes	Theorem 9
$\mathbb{R}^d$	$\text{supp}(\psi)$ is compact	$\mathscr{P}$	Yes	Corollary 10
$\mathbb{R}^d$	$\Omega \subsetneq \mathbb{R}^d, \text{int}(\Omega) \neq \emptyset$	$\mathscr{P}_1$	Yes	Theorem 12
$\mathbb{R}^d$	$\Omega \subsetneq \mathbb{R}^d$	$\mathscr{P}$	No	Theorem 9
$\mathbb{T}^d$	$A_\psi(0) \geq 0, A_\psi(n) > 0, \forall n \neq 0$	$\mathscr{P}$	Yes	Theorem 14
$\mathbb{T}^d$	$\exists n \neq 0 \,\vert\, A_\psi(n) = 0$	$\mathscr{P}$	No	Theorem 14

Table 1: The table should be read as: If "Property" is satisfied on "Domain", then k is characteristic (or not) to $\mathscr{Q}$. $\mathscr{P}$ is the set of all Borel probability measures on a topological space, M. See Section 1.2 for the definition of integrally strictly pd kernels. When $M = \mathbb{R}^d$, $k(x,y) = \psi(x-y)$, where ψ is a bounded, continuous positive definite function on $\mathbb{R}^d$. ψ is the Fourier transform of a finite nonnegative Borel measure, Λ, and $\Omega := \text{supp}(\Lambda)$ (see Theorem 3 and (2) for details). $\mathscr{P}_1 := \{\mathbb{P} \in \mathscr{P} : \phi_\mathbb{P} \in L^1(\mathbb{R}^d) \cup L^2(\mathbb{R}^d), \mathbb{P} \ll \lambda \text{ and } \text{supp}(\mathbb{P}) \text{ is compact}\}$, where $\phi_\mathbb{P}$ is the characteristic function of $\mathbb{P}$ and λ is the Lebesgue measure. $\mathbb{P} \ll \lambda$ denotes that $\mathbb{P}$ is absolutely continuous w.r.t. λ. When $M = \mathbb{T}^d$, $k(x,y) = \psi(x-y)$, where ψ is a bounded, continuous positive definite function on $\mathbb{T}^d$. $\{A_\psi(n)\}_{n\in\mathbb{Z}^d}$ are the Fourier series coefficients of ψ which are nonnegative and summable (see Theorem 13 for details).

Example 3 (Polynomial kernel of order 2) *Let $k(x,y) = (1+x^T y)^2$, $x, y \in \mathbb{R}^d$. Using this in (10), we have*

$$\begin{aligned}\gamma_k^2(\mathbb{P},\mathbb{Q}) &= \int\!\!\int_{\mathbb{R}^d} (1 + 2x^T y + x^T y y^T x)\, d(\mathbb{P}-\mathbb{Q})(x)\, d(\mathbb{P}-\mathbb{Q})(y) \\ &= 2\|\mu_\mathbb{P} - \mu_\mathbb{Q}\|_2^2 + \|\Sigma_\mathbb{P} - \Sigma_\mathbb{Q} + \mu_\mathbb{P}\mu_\mathbb{P}^T - \mu_\mathbb{Q}\mu_\mathbb{Q}^T\|_F^2,\end{aligned}$$

where $\Sigma_\mathbb{P}$ and $\Sigma_\mathbb{Q}$ represent the covariance matrices associated with $\mathbb{P}$ and $\mathbb{Q}$ respectively, that is, $\Sigma_\mathbb{P} := \int_{\mathbb{R}^d} xx^T\, d\mathbb{P}(x) - \mu_\mathbb{P}\mu_\mathbb{P}^T$. $\|\cdot\|_F$ represents the Frobenius norm. Since $\gamma_k(\mathbb{P},\mathbb{Q}) = 0 \Rightarrow (\mu_\mathbb{P} = \mu_\mathbb{Q}$ and $\Sigma_\mathbb{P} = \Sigma_\mathbb{Q}) \not\Rightarrow \mathbb{P} = \mathbb{Q}$ for all $\mathbb{P}, \mathbb{Q} \in \mathscr{P}$, k is not characteristic.

In the following sections, we address the question of when k is characteristic, that is, for what k is γ_k a metric on $\mathscr{P}$?

3.1 Integrally Strictly Positive Definite Kernels are Characteristic

Compared to the existing characterizations in literature (Gretton et al., 2007b; Fukumizu et al., 2008, 2009a), the following result provides a more natural and easily understandable characterization for characteristic kernels, namely that integrally strictly pd kernels are characteristic to $\mathscr{P}$.

Theorem 7 (Integrally strictly pd kernels are characteristic) *Let k be an integrally strictly positive definite kernel on a topological space M. Then k is characteristic to $\mathscr{P}$.*

Before proving Theorem 7, we provide a supplementary result in Lemma 8 that provides necessary and sufficient conditions for a kernel *not* to be characteristic. We show that choosing k to be integrally strictly pd violates the conditions in Lemma 8, and k is therefore characteristic to $\mathscr{P}$.

Lemma 8 *Let k be measurable and bounded on a topological space, M. Then $\exists \mathbb{P} \neq \mathbb{Q}$ where $\mathbb{P}, \mathbb{Q} \in \mathscr{P}$ such that $\gamma_k(\mathbb{P}, \mathbb{Q}) = 0$ if and only if there exists a finite non-zero signed Borel measure μ that satisfies:*

(i) $\int\int_M k(x,y)\, d\mu(x)\, d\mu(y) = 0$,

(ii) $\mu(M) = 0$.

Proof ($\Leftarrow$) Suppose there exists a finite non-zero signed Borel measure, μ that satisfies *(i)* and *(ii)* in Lemma 8. By the Jordan decomposition theorem (Dudley, 2002, Theorem 5.6.1), there exist unique positive measures μ^+ and μ^- such that $\mu = \mu^+ - \mu^-$ and $\mu^+ \perp \mu^-$ (μ^+ and μ^- are singular). By *(ii)*, we have $\mu^+(M) = \mu^-(M) =: \alpha$. Define $\mathbb{P} = \alpha^{-1}\mu^+$ and $\mathbb{Q} = \alpha^{-1}\mu^-$. Clearly, $\mathbb{P} \neq \mathbb{Q}$, $\mathbb{P}, \mathbb{Q} \in \mathscr{P}$. Then, by (10), we have

$$\gamma_k^2(\mathbb{P}, \mathbb{Q}) = \int\int_M k(x,y)\, d(\mathbb{P}-\mathbb{Q})(x)\, d(\mathbb{P}-\mathbb{Q})(y) = \alpha^{-2} \int\int_M k(x,y)\, d\mu(x)\, d\mu(y) \overset{(a)}{=} 0,$$

where *(a)* is obtained by invoking *(i)*. So, we have constructed $\mathbb{P} \neq \mathbb{Q}$ such that $\gamma_k(\mathbb{P}, \mathbb{Q}) = 0$.
($\Rightarrow$) Suppose $\exists \mathbb{P} \neq \mathbb{Q}, \mathbb{P}, \mathbb{Q} \in \mathscr{P}$ such that $\gamma_k(\mathbb{P}, \mathbb{Q}) = 0$. Let $\mu = \mathbb{P} - \mathbb{Q}$. Clearly μ is a finite non-zero signed Borel measure that satisfies $\mu(M) = 0$. Note that by (10),

$$\gamma_k^2(\mathbb{P}, \mathbb{Q}) = \int\int_M k(x,y)\, d(\mathbb{P}-\mathbb{Q})(x)\, d(\mathbb{P}-\mathbb{Q})(y) = \int\int_M k(x,y)\, d\mu(x)\, d\mu(y),$$

and therefore *(i)* follows. ■

Proof (of Theorem 7) Since k is integrally strictly pd on M, we have

$$\int\int_M k(x,y)\, d\eta(x) d\eta(y) > 0,$$

for any finite non-zero signed Borel measure η. This means there does not exist a finite non-zero signed Borel measure that satisfies *(i)* in Lemma 8. Therefore, by Lemma 8, there does not exist $\mathbb{P} \neq \mathbb{Q}, \mathbb{P}, \mathbb{Q} \in \mathscr{P}$ such that $\gamma_k(\mathbb{P}, \mathbb{Q}) = 0$, which implies k is characteristic. ■

Examples of integrally strictly pd kernels on $\mathbb{R}^d$ include the Gaussian, $\exp(-\sigma\|x-y\|_2^2)$, $\sigma > 0$; the Laplacian, $\exp(-\sigma\|x-y\|_1)$, $\sigma > 0$; inverse multiquadratics, $(\sigma^2 + \|x-y\|_2^2)^{-c}$, $c > 0$, $\sigma > 0$,

etc, which are translation invariant kernels on $\mathbb{R}^d$. A *translation variant* integrally strictly pd kernel, $\widetilde{k}$, can be obtained from a translation invariant integrally strictly pd kernel, k, as $\widetilde{k}(x,y) = f(x)k(x,y)f(y)$, where $f : M \to \mathbb{R}$ is a bounded continuous function. A simple example of a translation variant integrally strictly pd kernel on $\mathbb{R}^d$ is $\widetilde{k}(x,y) = \exp(\sigma x^T y)$, $\sigma > 0$, where we have chosen $f(\cdot) = \exp(\sigma\|\cdot\|_2^2/2)$ and $k(x,y) = \exp(-\sigma\|x-y\|_2^2/2)$, $\sigma > 0$. Clearly, this kernel is characteristic on compact subsets of $\mathbb{R}^d$. The same result can also be obtained from the fact that $\widetilde{k}$ is universal on compact subsets of $\mathbb{R}^d$ (Steinwart, 2001, Section 3, Example 1), recalling that universal kernels are characteristic (Gretton et al., 2007b, Theorem 3).

Although the condition for characteristic k in Theorem 7 is easy to understand compared to other characterizations in literature, it is not always easy to check for integral strict positive definiteness of k. In the following section, we assume $M = \mathbb{R}^d$ and k to be translation invariant and present a complete characterization for characteristic k which is simple to check.

3.2 Characterization for Translation Invariant k on $\mathbb{R}^d$

The complete, detailed proofs of the main results in this section are provided in Section 3.5. Compared to Sriperumbudur et al. (2008), we now present simple proofs for these results without resorting to distribution theory. Let us start with the following assumption.

Assumption 1 *$k(x,y) = \psi(x-y)$ where ψ is a bounded continuous real-valued positive definite function on $M = \mathbb{R}^d$.*

The following theorem characterizes all translation invariant kernels in $\mathbb{R}^d$ that are characteristic.

Theorem 9 *Suppose k satisfies Assumption 1. Then k is characteristic if and only if* $\text{supp}(\Lambda) = \mathbb{R}^d$, *where Λ is defined as in (11).*

First, note that the condition $\text{supp}(\Lambda) = \mathbb{R}^d$ is easy to check compared to all other, aforementioned characterizations for characteristic k. Table 2 shows some popular translation invariant kernels on $\mathbb{R}$ along with their Fourier spectra, $\widehat{\psi}$ and its support: Gaussian, Laplacian, B_{2n+1}-spline[5] (Schölkopf and Smola, 2002) and Sinc kernels are aperiodic while Poisson (Brémaud, 2001; Steinwart, 2001; Vapnik, 1998), Dirichlet (Brémaud, 2001; Schölkopf and Smola, 2002), Féjer (Brémaud, 2001) and cosine kernels are periodic. Although the Gaussian and Laplacian kernels are shown to be characteristic by all the characterizations we have mentioned so far, the case of B_{2n+1}-splines is addressed only by Theorem 9, which shows them to be characteristic (note that B_{2n+1}-splines being integrally strictly pd also follows from Theorem 9). In fact, one can provide a more general result on compactly supported translation invariant kernels, which we do later in Corollary 10. The Matérn class of kernels (Rasmussen and Williams, 2006, Section 4.2.1), given by

$$k(x,y) = \psi(x-y) = \frac{2^{1-\nu}}{\Gamma(\nu)}\left(\frac{\sqrt{2\nu}\|x-y\|_2}{\sigma}\right)^{\nu} K_\nu\left(\frac{\sqrt{2\nu}\|x-y\|_2}{\sigma}\right), \nu > 0, \sigma > 0, \qquad (18)$$

5. A B_{2n+1}-spline is a B_n-spline of odd order. Only B_{2n+1}-splines are admissible, that is, B_n-splines of odd order are positive definite kernels whereas those of even order have negative components in their Fourier spectrum $\widehat{\psi}$, and therefore are not admissible kernels. In Table 2, the symbol $*_1^{(2n+2)}$ represents the $(2n+2)$-fold convolution. An important point to be noted with the B_{2n+1}-spline kernel is that $\widehat{\psi}$ has vanishing points at $\omega = 2\pi\alpha, \alpha \in \mathbb{Z}\backslash\{0\}$, unlike Gaussian and Laplacian kernels which do not have vanishing points in their Fourier spectrum. Nevertheless, the spectrum of all these kernels has support $\mathbb{R}$.

Kernel	$\psi(x)$	$\widehat{\psi}(\omega)$	$\text{supp}(\widehat{\psi})$
Gaussian	$\exp\left(-\frac{x^2}{2\sigma^2}\right)$	$\sigma\exp\left(-\frac{\sigma^2\omega^2}{2}\right)$	$\mathbb{R}$
Laplacian	$\exp(-\sigma\lvert x\rvert)$	$\sqrt{\frac{2}{\pi}}\frac{\sigma}{\sigma^2+\omega^2}$	$\mathbb{R}$
B_{2n+1}-spline	$*_1^{(2n+2)}\mathbb{1}_{\left[-\frac{1}{2},\frac{1}{2}\right]}(x)$	$\frac{4^{n+1}}{\sqrt{2\pi}}\frac{\sin^{2n+2}\left(\frac{\omega}{2}\right)}{\omega^{2n+2}}$	$\mathbb{R}$
Sinc	$\frac{\sin(\sigma x)}{x}$	$\sqrt{\frac{\pi}{2}}\mathbb{1}_{[-\sigma,\sigma]}(\omega)$	$[-\sigma,\sigma]$
Poisson	$\frac{1-\sigma^2}{\sigma^2-2\sigma\cos(x)+1}, 0<\sigma<1$	$\sqrt{2\pi}\sum_{j=-\infty}^{\infty}\sigma^{\lvert j\rvert}\delta(\omega-j)$	$\mathbb{Z}$
Dirichlet	$\frac{\sin\frac{(2n+1)x}{2}}{\sin\frac{x}{2}}$	$\sqrt{2\pi}\sum_{j=-n}^{n}\delta(\omega-j)$	$\{0,\pm1,\ldots,\pm n\}$
Féjer	$\frac{1}{n+1}\frac{\sin^2\frac{(n+1)x}{2}}{\sin^2\frac{x}{2}}$	$\sqrt{2\pi}\sum_{j=-n}^{n}\left(1-\frac{\lvert j\rvert}{n+1}\right)\delta(\omega-j)$	$\{0,\pm1,\ldots,\pm n\}$
Cosine	$\cos(\sigma x)$	$\sqrt{\frac{\pi}{2}}\left[\delta(\omega-\sigma)+\delta(\omega+\sigma)\right]$	$\{-\sigma,\sigma\}$

Table 2: Translation invariant kernels on $\mathbb{R}$ defined by ψ, their spectra, $\widehat{\psi}$ and its support, $\text{supp}(\widehat{\psi})$. The first four are aperiodic kernels while the last four are periodic. The domain is considered to be $\mathbb{R}$ for simplicity. For $x\in\mathbb{R}^d$, the above formulae can be extended by computing $\psi(x)=\prod_{j=1}^d\psi(x_j)$ where $x=(x_1,\ldots,x_d)$ and $\widehat{\psi}(\omega)=\prod_{j=1}^d\widehat{\psi}(\omega_j)$ where $\omega=(\omega_1,\ldots,\omega_d)$. δ represents the Dirac-delta distribution.

is characteristic as the Fourier spectrum of ψ, given by

$$\widehat{\psi}(\omega)=\frac{2^{d+\nu}\pi^{d/2}\Gamma(\nu+d/2)\nu^\nu}{\Gamma(\nu)\sigma^{2\nu}}\left(\frac{2\nu}{\sigma^2}+4\pi^2\|\omega\|_2^2\right)^{-(\nu+d/2)},\ \omega\in\mathbb{R}^d, \tag{19}$$

is positive for any $\omega\in\mathbb{R}^d$. Here, Γ is the Gamma function, K_ν is the modified Bessel function of the second kind of order ν, where ν controls the smoothness of k. The case of $\nu=\frac{1}{2}$ in the Matérn class gives the exponential kernel, $k(x,y)=\exp(-\|x-y\|_2/\sigma)$, while $\nu\to\infty$ gives the Gaussian kernel. Note that $\widehat{\psi}(x-y)$ in (19) is actually the inverse multiquadratic kernel, which is characteristic both by Theorem 7 and Theorem 9.

By Theorem 9, the Sinc kernel in Table 2 is not characteristic, which is not easy to show using other characterizations. By combining Theorem 7 with Theorem 9, it can be shown that the Sinc, Poisson, Dirichlet, Féjer and cosine kernels are not integrally strictly pd. Therefore, for translation invariant kernels on $\mathbb{R}^d$, the integral strict positive definiteness of the kernel (or the lack of it) can be tested using Theorems 7 and 9.

Of all the kernels shown in Table 2, only the Gaussian, Laplacian and B_{2n+1}-spline kernels are integrable and their corresponding $\widehat{\psi}$ are computed using (4). The other kernels shown in Table 2

are not integrable and their corresponding $\widehat{\psi}$ have to be treated as distributions (see Folland, 1999, Chapter 9 and Rudin, 1991, Chapter 6 for details), except for the Sinc kernel whose Fourier transform can be computed in the L^2 sense.[6]

Proof (Theorem 9) We provide an outline of the complete proof, which is presented in Section 3.5. The sufficient condition in Theorem 9 is simple to prove and follows from Corollary 4*(i)*, whereas we need a supplementary result to prove its necessity, which is presented in Lemma 16 (see Section 3.5). Proving the necessity of Theorem 9 is equivalent to showing that if $\text{supp}(\Lambda) \subsetneq \mathbb{R}^d$, then $\exists \mathbb{P} \neq \mathbb{Q}, \mathbb{P}, \mathbb{Q} \in \mathscr{P}$ such that $\gamma_k(\mathbb{P}, \mathbb{Q}) = 0$. In Lemma 16, we present equivalent conditions for the existence of $\mathbb{P} \neq \mathbb{Q}$ such that $\gamma_k(\mathbb{P}, \mathbb{Q}) = 0$ if $\text{supp}(\Lambda) \subsetneq \mathbb{R}^d$, using which we prove the necessity of Theorem 9. ■

The whole family of compactly supported translation invariant continuous bounded kernels on $\mathbb{R}^d$ is characteristic, as shown by the following corollary to Theorem 9.

Corollary 10 *Suppose $k \neq 0$ satisfies Assumption 1 and* $\text{supp}(\psi)$ *is compact. Then k is characteristic.*

Proof Since $\psi \in C_b(\mathbb{R}^d)$ is compactly supported on $\mathbb{R}^d$, by (6), $\psi \in \mathscr{D}'_d$. Therefore, by the Paley-Wiener theorem (Theorem 29 in Appendix A), $\widehat{\psi}$ is the restriction to $\mathbb{R}^d$ of an entire function on $\mathbb{C}^d$, which means $\widehat{\psi}$ is an analytic function on $\mathbb{R}^d$. Suppose $\text{supp}(\widehat{\psi})$ is compact, which means there exists an open set, $U \subset \mathbb{R}^d$ such that $\widehat{\psi}(x) = 0, \forall x \in U$. But being analytic, this implies that $\widehat{\psi}(x) = 0, \forall x \in \mathbb{R}^d$, that is, $\psi = 0$, which leads to a contradiction. Therefore, $\widehat{\psi}$ cannot be compactly supported, that is, $\text{supp}(\widehat{\psi}) = \mathbb{R}^d$, and the result follows from Theorem 9. ■

The above result is interesting in practice because of the computational advantage in dealing with compactly supported kernels. Note that proving such a general result for compactly supported kernels on $\mathbb{R}^d$ is not straightforward (maybe not even possible) with the other characterizations.

As a corollary to Theorem 9, the following result provides a method to construct new characteristic kernels from a given one.

Corollary 11 *Let k, k_1 and k_2 satisfy Assumption 1. Suppose k is characteristic and $k_2 \neq 0$. Then $k + k_1$ and $k \cdot k_2$ are characteristic.*

Proof Since k, k_1 and k_2 satisfy Assumption 1, $k + k_1$ and $k_2 \cdot k$ also satisfy Assumption 1. In addition,

$$\begin{aligned}
(k+k_1)(x,y) &:= k(x,y) + k_1(x,y) = \psi(x-y) + \psi_1(x-y) = \int_{\mathbb{R}^d} e^{-i(x-y)^T\omega}\, d(\Lambda + \Lambda_1)(\omega), \\
(k \cdot k_2)(x,y) &:= k(x,y)k_2(x,y) = \psi(x-y)\psi_2(x-y) = \iint_{\mathbb{R}^d} e^{-i(x-y)^T(\omega+\xi)}\, d\Lambda(\omega)\, d\Lambda_2(\xi) \\
&\overset{(a)}{=}: \int_{\mathbb{R}^d} e^{-i(x-y)^T\omega}\, d(\Lambda * \Lambda_2)(\omega),
\end{aligned}$$

6. If $f \in L^2(\mathbb{R}^d)$, the Fourier transform $\mathcal{F}[f] := \widehat{f}$ of f is defined to be the limit, in the L^2-norm, of the sequence $\{\widehat{f}_n\}$ of Fourier transforms of any sequence $\{f_n\}$ of functions belonging to $\mathscr{L}_d$, such that f_n converges in the L^2-norm to the given function $f \in L^2(\mathbb{R}^d)$, as $n \to \infty$. The function $\widehat{f}$ is defined almost everywhere on $\mathbb{R}^d$ and belongs to $L^2(\mathbb{R}^d)$. Thus, $\mathcal{F}$ is a linear operator, mapping $L^2(\mathbb{R}^d)$ into $L^2(\mathbb{R}^d)$. See Gasquet and Witomski (1999, Chapter IV, Lesson 22) for details.

where (a) follows from the definition of convolution of measures (see Rudin 1991, Section 9.14 for details). Since k is characteristic, that is, $\text{supp}(\Lambda) = \mathbb{R}^d$, and $\text{supp}(\Lambda) \subset \text{supp}(\Lambda + \Lambda_1)$, we have $\text{supp}(\Lambda + \Lambda_1) = \mathbb{R}^d$ and therefore $k + k_1$ is characteristic. Similarly, since $\text{supp}(\Lambda) \subset \text{supp}(\Lambda * \Lambda_2)$, we have $\text{supp}(\Lambda * \Lambda_2) = \mathbb{R}^d$ and therefore, $k \cdot k_2$ is characteristic. ■

Note that in the above result, we do not need k_1 or k_2 to be characteristic. Therefore, one can generate all sorts of kernels that are characteristic by starting with a characteristic kernel, k.

So far, we have considered characterizations for k such that it is characteristic to $\mathscr{P}$. We showed in Theorem 9 that kernels with $\text{supp}(\Lambda) \subsetneq \mathbb{R}^d$ are not characteristic to $\mathscr{P}$. Now, we can question whether such kernels can be characteristic to some proper subset $\mathscr{Q}$ of $\mathscr{P}$. The following result addresses this. Note that these kernels, that is, the kernels with $\text{supp}(\Lambda) \subsetneq \mathbb{R}^d$ are usually not useful in practice, especially in statistical inference applications, because the conditions on $\mathscr{Q}$ are usually not easy to check. On the other hand, the following result is of theoretical interest: along with Theorem 9, it completes the characterization of characteristic kernels that are translation invariant on $\mathbb{R}^d$. Before we state the result, we denote $\mathbb{P} \ll \mathbb{Q}$ to mean that $\mathbb{P}$ is absolutely continuous w.r.t. $\mathbb{Q}$.

Theorem 12 *Let* $\mathscr{P}_1 := \{\mathbb{P} \in \mathscr{P} : \phi_{\mathbb{P}} \in L^1(\mathbb{R}^d) \cup L^2(\mathbb{R}^d),\ \mathbb{P} \ll \lambda$ *and* $\text{supp}(\mathbb{P})$ *is compact*$\}$*, where* λ *is the Lebesgue measure. Suppose* k *satisfies Assumption 1 and* $\text{supp}(\Lambda) \subsetneq \mathbb{R}^d$ *has a non-empty interior, where* Λ *is defined as in (11). Then* k *is characteristic to* $\mathscr{P}_1$.

Proof See Section 3.5. ■

Although, by Theorem 9, the kernels with $\text{supp}(\Lambda) \subsetneq \mathbb{R}^d$ are not characteristic to $\mathscr{P}$, Theorem 12 shows that there exists a subset of $\mathscr{P}$ to which a subset of these kernels are characteristic. This type of result is not available for the previously mentioned characterizations. An example of a kernel that satisfies the conditions in Theorem 12 is the Sinc kernel, $\psi(x) = \frac{\sin(\sigma x)}{x}$ which has $\text{supp}(\Lambda) = [-\sigma, \sigma]$. The condition that $\text{supp}(\Lambda) \subsetneq \mathbb{R}^d$ has a non-empty interior is important for Theorem 12 to hold. If $\text{supp}(\Lambda)$ has an empty interior (examples include periodic kernels), then one can construct $\mathbb{P} \neq \mathbb{Q}, \mathbb{P}, \mathbb{Q} \in \mathscr{P}_1$ such that $\gamma_k(\mathbb{P}, \mathbb{Q}) = 0$. This is illustrated in Example 5 of Section 3.5.

So far, we have characterized the characteristic property of kernels that satisfy (a) $\text{supp}(\Lambda) = \mathbb{R}^d$ or (b) $\text{supp}(\Lambda) \subsetneq \mathbb{R}^d$ with $\text{int}(\text{supp}(\Lambda)) \neq \emptyset$. In the following section, we investigate kernels that have $\text{supp}(\Lambda) \subsetneq \mathbb{R}^d$ with $\text{int}(\text{supp}(\Lambda)) = \emptyset$, examples of which include periodic kernels on $\mathbb{R}^d$. This discussion uses the fact that a periodic function on $\mathbb{R}^d$ can be treated as a function on $\mathbb{T}^d$, the d-Torus.

3.3 Characterization for Translation Invariant k on $\mathbb{T}^d$

Let $M = \times_{j=1}^d [0, \tau_j)$ and $\tau := (\tau_1, \ldots, \tau_d)$. A function defined on M with periodic boundary conditions is equivalent to considering a periodic function on $\mathbb{R}^d$ with period τ. With no loss of generality, we can choose $\tau_j = 2\pi, \forall\, j$ which yields $M = [0, 2\pi)^d =: \mathbb{T}^d$, called the d-Torus. The results presented here hold for any $0 < \tau_j < \infty, \forall\, j$ but we choose $\tau_j = 2\pi$ for simplicity. Similar to Assumption 1, we now make the following assumption.

Assumption 2 $k(x, y) = \psi((x - y)_{mod\ 2\pi})$*, where* ψ *is a continuous real-valued positive definite function on* $M = \mathbb{T}^d$.

Similar to Theorem 3, we now state Bochner's theorem on $M = \mathbb{T}^d$.

Theorem 13 (Bochner) *A continuous function $\psi : \mathbb{T}^d \to \mathbb{R}$ is positive definite if and only if*

$$\psi(x) = \sum_{n \in \mathbb{Z}^d} A_\psi(n)\, e^{ix^T n},\ x \in \mathbb{T}^d, \tag{20}$$

where $A_\psi : \mathbb{Z}^d \to \mathbb{R}_+$, $A_\psi(-n) = A_\psi(n)$ and $\sum_{n\in\mathbb{Z}^d} A_\psi(n) < \infty$. A_ψ are called the Fourier series coefficients of ψ.

Examples for ψ include the Poisson, Dirichlet, Féjer and cosine kernels, which are shown in Table 2. We now state the result that defines characteristic kernels on $\mathbb{T}^d$.

Theorem 14 *Suppose k satisfies Assumption 2. Then k is characteristic (to the set of all Borel probability measures on $\mathbb{T}^d$) if and only if $A_\psi(0) \geq 0$, $A_\psi(n) > 0, \forall\, n \neq 0$.*

The proof is provided in Section 3.5 and the idea is similar to that of Theorem 9. Based on the above result, one can generate characteristic kernels by constructing an infinite sequence of positive numbers that are summable and then using them in (20). It can be seen from Table 2 that the Poisson kernel on $\mathbb{T}$ is characteristic while the Dirichlet, Féjer and cosine kernels are not. Some examples of characteristic kernels on $\mathbb{T}$ are:

(1) $k(x,y) = e^{\alpha\cos(x-y)}\cos(\alpha\sin(x-y)), 0 < \alpha \leq 1 \leftrightarrow A_\psi(0) = 1, A_\psi(n) = \frac{\alpha^{|n|}}{2|n|!}, \forall\, n \neq 0.$

(2) $k(x,y) = -\log(1 - 2\alpha\cos(x-y) + \alpha^2), |\alpha| < 1 \leftrightarrow A_\psi(0) = 0, A_\psi(n) = \frac{\alpha^n}{n}, \forall\, n \neq 0.$

(3) $k(x,y) = (\pi - (x-y)_{mod\,2\pi})^2 \leftrightarrow A_\psi(0) = \frac{\pi^2}{3}, A_\psi(n) = \frac{2}{n^2}, \forall\, n \neq 0.$

(4) $k(x,y) = \frac{\sinh\alpha}{\cosh\alpha - \cos(x-y)}, \alpha > 0 \leftrightarrow A_\psi(0) = 1, A_\psi(n) = e^{-\alpha|n|}, \forall\, n \neq 0.$

(5) $k(x,y) = \frac{\pi\cosh(\alpha(\pi - (x-y)_{mod\,2\pi}))}{\alpha\sinh(\pi\alpha)} \leftrightarrow A_\psi(0) = \frac{1}{\alpha^2}, A_\psi(n) = \frac{1}{n^2+\alpha^2}, \forall\, n \neq 0.$

The following result relates characteristic kernels and universal kernels defined on $\mathbb{T}^d$.

Corollary 15 *Let k be a characteristic kernel satisfying Assumption 2 with $A_\psi(0) > 0$. Then k is also universal.*

Proof Since k is characteristic with $A_\psi(0) > 0$, we have $A_\psi(n) > 0, \forall\, n$. Therefore, by Corollary 11 of Steinwart (2001), k is universal. ■

Since k being universal implies that it is characteristic, the above result shows that the converse is not true (though almost true except that $A_\psi(0)$ can be zero for characteristic kernels). The condition on A_ψ in Theorem 14, that is, $A_\psi(0) \geq 0, A_\psi(n) > 0, \forall\, n \neq 0$ can be equivalently written as $\text{supp}(A_\psi) = \mathbb{Z}^d$ or $\text{supp}(A_\psi) = \mathbb{Z}^d \backslash \{0\}$. Therefore, Theorems 9 and 14 are of similar flavor. In fact, these results can be generalized to locally compact Abelian groups. Fukumizu et al. (2009b) shows that a bounded continuous translation invariant kernel on a locally compact Abelian group G is characteristic to the set of all probability measures on G if and only if the support of the Fourier transform of the translation invariant kernel is the dual group of G. In our case, $(\mathbb{R}^d, +)$ and $(\mathbb{T}^d, +)$ are locally compact Abelian groups with $(\mathbb{R}^d, +)$ and $(\mathbb{Z}^d, +)$ as their respective dual groups. In Fukumizu et al. (2009b), these results are also extended to translation invariant kernels on non-Abelian compact groups and the semigroup $\mathbb{R}^d_+$.

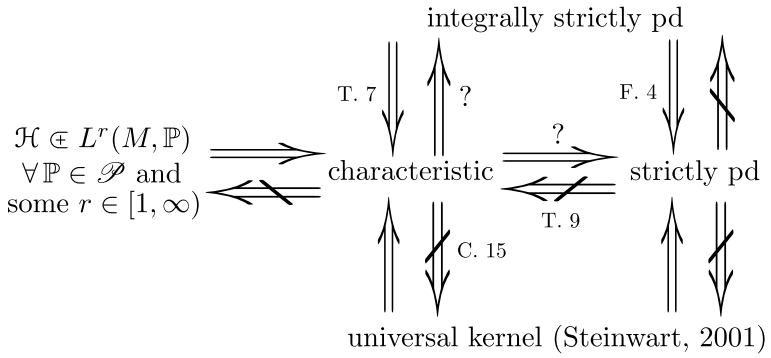

Figure 1: Summary of the relations between various families of kernels is shown along with the reference. The letters "C", "F", and "T" refer to Corollary, Footnote and Theorem respectively. For example, T. 7 refers to Theorem 7. The implications which are open problems are shown with "?". $A \Subset B$ indicates that A is a dense subset of B. Refer to Section 3.4 for details.

3.4 Overview of Relations Between Families of Kernels

So far, we have presented various characterizations of characteristic kernels, which are easily checkable compared with characterizations proposed in the earlier literature (Gretton et al., 2007b; Fukumizu et al., 2008, 2009b). We now provide an overview of various useful conditions one can impose on kernels (to be universal, strictly pd, integrally strictly pd, or characteristic), and the implications that relate some of these conditions. A summary is provided in Figure 1.

Characteristic kernels vs. Integrally strictly pd kernels: It is clear from Theorem 7 that integrally strictly pd kernels on a topological space M are characteristic, whereas the converse remains undetermined. When k is translation invariant on $\mathbb{R}^d$, however, then the converse holds. This is because if k is characteristic, then by Theorem 9, $\text{supp}(\Lambda) = \mathbb{R}^d$, where Λ is defined as in (11). It is easy to check that if $\text{supp}(\Lambda) = \mathbb{R}^d$, then k is integrally strictly pd.

Integrally strictly pd kernels vs. Strictly pd kernels: The relation between integrally strictly pd and strictly pd kernels shown in Figure 1 is straightforward, as one direction follows from Footnote 4, while the other direction is not true, which follows from Steinwart and Christmann (2008, Proposition 4.60, Theorem 4.62). However, if M is a finite set, then k being strictly pd also implies it is integrally strictly pd.

Characteristic kernels vs. Strictly pd kernels: Since integrally strictly pd kernels are characteristic and are also strictly pd, a natural question to ask is, "What is the relation between characteristic and strictly pd kernels?" It can be seen that strictly pd kernels need not be characteristic because the sinc-squared kernel, $k(x,y) = \frac{\sin^2(\sigma(x-y))}{(x-y)^2}$ on $\mathbb{R}$, which has $\text{supp}(\Lambda) = [-\sigma,\sigma] \subsetneq \mathbb{R}$ is strictly pd (Wendland, 2005, Theorem 6.11), while it is not characteristic by Theorem 9. However, for any general M, it is not clear whether k being characteristic implies that it is strictly pd. As a special case, if $M = \mathbb{R}^d$ or $M = \mathbb{T}^d$, then by Theorems 9 and 12, it follows that a translation invariant k being characteristic also implies that it is strictly pd.

Universal kernels vs. Characteristic kernels: Gretton et al. (2007b) have shown that if k is universal in the sense of Steinwart (2001), then it is characteristic. As mentioned in Section 3.3, the converse is not true, that is, if a kernel is characteristic, then it need not be universal, which

follows from Corollary 15. Note that in this case, M is assumed to be a compact metric space. The notion of universality of kernels was extended to non-compact domains by Micchelli et al. (2006): k is said to be universal on a non-compact Hausdorff space, M, if for any compact $Z \subset M$, the set $K(Z) := \overline{\text{span}}\{k(\cdot, y) : y \in Z\}$ is dense in $C_b(Z)$ w.r.t. the supremum norm. It is to be noted that when M is compact, this notion of universality is same as that of Steinwart (2001). Micchelli et al. (2006, Proposition 15) have provided a characterization of universality for translation invariant kernels on $\mathbb{R}^d$: k is universal if $\lambda(\text{supp}(\Lambda)) > 0$, where λ is the Lebesgue measure and Λ is defined as in (11). This means if a translation invariant kernel on $\mathbb{R}^d$ is characteristic, that is, $\text{supp}(\Lambda) = \mathbb{R}^d$, then it is also universal in the sense of Micchelli et al. (2006), while the converse is not true (e.g., sinc-squared kernel is not characteristic as $\text{supp}(\Lambda) = [-\sigma, \sigma] \subsetneq \mathbb{R}$ but universal in the sense of Micchelli as $\lambda(\text{supp}(\Lambda)) = 2\sigma > 0$). The relation between these notions for a general non-compact Hausdorff space M (other than $\mathbb{R}^d$) remains to be determined (whether or not the kernel is translation invariant).

Fukumizu et al. (2008, 2009b) have shown that k is characteristic if and only if $\mathcal{H} + \mathbb{R}$ is dense in $L^r(M, \mathbb{P})$ for all $\mathbb{P} \in \mathscr{P}$ and for some $r \in [1, \infty)$. Using this, it is easy to see that if $\mathcal{H}$ is dense in $L^r(M, \mathbb{P})$ for all $\mathbb{P} \in \mathscr{P}$ and for some $r \in [1, \infty)$, then k is characteristic. Clearly, the converse is not true. However, if constant functions are included in $\mathcal{H}$, then it is easy to see that the converse is also true.

Universal kernels vs. Strictly pd kernels: If a kernel is universal, then it is strictly pd, which follows from Steinwart and Christmann (2008, Definition 4.53, Proposition 4.54, Exercise 4.11). On the other hand, if a kernel is strictly pd, then it need not be universal, which follows from the results due to Dahmen and Micchelli (1987) and Pinkus (2004) for Taylor kernels (Steinwart and Christmann, 2008, Lemma 4.8, Corollary 4.57). Refer to Steinwart and Christmann (2008, Section 4.7, p. 161) for more details.

Recently, Sriperumbudur et al. (2010a,b) carried out a thorough study relating characteristic kernels to various notions of universality, addressing some open questions mentioned in the above discussion and Figure 1. This is done by relating universality to the injective embedding of regular Borel measures into an RKHS, which can therefore be seen as a generalization of the notion of characteristic kernels, as the latter deal with the injective RKHS embedding of probability measures.

3.5 Proofs

First, we present a supplementary result in Lemma 16 that will be used to prove Theorem 9. The idea of Lemma 16 is to characterize the equivalent conditions for the existence of $\mathbb{P} \neq \mathbb{Q}$ such that $\gamma_k(\mathbb{P}, \mathbb{Q}) = 0$ when $\text{supp}(\Lambda) \subsetneq \mathbb{R}^d$. Its proof relies on the properties of characteristic functions, which we have collected in Theorem 27 in Appendix A.

Lemma 16 *Let $\mathscr{P}_0 := \{\mathbb{P} \in \mathscr{P} : \phi_{\mathbb{P}} \in L^1(\mathbb{R}^d) \cup L^2(\mathbb{R}^d)$ and $\mathbb{P} \ll \lambda\}$, where λ is the Lebesgue measure. Suppose k satisfies Assumption 1 and $\text{supp}(\Lambda) \subsetneq \mathbb{R}^d$, where Λ is defined as in (11). Then, for any $\mathbb{Q} \in \mathscr{P}_0$, $\exists\, \mathbb{P} \neq \mathbb{Q}$, $\mathbb{P} \in \mathscr{P}_0$ such that $\gamma_k(\mathbb{P}, \mathbb{Q}) = 0$ if and only if there exists a non-zero function $\theta : \mathbb{R}^d \to \mathbb{C}$ that satisfies the following conditions:*

(i) $\theta \in (L^1(\mathbb{R}^d) \cup L^2(\mathbb{R}^d)) \cap C_b(\mathbb{R}^d)$ *is conjugate symmetric, that is,* $\overline{\theta(x)} = \theta(-x), \forall x \in \mathbb{R}^d$,

(ii) $\theta^\vee \in L^1(\mathbb{R}^d) \cap (L^2(\mathbb{R}^d) \cup C_b(\mathbb{R}^d))$,

(iii) $\int_{\mathbb{R}^d} |\theta(x)|^2 \, d\Lambda(x) = 0$,

(iv) $\theta(0) = 0$,

(v) $\inf_{x\in\mathbb{R}^d}\{\theta^\vee(x) + q(x)\} \geq 0$.

Proof Define $L^1 := L^1(\mathbb{R}^d)$, $L^2 := L^2(\mathbb{R}^d)$ and $C_b := C_b(\mathbb{R}^d)$.

($\Leftarrow$) Suppose there exists a non-zero function θ satisfying *(i) – (v)*. For any $\mathbb{Q} \in \mathscr{P}_0$, we have $\phi_\mathbb{Q} \in L^1 \cup L^2$ and $\phi_\mathbb{Q} \in C_b$ (by Theorem 27), that is, $\phi_\mathbb{Q} \in (L^1 \cup L^2) \cap C_b$. Now, consider the case of $\phi_\mathbb{Q} \in L^1 \cap C_b$. Since $\phi_\mathbb{Q} \in L^1$, by the inversion theorem for characteristic functions (Dudley, 2002, Theorem 9.5.4), $\mathbb{Q}$ is absolutely continuous w.r.t. λ. If q is the Radon-Nikodym derivative of $\mathbb{Q}$ w.r.t. λ, then $q = [\overline{\phi_\mathbb{Q}}]^\vee \in L^1$. In addition, by the Riemann-Lebesgue lemma (Lemma 28 in Appendix A), we have $q \in C_0(\mathbb{R}^d) \subset C_b$, which therefore implies $q \in L^1 \cap C_b$. When $\phi_\mathbb{Q} \in L^2 \cap C_b$, the Fourier transform in the L^2 sense (see Footnote 6) implies that $q = [\overline{\phi_\mathbb{Q}}]^\vee \in L^1 \cap L^2$. Therefore, $q \in L^1 \cap (L^2 \cup C_b)$. Define $p := q + \theta^\vee$. Clearly $p \in L^1 \cap (L^2 \cup C_b)$. In addition, $\overline{\phi_\mathbb{P}} = \widehat{p} = \widehat{q} + \widehat{\theta^\vee} = \overline{\phi_\mathbb{Q}} + \theta \in (L^1 \cup L^2) \cap C_b$. Since θ is conjugate symmetric, $\theta^\vee$ is real valued and so is p. Consider

$$\int_{\mathbb{R}^d} p(x)\,dx = \int_{\mathbb{R}^d} q(x)\,dx + \int_{\mathbb{R}^d} \theta^\vee(x)\,dx = 1 + \theta(0) = 1.$$

(v) implies that p is non-negative. Therefore, p is the Radon-Nikodym derivative of a probability measure $\mathbb{P}$ w.r.t. λ, where $\mathbb{P}$ is such that $\mathbb{P} \neq \mathbb{Q}$ and $\mathbb{P} \in \mathscr{P}_0$. By (12), we have

$$\gamma_k^2(\mathbb{P},\mathbb{Q}) = \int_{\mathbb{R}^d} |\phi_\mathbb{P}(x) - \phi_\mathbb{Q}(x)|^2\, d\Lambda(x) = \int_{\mathbb{R}^d} |\theta(x)|^2\, d\Lambda(x) = 0.$$

($\Rightarrow$) Suppose that there exists $\mathbb{P} \neq \mathbb{Q}, \mathbb{P}, \mathbb{Q} \in \mathscr{P}_0$ such that $\gamma_k(\mathbb{P},\mathbb{Q}) = 0$. Define $\theta := \phi_\mathbb{P} - \phi_\mathbb{Q}$. We need to show that θ satisfies *(i) – (v)*. Recalling Theorem 27 in the appendix, $\mathbb{P}, \mathbb{Q} \in \mathscr{P}_0$ implies $\phi_\mathbb{P}, \phi_\mathbb{Q} \in (L^1 \cup L^2) \cap C_b$ and $p, q \in L^1 \cap (L^2 \cup C_b)$. Therefore, $\theta = \overline{\phi}_\mathbb{P} - \overline{\phi}_\mathbb{Q} \in (L^1 \cup L^2) \cap C_b$ and $\theta^\vee = p - q \in L^1 \cap (L^2 \cup C_b)$. By Theorem 27 (see Appendix A), $\phi_\mathbb{P}$ and $\phi_\mathbb{Q}$ are conjugate symmetric and so is θ. Therefore θ satisfies *(i)* and $\theta^\vee$ satisfies *(ii)*. θ satisfies *(iv)* as

$$\theta(0) = \int_{\mathbb{R}^d} \theta^\vee(x)\,dx = \int_{\mathbb{R}^d} (p(x) - q(x))\,dx = 0.$$

Non-negativity of p yields *(v)*. By (12), $\gamma_k(\mathbb{P},\mathbb{Q}) = 0$ implies *(iii)*. ■

Remark 17 *Note that the dependence of* θ *on the kernel appears in the form of (iii) in Lemma 16. This condition shows that* $\lambda(\mathrm{supp}(\theta) \cap \mathrm{supp}(\Lambda)) = 0$*, that is, the supports of* θ *and* Λ *are disjoint w.r.t. the Lebesgue measure,* λ*. In other words,* $\mathrm{supp}(\theta) \subset \mathrm{cl}(\mathbb{R}^d \backslash \mathrm{supp}(\Lambda))$*. So, the idea is to introduce the perturbation,* θ *over an open set,* U *where* $\Lambda(U) = 0$*. The remaining conditions characterize the nature of this perturbation so that the constructed measure,* $p = q + \theta^\vee$*, is a valid probability measure. Conditions (i), (ii) and (iv) simply follow from* $\theta = \phi_\mathbb{P} - \phi_\mathbb{Q}$*, while (v) ensures that* $p(x) \geq 0, \forall x$*.*

Using Lemma 16, we now present the proof of Theorem 9.

Proof(Theorem 9) The sufficiency follows from (12): if $\mathrm{supp}(\Lambda) = \mathbb{R}^d$, then $\gamma_k^2(\mathbb{P},\mathbb{Q}) = \int_{\mathbb{R}^d} |\phi_\mathbb{P}(x) - \phi_\mathbb{Q}(x)|^2\, d\Lambda(x) = 0 \Rightarrow \phi_\mathbb{P} = \phi_\mathbb{Q}$, a.e. Recalling from Theorem 27 that $\phi_\mathbb{P}$ and $\phi_\mathbb{Q}$ are uniformly continuous on $\mathbb{R}^d$, we have that $\mathbb{P} = \mathbb{Q}$, and therefore k is characteristic. To prove necessity, we need to show that if $\mathrm{supp}(\Lambda) \subsetneq \mathbb{R}^d$, then there exists $\mathbb{P} \neq \mathbb{Q}$, $\mathbb{P}, \mathbb{Q} \in \mathscr{P}$ such that $\gamma_k(\mathbb{P},\mathbb{Q}) = 0$. By Lemma 16, this is equivalent to showing that there exists a non-zero θ satisfying the conditions in

Lemma 16. Below, we provide a constructive procedure for such a θ when $\text{supp}(\Lambda) \subsetneq \mathbb{R}^d$, thereby proving the result.

Consider the following function, $f_{\beta,\omega_0} \in C^\infty(\mathbb{R}^d)$ supported in $[\omega_0 - \beta, \omega_0 + \beta]$,

$$f_{\beta,\omega_0}(\omega) = \prod_{j=1}^{d} h_{\beta_j,\omega_{0,j}}(\omega_j) \text{ with } h_{a,b}(y) := \mathbb{1}_{[-a,a]}(y-b)\, e^{-\frac{a^2}{a^2-(y-b)^2}},$$

where $\omega = (\omega_1, \ldots, \omega_d)$, $\omega_0 = (\omega_{0,1}, \ldots, \omega_{0,d})$, $\beta = (\beta_1, \ldots, \beta_d)$, $a \in \mathbb{R}_{++}$, $b \in \mathbb{R}$ and $y \in \mathbb{R}$. Since $\text{supp}(\Lambda) \subsetneq \mathbb{R}^d$, there exists an open set $U \subset \mathbb{R}^d$ such that $\Lambda(U) = 0$. So, there exists $\beta \in \mathbb{R}^d_{++}$ and $\omega_0 > \beta$ (element-wise inequality) such that $[\omega_0 - \beta, \omega_0 + \beta] \subset U$. Let

$$\theta = \alpha(f_{\beta,\omega_0} + f_{\beta,-\omega_0}), \alpha \in \mathbb{R}\backslash\{0\},$$

which implies $\text{supp}(\theta) = [-\omega_0 - \beta, -\omega_0 + \beta] \cup [\omega_0 - \beta, \omega_0 + \beta]$ is compact. Clearly $\theta \in \mathscr{D}_d \subset \mathscr{S}_d$ which implies $\theta^\vee \in \mathscr{S}_d \subset L^1(\mathbb{R}^d) \cap L^2(\mathbb{R}^d)$. Therefore, by construction, θ satisfies *(i) – (iv)* in Lemma 16. Since $\int_{\mathbb{R}^d} \theta^\vee(x)\, dx = \theta(0) = 0$ (by construction), $\theta^\vee$ will take negative values, so we need to show that there exists $\mathbb{Q} \in \mathscr{P}_0$ such that *(v)* in Lemma 16 holds. Let $\mathbb{Q}$ be such that it has a density given by

$$q(x) = C_l \prod_{j=1}^{d} \frac{1}{(1+|x_j|^2)^l}, l \in \mathbb{N} \text{ where } C_l = \prod_{j=1}^{d} \left(\int_{\mathbb{R}} (1+|x_j|^2)^{-l}\, dx_j \right)^{-1},$$

and $x = (x_1, \ldots, x_d)$. It can be verified that choosing α such that

$$0 < |\alpha| \leq \frac{C_l}{2 \sup_x \left| \prod_{j=1}^{d} h^\vee_{\beta_j,0}(x_j)(1+|x_j|^2)^l \cos(\omega_0^T x) \right|} < \infty,$$

ensures that θ satisfies *(v)* in Lemma 16. The existence of finite α is guaranteed as $h_{a,0} \in \mathscr{D}_1 \subset \mathscr{S}_1$ which implies $h^\vee_{a,0} \in \mathscr{S}_1, \forall a$. We conclude there exists a non-zero θ as claimed earlier, which completes the proof. ■

To elucidate the necessity part in the above proof, in the following, we present a simple example that provides an intuitive understanding about the construction of θ such that for a given $\mathbb{Q}, \mathbb{P} \neq \mathbb{Q}$ can be constructed with $\gamma_k(\mathbb{P}, \mathbb{Q}) = 0$.

Example 4 *Let $\mathbb{Q}$ be a Cauchy distribution in $\mathbb{R}$, that is, $q(x) = \frac{1}{\pi(1+x^2)}$ with characteristic function, $\phi_{\mathbb{Q}}(\omega) = \frac{1}{\sqrt{2\pi}} e^{-|\omega|}$ in $L^1(\mathbb{R})$. Let ψ be a Sinc kernel, that is, $\psi(x) = \sqrt{\frac{2}{\pi}} \frac{\sin(\beta x)}{x}$ with Fourier transform given by $\widehat{\psi}(\omega) = \mathbb{1}_{[-\beta,\beta]}(\omega)$ and $\text{supp}(\widehat{\psi}) = [-\beta, \beta] \subsetneq \mathbb{R}$. Let θ be*

$$\theta(\omega) = \frac{\alpha}{2i} \left[*_1^N \mathbb{1}_{\left[-\frac{\beta}{2}, \frac{\beta}{2}\right]}(\omega) \right] * [\delta(\omega - \omega_0) - \delta(\omega + \omega_0)],$$

where $|\omega_0| \geq \left(\frac{N+2}{2}\right)\beta, N \geq 2$ and $\alpha \neq 0$. $*_1^N$ represents the N-fold convolution. Note that θ is such that $\text{supp}(\theta) \cap \text{supp}(\widehat{\psi})$ is a null set w.r.t. the Lebesgue measure, which satisfies (iii) in Lemma 16. It is easy to verify that $\theta \in L^1(\mathbb{R}) \cap L^2(\mathbb{R}) \cap C_b(\mathbb{R})$ also satisfies conditions (i) and (iv) in Lemma 16. $\theta^\vee$ can be computed as

$$\theta^\vee(x) = \frac{2^N \alpha}{\sqrt{2\pi}} \sin(\omega_0 x) \frac{\sin^N\left(\frac{\beta x}{2}\right)}{x^N},$$

and $\theta^\vee \in L^1(\mathbb{R}) \cap L^2(\mathbb{R}) \cap C_b(\mathbb{R})$ *satisfies* (ii) *in Lemma 16. Choose*

$$0 < |\alpha| \leq \frac{\sqrt{2}}{\sqrt{\pi}\beta^N \sup_x \left| (1+x^2) \sin(\omega_0 x) \mathrm{sinc}^N\left(\frac{\beta x}{2\pi}\right)\right|},$$

where $\mathrm{sinc}(x) := \frac{\sin(\pi x)}{\pi x}$. *Define* $g(x) := \sin(\omega_0 x)\mathrm{sinc}^N\left(\frac{\beta x}{2\pi}\right)$. *Since* $g \in \mathscr{S}_1$, $0 < \sup_x |(1+x^2)g(x)| < \infty$ *and, therefore,* α *is a finite non-zero number. It is easy to see that* θ *satisfies* (v) *of Lemma 16. Then, by Lemma 16, there exists* $\mathbb{P} \neq \mathbb{Q}$, $\mathbb{P} \in \mathscr{P}_0$, *given by*

$$p(x) = \frac{1}{\pi(1+x^2)} + \frac{2^N \alpha}{\sqrt{2\pi}} \sin(\omega_0 x) \frac{\sin^N\left(\frac{\beta x}{2}\right)}{x^N},$$

with $\phi_{\mathbb{P}} = \phi_{\mathbb{Q}} + \theta = \phi_{\mathbb{Q}} + i\theta_I$ *where* $\theta_I = \mathrm{Im}[\theta]$ *and* $\phi_{\mathbb{P}} \in L^1(\mathbb{R})$. *So, we have constructed* $\mathbb{P} \neq \mathbb{Q}$, *such that* $\gamma_k(\mathbb{P},\mathbb{Q}) = 0$. *Figure 2 shows the plots of* ψ, $\widehat{\psi}$, θ, $\theta^\vee$, q, $\phi_{\mathbb{Q}}$, p *and* $|\phi_{\mathbb{P}}|$ *for* $\beta = 2\pi$, $N = 2$, $\omega_0 = 4\pi$ *and* $\alpha = \frac{1}{50}$.

We now prove Theorem 12.

Proof(Theorem 12) Suppose $\exists\, \mathbb{P} \neq \mathbb{Q}, \mathbb{P}, \mathbb{Q} \in \mathscr{P}_1$ such that $\gamma_k(\mathbb{P},\mathbb{Q}) = 0$. Since any positive Borel measure on $\mathbb{R}^d$ is a distribution (Rudin, 1991, p. 157), $\mathbb{P}$ and $\mathbb{Q}$ can be treated as distributions with compact support. By the Paley-Wiener theorem (Theorem 29 in Appendix A), $\phi_{\mathbb{P}}$ and $\phi_{\mathbb{Q}}$ are restrictions to $\mathbb{R}^d$ of entire functions on $\mathbb{C}^d$. Let $\theta := \phi_{\mathbb{P}} - \phi_{\mathbb{Q}}$. Since $\gamma_k(\mathbb{P},\mathbb{Q}) = 0$, we have from (12) that $\int_{\mathbb{R}^d} |\theta(\omega)|^2 d\Lambda(\omega) = 0$. From Remark 17, it follows that $\mathrm{supp}(\theta) \subset \mathrm{cl}(\mathbb{R}^d \backslash \mathrm{supp}(\Lambda))$. Since $\mathrm{supp}(\Lambda)$ has a non-empty interior, we have $\mathrm{supp}(\theta) \subsetneq \mathbb{R}^d$. Thus, there exists an open set, $U \subset \mathbb{R}^d$ such that $\theta(x) = 0, \forall x \in U$. Since θ is analytic on $\mathbb{R}^d$, we have $\theta = 0$, which means $\phi_{\mathbb{P}} = \phi_{\mathbb{Q}} \Rightarrow \mathbb{P} = \mathbb{Q}$, leading to a contradiction. So, there does not exist $\mathbb{P} \neq \mathbb{Q}, \mathbb{P}, \mathbb{Q} \in \mathscr{P}_1$ such that $\gamma_k(\mathbb{P},\mathbb{Q}) = 0$, and k is therefore characteristic to $\mathscr{P}_1$. ■

The condition that $\mathrm{supp}(\Lambda)$ has a non-empty interior is important for Theorem 12 to hold. In the following, we provide a simple example to show that $\mathbb{P} \neq \mathbb{Q}, \mathbb{P}, \mathbb{Q} \in \mathscr{P}_1$ can be constructed such that $\gamma_k(\mathbb{P},\mathbb{Q}) = 0$, if k is a periodic translation invariant kernel for which $\mathrm{int}(\mathrm{supp}(\Lambda)) = \emptyset$.

Example 5 *Let* $\mathbb{Q}$ *be a uniform distribution on* $[-\beta,\beta] \subset \mathbb{R}$, *that is,* $q(x) = \frac{1}{2\beta}\mathbb{1}_{[-\beta,\beta]}(x)$ *with its characteristic function,* $\phi_{\mathbb{Q}}(\omega) = \frac{1}{\beta\sqrt{2\pi}} \frac{\sin(\beta\omega)}{\omega} \in L^2(\mathbb{R})$. *Let* ψ *be the Dirichlet kernel with period* τ, *where* $\tau \leq \beta$, *that is,* $\psi(x) = \frac{\sin\frac{(2l+1)\pi x}{\tau}}{\sin\frac{\pi x}{\tau}}$ *and* $\widehat{\psi}(\omega) = \sqrt{2\pi}\sum_{j=-l}^{l} \delta\left(\omega - \frac{2\pi j}{\tau}\right)$ *with* $\mathrm{supp}(\widehat{\psi}) = \left\{\frac{2\pi j}{\tau} : j \in \{0, \pm 1, \ldots, \pm l\}\right\}$. *Clearly,* $\mathrm{supp}(\widehat{\psi})$ *has an empty interior. Let* θ *be*

$$\theta(\omega) = \frac{8\sqrt{2}\alpha}{i\sqrt{\pi}} \sin\left(\frac{\omega\tau}{2}\right) \frac{\sin^2\left(\frac{\omega\tau}{4}\right)}{\tau\omega^2},$$

with $\alpha \leq \frac{1}{2\beta}$. *It is easy to verify that* $\theta \in L^1(\mathbb{R}) \cap L^2(\mathbb{R}) \cap C_b(\mathbb{R})$, *so* θ *satisfies* (i) *in Lemma 16. Since* $\theta(\omega) = 0$ *at* $\omega = \frac{2\pi l}{\tau}$, $l \in \mathbb{Z}$, $\mathrm{supp}(\theta) \cap \mathrm{supp}(\widehat{\psi}) \subset \mathrm{supp}(\widehat{\psi})$ *is a set of Lebesgue measure zero, so* (iii) *and* (iv) *in Lemma 16 are satisfied.* $\theta^\vee$ *is given by*

$$\theta^\vee(x) = \begin{cases} \frac{2\alpha\left|x+\frac{\tau}{2}\right|}{\tau} - \alpha, & -\tau \leq x \leq 0 \\ \alpha - \frac{2\alpha\left|x-\frac{\tau}{2}\right|}{\tau}, & 0 \leq x \leq \tau \\ 0, & \text{otherwise,} \end{cases}$$

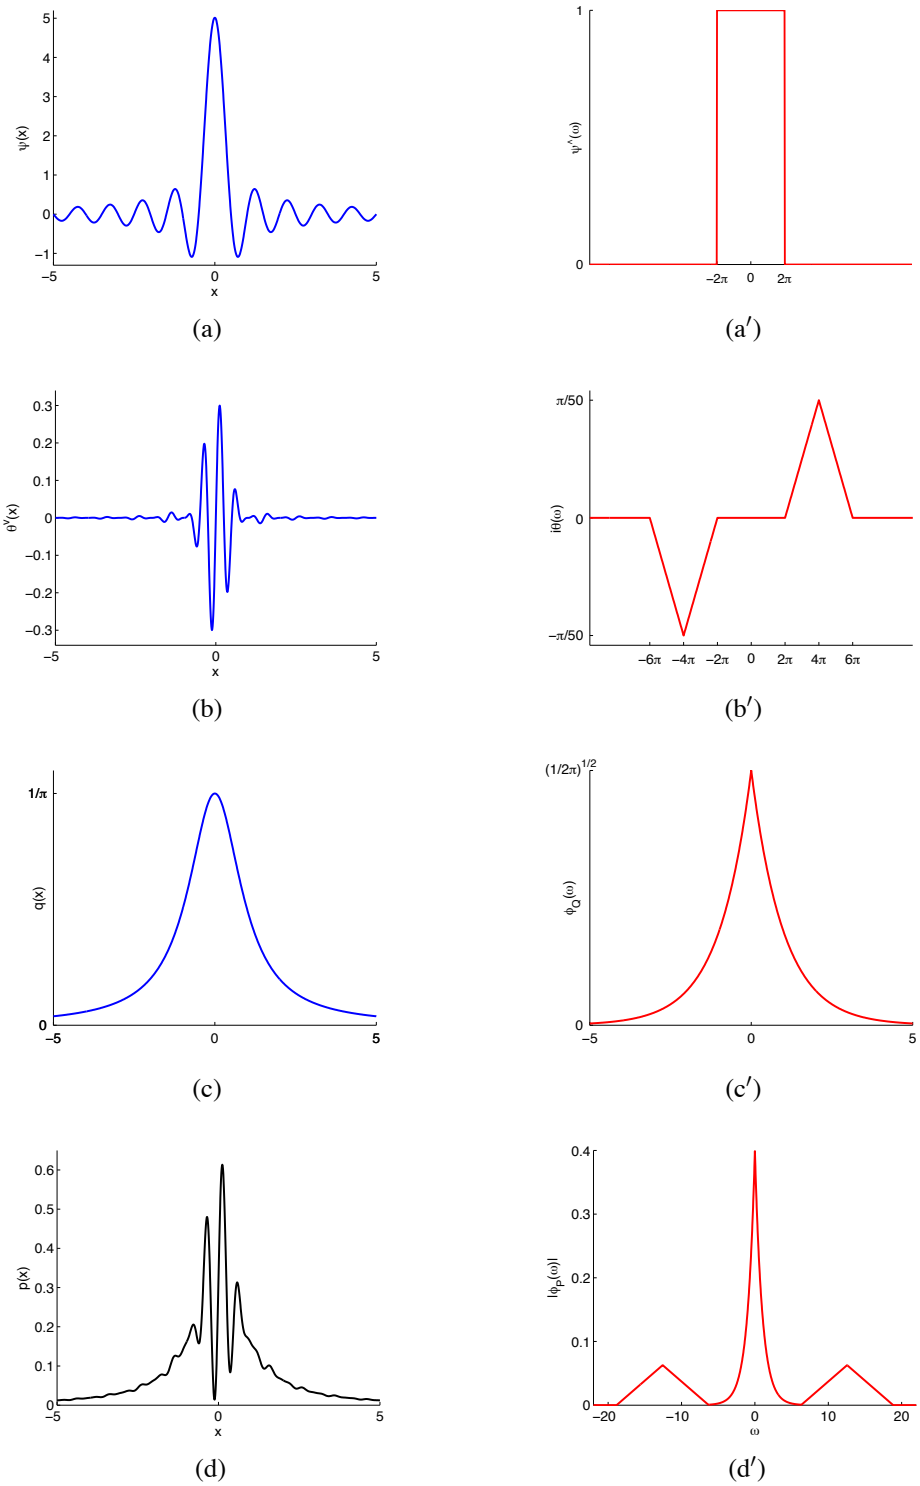

Figure 2: (a-a′) ψ and its Fourier spectrum $\widehat{\psi}$, (b-b′) $\theta^\vee$ and $i\theta$, (c-c′) the Cauchy distribution, q and its characteristic function $\phi_{\mathbb{Q}}$, and (d-d′) $p = q + \theta^\vee$ and $|\phi_{\mathbb{P}}|$. See Example 4 for details.

where $\theta^\vee \in L^1(\mathbb{R}) \cap L^2(\mathbb{R}) \cap C_b(\mathbb{R})$ *satisfies* (ii) *in Lemma 16. Now, consider* $p = q + \theta^\vee$, *which is given as*

$$p(x) = \begin{cases} \frac{1}{2\beta}, & x \in [-\beta, -\tau] \cup [\tau, \beta] \\ \frac{2\alpha\left|x+\frac{\tau}{2}\right|}{\tau} + \frac{1}{2\beta} - \alpha, & x \in [-\tau, 0] \\ \alpha + \frac{1}{2\beta} - \frac{2\alpha\left|x-\frac{\tau}{2}\right|}{\tau}, & x \in [0, \tau] \\ 0, & \text{otherwise}. \end{cases}$$

Clearly, $p(x) \geq 0, \forall x$ *and* $\int_{\mathbb{R}} p(x)\,dx = 1$. $\phi_{\mathbb{P}} = \phi_{\mathbb{Q}} + \theta = \phi_{\mathbb{Q}} + i\theta_I$ *where* $\theta_I = \mathrm{Im}[\theta]$ *and* $\phi_{\mathbb{P}} \in L^2(\mathbb{R})$. *We have therefore constructed* $\mathbb{P} \neq \mathbb{Q}$, *such that* $\gamma_k(\mathbb{P}, \mathbb{Q}) = 0$, *where* $\mathbb{P}$ *and* $\mathbb{Q}$ *are compactly supported in* $\mathbb{R}$ *with characteristic functions in* $L^2(\mathbb{R})$, *that is,* $\mathbb{P}, \mathbb{Q} \in \mathscr{P}_1$. *Figure 3 shows the plots of* ψ, $\widehat{\psi}$, θ, $\theta^\vee$, q, $\phi_{\mathbb{Q}}$, p *and* $|\phi_{\mathbb{P}}|$ *for* $\tau = 2$, $l = 2$, $\beta = 3$ *and* $\alpha = \frac{1}{8}$.

We now present the proof of Theorem 14, which is similar to that of Theorem 9.

Proof (Theorem 14) ($\Leftarrow$) From (10), we have

$$\begin{aligned} \gamma_k^2(\mathbb{P}, \mathbb{Q}) &= \iint_{\mathbb{T}^d} \psi(x-y)\,d(\mathbb{P}-\mathbb{Q})(x)\,d(\mathbb{P}-\mathbb{Q})(y) \\ &\overset{(a)}{=} \iint_{\mathbb{T}^d} \sum_{n\in\mathbb{Z}^d} A_\psi(n)\, e^{i(x-y)^T n}\,d(\mathbb{P}-\mathbb{Q})(x)\,d(\mathbb{P}-\mathbb{Q})(y) \\ &\overset{(b)}{=} \sum_{n\in\mathbb{Z}^d} A_\psi(n) \left| \int_{\mathbb{T}^d} e^{-ix^T n}\,d(\mathbb{P}-\mathbb{Q})(x) \right|^2 \\ &\overset{(c)}{=} (2\pi)^{2d} \sum_{n\in\mathbb{Z}^d} A_\psi(n)\,|A_{\mathbb{P}}(n) - A_{\mathbb{Q}}(n)|^2, \end{aligned} \tag{21}$$

where we have invoked Bochner's theorem (Theorem 13) in (a), Fubini's theorem in (b) and

$$A_{\mathbb{P}}(n) := \frac{1}{(2\pi)^d} \int_{\mathbb{T}^d} e^{-in^T x}\,d\mathbb{P}(x),\ n \in \mathbb{Z}^d,$$

in (c). $A_{\mathbb{P}}$ is the Fourier transform of $\mathbb{P}$ in $\mathbb{T}^d$. Since $A_\psi(0) \geq 0$ and $A_\psi(n) > 0, \forall n \neq 0$, we have $A_{\mathbb{P}}(n) = A_{\mathbb{Q}}(n), \forall n$. Therefore, by the uniqueness theorem of Fourier transform, we have $\mathbb{P} = \mathbb{Q}$.

($\Rightarrow$) Proving the necessity is equivalent to proving that if $A_\psi(0) \geq 0$, $A_\psi(n) > 0$, $\forall n \neq 0$ is violated, then k is not characteristic, which is equivalent to showing that $\exists\, \mathbb{P} \neq \mathbb{Q}$ such that $\gamma_k(\mathbb{P}, \mathbb{Q}) = 0$. Let $\mathbb{Q}$ be a uniform probability measure with $q(x) = \frac{1}{(2\pi)^d}, \forall x \in \mathbb{T}^d$. Let k be such that $A_\psi(n) = 0$ for some $n = n_0 \neq 0$. Define

$$A_{\mathbb{P}}(n) := \begin{cases} A_{\mathbb{Q}}(n), & n \neq \pm n_0 \\ A_{\mathbb{Q}}(n) + \theta(n), & n = \pm n_0 \end{cases},$$

where $A_{\mathbb{Q}}(n) = \frac{1}{(2\pi)^d}\delta_{0n}$ and $\theta(-n_0) = \overline{\theta(n_0)}$. So,

$$p(x) = \sum_{n\in\mathbb{Z}^d} A_{\mathbb{P}}(n) e^{ix^T n} = \frac{1}{(2\pi)^d} + \theta(n_0) e^{ix^T n_0} + \theta(-n_0) e^{-ix^T n_0}.$$

Choose $\theta(n_0) = i\alpha$, $\alpha \in \mathbb{R}$. Then, $p(x) = \frac{1}{(2\pi)^d} - 2\alpha \sin(x^T n_0)$. It is easy to check that p integrates to one. Choosing $|\alpha| \leq \frac{1}{2(2\pi)^d}$ ensures that $p(x) \geq 0, \forall x \in \mathbb{T}^d$. By using $A_{\mathbb{P}}(n)$ in (21), it is clear that $\gamma_k(\mathbb{P}, \mathbb{Q}) = 0$. Therefore, $\exists\, \mathbb{P} \neq \mathbb{Q}$ such that $\gamma_k(\mathbb{P}, \mathbb{Q}) = 0$, which means k is not characteristic. ■

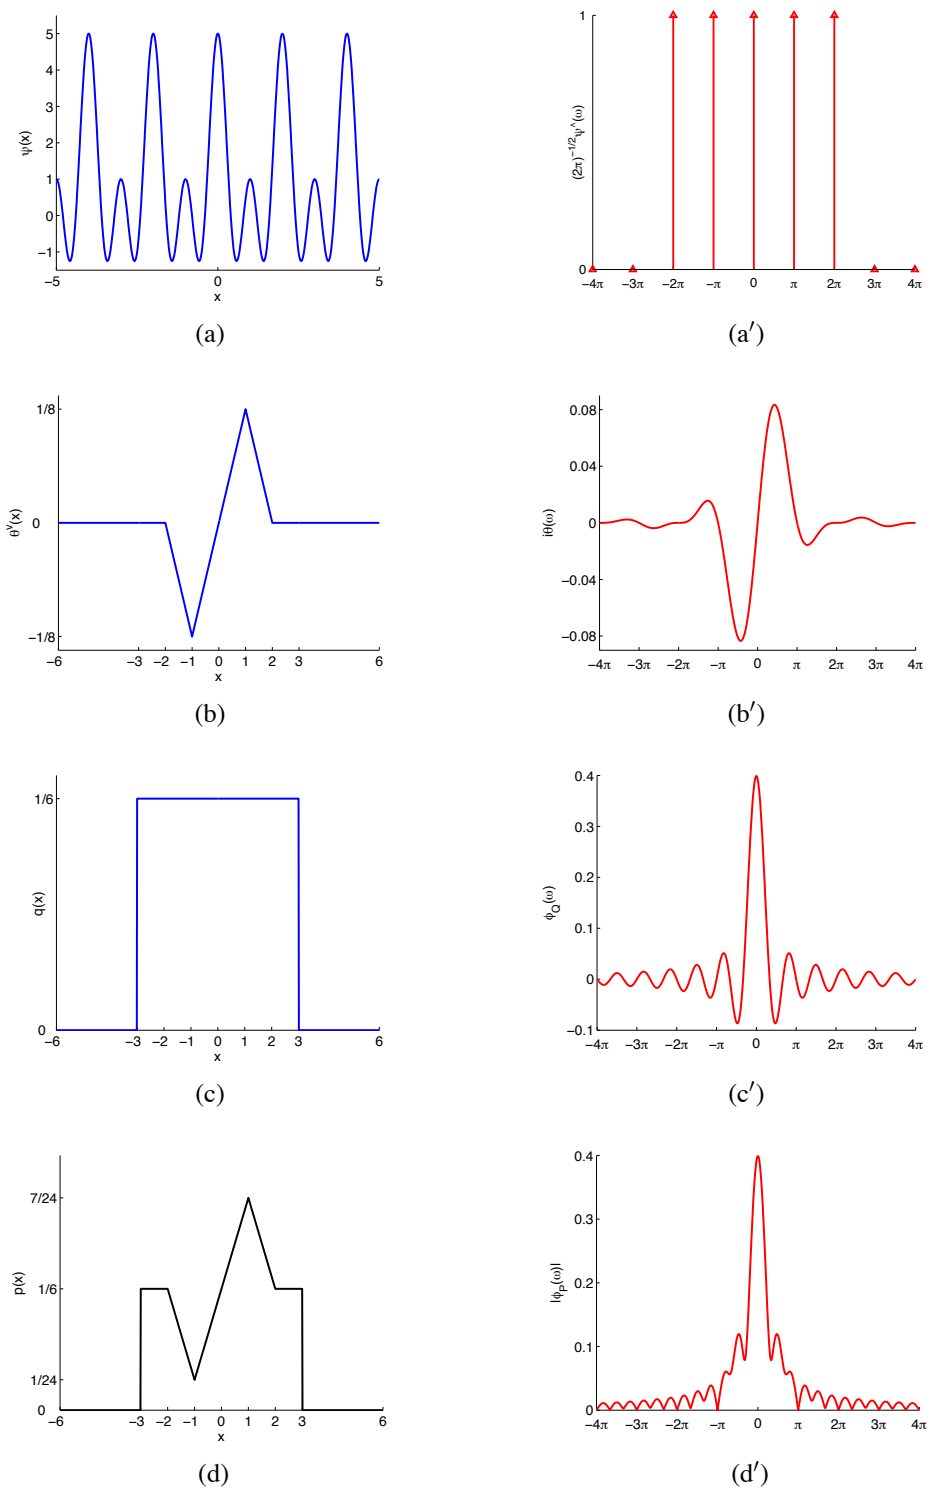

Figure 3: (a-a′) ψ and its Fourier spectrum $\widehat{\psi}$, (b-b′) $\theta^\vee$ and $i\theta$, (c-c′) the uniform distribution, q and its characteristic function $\phi_{\mathbb{Q}}$, and (d-d′) $p = q + \theta^\vee$ and $|\phi_{\mathbb{P}}|$. See Example 5 for details.

4. Dissimilar Distributions with Small γ_k

So far, we have studied different characterizations for the kernel k such that γ_k is a metric on $\mathscr{P}$. As mentioned in Section 1, the metric property of γ_k is crucial in many statistical inference applications like hypothesis testing. Therefore, in practice, it is important to use characteristic kernels. However, in this section, we show that characteristic kernels, while guaranteeing γ_k to be a metric on $\mathscr{P}$, may nonetheless have difficulty in distinguishing certain distributions on the basis of finite samples. More specifically, in Theorem 19 we show that for a given kernel k and for any $\varepsilon > 0$, there exist $\mathbb{P} \neq \mathbb{Q}$ such that $\gamma_k(\mathbb{P},\mathbb{Q}) < \varepsilon$. Before proving the result, we motivate it through the following example.

Example 6 *Let $\mathbb{P}$ be absolutely continuous w.r.t. the Lebesgue measure on $\mathbb{R}$ with the Radon-Nikodym derivative defined as*

$$p(x) = q(x) + \alpha q(x)\sin(\nu\pi x), \tag{22}$$

where q is the Radon-Nikodym derivative of $\mathbb{Q}$ w.r.t. the Lebesgue measure satisfying $q(x) = q(-x)$, $\forall x$ and $\alpha \in [-1,1]\backslash\{0\}$, $\nu \in \mathbb{R}\backslash\{0\}$. It is obvious that $\mathbb{P} \neq \mathbb{Q}$. The characteristic function of $\mathbb{P}$ is given as

$$\phi_{\mathbb{P}}(\omega) = \phi_{\mathbb{Q}}(\omega) - \frac{i\alpha}{2}\left[\phi_{\mathbb{Q}}(\omega-\nu\pi) - \phi_{\mathbb{Q}}(\omega+\nu\pi)\right], \omega \in \mathbb{R},$$

where $\phi_{\mathbb{Q}}$ is the characteristic function associated with $\mathbb{Q}$. Note that with increasing $|\nu|$, p has higher frequency components in its Fourier spectrum, as shown in Figure 4. In Figure 4, (a-c) show the plots of p when $q = \mathcal{U}[-1,1]$ (uniform distribution) and (a′-c′) show the plots of p when $q = \mathcal{N}(0,2)$ (zero mean normal distribution with variance 2) for $\nu = 0, 2$ and 7.5 with $\alpha = \frac{1}{2}$.

Consider the B_1-spline kernel on $\mathbb{R}$ given by $k(x,y) = \psi(x-y)$ where

$$\psi(x) = \begin{cases} 1-|x|, & |x| \leq 1 \\ 0, & \text{otherwise} \end{cases}, \tag{23}$$

with its Fourier transform given by

$$\widehat{\psi}(\omega) = \frac{2\sqrt{2}}{\sqrt{\pi}}\frac{\sin^2\frac{\omega}{2}}{\omega^2}.$$

Since ψ is characteristic to $\mathscr{P}$, $\gamma_k(\mathbb{P},\mathbb{Q}) > 0$ (see Theorem 9). However, it would be of interest to study the behavior of $\gamma_k(\mathbb{P},\mathbb{Q})$ as a function of ν. We study the behavior of $\gamma_k^2(\mathbb{P},\mathbb{Q})$ through its unbiased, consistent estimator,[7] $\gamma_{k,u}^2(m,m)$ as considered by Gretton et al. (2007b, Lemma 7).

Figure 5(a) shows the behavior of $\gamma_{k,u}^2(m,m)$ as a function of ν for $q = \mathcal{U}[-1,1]$ and $q = \mathcal{N}(0,2)$ using the B_1-spline kernel in (23). Since the Gaussian kernel, $k(x,y) = e^{-(x-y)^2}$ is also a characteristic kernel, its effect on the behavior of $\gamma_{k,u}^2(m,m)$ is shown in Figure 5(b) in comparison to that of the B_1-spline kernel.

In Figure 5, we observe two circumstances under which γ_k^2 may be small. First, $\gamma_{k,u}^2(m,m)$ decays with increasing $|\nu|$, and can be made as small as desired by choosing a sufficiently large $|\nu|$. Second,

7. Let $\{X_j\}_{j=1}^m$ and $\{Y_j\}_{j=1}^m$ be random samples drawn i.i.d. from $\mathbb{P}$ and $\mathbb{Q}$ respectively. An unbiased *empirical estimate* of $\gamma_k^2(\mathbb{P},\mathbb{Q})$, denoted as $\gamma_{k,u}^2(m,m)$ is given by $\gamma_{k,u}^2(m,m) = \frac{1}{m(m-1)}\sum_{l\neq j}^m h(Z_l,Z_j)$, which is a one-sample U-statistic with $h(Z_l,Z_j) := k(X_l,X_j) + k(Y_l,Y_j) - k(X_l,Y_j) - k(X_j,Y_l)$, where $Z_1,\ldots,Z_m$ are m i.i.d. random variables with $Z_j := (X_j,Y_j)$. See Gretton et al. (2007b, Lemma 7) for details.

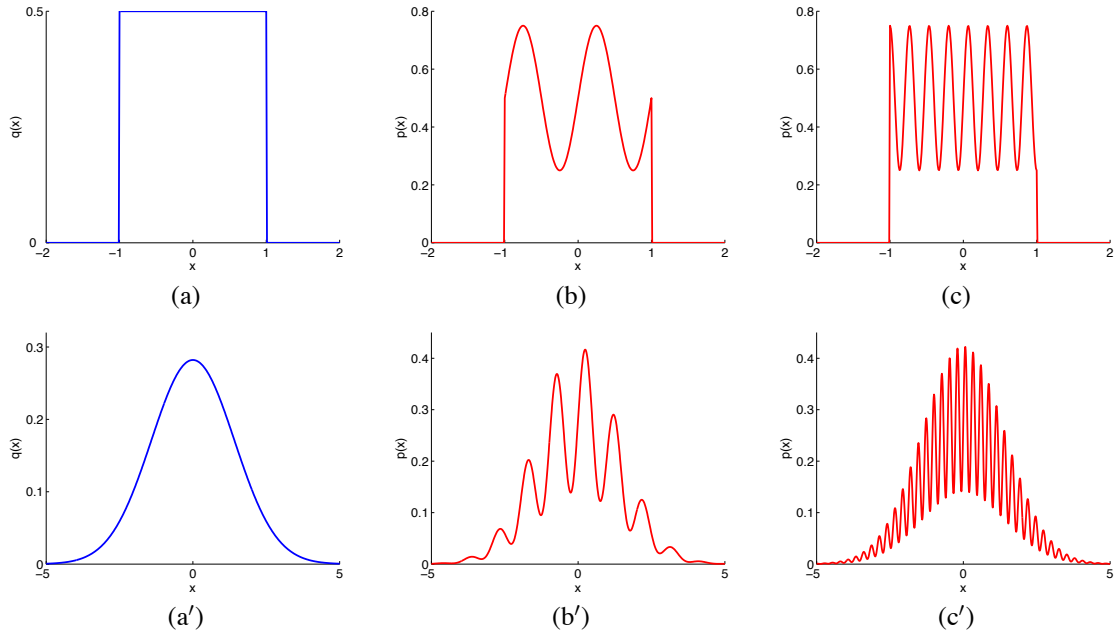

Figure 4: (a) $q = \mathcal{U}[-1,1]$, (a′) $q = \mathcal{N}(0,2)$. (b-c) and (b′-c′) denote $p(x)$ computed as $p(x) = q(x) + \frac{1}{2}q(x)\sin(\nu\pi x)$ with $q = \mathcal{U}[-1,1]$ and $q = \mathcal{N}(0,2)$ respectively. ν is chosen to be 2 in (b,b′) and 7.5 in (c,c′). See Example 6 for details.

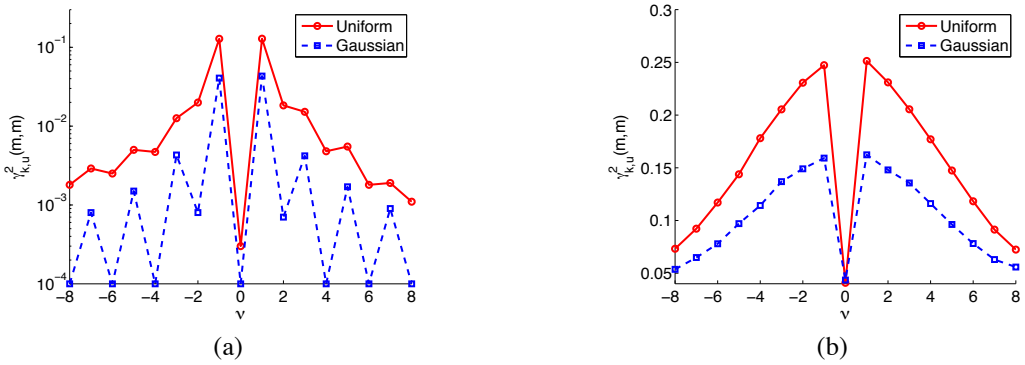

Figure 5: Behavior of the empirical estimate of $\gamma_k^2(\mathbb{P},\mathbb{Q})$ w.r.t. ν for (a) the B_1-spline kernel and (b) the Gaussian kernel. $\mathbb{P}$ is constructed from $\mathbb{Q}$ as defined in (22). "Uniform" corresponds to $\mathbb{Q} = \mathcal{U}[-1,1]$ and "Gaussian" corresponds to $\mathbb{Q} = \mathcal{N}(0,2)$. $m = 1000$ samples are generated from $\mathbb{P}$ and $\mathbb{Q}$ to estimate $\gamma_k^2(\mathbb{P},\mathbb{Q})$ through $\gamma_{k,u}^2(m,m)$. This is repeated 100 times and the average $\gamma_{k,u}^2(m,m)$ is plotted in both figures. Since the quantity of interest is the average behavior of $\gamma_{k,u}^2(m,m)$, we omit the error bars. See Example 6 for details.

in Figure 5(a), $\gamma_{k,u}^2(m,m)$ has troughs at $\nu = \frac{\omega_0}{\pi}$ where $\omega_0 = \{\omega : \widehat{\psi}(\omega) = 0\}$. Since $\gamma_{k,u}^2(m,m)$ is a consistent estimate of $\gamma_k^2(\mathbb{P},\mathbb{Q})$, one would expect similar behavior from $\gamma_k^2(\mathbb{P},\mathbb{Q})$. This means that, although the B_1-spline kernel is characteristic to $\mathscr{P}$, in practice, it becomes harder to distinguish

between $\mathbb{P}$ and $\mathbb{Q}$ with finite samples, when $\mathbb{P}$ is constructed as in (22) with $\nu = \frac{\omega_0}{\pi}$. In fact, one can observe from a straightforward spectral argument that the troughs in $\gamma_k^2(\mathbb{P},\mathbb{Q})$ can be made arbitrarily deep by widening q, when q is Gaussian.

For characteristic kernels, although $\gamma_k(\mathbb{P},\mathbb{Q}) > 0$ when $\mathbb{P} \neq \mathbb{Q}$, Example 6 demonstrates that one can construct distributions such that $\gamma_{k,u}^2(m,m)$ is indistinguishable from zero with high probability, for a given sample size m. Below, in Theorem 19, we explicitly construct $\mathbb{P} \neq \mathbb{Q}$ such that $|\mathbb{P}\varphi_l - \mathbb{Q}\varphi_l|$ is large for some large l, but $\gamma_k(\mathbb{P},\mathbb{Q})$ is arbitrarily small, making it hard to detect a non-zero value of $\gamma_k(\mathbb{P},\mathbb{Q})$ based on finite samples. Here, $\varphi_l \in L^2(M)$ represents the bounded orthonormal eigenfunctions of a positive definite integral operator associated with k. Based on this theorem, for example, in Example 6, the decay mode of γ_k for large $|\nu|$ can be investigated.

Consider the formulation of $\gamma_{\mathcal{F}}$ with $\mathcal{F} = \mathcal{F}_k$ in (1). The construction of $\mathbb{P}$ for a given $\mathbb{Q}$ such that $\gamma_k(\mathbb{P},\mathbb{Q})$ is small, though not zero, can be intuitively understood by re-writing (1) as

$$\gamma_k(\mathbb{P},\mathbb{Q}) = \sup_{f \in \mathcal{H}} \frac{|\mathbb{P}f - \mathbb{Q}f|}{\|f\|_{\mathcal{H}}}.$$

When $\mathbb{P} \neq \mathbb{Q}$, $|\mathbb{P}f - \mathbb{Q}f|$ can be large for some $f \in \mathcal{H}$. However, $\gamma_k(\mathbb{P},\mathbb{Q})$ can be made small by selecting $\mathbb{P}$ such that the maximization of $\frac{|\mathbb{P}f-\mathbb{Q}f|}{\|f\|_{\mathcal{H}}}$ over $\mathcal{H}$ requires an f with large $\|f\|_{\mathcal{H}}$. More specifically, higher order eigenfunctions of the kernel (φ_l for large l) have large RKHS norms, so, if they are prominent in $\mathbb{P}$ and $\mathbb{Q}$ (i.e., highly non-smooth distributions), one can expect $\gamma_k(\mathbb{P},\mathbb{Q})$ to be small even when there exists an l for which $|\mathbb{P}\varphi_l - \mathbb{Q}\varphi_l|$ is large. To this end, we need the following lemma, which we quote from Gretton et al. (2005b, Lemma 4).

Lemma 18 (Gretton et al., 2005b) *Let $\mathcal{F}$ be the unit ball in an RKHS $(\mathcal{H},k)$ defined on a compact topological space, M, with k being measurable. Let $\varphi_l \in L^2(M,\mu)$ be absolutely bounded orthonormal eigenfunctions and λ_l be the corresponding eigenvalues (arranged in decreasing order for increasing l) of a positive definite integral operator associated with k and a σ-finite measure, μ. Assume λ_l^{-1} increases super-linearly with l. Then, for $f \in \mathcal{F}$ where $f(x) = \sum_{j=1}^{\infty} \widetilde{f}_j \varphi_j(x)$, $\widetilde{f}_j := \langle f, \varphi_j \rangle_{L^2(M,\mu)}$, we have $\sum_{j=1}^{\infty} |\widetilde{f}_j| < \infty$ and for every $\varepsilon > 0$, $\exists\, l_0 \in \mathbb{N}$ such that $|\widetilde{f}_l| < \varepsilon$ if $l > l_0$.*

Theorem 19 ($\mathbb{P} \neq \mathbb{Q}$ can have arbitrarily small γ_k) *Suppose the conditions in Lemma 18 hold. Then there exist probability measures $\mathbb{P} \neq \mathbb{Q}$ defined on M such that $\gamma_k(\mathbb{P},\mathbb{Q}) < \varepsilon$ for any arbitrarily small $\varepsilon > 0$.*

Proof Suppose q be the Radon-Nikodym derivative associated with $\mathbb{Q}$ w.r.t. the σ-finite measure, μ (see Lemma 18). Let us construct $p(x) = q(x) + \alpha_l e(x) + \tau\varphi_l(x)$ where $e(x) = \mathbb{1}_M(x)$. For $\mathbb{P}$ to be a probability measure, the following conditions need to be satisfied:

$$\begin{aligned} \int_M [\alpha_l e(x) + \tau\varphi_l(x)]\, d\mu(x) &= 0, \\ \min_{x \in M} [q(x) + \alpha_l e(x) + \tau\varphi_l(x)] &\geq 0. \end{aligned} \tag{24}$$

Expanding $e(x)$ and $f(x)$ in the orthonormal basis $\{\varphi_l\}_{l=1}^{\infty}$, we get $e(x) = \sum_{l=1}^{\infty} \widetilde{e}_l \varphi_l(x)$ and $f(x) = \sum_{l=1}^{\infty} \widetilde{f}_l \varphi_l(x)$, where $\widetilde{e}_l := \langle e, \varphi_l \rangle_{L^2(M,\mu)}$ and $\widetilde{f}_l := \langle f, \varphi_l \rangle_{L^2(M,\mu)}$. Therefore,

$$\begin{aligned} \mathbb{P}f - \mathbb{Q}f &= \int_M f(x)\, [\alpha_l e(x) + \tau\varphi_l(x)]\, d\mu(x) \\ &= \int_M \left[\alpha_l \sum_{j=1}^{\infty} \widetilde{e}_j \varphi_j(x) + \tau\varphi_l(x)\right] \left[\sum_{t=1}^{\infty} \widetilde{f}_t \varphi_t(x)\right] d\mu(x) = \alpha_l \sum_{j=1}^{\infty} \widetilde{e}_j \widetilde{f}_j + \tau \widetilde{f}_l, \end{aligned} \tag{25}$$

where we used the fact that $\langle \varphi_j, \varphi_t \rangle_{L^2(M,\mu)} = \delta_{jt}$ (here, δ is used in the Kronecker sense). Rewriting (24) and substituting for $e(x)$ gives

$$\int_M [\alpha_l e(x) + \tau\varphi_l(x)]\, d\mu(x) = \int_M e(x)[\alpha_l e(x) + \tau\varphi_l(x)]\, d\mu(x) = \alpha_l \sum_{j=1}^{\infty} \widetilde{e}_j^2 + \tau\widetilde{e}_l = 0,$$

which implies

$$\alpha_l = -\frac{\tau\widetilde{e}_l}{\sum_{j=1}^{\infty} \widetilde{e}_j^2}. \tag{26}$$

Now, let us consider $\mathbb{P}\varphi_t - \mathbb{Q}\varphi_t = \alpha_l \widetilde{e}_t + \tau\delta_{tl}$. Substituting for α_l gives

$$\mathbb{P}\varphi_t - \mathbb{Q}\varphi_t = \tau\delta_{tl} - \tau\frac{\widetilde{e}_t\widetilde{e}_l}{\sum_{j=1}^{\infty} \widetilde{e}_j^2} = \tau\delta_{tl} - \tau\rho_{tl},$$

where $\rho_{tl} := \frac{\widetilde{e}_t\widetilde{e}_l}{\sum_{j=1}^{\infty} \widetilde{e}_j^2}$. By Lemma 18, $\sum_{l=1}^{\infty} |\widetilde{e}_l| < \infty \Rightarrow \sum_{j=1}^{\infty} \widetilde{e}_j^2 < \infty$, and choosing large enough l gives $|\rho_{tl}| < \eta, \forall t$, for any arbitrary $\eta > 0$. Therefore, $|\mathbb{P}\varphi_t - \mathbb{Q}\varphi_t| > \tau - \eta$ for $t = l$ and $|\mathbb{P}\varphi_t - \mathbb{Q}\varphi_t| < \eta$ for $t \neq l$, which means $\mathbb{P} \neq \mathbb{Q}$. In the following, we prove that $\gamma_k(\mathbb{P}, \mathbb{Q})$ can be arbitrarily small, though non-zero.

Recall that $\gamma_k(\mathbb{P}, \mathbb{Q}) = \sup_{\|f\|_{\mathcal{H}} \leq 1} |\mathbb{P}f - \mathbb{Q}f|$. Substituting (26) in (25) and replacing $|\mathbb{P}f - \mathbb{Q}f|$ by (25) in $\gamma_k(\mathbb{P}, \mathbb{Q})$, we have

$$\gamma_k(\mathbb{P}, \mathbb{Q}) = \sup_{\{\widetilde{f}_j\}_{j=1}^{\infty}} \left\{ \tau \sum_{j=1}^{\infty} \nu_{jl} \widetilde{f}_j \ : \ \sum_{j=1}^{\infty} \frac{\widetilde{f}_j^2}{\lambda_j} \leq 1 \right\}, \tag{27}$$

where we used the definition of RKHS norm as $\|f\|_{\mathcal{H}} := \sum_{j=1}^{\infty} \frac{\widetilde{f}_j^2}{\lambda_j}$ and $\nu_{jl} := \delta_{jl} - \rho_{jl}$. (27) is a convex quadratically constrained quadratic program in $\{\widetilde{f}_j\}_{j=1}^{\infty}$. Solving the Lagrangian yields $\widetilde{f}_j = \frac{\nu_{jl}\lambda_j}{\sqrt{\sum_{j=1}^{\infty} \nu_{jl}^2 \lambda_j}}$. Therefore,

$$\gamma_k(\mathbb{P}, \mathbb{Q}) = \tau \sqrt{\sum_{j=1}^{\infty} \nu_{jl}^2 \lambda_j} = \tau \sqrt{\lambda_l - 2\rho_{ll}\lambda_l + \sum_{j=1}^{\infty} \rho_{jl}^2 \lambda_j} \xrightarrow{l \to \infty} 0,$$

because *(i)* by choosing sufficiently large l, $|\rho_{jl}| < \varepsilon, \forall\, j$, for any arbitrary $\varepsilon > 0$, and *(ii)* $\lambda_l \to 0$ as $l \to \infty$ (Schölkopf and Smola, 2002, Theorem 2.10). Therefore, we have constructed $\mathbb{P} \neq \mathbb{Q}$ such that $\gamma_k(\mathbb{P}, \mathbb{Q}) < \varepsilon$ for any arbitrarily small $\varepsilon > 0$. ■

5. Metrization of the Weak Topology

So far, we have shown that a characteristic kernel k induces a metric γ_k on $\mathscr{P}$. As motivated in Section 1.1.3, an important question to consider that is useful both in theory and practice would be: "How strong or weak is γ_k related to other metrics on $\mathscr{P}$?" This question is addressed in Theorem 21, where we compare γ_k to other metrics on $\mathscr{P}$ like the Dudley metric (β), Wasserstein distance (W), total variation distance (TV), and show that γ_k is weaker than all these metrics (see Footnote 3 for the definition of "strong" and "weak" metrics). Since γ_k is weaker than the Dudley metric, which

is known to induce a topology on $\mathscr{P}$ that coincides with the standard topology on $\mathscr{P}$, called the weak-* (weak-star) topology (usually called the weak topology in probability theory), the next question we are interested in is to understand the topology that is being induced by γ_k. In particular, we are interested in determining the conditions on k for which the topology induced by γ_k coincides with the weak topology on $\mathscr{P}$. This is answered in Theorems 23 and 24, where Theorem 23 deals with compact M and Theorem 24 provides a sufficient condition on k when $M = \mathbb{R}^d$. The proofs of all these results are provided in Section 5.1. Before we motivate the need for this study and its implications, we present some preliminaries.

The *weak topology* on $\mathscr{P}$ is the weakest topology such that the map $\mathbb{P} \mapsto \int_M f\,d\mathbb{P}$ is continuous for all $f \in C_b(M)$. For a metric space (M,ρ), a sequence $\mathbb{P}_n$ of probability measures is said to *converge weakly* to $\mathbb{P}$, written as $\mathbb{P}_n \xrightarrow{w} \mathbb{P}$, if and only if $\int_M f\,d\mathbb{P}_n \to \int_M f\,d\mathbb{P}$ for every $f \in C_b(M)$. A metric γ on $\mathscr{P}$ is said to *metrize* the weak topology if the topology induced by γ coincides with the weak topology, which is defined as follows: if, for $\mathbb{P},\mathbb{P}_1,\mathbb{P}_2,\ldots \in \mathscr{P}$, $(\mathbb{P}_n \xrightarrow{w} \mathbb{P} \Leftrightarrow \gamma(\mathbb{P}_n,\mathbb{P}) \xrightarrow{n\to\infty} 0)$ holds, then the topology induced by γ coincides with the weak topology.

In the following, we collect well-known results on the relation between various metrics on $\mathscr{P}$, which will be helpful in understanding the behavior of these metrics, both with respect to each other and to ours. Let (M,ρ) be a separable metric space. The *Prohorov metric* on (M,ρ), defined as

$$\varsigma(\mathbb{P},\mathbb{Q}) := \inf\{\varepsilon > 0 : \mathbb{P}(A) \le \mathbb{Q}(A^\varepsilon) + \varepsilon, \forall \text{Borel sets } A\},$$

metrizes the weak topology on $\mathscr{P}$ (Dudley, 2002, Theorem 11.3.3), where $\mathbb{P},\mathbb{Q} \in \mathscr{P}$ and $A^\varepsilon := \{y \in M : \rho(x,y) < \varepsilon \text{ for some } x \in A\}$. Since the Dudley metric is related to the Prohorov metric as

$$\frac{1}{2}\beta(\mathbb{P},\mathbb{Q}) \le \varsigma(\mathbb{P},\mathbb{Q}) \le 2\sqrt{\beta(\mathbb{P},\mathbb{Q})}, \tag{28}$$

it also metrizes the weak topology on $\mathscr{P}$ (Dudley, 2002, Theorem 11.3.3). The Wasserstein distance and total variation distance are related to the Prohorov metric as

$$\varsigma^2(\mathbb{P},\mathbb{Q}) \le W(\mathbb{P},\mathbb{Q}) \le (\operatorname{diam}(M)+1)\varsigma(\mathbb{P},\mathbb{Q}), \tag{29}$$

and

$$\varsigma(\mathbb{P},\mathbb{Q}) \le TV(\mathbb{P},\mathbb{Q}),$$

where $\operatorname{diam}(M) := \sup\{\rho(x,y) : x,y \in M\}$ (Gibbs and Su, 2002, Theorem 2). This means W and TV are stronger than ς, while W and ς are equivalent (i.e., induce the same topology) when M is bounded. By Theorem 4 in Gibbs and Su (2002), TV and W are related as

$$W(\mathbb{P},\mathbb{Q}) \le \operatorname{diam}(M) TV(\mathbb{P},\mathbb{Q}),$$

which means W and TV are comparable if M is bounded. See Shorack (2000, Chapter 19, Theorem 2.4) and Gibbs and Su (2002) for further detail on the relationship between various metrics on $\mathscr{P}$.

Let us now consider a sequence of of probability measures on $\mathbb{R}$, $\mathbb{P}_n := \left(1-\frac{1}{n}\right)\delta_0 + \frac{1}{n}\delta_n$ and let $\mathbb{P} := \delta_0$. It can be shown that $\beta(\mathbb{P}_n,\mathbb{P}) \to 0$ as $n \to \infty$ which means $\mathbb{P}_n \xrightarrow{w} \mathbb{P}$, while $W(\mathbb{P}_n,\mathbb{P}) = 1$ and $TV(\mathbb{P}_n,\mathbb{P}) = 1$ for all n. $\gamma_k(\mathbb{P}_n,\mathbb{P})$ can be computed as

$$\gamma_k^2(\mathbb{P}_n,\mathbb{P}) = \frac{1}{n^2}\iint_{\mathbb{R}} k(x,y)\,d(\delta_0-\delta_n)(x)\,d(\delta_0-\delta_n)(y) = \frac{k(0,0)+k(n,n)-2k(0,n)}{n^2}.$$

If k is, for example, a Gaussian, Laplacian or inverse multiquadratic kernel, then $\gamma_k(\mathbb{P}_n, \mathbb{P}) \to 0$ as $n \to \infty$. This example shows that γ_k is weaker than W and TV. It also shows that, for certain choices of k, γ_k behaves similarly to β, which leads to several questions: Does γ_k metrize the weak topology on $\mathscr{P}$? What is the general behavior of γ_k compared to other metrics? In other words, depending on k, how weak or strong is γ_k compared to other metrics on $\mathscr{P}$? Understanding the answer to these questions is important both in theory and practice. If k is such that γ_k metrizes the weak topology on $\mathscr{P}$, then it can be used as a theoretical tool in probability theory, similar to the Prohorov and Dudley metrics. On the other hand, the answer to these questions is critical in applications as it will have a bearing on the choice of kernels to be used. In applications like density estimation, one would need a strong metric to ascertain that the density estimate is a good representation of the true underlying density. For this reason, the total variation distance, Hellinger distance or Kullback-Leibler distance are generally used. However, it is not always possible to show the convergence of a density estimate to the true underlying density using a stronger metric and so, in such cases, one would need a weak metric to analyze the quality of estimate. Therefore, studying the relation between γ_k and these other metrics will provide an understanding of the choice of kernels to be used, depending on the application.

With the above motivation, we first compare γ_k to β, W and TV. Since β is equivalent to ς, we do not compare γ_k to ς. Before we provide the main result in Theorem 21 that compares γ_k to other metrics, we present an upper bound on γ_k in terms of the coupling formulation (Dudley, 2002, Section 11.8), which is not only useful in deriving the main result but also interesting in its own right.

Proposition 20 (Coupling bound) *Let k be measurable and bounded on M. Then, for any $\mathbb{P}, \mathbb{Q} \in \mathscr{P}$,*

$$\gamma_k(\mathbb{P}, \mathbb{Q}) \leq \inf_{\mu \in \mathcal{L}(\mathbb{P}, \mathbb{Q})} \iint_M \|k(\cdot, x) - k(\cdot, y)\|_{\mathcal{H}} d\mu(x, y), \tag{30}$$

where $\mathcal{L}(\mathbb{P}, \mathbb{Q})$ represents the set of all laws on $M \times M$ with marginals $\mathbb{P}$ and $\mathbb{Q}$.

Proof For any $\mu \in \mathcal{L}(\mathbb{P}, \mathbb{Q})$, we have

$$\begin{aligned} \left| \int_M f \, d(\mathbb{P} - \mathbb{Q}) \right| &= \left| \iint_M (f(x) - f(y)) \, d\mu(x, y) \right| \leq \iint_M |f(x) - f(y)| \, d\mu(x, y) \\ &= \iint_M |\langle f, k(\cdot, x) - k(\cdot, y) \rangle_{\mathcal{H}}| \, d\mu(x, y) \leq \|f\|_{\mathcal{H}} \iint_M \|k(\cdot, x) - k(\cdot, y)\|_{\mathcal{H}} d\mu(x, y). \end{aligned} \tag{31}$$

Taking the supremum over $f \in \mathcal{F}_k$ and the infimum over $\mu \in \mathcal{L}(\mathbb{P}, \mathbb{Q})$ in (31), where $\mathbb{P}, \mathbb{Q} \in \mathscr{P}$, gives the result in (30). ■

We now present the main result that compares γ_k to β, W and TV.

Theorem 21 (Comparison of γ_k to β, W and TV) *Assume $\sup_{x \in M} k(x, x) \leq C < \infty$, where k is measurable on M. Let*

$$\widetilde{\rho}(x, y) = \|k(\cdot, x) - k(\cdot, y)\|_{\mathcal{H}}. \tag{32}$$

Then, for any $\mathbb{P}, \mathbb{Q} \in \mathscr{P}$,

(i) $\gamma_k(\mathbb{P}, \mathbb{Q}) \leq W(\mathbb{P}, \mathbb{Q}) \leq \sqrt{\gamma_k^2(\mathbb{P}, \mathbb{Q}) + 4C}$ *if $(M, \widetilde{\rho})$ is separable.*

(ii) $\frac{\gamma_k(\mathbb{P},\mathbb{Q})}{(1+\sqrt{C})} \leq \beta(\mathbb{P},\mathbb{Q}) \leq 2(\gamma_k^2(\mathbb{P},\mathbb{Q})+4C)^{\frac{1}{3}}$ *if* $(M,\widetilde{\rho})$ *is separable.*

(iii) $\gamma_k(\mathbb{P},\mathbb{Q}) \leq \sqrt{C}\,TV(\mathbb{P},\mathbb{Q})$.

The proof is provided in Section 5.1. Below are some remarks on Theorem 21.

Remark 22 *(a) First, note that, since k is bounded,* $(M,\widetilde{\rho})$ *is a bounded metric space. In addition, the metric,* $\widetilde{\rho}$*, which depends on the kernel as in (32), is a Hilbertian metric*[8] *(Berg et al., 1984, Chapter 3, Section 3) on M. A popular example of such a metric is* $\widetilde{\rho}(x,y) = \|x-y\|_2$*, which can be obtained by choosing M to be a compact subset of* $\mathbb{R}^d$ *and* $k(x,y) = x^T y$.

(b) Theorem 21 shows that γ_k *is weaker than* β*, W and TV for the assumptions being made on k and* $\widetilde{\rho}$*. Note that the result holds irrespective of whether or not the kernel is characteristic, as we have not assumed anything about the kernel except it being measurable and bounded. Also, it is important to remember that the result holds when* $\widetilde{\rho}$ *is Hilbertian, as mentioned in (32) (see Remark 22(d)).*

(c) Apart from showing that γ_k *is weaker than* β*, W and TV, the result in Theorem 21 can be used to bound these metrics in terms of* γ_k*. For* β*, which is primarily of theoretical interest, we do not know a closed form expression, and likewise a closed form expression for W is known only for* $\mathbb{R}$ *(Vallander, 1973).*[9] *Since* γ_k *is easy to compute (see (9) and (10)), bounds on W can be obtained from Theorem 21 in terms of* γ_k*. A closed form expression for TV is available if* $\mathbb{P}$ *and* $\mathbb{Q}$ *have Radon-Nikodym derivatives w.r.t. a* σ*-finite measure. However, from Theorem 21, a simple lower bound can be obtained on TV in terms of* γ_k *for any* $\mathbb{P},\mathbb{Q} \in \mathscr{P}$.

(d) In Theorem 21, the kernel is fixed and $\widetilde{\rho}$ *is defined as in (32), which is a Hilbertian metric. On the other hand, suppose a Hilbertian metric* $\widetilde{\rho}$ *is given. Then the associated kernel k can be obtained from* $\widetilde{\rho}$ *(Berg et al., 1984, Chapter 3, Lemma 2.1) as*

$$k(x,y) = \frac{1}{2}[\widetilde{\rho}^2(x,x_0) + \widetilde{\rho}^2(y,x_0) - \widetilde{\rho}^2(x,y)],\ x,y,x_0 \in M, \tag{33}$$

which can then be used to compute γ_k.

The discussion so far has been devoted to relating γ_k to β, W and TV to understand the strength or weakness of γ_k w.r.t. these metrics. In a next step, we address the second question of when γ_k metrizes the weak topology on $\mathscr{P}$. This question would have been answered had the result in Theorem 21 shown that under some conditions on k, γ_k is equivalent to β. Since Theorem 21 does not help in this regard, we approach the problem differently. In the following, we provide two results related to the question. The first result states that when (M,ρ) is compact, γ_k induced by universal kernels metrizes the weak topology. In the second result, we relax the assumption of compactness but restrict ourselves to $M = \mathbb{R}^d$ and provide a sufficient condition on k such that γ_k metrizes the weak topology on $\mathscr{P}$. The proofs of both theorems are provided in Section 5.1.

Theorem 23 (Weak convergence-I) *Let* (M,ρ) *be a compact metric space. If k is universal, then* γ_k *metrizes the weak topology on* $\mathscr{P}$.

8. A metric ρ on M is said to be *Hilbertian* if there exists a Hilbert space, H and a mapping Φ such that $\rho(x,y) = \|\Phi(x) - \Phi(y)\|_H$, $\forall x,y \in M$. In our case, $H = \mathcal{H}$ and $\Phi : M \to \mathcal{H}, x \mapsto k(\cdot,x)$.
9. The explicit form for the Wasserstein distance is known for $(M,\rho(x,y)) = (\mathbb{R},|x-y|)$, and is $W(\mathbb{P},\mathbb{Q}) = \int_{\mathbb{R}} |F_{\mathbb{P}}(x) - F_{\mathbb{Q}}(x)|\,dx$, where $F_{\mathbb{P}}(x) = \mathbb{P}((-\infty,x])$. It is easy to show that this explicit form can be extended to $(\mathbb{R}^d, \|\cdot\|_1)$.

From Theorem 23, it is clear that γ_k is equivalent to ς, β and W (see (28) and (29)) when M is compact and k is universal.

Theorem 24 (Weak convergence-II) *Let $M = \mathbb{R}^d$ and $k(x,y) = \psi(x-y)$, where $\psi \in C_0(\mathbb{R}^d) \cap L^1(\mathbb{R}^d)$ is a real-valued bounded strictly positive definite function. If there exists an $l \in \mathbb{N}$ such that*

$$\int_{\mathbb{R}^d} \frac{1}{\widehat{\psi}(\omega)(1+\|\omega\|_2)^l}\, d\omega < \infty, \tag{34}$$

then γ_k metrizes the weak topology on $\mathscr{P}$.

The entire Matérn class of kernels in (18) satisfies the conditions of Theorem 24 and, therefore, the corresponding γ_k metrizes the weak topology on $\mathscr{P}$. Note that Gaussian kernels on $\mathbb{R}^d$ do not satisfy the condition in Theorem 24. The characterization of k for general non-compact domains M (not necessarily $\mathbb{R}^d$), such that γ_k metrizes the weak topology on $\mathscr{P}$, still remains an open problem.

5.1 Proofs

We now present the proofs of Theorems 21, 23 and 24.

Proof (Theorem 21) *(i)* When (M,ρ) is separable, $W(\mathbb{P},\mathbb{Q})$ has a coupling formulation (Dudley, 2002, p. 420), given as

$$W(\mathbb{P},\mathbb{Q}) = \inf_{\mu \in \mathcal{L}(\mathbb{P},\mathbb{Q})} \iint_M \rho(x,y)\, d\mu(x,y), \tag{35}$$

where $\mathbb{P},\mathbb{Q} \in \{\mathbb{P} \in \mathscr{P} : \int_M \rho(x,y)\, d\mathbb{P}(y) < \infty, \forall x \in M\}$. In our case $\rho(x,y) = \|k(\cdot,x) - k(\cdot,y)\|_{\mathcal{H}}$. In addition, (M,ρ) is bounded, which means (35) holds for all $\mathbb{P},\mathbb{Q} \in \mathscr{P}$. The lower bound therefore follows from (30). The upper bound can be obtained as follows. Consider $W(\mathbb{P},\mathbb{Q}) = \inf_{\mu \in \mathcal{L}(\mathbb{P},\mathbb{Q})} \iint_M \|k(\cdot,x) - k(\cdot,y)\|_{\mathcal{H}} d\mu(x,y)$, which can be bounded as

$$\begin{aligned}
W(\mathbb{P},\mathbb{Q}) &\leq \iint_M \|k(\cdot,x) - k(\cdot,y)\|_{\mathcal{H}} d\mathbb{P}(x)\, d\mathbb{Q}(y) \\
&\overset{(a)}{\leq} \left[\iint_M \|k(\cdot,x) - k(\cdot,y)\|^2_{\mathcal{H}} d\mathbb{P}(x)\, d\mathbb{Q}(y)\right]^{\frac{1}{2}} \\
&\leq \left[\int_M k(x,x)\, d(\mathbb{P}+\mathbb{Q})(x) - 2\iint_M k(x,y)\, d\mathbb{P}(x)\, d\mathbb{Q}(y)\right]^{\frac{1}{2}} \\
&\leq \left[\gamma_k^2(\mathbb{P},\mathbb{Q}) + \iint_M (k(x,x) - k(x,y))\, d(\mathbb{P}\otimes\mathbb{P} + \mathbb{Q}\otimes\mathbb{Q})(x,y)\right]^{\frac{1}{2}} \\
&\leq \sqrt{\gamma_k^2(\mathbb{P},\mathbb{Q}) + 4C},
\end{aligned} \tag{36}$$

where we have used Jensen's inequality (Folland, 1999, p. 109) in (a).

(ii) Let $\mathcal{F} := \{f : \|f\|_{\mathcal{H}} < \infty\}$ and $\mathcal{G} := \{f : \|f\|_{BL} < \infty\}$. For $f \in \mathcal{F}$, we have

$$\begin{aligned}
\|f\|_{BL} &= \sup_{x \neq y} \frac{|f(x) - f(y)|}{\rho(x,y)} + \sup_{x \in M} |f(x)| = \sup_{x \neq y} \frac{|\langle f, k(\cdot,x) - k(\cdot,y)\rangle_{\mathcal{H}}|}{\|k(\cdot,x) - k(\cdot,y)\|_{\mathcal{H}}} + \sup_{x \in M} |\langle f, k(\cdot,x)\rangle_{\mathcal{H}}| \\
&\leq (1 + \sqrt{C})\|f\|_{\mathcal{H}} < \infty,
\end{aligned}$$

which implies $f \in \mathcal{G}$ and, therefore, $\mathcal{F} \subset \mathcal{G}$. For any $\mathbb{P}, \mathbb{Q} \in \mathscr{P}$,

$$\begin{aligned}\gamma_k(\mathbb{P},\mathbb{Q}) &= \sup\{|\mathbb{P}f - \mathbb{Q}f| : f \in \mathcal{F}_k\} \\ &\leq \sup\{|\mathbb{P}f - \mathbb{Q}f| : \|f\|_{BL} \leq (1+\sqrt{C}), f \in \mathcal{F}\} \\ &\leq \sup\{|\mathbb{P}f - \mathbb{Q}f| : \|f\|_{BL} \leq (1+\sqrt{C}), f \in \mathcal{G}\} \\ &= (1+\sqrt{C})\beta(\mathbb{P},\mathbb{Q}).\end{aligned}$$

The upper bound is obtained as follows. For any $\mathbb{P}, \mathbb{Q} \in \mathscr{P}$, by Markov's inequality (Folland, 1999, Theorem 6.17), for all $\varepsilon > 0$, we have

$$\varepsilon^2 \mu(\|k(\cdot,X) - k(\cdot,Y)\|_{\mathcal{H}} > \varepsilon) \leq \iint_M \|k(\cdot,x) - k(\cdot,y)\|^2_{\mathcal{H}} d\mu(x,y),$$

where X and Y are distributed as $\mathbb{P}$ and $\mathbb{Q}$ respectively. Choose ε such that $\varepsilon^3 = \iint_M \|k(\cdot,x) - k(\cdot,y)\|^2_{\mathcal{H}} d\mu(x,y)$, such that $\mu(\|k(\cdot,X) - k(\cdot,Y)\|_{\mathcal{H}} > \varepsilon) \leq \varepsilon$. From the proof of Theorem 11.3.5 in Dudley (2002), when (M,ρ) is separable, we have

$$\mu(\rho(X,Y) \geq \varepsilon) < \varepsilon \Rightarrow \varsigma(\mathbb{P},\mathbb{Q}) \leq \varepsilon,$$

which implies that

$$\begin{aligned}\varsigma(\mathbb{P},\mathbb{Q}) &\leq \left(\inf_{\mu \in \mathcal{L}(\mathbb{P},\mathbb{Q})} \iint_M \|k(\cdot,x) - k(\cdot,y)\|^2_{\mathcal{H}} d\mu(x,y)\right)^{\frac{1}{3}} \\ &\leq \left(\iint_M \|k(\cdot,x) - k(\cdot,y)\|^2_{\mathcal{H}} d\mathbb{P}(x)\, d\mathbb{Q}(y)\right)^{\frac{1}{3}} \overset{(b)}{\leq} \left(\gamma_k^2(\mathbb{P},\mathbb{Q}) + 4C\right)^{\frac{1}{3}},\end{aligned}$$

where (b) follows from (36). The result follows from (28).

(iii) The proof of this result was presented in Sriperumbudur et al. (2009b) and is provided here for completeness. To prove the result, we use (30) and the coupling formulation for TV (Lindvall, 1992, p. 19), given as

$$\frac{1}{2} TV(\mathbb{P},\mathbb{Q}) = \inf_{\mu \in \mathcal{L}(\mathbb{P},\mathbb{Q})} \mu(X \neq Y),$$

where $\mathcal{L}(\mathbb{P},\mathbb{Q})$ is the set of all measures on $M \times M$ with marginals $\mathbb{P}$ and $\mathbb{Q}$. Here, X and Y are distributed as $\mathbb{P}$ and $\mathbb{Q}$ respectively. Consider

$$\|k(\cdot,x) - k(\cdot,y)\|_{\mathcal{H}} \leq \mathbb{1}_{\{x \neq y\}} \|k(\cdot,x) - k(\cdot,y)\|_{\mathcal{H}} \leq 2\sqrt{C}\mathbb{1}_{\{x \neq y\}}. \tag{37}$$

Taking expectations w.r.t. μ and the infimum over $\mu \in \mathcal{L}(\mathbb{P},\mathbb{Q})$ on both sides of (37) gives the desired result, which follows from (30). ■

Proof (Theorem 23) We need to show that for measures $\mathbb{P}, \mathbb{P}_1, \mathbb{P}_2, \ldots \in \mathscr{P}$, $\mathbb{P}_n \xrightarrow{w} \mathbb{P}$ if and only if $\gamma_k(\mathbb{P}_n,\mathbb{P}) \to 0$ as $n \to \infty$. One direction is trivial as $\mathbb{P}_n \xrightarrow{w} \mathbb{P}$ implies $\gamma_k(\mathbb{P}_n,\mathbb{P}) \to 0$ as $n \to \infty$. We prove the other direction as follows. Since k is universal, $\mathcal{H}$ is dense in $C_b(M)$, the space of bounded continuous functions, w.r.t. the uniform norm, that is, for any $f \in C_b(M)$ and every $\varepsilon > 0$, there exists a $g \in \mathcal{H}$ such that $\|f - g\|_\infty \leq \varepsilon$. Therefore,

$$\begin{aligned}|\mathbb{P}_n f - \mathbb{P}f| &= |\mathbb{P}_n(f-g) + \mathbb{P}(g-f) + (\mathbb{P}_n g - \mathbb{P}g)| \\ &\leq \mathbb{P}_n|f-g| + \mathbb{P}|f-g| + |\mathbb{P}_n g - \mathbb{P}g| \\ &\leq 2\varepsilon + |\mathbb{P}_n g - \mathbb{P}g| \leq 2\varepsilon + \|g\|_{\mathcal{H}} \gamma_k(\mathbb{P}_n,\mathbb{P}).\end{aligned}$$

Since $\gamma_k(\mathbb{P}_n, \mathbb{P}) \to 0$ as $n \to \infty$ and ε is arbitrary, $|\mathbb{P}_n f - \mathbb{P} f| \to 0$ for any $f \in C_b(M)$. ■

Proof (Theorem 24) As mentioned in the proof of Theorem 23, one direction of the proof is straightforward: $\mathbb{P}_n \xrightarrow{w} \mathbb{P} \Rightarrow \gamma_k(\mathbb{P}_n, \mathbb{P}) \to 0$ as $n \to \infty$. Let us consider the other direction. Since $\psi \in C_0(\mathbb{R}^d) \cap L^1(\mathbb{R}^d)$ is a strictly positive definite function, any $f \in \mathcal{H}$ satisfies (Wendland, 2005, Theorem 10.12)

$$\int_{\mathbb{R}^d} \frac{|\widehat{f}(\omega)|^2}{\widehat{\psi}(\omega)} d\omega < \infty.$$

Assume that

$$\sup_{\omega \in \mathbb{R}^d} (1 + \|\omega\|_2)^l |\widehat{f}(\omega)|^2 < \infty,$$

for any $l \in \mathbb{N}$, which means $f \in \mathscr{S}_d$. Let (34) be satisfied for some $l = l_0$. Then,

$$\begin{aligned} \int_{\mathbb{R}^d} \frac{|\widehat{f}(\omega)|^2}{\widehat{\psi}(\omega)} d\omega &= \int_{\mathbb{R}^d} \frac{|\widehat{f}(\omega)|^2 (1 + \|\omega\|_2)^{l_0}}{\widehat{\psi}(\omega)(1 + \|\omega\|_2)^{l_0}} d\omega \\ &\leq \sup_{\omega \in \mathbb{R}^d} (1 + \|\omega\|_2)^{l_0} |\widehat{f}(\omega)|^2 \int_{\mathbb{R}^d} \frac{1}{\widehat{\psi}(\omega)(1 + \|\omega\|_2)^{l_0}} d\omega < \infty, \end{aligned}$$

which means $f \in \mathcal{H}$, that is, if $f \in \mathscr{S}_d$, then $f \in \mathcal{H}$, which implies $\mathscr{S}_d \subset \mathcal{H}$. Note that $\mathscr{S}(\mathbb{R}^d)$ is dense in $C_0(\mathbb{R}^d)$. Since $\psi \in C_0(\mathbb{R}^d)$, we have $\mathcal{H} \subset C_0(\mathbb{R}^d)$ (see the proof of Theorem 4.61 in Steinwart and Christmann, 2008) and, therefore, $\mathcal{H}$ is dense in $C_0(\mathbb{R}^d)$ w.r.t. the uniform norm. Suppose $\mathbb{P}, \mathbb{P}_1, \mathbb{P}_2, \ldots \in \mathscr{P}$. Using a similar analysis as in the proof of Theorem 23, it can be shown that for any $f \in C_0(\mathbb{R}^d)$ and every $\varepsilon > 0$, there exists a $g \in \mathcal{H}$ such that $|\mathbb{P}_n f - \mathbb{P} f| \leq 2\varepsilon + |\mathbb{P}_n g - \mathbb{P} g|$. Since ε is arbitrary and $\gamma_k(\mathbb{P}_n, \mathbb{P}) \to 0$ as $n \to \infty$, the result follows. ■

6. Conclusion and Discussion

We have studied various properties associated with a pseudometric γ_k on $\mathscr{P}$, which is based on the Hilbert space embedding of probability measures. First, we studied the conditions on the kernel (called the characteristic kernel) under which γ_k is a metric, and showed that apart from universal kernels, a large family of bounded continuous kernels induces a metric on $\mathscr{P}$: (a) integrally strictly pd kernels and (b) translation invariant kernels on $\mathbb{R}^d$ and $\mathbb{T}^d$ that have the support of their Fourier transform to be $\mathbb{R}^d$ and $\mathbb{Z}^d$ respectively. Next, we showed that there exist distinct distributions which will be considered close according to γ_k (whether or not the kernel is characteristic), and thus may be hard to distinguish based on finite samples. Finally, we compared γ_k to other metrics on $\mathscr{P}$ and explicitly presented the conditions under which it induces a weak topology on $\mathscr{P}$. These results together provide a strong theoretical foundation for using the γ_k metric in both statistics and machine learning applications.

We now discuss two topics related to γ_k, concerning the choice of kernel parameter and kernels defined on $\mathscr{P}$.

An important question not covered in the present paper is how to choose a characteristic kernel. Let us consider the following setting: $M = \mathbb{R}^d$ and $k_\sigma(x, y) = \exp(-\sigma \|x - y\|_2^2)$, $\sigma \in \mathbb{R}_+$, a Gaussian kernel with σ as the bandwidth parameter. $\{k_\sigma : \sigma \in \mathbb{R}_+\}$ is the family of Gaussian kernels and $\{\gamma_{k_\sigma} : \sigma \in \mathbb{R}_+\}$ is the associated family of distance measures indexed by the kernel parameter, σ. Note that k_σ is characteristic for any $\sigma \in \mathbb{R}_{++}$ and, therefore, γ_{k_σ} is a metric on $\mathscr{P}$ for any $\sigma \in \mathbb{R}_{++}$.

In practice, one would prefer a single number that defines the distance between $\mathbb{P}$ and $\mathbb{Q}$. The question therefore to be addressed is how to choose an appropriate σ. Note that as $\sigma \to 0$, $k_\sigma \to 1$ and as $\sigma \to \infty$, $k_\sigma \to 0$ a.e., which means $\gamma_{k_\sigma}(\mathbb{P},\mathbb{Q}) \to 0$ as $\sigma \to 0$ or $\sigma \to \infty$ for all $\mathbb{P},\mathbb{Q} \in \mathscr{P}$. This behavior is also exhibited by $k_\sigma(x,y) = \exp(-\sigma\|x-y\|_1)$, $\sigma > 0$ and $k_\sigma(x,y) = \sigma^2/(\sigma^2 + \|x-y\|_2^2)$, $\sigma > 0$, which are also characteristic. This means choosing *sufficiently small* or *sufficiently large* σ (depending on $\mathbb{P}$ and $\mathbb{Q}$) makes $\gamma_{k_\sigma}(\mathbb{P},\mathbb{Q})$ arbitrarily small. Therefore, σ must be chosen appropriately in applications to effectively distinguish between $\mathbb{P}$ and $\mathbb{Q}$.

To this end, one can consider the following modification to γ_k, which yields a pseudometric on $\mathscr{P}$,

$$\gamma(\mathbb{P},\mathbb{Q}) = \sup\{\gamma_k(\mathbb{P},\mathbb{Q}) : k \in \mathcal{K}\} = \sup\{\|\mathbb{P}k - \mathbb{Q}k\|_{\mathcal{H}} : k \in \mathcal{K}\}. \tag{38}$$

Note that γ is the maximal RKHS distance between $\mathbb{P}$ and $\mathbb{Q}$ over a family, $\mathcal{K}$ of measurable and bounded positive definite kernels. It is easy to check that, if any $k \in \mathcal{K}$ is characteristic, then γ is a metric on $\mathscr{P}$. Examples for $\mathcal{K}$ include:

1. $\mathcal{K}_g := \left\{e^{-\sigma\|x-y\|_2^2}, x,y \in \mathbb{R}^d : \sigma \in \mathbb{R}_+\right\}$.
2. $\mathcal{K}_l := \left\{e^{-\sigma\|x-y\|_1}, x,y \in \mathbb{R}^d : \sigma \in \mathbb{R}_+\right\}$.
3. $\mathcal{K}_\psi := \left\{e^{-\sigma\psi(x,y)}, x,y \in M : \sigma \in \mathbb{R}_+\right\}$, where $\psi : M \times M \to \mathbb{R}$ is a negative definite kernel (Berg et al., 1984, Chapter 3).
4. $\mathcal{K}_{rbf} := \left\{\int_0^\infty e^{-\lambda\|x-y\|_2^2} d\mu_\sigma(\lambda), x,y \in \mathbb{R}^d, \mu_\sigma \in \mathscr{M}^+ : \sigma \in \Sigma \subset \mathbb{R}^d\right\}$, where $\mathscr{M}^+$ is the set of all finite nonnegative Borel measures, μ_σ on $\mathbb{R}_+$ that are not concentrated at zero, etc.
5. $\mathcal{K}_{lin} := \left\{k_\lambda = \sum_{j=1}^l \lambda_j k_j \,|\, k_\lambda \text{ is pd}, \sum_{j=1}^l \lambda_j = 1\right\}$, which is the linear combination of pd kernels $\{k_j\}_{j=1}^l$.
6. $\mathcal{K}_{con} := \left\{k_\lambda = \sum_{j=1}^l \lambda_j k_j \,|\, \lambda_j \geq 0, \sum_{j=1}^l \lambda_j = 1\right\}$, which is the convex combination of pd kernels $\{k_j\}_{j=1}^l$.

The idea and validity behind the proposal of γ in (38) can be understood from a Bayesian perspective, where we define a non-negative finite measure λ over $\mathcal{K}$, and average γ_k over that measure, that is, $\alpha(\mathbb{P},\mathbb{Q}) := \int_{\mathcal{K}} \gamma_k(\mathbb{P},\mathbb{Q})\, d\lambda(k)$. This also yields a pseudometric on $\mathscr{P}$. That said, $\alpha(\mathbb{P},\mathbb{Q}) \leq \lambda(\mathcal{K})\gamma(\mathbb{P},\mathbb{Q})$, $\forall\, \mathbb{P},\mathbb{Q}$, which means that, if $\mathbb{P}$ and $\mathbb{Q}$ can be distinguished by α, then they can be distinguished by γ, but not vice-versa. In this sense, γ is stronger than α and therefore studying γ makes sense. One further complication with the Bayesian approach is in defining a sensible λ over $\mathcal{K}$. Note that γ_{k_0} can be obtained by defining $\lambda(k) = \delta(k-k_0)$ in $\alpha(\mathbb{P},\mathbb{Q})$. Future work will include analyzing γ and investigating its utility in applications compared to that of γ_k (with a fixed kernel, k). Sriperumbudur et al. (2009a) describes preliminary work, showing that $\gamma(\mathbb{P}_m,\mathbb{Q}_n)$ is a $\sqrt{mn/(m+n)}$-consistent estimator of $\gamma(\mathbb{P},\mathbb{Q})$, for families of kernels $\mathcal{K}$ including those mentioned above.

We now discuss how kernels on $\mathscr{P}$ can be obtained from γ_k. As noted by Gretton et al. (2007b, Section 4), and following Hein et al. (2004), γ_k is a *Hilbertian metric* on $\mathscr{P}$: the associated kernel can be easily computed using (33),

$$K(\mathbb{P},\mathbb{Q}) = \left\langle \int_M k(\cdot,x)\, d\mathbb{P}(x), \int_M k(\cdot,x)\, d\mathbb{Q}(x) \right\rangle_{\mathcal{H}} = \int\int_M k(x,y)\, d\mathbb{P}(x)\, d\mathbb{Q}(y),$$

where the positive definite kernel $K : \mathscr{P} \times \mathscr{P} \to \mathbb{R}$ is a dot-product kernel on $\mathscr{P}$. Using the results in Berg et al. (1984, Chapter 3, Theorems 2.2 and 2.3), Gaussian and inverse multi-quadratic kernels on $\mathscr{P}$ can be defined as

$$K(\mathbb{P},\mathbb{Q}) = \exp\left(-\sigma\gamma_k^2(\mathbb{P},\mathbb{Q})\right), \sigma > 0 \text{ and } K(\mathbb{P},\mathbb{Q}) = \left(\sigma+\gamma_k^2(\mathbb{P},\mathbb{Q})\right)^{-1}, \sigma > 0$$

respectively. Further work on Hilbertian metrics and positive definite kernels on probability measures has been carried out by Hein and Bousquet (2005) and Fuglede and Topsøe (2003).

Acknowledgments

The authors thank the editor and reviewers for their constructive comments. B. K. S. and G. R. G. L. wish to acknowledge support from the Max Planck Institute (MPI) for Biological Cybernetics, the National Science Foundation (grant DMS-MSPA 0625409), the Fair Isaac Corporation and the University of California MICRO program. Part of this work was done while B. K. S. was an intern at the MPI, and part was done while A. G. was a project scientist at CMU, under grants DARPA IPTO FA8750-09-1-0141, ONR MURI N000140710747, and NSF NeTS-NOSS CNS-0625518. This work is also supported by the IST Program of the EC, under the FP7 Network of Excellence, ICT-216886-NOE. B. K. S. wishes to thank Agnes Radl for her comments on an earlier version of the manuscript.

Appendix A. Supplementary Results

For completeness, we present the supplementary results that were used to prove the results in this paper. The following result is quoted from Folland (1999, Theorem 8.14).

Theorem 25 *Suppose $\phi \in L^1(\mathbb{R}^d)$, $\int_{\mathbb{R}^d} \phi(x)\,dx = a$ and $\phi_t(x) = t^{-d}\phi(t^{-1}x)$ for $t > 0$. If f is bounded and uniformly continuous on $\mathbb{R}^d$, then $f * \phi_t \to af$ uniformly as $t \to 0$.*

By imposing slightly stronger conditions on ϕ, the following result quoted from Folland (1999, Theorem 8.15) shows that $f * \phi_t \to af$ almost everywhere for $f \in L^r(\mathbb{R}^d)$.

Theorem 26 *Suppose $|\phi(x)| \leq C(1 + \|x\|_2)^{-d-\varepsilon}$ for some $C, \varepsilon > 0$, and $\int_{\mathbb{R}^d} \phi(x)\,dx = a$. If $f \in L^r(\mathbb{R}^d)$ $(1 \leq r \leq \infty)$, then $f * \phi_t(x) \to af(x)$ as $t \to 0$ for every x in the Lebesgue set of f—in particular, for almost every x, and for every x at which f is continuous.*

Theorem 27 (Fourier transform of a measure) *Let μ be a finite Borel measure on $\mathbb{R}^d$. The Fourier transform of μ is given by*

$$\widehat{\mu}(\omega) = \int_{\mathbb{R}^d} e^{-i\omega^T x}\,d\mu(x),\ \omega \in \mathbb{R}^d,$$

which is a bounded, uniformly continuous function on $\mathbb{R}^d$. In addition, $\widehat{\mu}$ satisfies the following properties:

(i) $\overline{\widehat{\mu}(\omega)} = \widehat{\mu}(-\omega), \forall\, \omega \in \mathbb{R}^d$, *that is, $\widehat{\mu}$ is conjugate symmetric,*

(ii) $\widehat{\mu}(0) = 1$.

The following result, called the Riemann-Lebesgue lemma, is quoted from Rudin (1991, Theorem 7.5).

Lemma 28 (Riemann-Lebesgue) *If $f \in L^1(\mathbb{R}^d)$, then $\widehat{f} \in C_0(\mathbb{R}^d)$, and $\|\widehat{f}\|_\infty \leq \|f\|_1$.*

The following theorem is a version of the *Paley-Wiener theorem* for distributions, and is proved in Rudin (1991, Theorem 7.23).

Theorem 29 (Paley-Wiener) *If $f \in \mathscr{D}'_d$ has compact support, then $\widehat{f}$ is the restriction to $\mathbb{R}^d$ of an entire function on $\mathbb{C}^d$.*

Abstract

For undiscounted reinforcement learning in Markov decision processes (MDPs) we consider the *total regret* of a learning algorithm with respect to an optimal policy. In order to describe the transition structure of an MDP we propose a new parameter: An MDP has *diameter D* if for any pair of states s, s' there is a policy which moves from s to s' in at most D steps (on average). We present a reinforcement learning algorithm with total regret $\tilde{O}(DS\sqrt{AT})$ after T steps for any unknown MDP with S states, A actions per state, and diameter D. A corresponding lower bound of $\Omega(\sqrt{DSAT})$ on the total regret of any learning algorithm is given as well.

These results are complemented by a sample complexity bound on the number of suboptimal steps taken by our algorithm. This bound can be used to achieve a (gap-dependent) regret bound that is logarithmic in T.

Finally, we also consider a setting where the MDP is allowed to change a fixed number of ℓ times. We present a modification of our algorithm that is able to deal with this setting and show a regret bound of $\tilde{O}(\ell^{1/3}T^{2/3}DS\sqrt{A})$.

Keywords: undiscounted reinforcement learning, Markov decision process, regret, online learning, sample complexity

1. Introduction

In a Markov decision process (MDP) M with finite state space $\mathcal{S}$ and finite action space $\mathcal{A}$, a learner in some state $s \in \mathcal{S}$ needs to choose an action $a \in \mathcal{A}$. When executing action a in state s, the learner receives a random reward r drawn independently from some distribution on $[0,1]$ with mean $\bar{r}(s,a)$. Further, according to the transition probabilities $p(s'|s,a)$, a random transition to a state $s' \in \mathcal{S}$ occurs.

Reinforcement learning of MDPs is a standard model for learning with delayed feedback. In contrast to important other work on reinforcement learning—where the performance of the *learned* policy is considered (see, e.g., Sutton and Barto 1998, Kearns and Singh 1999, and also the discussion and references given in the introduction of Kearns and Singh 2002)—we are interested in the performance of the learning algorithm *during learning*. For that, we compare the rewards collected by the algorithm during learning with the rewards of an optimal policy.

*. An extended abstract of this paper appeared in *Advances in Neural Information Processing Systems* 21 (2009), pp. 89–96.

An algorithm $\mathfrak{A}$ starting in an initial state s of an MDP M chooses at each time step t (possibly randomly) an action a_t. As the MDP is assumed to be unknown except the sets $\mathcal{S}$ and $\mathcal{A}$, usually an algorithm will map the history up to step t to an action a_t or, more generally, to a probability distribution over $\mathcal{A}$. Thus, an MDP M and an algorithm $\mathfrak{A}$ operating on M with initial state s constitute a stochastic process described by the states s_t visited at time step t, the actions a_t chosen by $\mathfrak{A}$ at step t, and the rewards r_t obtained ($t \in \mathbb{N}$). In this paper we will consider *undiscounted* rewards. Thus, the *accumulated reward* of an algorithm $\mathfrak{A}$ after T steps in an MDP M with initial state s, defined as

$$R(M,\mathfrak{A},s,T) := \sum_{t=1}^{T} r_t,$$

is a random variable with respect to the mentioned stochastic process. The value $\frac{1}{T}\mathbb{E}[R(M,\mathfrak{A},s,T)]$ then is the expected average reward of the process up to step T. The limit

$$\rho(M,\mathfrak{A},s) := \lim_{T\to\infty} \tfrac{1}{T}\mathbb{E}[R(M,\mathfrak{A},s,T)]$$

is called the *average reward* and can be maximized by an appropriate stationary *policy* $\pi : \mathcal{S} \to \mathcal{A}$ which determines an optimal action for each state (see Puterman, 1994). Thus, in what follows we will usually consider policies to be stationary.

The difficulty of learning an optimal policy in an MDP does not only depend on the MDP's size (given by the number of states and actions), but also on its transition structure. In order to measure this transition structure we propose a new parameter, the *diameter D* of an MDP. The diameter D is the time it takes to move from any state s to any other state s', using an appropriate policy for each pair of states s, s':

Definition 1 *Consider the stochastic process defined by a stationary policy $\pi : \mathcal{S} \to \mathcal{A}$ operating on an MDP M with initial state s. Let $T(s'|M,\pi,s)$ be the random variable for the first time step in which state s' is reached in this process. Then the* diameter *of M is defined as*

$$D(M) := \max_{s\neq s'\in\mathcal{S}} \min_{\pi:\mathcal{S}\to\mathcal{A}} \mathbb{E}\left[T(s'|M,\pi,s)\right].$$

In Appendix A we show that the diameter is at least $\log_{|\mathcal{A}|}|\mathcal{S}| - 3$. On the other hand, depending on the existence of states that are hard to reach under any policy, the diameter may be arbitrarily large. (For a comparison of the diameter to other mixing time parameters see below.)

In any case, a finite diameter seems necessary for interesting bounds on the *regret* of any algorithm with respect to an optimal policy. When a learner explores suboptimal actions, this may take him into a "bad part" of the MDP from which it may take up to D steps to reach again a "good part" of the MDP. Thus, compared to the simpler multi-armed bandit problem where each arm a is typically explored $\frac{\log T}{g}$ times (depending on the gap g between the optimal reward and the reward for arm a)—see, for example, the regret bounds of Auer et al. (2002a) for the UCB algorithms and the lower bound of Mannor and Tsitsiklis (2004)—the best one would expect for the general MDP setting is a regret bound of $\Theta\big(D|\mathcal{S}||\mathcal{A}|\log T\big)$. The alternative gap-independent regret bounds of $\tilde{O}(\sqrt{|\mathcal{B}|T})$ and $\Omega(\sqrt{|\mathcal{B}|T})$ for multi-armed bandits with $|\mathcal{B}|$ arms (Auer et al., 2002b) correspondingly translate into a regret bound of $\Theta(\sqrt{D|\mathcal{S}||\mathcal{A}|T})$ for MDPs with diameter D.

For MDPs with finite diameter (which usually are called *communicating*, see, e.g., Puterman 1994) the optimal average reward ρ^* does not depend on the initial state (cf. Puterman 1994, Section 8.3.3), and we set

$$\rho^*(M) := \rho^*(M,s) := \max_{\pi} \rho(M,\pi,s).$$

The optimal average reward is the natural benchmark[1] for a learning algorithm $\mathfrak{A}$, and we define the *total regret* of $\mathfrak{A}$ after T steps as

$$\Delta(M,\mathfrak{A},s,T) := T\rho^*(M) - R(M,\mathfrak{A},s,T).$$

In the following, we present our reinforcement learning algorithm UCRL2 (a variant of the UCRL algorithm of Auer and Ortner, 2007) which uses upper confidence bounds to choose an optimistic policy. We show that the total regret of UCRL2 after T steps is $\tilde{O}(D|\mathcal{S}|\sqrt{|\mathcal{A}|T})$. A corresponding lower bound of $\Omega(\sqrt{D|\mathcal{S}||\mathcal{A}|T})$ on the total regret of any learning algorithm is given as well. These results establish the diameter as an important parameter of an MDP. Unlike other parameters that have been proposed for various PAC and regret bounds, such as the *mixing time* (Kearns and Singh, 2002; Brafman and Tennenholtz, 2002) or the *hitting time* of an optimal policy (Tewari and Bartlett, 2008) (cf. the discussion below) the diameter only depends on the MDP's transition structure.

1.1 Relation to Previous Work

We first compare our results to the PAC bounds for the well-known algorithms E^3 of Kearns and Singh (2002), and R-Max of Brafman and Tennenholtz (2002) (see also Kakade, 2003). These algorithms achieve ε-optimal average reward with probability $1-\delta$ after time polynomial in $\frac{1}{\delta}$, $\frac{1}{\varepsilon}$, $|\mathcal{S}|$, $|\mathcal{A}|$, and the mixing time $T_\varepsilon^{\text{mix}}$ (see below). As the polynomial dependence on ε is of order $\frac{1}{\varepsilon^3}$, the PAC bounds translate into $T^{2/3}$ regret bounds at the best. Moreover, both algorithms need the ε-*return mixing time* $T_\varepsilon^{\text{mix}}$ of an optimal policy π^* as input parameter.[2] This parameter $T_\varepsilon^{\text{mix}}$ is the number of steps until the average reward of π^* over these $T_\varepsilon^{\text{mix}}$ steps is ε-close to the optimal average reward ρ^*. It is easy to construct MDPs of diameter D with $T_\varepsilon^{\text{mix}} \approx \frac{D}{\varepsilon}$. This additional dependence on ε further increases the exponent in the above mentioned regret bounds for E^3 and R-max. Also, the exponents of the parameters $|\mathcal{S}|$ and $|\mathcal{A}|$ in the PAC bounds of Kearns and Singh (2002) and Brafman and Tennenholtz (2002) are substantially larger than in our bound. However, there are algorithms with better dependence on these parameters. Thus, in the sample complexity bounds for the Delayed Q-Learning algorithm of Strehl et al. (2006) the dependence on states and actions is of order $|\mathcal{S}||\mathcal{A}|$, however at the cost of a worse dependence of order $\frac{1}{\varepsilon^4}$ on ε.

The MBIE algorithm of Strehl and Littman (2005, 2008)—similarly to our approach—applies confidence bounds to compute an optimistic policy. However, Strehl and Littman consider only a discounted reward setting. Their definition of regret measures the difference between the rewards[3] of an optimal policy and the rewards of the learning algorithm *along the trajectory taken by the learning algorithm*. In contrast, we are interested in the regret of the learning algorithm in respect to the rewards of the optimal policy *along the trajectory of the optimal policy*.[4] Generally, in discounted reinforcement learning only a finite number of steps is relevant, depending on the discount

1. It can be shown that $\max_{\mathfrak{A}} \mathbb{E}[R(M,\mathfrak{A},s,T)] = T\rho^*(M) + O(D(M))$ and $\max_{\mathfrak{A}} R(M,\mathfrak{A},s,T) = T\rho^*(M) + \tilde{O}(\sqrt{T})$ with high probability.
2. The knowledge of this parameter can be eliminated by guessing $T_\varepsilon^{\text{mix}}$ to be $1,2,\ldots$, so that sooner or later the correct $T_\varepsilon^{\text{mix}}$ will be reached (cf. Kearns and Singh 2002; Brafman and Tennenholtz 2002). However, since there is no condition on when to stop increasing $T_\varepsilon^{\text{mix}}$, the assumed mixing time eventually becomes arbitrarily large, so that the PAC bounds become exponential in the true $T_\varepsilon^{\text{mix}}$ (cf. Brafman and Tennenholtz, 2002).
3. Actually, the state values.
4. Indeed, one can construct MDPs for which these two notions of regret differ significantly. E.g., set the discount factor $\gamma = 0$. Then any policy which maximizes immediate rewards achieves 0 regret in the notion of Strehl and Littman. But such a policy may not move to states where the optimal reward is obtained.

factor. This makes discounted reinforcement learning similar to the setting with trials of constant length from a fixed initial state as considered by Fiechter (1994). For this case logarithmic online regret bounds in the number of trials have already been given by Auer and Ortner (2005). Also, the notion of regret is less natural than in undiscounted reinforcement learning: when summing up the regret in the individual visited states to obtain the total regret in the discounted setting, somehow contrary to the principal idea of discounting, the regret at each time step counts the same.

Tewari and Bartlett (2008) propose a generalization of the *index policies* of Burnetas and Katehakis (1997). These index policies choose actions optimistically by using confidence bounds only for the estimates in the current state. The regret bounds for the *index policies* of Burnetas and Katehakis (1997) and the OLP algorithm of Tewari and Bartlett (2008) are *asymptotically* logarithmic in T. However, unlike our bounds, these bounds depend on the gap between the "quality" of the best and the second best action, and these asymptotic bounds also hide an additive term which is exponential in the number of states. Actually, it is possible to prove a corresponding gap-dependent logarithmic bound for our UCRL2 algorithm as well (cf. Theorem 4 below). This bound holds uniformly over time and under weaker assumptions: While Tewari and Bartlett (2008) and Burnetas and Katehakis (1997) consider only *ergodic* MDPs in which *any* policy will reach every state after a sufficient number of steps, we make only the more natural assumption of a finite diameter.

Recently, Bartlett and Tewari (2009) have introduced the REGAL algorithm (inspired by our UCRL2 algorithm) and show—based on the methods we introduce in this paper—regret bounds where the diameter is replaced with a smaller transition parameter D_1 (that is basically an upper bound on the span of the *bias* of an optimal policy). Moreover, this bound also allows the MDP to have some *transient* states that are not reachable under any policy. However, the bound holds only when the learner knows an upper bound on this parameter D_1. In case the learner has no such upper bound, a doubling trick can be applied, but then the bound's dependence on $|\mathcal{S}|$ deteriorates from $|\mathcal{S}|$ to $|\mathcal{S}|^{3/2}$. Bartlett and Tewari (2009) also modify our lower bound example to obtain a lower bound of $\Omega(D_1\sqrt{|\mathcal{S}||\mathcal{A}|T})$ with respect to their new transition parameter D_1. Still, in the given example $D_1 = \sqrt{D}$, so that in this case their lower bound matches our lower bound.

2. Results

We summarize the results achieved for our algorithm UCRL2 (which will be described in the next section), and also state a corresponding lower bound. We assume an unknown MDP M to be learned, with $S := |\mathcal{S}|$ states, $A := |\mathcal{A}|$ actions, and finite diameter $D := D(M)$. Only $\mathcal{S}$ and $\mathcal{A}$ are known to the learner, and UCRL2 is run with confidence parameter δ.

Theorem 2 *With probability of at least* $1-\delta$ *it holds that for any initial state* $s \in \mathcal{S}$ *and any* $T > 1$*, the regret of* UCRL2 *is bounded by*

$$\Delta(M, \text{UCRL2}, s, T) \;\leq\; 34 \cdot DS\sqrt{AT\log\left(\tfrac{T}{\delta}\right)}.$$

It is straightforward to obtain from Theorem 2 the following sample complexity bound.

Corollary 3 *With probability of at least* $1-\delta$ *the average per-step regret of* UCRL2 *is at most* ε *for any*

$$T \;\geq\; 4 \cdot 34^2 \cdot \frac{D^2S^2A}{\varepsilon^2}\log\left(\frac{34DSA}{\delta\varepsilon}\right)$$

steps.

It is also possible to give a sample complexity bound on the number of suboptimal steps UCRL2 takes, which allows to derive the following gap-dependent logarithmic bound on the expected regret.

Theorem 4 *For any initial state $s \in \mathcal{S}$, any $T \geq 1$ and any $\varepsilon > 0$, with probability of at least $1 - 3\delta$ the regret of* UCRL2 *is*

$$\Delta(M, \text{UCRL2}, s, T) \;\leq\; 34^2 \cdot \frac{D^2 S^2 A \log\left(\frac{T}{\delta}\right)}{\varepsilon} + \varepsilon T.$$

Moreover setting

$$g := \rho^*(M) - \max_{s \in \mathcal{S}} \max_{\pi : \mathcal{S} \to \mathcal{A}} \left\{ \rho(M, \pi, s) : \rho(M, \pi, s) < \rho^*(M) \right\}$$

to be the gap in average reward between best and second best policy in M, the expected regret of UCRL2 *(with parameter $\delta := \frac{1}{3T}$) for any initial state $s \in \mathcal{S}$ is*

$$\mathbb{E}\left[\Delta(M, \text{UCRL2}, s, T)\right] < 34^2 \cdot \frac{D^2 S^2 A \log(T)}{g} + 1 + \sum_{s,a} \left[1 + \log_2\Big(\max_{\pi : \pi(s) = a} T_\pi\Big)\right] \max_{\pi : \pi(s) = a} T_\pi,$$

where T_π is the smallest natural number such that for all $T \geq T_\pi$ the expected average reward after T steps is $\frac{g}{2}$-close to the average reward of π. Using the doubling trick to set the parameter δ, one obtains a corresponding bound (with larger constant) without knowledge of the horizon T.

These new bounds are improvements over the bounds that have been achieved by Auer and Ortner (2007) for the original UCRL algorithm in various respects: the exponents of the relevant parameters have been decreased considerably, the parameter D we use here is substantially smaller than the corresponding mixing time of Auer and Ortner (2007), and finally, the ergodicity assumption is replaced by the much weaker and more natural assumption that the MDP has finite diameter.

The following is an accompanying lower bound on the expected regret.

Theorem 5 *For any algorithm $\mathfrak{A}$, any natural numbers $S, A \geq 10$, $D \geq 20 \log_A S$, and $T \geq DSA$, there is an MDP M with S states, A actions, and diameter D,*[5] *such that for any initial state $s \in \mathcal{S}$ the expected regret of $\mathfrak{A}$ after T steps is*

$$\mathbb{E}\left[\Delta(M, \mathfrak{A}, s, T)\right] \geq 0.015 \cdot \sqrt{DSAT}\,.$$

Finally, we consider a modification of UCRL2 that is also able to deal with changing MDPs.

Theorem 6 *Assume that the MDP (i.e., its transition probabilities and reward distributions) is allowed to change $(\ell - 1)$ times up to step T, such that the diameter is always at most D. Restarting* UCRL2 *with parameter $\frac{\delta}{\ell^2}$ at steps $\left\lceil \frac{i^3}{\ell^2} \right\rceil$ for $i = 1, 2, 3 \ldots$, the regret (now measured as the sum of missed rewards compared to the ℓ optimal policies in the periods during which the MDP remains constant) is upper bounded by*

$$65 \cdot \ell^{1/3} T^{2/3} DS \sqrt{A \log\left(\tfrac{T}{\delta}\right)}$$

with probability of at least $1 - \delta$.

5. As already mentioned, the diameter of any MDP with S states and A actions is at least $\log_A S - 3$.

For the simpler multi-armed bandit problem, similar settings have already been considered by Auer et al. (2002b), and more recently by Garivier and Moulines (2008), and Yu and Mannor (2009). The achieved regret bounds are $O(\sqrt{\ell T \log T})$ in the first two mentioned papers, while Yu and Mannor (2009) derive regret bounds of $O(\ell \log T)$ for a setting with side observations on past rewards in which the number of changes ℓ need not be known in advance.

MDPs with a different model of changing rewards have already been considered by Even-Dar et al. (2005) and Even-Dar et al. (2009), respectively. There, the transition probabilities are assumed to be fixed and known to the learner, but the rewards are allowed to change at every step (however, independently of the history). In this setting, an upper bound of $O(\sqrt{T})$ on the regret against an optimal stationary policy (with the reward changes known in advance) is best possible and has been derived by Even-Dar et al. (2005). This setting recently has been further investigated by Yu et al. (2009), who also show that for achieving sublinear regret it is essential that the changing rewards are chosen obliviously, as an opponent who chooses the rewards depending on the learner's history may inflict linear loss on the learner. It should be noted that although the definition of regret in the nonstochastic setting looks the same as in the stochastic setting, there is an important difference to notice. While in the stochastic setting the average reward of an MDP is always maximized by a stationary policy $\pi : \mathcal{S} \to \mathcal{A}$, in the nonstochastic setting obviously a dynamic policy adapted to the reward sequence would in general earn more than a stationary policy. However, obviously no algorithm will be able to compete with the best dynamic policy for all possible reward sequences, so that—similar to the nonstochastic bandit problem, compare to Auer et al. (2002b)—one usually competes only with a finite set of experts, in the case of MDPs the set of stationary policies $\pi : \mathcal{S} \to \mathcal{A}$. For different notions of regret in the nonstochastic MDP setting see Yu et al. (2009).

Note that all our results scale linearly with the rewards. That is, if the rewards are not bounded in $[0,1]$ but taken from some interval $[r_{\min}, r_{\max}]$, the rewards can simply be normalized, so that the given regret bounds hold with additional factor $(r_{\max} - r_{\min})$.

3. The UCRL2 Algorithm

Our algorithm is a variant of the UCRL algorithm of Auer and Ortner (2007). As its predecessor, UCRL2 implements the paradigm of "optimism in the face of uncertainty". That is, it defines a set $\mathcal{M}$ of statistically *plausible* MDPs given the observations so far, and chooses an optimistic MDP $\tilde{M}$ (with respect to the achievable average reward) among these plausible MDPs. Then it executes a policy $\tilde{\pi}$ which is (nearly) optimal for the optimistic MDP $\tilde{M}$. More precisely, UCRL2 (see Figure 1) proceeds in episodes and computes a new policy $\tilde{\pi}_k$ only at the beginning of each episode k. The lengths of the episodes are not fixed a priori, but depend on the observations made. In Steps 2–3, UCRL2 computes estimates $\hat{r}_k(s,a)$ and $\hat{p}_k(s'|s,a)$ for the mean rewards and the transition probabilities from the observations made before episode k. In Step 4, a set $\mathcal{M}_k$ of plausible MDPs is defined in terms of confidence regions around the estimated mean rewards $\hat{r}_k(s,a)$ and transition probabilities $\hat{p}_k(s'|s,a)$. This guarantees that with high probability the true MDP M is in $\mathcal{M}_k$. In Step 5, *extended value iteration* (see below) is used to choose a near-optimal policy $\tilde{\pi}_k$ on an optimistic MDP $\tilde{M}_k \in \mathcal{M}_k$. This policy $\tilde{\pi}_k$ is executed throughout episode k (Step 6). Episode k ends when a state s is visited in which the action $a = \tilde{\pi}_k(s)$ induced by the current policy has been chosen *in* episode k equally often as *before* episode k. Thus, the total number of occurrences of

any state-action pair is at most doubled during an episode. The counts $v_k(s,a)$ keep track of these occurrences in episode k.[6]

3.1 Extended Value Iteration: Finding Optimistic Model and Optimal Policy

In Step 5 of the UCRL2 algorithm we need to find a near-optimal policy $\tilde{\pi}_k$ for an optimistic MDP $\tilde{M}_k$. While value iteration typically calculates an optimal policy for a fixed MDP, we also need to select an optimistic MDP $\tilde{M}_k$ that gives almost maximal optimal average reward among all plausible MDPs.

3.1.1 PROBLEM FORMULATION

We can formulate this as a general problem as follows. Let $\mathcal{M}$ be the set of all MDPs with (common) state space $\mathcal{S}$, (common) action space $\mathcal{A}$, transition probabilities $\tilde{p}(\cdot|s,a)$, and mean rewards $\tilde{r}(s,a)$ such that

$$\|\tilde{p}(\cdot|s,a) - \hat{p}(\cdot|s,a)\|_1 \leq d(s,a), \tag{1}$$

$$|\tilde{r}(s,a) - \hat{r}(s,a)| \leq d'(s,a) \tag{2}$$

for given probability distributions $\hat{p}(\cdot|s,a)$, values $\hat{r}(s,a)$ in $[0,1]$, $d(s,a) > 0$, and $d'(s,a) \geq 0$. Further, we assume that $\mathcal{M}$ contains at least one communicating MDP, that is, an MDP with finite diameter.

In Step 5 of UCRL2, the $d(s,a)$ and $d'(s,a)$ are obviously the confidence intervals as given by (4) and (3), while the communicating MDP assumed to be in $\mathcal{M}_k$ is the true MDP M. The task is to find an MDP $\tilde{M} \in \mathcal{M}$ and a policy $\tilde{\pi} : \mathcal{S} \to \mathcal{A}$ which maximize $\rho(\tilde{M}, \tilde{\pi}, s)$ for all states s.[7] This task is similar to *optimistic optimality* in *bounded parameter MDPs* as considered by Tewari and Bartlett (2007). A minor difference is that in our case the transition probabilities are bounded not individually but by the 1-norm. More importantly, while Tewari and Bartlett (2007) give a converging algorithm for computing the optimal value function, they do not bound the error when terminating their algorithm after finitely many steps. In the following, we will extend standard undiscounted value iteration (Puterman, 1994) to solve the set task.

First, note that we may combine all MDPs in $\mathcal{M}$ to get a single MDP with extended action set $\mathcal{A}'$. That is, we consider an MDP $\tilde{M}^+$ with continuous action space $\mathcal{A}'$, where for each action $a \in \mathcal{A}$, each admissible transition probability distribution $\tilde{p}(\cdot|s,a)$ according to (1) and each admissible mean reward $\tilde{r}(s,a)$ according to (2) there is an action in $\mathcal{A}'$ with transition probabilities $\tilde{p}(\cdot|s,a)$ and mean reward $\tilde{r}(s,a)$.[8] Then for each policy $\tilde{\pi}^+$ on $\tilde{M}^+$ there is an MDP $\tilde{M} \in \mathcal{M}$ and a policy $\tilde{\pi} : \mathcal{S} \to \mathcal{A}$ on $\tilde{M}$ such that the policies $\tilde{\pi}^+$ and $\tilde{\pi}$ induce the same transition probabilities and mean rewards on the respective MDP. (The other transition probabilities in $\tilde{M}$ can be set to $\hat{p}(\cdot|s,a)$.) On the other hand, for any given MDP $\tilde{M} \in \mathcal{M}$ and any policy $\tilde{\pi} : \mathcal{S} \to \mathcal{A}$ there is a policy $\tilde{\pi}^+$ on $\tilde{M}^+$ so that again the same transition probabilities and rewards are induced by $\tilde{\pi}$ on $\tilde{M}$ and $\tilde{\pi}^+$ on $\tilde{M}^+$. Thus, finding an MDP $\tilde{M} \in \mathcal{M}$ and a policy $\tilde{\pi}$ on $\tilde{M}$ such that $\rho(\tilde{M}, \tilde{\pi}, s) = \max_{M' \in \mathcal{M}, \pi, s'} \rho(M', \pi, s')$ for all initial states s, corresponds to finding an average reward optimal policy on $\tilde{M}^+$.

6. Since the policy $\tilde{\pi}_k$ is fixed for episode k, $v_k(s,a) \neq 0$ only for $a = \tilde{\pi}_k(s)$. Nevertheless, we find it convenient to use a notation which explicitly includes the action a in $v_k(s,a)$.
7. Note that, as we assume that $\mathcal{M}$ contains a communicating MDP, if an average reward of ρ is achievable in one state, it is achievable in all states.
8. Note that in $\tilde{M}^+$ the set of available actions now depends on the state.

Input: A confidence parameter $\delta \in (0,1)$, $\mathcal{S}$ and $\mathcal{A}$.

Initialization: Set $t := 1$, and observe the initial state s_1.

For episodes $k = 1,2,\ldots$ **do**

Initialize episode k:

1. Set the start time of episode k, $t_k := t$.
2. For all (s,a) in $\mathcal{S} \times \mathcal{A}$ initialize the state-action counts for episode k, $v_k(s,a) := 0$. Further, set the state-action counts prior to episode k,

$$N_k(s,a) := \#\{\tau < t_k : s_\tau = s, a_\tau = a\}.$$

3. For $s,s' \in \mathcal{S}$ and $a \in \mathcal{A}$ set the observed accumulated rewards and the transition counts prior to episode k,

$$R_k(s,a) := \sum_{\tau=1}^{t_k-1} r_\tau \mathbb{1}_{s_\tau=s, a_\tau=a},$$

$$P_k(s,a,s') := \#\{\tau < t_k : s_\tau = s, a_\tau = a, s_{\tau+1} = s'\}.$$

Compute estimates $\hat{r}_k(s,a) := \frac{R_k(s,a)}{\max\{1,N_k(s,a)\}}$, $\hat{p}_k(s'|s,a) := \frac{P_k(s,a,s')}{\max\{1,N_k(s,a)\}}$.

Compute policy $\tilde{\pi}_k$:

4. Let $\mathcal{M}_k$ be the set of all MDPs with states and actions as in M, and with transition probabilities $\tilde{p}(\cdot|s,a)$ close to $\hat{p}_k(\cdot|s,a)$, and rewards $\tilde{r}(s,a) \in [0,1]$ close to $\hat{r}_k(s,a)$, that is,

$$\left|\tilde{r}(s,a) - \hat{r}_k(s,a)\right| \leq \sqrt{\frac{7\log(2SAt_k/\delta)}{2\max\{1,N_k(s,a)\}}} \quad \text{and} \tag{3}$$

$$\left\|\tilde{p}(\cdot|s,a) - \hat{p}_k(\cdot|s,a)\right\|_1 \leq \sqrt{\frac{14S\log(2At_k/\delta)}{\max\{1,N_k(s,a)\}}}. \tag{4}$$

5. Use extended value iteration (see Section 3.1) to find a policy $\tilde{\pi}_k$ and an optimistic MDP $\tilde{M}_k \in \mathcal{M}_k$ such that

$$\tilde{\rho}_k := \min_s \rho(\tilde{M}_k, \tilde{\pi}_k, s) \geq \max_{M' \in \mathcal{M}_k, \pi, s'} \rho(M', \pi, s') - \frac{1}{\sqrt{t_k}}.$$

Execute policy $\tilde{\pi}_k$:

6. **While** $v_k(s_t, \tilde{\pi}_k(s_t)) < \max\{1, N_k(s_t, \tilde{\pi}_k(s_t))\}$ **do**
   (a) Choose action $a_t = \tilde{\pi}_k(s_t)$, obtain reward r_t, and observe next state s_{t+1}.
   (b) Update $v_k(s_t,a_t) := v_k(s_t,a_t) + 1$.
   (c) Set $t := t+1$.

Figure 1: The UCRL2 algorithm.

Input: Estimates $\hat{p}(\cdot|s,a)$ and distance $d(s,a)$ for a state-action pair (s,a), and the states in $\mathcal{S}$ sorted descendingly according to their u_i value. That is, let $\mathcal{S} := \{s'_1, s'_2, \ldots, s'_n\}$ with $u_i(s'_1) \geq u_i(s'_2) \geq \ldots \geq u_i(s'_n)$.

1. Set

$$\begin{aligned} p(s'_1) &:= \min\left\{1, \hat{p}(s'_1|s,a) + \tfrac{d(s,a)}{2}\right\}, \text{ and} \\ p(s'_j) &:= \hat{p}(s'_j|s,a) \text{ for all states } s'_j \text{ with } j > 1. \end{aligned}$$

2. Set $\ell := n$.
3. **While** $\sum_{s'_j \in \mathcal{S}} p(s'_j) > 1$ **do**
   (a) Reset $p(s'_\ell) := \max\{0, 1 - \sum_{s'_j \neq s'_\ell} p(s'_j)\}$.
   (b) Set $\ell := \ell - 1$.

Figure 2: Computing the inner maximum in the extended value iteration (5).

3.1.2 EXTENDED VALUE ITERATION

We denote the state values of the i-th iteration by $u_i(s)$. Then we get for undiscounted value iteration (Puterman, 1994) on $\tilde{M}^+$ for all $s \in \mathcal{S}$:

$$\begin{aligned} u_0(s) &= 0, \\ u_{i+1}(s) &= \max_{a \in \mathcal{A}} \left\{ \tilde{r}(s,a) + \max_{p(\cdot) \in \mathcal{P}(s,a)} \left\{ \sum_{s' \in \mathcal{S}} p(s') \cdot u_i(s') \right\} \right\}, \end{aligned} \tag{5}$$

where $\tilde{r}(s,a) := \hat{r}(s,a) + d'(s,a)$ are the maximal possible rewards according to condition (2), and $\mathcal{P}(s,a)$ is the set of transition probabilities $\tilde{p}\left(\cdot|s,a\right)$ satisfying condition (1).

While (5) is a step of value iteration with an infinite action space, $\max_p \boldsymbol{p} \cdot \boldsymbol{u}_i$ is actually a linear optimization problem over the convex polytope $\mathcal{P}(s,a)$. This implies that (5) can be evaluated considering only the finite number of vertices of this polytope.

Indeed, for a given state-action pair the inner maximum of (5) can be computed in $O(S)$ computation steps by an algorithm introduced by Strehl and Littman (2008). For the sake of completeness we display the algorithm in Figure 2. The idea is to put as much transition probability as possible to the state with maximal value $u_i(s)$ at the expense of transition probabilities to states with small values $u_i(s)$. That is, one starts with the estimates $\hat{p}(s'_j|s,a)$ for $p(s'_j)$ except for the state s'_1 with maximal $u_i(s)$, for which we set $p(s'_1) := \hat{p}(s'_1|s,a) + \frac{1}{2}d(s,a)$. In order to make $\boldsymbol{p}$ correspond to a probability distribution again, the transition probabilities from s to states with small $u_i(s)$ are reduced in total by $\frac{1}{2}d(s,a)$, so that $\|\boldsymbol{p} - \hat{p}\left(\cdot|s,a\right)\|_1 = d(s,a)$. This is done iteratively. Updating $\sum_{s'_j \in \mathcal{S}} p(s'_j)$ with every change of $\boldsymbol{p}$ for the computation of $\sum_{s'_j \neq s'_\ell} p(s'_j)$, this iterative procedure takes $O(S)$ steps. Thus, sorting the states according to their value $u_i(s)$ at each iteration i once, $\boldsymbol{u}_{i+1}$ can be computed from $\boldsymbol{u}_i$ in at most $O\left(S^2 A\right)$ steps.

3.1.3 CONVERGENCE OF EXTENDED VALUE ITERATION

We have seen that value iteration on the MDP $\tilde{M}^+$ with continuous action is equivalent to value iteration on an MDP with finite action set. Thus, in order to guarantee convergence, it is sufficient to assure that extended value iteration never chooses a policy with periodic transition matrix. (Intuitively, it is clear that optimal policies with periodic transition matrix do not matter as long as it is guaranteed that such a policy is not chosen by value iteration, compare to Sections 8.5, 9.4, and 9.5.3. of Puterman 1994. For a proof see Appendix B.) Indeed, extended value iteration always chooses a policy with aperiodic transition matrix: In each iteration there is a single fixed state s'_1 which is regarded as the "best" target state. For each state s, in the inner maximum an action with positive transition probability to s'_1 will be chosen. In particular, the policy chosen by extended value iteration will have positive transition probability from s'_1 to s'_1. Hence, this policy is aperiodic and has state independent average reward. Thus we obtain the following result.

Theorem 7 *Let $\mathcal{M}$ be the set of all MDPs with state space $\mathcal{S}$, action space $\mathcal{A}$, transition probabilities $\tilde{p}(\cdot|s,a)$, and mean rewards $\tilde{r}(s,a)$ that satisfy* (1) *and* (2) *for given probability distributions $\hat{p}(\cdot|s,a)$, values $\hat{r}(s,a)$ in $[0,1]$, $d(s,a) > 0$, and $d'(s,a) \geq 0$. If $\mathcal{M}$ contains at least one communicating MDP, extended value iteration converges. Further, stopping extended value iteration when*

$$\max_{s\in S}\left\{u_{i+1}(s) - u_i(s)\right\} - \min_{s\in S}\left\{u_{i+1}(s) - u_i(s)\right\} < \varepsilon,$$

the greedy policy with respect to $\boldsymbol{u}_i$ is ε-optimal.

Remark 8 *When value iteration converges, a suitable transformation of $\boldsymbol{u}_i$ converges to the bias vector of an optimal policy. Recall that for a policy π the bias $\lambda(s)$ in state s is basically the expected advantage in total reward (for $T \to \infty$) of starting in state s over starting in the stationary distribution (the long term probability of being in a state) of π. For a fixed policy π, the Poisson equation*

$$\boldsymbol{\lambda} = \boldsymbol{r} - \rho\mathbf{1} + \boldsymbol{P}\boldsymbol{\lambda}$$

relates the bias vector $\boldsymbol{\lambda}$ to the average reward ρ, the mean reward vector $\boldsymbol{r}$, and the transition matrix $\boldsymbol{P}$. Now when value iteration converges, the vector $\boldsymbol{u}_i - \min_s u_i(s)\mathbf{1}$ converges to $\boldsymbol{\lambda} - \min_s \lambda(s)\mathbf{1}$. As we will see in inequality (11) *below, the so-called* span $\max_s u_i(s) - \min_s u_i(s)$ *of the vector $\boldsymbol{u}_i$ is upper bounded by the diameter D, so that this also holds for the span of the bias vector $\boldsymbol{\lambda}$ of the optimal policy found by extended value iteration, that is, $\max_s \lambda(s) - \min_s \lambda(s) \leq D$. Indeed, one can show that this holds for any optimal policy (cf. also Section 4 of Bartlett and Tewari, 2009).*

Remark 9 *We would like to note that the algorithm of Figure 2 can easily be adapted to the alternative setting of Tewari and Bartlett (2007), where each single transition probability $p(s'|s,a)$ is bounded as $0 \leq b^-(s',s,a) \leq p(s'|s,a) \leq b^+(s',s,a) \leq 1$. However, concerning convergence one needs to make some assumptions to exclude the possibility of choosing optimal policies with periodic transition matrices. For example, one may assume (apart from other assumptions already made by Tewari and Bartlett 2007) that for all s', s, a there is an admissible probability distribution $p(\cdot|s,a)$ with $p(s'|s,a) > 0$. Note that for Theorem 7 to hold, it is similarly essential that $d(s,a) > 0$. Alternatively, one may apply an aperiodicity transformation as described in Section 8.5.4 of Puterman (1994).*

Now returning to Step 5 of UCRL2, we stop value iteration when

$$\max_{s\in S}\{u_{i+1}(s)-u_i(s)\}-\min_{s\in S}\{u_{i+1}(s)-u_i(s)\}<\frac{1}{\sqrt{t_k}}, \tag{6}$$

which guarantees by Theorem 7 that the greedy policy with respect to $\boldsymbol{u}_i$ is $\frac{1}{\sqrt{t_k}}$-optimal.

4. Analysis of UCRL2 (Proofs of Theorem 2 and Corollary 3)

We start with a rough outline of the proof of Theorem 2. First, in Section 4.1, we deal with the random fluctuation of the rewards. Further, the regret is expressed as the sum of the regret accumulated in the individual episodes. That is, we set the *regret in episode k* to be

$$\Delta_k := \sum_{s,a} v_k(s,a)\big(\rho^* - \bar{r}(s,a)\big),$$

where $v_k(s,a)$ now denotes the final counts of state-action pair (s,a) in episode k. Then it is shown that the total regret can be bounded by

$$\sum_k \Delta_k + \sqrt{\tfrac{5}{2}T\log\big(\tfrac{8T}{\delta}\big)}$$

with high probability.

In Section 4.2, we consider the regret that is caused by failing confidence regions. We show that this term can be upper bounded by $\sqrt{T}$ with high probability. After this intermezzo, the regret of episodes for which the true MDP $M\in\mathcal{M}_k$ is examined in Section 4.3. Analyzing the extended value iteration scheme in Section 4.3.1 and using vector notation, we show that

$$\Delta_k \;\le\; \boldsymbol{v}_k\big(\tilde{\boldsymbol{P}}_k-\boldsymbol{I}\big)\boldsymbol{w}_k + 2\sum_{s,a} v_k(s,a)\sqrt{\tfrac{7\log(2SAt_k/\delta)}{2\max\{1,N_k(s,a)\}}} + 2\sum_{s,a}\frac{v_k(s,a)}{\sqrt{t_k}},$$

where $\tilde{\boldsymbol{P}}_k$ is the assumed transition matrix (in $\tilde{M}_k$) of the applied policy in episode k, $\boldsymbol{v}_k$ are the visit counts at the end of that episode, and $\boldsymbol{w}_k$ is a vector with $\|\boldsymbol{w}_k\|_\infty \le \frac{D(M)}{2}$. The last two terms in the above expression stem from the reward confidence intervals (3) and the approximation error of value iteration. These are bounded in Section 4.3.3 when summing over all episodes. The first term on the right hand side is analyzed further in Section 4.3.2 and split into

$$\begin{aligned}\boldsymbol{v}_k(\tilde{\boldsymbol{P}}_k-\boldsymbol{I})\boldsymbol{w}_k &= \boldsymbol{v}_k(\tilde{\boldsymbol{P}}_k-\boldsymbol{P}_k)\boldsymbol{w}_k + \boldsymbol{v}_k(\boldsymbol{P}_k-\boldsymbol{I})\boldsymbol{w}_k\\ &\le \big\|\boldsymbol{v}_k(\tilde{\boldsymbol{P}}_k-\boldsymbol{P}_k)\big\|_1\|\boldsymbol{w}_k\|_\infty + \boldsymbol{v}_k(\boldsymbol{P}_k-\boldsymbol{I})\boldsymbol{w}_k,\end{aligned}$$

where $\boldsymbol{P}_k$ is the true transition matrix (in M) of the policy applied in episode k. Substituting for $\tilde{\boldsymbol{P}}_k-\boldsymbol{P}_k$ the lengths of the confidence intervals as given in (4), the remaining term that needs analysis is $\boldsymbol{v}_k(\boldsymbol{P}_k-\boldsymbol{I})\boldsymbol{w}_k$. For the sum of this term over all episodes we obtain in Section 4.3.2 a high probability bound of

$$\sum_k \boldsymbol{v}_k(\boldsymbol{P}_k-\boldsymbol{I})\boldsymbol{w}_k \;\le\; D\sqrt{\tfrac{5}{2}T\log\big(\tfrac{8T}{\delta}\big)} + Dm,$$

where m is the number of episodes—a term shown to be logarithmic in T in Appendix C.2. Section 4.3.3 concludes the analysis of episodes with $M\in\mathcal{M}_k$ by summing the individual regret terms over all episodes k with $M\in\mathcal{M}_k$. In the final Section 4.4 we finish the proof by combining the results of Sections 4.1–4.3.

4.1 Splitting into Episodes

Recall that r_t is the (random) reward UCRL2 receives at step t when starting in some initial state s_1. For given state-action counts $N(s,a)$ after T steps, the r_t are independent random variables, so that by Hoeffding's inequality

$$\mathbb{P}\left\{ \sum_{t=1}^{T} r_t \le \sum_{s,a} N(s,a)\bar{r}(s,a) - \sqrt{\tfrac{5}{8}T\log\left(\tfrac{8T}{\delta}\right)} \,\middle|\, \big(N(s,a)\big)_{s,a} \right\} \le \left(\frac{\delta}{8T}\right)^{5/4} < \frac{\delta}{12T^{5/4}}. \tag{7}$$

Thus we get for the regret of UCRL2 (now omitting explicit references to M and UCRL2)

$$\Delta(s_1,T) \;=\; T\rho^* - \sum_{t=1}^{T} r_t \;<\; T\rho^* - \sum_{s,a} N(s,a)\bar{r}(s,a) + \sqrt{\tfrac{5}{8}T\log\left(\tfrac{8T}{\delta}\right)}$$

with probability at least $1-\frac{\delta}{12T^{5/4}}$. Denoting the number of episodes started up to step T by m, we have $\sum_{k=1}^{m} v_k(s,a) = N(s,a)$ and $\sum_{s,a} N(s,a) = T$. Therefore, writing $\Delta_k := \sum_{s,a} v_k(s,a)\big(\rho^* - \bar{r}(s,a)\big)$, it follows that

$$\Delta(s_1,T) \;\le\; \sum_{k=1}^{m} \Delta_k + \sqrt{\tfrac{5}{8}T\log\left(\tfrac{8T}{\delta}\right)} \tag{8}$$

with probability at least $1-\frac{\delta}{12T^{5/4}}$.

4.2 Dealing with Failing Confidence Regions

Let us now consider the regret of episodes in which the set of plausible MDPs $\mathcal{M}_k$ does not contain the true MDP M, $\sum_{k=1}^{m} \Delta_k \mathbb{1}_{M\notin\mathcal{M}_k}$. By the stopping criterion for episode k we have (except for episodes where $v_k(s,a)=1$ and $N_k(s,a)=0$, when $\sum_{s,a} v_k(s,a) = 1 \le t_k$ holds trivially)

$$\sum_{s,a} v_k(s,a) \;\le\; \sum_{s,a} N_k(s,a) = t_k - 1.$$

Hence, denoting $\mathcal{M}(t)$ to be the set of plausible MDPs as given by (3) and (4) using the estimates available at step t, we have due to $\rho^* \le 1$ that

$$\begin{aligned}
\sum_{k=1}^{m} \Delta_k \mathbb{1}_{M\notin\mathcal{M}_k} \;&\le\; \sum_{k=1}^{m}\sum_{s,a} v_k(s,a)\mathbb{1}_{M\notin\mathcal{M}_k} \;\le\; \sum_{k=1}^{m} t_k \mathbb{1}_{M\notin\mathcal{M}_k} \;=\; \sum_{t=1}^{T} t \sum_{k=1}^{m} \mathbb{1}_{t_k=t, M\notin\mathcal{M}_k} \\
&\le\; \sum_{t=1}^{T} t\mathbb{1}_{M\notin\mathcal{M}(t)} \;\le\; \sum_{t=1}^{\lfloor T^{1/4}\rfloor} t\mathbb{1}_{M\notin\mathcal{M}(t)} + \sum_{t=\lfloor T^{1/4}\rfloor+1}^{T} t\mathbb{1}_{M\notin\mathcal{M}(t)} \\
&\le\; \sqrt{T} + \sum_{t=\lfloor T^{1/4}\rfloor+1}^{T} t\mathbb{1}_{M\notin\mathcal{M}(t)}.
\end{aligned}$$

Now, $\mathbb{P}\left\{M\notin\mathcal{M}(t)\right\} \le \frac{\delta}{15t^6}$ (see Appendix C.1), and since

$$\sum_{t=\lfloor T^{1/4}\rfloor+1}^{T} \frac{1}{15t^6} \;\le\; \frac{1}{15T^{6/4}} + \int_{T^{1/4}}^{\infty} \frac{1}{15t^6}\,dt \;=\; \frac{1}{15T^{6/4}} + \frac{1}{75T^{5/4}} \;\le\; \frac{6}{75T^{5/4}} \;<\; \frac{1}{12T^{5/4}},$$

we have $\mathbb{P}\{\exists t : T^{1/4} < t \le T : M\notin\mathcal{M}(t)\} \le \frac{\delta}{12T^{5/4}}$. It follows that with probability at least $1-\frac{\delta}{12T^{5/4}}$,

$$\sum_{k=1}^{m} \Delta_k \mathbb{1}_{M\notin\mathcal{M}_k} \;\le\; \sqrt{T}. \tag{9}$$

4.3 Episodes with $M \in \mathcal{M}_k$

Now we assume that $M \in \mathcal{M}_k$ and start by considering the regret in a single episode k. The optimistic average reward $\tilde{\rho}_k$ of the optimistically chosen policy $\tilde{\pi}_k$ is essentially larger than the true optimal average reward ρ^*, and thus it is sufficient to calculate by how much the optimistic average reward $\tilde{\rho}_k$ overestimates the actual rewards of policy $\tilde{\pi}_k$. By the assumption $M \in \mathcal{M}_k$, the choice of $\tilde{\pi}_k$ and $\tilde{M}_k$ in Step 5 of UCRL2, and Theorem 7 we get that $\tilde{\rho}_k \geq \rho^* - \frac{1}{\sqrt{t_k}}$. Thus for the regret Δ_k accumulated in episode k we obtain

$$\Delta_k \;\leq\; \sum_{s,a} v_k(s,a)\big(\rho^* - \bar{r}(s,a)\big) \;\leq\; \sum_{s,a} v_k(s,a)\big(\tilde{\rho}_k - \bar{r}(s,a)\big) + \sum_{s,a} \frac{v_k(s,a)}{\sqrt{t_k}}\,. \tag{10}$$

4.3.1 EXTENDED VALUE ITERATION REVISITED

To proceed, we reconsider the extended value iteration of Section 3.1. As an important observation for our analysis, we find that for any iteration i the range of the state values is bounded by the diameter of the MDP M, that is,

$$\max_s u_i(s) - \min_s u_i(s) \leq D. \tag{11}$$

To see this, observe that $u_i(s)$ is the total expected i-step reward of an optimal non-stationary i-step policy starting in state s on the MDP $\tilde{M}^+$ with extended action set (as considered for extended value iteration). The diameter of this extended MDP is at most D as it contains by assumption the actions of the true MDP M. Now, if there were states s', s'' with $u_i(s'') - u_i(s') > D$, then an improved value for $u_i(s')$ could be achieved by the following nonstationary policy: First follow a policy which moves from s' to s'' most quickly, which takes at most D steps on average. Then follow the optimal i-step policy for s''. Since only D of the i rewards of the policy for s'' are missed, this policy gives $u_i(s') \geq u_i(s'') - D$, contradicting our assumption and thus proving (11).

It is a direct consequence of Theorem 8.5.6. of Puterman (1994), that when the convergence criterion (6) holds at iteration i, then

$$|u_{i+1}(s) - u_i(s) - \tilde{\rho}_k| \leq \frac{1}{\sqrt{t_k}} \tag{12}$$

for all $s \in \mathcal{S}$, where $\tilde{\rho}_k$ is the average reward of the policy $\tilde{\pi}_k$ chosen in this iteration on the optimistic MDP $\tilde{M}_k$.[9] Expanding $u_{i+1}(s)$ according to (5), we get

$$u_{i+1}(s) \;=\; \tilde{r}_k(s,\tilde{\pi}_k(s)) + \sum_{s'} \tilde{p}_k\left(s'|s,\tilde{\pi}_k(s)\right) \cdot u_i(s')$$

and hence by (12)

$$\left|\left(\tilde{\rho}_k - \tilde{r}_k(s,\tilde{\pi}_k(s))\right) - \left(\sum_{s'} \tilde{p}_k\left(s'|s,\tilde{\pi}_k(s)\right) \cdot u_i(s') - u_i(s)\right)\right| \leq \frac{1}{\sqrt{t_k}}. \tag{13}$$

Setting $\boldsymbol{r}_k := \big(\tilde{r}_k\big(s,\tilde{\pi}_k(s)\big)\big)_s$ to be the (column) vector of rewards for policy $\tilde{\pi}_k$, $\tilde{\boldsymbol{P}}_k := \big(\tilde{p}_k\left(s'|s,\tilde{\pi}_k(s)\right)\big)_{s,s'}$ the transition matrix of $\tilde{\pi}_k$ on $\tilde{M}_k$, and $\boldsymbol{v}_k := \big(v_k\big(s,\tilde{\pi}_k(s)\big)\big)_s$ the (row)

9. This is quite intuitive. We expect to receive average reward $\tilde{\rho}_k$ per step, such that the difference of the state values after $i+1$ and i steps should be about $\tilde{\rho}_k$.

vector of visit counts for each state and the corresponding action chosen by $\tilde{\pi}_k$, we can use (13)—recalling that $v_k(s,a) = 0$ for $a \neq \tilde{\pi}_k(s)$—to rewrite (10) as

$$\begin{aligned}\Delta_k &\leq \sum_{s,a} v_k(s,a)\big(\tilde{\rho}_k - \bar{r}(s,a)\big) + \sum_{s,a} \frac{v_k(s,a)}{\sqrt{t_k}} \\ &= \sum_{s,a} v_k(s,a)\big(\tilde{\rho}_k - \tilde{r}_k(s,a)\big) + \sum_{s,a} v_k(s,a)\big(\tilde{r}_k(s,a) - \bar{r}(s,a)\big) + \sum_{s,a} \frac{v_k(s,a)}{\sqrt{t_k}} \\ &\leq \boldsymbol{v}_k\big(\tilde{\boldsymbol{P}}_k - \boldsymbol{I}\big)\boldsymbol{u}_i + \sum_{s,a} v_k(s,a)\big(\tilde{r}_k(s,a) - \bar{r}(s,a)\big) + 2\sum_{s,a} \frac{v_k(s,a)}{\sqrt{t_k}}.\end{aligned}$$

Since the rows of $\tilde{\boldsymbol{P}}_k$ sum to 1, we can replace $\boldsymbol{u}_i$ by $\boldsymbol{w}_k$ where we set

$$w_k(s) := u_i(s) - \frac{\min_s u_i(s) + \max_s u_i(s)}{2},$$

such that it follows from (11) that $\|\boldsymbol{w}_k\| \leq \frac{D}{2}$. Further, since we assume $M \in \mathcal{M}_k$, $\tilde{r}_k(s,a) - \bar{r}(s,a) \leq |\tilde{r}_k(s,a) - \hat{r}_k(s,a)| + |\bar{r}(s,a) - \hat{r}_k(s,a)|$ is bounded according to (3), so that

$$\Delta_k \leq \boldsymbol{v}_k\big(\tilde{\boldsymbol{P}}_k - \boldsymbol{I}\big)\boldsymbol{w}_k + 2\sum_{s,a} v_k(s,a)\sqrt{\tfrac{7\log(2SAt_k/\delta)}{2\max\{1,N_k(s,a)\}}} + 2\sum_{s,a} \frac{v_k(s,a)}{\sqrt{t_k}}. \tag{14}$$

Noting that $\max\{1,N_k(s,a)\} \leq t_k \leq T$ we get from (14) that

$$\Delta_k \leq \boldsymbol{v}_k\big(\tilde{\boldsymbol{P}}_k - \boldsymbol{I}\big)\boldsymbol{w}_k + \left(\sqrt{14\log\left(\tfrac{2SAT}{\delta}\right)} + 2\right)\sum_{s,a} \frac{v_k(s,a)}{\sqrt{\max\{1,N_k(s,a)\}}}. \tag{15}$$

4.3.2 THE TRUE TRANSITION MATRIX

Now we want to replace the transition matrix $\tilde{\boldsymbol{P}}_k$ of the policy $\tilde{\pi}_k$ in the optimistic MDP $\tilde{M}_k$ by the transition matrix $\boldsymbol{P}_k := \big(p(s'|s,\tilde{\pi}_k(s))\big)_{s,s'}$ of $\tilde{\pi}_k$ in the true MDP M. Thus, we write

$$\begin{aligned}\boldsymbol{v}_k\big(\tilde{\boldsymbol{P}}_k - \boldsymbol{I}\big)\boldsymbol{w}_k &= \boldsymbol{v}_k\big(\tilde{\boldsymbol{P}}_k - \boldsymbol{P}_k + \boldsymbol{P}_k - \boldsymbol{I}\big)\boldsymbol{w}_k \\ &= \boldsymbol{v}_k\big(\tilde{\boldsymbol{P}}_k - \boldsymbol{P}_k\big)\boldsymbol{w}_k + \boldsymbol{v}_k\big(\boldsymbol{P}_k - \boldsymbol{I}\big)\boldsymbol{w}_k.\end{aligned} \tag{16}$$

The first term. Since by assumption $\tilde{M}_k$ and M are in the set of plausible MDPs $\mathcal{M}_k$, the first term in (16) can be bounded using condition (4). Thus, also using that $\|\boldsymbol{w}_k\|_\infty \leq \frac{D}{2}$ we obtain

$$\begin{aligned}\boldsymbol{v}_k\big(\tilde{\boldsymbol{P}}_k - \boldsymbol{P}_k\big)\boldsymbol{w}_k &= \sum_s \sum_{s'} v_k\big(s,\tilde{\pi}_k(s)\big)\cdot\Big(\tilde{p}_k\left(s'|s,\tilde{\pi}_k(s)\right) - p\big(s'|s,\tilde{\pi}_k(s)\big)\Big)\cdot w_k(s') \\ &\leq \sum_s v_k\big(s,\tilde{\pi}_k(s)\big)\cdot\big\|\tilde{p}_k\left(\cdot\,|s,\tilde{\pi}_k(s)\right) - p(\cdot|s,\tilde{\pi}_k(s))\big\|_1\cdot\|\boldsymbol{w}_k\|_\infty \\ &\leq \sum_s v_k\big(s,\tilde{\pi}_k(s)\big)\cdot 2\sqrt{\frac{14S\log\left(2AT/\delta\right)}{\max\{1,N_k\left(s,\tilde{\pi}_k(s)\right)\}}}\cdot\frac{D}{2} \\ &\leq D\sqrt{14S\log\left(\tfrac{2AT}{\delta}\right)}\sum_{s,a}\frac{v_k(s,a)}{\sqrt{\max\{1,N_k(s,a)\}}}.\end{aligned} \tag{17}$$

This term will turn out to be the dominating contribution in our regret bound.

The second term. The intuition about the second term in (16) is that the counts of the state visits $\boldsymbol{v}_k$ are relatively close to the stationary distribution $\boldsymbol{\mu}_k$ of the transition matrix $\boldsymbol{P}_k$, for which $\boldsymbol{\mu}_k \boldsymbol{P}_k = \boldsymbol{\mu}_k$, such that $\boldsymbol{v}_k\big(\boldsymbol{P}_k - \boldsymbol{I}\big)$ should be small. For the proof we define a suitable martingale and make use of the Azuma-Hoeffding inequality.

Lemma 10 (Azuma-Hoeffding inequality, Hoeffding 1963) *Let $X_1, X_2, \ldots$ be a martingale difference sequence with $|X_i| \leq c$ for all i. Then for all $\varepsilon > 0$ and $n \in \mathbb{N}$,*

$$\mathbb{P}\big\{ \textstyle\sum_{i=1}^n X_i \geq \varepsilon \big\} \;\leq\; \exp\big(-\frac{\varepsilon^2}{2nc^2}\big).$$

Denote the unit vectors with i-th coordinate 1 and all other coordinates 0 by $\boldsymbol{e}_i$. Let $s_1, a_1, s_2, \ldots, a_T$, s_{T+1} be the sequence of states and actions, and let $k(t)$ be the episode which contains step t. Consider the sequence $X_t := \big(p\,(\cdot|s_t,a_t) - \boldsymbol{e}_{s_{t+1}}\big)\,\boldsymbol{w}_{k(t)} \mathbb{1}_{M \in \mathcal{M}_{k(t)}}$ for $t = 1, \ldots, T$. Then for any episode k with $M \in \mathcal{M}_k$, we have due to $\|\boldsymbol{w}_k\|_\infty \leq \frac{D}{2}$ that

$$\begin{aligned}
\boldsymbol{v}_k(\boldsymbol{P}_k - \boldsymbol{I})\boldsymbol{w}_k &= \sum_{t=t_k}^{t_{k+1}-1} \big(p\,(\cdot|s_t,a_t) - \boldsymbol{e}_{s_t}\big)\boldsymbol{w}_k \\
&= \left(\sum_{t=t_k}^{t_{k+1}-1} p\,(\cdot|s_t,a_t) - \sum_{t=t_k}^{t_{k+1}-1} \boldsymbol{e}_{s_{t+1}} + \boldsymbol{e}_{s_{t_{k+1}}} - \boldsymbol{e}_{s_{t_k}}\right)\boldsymbol{w}_k \\
&= \sum_{t=t_k}^{t_{k+1}-1} X_t + w_k(s_{t_{k+1}}) - w_k(s_{t_k}) \\
&\leq \sum_{t=t_k}^{t_{k+1}-1} X_t + D.
\end{aligned}$$

Also due to $\|\boldsymbol{w}_k\|_\infty \leq \frac{D}{2}$, we have $|X_t| \leq (\|p\,(\cdot|s_t,a_t)\|_1 + \|\boldsymbol{e}_{s_{t+1}}\|_1)\frac{D}{2} \leq D$. Further, $\mathbb{E}\big[X_t \big| s_1, a_1, \ldots, s_t, a_t\big] = 0$, so that X_t is a sequence of martingale differences, and application of Lemma 10 gives

$$\mathbb{P}\left\{\sum_{t=1}^T X_t \geq D\sqrt{2T \cdot \tfrac{5}{4}\log\big(\tfrac{8T}{\delta}\big)}\right\} \leq \left(\frac{\delta}{8T}\right)^{5/4} < \frac{\delta}{12T^{5/4}}.$$

Since for the number of episodes we have $m \leq SA\log_2\big(\frac{8T}{SA}\big)$ as shown in Appendix C.2, summing over all episodes yields

$$\begin{aligned}
\sum_{k=1}^m \boldsymbol{v}_k(\boldsymbol{P}_k - \boldsymbol{I})\boldsymbol{w}_k \mathbb{1}_{M \in \mathcal{M}_k} &\leq \sum_{t=1}^T X_t + mD \\
&\leq D\sqrt{\tfrac{5}{2}T\log\big(\tfrac{8T}{\delta}\big)} + DSA\log_2\big(\tfrac{8T}{SA}\big) \qquad (18)
\end{aligned}$$

with probability at least $1 - \frac{\delta}{12T^{5/4}}$.

4.3.3 SUMMING OVER EPISODES WITH $M \in \mathcal{M}_k$

To conclude Section 4.3, we sum (15) over all episodes with $M \in \mathcal{M}_k$, using (16), (17), and (18), which yields that with probability at least $1 - \frac{\delta}{12T^{5/4}}$

$$\begin{aligned}
\sum_{k=1}^{m} \Delta_k \mathbb{1}_{M\in\mathcal{M}_k} &\leq \sum_{k=1}^{m} \boldsymbol{v}_k\big(\tilde{\boldsymbol{P}}_k - \boldsymbol{P}_k\big)\boldsymbol{w}_k \mathbb{1}_{M\in\mathcal{M}_k} + \sum_{k=1}^{m} \boldsymbol{v}_k\big(\boldsymbol{P}_k - \boldsymbol{I}\big)\boldsymbol{w}_k \mathbb{1}_{M\in\mathcal{M}_k} \\
&\quad + \sum_{k=1}^{m} \left(\sqrt{14\log\left(\tfrac{2SAT}{\delta}\right)} + 2\right) \sum_{s,a} \frac{v_k(s,a)}{\sqrt{\max\{1, N_k(s,a)\}}} \\
&\leq D\sqrt{14S\log\left(\tfrac{2AT}{\delta}\right)} \cdot \sum_{k=1}^{m} \sum_{s,a} \frac{v_k(s,a)}{\sqrt{\max\{1, N_k(s,a)\}}} \\
&\quad + D\sqrt{\tfrac{5}{2}T\log\left(\tfrac{8T}{\delta}\right)} + DSA\log_2\left(\tfrac{8T}{SA}\right) \\
&\quad + \left(\sqrt{14\log\left(\tfrac{2SAT}{\delta}\right)} + 2\right) \sum_{k=1}^{m} \sum_{s,a} \frac{v_k(s,a)}{\sqrt{\max\{1, N_k(s,a)\}}} \,. \qquad (19)
\end{aligned}$$

Recall that $N(s,a) := \sum_k v_k(s,a)$ such that $\sum_{s,a} N(s,a) = T$ and $N_k(s,a) = \sum_{i<k} v_i(s,a)$. By the criterion for episode termination in Step 6 of the algorithm, we have that $v_k(s,a) \leq N_k(s,a)$. Using that for $Z_k = \max\left\{1, \sum_{i=1}^{k} z_i\right\}$ and $0 \leq z_k \leq Z_{k-1}$ it holds that (see Appendix C.3)

$$\sum_{k=1}^{n} \frac{z_k}{\sqrt{Z_{k-1}}} \leq \left(\sqrt{2}+1\right)\sqrt{Z_n},$$

we get

$$\sum_{s,a}\sum_{k} \frac{v_k(s,a)}{\sqrt{\max\{1, N_k(s,a)\}}} \leq \left(\sqrt{2}+1\right)\sum_{s,a}\sqrt{N(s,a)}.$$

By Jensen's inequality we thus have

$$\sum_{s,a}\sum_{k} \frac{v_k(s,a)}{\sqrt{\max\{1, N_k(s,a)\}}} \leq \left(\sqrt{2}+1\right)\sqrt{SAT}, \qquad (20)$$

and we get from (19) after some minor simplifications that with probability at least $1 - \frac{\delta}{12T^{5/4}}$

$$\begin{aligned}
\sum_{k=1}^{m} \Delta_k \mathbb{1}_{M\in\mathcal{M}_k} &\leq D\sqrt{\tfrac{5}{2}T\log\left(\tfrac{8T}{\delta}\right)} + DSA\log_2\left(\tfrac{8T}{SA}\right) \\
&\quad + \left(2D\sqrt{14S\log\left(\tfrac{2AT}{\delta}\right)} + 2\right)\left(\sqrt{2}+1\right)\sqrt{SAT} \,. \qquad (21)
\end{aligned}$$

4.4 Completing the Proof of Theorem 2

Finally, evaluating (8) by summing Δ_k over all episodes, we get by (9) and (21)

$$\begin{aligned}
\Delta(s_1, T) &\leq \sum_{k=1}^{m} \Delta_k \mathbb{1}_{M\notin\mathcal{M}_k} + \sum_{k=1}^{m} \Delta_k \mathbb{1}_{M\in\mathcal{M}_k} + \sqrt{\tfrac{5}{8}T\log\left(\tfrac{8T}{\delta}\right)} \\
&\leq \sqrt{\tfrac{5}{8}T\log\left(\tfrac{8T}{\delta}\right)} + \sqrt{T} + D\sqrt{\tfrac{5}{2}T\log\left(\tfrac{8T}{\delta}\right)} + DSA\log_2\left(\tfrac{8T}{SA}\right) \\
&\quad + \left(2D\sqrt{14S\log\left(\tfrac{2AT}{\delta}\right)} + 2\right)\left(\sqrt{2}+1\right)\sqrt{SAT} \qquad (22)
\end{aligned}$$

with probability at least $1-\frac{\delta}{12T^{5/4}}-\frac{\delta}{12T^{5/4}}-\frac{\delta}{12T^{5/4}}$. Further simplifications (given in Appendix C.4) yield that for any $T>1$ with probability at least $1-\frac{\delta}{4T^{5/4}}$

$$\Delta(s_1,T) \;\le\; 34DS\sqrt{AT\log\left(\tfrac{T}{\delta}\right)}. \tag{23}$$

Since $\sum_{T=2}^{\infty}\frac{\delta}{4T^{5/4}}<\delta$ the statement of Theorem 2 follows by a union bound over all possible values of T. ■

4.5 Proof of Corollary 3

In order to obtain the PAC bound of Corollary 3 we simply have to find a sufficiently large T_0 such that for all $T\ge T_0$ the per-step regret is smaller than ε. By Theorem 2 this means that for all $T\ge T_0$ we shall have

$$\frac{34DS\sqrt{AT\log\left(\frac{T}{\delta}\right)}}{T}<\varepsilon, \text{ or equivalently} \quad T>\frac{34^2D^2S^2A\log\left(\frac{T}{\delta}\right)}{\varepsilon^2}. \tag{24}$$

Setting $T_0:=2\alpha\log\left(\frac{\alpha}{\delta}\right)$ for $\alpha:=\frac{34^2D^2S^2A}{\varepsilon^2}$ we have due to $x>2\log x$ (for $x>0$)

$$T_0 \;=\; \alpha\log\left(\frac{\alpha}{\delta}\cdot\frac{\alpha}{\delta}\right)>\alpha\log\left(2\frac{\alpha}{\delta}\log\left(\frac{\alpha}{\delta}\right)\right)=\alpha\log\left(\tfrac{T_0}{\delta}\right),$$

so that (24) as well as the corollary follow. ■

5. The Logarithmic Bound (Proof of Theorem 4)

To show the logarithmic upper bound on the expected regret, we start with a bound on the number of steps in suboptimal episodes (in the spirit of *sample complexity bounds* as given by Kakade, 2003). We say that an episode k is ε-*bad* if its average regret is more than ε, where the average regret of an episode of length ℓ_k is $\frac{\Delta_k}{\ell_k}$ with[10] $\Delta_k=\sum_{t=t_k}^{t_{k+1}-1}(\rho^*-r_t)$. The following result gives an upper bound on the number of steps taken in ε-bad episodes.

Theorem 11 *Let $L_\varepsilon(T)$ be the number of steps taken by* UCRL2 *in ε-bad episodes up to step T. Then for any initial state $s\in\mathcal{S}$, any $T>1$ and any $\varepsilon>0$, with probability of at least $1-3\delta$*

$$L_\varepsilon(T) \;\le\; 34^2\frac{D^2S^2A\log\left(\frac{T}{\delta}\right)}{\varepsilon^2}.$$

Proof The proof is an adaptation of the proof of Theorem 2 which gives an upper bound of $O\Big(DS\sqrt{L_\varepsilon A\log(AT/\delta)}\Big)$ on the regret $\Delta'_\varepsilon(s,T)$ in ε-bad episodes in terms of L_ε. The theorem then follows due to $\varepsilon L_\varepsilon\le\Delta'_\varepsilon(s,T)$.

Fix some $T>1$, and let K_ε and J_ε be two random sets that contain the indices of the ε-bad episodes up to step T and the corresponding time steps taken in these episodes, respectively. Then by an application of Hoeffding's inequality similar to (7) in Section 4.1 and a union bound over all possible values of L_ε, one obtains that with probability at least $1-\delta$,

$$\sum_{k\in K_\varepsilon}\sum_{t=t_k}^{t_{k+1}-1}r_t \;\ge\; \sum_{k\in K_\varepsilon}\sum_{s,a}v_k(s,a)\bar{r}(s,a)-\sqrt{2L_\varepsilon\log\left(\tfrac{T}{\delta}\right)}\,.$$

10. In the following we use the same notation as in the proof of Theorem 2.

Further, by summing up all error probabilities $\mathbb{P}\left\{M \notin \mathcal{M}(t)\right\} \leq \frac{\delta}{15t^6}$ for $t = 1, 2, \ldots$ one has

$$\mathbb{P}\left\{ \sum_{k \in K_\varepsilon} \Delta_k \mathbb{1}_{M \notin \mathcal{M}_k} > 0 \right\} \leq \delta \,.$$

It follows that with probability at least $1 - 2\delta$

$$\Delta'_\varepsilon(s,T) \;\leq\; \sqrt{2L_\varepsilon \log\left(\tfrac{T}{\delta}\right)} + \sum_{k \in K_\varepsilon} \Delta_k \mathbb{1}_{M \in \mathcal{M}_k}. \tag{25}$$

In order to bound the regret of a single episode with $M \in \mathcal{M}_k$ we follow the lines of the proof of Theorem 2 in Section 4.3. Combining (15), (16), and (17) we have that

$$\Delta_k \;\leq\; \boldsymbol{v}_k\big(\boldsymbol{P}_k - \boldsymbol{I}\big)\boldsymbol{w}_k + \left(2D\sqrt{14S\log\left(\tfrac{2AT}{\delta}\right)} + 2\right) \sum_{s,a} \frac{v_k(s,a)}{\sqrt{\max\{1, N_k(s,a)\}}} \,. \tag{26}$$

In Appendix D we prove an analogon of (20), that is,

$$\sum_{k \in K_\varepsilon} \sum_{s,a} \frac{v_k(s,a)}{\sqrt{\max\{1, N_k(s,a)\}}} \;\leq\; \left(\sqrt{2}+1\right)\sqrt{L_\varepsilon SA} \,. \tag{27}$$

Then from (25), (26), and (27) it follows that with probability at least $1 - 2\delta$

$$\begin{aligned} \Delta'_\varepsilon(s,T) \;\;\leq\;\; & \sqrt{2L_\varepsilon \log\left(\tfrac{T}{\delta}\right)} + \left(2D\sqrt{14S\log\left(\tfrac{2AT}{\delta}\right)} + 2\right) \cdot \left(\sqrt{2}+1\right) \cdot \sqrt{L_\varepsilon SA} \\ & + \sum_{k \in K_\varepsilon} \boldsymbol{v}_k(\boldsymbol{P}_k - \boldsymbol{I})\boldsymbol{w}_k \mathbb{1}_{M \in \mathcal{M}_k} \,. \end{aligned} \tag{28}$$

For the regret term of $\sum_{k \in K_\varepsilon} \boldsymbol{v}_k(\boldsymbol{P}_k - \boldsymbol{I})\boldsymbol{w}_k \mathbb{1}_{M \in \mathcal{M}_k}$ we use an argument similar to the one applied to obtain (18) in Section 4.3.2. Here we have to consider a slightly modified martingale difference sequence

$$X_t = \big(p(\cdot|s_t, a_t) - \boldsymbol{e}_{s_{t+1}}\big)\boldsymbol{w}_{k(t)} \mathbb{1}_{M \in \mathcal{M}_{k(t)}} \mathbb{1}_{t \in J_\varepsilon}$$

for $t = 1, \ldots, T$ to get (using the bound on the number of episodes given in Appendix C.2)

$$\begin{aligned} \sum_{k \in K_\varepsilon} \boldsymbol{v}_k(\boldsymbol{P}_k - \boldsymbol{I})\boldsymbol{w}_k \mathbb{1}_{M \in \mathcal{M}_k} \;\;&\leq\;\; \sum_{t \in J_\varepsilon} X_t + DSA\log_2\left(\tfrac{8T}{SA}\right) \\ &\leq\;\; \sum_{t=1}^{T(L_\varepsilon)} X_t + DSA\log_2\left(\tfrac{8T}{SA}\right) \,, \end{aligned} \tag{29}$$

where we set $T(L) := \min\left\{t : \#\{\tau \leq t, \tau \in J_\varepsilon\} = L\right\}$. The application of the Azuma-Hoeffding inequality in Section 4.3.2 is replaced with the following consequence of Bernstein's inequality for martingales.

Lemma 12 (Freedman 1975) *Let $X_1, X_2, \ldots$ be a martingale difference sequence. Then*

$$\mathbb{P}\left\{ \sum_{i=1}^n X_i \geq \kappa,\; \sum_{i=1}^n X_i^2 \leq \gamma \right\} \;\leq\; \exp\left(-\frac{\kappa^2}{2\gamma + \frac{2\kappa}{3}}\right).$$

Application of Lemma 12 with $\kappa = 2D\sqrt{L\log(T/\delta)}$ and $\gamma = D^2 L$ yields that for $L \geq \frac{\log(T/\delta)}{D^2}$ it holds that

$$\mathbb{P}\left\{ \sum_{t=1}^{T(L)} X_t > 2D\sqrt{L\log\left(\tfrac{T}{\delta}\right)} \right\} < \frac{\delta}{T}. \tag{30}$$

On the other hand, if $L < \frac{\log(T/\delta)}{D^2}$, we have

$$\sum_{t=1}^{T(L)} X_t \;\leq\; DL \;=\; D\sqrt{L}\sqrt{L} \;<\; \sqrt{L}\sqrt{\log\left(\tfrac{T}{\delta}\right)} \;<\; 2D\sqrt{L\log\left(\tfrac{T}{\delta}\right)}. \tag{31}$$

Hence, (30) and (31) give by a union bound over all possible values of L_ε that with probability at least $1-\delta$

$$\sum_{t=1}^{T(L_\varepsilon)} X_t \;\leq\; 2D\sqrt{L_\varepsilon \log\left(\tfrac{T}{\delta}\right)}.$$

Together with (29) this yields that with probability at least $1-\delta$

$$\sum_{k\in K_\varepsilon} \boldsymbol{v}_k(\boldsymbol{P}_k - \boldsymbol{I})\boldsymbol{w}_k \mathbb{1}_{M\in\mathcal{M}_k} \;\leq\; 2D\sqrt{L_\varepsilon \log\left(\tfrac{T}{\delta}\right)} + DSA\log_2\left(\tfrac{8T}{SA}\right).$$

Thus by (28) we obtain that with probability at least $1-3\delta$

$$\begin{aligned}\Delta'_\varepsilon(s,T) \;\leq\; & \sqrt{2L_\varepsilon \log\left(\tfrac{T}{\delta}\right)} + \left(2D\sqrt{14S\log\left(\tfrac{2AT}{\delta}\right)} + 2\right)\cdot\left(\sqrt{2}+1\right)\cdot\sqrt{L_\varepsilon SA} \\ & + 2D\sqrt{L_\varepsilon \log\left(\tfrac{T}{\delta}\right)} + DSA\log_2\left(\tfrac{8T}{SA}\right).\end{aligned}$$

This can be simplified to

$$\Delta'_\varepsilon(s,T) \leq 34DS\sqrt{L_\varepsilon A\log\left(\tfrac{T}{\delta}\right)} \tag{32}$$

by similar arguments as given in Appendix C.4. Since $\varepsilon L_\varepsilon \leq \Delta'_\varepsilon(s,T)$, we get

$$L_\varepsilon \leq 34^2 \cdot \frac{D^2 S^2 A\log\left(\tfrac{T}{\delta}\right)}{\varepsilon^2}, \tag{33}$$

which proves the theorem. ■

Now we apply Theorem 11 to obtain the claimed logarithmic upper bound on the expected regret.

Proof of Theorem 4 Upper bounding L_ε in (32) by (33), we obtain for the regret $\Delta'_\varepsilon(s,T)$ accumulated in ε-bad episodes that

$$\Delta'_\varepsilon(s,T) \leq 34^2 \cdot \frac{D^2 S^2 A\log\left(\tfrac{T}{\delta}\right)}{\varepsilon}$$

with probability at least $1-3\delta$. Noting that the regret accumulated outside of ε-bad episodes is at most εT implies the first statement of the theorem.

For the bound on the expected regret, first note that the expected regret of each episode in which an optimal policy is executed is at most D, whereas due to Theorem 11 the expected regret in $\frac{g}{2}$-bad

episodes is upper bounded by $34^2 \cdot \frac{2 \cdot D^2 S^2 A \log(T)}{g} + 1$, as $\delta = \frac{1}{3T}$. What remains to do is to consider episodes k with expected average regret smaller than $\frac{g}{2}$ in which however a non-optimal policy $\tilde{\pi}_k$ was chosen.

First, note that for each policy π there is a T_π such that for all $T \geq T_\pi$ the expected average reward after T steps is $\frac{g}{2}$-close to the average reward of π. Thus, when a policy π is played in an episode of length $\geq T_\pi$ either the episode is $\frac{g}{2}$-bad (in expectation) or the policy π is optimal. Now we fix a state-action pair (s,a) and consider the episodes k in which the number of visits $v_k(s,a)$ in (s,a) is doubled. The corresponding episode lengths $\ell_k(s,a)$ are not necessarily increasing, but the $v_k(s,a)$ are monotonically increasing, and obviously $\ell_k(s,a) \geq v_k(s,a)$. Since the $v_k(s,a)$ are at least doubled, it takes at most $\lceil 1 + \log_2(\max_{\pi:\pi(s)=a} T_\pi) \rceil$ episodes until $\ell_k(s,a) \geq v_k(s,a) \geq \max_{\pi:\pi(s)=a} T_\pi$, when any policy π with $\pi(s) = a$ applied in episode k that is not $\frac{g}{2}$-bad (in expectation) will be optimal. Consequently, as only episodes of length smaller than $\max_{\pi:\pi(s)=a} T_\pi$ have to be considered, the regret of episodes k where $v_k(s,a) < \max_{\pi:\pi(s)=a} T_\pi$ is upper bounded by $\lceil 1 + \log_2(\max_{\pi:\pi(s)=a} T_\pi) \rceil \max_{\pi:\pi(s)=a} T_\pi$. Summing over all state-action pairs, we obtain an additional additive regret term of

$$\sum_{s,a} \left\lceil 1 + \log_2\Big(\max_{\pi:\pi(s)=a} T_\pi \Big) \right\rceil \max_{\pi:\pi(s)=a} T_\pi,$$

which concludes the proof of the theorem. ■

6. The Lower Bound (Proof of Theorem 5)

We first consider the two-state MDP depicted in Figure 3. That is, there are two states, the initial state $s_\circ$ and another state s_1, and $A' = \left\lfloor \frac{A-1}{2} \right\rfloor$ actions. For each action a, let the deterministic rewards be $r(s_\circ, a) = 0$ and $r(s_1, a) = 1$. For all but a single "good" action a^* let $p(s_1|s_\circ, a) = \delta := \frac{4}{D}$, whereas $p(s_1|s_\circ, a^*) = \delta + \varepsilon$ for some $0 < \varepsilon < \delta$ specified later in the proof. Further, let $p(s_\circ|s_1, a) = \delta$ for all a. The diameter of this MDP is $D' = \frac{1}{\delta} = \frac{D}{4}$. For the rest of the proof we assume that[11] $\delta \leq \frac{1}{3}$.

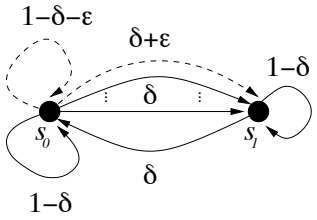

Figure 3: The MDP for the lower bound. The single action a^* with higher transition probability from state $s_\circ$ to state s_1 is shown as dashed line.

Consider $k := \left\lfloor \frac{S}{2} \right\rfloor$ copies of this MDP where only one of the copies has such a "good" action a^*. To complete the construction, we connect the k copies into a single MDP with diameter less than D,

11. Otherwise we have $D < 12$, so that due to the made assumptions $A > 2S$. In this case we employ a different construction: Using $S-1$ actions, we connect all states to get an MDP with diameter 1. With the remaining $A - S + 1$ actions we set up a bandit problem in each state as in the proof of the lower bound of Auer et al. (2002b) where only one state has a better action. This yields $\Omega(\sqrt{SAT})$ regret, which is sufficient, since D is bounded in this case.

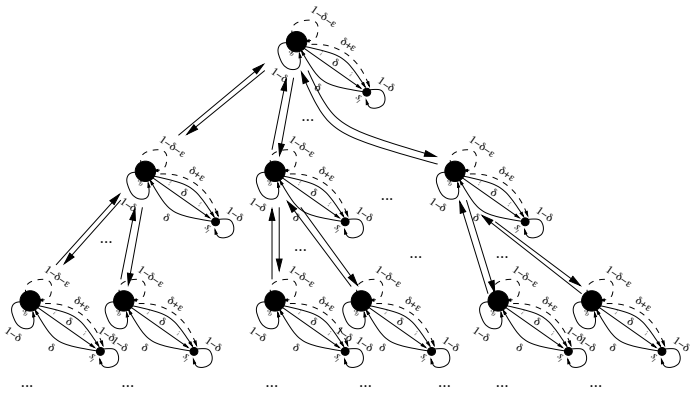

Figure 4: The composite MDP for the lower bound. Copies of the MDP of Figure 3 are arranged in an A'-ary tree, where the $s_\circ$-states are connected.

using at most $A - A'$ additional actions. This can be done by introducing $A'+1$ additional actions per state with deterministic transitions which do not leave the $s_|$-states and connect the $s_\circ$-states of the k copies by inducing an A'-ary tree structure on the $s_\circ$-states (one action for going toward the root, A' actions going toward the leaves—see Figure 4 for a schematic representation of the composite MDP). The reward for each of those actions is zero in any state. The diameter of the resulting MDP is at most $2(\frac{D}{4} + \lceil \log_{A'} k \rceil)$, which is twice the time it takes to travel to or from the root for any state in the MDP. Thus we have constructed an MDP M with $\leq S$ states, $\leq A$ actions, and diameter $\leq D$, for which we will show the claimed lower bound on the regret.

Actually, in the analysis we will consider the simpler MDP where all $s_\circ$-states are identified. We set this state to be the initial state. This MDP is equivalent to a single MDP M' like the one in Figure 3 with kA' actions which we assume in the following to be taken from $\{1,\ldots,kA'\}$. Note that learning this MDP is easier (as the learner is allowed to switch between different $s_\circ$-states without any cost for transition), while its optimal average reward is the same.

We prove the theorem by applying the same techniques as in the proof of the lower bound for the multi-armed bandit problem of Auer et al. (2002b). The pair $(s^*_\circ, a^*)$ identifying the copy with the better action and the better action is considered to be chosen uniformly at random from $\{1,\ldots,k\} \times \{1,\ldots,A'\}$, and we denote the expectation with respect to the random choice of $(s^*_\circ, a^*)$ as $\mathbb{E}_*[\cdot]$. We show that ε can be chosen such that M' and consequently also the composite MDP M forces regret $\mathbb{E}_*[\Delta(M, \mathfrak{A}, s_\circ, T)] \geq \mathbb{E}_*[\Delta(M', \mathfrak{A}, s^*_\circ, T)] > 0.015\sqrt{D'kA'T}$ on any algorithm $\mathfrak{A}$.

We write $\mathbb{E}_{\text{unif}}[\cdot]$ for the expectation when there is no special action (i.e., the transition probability from $s_\circ$ to $s_|$ is δ for all actions), and $\mathbb{E}_a[\cdot]$ for the expectation conditioned on a being the special action a^* in M'. As already argued by Auer et al. (2002b), it is sufficient to consider deterministic strategies for choosing actions. Indeed, any randomized strategy is equivalent to an (apriori) random choice from the set of all deterministic strategies. Thus, we may assume that any algorithm $\mathfrak{A}$ maps the sequence of observations up to step t to an action a_t.

Now we follow the lines of the proof of Theorem A.2 as given by Auer et al. (2002b). Let the random variables $N_|, N_\circ$ and $N^*_\circ$ denote the total number of visits to state $s_|$, the total number of visits to state $s_\circ$, and the number of times action a^* is chosen in state $s_\circ$, respectively. Further, write s_t as

usual for the state observed at step t. Then since $s_\circ$ is assumed to be the initial state, we have

$$\begin{aligned}
\mathbb{E}_a[N_\shortmid] &= \sum_{t=1}^{T} \mathbb{P}_a[s_t = s_\shortmid] = \sum_{t=2}^{T} \mathbb{P}_a[s_t = s_\shortmid] = \\
&= \sum_{t=2}^{T} \left(\mathbb{P}_a[s_t = s_\shortmid | s_{t-1} = s_\circ] \, \mathbb{P}_a[s_{t-1} = s_\circ] + \mathbb{P}_a[s_t = s_\shortmid | s_{t-1} = s_\shortmid] \, \mathbb{P}_a[s_{t-1} = s_\shortmid] \right) \\
&\leq \delta \sum_{t=2}^{T} \mathbb{P}_a[s_{t-1} = s_\circ, a_t \neq a^*] + (\delta + \varepsilon) \sum_{t=2}^{T} \mathbb{P}_a[s_{t-1} = s_\circ, a_t = a^*] + (1-\delta)\mathbb{E}_a[N_\shortmid] \\
&\leq \delta \mathbb{E}_a[N_\circ - N_\circ^*] + (\delta + \varepsilon)\mathbb{E}_a[N_\circ^*] + (1-\delta)\mathbb{E}_a[N_\shortmid].
\end{aligned}$$

Taking into account that choosing a^* instead of any other action in $s_\circ$ reduces the probability of staying in state $s_\circ$, it follows that (using $D' = \frac{1}{\delta}$)

$$\begin{aligned}
\mathbb{E}_a\left[R(M', \mathfrak{A}, s, T)\right] \leq \mathbb{E}_a[N_\shortmid] &\leq \mathbb{E}_a[N_\circ - N_\circ^*] + \tfrac{\delta+\varepsilon}{\delta}\mathbb{E}_a[N_\circ^*] \\
&= \mathbb{E}_a[N_\circ] + \mathbb{E}_a[N_\circ^*]\,\varepsilon D' \\
&\leq \mathbb{E}_{\text{unif}}[N_\circ] + \mathbb{E}_a[N_\circ^*]\,\varepsilon D' \\
&= \mathbb{E}_{\text{unif}}[T - N_\shortmid] + \mathbb{E}_a[N_\circ^*]\,\varepsilon D' \\
&= T - \mathbb{E}_{\text{unif}}[N_\shortmid] + \mathbb{E}_a[N_\circ^*]\,\varepsilon D'. \qquad (34)
\end{aligned}$$

Now denoting the step where the first transition from $s_\circ$ to $s_\shortmid$ occurs by $\tau_{\circ\shortmid}$, we may lower bound $\mathbb{E}_{\text{unif}}[N_\shortmid]$ by the law of total expectation as

$$\begin{aligned}
\mathbb{E}_{\text{unif}}[N_\shortmid] &= \sum_{t=1}^{T} \mathbb{E}_{\text{unif}}[N_\shortmid | \tau_{\circ\shortmid} = t] \, \mathbb{P}_{\text{unif}}[\tau_{\circ\shortmid} = t] = \sum_{t=1}^{T} \mathbb{E}_{\text{unif}}[N_\shortmid | \tau_{\circ\shortmid} = t] \, (1-\delta)^{t-1}\delta \\
&\geq \sum_{t=1}^{T-1} \frac{T-t}{2}(1-\delta)^{t-1}\delta = \frac{\delta T}{2}\sum_{t=1}^{T-1}(1-\delta)^{t-1} - \frac{\delta}{2}\sum_{t=1}^{T-1} t(1-\delta)^{t-1} \\
&= \frac{\delta T}{2} \cdot \frac{1-(1-\delta)^{T-1}}{\delta} - \frac{\delta}{2}\left(\frac{1-(1-\delta)^T}{\delta^2} - \frac{T(1-\delta)^{T-1}}{\delta} \right) \\
&= \frac{T - T(1-\delta)^{T-1}}{2} - \frac{1}{2\delta} + \frac{(1-\delta)^T}{2\delta} + \frac{T(1-\delta)^{T-1}}{2} \\
&= \frac{T}{2} - \frac{1}{2\delta} + \frac{(1-\delta)^T}{2\delta} \geq \frac{T}{2} - \frac{1}{2\delta} = \frac{T}{2} - \frac{D'}{2}. \qquad (35)
\end{aligned}$$

Therefore, combining (34) and (35) we obtain

$$\mathbb{E}_a\left[R(M', \mathfrak{A}, s, T)\right] \leq \frac{T}{2} + \mathbb{E}_a[N_\circ^*]\,\varepsilon D' + \frac{D'}{2}. \qquad (36)$$

As $\mathfrak{A}$ chooses its actions deterministically based on the observations so far, $N_\circ^*$ is a function of the observations up to step T, too. A slight difference to Auer et al. (2002b) is that in our setting the sequence of observations consists not just of the rewards but also of the next state, that is, upon playing action a_t the algorithm observes s_{t+1} and r_t. However, since the immediate reward is fully determined by the current state, $N_\circ^*$ is also a function of just the state sequence, and we may bound $\mathbb{E}_a[N_\circ^*]$ by the following lemma, adapted from Auer et al. (2002b).

Lemma 13 *Let $f : \{s_\circ, s_\downarrow\}^{T+1} \to [0,B]$ be any function defined on state sequences $\boldsymbol{s} \in \{s_\circ, s_\downarrow\}^{T+1}$ observed in the MDP M'. Then for any $0 \le \delta \le \frac{1}{2}$, any $0 \le \varepsilon \le 1-2\delta$, and any $a \in \{1,\ldots,kA'\}$,*

$$\mathbb{E}_a[f(\boldsymbol{s})] \;\le\; \mathbb{E}_{\text{unif}}[f(\boldsymbol{s})] + \frac{B}{2} \cdot \frac{\varepsilon}{\sqrt{\delta}} \sqrt{2\mathbb{E}_{\text{unif}}[N_\circ^*]}.$$

The proof of Lemma 13 is a straightforward modification of the respective proof given by Auer et al. (2002b). For details we refer to Appendix E.

Now let us assume that $\varepsilon \le \delta$. (Our final choice of ε below will satisfy this requirement.) By our assumption of $\delta \le \frac{1}{3}$ this yields that $\varepsilon \le \delta \le \frac{1}{3} \le 1-2\delta$. Then, since $N_\circ^*$ is a function of the state sequence with $N_\circ^* \in [0,T]$, we may apply Lemma 13 to obtain

$$\mathbb{E}_a[N_\circ^*] \;\le\; \mathbb{E}_{\text{unif}}[N_\circ^*] + \frac{T}{2}\varepsilon\sqrt{D'}\sqrt{2\mathbb{E}_{\text{unif}}[N_\circ^*]}. \tag{37}$$

An immediate consequence of (35) is that $\sum_{a=1}^{kA'} \mathbb{E}_{\text{unif}}[N_\circ^*] \le \frac{T}{2} + \frac{D'}{2}$, which yields by Jensen's inequality that $\sum_{a=1}^{kA'} \sqrt{2\mathbb{E}_{\text{unif}}[N_\circ^*]} \le \sqrt{kA'(T+D')}$. Thus we have from (37)

$$\begin{aligned}
\sum_{a=1}^{kA'} \mathbb{E}_a[N_\circ^*] &\le \frac{T}{2} + \frac{D'}{2} + \frac{\varepsilon T}{2}\sqrt{D'}\sqrt{kA'(T+D')} \\
&\le \frac{T}{2} + \frac{D'}{2} + \frac{\varepsilon T}{2}\sqrt{D'kA'T} + \frac{\varepsilon T D'}{2}\sqrt{kA'}.
\end{aligned}$$

Together with (36) this gives

$$\begin{aligned}
\mathbb{E}_*\left[R(M',\mathfrak{A},s,T)\right] &= \frac{1}{kA'}\sum_{a=1}^{kA'} \mathbb{E}_a[R(M,\mathfrak{A},s,T)] \\
&\le \frac{T}{2} + \frac{\varepsilon T D'}{2kA'} + \frac{\varepsilon D'^2}{2kA'} + \frac{\varepsilon^2 T D'}{2kA'}\sqrt{D'kA'T} + \frac{\varepsilon^2 T D'^2}{2kA'}\sqrt{kA'} + \frac{D'}{2}.
\end{aligned}$$

Calculating the stationary distribution, we find that the optimal average reward for the MDP M' is $\frac{\delta+\varepsilon}{2\delta+\varepsilon}$. Hence, the expected regret with respect to the random choice of a^* is at least

$$\begin{aligned}
&\mathbb{E}_*\left[\Delta(M',\mathfrak{A},s,T)\right] = \frac{\delta+\varepsilon}{2\delta+\varepsilon}T - \mathbb{E}_*[R(M,\mathfrak{A},s,T)] \\
&\ge \frac{\delta+\varepsilon}{2\delta+\varepsilon}T - \frac{T}{2} - \frac{\varepsilon T D'}{2kA'} - \frac{\varepsilon D'}{2kA'}\cdot D' - \frac{\varepsilon^2 T D'}{2kA'}\sqrt{D'kA'T} - \frac{\varepsilon^2 T D'}{2kA'}\sqrt{D'kA'}\cdot\sqrt{D'} - \frac{D'}{2}.
\end{aligned}$$

Since by assumption we have $T \ge DSA \ge 16D'kA'$ and thus $D' \le \frac{T}{16kA'}$, it follows that

$$\begin{aligned}
&\mathbb{E}_*\left[\Delta(M',\mathfrak{A},s,T)\right] \\
&\ge \frac{\varepsilon T}{4\delta+2\varepsilon} - \frac{\varepsilon T D'}{2kA'} - \frac{\varepsilon D'}{2kA'}\cdot\frac{T}{16kA'} - \frac{\varepsilon^2 T D'}{2kA'}\sqrt{D'kA'T} - \frac{\varepsilon^2 T D'}{2kA'}\sqrt{D'kA'}\sqrt{\frac{T}{16kA'}} - \frac{D'}{2} \\
&= \frac{\varepsilon T}{4\delta+2\varepsilon} - \varepsilon T D'\left(\frac{1}{2kA'} + \frac{1}{32k^2A'^2}\right) - \frac{\varepsilon^2 T D'}{kA'}\sqrt{D'kA'T}\left(\frac{1}{2} + \frac{1}{8\sqrt{kA'}}\right) - \frac{D'}{2}.
\end{aligned}$$

Now we choose $\varepsilon := c\sqrt{\frac{kA'}{TD'}}$, where $c := \frac{1}{5}$. Then because of $\frac{1}{\delta} = D' \leq \frac{T}{16kA'}$ it follows that $\varepsilon \leq c\frac{1}{4D'} = \frac{\delta}{20}$ (so that also $\varepsilon \leq \delta$ as needed to get (37)), and further $\frac{1}{4\delta+2\varepsilon} \geq \frac{1}{4+1/8}D'$. Hence we obtain

$$\mathbb{E}_*\left[\Delta(M',\mathfrak{A},s,T)\right] \;\geq\; \left(\frac{c}{4+\frac{1}{8}} - \frac{c}{2kA'} - \frac{c}{32k^2A'^2} - \frac{c^2}{2} - \frac{c^2}{8\sqrt{kA'}}\right)\sqrt{D'kA'T} - \frac{D'}{2}.$$

Finally, we note that

$$\frac{D'}{2} \leq \tfrac{1}{2}\sqrt{D'}\sqrt{\frac{T}{16kA'}} = \frac{1}{8kA'}\sqrt{D'kA'T},$$

and since by assumption $S,A \geq 10$ so that $kA' \geq 20$, it follows that

$$\mathbb{E}_*\left[\Delta(M',\mathfrak{A},s,T)\right] \;>\; 0.015\sqrt{D'kA'T},$$

which concludes the proof. ■

7. Regret Bounds for Changing MDPs (Proof of Theorem 6)

Consider the learner operates in a setting where the MDP is allowed to change ℓ times, such that the diameter never exceeds D (we assume an initial change at time $t = 1$). For this task we define the regret of an algorithm $\mathfrak{A}$ up to step T with respect to the average reward $\rho^*(t)$ of an optimal policy at step t as

$$\Delta'(\mathfrak{A},s,T) := \sum_{t=1}^{T} \rho^*(t) - r_t,$$

where r_t is as usual the reward received by $\mathfrak{A}$ at step t when starting in state s.

The intuition behind our approach is the following: When restarting UCRL2 every $\left(\frac{T}{\ell}\right)^{2/3}$ steps, the total regret for periods in which the MDP changes is at most $\ell^{1/3}T^{2/3}$. For each other period we have regret of $\tilde{O}\big((\frac{T}{\ell})^{1/3}\big)$ by Theorem 2. Since UCRL2 is restarted only $T^{1/3}\ell^{2/3}$ times, the total regret is $\tilde{O}\big(\ell^{1/3}T^{2/3}\big)$.

Because the horizon T is usually unknown, we use an alternative approach for restarting which however exhibits similar properties: UCRL2′ restarts UCRL2 with parameter $\frac{\delta}{\ell^2}$ at steps $\tau_i = \left\lceil \frac{i^3}{\ell^2} \right\rceil$ for $i = 1,2,3,\ldots$. Now we prove Theorem 6, which states that the regret of UCRL2′ is bounded by

$$\Delta'(\text{UCRL2}',s,T) \leq 65 \cdot \ell^{1/3}T^{2/3}DS\sqrt{A\log\left(\tfrac{T}{\delta}\right)}$$

with probability at least $1-\delta$ in the considered setting.

Let n be the largest natural number such that $\left\lceil \frac{n^3}{\ell^2} \right\rceil \leq T$, that is, n is the number of restarts up to step T. Then $\frac{n^3}{\ell^2} \leq \tau_n \leq T \leq \tau_{n+1} - 1 < \frac{(n+1)^3}{\ell^2}$ and consequently

$$\ell^{2/3}T^{1/3} - 1 \;\leq\; n \;\leq\; \ell^{2/3}T^{1/3}. \tag{38}$$

The regret Δ_c incurred due to changes of the MDP can be bounded by the number of steps taken in periods in which the MDP changes. This is maximized when the changes occur during the ℓ

longest periods, which contain at most $\tau_{n+1} - 1 - \tau_{n-\ell+1}$ steps. Hence we have

$$\begin{aligned}\Delta_c &\leq \tau_{n+1} - 1 - \tau_{n-\ell+1} \\ &\leq \tfrac{1}{\ell^2}(n+1)^3 - \tfrac{1}{\ell^2} - \tfrac{1}{\ell^2}(n-\ell+1)^3 \\ &= 3\tfrac{n^2}{\ell} + 6\tfrac{n}{\ell} - 3n - \tfrac{1}{\ell^2} + \ell - 3 + 3\tfrac{1}{\ell}. \end{aligned} \tag{39}$$

For $\ell \geq 2$ we get by (39) and (38) that

$$\Delta_c \leq 3\frac{n^2}{\ell} + \ell \leq 3\frac{\ell^{4/3}T^{2/3}}{\ell} + \ell = 3\ell^{1/3}T^{2/3} + \ell,$$

while for $\ell = 1$ we obtain also from (39) and (38) that

$$\Delta_c \leq 3n^2 + 3n \leq 3T^{2/3} + 3T^{1/3}.$$

Thus the contribution to the regret from changes of the MDP is at most

$$\begin{aligned}\Delta_c &\leq 3\ell^{1/3}T^{2/3} + 3T^{1/3} + \ell \\ &\leq 6\ell^{1/3}T^{2/3} + \ell^{1/3}\ell^{2/3} \\ &\leq 6\ell^{1/3}T^{2/3} + \ell^{1/3}T^{2/3} \\ &\leq 7\ell^{1/3}T^{2/3}. \end{aligned} \tag{40}$$

On the other hand, if the MDP does not change between the steps τ_i and $\min\{T, \tau_{i+1}\}$, the regret $\Delta(s_{\tau_i}, T_i)$ for these $T_i := \min\{T, \tau_{i+1}\} - \tau_i$ steps is bounded according to Theorem 2 (or more precisely (23)). Therefore, recalling that the confidence parameter is chosen to be $\frac{\delta}{\ell^2}$, this gives

$$\Delta(s_{\tau_i}, T_i) \leq 34DS\sqrt{T_i A \log\left(\tfrac{\ell^2 T_i}{\delta}\right)} \leq 34\sqrt{3}DS\sqrt{T_i}\sqrt{A\log\left(\tfrac{T}{\delta}\right)}$$

with probability $1 - \frac{\delta}{4\ell^2 T_i^{5/4}}$. As $\sum_{i=1}^n T_i = T$, we have by Jensen's inequality $\sum_{i=1}^n \sqrt{T_i} \leq \sqrt{n}\sqrt{T}$. Thus, summing over all $i = 1, \ldots, n$, the regret Δ_f in periods in which the MDP does not change is by (38)

$$\begin{aligned}\Delta_f &\leq \sum_{i=1}^n \Delta(s_{\tau_i}, T_i) \leq 34\sqrt{3}DS\sqrt{n}\sqrt{T}\sqrt{A\log\left(\tfrac{T}{\delta}\right)} \\ &\leq 34\sqrt{3}DS\,\ell^{1/3}\,T^{2/3}\,\sqrt{A\log\left(\tfrac{T}{\delta}\right)} \end{aligned} \tag{41}$$

with probability at least $1 - \sum_{i=1}^n \frac{\delta}{4\ell^2 T_i^{5/4}}$. We conclude the proof by bounding this latter probability. For $\left\lfloor \frac{\ell^2}{3} \right\rfloor < i < n$,

$$\begin{aligned}T_i &= \left\lceil \frac{(i+1)^3}{\ell^2} \right\rceil - \left\lceil \frac{i^3}{\ell^2} \right\rceil \\ &\geq \frac{(i+1)^3}{\ell^2} - \frac{i^3}{\ell^2} - \frac{\ell^2 - 1}{\ell^2} \\ &= \frac{3i^2}{\ell^2} + \frac{3i + 2 - \ell^2}{\ell^2} \geq \frac{3i^2}{\ell^2}, \end{aligned}$$

and consequently $\frac{1}{\ell^2 T_i^{5/4}} \leq \frac{1}{i^2}$. This together with $T_i \geq 1$ then yields

$$\begin{aligned} 1 - \sum_{i=1}^{n} \frac{\delta}{4\ell^2 T_i^{5/4}} &\geq 1 - \sum_{i=1}^{\lfloor \ell^2/3 \rfloor} \frac{\delta}{4\ell^2} - \sum_{i=\lfloor \ell^2/3 \rfloor + 1}^{n-1} \frac{\delta}{4i^2} - \frac{\delta}{4\ell^2} \\ &> 1 - \frac{\ell^2}{3} \cdot \frac{\delta}{4\ell^2} - \frac{\delta}{4} \sum_{i=1}^{\infty} \frac{1}{i^2} - \frac{\delta}{4} \\ &= 1 - \frac{\delta}{3} - \frac{\delta}{4} \cdot \frac{\pi^2}{6} > 1 - \delta. \end{aligned}$$

As $\Delta'(\text{UCRL2}', s, T) \leq \Delta_c + \Delta_f$, combining (40) and (41) yields

$$\Delta'(\text{UCRL2}', s, T) \leq 7\ell^{1/3} T^{2/3} + 34\sqrt{3} DS\, \ell^{1/3}\, T^{2/3} \sqrt{A \log\left(\tfrac{T}{\delta}\right)}$$

with probability at least $1 - \delta$, and Theorem 6 follows, since the claimed bound holds trivially for $A \log\left(\frac{T}{\delta}\right) < \log 4$. ■

8. Open Problems

There is still a gap between the upper bound on the regret of Theorem 2 and the lower bound of Theorem 5. We conjecture that the lower bound gives the right exponents for the parameters S and D (concerning the dependence on S compare also the sample complexity bounds of Strehl et al., 2006). The recent research of Bartlett and Tewari (2009) also poses the question whether the diameter in our bounds can be replaced by a smaller parameter, that is, by the span of the bias of an optimal policy. As the algorithm REGAL.C of Bartlett and Tewari (2009) demonstrates, this is at least true when this value is known to the learner. However, in the case of ignorance, currently this replacement of the diameter D can only be achieved at the cost of an additional factor of $\sqrt{S}$ in the regret bounds (Bartlett and Tewari, 2009). The difficulty in the proof is that while the span of an optimal policy's bias vector in the *assumed* optimistic MDP can be upper bounded by the diameter of the *true* MDP (cf. Remark 8), it is not clear how the spans of optimal policies in the assumed and the true MDP relate to each other.

A somehow related question is that of *transient* states, that is, the possibility that some of the states are not reachable under any policy. In this case the diameter is unbounded, so that our bounds become vacuous. Indeed, our algorithm cannot handle transient states: for any time step and any transient state s, UCRL2 optimistically assumes maximal possible reward in s and a very small but still positive transition probability to s from any other state. Thus insisting on the possibility of a transition to s, the algorithm fails to detect an optimal policy.[12] The assumption of having an upper bound on an optimal policy's bias resolves this problem, as this bound indirectly also gives some information on what the learner may expect from a state that has not been reached so far and thus may be transient. Consequently, with the assumed knowledge of such an upper bound, the REGAL.C algorithm of Bartlett and Tewari (2009) is also able to deal with transient states.

12. Actually, one can modify UCRL2 to deal with transient states by assuming transition probability 0 for all transitions not observed so far. This is complemented by an additional exploration phase between episodes where, for example, the state-action pair with the fewest number of visits is probed. While this algorithm gives asymptotically the same bounds, these however contain a large additive constant for all the episodes that occur before the transition structure assumed by the algorithm is correct.

Appendix A. A Lower Bound on the Diameter

We are going to show a more general result, from which the bound on the diameter follows. For a given MDP, let $T^*(s|s_0)$ be the minimal expected time it takes to move from state s_0 to state s.

Theorem 14 *Consider an MDP with state space $\mathcal{S}$ and A states. Let d_0 be an arbitrary distribution over $\mathcal{S}$, and $\mathcal{U} \subseteq \mathcal{S}$ be any subset of states. Then the sum of the minimal expected transition times to states in $\mathcal{U}$ when starting in an initial state distributed according to d_0 is bounded as follows:*

$$\mathcal{T}(\mathcal{U}|d_0) := \sum_{s\in\mathcal{U}} \sum_{s_0\in\mathcal{S}} d_0(s_0)\, T^*(s|s_0) \;\geq \min_{\substack{0\leq n_k\leq A^k, k\geq 0,\\ \sum_k n_k = |\mathcal{U}|}} \sum_k k\cdot n_k.$$

We think this bound is tight. The minimum on the right hand side is attained when the n_k are maximized for small k until $|\mathcal{U}|$ is exhausted. For $A \geq 2$, this gives an average (over the states in $\mathcal{U}$) expected transition time of at least $\log_A|\mathcal{U}| - 3$ to states in $\mathcal{U}$. Indeed, for $|\mathcal{U}| = \sum_{k=0}^{m-1} A^k + n_m$ we have $\frac{A^{m+1}-A}{(A-1)^2} < |\mathcal{U}|\left(1+\frac{1}{A-1}\right)$ as well as $m \geq \log_A\left(\frac{|\mathcal{U}|}{2}\right)$, so that

$$\begin{aligned}
\sum_{k=0}^{m-1} kA^k + m\cdot n_m &= m|\mathcal{U}| + \sum_{k=0}^{m-1}(k-m)A^k \\
&= m|\mathcal{U}| + \frac{m}{A-1} - \frac{A^{m+1}-A}{(A-1)^2} \\
&> |\mathcal{U}|\left(m-1-\tfrac{1}{A-1}\right) \\
&\geq |\mathcal{U}|\left(\log_A\left(\tfrac{|\mathcal{U}|}{2}\right) - 1 - \tfrac{1}{A-1}\right) \\
&\geq |\mathcal{U}|\left(\log_A|\mathcal{U}| - 3\right).
\end{aligned}$$

In particular, choosing $\mathcal{U} = \mathcal{S}$ gives the claimed lower bound on the diameter.

Corollary 15 *In any MDP with S states and $A \geq 2$ actions, the diameter D is lower bounded by $\log_A S - 3$.*

Remark 16 *For given S, A the minimal diameter is not always assumed by an MDP with deterministic transitions. Consider for example $S = 4$ and $A = 2$. Any deterministic MDP with four states and two actions has diameter at least 2. However, Figure 5 shows a corresponding MDP whose diameter is $\frac{3}{2}$.*

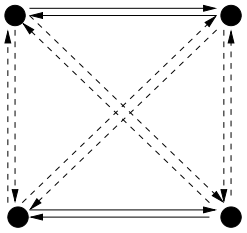

Figure 5: An MDP with four states and two actions whose diameter is $\frac{3}{2}$. In each state two actions are available. One action leads to another state deterministically, while the other action causes a random transition to each of the two other states with probability $\frac{1}{2}$ (indicated as dashed lines).

Proof of Theorem 14 Let $a^*(s_0,s)$ be the optimal action in state s_0 for reaching state s, and let $p(s|s_0,a)$ be the transition probability to state s when choosing action a in state s_0.

The proof is by induction on the size of $\mathcal{U}$. For $|\mathcal{U}| = 0,1$ the statement holds.

For $|\mathcal{U}| > 1$ we have

$$\begin{aligned}
\mathcal{T}(\mathcal{U}|d_0) &= \sum_{s_0\in\mathcal{S}}\sum_{s\in\mathcal{U}} d_0(s_0)\,T^*(s|s_0) \\
&= \sum_{s_0\in\mathcal{S}}\sum_{s\in\mathcal{U}\setminus\{s_0\}} d_0(s_0)\,T^*(s|s_0) \\
&= \sum_{s_0\in\mathcal{S}}\sum_{s\in\mathcal{U}\setminus\{s_0\}} d_0(s_0)\left(\sum_{s_1\in\mathcal{S}} p\big(s_1|s_0,a^*(s_0,s)\big)\,T^*(s|s_1)+1\right) \\
&= \sum_{s_0\in\mathcal{S}} d_0(s_0)\sum_a \sum_{\substack{s\in\mathcal{U}\setminus\{s_0\},\\ a^*(s_0,s)=a}} \left(\sum_{s_1\in\mathcal{S}} p(s_1|s_0,a)\,T^*(s|s_1)+1\right) \\
&= \sum_{s_0\in\mathcal{S}} d_0(s_0)\sum_a \left(\sum_{s_1\in\mathcal{S}}\sum_{s\in\mathcal{U}_{s_0,a}} p(s_1|s_0,a)\,T^*(s|s_1)+|\,\mathcal{U}_{s_0,a}|\right),
\end{aligned}$$

where $\mathcal{U}_{s_0,a} := \big\{s\in\mathcal{U}\setminus\{s_0\} : a^*(s_0,s)=a\big\}$.

If all $\mathcal{U}_{s_0,a}\subset\mathcal{U}$, we apply the induction hypothesis and obtain for suitable $n_k(s_0,a)$

$$\begin{aligned}
&\sum_{s_0\in\mathcal{S}} d_0(s_0)\sum_a \left(\sum_{s_1\in\mathcal{S}}\sum_{s\in\mathcal{U}_{s_0,a}} p(s_1|s_0,a)\,T^*(s|s_1)+|\,\mathcal{U}_{s_0,a}|\right) \\
&\quad\geq \sum_{s_0\in\mathcal{S}} d_0(s_0)\sum_a \left(\sum_k k\cdot n_k(s_0,a)+|\,\mathcal{U}_{s_0,a}|\right) \\
&\quad= \sum_{s_0\in\mathcal{S}} d_0(s_0)\sum_a\sum_k (k+1)\cdot n_k(s_0,a),
\end{aligned}$$

since $\sum_k n_k(s_0,a) = |\,\mathcal{U}_{s_0,a}|$. Furthermore, $n_k(s_0,a)\leq A^k$ and $|\mathcal{U}|-1\leq\sum_a|\,\mathcal{U}_{s_0,a}|\leq|\mathcal{U}|$. Thus setting $n'_k = \sum_{s_0} d_0(s_0)\sum_a n_{k-1}(s_0,a)$ for $k\geq 1$ and $n'_0 = |\mathcal{U}| - \sum_{k\geq 1} n'_k$ satisfies the conditions of the statement. This completes the induction step for this case.

If $\mathcal{U}_{s_0,a} = \mathcal{U}$ for some pair (s_0,a) (i.e., for all target states $s \in \mathcal{U}$ the same action is optimal in s_0), then we construct a modified MDP with shorter transition times. This is achieved by modifying one of the actions to give a deterministic transition from s_0 to some state in $\mathcal{U}$ (which is not reached deterministically by choosing action a). For the modified MDP the induction step works and the lower bound can be proven, which then also holds for the original MDP. ■

Appendix B. Convergence of Value Iteration (Proof of Theorem 7)

As sufficient condition for convergence of value iteration, Puterman (1994) assumes only that all optimal policies have aperiodic transition matrices. Actually, the proof of Theorem 9.4.4 of Puterman (1994)—the main result on convergence of value iteration—needs this assumption only at one step, that is, to guarantee that the optimal policy identified at the end of the proof has aperiodic transition matrix. In the following we give a proof sketch of Theorem 7 that concentrates on the differences to the convergence proof given by Puterman (1994).

Lemma 9.4.3 of Puterman (1994) shows that value iteration eventually chooses only policies π that satisfy $\boldsymbol{P}_\pi \boldsymbol{\rho}^* = \boldsymbol{\rho}^*$, where $\boldsymbol{P}_\pi$ is the transition matrix of π and $\boldsymbol{\rho}^*$ is the optimal average reward vector. More precisely, there is an i_0 such that for all $i \geq i_0$

$$\max_{\pi:\mathcal{S}\to\mathcal{A}} \{\boldsymbol{r}_\pi + \boldsymbol{P}_\pi \boldsymbol{u}_i\} = \max_{\pi\in E} \{\boldsymbol{r}_\pi + \boldsymbol{P}_\pi \boldsymbol{u}_i\},$$

where $\boldsymbol{r}_\pi$ is the reward vector of the policy π, and $E := \{\pi : \mathcal{S} \to \mathcal{A} \,|\, \boldsymbol{P}_\pi \boldsymbol{\rho}^* = \boldsymbol{\rho}^*\}$.

Unlike standard value iteration, extended value iteration always chooses policies with aperiodic transition matrix (cf. the discussion in Section 3.1.3). Thus when considering only aperiodic policies $F := \{\pi : \mathcal{S} \to \mathcal{A} | \, \boldsymbol{P}_\pi \text{ is aperiodic}\}$ in the proof of Lemma 9.4.3, the same argument shows that there is an i_0' such that for all $i \geq i_0'$

$$\max_{\pi\in F} \{\boldsymbol{r}_\pi + \boldsymbol{P}_\pi \boldsymbol{u}_i\} = \max_{\pi\in E\cap F} \{\boldsymbol{r}_\pi + \boldsymbol{P}_\pi \boldsymbol{u}_i\}. \tag{42}$$

Intuitively, (42) shows that extended value iteration eventually chooses only policies from $E \cap F$.

With (42) accomplished, the proof of Theorem 9.4.4, the main result on convergence of value iteration, can be rewritten word by word from Puterman (1994), with E replaced with $E \cap F$ and using (42) instead of Lemma 9.4.3. Thus, unlike in the original proof where the optimal policy π^* identified at the end of the proof is in E, in our case π^* is in $E \cap F$. Here Puterman (1994) uses the assumption that *all* optimal policies have aperiodic transition matrices to guarantee that π^* has aperiodic transition matrix. In our case, π^* has aperiodic transition matrix by definition, as it is in $E \cap F$.

Then by the aperiodicity of $\boldsymbol{P}_{\pi^*}$, the result of Theorem 9.4.4 follows, and one obtains analogously to Theorem 9.4.5 (a) of Puterman (1994) that

$$\lim_{i\to\infty} (\boldsymbol{u}_{i+1} - \boldsymbol{u}_i) = \boldsymbol{\rho}^*. \tag{43}$$

As the underlying MDP $\tilde{M}^+$ is assumed to be communicating (so that ρ^* is state-independent), analogously to Corollary 9.4.6 of Puterman (1994) convergence of extended value iteration follows from (43). Finally, with the convergence of extended value iteration established, the error bound for the greedy policy follows from Theorem 8.5.6 of Puterman (1994). ■

Appendix C. Technical Details for the Proof of Theorem 2

This appendix collects some technical details, starting with an error bound for our confidence intervals.

C.1 Confidence Intervals

Lemma 17 *For any $t \geq 1$, the probability that the true MDP M is not contained in the set of plausible MDPs $\mathcal{M}(t)$ at time t (as given by the confidence intervals in* (3) *and* (4)*) is at most $\frac{\delta}{15t^6}$, that is*

$$\mathbb{P}\left\{M \notin \mathcal{M}(t)\right\} \;<\; \frac{\delta}{15t^6}.$$

Proof Consider a fixed state-action pair (s,a) and assume some given number of visits $n>0$ in (s,a) before step t. Denote the estimates for transition probabilities and rewards obtained from these n observations by $\hat{p}\,(\cdot|s,a)$ and $\hat{r}\,(s,a)$, respectively. Let us first consider the probability with which a confidence interval for the transition probabilities fails. The random event observed for the transition probability estimates is the state to which the transition occurs. Generally, the L^1-deviation of the true distribution and the empirical distribution over m distinct events from n samples is bounded according to Weissman et al. (2003) by

$$\mathbb{P}\Big\{\left\|\hat{p}\,(\cdot)-p\,(\cdot)\right\|_1 \geq \varepsilon\Big\} \leq (2^m-2)\exp\left(-\tfrac{n\varepsilon^2}{2}\right). \tag{44}$$

Thus, in our case we have $m=S$ (for each possible transition there is a respective event), so that setting

$$\varepsilon = \sqrt{\frac{2}{n}\log\left(\tfrac{2^S 20SAt^7}{\delta}\right)} \leq \sqrt{\frac{14S}{n}\log\left(\tfrac{2At}{\delta}\right)},$$

we get from (44)

$$\begin{aligned}\mathbb{P}\left\{\left\|p\,(\cdot|s,a)-\hat{p}\,(\cdot|s,a)\right\|_1 \geq \sqrt{\frac{14S}{n}\log\left(\tfrac{2At}{\delta}\right)}\right\} \;&\leq\; 2^S\exp\left(-\frac{n}{2}\cdot\frac{2}{n}\log\left(\tfrac{2^S 20SAt^7}{\delta}\right)\right)\\ &=\; \frac{\delta}{20t^7SA}.\end{aligned}$$

For the rewards we observe real-valued, independent identically distributed (i.i.d.) random variables with support in $[0,1]$. Hoeffding's inequality gives for the deviation between the true mean $\bar{r}$ and the empirical mean $\hat{r}$ from n i.i.d. samples with support in $[0,1]$

$$\mathbb{P}\Big\{\left|\hat{r}-\bar{r}\right| \geq \varepsilon_r\Big\} \leq 2\exp\Big(-2n\varepsilon_r^2\Big).$$

Setting

$$\varepsilon_r = \sqrt{\frac{1}{2n}\log\left(\tfrac{120SAt^7}{\delta}\right)} \leq \sqrt{\frac{7}{2n}\log\left(\tfrac{2SAt}{\delta}\right)},$$

we get for state-action pair (s,a)

$$\begin{aligned}\mathbb{P}\left\{\left|\hat{r}\,(s,a)-\bar{r}(s,a)\right| \geq \sqrt{\frac{7}{2n}\log\left(\tfrac{2SAt}{\delta}\right)}\right\} \;&\leq\; 2\exp\left(-2n\cdot\frac{1}{2n}\log\left(\tfrac{120SAt^7}{\delta}\right)\right)\\ &=\; \frac{\delta}{60t^7SA}.\end{aligned}$$

Note that when there haven't been any observations, the confidence intervals trivially hold with probability 1 (for transition probabilities as well as for rewards). Hence a union bound over all possible values of $n = 1, \ldots, t-1$ gives (now writing $N(s,a)$ for the number of visits in (s,a))

$$\mathbb{P}\left\{ \left|\hat{r}(s,a) - \bar{r}(s,a)\right| \geq \sqrt{\frac{7\log\left(\frac{2SAt}{\delta}\right)}{2\max\{1,N(s,a)\}}} \right\} \;\leq\; \sum_{n=1}^{t-1} \frac{\delta}{60t^7SA} < \frac{\delta}{60t^6SA} \quad \text{and}$$

$$\mathbb{P}\left\{ \left\| p(\cdot|s,a) - \hat{p}(\cdot|s,a) \right\|_1 \geq \sqrt{\frac{14S\log\left(\frac{2At}{\delta}\right)}{\max\{1,N(s,a)\}}} \right\} \;\leq\; \sum_{n=1}^{t-1} \frac{\delta}{20t^7SA} < \frac{\delta}{20t^6SA}.$$

Summing these error probabilities over all state-action pairs we obtain the claimed bound $\mathbb{P}\{M \notin \mathcal{M}(t)\} < \frac{\delta}{15t^6}$. ■

C.2 A Bound on the Number of Episodes

Since in each episode the total number of visits to at least one state-action pair doubles, the number of episodes m is logarithmic in T. Actually, the number of episodes becomes maximal when all state-action pairs are visited equally often, which results in the following bound.

Proposition 18 *The number m of episodes of* UCRL2 *up to step $T \geq SA$ is upper bounded as*

$$m \;\leq\; SA\log_2\left(\tfrac{8T}{SA}\right).$$

Proof Let $N(s,a) := \#\{\tau < T+1 : s_\tau = s, a_\tau = a\}$ be the total number of observations of the state-action pair (s,a) up to step T. In each episode $k < m$ there is a state-action pair (s,a) with $v_k(s,a) = N_k(s,a)$ (or $v_k(s,a) = 1, N_k(s,a) = 0$). Let $K(s,a)$ be the number of episodes with $v_k(s,a) = N_k(s,a)$ and $N_k(s,a) > 0$. If $N(s,a) > 0$, then $v_k(s,a) = N_k(s,a)$ implies $N_{k+1}(s,a) = 2N_k(s,a)$, so that

$$N(s,a) \;=\; \sum_{k=1}^{m} v_k(s,a) \;\geq\; 1 + \sum_{k:v_k(s,a)=N_k(s,a)} N_k(s,a) \;\geq\; 1 + \sum_{i=1}^{K(s,a)} 2^{i-1} \;=\; 2^{K(s,a)}.$$

On the other hand, if $N(s,a) = 0$, then obviously $K(s,a) = 0$, so that generally, $N(s,a) \geq 2^{K(s,a)} - 1$ for any state-action pair (s,a). It follows that

$$T \;=\; \sum_{s,a} N(s,a) \;\geq\; \sum_{s,a} \left(2^{K(s,a)} - 1\right). \tag{45}$$

Now, in each episode a state-action pair (s,a) is visited for which either $N_k(s,a) = 0$ or $N_k(s,a) = v_k(s,a)$. Hence, $m \leq 1 + SA + \sum_{s,a} K(s,a)$, or equivalently $\sum_{s,a} K(s,a) \geq m - 1 - SA$. This implies

$$\sum_{s,a} 2^{K(s,a)} \;\geq\; SA\, 2^{\sum_{s,a} K(s,a)/SA} \;\geq\; SA\, 2^{\frac{m-1}{SA}-1}.$$

Together with (45) this gives

$$T \;\geq\; SA\left(2^{\frac{m-1}{SA}-1} - 1\right),$$

which yields

$$m \;\leq\; 1 + 2SA + SA\log_2\left(\tfrac{T}{SA}\right),$$

and the claimed bound on m follows for $T \geq SA$. ■

C.3 The Sum in (19)

Lemma 19 *For any sequence of numbers $z_1,\dots,z_n$ with $0 \le z_k \le Z_{k-1} := \max\left\{1, \sum_{i=1}^{k-1} z_i\right\}$*

$$\sum_{k=1}^{n} \frac{z_k}{\sqrt{Z_{k-1}}} \le \left(\sqrt{2}+1\right)\sqrt{Z_n}\,.$$

Proof We prove the statement by induction over n.
Base case: We first show that the lemma holds for all n with $\sum_{k=1}^{n-1} z_k \le 1$. Indeed, in this case $Z_k = 1$ for $k \le n-1$ and hence $z_n \le 1$. It follows that

$$\sum_{k=1}^{n} \frac{z_k}{\sqrt{Z_{k-1}}} = \sum_{k=1}^{n-1} z_k + z_n \le 1+1 < \left(\sqrt{2}+1\right) Z_n.$$

Note that this also shows that the lemma holds for $n=1$, since $\sum_{k=1}^{0} z_k = 0 \le 1$.
Inductive step: Now let us consider natural numbers n such that $\sum_{k=1}^{n-1} z_k > 1$. By the induction hypothesis we have

$$\sum_{k=1}^{n} \frac{z_k}{\sqrt{Z_{k-1}}} \le \left(\sqrt{2}+1\right)\sqrt{Z_{n-1}} + \frac{z_n}{\sqrt{Z_{n-1}}}\,.$$

Since $z_n \le Z_{n-1} = \sum_{k=1}^{n-1} z_k$ and $Z_{n-1} + z_n = Z_n$, we further have

$$\begin{aligned}
\left(\sqrt{2}+1\right)\sqrt{Z_{n-1}} + \frac{z_n}{\sqrt{Z_{n-1}}} &= \sqrt{\left(\sqrt{2}+1\right)^2 Z_{n-1} + 2\left(\sqrt{2}+1\right) z_n + \frac{z_n^2}{Z_{n-1}}} \\
&\le \sqrt{\left(\sqrt{2}+1\right)^2 Z_{n-1} + \left(2+2\sqrt{2}+1\right) z_n} \\
&= \sqrt{\left(\sqrt{2}+1\right)^2 Z_{n-1} + \left(\sqrt{2}+1\right)^2 z_n} \\
&= \left(\sqrt{2}+1\right)\sqrt{Z_{n-1}+z_n} = \left(\sqrt{2}+1\right)\sqrt{Z_n}\,,
\end{aligned}$$

which proves the lemma. ■

C.4 Simplifying (22)

Combining similar terms, (22) yields that with probability at least $1 - \frac{\delta}{4T^{5/4}}$

$$\begin{aligned}
\Delta(s_1,T) \;\le\; & DS\sqrt{AT}\left(\tfrac{3}{2}\sqrt{\tfrac{1}{A}\cdot\tfrac{5}{2}\log\left(\tfrac{8T}{\delta}\right)} + 2\left(\sqrt{2}+1\right)\sqrt{14\log\left(\tfrac{2AT}{\delta}\right)} + \sqrt{8} + 2 + \tfrac{1}{\sqrt{A}}\right) \\
& + DSA\log_2\left(\tfrac{8T}{SA}\right). \qquad (46)
\end{aligned}$$

We assume $A \ge 2$, since the bound is trivial otherwise. Also, for $1 < T \le 34^2 A\log\left(\frac{T}{\delta}\right)$ we have $\Delta(s_1,T) \le 34\sqrt{AT\log\left(\frac{T}{\delta}\right)}$ trivially. Considering $T > 34A\log\left(\frac{T}{\delta}\right)$ we have $A < \frac{1}{34\log\left(\frac{T}{\delta}\right)}\sqrt{AT\log\left(\frac{T}{\delta}\right)}$ and also $\log_2(8T) < 2\log(T)$, so that

$$DSA\log_2\left(\tfrac{8T}{SA}\right) \;<\; \tfrac{2}{34}DS\sqrt{AT\log\left(\tfrac{T}{\delta}\right)}\,.$$

Further, $T > 34A\log\left(\frac{T}{\delta}\right)$ also implies $\log\left(\frac{2AT}{\delta}\right) \le 2\log\left(\frac{T}{\delta}\right)$ and $\log\left(\frac{8T}{\delta}\right) \le 2\log\left(\frac{T}{\delta}\right)$. Thus, we have by (46) that for any $T > 1$ with probability at least $1 - \frac{\delta}{4T^{5/4}}$

$$\begin{aligned}\Delta(s_1,T) &\le DS\sqrt{AT\log\left(\tfrac{T}{\delta}\right)}\left(\tfrac{3}{2}\sqrt{\tfrac{5}{2}} + 2\left(\sqrt{2}+1\right)\sqrt{28} + \sqrt{8} + 2 + \tfrac{1}{\sqrt{2}} + \tfrac{2}{34}\right)\\ &\le 34DS\sqrt{AT\log\left(\tfrac{T}{\delta}\right)}.\end{aligned}$$

Appendix D. Technical Details for the Proof of Theorem 4: Proof of (27)

For a given index set K_ε of episodes we would like to bound the sum

$$\sum_{k\in K_\varepsilon}\sum_{s,a}\frac{v_k(s,a)}{\sqrt{\max\{1,N_k(s,a)\}}} = \sum_{s,a}\sum_{k=1}^{m}\frac{v_k(s,a)}{\sqrt{\max\{1,N_k(s,a)\}}}\mathbb{1}_{k\in K_\varepsilon}.$$

We will do this by modifying the sum so that Lemma 19 becomes applicable. Compared to the setting of Lemma 19 there are some "gaps" in the sum caused by episodes $\notin K_\varepsilon$. In the following we show that the contribution of episodes that occur after step $L_\varepsilon := \sum_{k\in K_\varepsilon}\sum_{s,a} v_k(s,a)$ is not larger than the missing contributions of the episodes $\notin K_\varepsilon$. Intuitively speaking, one may fill the episodes that occur after step L_ε into the gaps of episodes $\notin K_\varepsilon$ as Figure 6 suggests.

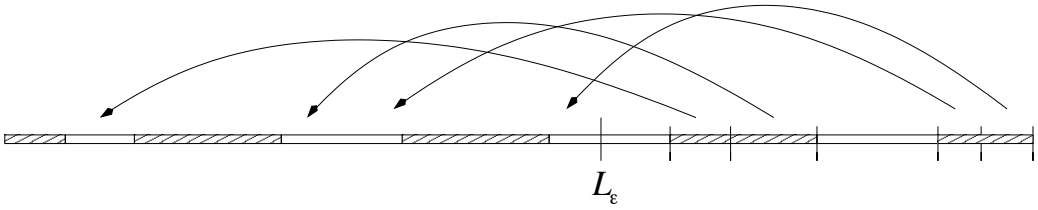

Figure 6: Illustration of the proof idea. Shaded boxes stand for episodes $\in K_\varepsilon$, empty boxes for episodes $\notin K_\varepsilon$. The contribution of episodes after step L_ε can be "filled into the gaps" of episodes $\notin K_\varepsilon$ before step L_ε.

Let $\ell_\varepsilon(s,a) := \sum_{k\in K_\varepsilon} v_k(s,a)$, so that $\sum_{s,a}\ell_\varepsilon(s,a) = L_\varepsilon$. We consider a fixed state-action pair (s,a) and skip the reference to it for ease of reading, so that N_k refers to the number of visits to (s,a) up to episode k, and N denotes the total number of visits to (s,a). Further, we abbreviate $d_k := \sqrt{\max\{1,N_k\}}$, and let $m_\varepsilon := \max\{k : N_k < \ell_\varepsilon\}$ be the episode containing the ℓ_ε-th visit to (s,a). Due to $v_k = N_{k+1} - N_k$ we have

$$v_{m_\varepsilon} = (N_{m_\varepsilon+1} - \ell_\varepsilon) + (\ell_\varepsilon - N_{m_\varepsilon}). \tag{47}$$

Since $N_{m_\varepsilon} = \sum_{k=1}^{m_\varepsilon-1} v_k$, this yields

$$\begin{aligned}\ell_\varepsilon - N_{m_\varepsilon} + \sum_{k=1}^{m_\varepsilon-1} v_k &= \ell_\varepsilon = \sum_{k=1}^{m} v_k\mathbb{1}_{k\in K_\varepsilon}\\ &= \sum_{k=1}^{m_\varepsilon-1} v_k\mathbb{1}_{k\in K_\varepsilon} + \left(N_{m_\varepsilon+1} - \ell_\varepsilon\right)\mathbb{1}_{m_\varepsilon\in K_\varepsilon} + \left(\ell_\varepsilon - N_{m_\varepsilon}\right)\mathbb{1}_{m_\varepsilon\in K_\varepsilon} + \sum_{k=m_\varepsilon+1}^{m} v_k\mathbb{1}_{k\in K_\varepsilon},\end{aligned}$$

or equivalently,

$$\left(N_{m_\varepsilon+1}-\ell_\varepsilon\right)\mathbb{1}_{m_\varepsilon\in K_\varepsilon}+\sum_{k=m_\varepsilon+1}^{m} v_k\mathbb{1}_{k\in K_\varepsilon} \;=\; \left(\ell_\varepsilon-N_{m_\varepsilon}\right)\mathbb{1}_{m_\varepsilon\notin K_\varepsilon}+\sum_{k=1}^{m_\varepsilon-1} v_k\mathbb{1}_{k\notin K_\varepsilon}. \tag{48}$$

By (47) and due to $d_k \geq d_{m_\varepsilon}$ for $k \geq m_\varepsilon$ we have

$$\begin{aligned}\sum_{k=1}^{m}\frac{v_k}{d_k}\mathbb{1}_{k\in K_\varepsilon} \;\leq\; & \sum_{k=1}^{m_\varepsilon-1}\frac{v_k}{d_k}\mathbb{1}_{k\in K_\varepsilon}+\frac{\ell_\varepsilon-N_{m_\varepsilon}}{d_{m_\varepsilon}}\mathbb{1}_{m_\varepsilon\in K_\varepsilon}\\ & +\frac{1}{d_{m_\varepsilon}}\left(\left(N_{m_\varepsilon+1}-\ell_\varepsilon\right)\mathbb{1}_{m_\varepsilon\in K_\varepsilon}+\sum_{k=m_\varepsilon+1}^{m} v_k\mathbb{1}_{k\in K_\varepsilon}\right).\end{aligned}$$

Hence, we get together with (48), using that $d_k \leq d_{m_\varepsilon}$ for $k \leq m_\varepsilon$

$$\begin{aligned}\sum_{k=1}^{m}\frac{v_k}{d_k}\mathbb{1}_{k\in K_\varepsilon} \;\leq\; & \sum_{k=1}^{m_\varepsilon-1}\frac{v_k}{d_k}\mathbb{1}_{k\in K_\varepsilon}+\frac{\ell_\varepsilon-N_{m_\varepsilon}}{d_{m_\varepsilon}}\mathbb{1}_{m_\varepsilon\in K_\varepsilon}\\ & +\frac{1}{d_{m_\varepsilon}}\left(\left(\ell_\varepsilon-N_{m_\varepsilon}\right)\mathbb{1}_{m_\varepsilon\notin K_\varepsilon}+\sum_{k=1}^{m_\varepsilon-1} v_k\mathbb{1}_{k\notin K_\varepsilon}\right)\\ \leq\; & \sum_{k=1}^{m_\varepsilon-1}\frac{v_k}{d_k}\mathbb{1}_{k\in K_\varepsilon}+\frac{\ell_\varepsilon-N_{m_\varepsilon}}{d_{m_\varepsilon}}\mathbb{1}_{m_\varepsilon\in K_\varepsilon}+\frac{\ell_\varepsilon-N_{m_\varepsilon}}{d_{m_\varepsilon}}\mathbb{1}_{m_\varepsilon\notin K_\varepsilon}+\sum_{k=1}^{m_\varepsilon-1}\frac{v_k}{d_k}\mathbb{1}_{k\notin K_\varepsilon}\\ =\; & \sum_{k=1}^{m_\varepsilon-1}\frac{v_k}{d_k}+\frac{\ell_\varepsilon-N_{m_\varepsilon}}{d_{m_\varepsilon}}.\end{aligned}$$

Now define v'_k as follows: let $v'_k := v_k$ for $k < m_\varepsilon$ and $v'_{m_\varepsilon} := \ell_\varepsilon - N_{m_\varepsilon}$. Then we have just seen that

$$\sum_{k=1}^{m}\frac{v_k}{d_k}\mathbb{1}_{k\in K_\varepsilon} \;\leq\; \sum_{k=1}^{m_\varepsilon}\frac{v'_k}{d_k}.$$

Since further $\sum_{k=1}^{m_\varepsilon} v'_k = \ell_\varepsilon$ we get by Lemma 19 that

$$\sum_{k=1}^{m_\varepsilon}\frac{v'_k}{d_k} \;\leq\; \left(\sqrt{2}+1\right)\sqrt{\ell_\varepsilon}\,.$$

As $\sum_{s,a}\ell_\varepsilon(s,a) = L_\varepsilon$, we finally obtain by Jensen's inequality

$$\sum_{k\in K_\varepsilon}\sum_{s,a}\frac{v_k(s,a)}{\sqrt{\max\{1,N_k(s,a)\}}} \;\leq\; \left(\sqrt{2}+1\right)\sqrt{L_\varepsilon SA}\,,$$

as claimed. ■

Appendix E. Proof of Lemma 13

Let us first recall some notation from Section 6. Thus $\mathbb{P}_a[\cdot]$ denotes the probability conditioned on a being the "good" action, while the probability with respect to a setting where all actions in state $s_\circ$ are equivalent (i.e., $\varepsilon = 0$) is denoted by $\mathbb{P}_{\text{unif}}[\cdot]$. Let $\mathcal{S} := \{s_\circ, s_1\}$ and denote the state

observed at step τ by s_τ and the state-sequence up to step τ by $s^\tau = s_1, \ldots, s_\tau$. Basically, the proof follows along the lines of the proof of Lemma A.1 of Auer et al. (2002b). The first difference is that our observations now consist of the sequence of $T+1$ states instead of a sequence of T observed rewards. Still it is straightforward to get analogously to the proof of Auer et al. (2002b), borrowing the notation, that for any function f from $\{s_\circ, s_1\}^{T+1}$ to $[0,B]$,

$$\mathbb{E}_a[f(s)] - \mathbb{E}_{\text{unif}}[f(s)] \;\leq\; \frac{B}{2}\sqrt{2\log(2)\,\mathrm{KL}\left(\mathbb{P}_{\text{unif}} \middle\| \mathbb{P}_a\right)}, \tag{49}$$

where $\mathrm{KL}(P\|Q)$ denotes for two distributions P, Q the *Kullback-Leibler divergence* defined as $\mathrm{KL}(P\|Q) := \sum_{s\in\mathcal{S}^{T+1}} P\{s\}\log_2\left(\frac{P\{s\}}{Q\{s\}}\right)$. It holds that (cf. Auer et al., 2002b)

$$\mathrm{KL}\left(\mathbb{P}_{\text{unif}} \middle\| \mathbb{P}_a\right) = \sum_{t=1}^{T} \mathrm{KL}\left(\mathbb{P}_{\text{unif}}\left[s_{t+1}\middle|s^t\right] \middle\| \mathbb{P}_a\left[s_{t+1}\middle|s^t\right]\right), \tag{50}$$

where $\mathrm{KL}(P\{s_{t+1}|s^t\}\|Q\{s_{t+1}|s^t\}) := \sum_{s^{t+1}\in\mathcal{S}^{t+1}} P\{s^{t+1}\}\log_2\left(\frac{P\{s_{t+1}|s^t\}}{Q\{s_{t+1}|s^t\}}\right)$. By the Markov property and the fact that the action a_t is determined by a sequence $s^t \in \mathcal{S}^t$ we have (similar to Auer et al., 2002b)

$$\begin{aligned}
&\mathrm{KL}\left(\mathbb{P}_{\text{unif}}\left[s_{t+1}\middle|s^t\right] \middle\| \mathbb{P}_a\left[s_{t+1}\middle|s^t\right]\right) = \sum_{s^{t+1}\in\mathcal{S}^{t+1}} \mathbb{P}_{\text{unif}}\left[s^{t+1}\right]\log_2\left(\frac{\mathbb{P}_{\text{unif}}\left[s_{t+1}|s^t\right]}{\mathbb{P}_a\left[s_{t+1}|s^t\right]}\right)\\
&= \sum_{s^t\in\mathcal{S}^t} \mathbb{P}_{\text{unif}}\left[s^t\right] \sum_{s'\in\mathcal{S}} \mathbb{P}_{\text{unif}}\left[s_{t+1}=s'|s^t\right]\log_2\left(\frac{\mathbb{P}_{\text{unif}}\left[s'|s^t\right]}{\mathbb{P}_a\left[s'|s^t\right]}\right)\\
&= \sum_{s^{t-1}\in\mathcal{S}^{t-1}} \mathbb{P}_{\text{unif}}\left[s^{t-1}\right] \sum_{(s'',a')\in\mathcal{S}\times\mathcal{A}} \mathbb{P}_{\text{unif}}\left[s_t=s'', a_t=a'|s^{t-1}\right]\\
&\qquad \cdot \sum_{s'\in\mathcal{S}} \mathbb{P}_{\text{unif}}\left[s_{t+1}=s'|s^{t-1}, s_t=s'', a_t=a'\right]\log_2\left(\frac{\mathbb{P}_{\text{unif}}\left[s'|s^{t-1}, s_t=s'', a_t=a'\right]}{\mathbb{P}_a\left[s'|s^{t-1}, s_t=s'', a_t=a'\right]}\right)\\
&= \sum_{s^{t-1}\in\mathcal{S}^{t-1}} \mathbb{P}_{\text{unif}}\left[s^{t-1}\right] \sum_{a'=1}^{kA'} \sum_{s''\in\mathcal{S}} \mathbb{P}_{\text{unif}}\left[s_t=s'', a_t=a'|s^{t-1}\right]\\
&\qquad\qquad \cdot \sum_{s'\in\mathcal{S}} \mathbb{P}_{\text{unif}}\left[s'|s'', a'\right]\log_2\left(\frac{\mathbb{P}_{\text{unif}}\left[s'|s'', a'\right]}{\mathbb{P}_a\left[s'|s'', a'\right]}\right).
\end{aligned}$$

Since $\log_2\left(\frac{\mathbb{P}_{\text{unif}}[s'|s'',a']}{\mathbb{P}_a[s'|s'',a']}\right) \neq 0$ only for $s'' = s_\circ$ and a' being the special action a, we get

$$\begin{aligned}
&\mathrm{KL}\left(\mathbb{P}_{\text{unif}}\left[s_{t+1}\middle|s^t\right] \middle\| \mathbb{P}_a\left[s_{t+1}\middle|s^t\right]\right) =\\
&= \sum_{s^{t-1}\in\mathcal{S}^{t-1}} \mathbb{P}_{\text{unif}}\left[s^{t-1}\right]\mathbb{P}_{\text{unif}}\left[s_t=s_\circ, a_t=a|s^{t-1}\right] \cdot \sum_{s'\in\mathcal{S}} \mathbb{P}_{\text{unif}}\left[s'|s_\circ,a\right]\log_2\left(\frac{\mathbb{P}_{\text{unif}}\left[s'|s_\circ,a\right]}{\mathbb{P}_a\left[s'|s_\circ,a\right]}\right)\\
&= \mathbb{P}_{\text{unif}}[s_t=s_\circ, a_t=a] \sum_{s'\in\mathcal{S}} \mathbb{P}_{\text{unif}}\left[s'|s_\circ,a\right]\log_2\left(\frac{\mathbb{P}_{\text{unif}}\left[s'|s_\circ,a\right]}{\mathbb{P}_a\left[s'|s_\circ,a\right]}\right)\\
&= \mathbb{P}_{\text{unif}}[s_t=s_\circ, a_t=a]\left(\delta\log_2\left(\frac{\delta}{\delta+\varepsilon}\right) + (1-\delta)\log_2\left(\frac{1-\delta}{1-\delta-\varepsilon}\right)\right).
\end{aligned} \tag{51}$$

To complete the proof we use the following lemma.

Lemma 20 *For any* $0 \le \delta \le \frac{1}{2}$ *and* $\varepsilon \le 1-2\delta$ *we have*

$$\delta \log_2\left(\frac{\delta}{\delta+\varepsilon}\right) + (1-\delta)\log_2\left(\frac{1-\delta}{1-\delta-\varepsilon}\right) \;\le\; \frac{\varepsilon^2}{\delta \log(2)}\,.$$

Indeed, application of Lemma 20 together with (50) and (51) gives that

$$\begin{aligned} \mathrm{KL}\left(\mathbb{P}_{\mathrm{unif}} \middle\| \mathbb{P}_a\right) &= \sum_{t=1}^{T} \mathrm{KL}\left(\mathbb{P}_{\mathrm{unif}}\left[s_{t+1}\middle|\boldsymbol{s}^t\right] \middle\| \mathbb{P}_a\left[s_{t+1}\middle|\boldsymbol{s}^t\right]\right) \\ &\le \sum_{t=1}^{T} \mathbb{P}_{\mathrm{unif}}[s_t = s_\circ, a_t = a]\,\frac{\varepsilon^2}{\delta\log(2)} \;=\; \mathbb{E}_{\mathrm{unif}}[N_\circ^*]\,\frac{\varepsilon^2}{\delta\log(2)}, \end{aligned}$$

which together with (49) yields

$$\mathbb{E}_a[f(\boldsymbol{s})] - \mathbb{E}_{\mathrm{unif}}[f(\boldsymbol{s})] \le \frac{B}{2}\cdot\frac{\varepsilon}{\sqrt{\delta}}\sqrt{2\mathbb{E}_{\mathrm{unif}}[N_\circ^*]},$$

as claimed by Lemma 13.

Proof of Lemma 20 Consider

$$h_\delta(\varepsilon) := \frac{\varepsilon^2}{\delta} - \delta\log\left(\frac{\delta}{\delta+\varepsilon}\right) - (1-\delta)\log\left(\frac{1-\delta}{1-\delta-\varepsilon}\right).$$

We show that $h_\delta(\varepsilon) \ge 0$ for $\delta \le \frac{1}{2}$ and $0 \le \varepsilon \le \varepsilon_0$, where

$$\varepsilon_0 := \frac{1}{2} - \delta + \frac{1}{2}\sqrt{1-2\delta}.$$

Indeed, $h_\delta(0) = 0$ for all δ, while for the first derivative

$$h'_\delta(\varepsilon) := \frac{\partial}{\partial\varepsilon} h_\delta(\varepsilon) \;=\; 2\cdot\frac{\varepsilon}{\delta} + \frac{\delta}{\delta+\varepsilon} - \frac{1-\delta}{1-\delta-\varepsilon}$$

we have $h'_\delta(\varepsilon) \ge 0$ for $\delta \le \frac{1}{2}$ and $0 \le \varepsilon \le \varepsilon_0$. It remains to show that $\delta \le \frac{1}{2}$ and $\varepsilon \le 1-2\delta$ imply $\varepsilon \le \varepsilon_0$. Indeed, for $\delta \le \frac{1}{2}$ and $\varepsilon \le 1-2\delta$ we have

$$\varepsilon - \varepsilon_0 \;\le\; 1-2\delta-\varepsilon_0 = \frac{1}{2} - \delta - \frac{1}{2}\sqrt{1-2\delta} \;=\; \frac{1}{2}\left((1-2\delta) - \sqrt{1-2\delta}\right) \;\le\; 0.$$

Abstract

Massive **O**nline **A**nalysis (MOA) is a software environment for implementing algorithms and running experiments for online learning from evolving data streams. MOA includes a collection of offline and online methods as well as tools for evaluation. In particular, it implements boosting, bagging, and Hoeffding Trees, all with and without Naïve Bayes classifiers at the leaves. MOA supports bi-directional interaction with WEKA, the Waikato Environment for Knowledge Analysis, and is released under the GNU GPL license.

Keywords: data streams, classification, ensemble methods, java, machine learning software

1. Introduction

Green computing is the study and practice of using computing resources efficiently. A main approach to green computing is based on algorithmic efficiency. In the data stream model, data arrive at high speed, and an algorithm must process them under very strict constraints of space and time.

MOA is an open-source framework for dealing with massive evolving data streams. MOA is related to WEKA, the Waikato Environment for Knowledge Analysis, which is an award-winning open-source workbench containing implementations of a wide range of batch machine learning methods.

A data stream environment has different requirements from the traditional batch learning setting. The most significant are the following:

Requirement 1 Process an example at a time, and inspect it only once (at most)

Requirement 2 Use a limited amount of memory

Requirement 3 Work in a limited amount of time

Requirement 4 Be ready to predict at any time

Figure 1 illustrates the typical use of a data stream classification algorithm, and how the requirements fit in a repeating cycle:

1. The algorithm is passed the next available example from the stream (Requirement 1).

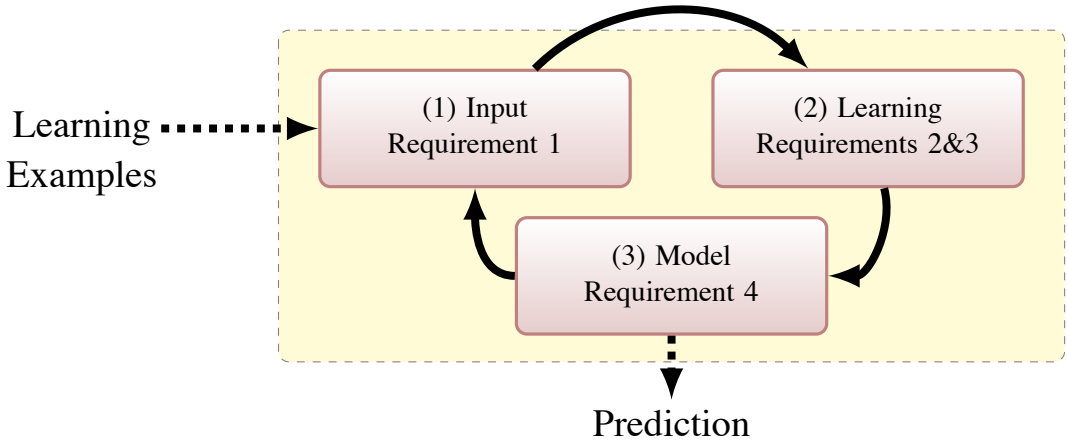

Figure 1: The data stream classification cycle

2. The algorithm processes the example, updating its data structures. It does so without exceeding the memory bounds set on it (requirement 2), and as quickly as possible (Requirement 3).

3. The algorithm is ready to accept the next example. On request it is able to predict the class of unseen examples (Requirement 4).

In traditional batch learning the problem of limited data is overcome by analyzing and averaging multiple models produced with different random arrangements of training and test data. In the stream setting the problem of (effectively) unlimited data poses different challenges. One solution involves taking snapshots at different times during the induction of a model to see how much the model improves.

The evaluation procedure of a learning algorithm determines which examples are used for training the algorithm, and which are used to test the model output by the algorithm.When considering what procedure to use in the data stream setting, one of the unique concerns is how to build a picture of accuracy over time. Two main approaches arise:

- **Holdout**: When traditional batch learning reaches a scale where cross-validation is too time consuming, it is often accepted to instead measure performance on a single holdout set. This is most useful when the division between train and test sets has been pre-defined, so that results from different studies can be directly compared.

- **Interleaved Test-Then-Train or Prequential**: Each individual example can be used to test the model before it is used for training, and from this the accuracy can be incrementally updated. When intentionally performed in this order, the model is always being tested on examples it has not seen. This scheme has the advantage that no holdout set is needed for testing, making maximum use of the available data. It also ensures a smooth plot of accuracy over time, as each individual example will become increasingly less significant to the overall average (Gama et al., 2009).

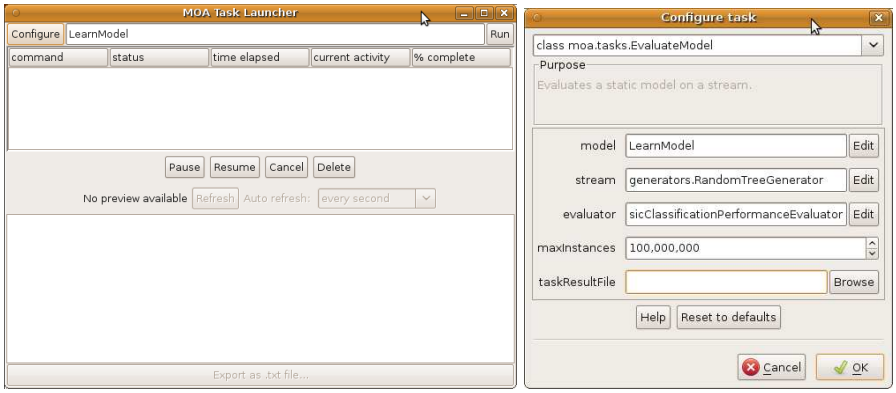

Figure 2: MOA Graphical User Interface

As data stream classification is a relatively new field, such evaluation practices are not nearly as well researched and established as they are in the traditional batch setting. The majority of experimental evaluations use less than one million training examples. In the context of data streams this is disappointing, because to be truly useful at data stream classification the algorithms need to be capable of handling very large (potentially infinite) streams of examples. Demonstrating systems only on small amounts of data does not build a convincing case for capacity to solve more demanding stream applications (Kirkby, 2007).

MOA permits evaluation of data stream classification algorithms on large streams, in the order of tens of millions of examples where possible, and under explicit memory limits. Any less than this does not actually test algorithms in a realistically challenging setting.

2. Experimental Framework

MOA is written in Java. The main benefits of Java are portability, where applications can be run on any platform with an appropriate Java virtual machine, and the strong and well-developed support libraries. Use of the language is widespread, and features such as automatic garbage collection help to reduce programmer burden and error.

MOA contains stream generators, classifiers and evaluation methods. Figure 2 shows the MOA graphical user interface. However, a command line interface is also available.

Considering data streams as data generated from pure distributions, MOA models a concept drift event as a weighted combination of two pure distributions that characterizes the target concepts before and after the drift. Within the framework, it is possible to define the probability that instances of the stream belong to the new concept after the drift. It uses the sigmoid function, as an elegant and practical solution (Bifet et al., 2009a,b).

MOA contains the data generators most commonly found in the literature. MOA streams can be built using generators, reading ARFF files, joining several streams, or filtering streams. They allow for the simulation of a potentially infinite sequence of data. The following generators are currently available: Random Tree Generator, SEA Concepts Generator, STAGGER Concepts Generator, Rotating Hyperplane, Random RBF Generator, LED Generator, Waveform Generator, and Function Generator.

MOA contains several classifier methods such as: Naive Bayes, Decision Stump, Hoeffding Tree, Hoeffding Option Tree (Pfahringer et al., 2008), Bagging, Boosting, Bagging using ADWIN, and Bagging using Adaptive-Size Hoeffding Trees (Bifet et al., 2009b).

2.1 Website, Tutorials, and Documentation

MOA can be found at: http://moa.cs.waikato.ac.nz/.

The website includes a tutorial, an API reference, a user manual, and a manual about mining data streams. Several examples of how the software can be used are available. For example, a non-trivial example of the EvaluateInterleavedTestThenTrain task creating a comma separated values file, training the HoeffdingTree classifier on the WaveformGenerator data, training and testing on a total of 100 million examples, and testing every one million examples, is encapsulated by the following commandline:

```
java -cp .:moa.jar:weka.jar -javaagent:sizeofag.jar moa.DoTask \
  "EvaluateInterleavedTestThenTrain -l HoeffdingTree \
  -s generators.WaveformGenerator \
  -i 100000000 -f 1000000" > htresult.csv
```

MOA is easy to use and extend. A simple approach to writing a new classifier is to extend moa.classifiers.AbstractClassifier, which will take care of certain details to ease the task. Although the current focus in MOA is on classification, we plan to extend the framework to include data stream clustering, regression, and frequent pattern learning (Bifet, 2010).

Abstract

We consider *selective classification*, a term we adopt here to refer to 'classification with a reject option.' The essence in selective classification is to trade-off classifier coverage for higher accuracy. We term this trade-off the *risk-coverage (RC) trade-off*. Our main objective is to characterize this trade-off and to construct algorithms that can optimally or near optimally achieve the best possible trade-offs in a controlled manner. For noise-free models we present in this paper a thorough analysis of selective classification including characterizations of RC trade-offs in various interesting settings.

Keywords: classification with a reject option, selective classification, perfect learning, high performance classification, risk-coverage trade-off

1. Introduction

In this paper we study the trade-off between coverage and accuracy of classifiers with a reject option, a trade-off we refer to as the *risk-coverage (RC) trade-off*. Our main goal is to characterize this trade-off and to construct algorithms that can optimally or near optimally control it. Throughout the paper we use the term *selective classification* to refer to 'classification with a reject option.' Selective classification was introduced a number of decades ago and among the earliest studies are papers authored by Chow (1957, 1970), focusing on Bayesian solutions for the case where the underlying distributions are fully known. Through the years, selective classification continued to draw attention and numerous papers have been published. The attraction of effective selective classification is rather obvious in applications where one is not concerned with, or can afford partial coverage of the domain, and/or in cases where extremely low risk is a must but is not achievable in standard classification frameworks. Classification problems in medical diagnosis and in bioinformatics are often instances of such applications (Meltzer et al., 2001; Hanczar and Dougherty, 2008).

Despite the relatively large number of research publications on selective classification, the vast majority of these works have been concerned with implementing a reject option within specific learning schemes, by endowing a learning scheme (e.g., neural networks, SVMs) with a reject mechanism. Most of the reject mechanisms were based on "ambiguity" or (lack of) "confidence" principles: "when confused or when in doubt, refuse to classify." While there are many convincing accounts for the potential effectiveness of selective classification in reducing the risk, we are not familiar with a thorough or conclusive discussions on the relative power of the numerous rejection mechanisms that have been considered so far. The very few theoretical works that considered se-

lective classification (see Section 10) do provide some risk or coverage bounds for specific schemes (e.g., ensemble methods) or learning principles (e.g., ERMs), but altogether characterizations of achievable (or non-achievable) RC trade-offs are absent in the current literature. In particular, the work done so far has not facilitated formal discussions of RC trade-off *optimality*.

A thorough understanding and effective use of selective classification requires characterization of the theoretical and practical boundaries of RC trade-offs, which are essential elements in any discussion of *optimality* in selective classification. These missing elements in the current literature are critical when constructing and exploring selective classification schemes and selective classification algorithms that aim at achieving optimality in controlling the RC trade-off.

One of our longer term goals is to provide such characterizations and introduce a notion of optimality for selective classification in the most general agnostic model. As a first step, however, we focus in this work on noiseless settings whereby a perfect hypothesis for the problem at hand exists (the so called "realizable case"). Moreover, we place special emphasis on the extreme case where zero risk has to be guaranteed. For this extreme case, which we call "perfect learning," we provide a thorough analysis that includes tight positive and negative results for the most general types of realizable settings (distribution independent, infinite hypothesis spaces). We also discuss some specific settings (linear classifiers, specific distribution families) and show an efficient algorithm for linear classifiers that achieves "perfect learning" with guaranteed coverage. Our results on "perfect learning" are instrumental in exploring entire RC trade-offs. Recalling known results on optimal standard realizable learning (no rejection is allowed), we show how to "interpolate" bounds and strategies for these two extreme cases (perfect learning and standard learning) so as to reveal upper and lower envelopes of optimal RC trade-offs.

2. Selective Classification: Preliminary Definitions

Let $\mathcal{X}$ be some feature space, for example, d-dimensional vectors in $\mathbb{R}^d$. In standard binary classification, the goal is to learn a binary classifier $f : \mathcal{X} \to \{\pm 1\}$, using a finite training sample of m labeled examples, $S_m = \{(x_i, y_i)\}_{i=1}^m$, assumed to be sampled i.i.d. from some *unknown* underlying distribution $P(X,Y)$ over $\mathcal{X} \times \{\pm 1\}$. We assume that the classifier is to be selected from a hypothesis space $\mathcal{F}$ and focus on the *realizable* setting where the labels are determined by some *unknown target hypothesis* $f^* \in \mathcal{F}$. Thus, it is assumed that P satisfies $\mathrm{Pr}_P(Y = f^*(X)|X) = 1$.

In *selective classification* the learner should output a binary *selective classifier* defined to be a pair (f,g), with f being a standard binary classifier, and $g : \mathcal{X} \to [0,1]$ a *selection function* whose meaning is as follows. When applying the selective classifier to a sample x, its output is:

$$(f,g)(x) \triangleq \begin{cases} \mathit{reject}, & \text{w.p. } 1-g(x); \\ f(x), & \text{w.p. } g(x). \end{cases} \tag{1}$$

Thus, in its most general form, the selective classifier is *randomized*. Whenever the selection function is a zero-one rule, $g : \mathcal{X} \to \{0,1\}$, we say that the selective classifier is deterministic. Note that "standard learning" (i.e., no rejection is allowed) is the special case of selective classification where $g(x)$ selects all points (i.e., $g(x) \equiv 1$).

The two main characteristics of a selective classifier are its *coverage* and its *risk* (or "true error").

Definition 1 (coverage) *The* coverage *of a selective classifier (f,g) is the mean value of the selection function $g(X)$ taken over the underlying distribution P,*

$$\Phi(f,g) \triangleq \mathbf{E}\left[g(X)\right].$$

Definition 2 (risk) *For a bounded loss function $\ell : \mathcal{Y} \times \mathcal{Y} \to [0,1]$, we define the risk of a selective classifier (f,g) as the average loss on the accepted samples,*

$$R(f,g) \triangleq \frac{\mathbf{E}\left[\ell(f(X),Y)\cdot g(X)\right]}{\Phi(f,g)}.$$

This risk definition clearly reduces to the standard definition of risk if $g(x) \equiv 1$. Note that (at the outset) both the coverage and risk are *unknown quantities* because they are defined in terms of the unknown underlying distribution P.

We define a learning algorithm ALG to be a (random) function that, given a sample S_m, chooses a selective classifier (f,g). We evaluate learners with respect to their coverage and risk and derive both positive and negative results on achievable risk and coverage. Our model is a slight extension of the standard minimax model for standard statistical learning as described, for example, by Antos and Lugosi (1998). Thus, we consider the following game between the learner and an adversary. The parameters of the game are a domain $\mathcal{X}$ and an hypothesis class $\mathcal{F}$.

1. A tolerance level δ and a training sample size m are given.
2. The learner chooses a learning algorithm ALG.
3. With full knowledge of the learner's choice, the adversary chooses a distribution $P(X)$ over $\mathcal{X}$, and a target hypothesis $f^* \in \mathcal{F}$ (or a distribution over $\mathcal{F}$ according to which f^* is selected).
4. A training sample S_m is drawn i.i.d. according to P and f^*.
5. ALG is applied on S_m and outputs a selective classifier (f,g).

The result of the game is evaluated in terms of the risk and coverage obtained by the chosen selective classifier and clearly, these are random quantities that trade-off each other. A *positive result* in this model is a pair of bounds, $B_R = B_R(\mathcal{F},\delta,m)$ and $B_\Phi = B_\Phi(\mathcal{F},\delta,m)$, for risk and coverage, respectively, that for any δ and m, hold with high probability, of at least $1-\delta$ for *any* distribution P; namely,

$$\Pr\{R(f,g) \le B_R \ \wedge \ \Phi(f,g) \ge B_\Phi\} \ge 1-\delta.$$

The probability is taken w.r.t. the random choice of training samples S_m, as well as w.r.t. all other random choices introduced, such as a random choice of f^* by the adversary (if applicable), a random choice of (f,g) by ALG (if applicable), and the randomized selection function (Equation (1)).

A *negative result* is a probabilistic statement on the impossibility of any positive result. Thus, in its most general form a negative result is a pair of bounds B_R and B_Φ that, for any δ, satisfy

$$\Pr\{R(f,g) \ge B_R \ \vee \ \Phi(f,g) \le B_\Phi\} \ge \delta,$$

for *some* probability P. Here again, probability is taken w.r.t. the random choice of the training samples S_m, as well as w.r.t. all other random choices.

For a selective classifier (f,g) with coverage $\Phi(f,g)$ we can specify a Risk-Coverage (RC) trade-off as a bound on the risk $R(f,g)$, expressed in terms of $\Phi(f,g)$. Thus, a *positive result on the RC trade-off* is a probabilistic statement of the following form

$$\Pr\{R(f,g) \le B(\Phi(f,g),\delta,m)\} \ge 1-\delta.$$

Similarly, a *negative result on the RC trade-off* is a statement of the form,

$$\Pr\{R(f,g) \geq B(\Phi(f,g),\delta,m)\} \geq \delta.$$

Clearly, all results (positive and negative) are qualified by the model parameters, namely the domain $\mathcal{X}$ and the hypothesis space $\mathcal{F}$, and the quality/generality of a result should be assessed w.r.t. generality of these parameters. An additional major consideration is, of course, the computational complexity of the learning algorithm.

Finally, in the sequel we rely on the following standard definition of the version space (Mitchell, 1977).

Definition 3 (version space) *Given an hypothesis class $\mathcal{F}$ and a training sample S_m, the version space $VS_{\mathcal{F},S_m}$ is the set of all hypotheses in $\mathcal{F}$ that classify S_m correctly.*

3. Contributions

The purpose of this section is to provide a high level technical overview of our contributions. Using a training sample S_m, the goal in selective classification is to output a selective classifier (f,g) that has sufficiently low risk with sufficiently high coverage. Obviously, these two quantities trade-off each other. We call the trade-off between risk and coverage the *risk-coverage (RC) trade-off*. The best way to benefit from selective classification is to *control* the creation of the classifier so as to meet a prescribed error/coverage specification along the RC trade-off. For example, it might be desirable to devise a learning system that will receive as input an error constraint (say, 2% error) and, based on a finite (and small) training sample, will be capable of generating a classifier whose ensured test error (w.h.p.) is not larger than 2%, while having the maximum possible coverage of the domain. If the RC trade-off is revealed, it is possible to know if the 2% error constraint can be met and what would be the corresponding coverage.

In Figure 1 we schematically depict elements of the RC trade-off. The x-axis measures risk (error in the case of the $0/1$ loss) and the y-axis is coverage. The entire region depicted, called the *RC plane*, consisting of all (r,c) points in the rectangle of interest, where r is a risk (error) coordinate and c is a coverage coordinate. Assume a fixed problem setting (including an unknown underlying distribution P, m training examples drawn i.i.d. from P, an hypothesis space $\mathcal{F}$ and a tolerance parameter δ). To fully characterize the RC trade-off we need to determine for each point (r,c) on the RC plane if it is (efficiently) "achievable." We say that (r,c) is (efficiently) *achievable* if there is an (efficient) learning algorithm that will output a selective classifier (f,g) such that with probability of at least $1-\delta$, its coverage is at least c and its risk is at most r.

Notice that point r^* (the coordinate $(r^*,1)$) where the coverage is 1 represents "standard learning." At this point we require full coverage with certainty and the achievable risk represents the lowest possible risk in our fixed setting (which should be achievable with probability of at least $1-\delta$). Point r^* represent one extreme of the RC trade-off. The other extreme of the RC trade-off is point c^*, where we require zero risk *with certainty*. The coverage at c^* is the optimal (highest possible) in our setting when zero error is required. We call point c^* *perfect learning* because achievable perfect learning means that we can generate a classifier that never errs with certainty for the problem at hand. Note that at the outset, it is not at all clear if non-trivial perfect learning (with guaranteed positive coverage) can be accomplished.

The full RC trade-off is some (unknown) curve connecting points c^* and r^*. This curve passes somewhere in the zone labeled with a question mark and represents optimal selective classification.

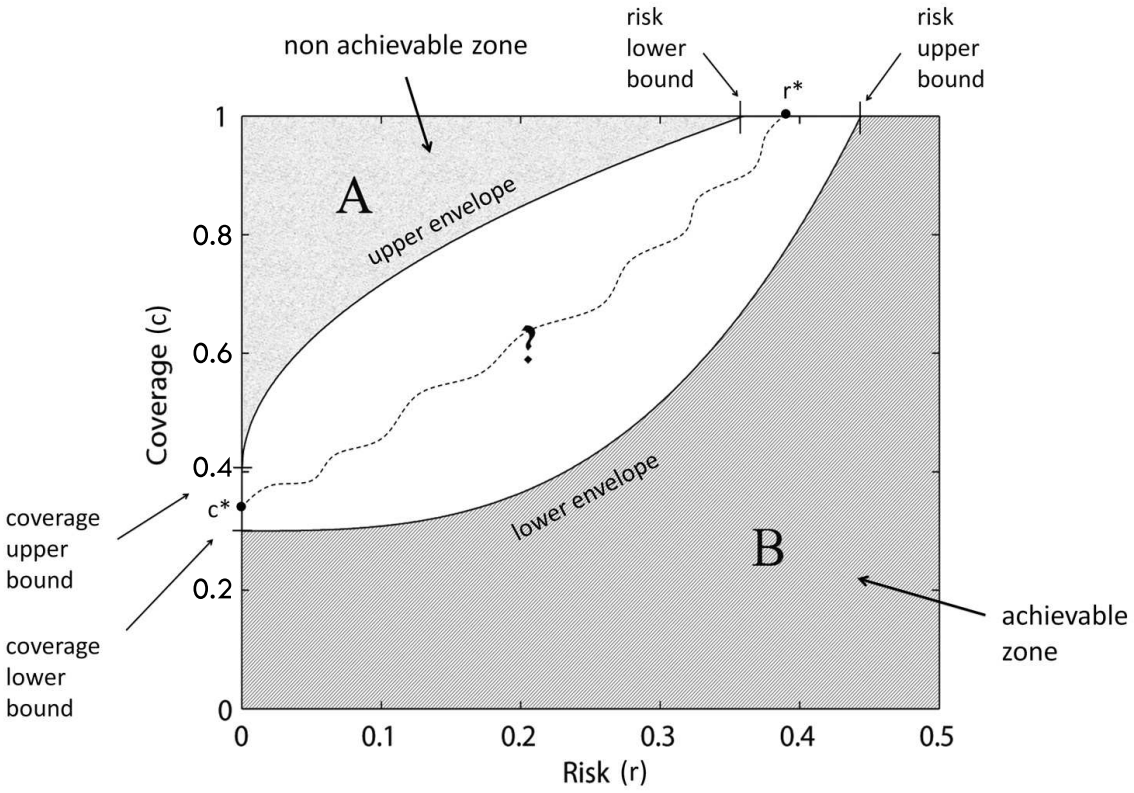

Figure 1: The RC plane and RC trade-off

Points above this curve (e.g., at zone *A*) are not achievable. Points below this curve (e.g., at zone *B*) are achievable. One of the main goals of this paper is to study the RC curve and provide as tight as possible boundaries for it. To this end we characterize upper and lower envelopes of the RC curve as schematically depicted in Figure 1. The upper envelop is a boundary of a "non-achievable zone" (zone A) and therefore we consider any upper envelop as a "negative result." The lower envelop is a boundary of an "achievable zone" (zone B) and is therefore considered as a "positive result." Note that upper and lower envelopes, as depicted in the figure, represent two different things, which are formally defined in Section 2 as probabilistic statements on possibility and impossibility.

Point r^* on the RC curve ("standard learning") was extensively studied in the literature. Perfect learning (point c^*) was never considered. For the most part, the existing work on selective classification exhibited (either empirically or theoretically) specific but anecdotal points or curves in the achievable zone (B) but, to the best of our knowledge no systematic attempts were ever made to characterize the RC-curve, which corresponds to *optimal selective classification*. In particular, there are currently no "negative" results attempting to characterize non achievable zones in the RC plane.

Our technical exposition begins by focusing on perfect learning (point c^* in the RC plane). Given the training set S_m, we are required to generate a "perfect" selective classifier (f,g) for which

it is known *with certainty* that $R(f,g) = 0$.[1] Obviously, zero risk is trivially achieved by taking g that rejects the entire input space $\mathcal{X}$. But is it possible to achieve perfect learning on a guaranteed fraction of the effective volume of $\mathcal{X}$?

Our first observation is Theorem 8, stating that for any finite hypothesis class $\mathcal{F}$, perfect learning with guaranteed coverage is achievable by a particular selective classification strategy. For any tolerance δ, with probability of at least $1-\delta$, it is guaranteed that the coverage achieved by this strategy will be at least

$$1 - \frac{1}{m} O(|\mathcal{F}| + \ln(1/\delta)). \tag{2}$$

The learning strategy that achieves this performance is simple and natural and can be termed *consistent selective strategy (CSS)*: take f to be any hypothesis from the version space (with respect to S_m), and construct a g that deterministically rejects any point that is not classified unanimously by all version space hypotheses. This CSS strategy is optimal for perfect learning. We show in Theorem 7 that any other strategy that achieves perfect learning cannot have larger coverage than CSS. It is interesting to note that the optimal selection function is not obtained by thresholding soft classification values, which is the commonly used heuristic.

It is easy to see why the classifier (f,g) selected by CSS has zero risk with certainty. Since f^* is assumed to be in the version space, and since g rejects all instances that are not classified unanimously by all the hypotheses in the version space, any selection of f from the version space will have identical classification to f^*. Nonetheless, it is surprising at the outset that the selection function g doesn't reject a lot and in fact, its rejection rate can be very small for sufficiently large m as it decreases at rate $1/m$.

This distribution-free coverage guarantee (2) is proven to be nearly tight for CSS and therefore, it is the best possible bound for any selective learner. Specifically, as shown in Theorem 11, there exist a particular finite hypothesis class and a particular underlying distribution for which a matching negative result (up to multiplicative constants) holds for any *consistent selective* learner. This result is readily extended to any selective learner by the CSS coverage optimality of Theorem 7.

What about infinite hypothesis spaces? We show in Theorem 14 that it is impossible to provide any coverage guarantees for perfect learning, in the general case. Specifically, for linear classifiers, we show a bad distribution for which any selective learner ensuring zero risk will be forced to reject the entire volume of $\mathcal{X}$, thus failing to guarantee more than zero coverage. Thus, in the general case, point c^* is simply the coordinate $(0,0)$ on the RC plane. The implication of this result is that when aiming at very small risks, the rejection rate might in general be very high (very small coverage), which may be unacceptable in many applications.

So the bad news is that perfect learning with guaranteed coverage cannot in general be achieved if the hypothesis space is infinite. Fortunately, however, this observation does not preclude non-trivial perfect learning in less adverse situations. What can be accomplished are both data-dependent and distribution-dependent guarantees. For any selective hypothesis (f,g), that is consistent with a sample S_m, Theorem 21 ensures perfect learning with a high probability coverage guarantee of the following form:

$$\Phi(f,g) \geq 1 - \frac{1}{m} O\left(\gamma(\mathcal{F},\hat{n}) \ln \frac{m}{\gamma(\mathcal{F},\hat{n})} + \ln \frac{m}{\delta}\right), \tag{3}$$

1. The requirement that in perfect learning the risk is zero *with certainty* is dual to the requirement that the coverage is 100% *with certainty* in standard learning.

where $\hat{n}$ is a new empirical quantity measuring the version space compression set size (see Definition 15), and $\gamma(\mathcal{F},k)$ is a new complexity measure of the set of all possible version spaces generated by training samples of size k. We call $\gamma(\mathcal{F},k)$ the "order-k characterizing set complexity" of $\mathcal{F}$, and it is derived using VC-dimension arguments (see Definition 18).

This general data-dependent bound is then applied to linear classifiers. Relying on a classical result in combinatorial geometry that bounds the number of facets of polytopes, we derive in Theorem 27 the following upper bound on the order-k characterizing set complexity of linear classifiers in $\mathbb{R}^d$,

$$\gamma(\mathcal{F},k) \leq O(d^3(k/d)^{d/2}\log k).$$

Plugging this bound to (3) results in a data-dependent compression bound for linear classifiers in terms of $\hat{n}$, the size of the compression set of the version space.

We then consider the evaluation of the compression set size $\hat{n}$ for specific distributions. Using a classical result in geometric probability theory on the average number of maximal random vectors, we show in Lemma 32 that if the underlying distribution is any (unknown) finite mixture of arbitrary multi-dimensional Gaussians in $\mathbb{R}^d$, then the compression set size of the version space obtained using m labeled examples satisfies, with probability of at least $1-\delta$,

$$\hat{n} = O\left((\log m)^d/\delta\right).$$

This bound immediately yields a coverage guarantee for perfect learning of linear classifiers, as stated in Corollary 33. This is a powerful result providing strong indication on the potential effectiveness of perfect learning with guaranteed coverage in a variety of applications.

In Section 7 we derive upper and lower envelopes for the RC curve. Our results on perfect learning described above play a major role in the derivation of these envelopes. We generalize the CSS strategy and define a "controllable selective strategy" (Definition 34). This strategy is parameterized by a number $\alpha \in [0,1]$ which controls the rejection rate by interpolating perfect learning and optimal standard learning. In particular, this strategy, applied with $\alpha = 0$ is perfect learning, and with $\alpha = 1$ it is optimal standard learning (full coverage), which in the realizable case is known to be achieved by any consistent learner. For any finite hypothesis space, the lower envelop we present in Theorem 36 is

$$R_\alpha(f,g) \leq \left(\frac{1-\Phi_0/\Phi_\alpha(f,g)}{1-\Phi_0}\right)\cdot\frac{1}{m}\left(\ln|\mathcal{F}|+\ln\frac{2}{\delta}\right),$$

where Φ_0 is the coverage guarantee of perfect learning in Equation (2), $R_\alpha(f,g)$ is the risk of the "controllable selective strategy" with control parameter α, and $\Phi_\alpha(f,g)$ is the matching coverage.

The upper envelop on the RC curve is then derived in Theorem 37 for any selective classifier (f,g) by constructing a particular bad distribution for which

$$R(f,g) \geq \frac{1}{4\Phi}\cdot\min\left(2\Phi-1, 2\Phi-2+\frac{1}{4m}\cdot\left[VCdim(\mathcal{F})-\frac{16}{3}\ln\frac{1}{1-2\delta}\right]\right).$$

An exact implementation of the CSS strategy appears as if it should be computationally difficult. Given a particular training set, CSS must reject a point iff it is not classified the same by all hypotheses in the current version space. In Section 8 we show an efficient algorithm that implements CSS of linear classifiers. The main idea leading to this construction is the following observation. Given a test point x we examine if the inclusion of x with either positive or negative labels in the

training sets results in linearly separable sets. Clearly, CSS must reject x iff both these augmented sets are linearly separable. Thus, the construction of the CSS selection function can be reduced to two tests of linear separability, which can be efficiently accomplished using known techniques for testing linear separability. Note that we do not construct the selection function explicitly during the training process, a task that may indeed require intensive computation. Rather, we benefit from a "lazy learning" approach whereby the selection function is constructed at test time per each example (as in nearest neighbor algorithms).

4. Perfect Learning with Finite Hypothesis Spaces

In this section we consider the simplest case of realizable learning with a finite hypothesis space $\mathcal{F}$. We show that perfect selective classification with guaranteed coverage is achievable (from a learning-theoretic perspective) by a learning strategy termed *consistent selective strategy (CSS)*. Moreover, CSS is shown to be optimal in its coverage rate, which is fully characterized by providing lower and upper bounds that match in their asymptotic behavior in the sample size m. We start by defining a region in $\mathcal{X}$, which is termed the "maximal agreement set." Any hypothesis that is consistent with the sample S_m is guaranteed to be consistent with the target hypothesis f^* on this entire region.

Definition 4 (agreement set) *Let $\mathcal{G} \subseteq \mathcal{F}$. A subset $\mathcal{X}' \subseteq \mathcal{X}$ is an* agreement set *with respect to $\mathcal{G}$ if all hypotheses in $\mathcal{G}$ agree on every instance in $\mathcal{X}'$, namely,*

$$\forall \ g_1, g_2 \in \mathcal{G}, \ \ x \in \mathcal{X}', \quad g_1(x) = g_2(x).$$

Definition 5 (maximal agreement set) *Let $\mathcal{G} \subseteq \mathcal{F}$. The* maximal agreement set *with respect to $\mathcal{G}$ is the union of all agreement sets with respect to $\mathcal{G}$.*

Recall that the version space $VS_{\mathcal{F},S_m} \subseteq \mathcal{F}$ is the set of all hypotheses that classify S_m correctly (Definition 3).

Definition 6 (consistent selective strategy (CSS)) *Given S_m, a* consistent selective strategy (CSS) *is a selective classification strategy that takes f to be any hypothesis in $VS_{\mathcal{F},S_m}$ (i.e., a consistent learner), and takes a (deterministic) selection function g that equals one for all points in the maximal agreement set with respect to $VS_{\mathcal{F},S_m}$, and zero otherwise.*

Recall that the (unknown) labeling hypothesis f^* is in $VS_{\mathcal{F},S_m}$. Thus, CSS simply rejects all points that might incur an error with respect to f^*. An immediate consequence is that any CSS selective hypothesis (f,g) always satisfies $R(f,g) = 0$. The main concern, however, is whether its coverage $\Phi(f,g)$ can be bounded from below and whether any other strategy that achieves perfect learning with certainty can achieve better coverage. The following theorem proves that CSS has the largest possible coverage among all strategies.

Theorem 7 (CSS coverage optimality) *Given S_m, let (f,g) be a selective classifier chosen by any strategy that ensures zero risk with certainty for* any *unknown distribution P and* any *target concept $f^* \in \mathcal{F}$. Let (f_c,g_c) be a selective classifier selected by CSS using S_m. Then, $\Phi(f,g) \leq \Phi(f_c,g_c)$.*

Proof For the sake of simplicity we limit the discussion to deterministic strategies. The extension to stochastic strategies is omitted but is straightforward. Given a hypothetical sample $\tilde{S}_m$ of size m, let $(\tilde{f}_c, \tilde{g}_c)$ be the selective classifier chosen by CSS and let $(\tilde{f}, \tilde{g})$ be the selective classifier chosen by any competing strategy. Assume that there exists $x_0 \in \mathcal{X}$ ($x_0 \notin \tilde{S}_m$) such that $\tilde{g}(x_0) = 1$ and $\tilde{g}_c(x_0) = 0$. According to the CSS construction of $\tilde{g}_c$, since $\tilde{g}_c(x_0) = 0$, there are at least two hypotheses $h_1, h_2 \in VS_{\mathcal{F},\tilde{S}_m}$ such that $h_1(x_0) \neq h_2(x_0)$. Assume, without loss of generality, that $h_1(x_0) = \tilde{f}(x_0)$. We will now construct a new "imaginary" classification problem and show that, under the above assumption, the competing strategy fails to guarantee zero risk with certainty. Let the imaginary target concept f'^* be h_2 and the imaginary underlying distribution P' be

$$P'(x) = \begin{cases} (1-\varepsilon)/m, & \text{if } x \in \tilde{S}_m; \\ \varepsilon, & \text{if } x = x_0; \\ 0, & \text{otherwise.} \end{cases}$$

Imagine a random sample S'_m drawn i.i.d from P'. There is a positive (perhaps small) probability that S'_m will equal $\tilde{S}_m$, in which case $(f', g') = (\tilde{f}, \tilde{g})$. Since $g'(x_0) = \tilde{g}(x_0) = 1$ and $f^*(x_0) \neq f'(x_0)$, with positive probability $R(f', g') = \varepsilon > 0$. Contradiction to the assumption that the competing strategy achieves perfect learning with certainty. It follows that for any sample $\tilde{S}_m$ and for any $x \in \mathcal{X}$, if $\tilde{g}(x) = 1$ then $\tilde{g}_c(x) = 1$. Consequently, for any unknown distribution P, $\Phi(\tilde{f}, \tilde{g}) \leq \Phi(\tilde{f}_c, \tilde{g}_c)$. ■

The next result establishes the existence of perfect learning with guaranteed coverage in the finite case.

Theorem 8 (guaranteed coverage) *Assume a finite $\mathcal{F}$ and let (f, g) be a selective classifier selected by CSS. Then, $R(f, g) = 0$ and for any $0 \leq \delta \leq 1$, with probability of at least $1 - \delta$,*

$$\Phi(f, g) \geq 1 - \frac{1}{m}\left((\ln 2)\min\{|\mathcal{F}|, |\mathcal{X}|\} + \ln\frac{1}{\delta}\right). \tag{4}$$

Proof For any ε, let $G_1, G_2, \ldots, G_k$, be all the hypothesis subsets of $\mathcal{F}$ with corresponding maximal agreement sets, $\lambda_1, \lambda_2, \ldots, \lambda_k$, such that each λ_i has volume of at most $1 - \varepsilon$ with respect to P. For any $1 \leq i \leq k$, the probability that a single point will be randomly drawn from λ_i is thus at most $1 - \varepsilon$. The probability that all training points will be drawn from λ_i is therefore at most $(1-\varepsilon)^m$. If a training point x is in $\mathcal{X} \setminus \lambda_i$, then there are at least two hypotheses $f_1, f_2 \in G_i$ that do not agree on x. Hence,

$$\Pr_P(G_i \subseteq VS_{\mathcal{F},S_m}) \leq (1-\varepsilon)^m.$$

We note that

$$k \leq 2^{\min\{|\mathcal{F}|, |\mathcal{X}|\}},$$

and by the union bound,

$$\Pr_P(\exists G_i \quad G_i \subseteq VS_{\mathcal{F},S_m}) \leq k \cdot (1-\varepsilon)^m \leq 2^{\min\{|\mathcal{F}|, |\mathcal{X}|\}} \cdot (1-\varepsilon)^m.$$

Therefore, with probability of at least $1 - 2^{\min\{|\mathcal{F}|, |\mathcal{X}|\}} \cdot (1-\varepsilon)^m$, the version space $VS_{\mathcal{F},S_m}$ differs from any subset G_i, and hence it has a maximal agreement set with volume of *at least* $1 - \varepsilon$. Using the inequality $1 - \varepsilon \leq \exp(-\varepsilon)$, we have

$$2^{\min\{|\mathcal{F}|, |\mathcal{X}|\}} \cdot (1-\varepsilon)^m \leq 2^{\min\{|\mathcal{F}|, |\mathcal{X}|\}} \cdot \exp(-m\varepsilon).$$

Equating the right-hand side to δ and solving for ε completes the proof. ■

A leading term in the coverage guarantee (4) is $|\mathcal{F}|$. In corresponding results in standard consistent learning (Haussler, 1988) the corresponding term is $\log|\mathcal{F}|$. This may raise a concern on the tightness of (4). However, as shown in Corollary 13, this bound is tight (up to multiplicative constants). To prove the Corollary we will require the following two definitions.

Definition 9 (binomial tail distribution) *Let $Z_1, Z_2, \ldots Z_m$ be m independent Bernoulli random variables each with a success probability p. Then for any $0 \leq k \leq m$ we define*

$$Bin(m,k,p) \triangleq \Pr\left(\sum_{i=1}^{m} Z_i \leq k\right).$$

Definition 10 (binomial tail inversion, Langford, 2005) *For any $0 \leq \delta \leq 1$ we define*

$$\overline{Bin}(m,k,\delta) \triangleq \max_p \{p : Bin(m,k,p) \geq \delta\}.$$

Theorem 11 (non-achievable coverage, implicit bound) *Let $0 \leq \delta \leq \frac{1}{2}$, m, and $n > 1$ be given. There exist a distribution P, that depends on m and n, and a finite hypothesis class $\mathcal{F}$ of size n, such that for any selective classifier (f,g), chosen from $\mathcal{F}$ by CSS (so $R(f,g) = 0$) using a training sample S_m drawn i.i.d. according to P, with probability of at least δ,*

$$\Phi(f,g) \leq 1 - \frac{1}{2} \cdot \overline{Bin}\left(m, \frac{|\mathcal{F}|}{2}, 2\delta\right).$$

Proof Let $\mathcal{X} \triangleq \{e_1, e_2, \ldots e_{n+1}\}$ be the standard (vector) basis of $\mathbb{R}^{n+1}$, $\mathcal{X}' \triangleq \mathcal{X} \setminus \{e_{n+1}\}$ and P be the source distribution over $\mathcal{X}$ satisfying

$$P(e_i) \triangleq \begin{cases} \overline{Bin}\left(m, \frac{n}{2}, 2\delta\right)/n, & \text{if } i \leq n; \\ 1 - \overline{Bin}\left(m, \frac{n}{2}, 2\delta\right), & \text{otherwise;} \end{cases}$$

where $\overline{Bin}(m,k,\delta)$ is the binomial tail inversion (Definition 10). Since

$$\overline{Bin}\left(m, \frac{n}{2}, 2\delta\right) \triangleq \max_p \left\{p : Bin\left(m, \frac{n}{2}, p\right) \geq 2\delta\right\},$$

and S_m is drawn i.i.d. according to P, we get that with probability of at least 2δ,

$$\left|\left\{x \in S_m : x \in \mathcal{X}'\right\}\right| \leq \frac{n}{2}.$$

Let $\mathcal{F}$ be the class of singletons such that

$$f_i(e_j) \triangleq \begin{cases} 1, & \text{if } i = j; \\ -1, & \text{otherwise.} \end{cases}$$

Taking $f^* \triangleq f_{i^*}$, for some $1 \leq i^* \leq n$, we have,

$$\begin{aligned} & \Pr\left(e_{i^*} \notin S_m, \left|\left\{x \in S_m : x \in \mathcal{X}'\right\}\right| \leq \frac{n}{2}\right) \\ = \; & \Pr\left(e_{i^*} \notin S_m \,\middle|\, \left|\left\{x \in S_m : x \in \mathcal{X}'\right\}\right| \leq \frac{n}{2}\right) \cdot \Pr\left(\left|\left\{x \in S_m : x \in \mathcal{X}'\right\}\right| \leq \frac{n}{2}\right) \\ \geq \; & \left(1 - \frac{1}{n}\right)^{\frac{n}{2}} \cdot 2\delta \geq \delta. \end{aligned}$$

If $e_{i^*} \notin S_m$ then all samples in S_m are negative, so each sample in $\mathcal{X}'$ can reduce the version space $VS_{\mathcal{F},S_m}$ by at most one hypothesis. Hence, with probability of at least δ,

$$|VS_{\mathcal{F},S_m}| \geq |\mathcal{F}| - \frac{n}{2} = \frac{n}{2}.$$

Since the coverage $\Phi(f,g)$ is the volume of the maximal agreement set with respect to the version space $VS_{\mathcal{F},S_m}$, it follows that

$$\Phi(f,g) \;\; = \;\; 1 - |VS_{\mathcal{F},S_m}| \cdot \frac{\overline{Bin}\left(m, \frac{n}{2}, 2\delta\right)}{n} \leq 1 - \frac{1}{2} \cdot \overline{Bin}\left(m, \frac{|\mathcal{F}|}{2}, 2\delta\right).$$

■

Remark 12 *The result of Theorem 11 is based on the use of the class of singletons. Augmenting this class by the empty set and choosing a uniform distribution over $\mathcal{X}$ results in a tighter bound. However, the bound will be significantly less general as it will hold only for a single hypothesis in $\mathcal{F}$ and not for any hypothesis in $\mathcal{F}$.*

Corollary 13 (non-achievable coverage, explicit bound) *Let $0 \leq \delta \leq \frac{1}{4}$, m, and $n > 1$ be given. There exist a distribution P, that depends on m and n, and a finite hypothesis class $\mathcal{F}$ of size n, such that for any selective classifier (f,g), chosen from $\mathcal{F}$ by CSS (so $R(f,g) = 0$) using a training sample S_m drawn i.i.d. according to P, with probability of at least δ,*

$$\Phi(f,g) \leq \max\left\{0, 1 - \frac{1}{8m}\left(|\mathcal{F}| - \frac{16}{3}\ln\frac{1}{1-2\delta}\right)\right\}.$$

Proof Applying Lemma 43 we get

$$\overline{Bin}\left(m, \frac{|\mathcal{F}|}{2}, 2\delta\right) \geq \min\left\{1, \frac{|\mathcal{F}|}{4m} - \frac{4}{3m}\ln\frac{1}{1-2\delta}\right\}.$$

Applying Theorem 11 completes the proof. ■

5. Consistent Selective Classification Over Infinite Hypothesis Spaces

In this section we consider an infinite hypothesis space $\mathcal{F}$. We show that in the general case, perfect selective classification with guaranteed (non-zero) coverage is not achievable even when $\mathcal{F}$ has a finite VC-dimension. We then derive a meaningful coverage guarantee using posterior information on the source distribution (data-dependent bound).

We start this section with a negative result that precludes non-trivial perfect learning when $\mathcal{F}$ is the set of linear classifiers. The result is obtained by constructing a particularly bad distribution.

Theorem 14 (non-achievable coverage) *Let m and $d > 2$ be given. There exist a distribution P, an infinite hypothesis class $\mathcal{F}$ with a finite VC-dimension d, and a target hypothesis in $\mathcal{F}$, such that $\Phi(f,g) = 0$ for any selective classifier (f,g), chosen from $\mathcal{F}$ by CSS using a training sample S_m drawn i.i.d. according to P.*

Proof Let $\mathcal{F}$ be the class of all linear classifiers in $\mathbb{R}^2$ and let P be a uniform distribution over the arcs,

$$(x-2)^2 + y^2 = 2, \quad x < 1,$$

and

$$(x+2)^2 + y^2 = 2, \quad x > -1.$$

Figure 2 depicts this construction. The training set S_m consists of points on these arcs, labeled by any linear classifier that passes between the arcs. The maximal agreement set, A, with respect to the version space $VS_{\mathcal{F},S_m}$ is partitioned into two subsets A^+ and A^- according to the labels obtained by hypotheses in the version space. Clearly, A^+ is confined by a polygon whose vertices lie on the right-hand side arc. Since P is concentrated on the arc, the probability volume of A^+ is exactly zero for any finite m. The same analysis holds for A^-, and therefore the coverage is forced to be zero. The VC-dimension of the class of all linear classifiers in $\mathbb{R}^2$ is 3. Embedding the distribution P in a higher dimensional space $\mathbb{R}^d$ and using the class of all linear classifiers in $\mathbb{R}^d$ completes the proof. ■

A direct corollary of Theorem 14 is that, in the general case, perfect selective classification with distribution-free guaranteed coverage is not achievable for infinite hypothesis spaces. However, this is certainly not the end of the story for perfect learning. In the remainder of this paper we derive meaningful coverage guarantees using posterior or prior information on the source distribution (data- and distribution-dependent bounds).

In order to guarantee meaningful coverage we first need to study the complexity of the selection function $g(x)$ chosen by CSS. The complexity of the classification function $f(x)$ is determined only by the hypothesis class $\mathcal{F}$ and it is independent of the sample size itself. However, the complexity of $g(x)$ (the maximal agreement set) chosen by CSS generally depends on the sample size. Therefore, increasing the training sample size does not necessarily guarantee non-trivial coverage. Our main task is to find the complexity class of the family of maximal agreement sets from which $g(x)$ is chosen. Let us define the family of all maximal agreement sets as $\mathcal{H} = \bigcup \mathcal{H}_n$ such that $\mathcal{H}_1 \subset \mathcal{H}_2 \subset \mathcal{H}_3 \subset \ldots$. We can now exploit the fact that CSS chooses a maximal agreement set that belongs to a specific subclass $\mathcal{H}_n$ with a complexity measured in terms of the VC dimension of $\mathcal{H}_n$. We term this approach *Structural Coverage Maximization (SCM)* following the analogous and familiar *Structural*

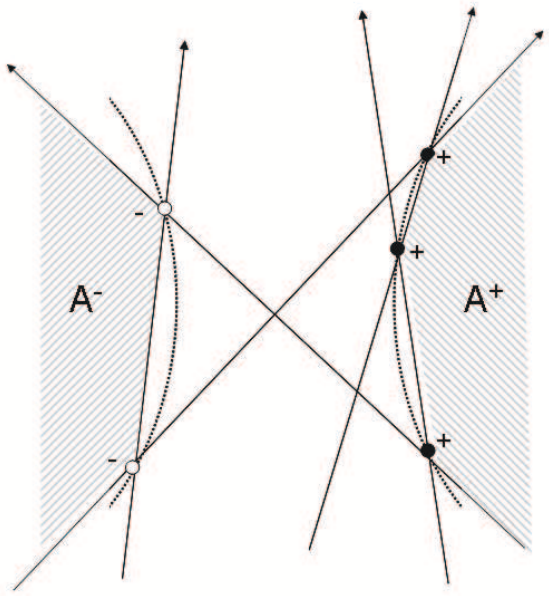

Figure 2: A worst-case distribution for linear classifiers: points are drawn uniformly at random on the two arcs and labeled by a linear classifier that passes between these arcs. The probability volume of the maximal agreement set is zero.

Risk Minimization (SRM) approach (Vapnik, 1998). A useful way to parameterize $\mathcal{H}$ is to use the size of the "version space compression set" (Definition 15).

Definition 15 (version space compression set) *Let S_m be a labeled sample of m points and let $VS_{\mathcal{F},S_m}$ be the induced version space. The* version space compression set, *$S_{\hat{n}} \subseteq S_m$ is a smallest subset of S_m satisfying $VS_{\mathcal{F},S_m} = VS_{\mathcal{F},S_{\hat{n}}}$. Note that for any given $\mathcal{F}$ and S_m, the size of the version space compression set, denoted $\hat{n} = \hat{n}(\mathcal{F}, S_m)$, is unique.*

Since a maximal agreement set is a region in $\mathcal{X}$, rather than an hypothesis, we formally define the dual hypothesis that matches every maximal agreement set.

Definition 16 (characterizing hypothesis) *Let $\mathcal{G} \subseteq \mathcal{F}$ and let $A_{\mathcal{G}}$ be the maximal agreement set with respect to $\mathcal{G}$. The* characterizing hypothesis *of $\mathcal{G}$, $f_{\mathcal{G}}(x)$ is a binary hypothesis over $\mathcal{X}$ obtaining positive values over $A_{\mathcal{G}}$ and zero otherwise.*

We are now ready to formally define $\mathcal{H}_n$, a class we term "order-n characterizing set."

Definition 17 (order-n characterizing set) *For each n, let $\mathcal{S}_n$ be the set of all possible labeled samples of size n (all n-subsets, each with all possible labelings). The order-n* characterizing set *of $\mathcal{F}$, denoted $\mathcal{H}_n$, is the set of all characterizing hypotheses $f_{\mathcal{G}}(x)$, where $\mathcal{G} \subseteq \mathcal{F}$ is a version space induced by some member of $\mathcal{S}_n$.*

Definition 18 (characterizing set complexity) *Let $\mathcal{H}_n$ be the order-n characterizing set of $\mathcal{F}$. The order-n* characterizing set complexity *of $\mathcal{F}$, denoted $\gamma(\mathcal{F}, n)$, is the VC-dimension of $\mathcal{H}_n$.*

Lemma 19 *The characterizing hypothesis $f_{VS_{\mathcal{F},S_m}}(x)$ belongs to the order-$\hat{n}$ characterizing set of $\mathcal{F}$, where $\hat{n} = \hat{n}(\mathcal{F}, S_m)$ is the size of the version space compression set.*

Proof According to Definition 15, there exists a subset $S_{\hat{n}} \subset S_m$ of size $\hat{n}$ such that $VS_{\mathcal{F},S_m} = VS_{\mathcal{F},S_{\hat{n}}}$. The rest of the proof follows immediately from Definition 17. ■

Before stating the main result of this section, we state a classical result that will be used later.

Theorem 20 (Vapnik and Chervonenkis, 1971; Anthony and Bartlett, 1999, p.53) *Let $\mathcal{F}$ be a hypothesis space with VC-dimension h. For any probability distribution P on $\mathcal{X} \times \{\pm 1\}$, with probability of at least $1-\delta$ over the choice of S_m from P^m, any hypothesis $f \in \mathcal{F}$ consistent with S_m satisfies*

$$R(f) \leq \varepsilon(h, m, \delta) = \frac{2}{m}\left[h \ln \frac{2em}{h} + \ln \frac{2}{\delta}\right], \tag{5}$$

where $R(f) \triangleq \mathbf{E}\left[\mathbb{I}(f(x) \neq f^*(x))\right]$ is the risk of f.

We note that inequality (5) actually holds only for $h \leq m$. For any $h > m$ it is clear that no meaningful upper bound on the risk can be achieved. It is easy to fix the inequality for the general case by replacing $\ln\left(\frac{2em}{h}\right)$ by $\ln_+\left(\frac{2em}{h}\right)$, where $ln_+(x) \triangleq \max(\ln(x), 1)$.

Theorem 21 (data-dependent coverage guarantee) *For any m, let $a_1, a_2, \ldots, a_m \in \mathbb{R}$ be given, such that $a_i \geq 0$ and $\sum_{i=1}^m a_i \leq 1$. Let (f,g) be a selective CSS classifier. Then, $R(f,g) = 0$, and for any $0 \leq \delta \leq 1$, with probability of at least $1-\delta$,*

$$\Phi(f,g) \geq 1 - \frac{2}{m}\left[\gamma(\mathcal{F}, \hat{n}) \ln_+\left(\frac{2em}{\gamma(\mathcal{F}, \hat{n})}\right) + \ln \frac{2}{a_{\hat{n}}\delta}\right],$$

where $\hat{n}$ is the size of the version space compression set, $\gamma(\mathcal{F}, \hat{n})$ is the order-$\hat{n}$ characterizing set complexity of $\mathcal{F}$.

Proof Given our sample $S_m = \{(x_i, f^*(x_i))\}_{i=1}^m$ (labeled by the unknown target function f^*), we define the "synthetic" sample $S'_m = \{(x_i, 1)\}_{i=1}^m$. S'_m can be assumed to have been sampled i.i.d from the marginal distribution of X with positive labels (P').

Theorem 20 can now be applied on the synthetic problem with the training sample S'_m, the distribution P', and the hypothesis space taken to be $\mathcal{H}_i$, the order-i characterizing set of $\mathcal{F}$. It follows that for all $f \in VS_{\mathcal{H}_i, S'_m}$, with probability of at least $1 - a_i\delta$ over choices of S'_m from $(P')^m$,

$$\Pr_{P'}(f(x) \neq 1) \quad \leq \quad \frac{2}{m}\left[h_i \ln\left(\frac{2em}{h_i}\right) + \ln \frac{2}{a_i\delta}\right], \tag{6}$$

where h_i is the VC-dimension of $\mathcal{H}_i$. Then, applying the union bound yields, with probability of at least $1-\delta$, that inequality (6) holds simultaneously for all $1 \leq i \leq m$.

All hypotheses in the version space $VS_{\mathcal{F},S_m}$ agree on all samples in S_m. Hence, the characterizing hypothesis $f_{VS_{\mathcal{F},S_m}}(x) = 1$ for any point $x \in S_m$. Let $\hat{n}$ be the size of the version space compression set. According to Lemma 19, $f_{VS_{\mathcal{F},S_m}}(x) \in \mathcal{H}_{\hat{n}}$. Noting that $f_{VS_{\mathcal{F},S_m}}(x) = 1$ for any $x \in S'_m$, we learn that $f_{VS_{\mathcal{F},S_m}}(x) \in VS_{\mathcal{H}_{\hat{n}}, S'_m}$. Therefore, with probability of at least $1-\delta$ over choices of S_m,

$$\Pr_P(f_{VS_{\mathcal{F},S_m}}(x) \neq 1) \leq \frac{2}{m}\left[h_{\hat{n}} \ln\left(\frac{2em}{h_{\hat{n}}}\right) + \ln \frac{2}{a_{\hat{n}}\delta}\right].$$

Since $\Phi(f,g) = \Pr_P(f_{VS_{\mathcal{F},S_m}}(x) = 1)$, and $h_{\hat{n}}$ is the order-$\hat{n}$ characterizing set complexity of $\mathcal{F}$, the proof is complete. ■

6. Consistent Selective Classification With Linear Classifiers

The data dependent bound in Theorem 21 is stated in terms of a new complexity measure (the "characterizing set complexity" of Definition 18). Can this measure be explicitly evaluated or bounded for some interesting hypothesis classes? In this section we consider the class of linear classifiers in $\mathbb{R}^d$. Relying on a classical result from combinatorial geometry, we infer an explicit upper bound on the characterizing set complexity for linear classifiers. Combining this bound with Theorem 21, we immediately obtain a data-dependent compression coverage guarantee, as stated in Corollary 28. We then show that if the unknown underlying distribution is a finite mixture of Gaussians, then CSS will ensure perfect learning with guaranteed coverage. This powerful result, which is stated in Corollary 33, indicates that consistent selective classification might be relevant in various applications of interest.

Fix any positive integer d, and let $\mathcal{F} \triangleq \{f_{\bar{w},\phi}(\bar{x})\}$ be the class of all linear binary classifiers in $\mathbb{R}^d$, where $\bar{w}$ are d-dimensional real vectors, ϕ are scalars, and

$$f_{\bar{w},\phi}(\bar{x}) = \begin{cases} +1, & \bar{w}^T\bar{x} - \phi \geq 0; \\ -1, & \bar{w}^T\bar{x} - \phi < 0. \end{cases}$$

Given a binary labeled training sample S_m, define $R^+ \triangleq R^+(S_m) \subseteq \mathbb{R}^d$ to be the subset of the maximal agreement set with respect to the version space $VS_{\mathcal{F},S_m}$, consisting of all points with positive labels. R^+ is called the 'maximal positive agreement set.' The 'maximal negative agreement set', $R^- \triangleq R^-(S_m)$, is defined similarly. Before continuing, we define a new symmetric hypothesis class $\tilde{\mathcal{F}}$ that allows for a simpler analysis. Let $\tilde{\mathcal{F}} \triangleq \{f_{\bar{w},\phi}(\bar{x})\}$ be the function class

$$\tilde{f}_{\bar{w},\phi}(\bar{x}) = \begin{cases} +1, & \text{if } \bar{w}^T\bar{x} - \phi > 0; \\ 0, & \text{if } \bar{w}^T\bar{x} - \phi = 0; \\ -1, & \text{if } \bar{w}^T\bar{x} - \phi < 0, \end{cases}$$

where we interpret 0 as a classification that agrees with both $+1$ and -1. Given a sample S_m, we define $\tilde{R}^+ \subseteq \mathbb{R}^d$ to be the region in $\mathbb{R}^d$ for which any hypothesis in the version space[2] $VS_{\tilde{\mathcal{F}},S_m}$ classifies either $+1$ or 0 (i.e., this is the maximal positive agreement set). We define $\tilde{R}^-$ analogously with respect to negative or zero classifications. While $\mathcal{F}$ and $\tilde{\mathcal{F}}$ are not identical, the maximal agreement sets they induce are identical. This is stated in the following technical lemma whose proof appears in the appendix.

Lemma 22 (maximal agreement set equivalence) *For any linearly separable sample S_m, $R^+ = \tilde{R}^+$ and $R^- = \tilde{R}^-$.*

The next technical lemma, whose proof also appears in the appendix, provides useful information on the geometry of the maximal agreement set for the class of linear classifiers.

2. Any hypothesis in $\tilde{\mathcal{F}}$ that classifies every sample in S_m correctly or as 0 belongs to the version space.

Lemma 23 (maximal agreement set geometry I) *Let S_m be a linearly separable labeled sample that is a spanning set of $\mathbb{R}^d$. Then the regions R^+ and R^- are each an intersection of a finite number of half-spaces, with at least d samples on the boundary of each half-space.*

Our goal is to bound the characterizing set complexity of $\mathcal{F}$. As we show below, this complexity measure is directly related to the number of facets of the convex hull of n points in $\mathbb{R}^d$. The following classical combinatorial geometry theorem by Klee (see Preparata and Shamos, 1990, page 98) is thus particularly useful. The statement of Klee's theorem provided here is readily obtained from the original by using the Stirling approximation of the binomial coefficient.

Theorem 24 (Klee, 1966) *The number of facets of a d-polytope with n vertices is at most*

$$2 \cdot \left(\frac{en}{\lfloor d/2 \rfloor} \right)^{\lfloor d/2 \rfloor}. \tag{7}$$

An immediate conclusion is that (7) upper bounds the number of facets of the convex hull of n points in $\mathbb{R}^d$ (which is of course a d-polytope).

Lemma 25 (maximal agreement set geometry II) *Let S_n be a linearly separable sample consisting of $n \geq d+1$ labeled points. Then the regions $R^+(S_n)$ and $R^-(S_n)$ are each an intersection of at most*

$$2(d+1) \cdot \left(\frac{2en}{d} \right)^{\lfloor \frac{d+1}{2} \rfloor}$$

half-spaces in $\mathbb{R}^d$.

Proof For the sake of clarity, we limit the analysis to a sample S_n in general position; that is, we assume that no more than d points lie on a $(d-1)$-dimensional plane. Handling a sample S_n in arbitrary position can be straightforwardly treated by including an appropriate infinitesimal displacement of the points (the technical proof is omitted).

By Lemma 22, we can limit our discussion to the hypothesis space $\tilde{\mathcal{F}}$ (rather than $\mathcal{F}$). Since S_n includes more than d samples in general position it is a spanning set of $\mathbb{R}^d$. According to Lemma 23, R^+ is an intersection of a finite number of half-spaces, with at least d samples on the boundary of each half-space (and *exactly* d in the general position). Let $S^+ \subseteq S_n$ be the subset of all positive samples in S_n, and $S^- \subseteq S_n$, the negative ones. Let $\tilde{f}_{\bar{w},\phi}$ be one of the half-spaces defining R^+. Then,

$$\forall \bar{x} \in S_n \quad \begin{cases} \bar{w}^T \bar{x} - \phi \geq 0, & \text{if } \bar{x} \in S^+; \\ \bar{w}^T \bar{x} - \phi \leq 0, & \text{if } \bar{x} \in S^-. \end{cases}$$

Also, exactly d samples, $\bar{x}$, satisfy $\bar{w}\bar{x} - \phi = 0$.

We now embed the samples in $\mathbb{R}^{d+1}$ using the following transformation, $\bar{x} \to \bar{x}'$:

$$\bar{x}' \triangleq \begin{cases} (0, \bar{x}), & \text{if } \bar{x} \in S^+; \\ (1, -\bar{x}), & \text{if } \bar{x} \in S^-. \end{cases}$$

For each half-space $(\bar{w}, \phi)$ in $\mathbb{R}^d$ we define a unique half-space, $(\bar{w}', \phi')$, in $\mathbb{R}^{d+1}$,

$$\bar{w}' \triangleq (2\phi, \bar{w}), \quad \phi' \triangleq \phi.$$

We observe that

$$\bar{w}'^T\bar{x}'-\phi'=\begin{cases}\bar{w}^T\bar{x}-\phi\geq 0, & \text{if } \bar{x}\in S^+;\\ 2\phi-\bar{w}^T\bar{x}-\phi=-(\bar{w}^T\bar{x}-\phi)\geq 0, & \text{if } \bar{x}\in S^-,\end{cases}$$

and for exactly d samples we have

$$\bar{w}'^T\bar{x}'-\phi'=\begin{cases}\bar{w}^T\bar{x}-\phi=0, & \text{if } \bar{x}\in S^+;\\ 2\phi-\bar{w}^T\bar{x}-\phi=-(\bar{w}^T\bar{x}-\phi)=0, & \text{if } \bar{x}\in S^-.\end{cases}$$

Let $\bar{v}$ be any orthogonal vector to the d samples on the boundary of the half-space. Defining

$$\bar{w}''\triangleq\bar{w}'+\alpha\bar{v},\quad \phi''\triangleq\phi',$$

with an appropriate choice of α we have,

$$\forall\bar{x}'\in S_n\quad \bar{w}''^T\bar{x}'-\phi''=\bar{w}'^T\bar{x}'-\phi'+\alpha\bar{v}'^T\bar{x}'\geq 0,$$

and for exactly $d+1$ samples (including the original d samples),

$$\bar{w}''\bar{x}'-\phi''=0.$$

We observe that $\tilde{f}_{\bar{w}'',\phi''}$ is a facet of the convex hull of the samples in $\mathbb{R}^{d+1}$. Up to $d+1$ different half-spaces in $\mathbb{R}^d$ can be transformed into a single half-space in $\mathbb{R}^{d+1}$ (the number of combinations of choosing d samples out of $d+1$ samples on the boundary). Using Theorem 24, we bound the number $F(d)$ of facets of the convex hull of the points in $\mathbb{R}^{d+1}$ as follows:

$$F(d)\leq 2\cdot\left(\frac{en}{\lfloor\frac{d+1}{2}\rfloor}\right)^{\lfloor\frac{d+1}{2}\rfloor}\leq 2\cdot\left(\frac{2en}{d}\right)^{\lfloor\frac{d+1}{2}\rfloor}.$$

Since up to $d+1$ half-spaces in $\mathbb{R}^d$ can be mapped onto a single facet of the convex hull in $\mathbb{R}^{d+1}$, we can bound the number of half-spaces in $\mathbb{R}^d$ by

$$(d+1)\cdot F(d)\leq 2(d+1)\cdot\left(\frac{2en}{d}\right)^{\lfloor\frac{d+1}{2}\rfloor}.$$

■

Lemma 26 (*Blumer et al., 1989, Lemma 3.2.3*) *Let $\mathcal{F}$ be a binary hypothesis class of finite VC dimension $h\geq 1$. For all $k\geq 1$, define the k-fold intersection,*

$$\mathcal{F}_{k\cap}\triangleq\left\{\cap_{i=1}^k f_i : f_i\in\mathcal{F}, 1\leq i\leq k\right\},$$

and the k-fold union,

$$\mathcal{F}_{k\cup}\triangleq\left\{\cup_{i=1}^k f_i : f_i\in\mathcal{F}, 1\leq i\leq k\right\}.$$

Then, for all $k\geq 1$,

$$VC(\mathcal{F}_{k\cap}), VC(\mathcal{F}_{k\cap})\leq 2hk\log(3k).$$

Lemma 27 (characterizing set complexity) *Fix $d \geq 2$ and $n > d$. Let $\mathcal{F}$ be the class of all linear binary classifiers in $\mathbb{R}^d$. Then, the order-n characterizing set complexity of $\mathcal{F}$ satisfies*

$$\gamma(\mathcal{F},n) \leq 83 \cdot (d+1)^3 \cdot \left(\frac{2en}{d}\right)^{\left\lfloor \frac{d+1}{2} \right\rfloor} \cdot \log n.$$

Proof Let $\mathcal{G} = \mathcal{F}_{k\cap}$ be the class of k-fold intersections of half-spaces in $\mathbb{R}^d$. Since the VC dimension of the class of all half-spaces in $\mathbb{R}^d$ is $d+1$, we obtain, using Lemma 26, that the VC dimension of $\mathcal{G}$ satisfies

$$VC(\mathcal{G}) \leq 2k\log(3k)(d+1).$$

Let $\mathcal{H}_n$ be the order-n characterizing set of $\mathcal{F}$. From Lemma 25 we know that any hypothesis $f \in \mathcal{H}_n$ is a union of two regions, where each region is an intersection of no more than

$$k = 2(d+1) \cdot \left(\frac{2en}{d}\right)^{\left\lfloor \frac{d+1}{2} \right\rfloor}$$

half-spaces in $\mathbb{R}^d$. Therefore, $\mathcal{H}_n \subset \mathcal{G}_{2\cup}$. Using Lemma 26, we get

$$\begin{aligned} VC(\mathcal{H}_n) &\leq VC(\mathcal{G}_{2\cup}) \leq 4\log(6) \cdot VC(\mathcal{G}) \leq 8k\log(6)\log(3k)(d+1) \\ &\leq 16(d+1)^2 \cdot \left(\frac{2en}{d}\right)^{\left\lfloor \frac{d+1}{2} \right\rfloor} \cdot \log(6) \cdot \log\left(6(d+1) \cdot \left(\frac{2en}{d}\right)^{\left\lfloor \frac{d+1}{2} \right\rfloor}\right). \end{aligned}$$

For $n > d \geq 2$ we get

$$\begin{aligned} &\log\left(6(d+1) \cdot \left(\frac{2en}{d}\right)^{\left\lfloor \frac{d+1}{2} \right\rfloor}\right) \leq \log(6n) + \left\lfloor \frac{d+1}{2} \right\rfloor \cdot \log\frac{2en}{d} \\ \leq\ & 3 \cdot \log n + \left\lfloor \frac{d+1}{2} \right\rfloor \cdot \log n^2 \leq (d+4) \cdot \log n \leq 2 \cdot (d+1) \cdot \log n. \end{aligned}$$

Therefore,

$$VC(\mathcal{H}_n) \leq 83 \cdot (d+1)^3 \cdot \left(\frac{2en}{d}\right)^{\left\lfloor \frac{d+1}{2} \right\rfloor} \cdot \log n$$

■

Corollary 28 (data-dependent coverage guarantee) *Let $\mathcal{F}$ be the class of linear binary classifiers in $\mathbb{R}^d$ and assume that the conditions of Theorem 21 hold. Then, $R(f,g) = 0$, and for any $0 \leq \delta \leq 1$, with probability of at least $1-\delta$,*

$$\Phi(f,g) \geq 1 - \frac{2}{m}\left[83(d+1)^3 \Lambda_{\hat{n},d} \ln_+\left(\frac{2em}{\Lambda_{\hat{n},d}}\right) + \ln\frac{2}{a_{\hat{n}}\delta}\right],$$

where $\hat{n}$ is the size of the empirical version space compression set, and

$$\Lambda_{\hat{n},d} = \left(\frac{2e\hat{n}}{d}\right)^{\left\lfloor \frac{d+1}{2} \right\rfloor} \cdot \log\hat{n}.$$

Proof Define

$$\Psi(\gamma(\mathcal{F},n)) \triangleq 1-\frac{2}{m}\left[\gamma(\mathcal{F},n)\ln_+\left(\frac{2em}{\gamma(\mathcal{F},n)}\right)+\ln\frac{2}{a_n\delta}\right].$$

We note that $\Psi(\gamma(\mathcal{F},n))$ is a continues function. For any $\gamma(\mathcal{F},n)<2m$

$$\frac{\partial\Psi(\gamma(\mathcal{F},n))}{\partial\gamma(\mathcal{F},n)}=-\frac{2}{m}\ln\frac{2em}{\gamma(\mathcal{F},n)}+\frac{2}{m}<0,$$

and for any $\gamma(\mathcal{F},n)>2m$

$$\frac{\partial\Psi(\gamma(\mathcal{F},n))}{\partial\gamma(\mathcal{F},n)}=-\frac{2}{m}<0.$$

Thus, $\Psi(\gamma(\mathcal{F},n))$ is monotonically decreasing. Noting that $\ln_+(x)$ is monotonically increasing, by applying Theorem 21 together with Lemma 27 the proof is complete. ■

As long as the empirical version space compression set size $\hat{n}$ is sufficiently small compared to m, Corollary 28 provides a meaningful coverage guarantee. Since $\hat{n}$ might depend on m, it is hard to analyze the effective rate of the bound. To further explore this guarantee, we now bound $\hat{n}$ in terms of m for a specific family of source distributions and derive a distribution-dependent coverage guarantee.

Theorem 29 (Bentley, Kung, Schkolnick, and Thompson, 1978) *If m points in d dimensions have their components chosen independently from any set of continuous distributions (possibly different for each component), then the expected number of convex hull vertices v is*

$$\mathbf{E}[v]=O\left((\log m)^{d-1}\right).$$

Definition 30 (sliced multivariate Gaussian distribution) *A* sliced multivariate Gaussian *distribution, $\mathcal{N}(\Sigma,\mu,w,\phi)$, is a multivariate Gaussian distribution restricted by a half space in $\mathbb{R}^d$. Thus, if Σ is a non-singular covariance matrix, the pdf of the sliced Gaussian is*

$$\frac{1}{C}e^{-\frac{1}{2}(x-\mu)^T\Sigma^{-1}(x-\mu)}\cdot\mathbb{I}(w^Tx-\phi\geq 0),$$

where $\mu=(\mu_1,\ldots,\mu_d)^T$, $\mathbb{I}$ is the indicator function and C is an appropriate normalization factor.

Lemma 31 *Let P be a sliced multivariate Gaussian distribution. If m points are chosen independently from P, then the expected number of convex hull vertices is $O\left((\log m)^{d-1}\right)$.*

Proof Let $X\sim\mathcal{N}(\Sigma,\mu,w,\phi)$ and $Y\sim\mathcal{N}(\Sigma,\mu)$. There is a random vector Z, whose components are independent standard normal random variables, a vector μ, and a matrix A such that $Y=AZ+\mu$. Since

$$w^Ty-\phi=w^T(Az+\mu)-\phi=w^TAz+w^T\mu-\phi,$$

we get that $X=AZ_0+\mu$, where $Z_0\sim\mathcal{N}(I,0,w^TA,\phi-w^T\mu)$. Due to the spherical symmetry of Z, we can choose the half-space $(w^TA,\phi-w^T\mu)$ to be axis-aligned by rotating the axes. We note that the d components of Z are chosen independently and that the axis-aligned half-space enforces

restriction only on one of the axes. Therefore, the components of Z_0 are chosen independently as well. Applying Theorem 29, we get that if m points are chosen independently from Z_0, then the expected number of convex hull vertices is $O\left((\log m)^{d-1}\right)$. The proof is complete by noting that the number of convex hull vertices is preserved under affine transformations. ■

Lemma 32 (version space compression set size) *Let $\mathcal{F}$ be the class of all linear binary classifiers in $\mathbb{R}^d$. Assume that the underlying distribution P is a mixture of a fixed number of Gaussians. Then, for any $0 \leq \delta \leq 1$, with probability of at least $1-\delta$, the empirical version space compression set size is*

$$\hat{n} = O\left(\frac{(\log m)^{d-1}}{\delta}\right).$$

Proof Let S_n be a version space compression set. Consider $\bar{x}_0 \in S_n$. Since S_n is a compression set there is a half-space, $(\bar{w}, \phi)$, such that $f_{\bar{w},\phi} \in VS_{\mathcal{F},S_n \setminus \{\bar{x}_0\}}$ and $f_{\bar{w},\phi} \notin VS_{\mathcal{F},S_n}$. W.l.o.g. assume that $\bar{x}_0 \in S_n$ is positive; thus $\bar{w}^T \bar{x}_0 - \phi < 0$, and for any other positive point $\bar{x} \in S_n$, $\bar{w}^T \bar{x} - \phi \geq 0$. For an appropriate $\phi' < \phi$, there exists a half-space $(\bar{w}, \phi')$ such that $\bar{w}^T \bar{x}_0 - \phi' = 0$, and for any other positive point $\bar{x} \in S_n$, $\bar{w}^T \bar{x} - \phi' > 0$. Therefore, $\bar{x}_0$ is a convex hull vertex. It follows that we can bound the number of positive samples in S_n by the number of vertices of the convex hull of all the positive points. Defining v as the number of convex hull vertices and using Markov's inequality, we get that for any $\varepsilon > 0$,

$$\Pr(v \geq \varepsilon) \leq \frac{\mathbf{E}[v]}{\varepsilon}.$$

Since f^* is a linear classifier, the underlying distribution of the positive points is a mixture of sliced multivariate Gaussians. Using Lemmas 31 and 44, we get that with probability of at least $1-\delta$,

$$v \leq \frac{\mathbf{E}[v]}{\delta} = O\left(\frac{(\log m)^{d-1}}{\delta}\right).$$

Repeating the same arguments for the negative points completes the proof. ■

Corollary 33 (distribution-dependent coverage guarantee) *Let $\mathcal{F}$ be the class of all linear binary classifiers in $\mathbb{R}^d$, and let P be a mixture of a fixed number of Gaussians. Then, $R(f,g) = 0$, and for any $0 \leq \delta \leq 1$, with probability of at least $1-\delta$,*

$$\Phi(f,g) \geq 1 - O\left(\frac{(\log m)^{d^2}}{m} \cdot \frac{1}{\delta^{(d+3)/2}}\right).$$

Proof

$$\Lambda_{\hat{n},d} = \left(\frac{2e\hat{n}}{d}\right)^{\left\lfloor \frac{d+1}{2} \right\rfloor} \cdot \log \hat{n} \leq \left(\frac{2e}{d}\right)^{\left\lfloor \frac{d+1}{2} \right\rfloor} \cdot \hat{n}^{\frac{d+3}{2}}.$$

Applying Lemma 32,

$$\Lambda_{\hat{n},d} = O\left(\frac{(\log m)^{d^2}}{\delta^{(d+3)/2}}\right).$$

The proof is complete by noting that $\Lambda_{\hat{n},d} \geq 1$ and using Corollary 28 with $a_i = 2^{-i}$. ■

7. Risk-coverage Trade-off Envelopes

In previous sections we have shown that by compromising the coverage we can achieve zero risk. This is in contrast to the classical setting, where we compromise risk to achieve full coverage. Is it possible to learn a selective classifier with full control over this trade-off? What are the performance limitations of this trade-off control?

In this section we present some answers to these questions thus deriving lower and upper envelopes for the risk-coverage (RC) trade-off. These results heavily rely on the previous results on perfect learning and on classical results on standard learning without rejection. The envelopes are obtained by interpolating bounds on these two extreme types of learning. We begin this section by deriving a lower envelop; that is, we introduce a strategy that can control the RC trade-off.

7.1 Lower Envelop: Controlling the Coverage-risk Trade-off

Our lower RC envelop is facilitated by the following strategy, which is a generalization of the consistent selective classification strategy (CSS) of Definition 6.

Definition 34 (controllable selective strategy) *Given a* mixing *parameter* $0 \leq \alpha \leq 1$, *the* controllable selective strategy *chooses a selective classifier* (f,g) *such that* f *is in the version space* $VS_{\mathcal{F},S_m}$ *(as in CSS), and* g *is defined as follows:* $g(x) = 1$ *for any* x *in the maximal agreement set,* A*, with respect to* $VS_{\mathcal{F},S_m}$*, and* $g(x) = \alpha$ *for any* $x \in \mathcal{X} \setminus A$.

Clearly, CSS is a special case of the controllable selective strategy obtained with $\alpha = 0$. Standard consistent learning (in the classical setting) is the special case obtained with $\alpha = 1$. We now state a well known (and elementary) upper bound for classical realizable learning.

Theorem 35 (Haussler, 1988) *Let* $\mathcal{F}$ *be any finite hypothesis class. Let* $f \in VS_{\mathcal{F},S_m}$ *be a classifier chosen by any consistent learner. Then, for any* $0 \leq \delta \leq 1$, *with probability of at least* $1-\delta$,

$$R(f) \leq \frac{1}{m}\left(\ln|\mathcal{F}| + \ln\frac{1}{\delta}\right),$$

where $R(f)$ *is standard risk (true error) of the classifier* f.

The following result provides a distribution independent upper bound on the risk of the controllable selective strategy as a function of its coverage.

Theorem 36 (lower envelop) *Let* $\mathcal{F}$ *be any finite hypothesis class. Let* (f,g) *be a selective classifier chosen by a controllable selective learner after observing a training sample* S_m*. Then, for any* $0 \leq \delta \leq 1$, *with probability of at least* $1-\delta$,

$$R(f,g) \leq \left(\frac{1-\Phi_0/\Phi(f,g)}{1-\Phi_0}\right) \cdot \frac{1}{m}\left(\ln|\mathcal{F}| + \ln\frac{2}{\delta}\right),$$

where

$$\Phi_0 \triangleq 1 - \frac{1}{m}\left((\ln 2)|\mathcal{F}| + \ln\frac{2}{\delta}\right).$$

Proof For any controllable selective learner with a mixing parameter α we have,

$$\Phi(f,g) \quad = \quad \mathbf{E}[g(X)] = \mathbf{E}[\mathbb{I}(g(X)=1)] + \alpha \mathbf{E}[\mathbb{I}(g(X)\neq 1)].$$

By Theorem 8, with probability of at least $1-\frac{\delta}{2}$,

$$\mathbf{E}[\mathbb{I}(g(X)=1)] \geq 1 - \frac{1}{m}\left((\ln 2)|\mathcal{F}| + \ln\frac{2}{\delta}\right) \triangleq \Phi_0.$$

Therefore, since $\Phi(f,g) \leq 1$,

$$\alpha = \frac{\Phi(f,g) - \mathbf{E}[\mathbb{I}(g(X)=1)]}{1-\mathbf{E}[\mathbb{I}(g(X)=1)]} \leq \frac{\Phi(f,g)-\Phi_0}{1-\Phi_0}.$$

Using the law of total expectation we get

$$\begin{aligned}
\mathbf{E}[\ell(f(X),Y)\cdot g(X)] &= \overbrace{\mathbf{E}[\ell(f(X),Y)\cdot g(X) \mid g(x)=1]}^{0} \cdot \Pr(g(X)=1) \\
&+ \mathbf{E}[\ell(f(X),Y)\cdot g(X) \mid g(x)=\alpha] \cdot \Pr(g(X)=\alpha) \\
&= \alpha \cdot \mathbf{E}[\ell(f(X),Y) \mid g(x)=\alpha] \cdot \Pr(g(X)=\alpha) \\
&= \alpha \cdot \mathbf{E}[\ell(f(X),Y)].
\end{aligned}$$

According to Definition 2.2

$$R(f,g) \quad = \quad \frac{\mathbf{E}[\ell(f(X),Y)\cdot g(X)]}{\Phi(f,g)} = \frac{\alpha\cdot\mathbf{E}[\ell(f(X),Y)]}{\Phi(f,g)} = \frac{\alpha\cdot R(f,g)}{\Phi(f,g)}.$$

Applying Theorem 35 together with the union bound completes the proof. ■

7.2 Upper Envelop: Trade-off Control Limitation

We now present a negative result which identifies a region of non-achievable coverage-risk trade-off on the RC plane. The statement is a probabilistic lower bound on the risk of *any* selective classifier expressed as a function of the coverage. It negates any high probability upper bound on the risk of the classifier (where the probability is over choice of S_m and the target hypothesis).

Theorem 37 (non-achievable coverage-risk trade-off) *Let $\mathcal{F}$ be any hypothesis class and let $0 \leq \delta \leq \frac{1}{4}$ and m be given. There exists a distribution P (that depends on $\mathcal{F}$), such that for any selective classifier (f,g), chosen using a training sample S_m drawn i.i.d. according to P, with probability of at least δ,*

$$R(f,g) \geq \min\left(\frac{1}{2} - \frac{1}{4\Phi(f,g)}, \frac{1}{2} - \frac{1}{2\Phi(f,g)} + \frac{1}{16m\cdot\Phi(f,g)}\cdot\left[VCdim(\mathcal{F}) - \frac{16}{3}\ln\frac{1}{1-2\delta}\right]\right)$$

Proof If η is the VC-dimension of hypothesis class $\mathcal{F}$, there exists a set of data points $\mathcal{X}' = \{e_1, e_2, \ldots e_\eta\}$ shattered by $\mathcal{F}$. Let $\mathcal{X} \triangleq \mathcal{X}' \cup \{e_{\eta+1}\}$. The bad distribution is constructed as follows. Define $\overline{Bin}(m,k,\delta)$, the binomial tail inversion,

$$\overline{Bin}\left(m, \frac{\eta}{2}, 2\delta\right) \triangleq \max_p \left\{p : Bin\left(m, \frac{\eta}{2}, p\right) \geq 2\delta\right\},$$

where $Bin(m,k,p)$ is the binomial tail. Define P to be the source distribution over $\mathcal{X}$ satisfying

$$P(e_i) \triangleq \begin{cases} \overline{Bin}\left(m, \frac{\eta}{2}, 2\delta\right)/\eta, & \text{if } i \leq \eta; \\ 1 - \overline{Bin}\left(m, \frac{\eta}{2}, 2\delta\right), & \text{otherwise,} \end{cases}$$

Assuming that the training sample is selected i.i.d. from P, it follows that with probability of at least 2δ,

$$\left|\left\{x \in S_m : x \in \mathcal{X}'\right\}\right| \leq \frac{\eta}{2}.$$

$\mathcal{F}$ shatters $\mathcal{X}'$ thus inducing all dichotomies over $\mathcal{X}'$. Every sample from $\mathcal{X}'$ can reduce the version space by half, so with probability of at least 2δ, the version space $VS_{\mathcal{F},S_m}$ includes all dichotomies over at least $\frac{\eta}{2}$ instances. Therefore, over these instances (referred to as $x_1, x_2, \ldots, x_{\eta/2}$), with probability of $1/2$ the error is at least $\frac{1}{2}$.[3]

$$\begin{aligned} \Phi(f,g) &= \sum_{i=1}^{\eta+1} \{P(e_i)\cdot g(e_i)\} = P(e_1)\cdot\sum_{i=1}^{\eta} g(e_i) + P(e_{\eta+1})\cdot g(e_{\eta+1}) \\ &\leq P(e_1)\cdot\sum_{i=1}^{\frac{\eta}{2}} g(x_i) + \frac{\eta}{2}\cdot P(e_1) + P(e_{\eta+1}) = P(e_1)\cdot\sum_{i=1}^{\frac{\eta}{2}} g(x_i) + 1 - \frac{\eta}{2}\cdot P(e_1) \\ \Longrightarrow\ & P(e_1)\cdot\sum_{i=1}^{\frac{\eta}{2}} g(x_i) \geq \Phi(f,g) + \frac{\eta}{2}\cdot P(e_1) - 1. \end{aligned}$$

$$\begin{aligned} \Phi(f,g)\cdot R(f,g) &= \sum_{i=1}^{\eta+1} \{P(e_i)\cdot g(e_i)\cdot \mathbb{I}(f(e_i)\neq f^*(e_i))\} \geq \sum_{i=1}^{\frac{\eta}{2}} \left\{P(x_i)\cdot g(x_i)\cdot\frac{1}{2}\right\} \\ &\geq \frac{\Phi(f,g)-1}{2} + \frac{\eta}{4}\cdot P(e_1) = \frac{\Phi(f,g)-1}{2} + \frac{1}{4}\cdot\overline{Bin}\left(m,\frac{\eta}{2},2\delta\right). \end{aligned}$$

Applying Lemma 43 we get

$$R(f,g) \geq \min\left(\frac{1}{2} - \frac{1}{4\Phi(f,g)}, \frac{1}{2} - \frac{1}{2\Phi(f,g)} + \frac{1}{16m\cdot\Phi(f,g)}\cdot\left[VCdim(\mathcal{F}) - \frac{16}{3}\ln\frac{1}{1-2\delta}\right]\right)$$

■

Corollary 38 *Let $0 \leq \delta \leq \frac{1}{4}$, m, and $n > 1$ be given. There exist a distribution P, that depends on m and n, and a finite hypothesis class $\mathcal{F}$ of size n, such that for any selective classifier (f,g), chosen using a training sample S_m drawn i.i.d. according to P, with probability of at least δ, if*

$$\Phi(f,g) \geq max\left\{\frac{3}{4}, 1 - \frac{1}{16m}\cdot\left[VCdim(\mathcal{F}) - \frac{16}{3}\ln\frac{1}{1-2\delta}\right]\right\}$$

then

$$R(f,g) \geq \frac{1}{16m}\cdot\left[VCdim(\mathcal{F}) - \frac{16}{3}\ln\frac{1}{1-2\delta}\right].$$

3. According to the game theoretic setting the adversary can choose a distribution over $\mathcal{F}$. In this case the expectation in the risk is averaged over random instances and random labels. Therefore, the error over the instances $x_1, x_2, \ldots, x_{\eta/2}$ is exactly $1/2$ and we can replace the term 2δ with δ.

Proof Assuming

$$\Phi(f,g) \geq max\left\{\frac{3}{4}, 1-\frac{1}{16m}\cdot\left[VCdim(\mathcal{F})-\frac{16}{3}\ln\frac{1}{1-2\delta}\right]\right\},$$

we apply Theorem 37 to complete the proof. ■

8. CSS Implementation: Lazy CSS

In previous sections we analyzed the performance of CSS and proved that (in the realizable case) it can achieve sharp coverage rates under reasonable assumptions on the source distribution while guaranteeing zero error on the accepted samples. However, it remains unclear whether an efficient implementation of CSS is at reach. In this section we propose an algorithm for CSS and show that it can be efficiently implemented for linear classifiers.

The following method, which we term *lazy CSS*, is very similar to the implicit selective sampling algorithm of Cohn et al. (1994). Instead of explicitly constructing the CSS selection function g during training (which indeed can be a very complex task), we adapt a "lazy learning" approach that can potentially facilitate an efficient CSS implementation during test time. In particular, we propose to evaluate $g(x)$ at any given test point x during the classification process. For the training set S_m and a test point x we define the following two sets:

$$S^+_{m,x} \triangleq S_m \cup \{(x,+1)\}, \quad S^-_{m,x} \triangleq S_m \cup \{(x,-1)\};$$

that is, $S^+_{m,x}$ is the (labeled) training set S_m augmented by the test point x labeled positively, and $S^-_{m,x}$ is S_m augmented by x labeled negatively. The selection value $g(x)$ is determined as follows: $g(x)=0$ (i.e., x is rejected) iff there exist hypotheses $f^+, f^- \in \mathcal{F}$ that are consistent with $S^+_{m,x}$ and $S^-_{m,x}$, respectively.

The following lemma states that the selection function $g(x)$ constructed by lazy CSS is a precise implementation of CSS.

Lemma 39 *Let $\mathcal{F}$ be any hypothesis class, S_m a labeled training set, and x, a test point. Then x belongs to the maximal agreement set of $VS_{\mathcal{F},S_m}$ iff there is no hypothesis $f \in \mathcal{F}$ that is consistent with either $S^+_{m,x}$ or $S^-_{m,x}$.*

Proof If there exist hypotheses $f^+, f^- \in \mathcal{F}$ that are consistent with $S^+_{m,x}$ and $S^-_{m,x}$, then there exist two hypotheses in $\mathcal{F}$ that correctly classify S_m (therefore they belong to $VS_{\mathcal{F},S_m}$) but disagree on x. Hence, x does not belong to the maximal agreement set of $VS_{\mathcal{F},S_m}$. Conversely, if x does not belong to the maximal agreement set of $VS_{\mathcal{F},S_m}$, then there are two hypotheses, f_1 and f_2, which correctly classify S_m but disagree on x. Let's assume, without loss of generality, that f_1 classifies x positively. Then, f_1 is consistent with $S^+_{m,x}$ and f_2 is consistent with $S^-_{m,x}$. Thus there exist hypotheses $f^+, f^- \in \mathcal{F}$ that are consistent with $S^+_{m,x}$ and $S^-_{m,x}$. ■

For the case of linear classifiers it follows that computing the lazy CSS selection function for any test point is reduced to two applications of a linear separability test. Yogananda et al. (2007) recently presented a fast linear separability test with a worst case time complexity of $O(mr^3)$ and space complexity of $O(md)$, where m is the number of points, d is the dimension and $r \leq \min(m, d+1)$.

Remark 40 *For the realizable case we can modify* any *rejection mechanism by restricting rejection* only *to the region chosen for rejection by CSS. Since CSS accepts only samples that are guaranteed to have zero test error, the overall performance of the modified rejection mechanism is guaranteed to be at least as good as the original mechanism. Using this technique we were able to improve the performance (RC curve) of the most commonly used rejection mechanism for linear classifiers, which rejects samples according to a simple symmetric distance from the decision boundary (a "margin").*

9. Which Rejection Model?

In classical classification and Bayes decision theory the goal is to minimize a cost function (or a loss function), where the cost is specified by a $K \times K$ cost matrix ($K = 2$ for the binary case). Given the cost matrix, the objective is to select a classifier that minimizes the average weighted cost (over unobserved instances) as specified by this matrix. When introducing rejection it is necessary to introduce a suitable optimization criterion (which is referred here also as a 'rejection model'). Obviously, the desired criterion should take into account both the risk of the classifier and its coverage. The question we discuss in this section is: what would be an appropriate optimization criterion for selective classification?

A very common rejection model in the literature is the *cost model*, whereby a specific cost d is associated with rejection (see, e.g., Tortorella, 2001) and the objective is to minimize the generalized *rejective risk function*,

$$\ell_c(f,g) \quad \triangleq \quad d \cdot \mathbf{E}\left[1 - g(X)\right] + \mathbf{E}\left[\mathbb{I}(f(X) \neq Y) \cdot g(X)\right]. \tag{8}$$

Given our definitions of risk and coverage, the function (8) can be easily expressed as a function over the RC plane of Figure 1,

$$\ell_c(R,\Phi) = d\,(1 - \Phi(f,g)) + R(f,g)\Phi(f,g). \tag{9}$$

For any fixed d, Equation (9) defines level sets (or elevation contour lines) over the RC plane. For example, Figure 3(a) depicts elevation contour lines induced by (9) with a rejection cost $d = 0.3$. The thick line in this figure represent our knowledge of the optimal RC trade-off. Thus, an optimal classifier, according to this cost model, has a risk-coverage profile that minimizes the cost (9) with respect to all choices on the RC trade-off curve. This optimal choice is depicted in Figure 3(a) by the black dot. This popular cost model was refined to accommodate differentiation between the cost of false positive and false negative as well as different costs for rejection of positive and negative samples (Herbei and Wegkamp, 2006; Pietraszek, 2005; Tortorella, 2001; Santos-Pereira and Pires, 2005). Such extensions or refinements are appealing because they allow for additional control and more flexibility in modeling the problem at hand. Nevertheless, these cost models are often criticized for lack of usability in applications where it is impossible or hard to precisely quantify the cost of rejection. It is interesting to note that for an ideal Bayesian setting, where the underlying distribution is completely known, Chow showed (Chow, 1970) that the cost d upper bounds the probability of misclassification. In this case one can control the classification error by specifying a matching rejection cost.

In Pietraszek (2005) two additional optimization models are introduced. The first, *bounded-improvement* model, is depicted as contour elevation lines over the RC plane in Figure 3(c). In this

model, given a constraint on the misclassification cost, the classifier should reject as few samples as possible. The constraint is specified by the ∞ symbol in the RC plane, which is the cost defined for the entire rectangle containing all risk-coverage profiles having risk larger than the constraint (0.3 in this example). In the second, *bounded-abstention* model (depicted in Figure 3(b)), given a constraint on the coverage (0.5 in this example), the classifier should have the lowest misclassification cost. It is argued in Pietraszek (2005) that these models are more suitable than the above cost model in many applications, for instance, when a classifier with limited classification throughput (e.g., a human expert) should handle the rejected instances, and in a medical and quality assurance applications, where the goal is to reduce the misclassification cost to a user-defined value.

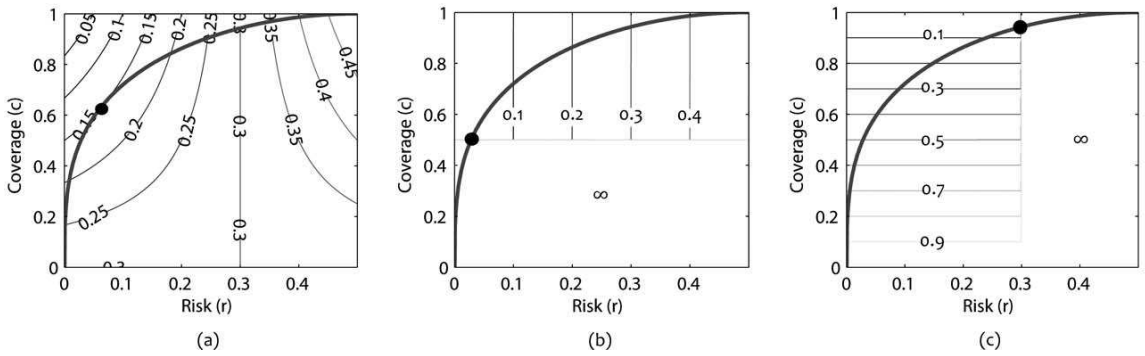

Figure 3: Rejection models: (a) cost (b) bounded-abstention (c) bounded-improvement

Which cost model among the above three is the right model? This question is, obviously, ill-defined and the answer depends on the application. Thus, when deriving bounds for a specific generalized rejective risk function the results are limited to only one specific model. Instead, one can handle *any* rejective risk function over the RC plane by identifying the RC trade-off. Specifically, by bounding the coverage and the risk separately (as we do in this paper) we can in principle optimize *any* generalized rejective risk function according to any desired rejection model including the cost, the bounded-improvement and bounded-abstention models.

10. Related Work

The idea of classification with a reject option dates back to Chow's seminal papers (Chow, 1957, 1970). These papers analyzed both the Bayes-optimal reject decision and the reject-rate vs. error trade-off. This is done under the 0-1 loss function, assuming that the underlying distribution is completely known. The Bayes-optimal rejection policy is based, as in standard classification, on maximum a posteriori probabilities. Instances should be rejected whenever none of the posteriori probabilities are sufficiently distinct. This type of rejection can be termed *ambiguity-based* rejection. Referring to the diagram in Figure 1, one of Chow's main results (for the case of complete probabilistic knowledge), is that the optimal RC trade-off (depicted by the dotted line) is monotonically increasing.

While the optimal decision can be identified in the case of complete probabilistic knowledge, it was argued (Fumera et al., 2000) that when the a posteriori probabilities are estimated with errors, Chow's rule (Chow, 1970) does not provide the optimal error-reject trade-off. Tortorella (2001) and Santos-Pereira and Pires (2005) discussed Bayesian-optimal decisions in the case of arbitrary cost

matrices. In these papers the optimal reject rule was chosen based on the ROC curve evaluated on a subset of the training data. As in most papers on the subject emerging from the engineering community (see, e.g., Fumera et al., 2000; Fumera and Roli, 2002; Pietraszek, 2005; Bounsiar et al., 2006; Landgrebe et al., 2006) no probabilistic or other guarantees are provided for the misclassification error.

Very few studies have focused on error bounds for classifiers with a reject option. Hellman (1970) proposed and analyzed two rejection rules for the nearest neighbor algorithm. Extending Cover and Hart's classic result for the 1-nearest neighbor algorithm (Cover and Hart, 1967), Hellman showed that the test error (over non-rejected points) of a nearest neighbor algorithm with a reject option can be bounded *asymptotically* (as the sample size approaches infinity) by some factor of the Bayes error (with reject). To the best of our knowledge, this excess risk bound is the first that has been introduced in the context of classification with a reject option.

Herbei and Wegkamp (2006) developed excess risk bounds for the classification with a reject option setting where the loss function is the 0-1 loss, extended such that the cost of each reject point is $0 \leq d \leq 1/2$ (cost model; see Section 9). This result generalizes the excess risk bounds of Tsybakov (2004) for standard binary classification without reject (which is equivalent to the case $d = 1/2$). The bound applies to any empirical error minimization technique. This result is further extended in Bartlett and Wegkamp (2007) and Wegkamp (2007) in various ways, including the use of the hinge loss function for efficient optimization. The main results of Herbei and Wegkamp (both for plug-in rules and empirical risk minimization) degenerate, in the realizable case, to a meaningless bound, where classification with a reject option is not guaranteed to be any better than classification without reject. These results are also limited only to the cost model (see discussion on Section 9). Saying that, we must also note that comparing bounds that were derived for the agnostic setting with our results can be misleading or "unfair" since the agnostic setting is much more difficult. The only purpose of this comparison is to clarify that the results here are not special cases of any of the currently known agnostic bounds.

Freund et al. (2004) studied a simple ensemble method for binary classification. Given an hypothesis class $\mathcal{F}$, the method outputs a weighted average of all the hypotheses in $\mathcal{F}$ such that the weight of each hypothesis exponentially depends on its individual training error. Their algorithm abstains from prediction whenever the weighted average of all individual predictions is inconclusive (i.e., sufficiently close to zero). Two regret bounds for this algorithm were derived. The first bounds the probability of error when the classifier decides not to reject. If ε is the error of the best hypothesis in $\mathcal{F}$, the error of the aggregating algorithm is bounded above (w.h.p.) by $2\varepsilon + O(\frac{1}{m^{1/2-\theta}})$, where $0 < \theta < 1/2$ is an hyperparameter. The authors also proved that for a sufficiently large training sample size, $m = \Omega((\sqrt{ln(1/\delta)ln(|\mathcal{F}|)})^{1/\theta})$, the probability that the algorithms will abstain from prediction is bounded above by $5\varepsilon + O(\frac{\ln|\mathcal{F}|}{\sqrt{m^{1/2-\theta}}})$. To the best of our knowledge, these bounds are the first to provide some guarantee for both the error of the classifier and the coverage. Therefore, these results are related to the bounded-improvement and bounded-abstention models (see Section 9). As was rightfully stated by the authors, the final aggregated hypothesis can significantly outperform the best base-hypothesis in $\mathcal{F}$ in some favorable situations. Unfortunately, the regret bound provided does not exploit these situations, as it is bounded by twice the generalization error of the best hypothesis. Referring to the diagram in Figure 1, The results of Freund et al. can be depicted as a curve in region *B* (thus characterizing some achievable zone). For the realizable case, the bounds of Freund et al. achieve much slower rates than those we derive in this paper.

Selective classification is related to selective sampling (Atlas et al., 1990). In selective sampling the learner sequentially processes unlabeled examples, and for each one determines whether or not to request a label. One of the earliest active learning algorithms for the realizable case (termed "mellow active learner") was proposed by Cohn et al. (1994). Their well motivated approach is to request labels only for samples that belong to the region of disagreement (the complement of our maximal agreement set). As mentioned in Section 8, this is very similar to our CSS. Hanneke studied the rate for which the region of disagreement collapses as the algorithm processes examples (Hanneke, 2007, 2009). He introduced the notion of *disagreement coefficient* and derived upper bounds on the label complexity in active learning expressed in terms of this coefficient. While his results capture the convergence rate of the region of disagreement as a function of the number of *label requests*, in selective classification we are interested in convergence rates as a function of the size of the *training set* (in selective sampling the number of labels does not necessarily match the number of samples). Specific disagreement coefficient values were recently derived for some interesting hypothesis classes including homogeneous linear classifiers in $\mathbb{R}^d$ under uniform data distribution (Hanneke, 2007) and linear classifiers in $\mathbb{R}^d$ under smooth data density bounded away from zero (Friedman, 2009). While coverage bounds and label complexity bounds cannot be directly compared, we conjecture that formal connections between these two settings exist because the disagreement region plays a key role in both. The precise relation between these two settings is yet to be discovered.

11. Concluding Remarks

Selective classification is well recognized as a very attractive technique for improving classification accuracy. In fact, it is among very few methods that can help in practical applications where sufficiently low error cannot be achieved in the standard model. Nevertheless, not enough is known about selective classification in order to harness its power in a controlled, optimal way, or to avoid its use in cases where it cannot sufficiently help.

In this work we made a first step toward a rigorous analysis of selective classification by revealing properties of the risk-coverage trade-off, which represents optimal selective classification. By focusing on the extreme case of perfect learning we were able to derive initial results for entire risk-coverage trade-offs.

Many interesting questions are left open. Among the most important open questions are the following. What would be an analogous concept to perfect learning in the fully agnostic (non-realizable) setting? What is the precise relation between selective classification and selective sampling? Is it possible to implement efficiently the CSS strategy and prove useful bounds for other natural hypothesis classes? Can selective classification be rigorously analyzed in transductive, semi-supervised or active settings? With respect to agnostic extensions, while it doesn't make much sense to talk about "perfect learning" in a noisy setting, it is meaningful and interesting to consider the analogous concept to regret (or excess risk) bounds. Here we could employ a selective strategy aiming at achieving the error rate of the best hypothesis in the class precisely (and perhaps with certainty).

Acknowledgments

We thank Charles Elkan for useful discussions and the anonymous referees for excellent comments.

Appendix A.

Lemma 41 *For $u > \sqrt{2}v > 0$,*

$$\frac{u-v}{u+v} \geq 1 - 4 \cdot \frac{v}{u}.$$

Proof

$$\frac{u-v}{u+v} = 1 - \frac{2v}{u+v} = 1 - 2v\frac{u-v}{u^2-v^2} \geq 1 - 2v\frac{u}{u^2-v^2}.$$

Since $u > \sqrt{2}v$, we have

$$u^2 - v^2 > \frac{u^2}{2}.$$

Applying to the previous inequality completes the proof. ■

Lemma 42 (Bernstein's inequality Hoeffding, 1963) *Let $X_1, \ldots, X_n$ be independent zero-mean random variables. Suppose that $|X_i| \leq M$ almost surely, for all i. Then for all positive t,*

$$\Pr\left(\sum_{i=1}^{n} X_i > t\right) \leq \exp\left\{-\frac{t^2/2}{\sum \mathbf{E}\left[X_j^2\right] + Mt/3}\right\}.$$

Lemma 43 (binomial tail inversion lower bound) *For $k > 0$ and $\delta \leq \frac{1}{2}$,*

$$\overline{Bin}(m,k,\delta) \geq \min\left(1, \frac{k}{2m} - \frac{4}{3m}\ln\frac{1}{1-\delta}\right).$$

Proof Let $Z_1, \ldots Z_m$ be independent Bernoulli random variables each with a success probability $0 \leq p \leq 1$. Setting $W_i \triangleq Z_i - p$,

$$\begin{aligned} Bin(m,k,p) &= \Pr_{Z_1,\ldots,Z_m \sim B(p)^m}\left(\sum_{i=1}^{m} Z_i \leq k\right) = 1 - \Pr\left(\sum_{i=1}^{m} Z_i > k\right) \\ &= 1 - \Pr\left(\sum_{i=1}^{m} W_i > k - mp\right). \end{aligned}$$

Clearly, $\mathbf{E}[W_i] = 0$, $|W_i| \leq 1$, and $\mathbf{E}\left[W_i^2\right] = p \cdot (1-p)^2 + (1-p) \cdot p^2 = p \cdot (1-p)$. Using Lemma 42 (Bernstein's inequality) we thus obtain,

$$Bin(m,k,p) \geq 1 - \exp\left(-\frac{(k-mp)^2/2}{mp(1-p) + (k-mp)/3}\right).$$

Since $(1-p) \leq 1$,

$$\begin{aligned}\frac{(k-mp)^2/2}{mp(1-p)+(k-mp)/3} &\geq \frac{(k-mp)^2}{2mp+\frac{2}{3}\cdot(k-mp)} = \frac{(k-mp)^2}{\frac{4}{3}mp+\frac{2}{3}\cdot k} \\ &\geq \frac{k^2-2mpk}{\frac{4}{3}mp+\frac{2}{3}\cdot k}.\end{aligned}$$

Therefore,

$$Bin(m,k,p) \geq 1-e^{-\frac{k^2-2mpk}{\frac{4}{3}mp+\frac{2}{3}\cdot k}}.$$

Equating the right-hand side to δ and solving for p, we have

$$p \leq \frac{k}{2m}\cdot\frac{k-\frac{2}{3}t}{k+\frac{2}{3}\cdot t},$$

where $t \triangleq \ln\frac{1}{(1-\delta)}$. Choosing

$$p = \min\left\{1, \frac{1}{2m}\left(k-\frac{8}{3}\ln\frac{1}{1-\delta}\right)\right\} = \min\left\{1, \frac{k}{2m}\cdot\left(1-4\cdot\frac{\frac{2}{3}t}{k}\right)\right\},$$

using the fact that $k \geq 1 > \frac{2\sqrt{2}}{3}\ln\frac{1}{1/2} \geq \frac{2\sqrt{2}}{3}t$, and applying Lemma 41, we get

$$p \leq \frac{k}{2m}\cdot\frac{k-\frac{2}{3}t}{k+\frac{2}{3}\cdot t}.$$

Therefore, $Bin(m,k,p) \geq \delta$. Since $\overline{Bin}(m,k,\delta) = \max_p\{p : Bin(m,k,p) \geq \delta\}$, we conclude that

$$\overline{Bin}(m,k,\delta) \geq p = \min\left(1, \frac{k}{2m} - \frac{4}{3m}\ln\frac{1}{1-\delta}\right).$$

■

Lemma 44 *Let S_1 and S_2 be two sets in $\mathbb{R}^d$. Then,*

$$H(S_1 \cup S_2) \leq H(S_1) + H(S_2),$$

where $H(S)$ is the number of convex hull vertices of S.

Proof Assume $x \in S_1 \cup S_2$ is a convex hull vertex of $S_1 \cup S_2$. Then, there is a half-space (w,ϕ) such that, $w\cdot x - \phi = 0$, and any other $y \in S_1 \cup S_2$ satisfies $w\cdot y - \phi > 0$. Assume w.l.o.g. that $x \in S_1$. Then it is clear that any $y \in S_1$ satisfies $w\cdot y - \phi > 0$. Therefore, x is a convex hull vertex of S_1. ■

Proof of Lemma 22 Let $S^+ \subseteq S_m$ be the set of all positive samples in S_m, and $S^- \subseteq S_m$ be the set of all negative samples. Let $\bar{x}_0 \in R^+$. There exists a hypothesis $f_{\bar{w},\phi}(\bar{x})$ such that

$$\begin{aligned}&\forall \quad \bar{x} \in S^+, \quad \bar{w}^T\bar{x} - \phi \geq 0; \\ &\forall \quad \bar{x} \in S^-, \quad \bar{w}^T\bar{x} - \phi < 0,\end{aligned}$$

and

$$\bar{w}^T \bar{x}_0 - \phi \geq 0.$$

Let's assume that $\bar{x}_0 \notin \tilde{R}^+$. Then, there exists a hypothesis $\tilde{f}_{\bar{w}',\phi'}(\bar{x})$ such that

$$\begin{aligned} \forall \quad \bar{x} \in S^+, \quad & \bar{w}'^T \bar{x} - \phi' \geq 0; \\ \forall \quad \bar{x} \in S^-, \quad & \bar{w}'^T \bar{x} - \phi' \leq 0, \end{aligned}$$

and

$$\bar{w}'^T \bar{x}_0 - \phi' < 0.$$

Defining

$$\bar{w}_0 \triangleq \bar{w} + \alpha \bar{w}', \qquad \phi_0 \triangleq \phi + \alpha \phi',$$

where

$$\alpha > \left| \frac{\bar{w}^T \bar{x}_0 - \phi}{\bar{w}'^T \bar{x}_0 - \phi'} \right|,$$

we deduce that there exists a hypothesis $f_{\bar{w}_0,\phi_0}(\bar{x})$ such that

$$\begin{aligned} \forall \quad \bar{x} \in S^+, \quad & \bar{w}_0^T \bar{x} - \phi_0 \geq 0; \\ \forall \quad \bar{x} \in S^-, \quad & \bar{w}_0^T \bar{x} - \phi_0 < 0, \end{aligned}$$

and

$$\begin{aligned} \bar{w}_0^T \bar{x}_0 - \phi_0 &= \bar{w}^T \bar{x}_0 - \phi + \alpha \left[\bar{w}'^T \bar{x}_0 - \phi' \right] = \bar{w}^T \bar{x}_0 - \phi - \alpha \left| \bar{w}'^T \bar{x}_0 - \phi' \right| \\ &< \bar{w}^T \bar{x}_0 - \phi - \left| \bar{w}^T \bar{x}_0 - \phi \right| = 0. \end{aligned}$$

Therefore, $\bar{x}_0 \notin R^+$. Contradiction. Hence, $\bar{x}_0 \in \tilde{R}^+$ and $R^+ \subseteq \tilde{R}^+$. The proof that $R^- \subseteq \tilde{R}^-$ follows the same argument.

To prove that $\tilde{R}^+ \subseteq R^+$, we look at $VS_{\tilde{\mathcal{F}},S_m}$:

$$\forall \tilde{f}_{\bar{w},\phi} \in VS_{\tilde{\mathcal{F}},S_m}, \bar{x} \in \tilde{R}^+ \quad \bar{w}^T \bar{x} - \phi \geq 0.$$

We observe that if $f_{\bar{w},\phi} \in VS_{\mathcal{F},S_m}$, then $\tilde{f}_{\bar{w},\phi} \in VS_{\tilde{\mathcal{F}},S_m}$. Therefore,

$$\forall f_{\bar{w},\phi} \in VS_{\mathcal{F},S_m}, \bar{x} \in \tilde{R}^+ \quad \bar{w}^T \bar{x} - \phi \geq 0.$$

Hence, $\tilde{R}^+ \subseteq R^+$.

It remains to prove that $\tilde{R}^- \subseteq R^-$. Assuming $\bar{x}_0 \notin R^-$ implies that there exists a hypothesis $f_{\bar{w},\phi}(\bar{x})$ such that

$$\begin{aligned} \forall \quad \bar{x} \in S^+, \quad & \bar{w}^T \bar{x} - \phi \geq 0; \\ \forall \quad \bar{x} \in S^-, \quad & \bar{w}^T \bar{x} - \phi < 0, \end{aligned}$$

and

$$\bar{w}^T \bar{x}_0 - \phi \geq 0.$$

Defining[4]

$$\bar{w}_0 \triangleq \bar{w}, \quad \phi_0 \triangleq \phi - \left| \max_{\bar{x} \in S^-} \left(\bar{w}^T \bar{x} - \phi \right) \right|,$$

we conclude that there exists a hypothesis $\tilde{f}_{\bar{w}_0,\phi_0}(\bar{x})$ such that

$$\begin{aligned} &\forall \quad \bar{x} \in S^+ \quad \bar{w}_0^T \bar{x} - \phi_0 \geq 0; \\ &\forall \quad \bar{x} \in S^- \quad \bar{w}_0^T \bar{x} - \phi_0 \leq \max_{\bar{x} \in S^-} \left(\bar{w}^T \bar{x} - \phi \right) + \left| \max_{\bar{x} \in S^-} \left(\bar{w}^T \bar{x} - \phi \right) \right| = 0, \end{aligned}$$

and

$$\bar{w}_0^T \bar{x}_0 - \phi_0 > 0.$$

Therefore, $\bar{x}_0 \notin \tilde{R}^-$, so $\tilde{R}^- \subseteq R^-$. ■

Proof of Lemma 23 According to Lemma 22, $R^+ = \tilde{R}^+$ and $R^- = \tilde{R}^-$. Therefore, we can restrict our discussion to the hypothesis class $\tilde{\mathcal{F}}$. Due to the symmetry of the hypothesis class $\tilde{\mathcal{F}}$ we will concentrate only on the positive region R^+. Set $G \triangleq VS_{\tilde{\mathcal{F}},S_m}$. By definition,

$$\tilde{R}^+ = \bigcap_{f'_{\bar{w},\phi} \in G} f'_{\bar{w},\phi},$$

where $f'_{\bar{w},\phi}$ denotes the region in $\mathcal{X}$ for which the linear classifier $f'_{\bar{w},\phi}$ obtains the value one or zero. Let $f_{\bar{w},\phi} \in G$ be a half-space with $k < d$ points on its boundary. We will prove that there exist two half-spaces in G ($f_{\bar{w}_1,\phi_1}, f_{\bar{w}_2,\phi_2}$) such that each has at least $k+1$ samples on its boundary and

$$f_{\bar{w},\phi} \bigcap f_{\bar{w}_1,\phi_1} \bigcap f_{\bar{w}_2,\phi_2} = f_{\bar{w}_1,\phi_1} \bigcap f_{\bar{w}_2,\phi_2}.$$

Therefore,

$$\tilde{R}^+ = \bigcap_{f'_{\bar{w},\phi} \in G \setminus \{f_{\bar{w},\phi}\}} f'_{\bar{w},\phi}.$$

Repeating this process recursively with every half-space in G, with less than d points on its boundary, completes the proof.

Before proceeding with the rigorous analysis let's review the main idea behind the proof. If a half-space in $\mathbb{R}^d$ has less than d points on its boundary, it has at least one degree of freedom. Rotating the half-space clockwise or counterclockwise around a specific axis (defined by the points on the boundary) by sufficiently small angles will maintain correct classification over S_m. We will rotate the half-space clockwise and counterclockwise until "touching" the first point in S_m on each direction. This operation will maintain correct classification but will result in having one additional point on the boundary. Then we only have to show that the intersection of the three half-spaces (original and two rotated ones) is the same as the intersection of the two rotated ones.

4. If S^- is an empty set we can arbitrarily define $\phi_0 \triangleq \phi - 1$.

Let $f_{\bar{w},\phi} \in G$ be a half-space with $k < d$ points on its boundary. Without loss of generality assume that these points are $S_m^0 \triangleq \{\bar{x}_1, \bar{x}_2, ..., \bar{x}_k\}$. For the sake of simplicity we will first *translate* the space such that $\bar{x}_1$ will lie on the origin. Since $\bar{x}_1$ is on the boundary of the half-space we get

$$\bar{w}^T \bar{x}_1 - \phi = 0 \quad \Longrightarrow \quad \phi = \bar{w}^T \bar{x}_1.$$

Therefore,

$$\forall \bar{x} \in S_m^0 \quad 0 = \bar{w}^T \bar{x} - \phi = \bar{w}^T \bar{x} - \bar{w}^T \bar{x}_1 = \bar{w}^T (\bar{x} - \bar{x}_1).$$

Hence, the weight vector $\bar{w}$ is orthogonal to all the translated samples $(\bar{x}_1 - \bar{x}_1), \ldots, (\bar{x}_k - \bar{x}_1)$. We now have $k < d$ vectors in $\mathbb{R}^d$ (including the weight vector) so we can always find at least one vector $\bar{v}$ which is orthogonal to all the rest. We now *rotate* the translated samples around the origin so as to align the vector $\bar{w}$ with the first axis, and align the vector $\bar{v}$ with the second axis. From now on all translated and rotated coordinates and vectors will be marked with prime. Define the following rotation matrix in $\mathbb{R}^d$,

$$R_\theta \triangleq \begin{pmatrix} \cos\theta & \sin\theta & 0 & 0 & \ldots \\ -\sin\theta & \cos\theta & 0 & 0 & \ldots \\ 0 & 0 & 1 & 0 & \ldots \\ 0 & 0 & 0 & 1 & \\ \vdots & \vdots & \vdots & & \ddots \end{pmatrix}.$$

We can now define two new half-spaces in the translated and rotated space, $f_{R_\alpha \bar{w}',0}$ and $f_{R_{-\beta} \bar{w}',0}$, where

$$\alpha = \max_{0 < \alpha' \leq \pi} \{\alpha' \quad | \quad \forall \bar{x}' \in S_m \quad (\bar{w}'^T \bar{x}') \cdot (R_{\alpha'} \bar{w}')^T \bar{x}' \geq 0\}, \tag{10}$$

and

$$\beta = \max_{0 < \beta' \leq \pi} \{\beta' \quad | \quad \forall \bar{x}' \in S_m \quad (\bar{w}'^T \bar{x}') \cdot (R_{-\beta'} \bar{w}')^T \bar{x}' \geq 0\}. \tag{11}$$

According to Claim 45, both $f_{R_\alpha \bar{w}',0}$ and $f_{R_{-\beta} \bar{w}',0}$ correctly classify S_m and have at least $k+1$ samples on their boundaries.

Now we examine the intersection of $f_{R_\alpha \bar{w}',0}$ and $f_{R_{-\beta} \bar{w}',0}$. According to Claim 46, if $(R_\alpha \bar{w}')^T \bar{x}' \geq 0$ and $(R_{-\beta} \bar{w}')^T \bar{x}' \geq 0$, then $\bar{w}'^T \bar{x}' \geq 0$. The intersection of $f_{R_\alpha \bar{w}',0}$, $f_{R_{-\beta} \bar{w}',0}$ and $f_{\bar{w}',0}$ thus equals the intersection of $f_{R_\alpha \bar{w}',0}$ and $f_{R_{-\beta} \bar{w}',0}$, as required. ■

Claim 45 *Both $f_{R_\alpha \bar{w}',0}$ and $f_{R_{-\beta} \bar{w}',0}$ correctly classify S_m and have at least $k+1$ samples on their boundaries.*

Proof We note that after translation all half-spaces pass through the origin, so $\phi' = 0$. Recall the definitions of α and β as maximums (Equations (10) and (11), respectively). We show that the maximums over α' and β' are well defined. Let $\bar{x}' = (x'_1, x'_2, \cdots x'_d)^T$. Since $\bar{w}' = (1, 0, 0, \cdots)^T$ we get that $R_\alpha \bar{w}' = (\cos\alpha, -\sin\alpha, 0, \ldots)^T$ and

$$(\bar{w}'^T \bar{x}') \cdot (R_{\alpha'} \bar{w}')^T \bar{x}' = {x'_1}^2 \cos\alpha - x'_1 \cdot x'_2 \cdot \sin\alpha.$$

Since S_m is a spanning set of $\mathbb{R}^d$, at least one sample has a vector with component $x'_1 \neq 0$. As all components are finite and ${x'_1}^2 > 0$, we can always find a sufficiently small α' such that ${x'_1}^2 \cos\alpha' -$

$x'_1 \cdot x'_2 \cdot \sin\alpha' > 0$. Hence, the maximum exists. Furthermore, for $\alpha' = \pi$ we have ${x'_1}^2 \cos\pi - x'_1 \cdot x'_2 \cdot \sin\pi = -{x'_1}^2 < 0$. Noticing that ${x'_1}^2 \cos\alpha - x'_1 \cdot x'_2 \cdot \sin\alpha$ is continuous in α, and applying the intermediate value theorem, we know that $0 < \alpha < \pi$ and ${x'_1}^2 \cos\alpha - x'_1 \cdot x'_2 \cdot \sin\alpha = 0$. Therefore, there exists a sample in S_m that is not on the boundary of $f_{\bar{w}',0}$ (since $x'_1 \neq 0$) but on the boundary of $f_{R_\alpha \bar{w}',0}$. Recall that all points in S_m^0 are orthogonal to $\bar{w}' = (1,0,0,\cdots)^T$ and $\bar{v} = (0,1,0,\cdots)^T$. Therefore,

$$\forall \bar{x}' \in S_m^0 \quad (R_\alpha \bar{w}')^T \bar{x}' = x'_1 \cdot \cos\alpha - x'_2 \cdot \sin\alpha = \bar{w}'^T \bar{x} \cdot \cos\alpha - \bar{v}'^T \bar{x} \cdot \sin\alpha = 0,$$

and they reside on the boundary of $f_{R_\alpha \bar{w}',0}$. Overall, $f_{R_\alpha \bar{w}',0}$ correctly classifies S_m and has at least $k+1$ samples on its boundary. The same argument applies for β by symmetry. ■

Claim 46 *Using the notation introduced in the proof of Lemma 23, if* $(R_\alpha \bar{w}')^T \bar{x}' \geq 0$ *and* $(R_{-\beta} \bar{w}')^T \bar{x}' \geq 0$*, then*

$$\bar{w}'^T \bar{x}' \geq 0.$$

Proof If $(R_\alpha \bar{w}')^T \bar{x}' \geq 0$ and $(R_{-\beta} \bar{w}')^T \bar{x}' \geq 0$, then

$$\begin{cases} x'_1 \cos\alpha - x'_2 \cdot \sin\alpha \geq 0, \\ x'_1 \cos\beta + x'_2 \cdot \sin\beta \geq 0. \end{cases}$$

Multiplying the first inequality by $\sin\beta > 0$, the second inequality by $\sin\alpha > 0$, and adding the two we have

$$\sin(\alpha+\beta) \cdot x'_1 \geq 0.$$

According to Claim 47 below, $\sin(\alpha+\beta) \geq 0$. If $\sin(\alpha+\beta) = 0$, then $(\alpha+\beta) = \pi$ and $\cos(\alpha+\beta) = -1$. Using the trigonometric identities

$$\begin{aligned} \cos(\alpha-\beta) &= \cos\alpha\cos\beta + \sin\alpha\sin\beta; \\ \sin(\alpha-\beta) &= \sin\alpha\cos\beta - \cos\alpha\sin\beta, \end{aligned}$$

we get that

$$\cos\beta = \cos(\beta+\alpha-\alpha) = \cos(\alpha+\beta) \cdot \cos\alpha + \sin(\alpha+\beta) \cdot \sin\alpha = -\cos\alpha,$$

and

$$\sin\beta = \sin(\beta+\alpha-\alpha) = \sin(\alpha+\beta) \cdot \cos\alpha - \cos(\alpha+\beta) \cdot \sin\alpha = \sin\alpha.$$

Therefore, for any $x'_1 \cos\alpha - x'_2 \cdot \sin\alpha > 0$, it holds that $x'_1 \cos\beta + x'_2 \cdot \sin\beta < 0$ and $\tilde{R}^+$ is degenerated. Contradiction to the fact that S_m is a spanning set of the $\mathbb{R}^d$. Therefore, $\sin(\alpha+\beta) > 0$, $x'_1 \geq 0$ and $\bar{w}'^T \bar{x}' \geq 0$. ■

Claim 47 *Using the notation introduced in the proof of Lemma 23,*

$$\sin(\alpha+\beta) \geq 0.$$

Proof By definition we get that for all samples in S_m,

$$\begin{cases} {x'_1}^2 \cos\alpha - x'_1 \cdot x'_2 \cdot \sin\alpha \geq 0, \\ {x'_1}^2 \cos\beta + x'_1 \cdot x'_2 \cdot \sin\beta \geq 0. \end{cases}$$

Multiplying the first inequality by $\sin\beta > 0$ ($0 < \beta < \pi$), the second inequality by $\sin\alpha > 0$, adding the two, and using the trigonometric identity

$$\sin(\alpha+\beta) = \sin\alpha\cos\beta + \cos\alpha\sin\beta,$$

we have

$$\sin(\alpha+\beta) \cdot {x'_1}^2 \geq 0.$$

Since there is a sample in S_m with a vector component $x'_1 \neq 0$, we conclude that $\sin(\alpha+\beta) \geq 0$. ■

Abstract

The goal of many sciences is to understand the mechanisms by which variables came to take on the values they have (that is, to find a generative model), and to predict what the values of those variables would be if the naturally occurring mechanisms were subject to outside manipulations. The past 30 years has seen a number of conceptual developments that are partial solutions to the problem of causal inference from observational sample data or a mixture of observational sample and experimental data, particularly in the area of graphical causal modeling. However, in many domains, problems such as the large numbers of variables, small samples sizes, and possible presence of unmeasured causes, remain serious impediments to practical applications of these developments. The articles in the Special Topic on Causality address these and other problems in applying graphical causal modeling algorithms. This introduction to the Special Topic on Causality provides a brief introduction to graphical causal modeling, places the articles in a broader context, and describes the differences between causal inference and ordinary machine learning classification and prediction problems.

Keywords: Bayesian networks, causation, causal inference

1. Introduction

The goal of many sciences is to understand the mechanisms by which variables came to take on the values they have (that is, to find a generative model), and to predict what the values of those variables would be if the naturally occurring mechanisms were subject to outside manipulations. For example, a randomized experiment is one kind of manipulation that substitutes the outcome of a randomizing device to set the value of a variable (for example, whether or not a particular new medication is given to a patient who has agreed to participate in a drug trial) in place of the naturally occurring mechanism that determines the variable's value. In non-experimental settings, biologists gather data about the gene activation levels in normally functioning systems in order to understand which genes affect the activation levels of which other genes, and to predict what the effects of manipulating the system to turn some genes on or off would be. Epidemiologists gather data about dietary habits and life expectancy in the general population and seek to find what dietary factors affect life expectancy and predict the effects of advising people to change their diets. Finding answers to questions about the mechanisms by which variables come to take on values, or predicting the value of a variable after some other variable has been manipulated, is characteristic of causal inference. If only non-experimental data are available, predicting the effects of manipulations typically involves drawing samples from one probability density (in the unmanipulated population)

and making inferences about the values of a variable in a population that has a different probability density (in the manipulated population).

The rapid spread of interest in the last three decades in principled methods of search or estimation of causal relations has been driven in part by technological developments, especially the changing nature of modern data collection and storage techniques, and the increases in the processing power and storage capacities of computers. Statistics books from 30 years ago often presented examples with fewer than 10 variables, in domains where some background knowledge was plausible. In contrast, in new domains such as climate research (where satellite data now provide daily quantities of data unthinkable a few decades ago), fMRI brain imaging, and microarray measurements of gene expression, the number of variables can range into the tens of thousands, and there is often limited background knowledge to reduce the space of alternative causal hypotheses. Even when experimental interventions are possible, performing the many thousands of experiments that would be required to discover causal relationships between thousands or tens of thousands of variables is often not practical. In such domains, non-automated causal discovery techniques from sample data, or sample data together with a limited number of experiments, appears to be hopeless, while the availability of computers with increased processing power and storage capacity allow for the practical implementation of computationally intensive automated search algorithms over large search spaces.

The past 30 years has also seen a number of conceptual developments that are partial solutions to these causal inference problems, particularly in the area of graphical causal modeling. Sections 3 and 4 of this paper describe some of these developments: a variety of well defined mathematical objects to represent causal relations (for example, directed acyclic graphs); well defined connections between aspects of these objects and sample data (for example, the Causal Markov and Causal Faithfulness Assumptions); ways to compute those connections (for example, d-separation); and a theory of representation and calculation of the effects of manipulations (for example, by breaking edges in a graph); and search algorithms (for example, the PC algorithm). However, in many domains, problems such as the large numbers of variables, small samples sizes, and possible presence of unmeasured causes, remain serious impediments to practical applications of these developments.

The articles in the Special Topic on Causality (containing articles from 2007 to 2009) address these and other problems in making causal inferences. Although there are some superficial similarities between traditional supervised machine learning problems and causal inference (for example, both employ model search and feature selection, the kinds of models employed overlap, some model scores can be used for both purposes), these similarities can mask some very important differences between the two kinds of problems. This introduction to the Special Topic on Causality provides a brief introduction to graphical causal modeling, places the articles in a broader context, and describes the differences between causal inference and ordinary machine learning classification or prediction problems; it is not intended to provide a broad overview or a tutorial surveying all methods of causal inference.

Section 2 describes the problem of causal inference in more detail, and differentiates it from the typical machine learning supervised classification or prediction problem; Section 3 describes several different kinds of causal models; Section 4 describes some problems associated with search for causal models, and why algorithms appropriate for the discovery of good classification or prediction models in machine learning are not always appropriate for the discovery of good causal models; and Section 5 describes some major open problems in the field. The various articles in the Special Topic on Causality are described throughout this article, depending upon which topic they address.

2. Manipulating Versus Conditioning

This section will describe three different kinds of problems (one typical machine learning or statistical problem, and two kinds of causal problems), and three different kinds of probability densities (conditional, manipulated, and counterfactual) that are useful for solving the problems.

2.1 Conditional Probabilities

Suppose that there is a population of individuals with the following random variables at time t: rw_t is the average number of glasses of red wine consumed per day in the 5 years prior to t, bmi_t is the body mass index of a person at time t, sex_t is the person's sex (0 = male, 1 = female) at time t, and ha_t is whether or not an individual had a heart attack in the 5 years prior to t. Since sex_t is rarely time-dependent, it will be replaced simply by sex.

Suppose an insurance company at time t wants to determine what rates to charge an individual for health insurance who has $rw_t = 1$, $bmi_t = 25$, and $sex = 0$, and that this rate is partly based on the probability of the individual having a heart attack in the next 5 years. This can be estimated by using the rate of heart attacks among the subpopulation matching the subject, that is $rw_t = 1$, $bmi_t = 25$, $sex = 0$. It is impossible to measure the values of ha_{t+5} at time t, because they haven't occurred yet, but if the probability density is stable across time, the density of ha_{t+5} among the subset of the population with $rw_t = 1$, $bmi_t = 25$, and $sex = 0$ will be the same as the density of ha_t among the subpopulation for which $rw_{t-5} = 1$, $bmi_{t-5} = 25$, and $sex = 0$. The density in a subpopulation is a conditional density, in this case $P(ha_t \mid rw_{t-5} = 1, bmi_{t-5} = 25, sex = 0)$.

Conditioning maps a given joint density, and a given subpopulation (typically specified by a set of values for random variables) into a new density. The conditional density is a function of the joint density over the random variables, and a set of values for a set of random variables.[1] The estimation of a conditional probability is often non-trivial because the number of people with $rw_{t-5} = 1$, $bmi_{t-5} = 25$, $sex = 0$ might be small. A large part of statistics and machine learning is devoted to estimating conditional probabilities from realistic sample sizes under a variety of assumptions.

If the insurance company is not attempting to change anyone's behavior then the question of whether drinking the right amount of red wine *prevents* heart attacks is irrelevant to their concerns; the only relevant question is whether the amount of red wine that someone drinks *predicts* heart attack rates. It is possible that people who drink an average of between 1 and 2 glasses of red wine per day for 5 years have lowered rates of heart attacks because of socio-economic factors that both cause average daily consumption of red wine and other life-style factors that prevent heart attacks. But even if moderate red wine consumption does not prevent heart attacks, the insurance company can still use the conditional probability to help determine the rates to charge.

If $\mathbf{X}$ is a set of measured variables, the conditional probability density $P(\mathbf{Y} \mid \mathbf{X})$ is not only useful for predicting future values of $\mathbf{Y}$, it is also useful for predicting current unmeasured values of $\mathbf{Y}$, and for classifying individuals in cases where $\mathbf{Y}$ is categorical.

Problem 1: Predictive Modeling

Input: Samples from a density $P(\mathbf{O})$ (where $\mathbf{O}$ is a set of observed random variables), and two sets of variables $\mathbf{X}, \mathbf{Y} \subseteq \mathbf{O}$.

Output: A consistent, efficient estimate of $P(\mathbf{Y} \mid \mathbf{X})$.

1. In order to avoid technicalities, I will assume that the set of values conditioned on do not have measure 0.

2.2 Manipulated Probabilities

In contrast to the previous case, suppose that an epidemiologist is deciding whether or not to recommend providing very strong incentives for adults to drink an average of 1 to 2 glasses of red wine per day in order to prevent heart attacks. Suppose further that if adopted the incentives will be very widely effective. The density of heart attacks observationally *conditional* on drinking an average of 1 to 2 glasses of red wine per day is not the density relevant to answering this question, and the question of whether drinking red wine prevents heart attacks is crucial. Suppose drinking red wine does not prevent heart attacks, but the heart attack rate is lower among moderate red wine drinkers because some socio-economic variable causes both moderate red wine drinking and other healthy life-styles choices that prevent heart attacks. In that case, after the incentives to drink red wine are in place, the density of socioeconomic status among red wine drinkers will be different than prior to the incentives, and the conditional density of heart attacks among moderate red wine drinkers will not be the same after the incentives were adopted as prior to their adoption. Thus, using observational conditional densities to predict heart attacks after the incentives are in place will lead to incorrect predictions.

The density that is relevant to determining whether or not to recommend drinking a moderate amount of red wine is not the density of heart attacks among people who have chosen to drink red wine (choice being the mechanism for determining red wine consumption in the unmanipulated population), but the density of heart attacks among people who would drink red wine after the incentives are in place. If the incentives are very effective, the density of heart attacks among people who would drink red wine after the incentives are in place is approximately equal to the density of heart attacks among people who are assigned to drink moderate amounts of red wine in an experimental study.

The density of heart attacks among people who have been *assigned* to drink red wine (as opposed to those who have *chosen* to drink red wine, as is currently the case) is a *manipulated* density, that results from taking action on a given population - it may or may not be equal to any observational conditional density, depending upon what the causal relations between variables are. Manipulated probability densities are the appropriate probability densities to use when making predictions about the effects of taking actions ("manipulating" or "doing") on a given population (for example, assigning red wine drinking), rather than observing ("seeing") the values of given variables. Manipulated probabilities are the probabilities that are implicitly used in decision theory, where the different actions under consideration are manipulations.[2]

A simple form of manipulation specifies what new density P' is assigned to some variable in a population at a given time. For example, forcing everyone in an (adult) population to drink an average of 1 glass of red wine daily from t–10 to t–5, assigns $P'(rw_{t-5} = 1) = 1$. (Since rw_{t-5} measures red wine drinking for the past 5 years, an intervention on rw_{t-5} begins at t–10.) After this density has been assigned, there is a resulting joint density for the random variables at time t, denoted by $P(sex, bmi_{t-5}, ha_{t-5}, rw_{t-5}, bmi_t, ha_t, rw_t \,||\, P'(rw_{t-5} = 1) = 1)$, where the double bar indicates the density that has been assigned to rw_{t-5}, in this case that everyone has been assigned the value $rw_{t-5} = 1$.[3] This is in contrast to the conditional density $P(sex, bmi_{t-5}, ha_{t-5}, rw_{t-5}, bmi_t, ha_t,$

2. The use of manipulated probability densities in decision theory is often not explicit. The assumption that the density of states of nature are independent of the actions taken (act-state independence) is one way to ensure that the manipulated densities that are needed are equal to observed conditional densities that can be measured.
3. There is no completely standard notation for denoting a manipulated density. This notation is adapted from Lauritzen (1999).

$rw_t \mid rw_{t-5} = 1)$, which is the density of the variables in the subpopulation where $rw_{t-5} = 1$ because people have been observed to drink that amount of red wine, as in the unmanipulated population.

$P(sex, bmi_{t-5}, ha_{t-5}, rw_{t-5}, bmi_t, ha_t, rw_t \mid\mid P'(rw_{t-5} = 1) = 1)$ is a density, so it is possible to form marginal and conditional probability densities from it. For example, $P(ha_t \mid bmi_{t-5} = 25 \mid\mid P'(rw_{t-5} = 1) = 1)$ is the probability of having had a heart attack between t–5 and t among people who have a *bmi* of 25 at t–5, everyone having been assigned to drink an average of 1 glass of red wine daily between t–10 and t–5. In this paper, in order to simplify the exposition, it will be assumed that all attempted manipulations are successful; that is, if $P'(rw_{t-5} = 1) = x$ then $P(rw_{t-5} = 1 \mid\mid P'(rw_{t-5} = 1) = x) = x$ (that is, if rw_{t-5} is manipulated to have value 1 with probability x, then in the manipulated population, rw_{t-5} has value 1 with probability x.) For example, if it is assumed that $P'(rw_{t-5} = 1) = 1$ then $P(rw_{t-5} = 1 \mid\mid P'(rw_{t-5} = 1) = 1) = 1$, that is if everyone has been assigned to drink an average of 1 glass of red wine per day for 5 years (denoted $P'(rw_{t-5} = 1) = 1$), that everyone has done so.

In a randomized trial, a manipulation could set $P'(rw_{t-5} = 1) = 0.5$ and $P'(rw_{t-5} = 0) = 0.5$, in which case the resulting density is $P(sex, bmi_{t-5}, ha_{t-5}, rw_{t-5}, bmi_t, ha_t, rw_t \mid\mid \{P'(rw_{t-5} = 1) = 0.5, P'(rw_{t-5} = 0) = 0.5\})$.

In more complex manipulations, different probabilities can be assigned to different subpopulations. For example, the amount of red wine someone is assigned to drink could be based on *sex*: $P'(rw_{t-5} = 0 \mid sex = 0) = 0.25, P'(rw_{t-5} = 1 \mid sex = 0) = 0.75, P'(rw_{t-5} = 0 \mid sex = 1) = 0.\ 5, P'(rw_{t-5} = 2 \mid sex = 1) = 0.5$. The resulting density is $P(sex, bmi_{t-5}, ha_{t-5}, rw_{t-5}, bmi_t, ha_t, rw_t \mid\mid \{P'(rw_{t-5} = 0 \mid sex = 0) = 0.25, P'(rw_{t-5} = 1 \mid sex = 0) = 0.75, P'(rw_{t-5} = 0 \mid sex = 1) = 0.5, P'(rw_{t-5} = 2 \mid sex = 1) = 0.5\})$. In general, which manipulations are performed on which subpopulations can be a function both of the values of various random variables, and of what other past manipulations have been performed.

In many cases the values of some variables in the pre-manipulation density are stable, and the temporal indices on those variables are omitted. Similarly, if it is assumed that variables in the post-manipulation population eventually stabilize to fixed values, the time indices of those variables are omitted in the post-manipulation density, and the time-independent variables refer to the stable values. Both of these kinds of omissions of time indices are illustrated by the use of *sex* in the example.

In contrast to conditional probabilities, which can be estimated from samples from a population, typically the gold standard for estimating manipulated densities is an experiment, often a randomized trial. However, in many cases experiments are too expensive, too difficult, or not ethical to carry out. This raises the question of what can be determined about manipulated probability densities from samples from a population, possibly in combination with a limited number of randomized trials. The problem is even more difficult because the inference is made from a set of measured random variables $\mathbf{O}$ from samples that might not contain variables that are causes of multiple variables in $\mathbf{O}$.

Problem 2: Causal Predictive Modeling

Input: Samples from a population with density $P(\mathbf{O})$, and a (possibly empty) set of manipulated densities $P(\mathbf{O} \mid\mid M_1), \ldots\ P(\mathbf{O} \mid\mid M_n)$, a manipulation M, and sets $\mathbf{X}, \mathbf{Y} \subseteq \mathbf{O}$.
Output: A consistent, efficient estimate of $P(\mathbf{Y} \mid \mathbf{X} \mid\mid M)$ if possible, and an output of "not possible" otherwise.

With causal inference, as with statistical inference, it is generally the case that in order to make inference tractable both computationally and statistically, simplifying assumptions are made. One kind of simplifying assumption common to both statistical and causal inference is the assumption that the population distribution lies in some parametric family (for example, Gaussian) or that relationships between variables are exactly linear. An example of a simplifying assumption unique to causal inference is that multiple causal mechanisms relating variables do not exactly cancel (Section 3). So, although the goal of Problem 2 is stated as finding a consistent estimate of a manipulated density, it is more realistic to state the goal as finding a sufficiently good estimate of a manipulated density when the sample size is large enough.

Problem 2 is usually broken into two parts: finding a set of causal models from sample data, some manipulations (experiments) and background assumptions (Sections 3 and 4), and predicting the effects of a manipulation from a set of causal models (Section 3). Here, a "causal model" (Section 3) specifies for each possible manipulation that can be performed on the population (including the manipulation that does nothing to a population) a post-manipulation density over a given set of variables. In some cases, the inferred causal models may contain unmeasured variables as well as measured variables.

Problem 3: Constructing Causal Models from Sample Data

Input: Samples from a population with density $P(\mathbf{O})$, a (possibly empty) set of manipulated densities $P(\mathbf{O}||M_1), \ldots\ P(\mathbf{O}||M_n)$, and background assumptions.

Output: A set of causal models that is as small as possible, and contains a true causal model that contains at least the variables in $\mathbf{O}$.

Problem 4: Predicting the Effects of Manipulations from Causal Models

Input: An unmanipulated density $P(\mathbf{O})$, a set $\mathbf{C}$ of causal models that contain at least the variables in $\mathbf{O}$, a manipulation M, and sets $\mathbf{X}, \mathbf{Y} \subseteq \mathbf{O}$.

Output: A function g such that $P(\mathbf{Y} \mid \mathbf{X} \,||\, M) = g(P(\mathbf{O}), \mathbf{C}, M, \mathbf{X}, \mathbf{Y})$ if one exists, and an output of "no function" otherwise.

In analogy to the goals of statistical modeling, it would be more accurate but much more vague to state that the goal in Problem 3 is to find a useful (for example, sufficiently simple, sufficiently accurate, etc.) causal model, rather than a true causal model.

The reason that the stated goal for the output of Problem 3 is a set of causal models, is that it is generally not possible to reliably find a true causal model given the inputs. Furthermore, in contrast to predictive models, even if a true causal model can be inferred from a sample from the unmanipulated population, it generally cannot be validated on a sample from the unmanipulated population, because a causal model contains predictions about a manipulated population that might not actually exist. This has been a serious impediment to the improvement of algorithms for constructing causal models, because it makes evaluating the performance of such algorithms difficult. It is possible to evaluate causal inference algorithms on simulated data, to employ back-

ground knowledge to check the performance of algorithms, and to conduct limited (due to expense, time, and ethical constraints) experiments, but these serve as only partial checks how algorithms perform on real data in a wide variety of domains. For examples, see the Causality Challenge (http://www.causality.inf.ethz.ch/challenge.php).

In the Special Topic on Causality in this journal, Shpitser and Pearl (2008) and Zhang (2008) address Problem 4. Bromberg and Margaritis (2009), Pellet and Elisseeff (2008), He and Geng (2009), and (indirectly) Kang and Tian (2009), Aliferis et al. (2010a), and Aliferis et al. (2010b) address Problem 3. Both the problems and the papers will be described in more detail in subsequent sections.

2.3 Effects of Counterfactual Manipulations

There are cases in ethics, the law, and epidemiology in which there are questions about applying a manipulation to a subpopulation whose membership cannot be measured at the time that the manipulation is applied. For example, epidemiologists sometimes want to know what would the effect on heart attacks have been, if a manipulation such as assigning moderate drinking of red wine from t–10 to t–5, had been applied to the subpopulation which has *not* moderately drunk red wine from t–10 to t–5. When the manipulation under consideration assigns a value to a random variable to a subpopulation with a different actual value of the random variable, the probability in question is a *counterfactual* probability. If the subpopulation that did not moderately drink red wine between t–10 and t–5 differs systematically from the rest of the population with respect to causes of heart attacks, the subpopulations' response to being assigned to drink red wine would be different than the rest of the population.

Questions about counterfactual probabilities arise naturally in assigning blame in ethics or in the law. For example, the question of whether tobacco companies were negligent in the case of someone who smoked and developed lung cancer depends upon the probability that person would not have gotten lung cancer if they had not smoked.

A counterfactual probability cannot be estimated directly from a randomized experiment, because it is impossible to perform a randomized experiment that assigns moderate red wine drinking between t–10 to t–5 to a group of people who already have not been moderate wine drinkers between t–10 and t–5. This raises the question of how counterfactual probabilities can be estimated. One general approach is to assume that the value of red wine drinking between t–10 and t–5 contains information about hidden causes of red wine drinking that are also causes of heart attacks.

Problem 5: Counterfactual predictive modeling
Input: An unmanipulated density $P(\mathbf{O})$, a set $\mathbf{C}$ of causal models that contain at least the variables in $\mathbf{O}$, a counterfactual manipulation M, and sets $\mathbf{X}, \mathbf{Y} \subseteq \mathbf{O}$.
Output: A function g such that $P(\mathbf{Y} \mid \mathbf{X} \,||\, M) = g(P(\mathbf{O}), \mathbf{C}, M, \mathbf{X}, \mathbf{Y})$ if one exists, and an output of "no function" otherwise.

In the Special Topic on Causality in this journal, Shpitser and Pearl (2008) describes a solution to Problem 5 in the case where the causal graph is known, but may contain unmeasured common causes.

3. Causal Models

This section describes several different kinds of commonly used causal models, and how to use them to calculate the effects of manipulations. The next section describes search algorithms for discovering causal models.

A (parametric) *statistical model* (with free parameters) is a set of probability densities that can be mapped into a single density by specifying the values of the free parameters (for example, a family of multivariate Gaussian densities).[4] For example, a Hidden Markov Model with a fixed structure but free parameters is a statistical model that represents a certain set of probability densities. A *causal model with free parameters* also specifies a set of probability densities over a given set of variables; however, in addition, for each manipulation that can be performed on the population it also specifies a set of post-manipulation probability densities over a given set of variables. A causal model with free parameters together with the values of the free parameters is a *causal model with fixed parameters*; a causal model with fixed parameters is mapped to a single density given a specification of a manipulation.

Often, a causal model is specified in two parts: a statistical model, and a causal graph that describes the causal relations between variables. The most frequently used causal models belong to two broad families: (1) causal Bayesian networks, (2) structural equation models. Causal Bayesian networks (and related models), specify a density for a variable as a function of the values of its causes. Structural equation models (SEMs) specify the value of a variable as a function of the values of its causes (typically including some unmeasured noise terms.) However, not surprisingly, the two kinds of models are closely linked, as explained in Section 3.2.

The statistical setup for both causal Bayesian networks and structural equation models is a standard one. There is a population of units, where depending upon the problem, the units could be people, cities, cells, genes, etc. It is assumed that there is a density over the population, which assigns probabilities to each measurable subset (event) of the population. Each unit also has a set of properties at a time, where the properties are represented by random variables, which are functions from the units to real numbers. The following sections describe the causal part of the model.

3.1 Causal Bayesian Networks

A *Bayesian network* is a pair $\langle G, P \rangle$, where G is a directed acyclic graph (DAG) whose vertices are random variables, and P is a density such that each variable V in G is independent of variables that are neither descendants nor parents of V in G,[5] conditional on the parents of V in G. In this case P is said to satisfy the *local directed Markov condition* for G.

There are two conditions that are equivalent to the local directed Markov condition described below that are useful in causal inference: the global directed Markov condition, and factorization according to G, both of which are described next.

The conditional independence relations specified by satisfying the local directed Markov condition for DAG G might also entail other conditional independence relations. There is a fast algorithm for determining from G whether a given conditional independence relation is entailed by satisfying the local directed Markov condition for G, that uses the d-separation relation, a relation among the

4. In the nomenclature of machine learning, what this article calls a "model (with free parameters)" is often called a "model family" or "learning machine" and a "model (with fixed parameter values)" is often called a "model instance" or "model".

5. X is a *parent* of Y if the graph contains the edge $X \rightarrow Y$. Y is a *descendant* of X if there is a directed path from X to Y.

vertices of G. A variable B is a *collider* (*v-structure*) *on a path* U if and only if U contains a subpath $A \rightarrow B \leftarrow C$. For disjoint sets of vertices $\mathbf{X}$, $\mathbf{Y}$, and $\mathbf{Z}$ in a DAG G, $\mathbf{X}$ is *d-connected* to $\mathbf{Y}$ given $\mathbf{Z}$ if and only if there is an acyclic path U between some member X of $\mathbf{X}$, and some member Y of $\mathbf{Y}$, such that every collider on U is either a member of $\mathbf{Z}$ or an ancestor of a member of $\mathbf{Z}$, and every non-collider on U is not in $\mathbf{Z}$.[6] For disjoint sets of vertices, $\mathbf{X}$, $\mathbf{Y}$, and $\mathbf{Z}$, $\mathbf{X}$ is *d-separated* from $\mathbf{Y}$ given $\mathbf{Z}$ if and only if $\mathbf{X}$ is not d-connected to $\mathbf{Y}$ given $\mathbf{Z}$. $\mathbf{X}$ is d-separated from $\mathbf{Y}$ conditional on $\mathbf{Z}$ in DAG G if and only if $\mathbf{X}$ is independent of $\mathbf{Y}$ conditional on $\mathbf{Z}$ in every density that satisfies the local directed Markov condition for G (Pearl, 1988). If $\mathbf{X}$ is independent of $\mathbf{Y}$ conditional on $\mathbf{Z}$ in P whenever $\mathbf{X}$ is d-separated from $\mathbf{Y}$ conditional on $\mathbf{Z}$ in G, then P satisfies the *global directed Markov condition* for G.

For the set of random variables $\mathbf{V}$ in G, a density $P(\mathbf{V})$ *factors according to* DAG G iff

$$P(\mathbf{V}) = \prod_{V \in \mathbf{V}} P(V|\mathbf{Parents}(V,G))$$

where **Parents**(V,G) is the set of parents of V in G.

The local directed Markov condition, the global directed Markov condition, and factorization according to a DAG G are all equivalent under mild regularity assumptions (Lauritzen et al., 1990).

A DAG can also be used to represent causal relations between variables. A is a *direct cause* of B relative to a set of variables $\mathbf{V}$ in a population when there exist two manipulations of $\mathbf{V}\backslash\{B\}$ (that is, all the variables in $\mathbf{V}$, except B, are manipulated to specific values) that differ only in the values assigned to A and that produce different probability densities of B. A *causal DAG* G for a population contains an edge $A \rightarrow B$ iff A is a direct cause of B in the specified population.

In order to use samples from probability densities to make causal inferences, some assumptions relating causal relations to probability densities need to be made. The following Causal Markov Assumption is commonly made, if only implicitly. A set of variables $\mathbf{V}$ is *causally sufficient* iff there is no variable C not in $\mathbf{V}$ that is a direct cause of more than one variable in $\mathbf{V}$ (relative to $\mathbf{V} \cup \{C\}$).

Causal Markov Assumption: For a causally sufficient set of variables $\mathbf{V}$ in a population N with density $P(\mathbf{V})$, $P(\mathbf{V})$ satisfies the local directed Markov condition for the causal DAG of N.

Under the Causal Markov Assumption, in a causal Bayesian network a manipulation of X to $P'(X \mid \mathbf{Y})$ (where $\mathbf{Y}$ is assumed to contain only non-descendants of X in a causal DAG G) simply replaces the term $P(X \mid \mathbf{Parents}(X,G))$ in the factorization of the joint density by the manipulated density $P'(X \mid \mathbf{Y})$:

$$P(\mathbf{V}||P'(X|\mathbf{Y})) = P'(X|\mathbf{Y}) \prod_{V \in \mathbf{V}\backslash\{X\}} P(V|\mathbf{Parents}(V,G)).$$

This is called the *manipulation rule*. The importance of the manipulation rule is that if the causal DAG is known, and the unmanipulated density can be estimated from a sample, it allows the prediction of the effect of an unobserved manipulation. Hence the manipulation rule is the solution to Problem 4, in the special case where the observed variables are causally sufficient, and the unique correct causal DAG is known.

6. For both the d-separation relation and the independence relation, if $\mathbf{X}$ contains a single vertex X, then X will be written instead of $\{X\}$, and similarly for $\mathbf{Y}$ and $\mathbf{Z}$. D-connection can also be defined for cyclic graphs and graphs with double-headed arrows (Spirtes, 1995; Koster, 1999; Cox and Wermuth, 1996).

The solution to Problem 4 is more difficult when the set of observed variables is not causally sufficient. There are sufficient and (almost) necessary rules for determining which manipulated conditional probability densities are invariant under a given manipulation (that is, which densities are the same in the unmanipulated population and the manipulated population) and rules for how to express some non-invariant conditional densities as functions of observed densities (Spirtes et al., 1993). Pearl's do-calculus extended the sufficient and (almost) necessary conditions for determining which conditional densities were invariant from single manipulations to sequences of manipulations, and showed how a broader range of non-invariant manipulated densities could be expressed in terms of observed densities (Pearl, 1995). In the Special Topic on Causality of this journal, Shpitser and Pearl (2008) describe an algorithm that has recently been developed and show that it is a complete solution to Problem 4 in the special case where a unique causal DAG is known (Shpitser and Pearl, 2006a,b; Huang and Valtorta, 2006).

Calculation of the effect of a counterfactual manipulation when causal sufficiency does not hold among the observed variables is a complex operation that requires several copies of the causal graph in order to keep track both of the actual value of the variable being manipulated, and the counterfactual value of the variable being manipulated. In the Special Topic on Causality, Shpitser and Pearl (2008) describe for the first time an algorithm that is a complete solution to Problem 5 in the special case where a unique causal DAG is known, even if the set of observed variables is not causally sufficient.

3.2 Structural Equation Models (SEMs)

Structural equation models are widely used in the social sciences (Bollen, 1989) and in some natural sciences. The set of random variables in a structural equation model (SEM) can be divided into two subsets, the "error variables" or "error terms," and the substantive variables (for which there is no standard terminology in the literature). The substantive variables are the variables of interest, but they are not necessarily all observed. Which variables are substantive, and which variables are error terms can vary with the analysis of the problem. Each substantive variable is a function of other substantive variables and a unique error term. The joint density over the substantive variables is a function of the density over the error terms and of the functions relating each variable to its causes. There is an edge $A \rightarrow B$ in the graph ("path diagram") of a SEM when A is a non-trivial argument in the function for B. A manipulation of a variable B to a constant c is represented in a SEM by replacing the equation for B with $B = c$.

In general, the graph of a SEM may have cycles (that is, directed paths from a variable to itself), and may explicitly include error terms with double-headed arrows between them to represent that the error terms are dependent (for example, $\varepsilon_A \leftrightarrow \varepsilon_B$); if no such double-headed edge exists in the graph, the error terms are assumed to be independent of each other. An error term is not explicitly included in the graph unless it is the endpoint of a double-headed arrow; otherwise, an error term occurs in the SEM model, but is not shown in the graph. If the graph has no directed cycles and no double-headed arrows, then the graph is a DAG and the SEM is said to be *recursive*; otherwise it is said to be *non-recursive*.

In a recursive SEM, if the marginal density over the substantive variables is $P(\mathbf{V})$, then $\langle G, P(\mathbf{V})\rangle$ is a Bayesian network (Spirtes et al., 2001; Pearl, 2000); for short, say that a SEM with an associated graph that is a DAG is a Bayesian network (although the SEM contains some extra structure in that it

entails that any non-determinism among the substantive variables is only due to the marginalization of the error terms.)

Non-recursive SEMs are of interest because they allow for the representation of feedback (with cycles) or unmeasured common causes (represented by double-headed arrows.) In the case of linear non-recursive SEMs, it is still possible to deduce the conditional independencies (or more generally the zero partial correlations) entailed for all Gaussian SEMs (or more generally linear SEMs) from the graph G of a non-recursive linear SEM using a minor modification of the d-separation relation (Koster, 1999; Spirtes, 1995).

For both theoretical interest and for the purposes of efficient (constraint-based) search of the space of linear non-recursive SEMs without cycles (Section 4.2), it is of interest to find some proper subset of the set of all conditional independence relations entailed by the (modified) d-separation which entail all the rest, that is, a modified form of the local directed Markov condition. (In contrast to the recursive case, where such a subset is given by the independencies entailed by the local directed Markov condition, in the non-recursive case SEMs do not generally satisfy the local directed Markov condition). One such subset of conditional independencies was described by Richardson (2003). In this special issue, the paper by Kang and Tian (2009) describes another such subset, which is often smaller than the one described by Richardson, and hence might be more useful for the purposes of search.

4. Model Search

Traditionally, there have been a number of different approaches to causal discovery. The gold standard of causal discovery has typically been to perform planned or randomized experiments (Fisher, 1971). There are obvious practical and ethical considerations that limit the application of experiments in many instances, particularly on human beings. Moreover, recent data collection techniques and causal inference problems raise several practical difficulties regarding the number of experiments that need to be performed in order to answer all of the outstanding questions.

In the absence of experiments, in practice (particularly in the social sciences) search for causal models is often informal, and based on a combination of background assumptions about causal relations together with statistical tests of the causal models. If a model is rejected by a statistical test, the researcher looks for a modification of the original hypothesized model that will pass a statistical test. The search typically halts when a model that is compatible with background knowledge does not fail a statistical test (Rodgers and Maranto, 1989). Often, the final model is presented, and the search itself is not described. Informal searches of this kind fail to account for multiple testing problems, and can potentially lead to severe overfitting problems. The reliability of such a search depends upon the correctness of the background assumptions, and the extent to which the space of alternatives compatible with the background assumptions was searched. Furthermore, unless the background assumptions are very extensive, or the number of variables is tiny, it is not feasible to estimate and test all of the models compatible with background assumptions. This is further complicated by the fact that, as explained below, for reliable causal inference it is not sufficient to find one model that passes a statistical test; instead it is necessary to find all such models. Recent developments in automated model search have attempted to address these problems with traditional methods of search.

There are several major differences between model search in the case of predicting the unmanipulated value of Y, and model search in the case of predicting the post-manipulation value of Y, based on the different uses of statistical models and causal models described in the following section.

4.1 Underdetermination of Causal Models by Data

Causal model (with fixed parameter) search is often broken into two parts: search for a causal graph, and estimation of the free parameters from sample data and the causal graph. (In some cases, the prediction of the effects of manipulations does not require estimating all of the free parameters, but does require estimating functionals of the free parameters.) Generally, the estimation of the free parameters employs standard statistical methods. For example, in a linear SEM with a recursive DAG, no unmeasured variables, and Gaussian errors, the maximum likelihood estimate of the edge coefficients is given by regressing each variable on its parents in the DAG. This section concentrates on the search for causal graphs, because the search for causal graphs is significantly different than the search for graphs that are to be used only as statistical models.

In causal model search based on unmanipulated data, if no preference for simpler models over more complex models is made, then the causal models are underdetermined to such an extent that useful causal inference is impossible for many important parametric families (for example, Gaussian or multinomial) or unrestricted probability densities. There are a variety of simplicity assumptions that select simpler models over more complex models that can be made. In the case of search based upon maximizing some model score given sample data (such as the Bayesian Information Criterion), the simplicity assumption is a penalty for complexity built into the score (Chickering, 2002). For search that is not based upon model scores, the following simplicity assumption is often, if implicitly made:

Causal Faithfulness Assumption: For a causally sufficient set of variables **V** in a population N, every conditional independence relation true in the density over **V** is entailed by the local directed Markov condition for the causal DAG of N.

There are several other versions of the assumption that are considerably weaker than the one stated here (and more intuitively justifiable) but still permit reliable causal inference, at the cost of requiring more complicated algorithms with more complex and somewhat less informative output (Ramsey et al., 2006).

However, even given the Causal Markov and Faithfulness Assumptions and the assumption that the observed variables are causally sufficient, the true causal model is underdetermined by the available evidence and background assumptions, because of the hierarchy of equivalence relations described below.

Two different DAGs G and G' that have the same set of d-separation relations are said to be *Markov* (*conditional independence*, *d-separation*) *equivalent*.

For each DAG G, there is a set **P** of probability densities that satisfy the local directed Markov condition for G, denoted $\mathbf{P}(G)$ that are said to be *represented* by G. In many cases, some subset of **P** that belongs to a parametric or semi-parametric family **F** is of interest; for example, the Gaussian subset of **P**. Two DAGs G and G' are *statistically equivalent with respect to* **F** iff $\mathbf{P}(G) \cap \mathbf{F} = \mathbf{P}(G') \cap \mathbf{F}$. Two DAGs that are statistically equivalent with respect to **F** are the same statistical model with respect to **F**.

Two DAGs are *causally equivalent* (with respect to a family of densities **F**) iff they represent the same set of probability densities (in family **F**) for every manipulation (including the null ma-

nipulation.) It is easy to see that no pair of DAGs that differ in their structure can be causally equivalent.

As an example, $A \rightarrow B \leftarrow C \leftarrow D$ and $A \rightarrow B \leftarrow C \rightarrow D$ are Markov equivalent, but not causally equivalent. They are statistically equivalent with respect to Gaussian SEMs, but they are not statistically equivalent with respect to linear SEMs with at most one Gaussian error term, and no determinism among the substantive variables (Shimizu et al., 2006).[7]

In the absence of further information (for example, samples from manipulated densities or background domain knowledge) all of the DAGs in a statistical equivalence class fit the data and the background assumptions equally well, and are equally simple. Hence standard scores such as Bayesian Information Criterion, Minimum Description Length, chi-squared statistics, etc. all produce equal scores for the alternative DAGs in a statistical equivalence class for all data sets -- in general, there is no one DAG with the highest score, but rather, there is a set of DAGs with equally high scores. Furthermore, for computational and statistical reasons, it is sometimes easier to search for the Markov equivalence class of DAGs, even if it is known that the statistical equivalence class is a proper subset of the Markov equivalence class.

If the DAG is to be used to estimate observational (not manipulated) conditional densities, this is not a problem, because all of the statistically equivalent models will produce the same estimate. However, if the DAG is to be used to predict the effects of manipulations, then the different models will make different predictions about at least some manipulations. So in the case of causal modeling, unlike observational statistical modeling, it is not enough to simply output one arbitrarily selected DAG from a set of highest scoring DAGs -- it is important to output the entire set, so that all of the different answers given by the different models can be taken into account. Once the set of highest scoring DAGs is found, the problem of dealing with the underdetermination of the effects of manipulations must also be dealt with. These problems are described in more detail in the next two subsections.

If the assumption of causal sufficiency of the observed variables is not made, all three kinds of equivalence classes have corresponding equivalence classes over the set of observed variables, and the problem of causal underdetermination becomes much more severe. For example, for a given set of observed variables **O**, the Markov equivalence class relative to **O** consists of the set of all DAGs (possibly containing variables not in **O**) that have the same set of d-separation relations among the variables in **O**; this might be much larger than the Markov equivalence class that consists of the set of DAGs (containing only variables in **O**) that have the same set of d-separation relations among the variables in **O**.

4.2 Constraint-based Search

First, the problem where only sample data from the unmanipulated population density is available will be considered. The number of DAGs grows super-exponentially with the number of vertices, so even for modest numbers of variables it is not possible to examine each DAG to determine whether it is compatible with the population density given the Causal Markov and Faithfulness Assumptions. Constraint based search algorithms, given as input an oracle that returns answers about conditional independence in the population and optional background knowledge about orientations of edges, return a representation of a Markov equivalence class (or if there is background knowl-

7. In a linear SEM it is assumed that each variable is a linear function of its causal parents and a unique error term; in a Gaussian SEM it is assumed in addition that the errors term are Gaussian.

edge, a subset of a Markov equivalence class) on the basis of oracle queries. One example of a constraint-based algorithm is the PC algorithm (Spirtes and Glymour, 1991). If the oracle always gives correct answers, and the Causal Markov and Causal Faithfulness Assumptions hold, then the PC algorithm always outputs a Markov equivalence class that contains the true causal model, even though the algorithm does not check each directed acyclic graph. In the worse case, it is exponential in the number of variables, but for sparse graphs it can run on hundreds of variables in an acceptable amount of time (Spirtes and Glymour, 1991; Spirtes et al., 1993; Meek, 1995). Kalisch and Buhlmann (2007) showed that under a strengthened version of the Causal Faithfulness Assumption, the PC algorithm is uniformly consistent for very high-dimensional, sparse DAGs where the number of nodes is allowed to quickly grow with sample size n, as fast as $O(n^a)$ for any $0 < a < \infty$. In practice, the judgments about conditional independence are made by performing (fallible) statistical tests. A number of other variants of constraint-based algorithms have been proposed that improve on either the accuracy or speed of the PC algorithm, or to weaken the assumptions under which it is guaranteed to be correct.

There are both advantages and disadvantages of constraint based searches as compared to either a Bayesian approach to the problem of causal discovery (Heckerman and Geiger, 1995), or an approach based upon assigning a score to each causal model for a given data set (for example, Bayesian information criterion) and searching for the set of causal models that maximize the score (Chickering, 2002).

The disadvantages of constraint-based search include that the output of constraint-based searches give no indication of how much better the best set of output models is compared to the next best set of models; at small sample sizes tests of conditional independence have low power, particularly when many variables are conditioned on; mistakes made early in a constraint based searches can lead to later mistakes; and if the only constraints used are conditional independence constraints, as is often but not always the case, then at best the search outputs a Markov equivalence class, rather than a statistical equivalence class.[8] In addition, constraint-based methods have the problem of multiple testing. If no control is made for multiple testing, the models may overfit the data. However, adjustments to control for overfitting, such as the Bonferroni correction, are often too conservative and as a result the corrected statistical tests are not very powerful. The issue of multiple testing appears in Bayesian approaches to causal discovery as multiple causal model scoring. The issue is handled automatically by Bayesian methods by their use of prior probabilities (Heckerman et al., 1999).

The advantages of constraint-based algorithms are that they are easier to generalize to the case where the observed variables are not causally sufficient, they are generally fast, and given recent developments of non-parametric conditional independence tests, they are applicable without parametric assumptions (Tillman et al., 2009).

In the Special Topic on Causation, Bromberg and Margaritis (2009) models the problem of low power of statistical tests as a knowledge base containing a set of independence facts related through conditional independence axioms that may contain errors due to errors in the tests of conditional independence. The inconsistencies are resolved through the use of a defeasible logic called argumentation that is augmented with a preference function. The logic is used to reason about and possibly correct errors in these tests. Experimental evaluation shows significant improvements in the accuracy of argumentative over purely statistical tests, and improvements on the accuracy of causal

8. For searches that use non-conditional independence constraints see Silva et al. (2006) and Shpitser et al. (2009).

structure discovery from sampled data from randomly generated causal models and on real-world data sets.

The contributions to the Special Topic on Causality by Aliferis et al. (2010a) and Aliferis et al. (2010b) show that a general framework for localized causal membership structure learning is very accurate even in small sample situations and can thus be used as a first step for efficient global structure learning, as well as accurate prediction and feature selection. It also provides extensive empirical comparisons of state of the art causal learning methods with non-causal methods for the above tasks. In addition, they show that unexpectedly some constraint-based methods are self-correcting with respect to multiple testing, and this may constitute a new methodology for control of multiple statistical testing.

Another problem with constraint-based algorithms is to make them feasible for even higher dimensional data sets. In the Special Topic on Causality, Pellet and Elisseeff (2008) link the causal model search problem to a classic machine learning prediction problem. They show how a generic feature-selection algorithm returning strongly relevant variables can be turned into a causal model search algorithm. Under the Causal Markov and Causal Faithfulness Assumptions, the smallest set of features relevant to predicting a vertex V is the set of parents, children, and parents of children of V. Ideally, the variables returned by a feature-selection algorithm identify those features of the causal graph. Then further processing removes the extra edges (between V and those variables that are parents of children of V but that are neither parents nor children of V) and provides as many orientations as possible. This algorithm is more accurate than PC and other constraint-based algorithms, and has the advantage that it can use arbitrary feature-selection techniques developed for high-dimensional data sets under different assumptions to provide causal model learning algorithms for high-dimensional data under those assumptions.

4.3 Dealing with Underdetermination

One possibility for dealing with the underdetermination of causal models by observational data is to strengthen the available information by sampling from manipulated densities, or in other words, performing experiments.

In the Special Topic on Causality, He and Geng (2009) propose an algorithm for distinguishing between members of a Markov equivalence class by a set of optimally designed experiments. They consider several kinds of experiments, and both a batch-design and a sequential design to minimize the required number of manipulations using both minimax and maximum entropy criteria.

If some members of the Markov equivalence class cannot be eliminated through experimentation, there are several different approaches to using the entire Markov equivalence class to predict the effects of manipulations. (This is Problem 4 in the case where the predictions are made from a set of causal models $\mathbf{C}$ rather than a single causal model, and the set of observed variables may not be causally sufficient.) One possibility is to predict an interval for the potential effects of the manipulated quantity, instead of a point value. Theoretically, an interval could be obtained by calculating the manipulated quantity for each DAG G in the Markov equivalence class, and taking the lower and upper limits. Depending upon how many different SEMs there are in the output, this is sometimes computationally feasible (Maathuis et al., 2009).

A second possibility is to use a Bayesian approach, and perform model averaging. That is, a prior probability is placed over each causal DAG G, and a posterior probability for each G is calculated. Then the manipulated quantity is calculated for each G in the output of the search,

and the results are averaged together. This requires putting a prior probability over each graph; in addition, if there are many graphs in the output, then this may not be computationally feasible (Hoeting et al., 1999).

A third alternative is to have an algorithm that determines whether each DAG in the Markov equivalence class predicts the same effect of a given manipulation. For example, if the Markov equivalence class contains $A \rightarrow B \leftarrow C \rightarrow D$ and $A \rightarrow B \leftarrow C \leftarrow D$, then the two causal DAGs disagree about the effect of manipulating D on C, but agree about the effect of manipulating A on B. Even when the observed variables are not causally sufficient there is an algorithm (the Prediction Algorithm) for determining when all of the DAGs in a Markov equivalence class relative to the observed variables agree about the effect of a particular manipulation, and returns the common value of the predicted manipulation when they do all agree (Spirtes et al., 1993). However, this algorithm is known to be correct but incomplete (that is, it sometimes returns "don't know" even when all models in the equivalence class agree on the effect of a particular manipulation). In this special issue, Zhang (2008) provides a modified version of Pearl's do-calculus that is more complete than the Prediction algorithm.

5. Open Questions

The following is an overview of important problems that remain in the domain of causal modeling.

1. Matching causal models and search algorithms to causal problems. There are a wide variety of causal models that have been employed in different disciplines. What new models and search algorithms are appropriate for different domains such as feedback or reversible systems (Richardson, 1996)? What search algorithms are appropriate for different combinations of kinds of data, such as experimental and observational data (Eberhardt et al., 2005; Cooper and Yoo, 1999; Yoo and Cooper, 2004; He and Geng, 2009)? What search algorithms are appropriate for different kinds of background knowledge, and different families of probability densities?

2. Model selection, and prior knowledge. What kind of scores can be used to best evaluate causal models from various kinds of data? In a related vein, what are good families of prior densities that capture various kinds of background knowledge?

3. Improve efficiency and efficacy of search algorithms. How can search algorithms be improved to incorporate different kinds of background knowledge, search over different classes of causal models, run faster, handle more variables and larger sample sizes, be more reliable at small sample sizes, and produce output that is as informative as possible?

4. Characterization of search algorithms. For causal search algorithms, what are their semantic and syntactic properties (for example, soundness, consistency, maximum informativeness)? What are their statistical properties (pointwise consistency, uniform consistency, sample efficiency)?[9] What are their computational properties (computational complexity)?

5. Adding or relaxing simplifying assumptions. What plausible alternatives are there to the Causal Markov and Faithfulness Assumptions? Are there other assumptions that might be weaker and hold in more domains and applications without much loss about what can be reliably inferred?

9. Intuitively, an estimator is pointwise consistent when as the sample size increases without limit, regardless of the true value, with probability 1 the absolute value of the difference between the estimator and the true value approaches zero. An estimator is uniformly consistent if for any given ε and δ, there is a single sample size such that in the worst case, the probability is less than ε that the absolute value of the difference between the estimator and the true value is greater than δ. For precise definitions in the causal context, see Robins et al. (2003).

Are there stronger assumptions that are plausible for some domains that might allow for stronger causal inferences? How often are these assumptions violated, and how much do violations of these assumptions lead to incorrect inferences? Can various statistical assumptions be relaxed? For example, what if the sample selection process is not i.i.d., but may be causally affected by variables of interest?

6. Derivation of consequences from causal graph and unmanipulated densities. Shpitser and Pearl have given complete algorithms for deriving the consequences of various causal models with hidden common causes in terms of the unmanipulated density and the given manipulation (Shpitser and Pearl, 2008). Partial extensions of these results to deriving consequences from sets of causal models have been given (Zhang, 2008); are there further extensions to derivations from sets of causal models?

7. New constraints for structure learning. The Causal Markov and Causal Faithfulness Assumptions, in addition to entailing conditional independence constraints on densities, also entail other constraints on densities. For example, in a linear SEM, if an unobserved variable T causes observed variables X_1, X_2, X_3, X_4, and there are no other causal relations among these variables, then there are no entailed conditional independence relations among just the observed variables X_1, X_2, X_3, X_4. However, the SEM entails $\text{cov}(X_1,X_2)\ \text{cov}(X_3,X_4) = \text{cov}(X_1,X_3)\ \text{cov}(X_2,X_4) = \text{cov}(X_1,X_4)\ \text{cov}(X_2,X_3)$ regardless of the values of the free parameters. This information is useful in finding causal structure with unmeasured variables. In addition, there are sometimes constraints that are not conditional independence constraints on the density of the observed variables that do not depend upon any parametric assumptions (Shpitser et al., 2009). How can these non-parametric constraints be incorporated into search algorithms?

8. Find variable definitions. In many domains, such as fMRI research, there are thousands of variables, but the measured variables do not correspond to functional units of the brain. How is it possible to define new variables that are functions of the measured variables, but more useful for causal inference and more meaningful?

9. Find new applications of causal inference. Applications of causal inference algorithms in many domains (Cooper and Glymour, 1999) help test and improve causal inference algorithms, suggest new problems, and produce domain knowledge.

10. Creating good benchmarks. What are the most appropriate performance measures for causal inference algorithms? What benchmarks can be established? What is the best research design for testing causal inference algorithms?

11. Formal connections between different causal modeling approaches. Many different fields have studied causal discovery including Artificial Intelligence, Econometrics, Operations Research, Control Theory, and Statistics. What are the formal connections between the different models, assumptions, and algorithms used in each of these fields? What can each of these domains learn from the others?

Abstract

This paper develops algorithms to train support vector machines when training data are distributed across different nodes, and their communication to a centralized processing unit is prohibited due to, for example, communication complexity, scalability, or privacy reasons. To accomplish this goal, the centralized linear SVM problem is cast as a set of decentralized convex optimization subproblems (one per node) with consensus constraints on the wanted classifier parameters. Using the alternating direction method of multipliers, fully distributed training algorithms are obtained without exchanging training data among nodes. Different from existing incremental approaches, the overhead associated with inter-node communications is fixed and solely dependent on the network topology rather than the size of the training sets available per node. Important generalizations to train nonlinear SVMs in a distributed fashion are also developed along with sequential variants capable of online processing. Simulated tests illustrate the performance of the novel algorithms.[1]

Keywords: support vector machine, distributed optimization, distributed data mining, distributed learning, sensor networks

1. Introduction

Problems calling for *distributed learning* solutions include those arising when training data are acquired by different nodes, and their communication to a central processing unit, often referred to as fusion center (FC), is costly or even discouraged due to, for example, scalability, communication overhead, or privacy reasons. Indeed, in applications involving wireless sensor networks (WSNs) with battery-operated nodes, transferring each sensor's data to the FC maybe prohibited due to power limitations. In other cases, nodes gathering sensitive or private information needed to design the classifier may not be willing to share their training data.

For *centralized learning* on the other hand, the merits of support vector machines (SVMs) have been well documented in various supervised classification tasks emerging in applications such as medical imaging, bio-informatics, speech, and handwriting recognition, to name a few (Vapnik, 1998; Schölkopf and Smola, 2002; El-Naqa et al., 2002; Liang et al., 2007; Ganapathiraju et al., 2004; Li, 2005; Markowska-Kaczmar and Kubacki, 2005). Centralized SVMs are maximum-margin

linear classifiers designed based on a centrally available training set comprising multidimensional data with corresponding classification labels. Training an SVM requires solving a quadratic optimization problem of dimensionality dependent on the cardinality of the training set. The resulting linear SVM discriminant depends on a subset of elements from the training set, known as support vectors (SVs). Application settings better suited for nonlinear discriminants have been also considered by mapping vectors at the classifier's input to a higher dimensional space, where linear classification is performed. In either linear or nonlinear SVMs designed with centrally available training data, the decision on new data to be classified is based solely on the SVs.

For this reason, recent designs of *distributed SVM* classifiers rely on SVs obtained from local training sets (Flouri et al., 2006, 2008; Lu et al., 2008). These SVs obtained locally per node are incrementally passed on to neighboring nodes, and further processed at the FC to obtain a discriminant function approaching the centralized one obtained as if all training sets were centrally available. Convergence of the *incremental* distributed (D) SVM to the centralized SVM requires multiple SV exchanges between the nodes and the FC (Flouri et al., 2006); see also Flouri et al. (2008), where convergence of a gossip-based DSVM is guaranteed when classes are linearly separable. Without updating local SVs through node-FC exchanges, DSVM schemes can approximate but not ensure the performance of centralized SVM classifiers (Navia-Vazquez et al., 2006).

Another class of DSVMs deals with *parallel* designs of centralized SVMs—a direction well motivated when training sets are prohibitively large (Chang et al., 2007; Do and Poulet, 2006; Graf et al., 2005; Bordes et al., 2005). Partial SVMs obtained using small training subsets are combined at a central processor. These parallel designs can be applied to distributed networked nodes, only if a central unit is available to judiciously combine partial SVs from intermediate stages. Moreover, convergence to the centralized SVM is generally not guaranteed for any partitioning of the aggregate data set (Graf et al., 2005; Bordes et al., 2005).

The novel approach pursued in the present paper trains an SVM in a *fully distributed* fashion that does not require a central processing unit. The centralized SVM problem is cast as a set of coupled decentralized convex optimization subproblems with consensus constraints imposed on the desired classifier parameters. Using the alternating direction method of multipliers (ADMoM), see, for example, Bertsekas and Tsitsiklis (1997), distributed training algorithms that are provably convergent to the centralized SVM are developed based solely on message exchanges among neighboring nodes. Compared to existing alternatives, the novel DSVM classifier offers the following distinct features.

- **Scalability and reduced communication overhead**. Compared to approaches having distributed nodes communicate training samples to an FC, the DSVM approach here relies on *in-network* processing with messages exchanged only among single-hop neighboring nodes. This keeps the communication overhead per node at an affordable level within its neighborhood, even when the network scales to cover a larger geographical area. In FC-based approaches however, nodes consume increased resources to reach the FC as the coverage area grows. Different from, for example, Lu et al. (2008), and without exchanging SVs, the novel DSVM incurs a fixed overhead for inter-node communications per iteration regardless of the size of the local training sets.

- **Robustness to isolated point(s) of failure**. If the FC fails, an FC-based SVM design will fail altogether—a critical issue in tactical applications such as target classification. In contrast, if a single node fails while the network remains connected, the proposed algorithm will converge

to a classifier trained using the data of nodes that remain operational. But even if the network becomes disconnected, the proposed algorithm will stay operational with performance dependent on the number of training samples per connected sub-network.

- **Fully decentralized network operation**. Alternative distributed approaches include incremental and parallel SVMs. Incremental passing of local SVs requires identification of a Hamiltonian cycle (going through all nodes once) in the network (Lu et al., 2008; Flouri et al., 2006). And this is needed not only in the deployment stage, but also every time a node fails. However, Hamiltonian cycles do not always exist, and if they do, finding them is an NP-hard task (Papadimitriou, 2006). On the other hand, parallel SVM implementations assume full (any-to-any) network connectivity, and require a central unit defining how SVs from intermediate stages/nodes are combined, along with predefined inter-node communication protocols; see, for example, Chang et al. (2007), Do and Poulet (2006) and Graf et al. (2005).

- **Convergence guarantees to centralized SVM performance**. For linear SVMs, the novel DSVM algorithm is *provably convergent* to a centralized SVM classifier, as if all distributed samples were available centrally. For nonlinear SVMs, it converges to the solution of a modified cost function whereby nodes agree on the classification decision for a subset of points. If those points correspond to a classification query, the network "agrees on" the classification of these points with performance identical to the centralized one. For other classification queries, nodes provide classification results that closely approximate the centralized SVM.

- **Robustness to noisy inter-node communications and privacy preservation**. The novel DSVM scheme is robust to various sources of disturbance that maybe present in message exchanges. Those can be due to, for example, quantization errors, additive Gaussian receiver noise, or, Laplacian noise intentionally added for privacy (Dwork et al., 2006; Chaudhuri and Monteleoni, 2008).

The rest of this paper is organized as follows. To provide context, Section 2 outlines the centralized linear and nonlinear SVM designs. Section 3 deals with the novel fully distributed linear SVM algorithm. Section 3.1 is devoted to an online DSVM algorithm for synchronous and asynchronous updates, while Section 4 generalizes the DSVM formulation to allow for nonlinear classifiers using kernels. Finally, Sections 5 and 6 present numerical results and concluding remarks.

General notational conventions are as follows. Upper (lower) bold face letters are used for matrices (column vectors); $(\cdot)^T$ denotes matrix and vector transposition; the ji-th entry of a matrix (j-th entry of a vector) is denoted by $[\cdot]_{ji}$ ($[\cdot]_j$); diag($\mathbf{x}$) denotes a diagonal matrix with $\mathbf{x}$ on its main diagonal; diag$\{\cdot\}$ is a (block) diagonal matrix with the elements in $\{\cdot\}$ on its diagonal; $|\cdot|$ denotes set cardinality; $\succeq$ ($\preceq$) element-wise $\geq$ ($\leq$); $\{\cdot\}$ ($[\cdot]$) a set (matrix) of variables with appropriate elements (entries); $\|\cdot\|$ the Euclidean norm; $\mathbf{1}_j$ ($\mathbf{0}_j$) a vector of all ones (zeros) of size N_j; $\mathbf{I}_M$ stands for the $M \times M$ identity matrix; $\mathbb{E}\{\cdot\}$ denotes expected value; and $\mathcal{N}(m,\Sigma)$ for the multivariate Gaussian distribution with mean m, and covariance matrix Σ.

2. Preliminaries and Problem Statement

With reference to Figure 1, consider a network with J nodes modeled by an undirected graph $\mathcal{G}(\mathcal{J},\mathcal{E})$ with vertices $\mathcal{J} := \{1,\ldots,J\}$ representing nodes, and edges $\mathcal{E}$ describing links among com-

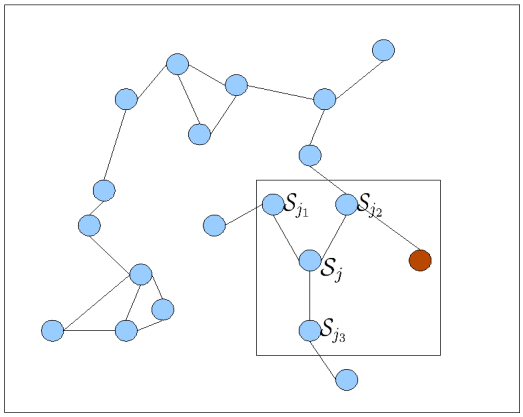

Figure 1: Network example where connectivity among nodes, represented by colored circles, is denoted by a line joining them.

municating nodes. Node $j \in \mathcal{J}$ only communicates with nodes in its one-hop neighborhood (ball) $\mathcal{B}_j \subseteq \mathcal{J}$. The graph $\mathcal{G}$ is assumed connected, that is, any two nodes in $\mathcal{G}$ are connected by a (perhaps multihop) path in $\mathcal{G}$. Notice that nodes do not have to be fully connected (any-to-any), and $\mathcal{G}$ is allowed to contain cycles. At every node $j \in \mathcal{J}$, a labeled training set $\mathcal{S}_j := \{(\mathbf{x}_{jn}, y_{jn}) : n = 1, \ldots, N_j\}$ of size N_j is available, where $\mathbf{x}_{jn} \in \mathcal{X}$ is a $p \times 1$ data vector belonging to the input space $\mathcal{X} \subseteq \mathbb{R}^p$, and $y_{jn} \in \mathcal{Y} := \{-1, 1\}$ denotes its corresponding class label.[2]

Given $\mathcal{S}_j$ per node j, the *goal* is to find a maximum-margin linear discriminant function $g(\mathbf{x})$ in a distributed fashion, and thus enable each node to classify any new input vector $\mathbf{x}$ to one of the two classes $\{-1, 1\}$ without communicating $\mathcal{S}_j$ to other nodes $j' \neq j$. Potential application scenarios include but are not limited to the following ones.

Example 1 *(Wireless sensor networks).* Consider a set of wireless sensors deployed to infer the presence or absence of a pollutant over a geographical area at any time t_n. Sensor j measures and forms a local binary decision variable $y_{jn} \in \{1, -1\}$, where $y_{jn} = 1(-1)$ indicates presence (absence) of the pollutant at the position vector $\mathbf{x}_j := [x_{j1},\ x_{j2},\ x_{j3}]^T$. (Each sensor knows its position $\mathbf{x}_j$ using existing self-localization algorithms Langendoen and Reijers, 2003.) The goal is to have each low-cost sensor improve the performance of local detection achieved based on $\mathcal{S}_j = \{([\mathbf{x}_j^T, t_n]^T, y_{jn}) : n = 1, \ldots, N_j\}$, and through collaboration with other sensors approach the global performance attainable if each sensor had available all other sensors data. Stringent power limitations prevent sensor j to send its set $\mathcal{S}_j$ to all other sensors or to an FC, if the latter is available. If these sensors are acoustic and are deployed to classify underwater unmanned vehicles, divers or submarines, then low transmission bandwidth and multipath effects further discourage incremental communication of the local data sets to an FC (Akyildiz et al., 2005).

Example 2 *(Distributed medical databases).* Suppose that $\mathcal{S}_j$ are patient data records stored at a hospital j. Each $\mathbf{x}_{jn}$ here contains patient descriptors (e.g., age, sex or blood pressure), and y_{jn} is a particular diagnosis (e.g., the patient is diabetic or not). The objective is to automatically diagnose

2. Although not included in this model for simplicity, K-ary alphabets $\mathcal{Y}$ with $K > 2$ can be considered as well.

(classify) a patient arriving at hospital j with descriptor $\mathbf{x}$, using all available data $\{\mathcal{S}_j\}_{j=1}^J$, rather than $\mathcal{S}_j$ alone. However, a nonchalant exchange of database entries $(\mathbf{x}_{jn}^T, y_{jn})$ can pose a privacy risk for the information exchanged. Moreover, a large percentage of medical information may require exchanging high resolution images. Thus, communicating and processing large amounts of high-dimensional medical data at an FC may be computationally prohibitive.

Example 3 *(Collaborative data mining).* Consider two different government agencies, a local agency A and a nation-wide agency B, with corresponding databases $\mathcal{S}_A$ and $\mathcal{S}_B$. Both agencies are willing to collaborate in order to classify jointly possible security threats. However, lower clearance level requirements at agency A prevents agency B from granting agency A open access to $\mathcal{S}_B$. Furthermore, even if an agreement granting temporary access to agency A were possible, databases $\mathcal{S}_A$ and $\mathcal{S}_B$ are confined to their current physical locations due to security policies.

If $\{\mathcal{S}_j\}_{j=1}^J$ were all centrally available at an FC, then the global variables $\mathbf{w}^*$ and b^* describing the *centralized* maximum-margin linear discriminant function $g^*(\mathbf{x}) = \mathbf{x}^T\mathbf{w}^* + b^*$ could be obtained by solving the convex optimization problem; see, for example, Schölkopf and Smola (2002, Ch. 7)

$$\begin{aligned} \{\mathbf{w}^*, b^*\} = \arg \min_{\mathbf{w}, b, \{\xi_{jn}\}} \quad & \frac{1}{2}\|\mathbf{w}\|^2 + C\sum_{j=1}^{J}\sum_{n=1}^{N_j}\xi_{jn} \\ \text{s.t.} \quad & y_{jn}(\mathbf{w}^T\mathbf{x}_{jn} + b) \geq 1 - \xi_{jn} \quad \forall j \in \mathcal{J},\ n = 1, \ldots, N_j \\ & \xi_{jn} \geq 0 \qquad\qquad\qquad\qquad \forall j \in \mathcal{J},\ n = 1, \ldots, N_j \end{aligned} \tag{1}$$

where the slack variables ξ_{jn} account for non-linearly separable training sets, and C is a tunable positive scalar.

Nonlinear discriminant functions $g(\mathbf{x})$ can also be found along the lines of (1) after mapping vectors $\mathbf{x}_{jn}$ to a higher dimensional space $\mathcal{H} \subseteq \mathbb{R}^P$, with $P > p$, via a nonlinear transformation $\phi : \mathcal{X} \to \mathcal{H}$. The generalized maximum-margin linear classifier in $\mathcal{H}$ is then obtained after replacing $\mathbf{x}_{jn}$ with $\phi(\mathbf{x}_{jn})$ in (1), and solving the following optimization problem

$$\begin{aligned} \{\mathbf{w}^*, b^*\} = \arg \min_{\mathbf{w}, b, \{\xi_{jn}\}} \quad & \frac{1}{2}\|\mathbf{w}\|^2 + C\sum_{j=1}^{J}\sum_{n=1}^{N_j}\xi_{jn} \\ \text{s.t.} \quad & y_{jn}(\mathbf{w}^T\phi(\mathbf{x}_{jn}) + b) \geq 1 - \xi_{jn} \quad \forall j \in \mathcal{J},\ n = 1, \ldots, N_j \\ & \xi_{jn} \geq 0 \qquad\qquad\qquad\qquad \forall j \in \mathcal{J},\ n = 1, \ldots, N_j. \end{aligned} \tag{2}$$

Problem (2) is typically tackled by solving its dual. Letting λ_{jn} denote the Lagrange multiplier corresponding to the constraint $y_{jn}(\mathbf{w}^T\phi(\mathbf{x}_{jn}) + b) \geq 1 - \xi_{jn}$, the dual problem of (2) is:

$$\begin{aligned} \max_{\{\lambda_{jn}\}} \quad & -\frac{1}{2}\sum_{j=1}^{J}\sum_{i=1}^{J}\sum_{n=1}^{N_j}\sum_{m=1}^{N_i}\lambda_{jn}\lambda_{im}y_{jn}y_{im}\phi^T(\mathbf{x}_{jn})\phi(\mathbf{x}_{im}) + \sum_{j=1}^{J}\sum_{n=1}^{N_j}\lambda_{jn} \\ \text{s.t.} \quad & \sum_{j=1}^{J}\sum_{n=1}^{N_j}\lambda_{jn}y_{jn} = 0 \\ & 0 \leq \lambda_{jn} \leq C \qquad\qquad \forall j \in \mathcal{J},\ n = 1, \ldots, N_j. \end{aligned} \tag{3}$$

Using the Lagrange multipliers λ_{jn}^* optimizing (3), and the Karush-Kuhn-Tucker (KKT) optimality conditions, the optimal classifier parameters can be expressed as

$$\begin{aligned} \mathbf{w}^* &= \sum_{j=1}^{J} \sum_{n=1}^{N_j} \lambda_{jn}^* y_{jn} \phi(\mathbf{x}_{jn}), \\ b^* &= y_{jn} - \mathbf{w}^{*T} \phi(\mathbf{x}_{jn}) \end{aligned} \tag{4}$$

with $\mathbf{x}_{jn}$ in (4) satisfying $\lambda_{jn}^* \in (0, C)$. Training vectors corresponding to non-zero λ_{jn}^*'s constitute the SVs. Once the SVs are identified, all other training vectors with $\lambda_{jn}^* = 0$ can be discarded since they do not contribute to $\mathbf{w}^*$. From this vantage point, SVs are the most informative elements of the training set. Solving (3) does not require knowledge of ϕ but only inner product values $\phi^T(\mathbf{x}_{jn})\phi(\mathbf{x}_{im}) := K(\mathbf{x}_{jn}, \mathbf{x}_{im})$, which can be computed through a pre-selected positive semi-definite kernel $K : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$; see, for example, Schölkopf and Smola (2002, Ch. 2). Although not explicitly given, the optimal slack variables ξ_{jn}^* can be found through the KKT conditions of (2) in terms of λ_{jn}^* (Schölkopf and Smola, 2002). The optimal discriminant function can be also expressed in terms of kernels as

$$g^*(\mathbf{x}) = \sum_{j=1}^{J} \sum_{n=1}^{N_j} \lambda_{jn}^* y_{jn} K(\mathbf{x}_{jn}, \mathbf{x}) + b^* \tag{5}$$

where $b^* = y_{jn} - \sum_{i=1}^{J} \sum_{m=1}^{N_i} \lambda_{im}^* y_{im} K(\mathbf{x}_{im}, \mathbf{x}_{jn})$ for any SV $\mathbf{x}_{jn}$ with $\lambda_{jn}^* \in (0, C)$. This so-called kernel trick allows finding maximum-margin linear classifiers in higher dimensional spaces without explicitly operating in such spaces (Schölkopf and Smola, 2002).

The objective here is to develop *fully distributed* solvers of the centralized problems in (1) and (2) while guaranteeing performance approaching that of a centralized equivalent SVM. Although incremental solvers are possible, the size of information exchanges required might be excessive, especially if the number of SVs per node is large (Flouri et al., 2008; Lu et al., 2008). Recall that exchanging all local SVs among all nodes in the network several times is necessary for incremental DSVMs to approach the optimal centralized solution. Moreover, incremental schemes require a Hamiltonian cycle in the network to be identified in order to minimize the communication overhead. Computing such a cycle is an NP-hard task and in most cases a sub-optimal cycle is used at the expense of increased communication overhead. In other situations, communicating SVs directly might be prohibited because of the sensitivity of the information bore, as already mentioned in Examples 2 and 3.

3. Distributed Linear Support Vector Machine

This section presents a reformulation of the maximum-margin linear classifier problem in (1) to an equivalent distributed form, which can be solved using the alternating direction method of multipliers (ADMoM) outlined in Appendix A. (For detailed exposition of the ADMoM, see, for example, Bertsekas and Tsitsiklis, 1997.)

To this end, consider replacing the common (coupling) variables $(\mathbf{w}, b)$ in (1) with auxiliary per-node variables $\{(\mathbf{w}_j, b_j)\}_{j=1}^{J}$, and adding consensus constraints to force these variables to agree across neighboring nodes. With proper scaling of the cost by J, the proposed *consensus-based*

reformulation of (1) becomes

$$\begin{aligned} \min_{\{\mathbf{w}_j, b_j, \xi_{jn}\}} \quad & \frac{1}{2}\sum_{j=1}^{J} \|\mathbf{w}_j\|^2 + JC\sum_{j=1}^{J}\sum_{n=1}^{N_j} \xi_{jn} \\ \text{s.t.} \quad & y_{jn}(\mathbf{w}_j^T \mathbf{x}_{jn} + b_j) \geq 1 - \xi_{jn} \qquad \forall j \in \mathcal{J},\ n = 1,\ldots,N_j \\ & \xi_{jn} \geq 0 \qquad \forall j \in \mathcal{J},\ n = 1,\ldots,N_j \\ & \mathbf{w}_j = \mathbf{w}_i,\ b_j = b_i \qquad \forall j \in \mathcal{J},\ i \in \mathcal{B}_j. \end{aligned} \tag{6}$$

From a high-level view, problem (6) can be solved in a distributed fashion because each node j can optimize only the j-dependent terms of the cost, and also meet all the consensus constraints $\mathbf{w}_j = \mathbf{w}_i,\ b_j = b_i$, by exchanging messages only with nodes i in its neighborhood $\mathcal{B}_j$. What is more, network connectivity ensures that consensus in neighborhoods enables network-wide consensus. And thus, as the ensuing lemma asserts, solving (6) is equivalent to solving (1) so long as the network remains connected.

Lemma 1 *If $\{(\mathbf{w}_j, b_j)\}_{j=1}^{J}$ denotes a feasible solution of* (6)*, and the graph $\mathcal{G}$ is connected, then problems* (1) *and* (6) *are equivalent, that is, $\mathbf{w}_j = \mathbf{w}$ and $b_j = b\ \forall j = 1,\ldots,J$, where $(\mathbf{w}, b)$ is a feasible solution of* (1)*.*

Proof See Appendix B. ■

To specify how (6) can be solved using the ADMoM, define for notational brevity the augmented vector $\mathbf{v}_j := [\mathbf{w}_j^T,\ b_j]^T$, the augmented matrix $\mathbf{X}_j := [[\mathbf{x}_{j1},\ldots,\mathbf{x}_{jN_j}]^T, \mathbf{1}_j]$, the diagonal label matrix $\mathbf{Y}_j := \text{diag}([y_{j1},\ldots,y_{jN_j}])$, and the vector of slack variables $\xi_j := [\xi_{j1},\ldots,\xi_{jN_j}]^T$. With these definitions, it follows readily that $\mathbf{w}_j = (\mathbf{I}_{p+1} - \Pi_{p+1})\mathbf{v}_j$, where Π_{p+1} is a $(p+1)\times(p+1)$ matrix with zeros everywhere except for the $(p+1, p+1)$-st entry, given by $[\Pi_{p+1}]_{(p+1)(p+1)} = 1$. Thus, problem (6) can be rewritten as

$$\begin{aligned} \min_{\{\mathbf{v}_j, \xi_j, \omega_{ji}\}} \quad & \frac{1}{2}\sum_{j=1}^{J} \mathbf{v}_j^T(\mathbf{I}_{p+1} - \Pi_{p+1})\mathbf{v}_j + JC\sum_{j=1}^{J} \mathbf{1}_j^T \xi_j \\ \text{s.t.} \quad & \mathbf{Y}_j\mathbf{X}_j\mathbf{v}_j \succeq \mathbf{1}_j - \xi_j \qquad \forall j \in \mathcal{J} \\ & \xi_j \succeq \mathbf{0}_j \qquad \forall j \in \mathcal{J} \\ & \mathbf{v}_j = \omega_{ji},\ \omega_{ji} = \mathbf{v}_i \qquad \forall j \in \mathcal{J},\ \forall i \in \mathcal{B}_j \end{aligned} \tag{7}$$

where the redundant variables $\{\omega_{ji}\}$ will turn out to facilitate the decoupling of the classifier parameters $\mathbf{v}_j$ at node j from those of their neighbors at neighbors $i \in \mathcal{B}_j$.

As in the centralized case, problem (7) will be solved through its dual. Toward this objective, let α_{ji1} (α_{ji2}) denote the Lagrange multipliers corresponding to the constraint $\mathbf{v}_j = \omega_{ji}$ (respectively $\omega_{ji} = \mathbf{v}_i$), and consider what we term surrogate augmented Lagrangian function

$$\begin{aligned} \mathcal{L}(\{\mathbf{v}_j\},\{\xi_j\},\{\omega_{ji}\},\{\alpha_{jik}\}) = & \frac{1}{2}\sum_{j=1}^{J} \mathbf{v}_j^T(\mathbf{I}_{p+1} - \Pi_{p+1})\mathbf{v}_j + JC\sum_{j=1}^{J}\mathbf{1}_j^T\xi_j + \sum_{j=1}^{J}\sum_{i\in\mathcal{B}_j}\alpha_{ji1}^T(\mathbf{v}_j - \omega_{ji}) \\ & + \sum_{j=1}^{J}\sum_{i\in\mathcal{B}_j}\alpha_{ji2}^T(\omega_{ji} - \mathbf{v}_i) + \frac{\eta}{2}\sum_{j=1}^{J}\sum_{i\in\mathcal{B}_j}\|\mathbf{v}_j - \omega_{ji}\|^2 + \frac{\eta}{2}\sum_{j=1}^{J}\sum_{i\in\mathcal{B}_j}\|\omega_{ji} - \mathbf{v}_i\|^2 \end{aligned} \tag{8}$$

where the adjective "surrogate" is used because $\mathcal{L}$ does not include the set of constraints $\mathcal{W} := \{\mathbf{Y}_j\mathbf{X}_j\mathbf{v}_j \succeq \mathbf{1}_j - \xi_j,\ \xi_j \succeq \mathbf{0}_j\}$, and the adjective "augmented" because $\mathcal{L}$ includes two quadratic terms (scaled by the tuning constant $\eta > 0$) to further regularize the equality constraints in (7). The role of these quadratic terms $||\mathbf{v}_j - \omega_{ji}||^2$ and $||\omega_{ji} - \mathbf{v}_i||^2$ is twofold: (a) they effect *strict* convexity of $\mathcal{L}$ with respect to (w.r.t.) ω_{ji}, and thus ensure convergence to the unique optimum of the global cost (whenever possible), even when the local costs are convex but not strictly so; and (b) through the scalar η, they allow one to trade off speed of convergence for steady-state approximation error (Bertsekas and Tsitsiklis, 1997, Ch. 3).

Consider now solving (7) iteratively by minimizing $\mathcal{L}$ in a cyclic fashion with respect to one set of variables while keeping all other variables fixed. The multipliers $\{\alpha_{ji1}, \alpha_{ji2}\}$ must be also updated per iteration using gradient ascent. The iterations required per node j are summarized in the following lemma.

Lemma 2 *The distributed iterations solving* (7) *are*

$$\{\mathbf{v}_j(t+1), \xi_j(t+1)\} = \arg \min_{\{\mathbf{v}_j, \xi_j\} \in \mathcal{W}} \mathcal{L}(\{\mathbf{v}_j\}, \{\xi_j\}, \{\omega_{ji}(t)\}, \{\alpha_{jik}(t)\}), \tag{9}$$

$$\{\omega_{ji}(t+1)\} = \arg \min_{\{\omega_{ji}\}} \mathcal{L}(\{\mathbf{v}_j(t+1)\}, \{\xi_j(t+1)\}, \{\omega_{ji}\}, \{\alpha_{jik}(t)\}), \tag{10}$$

$$\alpha_{ji1}(t+1) = \alpha_{ji1}(t) + \eta(\mathbf{v}_j(t+1) - \omega_{ji}(t+1)) \qquad \forall j \in \mathcal{J},\ \forall i \in \mathcal{B}_j, \tag{11}$$

$$\alpha_{ji2}(t+1) = \alpha_{ji2}(t) + \eta(\omega_{ji}(t+1) - \mathbf{v}_i(t+1)) \qquad \forall j \in \mathcal{J},\ \forall i \in \mathcal{B}_j. \tag{12}$$

and correspond to the ADMoM solver reviewed in Appendix A.

Proof See Appendix C. ■

Lemma 2 links the proposed DSVM design with the convergent ADMoM solver, and thus ensures convergence of the novel MoM-DSVM to the centralized SVM classifier. However, for the particular problem at hand it is possible to simplify iterations (9)-(12). Indeed, simple inspection of (8) confirms that with all other variables fixed, the cost in (10) is linear-quadratic in ω_{ji}; hence, $\omega_{ji}(t+1)$ can be found in closed form per iteration, and the resulting closed-form expression can be substituted back to eliminate ω_{ji} from $\mathcal{L}$. Furthermore, Appendix D shows that the two sets of multipliers α_{ji1} and α_{ji2} can be combined into one set α_j after appropriate initialization of the iterations (11) and (12), as asserted by the following lemma.

Lemma 3 *Selecting* $\alpha_{ji1}(0) = \alpha_{ji2}(0) = 0_{(p+1)\times 1}$ *as initialization* $\forall j \in \mathcal{J}$, $\forall i \in \mathcal{B}_j$, *iterations* (9)-(12) *reduce to*

$$\{\mathbf{v}_j(t+1), \xi_j(t+1)\} = \arg \min_{\{\mathbf{v}_j, \xi_j\} \in \mathcal{W}} \mathcal{L}'(\{\mathbf{v}_j\}, \{\xi_j\}, \{\mathbf{v}_j(t)\}, \{\alpha_j(t)\}), \tag{13}$$

$$\alpha_j(t+1) = \alpha_j(t) + \frac{\eta}{2} \sum_{i \in \mathcal{B}_j} [\mathbf{v}_j(t+1) - \mathbf{v}_i(t+1)] \quad \forall j \in \mathcal{J} \tag{14}$$

where $\alpha_j(t) := \sum_{i\in\mathcal{B}_j} \alpha_{ji1}(t)$, *and* $\mathcal{L}'$ *is given by*

$$\mathcal{L}'(\{\mathbf{v}_j\},\{\xi_j\},\{\mathbf{v}_j(t)\},\{\alpha_j(t)\}) = \frac{1}{2}\sum_{j=1}^{J}\mathbf{v}_j^T(\mathbf{I}_{p+1}-\Pi_{p+1})\mathbf{v}_j + JC\sum_{j=1}^{J}\mathbf{1}_j^T\xi_j + 2\sum_{j=1}^{J}\alpha_j^T(t)\mathbf{v}_j + \eta\sum_{j=1}^{J}\sum_{i\in\mathcal{B}_j}\left\|\mathbf{v}_j - \frac{1}{2}[\mathbf{v}_j(t)+\mathbf{v}_i(t)]\right\|^2. \quad (15)$$

Proof See Appendix D. ■

The optimization problem in (13) involves the reduced Lagrangian $\mathcal{L}'$ in (15), which is linear-quadratic in $\mathbf{v}_j$ and ξ_j. In addition, the constraint set $\mathcal{W}$ is linear in these variables. To solve this constrained minimization problem through its dual, let $\lambda_j := [\lambda_{j1},\ldots,\lambda_{jN_j}]^T$ denote Lagrange multipliers per node corresponding to the constraints $\mathbf{Y}_j\mathbf{X}_j\mathbf{v}_j \succeq \mathbf{1}_j - \xi_j$. Solving the dual of (13) yields the optimal λ_j at iteration $t+1$, namely $\lambda_j(t+1)$, as a function of $\mathbf{v}_j(t)$ and $\alpha_j(t)$; while the KKT conditions provide expressions for $\mathbf{v}_j(t+1)$ as a function of $\alpha_j(t)$, and the optimal dual variables $\lambda_j(t+1)$. Notwithstanding, the resultant iterations are decoupled across nodes. These iterations and the associated convergence guarantees can be summarized as follows.

Proposition 1 *Consider the per node iterates* $\lambda_j(t)$, $\mathbf{v}_j(t)$ *and* $\alpha_j(t)$, *given by*

$$\lambda_j(t+1) = \arg\max_{\lambda_j:\,\mathbf{0}_j\preceq\lambda_j\preceq JC\mathbf{1}_j} -\frac{1}{2}\lambda_j^T\mathbf{Y}_j\mathbf{X}_j\mathbf{U}_j^{-1}\mathbf{X}_j^T\mathbf{Y}_j\lambda_j + \left(\mathbf{1}_j + \mathbf{Y}_j\mathbf{X}_j\mathbf{U}_j^{-1}\mathbf{f}_j(t)\right)^T\lambda_j, \quad (16)$$

$$\mathbf{v}_j(t+1) = \mathbf{U}_j^{-1}\left[\mathbf{X}_j^T\mathbf{Y}_j\lambda_j(t+1) - \mathbf{f}_j(t)\right], \quad (17)$$

$$\alpha_j(t+1) = \alpha_j(t) + \frac{\eta}{2}\sum_{i\in\mathcal{B}_j}[\mathbf{v}_j(t+1) - \mathbf{v}_i(t+1)] \quad (18)$$

where $\mathbf{U}_j := (1+2\eta|\mathcal{B}_j|)\mathbf{I}_{p+1} - \Pi_{p+1}$, $\mathbf{f}_j(t) := 2\alpha_j(t) - \eta\sum_{i\in\mathcal{B}_j}[\mathbf{v}_j(t)+\mathbf{v}_i(t)]$, $\eta > 0$, *and arbitrary initialization vectors* $\lambda_j(0)$, $\mathbf{v}_j(0)$, *and* $\alpha_j(0) = \mathbf{0}_{(p+1)\times 1}$. *The iterate* $\mathbf{v}_j(t)$ *converges to the solution of* (7), *call it* $\mathbf{v}^*$, *as* $t\to\infty$; *that is,* $\lim_{t\to\infty}\mathbf{v}_j(t) = \mathbf{v}^*$.

Proof See Appendix E. ■

Similar to the centralized SVM algorithm, if $[\lambda_j(t)]_n \neq 0$, then $[\mathbf{x}_{jn}^T, 1]^T$ is an SV. Finding $\lambda_j(t+1)$ as in (16) requires solving a quadratic optimization problem similar to the one that a centralized SVM would solve, for example, via a gradient projection algorithm or an interior point method; see for example, Schölkopf and Smola (2002, Ch. 6). However, the number of variables involved in (16) per iteration per node is considerably smaller when compared to its centralized counterpart, namely N_j versus $\sum_{j=1}^{J} N_j$. Also, the optimal local slack variables ξ_j^* can be found via the KKT conditions for (13).

The ADMoM-based DSVM (MoM-DSVM) iterations (16)-(18) are summarized as Algorithm 1, and are illustrated in Figure 2. All nodes have available JC and η. Also, every node computes its local $N_j\times N_j$ matrix $\mathbf{Y}_j\mathbf{X}_j\mathbf{U}_j^{-1}\mathbf{X}_j^T\mathbf{Y}_j$, which remains unchanged throughout the entire algorithm. Every node then updates its local $(p+1)\times 1$ estimates $\mathbf{v}_j(t)$ and $\alpha_j(t)$; and the $N_j\times 1$ vector $\lambda_j(t)$.

At iteration $t+1$, node j computes vector $\mathbf{f}_j(t)$ locally to obtain its local $\lambda_j(t+1)$ via (16). Vector $\lambda_j(t+1)$ together with the local training set $\mathcal{S}_j$ are used at node j to compute $\mathbf{v}_j(t+1)$ via (17). Next, node j broadcasts its newly updated local estimates $\mathbf{v}_j(t+1)$ to all its one-hop neighbors $i \in \mathcal{B}_j$. Iteration $t+1$ resumes when every node updates its local $\alpha_j(t+1)$ vector via (18). Note that at any given iteration t of the algorithm, each node j can evaluate its own local discriminant function $g_j^{(t)}(\mathbf{x})$ for any vector $\mathbf{x} \in \mathcal{X}$ as

$$g_j^{(t)}(\mathbf{x}) = [\mathbf{x}^T, 1]\mathbf{v}_j(t) \tag{19}$$

which from Proposition 1 is guaranteed to converge to the same solution across all nodes as $t \to \infty$. Simulated tests in Section 5 will demonstrate that after a few iterations the classification performance of (19) outperforms that of the local discriminant function obtained based on the local training set alone. The effect of η on the convergence rate of MoM-DSVM will be tested numerically in Section 5.

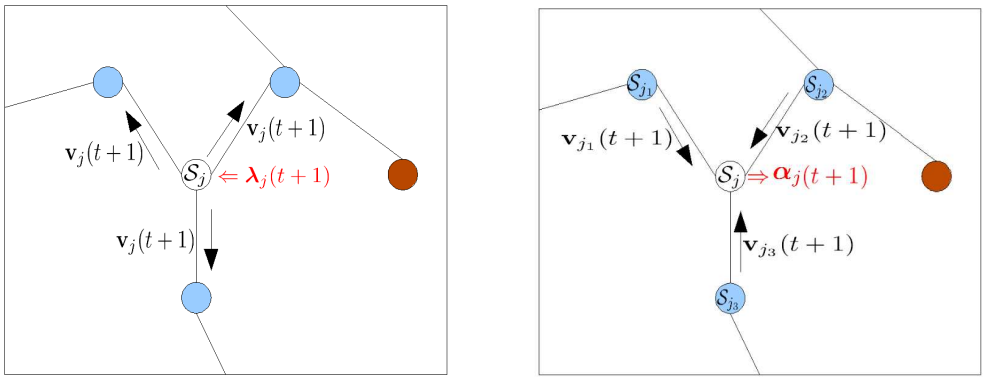

Figure 2: Visualization of iterations (16)-(18): (left) every node $j \in \mathcal{J}$ computes $\lambda_j(t+1)$ to obtain $\mathbf{v}_j(t+1)$, and then broadcasts $\mathbf{v}_j(t+1)$ to all neighbors $i \in \mathcal{B}_j$; (right) once every node $j \in \mathcal{J}$ has received $\mathbf{v}_i(t+1)$ from all $i \in \mathcal{B}_j$, it computes $\alpha_j(t+1)$.

Remark 1 *The messages exchanged among neighboring nodes in the MoM-DSVM algorithm correspond to local estimates $\mathbf{v}_j(t)$, which together with the local multiplier vectors $\alpha_j(t)$, convey sufficient information about the local training sets to achieve consensus globally. Per iteration and per node a message of* fixed size $(p+1)\times 1$ *is broadcasted (vectors α_j are not exchanged among nodes.) This is to be contrasted with incremental DSVM algorithms in, for example, Lu et al. (2008), Flouri et al. (2006) and Flouri et al. (2008), where the size of the messages exchanged between neighboring nodes depends on the number of SVs found at each incremental step. Although the SVs of each training set may be few, the overall number of SVs may remain large, thus consuming considerable power when transmitting SVs from one node to the next.*

Remark 2 *Real networks are prone to node failures, for example, sensors in a WSN may run out of battery during operation. Thanks to its fully decentralized mode of operation, the novel MoM-DSVM algorithm guarantees that the remaining nodes in the network will reach consensus as long as the*

node that fails, say $j_o \in \mathcal{J}$, does not correspond to a cut-vertex *of $\mathcal{G}$. In this case, the operational network graph $\mathcal{G}_o := \mathcal{G} - j_o$ remains connected, and thus surviving nodes can percolate information throughout $\mathcal{G}_o$. Of course, $\mathcal{S}_{j_o}$ will not participate in training the SVM. If j_o is a* cut-vertex *of $\mathcal{G}$, the algorithm will remain operational in each connected component of the resulting sub-graph $\mathcal{G}_o$, reaching consensus among nodes in each of the connected components.*

3.1 Online Distributed Support Vector Machine

In many distributed learning tasks data arrive sequentially, and possibly asynchronously. In addition, the processes to be learned may change with time. In such cases, training examples need to be added or removed from each local training set $\mathcal{S}_j$. Training sets of increasing of decreasing size can be expressed in terms of *time-varying* augmented data matrices $\mathbf{X}_j(t)$, and corresponding label matrices $\mathbf{Y}_j(t)$. An online version of DSVM is thus well motivated when a new training example $\mathbf{x}_{jn}(t)$ along with its label $y_{jn}(t)$ acquired at time t are incorporated into $\mathbf{X}_j(t)$ and $\mathbf{Y}_j(t)$, respectively. The corresponding modified iterations are given by (cf. (16)-(18))

$$\lambda_j(t+1) = \arg\max_{\lambda_j:\, \mathbf{0} \preceq \lambda_j \preceq JC\mathbf{1}_j(t+1)} -\frac{1}{2}\lambda_j^T \mathbf{Y}_j(t+1)\mathbf{X}_j(t+1)\mathbf{U}_j^{-1}\mathbf{X}_j(t+1)^T\mathbf{Y}_j(t+1)\lambda_j + \left(\mathbf{1}_j - \mathbf{Y}_j(t+1)\mathbf{X}_j(t+1)\mathbf{U}_j^{-1}\mathbf{f}_j(t)\right)^T \lambda_j, \quad (20)$$

$$\mathbf{v}_j(t+1) = \mathbf{U}_j^{-1}\left(\mathbf{X}_j(t+1)^T\mathbf{Y}_j(t+1)\lambda_j(t+1) - 2\alpha_j(t) + \eta\sum_{i\in\mathcal{B}_j}[\mathbf{v}_j(t) + \mathbf{v}_i(t)]\right), \quad (21)$$

$$\alpha_j(t+1) = \alpha_j(t) + \frac{\eta}{2}\sum_{i\in\mathcal{B}_j}[\mathbf{v}_j(t+1) - \mathbf{v}_i(t+1)]. \quad (22)$$

Note that the dimensionality of λ_j must vary to accommodate the variable number of $\mathcal{S}_j$ elements at every time instant t. The online MoM-DSVM classifier is summarized as Algorithm 2. For this algorithm to run, no conditions need to be imposed on how the sets $\mathcal{S}_j(t)$ increase or decrease. Their changes can be asynchronous and may comprise multiple training examples at once. In principle,

Algorithm 2 Online MoM-DSVM

Require: Randomly initialize $\mathbf{v}_j(0)$, and $\alpha_j(0) = \mathbf{0}_{(p+1)\times 1}$ for every $j \in \mathcal{J}$.

for $t = 0, 1, 2, \ldots$ **do**
  for all $j \in \mathcal{J}$ **do**
    Update $\mathbf{Y}_j(t+1)\mathbf{X}_j(t+1)\mathbf{U}_j^{-1}\mathbf{X}_j(t+1)^T\mathbf{Y}_j(t+1)$.
    Compute $\lambda_j(t+1)$ via (20).
    Compute $\mathbf{v}_j(t+1)$ via (21).

    Compute $\alpha_j(t+1)$ via (22).
  end for
end for

the parameters η and C can also become time-dependent. The effect of these parameters will be discussed in Section 5.

Intuitively speaking, if the training sets remain invariant across a sufficient number of time instants, $\mathbf{v}_j(t)$ will closely track the optimal linear classifier. Rigorous convergence analysis of Algorithm 2 for any given rate of change of the training set goes beyond the scope of this work. Simulations will however demonstrate that the modified iterations in (20)-(22) are able to track changes in the training sets even when these occur at every time instant t.

Remark 3 *Compared to existing* centralized *online SVM alternatives in, for example, Cauwenberghs and Poggio (2000) and Fung and Mangasarian (2002), the online MoM-DSVM algorithm of this section allows seamless integration of both distributed and online processing. Nodes with training sets available at initialization and nodes that are acquiring their training sets online can be integrated to jointly find the maximum-margin linear classifier. Furthermore, whenever needed, the online MoM-DSVM can return a partially trained model constructed with examples available to the network at any given time. Likewise, elements of the training sets can be removed without having to restart the MoM-DSVM algorithm. This feature also allows adapting MoM-DSVM to jointly operate with algorithms that account for concept drift (Klinkenberg and Joachims, 2000). In the classification context, concept drift defines a change in the true classification boundaries between classes. In general, accounting for concept drift requires two main steps, which can be easily handled by the online MoM-DSVM: (i) acquisition of updated elements in the training set that better describe the current concept; and (ii) removal of outdated elements from the training set.*

4. Distributed Nonlinear Support Vector Machine

In Section 3, problem (1) was reformulated to allow all nodes to consent on $\mathbf{v}^*$. However, applying an identical reformulation to the nonlinear classification problem in (2) would require updates in

(16)-(18) to be carried in $\mathcal{H}$. As the dimensionality P of $\mathcal{H}$ increases, the local computation and communication complexities become increasingly prohibitive.

Our approach to mitigate this well-known "curse of dimensionality" is to enforce consensus of the local discriminants g_j^* on a subspace of reduced rank $L < P$. To this end, we project the consensus constraints corresponding to (2) and consider the optimization problem (cf. (6))

$$\begin{aligned} \min_{\{\mathbf{w}_j, b_j, \boldsymbol{\xi}_j\}} \quad & \frac{1}{2}\sum_{j=1}^{J}\|\mathbf{w}_j\|^2 + JC\sum_{j=1}^{J}\mathbf{1}_j^T\boldsymbol{\xi}_j \\ \text{s.t.} \quad & \mathbf{Y}_j(\boldsymbol{\Phi}(\mathbf{X}_j)\mathbf{w}_j + \mathbf{1}_j b_j) \succeq \mathbf{1}_j - \boldsymbol{\xi}_j \quad \forall j \in \mathcal{J} \\ & \boldsymbol{\xi}_j \succeq \mathbf{0}_j \quad \forall j \in \mathcal{J} \\ & \mathbf{G}\mathbf{w}_j = \mathbf{G}\mathbf{w}_i \quad \forall j \in \mathcal{J}, i \in \mathcal{B}_j \\ & b_j = b_i \quad \forall j \in \mathcal{J}, i \in \mathcal{B}_j \end{aligned} \tag{23}$$

where $\boldsymbol{\Phi}(\mathbf{X}_j) := [\phi(\mathbf{x}_{j1}), \ldots, \phi(\mathbf{x}_{jN_j})]^T$, and $\mathbf{G} := [\phi(\boldsymbol{\chi}_1), \ldots, \phi(\boldsymbol{\chi}_L)]^T$ is a fat $L \times P$ matrix common to all nodes with preselected vectors $\{\boldsymbol{\chi}_l\}_{l=1}^L$ specifying its rows. Each $\boldsymbol{\chi}_l \in \mathcal{X}$ corresponds to a $\phi(\boldsymbol{\chi}_l) \in \mathcal{H}$, which at the optimal solution $\{\mathbf{w}_j^*, b_j^*\}_{j=1}^J$ of (23), satisfies $\phi^T(\boldsymbol{\chi}_l)\mathbf{w}_1^* = \cdots = \phi^T(\boldsymbol{\chi}_l)\mathbf{w}_J^* = \phi^T(\boldsymbol{\chi}_l)\mathbf{w}^*$. The projected constraints $\{\mathbf{G}\mathbf{w}_j = \mathbf{G}\mathbf{w}_i\}$ along with $\{b_j = b_i\}$ force all nodes to agree on the value of the local discriminant functions $g_j^*(\boldsymbol{\chi}_l)$ at the vectors $\{\boldsymbol{\chi}_l\}_{l=1}^L$, but not necessarily for all $\mathbf{x} \in \mathcal{X}$. This is the price paid for reducing the computational complexity of (23) to an affordable level. Clearly, the choice of vectors $\{\boldsymbol{\chi}_l\}_{l=1}^L$, their number L, and the local training sets $\mathcal{S}_j$ determine how similar the local discriminant functions g_j^* are. If $\mathbf{G} = \mathbf{I}_P$, then (23) reduces to (6), and $g_1^*(\mathbf{x}) = \ldots = g_J^*(\mathbf{x}) = g^*(\mathbf{x}), \forall \mathbf{x} \in \mathcal{X}$, but the high dimensionality challenge appears. At the end of this section, we will provide different design choices for $\{\boldsymbol{\chi}_l\}_{l=1}^L$, and test them via simulations in Section 5.

Because the cost in (23) is strictly convex w.r.t. $\mathbf{w}_j$, it guarantees that the set of optimal vectors $\{\mathbf{w}_j^*\}$ is unique even when $\mathbf{G}$ is a 'fat' matrix ($L < P$) and/or ill-conditioned (Bertsekas, 1999, Prop. 5.2.1). As in (2), having $\{\mathbf{w}_j^*\}$ known is of limited use, since the mapping ϕ may be unknown, or if known, evaluating vectors $\phi(\mathbf{x})$ may entail an excessive computational cost. Fortunately, the resulting discriminant function $g_j^*(\mathbf{x})$ admits a reduced-complexity solution because it can be expressed in terms of kernels, as shown by the following theorem.

Theorem 4 *For every positive semi-definite kernel $K(\cdot,\cdot)$, the discriminant functions $g_j^*(\mathbf{x}) = \phi^T(\mathbf{x})\mathbf{w}_j^* + b_j^*$ with $\{\mathbf{w}_j^*, b_j^*\}$ denoting the optimal solution of* (23)*, can be written as*

$$g_j^*(\mathbf{x}) = \sum_{n=1}^{N_j} a_{jn}^* K(\mathbf{x}, \mathbf{x}_{jn}) + \sum_{l=1}^{L} c_{jl}^* K(\mathbf{x}, \boldsymbol{\chi}_l) + b_j^*, \ \forall j \in \mathcal{J} \tag{24}$$

where $\{a_{jn}^*\}$ and $\{c_{jl}^*\}$ are real-valued scalar coefficients.

Proof See Appendix F. ■

The space of functions g_j described by (24) is fully determined by the span of the kernel function $K(\cdot,\cdot)$ centered at training vectors $\{\mathbf{x}_{jn}, n = 1, \ldots, N_j\}$ per node, and also at the vectors $\{\boldsymbol{\chi}_l\}_{l=1}^L$ which are common to all nodes. Thus, similarity of the discriminant functions g_j^* across nodes is

naturally constrained by the corresponding $\mathcal{S}_j$. Theorem 1 also reveals the effect of $\{\chi_l\}_{l=1}^L$ on the $\{g_j^*\}$. By introducing vectors $\{\chi_l\}_{l=1}^L$ common to all nodes, a subset of basis functions common to all local functional spaces is introduced a fortiori. Coefficients a_{jn}^* and c_{jl}^* are found so that all local discriminants g_j^* agree on their values at points $\{\chi_l\}_{l=1}^L$. Intuitively, at every node these coefficients summarize the global information available to the network.

Theorem 1 is an existence result whereby each nonlinear discriminant function g_j^* is expressible in terms of $\mathcal{S}_j$ and $\{\chi_l\}_{l=1}^L$. However, finding the coefficients a_{jn}^*, c_{jl}^* and b_j^* in a distributed fashion remains an issue. Next, it is shown that these coefficients can be obtained iteratively by applying the ADMoM solver to (23).

Similar to (7), introduce auxiliary variables $\{\omega_{ji}\}$ ($\{\zeta_{ji}\}$) to decouple the constraints $\mathbf{G}\mathbf{w}_j = \mathbf{G}\mathbf{w}_i$ ($b_j = b_i$) across nodes, and α_{jik} (β_{jik}) denote the corresponding Lagrange multipliers (cf. (8)). The surrogate augmented Lagrangian for problem (23) is then

$$\begin{aligned}\mathcal{L}(\{\mathbf{w}_j\},\{\xi_j\},\{\omega_{ji}\},\{\alpha_{jik}\},\{\zeta_{ji}\},\{\beta_{jik}\}) &= \frac{1}{2}\sum_{j=1}^J \|\mathbf{w}_j\|^2 + JC\sum_{j=1}^J \mathbf{1}_j^T\xi_j + \sum_{j=1}^J\sum_{i\in\mathcal{B}_j}\alpha_{ji1}^T(\mathbf{G}\mathbf{w}_j-\omega_{ji}) \\ &+ \sum_{j=1}^J\sum_{i\in\mathcal{B}_j}\alpha_{ji2}^T(\omega_{ji}-\mathbf{G}\mathbf{w}_i) + \sum_{j=1}^J\sum_{i\in\mathcal{B}_j}\beta_{ji1}(b_j-\zeta_{ji}) + \sum_{j=1}^J\sum_{i\in\mathcal{B}_j}\beta_{ji2}(\zeta_{ji}-b_i) \\ &+ \frac{\eta}{2}\sum_{j=1}^J\sum_{i\in\mathcal{B}_j}\|\mathbf{G}\mathbf{w}_j-\omega_{ji}\|^2 + \frac{\eta}{2}\sum_{j=1}^J\sum_{i\in\mathcal{B}_j}\|\omega_{ji}-\mathbf{G}\mathbf{w}_i\|^2 + \frac{\eta}{2}\sum_{j=1}^J\sum_{i\in\mathcal{B}_j}\|b_j-\zeta_{ji}\|^2 + \frac{\eta}{2}\sum_{j=1}^J\sum_{i\in\mathcal{B}_j}\|\zeta_{ji}-b_i\|^2.\end{aligned}$$

Following the steps of Lemma 2, and with $\{\alpha_{jik}\}$ and $\{\beta_{jik}\}$ initialized at zero, the ADMoM iterations take the form

$$\{\mathbf{w}_j(t+1), b_j(t+1), \xi_j(t+1)\} = \arg\min_{\{\mathbf{w}_j,b_j,\xi_j\}\in\mathcal{W}} \mathcal{L}'(\{\mathbf{w}_j\},\{b_j\},\{\xi_j\},\{\alpha_j(t)\},\{\beta_j(t)\}), \tag{25}$$

$$\alpha_j(t+1) = \alpha_j(t) + \frac{\eta}{2}\sum_{i\in\mathcal{B}_j}\mathbf{G}[\mathbf{w}_j(t+1) - \mathbf{w}_i(t+1)], \tag{26}$$

$$\beta_j(t+1) = \beta_j(t) + \frac{\eta}{2}\sum_{i\in\mathcal{B}_j}[b_j(t+1) - b_i(t+1)] \tag{27}$$

where $\mathcal{L}'$ is defined similar to (8), $\alpha_j(t)$ as in Lemma 3, and $\beta_j(t) := \sum_{i\in\mathcal{B}_j}\beta_{ji1}(t)$. The ADMoM iterations (25)-(27) will not be explicitly solved since iterates $\mathbf{w}_j(t)$ lie in the high-dimensional space $\mathcal{H}$. Nevertheless, our objective is not to find $\mathbf{w}_j^*$, but rather the discriminant function $g_j^*(\mathbf{x})$. To this end, let $\Gamma := [\chi_1,\ldots,\chi_L]^T$, and define the kernel matrices with entries

$$[\mathbf{K}(\mathbf{X}_j,\mathbf{X}_j)]_{n,m} := K(\mathbf{x}_{jn},\mathbf{x}_{jm}), \tag{28}$$

$$[\mathbf{K}(\mathbf{X}_j,\Gamma)]_{n,l} := K(\mathbf{x}_{jn},\chi_l), \tag{29}$$

$$[\mathbf{K}(\Gamma,\Gamma)]_{l,l'} := K(\chi_l,\chi_{l'}). \tag{30}$$

From Theorem 1 it follows that each local update $g_j^{(t)}(\mathbf{x}) = \phi^T(\mathbf{x})\mathbf{w}_j(t) + b_j(t)$ admits per iteration t a solution expressed in terms of kernels. The latter is specified by the coefficients $\{a_{jn}(t)\}$, $\{c_{jl}(t)\}$ and $\{b_j(t)\}$ that can be obtained in closed form, as shown in the next proposition.

Proposition 2 *Let* $\lambda_j := [\lambda_{j1},\ldots,\lambda_{jN_j}]^T$ *denote the Lagrange multiplier corresponding to the constraint* $\mathbf{Y}_j(\Phi(\mathbf{X}_j)\mathbf{w}_j+\mathbf{1}_j b_j) \succeq \mathbf{1}_j-\xi_j$, *and* $\widetilde{\mathbf{w}}_j(t) := \mathbf{G}\mathbf{w}_j(t)$. *The local discriminant function* $g_j^{(t)}(\mathbf{x})$ *at iteration* t *is*

$$g_j^{(t)}(\mathbf{x}) = \sum_{n=1}^{N_j} a_{jn}(t)K(\mathbf{x},\mathbf{x}_{jn}) + \sum_{l=1}^{L} c_{jl}(t)K(\mathbf{x},\chi_l) + b_j(t) \tag{31}$$

where $\mathbf{a}_j(t) := [a_{j1}(t),\ldots,a_{jN_j}(t)]^T$, $\mathbf{c}_j(t) := [c_{j1}(t),\ldots,c_{jL}(t)]^T$, *and* $b_j(t)$ *are given by*

$$\mathbf{a}_j(t) := \mathbf{Y}_j\lambda_j(t), \tag{32}$$

$$\mathbf{c}_j(t) := 2\eta|\mathcal{B}_j|\widetilde{\mathbf{U}}_j^{-1}\left[\mathbf{K}(\Gamma,\Gamma)\mathbf{f}_j(t)-\mathbf{K}(\Gamma,\mathbf{X}_j)\mathbf{Y}_j\lambda_j(t)\right]-\widetilde{\mathbf{f}}_j(t), \tag{33}$$

$$b_j(t) := \frac{1}{2\eta|\mathcal{B}_j|}\left[\mathbf{1}_j^T\mathbf{Y}_j\lambda_j(t)-h_j(t)\right] \tag{34}$$

with $\lambda_j(t)$ *denoting the vector multiplier update available at iteration* t, $\widetilde{\mathbf{U}}_j := \mathbf{I}_L+2\eta|\mathcal{B}_j|\mathbf{K}(\Gamma,\Gamma)$, $\widetilde{\mathbf{f}}_j(t) := 2\alpha_j(t)-\eta\sum_{i\in\mathcal{B}_j}[\widetilde{\mathbf{w}}_j(t)+\widetilde{\mathbf{w}}_i(t)]$ *and* $h_j(t) := 2\beta_j(t)-\eta\sum_{i\in\mathcal{B}_j}[b_j(t)+b_i(t)]$.

Proof See Appendix G. ■

Proposition 2 asserts that in order to find $\mathbf{a}_j(t)$, $\mathbf{c}_j(t)$ and $b_j(t)$ in (32), (33) and (34), it suffices to obtain $\lambda_j(t)$, $\widetilde{\mathbf{w}}_j(t)$, $b_j(t)$, $\alpha_j(t)$, and $\beta_j(t)$. Note that finding the $L\times 1$ vector $\widetilde{\mathbf{w}}_j(t)$ from $\mathbf{w}_j(t)$ incurs complexity of order $O(L)$. The next proposition shows how to iteratively update $\lambda_j(t)$, $\widetilde{\mathbf{w}}_j(t)$, $b_j(t)$, $\alpha_j(t)$, and $\beta_j(t)$ in a distributed fashion.

Proposition 3 *The iterates* $\lambda_j(t)$, $\widetilde{\mathbf{w}}_j(t)$, $b_j(t)$, $\alpha_j(t)$ *and* $\beta_j(t)$ *can be obtained as*

$$\begin{aligned}\lambda_j(t+1) = \arg\max_{\lambda_j:\,\mathbf{0}_j\preceq\lambda_j\preceq JC\mathbf{1}_j} &-\frac{1}{2}\lambda_j^T\mathbf{Y}_j\left(\mathbf{K}(\mathbf{X}_j,\mathbf{X}_j)-\widetilde{\mathbf{K}}(\mathbf{X}_j,\mathbf{X}_j)+\frac{\mathbf{1}_j\mathbf{1}_j^T}{2\eta|\mathcal{B}_j|}\right)\mathbf{Y}_j\lambda_j+\mathbf{1}_j^T\lambda_j\\ &-\left(\widetilde{\mathbf{f}}_j^T(t)\left(\mathbf{K}(\Gamma,\mathbf{X}_j)-\widetilde{\mathbf{K}}(\Gamma,\mathbf{X}_j)\right)+h_j(t)\frac{\mathbf{1}^T}{2\eta|\mathcal{B}_j|}\right)\mathbf{Y}_j\lambda_j,\end{aligned} \tag{35}$$

$$\widetilde{\mathbf{w}}_j(t+1) = \left[\mathbf{K}(\Gamma,\mathbf{X}_j)-\widetilde{\mathbf{K}}(\Gamma,\mathbf{X}_j)\right]\mathbf{Y}_j\lambda_j(t+1)-\left[\mathbf{K}(\Gamma,\Gamma)-\widetilde{\mathbf{K}}(\Gamma,\Gamma)\right]\widetilde{\mathbf{f}}_j(t), \tag{36}$$

$$b_j(t+1) = \frac{1}{2\eta|\mathcal{B}_j|}\left[\mathbf{1}_j^T\mathbf{Y}_j\lambda_j(t+1)-h_j(t)\right], \tag{37}$$

$$\alpha_j(t+1) = \alpha_j(t)+\frac{\eta}{2}\sum_{i\in\mathcal{B}_j}[\widetilde{\mathbf{w}}_j(t+1)-\widetilde{\mathbf{w}}_i(t+1)], \tag{38}$$

$$\beta_j(t+1) = \beta_j(t)+\frac{\eta}{2}\sum_{i\in\mathcal{B}_j}[b_j(t+1)-b_i(t+1)] \tag{39}$$

where $\widetilde{\mathbf{K}}(\mathbf{Z},\mathbf{Z}') := 2\eta|\mathcal{B}_j|\mathbf{K}(\mathbf{Z},\Gamma)\widetilde{\mathbf{U}}_j^{-1}\mathbf{K}(\Gamma,\mathbf{Z}')$. *With arbitrary initialization* $\lambda_j(0)$, $\widetilde{\mathbf{w}}_j(0)$, *and* $b_j(0)$*; and* $\alpha_j(0)=\mathbf{0}_{L\times 1}$ *and* $\beta_j(0)=0$, *the iterates* $\{a_{jn}(t)\}$, $\{c_{jl}(t)\}$ *and* $\{b_j(t)\}$ *in* (32), (33) *and* (34) *converge to* $\{a_{jn}^*\}$, $\{c_{jl}^*\}$ *and* $\{b_j^*\}$ *in* (24), *as* $t\to\infty$, $\forall\, j\in\mathcal{J}, n=1,\ldots,N_j$, *and* $l=1,\ldots,L$.

The iterations comprising the ADMoM-based non-linear DSVM (MoM-NDSVM) are summarized as Algorithm 3. It is important to stress that Algorithm 3 starts by having all nodes agree on the common quantities Γ, JC, η, and $K(\cdot,\cdot)$. Also, each node computes its local kernel matrices as in (28)-(30), which remain unchanged throughout. Subsequently, Algorithm 3 runs in a manner analogous to Algorithm 1, with the difference that every node communicates an $(L+1)\times 1$ vector (instead of $(p+1)\times 1$) for its neighbors to receive $\widetilde{\mathbf{w}}_j(t)$ and $b_j(t)$.

4.1 On the Optimality of NDSVM and the Selection of Common Vectors

By construction, Algorithm 3 produces local discriminant functions whose predictions for $\{\chi_l\}_{l=1}^L$ are the same for all nodes in the network; that is, $g_1^*(\chi_l)=\ldots=g_J^*(\chi_l)=g^*(\chi_l)$ for $l=1,\ldots,L$, where $g^*(\chi_l)=\phi^T(\chi_l)\mathbf{w}^*+b^*$, and $\{\mathbf{w}^*,b^*\}$ are the optimal solution of the centralized problem (2). Viewing $\{\chi_l\}_{l=1}^L$ as a classification query, the proposed MoM-NDSVM algorithm can be implemented as follows. Having this query presented at any node j entailing a set of unlabeled vectors $\{\chi_l\}_{l=1}^L$, the novel scheme first percolates $\{\chi_l\}_{l=1}^L$ throughout the network.[3] Problem (23) is subsequently solved in a distributed fashion using Algorithm 3. Notice that in this procedure no database information is shared.

Although optimal in the sense of being convergent to its centralized counterpart, the algorithm just described needs to be run for every new classification query. Alternatively, one can envision procedures to find discriminant functions in a distributed fashion that classify new queries without having to re-run the distributed algorithm. The key is to pre-select a *fixed* set $\{\chi_l\}_{l=1}^L$ for which g^* in (5) is (approximately) equivalent to g_j^* in (24) for all $j\in\mathcal{J}$. From Theorem 1, we know that all local functions g_j^* share a common space spanned by the χ_l-induced kernels $\{K(\cdot,\chi_l)\}$. If the space $\mathcal{H}$ where g^* lies is finite dimensional, for example, when adopting linear or polynomial

3. Percolating $\{\chi\}_{l=1}^L$ in a distributed fashion through the network can be carried in a finite number of iterations at most equal to the diameter of the network.

kernels in (5), one can always find a finite-size set $\{\chi_l\}_{l=1}^L$ such that the space spanned by the set of kernels $\{K(\cdot,\chi_l)\}$ contains $\mathcal{H}$, and thus $g_1^*(\mathbf{x}) = \ldots = g_J^*(\mathbf{x}) = g^*(\mathbf{x})\ \forall \mathbf{x} \in \mathcal{X}$ (Predd et al., 2006). Indeed, when using linear kernels, the MoM-NDSVM developed here boils down to the MoM-DSVM developed in Section 3 for a suitable finite-size set $\{\chi_l\}_{l=1}^L$.

In general, however, the space spanned by $\{K(\cdot,\chi_l)\}$ may have lower dimensionality than $\mathcal{H}$; thus, local functions g_j^* do not coincide at every point. In this case, MoM-NDSVM finds local approximations to the centralized g^* which accommodate information available to all nodes. The degree of approximation depends on the choice of $\{\chi_l\}_{l=1}^L$. In what follows, we describe two alternatives to constructing such a set $\{\chi_l\}_{l=1}^L$.

- **Grid-based designs**. Consider every entry k of the training vectors $\{\mathbf{x}_{jn}\}$, and form the intervals $I_k := [x_k^{\min}, x_k^{\max}]$, $k = 1,\ldots,p$, where $x_k^{\min} := \min_{j\in\mathcal{J},\, n=1,\ldots,N_j}[\mathbf{x}_{jn}]_k$ and $x_k^{\max} := \max_{j\in\mathcal{J},\, n=1,\ldots,N_j}[\mathbf{x}_{jn}]_k$. Take for convenience $L = M^p$, and partition uniformly each I_k to obtain a set of M equidistant points $Q_k := \{q_{k1},\ldots,q_{kM}\}$. The set $\{\chi_l\}_{l=1}^L$ can be formed by taking all M^p possible vectors with entries drawn from the Cartesian product $Q_1 \times \ldots, \times Q_p$. One possible set we use for generating the $\{\chi_l\}_{l=1}^L$ vectors is obtained by selecting the k-th entry of the l-th vector as $[\chi_l]_k = q_{k,\left(\frac{l}{M^{k-1}} \bmod M\right)+1}$, where $l = 1,\ldots,M^p$ and $k = 1,\ldots,p$. In this case, MoM-NDSVM performs a global consensus step on the entry-wise maxima and minima of the training vectors $\{\mathbf{x}_{jn}\}$. Global consensus on the entry-wise maxima and minima can be computed exactly in a finite number of iterations equal to at most the diameter of the graph $\mathcal{G}$.

- **Random designs**. Once again, we consider every entry k of the training vectors $\{\mathbf{x}_{jn}\}$. MoM-NDSVM starts by performing a consensus step on the entry-wise maxima and minima of the local training vectors $\{\mathbf{x}_{jn}\}$. The set $\{\chi_l\}_{l=1}^L$ is formed by drawing elements χ_l randomly from a uniform p-dimensional distribution with extreme points per entry given by the extreme points $x_k^{\min}$ and $x_k^{\max}$, $k = 1,\ldots,p$. To agree on the set $\{\chi_l\}_{l=1}^L$, all nodes in the network are assumed to share a common seed used to initialize the random sampling algorithms.

As mentioned earlier, the number of points L affects how close local functions are to each other as well as to the centralized one. The choice of L also depends on the kernel used, prior knowledge of the discriminant function, and the available local training data N_j. Increasing L guarantees that local functions will be asymptotically close to each other regardless of N_j; however, the communication cost and computational complexity per node will increase according to L [cf. Algorithm 3]. On the other hand, a small L reduces the communication overhead at the price of increasing the disagreement among the g_j^*'s. This trade-off will be further explored in the ensuing section through simulated tests.

5. Numerical Simulations

In this section, we analyze the performance of both MoM-DSVM and MoM-NDSVM algorithms using different networks with synthetic and real-world training sets. Although we focus on the binary classification case, it is worth remembering that K-ary classification problems with $K > 2$ can be solved via binary classification schemes, for example, by using one versus all classifiers, or all versus all classifiers (Duda et al., 2002, Ch. 5).

5.1 Linear Classifiers

In this section, we present experiments on synthetic and real data to illustrate the performance of our distributed method for training linear SVMs.

5.1.1 TEST CASE 1: SYNTHETIC TRAINING SET

Consider a randomly generated network with $J = 30$ nodes. The network is connected with algebraic connectivity 0.0448 and average degree per node 3.267. Each node acquires labeled training examples from two different classes $\mathcal{C}_1$ and $\mathcal{C}_2$ with corresponding labels $y_1 = 1$ and $y_2 = -1$. Classes $\mathcal{C}_1$ and $\mathcal{C}_2$ are equiprobable and consist of random vectors drawn from a two-dimensional Gaussian distribution with common covariance matrix $\mathbf{\Sigma} = [1,\ 0;\ 0,\ 2]$, and mean vectors $m_1 = [-1,\ -1]^T$ and $m_2 = [1,\ 1]^T$, respectively. Each local training set $\mathcal{S}_j$ consists of $N_j = N = 10$ labeled examples and was generated by: (i) randomly choosing class $\mathcal{C}_k, k = 1,2$; and, (ii) randomly generating a labeled example $(\mathbf{x}_{jn}^T, y_{jn} = \mathcal{C}_k)$ with $\mathbf{x}_{jn} \sim \mathcal{N}(m_k, \mathbf{\Sigma})$. Thus, the global training set contains $JN = 300$ training examples. Likewise, a test set $\mathcal{S}_{\text{Test}} := \{(\widetilde{\mathbf{x}}_n, \widetilde{y}_n),\ n = 1,\ldots,N_T\}$ with $N_T = 600$ examples, drawn as in (i) and (ii), is used to evaluate the generalization performance of the classifiers. The Bayes optimal classifier for this 2-class problem is linear (Duda et al., 2002, Ch. 2), with risk $\mathbf{R}_{\text{Bayes}} = 0.1103$. The empirical risk of the centralized SVM in (1) is defined as

$$\mathbf{R}_{\text{emp}}^{\text{central}} := \frac{1}{N_T} \sum_{n=1}^{N_T} \frac{1}{2} |\widetilde{y}_n - \hat{y}_n|$$

where $\hat{y}_n$ is the predicted label for $\widetilde{\mathbf{x}}_n$. The average empirical risk of the MoM-DSVM algorithm as a function of the number of iterations is defined as

$$\mathbf{R}_{\text{emp}}(t) := \frac{1}{JN_T} \sum_{j=1}^{J} \sum_{n=1}^{N_T} \frac{1}{2} |\widetilde{y}_n - \hat{y}_{jn}(t)| \tag{40}$$

where $\hat{y}_{jn}(t)$ is the label prediction at iteration t and node j for $\widetilde{\mathbf{x}}_n$, $n = 1,\ldots,N_T$ using the SVM parameters in $\mathbf{v}_j(t)$. The average empirical risk of the local SVMs across nodes $\mathbf{R}_{\text{emp}}^{\text{local}}$ is defined as in (40) with $\hat{y}_{jn}$ found using only locally-trained SVMs.

Figure 3 (left) depicts the risk of the MoM-DSVM algorithm as a function of the number of iterations t for different values of JC. In this test, $\eta = 10$ and a total of 500 Monte Carlo runs are performed with randomly drawn local training and test sets per run. The centralized and local empirical risks with $C = 10$ are included for comparison. The average local prediction performance is also evaluated. Clearly, the risk of the MoM-DSVM algorithm reduces as the number of iterations increases, quickly outperforming local-based predictions and approaching that of the centralized benchmark. To further visualize this test case, Figure 3 (right) shows the global training set, along with the linear discriminant functions found by the centralized SVM and the MoM-DSVM at two different nodes after 400 iterations with $JC = 20$ and $\eta = 10$. Local SVM results for two different nodes are also included for comparison.

5.1.2 TEST CASE 2: MNIST TRAINING SET

Here, the MoM-DSVM is tested on the MNIST database of handwritten images (Lecun et al., 1998). The MNIST database contains images of digits 0 to 9. All images are of size 28 by 28 pixels. We consider the binary problem of classifying digit 2 versus digit 9 using a linear classifier. For this

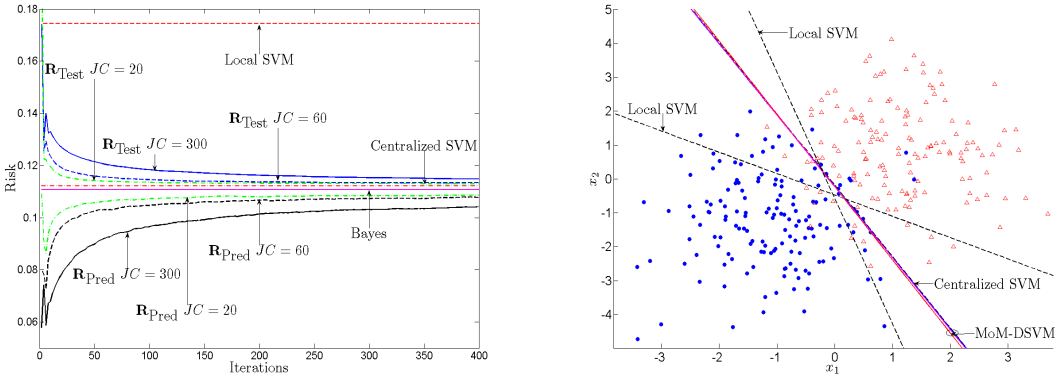

Figure 3: Evolution of the test error ($\mathbf{R}_{\text{Test}}$) and prediction error ($\mathbf{R}_{\text{Pred}}$) of MoM-DSVM for a two-class problem using synthetic data and a network with $J = 30$ nodes. Centralized SVM performance and average local SVMs performance are also plot for comparison (left). Decision boundary comparison among MoM-DSVM, centralized SVM and local SVM results for synthetic data generated from two Gaussian classes (right).

experiment each image is vectorized to a 784 by 1 vector. In particular, we take 5,900 training samples per digit, and a test set of 1,000 samples per digit. Both training and test sets used are as given by the MNIST database, that is, there is no preprocessing of the data. For simulations, we consider two randomly generated networks with $J = 25$, algebraic connectivity 3.2425, and average degree per node 12.80; and $J = 50$ nodes, algebraic connectivity 1.3961, and average degree per node 15.92. The training set is equally partitioned across nodes, thus every node in the network with $J = 25$ has $N_j = 472$ training vectors, and every node in the network with $J = 50$ has $N_j = 236$ samples. The distribution of samples across nodes influences the training phase of MoM-DSVM. For example, if data per node are biased toward one particular class, then the training phase may require more iterations to percolate appropriate information across the network. In the simulations, we consider the two extreme cases: (i) training data are evenly distributed across nodes, that is, every node has the same number of examples from digit 2 and from digit 9; and, (ii) highly biased local data, that is, every node has data corresponding to a single digit; thus, a local binary classifier cannot be constructed.

The figures in this section correspond to one run of the MoM-DSVM for a network with noiseless communication links. Figure 4 shows the evolution of the test error for the network with 25 nodes and highly biased local data. Likewise, Figure 5 shows the evolution of the test error for the network with 50 nodes and highly biased local data. Different values for the penalties JC and η were used to illustrate their effect on both the classification performance and the convergence rate of MoM-DSVM. The parameter JC controls the final performance of the classifier; but for a finite number of iterations, η also influences the final performance of the classifier. Larger values of η may be desirable; however, if η is too large, the algorithm first focuses on reaching consensus across nodes disregarding the classification performance. Although, MoM-DSVM is guaranteed to converge for all η, a very large choice for η may hinder the convergence rate.

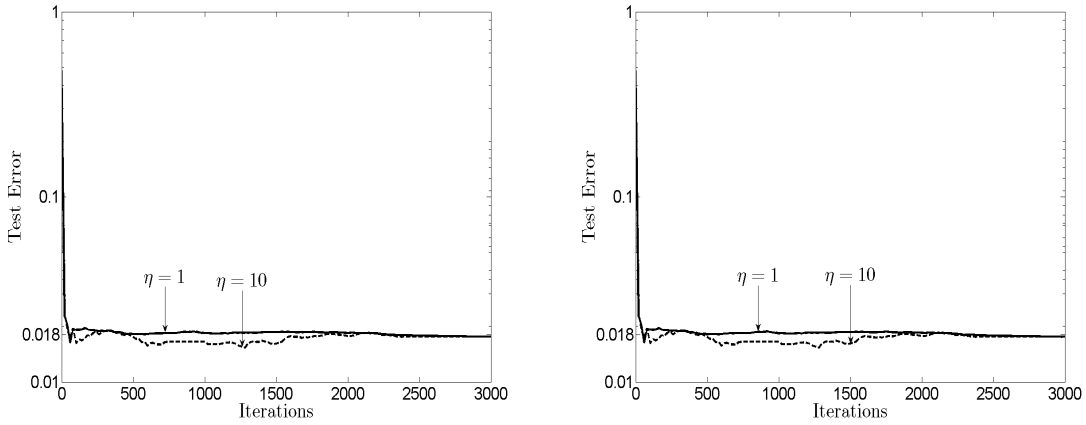

Figure 4: Evolution of the test error ($\mathbf{R}_{\text{Test}}$) of MoM-DSVM, with penalty coefficients $JC = 1$ (left) and $JC = 5$ (right), for a two-class problem using digits 2 and 9 from the MNIST data set unevenly distributed across nodes, and a network with $J = 25$ nodes.

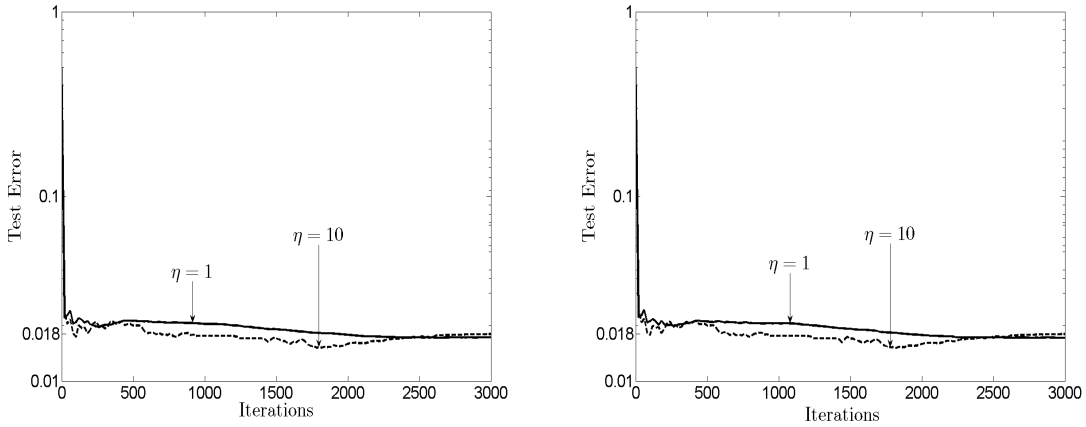

Figure 5: Evolution of the test error ($\mathbf{R}_{\text{Test}}$) of MoM-DSVM, with penalty coefficients $JC = 1$ (left) and $JC = 5$ (right), for a two-class problem using digits 2 and 9 from the MNIST data set unevenly distributed across nodes, and a network with $J = 50$ nodes.

Next, the dispersion of the solutions after 3,000 iterations for different values of η is tested. For our experiment, dispersion refers to how similar are the local $\mathbf{v}_j(t)$ at every node. The mean-squared error (MSE) of the solution across nodes is defined as $\Delta(t) := \frac{1}{J}\sum_{j=1}^{J} ||\mathbf{v}_j(t) - \bar{\mathbf{v}}(t)||^2$ where $\bar{\mathbf{v}}(t) := \frac{1}{J}\sum_{j=1}^{J} \mathbf{v}_j(t)$. Table 1 shows $\Delta(t)$ at $t = 3{,}000$ for different values of η and JC. Note that larger values of η lead to smaller dispersion in the solution; however, as illustrated in Figure 5, they do not imply faster convergence rates.

	$\Delta(t)$ at $t = 3{,}000$			
	$J = 25$		$J = 50$	
η	$JC = 1$	$JC = 5$	$JC = 1$	$JC = 5$
1	3.1849×10^{-7}	3.1870×10^{-7}	2.3749×10^{-7}	2.3227×10^{-7}
5	1.5591×10^{-8}	1.4760×10^{-8}	2.6613×10^{-8}	2.6646×10^{-8}
10	2.9280×10^{-10}	2.9112×10^{-10}	3.6028×10^{-9}	3.6207×10^{-9}

Table 1: MSE $\Delta(t)$ with MNIST data set and biased local data for different values of η and JC.

Consider next data that are evenly distributed across nodes. The MNIST training set is partitioned across nodes ensuring that every node has an equal number of examples from digit 2 and digit 9. Figure 6 shows the evolution of the test error for the network with $J = 25$ nodes and Figure 7 shows the evolution of the test error for the network with $J = 50$ nodes for different values for the penalties JC and η. In this case, local classifiers achieve low test error after one iteration of the MoM-DSVM. In subsequent iterations MoM-DSVM forces all local classifiers to consent, but the test error does not decrease monotonically across iterations. This variation is small, ranging between 0.015 and 0.02, since all local classifiers already have low test error. Both Figures 6 and 7 show that between iterations 500 and $2{,}000$, the global test reaches a minimum value, then it increases and converges to a larger value. This non-monotonic behavior can be attributed to the fact that the MoM-DSVM iterates are not guaranteed to be monotonic. Moreover, before consensus is reached across all nodes the test error at any given node and iteration index does not necessarily need to be greater than the centralized one.

It is also worth noticing the resemblance of the curves in the left and right panels of Figures 4, 5, 6 and 7. Although the test error is nearly identical for $JC = 1$ and $JC = 5$, this does not imply that the $\mathbf{v}_j(t)$ are nearly identical across iterations. Furthermore, the insensitivity w.r.t. small changes in JC reveals that in order to affect the classifier performance, the parameter JC must vary in the order of J. Relating the distributed setting with its centralized counterpart, it follows that with, for example, $J = 25$ a change in JC from 1 to 5 in the distributed setup of (6), corresponds to a change in C from 0.04 to 0.20 for the centralized setting of (1). Such a small change in C explains why the classification performance of the equivalent centralized scenarios is nearly identical as reflected in the figures.

In both biased and evenly distributed data, after a few iterations, MoM-DSVM yields an average performance close to the optimal one. It is also interesting to note that in the biased data case, nodes alone cannot construct an approximate classifier since they do not have samples from both classes. If an incremental approach were used it would need at least one full cycle through the network to enable construction of local estimators per node.

Finally, the effect of network connectivity on the performance of MoM-DSVM is explored. In this experiment, we consider a network with $J = 25$ nodes, ring topology and biased data distribution as before. The performance of MoM-DSVM is illustrated by Figure 8. It is clear that in this case a larger η improves the convergence rate. Also, note that after a few iterations the average performance of the classifier across the network is close to the optimal. In practice, a small reduction of performance over the centralized classifier may be acceptable in which case MoM-DSVM can stop after a small number of iterations. Note that the communication cost of MoM-DSVM can be easily computed at any iteration in terms of the number of scalars transmitted across the network.

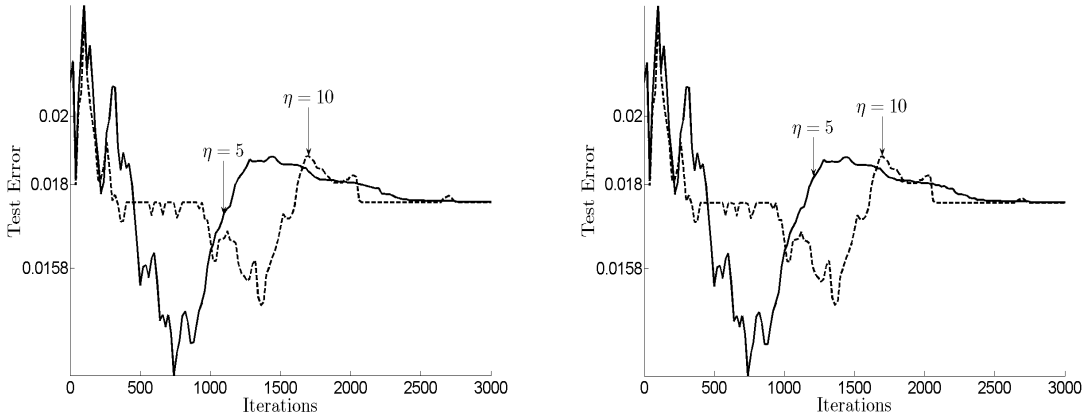

Figure 6: Evolution of the test error ($\mathbf{R}_{\text{Test}}$) of MoM-DSVM, with penalty coefficients $JC = 1$ (left) and $JC = 5$ (right), for a two-class problem using digits 2 and 9 from the MNIST data set evenly distributed across nodes, and a network with $J = 25$ nodes.

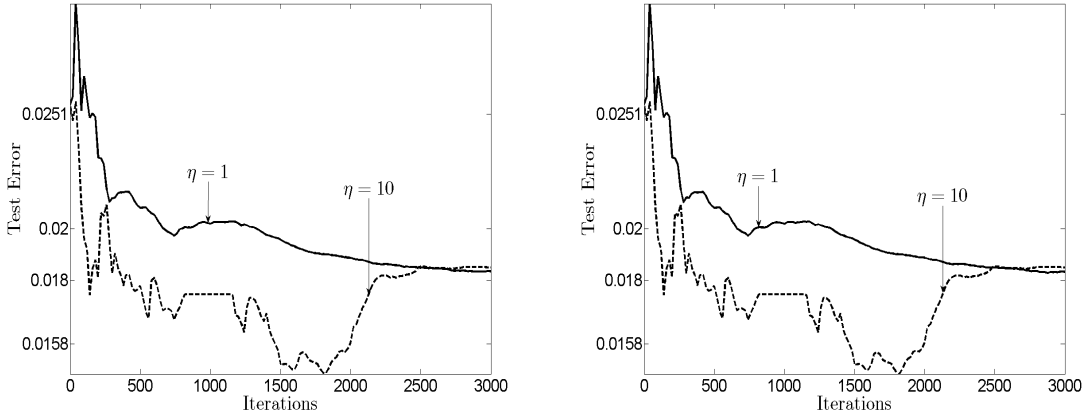

Figure 7: Evolution of the test error ($\mathbf{R}_{\text{Test}}$) of MoM-DSVM, with penalty coefficients $JC = 1$ (left) and $JC = 5$ (right), for a two-class problem using digits 2 and 9 from the MNIST data set evenly distributed across nodes, and a network with $J = 50$ nodes.

For the MNIST data set, the total communication cost up to iteration t is $785Jt$ scalars (cf. Section 3).

5.1.3 TEST CASE 3: SEQUENTIAL OPERATION

Consider a network with $J = 10$ nodes, algebraic connectivity 0.3267, and average degree per node 2.80. Data from two classes arrive sequentially at each node in the following fashion: at $t = 0$ each node has available one labeled training example drawn from the class distributions $\mathcal{C}_1$ and $\mathcal{C}_2$

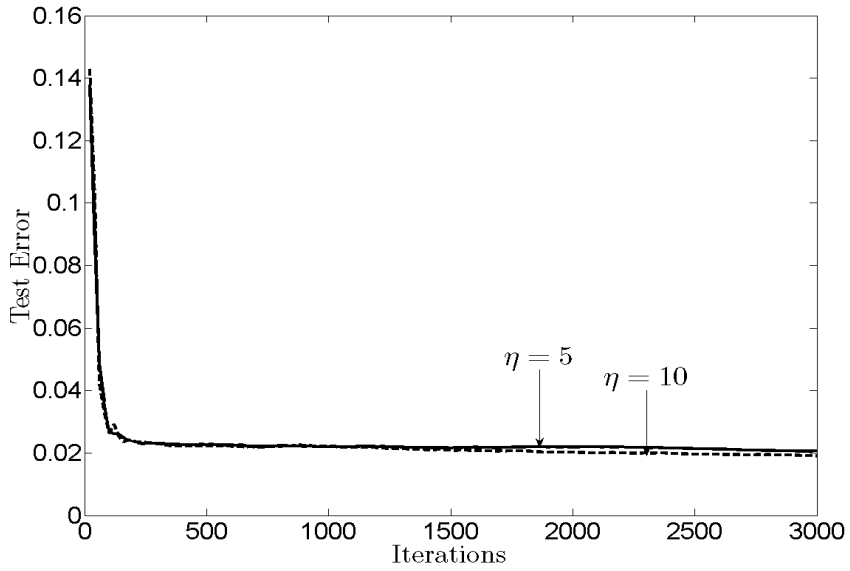

Figure 8: Evolution of the test error ($\mathbf{R}_{\text{Test}}$) of MoM-DSVM, with penalty coefficients $JC = 1$, for a two-class problem using digits 2 and 9 from the MNIST data set unevenly distributed across nodes, and a network with ring topology and $J = 25$ nodes.

described in Test Case 1. From $t = 0$ to $t = 19$, each node acquires a new labeled training example per iteration from this same distribution. From $t = 20$ to $t = 99$, no new training example is acquired. After iteration $t = 99$, the distribution from which training examples in class $\mathcal{C}_1$ were generated changes to a two-dimensional Gaussian distribution with covariance matrix $\Sigma_1 = [1,\ 0;\ 0,\ 2]$, and mean vector $m_1 = [-1,\ 5]^T$. From $t = 100$ to $t = 119$, each node acquires a new labeled training example per iteration using the new class-conditional distribution of $\mathcal{C}_1$, while the class-conditional distribution of C_2 remains unchanged. During these iterations, we remove the training examples from $\mathcal{C}_1$ that were generated during the interval $t = 0$ to $t = 19$, one per iteration. From $t = 120$ to $t = 299$ nodes do not acquire new labeled training examples. From iteration $t = 300$ to $t = 499$, we include 8 new training examples per node and per iteration drawn only from class $\mathcal{C}_1$ with the same class-conditional distribution as the one used at the beginning of the algorithm $t = 0$. Finally, at iteration $t = 500$ all labeled training samples drawn from $t = 300$ to $t = 499$ are removed at each node at once, returning to the global data set available prior to iteration $t = 300$. The algorithm continues without any further change in the training set until convergence.

Figure 10 illustrates the tracking capabilities of the online MoM-DSVM scheme for different values of η. A total of 100 Monte Carlo runs were performed. The figure of merit in this case is $\mathcal{V}(t) := \frac{1}{J}\sum_{j=1}^{J} \left\|\mathbf{v}_j(t) - \mathbf{v}_c(t)\right\|$, where $\mathbf{v}_c(t)$ contains the coefficients of the centralized SVM using the training set available at time t. The peaks in Figure 10 correspond to the changes described in our experiment. MoM-DSVM rapidly adapts the coefficients after the local training sets are modified. Clearly, the parameter η can be tuned to control the speed with which MoM-DSVM adapts. Notice that a large η may cause over-damping effects hindering the final performance of the algorithm. Figure 9 shows snapshots, for a single run of MoM-DSVM and $\eta = 30$, of the global training set

and local discriminant functions at different iterations. The solid training examples correspond to the current global SVs found by the online MoM-DSVM algorithm.

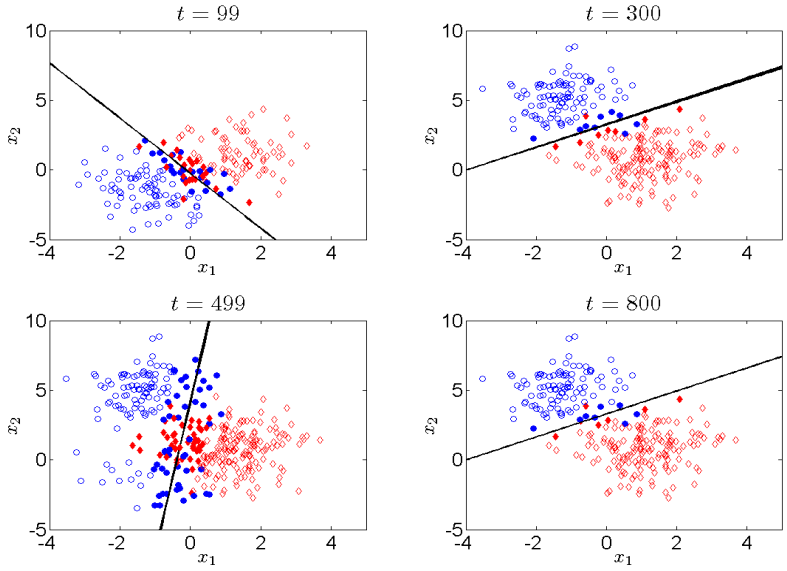

Figure 9: Snapshots of the global training data set and local linear discriminant $g_j^{(t)}(\mathbf{x})$ obtained with MoM-DSVM at all nodes for a synthetic training set evolving in time.

5.1.4 TEST CASE 4: COMMUNICATION COST COMPARISON

In this section, a comparison with the incremental SVM (ISVM) approach in Lu et al. (2008) is presented. The network with $J = 30$ nodes is considered again, where each node j has available a local training set with $N_j = N = 20$ with training vectors generated as in Test Case 1. A global test set with $N_T = 1,200$ was used, and 100 Monte Carlo runs were performed. The MoM-DSVM algorithm used $JC = 20$. The network topology is a ring; thus, ISVM entails no extra overhead due to inter-node communications. Nevertheless, in more general network topologies such overhead might dramatically increase the total communication cost incurred by ISVM. The communication cost is measured in terms of the number of scalars communicated per node. For MoM-DSVM, this cost is fixed per iteration and equal to $3J$ scalars; recall that per iteration every node broadcasts $\mathbf{v}_j(t)$ to its neighborhood (cf. Algorithm 1). The ISVM approach locally trains an SVM and passes its local SVs to the next node in the cycle; the algorithm continues traversing the network until no SVs are shared among neighboring nodes. Thus, the communication cost per iteration depends on the number of SVs found at each node, that is, $3 \times \{\#\text{ of SVs at node } j\}$. A contingency strategy to prevent SVs from being transmitted multiple times by the same node as well as to prevent repetition of training set elements at individual nodes is run in parallel with the ISVM algorithm.

Figure 11 depicts the cumulative communication cost for MoM-DSVM and ISVM as a function of their classification performance. In this particular case and with the most favorable network topology for an incremental approach, we observe that MoM-DSVM achieves a comparable risk to

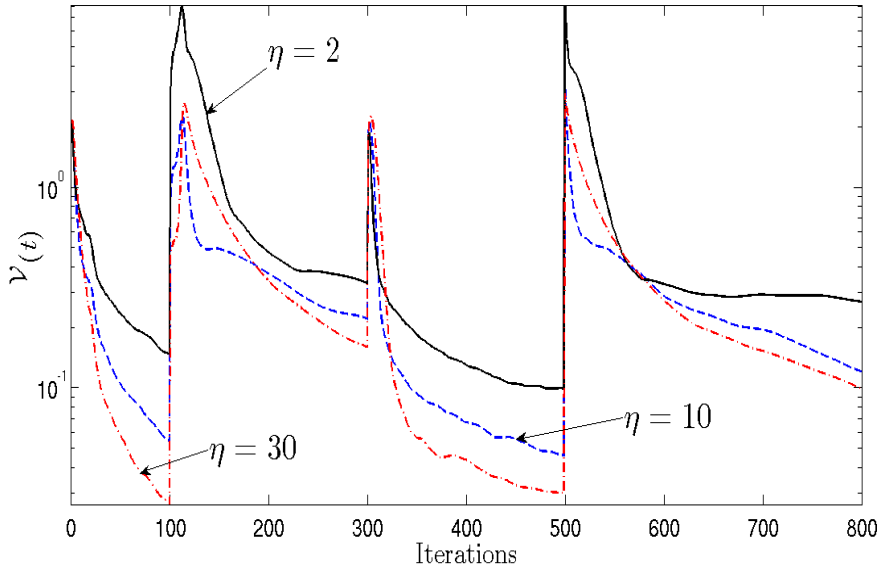

Figure 10: Average error $\mathcal{V}(t)$ of MoM-DSVM for a synthetic training set evolving in time evaluated for various values of η. The peaks correspond to iteration indexes where the local training sets were modified.

ISVM with a smaller number of transmitted scalars. Specifically, to achieve a risk of 0.1159, MoM-DSVM communicates on average 1,260 scalars whereas ISVM communicates on average 8,758 scalars. MoM-DSVM can largely reduce the amount of communications throughout the network, a gain that translates directly to lower power consumption, and thus, in the context of WSNs (see Example 1), longer battery life for individual nodes.

5.2 Nonlinear Classifier

In this section, we present experiments on synthetic and real data to illustrate the performance of our distributed method for training nonlinear SVMs.

5.2.1 TEST CASE 5: SYNTHETIC TRAINING SET

Consider the same network as in Test Case 1. Each node acquires labeled training examples from two different equiprobable classes $\mathcal{C}_1$ and $\mathcal{C}_2$. Class $\mathcal{C}_1$ contains now examples from a two-dimensional Gaussian distribution with covariance matrix $\Sigma_1 = [0.6, 0; 0, 0.4]$, and mean vector $m_1 = [0,0]^T$. Class $\mathcal{C}_2$ is a mixture of Gaussian distributions with mixing parameters $\pi_{21} = 0.3$ and $\pi_{22} = 0.7$; mean vectors $m_2 = [-1,-1]^T$ and $m_3 = [2,2]^T$; and, equal covariance matrix Σ. The optimal Bayes classifier here is clearly nonlinear.

We generate a matrix Γ with rows taken from a uniform two-dimensional grid of L points. The extreme values of the grid are chosen equal to the extreme points of the global training set. Local training sets are of size $N_j = 10\ \forall j \in \mathcal{J}$, and are generated from the distributions described in the previous paragraph. Each node uses its local training sets as well as the matrix Γ to build the local

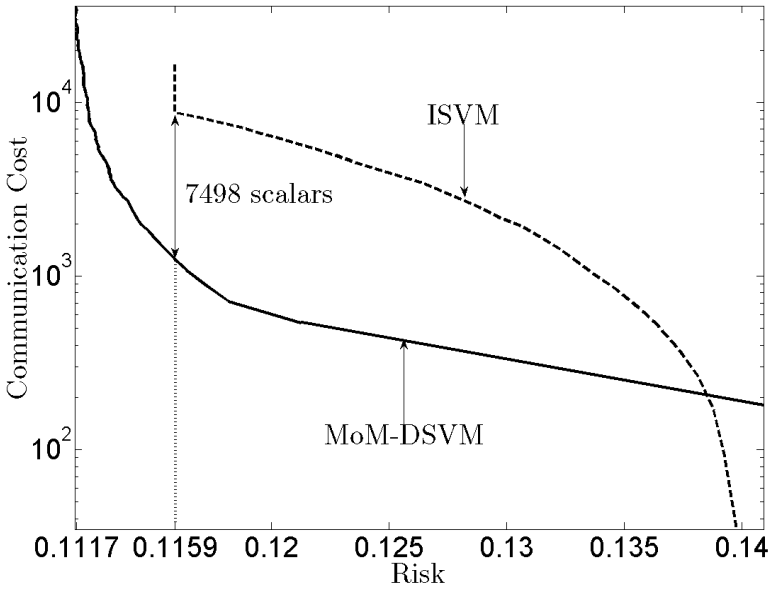

Figure 11: Communication cost, measured in terms of the number of scalars transmitted, of MoM-DSVM and ISVM for a network with ring topology and $J = 30$.

classifier, as described in (24). A Gaussian kernel with $\sigma^2 = 0.9$ and $\eta = 10$ was employed to construct a global nonlinear classifier. Figure 12 (left) shows the classification performance on the points $\{\chi_l\}_{l=1}^{L}$; that is, the classification performance when the testing set is given by $\{(\chi_l, y_l) : l = 1,\ldots,L\}$, where y_l indicates the class from which χ_l was originally drawn. For comparison, we have also included the Bayes risk, the centralized SVM empirical risk, and the local SVM risk. As expected, the classification performance of the distributed classifier approaches that of the centralized one.

Figure 12 (right) illustrates the performance of MoM-NDSVM on a randomly-generated test set of size $N_T = 600$ for various choices of L and JC. Matrix Γ was taken from a uniform two-dimensional grid of L points as before. A total of 500 Monte Carlo runs were performed. Clearly, the asymptotic performance of MoM-NDSVM rapidly outperforms the average performance of a locally-trained SVM and closely converges to the centralized SVM for larger values of L with all other parameters fixed. However, it is worth observing that the choice of the parameter JC also influences the performance. Large values for JC promote reduced number of prediction errors on the training set (possibly) leading to over-fitting. Various strategies, such as cross validation, can be implemented to select optimal values for both JC and σ^2 at the expense of training with MoM-NDSVM multiple times. To visualize the results, Figures 13 and 14 depicts the form of the discriminant function for several values of L at 6 different nodes in the network. Centralized and local discriminant functions are also included as benchmarks. Even though the nodes do not exactly agree on the final form of $g_j(\mathbf{x})$ at all points, their classification performance closely converges to the one obtained by the centralized SVM benchmark.

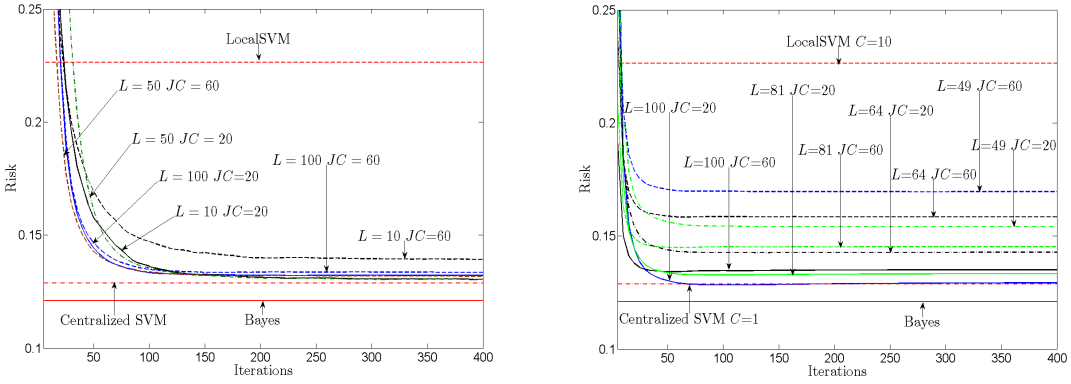

Figure 12: Evolution of prediction error $(\mathbf{R}_{\text{Pred}})$, where matrix Γ is considered a classification query of size L (left); and test error $(\mathbf{R}_{\text{Test}})$, where matrix Γ is constructed as a random grid with L points (right), for MoM-NDSVM applied to a two-class problem using synthetic data and a network with $J = 30$ nodes.

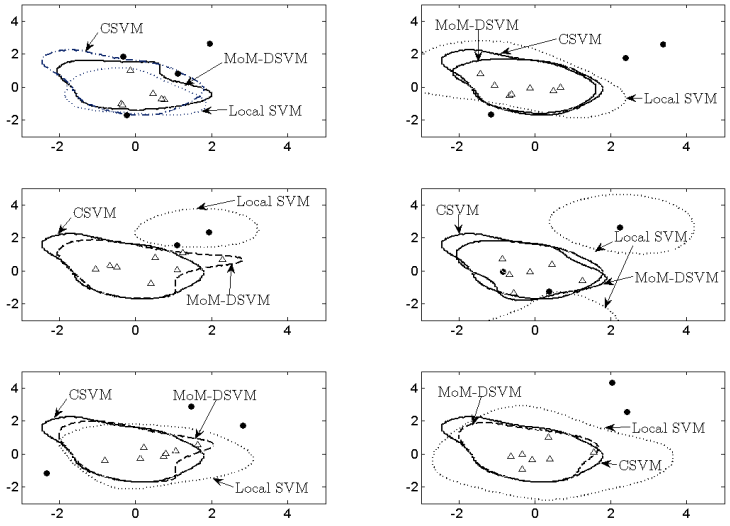

Figure 13: Comparison of the discriminant functions found by a centralized SVM, local SVMs, and the MoM-NDSVM algorithm at 6 different nodes of a network with $J = 30$ using synthetic data. A penalty term $JC = 20$ and a random grid with $L = 100$ were used.

5.2.2 TEST CASE 6: UCI TRAINING SETS

Four data sets from the UCI repository have been chosen to test our MoM-NDSVM algorithm: Iris, Wine, Puma Indians Diabetes, and Parkinsons (Asuncion and Newman, 2007). A brief description

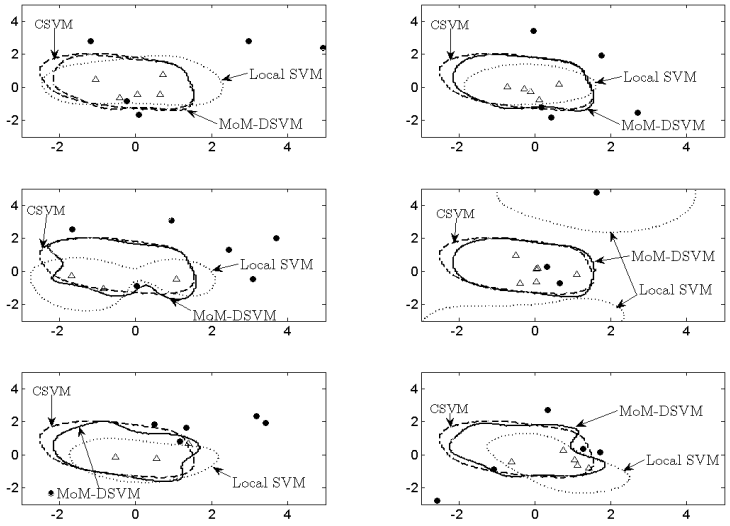

Figure 14: Comparison of the discriminant functions found by a centralized SVM, local SVMs, and the MoM-NDSVM algorithm at 6 different nodes of a network with $J = 30$ using synthetic data. A penalty term $JC = 60$ and a random grid with $L = 100$ were used.

Data set	Classes	Dim. Features	Size	Train. Set	Test Set
Iris	3	4	150	12	40
Wine	3	13	178	12	40
Diabetes	2	8	768	50	200
Parkinsons	2	23	197	12	40

Table 2: UCI data sets

of each of the data sets is shown in Table 2. Examples from the data sets are randomly split among $J = 5$ nodes in a fully-connected network. Focusing on the binary classification problem, only classes 2 and 3 from the Iris data set and classes 1 and 2 from the Wine data set are used. For simulation purposes, each local training set as well as the testing set have the same number of examples from each class.

Table 3 compares performance of the classifiers constructed via MoM-NDSVM with the average performance of the 5 local classifiers trained with local training sets only, and with the one of a centralized SVM trained with the training set available to the whole network. A total of 100 Monte Carlo runs were performed per data set, where both training and testing sets were drawn randomly per run. The MoM-NDSVM parameters JC and η were chosen via cross-validation for every training set as in Hastie et al. (2009, Ch. 7). Gaussian kernels as in the previous section were used. The local and centralized SVMs were trained using the Spider toolbox for MATLAB (Weston et al., 2006). To evaluate the local performance of the classifiers, each node trains a local SVM and its performance is compared with the one obtained via MoM-NDSVM. For each training set we

Data set	Local	Centralized	MoM-NDSVM $L = 150$	MoM-NDSVM $L = 300$	Class. Query
Iris	8.39%	4.43%	5.15%	5.26%	4.28%
Wine	15.71%	6.17%	7.37%	7.33%	6.60%
Diabetes	34.52%	24.40%	29.69%	28.92%	23.76%
Parkinsons 1	33.76%	18.45%	30.14%	31.13%	18.56%
Parkinsons 2	34.78%	18.86%	23.60%	24.05%	20.28%

Table 3: UCI data sets centralized versus local versus distributed performance comparison for $t = 1,000$. Parkinsons 2 is the normalized Parkinsons training set.

explore two cases: (i) local classifiers at each node; and (ii) Γ as a classification query. Figure 15 plots the training evolution of MoM-NDSVM for the Puma Indians Diabetes data set.

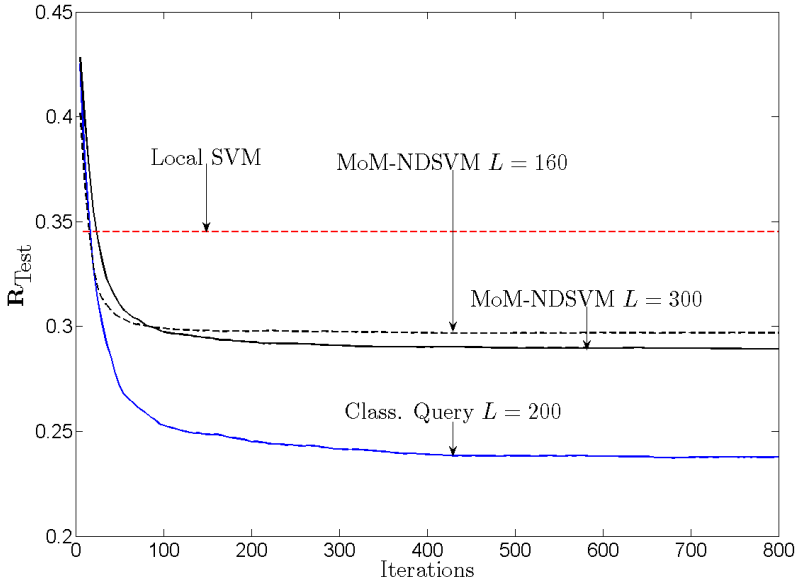

Figure 15: Evolution of test error ($\mathbf{R}_{\text{Test}}$) for Puma Indians Diabetes data set taken from the UCI repository, and a fully connected network with $J = 5$ nodes.

The performance of MoM-NDSVM for (i) depends heavily on the choice of Γ. To illustrate this point, the size of the local training sets per node has been chosen small when compared to the dimensionality of the feature space. Let $x_k^{\min}$ and $x_k^{\max}$ correspond to the smallest and largest values that the k-th feature can take. The row-elements of matrix Γ are chosen randomly and independently over the interval $[x_k^{\min}, x_k^{\max}]$ per component. Two different values of L were chosen to compare the performance of MoM-NDSVM. For small values of p, Γ can be chosen as a grid of M uniformly spaced points per dimension; therefore, $L = M^p$. The results summarized in Table 3 highlight

	$\eta = 10$		$\eta = 20$	
L	$p_0 = 49$	$p_0 = 81$	$p_0 = 49$	$p_0 = 81$
400	0.370%	1.246%	0.504%	1.448%
800	0.136%	0.242%	0.234%	0.654%

Table 4: Average MoM-NDSVM risk (Gaussian kernel) at iteration $t = 3{,}000$ for compressed MNIST data set with dimensionality p_0.

the fact that the classification performance at each node remains limited by the training examples available locally. However, in this extremely challenging case, collaboration among nodes improves the overall classification performance of the network.

Table 3 also illustrates how conditioning of the data together with the choice for the kernel function can impact the performance of MoM-NDSVM. In particular, its last two rows compare the classification performance achieved for the Parkinsons training set without normalization (Parkinsons 1) and with its features normalized to have maximum absolute size unity (Parkinsons 2). Although both centralized and local performance remain nearly unchanged, the MoM-NDSVM performance improves about 7% for both $L = 150$ and $L = 300$. An intuitive explanation follows from looking closer at the values of the features in the Parkinsons training set. Some features take values in the order of 10^2 while others take values in the order of 10^{-3}; thus, a Gaussian kernel that spans symmetrically along all directions is not the best kernel choice for this case. After normalization, a smaller number L of Gaussian kernels can be used to obtain a better representation of the decision surface. In conclusion, data across nodes must be preprocessed whenever possible to achieve a better trade off between classification performance and the computational complexity of MoM-NDSVM.

Note that the classification performance for case (ii) approaches the centralized SVM one. After a few iterations, the classification accuracy returned by the network surpasses that of locally trained SVMs. The speed of convergence might be hindered if L is chosen large. Fine tuning of η can achieve a desirable trade-off between speed of convergence and performance in terms of test error.

5.2.3 TEST CASE 7: MNIST TRAINING SET

Consider a network with $J = 25$, algebraic connectivity 3.2425, and average degree per node 12.8. Local training sets have been constructed based on the MNIST data set using digits 2 and 9 only. The nodes wish to train a nonlinear global classifier using a Gaussian kernel via MoM-NDSVM. Each node j has available a training set $\mathcal{S}_j$ with 472 examples from one class only, thus individual nodes cannot construct a classifier locally. The large size of the images in MNIST leads to an excessively large choice for $L = L_0 \gg 784$, hindering the convergence of MoM-NDSVM. Instead, each image has been compressed via principal component analysis (PCA) to vectors of dimensionality $p_0 < 784$. It was observed experimentally that after compression, the two classes become separable. Indeed, the centralized equivalent SVM yields test error zero. Figure 16 depicts the performance of MoM-NDSVM for various choices of η and p_0. Note that $\eta = 20$ leads to slower convergence of the average risk across the network. Table 4 summarizes the classification performance of MoM-NDSVM after 3,000 iterations. A larger value for L improves the average classification performance of the network. However, the number of iterations required for MoM-NDSVM to converge increases with L.

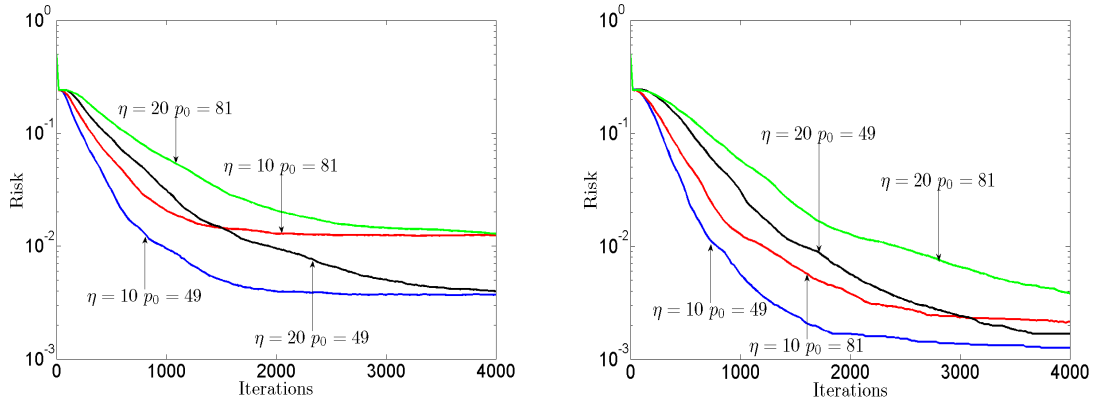

Figure 16: Average evolution of MoM-NDSVM risk (Gaussian kernel) for compressed MNIST data set for $L = 400$ (left), and $L = 800$ (right) in a network with $J = 25$ nodes. MNIST images have been compressed to dimensionality p_0 via PCA.

5.3 Noisy Inter-node Communications

This subsection presents robustness tests of the novel distributed classification scheme with noisy inter-node exchanges. Such noise is due to, for example, quantization error, additive Gaussian noise at the receiving ends, or, Laplacian noise intentionally added to transmitted samples in order to guarantee data privacy (Chaudhuri and Monteleoni, 2008; Dwork et al., 2006). Although focus is placed on MoM-DSVM, the results also carry over to MoM-NDSVM.

5.3.1 TEST CASE 8: MOM-DSVM WITH PERTURBED TRANSMISSIONS

In this setting, per iteration t, each node j purposely introduces a perturbation $\varepsilon_j(t)$ to the variable $\mathbf{v}_j(t)$ before transmission. Perturbed transmissions can be used to preserve data privacy (Dwork et al., 2006). Consider an eavesdropper accessing the noisy versions of $\mathbf{v}_j(t)$. The form and variance level Σ_j of the local perturbations $\varepsilon_j(t)$ can be adjusted per node to prevent the eavesdropper from learning $\mathcal{S}_j$. For instance, Dwork et al. (2006) suggests introducing zero-mean Laplacian random variable whose variance depends on the sensitivity of $\mathbf{v}_j(t)$ as a function of $\mathcal{S}_j$.

The MoM-DSVM iterations, with $JC = 5$ and $\eta = 10$, are modified by introducing local perturbations $\varepsilon_j(t)$ to $\mathbf{v}_j(t)$. Each $\varepsilon_j(t)$ is zero-mean Laplacian distributed and white across time and space, that is, $\mathbb{E}\{\varepsilon_j(t_1)\varepsilon_j^T(t_2)\} = 0$ if $t_1 \neq t_2$ and $\mathbb{E}\{\varepsilon_i(t)\varepsilon_j^T(t)\} = 0$ if $i \neq j\ \forall i, j \in \mathcal{J}$. The resulting MoM-DSVM iterations are

$$\begin{aligned}
\boldsymbol{\lambda}_j(t+1) &= \underset{\boldsymbol{\lambda}_j:\, \mathbf{0}_j \preceq \boldsymbol{\lambda}_j \preceq JC\mathbf{1}_j}{\arg\max} -\frac{1}{2}\boldsymbol{\lambda}_j^T \mathbf{Y}_j \mathbf{X}_j \mathbf{U}_j^{-1} \mathbf{X}_j^T \mathbf{Y}_j \boldsymbol{\lambda}_j + \left(\mathbf{1}_j + \mathbf{Y}_j \mathbf{X}_j \mathbf{U}_j^{-1} \mathbf{f}_j(t)\right)^T \boldsymbol{\lambda}_j, \\
\mathbf{v}_j(t+1) &= \mathbf{U}_j^{-1}\left[\mathbf{X}_j^T \mathbf{Y}_j \boldsymbol{\lambda}_j(t+1) - \mathbf{f}_j(t)\right], \\
\alpha_j(t+1) &= \alpha_j(t) + \frac{\eta}{2} \sum_{i \in \mathcal{B}_j} \left[(\mathbf{v}_j(t+1) + \varepsilon_j(t)) - (\mathbf{v}_i(t+1) + \varepsilon_i(t))\right]
\end{aligned}$$

where $\mathbf{U}_j = (1 + 2\eta|\mathcal{B}_j|)\mathbf{I}_{p+1} - \Pi_{p+1}$ and $\mathbf{f}_j(t) := 2\alpha_j(t) - \eta \sum_{i \in \mathcal{B}_j}[\mathbf{v}_j(t) + \varepsilon_j(t) + \mathbf{v}_i(t) + \varepsilon_i(t)]$ (cf. Proposition 1). In this case, MoM-DSVM operates in an analogous manner to Algorithm 1, differing

only in their broadcasting step. In the perturbed transmissions case, every node j broadcasts a perturbed vector $\mathbf{v}_j(t)+\varepsilon_j(t)$ (instead of $\mathbf{v}_j(t)$ alone) to its one-hop neighbors. Note that neighboring nodes $i \in \mathcal{B}_j$ only "see" the aggregate perturbed vector $\mathbf{v}_j(t)+\varepsilon_j(t)$ from node j.

Figure 17 illustrate the performance of MoM-DSVM after 100 Monte Carlo runs with perturbed transmissions for a network with $J = 8$ nodes, algebraic connectivity 0.4194, and average degree per node 2.5. Nodes collect observations from 2 classes $\mathcal{C}_1$ and $\mathcal{C}_2$, where $\mathcal{C}_1$ is $\mathcal{N}(m_1,\Sigma_1)$ with $m_1 = [0,\ 0]^T$, and $\Sigma_1 = [0.6,\ 0;\ 0,\ 0.4]$, and $\mathcal{C}_2$ is $\mathcal{N}(m_2,\Sigma_2)$ with $m_2 = [2,\ 2]^T$, and $\Sigma_2 = [1,\ 0;\ 0,\ 2]$. Each node collects an equal number of observations per class for a total of $N_j = N = 50$ observations. The noise $\varepsilon_j(t)$, inserted per transmission per node, has covariance matrix given by $\sigma^2\mathbf{I}_3$. The optimal classifier is determined by $\mathbf{v}^* = [-1.29,\ -0.76,\ 1.78]^T$, which is the one obtained by MoM-DSVM with $\sigma^2 = 0$. Interestingly, the average risk in the presence of perturbed transmissions remains close to the perturbation-free risk. Even for a large perturbation $\sigma^2 = 1$, the average risk hovers around 0.1075. Furthermore, the risk variance remains small. Indeed, it can be shown that the proposed scheme yields estimates $\mathbf{v}_j(t)$ with bounded variance.

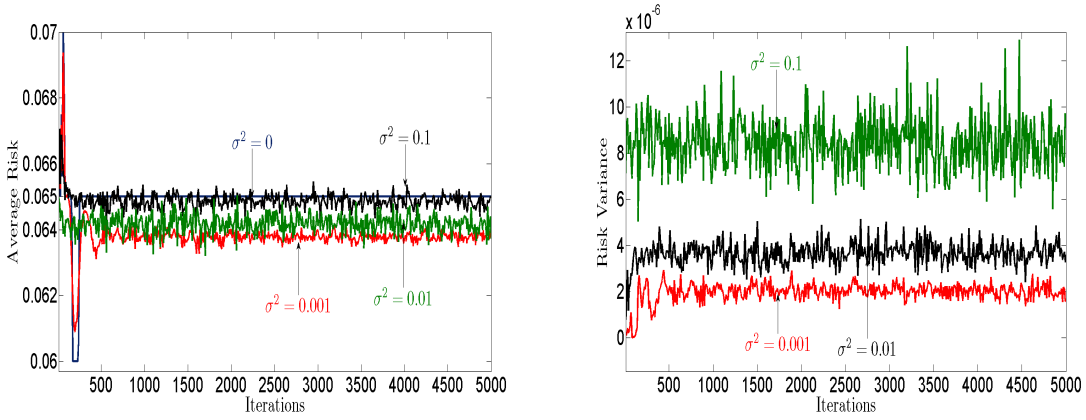

Figure 17: Average risk (left) and risk variance (right) for a network with $J = 8$, and a finite variance perturbation added to $\mathbf{v}_j(t)$ before it is broadcasted.

5.3.2 TEST CASE 9: NOISY COMMUNICATION LINKS

The MoM-DSVM is also robust to non-ideal inter-node links corrupted by additive noise due to, for example, quantization or additive Gaussian receiver noise. In this case, the noise is added at the receiver side. The MoM-DSVM must be modified to obtain a bounded variance on the estimates $\mathbf{v}_j(t)$, and the local Lagrange multipliers $\alpha_{ji}(t) := \alpha_{ji1}(t)$ must be exchanged among neighboring nodes; see Zhu et al. (2009) for similar approaches. Each communication link between node j and node $i \in \mathcal{B}_j$ introduces additive noise $\varepsilon^v_{ji}(t)$ ($\varepsilon^\alpha_{ji}(t)$) to the variable $\mathbf{v}_j(t)$ (α_{ji}). The perturbations $\{\varepsilon^v_{ji}(t)\}$ ($\{\varepsilon^\alpha_{ji}(t)\}$) are zero-mean random variables with covariance matrix Σ^v_{ji} (Σ^α_{ji}), white across

Algorithm 4 MoM-DSVM with noisy links

end for

time and space. The modified MoM-DSVM iterations are

$$\lambda_j(t+1) = \underset{\lambda_j:\, \mathbf{0}_j \preceq \lambda_j \preceq JC\mathbf{1}_j}{\arg\max} -\frac{1}{2}\lambda_j^T \mathbf{Y}_j \mathbf{X}_j \mathbf{U}_j^{-1} \mathbf{X}_j^T \mathbf{Y}_j \lambda_j + \left(\mathbf{1}_j + \mathbf{Y}_j \mathbf{X}_j \mathbf{U}_j^{-1} \mathbf{f}_j(t)\right)^T \lambda_j, \tag{41}$$

$$\mathbf{v}_j(t+1) = \mathbf{U}_j^{-1}\left[\mathbf{X}_j^T \mathbf{Y}_j \lambda_j(t+1) - \mathbf{f}_j(t)\right], \tag{42}$$

$$\alpha_{ji}(t+1) = \alpha_{ji}(t) + \frac{\eta}{2}[\mathbf{v}_j(t+1) - (\mathbf{v}_i(t+1) + \varepsilon_{ij}^v(t))] \tag{43}$$

where $\mathbf{f}_j(t) := \sum_{i\in\mathcal{B}_j}\left\{\alpha_{ji}(t) - (\alpha_{ij}(t) + \varepsilon_{ij}^{\alpha}(t)) - \eta[\mathbf{v}_j(t) + (\mathbf{v}_i(t) + \varepsilon_{ij}^v(t))]\right\}$. The resulting MoM-DSVM algorithm with noisy links is summarized as Algorithm 4.

The left panels of Figures 18 and 19 depict the average performance after 100 Monte Carlo runs of MoM-DSVM for the same network of Test Case 8. As seen, the variance of the estimates $\mathbf{v}_j(t)$ yielded by the modified MoM-DSVM algorithm remains bounded.

Incremental approaches are hindered by noisy communication links because noise added to the SVs perturbs and accumulates in the local training sets. In ISVM, SVs are bound to percolate across the network, and even to come back to the node where they originated. Due to the noise, however, nodes cannot recognize noisy feature vectors already in $\mathcal{S}_j$. This is problematic since the size of local problems being solved per node increases linearly with the size of the training set, thus requiring a heuristic size-control scheme. The right panels of Figures 18 and 19 show the performance of an ISVM for different levels of noise variance. Noise is added to the SVs and noisy labels are rounded to 1 or -1. Different from MoM-DSVM, the performance of ISVM quickly deteriorates, even for low noise levels since the average risk approaches 0.5 after a few iterations, which amounts to pure guessing of the binary classifier.

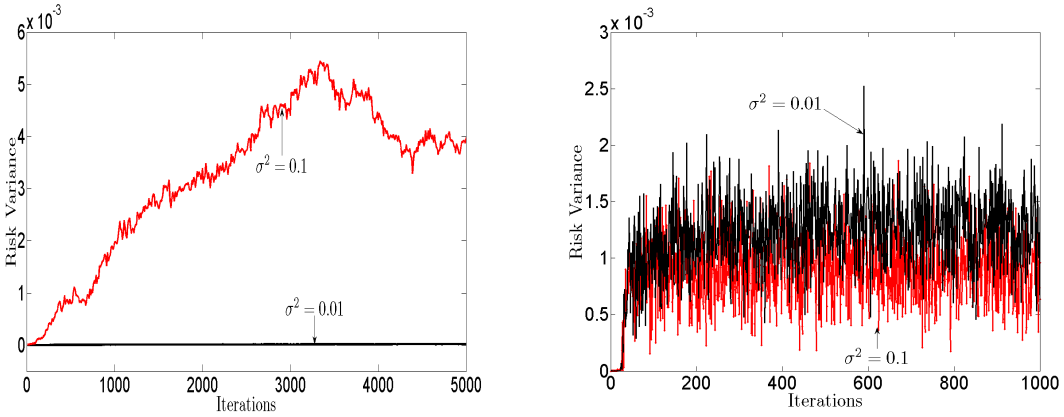

Figure 19: Risk variance for a network with $J = 8$ and noisy communication links corresponding to average risk in Figure 18. MoM-DSVM (left) and incremental SVM approach (right).

6. Conclusions

This work developed distributed SVM algorithms by reformulating the centralized SVM training problem into per-node separable sub-problems linked via consensus constraints, which can be solved using decentralized optimization tools. The novel algorithms are well suited for applications involving data that cannot be shared among collaborating nodes, which possibly operate under stringent resources, and may thus desire to reduce overhead of inter-node message exchanges.

Based on distributed training sets, the novel MoM-DSVM algorithm constructs a maximum-margin linear classifier iteratively. At every iteration, locally updated classifier vectors are exchanged among neighboring nodes. Convergence to the centralized linear SVM formulation is guaranteed. The approach lends itself naturally to online and asynchronous variants, which allow adaptation of the proposed DSVM to scenarios when elements of the local training sets become

available sequentially, or, when outdated elements need to be removed. Furthermore, the MoM-DSVM can be generalized to construct distributed nonlinear discriminant functions. The resulting iterative MoM-NDSVM algorithm is provably convergent to its centralized counterpart, and its complexity is kept at a manageable level by using the kernel trick. Local classifiers are limited by the span of their local training sets, and a set of basis common to all nodes.

Although not formally treated, the novel distributed classification algorithms can be readily extended to solve distributed support vector regression (DSVR) problems. The main characteristics of the present approach, such as its convexity, remain unchanged. Therefore, it is expected that linear and nonlinear estimators developed for MoM-DSVR, will enjoy convergence claims similar to those proved here for MoM-DSVM and MoM-NDSVM classifiers. To complement the distributed supervised classifiers introduced here, our current research deals with consensus-based distributed versions of the unsupervised k-means and expectation-maximization clustering algorithms.

Appendix A. The Alternating Direction Method of Multipliers

The ADMoM is a distributed optimization algorithm solving the following problem

$$\begin{aligned} \min_{\mathbf{v}} \quad & F_1(\mathbf{v}) + F_2(\mathbf{A}\mathbf{v}) \\ \text{s.t.} \quad & \mathbf{v} \in \mathcal{P}_1,\ \mathbf{A}\mathbf{v} \in \mathcal{P}_2 \end{aligned} \tag{44}$$

where $F_1 : \mathbb{R}^{p_1} \to \mathbb{R}$ and $F_2 : \mathbb{R}^{p_2} \to \mathbb{R}$ are convex functions, $\mathbf{A}$ is a $p_2 \times p_1$ matrix, while $\mathcal{P}_1 \subset \mathbb{R}^{p_1}$ and $\mathcal{P}_2 \subset \mathbb{R}^{p_2}$ denote non-empty polyhedral sets.

Upon introducing the auxiliary variable $\omega \in \mathbb{R}^{p_2}$, ADMoM solves the separable problem

$$\begin{aligned} \min_{\mathbf{v},\omega} \quad & F_1(\mathbf{v}) + F_2(\omega) \\ \text{s.t.} \quad & \mathbf{A}\mathbf{v} = \omega \\ & \mathbf{v} \in \mathcal{P}_1,\ \omega \in \mathcal{P}_2 \end{aligned} \tag{45}$$

which is clearly equivalent to (44). With $\alpha \in \mathbb{R}^{p_2}$ denoting the Lagrange multiplier corresponding to the constraint $\mathbf{Av} = \omega$, the augmented Lagrangian corresponding to (45) is

$$\mathcal{L}(\mathbf{v}, \omega, \alpha) = F_1(\mathbf{v}) + F_2(\omega) + \alpha^T(\mathbf{Av} - \omega) + \frac{\eta}{2}\|\mathbf{Av} - \omega\|^2 \tag{46}$$

where the parameter $\eta > 0$ controls the impact of the constraint violation in (45). The ADMoM minimizes alternately $\mathcal{L}$ in (46) w.r.t. the primal variable $\mathbf{v}$, then w.r.t. the auxiliary variable ω, and after each cycle it uses these iterates to update the multiplier. Specifically, with t denoting iteration index, the ADMoM iterates at $t+1$ are given by

$$\mathbf{v}(t+1) = \arg\min_{\mathbf{v}\in\mathcal{P}_1} \mathcal{L}(\mathbf{v}, \omega(t), \alpha(t)), \tag{47}$$

$$\omega(t+1) = \arg\min_{\omega\in\mathcal{P}_2} \mathcal{L}(\mathbf{v}(t+1), \omega, \alpha(t)), \tag{48}$$

$$\alpha(t+1) = \alpha(t) + \eta(\mathbf{Av}(t+1) - \omega(t+1)). \tag{49}$$

Thanks to the auxiliary variable ω, each of the optimization problems (47) and (48) can be run separately, possibly by different processors. The following proposition states the main claim regarding convergence of the ADMoM iterates, and its proof can be found in Bertsekas and Tsitsiklis (1997, Ch. 3, Proposition 4.2).

Proposition 4 *Assume that the optimal solution set v^* of* (44) *is non-empty, and either $\mathcal{P}_1$ is bounded, or, $\mathbf{A}^T\mathbf{A}$ is nonsingular. Then, a sequence $\{\mathbf{v}(t), \omega(t), \alpha(t)\}$ generated by the iterations* (47)-(49) *is bounded, and every limit point of $\{\mathbf{v}(t)\}$ is an optimal solution of* (44). *Furthermore, $\{\alpha(t)\}$ converges to an optimal solution α^* of the dual problem [cf.* (45)*]*

$$\min_{\alpha\in\mathbb{R}^{p_2}} \quad H_1(\alpha) + H_2(\alpha)$$

where for all $\alpha \in \mathbb{R}^{p_2}$

$$H_1(\alpha) := \inf_{\mathbf{v}\in\mathcal{P}_1} [F_1(\mathbf{v}) + \alpha^T\mathbf{Av}],$$
$$H_2(\alpha) := \inf_{\omega\in\mathcal{P}_2} [F_2(\omega) - \alpha^T\omega].$$

Appendix B. Proof of Lemma 1

First, the equality constraints $\{\mathbf{w}_j = \mathbf{w}_i\}$ and $\{b_j = b_i\}$ will be shown equivalent to $\mathbf{w}_1 = \cdots = \mathbf{w}_J$ and $b_1 = \cdots = b_J$, respectively, for any feasible solution of (6). Consider any two nodes j_0 and j_k both in $\mathcal{J}$. Since the network is connected, there exists a path $\{j_0 j_1 \ldots j_{k-1} j_k\}$ of length at least one, which connects nodes j_0 and j_k. Because $j_{\ell+1} \in \mathcal{B}_\ell$ for $\ell = 0, 1, \ldots, k-1$, it is immediate that $\mathbf{w}_{j_\ell} = \mathbf{w}_{j_1} = \cdots = \mathbf{w}_{j_{k-1}} = \mathbf{w}_{j_k}$. Since $j_\ell, j_k \in \mathcal{J}$ are arbitrary, it follows readily that $\mathbf{w}_1 = \cdots = \mathbf{w}_J$. A similar argument leads to $b_1 = \cdots = b_J$.

As any feasible solution of (6) satisfies $\mathbf{w}_1 = \cdots = \mathbf{w}_J = \mathbf{w}$ and $b_1 = \ldots = b_J = b$, problem (6) becomes

$$\begin{aligned} \min_{\mathbf{w},b,\{\xi_j\}} \quad & J\left(\frac{1}{2}\|\mathbf{w}\|^2 + C\sum_{j=1}^{J}\mathbf{1}_j^T\xi_j\right) \\ \text{s.t.} \quad & \mathbf{Y}_j(\mathbf{X}_j\mathbf{w} + b\mathbf{1}_j) \succeq \mathbf{1}_j - \xi_j \quad \forall j \in \mathcal{J} \\ & \xi_j \succeq \mathbf{0}_j \end{aligned} \tag{50}$$

which is equivalent to (1), since the constant J can be dropped from the cost function in (50).

Appendix C. Proof of Lemma 2

The objective here is to cast (7) in the form of (45), and thus show that iterations (9)-(12) correspond to the ADMoM iterations (47)-(49) in Appendix A. First, it will be shown that the set of consensus constraints in (7), namely $\{\mathbf{v}_j = \omega_{ji},\ \omega_{ji} = \mathbf{v}_i\ :\ \forall j \in \mathcal{J},\ \forall i \in \mathcal{B}_j\}$, can be written as the equality constraint $\mathbf{A}\mathbf{v} = \omega$ in (45). With this objective in mind, consider listing the constraints $\mathbf{v}_j = \omega_{ji}$ across nodes $j \in \mathcal{J}$ and neighbors $i \in \mathcal{B}_j$ as follows

$$\begin{aligned} \{\mathbf{v}_1 &= \omega_{1i}\}_{i\in\mathcal{B}_1} \\ &\vdots \\ \{\mathbf{v}_J &= \omega_{Ji}\}_{i\in\mathcal{B}_J}. \end{aligned} \tag{51}$$

Since for every $\mathbf{v}_j$ there are $|\mathcal{B}_j|$ constraints, the total number of equalities in (51) is $\sum_{j=1}^{J}|\mathcal{B}_j| = 2|\mathcal{E}|$, where $|\mathcal{E}|$ is the number of edges in the network. The factor 2 in $2|\mathcal{E}|$ is because for every edge $j \leftrightarrow i$ there are two constraints, namely $\mathbf{v}_j = \omega_{ji}$ and $\mathbf{v}_i = \omega_{ij}$.

The set of equalities in (51) can be written in matrix-vector form as

$$\begin{matrix} |\mathcal{B}_1| \text{ vectors} \\ |\mathcal{B}_J| \text{ vectors} \end{matrix} \left\{ \begin{bmatrix} \mathbf{v}_1 \\ \vdots \\ \mathbf{v}_1 \\ \vdots \\ \mathbf{v}_J \\ \vdots \\ \mathbf{v}_J \end{bmatrix} \right. = \underbrace{\begin{bmatrix} \underbrace{\begin{bmatrix} \mathbf{I}_{p+1} \\ \vdots \\ \mathbf{I}_{p+1} \end{bmatrix}}_{\mathbf{A}_1:=} & & \\ & \ddots & \\ & & \underbrace{\begin{bmatrix} \mathbf{I}_{p+1} \\ \vdots \\ \mathbf{I}_{p+1} \end{bmatrix}}_{\mathbf{A}_J:=} \end{bmatrix}}_{\mathbf{A}':=} \underbrace{\begin{bmatrix} \mathbf{v}_1 \\ \vdots \\ \mathbf{v}_J \end{bmatrix}}_{\mathbf{v}:=} = \underbrace{\begin{bmatrix} \{\omega_{1i}\}_{i\in\mathcal{B}_1} \\ \vdots \\ \{\omega_{Ji}\}_{i\in\mathcal{B}_J} \end{bmatrix}}_{\omega':=} \tag{52}$$

where $\mathbf{A}'\mathbf{v}$ replicates $\mathbf{v}$ in accordance with the left-hand-side (l.h.s.) of (51). Matrix $\mathbf{A}'$ in (52) is block-diagonal with block entries $\mathbf{A}_j := [\mathbf{I}_{p+1}, \ldots, \mathbf{I}_{p+1}]^T$ containing $|\mathcal{B}_j|$ identity matrices of size $(p+1)\times(p+1)$. Since $\mathbf{v}_j$ and ω_{ji} are $(p+1)\times 1$ vectors, $\mathbf{v}$ has size $(p+1)J \times 1$, and ω' has size $2(p+1)|\mathcal{E}| \times 1$.

Equation (52) shows that the constraints of the form $\mathbf{v}_j = \omega_{ji}$ can be compactly written as

$$\mathbf{A}'\mathbf{v} = \omega'. \tag{53}$$

Consider now the remaining constraints, which are of the form $\omega_{ji} = \mathbf{v}_i$, and can be listed explicitly as [cf. (51)]

$$\begin{aligned} \{\mathbf{v}_1 &= \omega_{j1}\}_{j\in\mathcal{B}_1} \\ &\vdots \\ \{\mathbf{v}_J &= \omega_{jJ}\}_{j\in\mathcal{B}_J}. \end{aligned} \tag{54}$$

Since the l.h.s. of (54) coincides with the l.h.s. of (51), the set of equations in (54) can be likewise written as [cf. (53)]

$$\mathbf{A}'\mathbf{v} = \omega'' \tag{55}$$

where now $\omega'' := [\{\omega_{j1}^T\}_{j\in\mathcal{B}_1},\ldots,\{\omega_{jJ}^T\}_{j\in\mathcal{B}_J}]^T$. Notice that ω'' is a permuted version of ω', since it can be obtained from ω' by replacing vector ω_{ji} in ω' with vector ω_{ij}. Hence, using a $2|\mathcal{E}|\times 2|\mathcal{E}|$ permutation matrix $\mathbf{E}$ and letting $\otimes$ denote the Kronecker product, ω'' can be related to ω' as

$$\omega'' = (\mathbf{E}\otimes\mathbf{I}_{p+1})\omega' \tag{56}$$

where $\mathbf{E} := [\{\mathbf{e}_{1i}\}_{i\in\mathcal{B}_1},\ldots,\{\mathbf{e}_{Ji}\}_{i\in\mathcal{B}_J}]$, and $\mathbf{e}_{ji}$ is a $2|\mathcal{E}|\times 1$ indicator vector given by

$$\mathbf{e}_{ji} := \left[\begin{array}{c} \mathbf{e}_1^{(ji)} \\ \vdots \\ \mathbf{e}_J^{(ji)} \end{array}\right]$$

with sub-blocks $\mathbf{e}_{i'}^{(ji)} := [\{\delta(j-j',i-i')\}_{j'\in\mathcal{B}_{i'}}]^T$, and $\delta(\cdot,\cdot)$ denoting Kronecker's delta function. Intuitively, $\mathbf{e}_{ji}$ identifies with a one the position where ω_{ji} in ω' is to be re-allocated in ω''.

Substituting (56) into (55) yields

$$\mathbf{A}'\mathbf{v} = (\mathbf{E}\otimes\mathbf{I}_{p+1})\omega'. \tag{57}$$

Concatenating (53) and (57) one arrives at

$$\mathbf{A}\mathbf{v} = \mathbf{E}'\omega' \tag{58}$$

where

$$\mathbf{A} := \left[\begin{array}{c} \mathbf{A}' \\ \mathbf{A}' \end{array}\right] \quad \text{and} \quad \mathbf{E}' := \left[\begin{array}{c} \mathbf{I}_{2(p+1)|\mathcal{E}|} \\ \mathbf{E}\otimes\mathbf{I}_{p+1} \end{array}\right]. \tag{59}$$

Using (58), problem (7) can be re-written as

$$\begin{array}{ll} \min\limits_{\mathbf{v},\omega,\{\xi_j\}} & \frac{1}{2}\sum\limits_{j=1}^{J}\mathbf{v}_j^T(\mathbf{I}_{p+1}-\Pi_{p+1})\mathbf{v}_j + JC\sum\limits_{j=1}^{J}\mathbf{1}_j^T\xi_j \\ \text{s.t.} & \mathbf{Y}_j\mathbf{X}_j\mathbf{v}_j \succeq \mathbf{1}_j - \xi_j \qquad \forall j\in\mathcal{J} \\ & \xi_j \succeq \mathbf{0}_j \qquad \forall j\in\mathcal{J} \\ & \mathbf{A}\mathbf{v} = \mathbf{E}'\omega'. \end{array} \tag{60}$$

It is known that the slack variables $\{\xi_j\}$ can be eliminated by introducing the hinge loss function $\ell(y,[\mathbf{x}^T,1]\mathbf{v}) := \max\{0,1-y[\mathbf{x}^T,1]\mathbf{v}\}$ (Schölkopf and Smola, 2002), which reduces (60) to its equivalent form

$$\begin{array}{ll} \min\limits_{\mathbf{v},\omega} & \frac{1}{2}\sum\limits_{j=1}^{J}\mathbf{v}_j^T(\mathbf{I}_{p+1}-\Pi_{p+1})\mathbf{v}_j + JC\sum\limits_{j=1}^{J}\sum\limits_{n=1}^{N_j}\ell(y_{jn},[\mathbf{x}_{jn}^T,1]\mathbf{v}_j) \\ \text{s.t.} & \mathbf{A}\mathbf{v} = \mathbf{E}'\omega'. \end{array} \tag{61}$$

Comparing the latter with (45), it follows readily that (61), which is equivalent to (7), belongs to the ADMoM-solvable class since (61) is subsumed by (45) with the special choices

$$\begin{aligned} F_1(\mathbf{v}) &:= \frac{1}{2}\sum_{j=1}^{J}\mathbf{v}_j^T(\mathbf{I}_{p+1}-\Pi_{p+1})\mathbf{v}_j + JC\sum_{j=1}^{J}\sum_{n=1}^{N_j}\ell(y_{jn},[\mathbf{x}_{jn}^T,1]\mathbf{v}_j), \\ F_2(\omega) &:= 0, \\ \mathcal{P}_1 &:= \mathbb{R}^{(p+1)J}, \\ \mathcal{P}_2 &:= \{\omega\in\mathbb{R}^{4(p+1)|\mathcal{E}|}\,|\,\omega=\mathbf{E}'\omega' \text{ for some } \omega'\in\mathbb{R}^{2(p+1)|\mathcal{E}|}\} \end{aligned} \tag{62}$$

where $\omega := \mathbf{E}'\omega'$ is now placed in the constraint set $\mathcal{P}_2$.

So far it has been proved that the problem in (7) can be cast as (45). The ADMoM iterations for (45) are (47)-(49), with corresponding iterates $\mathbf{v}(t)$, $\omega(t)$ and $\alpha(t)$. Given the constraint set $\mathcal{P}_2$ in (62), for every iterate $\omega(t)$ there exists a unique $\omega'(t)$ satisfying $\omega(t)=\mathbf{E}'\omega'(t)$, due to the fact that $\mathbf{E}'$ in (59) is full column rank. Hence, $\omega(t)$ can be replaced by $\mathbf{E}'\omega'(t)$ in iterations (47)-(49). Iteration (9) then follows by re-introducing the slack variables $\{\xi_j(t)\}$. Iteration (10) follows because now ω' is unconstrained. Finally, iterations (11) and (12) follow from (49) by splitting $\alpha(t)$ into appropriate sub-groups of vectors $\{\alpha_{ji1}(t)\}$ and $\{\alpha_{ji2}(t)\}$, respectively.

Appendix D. Proof of Lemma 3

The goal of this appendix is to show that iterations (9)-(12) reduce to (13)-(14). To start, notice that the cost in (10) is linear-quadratic w.r.t. ω_{ji}. Thus, setting the derivative of $\mathcal{L}$ w.r.t. ω_{ji} equal to zero, $\omega_{ji}(t+1)$ can be found in closed form as

$$\omega_{ji}(t+1)=\frac{1}{2\eta}(\alpha_{ji1}(t)-\alpha_{ji2}(t))+\frac{1}{2}(\mathbf{v}_j(t+1)+\mathbf{v}_i(t+1)). \tag{63}$$

Substituting (63) into (11) and (12), yields

$$\alpha_{ji1}(t+1) = \frac{1}{2}(\alpha_{ji1}(t)+\alpha_{ji2}(t))+\frac{\eta}{2}(\mathbf{v}_j(t+1)-\mathbf{v}_i(t+1)), \tag{64}$$

$$\alpha_{ji2}(t+1) = \frac{1}{2}(\alpha_{ji1}(t)+\alpha_{ji2}(t))+\frac{\eta}{2}(\mathbf{v}_j(t+1)-\mathbf{v}_i(t+1)). \tag{65}$$

Suppose now that $\alpha_{ji1}(t)$ and $\alpha_{ji2}(t)$ are initialized identically to zero at every node j; that is, $\alpha_{ji1}(0)=\alpha_{ji2}(0)=\mathbf{0}_{(p+1)\times 1}\ \forall j\in\mathcal{J}$ and $\forall i\in\mathcal{B}_j$. From (64) and (65), it follows easily that $\alpha_{ji1}(1)=\alpha_{ji2}(1)$. Similarly, if $\alpha_{ji1}(t-1)=\alpha_{ji2}(t-1)$, then by induction $\alpha_{ji1}(t)=\alpha_{ji2}(t)$. Thus, only one set of multipliers, say $\{\alpha_{ji1}\}$, needs to be stored and updated per node j.

Upon substituting $\omega_{ji}(t+1)=(1/2)(\mathbf{v}_j(t+1)+\mathbf{v}_i(t+1))$ into the objective function of (9) and using $\alpha_{ji1}(t)=\alpha_{ji2}(t)$, one obtains

$$\begin{aligned} \mathcal{L}'(\{\mathbf{v}_j\},\{\xi_j\},\{\mathbf{v}_j(t)\},\{\alpha_{ji1}(t)\}) &= \frac{1}{2}\sum_{j=1}^{J}\mathbf{v}_j^T(\mathbf{I}_{p+1}-\Pi_{p+1})\mathbf{v}_j + JC\sum_{j=1}^{J}\mathbf{1}_j^T\xi_j \\ &+\sum_{j=1}^{J}\sum_{i\in\mathcal{B}_j}\alpha_{ji1}^T(t)(\mathbf{v}_j-\mathbf{v}_i)+\frac{\eta}{2}\sum_{j=1}^{J}\sum_{i\in\mathcal{B}_j}\left\|\mathbf{v}_j-\frac{1}{2}[\mathbf{v}_j(t)+\mathbf{v}_i(t)]\right\|^2+\frac{\eta}{2}\sum_{j=1}^{J}\sum_{i\in\mathcal{B}_j}\left\|\mathbf{v}_i-\frac{1}{2}[\mathbf{v}_j(t)+\mathbf{v}_i(t)]\right\|^2. \end{aligned} \tag{66}$$

The first double sum in the right hand side (r.h.s.) of (66) can be rewritten as

$$\sum_{j=1}^{J}\sum_{i\in\mathcal{B}_j}\alpha_{ji1}^T(t)(\mathbf{v}_j-\mathbf{v}_i)=\sum_{j=1}^{J}\sum_{i\in\mathcal{B}_j}\mathbf{v}_j^T(\alpha_{ji1}(t)-\alpha_{ij1}(t))$$
$$=2\sum_{j=1}^{J}\mathbf{v}_j^T\sum_{i\in\mathcal{B}_j}\alpha_{ji1}(t) \tag{67}$$

where the first equality follows because $\sum_{j=1}^{J}\sum_{i\in\mathcal{B}_j}\alpha_{ji1}^T(t)\mathbf{v}_i=\sum_{j=1}^{J}\sum_{i\in\mathcal{B}_j}\alpha_{ij1}^T(t)\mathbf{v}_j$. Intuitively, the r.h.s. computes the sum by fixing a node j and adding the inner products of $\mathbf{v}_j$ with the incoming Lagrange multipliers $\alpha_{ij1}(t)$; while the left hand side performs the same sum by fixing a node j and adding the inner products of outgoing Lagrange multipliers $\alpha_{ji1}(t)$ and the corresponding $\mathbf{v}_i$ neighbors. The second equality on (67) holds because the all-zero initialization of the multipliers implies that $\alpha_{ji1}(t)=-\alpha_{ij1}(t)\ \forall t$ [cf. from (64)-(65)]. Likewise, the second and third double sums in the r.h.s. of (66) can be simplified to

$$\frac{\eta}{2}\sum_{j=1}^{J}\sum_{i\in\mathcal{B}_j}\left[\left\|\mathbf{v}_j-\frac{1}{2}[\mathbf{v}_j(t)+\mathbf{v}_i(t)]\right\|^2+\left\|\mathbf{v}_i-\frac{1}{2}[\mathbf{v}_j(t)+\mathbf{v}_i(t)]\right\|^2\right]=\eta\sum_{j=1}^{J}\sum_{i\in\mathcal{B}_j}\left\|\mathbf{v}_j-\frac{1}{2}[\mathbf{v}_j(t)+\mathbf{v}_i(t)]\right\|^2. \tag{68}$$

Lemma 3 follows after substituting (67) and (68) into (66), and defining $\alpha_j(t):=\sum_{i\in\mathcal{B}_j}\alpha_{ji1}(t)$.

Appendix E. Proof of Proposition 1

Letting $\lambda_j:=[\lambda_{j1},\ldots,\lambda_{jN_j}]^T$ and $\mu_j:=[\mu_{j1},\ldots,\mu_{jN_j}]^T$ denote Lagrange multipliers associated with the constraints $\mathbf{Y}_j\mathbf{X}_j\mathbf{v}_j\succeq\mathbf{1}_j-\xi_j$ and $\xi_j\succeq\mathbf{0}_j$, respectively, the Lagrangian corresponding to (13) is given by

$$\begin{aligned}&\mathcal{L}''(\{\mathbf{v}_j\},\{\xi_j\},\{\lambda_j\},\{\mu_j\},\{\mathbf{v}_j(t)\},\{\alpha_j(t)\})\\&\quad=\frac{1}{2}\sum_{j=1}^{J}\mathbf{v}_j^T(\mathbf{I}_{p+1}-\Pi_{p+1})\mathbf{v}_j+JC\sum_{j=1}^{J}\mathbf{1}_j^T\xi_j-\sum_{j=1}^{J}\lambda_j^T(\mathbf{Y}_j\mathbf{X}_j\mathbf{v}_j-\mathbf{1}_j+\xi_j)\\&\quad-\sum_{j=1}^{J}\mu_j^T\xi_j+2\sum_{j=1}^{J}\alpha_j^T(t)\mathbf{v}_j+\eta\sum_{j=1}^{J}\sum_{i\in\mathcal{B}_j}\left\|\mathbf{v}_j-\frac{1}{2}[\mathbf{v}_j(t)+\mathbf{v}_i(t)]\right\|^2.\end{aligned} \tag{69}$$

The KKT conditions yield per iteration the primal and dual variables in (69) as follows

$$\mathbf{v}_j(t+1) = \mathbf{U}_j^{-1}\left(\mathbf{X}_j^T\mathbf{Y}_j\lambda_j(t+1)-2\alpha_j(t)+\eta\sum_{i\in\mathcal{B}_j}(\mathbf{v}_j(t)+\mathbf{v}_i(t))\right), \tag{70}$$

$$\mathbf{0}_j = JC\mathbf{1}_j-\lambda_j-\mu_j \tag{71}$$

where $\lambda_j(t+1)$ is the optimal Lagrange multiplier after iteration $t+1$, and the inverse of $\mathbf{U}_j:=(1+2\eta|\mathcal{B}_j|)\mathbf{I}_{p+1}-\Pi_{p+1}$ always exists.

The KKT conditions also require $\lambda_j\succeq\mathbf{0}_j$ and $\mu_j\succeq\mathbf{0}_j$, which allows (71) to be replaced by $\mathbf{0}_j\preceq\lambda_j\preceq JC\mathbf{1}_j$. To carry out the iteration (70) at every node, the optimal values $\lambda_j(t+1)$ of the

Lagrange multipliers λ_j are found by solving the Lagrange dual problem associated with (69). The pertinent dual function is given by

$$\mathcal{L}_\lambda(\{\lambda_j\}) = \sum_{j=1}^{J} -\frac{1}{2}\lambda_j^T \mathbf{Y}_j \mathbf{X}_j \mathbf{U}_j^{-1} \mathbf{X}_j^T \mathbf{Y}_j \lambda_j + \left(\mathbf{1}_j - \mathbf{Y}_j \mathbf{X}_j \mathbf{U}_j^{-1} \mathbf{f}_j(t)\right)^T \lambda_j \tag{72}$$

where $\mathbf{f}_j(t) := 2\alpha_j(t) - \eta \sum_{i\in\mathcal{B}_j}[\mathbf{v}_j(t) + \mathbf{v}_i(t)]$. Note that the Lagrange multipliers $\{\mu_j\}$ are not present in $\mathcal{L}_\lambda$. From (72), the Lagrange dual problem can be decoupled if each node j has access to the $\mathbf{v}_i(t)$ estimates of its neighboring nodes. Thus, $\lambda_j(t+1)$ is given by

$$\lambda_j(t+1) = \arg \max_{\lambda_j:\, \mathbf{0}_j \preceq \lambda_j \preceq JC\mathbf{1}_j} -\frac{1}{2}\lambda_j^T \mathbf{Y}_j \mathbf{X}_j \mathbf{U}_j^{-1} \mathbf{X}_j^T \mathbf{Y}_j \lambda_j + \left(\mathbf{1}_j - \mathbf{Y}_j \mathbf{X}_j \mathbf{U}_j^{-1} \mathbf{f}_j(t)\right)^T \lambda_j \tag{73}$$

The dual variable update in (73) and the primal variable update in (70) coming from the KKT optimality, are precisely iterations (16) and (17) of Proposition 1, which together with (18) correspond to iterations (13) and (14). Lemma 3 shows that (13) and (14) are equivalent to (9)-(12). Lemma 2 establishes that (9)-(12) in turn correspond to the ADMoM iterations (47)-(49) of Appendix A. As stated in Proposition 4 in Appendix A, convergence of the ADMoM iterations (47)-(49) is guaranteed so long as: (i) $\mathcal{P}_1$ is bounded; or, (ii) $\mathbf{A}^T\mathbf{A}$ is nonsingular. Since for the problem at hand matrix $\mathbf{A}$ in (59) satisfies condition (ii), the iterates for (16)-(18) in Proposition 1 converge to the optimal solution of (7) for any $\eta > 0$.

Appendix F. Proof of Theorem 1

For simplicity, this theorem will be proved for purely linear discriminant functions $g(\mathbf{x}) = \mathbf{w}^T\mathbf{x}$. Consider the reproducing kernel Hilbert space (RKHS) $\mathcal{H}$ of functions $g(\mathbf{x})$ with corresponding positive semi-definite kernel $K : \mathcal{X}\times\mathcal{X} \to \mathbb{R}$, defined as

$$\mathcal{H} := \overline{\left\{ g(\cdot) = \sum_{n=1}^{N} \gamma_n K(\cdot, \mathbf{x}_n) :\ N \in \mathbb{N},\ \gamma_1, \ldots, \gamma_N \in \mathbb{R},\ \mathbf{x}_1, \ldots, \mathbf{x}_N \in \mathcal{X} \right\}}$$

with $\overline{\mathcal{A}}$ denotes the completion of the set $\mathcal{A}$.

The parameter optimization problem (23) can be written in terms of the Hinge loss function $\ell(y, g(\mathbf{x})) := \max\{0, 1 - yg(\mathbf{x})\}$, and the RKHS-induced norm $\|g\|_{\mathcal{H}}^2$ as a regularized optimization problem to obtain, (see, e.g., Schölkopf and Smola, 2002)

$$\begin{aligned} \min_{\{g_j\in\mathcal{H}\}} \quad & \frac{1}{2}\sum_{j=1}^{J} \left\|g_j\right\|_{\mathcal{H}}^2 + JC \sum_{j=1}^{J}\sum_{n=1}^{N_j} \ell(y_{jn}, g_j(\mathbf{x}_{jn})) \\ \text{s.t. } & g_j(\chi_l) = g_i(\chi_l) \quad \forall j \in \mathcal{J}, i \in \mathcal{B}_j, l = 1, \ldots, L. \end{aligned} \tag{74}$$

Given the optimal Lagrange multipliers ς_{jil}^* for the constraints $\{g_j(\chi_l) = g_i(\chi_l)\}$, the solution $\{g_j^*\}$ of (74) can be obtained from its Lagrangian as

$$\{g_j^*\} = \arg \min_{\{g_j\in\mathcal{H}\}} \frac{1}{2}\sum_{j=1}^{J} \left\|g_j\right\|_{\mathcal{H}}^2 + JC \sum_{j=1}^{J}\sum_{n=1}^{N_j} \ell(y_{jn}, g_j(\mathbf{x}_{jn})) + \sum_{j=1}^{J}\sum_{i\in\mathcal{B}_j}\sum_{l=1}^{L} \varsigma_{jil}^*(g_j(\chi_l) - g_i(\chi_l)). \tag{75}$$

Arguing as in (67), the last term in (75) can be written as

$$\sum_{j=1}^{J}\sum_{i\in\mathcal{B}_j}\sum_{l=1}^{L}\varsigma_{jil}^{*}(g_j(\chi_l)-g_i(\chi_l))=\sum_{j=1}^{J}\sum_{i\in\mathcal{B}_j}\sum_{l=1}^{L}(\varsigma_{jil}^{*}-\varsigma_{ijl}^{*})g_j(\chi_l)$$

thus rendering the cost in (75) separable across j. Hence, each g_j^* can be obtained per node as

$$g_j^{*}=\arg\min_{g_j\in\mathcal{H}}V(\mathbf{x}_{j1},\ldots,\mathbf{x}_{jN_j},y_{j1},\ldots,y_{jN_j},\{\chi_l\},g_j)+\frac{1}{2}\left\|g_j\right\|_{\mathcal{H}}^{2} \tag{76}$$

where $V(\mathbf{x}_{j1},\ldots,\mathbf{x}_{jN_j},y_{j1},\ldots,y_{jN_j},\{\chi_l\},g_j):=JC\sum_{n=1}^{N_j}\ell(y_{jn},g_j(\mathbf{x}_{jn}))+\sum_{i\in\mathcal{B}_j}\sum_{l=1}^{L}(\varsigma_{jil}^{*}-\varsigma_{ijl}^{*})g_j(\chi_l)$. Applying the Representer Theorem to (76) as in Wahba (1990) and Schölkopf and Smola (2002) one readily arrives at

$$g_j^{*}(\mathbf{x})=\sum_{n=1}^{N_j}a_{jn}^{*}K(\mathbf{x},\mathbf{x}_{jn})+\sum_{l=1}^{L}c_{jl}^{*}K(\mathbf{x},\chi_l). \tag{77}$$

Appendix G. Proof of Proposition 2

Recall that $\mu_j:=[\mu_{j1},\ldots,\mu_{jN_j}]^T$ denotes the Lagrange multiplier associated with the constraint $\xi_j\succeq\mathbf{0}_j$ (cf. Appendix E). The Lagrangian corresponding to (25) is given by

$$\begin{aligned}
&\mathcal{L}''(\{\mathbf{w}_j\},\{b_j\},\{\xi_j\},\{\lambda_j\},\{\mu_j\},\{\mathbf{w}_j(t)\},\{b_j(t)\},\{\alpha_j(t)\},\{\beta_j(t)\})\\
&\quad=\frac{1}{2}\sum_{j=1}^{J}\|\mathbf{w}_j\|^2+JC\sum_{j=1}^{J}\mathbf{1}_j^T\xi_j-\sum_{j=1}^{J}\lambda_j^T(\mathbf{Y}_j\Phi(\mathbf{X}_j)\mathbf{w}_j-\mathbf{1}_jb_j+\xi_j)\\
&\quad-\sum_{j=1}^{J}\mu_j^T\xi_j+2\sum_{j=1}^{J}\alpha_j^T(t)\mathbf{G}\mathbf{w}_j+2\sum_{j=1}^{J}\beta_j(t)b_j\\
&\quad+\eta\sum_{j=1}^{J}\sum_{i\in\mathcal{B}_j}\left\|\mathbf{G}\left[\mathbf{w}_j-\frac{1}{2}(\mathbf{w}_j(t)+\mathbf{w}_i(t))\right]\right\|^2+\eta\sum_{j=1}^{J}\sum_{i\in\mathcal{B}_j}\left\|b_j-\frac{1}{2}[b_j(t)+b_i(t)]\right\|^2.
\end{aligned}$$

From the KKT conditions for (25) it follows that

$$\mathbf{w}_j(t+1)=\widetilde{\mathbf{U}}_j^{-1}\left\{\Phi^T(\mathbf{X}_j)\mathbf{Y}_j\lambda_j(t+1)-\mathbf{G}^T\left[2\alpha_j(t)-\eta\sum_{i\in\mathcal{B}_j}\mathbf{G}(\mathbf{w}_j(t)+\mathbf{w}_i(t))\right]\right\}, \tag{78}$$

$$b_j(t+1)=\frac{1}{2\eta|\mathcal{B}_j|}\left[\mathbf{1}_j^T\mathbf{Y}_j\lambda_j(t+1)-2\beta_j(t)+\eta\sum_{i\in\mathcal{B}_j}(\beta_j(t)+\beta_i(t))\right] \tag{79}$$

where $\lambda_j(t+1)$ is the optimal Lagrange multiplier at iteration $t+1$, and $\widetilde{\mathbf{U}}_j:=\mathbf{I}_P+2\eta|\mathcal{B}_j|\mathbf{G}^T\mathbf{G}$. Using the Sherman-Morrison-Woodbury formula (Golub and Van Loan, 1996)

$$\widetilde{\mathbf{U}}_j^{-1}=\mathbf{I}_P-2\eta|\mathcal{B}_j|\mathbf{G}^T(\mathbf{I}_L+2\eta|\mathcal{B}_j|\mathbf{G}\mathbf{G}^T)^{-1}\mathbf{G}. \tag{80}$$

Substituting (80) into (78), left-multiplying by $\phi^T(\mathbf{x})$, and recalling that $\phi^T(\mathbf{x})\phi^T(\mathbf{x}')=K(\mathbf{x},\mathbf{x}')$, yields

$$\begin{aligned}
\phi^T(\mathbf{x})\mathbf{w}_j(t+1)=&\left(\mathbf{k}^T(\mathbf{x},\mathbf{X}_j)-2\eta|\mathcal{B}_j|\mathbf{k}^T(\mathbf{x},\Gamma)\widetilde{\mathbf{U}}_j^{-1}\mathbf{K}(\Gamma,\mathbf{X}_j)\right)\mathbf{Y}_j\lambda_j(t+1)\\
&-\left(\mathbf{k}^T(\mathbf{x},\Gamma)-2\eta|\mathcal{B}_j|\mathbf{k}^T(\mathbf{x},\Gamma)\widetilde{\mathbf{U}}_j^{-1}\mathbf{K}(\Gamma,\Gamma)\right)\widetilde{\mathbf{f}}_j(t+1)
\end{aligned} \tag{81}$$

where the entries of the kernel vector are $[\mathbf{k}(\mathbf{x},\mathbf{X}_j)]_n := K(\mathbf{x},\mathbf{x}_{jn})$ and $[\mathbf{k}(\mathbf{x},\Gamma)]_l := K(\mathbf{x},\chi_l)$.

Note that $g_j^{(t)}(\mathbf{x})$ in (31) follows from (77) and can be written as $g_j^{(t)}(\mathbf{x}) = \phi^T(\mathbf{x})\mathbf{w}_j(t) + b_j(t)$. Grouping terms in (81) that right-multiply $\mathbf{k}^T(\mathbf{x},\mathbf{X}_j)$ and those that right-multiply $\mathbf{k}^T(\mathbf{x},\Gamma)$, yields $\mathbf{a}_j(t)$ as in (32) and $\mathbf{c}_j(t)$ as in (33), respectively. Finally, $b_j(t)$ in (34) is given by (79).

Appendix H. Proof of Proposition 3

To obtain iteration (35), consider first the dual problem for (25), that is

$$\begin{aligned}\lambda_j(t+1) \;=\; \underset{\lambda_j:\,\mathbf{0}_j\preceq\lambda_j\preceq JC\mathbf{1}_j}{\arg\max} & -\frac{1}{2}\lambda_j^T\mathbf{Y}_j\left(\Phi(\mathbf{X}_j)\widetilde{\mathbf{U}}_j^{-1}\Phi^T(\mathbf{X}_j)+\frac{\mathbf{1}\mathbf{1}^T}{2\eta|\mathcal{B}_j|}\right)\mathbf{Y}_j\lambda_j \\ & +\left(\mathbf{1}_j-\mathbf{Y}_j\Phi(\mathbf{X}_j)\widetilde{\mathbf{U}}_j^{-1}\mathbf{G}^T\widetilde{\mathbf{f}}_j(t)-\frac{h_j(t)\mathbf{1}^T}{2\eta|\mathcal{B}_j|}\right)^T\lambda_j \end{aligned} \tag{82}$$

where $\widetilde{\mathbf{U}}_j^{-1}$ is given by (80), and $\widetilde{\mathbf{f}}_j(t)$ as in Proposition 2. Using (80), the term $\Phi(\mathbf{X}_j)\widetilde{\mathbf{U}}_j^{-1}\Phi^T(\mathbf{X}_j)$ can be written in terms of inner products, and summarized via kernels as

$$\Phi(\mathbf{X}_j)\widetilde{\mathbf{U}}_j^{-1}\Phi^T(\mathbf{X}_j) = \mathbf{K}(\mathbf{X}_j,\mathbf{X}_j) - 2\eta|\mathcal{B}_j|\mathbf{K}(\mathbf{X}_j,\Gamma)\widetilde{\mathbf{U}}_j^{-1}\mathbf{K}(\Gamma,\mathbf{X}_j). \tag{83}$$

Likewise, the term $\Phi(\mathbf{X}_j)\widetilde{\mathbf{U}}_j^{-1}\mathbf{G}^T\widetilde{\mathbf{f}}_j(t)$ can be expressed as

$$\Phi(\mathbf{X}_j)\widetilde{\mathbf{U}}_j^{-1}\mathbf{G}^T\widetilde{\mathbf{f}}_j(t) = \Big(\mathbf{K}(\mathbf{X}_j,\Gamma) - 2\eta|\mathcal{B}_j|\mathbf{K}(\mathbf{X}_j,\Gamma)\widetilde{\mathbf{U}}_j^{-1}\mathbf{K}(\Gamma,\Gamma)\Big)\widetilde{\mathbf{f}}_j(t). \tag{84}$$

Plugging (83) and (84) into (82), yields (35).

To obtain iteration (36), left-multiply $\mathbf{w}_j(t+1)$ in (78) by $\mathbf{G}$ to arrive at

$$\widetilde{\mathbf{w}}_j(t+1) \;=\; \mathbf{G}\widetilde{\mathbf{U}}_j^{-1}\Phi^T(\mathbf{X}_j)\mathbf{Y}_j\lambda_j - \mathbf{G}\widetilde{\mathbf{U}}_j^{-1}\mathbf{G}^T\left[2\alpha_j(t) - \eta\sum_{i\in\mathcal{B}_j}\left(\widetilde{\mathbf{w}}_j(t)+\widetilde{\mathbf{w}}_i(t)\right)\right]. \tag{85}$$

The terms $\mathbf{G}\widetilde{\mathbf{U}}_j^{-1}\Phi^T(\mathbf{X}_j)$ and $\mathbf{G}\widetilde{\mathbf{U}}_j^{-1}\mathbf{G}^T$ can be respectively written as

$$\mathbf{G}\widetilde{\mathbf{U}}_j^{-1}\Phi^T(\mathbf{X}_j) = \mathbf{K}(\Gamma,\Gamma) - 2\eta|\mathcal{B}_j|\mathbf{K}(\Gamma,\Gamma)\widetilde{\mathbf{U}}_j^{-1}\mathbf{K}(\Gamma,\mathbf{X}_j) \tag{86}$$

and

$$\mathbf{G}\widetilde{\mathbf{U}}_j^{-1}\mathbf{G}^T = \mathbf{K}(\Gamma,\Gamma) - 2\eta|\mathcal{B}_j|\mathbf{K}(\Gamma,\Gamma)\widetilde{\mathbf{U}}_j^{-1}\mathbf{K}(\Gamma,\Gamma)\,. \tag{87}$$

Substituting (86) and (87) into (85), yields (36), and completes the proof of the proposition.

Abstract

Analysis of causal effects between continuous-valued variables typically uses either autoregressive models or structural equation models with instantaneous effects. Estimation of Gaussian, linear structural equation models poses serious identifiability problems, which is why it was recently proposed to use non-Gaussian models. Here, we show how to combine the non-Gaussian instantaneous model with autoregressive models. This is effectively what is called a structural vector autoregression (SVAR) model, and thus our work contributes to the long-standing problem of how to estimate SVAR's. We show that such a non-Gaussian model is identifiable without prior knowledge of network structure. We propose computationally efficient methods for estimating the model, as well as methods to assess the significance of the causal influences. The model is successfully applied on financial and brain imaging data.

Keywords: structural vector autoregression, structural equation models, independent component analysis, non-Gaussianity, causality

1. Introduction

Analysis of causal influences or effects has become an important topic in statistics and machine learning, and has recently found applications in, for example, neuroinformatics (Roebroeck et al., 2005; Kim et al., 2007) and bioinformatics (Opgen-Rhein and Strimmer, 2007). While the deeper meaning of causality has been formalized in different ways (Pearl, 2000; Spirtes et al., 1993), we

∗. Also in Department of Computer Science and HIIT, University of Helsinki.

consider the problem here from a practical viewpoint, where coefficients in conventional statistical models are interpreted as causal influences.

For continuous-valued variables, such an analysis is typically performed in two different ways. First, if the time-resolution of the measurements is higher than the time-scale of causal influences, one can estimate a classic autoregressive (AR) model with time-lagged variables and interpret the autoregressive coefficients as causal effects. Second, if the measurements have a lower time resolution than the causal influences, or if the data has no temporal structure at all, one can use a model in which the influences are instantaneous, leading to Bayesian networks or structural equation models (SEM); see Bollen (1989).[1]

While estimation of autoregressive methods can be solved by classic regression methods, the case of instantaneous effects is much more difficult. Most methods suffer from lack of identifiability, because covariance information alone is not sufficient to uniquely characterize the model parameters. Prior knowledge of the structure (fixing some of the connections to zero) of the SEM is then necessary for most practical applications. However, a method was recently proposed which uses the non-Gaussian structure of the data to overcome the identifiability problem (Shimizu et al., 2006). If the disturbance variables (external influences) are non-Gaussian, no prior knowledge on the network structure is needed to estimate the linear SEM, except for the ubiquitous assumption of a directed acyclic graph (DAG) and the assumption of no latent variables. (The case of latent variables, that is, unobserved confounders, was later considered by Hoyer et al., 2008.)

Here, we consider the general case where causal influences can occur either instantaneously or with considerable time lags. Such models are one example of structural vector autoregressive (SVAR) models popular in econometric theory, in which numerous attempts have been made for its estimation, see, for example, Swanson and Granger (1997), Demiralp and Hoover (2003) and Moneta and Spirtes (2006). We propose to use non-Gaussianity to estimate the model. We show that this variant of the model is identifiable without other restrictions on the network structure than acyclicity and no latent variables. To our knowledge, no model proposed for this problem has been shown to be fully identifiable without prior knowledge of network structure. We further propose two computationally efficient methods for estimating the model based on the theory of independent component analysis or ICA (Hyvärinen et al., 2001).

The proposed non-Gaussian model not only allows estimation of both instantaneous and lagged effects; it also shows that taking instantaneous influences into account can change the values of the time-lagged coefficients quite drastically. Thus, we see that neglecting instantaneous influences can lead to misleading interpretations of causal effects. The framework further points towards generalizations of the well-known Granger causality measure (Granger, 1969).

The paper is structured as follows. We first define the model and discuss its relation to other models in Section 2. We motivate the key assumption of non-Gaussianity in Section 3. Next, we derive the likelihood and discuss some of its interpretations in Section 4. In Section 5 we propose two computationally efficient estimation methods and compare them with simulations. Assessement of the results using testing is considered in Section 6. Section 7 discusses some interesting phenomena concerning the interpretation of the estimated parameter values. Experiments on financial and neuroscientific data are made in Section 8. Some extensions of the model are discussed in Section 9, and Section 10 concludes the paper. Preliminary results were published in Hyvärinen et al. (2008) and Zhang and Hyvärinen (2009).

1. Here, we assume that the learning is unsupervised, that is, the inputs to the system are not known or used. If the inputs to the system are known, methods such as dynamic causal modelling can be used (Friston et al., 2003).

2. A Non-Gaussian Structural Vector Autoregressive Model

In this section, we define our new model.

2.1 Background and Notation

Let us denote the observed time series by $x_i(t), i = 1,\ldots,n, t = 1,\ldots,T$ where i is the index of the time series and t is the time index. All the time series (variables) are collected into a single column vector $\mathbf{x}(t)$. Without loss of generality, we can assume that the $x_i(t)$ have zero mean.

In autoregressive modelling, we would model the dynamics by a model of the form

$$\mathbf{x}(t) = \sum_{\tau=1}^{k} \mathbf{B}_\tau \mathbf{x}(t-\tau) + \mathbf{e}(t) \tag{1}$$

where k is the number of time-delays used, that is, the order of the autoregressive model, $\mathbf{B}_\tau, \tau = 1,\ldots,k$ are $n \times n$ matrices, and $\mathbf{e}(t)$ is the innovation process.

In structural equation models (SEM), or continuous-valued Bayesian networks, there is no time structure in the data, and the variables are simply modelled as functions of the other variables:

$$\mathbf{x} = \mathbf{B}\mathbf{x} + \mathbf{e} \tag{2}$$

where the vector $\mathbf{e}$ is the vector of disturbances or external influences. The diagonal of $\mathbf{B}$ is defined to be zero. It is typically assumed that we have a sample of observations which are independent and identically distributed.

2.2 Definition of Our Model

In many applications, the influences between the $x_i(t)$ can be both instantaneous and lagged. Thus, we combine the two models in (1) and (2) into a single model. Denote by $\mathbf{B}_\tau$ the $n \times n$ matrix of the causal effects between the variables x_i with time lag $\tau, \tau = 0,\ldots,k$. For $\tau > 0$, the effects are ordinary autoregressive effects from the past to the present, while for $\tau = 0$, the effects are "instantaneous".

We define our model by a straightforward combination of (1) and (2) as

$$\mathbf{x}(t) = \sum_{\tau=0}^{k} \mathbf{B}_\tau \mathbf{x}(t-\tau) + \mathbf{e}(t) \tag{3}$$

where the $e_i(t)$ are random processes modelling the disturbances. We make the following assumptions on the $e_i(t)$:

1. The $e_i(t)$ are are mutually independent, both of each other and over time. This is a typical assumption in autoregressive models.

2. The $e_i(t)$ are *non-Gaussian*, which is an important assumption which distinguishes our model from classic models, whether autoregressive models, structural-equation models, or Bayesian networks.

3. The matrix modelling instantaneous effects, $\mathbf{B}_0$, corresponds to an *acyclic* graph, as is typical in causal analysis. However this assumption may not be strictly necessary as will be discussed

in Section 9. The acyclicity is equivalent to the existence of a permutation matrix $\mathbf{P}$, which corresponds to a "causal" ordering of the variables x_i, such that the matrix $\mathbf{PB_0P}^T$ is lower-triangular (i.e., entries above the diagonal are zero). Acyclicity also implies that the entries on the diagonal are zero, even before such a permutation.

2.3 Relation to Other Models

Next, we discuss the relationships of our model with other models.

2.3.1 LINEAR NON-GAUSSIAN ACYCLIC MODEL

Our model is a generalization of the linear non-Gaussian acyclic model (LiNGAM) proposed in Shimizu et al. (2006). If the order of the autoregressive part is zero, that is, $k = 0$, the model is nothing else than the LiNGAM model, modelling instantaneous effects only. As shown in Shimizu et al. (2006), the assumption of non-Gaussianity of the e_i enables estimation of the model. This is because the non-Gaussian structure of the data provides information not contained in the covariance matrix which is the only source of information in most methods.

Non-Gaussianity enables model estimation using independent component analysis, which solves the non-identifiability of factor analytic models using the assumption of non-Gaussianity of the factors (Comon, 1994; Hyvärinen et al., 2001). In fact, the estimation method in Shimizu et al. (2006) uses an ICA algorithm as an essential part. This is because we can transform (2) into the factor-analytic model of ICA:

$$\mathbf{x} = (\mathbf{I} - \mathbf{B})^{-1}\mathbf{e} \tag{4}$$

where $\mathbf{e}$ is now a vector of latent variables. Under the assumptions of the model, in particular the independence and non-Gaussianity of the disturbances e_i, the model can be essentially estimated (Comon, 1994). The acyclicity assumption also ensures that $\mathbf{I} - \mathbf{B}$ is invertible.

However, there is an important indeterminacy which ICA cannot solve: the order of the components. In a SEM, each disturbance corresponds to one of the observed variables. In contrast, ICA, like most factor-analytic models, gives the factors in no particular order. Thus, after ICA estimation (or as part of the ICA estimation) we have to establish the correspondence between the x_i and the e_i. It was proven by Shimizu et al. (2006) that the correspondence can in fact be established based on the acyclicity of $\mathbf{B}$. Basically, only one of the possible orderings of the rows of $(\mathbf{I} - \mathbf{B})$ is such that all the elements on the diagonal are non-zero, and can thus be scaled to equal one, which has to be the case by definition.

Thus, the LiNGAM model can be estimated by basically first performing ICA estimation and then finding the right ordering of the components based on acyclicity.

2.3.2 AUTOREGRESSIVE MODELS

On the other hand, if the matrix $\mathbf{B}_0$ has all zero entries, the model in Eq. (3) is a classic vector autoregressive model in which future observations are linearly predicted from preceding ones. If we knew in advance that $\mathbf{B}_0$ is zero, the model could thus be estimated by classic regression techniques since we do not have the same variables on the left and right-hand sides of Eq. (3). However, our model would still be different from classic autoregressive models because the disturbances $e_i(t)$ are non-Gaussian.

It is important to note here that an autoregressive model can serve two different goals: prediction and analysis of causality. Our goal here is the latter: We estimate the parameter matrices $\mathbf{B}_\tau$ in order to interpret them as causal effects between the variables. This goal is distinct from simply predicting future outcomes when passively observing the time series, as has been extensively discussed in the literature on causality (Pearl, 2000; Spirtes et al., 1993). Thus, we emphasize that our model is not intended to reduce prediction errors if we want to predict $x_i(t)$ using (passively) observed values of the past $\mathbf{x}(t-1), \mathbf{x}(t-2), \ldots$; for such prediction, an ordinary autoregressive model is likely to be just as good.

2.3.3 STRUCTURAL VECTOR AUTOREGRESSIVE MODELS

Combinations of SEM and vector autoregressive models have been proposed in the econometric literature, and called structural vector autoregressive models (SVAR). Although many of them are quite similar to our model in spirit (Swanson and Granger, 1997; Demiralp and Hoover, 2003; Moneta and Spirtes, 2006), we are not aware of any method in which non-Gaussianity would be an essential assumption. We will see below how the assumption of non-Gaussianity is essential for the identifiability of the model, which has been a serious problem in previous methods. In the next section, we thus consider the justification of this assumption.

3. Why Disturbances Could be Non-Gaussian

Non-Gaussianity is the new assumption in our model. In this section, we attempt to justify why, in many applications, we can consider the $e_i(t)$ to be non-Gaussian. The arguments are based on heteroscedasticity. We do not by any means claim that we are the first to develop these arguments; some of them are well-known and we merely re-iterate them here.

The principle of heteroscedasticity means that the variance of $e_i(t)$ depends on t: in some parts of the time series, it is larger, and in other parts it is smaller. The shape of the distribution conditional to the variance is the same always: often it is assumed to be Gaussian (normal).

We argue that heteroscedasticity is an important reason why, in many cases, the $e_i(t)$ should be strongly non-Gaussian. Even if the Central Limit Theorem is applicable in the sense that $e_i(t)$ is a sum of many different latent independent variables, the disturbances can be very non-Gaussian if, for some reason, the variance of the $e_i(t)$ is changing.

The connection between heteroscedasticity and non-Gaussianity can be developed in a few simple equations. Denote by $z(t)$ a standardized Gaussian random variable. Assume that a disturbance $e(t)$ (dropping the index i for simplicity) is a product of z and a random "variance" variable $v(t)$:

$$e(t) = z(t)v(t)$$

where $z(t)$ and $v(t)$ are independent by definition. We can, in fact, drop the time indices and just consider these time series as random variables. The distribution of v can be of different kinds, whereas the distribution of z is fixed to standardized Gaussian. In the simplest case, v takes only two different values, which means that the data points belong to just two different classes, and the density is then a finite mixture of two Gaussian distributions.

We can simply show the following well-known result: If z is Gaussian, e has always positive kurtosis,[2] regardless of the distribution of v (as long as v^2 has non-zero variance). This is because

$$\text{kurt}(e) = E\{e^4\} - 3(E\{e^2\})^2 = E\{v^4 z^4\} - 3(E\{v^2 z^2\})^2 = 3[E\{v^4\} - (E\{v^2\})^2] \tag{5}$$

which is always positive because it is the variance of v^2 multiplied by three (Beale and Mallows, 1959). It is easy to generalize this result to show that even if z is not Gaussian, the kurtosis is still positive if the variance of v^2 is large enough.

Heteroscedastity can be seen in some important application areas of causal modelling, in particular:

1. In econometrics, heteroscedastic models have a long tradition (Engle, 1995). For example, in financial markets the volatility of a price is often assumed to be changing over time, and volatility is nothing but the variance in some scaling.

2. In brain imaging, the power of rhytmic activity as measured by electroencephalography or magnetoencephalography is non-constant (Hari and Salmelin, 1997). The power is essentially the same as the variance.

We emphasize that the assumption of non-Gaussianity is fundamentally an empirical assumption. It is fulfilled in some application areas and not in others. It can be validated by examining the distributions of the estimates of the $e_i(t)$, which are simply obtained by solving for $\mathbf{e}(t)$ in (3) after estimation of the model. Those estimates are linear functions of the data, which implies that if the data were Gaussian, the $e_i(t)$ would necessarily be Gaussian. Thus, any non-Gaussianity in the estimates is valid evidence for the Gaussianity of the underlying $e_i(t)$. In addition to visual inspection, any formal tests for non-Gaussianity can be used, such as the Shapiro-Wilk test or the Kolmogorov-Smirnov test. (Independence of the $e_i(t)$ can be validated in the same way, although it seems to be more difficult to investigate by visualization or testing.)

However, in practice the question is not whether the disturbances are non-Gaussian but whether they are sufficiently far from Gaussian to enable sufficiently accurate estimation. In the theory of ICA, it has been shown that the asymptotic variance of the estimators is a function of the non-Gaussianity of the components: When their distribution approaches Gaussianity, the asymptotic variance goes to infinity (Cardoso and Laheld, 1996; Hyvärinen et al., 2001). Thus, instead of testing non-Gaussianity it may be much more useful to simply measure the accuracy of the estimates by bootstrapping and similar methods. If the disturbances are Gaussian (or very close to Gaussian), our estimation method is likely to fail completely. Some other assumptions are then needed to obtain identifiability of the model.

It should be also noted that the assumptions of non-Gaussianity and independence cannot be easily disentangled from the assumption of linearity. If there are non-linearities in the system, these may, for example, lead to non-Gaussian residuals even if the original disturbances were Gaussian.

4. Likelihood of the Model

To estimate our model, we start by formulating its likelihood.

2. We use here the definition of kurtosis given in Eq. (5), which is sometimes called excess kurtosis. Thus, kurtosis can be either positive or negative.

4.1 Likelihood of LiNGAM

First, we derive the likelihood of the LiNGAM model (Shimizu et al., 2006) which has not yet been given in the literature. The starting point is the likelihood of the ICA model which is well-known, see, for example, Pham and Garrat (1997) and Hyvärinen et al. (2001). Denote the ICA model by

$$\mathbf{x} = \mathbf{A}\mathbf{s}$$

for a square invertible matrix $\mathbf{A}$, and independent non-Gaussian latent variables s_i. Denote the observed sample by $\mathbf{X} = (\mathbf{x}(1), \ldots, \mathbf{x}(T))$ and $\mathbf{W} = \mathbf{A}^{-1}$. The log-likelihood is then usually given in the form

$$\log L_0(\mathbf{X}) = \sum_t \sum_i \log p_i(\mathbf{w}_i^T \mathbf{x}(t)) + T \log \det |\mathbf{W}|$$

where the p_i are the density functions of the independent components (here: disturbances). Since the densities of the disturbances are not specified, we have in general a semi-parametric problem. Different methods have been developed for approximating $\log p_i$, for example, Pham and Garrat (1997), Karvanen and Koivunen (2002) and Chen and Bickel (2006). Here, we have to take into account the fact that those methods usually assume that the independent components have been normalized to unit variance, which is not the case in LiNGAM. Thus, we prefer to modify the formula by normalizing the densities as follows:

$$\log L_1(\mathbf{X}) = \sum_t \sum_i \log \tilde{p}_i(\frac{\mathbf{w}_i^T \mathbf{x}(t)}{\sigma_i}) - T \sum_i \log \sigma_i + T \log \det |\mathbf{W}| \tag{6}$$

where the $\tilde{p}_i$ are the densities of the disturbances standardized to unit variance, and the σ_i^2 are their variances before standardization.

In fact, in practice it has been realized that often one can just fix the $\tilde{p}_i$ to a single function and still obtain a satisfactory estimator. In particular, if we know that the disturbances are all super-Gaussian (i.e., have positive kurtosis), fixing

$$\log \tilde{p}_i(s) = -\sqrt{2}|s| + \text{const.}$$

is enough to provide a consistent estimator under weak constraints (Cardoso and Laheld, 1996; Hyvärinen and Oja, 1998).

In LiNGAM, we have from (4) that in terms of the ICA model, $\mathbf{A}^{-1} = \mathbf{W} = \mathbf{I} - \mathbf{B}_0$ (we use the subindex 0 for $\mathbf{B}$ in LiNGAM to comply with the notation below). Now, we can simplify the likelihood because of the DAG structure. The DAG structure means that for the right permutation of its rows (corresponding to the causal ordering), $\mathbf{W}$ is lower-triangular. The determinant of a triangular matrix is equal to the product of its diagonal elements, and a permutation does not change the determinant, so the determinant of $\mathbf{W}$ is equal to the product of the diagonal elements when the variables are ordered in the causal order. But by definition of $\mathbf{W}$ in LiNGAM, those diagonal elements are all equal to one, so the last term in (6) is zero. So, the likelihood of the LiNGAM model is finally given by

$$\begin{aligned} \log L(\mathbf{X}) &= \sum_t \sum_i \log \tilde{p}_i \left(\frac{\mathbf{w}_i^T \mathbf{x}(t)}{\sigma_i} \right) - T \sum_i \log \sigma_i \\ &= \sum_t \sum_i \log \tilde{p}_i \left(\frac{x_i(t) - \mathbf{b}_{0,i}^T \mathbf{x}(t)}{\sigma_i} \right) - T \sum_i \log \sigma_i \end{aligned} \tag{7}$$

where the variances of the components can be estimated by taking the empirical variances as

$$\sigma_i^2 = \frac{1}{T}\sum_t (x_i(t) - \mathbf{b}_{0,i}^T \mathbf{x}(t))^2.$$

(Alternatively, the σ_i could be obtained by a separate maximization of the likelihood, but this would be more complicated computationally and conceptually.) Here, $\mathbf{W}$ is constrained to correspond to a DAG, with ones added in the diagonal.

4.2 Likelihood of Our Model

Now we can derive the likelihood of our model. First note that from (3) we can derive

$$\mathbf{x}(t) = \sum_{\tau=0}^{k} \mathbf{B}_\tau \mathbf{x}(t-\tau) + \mathbf{e}(t) \Leftrightarrow (\mathbf{I} - \mathbf{B}_0)[\mathbf{x}(t) - \sum_{\tau=1}^{k} (\mathbf{I} - \mathbf{B}_0)^{-1} \mathbf{B}_\tau \mathbf{x}(t-\tau)] = \mathbf{e}(t),$$

which gives

$$\mathbf{x}(t) - \sum_{\tau=1}^{k} (\mathbf{I} - \mathbf{B}_0)^{-1} \mathbf{B}_\tau \mathbf{x}(t-\tau) = \mathbf{B}_0[\mathbf{x}(t) - \sum_{\tau=1}^{k} (\mathbf{I} - \mathbf{B}_0)^{-1} \mathbf{B}_\tau \mathbf{x}(t-\tau)] + \mathbf{e}(t)$$

which shows that the our model in (3) is a LiNGAM model for the residuals $\mathbf{x}(t) - \sum_{\tau=1}^{k} (\mathbf{I} - \mathbf{B}_0)^{-1} \mathbf{B}_\tau \mathbf{x}(t-\tau)$. Denoting

$$\mathbf{M}_\tau = (\mathbf{I} - \mathbf{B}_0)^{-1} \mathbf{B}_\tau \text{ and } \mathbf{W} = \mathbf{I} - \mathbf{B}_0 \tag{8}$$

and replacing $\mathbf{x}(t)$ in (7) by the residuals, we have

$$\log L(\mathbf{X}) = \sum_i \sum_t \log \tilde{p}_i \left(\frac{\mathbf{w}_i^T [\mathbf{x}(t) - \sum_{\tau=1}^{k} \mathbf{M}_\tau \mathbf{x}(t-\tau)]}{\sigma_i} \right) - \log \sigma_i \tag{9}$$

with

$$\sigma_i^2 = \frac{1}{T}\sum_t \left(\mathbf{w}_i^T [\mathbf{x}(t) - \sum_{\tau=1}^{k} \mathbf{M}_\tau \mathbf{x}(t-\tau)] \right)^2.$$

4.3 Information-Theoretic Interpretation

An interesting point to note is that the likelihood is now a sum of the negative entropies of the residuals. The differential entropy of a random variable s can be written using the standardized version of s, denoted by $\tilde{s}$, as follows:

$$H(s) = -\int p_s(u) \log p_s(u) du = -\int p_{\tilde{s}}(u) \log p_{\tilde{s}}(u) du + \log \sigma_s$$

where σ_s^2 is the variance of s. Thus, we can interpret the terms in (9) as the (negative) entropies of the residuals. So, estimation is accomplished by minimizing the "prediction errors" or "uncertainties" in the DAG if the entropies are interpreted as the prediction errors when each variable is predicted by its parents. Note that for Gaussian variables, the entropies are very simple functions of the squared errors (variances), while for non-Gaussian variables, they are also functions of the non-Gaussianity (shape) of the distribution.

5. Practical Estimation Methods

Next we propose two practical methods for estimating the model, and further show how to include a sparseness penalty which may be very useful in practice.

5.1 A Two-Stage Method with Least-Squares Estimation

Optimization of the likelihood is difficult because it contains a complicated combinatorial optimization part due to the constraint that $\mathbf{B}_0$ is acyclic. A conceptually simple way of reinforcing this constraint would be to go through all possible orderings of the observed variables, and for each of them, maximize the likelihood as a function of the $\mathbf{B}_\tau$ so that $\mathbf{B}_0$ is constrained to be lower triangular. This is obviously computationally very expensive since the number of ordering is equal to $n!$ where n is the number of variables. Only for a very small n can this be computationally feasible. (Another difficulty is that the likelihood contains a semiparametric part because we do not specify a parametric model of the non-Gaussian distributions, but this problem has already been extensively treated in the theory of ICA, and has been found not to be very serious in practice, see Hyvärinen et al., 2001.)

To avoid the computational problems with likelihood, we propose a computationally simpler two-stage method for estimating our model. The method combines classic least-squares estimation of an autoregressive (AR) model with LiNGAM estimation.

5.1.1 DEFINITION

The basic idea is that the $\mathbf{M}_\tau$ in (8) can be consistently, and computationally efficiently, estimated by classic least-squares methods. Then, since the model is essentially a LiNGAM model for the residuals of the predictions by the $\mathbf{M}_\tau$, we simply use our previously developed estimation methods for LiNGAM to estimate the rest of the parameters. These methods (Shimizu et al., 2006) seem to tackle the combinatorial optimization problem in a satisfactory way. The ensuing method will be justified in more detail below; it is defined as follows:

1. Estimate a classic autoregressive model for the data

$$\mathbf{x}(t) = \sum_{\tau=1}^{k} \mathbf{M}_\tau \mathbf{x}(t-\tau) + \mathbf{n}(t) \tag{10}$$

   using any conventional implementation of a least-squares method. Note that here $\tau > 0$, so it is really a classic AR model. Denote the least-squares estimates of the autoregressive matrices by $\hat{\mathbf{M}}_\tau$.

2. Compute the residuals, that is, estimates of $\mathbf{n}(t)$

$$\hat{\mathbf{n}}(t) = \mathbf{x}(t) - \sum_{\tau=1}^{k} \hat{\mathbf{M}}_\tau \mathbf{x}(t-\tau).$$

3. Perform the LiNGAM analysis (Shimizu et al., 2006) on the residuals. This gives the estimate of the matrix $\mathbf{B}_0$ as the solution of the instantaneous causal model

$$\hat{\mathbf{n}}(t) = \mathbf{B}_0 \hat{\mathbf{n}}(t) + \mathbf{e}(t).$$

4. Finally, compute the estimates of the causal effect matrices $\mathbf{B}_\tau$ for $\tau > 0$ as

$$\hat{\mathbf{B}}_\tau = (\mathbf{I} - \hat{\mathbf{B}}_0)\hat{\mathbf{M}}_\tau \text{ for } \tau > 0. \tag{11}$$

5.1.2 CONSISTENCY PROOF

We now prove that this provides a consistent estimator of $\mathbf{B}_\tau$. First, the basic model definition in (3) can be manipulated to yield

$$(\mathbf{I} - \mathbf{B}_0)\mathbf{x}(t) = \sum_{\tau=1}^{k} \mathbf{B}_\tau \mathbf{x}(t-\tau) + \mathbf{e}(t)$$

and thus

$$\mathbf{x}(t) = \sum_{\tau=1}^{k} (\mathbf{I} - \mathbf{B}_0)^{-1}\mathbf{B}_\tau \mathbf{x}(t-\tau) + (\mathbf{I} - \mathbf{B}_0)^{-1}\mathbf{e}(t). \tag{12}$$

Now, a well-known result is that least-squares estimation of an AR model as in (10) is consistent even if the innovation vector $\mathbf{n}(t)$ does not have independent or even uncorrelated elements (for fixed t), and even if it is heteroscedastic and non-Gaussian. Thus, comparing (12) with (10), in the limit we can equate the autoregressive matrices, which gives $(\mathbf{I} - \mathbf{B}_0)^{-1}\mathbf{B}_\tau = \mathbf{M}_\tau$ for $\tau \geq 1$, and thus (11) is justified. (In fact, we anticipated (11) in the notation used in the likelihood in (9).)

Second, comparison of (12) with (10) shows that the residuals $\hat{\mathbf{n}}(t)$ are, asymptotically, of the form $(\mathbf{I} - \mathbf{B}_0)^{-1}\mathbf{e}(t)$. This means

$$\hat{\mathbf{n}}(t) = (\mathbf{I} - \mathbf{B}_0)^{-1}\mathbf{e}(t) \Leftrightarrow (\mathbf{I} - \mathbf{B}_0)\hat{\mathbf{n}}(t) = \mathbf{e}(t) \Leftrightarrow \hat{\mathbf{n}}(t) = \mathbf{B}_0\hat{\mathbf{n}}(t) + \mathbf{e}(t)$$

which is the LiNGAM model for $\hat{\mathbf{n}}(t)$. This shows that $\mathbf{B}_0$ is obtained as the LiNGAM analysis of the residuals, and the consistency of our estimator of $\mathbf{B}_0$ follows from the consistency of LiNGAM estimation (Shimizu et al., 2006). Thus, our method is consistent for all the $\mathbf{B}_\tau$. This obviously proves, by construction, the identifiability of the model as well.

5.1.3 INTERPRETATION RELATED TO ICA OF RESIDUALS

An interesting viewpoint of the two-stage estimation method is analysis of the dependencies of the innovations after estimating a classic AR model. Suppose we just estimate an AR model as in (1), and interpret the coefficients as causal effects. Such an interpretation more or less presupposes that the innovations $e_i(t)$ are independent of each other, because otherwise there is some structure in the model which has not been modelled by the AR model. If the innovations are not independent, the causal interpretation may not be justified. Thus, it seems necessary to further analyze the dependencies in the innovations in cases where they are strongly dependent.

Analysis of the dependency structure in the residuals (which are, by definition, estimates of innovations) is precisely what leads to the two-stage estimation method. As a first approach, one could consider application of something like principal component analysis or independent component analysis on the residuals. The problem with such an approach is that the interpretation of the obtained results in the framework of causal analysis would be quite difficult. Our solution is to fit a causal model like LiNGAM to the residuals, which leads to a straightforward causal interpretation of the analysis of residuals which is logically consistent with the AR model.

5.2 Method Based on Multichannel Blind Deconvolution

While the two-stage method proposed above is computationally very efficient, it is far from being statistically optimal. The estimation of the autoregressive part takes in no way non-Gaussianity into account and is thus likely to be suboptimal. However, it is useful because it provides a good initial guess for any further iterative method.

Thus, to improve the results of the two-stage method, we further propose an estimation method based on the similarity of our model with convolutive versions of ICA which are also called multichannel blind deconvolution (MBD). Estimation of the model Eq. (3) is, in fact, closely related to the multichannel blind deconvolution problem with causal finite impulse response (FIR) filters (Cichocki and Amari, 2002; Hyvärinen et al., 2001). MBD, as a direct extension of ICA, assumes that the observed signals are convolutive mixtures of some spatially and independently and identically distributed (i.i.d.) sources.

Using MBD methods is justified here due to the possibility or transforming an autoregressive model into a moving-average model: In Eq. (3), the observed variables $x_i(t)$ can be considered as convolutive mixtures of the disturbances $e_i(t)$. Thus, we can find estimates of $\mathbf{B}_\tau$, as well as $e_i(t)$, in Eq. (3), by using MBD methods to estimate the filter matrices $\mathbf{W}_\tau$

$$\hat{\mathbf{e}}(t) = \sum_{\tau=0}^{k} \mathbf{W}_\tau \mathbf{x}(t-\tau). \tag{13}$$

Comparing (13) with (3), we can see that the $\mathbf{B}_\tau$ can then be recovered from the estimated $\mathbf{W}_\tau$; details are given below.

The basic statistical principle to estimate the MBD model is that the disturbances $e_i(t)$ should be mutually independent for different i and different t. Under the assumption that at most one of the sources is Gaussian, by making the estimated sources spatially and temporally independent, MBD can recover the mixing system (here corresponding to $e_i(t)$ and $\mathbf{B}_\tau$) up to some scaling, permutation, and time shift indeterminacies (Liu and Luo, 1998). This implies that our SVAR model is identifiable by MBD if at most one of the disturbances e_i is Gaussian.

There exist several well-developed algorithms for MBD. For example, one may adopt the one based on natural gradient (Cichocki and Amari, 2002). By extending the LiNGAM analysis procedure (Shimizu et al., 2006), we can find the estimate of $\mathbf{B}_\tau$ in the following three steps, based on the MBD estimates of $\mathbf{W}_\tau$.

1. Find the permutation of rows of $\mathbf{W}_0$ which yields a matrix $\widetilde{\mathbf{W}}_0$ with only significantly nonzero entries on the main diagonal. The permutation can be found using similar methods (e.g., the Hungarian algorithm) as in LiNGAM (Shimizu et al., 2006). Note that here we also need to apply the same permutations to rows of $\mathbf{W}_\tau$ ($\tau > 0$) to produce $\widetilde{\mathbf{W}}_\tau$.

2. Divide each row of $\widetilde{\mathbf{W}}_0$ and $\widetilde{\mathbf{W}}_\tau$ ($\tau > 0$) by the corresponding diagonal entry in $\widetilde{\mathbf{W}}_0$. This gives $\widetilde{\mathbf{W}}'_0$ and $\widetilde{\mathbf{W}}'_\tau$, respectively. The final estimates of $\mathbf{B}_0$ and $\mathbf{B}_\tau$ ($\tau > 0$) can then be computed as $\widehat{\mathbf{B}}_0 = \mathbf{I} - \widetilde{\mathbf{W}}'_0$ and $\widehat{\mathbf{B}}_\tau = -\widetilde{\mathbf{W}}'_\tau$, respectively.

3. To obtain the causal order in the instantaneous effects, find the permutation matrix $\mathbf{P}$ (applied equally to both rows and columns) of $\widehat{\mathbf{B}}_0$ which makes $\widetilde{\mathbf{B}}_0 = \mathbf{P}\widehat{\mathbf{B}}_0\mathbf{P}^T$ as close as possible to strictly lower triangular.

5.3 Sparsification of the Causal Connections

For the purposes of interpretability and generalizability, it is often useful to sparsify the causal connections, that is, to set insignificant entries of $\hat{\mathbf{B}}_\tau$ to zero. Analogously to the development of ICA with sparse connections (Zhang et al., 2009), we can incorporate an adaptive L_1 penalty into the likelihood of the MBD method to achieve fast model selection which performs such sparsification. We use a penalty-based approach because traditional model selection based on information criteria involves a combinatorial optimization problem whose complexity increases exponentially in the dimensionality of the parameter space. In the MBD problem, this is often not computationally feasible.

Thus, to make $\mathbf{W}_\tau$ in Eq. (13) as sparse as possible, we maximize the penalized likelihood defined as

$$pl(\{\mathbf{W}_\tau\}) = \log L(\{\mathbf{W}_\tau\}) - \lambda \sum_{i,j,\tau} |w_{i,j,\tau}|/|\hat{w}_{i,j,\tau}|, \tag{14}$$

where $L(\{\mathbf{W}_\tau\})$ is the likelihood, $w_{i,j,\tau}$ the (i,j)th entry of $\mathbf{W}_\tau$, and $\hat{w}_{i,j,\tau}$ a consistent estimate of $w_{i,j,\tau}$, such as the maximum likelihood estimate. The parameter λ is the general weight of the penalty.

The idea here is that we first compute an initial estimate of the $w_{i,j,\tau}$ by a conventional method (such as maximum likelihood) and then use those estimates to compute a parameter-wise weighting in the L_1 penalty. The end result is that those $w_{i,j,\tau}$ for which the initial estimates $\hat{w}_{i,j,\tau}$ were small are heavily penalized, and likely to be zero in the final estimate obtained by maximization of pl.

This penalized likelihood is a special case of adaptive Lasso and therefore has the same consistency in variable selection (Zou, 2006). In fact, it can also be used for selecting the order k of the autoregressive model. In particular, to achieve model selection similar to the Bayesian Information Criterion (BIC), one can set $\lambda = \log T$, where T is the sample size (Zhang et al., 2009).

It may be also useful to penalize groups of parameters. In particular, to see if the historical values of $x_i(t)$ causes $x_j(t)$ $(i \neq j)$, one needs to examine the combined effect of the group of parameters $[\hat{\mathbf{B}}_\tau]_{i,j}, \tau = 1, ..., p$, and therefore it makes sense to apply penalization on the parameter group. Combining the above approach with group Lasso (Bach, 2008) leads to the following penalized likelihood:[3]

$$pl(\{\mathbf{W}_\tau\}) = \log L(\{\mathbf{W}_\tau\}) - \lambda \sum_{i,j,\tau} |w_{i,j,0}|/|\hat{w}_{i,j,0}| - k\lambda \sum_{i,j} \Big(\sum_{\tau=1}^{k} w_{i,j,\tau}^2 \Big)^{1/2} \Big/ \Big(\sum_{\tau=1}^{k} \hat{w}_{i,j,\tau}^2 \Big)^{1/2},$$

where the last term has the coefficient k because the parameter group $w_{i,j,\tau}, \tau = 1, ..., k$ has k parameters.

5.4 Simulations

To investigate the performance of the proposed estimation methods, we conducted a series of simulations. We set the number of lags $k = 1$ and the dimensionality $n = 5$. We randomly constructed the strictly lower-triangular matrix $\mathbf{B}_0$ and matrix $\mathbf{B}_1$. To make the causal effects sparse, we set about 60% of the entries in the matrix $\mathbf{B}_1$ and the lower-triangular part of $\mathbf{B}_0$ to zero, while the magnitude of the others is uniformly distributed between 0.05 and 0.5 and the sign is random. Super-Gaussian

3. Here we treat the instantaneous effects separately. If one would like to see if the total influence from $x_i(t-\tau), \tau = 0, 1, ..., p$ to $x_j(t)$ is significant, all parameters $w_{i,j,\tau}, \tau = 0, 1, ..., p$ should be treated as a group.

disturbances $e_i(t)$ were generated by passing standardized i.i.d. Gaussian variables through a power nonlinearity with exponent between 1.5 and 2.0 while keeping the original sign. The observations $\mathbf{x}(t)$ were then generated according to the model in Eq. (3). Various sample sizes (T = 100, 300, and 1000) were tested. We compared the performance of the two-stage method (Section 5.1), the method by MBD (Section 5.2) and the MBD-based method with the sparsity penalty (Section 5.3). In the last method, we set the penalization parameter in Eq. (14) as $\lambda = \log T$ to make its results consistent with those obtained by BIC. The densities of the independent components were adaptively estimated using the method in Pham and Garrat (1997). In each case, we repeated the experiments for 5 replications.

Fig. 1 shows the scatter plots of the estimated parameters (including the strictly lower triangular part of $\mathbf{B_0}$ and all entries of $\mathbf{B}_1$) versus the true ones. Different subplots correspond to different sample sizes or different methods. The mean square error (MSE) of the estimated parameters is also given in each subplot. One can see that as the sample sizes increases, all methods give better results. For each sample size, the method based on MBD is always better than the two-stage method, showing that the estimate by the MBD-based method is more efficient. Furthermore, due to the prior knowledge that many parameters are zero, the MBD-based method with the sparsity penalty performed best.

6. Assessment of the Significance of Causality

In practice, we also need to assess the significance of the estimated causal relations. While the sparsification method in Section 5.3 is related to this goal, here we propose a more principled approach for testing the significance of the causal influences.

For the instantaneous effects $x_i(t) \to x_j(t)$ $(i \neq j)$, the significance of causality is obtained by assessing if the entries of $\hat{\mathbf{B}}_0$ are statistically significantly different from zero. For the lagged effects $x_i(t-\tau) \to x_j(t)$ $(i \neq j, \tau > 0)$, however, one is often not interested in the significance of any single coefficient in $\hat{\mathbf{B}}_\tau$: More frequently one aims to find out if the total effect from $x_i(t-\tau)$ to $x_j(t)$ is significant.

We propose two simple statistics. One is a measure of instantaneous variance contributed by $x_i(t)$ to $x_j(t)$: $S_0(i \leftarrow j) = [\mathbf{B}_0]_{ij}^2 \cdot \mathrm{var}(x_i(t))/\mathrm{var}(x_j(t))$. If all time series have the same variance, it is simplified to $S_0(i \leftarrow j) = [\mathbf{B}_0]_{ij}^2$. The other measures how strong the total lagged causal influence from $x_i(t)$ to $x_j(t)$ is; it is a measure of contributed variance from $x_i(t-\tau), \tau > 0$ to $x_j(t)$: $S_{lag}(i \leftarrow j) = \mathrm{var}(\sum_{\tau>0}[\mathbf{B}_\tau]_{ij} x_j(t-\tau))/\mathrm{var}(x_j(t))$. If all series $x_i(t)$ have the same variance and are approximately temporally uncorrelated, the above statistic can be approximated by $\sum_{\tau>0}[\mathbf{B}_\tau]_{ij}^2$. (Note that these quantities are not exactly proportions of variance explained because the explaining variables are not necessarily uncorrelated.)

The asymptotic distributions of these statistics under the null hypothesis (with no causal effects) are very difficult to derive, and they may also behave poorly in the finite sample case. Therefore, like in Diks and DeGoede (2001) and Theiler et al. (1992), we use bootstrapping with surrogate data to find the empirical distributions of each statistic under the null hypothesis. To generate the surrogate data under the null hypothesis, in each bootstrapping replication we "scramble" the original series $x_i(t)$, that is, each time series is randomly permuted in temporal order. We then calculate $\hat{S}^*$, the estimate of the statistic S (which may be $S_0(i \leftarrow j)$ or $S_{lag}(i \leftarrow j)$) for the surrogate data. Next, the α-level bootstrapping critical value $c_{t\alpha}^*$ is found as the α-th quantile of the bootstrapping distribution

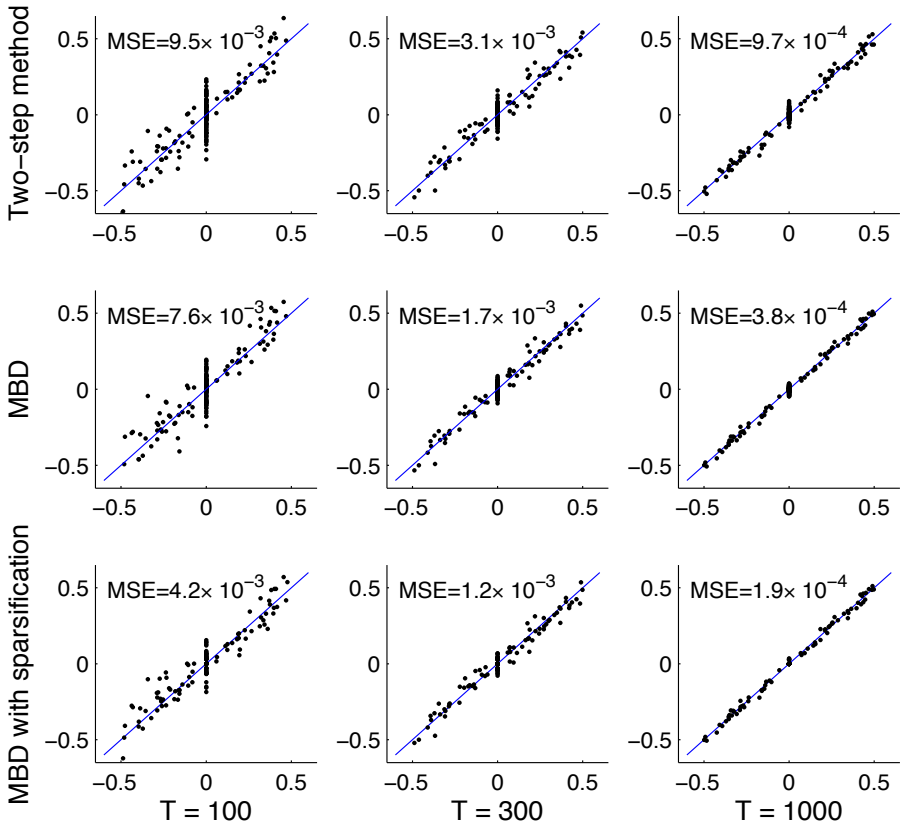

Figure 1: Scatter plots of the estimated coefficients (y axis) versus the true ones (x axis) for different sample sizes and different methods.

of $\hat{S}^*$. Finally, we reject the null hypothesis if $\hat{S} > c^*_{t\alpha}$, where $\hat{S}$ is the estimate of S for the original data.

7. Remarks on the Interpretation of the Parameters

In this section, we discuss how the autoregressive parameters are changed by taking into account the instantaneous effects, and how our model can be interpreted in the framework of Granger causality.

7.1 Interaction Between Instantaneous and Lagged Effects

Equation (11) shows the interesting fact already mentioned in the Introduction: Consistent estimates of the $\mathbf{B}_\tau$ are not obtained by a simple AR model fit even for $\tau > 0$. Taking instantaneous effects into account changes the estimation procedure for all the autoregressive matrices, if we want consistent estimators as we usually do. Of course, this is only the case if there are instantaneous effects, that is, $\mathbf{B}_0 \neq 0$; otherwise, the estimates are not changed.

While this phenomenon is, in principle, well-known in econometric literature (Swanson and Granger, 1997; Demiralp and Hoover, 2003; Moneta and Spirtes, 2006), Eq. (11) is seldom applied because estimation methods for $\mathbf{B}_0$ have not been well developed. To our knowledge, no estimation method for $\mathbf{B}_0$ has been proposed which is consistent for the whole matrix without strong prior assumptions on $\mathbf{B}_0$.

Next we present some theoretical examples of how the instantaneous and lagged effects interact based on the formula in (11).

7.1.1 EXAMPLE 1: AN INSTANTANEOUS EFFECT MAY SEEM TO BE LAGGED

Consider first the case where the instantaneous and lagged matrices are as follows:

$$\mathbf{B}_0 = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}, \qquad \mathbf{B}_1 = \begin{pmatrix} 0.9 & 0 \\ 0 & 0.9 \end{pmatrix}.$$

That is, there is an instantaneous effect $x_2 \to x_1$, and no lagged effects (other than the purely autoregressive $x_i(t-1) \to x_i(t)$). Now, if an AR(1) model is estimated for data coming from this model, without taking the instantaneous effects into account, we get the autoregressive matrix

$$\mathbf{M}_1 = (\mathbf{I} - \mathbf{B}_0)^{-1}\mathbf{B}_1 = \begin{pmatrix} 0.9 & 0.9 \\ 0 & 0.9 \end{pmatrix}.$$

Thus, the effect $x_2 \to x_1$ seems to be lagged although it is, actually, instantaneous.

7.1.2 EXAMPLE 2: SPURIOUS EFFECTS APPEAR

Consider three variables with the instantaneous effects $x_1 \to x_2$ and $x_2 \to x_3$, and no lagged effects other than $x_i(t-1) \to x_i(t)$, as given by

$$\mathbf{B}_0 = \begin{pmatrix} 0 & 0 & 0 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \end{pmatrix}, \qquad \mathbf{B}_1 = \begin{pmatrix} 0.9 & 0 & 0 \\ 0 & 0.9 & 0 \\ 0 & 0 & 0.9 \end{pmatrix}.$$

If we estimate an AR(1) model for the data coming from this model, we obtain

$$\mathbf{M}_1 = (\mathbf{I} - \mathbf{B}_0)^{-1}\mathbf{B}_1 = \begin{pmatrix} 0.9 & 0 & 0 \\ 0.9 & 0.9 & 0 \\ 0.9 & 0.9 & 0.9 \end{pmatrix}.$$

This means that the estimation of the simple autoregressive model leads to the inference of a direct lagged effect $x_1 \to x_3$, although no such direct effect exists in the model generating the data, for any time lag.

A more reassuring result is the following: if the data follows the same causal ordering for all time lags, that ordering is not contradicted by the neglect of instantaneous effect. A rigorous definition of this property is the following.

Theorem 1 *Assume that there is an ordering $i(j), j = 1 \ldots n$ of the variables such that no effect goes backward, that is,*

$$\mathbf{B}_\tau(i(j-\delta), i(j)) = 0 \text{ for } \delta > 0, \tau \geq 0, 1 \leq j \leq n. \tag{15}$$

(In the purely instantaneous case, existence of such an ordering is equivalent to acyclicity of the effects as noted in Section 2.2.) Then, the same property applies to the $\mathbf{M}_\tau, \tau \geq 1$ *as well. Conversely, if there is an ordering such that (15) applies to* $\mathbf{M}_\tau, \tau \geq 1$ *and* $\mathbf{B}_0$*, then it applies to* $\mathbf{B}_\tau, \tau \geq 1$ *as well.*

Proof: When the variables are ordered in this way (assuming such an order exists), all the matrices $\mathbf{B}_\tau$ are lower-triangular. The same applies to $\mathbf{I} - \mathbf{B}_0$. Now, the product of two lower-triangular matrices is lower-triangular; in particular the $\mathbf{M}_\tau$ are also lower-triangular according to (11), which proves the first part of the theorem. The converse part follows from solving for $\mathbf{B}_\tau$ in (11) and the fact that the inverse of a lower-triangular matrix is lower-triangular.

What this theorem means is that if the variables really follow a single "causal ordering" for all time lags, that ordering is preserved even if instantaneous effects are neglected and a classic AR model is estimated for the data. Thus, there is some limit to how (11) can change the causal interpretation of the results.

7.2 Generalizations of Granger Causality

The classic interpretation of causality in instantaneous SEMs would be that x_i causes x_j if the (j,i)-th coefficient in $\mathbf{B}_0$ is non-zero. On the other hand, in the time series context, the concept of Granger causality (Granger, 1969) formalizes causality as the ability to reduce prediction error. A simple operational definition of Granger causality can be based on the autoregressive coefficients $\mathbf{M}_\tau$: If at least one of the coefficients from $x_i(t-\tau), \tau \geq 1$ to $x_j(t)$ is (significantly) non-zero, then x_i Granger-causes x_j. This is because then the variable x_i reduces the prediction error in x_j in the mean-square sense if it is included in the set of predictors, which is the very definition of Granger causality.

In light of the results in this paper, we can generalize the concept of Granger causality in two ways. First we can combine the two aspects of instantaneous and lagged effects. In fact, such a concept of instantaneous causality was already alluded to by Granger (1969), but presumably due to lack of proper estimation methods, that paper as well as most future developments considered mainly non-instantaneous causality. The second generalization is to measure prediction error by the information-theoretic definition of Section 4.3, essentially using entropy instead of mean squared error. These two generalization are independent of each other in the sense that we can use any one of them, omitting the other.

Both of these extensions are implicit in estimation of our model. Thus, we define that *a variable* x_i *causes* x_j *if at least one of the coefficients* $\mathbf{B}_\tau(j,i)$*, giving the effect from* $x_i(t-\tau)$ *to* $x_j(t)$*, is (significantly) non-zero for* $\tau \geq 0$. The condition for τ is different from Granger causality since the value $\tau = 0$, corresponding to instantaneous effects, is included. Moreover, since estimation of the instantaneous effects changes the estimates of the lagged ones, the lagged effects used in our definition are different from those usually used with Granger causality. Using entropy instead of mean-squared error is implicit in this definition because non-Gaussianity is used in the estimation of the model. In general, entropy minimization is closely related to ICA estimation (Hyvärinen, 1999) as well as the estimation of the present model as was discussed in Section 4.3. Notice that we assume here, as in the general theory of Granger causality, that there are no unobserved confounders.

8. Real Data Experiments

We applied our model together with the estimation and testing method on both financial data and magnetoencephalography (MEG) data. In the former application, we used the sparsity penalty to select significant effects, while in the latter one, bootstrapping was used.

8.1 Application in Finance

First, we use the model in Eq. (3) to find the causal relations among several world stock indices. The chosen indices are Dow Jones Industrial Average (DJI) in USA, Nikkei 225 (N225) in Japan, Hang Seng Index (HSI) in Hong Kong, and the Shanghai Stock Exchange Composite Index (SSEC) in China. We used the daily dividend/split adjusted closing prices from 4th Dec 2001 to 11th Jul 2006, obtained from the Yahoo finance database. For the few days when the price is not available, we use simple linear interpolation to estimate the price. Denoting the closing price of the ith index on day t by $P_i(t)$, the corresponding return is calculated by $x_i(t) = \frac{P_i(t)-P_i(t-1)}{P_i(t-1)}$. The data for analysis are $\mathbf{x}(t) = [x_1(t), ..., x_4(t)]^T$, with $T = 1200$ observations.

We applied the MBD-based method with the sparsity penalty to $\mathbf{x}(t)$. The kurtoses of the estimated disturbances $\hat{e}_i$ are 3.9, 8.6, 4.1, and 7.6, respectively, implying that the disturbances are non-Gaussian. We found that more than half of the coefficients in the estimated $\mathbf{W}_0$ and $\mathbf{W}_1$ are exactly zero due to sparsity penalty. $\widehat{\mathbf{B}}_0$ and $\widehat{\mathbf{B}}_1$ were constructed based on $\mathbf{W}_0$ and $\mathbf{W}_1$, using the procedure given in Section 5.2. It was found that $\widehat{\mathbf{B}}_0$ can be permuted to a strictly lower-triangular matrix, meaning that the instantaneous effects follow a linear acyclic causal model. Finally, based on $\widehat{\mathbf{B}}_0$ and $\widehat{\mathbf{B}}_1$, one can plot the causal diagram, which is shown in Fig. 2.

Fig. 2 reveals some interesting findings. First, DJI_{t-1} has significant impacts on N225_t and HSI_t, which is a well-known fact in the stock market. Second, the causal relations $\text{DJI}_{t-1} \to \text{N225}_t \to \text{DJI}_t$ and $\text{DJI}_{t-1} \to \text{HSI}_t \to \text{DJI}_t$ are consistent with the time difference between Asia and USA. That is, the causal effects from N225_t and HSI_t to DJI_t, although seeming to be instantaneous, may actually be mainly caused by the time difference. Third, unlike SSEC, HSI is very sensitive to others; it is even strongly influenced by N225, another Asian index. Fourth, it may be surprising that there is a significant negative effect from DJI_{t-1} to DJI_t; however, it is not necessary for DJI_t to have significant negative autocorrelations, due to the positive effect from DJI_{t-1} to DJI_t going through N225_t and HSI_t.

8.2 Application on MEG Data

Second, we applied the proposed model on the magnitudes of brain sources obtained from magnetoencephalographic (MEG) signals to analyze their causal relationships. The raw recordings consisted of the 204 gradiometer channels measured by the Vectorview helmet-shaped neuromagnetometer (Neuromag Ltd., Helsinki, Finland) in a magnetically shielded room at the Brain Research Unit of the Low Temperature Laboratory of the Aalto University School of Science and Technology. They were obtained from a healthy volunteer and lasted about 12 minutes. The data was downsampled to 75 Hz.

To begin with, we separated sources underlying the recorded MEG data using a recently proposed blind source separation method, Fourier-ICA (Hyvärinen et al., 2010). We manually selected 17 sources which are expected to correspond to brain activity, rejecting clear artifacts based on the Fourier spectra and topographic distributions of the sources.

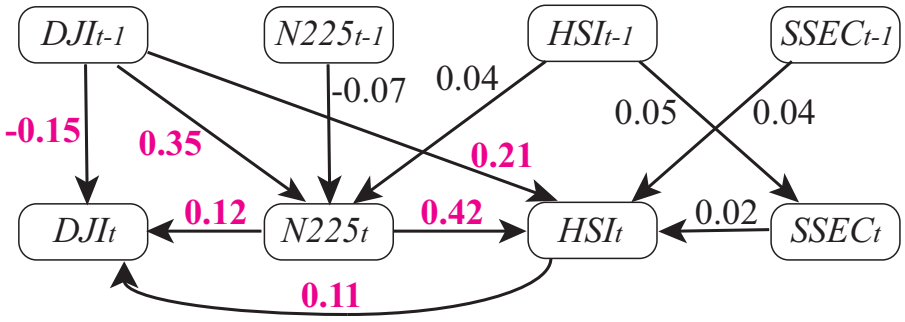

Figure 2: Results of application of our model to daily returns of the stock indices DJI, N225, HSI, and SSEC, with $k = 1$ lag. Large coefficients (greater than 0.1) are shown in bold and red.

Next, we fitted an ordinary vector autoregressive model with 10 lags on the estimated sources, finding the corresponding innovation series which we denote by $y_i(t), i = 1, ..., 17$. Our goal was to analyze if there are some influences between the magnitudes of these innovations. We prefer to analyze the innovations because the innovations are approximately white both temporally and spatially, and thus we can analyze the magnitudes with no contamination by linear (auto)correlations of the source signals. The autoregressive model order 10 was chosen because it was the smallest order that gave approximately white innovations.

We then fitted the SVAR model on the logarithmically transformed magnitudes $x_i(t) = \log(0.2 + |y_i(t)|), i = 1, ..., 17$. We determined the order k of our SVAR model by minimizing the AIC criterion (Akaike, 1973), which is the negative log-likelihood of the MBD model plus a term measuring the complexity of the model. The log-likelihood involves the densities of the MBD outputs $\hat{e}_i(t)$, which were modelled by a mixture of three Gaussians. From the candidate orders between 0 and 20, we found that $k = 2$ gave the minimum AIC.

After finding the estimate of the coefficients $\hat{\mathbf{B}}_\tau, \tau = 0, 1, 2$ with the MBD-based approach, one can easily calculate the estimates of the statistics $S_0(i \leftarrow j)$ and $S_{lag}(i \leftarrow j)$. The bootstrapping approach given in Section 6 was used to evaluate if these estimated statistics are significant. Here we need to test multiple hypotheses simultaneously; to reduce the type I error, we adopted the Bonferroni correction (Shaffer, 1995) for multiple testing correction. We used the significance level 5%. For both the instantaneous and lagged effects, one needs to perform $17 \times 16 = 272$ tests; therefore, the significance level for each individual test is then $0.05/272 \approx 2 \times 10^{-4}$. We used 10^4 replications for the bootstrapping.

For illustration, we give the empirical distribution of the statistics $S_0(7 \leftarrow 14)$ and $S_{lag}(7 \leftarrow 14)$, as well as their estimated values for the original series $x_i(t)$, in Fig. 3. Clearly $\hat{S}_0(7 \leftarrow 14)$ is significant, while $\hat{S}_{lag}(7 \leftarrow 14)$ is not.

Fig. 4 shows the resulting diagram of causal analysis with instantaneous effects between the magnitudes of the selected MEG sources, with the influences significant at 5% level (corrected for multiple testing). What we see is that the connections tend to be strong between sources which are close to each other. For example, the occipitoparietal sources such as #1, #2, #3, #8, and #11 have strong interconnections. Some perirolandic sources such as #5, #7, #10, and #14 are also interconnected. Sources #4 and #16 seems to mediate between these two groups.

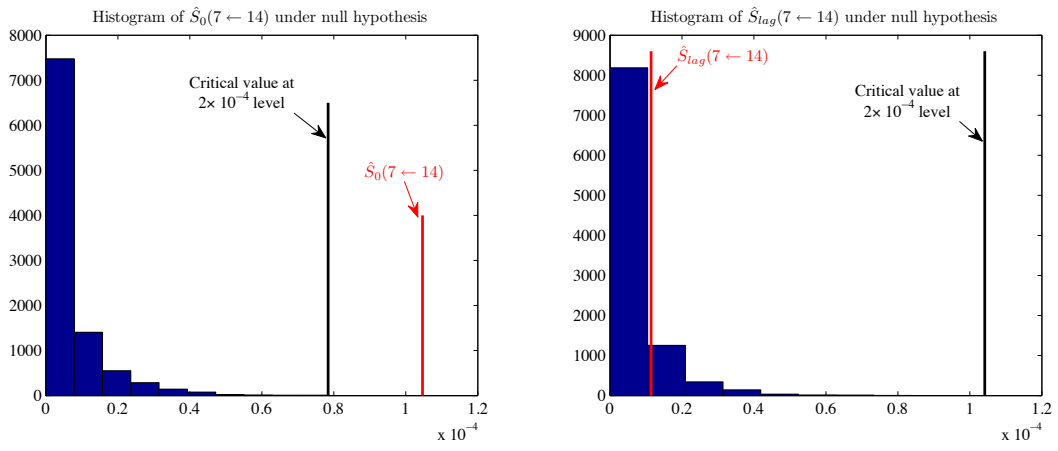

Figure 3: Illustration of the empirical distribution of the statistics under the null hypothesis obtained by bootstrapping. (a) For the statistic $S_0(7 \leftarrow 14)$. (b) For $S_{lag}(7 \leftarrow 14)$.

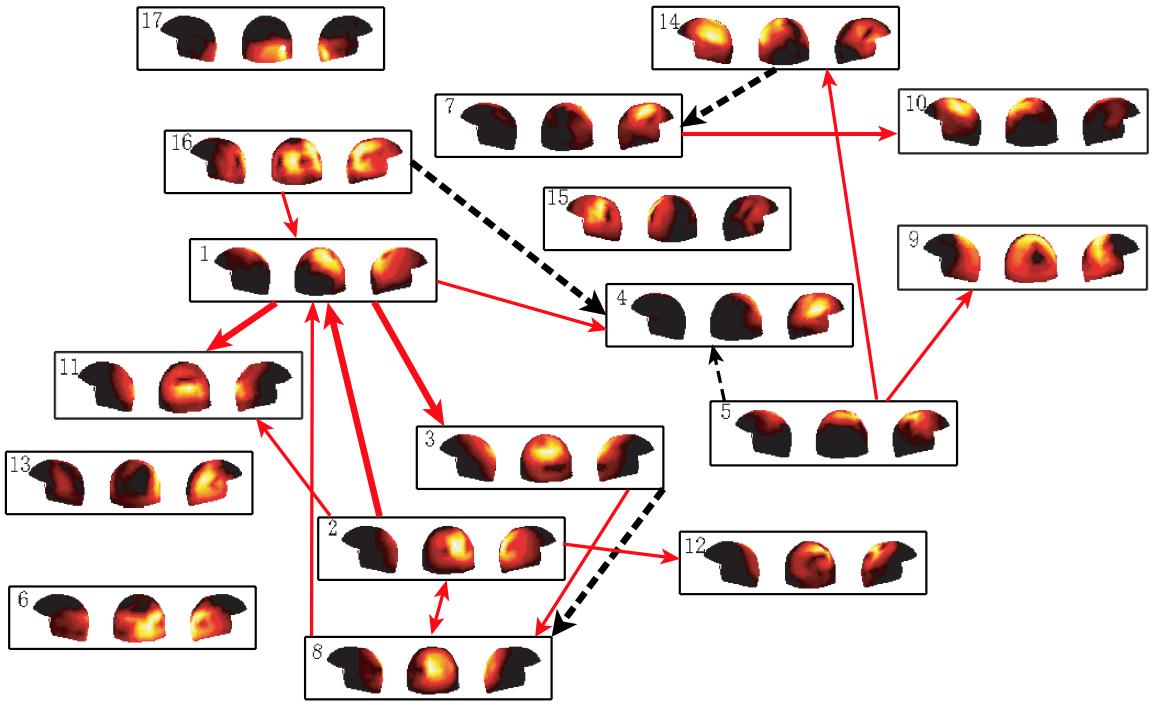

Figure 4: Results of application of our model on the log-magnitudes of the MEG sources (significant at 5% level, corrected for multiple testing). Black dashed line: instantaneous effect. Red solid line: lagged effect. The thickness of the lines indicates the strength of the influences.

9. Extensions of the Model

We have here assumed that $\mathbf{B}_0$ is acyclic, as is typical in causal analysis. However, this assumption is only made because we do not know very well how to estimate a linear non-Gaussian Bayesian network (or SEM) in the cyclic case. If we have a method which can estimate cyclic models, we do not need the assumption of acyclicity in our combined model either; see Lacerda et al. (2008) for one proposal. We could just use such a new method in our two-stage method instead of LiNGAM, and nothing else would be changed. However, development of methods for estimating cyclic models is orthogonal to the main contribution of our paper in the sense that we can use any such new method to estimate the instantaneous model in our framework.

In formulating the likelihood we had to assume that the $\mathbf{e}(t)$ are independent and identically distributed for different time points. However, in our two-stage estimation method, no such assumption was needed to guarantee consistency. In particular, the $\mathbf{e}(t)$ can be heteroscedastic, as long as $\mathbf{e}(t)$ and $\mathbf{e}(t')$ are uncorrelated for $t \neq t'$. In such a case, it might also be advantageous to change the LiNGAM estimation method so that the ICA part is replaced by methods estimating (4) explicitly based on temporal heteroscedasticity (Matsuoka et al., 1995; Hyvärinen, 2001; Pham and Cardoso, 2001); this is quite straightforward and necessitates no further changes in the method.

An interesting class of methods which is related to ours has been recently proposed by Gómez-Herrero et al. (2008). The idea is to combine blind source separation with a linear autoregressive model of the latent sources. The estimation of such a model can be accomplished by methods which are quite similar to our estimation methods, see also Haufe et al. (2009). However, the interpretation of the model is very different since, first, Gómez-Herrero et al. (2008) separate linear sources and analyze their (causal) connections whereas we analyze connections between the observed variables, and second, we estimate instantaneous causal influences whereas Gómez-Herrero et al. (2008) only estimate lagged ones.

10. Conclusion

We showed how non-Gaussianity enables estimation of a causal discovery model in which the linear effects can be either instantaneous or time-lagged. Like in the purely instantaneous case (Shimizu et al., 2006), non-Gaussianity makes the model identifiable without explicit prior assumptions on existence or non-existence of given causal effects. The theoretical developments are closely related to independent component analysis. The classic assumption of acyclicity was made, although it may not be necessary. From the practical viewpoint, an important implication is that considering instantaneous effects changes the coefficient of the time-lagged effects as well. We proposed methods for computationally efficient estimation of the model, as well as for sparsification and testing of the model coefficients.

Abstract

The FastInf C++ library is designed to perform memory and time efficient approximate inference in large-scale discrete undirected graphical models. The focus of the library is propagation based approximate inference methods, ranging from the basic loopy belief propagation algorithm to propagation based on convex free energies. Various message scheduling schemes that improve on the standard synchronous or asynchronous approaches are included. Also implemented are a clique tree based exact inference, Gibbs sampling, and the mean field algorithm. In addition to inference, FastInf provides parameter estimation capabilities as well as representation and learning of shared parameters. It offers a rich interface that facilitates extension of the basic classes to other inference and learning methods.

Keywords: graphical models, Markov random field, loopy belief propagation, approximate inference

1. Introduction

Probabilistic graphical models (Pearl, 1988) are a framework for representing a complex joint distribution over a set of n random variables $\mathcal{X} = \{X_1 \dots X_n\}$. A qualitative graph encodes probabilistic independencies between the variables and implies a decomposition of the joint distribution into a product of local terms:

$$P(\mathcal{X}) = \frac{1}{Z} \prod_i \psi_i(C_i),$$

where C_i are subsets of $\mathcal{X}$ defined by the cliques of the graph structure and $\psi_i(C_i)$ are the quantitative parameters (potential functions) that define the distribution. Computing marginal probabilities and likelihood in graphical models are critical tasks needed both for making predictions and to facilitate learning. Obtaining exact answers to these inference queries is often infeasible even for relatively

modest problems. Thus, there is a growing need for inference methods that are both efficient and can provide reasonable approximate computations. Despite few theoretical guarantees, the Loopy Belief Propagation (LBP, Pearl, 1988) algorithm has gained significant popularity in the last two decades due to impressive empirical success, and is now being used in a wide range of applications ranging from transmission decoding to image segmentation (Murphy and Weiss, 1999; McEliece et al., 1998; Shental et al., 2003). Recently there has been an explosion in practical and theoretical interest in propagation based inference methods, and a range of improvements to the convergence behavior and approximation quality of the basic algorithms have been suggested (Wainwright et al., 2003; Wiegerinck and Heskes, 2003; Elidan et al., 2006; Meshi et al., 2009).

We present the *FastInf* library for efficient approximate inference in large scale discrete probabilistic graphical models. While the library's focus is propagation based inference techniques, implementations of other popular inference algorithms such as mean field (Jordan et al., 1998) and Gibbs sampling are also included. To facilitate inference for a wide range of models, FastInf's representation is flexible allowing the encoding of standard Markov random fields as well as template-based probabilistic relational models (Friedman et al., 1999; Getoor et al., 2001), through the use of shared parameters. In addition, FastInf also supports learning capabilities by providing parameter estimation based on the Maximum-Likelihood (ML) principle, with standard regularization. Missing data is handled via the Expectation Maximization (EM) algorithm (Dempster et al., 1977).

FastInf has been used successfully in a number of challenging applications, ranging from inference in protein-protein networks with tens of thousands of variables and small cycles (Jaimovich et al., 2005), through protein design (Fromer and Yanover, 2008) to object localization in cluttered images (Elidan et al., 2006).

2. Features

The FastInf library was designed while focusing on generality and flexibility. Accordingly, a rich interface enables implementation of a wide range of probabilistic graphical models to which all inference and learning methods can be applied. A basic general-purpose propagation algorithm is at the base of all propagation variants and allows straightforward extensions.

A model is defined via a graph interface that requires the specification of a set of cliques $C_1 \ldots C_k$, and a corresponding set of tables that quantify the parametrization $\psi_i(C_i)$ for each joint assignment of the variables in the clique C_i. This general setting can be used to perform inference both for the directed Bayesian network representation and the undirected Markov one.

2.1 Inference Methods

FastInf includes implementations of the following inference methods:

- Exact inference by the Junction-Tree algorithm (Lauritzen and Spiegelhalter, 1988)
- Loopy Belief Propagation (Pearl, 1988)
- Generalized Belief Propagation (Yedidia et al., 2005)
- Tree Re-weighted Belief Propagation (Wainwright et al., 2005)
- Propagation based on convexification of the Bethe free energy (Meshi et al., 2009).
- Mean field (Jordan et al., 1998)
- Gibbs sampling (Geman and Geman, 1984)

By default, all methods are used with standard asynchronous message scheduling. We also implemented two alternative scheduling approaches that can lead to better convergence properties (Wainwright et al., 2002; Elidan et al., 2006). All methods can be applied to both sum and max product propagation schemes, with or without damping of messages.

2.2 Relational Representation

In many domains, a specific local interaction pattern can recur many times. To represent such domains, it is useful to allow multiple cliques to share the same parametrization. In this case a set of template table parametrizations $\psi_1, \ldots, \psi_T$ are used to parametrize all cliques using

$$P(\mathcal{X}) = \frac{1}{Z} \prod_t \prod_{i \in I(t)} \psi_t(C_i),$$

where $I(t)$ is the set of cliques that are mapped to the t'th potential. This template based representation allows the definition of large-scale models using a relatively small number of parameters.

2.3 Parameter Estimation

FastInf can also be used for learning the parameters of the model from evidence. This is done by using gradient-based methods with the Maximum-Likelihood (ML) objective. The library also handles partial evidence by applying the EM algorithm (Dempster et al., 1977). Moreover, FastInf supports L_1 and L_2 regularization that is added as a penalty term to the ML objective.

3. Documentation

For detailed instructions on how to install and use the library, examples for usage and documentation on the main classes of the library visit FastInf home page at: `http://compbio.cs.huji.ac.il/FastInf`.

Acknowledgments

We would like to acknowledge Menachem Fromer, Haidong Wang, John Duchi and Varun Ganapathi for evaluating the library and contributing implementations of various functions. This library was initiated in Nir Friedman's lab at the Hebrew University and developed in cooperation with Daphne Koller's lab at Stanford. AJ was supported by the Eshkol fellowship from the Israeli Ministry of Science. IM and GE were supported by the DARPA transfer learning program under contract FA8750-05-2-0249

Keywords: transfer learning, task transfer, evolutionary computation, neuroevolution, indirect encoding

Abstract

An important goal for machine learning is to transfer knowledge between tasks. For example, learning to play RoboCup Keepaway should contribute to learning the full game of RoboCup soccer. Previous approaches to transfer in Keepaway have focused on transforming the original representation to fit the new task. In contrast, this paper explores the idea that transfer is most effective if the representation is designed to be the *same* even across different tasks. To demonstrate this point, a *bird's eye view* (BEV) representation is introduced that can represent different tasks on the same two-dimensional map. For example, both the 3 vs. 2 and 4 vs. 3 Keepaway tasks can be represented on the same BEV. Yet the problem is that a raw two-dimensional map is high-dimensional and unstructured. This paper shows how this problem is addressed naturally by an idea from evolutionary computation called *indirect encoding*, which compresses the representation by exploiting its geometry. The result is that the BEV learns a Keepaway policy that transfers *without further learning* or manipulation. It also facilitates transferring knowledge learned in a different domain, Knight Joust, into Keepaway. Finally, the indirect encoding of the BEV means that its geometry can be changed without altering the solution. Thus static representations facilitate several kinds of transfer.

1. Introduction

Representation is a critical factor in the ability of any algorithm to learn autonomously (Clark, 1989). For example, a soccer player might represent the world through raw vision, distances and angles to other objects, or qualitative features such as close and far. Different such representations provide different perspectives to the learning algorithm. While one might be appropriate for learning physical control, another might better suit strategic planning. This paper focuses in particular on the effect of representation on *task transfer*, that is, bootstrapping knowledge gained learning one task to facilitate learning another, related task (Caruana, 1997; Talvitie and Singh, 2007; Taylor et al., 2007a). It turns out that representation not only affects the performance of such transfer, but also the elegance of its implementation. For example, transferring an artificial neural network (ANN) that takes as inputs parameters associated with objects (e.g., location, size, etc.) to a task with more such objects may require transforming the network by adding inputs for parameters associated with each new object (Taylor et al., 2007a). Yet such transformation can disrupt previous learning, thereby requiring the transformed network to undergo additional training to regain even its former

capabilities within the new scenario. As an alternative, this paper argues that an ideal representation would require no such transformations (i.e., it would remain static) when transferring to a new task.

The idea that input (i.e., state) representation might remain static during transfer is plausible because the raw inputs to biological organisms, for example, vision, remain the same even when new tasks are confronted. For example, when a child graduates from playing Keepaway to full-blown soccer, the number of photoreceptors in the eye do not change. The main idea in this paper is that such static representation, when possible, facilitates transfer by ensuring that the semantics of the representation are preserved even when the task changes.

To demonstrate the critical role of static representation in transfer, a novel state representation is introduced called a *bird's eye view* (BEV), which is a two-dimensional depiction of objects on the ground from above. Conceptually, the BEV is a metaphor for an internal representation of the state of the world from above. The BEV places objects into the context of the world geometry, allowing geometric relationships to be more easily learned. Another advantage is that its input dimensionality (i.e., number of inputs) is constant no matter how many objects are on the field. That way, even if the task is transferred to a version with more objects, the representation remains the same (i.e., static), significantly simplifying task transfer.

However, the challenge for the BEV is that representing a high-resolution two-dimensional field requires many input dimensions (i.e., many parameters), similarly to an eye. An outgrowth of evolutionary computation designed to address such high-dimensional problems is *indirect encoding*, which compresses the representation of the solution by reusing information. The particular indirect encoding in this paper, called a *compositional pattern producing network* (CPPN; Stanley 2007), represents artificial neural network (ANN) mappings between high-dimensional spaces by exploiting *regularities* in their geometry, which is well-suited to the BEV. An evolutionary algorithm called Hypercube-based NeuroEvolution of Augmenting Topologies (HyperNEAT; Gauci and Stanley 2008; Stanley et al. 2009; Gauci and Stanley 2010) that is designed to evolve CPPNs is therefore able to learn effectively from the BEV.

The HyperNEAT BEV is tested in the common RoboCup Keepaway soccer reinforcement-learning (RL) benchmark (Stone et al., 2005). Keepaway is important because it can potentially serve as a stepping stone to full-blown soccer in the future, which is a major current goal in machine learning (Kalyanakrishnan et al., 2007; Kitano et al., 1997; Kok et al., 2005; Kyrylov et al., 2005; Mackworth, 2009; Stolzenburg et al., 2006). One interesting result with the BEV is the longest holding time in the 3 vs. 2 variant of the task yet recorded. However, more importantly, unlike any method so far, HyperNEAT can transfer from 3 vs. 2 to 4 vs. 3 Keepaway with no change in representation and no further learning, demonstrating the critical role static representation plays in learning and transfer. Furthermore, these transferred policies can then be further trained on the new task without the need to alter the representation. Additional types of transfer within Keepaway are investigated wherein the *representation* of the policy (i.e., the CPPN, or indirect encoding) remains static while the BEV itself is changed by increasing resolution and by accommodating different field sizes. Finally, cross-domain transfer is demonstrated by training on a distinctly different domain, Knight Joust (Taylor et al., 2007a), which is a simple predator-prey type domain, and then transferring to 3 vs. 2 Keepaway.

The main result is that transfer through a static representation is consistently more robust and often provides immediate benefits even without any further training. While static representations are inherently high-dimensional because they must encompass many tasks, indirect encodings like HyperNEAT's CPPNs show that high-dimensionality need not be prohibitive. Thus, while machine

learning often focuses on the learning *algorithm*, the hope is that this paper provokes a fruitful conversation on the role of *representation* in transfer and learning in general.

It is finally important to acknowledge that the extent to which maintaining a static representation is realistic depends upon the learning method, state information, and differences between domains. Thus static representation is an ideal that when met can provide an advantage, as shown in this paper.

The next section describes the importance of representation in learning, prior research in transfer learning, and the methods that underlie the BEV representation. Section 3 explains how the BEV is configured, how information is represented in the BEV, and how HyperNEAT trains the BEV. In Section 4, the experiments that investigate the performance of the BEV in learning and transfer are described. Finally, Section 5 presents the results of the BEV, followed by a discussion in Section 6.

2. Background

This section examines the critical role of representation in RL and then explains the geometry-based methods that underlie the static representation investigated in this paper, and their relation to task transfer.

2.1 Representation in Learning

A convenient model for problems in RL is the *Markov decision process* (MDP). In the MDP, the learner knows its environment through a state observation $s \in S$, which is characterized by a set of state variables $s = \langle p_1, p_2, \cdots, p_n \rangle$, in which each p_i denotes a particular state parameter. By taking an action $a \in A$, the agent transitions to a new state in S through the transition function $T : S \times A \mapsto S$. The reward function $R : S \mapsto \mathbb{R}$ determines the instantaneous reward associated with reaching each state. Finally, the action that the agent takes from its current state is selected by the policy function $\pi : S \mapsto A$ (Puterman, 1994). For example, in the Keepaway soccer domain, the state space S for the keeper with the ball can be defined as the set of distances and angles to each other player. The set of actions A can be defined as a set of passes to teammates and holding the ball (Metzen et al., 2007; Stone et al., 2001; Stone and Sutton, 2001; Stone et al., 2005). A simple policy π would be to pass to the most open teammate when takers are close and hold the ball otherwise.

While the MDP framework provides a solid foundation for developing learning algorithms, it does not suggest how to select a state and action *representation* appropriate for both the domain and the learning algorithm. One popular approach to state representation, for example, in the RoboCup Keepaway soccer domain, is to express the state as distances and angles to the other players relative to the agent with the ball (Metzen et al., 2007; Stone et al., 2001, 2005; Taylor et al., 2006). However, this common representation is not the only one possible, which is important because representation critically influences what is learned (Gauci and Stanley, 2008; Diuk et al., 2008; Tadepalli et al., 2004; Tesauro, 1992).

To see the powerful effect of representation on learning, consider the common representation in 3 vs. 2 Keepaway of 13 state parameters that are value-attributes for distance and angle relationships among the players and the field. In contrast, 4 vs. 3 Keepaway, a similar task, requires an increased number of state parameters to represent the distances and angles for the additional players. These additional parameters mean that the same representation cannot be applied to both tasks, thereby complicating the transfer of knowledge between tasks. For example, the same concept must

be learned repeatedly when the same decisions are made separately for multiple objects, such as whether to pass to teammates who are out of bounds.

Relational RL addresses problems such as scaling and repetitious concepts by generalizing the representation of information for learning algorithms to a relational form (Deroski et al., 2001). For example, in the RoboCup Keepaway domain, instead of real-valued state parameters, general *relations* can be defined. An example for deciding to whom to pass in 3 vs. 2 Keepaway is:

$$Pass(Teammate) : -Threatened(PlayerWithBall), Open(Teammate).$$

The relational form provides a more expressive representation that can be combined with reinforcement-learning methods (Tadepalli et al., 2004). By focusing on the logic of relationships, instead of on individual parameter values, these relationships can be applied to any number of objects. Furthermore, once a relationship is learned for one set of objects, it is learned for all similar sets of objects.

One of relational RL's goals is to provide an easier representation for transferring knowledge. This transfer could be across objects in the domain or across different tasks. However, the design and definition of these relationships are dependent upon the human designer, requiring expert domain knowledge. Learning is dependent upon the a priori defined relations. Continuous and noisy domains present additional challenges to designing appropriate relations (Morales, 2003). Nevertheless, relational RL highlights the importance of representation to learning.

However, while state representation is important, it is not the only type of representation that affects learning. Also significant is the representation of the learner itself, which impacts which types of relationships can be learned and how easily they are found. For example, research in temporal difference learning can employ look-up tables or more compact representations (Sutton, 1988, 1996; Tesauro, 1992), which work by encoding regularities. An important difference between these representations is that the look-up table contains enough parameters to store associated actions with every state, while compact representations must encode the solution with significantly fewer parameters than states. To guarantee convergence with a *look-up table*, every state must be visited an infinite number of times (Sutton and Barto, 1998) while *compact* representations need only discover underlying regularities in the problem (Sutton, 1996; Tesauro, 1992).

Another important factor in representation is the geometry of the domain (e.g., which position is adjacent to which and in what direction). Geometry plays a critical role in learning. For example, if a checkers board is scrambled while the relationships among locations that have been moved remain the same, the game would become more difficult to learn. This effect has been investigated in checkers, wherein learning based on board geometry was demonstrated to enhance performance versus learning while blind to geometry (Gauci and Stanley, 2008, 2010). Ideally, the solution should be a function of the domain geometry, enabling the learner to take advantage of geometric regularities. This paper focuses further on the critical role of representing geometry, particularly in task transfer, which is described next.

2.2 Task Transfer

Task transfer means applying knowledge learned in one task to a new, related task (Caruana, 1997; Talvitie and Singh, 2007; Taylor et al., 2007a). It allows learning to be recycled instead of starting anew, thereby avoiding wasted computation. Additionally, a task may be so complex that it requires initial training on a simpler version to reduce learning time and increase performance (Caruana,

1997; Schmidhuber and Informatik, 1994; Tadepalli, 2008; Thrun and Mitchell, 1994). Thus the capability to transfer is becoming increasingly important as the tasks studied in RL increase in complexity. However, transfer learning faces several challenges: First, transfer is only effective among compatible tasks and the particular knowledge that can transfer from one task to another must be identified. Second, a method must be derived to actually implement the transfer of knowledge. Finally, cases in which transfer hinders performance, or *negative transfer*, must be avoided (Pan and Yang, 2008). There are several types of transfer learning problems and a variety of methods that exploit their characteristics. These methods include translating the knowledge learned in one task to another task (Ramon et al., 2007; Taylor et al., 2007a), choosing the best policy for the current task from a set of previously learned policies (Talvitie and Singh, 2007), extracting advice from previously learned tasks (Torrey et al., 2008a,b), and learning multiple tasks at the same time (Collobert and Weston, 2008). This section reviews several such approaches.

An intuitive approach to transfer learning is to transform the representation of knowledge learned in one task to a suitable form for a new task and then continue learning from that point. A successful method that takes this approach is *transfer via inter-task mapping for policy search methods* (TVITM-PS; Taylor et al. 2007a). TVITM-PS is such a leading method for transforming the policy learned in the source task into a policy usable in the target task. In TVITM-PS, a transfer functional ρ is defined to transform the policy π for a source task into the policy for a target task, such that $\rho(\pi_{source}) = \pi_{target}$. This functional is often hand-coded based on domain knowledge, though learning it is possible. When there are novel state variables or actions, an *incomplete mapping* is defined from the source to the target. TVITM-PS can be adapted to multiple representations. For example, in an ANN, input or output nodes whose connections are not defined in the mapping (i.e., it is incomplete) are made fully connected to the existing hidden nodes with random weights. This incomplete mapping implies that further training is needed to optimize the policies with respect to the new state variables and actions. However, it makes it possible to begin in the target domain from a better starting point than from scratch. TVITM-PS is a milestone in task transfer because it introduces a formal approach to moving from one domain to another that defines how ambiguous variables in the target domain should be treated. The performance of TVITM-PS is compared to results in this paper.

Another method of transfer, which is one that is explored in this paper, is to recycle the exact *same* policy from a source task in a later target task. The idea is that the policy can then continue to improve in the target task. An existing approach to recycling past policies is to maintain a *set* of policies and select among them. *Alternating trusting Exploration and suspicious exploitation* (AtEase; Talvitie and Singh 2007) is such a transfer method; it aims to recognize when tasks are related and when to exploit knowledge gained from previous tasks. It exploits knowledge from previous tasks by judging when to invoke the previously gained knowledge and from which policies. To facilitate this process, a set of policies previously developed by learning source tasks are first evaluated. This evaluation estimates the performance of these previously learned source policies on the new target task. Second, the strategies are ranked by their expected performance on the target task and the source policy with the best estimated performance is chosen. Finally, the chosen best policy is set as the current policy for the target task. It remains as the policy for the target task until the policy's actual performance on the task falls below expectation (i.e., the estimated performance from the evaluation of source policies is greater than the current performance) or reaches a maximum number of iterations (allowing other policies to be explored). If the expert policy falls below expectation, the next best policy is selected and is set as the current expert policy. This method

allows an accurate estimate of which policy from previously learned tasks is appropriate for the current task. In contrast to this approach, this paper focuses on how to effectively leverage knowledge gained in a *single* source policy to continue learning in the target domain. Thus the approach in this paper can potentially combine with a multi-policy approach such as AtEase.

An important consideration in transfer is whether a human can understand the knowledge being transferred among tasks. An alternative method to recycling previously learned policies directly is to take advice from learned policies to augment decision making. This advice may take the form of geometric knowledge, causal relationships, predictions, or any other type of information, allowing researchers to more easily interpret the transferred knowledge. *Rule extraction* is one such method that takes knowledge learned from a source domain and translates it into advice that aids a policy in a target domain (Torrey et al., 2008b). The advice is generated as a conditional, if-then statement. Torrey et al. (2008b) describe two methods for generating advice. One method is to compose rules by decomposing the policy learned on a source task. For example, Q-values can be examined directly and rules can be generated based on which actions are preferred. An alternative method for generating advice is to analyze the *behavior* (instead of the policy) of an agent to generate rules. Consider observing agents playing a game of Keepaway soccer. Through observation, it may be apparent that a learned policy always passes the ball if opponents approach within one meter, which may then be transformed into a rule to transfer to another task. These sets of rules have the advantage of being understandable to humans, allowing researchers to know what knowledge is being transferred and how it is contributing.

Interestingly, transfer learning does not always require a designated source and target task. Instead, knowledge may transfer among several tasks that are simultaneously being learned. By encoding the knowledge for multiple tasks within the same policy, the knowledge gained from each individual task may combine with and complement the knowledge from other tasks. For example, Collobert and Weston (2008) demonstrate transfer learning through multi-task training for natural language processing (NLP) with deep neural networks. There are many tasks related to NLP, including part-of-speech tagging, chunking, named entity recognition, semantic role labeling, language modeling, and relating words syntactically. The idea is that learning about one such task may contribute to learning the others. By training the policies simultaneously for all these capabilities, knowledge can be continually passed back and forth among all these tasks. In particular, Collobert and Weston (2008) show that this method improves generalization and achieves competitive results on the task of relating words with similar meaning.

This paper adds to our understanding of task transfer by focusing on the role of *representation*. The next section reviews the NEAT method, upon which this representation-centric approach is built.

2.3 NeuroEvolution of Augmenting Topologies (NEAT)

NEAT (Stanley and Miikkulainen, 2002, 2004) is a popular policy search method that evolves ANNs. The main idea in this paper focuses on an extension of NEAT called HyperNEAT. Nevertheless, the basic principles of NEAT still supply the foundation of the approach. Traditionally, ANNs evolved by NEAT control agents that select actions based on their sensor inputs. It is proven in a variety of challenging control and decision-making tasks (Aaltonen et al., 2009; Cardamone et al., 2009; Stanley and Miikkulainen, 2002, 2004; Stanley et al., 2005; Taylor et al., 2006; Whiteson, 2005; Whiteson and Whiteson, 2007). This section briefly reviews NEAT.

NEAT is an evolutionary algorithm that starts with a population of small, simple ANNs that increase their complexity over generations by adding new nodes and connections through mutation. That way, the topology of the network does not need to be known a priori and NEAT finds a suitable level of complexity for the task. NEAT is unlike many previous methods that evolved neural networks, that is, *neuroevolution* methods, which historically evolved either fixed-topology networks (Gomez and Miikkulainen, 1999; Saravanan and Fogel, 1995), or arbitrary random-topology networks (Angeline et al., 1993; Gruau et al., 1996; Yao, 1999). Unlike these approaches, NEAT begins evolution with a population of small, simple networks and increases the complexity of the network topology into *diverse species* over generations, leading to increasingly sophisticated behavior. A similar process of gradually adding new genes has been confirmed in natural evolution (Martin, 1999; Watson et al., 1987) and shown to improve adaptation in a few prior evolutionary (Altenberg, 1994) and neuroevolutionary (Harvey, 1993) approaches. However, a key feature that distinguishes NEAT from prior work in growing ANNs is its unique approach to maintaining a healthy diversity of increasingly complex structures simultaneously, as this section reviews. Complete descriptions of the NEAT method, including experiments confirming the contributions of its components, are available in Stanley and Miikkulainen (2002, 2004) and Stanley et al. (2005).

The NEAT method is based on three key ideas. First, to allow network structures to increase in complexity over generations, a method is needed to keep track of which gene is which. Otherwise, it is not clear in later generations which individual is compatible with which in a population of diverse structures, or how their genes should be combined to produce offspring. NEAT solves this problem by assigning a unique *historical marking* to every new piece of network structure that appears through a structural mutation. The historical marking is a number assigned to each gene corresponding to its order of appearance over the course of evolution. The numbers are inherited during crossover unchanged, and allow NEAT to perform crossover among diverse topologies without the need for expensive topological analysis.

Second, NEAT divides the population into species so that individuals compete primarily within their own niches instead of with the population at large. Because adding new structure is often initially disadvantageous, this separation means that unique topological innovations are protected and therefore have the opportunity to optimize their structure without direct competition from other niches in the population. The historical markings help NEAT determine to which species different individuals belong.

Third, many approaches that evolve network topologies and weights begin evolution with a population of random topologies (Gruau et al., 1996; Yao, 1999). In contrast, NEAT begins with a uniform population of simple networks with no hidden nodes, differing only in their initial random weights. Because of speciation, novel topologies gradually accumulate over evolution, thereby allowing diverse and complex phenotype topologies to be represented. No limit is placed on the size to which topologies can grow. New structures are introduced incrementally as structural mutations occur, and only those structures survive that are found to be beneficial through fitness evaluations. In effect, then, NEAT searches for a compact, appropriate topology by incrementally adding complexity to existing structure.

The important concept for the approach in this paper is that NEAT is a policy search method that discovers the right topology and weights of a network to maximize performance on a task. The next section reviews the extension of NEAT called HyperNEAT that allows it to exploit geometry through representation.

2.4 CPPNs and HyperNEAT

The primary reason that NEAT is chosen as the main vehicle to study alternate representations is that it is easily extended to become an *indirect encoding*, which means a *compressed* description of the solution network. Such compression makes the policy search practical even if the state space is high-dimensional. One effective approach to indirect encoding is to compute the network structure as a function of the domain's geometry. This section describes such an extension of NEAT, called Hypercube-based NEAT (HyperNEAT; Gauci and Stanley 2008; Stanley et al. 2009; Gauci and Stanley 2010), which enables the novel state representation in this paper from a bird's eye view. The effectiveness of the geometry-based learning in HyperNEAT has been demonstrated in multiple domains, such as checkers (Gauci and Stanley, 2008, 2010), multi-agent predator prey (D'Ambrosio and Stanley, 2008; D'Ambroiso and Stanley, 2010), visual discrimination (Stanley et al., 2009), and quadruped locomotion (Clune et al., 2009). For a full HyperNEAT description, see Stanley et al. (2009) and Gauci and Stanley (2010).

The main idea in HyperNEAT is that it is possible to learn geometric relationships in the domain through an indirect encoding that describes how the *connectivity* of the ANN can be *generated* as a function of the domain geometry. Unlike a *direct* representation, wherein every dimension in the policy space (i.e., each connection in the ANN) is described individually, an indirect representation can describe a pattern of parameters in the policy space without explicitly enumerating every such parameter. That is, information is reused in such an encoding, which is a major focus in the field of *generative and developmental systems* from which HyperNEAT originates (Bentley and Kumar, 1999; Hornby and Pollack, 2002; Lindenmayer, 1968; Turing, 1952). Such information reuse is what allows indirect encodings to search a compressed space. That is, HyperNEAT discovers the *regularities* in the domain geometry and learns a policy based on them.

The indirect encoding in HyperNEAT is called a *compositional pattern producing network* (CPPN; Stanley 2007), which encodes the *connectivity pattern* of an ANN (Gauci and Stanley, 2007, 2008; Stanley et al., 2009; Gauci and Stanley, 2010). The idea behind CPPNs is that a geometric pattern can be encoded by a *composition of functions* that are chosen to represent several common regularities. For example, because the Gaussian function is symmetric, when it is composed with any other function, the result is a symmetric pattern. The internal structure of a CPPN is a weighted network, similar to an ANN, that denotes which functions are composed and in what order. The appeal of this encoding is that it can represent a pattern of connectivity, with regularities such as symmetry, repetition, and repetition with variation, through a network of simple functions (i.e., the CPPN), which means that, instead of evolving ANNs directly, NEAT can evolve *CPPNs* that generate ANN connectivity patterns (Figure 1). Furthermore, the indirect encoding represents the connectivity of the ANN regardless of its size, which allows ANNs of arbitrary dimensionality to be represented.

Formally, CPPNs are *functions* of geometry (i.e., locations in space) that output connectivity patterns whose nodes are situated in n dimensions, where n is the number of dimensions in a Cartesian space. For each connection between two nodes in that space, the CPPN inputs their *coordinates* and outputs their connection weight. That way, NEAT can evolve CPPNs that represent ANNs with symmetries and regularities that are computed *directly* from the geometry of the state space. Consider a CPPN that takes four inputs labeled x_1, y_1, x_2, and y_2; this point in four-dimensional space can *also* denote the connection between the two-dimensional points (x_1, y_1) and (x_2, y_2). The output of the CPPN for that input thereby represents the weight of that connection (Figure 1). By querying

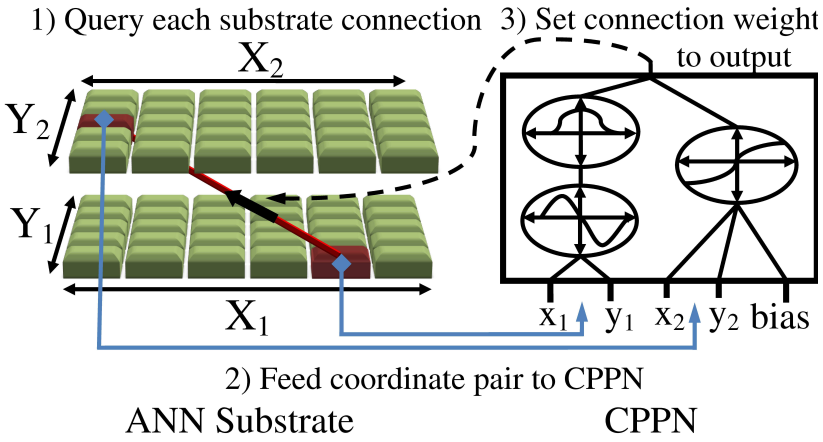

Figure 1: A CPPN Describes Connectivity. A grid of nodes, called the ANN *substrate*, is assigned coordinates. (1) Every connection between layers in the substrate is queried by the CPPN to determine its weight; the line connecting layers in the substrate represents a sample such connection. (2) For each such query, the CPPN inputs the coordinates of the two endpoints, which are highlighted on the input and output layers of the substrate. (3) The weight between them is output by the CPPN. Thus, CPPNs, whose internal topology and connection weights are evolved by HyperNEAT, can generate regular patterns of connections.

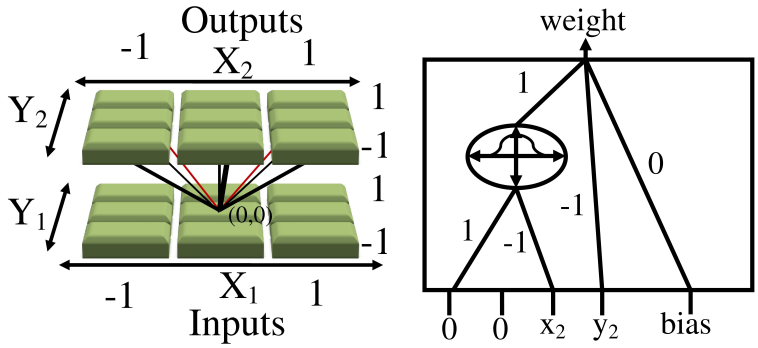
every pair of points in the space, the CPPN can produce an ANN, wherein each queried point is the position of a neuron. While CPPNs are themselves networks, the distinction in terminology between CPPN and ANN is important for explicative purposes because in HyperNEAT, CPPNs *encode* ANNs. Because the connection weights are produced as a function of their endpoints, the final structure is produced with *knowledge* of the domain geometry, which is literally depicted geometrically within the constellation of nodes. In other words, parameters p_i of the state vector s actually exist at *coordinates* in space, giving it a geometry.

To help explain how CPPNs can compactly encode regular connectivity patterns, Figure 2 shows how a very simple CPPN encodes a symmetric network. In effect, the CPPN paints a pattern within a four-dimensional hypercube that is interpreted as an isomorphic connectivity pattern. The example in Figure 2 illustrates the natural connection between the function embodied by the CPPN and the geometry of the resultant network.

Connectivity patterns produced by a CPPN in this way are called *substrates* so that they can be verbally distinguished from the CPPN, whose internal topology is independent of the substrate. The experimenter defines both the location and role (i.e., hidden, input, or output) of each node in the substrate. As a rule of thumb, nodes are placed on the substrate to reflect the geometry of the domain (i.e., the state), which makes the setup straightforward (Gauci and Stanley, 2007, 2008; Clune et al., 2009; Stanley et al., 2009; Gauci and Stanley, 2010). This way, the connectivity of the substrate becomes a direct function of the domain geometry, which means that knowledge about the problem can be injected into the search and HyperNEAT can exploit the regularities (e.g., adjacency,



(a) ANN Substrate (b) CPPN

Figure 2: Example CPPN Describing Connections from a Single Node. An example CPPN (b) with five inputs $(x_1, y_1, x_2, y_2, bias)$ and one output (*weight*) contains a single Gaussian node and five connections. The function produced is symmetric about x_1 and x_2 (because of the Gaussian) and linear with respect to y_2 (which directly connects to the CPPN output). For the given fixed input node coordinate $(x_1 = 0, y_1 = 0)$, the CPPN in effect produces the function Gaussian$(-x_2) - y_2$. This pattern of weights from input node $(0,0)$ is shown on the substrate (a). Weight magnitudes are indicated by thickness and black lines indicate positive values. Note that the pattern produces a set of weights that are symmetric about the x-axis and linearly decreasing as the values of y_2 increases. In this way, the function embodied by the CPPN encodes a geometric pattern of weights in space. HyperNEAT evolves the topologies and weights of such CPPNs.

or symmetry, which the CPPN sees) of a problem that are invisible to traditional encodings. For example, one way that geometric knowledge can be imparted is by including a hidden node in the CPPN that computes Gaussian$(x_2 - x_1)$, which imparts the concept of locality on the x-axis, an idea employed in the implementation in this paper. The HyperNEAT algorithm is outlined in algorithm 1.

In summary, instead of evolving the ANN directly, HyperNEAT, through the NEAT method, evolves the internal topology and weights of the CPPN that *encodes* it, which is significantly more compact. The next section explains how this encoding makes it possible to learn from a bird's eye view.

3. Approach: Bird's Eye View

A major challenge for the state representation in RL tasks is that specific state variables are often tied to agents or individual objects, which makes it difficult to add more such objects without expanding the state space (Taylor et al., 2007a). To address this problem, this section proposes a static representation, the bird's eye view (BEV) perspective, which enables scaling to higher complexity states without the need to alter the representation. The BEV is explained first, followed by its implementation, which is based on the HyperNEAT approach. Because it is relatively simple, the BEV is chosen in this paper to exemplify the advantage of static representation in task transfer.

```
   Input: Substrate Configuration
   Output: Solution CPPN
 1 Initialize population of minimal CPPNs with random weights;
 2 while Stopping criteria is not met do
 3     foreach CPPN in the population do
 4         foreach Possible connection in the substrate do
 5             Query the CPPN for weight w of connection;
 6             if Abs(w) >Threshold then
 7                 Create connection with a weight scaled proportionally to w (Figure 1);
 8             end
 9         end
10         Run the substrate as an ANN in the task domain to ascertain fitness;
11     end
12     Reproduce CPPNs according to the NEAT method to produce the next generation;
13 end
14 Output the Champion CPPN.
```

Algorithm 1: Basic HyperNEAT Algorithm

3.1 Bird's Eye View

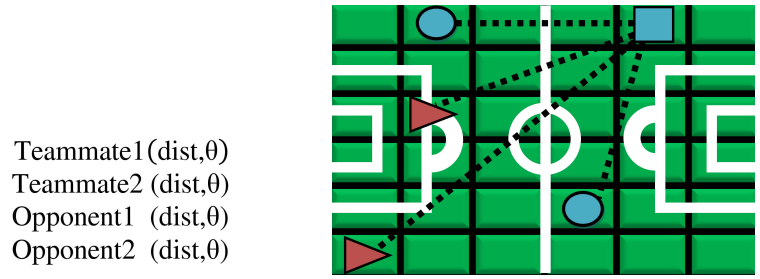
Humans often visualize data from a BEV. Examples include maps for navigation, construction blue prints, and sports play books. Key to these representations is that they remain the same (i.e., they are *static*) no matter how many objects are represented on them. For example, a city map does not change size or format when new buildings are constructed or new roads are created. Additionally, the physical geometry of such representations allow agents to understand spatial relationships among objects in the environment by placing them in the context of physical space. The BEV also implicitly represents its borders by excluding space outside them from its field of view. As suggested in Kuipers' Spatial Semantic Hierarchy (SSH), such *metrical* representation of the geometry of large-scale space is a critical component of human spatial reasoning (Kuipers, 2000).

A distinctive feature of the proposed representation is that not only is the agent state represented from a BEV, but it *also* requests *actions* within the same BEV perspective. For example, to request a pass the agent can indicate its target by simply highlighting it on a two-dimensional output array. That way, instead of making decisions blind to the geometry of physical space, it can be taken into account.

Egocentric data (Figure 3a) can be mapped to an equivalent BEV by translating from local (relative) coordinates to global coordinates established by static points of reference (i.e., fiducials). The global coordinates mark the location of objects in the BEV (Figure 3b). This translation allows mapping any number of objects into the static representation of the BEV.

Importantly, the continuous coordinate system must be discretized so that each variable in the state representation corresponds to a single discrete location. This discretization allows the two-dimensional field to be represented with a finite set of parameters. The values of these parameters denote objects in their respective regions.

Note that while the division of the field in Figure 3b appears reminiscent of *tile coding* (Sutton, 1996), that appearance is superficial because (1) a tile coding of the state variables in Figure 3a



(a) Egocentric view (b) BEV

Figure 3: Alternative Representations of a Soccer Field. Several parameters (a) represent the agent's relationship with other agents on a soccer field (taken from a standard RoboCup representation; Cheny et al. 2003). Each distance and angle pair represents a specific relationship of the agent to another agent. The BEV (b) represents the same relationships as paths in the geometric space. A square depicts the agent, circles depicts its teammates, and triangles its opponents. The overhead perspective also makes it possible to represent any number of agents without changing the representation.

would still be egocentric whereas the BEV is not, and (2) tile coding breaks the state representation into chunks that can be optimized separately whereas the HyperNEAT CPPN derives the connectivity of the policy network directly from the geometric relationships among the squares in Figure 3b, as explained next.

3.2 HyperNEAT: Learning from the BEV

Geometric patterns often exhibit spatial regularities. Examples include repetition and symmetry. Furthermore, important geometric relationships such as locality and topological connectedness often critically influence informed spatial decision-making. The challenge for machine learning is that learning is often blind to the geometry of the problem, making it difficult to exploit such relationships (Gauci and Stanley, 2008, 2010). To understand the impact of learning from the true geometry of the domain, consider a two-dimensional field converted to a traditional vector of parameters, which removes the geometry (Figure 4). For example, consider a set of input values to an ANN such as in to Figure 3a. Though each *dist* and θ pair is critically related in such a traditional representation, an ANN has no inherent knowledge or explicit access to this relationship. In contrast, HyperNEAT *sees* the task geometry, thereby exploiting geometric regularities and relationships, such as locality, which the BEV naturally makes explicit.

For HyperNEAT to exploit patterns in a two-dimensional BEV (e.g., in soccer), the geometry of the input layer of the substrate is made two-dimensional, as in Figure 5. That way, CPPNs can compute the connectivity of the substrate as a function of that geometry. The x and y coordinates of each input unit (i.e., each p_i) are in the range $[-1,1]$. Furthermore, the output layer of the substrate matches the dimensions of the BEV so that the CPPN can exploit the geometric relationship between the input space and output space as well (Figure 5). That the *outputs* are themselves a discretized two-dimensional plane is another significant difference from tile coding. Each coordinate in this substrate represents a discretized region of the overhead view of physical space. A four-dimensional CPPN with inputs x_1, y_1, x_2, and y_2 determines the weights between coordinates in the two-dimensional input layer and the two-dimensional output layer, creating a pattern of con-

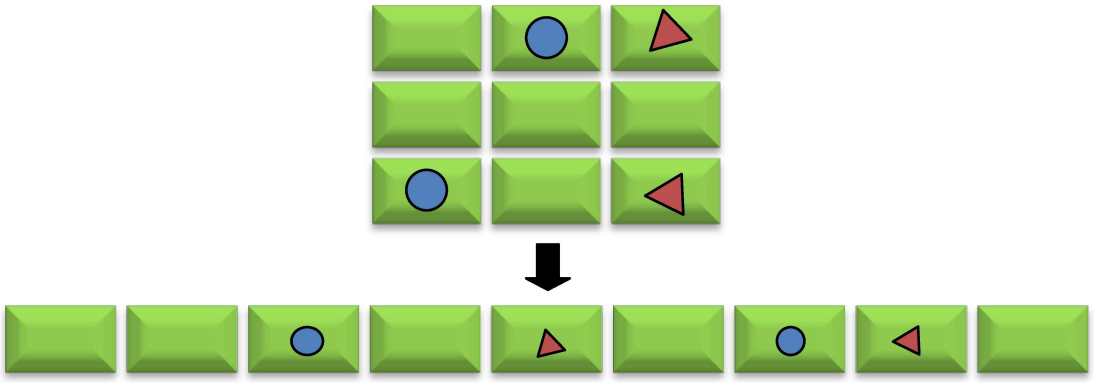


Figure 4: The Importance of True Geometry. A two-dimensional field transformed into a vector of parameters without any geometry forfeits knowledge of the geometry of the domain.

nections between regions in the physical space. To represent world state, objects and agents are literally "drawn" onto the input substrate, which is a static size, like marking a map. The generated network then can make decisions based on the relationships of such features in physical space and thereby learn the significance of certain kinds of geometric relationships among objects that are not identified a priori by the designer.

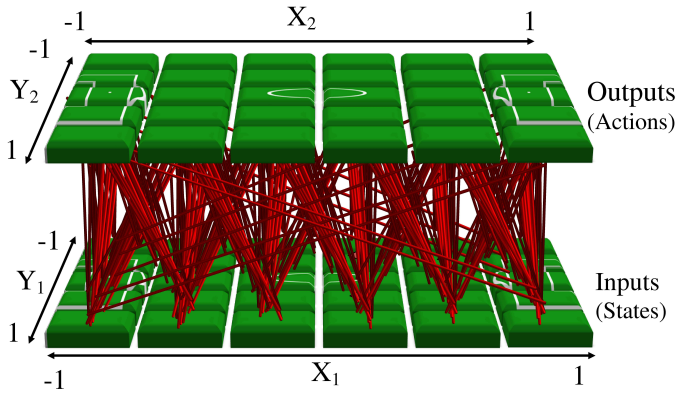

Figure 5: BEV Implemented in the Substrate. Each dimension ranges between $[-1, 1]$ and the input and output planes of the substrate are equivalently constructed to take advantage of geometric regularities between states and actions. Because CPPNs are an indirect encoding, the high dimensionality of the weights does not affect performance. (The CPPN is the search space.)

In this way, the BEV makes it possible to add new features (e.g., a new player) to the state space *without* the need to add new inputs. Instead, they can now simply be drawn onto the existing representation with no additional apparatus. That way, task transfer to different numbers of players is made simple through the static representation.

Interestingly, although the BEV is naturally held static its size or resolution can be changed *without* retraining. A unique feature of CPPNs (which encode the BEV connectivity) is that the same CPPN can query substrates of arbitrary size or resolution. It is important to note that even when size or resolution are changed, the *CPPN* itself remains the same. Thus the BEV can extend its representation to different field sizes or to different levels of detail (i.e., resolutions), as shown in Figure 6. In this way, the CPPN allows not only transfer to different numbers of players, but to different field sizes and resolutions, all without the need for retraining.

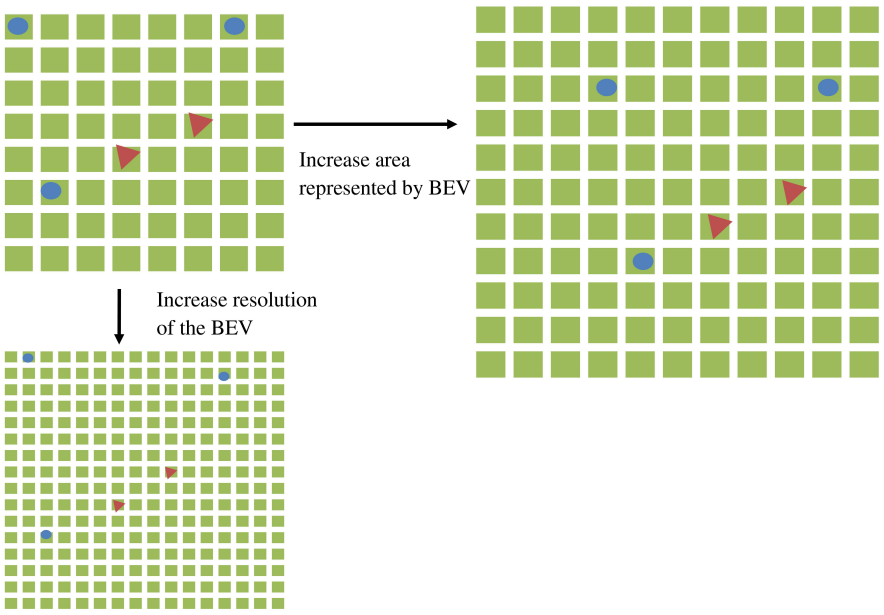

Figure 6: Changing the BEV. Two kinds of alterations are depicted in this figure. First, the BEV can be altered by increasing the *area* of the substrate while maintaining the size of each discrete cell by extrapolating new connection weights associated with previously unseen cells. Second, resolution is increased by increasing the number of cells and shrinking the area represented by each discrete cell. The CPPN automatically interpolates connection weights for the new locations. Thus, the BEV allows new forms of transfer to differing field sizes or levels of precision.

It is important to understand that the dimensionality of the search space in HyperNEAT is not the same as the dimensionality of the substrate because the search space is the *CPPN*, which is a compact encoding of the pattern of connections in the substrate. For example, if the substrate resolution is 20×20 then the number of possible connections in the substrate is $400 \times 400 = 160,000$. However, a CPPN that encodes this connectivity can itself contain orders of magnitude fewer connections. This fact also explains why resolution can increase without retraining. For example, if resolution increases to 40×40 (2,560,000 possible connections), there are new connections that connect locations that previously did not exist at 20×20. However, the same CPPN can simply query the (x_1, y_1, x_2, y_2) coordinate of the new connections, thereby interpolating the weights of the

new connections automatically. Although the number of connections in this example increases from 160,000 to 2,560,000, the dimensionality of the CPPN does not change at all.

The next section introduces the experiments that demonstrate the benefits of this geometric approach.

4. Experimental Setup

The experiments in this paper are designed to investigate the role of representation in task transfer. Of course, some representations are better suited to transfer in a given domain than others. Further, the ability to transfer between tasks is dependent on the similarity of the tasks. However, this paper focuses on the idea that a particularly effective representation for transfer is one that *does not need to change* from one task to the next. Because the representation is consistent, it has the potential to exhibit improved performance in the target domain immediately after transfer, without further learning. The advantage of a consistent representation is that the semantic relationships learned previously are preserved and then can be built upon. Because the BEV is the same irrespective of the number of players on either side, it satisfies this requirement and allows the hypothesis that consistent representation leads to immediate improvement in the target domain to be tested. This section explains the domains, the methods compared, and the experimental configurations.

4.1 RoboCup Keepaway Domain

RoboCup simulated soccer Keepaway (Stone et al., 2001) is well-suited to such an investigation because it is a popular RL performance benchmark and can be scaled to different numbers of agents to create new versions of the same task. All experiments are run on the Keepaway 0.6 player benchmark (Stone et al., 2006) and the RoboCup Simulator Soccer Server v. 12.1.1 (Cheny et al., 2003). RoboCup Keepaway is a popular benchmark (Metzen et al., 2007; Stone et al., 2005; Taylor et al., 2007a; Whiteson et al., 2005) in part because it includes a large state space, partially observable state, and noisy sensors and actuators. It is also a stepping stone to full-blown RoboCup Soccer, one of the hottest tasks in machine learning (Kalyanakrishnan et al., 2007; Kitano et al., 1997; Kok et al., 2005; Kyrylov et al., 2005; Mackworth, 2009; Stolzenburg et al., 2006). In Keepaway, *keepers* try to maintain possession of the ball within a fixed region and *takers* attempt to take it away. The number of agents and size of the field can be varied to make the task more or less difficult: The smaller the field and the more players in the game, the harder it becomes.

4.2 Keepaway Benchmark

Each learning method in this paper is initially compared in the standard benchmark setup (Stone et al., 2005) of the three keepers versus two takers task on a 20m$\times$20m field. In this setup, agents' sensors are noisy and their actions are nondeterministic. Takers follow static policies, wherein the first two takers go towards the ball and additional takers attempt to block open keepers. The learner only controls the keeper who possesses the ball; its choices are to hold the ball or pass to a specific teammate. The keepers' reward is the length of time they hold ball. In the 3 vs. 2 task, 13 variables represent the agent's state (Stone et al., 2005). These include each player's distance to the center of the field, the distance from the keeper with the ball to each other player, the distance from each other keeper to the closest taker, and the minimum angle between the other keepers and the takers (Figure 7). The three possible actions are holding the ball or passing to one of the other two keepers.

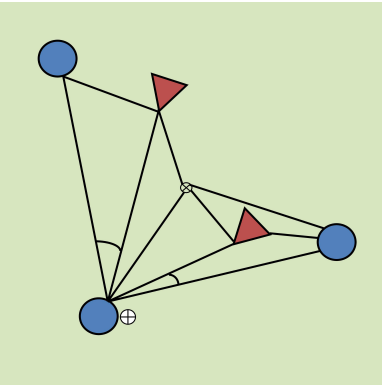

Figure 7: Visualization of Traditional State Variables in 3 vs. 2 Keepaway. The 13 state parameters that represent the state in the 3 vs. 2 Keepaway task are depicted in this figure. The three keepers are represented by the circles and the takers represented by the triangles. The state parameters include the distances from each player to the center of the field (marked by the circle with the $\times$), the distances from the keeper with the ball (denoted by the circle with the +) to each other player, the distance from each other keeper to the taker nearest them, and the angles along the passing lanes.

To investigate the ability of a static representation, that is, the HyperNEAT BEV, to learn this task, it is compared to both static policies (Stone et al., 2006) and the learning algorithms Sarsa (Rummery and Niranjan, 1994), NEAT (Stanley and Miikkulainen, 2004), and EANT (Metzen et al., 2007). Unlike the BEV, the traditional representation (with 13 state variables) through which these methods learn in 3 vs. 2 Keepaway must be changed for different versions of the task, such as 4 vs. 3 Keepaway. The static benchmarks are Always-Hold, Random, and a Hand-Coded policy, which holds the ball if no takers are within 10m (Stone and Sutton, 2001). These static benchmarks provide a baseline to validate that the BEV learns a non-trivial policy in the initial task.

State action reward state action (Sarsa; Rummery and Niranjan 1994) is an on-policy temporal difference RL method that learns the action-value function $Q(s,a)$. The quintuple (s,a,r,s',a') defines the update function for $Q(s,a)$ by determining for a current state (s) and action (a) what the reward (r) and the expected reward for the predicted next state (s') and action (a') will be. The update equation is:

$$Q(s,a) \leftarrow (1-\alpha)Q(s,a) + \alpha(r + \gamma Q(s',a')),$$

where α is the learning rate and γ is the discount factor for the future reward. The values in $Q(s,a)$ determine which action is taken in a given state by selecting the maximal value. Each keeper separately learns which action to take in a given state to maximize the reward it receives (Taylor et al., 2006).

Regular NEAT (Stanley and Miikkulainen, 2002) evolves ANNs to maximize a fitness function. The ANN receives the 13 state inputs (like Sarsa) to define the state of the system and produce three outputs to select an action. The fitness in RoboCup Keepaway is the average length of time that keepers can hold the ball over a number of trials (Taylor et al., 2006). EANT (Metzen et al., 2007) is an additional neuroevolution algorithm based on NEAT that learned Keepaway. Though similar to NEAT, it distinguishes itself by more explicitly controlling the ratio of exploration to exploitation

during the evolutionary process. These methods were chosen for comparison because they have been tested in the same Keepaway configuration.

As described in Section 3, the HyperNEAT BEV transforms the traditional state representation to explicitly capture the geometry. The standard substrate is a two-dimensional 20×20 input layer connected to a 20×20 output layer. Thus both the state and action spaces have 400 dimensions each ($p_1 \ldots p_{400}$ and $a_1 \ldots a_{400}$). As with Sarsa in Stone and Sutton (2001), this policy representation does not include a hidden layer. However, the CPPN that encodes its weights *does* evolve internal nodes. Each node in a substrate layer represents a 1m^2 discrete chunk of Keepaway field. Each keeper's position is marked on the input layer with a positive value of 1.0 in its containing node and takers are similarly denoted by -1.0. Paths are literally drawn from the keeper with the ball to the other players (as in Figure 8).

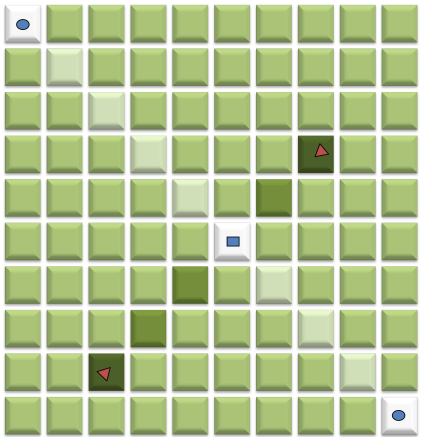

Figure 8: Visualizing the BEV Input Layer in 3 vs. 2 Keepaway. The input layer of the BEV is marked with the positions of keepers, takers and paths. The keeper with the ball is the small square, other keepers are circles, and the takers are triangles. Positive input values are denoted by lighter shades (for keepers and paths to keepers) and negative input values are denoted by darker shades (for takers and paths to takers). The middle shade represents an input of 0.0, the lightest shade is $+1.0$, and the darkest shade is -1.0. The BEV represents the distances and angles to other players in a geometric configuration, allowing geometric relationships to be exploited by HyperNEAT. Paths implicitly represent which keeper possesses the ball by converging on that keeper. (Note that the actual standard input layer in the experiments is 20×20.)

Positive values of 0.3 depict paths to other keepers and values of -0.3 depict paths to takers. These input values for agents and paths are experimentally determined and robust to minor variation. Actions are selected from among the output nodes (top layer of Figure 5) that correspond to where the keepers are located: If the highest output is the node where the keeper with the ball is located, it holds the ball. Otherwise, it passes to the teammate with the highest output at its node. This method of action selection thus corresponds exactly to the three actions available to Sarsa, NEAT, and EANT. A key property of this representation is that it is independent of the number of players on either side, unlike the representation in the traditional approaches.

The population size in HyperNEAT is 100. Available CPPN activation functions are absolute value, bipolar sigmoid, Gaussian, linear, sine, and step. Activation is signed, resulting in a node out-

put range of $[-1,1]$. By convention, a connection is not expressed if the magnitude the corresponding CPPN output is below a minimal threshold of 0.2 (Gauci and Stanley, 2007). The probability of adding a node to the CPPN is 0.05 and the probability of adding a connection is 0.18. The disjoint and excess node coefficients were both 1.0 and the weight difference coefficient was 1.0. The initial compatibility threshold was 20.0. These parameters were found to be robust to moderate variation in preliminary experimentation.

HyperNEAT evolves the CPPN that encodes the connectivity between the ANN layers in the substrate (up to 160,000 connections with a 20×20 resolution). Fitness is assigned according to the generated network's ball possession time averaged over at least 30 trials, with additional trials up to 100 assigned to those above the mean, following Taylor et al. (2006). Additionally, the CPPNs in the initial population are given the geometric concept of locality (Section 2.4).

4.3 Keepaway Transfer

Task transfer, the focus of this work, is first evaluated by training a HyperNEAT BEV on the 3 vs. 2 task on a 25m×25m field (instead of the standard 20m×20m) and then testing the trained BEVs on the 4 vs. 3 version of the task on the same field *without any further training*. The larger field is needed to accommodate the larger version of the task (Taylor et al., 2007b). To switch from 3 vs. 2 to 4 vs. 3, the additional players and paths are simply drawn on the input layer as usual, with no transformation of the representation or further training. The resulting performance on 4 vs. 3 is compared to TVITM-PS (Taylor et al. 2007b; described in Section 2.2), which is the leading transfer method for this task. TVITM-PS results are from policies represented by an ANN trained by NEAT (Taylor et al., 2007b). Unlike the HyperNEAT BEV, TVITM-PS requires further training after transfer because ρ expands the ANN by adding new state variables.

Additionally, two alternative forms of transfer are evaluated in Keepaway. The first is transfer to increasing field sizes, which is evaluated by first training individuals on a small (15m×15m) field size and then testing trained individuals on the trained and larger field sizes (each of 15m×15m, 20m×20m, and 25m×25m). To adjust for field size changes, the size of the HyperNEAT BEV substrate is changed to match the different field sizes (i.e., if the field size is 15m×15m, the substrate is 15×15; if it is 25m×25m, the substrate is 25×25). In this way, the relative meaning of each discrete input unit is held constant (e.g., $\frac{15\text{m}\times 15\text{m}}{15\times 15} = 1\text{m}^2$ per input and $\frac{25\text{m}\times 25\text{m}}{25\times 25} = 1\text{m}^2$ per input). The indirect encoding of the BEV extrapolates the trained knowledge from one field size to the other field sizes.

Second, transfer to substrates of different resolutions is evaluated by training individuals on a single field size, then doubling the resolution in each dimension of the substrate (i.e., an individual trained on a 20m×20m field with a 20×20 substrate is reevaluated on a substrate changed to 40×40). This increase in resolution results in a smaller section of the field being represented by each input (e.g., $\frac{20\text{m}\times 20\text{m}}{20\times 20} = 1\text{m}^2$ per input and $\frac{20\text{m}\times 20m}{40\times 40} = \frac{1}{4}\text{m}^2$ per input). The higher resolution BEV is then tested on the same field size to evaluate the ability to transfer knowledge between substrate resolutions. The new connections in the BEV are interpolated by the indirect encoding. In principle, this ability to raise resolution could allow computational cost to be reduced by training on a lower resolution and later raising resolution to increase the precision of the BEV.

4.4 Knight Joust

Knight Joust is a predator-prey variant domain wherein the player (prey) starts on one side of the field and the opponent (predator) starts on the opposite side (Taylor et al., 2007b). The player must then travel to the opposite side of the field while evading the opponent. The name *Knight Joust* reflects that the player is allowed three potential moves: move forward, knight jump left, and knight jump right, where a *knight jump* is two steps in the direction left or right and then forward (as in chess). The opponent follows a stochastic policy that attempts to intercept the player. The traditional state representation consists of the distance to the opponent, the angle between the opponent and the left side, and the angle between the opponent and the right side (Figure 9).

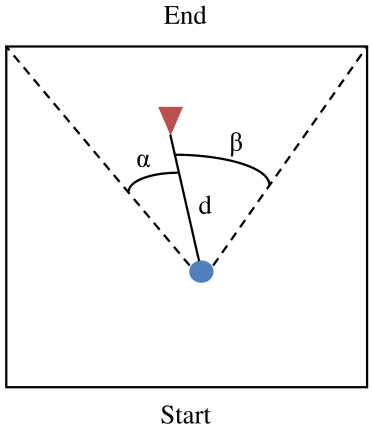

Figure 9: Knight Joust World. In Knight Joust, the player (circle) begins on the side marked *Start* and must reach the side marked *End*, while evading the opponent (triangle). The player is given the state information of the distance to the opponent, d, the angle between the opponent and the left side, α, and the angle between the opponent and the right side, β. This state information can similarly be drawn on the substrate of the BEV by marking the position of the player, opponent, the path between them, and the paths to the corners.

While Knight Joust is significantly different from Keepaway, a feature of both is that at each step the agent must make the decision that best avoids the opponent. However, Knight Joust is simpler, eliminating such complexity as multiple agents, noise, and kicking a ball, making it more tractable. The simplification makes it ideal for cross-domain transfer; because training is quicker and easier than in Keepaway, knowledge is more quickly bootstrapped. In Taylor et al. (2007a), cross-domain transfer from Knight Joust to Keepaway was shown to enhance learning. Additionally, the HyperNEAT BEV can represent the state information in Figure 9 by drawing the state information onto the inputs.

In particular, the player and opponent are indicated by $+1.0$ and -1.0 respectively. The path to the opponent is shown by values of -0.3 and the paths to the goal-side corners are marked with $+0.3$. Actions are selected from among the output nodes representing the position in front of the player (move forward), the left corner (knight jump left), and the right corner (knight jump right). This representation of state is similar to Keepaway, but the semantics are different: The player in Knight Joust is selecting a direction of movement instead of a passing position and the paths to the corners indicate the direction of the goal rather than teammate positions.

The evaluation of cross-domain transfer is completed by first training for 20 generations in the Knight Joust domain. Fitness is assigned to the individuals in Knight Joust by awarding 1 point for only moving forward and a bonus of 20 points for reaching the end. Next, the champions of these runs seed the runs for 3 vs. 2 Keepaway. Finally, Keepaway training is run for ten generations. The runs seeded with individuals trained in Knight Joust can then be compared to Keepaway runs without such transfer. This experiment is interesting because it can help to show that static transfer is beneficial with the BEV even in cases where the input semantics of the two tasks have slightly different meaning.

5. Results

This section describes the results of training the BEV on the Keepaway benchmark, the transfer performance among variations of the Keepaway task, and finally the performance of the BEV in cross-domain transfer from Knight Joust to Keepaway. Videos of evolved Keepaway behaviors are available at http://eplex.cs.ucf.edu/hyperneat-keepaway.html.

5.1 RoboCup Keepaway Performance Evaluation

In the RoboCup Keepaway benchmark, performance is measured by the number of seconds that the keepers maintain possession (Stone and Sutton, 2001; Stone et al., 2006; Taylor et al., 2007b). After training, the champion of each epoch is tested over 1,000 trials. Performance results are averaged over five runs with each consisting of 50 generations of evolution. This number of generations was selected because the corresponding *simulated* time spent in RoboCup during training equals simulated time (800-1,000 hours) for previous approaches (Taylor et al., 2006; Metzen et al., 2007). The test on the 3 vs. 2 benchmark is intended to validate that the BEV learns competitively with other leading methods.

In 3 vs. 2 Keepaway on the 20m$\times$20m field, the best keepers from each of the five runs controlled by a BEV substrate trained by HyperNEAT maintain possession of the ball on average for 15.4 seconds ($sd = 1.31$), which significantly outperforms ($p < 0.05$) all static benchmarks (Table 1). Furthermore, assuming similar variance, this performance significantly exceeds ($p < 0.05$) the current best reported average results (Stone et al., 2001, 2005; Taylor et al., 2006) on this task for both temporal difference learning (12.5 seconds) and NEAT (14.0 seconds), and matches EANT (14.9 seconds; Table 1). The important implication of this result is that the HyperNEAT BEV is at least competitive with the top learning algorithms on this task.

5.2 Keepaway Transfer Results

In transfer learning, the main focus of this work, the BEV is evaluated by testing individuals trained for 20 generations *only* on the 3 vs. 2 task on a 25m$\times$25m field. Learned policies are then tested on *both* the 3 vs. 2 and 4 vs. 3 tasks for 1,000 trials each without any further training. Note that this evaluation of transfer differs from Taylor et al. (2007b), in which teams trained on the smaller task are *further trained* on the larger task after the transfer because new parameters are added. In contrast, transfer within the BEV requires no changes or transformations. Performance is averaged over five runs, following Taylor et al. (2006). Figure 10 shows the average test performance on *both* 3 vs. 2 (trained) and 4 vs. 3 (untrained; immediately after transfer) of each generation champion.

METHOD	AVERAGE HOLD TIME
HYPERNEAT BEV	15.4S
EANT	14.9S
NEAT	14.0S
SARSA	12.5S
HAND-TUNED BENCHMARK	8.3S
ALWAYS HOLD BENCHMARK	7.5S
RANDOM BENCHMARK	3.4S

Table 1: Average Best Performance by Method. The HyperNEAT BEV holds the ball longer than previously reported best results for neuroevolution and temporal difference learning methods. Results are shown for Evolutionary Acquisition of Neural Topologies (EANT) from Metzen et al. (2007), NeuroEvolution of Augmenting Topologies (NEAT) from Taylor et al. (2006), and State action reward state action (Sarsa) from Stone and Sutton (2001).

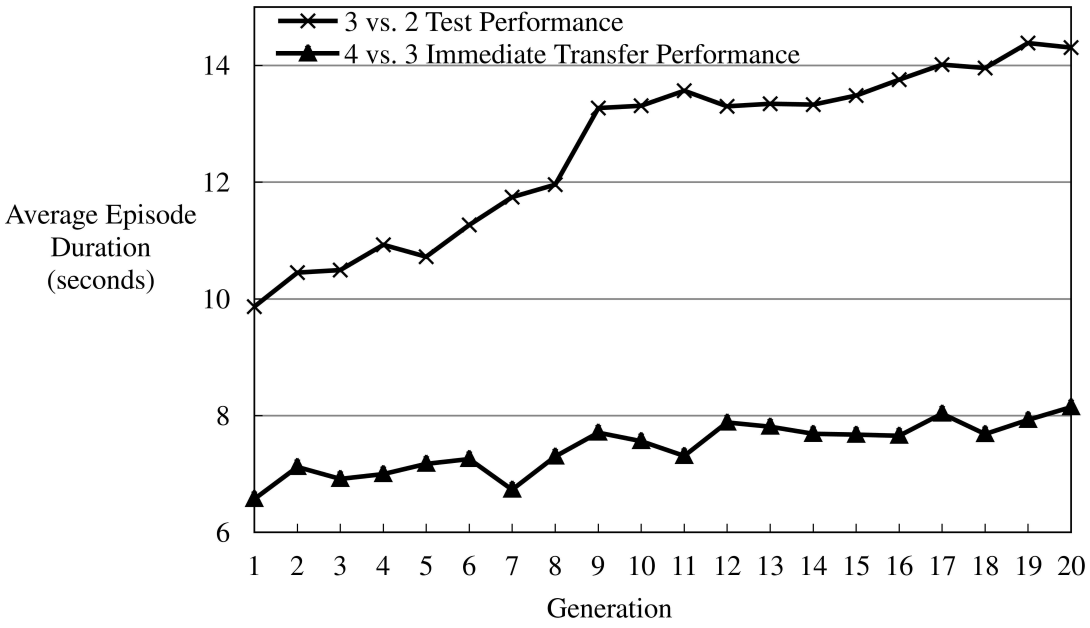

Figure 10: Transfer Learning From 3 vs. 2 to 4 vs. 3 Keepaway on a 25m×25m Field. As the performance (averaged over five runs) of the champion on the 3 vs. 2 task improves, the transfer performance on the 4 vs. 3 task also consequently improves from 6.6 seconds to 8.1 seconds without *ever* training for it. The improvement is positively correlated ($r = 0.87$).

Testing performance on the 3 vs. 2 task improves to 14.3 seconds on average over each run. At the same time, the test performance of these same individuals on the 4 vs. 3 task, which was not trained, improves from 6.6 seconds to 8.1 seconds on average. In contrast, the previous best approach to transfer learning in this domain required executing a transfer function and additional

training for between 50 and 200 hours (depending on the chosen transfer function) *beyond* the initial bootstrap training in 3 vs. 2 to achieve a comparable 8.0 second episode duration (Taylor et al., 2007b). Thus, because the BEV is static, transfer is instantaneous and requires no special adjustments to the representation to achieve the same result as many hours of *further* training with the TVITM-PS transfer method.

Although the BEV improves in 4 vs. 3 Keepaway even when only trained in 3 vs. 2, it is still informative to investigate the effect of further training in the 4 vs. 3 task. For this purpose, individuals are trained on the 3 vs. 2 task for 20 generations and then further trained on the 4 vs. 3 task for 30 generations. The performance of these policies is contrasted with keepers trained on 4 vs. 3 from scratch for 50 generations. Performance is averaged over five runs and generation champions are evaluated over 1,000 episodes. Figure 11 shows the average test performance of the generation champions. The individuals trained solely on 4 vs. 3 improve from 6.2 seconds to 8.0 seconds. Interestingly, this performance is equivalent to policies trained only in the 3 vs. 2 task and transferred to 4 vs. 3. However, individuals trained on 3 vs. 2 for the first 20 generations increase their test performance on 4 vs. 3 to 9.1 seconds over the last 30 generations. The final difference between further training after transfer and training from scratch is significant ($p < 0.05$).

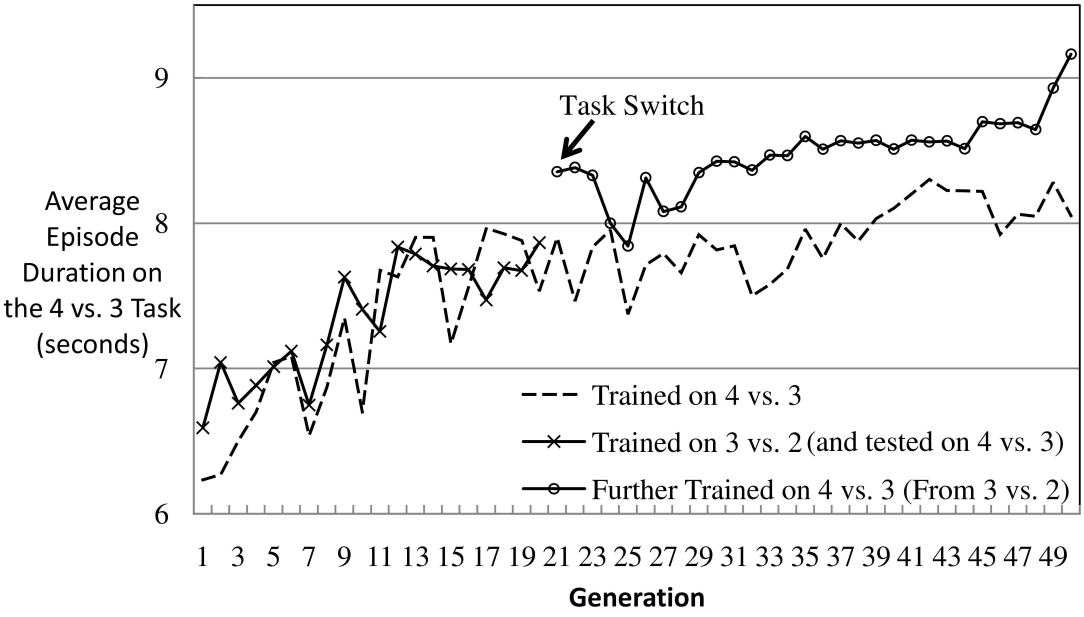

Figure 11: Further Training After Transfer From 3 vs. 2 to 4 vs. 3 Keepaway on a 25m×25m Field. Performance of individuals trained on 3 vs. 2 then transferred to 4 vs. 3 and further trained are contrasted with individuals solely trained on 4 vs. 3. All depicted results are performance on the 4 vs. 3 task. Prior training on 3 vs. 2 and transfer to the 4 vs. 3 enhances keeper performance by beginning in a more optimal area of the search space.

An important factor in the superior performance of the learner that was transferred is the behavior of the third taker in the 4 vs. 3 task, which seeks to block the most open player. This behavior differs from 3 vs. 2, in which the two takers attempt to take the ball only by always heading towards

it. When training on 4 vs. 3 without previously learning on 3 vs. 2, the third taker's behavior may inhibit performance by preventing important knowledge from being learned. For example, in 3 vs. 2 an important concept is to pass to the most open player. However, in 4 vs. 3 the most open player is *not* always the best choice because of the behavior of the third taker; therefore policies that learn the concept of passing to the most open player, which is still an important skill, are not discovered.

A thorough evaluation of transfer recognizes that there is more than one way to alter a task. Thus transfer learning is also evaluated by testing the best policy trained in 3 vs. 2 on varied field sizes. Stone et al. (2001) previously investigated this kind of transfer on their best Sarsa solution in an easier version of the Keepaway task that does not include noise by testing a single high-performing individual that was trained on a fixed field size (15m×15m) not only on the trained field size, but also on the other two field sizes. The best policy trained by the HyperNEAT BEV (which, unlike Sarsa, was subject to noise) on the 15m×15m field size was also tested in this way (Figure 12).

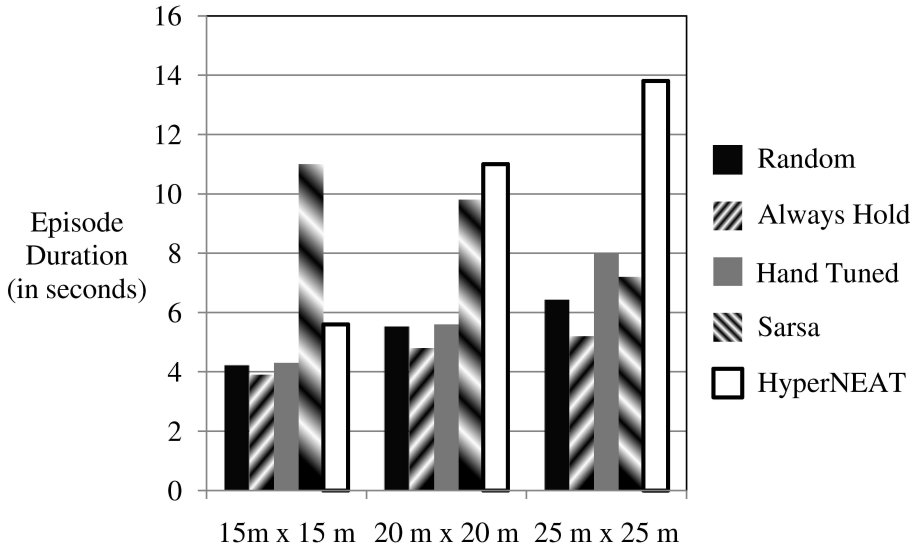

Figure 12: 3 vs. 2 Transfer Performance To Larger Field Sizes. Transfer to larger field sizes is evaluated by testing an individual trained on a single field size (15m×15m) on two larger field sizes (20m×20m and 25m×25m) as well. The BEV is scaled by matching the substrate size to the field size, thus maintaining the same field area represented by each discrete unit on the substrate. Depicted results from Stone and Sutton (2001) show that as a policy trained by Sarsa is transferred to larger field sizes, it *decreases* in performance. However, the task is *easier* as field size increases, as shown by the performance of hand-designed policies (Random, Always Hold, and Hand-Tuned) that *increase* in performance as field size increases. In contrast, the BEV learns a policy that outperforms the hand-designed policies and transfers to the larger field sizes, *significantly improving* performance.

The results are interesting because they show that the representation can cause performance to vary in unexpected ways. For example, even though larger field sizes are easier, Stone and Sutton (2001) report that the performance of the best keepers trained by Sarsa *declines* when they are

transferred to larger fields. However, even hard-coded policies, such as Random, Always Hold, or Hand Tuned, increase in performance as field size increases, demonstrating the decreased difficulty of the task. Also, in contrast to Sarsa, when transferred to larger fields, the keepers trained with the HyperNEAT BEV improve performance (as would be expected) from 5.6 seconds to 11.0 seconds and 13.8 seconds, respectively, and outperform the hand-designed policies (Figure 12). These improvements make sense because the task should become easier when there is more room on the field.

The BEV's advantage is that the geometric relationships encoded in the CPPN can be extrapolated as the field size increases, thereby extending the knowledge from the smaller field size to the newer areas of the larger field. For Sarsa, such extrapolation is not possible because as field size increases, the new areas represent previously unseen distances for which Sarsa was not trained. Sarsa has no means to extrapolate geometric knowledge from the distances it has seen because, unlike the CPPN, the knowledge learned is not a *function* of the domain geometry (i.e., the geometric relationships on a two-dimensional soccer field). Instead, Sarsa learns a function of the examples presented, which do not explicitly describe the geometry of the domain.

Another important lesson from changing the field size is that BEV performance requires a minimal resolution. When the field size is 15m×15m, the BEV performance appears to underperform compared to Sarsa. In part, this difference is because Sarsa was tested originally without noise (Stone et al., 2001). A later experiment with Sarsa trained on the 15m×15m with noise (Stone et al., 2005) shows that its performance is similar to the BEV. However, another factor is simply that when the field size is 15m×15m, the BEV resolution is *also* at 15×15, which may be too low to capture the detail necessary to succeed in the task. Confirming this hypothesis, if the BEV is trained at 30×30 resolution on a 15m×15m field, its performance rises significantly, to 7.1 seconds compared to 7.4s for Sarsa when it *is* trained with noise on 15m×15m (Stone et al., 2005). This result raises the interesting question of whether resolution can be *raised* above the training resolution without negative impact, as the next experiment addresses.

The final result in Keepaway is that the knowledge learned through the indirect encoding, that is, the CPPN, is not negatively impacted by later increasing resolution from that at which the BEV was trained. The substrate resolution of the champion individuals from five runs from training on three field sizes (15m×15m, 20m×20m, and 25m×25m) are doubled in each dimension and then tested again on the same field size. For example, a 20×20 BEV becomes 40×40, which means that each input represents one quarter as much of the space as before. This BEV quadruples the number of inputs and outputs while increasing the number of connections by a factor of 16 (from 160,000 to 2,560,000 connections). Table 2 shows that no matter the field size, even massively increasing the resolution does not degrade performance and can even lead to a *free* performance increase.

For the 15m×15m, 20m×20m, and 25m×25m field sizes, doubling the size of each dimension on average changes performance from 4.6 seconds to 5.3 seconds, 15.4 seconds to 15.9 seconds, and 16.8 seconds to 16.9 seconds respectively. In one instance, on the 20m×20m field, performance improved instantly from 16.6 seconds to 18.9 seconds. The advantage of this capability is that the BEV resolution can be selectively increased while maintaining the same performance, which makes possible further training with a higher resolution BEV.

	PERFORMANCE	
TRAINING FIELD SIZE	TRAINED RESOLUTION	INCREASED RESOLUTION
15M×15M	4.6S	5.3S
20M×20M	15.4S	15.9S
25M×25M	16.8S	16.9S

Table 2: Average Performance of the Best Individuals at Different Resolutions. The regularities learned by the indirect encoding are not dependent on the particular substrate resolution and may be extrapolated to higher resolutions. Increasing the number of connections in the substrate by a factor of 16 (by doubling the size of each dimension) does not degrade performance; in fact, it even improves it significantly in some cases.

5.3 Knight Joust Transfer Results

Cross-domain transfer is evaluated from the non-Keepaway task of Knight Joust on a 20×20 grid to 3 vs. 2 Keepaway on a 20m×20m field. Evolution is run for 20 generations on the Knight Joust task and then the champions seed the beginning generations of 3 vs. 2 Keepaway. Further training is then performed over ten additional generations of evolution. Performance in Keepaway of the champion players from Knight Joust is on average 0.3 seconds above the performance of initial random individuals. After one generation of evolution, the best individuals from transfer exceed the raw performance by 0.6 seconds. Finally, after ten further generations, the best individuals with transfer hold the ball for 1.1 seconds longer than without transfer (Figure 13).

The differences are significant ($p < 0.05$). Thus even preliminary learning in a significantly different domain proved beneficial to the BEV. In contrast, previous transfer results from Knight Joust to Keepaway from Taylor and Stone (2007) demonstrated an initial performance advantage, but after training for five simulator hours (which is less than the duration of ten generations) there was no performance difference between learning with transfer and without it.

Overall, the results establish that the BEV is highly effective in transfer in Keepaway. The next section discusses the deeper implications of these results.

6. Discussion and Future Work

Methods that alter representation remain important tools in task transfer for domains in which the representation must change with the task. However, the BEV shows that a carefully chosen representation with the right encoding can sometimes eliminate the need to change the representation, even across different domains.

The deeper lesson is the critical role of representation in transfer and the consequent need for algorithms that can learn from relatively high-dimensional static representations of task geometry. Indeed, the human eye contains *millions* of photoreceptors, which provide the same set of inputs to every visual task tackled by humans. No new photoreceptor is added for a new task. In effect, visual input to the human eye is a static representation (i.e., it does not alter when changing tasks) of state to the human brain. While it is true that the information from the eye is interpreted by the visual cortex, the set of inputs to the cortex, which are the photoreceptors of the eye, remains the same. In this paper, the BEV contains no hidden layers. However, by adding hidden layers it is possible to

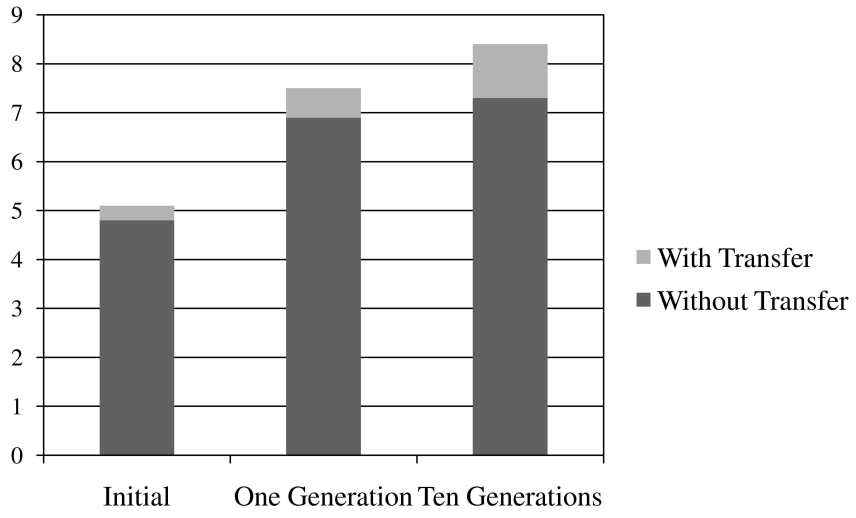

Figure 13: Transfer Results from Knight Joust to Keepaway. Direct transfer and further training performance averaged over 30 runs is shown. The performance of raw champions from Knight Joust on Keepaway outperforms initial random individual by 0.3 seconds. After one generation, this advantage from transfer increases to 0.6 seconds and at 10 generations the advantage is 1.1 seconds. Thus performance on Keepaway, both instantaneous and with further training, benefits from transfer from the Knight Joust domain with significance $p < 0.05$.

add the intervening interpretation of the input state analogously to how the visual cortex interprets data from the eye. HyperNEAT substrates with hidden layers have been shown to work in the past in domains without transfer (D'Ambrosio and Stanley, 2008; Clune et al., 2009; Gauci and Stanley, 2010). Thus the prospects are good for expanding the scope of static transfer. Nevertheless, of course the human eye represents an ideal, and not all possible domains are amenable to keeping the representation static. Yet for those that are, the investigation in this paper shows that it can provide an advantage.

The ability of a representation to remain static is dependent upon the particular differences between the tasks. Tasks that are semantically similar should be able to represent state information similarly in the BEV, requiring no changes to the representation. Tasks that are significantly different, either through state information or actions, may not allow the representation to remain the same. However, even then there are potential ways to allow the BEV to retain what was learned in the previous task and build upon it while being altered. For example, one option is to add new input layers or output layers. These new layers can denote new information or actions associated with new objects in the environment while the previously-trained input and output layers retain the prior knowledge. Geometry thus remains an advantage because state information that is connected with the same location (e.g., all the state data for a single agent) would be located at the same coordinate on separate layers. In contrast, an ANN without geometry would have no means to discern which original inputs are associated with which new inputs and would thus instead have to learn such relationships.

The role of representation in transfer is relevant to all approaches to learning because transfer is always an option for extending the scope of learning. Thus encoding research, such as in generative and developmental systems (Bentley and Kumar, 1999; Hornby and Pollack, 2002; Lindenmayer, 1968; Stanley, 2007; Bentley and Kumar, 1999; Turing, 1952), and representation research, such as in relational reinforcement learning (Deroski et al., 2001; Morales, 2003; Tadepalli et al., 2004), is important to machine learning in general. Static representations mean that instead of training a new policy, or retraining a previous one, the same policy can be transferred without change. Additionally, the static nature of the representation allows the same policy to train on multiple tasks simultaneously. For example, a soccer player does not practice by playing *only* soccer games. Players improve through multiple drills and continually practice in-between games to refine skills.

The encoding of the solution also impacts the kinds of policies that are found. For example, in this paper the policy is encoded by a CPPN that is expressed as a function of the task geometry, which enables the solution to exploit regularities in the geometry and extrapolate to previously unseen areas of the geometry. It should also be possible to simplify the search for a policy that is a function of the geometry in other learning approaches as well. The challenge is that gradient information (i.e., error) cannot directly pass through the indirection between the ANN and its generating CPPN. A method that solves this problem would open up the power of indirect encoding to all of RL.

6.1 Prospects for Full RoboCup Soccer

An exciting implication of this work is that the power of static transfer and indirect encoding can potentially bootstrap learning the complete game of soccer. After all, the key elements of soccer are present in Keepaway as well. In fact, the results in this paper demonstrate that a static representation can competitively learn to hold the ball in Keepaway and that this skill transfers immediately through the BEV to variations of that task. The static BEV state representation enables the learned policy to transfer to variations of the task in which the number of players is changed (e.g., 3 vs. 2 to 4 vs. 3). Furthermore, indirectly encoding the policy enables the same policy to be applied to variations of the task in which the geometry has been changed (e.g., moving from 20m$\times$20m to 25m$\times$25m field size) HyperNEAT has also been proven effective in a wide variety of tasks (D'Ambrosio and Stanley, 2008; Clune et al., 2009; Stanley et al., 2009; Gauci and Stanley, 2010).

Interestingly, the Keepaway domain was designed as a stepping stone to scaling machine learning methods to the full RoboCup soccer domain (Stone and Sutton, 2001). The same principles that enable the BEV to transfer among variations of the Keepaway domain *also* can potentially enable the BEV to scale to full Keepaway soccer. For example, because the representation remains static no matter how many players are on the field, training can begin with a small number of players, such as 3 vs. 3 soccer, and iteratively add more players, eventually scaling up to the full 11 vs. 11 soccer game. Furthermore, varying the substrate configuration while the solution encoding remains static makes it possible to train skills relevant to RoboCup on subsets of the full field, for example, half-field offense/defense. In this way, varying the number of players and varying the field size are *both* required to transfer from the RoboCup Keepaway domain to full RoboCup soccer. Thus this study suggests a novel path to learning full-fledged soccer.

A distinctive feature of the BEV representation is that actions are *also* selected in the BEV, that is, the outputs are in the same geometry as the field. In the RoboCup Keepaway domain, actions are constrained to holding the ball and directly passing to a teammate. However, there are many

other actions that are possible, such as clearing the ball, kicking the ball out of bounds, dribbling, and passing to a location close to a teammate. Furthermore, the BEV can potentially control players without the ball. By requesting actions in the BEV geometry, actions can be selected based on positions instead of objects.

For example, the keeper with the ball can potentially select *any* position on the BEV to which to kick the ball. That way, the BEV is not constrained in its actions. The player with the ball can then choose from passes to teammates, passes to positions near teammates, or dribble by kicking the ball to a nearby position and then pursuing the ball. Players without the ball can be controlled by interpreting the outputs of the BEV as the desired location towards which that player should move. Thus an interesting property of the BEV is that the state space can transfer, by accommodating new players or field sizes, and the action space can *also* transfer in the same way. Ultimately, the promise of such transfer is tied to the idea of static representation, whose potential was highlighted in this paper.

7. Conclusion

This paper introduced the BEV representation, which simplifies task transfer by making the state representation static. That way, no matter how many objects are in the domain, the size of the state representation remains the same. In contrast, in traditional representations, changing the number of players (e.g., in the RoboCup Keepaway task) forces changes in the representation by adding dimensions to the state space. In addition to results competitive with leading methods on the Keepaway benchmark, the BEV, which is enabled by an indirect encoding, achieved transfer learning from 3 vs. 2 to 4 vs. 3 Keepaway *without* further training. Improvement after further training then demonstrated that the knowledge gained from the transfer does indeed facilitate further learning the more difficult task. Transfer also proved successful not only among variations on the number of players, but also among different field sizes and substrate resolutions. Finally, cross-domain transfer was demonstrated, from Knight Joust to Keepaway. The cross-domain transfer improved not only immediate performance, but also enhanced further learning. All these results highlight the critical role that representation plays in learning and transfer. By altering the representation, transfer learning is simplified. Yet high-dimensional static representations require indirect encodings that take advantage of their expressive power, such as in HyperNEAT. The hope is that advanced representations in conjunction with indirect encoding can later contribute to scaling learning techniques to more challenging tasks, such as the complete RoboCup soccer domain.

Abstract

We describe a class of sparse latent factor models, called graphical factor models (GFMs), and relevant sparse learning algorithms for posterior mode estimation. Linear, Gaussian GFMs have *sparse, orthogonal* factor loadings matrices, that, in addition to sparsity of the implied covariance matrices, also induce conditional independence structures via zeros in the implied precision matrices. We describe the models and their use for robust estimation of sparse latent factor structure and data/signal reconstruction. We develop computational algorithms for model exploration and posterior mode search, addressing the hard combinatorial optimization involved in the search over a huge space of potential sparse configurations. A mean-field variational technique coupled with annealing is developed to successively generate "artificial" posterior distributions that, at the limiting temperature in the annealing schedule, define required posterior modes in the GFM parameter space. Several detailed empirical studies and comparisons to related approaches are discussed, including analyses of handwritten digit image and cancer gene expression data.

Keywords: annealing, graphical factor models, variational mean-field method, MAP estimation, sparse factor analysis, gene expression profiling

1. Introduction

Bayesian sparse modelling in multivariate analysis is of increasing interest in applications as diverse as life science, economics and information science, and is driving a need for effective computational methods for learning model structure, that is, sparse configurations. Parallel developments of sparse latent factor models (e.g., West, 2003; Griffiths and Ghahramani, 2006; Lucas et al., 2006; Wang et al., 2007; Archambeau and Bach, 2009; Carvalho et al., 2008; Guan and Dy, 2009; Rai and Daumé, 2009) and inherently sparsely structured graphical models (e.g., Jordan, 1999, 2004; Dobra et al., 2004; Jones et al., 2005; Carvalho and West, 2007) have explored Bayesian computations using a range of stochastic and deterministic search methods. With a view to scaling to higher dimensions and identification of regions of interest in model structure space, efficient and effective computation remains a challenge. We describe a previously undeveloped class of sparse graphical factor models (GFMs)—a subclass of linear, Gaussian latent factor models with sparse factor loadings that also induce sparse conditional independencies. In this context, we develop a compu-

tational technique for posterior mode evaluation using a hybrid of variational mean-field method (Attias, 1999; Wainwright and Jordan, 2008) and annealing-based optimization.

As a previously unexplored class of sparse (linear, Gaussian) factor models, the intrinsic graphical structure of the GFM arises from use of an orthogonal factor loadings matrix and appropriate scaling of its columns, together with the usual diagonal covariance matrix for latent factors (with no loss of generality). We show that this generally induces zero elements in the precision matrix of the GFM, as well as the covariance matrix. Particularly, the zero entries in the covariance matrix have corresponding zeros in the precision matrix. We also show that covariance matrices of fitted values (i.e., "data reconstructions") from such a model have the same sparse structure, and demonstrate aspects of robustness of the model in inferring variable-latent factor relationships in the presence of outliers. These properties are not shared in general by sparse factor models that lack the graphical structure on variables, nor of course by non-sparse approaches. These intrinsic properties of the GFM, along with relationships with earlier studies on sparse factor analyses, are discussed in Section 2.

Our *variational mean-field annealing algorithm (VMA2)* addresses the combinatorial optimization involved in aiming to compute approximate posterior modes for GFM parameters in the context of the huge space of zero/non-zero potential patterns in factor loadings. Using a prescribed schedule of decreasing temperatures, VMA2 successively generates tempered "artificial" posteriors that, at the limiting zero temperature, yield posterior modes for both GFM parameters and the 0/1 loadings indicators. Defined via an artificial, dynamic regularization on the posterior entropy of configured sparse structures, VMA2 is developed in Section 3.

Section 4 provides additional algorithmic details, including prior modelling for evaluating degree of sparseness, and a stochastic variant of VMA2 for higher-dimensional problems is described in Section 5. Performance and comparisons on artificial data appear in Section 6. Section 7 summarizes extensive, detailed empirical comparisons with related approaches in analyses of hand-written digit images and cancer gene expression data. Section 8 concludes with brief additional comments. A range of detailed supplementary materials, extended discussion on the gene expression studies and `R` code, is accessible from `http://daweb.ism.ac.jp/~yoshidar/anneals/`.

2. Sparse Graphical Factor Models

We describe the GFM with some intrinsic graphical properties, followed by connections to previously developed classes of sparse latent factor analyses.

2.1 GFM Form

Observed sample vectors $x_i \in \mathbb{R}^p$ in p dimensional feature space are each linearly related to independent, unobserved Gaussian latent factor vectors $\lambda_i \in \mathbb{R}^k$ with additional Gaussian noise. We are interested in sparse variable-factor relationships so that the bipartite mapping $\lambda \to x$ is sparse, with the underlying $p \times k$ matrix of coefficients—the *factor loadings matrix*—having a number of zero elements; the $p \times k$ binary matrix Z defines this *configured sparsity pattern*. We use a sparse, orthogonal loading matrix and diagonal covariance matrices for both latent factors and residuals; the model is mathematically identified in the usual sense in factor analysis (Anderson, 2003).

With Z as the $p \times k$ binary matrix with elements z_{gj} such that variable g is related to factor j if and only if $z_{gj} = 1$, the GFM is

$$x_i = \Psi^{1/2}\Phi_Z\lambda_i + \nu_i \quad \text{with } \lambda_i \sim \mathcal{N}(\lambda_i|0,\Delta) \text{ and } \nu_i \sim \mathcal{N}(\nu_i|0,\Psi)$$

where: *(a)* the factor loading matrix $\Psi^{1/2}\Phi_Z$ has $\Phi_Z \equiv \Phi \circ Z$ with $\circ$ representing element-wise product; *(b)* Φ_Z is orthogonal, that is, $\Phi_Z'\Phi_Z = I_k$; *(c)* the factors have diagonal covariance matrix $\Delta = \text{diag}(\delta_1,\ldots,\delta_k)$; and *(d)* the idiosyncratic Gaussian noise (or residual) ν_i is independent of λ_i and has covariance matrix $\Psi = \text{diag}(\psi_1,\ldots,\psi_p)$. The implied covariance matrix of the sampling model, Σ, and the corresponding *precision matrix*, Σ^{-1}, are

$$\Sigma = \Psi^{1/2}\{I + \Phi_Z\Delta\Phi_Z'\}\Psi^{1/2} \quad \text{and} \quad \Sigma^{-1} = \Psi^{-1/2}\{I - \Phi_Z T\Phi_Z'\}\Psi^{-1/2} \tag{1}$$

where $T = \text{diag}(\tau_1,\ldots,\tau_k)$ with $\tau_j = \delta_j/(1+\delta_j)$ $(j = 1:k)$. In general, sparse loading matrices induce some zero elements in the covariance matrix whether or not they are orthogonal, but *not* in the implied precision matrix. In the GFM here, however, a sparse factor model also induces off-diagonal zeros in Σ^{-1}. Zeros in the precision matrix defines a conditional independence or graphical model, hence the GFM terminology. In (1), the pattern of sparsity (location of zero entries) in the covariance and precision matrices are the same. The set of variables associated with one specific factor forms a clique in the induced graphical model, with sets of variables that have non-zero loadings on any two factors lying in the separating subgraph between the corresponding cliques. Hence, we have a natural and appealing framework in which sparse factor models and graphical models are reconciled and consistent.

2.2 Some Model Attributes

In general, a non-orthogonal factor model with the sparse loading matrix W—a sparse extension of probabilistic PCA (Bishop, 1999, 2006)—has the form

$$x_i = W\lambda_i + \nu_i \text{ with } \lambda_i \sim N(0,I) \text{ and } \nu_i \sim N(0,\Psi).$$

The GFM arises when a singular value decomposition is applied to the scaled-factor loading matrix $\Psi^{-1/2}W = \Phi_Z\Delta^{1/2}R$ with a $k \times k$ orthogonal matrix R being removed. This non-orthogonal model defines a Bayes optimal reconstruction of the data via the fitted values (or extracted signal)

$$\hat{x}(x_i) := W\mathbb{E}[\lambda_i|x_i] = WW'(WW'+\Psi)^{-1}x_i.$$

Then, asymptotically,

$$\frac{1}{n}\sum_{i=1}^{n}\hat{x}(x_i)\hat{x}(x_i)' \xrightarrow{p} \mathbb{C}ov[\hat{x}(x_i)] = WW'(WW'+\Psi)^{-1}WW'$$

and this is generally a non-sparse matrix (no zero entries) even though W is sparse. This is an inconsistency in the sense that data reconstructions should be expected to share the dominant patterns of covariance sparsity evident in the original covariance matrix $\mathbb{C}ov[x_i] = WW'+\Psi$. In the GFM, however, $\mathbb{C}ov[\hat{x}(x_i)] = \Psi^{1/2}\Phi_Z G\Phi_Z'\Psi^{1/2}$ where G is diagonal with entries $\delta_j^2/(1+\delta_j)$. In such cases, $\mathbb{C}ov[\hat{x}(x_i)]$ is sparse and shares the same 0 elements as $\mathbb{C}ov[x_i]$.

Another feature of the GFM is related to a robust property acquired by the implied graphical structure. Consider an example of 4 variables $x_i' = (x_{i1},x_{i2},x_{i3},x_{i4})$ and 2 factors $\lambda_i' = (\lambda_{i1},\lambda_{i2})$

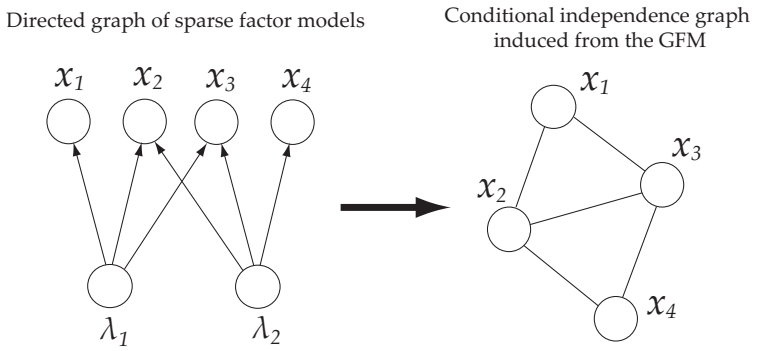

Figure 1: Graphical model structure of an example GFM.

with two cliques in the conditional independence graph; $\{x_{i1}, x_{i2}, x_{i3}\} \leftarrow \lambda_{i1}$ and $\{x_{i2}, x_{i3}, x_{i4}\} \leftarrow \lambda_{i2}$ (see Figure 1). The graph defines the decomposition of the joint density $p(x_{i1}, x_{i2}, x_{i3}, x_{i4}) = p(x_{i1}|x_{i2}, x_{i3})p(x_{i2}, x_{i3}|x_{i4})p(x_{i4})$ or $p(x_{i1}, x_{i2}, x_{i3}, x_{i4}) = p(x_{i4}|x_{i2}, x_{i3})p(x_{i2}, x_{i3}|x_{i1})p(x_{i1})$. This implies that presence of one or more outliers in the isolated feature variable, that is, x_{i1} or x_{i4}, associated with a single factor clique, has no effect on the variables, x_{i4} or x_{i1}, once the intermediate variables x_{i2} and x_{i3} are given. Then, the parameters involved in $p(x_{i1})$ or $p(x_{i4})$, for instance, the loading components and the noise variances corresponding to the isolated variable, can be estimated independently of the impact of outliers in x_{i4} or x_{i1}. The numerical experiment shown in Section 7.1 highlights this robustness property in terms of data compression/restoration tasks, with comparison to other sparse factor models.

2.3 Likelihood, Priors and Posterior

Denote by Θ the full set of parameters $\Theta = \{\Phi, \Delta, \Psi\}$. Our computations aim to explore model structures Z and corresponding posterior modes of parameters Θ under the posterior $p(Z, \Theta|X)$ using specified priors and based on the n observations forming the columns of the $p \times n$ data matrix X.

2.3.1 LIKELIHOOD FUNCTION

The likelihood function is

$$p(X|Z,\Theta) \propto |\Psi|^{-n/2}|I-T|^{n/2}\text{etr}(-S\Psi^{-1}/2 + \Psi^{-1/2}S\Psi^{-1/2}\Phi_Z T\Phi_Z'/2) \tag{2}$$

where $\text{etr}(A) = \exp(\text{trace}(A))$ for any square matrix A, and S is the sample sum-of-square matrix $S = XX'$ with elements s_{gh}. In (2), the factor loadings appear only in the last term and form the important statistic

$$\text{trace}(\Psi^{-1/2}S\Psi^{-1/2}\Phi_Z T\Phi_Z') = \sum_{j=1}^{k} \tau_j \phi_{z_j}' \Psi^{-1/2}S\Psi^{-1/2}\phi_{z_j}$$

where ϕ_{z_j} is column j of Φ_Z, or $\phi_{z_j} = \phi_j \circ z_j$ where ϕ_j is column j of Φ and z_j is column j of Z.

2.3.2 PRIORS ON Θ AND Z

Priors over non-zero factor loadings may reflect substantive *a priori* knowledge if available, and will then be inherently context specific. For examples here, however, we use uniform priors $p(\Theta|Z)$ for exposition. Note that, on the critical factor loadings elements Φ, this involves a uniform on the hypersphere defined by the orthogonality constraint that is then simply conditioned (by setting implied elements of Φ to zero) as we move across candidate models Z.

Concerning the sparse structure Z, we adopt independent priors on the binary variates z_{gj} with $\text{logit}(\Pr(z_{gj}=1|\zeta_{gj})) = -\zeta_{gj}/2$ where $\text{logit}(p) = \log(p/(1-p))$ and the parameters ζ_{gj} are assigned hyperpriors and included in the overall parameter set in later. Beta priors are obvious alternatives to this; the logit leads to a minor algorithmic simplification, but otherwise the choice is arbitrary. Using beta priors can be expected to lead to modest differences, if any of practical relevance, in many cases, and users are free to explore variants. The critical point is that including Bayesian inference on these $p \times k$ sparsity-determining quantities leads to "self-organization" as their posterior distributions concentrate on larger or smaller values. Examples in Section 6 highlight this.

2.4 MAP Estimation for (Θ, Z) in GFMs

Conditional on the $p \times k$ matrix of sparsity control hyperparameters ζ whose elements are the ζ_{gj}, it follows that posterior modes (Z, Θ) maximize

$$\begin{aligned} 2\log p(Z,\Theta|X,\zeta) &= 2\log p(\Theta|Z) - \sum_{g=1}^{p}\sum_{j=1}^{k} z_{gj}\zeta_{gj} - \sum_{g=1}^{p}(n\log\psi_g + s_{gg}\psi_g^{-1}) \\ &\quad + \sum_{j=1}^{k}(n\log(1-\tau_j) + \tau_j \phi_{zj}'\Psi^{-1/2}S\Psi^{-1/2}\phi_{zj}). \end{aligned} \tag{3}$$

The first two terms in (3) arise from the specified priors for Θ and Z, respectively. The quadratic form in the last term is $\phi_{zj}'\Psi^{-1/2}S\Psi^{-1/2}\phi_{zj} = \phi_j' S(z_j,\Psi)\phi_j$ for each j, where the key $p \times p$ matrices $S(z_j,\Psi)$ have elements $(S(z_j,\Psi))_{gh}$ given by

$$(S(z_j,\Psi))_{gh} = z_{gj}z_{hj}s_{gh}(\psi_g\psi_h)^{-1/2}, \qquad \text{for } g,h = 1:p. \tag{4}$$

The (relative) signal-to-noise ratios $\tau_j = \delta_j/(1+\delta_j)$ control the roles played by the last term in (3).

Optimizing (3) over Θ and Z involves many discrete variables and the consequent combinatorial computational challenge. Greedy hill-climbing approaches will get stuck at improper local solutions, often and quickly. The VMA2 method in Section 3 addresses this.

2.5 Links to Previous Sparse Factor Modelling and Learning

In the MAP estimation defined by (3), there are evident connections with traditional sparse principal component analyses (sparse PCA; Jolliffe et al., 2003, Zou et al., 2006 and d'Aspremont et al., 2007). If $\Psi = I$ and $\Delta = I$, the latter likelihood component in (3) is the pooled-variance of projections, that is, $\sum_{j=1}^{k}\phi_j' S(z_j,I)\phi_j$, constructed by the k sparse loading vectors. This is the central statistic optimized in many sparse PCAs. Differences among existing sparse PCAs arise in the way they regulate degrees of sparseness and whether or not orthogonality is imposed on the loading vectors.

The direct sparse PCA of d'Aspremont et al. (2007) imposes an upper-bound $d > 0$ on the cardinality of z_j (the number of non-zero elements), with a resulting semidefinite programming of computational complexity $O(p^4\sqrt{log(p)})$. The applicability of that approach is therefore limited to problems with p rather small. Such cardinality constraints can be regarded as suggestive of structure for the prior distribution on ζ in our model.

The SCoTLASS algorithm of Jolliffe et al. (2003) uses ℓ_1-regularization on loading vectors, later extended to SPCA using elastic nets by Zou et al. (2006). Recently, Mairal et al. (2009) presented a ℓ_1-based dictionary learning for sparse coding in which the method aims to explore sparsity on factor-sample mapping rather than that on factor-variable relations. Setting Laplace-like prior distributions on scale loadings is a counterpart of ℓ_1-based penalization (Jolliffe et al., 2003; Zou et al., 2006). However, our model-based perspective aims for a more probabilistic analysis, with advantages in probabilistic assessment of appropriate dimension of the latent factor space as well as flexibility in the determination of effective degrees of sparseness via the additional parameters ζ. Other than the preceding studies, ℓ_1-regularizations have widely been employed to make sparse latent factor analyses. Archambeau and Bach (2009) developed a general class of sparse latent factor analyses involving sparse probabilistic PCA (Guan and Dy, 2009) and a sparse variant of probabilistic canonical correlation analysis. A key idea of Archambeau and Bach (2009) is to place the automatic relevance determination (ARD) prior of Mackay (1995) on each loading component, and to apply a variational mean-field learning method.

Key advances in Bayesian sparse factor analysis build on non-parametric Bayesian modelling in Griffiths and Ghahramani (2006) and Rai and Daumé (2009), and developments in Carvalho et al. (2008) stemming from the original sparse Bayesian models in West (2003). Carvalho et al develop MCMC and stochastic search methods for posterior exploration. MCMC posterior sampling can be effective but is hugely challenged as the dimensions of data and factor variables increase. Our focus here is MAP evaluation with a view to scaling to increasingly large dimensions, and we leave open the opportunities for future work on MCMC methods in GFMs.

Most importantly, as remarked in Section 2.2, the GFM differs from some of the forgoing models in the conditional independence graphical structures induced. This characteristic contributes to preserving sparse structure in the data compression/reconstruction process and also to the outlier robustness issue. We leave further comparative discussion to Section 7.1, where we evaluate some of the foregoing methods relative to the sparse GFM analysis in an image processing study.

3. Variational Mean-Field Annealing for MAP Search

Finding MAP estimates of the augmented posterior distribution (3) involves many discrete variables z_{gj}. Then, commonly applied search methods such as greedy hill-climbing algorithm often get stuck in improper local solutions. Here, we present a general framework of VMA2 enabling us to escape local mode traps by exploiting annealing.

3.1 Basic Principle

Relative to (3), consider the class of extended objective functions

$$\mathcal{G}_T(\Theta,\omega) = \sum_{Z\in\mathcal{Z}} \omega(Z)\log p(X,Z,\Theta|\zeta) - T\sum_{Z\in\mathcal{Z}} \omega(Z)\log\omega(Z) \tag{5}$$

where $\omega(Z)$—the *sparsity configuration probability*—represents *any distribution* over $Z \in \mathscr{Z}$ that may depend on (X, Θ, ζ), and where $T \geq 0$. This modifies the original criterion (3) by taking the expectation of $p(X, Z, \Theta|\zeta)$ with respect to $\omega(Z)$—the expected complete data log-likelihood in the context of EM algorithm—and by the inclusion of Shannon's entropy of $\omega(Z)$ with the *temperature* multiplier T.

Now, view (5) as a criterion to maximize over (Θ, ω) jointly for any given T. The following is a key result:

Proposition 1 *For any given parameters* Θ *and temperature* T*, (5) is maximized with respect to* ω *at*

$$\omega_T(Z) \propto p(Z|X, \Theta, \zeta)^{1/T}. \tag{6}$$

Proof See the Appendix. ■

For any given Θ, a large T leads to $\omega_T(Z)$ being rather diffuse over sparse configurations Z so that iterative optimization—alternating between Θ and ω—will tend to move more easily and freely around the high-dimensional space Z. This suggests annealing beginning with the temperature T large and successively reducing towards zero. We note that:

- As $T \to 0$, $\omega_T(Z)$ converges to a distribution degenerate at the conditional mode $\hat{Z}(\Theta, \zeta)$ of $p(Z|X, \Theta, \zeta)$, so that
- joint maximization of $\mathcal{G}_T(\Theta, \omega)$ would approach the *global maximum of the exact posterior* $p(\Theta, Z|X, \zeta)$ as $T \to 0$.

The notion of the annealing operation is to realize a gradual move of successively-generated solutions for Θ and $\omega_T(Z)$, and to escape local mode traps by exploiting annealing. Note that, for any given tempered posterior (6), the expectation in the first term of (5) is virtually impossible to be taken due to the combinatorial explosion. In what follows, we introduce VMA2 as a mean-field technique coupled with the annealing-based optimization to overcome this central computational difficulty.

3.2 VMA2 based on Factorized, Tempered Posteriors

To define and implement a specific algorithm, we constrain the otherwise arbitrary *"artificial configuration probabilities"* ω, and do so using a construction that induces analytic tractability. We specify the simplest, factorized form

$$\omega(Z) = \prod_{g=1}^{p} \prod_{j=1}^{k} \omega(z_{gj}) := \prod_{g=1}^{p} \prod_{j=1}^{k} \omega_{gj}^{z_{gj}} (1 - \omega_{gj})^{1 - z_{gj}}$$

in the same way as conventional Variational Bayes (VB) procedures do. In this GFM context, the resulting optimization is eased using this independence relaxation as it gives rise to tractability in computing the conditional expectation in the first term of (5).

If $T = 1$, and given the factorized ω, the objective function $\mathcal{G}_1$ exactly agrees with the *free energy*, which bounds the posterior marginal as

$$\log \sum_{Z \in \mathscr{Z}} p(X, \Theta, Z|\zeta) \geq \mathcal{G}_1(\Theta, \omega).$$

The lower-bound $\mathcal{G}_1$ is the criterion that the conventional VB methods aim to maximize (Wainwright and Jordan, 2008). This indicates that any solutions corresponding to the VB inference can be obtained by stopping the cooling schedule at $T = 1$ in our method. Similar ideas have, of course, been applied in deterministic annealing EM and annealed VB algorithms (e.g., Ueda and Nakano, 1998). These methods exploit annealing schemes to escape from local traps during coordinate-basis updates in aiming to define variational approximations of posteriors.

Even with this relaxation, maximization over $\omega(Z)$ cannot be done for all elements of Z simultaneously and so is approached sequentially—sequencing through each ω_{gj} in turn while conditioning the others. For any given T this yields the optimizing value given by

$$\omega_{gj}(T) \propto \exp\Big\{\frac{1}{T}\sum_{\mathscr{Z}_{C\setminus\{g,j\}}}\prod_{h\neq g}\prod_{l\neq j}\omega(z_{hl})\log p(z_{gj}=1|X,Z_{C\setminus\{g,j\}},\Theta,\zeta)\Big\} \tag{7}$$

where $\mathcal{C}$ denotes the collection of all indices (g, j) for the p features and k factor variables, $\mathcal{C}\setminus\{g, j\}$ is the set of the paired indices (h,l) such that $(h,l) \neq (g, j)$, and $\mathscr{Z}_{C\setminus\{g,j\}}$ stands for the set of z_{hl}s other than z_{gj}.

Starting with $\omega_{gj} \simeq 1/2$ at an initial large value of T, (7) gradually concentrates to the point mass as T decays to zero slowly:

$$\hat{z}_{gj} := \lim_{T\downarrow 0}\omega_{gj}(T) = \begin{cases} 1, & \text{if } \displaystyle\sum_{\mathscr{Z}_{C\setminus\{g,j\}}}\prod_{h\neq g}\prod_{l\neq j}\omega(z_{hl})\log\frac{p(z_{gj}=1,X,Z_{C\setminus\{g,j\}},\Theta,\zeta)}{p(z_{gj}=0,X,Z_{C\setminus\{g,j\}},\Theta,\zeta)} > 0, \\ 0, & \text{otherwise.} \end{cases}$$

It remains true that, at the limiting zero temperature, the global maximum of $\mathcal{G}_T(\Theta,\omega)$ is the set of $p\times k$ point masses at the global posterior mode of $p(\Theta,Z|X,\zeta)$. This is seen trivially as follows: *(i)* As $T\to 0$, and with the non-factorized ω in (5), we have limiting value

$$\sup_Z \log p(X,\Theta,Z|\zeta) = \sup_\omega \mathcal{G}_0(\Theta,\omega) \tag{8}$$

with the point mass $\omega(Z) = \delta_{\hat{Z}}(Z)$ at the location of the global maximum $(\hat{Z})_{gj} = \hat{z}_{gj}$. Further, *(ii)* any point mass $\delta_{\hat{Z}}(Z)$ is representable by a fully factorized $p\times k$ point masses as $\delta_{\hat{Z}}(Z) = \prod_{g,j}\delta_{\hat{z}_{gj}}(z_{gj})$.

It is stressed that the coordinate-basis updates (7) cannot, of course, guarantee convergence to the *global* optimum even with prescribed annealing. Nevertheless, VMA2 represents a substantial advance in its ability to move more freely and escape local mode traps. We also note the generality of the idea, beyond factor models and also potentially using penalty functions other than entropy.

4. Sparse Learning in Graphical Factor Models

We first provide a specific form of VMA2 for the GFM, and then address the issue of evaluating relevant degrees of sparseness.

4.1 MAP Algorithm

Computations alternate between conditional maximization steps for ω and Θ while reducing the temperature T. At each step, the value of the objective function (5) is kept to refine until convergence where the temperature reaches to zero. Specifically:

1: Set a cooling schedule $\mathcal{T} = \{T_1, \ldots, T_d\}$ of length d where $T_d = 0$;
2: Set ζ;
3: Initialize Θ;
4: Initialize $\omega(Z)$;
5: $i \leftarrow 0$;
6: `while` ($\{$the loop is not converged $\} \wedge \{i \leq d\}$)
7: $i \leftarrow i + 1$;
8: Compute configuration probabilities $\omega_{gj}(T_i)$;
9: Optimize with respect to each column ϕ_j $(j = 1 : k)$ of Φ in turn under full-conditioning;
10: Optimize with respect to Δ under full-conditioning;
11: Optimize with respect to Ψ under full-conditioning;
12: Optimize with respect to ζ under full-conditioning;
13: `end while`

We now summarize key components in the iterative, annealed computation defined above.

4.2 Sparse Configuration Probabilities

First consider maximization with respect to each sparse configuration probability ω_{gj} conditional on all others. We note that the first term in (5) involves the expectation over Z with respect to the probabilities ω, denoted by $\mathbb{E}_\omega[\cdot]$. Accordingly, for the key terms $S(z_j, \Psi)$ we have

$$\mathbb{E}_\omega[S(z_j, \Psi)] = \Omega_j \circ (\Psi^{-1/2} S \Psi^{-1/2}) \text{ with } (\Omega_j)_{gh} = \begin{cases} \omega_{gj}, & \text{if } g = h, \\ \omega_{gj}\omega_{hj}, & \text{otherwise.} \end{cases} \tag{9}$$

Introduce the notation $\Psi^{-1/2} S \Psi^{-1/2} = (s_1(\Psi), \ldots, s_p(\Psi))$ to represent the p columns of the scaled-sample sum-of-square matrix here, and define the $p-$vector

$$\tilde{\omega}_{gj} = (\omega_{1j}, \ldots, \omega_{g-1,j}, 1, \omega_{g+1,j}, \ldots, \omega_{pj})'.$$

Then, the partial derivative of (5) with respect to ω_{gj} conditional on Θ and the other configuration probabilities leads to

$$\text{logit}(\omega_{gj}(T)) = H_{gj}(\zeta_{gj})/T \quad \text{where} \quad H_{gj}(\zeta_{gj}) := \tau_j \phi_{gj} (\phi_j \circ \tilde{\omega}_{gj})' s_g(\Psi) - \zeta_{gj}.$$

This directly yields the conditional maximizer for ω_{gj} in terms of the tempered negative energy $H_{gj}(\zeta_{gj})/T$. As the temperature T is reduced towards zero, the resulting estimate tends towards 0 or 1 according to the sign of $H_{gj}(\zeta_{gj})$.

4.3 Conditional Optimization over Φ

The terms in (5) that involve Φ are simply the expectation of the quadratic forms in the last term of (3), with the term for each column ϕ_j involving the key matrices $S(z_j, \Psi)$ defined in (4), for each $j = 1 : k$. At each step through the overall optimization algorithm in Section 4.1, we sequence through these columns of the loadings matrix in turn conditioning on the previously optimized

values of all other columns. In the context of the overall iterative MAP algorithm, this yields global optimization over Φ as $T \to 0$.

Conditional optimization then reduces to the following: for each $j = 1:k$, sequence through each column ϕ_j in turn and at each step

$$\begin{aligned} &\underset{\phi_j}{\text{maximize}} && \phi_j' \mathbb{E}_\omega[S(z_j, \Psi)]\phi_j \\ &\text{subject to} && \phi_j'\phi_j = 1 \quad \text{and} \quad \phi_m'\phi_j = 0 \text{ for } m \neq j, m = 1:k. \end{aligned} \tag{10}$$

The optimization conditions on the most recently updated values of all other columns $m \neq j$ at each step, and is performed as one sweep as the line 9 in the algorithm of Section 4.1. Column order can be chosen randomly or systematically each time while still maintaining convergence. In this step, we stress that the original orthogonality condition is modified to $\Phi_Z'\Phi_Z = I \to \Phi^T\Phi = I$ in (10). It remains the case that iteratively refined estimates obtained from (10) satisfy the original condition at the limiting zero temperature, yielding sparsity for $\mathbb{E}_\omega[S(z_j, \Psi)]$, as detailed in the mathematical derivations in supplementary material.

The specific computations required for the conditional optimization in (10) are as follows (with supporting details in the Appendix). Note that the central matrices $\mathbb{E}_\omega[S(z_j, \Psi)]$ required here are trivially available from Equation (9).

1: Compute the $p \times (k-1)$ matrix $\Phi_{(-j)} = \{\phi_m\}_{m \neq j}$ by simply deleting column j from Φ;

2: Compute the $p \times p$ projection matrix $N_j = I_p - \Phi_{(-j)}\Phi_{(-j)}'$;

3: Compute the eigenvector φ_j corresponding to the most dominant eigenvalue of $N_j\mathbb{E}_\omega[S(z_j, \Psi)]N_j$;

4: Compute the required optimal vector $\phi_j = N_j\varphi_j / \|N_j\varphi_j\|$.

This procedure solves (10) by optimizing over an eigenvector already constrained by the orthogonality conditions. Here N_j spans the null space of the current $k-1$ columns of $\Phi_{(-j)}$, so $N_j\mathbb{E}_\omega[S(z_j, \Psi)]N_j$ defines the projection of $\mathbb{E}_\omega[S(z_j, \Psi)]$ onto the orthogonal space and eigenvectors φ_j lie in the null space. It remains to ensure that the computed value ϕ_j is of unit length, which involves the normalization in the final step in part 4. Selecting the eigenvector with maximum eigenvalue ensures the conditional maximization in (10).

4.4 Conditional Optimization over Δ

The variances δ_j of the latent factors appear in Equations (3) and (5) in the sum over $j = 1:k$ of terms

$$-n\log(1+\delta_j) + \delta_j(1+\delta_j)^{-1}\phi_j'\mathbb{E}_\omega[S(z_j, \Psi)]\phi_j.$$

This is unimodal in δ_j with maximizing value

$$\hat{\delta}_j = \max\{0, n^{-1}\phi_j'\mathbb{E}_\omega[S(z_j, \Psi)]\phi_j - 1\}, \tag{11}$$

and so the update at the line 10 of the MAP algorithm of Section 4.1 computes these values in parallel for each factor $j = 1:k$. Note that this may generate zero values, indicating the removal of the corresponding factors from the model, and so inducing an intrinsic ability to prune the number

of factors as being redundant in a model specified initially with a larger, encompassing value of k. The configured sparse structure drives this pruning; any specific factor j that is inherently very sparse generates a smaller value of the projected "variance explained" $\phi_j' \mathbb{E}_\omega[S(z_j, \Psi)]\phi_j$, and so can lead to $\hat{\delta}_j = 0$ as a result.

4.5 Conditional Optimization over Ψ

The diagonal noise covariance matrix Ψ appears in the objective function of Equation (5) in terms that can be re-expressed as

$$-n \log|\Psi| - \text{trace}(S\Psi^{-1}) + \sum_{j=1}^{k} \tau_j \text{trace}(\phi_j \phi_j' \Psi^{-1/2} (\Omega_j \circ S) \Psi^{-1/2})$$

where $\tau_j = \delta_j/(1+\delta_j)$ for each j. Differentiating this with respect to $\Psi^{-1/2}$ yields the gradient equation:

$$n\text{diag}^{-1}(\Psi^{1/2}) - \text{diag}^{-1}(S\Psi^{-1/2}) + \sum_{j=1}^{k} \tau_j \text{diag}^{-1}(\phi_j \phi_j' \Psi^{-1/2} (\Omega_j \circ S)) = 0,$$

where $\text{diag}^{-1}(A)$ denotes the vector of the diagonal elements in A. Iterative solution of this non-linear equation in Ψ can be performed via the reduced implicit equation

$$\text{diag}^{-1}(\Psi) = n^{-1}\text{diag}^{-1}(\{I_p - \sum_{j=1}^{k} \tau_j (\phi_j \phi_j') \circ (\Psi^{-1/2} \Omega_j \Psi^{1/2})\} S).$$

4.6 Degrees of Sparseness

The prior over the logistic hyperparameters $\zeta = \{\zeta_{gj}\}$ defining the Bernoulli probabilities for the z_{gj} is important in encouraging relevant degrees of sparseness. Extending the model via an hierarchical prior for these parameters enables adaptation to data in evaluating relevant degrees of sparseness. One first class of priors is used here, taking the ζ_{gj} to be conditionally independent and drawn from the prior with positive part Gaussian distribution $N_+(\zeta_{gj}|\mu,\sigma)$ for some specified mean and variance (μ,σ). The annealing search can now be extended to include ζ, simply embedding conditional optimization of (5) under this prior within each step of the iterative search. The conditional independence structure of the model easily yields unique solutions for each of the ζ_{gj} in parallel as values satisfying

$$\omega_{gj} = \frac{\exp(-\zeta_{gj}/2)}{1+\exp(-\zeta_{gj}/2)} - \frac{\zeta_{gj}-\mu}{2\sigma}. \tag{12}$$

Solutions to (12) are trivially, iteratively computed. Evidently, as ω_{gj} approaches 0 or 1, the solution for ζ_{gj} is shifted to the corresponding boundary. ζ_{gj} as a function of ω_{gj} for several values of (μ,σ).

As mentioned earlier, the choice of this logit/truncated normal prior is a subjective preference and could be replaced by others, such as beta priors. Again, we expect that this would typically lead to modest differences, if any of practical relevance, in many cases.

5. A Stochastic Search Variant for Large p

In problems with larger numbers of variables, the computations quickly become challenging, especially in view of the repeated eigen-decompositions required for updating factor loading matrix. In our examples and experiments, analysis with dimensions $p \sim 500$ would be feasible using our own R code (`vma2gfm()` available from the supplementary web site), but computation time then rapidly increases with increasing p. More efficient low level coding will speed this, but nevertheless it is of interest to explore additional opportunities for increasing the efficiency of the MAP search.

To reduce the computational time, we explore a stochastic variant of the original deterministic VMA2 that uses realized Z matrices from current, conditional configuration probabilities $\omega_{gj}(T)$ at each stage of the search process. The realized binary matrix $Z = [z_1, \ldots, z_k]$ replaces the full matrix $\mathbb{E}_\omega[S(z_j, \Psi)]$ with a sparse alternative $S(z_j, \Psi)$. In larger, very sparse problems, this will enable us to greatly reduce the computing time as each eigen-decomposition can be computed based only on the components related to non-zero z_{gj} values. This leads to a stochastic annealing search with all other steps unchanged. We also have the additional benefit of the introduced randomness aiding in potentially moving away from the stuck in suboptimal solutions. It should be stressed that this is an optional complement to the deterministic algorithm and one that may be used for an initial period of time prior to enable swifter initial iterations from arbitrary initial values, prior to switching to the deterministic annealing once in the region of a posterior mode.

The modified search procedure over ϕ_j in Equation (10) is:

1. Draw a set of binary values $\hat{z}_{gj}, g = 1, \ldots, p$, according to the current configuration probabilities $\omega_{gj}(T)$;
2. Define the set of *active variables* by $\mathcal{A}_j = \{g | g \in 1:p, \hat{z}_{gj} = 1\}$; denote by $\phi_{j,\{\mathcal{A}_j\}}$ the sub-vector of ϕ_j for only the active variables, and $S_{\{\mathcal{A}_j\}}(z_j, \Psi)$ the submatrix of $S(z_j, \Psi)$ whose rows and columns correspond to only the active variables;
3. Solve the reduced optimization conditional on the $\mathcal{A}_j$, via:

$$\begin{aligned} \underset{\phi_{j,\{\mathcal{A}_j\}}}{\text{maximize}} \quad & \phi'_{j,\{\mathcal{A}_j\}} S_{\{\mathcal{A}_j\}}(\hat{z}_j, \Psi) \phi_{j,\{\mathcal{A}_j\}} \\ \text{subject to} \quad & \|\phi_{j,\{\mathcal{A}_j\}}\|^2 = 1 \ \text{ and } \ \phi'_{m,\{\mathcal{A}_j\}} \phi_{j,\{\mathcal{A}_j\}} = 0 \text{ for } m \neq j. \end{aligned}$$

4. Update the full $p-$vector ϕ_j with elements $\phi_{j,\{\mathcal{A}_j\}}$ for the active variables and all other elements zero.

For example, in a problem with $p = 5000$ but sparseness of the order of 5%, the $\mathcal{A}_j$ will involve a few hundred active variables, and eigenvalue decomposition will then be performed on matrices of that order rather than 5000×5000. We note also that this strategy requires a modification to the update operation for the configuration probabilities: the ω_{gj} will be updated at any one step only for the current indices $g \in \mathcal{A}_j$, keeping the remaining z_{gj} at values previously obtained.

6. Experimental Results on Synthetic Data

Performance and comparisons on artificial data are shown to highlight some learning properties of the GFM.

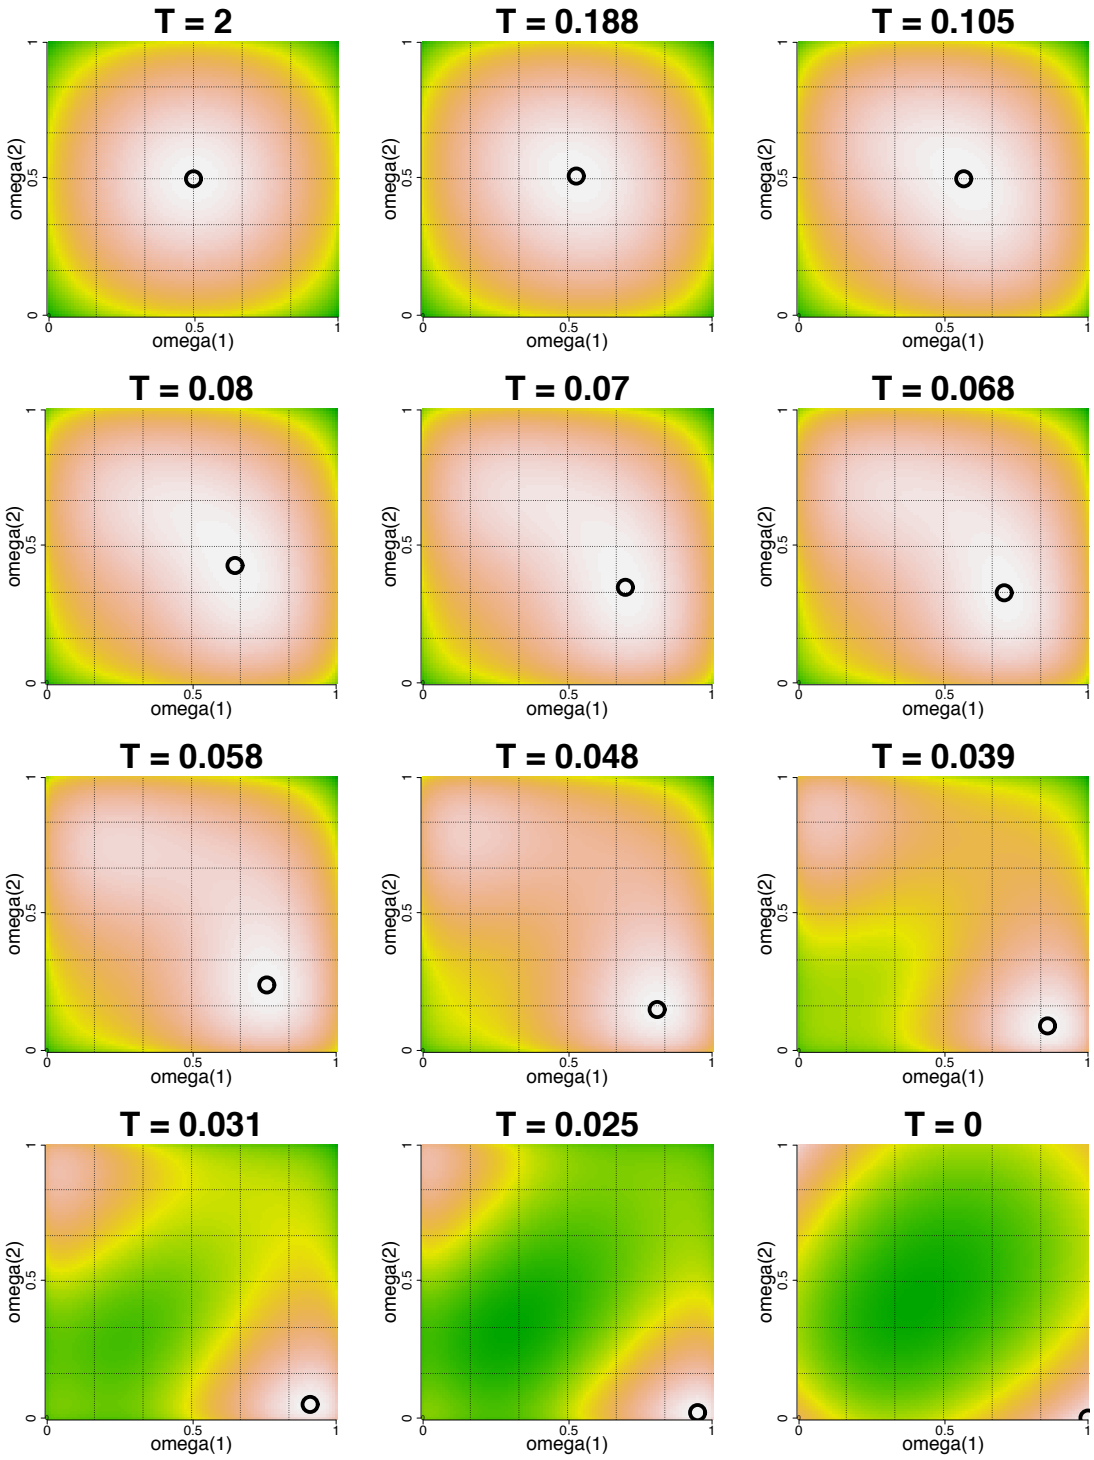

Figure 2: Display of evolving $\mathcal{G}_T(\hat{\Theta}, \omega)$ in the annealing process (from $T = 2$ to $T = 0$) with contour plots. The black circle in each panel indicates the maximum point, and that corresponding to $T = 0$ in the panel on the bottom-right corner indicates the optimal sparse structure.

6.1 Visual Tracking of Annealing Process with a Toy Problem

The first experiment shows how the VMA2 method can solve the combinatorial optimization. Consider 3 variables and 1 factor, so that $x_i = (\phi_1 \cdot z_1)\lambda_{1i} + \nu_i$ where all parameters except ϕ_1 are fixed as $\Psi = I$ and $\Delta = I$. The likelihood function in (2) is then $p(X|Z,\Theta) \propto \exp(\phi'_{z_1} S \phi_{z_1}/2)$. Assume that true edge on $z_{31} = 1$, indicating $x_{i3} \leftarrow \lambda_{i1}$, is known, but $z_{11} = 1$ and $z_{21} = 0$ are treated as unknown. Then, with the prior for z_{11} and z_{21} as $\text{logit}(\Pr(z_{11} = 1)) = \text{logit}(\Pr(z_{21} = 1)) = -1.5$, we explored values for ϕ_1 and ω_{g1}, $g = 1,2$, based on an artificial data set drawn from the GFM, so as to refine $\mathcal{G}_T(\Theta,\omega)$ under the factorized $\omega(Z) = \omega(z_{11})\omega(z_{21})$.

We can map the surface $\mathcal{G}_T(\Theta,\omega)$ over $(\omega_{11},\omega_{21})$ when Θ is set at the optimized value $\hat{\Theta}$ for each $(\omega_{11},\omega_{21})$. Figure 2 on the bottom-right corner displays a contour plot of $\mathcal{G}_0(\hat{\Theta},\omega)$. The maximum point lies in one of the four corners corresponding to $\omega_{g1} \in \{0,1\}$ and the global MAP estimate has $\omega_{11} = 1$ and $\omega_{21} = 0$.

Figure 2 also shows a tracking result of the VMA2 search process starting from $T = 2$ and stopping at $T = 0$. The change in $\mathcal{G}_T(\hat{\Theta},\omega)$ and the corresponding maximizing values of $(\omega_{11},\omega_{21})$ can be monitored through the contour plots at selected temperatures. Starting from the initial values, $\omega_{11} \approx 0.5$ and $\omega_{21} \approx 0.5$, at the highest temperature, the successively-generated maximum points gradually come closer to the global optimum ($\omega_{11} = 1$ and $\omega_{21} = 0$) as the annealing process proceeds. At higher temperatures, $\mathcal{G}_T(\hat{\Theta},\omega)$ is unimodal. In the overall search, the tempered criterion begins to become bimodal after the trajectory moves into regions close to the global maximum.

This simple illustrative example highlights the key to success in the search: moving the trajectory of solutions closer to the global maximum in earlier phases of the cooling schedule, before the tempered criterion function exhibits substantial multimodality. Looking ahead, we may be able to raise the power of the annealing search by, for example, using dynamic control of the cooling schedule or more general penalty functions for ω.

6.2 Snapshot of Algorithm with 30 Variables and 4 Factors

In what follows, we will show some simulation studies to provide insights and comparisons. The data sets have $n = 100$ data points drawn from the GFM with $p = 30$ and $k_{\text{true}} = 4$, and with $\Psi = 0.05I$ and $\Delta = \text{diag}(1.5, 1.2, 1.0, 0.8)$. The z_{gj} were independently generated with $\Pr(z_{gj} = 1) = 0.3$, yielding roughly 70% sparsity; then, non-zero elements of Φ where generated as independent standard normal variates, following which Φ_Z was constrained to orthogonality.

To explore sensitivity to the chosen temperature schedule for annealing, experiments were run using three settings:

- (Log-inverse decay) $T_i = 3/\log_2(i+1)$ for $i = 1,\ldots,6999$, and $T_{7000} = 0$
- (Linear decay) $T_i = 3 - 6 \times 10^3 \times (i-1)$ for $i = 1,\ldots,1999$, and $T_{2000} = 0$
- (Power decay) $T_i = 3 \times 0.99^{-(i-1)}$ for $i = 1,\ldots,1999$, and $T_{2000} = 0$

For each, we evaluated the resulting MAP search in terms of comparison with the true model and computational efficiency, in each case using a model with redundant factor dimension $k = 8$.

6.3 Annealing with Fixed Hyper-parameters

First analyses fixed $\zeta_{gj} = c$ and was run repeatedly across some grid points of $c \in [0,5]$. Figure 3 summarizes the evaluation of the receiver operating characteristics (ROC) for the three cooling

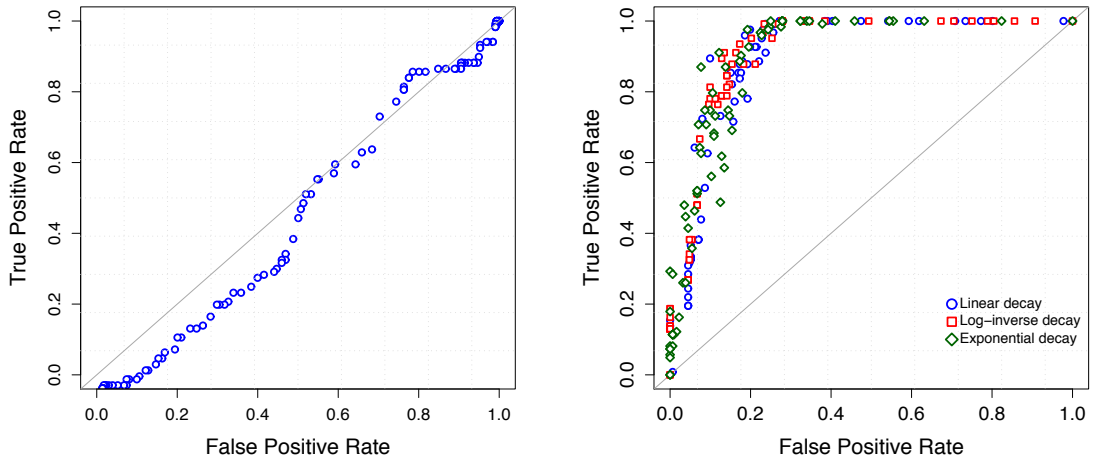

Figure 3: ROC for threshold PCA assuming a known, true $k = 4$ factors (left), compared to VMA2 estimation of the GFM under the three cooling schedules and with $k = 8$ (right). TPR (vertical) and FPR (horizontal) were calculated according to TP/P and FP/N where P and N denote the numbers of non-zero and zero elements in true loadings, TP and FP are the numbers of true positives and false positives, respectively.

schedules. The true positive (TPR) and false positive rates (FPR) were computed based on the correspondences between estimated and true values of the z_{gj}. For comparison, we used standard PCA, extracting the dominant 4 eigenvectors and setting entries below a threshold (in absolute value) to zero; sliding the threshold towards zero gives a range of truncated loadings vectors in the PCA that define the ROC curve for this approach. The resulting ROC curve, shown in the left panel, is very near to the 45° line, comparing very poorly with the annealed GFM; for the latter, each ROC curve indicates rather accurate identification of the sparse structure and the curves differ in small ways only as a function of cooling schedule. The choice of cooling schedule can, however, have a more marked influence on results if initialized at temperatures that are too low.

6.4 Inference on Degrees of Sparseness

A second analysis uses the sparsity prior $p(\zeta_{gj}) = \mathcal{N}_+(\zeta_{gj}|\mu,\sigma)$ with $\mu = 3$ and $\sigma = 6$, and adopts the log-inverse cooling schedule. As shown in the right panel of Figure 4, the analysis realized a reasonable control of FNR (15.4%) and FPR (0%), inducing a slightly less sparse solution than the true structure. The GFM analysis automatically prunes the redundant factors, identifying the true model dimension. Figure 5 displays a snapshot of evolving configuration probabilities ω_{gj} and hyper-parameters ζ_{gj} during the annealing schedule, demonstrating convergence over 2000 steps. At around $T_i \simeq 0.45$, all the configuration probabilities corresponding to the redundant four factors reached to zero.

We further evaluated sensitivity to the choice of cooling schedules; in addition to the previous three cooling schedules, we compared with:

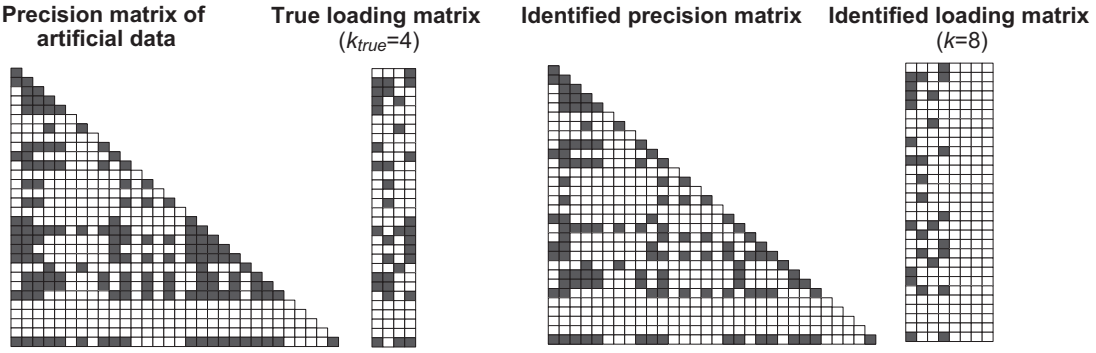

Figure 4: Result of the VMA2 estimation using the log-inverse rate cooling in analysis of synthetic data. (Left) Precision and factor loadings matrix used for generating the synthetic data ($p = 30$, $k_{\text{true}} = 4$). Non-zero elements are colored black. (Right) Estimated precision and factor loadings matrix ($k = 8$); note that the MAP estimate sets the last four loading vectors to zero and so identifies the true number of factors automatically.

- (Log-inverse decay) $T_i = 0.7/\log_2(i+1)$ for $i = 1,\ldots,6999$ and, $T_{7000} = 0$
- (Linear decay) $T_i = 0.7 - 6 \times 10^3 \times (i-1)$ for $i = 1,\ldots,1999$ and, $T_{2000} = 0$
- (Power decay) $T_i = 0.7 \times 0.99^{-(i-1)}$ for $i = 1,\ldots,1999$ and, $T_{2000} = 0$

The initial temperatures are reduced from 3 to 0.7. Figure 6 shows the variations of TPR and FPR in the use of the six cooling schedules, evaluated in 20 analyses with replicated synthetic models and data sets. The left and center panels indicate significant dominance of the annealing starting from the higher initial temperatures. Performance in identifying model structure seriously degrades when using a temperature schedule that starts too low, and the sensitivity to schedule is very limited when beginning with reasonably high initial temperatures.

The right panel in Figure 6 shows TPR and FPR for the sparse PCA (SPCA) proposed by Zou et al. (2006), evaluated on the same 20 data sets using the `R` code `spca()` available at CRAN (`http://cran.r-project.org/`). With `spca()`, we can specify the number of nonzero elements (cardinality) in each column of the factor loading matrix. We executed `spca()` after the assignment of the true cardinality as well as the known factor dimension $k_{\text{true}} = 4$. The figure indicates a better performance of GFM annealed with high initial temperature than the sparse PCA, and this is particularly notable in that the GFM analysis uses $k = 8$ and involves no *a priori* knowledge on the degree of sparseness. It is important to see that the conducted comparison is biased since the data were drawn from the GFM with the orthogonal loading matrix where SPCA does not make orthogonality assumptions. In Section 7.1, we provide deeper comparisons among several existing sparse factor analyses based on image processing in hand-written digits recognition.

6.5 Computing Time Questions

Figure 7 shows the CPU times required for the execution of the GFM analyses as above, repeated with increasing dimension $p \in \{100, 200, 300, 500, 700, 1000\}$. The data sets were again generated from GFMs with 4 factors and roughly 70% sparseness. We then performed the VMA2 using a

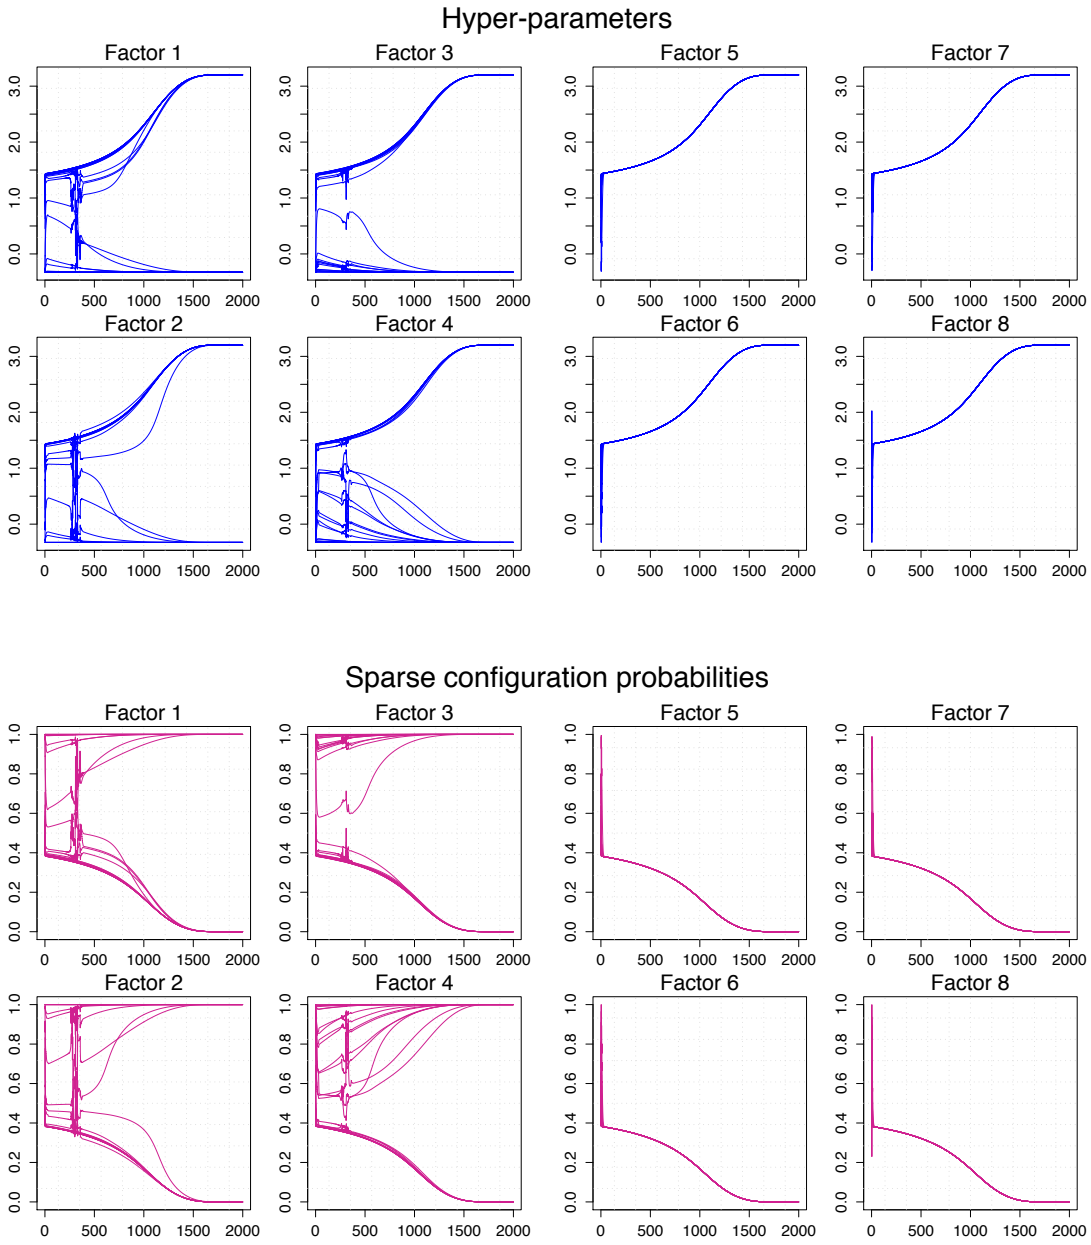

Figure 5: Convergence trajectories of the ζ_{gj} (upper) and ω_{gj} (lower) in analysis of synthetic data over 2000 steps of annealed MAP estimation.

linear decay cooling of length 2000, and using both deterministic and stochastic annealing in a model with $k = 8$. The deterministic algorithm was not used for $p \geq 500$ due to substantial increase in CPU times; this was eased via use of the stochastic search algorithm.

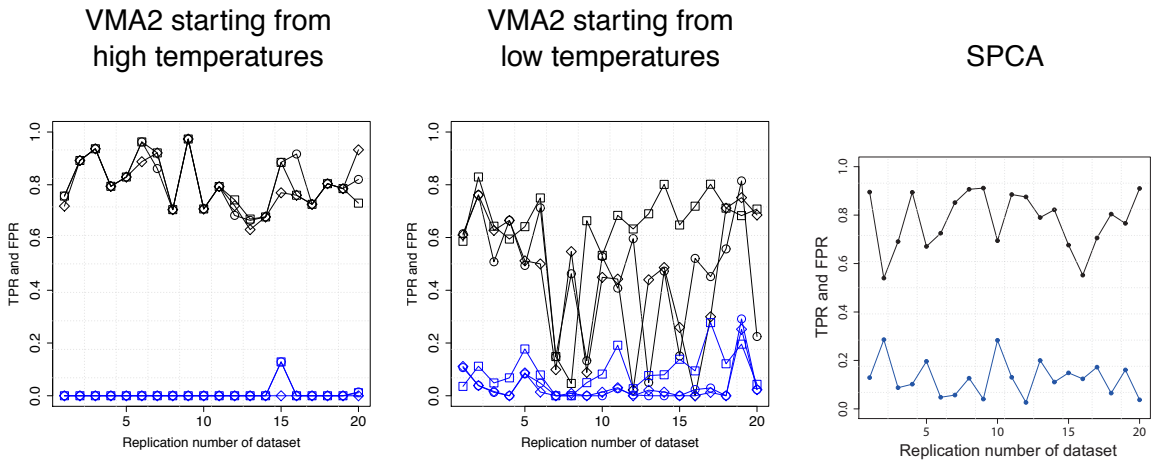

Figure 6: Performance tests on 20 synthetic data sets for different cooling schedules and comparison between the GFM and a sparse PCA (SPCA). For each panel, TPR (black) and FPR (blue) are plotted (vertical axis) against the 20 replicate simulations of artificial data. The results of annealing with the higher and lower initial temperatures are shown in the left and center panels respectively where the rates of cooling with log-inverse, linear and power decays are denoted by box, diamond and circle, respectively. The right panel shows the results of SPCA.

7. Real Data Applications

Experimental results on image analyses of hand-written digits (Section 7.1) and breast cancer gene expression data (Section 7.2) are shown to demonstrate practical relevance of the GFMs in analyses of high dimensional data.

7.1 Application: Hand-written Digit Recognition

We evaluate GFM in pattern recognition analyses of hand-written digit images, and make comparisons to three existing methods; (i) SPCA (Zou et al., 2006), (ii) sparse probabilistic PCA with ARD prior (Archambeau and Bach, 2009), and (iii) MCMC-driven sparse factor analysis (West, 2003; Carvalho et al., 2008). These three methods are all based on models with non-orthogonal sparse loading matrices. The training data set was made from 16×16 gray-scale images of 100 digits (i.e., $n = 100$, $p = 256$) of '3' that were randomly drawn from the postal zip code data available at `http://www-stat.stanford.edu/~tibs/ElemStatLearn/` (Hastie et al., 2001). To evaluate robustness of the four approaches, we added artificial outliers to 15 pixels (features) for about 5% of the original 100 images. Some of the contaminated images are shown in the top-left panels of Figure 8.

For the non-probabilistic method, that is, (i) SPCA, we performed data reconstruction in the standard manner; $x(x_i) = WW'x_i$ with W the matrix of sparse, non-orthogonal loading vectors. In applications of (ii) and (iii) that are inherently driven by probabilistic models, data reconstruction was made via the posterior mean $x(x_i) = W\mathbb{E}[\lambda_i|x_i]$ using obtained sparse loading matrix W. For all

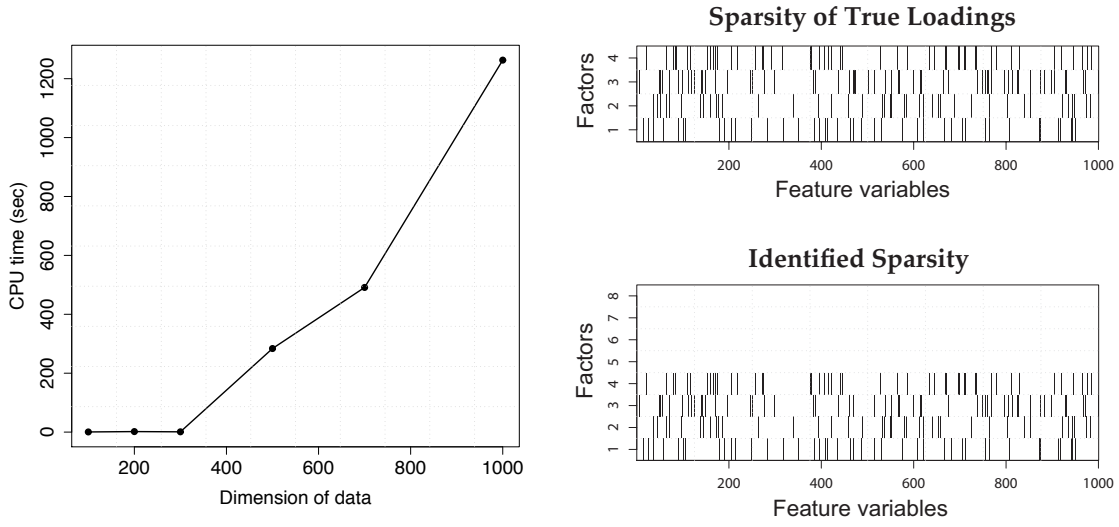

Figure 7: (Left) CPU times (in seconds; Intel(R) Core(TM)2 Duo processor, 2.60Ghz) versus model dimension p for the stochastic VMA2. For the deterministic VMA2, we terminated the tests with the data larger than $p = 300$. Execution times for the deterministic algorithm were approximately 468, 812 and 1100 sec for $p = 100$, 200 and 300. (Right) Identified sparse loadings matrix, displayed as transpose, for the case of $p = 1000$ where the MAP estimation achieved FPR $= 12.0\%$ and FNR $= 18.4\%$.

the methods, setting factor dimensions to $k = 10$, we explored sparse estimates so that the degrees of sparseness become approximately 30% (see Figure 8). For SPCA, we use the same number of non-zero elements in each loading vector as in the estimated GFM. The GFM was estimated using VMA2 with a fixed value for ζ and a linear cooling schedule of length 2000.

A set of 100 test data samples was created from the 100 samples above by adding outliers drawn from a uniform distribution to randomly-chosen pixels with probability 0.2. Performance of the four approaches to data compressions/reconstruction were assessed via mean square error (MSE) between $x(x_i)$s and the true, original test images without the outliers. The right four panels in Figure 8 show some digit images reconstructed by each method with the corresponding original/contaminated test data. The reconstruction errors for the training and test instances are also summarized in the figure. For the results on (ii) and (iii)—the non-orthogonal probabilistic analyses—the reconstructed digits were vaguely-outlined. Such poor reconstructions arise partly from effects of the outliers spread from pixel to pixel along the complete graph defined by non-sparse precision matrix. This empirical result indicates the vulnerability issue of non-restricted sparse factor models in presence of outliers. In the reconstructions of the test instances, the GFM could capture characteristics of original digits with the highest accuracy among the methods. SPCA attained the second highest accuracy in terms of MSE. These observations highlight the substantial merit of using sparse linear mapping in data reconstructions. The GFM and SPCA limit the propagations of outliers within some factor cliques, as most pixel images in the other isolated, non-adjacent factor cliques could be restored clearly.

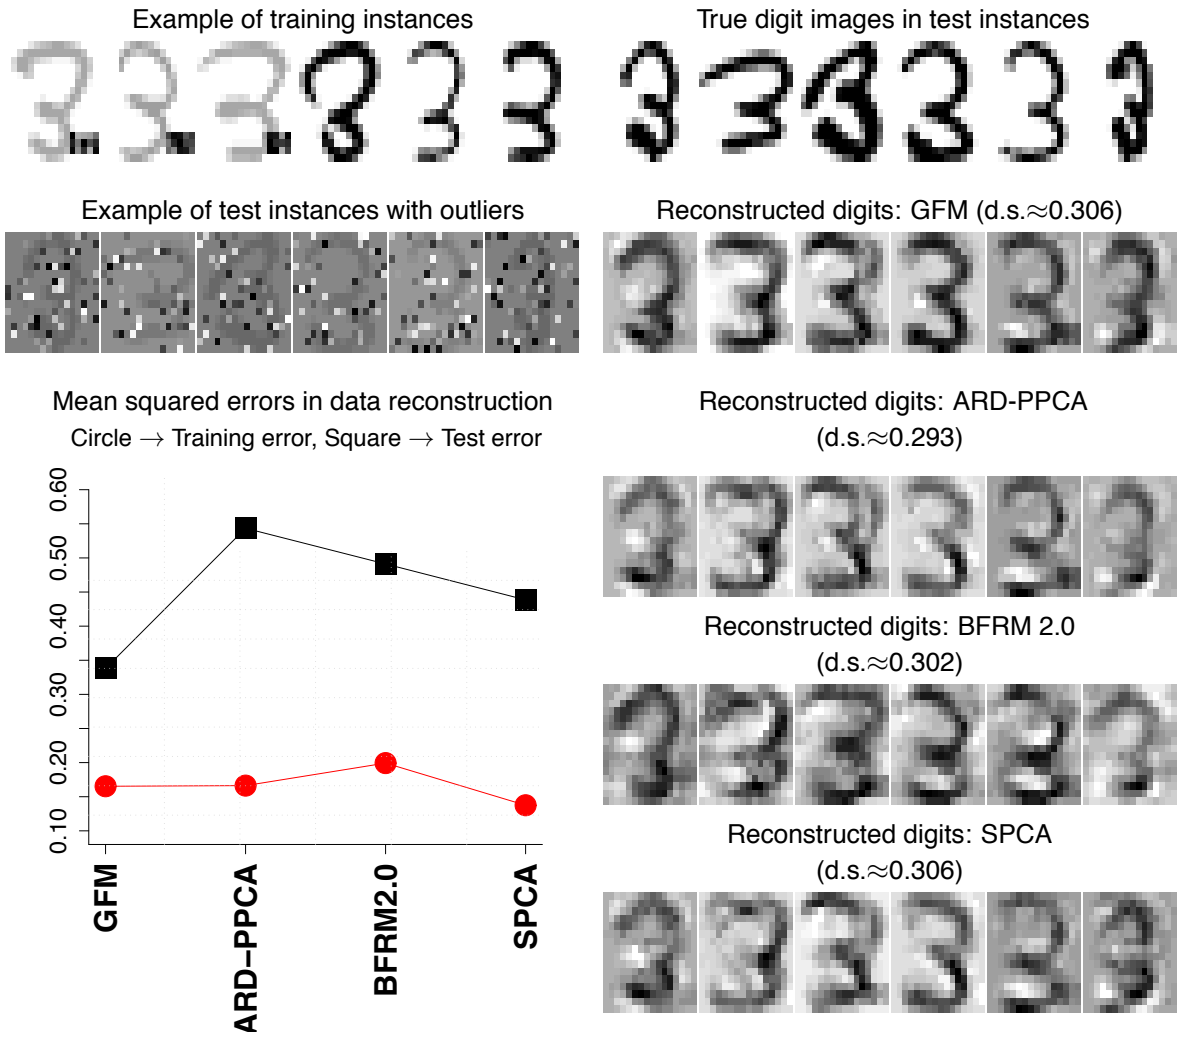

Figure 8: Comparison between GFM and the three alternative methods ((i)-(iii)) in the data reconstruction of outlier hand-written digit images. For the implementation of the sparse probabilistic PCA with ARD prior (ARD-PPCA), we prepared our own `R` function which is available at Supplementary web site. In the application of the MCMC-based sparse factor analysis, we used BFRM 2.0 distributed at http://www.stat.duke.edu/research/software/west/bfrm/. In the four panels on the bottom-right, $d.s.$ denotes the degree of sparseness.

7.2 Application: Breast Cancer Gene Expression Study

Latent factor models are being more used in microarray-based gene expression studies in both basic biological and clinical studies, such as cancer genomics. An example in breast cancer gene expression study here further illustrates the practical relevance of GFM structure and adds to comparisons with other approaches. In addition to the summary details below, a much extended discussion of

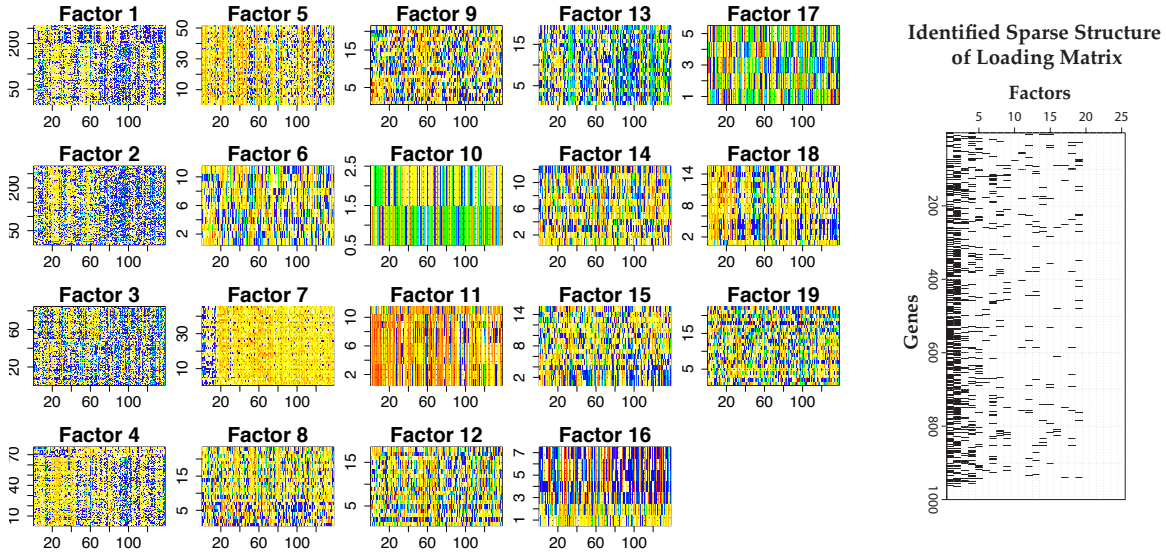

Figure 9: Identified factor probes (left) and sparse structure (right; binary matrix). In each image of the left panel, expression signatures of the probes associated with each factor are depicted across 138 samples (ordered along horizontal axis).

both statistical and biological aspects is available in supporting material at the first author's web site (see link below).

Among the goals of most such studies are identification of multiple factors that may represent underlying activity of biological pathways and provide opportunities for improved predictive models with estimated latent factors for physiological and clinical outcomes (e.g., Carvalho et al., 2008; Chang et al., 2009; Hirose et al., 2008; Lucas et al., 2006, 2009; West, 2003; Yoshida et al., 2004, 2006). Here we discuss an example application of our sparse GFM in analysis of data from previously published breast cancer studies (Cheng et al., 2006; Huang et al., 2003; Pittman et al., 2004; West et al., 2001).

The GFM approach was applied to a sample of gene expression microarray data collected in the CODeX breast cancer genomics study (Carvalho et al., 2008; Pittman et al., 2004; West et al., 2001) at the Sun-Yat Sen Cancer Center, Taipei, during 2001-2004. In addition to summary expression indices from Affymetrix Human Genome U95 arrays, the data set includes immunohistochemistry (IHC) test for key hormonal receptor proteins in clinical prognostics; ERBB2 (Her2) and estrogen (ER). The IHC measures are discrete: ER negative (ER=0), ER positive with low/high-level expression (ER=1 and ER=2), Her2 negative (Her2=0), and Her2 positive with low/high-level (Her2=1 and Her=2). We performed analysis of $p = 996$ genes with the expression levels that, on a log2 (fold change) scale, exceed a median level of 7 and a range of at least 3-fold changes across the tumors. The data set, including the expression data and the IHC hormonal measures, are available on-line as supplementary material.

The annealed estimation of GFM was run with $k = 25$, $\mu = 7$ and $\sigma = 10$. The cooling schedule was prescribed by a linearly-decreasing sequence of 2000 temperatures under which the decay rate and initial temperature were set to 0.006 and 3, respectively. The applied GFM identified 19 factors,

pruning from the model maximum $k = 25$. Heatmaps of gene expression for genes identified in each of the factors appear in Figure 9 with the identified sparse pattern of the loadings matrix.

Evaluation and Annotation of Inferred Factors: To investigate potential biological connections of the factors, we evaluated enrichment of the functional annotations shared by genes in each factor through the Gene Ontology (GO). This exploration revealed associations between some factors and GO biological processes; the complete and detailed results, including tables of the GO enrichment analyses for each factor and detailed biological descriptions, are available from the web site of supporting information.

Factors Related to ER: Figure 10 displays boxplots of fitted values of the factor scores for each sample, plotted across all 19 factors and stratified by levels of each of the clinical ER and Her2 (0/1/2) categories. For each sample i, the posterior mean of the factor vector, namely $\hat{\lambda}_i = (I_k + \Delta)^{-1}\Delta\Phi_Z'\Psi^{-1/2}x_i$, is evaluated at the estimated model, providing the fitted values displayed. We note strong association of ER status to factors 8 (GO: hormone metabolic process), 9 (GO: glucose metabolic process, negative regulation of MAPK activity), 12 (GO: C21-steroid hormone metabolic process), 14 (GO: apoptotic program, positive regulation of caspase activity), 18 (GO: M phase of meiotic cell cycle) and 19 (GO: regulation of Rab protein signal transduction). These clear relationships of ER status to multiple factors with intersecting but also distinct biological pathway annotations is consistent with the known complexity of the broader ER network, as estrogen receptor-induced signaling impacts multiple cellular growth and developmentally related downstream target genes and strongly defines expression factors linked to breast cancer progression.

Her2 Status and Oncogenomic Recombination Hotspot on 17q12: Figure 10 indicates factor 16 as strongly associated with Her2 status $(0,1)$ versus 2. Factor 16 significantly loads on only 7 genes that include STARD3, GRB7 and two probe sets on the locus of ERBB2 (which encodes Her2). This is consistent with earlier gene expression studies that have consistently identified a single expression pattern related to Her2 and a very small number of additional genes, and that have found the "low Her2 positives" level(1) to be generally comparable to negatives. Interestingly, we note that STARD3, GRB7 and ERBB2 are all located on the same chromosomal locus 17q12, which is known as PPP1R1B-STARD3-TCAP-PNMT-PERLD1-ERBB2-MGC14832-GRB7 locus. This locus has been reported in many studies (e.g., Katoh and Katoh, 2004) as an oncogenomic recombination hotspot which is amplified frequently in breast tumor cells, and the purely exploratory (i.e., unsupervised) GFM analysis clearly identifies the "Her2 factor" as strongly reflective of increased expression of genes in this hotspot, consistent with the amplification inducing Her2 positivity.

Comparison to Non-sparse Analysis: Finally, we show a comparison to non-sparse traditional PCA. Supplementary Fig.1 and 2 show the estimated factors (principal components) corresponding to the most dominant 19 eigenvalues, stratified by the levels of ER and Her2. The PCA failed to capture the existing factor relevant to Her2-specific phenotypes in the analysed data. Note that the foregoing sparse analysis identified the Her2-relevant factor only through the 7 non-zero loadings. Indeed, our post-analysis has found that the data set contains very few genes exhibiting significant fold change across the Her2 phenotypes. The non-sparse analysis would capture many irrelevant features through too redundant non-zero loadings. The failure of PCA signifies the importance of sparse modelling in handling high-dimensional data having inherently sparse structure.

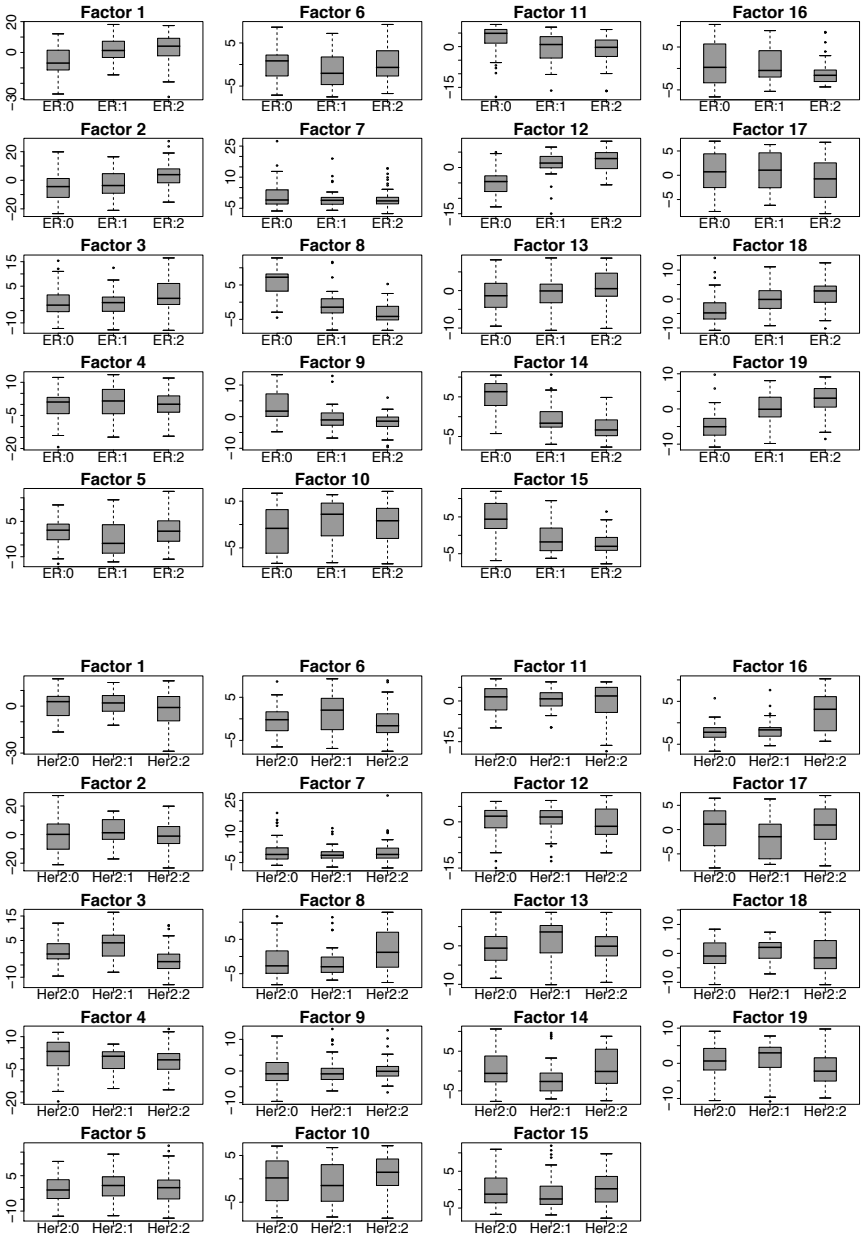

Figure 10: Boxplots of fitted values of breast tumor-specific factor scores, stratified by protein IHC determinations of clinical ER status (upper) and Her2 status (lower) in their 0/1/2 categories.

8. Additional Comments

The novel graphical property of GFMs provides a nice reconciliation of sparse covariance models with sparse precision models—sparse latent factor analysis and graphical models, respectively. Some of the practical benefits of this arise from the ability of GFM to define data reconstructions

exhibiting the same patterns of covariances as the model/data predict, and the potential to induce robustness to outliers relative to non-graphical factor models, whether sparse or not. Some theoretical questions remain about precise conditions under which the sparsity patterns of covariance and precision matrices are guaranteed to agree in general sparse Gaussian factor models other than the GFM form. Additionally, extensions to integrate non-parametric Bayesian model components for factors, following Carvalho et al. (2008), are of clear future interest.

The ability of the VMA2 to aid in the identification of model structure in sparse GFM, and to provide an additional computational strategy and tools to address the inherently challenging combinatorial optimization problem, has been demonstrated in our examples. Scaling to higher dimensional models is enabled by relaxation of the direct deterministic optimization viewpoint, with stochastic search components that promote greater exploration of model space and can speed up search substantially. Nevertheless, moving to higher dimensions will require new, creative computational implementations, such as using distributed computing, that will themselves require novel methodological concepts.

The annealed search methodology evidently will apply in other contexts beyond factor models. At one level, sparse factor models are an instance of problems of variable selection in multivariate regression, in which the regression predictors (feature variables) are themselves unknown (i.e., are the factors). The annealed entropy approach is therefore in principle applicable to problems involving regression model search and uncertainly in general classes of linear or nonlinear multivariate regression with potentially many predictor variables. Beyond this, the same can be said about potential uses in other areas of graphical modelling involving structural inference of directed or undirected graphical models, and also in multivariate time series problems where some of the sparse structure may relate to relationships among variables over time.

We also remark on generalization of the basic form of VMA2 here that might use penalty functions other than the Shannon's entropy used here. The central idea of the VMA2 is the design of a temperature-controlled iterative optimization that converges to the joint posterior distribution of model parameters and sparse structure indicators. The entropy formulation used in our GFM context was inspired by the form of the posterior itself, but similar algorithms—with the same convergent property—could be designed using other forms. This, along with computational efficiency questions and applications in models beyond the sparse GFM framework, and also potential extensions to consider heavy-tailed or Bayesian nonparametric distributions for latent factors and/or residuals (e.g., Carvalho et al., 2008), are open areas for future research.

Appendix A.

We present a proof of Proposition 1 and a derivation of optimization over Φ.

A.1 Proof of Proposition 1

Replace the objective function of (5) by multiplying by inverse temperature $1/T$:

$$\frac{1}{T}\mathcal{G}_T(\Theta,\omega) = \sum_{Z\in\mathscr{Z}} \omega(Z)\log p(X,Z,\Theta|\zeta)^{1/T} - \sum_{Z\in\mathscr{Z}} \omega(Z)\log\omega(Z).$$

An upper-bound of this modified criterion is derived as follows:

$$\begin{aligned}
\frac{1}{T}\mathcal{G}_T(\Theta,\omega) &= \sum_{Z\in\mathscr{Z}} \omega(Z)\log\frac{p(Z|X,\Theta,\zeta)^{1/T}p(X,\Theta|\zeta)^{1/T}}{\omega(Z)} \\
&= \sum_{Z\in\mathscr{Z}} \omega(Z)\log\frac{p(Z|X,\Theta,\zeta)^{1/T}}{\omega(Z)\sum_{Z'\in\mathscr{Z}} p(Z'|X,\Theta,\zeta)^{1/T}} + K_0 \\
&\leq K_0.
\end{aligned}$$

In the second equality, the terms irrelevant to $\omega(Z)$ are included in $K_0 = \log p(X,\Theta|\zeta)^{1/T} + \log\sum_{Z'\in\mathscr{Z}} p(Z'|X,\Theta,\zeta)^{1/T}$. The first term in the second line is the negative of the Kullback-Leibler divergence between $\omega(Z)$ and the normalized tempered posterior distribution. The lower-bound of the Kullback-Leibler divergence is attained if and only if

$$\omega(Z) = \frac{p(Z|X,\Theta,\zeta)^{1/T}}{\sum_{Z'\in\mathscr{Z}} p(Z'|X,\Theta,\zeta)^{1/T}},$$

as required.

A.2 Derivation: Optimization over Φ

Let ρ_j, $j\in\{1,\ldots,k\}$ be the Lagrange multipliers to ensure the restrictions in (10). We now write down the Lagrange function:

$$\phi_j'\mathbb{E}_\omega[S(z_j,\Psi)]\phi_j - \rho_j(\|\phi_j\|^2-1) - \sum_{m\neq j}\rho_m\phi_m'\phi_j. \tag{13}$$

Differentiation of (13) with respect to ϕ_j yields

$$\mathbb{E}_\omega[S(z_j,\Psi)]\phi_j - \rho_j\phi_j - \sum_{m\neq j}\rho_m\phi_m = 0. \tag{14}$$

In order to solve this equation, the first step to be addressed is to find the closed form solution for the vector of the Lagrange multipliers, $\rho_{(-j)} = \{\rho_m\}_{m\neq j}\in\mathbb{R}^{k-1}$. Multiplying (14) by each ϕ_m', $m\neq j$, from the left, we have the $k-1$ equations as follows:

$$\phi_m'\mathbb{E}_\omega[S(z_j,\Psi)]\phi_j - \sum_{m\neq j}\rho_m\phi_m'\phi_j = 0 \quad \text{for } m \text{ s.t. } m\neq j.$$

This yields the matrix representation

$$\Phi'_{(-j)}\mathbb{E}_\omega[S(z_j,\Psi)]\phi_j - \Phi'_{(-j)}\Phi_{(-j)}\rho_{(-j)} = 0,$$

which in turn leads to the solution for $\rho_{(-j)}$ as

$$\rho_{(-j)} = (\Phi'_{(-j)}\Phi_{(-j)})^{-1}\Phi'_{(-j)}\mathbb{E}_\omega[S(z_j,\Psi)]\phi_j.$$

Substituting this into the original Equation (14) yields the eigenvalue equation

$$N_j\mathbb{E}_\omega[S(z_j,\Psi)]\phi_j - \rho_j\phi_j = 0 \quad \text{with } N_j = I - \Phi_{(-j)}\Phi'_{(-j)}. \tag{15}$$

Now consider the alternative, symmetrized eigenvalue equation

$$N_j\mathbb{E}_\omega[S(z_j,\Psi)]N_j\varphi_j - \rho_j\varphi_j = 0. \tag{16}$$

Since N_j is idempotent, left-multiplication of (16) by N_j yields

$$N_j\mathbb{E}_\omega[S(z_j,\Psi)]N_j\varphi_j - \rho_j N_j\varphi_j = 0.$$

which is equivalent to the required Equation (15) when $\phi_j = N_j\varphi_j$.

Abstract

We have developed a machine learning toolbox, called SHOGUN, which is designed for unified large-scale learning for a broad range of feature types and learning settings. It offers a considerable number of machine learning models such as support vector machines, hidden Markov models, multiple kernel learning, linear discriminant analysis, and more. Most of the specific algorithms are able to deal with several different data classes. We have used this toolbox in several applications from computational biology, some of them coming with no less than 50 million training examples and others with 7 billion test examples. With more than a thousand installations worldwide, SHOGUN is already widely adopted in the machine learning community and beyond. SHOGUN is implemented in C++ and interfaces to *MATLAB*™ *R*, *Octave*, *Python*, and has a stand-alone command line interface. The source code is freely available under the GNU General Public License, Version 3 at `http://www.shogun-toolbox.org`.

Keywords: support vector machines, kernels, large-scale learning, Python, Octave, R

1. Introduction

With the great advancements of machine learning in the past few years, many new learning algorithms have been proposed, implemented in C/C++, and made publicly available. Their availability

has enabled systematic comparisons between newly developed methods, leading to an increased visibility, and supporting their broad adoption in the community of machine learning as well as in many others (see discussion in Sonnenburg *et al*., 2007). However, for example, there currently exist more than 20 different publicly available implementations of Support Vector Machine (SVM) solvers. Each one comes with its own interface, a small set of available kernel functions, and unique benefits and drawbacks. There is no single unified way of interfacing with these implementations, even though they all are based on essentially the same methodology of supervised learning. This restraints users from fully taking advantage of the recent developments in machine learning algorithms.

This motivated us to develop a machine learning toolbox that provides an easy, unified way for solving certain types of machine learning problems. The result is a toolbox, called SHOGUN, with a focus on large-scale learning using kernel methods and SVMs. It provides a generic interface to 15 SVM implementations, among them SVMlight, LibSVM, GPDT, SVMLin, LibLinear, and OCAS. The SVMs can be easily combined with more than 35 different kernel functions.[1] The toolbox not only provides efficient implementations of the most common kernels, like the linear, polynomial, Gaussian, and sigmoid, but also comes with several recently developed kernels such as the locality improved, Fisher, TOP, spectrum, and the WD kernels for sequence analysis (see Sonnenburg et al., 2007; Ben-Hur et al., 2008; Schweikert *et al*., 2009, and references therein). Moreover, it offers options for using precomputed kernels and allows easy integration of new implementations of kernels. One of SHOGUN's key features is the *combined kernel* to construct weighted linear combinations of multiple kernels that may even be defined on different input domains. Also, several Multiple Kernel Learning algorithms based on different regularization strategies are available to optimize the weighting of the kernels (e.g., Sonnenburg et al., 2006a; Kloft et al., 2010).

Currently, two- and multiclass classification and regression are best supported. In addition to kernel and distance based methods, SHOGUN implements many linear methods and features algorithms to train hidden Markov models. Furthermore, it provides the basic functionality for solving label sequence learning problems (Hidden Semi-Markov SVMs; cf. Rätsch and Sonnenburg, 2007; Schweikert *et al*., 2009). The input feature objects can be dense or sparse vectors of strings, integers (8, 16, 32 or 64 bit; signed or unsigned), or floating point numbers (32 or 64 bit), and can be converted into different feature types. Chains of "pre-processors" (e.g., subtracting the mean) can be attached to each feature object allowing on-the-fly pre-processing. Finally, several commonly used performance measures, like accuracy and area under ROC or precision-recall curves, are implemented in SHOGUN.

An important aspect in the design of SHOGUN was to enable very large-scale learning. It is structured in a way that there is as little as possible overhead for storing the data and intermediate results. Moreover, whenever possible, we implemented auxiliary routines that allow faster computation of combinations of kernel elements that lead to significant speedup during training (for some SVM implementations, e.g., SVMlight and GPDT) and evaluation (Sonnenburg et al., 2007). Furthermore, linear SVMs can be efficiently trained using on the fly computed feature spaces, even mixing sparse, dense and other data types.

This allowed us to use SHOGUN for solving several large-scale learning problems in biological sequence analysis, for example, splice site recognition with up to 50 million example sequences for training (Sonnenburg et al., 2007; Franc and Sonnenburg, 2009) and transcription start site recog-

1. Complete lists of SVM and kernel implementations together with user and developer documentation is available at `http://www.shogun-toolbox.org/doc`.

nition with almost 7 billion test sequences (Sonnenburg et al., 2006b). SHOGUN's core functions are encapsulated in a library (`libshogun`) and are easily accessible and extendible by C++ application developers. What sets SHOGUN apart from many other machine learning toolboxes, is that it provides interactive user interfaces to most major scripting languages that are currently used in scientific computing, in particular *Python*, *MATLAB*, *Octave*, *R*, and a command-line version.

All classes and functions are documented and come with over 600 examples and a tutorial for new users and developers is part of the release.[2] Furthermore, there is an open access tutorial on SVMs (Ben-Hur et al., 2008) that provides a SHOGUN-based command-line tool for illustrative examples (available at `http://svmcompbio.tuebingen.mpg.de`). Maintaining high code quality is ensured by a test suite that supports running the algorithms for each interface on predefined inputs in order to detect breakage. SHOGUN runs on POSIX platforms, such as *Linux*, *BSD*, *Mac OS X*, *Cygwin*, and *Solaris*.

2. Modular, Extendible Object-Oriented Design

SHOGUN is implemented in an object-oriented way using C++ as the programming language. All objects inherit from `CSGObject`, which provides means for garbage collection via reference counting, serialization, and versioning of the object. The implementations of many classes employ *templates* enabling SHOGUN's support of many different data types without code duplication. As the source code and user documentation is automatically generated using `doxygen` and written in-place in the header files, it also drastically reduces the amount of work needed to maintain the documentation. As an example of SHOGUNs object-oriented design, consider the class `CClassifier`: From this class, `CKernelMachine`, for example, is derived and provides basic functions for applying a trained kernel classifier (computing $f(\mathbf{x}) = \sum_{i=1}^{N} \alpha_i \mathrm{k}(\mathbf{x}, \mathbf{x}_i) + b$) thus enabling code re-use whenever possible. The same holds for `CDistanceMachine` and `CLinearClassifier` (which provides $f(\mathbf{x}) = \mathbf{w} \cdot \mathbf{x} + b$ etc.). Currently, SHOGUN implements 329 classes (see Figure 1 in supplementary material available at `http://www.shogun-toolbox.org/jmlr10` for a sketch of the main classes).[3]

3. Interfaces to Scripting Languages and Applications

Built around SHOGUN's core are two types of interfaces: A modular interface that makes use of the SWIG (`http://www.swig.org`), and a static interface. Thanks to SWIG, the modular interface provides the exact same objects in a modular object-oriented way that are available from C++ to other languages, such as *R*, *Python*, and *Octave*. Using so-called `typemaps`, it is convenient to provide type mappings from the native datatype used in the interface to SHOGUN. For example, a function `void set_features(double* features, int n, int m)` can be called directly from *Octave* with a single matrix argument, for example, `set_features(randn(3,4))`. The variables *n* and *m* are then automatically set to the matrix dimensions and together with a data pointer passed to the SHOGUN core.

SHOGUN also provides a static interface with the same structure for all supported plattforms , including the command-line interface where inputs are provided as either strings or files. It is

2. Examples are also accessible online at `http://www.shogun-toolbox.org/doc/examples.html`.
3. See `http://www.shogun-toolbox.org/doc/annotated.html` for the full annotated class listing.

implemented independent of the target language through the class `CSGInterface`, which provides abstract functions to deliver or obtain data from any particular plattform.

A community around SHOGUN is continuously developing, with a growing number of projects building on it (cf. `http://mloss.org/software/tags/shogun`) and a mailing list with more than 100 subscribed users.[4] By 10/2009, there had been at least 1,100 installations under the *Linux* distributions *Debian* and *Ubuntu*. We will continue to develop SHOGUN and are confident that it is and will continue to be useful, and will make an increasing impact beyond the machine learning community by benefiting diverse applications.

Editor: Carl Edward Rasmussen

Abstract

After building a classifier with modern tools of machine learning we typically have a black box at hand that is able to predict well for unseen data. Thus, we get an answer to the question *what* is the most likely label of a given unseen data point. However, most methods will provide no answer *why* the model predicted a particular label for a single instance and what features were most influential for that particular instance. The only method that is currently able to provide such explanations are decision trees. This paper proposes a procedure which (based on a set of assumptions) allows to explain the decisions of *any* classification method.

Keywords: explaining, nonlinear, black box model, kernel methods, Ames mutagenicity

1. Introduction

Automatic nonlinear classification is a common and powerful tool in data analysis. Machine learning research has created methods that are practically useful and that can classify unseen data after being trained on a limited training set of labeled examples.

Nevertheless, most of the algorithms do not *explain* their decision. However in practical data analysis it is essential to obtain an instance-based explanation, that is, we would like to gain an

∗. The first three authors contributed equally.
†. Also at Technische Universität Berlin, Franklinstr. 28/29, FR 6-9, 10587 Berlin, Germany.

understanding what input features made the nonlinear machine give its answer for each individual data point.

Typically, explanations are provided jointly for all instances of the training set, for example feature selection methods (including Automatic Relevance Determination) find out which inputs are salient for a good generalization (see Guyon and Elisseeff, 2003, for a review). While this can give a coarse impression about the global usefulness of each input dimension, it is still an ensemble view and does not provide an answer on an instance basis.[1] In the neural network literature also solely an ensemble view was taken in algorithms like input pruning (e.g., Bishop, 1995; LeCun et al., 1998). The only classification that does provide individual explanations are decision trees (e.g., Hastie et al., 2001).

This paper proposes a simple framework that provides local explanation vectors applicable to *any* classification method in order to help understanding prediction results for single data instances. The local explanation yields the features relevant for the prediction at the very points of interest in the data space, and is able to spot local peculiarities that are neglected in the global view, for example, due to cancellation effects.

The paper is organized as follows: We define local explanation vectors as class probability gradients in Section 2 and give an illustration for Gaussian Process Classification (GPC). Some methods output a prediction without a direct probability interpretation. For these we propose in Section 3 a way to estimate local explanations. In Section 4 we apply our methodology to learn distinguishing properties of Iris flowers by estimating explanation vectors for a k-NN classifier applied to the classic Iris data set. In Section 5 we discuss how our approach applied to a SVM classifier allows us to explain how digit "2" is distinguished from digit "8" in the USPS data set. In Section 6 we focus on a more real-world application scenario where the proposed explanation capabilities prove useful in drug discovery: Human experts regularly decide how to modify existing lead compounds in order to obtain new compounds with improved properties. Models capable of explaining predictions can help in the process of choosing promising modifications. Our automatically generated explanations match with chemical domain knowledge about toxifying functional groups of the compounds in question. Section 7 contrasts our approach with related work and Section 8 discusses characteristic properties and limitations of our approach, before we conclude the paper in Section 9.

2. Definitions of Explanation Vectors

In this Section we will give definitions for our approach of local explanation vectors in the classification setting. We start with a theoretical definition for multi-class Bayes classification and then give a specialized definition being more practical for the binary case.

For the multi-class case, suppose we are given data points $x_1, \ldots, x_n \in \Re^d$ with labels $y_1, \ldots, y_n \in \{1, \ldots, C\}$ and we intend to learn a function that predicts the labels of unlabeled data points. Assuming that the data is IID-sampled from some unknown joint distribution $P(X, Y)$, we define the

1. This point is illustrated in Figure 1 (Section 2). Applying feature selection methods to the training set (a) will lead to the (correct) conclusion that both dimensions are equally important for accurate classification. As an alternative to this ensemble view, one may ask: Which features (or combinations thereof) are most influential in the vicinity of each particular instance. As can be seen in Figure 1 (c), the answer depends on where the respective instance is located. On the hypotenuse and at the corners of the triangle, both features contribute jointly, whereas along each of the remaining two edges the classification depends almost completely on just one of the features.

Bayes classifier,

$$g^*(x) = \arg\min_{c \in \{1,\ldots,C\}} P(Y \neq c \mid X = x)$$

which is optimal for the 0-1 loss function (see Devroye et al., 1996).

For the Bayes classifier we define the *explanation vector* of a data point x_0 to be the derivative with respect to x at $x = x_0$ of the conditional probability of $Y \neq g^*(x_0)$ given $X = x$, or formally,

Definition 1

$$\zeta(x_0) := \frac{\partial}{\partial x} P(Y \neq g^*(x) \mid X = x)\Big|_{x=x_0}.$$

Note that $\zeta(x_0)$ is a d-dimensional vector just like x_0 is. The classifier g^* partitions the data space $\Re^d$ into up to C parts on which g^* is constant. We assume that the conditional distribution $P(Y = c \mid X = x)$ is first-order differentiable w.r.t. x for all classes c and over the entire input space. For instance, this assumption holds if $P(X = x \mid Y = c)$ is for all c first-order differentiable in x and the supports of the class densities overlap around the border for all neighboring pairs in the partition by the Bayes classifier. The vector $\zeta(x_0)$ defines on each of those parts a vector field that characterizes the flow away from the corresponding class. Thus entries in $\zeta(x_0)$ with large absolute values highlight features that will influence the class label decision of x_0. A positive sign of such an entry implies that increasing that feature would lower the probability that x_0 is assigned to $g^*(x_0)$. Ignoring the orientations of the explanation vectors, ζ forms a continuously changing (orientation-less) vector field along which the class labels change. This vector field lets us *locally* understand the Bayes classifier.

We remark that $\zeta(x_0)$ becomes a zero vector, for example, when $P(Y \neq g^*(x) \mid X = x)|_{x=x_0}$ is equal to one in some neighborhood of x_0. Our explanation vector fits well to classifiers where the conditional distribution $P(Y = c \mid X = x)$ is usually not completely flat in some regions. In the case of deterministic classifiers, despite of this issue, Parzen window estimators with appropriate widths (Section 3) can provide meaningful explanation vectors for many samples in practice (see also Section 8).

In the case of binary classification we directly define local explanation vectors as local gradients of the probability function $p(x) = P(Y = 1 \mid X = x)$ of the learned model for the positive class.

For a probability function $p : \Re^d \to [0,1]$ of a classification model learned from examples $\{(x_1, y_1), \ldots, (x_n, y_n)\} \in \Re^d \times \{-1, +1\}$ the explanation vector for a classified test point x_0 is the local gradient of p at x_0:

Definition 2

$$\eta_p(x_0) := \nabla p(x)|_{x=x_0}.$$

By this definition the explanation η is again a d-dimensional vector just like the test point x_0 is. The sign of each of its individual entries indicates whether the prediction would increase or decrease when the corresponding feature of x_0 is increased locally and each entry's absolute value gives the amount of influence in the change in prediction. The vector η gives the direction of the steepest ascent from the test point to higher probabilities for the positive class. For binary classification the negative version $-\eta_p(x_0)$ indicates the changes in features needed to increase the probability for the negative class which may be especially useful for x_0 predicted in the positive class.

For an example we apply Definition 2 to model predictions learned by Gaussian Process Classification (GPC), see Rasmussen and Williams (2006). GPC is used here for three reasons:
(i) In our real-world application we are interested in classifying data from drug discovery, which is an area where Gaussian processes have proven to show state-of-the-art performance, see, for example, Obrezanova and Segall (2010), Obrezanova et al., Schroeter et al. (2007c), Schroeter et al. (2007a), Schroeter et al. (2007b), Schwaighofer et al. (2007), Schwaighofer et al. (2008) and Obrezanova et al. (2008). It is natural to expect a model with high prediction accuracy on a complex problem to capture relevant structure of the data which is worth explaining and may give domain specific insights in addition to the values predicted. For an evaluation of the explaining capabilities of our approach on a complex problem from chemoinformatics see Section 6.
(ii) GPC does model the class probability function used in Definition 2 directly. For other classification methods such as Support Vector Machines that do not provide a probability function as its output we give an example for an estimation method starting from Definition 1 in Section 3.
(iii) The local gradients of the probability function can be calculated analytically for differentiable kernels as we discuss next.

Let $\overline{f}(x) = \sum_{i=1}^{n} \alpha_i k(x, x_i)$ be a Gaussian Process (GP) model trained on sample points $x_1, \ldots, x_n \in \Re^d$ where k is a kernel function and α_i are the learned weights of each sample point. For a test point $x_0 \in \Re^d$ let $\mathrm{var}_f(x_0)$ be the variance of $f(x_0)$ under the GP posterior of f. Because the posterior cannot be calculated analytically for GP classification models, we used an approximation by expectation propagation (EP) (Kuss and Ramussen, 2005). In the case of the probit likelihood term defined by the error function, the probability for being of the positive class $p(x_0)$ can be computed easily from this approximated posterior as

$$p(x_0) = \frac{1}{2}\mathrm{erfc}\left(\frac{-\overline{f}(x_0)}{\sqrt{2}\cdot\sqrt{1+\mathrm{var}_f(x_0)}}\right),$$

where erfc denotes the complementary error function (see Equation 6 in Schwaighofer et al., 2008). Then the local gradient of $p(x_0)$ is given by[2]

$$\nabla p(x)|_{x=x_0} = \frac{\exp\left(\frac{-\overline{f}(x_0)^2}{2(1+\mathrm{var}_f(x_0))}\right)}{\sqrt{2\pi}}\left(\frac{\nabla\overline{f}(x)|_{x=x_0}}{\sqrt{1+\mathrm{var}_f(x_0)}} - \frac{1}{2}\frac{\overline{f}(x_0)}{(1+\mathrm{var}_f(x_0))^{\frac{3}{2}}}\nabla\mathrm{var}_f(x)|_{x=x_0}\right). \quad (1)$$

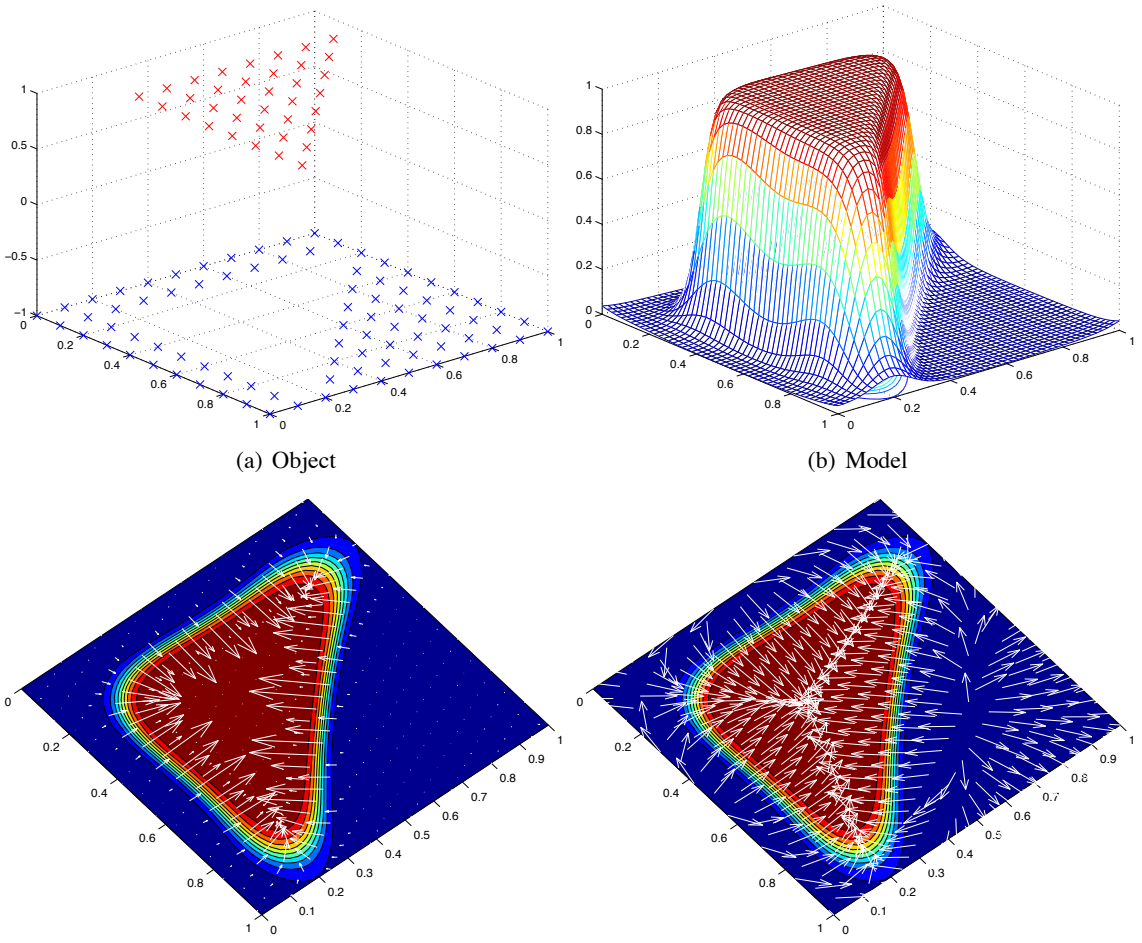
As a kernel function choose, for example, the RBF-kernel $k(x_0, x_1) = \exp(-w(x_0 - x_1)^2)$, which has the derivative $(\partial/\partial x_{0,j})k(x_0, x_1) = -2w\exp(-w(x_0 - x_1)^2)(x_{0,j} - x_{1,j})$ for $j \in \{1, \ldots, d\}$. Then the elements of the local gradient $\nabla\overline{f}(x)|_{x=x_0}$ are

$$\frac{\partial\overline{f}}{\partial x_{0,j}} = -2w\sum_{i=1}^{n}\alpha_i\exp(-w(x_0 - x_i)^2)(x_{0,j} - x_{i,j}) \quad \text{for } j \in \{1, \ldots, d\}.$$

2. For a detailed derivation, see Appendix A.1.

For $\text{var}_f(x_0) = k(x_0,x_0) - k_*^T(K+\Sigma)^{-1}k_*$ the derivative is given by[3]

$$\nabla \text{var}_f(x)|_{x=x_0} = \frac{\partial \text{var}_f}{\partial x_{0,j}} = \left(\frac{\partial}{\partial x_{0,j}}k(x_0,x_0)\right) - 2 * k_*^T(K+\Sigma)^{-1}\frac{\partial}{\partial x_{0,j}}k_* \quad \text{for } j \in \{1,\ldots,d\}.$$



(a) Object (b) Model

(c) Local explanation vectors (d) Direction of explanation vectors

Figure 1: Explaining simple object classification with Gaussian Processes

Panel (a) of Figure 1 shows the training data of a simple object classification task and panel (b) shows the model learned using GPC.[4] The data is labeled -1 for the blue points and $+1$ for the red points. As illustrated in panel (b) the model is a probability function for the positive class which gives every data point a probability of being in this class. Panel (c) shows the probability gradient of the model together with the local gradient explanation vectors. Along the hypotenuse and at the corners of the triangle explanations from both features interact towards the triangle class while along

3. Here $k_* = (k(x_0,x_1),\ldots,k(x_0,x_n))^T$ is the evaluation of the kernel function between the test point x_0 and every training point. Σ is the diagonal matrix of the variance parameter. For details see Rasmussen and Williams (2006, Chapter 3).
4. Hyperparameters were tuned by a gradient ascend on the evidence.

the edges the importance of one of the two feature dimensions dominates. At the transition from the negative to the positive class the length of the local gradient vectors represents the increased importance of the relevant features. In panel (d) we see that explanations close to the edges of the plot (especially in the right hand side corner) point away from the positive class. However, panel (c) shows that their magnitude is very small. For discussion of this issue see Section 8.

3. Estimating Explanation Vectors

Several classification methods directly estimate the decision rule, which often has no interpretation as the probability function in terms of Definition 2. For example Support Vector Machines estimate a decision function of the form

$$f(x) = \sum_{i=1}^{n} \alpha_i k(x_i, x) + b,$$

$\alpha_i, b \in \Re$. Suppose we have two classes (each with one cluster) in one dimension (see Figure 2) and train a SVM with RBF kernel. For points outside the data clusters $f(x)$ tends to zero. Thus, the derivative of $f(x)$ (shown as arrows above the curves) for points on the very left or on the very right side of the axis will point to the wrong side. In the following, we will explain how explanations can

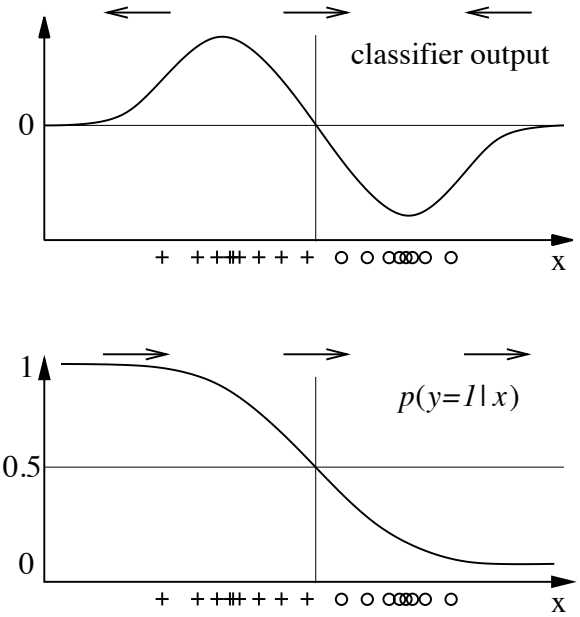


Figure 2: Classifier output of an SVM (top) compared to $p(y=1|x)$ (bottom).

be obtained for such classifiers.

In practice, we do not have access to the true underlying distribution $P(X,Y)$. Consequently, we have no access to the Bayes classifier as defined in Section 2. Instead, we can apply sophisticated learning machinery like Support Vector Machines (Vapnik, 1995; Schölkopf and Smola, 2002; Müller et al., 2001) that estimates some classifier g that tries to mimic g^*. For test data points $z_1, \ldots, z_m \in \Re^d$ which are assumed to be sampled from the same unknown distribution as the training data, g estimates labels $g(z_1), \ldots, g(z_m)$. Now, instead of trying to explain g^*, to which we have

no access, we will define explanation vectors that help us understand the classifier g on the test data points.

Since we do not assume that we have access to some intermediate real-valued classifier output here (of which g might be a thresholded version and which further might not be an estimate of $P(Y=c \mid X=x)$), we suggest to approximate g by another classifier $\hat{g}$, the actual form of which resembles the Bayes classifier. There are several choices for $\hat{g}$, for example, GPC, logistic regression, and Parzen windows.[5] In this paper we apply Parzen windows to the training points to estimate the weighted class densities $P(Y=c) \cdot P(X \mid Y=c)$, for the index set $I_c = \{i \mid g(x_i) = c\}$

$$\hat{p}_\sigma(x, y=c) = \frac{1}{n} \sum_{i \in I_c} k_\sigma(x - x_i) \tag{2}$$

and with $k_\sigma(z)$ being a Gaussian kernel $k_\sigma(z) = \exp(-0.5\, z^\top z/\sigma^2)/\sqrt{2\pi\sigma^2}$ (as always other kernels are also possible). This estimates $P(Y=c \mid X=x)$ for all c,

$$\hat{p}_\sigma(y=c|x) = \frac{\hat{p}_\sigma(x, y=c)}{\hat{p}_\sigma(x, y=c) + \hat{p}_\sigma(x, y\neq c)} \approx \frac{\sum_{i \in I_c} k_\sigma(x - x_i)}{\sum_i k_\sigma(x - x_i)} \tag{3}$$

and thus is an estimate of the Bayes classifier (that mimics g),

$$\hat{g}_\sigma(x) = \arg \min_{c \in \{1,\ldots,C\}} \hat{p}_\sigma(y \neq c \mid x).$$

This approach has the advantage that we can use our estimated classifier g to generate any amount of labeled data for constructing $\hat{g}$. The single hyper-parameter σ is chosen such that $\hat{g}$ approximates g (which we want to explain), that is,

$$\hat{\sigma} := \arg\min_\sigma \sum_{j=1}^{m} I\left\{ g(z_j) \neq \hat{g}_\sigma(z_j) \right\},$$

where $I\{\cdots\}$ is the indicator function. σ is assigned the constant value $\hat{\sigma}$ from here on and omitted as a subscript. For $\hat{g}$ it is straightforward to define explanation vectors:

Definition 3

$$\hat{\xi}(z) := \frac{\partial}{\partial x}\, \hat{p}(y \neq g(z) \mid x)\Big|_{x=z} = \frac{\left(\sum_{i \notin I_{g(z)}} k(z - x_i)\right)\left(\sum_{i \in I_{g(z)}} k(z - x_i)(z - x_i)\right)}{\sigma^2 \left(\sum_{i=1}^n k(z - x_i)\right)^2} - \frac{\left(\sum_{i \notin I_{g(z)}} k(z - x_i)(z - x_i)\right)\left(\sum_{i \in I_{g(z)}} k(z - x_i)\right)}{\sigma^2 \left(\sum_{i=1}^n k(z - x_i)\right)^2}.$$

This is easily derived using Equation (3) and the derivative of Equation (2), see Appendix A.3.1. Note that we use g instead of $\hat{g}$. This choice ensures that the orientation of $\hat{\xi}(z)$ fits to the labels assigned by g, which allows better interpretations.

In summary, we imitate the classifier g which we would like to explain locally by a Parzen window classifier $\hat{g}$ that has the same form as the Bayes estimator and for which we can estimate the

5. For Support Vector Machines Platt (1999) fits a sigmoid function to map the outputs to probabilities. In the following, we will present a more general method for estimating explanation vectors.

explanation vectors using Definition 3. Practically there are some caveats: The mimicking classifier $\hat{g}$ has to be estimated from g even in high dimensions; this needs to be done with care. However, in principle we have an arbitrary amount of training data available for constructing $\hat{g}$ since we may use our estimated classifier g to generate labeled data.

4. Explaining Iris Flower Classification by k-Nearest Neighbors

The Iris flower data set (introduced in Fisher, 1936) describes 150 flowers from the genus Iris by four features: sepal length, sepal width, petal length, and petal width, all of which are easily measured properties of certain leaves of the corolla of the flower. There are three clusters in this data set that correspond to three different species: *Iris setosa*, *Iris virginica*, and *Iris versicolor*.

Let us consider the problem of classifying the data points of *Iris versicolor* (class 0) against the other two species (class 1). We applied standard classification machinery to this problem as follows:

- Class 0 consists of all examples of *Iris versicolor*.
- Class 1 consists of all examples of *Iris setosa* and *Iris virginica*.
- Randomly split 150 data points into 100 training and 50 test examples.
- Normalize training and test set using the mean and variance of the training set.
- Apply k-nearest neighbor classification with $k = 4$ (chosen by leave-one-out cross-validation on the training data).
- Training error is 3% (i.e., 3 mistakes in 100).
- Test error is 8% (i.e., 4 mistakes in 50).

In order to estimate explanation vectors we mimic the classification results with a Parzen window classifier. The best fit (3% error) is obtained with a kernel width of $\sigma = 0.26$ (chosen by leave-one-out cross-validation on the training data).

Since the explanation vectors live in the input space we can visualize them with scatter plots of the initially measured features. The resulting *explanations* (i.e., vectors) for the test set are shown in Figure 3. The blue markers correspond to explanation vectors of *Iris setosa* and the red markers correspond to those of of *Iris virginica* (both class 1). Both groups of markers point to the green markers of *Iris versicolor*. The most important feature is the combination of petal length and petal width (see the corresponding panel), the product of which corresponds roughly to the area of the petals. However, the resulting explanations for the two species in class 1 are different:

- *Iris setosa* (class 1) is different from *Iris versicolor* (class 0) because its petal area is *smaller*.
- *Iris virginica* (class 1) is different from *Iris versicolor* (class 0) because its petal area is *larger*.

Also the dimensions of the sepal (another part of the blossom) are relevant, but not as distinguishing.

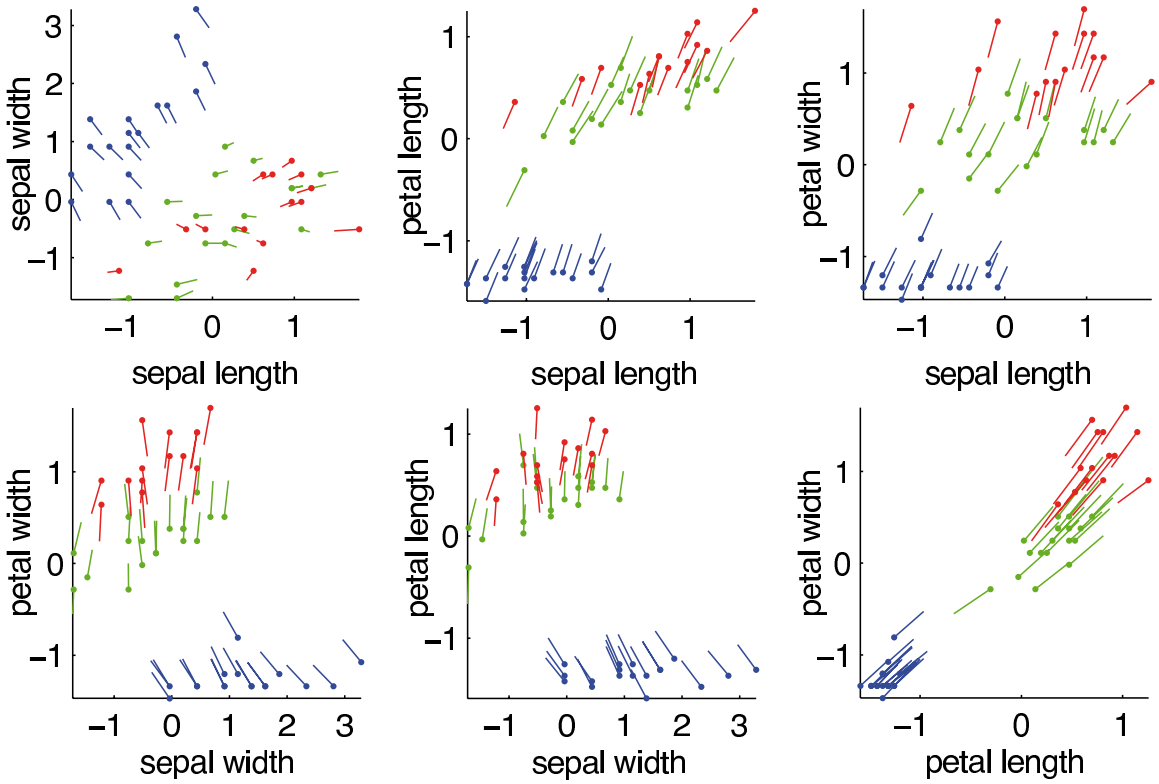

Figure 3: Scatter plots of the explanation vectors for the test data. Shown are all explanation vectors for both classes: class 1 containing *Iris setosa* (shown in blue) and *Iris virginica* (shown in red) versus class 0 containing only the species *Iris versicolor* (shown in green). Note that the explanations why an Iris flower is not an *Iris versicolor* is different for *Iris setosa* and *Iris virginica*.

5. Explaining USPS Digit Classification by Support Vector Machine

We now apply the framework of estimating explanation vectors to a high dimensional data set, the USPS digits. The classification problem that we designed for illustration purposes is detailed in the following list:

- digits: 16×16 images that are reshaped to 256×1 dimensional column vectors
- classifier: SVM from Schwaighofer (2002) with RBF kernel width $\sigma = 1$ and regularization constant $C = 10$ (chosen by grid search in cross-validation on the training data).
- training set: 47 "twos", 53 "eights"; training error 0.00
- test set: 48 "twos", 52 "eights"; test error 0.05

We approximated the estimated class labels obtained by the SVM with the Parzen window classifier (Parzen window size $\sigma = 10.2505$, chosen by grid search in cross-validation on the training data). The SVM and the Parzen window classifier only disagreed on 2% of the test examples, so a good

Figure 4: USPS digits (training set): "twos" (left) and "eights" (right) with correct classification. For each digit from left to right: (i) explanation vector (with black being negative, white being positive), (ii) the original digit, (iii-end) artificial digits along the explanation vector towards the other class.

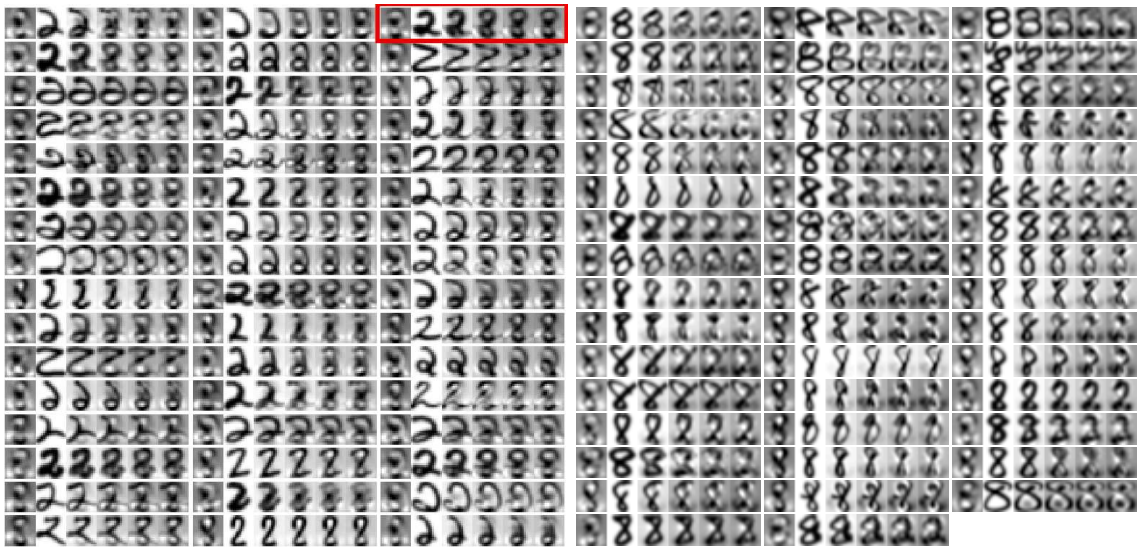

Figure 5: USPS digits (test set bottom part): "twos" (left) and "eights" (right) with correct classification. For each digit from left to right: (i) explanation vector (with black being negative, white being positive), (ii) the original digit, (iii-end) artificial digits along the explanation vector towards the other class.

fit was achieved. Figures 4 and 5 show our results. All parts show three examples per row. For each example we display from left to right: (i) the explanation vector, (ii) the original digit, (iii-end) artificial digits along the explanation vector towards the other class.[6] These artificial digits should help to understand and interpret the explanation vector. Let us first have a look at the results on the training set:

Figure 4 (left panel): Let us focus on the top example framed in red. The line that forms the "two" is part of some "eight" from the data set. Thus the parts of the lines that are missing show up in the explanation vector: if the dark parts (which correspond to the missing lines) are added to the "two" digit then it will be classified as an "eight". In other words, because of the lack of those parts the digit was classified as a "two" and not as an "eight". A similar explanation holds for the middle example framed in red in the same Figure. Not all examples transform easily to "eights": Besides adding parts of black lines, some existing black spots (that make the digit be a "two") must be removed. This is reflected in the explanation vector by white spots/lines. The bottom "two", framed in red, is actually a dash and is in the data set by mistake. However, its explanation vector shows nicely which parts have to be added and which have to be removed.

Figure 4 (right panel): We see similar results for the "eights" class. The explanation vectors again tell us how the "eights" have to change to become classified as "twos". However, sometimes the transformation does not reach the "twos". This is probably due to the fact that some of the "eights" are inside the cloud of "eights".

On the test set the explanation vectors are not as pronounced as on the training set. However, they show similar tendencies:

Figure 5 (left panel): We see the correctly classified "twos". Let's focus on the example framed in red. Again the explanation vector shows us how to edit the image of the "two" to transform it into an "eights", that is, exactly which parts of the digit were important for the classification result. For several other "twos" the explanation vectors do not directly lead to the "eights" but weight the different parts of the digits that were relevant for the classification.

Figure 5 (right panel): Similarly to the training data, we see that also these explanation vectors are not bringing all "eights" to "twos". Their explanation vectors mainly suggest to remove most of the "eights" (black pixels) and add some black in the lower part (the light parts, which look like a white shadow).

Overall, the explanation vectors tell us how to edit our example digits to change the assigned class label. Hereby, we get a better understanding of the reasons why the chosen classifier classified the way it did.

6. Explaining Mutagenicity Classification by Gaussian Processes

In the following Section we describe an application of our local gradient explanation methodology to a complex real world data set. Our aim is to find structure specific to the problem domain that has *not*

6. For the sake of simplicity, no intermediate updates were performed, that is, artificial digits were generated by taking equal-sized steps in the direction given by the original explanation vector calculated for the original digit.

been fed into training explicitly but is captured implicitly by the GPC model in the high-dimensional feature space used to determine its prediction. We investigate the task of predicting Ames mutagenic activity of chemical compounds. Not being mutagenic (i.e., not able to cause mutations in the DNA) is an important requirement for compounds under investigation in drug discovery and design. The Ames test (Ames et al., 1972) is a standard experimental setup for measuring mutagenicity. The following experiments are based on a set of Ames test results for 6512 chemical compounds that we published previously.[7]

GPC was applied as follows:

- Class 0 consists of non-mutagenic compounds.
- Class 1 consists of mutagenic compounds.
- Randomly split 6512 data points into 2000 training and 4512 test examples such that:
  - The training set consists of equally many class 0 and class 1 examples.
  - For the steroid compound class the balance in the training and test set is enforced.
- 10 additional random splits were investigated individually. This confirmed the results presented below.
- Each example (chemical compound) is represented by a vector of counts of 142 molecular substructures calculated using the DRAGON software (Todeschini et al., 2006).
- Normalize training and test set using the mean and variance of the training set.
- Apply GPC model with RBF kernel.
- Performance (84 % area under curve) confirms our previous results (Hansen et al., 2009). Error rates can be obtained from Figure 6.

Together with the prediction we calculated the explanation vector (as introduced in Definition 2) for each test point. The remainder of this Section is an evaluation of these local explanations.

In Figures 7 and 8 we show the distribution of the local importance of selected features across the test set: For each input feature we generate a histogram of local importance values, as indicated by its corresponding entry in the explanation vector of each of the 4512 test compounds. The features examined in Figure 7 are counts of substructures known to cause mutagenicity. We show all approved "specific toxicophores" introduced by Kazius et al. (2005) that are also represented in the DRAGON set of features. The features shown in Figure 8 are known to detoxify certain toxicophores (again see Kazius et al., 2005). With the exception of 7(e) the toxicophores also have a toxifying influence according to our GPC prediction model. Feature 7(e) seems to be mostly irrelevant for the prediction of the GPC model on the test points. In contrast the detoxicophores show overall negative influence on the prediction outcome of the GPC model. Modifying the test compounds by adding toxicophores will increase the probability of being mutagenic as predicted by the GPC model while adding detoxicophores will decrease this predicted probability.

7. See Hansen et al. (2009) for results of modeling this set using different machine learning methods. The data itself is available online at `http://ml.cs.tu-berlin.de/toxbenchmark`.

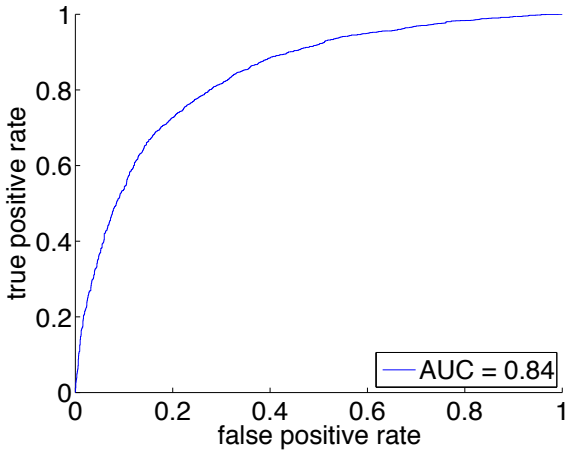

Figure 6: Receiver operating characteristic curve of GPC model for mutagenicity prediction

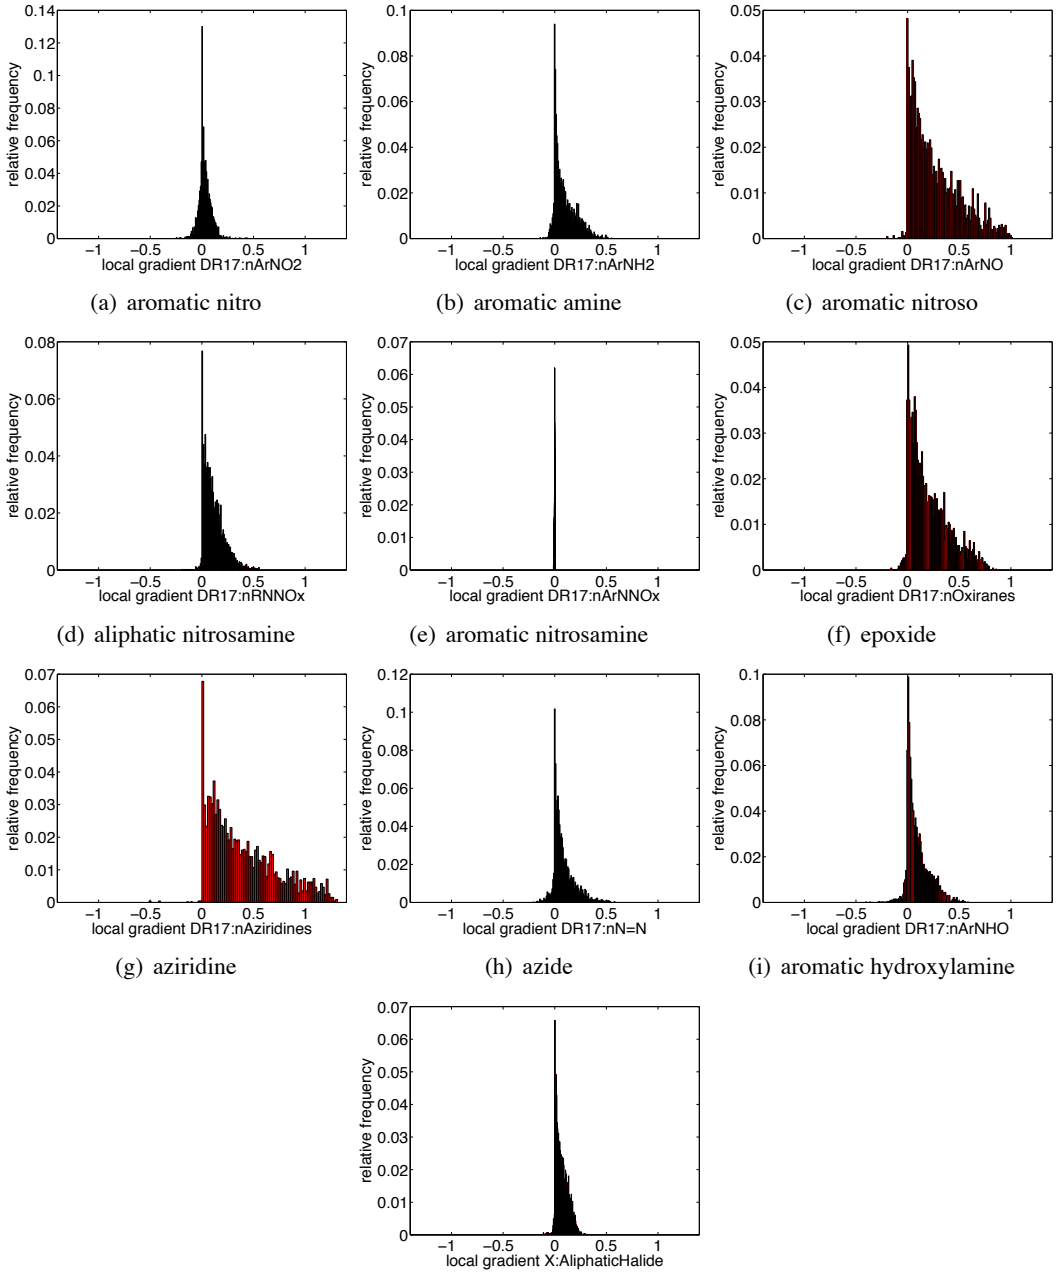
We have seen that the conclusions drawn from our explanation vectors agree with established knowledge about toxicophores and detoxicophores. While this is reassuring, such a sanity check required existing knowledge about which compounds are toxicophores and detoxicophores and which are not. Thus it is interesting to ask whether we also could have *discovered* that knowledge from the explanation vectors. To answer this question we ranked all 142 features by the means of their local gradients.[8] Clear trends result: 9 out of 10 known toxicophores can be found close to the top of the list (mean rank of 19). The only exception (rank 81) is the aromatic nitrosamine feature.[9] This trend is even stronger for the detoxicophores: The mean rank of these five features is 138 (out of 142), that is, they consistently exhibit the largest negative local gradients. Consequently, the established knowledge about toxicophores and detoxicophores could indeed have been *discovered* using our methodology.

In the following paragraph we will discuss steroids[10] as an example of an important compound class for which the meaning of features differs from this global trend, so that local explanation vectors are needed to correctly identify relevant features.

Figure 9 displays the difference in relevance of epoxide (a) and aliphatic nitrosamine (c) substructures for the predicted mutagenicity of steroids and non-steroid compounds. For comparison we also show the distributions for compounds chosen at random from the test set (b,d). Each subfigure contains two measures of (dis-)similarity for each pair of distributions. The p-value of the Kolmogorov-Smirnoff test (KS) gives the probability of error when rejecting the hypothesis that both relative frequencies are drawn from the same underlying distribution. The symmetrized

8. Tables resulting from this ranking are made available as a supplement to this paper and can be downloaded from the journals website.
9. This finding agrees with the result obtained by visually inspecting Figure 7(e). We found that only very few compounds with this feature are present in the data set. Consequently, detection of this feature is only possible if enough of these few compounds are included in the training data. This was not the case in the random split used to produce the results presented above.
10. Steroids are natural products and occur in humans, animals, and plants. They have a characteristic backbone containing four fused carbon-rings. Many hormones important to the development of the human body are steroids, including androgens, estrogens, progestagens, cholesterol and natural anabolics. These have been used as starting points for the development of many different drugs, including the most reliable contraceptives currently on the market.



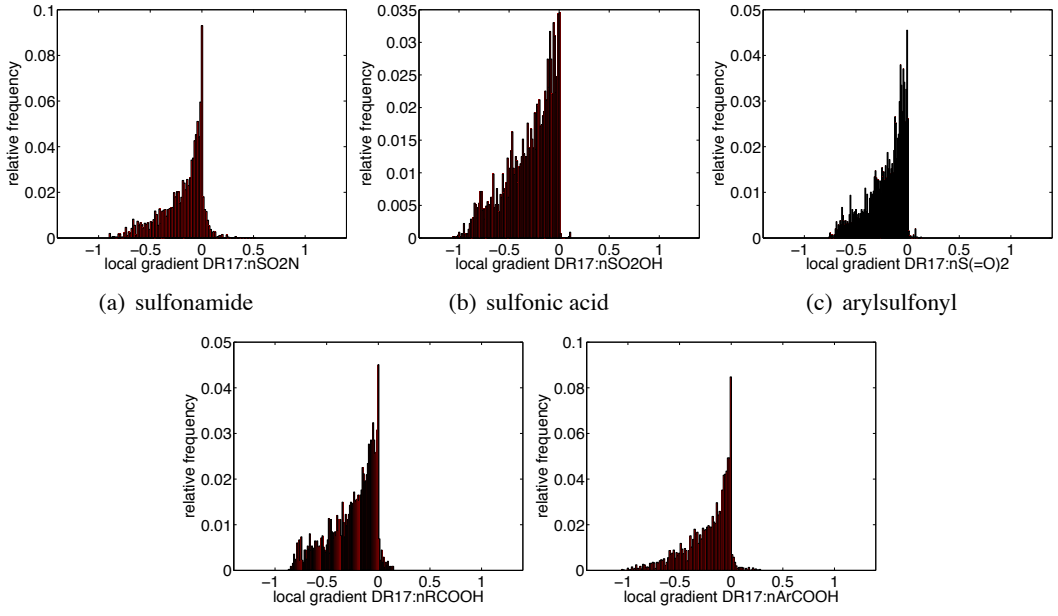
(a) aromatic nitro (b) aromatic amine (c) aromatic nitroso

(d) aliphatic nitrosamine (e) aromatic nitrosamine (f) epoxide

(g) aziridine (h) azide (i) aromatic hydroxylamine

(j) aliphatic halide

Figure 7: Distribution of local importance of selected features across the test set of 4512 compounds. Nine out of ten known toxicophores (Kazius et al., 2005) indeed exhibit positive local gradients.



(a) sulfonamide (b) sulfonic acid (c) arylsulfonyl

(d) aliphatic carboxylic acid (e) aromatic carboxylic acid

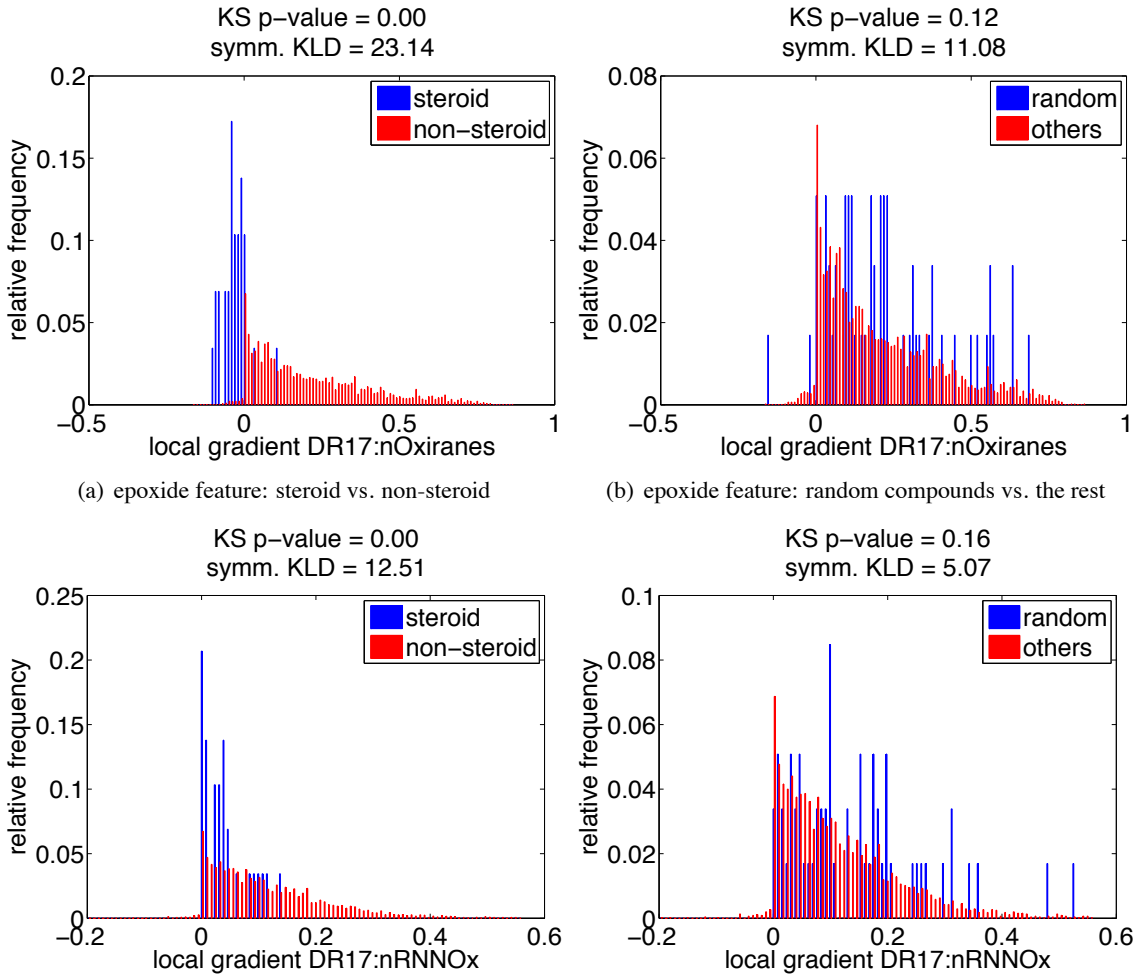
Figure 8: Distribution of local importance of selected features across the test set of 4512 compounds. All five known detoxicophores exhibit negative local gradients

Kullback-Leibler divergence (KLD) gives a metric of the distance between the two distributions.[11] While containing epoxides generally tends to make molecules mutagenic (see discussion above), we do not observe this effect for steroids: In Figure 9(a), almost all epoxide containing non-steroids exhibit positive gradients, thereby following the global distribution of epoxide containing compounds as shown in Figure 7(f). In contrast, almost all epoxide containing steroids exhibit gradients just below zero. "Immunity" of steroids to the epoxide toxicophore is an established fact and has first been discussed by Glatt et al. (1983). This peculiarity in chemical space is clearly exhibited by the local explanation given by our approach. For aliphatic nitrosamine, the situation in the GPC model is less clear but still the toxifying influence seems to be less in steroids than in many other compounds. To our knowledge, this phenomenon has not yet been discussed in the pharmaceutical literature.

In conclusion, we can learn from the explanation vectors that:

- Toxicophores tend to make compounds mutagenic (class 1).
- Detoxicophores tend to make compounds non-mutagenic (class 0).
- Steroids are immune to the presence of some toxicophores (epoxide, possibly also aliphatic nitrosamine).

11. Symmetry is achieved by averaging the two Kullback-Leibler divergences: $\frac{KL(P1,P2)+KL(P2,P1)}{2}$, compare to Johnson and Sinanovic (2000). To prevent zero-values in the histograms which would lead to infinite KL distances, an $\varepsilon > 0$ has been added to each bin count.



(a) epoxide feature: steroid vs. non-steroid

(b) epoxide feature: random compounds vs. the rest

(c) aliphatic nitrosamine feature: steroid vs. non-steroid

(d) aliphatic nitrosamine feature: random compounds vs. the rest

Figure 9: The local distribution of feature importance to steroids and random non-steroid compounds significantly differs for two known toxicophores. The small local gradients found for the steroids (shown in blue) indicate that the presence of each toxicophore is irrelevant to the molecules toxicity. For non-steroids (shown in red) the known toxicophores indeed exhibit positive local gradients.

7. Related Work

Assigning potentially different explanations to individual data points distinguishes our approach from conventional feature extraction methods that extract global features that are relevant for all data points, that is, those features that allow to achieve a small overall prediction error. Our notion of explanation is not related to the prediction error, but only to the label provided by the prediction algorithm. Even if the error is large, our framework is able to answer the question *why* the algorithm has decided on a data point the way it did.

The explanation vector proposed here is similar in spirit to sensitivity analysis which is common in various areas of information science. A classical example is outlier sensitivity in statistics (Hampel et al., 1986). In this case, the effects of removing single data points on estimated parameters are evaluated by an influence function. If the influence for a data point is significantly large, it is detected as an outlier and should be removed for the following analysis. In regression problems, leverage analysis is a procedure along similar lines. It detects leverage points which have potential to give large impact on the estimate of the regression function. In contrast to the influential points (outliers), removing a leverage sample may not actually change the regressor, if its response is very close to the predicted value. E.g., for linear regression the samples whose inputs are far from the mean are the leverage points. Our framework of explanation vectors considers a different view. It describes the influence of *moving* single data points locally and it thus answers the question which directions are locally most influential to the prediction. The explanation vectors are used to extract sensitive features that are relevant to the prediction results, rather than detecting/eliminating the influential samples.

In recent decades, explanation of results by expert systems has been an important topic in the Artificial Intelligence community. Especially for expert systems based on Bayesian belief networks, such explanation is crucial in practical use. In this context sensitivity analysis has also been used as a guiding principle (Horvitz et al., 1988). There the influence is evaluated by removing a set of variables (features) from the evidence and the explanation is constructed from those variables that affect inference (relevant variables). For example, Suermondt (1992) measures the cost of omitting a single feature E_i by the cross-entropy

$$H^{-}(E_i) = H(p(D|E); P(D|E\backslash E_i)) = \sum_{j=1}^{N} P(d_j|E) \log \frac{P(d_j|E)}{p(d_j|E\backslash E_i)},$$

where E denotes the evidence and $D = (d_1, \ldots, d_N)^T$ is the target variable. The cost of a subset $F \subset E$ can be defined similarly. This line of research is more connected to our work, because explanation can depend on the assigned values of the evidence E, and is thus local.

Similarly Robnik-Sikonja and Kononenko (2008) and Strumbelj and Kononenko (2008) try to explain the decision of trained kNN-, SVM-, and ANN-models for individual instances by measuring the difference in their prediction with sets of features omitted. The cost of omitting features is evaluated as the information difference, the log-odds ratio, or the difference of probabilities between the model with knowledge about all features and with omissions, respectively. To know what the prediction would be without the knowledge of a certain feature the model is retrained for every choice of features whose influence is to be explained. To save the time of combinatorial training Robnik-Sikonja and Kononenko (2008) propose to use neutral values which have to be estimated by a known prior distribution of all possible parameter values. As a theoretical framework for considering feature interactions, Strumbelj and Kononenko (2008) propose to calculate the differences between model predictions for every choice of feature subset.

For multi-layer perceptrons Fraud and Clrot (2002) measure the importance of individual input variables on clusters of test points. Therefore the change in the model output is evaluated for the change of a single input variable in a chosen interval while all other input variables are fixed. Lemaire and Feraud (2007) use a similar approach on an instance by instance basis. By considering each input variable in turn there is no way to measure input feature interactions on the model output (see LeCun et al., 1998).

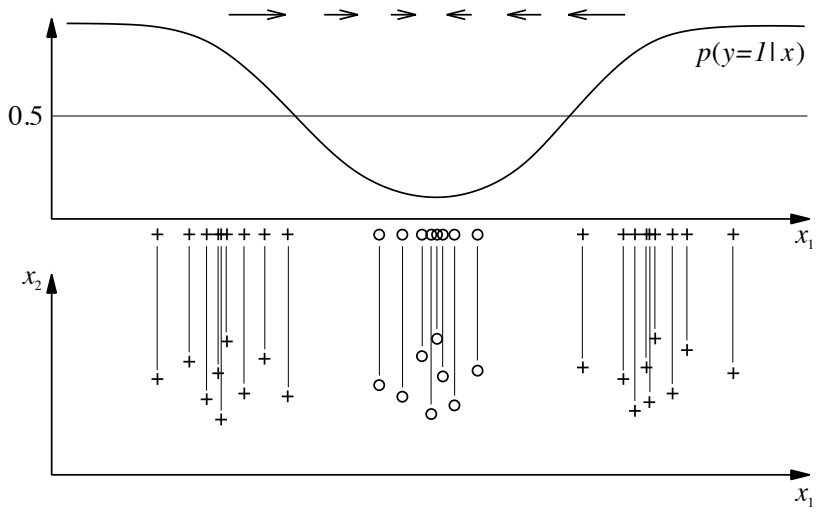


Figure 10: $\zeta(x)$ is the zero vector in the middle of the cluster in the middle.

The principal differences between our approach and these frameworks are: (i) We consider continuous features and no structure among them is required, while some other frameworks start from binary features and may require discretization steps with the need to estimate parameters for it. (ii) We allow changes in any direction, that is, any weighted combination of variables, while other approaches only consider one feature at a time or the omission of a set of variables.

8. Discussion

We have shown that our methods for calculating / estimating explanation vectors are useful in a variety of situations. In the following we discuss their limitations.

8.1 What Can We Do if the Derivative is Zero?

This situation is depicted in Figure 10. In the lower panel we see a two-dimensional data set consisting of three clusters. The middle cluster has a different class than the clusters on the left and on the right. Only the horizontal coordinate (i.e., x_1) is relevant for the classification. The upper panel shows the projected data and a representative slice of $\zeta(x)$. However, the explanation $\zeta(x)$ for the center point of the middle cluster is the zero vector, because at that point $p(Y=1|X=x)$ is maximal. What can we do in such situations? Actually, the (normalized) explanation vector is derived from the following optimization problem for finding the locally most influential direction: $\text{argmax}_{\|\varepsilon\|=1}\{p(Y\neq g^*(x_0)|X=x_0+\varepsilon)-p(Y\neq g^*(x_0)|X=x_0)\}$. In case that the first derivative of the above criterion is zero, its Taylor expansion starts from the second order term, which is a quadratic form of its Hessian matrix. In the example data set with three clusters, the explanation vector is constant along the second dimension. The most *interesting* direction is given by the eigenvector corresponding to the largest eigenvalue of the Hessian. This direction will be in our example along the first dimension. Thus, we can learn from the Hessian that the first coordinate is relevant for the classification, but we do not obtain an orientation for it. Instead it means that both directions (left and right) will influence the classification. However, if the conditional distri-

bution $P(Y = 1 \mid X = x)$ is flat in some regions, no meaningful explanation can be obtained by the gradient-based approach with the remedy mentioned above. Practically, by using Parzen window estimators with larger widths, the explanation vector can capture coarse structures of the classifier at the points that are not so far from the borders. In A.3.2 we give an illustration of this point. In the future, we would like to work on global approaches, for example, based on distances to the borders, or extensions of the approach by Robnik-Sikonja and Kononenko (2008). Since these procedures are expected to be computationally demanding, our proposal is useful in practice, in particular for probabilistic classifiers.

8.2 Does Our Framework Generate Different Explanations for Different Prediction Models?

When using the local gradient of the model prediction directly as in Definition 2 and Section 6, the explanation follows the given model precisely by definition. For the estimation framework this depends on whether the different classifiers classify the data differently. In that case the explanation vectors will be different, which makes sense, since they should explain the classifier at hand, even if its estimated labels were not all correct. On the other hand, if the different classifiers agree on all labels, the explanation will be exactly equal.

8.3 Which Implicit Limitations Do Analytical Gradients Inherit From Gaussian Process Models?

A particular phenomenon can be observed at the boundaries of the training data: Far from the training data, Gaussian Process Classification models predict a probability of 0.5 for the positive class. When querying the model in an area of the feature space where predictions are negative, and one approaches the boundaries of the space populated with training data, explanation vectors will point away from any training data and therefore also away from areas of positive prediction. This behavior can be observed in Figure 1(d), where unit length vectors indicate the direction of explanation vectors. In the right hand side corner, arrows point away from the triangle. However, we can see that the length of these vectors is so small that they are not even visible in Figure 1(c). Consequently, this property of GPC models does not pose a restriction for identifying the locally most influential features by investigating the features with the highest absolute values in the respective partial derivatives, as shown in Section 6.

8.4 Stationarity of the Data

Since explanation vectors are defined as local gradients of the model prediction (see Definition 2), no assumption on the data is made: The local gradients follow the predictive model in any case. If, however, the model to be explained assumes stationarity of the data, the explanation vectors will inherit this limitation and reflect any shortcomings of the model (e.g., when the model is applied to non-stationary data). Our method for estimating explanation vectors, on the other hand, assumes stationarity of the data.

When modeling data that is in fact non-stationary, appropriate measures to deal with such data sets should be taken. One option is to separate the feature space into stationary and non-stationary parts using Stationary Subspace Analysis as introduced by von Bünau et al. (2009). For further approaches to data set shift see Sugiyama et al. (2007b), Sugiyama et al. (2007a), and the book by Quionero-Candela et al. (2009).

9. Conclusion

This paper proposes a method that sheds light on the black boxes of nonlinear classifiers. In other words, we introduce a method that can explain the local decisions taken by arbitrary (possibly) nonlinear classification algorithms. In a nutshell, the estimated explanations are local gradients that characterize how a data point has to be moved to change its predicted label. For models where such gradient information cannot be calculated explicitly, we employ a probabilistic approximate mimic of the learning machine to be explained.

To validate our methodology we show how it can be used to draw new conclusions on how the various Iris flowers in Fisher's famous data set are different from each other and how to identify the features with which certain types of digits 2 and 8 in the USPS data set can be distinguished. Furthermore, we applied our method to a challenging drug discovery problem. The results on that data fully agree with existing domain knowledge, which was not available to our method. Even local peculiarities in chemical space (the extraordinary behavior of steroids) was discovered using the local explanations given by our approach.

Future directions are two-fold: First we believe that our method will find its way into the tool boxes of practitioners who not only want to automatically classify their data but who also would like to understand the learned classifier. Thus using our explanation framework in computational biology (see Sonnenburg et al., 2008) and in decision making experiments in psychophysics (e.g., Kienzle et al., 2009) seems most promising. The second direction is to generalize our approach to other prediction problems such as regression.

Acknowledgments

This work was supported in part by the FP7-ICT Programme of the European Community, under the PASCAL2 Network of Excellence, ICT-216886 and by DFG Grant MU 987/4-1. We would like to thank Andreas Sutter, Antonius Ter Laak, Thomas Steger-Hartmann and Nikolaus Heinrich for publishing the Ames mutagenicity data set (Hansen et al., 2009).

Appendix A.

In the following we present the derivation of direct local gradients and illustrate aspects like the effect of different kernel functions, outliers and local non-linearities. Furthermore we present the derivation of explanation vectors based on the parzen window estimation and illustrate how the quality of the fit of the Parzen window approximation affects the quality of the estimated explanation vectors.

A.1 Derivation of Direct Local Gradients

Equation (1) is derived by the following steps:

$$
\begin{aligned}
&\nabla p(x)|_{x=x_0} \\
=&\nabla \frac{1}{2}\operatorname{erfc}\left(\frac{-\overline{f}(x)}{\sqrt{2}*\sqrt{1+\operatorname{var}_f(x)}}\right)\Bigg|_{x=x_0} \\
=&\nabla \frac{1}{2}\left(1-\operatorname{erf}\left(\frac{-\overline{f}(x)}{\sqrt{2}*\sqrt{1+\operatorname{var}_f(x)}}\right)\right)\Bigg|_{x=x_0} \\
=&-\frac{1}{2}\nabla \operatorname{erf}\left(\frac{-\overline{f}(x)}{\sqrt{2}*\sqrt{1+\operatorname{var}_f(x)}}\right)\Bigg|_{x=x_0} \\
=&-\frac{\exp\left(\frac{-\overline{f}(x_0)^2}{2(1+\operatorname{var}_f(x_0))}\right)}{\sqrt{\pi}}\nabla\left(\frac{-\overline{f}(x)}{\sqrt{2}*\sqrt{1+\operatorname{var}_f(x)}}\right)\Bigg|_{x=x_0} \\
=&-\frac{\exp\left(\frac{-\overline{f}(x_0)^2}{2(1+\operatorname{var}_f(x_0))}\right)}{\sqrt{\pi}}\left(-\frac{1}{\sqrt{2}}\nabla\left(\frac{\overline{f}(x)}{\sqrt{1+\operatorname{var}_f(x)}}\right)\Bigg|_{x=x_0}\right) \\
=&\frac{\exp\left(\frac{-\overline{f}(x_0)^2}{2(1+\operatorname{var}_f(x_0))}\right)}{\sqrt{2\pi}}\left(\frac{\nabla\overline{f}(x)|_{x=x_0}}{\sqrt{1+\operatorname{var}_f(x_0)}}+\overline{f}(x_0)\left(\nabla\operatorname{var}_f(x)\big|_{x=x_0}*-\frac{1}{2}\left(1+\operatorname{var}_f(x_0)\right)^{-\frac{3}{2}}\right)\right) \\
=&\frac{\exp\left(\frac{-\overline{f}(x_0)^2}{2(1+\operatorname{var}_f(x_0))}\right)}{\sqrt{2\pi}}\left(\frac{\nabla\overline{f}(x)|_{x=x_0}}{\sqrt{1+\operatorname{var}_f(x_0)}}-\frac{1}{2}\frac{\overline{f}(x_0)}{\left(1+\operatorname{var}_f(x_0)\right)^{\frac{3}{2}}}\nabla\operatorname{var}_f(x)|_{x=x_0}\right).
\end{aligned}
$$

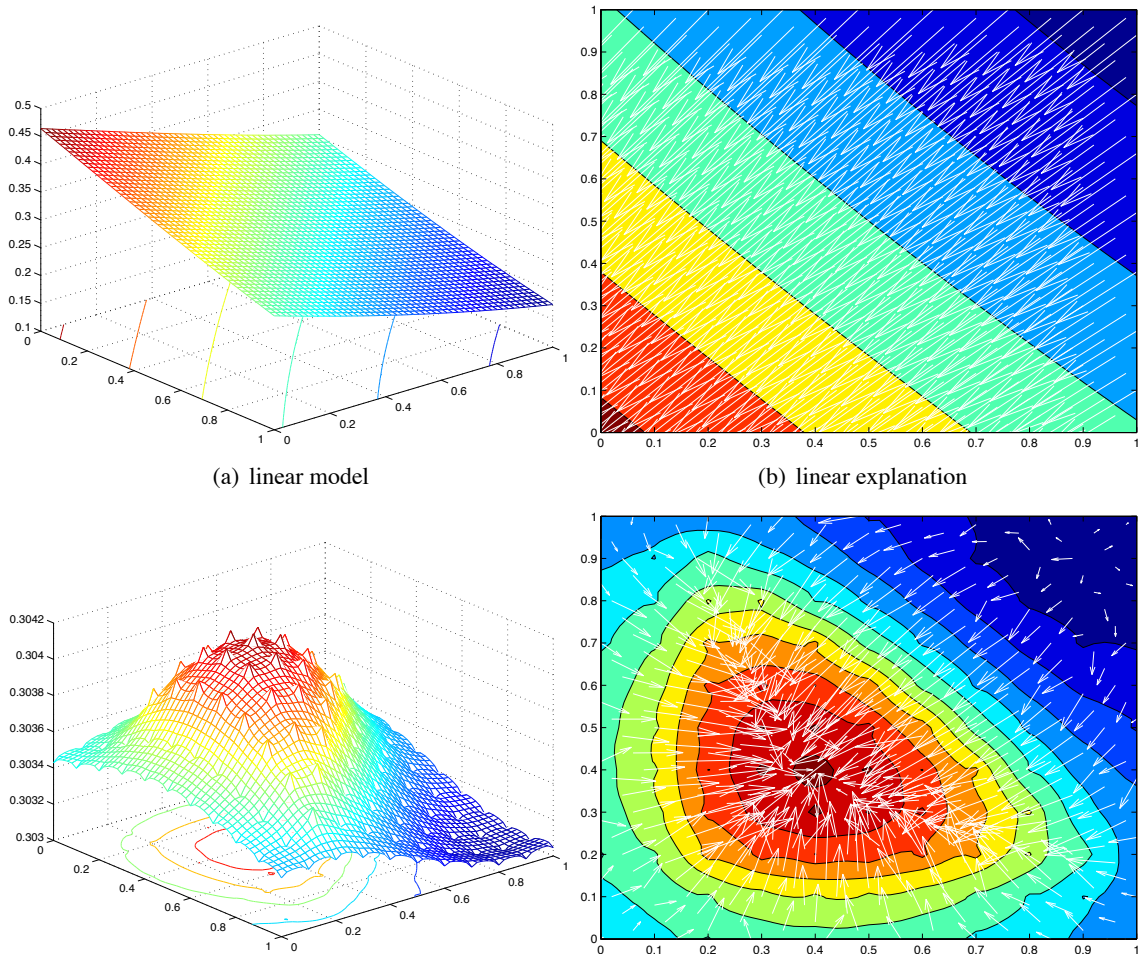
A.2 Illustration of Direct Local Gradients

In the following we give some illustrative examples of our method to explain models using local gradients. Since the explanation is derived directly from the respective model, it is interesting to investigate its acurateness depending on different model parameters and in instructive scenarios. We examine the effects that local gradients exhibit when choosing different kernel functions, when introducing outliers, and when the classes are not linearly separable locally.

A.2.1 CHOICE OF KERNEL FUNCTION

Figure 11 shows the effect of different kernel functions on the triangle toy data from Figure 1. The following observations can be made:

- In any case note that the local gradients explain the model, which in turn may or may not capture the true situation.
- In Subfigure 11(a) the linear kernel leads to a model which fails to capture the non-linear class separation. This model misspecification is reflected by the explanations given for this model in Subfigure 11(b).
- The rational quadratic kernel is able to more accurately model the non-linear separation. In Subfigure 11(c) a non-optimal degree parameter has been chosen for illustrative purposes.



(a) linear model

(b) linear explanation

(c) rational quadratic model

(d) rational quadratic explanation

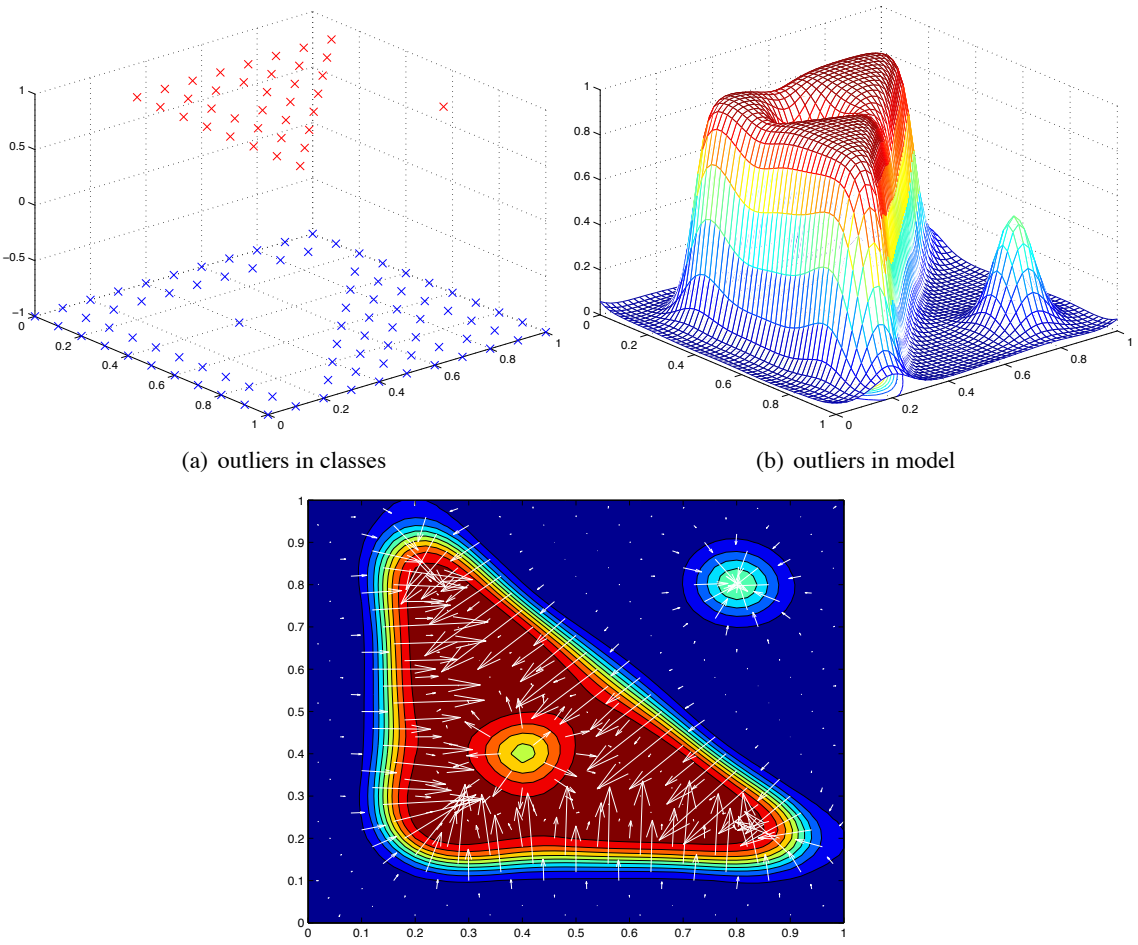
Figure 11: The effect of different kernel functions to the local gradient explanations

For other parameter values the rational quadratic kernel leads to similar results as the RBF kernel function used in Figure 1.

- The explanations in Subfigure 11(d) obtained for this model show local perturbations at the small "bumps" of the model but the trends towards the positive class are still clear. As previously observed in Figure 1, the explanations make clear that both features interact at the corners and on the hypotenuse of the triangle class.

A.2.2 OUTLIERS

In Figure 12 the effects of two outliers in the classification data to GPC with RBF kernel are shown. Once more, note that the local gradients explain the model, which in turn may or may not capture the true situation. The size of the region affected by the outliers depends on the kernel width parameter. We consider the following items:



(a) outliers in classes

(b) outliers in model

(c) outlier explanation

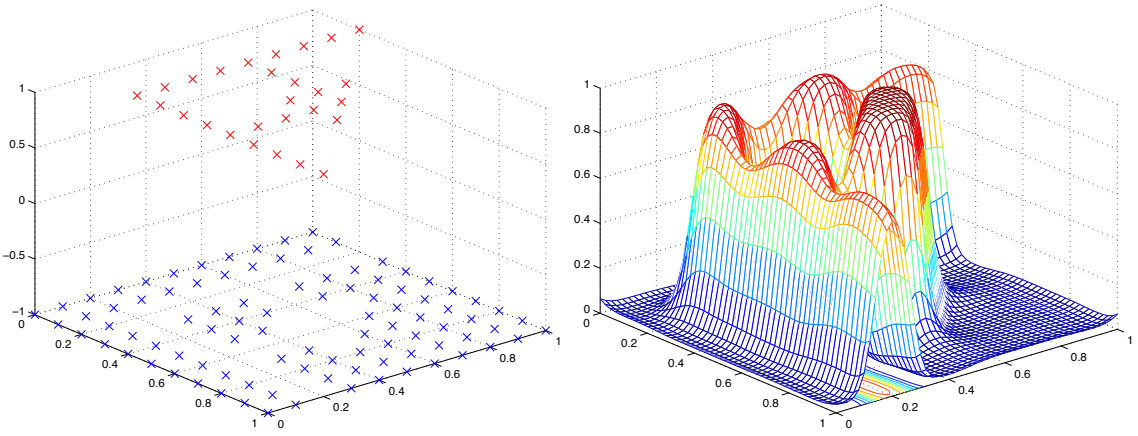
Figure 12: The effect of outliers to the local gradient explanations

- Local gradients are in the same way sensitive to outliers as the model which they try to explain. Here a single outlier deforms the model and with it the explanation which may be extracted from it.
- Being derivatives the sensitivity of local gradients to a nearby outlier is increased over the sensitivity of the model prediction itself.
- Thus the local gradient of a point near an outlier may not reflect a true explanation of the features important in reality. Nevertheless it is the model here which is wrong around an outlier in the first place.
- The histograms in the Figures 7, 8, and 9 in Section 6 show the trends of the respective features in the distribution of all test points and are thus not affected by single outliers.

To compensate for the effect of outliers to the local gradients of points in the affected region we propose to use a sliding window method to smooth the gradients around each point of interest.

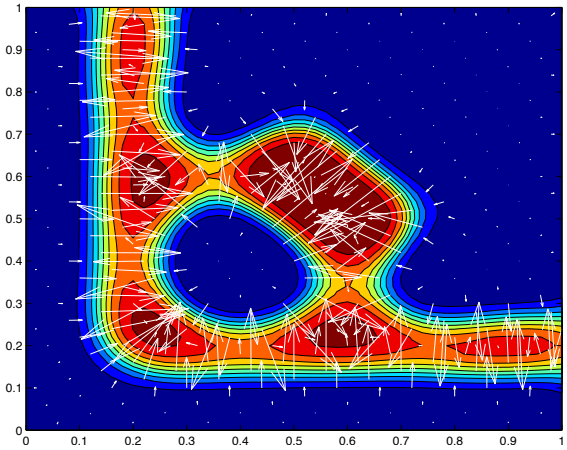
Thus for each point use the mean of all local gradients in the hypercube centered at this point and of appropriate size. This way the disrupting effect of an outlier is averaged out for an appropriately chosen window size.

A.2.3 LOCAL NON-LINEARITY



(a) locally non-linear object

(b) locally non-linear model



(c) locally non-linear explanation

Figure 13: The effect of local non-linearity to the local gradient explanations

The effect of locally non-linear class boundaries in the data is shown in Figure 13 again for GPC with an RBF kernel. The following points can be observed:

- All the non-linear class boundaries are accurately followed by the local gradients.
- The circle shaped region of negative examples surrounded by positive ones shows the full range of feature interactions towards the positive class.
- On the ridge of single positive instances the model introduces small valleys which are reflected by the local gradients.

A.3 Estimating by Parzen Window

Finally we elaborate on some details of our estimation approach of local gradients by Parzen window approximation. First we give the derivation to obtain the explanation vector and second we examine how the explanation varies with the goodness of fit of the Parzen window method.

A.3.1 DERIVATION OF EXPLANATION VECTORS

These are more details on the derivation of Definition 3. We use the index set $I_c = \{i \mid g(x_i) = c\}$:

$$\begin{aligned}
&\frac{\partial}{\partial x} k_\sigma(x) = -\frac{x}{\sigma^2} k_\sigma(x) \\
&\frac{\partial}{\partial x} \hat{p}_\sigma(x, y \neq c) = \frac{1}{n} \sum_{i \notin I_c} k_\sigma(x - x_i) \frac{-(x - x_i)}{\sigma^2} \\
&\frac{\partial}{\partial x} \hat{p}_\sigma(y \neq c | x) \\
&= \frac{\left(\sum_{i \notin I_c} k(x - x_i)\right)\left(\sum_{i=1}^n k(x - x_i)(x - x_i)\right)}{\sigma^2 \left(\sum_{i=1}^n k(z - x_i)\right)^2} \\
&- \frac{\left(\sum_{i \notin I_c} k(x - x_i)(x - x_i)\right)\left(\sum_{i=1}^n k(x - x_i)\right)}{\sigma^2 \left(\sum_{i=1}^n k(z - x_i)\right)^2} \\
&= \frac{\left(\sum_{i \notin I_c} k(x - x_i)\right)\left(\sum_{i \in I_c} k(x - x_i)(x - x_i)\right)}{\sigma^2 \left(\sum_{i=1}^n k(z - x_i)\right)^2} \\
&- \frac{\left(\sum_{i \notin I_c} k(x - x_i)(x - x_i)\right)\left(\sum_{i \in I_c} k(x - x_i)\right)}{\sigma^2 \left(\sum_{i=1}^n k(z - x_i)\right)^2}
\end{aligned}$$

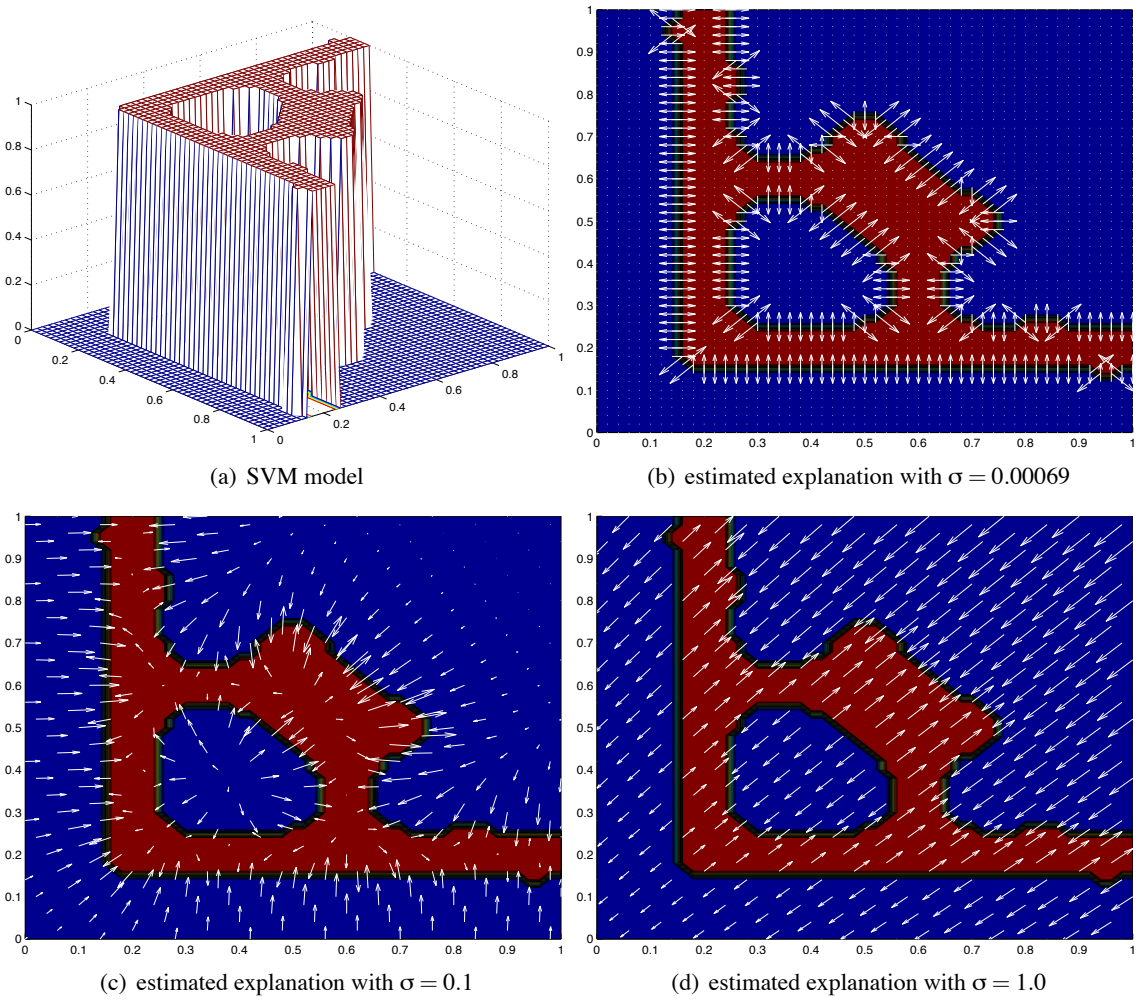
and thus for the index set $I_{g(z)} = \{i \mid g(x_i) = g(z)\}$

$$\begin{aligned}
\hat{\zeta}(z) &= \frac{\partial}{\partial x} \hat{p}(y \neq g(z) \mid x)\Big|_{x=z} \\
&= \frac{\left(\sum_{i \notin I_{g(z)}} k(z - x_i)\right)\left(\sum_{i \in I_{g(z)}} k(z - x_i)(z - x_i)\right)}{\sigma^2 \left(\sum_{i=1}^n k(z - x_i)\right)^2} \\
&- \frac{\left(\sum_{i \notin I_{g(z)}} k(z - x_i)(z - x_i)\right)\left(\sum_{i \in I_{g(z)}} k(z - x_i)\right)}{\sigma^2 \left(\sum_{i=1}^n k(z - x_i)\right)^2}.
\end{aligned}$$

A.3.2 GOODNESS OF FIT BY PARZEN WINDOW

In our estimation framework the quality of the local gradients depends on the approximation of the classifier we want to explain by Parzen windows for which we can calculate the explanation vectors as given by Definition 3.

Figure 14(a) shows an SVM model trained on the classification data from Figure 13(a). The local gradients estimated for this model by different Parzen window approximations are depicted in Subfigures 14(b), 14(c), and 14(d). We observe the following points:



(a) SVM model

(b) estimated explanation with $\sigma = 0.00069$

(c) estimated explanation with $\sigma = 0.1$

(d) estimated explanation with $\sigma = 1.0$

Figure 14: Good fit of Parzen window approximation affects the quality of the estimated explanation vectors

- The SVM model was trained with $C = 10$ and using an RBF kernel of width $\sigma = 0.01$.

- In Subfigure 14(b) a small window width has been chosen by minimizing the mean absolute error over the validation set of labels predicted by the SVM classifier. Thus we obtain explaining local gradients on the class boundaries but zero vectors in the inner class regions. While this resembles the piecewise flat SVM model most accurately it may be more useful practically to choose a larger width to obtain non-zero gradients pointing to the borders in this regions as well. For a more detailed discussion of zero gradients see Section 8.

- A larger width practically useful in this example is shown in Subfigure 14(c). Here the local gradients in the inner class regions point to the other class as well.

- For a too large window width in Subfigure 14(d) the approximation fails to obtain local gradients which closely follow the model. Here only two directions are left and the gradients for the blue class on the left and on the bottom point in the wrong direction.
